Titrations: Test solutions were assembled in the titration cell by combining an aliquot of the electrolyte solution (from an A-grade pipette) with a weighed portion of the ligand and, when appropriate, an aliquot of a metal stock solution. Care was taken to add the metal stock solution after dissolution of the ligand to avoid the possibility of metal ion hydrolysis. Concentrations in the range $2.4-9.2\times0^{-4}$ M H_8OHEC were used for protonation studies. Metal complexation experiments employed concentrations of $2.4-9.6\times10^{-4}$ M H_8OHEC and of $0.37-1.7\times10^{-3}$ M for the metal ion, with metal-to-ligand ratios ranging from 1:1 to 1.95:1. In titrations containing the weakly hydrolysed Ca^{2+} an excess of the metal above two equivalents was occasionally used, up to 2.2:1. The resulting solutions typically had an initial pH of ≈3 and were initially titrated to pH 11 with KOH, followed by back titration to pH 2.5 with HCl so that the equilibrium state was approached from both directions. Following addition of titrant the system was allowed to equilibrate for 90 s for ligand-only titrations, 180 s in the presence of a metal, after which time the electrode potential was measured. On obtaining 10 measurements with a standard deviation of ≤0.05 mV the electrode potential was considered stable, a pH measurement was recorded and the titration proceeded to the next point. Each titration contained approximately 120 points, collected between pH 2.5 and 11, each being a measurement of pH versus volume of titrant.

Data Treatment: Equilibrium constants were determined from the titration data by least-squares refinement using the computer program HYPERQUAD.[48] The data from each pair wise set of titrations, i.e. initial titration with KOH and back titration with HCl, were imported into the program along with values for the titrant concentration, initial volume and analytical concentrations of the reagents, as calculated from either the mass of ligand or volume of metal stock taken. The analytical concentration of protons was treated as a refinable parameter, always returning a value within 5% of the initial estimate. The "automatic" weighting scheme was selected with error estimates of 0.002 mL for the titre values and 0.002 pH. Following refinement of the equilibrium constants, the quality of fit was assessed with Σ, the scaled sum of squares, which has an expectation value of one for perfectly fit data. Obtained values ranged between 0.6 and 5.9 with an average of 2.4. Individual species were included into or rejected from the coordination model based on their effect upon Σ. Also, species that gave widely divergent equilibrium constants (standard deviation ≥ 0.5) between independent titrations were rejected. The resulting equilibrium constants, determined from a total of 53 titrations, are given in Table 6.

18-Crown-6 and Titanium Tetrafluoride − Preparation of the Ti^{IV} Fluoride Crown Ether Complexes $(TiF_4)_2$(18-Crown-6) and the Stabilization of *cis*-$TiF_4(H_2O)_2$ in [{*cis*-$TiF_4(H_2O)_2$}$_2$(18-Crown-6)]

Keywords: Titanium(IV) / Fluorides / Crown ether / Macrocyclic ligands / Coordination modes / Host-guest systems

Reaction of TiF_4 and 18-crown-6 in MeCN affords the molecular complex [(*cis*-$TiF_4)_2$(18-crown-6)] (**1**) only. Water and THF displace the 18-crown-6 in the tetrafluoro complex **1**, with the formation of *cis*-TiF_4L_2. The complex *cis*-$TiF_4(H_2O)_2$ and 18-crown-6 form [{*cis*-$TiF_4(H_2O)_2$}$_2$(18-crown-6)] (**2**), in which *cis*-$TiF_4(H_2O)_2$ and 18-crown-6 are connected by hydrogen bonding through the protons of coordinated H_2O in $TiF_4(H_2O)_2$ and the oxygen atoms of the crown ether. Complexes **1** and **2** were characterized by X-ray single crystal analysis, elemental analysis, IR, NMR and Mass spectroscopy. The relative basicities of the 18-crown-6 and the molecular donor ligands MeCN, THF, H_2O toward Ti^{IV} fluoride were established by NMR spectroscopic investigations of the substitution reactions. 18-crown-6 is slightly more basic than MeCN, similar to that of Et_2O, and less basic than THF and H_2O.

Introduction

Crown ethers are known as variable multidentate ligands that act as macrocycles and chelate ligands,[1] and form a variety of host guest complexes with the neutral molecules.[2] Interest in the crown ethers stems in part from its ability to stabilize metal cations,[1,2] cationic complexes, and aqua complexes of the transition metals.[1−3] Interaction of the transition metal chloride salt, for example $FeCl_3$, $CoCl_2$, $CuCl_2$, VCl_4, with the crown ether in the acetonitrile solution spontaneously yields cationic transition-metal complexes.[4] The group IV chlorides $TiCl_4$, $SnCl_4$,[5] and $TiCl_3$[3e] in the presence of moisture and 18-crown-6 give molecular donor-acceptor adducts with a rare bidentate bonding mode for the 18-crown-6 molecule. The crown ether pillared α-zirconium phosphonate phosphate $Zr_2(L)_{1.17}(PO_4)(HPO_4)_{0.83}F_2Cl_{0.17}(H_2O)_{1.69}$ (L = 1-aza-15-crown-5), according to the solid state NMR spectroscopy, contains the fluorine atom bonded to Zr, and was found to have selective ion exchange properties.[6] However, to the best of our knowledge, no structurally characterized group IV crown ether fluoride complexes are found in the literature.'

Titanium fluoride complexes have been attracting considerable attention for use in several fields including synthetic methodology, catalysis and theoretical studies. $TiHal_4$ (Hal = F, Cl) was used as a reference Lewis acid for the theoretical investigation of the nature of donor−acceptor bond in complexes of the type $TiHal_4L_2$ [L= $C(NH_2)_2$, NH_3, CO].[7] The complex $CpTiF_3$ is active in syndiospecific styrene polymerization in the presence of methylaluminoxane (MAO),[8] and $[TiF_2(NMe_2)_2]_4$ was found to have a relatively modest activity for the catalysis of olefin polymerizations in the presence of MAO.[9] An equimolar mixture of TiF_4 and (*S*)-(−/)-1,1′-bi-2-naphthol treated with 2 equiv. of allylsilane is an effective catalyst for enantioselective addition of allylsilanes to aldehydes.[10] In addition, titanium fluoride complexes have been extensively employed as complexing agents for LiF, NaF, MgF_2, CaF_2, Li_2O, ZnF_2, and preparation of hot-guest compounds, e. g. (Cp*$TiF_3)_4CaF_2$, [$(Cp^*TiF_3)_8(ZnF_2)_3$] etc., which are soluble in organic solvents.[11]

Our interest in the chemistry of titanium fluoride complexes is focused on the structure and reactivity of the complexes, and on the development of a simple high yield synthesis of the Ti^{IV} non-metallocene fluoride complexes. In this paper, we report the preparation, characterization and stability of the titanium(IV) fluoride complex with 18-

crown-6. In addition, 18-crown-6 was used to stabilize *cis*-$TiF_4(H_2O)_2$, which was found as an intermediate hydrolysis product of TiF_4.[12] The complex *cis*-$TiF_4(H_2O)_2$ was reported to be unstable to give $(H_3O)[TiF_4(OH)(H_2O)]$.[12]

Results and Discussion

Reaction of TiF_4 and Crown-6 in MeCN, Preparation of $[(TiF_4)_2(18\text{-Crown-6})]$ (1)

Interaction of 2 or 3 M TiF_4 and 1 M of 18-crown-6 in the MeCN led to the precipitation of crystalline $[(TiF_4)_2(18\text{-crown-6})]$ (**1**) with an isolated yield of approximately 50% (Scheme 1). Reaction of 1 M TiF_4 and 1 M 18-crown-6 in the same solvent led to the isolation of 18-crown-6 and complex **1**.

$$(2 \text{ or } 3)TiF_4 + [18\text{-Crown-6}] \xrightarrow{MeCN} [TiF_4]_2(18\text{-Crown-6}) \downarrow$$

Scheme 1

The structure of **1** consists of a discrete $[(TiF_4)(18\text{-crown-6})(TiF_4)]$ molecular complex (Figure 2),[13] with bidentate chelation by oxygen atoms of the crown ether to each titanium atom. The most related halogen containing complexes are $[PPh_4]_2[(VCl_4)_2(18\text{-crown-6})]$[3f] and $[TiCl_4(18\text{-crown-6})]$,[5] in which each metal atom is bidentately coordinated to oxygen atoms of 18-crown-6. Both M−O bond lengths in $[(VCl_4)_2(18\text{-crown-6})]$ [2.116(6) and 2.117(6) Å] and in $[TiCl_4(18\text{-crown-6})]$ [2.123(8) and 2.154(9) Å], and O−M−O angles 75.6(2)° and 75.5°, respectively, vary only slightly from those in **1** (Table 1). Complex **1** can also be compared with the binuclear anionic complex $[(TiF_4)(\mu\text{-}C_2O_4)(TiF_4)]^{2-}$,[14] in which each TiF_4 unit is coordinated to two oxygen atoms of the oxalato anion. The Ti−O bond lengths in **1** are similar to the corresponding bond lengths in the binuclear anion $[(TiF_4)(\mu\text{-}C_2O_4)(TiF_4)]^{2-}$.[14] The bidentate ligating mode of the crown ether is relatively rare and has been mostly observed for early transition metal chloride complexes of titanium and vanadium.[5,15]

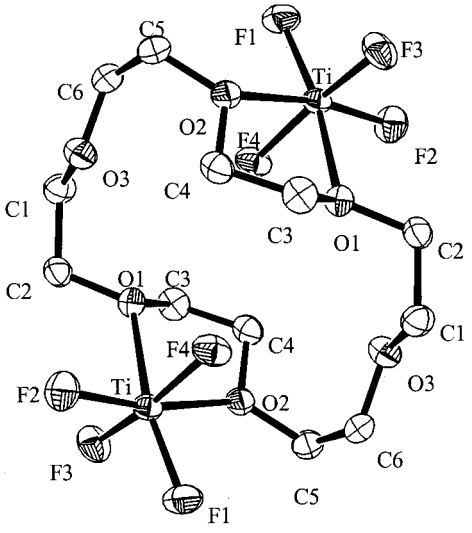

Figure 1. ORTEP drawing (50% thermal probability ellipsoids) of the crystal structure of $[(cis\text{-}TiF_4)_2(18\text{-crown-6})]$ (**1**) with atomic numbering scheme; hydrogen atoms are omitted for clarity

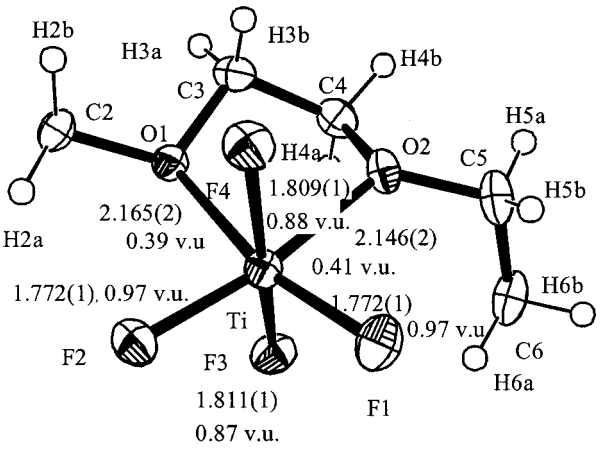

Figure 2. A portion of the $[(cis\text{-}TiF_4)_2(18\text{-crown-6})]$ (**1**) molecule showing the coordination sphere around titanium with the corresponding distances (Å) and bond valences (v.u.)[13]

Table 1. Selected bond lengths (Å) and angles (°) for **1** and **2**; symmetry transformations used to generate equivalent atoms in **1**: $1 - x + 1, -y + 1, -z + 2$; symmetry equivalent positions as x, y, z in **2**: $+x, +y, +z$; $1/2 - x, 1/2 + y, 1/2 - z$; $-x, -y, -z$; $1/2 + x, 1/2 - y, 1/2 + z$

Bond lengths (Å)		Angles (°)	
Complex **1**			
Ti−F(1)	1.772(2)	F(1)−Ti−F(2)	103.12(7)
Ti−F(2)	1.772(2)	F(1)−Ti−F(4)	94.61(6)
Ti−F(4)	1.809(2)	F(1)−Ti−O(1)	164.78(7)
Ti−F(3)	1.811(2)	F(1)−Ti−O(2)	88.95(6)
Ti−O(2)	2.146(2)	F(4)−Ti−F(3)	166.46(6)
Ti−O(1)	2.165(2)	O(2)−Ti−O(1)	75.86(6)
Complex **2**			
Ti−F(2)	1.831(3)	F(2)−Ti−F(3)	95.6(1)
Ti−F(3)	1.790(3)	F(2)−Ti−F(5)	93.4(1)
Ti−F(5)	1.808(3)	F(2)−Ti−O(4)	178.5(1)
Ti−F(6)	1.811(3)	F(2)−Ti−O(5)	92.7(1)
Ti−O(4)	2.087(3)	F(5)−Ti−F(6)	165.6(1)
Ti−O(5)	2.065(3)	O(4)−Ti−O(5)	86.0(1)

The Ti−F bonds of the *trans* F−Ti−O fragment of **1** are shorter than those of the ordinate F−Ti−F fragment due to the *trans* effect in octahedral Ti^{IV} complexes (Table 1). In previously reported *cis*-TiF_4L_2 (L=DMSO), Ph_3PO,[16,17] and $[(cis\text{-}TiF_4)(\mu\text{-}C_2O_4)(cis\text{-}TiF_4)]^{2-}$ [14] complexes, the *trans* effect was implied by the data, but the high Ti−F standard deviation and nonequivalence of all the Ti−F distances ruled out unambiguous interpretations. The Ti−F bond lengths for the F−Ti−F moiety in $[(TiF_4)(\mu\text{-}C_2O_4)(TiF_4)]^{2-}$ are 1.802(5) Å and 1.823(5) Å, and those for the F−Ti−O ordinate are 1.792(5) Å and 1.771(5) Å. In this work the standard deviation allows for the unambiguous observation of the *trans* effect in the titanium(IV) fluoride complex **1**. The average F−Ti−F angle of 96.0(1)°

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in **1** is substantially greater than the O−Ti−O angle of 75.9(1)°, reflecting the much greater Ti−F bond order (0.92 v.u. av.) than that of Ti−O (0.40 v.u. av.) and the presence of $p_\pi-d_\pi$ back bonding to titanium.[18]

Elemental analysis shows that complex **1** corresponds to $[TiF_4]_2$(18-crown-6). The crystals of **1** do not change appearance on storage in sealed ampoules at room temperature for several months, but decompose at 141 °C. The heaviest particle detected by EI-MS corresponds to the $[TiF_3(18\text{-crown-6})^+]$ cation. The $[(18\text{-crown-6})^+]$ and $[TiF_3^+]$ ions are also detected. Analysis of the isotope distribution from the EI-MS data also shows ions that are formed by the subtraction of $(CH_2)_2O$ and $O(CH_2)_2O$ from the 18-crown-6.

The observed bands due to Ti−F absorption of **1** [581(m), 648 (vs), 670 (vs) cm^{-1} (IR) and 582 (vs), 672 (vs) cm^{-1} (Raman)] are located in the 400−700 cm^{-1} region for Ti−F vibrations for known TiF_4L_2 complexes. For comparison, these absorptions are located at 560 (vs, br.) for *trans*-$TiF_4(bfq)_2$ (bfq = 5,6 benzoquinoline),[19a] 610 (vs) and 550 (s) for *cis*-$TiF_4(Me_2SO)_2$,[19b] 670 (vs, br.) and 585 (vs, br.) for *cis*-$TiF_4(DME)_2$ (DME = dimethoxyethane),[19b] and 634 (vs, br.) and 562 (s) for *cis*-$TiF_4(bipy)_2$ (bipy = 2,2′-bipyridyl).[19c]

The ^{19}F NMR spectrum of **1** in acetonitrile shows resonances assigned to $TiF_4(MeCN)_2$, $[Ti_2F_9]^-$, oligomeric complexes with bridging fluorine atoms, and *face*-$[TiF_3(MeCN)_3]^+$.[20,21] Two broad resonances at 230−232 and 156−159 ppm (−40 °C) are assigned to the titanium tetrafluoride crown ether complex [*cis*-TiF_4(18-crown-6)] (Supporting Information, Figure S1). Therefore, in the acetonitrile solution of **1**, a complex equilibrium is observed between oligomeric fluoride complexes with bridging fluorides, monomeric complexes of TiF_4 with acetonitrile and TiF_4 complexes with crown ether, since the donor properties of acetonitrile and 18-crown-6 toward TiF_4 are similar.

Resonances assigned to [TiF_4(18-crown-6)] as well as $[Ti_2F_9]^-$ are detected in the ^{19}F NMR spectrum of **1** in $CDCl_3$, which is a very poor donor toward Ti^{IV} fluorides. The corresponding cationic complex is not detected, possibly due to a rapid exchange process involving this complex.

Reaction of Complex 1 with THF and H_2O, Stabilization of *cis*-$TiF_4(H_2O)_2$ by Coordination with the Crown Ether

Complex **1** is very soluble in THF and insoluble in Et_2O. The NMR spectrum of **2** and excess THF in MeCN and $CDCl_3$ at room temperature and at low temperatures show resonances for *cis*-$TiF_4(THF)_2$,[22] as well as a single resonance for 18-crown-6. Therefore, THF displaces MeCN and 18-crown-6 in the titanium(IV) tetrafluoro complexes.

Complex **1** readily reacts with water. The ^{19}F NMR spectrum of **1** and 1−4 equivalents of water in MeCN shows resonances for $[Ti_2F_9]^-$,[21] four resonances for the intermediate oligomeric titanium fluoride complex (A) and *cis*-$TiF_4(H_2O)_2$. The relative concentration of the species in solution depends on the amount of added H_2O (Supporting Information, Figures S11 and S12).

Complex [{*cis*-$TiF_4(H_2O)_2$}$_2$(18-crown-6)] (**2**), formed from *cis*-$TiF_4(H_2O)_2$ and 18-crown-6, precipitates quantitatively as a white insoluble powder on reaction with 4 equivalents of H_2O in acetonitrile. Colorless crystals of **2** are formed from the acetonitrile solution and contain 2.2 mol of water per one mol of complex **1** at −24 °C.

The structure of **2** consists of $TiF_4(H_2O)_2$ and 18-crown-6 units connected through hydrogen bonding (Figure 3) between the protons H(14), H(15), and H(16) of the coordinated H_2O in $TiF_4(H_2O)_2$ and O1, O2, and O3 oxygen atoms of the crown ether. The H(14−16)···O(1−3) distances (Figure 4) in **2** are similar to the corresponding H···O distances in $TiCl_3(H_2O)$[18-crown-6][3e] (1.8 Å) and close to those observed in known hydrogen-bonded complexes

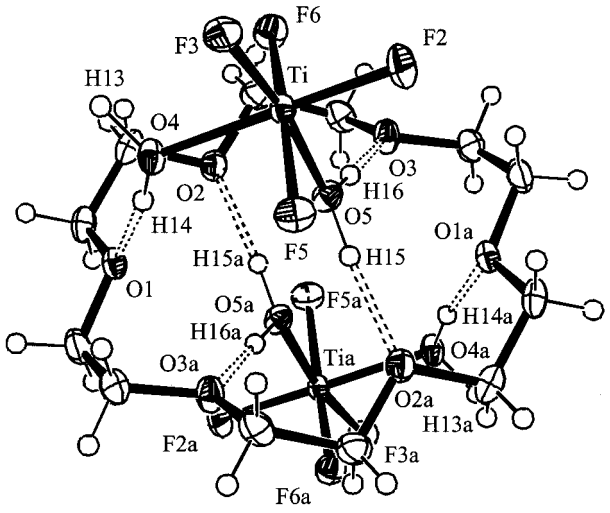

Figure 3. ORTEP drawing (50% thermal probability ellipsoids) of the crystal structure of [{*cis*-$TiF_4(H_2O)_2$}$_2$(18-crown-6)] (**2**) with atomic numbering scheme

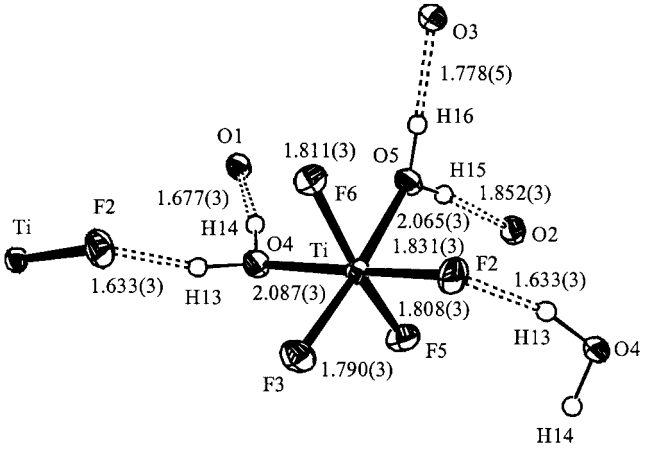

Figure 4. A portion of [{*cis*-$TiF_4(H_2O)_2$}$_2$(18-crown-6)] (**2**) showing the coordination sphere around titanium with the corresponding distances and hydrogen bonding between the protons H13−H16 of the coordinated H_2O and F2 of the neighboring $TiF_4(H_2O)_2$ unit and O1−O3 atoms of 18-crown-6

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(1.7−1.9 Å).[23] The $TiF_4(H_2O)_2$ units are joined together through H(13)···F(2) contacts 1.633(3) Å (Figure 4), which are similar to the H···F distances in related compounds, e.g. $CuF_2{\cdot}2H_2O$ (1.69 Å)[24] and $FeSiF_6{\cdot}6H_2O$ (1.86 Å).[24c]

Each titanium atom in the *cis*-$TiF_4(H_2O)_2$ moiety is connected to four fluorine atoms and two oxygen atoms to form a distorted octahedral environment around the titanium center (Figure 4). The Ti−F bond lengths are nonequivalent. The shortest bond is Ti−F(3) [1.790(3) Å, 0.92 v.u.] and involves the fluorine *trans* to H_2O. The two distances Ti−F(5) and Ti−F(6) in the *trans* F(5)−Ti−F(6) fragment of **2** [1.808(3) Å 0.88 v.u. and 1.811(3) Å 0.87 v.u.] are slightly greater than Ti−F(3) due to the *trans* effect in octahedral Ti^{IV} complexes. The hydrogen bonding between F(2) and H(13) leads to the longer Ti−F(2) bond [1.831(3) Å, 0.83 v.u.]. The titanium−oxygen bond length lies in the range for normal Ti−O distances [1.985(7)−2.160 (6) Å] in known complexes with the oxygen donor ligands.[14,16,17,25] The F−Ti−F, F−Ti−O and O−Ti−O angles (Table 1) around titanium are in agreement with VSEPR theory.[18]

Crystals of **2** change appearance in air due to reaction with H_2O. On storage in sealed ampoules at room temperature they are stable for several months, and decomposition occurs above 200 °C in sealed melting point tubes.

The EI-MS of the hydrolysis product shows $[M^+ - 2HF - C_6H_{12}O_3]$ {252 (2)} and $[M^+ - 2H_2F - C_6H_{12}O_3]$, as well as the cations $[TiF_2O^+]$ and $[TiF_3^+]$, which are formed by the decomposition of **2** during the EI-MS experiment. The strongest signals are for $[C_4H_8O_2^+]$, $[C_3H_6O^+]$, and $[C_2H_5O^+]$, which correspond to fragments of 18-crown-6.

Formation of OH···O hydrogen bonds in **2** is reflected by the strong, broad H_2O IR absorption band at 3350−3150 cm^{-1} (maximum at 3295 cm^{-1}). For comparison, the IR absorption bands for H_2O in $TiCl_3(H_2O){\cdot}$(18-crown-6) occurs at 3380 and 3328 cm^{-1}.[3e] Three TiF_4 absorption bands are observed at 667, 607, and 559 cm^{-1}. The skeletal stretches for 18-crown-6 (839, 900, 962 cm^{-1}) are shifted to higher frequencies relative to those of 18-crown-6 (827, 858, 943 cm^{-1})[26] due to interaction of the oxygen atoms of 18-crown-6 with the protons of the $TiF_4(H_2O)_2$ moieties.

The ^{19}F NMR spectra of **2** in MeCN at room temperature shows resonances assigned to $[Ti_2F_9]^-$, oligomeric titanium complex (A) and *cis*-$TiF_4(H_2O)_2$. Lowering the temperature leads to the disappearance of the resonances assigned to $[Ti_2F_9]^-$, and at −35 °C the ^{19}F NMR spectrum shows resonances for (A) and *cis*-$TiF_4(H_2O)_2$, which is consistent with a temperature-dependent equilibrium between the titanium fluoride complexes in solution.

Interaction between 18-crown-6 and *cis*-$TiF_4(H_2O)_2$ leads to a downfield shift of the proton resonance for 18-crown-6 detected at δ_H = 5.1 ppm [δ_H(18-crown-6) 4.3 ppm]. The proton resonance for the *cis*-$TiF_4(H_2O)_2$ moiety (δ_H = 7.4 ppm) detected at −35 °C also shifts 0.5 ppm downfield relative to that of *cis*-$TiF_4(H_2O)_2$ in MeCN, due to interaction of the protons of coordinated water with 18-crown-6 in solution.

An Estimation of the Basic Properties of 18-Crown-6 Toward Titanium Tetrafluoride

In order to establish the relative stability of the [TiF_4(18-crown-6)] complex, the relative basicity of the commonly used donors and 18-crown-6 was compared.

Previous authors have reported a linear relationship between Δδ (H NMR and F NMR spectroscopy) and ΔH^0 values for adduct formation between a series of bases and substituted phenols,[27] and a linear correlation between Δδ (F NMR spectroscopy) in [*cis*-TiF_4(L1)(L2)] (L1 = *N*,*N*-dimethylacetamide, L2 = *p*-substituted pyridine I-oxide) and the appropriate Hammett substituent parameters[28] and also the electronegativity of the substituent R in L1, L2−R_3PO.[29] A linear relationship was also observed between Δδ (F NMR spectroscopy) in $[TiF_5L]^-$ (L − neutral Lewis bases) and pK_α values.[30] This allows us the opportunity to estimate the donor properties of 18-crown-6 toward TiF_4 with the correlation between Δδ (F NMR) in *cis*-TiF_4L_2 and the donor properties of ligand L. We have observed a linear correlation between Δδ (F NMR) of F_A and F_x in *cis*-TiF_4L_2 (Table 2, Figure 5), and the relative basicities of the molecular ligands L (V.Gutmann, G. Olofsson).[31] From this dependence it was concluded that the basic properties of the crown ether (Table 2, Figure 5) are slightly greater than those of acetonitrile and similar to that of Et_2O.

Table 2. Chemical shifts for the *cis*-TiF_4L_2 complexes

Complex	Solvent	Temp. (K)	δ (CCl_3F) (ppm)	*J* (Hz)	Donor number L	Ref.

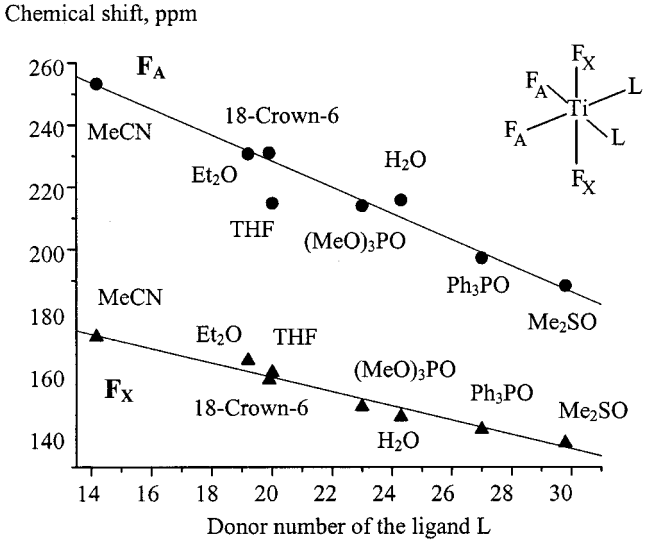

Figure 5. Relationship between the relative basicities of the ligands L (donor number) and chemical shifts of the ^{19}F resonances F_A and F_X in the *cis*-TiF_4L_2 complexes

The substitution reaction (Scheme 2) should proceed[32] if the donor strength of Base1 is greater than that of Base2. The displacement reactions involving TiF_4 and the above molecular donor ligands were studied[16,17,25,33–35] (this work, Supporting Information).

$$[TiF_4(\text{Base 1})] + (\text{Base 2}) \longrightarrow [TiF_4(\text{Base 2})] + (\text{Base 1})$$

Scheme 2

The 18-crown-6 displaces MeCN with the formation of complex **1** in acetonitrile, while THF and H_2O displace 18-crown-6 to give *cis*-TiF_4L_2 (L = THF, H_2O) in solution. Thus, 18-crown-6 is a stronger donor than MeCN, but weaker than THF and H_2O toward titanium tetrafluoride. The basicity of 18-crown-6 might be similar to that of Et_2O since the basic properties of the Et_2O are slightly weaker than those of THF and larger than that of MeCN. Our preliminary NMR spectroscopic study of TiF_4 in mixtures of MeCN and Et_2O show that the mixed complexes $[TiF_4(MeCN)_{2-x}(Et_2O)_x]$ and $[Ti_2F_9]^-$,oligomeric complexes with bridging fluoride atoms, are formed in solutions,[36] much like that in the solution of **1** in MeCN.

Finally, the order of the relative basicities of the ligands in the Ti^{IV} fluoride complexes was established to be MeCN $<$ Et_2O $\approx$ 18-crown-6 $<$ THF $<$ $(MeO)_3PO$ $<$ H_2O[37] $<$ Ph_3PO $<$ Me_2SO $<$ $[F]^-$.

Conclusions

Reaction of TiF_4 and 18-crown-6 in MeCN affords only one molecular complex [(*cis*-TiF_4)$_2$(18-crown-6)] (**1**). The crown ether 18-crown-6 bidentately coordinates through the oxygen atoms to titanium tetrafluoride in **1**, in a manner similar to that in the corresponding chloride complex [$TiCl_4$(18-crown-6)]. However, the stoichiometry of the fluoride and chloride complexes (2:1 and 1:1 respectively) differs from each other, and the complex [TiF_4(18-crown-6)] (1:1) was not isolated from the [TiF_4(18-crown-6)]/acetonitrile system.

Water and THF displaces 18-crown-6 in the tetrafluoro complex with the formation of *cis*-$TiF_4(L)_2$ (L= THF, H_2O) in solution. The complex *cis*-$TiF_4(H_2O)_2$ and 18-crown-6 form [{*cis*-$TiF_4(H_2O)_2$}$_2$(18-crown-6)] (**2**), in which *cis*-$TiF_4(H_2O)_2$ and 18-crown-6 are connected by hydrogen bonding through protons of coordinated H_2O in $TiF_4(H_2O)_2$ and oxygen atoms of the crown ether. Thus, reaction of TiF_4 and **2** with water yields the molecular adduct *cis*-$TiF_4(H_2O)_2$, which was observed in solution,[12] but has not hitherto been isolated and characterized.

The basic properties of 18-crown-6 toward TiF_4 were established from a linear correlation between $\Delta\delta$ (F NMR spectroscopy) of F_A and F_x in *cis*-TiF_4L_2 and the relative basicities of the molecular ligands L (V.Gutmann, G. Olofsson) as well as from the displacement reaction data involving complex **1**, MeCN, THF, and H_2O. The relative basicity of the ligands increase in the order MeCN $<$ Et_2O $\approx$ 18-crown-6 $<$ THF $<$ $(MeO)_3PO$ $<$ H_2O $<$ Ph_3PO $<$ Me_2SO $<$ $[F]^-$.

Thus the molecular donor ligands that have greater donor properties than Et_2O will displace 18-crown-6 in **1**, and THF, H_2O, Me_2SO, and other solvents cannot be used for the preparation and investigation of complex **1**.

Experimental Section

General Remarks: All operations were performed with standard Schlenk line techniques under a purified nitrogen atmosphere. Solid reagents and crystals were manipulated in a Vacuum Atmospheres Dri-Lab equipped with a Dri-Train (HE-493) and 1 kg of 3 Å molecular sieves contained in an internal circulating drying unit. Titanium tetrafluoride (99%, Across Organics) was purified by holding under 2.5 atm of F_2 for 4 days in the Monel metal vessel, 18-crown-6 (99.5%, Aldrich) was used as received, acetonitrile, THF, CH_2Cl_2, and $CDCl_3$ were dried over CaH_2 and degassed. NMR spectra were recorded with a Varian 400 NMR spectrometer. Proton shifts are reported in δ units downfield from Me_4Si, with the solvent as the reference signal. $CClF_3$ was used as a reference for the ^{19}F NMR spectra. NMR samples were prepared in 5 mm NMR tubes fitted with J. Young valves. Mass spectra were recorded on a KRATOS ms 50 TC mass spectrometer equipped with an EI source (30 eV), from samples sealed in dried glass m.p.t. tubes by the direct inlet method. FT-IR spectra were recorded on a Thermo Nicolet spectrometer (Nexus 470 FT-IR), and FT-Raman spectra were obtained from neat samples, sealed under a nitrogen atmosphere in glass capillaries, using an FT-IR spectrometer (Bruker IFS66)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

equipped with an FT-Raman accessory (Bruker FRA 106), incorporating a Nd-YAG laser (emission wavelength: 1064 nm; maximum laser power: 300 mW). Melting points were measured in sealed capillary tubes under nitrogen and are not corrected. Elemental analysis was carried out by Galbraith Laboratories, Inc.

Preparation of [$(TiF_4)_2$(18-Crown-6)] (1): Acetonitrile (30 mL) was condensed into the mixture of TiF_4 (0.8 g, 6.5 mmol) and 18-crown-6 (0.8 g, 3.0 mmol) at −79 °C, and the solution was warmed to 50 °C to dissolve the reagents. The obtained solution was filtered, concentrated to ca. 10−15 mL, and left at room temperature for 5 days. Colorless crystals were separated by filtration, washed three times with cold (−20 to −40 °C) CH_2Cl_2 (5 mL). Yield 0.8 g (50% based on 18-crown-6). M.p. 141−143 °C decomposition. $C_{12}H_{24}F_8O_6Ti_2$ (512.1): calcd. C 28.12, H 4.69, F 29.68; found C 28.00, H 4.55, F 29.20. EI-MS (30 eV, heating room temperature −170 °C): *m/z* = 368 (0.2) [TiF_3(18-crown-6)$^+$], 264 (5) [(18-crown-6)$^+$], 221 (8) [(18-crown-6)−$C_2H_4O^+$], 204 (1) [$TiF_2C_5O_3H_{10}^+$], 188 (3) [$TiF_2C_5H_{10}O_2^+$], 177 (50) [(18-crown-6)−$C_4H_8O_2^+$], 174 (12) [$TiF_2C_4H_8O_2^+$], 161 (3) [(18-crown-6)−$C_4H_8O_3^+$], 159 (3) [$TiF_2C_3H_5O_2^+$], 146 (4) [$TiF_2C_2H_4O_2^+$], 132 (65) [(18-crown-6)−$C_6H_{12}O_3^+$], 116 (35) [$TiF_2CH_2O^+$], 105 (90) [TiF_3^+], 88 (100) [$C_4H_8O_2^+$], calculated theoretical isotops distribution matched that experimentally observed for all peaks. ^{1}H NMR (400 MHz, $CDCl_3$, −60 °C, undissolved solid is present in the NMR ampoule): δ_H = 3.59 (br., 4 H, 7%), 3.64 (s, 4 H), 3.70 (s, 4 H), 3.73 (s, 4 H), sum of the relative intensities of the resonances 3.64, 3.70, 3.73 is 68%, 3.76 (s, 4 H, 2%), 3.80 (s, 4 H, 2%), 3.92 (br., 4 H, 7%), 4.36 (br., 4 H, 7%), 4.57 (br., 4 H, 7%) ppm. ^{19}F NMR (376.3 MHz, $CDCl_3$, −60 °C, undissolved solid is present in the NMR ampoule): δ_F = 260.1 (m, 6F, *face*-[TiF_3(μ-F)$_3$TiF_3]$^-$, 32%), 236.4 (br., [TiF_4(18-crown-6)], 26%), 149.7 (br., [TiF_4(18-crown-6)], 26%), −17.8 (br., 3F, *face*-[TiF$_3$(μ-*F*)$_3$TiF$_3$]$^-$, 16%), −51.3 (C−F), −69.1 (CDF_3), −73.8 (CDF_2Cl), −75.1 (CD*F*Cl$_2$) ppm. ^{19}F NMR (MeCN, room temperature): δ_F = 324 [*face*-TiF_3(MeCN)$_3$], 306 to −260 [{*face*-TiF_3(MeCN)$_x$(μ-F)$_{3-x}$}$_y$, *x* = 0−2], 263.5 (*face*-[TiF_3(μ-F)$_3$TiF_3]$^-$), 232 (br., [TiF_4(18-crown-6)]), 230.3 (br), 215 (br., *cis*-TiF_4-(MeCN)$_2$], 158 (br. Raman (solid): $\tilde{\nu}$ = 3026 (s), 3011 (s), 2965 (vs), 2932 (w), 2902 (m), 2874 (s), 2860 (m), 2826 (m), 2743 (w), 1473 (m), 1455 (s), 1425 (w), 1394 (w), 1378 (w), 1352(w), 1295 (m), 1268 (m), 1249 (m), 1236 (w), 1159 (w), 1139 (w), 1117 (w), 1098 (w), 1076 (w), 1060 (w), 1028 (w), 954 (w), 929 (m), 836 (m), 788 (m), 673 (vs, TiF_4), 589 (vs, TiF_4), 558 (w), 505 (w), 422 (w), 354 (w), 336 (w), 284 (m), 265 (m), 245 (m), 229 (w), 209 (w), 179 (w), 108 (w) cm^{-1}. Raman (160−4000 cm^{-1}) spectrum of the compound **1** is given in the Supporting Information (Figure S4).

Interaction of Complex 1 with H_2O: Complex **1** (0.1 g, 0.2 mmol) was loaded into a 5 mm NMR tube, and MeCN (0.7 mL) was added. Four aliquots of H_2O (4 × 0.003.510^{-3} mL) were added by means of a micro syringe. Addition of 3 or 4 equivalents of H_2O (0.6, 0.8 mmol of H_2O) to the solution of **1** leads to precipitation of the white product **2**. Finally, MeCN was removed by decantation, and the resulting solid dried under dynamic vacuum for 1 hour. Recovered 0.11 g of the solid **2**. Yield of **2** 95% (based on **1**). All NMR spectroscopic data are given in the Supporting Information. M.p. 205−207 °C decomposition. $C_{12}H_{32}O_{10}Ti_2F_8$ (584.2): calcd. Ti 16.43; found Ti 16.50. EI-MS (30 eV, heating room temperature −170 °C): *m/z* = 264 (1) [(18-crown-6)$^+$], 254 (2) [M^+ − 2HF − $C_6H_{12}O_3$], 252 (2) [M^+ − $2H_2F$ − $C_6H_{12}O_3$], 221 (1) [(18-crown-6)−$C_2H_4O^+$], 177 (6) [(18-crown-6)−$C_4H_8O_2^+$], 175 (2) [$TiF_2C_4H_9O_2^+$], 133 (10) [$TiFO_4H_2^+$], 117 (6) [$TiFO_3H_2^+$], 101 (20) [TiF_2O^+], 105 (15) [TiF_3^+], 88 (100) [$C_4H_8O_2^+$], 72 (30) [$C_4H_8O^+$], 58 (50) [$C_3H_6O^+$], 45 (100) [$C_2H_5O^+$], calculated theoretical isotope distribution matched that experimentally observed for all peaks. ^{1}H NMR (400 MHz, MeCN, room temperature): δ_H = 5.0 (br), 4.3 (18-crown-6) ppm. ^{1}H NMR (400 MHz, MeCN, −35 °C): δ_H = 7.5 (*H*$_2$O), 5.2 (br), 4.2 (18-crown-6) ppm. ^{19}F NMR (MeCN, room temperature): δ_F = 262.1 (m, 6F, *face*-[TiF_3(μ-F)$_3$TiF_3]$^-$, 10%), 233.0 (m, nF, 6%), 220.7 (m, 2nF, 12%), 214.5 (br., *cis*-TiF_4(H$_2$O)$_2$, 21%), 153.3 (br., *cis*-TiF_4(H$_2$O)$_2$, 21%), −11.7 (m, 2nF, 12%), −19.70 (m, 2nF, 12%), −21.6 (br., 3F, *face*-[TiF$_3$(μ-*F*)$_3$TiF$_3$]$^-$, 5%) ppm. ^{19}F NMR (MeCN, −35 °C): δ_F = 233.0 (m, nF, 7%), 220.7 (m, 2nF, 14%), 210.7 (*cis*-TiF_4(H$_2$O)$_2$, 24%), 148.3 (*cis*-TiF_4(H$_2$O)$_2$, 24%), −11.7 (m, 2nF, 14%), −19.70 (m, 2nF, 14%) ppm. IR (KBr, Perflouroalkyl ether, Fluorolube mull): $\tilde{\nu}$ = 3350−3150 [maximum 3295] (br., vs, H−O stretches), 2408 (w, H_2O), 1352 (s), 1298 (w), 1282 (m), 1269 (w) 1254 (m), 1244 (w), 1234 (w), 1197 (s), 1155 (m), 1124 (s), 1096 (vs), 962 (vs), 900 (s), 839 (s), 745 (m), 667 (s, TiF_4), 607 (s, TiF_4), 559 (s, TiF_4), 522 (m), 439 (w) cm^{-1}.

Reactions between TiF_4 and THF, and H_2O, leading to $TiF_4(THF)_2$ and $TiF_4(H_2O)_2$, respectively are described in the Supporting Information.

Crystal Growth and X-ray Crystallography: Crystals of **1** were grown by slow cooling of a saturated solution in acetonitrile from room temperature to +5 °C. Crystals of **2** were grown by slow diffusion of water vapor into a saturated solution of **1** at +5 °C. Single crystals were coated with Paratone-N oil, mounted using a glass fiber, and frozen in cold nitrogen and mounted on the goniometer. The structure of **1** was measured on a Bruker AXS P4/SMART 1000 diffractometer and that of **2** was measured on a Rigaku AFC5R diffractometer. The data of the major component of **1** and **2** were reduced (SAINT)[38] and corrected for absorption (SADABS).[39] The structures of **1** and **2** were solved by and expanded with Fourier techniques.[40] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were found in Fourier difference maps and refined isotropically. All calculations were performed with the SHELXTL[41a] (**1**) and teXsan[41] crystallographic software package of Molecular Structure Corporation (**2**). For the structure of **2**, neutral atom scattering factors were taken from Cromer and Waber.[42] Anomalous dispersion effects were included in $F_{calcd.}$;[43] the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley.[44] The values for the mass attenuation coefficients are those of Creagh and Hubbell.[45]

CCDC-35610 and CCDC-235611 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

1,2,4,5-Benzenetetracarboxylic Acid and 4,4′-Bipyridine as Ligands in Designing Low-Dimensional Coordination Polymers

Catalina Ruiz-Pérez,*[a] Pablo Lorenzo-Luis,[b] María Hernández-Molina,[a] M. Milagros Laz,[c] Fernando S. Delgado,[a] Pedro Gili,[b] and Miguel Julve[d]

Keywords: Hydrothermal / 1,2,4,5-Benzenetetracarboxylic acid / 4,4′-Bipyridine / Low-dimensional polymers / Manganese / Cobalt

The combined use of 1,2,4,5-benzenetetracarboxylic acid (H_4bta) and 4,4′-bipyridine (bpy) as ligands with Mn^{II} and Co^{II} ions afforded two polymeric compounds with the formulae [Mn(Hbta)(Hbpy)(H_2O)$_2$] (**1**) and [H_2bpy][Co(bta)(bpy)(H_2O)$_2$] (**2**). **1** and **2** were prepared under hydrothermal conditions (145 °C, 3 h) and characterized by elemental analysis, IR spectroscopy, TG-DTA analysis and single-crystal X-ray diffraction methods. **1** exhibits a novel double chain structure growing along the *b* axis where the manganese atoms are linked by tris-monodentate $Hbta^{3-}$ ligands. The values of the manganese···manganese intrachain separations are 7.627(2) Å [Mn(1)···Mn(1c); c = –x + 1/2, y – 1/2, –z] and 9.274(4) Å [Mn(1)···Mn(1d); *d* = x, y + 1, –z]. Adjacent double chains in **1** are further linked through hydrogen bonds between the NH fragment of the $Hbpy^+$ cation and one of the carboxylate groups of the $Hbta^{3-}$ anion along the *a* axis, resulting in a sheetlike structure. **2** exhibits a rectangular grid arrangement of cobalt atoms bridged by bis-monodentate bta^{4-} and bpy ligands in the *bc* plane, the cobalt···cobalt separations across them being 6.228(2) and 10.074 (2) Å, respectively. The metal atoms in **1** and **2** are six-coordinate with two water molecules in *trans* positions (**1** and **2**), three (**1**)/two (**2**) carboxylate oxygen atoms and one (**1**)/two (**2**) pyridyl nitrogen atoms forming a distorted octahedral environment. The varying nature of the divalent metal ions [Mn **1** and Co **2**] along with the differing degrees of protonation of the tetracaboxylate [$Hbta^{3-}$ **1** and bta^{4-} **2**] and bipyridyl [$Hbpy^+$ **1** and bpy and H_2bpy^{2+} **2**] species account for the structural differences between **1** and **2**.

Introduction

The crystal engineering of supramolecular architectures or metal-organic coordination polymers is a growing field and it has attracted much attention in the past decades.[1−4] With the recent development of self-assembly supramolecular chemistry, it is possible to rationally design and synthesize supramolecular architectures or metal-organic coordination polymers based on covalent or supramolecular contacts (such as forces resulting from intermolecular non-bonded, non-covalent electrostatic forces (due to static and oscillating fixed charge interactions) and dispersion forces (due to induced transient charge interactions).[5−7] However, the assembly of molecular materials from organic ligands and metal ion building blocks to generate new supramolecular architectures is still a challenge.[8−10] Two main methods can be envisaged in order to construct open supramolecular architectures on the basis of the different interactions between the building blocks: one takes advantage of the covalent bonds and the other focuses on the supramolecular contacts.[11] The use of covalent bonds to link metal ions and organic molecules such as polycarboxylic acids or 4,4′-bipyridine (bpy), has resulted in a large number of porous frameworks with different dimensionalities and topologies.[12−15]

It is worth noting that the coordination ability of aromatic polycarboxylic acids towards transition metal complexes has received considerable attention due to the variety of the bridging modes of the carboxylate group with regards to the formation of extended frameworks.[16,17] The goal in the search for organic porous frameworks is not simply to mimic inorganic materials by using different

building blocks. Some of the properties of organic compounds, such as low stability and low Lewis acidity, are inherently different. In this sense, 1,2,4,5-benzenetetracarboxylic acid (hereafter noted H_4bta) possesses several interesting characteristics: (a) it has four carboxylic groups whose deprotonation (partial or total) and subsequent coordination to the metal ions affords interesting structures with tunable dimensionality; (b) it can act not only as a hydrogen bond acceptor but also as a hydrogen bond donor, depending upon the degree of deprotonation; (c) due to steric hindrance, some of the carboxylic groups may not lie in the plane of the phenyl ring upon complexation to the metal ions, and thus, they can connect metal ions in different directions. Hence, H_4bta is a good choice for the construction of polymeric structures, as proved by the large number of metal-organic structures obtained from the Cambridge Structural Database (CSD).[18] The versatility of the deprotonated forms of H_4bta as ligands is illustrated by Scheme 1.

Our research group is engaged in the design of extended arrays of metal ions with mixed ligands, and recently, we obtained a supramolecular loop-chain network of pillared layers via 4,4′-bipyridine.[19] Our first attempts, using H_4bta and bpy as ligands towards first row transition metal ions, afforded the new coordination polymers [Mn(Hbta)(Hbpy)$(H_2O)_2$] (**1**) and H_2bpy[Co(bta)(bpy)$(H_2O)_2$] (**2**) (see Scheme 2). To the best of our knowledge,[18] compound **1** exhibits an unprecedented connection mode for the H_4bta ligand (see Scheme 1). The preparation, structural characterization, spectroscopic and thermal investigations of complexes **1** and **2** are presented here.

Results and Discussion

Description of the Structures

[Mn(Hbta)(Hbpy)$(H_2O)_2$]$_n$ (1)

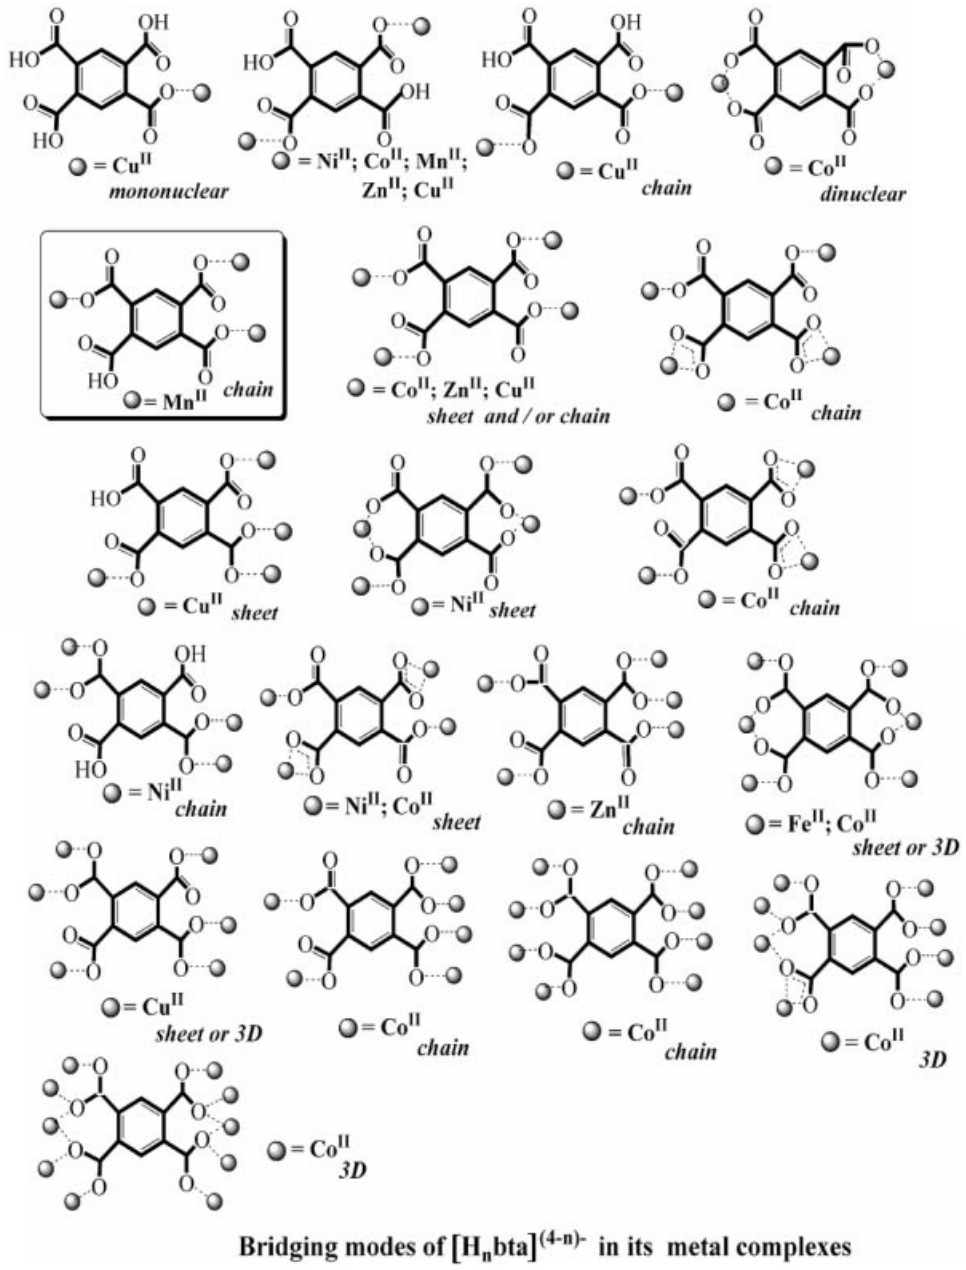
The structure of **1** is made up of neutral double zigzag chains of formula [Mn(Hbta)(Hbpy)$(H_2O)_2$] which run parallel to the *b* axis (Figure 1, a) with $Hbta^{3-}$ acting as a tris-monodentate bridging ligand. The resulting ribbon-like motifs are further linked via N−H···O hydrogen bonds involving the protonated pyridyl nitrogen of bpy [N(1)] and one of the carboxylate oxygen atoms [O(2b); b = $-x - 1/2, y - 1/2, z$] of the $Hbta^{3-}$ ligand (see Table 1) affording a sheet-like structure in the *ab* plane (Figure 1, b). The Mn(1) atom has a slightly distorted octahedral environment (MnO_5N) with two *trans* water molecules filling the axial positions (see Figure 2) The $Mn-O_{(carboxylate)}$ and $Mn-N_{(Hbpy^+)}$ bond lengths are in agreement with previous data of carboxylate- and bpy-containing manganese(II) complexes.[20] The $Hbta^{3-}$ anion is not planar since the dihedral angles between the COO groups and the aromatic ring of $Hbta^{3-}$ are 57.9(2) Å [O(1)−C(7)−O(2)], 64.5(2) Å [O(3)−C(8)−O(4)], 5.0(3) Å [O(5)−C(9)−O(6)] and 8.9(2) Å [O(7)−C(10)−O(8)]. The deprotonated carboxylate groups of each $Hbta^{3-}$ [O(1)−C(7)−O(2), O(3)−C(8)−O(4) and O(7)−C(10)−O(8)] are coordinated to three manganese atoms [Mn(1), Mn(1c) and Mn(1d) through O(7), O(1) and O(4), respectively; symmetry code: c = $-x + 1/2, y - 1/2, z$; d = $x, y + 1, -z$]. The values of the Mn···Mn separation through the $Hbta^{3-}$ ligand are 7.627(2) [Mn(1)···Mn(1c)] and 9.274(4) Å [Mn(1)···Mn(1d)]. The protonated carboxylic group remains uncoordinated but contributes to the stabilization of the structure through an extensive network of hydrogen bonds together with the water molecules and the free carboxylate oxygen atoms (see Table 1).

The pyridyl rings of the monoprotonated $Hbpy^+$ species are planar but the ligand as a whole is far from being planar [dihedral angle between the two pyridyl rings is 12.32(14)°]. $Hbpy^+$ acts as a terminal monodentate ligand being coordinated to the manganese atom through the nonprotonated N(2) pyridyl atom. The $Hbpy^+$ ligands are alternatively located right and left of each double chain (Figure 1, a) in such a way that the $Hbpy^+$ groups from two adjacent double chains are stacked along the *b* axis (Figure 1, b). The separation between the mean pyridyl planes of adjacent $Hbpy^+$ groups is 3.969(9) Å, a value that supports the occurrence of very weak π-π stacking interactions. Finally, weaker $C-H_{(Hbpy^+)}\cdots O_{(Hbta^{3-})}$ supramolecular interactions, the values of the C···O separations being less or equal than 3.22 Å (the sum of the van der Waals radii of the interacting atoms), are also observed.[18]

[H_2bpy]·[Co(bta)(bpy)$(H_2O)_2$]·(2)

The structure of this complex consists of a two-dimensional rectangular grid of *trans*-diaquacobalt(II) ions growing in the *ab* plane with bta^{4-} and bpy ligands acting as bis-monodentate bridges within each layer (Figure 3, a). These layers are connected to each other through hydrogen bonds between the protonated pyridyl nitrogen atoms of H_2bpy^{2+} [N(3)] and one of the uncoordinated carboxylate oxygen atoms [O(3)] (Figure 3, b and Table 1) to afford a three-dimensional network. In contrast to **1**, fully deprotonated bta^{4-} and both neutral bpy and diprotonated H_2bpy^{2+} are present in **2**. As in **1**, each Co^{II} ion has a somewhat distorted octahedral arrangement with two trans water molecules in the axial positions (Figure 4). The $Co-O_{(bta)}$ [2.077(2) Å] and $Co-N_{bpy}$ [2.169(3) Å] bond lengths are also in agreement with those reported for carboxylate- and bpy-containing cobalt(II) complexes.[21,22] The bta^{4-} ligand is not planar; the dihedral angles between the carboxylate groups and the mean plane of the phenyl ring are 56.75(10)° [C(1)−C(4)−O(1)−O(2)] and 33.94(9)° [C(5)−C(2)−O(3)−O(4)]. Each bta^{4-} group acts as a *trans* bis-monodentate ligand bridging two symmetry related Co^{II} ions thus affording a uniform chain of cobalt atoms along the (101) direction, the cobalt···cobalt separation across bridging H_2bta being 11.248(3) Å. These chains are cross-linked by bridging bis-monodentate bpy ligands along the *b* axis leading to a two dimensional quasi-square grid of cobalt atoms. The cobalt···cobalt separation through the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 1

bpy bridge is 11.476(2) Å. The pyridyl rings of bpy are practically planar within experimental error, but the ligand as a whole deviates significantly from planarity [the dihedral angle between the mean planes of the two pyridyl rings is 19.29(1)°]. Centrosymmetric H_2bpy^{2+} cations are placed between the layers and they link these layers into a three-dimensional network through hydrogen bonds of the type N−H···$O_{carboxylate}$, the shortest cobalt···cobalt interplanar separation being 8.977(3) Å. Additional hydrogen bonds involving coordinated water molecules and one carboxylate oxygen atom [2.728(4) Å for O(1w)···O(4c) (c = $-x, -y + 1, -z + 1$) contribute to the stabilization of this 3D network.

Infrared Spectra and TG-DTA Analysis

The infrared spectra of the two complexes are quite similar, with a broad band centered at ca. 3395−3370 which is due to the O−H stretching vibration of water molecules involved in extensive hydrogen bonding interactions.[23] Furthermore, they exhibit the $\nu_{as(OCO)}$ and $\nu_{s(OCO)}$ vibrations of the carboxylate groups which occur at 1690 and 1490 cm^{-1} for **1** and at 1680 and 1480 cm^{-1} for **2**, respectively. $\Delta\nu[\nu_{as(COO)} - \nu_{s(COO)}]$ is ca. 200 cm^{-1} for both complexes, a value which suggests the occurrence of monodentate coordination of the carboxylate groups.[24] This is also in agreement with the crystal structure (vide supra). Less

significant absorptions occur at 3050 (stretching vibrations of aromatic C−H groups), 820−700 (out-of-plane C−H bending of phenyl and pyridyl rings) and 557 cm^{-1} ($\nu_{(M-N)}$ vibration).[25,26]

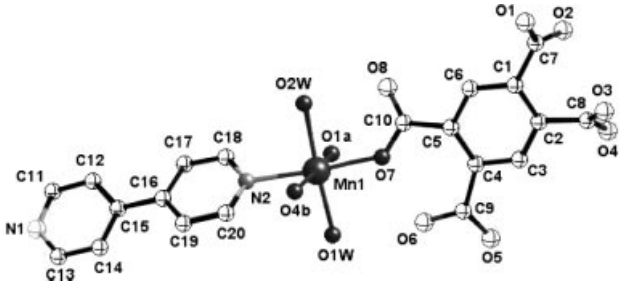

Figure 2. Coordination sphere of the manganese atom in $[Mn(Hbta)(Hbpy)(H_2O)_2]_n$ (**1**)

The $[Mn(Hbta)(Hbpy)(H_2O)_2]$ and H_2bpy $[Co(bta)(bpy)(H_2O)_2]$compounds show a similar thermal behavior. Two steps are observed in the TG-DTG/DTA curves of **1** and **2** (Figure S1, supplementary material): the first one, no thermal decomposition of the compounds occurs, confirming that the networks remain stable below ca. 174 °C; the second one, three overlapped weight loss peaks are observed {$[T_{strong\ peak}]_{DTG}$ ca. 230 °C; $[T_{little\ peak}]_{DTG}$ ca. 374 °C and $[T_{little\ peak}]_{DTG}$ ca. 455 °C}. This last process is followed by two strong endothermic peaks {$[T_{strong\ peaks}]_{DTA}$ ca. 190 and 233 °C for **1** and ca. 140 and 228 °C, for **2**} whose weight loss corresponds to the release of H_2O, H_4bta and bpy groups, in agreement with another similar complex $[H_2bpy][H_3bta]_2$, recently reported.[19]

Conclusion

Two polymeric complexes with chains or rectangular grids, $[Mn(Hbta)(Hbpy)(H_2O)_2]_n$ (**1**) and $[H_2bpy][Co(bta)(bpy)(H_2O)_2]$ (**2**), respectively, were constructed from 1,2,4,5-benzenetetracarboxylic acid (H_4bta) in the presence of an auxiliary ligand (4,4′-bipyridine) under hydrothermal conditions. The auxiliary ligand, play an important role in the synthesis of the complexes by engaging in coordination or acting as a template. The coordination modes of the H_4bta ligands in the two complexes are different, to the

best of our knowledge, where **1** exhibits an unprecedented connection mode. In both compounds, the introduction of mixed ligands provides the probability of generating multiple binding forces, such as coordination bonds, hydrogen bonding and other supramolecular interactions.

Experimental Section

General Remarks: Elemental analyses (C, N N) were carried out with an EA 1108 CHNS-0 automatic analyzer. FT-IR spectra were performed with a ThermoNicolet Avatar 360 FT-IR spectrometer on samples prepared as KBr pellets. Thermal analyses (TG-DTA) were done on a PerkinElmer Diamond TG-DTA system (SEGAI Service of the University of La Laguna) under a nitrogen atmosphere (flow rate: 80 $cm^3\ min^{-1}$) in the temperature range 290−550 °C. The samples [3.542 **1** and 1.351 mg **2**] were heated in an aluminium crucible (45 μL) at a rate of 10 °C min^{-1}. The TG curves were analyzed by mass loss as a function of temperature. The number of decomposition steps was identified by using the derivative thermogravimetric curve (DTG). The DTA curves were analyzed as differential thermal analysis [$\Delta T(\mu V)$].

$[Mn(Hbta)(Hbpy)(H_2O)_2]_n$ (1) and $[H_2bpy]\cdot[Co(bta)(bpy)(H_2O)_2]$ (2): The reagents and solvents were purchased from commercial sources (Aldrich) and used as received. These compounds were prepared similarly to $[H_2bpy][H_3bta]_2$.[19] Thus, for compound **1**, a sample of manganese acetate tetrahydrate (0.35 mmol) was dissolved in 5 mL of deionized water. 1,2,4,5-benzenetetracarboxylic acid H_4bta (0.39 mmol) was suspended in 5 mL of H_2O/NaOH (0.75 mmol) whilst stirring at ambient temperature for 10 min. A water solution of 4,4′-bipyridine bpy (0.75 mmol) was added dropwise to a 1,2,4,5-benzenetetracarboxylic acid solution. After that the clear solution, was mixed with the previously prepared manganese acetate whilst stirring. The mixture was then transferred to a

reaction vessel placed inside a preheated oven at 145° for 3 h. The compound **2**, was prepared similarly to the manganese compound from $Co(NO_3)_2{\cdot}6H_2O$ (0.36 mmol). After several days, crystals of **1** and **2** were manually harvested under the microscope and analyzed using single-crystal X-ray diffraction (see Table 2). (**1**) $C_{20}H_{16}MnN_2O_{10}$ (499.3): calcd. C 48.11, H 3.23, N 5.61; found C 48.21, H 3.45, N 5.76. (**2**) $C_{30}H_{24}CoN_4O_{10}$ (659.5): calcd. C 54.64, H 3.67, N 8.50; found C 53.82, H 3.58, N 8.05.

X-ray Crystallographic Study: Diffraction experiments for **1** and **2** were carried out with Mo-K_α radiation using a Nonius KappaCCD diffractometer at 273(1) K. A summary of the crystallography data and structure refinement is given in Table 2. Both structures were solved by direct methods and refined with the full-matrix least-squares technique on F^2 using the SHELXS-97[27] and SHELXL-97[28] programs. All non-hydrogen atoms were refined anisotropically. All hydrogen atoms bound to carbon were placed in calculated positions and refined isotropically. The hydrogen atoms of the water molecules and those of the carboxylic groups were found in a difference Fourier map and refined isotropically for compound **1**. The final full-matrix least-squares refinement was performed minimizing the function $\Sigma w(|F_o|^2 - |F|^2)$ with $w = 1/[\sigma^2(F_o)^2 + mP^2 + nP]$ and $P = (F_o^2 + 2F_c^2)/3$ with $m = 0.0197$ **1** and 0.0183 **2** and $n = 7.3045$ **1** and 12.1543 **2**. The values of the discrepancy indices $R1$ ($wR2$) for all data were 0.1437 (0.1186) for **1** and 0.1204 (0.1224) for **2**, whereas those listed in Table 2 correspond to the data with $I > 2\sigma(I)$. The final Fourier difference map showed maximum and minimum height peaks of 0.512 and −0.394 eÅ^{-3} for (**1**) and 0.523 and −0.515 eÅ^{-3} for (**2**). The final geometrical calculations and the graphical manipulations were carried out with PARST95[29] and PLATON[30] programs, respectively. Selected bond lengths (Å) and angles (°) for **1** and **2** are listed in Table 3 and Table 4, respectively. CCDC-231515 (for **1**) and -231516 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Investigation of a Neat versus Magnetically Diluted Powdered Mononuclear Mn^{II} Complex by High-Field and High-Frequency EPR Spectroscopy

Claire Mantel,[a,b] Christian Philouze,[c] Marie-Noëlle Collomb,*[b] and Carole Duboc*[a]

Keywords: Azide ligand / Electronic structure / EPR spectroscopy / Manganese / Magnetic dilution

The isolation, structural characterization and electronic properties of a new mononuclear, pentacoordinate Mn^{II} complex [Mn(*t*Buterpy)$(N_3)_2$] (**1**; *t*Buterpy = 4,4′,4′′-tri-*tert*-butyl-2,2′:6′,2′′-terpyridine) is reported. The X-ray structure of **1** reveals that the manganese ion lies in the center of a distorted trigonal bipyramid. The electronic properties of **1** were investigated by high-field and high-frequency EPR (HF-EPR) spectroscopy, allowing the determination of the spin-Hamiltonian parameters. HF-EPR spectra were recorded on a neat powder of **1** and also on **1** magnetically diluted in the corresponding zinc complex. From the neat powder HF-EPR spectra, the following *g* and zero-field-splitting terms, as well as the sign of *D*, were obtained: $D = -0.250(5)$ cm^{-1}, $E = 0.044(5)$ cm^{-1} and $g_x = g_y = g_z = 2.000(5)$. The magnetically diluted sample allows the determination of the hyperfine coupling constant *A* and confirms the values of the parameters determined with the neat powder: $|D| = 0.260(1)$ cm^{-1}, $E = 0.043(1)$ cm^{-1}, $g_x = g_y = 2.001(1)$ $g_z = 2.0005(5)$ and $A_{xx} = A_{yy} = A_{zz} = 77.5(5)$ G. A comparison between these two sets of spin-Hamiltonian parameters is discussed, as well as the correlation between the *D* parameter and the coordination number around the manganese ion for a coordination shell characterized by O and/or N atoms (i.e. Mn^{II}-containing proteins).

Introduction

Mononuclear Mn^{II} complexes are present in several metalloproteins implicated in various important biological processes. Examples include manganese superoxide dismutase, an antioxidant enzyme that catalyzes the dismutation of the superoxide radical,[1] concanavaline A, a saccharide-binding protein,[2] the fosfomycin resistance protein implicated in the resistance against the antibiotic fosfomycin,[3] and several others.[4] Since the manganese site is essential for their activity, a precise determination of the geometry and the coordination shell of the metallic ion is required to understand the reactivity of these proteins. One of the best techniques used to elucidate the electronic structure of a metallic center is EPR spectroscopy. In particular, X-band EPR spectroscopy (9.4 GHz) has been used to study several biological Mn^{II} sites.[1b−1d,2c,2d,3,4]

High-spin Mn^{II} ($3d^5$) is characterized by a fundamental electronic spin *S* of 5/2 and a nuclear spin *I* also of 5/2 (^{55}Mn, 100%). Its electronic properties are described by the spin-Hamiltonian of Equation (1).

$$H = \beta B \cdot g \cdot S + I \cdot A \cdot S + D[S_z^2 - 1/3S(S+1)] + E(S_x^2 - S_y^2) \quad (1)$$

The first two terms represent the electronic Zeeman and the electron nuclear hyperfine interactions, respectively, whereas the last two terms define the zero-field splitting (zfs) interaction, with *D* and *E* weighting the axial and rhombic parts.

A typical Mn^{II} EPR spectrum for mononuclear complexes with small zfs parameters, recorded under highly diluted conditions (in solution) and at high temperature, is characterized by a unique feature centered at $g \approx 2.0$ as a sextuplet. These six lines originate from the hyperfine splitting of the central transition $|5/2, -1/2> \rightarrow |5/2, +1/2>$, as shown in Figure 1. The shape of the sextuplet depends on the magnitude of the different spin-Hamiltonian terms. When the zfs terms increase, the X-band EPR spectrum becomes increasingly more complicated and almost impossible to interpret, with broad transitions between 0 and 0.5 mT. In this case, the way to simplify the Mn^{II} EPR spectra is to record them at higher microwave frequencies such as 35 GHz (Q-band EPR), 95 GHz or even up to 285 GHz

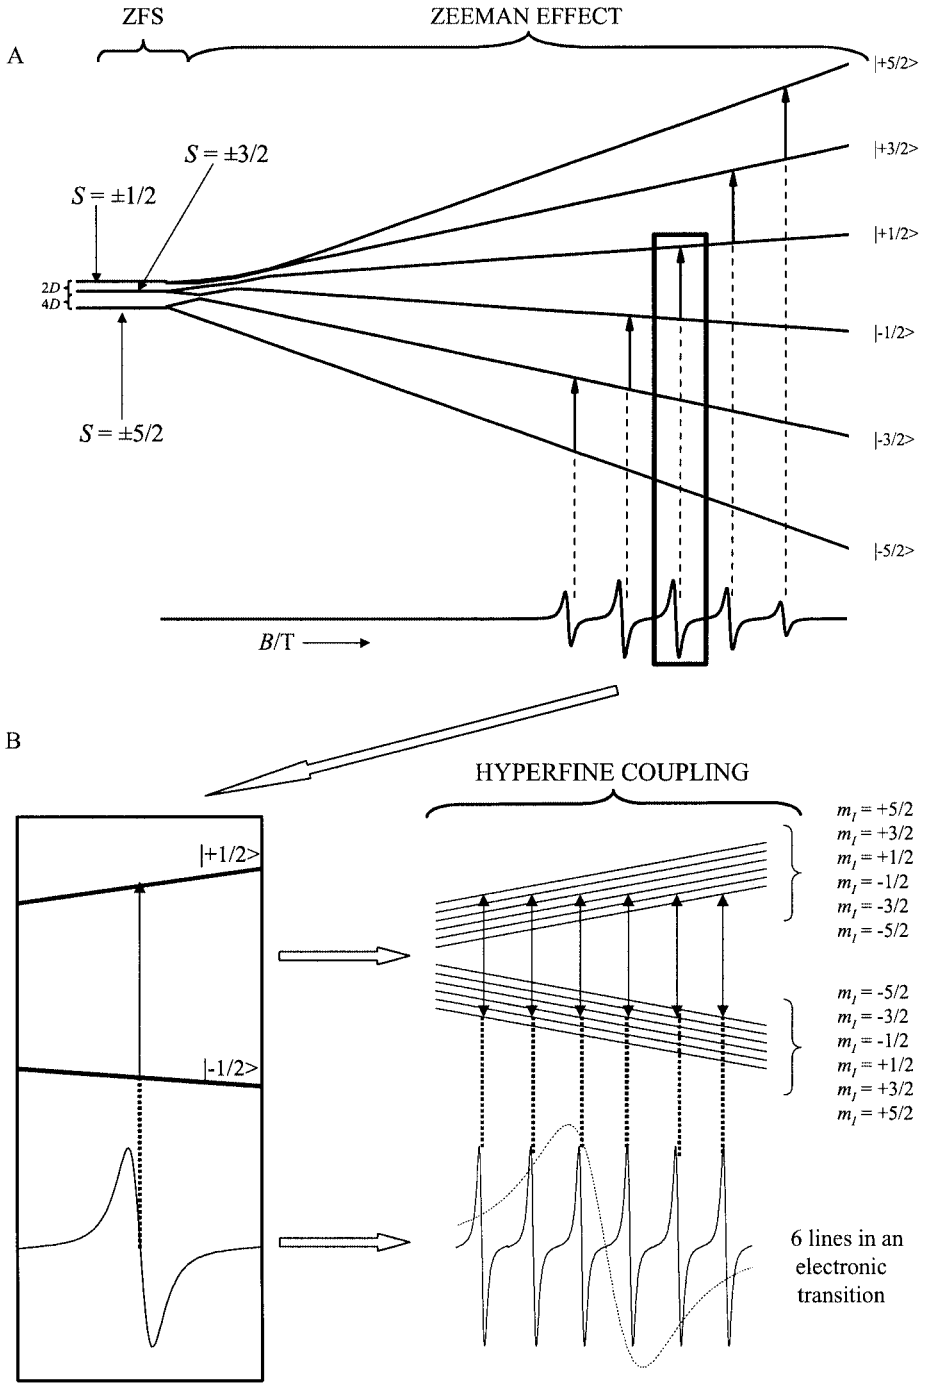

Figure 1. (A) Schematic representation of the energy level diagram of an $S = 5/2$ system undergoing axial zero field splitting (zfs) (negative D) and Zeeman effect with the field parallel to the z axis; (B) extended view of the $Ms = \pm 1/2$ energy levels showing the hyperfine levels for $I = 5/2$; arrows indicate the allowed transitions and the resulting spectra are given

(high-field EPR, HF-EPR). Indeed, HF-EPR spectroscopy (frequency 95 GHz) and derived techniques such as high-field ENDOR have proven to be useful tools.[1d,1e,2d,5] Under high-field conditions ($D << g\beta B$), EPR spectra recorded on an Mn^{II}-containing protein solution exhibit a simplified sextuplet from which the spin-Hamiltonian parameters can be extracted. However, when the magnitude of D is very large ($|D| > 0.2$ cm^{-1}), even at high field (285 GHz, $g = 2$ at 10.2 T), the central transition $|5/2, -1/2> \rightarrow |5/2, +1/2>$ appears as a signal characterized by more than six lines.[1d,1e] With such Mn^{II} systems, a multi-frequency HF-EPR study is necessary for a precise determination of the spin-Hamiltonian parameters.

Concerning the other transitions of the paramagnet $S = 5/2$ displayed in Figure 1, four others are expected along each magnetic axis. However, they are rarely observed and studied by X-band EPR spectroscopy, especially when the experiments are performed in solution.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

X- and Q-band EPR studies performed on powdered or crystalline samples of synthetic mononuclear Mn^{II} complexes have also been reported.[6] The analysis of the EPR spectra is feasible for systems with small *D* values due to the observation of some or all expected transitions. Nevertheless, Mn^{II} complexes are often characterized by relatively large axial zfs, and when *D* is larger than or similar to the energy provided by the EPR spectrometer, the spectra become more complicated and not interpretable. Furthermore, with neat powder samples the hyperfine interactions cannot be observed. In order to detect them, the manganese complexes need to be diluted into a diamagnetic host. In the few studies related to magnetic dilution,[7] the X- or Q-band EPR spectra show several transitions split by hyperfine interactions that can help with the determination of the spin-Hamiltonian parameters when *D* is relatively large.

Another way to obtain interpretable spectra of manganese(II) complexes with large *D* values is the use of HF-EPR spectroscopy. In this case, with neat powder samples more, or even all, transitions can be then observed than with X-band, allowing the precise determination of the spin-Hamiltonian parameters. To the best of our knowledge, only two HF-EPR studies, showing complete or quasi-complete EPR spectra of Mn^{II} complexes, have been reported so far.[8] The compounds were three series of synthetic mononuclear dihalo complexes with distorted octahedral[8a] or tetrahedral[8b] geometries. The HF-EPR experiments were carried out on neat powder samples at 94.5 and 250 GHz avoiding the observation of hyperfine splitting in the different electronic-spin transitions. The spin-Hamiltonian parameters were determined, although the sign of *D* was not extracted since the experiments were performed at room temperature.

In this paper, we report the synthesis, the crystallographic characterization and an HF-EPR study (190−285 GHz) of a new synthetic pentacoordinate inorganic complex: [Mn(*t*Buterpy)$(N_3)_2$] (**1**; *t*Buterpy = 4,4′,4′′-tri-*tert*-butyl-2,2′:6′,2′′-terpyridine). The EPR experiments were performed both on a neat powder of **1** and on the complex diluted into the corresponding zinc(II) complex, [Zn(Mn)(*t*Buterpy)$(N_3)_2$]. We chose this solid magnetic dilution rather than a dilution of **1** in a solvent in order to maintain the pentacoordination of **1**. This work allows us to compare the spin-Hamiltonian parameters obtained in both conditions (neat and magnetically diluted samples of **1**). We can thus discuss the validity of the approach developed for several Mn^{II} protein EPR studies in which only the sextuplet is used to determine the electronic structure of the Mn^{II} site.

Results

Description of the Crystal Structure of [Mn(*t*Buterpy)$(N_3)_2$] (1)

The crystal structure of complex **1** was determined by single-crystal X-ray crystallography and its structure is shown in Figure 2.[9] The principal crystallographic data are given in the Exp. Sect., while Table 1 summarizes selected bond lengths and angles.

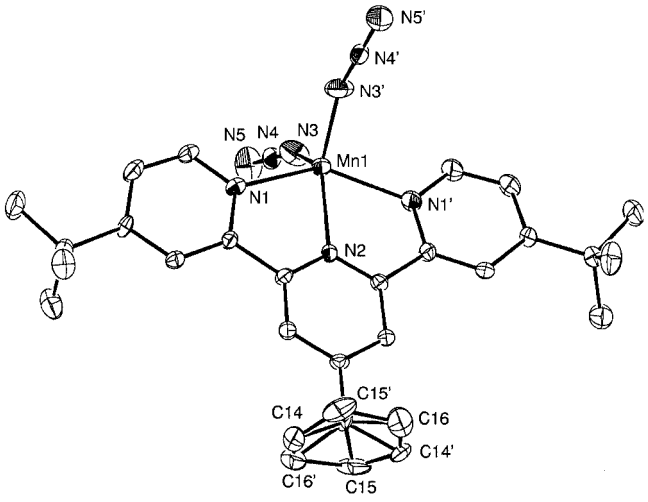

Figure 2. ORTEP view of [Mn(*t*Buterpy)$(N_3)_2$]; hydrogen atoms have been omitted for clarity

Table 1. Selected bond lengths [Å] and angles [°] for complex **1**

Mn−N(1)	2.249(5)	N(1)−Mn−N(1′)	144.1(2)
Mn−N(2)	2.206(5)	N(1)−Mn−N(3)	101.0(2)
Mn−N(3)	2.038(5)	N(1)−Mn−N(3′)	99.6(2)
N(1)−Mn−N(2)	72.0(1)	N(3)−Mn−N(3′)	108.8(3)
N(2)−Mn−N(3)	125.6(2)		

The manganese ion lies in the center of a distorted trigonal bipyramid. The equatorial plane is occupied by two nitrogen atoms of the two azide ligands [N(3) and N(3′)] and the central nitrogen atom [N(2)] of *t*Buterpy. The two distal *t*Buterpy nitrogen atoms [N(1) and N(1′)] are in the axial positions. The structure possesses a rotational C_2 symmetry axis passing through the Mn and N(2), atoms implying that the atoms N(3) and N(3′) are crystallographically equivalent, as are N(1) and N(1′). It can also be seen that the *tert*-butyl group of the central pyridine ring rotates around this C_2 axis. This implies that each carbon atom of the *tert*-butyl group [C(14), C(15) and C(16)] possesses two equivalent crystallographic sites whose occupancy ratio is 50%. The $Mn-N_{tButerpy}$ bond lengths and the angles N(1)−Mn−N(1′) and N(1)−Mn−N(2) are typical for mononuclear (terpy)Mn^{II} complexes.[10] The Mn−N(2) distance [2.206(5) Å] is shorter than the Mn−N(1) distance [2.249(5) Å].[10] The magnitude of the N(1)−Mn−N(1′) [144.1(2)°] is reduced from the theoretical value of 180° of an idealized trigonal bipyramid due to the rigidity of the *t*Buterpy ligand. The angles between the atoms in the equatorial positions are 125.6(2)° [N(2)−Mn−N(3){N(3′)}] and 108.8(3)° [N(3)−Mn−N(3′)]. These values are a measure of the distortion as a value of 120° is expected for an undistorted trigonal bipyramid. The $Mn-N_{azide}$ bonds [2.038(5)

Å] in **1** are slightly shorter than those observed in $[Mn(phen)_2(N_3)(H_2O)]^+$ (2.151 Å) or $[Mn(phen)_2(N_3)_2]$ (av. 2.138 Å) (phen: 1,10-phenanthroline).[11]

HF-EPR Spectroscopy of a Neat Powder of [Mn(*t*Buterpy)-$(N_3)_2$]

The electronic properties of a neat powder sample of complex **1** were investigated by a multi-frequency EPR study between 190 and 285 GHz and over a temperature range of 5−30 K. Figure 3 shows experimental and simulated 285 GHz HF-EPR spectra recorded at 5 and 10 K. At this frequency, the spectra show transitions located between 9.0 and 11.2 T. Since high-field limit conditions are reached ($D << g\beta B$), all of the transitions are allowed, permitting an easy interpretation of the experimental data.

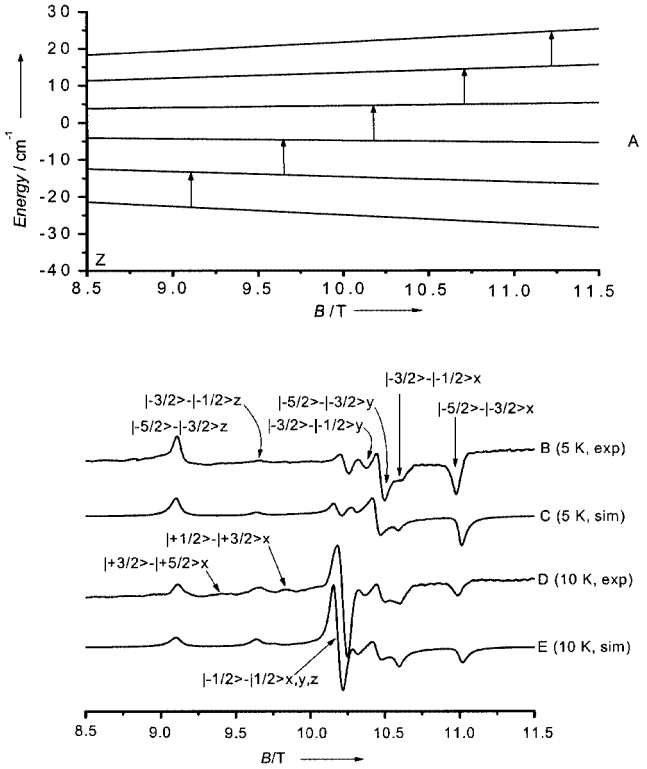

Figure 3. Plots of energy vs. field for the six levels arising from an $S = 5/2$ spin state using the parameters given below; the field is parallel to the molecular z axis (A); arrows indicate the observed resonances; experimental (B and D) and simulated (C and E) powder 285 GHz EPR spectra of **1**, recorded at 5 K (B and C) and 10 K (D and E); the parameters used for the simulation are: $D = -0.250(5)$ cm^{-1}, $E = 0.044(5)$ cm^{-1} and $g_x = g_y = g_z = 2.000(5)$

In the 5 K spectrum (Figure 3B), the furthest transition (9.11 T) from the center of the spectrum (close to $g = 2.00$ for Mn^{II};[12] 10.18 T at 285 GHz) is associated with the $|5/2,-5/2> \rightarrow |5/2,-3/2>$ transition along the z axis, since $D_{zz} > D_{xx}$ and D_{yy} (with $D_{zz} + D_{xx} + D_{yy} = 0$). This is in agreement with the fact that, at low temperature, only the first Zeeman levels (Ms) levels are populated ($|-5/2>$ and $|-3/2>$). From its field position, the sign and an estimate of the magnitude of D can be obtained. Since this transition is located in the low-field part of the spectrum at low temperature, we infer that the sign of D is negative. Its distance from the central field of the spectrum is $4D/g_z\beta$, implying a D value of 0.27 T or 0.25 cm^{-1} (with $g_z = 2.00$ as a first approximation). The intensity of the transition observed at 9.60 T increases from 5 to 10 K (Figure 3D), in agreement with the Boltzmann population of the Ms levels. Thus, it can be attributed to the $|5/2,-3/2> \rightarrow |5/2,-1/2>$ transition along z. Moreover, this transition is located at the expected field position of $+2D/g_z\beta$ from the $|5/2,-5/2> \rightarrow |5/2,-3/2>$ transition along z, confirming our analysis.

The other 5 K spectrum features are associated with x and y transitions. The 10.98 T and 10.59 T features are associated with the $|5/2,-5/2> \rightarrow |5/2,-3/2>$ and $|5/2,-3/2> \rightarrow |5/2,-1/2>$ transitions along the x axis, respectively. These assignments were confirmed thanks to the temperature effect on the intensity of the transitions. Indeed, the intensity of the first transition of the multiplet decreases on going from 5 to 10 K whereas the second feature increases. The E term can be extracted from the resonance-field difference of these two subsequent x transitions, which corresponds to $(3E - D)/g_x\beta$. This implies an E value of 0.038 cm^{-1}.

The transitions associated with the y axis for the $Ms = -5/2$ and $-3/2$ levels of **1** are observed at 10.47 T and 10.34 T, respectively, which yields a field difference of 0.13 T equal to $-(D + 3E)/g_y\beta$, giving an E value of 0.043 cm^{-1}. This value is similar to the previous one obtained from the x transitions.

Concerning the central feature located at $g = 2.0$ (10.18 T at 285 GHz), it corresponds to the contribution of the $|5/2,-1/2> \rightarrow |5/2,+1/2>$ transitions along the three magnetic axes. At 5 K, the major contribution comes from the y transition since the Ms level $|-1/2>$ is not populated in the x and z directions. On the contrary, at higher temperatures the $|5/2,-1/2> \rightarrow |5/2,+1/2>$ transitions along x, y and z contribute to the central feature. For this reason, this central transition is largely enhanced at 10 K compared to the other transitions.

The absence of observable splitting due to hyperfine interactions in the experimental spectra originates from the large line width of the spectral features. Different mechanisms can contribute to line broadening. In our case, the line width is not temperature-dependent, implying that the major contribution of the broadening comes from dipolar interactions between metallic centers.

As hyperfine interactions are not observable in the experimental data, the spin Hamiltonian of Equation (2) that describes our system under these conditions is simpler than in Equation (1).

$$H = \beta B \cdot g \cdot S + D[S_z^2 - 1/3S(S+1)] + E(S_x^2 - S_y^2) \quad (2)$$

The HF-EPR spectra were simulated using a full-matrix diagonalization procedure of the spin Hamiltonian [Equation (2)].[6a] The best simulation of the experimental spectra

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(Figure 3) was obtained using the following spin Hamiltonian parameters: $D = -0.250(5)$ cm^{-1}, $E = 0.044(5)$ cm^{-1} and $g_x = g_y = g_z = 2.000(5)$. These spin-Hamiltonian parameters also simulate successfully the HF-EPR spectra recorded at all temperatures and frequencies.

HF-EPR Spectroscopy of a Magnetically Diluted Powder of [Mn(tButerpy)(N$_3$)$_2$] in Zinc(II)

To experimentally observe the hyperfine interactions for determining the A term, one way is to minimize the line broadening by diluting the paramagnetic centers. A good way to magnetically dilute a paramagnetic center is to incorporate the sample in a diamagnetic host in order to decrease the dipolar interactions. We therefore diluted complex **1** in the corresponding zinc(II) complex at a concentration of approximately 5% by weight of manganese(II).

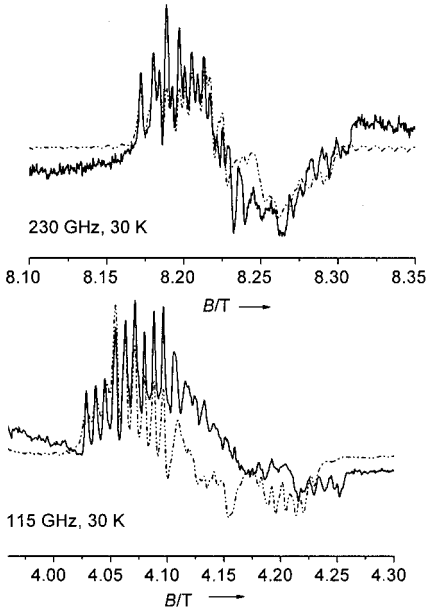

Figure 4. Experimental (bold line) and simulated (dashed line) EPR spectra recorded at 230 and 115 GHz of [Zn(Mn)(*t*Buterpy)(N$_3$)$_2$] at 30 K; the parameters used for the simulation are: $|D| = 0.260(1)$ cm^{-1}, $E = 0.043(1)$ cm^{-1}, $g_x = g_y = 2.001(1)$ $g_z = 2.0005(5)$ and $A_{xx} = A_{yy} = A_{zz} = 77.5$ (5) G

Figure 4 displays the 115 and 230 GHz experimental and simulated EPR spectra of [Zn(Mn)(*t*Buterpy)(N$_3$)$_2$]. As expected, this spectrum is characterized by a unique feature located at $g \approx 2.0$, split into multiple lines corresponding to the $|5/2,-1/2> \rightarrow |5/2,+1/2>$ transition along the three axes x, y and z. Since the two experimental spectra are centered at a g value of around 2.000, the Zeeman interaction is dominant above 4 T. As already observed by Un et al.,[1e] the total width of the spectra increases from 115 to 230 GHz (0.135 and 0.220 T, respectively) and the spectra appear better resolved at low field. Since the exact positions of all of these lines are dependent on the zfs terms (D and E) and g, simulations have been performed to extract the spin Hamiltonian parameters of these spectra.

A full-matrix diagonalization of Equation (1) was performed, and the best simulated spectra using $|D| = 0.260(1)$ cm^{-1}, $E = 0.043(1)$ cm^{-1}, $g_x = g_y = 2.001(1)$, $g_z = 2.0005(5)$ and $A_{xx} = A_{yy} = A_{zz} = 77.5$ (5) G are shown in Figure 4. The sign of D cannot be extracted from the multiplet.

Discussion and Conclusion

In this paper we have described the synthesis and the crystallographic characterization of a mononuclear Mn^{II} complex possessing two terminal azide ligands, [Mn(*t*Buterpy)(N$_3$)$_2$]. Such mononuclear complexes are not common since azide ions have mainly been used for their ability to bridge paramagnetic Mn^{II} centers into dimers, clusters, and polymers.[13] A large number of such compounds have been described in the literature including the dimer [Mn$_2^{II,II}$(μ-N$_3$)$_2$(terpy)$_2$](N$_3$)$_2$].[14]

We performed an HF-EPR study of **1** in order to determine the spin-Hamiltonian parameters of this complex. The experiments were performed in the solid state both on the neat compound and its magnetically diluted form. From the HF-EPR experiments carried out on the neat powder, we extracted the magnitude of g, D and E, as well as the sign of D. The unambiguous determination of the sign of D was possible by recording the spectra at low temperature. In previous HF-EPR studies on mononuclear Mn^{II} complexes, the sign of D was not determined since the experiments were performed at room temperature.[8] The experiments conducted under magnetically diluted conditions allow us to determine the A term and to confirm the value of the other spin-Hamiltonian parameters; the sign of D cannot

Table 2. Electronic characteristics and coordination number of Mn^{II} sites in enzymes

be extracted. Since both sets of parameters are essentially the same, a similar environment for each manganese ion can be postulated in both pure and diluted lattices.

In Table 2, we report the spin-Hamiltonian parameters of several mononuclear Mn^{II} complexes present in different metalloproteins. In all cases the spin-Hamiltonian parameters have been accurately determined from the EPR hyperfine split multiplet of the $|5/2,-1/2> \rightarrow |5/2,+1/2>$ transition using extended spectroscopic techniques such as Q-band EPR, HF-EPR or HF-ENDOR. The coordination number cannot be adequately correlated to A, although such a correlation has already been proposed.[4a,15] On the contrary, a good agreement is observed between the magnitude of D and the coordination number of the Mn^{II} ion. D is larger than 0.2 cm^{-1} for pentacoordinate complexes while it is smaller than 0.1 cm^{-1} for hexacoordinate ones. The D value found for **1** is in good agreement with a pentacoordinate complex. The large E/D value (0.176) reflects the distortions observed in the X-ray structure of complex **1**.

We found similar spin-Hamiltonian parameters to simulate both neat and magnetically diluted powder of **1**. This result shows that the analysis of the HF-EPR spectrum under diluted conditions is sufficient to allow an accurate determination of the electronic parameters of mononuclear Mn^{II} complexes. For the study of manganese sites present in metalloproteins, samples obviously correspond to diluted conditions where only the $|5/2,-1/2> \rightarrow |5/2,+1/2>$ transition can be observed. As shown in Table 2, where all spin-Hamiltonian parameters have been determined using Q-band or HF-EPR spectroscopy, the advantage of increasing the frequency is that the spectra are simpler than X-band spectra. Consistent with this view, our work confirms that HF-EPR spectroscopy permits the resolution of the electronic structure of mononuclear Mn^{II} complexes even for systems with a large D value, making it a promising tool for the study of Mn^{II} compounds, including metalloproteins.

Experimental Section

General: Reagents and solvents were purchased commercially and used as received. ***Caution:*** Both N_3^- and its complexes are potentially explosive; although we have encountered no such problems with complex **1**, it should still be handled with care; further, N_3^- releases explosive HN_3 on contact with acid solution!

Synthesis of [Mn(*t*Buterpy)$(N_3)_2$]: An ethanolic solution (10 mL) of *t*Buterpy (0.055 g, 0.136 mmol) was added, with stirring, to an aqueous solution (2 mL) of $MnCl_2$ (0.017 g, 0.136 mmol). An excess of solid NaN_3 was then added to the yellow solution. The solution was filtered to remove any impurities and the solvents were evaporated to dryness to give a yellow precipitate corresponding to complex **1**. Single crystals of [Mn^{II}(*t*Buterpy)$(N_3)_2$] were grown by slow diffusion of diethyl ether into a concentrated solution of **1** in a mixture of dichloromethane and acetonitrile (1:1). Yield: 0.032 g (22%). $C_{28}H_{38}MnN_9O_{0.5}$ (563): calcd. C 59.67, H 6.80, N 22.37; found C 60.42, H 6.70, N 22.40. IR (KBr): $\tilde{\nu}$ = 2959 (m) cm^{-1}, 2076 (vs), 1607 (s), 1549 (m), 1402 (m), 1364 (m), 1251 (m), 1013 (m), 845 (m).

Synthesis of [Zn(Mn)(*t*Buterpy)$(N_3)_2$]: $[Mn(O_2CCH_3)_2]\cdot 4H_2O$ (0.0032 g, 0.013 mmol) was added with stirring to a methanolic solution (5 mL) of $[Zn(O_2CCH_3)_2]\cdot 2H_2O$ (0.0551 g, 0.25 mmol). A solution of *t*Buterpy (0.1056 g, 0.263 mmol) in 100 mL of methanol was then added to this solution. Finally, an excess of solid NaN_3 was added. The solution was stirred for 1 h until formation of a white precipitate. The solution was filtered and the filtrate was concentrated to dryness to give a yellow precipitate of [Zn(Mn)(*t*Buterpy)$(N_3)_2$]. Yield: 0.045 g (31%).

Crystal-Structure Determination of [Mn(*t*Buterpy)$(N_3)_2$]: Diffraction data were collected with an Enraf-Nonius CAD4 diffractometer. The structures were solved by direct methods and refined using the TEXSAN software package (Single Crystal Structure Analysis Software, version 1.7, molecular structure corporation, 3200 Research Forest Drive, The Woodlands, TX 77381, USA, **1995**). Further details of the data collection and refinement are given in Table 3. CCDC-209520 (**1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Physical Measurements: IR spectra were obtained with a Perkin−Elmer Spectrum GX spectrophotometer, piloted by a Dell Optiplex GXa computer. Spectra were recorded with a solid sample at 1% in mass in a pellet of KBr. High-frequency and high-field EPR spectra were recorded with a home-made spectrometer.[16] Gunn diodes operating at 95 GHz and 115 GHz and equipped with a second-, third-, fourth-, and fifth-harmonic generator were used as the radiation source. The magnetic field was produced by a superconducting magnet (0−12 T). The HF-EPR experiments were performed on polycrystalline powder pellets of **1** in order to avoid magnetic orientation of crystals. Diluted samples of **1** were prepared by immobilizing the powder either in KBr or in *n*-icosane mull; identical HF-EPR spectra were obtained in both cases.

d- or f-Mononuclear and Related Heterodinuclear Complexes With [1+1] Asymmetric Compartmental Macrocycles

Andrea Caneschi,[a] Lorenzo Sorace,[a] Umberto Casellato,[b] Patrizia Tomasin,*[b] and Pietro Alessandro Vigato[b]

Keywords: Heterometallic complexes / Macrocyclic ligands / Compartmental Schiff bases / Magnetic properties / EPR spectroscopy

d- or f-mononuclear and d,f-heterodinuclear complexes with the [1+1] asymmetric compartmental macrocycles H_2L_A, H_2L_B, H_2L_C or H_2L_D, derived from the condensation of 1,2-diaminoethane or 1,3-diaminopropane with 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde) or 3,3′-(3,6-dioxaoctane-1,8-diyldioxy)bis(2-hydroxybenzaldehyde), have been synthesized and characterized, including by single-crystal X-ray structural determinations. The influence of coordinating size and the number of donor atoms of the two adjacent chambers on the preparation of stable d,f-heterodinuclear complexes has also been tested. The X-ray structure of the isostructural complexes $[MLn(L)(Cl)_3(CH_3OH)]$ (MLn = LaCu, LaZn, TbCu) shows the metal(II) ion residing in the N_2O_2 site in a square-pyramidal coordination, the fifth apical position being filled by a chloride ion, while each lanthanide(III) ion is located in the O_2O_4 site and reaches nona-coordination by linking six oxygen atoms of the macrocyclic ligand, two chloride ions and the oxygen atom of a methanol molecule. Magnetic susceptibility data, complemented by EPR spectroscopy, of the heterodinuclear complexes, studied over the range 2–300 K, show a ferromagnetic coupling for the CuGd complex, whereas, when comparing CeCu and TbCu derivatives with the corresponding Zn derivatives, no appreciable interaction could be detected for the former and a ferromagnetic interaction seems to dominate in the latter.

Introduction

A wide range of compartmental ligands, containing adjacent similar or dissimilar coordination sites, has been designed and used in the preparation of mono- and polynuclear complexes and in studying the peculiar properties arising from the close proximity of the metal ions.[1−9]

These ligands, acyclic or cyclic, often originate from the condensation of appropriately designed formyl and amine precursors. While the acyclic ligands are always asymmetric, the cyclic ligands can be symmetric or asymmetric. X-ray structural determinations or, when lacking suitable crystals, mass spectrometry reveals conveniently their molecular complexity.[10−16] Suitable infrared and NMR investigations have added the information necessary to identify exhaustively their nature.

Asymmetric compartmental ligands have received particular attention in the last decade as they can give rise to specific molecular recognition at the two adjacent, different compartments.[17−19] Thus, they can recognize two different metal ions; the resulting heterodinuclear complexes generally show considerably different chemical and physical behaviours from those derived from the sum of the related properties of the single metal ions surrounded by the same coordination moiety.

In addition, when homodinuclear complexes are formed, the two metal ions can be varied by appropriate reactions, i.e. the selective oxidation or reduction of one metal ion, the further ligand coordination to one metal ion with the consequent variation of the coordination polyhedron, etc. These reactions, however, are difficult to fine-tune and often do not occur. Further possibilities include the migration of one metal ion from one site to the other to afford positional isomers, the substitution of one metal ion by transmetallation (inducing a consequent migration from one site to the other), and modification of the coordination environment about one metal ion through its oxidation or reduction. These molecular movements can be reversed by changing the reaction conditions or the external stimulus. Such systems are potential molecular machines, and several molecular or nanomolecular sensors or devices based on these processes have been successfully proposed.[20−22]

We have investigated recently the coordinating properties of [1+1] asymmetric cyclic Schiff bases derived from the condensation of 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde) or 3,3′-(3,6-dioxaoctane-1,8-diyl-

dioxy)bis(2-hydroxybenzaldehyde) with a series of polyamines. These ligands contain an N_2O_2 or N_3O_2 Schiff base chamber and an adjacent O_2O_3 or O_2O_4 crown-ether-like chamber. They are particularly suitable for testing the chemical preference of different metal ions in coordinating one of the two adjacent coordination sites. Notably, d- or 4f-metal ions, when treated with these ligands, occupy the Schiff base or the crown-ether-like chamber, respectively, according to their "soft" or "hard" character.[23−25]

Conversely, in the presence of s-metal ions strongly coordinated in the crown-ether-like chamber, an incoming lanthanide ion is forced into the Schiff base moiety, affording well-defined heterodinuclear complexes without positional isomers, as ascertained for the complexes $[LnNa(L)(Cl)_2(CH_3OH)]$.[23] This chemical behaviour has been used successfully to design and use these systems as suitable shift reagents for the qualitative and quantitative recognition of the sodium ion. The ^{23}Na NMR resonance of the sodium cation is markedly shifted from that of the free ion by the paramagnetic Ln^{III} centre, making the heterodinuclear Ln−Na complexes very promising candidates for the development of highly effective shift reagents for metal cations of biological importance.[26−28]

Given the remarkable tendency of Schiff bases to coordinate the d-metal ions, combined with the high preference of the "hard" lanthanide(III) ions for the crown-ether site, we aimed to obtain positional pure heterodinuclear d,f complexes and studied the physicochemical properties arising from this aggregation. The two coordination chambers were progressively enlarged to find the most appropriate donor set configuration (coordination moiety) for pure, stable heterodinuclear d,f complexes.

Accordingly, the four macrocycles H_2L_A, H_2L_B,H_2Lc and H_2L_D were employed for the synthesis and physicochemical characterisation of a series of d- or f-mononuclear and d,f-heterodinuclear complexes. In particular, the X-ray single-crystal structures of some of these d,f complexes with H_2L_D and their magnetic properties were investigated in detail.

The paper aims to verify whether the reaction pathway of Scheme 1 can be followed, the difficulty encountered with the different synthetic methodologies, the best fit of the coordination chambers for the different metal ions and the physicochemical properties resulting from the close proximity of a d- and 4f-metal ion, particularly their magnetic behaviour.

Results and Discussion

Preparation of the Ligands and Related Complexes

The [1+1] asymmetric cyclic compartmental Schiff bases H_2L_A, H_2L_B, H_2L_C and H_2L_D were prepared by self-condensation of diformyl precursors 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde) or 3,3′-(3,3-dioxaoctane-1,8-diyldioxy)bis(2-hydroxybenzaldehyde)[23−25,29,31] with an equimolar amount of the appropriate diamine (1,2-diaminoethane or 1,3-diaminopropane). For the larger macrocycles H_2L_C and H_2L_D high-dilution conditions (methanol/diethyl ether, 1:200) are necessary; when high-dilution conditions are not employed, the [1+1] cyclic Schiff bases are variously contaminated by [2+2] or higher homologues.

These Schiff bases are yellow solids, stable in air, soluble in $CHCl_3$ and CH_3OH, and slightly soluble in C_2H_5OH. A

strong IR band at 1635−1627 cm^{-1} due to $\nu_{C=N}$, and the absence of bands attributable to $\nu_{C=O}$ or ν_{NH2}, show that condensation occurs. ^1H NMR spectroscopy provided further evidence of condensation reactions. In particular the peaks at δ = 9.94 ppm, due to the formyl protons (CH=O), disappear and new peaks at δ = 8.30−8.19 ppm, due to the iminic protons CH=N, are clearly detectable. The other peaks, due to aliphatic or the aromatic protons, also vary because of the condensation reaction.

The [1+1] cyclic nature of $H_2L_A\cdots H_2L_D$ was inferred by FAB and ESI mass spectrometry, which clearly show two peaks at the appropriate *m*/*z* value, characteristic of the protonated $[MH]^+$ and the cationized $[MNa]^+$.

The macrocyclic Schiff bases H_2L_A, H_2L_B, H_2L_C and H_2L_D contain two adjacent coordination sites, one N_2O_2 and one O_3O_2 or O_4O_2, that are sufficiently different to give rise to two different, well-defined complexation reactions with a d- or 4f-metal ion. The N_2O_2 Schiff base site is filled exclusively by the d-metal ion while the 4f-metal ions, owing to their "harder" character, invariably coordinate the crown-like O_2O_3 or O_2O_4 chamber. The small Schiff base cavity is unsuitable for 4f-metal ion encapsulation; conversely, the "crown-ether" character of the other chamber does not favour the coordination of d-metal ions. The result is the formation of pure positional mononuclear isomers.

The appropriate diformyl derivative, 3,3′-(3,6-dioxaoctane-1,8-diyldioxy)bis(2-hydroxybenzaldehyde) or 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde), reacts in methanol in a 1:1 molar ratio with 1,2-diaminoethane or 1,3-diaminopropane in the presence of the desired transition metal(II) chloride or acetate (Cu^{2+}, Ni^{2+}, Zn^{2+}) or lanthanide(III) chloride hydrate to form the corresponding mononuclear complexes $M(L)\cdot nH_2O$ or $[Ln(H_2L)(H_2O)_4](Cl)_3$. The crude product was recrystallised from an alcoholic solution and then characterized by the usual methods.

In particular, when copper(II) salts were used, the complexes $[Cu(L)]\cdot H_2O$ were obtained, as confirmed by ESI mass spectra, which exhibits the parent peak $[Cu(L)]^+$ at the appropriate *m*/*z* value. With the other metal ions M(L), M(HL)(X) or $M(H_2L)(X)_2$ (X = Cl^- or CH_3COO) are obtained, depending on the experimental conditions. In strong basic media the complexes $M(L)\cdot nH_2O$ are obtained. These data are in line with a parallel potentiometric study showing that the different complexes $[M(H_2L)]^{2+}$, $[M(HL)]^+$ and [M(L)] are the predominant species in particular pH ranges.[32] These investigations also prove that the coordination of a metal ion (i.e. Cu^{2+}) strongly stabilises the Schiff bases over a large pH range (2−12) and prevents their easy hydrolysis. Interestingly, this result affords the possible use of these systems in solutions usually forbidden to the Schiff bases.

Although the preformed Schiff base can give rise to the same d- or f-mononuclear complexes, when treated with the appropriate metal salt the above template procedure has to be preferred owing to the tedious and time-consuming procedure for obtaining the [1+1] macrocycle with acceptable purity. Moreover, template procedures increase considerably the yield of the complexes.

The formation of the mononuclear complexes $[Ln(H_2L)(H_2O)_n](Cl)_3$ was inferred by IR spectra, where the $\nu_{C=N}$ band was observed in the range 1637−1653 cm^{-1} depending on the macrocycle and the lanthanide ion. NMR spectra in CD_3OD were useful only for diamagnetic or weakly paramagnetic compounds, showing the HC=N signal at δ = 8.87−8.74 ppm for the lanthanum complexes and at δ = 12.47−10.56 ppm for the cerium ones.

Proton migration from the phenol to the iminic group upon complexation, which has been seen in other similar compounds,[33] was not seen in these complexes − the experimental conditions (the use of methanol as deuterated solvent) probably prevented this observation. Furthermore, X-ray structures of H_2L_B and $[La(H_2L_B)(H_2O)_4](Cl)_3$ show the lanthanum(III) ion residing in the O_3O_2 chamber, in a monocapped square-antiprismatic coordination environment, but does not allow us to define whether the protons are linked to the phenolic oxygen atom or to iminic C=N groups.[31] The same structure was found for other lanthanide(III) complexes with H_2L_B.

The three pathways summarized in Scheme 1 {reaction of $M(L)\cdot nH_2O$ with $LnCl_3\cdot nH_2O$, reactions of $[Ln(H_2L)(H_2O)_n](Cl)_3$ with metal(II) chloride, one-pot reaction} give rise to the same complexes although at times with a different solvent content. However, it was verified that the complexes $[Ln(H_2L)(H_2O)_4](Cl)_3$ are the most convenient "ligand" precursors and thus all the complexes were prepared by using the second procedure. The other two procedures were successfully tested to verify their feasibility. The one-pot reaction, in particular, clearly shows that these ligands have the correct coordination moiety for simultaneous recognition of a d- and a 4f-metal ion.

However, notably, the stability, especially in solution, of the heterodinuclear complexes $[LnM(L)(Cl)_3(CH_3OH)]$ varies considerably when changing the coordination shape of the two chambers. Thus, because the complexes $[LnM(L_A)(Cl)_3(CH_3OH)]$, though formed, are not stable enough in solution and attempts to crystallise them failed, we enlarged progressively the two bites. Again, with H_2L_B and H_2L_C, the resulting heterodinuclear complexes are unstable in solution and tend to eliminate partially one of the two metal ions. With the correct coordination shape, i.e. with ligand H_2L_D, enlarging the aliphatic chain from CH_2CH_2 to $CH_2CH_2CH_2$ in the N_2O_2 chamber and changing the crown-ether chain from O_2O_3 to O_2O_4 with the addition of a $-CH_2CH_2O-$ group, the resulting complexes are very stable in solution and readily crystallised.

Heterodinuclear complexes have been synthesised by treating $Ln(H_2L)Cl_3\cdot nH_2O$ in alcoholic solution with MCl_2 (M = Cu, Ni, Zn) in the presence of Et_3N. The solution was heated slightly during stirring: a precipitate usually formed after 20−30 min. The powder, collected by filtration and washed with $MeOH/Et_2O$, was then dissolved in an alcoholic solvent. Slow diffusion of diethyl ether into the resulting alcoholic solution produced crystals of $MLn(L_D)Cl_3\cdot nCH_3OH\cdot mEtOH$ (Ln = La, Ce, Gd, Tb; *n* =

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

0−1; m = 0−2). The IR spectra of $MLn(L)Cl_3$ show a strong band ($\nu_{C=N}$) in the range 1618−1638 cm^{-1} (NiLn) or 1625−1647 cm^{-1} (CuLn) with a general lowering, more or less evident, compared to the $Ln(H_2L)Cl_3$ compounds owing to the coordination of the transition metal(II) ion into the Schiff base site. ^1H NMR spectroscopy was useful only for characterizing diamagnetic and some paramagnetic compounds. Interestingly, the coordination of M^{2+} provokes a large shift of the C=N band (for LnNi at δ = 19.38−19.45 ppm, for CeCu at δ = 53.61 ppm), confirming coordination in the Schiff base site. In these heterodinuclear complexes the Ni^{II} ion is in a high-spin state; therefore, the analogous Zn^{II} compounds were chosen as diamagnetic references in the magnetic studies reported below. SEM-EDS analysis were very useful in confirming the homogeneity of the complexes and the presence of the two metal ions in the correct ratio (Ln/M/Cl = 1:1:3).

In conclusion, the ligand H_2L_D is designed correctly for the formation of stable heterodinuclear LnM complexes. Thus, while mononuclear complexes can be obtained with all the macrocycles, the formation of heterodinuclear complexes, and especially their stability in solution, strongly depends on the experimental conditions and, above all, on the size of the donor chambers. By obtaining pure, stable heterodinuclear complexes we have clearly shown the need for appropriate molecular design of the coordinating systems.

Crystal Structures of the Heterodinuclear Complexes

Crystals of La−Cu, La−Zn and Tb−Cu complexes $[LnM(L_D)(Cl)_3(CH_3OH)]$ were obtained by slow diffusion of diethyl ether in methanolic solutions. All three complexes are monoclinic (space group $P2_1/n$) and isostructural, with four molecules in the unit cell (see Exp. Sect.). Figures 1 and 2 show ORTEP representations of the crystal structure and the coordination surroundings of the only La−Cu complex.

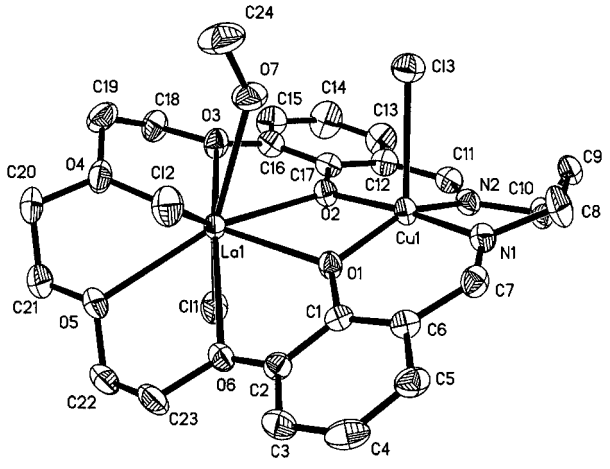

Figure 1. ORTEP diagram of the La−Cu complex showing the atom-labelling scheme; thermal ellipsoids are drawn at the 50% probability level; La−Zn and Tb−Cu complexes present an identical drawing

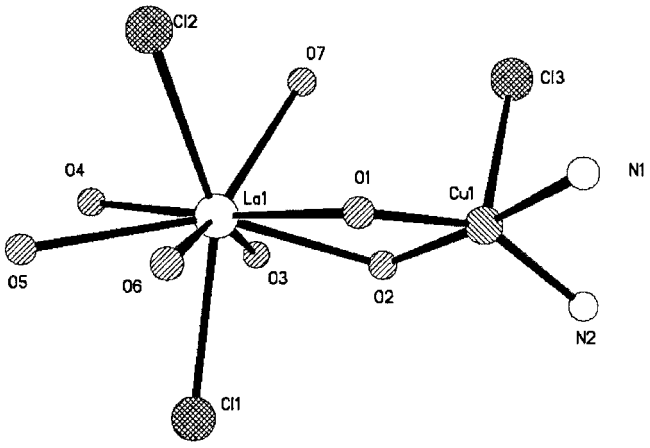

Figure 2. ORTEP diagram of the La−Cu coordination core showing the atom-labelling scheme

The macrocyclic ligand presents two coordination compartments: an N_2O_2 chamber and an O_2O_4 crown-like one. Each lanthanide metal ion is located in the O_2O_4 site and reaches the coordination number of nine by bonding six oxygen atoms of the ligand, two chlorine ions and the oxygen atom of one methanol molecule. O(3), O(4) O(5) and O(6) are etheric, whereas O(1) and O(2) are phenolic. The transition metal ions, copper and zinc, occupy the N_2O_2 chamber, the phenolic O(1) and O(2) atoms work as bridges between the coordinated metal ions.

The dimension change of the coordinated metal ions has little influence on the coordination geometry in the three complexes. Tb^{3+} (0.923Å) is smaller than La^{3+} (1.016 Å) and Cu^{2+} (0.72 Å) is smaller than Zn^{2+} (0.74 Å). Of the five possible coordination polyhedra with nine vertices, the tricapped trigonal prism and the capped square antiprism are the most stable and common in the lanthanide complexes. In our complexes, probably owing to the different nature of the coordinated oxygen atoms [etheric, phenolic and alcoholic, from O(1) to O(7)] and the presence of two chlorine ions, none of the above polyhedra can represent well the geometry around the lanthanide atoms. The best would be an hexagonal bipyramid where the base is formed by the two phenolic oxygen atoms and the four etheric oxygen atoms. One vertex is a chlorine ion, Cl(1), the other is the mid-point between the second chlorine ion, Cl(2), and the oxygen atom of the coordinated methanol molecule. The mean plane formed by the six oxygen atoms, O(1) to O(6), presents deviations in the range ±0.480 Å [the largest are +0.482 Å, for O(1), and −0.440 Å for O(4)] in both the lanthanum complexes, while the deviations are within ±0.580 Å (involving the same oxygen atoms) in the terbium complex. The lanthanide ions, in all complexes, are displaced by about 0.32 Å from the mean plane toward the Cl(2) and O(7) atoms (because of the larger hindrance of these two atoms) in relation to the only chlorine atom [Cl(1)] present in the opposite side, which forces the macrocyclic ligand to assume an umbrella-like shape. There are considerable differences in coordination bond angles on

changing the lanthanide ion or the transition metal ion in the complexes. Coordination bond lengths are affected by the ionic radii, which decrease on going from the lanthanum to the terbium ion and increase from the copper to the zinc ion (Tables 1 and 2).

The butterfly shape adopted by the cyclic ligand around the central ions has two phenyl rings as wings; they form a dihedral angle of between 37.3 and 38.9° in the three complexes.

The dihedral angles defined by M−O(1)−O(2) and Ln−O(1)−O(2) planes are similar in the La−Cu and Tb−Cu complexes [16.5(2) and 15.4(2)°, respectively] but is 22.9(2)° in the La−Zn complex. In the complexes, copper is more effectively replaced with zinc than lanthanum is with terbium. The polyhedron around the transition-metal ions, present in the coordination site N_2O_2, is well depicted as a square pyramid, where the base is formed by the two phenolic bridging oxygen atoms and by the two iminic nitrogen atoms, and the apex is occupied by the third chlorine ion, Cl(3). The transition-metal ion is displaced from the mean N_2O_2 plane by about 0.247 Å (mean) in the two copper-containing complexes and by 0.533 Å in the zinc complex.

The torsion angles of the ligands (O−C−C−O) and (N−C−C−C−N) are very similar (Table 3). No remarkable hydrogen-bond networks are present.

X-ray powder diffractograms of five dinuclear complexes, $CeCu(L_D)Cl_3{\cdot}CH_3OH$, $GdCu(L_D)Cl_3{\cdot}CH_3OH$, $CeZn(L_D)Cl_3{\cdot}CH_3OH$, $GdZn(L_D)Cl_3{\cdot}3H_2O$ and $TbZn(L_D)Cl_3{\cdot}EtOH$, have been compared with that obtained by calculation from single crystal diffraction data of the La−Cu complex. We conclude that Ce−Cu, Ce−Zn, Gd−Cu and La−Cu complexes are all isostructural.

Conversely, the diffractograms of Tb−Zn and Gd−Zn complexes differ from each other and from the La−Cu one. In any case, the results obtained through other physicochemical characterization techniques strongly suggest that the coordination environment of the metal ion is closely related to that observed in LaCu and isostructural compounds. This assumption, of particular importance in the following discussion on magnetic properties, is sound as the use of a compartmental ligand constrains the mutual positions of metal and bonding atoms to a fixed geometry. In this framework, the different powder diffractometric patterns observed should be ascribed more to differences in crystal packing and cell settings than to differences in coordination geometries.

Magnetic and ESR Data

The magnetic properties of coupled lanthanide ions have been the focus of intense research.[34] The main problem when dealing with these systems is the combination of the effects of the first-order angular momentum of the ground state of the lanthanide ions − with the exception of Gd^{III}− and of the crystal-field splitting, which is usually of the order of kT at room temperature. This implies that the thermal dependence of the populations of the Stark sublevels

has to be taken into account implicitly and an important anisotropy of the magnetic susceptibility is usually observed, preventing the use of a spin-only Hamiltonian for isotropic exchange to analyse the data. Consequently, the overwhelming majority of magnetic studies on Ln−M complexes concerns Gd^{III}-containing systems, for which the usual isotropic Heisenberg spin Hamiltonian can be employed and the interpretation of the data is straightforward.[35−40]

As a first step we determined the magnetic properties of the LaCu complex: its EPR spectrum clearly shows the features of an elongated tetragonal coordination of Cu^{II} with two broad transitions yielding $g_\perp = 2.078$ and $g_\parallel = 2.241$ (Figure 3). This is in the range usually observed for N_2O_2Cl coordination around the copper ion.[41] These results are confirmed by susceptibility measurements, which follow the Curie−Weiss law over the whole investigated temperature range (inset of Figure 3). Best-fit results to $1/\chi = (T + \theta)/C$, yielded $C = 0.422$ cm^3·K·mol^{-1} (cf. a theoretical value of 0.427 cm^3·K·mol^{-1} results from EPR) and a θ of 0.185 K, which indicates the existence of only weak antiferromagnetic intermolecular interactions.

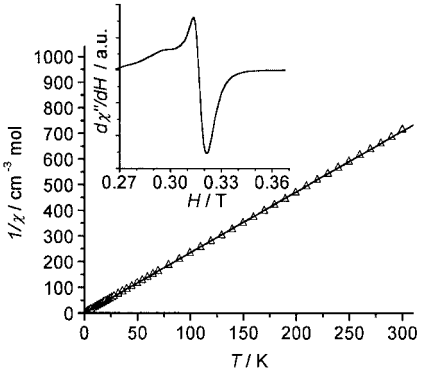

Figure 3. Curie−Weiss plot for the LaCu derivative between 2 and 300 K with the best-fit line (see text for details); inset: X-band EPR spectrum of the same complex ($g = 2.00$ is lying at $H = 0.33$ T)

The low-temperature X-band EPR spectrum of the GdZn derivative (Figure 4) exhibits fine structure due to zero-field splitting of the $S = 7/2$ state. The spectrum was satisfactorily simulated[42] by assuming a simple second-order spin Hamiltonian [$H = \beta\mathbf{B}\cdot\mathbf{g}\cdot\mathbf{S} + D\mathbf{S}_z^2 + E(\mathbf{S}_x^2-\mathbf{S}_y^2)$]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for $S = 7/2$. The best simulation was obtained using $g = 1.995 \pm .005$, $D = 0.058 \pm .002$ cm^{-1}, $E = 0.0125 \pm .001$ cm^{-1}.

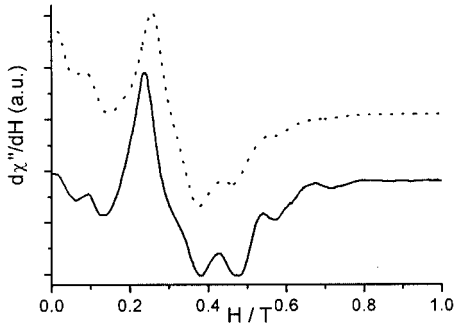

Figure 4. X-band EPR spectrum obtained for the GdZn derivative (continuous line) at 4 K, and best simulation (dotted line) obtained with parameters reported in the text; $g = 2.00$ lies at $H = 0.3300$ T

Independent determination of single-ion Cu^{II} and Gd^{III} properties was used successively to reduce the number of parameters used to fit the χT curve of GdCu (Figure 5). The χT room-temperature value obtained for this complex, 8.38 cm^3·K·mol^{-1}, is a little higher than the expected theoretical value for the two isolated $S = 1/2$ and $S = 7/2$ spins (assuming $g = 1.995$ for Gd^{III} and summing the values observed for LaCu gives 8.26 cm^3·K·mol^{-1}). On decreasing temperature, χT increases monotonically, indicating an intramolecular ferromagnetic coupling between Cu^{II} and Gd^{III} that is widely accounted for in similar systems.[35−38] The GdCu curve was then simulated by using the Hamiltonian $\mathbf{H} = J\,\mathbf{S}_{Gd}\cdot\mathbf{S}_{Cu}$ [43]

$$\chi = \frac{N\beta^2}{3kT}\cdot\frac{g_{S=4}{}^2 84 + g_{S=3}{}^2 180\exp\left(-\frac{4J}{kT}\right)}{7 + 9\exp\left(-\frac{4J}{kT}\right)}$$

where $g_{S=3} = 9/8g_{Gd} - 1/8g_{Cu}$ and $g_{S=4} = 7/8g_{Gd} + 1/8g_{Cu}$, and both g_{Cu} and g_{Gd} have been fixed to the value determined by EPR spectra of LaCu and GdZn, respectively.

Given the very small single-ion contribution to the zero-field splitting of Gd^{III} and the fairly large distance between magnetic centres of neighbouring molecules, which implies very weak intermolecular interactions, no correction[44] for these two phenomena was taken into account. The best-fit curve was obtained for $J = -2.49 \pm 0.05$ cm^{-1}, [$R^2 = \Sigma(\chi T_{calcd.} - \chi T_{obsd.})^2/\Sigma(\chi T_{obsd.})^2 = 0.9994$] meaning that the ground state $S = 4$ is separated in energy from the state $S = 3$ by about 10 cm^{-1}.

For the remaining lanthanides the situation is, as already noted, more difficult. However, some studies on the magnetic properties of anisotropic rare-earth ions coupled to either transition-metal ions or organic radicals have been reported recently.[45−50] In all these studies, the crystal-field effects on the magnetic properties of the lanthanides were determined separately by measuring a series of isomorphous complexes containing a diamagnetic counterpart (e.g. Zn^{II} or square-planar Ni^{II} in place of Cu^{II}). In the latter systems, deviation of the magnetic susceptibility compared to the Curie law is entirely due to the varying thermal population of the Ln^{III} Stark components, and this effect is assumed to be the same in systems with another paramagnetic species. In this framework, the variation with temperature of the curve obtained by subtracting the susceptibility of the complex containing the diamagnetic counterpart (e.g. LnZn) compared to that of the system with coupled centres (in our case, LnCu) ($\Delta\chi T_{LnM} = \chi T_{LnM} - \chi T_{LnZn}$) will only be due to exchange coupling interaction between the two paramagnetic centres. In detail, a positive variation of $\Delta\chi T_{LnM}$ on lowering T indicates a ferromagnetic coupling and a negative one an antiferromagnetic coupling. The same method can be applied to magnetisation measurements whenever a confirmation or a discrimination of the obtained results is needed.[47] Given the observed isostructurality of LaCu, CeCu, CeZn and TbCu, and the assumption of a closely related coordination environment for TbZn (see above), we applied this qualitative method to the family here described. Differences in crystal packing and intermolecular distances that, based on diffractometric powder pattern, might exist for TbZn are not important at this level of approximation as intermolecular interaction will not be considered.

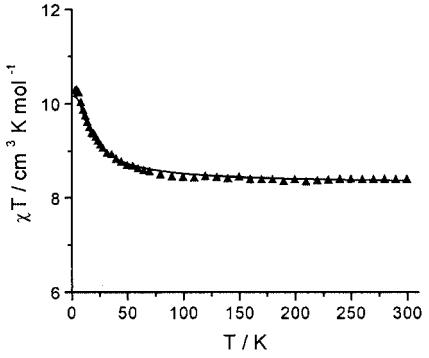

Figure 5. χT vs. T experimental curve measured between 2 and 300 K for GdCu (filled triangles), and the best-fit curve (continuous line) obtained with parameters reported in the text

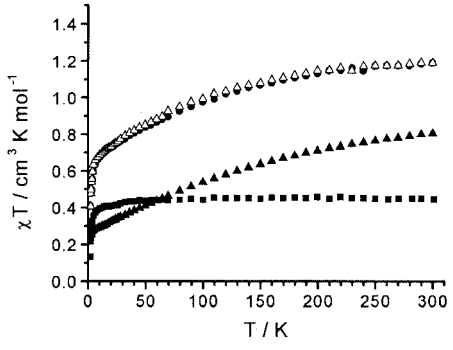

Figure 6. χT vs. T experimental curves measured between 2 and 300 K for CeCu (filled circles) and CeZn (filled triangles) and LaCu (filled squares) and the summed curve for LaCu + CeZn (open triangles)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The room-temperature value observed for the CeZn derivative, 0.80 $cm^3 \cdot K \cdot mol^{-1}$, agrees with that expected on the basis of spin-only behaviour,[51] the slow decrease observed on lowering the temperature being due to the progressive depopulation of $^2F_{5/2}$ excited Stark components (Figure 6).

Comparison of the curve resulting from the sum of LaCu and CeZn with that of CeCu clearly shows that no appreciable interaction can be observed, as the two curves are almost perfectly superimposable over the entire temperature range. Comparison of M vs. H curves measured at 2.5 K (Figure 7) might suggest the existence of a weak antiferromagnetic interaction.

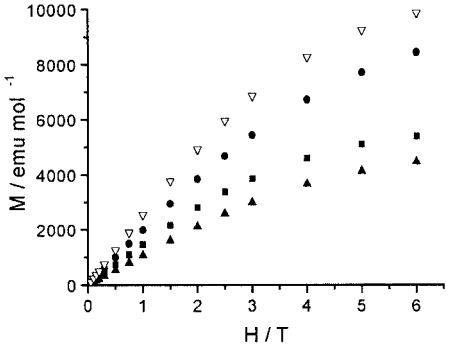

Figure 7. Comparison of the M vs. H curves at 2.5 K for CeCu (filled circles), CeZn (filled triangles), and LaCu (filled squares) with the sum (open inverted triangles) of the two latter curves

Indeed, the CeCu curve lies below the sum of LaCu and CeZn. However, in the absence of anisotropic magnetic data, diamagnetic substitution methods should not be pushed too far, and some caution should be exercised in deriving fine details.[52] In particular, some low-temperature discrepancies might well be due to small differences in crystal-field effects or intermolecular interactions and not to exchange coupling between 3d- and 4f-metal ions.

The observed χT values for the TbZn derivative at room temperature, 11.25 $cm^3 \cdot K \cdot mol^{-1}$, agrees with what is expected for this $^7F_6$ ion: on lowering the temperature the progressive depopulation of excited sublevels leads to the decrease of χT (Figure 8).

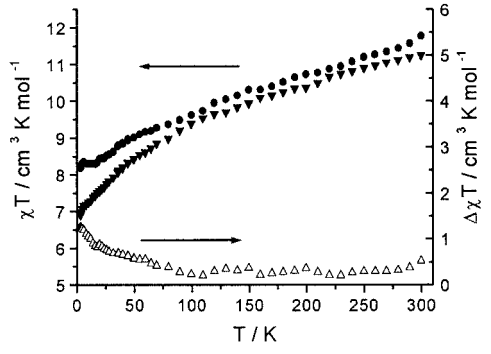

Figure 8. χT vs. T experimental curves measured between 2 and 300 K for TbCu (filled circles) and TbZn (filled inverted triangles) and their difference $\Delta\chi T$ (open triangles)

At 5 K a prominent EPR signal observed in zero field indicates that the two lowest sublevels are separated by $\Delta E = 0.3$ cm^{-1} (inset Figure 9). The results shown in Figure 8 for comparison of the χT curves of TbCu and TbZn clearly suggest a ferromagnetic coupling. Indeed, on lowering the temperature, $\Delta\chi T_{TbCu}$ increases from 0.415 $cm^3 \cdot K \cdot mol^{-1}$ at room temperature (in agreement with that observed for the LaCu derivative) to 1.25 $cm^3 \cdot K \cdot mol^{-1}$.

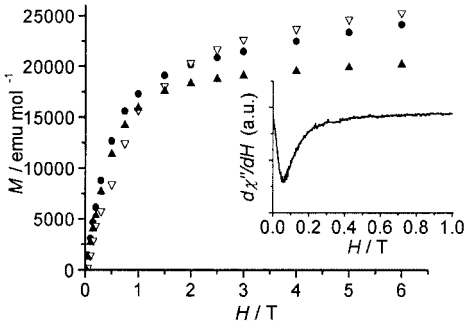

Figure 9. M vs. H curves at 2.5 K for TbCu (filled circles) and TbZn (filled triangles) compared with the sum of the latter and the experimental curve of LaCu (open inverted triangles); inset: low-temperature X-band EPR spectrum observed for the TbZn derivative

Ferromagnetic behaviour is confirmed by analysis of the M vs. H curves measured at 2.5 K (Figure 9). At low field the sum of LaCu and TbZn is lower than TbCu; however, for fields higher than 2 T the picture is reversed, which might suggest that the situation is not as simple as could be anticipated from the analysis of χT curves.

Conclusion

A series of LnM heterodinuclear complexes $[LnM(L)(Cl)_3(CH_3OH)]$ has been prepared, starting from the corresponding mononuclear complexes. It was confirmed that the transition-metal ion coordinates into the N_2O_2 Schiff base chamber while the lanthanide(III) ion prefers the O_2O_3 or O_2O_4 crown-like chamber. The two compartments of the asymmetric macrocyclic ligands have been progressively enlarged to find the best coordination moiety for heterodinuclear complexation. The larger macrocycle H_2L_D, derived from the condensation of 1,3-diaminopropane and 3,3′-(3,6-dioxaoctane-1,8-diyldioxy)bis(2-hydroxybenzoldehyde), has the most appropriate shape for forming stable heterodinuclear species. Furthermore, the large difference between two adjacent chambers assures the formation of only one species of heterodinuclear complexes, avoiding transmetallation, scrambling, migration reactions, etc. The ascertained stabilisation of the Schiff bases in consequence of the metal ion coordination opens up interesting possibilities in using these systems in solutions usually not allowed to Schiff bases.

The formation of isomerically pure, stable heterodinuclear complexes $[LnM(L_D)(Cl)_3\ (CH_3OH)]$ reported here

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

clearly shows the need for prior appropriate molecular design of the coordinating systems.

The prepared complexes are isostructural, with the exception of TbZn and GdZn complexes. These crystallographic differences may be ascribed more to different solvent content than to different coordination shapes about the two metal ions. Further work is in progress to clarify the origin of the crystallographic discrepancies.

As expected, we observed a ferromagnetic coupling for the GdCu complex, and the availability of a series of isomorphous LnM complexes allowed an empirical determination of the coupling interaction for two anisotropic LnCu derivatives. While no meaningful interaction was detected for the CeCu derivative, a clear sign of ferromagnetic coupling was observed for TbCu. In the absence of a simple model to explain the sign and magnitude of exchange coupling between a rare earth and an unpaired spin, we can only compare our data with the available literature results. In this respect, the observed ferromagnetic coupling for TbCu agrees with what has been found for all reported TbM couples (see ref.[49] and references cited therein), whereas a clear antiferromagnetic interaction has been reported for a different Schiff base containing CeCu complex.[45] Here, even subtle chemical and structural changes produced an observed variation of exchange coupling interaction with the Ce^{III} ion. This result points out again the need for a large wealth of data to build up a reliable magnetostrucutral correlation for complexes containing exchange-coupled lanthanide ions, in analogy to what has been done for 3d-metal ions.

Finally, functionalising these systems at the periphery of the coordination moiety with suitable hydrophilic or hydrophobic groups will increase their solubility in aqueous or non-aqueous solvents, and/or will favour their interaction and anchorage on suitable surfaces to obtain ferri- or ferromagnetic molecular nanosystems and devices. Preliminary results are very encouraging.

Experimental Section

General: All solvents, reagents and metal salts were purchased from Aldrich or Fluka and used without further purification. Dimethyl sulfoxide was purified by distillation.[53] The diformyl precursors 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde) and 3,3′-(3,6-dioxaoctane-1,8-diyldioxy)bis(2-hydroxybenzaldehyde) were prepared according to the literature.[29]

Physicochemical Characterization: Elemental analyses (C,H,N) were carried out using a Fison 1108 analyzer. IR spectra were recorded as KBr pellets with a Mattson 500 FT-IR spectrometer. ^1H and ^{13}C NMR spectra of the ligands and related complexes were performed with a Bruker AMX300 spectrometer, equipped with a 5-mm BB multinuclear probe, operating at 300.13 MHz for ^1H and 75.43 MHz for ^{13}C. 2D NOESY, 2D COSY and HMQC experiments for the ligands and complexes were performed with a Bruker AMX300 spectrometer. All the samples examined were dissolved in deuterated methanol or chloroform, which were used also as internal references. The morphology, homogeneity, and the metal/chlorine ratio of the complexes were investigated by using a Philips XL40 model scanning electron microscope equipped with an EDAXDX PRIME X-ray energy dispersive spectrometer. The solvent content (H_2O or MeOH) was evaluated by thermal analysis curves using Netzsch STA 429 thermoanalytical equipment; tests were performed under nitrogen (flux rate 250 mL/min, heating rate 5 °C min^{-1}) and in air under the same conditions. Neutral alumina (Carlo Erba, Milano, Italy) was used as reference material. ESI-MS data were recorded using a Finnigan LCQ mass spectrometer and methanolic solutions of the samples (10^{-3} M).[57] Mass spectrometric measurements were also performed using a ZAB2F instrument (Micromass, Manchester, UK) operating under FAB conditions. Nitrobenzyl alcohol solutions of the compounds were bombarded by 8 keV Xe atoms.[57] Magnetic susceptibilities of polycrystalline powders of LaCu, CeCu, CeZn, GdCu, GdZn, TbCu and TbZn were measured between 2 and 300 K with applied magnetic fields of 0.1 and 1 Tesla using a Cryogenic S600 SQUID magnetometer. To avoid the preferential orientation of polycrystalline powders, which might eventually result in a much higher apparent magnetic moment of the complexes, the powders were pressed in pellets. Data were corrected for the magnetism of the sample holder, which was determined separately in the same temperature range and field, and the underlying diamagnetism of each sample was estimated from Pascal's constants. Magnetisation measurements were performed on the same samples at 2.5 K with a field up to 6.0 T. Polycrystalline EPR powder spectra of the same complexes were recorded at the X-band (9.24 GHz) with a Varian E9 spectrometer equipped with a ^4He continuous-flow cryostat. Powders were blocked in wax to avoid preferential orientation of the crystallites.

Synthesis of Macrocycles and Complexes

H_2L_A: H_2L_A was prepared according to the literature.[31]

$Ln(H_2L_A)Cl_3{\cdot}nH_2O$ (Ln = La, Ce, Gd, Tb, Lu; n = 2−5): $LnCl_3{\cdot}6H_2O$ (2 mmol) in MeOH (5 mL) and, subsequently, ethylenediamine (120 mg, 2 mmol) in methanol (5 mL) were added to a pale yellow solution of 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde) (692 mg, 2 mmol) in methanol (50 mL). The obtained yellow solution was heated under reflux for 2.5 h and then reduced in volume. The addition of Et_2O (50 mL) to the resulting solution gave rise to a yellow precipitate that was filtered off, washed with MeOH/Et_2O (1:4), and dried in vacuo. 75% average yield.

$La(H_2L_A)Cl_3{\cdot}2H_2O$: 1004 mg, 77% yield. $C_{20}H_{22}Cl_3LaN_2O_5{\cdot}2H_2O$ (651.68): calcd. C 36.86, H 4.02, N 4.30; found C 36.14, H 3.82, N 4.27. IR: $\tilde{\nu}$ = 1648 cm^{-1} ($\nu_{C=N}$, s). ^1H NMR (300 MHz, CD_3OD, 25 °C): δ = 4.36 (m, 4 H, CH_2O), 4.39 (s, 4 H, CNCH_2), 4.45 (m, 4 H, CH_2O−Ar), 6.68 (t, 2 H, Ar−*H*), 7.15 (d, 2 H, Ar−*H*), 7.23 (d, 2 H, Ar−*H*), 8.78 (s, 2 H, *H*C=N). SEM-EDS: La/Cl = 1:3.

$Ce(H_2L_A)Cl_3{\cdot}1H_2O$: 990 mg, 78% yield. $C_{20}H_{22}CeCl_3N_2O_5{\cdot}H_2O$ (634.88): calcd. C 37.84, H 3.81, N 4.41; found C 37.62, H 3.68, N 4.54. IR: $\tilde{\nu}$ = 1649 cm^{-1} ($\nu_{C=N}$, s). ^1H NMR (300 MHz, CD_3OD, 25 °C): δ = −13.19 (d, 4 H, CH_2O), −1.19 (s, 4 H, CNCH_2), 4.20 (d, 4 H, CH_2O−Ar), 12.12 (t, 2 H, Ar−*H*), 12.47 (s, 2 H, *H*C=N), 13.05 (d, 2 H, Ar−*H*), 14.50 (d, 2 H, Ar−*H*). SEM-EDS: Ce/Cl = 1:3.

$Gd(H_2L_A)Cl_3{\cdot}2H_2O$: 994 mg, 74% yield. $C_{20}H_{22}Cl_3GdN_2O_5{\cdot}2H_2O$ (670.02): calcd. C 35.85, H 3.91, N 4.18; found C 35.16, H 4.49, N 4.63. IR: $\tilde{\nu}$ = 1637 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Gd/Cl = 1:3.

$Tb(H_2L_A)Cl_3{\cdot}2H_2O$: 994 mg, 74% yield. $C_{20}H_{22}Cl_3N_2O_5Tb{\cdot}2H_2O$ (671.70): calcd. C 35.76, H 3.90, N 4.17; found C 35.26, H 3.72, N 4.12. IR: $\tilde{\nu}$ = 1637 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Tb/Cl = 1:3.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Lu(H_2L_A)Cl_3·5H_2O: 1068 mg, 72% yield. $C_{20}H_{22}Cl_3LuN_2O_5$·5H_2O (741.78): calcd. C 32.38, H 4.35, N 3.78; found C 31.57, H 3.93, N 4.46. IR: $\tilde{\nu}$ = 1647cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Lu/Cl = 1:3.

Yb(H_2L_A)Cl_3·2H_2O: $YbCl_3$·6H_2O (765 mg, 2 mmol) in EtOH (20 mL) was added to a solution of H_2L_A (741 mg, 2 mmol) in chloroform (50 mL). The resulting solution was heated under reflux for 2.5 h and then reduced in volume. Addition of Et_2O (50 mL) to this solution afforded a yellow precipitate that was filtered off, washed with MeOH/Et_2O (1:4), and dried in vacuo. 878 mg, 64% yield. $C_{20}H_{22}N_2O_5YbCl_3$·2H_2O (685.81): calcd. C 35.03, H 3.82, N 4.08; found C 35.16, H 4.49, N 4.63. IR: $\tilde{\nu}$ = 1637 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Yb/Cl = 1:3.

NiLn(L_A)Cl_3·*n*H_2O (Ln = La, Ce, Gd, Tb, Yb, Lu; *n* = 0−5): $NiCl_2$·6H_2O (237.7 mg, 1 mmol) in MeOH (5 mL) was added to a yellow solution of Ln(H_2L_A)Cl_3·*n*H_2O (1 mmol) in methanol (50 mL). After 10 min, triethylamine (202 mg, 2 mmol) was added dropwise and the resulting yellow-red solution was heated under reflux for 2.5 h. After evaporation of the solvent to dryness, the residue was treated with $CHCl_3$ (25 mL) and stirred. The orange powder obtained was filtered off, washed with Et_2O and dried in vacuo. 60% average yield.

LaNi(L_A)Cl_3·2H_2O: 452 mg, 64% yield. $C_{20}H_{20}Cl_3LaN_2NiO_5$·2$H_2O$ (708.38): calcd. C 33.07, H 3.61, N 3.86; found (%) C 33.38, H 4.46, N 3.28. ZnLn(L_A)Cl_3·*n*H_2O (Ln = La, Ce, Tb; *n* = 0−5): $ZnCl_2$ (136.28 mg, 1 mmol) in MeOH (5 mL) was added to a yellow solution of Ln(H_2L_A)Cl_3·*n*H_2O (1 mmol) in methanol (50 mL). After 10 min, triethylamine (202 mg, 2 mmol) was added dropwise and the resulting yellow-red solution was heated under reflux for 2.5 h. After evaporation of the solvent to dryness, the resultant residue was treated with $CHCl_3$ (25 mL) and stirred. The pale yellow powder obtained was filtered off, washed with Et_2O and dried in vacuo. 60% average yield.

LaZn(L_A)Cl_3: 408 mg, 60% yield. $C_{20}H_{20}Cl_3LaN_2O_5Zn$ (679.01): calcd. C 35.38, H 2.97, N 4.13; found C 35.97, H 3.10, N 4.11. IR: $\tilde{\nu}$ = 1644 cm^{-1} ($\nu_{C=N}$, s). ^{1}H NMR (300 MHz, CD_3OD, 25 °C): δ = 3.57 (dd, 2 H, CH_2O), 3.88 (t, 2 H, CH_2O), 3.97 and 4.10 (dd, 4 H, CNCH_2), 4.31 (dd, 2 H, CH_2O), 4.88 (t, 2 H, CH_2O), 6.73 (t, 2 H, Ar−*H*), 7.18 (d, 2 H, Ar−*H*), 7.20 (d, 2 H, Ar−*H*), 8.62 (s, 2 H, *H*C=N). SEM-EDS: Zn/La/Cl = 1:1:3.

CeZn(L_A)Cl_3: 415 mg, 61% yield. $C_{20}H_{20}CeCl_3N_2O_5Zn$ (680.22): calcd. C 35.32, H 2.96, N 4.12; found C 36.08, H 3.33, N 4.17. IR data: $\tilde{\nu}$ = 1644 cm^{-1} ($\nu_{C=N}$, s). ^{1}H NMR (300 MHz, CD_3OD, 25 °C): δ = −9.88 (br. s, 2 H, CH_2O−Ar), −7.59(d, 2 H, CH_2O−Ar), −5.20 (s, 2 H, CH_2O), −3.33 (br. s, 2 H, CH_2O), 2.23 (d, 2 H, Ar−*H*), 5.48 (t, 2 H, Ar−*H*), 8.44 (s, 2 H, Ar−*H*), 8.80 (d, 2 H, CNCH_2), 9.82 (d, 2 H, CNCH_2), 12.82 (s, 2 H, *H*C=N). SEM-EDS: Zn/Ce/Cl = 1:1:3.

TbZn(L_A)Cl_3·H_2O: 422 mg, 59% yield. $C_{20}H_{20}Cl_3N_2O_5TbZn$·$H_2O$ (717.04): calcd. C 33.50, H 3.09, N 3.91; found C 33.13, H 3.34, N 3.85. IR: $\tilde{\nu}$ = 1641 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Zn/Tb/Cl = 1:1:3.

H_2L_B: H_2L_B was prepared according to the literature.[31]

Ln(H_2L_B)Cl_3·*n*H_2O (Ln = La, Ce, Tb; *n* = 0−3): $LnCl_3$·6H_2O (2 mmol) in MeOH (5 mL) and, subsequently, ethylenediamine (120 mg, 2 mmol) in methanol (5 mL) were added to a pale yellow solution of 3,3′-(3,6-dioxaoctane-1,8-diyldioxy)bis(2-hydroxybenz-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

aldehyde) (780.8 mg, 2 mmol) in methanol (50 mL). The obtained yellow solution was heated under reflux for 2.5 h and the resultant yellow precipitate was filtered off, washed with MeOH/Et_2O (1:4), and dried in vacuo. It was then recrystallised from MeOH/EtOH. 65% average yield.

$La(H_2L_B)Cl_3{\cdot}4H_2O$: 975 mg, 67% yield. $C_{22}H_{26}Cl_3LaN_2O_6{\cdot}4H_2O$ (731.76): calcd. C 36.11, H 4.68, N 3.83; found C 36.20, H 4.70, N 3.78 IR: $\tilde{\nu}$ = 1644 cm^{-1} ($\nu_{C=N}$, s). ^1H NMR (300 MHz, CD_3OD, 25 °C): δ = 4.21 (4 + 4 H, CH_2O + $CNCH_2$), 4.38 (t, 4 H, CH_2O), 4.55 (t, 4 H, CH_2O-Ar), 6.76 (t, 2 H, Ar−*H*), 7.23 (dd, 2 H, Ar−*H*), 7.37 (dd, 2 H, Ar−*H*), 8.87 (s, 2 H, *H*C=N). SEM-EDS: La/Cl = 1:3.

$Ce(H_2L_B)Cl_3$: 857 mg, 65% yield. $C_{22}H_{26}CeCl_3N_2O_6$ (660.91): calcd. C 39.98, H 3.97, N 4.24; found C 39.05, H 3.73, N 4.93. IR: $\tilde{\nu}$ = 1645 cm^{-1} ($\nu_{C=N}$, s). ^1H NMR (300 MHz, CD_3OD, 25 °C): δ = 0.14 (s, 4 H, CH_2O), 2.71 (s, 4 H, CH_2O), 4.50 (d, 2 H, Ar−*H*), 5.95 (t, 2 H, Ar−*H*), 6.24 (s, 4 H, $CNCH_2$), 7.63 (d, 2 H, Ar−*H*), 7.67 (s, 4 H, CH_2O), 10.56 (s, 2 H, *H*C=N). SEM-EDS: Ce/Cl = 1:3.

$Tb(H_2L_B)Cl_3{\cdot}3H_2O$: 931 mg, 63% yield. $C_{22}H_{26}Cl_3N_2O_6Tb{\cdot}3H_2O$ (733.76): calcd. C 36.01, H 4.40, N 3.82; found C 35.97, H 4.22, N 4.24. IR: $\tilde{\nu}$ = 1647 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Tb/Cl = 1:3.

$NiLa(L_B)Cl_3{\cdot}nH_2O$ and $CuLa(L_B)Cl_3{\cdot}nH_2O$: These compounds were prepared according to the literature.[31]

H_2L_C: A methanolic solution (3 mL) of 1,3-diaminopropane (74 mg, 1 mmol) was diluted with diethyl ether (400 mL). A $CHCl_3$ solution (5 mL) of 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde) (346 mg, 1 mmol) was then added dropwise at room temperature. The resultant yellow precipitate was stirred for 20 min, then filtered off, washed well with a diethyl ether/light petroleum solution and dried in vacuo. 211 mg, 55% yield. $C_{21}H_{24}N_2O_5$ (384.41): calcd. C 65.62, H 6.29, N 7.29; found C 66.52, H 6.41, N 7.41. IR: $\tilde{\nu}$ = 1631 cm^{-1} ($\nu_{C=N}$, s). ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 2.04 (quint, 2 H, $CNCH_2CH_2$), 3.66 (t, 4 H, $CNCH_2$), 3.96 (t, 4 H, CH_2O), 4.21 (t, 4 H, CH_2O-Ar), 6.73 (t, 2 H, Ar−*H*), 6.84 (dd, 2 H, Ar−*H*), 6.94 (dd, 2 H, Ar−*H*), 8.30 (s, 2 H, *H*C=N), 13.82 (br. s, OH) ppm. MS: 385 $[M + H]^+$.

$La(H_2L_C)Cl_3{\cdot}4H_2O$: $LaCl_3{\cdot}6H_2O$ (743 mg, 2 mmol) in MeOH (5 mL) and, subsequently, 1,3-propanediamine (148 mg, 2 mmol) in methanol (5 mL) were added to a pale yellow solution of 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde) (692 mg, 2 mmol) in methanol (50 mL). The resultant yellow solution was heated under reflux for 2.5 h and then reduced in volume. The obtained yellow precipitate was filtered off, washed with MeOH/Et_2O (1:4), and dried in vacuo. 1010 mg, 72% yield. It was then recrystallised from MeOH and slow diffusion of Et_2O. $C_{21}H_{24}Cl_3LaN_2O_5{\cdot}4H_2O$ (701.74): calcd. C 35.94, H 4.60, N 3.99; found C 35.34, H 4.41, N 4.85. IR: $\tilde{\nu}$ = 1651 cm^{-1} ($\nu_{C=N}$, s). ^1H NMR (300 MHz, CD_3OD, 25 °C): δ = 2.55 (quint, 2 H, $CNCH_2CH_2$), 4.08 (t, 4 H, $CNCH_2$), 4.44 (dd, 8 H, CH_2O), 6.62 (t, 2 H, Ar−*H*), 7.00 (dd, 2 H, Ar−*H*), 7.21 (dd, 2 H, Ar−*H*), 8.74 (s, 2 H, *H*C=N). SEM-EDS: La/Cl = 1:3.

$LaNi(L_C)Cl_3$: Triethylamine (202 mg, 2 mmol) and $NiCl_2{\cdot}6H_2O$ (237.7 mg, 1 mmol), dissolved in EtOH (2 mL), were added to a yellow solution of $La(H_2L_C)Cl_3{\cdot}4H_2O$ (702 mg, 1 mmol) in ethanol (20 mL) that was slightly heated (30 °C). After stirring for 10 min, a green precipitate formed. The suspension was stirred for further 20 min and then cooled to room temperature. The resultant green powder was collected by filtration, washed with Et_2O and dried in vacuo. 357 mg, 52% yield. $C_{21}H_{22}Cl_3LaN_2NiO_5$ (686.38): calcd. C 36.75, H 3.23, N 4.08; found C 36.05, H 3.53, N 3.80 IR: $\tilde{\nu}$ = 1627 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Ni/La/Cl = 1:1:3.

H_2L_D: A methanolic solution (3 mL) of 1,3-diaminopropane (74 mg, 1 mmol) was diluted with diethyl ether (400 mL). A $CHCl_3$ solution (5 mL) of 3,3′-(3,6-dioxaoctane-1,8-diyldioxy)bis(2-hydroxybenzaldehyde) (392 mg, 1 mmol) was then added dropwise at room temperature. The resultant yellow precipitate was stirred for 20 min, then filtered off, washed well with a diethyl ether/light petroleum solution and dried in vacuo. 300 mg, 70% yield. $C_{23}H_{28}N_2O_6$ (428.46): calcd. C 64.48, H 6.59, N 6.54; found C 64.02, H 6.42, N 6.45. IR: $\tilde{\nu}$ = 1635−1627 cm^{-1} ($\nu_{C=N}$, s). ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 2.03 (quint., 2 H, $CNCH_2CH_2$), 3.65 (t, 4 H, $CNCH_2$), 3.73 (s, 4 H, CH_2O), 3.88 (t, 4 H, CH_2O), 4.18 (t, 4 H, CH_2O-Ar), 6.72 (t, 2 H, Ar−*H*), 6.83 (dd, 2 H, Ar−*H*), 6.93 (dd, 2 H, Ar−*H*), 8.29 (s, 2 H, *H*C=N), 13.83 (br. s, OH) ppm. MS: 429 $[M + H]^+$.

$Ln(H_2L_D)Cl_3{\cdot}nH_2O$ (Ln = La, Ce, Gd, Tb; n = 0−7): $LnCl_3{\cdot}nH_2O$ (2 mmol) in MeOH (5 mL) and, subsequently, 1,3-diaminopropane (148 mg, 2 mmol) in methanol (5 mL) were added to a pale yellow solution of 3,3′-(3,6-dioxaoctane-1,8-diyldioxy)bis(2-hydroxybenzaldehyde) (780.8 mg, 2 mmol) in methanol (50 mL). This yellow solution was then heated under reflux for 2.5 h and subsequently reduced to dryness.

$La(H_2L_D)Cl_3$: The obtained yellow residue was recrystallised from MeOH/EtOH, filtered off and dried in vacuo. 997 mg, 74% yield. $C_{23}H_{28}Cl_3LaN_2O_6$ (673.73): calcd. C 41.00, H 4.19, N 4.16; found (%) C 40.60, H 4.43, N 3.79. IR: $\tilde{\nu}$ = 1648 cm^{-1} ($\nu_{C=N}$, s). ^1H NMR (300 MHz, CD_3OD, 25 °C): δ = 2.43 (quint, 2 H, $CNCH_2CH_2$), 4.01 (t, 4 H, $CNCH_2$), 4.21 (s, 4 H, CH_2O), 4.37 (t, 4 H, CH_2O), 4.54 (t, 4 H, CH_2O-Ar), 6.73 (t, 2 H, Ar−*H*), 7.18 (dd, 2 H, Ar−*H*), 7.33 (dd, 2 H, Ar−*H*), 8.79 (s, 2 H, *H*C=N). SEM-EDS: La/Cl = 1:3.

$Ce(H_2L_D)Cl_3$: The yellow residue was recrystallised from MeOH/*i*PrOH, filtered off, washed with Et_2O and dried in vacuo. 931 mg, 69% yield. $C_{23}H_{28}CeCl_3N_2O_6$ (674.94): calcd. C 40.93, H 4.18, N 4.15; found C 41.61, H 4.64, N 4.31. IR: $\tilde{\nu}$ = 1639 cm^{-1} ($\nu_{C=N}$, s). ^1H NMR (300 MHz, CD_3OD, 25 °C): δ = 0.56 (s, 4 H, CH_2O), 2.36 (t, 4 H, CH_2O), 3.63 (m, 2 H, $CNCH_2CH_2$), 5.24 (d, 2 H, Ar−*H*), 5.53 (t, 4 H, $CNCH_2$), 6.35 (t, 2 H, Ar−*H*), 7.41 (t, 4 H, CH_2O), 7.94 (d, 2 H, Ar−*H*), 10.57 (s, 2 H, *H*C=N). SEM-EDS: Ce/Cl = 1:3.

$Gd(H_2L_D)Cl_3{\cdot}2H_2O$: The yellow residue was recrystallised from EtOH/*i*PrOH, filtered off, washed with Et_2O and dried in vacuo. 1077 mg, 74% yield. $C_{23}H_{28}Cl_3GdN_2O_6{\cdot}2H_2O$ (728.10): calcd. C 37.94, H 4.43, N 3.85; found C 38.42, H 5.13, N 3.81. IR: $\tilde{\nu}$ = 1653 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Gd/Cl = 1:3.

$Tb(H_2L_D)Cl_3{\cdot}7H_2O$: The yellow residue was treated with MeOH/Et_2O and dried in vacuo. 1181 mg, 72% yield. $C_{23}H_{28}Cl_3N_2O_6Tb{\cdot}7H_2O$ (819.84): calcd. C 33.70, H 5.16, N 3.42; found C 33.39, H 4.65, N 3.86. IR: $\tilde{\nu}$ = 1637 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Tb/Cl = 1:3.

$NiLn(L_D)Cl_3{\cdot}nH_2O{\cdot}m$EtOH (Ln = La, Ce, Gd, Tb, n = 0−2, m = 0−2): Triethylamine (202 mg, 2 mmol) and $NiCl_2{\cdot}6H_2O$ (237.7 mg, 1 mmol), dissolved in MeOH (2 mL), were added to a yellow solution of $Ln(H_2L_D)Cl_3{\cdot}nH_2O$ (1 mmol) in MeOH/EtOH (for La) or MeOH/*i*PrOH (for Ce,Gd,Tb) (20 mL) that was slightly heated (30 °C). After stirring for 10 min, a pale green precipitate formed. The

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

suspension was then stirred for a further 20 min and subsequently cooled to room temperature. The resultant pale green powder was collected by filtration, washed with Et_2O and dried in vacuo. Slow diffusion of Et_2O into an EtOH/MeOH solution of the compound produced green crystals. 62% average yield.

$LaNi(L_D)Cl_3$: 464 mg, 63% yield. $C_{23}H_{26}Cl_3LaN_2NiO_6$ (730.42): calcd. C 37.82, H 3.59, N 3.84; found C 37.75, H 4.11, N 3.40 IR: $\tilde{\nu}$ = 1636 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Ni/La/Cl = 1:1:3.

$CeNi(L_D)Cl_3$: 461 mg, 63% yield. $C_{23}H_{26}CeCl_3N_2NiO_6$ (731.63): calcd. C 37.76, H 3.58, N 3.83; found C 37.57, H 4.28, N 3.72. IR: $\tilde{\nu}$ = 1634 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Ni/Ce/Cl = 1:1:3.

$GdNi(L_B)Cl_3{\cdot}2H_2O{\cdot}EtOH$: 516 mg, 62% yield. $C_{23}H_{26}Cl_3GdN_2NiO_6{\cdot}2H_2O{\cdot}EtOH$ (830.86): calcd. C 36.14, H 4.37, N 3.37; found C 36.50, H 5.08, N 3.45. IR: $\tilde{\nu}$ = 1638 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Ni/Gd/Cl = 1:1:3.

$TbNi(L_B)Cl_3{\cdot}2EtOH$: 504 mg, 60% yield. $C_{23}H_{26}Cl_3N_2NiO_6Tb{\cdot}2EtOH$ (842.57): calcd. C 38.49, H 4.55, N 3.32; found C 38.13, H 4.89, N 3.41. IR: $\tilde{\nu}$ = 1628 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Ni/Tb/Cl = 1:1:3.

$CuLn(L_D)Cl_3{\cdot}CH_3OH$ (Ln = La, Ce, Gd, Tb): Triethylamine (202 mg, 2 mmol) and $CuCl_2{\cdot}2H_2O$ (170.5 mg, 1 mmol), dissolved in MeOH (2 mL), were added to a yellow solution of $Ln(H_2L_D)Cl_3{\cdot}nH_2O$ (1 mmol) in methanol (for La) or MeOH/EtOH (for Ce,Gd, Tb) (20 mL) that was slightly heated (30 °C). After stirring for 10 min, a green precipitate formed; the suspension was stirred for further 20 min and then cooled to room temperature. The resultant green powder was collected by filtration, washed with Et_2O and dried in vacuo. Slow diffusion of Et_2O into an EtOH/MeOH solution of the compound produced green crystals. 63% average yield.

$LaCu(L_D)Cl_3{\cdot}CH_3OH$: 492 mg, 64% yield. $C_{23}H_{26}Cl_3CuLaN_2O_6{\cdot}CH_3OH$ (767.30): calcd. C 37.57, H 3.94, N 3.60; found C 38.49, H 3.77, N 3.60. IR: $\tilde{\nu}$ = 1625 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Cu/La/Cl = 1:1:3.

$CeCu(L_D)Cl_3{\cdot}CH_3OH$: 480 mg, 62% yield. $C_{23}H_{26}CeCl_3CuN_2O_6{\cdot}CH_3OH$ (768.51): calcd. C 37.51, H 3.93, N 3.65; found C 37.84, H 4.02, N 3.87. IR: $\tilde{\nu}$ = 1627 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Cu/Ce/Cl = 1:1:3.

$GdCu(L_D)Cl_3{\cdot}CH_3OH$: 495 mg, 63% yield. $C_{23}H_{26}Cl_3CuGdN_2O_6{\cdot}CH_3OH$ (785.64): calcd. C 36.69, H 3.85, N 3.57; found C 37.40, H 3.53, N 3.45. IR: $\tilde{\nu}$ = 1627 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Cu/Gd/Cl = 1:1:3.

$TbCu(L_D)Cl_3{\cdot}CH_3OH$: 494 mg, 63% yield. $C_{23}H_{26}N_2O_6TbCuCl_3{\cdot}CH_3OH$ (787.31): calcd. C 36.61, H 3.84, N 3.56; found C 36.82, H 3.94, N 3.74. IR: $\tilde{\nu}$ = 1627 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Cu/Tb/Cl = 1:1:3.

$ZnLn(L_D)Cl_3{\cdot}nH_2O{\cdot}mROH$ (Ln = La, Ce, Gd, Tb; n = 0−3; m = 0−1; R = CH_3, CH_3CH_2): Triethylamine (202 mg, 2 mmol) and $ZnCl_2$ (136.28 mg, 1 mmol), dissolved in MeOH (2 mL), were added to a yellow solution of $Ln(H_2L_D)Cl_3{\cdot}nH_2O$ (1 mmol) in methanol or MeOH/EtOH (for La, Gd) (20 mL) that was slightly heated (30 °C). After stirring for 10 min, a pale yellow precipitate formed. The suspension was then stirred for further 20 min and subsequently cooled to room temperature. The obtained pale yellow powder was collected by filtration, washed with Et_2O and dried in vacuo. Slow diffusion of Et_2O into an EtOH/MeOH solution of the compound produced pale yellow crystals. 55% average yield.

$LaZn(L_D)Cl_3{\cdot}CH_3OH$: 439 mg, 57% yield. $C_{23}H_{26}Cl_3LaN_2O_6Zn{\cdot}CH_3OH$ (769.12): calcd. C 37.48, H 3.93, N 3.64; found C 36.86, H 3.49, N 3.53. IR: $\tilde{\nu}$ = 1631 cm^{-1} ($\nu_{C=N}$, s). ^1H NMR (300 MHz, CD_3OD, 25 °C): δ = 2.19 (quint, 2 H, $CNCH_2CH_2$), 4.00 (t, 4 H, $CNCH_2$), 4.20 (s, 4 H, CH_2O), 4.37 (t, 4 H, CH_2O), 4.56 (t, 4 H, CH_2O−Ar), 6.85 (t, 2 H, Ar−*H*), 7.13 (dd, 2 H, Ar−*H*), 7.28 (dd, 2 H, Ar−*H*), 8.41 (s, 2 H, *H*C=N). SEM-EDS: Zn/La/Cl = 1:1:3.

$CeZn(L_D)Cl_3{\cdot}CH_3OH$: 412 mg, 53% yield. $C_{23}H_{26}CeCl_3N_2O_6Zn{\cdot}CH_3OH$ (770.33): calcd. C 37.42, H 3.93, N 3.64; found C 37.42, H 3.68, N 3.66. IR: $\tilde{\nu}$ = 1630 cm^{-1} ($\nu_{C=N}$, s). ^1H NMR (300 MHz, CD_3OD, 25 °C): δ = 0.80 (br. s, 4 H, CH_2O), 1.81 (br. s, 4 H, CH_2O), 2.97 (m, 2 H, $CNCH_2CH_2$), 4.59 (m, 4 H, $CNCH_2$), 5.81 (br. s, 2 H, Ar−*H*), 6.60 (t, 2 H, Ar−*H*), 7.26 (br. s, 4 H, CH_2O), 7.63 (d, 2 H, Ar−*H*), 9.28 (s, 2 H, *H*C=N). SEM-EDS: Zn/Ce/Cl = 1:1:3.

Table 4. Crystal and intensity data for La−Cu, La−Zn and Tb−Cu complexes

Coordinated metals	La−Cu	La−Zn	Tb−Cu
Empirical formula	$C_{24}H_{30}Cl_3CuLaN_2O_7$	$C_{24}H_{30}Cl_3LaN_2O_7Zn$	$C_{24}H_{30}Cl_3CuN_2O_7Tb$
Formula mass	764.30	769.13	787.31
Crystal system	monoclinic	monoclinic	monoclinic
Space group	$P2_1/n$ (No. 14)	$P2_1/n$ (No. 14)	$P2_1/n$ (No. 14)
a [Å]	11.041(2)	11.186(2)	10.967(2)
b [Å]	14.034(3)	14.076(3)	13.851(3)
c [Å]	18.590(4)	18.558(4)	18.625(4)
β [°]	102.74(3)	103.35 (3)	102.68(3)
Cell volume [$Å^3$]	2809(1)	2843(1)	2760(1)
Z	4	4	4
Calcd. density [g/cm^3]	1.814	1.797	1.895
Absorption μ [mm^{-1}] (Mo-K_α)	2.588	2.653	3.648
Range of relative transmission factors [%][a]	91−100	88−100	81−100
θ limits [°]	6.9−56	6.2−56	6.3−56
Data collected/unique	6215/6028	6156/5981	3789/3636
Data observed	5958 [$F \geq 3.5\sigma(F)$]	5878 [$F \geq 3.5\sigma(F)$]	3557 [$F \geq 3.5\sigma(F)$]
No. of parameters (observed per parameter)	320 (18.6)	320 (18.4)	320 (11.1)
R [$\Sigma(\|F_o\| - \|F_c\|)/\Sigma\|F_o\|$]	0.051	0.063	0.067
R_w [$\Sigma w(\|\|F_o\| - \|F_c\|\|)^2/\Sigma w(F_o)^2]^{1/2}$	0.130	0.14	0.15
Highest map residual [$e^-/Å^3$]	1.67	1.22	1.18

[a] Corrections: Lorentz polarization and absorption (empirical, ψ scan).

$GdZn(L_D)Cl_3 \cdot 3H_2O$: 445 mg, 55% yield. $C_{23}H_{26}Cl_3GdN_2O_6Zn \cdot 3H_2O$ (809.46): calcd. C 34.13, H 3.98, N 3.46; found C 33.43, H 3.90, N 3.53. IR: $\tilde{\nu}$ = 1631 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Zn/Gd/Cl = 1:1:3.

$TbZn(L_D)Cl_3 \cdot EtOH$: 439 mg, 55% yield. $C_{23}H_{26}Cl_3N_2O_6TbZn \cdot CH_3CH_2OH$ (803.16): calcd. C 37.39, H 4.02, N 3.49; found C 36.82, H 3.80, N 3.51. IR: $\tilde{\nu}$ = 1632 cm^{-1} ($\nu_{C=N}$, s). SEM-EDS: Zn/Tb/Cl = 1:1:3.

X-ray Crystallography: Diffraction data were collected at room temperature with a Philips PW1100 automatic four-circle diffractometer (FEBO System) using graphite-monochromated Mo-K_α radiation and the ω-2θ scan mode. Lattice parameters were obtained from least-squares refinement of the setting angles of 25 reflections with $10° \leq 2\theta \leq 24°$. Table 4 summarises the crystallographic data and structure refinement. No sign of crystal deterioration was revealed by monitoring three standard reflections after every 200 measurements. Structures were solved by standard Patterson methods and subsequently completed by a combination of least-squares techniques and Fourier syntheses with the SHELX program.[54] All benzene rings were refined as rigid bodies, hydrogen atoms were included in idealised positions with fixed C−H distances (0.97Å) and isotropic temperature factors fixed to 1.2 times U(eq) of the respective carbon atom. Selected bond lengths and angles pertinent to the coordination spheres are given in Tables 1 and 2 and representative torsion angles in Table 3. Additional crystallographic data, atomic coordinates, anisotropic thermal parameters, and full listings of bond lengths and angles are provided as supplementary material. CCDC-244706, -244707 and -244708 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk]. Final geometrical calculations and drawings were carried out with the PARST program[55] and the XP utility of the Siemens package,[56] respectively, running on a DIGITAL ALPHA-AXP 300 computer. X-ray powder diffraction measurements were carried out with a Philips X'Pert diffractometer (40 kV, 35 mA) using graphite-monochromated Cu-K_α radiation in the range $5° < 2\theta < 80°$. The simulated powder diffraction pattern was obtained by means of the SHELXTL program (Bruker ASX, 1998) using the single-crystal diffraction data of the La−Cu complex.

Acknowledgments

We thank Mr. A. Aguiari, Mr. E. Bullita and Mrs. A. Moresco for their technical assistance. We also thank MIUR project FIRB-RBNE019H9 K for financial support. A. C. and L. S. thank FIRB RBNE01YLKN and CNR, Italy.

Carbonyl-Nitrido Mixed-Metal Clusters: Synthesis, Reactivity, Electrochemical Behavior and Solid-State Structure of $[Co_5MoN(CO)_{14}]^{2-}$ and $[Co_5MoN(CO)_{14}AuPPh_3]^-$

Roberto Della Pergola,*[a] Alessandro Fumagalli,[b] Fabrizia Fabrizi de Biani,[c] Luigi Garlaschelli,[d] Franco Laschi,[c] Maria Carlotta Malatesta,[d] Mario Manassero,*[e] Elena Roda,[d] Mirella Sansoni,[e] and Piero Zanello[c]

Keywords: Cobalt / Molybdenum / Cluster compounds / Nitrides / Electrochemistry

The dianionic cluster $[Co_5MoN(CO)_{14}]^{2-}$ (**1**) was synthesized from $[Co_6N(CO)_{15}]^-$ and $[Mo_2(CO)_{10}]^{2-}$ in refluxing acetonitrile. The solid-state structure of the $[Ph_4P]^+$ salt was determined. It consists of an octahedral metal cage, enclosing a six-coordinate nitrido ligand. Typical bond lengths are: Co–N 1.88 Å, Mo–N 2.03 Å, Co–Co 2.61 Å and Co–Mo 2.84 Å, showing that there is very little, if any, preferential interaction of the interstitial atom with that of molybdenum. The cluster reacts with $Au(PPh_3)Cl$ in THF at room temperature forming the derivative $[Co_5MoN(CO)_{14}\{AuPPh_3\}]^-$ (**2**). The gold atom caps an $MoCo_2$ face of the octahedron, with short Au–Co (2.68 Å) and long Au–Mo (3.16 Å) bonds, showing that both metal atoms are necessary for coordination, but Au^I binds better with the cobalt atoms. Electrochemical studies have pointed out that cluster **1** has good redox capabilities in that it is able to support reversibly the progressive addition of three electrons. EPR measurements on the corresponding trianion confirm the lack of preferential interaction between the Mo site and the interstitial nitride atom.

Introduction

Recently, we described the synthesis and the chemical characterization of octahedral mixed-metal clusters of iron and a metal of group 6 (Mo or W), containing an interstitial nitride. Even if the yields were only just acceptable, they were obtained selectively, using different complexes with ligands of a different nature (CO, Cp, MeCN).[1] As an extension of this type of chemistry, we moved to the synthesis of Co−Mo nitrides. The choice of these two elements was based on the industrial relevance of Mo and Co in hydrodesulfurization (HDS) and hydrodenitrogenation (HDN) reactions.[2] Molecular organometallic complexes have many applications in this field, since they contribute to clarifying the mechanism of the hydrogenation of thio and aza compounds.[3] In this context, clusters are especially of value, since they can homogeneously catalyze the hydrogenation of heterocycles[4] or model the interaction between N- and S-donors with multimetallic sites.[5] Even more important, sulfido Co−Mo clusters can stoichiometrically desulfurize thio compounds by a mechanism that is believed to closely mimic heterogeneous HDS.[6] Additionally, dimetallic sulfides can be prepared from a molecular precursor, either by supporting heterometallic Co−Mo clusters,[7] or by co-impregnation of homometallic carbonyl complexes.[8]

We started these investigations hoping that clusters containing Co, Mo and N could help us to understand the mutual relationships between the three elements. The first results of our efforts is the reproducible synthesis of a new cluster, $[Co_5MoN(CO)_{14}]^{2-}$, which could be fully characterized through a combination of chemical, spectroscopic, electrochemical and X-ray analyses. The yields of the anion are moderate, but its preparation is much simpler than those reported for other Co−Mo nitride complexes,[9] mak-

ing the cluster available on a decigram scale for further investigations.

Results

Synthesis and Reactivity

With the aim of synthesizing a nitrido Co−Mo cluster, we tried the same synthetic approach as was successfully used for the Fe−Mo analogs,[1] i.e. the condensation of a cobalt nitride, having a small negative charge, with a highly reduced carbonyl anion of molybdenum. Thus, the new product $[Co_5MoN(CO)_{14}]^{2-}$ (**1**) was obtained by reaction of $[Co_6N(CO)_{15}]^-$ (K^+ salt) and $[Mo_2(CO)_{10}]^{2-}$ (NEt_4^+ salt) in refluxing acetonitrile. IR monitoring shows that the reaction proceeds smoothly, the only by-products detectable in solution being the mononuclear carbonyl complexes $[Co(CO)_4]^-$ and $[Mo(CO)_6]$.[10] However, a fairly large amount of decomposition product is formed, which can easily be eliminated by filtration. Dianion **1** can be purified by metathesis with $[Ph_4P]^+$ in MeOH, which induces precipitation. We tested other less reducing complexes of molybdenum, such as $[Mo(CO)_3(NCEt)_3]$ or $[HMo_2(CO)_{10}]^-$, but the resulting yields were even lower. Thus, the formation of **1** can be formally represented by the reaction

$$[Co_6N(CO)_{15}]^- + [Mo_2(CO)_{10}]^{2-} \rightarrow [Co_5MoN(CO)_{14}]^{2-} + [Mo(CO)_6] + [Co(CO)_4]^- + CO$$

The reactivity of **1** with several potential sources of S- or N-ligands (such as quinoline, $NOBF_4$, Ph_2S_2) was examined. In order to perform ligand substitution, we attempted both the direct carbonyl displacement and "oxidative substitution",[11] analogous with what has been used for other dianionic octahedral clusters.[12] Unfortunately, no stable derivatives were ever obtained. Attempts to add hydride ligands to **1** by protonation resulted in the formation of $[Co_6N(CO)_{15}]^-$, in keeping with a weak interaction between the nitrogen and the molybdenum atom. All these disappointing results led us to further investigate the redox capability of **1**, thus prompting electrochemical investigations (see later). By contrast, the reaction between **1** and $Au(PPh_3)Cl$ in THF at room temperature is fast and clean, quantitatively yielding $[Co_5MoN(CO)_{14}\{AuPPh_3\}]^-$ within a few minutes. The isolation of this adduct demonstrated that the poor reactivity of the dianion **1** cannot be attributed to the absence of nucleophilic character, nor steric crowding of its carbonyl ligands. Due to its composition of early-, late- and post-transition elements, the trimetallic $[Co_5MoN(CO)_{14}\{AuPPh_3\}]^-$ can be well classified among the "very-mixed"-metal carbonyl clusters.[13]

The Solid-State Structures

The crystal structure of cluster **1** was determined on the $[Ph_4P]_2$**1** salt, and the geometry of the anion is shown in Figure 1.[14] Average values of bond lengths are collected in Table 1, and compared with the corresponding parameters determined in **2**. The individual values are reported in Table S4 of the Supporting Information. The six metal atoms define an octahedron, centered by an interstitial nitride. As normally observed in Co clusters, the four unbridged edges are definitely longer than the bridged ones.[15] Examining the metal−metal and the metal−nitrogen bond lengths of other nitrido Co−Mo complexes,[9] Dahl discovered that Mo−N interactions are shorter than expected, and concluded that the Mo−N bond order was higher than the Co−N bond order. The same arguments were also used for nitrido Fe−Mo clusters,[1] with a strong interaction between the electron-deficient molybdenum atoms and the nitride (a well-known strong π-donor).[16] In the present case the uncertainty of the metallic radius of the cobalt atoms is high, since the Co−Co bond lengths are scattered by the

presence of bridged and unbridged bonds (the root mean square deviations are listed in Table 1). The average values in **1** are 2.61 ± 0.12 Å for the Co−Co distances and 2.84 ± 0.04 Å for the Mo−Co bonds. Therefore the metallic radius of the Co atom can be estimated as being 0.23 ± 0.12 Å smaller than that of Mo. On the other hand, the average Co−N bond is only 0.15 ± 0.01 Å shorter than the Mo−N distance. The discrepancy between the two values (0.08 Å) is obviously smaller than the root mean square deviations and statistically uninformative. Nevertheless, with this difference being similar to that of other related clusters,[9] one would be tempted to presume that in **1** a small displacement of the nitride towards the Mo atom occurs.

The idealized symmetry of the whole anion is C_s, with the mirror plane passing through Mo, N and the midpoint of the Co2−Co3 edge. The cluster is surrounded by ten terminal and four edge-bridging carbonyl groups, distributed in such a way that all metal atoms are connected to three ligands. The Mo and Co atoms differ in the bonding mode of the ligands, due to their different valence electrons: Mo is connected to terminal ligands only, Co1 and Co4 to two terminal and one bridging group, Co2 and Co3 to one terminal and two bridging CO groups. With respect to this, it is remarkable that the dimetallic cluster **1** displays the same arrangement of bridging ligands found in $[Co_6N(CO)_{13}]^-$, with four μ-CO groups "spanning a sequence of four bonds".[15] As a matter of fact the octahedral clusters of Rh and Co that contain an interstitial atoms and thirteen ligands, all adopt a different stereochemistry of the carbonyls.[15,17]

The solid-state structure of cluster **2** was determined on the $[Ph_4P]$**2** salt. The anion is shown in Figure 2, selected structural parameters are listed in Table S4 of the Supporting Information.

Also in this case, six metal atoms define an octahedron, centered by the interstitial nitride. The gold atom is situated on the triangular face composed of Mo, Co1 and Co4. The Co and Mo atoms bind differently to the gold atom. As in **1**, the Mo−N, Mo−CO and Mo−Co distances are longer by about 0.2 Å than the corresponding cobalt bonds, whereas the difference between Mo−Au and Co−Au is almost 0.5 Å. The different abilities of the two metals to coordinate gold can probably be explained by their electronic configuration: the Mo atom, already depleted of electron density, is less prone to adding the electrophilic fragment than the Co atom. The addition of the Au−PPh_3 moiety brings about little change to the average structural parameters, but several distortions on the individual values, which can be related to electronic rather than to steric factors. As a matter of fact, the Co1−Co4 edge becomes abnormally long (2.810 Å), suggesting some reduction in its electron density. To compensate, N−Co1 and N−Co4 bonds are shortened, whereas Mo−N is lengthened, in contrast to the expected effect between the N(−3) donor and the Au(+1) acceptor. Also in **2**, no convincing conclusions can be drawn on the strength of Co−N and Mo−N interactions, since the difference in metallic radii, estimated from

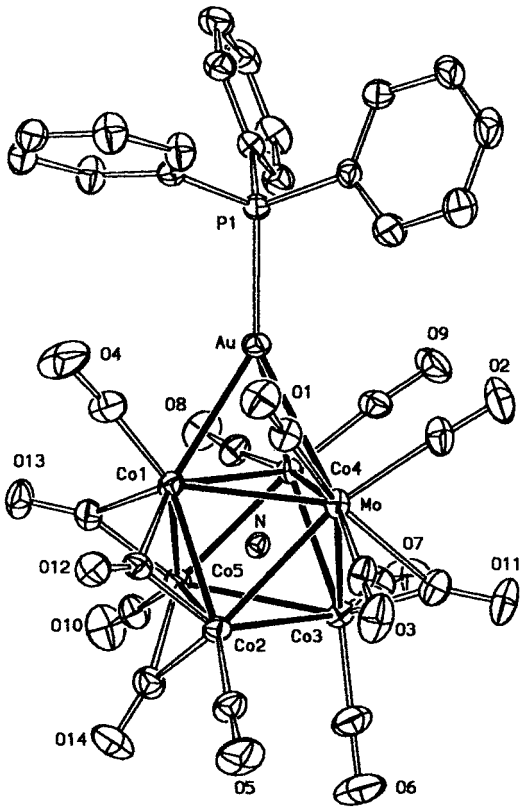

Figure 2. The solid-state structure of $[Co_5MoN(CO)_{14}\{AuPPh_3\}]^-$; carbon atoms are labeled using the oxygen atom to which they are attached

metal−metal and metal−nitrogen bond lengths, is even smaller than in **1** (0.07 ± 0.10 Å).

A very small lengthening of the M−CO (comparable, however, with uncertainties) might be indicative of reduced back-donation. The architecture of the bridging ligands is modified in **2**, and a "true" μ-CO group, spanning a Co−Mo edge, is formed. The other three bridging carbonyl groups are located on the edges of the Co1, Co2, Co5 cluster face, which has the shortest Co−Co bonds. Thus, the shortening effect of the bridging ligands can also be observed in **2**.

Electrochemistry and Joint EPR Measurements

Figure 3 illustrates the cyclic voltammetric behavior of $[Co_5MoN(CO)_{14}]^{2-}$ in MeCN solution.

Three sequential reductions with features of chemical reversibility are clearly detected together with an irreversible process interposed between the second and the third step. Taking into account that this latter process occurs at the same potential than that of an authentic sample of $[Ph_4P]Br$, we assign it to the countercation of the cluster dianion.

Controlled potential coulometry corresponding to the first reduction (E_w = −1.5 V) consumed one electron per molecule. In order to confirm the long-term chemical reversibility of such a process, cyclic voltammetry was performed on the exhaustively reduced solution, affording pro-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

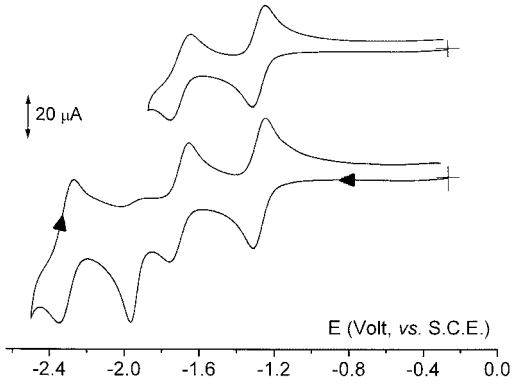

Figure 3. Cyclic voltammetric responses recorded at a gold electrode in an MeCN solution of $[Ph_4P]_2[Co_5MoN(CO)_{14}]$ (1.7×10^{-3} mol·dm^{-3}); $[Bu_4N][PF_6]$ (0.2 mol·dm^{-3}); scan rate 0.2 V s^{-1}

files quite complementary to the original ones. On this basis we assign the series of chemically reversible reduction steps to the four-membered sequence $[Co_5MoN(CO)_{14}]^{2-/3-/4-/5-}$.

Analysis of the $[Co_5MoN(CO)_{14}]^{2-/3-}$ process with scan rates increasing from 0.02 to 1.00 Vs^{-1} not only agrees with the chemical reversibility of the process (i_{pa}/i_{pc} constantly equal to unity), but also reveals its electrochemical reversibility (ΔE_p constantly equal to 59 mV), thus suggesting that no significant geometrical reorganization accompanies the electron addition.[18]

The formal electrode potentials of the processes discussed above are compiled in Table 2. Finally, we point out that $[Co_5MoN(CO)_{14}]^{2-}$ also exhibits an irreversible multielectron oxidation ($E_p = +0.13$ V).

In view of the chemical stability of the trianion $[Co_5MoN(CO)_{14}]^{3-}$, EPR investigations have been carried out on the complex after its electrogeneration at −20 °C. Figure 4 shows the X-band EPR spectrum of the MeCN solution of the trianion recorded under glassy conditions ($T = 100$ K).

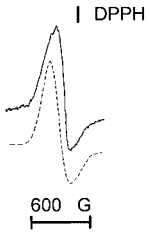

Figure 4. X-band EPR spectra of the frozen solution of $[Co_5MoN(CO)_{14}]^{3-}$; $T = 100$ K; MeCN solution; solid line: first derivative experimental spectrum; dashed line: simulated spectrum

The lineshape analysis is suitably carried out assuming an $S = 1/2$ axial electron spin hamiltonian with poor resolution of the overall anisotropic signal, which is constituted by two absorptions overlapped in the intermediate field.[19] The computed[20] g_i anisotropic parameters display a noticeable metal character ($g_\perp > g_\parallel > g_{electron} = 2.0023$):

$g_\parallel = 1.985(8)$, $g_\perp = 2.160(8)$; $<g> = 1/3(g_\parallel + 2g_\perp) = 2.102(8)$

$\Delta H_\parallel = 110(5)$ G; $\Delta H_\perp = 95(5)$ G

Neither Co (^{59}Co: $I = 7/2$; natural abundance = 100%) nor Mo (^{97}Mo, ^{99}Mo: $I = 5/2$; natural abundance = 15.8 and 9.6%, respectively) hyperfine (hpf) or superhyperfine (shpf) splittings are detected, as a consequence of the noticeable anisotropic line widths largely overlapping the underlying metal magnetic couplings, if any, i.e.

$\Delta H_\parallel = 110(5)$ G $\geq a_i(^{59}Co, ^{97,99}Mo, ^{14}N)$;

$\Delta H_\perp = 95(5)$ G $\geq a_i(^{59}Co, ^{97,99}Mo, ^{14}N)$

The actual paramagnetic features indicate the complete delocalization of the $S = 1/2$ unpaired spin density onto the octahedral metal frame without any evidence for significant individual metal interaction. The fact that the interstitial nitride nucleus (^{14}N: $I = 1$; natural abundance = 99.6%) does not exhibit resolved anisotropic splittings, confirms this.

Raising the temperature of the glassy-fluid transition phase ($T = 227.5$ K) results in the axial signal disappearing and the paramagnetic solution becoming EPR-mute. Rapidly refreezing the fluid solution only partially recovers the original anisotropic signal, indicating chemical lability of the electrogenerated trianion in fluid solution under a non-inert gas.

Conclusions

The synthesis of the new cluster $[Co_5MoN(CO)_{14}]^{2-}$ was pursued hoping that substitution or addition of nitrogen or sulfur donors would highlight the cooperativity of the two metals in the coordination of the ligands and the cleavage of C−N and C−S bonds.[3] Even if it does not react directly with these types of ligands, the formation of $[Co_5MoN(CO)_{14}\{AuPPh_3\}]^-$ shows that more ligands can be added to its metal cage, and that both metallic elements are important for activation and coordination of electrophiles. Moreover, in contrast with what has been found in related dimetallic compounds,[9] the solid-state structure of both clusters allows us to exclude a preference of the nitride for the Co or Mo atom. The redox reactivity of the anion was studied by electrochemical and ESR experiments, that may suggest an alternative way to achieve substitution, through Electron Chain Transfer Catalysis (ECTC).[21] Therefore, we feel that the isolation of this dimetallic cluster can be relevant for material sciences, since it can be used as a molecular precursor to provide dimetallic nitrides, which

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are active catalysts for the HDN reactions and for ammonia synthesis.[22] Additionally, after the discovery of an interstitial μ_6-N atom in the Fe−Mo cofactor of nitrogenase,[23] carbonyl-nitrido clusters will also play an important role in the field of bioinorganic chemistry and N_2 activation, either as starting materials for synthetic studies,[24] or as reliable references for spectroscopy.[25]

Experimental Section

General: All solvents were purified and dried by conventional methods and stored under nitrogen. All reactions were carried out under oxygen-free nitrogen using the Schlenk-tube technique.[26] $K[Co_6N(CO)_{15}]$,[27] $[Et_4N]_2[Mo_2(CO)_{10}]$,[28] were prepared by literature methods. Infrared spectra in solution were recorded with a Nicolet Avatar FT-IR spectrophotometer, using calcium fluoride cells previously purged with N_2. Elemental analyses were carried out by the staff of the Laboratorio di Analisi of the Dipartimento di Chimica Inorganica, Metallorganica e Analitica. The materials and apparatus for the electrochemistry and joint-EPR measurements have been described elsewhere.[29] All of the potential values were referenced to the saturated calomel electrode (SCE). Under the present experimental conditions, the one-electron oxidation of ferrocene occurs at +0.38 V.

Synthesis of $[Co_5MoN(CO)_{14}]^{2-}$ from $[Co_6N(CO)_{15}]^-$ and $[Mo_2(CO)_{10}]^{2-}$: $K[Co_6N(CO)_{15}]$ (1.21 g; 1.47 mmol) and $[Et_4N]_2[Mo_2(CO)_{10}]$ (0.58 g; 0.79 mmol) were dissolved in MeCN (70 mL) and refluxed, while monitoring by IR spectroscopy. After about 7 h, the starting materials were completely consumed, the solution was cooled to room temperature and filtered to eliminate the insoluble material. The solvent was removed in vacuo and the residue was dissolved with methanol. Addition of $[Ph_4P]Br$ caused precipitation of microcrystalline $[Ph_4P]_2$**1**, which was filtered off, washed with 2-propanol and dried. It was then dissolved in the minimum amount of THF, and the solution layered with 2-propanol. Crystals of the salt $[Ph_4P]_2$**1** were obtained in 20% yield. IR (THF; cm^{-1}): ν(CO) = 2019 w, 1960 vs, 1832 m (see Figure S5 of the Supporting Information). $C_{62}H_{40}Co_5MoNO_{14}P_2$ (1475.5): calcd. C 50.47, H 2.73, N 0.95; found C 50.24, H 2.15, N 0.85.

Synthesis of $[Co_5MoN(CO)_{14}\{AuPPh_3\}]^-$: $[Ph_4P]_2[Co_5MoN(CO)_{14}]$ (0.10 g; 0.064 mmol) and $Au(PPh_3)Cl$ (0.03 g; 0.062 mmol) were dissolved in THF (10 mL) and stirred at room temperature. After 15 min, the reaction was completed, the solvent was then removed in vacuo, and the solid was repeatedly washed with 2-propanol. It was then dissolved in a minimum amount of THF, and the solution was layered with 2-propanol. Yield 44 mg of $[Ph_4P]$**2** (43%). IR (THF; cm^{-1}): ν(CO) = 2038 m, 1986 vs, 1861 m, 1838 w in THF (see Figure S5 of the Supporting Information). $C_{56}H_{35}AuCo_5MoNO_{14}P_2$ (1595.4): calcd. C 42.16, H 2.21, N 0.88; found C 42.08, H 1.86, N 0.85. ^{31}P NMR (CD_2Cl_2): δ = 23.9 ppm ($[Ph_4P]^+$), 60.26 ppm ($AuPPh_3$).

X-ray Data Collections and Structure Determinations: Crystal data are summarized in Table 3; for further experimental details see Supporting Information and ref.[14] The diffraction experiments were carried out with a Bruker SMART CCD area-detector diffractometer at 223 K. The collected frames were processed with the software SAINT,[30] and an empirical absorption correction was applied (SADABS)[31] to the collected reflections. The calculations were performed using the Personal Structure Determination Package[32] and the physical constants tabulated therein.[33] The structures were solved by direct methods (SHELXS)[34] and refined by full-matrix least squares using all reflections and minimizing the function $\Sigma w(F_o^2 - kF_c^2)^2$ (refinement on F^2). Anisotropic thermal factors were refined for all the non-hydrogen atoms. The hydrogen atoms were placed in their ideal positions (C−H = 0.97 Å), with the thermal parameter B = 1.10 times that of the carbon atom to which they are attached, and not refined. For noncentrosymmetric $[Ph_4P]_2$**1** full refinement of the correct structure model led to R_2 = 0.064 and R_{2w} = 0.090, full refinement of the inverted structure led to R_2 = 0.065 and R_{2w} = 0.092. In the final Fourier maps the maximum residuals were 1.87(15) e·Å^{-3} at 0.78 Å from Co(3) and 0.92(18) e·Å^{-3} at 0.89 Å from Au for $[Ph_4P]_2$**1** and $[Ph_4P]$**2**, respectively.

endo and *exo* Coordination of Indanol: Synthesis, Isolation and Structural Characterisation of $[H_3Ru_3(endo\text{-Indanol})(C_6Me_6)_2(O)]^+$ and $[H_3Ru_3(exo\text{-Indanol})(C_6Me_6)_2(O)]^+$ as Their Tetrafluoroborate Salts

Ludovic Vieille-Petit,[a] Lydia Karmazin-Brelot,[a] Gaël Labat,[a] and Georg Süss-Fink*[a]

Keywords: Arene ligands / Biphasic catalysis / Cluster compound / Hydrogenation / Ruthenium

The reaction of 2,3,4,7-tetrahydro-1*H*-inden-2-ol with ruthenium chloride hydrate in refluxing ethanol yields the chloro-bridged dinuclear complex $[RuCl_2(indanol)]_2$ (**1**). The mononuclear complex $[Ru(indanol)(H_2O)_3]^{2+}$ (**2**), formed in situ from **1** in aqueous solution, reacts with the dinuclear complex $[H_3Ru_2(C_6Me_6)_2]^+$ to give a trinuclear arene-ruthenium cluster as a mixture of two isomers, the cations $[H_3Ru_3(endo\text{-indanol})(C_6Me_6)_2(O)]^+$ (**3a**) and $[H_3Ru_3(exo\text{-indanol})(C_6Me_6)_2(O)]^+$ (**3b**), in a 1:1 ratio. The hydroxy function of the indanol ligand is oriented towards the μ_3-oxo cap of **3a**, whereas the OH group is bent away from the metal skeleton of **3b**. These two isomers, which can easily be separated by silica-gel chromatography, were isolated and characterised as their tetrafluoroborate salts. The single-crystal X-ray structure analysis of $[\mathbf{3a}][BF_4]$ shows a strong intramolecular hydrogen bond between the μ_3-oxo ligand and the hydroxyl function, which even persists in acetone solution, as demonstrated by NMR spectroscopy. On the other hand, the hydroxy function of **3b** was found to be free in the solid state as well as in solution, as shown by an X-ray crystal structure analysis and by NMR spectroscopy. The catalytic activities of the water-soluble trinuclear cations **3a** and **3b** for the hydrogenation of benzene to give cyclohexane under biphasic conditions are considerably different, the *exo* isomer **3b** being more active than the *endo* isomer **3a**.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

We reported recently that the cluster cation $[H_3Ru_3(C_6H_6)(C_6Me_6)_2(O)]^+$, used as its water-soluble tetrafluoroborate salt, efficiently catalyses the hydrogenation of benzene to cyclohexane under biphasic conditions.[1] From experimental and molecular modelling studies we concluded that the substrate molecule is incorporated into the hydrophobic pocket spanned by the three arene ligands, suggesting that the catalytic reaction occurs within this host-guest complex without prior coordination of the substrate (''supramolecular cluster catalysis'').[2] Furthermore, we were able to isolate the catalyst-substrate host-guest complexes postulated for two hydroxyalkyl derivatives as their tetrafluoroborate or hexafluorophosphate salts $[C_6H_6{\subset}H_3Ru_3\{C_6H_5(CH_2)_2OH\}(C_6Me_6)_2(O)][PF_6]$ and $[C_6H_6{\subset}H_3Ru_3\{C_6H_5(CH_2)_3OH\}(C_6Me_6)_2(O)][BF_4]$.[3] However, on the basis of the data obtained so far,[4] we cannot exclude catalysis by ''soluble'' metallic species (nanoclusters or colloids), and we are presently engaged in a collaborative effort to refute or support this alternative hypothesis.[5a] In this context, we also tried to design new trinuclear arene-ruthenium cluster cations with functional substituents at one η^6-moiety which could give rise to more stable catalysts which may be particularly active or selective.

Herein we report the synthesis and characterisation of a new chloro-bridged arene-ruthenium dimer, $[RuCl_2(indanol)]_2$ (**1**), which is used to synthesise a trinuclear cluster cation containing indanol as one of the three arene ligands: $[H_3Ru_3(indanol)(C_6Me_6)_2(O)]^+$ (**3**). Surprisingly, **3** was obtained as a mixture of two isomers, **3a** and **3b**, which were easily separated by silica-gel chromatography. Single-crystal X-ray structure analyses of $[\mathbf{3a}][BF_4]$ and $[\mathbf{3b}][BF_4]$ have been performed to establish unambiguously the molecular structures of these two isomers. The different catalytic activities of **3a** and **3b** in the hydrogenation of benzene to cyclohexane under biphasic conditions are also discussed. This is the first time that indanol has been used as a ligand in ruthenium chemistry and that both the *endo* and the *exo* isomers of the corresponding complexes have been characterised by single-crystal X-ray crystallography.

Results and Discussion

The reaction of 2,3,4,7-tetrahydro-1*H*-inden-2-ol, accessible from the Birch reduction of commercially available 2-indanol,[6] with ruthenium(III) chloride hydrate, in refluxing ethanol, gives the chloro-bridged dimer $[RuCl_2(indanol)]_2$ (**1**), which is obtained quantitatively as an orange powder

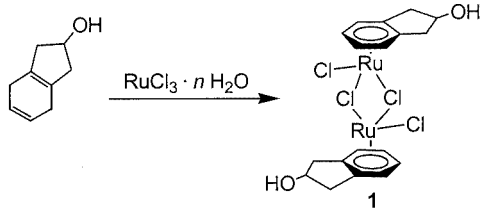
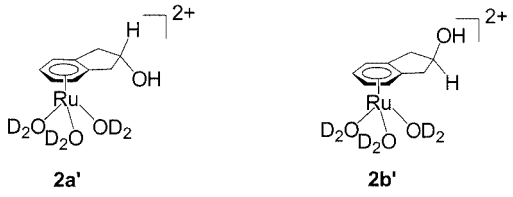
(Scheme 1). Compound **1** is expected to exist as a mixture of three possible isomers, since the OH groups of the two indanol ligands may be folded outwards (*exo*) or inwards (*endo*). Unfortunately, as **1** is insoluble in all solvents except water and dimethyl sulfoxide, in which **1** decomposes to give mononuclear species, we cannot tell whether or not the orange powder of **1** contains only one or all three possible isomers *exo*,*exo*-**1**, *exo*,*endo*-**1** and *endo*,*endo*-**1**. The molecular formula $[RuCl_2(indanol)]_2$ for **1** has been confirmed by electrospray-mass spectroscopy and micro-analysis.



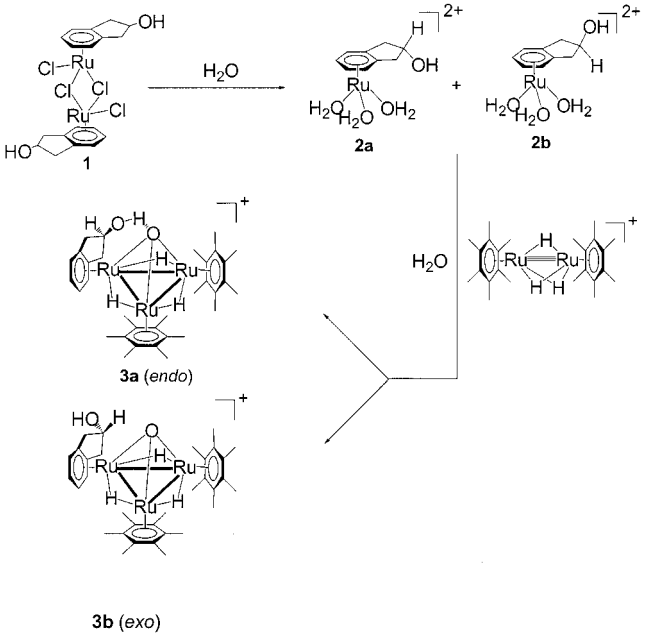
Scheme 1

In aqueous solution, the dimer **1** seems to form the mononuclear complex $[Ru(indanol)(H_2O)_3]^{2+}$ (**2**), an analogue of the known cation $[Ru(C_6H_6)(H_2O)_3]^{2+}$.[7] In order to characterise this intermediate by NMR spectroscopy, we prepared the deuterated analogue $[Ru(indanol)(D_2O)_3]^{2+}$ (**2′**) by cleavage of **1** with two equivalents of Ag_2SO_4 in deuterated water. The ^1H NMR spectrum of the solution obtained after elimination of the AgCl precipitate shows the expected two sets of well-defined signals which can be assigned to the two isomers $[Ru(endo\text{-indanol})(D_2O)_3]^{2+}$ (**2a′**) and $[Ru(exo\text{-indanol})(D_2O)_3]^{2+}$ (**2b′**) in a 10:7 ratio (Scheme 2).



Scheme 2

In aqueous solution, the mononuclear intermediate **2** (a mixture of isomers **2a** and **2b**) reacts with the dinuclear complex $[H_3Ru_2(C_6Me_6)_2]^+$ [8] to give a trinuclear arene-ruthenium cluster as a mixture of two isomers, the cations $[H_3Ru_3(endo\text{-indanol})(C_6Me_6)_2(O)]^+$ (**3a**) and $[H_3Ru_3(exo\text{-indanol})(C_6Me_6)_2(O)]^+$ (**3b**), in a 1:1 ratio. The oxo cap in the clusters **3a** and **3b** seems to arise from one of the H_2O ligands in the precursors **2a** and **2b**. The hydroxy function of the indanol ligand is oriented towards the μ_3-oxo cap of **3a**, whereas it is bent away from the metal skeleton of **3b** (Scheme 3). Compounds **3a** and **3b** are easily separated as their tetrafluroborate salts by preparative thin-layer silica-gel chromatography.



Scheme 3

Like the known analogues $[H_3Ru_3(\eta^6\text{-arene})(\eta^6\text{-arene}')_2(O)]^+$,[1,3,9] compounds **3a** and **3b** also give rise to two hydride signals each in the ^1H NMR spectra, a triplet centred at $\delta = -19.92$ ppm for **3a** and $\delta = -20.07$ ppm for **3b** and a doublet centred at $\delta = -19.30$ ppm for **3a** and $\delta = -19.41$ ppm for **3b**, integrating for one and two protons, respectively. The isolated compounds [**3a**][BF_4] and [**3b**][BF_4] were analysed by single-crystal X-ray crystallography. The molecular structures of [**3a**]$^+$ and [**3b**]$^+$ are shown in Figure 1.

While [**3b**][BF_4] crystallises in a monoclinic space group with one cation and one anion in the asymmetric unit, in the case of **3a** (triclinic space group) the asymmetric unit comprises two independent cations and two anions, two dichloromethane molecules, and half a molecule of dichloromethane disordered with half a water molecule. Only one molecule of **3a** is shown in Figure 1 as the other one is identical.

In both **3a** and **3b** the metal core consists of three ruthenium atoms, the three Ru−Ru distances being in accordance with a metal−metal single bond. The three ruthenium atoms are capped by a μ_3-oxo ligand which is almost symmetrically coordinated. Selected bond lengths and angles are listed in Table 1 and 2 for **3a** and **3b**, respectively. The indanol ligand adopts an envelope conformation in which the five-membered ring is folded towards the ruthenium atom. The *endo* conformation of the indanol ligand in **3a** allows a strong intramolecular hydrogen bond between the hydroxyl substituent and the μ_3-oxo cap, the distances between the oxygen atoms and the hydroxide protons being 1.90 Å for molecule 1 and 1.84 Å for molecule 2. The triruthenium framework of the *exo* conformation in **3b** shows intermolecular hydrogen bonds between the indanol ligand and the tetrafluoroborate ion, the distances between the hy-

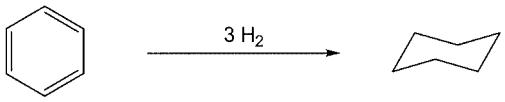
droxide proton and two of the fluorine atoms being 2.44 Å and 2.25 Å.

The strong intramolecular hydrogen bond found in the solid state for **3a** seems to persist also in acetone solution. The ^1H NMR spectrum of **3a** in $[D_6]$acetone shows a well-defined doublet centred at $\delta = 6.77$ ppm, attributed to the proton of the OH group coupled to the α-proton of the indanol ligand, the coupling constant being 13 Hz. On the other hand, the ^1H NMR spectrum of **3b** in $[D_6]$acetone shows a badly defined doublet centred at $\delta = 4.44$ ppm for the OH group, the coupling constant being 4.48 Hz (see Figure 2).

The water-soluble cations **3a** and **3b** are indeed found to be catalytically active for the hydrogenation of benzene to cyclohexane under biphasic conditions; they show a catalytic activity of 67 and 125 h^{-1} (average TOF), respectively, for a catalyst/substrate ratio of 1:1000, at 110 °C under 60 bar of H_2 during three hours. The catalytic activity of **3a** and **3b** is not as high as that of the benzene analogue $[H_3Ru_3(C_6H_6)(C_6Me_6)_2(O)]^+$, which under the same conditions has an average catalytic turnover frequency of 296 h^{-1}.[4]



After a catalytic run the cationic clusters **3a** or **3b** can be recovered unchanged from the aqueous phase in 90 to 95% yield. As a small quantity of black solid (presumably metallic ruthenium) is formed during the catalytic run, it is certainly possible, if not probable,[5a,5b] that the catalytic reaction involves highly dispersed metallic species ("nanoclusters") formed by partial degradation of the catalyst precursor under hydrogen pressure. The difference in the catalytic activity of **3a** and **3b** could be due to the different stability of these clusters with respect to the formation of nanopart-

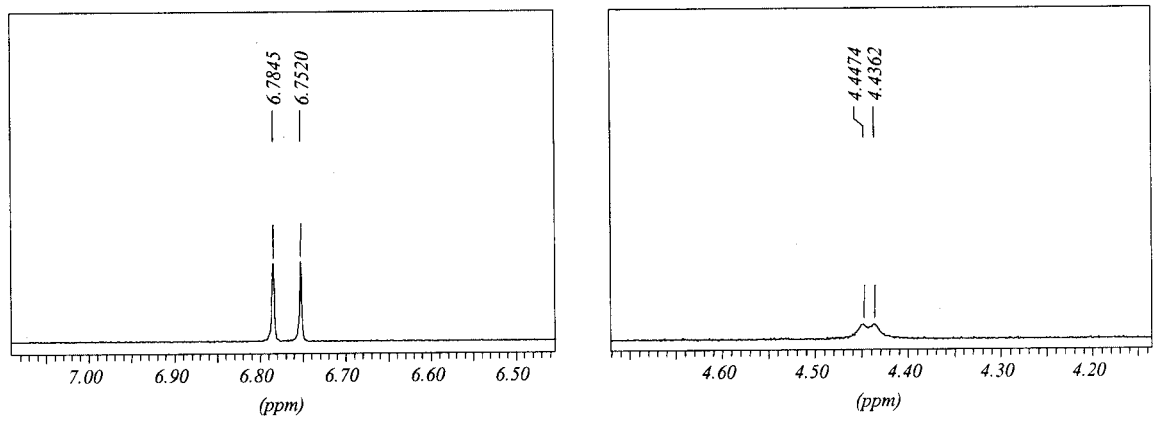

Figure 2. ^{1}H NMR spectra (O*H* signals) of **3a** (left) and **3b** (right) in [D$_6$]acetone (400 MHz)

icles under the catalytic conditions. Further work is underway in order to answer this question unequivocally.[5a]

Conclusion

Indanol, C_9H_9OH, has been used as a ligand in ruthenium chemistry for the first time. The new dimeric complex $[RuCl_2(indanol)]_2$ (**1**) serves as a dinuclear building block for the assembly of the isomeric trinuclear cluster cations $[H_3Ru_3(endo\text{-indanol})(C_6Me_6)_2(O)]^+$ (**3a**) and $[H_3Ru_3(exo\text{-indanol})(C_6Me_6)_2(O)]^+$ (**3b**), isolated as their tetrafluoroborate salts. For the first time, both *endo* and *exo* isomers of a ruthenium indanol complex have been characterised by X-ray crystallography.

Experimental Section

General Remarks: All manipulations were carried out under an inert argon atmosphere using standard Schlenk techniques. Doubly distilled water was degassed and saturated with argon prior to use. Organic solvents used for chromatography were distilled under argon prior to use. Silica-gel G used for preparative thin-layer (20 × 20 cm) chromatography was purchased from Macherey−Nagel GmbH. Deuterated NMR solvents were purchased from Cambridge Isotope Laboratories, Inc. NMR spectra were recorded using a Bruker 400 MHz spectrometer and treated using the 1D WIN NMR spectroscopy software. The mass spectra were recorded at the University of Fribourg by Prof. Titus Jenny. Microanalyses were carried out by the Mikroelementaranalytisches Laboratorium, ETH Zürich (Switzerland). 2,3,4,7-Tetrahydro-1*H*-inden-2-ol was prepared by sodium reduction of 2-indanol in liquid ammonia.[6] The starting dinuclear dichloro complex $[RuCl_2(C_6Me_6)]_2$ was synthesised according to published methods.[10]

$[RuCl_2(indanol)]_2$ (1): 2,3,4,7-Tetrahydro-1*H*-inden-2-ol (6 g, 44.4 mmol) was added to a solution of ruthenium trichloride hydrate (1.70 g, 6.5 mmol) in absolute degassed ethanol (100 mL) and the mixture was refluxed overnight. After cooling to room temperature, the resulting orange precipitate was filtered, washed with diethyl ether, and dried under vacuum to give pure $[RuCl_2(indanol)]_2$ as an orange powder. Yield: 1.90 g (95%). $C_{18}H_{20}Cl_4O_2Ru_2$ (612.30): calcd. C 35.31, H 3.29; found C 35.22, H 3.44. MS (ESI positive mode, methanol): m/z = 576.8 $[M - Cl]^+$.

$[Ru(endo\text{-indanol})(D_2O)_3]^{2+}$ (2a′) and $[Ru(exo\text{-indanol})(D_2O)_3]^{2+}$ (2b′): In a 250 mL brown-glass Schlenk tube, compound **1** (150 mg, 0.245 mmol) was mixed with a solution of Ag_2SO_4 (153 mg, 0.490 mmol) in 5 mL of D_2O. The suspension was stirred at room temperature until the orange solid had completely dissolved to give a yellow solution of **2a′** and **2b′**. The white precipitate of AgCl formed was removed from the aqueous solution by filtration through filter pulp and the resulting clear solution was directly analysed by NMR spectroscopy. ^{1}H NMR spectroscopic data for the mixture of **2a′** and **2b′** (400 MHz, D_2O, 25 °C): δ = 2.53 [dd, ^2J = 16.38, ^3J = 7.30 Hz, 2 H, (C*H*)$_2$CHOH], 2.81 [d, ^2J = 17.79 Hz, 2 H, (C*H*)$_2$CHOH], 2.98 [dd, ^2J = 17.79, ^3J = 5.50 Hz, 2 H, (C*H*)$_2$CHOH], 3.17 [dd, ^2J = 16.38, ^3J = 7.17 Hz, 2 H, (C*H*)$_2$CHOH], 4.83 [m, 1 H, (CH)$_2$C*H*OH], 4.89 [m, 1 H, (CH)$_2$C*H*OH], 5.83 to 6.00 (m, 8 H, H_{arom}) ppm.

$[H_3Ru_3(endo\text{-indanol})(C_6Me_6)_2(O)][BF_4]$ (cation 3a) and $[H_3Ru_3(exo\text{-indanol})(C_6Me_6)_2(O)\ [BF_4]$ (cation 3b): In a 250 mL brown-glass Schlenk tube, $[RuCl_2(C_6Me_6)]_2$ (300 mg, 0.449 mmol) was mixed with a solution of Ag_2SO_4 (282 mg, 0.904 mmol) in 30 mL of water. The suspension was stirred at room temperature until the orange solid had completely dissolved to give a yellow solution of $[Ru(C_6Me_6)(H_2O)_3]^{2+}$ (ca. one hour). The white precipitate of AgCl formed was removed from the aqueous solution by filtration through filter pulp. The resulting clear yellow filtrate was cooled in an ice bath for 30 minutes. In a separate 50 mL Schlenk tube, $NaBH_4$ (75 mg, 1.974 mmol) was dissolved in 15 mL of water at room temperature. After stirring for five minutes, the $NaBH_4$ solution was transferred very slowly through a cannula into the cooled $[Ru(C_6Me_6)(H_2O)_3][SO_4]$ solution. The colour of the solution changed to black, due to the formation of $[H_3Ru_2(C_6Me_6)_2]^+$. The resulting solution was immediately filtered trough filter pulp under argon to remove insoluble black particles. Solid $[RuCl_2(indanol)]_2$ (260 mg, 0.425 mmol) was added to the dark clear solution containing $[H_3Ru_2(C_6Me_6)_2]^+$. The mixture was stirred at room temperature until the orange solid had completely dissolved. The solution was then transferred under argon into a 300 mL closed Schlenk pressure-tube and stirred under argon pressure (two atmospheres) at 60 °C for 4 d. During this time the colour of the solution changed from black to red. After cooling to room temperature, the red solution containing **3a** and **3b** was filtered through filter pulp. A large excess (200 mg) of solid $NaBF_4$ was then added

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to the filtrate in order to precipitate the mixture of [**3a**][BF_4] and [**3b**][BF_4]. After stirring for one hour at room temperature, the red precipitate was centrifuged at 1500 rpm for 10 min and the aqueous solution was then removed from the centrifuge tube with a glass pipette. The red solid was dissolved in CH_2Cl_2 and again filtered through filter pulp, in order to eliminate unreacted $NaBF_4$. The solution was then concentrated to 15 mL in vacuo. The resulting concentrate was subjected to preparative thin-layer chromatography on silica-gel using CH_2Cl_2/acetone (2:1) as eluent. The pure compounds were extracted with acetone from the first ([**3a**][BF_4]) and the second ([**3b**][BF_4]) red bands. Evaporation of acetone under vacuum gave 62 mg of [**3a**][BF_4] and 65 mg of [**3b**][BF_4] as red powders (total yield: 32%). Crystals suitable for X-ray diffraction analyses were grown by slow diffusion of hexane into a CH_2Cl_2 solution of [**3a**][BF_4] or an acetone solution of [**3b**][BF_4]. $C_{33}H_{49}BF_4O_2Ru_3$ ([**3a**][BF_4]) (867.76): calcd. C 45.68, H 5.69; found C 45.42, H 5.81. $C_{33}H_{49}B_1F_4O_2Ru_3$ ([**3b**][BF_4]) (867.76): calcd. C 45.68, H 5.69; found C 45.44, H 5.87.

Spectroscopic Data for 3a: ^{1}H NMR (400 MHz, [D_6]acetone, 25 °C): $\delta = -19.92$ (t, $^2J = 3.83$ Hz, 1 H, hydride), −19.30 (d, $^2J = 3.83$ Hz, 2 H, hydride), 2.34 [s, 36 H, $C_6(CH_3)_6$], 2.43 [d, $^2J = 16.73$ Hz, 2 H, $(CH)_2$CHOH], 3.02 [dd, $^2J = 16.73$, $^3J = 5.54$ Hz, 2 H, $(CH)_2$CHOH], 4.52 [m, 1 H, $(CH)_2CH$OH], 5.69 [dd, $^3J = 3.83$, $^4J = 2.13$ Hz, 2 H, H_{arom}], 5.96 [dd, $^3J = 3.83$, $^4J = 2.13$ Hz, 2 H, H_{arom}], 6.77 [d, $^3J = 13.00$ Hz, 1 H, $(CH)_2$CHOH] ppm. $^{13}C\{^1H\}$ NMR (100 MHz, CD_2Cl_2, 25 °C): $\delta = 18.2$ [$C_6(CH_3)_6$], 40.8 [$(CH)_2$CHOH], 70.8 [$(CH)_2CH$OH], 78.0, 82.8, 95.3, 101.8 (C_{arom}) ppm. MS (ESI positive mode, acetone): $m/z = 782.1$ [M + H]$^+$.

Spectroscopic Data for 3b: ^{1}H NMR (400 MHz, [D_6]acetone, 25 °C): $\delta = -20.07$ (t, $^2J = 4.05$ Hz, 1 H, hydride), −19.41 (d, $^2J = 4.05$ Hz, 2 H, hydride), 2.32 [s, 36 H, $C_6(CH_3)_6$], 2.69 [dd, $^2J = 14.92$, $^3J = 7.88$ Hz, 2 H, $(CH)_2$CHOH)], 2.87 [dd, $^2J = 14.92$, $^3J = 6.82$ Hz, 2 H, $(CH)_2$CHOH], 4.44 [d, $^3J = 4.48$ Hz, 1 H, $(CH)_2CHOH$)], 4.84 [m, 1 H, $(CH)_2CH$OH], 5.53 [dd, $^3J = 3.83$, $^4J = 2.23$ Hz, 2 H, H_{arom}], 5.84 (dd, $^3J = 3.83$, $^4J = 2.23$ Hz, 2 H, H_{arom}] ppm. $^{13}C\{^1H\}$ NMR (100 MHz, CD_2Cl_2, 25 °C): $\delta = 18.1$ [$C_6(CH_3)_6$], 39.8 [$(CH)_2$CHOH], 72.1 [$(CH)_2CH$OH], 79.3, 81.3, 95.1, 101.0 (C_{arom}) ppm. MS (ESI positive mode, acetone): $m/z = 782.1$ [M + H]$^+$.

Catalytic Runs: In a typical experiment, a solution of [**3a**][BF_4] or [**3b**][BF_4] (10 mg) in 10 mL of water was placed in a 100 mL stainless-steel autoclave equipped with a glass-lined vessel, and the benzene substrate was added in a 1:1000 catalyst/substrate ratio. After purging four times with hydrogen, the autoclave was pressurised with hydrogen (60 bar), heated to 110 °C in an oil bath for 15 minutes, and the mixture stirred vigorously. After 3 h the autoclave was cooled in an ice-bath and the pressure released. The two-phase system was separated by decanting. The aqueous phase containing the catalyst was discarded and the organic phase containing cyclohexane and benzene was analysed by NMR spectroscopy and GC.

performed at −120 °C using Mo-K_α radiation (λ = 0.71073 Å). 193 Exposures (3 min per exposure) were obtained at an image plate distance of 70 mm with $0 < \varphi < 193°$ and with the crystal oscillating through 1° in θ. The resolution was D_{min} − D_{max} 12.45−0.81 Å.

The structure was solved by direct methods using the program SHELXS-97[11] and refined by full-matrix least-squares on F^2 with SHELXL-97.[12] The six hydrido ligands (H1, H2, H3, H4, H5 and H6) and the two hydrogen atoms (H5a and H5b) of the water molecule were derived from difference Fourier maps and refined with the Ru−H and O−H distances constrained to the theoretical value; the remaining hydrogen atoms were included in calculated positions and treated as riding atoms using the SHELXL-97 default parameters. All non-hydrogen atoms were refined anisotropically, except for one dichloromethane molecule which is shared with a water molecule. One BF_4 counteranion is disordered. An empirical absorption correction was applied using DIFABS (PLATON99,[13] $T_{min.}$ = 0.348, $T_{max.}$ = 0.768).

[3b][BF$_4$]: An orange crystal of [**3b**][BF_4] was mounted on a Stoe Mark II-Imaging Plate Diffractometer System (Stoe & Cie, 2002) equipped with a graphite monochromator. Data collection was performed at −120 °C using Mo-K_α radiation (λ = 0.71073 Å). 265 Exposures (3 min per exposure) were obtained at an image plate distance of 100 mm, 180 frames with $\varphi = 0°$ and $0 < \omega < 180°$, and 85 frames with $\varphi = 90°$ and $0 < \omega < 85°$, with the crystal oscillating through 1° in ω. The resolution was D_{min} − D_{max} 17.78−0.72 Å.

The structure was solved by direct methods using the program SHELXS-97[11] and refined by full-matrix least-squares on F^2 with SHELXL-97.[12] The three hydrido ligands H1, H2 and H3 were derived from difference Fourier maps and refined with the Ru−H distance constrained to the theoretical value; the remaining hydrogen atoms were included in calculated positions and treated as riding atoms using the SHELXL-97 default parameters. All non-hydrogen atoms were refined anisotropically. An empirical absorption correction was applied using DIFABS (PLATON99,[13] $T_{min.}$ = 0.139, $T_{max.}$ = 0.611). All of the tested crystals were twinned; the structure was solved and refined on data collected from one domain of such a crystal.

Crystallographic details are given in Table 3 and significant bond lengths and bond angles are listed in Table 1 (**3a**) and Table 2 (**3b**). The figures were drawn with ORTEP.[14]

CCDC-235554 (for [**3a**][BF_4]·1.25CH_2Cl_2·0.25H_2O) and -235555 (for [**3b**][BF_4]) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Spectroscopic Studies of Europium(III) and Gadolinium(III) Tris-β-diketonate Complexes with Diazabutadiene Ligands

José A. Fernandes,[a] Rute A. Sá Ferreira,[b] Martyn Pillinger,[a] Luís D. Carlos,*[b] Isabel S. Gonçalves,[a] and Paulo J. A. Ribeiro-Claro*[a]

Keywords: Ab initio calculations / Lanthanides / Luminescence / N ligands / Vibrational spectroscopy

Adducts of the type $Ln(NTA)_3$·L [Ln = Eu, Gd; NTA = 1-(2-naphthoyl)-3,3,3-trifluoroacetonate; L = 1,4-diaza-1,3-butadiene RN=CHCH=NR (R = *p*-tolyl, *o*-tolyl)] were prepared by treatment of $Ln(NTA)_3·2H_2O$ with one equivalent of the chelating N–N ligand. The mixed ligand complexes were characterised by elemental analysis, thermogravimetric analysis, IR and Raman spectroscopy, and photoluminescence (PL) spectroscopy. Ab initio calculations were carried out in order to predict coordination geometries and also to interpret the vibrational spectra. For the europium(III) compounds, new Raman-active bands at approximately 440 and 479 cm^{-1} are tentatively assigned to $(\nu Eu–N)_{sym}$ and $(\nu Eu–N)_{as}$ modes, respectively. A second band at 1185 cm^{-1} is associated with the symmetric stretching of the N–C(ring) and C–C (DAB) bonds, and is shifted about 20 cm^{-1} to a higher wavenumber relative to the corresponding band for the free ligand. The room-temperature PL spectra of the two Eu complexes are composed of the typical Eu^{3+} red emission, assigned to transitions between the first excited state ($^5D_0$) and the ground multiplet ($^7F_{0–4}$). Based on the room-temperature emission spectra and lifetime measurements, the quantum efficiencies of the $^5D_0$ Eu^{3+} excited state were estimated and found to be quite low (e.g. 2–3%). The low efficiencies are attributed to the presence of thermally activated nonradiative channels involving ligand-to-metal charge-transfer (LMCT) states. Indeed, a low-lying LMCT band was detected for the Eu complex containing the ligand *p*-tolyl-DAB by comparison of the room-temperature diffuse reflectance spectrum for this complex with that of the corresponding Gd analogue.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Over the past 40 years there has been considerable interest in the luminescence and lasing ability of certain diketonates of lanthanides, particularly europium(III) and terbium(III).[1–4] Two classes of complexes may be distinguished depending on whether the ratio of diketonate ion to metal ion in the product is 3:1 (tris complex) or 4:1 (tetrakis complex).[5,6] The tris-β-diketonates are usually coordinatively unsaturated and, therefore, form adducts with a variety of Lewis base ligands, to give seven-, eight- or even nine-coordinate complexes.[7–19] Some of us recently reported on the luminescence features and the absolute quantum yield of europium(III) tris[1-(2-naphthoyl)-3,3,3-trifluoroacetonate] complexes, $Eu(NTA)_3·2L$ (NTA = 1-(2-naphthoyl)-3,3,3-trifluoroacetonate, L = H_2O and DMSO).[19] The experimental quantum yield measured for $Eu(NTA)_3·2DMSO$ (0.75) is one of the highest so far reported for solid-state europium complexes. Replacement of the solvent molecules in these complexes by organic ligands is one way to further modify the luminescence properties of the parent tris complex. The complex with 2,2′-bipyridine (bipy) has already been reported.[9] In the present work, $Eu(NTA)_3$ complexes containing 1,4-diaza-1,3-butadienes (DAB) of the type RN=CR′CR′=NR (R = *p*-tolyl, *o*-tolyl; R′ = H) have been prepared and characterised. For comparison, the corresponding Gd^{III} complexes have also been prepared. To the best of our knowledge, very few studies have been carried out on diazabutadiene compounds of rare earths,[20–22] especially with regard to their photophysical properties. This is surprising since, as α-diimine ligands, DAB ligands have electronic and structural similarities to the more extensively studied heteroaromatic chelating agents bipy and 1,10-phenanthroline.[23] Added flexibility arises from the presence of the substituents R and R′, perhaps allowing luminescence behaviour to be tuned by variation of steric and electronic effects.

Results and Discussion

Synthesis and Thermogravimetric Analysis

The mononuclear complexes $Ln(NTA)_3$·*p*-tolyl−DAB [Ln = Eu (**1**), Gd (**3**)] and $Ln(NTA)_3$·*o*-tolyl−DAB [Ln =

[a] Department of Chemistry, CICECO, University of Aveiro, 3810-193 Aveiro, Portugal

Eu (**2**), Gd (**4**)] were prepared in reasonable yields by the treatment of solutions of $Ln(NTA)_3{\cdot}2H_2O$ in chloroform with one equivalent of the respective diazabutadiene ligand.

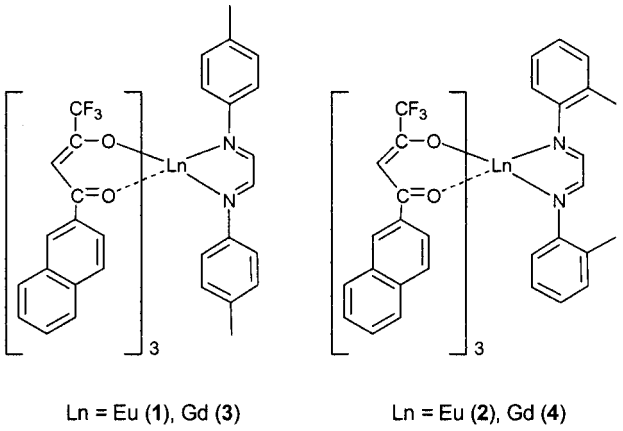

Figure 1 shows the TGA results for *o*-tolyl−DAB, $Eu(NTA)_3{\cdot}2H_2O$ and $Eu(NTA)_3{\cdot}$*o*-tolyl−DAB (**2**). Similar traces were obtained for the compounds *p*-tolyl−DAB, $Gd(NTA)_3{\cdot}2H_2O$ and $Ln(NTA)_3{\cdot}$L (**1**,**3**,**4**), respectively. The compounds *o*-tolyl−DAB and *p*-tolyl−DAB sublime in the temperature range 100−230 °C. The precursors $Ln(NTA)_3{\cdot}2H_2O$ undergo a mass loss up to 100 °C, which corresponds to the removal of coordinated water. Further decomposition takes place in two steps; the first of these occurs between 100 and 350 °C (54% mass loss for Eu, 63% for Gd), and the second between 350 and 600 °C (21% mass loss for Eu, 19% for Gd). Finally, a small mass loss of 2% occurs between 600 and 700 °C for both compounds, leaving a residual mass of 17.7% for Eu and 13.8% for Gd. The TGA curves of the adducts **1**−**4** are very similar to each other and to the reagents $Ln(NTA)_3{\cdot}2H_2O$, and all steps for these six compounds take place at the same temperatures. There is no step characteristic of "free" ligand, indicating that the ligands are coordinated to the metal centres. The first mass loss (3.0% for **1**) corresponds to the removal of water content. Following this, the mass loss for the step between 100 and 350 °C is smaller than that observed for the reagents (47.2% for compound **1**). Conversely, the step between 350 and 600 °C corresponds to a larger amount (34.3% for compound **1**). Finally, the TGA shows a mass loss of about 2% between 575 and 720 °C, leaving a residual mass of about 16% for compounds **1** and **2**, and 14% for compounds **3** and **4**.

Ab Initio Calculations and Vibrational Spectra

Figure 2 shows the calculated coordination geometry of DAB in **1** (NTA ligands are shown in wireframe). The complexed tolyl−DAB adopts a propeller-like configuration; the phenyl rings are rotated 33° and 42° from the N=C−C=N plane, in opposite directions. In the free ligand, the lowest energy form presents a similar rotation angle (approximately 37°), but to the same side of the N=C−C=N plane (therefore, the phenyl rings are co-planar). Similar results were obtained for the simulation of *o*-tolyl−DAB

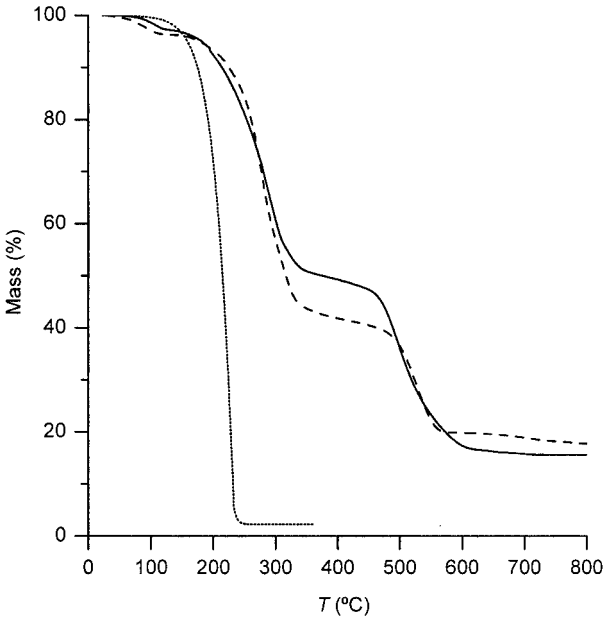

Figure 1. TGA of $Eu(NTA)_3{\cdot}$*o*-tolyl−DAB (**2**) (−), *o*-tolyl−DAB (···) and $Eu(NTA)_3{\cdot}2H_2O$ (− − −)

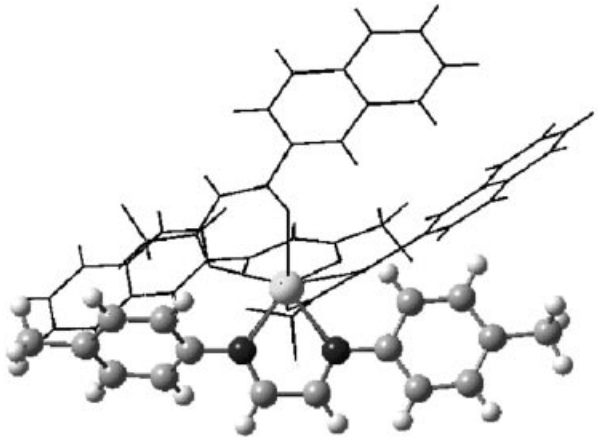

Figure 2. Lowest energy structure calculated for the model $Eu[O(CH)_3O]_3{\cdot}$*p*-tolyl−DAB; the $(NTA)_3$ framework was obtained from the X-ray single crystal structure for $Eu(NTA)_3{\cdot}$phenanthroline[24]

(**2**), with the exception of the twist angles of the phenyl ring, which are about 10° larger than those for **1** due to the presence of the *ortho* methyl groups. Calculated Eu−N distances are about 233 pm, and the N−Eu−N angle is 72° in both **1** and **2**. The Eu−N bond lengths are shorter than those calculated at the same level for the 2,2′-bipyrimidine and 1,10-phenanthroline derivatives,[24] suggesting a stronger Eu−N interaction in the case of the present ligands. As a result, the calculated frequencies for the Eu−N stretching modes are higher than those usually reported. In fact, ab initio calculations predict the νEu−N stretching modes at about 460 cm^{-1} (after scaling), with a moderately strong Raman intensity and weak IR intensity.

An important geometrical change upon complexation is revealed in the bond lengths of the diazabutadiene fragment. From the free DAB ligand to complex **1**, the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$C_{(ring)}-N$, C=N and C−C bond lengths are reduced by approximately 2.2, 1.8 and 3.3 pm, respectively. From the free ligand to complex **2**, the corresponding values are 1.7, 1.8 and 2.9 pm, respectively. The effect is residual in the aromatic C−C bonds (< 1 pm) and is absent in the $C-CH_3$ bonds. This contraction affects the vibrational modes involving the diazabutadiene fragment, which are predicted to be generally shifted to higher wavenumbers upon complexation. The effect is particularly evident in the mode combining the symmetric stretching of the $N-C_{(ring)}$ and C−C (DAB) bonds, with a strong Raman intensity, for which a shift of 20 cm^{-1} is predicted. The calculated scaled values are 1164 cm^{-1} for the free DAB ligands and 1184 cm^{-1} for the complex model. These predictions find experimental support from the vibrational spectra, as discussed below.

The vibrational spectra of **1** and **2** are well-described by the sum of the spectra of their reagents, with some additional details ascribed to the complexation process. Figure 3 shows two relevant regions in the Raman spectra of compound **1** [trace (c)], the reagents $Eu(NTA)_3{\cdot}2H_2O$ [trace (b)] and *p*-tolyl−DAB [trace (a)].

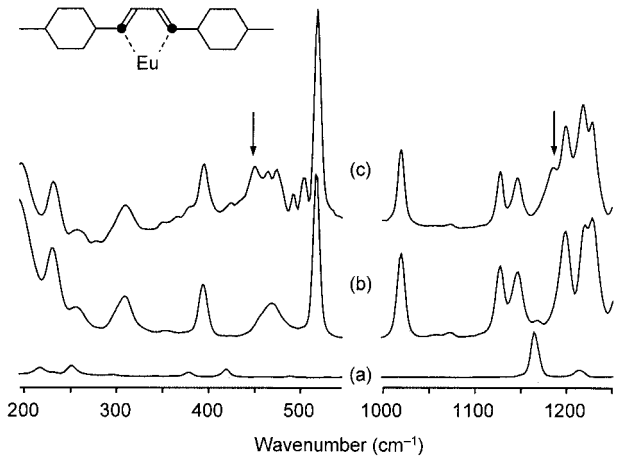

Figure 3. Raman spectra of (a) *p*-tolyl−DAB, (b) $Eu(NTA)_3{\cdot}2H_2O$ and (c) $Eu(NTA)_3$·*p*-tolyl−DAB (**1**); the arrows point to the bands assigned to the *ν*Eu−N modes (about 460 cm^{-1}) and symmetric stretching of the N−C(ring) and C−C (DAB) bonds (1185 cm^{-1})

The vibrational modes involving the Eu−N bonds were searched for in the low wavenumber region. The two bands observed at approximately 440 and 479 cm^{-1} are not present in the spectra of the reagents and fit the intensity and wavenumber predicted from ab initio calculations. In this way, they have been tentatively assigned to $(\nu Eu-N)_{sym}$ and $(\nu Eu-N)_{as}$, respectively. Identical bands are observed at 449 cm^{-1} and 473 cm^{-1} in the Raman spectrum of **2**, supporting this assignment. Analysis of the IR spectrum in this region was inconclusive, due to band overlap.

The effect of complexation can also be observed in the higher wavenumber region of Figure 3. The bands corresponding to the symmetric stretching of the $N-C_{(ring)}$ and C−C (DAB) bonds are easily identified in the spectra of the free ligands and products due to their strong Raman intensity. As can be seen, the strong band at 1165 cm^{-1} for the pure DAB ligand [trace (a)] moves to about 1185 cm^{-1} in **1** [trace (c)]. The ca. 20 cm^{-1} upwards shift upon complexation is in agreement with the contraction of the C−C and N−C bonds from the free ligand to the complexes.

Photoluminescence Studies

Figure 4 shows the room-temperature PL spectra of compounds **1** and **2** obtained under the excitation wavelength that maximises the emission intensity. Both spectra are composed of the typical Eu^{3+} red emission, assigned to transitions between the first excited state ($^5D_0$) and the ground multiplet ($^7F_{0-4}$). It is possible to identify 3 and 5 Stark components for the $^5D_0 \rightarrow {}^7F_{1-2}$ transitions, which indicates that the Eu^{3+} ions are located in a low site symmetry group, without an inversion centre according to the higher intensity of the $^5D_0 \rightarrow {}^7F_2$ transition. Changes in the excitation wavelength did not produce significant alterations either in the number of emission components or in their energy. The presence of only one component for the $^5D_0 \rightarrow {}^7F_0$ transition suggests only one Eu^{3+} local environment. However, the high value found for the full width at half maximum (fwhm) in both compounds(26 cm^{-1}) indicates a large distribution of local coordination sites,[25] probably induced by the amorphous nature of the compounds. The similarity between the two spectra is also apparent in the energy and fwhm of the $^5D_0 \rightarrow {}^7F_{0-2}$ transitions. This fact, in particular the comparable energies for the $^5D_0 \rightarrow {}^7F_0$ transition, indicates that the Eu^{3+} first coordination sphere might be very similar for the two compounds. This is based on the knowledge that the energy of this transition is usually related to the so-called *nephelauxetic* effect induced by the ion′s first neighbours.[26] Such conclusions are also supported by the PL spectra measured at 14 K. Apart from small changes in the relative intensity of the $^5D_0 \rightarrow {}^7F_2$ transition Stark components, the energy, fwhm and number of emission components of the intra-$4f^6$ transitions are essentially the same as observed at room

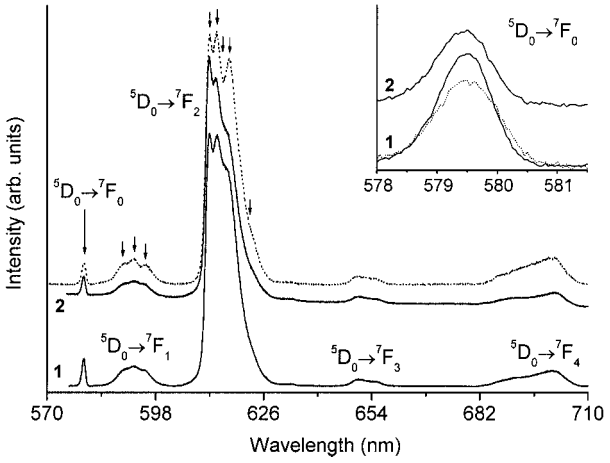

Figure 4. Room-temperature PL spectra of compounds **1** and **2** excited at 345 nm; The dotted line corresponds to the PL spectrum of **1** detected at 14 K and excited at 365 nm

temperature. However, the integrated intensity of the emission arising from the $^5D_0$ level strongly depends on the selected temperature, presenting the behaviour shown in Figure 5 for **1**. For both compounds, no emission from the ligands could be detected, suggesting an effective interaction between them and the Eu^{3+} ions.

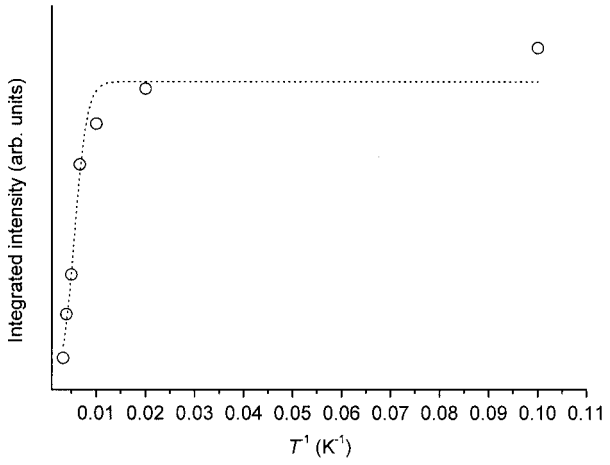

Figure 5. Temperature-dependence (14−300 K) of the Eu^{3+} $^5D_0$ emission for compound **1** (open circles); the dotted line is the best fit to the data using Equation (4)

The excitation spectra (PLE), monitored around the most intense line of the cation (Figure 6), enable us to draw the same conclusion. The spectra exhibit a large broad band between 280 and 420 nm, with a maximum at around 345 nm, and no lines associated with the direct excitation of the intra-$4f^6$ levels are detected. This strongly suggests an efficient sensitization process between the ligands and the metal ion. Lowering the temperature to 14 K induces a red-shift to 365 nm, and a low-intensity line associated with the excitation of the $^5D_2$ level is observed, as shown in Figure 6 for **1**. This large band may originate from the ligand levels involving the NTA and diimine components, since the PLE spectrum acquired for $Eu(NTA)_3{\cdot}2H_2O$ under identical experimental conditions is different from those plotted in Figure 6.[19]

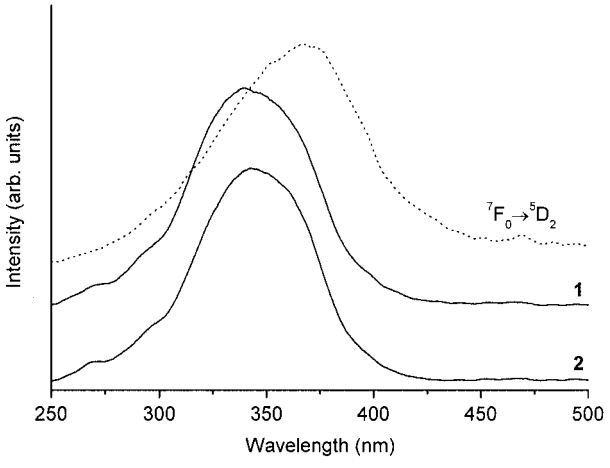

Figure 6. room-temperature PLE spectra of compounds **1** and **2** monitored around 612 nm; the dotted line is the PLE spectrum of **1** detected at 14 K

The $^5D_0$ lifetime, τ, was measured around the most intense PL line (not shown). For both compounds the data are well described by a single exponential function, revealing lifetime values of 0.038 ± 0.001 and 0.030 ± 0.001 ms for compounds **1** and **2**, respectively. These values are smaller than the lifetime value previously found for the precursor complex.[19]

Based on the room-temperature emission spectra and on the lifetime measurements we can estimate the efficiency, q, of the $^5D_0$ Eu^{3+} excited state, considering that only nonradiative and radiative processes are essentially involved in the depopulation of the $^5D_0$ state,[3,19,27,28] where k_r and k_{nr} are the radiative and nonradiative transition probabilities, respectively, ($k_{exp} = 1/\tau_{exp} = k_r + k_{nr}$).

$$q = \frac{k_r}{k_r + k_{nr}} \tag{1}$$

The emission intensity, I, taken as the integrated intensity, S, of the emission curves, for the $^5D_0 \rightarrow {}^7F_{0-4}$ transitions, is expressed by Equation (2): where i and j represent the initial ($^5D_0$) and final ($^7F_{0-6}$) levels, respectively, $\hbar w_{i\rightarrow j}$ is the transition energy, $A_{i\rightarrow j}$ corresponds to Einstein's coefficient of spontaneous emission and N_i is the population of the $^5D_0$ emitting level.[3,19,27,28]

$$I_{i\rightarrow j} = \hbar w_{i\rightarrow j} A_{i\rightarrow j} N_i \equiv S_{i\rightarrow j} \tag{2}$$

The radiative contribution may be calculated from the relative intensities of the $^5D_0 \rightarrow {}^7F_{0-6}$ transitions. Since the $^5D_0 \rightarrow {}^7F_1$ transition can be considered as a reference due to its dipolar magnetic nature, k_r can be calculated according to Equation (3), where $A_{0\rightarrow 1}$ is the Einstein's coefficient of spontaneous emission between the $^5D_0$ and the $^7F_1$ Stark levels.

$$k_r = A_{0\rightarrow 1} \frac{\hbar\omega_{0\rightarrow 1}}{S_{0\rightarrow 1}} \sum_{J=0}^{6} \frac{S_{0-J}}{\hbar\omega_{0-J}} \tag{3}$$

The $^5D_0 \rightarrow {}^7F_{5,6}$ transitions were not measured experimentally and so the branching ratio for these transitions, which is usually very small, can be neglected. Therefore, we can ignore their influence in the depopulation of the $^5D_0$ excited state. The $^5D_0 \rightarrow {}^7F_1$ transition does not depend on the local ligand field seen by Eu^{3+} ions and, thus, may be used as a reference for the whole spectrum; in vacuo $A(^5D_0 \rightarrow {}^7F_1) = 14.65\ s^{-1}$.[28] The values found for q, k_r and k_{nr} for compounds **1** and **2** are gathered in Table 1. An average index of refraction equal to 1.5 was considered for both compounds leading to an approximate $A(^5D_0 \rightarrow {}^7F_1)$ value of $50\ s^{-1}$.[29]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 1. Experimental $^5D_0$ lifetimes (τ) and decay rates (k_{exp}), calculated radiative (k_r) and nonradiative (k_{nr}) $^5D_0$ decay rates and quantum efficiency (q) for compounds **1** and **2**

	τ (ms)	k_{exp} (ms^{-1})	k_r (ms^{-1})	k_{nr} (ms^{-1})	q (%)
1	0.038 ± 0.001	26.32	0.82	25.50	3.1
2	0.030 ± 0.001	33.33	0.72	32.61	2.2

Compound **1** has the highest q value, induced by higher k_r (12%) and lower k_{nr} (22%) values. However, both compounds present lower values for the $^5D_0$ quantum efficiency compared with that found for the precursor complex $Eu(NTA)_3{\cdot}2H_2O$ (q = 29%)[19] that may be induced by the higher k_{nr} contribution found in **1** and **2**. In fact, the temperature-dependence of the Eu^{3+} emission-integrated intensity, I_{int} (Figure 5), suggests a thermally activated nonradiative mechanism. Such nonradiative de-excitation is well-described by the following expression:

$$I_{int} = \frac{1}{1 + A\exp(-E_a/K_BT)} \quad (4)$$

where A is related to the ratio between the nonradiative (at $T = 0$) and radiative rates, K_B is the Boltzmann constant and E_a is the energy of activation of the de-excitation channel with respect to the energy of the $^5D_0$ level. The energy activation obtained is 550 ± 136 cm^{-1}, which places the nonradiative level in a position resonant with the Eu^{3+} emitting level.

In Eu^{3+} complexes such thermally activated nonradiative channels may involve ligand-to-metal charge-transfer (LMCT) states, formed by the orbital overlap of the ligand and Eu^{3+} energy levels.[30−32] Quenching of the Eu^{3+} PL by low-lying thermally activated LMCT transitions is a well-known phenomenon in molecular solids and complexes in solution.[31−34] These states are usually difficult to detect by absorption and emission spectroscopy, and indeed their unequivocal assignment and detection have only been performed for a few lanthanide compounds.[3,31−34] Due to the difficulties in detecting LMCT states, they are usually claimed to exist in order to explain low PL quantum yields and/or the strong dependence of the emission intensity with temperature. The comparison of Eu^{3+} and Gd^{3+} reflectance spectra is a useful tool to perceive and ascribe the LMCT transitions, since the energetic difference between the Gd^{3+} first excited state and the fundamental levels is too high to allow the detection of a charge-transfer state in the UV/Vis range. Therefore, in the Gd^{3+} spectrum we expect to measure only the contributions that are not related with the LMCT processes.

Figure 7 shows the room-temperature diffuse reflectance spectra of compounds **1** and **3**. The arithmetic difference between the two curves is also represented, showing the presence of a low-lying LMCT band (centred at about 17800 cm^{-1}). As far as we know, this is one of the clearest examples where the arithmetic difference between the diffuse reflectance spectra of isostructural Eu^{3+} and Gd^{3+} compounds allows the explicit identification of ligand-to-metal charge transfer states by direct means. Unfortunately, and in agreement with the mentioned difficulties, these states cannot be identified so visibly in the reflectance spectra of compounds **2** and **4**.

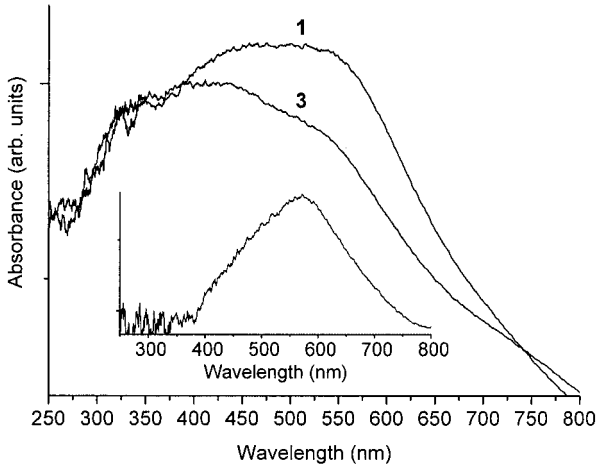

Figure 7. room-temperature diffuse reflectance spectra of compounds **1** and **3**; the arithmetic difference between the two curves is also represented

The charge-transfer band observed in the reflectance spectrum of compound **1** (Figure 7) does not appear at all as an excitation band (see the PLE spectra of Figure 6), indicating that the LMCT band in these compounds is predominantly a quenching channel. This is exactly the conclusion arrived at previously from the temperature-dependence of the Eu^{3+} emission integrated intensity of compound **1** (Figure 5). Actually, the energy of the thermally activated nonradiative level derived from Equation (4), 550 ± 136 cm^{-1} above the $^5D_0$ level (about 17256.3 cm^{-1}, Figure 4), is in excellent agreement with the maximum of the LMCT band discerned from the arithmetic difference between the reflectance spectra of **1** and **3** (approximately 17800 cm^{-1}, Figure 7). Therefore, the low $^5D_0$ quantum efficiency observed for compounds **1** and **2** can be reliably assigned to a nonradiative decay through the LMCT state of Eu^{3+}, which is at rather low energies in these diimine compounds. This is in agreement with previously reported experimental results that indicate that the $^5D_0$ quantum efficiency decreases as the energy of the LMCT states decreases.[31,32] Moreover, recent theoretical results on energy transfer mechanisms between these LMCT states and the ligand and Eu^{3+} levels demonstrate that the quantum yield of the complex (and thus the $^5D_0$ quantum efficiency) decreases drastically as the LMCT barycentre becomes resonant with the $^5D_0$ level.[35]

Concluding Remarks

New europium and gadolinium tris-β-diketonate complexes have been prepared, containing diazabutadiene (DAB) ligands coordinated to the metal centres. Accordingly, the complexes with the general formula $Ln(NTA)_3{\cdot}nL$ (Ln = Eu, Gd) are now known with L = H_2O, DMSO, 2,2′-bipyridine, 1,10-phenanthroline and DAB. Binuclear complexes of the type $[Ln(NTA)_3]_2{\cdot}$bpym (bpym = 2,2′-bipyrimidine) have also been reported. The motivation for the preparation of these derivatives stems from the fact that the experimental quantum yield measured for $Eu(NTA)_3{\cdot}2DMSO$ (0.75) is one of the highest so far reported for solid-state europium complexes. It has been found that the $^5D_0$ quantum efficiencies for these complexes vary considerably depending on the nature of L, decreasing in the order L = DMSO (62%), phen (40%), bpym (39%), H_2O (29%) and DAB (2−3%). The low $^5D_0$ quantum efficiencies for the diazabutadiene adducts can be reliably assigned to a nonradiative decay through the LMCT state of Eu^{3+}, which is at rather low energies in these diimine compounds. The use of photoluminescence spectroscopy, together with vibrational spectroscopy and ab initio calculations, therefore allows us to build up quite a detailed picture about the nature of the metal−ligand interactions in these tris-β-diketonate complexes.

Experimental Section

Materials and Methods: $Eu(NTA)_3{\cdot}2H_2O$,[36] $Gd(NTA)_3{\cdot}2H_2O$,[36] *p*-tolyl−DAB,[37] and *o*-tolyl−DAB[37] were prepared by literature methods.

Microanalyses were performed at the Instituto de Tecnologia Química e Biológica (ITQB), Lisbon. Thermogravimetric analyses (TGA) were performed using a Mettler TA3000 system at a heating rate of 5 K min^{-1} under a static atmosphere of air. IR spectra were obtained as KBr pellets with a FTIR Mattson-7000 infrared spectrophotometer. Raman spectra were recorded with a Bruker RFS100/S FT instrument (Nd:YAG laser, 1064 nm excitation, InGaAs detector). The photoluminescence spectra (PL) were recorded on a Jobin Yvon-Spex spectrometer (HR, 460) coupled to a R928 Hamamatsu photomultiplier (14−300 K). A 300 W Xe arc lamp coupled to a Jobin Yvon-Spex (TRIAX 180) monochromator was used as the excitation source. All the spectra were corrected for the response of the detector. The lifetime measurements were carried out at room temperature (r.t.) on a modular double grating excitation spectrofluorimeter with a TRIAX 320 emission monochromator (Fluorolog-3, Jobin Yvon-Spex) in front face mode coupled to a R928 Hamamatsu photomultiplier.

Preparation of Complexes: A solution of the diimine (0.102 g, 0.432 mmol) in $CHCl_3$ (5 mL) was added to a solution of $Ln(NTA)_3{\cdot}2H_2O$ (0.432 mmol) in $CHCl_3$ (15 mL). The reaction mixture was stirred for 3 h at room temperature. The solvent was then removed, and the resultant brown solid was washed with hexane and dried in vacuo.

$Eu(NTA)_3{\cdot}$*p*-tolyl−DAB (1): Yield: 0.455 g (89%). $C_{58}H_{40}EuF_9N_2O_6$ (1183.9): calcd. C 58.84, H 3.41, N 2.37; found C 58.89, H 3.46, N 2.37. IR (KBr, selected): $\tilde{\nu}_{max.}$ = 3065 (w), 2961 (w), 2927 (w), 1614 (s), 1593 (m), 1570 (m), 1531 (m), 1510 (m), 1460 (m), 1384 (w), 1353 (w), 1298 (s), 1251 (m), 1198 (m), 1135 (m), 1074 (w), 959 (w), 865 (w), 792 (m), 749 (w), 684 (m), 568 (w), 472 (w) cm^{-1}. Raman: 3058 (m), 1629 (s), 1596 (m), 1468 (s), 1432 (w), 1386 (s), 1298 (m), 1228 (w), 1199 (w), 1019 (w), 771 (m), 517 (m) cm^{-1}.

$Eu(NTA)_3{\cdot}$*o*-tolyl−DAB (2): Yield: 0.441 g (82%). $C_{58}H_{40}EuF_9N_2O_6$ (1183.9): calcd. C 58.84, H 3.41, N 2.37; found C 58.78, H 3.33, N 2.28. IR (KBr, selected): $\tilde{\nu}_{max.}$ = 3060 (w), 2959 (w), 2924 (w), 1613 (vs), 1593 (s), 1570 (s), 1532 (s), 1509 (s), 1460 (m), 1384 (w), 1353 (w), 1298 (vs), 1251 (m), 1198 (s), 1136 (s), 1074 (w), 958 (w), 864 (w), 793 (m), 749 (m), 684 (m), 569 (w), 519 (w), 472 (w) cm^{-1}. Raman: 3056 (m), 1628 (s), 1596 (m), 1532 (m), 1468 (s), 1432 (w), 1386 (s), 1297 (m), 1228 (w), 1198 (w), 1019 (w), 771 (m), 517 (m) cm^{-1}.

$Gd(NTA)_3{\cdot}$*p*-tolyl−DAB (3): Yield: 0.255 g (46%). $C_{58}H_{40}F_9GdN_2O_6$ (1189.2): calcd. C 58.58, H 3.39, N 2.36; found C 58.43, H 3.21, N 2.29. IR (KBr, selected): $\tilde{\nu}_{max.}$ = 3058 (w), 2960 (w), 2958 (w), 1615 (s), 1570 (m), 1532 (m), 1510 (m), 1384 (vs), 1299 (m), 1198 (m), 1135 (m), 959 (w), 792 (m), 684 (m), 570 (w), 471(w) cm^{-1}. Raman: 3057 (m), 1629 (s), 1596 (m), 1468 (s), 1432 (w), 1386 (s), 1299 (m), 1228 (w), 1198 (w), 1019 (w), 770 (m), 517 (m) cm^{-1}.

$Gd(NTA)_3{\cdot}$*o*-tolyl−DAB (4): Yield: 0.168 g (39%). $C_{58}H_{40}F_9GdN_2O_6$ (1189.2): calcd. C 58.58, H 3.39, N 2.36; found C 58.75, H 3.33, N 2.38. IR (KBr, selected): $\tilde{\nu}_{max.}$ = 3058 (w), 2960 (w), 2926 (w), 1614 (vs), 1594 (s), 1570 (s), 1531 (s), 1509 (s), 1460 (m), 1384 (m), 1353 (m), 1298 (s), 1251 (m), 1187 (s), 1135 (s), 1074 (w), 958 (w), 865 (w), 792 (m), 748 (m), 684 (m), 568 (w), 472 (w) cm^{-1}. Raman: 3057 (m), 1628 (s), 1596 (m), 1532 (m), 1467 (s), 1432 (w), 1386 (s), 1297 (m), 1227 (w), 1197 (w), 1019 (w), 770 (m), 517 (m) cm^{-1}.

Ab Initio Calculations: Ab initio calculations were performed using the G03w program package,[38] running on a personal computer. The fully optimised geometry, the harmonic vibrational frequencies, and the infrared and Raman intensities were obtained at the B3LYP level, using the Effective Core Potentials (ECP) of Pacios and Christiansen[39] and *f* function (zeta = 0.591) for the Eu atom, and the Stevens/Basch/Krauss[40,41] ECP minimal basis set (CEP-4G option of G03) for the remaining atoms. Due to the large size of the systems, the NTA ligands were replaced by the coordination fragment $[O(CH)_3O]^-$. This model consistently yields Eu−O and Eu−N bond lengths shorter than the reported X-ray values for the phenanthroline,[24] bipyridine,[24] and diaquo[42] analogues, by 16% and 7%, respectively. The calculated wavenumbers were scaled by a factor of 0.90 before comparison with the experimental values.

Formation of Thermotropic and Lyotropic Liquid Crystals of Bis(*N*-alkylethylenediamine)silver(I) Nitrate

Masayasu Iida,*[a] Michiko Inoue,[a] Tomoaki Tanase,[a] Takae Takeuchi,[a] Makiko Sugibayashi,[b] and Kazuchika Ohta[b]

Keywords: Silver / N ligands / Liquid crystals / Microemulsions

We have synthesized bis(*N*-hexylethylenediamine)silver(I) nitrate ([Ag(hex-en)$_2$]NO_3), bis(*N*-octylethylenediamine)silver(I) nitrate ([Ag(oct-en)$_2$]NO_3), and bis(*N*-dodecylethylenediamine)silver(I) nitrate ([Ag(dod-en)$_2$]NO_3) and investigated the aggregation behavior of [Ag(dod-en)$_2$]NO_3 and [Ag(oct-en)$_2$]NO_3 in the liquid state. An X-ray crystallographic analysis revealed that [Ag(dod-en)$_2$]NO_3 has a dinuclear structure in the crystalline state — the molecular composition unit is [Ag_2(dod-en)$_4$](NO_3)$_2$, where the two dod-en ligands bridge two silver ions that are coordinated by four nitrogen atoms. The dinuclear complex is appreciably dissociated into a mononuclear complex in solution. It was found that [Ag(oct-en)$_2$]NO_3 and [Ag(dod-en)$_2$]NO_3 form thermotropic liquid crystals in the temperature ranges 48–67 °C and 59–96 °C, respectively, and a lyotropic liquid crystal was also observed for [Ag(dod-en)$_2$]NO_3 in *n*-heptane at around room temperature in the presence of a small amount of water. The structures of the thermotropic and lyotropic liquid crystals of [Ag(dod-en)$_2$]NO_3 were identified as a typical smectic A (S_A) type and a nematic one, respectively.

Introduction

The field of metallomesogens has developed rapidly in recent years.[1−5] Despite this, however, the lyotropic behavior of thermotropic metallomesogens has rarely been studied.[3−5] Furthermore, although metallosurfactants have characteristic structures and unique properties that are not seen in conventional surfactants, detailed and systematic studies on their aggregation behavior in solutions have not been carried out even for simple types of surfactants.[6−11]

Bis(*N*-alkylethylenediamine)metal complex surfactants form a variety of aggregates, since they have a delicate hydrophile-lipophile balance, and their double-chained molecular shape is favorable for the formation of highly ordered aggregates.[8−11] They easily form aggregates with appropriate amounts of encapsulating water in organic solvents of low dielectric constant, such as benzene and chloroform. One (M. Iida) of the present authors and coworkers has systematically investigated the physical properties and structural characterizations of highly aggregated systems such as bis(*N*-alkylethylenediamine)zinc(II), with various anions, dichlorobis(*N*-octylethylenediamine)cadmium(II), and bis(*N*-octylethylenediamine)palladium(II) chloride complexes in water/benzene or water/chloroform systems.[10,11] In a series of these studies, we have revealed the change in the geometry of the hydrocarbon chains of *N*-octylethylenediamine ligands in the zinc(II) complex from *transoid* to *cisoid* upon transfer from the crystalline state to the water/benzene interface in a microemulsion using Atomic Face Microscope (AFM) and Transmission Electron Microscope (TEM) methodologies.[10,11b,11c] Furthermore, the same group has synthesized and isolated bis(*N*-hexadecylethylenediamine)silver(I) nitrate ([Ag(hexd-en)$_2$]NO_3).[12] This complex is highly soluble in neat *n*-heptane and can be reduced in contact with an aqueous sodium borohydride solution to form silver(0) nanoparticles. An assembly of the silver ions of [Ag(hexd-en)$_2$]NO_3 in the *n*-heptane solution is advantageous to control the formation of silver(0) nanoparticles by changing the concentrations of the solutions, although the aggregation behavior has not been studied. A detailed characterization of this complex has also not been performed, although we have confirmed its formula and purity by elemental analysis and by ^{13}C NMR spectra. This complex is appreciably hydrophobic and we observed that it hardly incorporates water in *n*-hexane and therefore aggregation does not occur to a large extent.

For mesophases of silver(I) complexes, silver alkoxystilbazole complexes, including dinuclear complexes, have been extensively prepared, and the formation of both lyotropic and thermotropic liquid crystals has been studied.[4,5b] Con-

cerning (amine)silver(I) complexes, the formation of thermotropic liquid crystal of $[Ag(n\text{-}C_nH_{2n+1}NH_2)_2]NO_3$ has been reported.[13] This complex shows a lamellar phase consisting of U-shaped (double-chained) molecules. For the *N*-alkyl-substituted (ethylenediamine)silver complexes, however, a detailed molecular structure and the molecular assembly in the liquid state have not been reported.

In the present study we have synthesized and investigated the molecular aggregation behavior of $[Ag(dod\text{-}en)_2]NO_3$ in comparison with $[Ag(hex\text{-}en)_2]NO_3$ and $[Ag(oct\text{-}en)_2]NO_3$ (the three complexes are represented by $[Ag(alkyl\text{-}en)_2]NO_3$ and found that the structure of $[Ag(dod\text{-}en)_2]NO_3$ is dinuclear from the X-ray crystallographic analysis and that a thermotropic liquid crystal is formed below 100 °C. We furthermore found that $[Ag(dod\text{-}en)_2]NO_3$ forms a lyotropic liquid crystal in *n*-heptane by incorporating small amounts of water. We performed the characterization of the lyotropic liquid crystals and the studies on the aggregation behavior of the complexes in water/organic mixed solvents. The aggregation behavior of the silver complexes in water/organic mixed solvent systems was mainly studied by measurement of the self-diffusion of the silver complexes.

Results and Discussion

X-ray Crystallographic Analysis

An ORTEP drawing of the complex is given in Figure 1; selected crystal data are given in the Exp. Sect. Four *N*-dodecylethylenediamine ligands coordinate to the two silver ions in the crystalline state; the coordination geometry around each silver ion is tetrahedral. The nitrate ions are arranged between the silver ions only as counterions. The diamine complexes previously reported tend to form ethylenediamine-bridged polymeric structures such as $[Ag(en)^+]_\infty$ and $[Ag(tn)^+]_\infty$ (tn = 1,3-propanediamine); in these systems, the coordination number of the silver ions is two.[14a,14c] In the present complex, on the other hand, polymerization does not occur and the dod-en ligands bridge two silver ions. The substitution of the diamine protons by alkyl chains in the silver complex obviously has a blocking effect on the polymerization. A related dinuclear silver complex, $[Ag_2H_2(en)_3]^{4+}$, has previously been identified by X-ray crystallographic analysis.[14b] In that case, the ethylenediamine bridges are cleaved by protonation to form a dinuclear complex where only one ethylenediamine ligand bridges two silver ions; the coordination number of the silver ion is two.

Although the present result reveals the structure in the crystalline state to be dinuclear, this complex should be appreciably dissociated into a mononuclear one in organic solvents, as will be described below, and thus we express the three silver complexes by the rational formula $[Ag(dod\text{-}en)_2]NO_3$ from here on.

Formation of Thermotropic Liquid Crystals

The formation of thermotropic liquid crystals was established by Differential Scanning Calorimetry (DSC) and polarizing microscopic observations for the neat complexes as follows. $[Ag(dod\text{-}en)_2]NO_3$ is crystalline below 59 °C and forms a mesophase over the temperature range 59−96 °C. Large and small endothermic peaks were observed in the DSC curves for the respective transitions. The transition data are listed in Table 1. This mesophase gave an oily streak texture accompanied by spontaneous homeotropic alignment, as shown in Figure 2; the oily streak means that the phase should be a smectic A one. Thus, X-ray diffraction measurement was carried out at 75 °C. The profile is

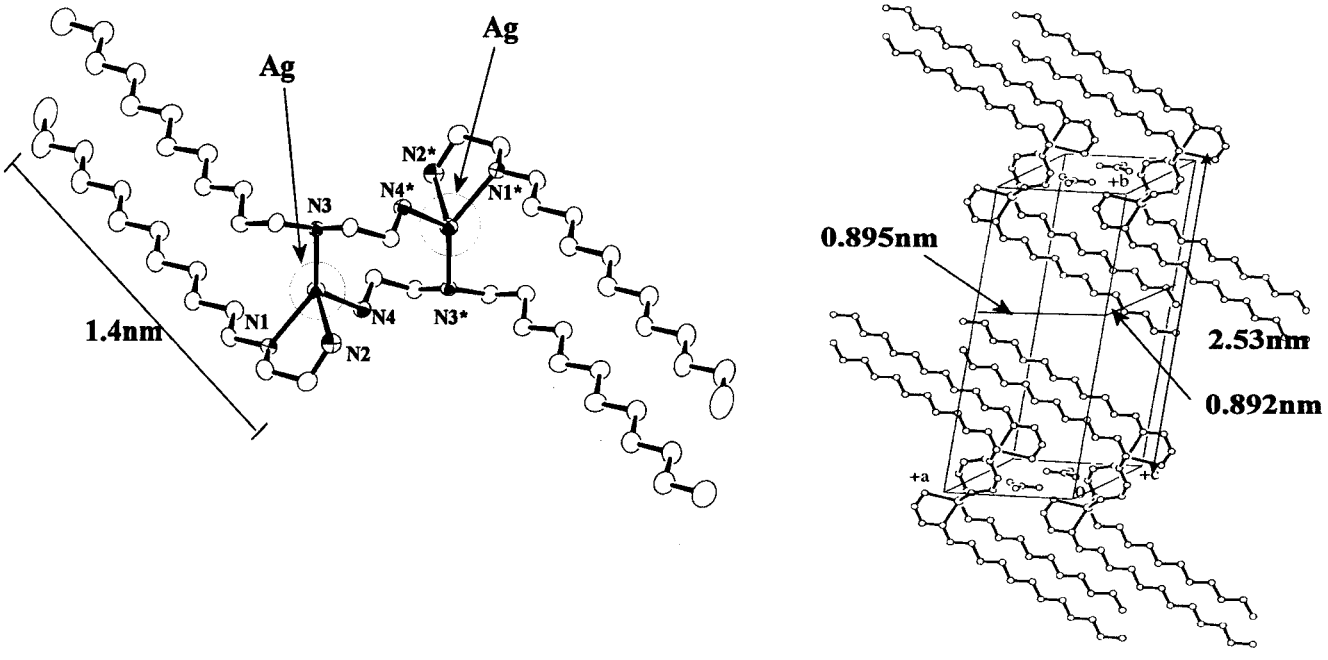

Figure 1. ORTEP diagram and atom-numbering system of $[Ag(dod\text{-}en)_2]No_3$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

described in Figure 3 and the peak data are summarized in Table 2. As can be seen in this table, it shows a series of periodic reflections characteristic of a lamellar structure. Therefore, this mesophase could be characterized as a smectic A phase, as illustrated in Figure 4. According to the X-ray crystallographic analysis (Figure 1), twice the alkyl chain length is around 2.8 nm (1.4 nm × 2), which is close to the lamellar layer length (3.1 nm). As shown in Figure 4, if the contribution of the headgroup to the layer length is significant, the alkyl chain is possibly shortened in the mesophase.

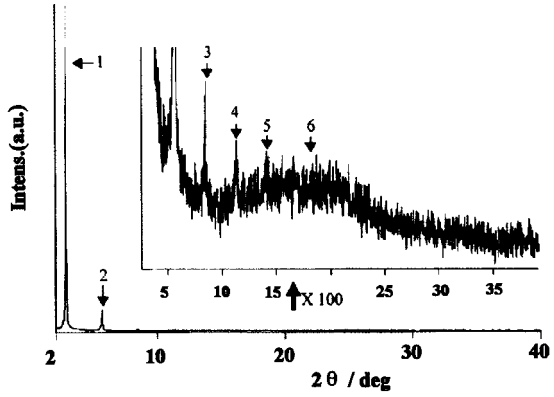

Figure 3. X-ray diffraction profile of the neat $[Ag(dod\text{-}en)_2]NO_3$ complex at 75 °C

$[Ag(oct\text{-}en)_2]NO_3$ also forms thermotropic liquid crystals but the formation is weaker than that for $[Ag(dod\text{-}en)_2]NO_3$. The thermal data are listed in Table 1; no liquid-crystalline phase was detected for $[Ag(hex\text{-}en)_2]NO_3$.

Solubility of $[Ag(alkyl\text{-}en)_2]NO_3$ in Organic Solvents and Formation of a Lyotropic Liquid Crystal of $[Ag(dod\text{-}en)_2]NO_3$ in Water/*n*-Heptane

$[Ag(dod\text{-}en)_2]NO_3$ is soluble in only a few solvents. At 25 °C this complex is soluble [> 10% (wt/v)] in dichloromethane, and sparingly soluble [a few % (wt/v)] in methanol and ethanol. The $[Ag(oct\text{-}en)_2]NO_3$ complex, on the other hand, is readily soluble in DMF, acetone, benzene, and 1,4-dioxane, and sparingly soluble in dichloromethane, ethyl acetate, diethyl ether, and chloroform. This complex is not stable in methanol and ethanol. The most hydrophilic complex, $[Ag(hex\text{-}en)_2]NO_3$, is readily soluble in many solvents, such as water, DMF, methanol, ethanol, acetone, dichloromethane, ethyl acetate, and 1,4-dioxane. As this complex seems to have similar properties to common surfactants, a detailed study of its aggregation behavior has not been performed.

It is noteworthy that the solubility of $[Ag(dod\text{-}en)_2]NO_3$ in *n*-heptane and 1,4-dioxane and that of $[Ag(oct\text{-}en)_2]NO_3$ in *n*-heptane are largely enhanced by the presence of small amounts of water. Such a solubility phenomenon does not

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

occur for $[Ag(hex\text{-}en)_2]NO_3$. This solubility enhancement suggests the formation of aggregates of the metal complexes surrounding a water "pool", where the hydrophilic sites of the silver complex ions would be collected. Figure 5 shows three-component phase diagrams of the $[Ag(dod\text{-}en)_2]NO_3$ and $[Ag(oct\text{-}en)_2]NO_3$ systems for the formation of transparent and homogeneous solutions in water/1,4-dioxane and water/*n*-heptane mixed solvent systems. It is interesting to compare the preferable interaction between the silver complexes and solvents with those of our previous studies for $[ZnCl_2(oct\text{-}en)_2]$, $[CdCl_2(oct\text{-}en)_2]$, and $[Pd(oct\text{-}en)_2]Cl_2$.[11,15] The zinc complex of a weak electrolyte and the palladium complex of a strong electrolyte are extensively dissolved in water/benzene and water/chloroform mixed solvents, respectively, to form large aggregates (microemulsions). The higher affinity of the $[Ag(dod\text{-}en)_2]NO_3$ and $[Ag(oct\text{-}en)_2]NO_3$ complexes for *n*-heptane than for more polar solvents such as benzene and chloroform indicates their higher hydrophobicity compared to $[ZnCl_2(oct\text{-}en)_2]$ and $[CdCl_2(oct\text{-}en)_2]$ despite their being strong electrolytes. The $[Ag(hexd\text{-}en)_2]NO_3$ complex previously reported is soluble in neat *n*-heptane without water[12] and does not incorporate even small amounts of water in *n*-heptane. The result of the $[Ag(dod\text{-}en)_2]NO_3$/water/*n*-heptane system (Figure 5b) shows that the transparent and homogeneous phase is especially large in the $[Ag(dod\text{-}en)_2]NO_3$ complex; this feature reflects the moderate hydrophile/lipophile balance of this complex. The dinuclear complex is almost completely changed to the mononuclear complex in solution, as will be described below. This structural change may also cause the unique solubility phenomena.

We also found a very narrow phase region of lyotropic liquid crystals in the $[Ag(dod\text{-}en)_2]NO_3$/water/*n*-heptane system (Figure 5b). The structural characterization and studies of the physical properties are discussed below.

Vapor-Pressure Depression, Electric Conductivity, and Mass Spectrometric Studies for the $[Ag(dod\text{-}en)_2]NO_3$ Complex in Some Organic Solvents

We measured the physical properties of solutions to determine the aggregation behavior of the $[Ag(dod\text{-}en)_2]NO_3$ complex. The apparent molecular weight (MW_{app}) of the complex was estimated from the vapor-pressure depression Δp [which is proportional to ΔT of Equation (2) in the Exp. Sect.] of the solutions (methanol, dichloromethane, and *n*-hexane systems) as a function of the silver complex concentrations (m; $g \cdot kg^{-1}$). As a first approximation, we estimated the MW_{app} values by assuming that the silver complex is a nonelectrolyte. The ΔT vs. m plots are slightly curved for dichloromethane and methanol solutions. The MW_{app}/MW ratios (R_{MW}) obtained for $[Ag(dod\text{-}en)_2]NO_3$ (626.72) were 1.5−2.5 in dichloromethane {$[Ag(dod\text{-}en)_2]NO_3$ =

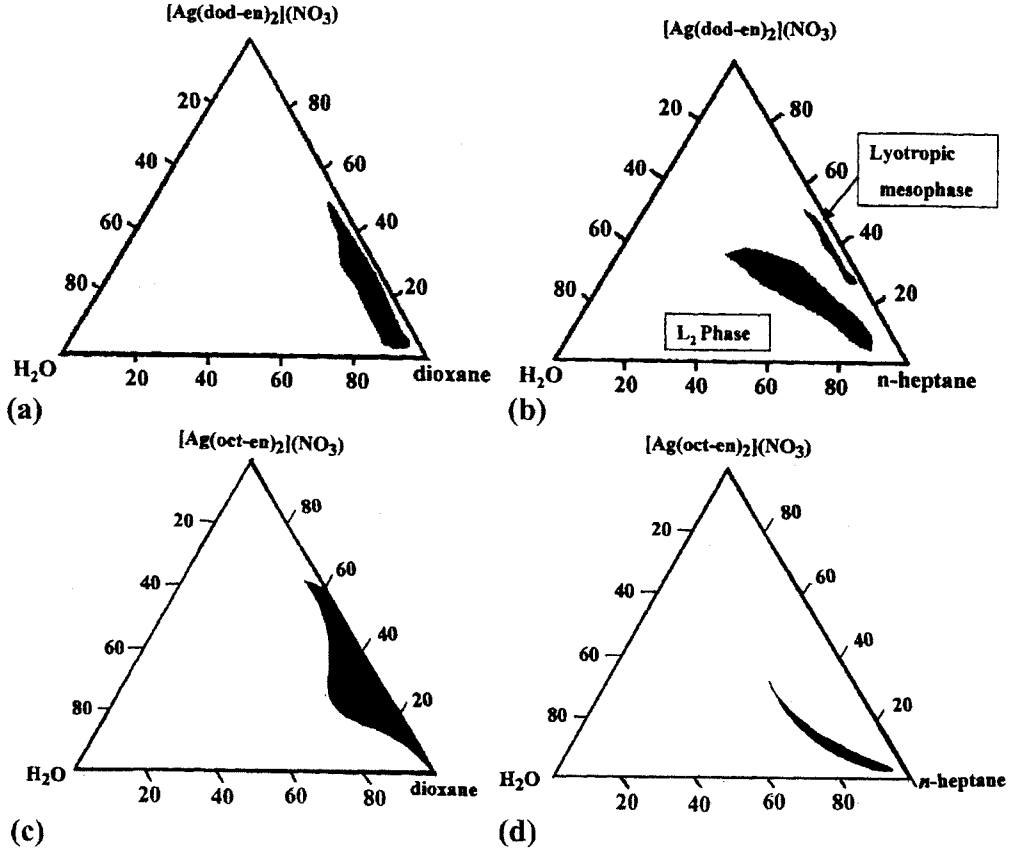

Figure 5. (a) Partial mass (wt.-%) ternary phase diagrams for the transparent and homogeneous solutions in the $[Ag(dod\text{-}en)_2]NO_3$/1,4-dioxane/water system at 30 °C; (b) partial mass (wt.-%) ternary phase diagrams for the homogeneous solutions in the $[Ag(dod\text{-}en)_2]NO_3$/*n*-heptane/water system at 30 °C; L_2 is water in oil phase

0.19−1.29 mol·kg^{-1}}, 0.8−1.1 in methanol {[Ag(dod-en)$_2$]NO_3 = 0.04−0.51 mol kg^{-1}}, and 15.5 in *n*-heptane {[Ag(dod-en)$_2$]NO_3 = 0.97−1.32 mol kg^{-1}}, where a small amount of water is present and the phase is a lyotropic liquid crystal. The obtained R_{MW} values are < 2 under some conditions. This is due to two factors, one of which is the dissociation of the salt into the silver complex ion and the nitrate ion and the other is the dissociation of the dinuclear complex into the mononuclear one. Concerning the former factor, we measured electric conductivities of the [Ag(dod-en)$_2$]NO_3 methanol solutions in the concentration range 0.01−0.12 mol·dm^{-3}. At lower concentrations, the molar electric conductivities depend on the concentration and almost obey the Onsager equation assuming a 1:1 electrolyte (Supporting Information; Figure S1a). As the dependence of the electric conductivity on the concentration is larger than that of the self-diffusion, we estimated the limiting molar conductivity of the silver complex ion in order to obtain a more accurate value by use of the self-diffusion coefficient of the silver complex ion according to the Nernst equation.[16] [The limiting molar conductivity (Λ^0) of the silver complex thus obtained was 8.7 × 10^{-3} S·m^2·mol^{-1} by using λ_0 = 6.1 × 10^{-3} S·m^2·mol^{-1} for the nitrate ion in methanol at 25 °C; this Λ^0 value is reasonable as an extrapolated value.] This result indicates that at lower concentrations in methanol this complex would be completely dissociated into [Ag(dod-en)$_2$]$^+$ and NO_3^-. At higher concentrations, where the vapor-pressure depression was measured, the Onsager plot is largely curved and the ionic interactions become stronger and more complicated. The R_{MW} value of 0.8−1.0 obtained from the VPO measurement in this concentration range means that the interaction between [Ag(dod-en)$_2$]$^+$ and NO_3^- is stronger than that at lower concentrations. In methanol, the electric conductivities (κ) are around 0.1−0.5 S·m^{-1} at 0.01−0.2 mol·dm^{-3}, whereas in dichloromethane they are around 0.1−0.2 S·m^{-1} at 0.12−0.90 mol·dm^{-3} (Supporting Information; Figure S1b). The significantly smaller electric conductivities in dichloromethane mean that the dissociation of the silver complex into the monomer or into the ions occurs to a lesser extent in dichloromethane than in methanol. This trend is consistent with the result of the vapor-pressure depression.

In order to determine the nature of the species in solution, we also measured nano-ESI mass spectra of the silver dod-en complexes in methanol and in dichloromethane. A typical spectrum is shown in Figure 6. The percentages of the peak areas of [Ag$_2$(dod-en)$_4$]NO_3^+ (*m*/*z* = 1188.82, $^{12}C_{56}{}^{1}H_{128}{}^{107}Ag_2{}^{14}N_9{}^{16}O_3$)/[Ag$_2$(dod-en)$_3$]$NO_3^+$ (*m*/*z* = 960.57, $^{12}C_{42}{}^{1}H_{96}{}^{107}Ag_2{}^{14}N_7{}^{16}O_3$)/[Ag(dod-en)$_2$]$^+$ (*m*/*z* = 563.42, $^{12}C_{28}{}^{1}H_{64}{}^{107}Ag^{14}N_4$) were as follows: 2.4%/4.6%/93% for a 0.048 mol·dm^{-3} methanol solution, 7.2%/7.2%/85.6% for a 0.064 mol·dm^{-3} dichloromethane solution, and 10.2%/15.6%/74.2% for a 0.16 mol·dm^{-3} dichloromethane solution. Although the percentages obtained do not necessarily reflect the distribution of each species in solution due to complicated ionization processes, this result does not conflict with the view that the dinuclear complex found in the crystalline state would be appreciably dissociated into the mononuclear complex even at moderate concentrations in organic solvents. A similar formation of mixed mononuclear and dinuclear ethylenediamine (en) complexes of silver such as Ag(en)$^+$, Ag$_2$(en)$^{2+}$, Ag(en)$_2^+$, and Ag$_2$(en)$_2^{2+}$ has been previously reported in water.[17] For the en complex, a

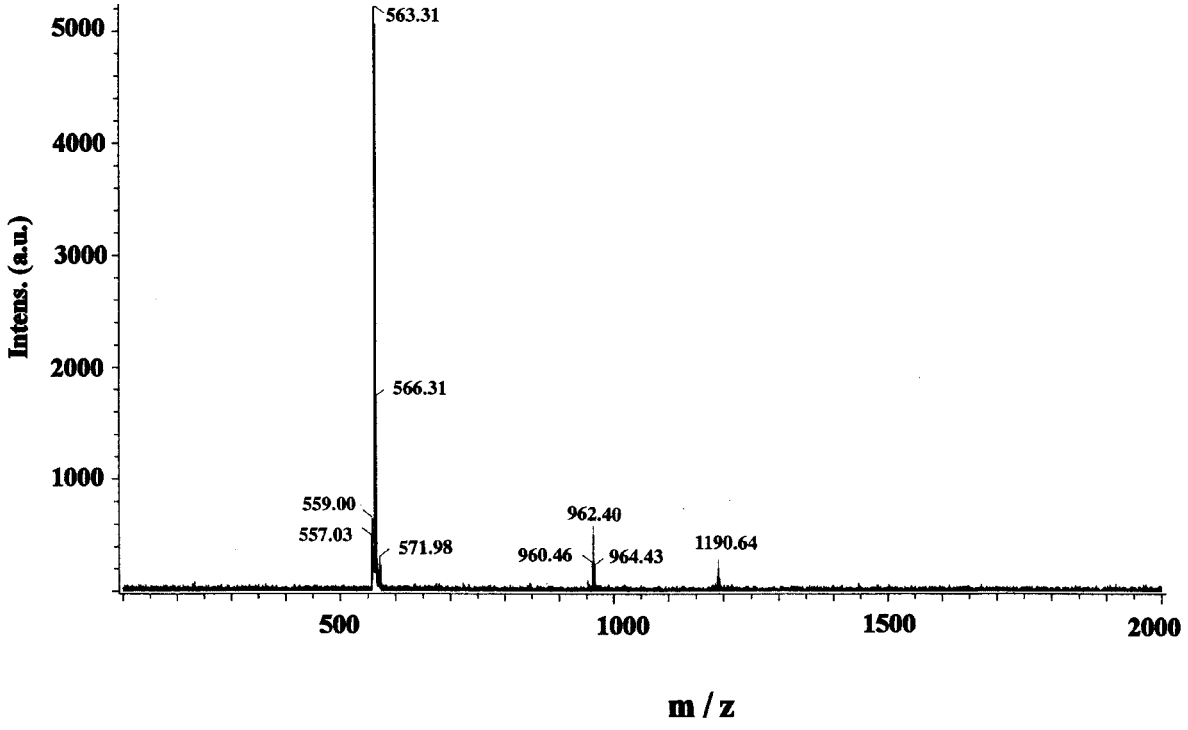

Figure 6. Nano-ESI-TOF mass spectrum of 0.16 M [Ag$_x$(dod-en)$_y$](NO$_3$)$_z$ complexes in dichloromethane

polynuclear structure in the solid state decomposes into the dinuclear and mononuclear complexes in water.

Observation of the Lyotropic Liquid Crystal by Micrograph for the [Ag(dod-en)$_2$]NO$_3$/Water/n-Heptane System

Figure 7 shows a photomicrograph of the lyotropic mesophase in [Ag(dod-en)$_2$]NO$_3$/water/*n*-heptane mixtures at room temperature. It gave a schlieren texture containing both two and four brushes, which is characteristic of a nematic phase.[18] Hence, this lyotropic mesophase can be identified as a nematic phase. As the molecular structure of this dinuclear and double-chained complex is favorable to form thermotropic liquid crystals at temperatures higher than room temperature, this molecule furthermore loses order in one dimension in the water-containing *n*-heptane to form a nematic lyotropic liquid crystal. The presence of small amounts of water plays an important role in the stabilization of the liquid-crystalline structure by assembling the headgroup of the silver complex and by organizing the supramolecules. This difference in the superstructure of this complex between the neat state and the solution state can be attributed to a loss of molecular orderings in the assemblies by the presence of *n*-heptane. It is notable that the dinuclear complex in the crystalline state would be significantly dissociated into a monomer in organic solvents as described above. The presence of small amounts of water will promote this dissociation. Thus, the lyotropic liquid crystal may be mainly composed of a mononuclear double-chained [Ag(dod-en)$_2$]NO$_3$ complex. As the dissociation of the nitrate ions from the silver salt in the water/*n*-heptane system may be slight because of a large excess of *n*-heptane over water in the lyotropic liquid crystalline phase, the R_{MW} value (15.5) obtained from the vapor-pressure depression in the water/*n*-heptane system will be close to the aggregation number of [Ag(dod-en)$_2$]NO$_3$ ion-pairs.

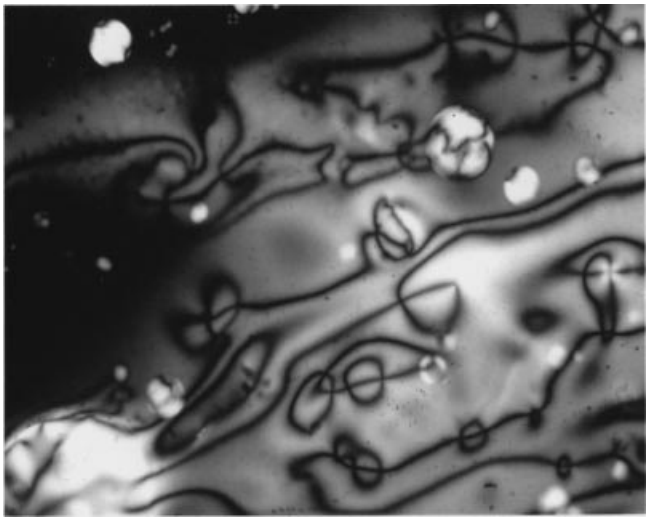

Figure 7. Optical texture observed for the lyotropic liquid crystal of the [Ag(dod-en)$_2$]NO$_3$/water/*n*-heptane system

^{2}H NMR Spectra and Small-Angle X-ray Scattering (SAXS) for the Lyotropic Mesophase

The lyotropic liquid crystal forms in very narrow composition and temperature ranges, and the small amounts of water play an important role in forming the mesophase. In order to monitor the formation of lyotropic mesophases containing water from a microscopic viewpoint, we expected the ^{2}H NMR spectra to provide useful information. As the water content in the present lyotropic mesophase is small (W_0 = [water]/[silver complex] < 2), most water molecules can be regarded as water of hydration. Thus, we can directly monitor the nature of the aggregates in the ne-

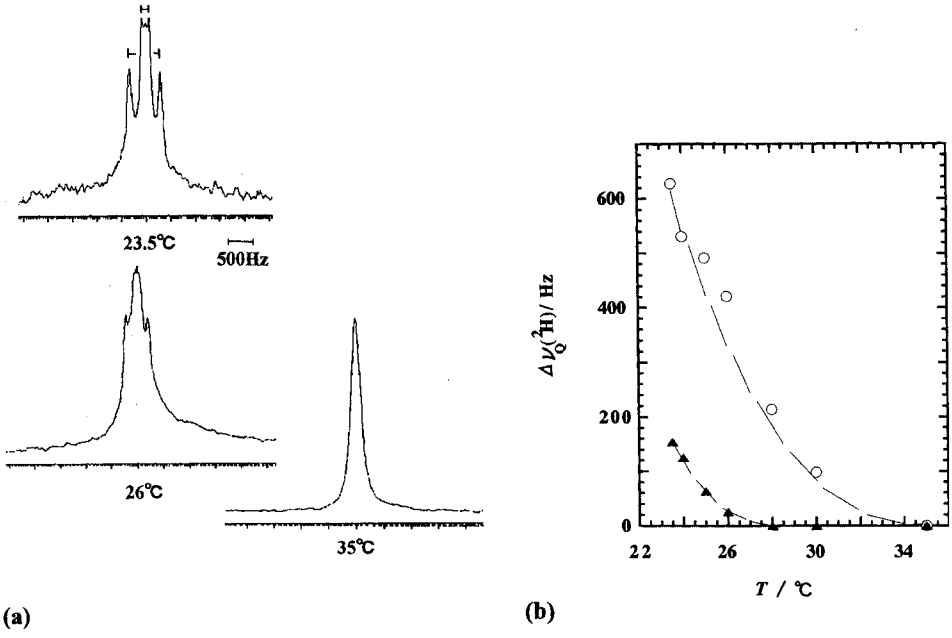

Figure 8. (a) ^{2}H NMR spectra of the trace water in the [Ag(dod-en)$_2$]NO$_3$/water/*n*-heptane system as a function of temperature (W_0 = 1.7 and m = 1.2 mol kg^{-1}); (b) change in the ^2H_2O quadrupole splitting for the two kinds of liquid crystalline peaks

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

matic lyotropic mesophase by ^{2}H NMR spectroscopy. Figure 8a shows the ^{2}H NMR spectra of trace water in the $[Ag(dod\text{-}en)_2]NO_3$/water/*n*-heptane system as a function of temperature. The ^{2}H NMR quadrupole splittings of the liquid-crystalline spectra as a function of temperature are shown in Figure 8b. The absolute values of the quadrupole splittings are consistent with a nematic phase.[19] This figure indicates the presence of two kinds of hydration modes. As the exchange of the hydration water between the two states is slow enough on the NMR timescale, the two kinds of water would reflect those of molecular assemblies.

We observed one SAXS peak at $2\theta = 1.4°$ ($d = 6.3$ nm, which is nearly twice the bilayer thickness of 3.1 nm) in the same lyotropic mesophase as used for the ^{2}H NMR spectra; no clear peak was observed in the SAXS spectrum for the isotropic microemulsions (L_2 phase in Figure 5b). Therefore, it is possible that the smaller ^{2}H NMR splitting arises from hydration of the domains close to the isotropic microemulsions.

The narrow temperature and concentration ranges of the nematic lyotropic mesophase mean that the mesophase could form because of the delicate balance of the hydrophilicity/lipophilicity of the silver complex and the selective hydration in *n*-heptane solution.

Self-Diffusion Studies for the Aggregation of $[Ag(dod\text{-}en)_2]NO_3$ in Solution

The self-diffusion coefficients of the solvent and solute were calculated to monitor the extent of aggregation, especially in mixed-component systems. We thus measured the diffusion coefficients of the $[Ag(dod\text{-}en)_2]NO_3$ complex and the solvents in water/*n*-heptane and dichloromethane in comparison with those in methanol where aggregation hardly occurs.

Figure 9 shows the results for water and the silver complex as a function of the silver complex concentrations. In the water/*n*-heptane system, the solute concentration is expressed for the neat *n*-heptane solvent (neglecting small amounts of water). In Figure 9a, the diffusion coefficients in methanol could be obtained only in a very narrow concentration range due to solubility limitations; those at low concentration are regarded as those of the monomer.

The diffusion coefficients obtained can be interpreted on the basis of the Stokes−Einstein equation at infinite dilution according to Equation (1), where R is the Stokes radius for the monomer, k the Boltzmann constant, T the absolute temperature, and η_0 the viscosity of the solvent.

$$R = kT/6\pi\eta_0 D_0 \quad (1)$$

We can estimate the Stokes radius for the silver complex in dilute methanol solution or in dichloromethane by an extrapolation of the diffusion coefficients to an infinite dilution in Figure 9a; we obtain a D_0 value in methanol of 6.8×10^{-10} m^2·s^{-1} and in dichloromethane of 8.4×10^{-10} m^2·s^{-1}. By using an η_0 value for methanol of 0.542 mPa s[20] and a value for dichloromethane of 0.41 mPa·s at 25 °C[20] the R values are 0.67 nm and 0.71 nm, respectively. The larger size in dichloromethane is consistent with the results of the vapor-pressure depression and mass spectrometric measurements. The significant decrease in the diffusion coefficients at higher concentrations indicates the extensive aggregation.[21]

As deuterated *n*-heptane is unobtainable, we measured the diffusion coefficients of the silver complex in water/*n*-heptane solutions indirectly as will be described in the Exp. Sect. The measurements of diffusion coefficients in the *n*-heptane/water system were performed in both the water in oil (w/o) microemulsion phase (larger W_0 regions) and the lyotropic liquid-crystalline phase (smaller W_0 regions) (Figure 9b). We can furthermore estimate the Stokes radius for the metal complex in *n*-heptane ($D_0 = 8.7 \times 10^{-11}$ m^2·s^{-1})

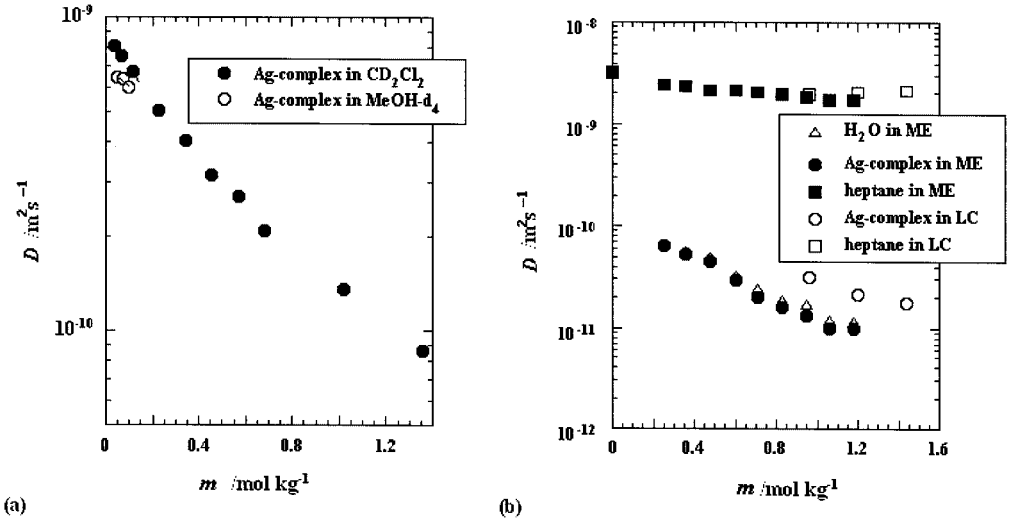

Figure 9. (a) Diffusion coefficients for the $[Ag(dod\text{-}en)_2]NO_3$ complex in $[D_4]$MeOH and $[D_2]$dichloromethane as a function of the mononuclear silver complex concentration; (b) diffusion coefficients for water, *n*-heptane, and the complex in the $[Ag(dod\text{-}en)_2](NO_3)_2$/*n*-heptane/water system [in the microemulsion (ME) and liquid crystal (LC) systems] as a function of the mononuclear silver complex concentrations ($W_0 = 30$ in the ME system and $W_0 = 1.7$ in the LC system)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

by neglecting small amounts of water. (η_0 = 0.397 mPa·s for *n*-heptane) The obtained value of 6.4 nm is appreciably larger than those in methanol and dichloromethane. This result clearly indicates that the silver complex is readily dissolved in *n*-heptane only when large aggregates are formed by incorporation of water.

We can see the other two characteristic features in Figure 9b. Firstly, the diffusion coefficient of water is appreciably smaller than that of *n*-heptane and is slightly larger than that of the silver complex. Secondly, the diffusion coefficients of the silver complex in the liquid-crystalline region are significantly larger and those of solvent *n*-heptane are also slightly larger than those in the microemulsion systems. The first feature in the water diffusion means that water tends to move together with the silver complex and is motionally restricted to a large extent. This indicates the formation of reversed micelles or W/O microemulsions. The second feature is consistent with a nematic liquid crystal characterized by a polarizing microscope, since the viscosity of the nematic lyotropic liquid crystal will be lower than that of the isotropic phase of the same surfactant concentration. The water content is appreciably smaller in the lyotropic liquid crystal than in the W/O microemulsion state in spite of the slightly larger concentration of the silver complex in the former state. This difference of the silver complex concentration will tend to make the diffusion coefficient in the liquid crystal phase smaller than that in the W/O microemulsion system. However, the result obtained is opposite to this prediction, which may reflect the lower viscosity of the nematic-type liquid crystal. Although *n*-heptane seems to be an unfavorable solvent to form lyotropic liquid crystals due to a lower molecular rigidity and a lower polarity, the rigid structure of the present complex and the small amounts of incorporated water may play important roles in forming the anisotropic superstructure.

In order to see the water effect on the aggregation, we furthermore measured the diffusion coefficients of the silver complexes depending on the water content in the 1,4-dioxane and *n*-heptane systems. Figure 10a shows that in the 1,4-dioxane/water system the diffusion coefficients of $[Ag(hex\text{-}en)_2]^+$, $[Ag(oct\text{-}en)_2]^+$, and $[Ag(dod\text{-}en)_2]^+$ slightly increase with increasing water content. In this figure, the silver complex concentration is expressed for the neat 1,4-dioxane solvent. The diffusion coefficients increase probably due to the dilution of the solution with an addition of water. The dod-en complex is dissolved in 1,4-dioxane in the presence of water and the effect of water on the aggregation of $[Ag(dod\text{-}en)_2]^+$ is only slight, contrary to the dilution effect. This result means that water assists the dissolution of this complex in 1,4-dioxane by the formation of aggregates.

This effect of water on the diffusion appears more clearly in the *n*-heptane system, as shown in Figure 10b, where it is characteristic that addition of water decreases the diffusion coefficients of the $[Ag(dod\text{-}en)_2]^+$ complex and of both solvents. In this system, water clusters move together with the silver complex aggregates and assist the aggregation of the silver complex. As the diffusion of *n*-heptane is also decreased by addition of water, water will assist the aggregation of the silver complex to form a W/O microemulsion more than in the 1,4-dioxane system. The effect of the aggregation on the diffusion would be larger than the opposite effect on aggregation due to dilution with an increase in the water content, and thus the diffusion is decreased by addition of water.

In conclusion, we have synthesized and characterized new amphiphilic alkylethylenediamine dinuclear silver complexes. Although the ligand is regarded as a simple and common type, a unique rigid structure of the tetrakis(dodecyl)-substituted complex gives rise to a formation of therm-

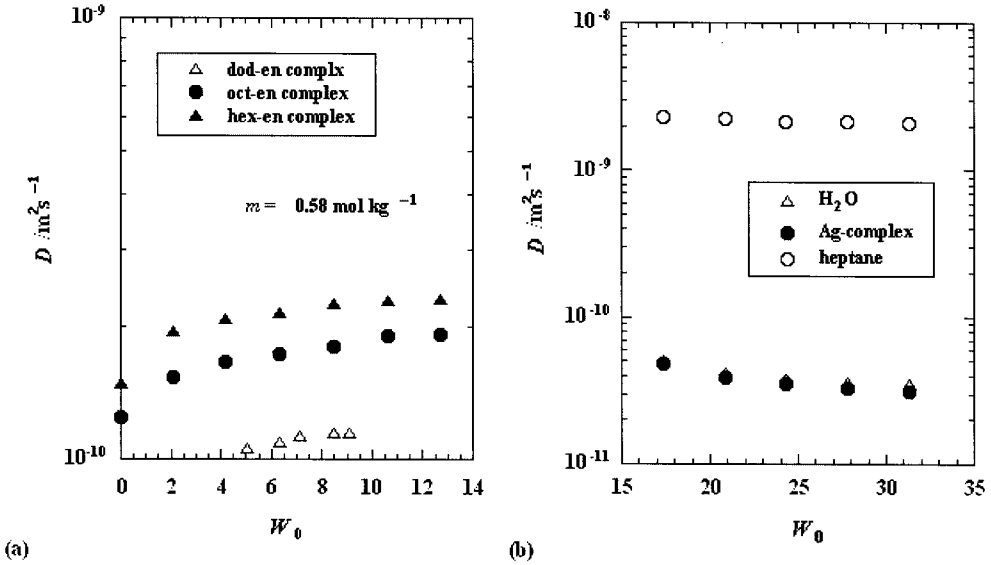

Figure 10. (a) Diffusion coefficients of $[Ag(hex\text{-}en)_2]^+$, $[Ag(oct\text{-}en)_2]^+$, and $[Ag(dod\text{-}en)_2]^+$ in water-containing $[D_8]$1,4-dioxane systems as a function of the water content; (b) diffusion coefficients of $[Ag(dod\text{-}en)_2]^+$ and the solvents in the water-containing *n*-heptane system as a function of the water content

otropic liquid crystals. Small amounts of water play an important role in concentrating the silver headgroup in the nanosized water pools and thereby aligning the assemblies of the silver complex for the superstructure.

Experimental Section

Materials: *N*-Hexylethylenediamine, *N*-octylethylenediamine, and *N*-dodecylethylenediamine were prepared according to reported procedures.[11a,11b] The silver complexes were synthesized according to a similar procedure as described for the *N*-hexadecylethylenediamine complex but the crystallization from the reaction mixtures was performed by the addition of cyclohexane to a methanol solution. The molecular formula and purity were determined by elemental analyses and ^{13}C NMR spectroscopy. The yields after recrystallization were about 80%. $[Ag(hex\text{-}en)_2]NO_3$: $C_{16}H_{40}AgN_5O_3$ (458.41): calcd. C 41.92, H 8.80, N 15.28; found C 41.69, H 8.80, N 15.17. $[Ag(oct\text{-}en)_2]NO_3$: $C_{20}H_{48}AgN_5O_3$ (514.50): calcd. C 46.69, H 9.40, N 13.61; found C 46.64, H 9.31, N 13.47. $[Ag(dod\text{-}en)_2]NO_3$: $C_{28}H_{64}AgN_5O_3$ (626.7): calcd. C 53.66, H 10.29, N 11.17; found C 53.92, H 10.15, N 11.20. Chloroform, dichloromethane, methanol, and 1,4-dioxane were guaranteed grades supplied by Wako Pure Chemical Industries. Chloroform was purified as previously reported.[11d] Dichloromethane was dried with calcium chloride and then distilled; the water content was $< 1 \times 10^{-3}$ %. Methanol and 1,4-dioxane were distilled once before use. Water was distilled twice. The deuterated solvents (D_2O, $[D_4]$MeOH, $[D_2]$dichloromethane, and $[D_8]$1,4-dioxane) were supplied by Merck Co.

Single-Crystal X-ray Diffraction Analysis for $[Ag(dod\text{-}en)_2]NO_3$: A colorless plate ($0.30 \times 0.25 \times 0.05$ mm) was fixed on the top of a glass fiber with Paraton N oil, and 3854 reflections ($6° < 2\theta < 52°$) were measured with a Rigaku/MSC Mercury CCD diffractometer with graphite-monochromated Mo-K_α radiation at −70 °C. An absorption correction by a spherical multiscan method was applied ($\mu = 6.1$ cm^{-1}). The structure was solved by direct methods using the program SIR92[22] and was refined with full-matrix least-squares techniques to $R = 0.061$ and $R_w = 0.066$ for 4517 independent reflections with $I > 2\sigma(I)$. All non-hydrogen atoms were refined anisotropically and the hydrogen atoms, located in ideal positions, were not refined. All calculations were performed with a Silicon Graphics O2 Station with the teXsan program system.[23] The crystal data and experimental details are summarized in Table 3. CCDC-244806 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Observations of the Structures of the Liquid Crystals: Thermotropic and lyotropic mesomorphisms were established using the samples exhibiting satisfactory elemental analysis data of C, H and N. For the thermotropic mesomorphism, the phase-transition phenomenon was observed using a polarizing microscope (Olympus BH2), equipped with a heating plate controlled by a thermo-regulator (Mettler FP80 hot stage, Mettler FP82 central processor), and measured by a differential scanning calorimeter (Shimadzu DSC-50). The X-ray diffraction measurement for the thermotropic liquid crystal was performed with Cu-K_α radiation (Rigaku RAD) equipped with a hand-made heating plate[24] controlled by a thermo-regulator. For the lyotropic system, the mesophase at room temperature was characterized by the polarizing microscope, ^2H_2O NMR spectroscopy, and small-angle X-ray scattering ($0.5° < 2\theta < 5°$) with Cu-K_α radiation (Rigaku RAD), where a plastic cell of 3 mm thickness with mica windows was used and the intensity distribution was measured with a position-sensitive proportional counter (PSPC).

R_w[a]	0.066
GOF[b]	1.50

[a] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $Rw = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ [$w = 1/\sigma^2(F_o)$]. [b] GOF $= [\Sigma w(|F_o| - |F_c|)^2/[N_o - N_p]^{1/2}$ (N_o = number of data, N_p = number of variables).

NMR Measurements: The aggregation behavior in solution was monitored by NMR spectroscopy. The ^2H NMR spectra were obtained with a JEOL JNM EX-270 FT NMR spectrometer operating at 41.5 MHz for 20% enriched ^2H_2O, small amounts of which are contained in the lyotropic liquid crystalline system. The self-diffusion coefficients were measured by the NMR PFG (Pulsed Field Gradient) technique.[25] The measurements were performed with a JEOL FX-90 spectrometer operating at 90 MHz for ^1H. The spectrometer was equipped with an apparatus that produced a field gradient in the range 0.3−1.0 T/m. For water, the change in the intensity of the ^1HDO signal was monitored. For the surfactant, the intensity of the methylene ^1H signals of the alkyl chains was monitored. In the *n*-heptane (deuterated reagent was not supplied) system, the ^1H peaks of the silver complex were completely covered by those of the solvent. However, the attenuation of the spin-echo amplitude after the Fourier transformation of the solvent peaks decayed much more rapidly with a change in the duration (δ) of the applied gradient pulses ($0.2 < \delta < 5$ ms) than that of the silver complex. Thus, we could obtain the diffusion coefficients of the silver complexes even in the *n*-heptane system. The accuracy of the measured diffusion coefficients is estimated to be better than ±5%, although that for the silver complex in the *n*-heptane system is somewhat worse.

Other Measurements: The vapor-pressure depressions for the solutions of methanol, dichloromethane, and *n*-heptane containing small amounts of water[26] were measured with a Knauer Vapor Pressure Osmometer (VPO) at 45 °C. The magnitude of the depression is proportional to the difference in temperatures (ΔT) between a solvent-wetted thermistor and a solution-wetted one. If the dissociation of the counterion is negligible, Equation (2) can be applied, where k is a constant depending on the solvent and the apparatus used, M_1 the apparent molecular weight of the solute, and m' the solute concentration in g·kg^{-1}.

$$\Delta T = km'/M_1 \quad (2)$$

The k value was determined from benzil solutions. The electric conductivities of the methanol and dichloromethane solutions were measured using an admittance linear bridge (FUSO 362A) operated at 1 kHz. The mass spectra of the silver dod-en complexes in methanol and dichloromethane were measured with a Jeol JMS-T100 (AccuTOF) ESI-TOF mass spectrometer.

[16] The diffusion coefficient at an infinite dilution can be correlated with the molar conductivity. According to the Nernst equation, the diffusion coefficient (D_{0j}) for a univalent ion j is simply correlated with its molar conductivity (λ_{0j}) at an infinite dilution: $D_{0j} = 2.68 \times 10^{-7}\ \lambda_{0j}$ at 25 °C. From this equation we estimated the λ_{0j} value to be 2.6×10^{-3} S·m^2·mol^{-1} for the silver ion.

Conformational Analysis of Bis(L-*N*,*N*-dimethylvalinato)copper(II) and Bis(L-*N*,*N*-dimethylleucinato)copper(II) in Different Solvents by EPR Spectroscopy and a Molecular Mechanics Study

Krunoslav Mirosavljević,[a] Jasmina Sabolović,[b] and Vesna Noethig-Laslo*[a]

Keywords: Complexes / Amino acids / N,O ligands / EPR spectroscopy / Force field

An EPR study on the Brownian motion of bis(L-*N*,*N*-dimethylvalinato)copper(II), Cu(L-Me_2Val)$_2$ and bis(L-*N*,*N*-dimethylleucinato)copper(II), Cu(L-Me_2Leu)$_2$, dissolved in different solvents (CD_3OD, CH_3CH_2OH, $CDCl_3$) as a function of temperature is presented. The theoretical fits of the EPR spectra revealed different EPR behaviour for the two copper(II) complexes in hydrogen bond making solvents. In order to examine whether the different behaviour could be explained on conformational (steric) grounds, a conformational analysis of the copper(II) complexes with L-*N*,*N*-dimethylated amino acids was performed with a molecular mechanics force field. The ability of the most stable conformations to bind a water molecule in the copper(II) first coordination sphere was also examined using the force field.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Copper(II) complexes with amino acids and small peptides have been intensively studied in relation to their biological importance and possible pharmacological activity (here we refer only to few).[1−7] These compounds are also regarded as good model systems for copper binding sites in copper-containing enzymes and other proteins (e.g. prions).[8−10] Most of the biologically important interactions are achieved by the side-chains of the amino acids in proteins. These interactions may have a significant role in the oxidation state changes of the copper ion in copper-containing metalloproteins.[11]

Amino acid side-chain interactions such as those of the van der Waals type may also be important in the low molecular-weight copper(II) complexes with amino acids. Sigel and co-workers[12,13] studied amino acid side-chain interactions in the copper(II) complexes by glass electrode potentiometry. They pointed out that intramolecular van der Waals interactions formed by the two amino acid side-chains in the bis(chelated) copper(II) complexes could be formed only when 2N/2O donor amino acid atoms were arranged in a *trans* position in the equatorial plane of the copper(II) coordination sphere. Only the *trans*-CuN_2O_2 configuration was confirmed in a number of copper(II) complexes with L-*N*,*N*-dialkylated amino acids (other than glycine) dissolved in organic solvents by EPR spectroscopy[14,15] as well as by X-ray structural methods.[16−19] However, the *trans*-isomer of bis(glycinato)copper(II) was found to be more stable that the *cis*-isomer in the solid and gaseous phases, with a very quick isomerization reaction form *cis* to *trans* in the gas phase at ambient temperature.[20]

The effect of water molecules dissolved in organic solvents on the electronic states of copper(II) complexes with L-*N*,*N*-dialkylated amino acids was studied.[15] It was suggested that if the amino acid side chains were long enough to form aliphatic intramolecular van der Waals contacts, then the presence of water in the organic solvent might induce the conformation change of the complex.

Thus, the effects of the water binding to the fifth (apical) position in the copper(II) coordination sphere on the length of the *N*-alkyl substituents in bis(chelates) with *N*,*N*-dialkyl amino acids were studied.[21,22] It was found that the water molecule bound to the copper(II) coordination sphere in the *N*,*N*-dialkylated alaninato complex could be easily released from the copper(II) but only when the *N*-alkyl chain was longer than methyl, whereas the apical water molecule was essential for the stability of the copper(II) complex with L-*N*,*N*-dimethylalanine.[21,22] However, EPR spectroscopic measurements of the copper(II) complexes of L-*N*,*N*-dimethylvaline or L-*N*,*N*-dimethylisoleucine revealed considerable influence of the water molecules dissolved in organic solvents on the resultant EPR spectra[15] and suggested that in these complexes, dissolved in organic solvents, the apically bound water molecule could be easily released from the copper(II) coordination sphere. Thus, considerable influence of the aliphatic amino acid residues on binding or release of

the water molecule from the copper(II) coordination sphere could be envisaged.[22,23] Namely, a change in the conformation of the isoleucine side-chains in bis(L-*N,N*-dimethylisoleucinato)copper(II), i.e. Cu(L-Me_2Ile)$_2$, dissolved in deuterated methanol associated with the water molecule released from the copper(II) coordination sphere was suggested from the first study on the temperature dependence of the Brownian motion of the copper(II) amino acid complexes using EPR spectroscopy recorded at different frequencies.[22]

EPR spectroscopy is a powerful technique for the study of the electronic structures of the copper(II) complexes in order to gain information about the solute-solvent interactions as a function of the solvent, temperature and pH.[24,25] Interpretation of the results is sometimes difficult because of the lack of structural data. On the other hand, a recently proposed molecular mechanics (MM) force field (FFW) developed for modelling of anhydrous and hydrated copper(II) amino acid complexes[26] offers a unique possibility to gain qualitative insight into the arrangements that a chosen number of water molecules may adopt around the studied complexes. A combination of EPR spectroscopy and molecular mechanics calculations has become a valuable tool for identifying the preferred structure between different conformers.[27,28]

As a continuation of our previous investigations, we herein present an EPR study of the temperature dependence of the Brownian motion of bis(L-*N,N*-dimethylvalinato)copper(II), Cu(L-Me_2Val)$_2$, and bis(L-*N,N*-dimethylleucinato)-copper(II), Cu(L-Me_2Leu)$_2$, dissolved in CD_3OD, CH_3CH_2OH and $CDCl_3$. These bis(L-dimethylamino acidato)copper(II) complexes have the two N-atoms in the copper(II) coordination sphere in the *trans*-position,[16−19] thus a similar temperature dependence of the ligand field parameters may be envisaged. The conformational analysis of these compounds was performed with the MM force field FFW[26,29] in order to find the most stable conformations. The ability of the most stable conformations to bind a water molecule in the copper(II) first coordination sphere (i.e. apical water) was examined. The combined EPR and MM studies are aimed at establishing whether different EPR behaviour of the copper(II) complexes examined in this work may be due to the aliphatic amino acid side-chain interactions, i.e. conformational (steric) in nature.

Results and Discussion

A) EPR Analysis

The EPR spectra and the rotational correlation time, τ_θ, of the complexes calculated from the spectra of Cu(L-Me_2-Leu)$_2$ dissolved in CD_3OD and in $CDCl_3$, respectively, are compared in Figure 1. The spectra of the complex dissolved in one particular solvent could be fitted well with the same spectral parameters (Table 1) characteristic for that solvent in the whole temperature interval examined (i.e. 277−317 K in CD_3OD and 274−304 K in $CDCl_3$). The spectra of the complex dissolved in $CDCl_3$ (c and d) exhibit five well resolved superhyperfine lines due to the two nitrogen atoms in the copper(II) coordination sphere in the *trans*-position.[30,31] The resolved superhyperfine lines in the spectra also depend on the rotational correlation time, τ_θ.[24,32] A negligible influence of the anisotropic components ($a_{N\parallel}$ and $a_{N\perp}$) of the superhyperfine coupling tensor can be determined from spectrum c.[33,34] Well resolved superhyperfine lines suggest that the copper and nitrogen atoms are positioned in the equatorial plane of the copper(II) coordination sphere. The spectra of the complex dissolved in CD_3OD which are characterised by different EPR parameters (Table 1), albeit with the similar τ_θ values[24,32] as in $CDCl_3$, show five much broader superhyperfine lines in the whole temperature range studied. This is due to a displacement of the nitrogen atoms from of the copper(II) equatorial plane most probably by the apical water molecule in the complex.[15,35] A larger hyperfine splitting constant a_o, concomitant with decreased g_o values (Table 1) was determined from the spectra c and d (Figure 1) in $CDCl_3$. A comparison of this with the values determined from the spectra a and b in CD_3OD suggests more covalent character for the Cu−ligand bonds of the complex in $CDCl_3$.[35] This is in accordance with the finding that small deviations from the square-planar coordination shifts the hyperfine splitting constant to smaller values (see Table 1).[36]

Figure 2 shows the EPR spectra of Cu(L-Me_2Val)$_2$ dissolved in $CDCl_3$ (a and b), CD_3OD (c and d) and CH_3CH_2OH (e and f) recorded at two temperatures and their corresponding theoretical fits. In $CDCl_3$ the spectra were fitted well with the same parameters (Table 1) in the whole temperature range studied. As in the case of the leuc-

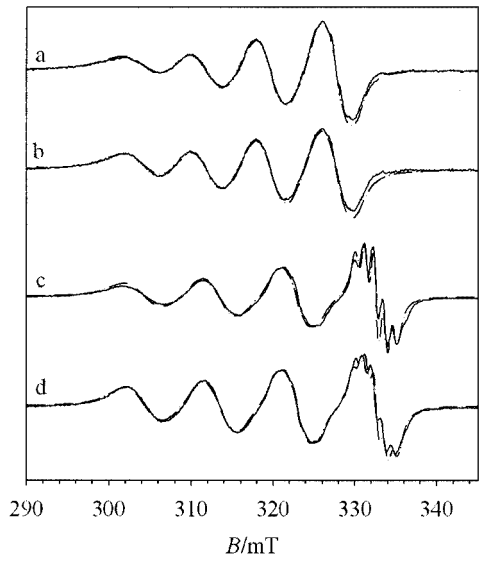

Figure 1. EPR spectra of Cu(L-Me_2Leu)$_2$ dissolved in CD_3OD taken at: (a) 294 K ($\tau_\theta = 9.1\cdot10^{-11}$ s), (b) 317 K ($\tau_\theta = 7.0\cdot10^{-11}$ s) and in $CDCl_3$ at (c) 274 K ($\tau_\theta = 8.6\cdot10^{-11}$ s), (d) 304 K ($\tau_\theta = 8.0\cdot10^{-11}$ s); full lines represent experimental spectra and dotted lines show the theoretical fit obtained with the EPR parameters a_o, g_o, $A_\parallel$ and $g_\parallel$ displayed in Table 1

inato complex, the spectra are characterised by well resolved superhyperfine structures due to the two nitrogen atoms in the copper(II) equatorial plane.

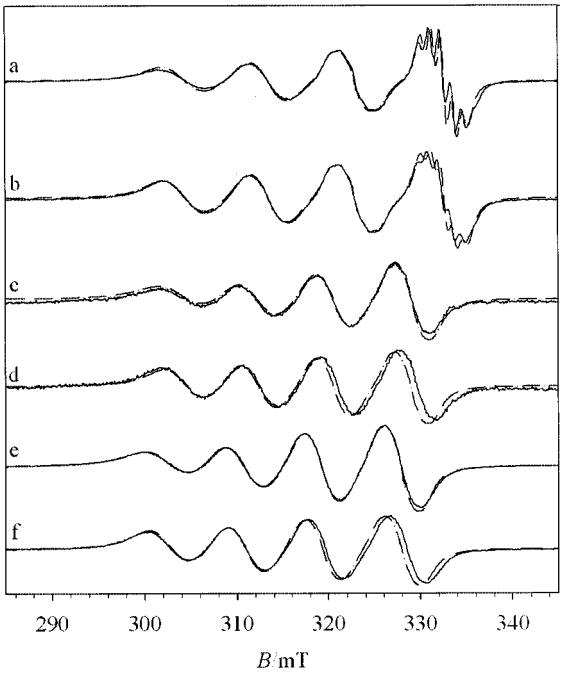

Figure 2. EPR spectra of Cu(L-Me_2Val)$_2$ dissolved in $CDCl_3$ at (a) 274 K ($\tau_\theta = 6.6\cdot10^{-11}$ s), (b) 304 K ($\tau_\theta = 5.4\cdot10^{-11}$ s); in CD_3OD at (c) 292 K ($\tau_\theta = 6.9\cdot10^{-11}$ s), (d) 316 K ($\tau_\theta = 4.3\cdot10^{-11}$ s); in CH_3CH_2OH at (e) 292 K ($\tau_\theta = 7.1\cdot10^{-11}$ s) and (f) 320 K ($\tau_\theta = 4.0\cdot10^{-11}$ s); full lines represent experimental spectra and dotted lines represent the theoretical fit with the EPR parameters of the lower-temperature ranges given in Table 1

However, in addition to the blurred superhyperfine structure of the spectra c−f (Figure 2), the theoretical fit of the spectra with the EPR parameters for the valine complex dissolved in CD_3OD and CH_3CH_2OH (i.e. in the hydrogen-bond making solvents) was satisfactory only in the lower temperature interval (see Table 1), assuming one type, the aqua complex, for the first copper(II) coordination sphere. In order to fit the experimental spectra d and f well (Figure 2), an increased a_o and a decreased g_o value, as determined from the experimental spectra were taken into account. This suggested an increase of the covalent character of the Cu−ligands bonds[36] of the complex represented by the experimental spectra d and f.

The reorientation correlation times, τ_θ, of the complexes which describe their Brownian motion in solution (see Methods) were calculated from the fitted spectra. Figure 3 shows a comparison of τ_θ calculated from the fit of the spectra of Cu(L-Me_2Leu)$_2$ and Cu(L-Me_2Val)$_2$ dissolved in CD_3OD.

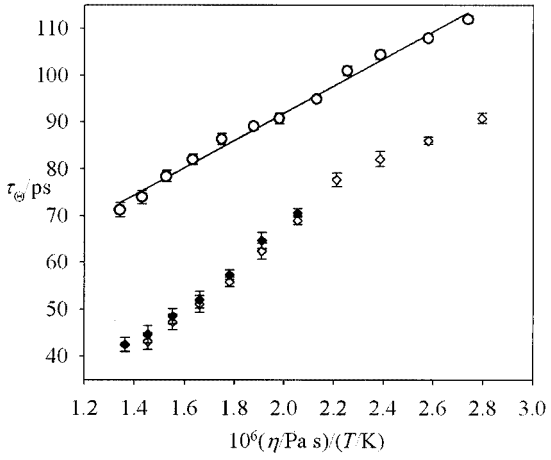

Figure 3. The reorientation correlation times, τ_θ, calculated from the fit of the spectra of Cu(L-Me_2Leu)$_2$ (white circles) and Cu(L-Me_2Val)$_2$ (white squares − fitted with the parameters required for the good fit of the spectra at the lower temperatures; black squares − fitted with parameters required for the good fit of the spectra at higher temperatures (see Table 1) dissolved in CD_3OD as a function of η/T

The linear dependence of τ_θ on η/T obtained with the parameters (Table 1) of the fitted spectra of Cu(L-Me_2Leu)$_2$ suggests an unchanged effective volume of the complex over the whole temperature range studied and indicates the presence of one conformation of the complex in the whole temperature interval examined. On the other hand, τ_θ calculated from the fit of the spectra of Cu(L-Me_2Val)$_2$ dissolved in CD_3OD, exhibited no linear dependence on η/T. An increase of a_o concomitant with a decrease of g_o which was determined from the spectra above 296 K (Table 1) is reflected in the function $\tau_\theta = f(\eta/T)$ as a deviation from linearity. Above 296 K increased a_o values (Table 1) suggest a higher covalent character of the Cu−ligand bonds whereas the nonlinearity of the function $\tau_\theta = f(\eta/T)$ suggests a changed solvated volume of the complex, indicating a conformation change.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

When the two complexes were dissolved in $CDCl_3$ (Figure 4), a linear function of τ_θ against η/T was obtained and the spectra were fitted well with a single value for a_o and a single value for g_o (Table 1) in the whole range of temperatures examined. It can be seen that the values of τ_θ, calculated from the spectra of the complexes, as well as the slopes of the straight lines, $\tau_\theta = f[V_{eff}(\eta/T)]$, ($V_{eff}$ denotes the effective volume of the solvated complexes), are different. This result suggests that the motion of Cu(L-Me_2Leu)$_2$ is slower than that of Cu(L-Me_2Val)$_2$.

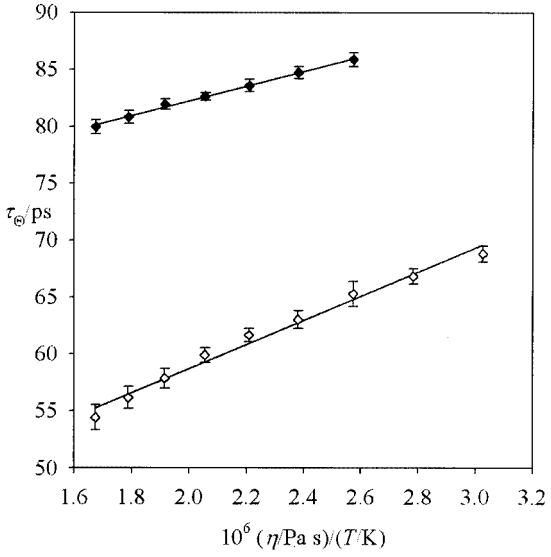

Figure 4. τ_θ calculated from the fit of the spectra of Cu(L-Me_2Val)$_2$ (white squares) and Cu(L-Me_2Leu)$_2$ (black squares) dissolved in $CDCl_3$ as a function of η/T using the parameters shown in Table 1

Cu(L-Me_2Val)$_2$ dissolved in CH_3CH_2OH exhibited a linear dependence of τ_θ on η/T (Figure 5), although an increase of a_o and a decrease of g_o were determined above 308 K. The linear dependence of τ_θ on η/T indicates that the solvated volume of the complex did not change above 308 K, although there was a change in the copper(II) electronic state resulting from an increase in the covalent character of the copper−ligand bonds.

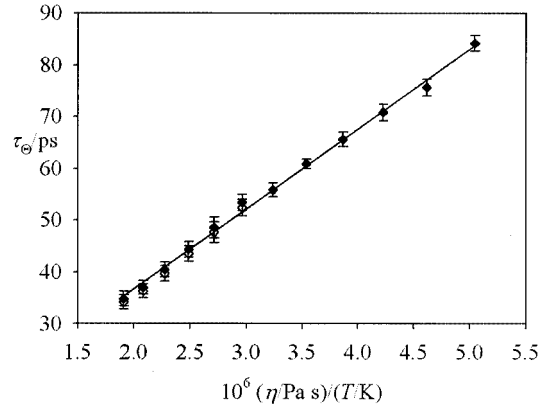

Figure 5. τ_θ calculated from the fit of the spectra of Cu(L-Me_2Val)$_2$ dissolved in CH_3CH_2OH as a function of η/T (black squares fit with g_o = 2.128, a_o = 8.4 mT; white squares fit with g_o = 2.125, a_o = 8.6 mT)

B) Conformational Analysis

The conformational analysis of Cu(L-Me_2Val)$_2$ and Cu(L-Me_2Leu)$_2$ were performed with the MM force field FFW[26,29] developed for anhydrous and hydrated copper(II) amino acid complexes.

From stereochemical considerations it can be proposed that each chelate ring of Cu(L-Me_2Val)$_2$ can have 6 conformations (3 conformers with the valine side-chains in the axial position and 3 conformers with them in the equatorial position with respect to the chelate ring planes) and that each chelate ring of Cu(L-Me_2Leu)$_2$ can have 18 conformations (9 conformers with the C^β-axial and 9 conformers with the C^β-equatorial positions). The results of in vacuo strain energy minimisations for the two systems, Cu(L-Me_2Val)$_2$ and Cu(L-Me_2Leu)$_2$, are listed in Table 2. Figure 6 shows their most stable conformations.

The conformational analysis was extended to the conformers interacting with water molecules (Table 2) in order to study the influence of amino acid side-chains on water binding in the first copper(II) coordination sphere. Due to the low number of water molecules dissolved in the studied organic solvents we limited the number of water molecules surrounding the copper complexes to 4. The initial atomic positions used for water oxygens and water hydrogens were the same for all the studied conformers.

The calculated equilibrium structures suggest that four water molecules may occur around the copper(II) amino acid complexes (Figures 7 and 8). It may be expected that FFW overestimates the distance between Cu and the axial water oxygen (denoted as O_w in Figures 7 and 8) by an average of 0.2 Å.[26] We suggest that every axially placed O_w at a distance longer than 3 Å cannot be considered as an apically bound water molecule.[37] The apically bound water molecule can be defined as the one that may influence the electronic structure of the copper(II), i.e. cause changes in the EPR spectral parameters.

The a6−a6 minimum of Cu(L-Me_2Val)$_2$ (Figure 6, Table 2) corresponds to the conformation of the anhydrous complex determined by the X-ray diffraction experiment.[16] The a6−e2 axial-equatorial minimum in the same compound (Figure 7) corresponds to the experimental crystalline conformation of the corresponding aqua-copper(II) complex.[18] The crystal structure of Cu(L-Me_2Leu)$_2$ has not yet been determined.

The conformers having the lowest strain conformational energies for the anhydrous complexes (Figure 6) also remained the most stable when four water molecules were present in the systems (Table 2). They have C^β in their axial positions as may be seen in Figures 6−8. Among the conformers with the same C^β-axial conformations in both chelate rings, only one conformer of Cu(L-Me_2Val)$_2$ (a5−a5, Table 2) can bind the apical water molecule in the first copper(II) coordination sphere when surrounded with more than two water molecules. In all other axial-axial conformers presented in Table 2, the methyl groups on the nitrogen atoms, as well as the close van der Waals contacts between two valine side-chains, prevent the apical water molecule

[a] Torsion angles φ*1*, φ*2* and φ*3* correspond to O−Cu−N−C_{methyl}, $C^\alpha-C^\beta-N-$Cu and $C^\gamma-C^\beta-C^\alpha$-N (see Figure 6). Torsion angle φ*4* corresponds to the angle $C^\delta-C^\gamma-C^\beta-C^\alpha$ for $Cu(L\text{-}Me_2Leu)_2$ (see Figure 6). Torsion angles are in degrees. [b] Strain energies are in kcal mol^{-1}. Zero point energies: −4844.11 kcal mol^{-1} for $Cu(L\text{-}Me_2Val)_2$; −5337.15 kcal mol^{-1} for $Cu(L\text{-}Me_2Val)_2{\cdot}4H_2O$; −5628.95 kcal mol^{-1} for $Cu(L\text{-}Me_2Leu)_2$ and −6124.77 kcal mol^{-1} for $Cu(L\text{-}Me_2Leu)_2{\cdot}4H_2O$.

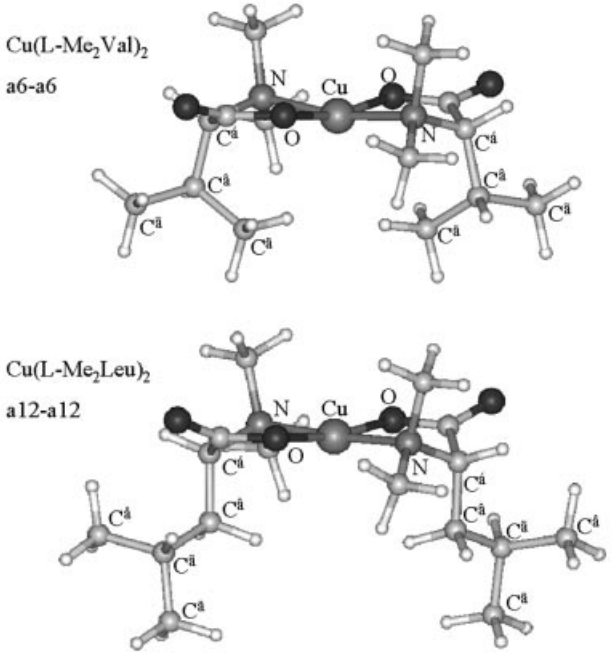

Figure 6. The most stable conformations of the two copper(II) complexes with L-*N*,*N*-dimethylated amino acids calculated with the FFW force field

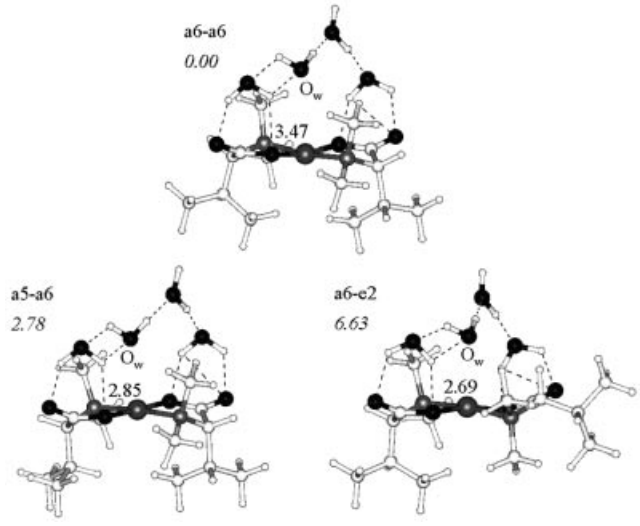

Figure 7. Three minima of $Cu(L\text{-}Me_2Val)_2{\cdot}4H_2O$ with the lowest conformation energy; the values in italics are energy values expressed in kcal mol^{-1}; the values in Å are copper(II) to O_w distances

from approaching Cu^{II} (e.g. see a6−a6 in Figure 7). However, the conformers with C^β-equatorial in both chelate rings and in the mixed axial-equatorial positions do not

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hinder the water molecule from closely approaching the copper(II) (Figure 7).

On the other hand, almost all the minima of Cu(L-Me_2-Leu)$_2$, including the most stable conformer a12-a12, can apically bind a water molecule to the axial position in the copper(II) coordination sphere when surrounded with more than two water molecules (Figure 8).

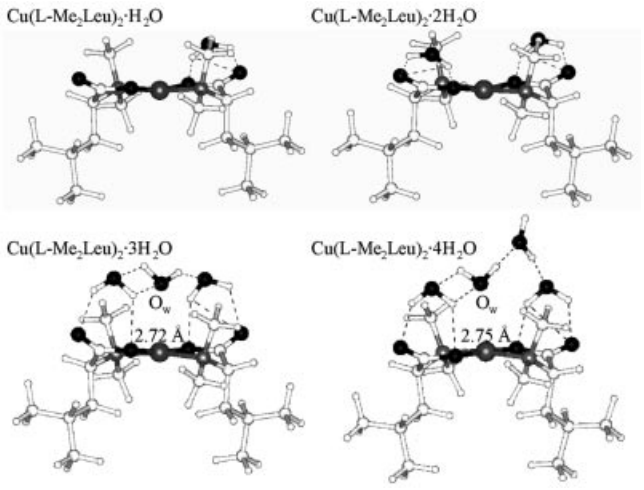

Figure 8. The a12−a12 conformer of Cu(L-Me_2Leu)$_2$ interacting with up to four water molecules; the values in Å are copper(II) to O_w distances.

According to the results obtained with the FFW force field, the interactions with four water molecules increase the energy differences between the most stable conformer and other conformations of Cu(L-Me_2Leu)$_2$, resulting in the a12−a12 as well as the11−a11 minima being even more stable than in the anhydrous system (Table 2). However, when four water molecules are present in Cu(L-Me_2Val)$_2$, the energy difference between the lowest energy minimum a6−a6 and the first above it becomes lower (Table 2 and Figure 7). These changes in the strain energy distributions among the conformers of the two theoretically examined systems, i.e. between the anhydrous system and the system containing four water molecules (Table 2), may suggest an even smaller energy difference between the hydrated conformers and the a6−a6 conformer of Cu(L-Me_2Val)$_2$ in more complicated system such as in real hydrogen-bond making solutions. With increased molecular vibrations at higher temperatures, the system may attain enough energy for the transformation from an equatorial-equatorial or an axial-equatorial to the axial-axial conformer, followed by the release of the water molecule from the copper(II) first coordination sphere. Such a conformer a12−a12 (the most stable for the two studied systems presented in Table 2, Figures 6 and 8) can easily accept and release the water molecule to and from the copper(II) coordination polyhedron.

Conclusions

The results of the EPR analysis of the temperature dependence of the Brownian motion point to different behaviour for Cu(L-Me_2Leu)$_2$ and Cu(L-Me_2Val)$_2$ dissolved in the hydrogen-bond making solvents CD_3OD and CH_3CH_2OH. This cannot be due to different temperature dependencies of the ligand field in the two complexes because both complexes have the same copper(II) coordination sphere.

For Cu(L-Me_2Leu)$_2$, a satisfactory match between the experimental and theoretical fits of the spectra with the EPR parameters characteristic for the chosen solution (Figure 1, Table 1) and the linear function $\tau_\theta = f(\eta/T)$ were obtained, suggesting an unchanged effective volume of the complex, i.e. an unchanged conformation of the side-chains.

For Cu(L-Me_2Val)$_2$, the unchanged effective volume was determined only from the spectra of the complex dissolved in $CDCl_3$. The non-linear dependence of τ_θ on (η/T) for Cu(L-Me_2Val)$_2$ in CD_3OD combined with changed a_o and g_o values above 296 K in CD_3OD, suggests a change in the effective volume of Cu(L-Me_2Val)$_2$ and consequently a different conformation. Different EPR parameters a_o and g_o observed for Cu(L-Me_2Val)$_2$ (Table 1) in the hydrogen-bond making solvents above a solvent dependent temperature reflect changes in the bonding and/or solvation of the complex. A decrease in g_o with a concomitant increase in a_o in the EPR spectra suggests more covalent character of the metal−ligand bonds in the equatorial plane of this complex. The isotropic hyperfine splitting constant a_o and the superhyperfine coupling constant a_N are highly sensitive to the geometric distortions. The changes in a_o and a_N determined from the spectra of Cu(L-Me_2Val)$_2$ on going from $CDCl_3$ to CH_3CH_2OH indicate pronounced flexibility of the copper(II) coordination polyhedron in this complex. This is in accordance with the findings[38] that with intramolecular and/or intermolecular strain the distortion of the copper(II) polyhedron from planarity was more energetically favourable than the changes in the valinato chelate rings' conformations. Thus, the non-linear dependence of τ_θ on (η/T) for Cu(L-Me_2Val)$_2$ in CD_3OD combined with a change in a_o suggests not only a change in the effective volume of Cu(L-Me_2Val)$_2$ above 296 K and consequently a different conformation, but also a differently distorted copper(II) coordination polyhedron.

The results of the theoretical conformational analysis offer an explanation for the differing EPR behaviour of Cu(L-Me_2Val)$_2$ and Cu(L-Me_2Leu)$_2$. The different behaviour may come from the lack of a bulky CH_3 group at C^β in Cu(L-Me_2Leu)$_2$ (Figure 6) compared with in Cu(L-Me_2Val)$_2$. The lack of the CH_3 group consequently allows the possibility of closer intramolecular contacts between aliphatic leucine side-chains in the two chelate rings upon water binding to the first copper(II) coordination sphere (Figure 8). That is, the most stable conformer of Cu(L-Me_2Val)$_2$ (a6−a6 in Figure 7) cannot accept a water molecule in the copper(II) first coordination sphere because of intramolecular steric effects. For Cu(L-Me_2Val)$_2$, we may conclude that the fifth copper(II) coordination site can be occupied only for some con-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

formations and that the conformational changes (most probably triggered by solute-solvent interactions) can open and close the copper(II) accessibility to the water molecule. Conversely, Cu(L-Me_2Leu)$_2$ can bind and release the apical water molecule without the need for the conformational changes.

Experimental Section

Methods

A) EPR Spectroscopy: The EPR spectra of bis(amino acidato)copper(II) complexes are characterized by four resonances arising from the hyperfine coupling between an electron spin (S = 1/2) of the copper(II) (configuration $3d^9$) and the nuclear spin of the copper (I_{Cu} = 3/2), determined by the hyperfine coupling tensor $\hat{A}$ and the g-tensor related to the spin-orbit coupling. In solution, the average of the diagonal tensor values g_o and a_o is observed. Further splitting of the hyperfine lines may reveal the coupling of the copper electron spin with the nuclear spin of two nitrogens (I_N = 1) bonded to the copper(II)[30,31] resulting in the superhyperfine structures of the spectra (see Figure 1).

In this study we simulated the experimental EPR spectra of the complexes with the WIN-EPR Simfonia software (BRUKER) and the fast motion approximation. τ_θ was calculated from the linewidth (ΔB/mT) of the spectra which is dependent on the nuclear magnetic moment m_{Cu}:

$$\Delta B(m_{Cu}) = a + bm_{Cu} + cm_{Cu}^2$$

where a, b, c, are parameters for the lineshape fit.

The calculations of the reorientation correlation time, τ_θ, describing McConnell's tumbling mechanism[39] were performed following the procedure given elsewhere.[21]

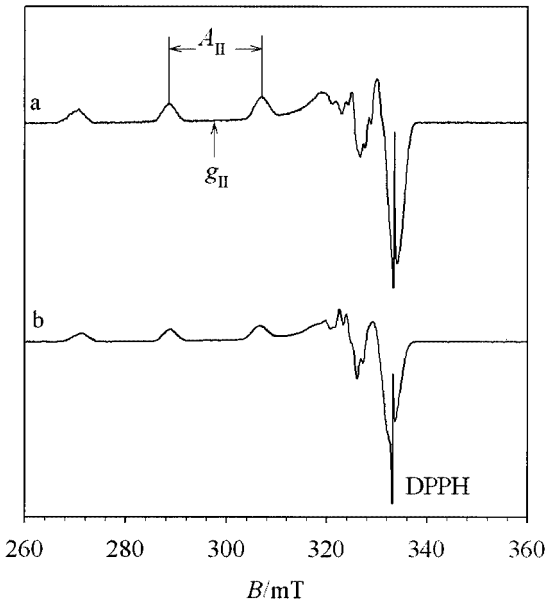

Figure 9. EPR spectra of (a) Cu(L-Me_2Val)$_2$ and (b) Cu(L-Me_2Leu)$_2$, dissolved in CD_3OD and recorded at 105 K (see Table 1)

The reorientation correlation time, τ_θ, of the complex describes the Brownian motion in solution and may be expressed as $\tau_\theta = (1/k)\, V_{eff}\, (\eta/T)\, \kappa$, where V_{eff} is the effective volume of the complex, η/T the viscosity over temperature, k is the Boltzmann constant and κ is the anisotropic interaction parameter, the second rank tensor related to EPR spectral parameters.[40] If the complex retains one conformation in the examined temperature interval, τ_θ will be a linear function of η/T with the coefficient of linearity proportional to the effective volume of the dissolved complex.[22]

The parameters $A_\parallel$ and $g_\parallel$ required for the calculation of τ_θ were determined from the EPR spectra of the glassy state recorded at 105 K (Figure 9). The spectra indicate only one type of the copper(II) complex in solution with axial symmetry ($g_\parallel > g_\perp$) of the ligand field with the $d_{x^2-y^2}$ ground state.

EPR spectra were measured using a Varian E-109 spectrometer (X-band) equipped with a BRUKER variable temperature control unit. The g-factor was measured relative to diphenyl-picryl-hydrazil (DPPH) as an external marker (g_{DPPH} = 2.0036 ± 0.0003). The temperature dependence of the viscosity η of the solvents was determined from published tables.[41]

B) Molecular Mechanics Calculations: The strain energy minimisations were performed with the CFF program for conformational analysis[42–44] with the FFW force field[26,29] suited for modelling anhydrous and hydrated copper(II) amino acid complexes with both a *trans*- and a *cis*-CuN_2O_2 coordination polyhedron. A detailed description of the potential energy functions used, the FFW's development as well as a discussion on the efficacy of the force field in simulation and prediction of experimental crystal and molecular structures and quantum-chemically calculated vacuum structures of a series of anhydrous and hydrated copper(II) amino acid complexes can be found in our earlier paper.[26] FFW correctly predicted the most stable conformations of the copper(II) amino acid complexes in vacuo and reproduced well the hydrogen-bonding pattern between water molecules and amino acid atoms.[26] It also simulates the result obtained from quantum chemical calculations for aqua-copper(II) glycinato systems[26,45] in which the formation of hydrogen bonds between water molecules and amino and carboxylato groups competes with axial Cu···OH_2 interactions.

Materials:

The ligands L-*N*,*N*-dimethylvaline and L-*N*,*N*-dimethylleucine were prepared using a modified method of Bowman and Stroud[46] (i.e. by methylation of the amino acids through condensation with formaldehyde, followed by a catalytic hydrogenation in an ethanol/water solution at room temperature). The corresponding copper(II) complexes were prepared according to the modified procedure of Nash and Schaefer[47] (i.e. by means of the reaction of copper(II) acetate monohydrate with the sodium salt of the ligand in dichloroethane solution to obtain Cu(L-Me_2Val)$_2$, and in dry dichloromethane to obtain Cu(L-Me_2Leu)$_2$). The C, N and Cu elemental analyses confirmed the compositions of the ligands and complexes.

Concentrations of approximately 0.1 mmol dm^{-3} of the copper(II) complexes (in CH_2CH_3OH, $CDCl_3$, CD_3OD) were used. Organic solvents were dried over Type 4 Linde Na–Al-silicate molecular sieves with a pore radius of 4 Å (SERVA, Heidelberg, Germany).

Acknowledgments

We would like to thank Dr. N. Paulic for the synthesis of the L-*N*,*N*-methylated amino acids and the copper(II) complexes. Financial support from the Ministry of Science and Technology of the Republic of Croatia, Grants 0022017 and 0098040, is acknowledged.

New *N*,*N*-Diisopropylcarbamato Complexes of Ruthenium(II) as Catalytic Precursors for Olefin Hydrogenation

Daniela Belli Dell'Amico,*[a] Fausto Calderazzo,[a] Ulli Englert,[b] Luca Labella,[a] Fabio Marchetti,[a] and Monica Specos[a]

Keywords: *N*,*N*-Dialkylcarbamato complexes / Ruthenium / Hydrogenation

During the synthesis of $[Ru(O_2CN\mathit{i}Pr_2)_2(PPh_3)_2]$ (**1**), the $[RuCl_2(PPh_3)_3]/NH\mathit{i}Pr_2/CO_2$ system produces the intermediates $[NH_2\mathit{i}Pr_2][Ru_2Cl_2(\mu\text{-}Cl)_3(PPh_3)_4]$ (**2**) and $[RuCl(O_2CN\mathit{i}Pr_2)(PPh_3)_3]$ (**3**) which have been isolated and fully characterised. Compound **2** contains the dinuclear anionic triply chloride-bridged ruthenium(II) species. Compound **3** is mononuclear, the octahedral ruthenium centre being coordinated to the bidentate carbamato ligand. The reactions of compounds **1** and **3** with dihydrogen have been studied at room temperature and atmospheric pressure with respect to their catalytic hydrogenation of 1-octene.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Olefin hydrogenation using ruthenium(II) complexes has been studied extensively.[1] Some precursors containing carboxylato ligands have been shown to be catalytically active under homogeneous conditions.[2] *N*,*N*-Dialkylcarbamato complexes of ruthenium(II) with tertiary phosphanes as ancillary ligands have been prepared in our laboratories[3] and elsewhere.[4] The *N*,*N*-dialkylcarbamato group, R_2NCO_2, is geometrically similar to the carboxylato ligand and is a good leaving group, prompt CO_2 evolution being observed in the presence of proton-active substances.[5] Moreover, this ligand may undergo a change of hapticity from bidentate to monodentate, thus allowing coordination of a further ligand. This observation has been established for the reaction of **1** with CO, the two bidentate carbamato groups being sequentially converted into monodentate groups by addition of carbon monoxide yielding $[Ru(O_2CN\mathit{i}Pr_2)_2(CO)(PPh_3)_2]$ and $[Ru(O_2CN\mathit{i}Pr_2)_2(CO)_2(PPh_3)_2]$.[3a] This is reminiscent of earlier data on the hexacoordinate ruthenium(II) cation $[Ru(O_2CNMe_2)(PMe_2Ph)_4]^+$ which is converted into $[Ru(CO)(O_2CNMe_2)(PMe_2Ph)_4]^+$. Both were isolated as their hexafluorophosphate derivatives.[4a,4b] Such coordination flexibility is an important prerequisite for catalysis.

In relation to the use of carboxylato and carbamato derivatives of ruthenium(II) in catalysis, $[Ru(O_2CMe)_2(PPh_3)_2]$ was reported to assist olefin hydrogenation in the presence of strong protic acids such as CF_3SO_3H,[2a] with $[Ru(PPh_3)_n]^{2+}$ being postulated as the catalytically active species. Moreover, it is worth noting that in the ruthenium-catalysed conversion of $CO_2/HNMe_2/H_2$ to $HCONMe_2$ at 125 °C, the intermediacy of a (carbamato)ruthenium complex was excluded on the basis of deuteration studies.[6a] The possible role played by the *N*,*N*-dialkylcarbamato group in this process urged us to study the behaviour of this ligand in ruthenium-promoted catalytic hydrogenation. This paper reports some new data regarding the reaction of $[RuCl_2(PPh_3)_3]$, a pentacoordinate mononuclear ruthenium complex,[6b] with the $NH\mathit{i}Pr_2/CO_2$ system leading to new derivatives of ruthenium(II). Moreover, results are presented on the reaction of the (carbamato)ruthenium(II) complexes with dihydrogen, some of them acting as catalyst precursors for olefin hydrogenation.

Results and Discussion

Synthesis and Characterisation of the Ruthenium Complexes

The reaction of $[RuCl_2(PPh_3)_3]$ with $NH\mathit{i}Pr_2$ and CO_2 to afford **1** is rather slow, the conversion of 4 g of the precursor requiring several days at room temperature in the presence of a large excess of the amine [Equation (1)].[3a]

$$[RuCl_2(PPh_3)_3] + 4\ NH\mathit{i}Pr_2 + 2\ CO_2 \longrightarrow \underset{\mathbf{1}}{[Ru(O_2CN\mathit{i}Pr_2)_2(PPh_3)_2]} + 2\ [NH_2\mathit{i}Pr_2]Cl + PPh_3 \quad (1)$$

A more appropriate synthesis of **1** has now been found (vide infra) and this required further work on the reactivity of $[RuCl_2(PPh_3)_3]$. In spite of its low solubility in toluene, $[RuCl_2(PPh_3)_3]$ rapidly dissolves in the presence of $NHiPr_2$ and CO_2. We have now found that two intermediates, **2** and **3**, can be intercepted, presumably formed according to Equation (2).

$$3\,[RuCl_2(PPh_3)_3] + 2\,NHiPr_2 + CO_2 \longrightarrow \underset{\mathbf{2}}{[NH_2iPr_2][Ru_2Cl_5(PPh_3)_4]} + \underset{\mathbf{3}}{[RuCl(O_2CNiPr_2)(PPh_3)_3]} + 2\,PPh_3 \quad (2)$$

It is reasonable to assume that the relatively slow substitution of one chloro ligand by the carbamate anion $[O_2CNiPr_2]^-$, formed in situ from carbon dioxide and the amine, yields **3** and $[NH_2iPr_2]Cl$, the latter being promptly sequestered by the unchanged starting material to afford **2**. The formation of **2** in a 69% yield has been established independently by treating $[RuCl_2(PPh_3)_3]$ with $[NH_2iPr_2]Cl$ in toluene in a molar ratio of 2 [Equation (3)].

$$2\,[RuCl_2(PPh_3)_3] + [NH_2iPr_2]Cl \longrightarrow \underset{\mathbf{2}}{[NH_2iPr_2][Ru_2Cl_5(PPh_3)_4]} + 2\,PPh_3 \quad (3)$$

The successful replacement of the phosphane ligand by chloride in this reaction can be easily understood since the starting compound $[RuCl_2(PPh_3)_3]$, which is mononuclear with a pentacoordinate ruthenium atom, is converted into the anionic dinuclear product containing a hexacoordinate ruthenium atom (vide infra).

The salt-like product **2** has been found to be a convenient starting material for the synthesis of **1**. Since it contains two phosphane ligands per ruthenium atom, the poorly soluble phosphane is not released and **1** is obtained pure, in a satisfactory yield of about 55%, without contamination by **3** [Equation (4)].

$$\underset{\mathbf{2}}{[H_2NiPr_2][Ru_2Cl_5(PPh_3)_4]} + 8\,NHiPr_2 + 4\,CO_2 \longrightarrow 2\,\underset{\mathbf{1}}{[Ru(O_2CNiPr_2)_2(PPh_3)_2]} + 5\,[NH_2iPr_2]Cl \quad (4)$$

The ^{31}P NMR spectrum of **2** in C_6D_6 shows a singlet at $\delta = 46.8$ ppm. This suggests a symmetrical arrangement of the ligands which was subsequently confirmed by X-ray diffraction methods.

The anion contains two hexacoordinate ruthenium centres bridged by three chloro ligands, the coordination of each ruthenium atom being completed by two phosphane ligands and one terminal chloro ligand (Figure 1). In addition, hydrogen interactions are present between the cation and the terminal chloro ligands of the anion, the N(1)···Cl(4) and N(1)···Cl(5) distances being 3.29 and 3.23 Å, respectively. Similar interactions have already been reported in $[Et_2NH_2][Ru_2Cl_2(\mu\text{-}Cl)_3(DPB)_2]$ [DPB = 1,2-bis(diphenylphosphanyl)benzene],[7a] $[tBu_2MePH][Ru_2Cl_2(\mu\text{-}Cl)_3(CO)_2(PtBu_2Me)_2]$[7b] and in $[Et_2NH_2][Ru_2Cl_2(\mu\text{-}Cl)_3\{(R)\text{-}p\text{-MeO-BINAP})\}_2]$ [*p*-MeO-BINAP = 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl].[8a] The formation of ion pairs is presumably responsible for the high solubility of these species in aromatic solvents. Crystal packing is created by the ion pairs where the two partners are tightly linked, the shortest distance separating the centroids of neighbouring pairs being 11.8 Å.

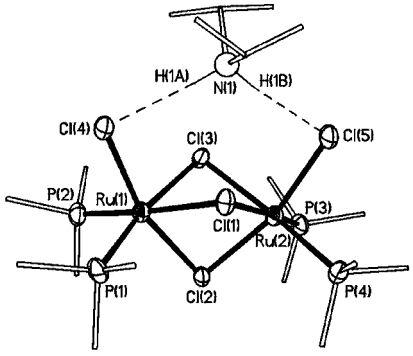

Figure 1. View of the molecular structure of the ion pair $[iPr_2NH_2][Ru_2Cl_2(\mu\text{-}Cl)_3(PPh_3)_4]$ (**2**) with thermal ellipsoids at the 30% probability level; the phenyl groups of triphenylphosphane and the isopropyl hydrogen atoms have been omitted for clarity

Table 1. Bond lengths [Å] and angles [°] around the Ru atoms in **2**

Ru(1)−Cl(1)	2.466(7)	Ru(2)−Cl(1)	2.437(6)

Cl(4)−Ru(1)−Cl(2)	162.5(2)	P(3)−Ru(2)−Cl(1)	169.0(3)
P(1)−Ru(1)−Cl(1)	90.3(2)	Cl(5)−Ru(2)−Cl(1)	89.4(2)
P(2)−Ru(1)−Cl(1)	170.7(3)	Cl(2)−Ru(2)−Cl(1)	79.7(2)
Cl(4)−Ru(1)−Cl(1)	88.2(2)	P(4)−Ru(2)−Cl(3)	167.5(2)
Cl(2)−Ru(1)−Cl(1)	78.6(2)	P(3)−Ru(2)−Cl(3)	92.2(2)
P(1)−Ru(1)−Cl(3)	167.5(2)	Cl(5)−Ru(2)−Cl(3)	88.9(2)
P(2)−Ru(1)−Cl(3)	93.2(2)	Cl(2)−Ru(2)−Cl(3)	77.2(2)
Cl(4)−Ru(1)−Cl(3)	89.1(2)	Cl(1)−Ru(2)−Cl(3)	78.0(2)
Cl(2)−Ru(1)−Cl(3)	76.9(2)	Ru(2)−Cl(1)−Ru(1)	86.8(2)
Cl(1)−Ru(1)−Cl(3)	77.6(2)	Ru(2)−Cl(2)−Ru(1)	88.0(2)
P(4)−Ru(2)−P(3)	100.1(3)	Ru(1)−Cl(3)−Ru(2)	85.5(2)
P(4)−Ru(2)−Cl(5)	91.6(3)		

As can be seen in Table 1, the coordination environment around the ruthenium centre is pseudo-octahedral. The Ru(1)···Ru(2) distance is 3.370 Å, a value beyond the maximum generally accepted for a bonding interaction. A significant difference is found between the ruthenium−chlorine distances *trans* to the phosphane ligands (mean value 2.467 Å) and those *trans* to the terminal chloro ligands (mean value 2.425 Å).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

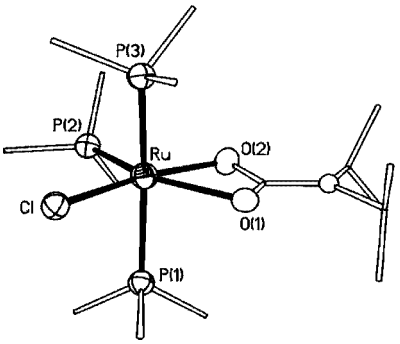

Figure 2. View of the molecular structure of [RuCl(O_2CN*i*Pr_2)(PPh_3)$_3$] (**3**) with thermal ellipsoids at the 30% probability level; the phenyl groups of the triphenylphosphane and isopropyl hydrogen atoms have been omitted for clarity

The presence of two face-bridged octahedra with three bridging chloro ligands is common in ruthenium chemistry. On the other hand, a few examples exist in the literature of *anionic* species containing tertiary phosphanes as ligands, namely those mentioned above as well as [Et_2NH_2][Ru_2Cl_2(μ-Cl)$_3$(dppb)$_2$] [dppb = 1,4-bis(diphenylphosphanyl)butane].[8b] A rational synthesis of this class of anionic species was reported for [H_2NR_2][(Ru_2Cl_2(μ-Cl)$_3$(dppb)$_2$][8b] involving the addition of [R_2NH_2]Cl to the pentacoordinate [$RuCl_2$(dppb)(PPh_3)]. Closely connected are the results by Caulton and co-workers[7b] on the reaction of $RuX_2(CO)L_2$ with M^IX (M^I = alkali metal; X = halide) which affords $M^I[Ru_2X_5(CO)_2L_2]$. Reactions which involve elimination of a ligand L from the metal coordination sphere, followed by dimerization of the metal-containing fragments through bridging halo ligands, can be explained by the need torelieve steric congestion and to obtain the 18-electron configuration in the triply bridged anion.

To obtain pure **3**, it is necessary to use an excess of the amine (amine/Ru molar ratio ca. 4) in a relatively dilute toluene solution [Equation (5)]. In fact, with a *i*Pr_2NH/[$RuCl_2$(PPh_3)$_3$] molar ratio of 2, the reaction according to Equation (2) still operates and a mixture of **2** and **3** was found even after long reaction times together with unchanged starting material. It is important to note that contamination of **3** with **1** does not occur since complete removal of the chloro ligands from the ruthenium atom requires a large excess of the amine [Equation (1)]. The reaction of **3** towards the amine/(carbon dioxide) system is slow [Equation (6)].

$$[RuCl_2(PPh_3)_3] + 2\ NHiPr_2 + CO_2 \rightleftharpoons \underset{\mathbf{3}}{[RuCl(O_2CNiPr_2)(PPh_3)_3]} + [NHiPr_2]Cl \quad (5)$$

$$\underset{\mathbf{3}}{[RuCl(O_2CNiPr_2)(PPh_3)_3]} + 2\ NHiPr_2 + CO_2 \longrightarrow \underset{\mathbf{1}}{[Ru(O_2CNiPr_2)_2(PPh_3)_2]} + [NHiPr_2]Cl + PPh_3 \quad (6)$$

Moreover, the formation of **1** would be accompanied by PPh_3 elimination which is clearly counteracted by the presence of free triphenylphosphane. Thus, when good yields of pure **3** are required, addition of some free triphenylphosphane to the reaction mixture totally prevents the formation of **1**. A similar situation has already been encountered with [RuCl(O_2CNR_2)(η^6-cymene)] (R = Et, *i*Pr) which does not yield [Ru(O_2CNR_2)$_2$(η^6-cymene)] even under severe conditions of temperature and pressure and with elevated amine/Ru molar ratios.[3c]

The ruthenium complex **3**, recrystallized from a toluene/heptane mixture, has been studied by single-crystal X-ray diffraction (Figure 2, Table 2). The compound has a mononuclear structure with the metal centre in a distorted octahedral geometry. The coordination sites are occupied by a chloro ligand, an asymmetric bidentate carbamato ligand and three phosphane ligands in *mer* positions.

Table 2. Bond lengths [Å] and angles [°] around the Ru atom in **3**

Ru−Cl	2.415(6)	Ru−P(3)	2.419(7)
Ru−P(1)	2.375(7)	Ru−O(1)	2.27(2)
Ru−P(2)	2.271(6)	Ru−O(2)	2.12(2)
O(2)−Ru−P(2)	91.2(5)	O(1)−Ru−Cl	106.5(4)
O(1)−Ru−O(2)	60.0(6)	P(1)−Ru−Cl	81.8(2)
P(2)−Ru−O(1)	151.1(4)	O(2)−Ru−P(3)	98.9(5)
O(2)−Ru−P(1)	94.9(5)	P(2)−Ru−P(3)	98.2(2)
P(2)−Ru−P(1)	98.8(2)	O(1)−Ru−P(3)	89.5(5)
O(1)−Ru−P(1)	82.4(5)	P(1)−Ru−P(3)	157.9(2)
O(2)−Ru−Cl	166.5(5)	Cl−Ru−P(3)	80.9(2)
P(2)−Ru−Cl	102.2(2)		

Major distortions from ideal octahedral geometry are due to the small O(1)−Ru−O(2) angle of 60.0° and the P(1)−Ru−P(3) bond angle, involving the two *trans*-phosphane ligands, of 157.9°. The Ru−O(1) bond of 2.27 Å is longer than Ru−O(2) (2.12 Å), possibly due to O(1) being *trans* to P(2). The Ru−P(2) bond is significantly shorter than the other two distances, as found elsewhere for other *mer* complexes.[9a,9b] The easy displacement of one of the weakly bonded phosphane ligands leading to [*cis*-Ru(O_2CN*i*Pr_2)$_2$(PPh_3)$_2$] can therefore be easily understood.

Compound **3** was subjected to conventional spectroscopic investigations. The presence of bidentate carbamato ligands was confirmed by the absence of IR bands above 1600 cm^{-1}.[5b] The ^{31}P NMR solution spectrum of **3** at −40 °C shows the presence of free PPh_3 with a signal at δ = −4.2 ppm and two doublets at δ = 27.7 and 51.0 ppm (J = 68 Hz) as well as a triplet at δ = 46.5 ppm coupled with the doublet at δ = 50.1 ppm (J = 66 Hz). For comparison, [RuCl(O_2CMe)(PPh_3)$_3$][9c] shows signals at δ = 31.0 (t) and 50.5 (d) ppm. At room temperature the signals of **3** are broad. These results may be explained by assuming that equilibrium [Equation (7)] occurs in solution, the dinuclear species being responsible for the additional signals.

$$2\ \underset{\mathbf{3}}{[RuCl(O_2CNiPr_2)(PPh_3)_3]} \rightleftharpoons [Ru_2(\mu\text{-}Cl)_2(O_2CNiPr_2)_2(PPh_3)_4] + 2\ PPh_3 \quad (7)$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Similar to other examples in the literature,[10] the equilibrium is suppressed by addition of an excess of phosphane. In the dinuclear compound, each ruthenium atom is assumed to be hexacoordinate with two bridging chloro ligands, two phosphane ligands and a terminal bidentate carbamato ligand, the ruthenium(II) centre again reaching the 18-electron configuration.[10a] The rather simple NMR spectra of $[RuCl(O_2CMe)(PPh_3)_3]$[9c] suggest the absence of ligand dissociation.

Reactivity of the Ruthenium Complexes with Dihydrogen

Olefin complexation is believed to be the primary process in a catalytic hydrogenation cycle and a few olefin complexes of ruthenium(II) have been isolated and crystallographically characterised.[11–15] $RuHCl(PPh_3)_3$[16] was reported to be unreactive towards 1-hexene, 1-heptene and 2-octene, whereas an alkyl derivative was detected (NMR) with ethylene at 35 atm. We have observed that the carbamato complexes **1** and **3** do not react with 1-octene, although it was conceivable that they could add the olefin by converting the carbamato ligand from a bidentate to a monodentate ligating mode.

Compound **3** is converted by dihydrogen at room temperature and atmospheric pressure in toluene solution into both the soluble $[Ru(H)_2(H_2)(PPh_3)_3]$ and the poorly soluble violet $[RuHCl(PPh_3)_3]$. These compounds have been identified on the basis of their spectroscopic data and by comparison with data in the literature.[16,17] The intermediate $[RuH(O_2CN\mathit{i}Pr_2)(PPh_3)_3]$ (**4**) was also detected by ^{31}P NMR spectroscopy in solution (vide infra). These results are consistent with the reactions shown in Equations (8) and (9). On the other hand, direct hydrogenation of **3** may lead to $[RuH(Cl)(PPh_3)_3]$ [Equation (10)]. We have also established that when **3** is hydrogenated in the presence of an excess of $NH\mathit{i}Pr_2$, only the soluble $[Ru(H)_2(H_2)(PPh_3)_3]$ is formed, together with $[NH_2\mathit{i}Pr_2]Cl$. HCl elimination from $[RuH(Cl)(PPh_3)_3]$ is favoured under these conditions. It is interesting to note that $[Ru(H)_2(H_2)(PPh_3)_3]$[17,18] is prepared by the action of relatively strong reducing agents such as $NaBH_4$ or AlR_3 on $[RuCl_2(PPh_3)_3]$.[19a,19b] Our synthesis operates under mild conditions in aromatic hydrocarbons.

$$\underset{\mathbf{3}}{[RuCl(O_2CN\mathit{i}Pr_2)(PPh_3)_3]} + H_2 \longrightarrow \underset{\mathbf{4}}{[RuH(O_2CN\mathit{i}Pr_2)(PPh_3)_3]} + HCl \quad (8)$$

$$\underset{\mathbf{4}}{[RuH(O_2CN\mathit{i}Pr_2)(PPh_3)_3]} + 2\,H_2 \rightleftharpoons [Ru(H)_2(H_2)(PPh_3)_3] + CO_2 + NH\mathit{i}Pr_2 \quad (9)$$

$$\underset{\mathbf{3}}{[RuCl(O_2CN\mathit{i}Pr_2)(PPh_3)_3]} + H_2 \longrightarrow [RuH(Cl)(PPh_3)_3] + CO_2 + NH\mathit{i}Pr_2 \quad (10)$$

The carbamato derivative **1** does not react with dihydrogen at room temperature and atmospheric pressure. By gradually increasing the temperature, a reaction was found to occur at about 80 °C, accompanied by some decomposition, presumably due to the low thermal stability of the intermediate $[Ru(H)_2(H_2)_2(PPh_3)_2]$.[17a,17b] The experiment at 80 °C was therefore repeated in the presence of 1 equiv. of triphenylphosphane. Under these conditions, $[Ru(H)_2(H_2)(PPh_3)_3]$ was detected as the sole final ruthenium-containing compound [Equation (11)].

$$[Ru(O_2CN\mathit{i}Pr_2)_2(PPh_3)_2] + 3\,H_2 + PPh_3 \longrightarrow [Ru(H)_2(H_2)(PPh_3)_3] + 2\,CO_2 + 2\,NH\mathit{i}Pr_2 \quad (11)$$

Upon monitoring the reaction by ^{31}P NMR spectroscopy, signals attributable to the intermediate formation of $[RuH(O_2CN\mathit{i}Pr_2)(PPh_3)_3]$ [Equation (12)] were detected, namely a triplet at $\delta = 76.8$ ppm coupled with a doublet at $\delta = 41.7$ ppm ($J = 68$ Hz). These signals can be attributed to three phosphane ligands in a *mer* configuration if a comparison is made with [*mer*-$RuH(O_2CMe)(PPh_3)_3$], the latter showing resonances at $\delta = 77.6$ (t) and 43.8 (d) ppm.[10b]

$$\underset{\mathbf{1}}{[Ru(O_2CN\mathit{i}Pr_2)_2(PPh_3)_2]} + H_2 + PPh_3 \longrightarrow [RuH(O_2CN\mathit{i}Pr_2)(PPh_3)_3] + CO_2 + NH\mathit{i}Pr_2 \quad (12)$$

The ^1H NMR spectrum of $[RuH(O_2CN\mathit{i}Pr_2)(PPh_3)_3]$ shows a quadruplet at $\delta = -17.6$ ppm, equivalent to an overlapping doublet of triplets which would be expected for the coupling with the three phosphorus atoms. This is analogous with the quadruplet at $\delta = -19.8$ ppm exhibited by $[RuH(O_2CMe)(PPh_3)_3]$.[1d] A possible structure for $[RuH(O_2CN\mathit{i}Pr_2)(PPh_3)_3]$, similar to that of **3** with three *mer*-phosphane ligands, is consistent with the observed spectrum (Figure 2).

The reaction according to Equation (9) is reversible: in toluene, $[Ru(H)_2(H_2)(PPh_3)_3]$ rapidly reverts to $[RuH(O_2CN\mathit{i}Pr_2)(PPh_3)_3]$ in the presence of $\mathit{i}Pr_2NH/CO_2$ (amine/ruthenium molar ratio ca. 8) which is the only species present in solution after 1 h. By adding a large excess of amine, $[Ru(O_2CN\mathit{i}Pr_2)_2(PPh_3)_2]$ was obtained after one week.

Catalysis

All ruthenium derivatives reported in this paper have been tested as potential catalysts for the hydrogenation of 1-octene in toluene at room temperature, with activity being shown by **1** and **3**.

Once it was established that **1** does not react at room temperature and atmospheric pressure either with 1-octene or with H_2, hydrogenation of 1-octene was observed using $10^{-2}/10^{-3}$ M solutions of **1**, as evidenced by both gas chromatography, ^1H NMR spectroscopy and gas-volumetric measurements. Immediately after the catalyst precursor comes into contact with the reaction mixture, olefin hydrogenation occurs with no induction time being observed. The initial rate was found to correspond to approximately 300 mmol·L^{-1} h^{-1}, the olefin/ruthenium molar ratio being 28 and the initial olefin concentration being 2.6×10^{-1} M. After normalization with respect to the concentration of both the catalyst precursor and the olefin and to the H_2

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

partial pressure, the initial reaction rate (r_i), was calculated to be 163 mol·L^{-1} h^{-1}. No other ruthenium complexes other than the starting material were detected in solution by NMR spectroscopy after hydrogenation. More than 90% of **1** remained unchanged.[19c] It is reasonable to assume that in the course of the process, vacant sites for olefin or hydrogen coordination are made available on **1** by a haptic-ity change of the carbamato ligand from bidentate to monodentate.

Hydrogenation of 1-octene was also studied in the presence of **3** as a catalytic precursor. After about 6 h in toluene at room temperature, complete hydrogenation was established as indicated by gas chromatography and ruthenium was recovered as $[RuHCl(PPh_3)_3]$. No $[RuH_2(H_2)(PPh_3)_3]$ was present in the solution and gas-volumetric measurements showed that 89% of the olefin was hydrogenated in about 3 h.

In contrast to the earlier report on the use of the anionic complex $[Ru_2Cl_2(\mu\text{-}Cl)_3\{(R)\text{-}p\text{-MeO-BINAP})\}_2]^-$ [8a] in the asymmetric hydrogenation of olefins, $[iPr_2NH_2][Ru_2Cl_5(PPh_3)_4]$ was found to be inactive for the hydrogenation of 1-octene, the latter being slowly converted into (*E*)-4-octene. Similarly, in an attempted hydrogenation of 1-octene, the carbonyl complex $[Ru(CO)(O_2CNiPr_2)_2(PPh_3)_2]$ gave only a slow olefin isomerization.

Conclusions

In the reaction of $[RuCl_2(PPh_3)_3]$ with iPr_2NH and CO_2, optimum conditions have been identified for the preparation of the new species **3**. Moreover, a new convenient synthesis of **1** was carried out using **2** as a precursor.

The hydrogenation of some (carbamato)ruthenium(II) complexes was found to depend on the nature of the ligands. Compound **3** promptly reacts at room temperature, producing a mixture of $[RuHCl(PPh_3)_3]$ and $[RuH_2(H_2)(PPh_3)_3]$. When the reaction was carried out in the presence of an HCl scavenger, for instance iPr_2NH, only $[RuH_2(H_2)(PPh_3)_3]$ was detected as the final ruthenium-containing product through the intermediate $[RuH(O_2CNiPr_2)(PPh_3)_3]$.

No reaction with dihydrogen was observed for **1** at room temperature with $[RuH_2(H_2)(PPh_3)_3]$ being formed at 80 °C in the presence of PPh_3. Both **1** and **3** promote the hydrogenation of 1-octene at room temperature and atmospheric pressure, the highest activity being exhibited by the former which was largely recovered unchanged after catalysis in toluene. No other complexes were detected in solution by ^{31}P NMR spectroscopy. This suggests that catalysis does not require complete cleavage of the $Ru-O_2CNiPr_2$ bond. The flexibility of the carbamato ligand changing its coordination mode from η^2 to η^1 and allowing easy access to the metal atom may explain the results. Consistent with this interpretation both $[Ru(O_2CNiPr_2)_2CO(PPh_3)_2]$ and $[Ru(O_2CNiPr_2)_2(CO)_2(PPh_3)_2]$, which contain monodentate carbamato groups and strongly bonded ancillary ligands, are inactive towards olefin hydrogenation under comparable conditions. The importance of the carbamato ligand in the dihydrogen activation is apparent from the observation that the chloride-bridged anion of ruthenium(II) in the $[iPr_2NH_2][Ru_2Cl_5(PPh_3)_4]$ derivative was found to be inactive. As a result of recent mechanistic studies on ruthenium-catalysed hydrogenations,[20a–20c] the hydrogenation experiments reported in this paper will be extended to other unsaturated substrates.

Experimental Section

General: All procedures were carried out in standard Schlenk tubes. Solvents were freshly distilled from conventional drying agents under nitrogen and all manipulations were carried out under nitrogen, unless otherwise specified. The compounds $[RuCl_2(PPh_3)_3]$,[21] $[Ru(CO)(O_2CNiPr_2)_2(PPh_3)_2]$,[3a] and $[Ru(CO)_2(O_2CNiPr_2)_2(PPh_3)_2]$[3a] were prepared according to the literature. Commercial (Aldrich) triphenylphosphane, 1-octene and diisopropylamine were purified by conventional methods. Elemental analyses (C, H, N) were performed by the Laboratorio di Microanalisi della Facoltà di Farmacia, Università di Pisa, with a Carlo Erba model 1106 elemental analyser. IR spectra were recorded with a Perkin-Elmer FT-IR model 1725X spectrophotometer. Nuclear magnetic resonance spectra were recorded using a Varian Gemini 200BB instrument, the data being expressed in ppm relative to TMS for ^1H and ^{13}C and to 85% H_3PO_4 in D_2O for ^{31}P.

Synthesis of $[RuCl(O_2CNiPr_2)(PPh_3)_3]$ (3): To a solution of diisopropylamine (2.6 mL, 18.4 mmol) in toluene (300 mL), saturated with carbon dioxide, $[RuCl_2(PPh_3)_3]$ (4.35 g, 4.54 mmol) was quickly added together with PPh_3 (3.63 g, 13.8 mmol). After stirring under carbon dioxide for 4 d, $[iPr_2NH_2]Cl$ was removed by filtration. The ^{31}P NMR spectroscopic measurements on the filtrate gave the following results: δ = −4.2 ppm, 27.7 ppm (br. s), 46.5 (t, J = 66.0 Hz), 50.1 (d, J = 66.0 Hz), 51.0 (br., s) ppm. After removing the volatiles in vacuo, the resultant residue was dissolved in toluene (25 mL). By addition of heptane (75 mL), the title compound was recovered by filtration and then dried in vacuo at room temperature for 3 h (3.48 g, 71.8% yield). $C_{68}H_{75}ClNO_2P_3Ru$ (1167.8): calcd. C 69.9, H 6.5, N 1.2; found C 70.5, H 5.5, N 0.8. ^{31}P NMR (C_6D_6): δ = 27.7 (br. s), 46.5 (br. t, J = 68 Hz), 50.1 (br. d, J = 68 Hz), 51.0 (br. s) ppm. ^1H NMR (C_6D_6): δ = 0.9 (d, J = 68 Hz, C*H*$_3$ *i*Pr), 1.2 (d, C*H*$_3$ *i*Pr), 1.3 (d, C*H*$_3$ *i*Pr), 3.7 (m, C*H* *i*Pr), 4.4 (m, C*H* *i*Pr), 6.7 (m, 27 H, *m*,*p*-C*H*), 7.7 (m, 18 H, *o*-C*H*) ppm. ^{13}C NMR (C_6D_6): δ = 21.7 (s, *C*H$_3$ *i*Pr), 21.8 (s, *C*H$_3$ *i*Pr), 44.4 (s, *C*H *i*Pr), 44.5 (s, *C*H *i*Pr), 44.6 (s, *C*H *i*Pr), 163.5 (s) and 164.0 (s) (*C*O$_2$) ppm. Addition of triphenylphosphane caused the signals at δ = 27.7 and 51.0 ppm to decrease leading to a better resolution of the signals at δ = 50.1 (d) and 46.5 (t) ppm.

Synthesis of $[NH_2iPr_2][Ru_2Cl_5(PPh_3)_4]$ (2): A suspension of $[RuCl_2(PPh_3)_3]$ (0.44 g, 0.46 mmol) in toluene (25 mL) was treated with $[iPr_2NH_2]Cl$ (0.03 g, 0.22 mmol) under argon. The resultant dark-red solution showed a single ^{31}P NMR peak at δ = 46.9 ppm. After filtration and evaporation of the solvent to a small volume, the title crystalline compound was precipitated by addition of heptane (20 mL), filtered and dried in vacuo (0.23 g, 69% yield). $C_{78}H_{76}Cl_5NP_4Ru_2$ (1530.8): calcd. C 61.2, H 5.0, N 0.9; found C 59.6, H 5.2, N 0.6. ^{31}P NMR (C_6D_6): δ = 46.8 (s) ppm. ^1H NMR (C_6D_6): δ = 1.2 (dd, J = 6.0 Hz, 12 H, C*H*$_3$ *i*Pr), 3.5 (m, 2 H, C*H* *i*Pr), 6.8 (m, 36 H, *m*,*p*-C*H*), 7.6 (m, 24 H, *o*-C*H*), 8.2 (br. s, 2 H, N*H*) ppm. IR (nujol, KBr): $\tilde{\nu}$ = 3049 (m), 1586 (w),1482 (m), 1434 (s), 1311 (w) cm^{-1}.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Synthesis of $[Ru(O_2CN{i}Pr_2)_2(PPh_3)_2]$ (1) from $[NH_2{i}Pr_2][Ru_2Cl_5(PPh_3)_4]$ (2): Under carbon dioxide, iPr_2NH (25 mL) was added to a toluene solution of **2** prepared from $[RuCl_2(PPh_3)_3]$ (3.61 g, 3.76 mmol) and iPr_2NH_2Cl (0.25 g, 1.82 mmol). After stirring at ambient temperature for 4 d, the ammonium salt was removed by filtration and the filtrate was concentrated to dryness in vacuo. The resultant residue was suspended in heptane and the product was recovered by filtration and subsequent drying in vacuo (1.96 g, 57% yield). ^{31}P NMR (C_6D_6): δ = 66.2 (s) ppm. ^1H NMR (C_6D_6): δ = 1.1 (d, CH_3, *i*Pr), 3.6 (sept, CH, *i*Pr), range 6.6−7.5 (aromatic, m, CH) ppm.[3a]

Reaction of $[RuCl(O_2CN{i}Pr_2)(PPh_3)_3]$ (3) with H_2: A solution of **3** (1.21 g, 1.13 mmol) in toluene (100 mL) was placed under hydrogen. After 4 h, a violet precipitate was observed and a ^{31}P NMR spectrum of the liquid phase showed signals at δ = 58.5 $[RuH_2(H_2)(PPh_3)_3]$[17a] and 76.9 (t) and 41.7 (d) $\{[RuH(O_2CN{i}Pr_2)(PPh_3)_3]\}$ ppm. The latter signals disappeared with time such that after 1 d only the signal at δ = 58.5 was present. The violet solid was filtered and dried in vacuo (0.52 g, 49.6% yield). ^{31}P NMR ($C_2D_2Cl_4$): δ = 59.0 (br. s) ppm. ^1H NMR ($C_2D_2Cl_4$): δ = −18.4 (q, *J* = 26.0 Hz), 1.4 (br. s, CH_3), 3.4 (m, CH *i*Pr), 6.9 (m, *m*,*p*-CH), 7.7 (m, *o*-CH), 9.0 (br. s, NH) ppm. IR (Nujol, KBr, range 2200−1900 cm^{-1}): $\tilde{\nu}$ = 2030 cm^{-1}. To a solution of $[RuCl(O_2CN{i}Pr_2)(PPh_3)_3]$ (0.73 g, 0.68 mmol) in toluene (50 mL), iPr_2NH (0.4 mL, 2.86 mmol) was added and the mixture was stirred under dihydrogen for 4 h. The ^{31}P NMR spectrum of the liquid phase showed peaks due to $[RuH(O_2CN{i}Pr_2)(PPh_3)_3]$. After 24 h of stirring, the ^{31}P NMR of the liquid phase showed only a signal at δ = 58.5 $\{[RuH_2(H_2)(PPh_3)_3]\}$ ppm.[17a]

Treatment of $[Ru(O_2CN{i}Pr_2)_2(PPh_3)_2]$ with H_2. Reversible Formation of $[RuH_2(H_2)(PPh_3)_3]$: A solution of $[Ru(O_2CN{i}Pr_2)_2(PPh_3)_2]$ (0.38 g, 0.42 mmol) in toluene (50 mL) was stirred under hydrogen at room temperature for 3 h. No change was indicated by ^{31}P NMR spectroscopy even after treatment at 30 and 60 °C. Treatment at 80 °C for 4 h led to a mixture with a complex ^{31}P NMR spectrum containing a resonance at δ = 58.5 $\{[RuH_2(H_2)(PPh_3)_3]\}$ ppm. Longer treatment led to extensive decomposition. In an experiment where 1 equiv. of PPh_3 had been added, a solution of $[Ru(O_2CN{i}Pr_2)_2(PPh_3)_2]$ (0.32 g, 0.35 mmol) and PPh_3 (0.10 g, 0.38 mmol) in C_6D_6 (4 mL) was treated with hydrogen at atmospheric pressure. As in the previous experiment, no NMR spectroscopic changes were noted at room temperature, 40 or 60 °C, whereas a reaction did occur at 80 °C. After 12 h at 80 °C under hydrogen, the solution showed the following ^{31}P NMR resonances: δ = 76.8 (t, *J* = 68 Hz) and 41.7 (d, *J* = 68 Hz) $\{[RuH(O_2CN{i}Pr_2)(PPh_3)_3]\}$, 58.5 $\{$s, $[RuH_2(H_2)(PPh_3)_3]\}$ ppm. ^1H NMR: δ = −17.6 (q, *J* = 26.0 Hz), −7.1 (br. s), 0.75 (d, CH_3), 0.9 (d, CH_3 of free amine), 1.05 (d, CH_3 of the carbamato group), 2.7 (m, C*H* of free amine), 3.1 and 4.1 (m, C*H*), range 6.6−7.8 (aromatic C*H*), 9.0 (s, amine N*H*) ppm. ^{13}C NMR: δ = 164.6 (br. s), 45.4 (amine *C*H), 44.0 (*C*H of the carbamato group), 23.7 (amine *C*H_3), 21.8 (*C*H_3 of the carbamato group) ppm. After an additional 12 h at 80 °C, the solution turned yellow and only the resonance at δ = 58.5 $\{[RuH_2(H_2)(PPh_3)_3]\}$ ppm was observed. To this solution was added iPr_2NH (0.2 mL, 1.42 mmol) under carbon dioxide. After 1 h, the solution turned red and had the following spectroscopic features. ^{31}P NMR: δ = 76.8 (t, *J* = 68 Hz), 41.7 (d, *J* = 68 Hz) and 58.5 ppm. ^1H NMR: δ = −17.6 (q, *J* = 26 Hz), −7.1 (br. s), 0.75 (d, CH_3 of the carbamato groups), 0.9 (d, amine CH_3), 1.05 (d, CH_3 of the carbamato groups), 2.7 (m, amine C*H*), 3.1 and 4.1 (m, C*H* of the carbamato groups), range 6.6−7.8 (aromatic C*H*), 9.0 (s, amine N*H*) ppm. After 12 h, the ^{31}P NMR showed signals at δ = 76.8 (t) and 41.6 (d) $\{[RuH(O_2CN{i}Pr_2)(PPh_3)_3]\}$ ppm. By addition of an excess (5 mL) of iPr_2NH, a signal at δ = 66.4 $\{$s, $[Ru(O_2CN{i}Pr_2)_2(PPh_3)_2]\}$ ppm[3a] was present in the ^{31}P NMR spectrum after 1 week.

Reaction of $[Ru(CO)_2(O_2CN{i}Pr_2)_2(PPh_3)_2]$ with H_2: A solution of $[Ru(CO)_2(O_2CN{i}Pr_2)_2(PPh_3)_2]$ (0.19 g, 0.19 mmol) in toluene (10 mL) was placed under hydrogen and heated at 50 °C for 1 d. ^{31}P NMR spectra of the solution showed the progressive decrease of the signal of the starting material (δ = 29.9 ppm), the presence of an intermediate signal at δ = 43.5 ppm and the increase of the final signal at δ = 57.8 ppm attributable to $[RuH_2(CO)_2(PPh_3)_2]$.[2g,22] Once the reaction was complete, the pale-yellow $[RuH_2(CO)_2(PPh_3)_2]$ precipitated upon cooling to room temperature (30 mg, 22.4% yield). ^{31}P NMR (C_6D_6): δ = 57.7(s) ppm. ^1H NMR (C_6D_6): δ = −6.35 (t, *J* = 25 Hz), range 6.9−7.8 (aromatic C*H*) ppm. IR (Nujol): $\tilde{\nu}$ = 2010, 1974 (CO stretching), 1880 and 1815 (Ru−H stretching) cm^{-1}.

Treatment of $[{i}Pr_2NH_2][Ru_2Cl_5(PPh_3)_4]$ (2) with 1-Octene and with 1-Octene/H_2: To a C_6D_6 (3 mL) solution of **2** (0.37 g, 0.24 mmol) was added 1-octene (0.1 mL, 0.64 mmol). The solution was monitored by ^{31}P NMR spectroscopy with no change being noted. After introducing hydrogen, ^1H NMR signals due to (*E*)-4-octene [δ = 5.4 (m), 1.9 (m), 1.5 (m), 0.85 (t) ppm] were noted in addition to those of 1-octene.

Hydrogenation of 1-Octene in the Presence of $[Ru(O_2CN{i}Pr_2)_2(PPh_3)_2]$ (1) or $[RuCl(O_2CN{i}Pr_2)(PPh_3)_3]$ (3): The olefin (1-octene, 1.46 mmol) in C_6D_6 (4 mL) was stirred under H_2 at room temperature in the presence of **1** (0.15 mmol). After 12 h, the ^1H NMR spectrum of the reaction mixture showed the absence of the signals of 1-octene, the latter being completely converted into octane (gas chromatography, ATWAX capillary column). A hydrogenation experiment was carried out directly in an NMR tube: 1-octene (1.02 mmol) and **1** (86 mg, 9.44 × 10^{-2} mmol) were dissolved in C_6D_6 (0.7 mL) under N_2 with aqueous 85% H_3PO_4 contained in a flame-sealed capillary being used as a reference. The ^{31}P NMR spectrum showed signals at δ = 0 ppm due to phosphoric acid and at δ = 66.2 ppm due to **1** with an intensity ratio of 7.3. The content of the tube was then exposed to H_2 (*p* = 760 Torr) for 3 d. A new ^{31}P NMR spectrum showed signals at δ = 0 and 66.2 ppm with a ratio of 7.7, corresponding to more than 90% of the original complex **1** being unconverted. No other resonances were observed, while the ^1H NMR spectrum showed that complete hydrogenation to octane had occurred. A solution of **3** (0.14 g, 0.13 mmol) and 1-octene (0.2 mL, 1.27 mmol) in toluene (50 mL) was stirred for a few hours with no change in the ^{31}P NMR spectrum being noted. The solution was then placed under H_2 and stirred for 6 h. A violet solid was formed. A gas chromatogram of the liquid phase with an ATWAX capillary column showed a single peak due to octane. The violet solid spectroscopically identified as $[RuHCl(PPh_3)_3]$ was filtered and dried (50 mg, 41.2% yield). ^{31}P NMR ($C_2D_2Cl_4$): δ = 59.0 (br. s) ppm. ^1H NMR ($C_2D_2Cl_4$): δ = −18.4 (q, $J_{H,P}$ = 26 Hz), range 6.9−7.8 (m) ppm. The hydrogenation of 1-octene was monitored by gas volumetry, using both **1** and **3** as catalytic precursors. In a typical experiment, the solution of the olefin in toluene (20 mL) was prepared and a fragile flame-sealed ampoule containing the ruthenium complex was introduced. After thermostatting the system under H_2 (p_{H2} = 740 Torr), the ampoule was broken by magnetic stirring and the hydrogen absorption with time was noted, no induction being observed. The hydrogenation of 1-octene (0.8 mL, 5.1 mmol) in the presence of **1** (0.16 g, 0.18 mmol) at 20.6 °C in toluene (20 mL) gave a dihydrogen absorption corresponding to a conversion of about 70% in 165 min, the initial rate being 300 mmol·L^{-1} h^{-1} ([Ru] = 9.0 × 10^{-3} M).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The hydrogenation of 1-octene (0.3 mL, 1.91 mmol) in the presence of **3** (0.21 g, 0.20 mmol) at 21.2 °C in toluene (20 mL) was similarly monitored, the absorption of dihydrogen corresponding to 88.8% of the theoretical amount in 165 min. The initial rate was 153 mmol·L^{-1} h^{-1}, the ruthenium concentration being 1.0×10^{-2} M.

X-ray Crystallographic Studies: The crystallographic measurements on both samples were carried out on four-circle diffractometers. Cu-K_α radiation ($\lambda = 1.54184$ Å) was used for **3** due to the length of the *b* parameter, whereas Mo-K_α radiation ($\lambda = 0.71073$ Å) was used for **2**. All data were collected in the ω-2θ scan mode and three standard reflections were monitored every 97 measurements in order to check for crystal decay and equipment stability. For both samples, particularly for **3**, weak diffractions which rapidly dropped below the observation threshold were measured at increasing 2θ angles. Data reduction was performed using the DARX2000 and SDP program packages.[23,24] Crystals of **2**, prepared as described before, are red-brown blocks. An approximately tetrahedral splinter cut from one of them, with the edge about 0.30 mm long, was sealed in a glass capillary under N_2 and the unit cell parameters listed in Table 3 were derived from the setting angles of 35 strong reflections. A set of 6633 reflections were collected between $\theta = 1.8$ and 22.5° which were corrected for Lorentz and polarization effects and for absorption using the Ψ-scan method. After merging the equivalent reflections $\{R_{int} = [\Sigma|F_o^2 - F_o^2(\text{mean})|/\Sigma(F_o^2)] = 0.0483\}$, 4553 unique reflections satisfying the condition $I > 2\sigma(I)$ were obtained. The systematic absences indicated the $P2_1/c$ space group. After location of all the heavy atoms of the $[Ru_2Cl_5(PPh_3)_4]^-$ anion and of the $[i\text{Pr}_2\text{NH}_2]^+$ cation and the introduction of the hydrogen atoms in calculated positions, several large peaks were found in the difference Fourier map in the cavities between the ion pairs. These peaks were attributed to a disordered lattice solvent (heptane), but a reliable model for this substance was not found. This contributed to the relatively high reliability factors of the refinement which was carried out with anisotropic thermal factors for the Ru, Cl and P atoms only. The final reliability factors are listed in Table 3. Calculations were carried out using the SHELX-97 program.[25] Crystals of **3** are red prisms. A crystal of dimensions 0.20 × 0.25 × 0.38 mm, sealed in a glass capillary under N_2, exhibited the cell parameters listed in Table 3. Due to the poor diffraction properties of the crystal, only 3157 independent intensities having $I > 2\sigma(I)$ were collected in the range $3.69° \le \theta \le 70.0°$. They were corrected for Lorentz and polarization effects and for absorption using the Ψ-scan method. The structure was solved in the $P2_1/n$ space group by direct methods and refined by least-squares methods based on *F* (SHELXTL).[26] As in the structure of **2**, several peaks present in the difference Fourier map were attributed to a disordered lattice solvent (heptane) molecule. The last refinement cycle was carried out using anisotropic thermal factors for Ru, Cl and P atoms only. The final reliability factors are listed in Table 3. Final atomic parameters, thermal factors and the details of the structural determinations have been deposited in the form of a CIF file with the Cambridge Crystallographic Data Centre. CCDC-228267 (for **2**) and -228268 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Table 3. Crystal data and structural refinements for **2** and **3**

	2·heptane	**3**·heptane

Transition Metal Ion Directed Self-Assembly of Polynuclear Coordination Complexes: Structural Characterization and Magnetic Properties

Yongli Wei,[a] Hongwei Hou,*[a] Yaoting Fan,[a] and Yu Zhu[a]

Keywords: Magnetic properties / Multidentate ligands / Organic-inorganic hybrid composites / Self-assembly / Transition metals

The reactions of different transition metals with the multidentate ligand *N*,*N*′-bis(1,3,4-thiadiazol-2-yl)-2,6-pyridinedicarboxamide (btapca) afford six new polynuclear complexes: the hexanuclear complexes [{$Zn_6(O)_2(btapca)_4$}·3DMF·2H_2O] (**1**) and [{$Zn_6(O)_2(btapca)_4$}·DMF·MeOH·H_2O] (**2**); the pentanuclear complexes [{$Zn_5(OH)_2(btapca)_4$}·4DMF·H_2O] (**3**), [{$Co_5(OH)_2(btapca)_4$}·4DMF·MeOH·H_2O] (**4**) and [{$Ni_5(OH)_2(btapca)_4$}·4DMF·MeOH] (**5**); and the trinuclear complex [{$Fe_3(OH)(btapca)_3$}·2DMF·2MeOH] (**6**). The dominant characteristic of these polynuclear complexes is that there are μ_3- or μ_4-oxygen atoms in the metal polyhedrons. The hexanuclear complexes **1** and **2** show similar octahedral features based on zinc centers. The five metal centers in complexes **3**, **4** and **5** arrange into two triangles with one common vertex. As for complex **6**, three iron(II)/iron(III) atoms form a plane with a μ_3-OH^- in the center. We also report the magnetic properties of complexes **4**, **5** and **6**. Complex **4** exhibits intramolecular antiferromagnetic exchange, while the analogous complex **5** is dominated by very strong intramolecular ferromagnetic coupling. The trinuclear complex [{$Fe_3(OH)(btapca)_3$}·2DMF·2MeOH] (**6**) shows comparable weak antiferromagnetic coupling.

Introduction

"Self-assembly", defined by Whitesides as "the spontaneous assembly of molecules into structured, stable, noncovalently joined aggregates",[1] was borrowed from biology and since then has been widely used in modern coordination chemistry.[2] In traditional studies of supramolecular self-assembly, hydrogen bonds are most frequently employed, as they are in all biological systems.[3] In recent years, strong metal−ligand interactions in supramolecular architectures aroused great interest. Consequently, the self-assembly of organic ligands and inorganic metal ions became one of the most efficient and widely utilized approaches to the construction of organic/inorganic coordination superarchitectures,[4] which have intriguing properties induced by direct or indirect M−M interactions or a consequence of the positioning and identity of the coordination pockets within the ligand and the ability of metal ion to read these sites in terms of its own coordination algorithms.[5] Thus, such architectures exhibit potential applications in catalysis, electrical conductivity, molecular-based magnets, and host-guest chemistry,[6] and can be exploitated for the design of new materials with desirable properties and the manufacturing of devices and molecular machinery.[7−9]

Thus far, various sophisticated supramolecules have been constructed by self-assembly, such as squares, helices, metallacoronates, cages, capsules, tubes, cylinders, and many high-dimensional structures.[3a,10−17] Amongst these diverse architectures, polynuclear metal clusters have attracted much attention.[18−20] For the preparation of such architectures, well-designed organic ligands with the appropriate choice of donors and bridging groups have become the focus of a great deal of research work. It is well-known that polypyridyl groups have been very useful as programmed components in self-assembly processes,[21] and many polypyridyl ligands have been proved to be very useful in the construction of polynuclear complexes. For example, the alkoxy-diazine ligands have produced a series of high-nuclearity complexes;[5] the pendent-arm ligand 1,4,7-tris-(acetophenoneoxime)-1,4,7-triazacyclononane has resulted in the formation of Cu^{II}, $Co^{II,III}$, Ni_4^{II}, and $Mn_3^{II,III}$ complexes;[22] the bis-chelating ligand 1,2-bis(2,2′-bipyridine-6-yl)ethane has afforded a number of Mn complexes.[18] In most cases, combining with the chelating ligands, oxide bridges are always dominant in these polynuclear species, and they enhance the superexchange between paramagnetic metal ions. Chemists have also paid a great deal of attention to magnetic properties in addition to the versatile structures,[23] and have found that such complexes exhibit unusual supramolecular magnetic properties.[18,22,24−30]

In recent years, our group has been engaged in the study of functional coordination complexes, including polymers[31−34] and polynuclear complexes.[35,36] The design

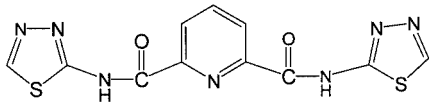
of ideal multifunctional ligands is one of our main themes. In this context, we prepared the ligand *N*,*N*′-bis(1,3,4-thiadiazol-2-yl)-2,6-pyridinedicarboxamide (btapca) and explored its coordination properties. We found that it can produce different polynuclear complexes when reacted with different metal ions: the hexanuclear complexes $[\{Zn_6(O)_2(btapca)_4\}\cdot 3DMF\cdot 2H_2O]$ (**1**) and $[\{Zn_6(O)_2(btapca)_4\}\cdot DMF\cdot MeOH\cdot H_2O]$ (**2**); the pentanuclear complexes $[\{Zn_5(OH)_2(btapca)_4\}\cdot 4DMF\cdot H_2O]$ (**3**), $[\{Co_5(OH)_2(btapca)_4\}\cdot 4DMF\cdot MeOH\cdot H_2O]$ (**4**) and $[\{Ni_5(OH)_2(btapca)_4\}\cdot 4DMF\cdot MeOH]$ (**5**); and the trinuclear complex $[\{Fe_3(OH)(btapca)_3\}\cdot 2DMF\cdot 2MeOH]$ (**6**). The magnetic properties of complexes **4**, **5**, and **6** are also reported here. The occurrence of indirect metal−metal interactions and metal-oxygen-metal bridging functions leads to dominant magnetic superexchange interactions.



btapca

Results and Discussion

Synthesis

Complexes **1**−**6** were synthesized by the reaction of *N*,*N*′-bis(1,3,4-thiadiazol-2-yl)-2,6-pyridinedicarboxamide (btapca) with different metal salts MX_2 (M = Zn^{II}, Co^{II}, Ni^{II}, Fe^{II}; X = NO_3, OAc, Cl, I) in methanol and DMF solution.

The reaction of $Zn(NO_3)_2\cdot 6H_2O$ with btapca in methanol and DMF (1:1) yielded the hexanuclear complex $[\{Zn_6(O)_2(btapca)_4\}\cdot 3DMF\cdot 2H_2O]$ (**1**). Replacement of $Zn(NO_3)_2\cdot 6H_2O$ with $Zn(OAc)_2\cdot 2H_2O$ in the above reaction led to the related hexanuclear complex $[\{Zn_6(O)_2(btapca)_4\}\cdot DMF\cdot MeOH\cdot H_2O]$ (**2**), which crystallized in a different crystal system and space group to those of complex **1**. In contrast to complexes **1** and **2**, we found that the reaction of ZnI_2 with btapca in a mixture of THF and DMF (1:1) did not afford the hexanuclear complex, but gave the pentanuclear complex $[\{Zn_5(OH)_2(btapca)_4\}\cdot 4DMF\cdot H_2O]$ (**3**) instead, which exhibits a "bow-tie" backbone. Interestingly, we also obtained pentanuclear complexes $[\{Co_5(OH)_2(btapca)_4\}\cdot 4DMF\cdot MeOH\cdot H_2O]$ (**4**) and $[\{Ni_5(OH)_2(btapca)_4\}\cdot 4DMF\cdot MeOH]$ (**5**) in the presence of $CoCl_2\cdot 6H_2O$ and $Ni(NO_3)_2\cdot 6H_2O$, respectively, their structures are similar to that of complex **3**. The reaction of $FeCl_2\cdot 4H_2O$ with btapca led to the trinuclear complex $[\{Fe_3(OH)(btapca)_3\}\cdot 2DMF\cdot 2MeOH]$ (**6**), which has a planar unit completely different from the structures of the other five complexes.

The following chart illustrates the syntheses and structural relationships based on the above discussions.

Crystal Structure of $[\{Zn_6(O)_2(btapca)_4\}\cdot 3DMF\cdot 2H_2O]$ (1)

The crystal structure of complex **1** is illustrated in Figure 1. In the structure, there are six Zn^{II} ions bound by four ligands in the available coordination polyhedron. These six zinc atoms show two different kinds of coordination environments. The inner Zn(3) and Zn(4) atoms are coordinated in a roughly tetrahedral fashion, with two N atoms from different btapca ligands, and O(9) and O(10). The Zn(3)−N(O) bond lengths lie in a fairly narrow range [1.979(9)−2.022(14) Å], and the N−Zn(3)−O angles vary from 109.5° to 117.2°. The corresponding bond lengths and angles around Zn(4) are identical to those of Zn(3), in the range 1.964(9)−2.00(2) Å and 107.7(5)−115.8(5)°, respectively. The Zn(3)···Zn(4) distance is 2.802(2) Å, suggesting that there is a strong interaction between Zn(3) and Zn(4). Such short Zn···Zn distances are unusual in polynuclear zinc complexes.[37−43]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

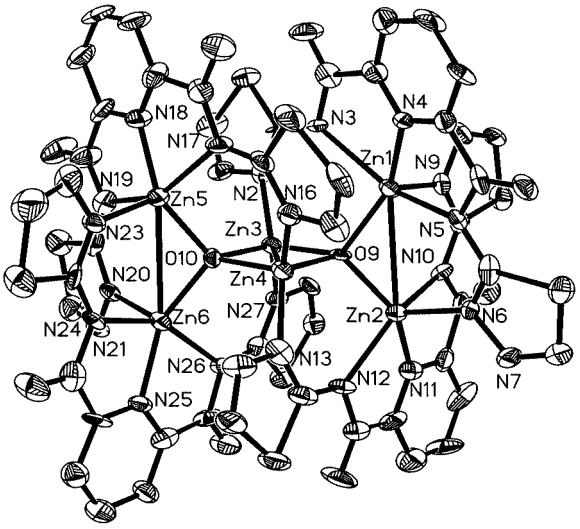


Figure 1. The hexanuclear backbone of $[\{Zn_6(O)_2(btapca)_4\}\cdot 3DMF\cdot 2H_2O]$ (**1**)

The other four zinc atoms Zn(1), Zn(2), Zn(5) and Zn(6) are connected to Zn(3) and Zn(4) through the O(9) and O(10) atoms. All these four Zn atoms are five coordinate and exhibit an approximately tetragonal pyramidal coordination geometry. In the polyhedron of Zn(5), N(17), N(18), N(19), O(10) lie in the basal plane, with a best least-squares deviation of 0.1274 Å, and N(23) occupies the apex. Zn(6) is identical to Zn(5). The slightly longer Zn(1)···Zn(2) [3.129(3) Å] and Zn(5)···Zn(6) [3.144(3) Å] distances suggest weaker interactions between the Zn atoms than Zn(3)···Zn(4), but still show a close Zn···Zn contact compared to those in the literature (falling in the range 3.0−4.4 Å).[37−43]

Considering the six zinc atoms as the symmetry core, the motif can be described as a rough octahedron. There is a pseudo-fourfold axis along Zn(3) and Zn(4). The basal plane is made up of Zn(1), Zn(2), Zn(5) and Zn(6), with a deviation of 0.0540 Å, and the four edges are 3.129, 3.144, 4.995 and 5.161 Å, respectively. Zn(3) and Zn(4) occupy the two apical sites.

The skeleton of **1** can also be described as edge-shared double tetrahedrons. Two isolated oxygen atoms are located in the center of each tetrahedron, and Zn(3)···Zn(4) is the common edge. In the outside of the Zn_6O_2 core, four ligands coil in a tetra-helical style.

The asymmetric unit contains two formula units; all the asymmetric units pack in a three-dimensional fashion based on hydrogen bonding. Along the crystallographic *a* direction, every $[Zn_6(O)_2(btapca)_4]$ unit is linked through O(2)···S(7) and O(2)···H−C(7). O(3)···H−C(33) hydrogen bonds form in the *b* direction, and O(8)···H−C(28) and O(1)···H−C(17) bonds in the *c* direction. All these contacts are weak van der Waals interactions, whose distances are in the range 2.375−3.140 Å. Although these interactions are comparatively weak, they may play a role in the stabilization of the crystal structure. The solvent DMF and H_2O molecules do not influence the structure of $[Zn_6(O)_2(btapca)_4]$, and are dispersed in the spaces of the structure.

Crystal Structure of $[\{Zn_6(O)_2(btapca)_4\}\cdot DMF\cdot MeOH\cdot H_2O]$ (2)

Complex **2** has a different space group from complex **1**, but its crystal structure is similar to that of **1** except for the solvent molecules. The two Zn−N distances are in the ranges 2.020(6)−2.284(6) Å and 1.972(6)−1.996(6) Å, and the Zn−O distances are in the range 1.939(5)−1.989(5) Å, slightly shorter than the corresponding distances in **1**. The shortest Zn···Zn distance is 2.8103 Å, and the longest 3.1456 Å. The asymmetric units also pack in a three-dimensional fashion through hydrogen bonding [O(4)···H(47), O(13)···H(11), O(2)···H(7) and S(6)···H(5)]. The lengths of these hydrogen bonds range from 2.470 to 2.934 Å.

The crystal structures of hexanuclear complexes **1** and **2** are very novel, although various Zn-containing polynuclear complexes have been reported previously. For example, in the hexanuclear zinc(II) cage $[Zn_6Cl_4(3,5\text{-}Me_2PzH)_8(PhPO_3)_4]$ (Me_2PzH = 3,5-dimethylpyrazole), the six zinc centers are arranged in a chair-like conformation.[38] The tetranuclear complex $[Zn_2L(\mu_{1,1}\text{-}HCO_2)(\mu_{1,3}\text{-}HCO_2)]_2(ClO_4)_2$ {L = 2,6-bis[*N*-2-(2′-pyridylethyl)formimidoyl]-4-methylphenol}[37] consists of two identical dinuclear $[Zn_2L(\mu_{1,1}\text{-}HCO_2)(\mu_{1,3}\text{-}HCO_2)]^+$ subunits which connect to each other through an interaction between the dangling oxygen of the formate and the zinc atom of the other subunit. The structure of the trinuclear compound $[Zn_3Cl(3,5\text{-}Me_2Pz)_4(t\text{BuPO}_3)_2]$[38] contains a planar trizinc assembly containing two bicapping $\mu_3[t\text{BuPO}_3]^{2-}$ ligands and terminal pyrazole and chloride ligands. The trinuclear complex $[Zn_3L(NH_3)_3(H_2O)_3]Cl\cdot H_2O$[44] [L = tris(2-hydroxybenzylidene)triaminoguanidine] adopts a propeller-like conformation. The six zinc centers in complexes **1** and **2** arrange in a completely different way, with a roughly octahedral conformation.

Crystal Structure of $[\{Zn_5(OH)_2(btapca)_4\}\cdot 4DMF\cdot H_2O]$ (3)

The pentanuclear backbone is based on a $Zn_5(\mu_3\text{-}OH)_2$ "bow-tie" cluster in which two triangles share one vertex [Zn(2)]. The three edges of each triangle are 3.413, 3.269, 3.269 Å, respectively, making it close to isosceles. The structural unit is illustrated in Figure 2. There is a 4(1)/*n* symmetry axis running through the central Zn(2) atom, and each asymmetric unit contains two formula units.

Zn(1) is six-coordinate by N(3), N(4), N(5), O(3), N(2), N(7) from three ligands. N(3), N(4), N(5) and O(3) comprise the equatorial plane, with a deviation of 0.0622 Å, and N(2) and N(7) occupy the two axial positions. Zn(2) is also in an octahedral coordination environment, with four N atoms in the equatorial plane and two O atoms at the axis. The Zn(2)−O distances fall in the range 1.940(11)−2.041(8) Å. O(3) is located in the mean plane of Zn(1)−Zn(1A)−Zn(2) with a best least-squares deviation of 0.1751 Å. The Zn−O−Zn angles fall in a fairly narrow range [110.4(4)−119.2(6)°]. The Zn−O and Zn−N bond

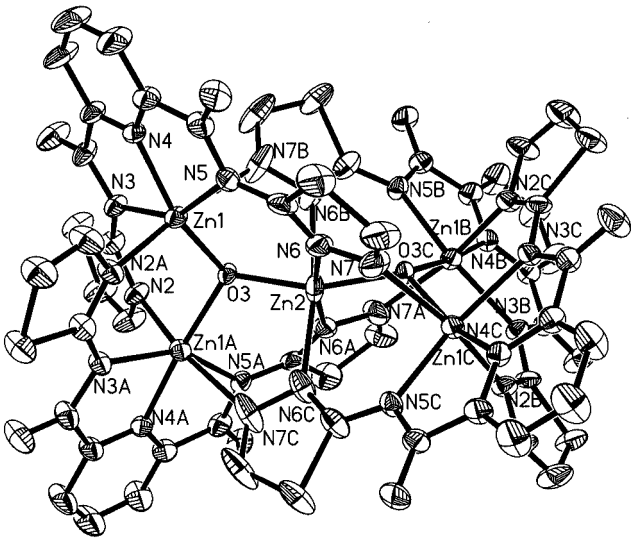

Figure 2. The pentanuclear unit of $[\{Zn_5(OH)_2(btapca)_4\}\cdot 4DMF\cdot H_2O)$ (**3**)

lengths are similar to those reported in the literature,[9,39,40,45–47] which are in the range 1.92–2.42 Å.

Complex **3** has a cage-like skeleton taking into account the hydrogen bonds. The solvent DMF and H_2O molecules are located in the cages and do not take part in the hydrogen bonding. The hydrogen bonds are formed between O(2)···H(1) and O(1)···H(11) with distances of 2.561 and 2.557 Å, respectively; the O(2)···S(1) distance is 3.180 Å, which indicates a weak van der Waals interaction.

Crystal Structure of $[Co_5(OH)_2(btapca)_4]\cdot 4DMF\cdot MeOH\cdot H_2O]$ (4)

The molecular structure of complex **4** is depicted in Figure 3. The pentanuclear backbone is similar to **3**: a 4(1)/*n* symmetry axis runs through the central Co(2) atom and each asymmetric unit contains two formula units. Each triangle has a μ_3-OH at its center and is held together by four peripheral ligands in a manner similar to the polymer $[\{Co_5(OH)_2\{1,2,4,5\text{-}(O_2C)_4C_6H_2\}_2(H_2O)_4\}\cdot xH_2O\}_n$.[48] Five cobalt centers share four ligands. Co(1) is coordinated by three ligands and two oxygens, while Co(2) is bound to four ligands and two oxygens. The two Co_3 triangles, joined through a Co(2) vertex, are almost isosceles, with edges of 3.346, 3.359, 3.359 Å, respectively. The dihedral angle of the two triangles is 90.0°. The longer distances Co(1B)···Co(1A) and Co(1B)···Co(1) are 6.288 Å. Consequently, a virtual S_2 axis through Co(2) atom can be postulated from the Co_5 core. In the tetranuclear $[Co_4O_4(O_2CR)_2(bpy)_4]^{3+}$ (bpy = 2,2′-bipyridine) salts,[49] the Co···Co distances are in the range 2.874(1)–2.641(1) Å; such short Co···Co distances are the result of short bridges formed only by oxygen atoms. On the contrary, the Co···Co distances in the trinuclear cation $[L_2Co_2^{III}Co^{II}]^{2+}$ [H_3L = 1,4,7-tris(acetophenoneoxime)-1,4,7-triazacyclononane][22] are much longer [3.402(2) and 6.805(4) Å, respectively]. Generally, the reported Co···Co distances range from 2.4 Å to 3.5 Å.[50–53] The Co···Co distances in **4** (about 3.3 Å) are in this range.

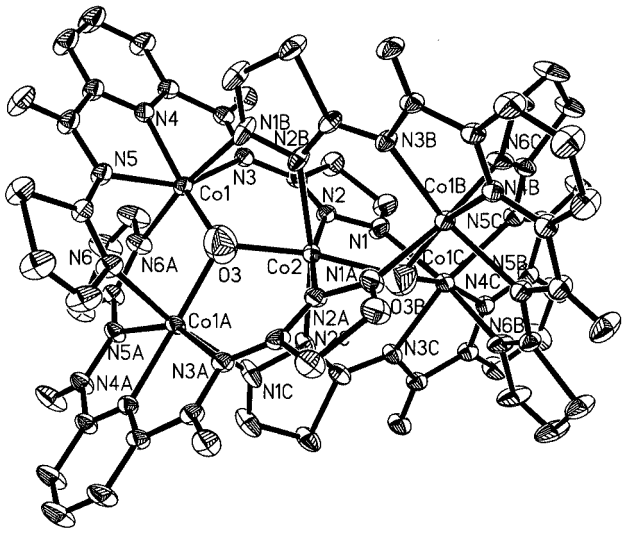

Figure 3. The pentanuclear unit of $[\{Co_5(OH)_2(btapca)_4\}\cdot 4DMF\cdot MeOH\cdot H_2O)$ (**4**) in which two triangles share one common vertex based on cobalt centers

Complex **4** can also be described as four Co(btapca) fragments joined to the Co(2) atom through oxygen bridges. The central Co(2) is bonded by N(2), N(2A), N(2B) and N(2C) from different ligands and two μ_3-O(3) atoms. The four nitrogen atoms from the equatorial plane and the two oxygen atoms occupy the axial positions. The O(3)–Co(2)–O(3B) bond angle of 158.0(3)° is far from the octahedral value of 180°. The Co(2)–O(3) distance [2.021(7) Å] is significantly shorter than the Co–O distance [2.082(3) Å] in the cation $[L_2Co_2^{III}Co^{II}]^{2+}$.[22] This phenomenon is expected for an axially compressed Jahn–Teller ion: "The high-spin Co^{II} ($t_{2g}^5e_g^2$) complexes are susceptible to Jahn–Teller distortions although the structural effect would be expected to be considerably less pronounced, since the degeneracy occurs in the t_{2g} d-orbital set rather than in the e_g set".[22] The antiferromagnetic effect of complex **4** further confirms the high-spin d^7 electronic configuration of the Co centers.

Each Co(1) atom is also in a distorted octahedral environment surrounded by N(3), N(4), N(5), N(6), N(1) and O(3). The Co(1B) atom is located in the mean plane of N(3B)–N(4B)–N(5B)–O(3B) with a deviation of 0.0912 Å. Along the axial direction, the two apical positions are occupied by N(1A) and N(6C), which come from another two ligands. The Co(1)–N(O) distances are in the range 1.998(10)–2.262(5) Å, and are in agreement with the high-spin description of the Co^{II} centers.

All the structural units are loosely packed in line along the *a* axis, and there are only weak O(1)···S(2) (3.228 Å) interactions between every two units. Solvent molecules occupy the space between the units.

Crystal Structure of [{$Ni_5(OH)_2(btapca)_4$}·4DMF·MeOH] (5)

As in the cases of **3** and **4**, the structure of **5** also consists of a pentanuclear [$Ni_5(OH)_2(btapca)_4$], a 4(1)/*n* symmetry axis runs through the central Ni(2) atom, and each asymmetric unit contains two formula units. The structural unit is illustrated in Figure 4. Five Ni^{II} ions are bridged by 24 nitrogen atoms, with four ligands coiling round the [$Ni_5(OH)_2$] core. The distance between two adjacent Ni(1) atoms is 3.444 Å, and the Ni(1)···Ni(2) distances are 3.287 Å. In this point it is similar to **3**, in which the distances between two adjacent Zn(1) atoms are about 3.4 Å, while the Zn(1)···Zn(2) distances are much shorter (about 3.2 Å). The $Ni(1)-N_{(amide)}$ distances fall in the range 2.129(7)−2.151(7) Å, and the $Ni(2)-N_{(thiazole)}$ distances are slightly longer [2.276(7) Å]; the $Ni-N_{(py)}$ distance [1.966(7) Å] is much shorter.

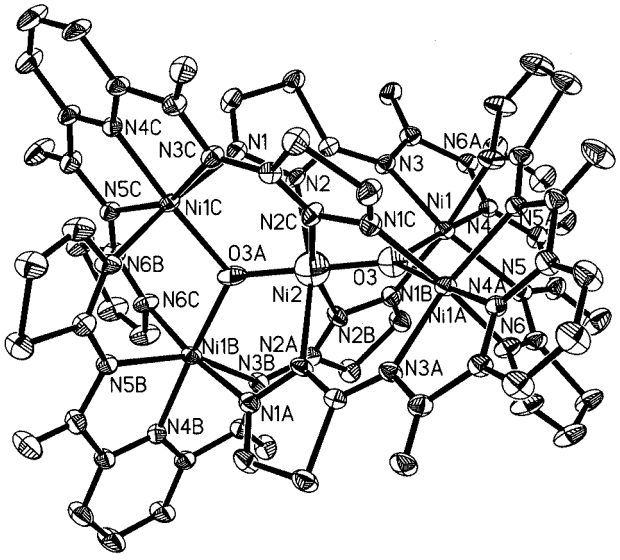

Figure 4. The pentanuclear structure of [{$Ni_5(OH)_2(btapca)_4$}·4DMF·MeOH) (**5**), showing similar feature to those of complex **3** and **4**; the μ_3-OH has been located exactly

The structure of **5** is loosely packed in three dimensions. O(1)···S(2) (3.236 Å) and S(1)···H(7) (2.941 Å) hydrogen bonds are found to connect the whole structure. Channels can be easily seen along the direction perpendicular to the *ac* plane, and the solvent molecules are found in these channels.

Although the skeleton of **5** is similar to those of **3** and **4**, there is a major difference between them. In **3** or **4**, the μ_3-OH is disordered in the center of the M_3 core whereas in **5**, μ_3-OH can be located exactly, with a $Ni(1)-O_{(\mu3)}$ distance of 2.041(6) Å and a $Ni(2)-O_{(\mu3)}$ distance of 1.703(10) Å. The short length of the $Ni(1)-O_{(\mu3)}-Ni(2)$ bridge (about 3.74 Å) leads to active superexchange between the metal ions, as shown by their magnetic-exchange phenomena.

There are many Ni-based complexes with nuclearities ranging from two to eight. The octanuclear ring [$Ni_8(DPKOH\text{-}2H)_4(H_2O)_8](BF_4)_8\cdot 16H_2O$[54] {DPKOH-2H = 1,2-bis[di(pyridin-2-yl)methyleneamino]oxalodiimidic acid}, for example, has a square grouping of six-coordinate Ni^{II} centers arranged in the external ligand pockets. Tetranuclear Ni^{II} complexes are also common,[22,28,29,55−57] for example the [2 × 2] square tetranuclear grid [$Ni_4(POAP\text{-}H)_4(H_2O)_4](NO_3)_4\cdot 8H_2O$ (POAP = alkoxydiazine ligand),[55] the dimer of dimers complex [$Ni_4(ICIMP)_2(Ph_2Ac)_2(urea)(H_2O)][ClO_4]_2$ [56] [ICIMP = 2-{*N*-isopropyl-*N*-[(1-methylimidazolyl)methyl]aminomethyl}-6-{*N*-carboxylmethyl)-*N*-[(1-methylimidazolyl)methyl]aminomethyl}-4-methylphenol], the cation [{$(L^2)Ni_2(\mu\text{-}pydz)(N_3)_2\}_2]^{2+}$ {L^2 = *N*,*N*′-bis[(2-thio-3-aminomethyl-5-*tert*-butylbenzyl)-propane-1,3-diamine]},[57] which contains a rectangular array of four Ni^{II} ions, tetrameric [$Ni_4L_3(H_2O)][ClO_4]_2\cdot 2H_2O$ [H_2L = bis(3-propionyloxy)-1,5-diazacyclooctane],[29] which has a planar triangular Ni_4 topology, the dicubane-like tetramer [Ni(dpk·OH)$(N_3)]_4\cdot 2H_2O$ [dpk = di(2-pyridyl) ketone],[28] and the planar trigonal-shaped tetranuclear Ni^{II} species $[Ni_4(HL)_3]^{2+}$[22] [HL = 1,4,7-tris(acetophenone-oxime)1,4,7-triazacyclononane]. There are also several reported dinuclear nickel(II) complexes,[58−60] while only a limited number of pentanuclear Ni^{II} complexes have been reported, such as the five-membered ring [$Ni_5(bptz)_5(CH_3CN)_{10}][SbF_6]_{10}$ [bptz = 3,6-bis(2-pyridyl)1,2,4,5-tetrazine].[61] As for the pentanuclear Ni^{II} species **5**, its conformation is completely different. The pentanuclear backbone is based on a $Ni_5(\mu_3\text{-}OH)_2$ "bow-tie" cluster, in which two triangles have a common vertex. Comparing complex **5** with these reported Ni^{II} complexes, we found that all of them have O atoms as bridges and similar Ni···Ni distances and Ni−O−Ni angles.

Crystal Structure of [{$Fe_3(OH)(btapca)_3$]·2DMF·2MeOH] (6)

The molecular structure of complex **6** (Figure 5) is based on an isosceles triangular Fe_3 fragment with a bridging μ_3-OH at the center of the triangle. A C_2 symmetry axis through Fe(2) and the central O(4) atom can be found. Three ligands join three iron atoms through nitrogen atoms from the thiadiazole ring; the bridging μ_3-OH reinforces the trianglar framework. The Fe(1)−Fe(1A), Fe(1)−Fe(2) and Fe(1A)−Fe(2) distances are 3.261, 3.227 and 3.227 Å, respectively, within the range of 2.93−3.65 Å reported in the literature.[26,62] A μ_3-O(4) atom bridges three iron atoms [Fe(1), Fe(1A) and Fe(2)] with Fe−O distances of 1.878(3), 1.878(3) and 1.853(7) Å, respectively. The distance of 1.853(7) Å is typical for $Fe^{3+}-O^{2-}$ bonds in trinuclear (carboxylato)(μ_3-oxo) complexes.[63] A comparison of the μ_3-O−Fe distances in complex **6** with corresponding distances in [$Fe_3O(O_2CC(CH_3)_3]_6(C_5H_5N)_3$] ($\mu_3$-O−$Fe^{3+}$ 1.85, at 295 K),[64] favors the assumption that the oxidation state of the Fe(2) atom is +3. The valence of the other two Fe atoms remains to be +2.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

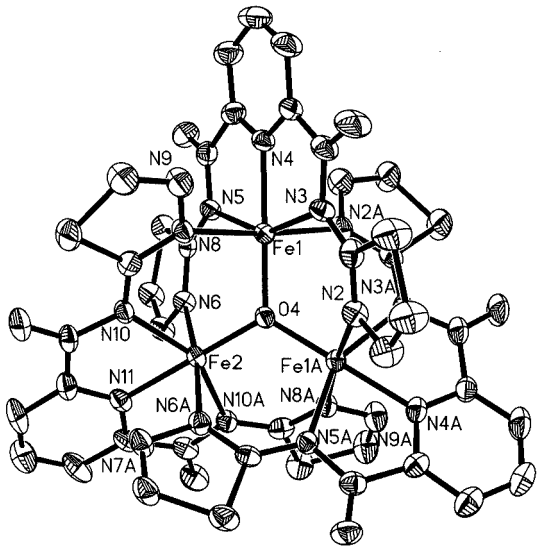

Figure 5. The triangle plane of [{$Fe_3(OH)(btapca)_3$}·2DMF·2MeOH) (**6**), consisting of mixed-valence Fe^{II} and Fe^{III} ions connected together through a μ_3-OH group

Both the Fe^{II} and Fe^{III} ions in **6** have a distorted octahedral geometry with a μ_3-oxygen and five nitrogen atoms. Each Fe center is coordinated simultaneously by three ligands. For example, in the coordination environment of Fe(1), the N(3), N(4) and N(5) donors come from one ligand, N(2A) from the other, and N(8) from the third. μ_3-O(4) and $N(4)_{(py)}$ are at the *trans* positions for all three Fe centers. The four equatorial coordination sites are occupied by N(3), N(4), N(5) and O(4), which are essentially coplanar, with a deviation of 0.0015 Å. Fe(1) is almost in the center of the coordination plane, which deviates from the mean plane by only 0.0019 Å. N(2A) and N(8) from the other two ligands bond to the Fe(1) axial positions to complete the octahedral geometry. The Fe−N distances fall in the range 2.085(9)−2.229(6) Å, which is the typical range for these systems. Three ligands overlap each other like a Chinese knot. Three iron atoms support the triangle knot through a μ_3-oxygen atom. Thus, a closer Fe···Fe contact is found in complex **6**, which benefits the magnetic exchange between the iron centers.

The structure of **6** packs in a large cage-like fashion, in which all the [$Fe_3(OH)(btapca)_3$] units are linked through hydrogen bonding [O(1)···H(11): 2.468 Å; O(3)···H(1): 2.535 Å]. DMF and MeOH solvent molecules occupy the large cages, and the DMF molecules form further hydrogen bonds with [$Fe_3(OH)(btapca)_3$] units [O(5)···H(6): 2.526 Å].

Magnetic Study

The magnetic characterization of **4**−**6** was carried out by measurement of the thermal variation of the paramagnetic susceptibilities χ_p under a magnetic field of 500 G. Because Zn^{II} has no unpaired electrons, complexes **1**−**3** are expected to be diamagnetic.

The magnetic properties of **4** were investigated as described in Figure 6. The χ_pT product exhibits a regular decrease from 3.36 $cm^3·K·mol^{-1}$ at 241 K to 0.97 $cm^3·K·mol^{-1}$ at 5 K, indicating a dominant antiferromagnetic interaction and the spin-orbit coupling of the octahedral Co^{II} centers. Because of this, the μ_{eff} value (5.15 μ_B) of **4** at room temperature is larger than the spin-only value of high-spin cobalt(II) (3.87 μ_B; $\mu_{so} = [4S(S + 1)]^{1/2}$; $S = 3/2$). From 241 to 261 K, χ_pT gradually decreases from 3.36 to 3.24 $cm^3·K·mol^{-1}$, which is an anomaly. This may be due to a transition, possibly associated with the freezing of solvent molecules in the structure and some structural modification. From 261 to 299 K, χ_pT gradually increases from 3.24 to 3.32 $cm^3·K·mol^{-1}$. The close agreement between the experimental and expected μ_{eff} values when the spin momentum and orbital momentum exist independently [5.20 μ_B; $\mu_{1s} = [L(L + 1) + 4S(S + 1)]^{1/2}$; $L = 3$,

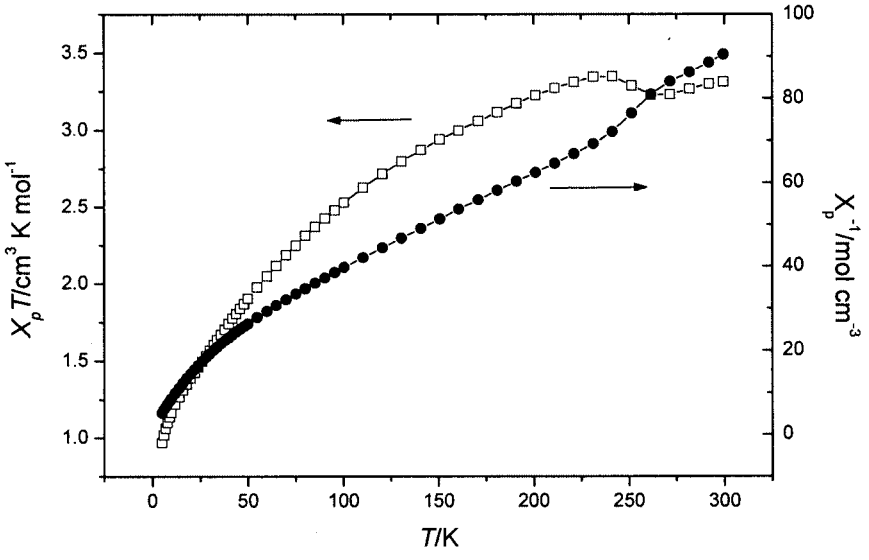

Figure 6. Thermal evolution of χ_pT and χ_p^{-1} of [{$Co_5(OH)_2(btapca)_4$}·4(DMF·MeOH·H_2O) **4**. (χ_p is the paramagnetic susceptibility of **4**)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$S = 3/2$] suggests that there is a contribution of the orbital angular momentum typical for the $^4T_{1g}$ ground state.

The inverse susceptibility varies linearly with temperatures in the experimental regime (85 K $\leq T \leq$ 242 K) and is well fitted in this region by using the Curie−Weiss law, giving $C = 3.71$ cm^3·K·mol^{-1} and $\theta = -37$ K, which further prove the antiferromagnetic exchange. At lower and higher temperatures, χ_p^{-1} shows a characteristic curvature.

In complex **4** there are three kinds of magnetic exchange pathways, namely a Co^{II}-Co^{II} interaction via the μ_3-OH bridge, a magnetic coupling between Co^{II} and Co^{II} through the $N_{(thiazole)}-N_{(thiazole)}$ pathway (5.89 Å), and a Co^{II}-Co^{II} interaction via the $N_{(amide)}-C-N_{(thiazole)}$ bridge (7.077 Å). In consideration of the structural framework, the spin-bearing centers would like to couple antiferromagnetically in triangular or tetrahedral arrays.[65,66] When the unpaired electrons are aligned at 120° and 109° in the triangular and tetrahedral units, respectively, the overall spin vector is equal to zero, as is required for antiferromagnetic coupling.[65] In the spin Co_3O core the Co−O−Co bond angles are about 113°, in accordance with antiferromagnetic behaviour.

The magnetic properties of **5** were studied in the range 5−302 K and the results are given in Figure 7 in the form of χ_pT vs. T and χ_p^{-1} vs. T plots. The variation of χ_p^{-1} is well described by the Curie−Weiss law from 302 to 5 K. The value $C_m = 5.07$ cm^3·K·mol^{-1} and Weiss temperature $\theta = +2$ K are characteristic of a ferromagnetic superexchange. The magnitude of χ_pT increases continuously with decreasing temperature from 5.11 cm^3·K·mol^{-1} (five Ni atoms) at room temp., with a small peak of 5.46 cm^3·K·mol^{-1} at 50 K. From 50 to 44 K, the value of χ_pT decreases slightly from 5.46 to 5.43 cm^3·K·mol^{-1}. After further cooling, the curve rapidly increases to 6.25 cm^3·K·mol^{-1} at 6 K, and then χ_pT begins to decrease. The small peak at around 50 K may be due to molecular oxygen. These results are indicative of the occurrence of ferromagnetic coupling between the metallic centers. The effective magnetic moment at room temperature is 6.4 μ_B, which agrees very well with the spin-only value for five Ni atoms (6.32 μ_B).

In spite of their structural similarity, complex **5** exhibits quite different magnetic behaviour from **4**. We attributed this to the different exchange centers. The metallic centers have superexchange through different pathways, including the btapca ligands and a μ_3-O. Regularly, if the Ni−O−Ni angle is 120°, the complex will exhibit an antiferromagnetic behavior.[67] For face-sharing dioctahedral nickel complexes, Ni−X−Ni bridging angles of (90 ± 14°) are an indication of a ferromagnetic interaction.[29,57,68] The Ni−O−Ni angles in structure **5** are 115.1(5)° and 122.5(2)°, but we can still see a ferromagnetic interaction from the experimental data. Thus, the magnetic exchange through the btapca ligands could dominate even though the pathway through the μ_3-O is much shorter. The low efficiency of these exchange pathways explains the weak ferromagnetic behavior observed for **5**, although the magnetic exchange centers are relatively close to each other. Moreover, the distortions of octahedral geometry around the Ni ion [Ni−N distances ranging from 1.966(7) to 2.276(7) Å with Ni−O lengths of 2.041(6) and 1.704(10) Å] account for the slight weakening of the observed ferromagnetic coupling. Consequently, differences in the bond lengths around Ni ions are directly related to the overlap between the d_{x2-y2} orbital and thus affect the magnitude of the ferromagnetic coupling.

The magnetic behavior of complex **6** is shown in Figure 8 in the form of a χ_pT vs. T plot. χ_pT decreases continuously from 3.14 cm^3·K·mol^{-1} at 302 K to 0.67 cm^3·K·mol^{-1} at 4 K. This behavior is consistent with an antiferromagnetic interaction between the exchange centers. The magnetic susceptibility, plotted as χ_p^{-1} vs. T in Figure 8, follows the Curie−Weiss expression $\chi_p = C/(T - \theta)$ between 110 K and 300 K, with a Curie constant of 3.30 cm^3·K·mol^{-1} and a

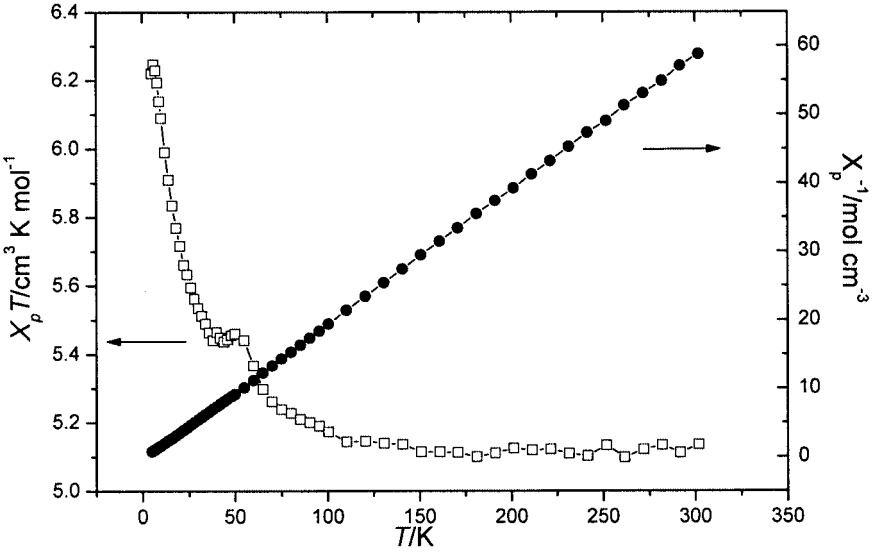

Figure 7. Thermal evolution of χ_pT and χ_p^{-1} of [{$Ni_5(OH)_2(btapca)_4$}·4DMF·MeOH) (**5**); χ_p is the paramagnetic susceptibility of **5**

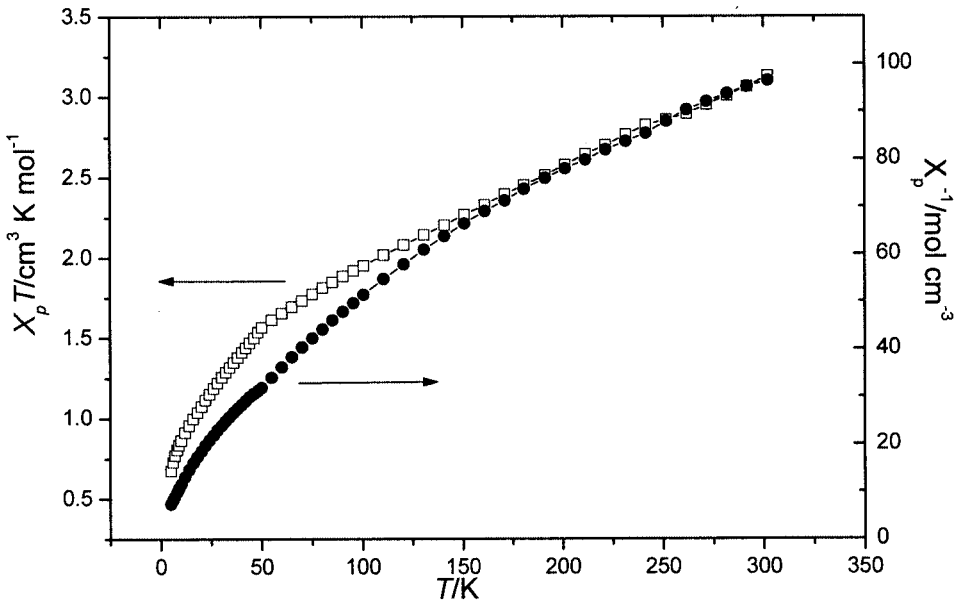

Figure 8. Plots of $\chi_p T$ and χ_p^{-1} vs. T for [{Fe_3(OH)(btapca)$_3$}·2DMF·2MeOH) (**6**); χ_p is the paramagnetic susceptibility of **6**

Curie−Weiss temperature, θ, of −49 K. Below 110 K, the data do not strictly obey the Curie−Weiss law. The effective paramagnetic moment, μ_{eff}, is 5.0 μ_B, indicating a high-spin state for both Fe^{II} (S = 2) and Fe^{III} (S = 5/2) centers. The negative sign for θ suggests an overall antiferromagnetic coupling between the mixed-valence Fe^{II}-Fe^{III} centers.

The magnetic interactions between Fe ions in **6** are achieved mainly through the μ_3-O atom. Although the presence of N−C−N bridges provides an additional exchange pathway (Fe-*N*-C-*N*-Fe about 7.04 Å), they can be neglected due to the shorter Fe−O−Fe bridges (Fe−O−Fe about 3.73 Å). The Fe···Fe distances (about 3.2 Å) differ by only 0.04 Å, and the average Fe−O−Fe angle is 120°. The restricted Fe−O−Fe angle in the iron-$O_{\mu 3}$ plane structures allows magneto-structural correlations. The typical obtuse angle of 120° induces an antiferromagnetic interaction.

The Mössbauer spectrum of complex **6** is similar to that observed for another trimeric, mixed-valent, oxo-centered complex,[69] although it is remarkably different from other trimeric, mixed-valence, oxo-centered complexes.[70,71] The doublets in the Mössbauer spectrum of **6** at room temperature are far from the ratio of 2:1, with isomer shifts and quadrupole splittings of δ_I = 0.27 mm·s^{-1}, ΔE_{QI} = 1.75 mm·s^{-1} and δ_{II} = 0.72 mm·s^{-1}, ΔE_{QII} = 2.63 mm·s^{-1} (Figure 9). This denotes some degree of delocalization (valence detrapping) of the extra electron over the three Fe sites. At room temperature only one doublet is usually found for trimeric, mixed-valent, oxo-centered transition metal complexes due to full delocalization of the "excess" electron over the three iron sites ("valence-detrapped state").[69,70] Complex **6** exhibits a partially valence-delocalized (partially valence-detrapped) state which is similar to the case of a reported Fe^{II}/Fe^{III} complex.[69]

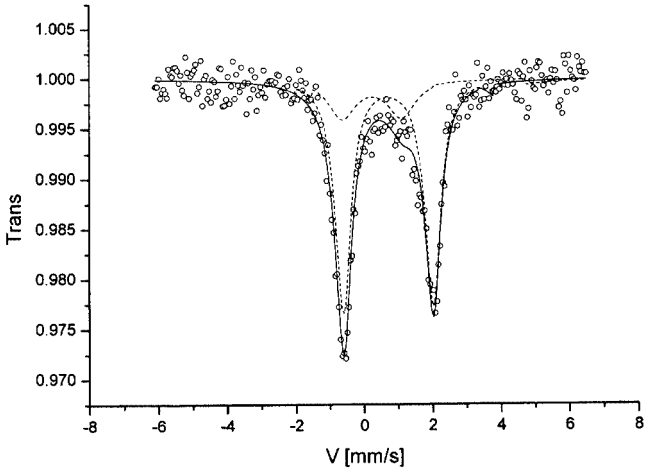

Figure 9. The Mössbauer spectrum of complex [{Fe_3(OH)(btapca)$_3$}·2DMF·2MeOH) (**6**) at room temperature

Conclusion

We have succeeded in obtaining a series of polynuclear complexes constructed from polydentate ligands and different transition-metal salts. The number of metal atoms in these polynuclear complexes ranges from 3 to 6. A μ_3-O atom is a dominant feature in the formation of all these structures. The magnetic behavior of complex **5** shows a ferromagnetic interaction between the Ni^{II} ions, while complexes **4** and **6** both exhibit typical antiferromagnetic exchange between the metal centers.

Experimental Section

General Techniques: 2-Amino-1,3,4-thiadiazole (TBA) was prepared according to a published method.[72] All the other starting chemicals and solvent were commercially available with analytical purity and were used without further purification. A PE 240C Elemental Analyzer was used to perform the elemental analysis. Infrared spectra were measured on a Bruker Tensor 27 infrared spectrophotometer. Fast atom bombardment (FAB) mass spectra were obtained on a Bruker Esquire 3000 mass spectrometer. NMR spectra were obtained using a Bruker DPX-400 spectrometer.

Preparation of *N*,*N*′-Bis(1,3,4-thiadiazol-2-yl)-2,6-pyridinedicarboxamide (btapca): 2,6-Pyridinedicarboxylic acid (1.67 g, 10 mmol) was dissolved in 20 mL of $SOCl_2$. The mixture was refluxed until the white powder dissolved completely. The residual $SOCl_2$ was then removed under reduced pressure. The resulting 2,6-pyridinedicarbonyl dichloride was dissolved in 10 mL of anhydrous pyridine. This pyridine solution of 2-aminodithiazole (2.02 g, 20 mmol) was added dropwise to the 2,6-pyridinedicarbonyl dichloride whilst stirring in an ice bath. Stirring for 4 h resulted in the formation of a white precipitate, which was filtered under reduced pressure and washed with water and methanol. Yield: 2.25 g (70%). $C_{11}H_7N_7O_2S_2$ (333.01): calcd. C 39.64, H 2.12, N 29.41; found C 39.84, H 2.27, N 28.11. ^{1}H NMR (400 MHz, DMSO): δ = 8.39 (q, H), 8.50 (d, 2 H), 9.36 (s, 2 H), 13.73 (d, 2 H) ppm. Positive-ion, ESI-MS: m/z = 333.9 [btapca + H^-].

Synthesis of [{$Zn_6(O)_2$(btapca)$_4$}·3DMF·2H_2O] (1): A DMF solution (5 mL) of btapca (0.1 mmol, 0.0333 g) was added to a methanol solution (5 mL) of $Zn(NO_3)_2$·6H_2O (0.2 mmol, 0.0595 g). The mixture solution was then evaporated to 30% of the original volume at room temperature. Colorless crystals were collected after two weeks with a yield of 30%. IR (KBr pellets): $\tilde{\nu}$ = 3082, 1625, 1667, 1293 cm^{-1}. $C_{53}H_{45}N_{31}O_{15}S_8Zn_6$ (2004.9): calcd. C 31.72, H 2.24, N 21.65; found C 31.51, H 2.31, N 21.22.

Synthesis of [{$Zn_6(O)_2$(btapca)$_4$}·DMF·MeOH·H_2O] (2): A DMF solution (5 mL) of btapca (0.1 mmol, 0.0333 g) was added to a methanol solution (5 mL) of $Zn(OAc)_2$·2H_2O (0.2 mmol, 0.0439 g). The mixture was allowed to stand in air at room temperature for a week resulting in colorless crystals suitable for X-ray diffraction. Yield: 46%. IR (KBr pellets): $\tilde{\nu}$ = 3450, 1626, 1467, 1427, 1376, 1070, 959, 885, 529 cm^{-1}. $C_{48}H_{33}N_{29}O_{13}S_8Zn_6$ (1872.7): calcd. C 30.76, H 1.76, N 21.68; found C 30.95, H 1.58, N 22.01.

Synthesis of [{$Zn_5(OH)_2$(btapca)$_4$}·4DMF·H_2O] (3): A DMF solution (5 mL) of btapca (0.1 mmol, 0.0333 g) was added to a THF solution (5 mL) of ZnI_2 (0.2 mmol, 0.0638 g). A light-yellow solution was obtained after filtration, and this was placed under air. Colorless polyhedral crystals appeared after two weeks. Yield: 25%. IR (KBr pellets): $\tilde{\nu}$ = 3445, 3095, 1639, 1538, 1466, 1444, 1377, 1075, 959, 889 cm^{-1}. $C_{56}H_{52}N_{32}O_{15}S_8Zn_5$ (1996.6): calcd. C 33.66, H 2.60, N 22.44; found C 33.36, H 2.83, N 22.37.

Synthesis of [{$Co_5(OH)_2$(btapca)$_4$}·4DMF·MeOH·H_2O] (4): A DMF solution (5 mL) of btapca (0.1 mmol, 0.0333 g) was added dropwise to a methanol solution (5 mL) of $CoCl_2$·6H_2O (0.2 mmol, 0.0476 g). The resulting red solution produced dark-red crystals suitable for X-ray analysis after four days. Yield: 52%. IR (KBr

pellets): $\tilde{\nu}$ = 3435, 3069, 1709, 1667, 1612, 1437, 1366, 1077, 954, 888 cm^{-1}. $C_{57}H_{52}Co_5N_{32}O_{17}S_8$ (2008.4): calcd. C 34.06, H 2.59, N 22.31; found C 35.22, H 2.27, N 22.65.

Synthesis of [{$Ni_5(OH)_2(btapca)_4$}·4DMF·MeOH] (5): $Ni(NO_3)_2·6H_2O$ (0.1 mmol, 0.0291 g) was dissolved in 5 mL methanol, and a DMF solution (5 mL) of btapca (0.1 mmol, 0.0333 g) was added dropwise to the above solution. The resulting solution was kept at room temperature. Brown crystals suitable for X-ray diffraction were obtained. Yield: 33%. IR (KBr pellets): $\tilde{\nu}$ = 3442, 3075, 1637, 1598, 1465, 1360, 1074, 959, 889 cm^{-1}. $C_{57}H_{54}N_{32}Ni_5O_{15}S_8$ (1977.4): calcd. C 34.59, H 2.73, N 22.66; found C 34.89, H 2.57, N 22.74.

Synthesis of [{$Fe_3(OH)(btapca)_3$}·2DMF·2MeOH] (6). Solutions of btapca (0.1 mmol, 0.0333 g) in DMF and $FeCl_2·4H_2O$ (0.2 mmol, 0.0398 g) in methanol were mixed. Dark-red microcrystals were obtained at room temperature. Yield: 62%. IR (KBr pellets): $\tilde{\nu}$ = 3452, 3079, 1636, 1422, 1358, 1283, 1158, 1043, 959, 888 cm^{-1}.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$C_{41}H_{38}Fe_3N_{23}O_{11}S_6$ (1388.9): calcd. C 35.42, H 2.74, N 23.18; found C 35.12, H 2.80, N 23.52.

Magnetic Studies: Temperature-dependent magnetic-susceptibility measurements on powdered solid samples were carried out on a SQUID magnetometer (MPMS Quantum Design) over the temperature range 5−300 K. The magnetic field applied was 500 G. The observed susceptibility data were corrected for underlying diamagnetism by using Pascal's constants.[73]

Mössbauer Measurement: Mössbauer spectra were obtained in transmission mode using a ^{57}Co source in a Rh matrix. 64.8 mg of the samples was used and the spectra were measured on an Austin S-600 Mössbauer spectrometer. The spectra were recorded at room temperature at a speed of 6 mm/s. The source was kept at room temperature. The hyperfine field parameters were obtained by fitting the raw data with Lorentz-shaped lines using the program "Mössbauer spectra for Fitting" by Prof. Z. X. Xu (Material Physics and Chemistry Department, University of Science and Technology Beijing). The hyperfine field data are referenced against α-Fe.

X-ray Crystallographic Study: The diffraction intensities of prismatic crystals of complexes **1**, **2**, **3**, **4**, **5** and **6** were collected with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) using a Rigaku R-AXIS-IV diffractometer at 291(2) K to a maximum 2θ value of 50°. The unit-cell parameters were determined from the reflections collected on oscillation frames and were then refined. The data were corrected for Lorentz and polarization effects. The structures were solved by direct methods with SHELXS-97[74] and subsequent Fourier-difference synthesis and refined by the full-matrix least-squares method on F^2 with SHELXL-97.[75] All non-hydrogen atoms, except atoms in disordered parts, were refined anisotropically; hydrogen atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters. Crystal data and structure refinement details for the seven compounds are given in Table 1. Selected bond lengths and angles of complexes **1**−**6** are listed in Table 2 and 3.
CCDC-212348 (for **1**), -212349 (for **2**), -212351 (for **3**), -212350 (for **4**), -212352 (for **5**) and -212354 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

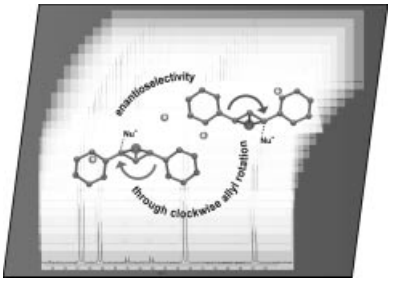
COVER PICTURE

The cover picture shows the low-temperature ^{31}P NMR signals and simplified 3D representations of *exo* and *endo* isomers of an (η^3-1,3-diphenylallyl)palladium(II) complex in which the metal center is coordinated by a chiral xanthene-derived diphospholane ligand. Such complexes are intermediates in palladium-catalyzed allylic substitution, and their structures determined by 2D NMR spectroscopy allow for the interpretation of the enantioselectivities of the catalytic process in terms of preferential rotation of the allyl group. Key methyl groups of the chiral ligand that govern this rotation are represented by yellow spheres in the background. Details on these complexes and others and on asymmetric catalysis can be found in the article by J. A. Osborn, L. Barloy et al. on p. 3987ff. The authors are indebted to Bernard Lafleuriel (CURRI-Visu) for his help concerning the artwork of the cover picture.

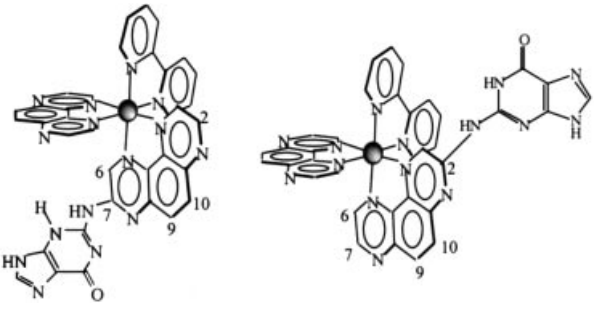


MICROREVIEW

Contents

3971 **R. Blasius, C. Moucheron, A. Kirsch-De Mesmaeker***

Photoadducts of Metallic Compounds with Nucleic Acids – Role Played by the Photoelectron Transfer Process and by the TAP and HAT Ligands in the Ru^{II} Complexes



Keywords: Photoadducts / Electron transfer / Ruthenium(II) complexes / GMP / DNA

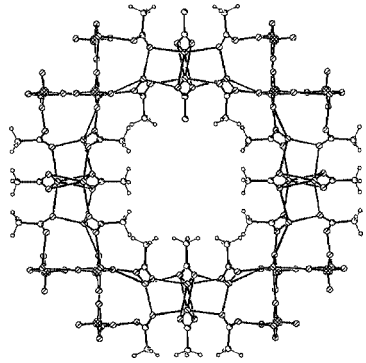
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

SHORT COMMUNICATIONS

3981 **A. Lavalette, G. A. Lawrance, N. W. Alcock,* M. J. Hannon***

Channel Structures in a Simple Inorganic Salt − An Open Framework Formed through Structural Integration of Distinct Sodium Acetate and Sodium Perchlorate Domains

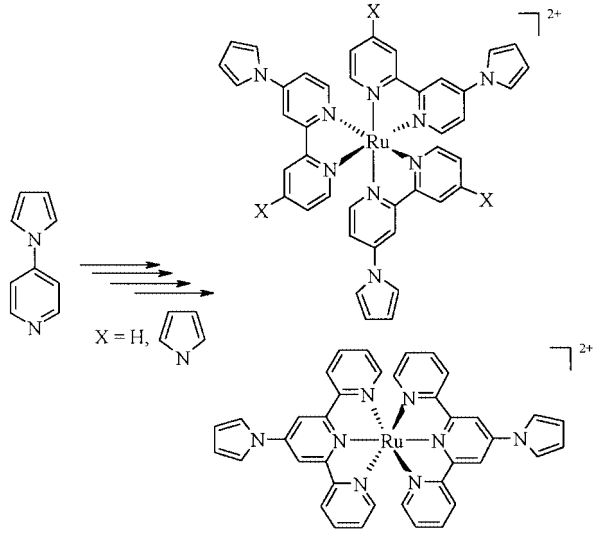
Keywords: Channel structures / Microporous materials / Crystal engineering / Zeolite analogues



3984 **D. Martineau, P. Gros,* M. Beley,* Y. Fort**

New Ruthenium Complexes with 4-(1*H*-Pyrrol-1-yl)-Substituted Polypyridine Ligands − Electrochemical and Spectroscopic Properties

Keywords: Nitrogen heterocycles / Ruthenium / N donor ligands

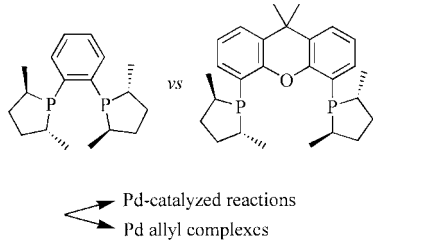


FULL PAPERS

3987 **G. Malaisé, S. Ramdeehul, J. A. Osborn,* L. Barloy,* N. Kyritsakas, R. Graff**

Palladium Complexes with Chiral Diphospholane Ligands: Comparative Catalytic Properties and Analysis of (η^3-Allyl)palladium Species

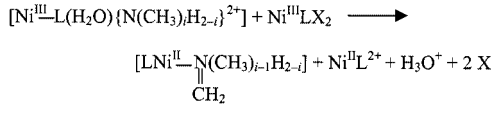
Keywords: Palladium / Allyl ligands / Reaction intermediates / Asymmetric catalysis / Enantioselectivity



4002 **D. Shamir,* I. Zilbermann, E. Maimon, D. Meyerstein**

Oxidation of CH_3NH_2 and $(CH_3)_2NH$ by $Ni^{III}(cyclam)(H_2O)_2^{3+}$ in Aqueous Solutions

Keywords: Pendant primary amines / Amines / Cyclam / Nickel / Electrocatalysts



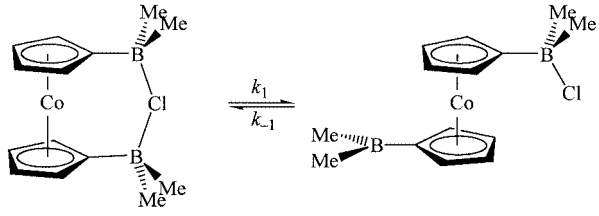
4006 **O. S. Oleneva, A. V. Olenev, E. V. Dikarev, A. V. Shevelkov***

From Discrete to Extended Guests: A Novel Supramolecular $[Hg_6As_4](AgCl_3)_2$ Assembly Featuring One-Dimensional $(AgCl_3)^{2-}$ Anions

Keywords: Arsenic / Host–guest systems / Mercury / Silver / Supramolecular chemistry

4011 **G. E. Herberich,* U. Englert, A. Fischer, D. Wiebelhaus**

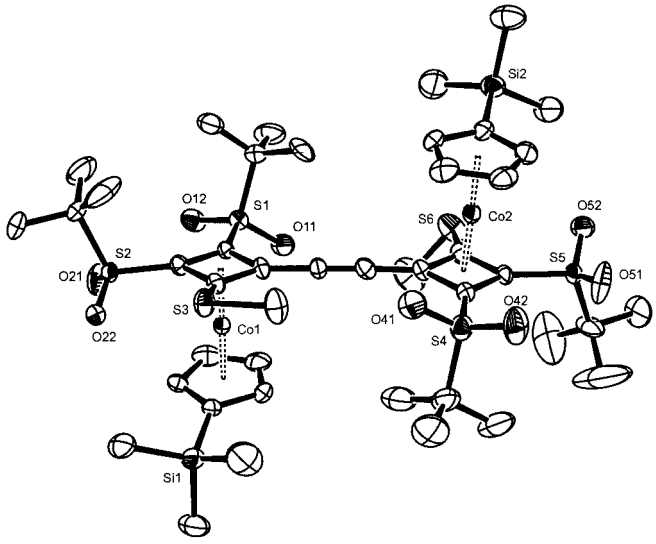
Anion Binding of 1,1′-Bis(dialkylboryl)cobaltocenium Complexes – Structures of $[Co\{C_5H_4(BMe_2)\}_2]PF_6$, $Co[C_5H_4(BMe_2)][C_5H_4(BMe_2Cl)]$, $Co[C_5H_4(BiPr_2)]_2(\mu\text{-}F)$ and $NMe_4[Co\{C_5H_4(BiPr_2F)\}_2]$



Keywords: Anion binding / Borates / Boron / Cobalt / Sandwich complexes

4021 **D. B. Werz, R. Gleiter,* F. Rominger**

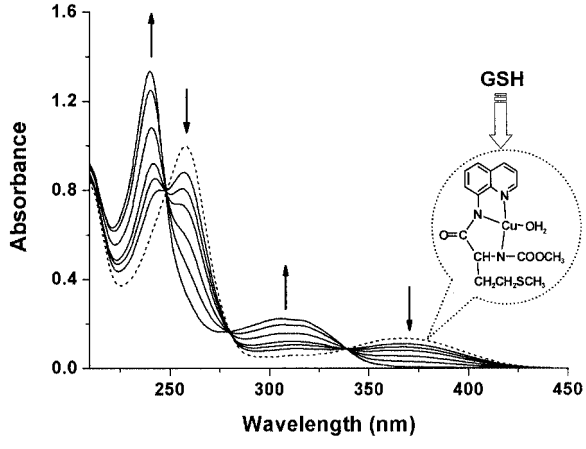
Mono(alkyne)cobalt Complexes and Electron-Rich Alkynes – The Formation of an Alkyne-Bridged Dinuclear Cobalt Complex by a One-Pot Procedure



Keywords: Alkynes / Chalcogens / Cobalt / Cyclobutadiene complexes

4028 **S. Zhang, C. Tu, X. Wang, Z. Yang, J. Zhang, L. Lin, J. Ding, Z. Guo***

Novel Cytotoxic Copper(II) Complexes of 8-Aminoquinoline Derivatives: Crystal Structure and Different Reactivity towards Glutathione



Keywords: Antitumor agents / Bioinorganic chemistry / Copper / N ligands

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

4036 **I. A. Koval, M. Huisman, A. F. Stassen, P. Gamez, O. Roubeau, C. Belle,* J.-L. Pierre, E. Saint-Aman, M. Lüken, B. Krebs, M. Lutz, A. L. Spek, J. Reedijk***

Dinuclear Cu^{II} Complexes with a New Phenol-Based Ligand Bearing Pyridine and Thiophene Substituents: Synthesis, Characterization and Interaction with Catechol Substrates

Keywords: Copper / Dinuclear complexes / Catechol oxidase / Magnetochemistry / Electrochemistry

Photoadducts of Metallic Compounds with Nucleic Acids − Role Played by the Photoelectron Transfer Process and by the TAP and HAT Ligands in the Ru^{II} Complexes

Romain Blasius,[a][‡] Cécile Moucheron,[a] and Andrée Kirsch-De Mesmaeker*[a]

Keywords: Photoadducts / Electron transfer / Ruthenium(II) complexes / GMP / DNA

The properties that are characteristic of TAP (1,4,5,8-tetraazaphenanthrene) and HAT (1,4,5,8,9,12-hexaazatriphenylene) Ru^{II} complexes under illumination are highlighted and compared with those of other metallic complexes. In particular, the photo-oxidizing power of their ^{3}MLCT states leads to a quenching of luminescence accompanied by a photoreaction when they are in presence of nucleic acids. The proton-coupled photoinduced electron transfer with the guanine nucleobases produces metallic adducts on DNA guanine units. The mechanism of formation, structure, and possible applications of these photoadducts are discussed and compared with other DNA metallic adducts currently in the literature.

Introduction

During the last 15 years, transition-metal complexes have been extensively studied in the presence of nucleic acids. The interest focused on these complexes stems mainly from their photophysical and photochemical properties, which can be easily tuned by the type of ligands and nature of the metallic centre. The platinum complexes such as *cis*-$[PtCl_2(NH_3)_2]$, known as cisplatin, and its derivatives are well-known examples of metallic compounds that have been widely applied in anticancer chemotherapy.[1−4] They have turned testicular cancer into a curable disease. The activity of these platinum complexes against a variety of cancers is

Romain Blasius was born in 1976 in Luxembourg. In 1995 he moved to the Université Libre de Bruxelles (Brussels, Belgium), where he received his BSc degree in chemistry in 1999. He then went on to complete his Ph.D. studies under the supervision of A. Kirsch and C. Moucheron in the area of photochemistry and photophysics of transition metal complexes with DNA and received his Ph.D. in 2003. He subsequently moved to the Laboratoire de Biologie Moléculaire et Cellulaire du Cancer in Luxembourg, where he is currently carrying out his research on the resistance of cancer cells towards chemotherapeutic drugs and the inhibition of this resistance through the use of natural compounds.

Cécile Moucheron was born in 1966 in Leuven. She received her doctoral degree in 1992 at the Université Libre de Bruxelles (ULB, Belgium) in the area of aromatic synthesis and coordination chemistry. She worked with Dr. J.-P. Sauvage on semicatenanes and copper(I) complexes at the Université Louis Pasteur in Strasbourg. She then joined the laboratory of photochemistry at the ULB. In 1994, she spent several months at the Université Joseph Fourier in Grenoble (UJF, France) where she contributed to research on new intercalating derivatives with Prof. J. Lhomme and Dr. M. Demeunynck. She continued her career as assistant professor at the ULB. From 2003, she was elected as Professor in the Department of Chemistry at the ULB. Her research includes the synthesis of polyazaaromatic complexes and their study with DNA or as antenna systems.

Andrée Kirsch-De Mesmaeker received her doctoral degree in 1972 at the Université Libre de Bruxelles (ULB, Belgium) in the area of photochemistry and electrochemistry. She subsequently moved to Germany at the Max Planck Institut für Strahlenchemie in Mülheim a.d. Ruhr to carry out post-doctoral research with Professor Schulte-Frohlinde and Dr von Sonntag on γ and pulsed radiolysis of sugar (1972−1974). She then moved to the University of North Carolina at Chapel Hill (USA) (1974−1975) where she contributed to research on dyes photochemistry with Dr. G. Wyman. Back at the ULB as FNRS researcher (Fonds National pour la Recherche Scientifique, Belgium), she performed research in photoelectrochemistry and has obtained an award from the Belgian Academy of Sciences. She continued her career as Director of Research at the FNRS and spent a sabbatical year at Columbia University in New York in 1989. From 1999 she was elected as full Professor in the Department of Chemistry at the ULB. Her current research includes photochemistry and photophysics of transition metal complexes with DNA.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

attributed to their reactivity with nucleic acids, mainly by substitution of their chloride ligands by water and ultimately by two adjacent guanines of DNA,[5,6] which results in covalent binding of the metallic species to the genetic material. However, treatment by these drugs leads to important toxic side effects. Therefore, there is still an urgent need for other metallic compounds that would be active mainly at the level of the genetic material and that could exhibit an equal or higher activity against other types of cancer but with a lower toxicity.

The use of a photoreactive metallic drug would be rather advantageous because the action of the drug could be triggered at a chosen time and at selected sites by using optical fibers. There is thus a motivation to develop metallic compounds that are photoreactive towards DNA. The illumination of metallic complexes that interact with DNA generally leads to cleavage (direct cleavage and a cleavage that is revealed by treatment with piperidine) or to the formation of photoadducts with a covalent bond between the metallic compound and a DNA base. These metallic photoadducts could play an important role in chemotherapy in the future, a role similar to that played by the Pt compounds. Some of them have indeed been shown to inhibit DNA replication or synthesis so that they may be regarded as potential antitumor drugs.[7]

In this review, we describe different mechanisms for the formation of metallic photoadducts with DNA and polynucleotides. The particular role played by the Ru^{II} complexes formed with the ligands TAP and HAT (TAP = 1,4,5,8-tetraazaphenanthrene, HAT = 1,4,5,8,9,12-hexaazatriphenylene, Figure 1) is highlighted. The Ru^{II} complexes can be used also as photoprobes of DNA structures or topologies, and for this particular aspect, the reader should refer to already published reviews.[8−14]

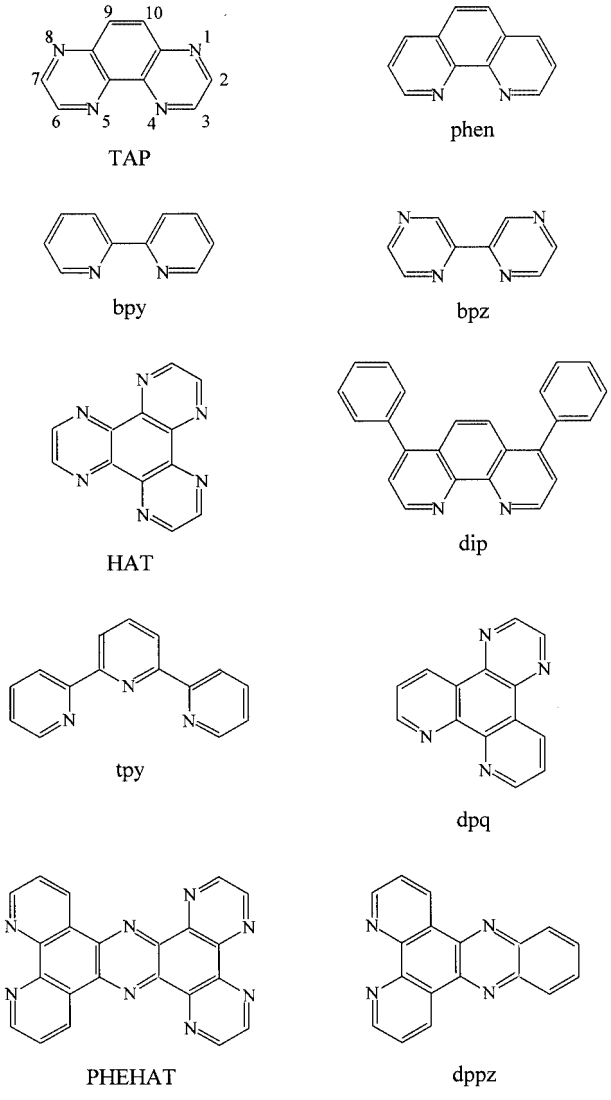

Figure 1. Structure of the different ligands

Different Types of Metallic Photoadducts with DNA

1. With Rhodium, Chromium, and Ruthenium Complexes. Photoadducts Formed by Ligand Substitution

Morrison's team has shown that irradiation of *cis*-dichlorobis(1,10-phenanthroline)rhodium(III) chloride (Figure 2) in the presence of 2′-deoxyguanosine (Figure 2) under aerobic conditions gives rise to the formation of a photoproduct in which the metal is bound to the N1 site of the deoxyguanosine (Figure 3, A); another photoproduct in which Rh^{III} is bound to the guanine either through the oxygen atom at C6 or the amino group at C2[15,16] is also formed. The illumination of the same starting complex, un-

der aerobic conditions, in the presence of calf thymus DNA leads to the identical photoadduct (linked through the N1 position of the guanine) that was isolated after enzymatic digestion of the nucleic acid.[15]

Under anaerobic conditions, illumination of the Rh^{III} complex in the presence of 2′-deoxyguanosine also forms a photoadduct, but in this case, the metal centre is linked to the N7 atom of the guanine moiety (Figure 3B).[17] Furthermore, this photoreaction (in the absence of oxygen) proceeds with a quantum efficiency greater than 1, which has been explained by a chain reaction initiated by a photoinduced electron transfer.[17] However, the irradiation of *cis*-dichlorobis(1,10-phenanthroline)Rh^{III} chloride in the presence of calf thymus DNA under anaerobic conditions leads to the same photoadduct as that detected in the presence of oxygen.[18]

The key step of the mechanism for the formation of these photoadducts is an electron transfer from the guanine base to the excited-state metal complex (step 2).[15,16]

$$cis\text{-}[Rh^{III}(phen)_2Cl_2]^+ \xrightarrow{h\nu} cis\text{-}[Rh^{III}(phen)_2Cl_2]^{+*} \quad (1)$$

$$cis\text{-}[Rh^{III}(phen)_2Cl_2]^{+*} + dG \longrightarrow cis\text{-}[Rh^{II}(phen)_2Cl_2] + dG^{\bullet+} \quad (2)$$

A chain reaction begins with the loss of one Cl^- ligand from the Rh^{II} complex (step 3). In the absence of oxygen, a subsequent reaction with the most nucleophilic site of dG leads to an N7−guanine adduct on the Rh complex (step 4). Another electron transfer (in the dark) between the Rh^{II} adduct and the starting dichloro complex completes the first turnover of this chain reaction and leads to the formation of the final Rh^{III} photoadduct under anaerobic conditions (step 5). Finally, the chain reaction is terminated by a back electron-transfer from the Rh^{II} intermediate species to $dG^{\cdot+}$ (step 6).

Under aerobic conditions, however, oxygen can kill the chain propagation by oxidising the *cis*-$[Rh^{II}(phen)_2Cl]^+$ species formed during step 3, with the simultaneous addition of a water molecule and production of a chloroaquo complex and a superoxide anion (step 4a).

The formation of this chloroaquo compound and its reaction with $dG^{\cdot}$ (obtained by chemical oxidation−deprotonation of the guanosine) finally leads to the adduct.[16] Different sites have been proposed for the radical position on the guanine; the localisation on N1 explains the structure of the *cis*-$[Rh^{III}(phen)_2(N1-dG)(OH_2)]^{3+}$ adduct formed under aerobic conditions. Coupling with the radical at either the oxygen atom at C6 or the amino group at C2 has been postulated to explain the unidentified adduct.

In conclusion, the preferential binding of *cis*-$[Rh^{III}(phen)_2Cl_2]^+$ to guanine moieties rather than other nucleobases is due to the initiation step of the chain reaction, i.e. a primary electron transfer from a base to the excited complex. This process occurs, of course, preferentially with a guanine because it is the nucleobase with the lowest reduction potential for the cation radical.

Interestingly, thanks to this Rh photoreactivity, irradiation of *cis*-dichlorobis(1,10-phenanthroline)rhodium(III) chloride in the presence of packaging RNA (which forms a hexameric complex to gear the DNA translocation process) leads to some crosslinking of this RNA.[18,19]

It has also been reported that [*cis*-$Cr(phen)_2Cl_2$] upon excitation with visible light in the presence of DNA leads to the covalent attachment of the metal.[20] This Cr complex also undergoes aquation, which originates from both thermal and photochemical pathways. The photochemical pathway stems again from an electron transfer from dG to the excited state metal complex, with the exchange of one or two Cl^- ligands.[20]

The photoreactivity of complexes such as $[Ru(tpy)(X)Cl]^+$ {tpy = 2,2′:6′,2′′-terpyridine; X = bipyridine (bpy), 1,10-phenanthroline (phen) and dipyrido[3,2-*a*:2′,3′-*c*]phenazine (dppz)},[21] has also been investigated in the frame of the search for novel photoreagents that are reactive towards DNA. When these Ru complexes are photolysed, the Cl^- ligand is easily substituted by a H_2O molecule, which leads to the aquaruthenium complex. This latter complex, like the Rh species, is reactive towards the DNA bases and forms a coordination bond with a heterocyclic nitrogen atom[22] of a nucleobase. The covalent binding of such aqua Ru complexes to DNA has been demonstrated by ultrafiltration, extensive dialysis and ethanol precipitation.[23,24] However, the reaction between $[Ru(tpy)(X)(H_2O)]^{2+}$ and double-stranded DNA proceeds with a rather poor yield ($[Ru]_{bound}$/[DNA-nucleotide] is approximately 0.02) because of the important steric hindrance due to the presence of the polypyridyl (X) ligands and the incoming reactive DNA base.[22]

2. The Ru^{II} Complexes Containing TAP and HAT Ligands

2a. Formation of Photoadduct by Substitution

In 1994 Lecomte et al. showed that $[Ru(TAP)_3]^{2+}$ can form photoadducts with AMP (adenosine 5′-monophosphate) by photosubstitution of one TAP ligand.[25] This

$$cis\text{-}[Rh^{II}(phen)_2Cl_2] \longrightarrow cis\text{-}[Rh^{II}(phen)_2Cl]^+ + Cl^- \quad (3)$$

$$cis\text{-}[Rh^{II}(phen)_2Cl]^+ + dG \longrightarrow cis\text{-}[Rh^{II}(phen)_2(N7\text{–}dG)Cl]^+ \quad (4)$$

$$cis\text{-}[Rh^{II}(phen)_2(N7\text{–}dG)Cl]^+ + cis[Rh^{III}(phen)_2Cl_2]^+ \longrightarrow cis[Rh^{III}(phen)_2(N7\text{–}dG)Cl]^{2+} + cis[Rh^{II}(phen)_2Cl_2] \quad (5)$$

$$cis\text{-}[Rh^{II}(phen)_2(N7\text{–}dG)Cl]^+ + dG^{\bullet+} \longrightarrow cis\text{-}[Rh^{III}(phen)_2(N7\text{–}dG)Cl]^{2+} + dG \quad (6)$$

$$cis\text{-}[Rh^{II}(phen)_2Cl]^+ + O_2 \xrightarrow{H_2O} cis\text{-}[Rh^{III}(phen)_2Cl(OH_2)]^{2+} + O_2^{\bullet-} \quad (4a)$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

photoreactivity is thus similar to that discussed above in which the initial chelation sphere around the Ru^{II} centre is transformed. The origin of this photoreactivity can easily be explained. It has been demonstrated (see later) that the ^{3}MLCT (metal to ligand charge-transfer) state of this complex is efficiently thermally activated to a ^{3}MC (metal-centred) state, which produces a rather high quantum yield of photodechelation (loss of a ligand under illumination).[26] Therefore, $[Ru(TAP)_3]^{2+}$ exhibits, under illumination, a higher probability of substitution of one of its TAP ligands by a DNA base than complexes with lower photodechelation quantum yields. The photoreactivity of this complex in the presence of AMP has been studied by UV/Vis absorbance and laser flash photolysis,[25] and it indicates the formation of $[Ru(TAP)_2(AMP)(X)]^{n+}$ (X = H_2O, Cl^-), which absorbs in the 500 nm region. It is important to note that such photosubstitution reactions are not observed with GMP as mononucleotide (see further for the explanation).

In conclusion, in the photoadducts described up to now in which a metal−nitrogen bond is formed, the chelation sphere around the metal centre is destroyed relative to that in the starting complex. This ligand substitution can be triggered either by a photoelectron transfer, as is the case for the Rh complexes, or by crossing from the ^{3}MLCT state to the ^{3}MC state at room temperature, as observed with $[Ru(TAP)_3]^{2+}$ in the presence of AMP.

2b. Formation of a New Type of Photoadduct

Quite different photoadducts were seen for the first time when analyses of the illuminated solution of $[Ru(TAP)_3]^{2+}$ in the presence of ^{32}P-labeled oligonucleotides were performed by denaturing polyacrylamide gel electrophoresis (PAGE). These PAGE experiments exhibit the unexpected appearance of bands of lower mobility than the starting 5′-^{32}P-labeled single-stranded oligomer,[27,28] whereas $[Ru(phen)_3]^{2+}$ or $[Ru(bpy)_3]^{2+}$ lead to photoinduced strand breaks by a mechanism involving singlet oxygen.[29,30] The slower bands were attributed to covalent photoadducts of $[Ru(TAP)_3]^{2+}$ with the oligonucleotide. Interestingly, such low mobility bands have also been observed with $[Ru(TAP)_2(bpy)]^{2+}$, but not with $[Ru(bpy)_2(TAP)]^{2+}$.[27] Further evidence for photoadduct formation was obtained by dialysis experiments coupled with detection by UV/visible spectroscopy.[28] The absorption spectrum indicates that the photoproduct cannot originate from dechelation/substitution, as discussed in Section 2a of this article, because no increasing absorption is detected around 500 nm, but a strong hypsochromic shift with a hyperchromic effect appears in the 350−400 nm region. The same spectral changes appear after illumination of $[Ru(TAP)_3]^{2+}$ in the presence of GMP, and are thus different from those described above in the presence of AMP.

Further evidence for the formation of a new type of photoadduct is furnished by electrospray mass spectrometry (ESMS).[31,32] Strong peaks corresponding to $[M - 2H - 2PF_6^-]^{2+}$ and $[M - 2H - PF_6^-]^+$, where M = [Ru(TAP)$_3$(PF$_6$)$_2$ + guanine or + guanosine monophosphate], are typical of the mass of the purified adduct as the PF_6^- salt, isolated after illumination of $[Ru(TAP)_3]^{2+}$ in the presence of GMP or $[Ru(TAP)_2(bpy)]^{2+}$ and DNA after hydrolysis of the DNA.[32] Thus, the results show that in the photoadduct, the chelation sphere has remained intact and a covalent bond between one of the ligands of the Ru complex and guanine is formed with the simultaneous loss of two hydrogen atoms.

In 1997, Vicendo et al. showed by ICP (inductively coupled plasma) and absorption spectroscopy that $[Ru(bpz)_3]^{2+}$ (bpz = 2,2′-bipyrazine) also forms photoadducts with calf thymus DNA[33] and dGMP. Spectroscopic changes similar to those described with the TAP complexes, appear after illumination of $[Ru(bpz)_3]^{2+}$ in the presence of DNA or dGMP. Subsequently, the same research team confirmed the occurrence of a photoadduct by gel electrophoresis experiments performed on illuminated $[Ru(bpz)_3]^{2+}$ with single- and double-stranded oligonucleotides.[34]

Quite recently, photoadduct formation has also been detected by visible illumination of $[Ru(HAT)_2(phen)]^{2+}$ in the presence of GMP, calf thymus DNA and synthetic oligonucleotides.[35] ESMS analyses of the isolated photoproduct with GMP confirms the addition of one GMP to the Ru complex, without loss of the polyazaaromatic ligands. Furthermore, photoadduct formation with $[Ru(HAT)_2(phen)]^{2+}$ appears only with guanine-containing synthetic oligonucleotides,[35] as shown by gel electrophoresis experiments.

In conclusion, TAP, HAT, and bpz Ru^{II} complexes containing at least two such ligands form photoadducts with GMP or G-containing polynucleotides that are quite different from those formed with Pt, Rh or other Ru complexes.

Mechanism for Formation of the New Photoadducts

In order to provide evidence for the primary processes responsible for the formation of the photoadducts, photophysical and redox properties of these particular complexes have to be considered. Figure 4 represents the classical photophysical scheme proposed for most Ru^{II} complexes with three bidentate ligands such as $[Ru(bpy)_3]^{2+}$.[36,37] Illumination of such polyazaaromatic complexes leads to the population of a ^{1}MLCT state, which deactivates rapidly

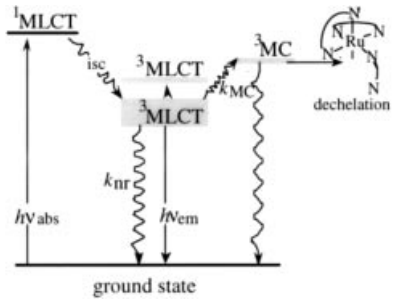

Figure 4. Photophysical scheme for $[Ru(bpy)_3]^{2+}$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(less than 1 ps) by intersystem crossing to a ^{3}MLCT state with a quantum yield of unity.[38] This ^{3}MLCT state can deactivate radiatively (k_r), giving rise to the emission of the complex, or nonradiatively (k_{nr}). A conversion into a higher ^{3}MC state can also take place by thermal activation from the ^{3}MLCT. The ^{3}MC state can either deactivate nonradiatively or lead to dechelation (the loss of one polyazaaromatic ligand). This process is important for $[Ru(TAP)_3]^{2+}$ and is responsible for the formation of the first type of photoadduct with AMP, as discussed in section 2a.

The emission and the excited state lifetime associated with the ^{3}MLCT state strongly depends on the environment. Generally, the interaction of such compounds with polynucleotides leads to an increase in the luminescence intensity and lifetime. This effect is attributed to the protection of the metallic complex by the DNA hydrophobic environment (protection from water and oxygen quenching). However, the behaviour of TAP or HAT complexes that contain at least two or three TAP (or HAT) ligands (thus with $[Ru(bpy)_n(TAP/HAT)_{3-n}]^{2+}$ when $n = 0$ or 1) is different. Instead of a luminescence enhancement, a luminescence quenching appears in the presence of CT-DNA and poly(dG-dC)$_2$[27,39,40] (see also Figure 5 for $[Ru(HAT)_2(phen)]^{2+}$). The emission is thus quenched by G-C containing polynucleotides. As described below this quenching is due to a photoelectron transfer. In Table 1 we have presented the results on the effect of increasing polynucleotide concentrations on the luminescence of different Ru^{II} complexes.

An emission quenching for the same complexes also appears in the presence of mononucleotides. Large quenching rate constants of luminescence (of the order of 10^9 M^{-1}·s^{-1}) by GMP are characteristic of complexes containing two or three TAP (or HAT) ligands, whereas the other complexes exhibit extremely weak or no quenching at all by GMP.

Actually, the ruthenium(II) complexes containing at least two π-deficient ligands (TAP or HAT) with low-lying unoccupied molecular orbitals centred on the ligand are strongly oxidising in their ^{3}MLCT state.[41] Therefore, this excited

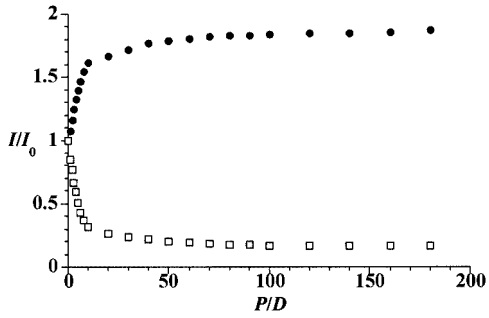

Figure 5. Effect of the polynucleotide/dye (P/D, D = ruthenium complex) ratio on the emission intensity of $[Ru(HAT)_2(phen)]^{2+}$; [Ru] = 5.2×10^{-5} M in 10 mm TRIS buffer; the excitation has been performed at 410 nm; I = emission intensity in the presence of the polynucleotide; I_0 = emission intensity in the absence of the polynucleotide; solid circles: effect of [poly(dA-dT)]$_2$. open squares: effect of DNA

species can abstract one electron from a guanine unit of DNA or GMP. The oxidising power can be estimated from the reduction potentials of the ground state and the energy of the emission maximum ($\Delta E_{\lambda_{max}}$) (Table 2):

$$E_{red}^* \approx E_{red} + \Delta E_{\lambda_{max}}$$

Taking into account the oxidation potential of GMP (E_{ox} = +0.92 V vs. SCE[11] or +1.35 V vs. SCE[42]) it is concluded that depending on the value, the excited complexes may or may not be able to oxidise GMP.

The plot of the logarithms of the quenching rate constants (k_q in water) as a function of the reduction potential of the excited state of different TAP and HAT complexes in MeCN (Figure 6) gives a curve typical of quenching by electron transfer; one where a plateau value is reached, and which corresponds to the diffusion rate constant. Actually, it has been demonstrated for some complexes that the electron transfer is coupled to a proton transfer in water,[43] as evidenced from a decrease in k_q from H_2O to D_2O. This

proton coupling could explain the appearance of quenching by electron transfer, even with an oxidation potential value for GMP as positive as +1.35 V/SCE.

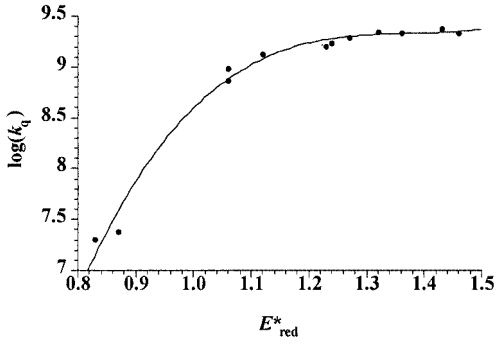

Figure 6. Plot of $\log(k_q)$ in water as a function of the estimated reduction potentials of the excited complexes (E^*_{red}) in MeCN; k_q = luminescence quenching rate constant

The electron transfer generates an oxidised $GMP^{\cdot+}$ species and a reduced complex $[Ru(L_2)(L^{\cdot-})]^+$ (the percentage of protonated reduced species depends on the pH). If instead of GMP, AMP is present, the excited ^{3}MLCT state cannot be quenched reductively, therefore its thermal crossing to the ^{3}MC state is possible and is accompanied by the loss of a TAP ligand and by a possible substitution by AMP (see section 2a).

The presence of an electron-transfer process with guanine units was demonstrated by laser flash photolysis experiments. The monoreduced complex and monooxidized GMP could be detected after the laser pulse.[40,44]

$$[Ru(L)_3]^{2+*} + GMP \rightarrow [Ru(L)_2(L^{\cdot-})]^+ + GMP^{\cdot+}$$
$$[Ru(L)_2(L^{\cdot-})]^+ + GMP^{\cdot+} \rightarrow [Ru(L)_3]^{2+} + GMP$$

The differential transient absorption measured at about 500−550 nm, characteristic of the absorption of the monoreduced complex, disappears according to a bimolecular, equimolecular process in the absence of oxygen, which indicates the presence of a back electron-transfer process in a few hundred μs. In the presence of oxygen, the decay of the transient at the same wavelength becomes pseudo-monomolecular and takes place in a few ten μs, due to the reoxidation of the reduced complex by oxygen. The remaining absorption still present after this decay corresponds to the absorption of the deprotonated radical cation of $GMP^{\cdot+}$. By flash photolysis experiments with DNA, a transient absorption at the same wavelength could also be observed; however, the amplitude of the decay is too small to perform a kinetic analysis of the signal, which indicates that the back electron-transfer is faster with DNA than with GMP. Moreover, the signal does not decay to zero but to a permanent absorption corresponding to that of the photoadduct.

In conclusion, the results with the mononucleotides and polynucleotides highlight a correlation between the reduction potential of the excited complex (thus the oxidation power of the excited state), the proton-coupled photoinduced electron transfer from guanine units, and the formation of photoadducts. Thus, the latter could result from the reaction of the intermediate radicals produced by the electron transfer. Determination of the structure of the photoadduct is a key element, which allows the confirmation of this conclusion.

Structure of the New Photoadducts

The determination of the structure of the photoadducts formed between the TAP and HAT complexes and GMP was performed mainly by NMR spectroscopy, first with the system $[Ru(TAP)_3]^{2+}$ and GMP.[31] From the integration of the different peaks in the NMR spectra, two protons are missing relative to the spectrum of one equivalent of $[Ru(TAP)_3]^{2+}$ and one equivalent of GMP. This indicates that the photoadduct, as concluded from the ESMS data, contains the starting complex plus one GMP, minus two H. One of the missing hydrogen atoms corresponds to that on position 2 of the TAP ligand (see Figure 1 for the numbering), which indicates the formation of a covalent bond between the position 2 of TAP and a guanine moiety. This is in agreement with the chemical shift of proton 3 of TAP, which is induced by this addition.[31] The other hydrogen atom missing belongs to the exocyclic amine (position 2 on GMP); the signal for the remaining amine proton is shifted downfield by δ = 5 ppm relative to that for the exocyclic amine protons of the free guanine. Thus, the covalent bond with the TAP ligand is formed with the exocyclic N atom of the guanine.[31] The structure of this photoadduct, as deduced from the NMR-COSY spectrum and the above arguments, is depicted in Figure 7.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

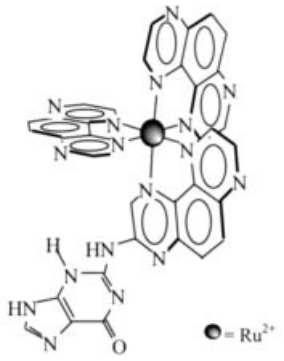

Figure 7. Structure of the photoadduct formed after illumination of $[Ru(TAP)_3]^{2+}$ in the presence of GMP; the structure shown corresponds to the photoadduct after acid hydrolysis to remove the sugar-phosphate moiety

The structure of the photoadduct formed between $[Ru(TAP)_2(bpy)]^{2+}$ and CT-DNA has also been studied. In that case, CT-DNA was hydrolysed or digested by enzymes after illumination.[32] The NMR spectrum obtained corresponds to a mixture of two products, i.e. two geometrical isomers (Figure 8), the covalent bond forms with the exocyclic-N of the guanine residue.[32] This was confirmed by mass spectrometry data that showed a fragmentation product corresponding to $[Ru(TAP\text{-}NH_2)(TAP)(bpy)]^{2+}$.

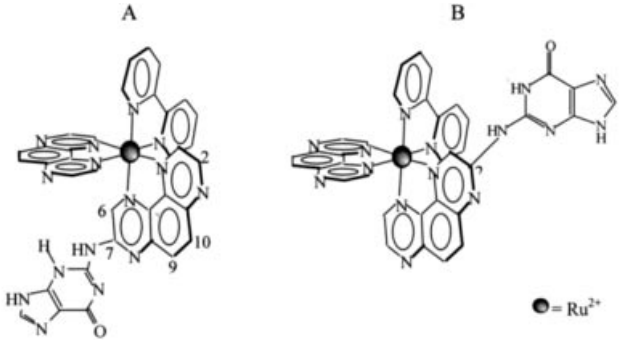

Figure 8. Structure of the two geometrical isomers for the photoadducts formed after illumination of $[Ru(TAP)_2(bpy)]^{2+}$ in the presence of CT-DNA; the structures have been obtained after enzymatic digestion and acidic treatment of CT-DNA

More recently, the structure of the photoadducts between a HAT-containing complex, i.e. $[Ru(HAT)_2(phen)]^{2+}$ and GMP, was examined.[35] In this case, two geometrical isomers were also detected from the NMR spectroscopic data, as with $[Ru(TAP)_2(bpy)]^{2+}$. However, a difference appears at the level of the protons of the guanine moiety, which suggests that the covalent bond with the HAT ligand is formed, in this case, with the O6 atom of the guanine unit. The difference in the structures of the photoadducts with the HAT and TAP complexes (i.e. addition at the O6 or at the exocyclic-N of the guanine unit) cannot be explained. With $[Ru(HAT)_2(phen)]^{2+}$ illuminated in the presence of GMP, in addition to the two geometrical isomers mentioned above, two supplementary photoadducts were detected by ESMS analyses :(i) a photoproduct containing a supplementary oxygen atom, which could correspond, for example, to the addition of an 8-oxoguanosine monophosphate to the complex; and (ii) a photoproduct not involving a 1:1 stoichiometry, i.e. a biadduct corresponding to the addition of two guanosine monophosphate moieties to one ruthenium(II) complex.[35] The structure of these species has not yet been determined.

On the other hand, the origin of the structures of the photoadducts with one GMP can be explained on the basis of the proton-coupled photoinduced electron transfer,[40,44] i.e.:

$$[Ru(TAP/HAT)_2phen]^{2+}* + GMP \rightarrow \{[Ru(TAP/HAT)(phen)(TAPH^{\cdot}/HATH^{\cdot}]^{+},(GMP-H)^{\cdot}\}$$

The proton transferred to the $TAP^{\cdot -}$ or $HAT^{\cdot -}$ moiety can stem from the GMP radical cation. Indeed the radical cation of guanine has a pK_a of 3.9, $GMP^{\cdot +}$ [45–47] thus deprotonates at pH 7 to give a guanine radical. Monoreduced $[Ru(TAP)_3]^{2+}$ has a pK_a of 7.6, which means that it should be protonated after electron transfer.[44] Similar pK_a values can be expected for complexes like $[Ru(TAP)_2(bpy)]^{2+}$ and $[Ru(HAT)_2(phen)]^{2+}$. In conclusion, the coupling of the two radical species resulting from the proton-coupled electron transfer, followed by rearomatisation, could explain the formation of the isolated photoadducts (reactions 7 and 8).

The formation of photoadducts with nucleic acids should obviously be preceded by the interaction of the two partners. The question which may be raised is whether the geometry of interaction of the complexes with the polynucleotides would play an important role in photoadduct formation.

Actually, it has been shown that $[Ru(TAP)_3]^{2+}$ and $[Ru(TAP)_2(bpy)]^{2+}$ [27,48] bind to the surface DNA grooves and interact with a rather low affinity (10^3-10^4 M^{-1}). In contrast, $[Ru(HAT)_2(phen)]^{2+}$, as probed by monitoring of the spectroscopic changes of the complex while interacting with DNA and by DNA viscosity measurements, intercalates one of its HAT ligands between the stacking of bases, and its affinity for the polynucleotides reaches $3.8 \cdot 10^5$ M^{-1}.[35] We may thus conclude that both geometries of interaction, adsorption or intercalation, produce photoadducts since they are detected in both cases.

Applications

One major disadvantage of metallic complexes that react in the dark with DNA, like cisplatin, or that photoreact

$$\{[Ru(TAP)(phen)(TAPH^{\bullet})]^{2+},GMP(-H)^{\bullet}\} \longrightarrow [Ru(TAP)(phen)(TAPH\text{-}GMP(-H))]^{2+} \quad (7)$$

$$[Ru(TAP)(phen)(TAPH\text{-}GMP(-H))]^{2+} \xrightarrow{-2H} [Ru(TAP)(phen)(TAP(-H)\text{-}GMP(-H))]^{2+} \quad (8)$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with DNA, like the TAP and HAT complexes, is their non-specificity of (photo)reaction. Indeed, they do not interact with a specific targeted gene, thus a specific base sequence. This represents a drawback if the expression of this sequence has to be inhibited by using the Ru complex as DNA photoreagent. The antigene or antisense strategies are well-known to provide means to inhibit such genes. Unfortunately, after hybridization with the synthetic oligonucleotide, the system formed (double helix for the antisense and triple helix for the antigene strategy) is recognised by the enzymes and destroyed. Many efforts have been focused on different possible ways of increasing the stability of the pairing of the synthetic oligonucleotide with the targeted sequence. In this context, the use of synthetic oligonucleotides derivatised by photoreactive Ru^{II} complexes could be promising as one can take advantage of the formation of the photoadduct on the nucleobases. This strategy has been developed with complexes that show the two types of photoadducts (without and with destruction of the chelation sphere), thus (i) with the TAP complexes and (ii) with the precursors of aqua complexes. (i) A photoreactive TAP complex is chemically anchored to an oligonucleotide with a sequence complementary to the sequence of the targeted gene. After hybridization of the Ru^{II}-labeled sequence to the target sequence, and after illumination of the attached complex, the formation of the photoadduct can be "directed" towards a specific guanine unit of the target strand. Such a photoreaction should result in the photocrosslinking of the two strands and could inhibit the expression of the specific gene. The existence of such photocrosslinkings was demonstrated by gel electrophoresis with $[Ru(TAP)_2(dip)]^{2+}$ (dip = 4,7-diphenylphenanthroline) tethered on different probe sequences (Figure 9).[49−53] Moreover, it was shown that enzymes such as DNA polymerase and exonuclease III are blocked at the level of the photocrosslinking.[54] Thus, a 17-*mer* Ru^{II}-labeled oligodesoxyribonucleotide was hybridised to its complementary sequence located on the 5′-side of a 40-*mer* matrix. After illumination, the elongation of a 13-*mer* DNA primer hybridised to the 3′-end of the same matrix stopped at a position corresponding to the formation of the photoadduct with an efficiency of 100%.

(ii) On the other hand, oligonucleotide conjugates bearing a Ru^{II} complex such as $[Ru(tpy)(dppz)(CH_3CN)]^{2+}$ (tpy = 2,2′:6′,2″-terpyridine)[22] have also been tested. This complex, chemically attached to a probe sequence, can lead to successful crosslinkings with the complementary sequence. Actually, the attached $[Ru(tpy)(dppz)(CH_3CN)]^{2+}$ is simply transformed under illumination into the corresponding aqua complex $[Ru(tpy)(dppz)(H_2O)]^{2+}$ which reacts (dark reaction) with a base unit of the complementary strand.

It should be stressed at this stage that the use of the above complexes in the frame of the antisense strategy would be limited to treatments of specific cancer cells in dermatology or hematopoietic cells that can be illuminated outside the patient. Indeed the visible light (in contrast to IR wavelengths) does not penetrate deeply in tissues, which would prevent an efficient treatment. However, it should be noted

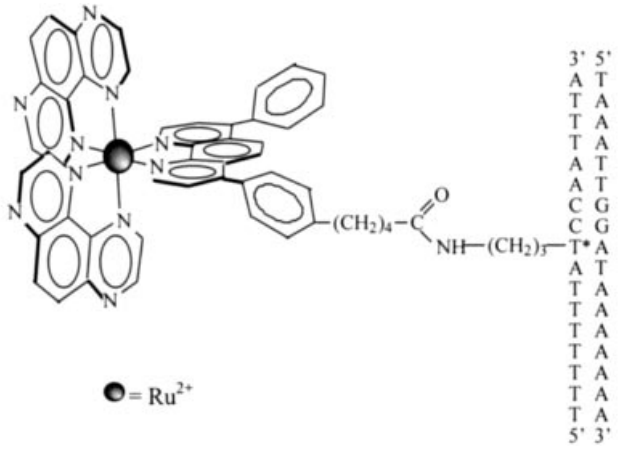

Figure 9. $[Ru(TAP)_2(dip)]^{2+}$-labeled oligonucleotide in the presence of its complementary sequence

that the recognition of a target nucleotidic sequence by an oligonucleotide probe derivatized with a photoreactive complex, followed by photocrosslinking between the two strands as described above, could also be applied in biotechnology without problems with the visible illumination in this case.

Conclusions

In this review, we tried to highlight the properties brought about by π-deficient TAP or HAT ligands in the resulting Ru^{II} complexes. Thus the complexes with at least 2 of these ligands induce a photoinduced electron-transfer with the guanine bases of DNA, a process that generates an adduct between the two partners. In this photoadduct, the complex and the guanine species are attached by a covalent bond without destruction of the chelation sphere.

One could speculate on the important role which could be played in the future by these complexes. For example, as outlined above, the Ru derivatised oligonucleotides could be applied in biotechnology or for treatments of specific cancers in the frame of the antigene or antisense strategy, whose effect could be triggered by light. The important problem which remains to be solved is the penetration and transport of the photoreactive agent into the cell. Research, with this aim, is presently being carried out.

Channel Structures in a Simple Inorganic Salt − An Open Framework Formed through Structural Integration of Distinct Sodium Acetate and Sodium Perchlorate Domains

Arnaud Lavalette,[a] Geoffrey A. Lawrance,[b] Nathaniel W. Alcock,*[a] and Michael J. Hannon*[a]

Keywords: Channel structures / Microporous materials / Crystal engineering / Zeolite analogues

The novel mixed salt of sodium acetate and perchlorate reported herein, $Na_4(OAc)_3(ClO_4)$, has a distinctive lattice structure formed from sodium acetate planes linked together by sodium perchlorate cylinders. In total contrast to the component salts, the structure contains channels parallel to the *c* axis. The integration of the two molecular-level structural motifs of the two component salts thus leads to a supramolecular/macromolecular-level structure which is very different from those of the components. A template mechanism is implicated in the formation.

Introduction

The design of new porous materials is a field of much current activity driven by the plethora of applications based around zeolite chemistry.[1] Much of the work has focused on crystal engineering approaches based on organic ligands or metallo-organic coordination frameworks in which supramolecular assembly principles are extended to polymeric solid-state materials.[2] However, relatively simple inorganic salts can also be used to create porous materials - the encapsulation of fullerene molecules inside the pores of a silver nitrate framework is a particularly striking example.[3] We have fortuitously prepared a remarkable mixed inorganic salt of sodium acetate and perchlorate, which has a distinctive lattice structure containing porelike channels (that hold a small amount of disordered solvent), and we report this finding herein.

Results

The mixed salt $Na_4(OAc)_3(ClO_4)\cdot 0.25(MeOH)$ was obtained serendipitously in the course of our studies on aggregation of supramolecular units into larger polymeric solid-state arrays[4] during the attempted preparation of the Ag complex of a chiral bispyridylimine ligand.[5] A methanolic solution of 5-hydroxypyridine-2-carboxaldehyde and (*S*)-(−)-1,1′-binaphthalene-2,2′-diamine was heated at reflux and then treated with silver acetate. Following further heating, the solution was treated with excess sodium perchlorate. Crystals were observed 4 days after addition of diethyl ether. It appears that the presence of the organic ligand or its constituents are significant in this preparation (possibly by a templating/nucleating mechanism) as extensive attempts to prepare the material from mixtures of sodium acetate and perchlorate were unsuccessful, generally leading to the formation of either hydrated sodium acetate or sodium perchlorate. The crystal structure determination indicates that Ag is absent from the crystals.

A search of the Cambridge Crystallographic Database[6] indicates that the complex is the only known simple, mixed acetate-perchlorate salt. The crystal structure determination reveals a remarkable supramolecular structure in a large high-symmetry cell, and channels run through the structure parallel to the *c* axis (Figure 1). These channels are lined with inward-pointing methyl groups. The channel diameters are about 8 Å (H···H) and contain a small amount of highly disordered solvent.

The presence of the channels is particularly striking since the structures of neither of the individual component salts contain cavities: Structures of two polymorphs of anhydrous sodium acetate have been reported.[7] Both forms contain two-dimensional layers in which a sodium carboxylate framework is lined on each side by the acetate methyl groups. In each form, the sodium ions are six-coordinate and bound to one bidentate acetate and four unidentate acetate groups with Na−O distances in the range

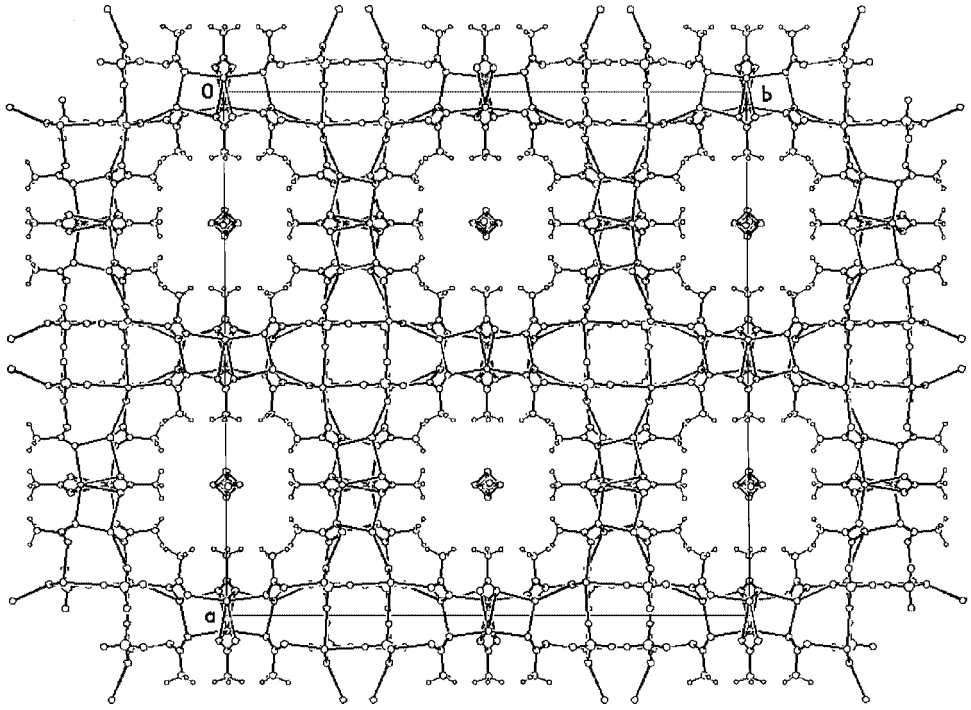

Figure 1. The $Na_4(OAc)_3(ClO_4).0.25(MeOH)$ structure viewed down the *c* axis, showing the channels through the structure

2.34−2.67 Å. Sodium perchlorate has orthorhombic symmetry and contains eight-coordinate sodium cations bound to two bidentate and four unidentate perchlorate ions with Na−O distances in the range 2.38−2.71 Å.[8] Above 581 K it undergoes a phase change and adopts a cubic structure (as NaCl) with rotating perchlorate anions.[9]

Inspection of the structure of the present mixed acetate-perchlorate salt reveals that the structure is made up of discrete domains of sodium acetate linked by domains of sodium perchlorate: the four sides of the channels are formed from planes containing six-coordinate sodium ions surrounded by acetate ions. The sodium atoms have two environments within these planes: one sodium atom [Na(1)] is bound to one bidentate acetate and four unidentate acetate groups (Na−O 2.36−2.56 Å), while the other [Na(3)] binds one bidentate and three unidentate acetate groups and its coordination sphere is completed by a unidentate perchlorate group (Na−O 2.34−2.80 Å) that links the planes to the sodium perchlorate domains. The structure of the planes is very similar to the two-dimensional layers in polymorph (I) of sodium acetate, but is approximately 8.5 Å in width (corresponding to three sodium atoms and three acetate groups) in one direction (rather than infinite).

These sodium acetate planes are held together by cylindrical sodium perchlorate domains that form the corners of the square channels and are very similar to the cubic phase of sodium perchlorate (without the perchlorate orientational disorder associated with that phase). The sodium [Na(2)] in this domain is bound to four perchlorate and two unidentate acetate groups to give an apparent coordination number of 6 (Na−O 2.39−2.50 Å). However two of the perchlorate groups form additional long contacts (Na−O 2.98 Å) and, if regarded as bidentate, increase the coordination number to eight. The different coordination spheres of the three types of sodium(I) centres in the structure are illustrated in Figure 2, and figures illustrating the structural similarities between the discrete domains and the corresponding bulk materials (sodium acetate and sodium perchlorate) are included in the Supporting Information.

The perchlorate domains act as four-way connectors linking linear sodium acetate planes into the grid-like framework. It is significant that this can be achieved without major distortions to the known structural motifs of the individual salts. While the molecular-level structures are retained, their integration gives rise to a very different (cavity containing) supramolecular-level structure from the components. Although open-frame network structures have been prepared by combining ligands and metals,[2] and ligands and salts,[1] this appears to be the first example in which discrete salt domains are linked by other discrete salt domains to give rise to such structures.

Although a serendipitous finding, the structure herein represents a remarkable example of a porous network assembled from very simple inorganic components. Guest-framework interactions have previously been identified as key factors in the creation of porous materials from simple inorganic salts. For example, silver···fullerene interactions appear significant in the formation of the remarkable fullerene-encapsulated silver nitrate network mentioned above.[3] However, no such interactions seem to be at work herein (indeed the solvent is disordered, consistent with a lack of specific interactions, and the channels only partially occupied). Nevertheless, the inability to recreate the network simply by mixing the individual components implicates

some form of templated nucleation in its formation. Indeed the size of cavity is defined by the length of the sodium acetate domains, which the template nucleation might affect or determine. Organic ligands and metal complexes have been used to direct formation of open-framework structures;[10] however, the template is usually included in the resulting structure. We can also suggest a relationship between the formation of this unusual structure and the nucleation of simple inorganic salts to afford complex and differing structures, which is a common theme in biological systems, particularly with regard to biomineralisation of calcium phosphate and carbonate salts, and which has also been exploited in chemical systems.[11]

CCDC-230080 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information (see also the footnote on the first page of this article): Figures illustrating the structural similarity between the discrete domains and the corresponding bulk materials (sodium acetate and sodium perchlorate), synthetic and crystallographic experimental details.

New Ruthenium Complexes with 4-(1*H*-Pyrrol-1-yl)-Substituted Polypyridine Ligands − Electrochemical and Spectroscopic Properties

David Martineau,[b] Philippe Gros,*[a] Marc Beley,*[b] and Yves Fort[a]

Keywords: Nitrogen heterocycles / Ruthenium / N donor ligands

Three new pyrrole-containing ligands and their ruthenium complexes have been prepared. The pyrrole ring bound by nitrogen to pyridine was found to significantly modify photophysical and electrochemical properties compared to parent bi- and terpyridines.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The design of new ruthenium(II) complexes that are able to harvest light and turn it into electricity has been the focus of many research works for the development of organic solar cells or luminescence sensors.[1] The nature of the ligands around the metal has been found to play a crucial role during the energy conversion process. Particularly, modification of the classically used bpy and tpy ligands with electron-donor substituents have been found to dramatically improve the absorption in the visible region, which is necessary for sunlight collection. Studies dealing with the effect of several substituents on bipyridines (bpy) in the $Ru(bpy)_3^{2+}$ series revealed that the highest values for $\lambda_{max.}$ were obtained with dimethylamino groups.[2] Moreover, the introduction of a 2-thienyl moieties at the 4′-position in terpyridine (tpy) also led to efficient visible light absorption.[3] From these data, the binding of a nitrogen-containing electron-rich ring such as pyrrole could be expected to tune the photophysical and electrochemical properties of the corresponding complexes. Herein, we report on the preparation of the new homoleptic ruthenium complexes **4a**, **5a** and **7a** from 4-(1*H*-pyrrol-1-yl)pyridine-containing ligands and on the study of their photophysical and electronic properties.

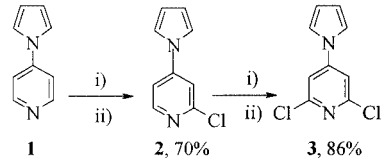
Results and Discussion

Synthesis

We first synthesized the C-2 chlorinated precursors **2** and **3** needed for further organometallic couplings (Scheme 1). The electron-releasing effect of the pyrrole moiety was exploited to selectively direct lithiation at the position alpha to the pyridine nitrogen atom,[4] thus allowing for introduction of the halogens in high yield. An efficient iterative lithiation of compound **2** afforded the expected 2,6-dichloro derivatives **3** (Scheme 1).



1 **2**, 70% **3**, 86%

Scheme 1. Preparation of **2** and **3**: i) BuLi/$Me_2N(CH_2)_2OLi$ (3 equiv.), toluene, −78 °C, 1 h; ii) C_2Cl_6 (3.5 equiv.), toluene, −78 °C to room temperature

The symmetrical ligand **4** was then prepared efficiently by nickel-catalysed homocoupling of **2**, while **5** and **7** were obtained by Stille cross-coupling of 2-(tributylstannyl)pyridine with **2** and **6**, respectively (Scheme 2).[5] Attempts to obtain **7** by a one-pot coupling remained limited to the formation of compound **6**, and the two-step procedure was preferred for the formation of **7** in an acceptable 50% yield after crystallization in ether.

We then turned our focus to the preparation of the corresponding homoleptic ruthenium complexes **4a**, **5a** and **7a** (Scheme 3). In our first attempts, stoichiometric proportions of the ligands classically reacted overnight with $RuCl_3(H_2O)_x$ in refluxing DMF. Unfortunately, incomplete incorporation of the ligands was observed leading only to complex mixtures. This is assumed to be a result of the pyr-

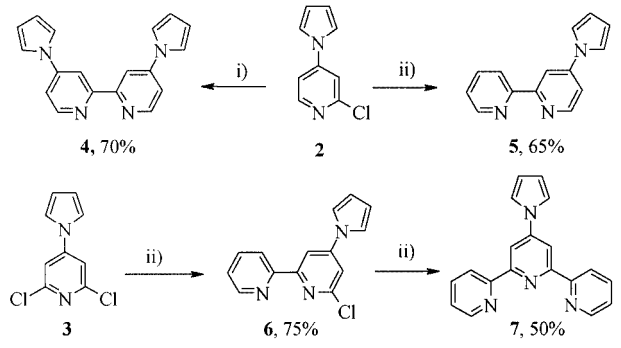
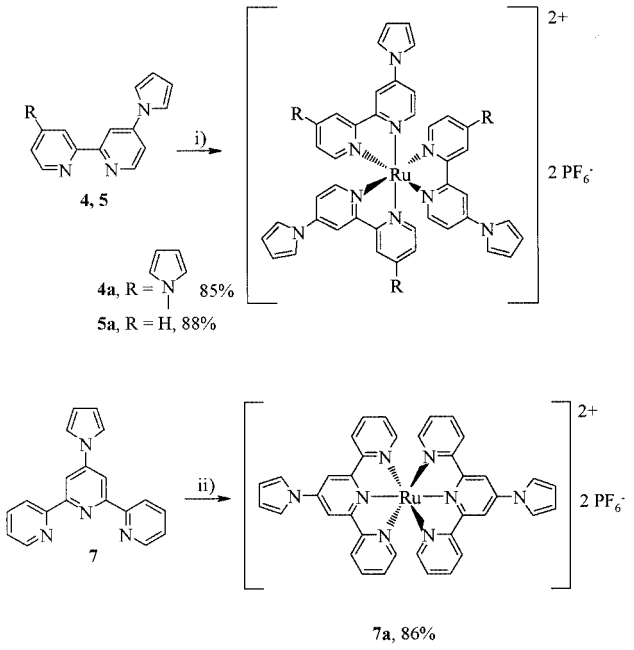


Scheme 2. Preparation of ligands **4**−**7**: i) $NiCl_2$ (1.1 equiv.), PPh_3 (4.4 equiv.), Zn (1.1 equiv.), degassed DMF, 50 °C, 1.5 h, ii) 2-(tributylstannyl)pyridine (1.1 equiv.), $[PdCl_2(PPh_3)_2]$ (5 mol %), PPh_3 (10 mol %), degassed xylene, reflux, 24 h



Scheme 3. Preparation of ruthenium complexes: i) $RuCl_3(H_2O)_x$ (0.33 equiv.), *N*-ethylmorpholine (2 drops), ethylene glycol, microwave irradiation, 200 °C, 5 min, ii) $RuCl_3(H_2O)_x$ (0.5 equiv.), *N*-ethylmorpholine (2 drops), ethylene glycol, microwave irradiation, 200 °C, 5 min

role-induced lower π-accepting power of the ligands. Indeed, the corresponding unsubstituted bpys and tpy are known to react smoothly under the same conditions leading to $[Rubpy_3]^{2+}$ and $[Rutpy_2]^{3+}$ complexes, respectively.[5] Complexation under microwave irradiation was then attempted (see Exp. Sect.). We were pleased to observe the formation of the target complexes **4a**, **5a** and **7a** in high yields after 3 min at 200 °C in ethylene glycol (Scheme 3).

Properties

Electrochemical and photophysical data of **4a**, **5a** and **7a** are reported in Table 1 and are compared with those of the corresponding parent complexes.

All complexes display a reversible Ru^{II} to Ru^{III} oxidation wave. No ligand reduction waves are detected for **7a**. This may be attributed to the formation of a nonconducting layer by adsorption at the electrode surface.[3b] An irreversible oxidation wave of the pyrrole moiety is distinctively observed only with complex **7a** at 0.8V, while overlap with the Ru^{III}/Ru^{II} oxidation wave is observed for **4a** and **5a**. The oxidation of pyrrole-containing complexes is observed at a less positive voltage than those of $[Rubpy_3]^{2+}$ and $[Rutpy_2]^{3+}$.

Comparison of the values obtained for **4a** and **5a** show that the introduction of a second pyrrole unit on the bpy ligand has a much lower effect than the introduction of the first unit. All these results indicate a significant destabilisation of the metal d orbital due to the electron-donor effect induced by the pyrrole substituent bound by the nitrogen atom to the pyridine ring. This property is also clearly evidenced by electronic transition spectra in acetonitrile. Indeed, all the MLCT absorptions in the visible region are red-shifted. Values for $\lambda_{max.}$ from 465 to 490 nm are observed; the larger effect is observed for complex **4a** bearing ligands with two pyrrole units. Electron-donor groups like pyrrol-1-yl destabilise the HOMO (π t_{2g}) metal orbital more than the LUMO (π^*) ligand orbital.[8] Consequently, both absorption and emission maxima of **4a**, **5a** and **7a** are shifted to longer wavelengths than those of $[Ru(bpy)_3]^{2+}$and $[Ru(terpy)_2]^{2+}$. For the same reasons the oxidation processes on **4a**, **5a** and **7a** occur with greater ease than those on their parent complexes. A consequence of the electron-donor effect is a $^3MLCT \rightarrow {}^3MC$ energy gap decrease,[9] and thus, the following order is obtained for quantum yields $\Phi_{\mathbf{5a}} < \Phi_{\mathbf{4a}} < \Phi_{[Ru(bpy)_3]^{2+}}$.

However, for **4a** and **5a** the reduction potentials are shifted to higher values than for $[Rubpy_3]^{2+}$. The corresponding stabilization of the LUMO (π^*) ligand orbital

does not correspond to an electron-donor effect. A possible explanation may be based on the fact that the observed electronic transitions involve the HOMO and the SLUMO (second lowest unoccupied MO) centred on the pyridine ring, whereas the electrochemical reduction processes involve the LUMO localised on the remote *N*-pyrrolyl group. Such an anomalous electrochemical and/or spectroscopic behaviour has been observed in the case of $[Ru(taphen)_3]^{2+}$(taphen = dipyrido[3,2-*c*:2′,3′-*e*]pyridazine).[10] On the taphen ligand, the LUMO is strongly localised on the −N=N− bridge between the two pyridine rings.

Also of high interest is the dramatic increase in the ε values induced by incorporation of the pyrrole units on the ligands in complexes **4a** and **7a**, while a surprising decrease is observed with **5a**. In the latter case, dissymmetry of ligand **5** allows for the formation of the *fac*- and *mer*-isomers of complex **5a**.[11] The expected strongly different dipole moments of the two isomers may be responsible for the decrease in the ε value. The incorporation of a second pyrrole on the bpy ligand induces a huge increase from 8600 in **5a** to 22200 $M^{-1}cm^{-1}$ in **4a**. For **7a**, the value (38400 $M^{-1}cm^{-1}$) is similar to that obtained with the complex $[Ru(tsite)_2]^{2+}$ (tsite = 4,4′,4′′-triphenyl-2,2′,2′′-terpyridine), which displays one of the highest known ε values (38400 $M^{-1}cm^{-1}$) in terpy complex series.[12]

Conclusion

In summary, we have prepared new homoleptic ruthenium complexes from bpy and tpy pyrrole-containing ligands. The electron-donor effect of the pyrrole moiety was clearly demonstrated by the lower Ru^{II}/Ru^{III} oxidation potential and by the significant red-shifted MLCT absorption and emission maxima relative to those of the unsubstituted ligands. The use of bpy ligands bearing two pyrrole units leads to a high ε value. These new complexes are promising for developing novel solar harvesting devices. Work is now in progress to investigate the electropolymerisation of the pyrrole moiety for preparation of new photosensitising materials.

Experimental Section

General Procedure for Preparation of Complexes 4a, 5a and 7a: The ligand **4** or **5** (0.19 mmol) or **7** (35.9 mg, 0.12 mmol) and $RuCl_3(H_2O)_x$ (15.7 mg, 0.06 mmol) were dissolved in ethylene glycol (5 mL) and *N*-ethylmorpholine (2 drops) was added. The reaction mixture was then placed into a synthesis microwave oven and irradiated at 200 °C (300 W) for 3 min. After cooling down to room temperature, a saturated aqueous solution of KPF_6 (25 mL) was poured into the glazing orange mixture. The resulting orange precipitate was filtered and washed with diethyl ether and toluene to remove uncomplexed ligands. The filter cake was then dissolved in a minimum amount of acetonitrile and poured into deionised water. After filtration and drying, complexes were obtained in almost quantitative yields. The complexes were characterized by ^1H NMR (CD_3CN) and mass spectrometry. Spectral data for complexes: **4a:** ^1H NMR (200 MHz, CD_3CN): δ = 8.51−8.74 (m, 6 H), 7.69−8.0 (m, 6 H), 7.53−7.65 (m, 12 H), 7.40−7.54 (m, 6 H), 6.30−6.73 (m, 12 H) ppm. MS (ESI): *m*/*z* = 1105.3 $[M - PF_6]^+$, 961.4 $[M - 2PF_6]^+$, 480.2 $[M - 2PF_6]^{2+}$. UV/Vis (CH_3CN): $\lambda_{max.}$ ($\varepsilon_{max.}$, $L \cdot mol^{-1} \cdot cm^{-1}$) = 480 nm (22200). **5a:** ^1H NMR (200 MHz, CD_3CN): δ = 8.58−8.82 (m, 3 H), 8.39−8.57 (m, 3 H), 7.98−8.22 (m, 3 H), 7.61−7.96 (m, 6 H), 7.25−7.60 (m, 12 H), 6.25−6.72 (m, 6 H) ppm. MS (ESI): *m*/*z* = 910.2 $[M - PF_6]^+$, 764.2 $[M - 2PF_6]^+$, 382.6 $[M - 2PF_6]^{2+}$. UV/Vis (CH_3CN): $\lambda_{max.}$ ($\varepsilon_{max.}$, $L \cdot mol^{-1} \cdot cm^{-1}$) = 465 nm (8600). **7a:** ^1H NMR (200 MHz, CD_3CN): δ = 8.79−8.97 (m, 4 H), 8.59−8.73 (m, 4 H), 7.92−8.09 (m, 4 H), 7.83−7.92 (m, 4 H), 7.44−7.54 (m, 4 H), 7.15−7.34 (m, 4 H), 6.58−6.78 (m, 4 H) ppm. MS (ESI): *m*/*z* = 985.3 $[M^+]$, 843.2 $[M - PF_6]^+$, 697.2 $[M - 2PF_6]^+$, 349.1 $[M - 2PF_6]^{2+}$. UV/Vis (CH_3CN): $\lambda_{max.}$ ($\varepsilon_{max.}$, $L \cdot mol^{-1} \cdot cm^{-1}$) = 490 nm (38500).

Palladium Complexes with Chiral Diphospholane Ligands: Comparative Catalytic Properties and Analysis of (η^3-Allyl)palladium Species

Grégory Malaisé,[a] Shailesh Ramdeehul,[a] John A. Osborn,*[a][†] Laurent Barloy,*[a] Nathalie Kyritsakas,[b] and Roland Graff[c]

Dedicated to the memory of Jean-Marc Kern

Keywords: Palladium / Allyl ligands / Reaction intermediates / Asymmetric catalysis / Enantioselectivity

The chiral diphospholane ligands Duphos (**1**) and Duxantphos (**2**), which can be differentiated by their bite angle, were applied to palladium-catalysed asymmetric reactions, essentially allylic alkylations with symmetrically (**3a**–**d**) or unsymmetrically (**5a**,**b**) substituted allylic acetates as substrates. The most interesting results were found with the first series of substrates in which **2** was more reactive and/or selective than **1**. The model complexes of the catalytic intermediates [Pd{(*S*,*S*)-**1**}(η^3-cyclohexenyl)](BF_4) (**10**) and *exo*-[Pd{(*R*,*R*)-**2**}(η^3-cyclohexenyl)](SbF_6) (**11**) could be characterised by X-ray crystallography. ^{1}H and ^{31}P NMR spectroscopic analyses of [Pd{(*R*,*R*)-**2**}(η^3-diphenylallyl)](SbF_6) (**12**) and [Pd{(*R*,*R*)-**2**}(η^3-allyl)](SbF_6) (**13**) revealed the presence of exchanging isomers in solution. Structural data provided by these techniques combined with the preferential rotation model led to a satisfactory interpretation of the catalytic allylic alkylation results. It appears that the bite angle plays a crucial role in the positioning of the proximal methyl groups, which determines the distribution of allyl isomeric intermediates and the balance between clockwise and anticlockwise rotations in the enantioselective step.

Introduction

Asymmetric palladium-catalysed reactions have attracted enormous interest over the past years, especially for allylic substitutions[1,2a] or the Heck reaction.[2b] Allylic alkylation is of considerable use in organic synthesis and proceeds smoothly under mild conditions. A large amount of work has been devoted to the design and synthesis of chiral ligands, with the aim of increasing the enantioselectivity of the catalysts. Very good asymmetric inductions have been achieved, most of them with the benchmark substrate 1-acetoxy-1,3-diphenylprop-2-ene, but also with sterically less demanding substrates such as 1-acetoxycyclohex-2-ene.[1,2a] Structural analyses of allyl palladium intermediates have been helpful in understanding the intimate steric and/or electronic grounds for enantioselectivity.[1a−1c,2a,3]

The catalytic properties of two chiral xanthene-derived ligands for use in allylic alkylations have been previously reported in the laboratory.[4] These ligands combine the advantages of having chiral phospholane donor groups, which have met with great success in catalysis,[5] and a wide bite angle. The advantages of large bite angle ligands in homogeneous catalysis are well known[6] and, furthermore, an increase of the P−Pd−P angle imposed by the ligand is likely to improve the control of allylic alkylation enantioselectivity through enhancement of the depth of the chiral pocket.[1b]

The purpose of this paper is to report a systematic comparison between one of these ligands, 4,5-bis[(2*R*,5*R*)-2,5-dimethylphospholanyl)]-9,9-dimethylxanthene, hereafter abbreviated (*R*,*R*)-Duxantphos [(*R*,*R*)-**2**], with the homologous bidentate, narrow bite angle ligand (*R*,*R*)-Duphos[5] [(*R*,*R*)-**1**] or its enantiomer (*S*,*S*)-**1**. This comparison relates to their application in palladium-catalysed asymmetric reactions and to the three-dimensional structural properties of their respective allyl palladium(II) complexes in order to rationalise their catalytic behaviour.

Results

Homogeneous Catalysis

The ligands Duphos (**1**) and Duxantphos (**2**) were first tested in palladium-catalysed allylic alkylation with the racemic allylic acetates **3**−**6** as substrates, the standard dimethyl malonate anion as the nucleophile and $[Pd(C_3H_5)Cl]_2$ as the palladium source. The results are shown in Table 1. All tests were run using ligands with the (*R*,*R*) configuration, except one (Entry 11). The nucleophile was generated from dimethyl malonate either using sodium hydride, or in situ with *N*,*O*-bis(trimethylsilyl)acetamide (BSA) and a catalytic amount of sodium acetate.

These results show interesting differences between **1** and **2** with regard to reactivity and selectivity. In general, the Pd catalyst is less reactive with ligand **1** than with ligand **2**. BSA does not appear to be an appropriate base for **1** (Entries 6, 9, 11), leading at best to low yields (0−30%). Quantitative yields are obtained only with NaH. On the contrary, the catalytic alkylation reactions are complete with ligand **2** whatever the base, solvent or temperature. Furthermore, with the cyclic substrates 1-acetoxycyclohex-2-ene (**3c**) or 1-acetoxycyclopent-2-ene (**3d**), the reactions are finished within very short time ranges (5−10 min, see Entries 10, 12−14).

With 1-acetoxy-1,3-diphenylprop-2-ene (**3a**) as substrate, both ligands give rise to high *ee* values which is also the case for a host of chiral ligands reported in the literature.[1] Under the same conditions, ligand **1** leads to a 97% *ee* in 4 h, whereas ligand **2** affords a faster reaction (1 h) but with a lower enantioselectivity (85% *ee*) (Entries 1 and 2). Although the configurations of **1** and **2** are the same [viz (*R*,*R*)], the configurations of the major enantiomer of product **4a** are the opposite. The *ee* value found for **1** is practically identical to that reported by Pregosin et al. (98%) for the same reaction run with (*R*,*R*)-**1** but with conditions slightly different from ours (BSA/CH_2Cl_2).[7] With ligand **2**, the *ee* could be increased to up to 97% by modifying the base and solvent and to a higher extent by lowering the temperature (Entries 3 and 4).

The difference between both diphospholane ligands with regards to enantio-differentiation is far more striking with the sterically less demanding substrates **3b**−**d**, with a marked superiority of **2** over **1**. Low enantiomeric excesses were observed using ligand **1** (5−10%, Entries 5, 8, 11). In contrast, ligand **2** affords high *ee* values with 2-acetoxypent-3-ene (**3b**) and 1-acetoxycyclohex-2-ene (**3c**) (75%, Entry 7 and 83%, Entry 10, respectively). The performance of ligand (*R*,*R*)-**2** in terms of enantioselectivity is similar to that previously reported under somewhat different reaction conditions.[4] The asymmetric induction is, however, less efficient (50−54% *ee*) when one switches to the cyclopentenyl substrate **3d** (Entries 12−14) but **2** still remains superior to **1**. Incidentally, the configurations of the major enantiomers of **4c** and **4d** are the same (*S*) with ligand **2**.

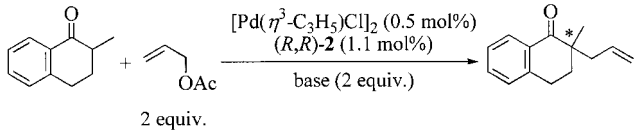
We were also interested in the regiochemical and stereochemical outcome of the alkylation by dimethylmalonate of unsymmetrically substituted allylic acetates, viz 2-acetoxy-4-phenylbut-3-ene (**5a**) and 3-acetoxy-2-methylhex-4-ene (**5b**), catalysed by palladium associated with the diphospholane ligands (Table 2). With substrate **5a** the conversion is always complete, but the reaction time strongly depends on the reaction conditions from 5 min (Entry 4) to 24 h (Entry 2). The nucleophile attacks overwhelmingly on the Me side of the allyl intermediate to yield **6a** as the major product, whatever the ligand. This is a general trend with this substrate,[8−10] due to delocalization of the C=C bond with the phenyl substituent. The *ee* values of **6a** are poor (3−16%), whereas they are far better for the minor regioisomer **7a** (up to 80%). This situation mirrors the predictions and experimental results reported by Norrby, Åkermark, Helquist et al. for the same substrate.[9] The differences between both ligands **1** and **2** are rather minor. Under the same conditions (BSA/CH_2Cl_2), Duphos (**1**) performs slightly better than Duxantphos (**2**) in terms of enantioselectivity (Entries 1 and 2), but the *ee* of **6a** can be improved to 16% with **2** using THF as the solvent (Entry 3). Substrate **5b** appears less reactive and it is necessary to use NaH as a base to achieve a good conversion (90%) with ligand **2**. Under the same conditions, ligand **1** is almost inactive (3% conversion in 24 h, Entry 5). Only one regioisomeric product, **6b**, was formed and no asymmetric induction was observed. Under our conditions, the allyl palladium intermediates derived from (*R*)-**5a**,**b** do not interconvert with those derived from (*S*)-**5a**,**b**. A powerful memory effect can therefore be expected which results in poor global *ee* values,[11] taking into account that allylic alkylation proceeds with overall retention of configuration and that the regioisomers **6a**,**b** are the overwhelmingly major catalysis products.[2a]

The good performance of ligand (*R*,*R*)-**2** with small substrates (vide supra) prompted us to carry out the alkylation of the simple allyl acetate (2 equiv.) with the prochiral nucleophile (1 equiv.) derived from 2-methyl-1-tetralone (Scheme 1).[12] However, the selectivity was disappointing. According to some of the experimental procedures of Trost and Schroeder,[13] we used LDA as a base either in THF or DME. Both experiments quantitatively afforded the allylation product, in 5 min and 1 h, respectively, but with a low enantioselectivity (12%). Replacement of LDA with the BSA/KOAc system only led to a 2% conversion in 24 h.



Scheme 1. Palladium-catalysed asymmetric allylic alkylation of allyl acetate with 2-methyl-1-tetralone

Finally, we tested the diphospholane ligands in another Pd-catalysed process, the benchmark asymmetric Heck reaction between phenyl triflate and 2,3-dihydrofuran (Scheme 2).[14] Ligand (*R*,*R*)-**2** associated with $Pd(OAc)_2$ as a palladium source led to very low yields and *ee* values [**8**: 5% yield, 12% *ee* (*S*); **9**: 5% yield, 2% *ee* (*R*)], whereas no reaction was observed under the same conditions with ligand (*R*,*R*)-**1**. With **2**, the Heck reaction with $Pd(DBA)_2$ instead of $Pd(OAc)_2$ gave racemic products in low yields (**8**: 3%; **9**: 8%).

Allylpalladium Complexes

In order to clarify how each of the chiral diphospholane ligands affects the stereochemical outcome of the catalytic reactions, we attempted to elucidate the three-dimensional structures of some cationic allyl palladium catalytic intermediates through solid-state (crystallography) and/or solution (NMR) studies. For this purpose, a series of cationic (η^3-allyl)palladium complexes (**10**−**13**) was synthesised in acceptable to very good yields (55−93%) according to a classical procedure. Abstraction of Cl^- from the chloride-bridged dimer $[Pd(\eta^3\text{-}C_6H_9)Cl]_2$ with $AgBF_4$ or $AgSbF_6$, followed by addition of (*S*,*S*)-**1** or (*R*,*R*)-**2** afforded the cyclohexenyl complexes **10** and **11**. Complexes **12** and **13** were obtained in a similar way from (*R*,*R*)-**2**, starting from $[Pd(\eta^3\text{-}Ph_2C_3H_3)Cl]_2$ or $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$. The synthesis, NMR analysis, and X-ray structure of the related compound [Pd{(*R*,*R*)-Duphos}(η^3-1,3-diphenylallyl)](CF_3SO_3) have been reported by Drago and Pregosin.[7]

Crystallographic Studies

Single-crystals of **10** and **11** suitable for X-ray diffraction analyses were obtained from slow liquid-phase diffusion of *n*-heptane and vapour-phase diffusion of pentane, respectively, into a dichloromethane solution of the complex. The X-ray crystallographic structures are depicted in Figures 1

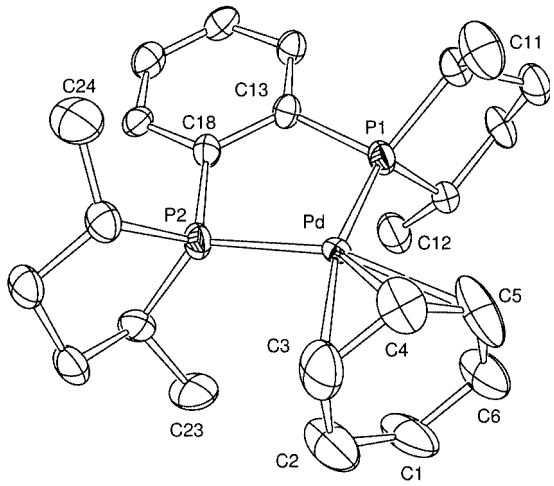

Figure 1. ORTEP drawing of [Pd{(*S*,*S*)-Duphos}(C_6H_9)](BF_4) (**10**) showing 30% probability thermal ellipsoids and the atom-numbering scheme; hydrogen atoms and the BF_4^- anion have been omitted for clarity

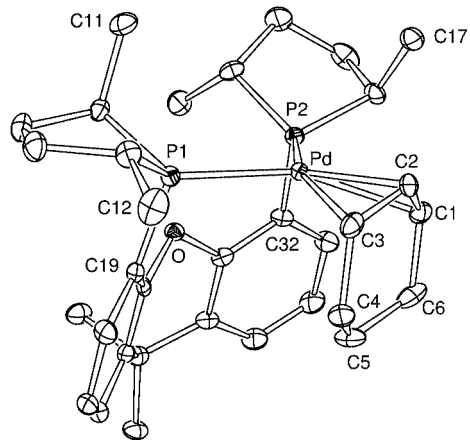

Figure 2. ORTEP drawing of [Pd{(*R*,*R*)-Duxantphos}(C_6H_9)](SbF_6) (**11**) showing 30% probability thermal ellipsoids and the atom-numbering scheme; hydrogen atoms and the SbF_6^- anion have been omitted for clarity

and 2 and selected bond lengths and angles are given in Tables 3 and 4. Complexes **10** and **11** crystallise as monocationic, pseudo-square-planar complexes with noncoordinating anions. Each metallic centre is coordinated by the three allylic carbon atoms and the two phosphorus atoms of the bidentate diphospholane **1** or **2**. Crystallographic disorder is present in the structure of **10**: the palladium atom occupies two positions (Pd and Pd′, 50% occupancy ratio each). Pd is bound to C3, C4, and C5, whereas Pd′, which is located slightly below, is bound to C6, C1, and C2. This

disorder results in large thermal ellipsoids for the 6 cyclohexenyl carbon atoms. For the sake of clarity, only Pd is shown in Figure 1.

The overall structure of **11** is very close to the reported structure of [Pd{(*R*,*R*)-Duthixantphospholane}(cyclohexenyl)]$^+$.[4a] The conformational characteristics of the Duxantphos ligand in complex **11** are similar to those of achiral xanthene-based ligands coordinated to palladium.[15,16] The main difference between **10** and **11** lies in the fact that in **10** the aromatic backbone of the ligand is approximately in the coordination plane and keeps a pseudo-C_2 symmetry axis, whereas in **11** the xanthene scaffold is almost perpendicular to the coordination plane. Indeed, the P1−Pd−P2 plane subtends an angle of only 14.8(1)° with the best-fit plane defined by the six aromatic Duphos carbons in **10**, while in **11** both xanthene aromatic rings (also defined by best-fit six-carbons planes) are bent by 77.08(4) and 75.67(4)° with regard to the P1−Pd−P2 plane. In **11**, the tricycle is folded along an O···CMe_2 axis, the oxygenated six-membered ring being in a boat conformation, and the angle between the mean aromatic planes reaches 45.32(4)°. Another marked difference is the angle between the mean phospholane planes (defined by their five atoms) and the P1−Pd−P2 plane: 70.6(1) and 78.3(1)° in **10** compared with only 13.41(4) and 34.52(4)° in **11**.

The loss of symmetry of the Duxantphos ligand upon coordination to the palladium centre induces *exo*/*endo* isomerism in the complex. The *exo* species can be defined as the conformer where the xanthene backbone is located on the same side of the coordination plane as the cyclohexenyl or, in a more general way, where the central allylic proton is on the opposite side with regard to the backbone.[4a] It is indeed the observed conformer for **11** as well as for [Pd{(*R*,*R*)-duthixantphospholane}(cyclohexenyl)]$^+$.

In both structures, the Pd−P bond lengths (2.278−2.335 Å) are within the expected range for complexes with phospholanes coordinated to palladium.[4a,7,17] As expected, the bite angle P1−Pd−P2 is much larger in **11** [105.02(4)°] than in **10** [86.40(9)°]. Because of the strong *trans* influence of the phospholanes, the palladium−terminal allylic carbon bonds (**10**: 2.39−2.41 Å; **11**: 2.206−2.247 Å) are longer than in other reported Pd−η^3-cyclohexenyl complexes.[17] In addition, they appear much longer in **10** than in **11** which is probably linked to the crystallographic disorder observed in **10** (vide supra). For the same reason, the cyclohexenyl carbons look, artificially, nearly coplanar in **10**, whereas in **11** the cyclohexenyl is in a chair conformation.

The ''twist angle'' τ defined by Helmchen et al.[18] is useful here for describing the inclination of the allyl in a front view. It corresponds to the dihedral angles P1−P2−C3−C5 in **10** and P1−P2−C1−C3 in **11** and reaches the values of −7.0(6)° and −8.7(2)°, respectively, which are very close. In other words, in a front view of the molecule where the allyl is positioned in the foreground, the allyl appears rotated slightly clockwise so that steric interactions between it and the proximal phospholane methyls (**10**: C11 and C23; **11**: C12 and C17) are minimised. It is worth noting that within the five-membered phospholane cycles, the proximal methyls of **10** are both *syn* with regard to the coordinating electron pair of the phosphorus atom, whereas in **11** C17 is *syn* but C12 is *anti*.

In **10** the mean phospholane planes are nearly parallel to the mean cyclohexenyl plane [5.7(2) and 9.0(1)°] and therefore the shortest spatial distance between a terminal allylic carbon and a chiral carbon of a phospholane is 4.015(20) Å (C3···C22). In contrast, the phospholanes of **11** make an angle of 72.94(5) and 89.57(6)° with the cyclohexenyl and the C3···C10 and C1···C13 distances are shorter at 3.878(7) and 3.548(7) Å, respectively. This observation mirrors exactly what Kamer et al. noted about palladium allyl complexes coordinated either by 1,2-bis(diphenylphosphanyl)-ethane or xantphos.[15] The consequence is a stronger protrusion of the proximal methyls into the cyclohexenyl ligand. Their distances from the cyclohexenyl mean plane are 2.031(2) Å (C12) and 1.962(2) Å (C17) in **11**, compared with 2.657(6) Å (C11) and 3.428(6) Å (C23) in **10**. In connection with the steric repulsion between C12 and the allyl of **11**, the P1−Pd−C3 angle is slightly but significantly larger than P2−Pd−C1 [96.7(1)° vs. 92.0(1)°] and Pd−P1−C10 is also larger than Pd−P2−C13 [124.2(2)° vs. 116.3(2)°].

NMR Investigations

We have also compared the NMR spectroscopic data of complexes **10** and **11** in solution. Like its crystallographic features, the NMR characteristics of **11** are closely akin to those of *exo*-[Pd{(*R*,*R*)-Duthixantphospholane}(cyclohexenyl)]$^+$. Upon coordination of the C_2-symmetric ligands **1** and **2** to the Pd centre, the loss of the symmetry axis is revealed by the $^{31}P\{^1H\}$, ^1H, and $^{13}C\{^1H\}$ NMR spectra. Many signals are duplicated, e.g. the phosphorus resonances which appear as an AB system, or the four ^1H NMR signals of the methyl groups borne by the phospholanes which are doublets of doublets. The $J_{P,P}$ values measured from the $^{31}P\{^1H\}$ spectra are slightly larger in **11** than in **10** (41 Hz vs. 36 Hz) which may be the consequence of an increased P−Pd−P angle.

The chemical shifts of the phosphorus nuclei are higher in the Duphos complex **10** (δ = 68.2 and 71.9 ppm) than in the Duxantphos complex **11** (δ = 33.7 and 35.5 ppm). This deshielding could be expected in view of the ring contribution (Δ_R) parameter[19] which reaches a high value for a five-membered metallacycle. The chemical shift difference between the terminal allylic ^{13}C signals is a useful tool to account for asymmetry in the allyl bonding.[7] Here, we observed that this difference is only Δδ = 5.2 ppm in **10**, but reaches Δδ = 12.0 ppm in **11**.

The case of complex [Pd{(*R*,*R*)-**2**}(η^3-1,3-diphenylallyl)](SbF_6) (**12**) appears to be more complicated. In spite of numerous efforts, we did not manage to grow single crystals for X-ray analysis. Its room-temperature $^{31}P\{^1H\}$ and ^1H NMR spectra exhibit broad signals which sharpen when the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

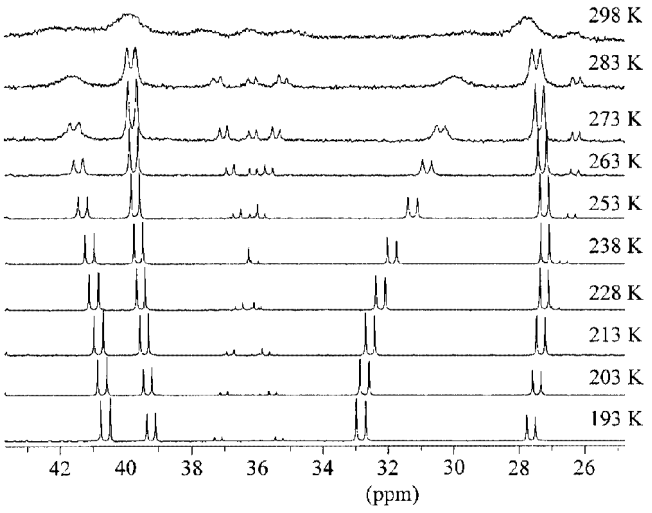

Figure 3. 202.5 MHz $^{31}P\{^1H\}$ NMR spectra of [Pd{(*R*,*R*)-Duxantphos}($Ph_2C_3H_3$)](SbF_6) (**12**) in CD_2Cl_2 in the range 193−298 K

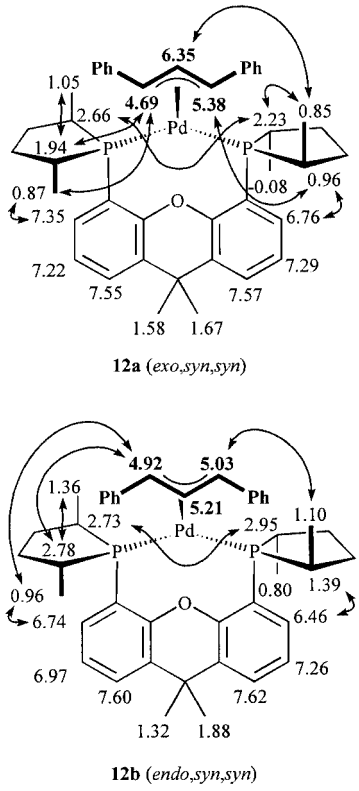
temperature is decreased (Figure 3). Below 273 K, the ^{31}P NMR spectra exhibit eight narrow doublets between δ = 26 and 42 ppm with 45 Hz < $J_{P,P}$< 57 Hz, values which are all close to those found for complex **11**. Measurement of the P−P coupling constants associated with a $^{31}P\{^1H\}$ COSY spectrum recorded at 193 K allowed us to identify them as four AB systems, corresponding to two major (**12a**,**b**) and two minor (**12c**,**d**) isomeric species where a Pd atom is chelated by the diphospholane. If we assume that we can rely on the integration of the $^{31}P\{^1H\}$ NMR signals, their relative ratios are 35:25:4:1 at 193 K. **12a** and **12b** are predominant whatever the temperature. Coalescence of the ^{31}P and ^1H signals of the four isomers upon warming to room temperature indicates that they undergo fast exchange processes.

2D-^1H NMR spectroscopy has proved to be a very useful tool for the investigation of the 3D structures of allyl Pd complexes.[3] Indeed, although many signals of the 1D-^1H NMR spectrum of **12** recorded at 193 K overlap, 2D-NMR analysis combined with phosphorus-decoupled proton NMR spectroscopy allowed us to assign most of the signals of both major isomers and identify them as *exo*,*syn*,*syn* (**12a**) and *endo*,*syn*,*syn* (**12b**) (Scheme 3). In each isomer, all the ^1H signals of the diphospholane ligand (except the methylene signals) could be assigned with the help of 2D-^1H COSY and ROESY spectra, each proton being connected to another by scalar coupling and/or by spatial proximity (NOE effect). The aromatic protons located in the *ortho* position with regard to the phospholane substituents are characterised by a $^3J_{H,P}$ value of ca. 7 Hz. We can unambiguously identify the signals of the key proximal phospholane methyl groups that point in the foreground towards the allyl moiety. In the 2D-^1H ROESY spectrum, the left-side proximal methyl group displays a strong NOE with the adjacent *ortho*-xanthene proton (e.g. at δ = 7.35 ppm in the *exo* isomer), whereas the other *ortho* proton (e.g. *exo*: δ = 6.76 ppm) shows an NOE with the methylidyne group that



Scheme 3. Representation of relevant NOE contacts in **12a** and **12b** from ^1H ROESY; for the sake of clarity, NOEs associated with scalar couplings are not shown

is geminal with the right-side proximal methyl group. In the background, NOEs are observed between both phospholane distal methylidyne groups (e.g. *exo*: δ = 2.23 and 2.66 ppm) which is an indication that the xanthene backbone is folded as in the X-ray structure of **11**.

Six allyl signals are spread over a rather large range, i.e. δ = 4.69−6.35 ppm. The *syn*,*syn* geometry of the allyl ligand was established in both isomers from NOE cross-peaks between the lateral allyl signals (δ = 4.69−5.38 and 4.92−5.03 ppm; see Scheme 4). This is also suggested by the large values of the coupling constants between the central and lateral allylic protons (10−14 Hz), although this fact alone would not be definite proof.[3a] We note, however, that within each allyl ligand, both values of $^3J_{H,H}$ are not equal which suggests that the allyl group undergoes deformations.

The assignment of the allyl configuration (*exo* or *endo*) is essentially based on the interligand NOEs that the lateral-right and central allylic protons cause or do not cause with the right-side proximal phospholane methyl group and its *gem*-methylidyne group (Scheme 3). The *endo* structure of isomer **12b** is supported by the very intense NOE cross-peak of the allyl proton signal at δ = 5.03 ppm with the methyl signal at δ = 1.10 ppm (Figure 4). In the *exo* isomer **12a**, the lateral allyl proton (δ = 5.38 ppm) shows a close NOE contact with the proximal methylidyne group (δ = 0.96 ppm) but not with the methyl group (δ = 0.85 ppm). In addition, an NOE signal between the *exo* central allyl signal at δ = 6.35 ppm and the proximal methyl signal at

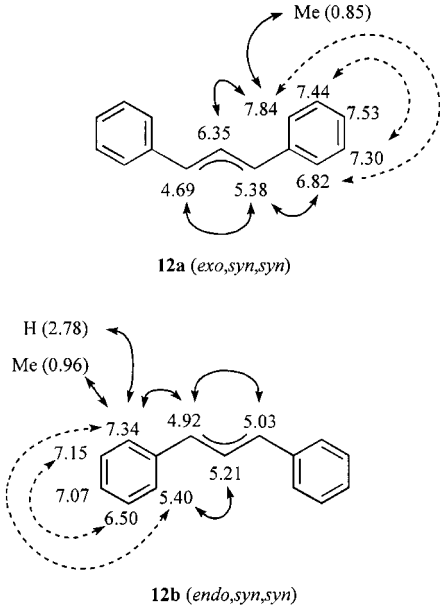

Scheme 4. Representation of relevant NOE contacts (plain arrows) and chemical exchanges (broken arrows) within the allyl ligand in **12a** and **12b** from ROESY experiments; for the sake of clarity, NOEs associated with scalar couplings are not shown

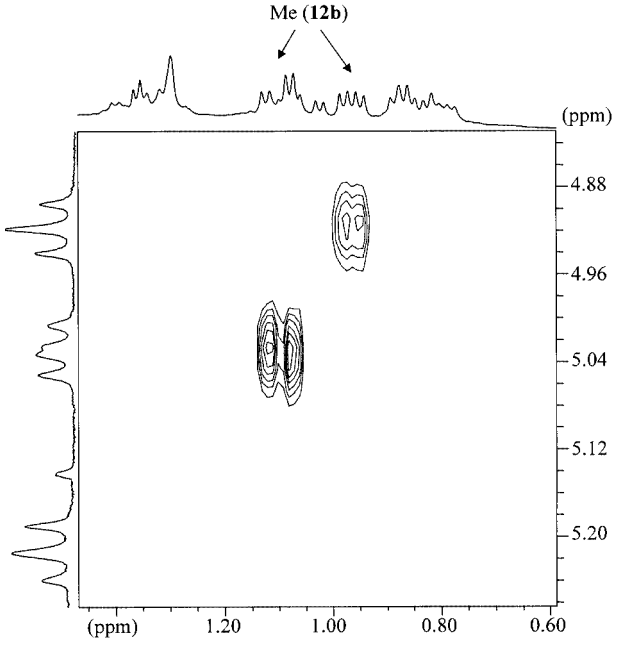

Figure 4. Section of the ^{1}H ROESY spectrum of **12** recorded in CD_2Cl_2 at 193 K; a section of the aliphatic region is represented horizontally and the three allylic proton signals of **12b** vertically

δ = 0.85 ppm can be observed. However, **12a** and **12b** cannot be differentiated by the left-side lateral allylic proton (**12a**: δ = 4.69 ppm; **12b**: δ = 4.92 ppm) because they both display NOEs with the proximal, left-side methyl group and methylidyne group.

The low frequency shift of some of the protons is consistent with their positioning in the anisotropy cone of the aromatic rings. The *exo* central allylic proton resonates in the normal range (δ = 6.35 ppm). In comparison, the chemical shift of the central proton of [Pd(Duphos)(1,3-diphenylallyl)]$^+$ is δ = 6.84 ppm, although the signal of the homologous proton of the *endo* isomer that lies in the anisotropy cone of both xanthene aromatic cycles is shifted upfield by more than 1 ppm (δ = 5.21 ppm). Conversely, the signals of several protons belonging to the diphospholane ligand are shifted upfield, such as (1) on the right side of the *exo* isomer, the *ortho*-xanthene proton (δ = 6.76 ppm), the proximal methylidyne group (δ = 0.96 ppm) and even the distal methyl group (δ = −0.08 ppm) as well as (2) on the *endo* isomer, both *ortho*-xanthene protons (δ = 6.46 and 6.74 ppm) and the proximal methylidyne group on the right (δ = 1.39 ppm). These shifts are probably related to the anisotropy cone of the phenyl substituents of the allyl moiety.

In each isomer, only the ^{1}H signals of one phenyl substituent can be identified, i.e. the right-side phenyl group in the *exo* form and the left-side one in the *endo* form (Scheme 4). For each of them, five distinct resonances can be observed. This means that their rotation is frozen at 193 K because of the steric effect of the proximal methyl groups. However, positive exchange (EXSY) cross-peaks related to this rotation, between the *ortho* and *meta* protons of each phenyl group, can be found in the ^{1}H ROESY spectrum. The protons oriented downwards resonate at low frequencies (e.g. the *endo*,*ortho* proton signal at δ = 5.40 ppm) because of their location in the anisotropy cone of the xanthene backbone (vide supra).

The ^{1}H NMR signals of both minor isomers **12c** and **12d** could hardly be detected in the spectra because of overlapping of the signals of the major isomers **12a** and **12b**. However, in view of related (1,3-diphenylallyl)palladium complexes,[3] it seems highly probable that they are *syn*,*anti* isomers (vide infra). Such *syn*,*anti* (1,3-diphenylallyl)palladium complexes are generally less stable than *syn*,*syn* isomers because of unfavorable $Ph_{anti}-H_{anti}$ steric interactions.

From the integration of the respective ^{1}H NMR signals of **12a** and **12b** in CD_2Cl_2, we observed that the [**12a**]/[**12b**] ratio in solution increased with the temperature and that a plot of ln$K$ (K = [**12a**]/[**12b**]) vs. 1/T is a straight line (Figure 5). This allowed us to estimate the thermodynamic data of the equilibrium, viz. $\Delta H° \approx 4$ kJ·mol^{-1} and $\Delta S° \approx 18$ J·mol^{-1}·K^{-1}. Upon warming form 193 to 298 K, the intensity of the AB system at δ ≈ 28 and 39 ppm in the ^{31}P NMR spectrum increased, whereas that of the AB pattern at δ ≈ 31−33 and 40−42 ppm decreased (Figure 3). We can, therefore, assign the first couple of signals to **12a** and the second to **12b**, by comparison with the variable-temperature ^{1}H NMR spectroscopic data.

The broadening of the ^{1}H and ^{31}P{^{1}H} NMR signals of **12** upon increasing the temperature from 193 K to room temperature is characteristic of fluxional processes. We tried to record a high-temperature (323 K) ^{31}P{^{1}H} NMR spectrum of **12** in CD_3NO_2 but unfortunately it decomposed upon heating before any narrowing of the signals could be observed. We envisioned that the equilibria between the isomers of **12** could be visualised by low-temperature 2D

exchange NMR spectroscopy. No exchange cross-peaks involving allylic protons were found in the ^1H ROESY spectrum, probably because the exchange rates are too low at 193 K. However, we could observe two cross-peaks which reveal very selective chemical exchanges of phosphorus nuclei in a $^{31}P\{^1H\}$ ROESY spectrum recorded at 263 K (Figure 6). This can be interpreted as the consequence of a conformational equilibrium between the major isomers **12a**

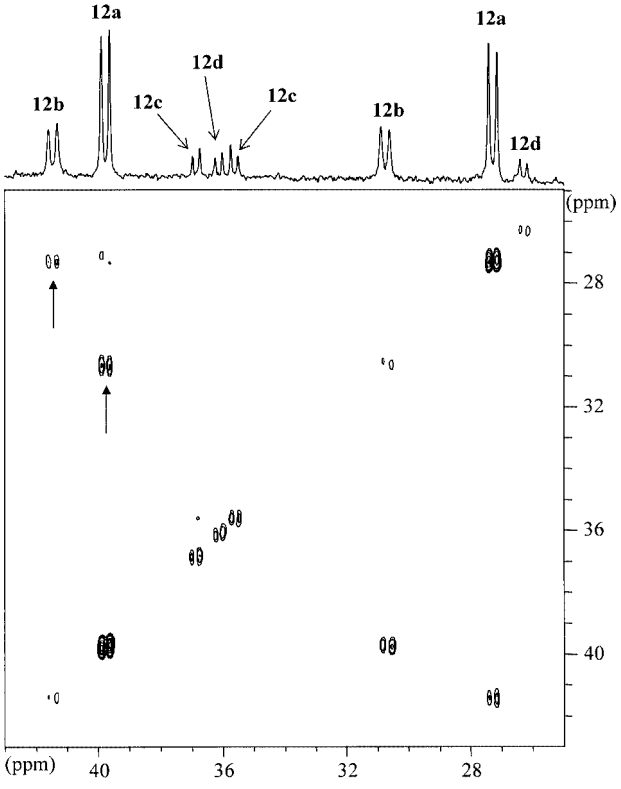

Figure 6. ^{31}P ROESY spectrum of **12** recorded in CD_2Cl_2 at 263 K; exchange cross-peaks between **12a** and **12b** are designated by arrows

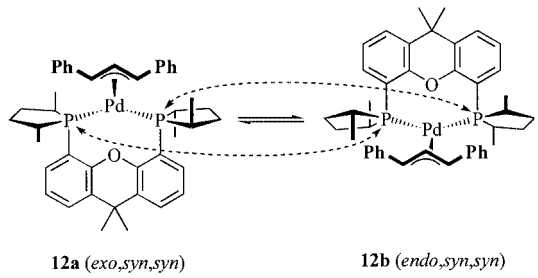

Scheme 5. Hypothetical conformational equilibrium between **12a** and **12b** accounting for the phosphorus nuclei exchanges (broken arrows) observed by ^{31}P ROESY

and **12b** (Scheme 5), where the xanthene backbone moves upwards rotating around the P···P axis (flip−flop). Very similar NMR observations of a Pd(diphosphane)(η^3-allyl) complex have been reported.[20] No exchange cross-peaks were found in the ^{31}P ROESY spectrum between the signals of the major *syn*,*syn* and the minor hypothetically *syn*,*anti* isomers, which means that $\eta^3-\eta^1-\eta^3$ isomerization is too slow to be observed at 263 K. It is plausible that this process, which involves Pd−C bond breaking, is slower than a conformational equilibrium.

A $^{13}C\{^1H\}$ NMR spectrum of **12** was recorded at 263 K in CD_3NO_2, a solvent in which the complex is reasonably soluble (a spectrum recorded in CD_2Cl_2 resulted in a poor signal-to-noise ratio). Although the spectrum is complicated because many species are present in solution, we assigned the most intense signals to **12a** which is by far the predominant species at this temperature. One of the terminal allylic carbon atoms has olefin-like character[3b] with a high-frequency chemical shift of δ = 100.2 ppm. As in the cyclohexenyl series, the $\Delta\delta_{C\ terminal\ allyl}$ value is much larger with Duxantphos (δ = 22.4 ppm) than with Duphos (δ = 10.3 ppm[7]). Indeed, δ = 22.4 ppm is particularly high for a (1,3-diphenylallyl)Pd complex chelated by two donor atoms of the same type.[3b] The terminal allyl carbon signals of **12a** are doublets (as in the cyclohexenyl analogue **11**) and the coupling constants with their respectively *trans*-positioned phosphorus atom are quite different (δ = 77.8 ppm, 30 Hz vs. δ = 100.2 ppm, 20 Hz). All these observations are consistent with an allyl deformation or tilt which was suggested by the values of the H-H coupling constants within the allyl (vide supra).

Like **12**, complex [Pd(*R*,*R*)-**2**](η^3-allyl)](SbF$_6$) (**13**) could not be analysed by X-ray crystallography. Instead, a detailed NMR spectroscopic analysis was carried out. Its low-temperature $^{31}P\{^1H\}$ NMR spectrum revealed the presence of *exo* and *endo* isomers in very different proportions, i.e. with a ratio > 10 (Figure 7). At 183 K, the major compound was characterised by an AB system at δ = 33.2 and 34.3 ppm ($J_{P,P}$ = 40 Hz), whereas only one doublet of the minor species was visible at δ = 31.3 ppm ($J_{P,P}$ = 40 Hz). Upon heating, we observed a coalescence of the signals which led to a single averaged AB system at room temperature. The coalescence temperature can be roughly estimated as 223 K. This suggests that the energy barrier of the fluxional process is lower for **13** than for **12**. A straightfor-

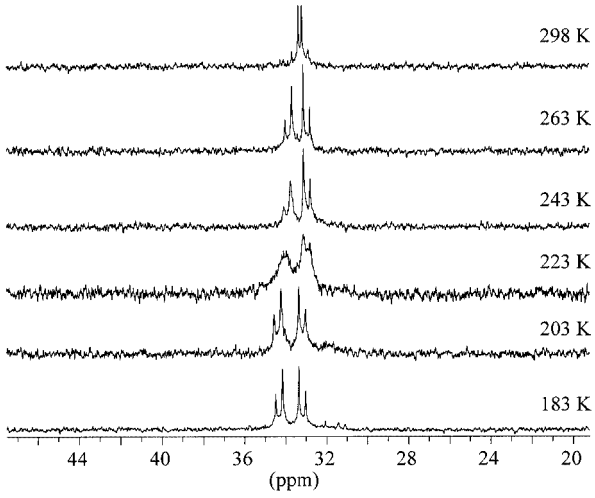

Figure 7. 121.5 MHz $^{31}P\{^1H\}$ NMR spectra of [Pd{(*R*,*R*)-Duxantphos}(C_3H_5)](SbF$_6$) (**13**) in CD_2Cl_2 in the range 183−298 K

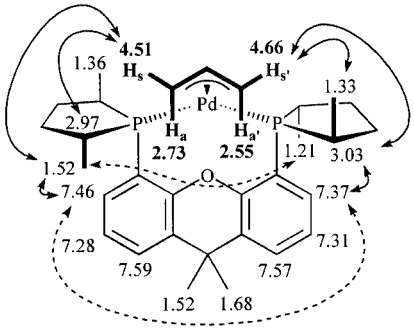
ward explanation based on the steric effect of the bulky 1,3-diphenylallyl moiety can be proposed.

It is highly probable that the major species at low temperature is also largely predominant at room temperature, i.e. above the coalescence temperature. Therefore, the diagnostic cross-peaks observed in the ^1H ROESY NMR spectrum recorded at room temperature must be characteristic of that major isomer. Most of the protons of Duxantphos in **13** could be identified with the help of that spectrum, in connection with key Me···H$_{ar}$ and CH···H$_{ar}$ NOE cross-peaks. Several indications tend to show that it corresponds to the *exo* isomer shown in Scheme 6. In an *endo* isomer, a strong NOE interaction between H$_{anti}$ (δ = 2.55 ppm) and the phospholane methyl group (δ = 1.33 ppm) on the right side would be expected, which is not the case. Furthermore, by comparison with reported [Pd(trialkylphosphane)$_2$(allyl)]$^+$ complexes,[21] the chemical shifts of the *anti* protons are rather low, possibly because they are located in the anisotropy cone of the backbone aromatic rings in the *exo* conformation. Unfortunately, this assignment is not unambiguous, since each allylic *syn* proton displays NOEs with a methyl group and a methylidyne group, whereas the allylic *anti* or central protons show no significant NOE with any of the Duxantphos protons.

We found two distinct chemical exchange (positive) cross-peaks in the ROESY spectrum between both *ortho*-xanthene protons and also between two methyl groups (Scheme 6). Other exchange cross-peaks involving Duxantphos protons could not be distinguished because the chemical shifts of the exchanging nuclei were too close. Besides, the four terminal allyl protons all exchange with each other. All these exchange cross-peaks can be interpreted as the result of a flip−flop of the diphospholane ligand similar to that shown in Scheme 5 (leading to the minor isomer), followed by an isomerization back to the major species through a classical $\eta^3-\eta^1-\eta^3$ allyl rearrangement mechanism.[1b]

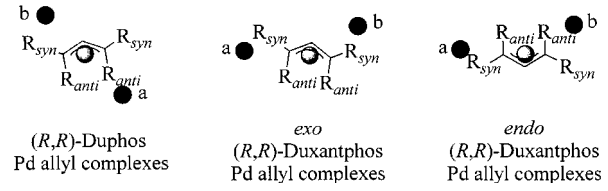


Scheme 6. Representation of relevant NOE contacts (plain arrows) and chemical exchanges (broken arrows) in **13** from ^1H ROESY; for the sake of clarity, NOEs associated with scalar couplings are not shown

Discussion

The purpose of this discussion is to try to establish a link between the structural information provided by the analysis of allyl palladium complexes and some of our most valuable results of palladium-catalysed allylic alkylations with diphospholane ligands, i.e. with substrates **3a** and **3c**.

As a result of the bite angle of the diphospholane, the conformation of the scaffold generates *exo*/*endo* isomerism in the Duxantphos complexes **11**−**13** and both forms are in equilibrium. In contrast, Duphos maintains a pseudo-C_2 symmetry when it is coordinated to the metal atom and there is no such isomerism. We have represented, in Scheme 7, some simplified front views of the allyl palladium complexes, in analogy with previously reported representations.[4] This allows us to visualise the interactions of the proximal methyl groups of the (*R*,*R*)-diphospholane ligands with the allyl moiety. The proximal methyl groups [(a) = down; (b) = up] have dramatically different positions depending on the ligand: with (*R*,*R*)-Duphos, (a) is on the right and (b) on the left, whereas the reverse is true with (*R*,*R*)-Duxantphos. However, this picture does not account for the distances between the methyl groups and the allyl plane which are shorter with Duxantphos than with Duphos (vide supra).



Scheme 7. Front-view representation of [Pd(diphospholane)(allyl)]$^+$ complexes; black circles = proximal methyl groups; gray circle = palladium centre

The example of the cyclohexenyl complex **11** {or of [Pd{(*R*,*R*)-Duthixantphospholane}(cyclohexenyl)]$^+$ [4a]} indicates that a methyl group (b) cannot accommodate an

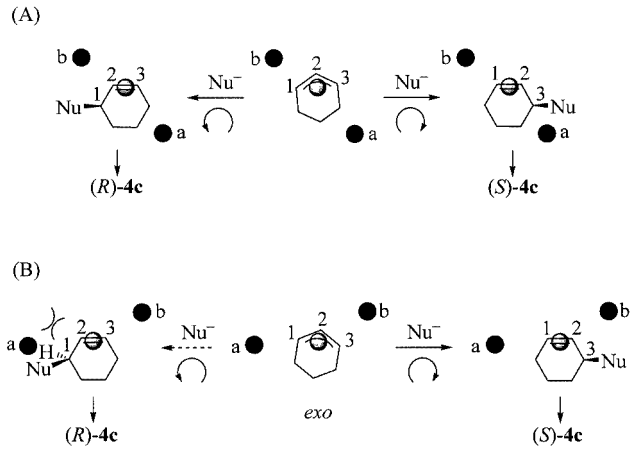
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

anti substituent on the right in the *endo* isomer. Therefore, an *endo* isomer of **11** could not be detected. On the other hand, when the allyl group is *syn*,*syn*-substituted with large phenyl groups (complex **12**), the *exo* and *endo* forms coexist in comparable proportions. Both undergo some internal steric congestion, as illustrated by the restricted rotation of some phenyl groups because of the proximity of phospholane methyl groups (Scheme 4, vide supra). *syn*,*anti* 1,3-Diphenylallyl complexes are normally destabilised by $H_{anti}-Ph_{anti}$ steric repulsion but can be present in significant quantity with a large, intrusive ancillary ligand.[22] Indeed, minor isomers of **12**, which are very probably *syn*,*anti*, coexist with the major *syn*,*syn* isomers, whereas [Pd(Duphos)(η^3-1,3-diphenylallyl)]$^+$ is exclusively *syn*,*syn*,[7] in connection with the fact that Duphos is less intrusive than Duxantphos. When Ph is replaced by a smaller Me on the Duxantphos complex, the *syn*,*anti* species become predominant.[4b] In brief, it appears that the proportion of each stereoisomer of a given allyl complex, whether it is related to *exo*/*endo* or to *syn*/*anti* isomerism, is the result of a subtle balance between various steric effects.

A general trend in our catalytic results in the field of allylic alkylation is a higher reactivity of ligand **2** compared with ligand **1**. Here, the reaction rate increases with the bite angle. Such an effect has already been reported in Pd-catalysed allylic alkylations, but it is not always the rule.[15,23] It can be interpreted as the consequence of a greater stability of the Pd^0-alkene complex which results from the nucleophilic attack on a $Pd^{II}-$allyl species, assuming that it is the rate-limiting step of the catalytic cycle.[24a] The origin of this stabilisation can be interpreted as the result of a decrease of the HOMO energy level, as suggested by Walsh diagrams.[6a]

With substrates that generate a symmetrically substituted η^3-allyl ligand (viz. substrates **3a**−**d**), the enantioselectivity of the catalytic process arises from the regioselectivity of the nucleophilic attack where the $Pd^{II}-\eta^3$-allyl complex is converted into a $Pd^0-\eta^2$-alkene complex. An interpretation of the origin of the enantioselectivity is provided by the concept of preferential rotation of the allyl group,[4,9] also referred to as torquoselectivity.[25] This interpretation is based on the hypothesis of a medium to late transition state[24] in which unhindered, thermodynamically more stable Pd^0-olefin products would be favoured. In the present case, enantiodiscrimination is governed by steric interactions between the proximal methyl groups and the coordinated alkene product (Schemes 7 and 8).

An explanation that accounts for the catalytic superiority of **2** over **1** with **3c** as the substrate is given in Scheme 8. In Scheme 8A, the methyl group (a) of (*R*,*R*)-Duphos is located low and far from the allylic carbon atoms and interacts very little with the cyclohexenyl moiety. Therefore, no major steric clash is expected whether the allyl group rotates clockwise or anticlockwise. This correlates well with the poor enantioselectivity of the reaction (5% *ee*). On the contrary, the situation with (*R*,*R*)-Duxantphos is the same as with (*R*,*R*)-Duthixantphos.[4] That is, an anticlockwise rotation is unfavourable because of the steric strain between



Scheme 8. Interpretation of the selectivity of the nucleophilic attack of the Pd−cyclohexenyl intermediate with (A) (*R*,*R*)-**1** or (B) (*R*,*R*)-**2** as ligands; Nu = $CH(COOMe)_2$

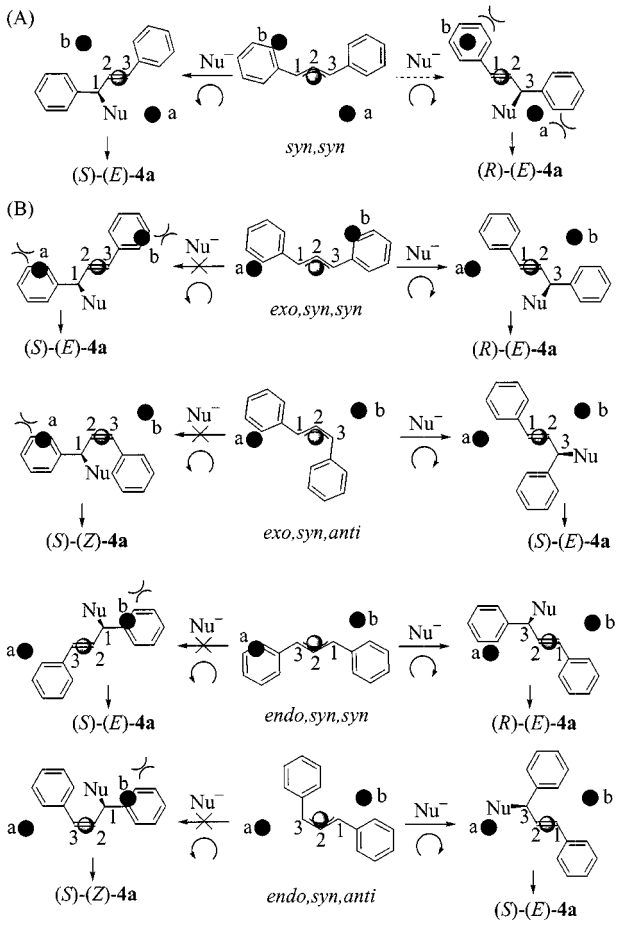
C1−H and the methyl group (a) in the Pd^0-olefin species, whereas no such strain hinders a clockwise rotation of the allyl group (Scheme 8B). Indeed, compound (*S*)-**4** is formed with a high *ee* (83%) in the catalytic process run with ligand (*R*,*R*)-**2**.

It has been reported that in palladium-catalysed asymmetric allylic alkylation, a twist of the allyl group (observed by X-ray crystallography) toward a product-like state might influence the regioselectivity of the nucleophilic attack.[16,24c] However, in complex [Pd{(*R*,*R*)-Duphos}(cyclohexenyl)]$^+$ which is the mirror image of **10**, the allyl group is twisted anticlockwise according to the crystal structure of **10**. Nevertheless, a clockwise rotation is slightly favoured. Hence, this is another argument against an early transition state with these ligands.

With the encumbered substrate **3a**, chirality transfer was very efficient in the catalytic reaction. The configurations of **4a** were found to be opposite with both diphospholane ligands, obviously because the positions of the proximal methyl groups (a) and (b), which undergo repulsive interaction with the phenyl substituents, are inverse (Scheme 9). If the nucleophile attacks the C3 atom of [Pd{(*R*,*R*)-Duphos}(cyclohexenyl)]$^+$, a very severe steric clash occurs between barrier (b) and the left-side phenyl group and, to a lesser extent, between barrier (a) and the right-side phenyl group (Scheme 9A). Nucleophilic attack at C1 accompanied with anticlockwise rotation of the allyl group does not experience a high energy barrier related to steric strain. This is in agreement with the formation of (*S*)-**4a** with 97% *ee*.

Things are more complicated with Duxantphos, with 4 diastereomers of the 1,3-diphenylallyl complex **12** being detected by $^{31}P\{^1H\}$ NMR spectroscopy (Scheme 9B). It is reasonable to suppose that the minor isomers **12c** and **12d** are the two *syn*,*anti* species shown in Scheme 9 (among four possible isomers), where no major steric clash exists between the proximal methyl groups and the phenyl substituents. *cis*-**4a** was not detected in the catalysed reaction. This implies that anticlockwise rotation upon nucleophilic attack

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 9. Interpretation of the selectivity of the nucleophilic attack of the Pd−1,3-diphenylallyl intermediate with (A) (*R*,*R*)-**1** or (B) (*R*,*R*)-**2** as ligands; Nu = $CH(COOMe)_2$

of the *syn*,*anti* allyl complexes is forbidden because of steric repulsion of one of the phenyl groups with the methyl group (a) (*exo*) or (b) (*endo*). This raises the question as to why a sterically hindered movement of the allyl group is forbidden and not just slowed down. We propose two arguments to explain this: (1) from the comparison with the Duxantphos cyclohexenyl complex, it appears that the *syn* substituent is a bulky phenyl group and not a proton and (2), as stated above, the proximal methyl groups of Duxantphos are much closer to the allyl plane than those of Duphos. Since the environment of C1 is the same in the *exo*,*syn*,*syn* and the *exo*,*syn*,*anti* species represented in Scheme 9, an anticlockwise rotation of the *exo*,*syn*,*syn* allyl group must also be forbidden. The same reasoning is valid for the *endo* species.

Hence, only clockwise rotations occur in the four isomers of **12**, in analogy with the interpretation reported for the 1,3-dimethylallyl system.[4b] Both major *syn*,*syn* isomers lead to the (*R*) alkylated product, whereas the minor *syn*,*anti* species lead to the (*S*) product. Our interpretation based on the hypothesis of Curtin−Hammett conditions[24a] is in agreement with the high measured *ee* values (85−89%) of (*R*)-**4a**. In comparison with the case of Duphos, the presence of *syn*,*anti* catalytic intermediates is detrimental to the enantioselectivity. We are, however, aware that the interpretation proposed here is qualitative since we know nothing of the relative nucleophilic attack rate on each diastereomer of **12**. In particular, it looks probable that this rate is superior for **12a** than for **12b**: in the latter, a clockwise rotation may be somewhat hindered by the methyl group (a).

Conclusion

In this paper we have compared the catalytic and structural properties of the two chiral diphospholane ligands coordinated to Pd, viz. **1** and **2** which differ in their bite angle. Palladium-catalysed allylic alkylation tests have confirmed the success of xanthene-based diphospholane with the "symmetrical" allylic substrates **3a**−**d**[4] but this success was found to be somewhat limited. Attempts to use other kinds of substrates or nucleophiles, for example, led to modest selectivities at best. However, a strong positive bite angle effect was found in allylic alkylation with small, sterically unhindered substrates such as **3b**−**d**, where Duxantphos was much superior to Duphos in terms of reactivity and especially enantioselectivity.

Investigations of the 3D structures of the allyl complexes **10**−**13** were carried out by NMR spectroscopy and, whenever possible, by X-ray crystallography. Overall, these analyses have provided accurate indications about the structural differences between Duphos and Duxantphos. The increase in the bite angle induces a loss of C_2 symmetry of the ligand upon coordination and renders its proximal methyl groups more intrusive towards the allyl group. These differences have major consequences on the nature and distribution of the Pd−allyl intermediates and, furthermore, on the intimate mechanism of catalytic selectivity which is based on steric factors. We applied the preferential rotation concept which proved to be a very suitable model to account for the catalytic results. With (*R*,*R*)-Duxantphos, we found that a clockwise rotation in the nucleophilic attack step is the preferred, and sometimes the exclusive motion of the allyl group. (*R*,*R*)-Duphos, on the other hand, leads to anticlockwise rotation but only if the allyl group carries bulky phenyl substituents. In conclusion, the comparison of Duphos (**1**) with Duxantphos (**2**) emphasises the advantages of large bite angle ligands.

Experimental Section

General Procedures: All experiments were carried out under nitrogen or argon using a vacuum line or Vacuum Atmospheres glovebox equipped with a Dri-Train HE-493 inert gas purifier. Pentane, benzene, diethyl ether, and THF were distilled from sodium and benzophenone whereas acetonitrile and dichloromethane were distilled over calcium hydride under nitrogen immediately before use. Column chromatography was carried out on Merck silica gel 60, 70−230 mesh ASTM and thin layer chromatography on Macherey−Nagel 0.25 mm Polygram® Sil G/UV_{254} precoated silica gel plates. Commercial reagents were used as received: Strem: (*R*,*R*)- and (*S*,*S*)-Duphos, $AgBF_4$; Aldrich: dimethyl malonate,

N,*O*-bis(trimethylsilyl)acetamide (BSA), potassium acetate, (*rac*)-2-methyl-1-tetralone, allyl acetate, 2,3-dihydrofuran, phenyl triflate, *N*,*N*-diisopropylethylamine, europium tris[3-(heptafluoropropylhydroxymethylene)-(+)-camphorate] [Eu(hfc)$_3$], $AgSbF_6$; Prolabo: *n*-heptane. NaH (60% in mineral oil; Fluka) was washed three times with pentane, dried in vacuo, and stored in the glovebox. (*R*,*R*)-Duxantphos was prepared according to ref.[4] The compounds listed hereafter were synthesised according to reported procedures: (*rac*)-(*E*)-1-acetoxy-1,3-diphenylprop-2-ene (**3a**),[26] (*rac*)-(*E*)-2-acetoxypent-3-ene (**3b**),[27] (*rac*)-1-acetoxycyclohex-2-ene (**3c**),[28] (*rac*)-1-acetoxycyclopent-2-ene (**3d**),[29] (*rac*)-(*E*)-2-acetoxy-4-phenylbut-3-ene (**5a**),[8] (*rac*)-(*E*)-3-acetoxy-2-methylhex-4-ene (**5b**),[30] bis[(η^3-allyl)chloropalladium],[31] bis[(η^3-cyclohexenyl)chloropalladium],[32] bis[(η^3-1,3-diphenylallyl)chloropalladium].[24f] NMR spectra were recorded at room temperature (unless otherwise indicated) with Bruker spectrometers. ^1H NMR spectra were recorded at 300.16 MHz (AC-300 instrument) or 500.13 MHz (ARX-500) and referenced to $SiMe_4$. The assignments and measurements of coupling constants were supported by irradiations. $^1H\{^{31}P\}$, ^1H COSY, and/or $^{31}P\{^1H\}$ COSY spectra were recorded with the ARX-500 instrument. $^{13}C\{^1H\}$ NMR spectra (broadband-decoupled) were recorded at 75.48 MHz (AC-300), 100.62 MHz (AM-400), or 125.76 MHz (ARX-500) and referenced to $SiMe_4$. The assignments were supported by DEPT-135°. $^{31}P\{^1H\}$ spectra (broadband-decoupled) were recorded at 121.51 MHz (AC-300) or 202.46 MHz (ARX-500) and referenced to 85% aqueous H_3PO_4. The phase-sensitive 2D ROESY spectra[33] were recorded with the ARX-500 spectrometer using mixing times of 0.25 s (^1H) or 0.1 s ($^{31}P\{^1H\}$). FAB MS spectra were carried out at the corresponding facilities at the Fédération de Recherche de Chimie, Université Louis Pasteur, Strasbourg and elemental analyses by the Service Central d'Analyses, CNRS, Vernaison. Optical rotations were checked with a Perkin−Elmer Otopol III polarimeter (λ = 589 nm). GC analyses were performed with a Hewlett Packard 5890 series II apparatus equipped with a 30 m × 0.25 mm SGE 25QC2 capillary column (for conversion measurements) or with a 30 m × 0.25 mm Restek Rt-βDEXse capillary column (for enantiomeric excess determinations). HPLC analyses were carried out with a Hewlett Packard series 1100 apparatus equipped with 250 mm × 4.6 mm Daicel Chiralcel® AD or OD analytical columns.

General Procedure for Palladium-Catalysed Allylic Alkylation with Dimethyl Malonate: A mixture of the diphospholane ligand (12 μmol) and [Pd(η^3-C_3H_5)Cl]$_2$ (1.8 mg, 5 μmol) in the appropriate solvent (CH_2Cl_2 or THF, 2 mL) was stirred at room temperature for 20 min. When BSA was used as a base, a suspension of KOAc (1 mg, 10 μmol) in the solvent (1 mL) was added to the catalyst solution, followed by a mixture of dimethyl malonate (264 mg, 2 mmol) and BSA (407 mg, 2 mmol) in the solvent (4 mL) and a solution of the substrate (1 mmol) in the solvent (1 mL). When NaH was used as a base, a solution of dimethyl sodiomalonate was prepared by allowing a solution of dimethyl malonate (264 mg, 2 mmol) in THF (1 mL) to react with a suspension of NaH (48 mg, 2 mmol) in THF (4 mL). A solution of the substrate (1 mmol) in THF (1 mL) was added to the catalyst solution, followed by the nucleophile solution. In both cases, the conversion was periodically monitored by GC. When the reaction was complete, water (25 mL) was added, and the organic phase was extracted with Et_2O (3 × 30 mL). The extract was dried with $MgSO_4$ and the solvent was removed under reduced pressure. The crude product was purified by column chromatography on silica gel with pentane/Et_2O (4:1, v/v). By comparison with literature data, the alkylation products were identified and, if necessary, their absolute stereochemistry was determined by polarimetry: dimethyl (*E*)-(1,3-diphenylprop-2-en-1-yl)malonate (**4a**),[34] dimethyl (*E*)-(pent-3-en-2-yl)malonate (**4b**),[35] dimethyl (cyclohex-2-en-1-yl)malonate (**4c**) and dimethyl (cyclopent-2-en-1-yl)malonate (**4d**),[36] dimethyl (*E*)-(4-phenylbut-3-en-2-yl)malonate (**6a**) and dimethyl (*E*)-(1-phenylbut-2-en-1-yl)malonate (**7a**),[8,9] dimethyl (*E*)-(5-methylhex-3-en-2-yl)malonate (**6b**) and dimethyl (*E*)-(2-methylhex-4-en-3-yl)malonate (**7b**).[35] The *ee* values were measured with the following methods: **4a**, chiral HPLC (Chiralcel AD, 1 mL·min^{-1}; eluent *n*-hexane/*i*PrOH, 95:5, v/v); **4b** and **4c**, chiral GC; **4d**, **6a**, **7a**, **6b**, and **7b**, ^1H NMR in $CDCl_3$ using Eu(hfc)$_3$ as a chiral shift reagent.

General Procedure for Palladium-Catalysed Allylic Alkylation with 2-Methyl-1-Tetralone: The procedure was adapted from ref.[13] To a solution or suspension of base (1.85 mmol) in THF (2 mL) was added 2-methyl-1-tetralone (150 mg, 0.94 mmol). A mixture of ligand **2** (4.4 mg, 10 μmol) and [Pd(η^3-C_3H_5)Cl]$_2$ (1.8 mg, 5 μmol) in THF (1 mL) was stirred at room temperature for 20 min. To the catalyst solution was added allyl acetate (187 mg, 1.87 mmol), followed by the nucleophile solution. The conversion was periodically monitored by GC. When the reaction was complete, the mixture was added to a 0.2 M aqueous HCl solution (25 mL) and extracted with Et_2O (3 × 30 mL). The extract was treated with saturated $NaHCO_3$ (aq.) and dried with $MgSO_4$. The solvent was removed under reduced pressure and the crude 2-allyl-2-methyl-1-tetralone purified by column chromatography on silica gel with pentane/EtOAc (v/v, 9:1; R_f = 0.52). The *ee* of the product was determined by chiral HPLC (Chiralcel OD, 0.7 mL·min^{-1}; eluent *n*-hexane/*i*PrOH, 99.9:0.1, v/v) and its absolute stereochemistry was assigned by comparison with ref.[13]

General Procedure for the Heck Reaction: The procedure was adapted from ref.[14] A mixture of diphospholane ligand (24 μmol) and the Pd source (12 μmol) in benzene (2 mL) was stirred at room temperature for 20 min. To the catalyst solution were successively added a solution of PhOTf (89 mg, 0.394 mmol) in benzene (1 mL), N*i*Pr$_2$Et (168 mg, 1.30 mmol), 2,3-dihydrofuran (155 mg, 2.21 mmol) and additional benzene (2 mL). The mixture was heated to reflux for 48 h. The solvent was removed under reduced pressure and the crude products were purified by column chromatography on silica gel with pentane/EtOAc (9:1, v/v). The absolute stereochemistry of the product was determined by comparing the sign of its optical rotation with data from ref.[14] The *ee* values were measured by chiral GC.

[Pd{(*S*,*S*)-Duphos}(η^3-cyclohexenyl)](BF$_4$) (10): To a solution of [Pd(η^3-C_6H_9)Cl]$_2$ (35 mg, 0.078 mmol) in acetonitrile (4 mL) was added dropwise in the dark at room temperature a solution of $AgBF_4$ (35 mg, 0.180 mmol) in acetonitrile (3 mL). After 10 min of stirring, the suspension was filtered through Celite and a suspension of (*S*,*S*)-Duphos (48 mg, 0,157 mmol) in acetonitrile (1 mL) was added to the colourless filtrate. A pale orange solution was obtained after 30 min of stirring. The solvent was evaporated in vacuo to afford a brown powder which was washed with diethyl ether. The product was recrystallized from dichloromethane/pentane as colourless crystals. Yield: 50 mg (55%). $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 121 MHz): δ = 68.2 (d, $^2J_{P,P}$ = 36 Hz, 1 P), 71.9 (d, $^2J_{P,P}$ = 36 Hz, 1 P) ppm. ^1H NMR (CD_3CN, 300 MHz): δ 0.62 (dd, $^3J_{H,H}$ = 7.0, $^3J_{H,P}$ = 15.6 Hz, 3 H, CH_3), 0.85 (dd, $^3J_{H,H}$ = 7.0, $^3J_{H,P}$ = 15.6 Hz, 3 H, CH_3), 1.12 (dd, $^3J_{H,H}$ = 7.0, $^3J_{H,P}$ = 20.8 Hz, 3 H, CH_3), 1.35 (dd, $^3J_{H,H}$ = 7.1, $^3J_{H,P}$ = 20.5 Hz, 3 H, CH_3), 1.60−3.20 (m, 18 H, CH + CH_2), 5.33 (t, $^3J_{H,H}$ = 7.1 Hz, 1 H, H^2), 5.90 (m, 2 H, H^1 + H^3), 7.60−7.90 (m, 4 H, H_{ar}) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 75 MHz): δ = 14.8 (s, 2 CH_3), 18.4 (d, $^2J_{C,P}$ = 12 Hz, CH_3), 18.7 (d, $^2J_{C,P}$ = 12 Hz, CH_3), 20.4 (s, CH_2), 28.1 (d, $^2J_{C,P}$ = 5 Hz, CH_2), 29.4 (d, $^2J_{C,P}$ = 5 Hz, CH_2), 36.2 (d,

X-ray Crystallographic Studies: Details of data collection parameters and refinement results are listed in Table 5. The structures were solved by direct methods. Hydrogen atoms were introduced as fixed contributors in calculated positions [C−H = 0.95 Å, *B*(H) = 1.3 B_{equiv}]. Final difference maps revealed no significant maxima. All calculations were performed using the Nonius OpenMoleN package.[37] Neutral atom scattering factor coefficients and anomalous dispersion coefficients were taken from a standard source.[38] CCDC-236309 (**10**) and -236310 (**11**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallography Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Oxidation of CH_3NH_2 and $(CH_3)_2NH$ by $Ni^{III}(cyclam)(H_2O)_2^{3+}$ in Aqueous Solutions

Dror Shamir,*[a] Israel Zilbermann,[a,b] Eric Maimon,[a,b] and Dan Meyerstein[a,c]

Keywords: Pendant primary amines / Amines / Cyclam / Nickel / Electrocatalysts

Ni^{II}(1,4,8,11-tetraazacyclotetradecane)$^{2+}$, $Ni^{II}L^{2+}$, is a good electrocatalyst for the oxidation of CH_3NH_2 and $(CH_3)_2NH$ but not of $(CH_3)_3N$. The oxidation kinetics of the amines by $Ni^{III}L(H_2O)_2^{3+}$ indicate that the amines are good axial ligands to the tervalent nickel complex. The complexes $Ni^{III}L[N(CH_3)_iH_{3-i}](H_2O)^{3+}$ are stronger oxidants than the complexes $Ni^{III}L[N(CH_3)_iH_{3-i}]_2^{3+}$. The oxidation is base-catalyzed and obeys a second-order rate law in $Ni^{III}LX_2$. It is proposed that the key step is Ni^{III}–$L(H_2O)[N(CH_3)_iH_{2-i}]^{2+}$ + Ni^{II}-$^{I}LX_2$ → LNi^{II}–$N(=CH_2)(CH_3)_{i-1}H_{2-i}$ + $Ni^{II}L^{2+}$ + H_3O^+ + 2 X. Naturally, $N(CH_3)_3$ is not oxidized by this mechanism. Of special interest is the observation that the axial ligands CH_3NH_2 and $(CH_3)_2NH$ are oxidized by the central cation, while the cyclam ligand, which has four secondary amine groups bound to the nickel(III) ion, and axially bound pendant primary amine groups, which are covalently linked to the macrocyclic ligand, are relatively stable. This difference in the behavior of axially bound amine groups is attributed to the free rotation of the axially bound $N(CH_3)_iH_{3-i}$ ligands that is required for the oxidation to proceed.

Introduction

$Ni^{III}L^i(H_2O)_2^{3+}$ complexes, where L^i is a neutral tetraazamacrocyclic ligand, are stabilized by axial coordination of a variety of anions.[1−3] The $Ni^{III}L^i$ complexes are also stabilized by pendant amine substituents of the macrocyclic ligands, which are capable of binding axially to the central nickel cation.[4−7] Therefore, it seemed reasonable to try and stabilize $Ni^{III}L^i(H_2O)_2^{3+}$ complexes by axial coordination of amines. As the ligating groups of L^i are four secondary amines and as the pendant substitutes studied were primary amines,[4−7] it seemed reasonable to assume that axially bound amines will not be oxidized by the central Ni^{III} cation. Surprisingly, it was observed that $Ni^{II}L^{2+}$, where L = 1,4,8,11-teraazacyclotetradecane, is an electrocatalyst for the oxidation of CH_3NH_2 and $(CH_3)_2NH$. The mechanism of the oxidation of the amines was studied and the plausible reasons for the different oxidation resistance of free axial and pendant amines are discussed.

Results and Discussion

Electrochemistry

Cyclic voltammograms of NiL^{2+} in the presence of methylamine and dimethylamine (Figures 1 and 2) clearly demonstrate that the nickel complex is an electrocatalyst for the oxidation of these amines. On the other hand, the voltammogram in the presence of trimethylamine (Figure 3) reveals that this amine is not electrocatalytically oxidized in the presence this complex. From the small shift of the wave in the presence of $N(CH_3)_3$, the pH, and the pK_a of $HN(CH_3)_3^+$ (pK_a = 9.8) one can calculate, with the use of the Nernst equation, that the binding constant of $N(CH_3)_3$ to $Ni^{III}L(H_2O)_2^{2+}$ is smaller than 4.0×10^5 M^{-1}.

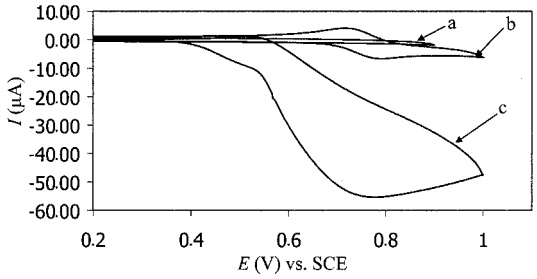

Figure 1. Voltammogram of NiL^{2+} in the presence of methylamine; solution composition: pH = 7.0; 0.1 M ($NaClO_4$); a: $NH_3CH_3^+$ 0.02 M; b: NiL^{2+} 0.0001 M; c: $NH_3CH_3^+$ 0.02 M, NiL^{2+} 0.0001 M; scan rate 50 mV/s

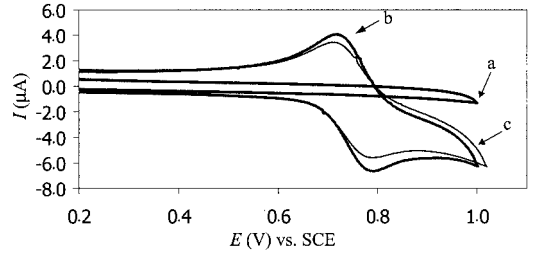

Figure 3. Voltammogram of NiL^{2+} in the presence of trimethylamine; solution composition: pH = 7.0; 0.1 M ($NaClO_4$); a: $NH(CH_3)_3^+$ 0.02 M; b: NiL^{2+} 0.0001 M; c: $NH(CH_3)_3^+$ 0.02 M, NiL^{2+} 0.0001 M; scan rate 50 mV/s

Kinetic Studies

When solutions containing 0.0001 M $Ni^{III}L(SO_4)_2^-$ are mixed with excess $NH_3CH_3^+$ or $NH_2(CH_3)_2^+$ at a constant ionic strength of 0.1 M ($NaClO_4$), fast disappearance of the spectrum due to the complex $Ni^{III}LX_2$ is observed, see for example Figure 4. The kinetics of this process fit a second-order rate law with respect to $[Ni^{III}LX_2]$.

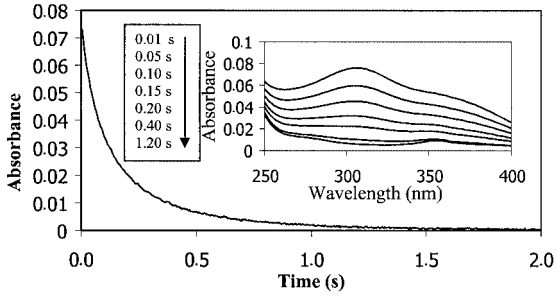

Figure 4. Oxidation of $NH_3CH_3^+$ by $Ni^{III}L(SO_4)_2^-$ at pH = 7.0; solution composition: $NH_3CH^+_3$ 0.01 M; $Ni^{III}L(SO_4)_2^-$ 0.0001 M; BIS TRIS buffer 0.0001 M; measured at 306 nm; inset: time-dependent spectra of the solution

Surprisingly, when the concentration of the amines is changed at constant pH, the rates of the processes decrease somewhat with an increase in the concentration of the amines (Table 1). These results clearly indicate that the equilibria according to Equations (1)−(3) exist in solution and that $Ni^{III}L[N(CH_3)_iH_{3-i}]_2^{3+}$ is more stable than $Ni^{III}L(H_2O)[N(CH_3)_iH_{3-i}]^{3+}$.

Table 1. Observed rates for the oxidation of amines by $Ni^{III}L(SO_4)_2^-$; solution composition: $NiL(SO_4)_2^-$ 0.0001 M; BIS TRIS buffer 0.0001 M; pH = 7.0

$2k$ [$M^{-1}s^{-1}$] for $NH_2(CH_3)_2^+$	$2k$ [$M^{-1}s^{-1}$] for $NH_3CH_3^+$	$NH_3CH_3^+$/ $NH_2(CH_3)_2^+$ [M]
5550 ± 50	49.0 ± 0.3	1.60×10^{-2}
5750 ± 50	63.5 ± 0.3	1.25×10^{-2}
5850 ± 40	72.5 ± 0.4	1.00×10^{-2}
5950 ± 40	85.0 ± 0.4	5.00×10^{-3}
6250 ± 50	88.0 ± 0.5	2.50×10^{-3}
6350 ± 50	92.0 ± 0.8	1.60×10^{-3}
6400 ± 50	97.0 ± 0.8	1.25×10^{-3}

$$Ni^{III}L_{aq} + N(CH_3)_iH_{3-i} \rightleftarrows Ni^{III}L(H_2O)N(CH_3)_iH_{3-i}^{3+} \ (i = 1 \text{or } 2) \quad (1)$$

$$Ni^{III}L(H_2O)N(CH_3)_iH_{3-i}^{3+} + N(CH_3)_iH_{3-i} \rightleftarrows Ni^{III}L[N(CH_3)_iH_{3-i}]_2^{3+} + H_2O \quad (2)$$

$$N(CH_3)_iH_{3-i} + H_3O^+ \rightleftarrows N(CH_3)_iH_{4-i}^+ \quad (3)$$

The maximum rate is observed at the lowest amine concentration studied, $[N(CH_3)_iH_{4-i}]^+ = 1.25 \times 10^{-3}$ M at pH = 7.0. This result indicates that already at this concentration at least one amine is bound to the nickel complex. From this value, assuming that at least 90% of the nickel(III) complexes have at least one bound amine at this pH, one calculates:

$$K_{1app} = \frac{[Ni^{III}L(H_2O)\{N(CH_3)_iH_{3-i}\}^{3+}]}{[Ni^{III}L(H_2O)_2^{3+}]\,[N(CH_3)_iH_{4-i}^+]} \geq 10 / 1.25\times10^{-3} = 8\times10^3\ M^{-1}$$

As the pK_a values of $N(CH_3)H_3^+$ and $N(CH_3)_2H_2^+$ are 10.64 and 10.72, respectively, one calculates from the results that (Supporting Information; see footnote on the first page of this article):

$$K_1 = \frac{[Ni^{III}L(H_2O)N(CH_3)H_2^{3+}]}{[Ni^{III}L(H_2O)_2^{3+}][N(CH_3)H_2]} \geq 3.4\times10^7\ M^{-1}$$

$$K_1 = \frac{[Ni^{III}L(H_2O)N(CH_3)H_2^{3+}]}{[Ni^{III}L(H_2O)_2^{3+}][N(CH_3)_2H]} \geq 4.1\times10^7\ M^{-1}$$

The estimation of the stability constant for the binding of the second amine molecule is considerably more difficult:

$$K_2 = \frac{[Ni^{III}L\{N(CH_3)_iH_{3-i}\}_2^{3+}]}{[Ni^{III}L(H_2O)\{N(CH_3)_iH_{3-i}\}^{3+}][N(CH_3)_iH_{3-i}]}$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

For this calculation one has to make one of two assumptions:

a) The rate of decomposition of $Ni^{III}L[N(CH_3)_iH_{3-i}]_2^{3+}$ is negligible relative to that of $Ni^{III}L(H_2O)[N(CH_3)_iH_{3-i}]^{3+}$. With this assumption, a lower limit for K_2 can be calculated.

b) The observed rate of decomposition at the highest concentration of $N(CH_3)_iH_{4-i}^{+}$ used is the rate of decomposition of $Ni^{III}L[N(CH_3)_iH_{3-i}]_2^{3+}$. With this assumption, an upper limit for K_2 is calculated.

Thus, $4.8 \times 10^5 < K_2 < 9.6 \times 10^6$ M^{-1} and $4.0 \times 10^5 < K_2 < 8.9 \times 10^6$ M^{-1} for $N(CH_3)H_2$ and $N(CH_3)_2H$, respectively, are obtained.

The pH effect on the rates of oxidation of CH_3NH_2 and $(CH_3)_2NH$ by $Ni^{III}L(SO_4)_2^{-}$ was studied. The results (Figure 5) indicate that the rate depends linearly on $[OH^-]$ over the entire pH range studied. This result is in agreement with the expectation that the axially bound amine has a pK_a, i.e.

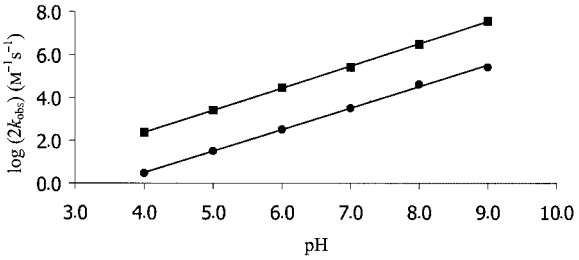

Figure 5. Dependence of the observed rate of oxidation of $NH_3CH_3^+$ (circles) and $NH_2(CH_3)_2^+$ (squares) on pH; solution composition: $NH_3CH_3^+/NH_2(CH_3)_2^+$ 0.01 M; $Ni^{III}L(SO_4)_2^-$ 0.0001 M; BIS TRIS buffer 0.0001 M (pH range 5.8−7.2); TRIS BASE buffer 0.0001 M (pH range 8.0−9.0); TRIS ACID buffer 0.0001 M (pH range 4.0−5.0)

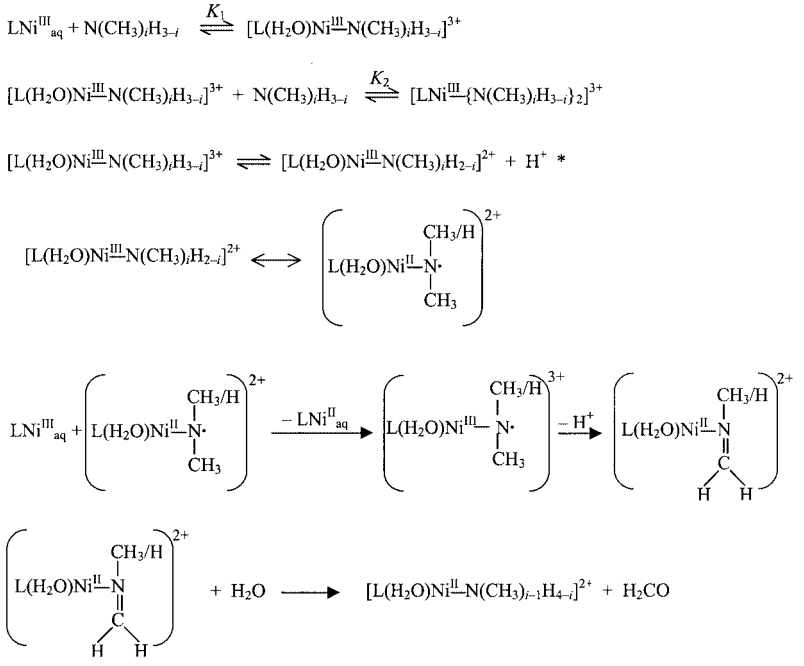
Thus, the kinetic results agree with the following mechanism for the oxidation of CH_3NH_2 and $(CH_3)_2NH$ by $Ni^{III}L(H_2O)_2^{3+}$; As the concentration of SO_4^{2-} in solution is 2×10^{-4} M, the complex loses the sulfate ligands when dissolved:[9]



* For simplicity only this possibility is drawn; however, clearly analogous reactions for $[LNi^{III}(N(CH_3)_iH_{3-i})_2]^{3+} \rightleftharpoons [L\{N(CH_3)_iH_{3-i}\}Ni^{III}N(CH_3)_iH_{2-i}]^{2+} + H^+$ have to be considered.

that one of its protons is lost and that the alkaline form $N(CH_3)_iH_{2-i}^{2+}$ is the one that is oxidized:

$$LNi^{III}-N(CH_3)_iH_{3-i}^{3+} + OH^- \rightleftarrows LNi^{III}-N(CH_3)_iH_{2-i}^{2+} + H_2O$$

The results indicate that the pK_a s of the bound amines are ≥ 10. The latter finding is in agreement with the suggestion that the secondary amines of the macrocyclic ligands in the Ni^{III} complexes have pK_a values > 10.[8]

This mechanism is in agreement with the suggested mechanism for the oxidation of the macrocyclic ligand by the central Ni^{III} ion, which occurs considerably slower.[8]

As the $N(CH_3)_iH_{3-i}$ ligands stabilize the central Ni^{III} ion by lowering the oxidation potential of the complex, $LNi^{III}-[N(CH_3)_iH_{3-i2}]$ decomposes slower than $L(H_2O)Ni^{III}N(CH_3)_iH_{3-i}$.

The proposed mechanism predicts that H_2CO will be one of the products of the reaction. Indeed, analysis indicates that the yield of H_2CO is 42 ± 4% of the $Ni^{III}L(SO_4)_2^-$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

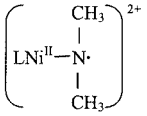
used; this is in good agreement with the proposed mechanism.

Concluding Remarks

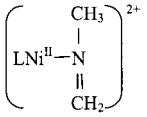
The results point out two relatively unexpected conclusions:

1. The binding constant of $N(CH_3)_3$ to $Ni^{III}L(H_2O)_2^{3+}$ is smaller by over two orders of magnitude than that of CH_3NH_2 and $(CH_3)_2NH$. This result is in agreement with previous results that show that tertiary amines are poor ligands to high-valent transition metal cations due to their hydrophobic nature.[10−12]

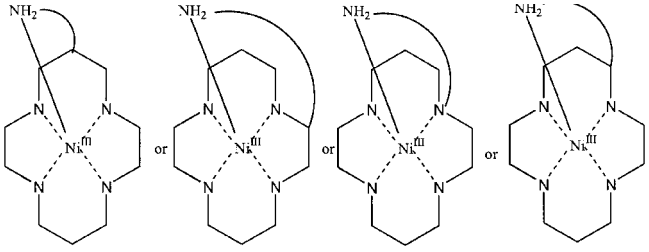
2. The free axial ligands $(CH_3)NH_2$ and $(CH_3)_2NH$ are oxidized faster by many orders of magnitude than axial pendant primary amines, which are bound as substituents to the macrocyclic ligand. The source of this difference seems to be that the transformation of



into



through oxidation requires a relatively free rotation around the $N-CH_3$ bond. This rotation is hindered around the C−N bonds of the macrocyclic ligand and around the C−N bonds in complexes with the general structure:



A similar interpretation was given previously to explain the different stabilities of the *rac* and *meso* diastereoisomers of Ni^{III}(5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane)$^{3+}$.[8]

Experimental Section

Materials: The ligand L = 1,4,8,11-tetraazacyclotetradecane and the complex $Ni^{II}L(ClO_4)_2$ were synthesized by a previously reported method.[13] All other chemicals used were of analytical grade, and were used without further purification. All solutions were prepared with heat-distilled water, which was further purified by passing through a Millipore Milli-Q water purification system, to a final resistance >10 $^{m}\Omega$.

Preparation of $Ni^{III}L(SO_4)_2$: The tervalent complex was prepared by oxidation of $Ni^{II}L^{2+}$ by $Na_2S_2O_8$ at pH = 3.0. The complex thus prepared is relatively stable in aqueous solutions, $t_{1/2}$ = several hours.[9] The yield was determined spectrophotometrically by measuring the absorption at λ = 306 nm (ε = 9600 $M^{-1}cm^{-1}$).[9]

Electrochemical Procedures: Cyclic voltammetric studies were carried out using an EG&G Princeton Applied Research potentiostat/galvanostat, model 263 A, operated by a Research Electrochemistry software EG&G PARC, with a three-electrode assembly consisting of a glassy carbon working electrode (A = 0.07 cm^2), a platinum counter electrode, and a saturated calomel electrode as the reference electrode.

Kinetic Studies: Slow reactions were monitored spectrophotometrically with an HP 8452-A diode array spectrophotometer, in an anaerobic UV/Vis quartz cell. Fast reactions were studied with a stopped-flow Applied Photo Physics, Model SX 18-MV apparatus.

H_2CO Analysis: Formaldehyde was determined by a colorimetric method[14] from its yellow complex with acetyl acetone (diacetyldihydrolutidine) measuring the absorption at 412 nm.

Acknowledgments

This study was supported in part by a grant from the Budgeting and Planning Committee of The Council of Higher Education and the Israel Atomic Energy Commission. D. M. wishes to express his thanks to Mrs. Irene Evens for her ongoing interest and support.

From Discrete to Extended Guests: A Novel Supramolecular $[Hg_6As_4](AgCl_3)_2$ Assembly Featuring One-Dimensional $(AgCl_3)^{2-}$ Anions

Olga S. Oleneva,[a] Andrei V. Olenev,[a] Evgeny V. Dikarev,[b] and Andrei V. Shevelkov*[a]

Keywords: Arsenic / Host–guest systems / Mercury / Silver / Supramolecular chemistry

A novel supramolecular assembly $[Hg_6As_4](AgCl_3)_2$ has been prepared and its structure determined. It crystallizes in the monoclinic system, space group $I2/a$ (no. 15), with the unit-cell dimensions a = 14.690(1), b = 9.1851(7), c = 20.285(1) Å, β = 93.17(1)°, and Z = 4. The crystal structure comprises a three-dimensional cationic host framework, $[Hg_6As_4]^{4+}$, built of mercury and arsenic atoms and one-dimensional $^1_\infty(AgCl_3)^{2-}$ guest anions built of corner-sharing $[AgCl_4]$ tetrahedra. The title compound is the first example of a perfectly ordered supramolecular architecture having an infinite chain anion as a guest moiety embedded into a mercury–pnicogen cationic framework.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The formation of supramolecular assemblies is usually controlled by the size, shape, and, where appropriate, charge of guest species that template the host framework.[1] The use of rigid guests enables prediction and successful realization of the desired host-framework topology. Supramolecular architectures form spontaneously through a self-assembly process; the resulting structures typically exhibit perfect ordering of the guests within the cavities of the framework. Such an ordering is achieved due to a reasonably large number of weak host–guest interactions.[2] The process of self-assembly is hard to follow and control in the case of high-temperature ampoule synthesis,[3] therefore only knowledge of typical host frameworks and guest units that can form in a given system can be used for predicting new architectures. Such knowledge is frequently based merely on trends in oxidation states, coordination numbers, and bond lengths.[4]

A broad family of supramolecular assemblies based on the mercury–pnicogen cationic frameworks has been reported in the past decade.[2,5] In these frameworks, mercury atoms possess linear coordination while pnicogen atoms have a tetrahedral environment. There are many possible arrangements of mercury and pnicogen atoms, leading to different topologies of the cationic framework guided by the size, shape, and charge of the guest anions. The guests that take their "assigned" positions within the cavities of the framework have been represented so far by discrete anions only. Octahedral,[5] tetrahedral,[6] pyramidal,[7] and triangular[2] anions have been successfully embedded into closed cavities of host frameworks of complementary topology. We therefore tried to find out if infinite anions could be accommodated by a mercury–pnicogen cationic matrix. Group 11 elements seemed to be a logical choice for such work since they frequently form infinite anions through condensation of different building units.[8] In particular, the $AgX_n^{(n-1)-}$ anions are well known[9,10] to form chains of condensed tetrahedra in the presence of different inorganic and organic cations.

In this article, we report the first supramolecular architecture in which a one-dimensional (1D) anionic chain, instead of a discrete anion, serves as a guest unit in an $[Hg_6As_4](AgCl_3)_2$ supramolecular assembly.

Results and Discussion

$[Hg_6As_4](AgCl_3)_2$ was prepared by a stoichiometric ampoule synthesis at elevated temperatures (see Exp. Sect. for details) as a bright-red, polycrystalline solid that is stable in moist air. It crystallizes in the monoclinic space group $I2/a$. The crystal structure comprises a three-dimensional (3D) host framework built of mercury and arsenic atoms and one-dimensional (1D) guest anions built of corner-sharing $[AgCl_4]$ tetrahedra (Figure 1).

There are six crystallographic positions occupied by mercury atoms (Table 1), each having linear coordination by two arsenic atoms. The Hg–As distances (Table 2) are similar to those reported in the literature.[5–7,11] The As–Hg–As angles (Table 3) deviate significantly from 180° only for the Hg(1) and Hg(2) atoms, each experiencing an influence of two distant chlorine atoms. The corresponding

[a] U_{eq} is defined as one third of the trace of the orthogonalized U_{ij} *tensor.*

Hg···Cl interactions (2.80−2.87 Å) are much longer than typical Hg−Cl covalent bonds of 2.27−2.29 Å,[12] but do not exceed the Hg···Cl host−guest separations of 3.07−3.34 Å observed in other supramolecular architectures of general formula $[Hg_6Pn_4](MCl_6)Cl$ (Pn = P or As; M = Ti, Mo, or In).[13]

All three crystallographically independent arsenic atoms display similar tetrahedral coordination. They each form one As−As bond and three Hg−As bonds. The As−As bond length (Table 2) is typical for a single bond,[14] which leads to the assignment of a −2 oxidation state to the arsenic atoms. Linear coordination of the mercury atoms with

no Hg−Hg bonds present points to a +2 oxidation state of mercury. Consequently, the host framework carries a +4 charge per formula unit that can be formulated as $[Hg_6As_4]^{4+}$. The formula of the cationic framework is the same as in the series of supramolecular complexes with general formula $[Hg_6As_4](MX_6)Y$ (M = Ti, Mo, Cr, Fe, In, Sb, Hg; Y = Cl, Br, I, Hg).[5] However, the frameworks of the latter assemblies have a different topology (Figure 2). They possess two types of symmetric cavities capable of trapping guests of two different sizes. The guests carry a total charge of −4 to compensate for the positive charge of the framework. In the case where M is a trivalent metal, this compensation is achieved by a combination of two guest anions, $M^{III}X_6^{3-}$ and Y^-, occupying the larger and smaller cavities, respectively. If M is a divalent metal, the octahedral $M^{II}X_6^{4-}$ anions do not require additional charge-compensating guests, whereas the smaller cavities either trap zerovalent mercury or remain empty. In the title compound, all the cavities are almost of the same size and less symmetric.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

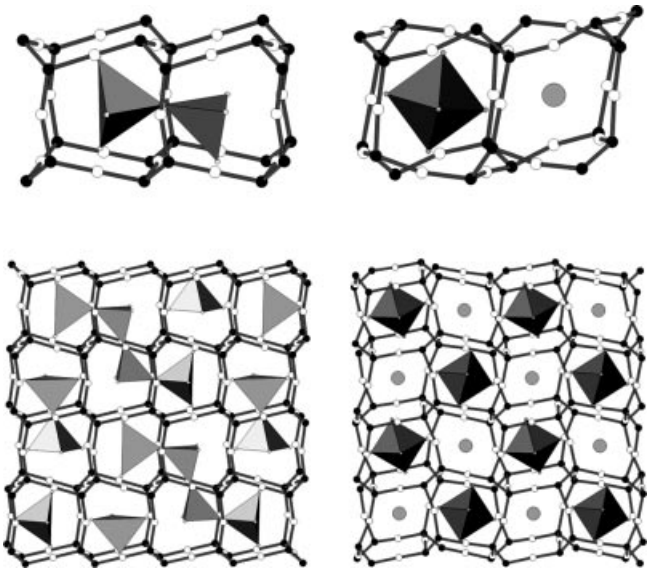

Figure 2. Topology of the $[Hg_6As_4]$ framework in the title compound (left) and in the $[Hg_6Pn_4](MX_6)Y$ complexes (right): two adjacent cages (top) and a 4×4 grid (bottom); mercury: open circles; pnicogen: filled circles; guest units are shown in polyhedral presentation save for the monoatomic guest shown as large gray circles

The difference in the framework topology reflects their different hierarchical origin. The title compound framework originates from a 4-connected As net having a lonsdaleite[15] topology in which three of four edges are expanded[16] by mercury atoms. On the other hand, the framework in the $[Hg_6As_4](MX_6)Y$ compounds originates from the γ-Si[17] topology. As a consequence, while the compositions of the frameworks are the same, their topologies are different.

The guest part of the structure is the 1D anionic chain composed of $AgCl_4$ tetrahedra sharing the corners (Figure 3). Two types of tetrahedra compose each chain; however, the environment of the Ag(1) and Ag(2) atoms centering the tetrahedra appears to be very similar. Each silver atom is surrounded by four chloride ions so that there are two short (2.48−2.49 Å) and two long (2.80−2.84 Å) Ag−Cl interactions involving terminal and bridging chlorine atoms, respectively. The Ag−Cl bond lengths fall in the range of 2.37−2.92 Å reported in the literature[9,18] for similar anions. The tetrahedral coordination of a silver atom by chloride ions is very common; moreover, there are examples of corner-sharing $[AgCl_4]$ tetrahedra in Cs_2AgCl_3 and Rb_2AgCl_3, for instance,[9] although the resulting chains are straight rather than spiral as in the title compound. The oxidation states for the silver and chlorine atoms apparently are +1 and −1, respectively, giving the formulation of the anionic chain as $^1_\infty(AgCl_3)^{2-}$. Hence, the notation of the supramolecular assembly as $[Hg_6As_4](AgCl_3)_2$ indicates the host−guest charge balance.

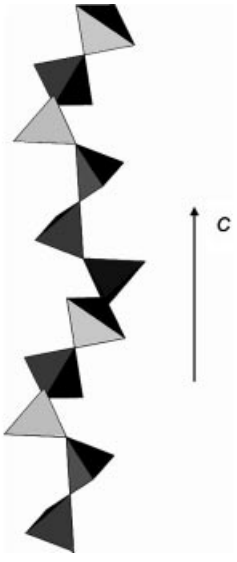

Figure 3. View of the 6-step $(AgCl_3)^{2-}$ anionic chain

The conformation of the 1D $(AgCl_3)^{2-}$ anion is best described as a 6-step spiral chain of tetrahedra,[19] reflecting the repeat unit (Figure 3). The chains are chiral; both enantiomers are present in the centrosymmetric structure. At this stage we cannot explain the observed conformation of the anionic chains. It is clear, though, that there are several factors that control the geometry and conformation of the guest unit. Firstly, a high negative charge of a single $AgCl_4^{3-}$ anion favors condensation of tetrahedra in a vertex-sharing fashion. Secondly, three of five independent chlorine atoms [Cl(1), Cl(2), and Cl(3)] have rather distant contacts with the mercury atoms of the host framework, ensuring that the host and guest units assemble into an ordered supramolecular architecture through weak host−guest interactions. The dimensions of the $[AgCl_4]$ tetrahedra and their fitting into the cavities of the framework should also be taken into account.

In general, this research confirms that it is possible to accommodate infinite anions within a host cationic framework. The title compound is the first example of a supramolecular architecture having a chiral tetrahedral chain as a guest moiety embedded into a mercury−pnicogen framework. The lack of structural data does not allow us to explain the observed features or to predict similar architectures. Nevertheless, the principal direction of a search for new compounds having infinite anions embedded into a mercury−pnicogen framework is clear. It is based on the propensity of the Group 11 elements to form condensed polyhedral anions of flexible geometry, with variable coordination and oxidation number of the central atom. A search for new compounds of this type is currently underway.

Experimental Section

Synthesis: A stoichiometric mixture of mercury(I) chloride, gray arsenic, and silver powder (all > 99.99% purity, total weight 0.5 g) was sealed in a silica tube, annealed at 680 K for 6 d, and then furnace-cooled. A comparison of the diffraction pattern [STADI-P (Stoe), Cu-$K_{\alpha 1}$ radiation] of the red, air-stable product with the theoretical one calculated on the basis of the data obtained during the crystal structure refinement revealed that the product was a desired new phase. However, the profile analysis of the diffractogram enabled us to suggest that only slight admixtures of mercury(II)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

chloride and silver chloride were present. For a single-crystal preparation, a mixture of Hg_2Cl_2, As, and Ag taken in a 3:4:2 molar ratio was annealed in a silica tube at 680 K for 5 d. Red crystals were found in the furnace-cooled product.

Crystal Structure Determination: A red crystal with approximate dimensions 0.09 mm × 0.04 mm × 0.03 mm was selected from the reaction product for X-ray crystallographic analysis. The X-ray intensity data were recorded at 173(2) K (Bruker KRYO-FLEX) with a Bruker SMART APEX CCD-based X-ray diffractometer system equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) operated at 1800 W. The detector was placed at a distance of 6.140 cm from the crystal. The data collection covered approximately a hemisphere of the reciprocal space. A total of 1850 frames were collected with a scan width of 0.3° in ω and an exposure time of 20 s/frame. The frames were integrated with the Bruker SAINT software package[20] using a narrow-frame integration algorithm. The integration of the data using a monoclinic unit-cell yielded a total of 11582 reflections to a maximum 2θ angle of 56.45° (0.75 Å resolution), of which 3204 were independent (R_{int} = 0.0389). The final cell constants are based upon the refinement of the *XYZ*-centroids of 4394 reflections above $20\sigma(I)$. Analysis of the duplicate reflections showed negligible decay during data collection. Data were corrected for absorption effects using the empirical method (SADABS),[21] the ratio of minimum/maximum apparent transmission was 0.3865. The structure was solved and refined by a full-matrix least-squares procedure on $|F^2|$ in the *I*2/*a* space group using the Bruker SHELXTL (Version 6.12) software package.[22] The positions of six mercury and three arsenic atoms were found in direct-method *E* maps. The remaining atoms were located from a combination of least-squares refinement and difference Fourier synthesis. The isotropic refinement of the obtained model led to $R1$ = 0.078 with the slightly enlarged thermal displacement parameters of both silver atoms. However, refinement of the occupancies of these atoms proved full occupation for the corresponding positions. Attempts to refine the structure with split positions of the silver atoms did not lead to satisfactory results. Final anisotropic refinement led to the composition $[Hg_6As_4](AgCl_3)_2$, that is in excellent agreement with synthesis data, and to the atomic and structural parameters listed in Tables 1 and 4, respectively. Further details of the crystal structure determination may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-413821.

Table 4. Data collection and structure refinement parameters for $[Hg_6As_4](AgCl_3)_2$

Empirical formula	$Ag_2As_4Cl_6Hg_6$
T [K]	173(2)
Space group	*I*2/*a*

Anion Binding of 1,1′-Bis(dialkylboryl)cobaltocenium Complexes − Structures of $[Co\{C_5H_4(BMe_2)\}_2]PF_6$, $Co[C_5H_4(BMe_2)][C_5H_4(BMe_2Cl)]$, $Co[C_5H_4(BiPr_2)]_2(\mu\text{-}F)$ and $NMe_4[Co\{C_5H_4(BiPr_2F)\}_2]$[‡]

Gerhard E. Herberich,*[a] Ulli Englert,[a] Andreas Fischer,[a][‡‡] and Dag Wiebelhaus[a][‡‡‡]

Keywords: Anion binding / Borates / Boron / Cobalt / Sandwich complexes

The cobaltocenium salts $[Co\{C_5H_4(BiPr_2)\}_2]PF_6$ [(**1a**)PF_6] and $[Co\{C_5H_4(BMe_2)\}_2]PF_6$ [(**1b**)PF_6] are strong Lewis acids. With pyridine (**1a**)PF_6 forms a mono-adduct **2** and a di-adduct **3** which show NMR spectra in the low-temperature regime of pyridine exchange. With chloride from PPh_4Cl the adduct formed is dynamic; quite remarkably, the formation of an anionic di-adduct is also observed. The mono-adducts (**1a**)X (X = F, Cl, Br, I, OH, and NH_2) and (**1b**)X (X = F, Cl, and OH) as well as the di-adduct salts $NMe_4[(\mathbf{1a})F_2]$ (**5**) and $K[(\mathbf{1a})(OH)_2]$ (**6**) are made by treating the salts (**1a**,**b**)PF_6 in CH_2Cl_2 or $MeNO_2$ with salts PPh_4X, NMe_4F, or powders of $NaNH_2$ or KOH in the appropriate ratios. X-ray single-crystal structures of the salt $[Co\{C_5H_4(BMe)_2\}_2]PF_6$ [(**1b**)PF_6], the semi-quaternized mono-adduct $Co[C_5H_4(BMe_2)][C_5H_4(BMe_2Cl)]$ (**4bd**) [B–Cl = 1.969(2) Å], the inverse chelate $Co[C_5H_4(BiPr_2)]_2(\mu\text{-}F)$ (**4ac**) with the very rare feature of fluorine bridging two boron centers [C_2 symmetric; B–F = 1.641(4) Å, B–F–B′ = 148.4(3)°], and the doubly quaternized di-adduct $NMe_4[Co\{C_5H_4(BiPr_2F)\}_2]$ (**5**) [exactly centrosymmetric; B–F = 1.477(4) Å] are given. Solution structures of the 1:1 products greatly depend on the nature of the anion, displaying i) exclusively ionic structures for (**1a**)PF_6 and (**1b**)PF_6, ii) semi-quaternized structures for the heavier halides (**1a**)Br (**4ae**) and (**1a**)I (**4af**) with some noticeable ionic dissociation, iii) semi-quaternized structures in equilibrium with minor amounts of inverse chelate isomers for (**1a**)F (**4ac**), (**1b**)Cl (**4bd**), and very likely for (**1a**)Cl (**4ad**), and iv) stable inverse chelate structures for $Co[C_5H_4(BiPr_2)]_2(\mu\text{-}NH_2)$ (**4aa**) (static in variable temperature NMR spectra, with diastereotopic Me groups), $Co[C_5H_4(BR_2)]_2(\mu\text{-}OH)$ [**4ab**: R = *i*Pr; **4bb**: R = Me; dynamic; for **4ab** T_c = 95 ± 5 °C, $\Delta G^{\neq}_{368}$ = 75(1) kJ·mol^{-1} for interchange of the diastereotopic Me groups], and $Co[C_5H_4(BMe_2)]_2(\mu\text{-}F)$ (**4bc**). The stability of the inverse chelates decreases in the order amide (**4aa**) > hydroxides (**4ab** and **4bb**) > fluorides (**4ac** and **4bc**) > chlorides (**4ad** and **4bd**), and also in the order BMe_2 > $BiPr_2$ (specifically **4bc** > **4ac**, and **4bd** > **4ad**). Variable temperature NMR spectra of solutions of **4bd** (CD_2Cl_2, 173–243 K) show that i) the ring-opening of the chelated chloride ($\Delta G^{\neq}_{368} \approx 45$ kJ·mol^{-1}) is energetically easier than for the chelated hydroxide **4ab**, ii) the predominance of the semi-quaternized isomer over the inverse chelate ($\Delta_R H$ = 2.5 ± 1.1 kJ·mol^{-1}, $\Delta_R S$ = 37.6 ± 5.4 kJ·mol^{-1}·K^{-1}) in the equilibrium is entropic in nature, and iii) the semi-quaternized isomer still undergoes fast chloride-exchange in the low-temperature regime of this equilibrium, proving the existence of an independent, intermolecular chloride-exchange mechanism.

Introduction

Anion recognition is one of the central themes of supramolecular chemistry,[3] and has been the subject of numerous reviews.[4] The binding of an anionic guest species to a host molecule may be caused mainly by one of three effects: electrostatic attraction by cationic centers, formation of polar bonds with Lewis-acidic centers, and formation of hydrogen bonds; these effects often act in combination.

The earliest example was the discovery in 1966, by Shriver and Biallas, that the 1,2-diborylethane $F_2BCH_2CH_2BF_2$ reacts with the trityl ether Ph_3COMe to give ether cleavage and formation of an inverse chelate $Ph_3C[(CH_2BF_2)_2(\mu\text{-}OMe)]$[5] with the anion being bonded simultaneously by two Lewis acid centers. Katz subsequently introduced 1,8-diborylnaphthalenes, which differ from the above-mentioned diborylethane in that they have their boron centers sterically fixed and thus are more close to the idea of a molecular pincer species.[6] This preorganization[7] of the chelating ligand ensures more efficient anion chelation since the reaction entropy is less unfavorable than in the case of the conformationally flexible 1,2-bis(difluoro-

[‡] Bis(boryl)metallocenes, 3; Part 2: Ref.[1] This work also forms part of a dissertation.[2]

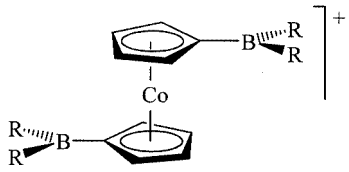
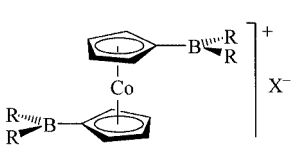
boryl)ethane. Conformationally rigid chelate ligands have also been made by other groups[8] and have recently been used for the construction of highly electrophilic anion pincers.[9]

In this paper we treat anion binding by cationic two-boron host species, the two 1,1′-bis(dialkylboryl)cobaltocenium cations **1a**$^+$ and **1b**$^+$, in the form of their hexafluorophosphate salts. These cationic anion pincers possess a skeletal flexibility similar to that of a diborylethane, but in contrast to the older two-boron examples, they are cationic and exert an electrostatic field effect which adds stability to their anion complexes.

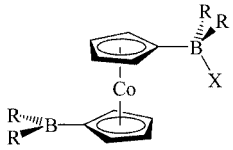


1a$^+$: R = *i*Pr; **1b**$^+$: R = Me

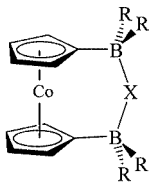
Cations of type **1** give rise to strong cation-anion interactions, and four structural types are encountered: type **A** with purely ionic interactions, a semi-quaternized type **B** with a zwitterionic situation, type **C** with an inverse chelate structure, and finally the doubly quaternized type **D**. In our preliminary communication of this topic we have already described one example each of types **A**−**C** [the compounds (**1a**)PF_6, (**1a**)Cl, and (**1a**)(OH), respectively],[10] while an example of type **D** structures will be given below for the first time.



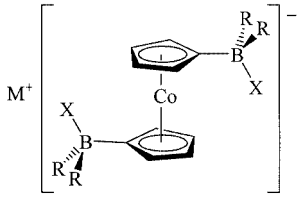
A



B



C



D

Before becoming more specific we note a detail of great analytical value. The pincer cation **1a** with the diisopropylboryl substituents will have diastereotopic methyl groups in the structures of type **C** and **D** and for one of the ligands of type **B**, provided these structures are not dynamic. In all other cases the methyl groups are equivalent. This feature will provide us with insights which remain hidden in case of the dimethylboryl analogue **1b**$^+$.

Results and Discussion

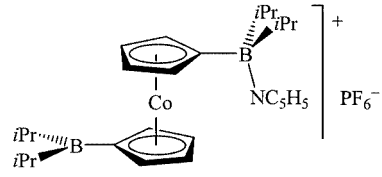
Synthesis of the Anion Binding Cobaltocenium Ions

The diisopropylboryl compound (**1a**)PF_6 can be made in a straightforward two-step synthesis.[10] First, the cobaltocene **1a** is prepared from Li[C_5H_4(B*i*Pr$_2$)][11]/$CoBr_2$(DME). Subsequent oxidation with [$FeCp_2$]PF_6 [12] in dichloromethane affords the desired compound, which was characterized structurally as an ionic compound without specific cation-anion interactions.

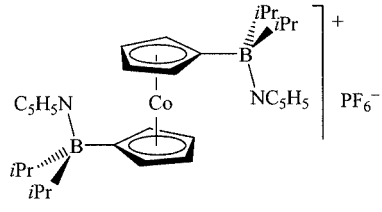
The dimethylboryl analogue (**1b**)PF_6 could potentially be made by an analogous sequence. For practical reasons it seemed more convenient to synthesize it by a different route. First we prepared the cobaltocene Co[C_5H_4-{B(NEt_2)$_2$}]$_2$ and, by quantitative oxidation with C_2Cl_6, the corresponding chloride [Co{C_5H_4[B(NEt_2)$_2$]}$_2$]Cl.[1] Subsequent treatment with BCl_3 and then with Al_2Me_6 afforded the salt (**1b**)$AlCl_4$, and, by anion metathesis, (**1b**)PF_6.[1]

First Observations

In a first series of NMR-tube experiments a solution of (**1a**)PF_6 in CD_2Cl_2 was treated with varying amounts of pyridine. Formation of a mono-adduct **2** and of a di-adduct **3** was observed, quite as expected. If the ratio of the reactants py/**1a**$^+$ is chosen close to 1:1 or to 2:1 the respective adducts can be isolated by crystallization at −30 °C; they were not characterized in detail.



2



3

Several observations are of interest. First, the reaction mixtures are close to the slow-exchange regime, and all species involved can be observed separately in the ^1H, ^{13}C, and ^{11}B NMR spectra. However, the hyperfine structure of the ring protons is blurred and the two different rings of **2** cannot be distinguished in the $^1H\{^1H\}$ NOE difference

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

spectrum, indicating a slow exchange of the pyridine. The adduct-formation equilibria are far on the right side as no free pyridine is seen at py/**1a**$^+$ ratios below two. Also, the adduct formation to give **3** is less strong than the formation of **2** as no di-adduct **3** is seen at py/**1a**$^+$ ratios lower than one. These observations are remarkable since the pyridine adducts of the known uncharged complexes $M(CO)_2\{C_5H_4(BMe_2)\}$ (M = Co, Rh) show fast exchange with excess pyridine.[13] Hence the cation **1a**$^+$ is a comparatively stronger Lewis acid, even in the second stage.

In a second experiment we titrated (**1a**)PF_6 with PPh_4Cl in dichloromethane solution and monitored the ensuing reaction by ^{11}B NMR spectroscopy (Figure 1). Only one ^{11}B NMR signal is seen over the entire range of the titration, indicating a fast-exchange regime for the interaction of cation **1a**$^+$ and Cl^-.

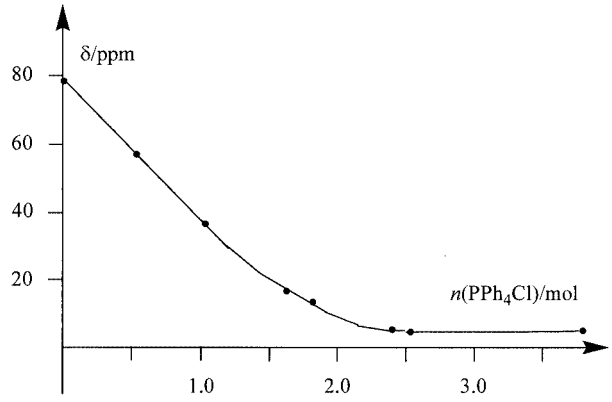


Figure 1. Boron chemical shifts during titration of (**1a**)PF_6 with PPh_4Cl in CD_2Cl_2

The chemical shift at the beginning of the titration (δ = 79 ppm) is that of **1a**$^+$ and conforms to the expected value for dialkylarylboranes, while the final chemical shift (δ = 5 ppm) indicates the presence of a fully quaternized species, the anionic species $[(\mathbf{1a})Cl_2]^-$.[14] The first addition of Cl^- to **1a**$^+$ is energetically rather favorable since we observe a straight line for the chemical-shift values up to a ratio of $Cl^-/\mathbf{1a}^+ \leq 1$. The product (**1a**)Cl is dynamic and shows a chemical shift (δ = 37 ppm) which can be understood as the mean of the chemical shifts for one trigonal and one tetrahedral boron center. Hence, the product (**1a**)Cl possesses the same semi-quaternized structure in solution that has also been found in the crystal.[10] The second addition of Cl^- is less favorable energetically, as indicated by the curvature of the line, and an excess of Cl^- (almost 2.5 mol) is needed to complete the formation of $PPh_4[(\mathbf{1a})Cl_2]$, the doubly quaternized end-product. Below we shall discuss the nature of the observed chloride-exchange process for (**1a**)Cl and also give a more thorough comment on its solution structure.

Synthetic Methods I: Uncharged Complexes

Complexes of types **B** and **C** were made by essentially the same general method. We treated the salts (**1a**,**b**)PF_6 in CH_2Cl_2, or occasionally in nitromethane, with a second salt such as NMe_4F, PPh_4Cl, PPh_4Br, and PPh_4I in a 1:1 ratio. The large organic cations ensured a sufficient solubility. If such salts were not readily available, inorganic salts such as KOH and $NaNH_2$ had to be used in powdered form, and long reaction times were required. After completion of the reaction the polar solvent was removed. The product was then extracted with toluene and isolated from that solvent. When crystals were desired the material was recrystallized from CH_2Cl_2/toluene. Yields were mostly very good, but no reactions were achieved with NMe_2^-, OMe^-, and OPh^-, and attempted addition of hydride induced decomposition. In some cases oxidation of the cobaltocene **1a** could be used as an alternative method, and (**1a**)Cl (**4ad**) and (**1a**)(OH) (**4ab**) were made in this way (Scheme 1).[10]

$$[Co\{C_5H_4(BR_2)\}_2]PF_6 \xrightarrow[-ZPF_6]{+ZX} Co[C_5H_4(BR_2)]_2 * X$$

(**1a**,**b**)PF_6 — **4**

R = Me		**bb**	**bc**	**bd**		
X	NH_2	OH	F	Cl	Br	I

Scheme 1

Synthetic Methods II: Doubly Quaternized Complexes

The salt $PPh_4[(\mathbf{1a})Cl_2]$ that was observed in the titration experiment was not stable enough to be isolated. However, with the more Lewis basic anions F^- and OH^- salts with doubly quaternized anionic complexes could be isolated. When (**1a**)PF_6 in CH_2Cl_2 was treated with NMe_4F in a 1:2 ratio, the ammonium fluoride dissolved despite its low solubility in that solvent (Scheme 2). Since the resulting robust product $NMe_4[(\mathbf{1a})F_2]$ (**5**) readily dissolves in toluene it can be isolated by the same general technique described above. It was crystallized by slowly concentrating its solution in toluene or by recrystallization from CH_2Cl_2/Et_2O. The analogous treatment of (**1a**)PF_6 in CH_2Cl_2 with an excess of finely ground KOH afforded the potassium salt $K[(\mathbf{1a})(OH)_2]$ (**6**), which can be crystallized from toluene/hexane. Treatment of the hydroxide **4ab** with KOH also produces complex **6**. The conceivable alternative of a deprotonation is not observed.

$$[Co\{C_5H_4(BiPr_2)\}_2]PF_6 \xrightarrow[-ZPF_6]{+2\,ZX} Z[Co\{C_5H_4(BiPr_2X)\}_2]$$

Crystal Structures of (1b)PF_6, 4bd, 4ac, and 5

We present four crystal structures which exemplify the four archetypal cation-anion interactions (**A**−**D**) mentioned

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

above. Compound (**1b**)PF_6 is ionic with essentially purely electrostatic interaction between the anion and **1b**$^+$ (type **A**; Figure 2). The chloride **4bd** displays a semi-quaternized structure (type **B**; Figure 3). For **4ac** an inverse chelate type is observed (type **C**; Figure 4), and **5** finally has a doubly quaternized structure (type **D**; Figure 5).

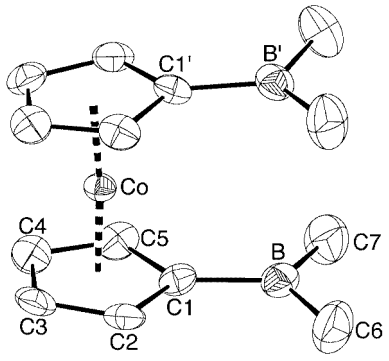

Figure 2. Structure of the cation of (**1b**)PF_6 (PLATON plot[15] at the 50% probability level); selected bond lengths (Å): Co−C 2.032 (av.) [range 2.021(3)−2.055(4)], C1−B 1.566(6), C6−B 1.554(6), C7−B 1.542(7)

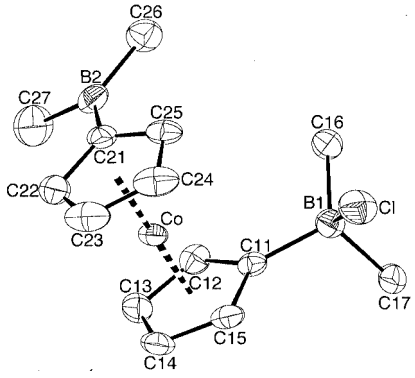

Figure 3. Structure of the chloride **4bd** (PLATON plot[15] at the 50% probability level); selected bond lengths (Å): Co−C(Cp1) 2.034 (av.) All structures contain a cobaltocenium moiety with the usual metal−ring distance for formal cobalt(III) (close to 1.63 Å), regardless of its actual overall charge. The salt (**1b**)PF_6 displays crystallographic mirror symmetry and hence an exactly eclipsed conformation. The resulting transannular repulsion is reflected in a ring tilt of 6.3(2)°; all other structures contain parallel planar ring systems. The torsion angle (B−cog-cog′−B′)[16] varies from exactly 0° for (**1b**)PF_6 through 26° for **4ac** and 83° for **4bd** to exactly 180° for **5**. This last compound displays crystallographic centrosymmetry which places the two negative charge centers of the anion $[Co\{C_5H_4(BiPr_2F)\}_2]^-$ at maximum distance. In all other cases the ring-ring torsional mode should be very soft, and the torsional angle observed should largely be determined by lattice forces.

Next we consider the distance B···B′. This distance is 3.543(7) Å in the structure of (**1b**)PF_6, and would be 3.270 Å for the same cation with parallel eclipsed rings. In the inverse chelate $Co[C_5H_4(BF_2)]_2(\mu\text{-}OH)$ it amounts to only 2.752(4) Å,[1] demonstrating a variation of the B···B′ distance of up to 0.8 Å for eclipsed conformations. Ring-ring rotation adds further variability to the pincer bite of the cations **1a**,**b**$^+$.

Of general interest are the boron−anion distances as they should be related qualitatively to the strength of the cation−anion interaction. Bond lengths for chlorine fixed to a quaternized boron center vary within a wide range of 1.76 to 1.92 Å.[17] The average value is about 1.83 Å[18] and distances at the higher end of the given range are considered as weak.[17a] We should, however, remember in this context that the sizeable electrostatic contribution to the bonding interaction varies roughly with 1/*r* and thus is only weakly affected by small bond-length variations. The B−Cl distance for the *B*-methyl compound **4bd** is even longer, with a value of 1.969(2) Å. The same distance in the *B*-*i*Pr compound **4ad** [1.982(3) Å] is marginally longer;[10] a marked steric influence of the isopropyl groups is not seen here.

The reported B−F bond lengths (for bonds with terminal fluorine) lie in a comparatively narrow range from 1.36 to 1.43 Å for quaternized boron centers.[19] All of these dis-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tances are from compounds with more than one fluorine atom directly attached to boron. Substitution of fluorine with an alkyl substituent leads to less-positive boron centers and, consequently, to longer distances for the remaining B−F bonds. Thus, for BF_4^- an average of 1.37 Å has been found,[18] whereas for $MeBF_3^-$ a value of 1.424 Å has been reported.[19e] Therefore the observed value of 1.477(4) Å for **5** seems to conform to expectations for a fluorotriorganoborate.

Before discussing the B−F distance in **4ac**, we have to consider the identity of the material isolated as **4ac**. In our previous work an attempted synthesis of $Co[C_5H_4(BF_2)]_2(\mu\text{-}F)$ resulted in the isolation of $Co[C_5H_4(BF_2)]_2(\mu\text{-}OH)$,[1] thus indicating a strong preference for OH^- binding of the corresponding pincer cation. In the present case, the ^1H NMR spectra showed the presence of small admixtures of the hydroxo compound **4ab** which increased when the material was manipulated, for instance in a recrystallization procedure. The structural data for **4ac** are very similar to those reported for **4ab**,[10] showing the same space group (*Pccn* no. 56), the same crystallographic C_2 symmetry of the inverse chelate, and rather similar atomic coordinates, bond lengths, and angles. These observations suggested that the two compounds might cocrystallize; hence the structure was refined assuming cocrystallization of **4ac** and **4ab**. The refinement converged for a **4ac/4ab** ratio of 79(3)/21(3). Thus, a high predominance of the fluoride **4ac** in the crystal picked for the structure determination can be considered as certain.

The structure of the inverse chelate **4ac** is highly unusual in that it displays a fluorine bridging two boron centers. A search in the Cambridge Structural Database (CSD)[20,21] resulted in only two hits, a structure with the heptafluorodiborate ion $B_2F_7^-$ [B−F = 1.50(1) and 1.51(1) Å with B−F−B = 128.1(7)°],[22] and the structure of 9-fluoro-9-borabicyclo[3.3.1]nonane, which displays an unsymmetrical self-association with a long bond between a tetracoordinate boron center and a bridging fluorine [B−F = 1.652(5) Å].[23] For the inverse chelate **4ac** the B−F bond length [1.641(4) Å] is, not surprisingly, longer than in $B_2F_7^-$ and similar to that of the comparable bond of 9-fluoro-9-borabicyclo[3.3.1]nonane**.** The bond angle around the bridging fluorine of 148.4(3)° seems remarkably large; a shift of the fluorine atom toward the cobalt center decreases the transannular repulsion of the two B*i*Pr$_2$ groups (for evidence of this repulsion see below) and increases the electrostatic attraction between the negative fluorine and the positive metallocenium region of **4ac**.

Structure in Solution I

Boron chemical shifts give first indications as to which structures exist in solution. Figure 6 gives an overview over the chemical-shift values observed. Three regions may be distinguished. At the high (left) end of the scale the salts (**1a**,**b**)PF_6 mark the position of the "naked" trigonal boron (δ = 78 ppm). At the low end are the inverse chelate molecules (δ = 1.4 to −8.5 ppm) with exclusively tetrahedral boron centers which, in fact, display their signal in the same region as the doubly quaternized salts **5** and **6**. In the central region the chlorides **4ad** and **4bd** mark the region of the semi-quaternized molecules (δ = 37 ppm) with a mean chemical shift for one trigonal (δ = 78 ppm) and one tetrahedral boron (roughly δ = 0 ppm). The higher chemical-shift values for the bromide **4ae** and even more so for the iodide **4af** indicate that there is more tricoordinate boron than tetracoordinate boron, in other words, that there is a dissociation equilibrium (Scheme 3). Finally, while the fluoride **4bc** fits the overall picture, the sterically more crowded diisopropylboryl analogue **4ac** shows an anomalously high chemical shift which will be discussed further below.

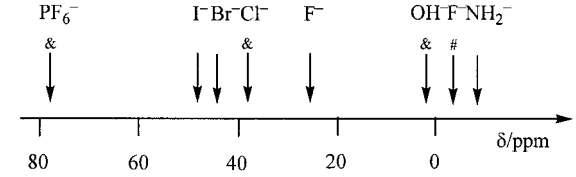

Figure 6. Boron chemical shifts of the combinations (**1a**)PF_6/X^-; &: the related combination (**1b**)PF_6/X^- shows the same chemical shift; #: the signal for (**1b**)PF_6/F^- appears at higher field

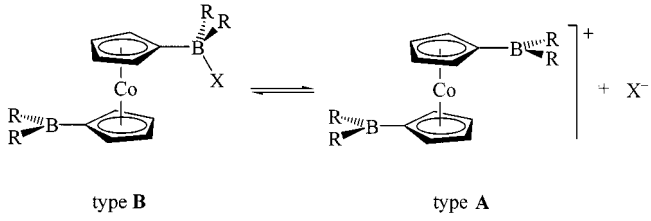


R = *i*Pr, Me; X = Cl−, Br−, I−

Scheme 3

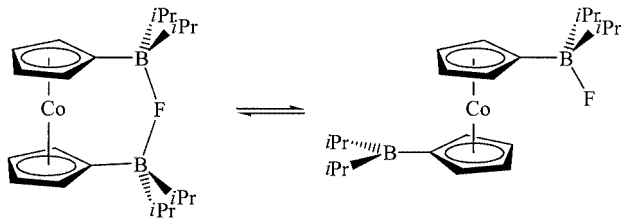
Structure in Solution II: Inverse Chelates

The inverse chelate complexes **4aa**, **4ab**, and **4ac** possess two types of diastereotopic methyl groups (within their B*i*Pr$_2$ groups) which should give rise to two doublets in the ^1H NMR spectra. In the case of the rather stable hydroxide **4ab**[10] these two doublets are seen at ambient temperature. However, when a solution of **4ab** in $C_2D_2Cl_4$ is warmed up, line-broadening sets in at 60 °C. Despite the onset of decomposition fast measurements give a coalescence temperature, T_c, of 95 ± 5 °C which corresponds to a barrier $\Delta G^{\neq}_{368}$ of 75(1) kJ·mol^{-1}. The underlying dynamic process must imply ring-opening of the chelate and rotation of a diisopropylboryl group. In the case of the robust amide **4aa** the doublets are sharp even at 115 °C. Thus the chelate structure of the amide is more stable than that of the hydroxide. On the other hand, the fluoride **4ac** is already dynamic at ambient temperature, showing only one doublet. These observations show that the stability of the inverse

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

chelate forms increases in the order fluoride **4ac** < hydroxide **4ab** < amide **4aa**.

The anomalously high chemical shift for **4ac** mentioned above indicates a fast equilibrium between the semi-quaternized form **4ac-B** and the chelate form **4ac-C** (Scheme 4). We may take the shift of the methyl compound **4bc** (δ = −2.5 ppm) as representative of the chelate form **4ac-C**, and estimate a 65% contribution of the open form **4ac-B** to the equilibrium mixture (NMR tube, ambient temperature). Furthermore, the comparison of **4ac** and **4bc** proves that the sterically more demanding isopropyl groups effect a marked destabilization of the chelate structure **C**.

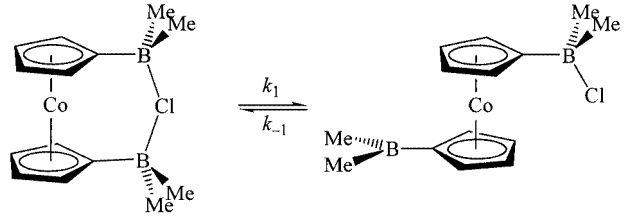


4ac-C **4ac-B**

Scheme 4

Structure in Solution III: The Chlorides 4ad and 4bd

A more direct observation of the equilibrium between semi-quaternized form **B** and chelate form **C** (cf. Scheme 4) seemed desirable. Variable temperature NMR spectra (173−243 K) of the chloride **4bd** in CD_2Cl_2 solutions revealed that this chloride may also form a chelate isomer (Scheme 5). The exchange reaction is slow below 200 K, and the chelate isomer contributes 5−7% to the equilibrium mixture. Note in this context that a chloride bridging two boron centers has previously been observed in the structurally characterized compound $(Ph_3PNPPh_3)[1,8\text{-}C_{10}H_6(BCl_2)_2(\mu\text{-}Cl)]$ derived from the rigid pincer molecule 1,8-bis(dichloroboryl)naphthalene.[6c]



4bc-C **4bc-B**

Scheme 5

The equilibrium is close to thermoneutral ($\Delta_R H$ = 2.5 ± 1.1 kJ·mol^{-1}), showing that the bond strength for the bridging B−Cl bond is about half that of the terminal B−Cl bond. Ring-opening of the chelate **4bd-C** is endotropic ($\Delta_R S$ = 37.6 ± 5.4 kJ·mol^{-1}·K^{-1}), and the equilibrium is entropy driven in the accessible temperature range. The sign of the reaction enthalpy suggests, though with only moderate significance, that the major isomer **4bd-B** does not represent the ground-state isomer.

Line-shape analysis (^{1}H and ^{13}C NMR, 193−243 K) with the help of the program D NMR-SIM[24] provided rate constants, and from these activation parameters.[25] The estimated free enthalpy of activation for the ring-opening of **4bd-C** is estimated to be about 45 kJ·mol^{-1}, much less than in the case of the hydroxide **4ab** discussed above, as expected.

The low-temperature NMR spectra hold another surprise: the major isomer **4bd-B**, quite unexpectedly, shows only a single ligand pattern of effective C_{2v} symmetry. Since we do see separate spectra for the two isomers, the *intra*molecular chloride exchange implied in Scheme 5 is frozen out at 200 K. What is still possible is an *inter*molecular chloride-exchange mechanism with the chloride migrating from the boron in one open molecule **4bd-B** to the next one. Several detailed mechanisms are conceivable; for instance, a dissociation with formation of $\mathbf{1b}^+$ and free Cl^- analogous to Scheme 3 and subsequent chloride transfer between **4bd-B** and the trace cation $\mathbf{1b}^+$ is a likely possibility.

In the case of the chloride **4ad** variable temprature NMR spectra revealed line-broadening in an intermediate temperature range (as for **4bd**), but no chelate isomer **4ad-C** could be detected in the low-temperature regime (< 200 K). This seemingly puzzling situation can now easily be understood. From what we have seen in the fluoride cases we should expect that the contribution of the chelate form **4ad-C** is smaller than for the methyl compound **4bd**. Experimentally it is obviously below the level of detection (< 2%), but the line-broadening still observed is again evidence of a dynamic process, most likely analogous to that of Scheme 5.

Concluding Remarks

The chelating properties of pincer molecules may be influenced (inter alia) by preorganization of the coordinating centers and by field effects. The pincer cations $\mathbf{1a,b}^+$ allow ring-ring rotation, and thus have little preorganization, but they possess a positive charge which favors anion binding. Three features are particularly noteworthy: formation of Lewis base adducts in the slow-exchange regime (with pyridine), formation of anionic di-adducts with anions (with F^-, OH^-, and in solution with Cl^-), and formation of inverse chelates with monoatomic anions, surprisingly including F^-. In summary, our observations strongly underline the favorable effect of the positive charge on the anion binding properties of pincer cations such as $\mathbf{1a,b}^+$.

Experimental Section

General Remarks: Reactions were carried out under an atmosphere of dinitrogen by means of conventional Schlenk techniques. Hexane was distilled from potassium, THF from sodium benzophenone ketyl, dichloromethane from calcium hydride and nitromethane was condensed after passing through a column of acti-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

vated alumina. Silica and alumina were heated under vacuum at 300 °C and kept under dinitrogen.

KOH was prepared from KH and water in THF. $NaNH_2$ was bought as a suspension in xylene, washed with hexane and dried under vacuum to yield a grey powder. NMe_4F was bought from Acros; all other reagents were from Aldrich and were used without purification.

NMR spectra were recorded on a Varian Unity 500 spectrometer (^{1}H: 500 MHz; ^{13}C: 125.7 MHz), a Varian VXR 300 (^{1}H: 300 MHz; ^{13}C: 75.4 MHz), Bruker WM-250 FT (^{1}H: 250 MHz; ^{13}C: 62.9 MHz) or a Rototec/Piccinotti Mini-FID (^{11}B: 29 MHz) and calibrated using referenced solvent signals. Mass spectra were recorded on a Finningan MAT-95 spectrometer. Elemental analyses were determined by the Analytische Laboratorien Malissa and Reuter, Lindlar, Germany.

Pyridine Adducts 2 and 3: A solution of (**1a**)PF_6 in CD_2Cl_2 was treated with defined successive portions of pyridine (from 0.7 to 2.2 equivalents). After each addition NMR spectra were recorded.
2: ^{1}H NMR (500 MHz, CD_2Cl_2): δ = 0.52 and 0.63 (d, $^3J \approx$ 6.8 Hz, 2 × 6 H, 2 Me′ each), 1.15 (d, ^3J = 7.3 Hz, 4 Me), 1.23 (sept, ^3J = 7.3 Hz, 2 BCH′), 1.99 (sept, ^3J = 7.3 Hz, 2 BCH), 5.20 (br. s, 2-/5-H′), 5.51 (br. s, 3-/4-H′), 5.84 (br. s, 2-/5-H), 5.95 (br. s, 3-/4-H), 7.91 (m, 2 H_m), 8.25 (m, H_p), 8.76 (m, 2 H_o) ppm. ^{11}B{^{1}H} NMR (160 MHz, CD_2Cl_2): δ = 78.7, 2.0 ppm. ^{13}C{^{1}H} NMR (126 MHz, CD_2Cl_2): δ = 18.5 (br., BCH′), 18.66 (Me), 18.94 and 19.99 (Me′), 23.26 (br., BCH), 82.08 (C-2′,5′), 87.13 (C-3′,4′), 89.91 (C-2,5), 90.27 (C-3,4) ppm; pyridine: δ = 126.58 (C-3,5), 141.92 (C-4), 145.86 (C-2,6) ppm.
3: ^{1}H NMR (500 MHz, CD_2Cl_2): δ = 0.58 and 0.65 (br. d, $^3J \approx$ 7.0 Hz, 2 × 12 H, 4 Me each), 1.26 (sept, 4 BCH), 5.18 (m, 2 2-/5-H), 5.60 (m, $N = {}^3J_{2,3} + {}^4J_{2,4}$ = 3.7 Hz, 2-/3-/4-H), 7.83 (m, 4 H_m), 8.22 (m, 2 H_p), 8.82 (m, 4 H_o) ppm. ^{11}B{^{1}H} NMR (160 MHz, CD_2Cl_2): δ = 2.3 ppm. ^{13}C{^{1}H} NMR (126 MHz, CD_2Cl_2): δ = 18.7 (br., BCH), 19.17 and 20.18 (Me), 83.76 (C-3,4), 86.70 (C-2,5) ppm; pyridine: δ = 126.28 (C-3,5), 141.70 (C-4), 146.02 (C-2,6) ppm.

Co[C_5H_4(B*i*Pr$_2$)]$_2$(μ-F) (4ac): Solid NMe_4F (206.5 mg, 2.22 mmol) was added with stirring to a solution of (**1a**)PF_6 (1.17 g, 2.22 mmol) in CD_2Cl_2 (20 mL) at room temperature. After 30 minutes all volatiles were removed under vacuum. The yellow powdery residue was transferred to a frit and extracted with toluene until the filtrate remained colorless. The combined solutions were freed from solvent to give the product **4ac** (428.3 mg, 49%) as a yellow microcrystalline solid, m.p. 127 °C (dec.); the product always contained an admixture of the hydroxy compound **4ab**. $C_{22}H_{36}B_2CoF$ (400.1) calcd. C 66.05, H 9.07; found C 66.35, H 9.32. SIMS (K/T): positive ions *m*/*z* (%) = 381 (100) [M^+ − F], 357 (31) [M^+ − *i*Pr]; negative ions *m*/*z* (%) = 400 (100) [M^-], 357 (17) [M^- − *i*Pr], 137 (23) [C_5H_4B*i*PrF$^-$], 65 (35) [Cp^-]. ^{1}H NMR (500 MHz, CD_2Cl_2): δ = 0.92 (d, ^3J = 7.3 Hz, 8 Me), 1.15 (sept, ^3J = 7.3 Hz, 4 BCH), 5.40 (m, 2 C_5H_4) ppm. ^{11}B{^{1}H} NMR (160 MHz, CD_2Cl_2): δ = 26.4 ppm. ^{13}C{^{1}H} NMR (126 MHz, CD_2Cl_2): δ = 20.50 (Me), 21.6 (br., BCH), 83.68 (C-3,4), 87.92 (C-2,5) ppm. ^{19}F NMR (470 MHz, C_6D_6): δ = −158 ($\nu_{1/2}$ = 207 Hz).

Co[C_5H_4(BMe$_2$)]$_2$(μ-F) (4bc): A preparation as described for (**1a**)F from NMe_4F (58.2 mg, 0.410 mmol) and (**1b**)PF_6 (171.0 mg, 0.413 mmol) gave **4bc** (113.0 mg, 96%) as a yellow powder which could be recrystallized from toluene/CD_2Cl_2. SIMS (DTE/DTT/Sul): positive ions *m*/*z* (%) = 269 (100) [M^+ − F], 229 (64) [CoCp{C_5H_4(BMe$_2$)}$^+$]. ^{1}H NMR (250 MHz, CD_2Cl_2): δ = −0.10 (s, 4 Me), 5.19 (m, 2 2-/5-H), 5.25 (m, N = 3.7 Hz, 2 3-/4-H) ppm. ^{11}B{^{1}H} NMR (29 MHz, CD_2Cl_2): δ = −2.5 ppm. ^{13}C{^{1}H} NMR (63 MHz, CD_2Cl_2): δ = 11.5 (br., Me), 82.79 (C-3,4), 87.45 (C-2,5) ppm.

Co[C_5H_4(B*i*Pr$_2$)][C_5H_4(B*i*Pr$_2$Cl)] (4ad): Solutions of (**1a**)PF_6 (281.7 mg, 0.536 mmol) and PPh_4Cl (206.5 mg, 0.551 mmol) in CD_2Cl_2 (5 mL each) were combined with stirring. After 10 minutes the solvent was removed under vacuum. The residue was suspended in toluene and transferred to a frit with a layer of silica. After filtration the solid was extracted with more toluene until the filtrate remained colorless. The combined solutions were concentrated to a volume of less than 5 mL and left for crystallization at −30 °C to give **4ad** (163.9 mg, 73%) as yellow crystals. $C_{22}H_{36}B_2CoCl$ (416.5) calcd. C 63.44, H 8.71; found C 63.30, H 8.52. ^{1}H NMR (250 MHz, $CDCl_3$): δ = 0.96 (d, ^3J = 7.3 Hz, 8 Me), 1.43 (sept, ^3J = 7.3 Hz, 4 BCH), 5.52 (m, 2 2-/5-H), 5.54 (m, 2 3-/4-H) ppm. ^{11}B{^{1}H} NMR (160 MHz, CD_2Cl_2): δ = 36.9 ppm. ^{13}C{^{1}H} NMR (63 MHz, $CDCl_3$): δ = 20.02 (Me), 22.0 (br., BCH), 85.12 (C-3,4), 88.24 (C-2,5) ppm.

Co[C_5H_4(BMe$_2$)][C_5H_4(BMe$_2$Cl)] (4bd): A preparation as described for (**1a**)Cl from (**1b**)$AlCl_4$ [1] (437.4 mg, 1.00 mmol) and PPh_4Cl (368.3 mg, 0.98 mmol) gave **4bd** (299.0 mg, 100%) as a yellow powder which was crystallized from Et_2O/CD_2Cl_2 at −30 °C; m.p. 96 °C (dec.). [The use of (**1b**)$AlCl_4$ instead of (**1b**)PF_6 is more convenient here since (**1b**)PF_6 was made from (**1b**)$AlCl_4$ by anion metathesis.] $C_{14}H_{20}B_2ClCo$ (304.3) calcd. C 55.26, H 6.62; found C 54.68, H 6.84. SIMS (DTE/DTT/Sul): positive ions *m*/*z* (%) = 269 (100) [M^+ − Cl], 229 (16) [CoCp{C_5H_4(BMe$_2$)}$^+$]. ^{1}H NMR (500 MHz, CD_2Cl_2, room temp.): δ = 0.54 (s, 4 Me), 5.48 (m, 2 2-/5-H), 5.51 (m, N = 3.7 Hz, 2 3-/4-H) ppm; the assignment for the ring protons is based on ^{1}H{^{1}H}NOE difference spectra. ^{11}B{^{1}H} NMR (160 MHz, CD_2Cl_2, room temp.): δ = 36.8 ppm. ^{13}C{^{1}H} NMR (126 MHz, CD_2Cl_2, room temp.): δ = 13.0 (br., Me), 85.69 (C-3,4), 87.94 (C-2,5) ppm; the assignment for the ring-carbon nuclei is based on heteronuclear correlation spectra or (^{1}H, ^{13}C) HMQC spectra.

Variable Temperature NMR Spectra of 4bd in CD_2Cl_2: ^{1}H and ^{13}C{^{1}H} NMR spectra of **4bd** in CD_2Cl_2 show decoalescence and the presence of two species at low temperatures (Scheme 5). Both species display effective C_{2v} symmetry, but their constitutions could be assigned by means of systematic comparisons of the chemical shifts observed for various species **4**; note especially the large difference of chemical shifts for the B-Me groups [δ = 0.60 ppm for **4bd-B** and δ = −0.15 ppmfor **4bd-C**]. The semi-quaternized isomer **4bd-B** is the major isomer and the chelate form **4bd-C** the minor isomer over the entire temperature range. The relative concentrations measured and the deduced thermodynamic parameters are collected in Table 1. Rate constants for the ring-opening reaction were obtained from line-shape analyses for the spectra of the minor isomer. The ^{1}H signals of the B-Me groups and the ^{13}C{^{1}H} signals of the carbon atoms C-2,5 and C-3,4 were suitable; the remaining signals were not used because the coupling constants of the ring

Data for 4bd-B: C_s symmetry, 94.7% at −90 °C. ^{1}H NMR (500 MHz, CD_2Cl_2, −90 °C): δ = 0.60 (s, 4 Me), 5.56 (s, 2 C_5H_4) ppm. $^{13}C\{^1H\}$ NMR (126 MHz, CD_2Cl_2, −90 °C): δ = 12.9 (br., Me), 86.28 (C-3,4), 87.77 (C-2,5) ppm.
Data for 4bd-C: C_{2v} symmetry, 5.3% at −90 °C. ^{1}H NMR (500 MHz, CD_2Cl_2, −90 °C): δ = −0.15 (s, 4 Me), 5.26 (s, 2 C_5H_4) ppm. $^{13}C\{^1H\}$ NMR (126 MHz, CD_2Cl_2, −90 °C): δ = 10.6 (br., Me), 83.20 (C-3,4), 86.99 (C-2,5) ppm.

Co[C_5H_4(B*i*Pr$_2$)][C_5H_4(B*i*Pr$_2$Br)] (4ae) and Co[C_5H_4(B*i*Pr$_2$)][C_5H_4(B*i*Pr$_2$I)] (4af): These compounds were prepared as described for **4ac** and **4ad** with PPh_4Br and PPh_4I, respectively. $^{11}B\{^1H\}$ NMR (160 MHz, CD_2Cl_2): δ = 43.8 for **4ae** and δ = 48.5 ppm for **4af**.

Co[C_5H_4(B*i*Pr$_2$)]$_2$(μ-OH) (4ab): Freshly powdered KOH (25.6 mg, 0.46 mmol) was added to (**1a**)PF_6 (253.1 mg, 0.48 mmol) in CH_2Cl_2 (15 mL). The suspension was then stirred for 1 d. Workup as described for **4ac** gave **4ab** (124.3 mg, 69%) as a brownish yellow solid. ^{1}H NMR (500 MHz, CD_2Cl_2): δ = 0.86 (s, 4 Me + 4 BCH), 1.01 (br. d, ^3J = 5.8 Hz, 4 Me), 2.37 (s, OH), 5.19 (m, 2 2-/5-H), 5.24 (m, 2 3-/4-H) ppm. $^{11}B\{^1H\}$ NMR (160 MHz, CD_2Cl_2): δ = 1.4 ppm. $^{13}C\{^1H\}$ NMR (126 MHz, CD_2Cl_2): δ = 21.48 and 22.28 (Me), 22.1 (br., BCH), 82.81 (C-3,4), 88.04 (C-2,5) ppm.

Co[C_5H_4(BMe$_2$)]$_2$(μ-OH) (4bb): Preparation from powdered KOH (27.3 mg, 0.49 mmol) and (**1b**)PF_6 (212.0 mg, 0.51 mmol) in nitromethane instead of CH_2Cl_2 gave **4bb** (128.6 mg, 92%) as an orange microcrystalline solid; m.p. 125 °C. $C_{14}H_{21}B_2CoO$ (285.9) calcd. C 58.82, H 7.40; found C 58.82, H 7.41. SIMS (DTE/DTT/Sul): positive ions m/z (%) = 269 (100) [M^+ − OH]. ^{1}H NMR (500 MHz, CD_2Cl_2): δ = −0.12 (s, 4 Me), 1.95 (s, OH), 5.17 (m, $N \approx$ 3.8 Hz, 2 2-/5-H), 5.24 (m, 2 3-/4-H) ppm. $^{11}B\{^1H\}$ NMR (160 MHz, CD_2Cl_2): δ = −1.9 ppm. $^{13}C\{^1H\}$ NMR (126 MHz, CD_2Cl_2): δ = 10.8 (br., Me), 82.71 (C-3,4), 87.30 (C-2,5) ppm.

Co[C_5H_4(B*i*Pr$_2$)]$_2$(μ-NH$_2$) (4aa): A solution of (**1a**)PF_6 (641.4 mg, 1.22 mmol) in CH_2Cl_2 (20 mL) was added to solid sodium amide (254.8 mg, 6.53 mmol). The resulting suspension was stirred for 7 d. The solvent was then removed under vacuum. The residue was suspended in toluene and filtered through silica. Removal of the solvent left **4aa** (434.0 mg, 90%) as a brown-orange solid which was recrystallized from toluene at −30 °C; m.p. 152 °C. $C_{22}H_{38}B_2CoN$ (397.1) calcd. C 66.54, H 9.65, N 3.53. SIMS (K/T): positive ions m/z (%) = 396 (2) [M^+ − H], 354 (100) [M^+ − *i*Pr], 228 (19) [M^+ − *i*Pr − $2C_3H_6$]; negative ions m/z (%) = 397 (100) [M^-], 354 (22) [M^- − *i*Pr], 161 (6) [C_5H_4B*i*Pr$_2^-$]. ^{1}H NMR (250 MHz, CD_2Cl_2): δ = 0.86 (overlapping, 4 BCH), 0.88 (d, J = 5.5 Hz, 4 Me), 0.96 (d, J = 6.2 Hz, 4 Me), 2.19 (br. s, NH_2), 5.15 (m, 2 2-/5-H), 5.17 (m, 2 3-/4-H) ppm; coupling constants in C_6D_6 solution: N = 3.7 Hz for C_5H_4 part and $^3J \approx$ 7.2 Hz for *i*Pr groups. $^{11}B\{^1H\}$ NMR (160 MHz, C_6D_6): δ = −8.5 ppm. $^{13}C\{^1H\}$ NMR (63 MHz, CD_2Cl_2): δ = 22.20 and 22.97 (Me), 82.23 (C-3,4), 87.59 (C-2,5) ppm.

NMe$_4$[Co{C_5H_4(B*i*Pr$_2$F)}$_2$] (5): A solution of (**1a**)PF_6 (456.6 mg, 0.868 mmol) in CH_2Cl_2 (10 mL) was added to solid NMe_4F (172.4 mg, 1.851 mmol). After stirring for 3 h all volatiles were removed under vacuum. The residue was suspended in toluene and filtered through a frit. The remaining solid was intensively washed with more toluene. The combined filtrates were liberated from solvent to give **5** (380 mg, 89%) as orange microcrystals; m.p. 160 °C (dec.). $C_{26}H_{48}B_2CoF_2N$ (493.2) calcd. C 63.31, H 9.81, N 2.84; found C 63.44, H 10.01, N 2.91. SIMS (K/T): positive ions m/z (%) = 74 (100) [NMe_4^+]; negative ions m/z (%) = 419 (100) [M^- − NMe_4], 400 (10) [419 − F], 376 (23) [419 − C_3H_7], 333 (7) [Co(C_5H_4B*i*PrF)$_2^-$]. ^{1}H NMR (500 MHz, CD_2Cl_2): δ = 0.62 (sept, 4 BCH), 0.71 and 0.75 (d, ^3J = 7.0 Hz, 4 Me each), 3.36 (s, NMe_4), 5.05 (m, 2 2-/5-H), 5.16 (br. m, N = 3.7 Hz, 2 3-/4-H) ppm. $^{11}B\{^1H\}$ NMR (160 MHz, CD_2Cl_2): δ = 3.4 (d, $^1J_{F,B}$ = 61 Hz) ppm. $^{13}C\{^1H\}$ NMR (126 MHz, CD_2Cl_2): δ = 21.14 and 21.21 (d, $^3J_{F,C}$ = 5.5 Hz, Me), 21.6 (br., BCH), 56.41 (t, $^1J_{N,C}$ = 3.8 Hz, NMe_4), 80.70 (C-3,4), 85.29 (d, $^3J_{F,C}$ = 5.5 Hz, C-2,5) ppm. ^{19}F NMR (470 MHz, C_6D_6): δ = −194 ($\nu_{1/2}$ = 153 Hz) ppm.

K[Co{C_5H_4(B*i*Pr$_2$OH)}$_2$] (6): Freshly powdered KOH (24.5 mg, 0.44 mmol) was added to a solution of **4ab** (135.2 mg, 0.34 mmol) in THF (10 mL). After stirring the suspension for 24 h it was filtered through silica. The volatiles were removed from the orange filtrate under vacuum. The resulting brown oil was dissolved in toluene (3 mL) and diluted with hexane (10 mL). After standing for several days at room temperature brownish yellow needles of **6** (67.7 mg, 44%) had formed; m.p. > 210 °C. $C_{22}H_{38}B_2CoKO_2$ (454.2) calcd. C 58.18, H 8.43; found C 58.04, H 8.53. SIMS (K/T): negative ions m/z (%) = 471 (100) [M + OH^-]; positive ions m/z (%) = 303 (100) [K^+ + [18]-crown-6]. ^{1}H NMR (500 MHz, [D_8]THF): δ = 0.07 (br. s, 2 OH), 0.54 (sept, 4 BCH), 0.69 and 0.73 and (d, ^3J = 7.1 Hz, 4 Me each), 5.09 (m, 2 × 2-/5-H), 5.11 (m, 2 × 3-/4-H) ppm. $^{11}B\{^1H\}$ NMR (160 MHz, [D_8]THF): δ = −3.1 ppm. $^{13}C\{^1H\}$ NMR (126 MHz, [D_8]THF): δ = 21.40 and 21. 76 (Me), 22.7 (br., BCH), 80.19 (C-3,4), 86.10 (C-2,5) ppm.

X-ray Crystal Structure Determinations: Geometry and intensity data were collected with ENRAF-Nonius CAD4 diffractometers (Mo-K_α radiation with graphite monochromators). Crystal data, data-collection parameters, and convergence results for the compounds (**1b**)PF_6, **4bd**, **4ac**, and **5** are listed in Table 3. The structures of (**1b**)PF_6, **4bd**, and **5** were solved by direct methods[26a] and subsequent Fourier difference syntheses, whereas the coordinates of the corresponding hydroxo compound **4ab** provided the structure model for **4ac**. In the full-matrix least-squares refinements on intensities[26b] non-hydrogen atoms were assigned anisotropic displacement parameters and hydrogen atoms were included with standard geometry. The refinement of **4ac** deserves a comment: This compound is isomorphous with the hydroxide **4ab** with similar, but significantly different, lattice parameters. Refinement of the chelated anion site with the scattering factor for *F* results in clearly superior reliability factors than a model for chelated hydroxide. The best results were obtained when a mixed occupancy of the anion site was refined; convergence was reached for an approximate F:O ratio of 4:1, in good agreement with spectroscopic evidence. CCDC-232238 for (**1b**)PF_6, -232239 for **4bd**, -232240 for **4ac**, and -232241 for **5** contain the supplementary crystallographic data of

Mono(alkyne)cobalt Complexes and Electron-Rich Alkynes − The Formation of an Alkyne-Bridged Dinuclear Cobalt Complex by a One-Pot Procedure

Daniel B. Werz,[a] Rolf Gleiter,*[a] and Frank Rominger[a]

Keywords: Alkynes / Chalcogens / Cobalt / Cyclobutadiene complexes

[η^2-Bis(*tert*-butylsulfonyl)acetylene](carbonyl)(η^5-trimethylsilylcyclopentadienyl)cobalt (**2c**) proved to be reactive towards bis(telluro)- and bis(seleno)-substituted alkynes **3** and **4**, respectively, to yield *push-pull*-substituted CpCo-stabilized cyclobutadiene complexes. By utilizing the unsymmetrical diyne **6** and the symmetrical bis(thio)-substituted triyne **7** it was shown that only the most electron-rich triple bond was attacked by the electrophilic compound **2c**. In the case of **7** a dinuclear CpCo-stabilized cyclobutadiene complex **14** bridged by one acetylene moiety was obtained. All the reactions could be carried out at room temperature under rather mild conditions. X-ray investigations of **8**, **12**, **14a**, and **15** show almost equal C–C bond lengths in the cyclobutadiene moieties.

Introduction

Nearly 50 years ago dicarbonyl(η^5-cyclopentadienyl)cobalt [$CpCo(CO)_2$] was synthesized for the first time.[1,2] Since that time this compound has proved to be a very convenient and efficient reagent for the di- and trimerization of alkynes.[3] Several useful and theoretically attractive molecules like cyclobutadienes,[4] cyclopentadienones,[5,6] and benzene derivatives[7] have been synthesized by this reagent. As one possible mechanism, the subsequent replacement of the CO units by acetylene fragments was proposed yielding first a monoacetylene, then a diacetylene complex that is converted by a metal-mediated cycloaddition process into a 16-electron metallacycle.[7,8] The latter species has the ability to react with a further acetylene fragment or to form the cyclobutadiene[4] by a reductive elimination process. To obtain more insight into the mechanism, several intermediates were isolated and characterized crystallographically. Krebs and Jessel succeeded in the isolation of a mono(alkyne)cobalt complex **1** by using the highly strained 3,3,6,6-tetramethyl-1-thiacycloheptyne.[9] Our group was able to synthesize a variety of mono(alkyne)cobalt complexes[10] **2a**−**f** with the very electron-deficient compound bis(*tert*-butylsulfonylacetylene) (BTSA).[11]

In the course of our in-depth study of electron-rich alkynes[12−14] and their reactions with electrophilic metal fragments, we elucidated the reaction of our mono(alkyne)-cobalt complexes **2a**−**f** with several electron-rich alkynes under mild conditions.[15] Until now we have treated only thio- or carbon-substituted symmetrical acetylene fragments with the mono(alkyne) cobalt complexes.[15] The more electron-rich thio-substituted acetylenes reacted faster and with greater ease than the carbon-substituted compounds, for which heating was needed to initiate the reaction.[15] Therefore, we raised the question whether other elements such as selenium or tellurium are also able to act in the same way as sulfur. Furthermore, we are interested in the reaction of polyacetylene systems in which the mono(alkyne) complex has the choice to discriminate between acetylene units with slightly different electron densities, or even to react twice with the polyalkyne molecule. As model compounds we chose bis(methylseleno)acetylene (**3**),[16] bis(methyltelluro)acetylene (**4**),[17] bis(methylthio)butadiyne (**5**),[14b] (methylthio)(trimethylsilyl)butadiyne (**6**),[14b] and bis(methylthio)hexatriyne (**7**).[14b]

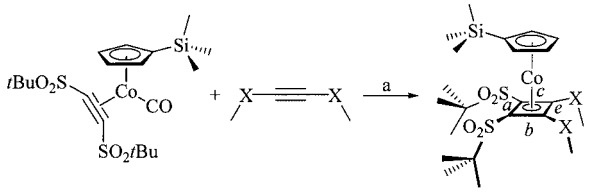
Results and Discussion

To ensure reasonable solubilities of the products, we chose **2c** because the $Si(CH_3)_3$ substituent at the Cp ring enhances the solubility in toluene.[10] The reaction between the mono(alkyne)cobalt complex **2c** and alkynes **3**−**7** were carried out in toluene at room temperature and in the dark since the electron-rich alkynes are light-sensitive. The two monoacetylenic substrates **3** and **4** afforded the selenium- and tellurium-substituted cyclobutadiene complexes **8** and **9**, respectively, in 54−63% yield (Scheme 1). Due to the high-lying HOMO of **3** and **4**, the activation energy of this reaction is low.

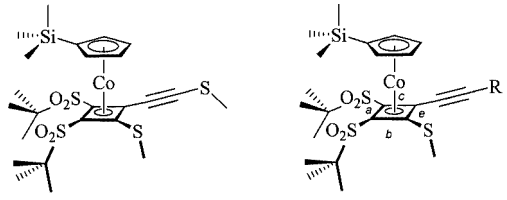


2c **3** (X = Se), **4** (X = Te) **8** (X = Se) 54%, **9** (X = Te) 63%

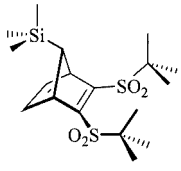
a) toluene, r.t.

Scheme 1

The reaction of **2c** with the two butadiynes **5** and **6** yielded cyclobutadiene complexes **10** and **12**, respectively. Even by using a high excess of mono(alkyne)cobalt complex, a second attack to the still unchanged triple bond did not take place. Complex **12** was obtained as the only product in the reaction of **2c** with **6**. The subtle differences in the electron density between the two triple bonds in **6** should therefore be important in determining the regioselectivity of the electrophilic attack by the mono(alkyne) complex. Furthermore, in the reaction of **2c** with **5**, a decomposition process of the mono(alkyne)cobalt species took place: the highly electron-deficient BTSA reacted in a Diels−Alder reaction with the CpH(TMS) moiety to afford the norbornadiene derivative **11** in 40% yield.



10 **12** (R = $SiMe_3$), **15** (R = H)



11

We ascribe the observation that the second triple bond in **5** did not react to steric repulsion between the two adjacent cobalt fragments. Thus, the reaction of the electron-rich hexatriyne **7** with excess **2c** was now even more interesting. The analysis of the reaction products showed that only the terminal triple bonds with the higher electron density (relative to the central one) were attacked. Two compounds resulted, the mono- and the disubstituted products **13** and **14**.

Scheme 2

For the dinuclear compound, three stereoisomers **14a** and **14b** are possible. NMR spectroscopic investigations revealed their ratio to be approximately 1:1. Separation by column chromatography proved to be unsuccessful, and therefore recrystallization experiments were carried out instead. From a mixture of dichloromethane and diethyl ether the C_i-symmetrical stereoisomer **14a** was obtained as a pure compound.

This reaction reveals an interesting alternative route to bridged dinuclear cyclobutadiene complexes;[18] this is important especially because the introduction of only one acetylene fragment between two metal-stabilized cyclobutadiene fragments is still a difficult goal to reach. The usual method by Bunz et al. is a multi-step sequence starting with the lithiation of metal-capped cyclobutadiene complexes to afford, after treatment with iodine, the corresponding iodides. According to this, with a Stille-type reaction, coupling with the acetylene fragment takes place.[18,19] Even tri- and tetranuclear complexes have been achieved in combination with Glaser-type reactions in this manner.[18,19] Efforts to synthesize dinuclear complexes with bridging butadiyne moieties by a deprotection reaction of **12** (yielding **15**) and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a subsequent Glaser coupling of the deprotected cobalt complex **15** failed. We ascribe this behavior to the divalent sulfur atom in the starting material that may hinder the catalytic activity of the copper species.

All the cyclobutadiene complexes were yellow to red in color, and were remarkably stable as they are inert towards moisture and air. The characteristic features of the ^{13}C NMR spectra are the chemical shifts of the cyclobutadiene ring atoms that show values between $\delta = 75$ and 85 ppm. Only in the case of the tellurium-substituted cyclobutadiene complex **9** do we encounter signals at $\delta = 53.6$ ppm for the carbon atoms adjacent to the tellurium atoms. Such a "heavy-atom effect" that influences this relatively low-frequency resonance has been reported before.[14a,20]

Four cyclobutadiene complexes **8**, **12**, **14a**, and **15** yielded single crystals which could be investigated by X-ray crystal-

lography. As examples, we show the molecular structures of the mononuclear complexes **8** and **12** in Figure 1 and the dinuclear cobalt complex **14a** in Figure 2.

All the conformations in the solid state are highly influenced by the rather bulky *tert*-butylsulfonyl groups. In all cases they point away from the metal center, and to avoid steric interactions with the rather voluminous $Si(CH_3)_3$ substituent at the Cp ring, the latter points in the opposite direction. This behavior allows an almost parallel orientation of the Cp and the Cbd rings. In Table 1, we have compared the interplanar angles of the π-systems as well as the most relevant distances.

The mean distance between the cobalt atom and the four-membered cycle is slightly larger than the distance between the cobalt atom and the five-membered cycle. An examination of the CpCo-stabilized cyclobutadiene systems shows only weak variations. Due to steric repulsions, the longest bond is found to be between the two adjacent *tert*-butylsulfonyl groups (*a*). Any indication of bond alternation in the four-membered ring was not found as can be seen in Table 1. Relative to the unsubstituted $CpCo(C_4H_4)$[21] ($a = b = c = e = 144$ pm), the cyclobutadiene moiety in our systems is slightly enlarged due to the repulsion described above.

Conclusions

We have shown that the CO group in mono(alkyne)cobalt complexes can be replaced by seleno- and telluro-substituted alkynes to yield seleno- and telluro-substituted cyclobutadiene complexes. An important parameter that affects this substitution reaction under mild conditions is the HOMO energy of the alkyne and not the type of heteroatom attached to it. Furthermore, our studies reveal that mono(alkyne)cobalt complexes are able to differentiate between triple bonds with slightly different electron densities in a polyalkyne system, where the attack always takes place at the most electron-rich triple bond. In the case of a hexatriyne system, the attack of two mono(alkyne)cobalt complexes affords a dinuclear complex bridged by one triple bond. Our X-ray investigations reveal that the various substitution patterns do not strongly influence the C−C bond lengths within the metal-capped π-system.

Experimental Section

General Methods: Moisture- and oxygen-sensitive reactions were conducted in oven-dried glassware under argon using dried solvents. Materials used for column chromatography: Neutral alumina (Merck), Celite (Fluka). Elemental analyses were carried out by the Mikroanalytisches Laboratorium der Universität Heidelberg. All melting points are uncorrected. ^{1}H NMR and ^{13}C NMR spectra were recorded with a Bruker WH 300 (^{1}H at 300 MHz and ^{13}C at 75.47 MHz) and Bruker Avance 500 (^{1}H at 500 MHz and ^{13}C at 125.77 MHz) using the solvent as internal standard. IR spectra were recorded with a Bruker Vector 22 FT-IR. UV light absorption data were recorded with a Hewlett Packard 8452A spectrometer. High resolution mass spectra were recorded using a JEOL JMS-700. The starting materials **3**−**7** were prepared according to literature methods.[10][14b,16,17]

General Procedure for the Preparation of the Cyclobutadiene Complexes from Mono(alkyne)cobalt Complex 2c and Electron-Rich Alkynes: To a solution of the mono(alkyne)cobalt complex **2c** in toluene (50 mL) was added the corresponding electron-rich polyalkyne in one portion. To avoid any light, the reaction flask was wrapped with aluminum foil. The reaction mixture was stirred at room temperature for 7−14 d. After completion of the reaction (shown by thin-layer chromatography), the solvent was removed by rotary evaporation, and the crude product was purified by column chromatography.

[η^4-1,2-Bis(*tert*-butylsulfonyl)-3,4-bis(methylseleno)cyclobutadiene](η^5-trimethylsilylcyclopentadienyl)cobalt(I) (8): Starting materials: $CpSiMe_3Co(CO)(BTSA)$ (**2c**) (100 mg, 0.20 mmol) and 2,5-diselenahex-3-yne (**3**) (47 mg, 0.20 mmol). Column chromatography with light petroleum/diethyl ether (2:1) as eluent afforded 73 mg (54%) of **8** as a yellow solid. M.p. 135 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.32 (s, 9 H, CH_3), 1.45 (s, 18 H, CH_3), 2.31 (s, 6 H, CH_3), 5.20 (ps, 2 H, CpH), 5.74 (ps, 2 H, CpH) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = −0.2 (CH_3), 10.5 (CH_3), 24.8 (CH_3), 61.6 (C), 77.0 (C), 78.1 (C), 88.5 (CH), 89.5 (CH), 94.1 (C) ppm. [η^4-1,2-Bis(*tert*-butylsulfonyl)-3-(methylthio)-4-(ethynyl)cyclobutadiene](η^5-trimethylsilylcyclopentadienyl)cobalt(I) (15): Starting materials: **12** (59 mg, 0.09 mmol) and a solution of sodium hydroxide (0.3 mL, 0.30 mmol of 1.0 N) in methanol (30 mL). The mixture was stirred for 3 h and extracted with diethyl ether. Column chromatography with hexane → hexane/diethyl ether (1:1) as eluent afforded 31 mg (59%) of **15** as a yellow solid. M.p. 130 °C (dec.). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 0.33 (s, 9 H, CH_3), 1.43 (s, 9 H, CH_3), 1.43 (s, 9 H, CH_3), 2.47 (s, 3 H, CH_3), 3.39 (s, 1 H, CH), 5.20 (ps, 1 H, CpH), 5.35 (ps, 1 H, CpH), 5.74 (ps, 1 H, CpH), 5.83 (ps, 1 H, CpH) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = −0.5 (CH_3), −18.4 (CH_3), 24.5 (CH_3), 24.7 (CH_3), 61.4 (C), 61.7 (C), 63.1 (C), 76.6 (C), 77.0 (C), 77.6 (C), 85.1 (C), 85.8 (CH), 88.3 (CH), 88.7 (CH), 89.2 (CH), 90.9 (CH), 93.7 (C) ppm. UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 258 (4.48), 282 (4.27), 320 (4.31), 376 (3.55) nm. IR (KBr): $\tilde{\nu}$ = 2969, 1628, 1461, 1416, 1312, 1249, 1164 cm^{-1}. HRMS (FAB+): calcd. for $C_{23}H_{35}CoO_4S_3Si$ 558.0735 [M$^+$]; found 558.759. $C_{23}H_{35}CoO_4S_3Si$ (558.1): calcd. C 49.44, H 6.31, S, 17.22; found C 49.10, H 6.32, S 16.80.

X-ray Diffraction Analyses: The reflections were collected at 200(2) K with a Bruker Smart CCD diffractometer (Mo-K_α radiation, graphite monochromator). Intensities were corrected for Lorentz and polarization effects, an empirical absorption correction was applied using SADABS[22] based on the Laue symmetry of the reciprocal space. The structures were solved by direct methods. The structural parameters of the non-hydrogen atoms were refined anisotropically according to a full-matrix least-squares technique (F^2). The hydrogen atoms were calculated according to stereochemical aspects. In the case of **12**, two independent molecules were found in the asymmetric unit. In **15**, the ethynyl moiety and the methylthio unit were disordered (2:1). Structure solution and refinement were carried out with the SHELXTL (5.10) software package.[22] ORTEP drawings were obtained using the ORTEP-3 for Windows program by L. Farrugia.[23] Table 2 contains the crystallographic information and details of the refinement procedure. CCDC-225694 to -225698 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: data_request@ccdc.cam.ac.uk].

Novel Cytotoxic Copper(II) Complexes of 8-Aminoquinoline Derivatives: Crystal Structure and Different Reactivity towards Glutathione

Shouchun Zhang,[a] Chao Tu,[a] Xiongyong Wang,[a] Zhen Yang,[a] Junyong Zhang,[a] Liping Lin,[b] Jian Ding,[b] and Zijian Guo*[a]

Keywords: Antitumor agents / Bioinorganic chemistry / Copper / N ligands

Two novel Cu^{II} complexes [Cu(CMQA)(H_2O)] (**1**) (CMQA = *N*-carboxymethyl-L-methionine-*N*′-8-quinolylamide) and [Cu(MQA)(OAc)] (**2**) (MQA = L-methionine-*N*′-8-quinolylamide, OAc = CH_3COO^-) have been synthesized and structurally characterized. Complex **1** crystallizes in the orthorhombic system with space group $P2_12_12_1$ [a = 5.556(1) Å, b = 15.002(3) Å, c = 20.886(4) Å] while complex **2** crystallizes in the monoclinic system with space group $C2$ [a = 28.463(6) Å, b = 5.264(1) Å, c = 13.345(3) Å, β = 109.142(3)°]. In both complexes the Cu^{II} center is coordinated by three N atoms of the ligand and one O atom of H_2O (**1**) or OAc (**2**). The in vitro cytotoxicity of both complexes and their corresponding ligands have been tested against the murine leukemia P-388 and lung adenocarcinoma A-549 cell lines. Complex **2** shows a potent activity against both cell lines with an inhibitory rate of 100% for the murine leukemia P-388 cell line and 93.4% for the lung adenocarcinoma A-549 cell line at a concentration of 10^{-6} mol·L^{-1}, while complex **1** shows only a marginal activity against the same cell lines. The reactivity of the two complexes towards γ-glutathione (GSH) has been investigated and is discussed in association with their different cytotoxicity.

Introduction

The application of metal complexes in medicine has become increasingly prevalent since the clinical success of cisplatin for treatment of several human malignant tumors decades ago.[1−4] Copper has a long history of medical use, and its potential antitumor properties have attracted attention recently because it is thought to be less toxic than nonessential metals such as platinum.[5] For example, Cu^{II} complexes of thiosemicarbazone are a family of the most promising non-platinum compounds with antitumor potential.[6−8] Some tertiary Cu^{II}-amino acid-phenanthroline complexes (Casiopeinas) exhibit high antitumor activity towards a variety of tumor cell lines.[9,10] More recently, some Cu^{II} complexes with macrocyclic ligands[11,12] or nitrogen-containing heterocyclic ligands[13,14] have also been reported to show potent antitumor activities.

As a part of our interest in the design of quinoline-based metallo-antitumor complexes,[15−17] we describe here the crystal structure and in vitro cytotoxicity of two novel copper complexes [Cu(CMQA)(H_2O)] (**1**) and [Cu(MQA)(OAc)] (**2**; Scheme 1). The interactions of complexes **1** and **2** with γ-glutathione (GSH) have been studied and the implications for their cytotoxicity are discussed.

Results and Discussion

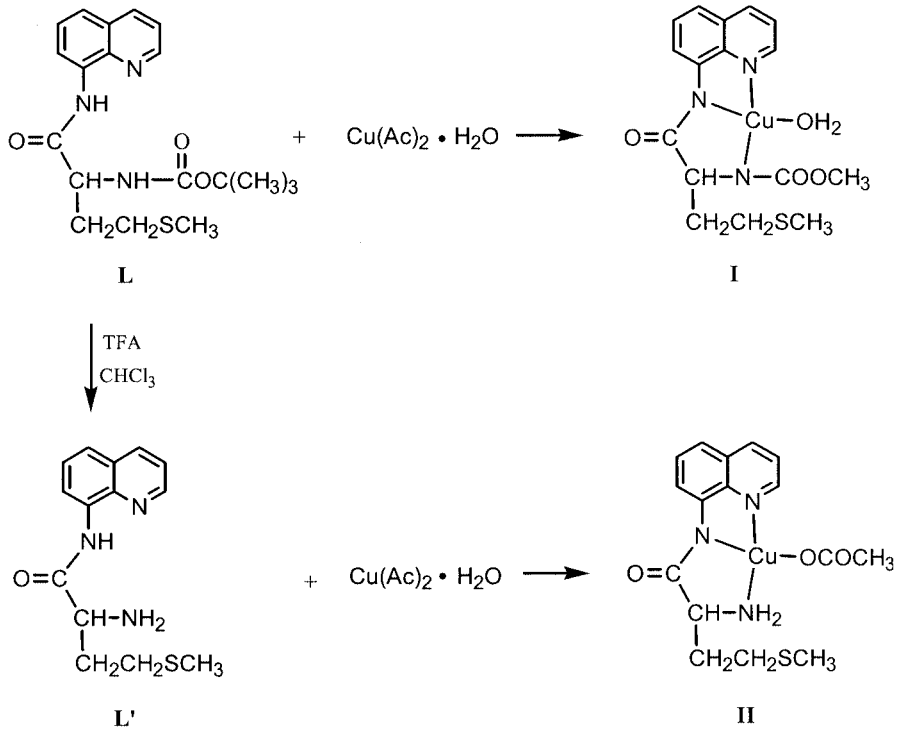
Synthesis

The reaction of $Cu(OAc)_2·H_2O$ with ligands **L** and **L**′ resulted in two related complexes **1** and **2** (Scheme 1). In the reaction of **L** with $Cu(OAc)_2·H_2O$, the $OC(CH_3)_3$ group of **L** is replaced by OCH_3 from the solvent methanol. This ester-exchange reaction has been reported previously in similar reactions.[17] During Cu^{II} coordination all the amide groups of the ligands are deprotonated, giving rise to a stable delocalized electronic system.[18,19] Complex **1** dissolves readily in CH_3OH, DMSO, and DMF but barely in H_2O, while complex **2** can dissolve fairly well both in organic solvents such as CH_3OH, DMSO, DMF and in water.

Structures

The crystal data, data collection, structural solution and refinement parameters for ligand **L** and complexes **1** and **2** are summarized in the Exp. Sect; selected bond lengths and angles are listed in Table 1. The crystal structure of ligand **L** is shown in Figure 1. All the bond lengths and bond

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200400357



Scheme 1

angles of **L** are within the normal ranges. The N(2)−C(8) and N(2)−C(10) bond lengths are similar to those of similar ligands.[20,21] The crystal packing of ligand **L** is shown in Figure S1. The distance between the two adjacent quinoline planes is 3.390 Å, suggesting the presence of strong intermolecular p-π stacking interactions between the adjacent molecules. Intermolecular hydrogen bonds between the hydrogen atom on N(1) and the O(2) atom of a neighboring molecule are observed. The D···A separation is 2.968 Å for N(1)···O(2) (symmetry code: $x + 1$, y, z) and the D−H···A angle is about 156.72° for N(1)−H(1A)···O(2). The crystal structures of complexes **1** and **2** are shown in Figure 2 and 3, respectively. In both complexes the ligand acts as a tridentate chelator coordinated to Cu^{II} through the quinolyl N(3) and amide N(1) and N(2) atoms. The fourth coordination position of Cu^{II} is occupied by either a water molecule through O(1W) in complex **1** or an acetate through O(2) in complex **2**. In general, the $Cu-N_{amido}$ and $Cu-N_{quinolyl}$ bond lengths and the bond angles in **1** and **2** are similar to those of related complexes.[17] The bond angles show that the geometry around Cu^{II} is slightly distorted from the regular square-planar geometry in both complexes. For example, the N(1)−Cu(1)−N(3) and N(2)−Cu(1)−O(1W or 2) angles are contracted from the ideal value of 180° for a regular square-planar structure. Such distortion is often observed in Cu^{II} complexes of tridentate chelating agents.[22−24] It is notable that the CuN_3O [Cu(1), N(1), N(2), N(3), O(1W) (for **1**) or O(2) (for **2**)] plane is nearly co-planar with the quinoline ring in both complexes (see Figure S2 and Figure S3 in the Supporting Information for this article; see also the footnote on the first page of this article), and the mean deviation from the large best plane is 0.004 Å for **1** and 0.026 Å for **2**. There are strong intermolecular π-π stacking interactions between the adjacent molecules in both complexes, and the distance between the adjacent planes is 3.506 Å for **1** and 3.574 Å for **2**. There is an intramolecular hydrogen bond (Table S1) in the crystal structure of complex **1**; the D···A separation is 2.545 Å for O(1W)···O(2). The D−H···A angle is about 151° for O(1W)−H(1WA)···O(2). This intramolecular hydrogen bond may be responsible for the poor solubility of complex **1** in water. Intermolecular hydrogen bonds are observed in complex **2** between the hydrogen atoms of the solvent water molecule and N(1) and O(3). No intramolecular hydrogen bond is observed in **2**.

Cytotoxic Activity

The in vitro cytotoxicity of ligands **L** and **L′** and their copper complexes **1** and **2** was evaluated against the murine leukemia P-388 and lung adenocarcinoma A-549 cell lines with cisplatin as a positive control. The cytotoxicity profiles are shown in Figure 4. The results indicate that the inhibitory rates of complexes **1** and **2** are significantly higher than those of ligands **L** and **L′**, which are inactive to the tested cell lines. This observation is in accordance with the general phenomenon that copper complexes demonstrate enhanced biological activity than their parent ligands.[25,26] Complex **2** is far more active than complex **1** against both cell lines under the same conditions, with the latter being active only at concentrations as high as 10^{-4} mol·L^{-1}. At a concentration of 10^{-6} mol·L^{-1}, complex **2** still retains a high in-

hibitory rate against both the murine leukemia P-388 cell line (100%) and lung adenocarcinoma A-549 cell line (93.4%), and is about two to three times more potent than cisplatin. In fact, the activity of complex **2** is more potent than cisplatin at most experimental concentrations.

Interactions with DNA and GSH

It is commonly believed that DNA is the main cellular target of metal-based antitumor agents.[27] DNA-binding studies were therefore carried out to reveal the potential biological target for complexes **1** and **2**. To our surprise, the CD data (Figure S3, Supporting Information) do not show significant changes upon addition of the complexes to calf thymus DNA. The UV data (Figure S4, Supporting Information) also suggest that these complexes do not bind to DNA under the experimental conditions studied. This result suggests that another biological target may exist for complexes **1** and **2**.

As one of the most widely distributed intracellular reductants, GSH also plays an important role in metal detoxification.[28−31] Recently, a quantitative study has shown that GSH is a crucial contributor to protect against Cu cytotoxicity and it may function both in concert with, or

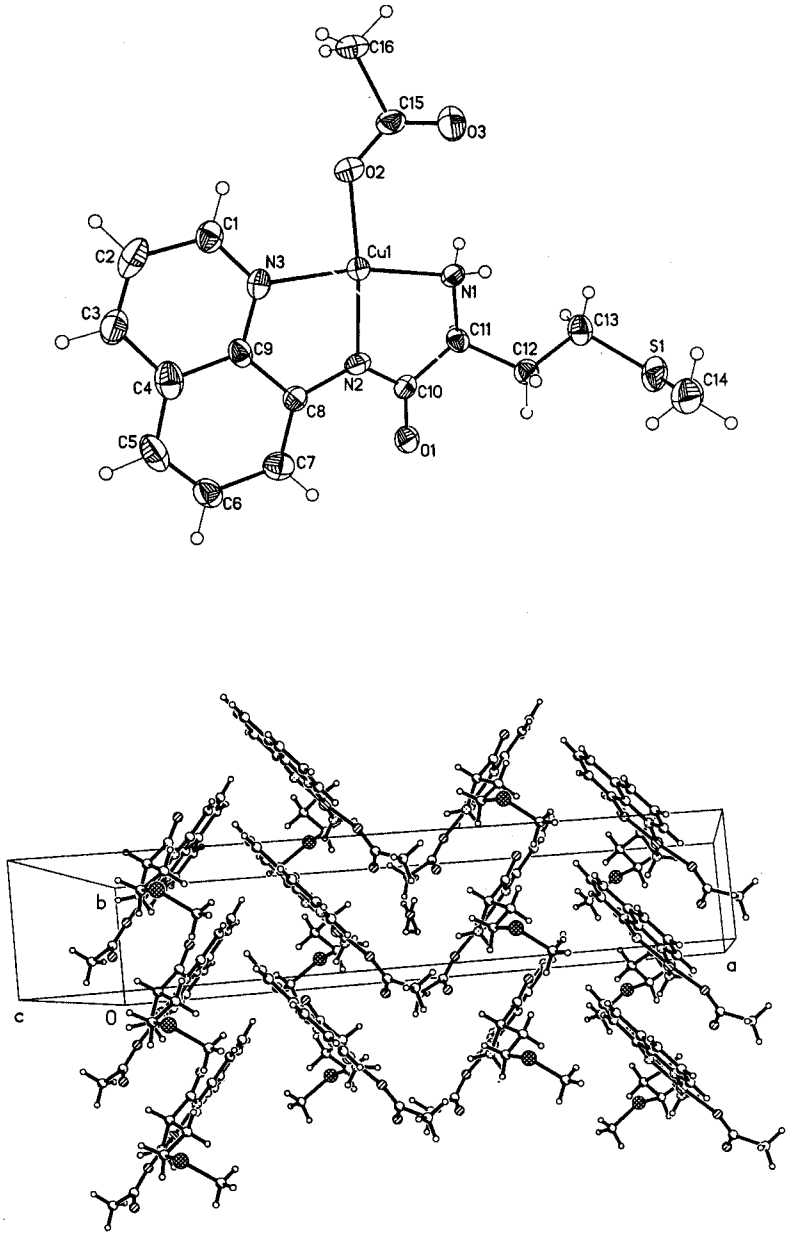

Figure 3. Crystal structure (ORTEP drawing) (top) and structure packed along the *b* axis (bottom) of complex **2**

independently of, metallothionein.[32] We thus studied the interaction of complexes **1** and **2** with GSH. As shown in Figure 5, the absorbances of complex **1** at 259 and 365 nm decrease gradually while the absorbances at about 241 and 302 nm increase upon the addition of GSH. When the concentration of GSH was increased to 3.33×10^{-5} mol·L^{-1}, equivalent to that of complex **1**, the absorption bands at 259 and 365 nm disappeared completely. In contrast to complex **1**, no new absorption bands and only inconspicuous absorption changes were observed in the UV spectra upon addition of GSH to a solution of **2**. Interestingly, this result is closely correlated with the cytotoxicity of these complexes. The GSH-reactive complex **1** is biologically inactive against tumor cells, while GSH-inactive complex **2** is biologically active. This relationship between reactivity and cytotoxicity may result from the Cu detoxification by intracellular GSH. Upon entering tumor cells, complex **1** would react with intracellular GSH and thus prevent it from reaching its desired target and exhibiting cytotoxicity. Complex **2** does not react with GSH, therefore its cytotoxicity in tumor cells is retained. It is therefore tempting to suggest that GSH could be used as a probe to select cytotoxic copper(II) complexes, although many more complexes need to be tested.

The electrochemical behavior of complexes **1** and **2** was also studied to explain the different reactivity of both complexes toward GSH (Figure S5). Complex **2** undergoes a reduction process at about −900 mV, which is far more negative than that of complex **1** (about −600 mV). The difference in activation energies ($\Delta G^{\ddagger}$) of both complexes re-

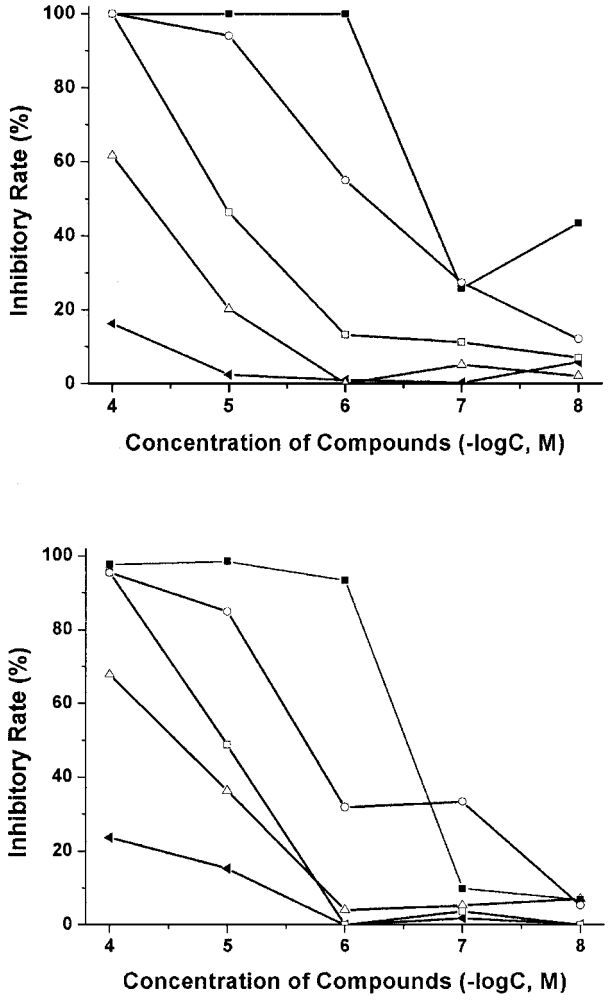

Figure 4. Cytotoxic activity of compounds against murine leukemia P-388 cell line (top) and lung adenocarcinoma A-549 cell line (bottom) (solid triangle: ligand **L**; hollow triangle: ligand **L′**; hollow square: complex **1**; solid square: complex **2**; hollow circle: cisplatin)

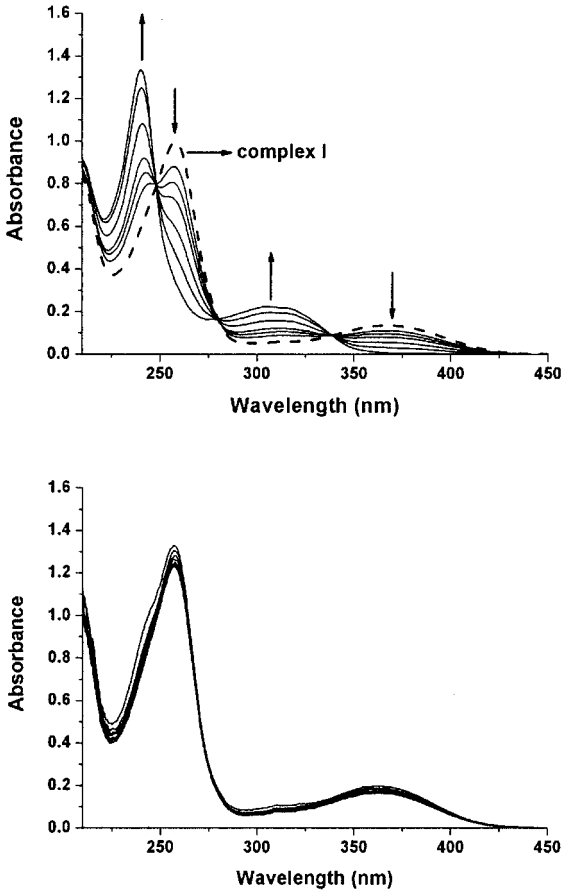

Figure 5. UV absorption spectra of complexes **1** (top) and **2** (bottom) in methanol with increasing concentration of GSH. [**1**] = [**2**] = 3.33×10^{-5} mol·L^{-1}; [GSH] = 0, 0.55×10^{-5}, 0.83×10^{-5}, 1.11×10^{-5}, 1.67×10^{-5}, 2.22×10^{-5}, 3.33×10^{-5} mol·L^{-1}; the time span between two successive spectra was 10 min

duced on the surface of the electrode was about 29 kJ·mol^{-1}, indicating that a higher activation energy is needed to drive the charge-transfer process for complex **2** than for **1**, which is consistent with their different reactivity toward GSH. Additionally, the poor cytotoxicity of complex **1** may also result from its low solubility. The adequate solubility of complex **2** in both organic solvents and water facilitates its transport and absorption in cells, and makes it easier to reach the target.

Conclusion

Although complex **1** and **2** have similar distorted square-planar configurations, their cytotoxicity and reactivity toward GSH are very different. The in vitro cytotoxicity of complex **2** against murine leukemia P-388 and lung adenocarcinoma A-549 cell lines is more potent than cisplatin at most experimental concentrations, whereas complex **1** only shows a marginal cytotoxicity against the same cells. Complex **1** is reactive toward GSH while complex **2** is inert. This fact implies that GSH may be used as a useful probe to predict the cytotoxicity of copper complexes.

Experimental Section

General Remarks: Solvents such as methanol, tetrahydrofuran, acetone, anhydrous diethyl ether, chloroform, *N*,*N*-dimethylformamide (DMF) and common reagents such as $Cu(OAc)_2 \cdot H_2O$, triethylamine and trifluoroacetic acid (TFA) were all of analytical grade and used as received. 8-Aminoquinoline and di-*tert*-butyl dicarbonate were purchased from Acros Organics. L-Methionine, the disodium salt of calf thymus DNA (CT DNA) and the reduced γ-glutathione were purchased from Sigma. The infrared spectra were recorded on a Bruker VECTOR22 spectrometer as KBr pellets (4000−500 cm^{-1}), and elemental analysis was performed on a Perkin−Elmer 240C analytical instrument. Electrochemical measurements were made at 20 °C on an EG&G PAR Model 273 potentiostat. A three-electrode setup comprising a platinum working electrode, platinum wire auxiliary electrode, and an Ag/AgCl reference electrode was used for voltammetric work. Tetrabutylammonium perchlorate (TBAP) was used as the supporting electrolyte in DMF.

N-(*tert*-Butoxycarbonyl)-L-methionine-*N*′-8-quinolylamide (**L**) and its deprotected counterpart L-methionine-*N*′-8-quinolylamide (**L**′) were synthesized following a procedure described previously.[17] Colorless single crystals of **L** suitable for X-ray diffraction were obtained by slow evaporation of an acetone solution.

Complex 1: This complex was prepared by mixing a methanol solution of $Cu(OAc)_2 \cdot H_2O$ (0.5 mmol, 6 mL) and **L** (6 mL) in a 1:1 molar ratio. The resulting solution was refluxed for about 2 h, and then cooled to room temperature. Brownish-red single crystals suitable for X-ray diffraction were obtained by slow evaporation of the solvent. Yield 164 mg (80%). $C_{16}H_{19}CuN_3O_4S$ (412.94): calcd. C 45.2, H 4.27, N 10.5; found C 45.5, H 4.33, N 10.4. IR (KBr): $\tilde{\nu}$ = 3446.8 (m), 3207.9 (m), 1600.7 (s), 1567.6 (s), 1498.3 (m), 1468.1 (m), 1417.4 (m), 1347.3 (s), 1072.9 (w), 1013.4 (w), 829.9 (m), 752.1 (w) cm^{-1}.

Complex 2: This complex was synthesized following the same procedure as for complex **1** except the starting ligand was replaced by **L**′. Dark-purple single crystals suitable for X-ray diffraction were obtained by slow evaporation of the solvent. Yield 166 mg (82%). $C_{16}H_{20}CuN_3O_{3.50}S$ (405.95): calcd. C 47.4, H 4.79, N 10.6; found C 47.0, H 4.76, N 10.5. IR (KBr): $\tilde{\nu}$ = 3472.1 (m), 1685.1 (s), 1594.0 (s), 1571.8 (s), 1501.8 (m), 1467.4 (m), 1412.5 (s), 1206.3 (s), 1140.0 (m), 830.9 (m), 788.6 (w), 725.5 (w) cm^{-1}.

X-ray Crystallographic Study: The main crystallographic data for ligand **L** and complexes **1** and **2** are summarized in Table 2. The crystals of ligand **L** and complex **1** were determined on a Siemens P4 four-circle diffractometer at 293 K. An empirical absorption correction was made (ψ-scan). The structure was solved by Patterson methods and completed by iterative cycles of least-squares refinement and ΔF syntheses. H-atoms were located in their calculated positions and treated as riding on the atoms to which they are attached. All non-hydrogen atoms were refined anisotropically. All calculations were carried out with the SHELXTL program.[33] The crystal of complex **2** was determined on a Siemens SMART CCD diffractometer at 293 K. The program SAINT[34] was used for data reduction and an empirical absorption correction was carried out using the SADABS program.[35] The structure was solved by Patterson methods that revealed the position of all non-hydrogen atoms and refined using the full-matrix least-squares method on F^2_{obs} with the SHELXTL software package.[33] All non-hydrogen atoms were placed in calculated positions. Atomic scattering factors and anomalous dispersion corrections were taken from ref.[36] CCDC-223042 (for **L**), -223043 (for **1**) and -223044 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Cytotoxicity Assays: The cytotoxicity assays of **L** and **L**′ and their Cu^{II} complexes **1** and **2** were performed as follows. Tumor cell lines were grown in RPMI-1640 medium supplemented with 10% (v/v) heat-inactivated fetal bovine serum, 2 mM glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin (GIBCO, Grand Island, NY) in a highly humidified atmosphere of 95% air with 5% CO_2 at 310 K.

The growth inhibitory effect on the murine leukemia P-388 cell line was measured by the microculture tetrazolium [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide, MTT] assay.[37] Briefly, cells in 100 μL of culture medium were plated in each well of 96-

well plates (Falcon, Calif.). The cells were treated in triplicate with grade concentrations of the ligands, copper complexes and the reference drug cisplatin at 310 K for 48 h. A 20 μL aliquot of MTT solution (5 mg/mL) was added directly to all the appropriate wells. The culture was then incubated for 4 h. Then 100 μL of "triplex solution" (10% SDS/5% isobutanol/12 mM HCl) was added. After incubating the plates at 310 K overnight, they were measured by the absorbance at 570 nm using a multiwell spectrophotometer (VERSA Max, Molecular Devices, USA).

For the lung adenocarcinoma A-549 cell line, the growth inhibition was analyzed by the sulforhodamine B (SRB) assay.[38] Briefly, adherent cells in 100 μL of medium were seeded in 96-well plates and allowed to attach for 24 h before drug addition. The cell densities were selected based on preliminary tests to maintain control cells in an exponential phase of growth during the period of the experiment and to obtain a linear relationship between the optical density (OD) and the number of viable cells. Each cell line was exposed to grade concentrations of the compounds at desired final concentrations for 72 h and each concentration was tested in triplicate wells. After exposure, cells were fixed by gentle addition of 100 μL of cold (277 K) 10% trichloroacetic acid to each well, followed by incubation at 277 K for 1 h. The plates were washed with deionized water five times and allowed to dry in air. The cells were stained by addition of 100 μL of SRB solution [0.4% SRB (w/v) in 1% acetic acid (v/v)] to the wells for 15 min. The plates were then quickly washed five times with 1% acetic acid to remove any unbound dye and allowed to dry in air. Bound dye was solubilized with 10 mmol·mL^{-1} Tris (pH 10.5) prior to reading the plates. The OD value was read at a wavelength of 515 nm. Media and DMSO control wells, in which compounds were absent, were included in all the experiments. The growth inhibitory rate of treated cells was calculated by $(OD_{control} - OD_{test})/OD_{control} \times 100\%$.

Spectral Studies of Interactions with DNA and GSH: The concentration of DNA was determined by measuring the UV absorption at 260 nm and taking the molar absorption coefficient (ε_{260}) of CT-DNA as 6600 L·mol^{-1}·cm^{-1}.[39] Circular dichroism (CD) spectra were recorded on a Jasco J-810 spectropolarimeter. Each sample solution was scanned in the range 225−300 nm. A CD spectrum was generated which represented the mean of three scans from which the solvent background had been subtracted. The UV/Vis spectra of complexes **1** and **2** on addition of CT DNA were obtained on a UV-3100 spectrometer at a molar ratio (DNA/copper) of 0.0, 0.2, 0.4, 0.6. The UV/Vis spectroscopic titrations were carried out at room temperature by adding increasing amounts of GSH (0, 0.55×10^{-5}, 0.83×10^{-5}, 1.11×10^{-5}, 1.67×10^{-5}, 2.22×10^{-5}, 3.33×10^{-5} mol·L^{-1}) to a solution of complexes **1** or **2** at a fixed concentration (3.33×10^{-5} mol·L^{-1}) contained in a quartz cell. The time span between two successive spectra was 10 min.

Dinuclear Cu^{II} Complexes with a New Phenol-Based Ligand Bearing Pyridine and Thiophene Substituents: Synthesis, Characterization and Interaction with Catechol Substrates

Iryna A. Koval,[a] Mieke Huisman,[a] Arno F. Stassen,[a] Patrick Gamez,[a] Olivier Roubeau,[b] Catherine Belle,*[c] Jean-Louis Pierre,[c] Eric Saint-Aman,[d] Matthias Lüken,[e] Bernt Krebs,[e] Martin Lutz,[f] Anthony L. Spek,[f] and Jan Reedijk*[a]

Keywords: Copper / Dinuclear complexes / Catechol oxidase / Magnetochemistry / Electrochemistry

The reaction of the phenol-based ligand 4-methyl-2,6-bis{[(2-methylpyridyl)(2-methylthiophenyl)amino]methyl}phenol-(Hpy2th2s), containing pyridine and thiophene substituents, with copper(II) chloride and bromide yields two new dinuclear complexes with the composition $[Cu_2(py2th2s)X_3]$, where X = Cl or Br. In both complexes, the copper(II) ions are pentacoordinate and bridged by the deprotonated phenolate anion and by one halogen anion. Both complexes exhibit geometric asymmetry, as the coordination environment around one of the two copper ions is square-pyramidal, whereas the geometry around the other can be best described as a distorted trigonal bipyramid. The complexes were characterized by means of X-ray single-crystal diffraction, ligand field and EPR spectroscopy, mass spectrometry, and electrochemically. Magnetic susceptibility measurements indicate an antiferromagnetic coupling between the two metal centers ($2J \approx -200$ cm^{-1}). The interaction of the complexes with model substrates 3,5-di-*tert*-butylcatechol and tetrachlorocatechol is reported.

Introduction

The copper-containing proteins with a type-3 active site, e.g. hemocyanin, tyrosinase and catechol oxidase, have the ability to reversibly bind and activate dioxygen at ambient conditions.[1] For this reason, modeling of the active site of these proteins has attracted significant scientific interest during the last few decades.[2−8] Hemocyanin functions as a dioxygen-carrier protein in some mollusks and arthropods, whereas tyrosinase and catechol oxidase utilize dioxygen to perform selective oxidation of various organic substrates. Tyrosinase catalyzes the hydroxylation of tyrosine to dopa [3-(3,4-dihydroxyphenyl)alanine] (cresolase activity) and its subsequent oxidation to dopaquinone (catecholase activity), the initial steps in melanin biosynthesis. Catechol oxidase lacks the cresolase activity of tyrosinase and only catalyzes the aerial oxidation of *o*-diphenols to the corresponding *o*-diquinones.

The crystal structure of catechol oxidase has been determined in 1998 by Krebs and co-workers.[9] Its active site is characterized by a dinuclear copper center, in which each copper ion is surrounded by nitrogen donor atoms of three histidine residues from a protein backbone. A catalytic cycle for catechol oxidase activity has been proposed from a combination of biochemical, spectroscopic, and structural data[10] and by comparison with the tyrosinase-related cycle.[1] It begins with the interaction of the catechol substrate with the met form of the enzyme, which contains two copper(II) ions singly bridged by a hydroxo group, resulting in the formation of a stoichiometric amount of the quinone.

Dinucleating phenol-based compartmental ligands have been previously successfully applied to model the type-3 active site.[6,7,11,12] Recent studies on the copper complexes of H-BPMP ligand, published by some of us,[7] allowed to propose a new catalytic mechanism, emphasizing the role of the μ-hydroxo bridge between the two metal centers. It includes the monodentate coordination of the substrate to one of the metal centers with the concomitant cleavage of the OH bridge, and the subsequent proton transfer from

the second OH group of the catechol substrate to the hydroxy group bound to the second copper center.[7] The release of a water molecule results in a bridging coordination of the catecholate, which undergoes an oxidation to quinone. In order to further demonstrate the importance of a μ-hydroxo bridge on the catalytic cycle, we report the synthesis of two dinuclear copper(II) chloride and bromide complexes with the new phenol-based ligand 4-methyl-2,6-bis[[(2-methylpyridyl)(2-methylthiophenyl)amino]methyl}phenol (abbreviated as Hpy2th2s), their structural, spectroscopic, magnetic and electrochemical properties, and their interaction with the model substrates 3,5-di-*tert*-butylcatechol (3,5-DTBC) and tetrachlorocatechol (TCC). In these complexes, the two metal ions are doubly bridged by the oxygen atom of the phenolate group and a halogen anion. It can be expected that the substitution of the μ-hydroxo group by a halogen anion should hamper the cleavage of the bridge and the subsequent proton transfer, thereby preventing the coordination of the catecholate in the bridging bidentate fashion, and thus hampering the catalytic cycle.

Results and Discussion

Synthesis

An interesting structural feature encountered in the active site of catechol oxidase from sweet potatoes (*Ipomoea batatas*)[9] and in active sites of some hemocyanins[13,14] is an unusual thioether bond between a carbon atom of one of the histidine ligands and the sulfur atom of a nearby cysteine residue from the protein backbone. There is also sequence homology evidence for this type of bridge in tyrosinase from *Neurospora crassa*.[15] Such a moiety was also encountered in the mononuclear copper enzyme galactose oxidase, in which it was proposed to stabilize the tyrosine radical generated during catalysis. However, the absence of this bridge in hemocyanins of arthropods and in human tyrosinase does not support the hypothesis about its direct involvement in the electron transfer process.[9]

Although a very large number of synthetic models of the type-3 active site appeared in the literature in the past few decades, relatively little attention has been paid to this thioether bond. In an attempt to mimic this quite unusual structural feature we prepared a new dinucleating phenol-based ligand Hpy2th2s with two pendant arms, containing pyridine and thiophene residues. The synthesis of this ligand is depicted in Figure 1.

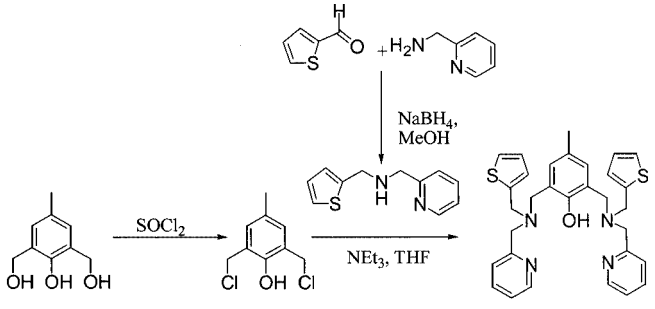

Figure 1. Reaction scheme of the synthesis of the ligand Hpy2th2s

The starting compound for the ligand synthesis, (2-picolyl)(2-thiophenyl)amine, was prepared by reaction of the commercially available 2-formylthiophene and (pyridin-2-ylmethyl)amine, followed by the reduction of the in situ generated imine by $NaBH_4$. Another starting compound 2,6-bis(chloromethyl)-4-methylphenol was prepared as described previously.[16] The reaction of 2,6-bis(chloromethyl)-4-methylphenol with a stoichiometric amount of (2-picolyl)(2-thiophenyl)amine in the presence of excess NEt_3 resulted in the formation of the ligand, which was isolated as a transparent light yellow oil. The reaction of Hpy2th2s with copper(II) chloride and bromide led to the formation of two new dinuclear copper complexes, which were isolated as dark brown and dark purple crystals, respectively.

Characterization of the Complexes

Crystal Structure Descriptions

[Cu_2(py2th2s)Cl_3]·CH_3OH (1)

Rectangular reddish-brown crystals of complex **1** were obtained by diethyl ether diffusion into a methanol solution containing stoichiometric amounts of copper(II) chloride and the ligand. A Platon[17] projection of the crystal structure of the complex is shown in Figure 2. Selected bond lengths and angles are presented in Table 1. The complex crystallizes as methanol solvate in space group $P2_1/n$ with four formula units present per unit cell. The dinuclear core is composed of two copper(II) ions, bridged on the one side by the endogenous cresolato bridge and on the other side by the chloride anion. The Cu···Cu separation in the complex is 3.185(1) Å. Both copper(II) ions are pentacoordinate with an identical N_2OCl_2 donor sets. However, the complex possesses geometrical asymmetry, as the coordination geometry around Cu1 is almost a regular square pyramid (τ = 0.10),[18] whereas the coordination environment around the Cu2 ion can be best described as a heavily distorted trigonal bipyramid (τ = 0.63).[18] The basal plane of the square pyramid around the Cu1 ion is made up of the nitrogen atom N1 of the tertiary amine group, the N2 atom of the pyridine ring, the oxygen atom O1 of the cresolate moiety, and the bridging chloride atom Cl1, whereas another chloride anion Cl2 occupies the apical position. In the case of the Cu2 ion, the nitrogen atom N3 of the tertiary amine group, the bridging chloride anion Cl1, and the chloride anion Cl3 form the equatorial plane of the trigonal bipyramid. The axial positions are occupied by the nitrogen atom N4 of the pyridine ring and the oxygen atom O1 of the cresolate group. The thiophene rings of the ligand remain noncoordinated; the Cu···S separations are > 5 Å. One of the thiophene rings shows disorder; the sulfur atom is refined on two independent positions, with occupancy factors of 78% (S1) and 22% (S1a). One noncoordinated disordered

methanol molecule is present per formula unit, which is hydrogen-bonded to the chloride anion Cl3.

[Cu₂(py2th2s)Br₃] (2)

Very dark purple needles of complex **2** were obtained by slow concentration of an acetonitrile solution containing stoichiometric amounts of copper(II) bromide and the ligand. A Platon[17] projection of the crystal structure is shown in Figure 3. Selected bond lengths and angles are presented in Table 2. The complex crystallizes in space group $P\bar{1}$. The asymmetric unit consists of two independent formula units. As in the case of the chloride complex **1**, two copper(II) ions are doubly bridged by the oxygen atom of the cresolate moiety and the halogen anion. The Cu···Cu distances are 3.2710(10) and 3.2394(10) Å, respectively. The copper ions are pentacoordinate, with N_2OBr_2 donor sets. One of the two independent formula units (Cu11, Cu12) possesses geometrical asymmetry. The geometry around the Cu11 ion is a slightly distorted square pyramid (τ = 0.17),[18] whereas the geometry around the Cu12 ion is a very distorted trigonal bipyramid (τ = 0.58).[18] The nitrogen atom N11 of the tertiary amine group, the nitrogen atom N12 of the pyridine ring, the bridging oxygen atom O11, and the bridging bromide anion Br11 form the basal plane of the square pyramid around the Cu11 ion, whereas the monocoordinated bromide anion Br12 occupies the axial position. The equatorial plane of the trigonal bipyramid around the Cu12 ion is formed by the nitrogen atom N13 of the tertiary amine group and the bromide atoms Br11 and Br13. The axial positions of the bipyramid are occupied by the bridging oxygen atom of the cresolate group and the nitrogen atom N14 of the pyridine ring. One of the noncoordinated thiophene rings is rotationally disordered. Thus, the first orientation has an occupancy factor of 85%, while the 180° rotated orientation has an occupancy factor of 15%.

In the second independent formula unit, both copper(II) ions (Cu21 and Cu22) have significantly distorted square-pyramidal surroundings (τ = 0.26 for the Cu21 ion and 0.45 for the Cu22 ion)[18]. The basal plane around the Cu21 ion is made up of, as in the case of the Cu11 ion, the two nitrogen atoms N21 and N22, the oxygen atom O21 of the cresolate group, and the bridging halogen atom Br21, whereas the bromide anion Br22 occupies the apical position. For the Cu22 ion, the nitrogen atom N23 of the ter-

tiary amine group, the nitrogen atom N24, the bridging oxygen atom O21, and the bridging bromide anion Br21 form the basal plane of the square pyramid, and its apical position is occupied by the Br23 atom. Thus, two square pyramids share one side through the atoms O21 and Br21, with their apical positions *trans*-located to each other. Both thiophene rings of the ligand remain noncoordinated (Cu···S separations are > 5 Å) and exhibit rotational disorder. Thus, the thiophene ring at S21 was refined on two orientations with occupancies of 0.72 and 0.28, respectively, and the thiophene ring at S22 with occupancies of 0.55 and 0.45, respectively.

Physical Methods

Ligand Field Spectroscopy

The ligand field spectra of both complexes, recorded in the solid state (diffuse reflectance), exhibit almost identical features. Both spectra are characterized by the presence of the charge-transfer band from the phenolate moiety to the copper ions[11] around 500 nm (483 nm for complex **1** and 521 nm for complex **2**) and the d-d transition band of the copper(II) ions. The latter band, observed at 774 nm for the chloride complex and at 806 nm for the bromide complex, is asymmetric in both cases, with a shoulder observed at higher wavelengths. As shown previously, such spectroscopic behavior (high-energy absorption band in the visible region with a low-energy shoulder) is typical for square-pyramidal copper(II) complexes.[19] In acetonitrile solution, the charge-transfer band is observed at 472 nm for complex **1** (ε = 1851 $M^{-1}\cdot cm^{-1}$) and at 500 nm for complex **2** (ε = 1812 $M^{-1}\cdot cm^{-1}$). The d-d band is located at 771 nm (ε = 464 $M^{-1}\cdot cm^{-1}$) for complex **1** and 791 nm (ε = 534 $M^{-1}\cdot cm^{-1}$) for complex **2**. A small shift of the d-d bands upon dissolution of the complexes in acetonitrile may suggest the coordination of the solvent to the metal centers. However, the partial dissociation of the complexes due to the exchange of the halide anions with acetonitrile molecules can also not be excluded.

EPR and Magnetic Susceptibility Studies

Both complexes **1** and **2** are EPR-silent in the solid state and in a frozen acetonitrile solution at 100 K, suggesting an antiferromagnetic coupling between the copper ions. Such a behavior is confirmed by the temperature dependence of the molar magnetic susceptibility χ_M depicted in Figure 4, which is typical for complexes of antiferromagnetically coupled copper(II) dimers. Indeed the χ_M vs. T curves present a broad maximum centered around 160 and 190 K for **1** and **2**, respectively, while the values of χ_M at high temperatures (2.10×10^{-3} and 1.85×10^{-3} $cm^3\cdot mol^{-1}$ at 300 K, respectively) are slightly lower than expected for two uncoupled copper(II) ions (2.5×10^{-3} $cm^3\cdot mol^{-1}$ for g = 2). Below 40 K, a Curie tail ascribed to paramagnetic impurity is observed, which is usual in such copper(II) complexes. These experimental data were reproduced correctly using

the modified Bleaney−Bowers equation [Equation (1)], where χ_M is the magnetic susceptibility per dimer. In this equation, $2J$ corresponds to the singlet-triplet energy gap, ρ to the fraction of paramagnetic impurity, and TIP to a term to account for temperature-independent paramagnetism, while N_A, β, k_B, and g have their usual meaning. The paramagnetic impurity was assumed to be a mononuclear copper(II) species and g was fixed to 2. The best-fit parameters were then obtained as $2J = -177(2)$ cm^{-1}, ρ = 1.8(1)% and TIP = 2.9(1) × 10^{-4} cm^3·mol^{-1} for complex **1**, and $2J = -219(1)$ cm^{-1}, ρ = 0.6(1)% and TIP = 2.0(1) × 10^{-4} cm^3·mol^{-1} for complex **2**.

$$\chi_M = (1-\rho)\frac{2N_A\beta^2g^2}{k_BT}\left[3+\exp(-2J/k_BT)\right]^{-1} + 2\rho\left(\frac{N_A\beta^2}{k_BT}\right) + TIP \quad (1)$$

These medium antiferromagnetic couplings should be correlated to a significant overlap between the two magnetic orbitals of the two copper(II) ions in complexes **1** and **2**, through both the halide and phenolate bridges. The short

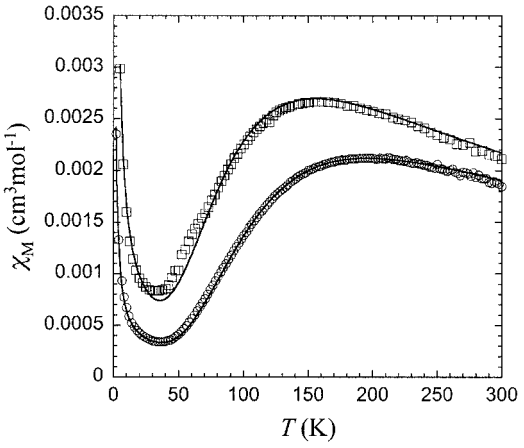

Figure 4. χ_M vs. T curve for complexes **1** (squares) and **2** (circles); see text for further details

Cu−O bonds and the large Cu−O−Cu angles of the phenolate bridge in **1** and **2**, relative to the long Cu−X bonds, point at a dominant coupling through the phenolate bridge. The coordination sphere around one of the two copper ions is intermediate between a square pyramid and a trigonal bipyramid, while the other has a square-pyramidal environment. In the former case, the unpaired electron of copper(II) occupies either the d_{z^2} or the $d_{x^2-y^2}$ orbital, which would both point along the Cu−O(phenolate) bond. Short Cu−O bonds and large Cu−O−Cu angles in square-pyramidal phenolate-bridged Cu dimers result in a strong overlap of $d_{x^2-y^2}$ orbitals and thus produce strong to very strong antiferromagnetic couplings.[20] On the other hand, if one of the copper ions in such dimers has a trigonal-bipyramidal environment, weaker overlap is expected, and even weak ferromagnetic coupling has been observed.[21,22] Therefore, the smaller singlet-triplet energy gap in **1** can be related to a smaller Cu−O−Cu angle in **1** (ca. 112°) relative to **2** (on average over the two dimeric units about 115.3°), but also to a more distorted trigonal-bipyramidal coordination sphere in **2** (τ = 0.58, Cu12) than in **1** (τ = 0.63, Cu2). Most likely, the difference in the singlet-triplet energy gap results from both structural differences.

Electrochemistry

The electrochemical behavior of both complexes was investigated by cyclic voltammetry (CV) and rotating disk electrode voltammetry (RDE) in acetonitrile solution, with tetra-*n*-butylammonium perchlorate (TBAP) as supporting electrolyte (0.1 M). The potentials were referred to an Ag/10 mM $AgNO_3$ + CH_3CN +0.1 M TBAP reference electrode.

When scanning towards the negative region of potentials, the CV curve for both complexes **1** and **2** is characterized by three successive electrochemical signals (Figures 5 and 6). The first signal for **1**, at $E_{pc} = -0.52$ V, is irreversible, and re-oxidation of the reduced species is seen on the reverse scan at +0.23 V (Figure 5, curve a), while that for **2** appears to be weakly reversible at $E_{1/2} = -0.34$ V (ΔE_p =

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

0.12 V, Figure 6, curve a). Coulometric titrations give n = 1 for the exchanged electron per complex, allowing to attribute this electrochemical process to the complexed $Cu_2^{II,II}/Cu_2^{II,I}$ redox couple. The UV/Vis spectra of the one-electron reduced complexes exhibit one very broad band around 680 nm. The lack of reversibility of the first electrochemical reduction of **1** and **2** suggests a change in the coordination sphere around the metal center upon reduction, likely a partial dissociation of the exogenous halide ligand and a change in the geometry of the coordination sphere. Additional electrochemical measurements performed at −40 °C showed that the course of these coupled chemical reactions is not prevented at low temperature. The second electrochemical signal, weakly reversible at $E_{1/2}$ = −0.78 V for **1** and at $E_{1/2}$ = −0.72 V for **2**, also corresponds to a one-electron process, leading to the complexed $Cu_2^{II,I}/Cu_2^{I,I}$ redox couple. Finally, the third electrochemical signal at E_{pc} = −1.45 V for **1** and −1.04 V for **2** corresponds to a two-electron process, suggesting the reduction of Cu^{I} ions to the Cu^0 state and the deposition of metallic copper on the electrode surface. Accordingly, an additional sharp anodic peak is observed on the reverse scan, which is caused by the redissolution of metallic copper.

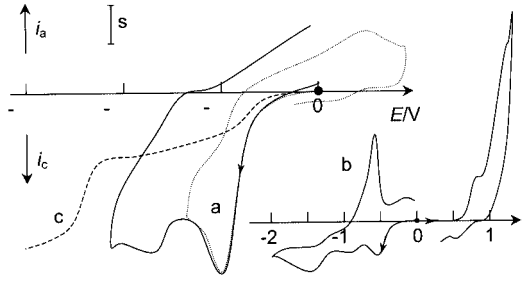

Figure 5. Electrochemical curves recorded in a 0.67 mM solution of **1** in CH_3CN + TBAP 0.1 M on a Pt disc [diameter = 5 (a, b) or 3 (c) mm]; curves a, b: CV curves, ν = 0.1 $V{\cdot}s^{-1}$; curve c: RDE curve, N = 600 rpm; V vs. $Ag/AgNO_3$ mM + CH_3CN + TBAP 0.1 M; scale s = 20 μA (curve a), 120 μA (curve b) or 10 μA (curve c)

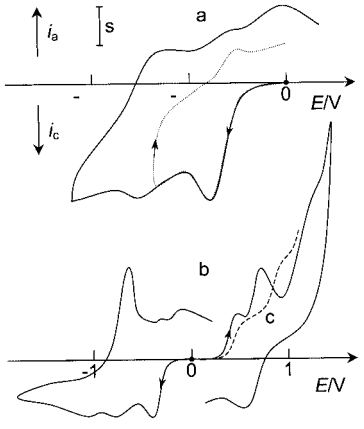

Figure 6. Electrochemical curves recorded in a 0.67 mM solution of **2** in CH_3CN + TBAP 0.1 M on a Pt disc [diameter = 5 (a, b) or 3 (c) mm]; curves a, b: CV curves, ν = 0.1 $V{\cdot}s^{-1}$; curve c: RDE curve, N = 600 rpm; V vs. $Ag/AgNO_3$ mM + CH_3CN + TBAP 0.1 M; scale s = 20 μA (curve a), 40 μA (curve b, c)

The anodic behavior of complexes **1** and **2** differs. The anodic part of the CV curve for **1** (Figure 5, b) is characterized by two electrochemical signals, whereas three signals are observed on the CV curve for **2** (Figure 6, b). For **1**, the first signal at $E_{1/2}$ = 0.64 V (ΔE_p = 0.26 V) corresponds to a one-electron quasi-reversible oxidation of **1**. The electron transfer is likely to be centered on the phenolate bridge, as previously shown for other phenolate-bridged dinuclear copper(II) complexes.[11,23] This process is followed by the oxidation of the chloride anions, which is seen as a shoulder at the negative foot of the over-oxidation wave of the complex (free chloride anions are reversibly oxidized at 0.72 V under our experimental conditions). The CV curve recorded in a solution of **2** shows an additional fully irreversible one-electron process at E_{pa} = 0.47 V. This is assumed to be due to the one-electron oxidation of bromide anions; free bromide anions are irreversibly oxidized at E_{pa} = 0.39 V under our experimental conditions. The one-electron phenolate-based oxidation of complex **2**, similarly to **1**, is observed as a quasi-reversible pair of peaks at $E_{1/2}$ = 0.76 V (ΔE_p = 0.18 V), and is followed at higher potentials by the over-oxidation of the complex.

These results have been confirmed by rotating disk electrode (RDE) voltammetric experiments (Figures 5 and 6). The RDE curves display one anodic wave at $E_{1/2}$ = 0.84 V for **1** and two successive well-behaved anodic waves at $E_{1/2}$ = 0.42 V and 0.82 V (Figure 6, curve c) for **2**. For both complexes, three successive cathodic waves are seen. For **1** and **2**, the first one at $E_{1/2}$ = −0.42 V and −0.40 V, respectively, is followed by a second ill-behaved wave at $E_{1/2}$ = −0.78 V and −0.80 V, respectively. The third cathodic wave corresponding to the deposition of metallic copper onto the electrode surface is observed at $E_{1/2}$ = −1.22 V and −1.20 V, respectively.

Conductivity Measurements

The conductivity measurements of the complexes **1** and **2** were performed on 0.5 mM solutions of the complexes in acetonitrile. The calculated values for equivalent conductivities of both compounds are roughly the same and are equal to 52 $cm^2{\cdot}mol^{-1}{\cdot}\Omega^{-1}$ for complex **1** and 55 $cm^2{\cdot}mol^{-1}{\cdot}\Omega^{-1}$ for complex **2**. Previously, the conductivity range for complexes corresponding to the 1:1-type electrolytes was suggested to lie between 120 and 160 $cm^2{\cdot}mol^{-1}{\cdot}\Omega^{-1}$ if acetonitrile was utilized as a solvent.[24] Although values as low as 90 $cm^2{\cdot}mol^{-1}{\cdot}\Omega^{-1}$ were also reported in some cases, the observed conductivities of both complexes **1** and **2** are still too low for them to be considered as 1:1 electrolytes. As shown previously,[25] such small conductivity values in acetonitrile are often found for nonelectrolytes, due to coordinating and solvating properties of this solvent. Some authors[25] argue that they may indicate a partial exchange of counter anions with the solvent molecules. Small changes in the positions of UV/Vis/NIR d-d bands of the complexes upon their dissolution in acetonitrile, observed in our case, appear to sustain this assumption.

Interaction of the Complexes with the Model Substrates

Catecholase Activity Measurements

To evaluate the ability of the complexes to behave as functional models of catechol oxidase, they were tested as catalysts in the oxidation of 3,5-di-*tert*-butylcatechol (3,5-DTBC), a widely used model substrate, to the respective quinone. Both complexes exhibit only negligible catecholase activity (TON $<$ 1 after 30 min), making a detailed kinetic analysis dispensable. These results are as expected, confirming that the substitution of the μ-hydroxo bridge by a halogen anion precludes catecholase activity. However, these results do not provide information on whether or not the binding of the substrate to the metal centers takes place *at all*. Reim et al. have previously shown that, in the case of essentially inactive complexes, no interaction between the dimetal core and the substrate occurred.[6] To evaluate whether or not the first step of the catalytic cycle, e.g. the binding of catechol to the metal centers, takes place, we studied the interaction of the complexes with tetrachlorocatechol (TCC). The latter catechol has a very high oxidation potential due to its electron-withdrawing substituents and is not oxidized by copper complexes.

TCC Binding Studies

The titration of 5×10^{-4} M solutions of the complexes in acetonitrile with TCC was monitored by means of UV/Vis and EPR spectroscopy. The changes observed in the UV/Vis spectra of complex **1** upon addition of TCC (up to 4 equiv.) are depicted in Figure 7. Quite significant changes in the spectrum of the original complex indicate the interaction between the substrate and the metal centers. The presence of two isosbestic points at 570 nm and 724 nm shows the presence of only two absorbing species in solution. The Cu^{II} d-d transition band shifts gradually from 789 nm to 718 nm, whereas its absorbance decreases to about 50% of its initial value. Also, the extinction coefficient of the LMCT band decreases from 1851 to about 1600 $M^{-1}\cdot cm^{-1}$ (Figure 7).

Whereas the chloride complex obviously reacts with TCC, no changes were observed in the UV/Vis spectrum upon addition of TCC to the bromide complex. Taking into account the great structural similarity between the two complexes, it seems reasonable to us to suggest that the difference in their behavior is caused by the different halogen anions coordinated to the copper ions. The Cu−Cl bond has a more ionic character than the Cu−Br bond, which facilitates the substitution of (at least one of) the chloride anions by catechol, whereas no exchange of Br anions by TCC occurs.

Titration of complex **1** with TCC, monitored by X-band EPR spectroscopy, revealed that no evolution of the EPR signal is observed upon addition of TCC. This indicates that the two copper ions are strongly antiferromagnetically coupled, suggesting that they probably remain doubly bridged by the phenolate group and the chloride anion. Although a few structures of copper(II) complexes with bridging catecholate were previously described,[8,26] no magnetic properties of these compounds have been reported. However, we believe that the cleavage of the halide bridge would lead to a decrease in strength of the magnetic coupling, similarly to the behavior seen in previously reported μ-hydroxo complexes with phenol-based ligands[7] after the cleavage of the hydroxo bridge. Thus, the reaction of TCC with the chloride complex probably results in the substitution of at least one of the apical chloride anions.

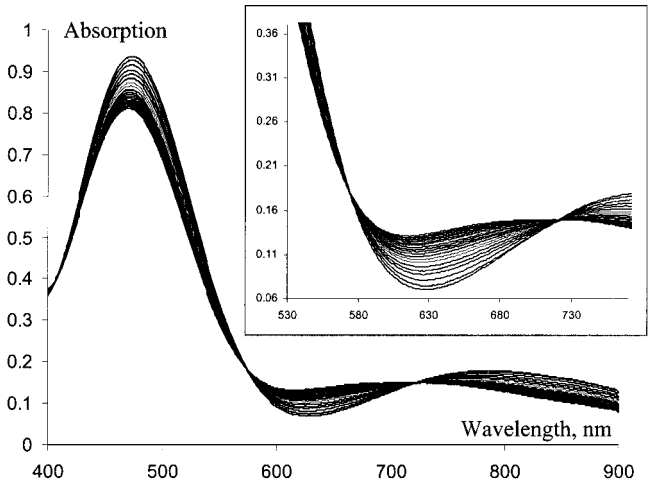

Figure 7. UV/Vis titration of complex **1** (0.5 mM solution in acetonitrile) with TCC (from 0 to 4 equiv.); the inset shows the enlargement of the spectroscopic curves in the range 530−780 nm

In order to further confirm this hypothesis, the conductivity of complex **1** in acetonitrile solution before and after addition of TCC was studied. The equivalent conductivity of TCC itself is negligible.

The values of the equivalent conductance observed after addition of 1−4 equiv. of TCC to 0.5 mM solution of complex **1** are listed in Table 3. As can be seen, a substantial increase is observed after 1 equiv. of TCC has been added. Further addition of TCC leads to a slight increase in conductivity, until a final value of 118 $cm^2\cdot mol^{-1}\cdot\Omega^{-1}$ is reached. This value fits perfectly in a range suggested for the 1:1 electrolytes in acetonitrile.[24] The interaction of **1** with TCC leads to the release of one chloride anion in solution; complete release is reached in the presence of an excess of TCC as shown by the slight increase in the conductivity above 1 mol-equiv. added. The reversible nature of this process is further confirmed by UV/Vis titration experiments

Table 3. Calculated values of equivalent conductivity upon treating 0.5 mM solution of **1** in acetonitrile with TCC

Number of equiv. of TCC	Equivalent conductivity [$cm^2\cdot mol^{-1}\cdot\Omega^{-1}$]
0	52
1	100
2	110
3	117
4	118

that showed that the maximal perturbation in the UV/Vis spectra was reached in the presence of at least 3 equiv. of TCC (Figures 7 and 8).

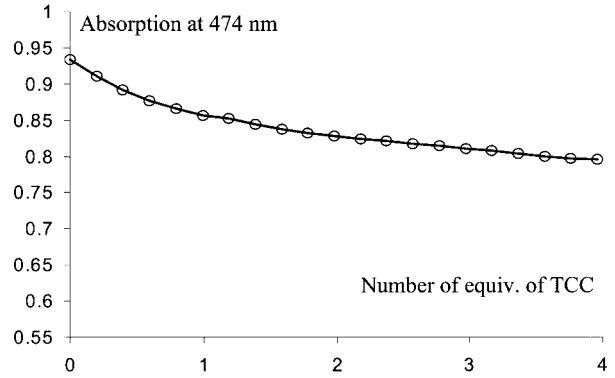

Figure 8. Decrease in the LMCT band (474 nm) upon titration of the solution of **1** (0.5 mM) in acetonitrile with TCC

Not surprisingly, additions of TCC to the bromide complex do not lead to an increase in conductivity, in complete agreement with the hypothesis that substitution of Br^- anions by TCC is not possible.

General Discussion

Previously, many attempts to establish a correlation between the structural parameters of the complexes and their catalytic activity in the oxidation of catechols were described in the literature. Three most important criteria influencing the catalytic properties of the complexes can now be distinguished: (i) the distance between the metal centers,[11,27,28] (ii) the nature of the bridging group between the metal ions,[29,30] (iii) the electronic properties of the complexes.[23] Some other factors, e.g. the imposed strain in the complex due to the rigidity of either the ligand and/or the bridging group, may also play a role.[6] Results published by Reim et al.[6] indicate that complexes with strained structures show catalytic activity, whereas complexes present in relaxed and energetically favored conformations are essentially inactive towards catechol oxidation. In the chloride and bromide complexes **1** and **2**, the metal−metal distance and the redox potentials of the metal ions are similar to the values previously determined for catalytically active complexes;[6,11,29] thus, the absence of catalytic activity is not likely to be due to these two factors. Also, the coordination spheres around the copper ions in both complexes exhibit quite a large distortion from a regular square-pyramidal geometry, resulting in relatively strained structures. Thus, the main reason for the absence of catalytic activity lies in the nature of the bridging groups between the two copper ions in the complexes. As discussed above, the crucial steps of the mechanism that was proposed earlier[7] is the cleavage of the OH bridge between the two metal ions and the subsequent proton transfer from the catechol substrate to the hydroxy anion, leading to the release of one water molecule. We have shown that the reaction of catechol with the complexes **1** and **2** does not result in a cleavage of the bridge, although binding of the substrate to the chloride complex undoubtedly takes place. These results thus emphasize the influence of the bridging group between the copper centers on the catecholase activity of the complexes and underline the importance of the exogenous hydroxo bridge for the catalytic mechanism. This hydroxo ligand appears to be the key factor to achieve the complete deprotonation of catechol, leading to a bridging catecholate prior to the electron transfer. Upon substitution of the hydroxo bridge with the halogen anion, no proton transfer can occur, precluding the binding of catecholate in a bidentate bridging fashion, and thus the subsequent catalytic cycle.

Conclusion

The synthesis of a new phenol-based ligand Hpy2th2s bearing thiophene- and pyridine-containing pendant arms was successfully accomplished. Two dinuclear copper(II) complexes with this ligand were isolated and characterized by means of single-crystal X-ray analysis, UV/Vis and EPR spectroscopy, magnetochemistry and electrochemistry. Both complexes were found to be essentially inactive in the catalytic oxidation of 3,5-di-*tert*-butylcatechol to the respective quinone. The presence of chloride and bromide anions as bridging ligands between the two metal centers precludes the deprotonation of catechol and its binding in a bidentate bridging fashion to the copper ions, and thus from further oxidation. Studies to establish a better structure-activity relationship for dinuclear copper(II) complexes as structural models of catechol oxidase are currently in progress.

Experimental Section

General Remarks: All starting materials were commercially available and used as purchased. 2,6-Bis(chloromethyl)-4-methylphenol was prepared as described previously.[16] The NMR spectra were recorded with a JEOL FX-200 (200 MHz) FT NMR spectrometer. The ligand field spectra of the solids (300−2000 cm^{-1}, diffuse reflectance) were taken with a Perkin−Elmer 330 spectrophotometer equipped with a data station. The ligand field spectra in solution were recorded with a Varian Cary 50 Scan UV/Vis spectrophotometer. Electrospray mass spectra (ESI-MS) in acetonitrile solutions were recorded with a Thermo Finnigan AQA apparatus. X-band electron paramagnetic resonance (EPR) measurements were performed at 77 K in the solid state with a Jeol RE2x electron spin resonance spectrometer, using DPPH (g = 2.0036) as a standard, and at 100 K as acetonitrile frozen solutions with a Bruker ESP 300E spectrometer operating at 9.4 GHz (X-band). The conductivity measurements were performed with a Philips PW9526 digital conductivity meter and PW 9552/60 measuring cell with 0.5 mM solutions of the complexes in acetonitrile. The electrochemical behavior of the complexes was investigated in a 0.1 M solution of tetra-*n*-butylammonium perchlorate (TBAP) in acetonitrile using an EGG 273 potentiostat coupled with a Kipp&Zonen *x*-*y* recorder. The experiments were performed at room temperature or at −40 °C in a three-compartment cell. Potentials are referred to

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

an Ag/10 mM $AgNO_3$ + CH_3CN +0.1 M TBAP reference electrode. The working electrode was a platinum disk with a 5 mm diameter for the cyclic voltammetry (CV, 0.1 V/s) experiments or 3 mm diameter for the rotating disk electrode (RDE, 600 rpm) voltammetry experiments. The working electrode was polished with 1 μm diamond paste prior to each recording. Bulk magnetizations of polycrystalline samples were performed on the crystals of complexes **1** (11.11 mg) and **2** (16.88 mg) in the temperature range 5−400 K with a Quantum Design MPMS-5S SQUID magnetometer in a 1 kG applied field. The data were corrected for the experimentally determined contribution of the sample holder. Corrections for the diamagnetic responses of the complexes, as estimated from Pascal's constants, were applied.[31]

Catecholase Activity Study: The catecholase activity of the complexes was evaluated by reaction with 3,5-di-*tert*-butylcatechol at 25 °C. The absorption at 400 nm, characteristic of the formed quinone, was measured as a function of time. The experiments were performed under 1 atm of dioxygen; 3 mL of $2.5 \cdot 10^{-4}$ M solution of complex in acetonitrile was placed in 1-cm path-length cell, and 75 μL of a 1 M solution of the substrate in the same solvent was added. After thorough shaking, the changes in UV/Vis spectra were recorded over 30 min. The titration of the complexes with tetrachlorocatechol (TCC) was carried out by adding 3 μL aliquots of 0.1 M solution of TCC (corresponding to 0.198 equiv. of TCC/1 equiv. of the complex) to 3 mL of 5×10^{-4} M solution of complex in acetonitrile.

(2-Picolyl)(2-thiophenyl)amine: A solution of (pyridin-2-ylmethyl)-amine (2.00 g, 18.5 mmol) was added dropwise, while stirring, to a solution of 2-formylthiophene (2.08 g, 18.5 mmol) in MeOH. The resulting solution was stirred at room temperature overnight. Afterwards, $NaBH_4$ (2.1 g, 56 mmol, 3 equiv. per 1 CH=N) was added slowly, and the resulting solution was heated at 50 °C for 3 h. After concentration, the obtained oil was redissolved in a mixture of dichloromethane and water. The organic and aqueous layers were separated, and the water layer was washed twice with a small amount of dichloromethane. After combining and drying of the dichloromethane layers with Na_2SO_4 and concentration, the pure product was obtained as a light yellow oil. The product is light-sensitive and should preferably be stored in darkness at low temperatures. Yield: 3.59 g (95%). ^{1}H NMR ($CDCl_3$): δ = 2.28 (s, 1 H, NH), 3.95 (s, 2 H, NHCH_2th), 4.03 (s, 2 H, NHCH_2py), 6.93 (d, 1 H, 3′th), 6.96 (s, 1 H, 4′th), 7.20 (d, 1 H, 5′th), 7.15 (t, 1 H, 5′py), 7.30 (d, 1 H, 3′py), 7.62 (t, 1 H, 4′py), 8.55 (d, 1 H, 6′py) ppm.

4-Methyl-2,6-bis{[(2-methylpyridyl)(2-methylthiophenyl)amino]-methyl}phenol (Hpy2th2s): A solution of (2-picolyl)(2-thiophenyl)-amine (0.7 g, 3.4 mmol) and Et_3N (0.7 g, 7 mmol) in THF was added dropwise, while stirring, to a solution of 2,6-bis(chloromethyl)-4-methylphenol (0.35 g, 1.7 mmol) in THF. After refluxing for 2 h, the solution was cooled to room temperature. Filtration of the triethylammonium salt and subsequent evaporation of the solvent resulted in an oil, which was dissolved in acidified water and washed with dichloromethane. The water layer was made alkaline by adding a concentrated aqueous solution of NH_3, and the resulting suspension was extracted three times with dichloromethane. The combined organic layers were dried with Na_2SO_4 and the solvents evaporated under reduced pressure. The resulting oil was found to be the pure product. Yield: 0.77 g (84%). ^{1}H NMR ($CDCl_3$): δ = 2.28 (s, 3 H, CH_3), 3.82 (s, 4 H, NCH_2th), 3.85 (s, 4 H, phCH_2N), 3.89 (s, 4 H, NCH_2py), 6.95 (m, 4 H, 3′th + 4′th), 7.04 (s, 2 H, 3′ph + 5′ph), 7.15 (t, 2 H, 5′th), 7.24 (d, 2 H, 3′py), 7.53 (d, 2 H, 5′th), 7.66 (t, 2 H, 4′py), 8.56 (d, 2 H, 6′py), 10.40 (1 H, OH) ppm. ESI-MS: m/z = 541 [M + H$^+$].

[Cu_2(py2th2s)(μ-Cl)Cl_2]·CH_3OH (1): Hpy2th2s (0.15 g, 0.28 mmol) and copper chloride (0.10 g, 0.54 mmol) were dissolved in methanol (10 mL). Addition of diethyl ether (20 mL) resulted in the precipitation of the complex as a dark brown powder. Yield: 102 mg (46%). Single crystals of the complex were obtained by slow diffusion of diethyl ether into a 0.01 M solution of the complex. [Cu_2(symth2py2)Cl_3]·CH_3OH. $C_{32}H_{36}Cl_3Cu_2N_4O_2S_2$ (806.2): calcd. C 47.73, H 4.38, N 6.96, S 7.96; found C 45.73, H 4.14, N 7.25, S 7.91. ESI-MS: m/z = 737 [Cu_2(py2th2s)Cl_2]$^+$.

[Cu_2(py2th2s)(μ-Br)Br_2] (2): Hpy2th2s (0.15 g, 0.28 mmol) and copper bromide (0.12 g, 0.54 mmol) were dissolved in of methanol (10 mL). After addition of diethyl ether to the resulting solution, the complex precipitated as a dark purple crystalline powder. Yield: 155 mg (64%). Crystals suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether into a 0.01 M solution of the complex in acetonitrile. $C_{31}H_{31}Br_3Cu_2N_4OS_2$ (906.5): calcd. C 40.95, H 3.76, N 5.97, S 6.83; found C 39.76, H 3.42, N 6.07, S 6.50. ESI-MS: m/z = 827 [Cu_2(py2th2s)Br_2]$^+$.

X-ray Structures

Compound 1: A single crystal of [Cu_2(py2th2s)(μ-Cl)Cl_2]·CH_3OH (**1**) was mounted at 150 K on a ᵇruker AXS SMART 6000 diffractometer, equipped with Cu-K_α radiation (λ = 1.54184 Å). $C_{32}H_{35}Cl_3Cu_2N_4O_2S_2$, M = 802.17, rectangular reddish-brown plate, 0.23 × 0.21 × 0.05 mm, a = 7.984(2) Å, b = 34.589(7) Å, c = 12.554(3) Å, β = 94.31(3)°, Z = 4, V = 3457(2) Å^3, $\rho_{calcd.}$ = 1.541 g·cm^{-3}, μ = 5.068 mm^{-1}, absorption correction with SADABS,[32] monoclinic, space group $P2_1/n$ (no. 14), 19864 reflections collected, 6317 independent reflections (R_{int} = 0.0386). The structure was solved by direct methods and refined using the SHELX program package.[33,34] All hydrogen atoms were placed on idealized positions riding on their carrier atoms with isotropic displacement parameters. The final cycle of full-matrix least-squares refinement, including 438 parameters, converted into $R1$ = 0.0352 ($R1$ = 0.0430 all data) and $wR2$ = 0.1009 ($wR2$ = 0.1038 all data) with a maximum (minimum) residual electron density of 0.535 (−0.466) e·Å^{-3}.

Compound 2: $C_{31}H_{31}Br_3Cu_2N_4OS_2$ + solvent, M = 906.53, red needle, 0.60 × 0.06 × 0.03 mm, triclinic, $P\bar{1}$ (no. 2), a = 8.4207(2) Å, b = 17.9812(4) Å, c = 24.2238(6) Å, α = 71.2709(9), β = 81.2708(7), γ = 80.6146(11)°, V = 3407.66(14) Å^3, Z = 4, $\rho_{calcd.}$ = 1.767 g·cm^{-3}, 43713 measured reflections, 12061 unique reflections (R_{int} = 0.0734), 8080 observed reflections [$I > 2\sigma(I)$], 775 refined parameters, no restraints; R (obsd. refl.): $R1$ = 0.0461, $wR2$ = 0.1121; R (all data): $R1$ = 0.0776, $wR2$ = 0.1286; S = 1.085; residual electron density between −1.08 and 1.17 e·Å^{-3}. Intensities were measured with a Nonius KappaCCD diffractometer with rotating anode (Mo-K_α, λ = 0.71073 Å) at a temperature of 150 K. An absorption correction based on multiple measured reflections was applied (μ = 4.920 mm^{-1}, 0.59−0.86 transmission). The structure was solved with direct methods with the program SHELXS-97,[35] and refined with the program SHELXL-97[34] against F^2 of all reflections up to a resolution of $(\sin/\lambda)_{max.}$ = 0.60 Å^{-1}. Non-hydrogen atoms were refined freely with anisotropic displacement parameters. Hydrogen atoms were refined as rigid groups. Three of the thiophene rings were rotationally disordered and refined with occupancies of 0.85:0.15, 0.72:0.28, and 0.55:0.45, respectively. The crystal structure contains large voids (150.9 Å^3/unit cell) filled with disordered solvent molecules. Their contribution to the structure factors was secured by back-Fourier transformation (program

Reactions of the Aluminum(I) Monomer LAl [L = HC{(CMe)(NAr)}$_2$; Ar = 2,6-*i*Pr$_2$C$_6$H$_3$] with Imidazol-2-ylidene and Diphenyldiazomethane. A Hydrogen Transfer from the L Ligand to the Central Aluminum Atom and Formation of the Diiminylaluminum Compound LAl(N=CPh$_2$)$_2$

Hongping Zhu,[a] Jianfang Chai,[a] Andreas Stasch,[a] Herbert W. Roesky,*[a] Torsten Blunck,[a] Denis Vidovic,[a] Jörg Magull,[a] Hans-Georg Schmidt,[a] and Mathias Noltemeyer[a]

Dedicated to Professor Axel Zeeck on the occasion of his 65th birthday

Keywords: Aluminum / Carbenes / Diazo compounds / Hydrogen transfer / N ligands

The solid-state reaction of LAl and imidazol-2-ylidene at elevated temperature (120 °C) yielded the aluminum monohydride *N*-heterocyclic carbene adduct [{HC[C(CH$_2$)NAr](CMeNAr)}AlH-{CN(R)C$_2$Me$_2$N(R)}] [R = *i*Pr (**1**), Me (**2**)]. Compounds **1** and **2** have been characterized by spectroscopic (IR, and ^{1}H and ^{13}C NMR), mass spectrometric, and elemental analyses, and **1** was further characterized by X-ray structural analysis. These experimental data indicate that the Al–H bond is formed by hydrogen migration from one of the methyl groups of the β-diketiminato ligand backbone. The reaction of LAl with two equivalents of diphenyldiazomethane afforded the diiminylaluminum compound LAl(N=CPh$_2$)$_2$ (**3**), while an excess of diphenyldiazomethane resulted in the formation of Ph$_2$C=N–N=CPh$_2$. This suggests that Ph$_2$C=N–N=CPh$_2$ is initially generated and then reacts further by oxidative addition to yield **3**. The X-ray structural analysis reveals that compound **3** contains the shortest Al–N$_{iminyl}$ bond among those with a four-coordinate aluminum center.

Introduction

Monovalent group-13 species are of considerable interest not only for their syntheses, structures, and theoretical investigations,[1] but also for their reactivity.[2] In the last decade, a variety of new reactions has been intensively explored for generating tetrameric aluminum(I) compounds.[3] The compound (Cp*Al)$_4$ has been reported to have a remarkable tendency to dissociate in solution and give a monomeric fragment in the gas phase.[4] Reactions involving such species have also been investigated to some extent and a number of novel compounds have been isolated and structurally characterized.[5] Recently, we have prepared the first monomeric aluminum(I) complex LAl [L = HC{(CMe)(NAr)}$_2$, Ar = 2,6-*i*Pr$_2$C$_6$H$_3$], which is stable at room temperature.[6] Ab initio calculations show that this monomer possesses a nonbonded electron pair at the central two-coordinate Al atom and is isoelectronic with a singlet carbene. Subsequent reaction of LAl with organic azides at low temperature or with P$_4$ at room temperature indicates its reactivity, leading to the formation of a five-membered AlN$_4$ heterocycle [LAl{(NSiMe$_3$)$_2$N$_2$}], a monomeric aluminum imide [LAl(*N*-2,6-trip$_2$C$_6$H$_3$)] (trip = 2,4,6-*i*Pr$_3$C$_6$H$_2$), and a sandwich compound [(LAl)$_2$P$_4$] containing a P$_4^{4-}$ unit.[7] These results are markedly different from those in which (Cp*Al)$_4$ is used in related reactions. Obviously, the steric and electronic stabilization of the bulky β-diketiminato ligand enables its monomeric nature and therefore its unique chemical behavior, and allows further investigation of its reactivity.

Imidazol-2-ylidene is a stable neutral *N*-heterocyclic carbene which has been prepared in recent years.[8] Diphenyldiazomethane can be used as an effective precursor for the generation of transient :CPh$_2$.[9] The reaction of imidazol-2-ylidene with monovalent group-13 compounds has only been reported for InBr; a disproportionation reaction is observed.[10] More recently, a handful of reactions involving treatment of imidazol-2-ylidene with trivalent group-13 species have been investigated; the *N*-heterocyclic carbene functions as a Lewis base.[11] The corresponding reactions of diphenyldiazomethane with monovalent group-13 species have not been described so far. We now report on the reaction of LAl with imdazol-2-ylidene and diphenyldiazome-

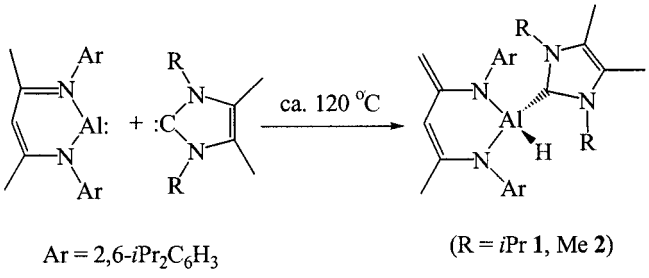
thane. The formation of the aluminum monohydride *N*-heterocyclic carbene adduct of composition [{HC[C(CH_2)NAr](CMeNAr)}AlH{CN(R)C_2Me_2N(R)}] [R = *i*Pr (**1**), Me (**2**)] indicates a hydrogen transfer from the L ligand to the aluminum center. The formation of a diiminylaluminum compound [LAl(N=CPh_2)$_2$] (**3**) might proceed through the initial generation of Ph_2C=N−N=CPh_2 followed by its oxidative addition to LAl.

Results and Discussion

Reaction of LAl with Imdazol-2-ylidenes

The initial reaction of LAl with 1,3-diisopropyl-4,5-dimethylimidazol-2-ylidene was conducted in toluene in the temperature range from 25 to 80 °C. However, due to the low solubility of the *N*-heterocyclic carbene, this reaction was not successful. Therefore both starting materials were mixed in the solid state at 120 °C for 5 h. A softening of 1,3-diisopropyl-4,5-dimethylimidazol-2-ylidene and a subsequent color change of LAl from red black to light yellow were observed. Extraction of the product with hot toluene and keeping the eluate at room temperature afforded crystalline [{HC[C(CH_2)NAr](CMeNAr)}AlH{CN(*i*Pr)C_2Me_2N(*i*Pr)}] (**1**, Scheme 1).



Scheme 1

Compound **1** is colorless and soluble in hot toluene and benzene while sparingly soluble in *n*-hexane and pentane. It was characterized by spectroscopic and elemental analyses. The mass spectrum exhibits the molecular ion of **1** {*m*/*z* (%) = 624 (5) [M^+], 609 (40) [M^+ − Me], 581 (100) [M^+ − *i*Pr]}. The ^{1}H and ^{13}C NMR spectra recorded in C_6D_6 are consistent with a pseudo-tetrahedral geometry and C_s symmetry about aluminum, giving rise to six isopropyl C*H* resonances and twelve diastereotopically split isopropyl CH_3 resonances due to the chiral environment of the Al center. The proton resonance of the β-CH_3 group on the L ligand backbone (δ = 1.72 ppm) integrates for three protons, while two other singlets are observed downfield (δ = 3.98 and 3.30 ppm) and integrate for one proton each. The former corresponds to the normal terminal CH_3−C group, and the latter is assigned to the terminal CH_2=C group which gives rise to two nonequivalent protons due to the restricted rotation about the C=C double bond. One broad proton resonance centered at δ = 4.80 ppm is characteristic for aluminum hydrides.[12] The IR spectrum exhibits a single band at 1809 cm^{-1} for Al−H absorption.[13]

Complex **1** was also characterized by X-ray structural analysis. The molecular structure of **1** is shown in Figure 1. Due to the poor quality of the crystal data the bond lengths and angles for **1** will not be discussed in detail. The quality of the crystals gave no improvement in the refinement of the structure even after recrystallization from several different solvents. Nonetheless, the structural solution of **1** offers important structural information which is in agreement with its spectral analysis. Compound **1** is monomeric and the central Al atom adopts a distorted tetrahedral geometry. The Al−N bond lengths [1.844(3) and 1.853(2) Å] appear to be shorter than other Al−$N_{\beta\text{-diketiminato}}$ bonds [1.875(4)−1.957(2) Å],[5,14] and are closer to those found in diamidoaluminum monohydride [{ArN(CH_2)$_3$NAr}-AlH(NMe_3)] [1.820(1) and 1.828(1) Å].[13c] In the ligand backbone, the terminal C−C bond lengths [C(4)−C(5): 1.507(4) Å; C(1)−C(2): 1.363(4) Å] are indicative of a single and double bond, respectively, as are the others within the backbone [C(2)−C(3): 1.458(4) Å; C(3)−C(4): 1.351(4) Å]. The adjacent N−C bond lengths [1.411(3) and 1.413(3) Å] are intermediate between N−C double and single bonds.

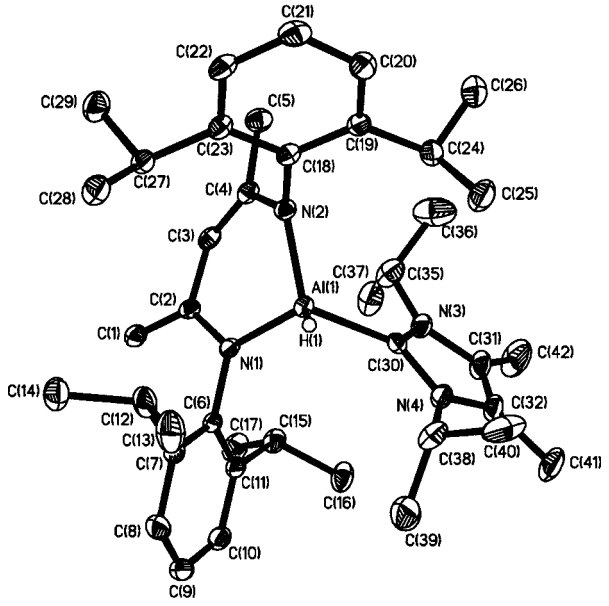


Figure 1. Molecular structure of **1**; H atoms are omitted for clarity except for the Al−H hydrogen atom

Obviously, the Al−H hydrogen comes from one of the terminal methyl groups of the L ligand, although whether this hydrogen transfer occurs via a proton, a hydrogen radical, or a hydride is not clear.

The reaction of LAl with less bulky *N*-substituted 1,3,4,5-tetramethylimidazol-2-ylidene was also performed in a similar manner (method A) to the preparation of **1** in order to investigate the effect of the steric bulk on the reaction product. As a result, [{HC[C(CH_2)NAr](CMeNAr)}AlH-{CN(Me)C_2Me_2N(Me)}] (**2**) was obtained in a relatively low yield. All the spectroscopic data (IR, EI mass, and ^{1}H and ^{13}C NMR) confirm a structure analogous to that of **1**.

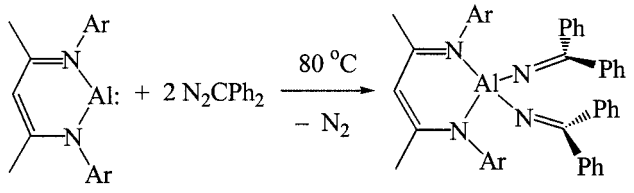
Reaction of LAl with N_2CPh_2

In the majority of organic and organometallic reactions diphenyldiazomethane is used as a precursor for the generation of transient :CPh_2 carbene.[9] Therefore, it was selected as another electron-rich species for the reaction with LAl. However, treatment of LAl with two equivalents of N_2CPh_2 under heating unexpectedly afforded [LAl(N=CPh_2)$_2$] (**3**; Scheme 2), the first example of a diiminylaluminum compound. When LAl was treated with an excess of N_2CPh_2 under the same conditions Ph_2C=N−N=CPh_2 was isolated.[15] Therefore, we assumed that the formation of **3** proceeds by the initial generation of Ph_2C=N−N=CPh_2 followed by its oxidative addition to LAl. In order to test this assumption a toluene solution of LAl was heated under reflux with one equivalent of Ph_2C=N−N=CPh_2 and complex **3** was formed, as expected, in an almost quantitative yield.[16]



Scheme 2

Complex **3** is an orange-yellow crystalline solid that is thermally stable, as indicated by its high melting point (344−346 °C). The most intense ion in the EI mass spectrum appears at m/z = 624 [M^+ − $NCPh_2$]; the peak at m/z = 805 (20%) is assigned to the molecular ion [M^+].

X-ray quality single crystals of **3** had formed from a 1:1 solvent mixture (*n*-hexane, diethyl ether) at 4 °C after two days. The structural analysis unambiguously ascertains the composition of **3**. The molecular structure is shown in Figure 2 and selected bond lengths and angles are listed in Table 1. The central Al atom is bound to two β-diketiminato nitrogen atoms and two iminyl nitrogen atoms. The AlN_4 core exhibits a distorted tetrahedral geometry with *trans*-N−Al−N angles ranging from 97.23(18)° to 117.6(2)°. The Al−$N_{\beta\text{-diketiminato}}$ bond lengths [1.899(4) and 1.901(4) Å] are in the expected range [1.875(4)−1.957(2) Å].[5,14] However, the Al−N_{iminyl} distances [1.774(4) and 1.785(4) Å] are the shortest yet found in four-coordinate Al−N complexes.[17] Comparable Al−N bond lengths have only been observed in three-coordinate [trip$_2$Al{N(H)dipp}] [1.784(3) Å],[18a] [MeAl(Ndipp)]$_3$ [1.782(4) Å][18b] and Al[N(SiMe$_3$)$_2$]$_3$ [1.78(2) Å].[18c] Surprisingly, the N−C distances of the iminyl group [1.249(6) and 1.269(6) Å] are shorter than that of a C=N bond.[19] The short Al−N_{iminyl} bond can be considered to be highly ionic, and the shortening of the N=C bond may be due to a charge delocalization over the phenyl groups. The Al(1)−N(4)−C(50) [163.4(5)°] and Al(1)−N(3)−C(30)

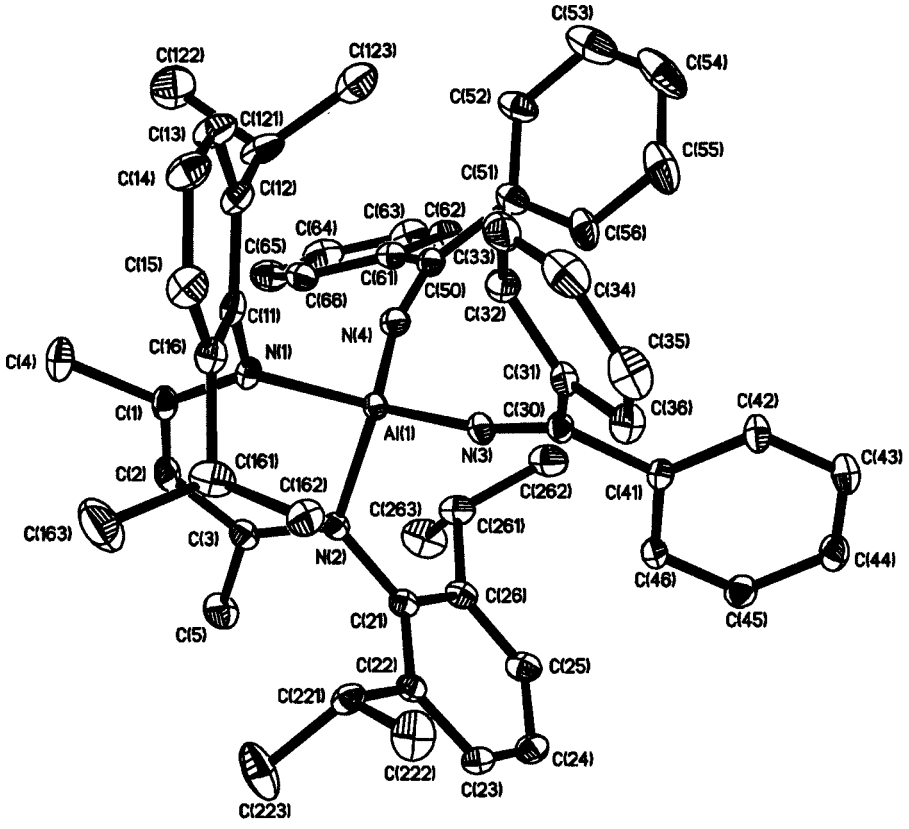


Figure 2. Molecular structure of **3**; H atoms are omitted for clarity

[169.4(4)°] angles show a less-bent arrangement of the Al−N=C group. The observation of two sets of resonances for the iminyl phenyl rings in the ^{1}H and ^{13}C NMR spectra suggests a restricted rotation of the phenyl rings around the N=C bond. This was confirmed by a high-temperature proton NMR spectral analysis (40, 60, and 80 °C), where two corresponding sets of resonances are always observed.

Table 1. Selected bond lengths (Å) and angles (deg) for compound **3**

Al(1)−N(1)	1.901(4)	Al(1)−N(2)	1.899(4)
Al(1)−N(3)	1.774(4)	Al(1)−N(4)	1.785(4)

Conclusions

In summary, we have reacted the aluminum(I) monomer LAl with imidazol-2-ylidene and diphenyldiazomethane and obtained the new compounds [{HC[C(CH$_2$)NAr]-(CMeNAr)}AlH{CN(R)C$_2$Me$_2$N(R)}] [R = *i*Pr (**1**), Me (**2**)] and [LAl(N=CPh$_2$)$_2$] (**3**). This further shows the unique reaction behavior of LAl, and exhibits its properties as a carbene analog. Inspired by these results, we are now exploring the reaction of LAl with metal carbonyl complexes to compare the electronic equivalence of LAl with CO.

Experimental Section

All manipulations were carried out under a purified nitrogen atmosphere using Schlenk techniques. The solvents were dried by standard methods. Chemicals were purchased from Aldrich or Fluka and used as received. LAl,[6] [CN(R)C$_2$Me$_2$N(R)] (R = Me, *i*Pr),[8] and N$_2$CPh$_2$ [9a] were prepared as described in the literature.

Elemental analyses were performed by the Analytisches Labor des Instituts für Anorganische Chemie der Universität Göttingen. ^{1}H (300.13 MHz), ^{13}C (125.76 MHz) and ^{27}Al NMR (65.17 MHz) spectra were recorded on a Bruker AM 200 or a Bruker AM 250 spectrometer and IR spectra on a Bio-Rad Digilab FTS-7 spectrometer. EI mass spectra were measured on a Finnigan MAT 8230 or a Varian MAT CH5 instrument. Melting points were measured in sealed glass tubes and are not corrected.

Synthesis of [{HC[C(CH$_2$)NAr](CMeNAr)}AlH{CN(*i*Pr)C$_2$Me$_2$-N(*i*Pr)}] (1). Method A: A suspension of LAlI$_2$ (2.08 g, 3.0 mmol) and finely divided potassium (0.25 g, 6.3 mmol) in toluene (50 mL) was stirred vigorously for 3 d at room temperature until all the potassium had disappeared. After filtration the dark-red filtrate was slowly dried in vacuo and some red microcrystals of LAl were observed to deposit on the walls of the flask. [CN(*i*Pr)C$_2$Me$_2$N-(*i*Pr)] (0.36 g, 2 mmol) was added to the resulting solid. The mixture was heated slowly to about 120 °C and kept for 5 h. After cooling to room temperature, the yellow product was extracted with hot toluene (30 mL) and the extract was kept at room temperature for 24 h to afford X-ray quality colorless block crystals, which were collected by filtration (0.42 g). The mother liquor was concentrated (ca. 5 mL) and kept at 4 °C for 24 h to give another crop of colorless crystals (0.25 g). Total yield of **1**: 0.67 g {47%, based on [CN(*i*Pr)C$_2$Me$_2$N(*i*Pr)]}. M.p. 298−300 °C (>250 °C decomp.). ^{1}H NMR (C$_6$D$_6$, 300 K): δ = 0.38, 0.50, 0.76, 0.82, 1.19, 1.32, 1.46, 1.50, 1.53, 1.55, 1.57, 1.59 [d, 12 × 3 H, CH*Me*$_2$ and N(CH*Me*$_2$)], 1.38, 1.62 (s, 2 × 3 H, C$_2$*Me*$_2$), 1.72 (s, 3 H, β-C*H*$_3$), 3.30, 3.98 (s, 2 × 1 H, β-C*H*$_2$), 3.28, 3.62, 4.18, 4.26 (sept, 4 × 1 H, *CH*Me$_2$), 4.80 (br., 1 H, Al-*H*), 5.60 (s, 1 H, γ-C*H*), 5.44, 5.62 [sept, 2 × 1 H, N(*CH*Me$_2$)], 7.10−7.38 (m, 6 H, *Ar*) ppm. ^{13}C NMR (C$_6$D$_6$, 300 K): δ = 9.9, 10.0 (C$_2$*Me*$_2$), 20.7, 21.1, 21.4, 22.0, 23.3, 23.7, 23.8, 24.4, 24.5, 24.7, 25.6, 25.7, 26.4, 27.1, 27.7, 28.4, 28.9 [N(CH*Me*$_2$), *CH*Me$_2$, CH*Me*$_2$ and β-*C*H$_3$], 50.9, 53.0 [N(*CH*Me$_2$)], 80.8 (β-*C*H$_2$), 106.6 (γ-*C*), 123.0, 124.5, 124.7, 124.9, 125.6, 126.6, 127.8, 128.5, 129.3, 143.4, 144.7, 145.6, 146.1, 147.2, 148.4, 149.0 (*Ar*, *C*N and *C*$_2$Me$_2$), 154.5 (Al-*C*) ppm. ^{27}Al NMR ([D$_8$]toluene, 300 K): no resonances were observed. IR (Nujol): ν_{Al-H} = 1809 cm^{-1} (m), $\nu_{C=C}$ = 1619 (m). MS (EI): *m*/*z* (%) = 624 (5) [M$^+$], 609 (40) [M$^+$ − Me], 581 (100) [M$^+$ − *i*Pr]. C$_{40}$H$_{61}$AlN$_4$ (624.94): calcd. C 76.87, H 9.84, N 8.97; found C 77.07, H 9.55, N 8.86.

Method B: A suspension of LAlI$_2$ (2.08 g, 3.0 mmol), [CN(*i*Pr)C$_2$Me$_2$N(*i*Pr)] (0.54 g, 3 mmol) and finely divided potassium (0.25 g, 6.3 mmol) in toluene (50 mL) was stirred vigorously for 3 d at room temperature until all the potassium had disappeared. After filtration the orange filtrate was concentrated (ca. 20 mL) and *n*-hexane (20 mL) was added. The solution was kept at 4 °C for one week to afford colorless block crystals (0.72 g). The mother liquor was further concentrated (ca. 5 mL) and kept at 4 °C for 2 d to give another crop of colorless crystals (0.32 g). Total yield of **1**·toluene: 1.04 g (48%). The IR, ^{1}H and ^{13}C NMR spectroscopic data are essentially the same as those of **1** except for one extra molecule of toluene.

Synthesis of [{HC[C(CH$_2$)NAr](CMeNAr)}AlH{CN(Me)C$_2$-Me$_2$N(Me)}] (2): Compound **2** was prepared in a similar manner (method A) as **1**. LAlI$_2$ (2.08 g, 3.0 mmol), finely divided potassium (0.25 g, 6.3 mmol) and [CN(Me)C$_2$Me$_2$N(Me)] (0.24 g, 2.0 mmol) were used. The extract (10 mL) was added to *n*-hexane (10 mL) and kept at −26 °C for 48 h to afford colorless crystals of **2** {yield: 0.42 g, 25%, based on [CN(Me)C$_2$Me$_2$N(Me)]}. M.p. 252−253 °C. ^{1}H NMR ([D$_8$]toluene, 300 K): δ = 1.45, 1.47 (s, 2 × 3 H, C$_2$*Me*$_2$), 0.29, 0.30, 1.16, 1.46, 1.58, 1.60, 1.61, 1.62 (d, 8 × 3 H, CH*Me*$_2$), 1.69 (s, 3 H, β-C*H*$_3$), 3.70, 3.75 (s, 2 × 3 H, N(*Me*)), 3.10, 3.85 (s, 2 × 1 H, β-C*H*$_2$), 3.21, 3.25, 4.15, 4.21 (sept, 4 × 1 H, C*H*Me$_2$), 4.80 (br., 1 H, Al-*H*), 5.39 (s, 1 H, γ-C*H*), 7.04−7.38 (m, 6 H, *Ar*) ppm. ^{13}C NMR ([D$_8$]toluene, 300 K): δ = 7.9, 8.0 (C$_2$*Me*$_2$), 23.6, 24.0, 24.2, 24.3, 24.8, 24.9, 25.4, 25.8, 26.0, 26.4, 26.5, 27.1, 27.8, 28.7, 29.0 [N(*Me*), *C*HMe$_2$, CH*Me*$_2$ and β-*C*H$_3$), 80.1 (β-*C*H$_2$), 102.3 (γ-*C*), 122.9, 123.7, 124.2, 124.6, 124.9, 125.1, 125.3, 127.7, 128.0, 143.2, 143.8, 145.4, 146.3, 147.4, 148.2, 149.0 (*Ar*, *C*N and *C*$_2$Me$_2$), 155.2 (Al-*C*) ppm. MS (EI): *m*/*z* (%) = 568 (15) [M$^+$], 553 (100) [M$^+$ − Me]. IR (Nujol): ν_{Al-H} = 1810 cm^{-1} (m), $\nu_{C=C}$ = 1616 (m). C$_{36}$H$_{53}$AlN$_4$ (568.83): calcd. C 76.01, H 9.29, N 9.85; found C 76.50, H 9.60, N 9.40.

Synthesis of LAl(NCPh$_2$)$_2$ (3): A solution of N$_2$CPh$_2$ (0.37 g, 1.90 mmol) in toluene (15 mL) was added to a solution of LAl (0.42 g, 0.94 mmol) in toluene (25 mL) at room temperature. The mixture was slowly heated to 60 °C and kept for 12 h; a yellow solution developed. All volatiles were then removed in vacuo and the residue was washed with *n*-hexane (5 mL) to afford an orange-yellow crystalline solid of **3** (0.36 g, 48%). M.p. 344−346 °C. ^{1}H NMR (C$_6$D$_6$, 300 K): δ = 0.82, 1.02 (d, 8 × 3 H, CH*Me*$_2$), 1.64 (s, 2 × 3 H, β-C*H*$_3$), 3.21 (sept, 4 × 1 H, C*H*Me$_2$), 5.28 (s, 1 H, γ-C*H*), 6.92−7.00 (m, 2 × 5 H, *Ph*), 7.00−7.08 (m, 2 × 5 H, *Ph*),

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

7.18−7.32 (m, 6 H, *Ar*) ppm. ^{13}C NMR (C_6D_6, 300 K): δ = 23.8, 24.4, 24.9, 28.5 (*C*HMe$_2$, CH*Me*$_2$, β-*C*H$_3$), 98.8 (γ-*C*), 124.5, 126.9, 127.6, 127.6, 127.9, 128.1, 128.3, 128.3, 129.4, 142.4, 143.1, 144.7 (*Ar*, *Ph*), 166.9 (N*C*Ph$_2$), 171.0 (*C*N) ppm. MS (EI): *m*/*z* (%) = 805 (20) [M$^+$], 790 (30) [M$^+$ − Me], 624 (100) [M$^+$ − NCPh$_2$]. IR (Nujol): $\nu_{C=C}$ = 1667 cm^{-1} (w), $\nu_{C=N}$ = 1624, 1554 (w). $C_{55}H_{61}AlN_4$ (805.10): calcd. C 82.05, H 7.64, N 6.96; found C 82.11, H 7.74, N 7.05. X-ray quality crystals were obtained by recrystallization from a 1:1 *n*-hexane/diethyl ether solution at 4 °C for one week.

X-ray Structure Determination and Refinement: The crystallographic data for compound **1** were collected on a Stoe IPDS II-array detector system and for **3** on a Stoe−Siemens−Huber four-circle-diffractometer coupled to a Siemens CCD area-detector. In both cases graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used. Both structures were solved by direct methods (SHELXS-96) and refined against F^2 using SHELXL-97.[20,21] All non-hydrogen atoms were located by difference Fourier synthesis and refined anisotropically, and hydrogen atoms were included using the riding model with U_{iso} tied to the U_{iso} of the parent atoms, except for the Al−H hydrogen atom, which was located by difference Fourier synthesis and refined isotropically. A summary of cell parameters, data collection, and structure solution and refinement is given in Table 2.

CCDC-231677 (for **1**) and -231678 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

[15] The azine $Ph_2C{=}N{-}N{=}CPh_2$ was obtained as colorless crystals with a melting point of 174 °C. Its spectroscopic data (EI mass, IR, ^1H and ^{13}C NMR) and elemental analysis confirmed the composition. It is well-known that many salts and complexes of Cu^I and Cu^{II} are used as catalysts for the decomposition of diphenyldiazomethane. The reaction of LAl and diphenyldiazomethane to give $Ph_2C{=}N{-}N{=}CPh_2$ may indicate that the LAl plays a catalytic role. [15a] W. Kirmse, *Carbene Chemistry* 2nd edition, Academic Press, New York, **1971**, 85−128, and references cited therein. [15b] D. Bethell, K. L. Handoo, S. A. Fairhurst, L. H. Sutcliffe, *J. Chem. Soc., Chem. Commun.* **1977**, 326−328.
[16] A mixture of equivalent amounts of LAl and $Ph_2C{=}N{-}N{=}CPh_2$ in toluene (20 mL) was allowed slowly to heat to reflux and kept for 3 h. After cooling to room temperature, the solution was dried in vacuo and the residue was washed with *n*-hexane (5 mL) to give an orange-yellow crystalline solid in almost quantitative (yield, > 90%). The melting point and the spectroscopic data (EI mass and IR) are essentially the same as those of **3**.

Adducts of Aluminum and Gallium Trichloride with a *N*-Heterocyclic Carbene and an Adduct of Aluminum Trichloride with a Thione

Andreas Stasch,[a] Sanjay Singh,[a] Herbert W. Roesky,*[a] Mathias Noltemeyer,[a] and Hans-Georg Schmidt[a]

Keywords: Adducts / Aluminum / Carbenes / Gallium / Lewis acids

The reactions of $AlCl_3$ and $GaCl_3$ with 1,3,4,5-tetramethylimidazole-2-ylidene in toluene at room temperature affords the 1:1 adducts **5** and **6**, respectively. The use of a bulky *N*-heterocyclic carbene (NHC) in toluene/THF and $AlCl_3$ results in the formation of an imidazolium salt **7** with the tetrachloroaluminate anion. A 1:1 adduct **8** of 1,3,4,5-tetramethylimidazole-2(3*H*)-thione with $AlCl_3$ is obtained in toluene. The crystal structures of **5**·0.5C_7H_8, **7**·THF and **8** were determined.

Introduction

The use of *N*-heterocyclic carbenes (NHC)[1,2] as good σ-donor molecules to stabilize trivalent group 13 compounds was established with the isolation of the first alane adduct of an imidazol-2-ylidene **1**.[3] The stability of these complexes is demonstrated by the melting point of **1** (246−247 °C). Compound **1** melts without decomposition, whereas AlH_3·NMe_3 decomposes above 100 °C.[4] The properties of the corresponding gallium and indium compounds allow their isolation and characterization.[5,6] However, adducts of a NHC with aluminum or gallium halides have not been reported. The reaction of a bidentate NHC ligand with $AlCl_3$ in diethyl ether resulted in an imidazolium salt in moderate yield and in by-products, although moisture was excluded from the reaction mixture.[7] Only adducts of a phosphanylsilylcarbene with MCl_3 (M = Al **2**, Ga **3**, In **4**) were reported and the X-ray single-crystal structure of **3** was determined.[8] From reactions of a NHC with InX_3 (X = Cl, Br) under different conditions, carbene adducts with a composition of 1:1 and 1:2 ratios as well as imidazolium salts of carbene-stabilized indates were obtained and structurally characterized.[9]

Results and Discussion

$AlCl_3$ was treated with one equivalent of 1,3,4,5-tetramethylimidazole-2-ylidene[10] in toluene at room temperature; $AlCl_3$ dissolved after 30 minutes. The mixture was filtered and concentrated. Colorless plates of **5** were obtained in 56% yield at low temperature. The ^{1}H NMR spectrum of **5** shows two singlets (δ = 1.15 and δ = 3.23 ppm) for the protons of the methyl groups of the carbene ligand. They are shifted upfield relative to the free carbene 1,3,4,5-tetramethylimidazole-2-ylidene (δ = 1.59 and δ = 3.35 ppm). No resonances for an imidazolium salt were detected. A weak and broad ^{13}C NMR resonance (δ = 154 ppm) can be assigned to the carbene carbon atom. The ^{27}Al NMR spectrum shows a resonance at δ = 103 ppm, which is typical for four-coordinate aluminum and in the region of the resonances for hydride derivatives. EI mass spectrometry presents a molecular ion peak at *m*/*z* = 256 in the correct isotopic pattern and free 1,3,4,5-tetramethylimidazole-2-ylidene as the base peak. Compound **5** crystallizes with half a molecule of toluene in the triclinic space group $P\bar{1}$. It exhibits the expected assembly (see Figure 1), and selected bond lengths and angles are given in Table 1. The Al−C distance in **5** is 2.009(5) Å, which is shorter than the corresponding bond length in the adduct of 1,3,4,5-tetra-

Al1−C1	2.009(5)	Al1−Cl1	2.134(4)
Al1−Cl2	2.121(5)	Al1−Cl3	2.131(3)
N1−C1	1.352(5)	N1−C2	1.392(5)
N2−C1	1.353(5)	N2−C3	1.387(5)
C2−C3	1.343(6)		
C1−Al1−Cl1	111.1(2)	Cl2−Al1−Cl1	110.43(17)
N2−C1−N1	104.8(3)	C3−C2−N1	106.9(4)

The gallium analogue of **5** could be prepared and crystallized by a comparable method in 62% yield. Due to the dimeric nature of $GaCl_3$ and its good solubility in hydrocarbon solvents, in contrast to polymeric $AlCl_3$ in the solid state, $GaCl_3$ was cooled with liquid nitrogen while a solution of 1,3,4,5-tetramethylimidazole-2-ylidene in toluene was added, and the mixture was slowly warmed to room temperature. No single crystals were obtained for **6** but the ^{1}H NMR spectrum shows a ratio of ca.1:0.70 ratio of **6** and toluene. The $GaCl_3$ adduct **6** is less soluble than **5**. The resonances for the methyl groups (δ = 1.05 and 3.19 ppm) are in the region of the resonances for **5**. A resonance for the carbene carbon atom was not observed in the ^{13}C NMR spectrum, as seen before for comparable compounds.[7,9] The EI mass spectrum shows the molecular ion peak M^+ at *m*/*z* = 300 with the expected isotopic pattern as well as $M^+ - Cl$ at *m*/*z* = 265. A gallium triiodide adduct of a NHC was very recently prepared in our group from the corresponding hydride and was structurally characterized.[12] The computed M−C distance for the adduct of MCl_3 (M = Al, Ga) with diaminocarbene are 2.060 Å for Al and 2.079 Å for Ga.[13] These bond lengths are nearly identical. We also found a very similar bond length for the carbene adduct of $Ga(C{\equiv}CtBu)_3$ with 1,3,4,5-tetramethylimidazole-2-ylidene [2.057(3) Å][14] and the corresponding aluminum compound [2.051(2) Å, see above]. The Ga−C bond length in **3** is 1.978(10) Å.

The reaction of a bulky imidazolylidene with $AlCl_3$ in THF/toluene afforded the imidazolium salt **7**·THF in moderate yield (Figure 2). The very poorly soluble compound **7**·THF was characterized by an X-ray single-crystal structure determination. Selected bond lengths and angles are summarized in Table 2. Only the cationic species for the corresponding imidazolium salt could be detected in the FAB mass spectrum at (*m*/*z* = 389), and no peak for the tetrachloroaluminate anion was observed. However, the EI-mass spectrum of the salt shows the ions for the corresponding $AlCl_3$ carbene adduct with one chlorine less (*m*/*z* = 484) and with only one chlorine (*m*/*z* = 451) in the expected isotopic pattern. It is known that $AlCl_3$ dissociates in THF[15,16] and other donor solvents[17,18] to form donor-stabilized salts of the type $[AlCl_2(Do)_x][AlCl_4]$. Moreover, we assume that the hydrogen atoms in the backbone (here on C2 and C3) of the imidazolylidene are responsible for the protonation and the formation of the imidazolium salt.

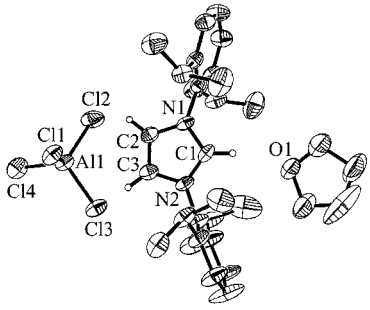

Figure 2. Crystal structure of **7**·THF; only hydrogen atoms on the imidazolium ring are shown

Table 2. Selected bond lengths (Å) and angles (°) of **7**·THF

Al1−Cl2	2.129(2)	Al1−Cl3	2.140(2)
C1−N1	1.334(6)	C1−N2	1.322(7)

Cl1−Al1−Cl2	109.34(10)	N2−C1−N1	108.6(4)

In a comparable route, 1,3,4,5-tetramethylimidazole-2(3*H*)-thione, which is a common starting material for the preparation of 1,3,4,5-tetramethylimidazole-2-ylidene by reduction with potassium in THF,[10] reacts with $AlCl_3$ in toluene to afford adduct **8** (Figure 3). The latter compound is less soluble than **5**. The ^{1}H NMR resonances of the ligand exhibit singlets at δ = 1.27 and δ = 3.12 ppm. Only the free thione was detected by EI mass spectrometry. Compound **8** crystallizes in the orthorhombic space group *Pbca*. Selected bond lengths and angles are given in Table 3. The Al−S bond length is 2.2661(13) Å. The C=S bond length

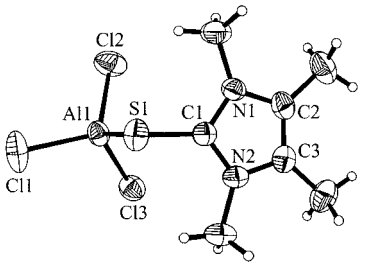

Figure 3. Crystal structure of **8**

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the free thione [1.690(2) Å][19] is elongated upon coordination with $AlCl_3$ in **8** [1.739(3) Å] by nearly 0.05 Å. The $AlCl_3$ moiety is coordinated to one lone pair of the sulfur atom to give a C1−S1−Al1 angle of 98.79(9)°. The adduct **8** is a model compound for the activation of a carbonyl function by a Lewis acid.

Table 3. Selected bond lengths (Å) and angles (°) of **8**

Al1−Cl1	2.1242(12)	Al1−Cl2	2.1300(13)
Al1−Cl3	2.1318(12)	Al1−S1	2.2661(13)
S1−C1	1.739(3)	C1−N1	1.347(4)
C1−N2	1.338(4)	N1−C2	1.399(4)
N2−C3	1.391(4)	C2−C3	1.351(4)
Cl1−Al1−Cl2	113.48(6)	Cl3−Al1−S1	110.09(5)
C1−S1−Al1	98.79(9)	N1−C1−S1	125.7(2)
C3−C2−N1	106.9(2)	N2−C1−N1	107.4(2)

The N1−C1−N2 angle in the imidazole ring of **5** [104.8(3)°] lies between the corresponding angles of the free carbene 1,3,4,5-tetramethylimidazole-2-ylidene [101.3(2)° from X-ray, and 101.9(1)° and 102.0(1)° from neutron diffraction experiments on the perdeuterated compound][20] and that of an imidazolium salt [e.g. 108.6(4)° in **7**·THF]. These findings are in agreement with those of previously reported compounds.[1,2] For comparison, the N1−C1−N2 angle in **8** is 107.4(2)°.

In summary, we have prepared the first NHC adducts of an aluminum and a gallium trihalide, and report the first X-ray crystal structure of an aluminum halide carbene adduct. Moreover, an imidazolium tetrachloroaluminate and a thione adduct of $AlCl_3$ were also synthesized and structurally characterized.

Experimental Section

All manipulations were performed under a dry and oxygen-free atmosphere (N_2 or Ar) using Schlenk line and glove box techniques. Melting points are not corrected. X-ray single-crystal structure analyses were performed on a Stoe−Siemens four circle (**5**·0.5C_7H_8 and **8**) or a Stoe IPDS2 (**7**·THF) diffractometer with Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods and refined with full-matrix least-squares on F^2 using SHELX-97.[21] Crystallographic data are summarized in Table 4. CCDC-234360 (**5**·0.5C_7H_8), -234361 (**7**·THF) and -234362 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation of 5: Toluene (30 mL) was added at room temperature to a mixture of $AlCl_3$ (0.64 g, 4.80 mmol, 1.12 equiv.) and 1,3,4,5-tetramethylimidazole-2-ylidene[10] (0.55 g, 4.27 mmol, 1.0 equiv.). The mixture was stirred for 30 min, and the $AlCl_3$ dissolved. The mixture was filtered and concentrated in vacuo to 15 mL. A brown

oily by-product was also formed and could be separated off during filtration. The solution was stored for two weeks at −25 °C to give colorless crystals of **5**. Colorless plates of **5**·0.5C_7H_8 suitable for X-ray single-crystal structure analysis were obtained from a concentrated solution in toluene at 4 °C. The crystals were dried in vacuo. Yield 0.62 g (2.41 mmol, 56%). M.p. 130 °C. ^{1}H NMR (500 MHz, C_6D_6): δ = 1.15 (s, 6 H, NCH_3), 3.23 (s, 6 H, CCH_3) ppm. ^{13}C NMR (126 MHz, C_6D_6): δ = 7.9 [C(4,5)*C*H$_3$], 34.0 (N*C*H$_3$), 125.6 [*C*(4,5)], 154 (very broad, carbene-*C*) ppm. ^{27}Al NMR (78.2 MHz, C_6D_6): δ = 103 ppm. MS (EI): *m*/*z* = 256 [M^+, 3], 221 (M^+ − Cl, 13), 124 ($C_7H_{12}N_2$, 100). IR (Nujol, KBr plates): $\tilde{\nu}$ = 1643, 1580, 1207, 1100, 1031, 487 cm^{-1}. $C_7H_{12}AlCl_3N_2$·$C_{3.5}H_4$ (257.52): calcd. C 32.65, H 4.70, N 10.88; found C 33.11, H 4.65, N 10.67.

Preparation of 6: A solution of 1,3,4,5-tetramethylimidazole-2-ylidene (0.40 g, 3.23 mmol, 1.0 equiv.) in toluene (18 mL) was slowly added to cooled (−196 °C) $GaCl_3$ (0.57 g, 3.24 mmol, ca. 1.0 equiv.). The mixture was slowly warmed to room temperature while stirring, and stirring was continued for an additional 30 min at this temperature. The mixture was concentrated to about 12 mL, filtered, and stored at −25 °C to afford a colorless crystalline material of **6**·0.70C_7H_8. Small amounts of a brown oily by-product formed during the reaction could be separated during filtration. Yield 0.73 g (2.00 mmol, 62%) of **6**·0.70C_7H_8. M.p. approximately 110 °C. ^{1}H NMR (300 MHz, C_6D_6) [toluene resonances are not given]: δ = 1.05 (s, 6 H, NCH_3), 3.19 (s, 6 H, CCH_3) ppm. ^{13}C NMR (126 MHz, C_6D_6): δ = 7.6 [C(4,5)*C*H$_3$], 33.8 (N*C*H$_3$), 125.6 [*C*(4,5)] ppm. MS (EI): *m*/*z* = 300 [M^+, 1], 265 (M^+ − Cl, 25), 124 ($C_7H_{12}N_2$, 100). IR (Nujol, KBr plates): $\tilde{\nu}$ = 1645, 1261, 1093, 1031, 848, 800, 570, 370 cm^{-1}. $C_7H_{12}Cl_3GaN_2$·$C_{4.9}H_{5.6}$ (364.77): calcd. C 39.18, H 4.68, N 7.68; found C 38.98, H 4.65, N 7.50.

Preparation of 7: Toluene (50 mL) and THF (50 mL) were added to a mixture of $AlCl_3$ (0.56 g, 4.20 mmol, 1.1 equiv.) and 1,3-bis(2,6-diisopropylphenyl)imidazole-2-ylidene (1.47 g, 3.80 mmol, 1.0 equiv.). The mixture was stirred for 1 h and subsequently filtered. Yellow crystals of **7**·THF were obtained at 2 °C. Yield 0.98 g (1.56 mmol, 41%). M.p. 260 °C: ^{1}H NMR (300 MHz, CD_3OD) [THF resonances are not given]: δ = 1.22 [d, *J* = 6.9 Hz, 12 H, CH(CH_3)$_2$], 1.34 [d, *J* = 6.9 Hz, 12 H, CH(CH_3)$_2$], 2.45 [sept, *J* = 6.9 Hz, 4 H, C*H*(CH$_3$)$_2$], 7.50 (d, *J* = 7.6 Hz, 4 H, *m*-ArH), 7.67 (t, *J* = 7.6 Hz, 2 H, *p*-ArH), 8.27 (d, *J* = 2.5 Hz, 2 H, C*H*), 9.97 (t, *J* = 2.5 Hz, 1 H, N_2CH) ppm. ^{13}C NMR (126 MHz, CD_3OD): δ = 23.9, 24.7, 30.4, 126.0, 127.6, 131.5, 133.4, 141.1, 146.5 ppm. MS (EI): *m*/*z* = 484 [$AlCl_2C_3N_2H(Dipp)_2^+$, 15], 451 [$AlClC_3N_2H(Dipp)_2^+$, 2], 389 [$C_3N_2H_3(Dipp)_2^+$, 100]. MS (FAB) cations: *m*/*z* = 389 [$C_3N_2H_3(Dipp)_2^+$, 100]. IR (Nujol, KBr plates): $\tilde{\nu}$ = 1643, 1600, 1540, 1331, 1206, 1062, 953, 804, 756, 683, 616, 491 cm^{-1}. $C_{27}H_{37}AlCl_4N_2$·C_4H_8O (630.49): calcd. C 59.05, H 7.19, N 4.44; found C 58.55, H 7.03, N 4.68.

Preparation of 8: Toluene (25 mL) was added to a mixture of $AlCl_3$ (0.50 g, 3.75 mmol, 1.0 equiv.) and 1,3,4,5-tetramethylimidazole-2(3*H*)-thione[10] (0.585 g, 3.75 mmol, 1.0 equiv.), stirred for 15 h at room temperature, 30 min at 50 °C, and finally filtered at this temperature. Storing the solution at 4 °C afforded crystals of **8**. Yield 0.63 g (2.18 mmol, 58%). M.p. approximately 165 °C (decomposed; in general decomposition at temperatures above about 100 °C). ^{1}H NMR (300 MHz, C_6D_6): δ = 1.27 (s, 6 H, NCH_3), 3.12 (s, 6 H, CCH_3) ppm. ^{13}C NMR (126 MHz, C_6D_6): δ = 8.4, 31.5, 120.1, 161.6 ppm. MS (EI): *m*/*z* = 156 [{MeCCN(Me)}$_2$C=S, 100]. IR (Nujol, KBr plates): $\tilde{\nu}$ = 1639, 1262, 1100, 1020, 801, 612 cm^{-1}. $C_7H_{12}AlCl_3N_2S$ (289.59): calcd. C 29.03, H 4.18, N 9.67; found C 28.70, H 4.22, N 9.44.

Methyl Substitution of Aluminum−Hydride Bonds in a Carbaalane and an Aluminum Imide

Andreas Stasch,[a] S. Shravan Kumar,[a] Vojtech Jancik,[a] Herbert W. Roesky,*[a] Jörg Magull,[a] and Mathias Noltemeyer[a]

Keywords: Aluminum / Cluster Compounds / Hydrides

The methylated compounds $[(AlMe)_6(AlNMe_3)_2(CCH_2Ph)_6]$ (**4**), $[(AlMe)_6(AlNMe_3)_2(CCH_2CH_2SiMe_3)_6]$ (**5**) and $[(AlMe)_6(NCH_2C_4H_3S)_6]$ (**6**) were synthesized in good yields from the corresponding hydride derivatives by treatment with $AlMe_3$ in toluene. The X-ray single crystal structures of **4**·xC_7H_8, **4**·4C_7H_8 and **6** were determined. In **4**·xC_7H_8 the solvent molecules are arranged in infinite channels along the *c* axis.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

The chemistry of carbaalanes and aluminum imide (or iminoalane) cage compounds is growing rapidly. After the synthesis of the cluster cores their derivatisation is an attractive goal for synthetic chemists. The aluminum−hydride bonds in the hydroalumination products can be converted into other functionalities. Recently, we have used various reagents to substitute the hydrides in the carbaalane $[(AlH)_6(AlNMe_3)_2(CCH_2R)_6]$ (R = Ph **1**, CH_2SiMe_3 **2**) and in the aluminum imide $[(AlH)_6(NCH_2C_4H_3S)_6]$ (**3**) to yield halogen and alkynyl derivatives.[1−6] Herein we report further attempts to substitute the hydrides by methyl groups.

Initial investigations were carried out with protic reagents such as alcohols and secondary amines. The reaction of **1** with six equivalents of isopropanol results in the formation of impure compounds and decomposition of the cluster. The reaction of **1** with six equivalents of R_2NH (R = Et, $SiMe_3$) in toluene gave no gas evolution either at room temperature or upon heating the mixture to its boiling point; crystals of **1** were recovered from the reaction mixture. Similar reactions were undertaken with **3**. Again, reactions with alcohols led to decomposition of the cage and amines did not properly react with the hydrides. A partial substitution of **1**, however, was achieved with a protic reagent: ethynylferrocene reacted at elevated temperatures leading to the formation of terminal alkynyl-substituted products.[3]

Bis(trimethylsilyl) ether $[(Me_3Si)_2O]$ reacts with neat iBu_2AlH under reflux conditions to form $(Me_3SiOAliBu_2)_2$, while $AlH_3{\cdot}NMe_3$ does not react under these conditions.[7] However, we found no reaction or significant solubility of **1** in neat boiling $(Me_3Si)_2O$ (b.p. 101 °C). $AlH_3{\cdot}NMe_3$ forms the soluble aluminum sulfide compounds $[(Me_3NAl)_4S_6]$ and $[(Me_3NAl)_2(Me_3NAlH)_2S_5]$ upon reaction with $(Me_3Si)_2S$ in hot toluene.[8] Treatment of **1** with an excess (ca. 18 equiv.) of $(Me_3Si)_2S$ in boiling toluene for one day, and subsequent workup, afforded crystals of the starting material in moderate yield. Moreover, $(Me_3Si)_2$ did not react with **1** under similar conditions and crystals of **1** were again recovered. No reaction of $(Me_3Si)_2$ with iBu_2AlH has been reported.[9]

When a suspension of **1** in toluene is treated with an excess of $AlMe_3$ at room temperature the solubility improves, and after several hours of stirring the precipitate that forms is converted into fine, colorless, needle- or rod-shaped crystals. Filtering off these crystals and storing the solution at 4 °C afforded additional crystals of the same shape. The X-ray single crystal structure analysis showed these to be the expected compound $[(AlMe)_6(AlNMe_3)_2(CCH_2Ph)_6]$ (**4**) with toluene. Crystals of $[(AlMe)_6(AlNMe_3)_2(CCH_2Ph)_6]{\cdot}4C_7H_8$ (**4**) 4C_7H_8) were obtained at −25 °C from the supernatant solution. The reaction of **2** with $AlMe_3$ for four hours afforded $[(AlMe)_6(AlNMe_3)_2(CCH_2CH_2SiMe_3)_6]$ (**5**) in good purity after removal of all volatiles at 50 °C in vacuo (Scheme 1).

In the same manner, the hexameric aluminum imide $[(AlH)_6(NCH_2C_4H_3S)_6]$ **3** was treated with $AlMe_3$ in toluene at room temperature to yield the methylated species $[(AlMe)_6(NCH_2C_4H_3S)_6]$ (**6**). The reaction of **3** with diethylzinc in THF/toluene at room temperature gave $[(AlEt)_6(NCH_2C_4H_3S)_6]$ (**7**), where the hydrides have been substituted by ethyl groups; no coordination of diethylzinc to the thiophenyl groups was found. The substitution of the hydridic hydrogens of hexameric aluminum imides, prepared from aluminum hydrides and primary amines, was first reported in the 1970s. Partially and fully alkylated

species were isolated from reactions with AlR_3 (R = Me, Et) giving rise to **6** and **7**, which were not structurally characterized.[10] Only substitution and no degradation of the cage or cluster structures is observed upon treatment with AlR_3 (R = Me, Et) in these reactions. Methyl-substituted aluminum imides prepared from primary amines and $AlMe_3$ at elevated temperatures often show different degrees of oligomerization depending on the size of the organic groups.[11] A prominent example is the planar alumazene.[12]

The first crystals of compound **4** with toluene crystallize in the trigonal space group $R\bar{3}$. The solvent molecules (toluene) are disordered and are located in channels along the *c* axis that are only partially occupied and could not be successfully refined. The packing of **4** is shown in Figure 1. The width of the channels is about 12.2 Å (calculated from the centers of the atoms), which is approximately the size of **4**. A similar packing was found in the crystal structure of an iron compound with seven hexane molecules within the channel.[13] Compound **4**·$4C_7H_8$ crystallizes at −25 °C in the monoclinic space group *C*2/*c* with one half of a molecule and two molecules of toluene in the asymmetric unit (Figure 2 and Table 1). Compound **6** crystallizes in the triclinic space group $P\bar{1}$ with half a molecule in the asymmetric unit (Figure 3 and Table 2). One thiophenyl group is distorted and two positions of the thiophene ring were refined for S(1). The basic structure of the new compounds is

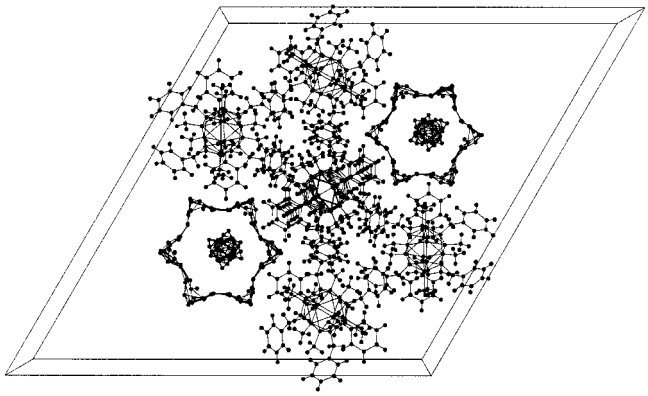

Figure 1. Packing diagram of **4**·xC_7H_8; perspective view along the *c* axis; the disordered solvent molecules are pictured as simple dots; the centers of the channels are located on the C_3 axes

nearly identical to their starting materials. The Al−C bond lengths for the methyl groups range from 1.973(2) Å to 1.976(2) Å in **4**·$4C_7H_8$ and 1.937(4) Å to 1.978(5) Å in **6**. For comparison, the Al−C bond lengths in the cluster **4** are longer [from 2.036(2) Å to 2.118(2) Å] than the single bonds of the methyl groups to aluminum.

Compound **4** is only poorly soluble and no NMR spectra of sufficient quality could be recorded. The EI mass spectrum only shows C−H fragments. The methyl groups of **5** appear as a singlet in the ^1H NMR spectrum (δ = 0.2 ppm).

C(6)−Al(2)−C(2)	112.4(1)	C(4)−Al(3)−C(2)	130.8(1)
C(4)−Al(3)−C(3)	112.4(1)	C(4)−Al(3)−C(3)	112.0(1)

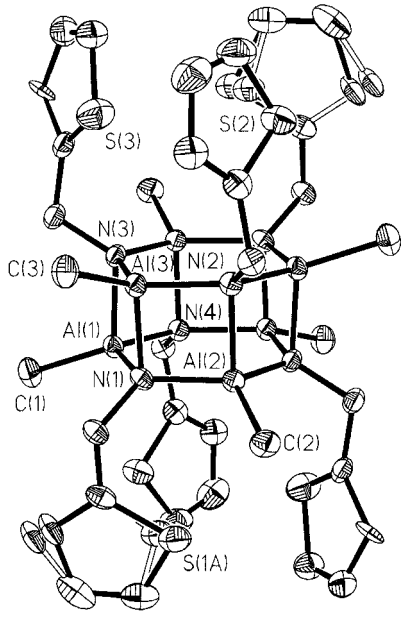

Figure 3. Molecular structure of **6**; hydrogen atoms are omitted for clarity

The cluster carbon atoms resonate at δ = 20.3 ppm in the ^{13}C NMR spectrum and a broad singlet (δ = 155.4 ppm) is observed in the ^{27}Al NMR spectrum of **5**. In general, the NMR resonances of **5** are shifted downfield compared to the starting material **2** and its halogen derivatives, except for the cluster carbon atoms in the ^{13}C NMR spectrum.

Table 2. Selected bond lengths (Å) and angles (°) for **6**

Al(1)−N(1)	1.886(4)	Al(1)−N(3)	1.986(3)
Al(1)−C(1)	1.978(5)	Al(2)−N(1)	1.877(3)
Al(2)−N(2)	1.982(3)	Al(2)−C(2)	1.937(4)
Al(3)−N(3)	1.879(3)	Al(3)−N(1)	1.986(3)
Al(3)−C(3)	1.94(1)		
N(4)−Al(1)−N(1)	113.8(2)	N(1)−Al(1)−N(3)	91.3(2)
N(1)−Al(1)−C(1)	119.3(2)	N(1)−Al(1)−C(1)	119.6(2)

The EI mass spectrum provides a molecular ion peak at m/z = 1102.6 for **5**. The singlet resonance for the protons of the methyl groups in the ^1H NMR spectrum of **6** is at δ = −0.52 ppm and is not shifted as far downfield as that for **5**. The NMR resonances are in agreement with the observed composition. The EI mass spectrum provides no molecular ion peak for **6**, although an ion corresponding to [$M^+ - CH_4$] was observed at m/z = 903.

In conclusion, the cluster cores of both the carbaalane and aluminum imide containing reactive Al−H bonds can be effectively replaced by methyl groups upon reaction with $AlMe_3$.

Experimental Section

General Remarks: All manipulations were performed under a dry and oxygen-free atmosphere (N_2 or Ar) using Schlenk-line and glove-box techniques. The samples for spectral measurements were prepared in a dry box. Solvents were purified according to conventional procedures and were freshly distilled prior to use. NMR spectra were recorded on a Bruker AM 200 instrument, and the chemical shifts are reported with reference to TMS. IR spectra were recorded on a Bio-Rad Digilab FTS7 spectrometer. Melting points were obtained on a HWS−SG 3000 apparatus and are uncorrected. CHN analyses were performed at the Analytical Laboratory of the Institute of Inorganic Chemistry at Göttingen, Germany.

Synthesis of [(AlMe)$_6$(AlNMe$_3$)$_2$(CCH$_2$Ph)$_6$] (4): $AlMe_3$ (1.90 mL of a 2.0 M solution in toluene, 3.80 mmol, 20 equiv.) was added to a fine suspension of **1** (0.18 g, 0.188 mmol, 1.0 equiv.) in toluene (20 mL). The mixture was stirred for 15 h during which time the solid turned into fine crystals. After filtration, additional needle- or rod-shaped crystals with of **4**·xC_7H_8 were obtained at 4 °C. Storing the supernatant solution at −25 °C gave crystals of **4**·4C_7H_8. The crystals were dried in vacuo. Yield 0.17 g (0.16 mmol, 87%). M.p.: ca. 240 °C (decomposition). IR (Nujol, KBr plates): $\tilde{\nu}$ = 1653, 1262, 1100, 971, 810, 750, 574 cm^{-1}. $C_{60}H_{78}Al_8N_2$ (1043.13): calcd. C 69.08, H 7.54, N 2.69; found 67.83, H 7.58, N 2.85.

Synthesis of [(AlMe)$_6$(AlNMe$_3$)$_2$(CCH$_2$CH$_2$SiMe$_3$)$_6$] (5): $AlMe_3$ (1.00 mL of a 2.0 M solution in toluene, 2.00 mmol, 15.6 equiv.) was added to a solution of **2** (0.13 g, 0.128 mmol, 1.0 equiv.) in toluene (5 mL). The solution was stirred for 4 h, all volatiles were removed in vacuo and the crude product was dried at 50 °C in vacuo giving **5** in a quantitative yield possibly admixed with a little Me_2AlH. M.p.: 210 °C (color change), 246 °C (full decomposition). ^1H NMR (300 MHz, C_6D_6): δ = 0.10 [s, 54 H, Si(CH_3)$_3$], 0.2 (br. s, 18 H, AlCH_3), 1.00 (ddd, J = 9.0, 4.1, 4.1 Hz, 12 H, Me_3SiCH_2), 2.16 (ddd, J = 9.0, 4.1, 4.1 Hz, 12 H, CCH_2), 2.17 [s, 18 H, N(CH_3)$_3$] ppm. ^{13}C NMR (126 MHz, C_6D_6): δ = −4.1 (broad, AlCH_3), −1.63 [Si(CH_3)$_3$], 20.3 (cluster-*C*), 25.9 (Me_3SiCH_2), 27.9

(CH_2C), 46.9 [N(CH_3)$_3$] ppm. ^{27}Al NMR (78.2 MHz, C_6D_6): δ = 155.4 (s, very broad) ppm. ^{29}Si NMR (99.4 MHz, CD): δ = −0.82 ppm. MS (EI): *m*/*z* (%) = 1102.6 (3) [M^+], 1043.5 (48) [M^+ − NMe], 998.5 (71) [M^+ − NMe − NHMe], 984.5 (100) [M^+ − 2NMe]. IR (Nujol, KBr plates): $\tilde{\nu}$ = 1318, 1258, 1182, 1022, 862, 828, 763, 723, 672, 593, 485 cm^{-1}. $C_{48}H_{114}Al_8N_2Si_6$ (1103.80): calcd. C 52.23, H 10.41, N 2.54; found C 51.98, H 10.34, N 2.61.

Synthesis of [(AlMe)$_6$(NCH$_2$C$_4$H$_3$S)$_6$] (6): $AlMe_3$ (2.7 mL of a 2.0 M solution in heptane, 5.40 mmol, 9.0 equiv.) was added dropwise to a solution of **3** (0.50 g, 0.60 mmol, 1.0 equiv.) in toluene (20 mL). The resultant mixture was stirred overnight at room temperature and filtered. The filtrate was reduced to 20 mL in vacuo and stored at 0 °C for several days to obtain colorless crystals of **6** (0.40 g, 0.435 mmol, 73%). M.p.: 246 °C (decomposition). ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): δ = −0.52 (s, 18 H, AlCH_3), 4.28 (s, 12 H, NCH_2), 6.70, 6.80, 7.20 (m, 18 H, C_4H_3S) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 25 °C, TMS): δ = −7.2 (Al−CH_3), 43.5 (NCH_2), 123.7, 124.9, 127.5, 148.3 (C_4H_3S) ppm. IR (nujol, NaCl plates): $\tilde{\nu}$= 1340 (m), 1254 (m), 1210 (s), 1167 (w), 1059 (w), 1014 (s), 980 (s), 965 (s), 943 (s), 848 (s), 747 (s), 734 (s), 683 (s) cm^{-1}. EI-MS: *m*/*z* (%) = 903 (100) [M^+ − CH_4], 835 (8) [$C_{30}H_{36}Al_6N_6S_6^+$], 113 (52) [$CH_2C_4H_3SNH_2^+$], 97 (72) [$CH_2C_4H_3S^+$]. $C_{36}H_{48}Al_6N_6S_6$ (919.04): calcd. C 47.05, H 5.26, N 9.14; found C 46.53, H 4.89, N 8.96.

X-ray Structure Determination of 4·4C$_7$H$_8$, 4·*x*C$_7$H$_8$ and 6: A suitable crystal of each compound was mounted on a glass fiber and coated with paraffin oil. Diffraction data for **4**·4C_7H_8 were collected on SMART instrument, and for **4**·*x*C_7H_8 and **6** the data were collected on a STOE IPDS2 diffractometer. The structures were solved by direct methods and refined with full-matrix least-squares on F^2 using SHELX-97.[14,15] All non-hydrogen atoms were refined anisotropically. Neutral-atom scattering factors (including anomalous scattering) were taken from the International Tables for X-ray Crystallography.[16] Hydrogen atoms were included at geometrically calculated positions and refined using a riding model. The restraints in **4**·4C_7H_8 are due to the distortions of the toluene molecules and in **6** the quality of the data is not as good as expected due to the breakdown of the low-temperature equipment and disorder in one of the thiophenyl groups. The crystallographic data is summarized in Table 3.

CCDC-237048 (for **4**·*x*C_7H_8), -237049 (for **4**·4C_7H_8) and -237050 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Dinuclear Zn^{II} Complexes of Polydentate Polyamines as Minimalist Models of Hydrolytic Reactions

Juan Aguilar,[a] Andrea Bencini,*[b] Emanuela Berni,[b] Antonio Bianchi,*[b] Enrique García-España,*[a] Laura Gil,[a] Angel Mendoza,[c] Lena Ruiz-Ramírez,[c] and Conxa Soriano[a]

Keywords: Enzyme models / Hydrolysis / Macrocycles / N ligands / NMR spectroscopy / Zinc

The synthesis of the novel macrocycle 2,6,9,12,16-pentaaza-[17](2,9)(1,10)phenanthrolinophane (L3) is reported. Speciation studies on the systems Zn^{II}–L3 and Zn^{II}–L2 (L2 = 2,6,10,13,17,21-hexaaza[22]metacyclophane) performed in aqueous solution show the formation of mono- and dinuclear Zn^{II} complexes. In the two systems, the dinuclear complexes readily hydroxylate, with the hydroxo species being the main ones in solution at relatively low pH values. This feature makes these complexes promising hydrolytic agents for carboxy and phosphate esters. The hydrolytic ability of the L1–L3 dinuclear complexes toward the carboxy and phosphate ester bond was tested by addition of *p*-nitrophenyl acetate (NA) and bis(*p*-nitrophenyl)phosphate (BNP). While in the case of NA the cleavage takes place through a simple bimolecular mechanism and the hydrolysis rate depends on the nucleophilicity of the Zn^{II}–OH functions, in the case of BNP the hydrolytic mechanism involves substrate interaction with the metal ions and nucleophilic attack of a Zn^{II}-bound hydroxide ion at the phosphorus atom. The L3 complex gives rise to the highest hydrolysis rate constant {$k = 62 \times 10^{-5}$ $M^{-1}\cdot s^{-1}$ vs. $k = 8 \times 10^{-5}$ and 4×10^{-5} $M^{-1}\cdot s^{-1}$ for $[Zn_2L2(OH)_2]^{2+}$ and $[Zn_2L1(OH)_2]^{2+}$, respectively}. This may be related to a stronger interaction with the substrate due to the synergetic role in BNP binding played by the phenanthroline unit, which can give π-stacking and hydrophobic interactions with the aromatic units of the substrate, and by the two Zn^{II} ions, which can act cooperatively in BNP coordination.

Introduction

A model compound of a metalloprotein can be defined as a structurally simpler metal complex, without the protein ligand, that is able to reproduce key features of its active center and/or its spectroscopic properties and/or its biochemical function. In this respect, throughout the last few years a great deal of experimental work has been addressed to the development of Zn^{II} complexes with unsaturated coordination spheres able to mimic features of the active site of Zn^{II} hydrolases.[1–23] Many of these enzymes use two Zn^{II} centers for the activation of the substrate and very often the nucleophile is a hydroxy group generated from deprotonation of a coordinated water molecule.[22,23] The right compromise between the thermodynamic stability of the complex and its rapid dynamic reorganization following the mechanism of the reaction, the hydrophilic/hydrophobic balance of the environment, the possibility of formation of hydrogen bonds with the substrate, and the presence of noncoordinated basic groups that can assist the process are other factors that influence the catalytic activity.

Macrocyclic structures are very appealing for the construction of these mimics because they intrinsically provide a certain organization of their reactive functions. In this context many aza or oxaaza macrocycles have been shown to yield interesting performances as models for the cleavage of carboxy or phosphate esters. One representative example was provided by the binucleating oxaaza ligand 1,4,7,16,19,22-hexaaza-10,13,25,28-tetraoxacyclotriacontane ([30]aneN_6O_4), which contains two triamine moieties separated by two dioxa chains.[24]

Here we report on the catalytic ability towards carboxy- and phosphate-ester cleavage of three compounds of different structure. L1 is an open-chain hexaamine consisting of a symmetrical array of four propylenic chains and one central ethylenic chain connecting the set of nitrogen atoms,[25] L2 presents a classical 1:1 cyclophane structure in which the

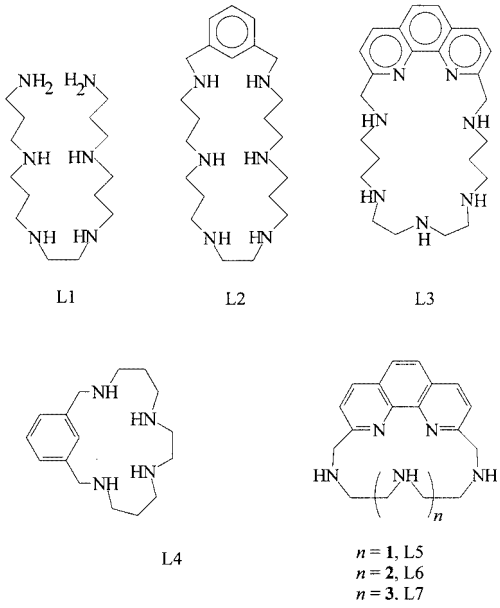
hexamine L1 has been linked through methylene groups to a *meta*-benzene spacer,[26] and L3 is a novel phenanthrolinophane ligand consisting of the pentaamine 4,7,10-triazatridecane-1,13-diamine linked through methylene groups to the 2- and 9-positions of a 1,10-phenanthroline moiety (Scheme 1). We present the synthesis of L3 and we discuss the Zn^{II} coordination capabilities of the three ligands L1, L2 and L3 as well as their potentialities as hydrolytic mimics.



Scheme 1

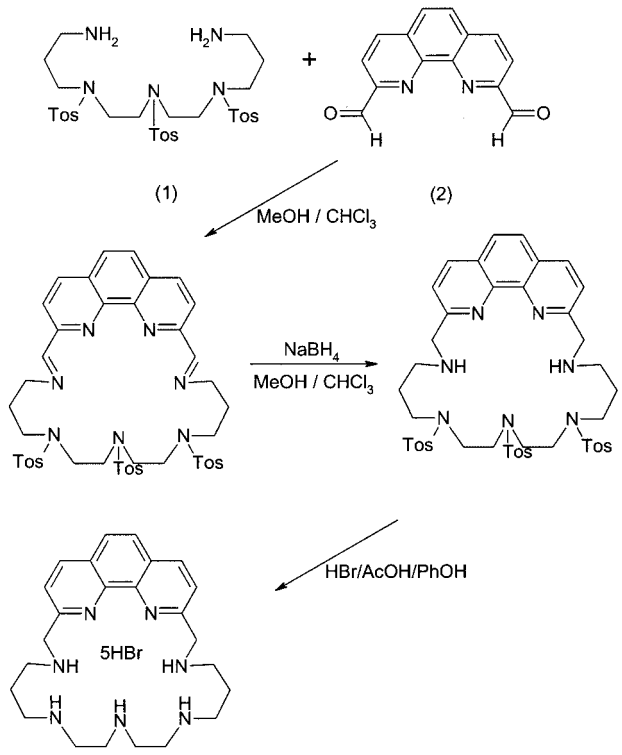
Results and Discussion

Synthesis of L3

The synthesis of L3 was achieved according to a route different to that reported for the preparation of related cyclophanes[27] and similar phenanthrolinophanes.[28] The procedure consists of a condensation reaction of the partly tosylated amine 4,7,10-tris(*p*-tolylsulfonyl)-4,7,10-triaazatridecane-1,13-diamine (**1**) with 1,10-phenanthroline-2,9-dicarboxaldehyde (**2**), which yields the tosylated imine **3**. Compound **3** is then reduced with $NaBH_4$ to give the partly tosylated macrocycle (**4**; Scheme 2). The reductive cleavage of the amine to give L3 was performed with HBr/AcOH in PhOH. L3 was handled as its hexahydrobromide salt. The overall yield of the reaction was about 40%.

Speciation Studies

Table 1 gathers the stability constants for the formation of Zn^{II} complexes of L1, L2 and L3. Formation of both mono- and dinuclear complexes was detected in all three systems. L1 and L2 form protonated mononuclear complexes with protonation degrees varying between 2 and 0 and between 2 and −1, respectively. The speciation studies



Scheme 2

for the Zn^{II}−L3 system show the formation of mononuclear complexes with stoichiometries $[ZnH_xL]^{(2+x)}$ with x ranging from 4 to 0. With respect to the dinuclear complexes, while in the systems Zn^{II}−L1 and Zn^{II}−L2 only hydroxylated species are detected, in the system Zn^{II}−L3 formation of a neutral and of a monoprotonated dinuclear complex is also observed.

In a previous report,[25] some of us analysed the coordination capabilities towards Zn^{II} of the open-chain ligand L1. Taking into account the values of the stability constants, the NMR spectra of the complex and the comparison with related polyamines and the other metal ions of the second part of the first transition series, a coordination number of four was confidently established for its mononuclear Zn^{II} complexes. A similar analysis can be performed for the system Zn^{II}−L2. First of all, a direct comparison with L1 shows that the formation constant of $[ZnL2]^{2+}$ is even a little bit lower than that of $[ZnL1]^{2+}$ (Table 1). The formation constant of $[ZnL2]^{2+}$ is, on the other hand, similar to those of open-chain tetraamines like 3,6-diazaoctane-1,8-diamine (trien) ($\log K_{ZnL/Zn\cdot L} = 12.0$) with all ethylenic chains, 4,7-diazadecane-1,10-diamine (2,2,2-tet, $\log K_{ZnL/Zn\cdot L} = 11.25$) with a symmetrical disposition of two propylenic and one ethylenic chain or 4,8-diazadecane-1,11-diamine (3,2,3-tet, $\log K_{ZnL/Zn\cdot L} = 10.46$) with all ethylenic chains and larger than those obtained for open-chain triamines like 3-azapentane-1,5-diamine (2,2-tri, $\log K_{ZnL/Zn\cdot L} = 8.8$).[29] If we compare tetraazacycloalkanes like 1,4,8,11-tetraazacyclotetredecane (cyclam, $\log K_{ZnL/Zn\cdot L} = 15.5$) or 1,4,7,10-tetraazacyclododecane (cyclen, $\log K_{ZnL/Zn\cdot L} = 16.2$), then the formation constant of $[ZnL]^{2+}$ is clearly

[a] Taken from ref.[25] [b] 0.15 M $NaClO_4$. [c] 0.15 M NaCl. [d] Just one decimal figure is included in the calculated stepwise constants.

lower as a result of the important macrocyclic effect that is operative in these small-sized saturated azamacrocycles. A comparison with the triazamacrocycles 1,4,7-triazacyclononane ([9]aneN_3, log $K_{ZnL/Zn\cdot L}$ = 11.6) and 1,5,10-triazacyclododecane ([12]aneN_3, log $K_{ZnL/Zn\cdot L}$ = 8.6) shows an intermediate constant for $[ZnL2]^{2+}$ between the macrocycle with all ethylenic chains and that with only propylenic chains. A last comparison of relevance refers to tetraazametacyclophanes like 2,6,9,13-tetraaza[14]metacyclophane (L4; Scheme 1) for which the number of coordinated nitrogen atoms was deduced to be three (log $K_{ZnL/Zn\cdot L}$ = 8.73).[30] Therefore, all these data suggest that in the Zn^{II}−L1 mononuclear complexes the metal ion is coordinated by four nitrogen donors of the macrocycle. The two high, stepwise protonation constants obtained for $[ZnL2]^{2+}$ also give support to the tetracoordination of the metal ion. The nitrogen atoms undergoing protonation would be noncoordinated ones and this is the reason for such high values of their protonation constants.

The analysis of the stability constants for the interaction of Zn^{II} with the phenanthrolinophane L3 leads to similar conclusions. Firstly, the value for the formation constant of $[ZnL3]^{2+}$ (Table 1) is of the same order of magnitude as found for the other polyamines studied in the present work (L1 and L2); this could indicate that, as has been just discussed, four is the most likely coordination number. However, in this case the presence of the strong π-acceptor phenanthroline spacer can produce some modification in the analysis. Therefore, it is interesting to compare L3 with similar phenanthrolinophanes reported previously.[31] Indeed the $[ZnL]^{2+}$ complex of the phenanthrolinophane receptor 2,5,8-triaza[9](2,9)(1,10)phenanthrolinophane (L5; Scheme 1) displays a stability constant of 16.15, which is much higher than those reported here for the analogous complexes of L1−L3. In spite of this, the crystal structure of its complex cation $[ZnL(H_2O)]^{2+}$ revealed that Zn^{II} is coordinated only by the phenanthroline donors, by the central nitrogen atom of the polyamine bridge and by a water molecule, with a tetrahedral disposition of the donor atoms. This again points out the difficulties of deriving coordination numbers just from free-energy terms. Nevertheless, one has to consider that such an enhancement of the stability of Zn^{II} complexes by ligands favoring tetrahedral arrangements is quite usual as can be seen from the relevant data for the tripodal tetraamine tris(2-aminoethyl)amine, which has a higher stability constant than any other open-chain tetraamine.[29]

However, the larger 2,5,8,11-tetraaza[12](2,9)(1,10)phenanthrolinophane (L6 in Scheme 1) and 2,5,8,11,13-pentaaza[14](2,9)(1,10)phenanthrolinophane (L7) have lower constants — log $K_{ZnL/Zn\cdot L}$ = 14.29 and 12.38, respectively.[31] In the case of L3, the stability constant obtained follows this tendency, being even lower (Table 1). Additionally, the number of protonated species found is very large. All this can be interpreted on the grounds of an increasing strained coordination geometry imposed by the macrocyclic conformation and to a low coordination number that should involve either three or at most four nitrogen donors, including those of the spacer.

The most relevant aspect with respect to the dinuclear complexes is the ready hydroxylation observed for the three systems at relatively low pH values (see Figure 1). In the case of L1 and L2, $[Zn_2L]^{4+}$ species are not even detected in solution due to the marked tendency of the dinuclear Zn^{II} complexes to form hydroxylated complexes. In the case of L3, a pK_a value of 7.8 for deprotonation of a Zn^{II}-coordinated water molecule of $[Zn_2L3]^{4+}$ was found. Similar low pK_a values are generally observed in the case of a bridging

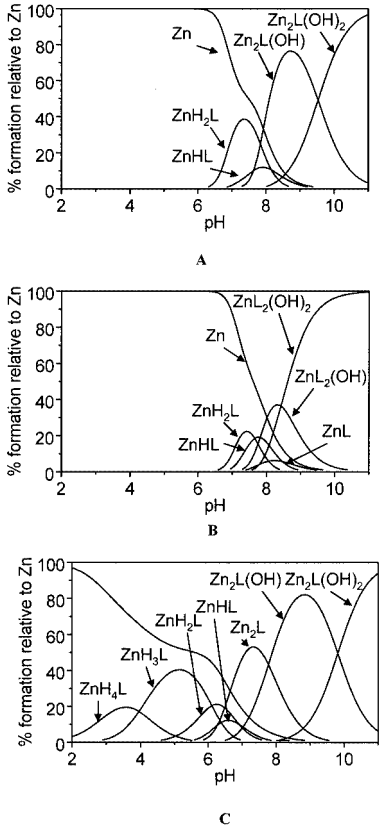

Figure 1. Distribution diagrams for the systems $Zn^{II}-L1$, $Zn^{II}-L2$ and $Zn^{II}-L3$ for molar ratios $Zn^{II}/L = 2:1$ ($[Zn^{II}] = 2 \times 10^{-3}$ M)

disposition of hydroxide between two metal ions[24,32,33] or in the case of mononuclear complexes containing a water molecule placed as a fourth ligand of a Zn^{II} moiety coordinated by three nitrogen donors.[4,30] Therefore, the coordinatively unsaturated first coordination spheres of these dinuclear complexes provide nucleophilic OH^- functions, which could play a key role in the hydrolytic process (vide infra).

Kinetics of p-Nitrophenyl Acetate (NA) Hydrolysis

NA hydrolysis was monitored by UV/Vis spectroscopy by monitoring the appearance of the *p*-nitrophenolate anion at 403 nm (298.1 K, $I = 0.15$ M $NaClO_4$). All ligands form dinuclear complexes in aqueous solution. In the case of L3 the formation of the dinuclear $[Zn_2L3]^{4+}$ complex takes place at a pH > 6, with almost simultaneous deprotonation of a coordinated water molecule to give the monohydroxo species $[Zn_2L3(OH)]^{3+}$. The rather low pK_a (7.8 log units) suggests a bridging coordination of the hydroxide ion between the two metal centers, as is often found in dizinc complexes with macrocyclic ligands, where the two metal atoms are kept at a short distance by the cyclic framework, thus favoring the assembly of $Zn_2(\mu\text{-OH})$ units.[24,32,33] The formation of a dihydroxo $[Zn_2L3(OH)_2]^{2+}$ complex is observed at alkaline pH values, with $pK_{a2} = 9.8$ (298 K). This pK_a value is higher than those usually found for bridging hydroxide ions and is generally related to the formation of a single-metal-bound hydroxide function.[24,32,33] L1 and L2 display a somewhat different behavior, since the formation of the $[Zn_2L]^{4+}$ complex is not observed and only the dinuclear hydroxylated species $[Zn_2L(OH)]^{3+}$ and $[Zn_2L(OH)_2]^{2+}$ are present in neutral and alkaline aqueous solutions, respectively. For all the three ligands, both the dinuclear complexes $[Zn_2L(OH)]^{3+}$ and $[Zn_2L(OH)_2]^{2+}$ promote NA hydrolysis; second-order kinetics is monitored at different pH values. As shown in Figure 2 for the dinuclear L1 complexes, plots of the k_{NA} values as a function of the percentages of $[Zn_2L1(OH)]^{3+}$ (Figure 2a) and $[Zn_2L1(OH)_2]^{2+}$ (Figure 2b) give rise to straight lines. Similar plots were also obtained for the dinuclear complexes with L2 and L3. For all the dinuclear complexes under investigation, no effect is observed at pH < 7.5, where such species are absent in solutions. Finally, experiments carried out on solutions containing ligands L1, L2 or L3 and Zn^{II} in a 1:1 molar ratio in the pH range 7−9 (under these conditions mononuclear complexes are largely prevalent in solution) do not show significant increases of the hydrolysis rate, indicating that the mononuclear Zn^{II} complexes are not active in this hydrolytic process.

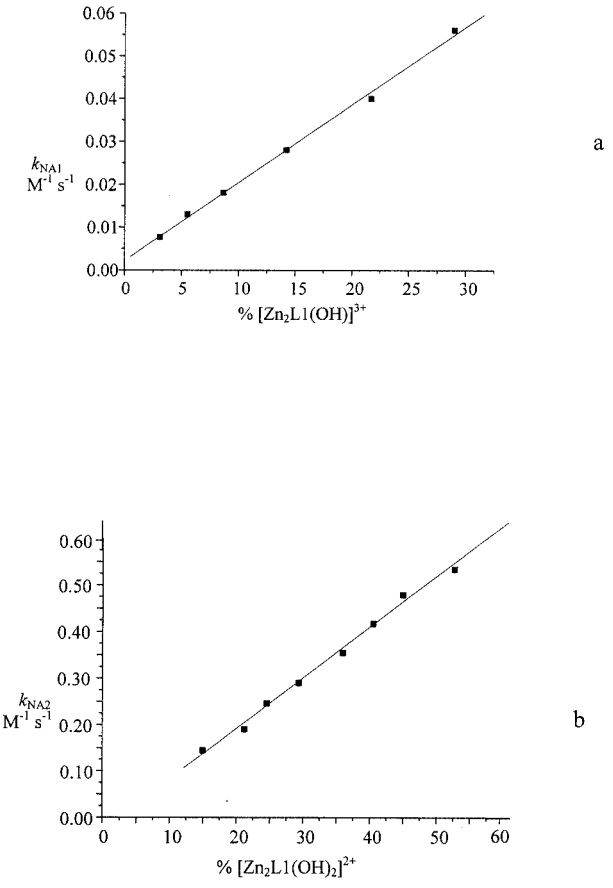

Figure 2. Second-order rate constants for NA hydrolysis (k_{NA}) as a function of the percentage of $[Zn_2L1(OH)]^{3+}$ (a) and as a function of the percentage of $[Zn_2L1(OH)_2]^{2+}$ (b)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Only the mono- and dihydroxo complexes $[Zn_2L(OH)]^{3+}$ and $[Zn_2L(OH)_2]^{2+}$ are the kinetically active species, meaning that the $Zn^{II}-OH$ function is indeed nucleophilic. Furthermore, Figure 2 clearly shows that the dihydroxo complex $[Zn_2L1(OH)_2]^{2+}$ is much more active in NA hydrolysis than the monohydroxo complex $[Zn_2L1(OH)]^{3+}$. Similarly, the dinuclear dihydroxo complexes with L2 and L3 show a higher activity in promoting NA cleavage than the monohydroxo ones.

The $[Zn_2L(OH)]^{3+}$ and $[Zn_2L(OH)_2]^{2+}$ complexes (L = L1, L2 or L3) are formed in at most 70% yield in the pH ranges used in the kinetic measurements. Therefore, in order to quantify the different activity in NA hydrolysis of the present complexes, second-order rate constants k'_{NA} have been determined from the maximum k_{NA} values by using the equation:

$$v = k_{NA}[\text{total } Zn^{II}\text{complex}][NA] = k'_{NA}[Zn_2L(OH)_x^{4-x}][NA];\ x = 1 \text{ or } 2$$

The k'_{NA} values for the present complexes are listed in Table 2, together with the rate constants found for Kimura's mononuclear Zn^{II} complexes **1** and **2** (Scheme 3).[34]

Table 2. Second-order rate constants k'_{NA} [M^{-1} s^{-1}] for hydrolysis of *p*-nitrophenyl acetate

Nucleophile	k'_{NA} [M^{-1} s^{-1}]	pK_a
$[Zn_2L1(OH)]^{3+}$	0.18 ± 0.01	–
$[Zn_2L1(OH)_2]^{2+}$	1.1 ± 0.05	9.5
$[Zn_2L2(OH)]^{3+}$	0.06 ± 0.003	–
$[Zn_2L2(OH)_2]^{2+}$	0.80 ± 0.4	8.4
$[Zn_2L3(OH)]^{3+}$	0.069 ± 0.04	7.8
$[Zn_2L3(OH)_2]^{2+}$	2.2 ± 0.05	9.8
1	0.041[a]	7.2
2	0.11[a]	7.9

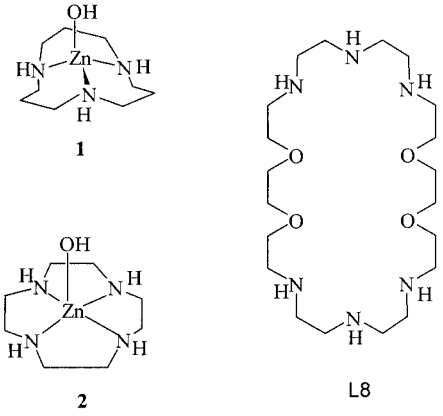

Scheme 3

Table 2 clearly shows that the monohydroxo $[Zn_2L(OH)]^{3+}$ complexes exhibit a remarkably lower rate constant than the corresponding dihydroxo $[Zn_2L(OH)_2]^{2+}$ complexes. The much lower hydrolytic properties of the $[Zn_2L(OH)]^{3+}$ species can be ascribed to the bridging coordination of the hydroxide ion, as is often found in dizinc complexes with hexa- and heptaamine ligands.[22,24,32] In fact, the simultaneous binding to two electrophilic metal centers reduces the nucleophilicity of the generated hydroxide ion. The k'_{NA} of $[Zn_2L(OH)]^{3+}$ is, however, similar to those found for the monohydroxo complexes **1** and **2**.

Addition of a second hydroxide anion to a Zn^{II} ion may lead to detachment of the bridging OH ion from one of the metal atoms or to a weakening of the Zn(μ-OH) bond, giving a more "open" conformation of the complex, which can leave catalytic sites accessible on the two Zn^{II} ions. As a matter of fact, the dihydroxo complexes $[Zn_2L(OH)_2]^{2+}$ give much higher rate constants in NA hydrolysis than the monohydroxo complexes **1** and **2**, indicating an enhanced nucleophilicity of the $Zn-OH$ functions in $[Zn_2L(OH)_2]^{2+}$. Actually, a bridging hydroxide ion in $[Zn_2L(OH)]^{3+}$ reduces the positive charge on the metal ions. This determines the rather high pK_{a2} values found for deprotonation of a Zn^{II}-bound water molecule to give the $[Zn_2L(OH)_2]^{2+}$ complexes and increases the nucleophilic character of the resulting $Zn-OH$ functions.

Comparing the different abilities of these species in NA cleavage, Table 2 shows that the k'_{NA} values increase in the sequence L2 < L1 < L3. The mechanism generally accepted for NA hydrolysis involves a simple nucleophilic attack of the metal-bound hydroxide ion to the carbonyl group of the ester and release of *p*-nitrophenolate.[8,35] The two Zn^{II} ions do not play any cooperative role in substrate activation and a simple bimolecular mechanism is predominant. For this reason, for a series of analogous complexes, such as **1** and **2**, the ability of $Zn-OH$ functions in NA hydrolysis increases with their pK_a values. From this point of view, the increasing pK_{a2} value observed on passing from L2 to L1 would explain the higher k'_{NA} value found for $[Zn_2L1(OH)_2]^{2+}$ with respect to $[Zn_2L2(OH)_2]^{2+}$. On the other hand the $[Zn_2L3(OH)_2]^{2+}$ complex displays a pK_{a2} value similar to that of the corresponding L1 complex {pK_{a2} = 9.8 and 9.5 for $[Zn_2L3(OH)_2]^{2+}$ and $[Zn_2L1(OH)_2]^{2+}$, respectively}, but, at the same time, is twice as active in NA hydrolysis {k'_{NA} = 2.2 and 1.1 $M^{-1}{\cdot}s^{-1}$ for $[Zn_2L3(OH)_2]^{2+}$ and $[Zn_2L1(OH)_2]^{2+}$, respectively}. A tentative explanation for this behavior could reside in the presence of a large heteroaromatic unit — phenanthroline — in the L3 cyclic framework. It is known, in fact, that phenanthroline-containing receptors can give host–guest adducts with substrates containing aromatic moieties, stabilized by strong π-stacking and hydrophobic interactions between the two aromatic units.[2,36–38] In the present case, these interactions between phenanthroline and the aromatic moiety of NA would stabilise the transient state of the nucleophilic attack, leading to the observed higher hydrolytic ability of the L3 complex. At the same time phenanthroline is poorly solvated in water. Therefore, the presence of this unit within the cyclic framework can provide a rather hydrophobic environment for the $Zn-OH$ function, enhancing its nucleophilic activity.

The high activity of the present complexes in NA hydrolysis prompted us to study their hydrolytic ability toward the phosphate ester bond, by using bis(*p*-nitrophenyl)phosphate (BNP) as substrate. It is known, in fact, that BNP hydrolysis in the presence of Zn^{II} complexes generally takes place through an "associative" mechanism,[33−35] in which substrate binding and activation by the metal center is followed by a nucleophilic attack at the phosphorus atom. Hydrophobic and π-stacking interactions would lead, in principle, to a stronger association between BNP and the Zn^{II} complex with L3, and, therefore, to an increased substrate activation of the hydrolytic process

BNP Binding by the Zn^{II} Complexes with L1−L3

Binding of BNP to the Zn^{II} complexes with ligands L1−L3 was monitored by means of ^{31}P NMR spectra recorded on MeOD/CD_3CN (50:50, v/v) solutions containing BNP (1×10^{-2} M) and the complexes in different molar ratios. Solutions containing BNP and increasing amounts of the dinuclear complexes display a progressive upfield shift of the BNP signals (Figure 3). In the case of the dizinc complexes with L3 (Figure 3c), the plot of $\Delta\delta$ (where $\Delta\delta$ is the difference between the chemical shift of BNP in the presence and in absence of the complex) as a function of the $[Zn_2L3](ClO_4)_4{\cdot}2H_2O$/[BNP] molar ratio ($R$) gives a straight line for $R < 0.8$. Then, the slope changes almost suddenly to give a straight line parallel to the x axis for $R > 1.2$ (at this point $\Delta\delta = 2.8$ ppm). This behavior indicates the formation of a stable 1:1 complex between the dizinc complex and BNP. A similar plot is obtained with the dizinc complex with L2; the slope change, however, is less sudden than in the case of the L3 complex and a lower $\Delta\delta$ value ($\delta = 1.9$ ppm) is reached for $R > 1.5$ (Figure 3b). Finally, in the presence of the dizinc complex with L1 a very smooth curve is observed up to $R = 5$ ($\Delta\delta = 0.55$ ppm), where precipitation of a 1:1 complex between the dizinc complex and BNP takes place. {A solid compound of stoichiometry $[Zn_2L1](BNP)(ClO_4)_3{\cdot}2H_2O$ was isolated and characterized by elemental analysis. $C_{26}H_{48}Cl_3N_8O_{20}PZn_2$ (1060.82): calcd. C 29.54, H 4.58, N 10.61, P 2.93; found C 28.99, H 4.50, N 10.25, P 2.73.} These data are in agreement with the formation of 1:1 complexes with BNP, whose stability increases in the order $[Zn_2L1]^{4+} < [Zn_2L2]^{4+} < [Zn_2L3]^{4+}$. Furthermore, the rather large shift for the signal of the phosphate ester bound to the L2 and L3 dinuclear complexes would suggest interaction of BNP with both Zn^{II} ions through a bridging coordination of the phosphate anion. From this point of view, it is of interest to note that no shift of the BNP signal is observed in the presence of the mononuclear Zn^{II} complexes with ligands L1−L3. Most likely, in the mononuclear complexes the Zn^{II} ion is almost coordinately saturated by the ligand donors and no free binding site is available at the metal for BNP coordination.

The ^{31}P NMR spectra recorded in D_2O solution display minor shifts of the BNP signal, even in the presence of a large excess of the dinuclear complexes ($\delta = 0.5$ and 0.3 ppm in the case of L3 and L2, respectively, and $\delta \approx$ 0.1 ppm for L1), probably due to a much lower percentage of coordinated BNP in this more solvating medium. In the case of L2 and L3, ^{31}P NMR titrations at pD = 10 (see Supporting Information), carried out by adding increasing amounts of $[Zn_2L3](ClO_4)_4{\cdot}2H_2O$ or $[Zn_2L2](ClO_4)_4{\cdot}4H_2O$ to a BNP solution lead to calculate a log K value of 2.5 ± 0.2 and 1.7 ± 0.1 for the addition of BNP to the dinuclear

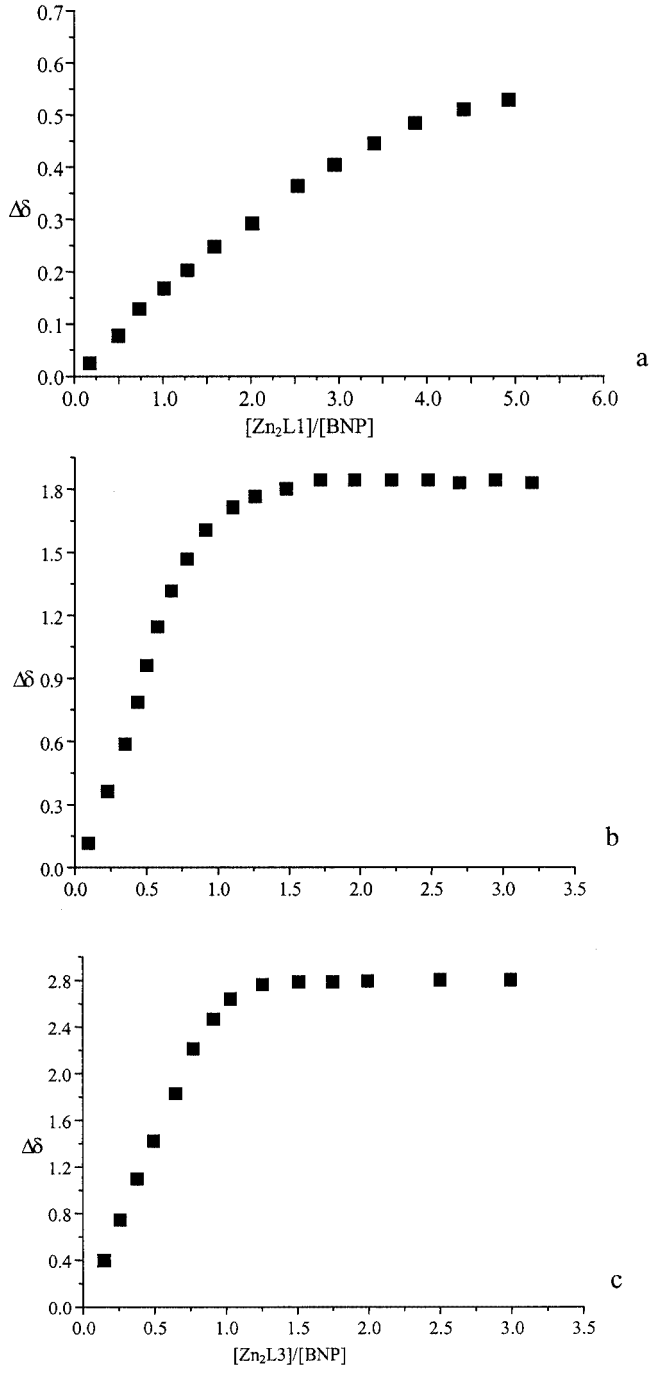

Figure 3. Plot of the ^{31}P NMR chemical shifts of BNP ($\Delta\delta = \delta_{BNP} - \delta_{OBS}$, where δ_{BNP} = chemical shift of the unbound BNP ester and δ_{OBS} = observed chemical shift in the presence of the dinuclear complexes with L1−L3) as a function of the [$[Zn_2L1](ClO_4)_4{\cdot}2H_2O$]/[BNP] (a), [$[Zn_2L2](ClO_4)_4{\cdot}4H_2O$]/[BNP] (b) and [$[Zn_2L3](ClO_4)_4{\cdot}2H_2O$]/[BNP] molar ratios (MeOD/CD_3CN solution, 298 K, [dizinc complex] = 1×10^{-2} M)

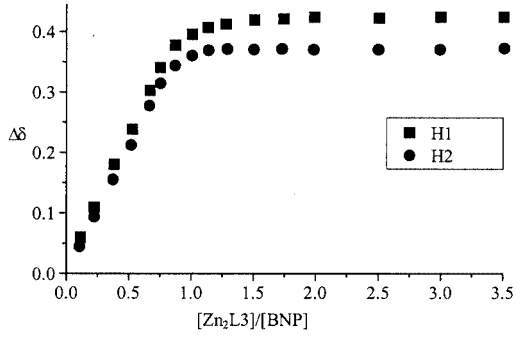
Zn^{II} complex with L3 and L2, respectively. In the case of the dizinc complex with L1, the observed shift of the ^{31}P NMR signal is too low to confidently determine the addition constant of BNP to the complex.

To obtain further information on the interaction mode of the BNP anion with our dizinc complexes, we also recorded ^{1}H NMR spectra of solutions containing BNP and increasing amounts of dinuclear Zn^{II} complexes with L1−L3. Although the ^{1}H NMR spectra of the ligands in their Zn^{II} complexes are rather fluxional and do not allow a correct determination of the ^{1}H chemical shifts, the resonances of the aromatic protons of BNP [two doublets at δ = 7.98 (H1; for atom labelling see Figure 4) and δ = 7.13 ppm (H2) in the absence of the Zn^{II} complexes] are generally easily recognizable. The ^{1}H NMR signals of BNP are almost unaffected by the presence, even in large excess, of the dizinc complexes with ligand L1 and L2. On the contrary, addition of the dizinc complex with L3 to a BNP solution gives rise to a significant upfield shift of both the BNP signals (Figure 4). As in the case of the ^{31}P NMR spectra, the plot of the $\Delta\delta$ values as a function of the [dinuclear L3 complex]/[BNP] molar ratio (R) gives a straight line for $R < 0.8$; subsequently, the slope changes to give a straight line parallel to the x axis for $R > 1.2$ (at this point $\Delta\delta$ = 0.42 and 0.37 ppm for the protons H1 and H2, respectively). The upfield shifts observed for the BNP signals are indicative of a π-stacking interaction between the aromatic rings of the ester and the large phenanthroline unit. This interaction seems to be absent in the case of the zinc complexes with L2, which contains a smaller aromatic unit.



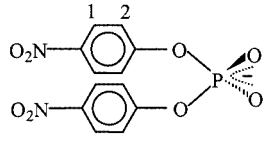


Figure 4. Plot of the ^{1}H NMR chemical shifts of BNP ($\Delta\delta = \delta_{BNP} - \delta_{OBS}$, where δ_{BNP} = chemical shift of the unbound BNP ester and δ_{OBS} = observed chemical shift in the presence of the dinuclear complexes with L1−L3) as a function of the $[[Zn_2L3](ClO_4)_4{\cdot}2H_2O]$/[BNP] molar ratios (MeOD/CD_3CN solution, 298 K, $[[Zn_2L3](ClO_4)_4{\cdot}2H_2O] = 1 \times 10^{-2}$ M)

Both the ^{31}P and ^{1}H NMR experiments account for a higher overall interaction between the phosphate ester and the dizinc complex with L3, probably due to the synergetic effect in BNP binding exerted by the two metal centers, which can act cooperatively in substrate coordination, and by the phenanthroline moiety, which can interact with BNP by π-stacking.

To shed further light on the role played by substrate interaction and activation by the present metal complexes, we decided to carry out a comparative kinetic study on the ability of the L1−L3 complexes to hydrolyze BNP.

BNP Hydrolysis Promoted by the Zn^{II} Complexes with L1−L3

A kinetic analysis of BNP cleavage shows that only the dinuclear complexes with L1−L3 promote BNP hydrolysis, while the mononuclear complexes are totally unable to hydrolyze this ester. Figure 5 shows the second-order rate constants for BNP cleavage (k_{BNP}) in the presence of the ligand L3 and increasing amounts of Zn^{II} at pH = 10. No hydrolytic effect is observed with molar ratios $R < 1$ for Zn^{II}/L3, when only mononuclear complexes are formed in aqueous solutions; for $1 < R < 2$, the k_{BNP} values increase almost linearly with R, due to the formation of increasing amounts of the dinuclear complex. The maximum k_{BNP} value is obtained when $R = 2$, where only the dinuclear complex is present in solution at pH = 10. Addition of further Zn^{II} ($R > 2$) does not change the hydrolysis rate.

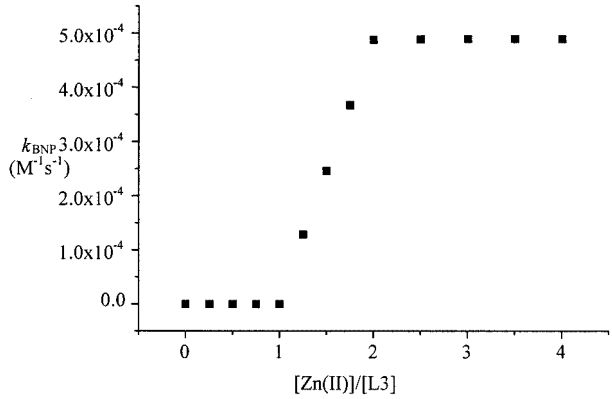

Figure 5. Second-order rate constants for BNP cleavage (k_{BNP}) as a function of the $[Zn^{II}]$/[L3] molar ratio at pH = 10 (CHES buffer)

For all the three ligands, only the dihydroxo complexes $[Zn_2L(OH)_2]^{2+}$ promote BNP hydrolysis in aqueous solution, to give mono(*p*-nitrophenyl phosphate) (MNP) and *p*-nitrophenolate, while the monohydroxo species $[Zn_2L(OH)]^{3+}$ do not promote this process (Figure 5), in agreement with the very much lower activity in NA hydrolysis found for this species. Plots of the second-order rate constants k_{BNP} for the L1, L2 and L3 dizinc complexes as a function of pH fit the distribution curves of the $[Zn_2L1(OH)_2]^{2+}$, $[Zn_2L2(OH)_2]^{2+}$, and $[Zn_2L3(OH)_2]^{2+}$ species (Figure 6), pointing out that these dihydroxo complexes are the kinetically active species. As in the case of NA hydrolysis, second-order rate constants k'_{BNP} can be

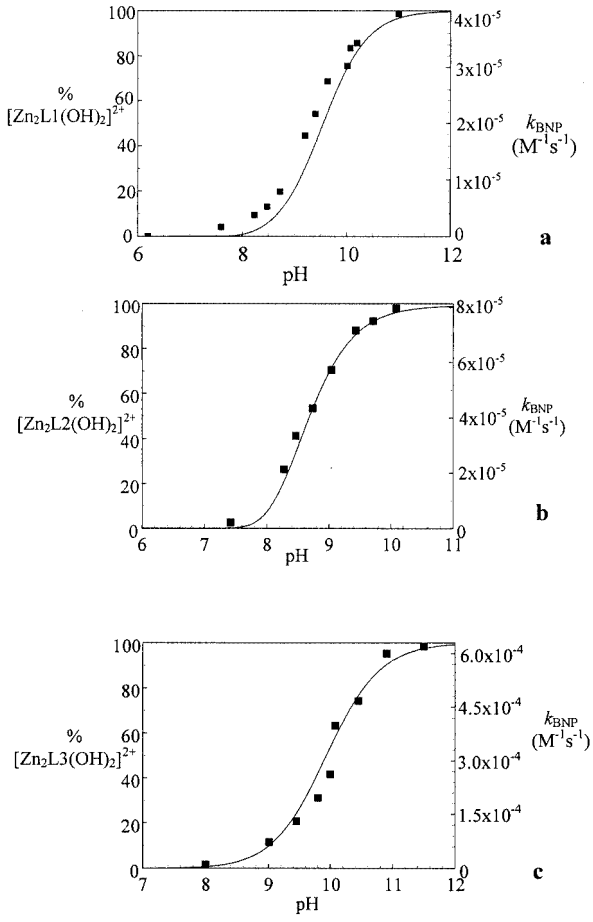

Figure 6. Plots of the distribution curves of $[Zn_2L1(OH)_2]^{2+}$ (a), $[Zn_2L2(OH)_2]^{2+}$ (b) and $[Zn_2L3(OH)_2]^{2+}$ (c) (solid line, right *y* axes) and k_{BNP} values (squares, left *y* axes) as a function of pH

calculated from the maximum k_{BNP} value by using the expression:

$$v = k_{BNP}[\text{total } Zn^{II}\text{complex}][BNP] = k'_{BNP}[Zn_2L(OH)_2{}^{2+}][BNP]$$

Table 3. Second-order rate constants *k'BNP* [M^{-1} s^{-1}] for hydrolysis of bis(4-nitrophenyl)phosphate

Nucleophile	$k'_{BNP}\cdot10^5$ [M^{-1} s^{-1}]	pK_a
$[Zn_2L1(OH)_2]^{2+}$	4.0 ± 0.2	9.5
$[Zn_2L2(OH)_2]^{2+}$	8.0 ± 0.4	8.4
$[Zn_2L3(OH)_2]^{2+}$	62 ± 3	9.8
1	8.5[a]	7.2
2	2.1[a]	7.9
$[Zn_2L8(OH)_2]^{2+}$	11.0[b]	9.1

[a] From ref.[40]; I = 0.15 M $NaClO_4$. [b] From ref.[24]; I = 0.1 M NaCl.

Table 3 reports the k'_{BNP} values for the $[Zn_2L(OH)_2]^{2+}$ complexes, in comparison with the corresponding pK_{a2} values. The k'_{BNP} values reported for the mononuclear complexes **1** and **2**[34] and for the dinuclear complex with L8[24] (Scheme 3) are also reported for comparison. Considering L1 and L2, the activity of their complexes in BNP hydrolysis decreases from L2 to L1, i.e., the hydrolytic properties decrease as the pK_a of the complexes increases, which is the opposite behavior to that found in NA cleavage. Thus, in BNP cleavage the hydrolytic properties of these complexes are not only determined by the nucleophilicity of the Zn−OH functions. This behavior has been already observed in both mono- and dinuclear Zn^{II} complexes and can be explained in terms of an "associative" mechanism,[24,32−34] in which the substrate approaches the $[Zn_2L(OH)_2]^{2+}$ complexes and the oxygen atoms of BNP associate with the electrophilic Zn^{II} ions, probably through a bridging coordination. A zinc-bound hydroxide ion then nucleophilically attacks the substrate (Figure 7). Lower pK_a values generally imply a better ability in substrate binding. The L2 complex, which contains the less nucleophilic Zn^{II}−OH functions, would give a stronger interaction with BNP during the hydrolytic process, leading to enhanced substrate activation and to higher rate acceleration. This is in agreement with the ^{31}P NMR results, which point out a higher interaction of BNP with the dinuclear L2 complex.

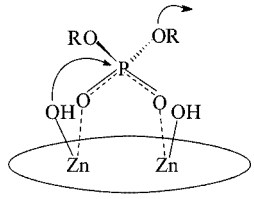

Figure 7. Proposed mechanism for BNP hydrolysis promoted by the dinuclear Zn^{II} complex with L2 and L3

Actually, the hydrolytic activity of the dinuclear complex with L2 is similar to that found for the mononuclear complex **1** and somewhat lower than that of the dinuclear Zn^{II} complex with [30]aneN_6O_4 (L8 in Scheme 3). The L2 complex, however, shows a better ability in BNP hydrolysis than the mononuclear complex **2**. However, experiments performed on solutions containing ligand L2 and Zn^{II} in 1:1 molar ratio in the alkaline pH region (pH = 7−10) showed that the mononuclear complex with L2 is completely unable to promote BNP hydrolysis. This suggests a cooperative effect of the two metal ions in BNP hydrolysis through a bridging coordination of the substrate to the two Zn^{II} ions, as actually confirmed by the marked upfield shift observed for the ^{31}P NMR signal of BNP upon coordination to the L2 complex.

The most interesting finding in Table 2, however, is the remarkably high k_{BNP} value found for $[Zn_2L3(OH)_2]^{2+}$, which is almost eight times more active than the corresponding L2 complex. A tentative explanation for this effect could reside in the stronger interaction of the L3 complex with BNP suggested by the ^1H and ^{31}P NMR results. Although precipitation of a solid complex {a compound of stoichiometry $[Zn_2L3](BNP)_2(ClO_4)_2$ precipitates at pH = 10 with a molar ratio of BNP/dizinc complex > 5; $C_{48}H_{56}Cl_2N_{11}O_{24}P_2Zn_2$ (1434.67): calcd. C 40.22, H 3.93, N 10.74, P 4.32; found C 40.76, H 4.08, N 10.55, P 4.5} at high molar ratios between BNP and the L3 dizinc complex prevents a Michaelis−Menten analysis of this hydrolytic

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

process, the simultaneous bridging coordination of the phosphate ester to the two metal centers and π-stacking and/or hydrophobic interactions between phenanthroline and the *p*-nitrophenylene groups of BNP could reinforce the interaction between the dizinc complex and the substrate.

Conclusions

Ligands L1−L3 present similar binding features toward Zn^{II}, giving rise to both mono- and dinuclear complexes in aqueous solutions. The dizinc complexes are characterized by a marked tendency to form hydroxo species; the relatively low number of nitrogen donors, in fact, cannot fulfil the coordination sphere of two metal ions and, therefore, facile deprotonation of Zn^{II}-bound water molecules occurs on going from from neutral to alkaline pH values. This feature parallels the behavior of Zn^{II}-based hydrolytic enzymes, where Zn−OH functions behave as nucleophilic agents in the overall catalytic process.

Despite the similar coordination properties of L1−L3, their dizinc complexes display remarkably different hydrolytic ability. While the dinuclear Zn^{II} complexes with L1 and L2 show a hydrolytic activity toward NA and BNP similar to that reported for other Zn^{II} complexes developed as functional models for hydrolytic metalloenzymes, the dinuclear Zn^{II} complexes with L3, which contain a large and hydrophobic heteroaromatic moiety, give remarkably higher rate enhancements; among synthetic dizinc complexes, the L3 complex is one of the most active in both NA and BNP hydrolysis. The synergetic role in BNP binding of phenanthroline, which can give π-stacking and hydrophobic interactions with the aromatic rings of the substrate, and of the two metal ions, which act cooperatively in substrate coordination, probably gives a higher BNP activation.

Experimental Section

General Procedures: Ligands L1 and L2 were prepared as described elsewhere and handled as their hydrochloride salts.[25,26] UV/Vis spectra were recorded with a Shimadzu UV-2101PC spectrophotometer.

NMR Measurements: The ^1H and ^{13}C NMR spectra were recorded with Varian UNITY 300 and UNITY 400 spectrometers, operating at 299.95 and 399.95 MHz for ^1H and at 75.43 and 100.58 MHz for ^{13}C. The spectra were obtained at room temperature in D_2O or $CDCl_3$ solutions. For the ^{13}C NMR spectra dioxane was used as a reference standard (δ = 67.4 ppm) and for the ^1H NMR spectra the solvent signal. Adjustments to the desired pH were made by adding drops of DCl or NaOD solutions. The pH was calculated from the measured pD values using the correlation pH = pD − 0.4.[39] In the ^{31}P and ^1H NMR titrations, increasing amounts of 1 × 10^{-2} M solutions in MeOD/CD_3CN (50:50, v/v) or in D_2O at pH = 10 of the preformed Zn^{II} complexes with L1−L3 (see below) were added to a 5 × 10^{-3} M solution of BNP. The addition constants of BNP to dizinc complexes with L2 and L3 were calculated by means of the HYP NMR program.[40] TMS or DSS were used as internal standard.

2,6,9,12,16-Pentaaza[17](2,9)(1,10)phenanthrolinophane Pentahydrobromide (L3·5HBr): 4,7,10-Tris(*p*-tolylsulfonyl)-4,7,10-triaazatridecane-1,13-diamine (2.5 g, 3.68 mmol)[41] and 1,10-phenanthroline-2,9-dicarboxaldehyde (0.88 g, 3.73 mmol) were stirred overnight in a mixture of $CHCl_3$ and MeOH (1:5; 300 mL) to give the imine. Sodium borohydride (0.57 g, 15.2 mmol) was added and the mixture was stirred at room temperature for 24 h. The solvent was then removed at reduced pressure. The resulting residue was treated with water (50 mL) and extracted with dichloromethane (2 × 45 mL). Then, it was dried with Na_2SO_4 and the solvent removed by rotary evaporation. The tosyl groups of tritosylated L3 (3 g, 3.39 mmol) were removed by reductive cleavage with a 33% HBr/AcOH mixture (120 mL) and phenol (15 g, 160 mmol) heating at 90 °C for 18 h and then cooling to obtain a white solid. The resulting solid was filtered off and washed several times with CH_2Cl_2 and EtOH. The macrocycle was obtained as its hydrobromide salt (1.2 g, yield 44%). ^1H NMR (D_2O): δ = 1.95−2.03 (m, 4 H), 2.99 (t, J = 8 Hz, 4 H), 3.12 (t, J = 8 Hz, 4 H), 3.31−3.39 (m, 8 H), 4.6 (s, 4 H), 7.63 (d, J = 8 Hz, 2 H), 7.75 (s, 2 H), 8.34 (d, 2 H) ppm. ^{13}C NMR (D_2O): δ = 22.9, 43.3, 43.7, 45.1, 45.5, 51.9, 123.7, 127.5, 129.4, 139.9, 150.9 ppm. $C_{24}H_{40}N_7$·5HBr (831.19): calcd. C 34.89, H 4.88, N 11.88; found C 35.0, H 4.9, N 12.0.

Synthesis of the Dinuclear Zn^{II} Complexes with L1−L3: The Zn^{II} complexes $[Zn_2L1](ClO_4)_4$·$2H_2O$, $[Zn_2L2](ClO_4)_4$·$4H_2O$ and $[Zn_2L3](ClO_4)_4$·$2H_2O$ were obtained by slow evaporation of the solvent from butanol solutions containing ligands L1−L3 and $Zn(ClO)_4$·$6H_2O$ in a 1:2 molar ratio and characterized by means of elemental analysis. $[Zn_2L1](ClO_4)_4$·$2H_2O$: $C_{14}H_{40}Cl_4N_6O_{18}Zn_2$ (853.19): calcd. C 19.71, H 4.73, Cl 16.62, N 9.85; found C 19.99, H 4.78, Cl 16.3, N 10.01. $[Zn_2L2](ClO_4)_4$·$4H_2O$: $C_{22}H_{50}Cl_4N_6O_{20}Zn_2$ (991.26): calcd. C 26.66, H 5.08, Cl 14.31, N 8.48; found C 26.75, H 5.12, Cl 14.2, N 8.57. $[Zn_2L3](ClO_4)_4$·$2H_2O$: $C_{24}H_{39}Cl_4N_7O_{18}Zn_2$ (986.20): calcd. C 29.23, H 3.39, Cl 14.38, N 9.94; found C 29.79, H 3.51, Cl 14.2, N 10.05.

emf Measurements: The potentiometric titrations were carried out at 298.1 ± 0.1 K using 0.15 M $NaClO_4$ as supporting electrolyte. The experimental procedure (burette, potentiometer, cell, stirrer, microcomputer, etc.) has been fully described elsewhere.[42] The acquisition of the emf data was performed with the computer program PASAT.[43] The reference electrode was an Ag/AgCl electrode in saturated KCl solution. The glass electrode was calibrated as a hydrogen-ion-concentration probe by titration of previously standardized amounts of HCl with CO_2-free NaOH solutions and determining the equivalent point by Gran's method,[44] which gives the standard potential, $E^{0\prime}$, and the ionic product of water [pK_w = 13.73(1)]. The computer program HYPERQUAD was used to calculate the protonation and stability constants.[45] The protonation constants of L1 and L2 were taken from refs.[25,26], respectively. Protonation constants of L3 determined in 0.15 M NaCl at 298.1 K are as follows: log $K_{HL/H\cdot L}$ = 10.0(1), log $K_{H2L/HL\cdot H}$ = 9.15(1), log $K_{H3L/H2L\cdot H}$ = 7.81(1), log $K_{H4L/H3L\cdot H}$= 6.42(1), log $K_{H5L/H4L\cdot H}$ = 2.97(2). The pH range investigated was 2.5−10.5 and the concentration of the Zn^{II} ions and that of the ligands ranged from 1 × 10^{-3} to 5 × 10^{-3} M with Zn^{II}/L molar ratios varying between 2:1 and 1:2. The different titration curves for each system (at least two) were treated either as a single set or as separate curves without significant variations in the values of the stability constants. Finally, the sets of data were merged and treated simultaneously to give the final stability constants.

Kinetics of *p*-Nitrophenyl Acetate (NA) and Bis(*p*-nitrophenyl)phosphate (BNP) Hydrolysis: The hydrolysis rate of 4-nitrophenyl acetate in the presence of the dizinc complexes of L1, L2 and L3 was

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

measured by an initial-slope method monitoring the increase in the 403-nm absorption of the released 4-nitrophenolate ion at 298.1 ± 0.1 K by using the procedure reported previously.[24] The ionic strength was adjusted to 0.15 M with $NaClO_4$. The reaction solution was maintained at 298.1 ± 0.1 K. MOPS (pH = 7.0−7.8), TAPS (pH = 7.8−8.9), CHES (pH = 8.9−9.7) and CAPSO (pH = 9.1−10.2) buffers were used (50 mM). In a typical experiment, after 4-nitrophenyl acetate and the dizinc complexes $[Zn_2L1](ClO_4)_4{\cdot}2H_2O$, $[Zn_2L2](ClO_4)_4{\cdot}4H_2O$ and $[Zn_2L3](ClO_4)_4{\cdot}2H_2O$ (0.1−1.0 mM) in 10% CH_3CN solutions at appropriate pH (the reference experiment does not contain the Zn^{II} complex) were mixed, the UV absorption decay was recorded immediately and was monitored generally until 2% decay of 4-nitrophenyl acetate. For all three ligands, two species — $[Zn_2LOH]^{3+}$ and $[Zn_2L(OH)_2]^{2+}$ — promote NA hydrolysis; in the case of L1, measurements in the pH range 7.5−8.2, where the $[Zn_2L1(OH)_2]^{2+}$ complex is absent from the solution, allowed us to determine second-order k_{NA1} rate constants for promoted hydrolysis by the monohydroxo species $[Zn_2L1OH]^{3+}$ and to extrapolate the k_{NA2} values for this species in the pH range 8.7−10.0, where both species are present in solution. Measurements in the pH range 8.7−10.0 allowed us to determine k_{OBS} values. The second-order rate constants k_{NA2} for the dihydroxo complex $[Zn_2L1(OH)_2]^{2+}$ are calculated by subtracting from the k_{OBS} value at a given pH the k_{NA1} value at the same pH. An analogous procedure was used for the L2 and L3 complexes. Errors in k_{NA} values were generally 5%. The hydrolysis rate of BNP to give mono(*p*-nitrophenyl)phosphate (MNP) and *p*-nitrophenolate (the hydrolysis products were identified by means of ^1H and ^{31}P NMR spectroscopy) in the presence of the dizinc complexes with L1−L3 was measured by an initial-slope method monitoring the increase in the 403 nm absorption of the *p*-nitrophenolate at 308.1 ± 0.1 K using a similar procedure to that reported for NA. The ionic strength was adjusted to 0.1 with NMe_4NO_3. The reaction solution was maintained at 308.1 ± 0.1 K. MOPS (pH = 6.5−7.8), TAPS (pH = 7.8−8.9), CHES (pH = 8.9−10.1) and CAPS (pH = 10.1−11.4) buffers were used (50 mM). Freshly prepared stock solutions of the zinc complexes and of BNP (1−10 mM) where used in the measurements. In a typical experiment, immediately after BNP and the zinc complexes were mixed in aqueous solutions at the appropriate pH value (the reference experiment does not contain the Zn^{II} complex), the UV absorption spectrum was recorded and monitored generally until 2% decay of BNP (for each second-order rate constant determination at least five experiments were monitored until 20−30%). For all systems, only the dihydroxo complexes $[Zn_2L(OH)_2]^{2+}$ (L = L1−L3) promote BNP hydrolysis. A plot of the hydrolysis rate vs. BNP concentration (0.1−1.0 mM) at a given pH value gave a straight line, and then we determined the slope/[zinc complex] ratio as the second-order rate constants k_{BNP} [M^{-1} s^{-1}]. Errors in k_{BNPP} values were about 5%.

Microwave-Induced Polyol-Process Synthesis of Copper and Copper Oxide Nanocrystals with Controllable Morphology

Yu Zhao,[a] Jun-Jie Zhu,*[a] Jian-Min Hong,[a] Ningsheng Bian,[a] and Hong-Yuan Chen[a]

Keywords: Copper / Copper oxides / Microwaves / Nanostructures / UV / Vis spectroscopy

Different morphologies of copper and copper oxide nanocrystallites, including radially arrayed whiskers, cubic particles and sphere particles, have been successfully synthesized by a microwave-induced method under ambient conditions. In aqueous solution containing different ethylene glycol concentrations, copper acetate hydrate produces different reduction products. The as-prepared copper and copper oxide crystallites were characterized by various techniques, including X-ray powder diffraction, transmission electron microscopy, selected-area electron diffraction and UV/Vis absorption spectroscopy. It was found that microwave irradiation plays a critical role in the formation of the products; temperature was also found to be important in the reaction. The irradiation time and copper acetate concentration also affect the morphology of the products. The possible formation mechanism is also discussed.

Introduction

Nanometer-sized metals, semiconductors, and oxides are of great interest because they can have physical and chemical properties that are not characteristic of the atoms or of their bulk counterparts. The large surface area to volume ratio can contribute to some of the unique properties of nanoparticles.[1−5] Among them, Cu, Cu_2O and CuO are industrially important materials that are widely used in fields such as magnetic storage media, solar energy transformation, electronics, sensors, catalysis, batteries, resonance imaging and so forth.[6−12] In the past, some successful attempts have been made to synthesize nanoparticles of copper and copper oxides, such as sonochemical methods,[13−15] microwave irradiation,[16] photochemical methods,[17−20] hydrothermal and solvothermal methods,[21,22] electrochemical methods,[23−31] sol-gel methods,[32−35] solid-state reactions,[36] chemical reduction and decomposition route[37−42] and so on.

Microwaves are a portion of the electromagnetic spectrum with frequencies in the range of 300 MHz to 300 GHz. The corresponding wavelengths of these frequencies are 1 m to 1 mm. The most commonly used frequency is 2.45 GHz. The degree of interaction of microwaves with a dielectric medium is related to the material′s dielectric constant and dielectric loss.[43] When microwaves penetrate and propagate through a dielectric solution or suspension, the internal electric fields generated within the affected volume induce translation motions of free or bound charges such as electrons or ions and rotate charged complexes such as dipoles.[43] The resistance of these induced motions due to inertial, elastic, and frictional force, which are frequency dependent, causes losses and attenuates the electric field. Compared to ultrasonic irradiation, there is no similar bubble formation during microwave heating, although superheating occurs in localized spots. The main advantages of microwave-assisted reactions over conventional methods in synthesis are: (a) the kinetics of the reaction are increased by one to two orders of magnitude, (b) novel phases are formed, (c) the initial heating is rapid, which can lead to energy savings, and (d) selective formation of one phase over another often occurs.[44−46] One possible hypothesis for these microwave-induced effects is the generation of localized high temperatures at the reaction sites to enhance reaction rates in an analogous manner to that of ultrasonic waves,[47] where both high temperatures and pressures have been reported during reactions. The enhanced kinetics of crystallization can lead to energy savings of up to 90%.[48]

The polyol method is a low-temperature process that is environmentally benign because the reactions are carried out under closed-system conditions. It was first introduced to produce metal submicron-sized powders.[49−51] In this method, a suitable solid metal salt is suspended in a liquid polyol. The suspension is stirred and heated to a certain temperature; the reduction of the starting compound yields fine metal powders. The polyol itself acts not only as a solvent in the process but also as a stabilizer, limiting particle growth and prohibiting agglomeration.[52−54] Recently, this method has also been extended to the preparation of metal oxides[55−57] and metal chalcogenides.[58−60] Tarascon and co-workers have demonstrated that in these reactions the

temperature is a dominant factor in affecting the reactivity. Three factors are influenced by the temperature: (1) the reduction potential of ethylene glycol, (2) the rupture and creation of chemical bonds, and (3) diffusion.[61] All these factors make microwave-heating techniques favorable for the fabrication of metal and metal oxides by using ethylene glycol as a solvent. The ethylene glycol is an excellent susceptor for the microwave radiation because of its high permanent dipole. The metallic particles produced as intermediates in the polyol reaction are also good for this purpose.

In this paper, we present a novel microwave-induced polyol route to synthesize different morphologies of Cu, Cu_2O and CuO nanoparticles. Ethylene glycol (EG) aqueous solutions with different concentration were used in order to control the reaction temperature during the microwave heating. Cu, Cu_2O or CuO were formed in the different conditions. The effect on the morphology of the nanoparticles was also investigated. It was found to be a fast, convenient, mild, energy efficient and environmentally friendly route to produce nanoparticles of Cu, Cu_2O and CuO.

Results and Discussion

In order to study the nature and morphology of the products, various techniques such as X-ray diffraction (XRD), transmission electron microscopy (TEM), selected-area electron diffraction (SAED) and UV/Vis absorption spectroscopy were employed.

The results of the powder XRD analysis are shown in Figure 1 (see a−e). The diffraction peaks correspond to the reflection of: (a) CuO (CCID file no. 801916 monoclinic), (b) CuO mixed with Cu_2O, (c) Cu_2O (CCID file no. 782076 cubic), (d) Cu_2O mixed with Cu, and (e) Cu (CCID file no. 040836 cubic). In all the reactions, highly crystalline products were obtained. The positions of the peaks are in good agreement with literature values.

TEM images of the products are presented in Figure 2 (see a−e), where the different morphologies that be achieved simply by changing the water/EG ratio of the solvent can be clearly observed. Figure 2 (a) depicts the morphology of CuO, which shows radially arrayed whiskers. In this image, a single whisker is calculated to be about 80 nm in length and less than 10 nm in diameter; the SAED pattern of the products is shown in the inset. Figure 2 (b) shows a mixture of whiskers and cubic particles. Two different phases can be observed clearly in this picture. According to the SEAD images, and compared with the other SEAD patterns shown in Figure 2 (see a and c), it can be concluded that the whiskers are CuO of monoclinic phase [SAED pattern inset top right in Figure 2 (b)], and the cubes are Cu_2O in the cubic phase (SAED pattern inset bottom left). Cu_2O particles are observed as shown in Figure 2 (c); they are around 50 nm cubic nanoparticles. The SAED pattern of a single crystal of one of these particles is shown in the inset. Figure 2 (d) depicts Cu mixed with Cu_2O particles; the products are not clearly separated. We conclude it to be mixture only by the XRD pattern in Figure 1. Figure 2 (e) depicts Cu particles, the size of which ranges from 100−120 nm. The SEAD pattern of these copper particles is inset.

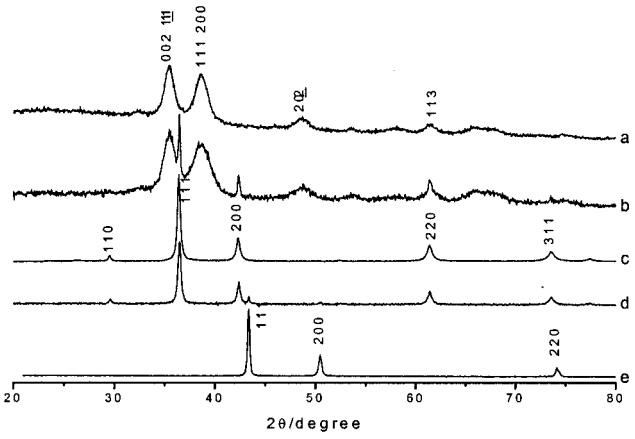

Figure 1. XRD patterns of: (a) CuO; (b) CuO mixed with Cu_2O; (c) Cu_2O; (d) Cu_2O mixed with Cu; (e) Cu

In order to elucidate the mechanism of temperature control in the EG aqueous solution, we first supposed that the ethylene glycol and water mixture is an ideal binary system, which therefore behaves according to Raoults Law

$$y_A = x_A \cdot P^*_A / P$$

with y_A = mol fraction of substance A in the vapor phase equilibrium with the solution, X_A = mol fraction of substance A in the solution; P^*_A = equilibrium vapor pressure of substance A; P = vapor pressure of the whole system.

We calculated the theoretical boiling point of the system at different water volume ratios; the results are depicted in Figure 3. In our microwave dielectric heating process, the system temperature elevates rapidly. The reaction temperatures measured fit well with the theoretical values. As a result, an accurate and average temperature can be controlled in our microwave dielectric heating system.

As far as we know, when the solvent is pure ethylene glycol copper acetate is only partly dissolved and no chemical reaction occurs at 108 °C; when the solvent is water, copper acetate is completely soluble. On the contrary, in the EG aqueous solution, when the reaction temperature varies between 90 and 108 °C, CuO can be produced. We propose the process of producing CuO as follows: first, copper acetate hydrate dissolves in the solution; then EG esterifies with OAc^- to produce ethylene glycol monoacetate and OH^-; finally OH^- and Cu^{2+} ion combine in solution and then dehydrate to form CuO. The reaction can be schematized as follows:

$$CH_3COO^- + HOCH_2CH_2OH \xrightarrow{\Delta} CH_3COOCH_2CH_2OH + OH^- \quad (1)$$

$$Cu^{2+} + 2\,OH^- \xrightarrow{\Delta} CuO\,(s) + H_2O \quad (2)$$

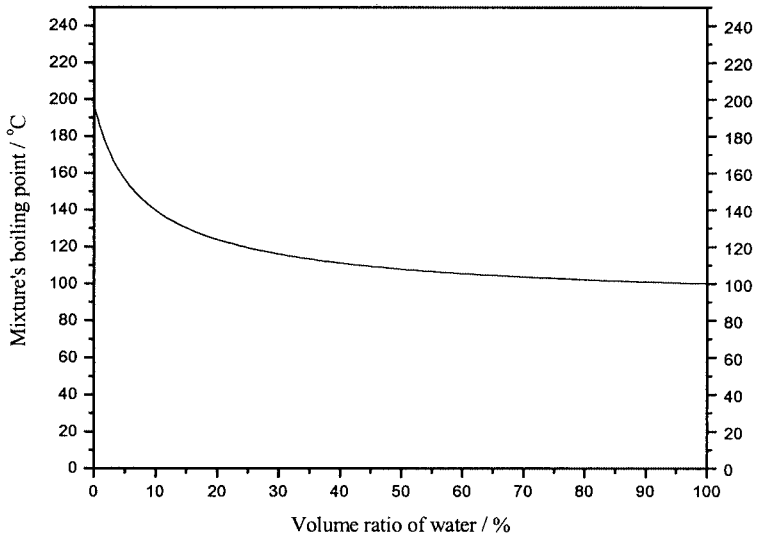

Figure 3. Theoretical boiling points with different EG volume ratios in the EG aqueous system

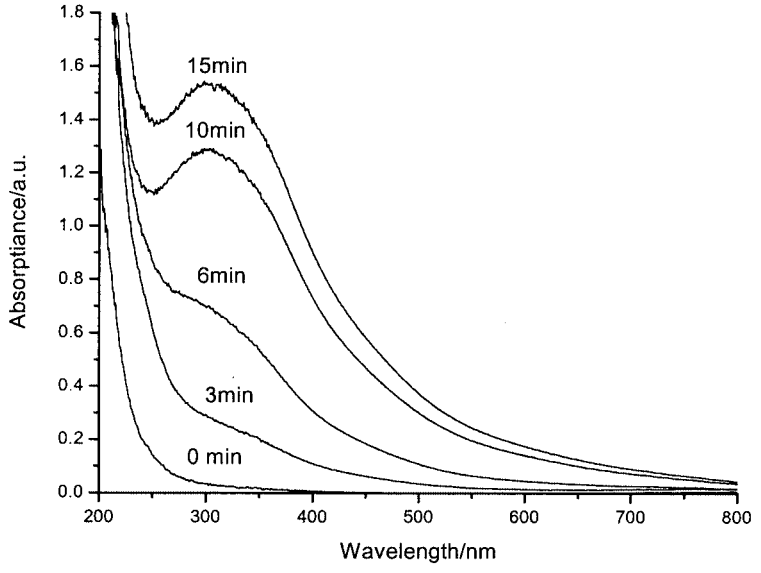

Figure 4. The UV/Vis absorption spectra of a suspension of copper acetate (0.03 g/40 mL) suspended in 49% EG aqueous solution after different microwave irradiation times; the numbers on the spectra indicate the time of irradiation; path length = 1 cm

To prove the reaction mechanism, we removed the water from the solvent for GC-MS detection after removing the precipitate by centrifugation. The results show that ethylene glycol monoacetate is the only reaction product remaining in solution.

To demonstrate the formation process of CuO nanocrystals, we recorded UV/Vis absorption spectra at different reaction times (Figure 4). There is no absorption present at the beginning of the reaction (0 min). As the reaction proceeds, however, an absorption shoulder appears at around 310 nm. After 15 minutes irradiation, the suspension becomes dark-brown, and a broad absorption peak centered at 310 nm can be observed. There is no obvious shift of the absorption peak with time. This means that the crystal size changes very little during the whole precipitation process. As an ionic reaction, reaction 2 is comparatively fast, so the formation of CuO nanocrystals is determined by reaction 1. In this process, the single whiskers prepared from different copper acetate concentration have the same size.

Figure 5 (see a−d) shows the change in morphology of as-prepared CuO as a function of time. The growth of CuO-whisker arrays can be described by three steps. First, crystal seeds of CuO are formed. These seeds then grown into whiskers, and, in the end, the CuO whiskers assemble into radially arrayed whiskers.

The concentration of copper acetate also plays a dramatic role in determining the morphology (Figure 6). In the case of a single whisker of the CuO nanocrystals, the crystal size is almost the same for all copper acetate concentration, but the morphology varies: the higher the concentration is, the denser the radial arrays will be. As we can see, when the

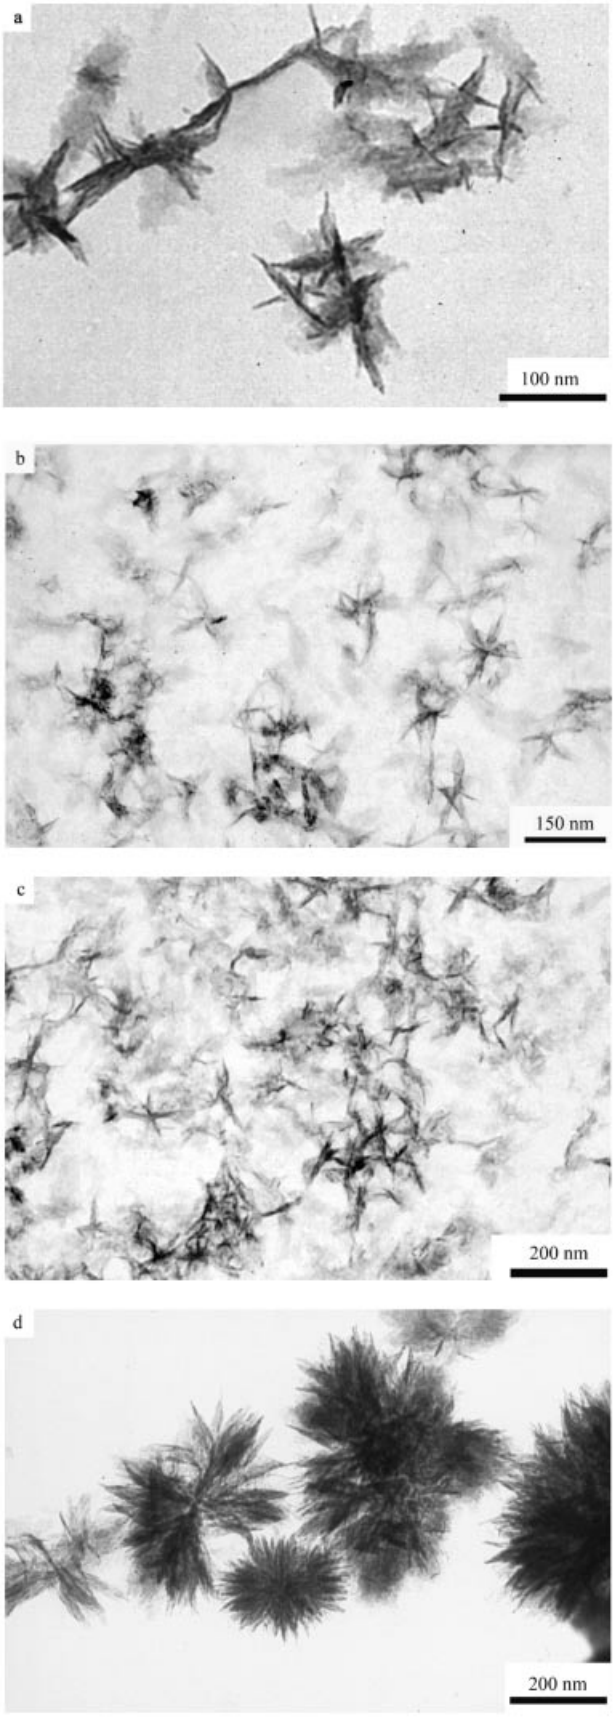

Figure 5. TEM images of CuO as a function of reaction time: a) 3 min; b) 6 min; c) 10 min; d) 15 min (0.03 g/40 mL copper acetate in 49% EG aqueous solution)

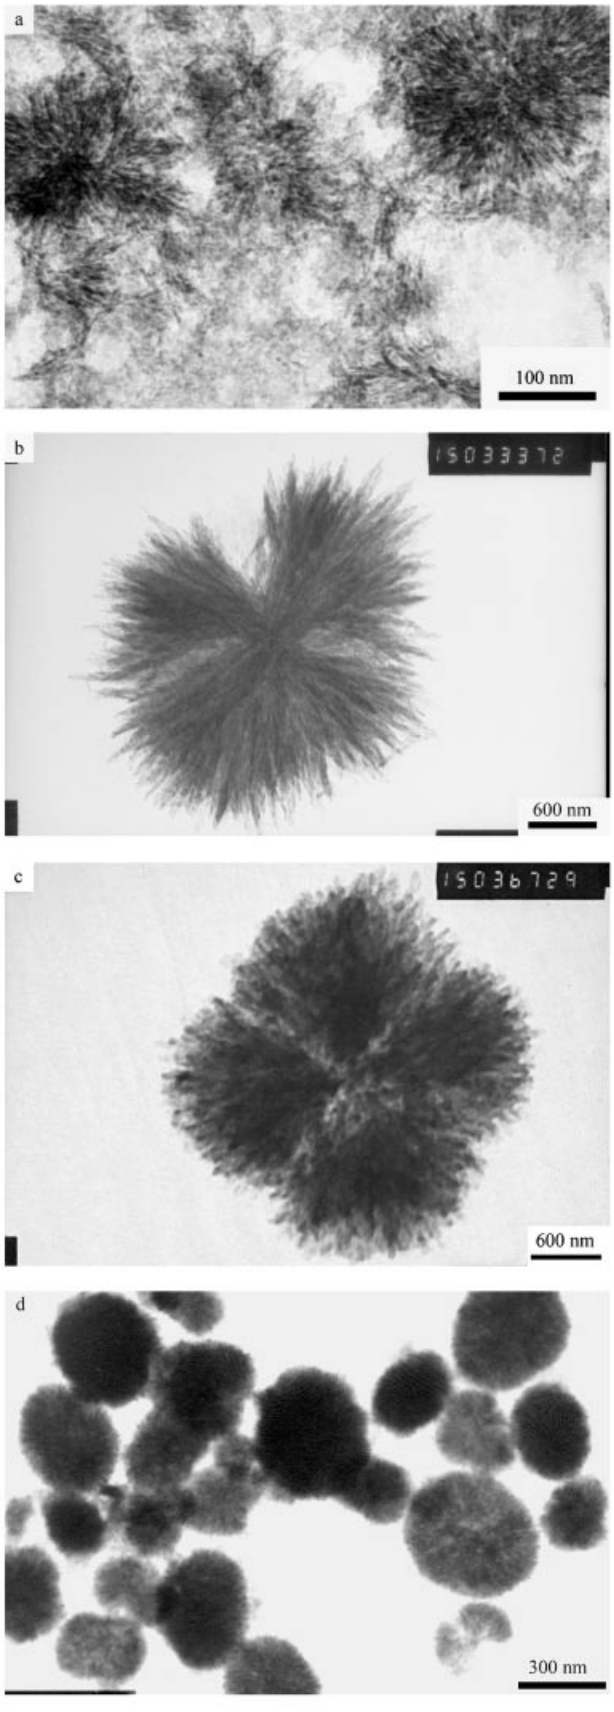

Figure 6. TEM images of CuO at various copper acetate concentrations: a) 0.03 g; b) 0.30 g; c) 0.70 g; d) 1.00 g (in 40 mL 49% EG aqueous solution)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

copper acetate concentration increases to 0.70 g/40 mL, the CuO radical arrays are so dense that they look like a sphere (see d in Figure 6). Interestingly we also found that the growth of the radial whisker arrays is directed mainly along the axes of a tetrahedron.

Cu and Cu_2O nanocrystals can also be prepared by this method; they follow a reduction mechanism. At 197 °C, the reduction product is Cu. Fievet et al.[2] have proposed that the metal particles are formed by nucleation and growth from the solution. According to this mechanism, we have proposed a formation process for the Cu nanoparticles: first, under dielectric heating, copper acetate hydrate dissolves completely in ethylene glycol, and then the intermediate solid phase between the starting material and the final metal powder is formed; during the second stage of the reaction the re-dissolution of the intermediate solid phase takes place. The reduction action of ethylene glycol is due to diacetyl, which is formed by a duplicative oxidation of acetaldehyde previously produced by dehydration of ethylene glycol.

The reaction can be schematized as follows:

$$2\ CH_2OH\text{-}CH_2OH \xrightarrow{-H_2O} 2\ CH_3CHO$$

Intermediate phase

$$\longrightarrow CH_3\text{-}CO\text{-}CO\text{-}CH_3 + H_2O + 2\ Cu$$

UV/Vis spectra were taken as a function of time (Figure 7). After six minutes irradiation, an absorption shoulder appears at around 490 nm, which indicates an intermediate phase. The phase will be shown to be Cu_2O later. After nine minutes, colloidal copper has formed with an absorption peak at 580 nm. This absorption can be attributed to the plasma resonance absorption of the copper particles. As the reaction progresses, the copper colloid aggregates and precipitates. As a result, after 15 minutes the absorption peak at 580 nm has almost disappeared.

Figure 8 (a−d) depict the change in morphology of copper as a function of time. After six minutes, Cu_2O cubic particles of about 300 nm have formed. This Cu_2O is continuously being reduced to give dispersedCu particles with a dispersed particle size of about 15 nm in diameter (c in Figure 8). However, after reaction for 15 minutes, the Cu aggregates into particles of about 60 nm.

Cu_2O is obtained at 140 °C. UV/Vis absorption spectra were recorded after different reaction times to investigate the reaction (Figure 9). Only after 12 minutes did the absorption shoulder at around 460 nm appear. This peak can be attributed to Cu_2O, and corresponds well with the absorption band of the intermediate phase in the preparation of Cu nanoparticles.

The growth of Cu_2O nanoparticles was also investigated (Figure 10). As can be seen from the morphology of Cu_2O after different reaction times, the Cu_2O is formed as cubes of about 40 nm (Figure 10, a). As the reaction proceeds the particles grow further. It is interesting that hexagons [Figure 10 (d)] and truncated cubes [Figure 10 (e)] are also found in the reaction products; they can be regarded as intermediate morphologies en route to cubic particles. An SEAD pattern was also measured. As calculated, the inserted SEAD pattern of a truncated cube in Figure 10 (d) shows the (001) face and the hexagon in Figure 10 (e) shows the (111) face; they are both Cu_2O of primitive cubic phase. As the reaction time is prolonged to 30 minutes, we can get cubic Cu_2O as large as 500 nm. It is therefore possible to control the size of the Cu_2O crystals.

Conclusion

Using a novel microwave-induced polyol process, we have successfully synthesized copper, cuprites and copper(II) oxides systematically. The EG aqueous solution was heated by microwave irradiation, easy and precise control on the temperature was realized. By varying the conditions we

were able to prepare products with different morphology and particle sizes. A formation mechanism of the as-prepared products was proposed and the effects on the morphology and size were investigated. This kind of method is advantageous as it is a one-step reaction that occurs at relatively mild temperatures and gives well-dispersed products. Its extension to the preparation of other materials is currently being investigated.

Experimental Section

General: All the experiments were performed in a modified National frequency-convertible microwave oven (NN-S570MFS). A reflux system was connected to the microwave oven. X-ray powder diffraction (XRD) measurements were performed on a Philips X′pert X-ray diffractometer at a scanning step of 0.03°, continue time 10 seconds, in the 2q range from 20° to 80°, with graphite monochromated Cu-K_a radiation (l = 0.15418 nm) and a nickel filter. Transmission electron microscopy (TEM) images and selected-area electron diffraction (SAED) images were recorded on a JEOL-JEM 200CX transmission electron microscope, at an accelerating voltage of 200 kV. The samples used for TEM observations were prepared by dispersing some products in ethanol followed by ultrasonic vibration for 30 min, then placing a drop of the dispersion onto a copper grid coated with a layer of amorphous carbon. A Shimazu UV-2401PC photospectrometer was used to record the UV/Vis absorption spectra of the as-prepared samples dispersed in water.

Synthesis of Copper and Copper Oxides: In a typical procedure, the appropriate amount of $Cu(OAc)_2 \cdot H_2O$ was added into an 80 mL round-bottomed flask, and then 40 mL of EG aqueous solution was added into the same flask. The mixture was placed into the microwave reflux system and the reaction was carried out under ambient conditions for 15 minutes at a power of 365 W. The detailed reaction conditions in various EG aqueous solutions are listed in Table 1. The reactants dissolved in the EG aqueous solution after irradiating for 3 min. As the reaction progressed a large amount of precipitate formed (dark-brown for CuO, reddish yellow for Cu_2O, and red for Cu). After the reaction, the suspension was

Phenylmalonate-Containing Copper(II) Complexes: Synthesis, Crystal Structure and Magnetic Properties

Jorge Pasán,[a] Joaquín Sanchiz,[b] Catalina Ruiz-Pérez,*[a] Francesc Lloret,[c] and Miguel Julve[c]

Keywords: Copper / Magnetic properties / N ligands / O ligands

Three new copper(II) complexes of formula [Cu(2,2′-bpy)(Phmal)(H_2O)]·2H_2O (**1**), [{Cu(2,2′-bpym)(Phmal)}]$_n$ (**2**) and [{Cu(phen)(Phmal)}]$_n$·3$n$$H_2O$ (**3**) (Phmal = phenylmalonate; 2,2′-bpy = 2,2′-bipyridine; 2,2′-bpym = 2,2′-bipyrimidine; phen = 1,10-phenanthroline) have been prepared and their structures determined by X-ray diffraction techniques. Complex **1** is mononuclear whereas **2** and **3** are uniform chain compounds. The copper atoms in **1**–**3** are distorted square-pyramidal: two nitrogen atoms from the bidentate nitrogen heterocycle and two carboxylate oxygen atoms from the phenylmalonate ligand build the equatorial plane; the axial position is filled either by a water molecule (**1**) or a carboxylate oxygen atom from another phenylmalonate group (**2** and **3**). The values of the intrachain copper–copper separation through the phenylmalonate-carboxylate bridge in the *anti-syn* conformation are 4.6853(7) (**2**) and 5.014(3) Å (**3**). The phenyl ring of the Phmal ligand in **1** produces an unusual intramolecular π–π stacking interaction with the Cu^{II}–(aromatic 2,2′-bpy) chelate ring. Intrachain edge-to-face phenyl–pyridyl and offset phen–phen-type interactions occur in **2** and **3**, respectively. Magnetic susceptibility measurements of **2** and **3** in the temperature range 1.9–290 K show the occurrence of weak intrachain ferromagnetic interactions between the copper(II) ions through the phenylmalonate-carboxylate bridge [J = +0.10(1) (**2**) and +0.31(1) cm^{-1} (**3**)]. These values are compared with those reported for malonate-containing copper(II) complexes with the same exchange pathway through the *anti-syn* carboxylate bridge.

Introduction

The design of synthetic pathways to obtain systems with desired properties continues to be a challenge for inorganic chemists. In this context, a great interest has been devoted to the development of rational synthetic routes to novel polynuclear compounds of tuneable dimensionality which may have applications as molecule-based magnetic materials.[1−3] Many recent reports have focused on the synthesis and magneto-structural characterization of polymeric transition metal compounds using malonate (dianion of propanedioic acid, H_2mal) as both blocking and bridging ligand.[4−10] In the framework of our research with malonate-containing metal complexes[8−13] we have been able to prepare a large number of compounds with different structures and properties whose dimensionality goes from zero in the mononuclear species [Cu(mal)(2,2′-bpym)][14] (2,2′-bpym = 2,2′-bipyrimidine) to three in the compound [Cu(mal)(pyz)]$_n$ (pyz = pyrazine).[15] The variety of the coordination modes of the malonate ligand in these compounds has been reviewed very recently.[9] From a magnetic point of view, the parameters governing the nature and magnitude of the magnetic interactions between copper(II) ions are the conformation of the bridge (*anti-anti*, *anti-syn*, *syn-syn*), the environment of the metal atom,[16,17] and the relative orientation of the malonate-carboxylate bridge with respect to the metal environment (equatorial-equatorial, equatorial-apical and apical-apical with relatively strong, weak and negligible interactions, respectively), in addition to the Cu−O(carboxylate) distances.[10]

More recently, we have started a systematic study on copper(II) complexation by substituted malonate ligands such as phenylmalonate (dianion of phenylmalonic acid, H_2Phmal). One of the aims of this study is to analyze the influence that factors such as the withdrawing effect, the rigidity and the possibility of specific attractive interactions between phenyl rings can exert on the structure and magnetic coupling of phenylmalonate-containing copper(II) complexes.[17] In a previous work, we have observed that

the complex $[\{Cu(H_2O)_3\}\{Cu(Phmal)_2\}]_n$ has a layered structure induced by the phenyl groups and intralayer ferromagnetic couplings through phenylmalonate-carboxylate and -oxo bridges. Here we show how the structure and magnetic properties of this layered system are modified by the presence of coligands such as 2,2′-bipyridine (2,2′-bpy), 2,2′-bipyrimidine (2,2′-bpym) and 1,10-phenanthroline (phen). These are all aromatic nitrogen heterocycles that, in addition to their good coordinating ability (metal−ligand bonds), can interact with the phenyl ring of the Phmal group (supramolecular interactions), making this system very appropriate to illustrate the effects of both types of interactions.

We report herein the synthesis, crystallographic analysis and magnetic study of the copper(II) complexes of formula $[Cu(2,2'\text{-bpy})(Phmal)(H_2O)]\cdot 2H_2O$ (**1**), $[\{Cu(2,2'\text{-bpym})(Phmal)\}]_n$ (**2**) and $[\{Cu(phen)(Phmal)\}]_n\cdot 3nH_2O$ (**3**). Complex **1** is a magnetically isolated mononuclear species whereas **2** and **3** are uniform chains with intrachain ferromagnetic interactions.

Results and Discussion

Synthesis of the Complexes

Complexes **1**−**3** were prepared by reaction of stoichiometric amounts copper(II) phenylmalonate with the appropriate heterocyclic N-donor in a methanol water mixture. X-ray quality crystals of the mononuclear complex **1** and the chain compounds **2** and **3** were grown from concentrated solutions by slow solvent evaporation.

Description of the Crystal Structures

[Cu(2,2′-bpy)(Phmal)(H$_2$O)]·2H$_2$O (1)

The structure of **1** consists of neutral [Cu(Phmal)(2,2′-bpy)(H$_2$O)] mononuclear entities (Figure 1a) and crystallization water molecules. The molecular units are linked by hydrogen bonding involving the uncoordinated phenylmalonate oxygen atoms and the crystallization water molecules, with O···O distances ranging from 2.667(3) to 2.972(4) Å (see Table 1). A surprising two-dimensional (6,3) net results (Figure 2) which contributes to the stabilization of the whole structure. Adjacent layers are linked by weak offset π−π-stacking interactions between pyridyl rings. The shortest offset angle between pyridyl rings is 28.5° while the shortest centroid−centroid contact is 3.966(4) Å, values which are slightly larger than the average values in π−π interactions with pyridine-like groups previously reported.[18]

The molecular structure of **1** is remarkably similar to that of the recently reported[19,20] complexes $[Cu(Bzmal)(phen)(H_2O)]\cdot 3H_2O$ and $[Cu(Bzmal)(2,2'\text{-bpy})(H_2O)]\cdot 2H_2O$ (Bzmal = 2-benzylmalonate) compounds. The phenyl rings of Bzmal and Phmal are located over the N−C−C−N−Cu chelate ring in the three complexes and metalloaromaticity was pointed out to be the factor responsible for this structural feature.[19] A search in the Cambridge Structural Database has shown the existence of several compounds which present the same conformation (listed in Table 2). The value of the dihedral angle between the mean planes in complex **1** is larger (25.5°) than in the other compounds (1.2−14.5°) due to geometrical constraints that preclude the parallel arrangement of the phenyl group above the chelate ring. All the structures found in the search contain a ligand with the nitrogen atoms inside the aromatic rings (i.e. always 2,2′-bpy or phen but never *N*,*N*′-ethylenediamine). According to Janiak,[18] phenyl rings do not like to stack above each other but to adopt an offset (parallel displaced) arrangement, thus leading to C−H···π-type interactions. Therefore, we suggest that this is responsible for the situation of the phenyl group above the chelate ring (i.e. displaced from the stacked position over the pyridyl groups). We can compare this structure with that of the reported mononuclear complex $[Cu(2,2'\text{-bpy})(mal)(H_2O)]\cdot H_2O$,[30] where the monomeric units are distributed in bilayers in the *bc* plane through hydrogen bonds involving the malonate-carboxylate groups and the coordinated and uncoordinated water molecules. The hydrophobic interactions in **1** form layers of different hydrophilic character with the aromatic rings in one and the phenylmalonate oxygen atoms and water molecules in the other one. A remarkable difference between both compounds is the position of the methylene group: it is directed toward the coordinated water molecule in the malonate compound whereas the metalloaromaticity in the case of **1** causes the methylene C−H bond to point towards the opposite side of the coordinated water molecule.

Each copper atom in **1** exhibits a somewhat distorted square-pyramidal environment, with a τ value[31] of 0.14. The copper atom is bound to two 2,2′-bpy nitrogen atoms [2.001(2) and 1.998(2) Å for Cu(1)−N(1) and Cu(1)−N(2), respectively] and to two carboxylate oxygen atoms from the Phmal ligand [1.954(2) and 1.933(2) Å for Cu(1)−O(2) and Cu(1)−O(4)] in the basal plane, and to a water molecule in the apical position [2.143(2) Å for Cu(1)−O(1w)]. The 2,2′-bpy and Phmal groups in **1** adopt a bidentate coordination mode, the values of the angles subtended at the copper atom by them being 80.53(8)° and 90.09(7)°, respectively. The 2,2′-bpy ligand is practically planar [the value of the dihedral angle between the mean pyridyl planes is 1.1(1)°] and its bond lengths and angles are in agreement with those reported for free 2,2′-bpy.[32] The Phmal group exhibits the boat conformation as in $[\{Cu(H_2O)_3\}\{Cu(Phmal)_2\}]_n$.[17] However, the Phmal group in this last compound simultaneously exhibits bidentate (through two oxygen atoms of the two carboxylate groups) and bis(monodentate) (through two *trans* carboxylate oxygen atoms from two Phmal ligands) coordination modes, leading to a layered structure. The $[Cu(Phmal)_2]^{2-}$ units in this compound tend also to align their aromatic rings in the same direction, preventing the occupation of one of the axial positions of the copper(II) coordination sphere, while the other apical site is filled by another $[Cu(Phmal)_2]^{2-}$ unit. This also occurs in **1** where the aromatic ring practically fills one of the axial

positions of the copper coordination sphere and the other one is occupied by a water molecule. The shortest intermolecular copper−copper separation in **1** is 7.6494(5) Å [Cu(1)−Cu(1a); (a) = $-x + 2, -y, -z + 2$].

[{Cu(2,2′-bpym)(Phmal)}]$_n$ (2)

The structure of **2** consists of chains of [Cu(2,2′-bpym)(Phmal)] units that are linked through one phenylmalonate-carboxylate group in an *anti-syn* conformation (Figure 1b). These chains run parallel to the *a* axis and interact between themselves by means of π−π- and C−H···π-type interactions (Figure 3). There are two hydrophobic cavities where 2,2′-bpym molecules and the phenyl rings from the Phmal groups are constrained. The 2,2′-bpym groups are involved in π−π interactions, with the shortest centroid−centroid contact being 3.798(6) Å and the shortest parallel displacement angle between pyrimidyl rings being 25.7°, values which are similar to the average ones observed in π−π interactions with pyridine-like groups.[18] Weak C−H···π interactions are also present between the phenyl rings and 2,2′-bpym groups inside the chains and between phenyl groups of different chains, with the shortest H···centroid distance being 2.86(4) Å, and C−H···centroid

groups being almost collinear. The building units of the chain are rotated 90° through the normal axis of the planar 2,2′-bpym group in a twist fashion (i.e. odd units in the same position and even units rotated by 90°; Figure 3).

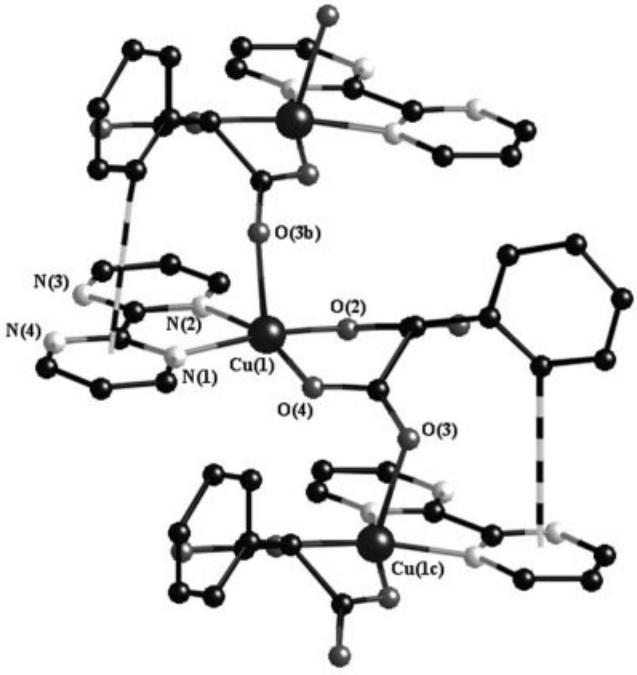

Figure 3. Fragment of the uniform chain of compound **2** showing the rotation of the units by 90° and the intrachain C−H···π interaction (dashed line)

Each copper(II) atom has a slightly distorted square-pyramidal surrounding, the τ value[31] being 0.08. Two nitrogen atoms of the 2,2′-bpym ligand [N(1) and N(2)] and two carboxylate oxygen atoms from the Phmal ligand [O(2) and O(4)] build the basal plane, whereas the symmetry-related carboxylate oxygen atom [O(3b); (b) = $-1/2 + x$, $1/2 - y$, z] occupies the apical position. The equatorial bond lengths vary in the range 1.900(3)−2.003(3) Å and the apical bond length is 2.262(3) Å. The 2,2′-bpym ligand is quasi planar [the dihedral angle between the pyrimidyl rings being 3.5(1)°] and it acts as a bidentate ligand through two [N(1) and N(2)] of its four nitrogen atoms. This coordination mode has previously been observed in several mono- and polynuclear 2,2′-bpym-containing copper(II) complexes.[14,33,34] The outer N(3) and N(4) 2,2′-bpym nitrogen atoms remain free, the N(3)···N(4) bite distance being somewhat longer [2.811(6) Å] than the N(1)···N(2) one [2.584(5) Å] due to the bidentate coordination of the 2,2′-bpym to the copper atom through N(1) and N(2). The inter-ring carbon−carbon bond length of 2,2′-bpym in **2** [1.480(6) Å for C(13)−C(14)] is close to that found in the free ligand in the solid state [1.497(1) and 1.502(4) Å].[35] As in **1**, the Phmal ligand adopts a boat conformation; the phenyl ring in **2** is placed perpendicular to the boat skeleton of the malonate in order to establish the weak intrachain C−H(phenyl)···π (pyrimidyl) interactions mentioned above. Finally, a comparison between the structure of **2** and that of the related mononuclear complex [Cu(2,2′-bpym)(mal)(H$_2$O)]·6H$_2$O[14] shows once more the structural influence of the hydrophobic phenyl ring of the Phmal ligand. The complexation reaction between the preformed [Cu(2,2′-bpym)]$^{2+}$ species and the dicarboxylate mal and Phmal ligands affords neutral hydrated mononuclear (mal) and anhydrous chain (Phmal, **2**) compounds. The structure of the former exhibits extensive hydrogen bonds involving coordinated and uncoordinated water molecules, whereas carboxylate-bridging and supramolecular C−H···π-type interactions counterbalance the lack of hydrogen bonds in the latter.

The shortest intrachain copper−copper separation in **2** is 4.6853(7) Å [Cu(1)···Cu(1c); (c) = $1/2 + x$, $1/2 - y$, z], a value which is much shorter than the shortest interchain metal−metal distance [7.3634(8) Å for Cu(1)···Cu(1d); (d) = $-x$, $1 - y$, $1 - z$].

[{Cu(phen)(Phmal)}]$_n$·3nH$_2$O (3)

The structure of complex **3** consists of chains of [Cu(phen)(Phmal)] units linked through *anti-syn* carboxylate bridges and crystallization water molecules (Figure 1c). The chains run parallel to the *a* axis and they are linked by pairs along the [011] direction through hydrogen bonds involving the water molecules and noncoordinated carboxylate oxygen atoms [the values of the O···O distance range from 2.338(13) to 3.084(5) Å; Figure 4]. Intrachain offset π−π interactions between phen ligands occur, the shortest centroid−centroid distance being 3.907(4) Å and parallel displacement angle being 28.6°, in agreement with previously reported values.[18]

Each copper(II) atom presents a slightly distorted square-pyramidal environment, with a τ value[31] of 0.10. Two carboxylate oxygen atoms from the Phmal ligand [O(2) and O(4)] and the two nitrogen atoms of phen [N(1) and N(2)] form the equatorial plane, whereas a symmetry-related carboxylate oxygen atom [O(3e); (e) = $x + 1$, y, z] occupies the apical position. The equatorial bond lengths vary in the range 1.913(2)−2.026(3) Å and the apical bond amounts to 2.314(3) Å. The angle subtended by the planar bidentate phen ligand at the copper atom is 81.86(11)°. The bond lengths and angles of the phen ligand in **3** agree well with those reported for the free molecule.[36] The conformation and coordination mode of the Phmal ligand in **3** are identical to those in **2**. However, π−π stacking between phen ligands occurs in **3** instead of the C−H(phenyl)···π(N-heterocycle)-type interaction which occurs in **2**. Moreover, the [Cu(phen)(Phmal)] chain units in **3** are not rotated by 90°, in contrast to what it is observed in **2**; this modification of the crystal packing in **3** is due most likely to the crystallization water molecules which are present in the structure of the latter compound. A comparison between the structure of **3** and that of the mononuclear complex [Cu(phen)(mal)(H$_2$O)]·1.5H$_2$O[37] reveals that weak π−π stacking interactions between phen ligands are present in both compounds. However, the mononuclear units are grouped by pairs in the malonato-containing complex, whereas a uniform chain is formed in **3**.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

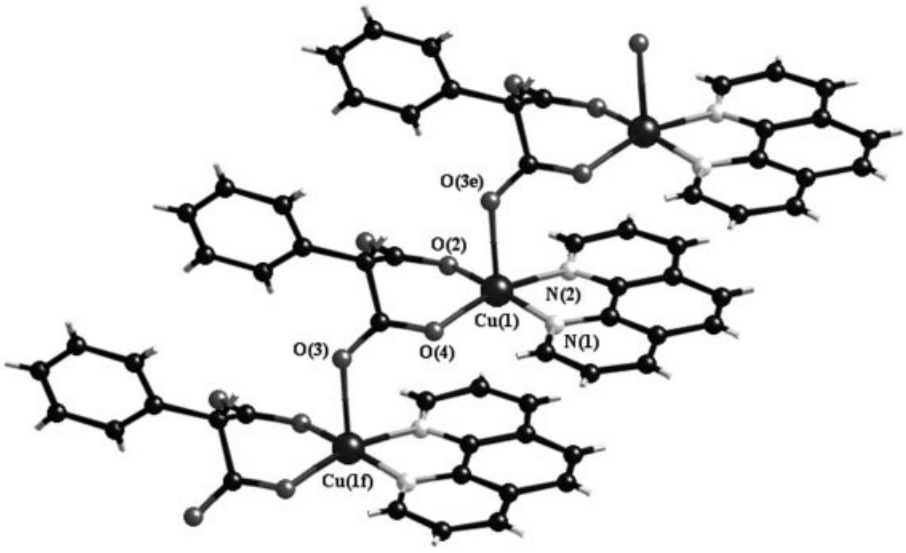

Figure 4. View of the uniform chain of compound **3** showing the phenylmalonate-carboxylate bridge in axial-equatorial *anti-syn* conformation

The shortest intrachain copper−copper separation is 5.014(3) Å [Cu(1)−Cu(1f); (f) = −1 + *x*, *y*, *z*], a value which is much shorter than the shortest interchain metal−metal distance [7.5872(16) Å for Cu(1)−Cu(1g); (g) = −1/2 + *x*, 1/2 − *y*, −1/2 + *z*].

Magnetic Properties

The $\chi_M T$ product of compound **1** obeys the Curie law in the 5−300 K temperature range. Its value is 0.365 $cm^3mol^{-1}K$, as expected for a magnetically isolated spin doublet of a copper(II) ion. This is in agreement with its mononuclear nature.

The magnetic properties of compounds **2** and **3** in the form of $\chi_M T$ vs. *T* plots [χ_M being the molar susceptibility per copper(II) ion] are shown in Figure 5; $\chi_M T$ at room temperature is 0.41 $cm^3mol^{-1}K$ for both compounds, a value which is as expected for a magnetically isolated spin doublet. Upon cooling, $\chi_M T$ remains almost constant for compound **2** down to 10 K and then smoothly increases at lower temperatures to reach a value of 0.44 $cm^3mol^{-1}K$ at 1.9 K; $\chi_M T$ remains constant upon cooling down to 25 K for compound **3** and then it increases at lower temperatures reaching a value of 0.50 $cm^3mol^{-1}K$ at 2.0 K. These features are indicative of an overall weak ferromagnetic coupling between the copper(II) ions in both compounds. Given that the structures of **2** and **3** consist of uniform chains, where the copper(II) ions are bridged by the phenylmalonate-carboxylate group, we analyzed their magnetic properties through the numerical expression proposed by Baker and Rushbrooke[38] for a ferromagnetic uniform copper(II) chain [Equation (1)]:

$$\chi_M = (N\beta^2 g^2/4kT)(A/B)^{2/3} \quad (1)$$

where

$$A = 1.0 + 5.7979916y + 16.902653y^2 + 29.376885y^3 + 29.832959y^4 + 14.036918y^5 \quad (2)$$

$$B = 1.0 + 2.7979916y + 7.0086780y^2 + 8.6538644y^3 + 4.5743114y^4 \quad (3)$$

and $y = J/2kT$, the spin Hamiltonian, *H*, being defined as $\Sigma_i -J\, S_i\, S_{i+1}$; *J* is the intrachain magnetic-coupling parameter and *N*, *g*, and β have their usual meanings.

The best fit obtained using a nonlinear regression analysis leads to $J = +0.10(1)$ cm^{-1}, $g = 2.091(1)$ and $R = 2.6 \times 10^{-5}$ for compound **2** and $J = +0.31(1)$ cm^{-1}, $g = 2.092(1)$ and $R = 2.1 \times 10^{-6}$ for compound **3** (*R* is the agreement factor defined as $\Sigma_i[(\chi_M T)_{obsd.}(i) - (\chi_M T)_{calcd.}(i)]^2/\Sigma[(\chi_M T)_{obsd.}(i)]^2$. The calculated curves match very well the experimental data in the whole temperature range, as seen in Figure 5. The fact that the magnetization data of **3** at 2.0 K (see inset of Figure 5) are clearly above the Brillouin function for a magnetically isolated spin doublet (this is also observed for the corresponding plot in **2**) confirms the ferromagnetic nature of the intrachain magnetic coupling.

The weak ferromagnetic interactions in **2** and **3** can be understood in a simple manner by analysing the exchange pathway which is involved and the relative arrangement of the magnetic orbitals. The unpaired electron of the copper(II) ion in **2** and **3** (square-pyramidal environment) lies in the equatorial plane [N(1)N(2)O(2)O(4)] and it is defined by a $d_{x^2-y^2}$-type magnetic orbital [the *x* and *y* axes corre-

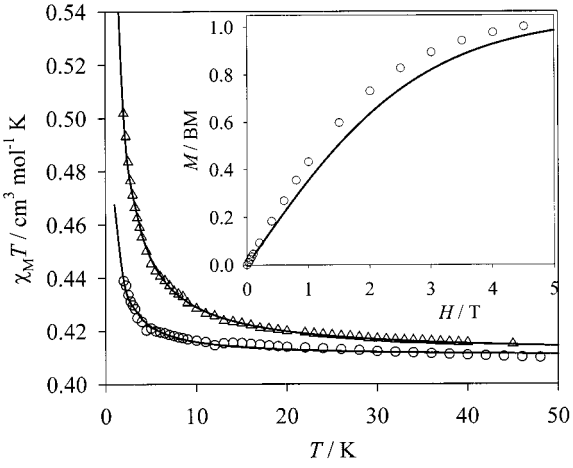

Figure 5. Experimental temperature dependence of the $\chi_M T$ product of **2** (circles) and **3** (triangles) at $T < 50$ K; (—) curves calculated from Equation (1); the inset shows the magnetization versus H plot for **3** at 2.0 K, experimental data (circles), (—) Brillouin function for a magnetically isolated spin doublet with $g = 2.09$

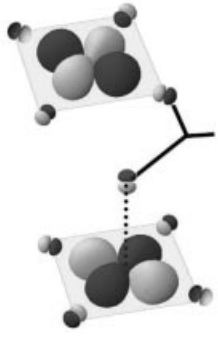
sponding roughly to the equatorial bonds to the copper atom]. The O(4)C(3)O(3) carboxylate bridge provides the intrachain exchange pathway in **2** and **3**: it links one equatorial position from Cu(1) [O(4)] with the axial one [O(3)] at Cu(1c) (**2**) and Cu(1f) (**3**) (see Scheme 1) adopting the *anti-syn* bridging mode. This exchange pathway produces a very poor overlap between the magnetic orbitals due to the weak spin density in the apical site.[39] Thus, the antiferromagnetic contribution, which is proportional to the square of the overlap between the magnetic orbitals, is minimized and the resulting magnetic coupling is most likely ferromagnetic, as observed.[40]



Scheme 1

Previous examples of carboxylate-(*anti-syn*-)bridged copper(II) complexes with an axial-equatorial exchange pathway exhibit ferromagnetic couplings with values of J ranging from +0.05 to +1.9 cm^{-1} (see Table 3).[8,10,16,41–43] The intensity of the magnetic coupling is affected by the Cu–O(axial) distance and the distortion of the metal environment — the longer the distance and the greater the distortion, the weaker the coupling is. The values of J for **2** and **3** fall in this range, but they are smaller than those with similar structural parameters [distortion and Cu–O(axial) distance]. The low value observed for the coupling constant for **2** [$J = +0.10(1)$ cm^{-1}] could be due to the greater value of the angle between the apical-oxygen-to-copper vector and the normal to the equatorial mean plane of the copper atom (7° in **2** and only 3.6° in **3**). In general, this shift influences the effectiveness of the bridge in the transmission of the magnetic coupling because it modifies the overlap between the magnetic orbitals.

Another interesting point looking at the results listed in Table 3 concerns compounds **3** and [{Cu(mal)(Im)}]$_n$. Although the structural parameters of **3** are similar to those of [{Cu(mal)(Im)}]$_n$, the value of the ferromagnetic coupling for **3** is somewhat smaller. Most likely, the carboxylate group of the phenylmalonate is less effective in the transmission of the magnetic coupling than the carboxylate group of the malonate ligand. The magnetic coupling is essentially an electronic effect and the phenylene ring of the phenylmalonate exerts an electron-withdrawing effect that delocalizes some electron density of the copper(II) towards the aromatic ring, decreasing the electronic delocalization towards the carboxylate bridge. The decrease of the electron delocalization towards the bridge would decrease the size of the magnetic coupling. This could be one of the factors to account for the weaker magnetic interaction between the copper(II) ions in **3** (and also in **2**) through the phenylmalonate-carboxylate bridge with respect to the malonate-carboxylate one.

Conclusions

Three new compounds have been prepared in which the phenylmalonate ligand acts either as blocking (**1**) or as bridging ligand (**2** and **3**). Weak interactions (hydrogen bonding and π–π stacking) govern the structure of the compounds leading to molecular (**1**) and one-dimensional (**2** and **3**) structures. A comparison with the related malonato-containing complexes reveals that the influence of the phenyl group in the Phmal compounds is decisive: [Cu(2,2′-bpy)(mal)(H_2O)]·H_2O presents different conformation and crystal packing of the mononuclear units from those in compound **1**; compounds **2** and **3** are uniform chains whereas the malonato-containing copper(II) complexes of 2,2′-bpym and phen are mononuclear compounds. The nature of the magnetic coupling between copper(II) ions through the phenylmalonate-carboxylate bridge (ferromagnetic) is the same as that through the malonate-carboxylate, but its magnitude is somewhat smaller, probably due to the electron-withdrawing effect which is exerted by the phenyl ring. In the near future, magneto-structural studies on phenylmalonate-containing copper(II) complexes will be pursued to check this observation and to gain further insights into the structural possibilities they provide.

Experimental Section

General: Phenylmalonic acid (H_2Phmal), copper(II) acetate hydrate ([Cu($CH_3COO)_2$·H_2O]), 2,2′-bipyridine (2,2′-bpy), 2,2′-bipyrim-

[a] Abbreviations: Im = imidazole; 2-MeIm = 2-methylimidazole; bpe = 1,2-bis(4-pyridyl)ethylene. [b] Values of the coupling constant (J). [c] Octahedral.

idine (2,2′-bpym), 1,10-phenanthroline (phen) and methanol were purchased from Aldrich and used as received. Elemental analyses (C, H and N) were performed with an EA 1108 CHNS-O microanalytical analyzer. IR spectra (450−4000 cm^{-1}) were recorded with a Bruker IF S55 spectrophotometer with the sample prepared as KBr pellets. Magnetic susceptibility measurements on polycrystalline samples of compounds **1**−**3** were carried out in the temperature range 1.9−290 K with a Quantum Design SQUID magnetometer. Diamagnetic corrections of the constituent atoms were estimated from Pascal's constants[44] as -228×10^{-6}, -189×10^{-6} and -251×10^{-6} cm^3·mol^{-1} for compounds **1**, **2** and **3**, respectively. Experimental susceptibilities were also corrected for the temperature-independent paramagnetism (60×10^{-6} cm^3·mol^{-1} per Cu^{II}) and the magnetization of the sample holder.

Synthesis: The general procedure to prepare compounds **1**−**3** starts with the preparation of an aqueous solution (15 mL) of copper(II) phenylmalonate (1 mmol) which was prepared by adding phenylmalonic acid (0.180 g, 1 mmol) to a warm methanolic solution (20 mL) of copper(II) acetate (1 mmol, 0.200 g) under continuous stirring. The resulting pale-blue solution was concentrated to dryness in a rotary evaporator. The green solid obtained was washed thoroughly with acetone to remove the acetic acid and then the green product was dissolved in water (15 mL).

$[Cu(2,2'\text{-bpy})(Phmal)(H_2O)]\cdot 2H_2O$ (1): 2,2′-Bipyridine (0.156 g, 1 mmol) was dissolved in methanol/water (50:50, 10 mL) and then an aqueous solution (15 mL) of copper(II) phenylmalonate was added whilst stirring. The solution was allowed to concentrate in a fumehood at room temperature. Prismatic blue single crystals of **1** had grown after a few days. Yield: 0.34 g (75% based on copper). $C_{19}H_{20}CuN_2O_7$ (451.55): calcd. C 50.49, H 4.43, N 6.20; found C 50.41, H 4.40, N 6.05. IR (KBr): ν(C−H, =C−H): 3090, 3062, 2950, 2923; ν(C=C, COO): 1637, 1605, 1590, 1577, 1445, 1409 cm^{-1}.

$[\{Cu(2,2'\text{-bpym})(Phmal)\}]_n$ (2): Compound **2** was prepared similarly to **1** but using a solution of 2,2′-bpyrimidine (0.158 g, 1 mmol) instead of 2,2′-bipyridine. Prismatic greenish-blue single crystals of **2** were grown after a few days. Yield: 0.24 g (60% based on copper).

$C_{17}H_{12}CuN_4O_4$ (399.55): calcd. C 51.05, H 3.00, N 14.02; found C 51.20, H 3.14, N 14.10. IR (KBr): ν(C−H, =C−H): 3057, 3027, 2925; ν(C=C, COO): 1646, 1606, 1578, 1557, 1420, 1403 cm^{-1}.

[{Cu(phen)(Phmal)}]$_n$·3nH$_2$O (3): Compound **3** was prepared similarly to **1** but using a solution of 1,10-phenanthroline (0.180 g, 1 mmol) instead of 2,2′-bipyridine. Prismatic blue single crystals of **3** separated from the mother liquor on standing at room temperature after a week. Yield: 0.38 g (80% based on copper). $C_{21}H_{20}CuN_2O_7$ (475.55): calcd. C 52.99, H 4.21, N 5.89; found C 52.79, H 4.32, N 5.80. IR (KBr): ν(C−H, =C−H): 3060, 3030, 2923, 2850; ν(C=C, COO): 1628, 1615, 1595, 1576, 1425, 1405 cm^{-1}.

X-ray Crystallographic Study: Single crystals of **1**−**3** were used for data collection with a Nonius KappaCCD diffractometer. The data collection was carried out at 293 K using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). A summary of the crystallographic data and structure refinement is given in Table 4 and selected interatomic distances and angles are listed in Table 5. The structures were solved by direct methods and refined with a full-matrix least-squares technique on F^2 using the SHELXL-97[45] program included in the WINGX[46] software package. All non-hydrogen atoms were refined anisotropically. All hydrogen atoms of structures **1**−**3** were located from difference maps and refined with isotropic temperature factors, except those of the water molecules of complex **3**. The final geometrical calculations and graphical manipulations were carried out with PARST97[47] and CRYSTALMAKER[48] programs. CCDC-235074 (**1**), -235075 (**2**) and -235076 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Characterization of Alkyllanthanum Biphenolate Complexes as Catalysts for Hydroamination/Cyclization and Hydrosilylation

Denis V. Gribkov,[a] Frank Hampel,[a] and Kai C. Hultzsch*[a]

Keywords: Asymmetric catalysis / Hydroamination / Hydrosilylation / Lanthanum / O ligands

The homochiral, dimeric biphenolate alkyllanthanum complex [La{(*R*)-Biphen}{CH(SiMe$_3$)$_2$}]$_2$ can be prepared by facile alkane elimination starting from [La{CH(SiMe$_3$)$_2$}$_3$] and enantiopure (*R*)-3,3′-di-*tert*-butyl-5,5′,6,6′-tetramethyl-1,1′-biphenyl-2,2′-diol [H$_2${(*R*)-Biphen}]. Single-crystal X-ray diffraction revealed that the two La{(*R*)-Biphen}{CH(SiMe$_3$)$_2$} fragments are connected through bridging phenolate groups of the biphenolate ligands. The two different phenolate groups undergo an intramolecular exchange process in solution leading to their equivalence on the NMR timescale. The biphenolate alkyl complex shows high catalytic activity for hydroamination/cyclization of aminoalkenes, similar to previously known lanthanocene catalysts, but only low enantioselectivity. Addition of THF to [La{(*R*)-Biphen}{CH(SiMe$_3$)$_2$}]$_2$ leads to a monomeric tris-THF adduct [La{(*R*)-Biphen}{CH(SiMe$_3$)$_2$}(THF)$_3$] with higher catalytic activity than the THF-free homochiral dimer in the cyclization of 2,2-dimethylpent-4-enylamine, suggesting that the dimeric structure of the catalyst system prevails under catalytic conditions in the absence of THF. Addition of HN(SiHMe$_2$)$_2$ to [La{(*R*)-Biphen}{CH(SiMe$_3$)$_2$}(THF)$_3$] results in the formation of [La{(*R*)-Biphen}{N(SiHMe$_2$)$_2$}(THF)$_3$] which is in equilibrium with its homochiral dimer [La{(*R*)-Biphen}{N(SiHMe$_2$)$_2$}(THF)]$_2$ at elevated temperatures. The biphenolate alkyl complexes exhibit good catalytic activity and diastereoselectivity in the hydrosilylation of styrene. Hydrosilylation of 1-hexene and norbornene also proceeds with high diastereoselectivity but rather low activity.

Introduction

The chemistry of organometallic rare-earth-metal compounds has advanced significantly over the last two decades and many catalytic applications of these species in polymer chemistry[1,2] and organic synthesis,[3] notably hydroamination,[4−25] hydrophosphination,[26,27] hydrosilylation,[28−47] and hydroboration,[48,49,50] have been investigated. Most catalytic studies have relied on catalyst systems based on organometallic rare-earth-metal complexes containing at least one cyclopentadienyl-type ligand.[51] The chemistry of non-metallocene complexes[52−54] is much less developed and only a limited number of catalytic investigations have been reported.[45,55−69] One significant disadvantage of cyclopentadienyl-based chiral rare-earth-metal catalysts is their facile epimerisation in the presence of donor molecules, such as ethers and amines.[15,70−73] Cyclopentadienyl-free catalyst systems could solve this problem by providing a configurationally stable catalytic site and we[60,65] and others[59,62−64] have reported significant progress over the last year.

Recently we reported the synthesis of monomeric biphenolate and binaphtholate rare-earth-metal amido complexes of the type [Ln{diolate}{N(SiHMe$_2$)$_2$}(THF)$_2$] (**1**) as well as their application in enantioselective hydroamination/cyclization reactions.[60] Based on the high thermal stability of the complexes and the small decrease of enantioselectiv-

E-mail: hultzsch@chemie.uni-erlangen.de

ity with increasing temperature, these complexes are assumed to be configurationally stable under catalytic conditions, even at temperatures as high as 100 °C. Although these catalysts can be prepared quite conveniently by a simple amine-elimination reaction, they require relatively high reaction temperatures (≥ 50 °C) in order to achieve reasonable turnover frequencies.[74] Additionally, we found that complexes derived from the sterically less-hindered racemic 3,3′-di-*tert*-butyl-5,5′,6,6′-tetramethyl-1,1′-biphenyl-2,2′-diol [H_2(Biphen)][75][76] readily dimerize to give a phenolate-bridged heterochiral dimer. A presumably homochiral dimeric amidolanthanum species could be observed in situ upon heating heterochiral (*R*,*S*)-[La(Biphen){N(SiHMe$_2$)$_2$}(THF)]$_2$ [(*R*,*S*)-**2b**],[60] but all attempts to obtain the former in pure form starting from enantiopure Biphen ligand have failed to date.

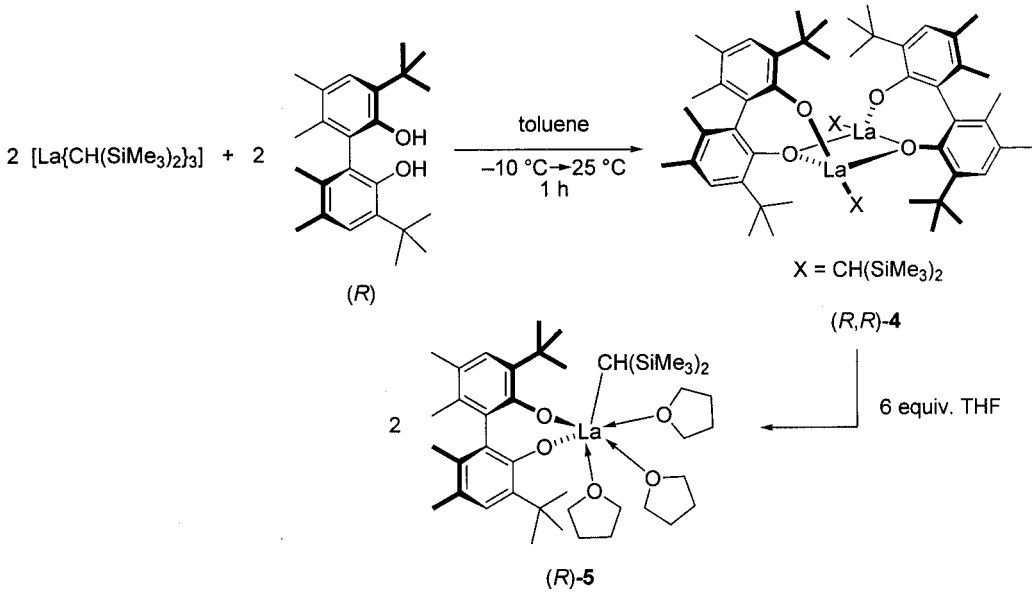
We therefore became interested in understanding the source of the low catalytic activity of complexes [Ln{diolate}{N(SiHMe$_2$)$_2$}(THF)$_2$] (**1**). Possible reasons could be inhibition by THF coordination, sluggish initiation caused by the low basicity of the bis(dimethylsilyl)-amido ligand or the electronic properties of our chiral chelating diolate ligand system.

Schaverien reported the synthesis of biphenolate and binaphtholate alkyllanthanum complexes in 1992,[77] but little is known about their reactivity or catalytic activity. Although the structure of the monomeric tris-THF adduct [La{1,1′-(2-OC$_6$H$_2$*t*Bu$_2$-3,5)$_2$}{CH(SiMe$_3$)$_2$}(THF)$_3$] (**3**) was elucidated by single-crystal X-ray diffraction analysis, the structure of its base-free precursor, formulated as the monomeric species [La{1,1′-(2-OC$_6$H$_2$*t*Bu$_2$-3,5)$_2$}{CH(SiMe$_3$)$_2$}], remained unknown.

Herein we report the synthesis, characterization and catalytic activity of related biphenolate alkyllanthanum complexes derived from (*R*)-Biphen. As it turned out, the initial base-free lanthanum complex of this chiral biphenolate ligand exists as a homochiral dimer.[78]

Results and Discussion

Reaction of (*R*)-H_2(Biphen)[76] with the trialkyllanthanum complex [La{CH(SiMe$_3$)$_2$}$_3$][79] at −10 °C in toluene solution resulted in the smooth formation of a single species **4** of the general formula "La{(*R*)-Biphen}{CH(SiMe$_3$)$_2$}" (Scheme 1). Although the reaction seems to proceed relatively cleanly according to NMR spectroscopy, we could only obtain 35% of the product in isolated yield due to its high solubility in pentane. The ^{1}H NMR spectrum at room temperature exhibits only one broad set of signals for the biphenolate ligand, suggesting that both phenolate rings are equivalent at this temperature, as well as two signals for the diastereotopic trimethylsilyl groups (Figure 1). The lanthanum-bound methyne carbon atom resonates in the ^{13}C NMR spectrum at δ = 55.0 ppm ($^1J_{C,H}$ = 101 Hz). The signals of the biphenolate ligand decoalesce into two separate sets of signals for the two phenolate rings upon cooling to 0 °C. Similar temperature-dependent spectroscopic features of the biphenolate ligand have been observed in the heterochiral dimer (*R*,*S*)-[La(Biphen){N(SiHMe$_2$)$_2$}(THF)]$_2$ [(*R*,*S*)-**2b**].[60] The equivalence of both phenolate rings in (*R*,*S*)-**2b** on the NMR timescale at 25 °C is caused by an intramolecular exchange process of terminal and bridging phenolate groups. An analogous intramolecular exchange process of terminal and bridging phenolate groups seems to be operational for (*R*,*R*)-**4** (Scheme 2). The homochiral dimeric structure of (*R*,*R*)-**4** was also confirmed by X-ray crystallographic analysis (vide infra). It seems likely that the related complex [La{1,1′-(2-OC$_6$H$_2$*t*Bu$_2$-3,5)$_2$}{CH(SiMe$_3$)$_2$}] pre-



Scheme 1

pared by Schaverien[77] from [La{CH(SiMe$_3$)$_2$}$_3$] and 3,3′,5,5′-tetra-*tert*-butylbiphenyl-2,2′-diol is also dimeric. The signal of the lanthanum-bound methyne proton of this species appears at $\delta = -1.46$ ppm in the ^{1}H NMR spectrum and the lanthanum-bound carbon atom is found at $\delta =$ 59.4 ppm ($^1J_{C,H} = 95$ Hz).[77] Based on the differences in the NMR spectra of [La{1,1′-(2-OC$_6$H$_2$*t*Bu$_2$-3,5)$_2$}{CH(SiMe$_3$)$_2$}] and (*R*,*R*)-**4** one can rule out a homochiral dimeric structure. A heterochiral[78] dimeric structure is more likely and should be thermodynamically more stable due to the absence of unfavorable steric interactions.

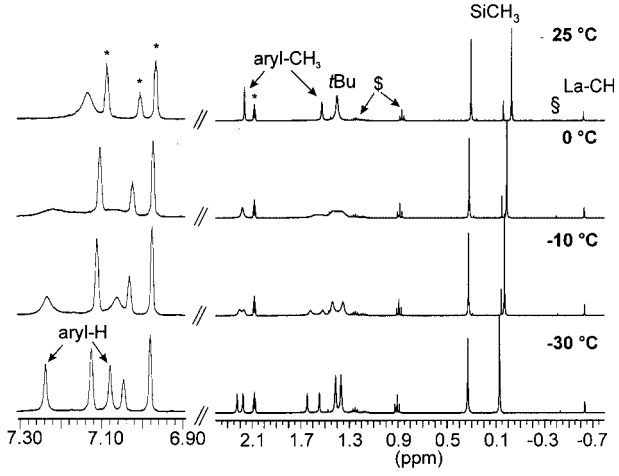


Figure 1. Variable temperature ^{1}H NMR spectra of (*R*,*R*)-**4** in [D$_8$]toluene (*) showing the aliphatic (right) and aromatic region (left, threefold expanded) [$ = *n*-pentane, § = CH$_2$(SiCH$_3$)$_2$]

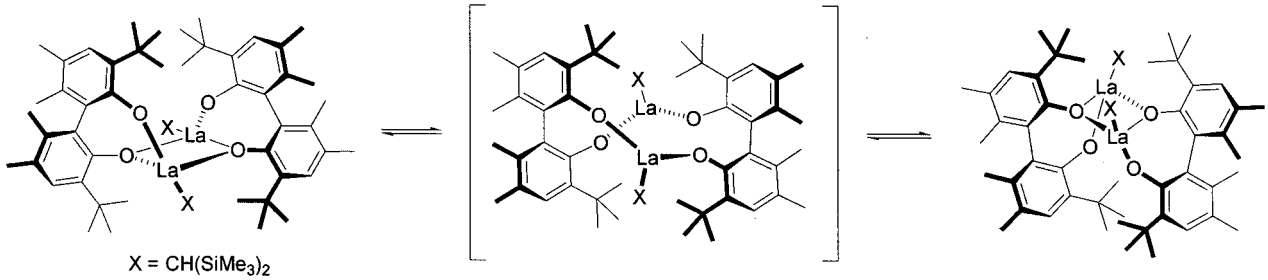
Addition of six equivalents of THF to (*R*,*R*)-**4** led to the formation of a monomeric species (*R*)-**5** (Scheme 1), which is analogous to the crystallographically characterized biphenolate lanthanum complex **3**.[77] Formation of (*R*)-**5** from (*R*,*R*)-**4** does not proceed instantaneously, but within 30 min. The signal of the lanthanum-bound methyne proton is shifted to higher field at $\delta = -1.64$ ppm in the ^{1}H NMR spectrum and the methyne carbon atom resonates in the ^{13}C NMR spectrum at $\delta = 51.5$ ppm with a $^1J_{C,H}$ value of 97.6 Hz. Addition of three equivalents of THF yields a mixture of (*R*,*R*)-**4**, (*R*)-**5** and a new species at $\delta = -1.12$ ppm, which we believe to be a dimeric mono-THF adduct [La{(*R*)-Biphen}{CH(SiMe$_3$)$_2$}(THF)]$_2$ in a 1:1.2:1.2 ratio (based on the integration of the lanthanum-bound methyne proton signals in the ^{1}H NMR spectrum). Unfortunately, isolation of (*R*)-**5** on a preparative scale was hampered by its high solubility in pentane at −78 °C as well as partial loss of THF under reduced pressure, giving a mixture of the tris-THF adduct (*R*)-**5**, the mono-THF adduct and the THF-free starting material (*R*,*R*)-**4**. Furthermore, (*R*)-**5** could only be obtained when THF was added to complex (*R*,*R*)-**4**, whereas reaction of [La{CH(SiMe$_3$)$_2$}$_3$] with (*R*)-H$_2$(Biphen) in the presence of THF (5 equiv.) in [D$_6$]benzene solution resulted in the slow formation of several products. Complex (*R*)-**5** accounted for only 15% of this mixture after 70% consumption of [La{CH(SiMe$_3$)$_2$}$_3$]. Reactions of (*R*)-H$_2$(Biphen) with [Y{CH(SiMe$_3$)$_2$}$_3$] performed in the presence or absence of THF were unsuccessful as well, producing a mixture of products which did not contain an yttrium−carbon bond.

Interestingly, attempts to synthesize the racemic analogue of (*R*,*R*)-**4** from [La{CH(SiMe$_3$)$_2$}$_3$] and racemic H$_2$(Biphen) yielded only a mixture of complexes. This contrasts our previous observation in the preparation of biphenolate amido complexes using the tris(amido) complex [La{N(SiHMe$_2$)$_2$}$_3$(THF)$_2$] as starting material, which gave isolable products only when racemic H$_2$(Biphen) was used.[60] Attempts to synthesize an enantiopure biphenolate lanthanum amido complex resulted in the formation of a mixture of at least three products. In the present study the reactivity seems to be opposite. Using the trialkyllanthanum complex [La{CH(SiMe$_3$)$_2$}$_3$] we were able to prepare the homochiral dimer (*R*,*R*)-**4**, while the synthesis of a racemic complex failed. The formation of biphenolate rare-earth-metal complexes by amine or alkane elimination is very sensitive to the reactivity and steric hindrance of the rare-earth-metal precursor. The desired biphenolate rare-earth-metal alkyl or amido complexes are obtained as kinetic products.

The X-ray diffraction analysis of (*R*,*R*)-**4** (orthorhombic, space group $P2_12_12$) reveals a C_2-symmetric homochiral dimeric structure (Figure 2). It shows a similar binding motif for the biphenolate ligand as was observed in the heterochiral dimer (*R*,*S*)-**2b** and the thiobinaphtholate complex [Sm{1,1′-S(2-OC$_{10}$H$_4$*t*Bu$_2$-3,6}(OC$_6$H$_3$*t*Bu$_2$-2,6)]$_2$.[80] Selected bond lengths and angles of (*R*,*R*)-**4** and (*R*,*S*)-**2b** are summarized in Table 1 for a better comparison.

The two biphenolate metal moieties are connected by two bridging phenolate units and the tetrahedral geometry



Scheme 2

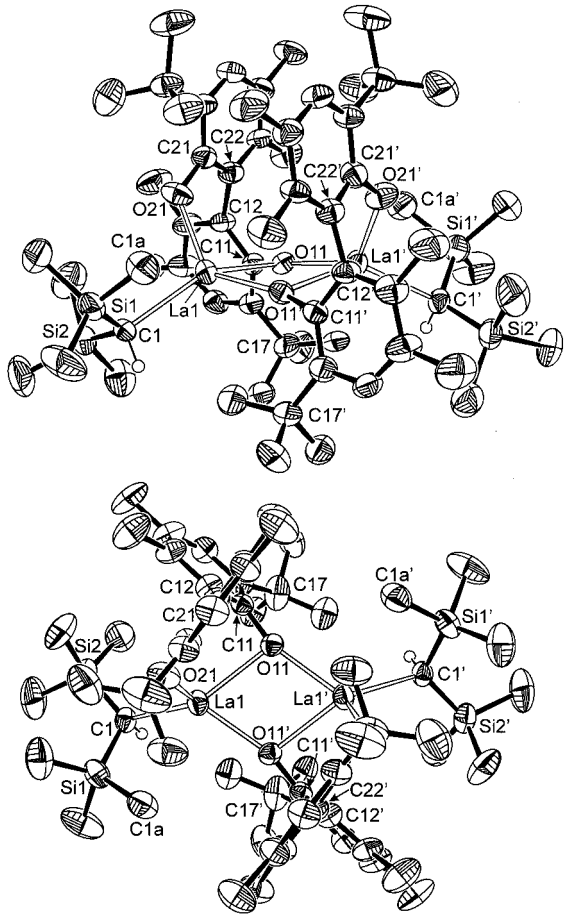

Figure 2. ORTEP diagram of the molecular structure of (*R*,*R*)-**4** (top) and alternative view from the top (bottom); thermal ellipsoids are drawn at the 50% probability level; hydrogen atoms, except for those on C1 and C1′, as well as one position of the disordered *tert*-butyl group on C17 have been omitted for the sake of clarity

around lanthanum is significantly distorted. Both terminal phenolate groups have a *syn* relationship relative to the La_2O_2 core, with their aromatic rings being stacked parallel to each other in order to avoid destabilizing steric interactions of the *tert*-butyl groups.

The La_2O_2 core displays an even more distorted geometry than was observed in (*R*,*S*)-**2b**[60] (Table 1). The lanthanum−oxygen bond to the bridging phenolate oxygen atom of the same biphenolate metal moiety (La1−O11) is 0.14 Å longer than the corresponding bond to the bridging phenolate oxygen atom of the other biphenolate metal moiety (La1−O11′). The terminal lanthanum−oxygen bond La1−O21 is 0.34 Å (for La1−O11) and 0.20 Å (for La1−O11′) shorter than the bond to the bridging phenolates [typical range La−OAr(term.) = 2.17−2.32 Å; La−OAr(bridg.) = 2.32−2.43 Å].[60] The dihedral angle between the two phenol rings [−97.0(7)° for (*R*,*R*)-**4**] is about 9° larger than in (*R*,*S*)-**2b** [87.8(4)°][60] and 24° larger than in [La{1,1′-(2-$OC_6H_2tBu_2$-3,5)$_2$}{$CH(SiMe_3)_2$}$(THF)_3$] (**3**) [72.9(1.9)°],[77] due to its lower coordination number. The O11−La1−O21 bite angle of the biphenolate ligand for (*R*,*R*)-**4** [95.86(12)°] is larger than the values of 88.83(7)° for (*R*,*S*)-**2b**[60] and 88.1(3)° for [La{1,1′-(2-$OC_6H_2tBu_2$-3,5)$_2$}{$CH(SiMe_3)_2$}$(THF)_3$].[77] The La···La separation [3.8750(5) Å] is the shortest observed for complexes with an La_2O_2 core (usual range for La: 3.96−4.02 Å),[60][81−84] in accordance with the observations mentioned earlier.

Table 1. Comparison of selected bond lengths (Å), atomic distances (Å) and angles (°) for (*R*,*R*)-**4** (E = C1) and (*R*,*S*)-**2b**[60] (E = N1)

	(*R*,*R*)-**4** E = C1	(*R*,*S*)-**2b**[60] E = N1
La1−O21	2.169(4)	2.234(2)
La1−O11	2.506(3)	2.503(2)
La1−O11′	2.364(3)	2.407(2)
La1−E	2.543(5)	2.416(3)

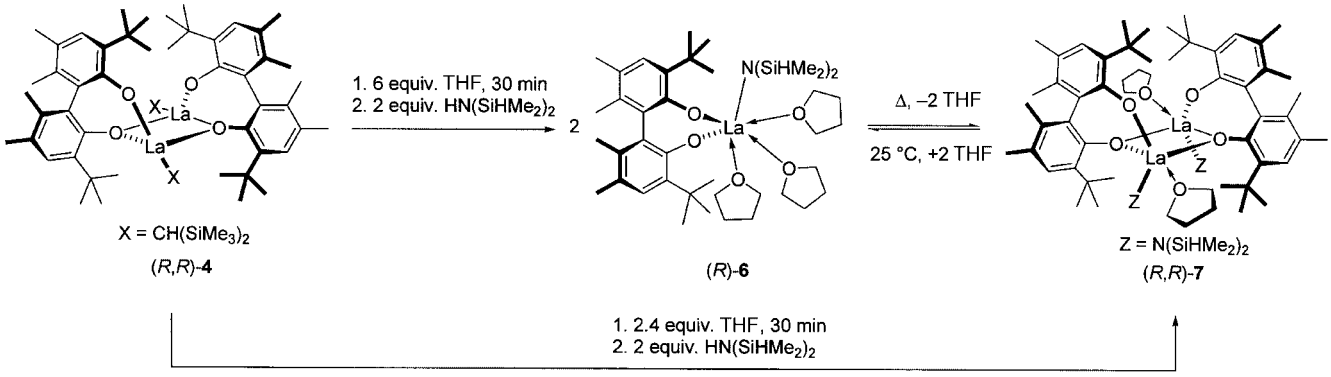
La1···C1A	3.088(7)	−
La1···Si1	3.3685(16)	3.5240(11)
La1···Si2	3.8643(18)	3.3703(10)
O11−La1−O21	95.86(12)	88.83(7)
O11−La1−O11′	73.24(11)	71.10(8)
O21−La1−O11′	124.07(13)	108.79(8)
E−La1−O11	137.47(16)	123.41(9)
E−La1−O11′	119.42(15)	142.14(9)
E−La1−O21	105.51(17)	106.41(9)
La1−O11−La1′	105.39(11)	108.90(8)
La1−O11−C11	91.9(3)	92.81(16)
La1−O21−C21	125.0(4)	132.5(2)
La1−E−Si1	99.2(2)	116.17(14)
La1−E−Si2	124.0(3)	109.56(14)
Si1−E−Si2	118.4(3)	133.94(17)
C11−C12−C22−C21	−97.0(7)	87.8(4)

The lanthanum−carbon bond [2.543(5) Å] in (*R*,*R*)-**4** is similar in length to that in [La(Cp*){$CH(SiMe_3)_2$}$_2$] [2.537(5) and 2.588(4) Å],[85] but significantly shorter than in [La{1,1′-(2-$OC_6H_2tBu_2$-3,5)$_2$}{$CH(SiMe_3)_2$}$(THF)_3$] (**3**) [2.676(13) Å][77] and [La(Cp*){$CH(SiMe_3)_2$}$_2$(THF)] [2.651(8) and 2.627(10) Å].[85] The alkyl ligand avoids unfavorable steric interactions with the bridging phenolate groups by increasing C1−La1−O11 [137.47(16)°] and C1−La1−O11′ [119.42(15)°], while C1−La1−O21 [105.51(17)°] is slightly decreased from an ideal tetrahedral geometry around lanthanum. The geometry of the alkyl ligand displays a β-SiC monoagostic interaction [La−C−Si = 99.2(2)°, 124.0(3)°; La···C = 3.088(7) Å] resembling those found in previously characterized coordinatively unsaturated bis(trimethylsilyl)methyl rare-earth-metal complexes[86][87] such as [La(Cp*){$CH(SiMe_3)_2$}$_2$] [La−C−Si = 99.6(3)°, 126.4(4)° and 98.8(3)°, 129.6(3)°; La···C = 2.978(6), 2.988(6) Å],[85] [La(Cp*)-{$CH(SiMe_3)_2$}$_2$(THF)] [La−C−Si = 102.9(4)°, 134.8(6)° and 103.6(4)°, 131.1(5)°; La···C = 3.241(19), 3.265(14) Å].[85] One silicon−carbon bond is distorted towards the metal center with La1···Si1 [3.3685(16) Å] and La1···C1A [3.088(7) Å] being within the sum of the van der Waals radii. Note that the coordinatively saturated monomeric biphenolate complex **3** [La−C−Si = 116.5(7)° and 118.7(6)°][77] does not display such an agostic interaction.

Reaction of (*R*,*R*)-**4** with tetramethyldisilazane in the presence of six equivalents of THF results in the formation

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3

of [La{(*R*)-Biphen}{N(SiHMe$_2$)$_2$}(THF)$_3$] [(*R*)-**6**] as the major product (Scheme 3), which is not available from the reaction of (*R*)-H$_2$(Biphen) with [La{N(SiHMe$_2$)$_2$}$_3$-(THF)$_2$]. The ^{1}H NMR spectrum of (*R*)-**6** has similar features to the previously characterized (*R*)-**1a**,[60] showing two doublets for the methyl groups on silicon at δ = 0.24 and 0.28 ppm ($^3J_{H,H}$ = 2.9, 3.0 Hz) and a septet for SiH at δ = 5.00 ppm in (*R*)-**6** compared to δ = 0.32 and 0.38 ppm ($^3J_{H,H}$ = 3.0 Hz) and δ = 5.12 ppm in (*R*)-**1a**. In addition to the signals of (*R*)-**6**, small quantities of a second species can be observed to appear over the course of 2 h in the ^{1}H NMR spectrum. The equilibrium is shifted towards this second species upon heating, which we believe to be the homochiral dimer [La{(*R*)-Biphen}{N(SiHMe$_2$)$_2$}(THF)]$_2$ [(*R*,*R*)-**7**]. The equilibrium between (*R*)-**6** and (*R*,*R*)-**7** is shifted from 3:1 at 25 °C to 1:1.5 at 60 °C and 1:3.2 at 80 °C (Figure 3). Formation of (*R*,*R*)-**7** is reversible and the initial 3:1 ratio of (*R*)-**6** to (*R*,*R*)-**7** is regenerated upon cooling back to 25 °C (however, equilibration generally requires 1−2 h at room temperature). (*R*,*R*)-**7** has identical spectroscopic data to the species that is formed upon heating (*R*,*S*)-**2b** in [D$_8$]toluene.[60] Reaction of (*R*,*R*)-**4** with tetramethyldisilazane in the presence of only 2.4 equivalents of THF gives (*R*,*R*)-**7** as the major product.

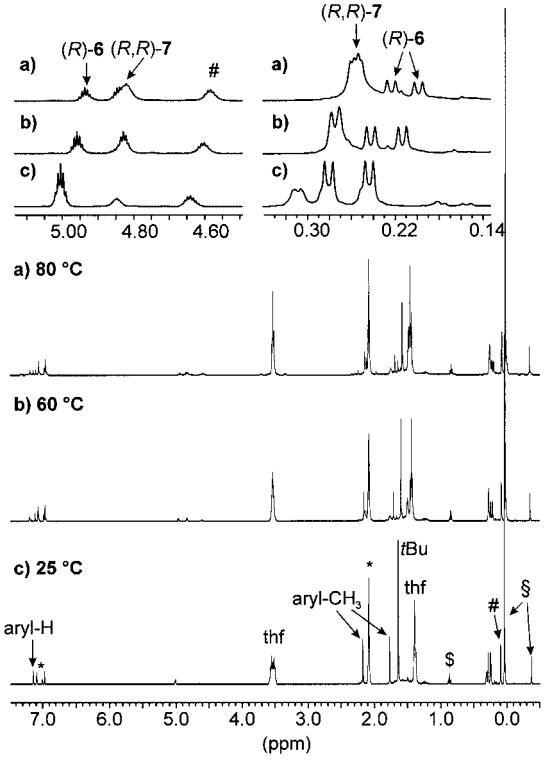


Figure 3. ^{1}H NMR spectrum of the equilibrium between (*R*)-**6** and (*R*,*R*)-**7** in [D$_8$]toluene at: a) 80 °C, b) 60 °C and c) 25 °C [# = HN(SiHMe$_2$)$_2$, § = CH$_2$(SiMe$_3$)$_2$, $ = pentane]

Catalytic Evaluation

Complexes (*R*,*R*)-**4** and (*R*)-**5** were evaluated for their catalytic activity in hydroamination/cyclization and hydrosilylation reactions (Table 2 and 3 respectively). The most notable feature of alkyl complexes (*R*,*R*)-**4** and (*R*)-**5** in comparison to bis(dimethylsilylamido) complexes **1** and **2** is their significantly higher catalytic activity for the hydroamination/cyclization of aminoalkenes. Especially noteworthy seems to be the almost twofold increase in catalytic activity of complex (*R*)-**5** compared to the dimer (*R*,*R*)-**4** in the cyclization of 2,2-dimethylpent-4-enylamine (**8**; Table 2, entries 1 and 2). This strongly suggests that (*R*,*R*)-**4** remains dimeric under the catalytic conditions, which is in accordance with our earlier finding that (*R*,*S*)-**2a** has a lower catalytic activity than **1a**. However, (*R*,*R*)-**4** and (*R*)-**5** show similar rates in the cyclization of the sterically less bulky pent-4-enylamine **10** (Table 2, entry 3 and 4).

The turnover frequency of 61 h^{-1} for complex (*R*)-**5** in the cyclization of substrate **8** is of the same magnitude as that of other highly active lanthanocene catalysts, such as [Cp*$_2$LaCH(SiMe$_3$)$_2$] (95 h^{-1} at 25 °C),[13] and twice as active as the lanthanum bisoxazoline complex [{(4*R*,5*S*)-Ph$_2$Box}La{N(SiMe$_3$)$_2$}$_2$] (25 h^{-1} at 23 °C).[25] Unfortunately, both lanthanum catalysts (*R*,*R*)-**4** and (*R*)-**5** achieve significantly lower enantioselectivities than the yttrium biphenolate complex (*R*)-**1a**[60] — pyrrolidines **9** and **11** are produced in essentially racemic form. The larger atomic radius (0.900 Å for Y vs. 1.032 Å for La)[88] concomitant with the low steric hindrance presented by the *tert*-butyl substituents of the biphenolate ligand results in a low level of stereodifferentiation.

[a] Reaction conditions: 2 mol % cat., C_6D_6, 1 equiv. $PhSiH_3$, 60 °C, Ar atm. [b] Reaction time. [c] Determined by ^1H NMR spectroscopy. [d] 4 mol % cat.

The amino diolefin **12** cyclizes very rapidly to diastereomeric 4-allyl-2,4-dimethylpyrrolidine (**13**) with a similarly low diastereoselectivity [1.15:1 for (*R*,*R*)-**4** and 1.4:1 for (*R*)-**5**] as observed for (*R*)-**1b**.[60] Interestingly, whereas (*R*)-**1b** gave both diastereomers in almost identical enantiomeric ratios,[60] (*R*,*R*)-**4** and (*R*)-**5** deliver the minor diastereomer with higher enantioselectivity than the almost racemic major diastereomer.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Cyclization of 1-methylpent-4-enylamine (**14**) in the presence of (*R*,*R*)-**4** at 25 °C gives 2,5-dimethylpyrrolidine (**15**) with a good diastereoselectivity of 9:1 (*trans*:*cis*). The monomeric catalyst (*R*)-**5** produces **15** with a somewhat lower diastereoselectivity of 5.3:1, albeit at 60 °C. Cyclization of 1-methylhex-5-enylamine (**16**), on the other hand, yields preferentially *cis*-2,5-dimethylpiperidine (*cis*-**17**) in a roughly 1:4 ratio (*trans:cis*) using either (*R*,*R*)-**4** or (*R*)-**5**, which is similar to the diastereoselectivity observed with a catalyst system prepared from [Y{N(SiMe$_3$)$_2$}$_3$] and *N*,*N*′-diarylethane-1,2-diamines.[58] Formation of the six-membered ring requires heating to 80 °C for both biphenolate lanthanum catalysts. Preferred formation of *trans*-2,5-dimethylpyrrolidine can be rationalized by a minimization of the 1,3-diaxial interaction in the seven-membered cyclization transition state.[23] Similar considerations explain the preferred formation of *cis*-2,5-dimethylpiperidine via an eight-membered transition state.[22]

Cyclization of 2,2-dimethylpent-4-enylamine (**8**) using (*R*,*R*)-**4** or (*R*)-**5** as catalysts proceeds with a zero-order rate dependence on substrate concentration (Figure 4). This result is in accordance with the generally accepted mechanism of lanthanocene-catalyzed hydroamination reactions, in which olefin insertion into the rare-earth-metal amido bond is the rate-determining step.[13] However, this result contrasts our previous finding that ring-closing of **8** using bis(dimethylsilyl)amido complexes **1** and **2** proceeds with a first- [(*R*)-**1b** and **2**] or second-order rate dependence [(*R*)-**1a**] on substrate concentration.[60]

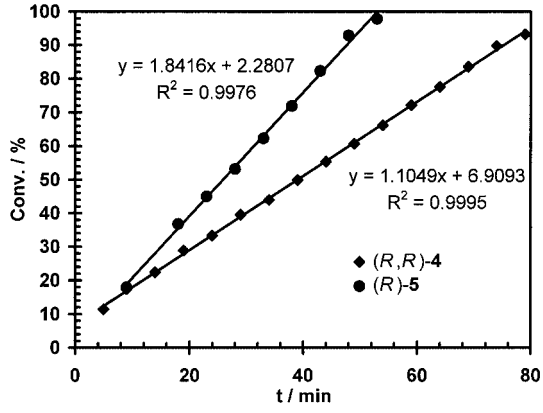

Figure 4. Hydroamination/cyclization of **8** (0.63 M) with 1 mol % (*R*,*R*)-**4** (= 2 mol % La) and 2 mol % (*R*)-**5** at 25 °C in C_6D_6

(*R*,*R*)-[La(Biphen){N(SiHMe$_2$)$_2$}(THF)] [(*R*,*R*)-**7**], prepared in situ by reaction of (*R*,*R*)-**4** with HN(SiHMe$_2$)$_2$ and one equivalent of THF, shows a significantly reduced catalytic activity in the ring-closing of substrate **8**, with an initial rate of 0.36 h^{-1} at 60 °C. Similar to the amidoyttrium biphenolate complex (*R*)-**1a**, ring-closing of **8** with (*R*,*R*)-**7** proceeds with a second-order rate dependence (**1a**) on substrate concentration. The ^{1}H NMR spectra of the catalytic reaction show free tetramethyldisilazane as well as unchanged catalyst, indicating that only 36% of the catalyst is activated. The unchanged catalyst most likely exists as a monomeric species of the general type [La{(*R*)-Biphen}{N(SiHMe$_2$)$_2$}(THF)(L)$_n$] (L = substrate **8** or pyrrolidine **9**; n = 1 or 2) based on the well-separated doublets for the amido silicon methyl groups at δ = 0.30 and 0.35 ppm ($^3J_{H,H}$ = 2.9 Hz) in the ^{1}H NMR spectrum, which is typical for the monomeric biphenolate complexes (*R*)-**1a** and (*R*)-**6**. Therefore, the low catalytic activity of bis(dimethylsilyl)amido complexes **1**, **2** and (*R*)-**6** in comparison to alkyl catalysts (*R*,*R*)-**4** and (*R*)-**5** has to be attributed mainly to the low basicity of the bis(dimethylsilyl)amido ligand resulting in incomplete protonolysis of the amido ligand by the aminoalkene substrate [Scheme 4, X = N(SiHMe$_2$)$_2$, K_{eq} < 1]. Protonolysis of the biphenolate alkyl complexes, on the other hand, is instantaneous and quantitative [Scheme 4, X = CH(SiMe$_3$)$_2$, K_{eq} >> 1]. Complexes with the bis(trimethylsilyl)amido ligand generally give similar catalytic activity to that of alkyl complexes.[13][89] Tetramethyldisilazane (pK_a = 22.8)[90] is more acidic than hexamethyldisilazane (pK_a = 25.8).[91] Obviously, this slight difference in basicity between the two amido ligands renders the bis(dimethylsilyl)amido ligand an unsuitable leaving group for the catalyst precursor.[92] Coordinated THF in the bis(dimethylsilyl)amido complexes cannot contribute significantly to the low catalytic activity, because rare-earth-metal-based hydroamination catalysts generally show only a small decrease in rate in the presence of THF.[13,65,66]

Both complexes (*R*,*R*)-**4** and (*R*)-**5** are also active in the hydrosilylation of various olefinic substrates (Table 3).[93] However, catalytic activity for the monomeric tris-THF adduct (*R*)-**5** is generally lower than for the THF-free dimer (*R*,*R*)-**4**.

Hydrosilylation of styrene proceeds with good activity to give the Markovnikov product with high selectivity. Plausible reasons for the preferred formation of this isomer can be derived from the electronically preferred secondary insertion of styrene into the metal−hydride bond of the catalytically active rare-earth-metal hydrido species.[33,94] In contrast to previously investigated lanthanocene[33] and diamidobiphenyl[45] catalyst systems, the catalytic activities of complexes (*R*,*R*)-**4** and (*R*)-**5** in the hydrosilylation of 1-hexene or norbornene are significantly lower than for styrene, and higher catalyst loadings are required to complete the reaction. The stereoselectivity substrates is very high for these, giving exclusively 1,2-addition for 1-hexene and the *exo* adduct for norbornene.

The reason for the low catalytic activity in the hydrosilylation of 1-hexene and norbornene is not completely clear at present. NMR spectroscopic investigation could not reveal an identifiable species during the catalysis, for example a lanthanum hydride species. Schaverien noted that replacing a six-electron π-donor cyclopentadienyl ligand in a lanthanocene complex by a four-electron donating aryloxide ligand results in reduced activity in the polymerization of α-olefins due to the formation of deactivated μ-hydrido and μ-alkyl species.[95] Insertion of linear terminal olefins proceeded exclusively in a 1,2-fashion and no μ-isoalkyls were observed. Similarly, the highly electrophilic biphenolate lanthanum complexes can be expected to form stable μ-hydrido

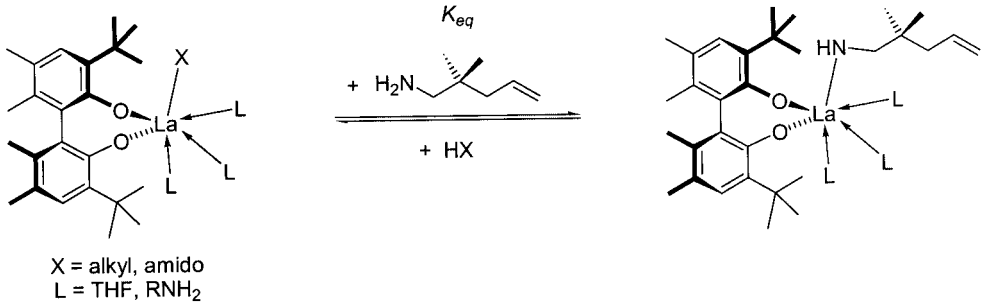
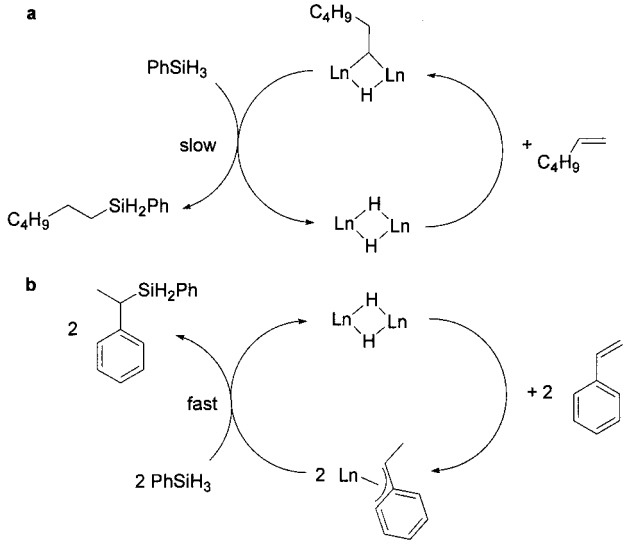


Scheme 4

and μ-alkyl species[96] with reduced reactivity towards olefin insertion or phenylsilane σ-bond metathesis (Scheme 5a). Whereas insertion of 1-hexene into a terminal lanthanum hydride species is expected to give an appreciable amount of branched product[33,39] due to the sterically undemanding features of the biphenolate ligand, insertion into a bridging μ-hydrido would explain the high regioselectivity observed in the hydrosilylation of 1-hexene. The secondary insertion product formed in the reaction of the lanthanum hydride species with styrene on the other hand should adopt an η^3-benzylic coordination mode[94] rather than a bridging μ-benzyl arrangement. The terminal η^3-benzyl group should be significantly more reactive towards phenylsilane than a μ-alkyl species.



Scheme 5

Conclusion

We have presented here the facile synthesis of chiral biphenolate alkyllanthanum complexes. These complexes show good catalytic activity for the hydroamination/cyclization of aminoalkenes, which is of comparable magnitude to well established lanthanocene catalysts. The catalytic activity is significantly higher than previously prepared biphenolate bis(dimethylsilyl)amido complexes. This can be attributed to a sluggish catalyst initiation in the case of the amido complexes caused by the low basicity of the bis(dimethylsilyl)amido ligand. Despite their high catalytic activity, practical use of the biphenolate alkyl complexes for asymmetric hydroamination is limited by the low enantiomeric excess in the product heterocycles, because the *tert*-butyl groups of the biphenolate ligand have an insufficient stereodifferentiating effect. However, catalysts with larger substituents should be more enantioselective, as shown by yttrium complexes bearing tris(aryl) substituted binaphtholate ligands,[65] while retaining the high catalytic activity. Although the biphenolate lanthanum complexes show good regioselectivity in the hydrosilylation of olefins, they are less attractive catalysts than lanthanocene complexes due to their lower catalytic activity.

Experimental Section

General Remarks: All operations were performed under an inert atmosphere of nitrogen or argon using standard Schlenk-line or glovebox techniques. After drying over KOH, THF was distilled from sodium benzophenone ketyl. Hexanes, pentane and toluene were purified by distillation from sodium/triglyme benzophenone ketyl. [Ln{$CH(SiMe_3)_2$}$_3$] (Ln = Y, La),[79] (*R*)-H_2(Biphen)[76] and substrates **8**,[97] **10**,[13] **12**,[60] **14**[98][99] and **16**[58] were synthesized as described in the literature. Olefins for hydrosilylation reactions were distilled from sodium and stored over molecular sieves. The substrates were dried by distillation from CaH_2 and stored over molecular sieves. (*R*)-(+)-α-Methoxy-α-trifluoromethylphenylacetic acid (RCA, Freiburg, Germany) was transformed into its acid chloride by reaction with oxalyl chloride/DMF in hexanes.[100] Mosher amides were prepared and analyzed by ^{19}F NMR spectroscopy as described earlier.[60] All other chemicals were commercially available and used as received. ^1H, ^{13}C and ^{19}F NMR spectra were recorded on a Bruker Avance 300 (300.1, 75.5 and 282.4 MHz for ^1H, ^{13}C, and ^{19}F, respectively) or Avance 400 (400.1 and 100.6 MHz for ^1H and ^{13}C, respectively) spectrometer. Spectra were referenced internally using the residual solvent resonances (^1H, ^{13}C) or referenced externally to $CFCl_3$ (^{19}F; δ = 0 ppm). Elemental analyses were performed by the Microanalytical Laboratory of this department. Although metal complexes were combusted with V_2O_5 as burning aid, analyses often gave low carbon content repeatedly, presumably due to carbide formation.

(*R*,*R*)-[La(Biphen){$CH(SiMe_3)_2$}]$_2$ [(*R*,*R*)-4]: A solution of (*R*)-H_2(Biphen) (156 mg, 0.44 mmol) in toluene (1 mL) was added to a solution of [La{$CH(SiMe_3)_2$}$_3$] (280 mg, 0.454 mmol) in toluene (1 mL) over 10 min at −10 °C with a syringe. The mixture was stirred at room temperature for 1 h and the solvent was evaporated

in vacuo. The remaining yellow residue was dried in vacuo. Pentane (2 mL) was added to the residue and the mixture was heated to 50 °C and left in a fridge overnight. The solvent was decanted at −30 °C, acetone bath) from a slightly yellow crystalline precipitate, and the precipitate was washed with pentane (0.5 mL) and dried in vacuo. Yield 110 mg (35%). The crystals contain one equiv. of pentane per molecule of the dimer. ^{1}H NMR (400.1 MHz, [D$_8$]toluene, 25 °C): δ = 7.13 (br. s, 4 H, Biphen), 2.16 (br. s, 12 H, aryl-CH$_3$), 1.53 (br. s, 12 H, aryl-CH$_3$), 1.40 (br. s, 36 H, C(CH$_3$)$_3$], 0.30 [s, 18 H, Si(CH$_3$)$_3$], −0.03 [s, 18 H, Si(CH$_3$)$_3$], −0.62 (s, 2 H, LaCH). ^{1}H NMR (400.1 MHz, [D$_8$]toluene, −30 °C): δ = 7.24 (s, 2 H, Biphen), 7.08 (s, 2 H, Biphen), 2.22 (s, 6 H, aryl-CH$_3$), 2.18 (s, 6 H, aryl-CH$_3$), 1.65 (s, 6 H, aryl-CH$_3$), 1.55 (s, 6 H, aryl-CH$_3$), 1.41 [s, 18 H, C(CH$_3$)$_3$], 1.37 [s, 18 H, C(CH$_3$)$_3$], 0.33 [s, 18 H, Si(CH$_3$)$_3$], 0.07 [s, 18 H, Si(CH$_3$)$_3$], −0.63 (s, 2 H, LaCH) ppm. ^{13}C{^{1}H} NMR (100.6 MHz, [D$_8$]toluene, −30 °C): δ = 156.1, 150.3, 137.8, 137.3, 137.2, 137.0, 135.0, 133.4, 131.2, 130.1, 128.5, 126.6, (aryl), 55.0 (LaCH), 35.0 [*C*(CH$_3$)$_3$], 32.2, 30.7 [C(*C*H$_3$)$_3$], 20.0, 17.5 (aryl-CH$_3$), 4.8, 4.5 [Si(CH$_3$)$_3$] ppm. C$_{62}$H$_{102}$La$_2$O$_4$Si$_4$·(C$_5$H$_{12}$) (1373.8): calcd. C 58.58, H 8.36; found C 57.73, H 8.10.

(*R*)-[La(Biphen){CH(SiMe$_3$)$_2$}(THF)$_3$] [(*R*)-5]: THF (7.2 μL, 89 μmol, 3 equiv. per lanthanum) was added to a solution of (*R*,*R*)-**4** (20 mg, 14.6 μmol) in [D$_6$]benzene (0.5 mL). Removal of the solvent in vacuo led to partial loss of THF, therefore the catalyst was always prepared in situ directly prior to use. ^{1}H NMR (400.1 MHz, [D$_6$]benzene): δ = 7.17 (s, 2 H, Biphen), 3.55 (br. m, 12 H, THF), 2.15 (s, 6 H, aryl-CH$_3$), 1.74 (s, 6 H, aryl-CH$_3$), 1.63 [s, 18 H, C(CH$_3$)$_3$], 1.30 (br. m, 12 H, THF), 0.35 (s, 9 H, SiMe$_3$), 0.33 (s, 9 H, SiMe$_3$), −1.64 [s, 1 H, *CH*(SiMe$_3$)$_2$] ppm. ^{13}C{^{1}H} NMR (100.6 MHz, [D$_6$]benzene): δ = 156.3, 138.3, 136.4, 130.7, 128.9, 124.4 (aryl), 68.9 (THF), 51.5 (LaCH), 35.2 [*C*(CH$_3$)$_3$], 30.7 [C(*C*H$_3$)$_3$], 25.4 (THF), 20.4 (aryl-CH$_3$), 16.2 (aryl-CH$_3$), 5.1 (SiMe$_3$), 5.0 (SiMe$_3$) ppm.

(*R*)-[La(Biphen){N(SiHMe$_2$)$_2$}(THF)$_3$] [(*R*)-6]: THF (6.3 μL, 78 μmol, 3.5 equiv. per lanthanum) was added to a solution of (*R*,*R*)-**4** (15 mg, 10.9 μmol) in [D$_8$]toluene (0.5 mL). The solution was kept at 25 °C for 30 min and then tetramethyldisilazane (4.0 μL, 23 μmol) was added. Removal of the solvent in vacuo led to partial loss of THF. ^{1}H NMR (400.1 MHz, [D$_8$]toluene, 25 °C): δ = 7.14 (s, 2 H, Biphen), 5.00 (sept, $^3J_{H,H}$ = 3.0 Hz, 2 H, SiH), 3.55 (m, THF), 3.50 (br. m, THF), 2.17 (s, 6 H, aryl-CH$_3$), 1.77 (s, 6 H, aryl-CH$_3$), 1.64 [s, 18 H, C(CH$_3$)$_3$], 1.38 (m, THF), 0.28 [d, $^3J_{H,H}$ = 3.0 Hz, 6 H, SiH(C*H*$_3$)$_2$], 0.24 [d, $^3J_{H,H}$ = 2.9 Hz, 6 H, SiH(C*H*$_3$)$_2$] ppm. ^{13}C{^{1}H} NMR (100.6 MHz, [D$_8$]toluene, 25 °C): δ = 156.6, 139.1, 136.3, 131.4, 128.4, 123.9 (aryl), 68.6 (THF), 35.3 [*C*(CH$_3$)$_3$], 30.6 [C(*C*H$_3$)$_3$], 25.6 (THF), 16.2 (aryl-CH$_3$), 3.0 [SiH(CH$_3$)$_2$], 2.9 [SiH(CH$_3$)$_2$] ppm.

(*R*,*R*)-[La(Biphen){N(SiHMe$_2$)$_2$}(THF)]$_2$ [(*R*,*R*)-7]: THF (1.4 μL, 17.3 μmol, 1.2 equiv. per lanthanum) was added to a solution of (*R*,*R*)-**4** (10 mg, 7.3 μmol) in [D$_6$]benzene (0.5 mL). The solution was kept at 25 °C for 30 min and then tetramethyldisilazane (3.1 μL, 17.8 μmol) was added. The ^{1}H and ^{13}C NMR spectra show broad signals for the biphenolate ligand at room temperature. ^{1}H NMR (400.1 MHz, [D$_6$]benzene, 60 °C): δ = 7.23 (s, 2 H, Biphen), 4.90 (br. sept, 2 H, SiH), 3.58 (br. m, THF), 3.50 (br. m, THF), 2.15 (br. s, 6 H, aryl-CH$_3$), 1.80 (br. s, 6 H, aryl-CH$_3$), 1.54 [br. s, 18 H, C(CH$_3$)$_3$], 1.33 (m, THF), 0.32 [m, 12 H, SiH(C*H*$_3$)$_2$] ppm. ^{13}C{^{1}H} NMR (100.6 MHz, [D$_6$]benzene, 60 °C): δ = 138.4, 137.3, 136.2, 129.6, 128.6, 124.7 (aryl), 69.3 (THF), 35.3 [*C*(CH$_3$)$_3$], 34.9 [*C*(CH$_3$)$_3$], 30.7 [C(*C*H$_3$)$_3$], 30.5 [C(*C*H$_3$)$_3$], 25.3 (THF), 20.0, 16.3 (aryl-CH$_3$), 3.2 [SiH(CH$_3$)$_2$], 3.1 [SiH(CH$_3$)$_2$] ppm.

X-ray Crystallographic Study: Clear, colourless crystals of (*R*,*R*)-**4** suitable for X-ray diffraction analysis were obtained by cooling a concentrated pentane solution to −30 °C. Data were collected on a Nonius KappaCCD area detector. Crystal data: C$_{62}$H$_{102}$La$_2$O$_4$Si$_4$·C$_5$H$_{12}$, M_r = 1373.78, crystal size 0.10 × 0.10 × 0.10 mm, orthorhombic, space group $P2_12_12$ (No. 18), a = 16.3814(7) Å, b = 17.5277(5) Å, c = 12.9592(6) Å, V = 3721.0(3) Å^3, Z = 2, $\rho_{calcd.}$ = 1.225 g cm^{-3}, F(000) = 1434, Mo-K_α radiation (λ = 0.71073 Å), T = 173(2) K, μ = 1.237 mm^{-1}, 8519 independent reflections measured, GOF = 0.945, R [$I > 2\sigma(I)$] = 0.0473, wR_2 (all data) = 0. 1084, absolute structure parameter = −0.04(2), largest e-max, e-min = 0.555 and −0.767 e·Å^{-3}. Cell parameters for (*R*,*R*)-**4** were obtained from 10 frames using a 10° scan and refined with 4689 reflections. Lorentz, polarization, and empirical absorption corrections were applied.[101,102] The space group was determined from systematic absences and subsequent least-squares refinement. The structures were solved by direct methods. The parameters were refined with all data by full-matrix least-squares on F^2 using SHELXL-97.[103] Hydrogen atoms were fixed in idealized positions using a riding model. Non-hydrogen atoms were refined anisotropically. The methyl groups attached to C17 are disordered and were refined with two independent orientations (position occupation of 48.52% and 51.48%, respectively). Scattering factors and $\Delta f'$ and $\Delta f''$ values were taken from the literature.[104] Graphical representations were prepared with ORTEP-III for Windows.[105] CCDC-235041 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

General Procedure for NMR-Scale Catalytic Hydroamination/Cyclization Reactions: In a glovebox, a screw-cap NMR tube was charged with 10 μmol of the catalyst, C$_6$D$_6$ (0.5 mL) and the substrate (0.33 mmol) in that order. The NMR tube was then placed in a pre-heated oil bath and conversion followed by ^{1}H NMR spectroscopy (for acquisition parameters see below). Final conversion was determined by ^{1}H NMR spectroscopy (disappearance of olefinic signals) and by GC analysis. Diastereomeric ratios of pyrrolidines **13** and **15** as well as piperidine **17** were determined by vacuum-transfer of all volatiles and subsequent ^{1}H NMR spectroscopic analysis of characteristic signals.

General Procedure for Kinetic Catalytic Hydroamination/Cyclization Reactions: In a glovebox, a screw-cap NMR tube was charged with 10 μmol of the catalyst, C$_6$D$_6$ (0.5 mL) and the substrate (0.33 mmol) in that order. The NMR tube was then placed in the thermostatted probe (± 0.5 °C) of the Bruker Avance 400 spectrometer. The conversion was monitored by ^{1}H NMR spectroscopy by following the disappearance of the olefinic signals of the substrate relative to the internal standard CH$_2$(SiMe$_3$)$_2$. NMR spectra were taken at 5 min time intervals using the *multizg* script from the Bruker XWin NMR software package. In order to ensure accurate integration, a 10 s delay between 30° pulses was utilized (number of scans = 4, acquisition time = 4 s). Substrate and catalyst concentration was verified by comparison of the integrals of characteristic signals [olefinic signals for substrates; Si(CH$_3$) signal of CH$_2$(SiMe$_3$)$_2$]. The linear part of the data (minimum two half-lives) was fit by least-squares analysis and the turnover frequency (TOF) was determined from the slope a. TOF = a × [subst]$_0$/[cat]

General Procedure for NMR-Scale Catalytic Hydrosilylation Reactions: In the glovebox, a screw-cap NMR tube was charged with (*R*,*R*)-**4** (5.0 mg, 3.6 μmol), C$_6$D$_6$ (0.5 mL), the olefin (0.30 mmol) and phenylsilane (33 mg, 0.30 mmol) in that order. The NMR tube

Novel Cadmium(II) Adipate Coordination Polymers with Structural Transformation via Oxalate Ligand: Syntheses, Structures and Fluorescence Properties

Na Hao,[a] Enhong Shen,*[a] Yang-Guang Li,[a] En-Bo Wang,*[a] Chang-Wen Hu,[a] and Lin Xu[a]

Keywords: Cadmium / Coordination polymers / Fluorescence / Hydrothermal synthesis / Interpenetration

Two novel cadmium adipate coordination polymers $[Cd\{O_2C(CH_2)_4CO_2\}\{1,10\text{-phen}\}]_n$ (**1**) and $[Cd_2(C_2O_4)\{O_2C(CH_2)_4CO_2(OH_2)_2\}\{2,2'\text{-bipy}\}]\cdot H_2O$ (**2**) [adipic acid = $HO_2C(CH_2)_4CO_2H$] have been hydrothermally synthesized and characterized by elemental analyses, IR spectroscopy, thermogravimetric analysis and single-crystal X-ray diffraction. Crystallographic data for **1**: monoclinic, *C*2/*c*, *a* = 16.186(3) Å, *b* = 15.487(3) Å, *c* = 14.052(3) Å, *β* = 112.73(3)°, *Z* = 8. Crystal data for **2**: monoclinic, *Cc*, *a* = 23.448(5) Å, *b* = 11.826(2) Å, *c* = 8.3163(17) Å, *β* = 99.08(3)°, *Z* = 4. The structural analysis reveals that **1** forms a novel one-dimensional chain in which the binuclear Cd centers are linked by adipate anions. Compound **2** is the first example in which both a 2,2′-bipy ligand and an oxalate group are found in the {M/adipate} system. Compound **2** possesses one-dimensional sine- or cosine-type chains, which are alternately connected together by the oxalate group to form a three-dimensional framework. The structural determination reveals that the introduction of the oxalate ligand causes the dimensional transformation of the compounds. Compounds **1** and **2** show strong fluorescent properties at room temperature.

Introduction

Research on metal-templated coordination polymers with different dimensions is of current interest in the field of supramolecular chemistry and crystal engineering, not only because of their intriguing structural motifs but also because of their potential applications due to their unique electro-conductive, nonlinear optical and magnetic properties.[1−6] In this respect, the selection of inorganic and organic building blocks possessing specific features to fulfil special needs of transition metals, such as versatile binding modes and coordination abilities to form hydrogen bonding, is the key to the construction of a desired framework.[7,8] It is noteworthy that dicarboxylates such as malonate, fumarate and 1,4-benzenedicarboxylate have been widely used in constructing novel different dimensional metal-organic hybrid compounds.[9] In contrast, the dicarboxylate ligand adipate has rarely been used. There are at least three intriguing structural features of the adipate ligand. In the first place, it contains two bridging moieties, which leads to a variety of connection modes with transitional metal centers and provides abundant structural motifs. In the second place, it can act both as a hydrogen-bond donor and acceptor. And finally, it contains six carbon atoms that may construct high dimensional and pore structures. Although several interesting compounds containing adipate have been reported by Jung, Ribas, Bakalbassis and their co-workers,[10] the introduction of chelating ligands containing N- or O-donors, such as 2,2′-bipy, 1,10-phen and oxalate anion ($C_2O_4^{2-}$), to the {M/adipate} system has not been explored hitherto. A chelating N-containing ligand usually inhibits the expansion of polymeric frameworks due to the "passivation" of the metal sites by the N donors of the organic groups, which may decrease the dimensionality of these metal-organic hybrid compounds.[11,12] However, the O-containing ligand $C_2O_4^{2-}$ has more geometrical coordination modes to provide both rigidity and preferred coordination specificity for metal centers,[7] thus making it easier to form 1-D chains and thereby allow the formation of higher-dimensional frameworks. Taking into account these factors, we became motivated to design and synthesize novel metal-organic coordination polymers containing adipate and one or more kind of organic ligands containing N- or O-donors under hydrothermal conditions.

In this paper, we report two novel cadmium-containing coordination polymers $[Cd\{O_2C(CH_2)_4CO_2\}\{1,10\text{-phen}\}]_n$ (**1**) and $[Cd_2(C_2O_4)\{O_2C(CH_2)_4CO_2(OH_2)_2\}\{2,2'\text{-bipy}\}]\cdot H_2O$ (**2**). Compounds **1** and **2** possess different dimensionality due to the introduction of the oxalate ligand. Compound **1**

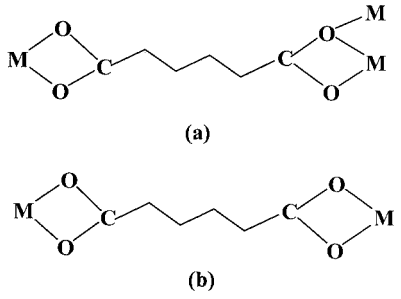
exhibits an interesting 1-D chain in which the binuclear Cd centers are linked by adipate anions. Compound **2** not only has 1-D sine- or cosine-type chains, but also exhibits a novel three-dimensional framework in which the sine- and cosine-type curves are connected alternately by oxalate anions along the *c* axis. Furthermore, both compounds show intense fluorescence at room temperature.

Results and Discussion

The hydrothermal reaction of a solution of $Cd(NO_3)_2{\cdot}4H_2O$, adipic acid, 1,10-phenanthroline (1,10-phen), NaOH and H_2O gives rise to **1** as colorless crystals. Single crystal X-ray diffraction analysis reveals that **1** is a 1-D chain-like polymer with one crystallographically unique Cd center in the asymmetric unit (see Figure S1 in the Supporting Information). The Cd(1) site coordinates to two nitrogen atoms of one 1,10-phen group and five carboxyl oxygen atoms of different adipate ligands. The average Cd−N bond length is 2.346 Å and the Cd−$O_{(carboxyl)}$ bond lengths are in the range 2.289(2)−2.587(3) Å. The N(O)−Cd−O(N) bond angles range from 80.65(9)° to 153.85(10)° (see Table S2 in the Supporting Information). Thus, the Cd center displays a distorted pentagonal bipyramidal geometry to form one $[CdO_5N_2]$ unit. Two such $[CdO_5N_2]$ units are connected together by μ_3-O atoms in an edge-sharing mode to form dinuclear Cd centers. In addition, two carboxylate groups of the adipate ligand exhibit two kinds of coordination modes with Cd centers (see a in Scheme 1) — one carboxylate group acts as a bis-chelating ligand to bridge one Cd center, while the other exhibits an unusual bidentate bridging mode to link two Cd centers. Thus, one adipate ligand is connected to three different Cd centers, which has not been observed previously. To the best of our knowledge, this is the first example for adipate anions in which the carboxylates exhibit a bis-chelating and bidentate bridging mode toward metal centers. On the basis of this connection mode, all dinuclear Cd centers are linked by four bridging adipate ligands to form a 1-D chain along the *a* axis (see Figure 1). In contrast to the reported compounds in the {M/adipate} (M = transition metal ions) system, compound **1** is the first dinuclear compound connected by mixed adipate and 1,10-phen ligands. In the packing arrangement of **1**, the adjacent 1-D chains are parallel to each other and construct a 2-D framework through π-π interactions between the aromatic groups of the 1,10-phen ligands.[13a] The narrowest interplanar distance of the aromatic units is about 3.41 Å. Adjacent 2-D frameworks are further connected together to form a 3-D network by hydrogen-bonding interactions. The π-π interactions and the hydrogen bonds enhance the stability of the compound.

Valence-sum calculations give a value of 1.92 for the Cd atom, indicating that the Cd center is in the +2 oxidation state. Atoms O(1)−O(4) have bond-valence sums of 1.66,



Scheme 1. Coordination modes of the adipate ligand in compounds **1** (a) and **2** (b)

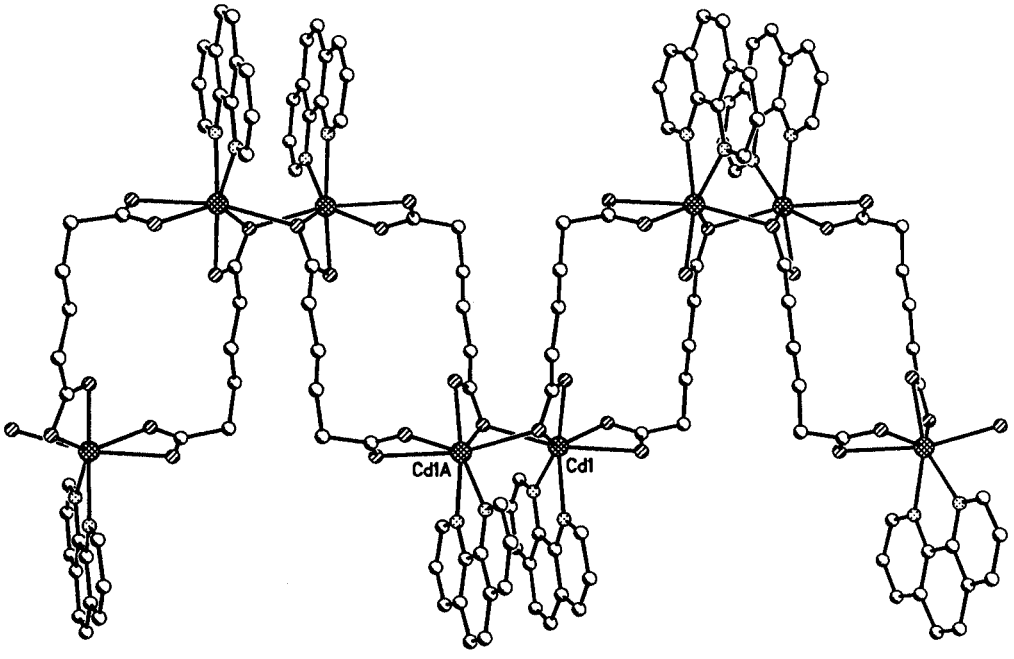


Figure 1. The 1-D chain of compound **1** viewed along the *b* axis

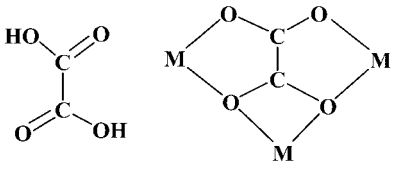
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1.79, 1.85, and 1.62, respectively, suggesting that all carboxyl groups are deprotonated.[13b] These results are consistent with the charge-balance considerations and alkaline synthetic conditions of compound **1**.

The hydrothermal reaction of a solution of $Cd(NO_3)_2{\cdot}4H_2O$, adipic acid, 2,2′-bipy, $H_2C_2O_4$, NaOH and H_2O gives rise to **2** as colorless crystals. X-ray crystallographic analysis reveals that compound **2** forms an interesting 3-D network. There are two crystallographically unique Cd centers in the asymmetric unit (see Figure S2). The Cd(1) center is coordinated by two oxygen atoms [Cd(1)−O(3) 2.438(6) Å, Cd(1)−O(4) 2.302(6) Å] of one carboxylate group, four oxygen atoms of two different oxalate anions, including one μ_3-oxygen atom [Cd(1)−O(6) 2.630(6) Å], and one oxygen atom of a water molecule [Cd(1)−$O_{(water)}$ 2.267(6) Å]. The O−Cd(1)−O bond angles range from 52.66(17)° to 166.6(2)°. The Cd(2) center is bonded to two nitrogen atoms of one 2,2′-bipy ring with an average Cd(2)−N bond length of 2.347(6) Å, two oxygen atoms [Cd(2)−O(1) 2.467(6) Å, Cd(2)−O(2) 2.320(6) Å] of one carboxylate group, and two oxygen atoms of one oxalate anion [Cd(2)−O(5) 2.406(5) Å, Cd(2)−O(6) 2.353(5) Å]. The O−Cd(2)−O bond angles range from 54.1(2)° to 156.29(19)°, and the O(N)−Cd(2)−N(O) bond angles range from 81.1(2)° to 166.9(2)° (shown in Table S3). Therefore, both Cd centers display a distorted pentagonal bipyramidal geometry. The [CdO_7] unit and [CdO_5N_2] unit are linked by $C_2O_4^{2-}$ anions to form a pseudo-binuclear Cd center through the μ_3-O(6) atom. The Cd(1)···Cd(2) distance bridged by one μ_3-O(6) atom is 4.881 Å. As opposed to compound **1**, the two carboxyl groups of the adipate ligand in compound **2** exhibit another kind of coordination mode with the Cd atoms, as shown in Scheme 1b — all the carboxyl groups adopt a bis-chelating mode to connect the two Cd atoms. These pseudo-binuclear Cd centers are connected to each other by adipate anions to form a 1-D wave-like chain along the *c* axis, just like a sine- or cosine-type curve (see Figure 2). Furthermore, the $C_2O_4^{2-}$ anions also display two interesting kinds of connection mode with the Cd centers, as shown in Scheme 2. One carboxylate group binds in a bis-chelating mode to bridge one Cd center, while the two oxygen atoms from two different carboxyl groups exhibit an unusual bidentate bridging mode to link with another Cd center. Thus, one $C_2O_4^{2-}$ anion is connected with three Cd centers, as shown in Figure 3. To the best of our knowledge, this is the first example containing $C_2O_4^{2-}$ anions in which the oxalate group binds in both a bis-chelating and a bridging mode toward the metal centers. Based on the connection mode of $C_2O_4^{2-}$ anions, the sine-type and cosine-type chains are connected alternately by $C_2O_4^{2-}$ anions, forming a novel 3-D framework (see Figure 4). It is noteworthy that this 3-D network contains approximately square channels constructed by the adipate and oxalate ligands and the Cd centers, where the 2,2′-bipy ligands reside.



Scheme 4. Coordination modes of the oxalate ligand in compound **2**

Compound **2** is the first example in which both 2,2′-bipy and oxalate ligands are introduced into the {M/adipate} system. Furthermore, the introduction of the oxalate ligand leads to the dimensional transformation of the metal adipate coordination polymers.

Valence-sum calculations give values of 2.17 and 1.98 for the Cd(1) and Cd(2) atoms, respectively, indicating that each Cd center is in the +2 oxidation state. The coordinated oxygen atoms Ow(1) and Ow(2) have bond-valence sums of 0.27 and 0.37, respectively, suggesting that Ow is a coordinated water molecule. Atoms O(1)−O(8) have bond valence sums of 1.69, 1.77, 1.78, 1.83, 1.73, 1.71, 1.76 and 1.76, respectively, showing that all the carboxyl groups have been deprotonated.[13b] These results are consistent with charge-balance considerations and the alkaline synthetic conditions of compound **2**.

The IR spectrum of compound **1** shows characteristic bands of carboxyl groups at 1560 cm^{-1} for the antisymmetric stretching and at 1447 and 1409 cm^{-1} for symmetric

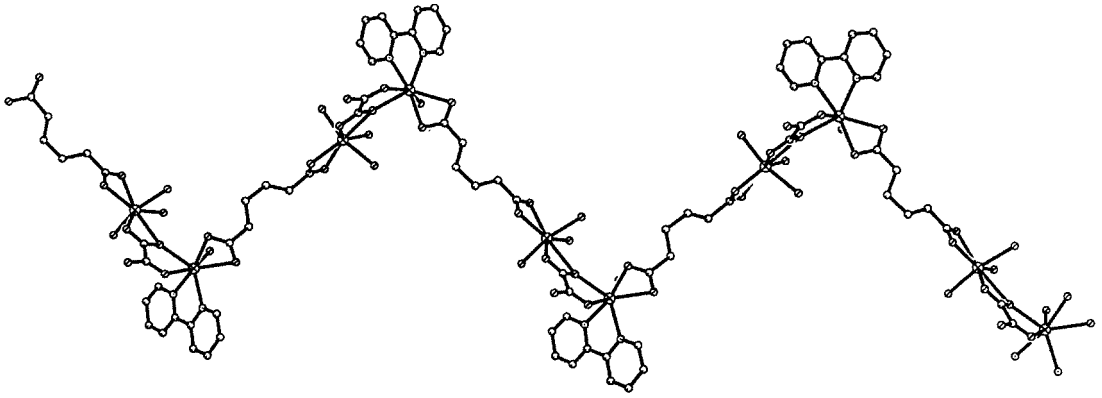


Figure 2. The 1-D chain of compound **2** viewed along the *c* axis

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

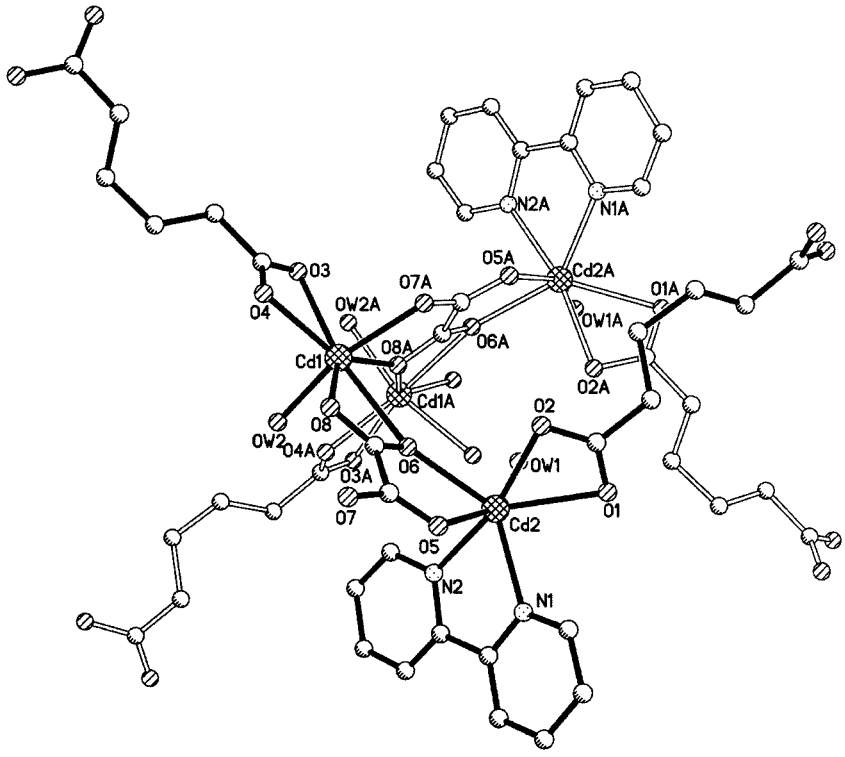

Figure 3. Perspective view of the connection mode of sine- and cosine-type chains connected to each other by oxalate in compound **2**

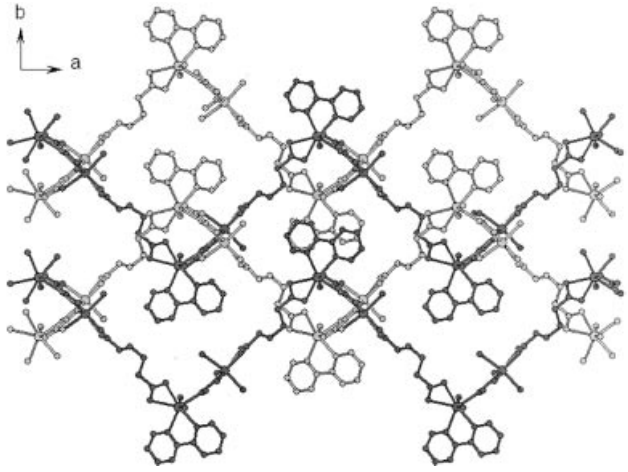

Figure 4. The 3-D framework of compound **2** along the *c* axis

stretching (see Figure S3a). The separations ($\Delta\nu$) between $\nu_{asym}(CO_2)$ and $\nu_{sym}(CO_2)$ indicate the presence of both chelating (113 cm^{-1}) and monodentate (151 cm^{-1}) coordination modes in compound **1**. The IR spectrum of compound **2** exhibits characteristic bands of carboxyl groups at 1630 cm^{-1} and 1603 cm^{-1} for the antisymmetric stretching and at 1437 cm^{-1} for symmetric stretching (see Figure S3b). The separations ($\Delta\nu$) between the $\nu_{asym}(CO_2)$ and $\nu_{sym}(CO_2)$ bands show that the carboxylate groups bind in a bis-chelating fashion to the metal centers.[14]

In the TGA curve of compound **1** (see Figure S4a), there is only one weight loss of 70.50% in the range 320−540 °C, corresponding to the release of 1,10-phen and adipate ligands (calcd. 70.60%). The remaining weight of 29.50% corresponds to the percentage (29.40%) of Cd and O components, indicating that the final product is CdO. The TGA curve of compound **2** exhibits three weight-loss stages. The first weight loss is 3.09% (calcd. 2.70%) in the range of 133−185 °C, corresponding to the release of water molecules of crystallization. The second weight loss is 18.27% (calcd. 18.59%) in the range 265−360 °C, corresponding to the release of coordinated water and oxalate ligand. The last weight loss is 40.48% (calcd. 40.22%) in the temperature range 375−565 °C, corresponding to the release of 2,2′-bipy and adipate ligands. The residue is CdO. The whole weight loss (61.84%) is in good agreement with the calculated value (61.51%; see Figure S4b).

Photoluminescence Properties

The emission spectra of compounds **1** and **2** in the solid state at room temperature are depicted in Figure 5, with intense emissions at 443 nm (see a in Figure 5, λ_{ex} = 383 nm) for **1** and 422 nm (see b in Figure 5, λ_{ex} = 346 nm) for **2**. The difference between the two emission bands may be due to the different coordination environments of the Cd atom in these compounds. According to the literature,[15] the emissions at 443 nm and 422 nm can be assigned to ligand-to-metal charge-transfer (LMCT) bands. These observations indicate that compounds **1** and **2** may be excellent candidates for photoluminescent materials.

Conclusion

We have successfully combined the merits of Cd metal and adipate with other organic ligands and synthesized two novel coordination polymers — $[Cd\{O_2C(CH_2)_4CO_2\}\{1,10\text{-phen}\}]_n$ (**1**) and $[Cd_2(C_2O_4)\{O_2C(CH_2)_4CO_2(OH_2)_2\}\{2,2'\text{-bipy}\}]\cdot H_2O$ (**2**) — with different dimensionalities and different coordination architectures. Comparing the structures of **1** and **2**, it has been found that the different coordination modes of the ligand may have a significant effect on the formation and dimension of the resulting structures. The successful preparation of compounds **1** and **2** provides a valuable approach for the construction of many other coordination polymers with different dimensional structures by the introduction of another kind of organic ligand. Furthermore, the strong fluorescent properties of compounds **1** and **2** make them excellent candidates for potential photoactive materials.

Experimental Section

General Methods: All chemicals were commercially purchased and used without further purification. Elemental analyses (C, H and N) were performed with a Perkin-Elmer 2400 CHN Elemental Analyzer; Cd was determined with a PLASMA-SPEC(I) ICP atomic emission spectrometer. IR spectra were recorded in the range 400−4000 cm^{-1} with an Alpha Centaurt FT/IR Spectrophotometer using KBr pellets. TG analyses were performed with a Perkin-Elmer TGA7 instrument in flowing N_2 with a heating rate of 10 °C·min^{-1}. Excitation and emission spectra were obtained with a Spex FL-2T2 spectrofluorometer equipped with a 450-W-xenon lamp as the excitation source.

Synthesis of 1: Compound **1** was synthesized from a reaction mixture containing $Cd(NO_3)_2\cdot 4H_2O$ (0.15 g, 0.5 mmol), adipic acid (0.073 g, 0.5 mmol), 1,10-phen (0.018 g, 0.1 mmol), NaOH (0.04 g, 1.0 mmol) and H_2O (6 mL, 333 mmol) in an 18-mL Teflon-lined autoclave under autogenous pressure at 160 °C for four days, followed by slow cooling (10 °C/h) to room temperature. The product was washed with distilled water and air-dried. The product was of high quality in the form of colorless crystals. Yield: 0.112 g (75% based on Cd). Elemental analyses. $C_{18}H_{16}CdN_2O_4$: calcd. C 49.5, H 3.7, N 6.4, Cd 25.7; found C 49.6, H 3.5, N 6.5, Cd 25.9. Selected FT-IR data (KBr pellet): $\tilde{\nu}$ = 3427 (s), 3053 (w), 2991 (m), 1560 (s), 1516 (w), 1418 (s), 1409 (s), 1355 (w), 1316 (m), 1103 (s), 1053 (s), 858 (s), 787 (m), 753 (m), 730 (s), 638 (m), 601 (w), 470 (s), 420 (w) cm^{-1}.

Synthesis of 2: Compound **2** was synthesized from a reaction mixture containing $Cd(NO_3)_2\cdot 4H_2O$ (0.15 g, 0.5 mmol), adipic acid (0.073 g, 0.5 mmol), 2,2′-bipy (0.023 g, 0.15 mmol), $H_2C_2O_4$ (0.009 g, 0.1 mmol), NaOH (0.04 g, 1.0 mmol) and H_2O (6 mL, 333 mmol) in na 18-mL Teflon-lined autoclave under autogenous pressure at 160 °C for four days, followed by slow cooling (10 °C/h) to room temperature. The product was washed with distilled water and air-dried. The product was of high quality in the form of colorless crystals. Yield: 0.108 g (72% based on Cd). $C_{18}H_{22}Cd_2N_2O_{11}$: calcd. C 32.4, H 3.3, N 4.2, Cd 33.7; found C 32.5, H 3.2, N 4.4, Cd 33.9. Selected FT-IR data (KBr pellet): $\tilde{\nu}$ = 3382 (s), 3269 (w), 2876 (w), 1639 (m), 1603 (m), 1550 (s), 1460 (w), 1437 (s), 1361 (w), 1309 (s), 1214 (m), 1176 (w), 1155 (m), 1073 (w), 1060 (w), 1018 (s), 971 (w), 910 (w), 804 (s), 765 (s), 737 (m), 651 (m), 627 (w), 583 (w), 493 (m), 449 (w) cm^{-1}.

X-ray Crystallography: Single crystals of compounds **1** and **2** with dimensions 0.532 × 0.485 × 0.396 mm and 0.467 × 0.413 × 0.345 mm, respectively, were glued onto a glass fiber. Data were collected on a Rigaku R-AXIS RAPID IP diffractometer with Mo-K_α graphite-monochromated radiation (λ = 0.71073 Å) at 293 K in the range $1.89 < \theta < 27.48°$ and $1.76 < \theta < 27.44°$, respectively. An empirical absorption correction was applied. The structures were solved by direct methods and refined by the full-matrix least-squares method on F^2 using the SHELXL crystallographic software package.[16] Anisotropic thermal parameters were used to refine all non-hydrogen atoms. Hydrogen atoms were located from difference Fourier maps. The space group of the compound **2** was selected to be *Cc*. Although *Cc* and *C*2/*c* possess the same extinction rules, it can be presumed that the structure of compound **2** is noncentrosymmetric based on the lower CFOM value and the mean value of $<E^2-1>$ 0.651, which is lower than 0.736. Furthermore, as the value of $<E^2-1>$ is very low, the structure may be twinned. Thus, during the structural absolute refinement, a twin refinement was used. The final structural Flack parameter (k = 0.00), suggesting the absolute configuration of compound **2**, was confirmed. Selection of the *C*2/*c* space group to solve the structure did not give the correct structural model.

Crystal Data for 1: $C_{18}H_{16}CdN_2O_4$, M_r = 436.73, monoclinic, *C*2/*c*, a = 16.186(3) Å, b = 15.487(3) Å, c = 14.052(3) Å, $\alpha = \gamma = 90°$, β = 112.73(3)°, U = 3248.7(11) $Å^3$, Z = 8, D_c = 1.786 g·cm^{-3}, μ = 1.371 mm^{-1}, $F(000)$ = 1744, $R1$ = 0.0305, $wR2$ = 0.0685 and

A New Synthetic Method and Solution Equilibria for the Chlorotitanate(IV) Anions − Evidence for the Existence of a New Species: $[Ti_2Cl_{11}]^{3-}$

Emmanuel Robé,[a] Jean-Claude Daran,[b] Sandrine Vincendeau,[b] and Rinaldo Poli*[a]

Keywords: Anions / Electrochemistry / Infrared spectroscopy / Titanium

$TiCl_3$ is oxidized by $SOCl_2$ in the presence of the appropriate amount of $[NEt_3Bz]Cl$ or $[PPN]Cl$ [Bz = benzyl; PPN = bis(triphenylphosphanyl)iminium] to afford the corresponding salts of $[Ti_2Cl_9]^-$, $[Ti_2Cl_{10}]^{2-}$ or $[TiCl_6]^{2-}$. The results of cyclic voltammetric and solution IR studies in the Ti–Cl stretching region are interpreted in terms of a rapid chloride-redistribution equilibrium between $[Ti_2Cl_{10}]^{2-}$ on one side and a mixture of $[Ti_2Cl_9]^-$ and a previously unreported $[Ti_2Cl_{11}]^{3-}$ species on the other side. In the solid state, however, a compound with the $[PPN]_3[Ti_2Cl_{11}]$ stoichiometry exists as a mixture of $[PPN]_2[Ti_2Cl_{10}]$ and $[PPN]_2[TiCl_6]$. The PPN salt of $[Ti_2Cl_9]^-$ has been structurally characterized by X-ray diffractometry.

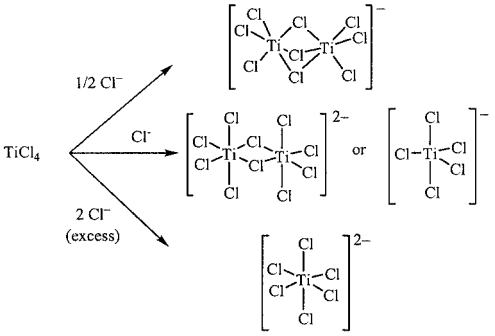
Introduction

Homoleptic chlorometallates are a wide class of fundamentally important coordination compounds. They are in general easily accessible by addition of the required amount of halide ions to the neutral metal halide. For Ti^{IV}, four different anionic complexes are known, the enneachlorodititanate $[Ti_2Cl_9]^-$, the decachlorodititanate $[Ti_2Cl_{10}]^{2-}$, the pentachlorotitanate $[TiCl_5]^-$, and the hexachlorotitanate $[TiCl_6]^{2-}$, formally related to $TiCl_4$ by the addition of one half, one, or two Cl^- ions per titanium, respectively (Scheme 1).[1] The choice between mononuclear or dinuclear pentachlorotitanate seems to be controlled by the size of the counterion.[2] Since $TiCl_3$ is used extensively as a precursor of Ziegler−Natta polymerization catalysts,[3−8] its coordination chemistry has been widely explored. However, the only reported chlorotitanate(III) anions are apparently the edge-sharing bioctahedral $[Ti_2Cl_9]^{3-}$ and the mononuclear octahedral $[TiCl_6]^{3-}$.[9−11] Furthermore, these ions are prepared at high temperatures in the solid state (no solvent),[12,13] and therefore little information is available on their properties in solution.

In an attempt to gain access to soluble versions of these anionic complexes and perhaps to prepare the as-yet unknown[14] decachlorodititanate(III) tetraanion $[Ti_2Cl_{10}]^{4-}$, we have investigated the interaction between $TiCl_3$ and chloride salts in solution. Given the hydrolytic sensitivity of Ti^{III}, our approach consists of the use of $SOCl_2$ as solvent, since this is a well-known medium for ensuring anhydrous conditions for transition metal chlorides.[15] The results of this interaction, yielding metal oxidation, are reported here. Furthermore, we present new information on the solution behavior of the $[Ti_2Cl_{10}]^{2-}$ ion and spectroscopic and electrochemical evidence for the existence of a previously unreported $[Ti_2Cl_{11}]^{3-}$ ion in solution.



Scheme 1

Results and Discussion

Syntheses

The addition of one equivalent of chloride, either as the triethylbenzylammonium (Et_3BzN) or the bis(triphenylphosphanyl)iminium (PPN) salt, to $TiCl_3$ in $SOCl_2$ results in a smooth reaction at room temperature accompanied by a sharp color change from dark purple to yellow. The color is

indicative of chloro complexes of Ti^{IV}. Indeed, the selective product of the reactions are the decachlorodititanate(IV) salts [Equation (1)]. The products were obtained in a pure state and in good yields. They are moderately soluble in dichloromethane, the PPN salt being more soluble than the ammonium salt. The dinuclear nature of these salts is demonstrated by their IR properties (vide infra).

$$2\ TiCl_3 + 2\ [Cat]Cl + 2\ \{Cl\} \xrightarrow{SOCl_2} [Cat]_2[Ti_2Cl_{10}] \quad (1)$$

(Cat = NEt_3Bz, PPN)

By changing the stoichiometry to one or four equivalents of chloride salt per two of $TiCl_3$, the ennachlorodititanate(IV) $[Ti_2Cl_9]^-$, and the hexachlorotitanate(IV) $[TiCl_6]^{2-}$ were obtained in good yields [Equation (2) and Equation (3), respectively]. We have also obtained a product with the stoichiometry $[PPN]_3[Ti_2Cl_{11}]$ by using a 3:2 PPNCl/$TiCl_3$ ratio. The solid state and solution nature of these products will be discussed in the next section. The necessary chlorine atoms for the stoichiometries of Equation (1), Equation (2) and Equation (3) are undoubtedly provided by the thionyl chloride solvent, which must therefore be reduced. The oxidizing properties of thionyl chloride relative to low-valent metal halides do not appear to have been extensively explored. A metal oxidation process has been witnessed for the dehydration of $SnCl_2{\cdot}2H_2O$ (leading to $SnCl_4$ while elemental sulfur was found amongst the reduction products), whereas the dehydration of $TlCl_3{\cdot}xH_2O$, which is affected by a spontaneous reduction to TlCl when the salt is thermally dehydrated, leads to pure $TlCl_3$ when using $SOCl_2$.[15] Another potentially reducing metal chloride is $CrCl_2$, although the dehydration of the corresponding hydrate with $SOCl_2$ has apparently never been described[16] (whereas it *is* known with $COCl_2$).[15] Unlike the above-mentioned dehydration of $SnCl_2$, we have not witnessed the formation of any elemental sulfur. It is known that $SOCl_2$ decomposes at high temperatures to yield Cl_2, SO_2 and S_2Cl_2,[17,18] but, remarkably, the Ti oxidation process that we report here occurs smoothly at room temperature. We have not explored the nature of the reduced sulfur products in this reaction further.

$$2\ TiCl_3 + [PPN]Cl + 2\ \{Cl\} \xrightarrow{SOCl_2} [PPN][Ti_2Cl_9] \quad (2)$$

$$TiCl_3 + 2\ [PPN]Cl + \{Cl\} \xrightarrow{SOCl_2} [PPN]_2[TiCl_6] \quad (3)$$

Electrochemical and Spectroscopic Characterization

Still with the goal in mind of exploring the solution chemistry of the chlorotitanate(III) complexes, we have carried out electrochemical investigations of the chlorotitanate(IV) anions. Previous electrochemical investigations on Ti^{IV} chloride systems appear to be limited to $TiCl_4$ in $AlCl_3$/chloride melts.[19,20] Basic melts (Cl/Al > 4) exhibit only a reversible reduction that has been attributed to the $[TiCl_6]^{2-}$ ion,[19] whereas Lewis-acidic melts show less reversible features that are attributed to less chloride-rich anions, whose nature depends on the melt composition.[20] It is reasonable to expect that the reduction process to Ti^{III} correlates with the effective charge at the metal center, a greater electron density leading to a more difficult reduction process. Therefore, one could reasonably expect a trend of reduction potentials in the order $[TiCl_6]^{2-} < [Ti_2Cl_{10}]^{2-} < [Ti_2Cl_9]^-$.

A cyclic voltammetric analysis of $[Ti_2Cl_{10}]^{2-}$ in CH_2Cl_2 shows that the Ti^{IV} center undergoes the expected reduction process, which is irreversible. This irreversibility is probably linked to loss of chloride ions upon reduction, induced by the accumulation of too much negative charge and by the possible rearrangement to a triply bridged, face-sharing bioctahedral $[Ti_2Cl_9]^{2-}$ species. Such a mixed-valence complex is apparently not yet known. The surprising observation, however, is the complexity of the reduction wave (see Figure 1), which shows at least two distinct processes, the main one having a cathodic peak potential, $E_{p,c}$, of −1.03 V, with a broad shoulder between about −0.8 and −0.6 V.

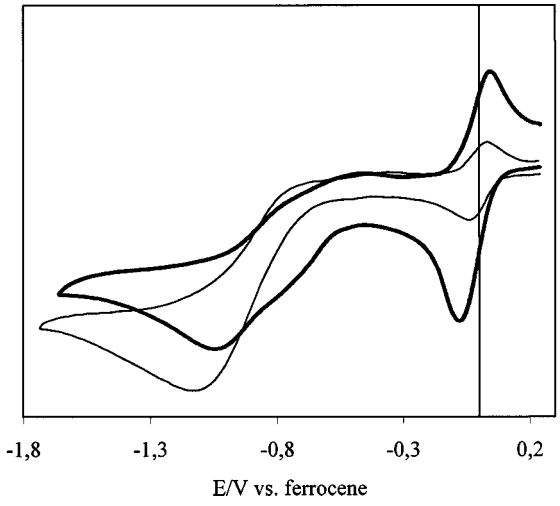

Figure 1. Cyclic voltammograms of solutions of $[NBzEt_3]_2[Ti_2Cl_{10}]$ alone (thicker line) and with two equiv. of $[NBzEt_3]Cl$ (thinner line); both solutions also contain the internal ferrocene standard (reversible wave at $E_{1/2} = 0$); solvent: CH_2Cl_2

The possibility that the complexity of this voltammetric response could result from sample impurities was soon excluded by the reproducibility when measuring several samples obtained from different syntheses. The key to understanding this complexity comes from the voltammetric measurement after the addition of excess chloride ions, which should quantitatively convert the electroactive species to the $[TiCl_6]^{2-}$ ion (see Scheme 1), according to the literature. The single irreversible reduction wave at $E_{p,c} = -1.13$ V that is obtained under these conditions (see Figure 1) may therefore be attributed to the reduction of this ion. Note that this wave is irreversible, whereas full reversibility is observed in an $AlCl_3$/chloride melt.[19] This obser-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

vation agrees fully with the likely instability of a reduced $[TiCl_6]^{3-}$ ion towards chloride-ion loss. This wave occurs at a very similar potential as the main wave of the $[Ti_2Cl_{10}]^{2-}$ solution in the absence of free chloride ions. The second species is reduced at a less negative potential, therefore it must contain a higher effective positive charge on the metal center (lower Cl/Ti ratio). A logical hypothesis is to assign this wave to the $[Ti_2Cl_9]^-$ ion. Indeed, the cyclic voltammogram for a solution prepared from the isolated $[Ti_2Cl_9]^-$ salt shows an irreversible wave with $E_{p,c} = -0.76$ V, corresponding closely to the shoulder of the $[Ti_2Cl_{10}]^{2-}$ solution in the absence of free chloride ions. Therefore, we conclude that a chloride-dissociation equilibrium exists in solution starting from the dianionic decachloro species, according to Equation (4). The chloride ions that are freed up in solution can then break the bridge bonds of the decachloro species to yield a more chloride-rich species. It would seem reasonable to assume that this species is the mononuclear dianion $[TiCl_6]^{2-}$. However, the results obtained from a parallel IR investigation tell a different story.

$$[Ti_2Cl_{10}]^{2-} \rightleftharpoons [Ti_2Cl_9]^- + Cl^- \quad (4)$$

An independent investigation of the solution equilibria is complicated by the absence of available spectroscopic probes such as spin-1/2 nuclei for an NMR investigation or unpaired electrons for an EPR investigation. The use of ^{47}Ti and ^{49}Ti NMR spectroscopy is unsatisfactory for compounds where the Ti center has lower than cubic symmetry.[20,21] A suitable solution is provided by infrared spectroscopy in the low wavenumber region, which is sensitive to the Ti−Cl stretching vibrations. Infrared studies of chlorotitanate ions have been published previously, but these have mostly been confined to solid samples[2,22−24] as the solubility of most available salts (e.g. with K^+, Rb^+, Cs^+, $Et_2NH_2^+$, and Et_4N^+)[23] is too low. The PPN salts reported here are sufficiently soluble in dichloromethane to yield reasonable intensities ($A > 1$ for some bands in 0.5 mm pathlength polyethylene cells, see Figure 2). It should be noted that the PPN^+ ion does not interfere in the investigated region, since it shows only a very weak band at 464 cm^{-1}.

First, we shall comment on the dichotomy between $[Ti_2Cl_{10}]^{2-}$ and its mononuclear version, the pentachlorotitanate(IV) anion $[TiCl_5]^-$,[2,22,25−27] and then on the species with a different Cl/Ti ratio. Previous studies have shown that, in the solid state, the pentachlorotitanate(IV) salts feature a dichloro-bridged bioctahedral geometry for the anion in the presence of small cations, whereas salts of larger cations are mononuclear.[2] The PCl_4^+ salt has been shown to undergo a temperature-dependent monomer-dimer equilibrium.[22] The solid-state spectrum of the mononuclear salt is characterized by a very strong band at 348 cm^{-1}, which is absent from the solution spectrum of $[PPN]_2[Ti_2Cl_{10}]$. On the other hand, the solid-state spectra of dinuclear anions are characterized by a very strong band at around 380 cm^{-1} (385 cm^{-1} for the NEt_4 salt and 377 cm^{-1} for the PCl_4 salt).[2] A band in this region is indeed observed in the solution spectrum of $[PPN]_2[Ti_2Cl_{10}]$ (maximum at 370 cm^{-1}). The solid-state spectrum of $[PPN]_2[Ti_2Cl_{10}]$ (see a in Figure 3), is characterized by a strong band at around 365 cm^{-1}, in-between those previously reported for the mono- and dinuclear ions, but quite close to the major band that is observed in solution. The overall shape of the two spectra, in dichloromethane solution and in the solid state, is very similar. We conclude that the compound structure is most certainly dinuclear both in solution and in the solid state. Thus, the rule stating that the pentachlorotitanate(IV) is mononuclear with large cations does not appear to have general validity, since PPN^+ is perhaps the largest cation with which this anion has ever been crystallized.

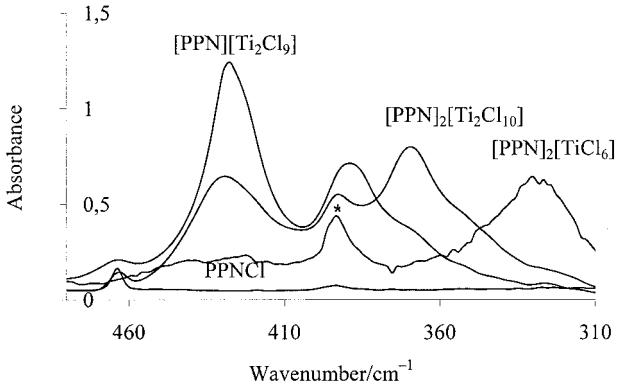

Figure 2. Infrared spectra of various chlorotitanate(IV) PPN salts in CH_2Cl_2 solution (Ti concentration = 2×10^{-2} M); the starred peak corresponds to an oxo impurity (see text)

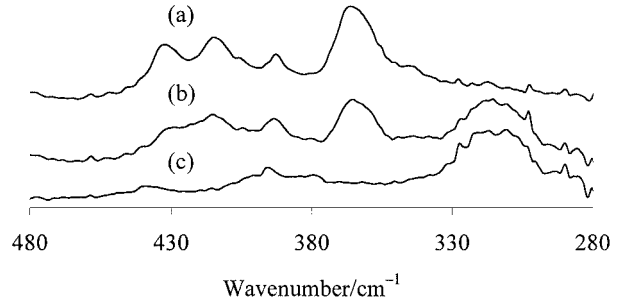

Figure 3. Solid state (nujol mull) infrared spectra of: (a) $[PPN]_2[Ti_2Cl_{10}]$, (b) $[PPN]_3[Ti_2Cl_{11}]$, and (c) $[PPN]_2[TiCl_6]$

The spectra of the $[Ti_2Cl_9]^-$ and $[TiCl_6]^{2-}$ salts, also shown in Figure 2, are quite different from that of the $[Ti_2Cl_{10}]^{2-}$ ion, demonstrating the suitability of IR spectroscopy in this spectral region for the analysis of the species present in solution. Complex $[Ti_2Cl_9]^-$ has a very strong band centered at 428 cm^{-1} and a strong band at 390 cm^{-1}. The shoulder on the right-hand side of the latter band may be due to minor amounts of the $[Ti_2Cl_{10}]^{2-}$ salt. Complex $[TiCl_6]^{2-}$, on the other hand, is characterized by a strong and broad band centered at 327 cm^{-1}. This corresponds to the frequency reported in the literature for the IR-active stretching vibration (ν_3, T_{1u}) of this ion (ca. 330 cm^{-1} depending on the counterion).[23,24,28] It is worth noting the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

weak band observed at 392 cm^{-1}. Only two IR-active bands (the ν_3 stretching and the ν_4 bending, both of T_{1u} type) are expected for the O_h $[TiCl_6]^{2-}$ ion. According to the literature, these are located around 330 cm^{-1} and 183 cm^{-1}, respectively. Therefore, the weak band at 392 cm^{-1} cannot belong to this ion. We believe that this band is due to oxo impurities deriving from a small amount of hydrolysis, given the extreme moisture sensitivity of the $Ti^{IV}-Cl$ bonds. In support of this hypothesis, we have observed that the relative intensity of this band changes as a function of the care with which the solutions are handled and increases when undried dichloromethane is used as solvent, but we have been unable to completely eliminate it. The reported spectrum was recorded in carefully dried solvent and all glassware and transfer syringes were silylated by rinsing with a 10% v/v chloroform solution of Me_3SiCl. It is possible that some hydrolysis occurred during the isolation procedure (washings and transfer into the storage ampoules), as suggested by the observation of the same weak band in the IR spectrum of the solid sample (see c in Figure 3). Following this consideration, the band observed at about 390 cm^{-1} for the $[Ti_2Cl_{10}]^{2-}$ solution may also be due to a product of partial hydrolysis.

The spectrum of the $[TiCl_6]^{2-}$ salt was also reproduced (except for the variable relative intensity of the 392 cm^{-1} band as outlined above) upon addition of ≥ 2 equivalents of PPNCl to the solution of $[Ti_2Cl_{10}]^{2-}$. The addition of just one equivalent of PPNCl to the same solution, on the other hand, shows the complete disappearance of the bands of $[Ti_2Cl_{10}]^{2-}$ and the appearance of a very strong band centered at 355 cm^{-1} (Figure 4). It should be noted that the band of $[TiCl_6]^{2-}$ is also absent from this spectrum. This suggests the formation of a complex having the stoichiometry $[Ti_2Cl_{11}]^{3-}$. Addition of PPNCl to this solution generated again the spectrum of $[TiCl_6]^{2-}$.

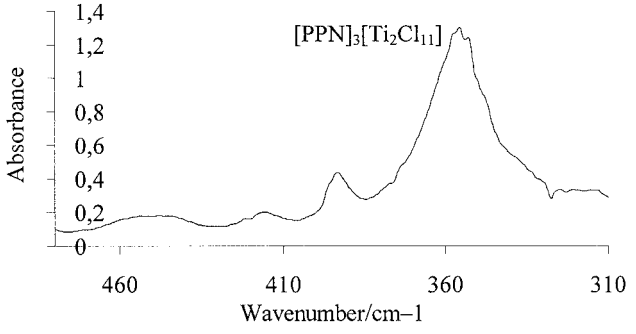

Figure 4. Infrared spectrum of a CH_2Cl_2 solution of $[PPN]_3[Ti_2Cl_{11}]$ (Ti concentration = 2×10^{-2} M)

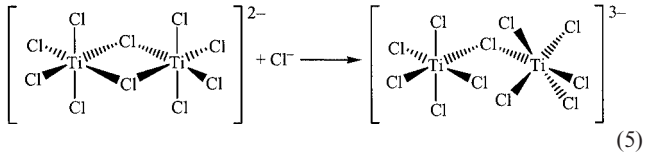
The $[Ti_2Cl_{11}]^{3-}$ anion does not appear to have been reported in the literature. Its structure most likely corresponds to a corner-sharing bioctahedron [Equation (5)]. On the basis of VSEPR theory, the geometry around the bridging Cl atom should be bent and the IR spectrum can be predicted to be quite similar to that of mononuclear octahedral $[TiCl_6]^{2-}$ if vibrational coupling across the Cl bridge is weak. Thus, the slight shift to higher frequency on going from $[TiCl_6]^{2-}$ to $[Ti_2Cl_{11}]^{3-}$ (327 to 355 cm^{-1}) suggests a force-constant increase upon reduction of the metal effective charge. Although the weak band at 392 cm^{-1} is identical to that observed for the $[TiCl_6]^{2-}$ solution, and is therefore attributable to minor amounts of a hydrolytic product, its attribution to a genuine normal mode of the $[Ti_2Cl_{11}]^{3-}$ cannot be excluded. Once again, this spectrum was found to depend highly on the rigor with which the solution was prepared, and the band at 392 cm^{-1} could never be completely eliminated. The reported spectrum was obtained from a solution prepared in silylated glassware and in carefully dried dichloromethane, from a solid sample that was obtained by direct synthesis in $SOCl_2$, according to the stoichiometry of Equation (6).



(5)

$$2\ TiCl_3 + 3\ [PPN]Cl + 2\ \{Cl\} \xrightarrow{SOCl_2} [PPN]_3[Ti_2Cl_{11}] \quad (6)$$

An additional interesting feature is shown by the IR spectrum of the $[PPN]_3[Ti_2Cl_{11}]$ compound in the solid state (see b in Figure 3). This is quite clearly the superposition of the spectra of the $[PPN]_2[Ti_2Cl_{10}]$ and $[PPN]_2[TiCl_6]$ salts that are shown in the same figure, whereas the band observed for the same compound in solution is absent. This observation demonstrates that the species $[Ti_2Cl_{11}]^{3-}$ exists only in solution, and the crystallization process forces a ligand redistribution to yield $[Ti_2Cl_{10}]^{2-}$ and $[TiCl_6]^{2-}$. In other words, the ligand-redistribution equilibrium shown in Equation (7) lies on the left in dichloromethane solution and on the right in the solid state for PPN salts.

$$2\ [Ti_2Cl_{11}]^{3-} \rightleftharpoons [Ti_2Cl_{10}]^{2-} + 2\ [TiCl_6]^{2-} \quad (7)$$

As a final relevant observation, note that the solution spectrum of the $[Ti_2Cl_{10}]^{2-}$ salt (Figure 2) does not show a significant absorption at 355 cm^{-1}, thus excluding the presence of large amounts of $[Ti_2Cl_{11}]^{3-}$ at equilibrium. A shoulder on the low-frequency side of the 368 cm^{-1} band signals the possible presence of minor amounts of $[Ti_2Cl_{11}]^{3-}$, which could be related to an imprecise stoichiometry during the synthesis, or to a chloride-redistribution equilibrium as shown in Equation (8). In the latter case, the equilibrium must necessarily be shifted almost completely towards the $[Ti_2Cl_{10}]^{2-}$ ion.

$$2\ [Ti_2Cl_{10}]^{2-} \rightleftharpoons [Ti_2Cl_9]^{-} + [Ti_2Cl_{11}]^{3-} \quad (8)$$

In the light of the IR study, we can now re-interpret the result of the cyclic voltammetric experiment on the $[Ti_2Cl_{10}]^{2-}$ salt by assigning the wave at -1.03 V to the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

reduction of the $[Ti_2Cl_{11}]^{3-}$ complex and the shoulder at about −0.7 V to the reduction of $[Ti_2Cl_9]^-$. The cyclic voltammetric results seem to indicate the presence of large amounts of the $[Ti_2Cl_9]^-$ + $[Ti_2Cl_{11}]^{3-}$ species, i.e. the equilibrium of Equation 8 seems shifted extensively toward the right-hand side. This, however, contrasts with the IR results (see above). There is in fact no contradiction between these two results because of the dynamic nature of the electrochemical experiment. Since the equilibration process described in Equation (8) may be quite fast, and since the $[Ti_2Cl_9]^-$ complex is reduced at a less-negative potential, its consumption by the reduction process shifts the equilibrium to the right-hand side at the expense of the $[Ti_2Cl_{10}]^{2-}$ ion in the electrode diffusion layer.

Structural Characterization of [PPN][Ti_2Cl_9]

Single crystals of the PPN salt of the $[Ti_2Cl_9]^-$ species were grown from dichloromethane/pentane solution and were investigated by X-ray diffraction. The structure confirms the expected face-sharing bioctahedral geometry (see Figure 5). The bond lengths and angles within the anion are given in the Exp. Sect. The Ti−Cl bond lengths involving the bridging chlorine atoms are longer [2.4775(8) Å to 2.5098(8) Å] than the terminal ones [2.1955(8) Å to 2.2216(8) Å] as reported for related compounds containing the $[Ti_2Cl_9]^-$ anion.[1,29−33]

Conclusions

The two main novelties of this new study of the well-developed coordination chemistry of chlorititanate(IV) complexes are: (*i*) the oxidation of $TiCl_3$ by thionyl chloride in the presence of chloride salts, and (*ii*) the complex chloride dissociation and redistribution equilibria that are established by these anions, with the unambiguous identification in solution of the previously unknown, yet simple, $[Ti_2Cl_{11}]^{3-}$ species. The combined IR and electrochemical study has shown that: (*i*) complex $[Ti_2Cl_{10}]^{2-}$ is dinuclear in dichloromethane solution and in the solid state as a PPN^+ salt; (ii) this ion is stable in dichloromethane but a chloride-redistribution equilibrium to yield a mixture of $[Ti_2Cl_9]^-$ and the novel $[Ti_2Cl_{11}]^{3-}$ complex is induced by the more facile electrochemical reduction of the former species; (*iii*) $[PPN]_3[Ti_2Cl_{11}]$ is not a stable species in the solid state and redistributes to a mixture of $[PPN]_2[Ti_2Cl_{10}]$ and $[PPN]_2[TiCl_6]$ upon crystallization.

Experimental Section

General Procedures. All manipulations were carried out under an atmosphere of dry and oxygen-free argon with standard Schlenk techniques. CH_2Cl_2 was purified by reflux and distillation over P_4O_{10} under argon. Pentane was purified by reflux over sodium benzophenone ketyl and distilled under argon. Cyclic voltammograms were recorded with an EG&G 362 potentiostat connected to a Macintosh computer through MacLab hardware/software. The electrochemical cell was fitted with an Ag-AgCl reference electrode, a platinum disk working electrode and a platinum wire counter-electrode. $[Bu_4N]PF_6$ (ca. 0.1 M) was used as supporting electrolyte in CH_2Cl_2. All potentials are reported relative to the ferrocene standard, which was added to each solution and measured at the end of the experiments. The infrared spectra were recorded on a Bruker Vector 22 instrument equipped with a Globar (MIR) source. The solution spectra in the far IR (480−300 cm^{-1}) region were obtained from CH_2Cl_2 solutions in polyethylene cells (0.5 mm path length). The elemental analyses were carried out by the analytical services of LSEO and LCC with Fisons EA 1108 and Perkin−Elmer 2400 instruments, respectively. Titanium(III) chloride (Aldrich), triethylbenzylammonium chloride (Aldrich) and bis(triphenylphosphanyl)iminium (PPN) chloride (Aldrich) were used as received.

Synthesis of [$NEt_3Bz]_2[Ti_2Cl_{10}$]: A Schlenk tube was charged with $TiCl_3$ (0.114 g, 0.74 mmol) and $[NEt_3Bz]Cl$ (0.174 g, 0.76 mmol). Thionyl chloride (20 mL) was added by syringe under magnetic stirring and the apparatus was connected to an oil bubbler. ***Warning****: The reaction between $SOCl_2$ and water (potentially present as a contaminant in the starting salts) produces toxic SO_2 and HCl, therefore the reaction must be carried out under a well-ventilated fume hood.* The dark-purple suspension transformed gradually into a yellow solution. After four hours of stirring at room temperature, pentane (50 mL) was added, causing the precipitation of the product as a yellow powder. After filtration, the solid was washed with pentane and dried under vacuum for three hours. Yield: 0.276 g (45%). $C_{26}H_{44}Cl_{10}N_2Ti_2$: calcd. C 37.4, H 5.3, N 3.4; found C 37.8, H 5.1, N 3.3.

Synthesis of [PPN]$_2$[Ti_2Cl_{10}]: Following an identical procedure as described above for $[NEt_3Bz]_2[Ti_2Cl_{10}]$, 0.834 g (88%) of $[PPN]_2[Ti_2Cl_{10}]$ was obtained starting from $TiCl_3$ (0.192 g, 1.24 mmol) and PPNCl (0.715 g, 1.25 mmol). $C_{72}H_{60}Cl_{10}N_2P_4Ti_2$: calcd. C 56.6, H 4.0, N 1.8; found C 56.0, H 3.7, N 1.8.

Synthesis of [PPN][Ti_2Cl_9]: A Schlenk tube was charged with $TiCl_3$ (0.565 g, 3.67 mmol) and PPNCl (1.050 g, 1.83 mmol). Thionyl chloride (30 mL) was added by syringe under magnetic stirring and the apparatus was connected to an oil bubbler. ***Warning****: the reaction between $SOCl_2$ and water (potentially present as a contaminant in the starting salts) produces toxic SO_2 and HCl, therefore the reaction must be carried out under a well ventilated fume hood.* The dark-purple suspension transformed gradually into a yellow solution. After cooling to room temperature, it was concentrated until approximately 10 mL and pentane (60 mL) was added, causing the precipitation of the product as a yellow powder. After filtration, the solid was washed with pentane and dried under vacuum. Yield:

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1.574 g (87%). $C_{36}H_{30}Cl_9NP_2Ti_2$: calcd. C 45.3, H 3.2; found C 44.3, H 2.8.

Synthesis of $[PPN]_2[TiCl_6]$: Following an identical procedure as described above for $[PPN][Ti_2Cl_9]$, 0.822 g (96%) of $[PPN]_2[TiCl_6]$ was obtained starting from $TiCl_3$ (0.099 g, 0.64 mmol) and PPNCl (0.740 g, 1.29 mmol). $C_{72}H_{60}Cl_{10}N_2P_4Ti_2$: calcd. C 64.6, H 4.5, N 2.1; found C 63.8, H 4.1, N 2.0. The solid state and solution IR characterization is presented in the Results and Discussion section.

Synthesis of a Product with Stoichiometry $[PPN]_3[Ti_2Cl_{11}]$: Following an identical procedure as described above for $[PPN][Ti_2Cl_9]$, $TiCl_3$ (0.112 g, 0.73 mmol) and PPNCl (0.628 g, 1.09 mmol) yielded 0.712 g (93%) of a solid product corresponding to the $[PPN]_3[Ti_2Cl_{11}]$ stoichiometry. $C_{108}H_{90}Cl_{11}N_3P_6Ti_2$: calcd. C 61.7, H 4.3, N 2.0; found C 60.6, H 3.8, N 1.9. The solid state and solution IR characterization is presented in the Results and Discussion section.

X-ray Structural Determinations for Compound $[PPN][Ti_2Cl_9]$: A single crystal was mounted under inert perfluoropolyether at the tip of a glass fiber and cooled in the cryostream of the Oxford-Diffraction XCALIBUR CCD diffractometer. Data were collected using monochromatic Mo-K_α radiation (λ = 0.71073). The structures was solved by direct methods (SIR97)[34] and refined by least-squares procedures on F^2 using SHELXL-97.[35] All H-atoms attached to carbon were introduced in calculation in idealised positions [d(CH) = 0.96 Å] and treated as riding models. The drawing of the molecules (Figure 1) was realised with the help of ORTEP32.[36] Crystal data and refinement parameters are shown in Table 1 and selected bond lengths and angles are listed in Table 2. CCDC-233004 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Table 1 Crystal data and structure refinement for $[PPN][Ti_2Cl_9]$

Empirical formula	$C_{36}H_{30}Cl_9NP_2Ti_2$
Molecular mass	953.40
Temperature	293(2) K
Wavelength	0.71073 Å
Crystal system	triclinic
Space group	$P\bar{1}$
Unit cell dimensions	a = 9.9904(10) Å
	b = 12.0458(12) Å
	c = 17.4335(14) Å
	α = 86.057(8)°
	β = 82.379(8)°
	γ = 83.861(8)°
Volume	2064.4(3) Å^3
Z	2
Density (calculated)	1.534 Mg/m^3
Absorption coefficient	1.075 mm^{-1}
F(000)	960
Crystal size	0.16 × 0.09 × 0.04 mm^3
Theta range for data collection	2.95 to 26.37°
Index ranges	$-12 \le h \le 9$
	$-15 \le k \le 15$
	$-21 \le l \le 21$
Reflections collected	16046
Independent reflections	8414 [R(int) = 0.0421]
Completeness to theta = 26.37°	99.7%
Absorption correction	analytical
Max. and min. transmission	0.92334 and 0.78155
Refinement method	full-matrix least-squares on F^2
Data/restraints/parameters	8414/0/451
Goodness-of-fit on F^2	0.795
Final R(int) [$I > 2\sigma(I)$]	$R1$ = 0.0348, $wR2$ = 0.0496
R(int) (all data)	$R1$ = 0.0706, $wR2$ = 0.0554
Largest diff. peak and hole	0.349 and −0.428 e·Å^{-3}

Copper(II) and Nickel(II) Complexes of *N*,*N*-Bis(2-hydroxyethyl)octamethyl-1,4,8,11-tetraazacyclotetradecane

Tapashi G. Roy,*[a] Saroj K. S. Hazari,[a] Benu K. Dey,[a] Hazarat A. Miah,[a] Cerstin Bader,[b] and Dieter Rehder*[b]

Keywords: Antimicrobial activity / Copper / Macrocyclic ligands / N ligands / Nickel

Reaction of ethylene oxide with the 1,4,8,11-tetraazacyclotetradecanes Me_8[14]ane L_B (diaxial-diequatorial with respect to the methyl substituents at the secondary ring carbons) and L_C (axial-triequatorial) yielded the N4,N11-disubstituted 2-hydroxyethyl (Y) derivatives L_{BY} (diaxial-diequatorial) and L_{AY} (all-equatorial). These new ligands interact with $Cu(ClO_4)_2$ to produce octahedral blue-violet $[CuL_{BY}][ClO_4]_2$ and deep-blue $[CuL_{AY}][ClO_4]_2$, with the hydroxyl groups of the $-CH_2-CH_2-OH$ arms in axial positions. Reaction of L_{BY} with nickel(II) acetate and subsequent addition of $Li(ClO_4)$ yielded square-planar yellow $[NiL_{BY}][ClO_4]_2$. Characterisation has been carried out on the basis of analytical, spectroscopic, conductometric and magneto-chemical data. The structures of L_{BY} and $[CuL_{AY}][ClO_4]_2$ have been confirmed by X-ray diffraction analyses. The antifungal and antibacterial activities of these compounds have been studied against some phytopathogenic fungi and bacteria.

Introduction

Biogenic macrocyclic tetraaza ligands employed in metal-ion complexation such as in heme proteins, chlorophyll, vitamin B_{12}, or the factor F_{430} of methyl-coenzyme-M reductase in methanogenesis are structurally complex systems which, generally and perhaps simplistically, may be considered rigid planar cyclic structures carrying pendent functional groups acting as functional components at the coordination sites.[1,2] The design and synthesis of macrocyclic systems carrying such functional groups, mimicking the properties of their natural counterparts, is thus a multifarious problem.

In order to synthesise the requisite type of super-structured macrocycles, the obvious approach is to first prepare the more basic macrocyclic ligand, and then attach suitable pendent hydrocarbon chains to the periphery. Thus, a number of macrocycles carrying N-substituents have been prepared by alkylation reactions,[3] starting from the basic isomeric octamethyltetraazacyclotetradecanes Me_8[14]anes L_A, L_B and L_C, where the indexes A, B and C denote the differing stereochemistries with respect to the methyl substituents attached to the chiral carbons of the [14]ane in its chair conformation. Thus, A represents all-equatorial, B diaxial-diequatorial and C axial-triequatorial orientations.[4,5] To approach the biogenic ligands, attempts have been made to attach pendent functional groups to the N donors and consequently to influence the ligating ability of the original N-donor ligands. Thus, in the reactions of L_B with acrylonitrile, two of the NH protons have been substituted by $-CH_2CH_2CN$.[6] This bis(2-cyanoethyl) derivative of L_B has been designated L_{BX}, and the dimethyl derivatives of L_B and L_C, prepared by methylation with methyl iodide,[7] have been denoted L_{BZ} and L_{CZ}. The structures of L_{BX} [6] and L_{BZ} [7] have been confirmed by X-ray crystallography. In the present contribution, we report on the synthesis and coordination behaviour towards Cu^{II} and Ni^{II} of the reaction products obtained by reacting L_B and L_C with ethylene oxide, yielding the bis(2-hydroxyethyl)-substituted ligands L_{BY} and L_{AY} where, in the case of the formation of L_{AY}, a conformational change took place.

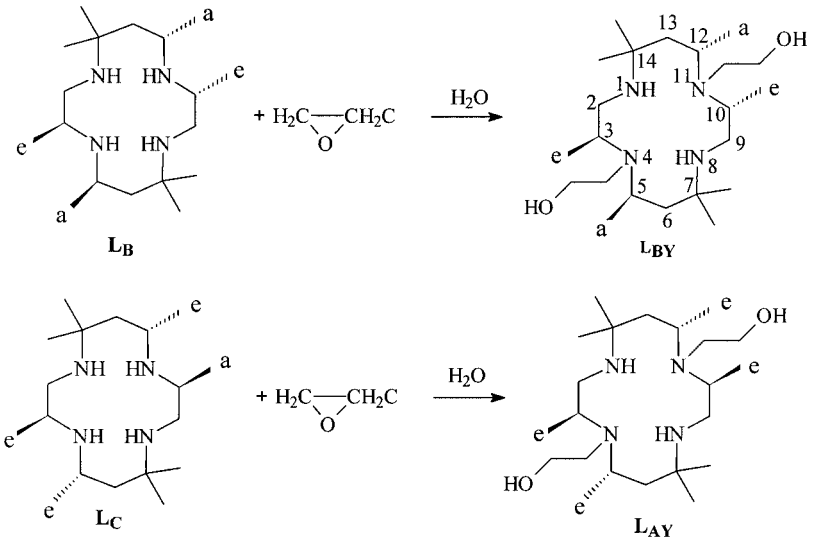
Results and Discussion

Ligands L_{BY} and L_{AY}

Passage of ethylene oxide through aqueous suspensions of L_B and L_C, and subsequent extraction with chloroform, evaporation of the $CHCl_3$ extracts and re-crystallisation from $CH_3OH/CHCl_3$ (L_{BY}) or CH_3OH/Et_2O (L_{AY}) yielded the ligands in the form of white products (Scheme 1). The melting points of L_{BY} (175 °C) and L_{AY} (160 °C) clearly differ from those of the parent ligands L_B (122 °C) and L_C (85 °C). Formation of the bis- rather than the tetrakis(2-hydroxyethyl) derivatives observed in case of the analogous cyclam-type macrocycles[8] can be attributed to steric effects



Scheme 1

created by the eight peripheral methyl groups. The fragmentation patterns obtained from the mass spectra of L_{BY} and L_{AY} (vide infra) clearly indicate that substitution of N−H protons by $-CH_2CH_2-OH$ groups has taken place at N4 and N11 only. This substitution was confirmed by the X-ray structure of L_{BY} and the copper(II) complex of L_{AY}. X-ray and ^1H NMR analyses (vide infra) of L_{BY} and L_{AY} reveal that the diaxial-diequatorial arrangement for L_{BY} is retained, while the configuration has changed to all-equatorial in the case of L_{AY}.

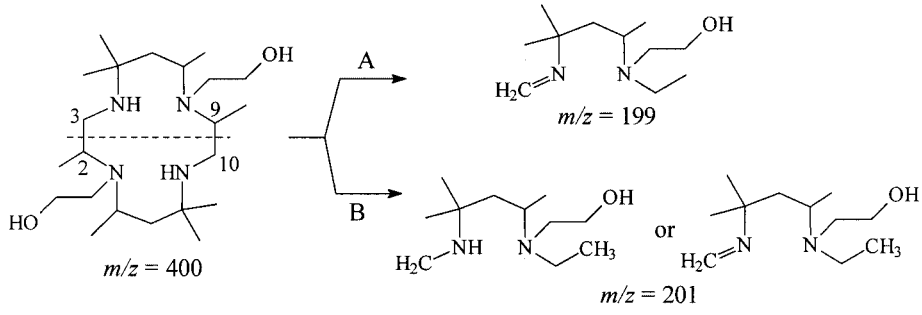
The infrared spectra (Table 1) show the ν_{N-H}, ν_{C-H}, ν_{C-C} and ν_{CH_3} stretching bands in the expected region. A band at 3740 cm^{-1} for L_{BY}, and 3500 cm^{-1} for L_{AY}, indicates the presence of the OH group in these compounds, as do the ν_{C-OH} bands at 1260 and 1060 cm^{-1}; the primary alcoholic hydroxyl group usually shows strong ν_{CO} stretching bands at 1350 to 1260, and 1050 cm^{-1}.

Table 1. Selected IR data (cm^{-1})

	ν_{N-H}	ν_{C-H}	ν_{CH_3}	ν_{C-C}	ν_{M-N}	ν_{ClO_4}	ν_{OH}
L_{BY}	3110	2990	1360	1160	–	–	3740
L_{AY}	3250	2970	1380	1135	–	–	3500
$[NiL_{BY}][ClO_4]_2$	3100	2985	1390	1180	540	1110, 625	3720
$[CuL_{BY}][ClO_4]_2$	3200	2990	1390	1175	570	1140, 625	3500
$[CuL_{AY}][ClO_4]_2$	3190	2995	1380	1175	525	1100, 620	3400

The mass spectrum of L_{BY} exhibits the molecular-ion peak at m/z = 400, while that of L_{AY} is at m/z = 403, corresponding to $[M + 3]^+$. Both the isomeric ligands show more or less the same fragmentation pattern, although the intensities of the peaks differ. The basic peaks are at m/z = 199 for L_{BY} and 171 for L_{AY}. This difference may reflect the stereochemical differences. The prominent fragmentations are presented in Schemes 2−5. The basic peak at m/z = 199 for L_{BY} comes about by the concomitant cleavage of the C2−C3 and C9−C10 bonds (α-cleavage),[4,9,10] followed by the loss of one H atom (path A in Scheme 2). The second intense peak at m/z = 201 also arises from this cleavage with capture of an H atom (path B). The molecular ion can also undergo fragmentation by C−N bond rupture of one of the N-pendent groups with elimination of vinyl alcohol, followed by hydrogen rearrangement and elimination of an H_2O molecule from the other 2-hydroxyethyl group, providing an ion at m/z = 340 (Scheme 3).

Additionally, the molecular ion can successively lose two methyl radicals from the more crowded α-carbons C7 and C14 to form ions at m/z = 370, from which removal of vinyl alcohol by C−N bond rupture in one of the N-pendent groups, followed by rearrangement of H atoms and finally



Scheme 2

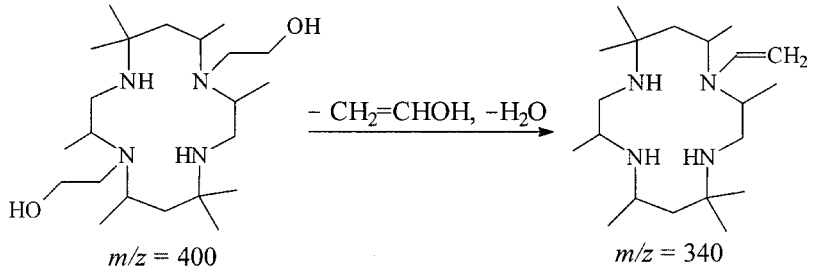
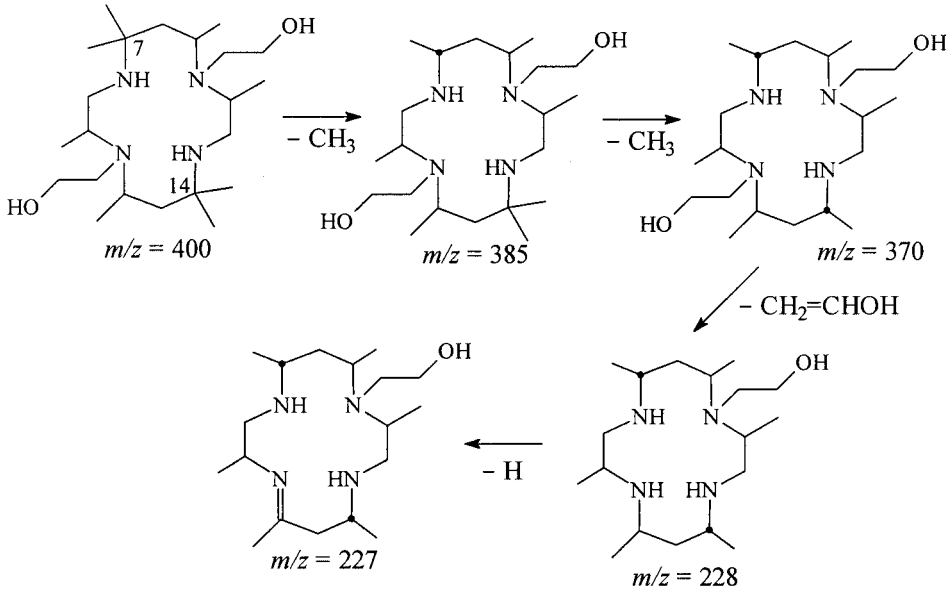


Scheme 3



Scheme 4

elimination of H_2, results in an ion at m/z = 227 (Scheme 4).

Alternatively, the basic peak at m/z = 171 for L_{AY} (Scheme 5) may arise from the m/z = 201 fragment by C3−N4 bond rupture with elimination of ethylene, followed by rearrangement and successive removal of H_2. The resulting fragment at m/z = 171 can further lose a hydrogen molecule to provide the peak at m/z = 169. This fragment, on removal of hydrogen cyanide, yields an ion at m/z = 142 which, by C15−N4 bond cleavage and elimination of vinyl alcohol, can produce the ion at m/z = 98.

The ^{1}H NMR spectrum of ligand L_{BY} (Table 2) shows two singlets at δ = 1.108 and 1.147 ppm corresponding to six protons each that can be assigned to the geminal bis(methyl) groups. In addition, there are two doublets at δ = 0.982 and 0.879 ppm, each corresponding to six protons. This requires that C3,C10 and C5,C12 should be in pairwise equivalent configurations. The upfield doublet can be

Table 2. ^{1}H NMR spectroscopic data of the ligands[a]

Ligands	Geminal dimethyl	Methyl on chiral carbon atoms	CH_2, CH and NH	OH
L_{BY}	1.108 s (*e*, 6 H) 1.147 s (*a*, 6 H)	0.982 d (*a*, 6 H) 0.879 d (*e*, 6 H)	2.047 m 2.353 m 3.168 m 3.408 m	not resolved
L_{AY}	1.082 s (*e*, 6 H) 1.369 s (*a*, 6 H)	1.145 d (*e*, 6 H) 1.199 d (*e*, 6 H)	2.20−2.45 m 3.10−3.35 m	2.897 br

[a] s = singlet, d = doublet, *a* = axial, *e* = equatorial, br = broad, m = multiplet.

assigned to the equatorial and the downfield doublet to the axial methyls. Thus, a diaxial-diequatorial arrangement has been assigned to L_{BY}, in analogy to its parent ligand L_B, an assignment which is confirmed by its X-ray structure. The presence of a hydroxyl group in L_{BY}, confirmed by IR spectroscopy, is not reflected by any clear singlet for OH protons in the ^{1}H NMR spectroscopy. This may be due to rapid intermolecular chemical exchange of the hydroxyl protons. The α- and β-methylene, methine and NH protons appear as poorly resolved multiplets at δ = 2.047, 2.353, 3.168 and 3.408 ppm, respectively.

The geminal bis(methyl) groups of L_{AY} are represented by two singlets at δ = 1.082 (equatorial) and 1.369 ppm (axial). Two doublets at δ = 1.145 and 1.199 ppm, each representing six protons, correspond to the methyl groups C3, C5, C10 and C12 in the equatorial positions. This all-equatorial arrangement was also confirmed by the X-ray structure of $[CuL_{AY}][ClO_4]_2$ (see below). A sharp singlet at δ = 2.897 ppm in the ^{1}H NMR spectrum of ligand L_{AY} can be assigned to the OH protons. The signals due to methylene, methine and N−H protons overlap and could not be resolved clearly.

Representations of the molecular structure of L_{BY}, including the numbering scheme, and the unit cell are shown in Figure 1, the caption of which also contains selected bonding parameters. The molecules are pairwise related to each other by an inversion centre. The cyclic [14]ane skeleton is in the chair conformation, with the methyl groups on the secondary ring carbons (C5, C9, C16, C20) alternately in the axial and the equatorial positions. The angles between the normals of the mean planes constituting the two chairs are as follows (cf. also Figure 1, bottom): molecule 1: C5,C11,C2A,N1A,C4A,C11A,C3,N1,C4 (plane 1)/C5,N2,C9,C11 = 92.6°; (plane 1)/C5A,N2A,C9A,C11A =

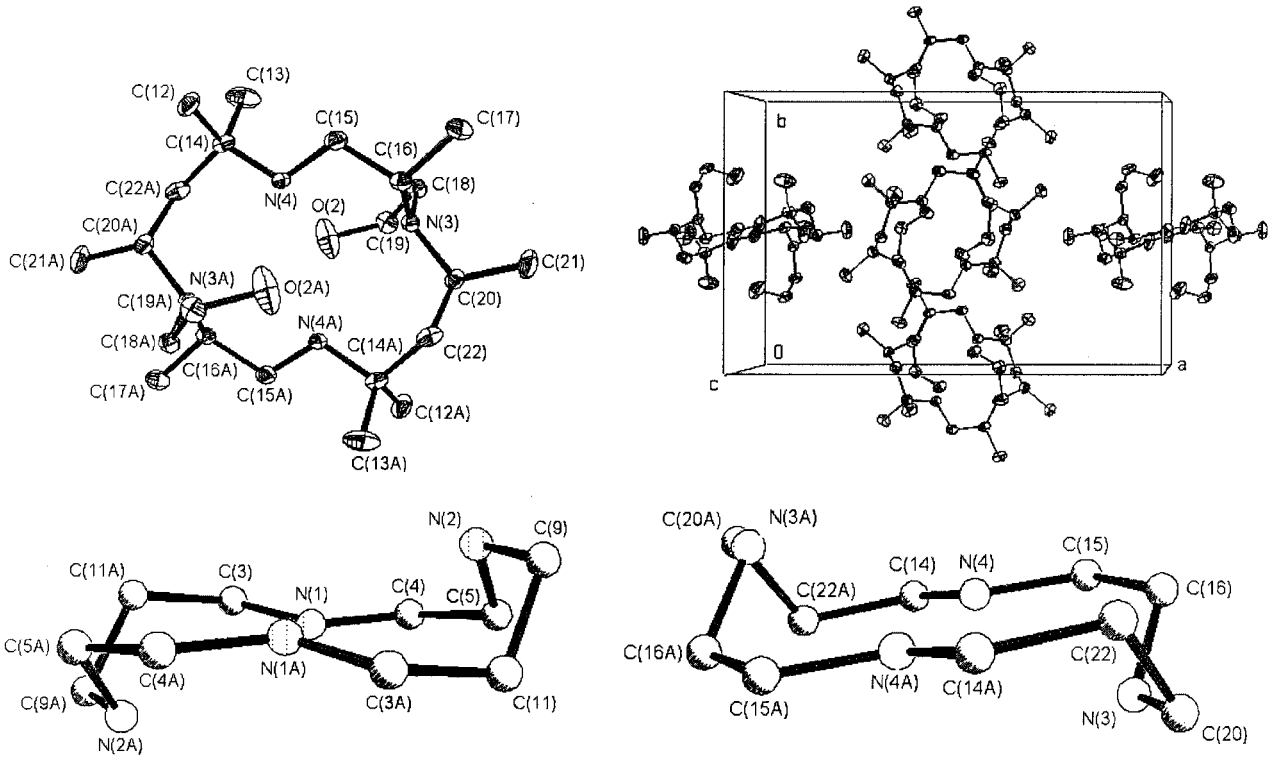

Figure 1. ORTEP presentation of the molecular structure (top left), cell drawing (top right) and the [14]ane skeletons (bottom) of L_{BY}; selected bond lengths (Å) and angles (°): N1−C4 1.464(2), N1−C3 1.484(2), N2−C5 1.4709(19), N2−C9 1.473(2), N2−C7 1.4591(19), C7−C8 1.528(2), C8−O1 1.409(2); C3−N1−C4 115.60(12), C5−N2−C9 117.87(12), C7−N2−C9 113.06(12), C7−N2−C5 115.66(12), N2−C7−C8 111.74(12), C7−C8−O1 112.88(13)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

72.3°; molecule 2: C16,C22,C14A,N4A,C15A,C16A,-C22A,C14,N4,C15 (plane 2)/C16,N3,C20,C22 = 87.7°; (plane 2)/C16A,N3A,C20A,C22A = 106.6°. The pendent ethanol substituents on N2 and N3 are oriented axially, with the OH groups bent towards the cavity spanned by the four nitrogens. Only one of the OH groups, O1, is involved in an intramolecular hydrogen bonding interaction [*d*(OH···N2) = 2.839Å].

Complexes $[Ni(L_{BY})][ClO_4]_2$ and $[CuL][ClO_4]_2$ (L = L_{BY} or L_{AY})

The reaction of nickel(II) acetate tetrahydrate with L_{BY} and subsequent addition of lithium perchlorate in methanolic solution yielded yellow, square-planar $[Ni(L_{BY})][ClO_4]_2$. The formulation is assigned on the basis of analytical data, conductance and magneto-chemical measurements, and IR- and UV-spectral analyses. The IR spectrum (Table 1) of the complex shows a ν_{N-H} band at around 3200 cm^{-1}, and the perchlorate bands around 1100 cm^{-1} and 620 cm^{-1}. A band at 3720 cm^{-1} demonstrates the presence of the pendent OH group. The molar conductivity value of 173 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ (Table 3) in acetonitrile correspond to a 1:2 electrolyte — the two ClO_4^- anions are outside the coordination sphere. Similar results were found in aqueous solution (Table 3). The magneto-chemical measurement of $[Ni(L_{BY})][ClO_4]_2$ is in good agreement with square-planar diamagnetic nickel(II). The stereochemical assignment was based on ^1H NMR spectroscopy.

The electronic absorption spectrum of $[Ni(L_{BY})][ClO_4]_2$ displays a *d*-*d* band at 474 nm, which can be assigned to the $^1A_1g \rightarrow {}^1B_1g$ transition. The results of our complexes fit well with those for Ni^{II} complexes of other saturated aza macrocycles.[11] The relatively high ε_{max} value of 82 $dm^3\cdot mol^{-1}\cdot cm^{-1}$ indicates that the axial positions are free. Octahedral Ni^{II} complexes have low extinction coefficients in the range of 20−30 $dm^3\cdot mol^{-1}\cdot cm^{-1}$. The pendent hydroxy groups of L_{BY} in principle do have coordinating properties. The experimental evidence — the yellow colour, the comparatively high ε for the transition in the visible, and the lack of a shift of the IR band corresponding to OH —, however, shows that this group does not coordinate in the present case. The absorption band at 237 nm in the UV region is assigned to a charge-transfer transition. This band does not provide any information related to the geometry of these complexes. On complexation, the "up" and "down" positions of methyls on chiral carbons in the ligand are retained — no configurational change in the ligand system is to be expected as L_{BY} coordinates.[11,12] The proposed structure of $[Ni(L_{BY})][ClO_4]_2$ is shown in Scheme 6.

Interaction of copper(II) perchlorate hexahydrate with the ligands L_{BY} or L_{AY} in methanolic solution yields the blue-violet to deep-blue complexes $[CuL][ClO_4]_2$. The infrared spectra (Table 1) show ν_{N-H} bands around 3200 cm^{-1} and the perchlorate bands at 1100 and 620 cm^{-1}, as well as the ν_{C-H}, ν_{C-C}, ν_{CH_3} and ν_{Cu-N} bands in the expected positions. For $[CuL][ClO_4]_2$, a strong band at 3500 (L = L_{BY}) and a broad band at 3400 cm^{-1} (L = L_{AY}) are found, corresponding to OH. The low-frequency shift of these bands with respect to the free ligands indicates coordination of OH to the copper(II) ion, forming octahedral complexes, a coordination mode which was confirmed by the X-ray structure analysis of $[Cu(L_{AY})][ClO_4]_2$.

The molar conductivity of 168−170 in aqueous solution and 148−165 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ in acetonitrile corresponds to 1:2 electrolytes — an ionic situation. The colour change (from blue-violet and deep-blue to pink) as these complexes are dissolved in water indicates the formation of new complexes in water. The most obvious explanation is the replacement of the hydroxy ligands by water — the formation of diaqua complexes $[CuL(H_2O)_2]^{2+}$ — as in the Cu^{II} complexes with the parent ligands L_B and L_C.[13] On the other hand, solutions of $[Cu(L_{BY})][ClO_4]_2$ and $[Cu(L_{AY})][ClO_4]_2$ in chloroform do not show any conductance, suggesting that the ClO_4^- ions have entered into the coordination sphere to form octahedral bis(perchlorato) complexes $[CuL(ClO_4)_2]$.

The complexes $[CuL][ClO_4]_2$ show broad *d*-*d* bands at 507−564 nm in acetonitrile, as do other Cu^{II} complexes with tetraza macrocycles.[14,15] Bands around 300 nm can be attributed to copper-ligand charge-transfer transitions. The magnetic moments of 1.68−1.83 μ_B are in good agreement with "normal" copper(II) complexes having one unpaired electron. As the ^1H NMR spectra could not be measured for these paramagnetic complexes, the exact stereochemistry (i.e. axial and equatorial positions of methyls on chiral carbons) could not be determined by NMR spectroscopy. As in the case of the nickel complex (vide supra), and based on the structural determination of the Cu^{II} complex with

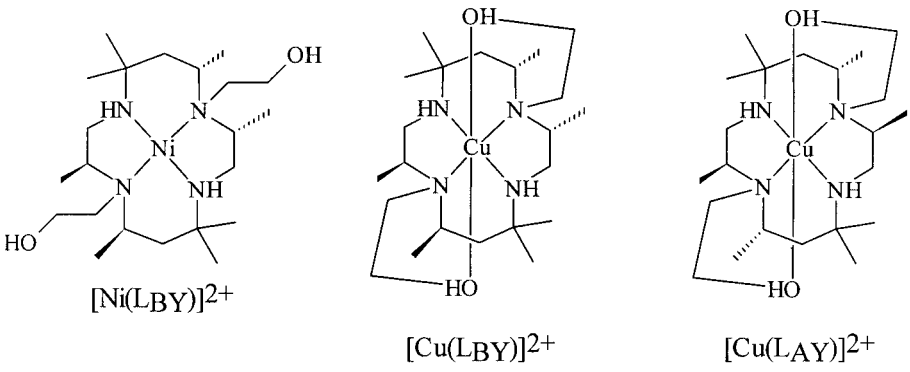

Scheme 6

L_{AY}, configurational changes on complexation are not expected. For structural formulae of the two copper complexes see Scheme 6.

An ORTEP drawing of the molecular structure of the cation $[Cu(L_{AY})]^{2+}$ is represented in Figure 2, showing the distorted octahedral coordination geometry for the copper ion. For selected bonding parameters see the caption to Figure 2. Cu lies on a crystallographic inversion centre. The two ring carbons C6 and C7, and the methyl group C9 (attached to C6), are disordered over two equally populated positions. Together with the four nitrogen donors, the copper ion forms an ideal plane. The deviations of the ring carbons from this plane are as follows (in Å): C3 −0.648, C4 −0.029, C6 −0.47, C6# −1.045, C7 −1.517, C7# −0.606, C8 −0.921. The OH functions are above and below this plane. The O1−Cu−O1A axis is not exactly perpendicular to this plane, but inclined towards the axis N1−Cu−N1A by 13.7°, and towards the axis N2−Cu−N2A by 4.3° (average angle between the normal of the plane and the O1−Cu−O1A axis: 95.6°). The Cu−O distances [2.432(3) Å] are rather long, indicating relatively weak coordination and thus the above-mentioned possibility of the replacement of the two axial positions by water or perchlorate. These OH functions are additionally hydrogen-bonded to the axially oriented perchlorate anions [$d(ClO_4^-\cdots OH)$ = 2.797 and 3.206 Å]. The angles at the carbons of the 2-hydroxyethyl arm of coordinated L_{AY} deviate somewhat from those of the free ligand L_{BY} (116.5° at C1 vs. 111.5°; 108.6° at C2 vs. 113.6°). The angles at N1 are 111.5° (C1−N1−C3) and 121.7° (C1−N1−C6), as compared to 115.6° and 113.1° of the corresponding angles in free L_{BY} — coordination of the hydroxyethyl arms to Cu^{II} can only be achieved by moving the arms towards the coordination centre.

Antimicrobial Activity Studies

Since only a few recent reports exist on the antifungal activities of macrocycles and their complexes,[13,15] it ap-

peared interesting to see whether the compounds involved in the present study exhibit any such activity. We therefore investigated the antifungal potential of the ligands L_{BY} and L_{AY}, and their Cu^{II} and Ni^{II} complexes against five selective phytopathogenic fungi — (i) *Macrophomina phaseolina*, (ii) *Alternaria alternata*, (iii) *Fusarium equiseti*, (iv) *Colletotrichum corcolei*, and (v) *Botrgodiplodia theobromal*. It is evident from the results (Table 4) that the macrocycles and their complexes under investigation show some antifungal behaviour, which is more pronounced against *M. phaseolina* than against the other four organisms. The activity decreases upon coordination of the ligands to Cu^{II} and Ni^{II} in most cases, with the nickel complex showing the lowest activity. It has been noted that the N-substituted ligands (such as L_{BY}) exhibit a higher rate of inhibition on mycelial growth than their parent ligands (such as L_B).[13] The antifungal potential of the coordinated *N*-substituted ligands thus compares to that of the parent ligands; it also compares to the activities of copper[13] and nickel complexes[16] of the parent L_B and L_C.

Antibacterial activities of the macrocycles and their complexes have not been studied so far. Here, we report on the antibacterial activities against *Salmonella typhi*, *Shigella dysenteriae*, *Escherichia coli* and *Bacillus cerelus.* The results are contained in Table 5, which shows that the ligands do not exhibit any antibacterial activity, although some activity is noted for the complexes. Hence, unlike their behaviour towards fungi, some of the complexes exhibit higher antibacterial activities than their corresponding ligands. For a clear understanding, however, of the differentiation in function towards microorganisms, additional systematic studies will be necessary.

Conclusion

Two new tetraaza macrocyclic ligands belonging to the Me_8[14]ane family, and carrying pendent 2-hydroxyethyl substituents (Y) on two of the nitrogen functions, have been obtained by reacting the basic tetraaza ligands L_B and L_C with ethylene oxide. In the case of diaxial-diequatorial (with respect to the four methyl groups attached to chiral carbons) L_B as the starting product, the diaxial-diequatorial ligand L_{BY} is formed. When the reaction is carried out with axial-triequatorial L_C, a configurational change to all-equatorial L_{AY} was observed. With Ni^{II}, L_{BY} yields a square-planar complex $[Ni(L_{BY})]^{2+}$, where the hydroxyethyl functions are coordinatively inert towards Ni^{II}. With Cu^{II}, however, the octahedral complexes $[Cu(L)]^{2+}$ (L = L_{BY} and L_{AY}) are formed, in which the OH functions weakly coordinate in the axial positions [Cu−O = 2.432(3) Å]. The counterion in the Ni and Cu complexes is ClO_4^-; the ionic nature has been confirmed by conductivity measurements in acetonitrile. In water, $[Cu(L)]^{2+}$ converts to $[Cu(L)(H_2O)_2]^{2+}$, whereas in chloroform the axial positions are occupied by perchlorate — the neutral complex $[Cu(L)(ClO_4)_2]$ is formed. Contrasting the ligands, the complexes show some anti-bacterial activity, while the anti-fungal activity of the complexes is generally lower than that of the ligands.

Experimental Section

Materials and Equipment: All chemicals were of analytical reagent grade and used without further purification. Synthesis of the parent ligand 3,10-*C*-*meso*-Me_8[14]diene dihydroperchlorate, reduction of this diene with $NaBH_4$ and separation into the three isomers of Me_8[14]ane (L_A, L_B and L_C) was carried out according to literature procedures.[4,17]

Caution*: *Perchlorates can be explosive in the presence of organic materials.

Microanalyses (C,H,N) were carried out by the combustion method at the Analytical Section of the Chemistry Department, University of Hamburg. For nickel and copper, standard titrimetric methods have been employed.

Infrared spectra were taken as KBr pellets in the range 4000−400 cm^{-1} on a Perkin−Elmer 883 infrared spectrophotometer. Electronic absorption spectra were recorded on a Schimadzu UV/Visible spectrophotometer. The mass spectral measurement of the li-

gands was carried out with the help of a Varian MAT 311A (70 eV, EI) instrument. ^{1}H and ^{13}C NMR spectra were recorded on a 200 MHz Varian Gemini instrument. Conductance measurements of the metal complexes were done in water, acetonitrile and chloroform solutions, using a HANNA instrument equipped with a HI 8820N conductivity cell. Magnetic measurements were carried out at room temperature with a Gouy balance, calibrated against $Hg[Co(NCS)_4]$; susceptibilities were corrected for diamagnetic increments.

Ligand Syntheses: Ligands were synthesised by modified literature procedures for analogous, N-pendent ligands.[8]

***trans*-4,11-Bis(2-hydroxyethyl)-3,5,7,7,10,12,14,14-octamethyl-1,4,8,11-tetraazacyclotetradecane (L_{BY}):** L_B (0.312 g, 1.0 mmol) was suspended in 25 mL of distilled water and the temperature was maintained at 16 ± 2 °C. The mixture was stirred while a gentle stream of ethylene oxide was passed through the suspension for 5 h. The reaction mixture became milky and then oily. Undissolved compounds were removed by filtration and the clear filtrate was extracted with 200 mL (four 50 mL portions) of chloroform. On evaporation of the chloroform extract, a sticky material was obtained, which was washed three times with 2 mL portions of methanol to give L_{BY} as a crude, white solid. This was re-crystallised from 10 mL of a 1:2 chloroform/methanol mixture and dried in vacuo over silica gel to yield pure L_{BY}. Melting point: 175 °C. Yield 0.202 g (50%). $C_{22}H_{48}N_4O_2$ (400.65): calcd. C 65.95, H 12.08, N 13.98; found C 65.86, H 11.95, N 13.88.

***trans*-4,11-Bis(2-hydroxyethyl)-3,5,7,7,10,12,14,14-octamethyl-1,4,8,11-tetraazacyclotetradecane (L_{AY}):** L_{AY} was prepared analogously to L_{BY} from L_C (0.312 g, 1.0 mmol) and ethylene oxide at a temperature of 10 ± 2 °C. Evaporation of the chloroform left behind a pasty substance, which was dissolved in 10 mL of methanol and filtered. The filtrate, on evaporation, yielded white, solid L_{AY}, which was re-crystallised three times from 10 mL portions of diethyl ether and dried under vacuum over silica gel. Melting point: 160 °C. Yield 0.22 g (50%). $C_{22}H_{48}N_4O_2$ (400.65): calcd. C 65.95, H 12.08, N 13.98; found C 65.79, H 11.91, N 14.06.

$[NiL_{BY}][ClO_4]_2$: L_{BY} (0.400 g, 1.0 mmol) and nickel(II) acetate (0.256 g, 1.05 mmol) tetrahydrate were dissolved separately in 50 mL of cold, dry methanol. The ligand solution was added dropwise to the boiling nickel(II) acetate solution with stirring. The reaction mixture was heated on a steam bath for one hour, and the volume reduced to 20 mL. An orange colour developed. After adding 0.5 g of lithium perchlorate trihydrate, the solution was heated for another 10 min and allowed to stand for about 2 h. The yellow product $[NiL_{BY}][ClO_4]_2$ was filtered off, washed with methanol and diethyl ether, and dried in vacuo. Yield 0.165 g (25%). $C_{22}H_{48}Cl_2N_4NiO_{10}$ (658.24): calcd. C 40.14, H 7.35, N 8.51, Ni 8.92; found C 39.88, H 7.30, N 8.48, Ni 8.88.

$[CuL_{BY}][ClO_4]_2$: L_{BY} (0.40 g, 1.0 mmol) and copper(II)perchlorate hexahydrate (0.371 g, 1.0 mmol) were dissolved separately in 25 mL of dry, hot methanol and mixed while hot. A pink colour appeared. The volume was reduced to 20 mL by heating the mixture on a water bath. On cooling, pink $[CuL_{BY}][ClO_4]_2$ crystallised out, which was separated by filtration, washed with methanol and re-crystallised from 10 mL of acetonitrile/methanol (1:2). The product was dried in a vacuum desiccator over silica gel. Yield 0.221 g (33%). $C_{22}H_{48}Cl_2CuN_4O_{10}$ (663.09): calcd. C 39.85, H 7.30, N 8.45, Cu 9.58; found C 39.80, H 7.32, N 8.36, Cu 9.49.

$[CuL_{AY}][ClO_4]_2$: L_{AY} (0.40 g, 1.0 mmol) and copper(II)perchlorate hexahydrate (0.371 g, 1.0 mmol) were dissolved separately in 20 mL of dry, hot methanol. The solutions were mixed while hot. The deep-blue reaction mixture was heated on a water bath to reduce the volume to 10 mL. On cooling, a blue solid precipitated out, which was separated by filtration and re-crystallised from 10 mL of acetonitrile/methanol (1:1), and dried in vacuo over silica gel. Yield 0.331 g (50%). $C_{22}H_{48}Cl_2CuN_4O_{10}$ (663.09): calcd. C 39.85, H 7.30, N 8.45, Cu 9.58; found C 39.79, H 7.24, N 8.43, Cu 9.48.

Crystals of $[CuL_{AY}][ClO_4]_2$ suitable for the X-ray diffraction study were prepared by slow evaporation of acetonitrile-methanol solution of the complex.

X-ray Crystallographic Determination: X-ray structure analyses were performed with Mo-K_α irradiation (λ = 0.71073 Å, graphite monochromator), on a Smart Apex CCD diffractometer. The hydrogen atoms of the hydroxy groups of L_{BY} and $[Cu(L_{AY})][ClO_4]_2$ and the NH groups of $[Cu(L_{AY})][ClO_4]_2$ were found; other H atoms were calculated at their idealized positions and included in the last cycles of refinement. Absorption corrections were carried out automatically by Mult Scan. Crystal data and details of the data collection and refinement are collated in Table 6.
CCDC-235762 (for L_{BY}) and -235880 (for $[Cu(L_{AY})][ClO_4]_2$) contain the supplementary crystallographic data of this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving/html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk).

Antimicrobial Activity: The in vitro antifungal activities of the compounds against selected phytopathogenic fungi were assessed by the poisoned food technique. Potato Dextros Agar (PDA) was used as a growth medium. DMF was used as the solvent to prepare solutions of the compounds. The solutions were then mixed with the sterilized PDA so as to maintain concentrations of the compounds of 0.01%. 20 mL portions of this mixture were poured into petri dishes. After the medium had solidified, a 5 mm mycelial disc of the fungus was placed in the centre of each assay plate, including a control. Linear growth of the fungus (in mm) was noted after five days of incubation at 25 ± 2 °C.
The antibacterial activities of the test materials were measured by the disc diffusion method. Paper discs of 6 mm diameter, and petri dishes (70 mm in diameter) were used throughout. Pour plates were prepared from sterilized molten NA (Nutrient Agar) at 45 °C. After solidification of the pour plates, suspensions of the test organisms were spread uniformly over the pour plate with a sterilised glass rod. After soaking the paper discs with the test chemicals (1% in $CHCl_3$ solutions), they were placed in the centre of the inoculated pour plate. A control plate was maintained in each case with $CHCl_3$. The plates were kept for 4 h at low temperature (4 °C) in order to allow the test chemicals to diffuse from the paper disc to the surrounding medium. The plates were then incubated at 35 ± 2 °C for growth of the test organisms, and checked at 24-hour intervals. The antibacterial activity was expressed in terms of the diameter (in mm) of the zone of inhibition. Each experiment was repeated three times.

Acknowledgments

The authors thank the University Grants Commission of Bangladesh for a fellowship to H. A. M. and the Ministry of Science and Technology, Government of People's Republic of Bangladesh, for a grant to T. G. R. and for providing a fellowship to H. A. M., and the German Academic Exchange Service (DAAD) for granting a stipend to T. G. R. Further, we wish to thank Prof. Dr. N. Anwar, Department of Microbiology, University of Chittagong, for his support of the antifungal and antibacterial studies.

Boranophosphate Salts as an Excellent Mimic of Phosphate Salts: Preparation, Characterization, and Properties

Victoria Nahum[a] and Bilha Fischer*[a]

Keywords: Bioisosters / Boranophosphates / NMR spectroscopy / Phosphate mimics

We report on the preparation of boranophosphate salts, BPi (**2**), and the exploration of their properties with a view to developing a new mimic of the parent phosphate. BPi salts were easily prepared in excellent yield in a one-pot two-step reaction from tris(trimethylsilyl) phosphite, and were characterized by X-ray crystallography and IR, ^{1}H and ^{31}P NMR spectroscopy. We evaluated the acid/base character of BPi by determining its acidity constants. Likewise, we evaluated the stability of BPi at various pH values, and calculated the decomposition-rate constants at highly acidic pH. We also monitored the H-bonded clustering of BPi in organic solvents, including MeOH. Finally, we explored the chemical behavior of BPi with respect to various organic and inorganic reagents. BPi is stable under the following conditions: both basic and acidic pH (pH $>$ 2), in the presence of amines, and in the presence of Mg^{2+} ions. However, a P–B bond cleavage is observed upon the reaction of BPi with carbodiimides or upon catalytic hydrogenation. The reducing nature of the BH_3 moiety is drastically decreased in BPi. Likewise, the nucleophilicity of BPi's oxygen atom is lower than in phosphate, Pi, salts. Based on its water solubility, acid-base character, and H-bonding properties, BPi appears as a perfect mimic of Pi and is an attractive alternative to the known phosphate isosters.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Phosphates and phosphate-containing molecules play a major role in numerous biological systems.[1] However, the unwanted lability of the ester P−O bond has promoted the search for suitable bioisosters — phosphate analogues — which retain the biological activity but possess diminished lability. The search for bioisosters was initiated by the need to produce phosphate probes for various studies, such as probing the stereochemical requirements of enzymes.[2] In addition, phosphate bioisosters have been developed for improving the pharmacological effects of nucleotide-based drugs, for example anti-sense agents.[3]

A widely used isoster of phosphate is phosphorothioate and its analogues, proposed in the pioneering work of Eckstein et al.[4] In these analogues, the nonbridging oxygen atom is replaced by a sulfur atom. Other chemical modifications of the phosphate moiety include the substitution of the labile phosphate ester oxygen atom by a carbon or nitrogen atom, to give phosphonates and phosphoramidate analogues, respectively.[5]

During the last decade, pioneering studies by Spielvogel and Ramsay-Shaw have proposed boranophosphate anaclogues **1** as bioisosters of natural nucleotides[6] and as important tools for biochemists.[7]

This emerging field of novel nucleotide bioisosters has expanded significantly and has provided many important applications of the boranophosphate analogues. For instance, nonterminal *P*-boronated nucleotides, existing as a pair of diastereoisomers, have been used as stereochemical probes to elucidate enzymatic catalysis.[8] Oligodeoxyribonucleotides bearing boranophosphate linkages have been used for polymerase chain reaction (PCR) sequencing and DNA diagnostics,[9] and boranophosphate nucleotides have been found to be highly potent and stable P2Y-receptor agonists.[10] Oligonucleotides bearing boranophosphate linkages have also been considered as potentially useful anti-sense agents.[11] These analogues were also tested for the treatment of cancer as carriers of ^{10}B isotope in boron neutron-capture therapy.[12]

As mentioned above, the field of boranophosphates covers, in-depth, related nucleotide/oligonucleotide analogues. However, to the best of our knowledge, no attention has been given to the unique and chemically interesting inorganic boranophosphate **2** (BPi). Although the related dimethyl boranophosphate potassium salt **3** has been described by Imamoto et al.[13] and by Wada and Saigo,[14] the preparation of inorganic boranophosphate **2** has not been reported.

We present here the preparation, characterization, and unique chemical properties of inorganic boranophosphate. In addition, we demonstrate that BPi is an excellent mimic of phosphate.

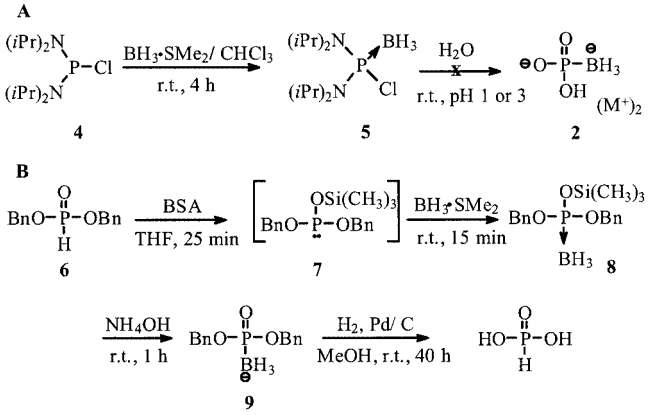
Results and Discussion

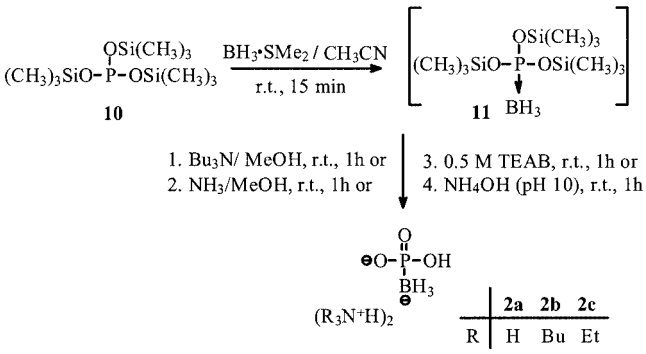
Synthesis

For the preparation of boranophosphate, we first attempted the treatment of chlorobis(diisopropylamino)phosphane (**4**) with BH_3·SMe_2 complex,[15] followed by acidic hydrolysis (pH = 3 or 1; Scheme 1A). This attempt resulted in a mixture of several phosphorus species. Alternatively, dibenzyl H-phosphonate **6** was treated with bis(silyl)acetamide, followed by boranation of intermediate **7** with BH_3·SMe_2, and hydrolysis of **8** with concentrated ammonium hydroxide. In this way, dibenzyl boranophosphate **9** was obtained in 71% overall yield (Scheme 1B). However, attempts to remove the benzyl groups by either catalytic hydrogenation or acidic hydrolysis (pH = 1.3) resulted in the cleavage of the P−B bond, leading to phosphorus acid instead of BPi.



Scheme 1

Eventually, we were able to obtain BPi in an excellent overall yield in a two-step, one-pot reaction starting from tris(trimethylsilyl) phosphite[16] (**10**; Scheme 2). Phosphite **10** was treated with BH_3·SMe_2 in dry acetonitrile under an inert gas for 15 min. Subsequently, intermediate **11** was treated with 2 M methanolic ammonia for 1 h to give the BPi **2a** as a white solid in 93% yield. No further purification was conducted, since volatile silyl derivatives and the unreacted BH_3·SMe_2 were removed by evaporation. Alternatively, intermediate **11** was treated with $NH_4OH_{(aq)}$ solution (pH = 10), Bu_3N in MeOH, or 0.5 M triethylammonium hydrogencarbonate buffer (pH = 7.5) and freeze-dried or concentrated to provide **2a**, **2b**, or **2c**, respectively.



Scheme 2

Product **2a** is highly water-soluble, whereas **2b** dissolves only in organic solvents such as MeOH, CH_3CN, DMF, and $CHCl_3$. Product **2c** is highly soluble both in water and in organic solvents.

Characterization

NMR Spectroscopy

Compound **2a** in water was characterized by ^{31}P NMR spectroscopy. It shows a signal at $\delta \approx 80$ ppm (Figure 1). The boranophosphate ^{31}P NMR spectrum shows a typical pattern including two overlapping signals: the larger signal is due to coupling of P to the ^{11}B isotope, and the smaller signal is due to coupling with the ^{10}B isotope. The relative height of the smaller peak to the larger one is 0.14 (Figure 1A).[17] BPi's hydrogen-coupled ^{31}P NMR spectrum shows further splitting of the lines into a quadruplet (Figure 1B). The ^1H NMR spectrum shows a typical doublet of quadruples pattern, at $\delta \approx 0.2$ ppm, due to coupling of H to both ^{11}B and ^{31}P (Figure 1C). This pattern overlaps a more complex pattern due to coupling of H to both ^{10}B and ^{31}P.

The chemical shift of BPi is pH-dependent. For instance, at pH = 4.87 and 13.20, the phosphorus atom of BPi resonates at δ = 84 and 63 ppm, respectively. Likewise, the P−B coupling constant is also pH-dependent, and is reduced as the pH decreases (e.g. 147 and 183 Hz for pH = 4.87 and 13.2, respectively). The pH-dependent BPi spectrum indicates structural changes of BPi, which are due to

X-ray crystal structure of BPi: A) unit cell includes eight BPi molecules, eight H-phosphonate molecules, and 24 ammonium ions; hydrogen atoms are omitted to clarify the BPi geometry; B) ORTEP drawing of BPi; crystal data of **2a**: monoclinic, $P2_1/c$; a = 23.616(5) Å, b = 6.3470(13) Å, c = 15.325(3) Å; V = 2172.9(8) Å^3; Z = 12; $D_{calcd.}$ = 1.623 g/cm^3; $F(000)$ = 1104; 3094 reflections collected, R = 0.1015, Rw = 0.2345, GOF = 1.286; selected bond lengths [Å] and angles [°]: P(1)−O(1A) 1.524(7), P(1)−O(1B) 1.617(7), P(1)−O(1C) 1.583(7), P(1)−B(1) 1.891(11); O(1A)−P(1)−O(1C) 104.0(4), O(1A)−P(1)−O(1B) 105.3(4), O(1C)−P(1)−O(1B) 104.4(4), O(1A)−P(1)−B(1) 118.2(5), O(1C)−P(1)−B(1) 113.0(5), O(1B)−P(1)−B(1) 110.7(5)

the reduction of O−P−O angles upon protonation of the molecule.

X-ray Crystallography

To obtain structural information on BPi, compound **2a** was crystallized from an aqueous solution (pH = 7). In addition to compound **2a**, the crystal contained phosphorus acid (H-phosphonate) in a 1:1 ratio. This unexpected ratio does not reflect the molar ratio in the original BPi solution, in which phosphorus acid was less than 5%.

The unit cell contains eight BPi ions, eight H-phosphonate ions, and 24 ammonium ions (Figure 2A). Apparently, for each BPi anion, one ammonium counterion is observed, whereas two ammonium counterions are observed around each H-phosphonate group.

For BPi, the average P−B bond length is 1.892 Å, whereas for the three P−O bonds, the average lengths are 1.585, 1.605 Å, and 1.524 Å, respectively (Figure 2B). A deviation from tetrahedral angles was observed with values of 111−118° for B−P−O, and 104−105° for the O−P−O angles.

Comparison with X-ray crystal data obtained for the related dimethyl boranophosphate salt (**3**)[13] indicated similar values for the B−P (1.895 Å) and O−P (1.490, 1.597 and 1.612 Å) bond lengths. For dimethyl boranophosphate, one potassium ion was found near one of the oxygen atoms at a distance of 2.66 Å. Based on a comparison of the bond lengths of dimethyl boranophosphate salt with BPi, we assume that the BPi bears two H atoms, which were not found in the crystallographic data.

The shortest P−O bond (1.524 Å) indicates a partial double-bond character, and is in accordance with values found in the structures of phosphate diesters (1.47−1.51 Å) and monoesters (1.49−1.53 Å). This P−O bond is significantly longer than the bond observed in phosphate triesters (1.38−1.44 Å).[18]

IR Spectroscopy

The IR spectra of **2a** or **2b** in KBr pellet indicated characteristic bands for P−B and B−H in addition to bands associated with P−OH and P=O. Specifically, three absorptions at 2350, 2381, 2407 cm^{-1} (s) correspond to B−H stretches, and the absorption at 654 cm^{-1} (m) is the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

P−B stretch.[19] Typical absorptions were observed for P−OH and P=O stretches at 900−1080 cm^{-1} and at 1140−1250 cm^{-1}, respectively.

For an evaluation of the effects of the solvents on the H-bonds between BPi ions, IR spectra of BPi **2a** in aqueous and methanolic solutions (see below "H-bonding of BPi") were measured in a germanium cell and compared to the corresponding spectrum of a neat sample of BPi (Figure 3B). Comparison of those spectra indicated only minor differences. For instance, a shift of about 10 cm^{-1} to lower frequencies was observed for the P=O stretch of BPi, either in the neat sample or in MeOH, relative to BPi in aqueous solution. This shift is probably due to H-bonding-based clustering in the neat sample and MeOH. The typical fine-structure for the P=O stretch in a neat sample of BPi, in the range of 1144−1178 cm^{-1}, which is possibly also due to H-bonded clusters, is lost in water. The corresponding spectrum in MeOH appears as an average of the neat sample and aqueous solution spectra, probably indicating the presence of both BPi clusters and solvent H-bonded species.

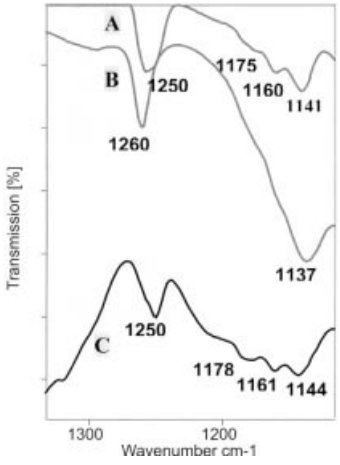

Figure 3. IR spectra of BPi **2c** (germanium cell; 1300−1100 cm^{-1}; cutoff: 680 cm^{-1}): A) methanolic solution; B) aqueous solution; C) neat sample

Chemical Properties

Acid/Base Properties

The acid/base character of BPi was studied by ^{31}P NMR-monitored pH-titration. The chemical shift of compound **2a** was plotted against the pH (Figure 4). For the pH range 4.8−13.2, two inflection points were observed. The second derivatives of the fitted function provided two pK_a values — 7.12 and 12.54 — with R^2 values of 0.999 and 0.997, respectively. These values are similar to the corresponding values of the second and third protonation equilibria of phosphoric acid (7.21 and 12.67), and they are higher than those for phosphorus acid (1.8 and 6.2).

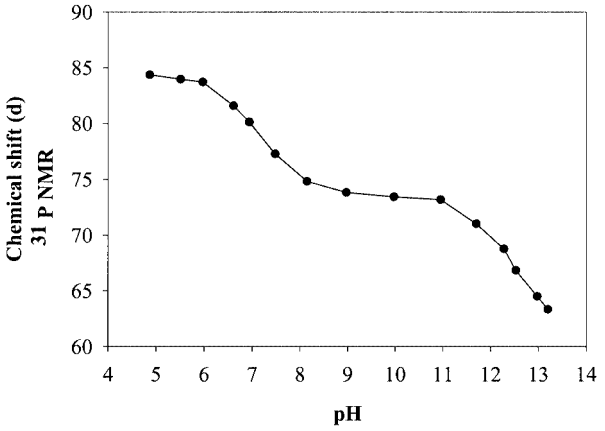

Figure 4. Determination of pK_a values of BPi; plot of BPi's ^{31}P NMR chemical shift in H_2O as a function of the pH; two inflection points are observed in the pH range 4.87−13.20

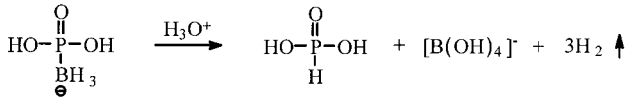
Stability of BPi

BPi is stable in neutral and basic solutions. For instance, after 48 h at room temperature at pH = 13.7, no degradation of BPi was observed by ^{31}P NMR spectroscopy. BPi is also relatively stable in acidic solution at pH values > 2. At pH = 2, BPi slowly degrades to phosphorus acid at a rate of 7×10^{-7} s^{-1}, $R^2 = 1.00$ ($t_{1/2}$ = 275 h), as monitored by ^{31}P NMR spectroscopy.

Under highly acidic conditions (pH < 2), the evolution of H_2 is clearly observed, the P−B bond is cleaved, and boric acid is formed together with phosphorus acid (Scheme 3).[20] Phosphorus acid was observed in the ^{31}P NMR spectrum as a doublet at δ = 3.5 ppm (J = 633 Hz). The borane reacts with water to liberate hydrogen gas and boric acid.



Scheme 3

The stability of inorganic boranophosphate, resulting from neutral hydrolysis of thymidine 5′-boranomonophosphate at 50 °C, has been reported earlier.[20]

H-Bonding of BPi

Solutions of **2b** or **2c** in organic solvents ($CHCl_3$, CH_3CN, DMF, and even MeOH), show unexpected ^{31}P NMR spectra. Product **2b** in MeOH apparently consists of three different but pattern-related signals. The signals with chemical shifts of δ = 80.0 (A), 86.2 (B), and 90.8 (C) ppm, each have an identical BPi-typical pattern (Figure 5).

Several minutes after the dissolution of **2b** in MeOH, signals A, B, and C are observed in the ^{31}P NMR spectrum, with A and B as the major peaks (C constitutes ca. 5% of the mixture). The composition of the initial mixture is time-dependent due to the interconversion of the species. When monitoring this process with 0.14 M **2b** in CD_3OD (ε = 33)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

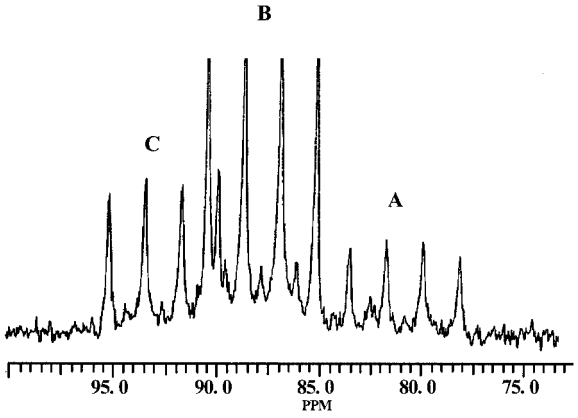


Figure 5. ^{31}P NMR spectrum of BPi **2b** in methanolic solution

at room temperature for 160 h, we noted the conversion of A and B to C, with a final C/B ratio of 4.4:1 (A disappeared completely). The ^{1}H-coupled ^{31}P NMR spectrum indicated H-split quadruplet signals for B and C — no D/H exchange occurred.

A spectrum similar to the one shown in Figure 5, and time-dependent interconversion of the species, was also observed for **2b** in DMF, CH_3CN, and $CHCl_3$.

The possibility that the additional BPi-like species are the corresponding mono- or dimethyl esters, due to a reaction of **2b** with MeOH, was ruled out because their ^{13}C and ^{1}H NMR spectra in $CDCl_3$ are devoid of a methyl ester signal.

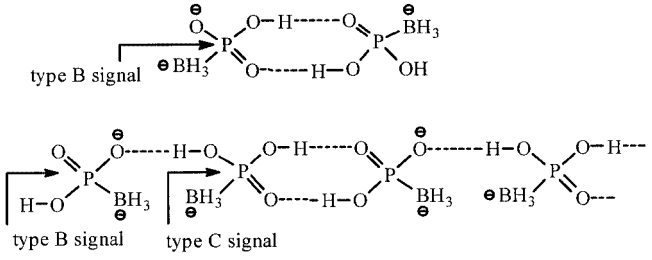
The three signals seen in the ^{31}P NMR spectrum of **2c** in organic solvents converged into one, probably A (δ = 79.8 ppm) after solvent evaporation and dissolution in D_2O. The possibility that signals B and C are due to boranophosphate anhydrides, resulting from **2c** in the NMR sample, is unlikely as the formation of the related phosphoric acid anhydrides requires drastic conditions (up to 250 °C at very low pH, or the presence of a condensation agent).[21] Obviously, these conditions do not exist in the NMR samples of BPi.

The possibility of B and C being anhydrides formed during the preparation of BPi, was also ruled out as the ^{31}P NMR spectrum of **2c**, which exhibits several signals in organic solvents, shows only one signal when measured in water. In contrast, the hydrolysis of condensed phosphates is known to be quite slow (i.e. several weeks at 60 °C, pH = 5).[22]

Phosphoric acid and its derivatives form strongly H-bonded clusters including cyclic dimers, trimers, and chains.[23,24] Dimerization occurs in the solid state,[25] in highly concentrated phosphoric acid,[24,26] in freons,[23b] or in aprotic organic solvents.[27,28] Therefore, it is likely that the new BPi-like signals are indicative of clustering of BPi in organic solvents, and even in a highly polar and H-bonding solvent such as MeOH. These clusters are not large (< 30 Å) based on light-scattering measurements.

To assess the possibility of observing different H-bond-clustered species on the NMR timescale, we measured the ^{31}P NMR spectrum of the parent phosphate bis(tributylammonium) salt in benzene, where clustering is known to occur.[28] Indeed, three signals were clearly observed at δ = 3.63, 3.23, and 2.93 ppm, demonstrating that different H-bonded phosphate clusters can be detected by ^{31}P NMR spectroscopy. These three phosphate signals, seen in benzene, converged into one in acetonitrile and MeOH, indicating the collapse of the Pi clusters in polar/protic solvents.

Based on our observations of the pH-dependent chemical shift of BPi, and on the determination of BPi's acidity constants (Figure 4), we propose the following assignment of signals A, B, and C. Signal A corresponds to the monomeric BPi, whose chemical shift at $\delta \approx 80$ ppm indicates that half the BPi monomer population bears two protons, and the other half bears one proton (Figure 4). Signal B, at δ = 86 ppm, corresponds to a BPi moiety that has one BPi H-bonded neighbor. Namely, signal B could result both from BPi dimers and higher clusters (Scheme 4). In these cases, each BPi is associated with an additional proton (Bu_3NH^+ ions neutralize the negative charges). Therefore, the chemical shift of the BPi dimer shifts downfield (δ = 86 ppm, as at pH = 4.7). As indicated by signal C, BPi also forms clusters, corresponding to a BPi moiety that has two H-bonded BPi neighbors (Scheme 4). A BPi moiety in the middle of a cluster is associated with three protons, resulting in an additional downfield shift to δ = 91 ppm, corresponding to that of BPi at pH = 2.



Scheme 4

Small H-bonded clusters (i.e. dimers and trimers) are formed almost instantaneously. This is probably the stage of nucleation. Once a critical nucleus is formed, a slow process of high-order clustering occurs. At this stage the concentration of A in solution is drastically reduced. This H-bonding-based clustering mechanism is also supported by the observation that, upon evaporation of the organic solvent from the species mixture and dissolution in water, only A is detected.

The fact that BPi forms clusters even in MeOH, whereas Pi forms clusters only in benzene, implies that BH_3 may play a role in the pre-organization of the BPi clusters. The lipophilic BH_3 moieties possibly form the core of the cluster due to hydrophobic interactions (in MeOH). This core is then further stabilized by P−O$^-$···HO−P hydrogen bonds.

Reactions of BPi with Selected Reagents

The reactivity of BPi towards various organic and inorganic reagents was explored as part of the characterization

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the chemical nature of BPi. These reagents include aqueous acid solution, nitrile, amide, carbodiimide, pyridine and imidazole, tosyl chloride, phosphorus oxychloride, H_2, and Zn^{2+} and Mg^{2+} ions.

Although BH_3, in complexes with a variety of sulfur/amine/oxygen compounds, is an efficient reducing agent, its reducing nature is drastically altered in BPi. For instance, while hydride transfer from "BH_3" to water occurs readily, the BH_3 moiety in BPi transfers hydride only in a highly acidic solution (pH $<$ 2). Likewise, while BH_3·THF complex readily reduces nitriles and amides to the corresponding amines,[29] the borane moiety in BPi does not reduce acetonitrile and dimethyl formamide, as evidenced by the complete stability of BPi in these solutions.

A carbodiimide reagent is used for the condensation of phosphate derivatives to provide the corresponding phosphoric anhydride. The reaction of **2a** with an excess of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (EDC) was explored in water (pH = 6.5) at 37 °C for 4 h. The addition of EDC to BPi resulted in excessive loss of this compound due to complete P−B bond cleavage of **2a** to yield phosphorus acid (72% of **2a** was degraded after 4 h, based on the ^{31}P NMR spectrum). This finding is in contrast to diethyl phosphite (cyano- or methoxycarbonyl)borane analogues, which are stable to dicyclohexylcarbodiimide (DCC).[30]

The P−B bond was also found to be sensitive to catalytic hydrogenation. Thus, when compound **9** was subjected to hydrogenation (in the presence of Pd/C), the P−B bond was also reduced, yielding phosphorus acid.

The reactivity of BPi with imidazole and pyridine was also studied. Specifically, a solution of BPi with 2 or 10 equiv. of imidazole in CD_3OD remained unchanged for 96 h, based on the ^{31}P NMR spectra. Likewise, only a negligible cleavage of the P−B bond was observed after 113 h for a solution of BPi in pyridine. BPi is apparently more stable to imidazole and pyridine than the related analogue tetramethyl boranopyrophosphate.[31] The reaction of 5′-DMT-2′-deoxythymidine with tetramethyl boranopyrophosphate in the presence of *N*-methylimidazole was reported to proceed with the partial removal of the borane group. Likewise, when pyridine was used as a solvent, partial removal of the borane group was observed.[31]

The presence of divalent metal ions such as Zn^{2+} and Mg^{2+} in DMF and water for 48 h and 4 h, respectively, left BPi unchanged.

Whereas dimethyl boranophosphate monopotassium salt (**3**) plays the role of an efficient nucleophile,[13] the related BPi is a poor nucleophile. Thus, when BPi was treated with tosyl chloride or mesyl chloride (with or without amine) in acetonitrile for 24 h, even at 60 °C, no reaction occurred. Likewise, the reaction of BPi with phosphorus oxychloride and its derivatives [P(O)Cl_2R] yielded no product. The reason for BPi's reduced nucleophilicity, as compared to **3**, might be due to the "carboxylate-like" nature of BPi, as compared to the "alkoxide-like" nature of dimethyl boranophosphate.

Conclusions

The quest for phosphate bioisosters over the last several decades has included the synthesis of phosphonates, α-halo phosphonates,[32,33] phosphorothioates,[4] and boranophosphate analogues.[6,34,35] Despite the extensive study of boranophosphate nucleoside analogues, the exploration of the parent inorganic boranophosphate has not been reported. The various potential applications of a phosphate isoster, together with the limitations of the currently available isosters, justify the continued search for the perfect inorganic phosphate mimic. Therefore, the unique and chemically interesting inorganic boranophosphate **2** has been investigated here as a mimic of phosphate with respect to properties such as water solubility, geometry, acid/base character, H-bonding, and chemical reactivity. The great similarity of BPi to the inorganic phosphate, Pi, is demonstrated here by the BPi's high water solubility, and geometry that is in accordance with that of the parent compound, except for the long P−B bond (1.892 Å) and B−P−O angles that are slightly larger than tetrahedral angles. Furthermore, the acid/base character of BPi is essentially not altered in comparison to Pi. This finding is in contrast to the corresponding phosphorothioate isoster, where there is a reduction of about two log units in the acidity relative to Pi.[36] Likewise, pK_{a2} values of α-mono- and -difluorophosphonate isosters are one and two log units, respectively, lower than the pK_{a2} value of phosphoric acid.[33]

Indications for H-bond-based clustering of BPi in organic solvents, including polar and protic solvents, were obtained from the IR and ^{31}P NMR spectra.

BPi is stable under both highly basic and acidic conditions (at pH $>$ 2). In addition, BPi is stable in the presence of imidazole, pyridine, and Mg^{2+} ions. However, the P−B bond cleavage is observed upon the reaction of BPi with carbodiimides. A loss of BPi's borane moiety also occurs at pH values $<$ 2.

A drastic alteration in the chemical nature of BPi as compared to Pi and BH_3 complexes is observed. While Pi is a nucleophile,[37] BPi is a poor nucleophile. Likewise, the reducing nature of the BH_3 group in BPi is drastically lower than in other BH_3 complexes.

Based on the geometry, water solubility, acid/base character, and H-bonding properties, BPi appears to be a perfect mimic of Pi, and an attractive alternative to the thiophosphate and α-halophosphonate isosters.

Experimental Section

General: All air- and moisture-sensitive reactions were performed in flame-dried, nitrogen-flushed flasks sealed with rubber septa; the reagents were introduced with a syringe. The progress of the reactions was monitored by TLC on precoated Merck silica-gel plates (60 K-254). Column chromatography was performed with Merck silica gel 60 (230−400 mesh). Compounds were characterized by NMR spectroscopy using Bruker DPX-300, DMX-600, or AC-200 spectrometers. NMR spectra were recorded with a Bruker AC-200 spectrometer with a ^{31}P NMR probe (isotope frequency of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

81 MHz) using 85% H_3PO_4 as an external reference. IR spectra of BPi in KBr pellets were recorded with a Nicolet Impact 400D spectrometer using the OMNIC program. IR spectra of BPi in solution were measured using a Bruker Vector 22 equipped with a liquid-nitrogen-cooled MCT detector. For the ATR measurements, a Harrick variable-angle ATR accessory was used. For one spectrum, 100 scans were co-added at a resolution of 4 cm^{-1}. The clean ATR germanium crystal (Harrick Scientific Corporation) was measured for the background spectra (cutoff 680 cm^{-1}). Crystallographic data were collected with a Nonius KappaCCD diffractometer at 120 K with scans of 1° collected at a speed of 1°/20 s; the merging *R*-factor on the data was 0.046 with 36867 reflections collected and 2979 unique. BPi crystals were obtained as colorless needles. Further details of the crystal structure investigation may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-413735. Melting points were measured using a Fisher-Johns melting-point apparatus. Apparent pH values were measured with a Hanna Instruments pH-meter (HI 8521), equipped with an Orion micro-combination pH electrode (9802). Compounds **2** are all inorganic boranophosphate salts having different ammonium counterions (ammonium in **2a**, tributylammonium in **2b**, triethylammonium in **2c**, and tetrabutylammonium in **2d**, see Experimental for **2a** below). The preparation of salts **2a**−**2c** for elemental analysis involved a freeze-drying process. Unfortunately, it was impossible to obtain reliable elemental analyses for salts **2a**−**2c** due to loss of some of the amine during this freeze-drying process (as observed in their ^1H NMR spectra). Therefore, we chose the tetrabutylammonium salt **2d** for performing a representative elemental analysis, since in this case there is no partial loss of the amine during freeze-drying.

Boranophosphate 2a: $BH_3{\cdot}SMe_2$ complex in THF (2 M, 1.35 mL, 2.7 mmol) was added to a solution of tris(trimethylsilyl) phosphite (600 μL, 1.795 mmol) in dry CH_3CN (5 mL) under N_2 at 0 °C. The resulting solution was kept at room temperature for 15 min. Dry MeOH (15 mL) and 2 M NH_3 in EtOH (1.8 mL, 3.6 mmol) were added and the mixture was stirred at room temperature for 1 h. The solvent was then removed under reduced pressure, and the product was obtained as a white solid in 93% yield (202 mg, 1.556 mmol), m.p. > 240 °C. ^1H NMR (D_2O, 200 MHz): δ = 0.27 (d of 1:1:1:1 quadruplet, $J_{P,H}$ = 22, $J_{B,H}$ = 87 Hz, 3 H) ppm. ^{31}P NMR (D_2O, 81 MHz): δ = 80.38 (1:1:1:1 quadruplet, J = 156 Hz; 1:1:1:1:1:1:1 septuplet, J = 52 Hz) ppm. IR (KBr): $\tilde{\nu}$ = 2412, 2378, 2352, 1181, 1149, 1077−903, 654 cm^{-1}. Compound **2a** was converted into the corresponding tetraethylammonium salt as follows: **2a** was passed through a Sephadex-CM C-25 − tetraethylammonium-form column (prepared from the corresponding sodium-form resin upon loading with excess Et_4NCl) and the column was washed with about 20 volumes of deionized water. The solution was freeze-dried to yield tetraethylammonium BPi (**2d**) as a white solid. Based on the pH value of the **2d** solution, the ^{31}P NMR spectrum, and correlation with the plot of BPi ^{31}P NMR shifts vs. pH (Figure 4), the expected empirical formula is $BH_3O_3PH_{1.5}(Et_4N)_{1.5}$ (289.3): calcd. H 11.9, P 10.7; found H 11.3, P 9.5.

Boranophosphate 2b: The tributylammonium salt of boranophosphate was prepared as described above for **2a**. However, Bu_3N (0.85 mL, 3.57 mmol) was added instead of NH_3/EtOH. The product was obtained as a white solid in 93% yield (645 mg, 1.385 mmol), m.p. 83−84 °C. IR (KBr): $\tilde{\nu}$: 2407, 2381, 2350, 1184, 1150, 1100−850, 655 cm^{-1}.

Determination of the pK_a Values of Boranophosphate 2a: The pK_a values of **2a** were evaluated by ^{31}P NMR spectroscopy at room temperature. Solutions of **2a** (0.15−0.18 M) at different pH values were prepared by adding dilute sodium hydroxide or hydrochloric acid solutions. The ^{31}P NMR chemical shift was monitored as a function of the pH. A five-parameter sigmoid function was fitted to the data using Sigma Plot 2000 (SPSS, Inc.): $\delta = \delta_0 + a/[1 + e^{-\{(pH-pH^\circ)/b\}}]^c$. The inflection point, which is determined by the second derivative of the fitted sigmoid function, is the pK_a value.

Determination of the Decomposition Rate of BPi 2a at pH = 2: The stability of **2a** in acidic solution was evaluated by ^{31}P NMR spectroscopy at room temperature, monitoring the formation of the deboranation product (phosphorus acid). A 0.16 M solution of **2a** at pH = 2 was prepared by adding dilute hydrochloric acid to a solution of inorganic boranophosphate (NH_4^+ salt) in H_2O and 10% D_2O. The percentage of decomposition of **2a** is based on integrations of PBi and phosphorus-acid signals (δ = 90.93 and 3.3 ppm, respectively). The decomposition rate was determined by measuring changes in the integration of the respective NMR signals within 96 h.

Acknowledgments

The authors would like to thank the Marcus Center for Medicinal Chemistry, and the German Bundesministerium fuer Bildung und Forschung (BMBF) and the Israeli Ministry of Science, Culture and Sport (MOS) for financial support (grant number 1812). In addition, the authors gratefully acknowledge Dr. D. T. Major for the calculation of the IR spectrum of BPi, Prof. S. Specher and I. Mastai for a helpful discussion, and Prof. C. Sukenik and Dr. T. Bayer for their help with IR measurements in a Ge cell.

Synthesis and Electrochemistry of the Monolacunary Dawson-Type Tungstoarsenate $[H_4AsW_{17}O_{61}]^{11-}$ and Some First-Row Transition-Metal Ion Derivatives

Israel-Martyr Mbomekalle,[a] Bineta Keita,[a] Yu Wei Lu,[a] Louis Nadjo,*[a] Roland Contant,[b] Nebebech Belai,[c] and Michael T. Pope[c]

Keywords: Polyoxometalates / Dawson dissymmetrical polyoxometalates / Arsenic / Tungsten / Electrochemistry / Electrocatalysis

The novel family of the Dawson-type tungstomonoarsenate $[H_4AsW_{18}O_{62}]^{7-}$ has been extended by preparing for the first time its monolacunary species and its first-row transition-metal ion substituted derivatives. All compounds were characterized by elemental analysis, IR and UV/Vis spectroscopy and representative examples by ^{183}W NMR spectroscopy. Several lines of experimental evidence converge to indicate that the substitution occurs in the α_2 position. The lacunary species, unlike its phosphorus analogue, was sufficiently stable for a few voltammetric runs. Therefore, the cyclic voltammetric properties of substituted compounds were studied as a function of pH and systematically compared with those of the lacunary precursor rather than with those of their analogues derived from the symmetrical species $[As_2W_{18}O_{62}]^{6-}$. The electrocatalytic properties of all compounds were illustrated by the reduction of nitrite by reduced $[H_4AsW_{18}O_{62}]^{7-}$ and of nitrate by reduced α_2-$[(H_2O)Cu(H_4AsW_{17}O_{61})]^{9-}$.

Introduction

Polyoxometalates (POMs) are early transition metal−oxygen anionic clusters. They simultaneously exhibit many properties that make them attractive for applications in catalysis, separations, imaging, materials science and medicine.[1−8] The scope for varying the atomic compositions of these complexes is virtually enormous and new structures continue to be discovered. Even though complete rationalisation of the construction of these structures is lacking at present, very many of them might be recognised as being derived, at least partly, from lacunary Keggin and Dawson fragments. Recently, we have been interested in the possibility of obtaining Dawson structures with two different central heteroatoms. We were stimulated by the pioneering work[9] of one of the present authors who reported the synthesis of the novel Dawson-type tungstophosphate $[H_4PW_{18}O_{62}]^{7-}$ and its lacunary and zinc-substituted derivatives $[H_4PW_{17}O_{61}]^{11-}$ and $[Zn(H_2O)(H_4PW_{17}O_{61})]^{9-}$. In these species, the two anionic halves are of the A-type with only one of them containing a central heteroatom in the +v oxidation state. Soon afterwards, our group confirmed the feasibility of this synthesis for the As^V-containing analogue,[10] also obtaining the corresponding trilacunary species and achieving the synthesis of two sandwich-type derivatives, $[Zn_4(H_2O)_2(H_4AsW_{15}O_{56})_2]^{18-}$ and $[Cu_4(H_2O)_2(H_4AsW_{15}O_{56})_2]^{18-}$. With a systematic study of the relevant parameters, we have also established[11] the best experimental conditions for the synthesis of $[H_4AsW_{18}O_{62}]^{7-}$ and demonstrated that these conditions are essentially different from those necessary to obtain the well-known symmetric species $[As_2W_{18}O_{62}]^{6-}$. The same kind of rationalisation was achieved in the comparable syntheses of $[P_2W_{18}O_{62}]^{6-}$ and $[H_4PW_{18}O_{62}]^{7-}$.[12,13] Recently, we have extended the work on this new family of dissymmetric Dawson-type heteropolyanions to the first-row transition-metal ion substituted derivatives of $[H_4PW_{18}O_{62}]^{7-}$.[13]

Herein, we report the synthesis, characterization and electrochemistry of the hitherto unknown monolacunary species of $[H_4AsW_{18}O_{62}]^{7-}$ and its first-row transition-metal ion substituted derivatives. Their electrochemistry reveals differences from the corresponding symmetric heteropolyanions and with the phosphorus analogues. In addition, an evaluation of their electrocatalytic properties for the reduction of nitrate and nitrite is provided.

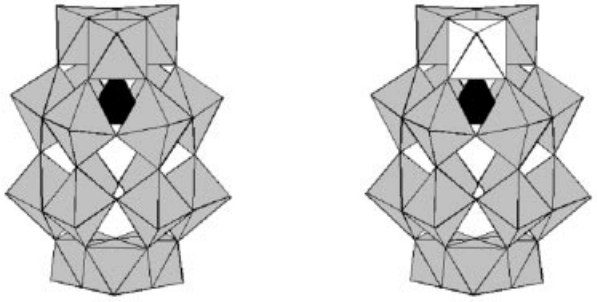
Results and Discussion

Prolonged heating of the reaction mixture during the synthesis of $[H_4AsW_{18}O_{62}]^{7-}$ results in the formation of the pure so-called α-isomer.[11] All the POMs in the present study are primarily derived from α-$[H_4AsW_{18}O_{62}]^{7-}$ (AsW_{18}) and their formulae will be written as $MAsW_{17}$, with omission of oxygen atoms and overall charges when no confusion is likely to arise; M represents the substituent metal cation. In close analogy with the case of α-$[H_4PW_{18}O_{62}]^{7-}$, the results of electrochemistry and IR spectroscopy demonstrate that the mild alkaline degradation of AsW_{18} results in the removal of a W atom from the "cap" in the half of this molecule containing the single As atom, thus creating the first vacancy in one of the so-called α_2 positions. Scheme 1 illustrates the α-structure proposed for α-$[H_4AsW_{18}O_{62}]^{7-}$ and one of its monosubstituted derivatives, α_2-$[M(H_2O)H_4AsW_{17}O_{61}]^{9-}$, where M represents a divalent transition metal ion and the water molecule is omitted.



Scheme 1. Schematic representations of the Dawson-type tungstomonoarsenate and a monosubstituted tungstomonoarsenate

Synthesis

The synthesis and purification of $[H_4AsW_{18}O_{62}]^{7-}$ has been described previously in detail.[11] As will be described in the Exp. Sect., the monolacunary derivative was obtained under mild conditions, provided the addition of $KHCO_3$ was sufficient to maintain the pH around 8 during the process. Two slightly different experimental conditions were applied for the synthesis of metal cation substituted derivatives, depending on the terminal ligand on the substituent metal atom in the final product. As is usual with Keggin- and Dawson-type POMs, the sixth coordination site on the metal atom in the 1:1 complexes may be occupied by a variety of ligands.[1,13] We were interested in two kinds of ligands: on one hand, in the substitution by $V^{5+/4+}$ or $Mo^{6+/5+}$, the terminal oxo group can be considered to reconstitute the structure of a saturated POM; on the other hand, for all other metal cations of interest in this work, the sixth position is occupied by a water molecule.

UV/Vis and IR Spectroscopic Characterisation

As expected, no specific fingerprint signals were found in the UV/Vis spectra in the series in order to distinguish one compound from the next. However, recording these spectra over a period of at least 24 h was helpful in assessing the stability of the complexes as a function of pH. This delay was selected as a compromise between the time needed for electrochemical characterisation of the complexes and that for eventual long-lasting or preparative-scale catalytic or electrocatalytic processes. The precursor lacunary H_4AsW_{17} was found to be sufficiently stable for a few cyclic voltammetric runs to be performed, a remarkable difference from its phosphorus analogue for which no stability domain could be found. The so-called "saturated" substituted compounds, $MAsW_{17}$ (M = Mo or V), show stabilities close to that of the unsubstituted compound, with complete stability observed from pH = 0.3 to 4. Table 1 shows complementary details as well as the stability domains for all the other substituted derivatives. Black indicates the domain in which a particular derivative is stable; dark grey corresponds to a decomposition less than or equal to 20% and light grey indicates a decomposition of between 20 and 70%. It is worth pointing out the complete identity of this behaviour with that of the corresponding phosphorus analogues, except for the difference in stability of their respective monolacunary derivatives.[12] The only exception concerns the Cu derivatives. $CuAsW_{17}$ is stable from pH = 0.3 to 5 and $CuPW_{17}$ is only stable from pH = 2 to 5.

The locations of the main IR bands are summarized in the Supporting Information and show a comparison between As_2W_{18} and AsW_{18} (Table SI1). Substitution into the vacancy of the lacunary species AsW_{17} can be expected to restore the symmetry present in AsW_{18}, at least as far as IR spectra are concerned. Then, only a relative weakening of the bond force constants would be mainly expected as a result of substitution. Table SI1 confirms this general trend, even though the observed variations are modest. Despite this, the IR spectra support the conclusion that no important structural changes appear from one compound to the next.

^{183}W NMR Spectroscopy

Table 2 shows the ^{183}W NMR chemical shifts for the Zn- and Ni-monosubstituted derivatives of the Dawson-type tungstomonophosphate and tungstomonoarsenate. The chemical shifts for the corresponding tungstodiphosphates were obtained from the pioneering work of Jorris and coworkers[14] and are shown for comparison. The chemical shifts measured in this work compare well with those of the corresponding MP_2W_{17}. In full agreement with expectations, all tungsten centres can be observed for the Zn-substituted anions, as shown in the Supporting Information (Figure SI1). Peak integrations confirm this observation (Table 2). The signals of all tungsten atoms, except two pairs, are seen for the Ni-substituted anions. It is likely that the two lines observed at low field are from the two remaining belt tungsten atoms in the XW_9 half of the anion. The Fe- and Cu-substituted derivatives were too paramagnetic to give useful results.

α_2-$[(D_2O)Zn^{2+}P_2W_{17}O_{61}]^{8-}$	−84.4 (2 W), −138.7 (2 W), −180 (1 W), −186.7 (2 W), -208.6 (2 W), −214.8 (6 W), −242.7 (2 W)	[14]
α_1-$[(D_2O)Zn^{2+}P_2W_{17}O_{61}]^{8-}$	−99.4, −117.4, −123.0, −146.1, −151.9, −157.7, −167.6, −174.2, −175.7, −177.3, −193.3, −200.1, −203.7, −210.3, −214.1, −214.6, −225.5 (each 1 W)	[14]
$[Zn(H_4PW_{17}O_{61})]^{9-}$	−98 (2 W), −135 (2 W), −147 (2 W), −176 (2 W), −195 (2 W), −200 (2 W), −205 (2 W), −208 (2 W), −222 (1 W)	this work
$[Zn(H_4AsW_{17}O_{61})]^{9-}$	−85 (2 W), −137 (2 W), −166 (2 W), −169 (2 W), −175 (2 W), −191 (4 W), −201 (2 W), −228 (1 W)	this work
α_2-$[(D_2O)Ni^{2+}P_2W_{17}O_{61}]^{8-}$	+468.3 (2 W), +338.7 (2 W), −142 and −146 (4 W), −200 and −202 (3 W), −230.5 (2 W)	[14]
$[Ni(H_4PW_{17}O_{61})]^{9-}$	+468 (2 W), +386 (2 W), −140 (2 W), −164 (2 W), −167 (2 W), −187 (2 W), −245 (1 W)	this work
$[Ni(H_4AsW_{17}O_{61})]^{9-}$	+613 (2 W), +349 (2 W), −140 (2 W), −153 (2 W), −160 (2 W), −175 (2 W), −246 (1 W)	this work

A comparison of the results in Table 2 strongly suggests that the substitution site is the α_2 position, in complete analogy with the phosphorus systems.[12]

Electrochemistry

We have previously shown by cyclic voltammetry, the difference in basicity between the several first reduction species of As_2W_{18} and AsW_{18}.[10] Typically, in a pH = 0.3 sulfate medium, the part of the pattern of As_2W_{18} of interest here consists of two one-electron waves followed by two two-electron waves. These waves correspond to reversible diffusion-controlled processes. In contrast, in the same medium, AsW_{18} exhibits three two-electron chemically reversible diffusion-controlled waves. As a cross-check, the first wave was also shown by controlled potential coulometry to feature a two-electron process. Furthermore, we found that this first wave split into two one-electron waves at pH = 4 while the pattern for As_2W_{18} did not change. This behaviour can be understood in terms of the higher basicity of the first several reduced species of AsW_{18} over those of As_2W_{18}. The complete analogy between this and the comparable behaviour of PW_{18} and P_2W_{18} must be stressed.[12] The electrochemistry of monosubstituted derivatives of AsW_{18} can be discussed straightforwardly in comparison with the corresponding As_2W_{18}-derived analogues. Owing to the marginal variations in the behaviour of the corresponding compounds from one series to the next, the main outcome of such a study turned out to be the confirmation that α_2-substituted derivatives were indeed formed in the $MAsW_{17}$ series.

In contrast to the lacunary species PW_{17}, its analogue AsW_{17} is sufficiently stable to allow a few voltammetric runs in the pH = 3 and pH = 5 media used. This observation opens up the way for comparison between the electrochemical behaviour of $MAsW_{17}$ derivatives with that of their precursor lacunary compound. Such a comparison is appropriate because those substituted derivatives bearing a terminal water molecule as the sixth ligand on the substituent metal cation are expected to behave much like the lacunary precursor, at least as far as the electrochemistry of the POM framework is concerned.[15−18] In addition, the differences brought about by the presence of As instead of P in MXW_{17} (X = P or As) were selected as a basis for further interesting comparisons. In short, two issues were

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

found pertinent for this electrochemical study: (i) the redox behaviour of the electroactive substituent cations within the POM framework and (ii) the influence of the nature of the substituent cation and of the central heteroatom on the reduction of the W^{VI} centre.

Redox Behaviour of the Electroactive Substituent Transition Metal Ions within $MAsW_{17}$

The reduction or oxidation peak potentials for reducible or oxidizable cations within the substituted POMs are listed in Table 3. In general, most of the peak potentials are pH-dependent, indicating proton intervention in the overall redox mechanism. The other trends observed for the phosphorus analogues are also seen here. Reduction of the Cu^{2+} centre is merged with the first tungsten reduction, precluding any accurate determination of its peak potential location. Oxidation of the Mn^{2+} centre is observed, but at a highly positive potential. Oxidation of the Co^{2+} centre is difficult to achieve.

Table 3. Potential locations of the cations which may be reduced or oxidized within α_2-$AsW_{17}M$ in a pH = 3.00 and a pH = 5.00 medium; E_{pc} = cathodic peak potential; E_{pa} = anodic peak potential; scan rate: 10 $mV{\cdot}s^{-1}$; working electrode: glassy carbon; reference electrode: SCE

Reducible cations	$-E_{pc}$ [V]	
	pH = 3	pH = 5
Fe^{3+} in $AsW_{17}Fe$	0.150	0.230
Cu^{2+} in $AsW_{17}Cu$	–	0.348
Mo^{6+} in $AsW_{17}Mo$	−0.096	−0.082
Oxidizable cations	E_{pa} [V]	
	pH = 3	pH = 5
V^{4+} in $AsW_{17}V^{IV}$	0.456	0.378
Mn^{2+} in $AsW_{17}Mn$	1.060	0.892
Co^{2+} in $AsW_{17}Co$	–	1.406

Influence of the Central Heteroatom on the First Tungsten Reduction Wave within $XW_{17}M$ (X = P or As)

Figure 1 (A and B) illustrate two typical examples of the limiting behaviour observed at pH = 3. For the Mn^{2+}-substituted derivatives, the peak potential for the first tungsten reduction wave is hardly displaced in Figure 1A, irrespective of whether the central heteroatom is As or P. In contrast, for the Cu^{2+} complexes, Figure 1B shows a 154 mV positive shift for the first tungsten reduction peak potential in the As compound compared with the P derivative. It must be pointed out that a combined Cu and W first wave was observed at pH = 3 for both P and As derivatives. In both cases, controlled potential coulometry beyond the peak potential of this composite wave consumes four electrons per molecule for complete reduction at pH = 3. Electrolysis conducted at the half-wave potential and combined with spectroelectrochemistry or simple inspection of the solution colour indicates that the two-electron reduction of the Cu^{2+} centre is completed before that of the W^{6+} centres begins. The first tungsten reduction peak potentials at pH = 3 are shown in Table 4 for all the substituted derivatives along with the value for H_4AsW_{17}. It appears from these data that the difference $\Delta E_p = E_p$(lacunary) − E_p(substituted), available only for As compounds, depends on the nature of the substituent. At pH = 3, the largest effect was obtained for $AsW_{17}Mo$ in which the first tungsten wave was driven 144 mV in the positive potential direction compared with the same wave in the lacunary precursor. All other differences are modest and range between +14 mV to −62 mV. The value of ΔE_p for the V^{4+} complex is remarkable and is comparable with those found for substituted derivatives bearing a terminal water molecule and not with a compound such as $AsW_{17}Mo$ bearing a terminal oxo group. Analogous trends were also obtained previously in the study of the α_1- and α_2-$P_2W_{17}M$ series.[16−18]

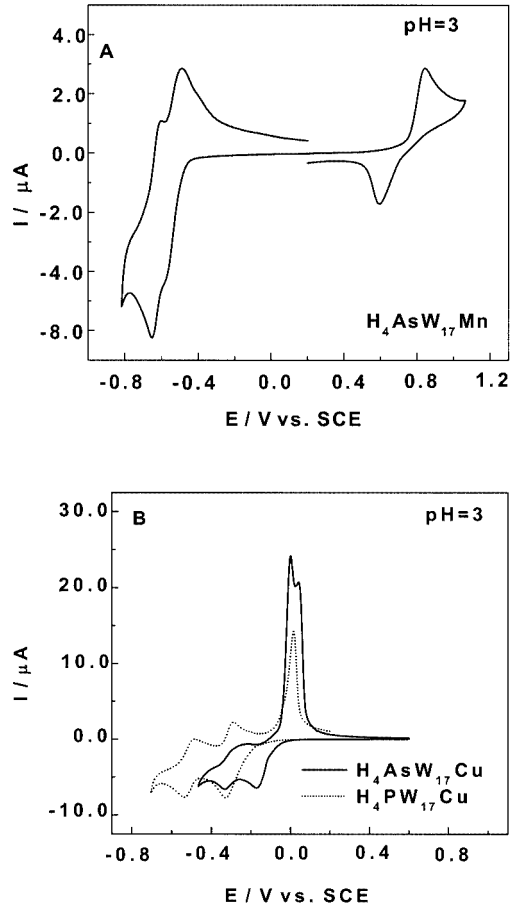

Figure 1. Cyclic voltammograms recorded on 5×10^{-4} M solutions of the relevant polyoxometalate in a pH = 3 medium (0.2 M Na_2SO_4 + H_2SO_4); scan rate: 10 $mV{\cdot}s^{-1}$; working electrode: glassy carbon; reference electrode: SCE; A: α-$[H_4Mn(H_2O)AsW_{17}O_{61}]^{9-}$; B: α-$[H_4Cu(H_2O)AsW_{17}O_{61}]^{9-}$ (solid line) and α-$[H_4Cu(H_2O)PW_{17}O_{61}]^{9-}$ (dotted line)

The influence of the nature of the central heteroatom X within $XW_{17}M$ (X = P or As) leads to modest peak potential shifts ranging between −30 mV and +30 mV, except in the case of the Cu^{2+}-substituted derivatives. In fact, the pK_a

Table 4. Potential locations of the first tungsten wave for $AsW_{17}M$ derivatives and their differences with the corresponding wave of the precursor lacunary species in a pH = 3 medium; scan rate: 10 mVs^{-1}; working electrode: glassy carbon; reference electrode: SCE; E_{pc}: cathodic peak potential; $\Delta E_{pc} = (E_{pc\ lacunary} - E_{pc\ substituted})$

Substituent	$-E_{pc}$ [mV]	ΔE_{pc} [mV]
Lacunary	372	0
V^{4+}	400	28
Mn^{2+}	358	−14
Fe^{3+}	434	62
Co^{2+}	432	60
Ni^{2+}	420	48
Zn^{2+}	388	16
Mo^{6+}	280	−144

values for the substituted complexes and for their reduction species might be different, thus rendering complicated any study of the nature of the central heteroatom and of the pH effect.

Electrocatalytic Reductions of Nitrite and Nitrate

The behaviour of AsW_{18} and its substituted derivatives $AsW_{17}M$ towards the electrocatalytic reductions of nitrite and nitrate were tested in the pH-stable ranges of these POMs. In the potential region explored, no direct reduction of nitrite or nitrate on the glassy carbon electrode surface could be observed.[19,20] It was also deemed interesting to look, in particular, for cases in which a catalytic current could be observed on the first wave or the first several waves of each POM, in such potential regions. Under these conditions, the processes occur in solution and, usually, no permanent modification of the electrode surface by the POM was obtained.[21] Conclusions from our previous work[10,12,20] were confirmed here and indicate that only Cu- and Ni-substituted derivatives catalyse the reduction of nitrate, while most derivatives catalyse the reduction of nitrite. Typically, Figure 2 (A and B) illustrates selected representative examples of electrocatalytic reductions of nitrite by AsW_{18} or by $AsW_{17}Cu$, respectively. At pH = 2 and in the absence of nitrite, the first two waves of AsW_{18} are closely spaced (Figure 2, A). Upon addition of even modest amounts of nitrite, a large cathodic current enhancement was observed (Figure 2, B). This cathodic current was slightly composite and no longer had any associated anodic counterpart. Increasing the concentration of nitrite through adjustment of the excess parameter γ ($\gamma = C_{NO_2^-}/C_{POM}$) still enhanced the cathodic current. Thus, efficient catalysis of nitrite reduction[22] was achieved during the reduction of AsW_{18}. This current increase can be expressed more quantitatively through the catalytic efficiency CAT defined as $CAT = 100 \times [I_{(POM + NO_2^-)} - I^d_{(POM)}]/I^d_{(POM)}$ where $I_{(POM + NO_2^-)}$ represents the reduction peak current of the POM in the presence of nitrite and $I^d_{(POM)}$ the reduction peak current for the POM alone.

In the experiment described in Figure 2, CAT was found to vary from 634% to 1185% for $\gamma = 10$ and $\gamma = 30$, respectively. While electrocatalysis by AsW_{18} is triggered by reduced W centres, a more complex pathway must be considered in the case of $AsW_{17}Cu$. Figure 2, C shows at pH = 3 the first combined Cu/W cathodic wave for this POM with the characteristic stripping oxidation pattern on potential reversal. Superimposed on this is the cyclic voltammogram obtained in the presence of nitrite. The main obser-

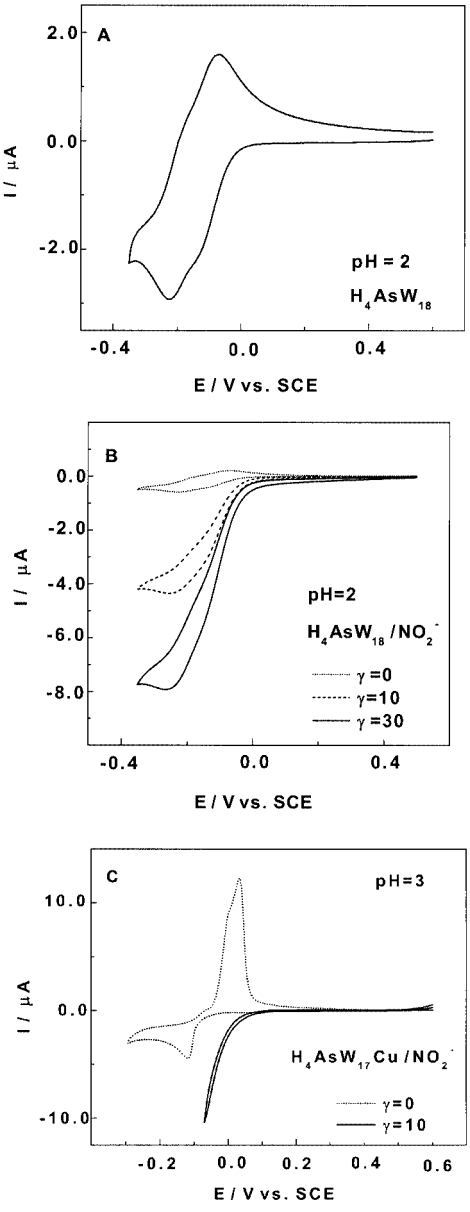

Figure 2. Cyclic voltammograms recorded on 5×10^{-4} M solutions of the relevant polyoxometalate; scan rate: 2 $mV \cdot s^{-1}$; working electrode: glassy carbon; reference electrode: SCE; for the definition of the excess parameter γ, see text; A: first two waves of α-$[H_4AsW_{18}O_{62}]^{7-}$ alone in a pH = 2 medium (0.2 M Na_2SO_4 + H_2SO_4); B: same conditions as in A with the addition of increasing amounts of nitrite; C: α-$[H_4Cu(H_2O)AsW_{17}O_{61}]^{9-}$ in the absence and presence of nitrite in a pH = 3 medium (0.2 M Na_2SO_4 + H_2SO_4)

vations can be summarized as follows: (i) copper deposition can be obtained upon scanning the first combined Cu/W cathodic wave; (ii) nitrite electrocatalytic reduction begins in a potential region in which the reduction current of $AsW_{17}Cu$ is very weak; (iii) the electrocatalytic reduction of nitrite is very fast, so that no copper deposition could be detected in the potential range explored, at least as far as cyclic voltammetry is concerned.

The electrocatalytic reduction of nitrate by reduced $AsW_{17}Cu$ adds a new example to the few described in our previous work.[10,12,20] Figure 3 summarises the observations at pH = 3 and 5. Figure 3, A (obtained at pH = 3) shows that the nitrate electrocatalytic reduction is effective and is enhanced with increasing γ values. A comparison of Figures 2 and 3, A requires, at the very least, the following two remarks: (i) the electrocatalytic reduction of nitrite begins at a potential substantially less negative than that for the nitrate; (ii) a much larger excess parameter value is needed to observe a clear catalytic effect in the case of nitrate compared with that of nitrite. Figure 3, B indicates that the electrocatalytic reduction of nitrate remains effective at pH = 5. It is worth noting that two cathodic steps

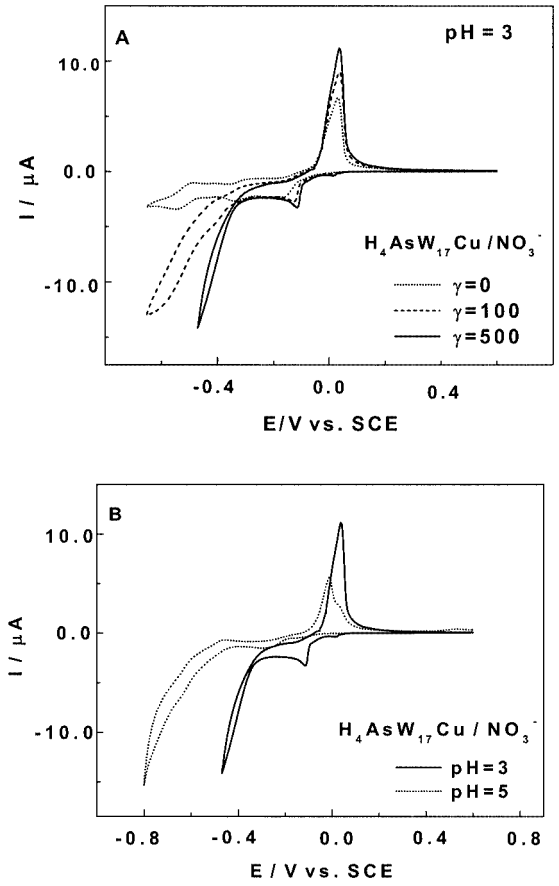

Figure 3. Cyclic voltammograms recorded on 5×10^{-4} M solutions of α-$[H_4Cu(H_2O)AsW_{17}O_{61}]^{9-}$ in the absence and presence of nitrate; scan rate: 2 mV·s^{-1}; working electrode: glassy carbon; reference electrode: SCE; for the definition of the excess parameter γ, see text; A: in a pH = 3 medium (0.2 M Na_2SO_4 + H_2SO_4), with increasing amounts of nitrate; B: comparison of the cyclic voltammograms run in the presence of nitrate in a pH = 3 medium and in a pH = 5 medium, respectively (0.4 M CH_3COONa + CH_3COOH)

were observed for copper reduction processes in this medium. The potential shift for nitrate reduction also falls in the range of 100 mV per pH unit. Finally, we found qualitatively that the central heteroatom X in $XW_{17}Cu$ (X = P or As) has little influence on the electrocatalytic reduction of nitrate.

Conclusions

The present work expands our earlier results which were previously limited to the synthesis and comparison of the electrochemical behaviour of AsW_{18} and its symmetrical analogue As_2W_{18}. The monolacunary species AsW_{17} was synthesized for the first time and served as a precursor to introduce first-row transition-metal ions in the framework of the novel Dawson-type tungstomonoarsenate. Several lines of experimental evidence converge to indicate that the substitution occurs in the α_2 position. The short-term stability of AsW_{17} in solution contrasts with the instability of its phosphorus analogue. This situation allows a comparison between the electrochemical behaviour of this lacunary POM and the transition-metal ion substituted systems. Most of the latter complexes were expected to behave like the lacunary precursor, at least with respect to the redox properties of the W framework. The results confirm this expectation. The efficiency of $AsW_{17}Cu$ towards the electrocatalytic reduction of nitrate is a new example in addition to the few previously published.

Experimental Section

Preparations: All chemicals were of reagent grade and were used as received. The isolated yields of the final pure products ranged constantly from 60 to 95% in all the preparations. α-$K_7[H_4AsW_{18}O_{62}]\cdot 18H_2O$ was synthesized as described previously.[11]

α-$K_{11}[H_4AsW_{17}O_{61}]\cdot 18H_2O$ (H_4AsW_{17}): A sample of α-$K_7[H_4AsW_{18}O_{62}]\cdot 18H_2O$ (8 g, 1.6 mmol) was dissolved in Millipore water (20 mL) with stirring. To the clear solution, was added $KHCO_3$ (17 mL of a 1 M solution) and a white precipitate gradually formed. Stirring was continued for roughly 1 h. The solid was then left to settle and was filtered, washed twice with ethyl alcohol, twice with diethyl ether and was air-dried by suction through a flask with an aspirator (yield 7.5 g, 95%). $K_{11}[H_4AsW_{17}O_{61}]\cdot 18H_2O$ (4934.5): calcd. As 1.52, K 8.72, W 63.34, H_2O 6.57; found As 1.59, K 8.91, W 62.81, H_2O 6.31.

α-$K_9[H_4Zn(H_2O)AsW_{17}O_{61}]\cdot 20H_2O$ ($AsW_{17}Zn$): A sample of $Zn(NO_3)_2\cdot 6H_2O$ (0.30 g, ca. 1 mmol) was dissolved in Millipore water (45 mL) and α-$K_{11}[H_4AsW_{17}O_{61}]\cdot 18H_2O$ (4 g, 0.82 mmol) was added in small portions while heating the mixture on a water bath (ca. 60 °C). After 30 min, the cloudy mixture was filtered hot and the clear filtrate left in a beaker. Large white crystals appeared upon cooling. This material was filtered, washed with ethyl alcohol and left to dry in the open air (yield 2.8 g, 70%). Recrystallization was performed with a minimum amount of Millipore water. $K_9[H_4Zn(H_2O)AsW_{17}O_{61}]\cdot 20H_2O$ (4975.7): calcd. As 1.51, K 7.10, W 63.07, Zn 1.32; found As 1.42, K 6.97, W 65.2, Zn 1.66.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

α-$K_9[H_4Cu(H_2O)AsW_{17}O_{61}]\cdot 18H_2O$ ($AsW_{17}Cu$): A sample of $Cu(NO_3)_2\cdot 3H_2O$ (0.25 g, ca. 1 mmol) was dissolved in Millipore water (45 mL) and α-$K_{11}[H_4AsW_{17}O_{61}]\cdot 18H_2O$ (4 g, 0.82 mmol) was added in small portions while heating the mixture on a water bath (ca. 60 °C). After 30 min, the cloudy greenish mixture was filtered hot and the green clear filtrate left in a beaker. Large green crystals appeared upon cooling. This material was filtered, washed with ethyl alcohol and left to dry in the open air. Recrystallization was performed from a minimum amount of Millipore water (yield 2.6 g, 65%). $K_9[H_4Cu(H_2O)AsW_{17}O_{61}]\cdot 18H_2O$ (4937.8): calcd. As 1.52, Cu 1.29, K 7.13, W 63.30; found As 1.60, Cu 1.27, K 7.26, W 62.81.

α-$K_9[H_4Ni(H_2O)AsW_{17}O_{61}]\cdot 21H_2O$ ($AsW_{17}Ni$): A sample of $Ni(NO_3)_2\cdot 6H_2O$ (0.30 g, ca. 1 mmol) was dissolved in Millipore water (45 mL) and α-$K_{11}[H_4AsW_{17}O_{61}]\cdot 18H_2O$ (4 g, 0.82 mmol) was added in small portions while heating the mixture on a water bath (ca. 60 °C). After 30 min, the green clear mixture was filtered hot and the green clear filtrate left in a beaker. A pale green yellow crystalline material appeared upon cooling. This material was filtered, washed with ethyl alcohol and left to dry in the open air. Recrystallization was performed from a minimum amount of Millipore water (yield 3.8 g, 95%). $K_9[H_4Ni(H_2O)AsW_{17}O_{61}]\cdot 21H_2O$ (4987): calcd. As 1.50, K 7.06, Ni 1.18, W 62.67; found As 1.32, K 7.03, Ni 1.24, W 63.16.

α-$K_9[H_4Co(H_2O)AsW_{17}O_{61}]\cdot 18H_2O$ ($AsW_{17}Co$): A sample of $Co(NO_3)_2\cdot 6H_2O$ (0.30 g, ca. 1 mmol) was dissolved in Millipore water (45 mL) and $K_{11}[H_4AsW_{17}O_{61}]\cdot 18H_2O$ (4 g, 0.82 mmol) was added in small portions while heating the mixture on a water bath (ca. 60 °C). After 30 min, the dark red cloudy mixture was filtered hot and the clear dark red filtrate left in a beaker. A clear sand-coloured crystalline material appeared upon cooling. This material was filtered, washed with ethyl alcohol and left to dry in the open air. Recrystallization was performed from a minimum quantity of Millipore water (yield 3.8 g, 95%). $K_9[H_4Co(H_2O)AsW_{17}O_{61}]\cdot 18H_2O$ (4933.2): calcd. As 1.52,Co 1.19, K 7.13, W 63.36; found As 1.46, Co 1.15, K 7.06, W 63.52.

α-$K_8[H_4Fe(H_2O)AsW_{17}O_{61}]\cdot 19H_2O$ ($AsW_{17}Fe$): A sample of $Fe(NO_3)_3\cdot 9H_2O$ (0.40 g, ca. 1 mmol) was dissolved in Millipore water (45 mL) and α-$K_{11}[H_4AsW_{17}O_{61}]\cdot 18H_2O$ (4 g, 0.82 mmol) was added in small portions while heating the mixture on a water bath (ca. 60 °C). After 30 min, the pale yellow suspension was filtered hot and the yellow clear filtrate transferred to a beaker. Upon treatment of this filtrate with KCl (10 g), a pale yellow crystalline material appeared. This material was filtered, washed with ethyl alcohol and left to dry in the open air. Recrystallization was performed from a minimum quantity of Millipore water (yield 2.4 g, 60%). $K_8[H_4Fe(H_2O)AsW_{17}O_{61}]\cdot 19H_2O$ (4909): calcd. As 1.53, Fe 1.14, K 6.37, W 63.67; found As 1.43, Fe 1.26, K 6.94, W 62.74.

α-$K_9[H_4Mn(H_2O)AsW_{17}O_{61}]\cdot 19H_2O$ ($AsW_{17}Mn$): A sample of $Mn(NO_3)_2\cdot 4H_2O$ (0.25 g, ca. 1 mmol) was dissolved in Millipore water (45 mL) and α-$K_{11}[H_4AsW_{17}O_{61}]\cdot 18H_2O$ (4 g, 0.82 mmol) was added in small portions while heating the mixture on a water bath (ca. 60 °C). After 30 min, the dark beige suspension was filtered hot and the dark beige clear filtrate left in a beaker. Large chestnut-coloured crystals appeared upon cooling. This material was filtered, washed with ethyl alcohol and left to dry in the open air. Recrystallization was performed from a minimum amount of Millipore water (yield 3.6 g, 90%). $K_9[H_4Mn(H_2O)AsW_{17}O_{61}]\cdot 19H_2O$ (4947.2): calcd. As 1.51, K 7.11, Mn 1.11, W 63.18; found As 1.47, K 7.23, Mn 1.24, W 62.40.

α-$K_9[H_4As^{IV}W_{17}O_{62}]\cdot 18H_2O$ ($AsW_{17}V^{IV}$): A sample of $VOSO_4\cdot 5H_2O$ (0.42 g, 1.7 mmol) was dissolved in Millipore water (90 mL) and acidified with 4 M HCl (8.5 mL). α-$K_{11}[H_4AsW_{17}O_{61}]\cdot 18H_2O$ (8 g, 1.64 mmol) was then added in small portions with stirring. The black solution was stirred for roughly 30 min and then filtered and treated with KCl (10 g). The grey black precipitate that resulted was filtered, washed with ethyl alcohol and dried in the open air. This material was recrystallized from a minimum of acidified water (HCl solution pH < 1) (yield 5.6 g, 70%). $K_9[H_4As^{IV}W_{17}O_{62}]\cdot 18H_2O$ (4923.2): calcd. As 1.52, K 7.15, V 1.03, W 63.48; found As 1.55, K 8.14, V 0.99, W 64.7.

α-$K_8[H_4As^{V}W_{17}O_{62}]\cdot 18H_2O$ ($AsW_{17}V^{V}$): A sample of $NaVO_3$ (0.21 g, 1.7 mmol) was dissolved in Millipore water (90 mL) and acidified with 4 M HCl (8.5 mL). α-$K_{11}[H_4AsW_{17}O_{61}]\cdot 18H_2O$ (8 g, 1.64 mmol) was then added in small portions with stirring. The yellow solution was stirred for roughly 30 min, filtered, then treated with KCl (10 g). The yellow precipitate that resulted was filtered, washed with ethyl alcohol and dried in the open air. This material was recrystallized from a minimum of acidified water (HCl solution pH < 1) (yield 4.8 g, 60%). $K_8[H_4P^{(5+)}W_{17}O_{62}]\cdot 18H_2O$ (4884.1): calcd. As 1.53, K 6.40, V 1.04, W 63.99; found As 1.61, K 6.27, V 1.00, W 63.2.

α-$K_7[H_4AsMoW_{17}O_{62}]\cdot 18H_2O$ ($AsW_{17}Mo$): A sample of $Na_2MoO_4\cdot 2H_2O$ (0.40 g, 1.7 mmol) was dissolved in Millipore water (90 mL) and acidified with 4 M HCl (8.5 mL). α-$K_{11}[H_4AsW_{17}O_{61}]\cdot 18H_2O$ (8 g, 1.64 mmol) was then added in small portions whilst stirring. The clear yellow solution was stirred for roughly 30 min, then filtered and treated with KCl (10 g). The fine yellow precipitate that resulted was filtered, washed with ethyl alcohol and dried in the open air. This material was recrystallized from a minimum of acidified water (HCl solution pH < 1) (yield 4.4 g, 55%). $K_7[H_4AsMoW_{17}O_{62}]\cdot 18H_2O$ (4890): calcd., As 1.53, K 5.60, Mo 1.96, W 63.92; found As 1.49, K 5.33, Mo 1.61, W 65.27.

General Methods and Materials: Pure water was used throughout. It was obtained by passing through a RiOs 8 unit followed by a Millipore-Q Academic purification set. All reagents were of high-purity grade and were used as purchased without further purification. Elemental analyses were performed by Kanti Labs Ltd, Mississauga, Canada. The IR spectra were recorded in KBr pellets with a Perkin-Elmer Spectrum One FT-IR spectrophotometer. The UV/Vis spectra were recorded with a Perkin-Elmer Lambda 19 spectrophotometer on 2.5×10^{-5} M solutions of the relevant polyanion. Matched 1.000-cm optical path quartz curvets were used. The compositions of the various media were as follows: for pH = 0.33: 0.5 M H_2SO_4; for pH = 1−3: 0.2 M Na_2SO_4 + H_2SO_4; for pH = 4 and 5: 0.4 M CH_3COONa + CH_3COOH; for pH = 6 and 7: 0.4 M NaH_2PO_4 + NaOH.

Electrochemical Experiments: The media used for UV/Vis spectroscopy were also used for electrochemistry except that the polyanion concentration was 5×10^{-4} M. All cyclic voltammograms were recorded at a scan rate of 10 $mV\cdot s^{-1}$ unless otherwise stated. The solutions were deoxygenated thoroughly for at least 30 min with pure argon and kept under a positive pressure of this gas during the experiments. The source, mounting and polishing of the glassy carbon (GC, Tokai, Japan) electrodes has been described.[23] The glassy carbon samples had a diameter of 3 mm. The electrochemical apparatus was an EG & G 273 A driven by a PC with the M270 software. Potentials are quoted relative to the saturated calomel electrode (SCE). The counter electrode was a platinum gauze of large surface area. All experiments were performed at room temperature.

Sequence-Specific Oxidative Degradation of Tripeptides by a Cobalt(III) Complex Containing a Terpyridine Ligand

Koichiro Jitsukawa,*[a] Hiroshi Takahashi,[a] Ryoji Hyuga,[a] Hidekazu Arii,[a] and Hideki Masuda*[a]

Keywords: Cleavage reactions / Cobalt / N ligands / Oxidation / Peptides

A sequence-specific oxidative degradation of an oligopeptide consisting of aliphatic amino acids was performed with a ternary cobalt(III) complex. Under aerobic conditions the reaction of [Co(CO_3)(OH)(terpy)] and an equimolar amount of tripeptide at 40 °C at pH 8.5 gave two fraction bands (**a** and **b**) with water and then two bands (**c** and **d**) with NaCl solution, respectively, after column separation. In the case of gly-gly-leu (ggl, **1**), [Co(gg′l)(terpy)] [**1a**, gg′l = glycyl(2-oxoglycyl)leucine], [Co(g′l)(terpy)] [**1b**, g′l = *N*-(2-oxoglycyl)leucine], [Co(ggl)(terpy)]$^{+}$ (**1c**), and [Co(terpy)$_2$]$^{3+}$ (**1d**) were obtained. The crystal structure of **1c**, which was the main product, revealed that the starting ggl ligand was cleaved to give a bis-amide compound, g′l, which might be generated by loss of N-terminal glycine and carbonylation of the α-carbon of the N-2 glycine residue. Although the source of the oxygen of the newly generated carbonyl group is not clear, gg′l is supposed to be an intermediate for g′l on the basis of time-dependent HPLC analyses. NMR investigation of other tripeptides [βala-gly-leu (**2**), gly-gly-phe (**3**), and gly-gly-ala (**4**)] containing a bulky C-terminal aliphatic side chain indicated the formation of the corresponding oxidation complexes. On the other hand, peptides containing a C-terminal glycine residue [gly-gly-gly (**5**) and phe-gly-gly (**6**)] or an N-2 β-alanine residue [gly-βala-leu (**7**)] did not give such a transformation product. The crystal structure of [Co(fgg)-(terpy)] (**6c**) revealed that the tripeptide is coordinated to cobalt with a tridentate N-terminal *N*-*N*-*N* geometry. Such sequence specificity demonstrated in the reaction of the aliphatic tripeptide complexes is interpreted by the interligand interaction between the side chain of the C-terminal amino acid residue and terpy.

Introduction

In oxidative transformation of proteins, which plays a major role in many oxidation processes within cells, the radicals generated damage both the peptide backbone and the side chains.[1] In C−N bond dissociation during the peptide degradation, active oxygen species, such as HO$^{\cdot}$, and HOO$^{\cdot}$, attack at the α-position of the amino-acid residues to generate a carbon-centered radical.[2,3] Once formed, this reacts further with molecular oxygen to form peroxy radicals, which expel superoxide species to give carbocations, and are then hydrolyzed to give the corresponding alcohols or are deprotonated to give the corresponding imines.[4,5] Some iron edta complexes attached to cysteine residue of proteins site-specifically cleaved the peptide backbone, in which the iron-hydroperoxo species directly attacked the amide carbonyl moiety.[6] Recently, we have reported selective α-hydroxylation of the C-terminal amino-acid residue of a dipeptide (DP) mediated by a ternary cobalt complex with the 2,2′:6′,2′′-terpyridine (terpy) ligand under aerobic conditions, which is a model reaction for the peptidylglycine α-hydroxylating monooxygenase (PHM) reaction.[7] The terpy ligand is known to accelerate the oxidative transformation of another ligand coordinated *trans* to it,[8] and a ternary complex with the terpy ligand could therefore cause the oxidative degradation of a peptide compound. Herein, we describe a sequence-specific oxidative degradation of tripeptides (TPs), such as GGL (**1**), BGL (**2**), and GGF (**3**), whose reactivities are compared with the cases of GGA (**4**),

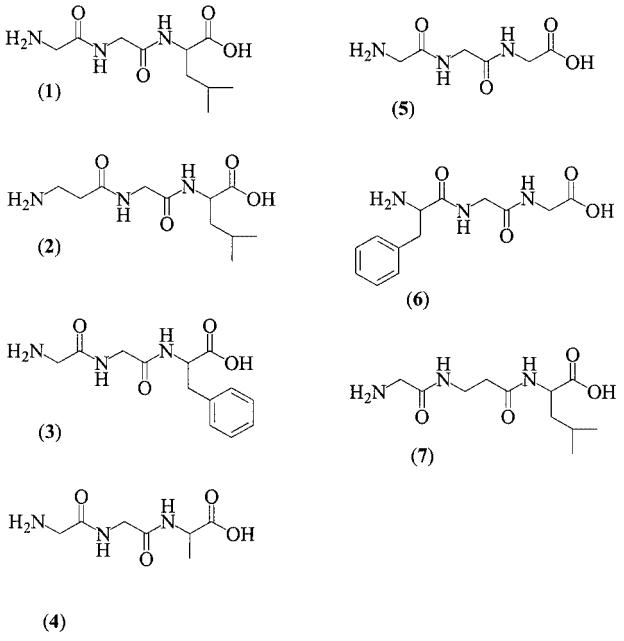
GGG (**5**), FGG (**6**), and GBL (**7**) (Scheme 1 and 2). Upon the formation of the ternary cobalt(III) complexes, some tripeptides containing bulky aliphatic amino acids at the C-terminus are cleaved to give unprecedented dipeptide derivatives on account of the assistance of the terpy ligand.



Scheme 2. Tripeptides employed: gly-gly-leu (GGL; **1**), βala-gly-leu (BGL; **2**), gly-gly-phe (GGF; **3**), gly-gly-ala (GGA; **4**), gly-gly-gly (GGG; **5**), phe-gly-gly (FGG; **6**), gly-βala-leu (GBL; **7**)

Results and Discussion

Characterization of the Ternary Complexes

The reaction of the cobalt carbonyl complex and an equimolar amount of tripeptides **1**−**7** was carried out at pH 8.5 and 40 °C in an aqueous solution for 10 h under aerobic conditions. After passing the reaction mixture through a cation-exchange column, four fractional bands containing cobalt(III) complexes (**a**−**d**) were obtained (see Exp. Sect.). In order to clarify the structure of the cobalt(III) complexes isolated from the column separation a ^{1}H NMR spectroscopic investigation was carried out. Transformation of the TP ligand was observed in the ternary complexes prepared from **1**−**3** (Table 1). Complex **1a** shows α-proton peaks of N-1 (N-terminal) at δ = 2.60 and 2.90 ppm, and that of the C-terminal (N-3) leucine at δ = 5.07 ppm, but no peaks corresponding to those of the N-2 (central) residue. Neither the α-proton peaks corresponding to N-1 nor N-2 glycine residues were detected in the spectrum of complex **1b**, while that of N-3 was detected at δ = 5.07 ppm. In complex **1c**, all α-proton peaks of GGL were detected. The spectroscopic and column behavior of the cobalt complexes prepared from BGL (**2**) and GGF (**3**) was similar to that of GGL (**1**), indicating that transformation of the glycine moieties takes place in the peptide backbone of **1a**, **1b**, **2a**, **2b**, **3a**, and **3b**.

Fortunately, a single crystal of **1b** suitable for X-ray analysis was obtained from the column eluent by allowing it to stand at room temperature. The crystal structure of **1b** (Figure 1)[11] reveals an unprecedented formation of the bisamide compound *N*-(2-oxoglycyl)leucine (G′L), as expected from the NMR spectroscopic data. The crystal data are summarized in the Exp. Sect. In order to determine the species substituted at the α-position of the N-2 residue in G′L, a positive-ion ESI mass spectrum of **1b** was measured. The obtained prominent peaks at *m*/*z* = 492.2 and 514.2 corresponding to the $[\{Co(g'l)(terpy)\} + H]^+$ and $[\{Co(g'l)(terpy)\} + Na]^+$ ions, respectively, indicate that the newly substituted atom is oxygen, although the oxygen source is not yet clear. Formation of a [Co(g′l)(terpy)] complex is also supported by the elemental analysis. Moreover, the relatively short bond length [1.22(2) Å] between the α-carbon [C(16)] and the newly generated atom [O(1)] and the sp^2 character around C(16) [O(1)−C(16)−N(4) = 128(1)° and O(1)−C(16)−C(17) = 119(1)°] in the crystal structure of **1b** indicate the formation of a C=O group at the α-position of the N-2 residue. The cleavage of the amide bond between the N-1 and N-2 residues in the GGL ligand took place in **1b**, but the α-protons of N-1 and N-3 moieties still remain in **1a** and **1c**.

In the case of GGA (**4**), complete column separation of **4a** and **4b** was not accomplished, although their ^{1}H NMR spectra indicated formation of the corresponding cleavage product. Due to the smaller size of the C-terminal side chain in **4** in comparison with the those in **1**−**3**, it is hard to separate complexes **4a** and **4b**. In the cases of some tripeptide ligands, for example GGG (**5**), FGG (**6**), and GBL (**7**), which have either an N-terminal glycine or N-2 β-alanine moiety, the main product was the $[Co(tp)(terpy)]^+$ complex (**5c**, **6c**, or **7c**), accompanied by a small amount of $[Co(terpy)_2]^{3+}$ (**d**).[9] Transformation compounds corresponding to **a** or **b** were not obtained. The ^{1}H NMR spectral patterns of the N1-, N2- and N3-α-proton moieties in **5c**, **6c**, and **7c** are very similar to that of **1c**. On the basis of the spectral analogy among the complexes **1c**−**7c**, the coordination mode of the tripeptide to cobalt is an N-terminal *N*-*N*-*N* form (N-1 terminal amine nitrogen, N-2 amide nitrogen, N-3 amide nitrogen), which agrees well with the empirical rule.[10,11] The tridentate coordination of FGG in **6c** is indicated by the upfield shift of the α-protons of the C-terminal glycine moiety (δ = 2.52 and 2.62 ppm) in comparison with the tetradentate coordination of FGG in $[Co(NH_3)_2(fgg)]$, where the corresponding protons are observed at δ = 4.00 ppm.[12] A complex-formation shift was not observed in the C-terminal α-position of **1c**−**7c**. The single-crystal structure of **6c**, shown in Figure 2, reveals that the cobalt ion is coordinated by two tridentate ligands, terpy and FGG, in which the coordination mode of the FGG to cobalt is an N-terminal *N*-*N*-*N* geometry, as expected from the NMR spectroscopic data. Moreover, the benzene ring of the N-terminal amino-acid side chain is very close to the terpy ring, with a distance of about 3.45 Å (the closest interatomic carbon-carbon distance).

Oxidative Degradation Pathway of the Peptide Bond

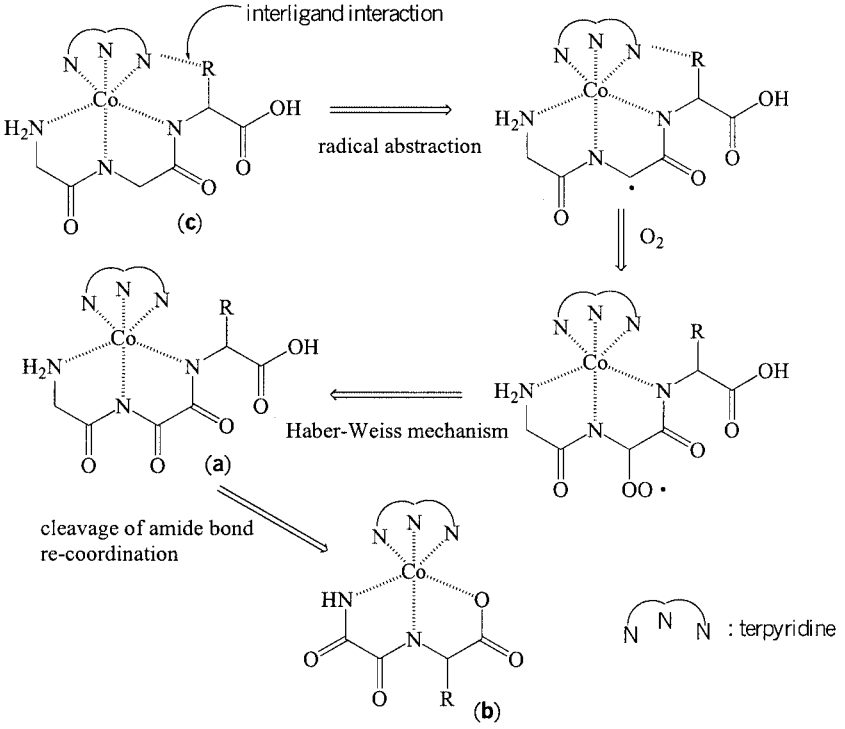
In this reaction, **1c** is considered as the starting compound for **1a** and **1b**, because the yield of **1c** decreases after a long reaction time. HPLC analysis of the reaction mixture also revealed that it is the primary product of the complex formation with Co-terpy and GGL. Similar time-dependent product distributions found by HPLC were observed in the reaction with BGL (**2**) and GGF (**3**). The reaction pathway from **1c** to **1b** is obviously different from the cobalt(III)-promoted hydrolysis, which generally gives both amine and carboxylic compounds.[11,13,14] The G′L ligand in **1b** is gen-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

erated by the loss of N-terminal glycine and oxygenation of the α-position of the N-2 glycine residue of the starting GGL. The structure of complex **1a**, a plausible intermediate for **1b**, is suggested by the positive ion ESI mass spectrum: The prominent peaks at m/z = 549.2 and 571.0 indicate the formation of a tripeptide complex containing glycyl(2-oxoglycyl)leucine (GG′L), which is consistent with the NMR spectroscopic data (no signal of N-2 protons in Table 1). Such an unprecedented cleavage reaction takes place only in tripeptides (**1**−**4**) with an alkyl side-chain at the C-terminal amino-acid residue, and not in the C-terminal glycine (**5** and **6**) and N-2 β-alanyl compounds (**7**). These results indicate that the oxidative degradation of the tripeptide ligand mediated by the ternary cobalt(III) terpy complex occurs sequence-specifically.

Although the detailed mechanism for this cleavage reaction is not yet clear, the downfield shift of the α-protons of the N-2 glycine moiety in **1c** relative to the metal-free GGL (δ = 4.01 and 4.03 ppm), might be essential for the reaction. Since the GGL ligand in **1c** strongly coordinates to the metal center in an N-terminal N-N-N manner, a nucleophile in aqueous solution (e. g. hydroxide ion) prefers to attack an electro-deficient state at the N-2 moiety. The α-proton of the glycine moiety is known to be easily abstracted to give a glycyl radical, whose stability is explained by the captodative effect.[15] In the oxidative transformation of the dipeptide ligand previously reported, the downfield shift of the α-proton attached to the N-2 residue of the dipeptide is important for the abstraction of the proton.[7] The radical intermediate generated at this position is attacked by dioxygen to give a peroxy radical, which decomposes by the Haber−Weiss mechanism to give the α-carbonyl compound **1a** because the transition metal-terpy system acts as a redox center for the electron-transfer reaction (Scheme 3).[8] Such an oxidative transformation of a methylene moiety adjacent to an amide group has also been reported in the case of iron(III) and cobalt(III) complexes with an *N*-(picolyl)picolinamide ligand under aerobic alkaline conditions, although the reaction mechanism is also unclear.[16] In aqueous conditions the amide complex **1a** might be hydrolyzed to give **1b**. Under anaerobic conditions, however, the transformation product **1b** was not detected in the HPLC analysis.

The terpy ligand is known to demonstrate very attractive features in electron-transfer, photochemical, and related reactions[8] and activate the *trans*-positioned ligand through the central metal,[17,18] which is attributed to the vacant low-lying π* orbitals that attract electron density from the metal.[19] Moreover, the assistance of terpy for hydrolysis of diribonucleoside monophosphate diesters has been demonstrated with a manganese(II) complex.[20] The interligand interaction caused by terpy is also known to regulate the α-hydroxylation of dipeptides.[7] From these results, we consider that the terpy ligand in this ternary cobalt(III) complex plays an important role in the oxidative transformation of the tripeptide. For sequence specificity, the interligand interaction between the C-terminal side chain and terpy in **1c** is important to abstract the α-proton or to stabilize the radical intermediate that gives **1a** under aerobic conditions. In the ternary complex **1c**, the CH-π interaction between the peptide and terpy ligands, as shown from the upfield shifts



Scheme 3. Plausible oxidation pathway of the cleavage reaction

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of γ-H (δ = 0.82 ppm) and the δ-H's (δ = 0.23 and 0.58 ppm) of the leucine moiety, seems to fix the C-terminal side chain of GGL on the terpy ring. On the other hand, in the ternary complexes **5c** or **6c**, where the C-terminal residues are glycine, such upfield shifts are not observed. Consequently, the corresponding oxidative-degradation compounds were not generated in the cases of **5** and **6**. It is clear that the interligand interaction caused by the bulkiness of the C-terminal side-chain controls the sequence specificity of this reaction. The reason why the cleavage reaction does not take place in GBL (**7**), which contains a C-terminal bulky side-chain might be explained by the difficulty of abstraction of the protons attached on the N-2 β-alanine residue.

Conclusion

A new type of oxidative transformation of peptide compounds is carried out nonenzymatically in the presence of transition metal complexes containing a terpy ligand. The sequence-specific cleavage of peptides consisting of C-terminal aliphatic amino acids occurs because of the interligand interactions. Previously, the regioselective hydrolysis of peptides containing histidine or methionine residues has been reported with palladium(II) complexes,[21] in which coordination of the functional group of the peptide side chain to the palladium center was the key step for generating the selectivity. As compared with the previous reactions, our finding that the bulkiness of the aliphatic side chain — a nonfunctional group of the amino-acid residue — controls the specificity is the first report of the oxidative degradation of a peptide due to intramolecular noncovalent interactions with a ternary cobalt(III) complex.

Experimental Section

General: Reagents used for synthesis were of the highest grade available and were employed without further purification. The starting cobalt(III) complex, [Co(CO_3)(OH)(terpy)], was prepared according to the reported method.[22] All solvents for spectroscopic measurements were purified by distillation before use. Electronic absorption spectra were recorded on a JASCO UVIDEC-660 spectrometer. ^{1}H NMR spectra were measured on a Varian VXR-300S or JEOL Lambda-500 spectrometer with TMS as an internal standard. Crystal-structure analyses were performed with an Enraf−Nonius CAD4-EXPRESS four-circle diffractometer. Single crystals of the complexes suitable for the X-ray diffraction measurement were mounted on a glass capillary. The diffraction data were collected with graphite-monochromated Mo-K_α radiation with the ω-2θ scan technique at room temperature. Crystal data and experimental details are listed in Table 2, in which weighted refinement values (Rw) are obtained as follows: $Rw = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$. At the appropriate time of the reaction with GGL, the yields of [Co(gg′l)(terpy)] (**1a**), [Co(g′l)(terpy)] (**1b**), and [Co(ggl)(terpy)] (**1c**) were determined by HPLC analysis (column, ODS CrestPak C18s. eluent, MeOH/water gradient method (5:95 → 35:65). UV-detector, wavelength = 513 nm). The ratio of these complexes varied during the reaction.

Complexation and Characterization of Ternary Cobalt(III) Complexes: Under aerobic conditions, the reaction of [Co(CO_3)(OH)(terpy)] (0.37 g, 2 mmol) and an equimolar amount of tripeptide [GGL (**1**), BGL (**2**), GGF (**3**), GGA (**4**), GGG (**5**), FGG (**6**), or GBL (**7**)] was carried out at pH 8.5 and 40 °C in an aqueous solution (50 mL). After 10 h, separation of the reaction mixture on a SP Sephadex C-25 column gave three separation patterns. In the cases of **1**−**3** as the first group separation pattern, two fraction bands (**a** and **b**) containing a neutral complex were eluted with water, one (**c**) containing a positively charged complex was eluted with 0.1 M NaCl solution, and one (**d**) was eluted with 0.2 M solution. In the case of **4** as the second group, one fraction band (**a** + **b**) was eluted with water, in which obvious separation of **4a** and **4b**

from the column was not accomplished, and two bands, containing (**4c**) and (**4d**), were eluted with 0.1 M NaCl, and 0.2 M NaCl solution, respectively. In the case of the reaction with **5**−**7**, no fractional band corresponding to **a** or **b** was eluted with water; one band (**c**) was eluted with 0.1 M NaCl solution and another (**d**) with 0.2 M NaCl solution. These column patterns for the fractional bands are typical for the sequence of tripeptides employed here. In all cases, the complex contained in the last band (**d**) was identified as $[Co(terpy)_2]^{3+}$.[9] In the case of GGL (**1**), the amounts of **1b** increased with increasing reaction time. The structure of **1b** was confirmed by elemental analysis as well as by X-ray single crystal and ^1H NMR analysis. Elemental analysis of **1b**: $[Co(g'l)(terpy)]\cdot 4H_2O$; $C_{23}H_{30}CoN_5O_8$ (563.45): calcd. C 49.03, H 5.37, N 12.43; found C 49.23, H 5.30, N 12.13.

After 24 h, the isolated yield of **1b** was over 70% based on the starting cobalt complex, while the total yields of **1a** and **1c** were under 10%. Reverse-phase HPLC analyses of the reaction mixture indicated that the primary product of the complex formation with Co-terpy and GGL at the initial stage of the reaction was **1c**, which was oxidized to **1a** under aerobic conditions. Under anaerobic conditions, however, **1a** was not detected in the HPLC analyses. Similar time-dependent product distributions were observed in the reaction with BGL (**2**) and GGF (**3**). In the case of GGG (**5**), FGG (**6**), and GBL (**7**), the positively charged complexes, **5c** (75%), **6c** (65%), and **7c** (60%), eluted with 0.1 M NaCl solution, were the main products, respectively; neutral products, corresponding to **5a**, **5b**, **6a**, **6b**, **7a**, and **7b**, were not detected even after 24 h. NMR measurement of all complexes isolated from the eluting solution was carried out in D_2O solution. These data are listed in Table 1. The X-ray analyses of the single crystals of **1b** and **6c** were performed according to the previous methods.[7] Crystal data are summarised in Table 2. During the crystallization of **6c** at room temperature, the positively charged complex eluted from the column changed to a neutral one (presumably, carbonate ions generated from carbon dioxide in the atmosphere might act as a reagent for charge neutralization), presumably because a neutral compound crystallizes more easily than a positive one.

COVER PICTURE

The cover picture shows the structure of the Fe^{III}-selective chelating agent ICL670 (R = COOH). ICL670 has a high potential for the oral treatment of iron overload, a condition that originates from regular blood transfusions, as are necessary in the treatment of β-Thalassaemia. However, a possible problem arising from this treatment is the production of $OH^{\cdot}$ radicals, which can be catalysed by redox-cycling of labile Fe^{II}/Fe^{III} species. For a conclusive consideration of potential oxidative stress, a careful elucidation of the stability and redox properties of the various Fe^{II}/Fe^{III} species, which are present at physiological conditions, has been performed. Details are discussed in the article by K. Hegetschweiler et al. on p. 4177 ff..

Transition Metal Chemistry of Low Valent Group 13 Organyls

Christian Gemel,[a] Tobias Steinke,[a] Mirza Cokoja,[a] Andreas Kempter,[a] and Roland A. Fischer*[a]

Keywords: Group 13 elements / Transition metals / Main group elements / Carbene homologues

The coordination of low-valent group 13 organyls E^IR [E = Al, Ga, In; R = Cp*, $C(SiMe_3)_3$] to transition metals has attracted increasing interest over the past decade. Complexes and cluster compounds of these new ligands with a number of transition metals have been isolated and characterised. The E^IR moiety is formally isolobal with CO and PR_3 (R = alkyl, Cp*) or carbenes (R = chelating group) with varying σ-donor and π-acceptor properties depending on the organic group R as well as the group 13 metal E. In this review, different ways of forming M–E bonds such as substitution reactions of labile ligands or insertion of E^IR into transition metal halide bonds are described. Furthermore, the reactivity of homoleptic complexes $M_a(E^IR)_b$ is discussed, outlining the use of these new complex types in bond activation reactions.

1. Introduction

Since the pioneering discovery by H. Schnöckel in 1989 that the low valent group 13 metals Al^I and Ga^I can be stabilised by coordination of Cp*[1−3] and the subsequent development of convenient synthetic procedures for AlCp*[4,5] and GaCp*[6,7] by H. Roesky and P. Jutzi, much work has been devoted to the coordination of these compounds to transition metal centres.[8,9]

The E^IR fragment is isolobal with CO and PR_3, i.e. it exhibits σ-donation as well as π-accepting properties. The extent of σ-donation and π-acceptance is, of course, dependent on the nature of the metals, but also to a large extent

Roland A. Fischer (far right), born in 1961 in Rosenheim, Germany, studied chemistry at the Technische Universität München (1981−1986). In 1989 he received his doctorate for his work on alkyne complexes of rhenium under the guidance of W. A. Herrmann. After a postdoctoral fellowship at the University of California at Los Angeles with H. D. Kaesz (1989−1990), he returned to the Technische Universität München and completed his habilitation in 1995 on the coordination chemistry of aluminium, gallium and indium at transition metals and on the use of these complexes as MOCVD sources for intermetallic phases. From 1996 to 1997 he was Professor of Inorganic Chemistry at the Ruprecht-Karls-University Heidelberg and in 1998 he moved to the Ruhr-Universität Bochum. His research interests deal with various aspects of organometallic and materials chemistry with some emphasis on precursor chemistry for MOCVD. His scientific work has been honoured among others with the Heinz-Meier-Leibnitz award from the Bundesministerium für Bildung und Forschung (Federal Ministry for Education and Science) (1993), a Karl-Winnacker scholarship (1995) and the award of the Alfried-Krupp-von-Bohlen-und-Halbach Foundation (1996).

Christian Gemel (centre) was born in 1971 in Vienna, Austria. From 1990−1996 he studied Chemistry at the Technical University of Vienna, receiving his Doctorate in 1997 for his work on organoruthenium chemistry in the group of Karl Kirchner. After postdoctoral visits to Kenneth G. Caulton, Indiana University (1998) and Klaus Richard Poerschke, MPI Mülheim (2000−2001), he joined the group of Prof. Roland Fischer in 2002. He became a permanent research staff member in 2004.

Tobias Steinke (far left), born in 1974 in Bochum, Germany trained as a teacher of chemistry from 1995−2000. In 2001 he started to work on his PhD under the guidance of Prof. Fischer on the coordination chemistry of ECp to transition metals. His doctoral work has been awarded with the Wolfgang-Seel-Preis.*

Mirza Cokoja (centre left) was born in 1979, Oberhausen, Germany and studied chemistry at the Ruhr University Bochum from 1998−2003. He received his Diploma in 2003 for his work on the insertion reactions of ECp into Ru−Cl Bonds.*

Andreas Kempter (centre right) was born in 1978, Sigmaringen, Germany and studied chemistry at the Ruhr University Bochum from 1999−2004. He received his Diploma in 2004 for his work on the coordination chemistry of sterically encumbered low valent group 13 metals.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

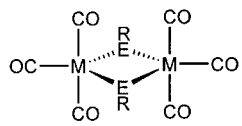
on the organic group R. For R = Cp*, for example, the vacant p-orbitals of the group 13 metal are partially populated by the π-donor orbitals of the Cp* groups thus diminishing the π-acceptor properties of the ligand. In fact, the contribution of the σ-donation has been calculated to be very large, resulting in the highest contribution of the bond energy being the electrostatic attraction between the partially positive group 13 metal and the partially negative transition metal, following the order Al > Ga > In.[10]

In contrast to the chemistry of transition metal borylene complexes which has been recently reviewed by H. Braunschweig,[11–13] the free ligands E^IR are stable and isolable. This facilitates access to their transition metal complexes since classic organometallic synthetic approaches can be applied. Substitution of labile ligands by E^IR is the most general route of forming transition metal-group 13 element bonds. Homoleptic as well as heteroleptic complexes $[M_a(E^IR)_bL_c]$ are accessible from a wide range of transition metal complexes such as carbonyl, olefin or phosphane complexes. The ease of oxidation of E^IR provides less common synthetic pathways. Thus, E^IR can act as in situ reducing agents towards higher oxidation state transition metal complexes $[L_nMX_n]$, giving either insertion products if the oxidised group 13 metal remains coordinated to the transition metal centre or low oxidation state complexes $[M_a(E^IR)_b]$ by cleavage of X_2ER.

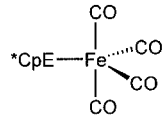
In this review we wish to highlight recent developments in this particular field from a mainly synthetic point of view. Fundamental bonding and general structural issues have been intensively discussed in the literature previously.[10,14–17] However, interest in E^IR has somewhat diminished during the last few years most likely because the chemistry of these new species has been considered to be quite unexciting. In contrast, our recent results which focus particularly on the transition metal chemistry of AlCp*, GaCp* and InCp* have revealed the unexpected potential of these compounds in classic organometallic and cluster chemistry. Herein we hope to convince the reader that these "exotic" ligands and related compounds hold much promise for the future.

2. Carbonyl Complexes $M_a(CO)_b(ER)_c$

Since the first isolation of E^IR, investigations of their properties as ligand towards transition metals have mostly involved metal carbonyl fragments. In particular, the reaction of E^IR with homoleptic transition metal carbonyls has been studied in detail. Hence, the complexes $[Mn_2(CO)_8\{\mu^2\text{-}[InC(SiMe_3)_3]\}_2]$,[18] $[Co_2(CO)_6(\mu^2\text{-}ECp^*)_2]$ (**1a**: E = Al,[19] **1b**: Ga[6]) or $[Ni_4(\mu^2\text{-}GaCp^*)_4(CO)_6]$[6] were obtained by treatment of the homoleptic metal carbonyl clusters with E^IR. The compounds $[Cr(CO)_5(ECp^*)]$ (E = Al,[20] Ga,[6] In[21]), $[(GaCp^*)_2Mo(CO)_4]$,[22] $[Fe_2(CO)_6\{\mu^2\text{-}In[C(SiMe_3)_3]\}_2]$ (**2**)[23] and $[Fe(CO)_4(GaCp^*)]$ (**3a**)[6] were obtained by substitution of chelating olefin ligands such as cyclooctene, norbornadiene, cyclooctatetraene and cycloheptatriene, respectively. Some carbonyl complexes, such as $[Fe(CO)_4(AlCp^*)]$ (**3b**),[24] are also available by salt metathesis from carbonylmetallates and $E^{III}RX_2$.[25–27]

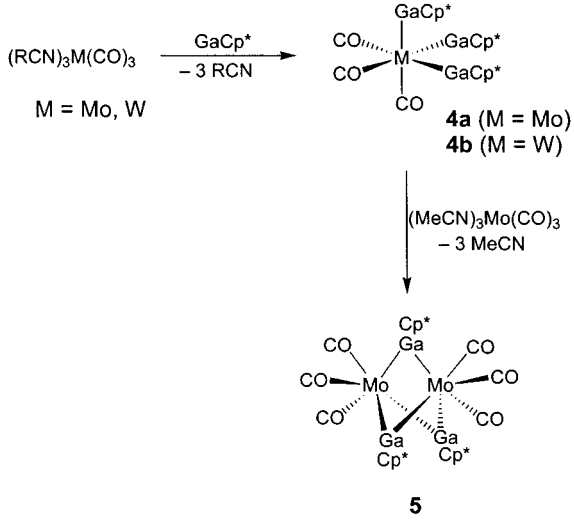


1a (M = Co, ER = AlCp*)
1b (M = Co, ER = GaCp*)
2 (M = Fe, ER = $InC(SiMe_3)_3$)



3a (E = Ga)
3b (E = Al)

A recent example of ligand substitution on metal carbonyl fragments is the reaction of [*fac*-$(RCN)_3M(CO)_3$] (R = Me, M = Mo; R = Et, M = W) with GaCp* giving the monomeric compounds [*fac*-$(GaCp^*)_3M(CO)_3$] (**4a**: M = Mo, **4b**: W).[28] It was shown that compound **4a** can act as a building block for the synthesis of dinuclear complexes affording $[Mo_2(CO)_6\{\mu^2\text{-}(GaCp^*)\}_3]$ (**5**) upon reaction with [*fac*-$(MeCN)_3Mo(CO)_3$] (Scheme 1).



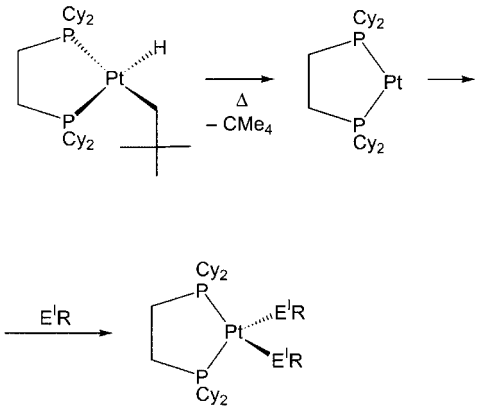
Scheme 1. Synthesis of $[Mo_2(CO)_6\{\mu^2\text{-}(GaCp^*)\}_3]$ (**5**)

In contrast to the well explored substitution reactions of ECp*, the addition to coordinatively unsaturated centres is only known for the in situ formed $[(dcpe)_2Pt]$ complex [dcpe = bis(dicyclohexylphosphanyl)ethane] leading to $[(dcpe)_2Pt(E^IR)_2]$.[29,30] The unsaturated 14 VE fragment $[(dcpe)_2Pt]$ is thermally formed from $[(dcpe)_2PtH(neopentyl)]$ and trapped in the presence of E^IR ligands (Scheme 2).

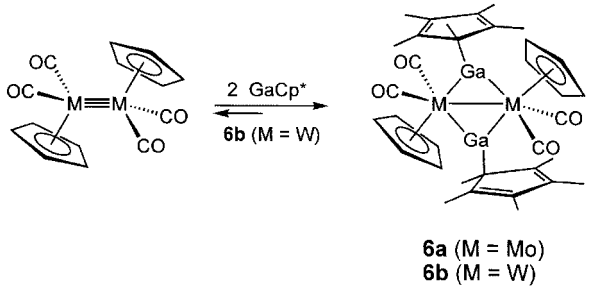
An unsaturated carbonyl system which has been studied in more detail is the reaction of GaCp* with the multiple bonded dimeric complexes $[CpM(CO)_2]_2$ (M = Mo, W). Reaction with GaCp* yields the addition products $[Cp(CO)_2M(\mu\text{-}GaCp^*)]_2$ (**6a**: M = Mo, **6b**: M = W) (Scheme 3).[28]

An unusual feature of **6a** and **6b** is the η^1-coordination mode of the Cp* moieties bound to the bridging Ga atoms, presumably a consequence of the steric overcrowding in the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 2. Trapping of the unsaturated fragment $[(dcpe)_2Pt]$ with E^IR



Scheme 3. Synthesis of $[Cp(CO)_2M(\mu\text{-}GaCp^*)]_2$ (**6a**: M = Mo, **6b**: M = W)

molecules. The GaCp* coordination in the tungsten complex is surprisingly weak and shows a temperature dependent association/dissociation equilibrium.

3. Homoleptic Complexes of the Type $[M_a(ECp^*)_b]$ (M = Ni, Pd, Pt)

3.1 Monomeric Complexes $[M(ECp^*)_4]$

The COD ligands in $[Pt(COD)_2]$ and $[Ni(COD)_2]$ (COD = 1,5-cyclooctadiene) can be readily replaced by ECp* or $E[C(SiMe_3)_3]$ yielding monomeric complexes of the type $[M(E^IR)_4]$ (M = Pt, Ni; R = Cp*; Figure 1).[22,31,32] Analogous Pd compounds can be obtained by treatment of $[Pd(tmeda)(CH_3)_2]$ with ECp*. In contrast to the reaction of $[Pd(tmeda)(CH_3)_2]$ (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) with PR_3 giving $Pd(PR_3)_n$ which usually proceeds via a ligand-assisted reductive elimination of ethane, the reaction with ECp* includes a methyl group migration and reduction of the palladium centre by ECp*.[33]

All complexes $[M(E^IR)_4]$ are kinetically inert, indicating the high bond energy of the ECp* to transition metal linkage. Substitution reactions with PR_3 or CO do not take place and a coalescence of $[M(E^IR)_4]$ and the free E^IR is not observed in the NMR spectra. Also, the synthesis of heteroleptic complexes $[M(ECp^*)_n(E'Cp^*)_m]$ ($n + m = 4$) is not possible by ligand substitution. Interestingly, in the series $[M(ECp^*)_4]$ (M = Ni, Pd, Pt and E = Al, Ga, In), only $[Pt(InCp^*)_4]$ seems to be thermally unstable, decomposing at temperatures above −30 °C. This indicates weaker σ-donor properties of InCp* compared with $InC(SiMe_3)_3$, AlCp* or GaCp*.

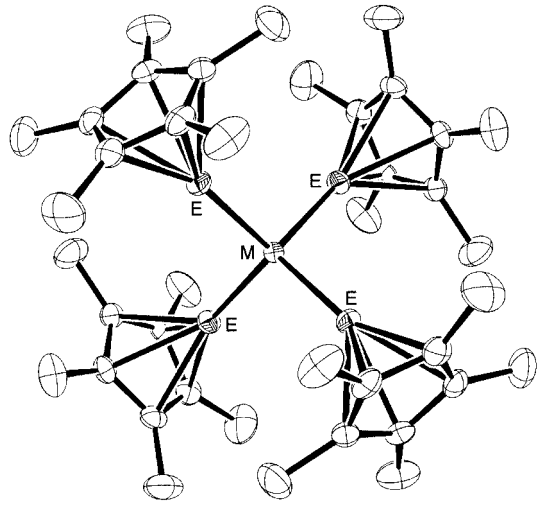


Figure 1. Monomeric Clusters $[M(ECp^*)_4]$

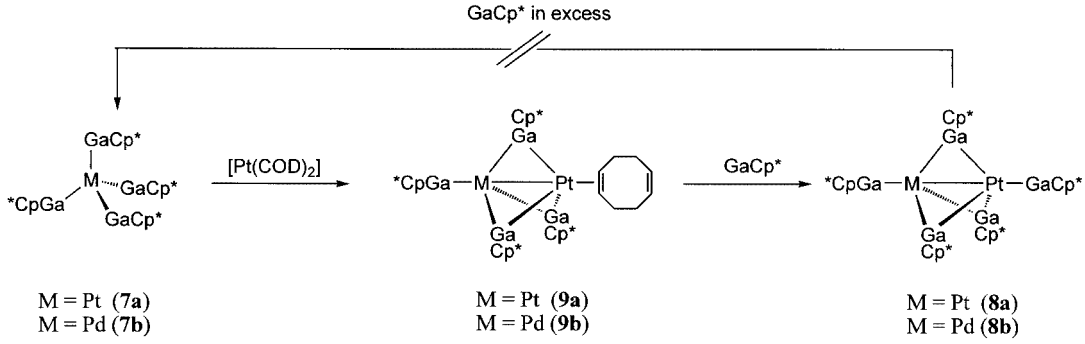
3.2 Cluster Complexes $[M_2(ECp^*)_5]$ and $[M_3(ECp^*)_8]$

Compared with the above examples, neutral homoleptic cluster compounds of the type $[M_a(ECp^*)_b]$ (M = Pd, Pt; $b > a > 1$) represent quite a novel and more promising field in the coordination chemistry of E^IR (E = Al, Ga, In). Recent studies concerning the synthesis of cluster compounds have been focused on the coordination of E^IR to transition metal carbonyl fragments $[(CO)_nM_a]$. Constitution and structural characteristics of new GaCp*-substituted Ni_4 [6] and Rh_6 carbonyl clusters[34] or $[\{(CpNi)(\mu_2\text{-}AlCp^*)\}_2]$[35] are directly related to classical transition metal carbonyl cluster structures. In contrast, the novel homoleptic series $[M_a(ECp^*)_b]$ has no direct structural analogue in classical carbonyl or phosphane cluster chemistry, although recently the coordination chemistry of PR_3 has been extended to include a bridging mode.[36] These complexes exhibiting bridging and terminal E^IR ligands are still rare in comparison with other M−E complexes. In principle, access to $[M_a(ECp^*)_b]$ proceeds via two different reaction pathways: (i) by building block synthesis and (ii) via direct methods. In both cases, E^IR reacts with a transition metal complex bearing labile ligands (e.g. olefins) with full substitution of the ligands, the nature of the products being determined mainly by kinetic factors.

3.2.1 Building Block Synthesis of Homoleptic Clusters $[MPt(GaCp^*)_5]$

The monomeric compounds $[M(GaCp^*)_4]$ (**7a**: M = Pt, **7b**: M = Pd; Figure 1) can serve as building blocks for the synthesis of the dinuclear cluster complexes $[MPt(GaCp^*)_5]$ (**8a**: M = Pt, **8b**: M = Pd) with terminal and bridging GaCp* ligands (Scheme 4). The reaction of $[Pt(COD)_2]$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 4. Building block synthesis of clusters $M_a(ECp^*)_b$

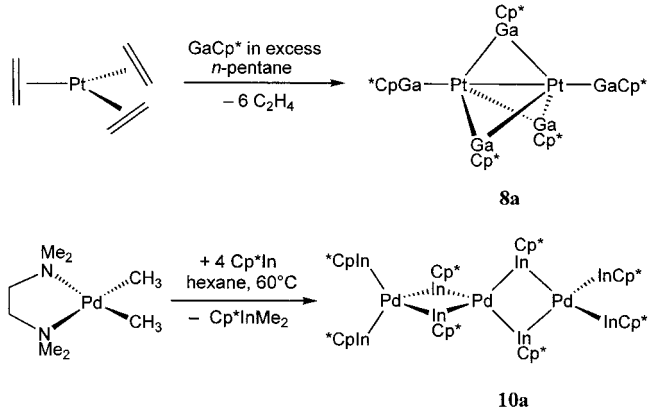
with an equimolar amount of $[M(GaCp^*)_4]$ and subsequent addition of GaCp* yields $[Pt_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ (**8a**) and the analogous "trimetallic" heterodinuclear compound $[PtPd(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ (**8b**).

It has been shown that the $[M(GaCp^*)_4]$ species form reactive yet isolable dinuclear associates with $[Pt(COD)_2]$. Based on variable temperature NMR spectroscopic data these intermediates were identified as $[Pt_2(GaCp^*)(\mu^2\text{-}GaCp^*)_3(\eta^2\text{-}COD)]$ (**9a**) and $[PtPd(GaCp^*)(\mu^2\text{-}GaCp^*)_3(\eta^2\text{-}COD)]$ (**9b**).[33]

3.2.2 Direct Synthesis of Homoleptic Clusters $[M_a(ECp^*)_b]$

The reaction of ECp* with transition metal complexes having olefin ligands generally leads to a full substitution of the olefins by ECp*. However, in most cases the ratio of the reactants does not directly determine the composition of the products. Instead, the formation of mono-, di- or trinuclear products is influenced by kinetic factors, i.e. by the reaction temperature, the nature of the transition metal-olefin complex or simply the solubilities of the starting materials and products.

The first direct synthesis of a homoleptic cluster complex was reported in 2000 (Scheme 5). $[Pt_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ (**8a**) is quantitatively formed from the reaction of $[Pt(C_2H_4)_3]$ with an excess of GaCp* and could be isolated in analytically pure form in high yields.[37]



Scheme 5. Synthesis of $[Pt_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ (**8a**) and $[Pd_3(InCp^*)_4(\mu^2\text{-}InCp^*)_4]$ (**10a**)

The monomeric complex $[Pt(GaCp^*)_4]$ (**7a**) which is quantitatively formed in the reaction of $[Pt(COD)_2]$ with GaCp* was not observed in this reaction. It was shown

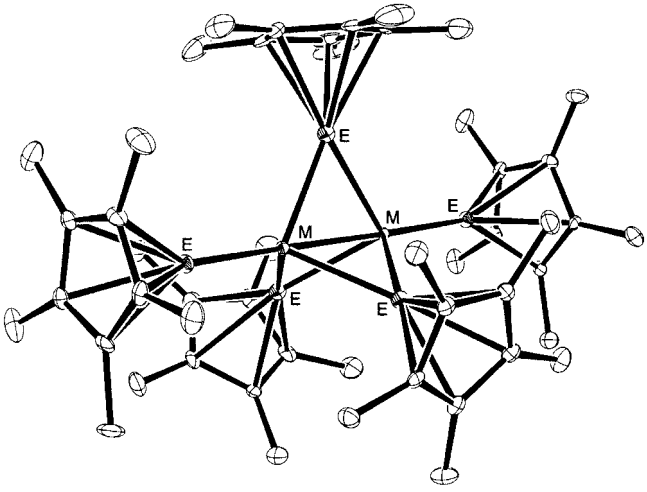


Figure 2. Dimeric clusters $[M_2(ECp^*)_5]$

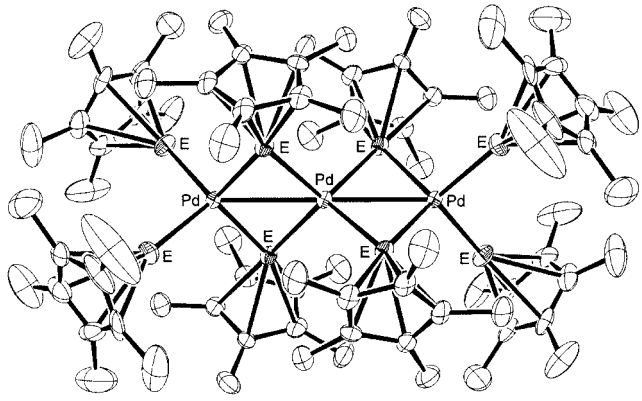

Figure 3. Trimeric clusters $[Pd_3(ECp^*)_8]$

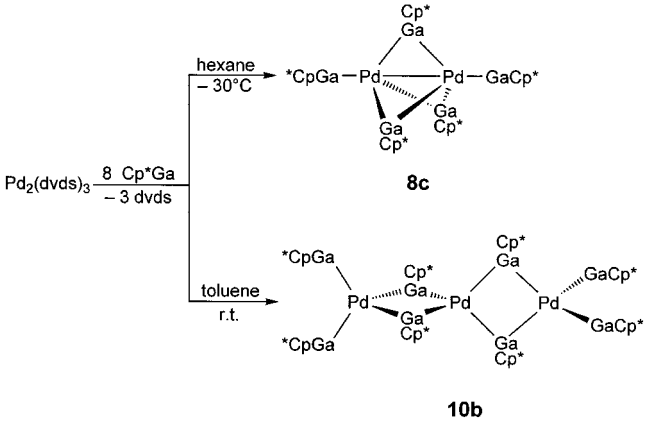
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

later that $[Pt_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ (**8a**) is also kinetically stable in the presence of free GaCp* and does not react to give $[Pt(GaCp^*)_4]$ (**7a**).[33]

When $[(tmeda)Pd(CH_3)_2]$ is treated with an excess of InCp*, the trinuclear complex $[Pd_3(InCp^*)_4(\mu^2\text{-}InCp^*)_4]$ (**10a**) is quantitatively formed. Complex **10a** is also kinetically inert and does not react to give mononuclear $[Pd(InCp^*)_4]$ in the presence of InCp*.[38]

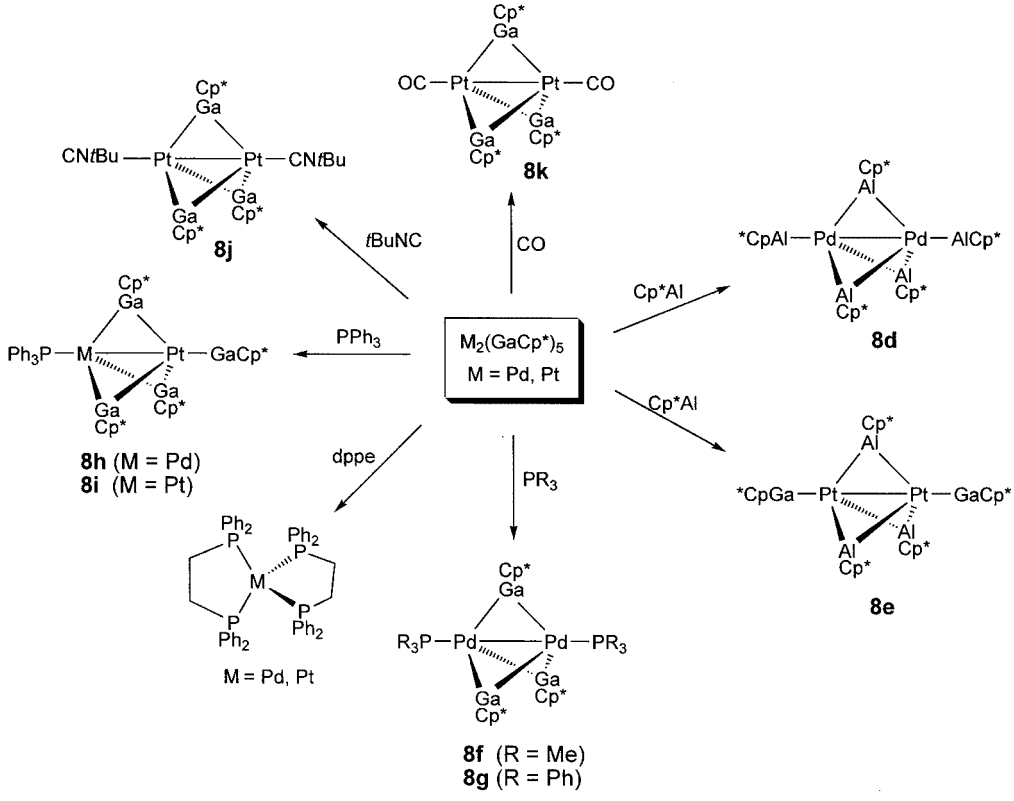
A good illustrative example of the subtle kinetic control of cluster formation is the reaction of $[Pd_2(dvds)_3]$ with GaCp* (dvds = 1,3 divinyl-1,1,3,3-tetramethyldisiloxane). Depending on the reaction conditions, two different homoleptic clusters are formed. At −30 °C in hexane the reaction yields the dinuclear compound $[Pd_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ (**8c**) in quantitative yields. Only trace amounts (< 3%) of the monomeric compound $[Pd(GaCp^*)_4]$ (**7b**) are observed. The reaction in toluene at room temperature yields the trinuclear complex $[Pd_3(GaCp^*)_4(\mu^2\text{-}GaCp^*)_4]$ (**10b**) in high yield, while the dimeric species **8c** is formed in only very small amounts (< 2%) under these conditions (Scheme 6).



Scheme 6. Synthesis of $[Pd_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ (**8c**) and $[Pd_3(GaCp^*)_4(\mu^2\text{-}GaCp^*)_4]$ (**10b**)

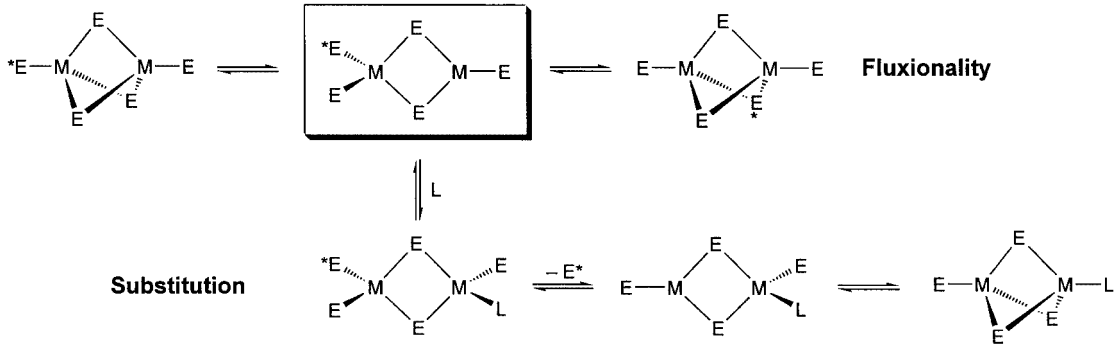
3.2.3 Reactivity of Homoleptic Cluster Complexes $[M_a(ECp^*)_b]$ (M = Pd, Pt)

While the syntheses and structural chemistry of M−E complexes and their use as precursors to new materials have attracted widespread interest, remarkably little is still known about their general chemical reactivity. The coordinate M−E bond in such complexes is relatively polar and strong when E = Al, Ga[16] and the steric demand of the E^IR ligands is rather large.[22] Thus, neither dissociative nor associative reactions are very likely to occur at the central metal. Hence, the organometallic chemistry of such compounds would appear to be rather unfruitful. Indeed, the electronically and sterically saturated monomeric complexes $[M(ECp^*)_4]$ turn out to be completely kinetically inert.[39] In sharp contrast, however, the related unsaturated cluster complexes $[M_a(ER)_b]$ ($b > a > 1$) react with a selection of ligands (Cp*Al, CO, phosphanes, isocyanides) to give new di- and trinuclear substitution products (Scheme 7).[40]



Scheme 7. Reactivity of $[M_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



On the basis of quantum chemical calculations by Frenking, the substitution of GaCp* or InCp* by AlCp* in homoleptic complexes is a thermodynamically favourable reaction.[16] Indeed, treatment of $[M_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ with AlCp* quantitatively yields the "trimetallic" compound $[Pt_2(GaCp^*)_2(\mu^2\text{-}AlCp^*)_3]$ (**8e**) or the fully substituted dinuclear complex $[Pd_2(AlCp^*)_2(\mu^2\text{-}AlCp^*)_3]$ (**8d**).

The reaction of $[M_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ with PPh_3 quantitatively yields the mono- or disubstituted complexes $[MPt(GaCp^*)(PPh_3)(\mu^2\text{-}GaCp^*)_3]$ (**8h**: M = Pd, **8i**: M = Pt) and $[Pd_2(PPh_3)_2(\mu^2\text{-}GaCp^*)_3]$ (**8g**). Whereas the substitution reactions at Pd centres giving **8f** and **8g** readily occur at room temperature, the substitution of GaCp* by PPh_3 in the related Pt_2Ga_5 complex **8a** requires both a longer reaction time and a higher temperature (90 °C). In the case of the "trimetallic" compound **8b**, the substitution can only be observed at the Pd centre, leaving the Pt-GaCp* bond unchanged. This is in good agreement with the fluxionality of $[M_2(E^IR)_5]$ in solution (vide infra). Whereas ligands attached to a palladium centre usually show fast exchange between the terminal and bridging positions, such processes are slower on platinum centres. A dissociative mechanism of the bridging ligands forming unsaturated metal centres as intermediates is assumed for the substitution reactions as well as for the fluxional processes of $[M_2(E^IR)_5]$.

Generally, heteroleptic monomeric complexes of the type $[M(GaCp^*)_{4-x}(L)_x]$ ($x = 1-4$) are not accessible via substitution reactions. However, when the chelating diphosphane ligand dppe [dppe = bis(diphenylphosphanylethane)] is added to $[M_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$, all Cp*Ga units are substituted and the monomeric complexes $[M(dppe)_2]$ (M = Pd, Pt) are formed quantitatively. The reaction of $[Pt_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ (**8a**) with the strong π-acceptors CN*t*Bu or CO gives the disubstitution products $[Pt_2(CNtBu)_2(\mu^2\text{-}GaCp^*)_3]$ (**8j**) and $[Pt_2(CO)_2(\mu^2\text{-}GaCp^*)_3]$ (**8k**), respectively, with the GaCp* ligands preferring the bridging positions.

In contrast to the substitution reactions of $[M_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ complexes, where the cluster core is always retained, the reaction of the trinuclear compound $[Pd_3(InCp^*)_8]$ (**10a**) with PPh_3 or dppe leads to a rearrangement of the linear Pd_3 core to give the triangular Pd_3 clusters $[Pd_3(InCp^*)_3(PPh_3)_3]$ (**10c**) and $[Pd_3(InCp^*)_3(dppe)_2]$ (**10d**) (Scheme 8).

In both complexes two InCp* units cap both faces of a Pd triangle resulting in a trigonal bipyramidal geometry.

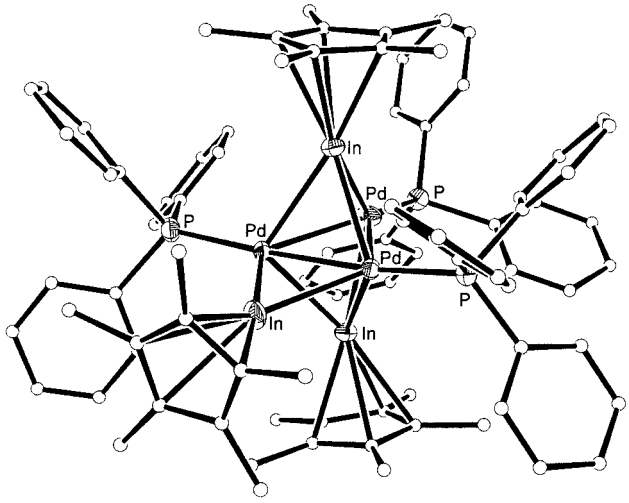


Figure 4. Triangular cluster **10c**

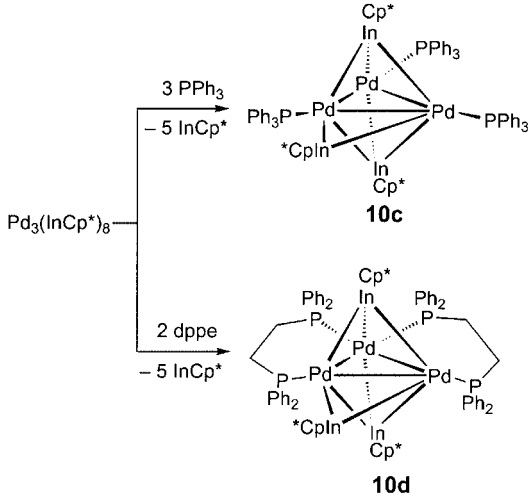


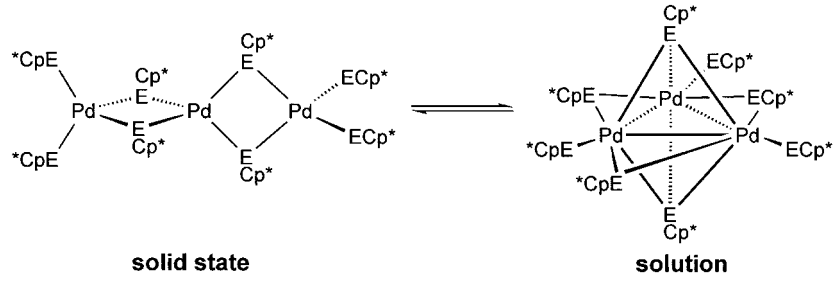
Scheme 8. Synthesis of $[Pd_3(InCp^*)_3(PPh_3)_3]$ (**10c**) and $[Pd_3(InCp^*)_3(dppe)_2]$ (**10d**)

The third InCp* ligand is found in a μ^2-coordination mode parallel to the Pd_3 plane. Additionally, each Pd centre is coordinated by one or two terminal phosphane ligands.

3.2.4 Solution Structures and NMR Spectroscopy

Whereas $[Pt_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ (**8a**) exhibits a static NMR spectrum at room temperature, i.e. two well dis-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



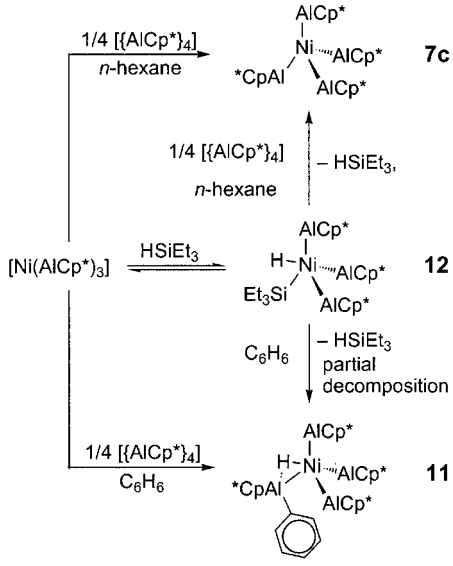
tinguishable signal sets (singlets) for the bridging and the terminal GaCp* ligands, the corresponding palladium cluster $[Pd_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ (**8c**) is dynamic in solution and gives rise to only one Cp* signal set. The ^1H NMR spectrum of $[PtPd(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ (**8b**) at room temperature shows two resonances with an integral ratio of 1:4. Clearly the fluxional process involves only the Pd centre of the dimeric structure, leaving the terminal Pt bound GaCp* unchanged. With regards to the dependence on the group 13 metal, it was found that the fluxional process in $[Pd_2(AlCp^*)_2(\mu^2\text{-}AlCp^*)_3]$ (**8d**) is slower than in $[Pd_2(GaCp^*)_2(\mu^2\text{-}GaCp^*)_3]$ (**8c**). These results are in very good agreement with the calculated bond energies in $[M\{E(CH_3)\}_4]$ (M = Ni, Pd, Pt; E = B − Tl) by Frenking.[16] For the transition metal the order Ni ≈ Pt > Pd can be observed, while for the group 13 elements the trend is B > Al > Ga ≈ In > Tl.

The ^1H NMR spectrum of $[Pd_3(GaCp^*)_4(\mu^2\text{-}GaCp^*)_4]$ (**10b**) at room temperature exhibits two resonances with an integral ratio of 1:3, whereas $[Pd_3(InCp^*)_4(\mu^2\text{-}InCp^*)_4]$ (**10a**) shows this signal splitting only at −80 °C. The reason for the unusual ratio of 1:3 is still uncertain and is not in agreement with the solid-state structure. A dissociation of the trinuclear component into two $[Pd(ECp^*)_3]$ fragments and one $[Pd(ECp^*)_2]$ (E = Ga, In) unit cannot be excluded. However, the addition of an excess of InCp* does not yield the saturated mononuclear species $[Pd(InCp^*)_4]$. The reactivity of these cluster complexes with phosphanes (PPh_3 or dppe) suggests that the nuclearity is sustained in solution (vide supra). Thus a triangular structure of **10a** and **10b** similar to the triangular phosphane clusters **10c** and **10d** in solution has been suggested. The structure bears two axial and six equatorial ligands. The equatorial ligands (terminal as well as bridging) are presumed to be fluxional in solution, giving a coalesced signal corresponding to six ligands.

3.3 Bond Activation Reactions by $M(ECp^*)_n$

The donor acceptor bond in $[L_nM\leftarrow ECp^*]$ has been calculated to be rather polar in the case of E = Al and Ga. The electron density of the transition metal centre on coordination should therefore increase considerably.[10,16,17,24,31,41] This is an intrinsically interesting feature especially from the point of view of classical bond activation reactions being relevant in organometallic chemistry (H_2, C−H, Si−H, B−H, etc.). Whereas CO, phosphanes or NHCs (nitrogen heterocyclic carbenes) are widely used as supporting and directing ligands for reactivity and selectivity in organometallic chemistry, almost nothing is known about the corresponding potential of E^IR ligands.

The reaction of $[Ni(COD)_2]$ with four equivalents of AlCp* in benzene does not yield the expected complex $[Ni(AlCp^*)_4]$ (**7c**) but instead gives $[NiH(AlCp^*)_3(AlCp^*Ph)]$ (**11**) in almost quantitative yields (Scheme 9).[39]



Scheme 9. Synthesis of **7c**, **11** and **12**

As shown by NMR spectroscopy, the C_6H_6 in **11** is not exchanged by C_6D_6, showing the kinetic inertness of complex **11**. It is assumed that the activation of benzene, which does not occur in the case of $[Ni(CO)_n]$, $[Ni(PR_3)_n]$ or other d^{10} Ni complexes, takes place on a reactive, low-coordinate fragment $[Ni(AlCp^*)_n]$ ($n < 4$) giving an intermediate of the type $[(AlCp^*)_nNi(H)(C_6H_5)]$. The reactive fragment $[Ni(AlCp^*)_n]$ is not formed from $[Ni(AlCp^*)_4]$ (**7c**) by a dissociative process but, rather, is an intermediate in the course of the formation of kinetically inert **7c** and is apparently trapped in the presence of suitable reaction partners prior to the formation of **11**. The subsequent migration of the phenyl group to an AlCp* ligand, accompanied by oxidation of the aluminium and formation of a strong Al−C bond, as well as the coordination of a fourth equivalent of AlCp* contribute to the driving force of the whole activation reaction.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Similarly, in the presence of $HSiEt_3$ (Scheme 9), the formation of the hydrosilyl complex $[Ni(AlCp^*)_3(H)(SiEt_3)]$ (**12**) can be observed. In contrast to **11**, the hydride may be found in a terminal and not in a bridging position, showing the electron deficient nature of the Al^{III} centre in **11**. Compound **12** selectively reacts with C_6H_6 giving **11** via cleavage of $HSiEt_3$, indicating that $[Ni(AlCp^*)_3]$ is the probable relevant intermediate for the C−H activation of benzene.

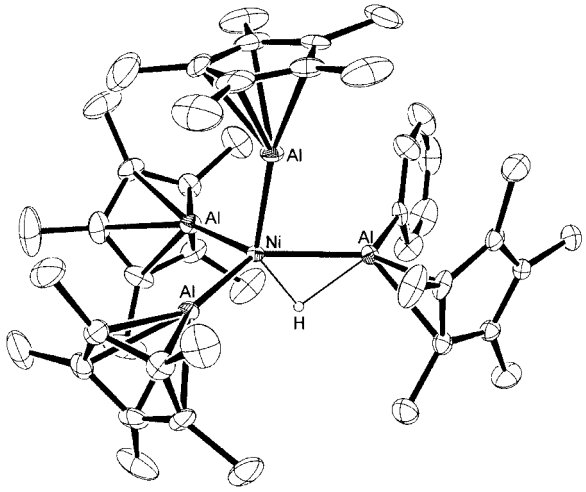


Figure 5. $[NiH(AlCp^*)_3(AlCp^*Ph)]$ (**11**)

Another example of C−H bond activation was found in the reaction of $[(\eta^6\text{-}C_6H_5CH_3)Fe(\eta^4\text{-}C_4H_8)]$ with AlCp* giving a product with the empirical formula $[Fe(AlCp^*)_5]$ (**13**).[42] The solid-state structure of **13** indeed exhibits a central iron atom in a distorted trigonal bipyramidal coordination environment. However, two C−H bonds of two Cp* ring methyl groups are attached to adjacent AlCp* ligands, giving an unusual $Cp^*Al-CH_2(C_5Me_4)Al-CH_2(C_5Me_4)Al$ chelating system (Figure 6). The hydrides occupy a bridging position between the Fe and Al centres. It is noteworthy that the Fe^0 source is inert in the presence of Cp*Ga or Cp*In, accentuating again the role of Cp*Al as a suitable ligand for bond activation reactions.

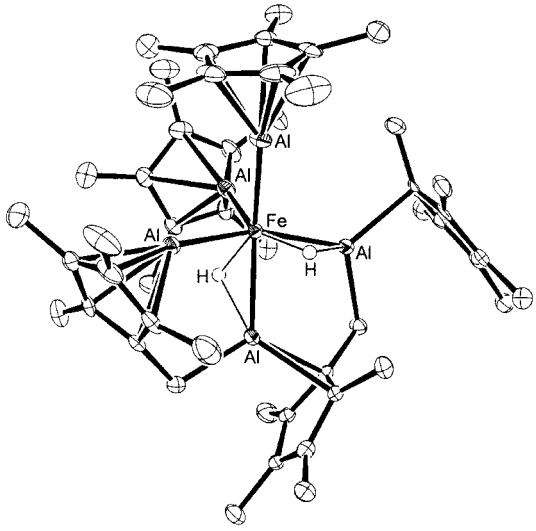

Figure 6. $[Fe(AlCp^*)_5]$ (**13**)

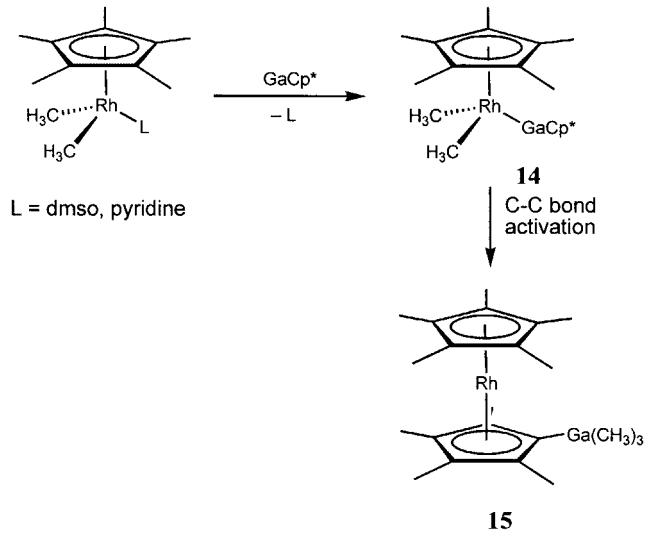
However, bond activations are not only restricted to Cp*Al, as shown by the reaction of $[Cp^*Rh(CH_3)_2L]$ (L = dimethyl sulfoxide, pyridine) with GaCp* (Scheme 10). In the first step of this reaction sequence, the ligand L is substituted by GaCp* giving $[Cp^*Rh(GaCp^*)(CH_3)_2]$ (**14**). This is isostructural with the starting complex. Complex **14** is thermally unstable and slowly reacts further in solution at room temperature to give the zwitterionic rhodium species $[Cp^*Rh\{(\eta^5\text{-}C_5Me_4)Ga(CH_3)_3\}]$ (**15**).[43]



Scheme 10. Reaction of $[Cp^*Rh(CH_3)_2L]$ (L = dmso, pyridine) with GaCp*

The mechanism of this reaction sequence is still uncertain. However, the driving force presumably includes the migration of the methyl groups to ECp* (E = Al, Ga) accompanied by oxidation of the group 13 metal centre and the formation of a strong E−C bond. This is a rather general point in the reactions of M−C bonds with ECp* and is very similar to the classical alkyl migration to transition metal bonded electrophilic π-ligands such as CO and olefins.

4. Insertion Reactions of ECp* into Metal−Halide and Metal−Metal Bonds

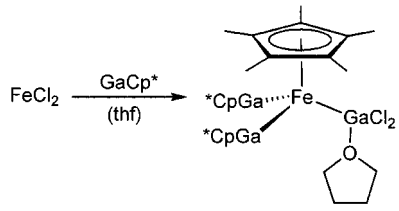
Insertion reactions of E^IX (X = halide) have been known for a long time and date back to the studies of Graham, Chatt and Hsieh more than 30 years ago. In particular, the insertion of InX (X = Cl, Br) has been the focus of much research. In the 1960s, Graham et al. reported insertions of InBr into the metal−metal bonds of $[Co_2(CO)_8]$ and $[Mn_2(CO)_{10}]$ which they assumed to give $[(\mu^2\text{-}Br)_2\text{-}In\{Co(CO)_4\}_2]_2$ and $[BrInMn(CO)_5]_2$, respectively.[44−47] Later, Chatt et al. studied the insertion of InCl into the Pt−Cl bond of [*trans*-$Pt(Cl)(SiPh_3)\{PMe_2(Ph)\}_2$] and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

claimed that the product was [*trans*-Pt($InCl_2$)($SiPh_3$)-(PMe_2Ph)$_2$].[48] A. T. T. Hsieh reported a number products from the insertion of InX into metal-metal and metal-halide bonds of carbonyl and carbonyl free complexes of tungsten, molybdenum, manganese, iron, mercury and the metals of the cobalt triad.[49−52] Hsieh also investigated the behaviour of InCl towards Ph_3PAuCl, suggesting the formation of $Ph_3PAuInCl_2$.[53] Due to the insolubility of the products, however, the structural proposals were solely based on infrared spectroscopy, elemental analyses and comparisons of the melting points.

The actual complexity of these reactions was first shown by H. Schmidbaur[54] who isolated gold/indium clusters from a reaction analogous to that of Hsieh.[53] Treatment of (PPh_3)AuCl with InCl in THF yielded the In^{II} dimer [$In_2Cl_4(THF)_4$], whereas addition of a chelating ligand such as dppe led to the cluster [(dppe)$_2Au_3In_3Cl_6(THF)_6$]. A slight change in the stoichiometry gave the ionic cluster [(dppe)$_2$Au]$^+$[(dppe)$_2Au_3In_3Br_7(THF)$]$^-$.[55] The reaction of InBr with [CpNi(Br)(PR_3)] (R = Me, Ph) typically yields ionic [CpNi(PR_3)$_2$]$^+$[$InBr_4$]$^-$ "*ate*" complexes,[56,57] while only special conditions such as the presence of strong Lewis-bases (e.g. Ph_3P=O, quinuclidine) suppress this reaction so that Ni−In bonded compounds can be isolated.

These examples clearly show that insertion reactions of E^IX are extremely sensitive to the reaction conditions and that many possible reaction pathways have to be considered. The access to E^IR species with enhanced solubility and their ability to stabilise intermediates stimulated a re-examination of these classic insertion reactions. Jutzi reported on the insertion of GaCp* into the Fe−Cl bonds of $FeCl_2$ giving [Cp*Fe(GaCp*)$_2$($GaCl_2$·thf)] (**16**) and revealing the potential of E^IR as reducing and Cp*-transfer reagents together with the capacity to behave as stabilising "spectators" (Scheme 11).[58]

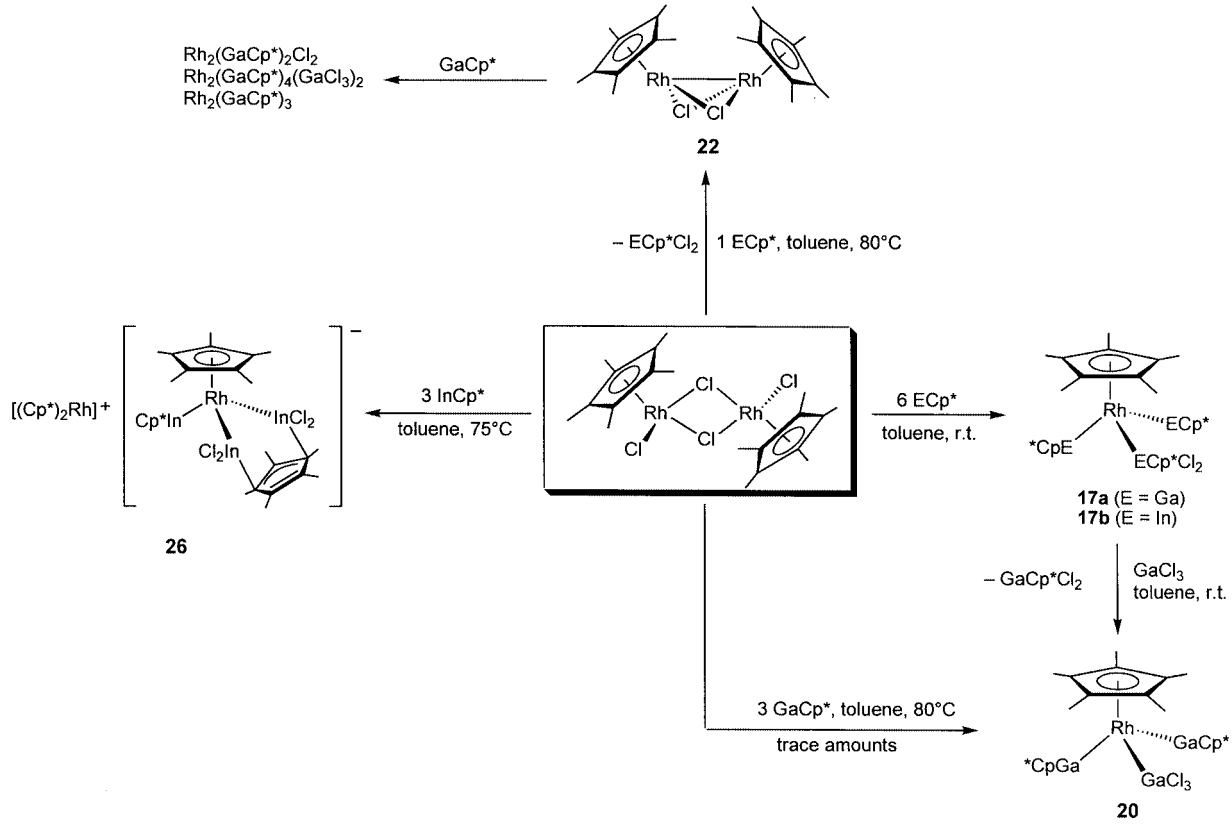


16

Scheme 11. Reaction of $FeCl_2$ with GaCp*

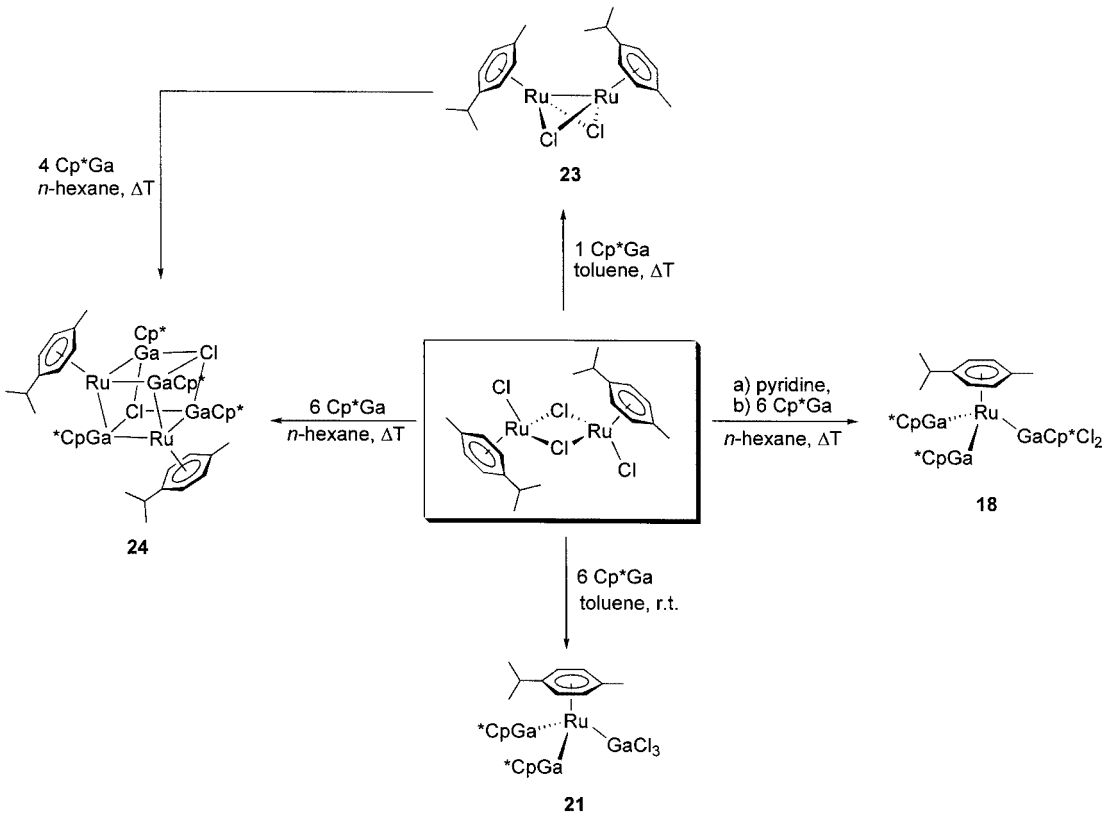
4.2 Rhodium- and Ruthenium−ECp* Coordination Compounds and Clusters

In general, depending on stoichiometry as well as reaction conditions, a variety of insertion products may be formed from the reactions of ECp* (E = Ga, In) and the isolobal d^6 complexes [{Cp*$RhCl_2$}$_2$][59,60] or [{(*p*-cymene)$RuCl_2$}$_2$][61] (Scheme 12 and 13). The reaction of [{RhCp*Cl_2}$_2$] with six equivalents of E^IR in toluene



Scheme 12. Reactions of ECp* with [{Cp*$RhCl_2$}$_2$]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 13. Reactions of GaCp* with $[\{(p\text{-cymene})RuCl_2\}_2]$

at room temperature leads to simple, monomeric insertion products $[RhCp^*(ECp^*)_3Cl_2]$ (**17a**: E = Ga**, 17b**: E = In). The analogous ruthenium complex $[(p\text{-cymene})Ru(GaCp^*)_3Cl_2]$ (**18**) can be obtained from the reaction of GaCp* with $[\{(p\text{-cymene})RuCl_2\}_2]$ only by prior treatment of the dimeric starting complex with pyridine. The formation of the intermediate monomer $[(p\text{-cymene})RuCl_2(pyridine)]$ is followed by insertion of GaCp* into the Ru−Cl bonds and substitution of pyridine by GaCp*. If dmso is used instead of pyridine, the substitution can be suppressed yielding $[(p\text{-cymene})Ru(GaCp^*)_2(Cl)_2(DMSO)]$ (**19**). However, in contrast to the isolobal Rh complex, only GaCp* gave defined reaction products, whereas InCp* yielded intractable product mixtures under all conditions tested.

The compound $[Cp^*Rh(GaCp^*)_3Cl_2]$ (**17a**) reacts readily in the presence of Lewis acids. When **17a** is treated with one equivalent of $GaCl_3$ in toluene, the Lewis acid-base adduct $[Cp^*Rh(GaCp^*)_2(GaCl_3)]$ (**20**) is immediately formed. Complex **20** is also formed as a side product in the thermal decomposition of complex **17a**, showing the lability of the Cp*−Ga bond. In the case of the Ru(*p*-cymene) fragment, the corresponding complex $[(p\text{-cymene})Ru(GaCp^*)_2(GaCl_3)]$ (**21**) can be isolated in the stoichiometrically quantitative yield of 67% ("quantitative" is based on the amount of chlorine in the starting material) if $[\{(p\text{-cymene})RuCl_2\}_2]$ is treated directly with GaCp* in the absence of pyridine. Clearly the dimeric structure starting material is retained in some of the reaction intermediates, facilitating the Cp*−Cl exchange between two Ga centres.

Changing the stoichiometric ratio of the reactants or the reaction conditions leads to new structural types for the insertion products. The reaction of $[\{RhCp^*Cl_2\}_2]$ with only one equivalent of ECp* gives the Rh^{II} dimer $[\{RhCp^*Cl\}_2]$ (**22**) which is also accessible from the reaction of the precursor with Na/Hg[62,63] or elemental gallium.[64] The analogous Ru^I-Ru^I complex $[\{(p\text{-cymene})RuCl\}_2]$ (**23**), which has not been reported in literature before, can be obtained by treatment of $[\{(p\text{-cymene})RuCl_2\}_2]$ with one equivalent of GaCp* in toluene. Several attempts to use classic reducing agents (Li, K, C_8K, sodium naphthalide) for this reduction failed, resulting only in the uncontrolled formation of Ru metal.

Further reaction of **23** with four equivalents of GaCp* gives the dimeric cage compound **24** in very good yields. The cube-like cage core consists of two Ru(*p*-cymene), four GaCp* ligands and two μ^3-bridging chlorine atoms. Complex **24** can also be prepared by direct treatment of GaCp* with $[\{(p\text{-cymene})RuCl_2\}_2]$, albeit in very low yields.

Several products can be obtained from the reaction of $[\{Cp^*RhCl\}_2]$ with ECp*. However, the molecular structures of these products are not clear yet. The homoleptic cluster complex $[(RhCp^*)_2(GaCp^*)_3]$ (**25**) could be isolated as a thermal decomposition product of one of these insertion products.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The reaction of $[\{Cp^*RhCl_2\}_2]$ with only three equivalents of InCp* (instead of six as in the synthesis of **17b**) leads to the salt $[Cp^*_2Rh][Cp^*Rh(InCp^*)\{In_2Cl_4(\mu^2\text{-}Cp^*)\}]$ (**26**). The molecular structure of the anionic part exhibits a distorted tetrahedral $RhIn_3$ core. The striking feature of the anion is the Cp* ring bridging two indium centres. The C_5 ring takes an almost parallel arrangement to the Cl−In−Cl planes with deviations smaller than 10°. Complex **26** is the first example of an intramolecular bridging Cp* ring. The only structural analogies are the solid-state structures of Et_2GaCp and $EtGaCp_2$, consisting of linear polymers with intermolecular bridging C_5H_5 ligands.[65]

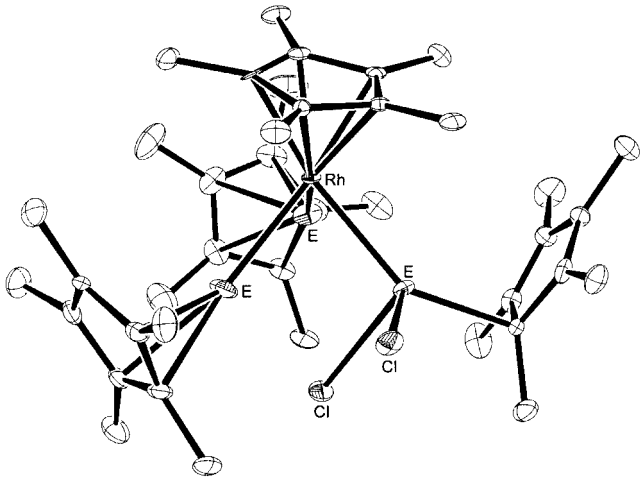


Figure 7. $[Cp^*Rh(ECp^*)_3Cl_2]$ (**17a**: E = Ga, **17b**: E = In)

4.2.1 Solution Structures and NMR Spectroscopy

The monomeric insertion products **17a** and **17b** as well as **18** can be regarded as acid-base adducts between Cp* ECl_2 and the basic d^8 transition metal centres in $[Cp^*Rh(ECp^*)_2]$ and $[(p\text{-cymene})Ru(ECp^*)_2]$, respectively. However, the NMR spectroscopic data are not consistent with simple acid-base adducts. Instead, in all these complexes the three ECp* ligands are equivalent on the NMR time scale down to −80 °C. Clearly a fast exchange of the chlorides between all group 13 atoms takes place, resulting in three coalesced ECp* ligands. A similar fluxional process was observed in the acid-base adducts of GaCp* and $GaCp^*X_2$ (X = Cl, Br). In this case, coalescence of the Cp* rings at −80 °C in $[D_8]$toluene was observed.[66] DFT calculations on the systems R_3E-ER and their isomers R_2E-ER_2 revealed that the difference in energy between these two forms is strongly dependent on both the groups R as well as the group 13 metal E. The adducts Cl_3B-GaH and Cl_3B-InH for example, exhibit bridging chlorines in the energetic minimum.[67]

Additionally, in solution, a fast Cp* exchange of the InCp* units in the anionic part of complex **26** can be assumed. The NMR spectra show three signal sets for the Cp* groups in a ratio of 2:2:1. Also, complex **26** does not show any decoalescence even at −80 °C.

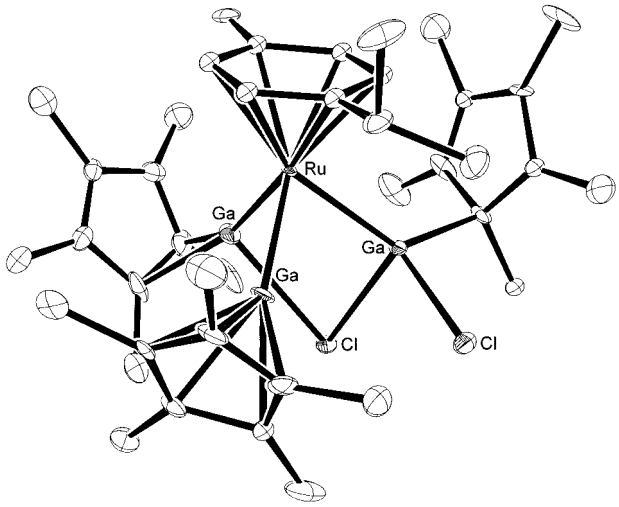

Figure 8. $[(p\text{-cymene})Ru(GaCp^*)_3Cl_2]$ (**18**)

4.2.2 Solid State Structures

The molecular structures of $[RhCp^*(ECp^*)_3Cl_2]$ (**17a**, **17b**) and $[(p\text{-cymene})Ru(GaCp^*)_3Cl_2]$ (**18**) exhibit cage-like motifs with E−Cl−E bridges. Generally, only one of the chlorine atoms is found in a bridging position, while the second chlorine is terminally coordinated. The strong difference in hapticity of the Cp* rings is a common feature of these structures. The Cp* ring on the ECl_2 unit is σ-bonded, while the Cp* group in the ECp* ligand showing no chloride interactions is clearly η^5-bonded. The bridging chloride atom exhibits some ground state *cis* effect on the coordination of the Cp* on the ECl unit which shows a "nonclassical" hapticity best described as η^3 or η^2. The free p-electron pairs at the Cl atoms effectively compete with the π-density at the Cp* for the empty p-orbitals on the group 13 metal centre. Therefore, the fluxional process in solution is reflected in the solid-state structures which can be re-

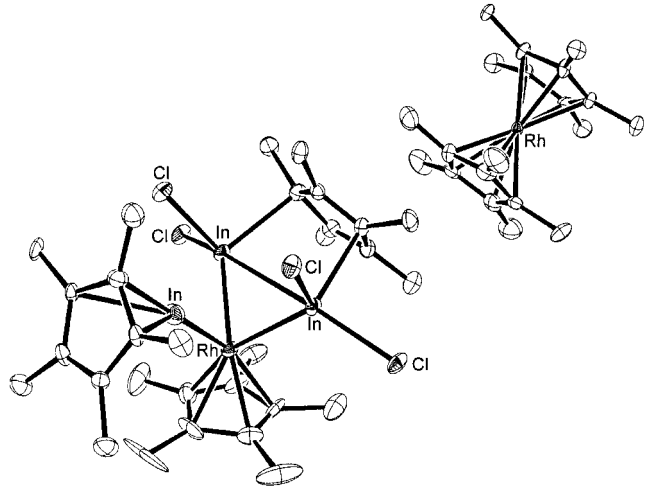

Figure 9. $[Cp^*_2Rh][Cp^*Rh(InCp^*)\{In_2Cl_4(\mu^2\text{-}Cp^*\}]$ (**26**)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

garded as trapped "intermediates" of a chlorine exchange between two ECp* centres.

In contrast, the $GaCl_3$ complexes $[Cp^*Rh(GaCp^*)_2(GaCl_3)]$ (**20**) and [(*p*-cymene)$Ru(GaCp^*)_2(GaCl_3)$] (**21**) are simple acid-base adducts without Ga−Cl−GaCp* interactions. Consequently, all Cp* units in both complexes are η^5-bonded to the Gallium centres.

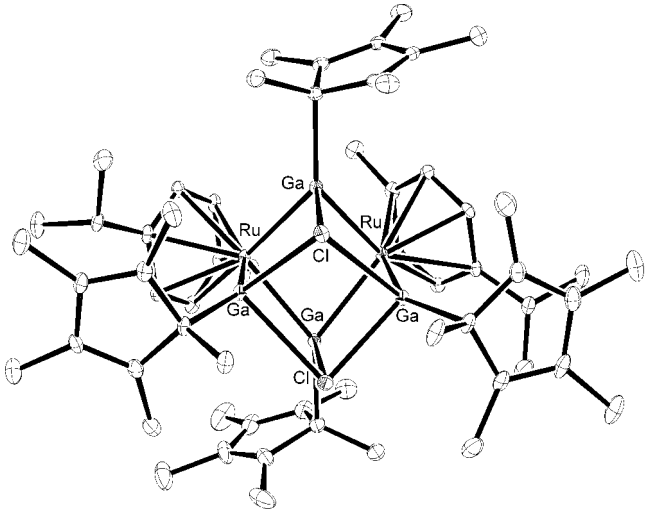

Figure 10. [Ru(*p*-cymene)$(GaCp^*)_2Cl]_2$ (**24**)

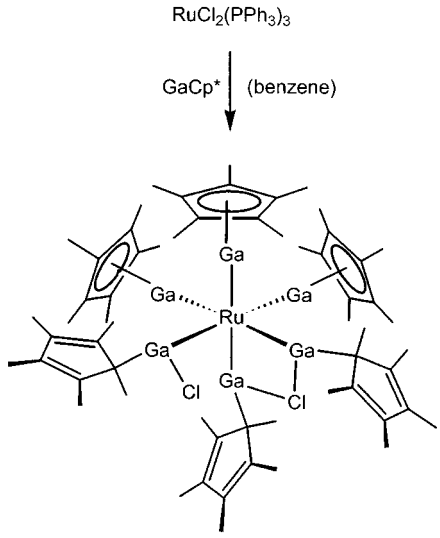
4.3 Reaction of ECp* with other Ruthenium Complexes

In contrast to [{(*p*-cymene)$RuCl_2\}_2$], [{$Cp^*RuCl\}_4$] reacts both with GaCp* and InCp* to give the monomeric "piano-stool" complexes $[Cp^*Ru(ECp^*)_3Cl]$ [E = Ga (**27a**), In (**27b**)] (Scheme 14).

In solution, all three ECp* ligands of **27a** and **27b** are equivalent on the NMR time scale down to −80 °C, due to a fast exchange of the chlorides between the three group 13 metals. In the solid state the chloride is either terminally coordinated to gallium (**27a**) or bridging two indium atoms (**27b**). As in complexes **17a**, **17b** and **18**, the influence of the chlorine coordination on the hapticity of adjacent Cp* ligands can be observed.

The reaction of ECp* with $[Cp^*RuCl]_4$ can be described as redox-neutral. The neutral *p*-cymene ligand is a stronger π-acceptor in comparison with the anionic Cp* ligand and thus has a more polarised bond to ruthenium. This situation leads to an increased electron density on all metal centres. Indeed, the chloride of compound **27a** can be easily removed by treatment with $NaBPh_4$, giving the cationic complex $[Cp^*Ru(GaCp^*)_3]^+[BPh_4]^-$ (**27c**). In contrast, **17a**, **17b** or **18** do not show any reaction with $NaBPh_4$. Notably, the cation **27c** can also be obtained by treatment of $[\{RuCp^*Cl_2\}_2]$ with GaCp*, thus having $[Cp^*GaCl_3]^-$ as the counterion instead of $[BPh_4]^-$.

The reaction of GaCp* with $[(Ph_3P)_3RuCl_2]$ leads to a complete substitution of the PPh_3 ligands and insertion of GaCp* into the ruthenium-halide bonds (Scheme 15). The product is the octahedral homoleptic complex $[Ru(GaCp^*)_6Cl_2]$ (**28**) which exhibits fluxional chloride ligands and coalescence of all GaCp* moieties.



28

Scheme 15. Reaction of GaCp* with $[(Ph_3P)_3RuCl_2]$

5. Coordination Chemistry of Sterically Bulky Ligands

While the coordination chemistry of ECp* is a well explored field, sterically encumbered low-valent group 13 ligands such as E^ITrip {E = Al, Ga, In; Trip = Bis[2,5-(2,4,6-*i*$Pr_3C_6H_3$)phenyl]},[14,15,68−73] E^ITp [E = Al, Ga, In; Tp = Tris(pyrazoyl)hydroborato][74−82] or E^I(DDP) (E = Al, Ga; DDP = 2-Diisopropylphenylamino-4-diisopropylphenylimino-2-pentene[83−88] have been little used as li-

27b (E = In)

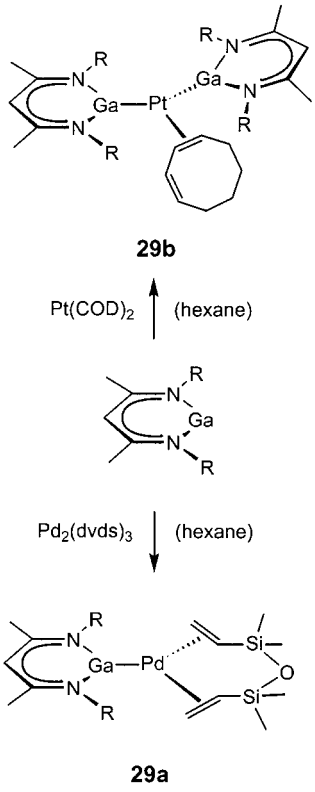
27c

Scheme 14. Synthesis of $[Cp^*Ru(E^ICp^*)_3Cl]$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gands in transition metal chemistry. The iron carbonyl complexes $[(CO)_4Fe-E^IR]$ (E = Ga; R = DDP, Trip, Tp; E = In, R = Tp)[14,89–91] and the tungsten complex $[(CO)_5W-In^ITp]$[91] are the only such complexes reported so far. The difference in the steric demand as well as in the electronic properties of these ligands compared with ECp* points to a different coordination chemistry. As an example for this class of bulky ligands, the coordination chemistry of Ga(DDP) has recently been studied in more detail.[92]

The reactions of ML_n (M = Ni, Pd, Pt; L = olefin) with GaCp* lead to a full substitution of the olefinic ligands and give homoleptic monomeric, di- or trimeric clusters in all cases (vide supra). However, according to Scheme 16, the reaction of $[Pd_2(dvds)_3]$ with Ga(DDP) does not lead to complete substitution but, rather, gives the monosubstituted complex [{(DDP)Ga}Pd(dvds)] (**29a**). Similarly, the reaction of $[Pt(COD)_2]$ with Ga(DDP) leads to the disubstituted complex $[(1,3\text{-}COD)Pt\{Ga(DDP)\}_2]$ (**29b**). Clearly, complete substitution of the olefins is prevented by the high steric demand of Ga(DDP).



Scheme 16. Reactions of Ga(DDP) with $[Pd_2(dvds)_3]$ and $[Pt(COD)_2]$

In contrast to $[M(ECp^*)_4]$ complexes, which are kinetically inert, the electronically unsaturated complexes **29a** and **29b** are substitutionally labile and form dimeric, Ga(DDP) bridged complexes on reaction with CO.

Ga(DDP) shows similar reducing abilities to GaCp*. However, the steric demand of the organic group as well as the reduced Lewis acidity of the gallium centre somehow

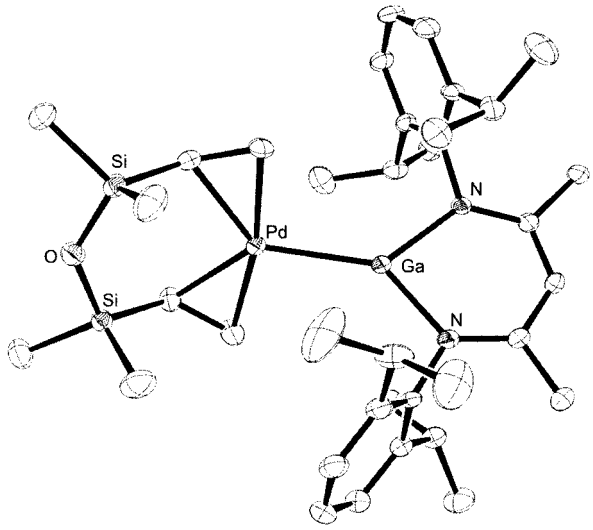


Figure 11. [{(DDP)Ga}Pd(dvds)] (**29a**)

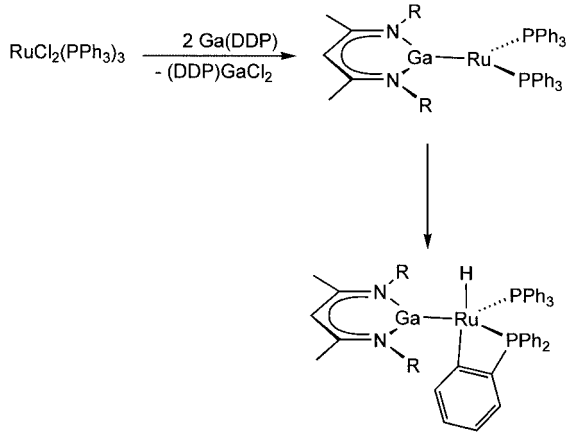
limits the kinetic access to halide transfer reactions. A reaction mixture of $[\{Cp^*RhCl_2\}_2]$ and Ga(DDP) shows oxidised gallium species but the highly reactive Rh^I-products are not stable under these conditions and nonspecific decomposition is observed.

A representative example of the difference between Ga(DDP) and GaCp* is their reactivity towards $[(Ph_3P)_3RuCl_2]$. Whereas GaCp* causes complete substitution of the Ph_3P ligands and the insertion of GaCp* into the ruthenium-halide bonds with the conservation of the oxidation state of Ru^{II} (vide supra), Ga(DDP) leads to a selective reduction of Ru^{II} to Ru^0. A free Ga^{III}-species was detected by ^1H NMR spectroscopy which, in contrast to Cp^*GaCl_2, is not acidic and does not stabilise the Ru^0 centre. Instead, the highly reactive Ru^0 is stabilised by orthometallation of one of the phenyl-rings by reoxidation of the ruthenium centre (Scheme 17). Similar orthometallation reactions are known to take place in the reactions of $[(PPh_3)_3RuCl_2]$ with other reducing agents such as potassium naphthalide.[93,94]



Scheme 17. Reaction of $[(PPh_3)_3RuCl_2]$ with Ga(DDP)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In contrast, reactions of Ga(DDP) with transition metal halides in the oxidation state +I do not give Ga(DDP)Cl_2 but, rather, lead to insertion of Ga(DDP) into the transition metal halide bond.

The Rh^I-compound [$(Ph_3P)_3RhCl$] reacts with Ga(DDP) to give the monomeric complex [$(PPh_3)_2RhCl${Ga(DDP)}] (**30**) (Figure 12). However, the chloride can be found in a bridging position between the gallium and the rhodium centre. This is the first example of a halide-bridged transition-metal group 13 metal complex reported so far. Interestingly, the Lewis acidic properties of coordinated Ga(DDP) are not sufficiently strong to cause a complete migration of the chlorine atom.

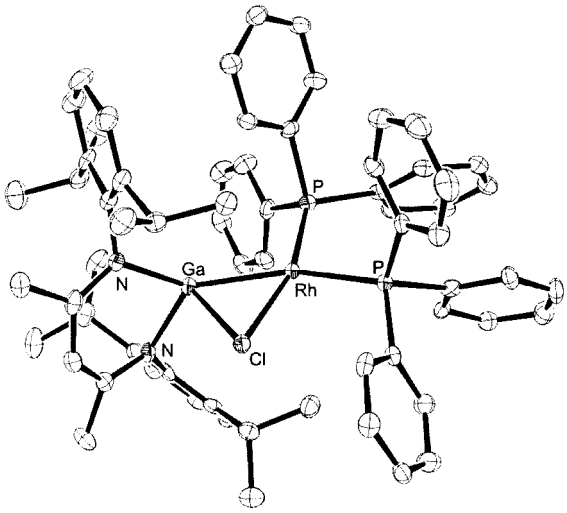


Figure 12. [$(PPh_3)_2RhCl${Ga(DDP)}] (**30**)

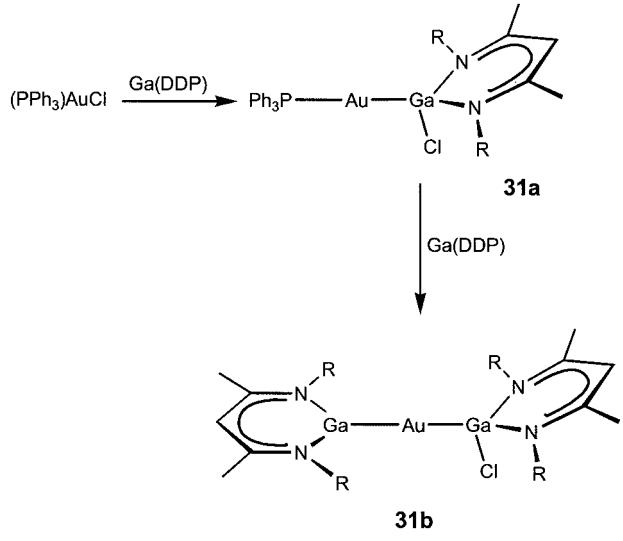
Whereas the reaction of [$(PPh_3)AuCl$] with GaCp* leads to unselective decomposition, the reaction with Ga(DDP) yields the complexes [$(Ph_3P)Au${Ga(DDP)}Cl] (**31a**) and [{(DDP)Ga}Au{Ga(DDP)}Cl] (**31b**) (Scheme 18). In these compounds, an insertion of a Ga(DDP) into a gold−halide bond with full migration of the chloride is observed.



Scheme 18. Reaction of [$(PPh_3)AuCl$] with Ga(DDP)

6. Summary and Outlook

Since their discovery, the low valent group 13 organyls GaCp* and AlCp* have attracted much attention as ligands towards transition metals. They are formally isolobal with CO, phosphanes and NHCs but in contrast, their bonds to transition metals have been calculated to be very polar, the strongest contribution being the coulombic attraction between the metals. Early research concentrated on transition metal carbonyl fragments in order to elucidate the general properties of this new class of ligand. However, recent research is focussing on more reactive transition metal fragments, without competing strong π-acceptor ligands such as CO. The strong polarity of the metal−metal bond is quite interesting in the context of organometallic chemistry. In particular, for bond activation reactions the high increase in electron density of transition metal centres by E^IR is potentially useful or, qualitatively speaking, it should facilitate oxidative addition reactions. In particular, the reactivity of the unsaturated fragments [$M(E^IR)_n$] is not understood and will necessitate further research. In addition, the chemistry of sterically demanding ligands E^IR with R = DDP, Tp^R or similar substituents holds much promise for the discovery of novel and unusual reactions. Based on the above examples we speculate that these exotic "metallic" ligands E^IR may well be very useful in a classical sense as ancillary ligands in organometallic chemistry. However, it should be mentioned here that the title compounds [$M_a(ECp^*)_b$] may also be regarded as the basic building blocks of Schnöckels elaborate cluster [$Al_{38}(AlCp^*)_{12}$][95] showing that ECp*, in general, seems to be a suitable stabilising ligand for large metal clusters. The use of [$M_a(E^IR)_b$] as building blocks for the synthesis of larger transition metal ECp* clusters as well as molecular precursors for intermetallic M/E nanoparticles seems worthy of exploration.

Complex Formation of ICL670 and Related Ligands with Fe^{III} and Fe^{II}

Stefan Steinhauser,[a] Uwe Heinz,[a] Mark Bartholomä,[a] Thomas Weyhermüller,[b] Hanspeter Nick,[c] and Kaspar Hegetschweiler*[a]

Keywords: Iron / Ligand design / Chelates / N,O ligands / Redox chemistry

Complex formation of 4-[3,5-bis(2-hydroxyphenyl)-1,2,4-triazol-1-yl]benzoic acid (ICL670, H_3L^x), 4-[3,5-bis(2-hydroxyphenyl)-1,2,4-triazol-1-yl]benzosulfonic acid (H_3L^y), and 3,5-bis(2-hydroxyphenyl)-1-phenyl-1,2,4-triazole (H_2L^z) with Fe^{3+} and Fe^{2+} was investigated in H_2O and in H_2O/DMSO mixtures by potentiometry, spectrophotometry and cyclic voltammetry. ICL670 has previously been considered as a promising drug for an oral treatment of iron overload. In this paper, the stability and redox properties of the various Fe^{II} and Fe^{III} complexes were elucidated with a particular focus on their potential involvement in the generation of oxidative stress. The overall stability constants of $[Fe^{III}(L^x)]$ and $[Fe^{III}(L^x)_2]^{3-}$ (25 °C, 0.1 M KCl in H_2O) are log β_1 = 22.0 and log β_2 = 36.9, respectively. The affinity of these ligands for Fe^{2+} is remarkably poor. In particular, the 1:2 complexes $[Fe^{II}(L^x)_2]^{4-}$ and $[Fe^{II}(L^y)_2]^{4-}$ were found to be less stable. As a consequence, the redox chemistry of the $[Fe^{III}(L^x)]/[Fe^{II}(L^x)]^-$ and the $[Fe^{III}(L^x)_2]^{3-}/[Fe^{II}(L^x)_2]^{4-}$ couples differs significantly. $[Fe^{III}(L^x)_2]^{3-}$ is a very weak oxidizing agent ($E_{1/2}$ is approximately –0.6 V versus NHE) and reduction of $[Fe^{III}(L^x)_2]^{3-}$ is not anticipated under physiological conditions. The reduction potential of the $[Fe^{III}(L^x)]/[Fe^{II}(L^x)]^-$ couple is considerably less negative and was estimated to be +0.1 V (versus NHE). The possible roles of the various Fe complexes as catalysts for the Fenton reaction in biological media are discussed. The crystal structures of H_3L^x, $Na[Fe(L^z)_2]\cdot 4EtOH$, $Na[Al(L^z)_2]\cdot 4EtOH$, and $[Cu(L^z)(pyridine)]_2$ were investigated by single-crystal X-ray diffraction, and the possible influence of the particular steric requirements of these ligands on the stability of the metal complexes has been analyzed.

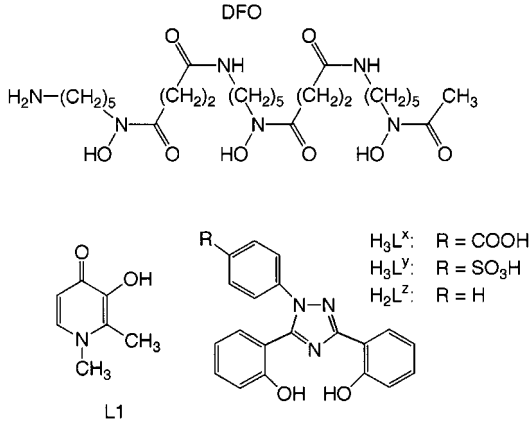
1. Introduction

Iron, an essential bioelement, is toxic when present in excess.[1] Iron overload is a particularly grave condition, because the human body lacks a physiological mechanism for actively excreting iron. There are a variety of different causes for the excessive loading of iron in a person; an important one is regular blood transfusions, necessary in the treatment of hematological defects such as β-Thalassaemia. Consequently, transfusion therapy must be combined with the administration of an iron-binding agent, transforming excess body iron into a chelated, excretable form. Presently, the microbial siderophore desferrioxamine (desferal, DFO) is used for this purpose (Scheme 1). This ligand, however, has some drawbacks. DFO is orally inactive and has a rather short plasma half-life. The need for new orally active iron chelators has been recognized for more than 30 years.[2] Deferiprone (L1), a hydroxy-pyridinone, can be taken orally; however, its application does suffer from some side effects.[3] The compound 4-[3,5-bis(2-hydroxyphenyl)-1,2,4-triazol-1-yl]benzoic acid (ICL670, deferasirox) is also an orally active iron chelator.[4] In previous animal studies, it proved to be more effective than parenteral DFO,[5] ICL670 is presently in Phase III of clinical trials.



Scheme 1

A potential problem associated with iron chelation is the generation of oxidative stress.[6] Reactive oxygen species (ROS), and in particular the $OH^{\cdot}$ radical, have a consider-

able potential to damage a variety of cellular components.[7] There has been – and still is – a debate on the precise mechanism of oxidative stress.[8–11] It has been proposed that $OH^{\cdot}$ is generated by an Fe-catalyzed process; Fe^{III} is reduced by $O_2^{\cdot-}$ to Fe^{II}, which in turn reduces H_2O_2 to $OH^{\cdot}$ and OH^-.[7] It has also been argued that the level of O_2 in the cell would be much higher than that of H_2O_2, and that the initial step of oxidative stress could be assigned to the reaction of Fe^{II} with O_2 rather than H_2O_2.[12] Moreover, the reduction of Fe^{III} to Fe^{II} is not necessarily mediated by $O_2^{\cdot-}$, but could occur through the use of abundant biological reducing agents such as ascorbate and thiols.[7]

Although the precise mechanism of oxidative stress is not completely understood, it is generally accepted that iron can catalyze the production of ROS in terms of redox cycling, when it is available in a labile, redox-active form.[6–9,13–15] It is noteworthy that either a very high or a very low redox potential of an iron complex prevents oxidative stress. Ligands such as desferrioxamine or 1,10-phenanthroline, having either a high preference for the ferric or the ferrous form, appear to be inactive in terms of oxygen toxicity, whereas aminopolycarboxylates such as NTA^{3-}, $EDTA^{4-}$ or $DTPA^{5-}$ efficiently catalyze the production of single and double strand breaks of DNA and of modified nucleobases.[14] The reduction potential of possible $Fe^{III}L_n$/$Fe^{II}L_m$ species is thus a crucial parameter when developing new iron chelators for therapeutic use (Figure 1).[16]

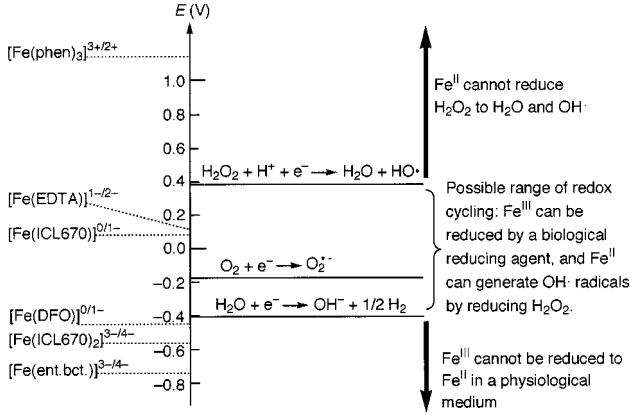

Figure 1. The possibility for redox cycling induced by different Fe^{III}/Fe^{II} complexes in biological media according to ref.[16]; the redox potentials are listed for pH 7, they were taken from refs.[16,18] and from this work (Fe–ICL670); the $O_2/O_2^{\cdot-}$ potential of −0.16 V refers to equal concentrations of dissolved O_2 and $O_2^{\cdot-}$, and not to the standard state (1 M $O_2^{\cdot-}$, 1 atm O_2); DFO = desferrioxamine, ent.bct = enterobactine, phen = 1,10-phenanthroline

In the present investigation, we address the problem of the possible redox activity of Fe–ICL670 complexes. For this purpose, we have studied the various species that form in solution, using a variety of physicochemical methods. Some preliminary results have already been published.[17] Herein, we present a comprehensive report on the complex formation of ICL670 (H_3L^x) and the related ligands H_3L^y and H_2L^z (Scheme 1) with Fe^{II} and Fe^{III}.[19–21]

2. Results

2.1. Solid-State Structures

2.1.1. Free Ligands

The unsubstituted derivative H_2L^z was first described by Ryabukhin.[21] We recently reported its crystal structure and documented the importance of the O–H···N hydrogen-bonding interactions between the phenolic hydroxy groups and N1 or N3 of the triazole ring.[22] Both O–H groups of H_2L^z are involved in intramolecular hydrogen bonds forming six-membered ring structures. O–H···N hydrogen bonding was also observed in the carboxylic acid derivative H_3L^x (ICL670), but in this ligand, only one of the hydroxy groups formed an intramolecular hydrogen bond (Figure 2). The other O–H···N bond was intermolecular, leading to infinite zigzag chains parallel to the crystallographic *z*-axis. These chains, which are further stabilized by some stacking interactions, are interconnected by the well-known pairing of the carboxylic acid moieties. The resulting two-dimensional sheets are oriented parallel to the *y*-*z* plane. Only one of the phenolic rings is roughly coplanar with the central triazole ring (the torsional angle is 2.3 °), while the other

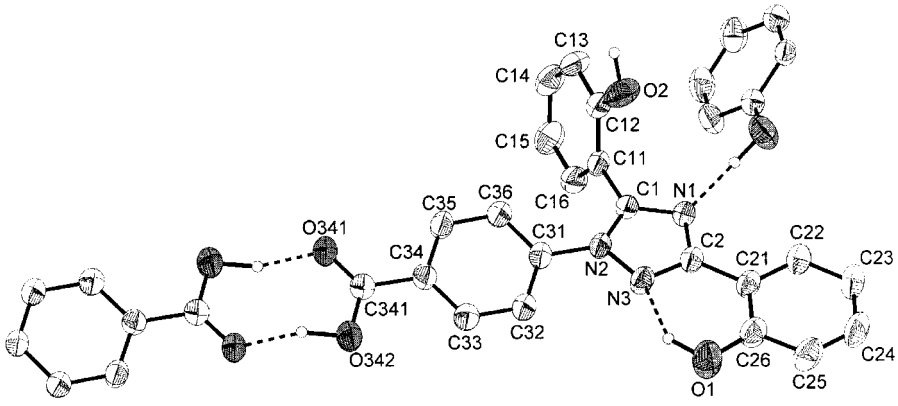

Figure 2. Molecular structure of H_3L^x (ICL670); the benzoic acid moiety and one phenol moiety of two neighboring H_3L^x molecules are also shown in order to illustrate the various types of intra- and intermolecular hydrogen bonding; atomic displacement ellipsoids are drawn at the 30% probability level; H(–O) hydrogen atoms are shown as spheres of arbitrary size; H(–C) hydrogen atoms are omitted for clarity. Bond lengths and angles are as expected

phenolic ring with a torsional angle of 77.7° stands almost perpendicular to the triazole moiety. The benzoic acid moiety is tilted slightly out of the triazole plane by an angle of 13.9°.

2.1.2. Metal Complexes

There have been several unsuccessful attempts to crystallize metal complexes with H_3L^x and H_3L^y. However, complex formation with H_2L^z yielded, a variety of crystalline materials. Single crystals of $Na[Fe(L^z)_2]\cdot 4EtOH$ were found to be very fragile and disintegrated rapidly in air (loss of EtOH). Moreover, the crystal structure of this complex proved to be severely disordered. Refinement of a data set collected at room temperature resulted in rather poor agreement factors.[23] This disorder could partially be resolved in a low-temperature experiment (100 K). Two superimposed conformers in a 2:1 ratio were located (Figure 3), and some constraints had to be used to model the C−C distances in the peripheral phenyl ring realistically. The $[Fe(L^z)_2]^-$ anion was located on a crystallographic C_2 axis. This resulted in additional disorder of the sodium counterion, which was found in proximity of this axis (the disorder remained when the data was refined in the lower-symmetry space group *C*/*c*). The structure of $Na[Al(L^z)_2]\cdot 4EtOH$ is isotypic, showing the same type of disorder as observed for the Fe complex.[24]

$[Fe(L^z)_2]^-$ adopts the expected bis-structure with a meridional coordination mode of the two L^z entities, a distorted octahedral coordination environment, and Fe−O distances at the short end of the range expected for high-spin Fe^{III}.[25] The Fe−N distance of 2.092(5) Å is also remarkably short. It is worth noting that the ligand in this complex is once again not planar. The torsional angles between the phenolate rings and the central triazole unit are 14.1° and 23.5° (for the isostructural $[Al(L^z)_2]^-$, the corresponding values are 14.0° and 19.6°).[24] The sodium counterion is associated with one phenoxo group of each ligand. Four EtOH moieties complete the roughly octahedral NaO_6 coordination environment.

The combination of solutions of $CuBr_2$, H_2L^z, and a base resulted in the precipitation of $Cu(L^z)$. A polymeric chain structure has been proposed by Ryabukhin for this compound.[21] The green solid redissolved in boiling pyridine, and addition of MeOH and water resulted in the deposition of green crystals with the composition $[Cu(L^z)(pyridine)]_2$ (Figure 4). The dimeric complex is centrosymmetric; the two Cu^{II} cations have a slightly distorted square-pyramidal coordination geometry. The basal plane is defined by the O−N−O donor set of L^z and the pyridine *N* donor *trans* to the triazole nitrogen atom. Two $[Cu(L^z)(pyridine)]$ units are paired by mutual bridging through a coordinated phenoxo group. This phenoxo bridge represents the apex of the CuN_2O_3 pyramid. The Cu−O bond lengths fall in expected ranges.[26] However, it is interesting to note that the two Cu−N lengths (1.935 and 2.052 Å) differ significantly, the distance to the pyridine donor being longer. The bridging interaction of the phenoxo group is asymmetric with a long Cu−O distance to the donor in apical position. The two phenoxo moieties are again twisted with torsional angles of 19.2° and 24.0°. The structure is stabilized by some stacking interactions between the triazole and the pyridine moieties. As expected, the dimeric complex shows antiferromagnetic coupling between the two Cu^{II} centers with an $S = 0$ ground state.

Figure 3. 2.2. pK_a Values of the Free Ligands

The pK_as were measured by potentiometric and spectrophotometric titrations (25 °C, 0.1 M KCl/KNO_3). In their fully protonated forms all three derivatives show rather low solubility in H_2O. Therefore, some of the deprotonation studies were performed in H_2O/DMSO solutions with $0.06 \leq x_{DMSO} \leq 0.20$ (x_{DMSO} is the mol fraction of DMSO). The dependence of the pK_as on x_{DMSO} was found to be roughly linear (Figure 5), and some of the missing values for pure H_2O could be estimated by extrapolation: $pK_{a,i}(x > 0) = pK_{a,i}(x = 0) + a \times x$, with $4.7 < a < 7.4$. Inspection of these data (Table 1) showed no significant differences for $pK_{a,2}$ and $pK_{a,3}$ between the three ligands H_3L^x, H_3L^y and H_2L^z. Moreover, the influence of the inert electrolyte (KCl or KNO_3) appears to be negligible, and the interpolation procedure yielded reliable estimates for the pK_as in H_2O, with an accuracy of about ±0.1. For an appropriate interpretation of these data, it is important to note that the ionic product (apparent $K_w = Q_c = [H^+] \times [OH^-]$) in the H_2O/DMSO system is considerably smaller than in pure H_2O.[27] As a consequence, the pH scale for $x_{DMSO} = 0.2$ is extended to a range of 0−15.6, and neutral solutions have a pH value of about 7.8.

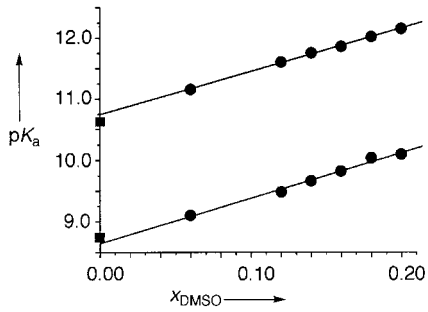

Figure 5. The dependence of the $pK_{a,2}$ and $pK_{a,3}$ of H_3L^y on x_{DMSO}; circles indicate values with $x_{DMSO} \geq 0.06$, squares refer the experimental values in pure water; the fitted line illustrates the reliability of the extrapolation procedure ($x_{DMSO} \rightarrow 0$) with an accuracy of the $x_{DMSO} = 0$ values of about ±0.1

The observed pK_a values can be grouped in three categories:

(a) $pK_a < 2$. Such low values could not be determined by conventional potentiometric methods and were therefore measured spectrophotometrically. All the investigated ligands showed significant spectral changes in the range $0 < pH < 2$. A ^1H NMR spectroscopic study of H_3L^x showed considerable shifts for the hydrogen atoms of the two phenol rings, whereas the resonances for the C_6H_4−COO hydrogen atoms (which appeared as a characteristic AA′XX′ spin system) remained virtually constant. Obviously, these changes must be attributed to protonation of a triazole nitrogen atom (for the unsubstituted 1,2,4-triazole, a pK_a of 2.19 is reported in the literature).[28] According to the ^1H

Table 1. pK_a values (25 °C, 0.1 M KCl or KNO_3) of H_3L^x, H_3L^y, and H_2L^z in H_2O and in H_2O/DMSO solutions with a mol fraction $x_{DMSO} = 0.2$; uncertainties (3σ) are given in parentheses

NMR spectroscopic characteristics, protonation of the nitrogen atom is also observed for the sulfonic acid derivative H_3L^y. Consequently, H_3L^y must be present predominantly in a zwitterionic form in strongly acidic aqueous media (Scheme S1, Supporting Information).

(b) $3 < pK_a < 5$ was only observed for H_3L^x and corresponds to the deprotonation of the carboxylic acid group.

(c) $pK_a > 8$. These values are characteristic of the deprotonation of the phenolic OH groups. Although the two OH groups are structurally inequivalent, it appears highly probable that they are deprotonated simultaneously, and that the observed pK_as represent averages of the individual (microscopic) acidity constants.[29]

2.3. Complex Formation with Fe^{III}

The formation of Fe^{III} complexes with H_3L^x, H_3L^y and H_2L^z was also studied in H_2O/DMSO by potentiometric and spectrophotometric methods. The overall stability constants, which are defined according to: $mFe^{3+} + nL^{u-} + qH^+ \rightleftarrows Fe_mL_nH_q^{3m-un+q}$, $\beta_{mnq} = [Fe_mL_nH_q^{3m-un+q}] \times [Fe^{3+}]^{-m} \times [L^{u-}]^{-n} \times [H^+]^{-q}$, ($L^x$, L^y: $u = 3$, L^z: $u = 2$), are summarized in Table 2.

In acidic solution (pH <3.5), formation of a 1:1 complex was verified by Job′s plots and was further confirmed by spectrophotometric batch titrations for all three ligands (Figures S5−S7, Supporting Information). Below pH 4, ICL670 forms a protonated complex $[Fe(HL^x)]^+$ (indicated as 111 in Scheme 2). This species could be deprotonated to $[Fe(L^x)]$ (110). We propose that the additional proton is bonded to the peripheral carboxylate group of the ligand. This assignment is consistent with the observation that a corresponding 111 species does not form with the sulfonic acid H_3L^y and the phenyl derivative H_2L^z. Clearly, the peripheral sulfonate group of H_3L^y is not sufficiently basic

Table 2. Overall formation constants (log β_{mnq}) of Fe^{III} complexes with H_3L^x, H_3L^y, and H_2L^z (25 °C, 0.1 M KCl or KNO_3) in H_2O or in H_2O/DMSO solutions with a mol fraction $x_{DMSO} = 0.20$; uncertainties (3σ) are given in parentheses

log β_{mnq}[a]	H_3L^x (ICL670)	H_3L^y	H_2L^z

to allow protonation in aqueous solution. Moreover, $[Fe(HL^x)]^+$ and $[Fe(L^x)]$ have very similar optical spectra (Figure 6b). Since the observed bands in the Vis spectra are mainly charge-transfer transitions, protonation of the peripheral carboxylate group does not modify the chromophore of this complex to a significant extent.

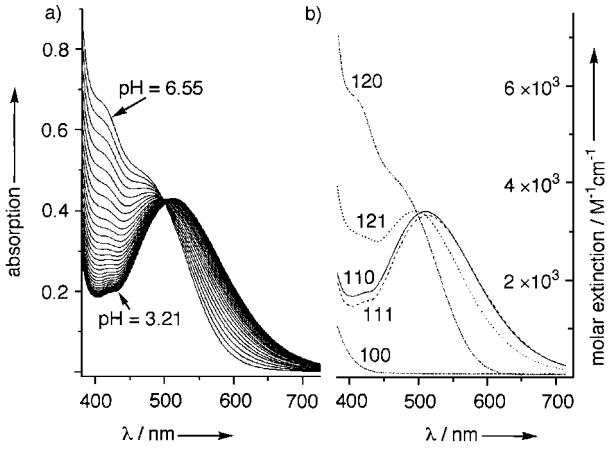

Figure 6. Determination of the formation constants log β_{mnq} of $[Fe_m(L^x)_nH_q]^{3m-3n+q}$; a) the sample spectra of the spectrophotometric titration with total [Fe]:total [L^x] = 1:3 in the range 3.2 < pH < 6.6 (x_{DMSO} = 0.2); b) calculated spectra of the individual $[Fe_m(L^x)_nH_q]^{3m-3n+q}$ species indicated as *mnq*; the spectra of Fe^{3+} (= 100) and of $[Fe(HL^x)]^+$ (= 111) were measured separately and were imported without refinement

At higher pH, complex formation with H_3L^x and H_3L^y was explored by continuous titrations (Figure 6). An additional ligand is bound to the metal center above pH 4, and a series of 1:2 complexes are formed. Experiments with H_2L^z could not be evaluated due to precipitation. Formation of a reddish-violet solid was always observed, even if a very low concentration of total Fe (10^{-4} M) and a large excess of ligand (total L^z: total Fe > 4) was used. The precipitation began after addition of about 1.2 equivalents of base, and the precipitate redissolved completely above pH 6. Obviously, a bis complex of zero charge is formed with a tentative composition $[Fe(L^z)(HL^z)]$ (indicated as 121 in Scheme 2). Formation of a similar 121 intermediate was also established for the sulfonic acid H_3L^y by potentiometric and spectrophotometric methods. However, due to the anionic nature of $[Fe(L^y)(HL^y)]^{2-}$, an insoluble solid did not form. The 121 complex deprotonated around pH 5−6 to form $[Fe(L^y)_2]^{3-}$ (= 120), which was then present as the sole species up to pH 12. The carboxylic acid H_3L^x behaved similarly, although an additional doubly protonated bis complex $[Fe(HL^x)_2]^-$ (= 122) was detected as a minor species in the region 4 < pH < 5.

For the mono complex, the reaction $[Fe(L^x)] + H^+ \rightarrow [Fe(HL^x)]^+$ was attributed to a simple protonation of the peripheral carboxylate group (vide supra). However, for the bis complexes, a different type of reaction must be considered, since $[Fe(L^y)_2]^{3-}$ and $[Fe(L^z)_2]^-$ have no peripheral sites available for protonation around pH 5 (Figure 7). Conclusive evidence for the nature of this complex is obtained from an analysis of the Vis spectroscopic data, which established that the spectra of $[Fe(L^x)(HL^x)]^{2-}$ (121) and $[Fe(L^x)_2]^{3-}$ (120) are distinctly different (Figure 6b). The situation is similar for $[Fe(L^y)(HL^y)]^{2-}$ and $[Fe(L^y)_2]^{3-}$ (see Figure S8, Supporting Information). Obviously, the two complexes must have different coordination spheres, and we therefore propose a bidentate coordination mode for one of the ligands in the 121 complex with the triazole nitrogen and one of the phenolic oxygen donors as the only coordinating atoms (Scheme 2). The second phenolic oxygen donor is protonated and probably hydrogen bonded to the free triazole nitrogen atom (as observed for the free ligands, see Figure 2). Further evidence for this particular structure is provided by FAB^+ MS (measured in EtOH). The spectrum shows the formation of the species $[Fe(L^z)_2(EtOH)]^+$ with rather high intensity. The binding of one (and only one) EtOH molecule can be nicely explained, if the complex is formulated as $[Fe(L^z)(HL^z)OEt]^+$, with a bidentate HL ligand and the sixth position in the coordination sphere occupied by an OEt^- moiety.

The spectra of the monoprotonated $[Fe(L^x)(HL^x)]^{2-}$ and the doubly protonated $[Fe(HL^x)_2]^-$ do not differ to any significant extent, and we therefore assign the reaction of $[Fe(L^x)(HL^x)]^{2-}$ with H^+ to a simple protonation of one of the peripheral carboxylate groups. The similarity of the two spectra, together with a rather low abundance of these species, prevents the determination of the formation constant β_{122} of $[Fe(HL^x)_2]^-$ by spectrophotometric methods. The value for log β_{122} could only be established by potentiometric titrations. In agreement with this assignment, the doubly protonated $[Fe(HL^y)_2]^-$ and $[Fe(HL^z)_2]^+$ species were not observed.

A comparison of the various log β values (Table 2) shows the following trends:

(a) *Dependence on DMSO concentration.* The sulfonic acid derivative has significantly enhanced solubility, and the entire range $0 \le x_{DMSO} \le 0.2$ could thus be investigated. A steady increase of log β was generally noted for an increase in the mol fraction of DMSO. The difference $\Delta\log\beta = \log\beta_{x(DMSO)=0.2} - \log\beta_{x(DMSO)=0}$ is 1.2 for $[Fe(L^y)]$, and 1.5 for $[Fe(L^y)_2]^{3-}$. Complex formation of H_3L^x with Fe^{3+} was performed in solutions with a mol fraction x_{DMSO} of 0.22, 0.20 and 0.18. The extrapolation $x_{DMSO} \rightarrow 0$ yielded $\Delta\log\beta_{110}$ = 1.3 and $\Delta\log\beta_{120}$ = 1.6. The similar behavior of the two ligands H_3L^x and H_3L^y and the linear dependence of log β on x as observed for H_3L^y justify application of the extrapolation procedure as described above for the pK_a values (Figure 5). As a result, we note that $Fe^{III}-L^x$ complexes with a peripheral COOH group are much stronger acids in H_2O than in H_2O/DMSO mixtures. Corresponding pK_a values derived from the overall formation constants (Table 2) are 2.3/2.2 (H_2O) and 4.2/4.3 (x_{DMSO} = 0.2) for $[Fe(HL^x)]^+$/$[Fe(HL^x)_2]^-$. We attribute this effect to the different solvation properties of the two media. Consequently, such protonated species appear in a substantial amount in the H_2O/DMSO mixture (Figure 7a), whereas in pure H_2O, their formation is of minor relevance or not significant at all (Figure 7b).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

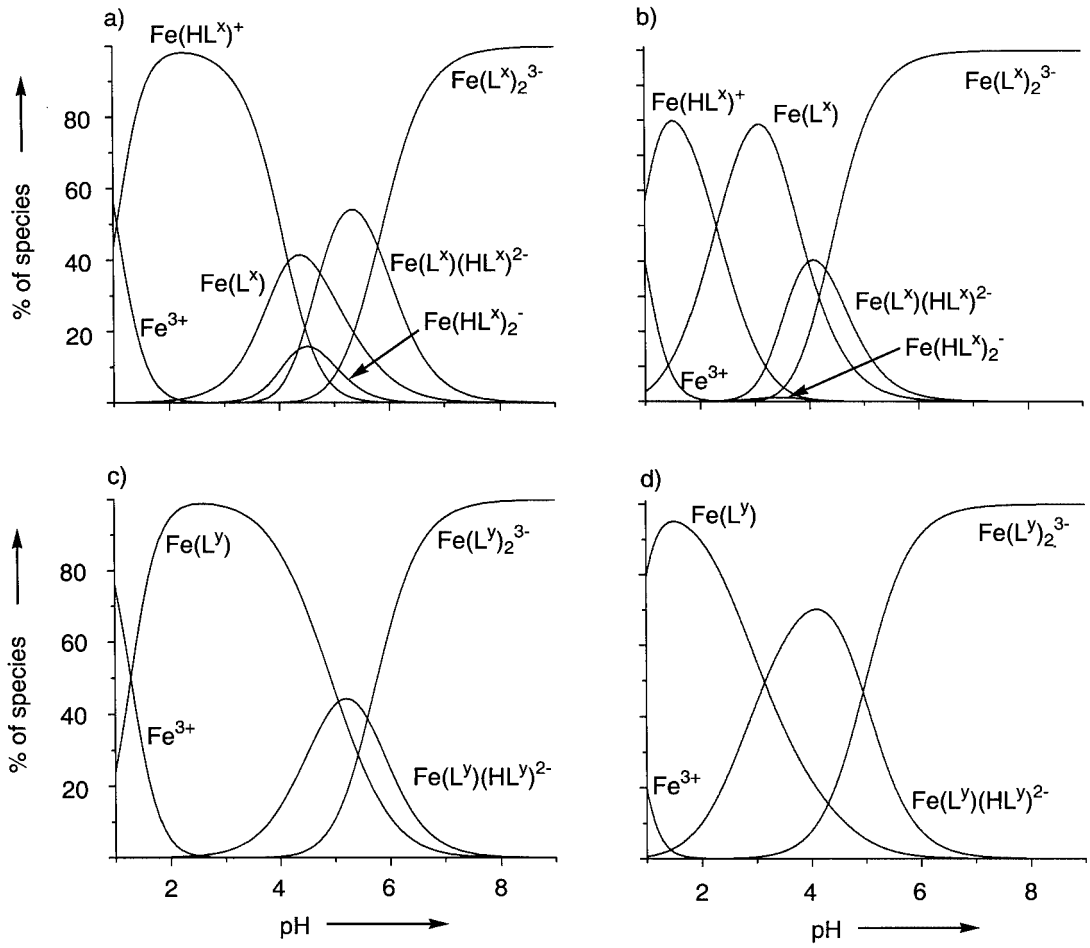

Figure 7. Species distribution plots for equilibrated solutions of $Fe^{III}-H_3L$ systems; a) H_3L^x, $x_{DMSO} = 0.2$; b) H_3L^x, $x_{DMSO} = 0.0$; c) H_3L^y, $x_{DMSO} = 0.2$; d) H_3L^y, $x_{DMSO} = 0.0$; total Fe and total ligand concentrations are 1.0 mM, and 2.0 mM, respectively; only metal-containing species are shown (total Fe = 100%); the equilibrium constants listed in Tables 1 and 2 were used for the calculations

(b) *Comparison of the different ligands.* The stability of [FeL] with $x_{DMSO} = 0.2$ decreases in the order $H_3L^x > H_2L^z > H_3L^y$. However, the differences are relatively minor. In general, the iron binding properties of H_3L^x and H_3L^y are indeed closely related: the pFe values[30] for H_3L^x and H_3L^y (total [L] = 10 μM, total Fe = 1 μM, pH = 7.4, H_2O, $I = 0.1$ M) are 21.5 and 20.6, respectively.

2.4. Complex Formation with Fe^{II}

The formation of Fe^{II} complexes with H_3L^y was again studied in H_2O/DMSO mixtures ($x_{DMSO} = 0.20$). However, a quantitative determination of the formation constants proved extremely difficult, because the ferrous complexes reacted as strong reducing agents and were readily oxidized to the corresponding Fe^{III} species. This oxidation process could easily be observed by the intense red or purple color of the Fe^{III} complexes (the Fe^{II} complexes are virtually colorless). It was thus of utmost importance to remove any traces of oxygen from the sample solutions. A series of potentiometric titrations was performed under Ar to determine the corresponding formation constants. However, it was not possible to suppress the oxidatively induced side reactions completely. In particular, the 1:2 complex $[Fe^{II}(L^y)_2]^{4-}$ was found to be a strong enough reducing agent to be oxidized even in the complete absence of oxygen. Corresponding CV measurements (see section 2.5.2) confirmed that $[Fe^{II}L_2]^{4-}$ is able to reduce H_2O (formation of H_2) in neutral solution. It was therefore not possible to determine any formation constant for the ferrous 1:2 complex with this method. The potentiometric measurements could, however, be used to investigate the formation of the 1:1 complex $[Fe^{II}(L^y)]^-$, according to the reaction $Fe^{2+} + H_3L^y \rightleftarrows [Fe(L^y)]^- + 3\ H^+$. The overall formation constant β_{110} (referring to the reaction $Fe^{2+} + L^{3-} \rightleftarrows [FeL]^-$) was determined in H_2O/DMSO ($x_{DMSO} = 0.2$) to be $\log \beta_{110} = 11.5(2)$. As expected, this number is substantially lower than the corresponding value for Fe^{3+} (22.5, see Table 2).

2.5. Redox Properties of the $Fe^{II}/Fe^{III}-H_3L$ System

2.5.1. Redox Chemistry in Acidic Solutions

Below pH 3, the 1:1 complexes $[Fe(HL^x)]^+$ and $[Fe(L^y)]$ are predominantly formed, even when the ligand is present in excess (Figure 7). The redox characteristics of these two complexes have been investigated thoroughly by means of cyclic voltammetry. The two complexes behave rather similarly, and we will focus here on the behavior of $[Fe(HL^x)]^+$ (Figure 8) and present the results for $[Fe(L^y)]$ in an abbrevi-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ated manner. A Pt working electrode was used exclusively in acidic solution, and all experiments were performed in a H_2O/DMSO medium ($x_{DMSO} = 0.2$) to avoid precipitation of the insoluble H_3L. The use of DMSO as a particularly useful solvent in electrochemistry is well-established.[31]

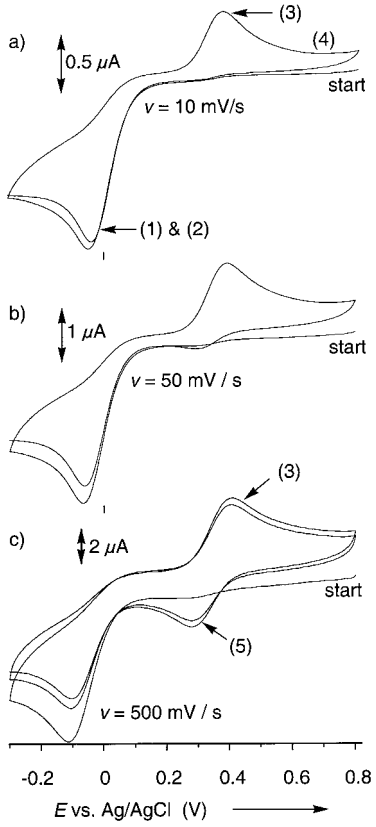

Figure 8. Cyclic voltammograms of $[Fe(HL^x)]^+$ (pH = 2.9, total [Fe] = 2.5 mM, total [L^x] = 5 mM, $x_{DMSO} = 0.2$ using a Pt working electrode at scan rates as indicated

Reduction of $[Fe(HL^x)]^+$ resulted in the formation of the corresponding Fe^{II} complex according to the reaction:

$$[Fe^{III}(HL^x)]^+ + e^- \rightarrow [Fe^{II}(HL^x)] \quad (1)$$

However, the ferrous complex is not stable and decomposes immediately and completely according to the reaction:

$$[Fe^{II}(HL^x)] + 2\,H^+ \rightarrow Fe^{2+} + H_3L^x \quad (2)$$

The electron uptake and complex decomposition described by the above reactions [Equation (1) and Equation (2)] was indicated by a characteristic irreversible peak in the range +100 mV to −150 mV (versus Ag/AgCl). As indicated by Equation (2), the decomposition is strongly pH dependent. The peak shifted to less positive values at higher pH with a slope of 109 mV/pH ([Fe(L^y)]: 129 mV/pH), indicating a transfer of two protons per electron (Figure S13, Supporting Information). The cathodic peak current was found to be linearly dependent on the square root of the scan rate, as expected for a diffusion controlled reaction (Figure S12, Supporting Information). The peak potential of the reduction slightly shifted to less positive values with increasing scan rate, and this is consistent with an irreversible process. As a result of the complete decomposition of the complex, the reverse scans showed a half wave indicative of the reoxidation of the free Fe^{2+} to Fe^{3+} at about 400 mV (versus Ag/AgCl) according to:

$$Fe^{2+} \rightarrow Fe^{3+} + e^- \quad (3)$$

This assignment is further supported by a characteristic time dependence, which was observed in subsequent scans. If a sufficiently slow scan rate was used (< 50 mV/s), enough time was available for the re-formation of the ferric complex after reoxidation of Fe^{2+} to Fe^{3+}, according to:

$$Fe^{3+} + H_3L^x \rightarrow [Fe^{III}(HL^x)]^+ + 2\,H^+ \quad (4)$$

Consequently, the second scan was identical to the first scan. Further scans did not result in any change in the behavior. However, if a higher scan rate of about 50−500 mV/s was applied, $[Fe^{III}(HL^x)]^+$ was only partially recovered [Equation (4)], and in the following scan, the solution still contained some free Fe^{3+}, which was reduced to Fe^{2+}:

$$Fe^{3+} + e^- \rightarrow Fe^{2+} \quad (5)$$

The above reaction [Equation (5)] resulted in the appearance of a new reduction wave at around 300 mV (versus Ag/AgCl), and as a consequence, two reduction waves [see Equation (1) and Equation (5)] were now observable. The ratio of their intensity varied characteristically with scan rate. Increasing scan rates resulted in an increase in the suppression of Equation (4), and therefore in an increase in the amount of free Fe^{3+} and a decrease in the amount of $[Fe^{III}(HL^x)]^+$. Consequently, the intensity of the peak at 300 mV increased with increasing scan rate, whereas that of the peak at around −100 mV (its counterpart) diminished. At a scan rate higher than 500 mV/s, the amount of complex formed after the first cycle was less than 50%, and the quasi-reversible pattern for the free Fe^{2+}/Fe^{3+} couple [Equation (3) and Equation (5)] was observed. This time-dependence was found to be in good agreement with the kinetics of $[Fe(HL^x)]^+$ formation, which was established previously by stopped flow experiments.[17]

If the pH was lowered to ≤2, the acidity of this medium was high enough to lead to the partial decomposition of $[Fe^{III}(HL^x)]^+$ (Figure 7):

$$[Fe^{III}(HL^x)]^+ + 2\,H^+ \rightarrow Fe^{3+} + H_3L^x \quad (6)$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Consequently, two reduction waves were observed already in the first scan, and it was not possible to suppress the peak at 300 mV by sufficiently slow scan rates.

2.5.2. Redox Chemistry in Neutral and Alkaline Solutions

Above pH 6, 1:2 complexes are predominantly formed, and the relevant reduction reaction is thus:

$$[Fe^{III}(L)_2]^{3-} + e^- \rightarrow [Fe^{II}(L)_2]^{4-} \quad (7)$$

However, CV experiments with an Au, Pt or glassy carbon working electrode did not show any redox activity for $[Fe^{III}(L)_2]^{3-}$. Obviously, $[Fe^{II}(L)_2]^{4-}$ is a stronger reducing agent than H_2 (see section 2.4), and the failure to observe any redox activity is due to the production of hydrogen prior to the reduction of the complex. An Hg (hanging drop) electrode was thus used to circumvent the problem of hydrogen formation, and the quasi-reversible reduction of $[Fe^{III}(L)_2]^{3-}$ [Equation (7)] could then be detected above pH 12 (Figure 9). The peak separations ΔE_P were 93 mV and 102 mV, and the reduction potentials for the $[Fe^{III/II}(L)_2]^{3-/4-}$ couple were −0.92 V and −0.89 V for H_3L^x and H_3L^y, respectively (x_{DMSO} = 0.2, vs. Ag/AgCl). As expected, this value does not depend on pH (Figure S14). Plots of the cathodic peak current vs. the square root of scan rate established a purely diffusion-controlled process (Figure S12). At pH <12, the two waves of to this redox process were still visible; however, additional peaks were observed in the reverse scan at more positive values (Figure S15). We attribute these characteristics to a partial dissociation of the ferrous complex [Equation (8)]:

$$[Fe^{II}L_2]^{4-} + nH^+ \rightarrow [Fe^{II}L]^- + H_nL^{n-3} \quad (8)$$

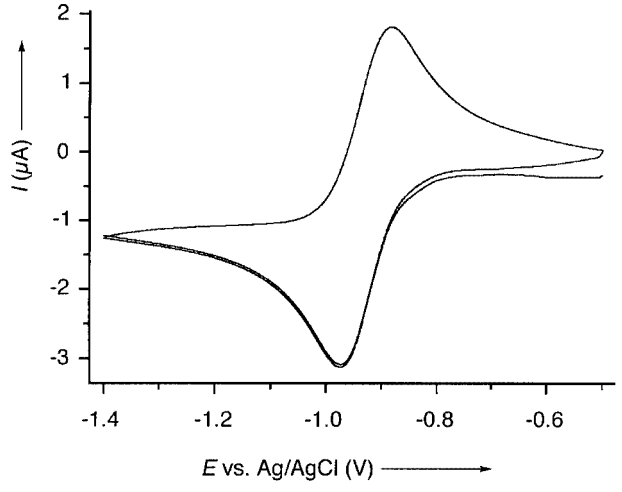

Figure 9. Cyclic voltammogram of $[Fe(L^x)_2]^{3-}$ (pH = 12.7, total [Fe] = 2.5 mM, total [L^x] = 5 mM, x_{DMSO} = 0.2 at a Hg (hanging drop) working electrode with a scan rate of 50 mV/s

For ICL670 (H_3L^x), the reduction of $[Fe^{III}(L)_2]^{3-}$ [Equation (7)] was also investigated in H_2O, and a very similar behavior was noted. The observed reduction potential was determined as −0.58 V (versus NHE). Excess ligand was used as buffer in our aqueous experiments, to stabilize the pH in the range 11−12 (the free ligand is electrochemically inactive). Moreover, the excess ligand also inevitably served to suppress the decomposition of $[Fe^{II}L_2]^{4-}$ [Equation (8)].

3. Discussion

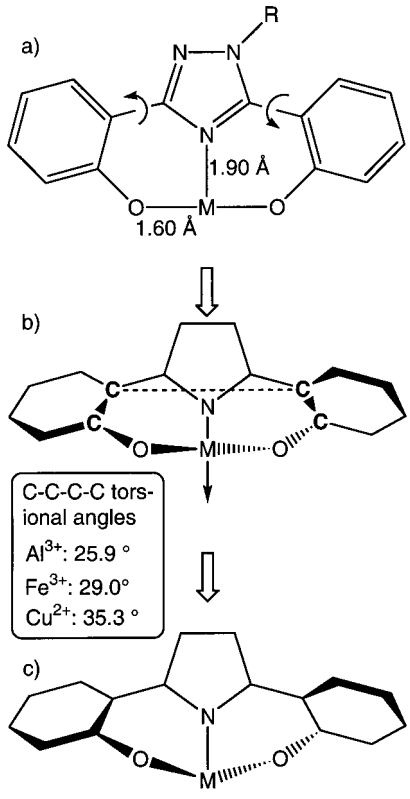
3.1. Structure and Selectivity

It has been suggested that the application of ICL670 in the therapy of iron overload could be problematic due to the lack of sufficient selectivity.[2] In particular, the presence of an sp^2 nitrogen atom would generate a donor set with a significant tendency to bind divalent biometal cations such as Zn^{2+}. Although the affinity of high-spin Fe^{III} for six negative oxygen donors generally appears to be overestimated,[32] it is true that an increasing number of nitrogen donors would enhance the stability of metal complexes with late divalent transition metal cations (Ni^{2+}, Cu^{2+}, Zn^{2+}), because an sp^2 nitrogen donor is somewhat softer than a negative oxygen donor.[33,34] However, the metal selectivity of a complexing agent cannot be explained simply in terms of the hardness of the donor set. Additional steric factors of the ligand must also be considered,[33] and it appears that in discussing the metal-ion selectivity of ICL670, these steric aspects have not received the necessary attention in some of the previous reports.

With regard to the particular steric properties of ICL670, it is important to recognize that an entirely planar L−M unit with an O−M−O angle of 180° (Scheme 3a) would imply an M−O bond length of 1.60 Å and an M−N bond length of 1.90 Å. Only very small cations are capable of forming such a short M−O bond. It has been shown by Hancock that ligands forming six-membered chelate rings have a distinct preference for small metal centers, whereas five-membered chelate rings are more suited for larger cations.[35] Clearly, with its rigid structure and its constraint of two six-membered chelate rings, ICL670 will have a strong preference to bind small metal cations. As a consequence, *all* complexes of ICL670 with di- and trivalent transition-metal cations must be regarded as strained, and this strain increases significantly with increasing ionic size. This result is of importance with regard to selectivity of this ligand in biological systems. It is noteworthy that most of the competing biometal cations such as Zn^{2+} are larger than Fe^{3+}, and binding of these elements to ICL670 is thus clearly discriminated on the basis of steric considerations. The bond strain in such complexes can be absorbed to a large extent by angle deformation, and the M−O distance can be widened by out-of-plane twisting of the two phenyl rings (Scheme 3b). As already noted in the results section (2.1.2), this type of twist has generally been observed in the crystal structures of such metal complexes, and the corresponding twist angle increases, as expected, with increasing ionic ra-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dius. However, the rotation of the two phenoxo rings inevitably results in a compression of the M−N bond. Corresponding M−N distances observed in the crystal structures are indeed rather short. Again, the compression is partially compensated by deformation of the *cis*−O−M−N and *trans*−O−M−O angles (Scheme 3c).



Scheme 3

The favored binding of small metal cations is nicely illustrated by the stability constants of $[M(L^x)]$ complexes with Mg^{2+} (log K = 7.6) and Ca^{2+} (log K = 5.5).[17] These values should be compared with values for other ligands that have a mixed *O*,*N* donor set such as NTA^{3-} (log K_{MgNTA} = 5.5, log K_{CaNTA} = 6.3) or EDTA (log K_{MgEDTA} = 8.8, log K_{CaEDTA} = 10.7).[36] The two aminopolycarboxylate ligands exclusively form five-membered chelate rings, and as a consequence, the complexes with the larger cation (Ca^{2+}) are more stable. For ICL670, the reverse trend is observed, and the complexes with the smaller Mg^{2+} are about two orders of magnitude more stable. Consequently, replacement of the ferric iron by the larger Zn^{2+} ion, according to $[Fe(L^x)_2]^{3-} + Zn^{2+} \rightleftarrows [Zn(L^x)_2]^{4-} + Fe^{3+}$, is strongly disfavored. The equilibrium constant for this reaction is 7.9×10^{-22}.[17] The significant stress, even in the ferric complex, also explains the rather unexpected formation of the protonated species $[Fe(L)(HL)]^{2-}$ (L = L^x, L^y) or [Fe(L)(HL)] (L = L^z) that was observed for all three ligands. Obviously, the transformation to a bidentate coordination mode arises because of the release of strain induced by the detachment of one of the coordinated phenoxo groups. Such a detachment of a basic donor atom by protonation is well-established for strained chelate rings.[37]

In the bis complexes of ICL670, the discussion of structure-stability correlations requires the analysis of additional interligand interactions. For this purpose, it is necessary to briefly discuss the different stereoisomers that are possible for such an ML_2 complex. In the simple ML unit, the twist of the two phenyl rings can either occur in a clockwise or counter-clockwise manner relative to the central triazole unit (Scheme 4a). By analogy with the usual nomenclature, the O···O line will be used in this work to refer to the two forms as the λ or δ enantiomer, and the combination in a bis complex would give either a λδ or a δδ (or λλ) form (Scheme 4b). The two forms adopt considerably different geometries. In the λδ isomer, the two ligands are oriented perpendicularly, whereas the δδ isomer has a rather flat shape with an almost parallel orientation of the four phenyl rings that allow for some π-stacking to occur. Due to the nonequivalence of the two noncoordinating nitrogen atoms, the symmetry of the λδ isomer is C_1. For the δδ isomer, the addition of a substituent to one of the nitrogen atoms results either in a *cisoid* or *transoid* structure. Both of these have C_2 symmetry. $[Fe^{III}(L^z)_2]^-$ and $[Al^{III}(L^z)_2]^-$ − as observed in the crystalline compounds − correspond to the C_2 isomer with the transoid configuration being predominant (Figure 3). Inspection of the different structures reveals that for all possible isomers, *repulsive* interligand interactions are relatively minor. The exclusive formation of the λλ/δδ form in the Fe^{III} and Al^{III} complexes may be attributed to the possible stabilization by intramolecular π-stacking and also to the better accessibility of the Na^+ counterion for its bonding to two phenoxo oxygen atoms (indicated by arrows in Scheme 4b).

3.2. Species Distribution and Redox Properties of the Fe^{III}−ICL670 System

As outlined in the introduction, the abundance and redox potential of every single component must be considered when discussing the problem of possible redox cycling. As a tridentate ligand, ICL670 can form ML and ML_2 complexes, and both species must be regarded as possible redox catalysts. A conventional species distribution diagram for the ICL670−Fe^{3+} system is shown in Figure 7 (see a and b). However, in this type of representation, the amount of total Fe in solution is arbitrary. In contrast, Figure 10 illustrates a situation in which the different ferric complexes are in equilibrium with solid FeOOH. The concentration of free Fe^{3+} is then mediated by the solubility product of this solid phase, and the total amount of dissolved Fe is a direct measure of the efficacy of a ligand for Fe^{III} chelation at a given pH.[38] This type of representation more closely reflects the condition in an iron-overloaded patient. Figure 10 shows the amount of dissolved Fe for total ligand concentrations of 100 μM, 1 μM, and 10 nM (the corresponding value in the serum of an iron-overloaded patient during oral treatment with ICL670 falls in the range 10 μM−100 μM).[4] As expected, ICL670 displays optimum activity in neutral and slightly alkaline solutions ($6 < pH < 10$).[38] High concentrations of H^+ or OH^- favor either competitive protonation of the ligand or render the solid hydroxide very insoluble. At physiological conditions, more than 80% of the ligand is still loaded with Fe^{III} as $[FeL_2]^{3-}$ even at low total L concentrations such as 1 μM, and the fraction of the 1:1 complex is less than 3%, even if the level of total L is 10 nM. The protonated 1:2 complex is not of importance at physiological conditions as well.

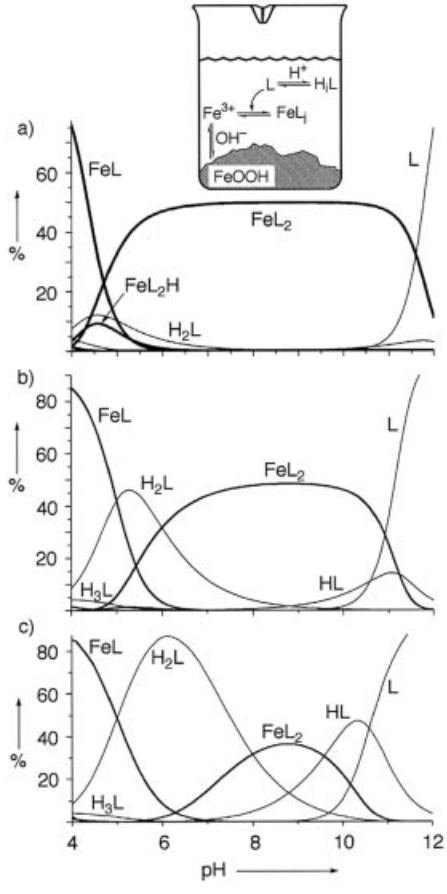

Figure 10. Sequestering ability of ICL670 in H_2O (0.1 M KCl, 25 °C) as a function of pH; the equilibrium concentration of the various species is shown as a fraction of total L concentration (= L_{tot}) with (a) L_{tot} = 100 μM, (b) L_{tot} = 1 μM, and (c) L_{tot} = 10 nM; the solubility product K_{S0}(FeOOH) = 10^{-39} M^4 corresponds to the solubility of ferrihydrite, (ref.[1]); the curves for iron-containing species are in bold

The stability of ferrous $[Fe^{II}(L^y)]^-$ (log β_{110} = 11.5) can be compared with the corresponding value log β_{110} = 13.3 reported for $[Zn(L^x)]^-$.[17] The ratio of these values corresponds closely to the expectations from a linear free energy relation $\Delta G^{Zn}/\Delta G^{Fe}$ = constant.[33] For a variety of ligands having similar, mixed *N*,*O* donor sets and a related charge or denticity, the ratio log $\beta_{110}([Zn^{II}L])$/log $\beta_{110}([Fe^{II}L])$ is 1.1−1.2 (Table 3). The corresponding ratio of 1.16 for log $\beta([Zn^{II}(L^x)]^-)$/log $\beta([Fe^{II}(L^y)]^-)$ corroborates the potentiometric results of the present investigation.[39] The value for β_{120} for the ferrous complex could not be determined directly due to instantaneous oxidation of $[FeL_2]^{4-}$. An analogous free energy relation as described for log β_{110} gave log β_{120} = 14.8 (x_{DMSO} = 0.2, see Table 3). With the use of an appropriate correction for $x_{DMSO} \rightarrow 0.0$ (Table 2), we estimate log β_{120} = 13.5 for pure water. This value is in good agreement with log β_{120} = 14.0 calculated from the reduction potential and from log β_{120} = 36.9 for $[Fe^{III}L_2]^{3-}$ (Scheme 5).

Table 3. Linear free energy relation for Zn^{2+} and Fe^{2+} complex formation

	Zn^{2+}		Fe^{2+}		log β (Zn^{2+})/log β (Fe^{2+})

[a] Abbreviation of ligands: nitrilotriacetic acid (H_3nta), iminodiacetic acid (H_2ida), dipicolinic acid (H_2dipic). [b] From ref.[36], 20 °C, *I* = 0.1 M. [c] From reference [36], 25 °C, *I* = 0.1 M. [d] From ref.[36], 25 °C, *I* = 1.0 M. [e] From ref.[17], L = L^x, x_{DMSO} = 0.20, 25 °C, *I* = 0.1 M. [f] Ref.[17] listed the value log β_2 = 17.5 for L = L^x, x_{DMSO} = 0.20. This value was adjusted for pure H_2O (x_{DMSO} = 0) by adding an increment of −1.5 (see Table 2). [g] This work, L = L^y, x_{DMSO} = 0.20, 25 °C, I = 0.1 M.[h] L = L^x, estimated for H_2O (25 °C, I = 0.1 M) from the reduction potential $E_{1/2}(FeL_2)$ = −0.58 V and log β_{120} (Fe^{3+}) = 36.9 (see Scheme 5 and Table 2).

The low stability of $[Fe^{II}L_2]^{4-}$ (L = L^x, L^y) is an important result from this investigation. This complex is not only a very strong reducing agent, but also dissociates very easily to give the 1:1 complex. The individual association constant for the second ligand has a value of log $K_2 \approx 4$, and the pH-dependent constant according to Equation (8), *n* = 2, $K = [Fe^{II}L^-] \times [H_2L^-] \times [Fe^{II}L_2{}^{4-}]^{-1} \times [H^+]^{-2}$, is log *K* = −15.4. At pH 7, this equilibrium is clearly shifted to the right, and $[Fe^{II}L_2]^{4-}$ is only stable at a relatively high ligand concentration and high pH. The very low stability of

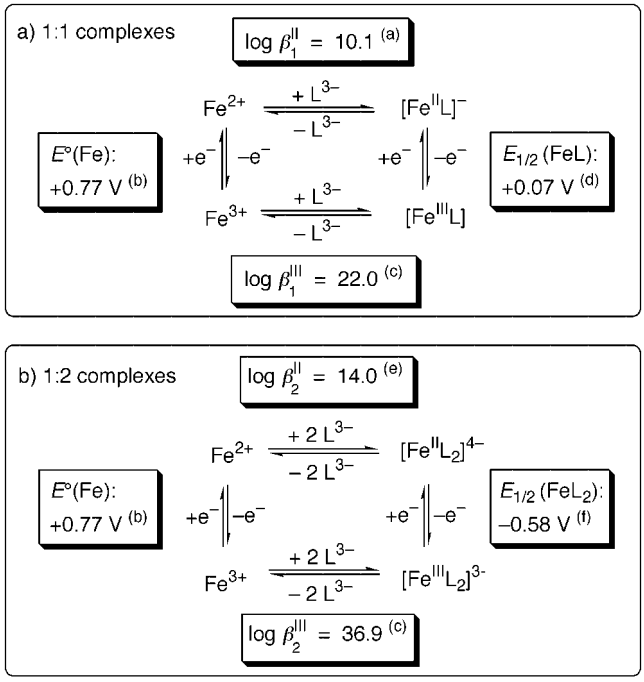

Scheme 5. Synopsis of complex stability and redox chemistry for iron complexes of H_3L^x in H_2O (0.1 M KCl, 25 °C); (a) this work (section 2.4), corrected for pure H_2O; (b) from ref.[18b]; (c) this work (see Table 2); (d) calculated as $E_{1/2}(FeL) = E^0(Fe) - 0.059V \times (\log \beta_1^{III} - \log \beta_1^{II})$; (e) calculated as $\log \beta_2^{II} = \log \beta_2^{III} - [E^0(Fe) - E_{1/2}(FeL_2)]/0.059V$; (f) this work (section 2.5.2)

the ferrous bis complex is attributed (a) to an unfavorable electrostatic repulsion between the two trianionic ligand entities, and (b) to the distinct selectivity of this ligand for small metal ions. As already discussed in section 3.1, *all* complexes of ICL670 with di- and trivalent transition metal cations must be regarded as significantly strained, and this strain increases with increasing ionic size. The addition of one electron to the ferric complex results in an increase in the effective ionic radius from 0.645 Å (high-spin Fe^{III}) to 0.780 Å (high-spin Fe^{II}).[40]

In addition to the complete dissociation of one ligand from $[Fe^{II}L_2]^{4-}$, the formation of a species with a partially coordinated and partially protonated ligand (e.g. $[Fe^{II}(L^x)(HL^x)]^{3-}$) must be taken into account. Moreover, it should be noted that $[Fe^{II}L]^-$ is susceptible to the binding of another ligating agent A^{m-} which may be present in the medium. Formation of such a ternary complex $[Fe^{II}(L^x)(A)]^{(1+m)-}$ appears to be particularly likely if this ligating agent could stabilize the ferrous form. The simple, pH-independent reduction potential [Equation (7)] must therefore be determined at a sufficiently high pH.[41] It is noteworthy that a cyclic voltammogram of the bis complex recorded at pH 12.6 showed a quasi-reversible electron transfer, whereas at lower pH, additional peaks were observed for the anodic wave at more positive potentials (Figure S15). This observation is a clear indication that additional species (protonation products of $[Fe^{II}L_2]^{4-}$ or ternary mixed ferrous complexes) are formed. However, at the present stage, it is not possible to derive any conclusive information about the nature of such species.

The formation of polynuclear species is another possibility for the stabilization of the 1:1 complex at the ferrous stage.[2] As already noted by Ryabukhin, the reaction of H_2L^z with divalent transition metal cations resulted in the precipitation of insoluble polymers.[21] A bis-bidentate coordination mode (binding of a first metal cation to N1 and O2, and a second cation to N3 and O1, see Figure 2) was proposed for the resulting $\{M(L^z)\}_n$ structure. In turn, each metal center would be chelated by two ligand entities. For H_3L^x, the corresponding oligomers $[\{Fe^{II}(L^x)\}_n]^{n-}$ would carry a negative charge at physiological pH, and they could therefore stay in solution. However, the smooth reaction of $Cu(L^z)$ with pyridine (Figure 4) demonstrates that such aggregates depolymerize readily in the presence of an additional coordinating agent.

With regard to the role of Fe^{III}−ICL670 complexes as possible catalysts for redox cycling, one can clearly state that the bis complex [Equation (7)] is redox inactive in any physiological medium. If partial dissociation and formation of the ternary $[Fe^{II}(L^x)(A)]^{(1+m)-}$ species at the ferrous stage is considered, then the result is unchanged, as long as the ligating agent A^{m-} further stabilizes the ferric form. This is indeed the case for many biological low-molecular-weight ligands such as citrate or ATP.

Although the reduction potential of $[Fe^{III}L]$ cannot be measured directly due to immediate decomposition of the complex after reduction in acidic solution (2.5.1), it can be calculated from the corresponding formation constants β_{110} for $[Fe^{II}L]^-$ and $[Fe^{III}L]$. The estimated $E_{1/2}$ for the 1:1 complex is +0.07 V (versus NHE), a value which is in good agreement with the irreversible cathodic wave (Figure 8) observed in acidic media in the range from +100 mV to −150 mV (versus Ag/AgCl). Clearly, $[Fe^{II}L]^-$ is a significantly weaker reducing agent than $[Fe^{II}L_2]^{4-}$. The redox potential of the 1:1 complex falls in a similar range to that of the $Fe^{III/II}$−EDTA couple (Figure 1).

4. Conclusions

A survey of the various formation constants and corresponding redox potentials of the Fe^{II} and Fe^{III} complexes with ICL670 (H_3L^x) in H_2O is summarized in Scheme 5. The other ligands (H_3L^y and H_2L^z) behave very similarly. Our study confirmed that these ligands are highly selective for Fe^{III}, and that the affinity for Fe^{II} is, in general, low. However, there is a distinct difference between the 1:1 and 1:2 complexes. $[Fe^{II}(L^x)]^-$ is sufficiently stable to be formed at moderate ligand concentrations around pH 6, whereas $[Fe^{II}(L^x)_2]^{4-}$ is generally not stable in aqueous solution. In view of a possible role in redox catalysis, reduction of $[Fe^{III}(L^x)_2]^{3-}$ is not possible in a physiological medium, and the 1:2 complex is thus redox inactive. On the other hand, the 1:1 complex $[Fe^{II}(L^x)]^-$ must be regarded as a somewhat milder reducing agent, and its formation from the ferric species could well be anticipated in the presence of a bio-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

logical electron donor. In particular, reduction by $O_2^{\cdot-}$ could occur (Figure 1), and reoxidation by H_2O_2 would also be possible. However, the formation of $[Fe^{III}(L^x)]$ is only relevant in acidic solutions. At pH 7−8, a ligand redistribution reaction, followed by precipitation of solid iron hydroxide according to: $2[Fe^{III}(L^x)] + 3OH^- \rightarrow FeOOH(s) + [Fe(L^x)_2]^{3-} + H_2O$, would be favored (Figure 10). Therefore, it appears rather unlikely that any possible enhancement of oxidative stress (Fenton chemistry etc.) needs to be considered under physiological conditions. This is clearly different at lower pH values, where $[Fe^{III}(L^x)_2]^{3-}$ will partially dissociate to $[Fe^{III}(L^x)]$, and this species can be reduced to $[Fe^{II}(L^x)]^-$. As a matter of fact, the partial dissociation of Fe^{III} complexes in slightly acidic solutions appears to be a general problem for di- and tridentate iron chelators such as L1 or ICL670.[42] This is, of course, different for ligands with a higher denticity such as DFO, where an "all-or-nothing" coordination mode prevents possible formation of partially coordinated, "dangerous" species.

Experimental Section

Materials, Instrumentation and Analyses: The chemicals used for the synthetic work were commercially available products of reagent grade quality and were used as obtained. H_2O was distilled twice (quartz apparatus). DMSO was from Fluka (puriss., p.a.). MeOH and EtOH (reagent grade) were purified by distillation prior to use. For the potentiometric and spectrophotometric titrations, metal salts of highest available quality (>99.95%) were used. $FeCl_3$ (anhydrous) was from Fluka, $(NH_4)_2Fe(SO_4)_2{\cdot}6H_2O$ (>99.997%) from Aldrich. ^1H and $^{13}C\{^1H\}$ NMR spectra were measured in [D$_6$]DMSO (28 °C) with a Bruker DRX 500 spectrometer (resonance frequencies: 500.13 MHz for ^1H and 125.9 MHz for ^{13}C). Chemical shifts (in ppm) are given relative to tetramethylsilane as an internal standard (= 0 ppm). EI^+-MS were measured on a Varian MAT 311 spectrometer (Dr. Graf, Universität des Saarlandes), and FAB^+-MS were recorded on a VG ZAB-VSEQ spectrometer (Dr. W. Amrein, R. Häfliger, ETH Zürich). Samples for FAB were dissolved in EtOH with 3-nitrobenzyl alcohol as a matrix. C,H,N analyses were performed by H. Feuerhake (Universität des Saarlandes).

2-(2-Hydroxyphenyl)-benzo-4*H*-[1,3]-oxazin-4-one:[43] Salicylic acid (24.9 g, 0.18 mol), salicylamide (20.6 g, 0.15 mol) and pyridine (1.5 mL) were refluxed in xylene (30 mL). Thionyl chloride (23.7 mL, 0.33 mol) was added with vigorous stirring over a period of 4 h. An intense evolution of SO_2 and HCl was noted. At the end of the addition, the product started to crystallize. Stirring was continued for an additional 30 min, and the xylene was removed by distillation at reduced pressure. The resulting solid residue was suspended in EtOH (60 mL) and acetic acid (1.5 mL). The mixture was heated gently and then allowed to cool to 20 °C. The precipitate was filtered and recrystallized from 2-methoxyethanol (70 mL). Yield: yellow needles (19.78 g, 82.7 mmol, 55%). The product decomposed slowly when exposed to moisture, forming bis(salicyl)-imide. $C_{14}H_9NO_3$ (239.2): calcd. C 70.29, H 3.79, N 5.85; found C 70.80, H 3.88, N 5.70. ^1H NMR ([D$_6$]DMSO): δ = 7.09 (m, 2 H), 7.62 (m; 2 H), 7.78 (d, 1 H), 7.94 (t, 1 H), 8.07 (d, 1 H), 8.20 (d, 1 H), 8.78 (OH) ppm. ^{13}C NMR ([D$_6$]DMSO): δ = 111.4, 117.4, 117.8, 117.9, 119.5, 126.7, 127.2, 129.0, 136.0, 136.7, 153.8, 161.8, 163.4, 164.8 ppm. UV/Vis (H_2O, 25 °C): λ_{max} = 371, 323 nm.

4-[3,5-Bis(2-hydroxyphenyl)-1,2,4-triazol-1-yl]benzoic Acid (H_3L^x):[19] 4-Hydrazino-benzoic acid (1.75 g, 11.5 mmol) and NEt_3 (1.16 g, 11.5 mmol) were dissolved in boiling EtOH (80 mL). To the clear solution was added 2-(2-Hydroxyphenyl)-4*H*-3,1-benzoxazin-4-one (2.50 g, 10.45 mmol), and the reaction mixture was refluxed for an additional 2 h. The solution was then allowed to cool to room temperature, and H_2O was added until some perturbation (i.e. a first sign of precipitation) was observed. The mixture was concentrated to a total volume of 50% under reduced pressure and aqueous 6 M HCl (40 mL) was added. The resulting solid was filtered and dried for 24 h in vacuo (3.11 g, 8.34 mmol, 80%). $C_{21}H_{15}N_3O_4$ (373.37): calcd. C 67.56, H 4.05, N 11.25; found C 67.76, H 3.85, N 11.14. ^1H NMR ([D$_6$]DMSO): δ = 6.90 (d, 1 H), 7.00−7.04 (m, 3 H), 7.37 (m, 2 H), 7.55 (d, 1 H), 7.58 (d, 2 H), 8.02 (d, 2 H), 8.08 (d, 1 H) 10.05 (s, OH), 10.81 (s, OH), 13.20 (broad, OH) ppm. ^{13}C NMR ([D$_6$]DMSO): δ = 113.6, 114.4, 116.2 (CH), 117.0 (CH), 119.4 (CH), 119.6 (CH), 123.2 (2 CH), 126.7 (CH), 130.2 (2 CH), 130.5, 131.0 (CH), 131.4 (CH), 132.5, 141.2 (CH), 152.0, 155.2, 156.4, 159.9, 166.4 ppm. UV/Vis (H_2O/DMSO, x_{DMSO} = 0.2, pH <2, 25 °C): λ_{max} (ε) = 284 nm (1.5×10^4), 296 (sh). FAB^+-MS: *m*/*z* = 374 (100%, $[H_4L^x]^+$). Single crystals of H_3L^x were grown by slow evaporation of a MeOH solution at room temperature. The solid was allowed to stand exposed to the air to form the monohydrate $H_3L^x{\cdot}H_2O$. $C_{21}H_{17}N_3O_5$ (391.39): calcd. C 64.45 H 4.38, N 10.74; found C 64.11, H 4.60, N 10.44.

4-[3,5-Bis(2-hydroxyphenyl)-1,2,4-triazol-1-yl]benzosulfonic Acid (H_3L^y):[20] 4-Hydrazino-benzosulfonic acid (2.4 g, 12.75 mmol) was suspended in EtOH (300 mL). The solid was dissolved by the addition of one equivalent of NEt_3 (1.29 g, 12.75 mmol). The solution was refluxed, and 2-(2-hydroxyphenyl)-4*H*-3,1-benzoxazin-4-one (3.00 g, 12.5 mmol) was added. Heating was continued for an additional 20 h. The clear solution was then allowed to cool to room temperature, and 6 M aqueous HCl (60 mL) was added. The resulting acidic solution was evaporated under reduced pressure until a white solid started to precipitate. A further portion of 6 M aqueous HCl (60 mL) was added. The solid was then separated by filtration and washed with a small portion of cold H_2O, and dried in vacuo over P_4O_{10} for 24 h (4.37 g, 10.67 mmol, 85%). $C_{20}H_{15}N_3O_5S$ (409.42): calcd. C 58.67, H 3.69, N 10.26; found C 58.99, H 3.90, N 9.88. ^1H NMR ([D$_6$]DMSO): δ = 6.91 (d, 1 H), 6.95−7.01 (m, 2 H), 7.05 (d, 1 H), 7.36−7.40 (m, 2 H), 7.46 (d, 2 H), 7.51 (d, 1 H), 7.72 (d, 2 H), 8.02 (d, 1 H) ppm. ^{13}C NMR (DEPT90, [D$_6$]DMSO): δ = 113.3, 113.4, 116.4 (CH), 117.1 (CH), 119.5 (CH), 119.8 (CH), 123.4 (2 CH), 126.7 (2 CH), 127.4 (CH), 131.2 (CH), 131.9 (CH), 132.9 (CH), 137.7, 148.1, 151.6, 155.5, 156.4, 158.4 ppm. UV/Vis (H_2O; pH <2; 25 °C): λ_{max} (ε) = 255 (1.4×10^4); 295 nm (1.2×10^4). FAB^+-MS: *m*/*z* = 410 (100) $[H_4L^y]^+$. The solid was allowed to stand exposed to the air, which resulted in the formation of the monohydrate $H_3L^y{\cdot}H_2O$. $C_{20}H_{17}N_3O_6S$ (427.44): calcd. C 56.20, H 4.01, N 9.83; found C 56.02, H 4.24, N 9.61.

3,5-Bis(2-hydroxyphenyl)-1-phenyl-1,2,4-triazole (H_2L^z):[43] Phenylhydrazine hydrochloride (1.45 g, 10.03 mmol) was dissolved in boiling EtOH (80 mL). 2-(2-hydroxyphenyl)-4*H*-3,1-benzoxazin-4-one (2.0 g, 8.36 mmol) was added, and the resulting clear yellow solution was heated under reflux for an additional 2 h. The yellow color disappeared, and the colorless solution was allowed to cool to room temperature. Addition of aqueous 1 M HCl (40 mL) resulted in precipitation of a white solid, which was filtered off and dried for 12 h in vacuo. Recrystallization from hot MeOH yielded a crystalline material that was suitable for single-crystal X-ray analysis. Yield: (1.72 g, 5.23 mmol, 62.5%). $C_{20}H_{15}N_3O_2$ (329.36): calcd. C 72.94, H 4.59, N 12.76; found C 72.61, H 4.36, N 12.64.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

^{1}H NMR ([D$_6$]DMSO): δ = 6.89 (d, 1 H), 6.94 (t, 1 H), 6.98−7.04 (m, 2 H), 7.37 (t, 2 H), 7.42−7.48 (m, 6 H), 7.85 (d, 1 H), 9.88 (s, OH), 10.71 (s, OH) ppm. ^{13}C NMR ([D$_6$]DMSO): δ = 113.7, 114.5, 116.0, 116.9, 119.1, 119.4, 123.6 (2 CH), 126.5, 128.5, 129.0 (2 CH), 130.8, 131.1, 132.1, 137.7, 151.6, 155.3, 156.2, 159.4 ppm. UV/Vis (H$_2$O/DMSO, x_{DMSO} = 0.2; pH <7; 25 °C): λ_{max} (ε) = 255 (1.5 × 10^4); 300 nm (1.2 × 10^4). MS-EI$^+$: m/z = 329.4 (100) [H$_2$L^z]$^+$.

Na[Fe(L^z)$_2$]·2H$_2$O·C$_2$H$_5$OH: FeCl$_3$ (324 mg, 2 mmol) dissolved in abs. EtOH (15 mL) was added to a solution of H$_2$L^z (660 mg, 2 mmol) in ethanol (15 mL). The resulting solution turned deep purple, indicating the formation of the 1:1 complex [Fe(L^z)]$^+$. In a separate reaction, solid Na was added to abs. EtOH to saturation.This NaOEt solution (1 mL) was then layered with the Fe^{III}−L^x solution (0.5 mL). After some hours, the deposition of deep red crystals was observed at the boundary of the two phases. It is important that the crystals remained in this intermediate medium and do not sink into the NaOEt solution. They were subsequently removed and immediately cooled to 100 K for the X-ray diffraction study. The single crystal analysis established the composition as Na[Fe(L^z)$_2$]·4C$_2$H$_5$OH. However, the crystal disintegrated rapidly and the compound that formed had the composition Na[Fe(L^z)]·2H$_2$O·C$_2$H$_5$OH. C$_{42}$H$_{36}$FeN$_6$NaO$_7$ (815.63): calcd. C 61.85, H 4.45, N 10.30; found C 62.49, H 4.15, N 10.02. FAB$^+$-MS: m/z = 709.5−714.5 (20%, superposition of [Fe(L^z)$_2$]$^+$, [Fe(L^z)(HL^z)]$^+$, [Fe(HL^z)$_2$]$^+$), 731.5−736.5 (100%, superposition of [NaFe(L^z)$_2$]$^+$ and [NaFe(L^z)(HL^z)]$^+$), 754.5−758.5 (79%, [Fe(L^z)$_2$(EtOH)]$^+$).

Na[Al(L^z)$_2$]·H$_2$O·C$_2$H$_5$OH: The procedure reported for the preparation of the corresponding Fe^{III} complex was used. Single crystals of composition Na[Al(L^z)$_2$]·4C$_2$H$_5$OH were obtained. They disintegrated rapidly to form Na[Al(L^z)$_2$]·H$_2$O·C$_2$H$_5$OH. C$_{42}$H$_{34}$AlN$_6$NaO$_6$ (768.75): calcd. C 65.62, H 4.46, N 10.93; found C 65.73, H 4.20, N 10.56.

Cu(L^z):[21] CuBr$_2$ (223 mg, 1 mmol) was added to a solution of H$_2$L^z (329 mg, 1 mmol) in EtOH (10 mL). The mixture was stirred until a green solid precipitated. The precipitation was completed by adding a concentrated solution of NaOMe in MeOH. Yield 290 mg (742 μmol, 74%). C$_{20}$H$_{13}$CuN$_3$O$_2$ (390.89): calcd. C 61.46, H 3.35, N 10.75; found C 61.96, H 3.35, N 10.73.

[Cu(L^z)(pyridine)]$_2$: The procedure, reported by Uhlemann and coworkers[44] for the preparation of a Cu^{II} complex with a related tridentate [O,N,O]-ligand, was used with some minor modifications: Solid Cu(L^z) (290 mg, 742 μmol) was dissolved in boiling pyridine (20 mL). This solution (2 mL) was mixed with MeOH (1 mL). H$_2$O (100 μL) was then layered on the resulting green solution. Dark green crystals of [Cu(L^z)(pyridine)]$_2$ suitable for single-crystal X-ray analysis grew within 24 h at 4 °C.

Potentiometric Measurements: All titrations were carried out at an ionic strength of 0.1 M (KCl or KNO$_3$) using a Metrohm 665 piston burette, a Metrohm 6.0222.100 glass electrode with an incorporated Ag/AgCl reference (aqueous), and a Metrohm 713 pH/mV meter. The pH meter and the piston burette were controlled by a PC.[45] The samples (50 mL) were placed in a double-jacketed beaker, and the temperature was maintained at 25.0 ± 0.1 °C using a Lauda ecoline103 thermostat. KOH (0.10 M, Merck Titrisol) having the same H$_2$O/DMSO molar ratio as the corresponding sample solution was used as titrant. The H$_2$O/DMSO samples were prepared using published values of the partial molar volumes of the two components (the H$_2$O/DMSO mixtures show a significant deviation from ideal behavior).[46] Titrations of the Fe^{II} complexes were performed under Ar, which was scrubbed with an alkaline solution of pyrogallol to remove traces of O$_2$. The other titrations were performed under N$_2$, which was passed through a 0.1 M aqueous KCl solution. The apparent ionization constant of the different H$_2$O/DMSO media was determined by multiple acid−base titrations. The pK_as of the ligands were measured using solid, analytically pure samples of H$_3$L^x, H$_3$L^y, and H$_2$L^z. The formation constants of the ferric complexes were determined using stock solutions of the ligands (0.01 M), which were standardized by acid−base titrations, and stock solutions of Fe^{III}, which were standardized photometrically as tris-phenanthroline-Fe^{II}.[47] Additional acid (HCl or HNO$_3$) was added to the Fe^{III} stock solutions to prevent partial hydrolysis prior to the titration. Complex formation with Fe^{III} was found to be sluggish, and additional back titrations were performed to ensure complete equilibration. A measuring time of 800−920 s per point proved necessary to avoid a significant hysteresis. Total ligand and total Fe concentrations ranged from 5×10^{-4} to 2×10^{-3} M.[48]

Spectrophotometric Titrations: The titration cell used for potentiometry was equipped with an immersion probe (HELLMA), which was connected to a diode array spectrophotometer (J&M, TIDAS-UV/NIR/100−1). A PC was used to trigger the recording of a spectrum just prior to the addition of each new aliquot of titrant.[45] For the pK_a determination of H$_3$L^x, H$_3$L^y, and H$_2$L^z, the total ligand concentration was about 10^{-5}−10^{-4} M, and absorption data in the range 250 < λ < 400 nm were collected. For the formation constants of the Fe^{III} complexes, total [Fe] was in the range 9.1×10^{-5}−3.5×10^{-4} M, and total [L] in the range 9.1×10^{-5}−9.7×10^{-4} M. The p$K_{a,1}$ of H$_3$L^y and the formation constants of [Fe(HL^x)]$^+$, [Fe(L^y)], and [Fe(L^z)]$^+$ were determined by a batch method with 10−40 individually sealed 10-mL samples in the range 1 < pH < 2 (25.0 °C) allowing an equilibration time of 24 h.[48]

Calculations of Equilibrium Constants: The computer programs HYPERQUAD[49] and SPECFIT[50] were used to evaluate the potentiometric and spectrophotometric data, respectively. All equilibrium constants were calculated as concentration constants, and pH was defined as −log [H$^+$]. For pure aqueous solutions, a pK_w of 13.78 was used.[36] In H$_2$O/DMSO solutions, the apparent ionization constant Q_c = [H$^+$]×[OH$^-$] depended linearly on x_{DMSO} in the range 0.1 ≤ x_{DMSO} ≤ 0.2 with pQ_c = 14.65 (x_{DMSO} = 0.10) and pQ_c = 15.59 (x_{DMSO} = 0.20). These values are in good agreement with those reported in the literature.[27] A graphical representation of pQ_c versus x_{DMSO} is shown in the supporting information (Figure S2). The pK_w (or pQ_c) and the total concentrations of the reactants were always treated as fixed values. Additionally, the protonation constants of the ligands were fixed when refining formation constants of metal-containing species. Because Fe(NH$_4$)$_2$(SO$_4$)$_2$·6H$_2$O was used as a Fe^{II} source, the pK_a of NH$_4^+$ was determined to be 8.90 (x_{DMSO} = 0.2). However, the formation of [Fe^{II}(L^y)]$^-$, which was investigated in the range of 5.9 < pH < 6.9, did not interfere with the deprotonation of NH$_4^+$. For the evaluation of the spectrophotometric titrations, the spectrum of free Fe^{3+} was measured separately for each H$_2$O/DMSO ratio, and was then imported and treated as fixed during refinement. Only absorption data with λ >400 nm were used for the evaluation of metal complex formation, and the free ligands and their protonation products could therefore be considered as colorless (see Figures S3 and S4).

Electrochemistry: Cyclic voltammograms were recorded in H$_2$O or H$_2$O/DMSO (x_{DMSO} = 0.2) using 0.1 M KCl as supporting electrolyte at ambient temperature (23 ± 3 °C). A BAS C2 cell equipped with a BAS 100B/W 2 potentiostat, a Pt counter electrode, and an

Ag/AgCl reference electrode was used. The total iron concentration was 2.5 mM. Measurements at pH <4 ($E > -200$ mV vs. Ag/AgCl) were performed using a Pt working electrode. For the high pH samples (pH >6, $E < -400$ mV vs. Ag/AgCl) a hanging Hg drop working electrode was used.

Crystal Structure Determination:[51] X-ray diffraction data of H_3L^x (215 K), $Na[Fe(L^z)_2]\cdot 4EtOH$ (293 K),[23] and $[Cu(L^z)(pyridine)]_2$ (293 K) were collected on a STOE IPDS diffractometer. Data collection of $Na[Al(L^z)_2]\cdot 4EtOH$ was performed on a Siemens SMART CCD diffractometer at 293(2) K. Additionally, a data set of the Fe complex was collected at 100(2) K on the SMART CCD diffractometer. Graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) was used for all structures. Crystallographic data for H_3L^x, the Fe complex at 100 K, and the Cu complex are summarized in Table 4. The Al complex proved to be isotypic with the Fe complex; however, the reflections were rather weak, and the data could not be refined satisfactorily.[24] All data sets were corrected for Lorentz and polarization effects, and an absorption correction was applied to the data of the Fe complex collected at 100 K. Minimal and maximal transmission factors were 0.5567 and 0.9625. All structures were solved by direct methods (SHELXS-97) and refined by full-matrix least-squares calculations on F^2 (SHELXL-97).[52] Anisotropic displacement parameters were refined for all non-hydrogen atoms of H_3L^x and $[Cu(L^z)(pyridine)]_2$. In the low-temperature structure of the Fe complex, the $[Fe(L^z)_2]^-$ anion was modeled as a superposition of two orientations, having the Fe center, the phenoxo rings, and the C−N−C moieties of the triazole rings in common. For the two outer nitrogen atoms (N2 and N3) and the peripheral phenyl ring, a major (66%) and a minor (34%) component were located. Non-hydrogen atoms of the nondisordered part and of the major component (except N2 and N3) of the anion, as well as the Na position and the C and O positions of a nondisordered EtOH molecule were refined with anisotropic displacement parameters. All C and N atoms of the minor component, N2 and N3 of the major component, and the C and O position of a second, disordered EtOH molecule were refined isotropically. The hydroxy hydrogen atom H(80) of the nondisordered EtOH was located and refined isotropically with $U_{iso} = 1.3 \times U_{eq}$ of the oxygen atom. All other H atom positions of the two metal complexes were calculated (riding model). Isotropic displacement parameters were used with $U_{iso} = 1.5 \times U_{eq}$(C) for methyl groups and $U_{iso} = 1.2 \times U_{eq}$(C) for all other hydrogen atoms. The H atom positions of H_3L^x could all be located. They were successfully refined with variable isotropic displacement parameters.

Acknowledgments

X-ray diffraction data for H_3L^x (ICL670), $Na[Fe(L^z)_2]\cdot 4EtOH$ (293 K) and $[Cu(L^z)(pyridine)]_2$ were recorded by Dr. Volker Huch (Saarbrücken). The structure of $[Cu(L^z)(pyridine)]_2$ was solved and refined by Dr. Jürgen Sander (Saarbrücken). Some of the CV measurements were performed by Michael Krämer (Saarbrücken). We thank Prof. G. Schwitzgebel (Saarbrücken, retired) for helpful discussions in interpreting the CV measurements, and Dr. Peter Osvath (Melbourne) for valuable advice.

Coordination Chemistry and Asymmetric Catalysis with a Chiral Diphosphonite

Jarl Ivar van der Vlugt,[a] Jos M. J. Paulusse,[a] Eric J. Zijp,[a] Jason A. Tijmensen,[a] Allison M. Mills,[b] Anthony L. Spek,[b] Carmen Claver,[c] and Dieter Vogt*[a]

Keywords: Diphosphonite compounds / Asymmetric hydrogenation / Palladium / Rhodium / Asymmetric hydroformulation / Enantioselectivity

The improved synthesis of the chiral diphosphonite, XantBino (**1**), based on a xanthene backbone and bearing chiral binaphthyl groups on both P-atoms is described together with its Pd^{II} and Rh^{I} complexes. The ^{31}P NMR spectra of both complexes point out that the two phosphorus atoms are chemically inequivalent. The complex *cis*-[$PdCl_2$(**1**)] (**2**) is structurally characterized by NMR spectroscopy and X-ray crystallography. The molecular structure reveals an unusually small bite angle for this member of the xantphos family of only 100°. The rhodium-catalyzed asymmetric hydroformylation of styrene and vinyl acetate as well as the asymmetric hydrogenation of methyl (Z)-2-acetamidocinnamate, applying this chiral diphosphonite **1**, are described. Low enantiomeric excesses are obtained in the asymmetric hydroformylation, while use of the catalyst precursor [Rh(cod)(**1**)]BF_4 (**3**) results in a promising enantiomeric excess in the Rh-catalyzed asymmetric hydrogenation.

Introduction

The rhodium-catalyzed asymmetric hydroformylation of vinylarenes, with styrene as a model substrate, using rhodium-based catalysts, is a typical benchmark reaction for the comparison of new catalyst systems.[1] A number of ligand classes have been applied in this reaction, aiming at a thorough understanding of both the kinetics and the origin of enantioselectivity, for example, diphosphanes,[2] phosphane-phosphites,[3] diphosphites,[4] aminophosphane-phosphinites,[5] aminophosphanes,[6] and other bifunctional systems.[7] However, only few catalytic systems show satisfactory enantioselectivity for the desired branched aldehyde, with BINAPHOS ($\mathbf{L_1}$) as the current benchmark ligand in many respects (Figure 1). Phosphonites have been largely overlooked in homogeneous catalysis to date. Recently, some reports have appeared on diphosphonites in asymmetric hydrogenation[8] as well as in hydroboration,[9] making use of several backbones. Next to this, monophosphonites have attracted some attention, especially for the asymmetric hydrogenation of enamides,[8c] the copper-catalyzed addition of diethylzinc to enones,[10] and the hydroformylation of octenes.[11] Little precedent exists on the application of (chiral) diphosphonites in the transition metal catalyzed hydroformylation of alkenes or vinyl arenes. Dahlenburg and coworkers reported on chiral dialkyl-derived diphosphonites $\mathbf{L_2}$, their platinum complexes, and the Pt/Sn-catalyzed hydroformylation of styrene, but only very low enantioselectivities were obtained.[12] The groups of Schmutzler and Börner published a joint study on calix[4]arene-based achiral diphosphonites $\mathbf{L_2}$ in the Rh-catalyzed hydroformylation of terminal alkenes. The regioselectivities remained well below 2, indicating only monodentate behavior of these ligands systems.[13]

We have previously reported on the use of chiral xanthene-based diphosphonites in the asymmetric hydrocyanation of vinyl arenes that showed good enantioselectivities of up to 63% for 4-isobutylstyrene.[14] We recently published on the synthesis and use of sterically constrained achiral diphosphonites $\mathbf{L_4}$ in the rhodium-catalyzed hydroformylation of alkenes and showed that these systems are well-suited for the conversion of 2-butene into *n*-pentanal.[15] Together with our studies on the coordination chemistry of these xanthene-derived diphosphonites towards various transition metals,[16] this prompted us to explore the potential of chiral diphosphonite **1** in various asymmetric catalytic reactions. In this paper we report on the improved synthesis of compound **1**, its coordination with palladium and

rhodium, and the use of this ligand in the rhodium-catalyzed asymmetric hydroformylation of styrene and vinyl acetate and in the asymmetric hydrogenation of methyl (*Z*)-2-acetamidocinnamate (Figure 2).

Results and Discussion

Synthesis of Diphosphonite 1 and Its Dichloropalladium Complex 2

Diphosphonite **1** was prepared in a straightforward manner, using a two-step procedure, as illustrated in Scheme 1. The [bis(diethylamino)]diphosphonite was derived from the commercial starting material 9,9-dimethylxanthene in mod-

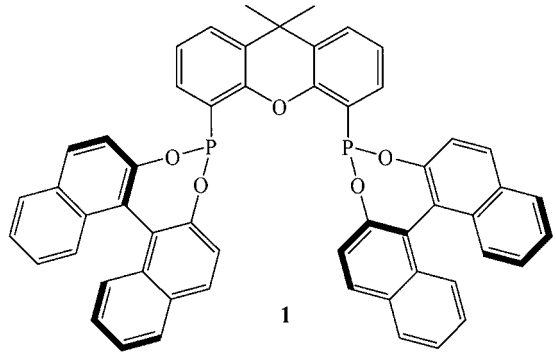

Figure 2. Chiral xanthene-based diphosphonite used in this study

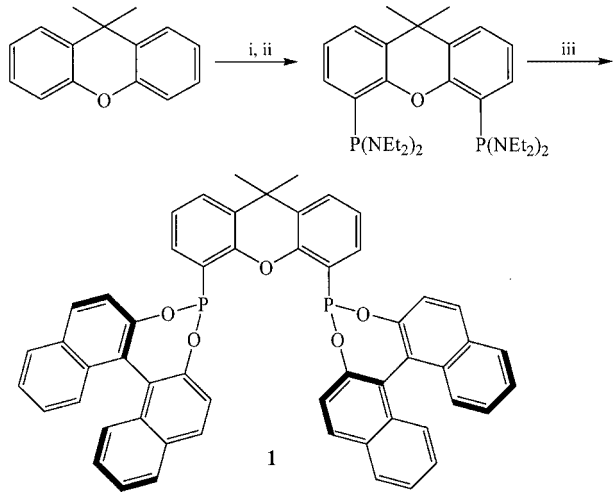

Scheme 1. Synthetic route to compound **1**: i) *n*BuLi, TMEDA, Et_2O, −40 °C, 16 h; ii) $ClP(NEt_2)_2$, pentane, −60 °C, 16 h.; iii) 2,2′-dihydroxy-1,1′-binaphthyl (2 equiv.), toluene, tetrazole, ΔT, 1 day

erate to good yield.[14] Subsequently, the chiral binaphthyl groups were introduced to obtain the desired chiral diphosphonite. This reaction is catalyzed by tetrazole as protonation agent, which is a slight but important modification of the literature procedure. Addition of tetrazole shortened the reaction time considerably, analogous to the synthesis of sterically constrained diphosphonites previously reported by our group.[15] The pure compound was obtained by layering a solution of the crude product in dichloromethane with acetonitrile. This was omitted in the earlier methodology. In general, the second step led to an unwanted side-product (<10%), most likely the monophosphonite, which justified the crystallization step. The ^{31}P NMR spectrum of the pure compound showed a singlet at $\delta = 178.0$ ppm, which seems remarkably low-field, even for a phosphonite moiety. This value reflects the fact that both electronic factors as well as conformational constraints strongly affect the chemical shift of the ^{31}P nucleus.

We were interested in the detailed coordination behavior of XantBino (**1**) towards palladium and rhodium. Previously, only the bischelate $Ni(\mathbf{1})_2$ was described.[14] From the reaction of $PdCl_2(cod)$ with ligand (*R*,*R*)-**1** at room temperature, a yellow compound was obtained, for which the ^{31}P NMR spectrum shows two doublets at $\delta = 143.1$ ppm

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and 137.4 ppm. The observed coupling constant $J_{P\text{-}P}$ is 46.5 Hz, apparently indicating that the phosphorus atoms are chemically inequivalent. This is attributed to the chiral, bulky binaphthyl units. From the ^{1}H NMR spectrum, it appears that the methyl groups in the backbone are also inequivalent, indicating that the aromatic skeleton of the xanthene is bent.[14,17]

Single crystals suitable for X-ray analysis were grown by layering a dichloromethane solution of complex **2** with acetonitrile. The molecular structure of *cis*-[$PdCl_2$(**1**)] is presented in Figure 3, together with selected bond lengths and angles. It is evident that ligand **1** acts as a bidentate ligand, coordinating in a *cis*-fashion to the palladium atom.

The coordination around the central palladium atom is distorted square-planar, with a P^1-Pd-P^2 angle of 99.99(3)°, while the $Cl^1-Pd-Cl^2$ angle is 90.15(4)°. There are few examples on palladium diphosphonite complexes known in literature. However, the bond lengths for Pd−P [$Pd-P^1$ is 2.2449(9) Å and $Pd-P^2$ is 2.2532(9) Å] and Pd−Cl [$Pd-Cl^1$ is 2.3412(10) Å and $Pd-Cl^2$ is 2.3442(9) Å] are normal, in agreement with those found by Agbossou[18] and Schmutzler.[19] Compared with crystal structures of Pd complexes known for xanthene diphosphane ligands, the bite angle of 100° for ligand **1** is unusually small. For instance, we previously reported on *trans*-coordinated diphosphonites[16] and both van Leeuwen et al.[20] and Buchwald et al.[21] reported on *trans*-Pd(Xantphos) complexes. Only in the case of Pd^0 complexes or with cationic palladium species has *cis*-coordination of Xantphos been observed by X-ray crystallography.[20,22] In complex **2**, the angles $Pd-P^1-C^{41}$ and $Pd-P^2-C^{54}$ were 109.87(11)° and 108.57(12)°, respectively (Figure 4). The dihedral angle between the metal plane $Cl^1-Pd-Cl^2$ and the ligand plane $P^1-P^2-C^{41}$ is 115.7°, indicating that the palladium is actually positioned outside the plane defined by the backbone and the phosphorus atoms, as illustrated in This is quite unusual for *cis*-Pd-diphosphorus complexes. A similar structural disposition of the metal atom, together with a small ligand bite angle, was found for an unexpected *ortho*-

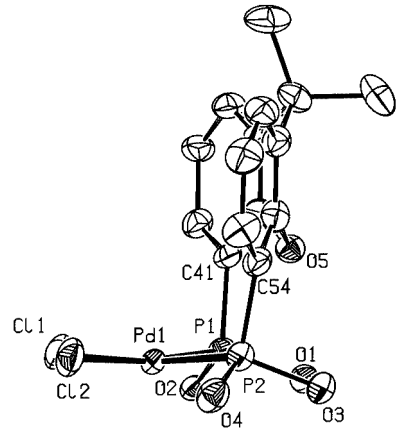

Figure 4. Illustration of the geometry around the square-planar palladium atom in complex **2**, showing the dihedral angle between the metal plane and the ligand plane

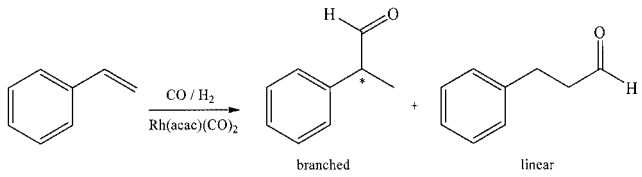
Figure 3. metallated Pd-diphosphonite species described previously by our group.[16]

The structure of complex **2** also bears close resemblance to the molecular structures for the related platinum complex of ligand **1**, which will be communicated elsewhere,[23] as well as for *cis*-[$PtCl_2$(Xantphos)].[24] This indicates that such dispositioning of the metal atom is highly favored in the crystal packing regardless of the metal atom involved. This phenomenon must therefore be based on steric crowding induced by the binaphthyl units. The dihedral angle of the two aromatic rings in the xanthene backbone is found to be 107.8°. The distance between the two phosphorus atoms is 3.4455(12) Å, while the distance between the palladium atom and the oxygen atom in the backbone is 3.284(2) Å, which is too long to expect any interaction.[25]

When ligand (*R*,*R*)-**1** was reacted with Rh(cod)(acac), the ^{31}P NMR spectrum reveals two doublets of doublets, ascribed to the cationic complex **3**, [Rh(cod)(**1**)]BF_4. The average signals appear at δ = 169.7 ppm and at δ = 161.4 ppm, with coupling constants $^1J_{Rh\text{-}P}$ of 218 Hz and $^2J_{P,P}$ of 24 Hz. Although no further characterization was performed on this compound, the existence of this ABX pattern implies that the two phosphorus atoms are chemically inequivalent in the rhodium complex, as in the palladium case. The Rh−P coupling constant is similar to values reported by Börner,[13] Puddephatt,[26] and Shum,[27] although the latter report dealt with a Rh(acac)-diphosphonite derivative, with a $^1J_{Rh\text{-}P}$ of 266 Hz.

Asymmetric Hydroformylation

In order to evaluate the catalytic properties of enantiomerically pure (*R*,*R*)-**1**, it was applied in the rhodium-catalyzed asymmetric hydroformylation of styrene (Scheme 2). To the best of our knowledge, no reports have appeared on the use of chiral diphosphonite ligands in rhodium-catalyzed asymmetric hydroformylation. As a rhodium precursor, Rh(acac)$(CO)_2$ was used. Before addition of the substrate, the catalytic system was activated for 1 h with 20 bar syngas at the reaction temperature to generate the catalytic resting state.



Scheme 2. General reaction scheme for the Rh-catalyzed hydroformylation of styrene

Several hydroformylation experiments were performed at different synthesis gas pressures (10 and 20 bar) and at different temperatures (40−100 °C). The amount of hydrogenation was usually less than 1% and no other side products were formed. The results obtained are summarized in Table 1. At 40 °C, a pressure of 20 bar instead of 10 bar led to an increase in the reaction rate of approximately 33%. The enantiomeric excess was found to be lower (entry 2 vs. 1). The selectivity for the branched aldehyde remained constant within experimental error. Turnover frequencies were determined at conversion levels of around 20−40% from the linear increase of conversion in time. Several samples were taken throughout the reaction without pressure loss.

The effect of pressure on the reaction rate is more significant at temperatures of 60 °C and higher. In all cases, the initial activity (TOF) is lower at higher pressures. Also, the enantioselectivity is lower at higher pressure. The regioselectivity shows a reverse trend, viz. a positive effect of pressure on the regioselectivity to branched product and a negative influence of the reaction temperature. This is more pronounced at a pressure of 10 bar, as the regioselectivity is only 56% at 100 °C and increases to 81% at 20 bar. In all cases, the enantiomeric excess (*ee*) is poor, with a maximum of 33% at 100 °C.

No attempts were made to modify the ligand system in order to obtain higher enantioselectivity. Goertz et al. already showed that for the asymmetric hydrocyanation, the introduction of bulky substituents in the 3,3′-positions of the binaphthyl units can lead to higher ee's.[14] Buisman et al. observed a similar effect in the asymmetric hydrofor-

mylation of styrene but with diphosphites derived from less rigid backbones.[4e] Furthermore, steric crowding around these positions led to a significant decrease in enantioselectivity.

As with thermodynamic control of the stereoselection, the *ee* decreases when the temperature is increased, and experiments are usually conducted at low temperature.[28–30] There are nonetheless some studies on the rhodium-catalyzed hydroformylation of styrene in which the enantioselectivity increased with increasing temperature.[31–34] Hanson et al. studied the Pt/Sn-catalyzed asymmetric hydroformylation with diamino-substituted versions of the known ligands CHIRAPHOS and BDPP. A linear decrease in the *ee* with temperature was observed using the CHIRAPHOS derivative, while with the BDPP ligand the sign of enantioselection changed with temperature. The (*S*)-enantiomer was formed in excess at low temperature, while the (*R*)-enantiomer was the major product at 60 °C and above. Furthermore, the enantioselectivity of the (*R*)-enantiomer increased with reaction temperature, contradictory to the "normal' behavior seen with CHIRAPHOS. This phenomenon, already discussed by Scharf in a review on dramatic temperature effects on selectivities in catalysis,[35] was explained by the existence of competing pathways of diastereomeric intermediates of a single chelate conformation of the catalyst system, hence indicating kinetic control.

For the catalytic system with ligand **1** we also observed a positive dependency of the enantiomeric excess on the reaction temperature, as illustrated in Figure 5. The highest *ee* of 33% is found at 100 °C and 10 bar. The *ee* is lower at higher pressure (for example, entries 3 and 4 vs. 5 and 6 in Table 1). A discussion on the proposed mechanism for this particular system is discussed hereafter (vide infra).

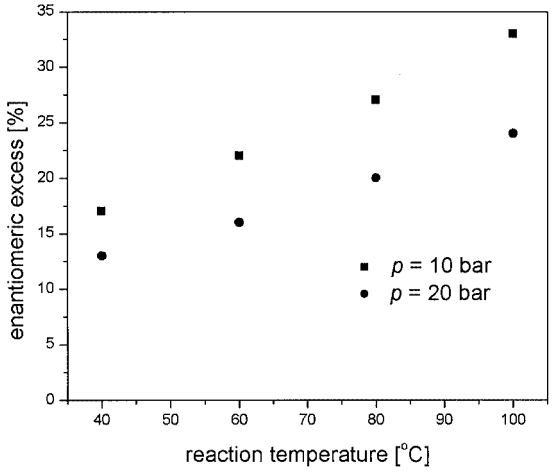

Figure 5. Plot of the positive relationship between the *ee* and the reaction temperature, at two pressures

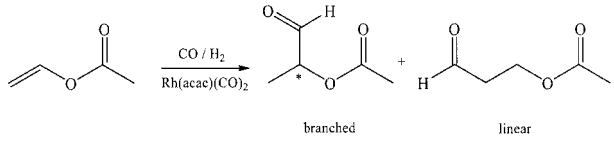
It is known that the results obtained in the rhodium-catalyzed asymmetric hydroformylation of vinyl acetate can be drastically different when applying the same catalytic system.[36] We were therefore interested to see how our Rh/(**1**) system would perform in this specific reaction (Scheme 3). The substrate vinyl acetate differs from styrene in two important aspects, viz. a) vinyl acetate cannot form η^3 complexes and b) the carbonyl oxygen can participate in bonding to the metal.

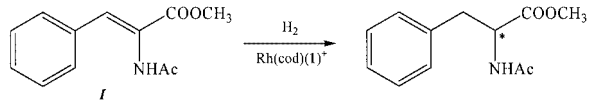


Scheme 3. General reaction scheme for the Rh-catalyzed hydroformylation of vinyl acetate

In all catalytic runs the catalyst was preformed for 1 hour at 60 °C and 10 bar. Reaction at 60 °C and 20 bar of H_2 led to an enantiomeric excess of 51%, which is significantly higher than for styrene. The regioselectivity was extremely high with an b/l ratio exceeding 90. The reaction of vinyl acetate showed the normal temperature dependence; the *ee* dropped to 33% at a reaction temperature of 80 °C. This supports the hypothesis that the η^3-benzyl intermediate might induce kinetic control of the *ee* with styrene as a substrate, leading to an unusual temperature effect. Since this intermediate species is absent in the case of vinyl acetate, no such dependence was found for this substrate.

Asymmetric Hydrogenation

As a third test reaction, diphosphonite **1** was applied in the Rh-catalyzed asymmetric hydrogenation of methyl (*Z*)-2-acetamidocinnamate (**I**) (Scheme 4).[37]



Scheme 4. General reaction scheme for the Rh-catalyzed hydrogenation of methyl (*Z*)-2-acetamidocinnamate

The catalysis was carried out at ambient temperature, with a substrate to rhodium ratio (S/Rh) of 100:1. Before addition of the substrate, a concentrated solution of [Rh(cod)(**1**)]BF_4, complex **3**, in methanol was stirred for 3 hours under 1.2 bar of H_2 in order to preform the catalyst. During catalysis a static H_2 pressure (1.2 or 5 bar) was applied. The reaction rate was constant up to 80% conversion for the reaction that applied 1.2 bar of H_2, indicating that the catalyst system remains stable and active. Also the *ee* remained constant at 54% over the full conversion range. Substrate depletion leads to the expected drop in reaction rate at even higher conversion. Under these nonoptimized conditions, the rates were low (about 40 h^{-1}) relative to rates reported by Reetz[8a] and Claver[8b] for the hydrogenation of different substrates that applied diphosphonites. For the paracyclophane-based diphosphonite system employed by Zanotti-Gerosa,[8c] TON's of up to 2000 h^{-1} were reported.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The enantioselectivity of 54% with the present [Rh(cod)(**1**)]BF_4 system **3** is promising, but still moderate compared with the diphosphonite systems mentioned before (vide supra). The (*S*)-enantiomer is formed in excess with the catalyst containing (*R*,*R*)-(**1**). Similar catalytic results were obtained when applying a pressure of 5 bar H_2. After 2 hours, the conversion reached 94%, with an *ee* of 47%. The higher activity is expected since the concentration of hydrogen is evidently increased.

Temperature Dependence in Asymmetric Hydroformylation of Styrene

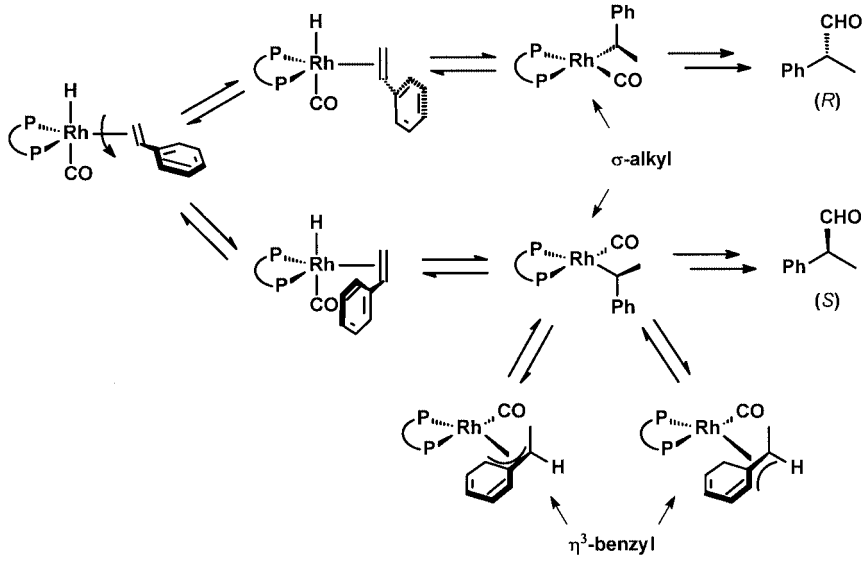
In the case of transition metal catalyzed functionalization of vinyl arenes, participation of η^3-benzyl intermediates (Scheme 5) have been discussed.[38−41] Depending on the ligand influence and on the temperature, pre-equilibria can exist that involve coordination of the substrate, σ-alkyl and η^3-benzyl intermediates. Obviously chirality is already induced during substrate binding but the direction could be influenced by a reversible insertion step. With (our) π-acceptor ligands the η^3-benzyl species could be favored, especially at low temperature giving rise to thermodynamic control over the enantioselection. At higher temperature, the σ-alkyl species could become more important, possibly resulting in a kinetically controlled process. This is in line with the pressure dependence of the *ee* and of the b/l ratio observed (vide supra) as higher CO pressure will slow down pre-equilibria and enhance product formation from intermediates once they are formed. Definitely, this effect is very interesting, and shedding more light on the underlying processes will give new insight into the stereoselection mechanism of the asymmetric hydroformylation. Unfortunately, the available data do not allow any conclusions yet. Detailed studies on this phenomenon are presently underway.

Conclusions

The synthesis of diphosphonite ligand **1** (XantBino) has been improved. The coordination chemistry of this ligand was explored for palladium and rhodium. The molecular structure for *cis*-[$PdCl_2$(**1**)], complex **2**, has been described, revealing an out-of-plane positioning of the metal atom at a dihedral angle of 115°. The bite angle of 100° of the diphosphonite ligand is unusually small for a xanthene-derived phosphorus ligand. The first application of a chiral diphosphonite in the rhodium-catalyzed asymmetric hydroformylation of styrene is reported, leading to high activities with turnover frequencies of up to 1420 h^{-1}. The maximum enantioselectivity obtained was low; however an interesting increase was observed at higher temperature. In the asymmetric hydrogenation of methyl (*Z*)-2-acetamidocinnamate, low activities were found, yet the enantioselectivity was promising, with an enantiomeric excess of 54%, which is encouraging, given the nonoptimized structure and conditions.

Experimental Section

General: Chemicals were purchased from Aldrich, Acros and Merck, and used as received. Synthesis gas (CO/H_2, 1:1) was purchased from Carburos Metalicos. All preparations were carried out under argon using standard Schlenk techniques. Solvents were distilled from sodium/benzophenone (THF, ether, toluene, hexane and ethanol) or calcium hydride (CH_2Cl_2 and $CDCl_3$) prior to use. All glassware was dried by heating under vacuum. The NMR spectra were recorded on a Varian Mercury 400 spectrometer (^1H, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$). Chemical shifts are given in ppm referenced to solvent (^1H, $^{13}C\{^1H\}$) or an 85% aqueous solution of H_3PO_4 ($^{31}P\{^1H\}$). GC spectra were recorded on a Hewlett−Packard 5890A Chromatograph equipped with a Ultra-2 column (styrene) or a Shimadzu 17A with a PONA column (vinyl acetate and hydro-



Scheme 5. Proposed stereoselection mechanism in the rhodium-catalyzed asymmetric hydroformylation of styrene (and other vinyl arenes)

genation). Enantiomeric excesses were determined on a Hewlett−Packard 5890A with a Cyclodex β-I/P column (styrene) a GC Vega 6000 equipped with a Cyclodex β-I/P column (vinyl acetate) or a Shimadzu 2010 equipped with a Chirasil-L-Val column (hydrogenation). $PdCl_2(cod)$,[42] $[Rh(cod)Cl]_2$,[43] and [Rh(cod)(acac)][44] were prepared according to literature procedures.

4,5-Bis[bis(diethylamino)phosphonito]-9,9-dimethylxanthene:[14] 9,9-dimethylxanthene (2.85 g, 13.56 mmol) and *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) (3.32 g, 28.48 mmol) were dissolved in diethyl ether (50 mL). The solution was cooled to −40 °C. *n*-Butyllithium (11.4 mL, 2.5 M in hexane) was added to the mixture dropwise. The solution was allowed to warm up to room temperature and stirred overnight. $ClP(NEt_2)_2$ (6.0 g, 18.99 mmol) was dissolved in diethyl ether (40 mL) and added to the reaction mixture at −80 °C. The solution was allowed to warm up to room temperature and stirred overnight. The solvent was removed by evaporation, and the resulting solid was dissolved in pentane (40 mL) and filtered to remove solids. Excess TMEDA was removed by azeotropic evaporation with toluene (3 × 20 mL). Pentane (10 mL) was added to the solid, and the mixture was stored overnight at −25 °C. The crystals that had formed were separated from the solution by filtration. The crystals were dried in vacuo, yielding a pure dark yellow solid. Yield (4.64 g, 61.3%). ^1H NMR ($CDCl_3$): δ = 7.38 (m, 4 H), 7.02 (d, 2 H), 3.05 (m, 16 H, NCH_2), 1.60 (6 H, CCH_3), 1.00 (m, 24 H, NCH_3) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 91.5 (s) ppm.

(*R*,*R*)-4,5-Bis(dinaphtho[*d*,*f*][1,3,2]dioxaphosphepin-4-yl)-9,9-dimethylxanthene (1): This is a modification of a literature procedure.[14] 4,5-Bis[bis(diethylamino)phosphonito]-9,9-dimethylxanthene (2.00 g, 3.58 mmol) and (*R*)-(+)-2,2′-dihydroxy-1,1′-binaphthyl (2.05 g, 7.16 mmol) were dissolved in toluene (50 mL). A catalytic quantity of tetrazole (about 10 mg, 0.14 mmol) was added as a protonation agent. The solution was heated to 90 °C for 16 hours. Diethylamine formed during the reaction was removed twice under vacuum. After reaction, the solvent was removed in vacuo, and the remaining crude product was dissolved in CH_2Cl_2 (5 mL) and layered with acetonitrile (20 mL). The precipitated product was isolated by filtration and washed with acetonitrile (10 mL). After drying, a yellow powder was obtained as a pure product (0.70 g, 31%). The other enantiomer can be obtained by the same procedure. ^1H NMR ($CDCl_3$): δ = 7.94 (d, ^1J = 8.8 Hz, 2 H, binolH), 7.90 (d, ^1J = 8.0 Hz, 2 H, binolH), 7.84 (d, ^1J = 8.0 Hz, 2 H, binolH), 7.63 (d, ^1J = 8.8 Hz, 2 H, binolH), 7.58 (d, ^1J = 8.8 Hz, 2 H, binolH), 7.55 (dd, ^1J = 8.0, ^2J = 0.8 Hz, 2 H, binolH), 7.42 (t, ^1J = 8.8 Hz, 6 H, ArH), 7.32 (d, ^1J = 8.4 Hz, 2 H, binolH), 7.28 (dquin, 4 H, ^1J = 8.0, ^2J = 1.2 Hz, binolH) 7.18 (d, ^1J = 8.8 Hz, 2 H, binolH), 6.92 (d, ^1J = 8.8 Hz, 2 H, binolH), 6.90 (d, ^1J = 7.2 Hz, 4 H, binolH), 1.79 [s, 6 H, $C(CH_3)_2$] ppm. ^{13}C NMR ($CDCl_3$): δ = 152.6, 149.9, 149.1, 133.0, 132.5, 131.5, 130.9, 130.4, 129.9, 129.0 (d, $J_{P,C}$ = 16.8 Hz), 128.5, 128.2 (d, $J_{P,C}$ = 6.8 Hz), 126.9 (d, $J_{P,C}$ = 3.8 Hz), 125.8 (d, $J_{P,C}$ = 19.0 Hz), 124.6 (d, $J_{P,C}$ = 20.6 Hz), 123.3, 121.9 (d, $J_{P,C}$ = 5.3 Hz), 34.1 [$C(CH_3)_2$], 31.9 [$C(CH_3)_2$] ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 178.0 (s) ppm. $C_{55}H_{36}O_5P_2$ (838.82 g mol^{-1}): calcd. C 78.75, H 4.33; found C 78.52, H 4.18%.

***cis*-[$PdCl_2$((*S*,*S*)-1)] (complex 2):** $PdCl_2(cod)$ (13.2 mg, 46.2 μmol) and (*S*,*S*)-**1** (38.7 mg, 46.2 μmol) were dissolved in CH_2Cl_2 (5 mL) and stirred for 1 hour at room temperature. The solvent was removed in vacuo to leave a light-yellow solid. Yellow block-shaped crystals of complex **2** were grown by slow diffusion of acetonitrile into a dichloromethane solution. ^1H NMR ($CDCl_3$): δ = 8.37 (d, ^1J = 8.8 Hz, 1 H), 8.20 (d, ^1J = 8.8 Hz, 1 H), 8.16 (d, ^1J = 8.8 Hz, 1 H), 8.08 (d, ^1J = 8.8 Hz, 1 H), 8.03 (t, ^1J = 8.8 Hz, 1 H), 8.00 (d, ^1J = 8.8 Hz, 1 H), 7.95 (dd, ^1J = 8.0, ^2J = 4.8 Hz, 2 H), 7.89 (d, ^1J = 8.8 Hz, 1 H), 7.81 (m, 2 H), 7.70 (m, 3 H), 7.65 (dt, ^1J = 8.4, ^2J = 1.2 Hz, 1 H), 7.58 (t, ^1J = 8.8 Hz, 1 H), 7.56 (t, ^1J = 8.0 Hz, 2 H), 7.51 (dd, ^1J = 7.2, ^2J = 1.2 Hz, 1 H), 7.46 (m, 1 H), 7.46 (t, ^1J = 8.0 Hz, 1 H), 7.34 (m, 2 H), 7.23 (m, 2 H), 7.21 (t, ^1J = 6.8 Hz, 1 H), 7.13 (m, 1 H), 7.09 (dd, ^1J = 6.4, ^2J = 2.0 Hz, 1 H), 6.90 (d, ^1J = 8.8 Hz, 1 H), 6.09 (d, ^1J = 9.6 Hz, 1 H), 1.96 (s, 3 H, CCH_3), 1.67 (s, 3 H, CCH_3) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 143.1 (d, $J_{P,P}$ = 46.5 Hz), 137.4 ($J_{P,P}$ = 46.5 Hz) ppm. $C_{55}H_{36}Cl_2O_5P_2Pd$ (1016.14 g mol^{-1}): calcd. C 65.01, H 3.57; found C 65.34, H 3.63%.

[Rh(cod)((*R*,*R*)-1)]BF_4 (complex 3): This is a modification of a generic literature procedure.[45] [Rh(cod)(acac)] (0.047 g, 0.15 mmol) was dissolved in THF (2 mL). HBF_4 (54% solution in diethyl ether) (0.053 g, 0.60 mmol) was added. During addition, the solution colored darker. (*R*,*R*)-**1** (0.126 g, 0.15 mmol) was dissolved in THF (2 mL) and added to the solution, yielding an orange suspension. Diethyl ether (approximately 20 mL) was added, and the mixture was stirred vigorously for 5 minutes. The yellow precipitate formed was isolated and washed with diethyl ether (10 mL). Volatiles were removed in vacuo to leave a yellow/orange solid. Yield 68% (0.14 g, 0.10 mmol). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 169.3 (dd, J_{Rh-P} = 219, J_{P-P} = 24 Hz), 161.1 (dd, J_{Rh-P} = 216, J_{P-P} = 24 Hz.) ppm.

Hydroformylation of Styrene: Reactions were performed using a stainless steel autoclave (75 mL) equipped with an inner glass beaker. Styrene was filtered through neutral alumina before use. Generally, $Rh(acac)(CO)_2$ (3.5 mg, 13.5 μmol) and **1** (1.2 equiv.) were both dissolved in toluene (5 mL), and the combined solution was brought into the preheated autoclave, which was then pressurized to 20 bar of synthesis gas. After the appropriate preformation time, the autoclave was depressurized, and the substrate solution, containing styrene (1.55 mL, 13.5 mmol) in toluene (3.45 mL) was added, and 20 bar of synthesis gas was applied. During catalysis, samples were withdrawn without pressure loss for GC analysis. After reaction, the autoclave was cooled and depressurized, and the reaction mixture taken out. Oxidation of the aldehydes to the carboxylic acids was done directly afterwards, to prevent racemization and to allow for analysis by chiral GC.

Hydroformylation of Vinyl Acetate: Reactions were performed using a stainless steel autoclave (75 mL) equipped with an inner glass beaker. Generally, $Rh(acac)(CO)_2$ (3.0 mg, 11.6 μmol) and **1** (2 equiv.) were both dissolved in benzene (10 mL), and the combined solution was charged into the autoclave, which was then pressurized to 20 bar of synthesis gas and heated to reaction temperature. After preformation, vinyl acetate (1.5 mL, 16.3 mmol) in benzene (5 mL) was added. After reaction, the reaction mixture was quantitatively withdrawn, and a weighed amount of ethyl propionate (0.5 mL, 4.4 mmol) was added. After a quantitative distillation, an aliquot was withdrawn for GC analysis (both for conversion and enantiomeric excess).

Hydrogenation of Methyl (*Z*)-2-Acetamidocinnamate (I): Reactions were carried out in a stainless steel autoclave (75 mL). **3** (11.4 mg, 0.01 mmol) was dissolved in methanol (1 mL), and the solution was activated under 1 bar of H_2 for 2 hours. Methyl (*Z*)-2-acetamidocinnamate (0.22 g, 1.00 mmol) was dissolved in methanol (9 mL), and the substrate solution was charged into the catalyst solution, and the appropriate H_2 pressure was applied. During reaction, samples were withdrawn for GC analysis.

Crystal Structure Determination of 2: Intensity data were collected using graphite-monochromated Mo-K_α radiation, on a Nonius KappaCCD diffractometer. A correction for absorption was con-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sidered unnecessary. The structure was solved by automated direct methods using SHELXS-97,[46] and refined on F^2 using SHELXL-97.[47] The absolute configuration of **2** was established by anomalous dispersion effects to be (*S*,*S*)-[$PdCl_2$(**1**)], Flack parameter 0.013(19). The crystal structure contains voids (1406.0 Å^3/unit cell) filled with disordered solvent molecules (dichloromethane/acetonitrile). Their contribution to the structure factors was ascertained using PLATON/SQUEEZE (499 e/unit cell). All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were constrained to idealized geometries and allowed to ride on their carrier atoms with an isotropic displacement parameter related to the equivalent displacement parameter of their carrier atoms. Structure validation and molecular graphics preparation were performed with the PLATON package.[48] CCDC-231720 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html (or from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk).

Structural and Magnetic Properties of Two Carboxylato-Bridged Manganese(II) Complexes with N-Donor Coligands

Sanjit Konar,[a] Subal Chandra Manna,[a] Ennio Zangrando,[b] Talal Mallah,[c] Joan Ribas,*[d] and Nirmalendu Ray Chaudhuri*[a]

Keywords: Manganese(II) / Dicarboxylates / N-donor ligands / Crystal structure / Magnetic study

Two polymeric Mn^{II} complexes, $[(m\text{-phth})(Mn)(bpp)_2]\cdot 0.5H_2O$ (**1**) and $[(mal)_2(Mn)_2(H_2O)_2(hmt)]$ (**2**) [mal = malonate; hmt = hexamethylenetetramine; bpp = 1,3-bis(4-pyridyl)propane; *m*-phth = 1,3-benzenedicarboxylate] have been synthesized. Complex **1** consists of 1D chains (with monocoordinated bpp) that are held together to form a 2D extended network of hydrogen bonding between lattice water molecules and uncoordinated bpp donors. Variable-temperature magnetic susceptibility data of the complex have been fitted applying the formula used for dinuclear complexes of Mn^{II} ions, considering interdimer interactions (J'). The following parameters were obtained from the best fit: $J = -0.88 \pm 0.02$ cm^{-1}, $J' = -0.1$ cm^{-1} and $g = 1.99 \pm 0.01$. The agreement factor $R = \Sigma(\chi_m T_{obsd.} - \chi_m T_{calcd.})^2/\Sigma(\chi_m T_{calcd.})^2$ is 1.1×10^{-5}. Complex **2** is a 3D polymeric network where *syn/anti*-bridging malonate ligands and Mn^{II} centers are assembled in the form of $[Mn(H_2O)(mal)]_n$ layers, which are further connected by hexamethylenetetramine. The magnetic data have been fitted considering the complex as a pseudo-two-dimensional sheet of Mn^{II} cations and malonate anions since the coupling through the hexamethylenetetramine ligand is almost zero. We have followed two approaches for fitting the data, (a) through the expansion series of Line's equation for the $S = 5/2$ antiferromagnetic quadratic layer and (b) by using the equation based on an infinite 2D square lattice composed of isotropically coupled classical spin $S = 5/2$. Both approaches result in excellent theoretical fits and similar J values of –0.24 cm^{-1} and –0.21 cm^{-1} for the Line's and Curély equations, respectively.

Introduction

Carboxylates are interesting ligands because of their wide variety of coordination modes which make them an attractive choice for the synthesis of polynuclear metal complexes, from discrete dimer to 1D, 2D, or 3D networks.[1] Metal-organic frameworks built up by transition metal cations and dicarboxylate anions are of interest from a variety of viewpoints, including magnetic materials,[2] open-framework structures with micropores for ion exchange or catalysis[3] and also compounds that are biologically relevant.[4] Therefore, a considerable number of transition metal compounds using dicarboxylates have been reported during the last decade.[1–8] In our own investigations we also prepared and characterized several coordination polymers of transition metals containing dicarboxylate groups in combination with multidentate N-donor coligands such as 4,4′-bipyridine, pyrazine, 1,2-bis(4-pyridyl)ethane etc.[5–8] In continuation of our interest in this research field, we have synthesized two new polynuclear Mn^{II}–dicarboxylate complexes. Complex **1**, $[(m\text{-phth})Mn(bpp)_2]\cdot 0.5H_2O$ [bpp = 1,3-bis(4-pyridyl)propane; *m*-phth = 1,3-benzenedicarboxylate], is a 1D chain comprising a rigid dicarboxylate and a flexible N-donor coligand, whereas complex **2**, $[(mal)_2(Mn)_2(H_2O)_2(hmt)]$ [mal = malonate; hmt = hexamethylenetetramine] is a 3D coordination polymer derived from a flexible dicarboxylate and a rigid N-donor coligand. Both complexes show weak antiferromagnetic interactions between the metal centers. Magnetic data have been fitted using different theoretical approaches.

Results and Discussion

Synthesis of the Complexes

The complexes have been synthesized adopting procedures which are schematically given below:

$$MnCl_2 \cdot 4H_2O + 2\ bpp + Na_2(m\text{-phth}) \xrightarrow[\text{water/methanol (2:1)}]{\text{refluxing (1h)}} [(m\text{-phth})Mn(bpp)_2] \cdot 0.5H_2O\ (\mathbf{1}) + 2\ NaCl + 3.5\ H_2O$$

$$2\ MnCl \cdot 4H_2O + hmt + 2\ Na_2(mal) \xrightarrow[\text{water/methanol (2:1)}]{\text{stirring (1h)}} [(mal)_2Mn_2(H_2O)_2(hmt)](\mathbf{2}) + 4\ NaCl + 6\ H_2O$$

Description of the Structures

Complex 1

The structure of **1** consists of 1D polymeric chains (see Figures 1 and 2), built up by distorted octahedral Mn^{II} centers with dicarboxylate anions and *trans*-situated monocoordinated 1,3-bis(4-pyridyl)propane. One of the carboxylate groups of *m*-phthalate acts as a chelating ligand while the other, in a distorted *syn-syn* conformation, as bismonodentate) towards two crystallographically related metal centers, yielding a ribbon running parallel to the *b* axis. The polymer displays centro-symmetric 8- and 16-membered rings with metal−metal separations of 4.397 and 7.276 Å, respectively (Figure 1). The benzene ring forms a dihedral angle of 25.6(1)° with the former carboxylate but is almost coplanar with the other [angle of 8.7(1)°], resulting in a rather undulated chain. Thus the hexacoordinate Mn center possesses an N_2O_4 environment by virtue of four carboxylate oxygen atoms, and two bpp nitrogen donors. In the equatorial plane, the Mn−O(3) and Mn−O(4) distances of 2.113(2) and 2.114(2) Å, respectively, are in the range of those observed in Mn(*m*-phth) structures containing 2,2′-bipy[9] or 1,10-phen[10] ligands. On the other hand, the Mn−O distances generated by the chelating carboxylate are somewhat longer [2.262(2) and 2.288(2) Å] and appear comparable in length with the axial Mn−N bonds [Mn−N(1) = 2.313(3), Mn−N(2) = 2.285(3) Å, Table 1]. The two crystallographically independent flexible bpp ligands assume *gauche*/*anti* and *gauche*/*gauche* conformations, with the torsion angles along the propane chain being 64.3(5), 171.6(4)° and 71.7(11), 67.8(11)°, respectively. A disordered lattice water molecule connects the uncoordinated bpp nitrogen atoms of adjacent chains (N−O distances of ca. 3.0 Å) through hydrogen bonds, promoting the dimensionality of the compound. However, based on the

peak height in the difference Fourier map, an occupancy factor of 0.5 was assigned to this water oxygen atom.

Complex 2

The X-ray structural determination of **2** evidences covalently bonded $[Mn(H_2O)(mal)]_n$ layers connected by hmt ligands to form a 3D polymer. The malonate anion, in its frequently found coordination mode[11−13] acts as a chelating and a bis(monodentate) ligand towards three metal ions. A selection of bond lengths and angles is reported in Table 1, and the structure with the atomic labeling scheme is shown in Figure 3. The octahedral coordination geometry of the metal atom consists of four planar equatorial carboxylate oxygen atoms [Mn−O(1) = 2.154(2) and Mn−O(2) = 2.163(2) Å], while the axial positions are occupied by an axial water molecule and an hmt nitrogen atom with significantly longer bond lengths [Mn−O(1w) = 2.235(3), Mn−N(1) 2.342(3) Å; Table 1]. These distances are similar to those found in the analogous $[Mn_2(mal)_2(4,4'\text{-bipy})(H_2O)_2]_n$,[11] with the exception of a slightly longer Mn−N(hmt) bond in the present case. In the square grids (4,4) of side dimension 5.517 Å, the coordinated water molecule forms two intralayer hydrogen bonds (2.719 Å) with the oxygen atoms of the anion chelating neighboring metal atoms (Figure 4). It is worth noting some features emerging from the 3D structure of the present compound and of the derivative containing the 4,4′-bipy ligands.[11] Figures 5, 6 and 7 show similar $[Mn(H_2O)(mal)]_n$ undulated layers with a zig-zag arrangement of the equatorial coordination planes. However, in the presently reported compound **2**, the sheets are separated by 8.029 Å and stack on top of each other with reference to a symmetry plane. The adamantoid hmt ligands connect the metal ions at 6.29 Å with angular Mn−N(hmt)−Mn links that outline a herringbone arrangement. A view of the packing along axis *c* indicates channels formed by the mal(Mn) layers and hmt ligands, the filled space being 74.8% (Figure 6). On the other hand, in $[Mn_2(mal)_2(4,4'\text{-bipy})(H_2O)_2]_n$, the distance between the mean planes through the sheets is slightly larger, 9.386 Å, but the rod-like 4,4′-bipy spacers cause sliding between the connected layers (Figure 7).

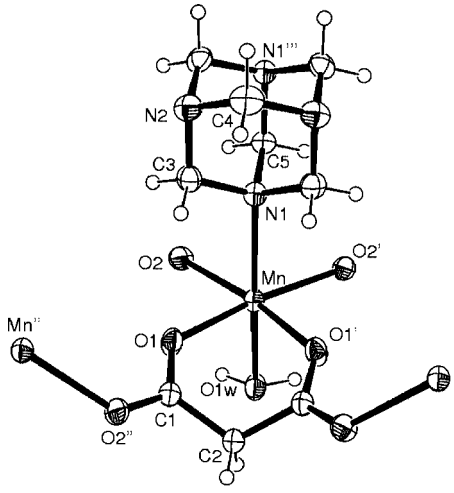

Figure 3. Structural fragment showing the Mn^{II} coordination sphere of **2** (ellipsoid probability at 40%); the hmt base is centered about an *mm2* crystallographic site (the twofold axis passing through C4−C5)

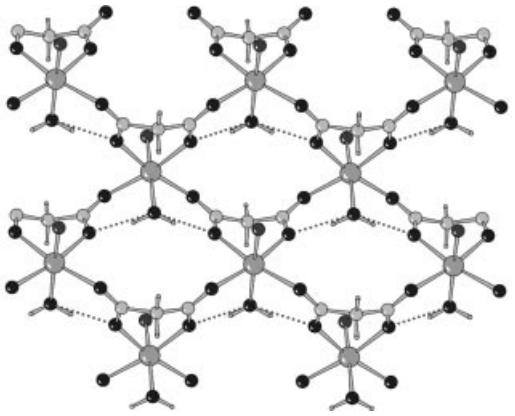

Figure 4. The $[Mn(H_2O)(malonate)]_n$ layer of complex **2** in the *bc* plane with hydrogen bonds (indicated by dotted lines) formed by the water molecules (for hmt only N donors are indicated)

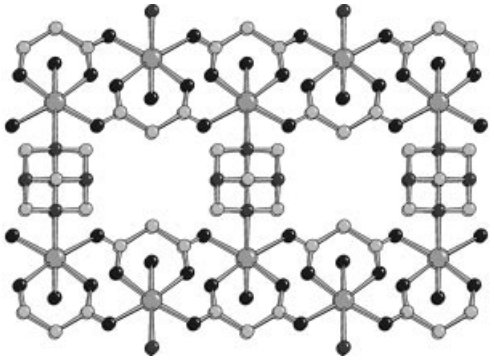

Figure 6. View of crystal packing in **2** along axis *c*, evidencing voids between hmt ligands

Magnetic Properties

Complex 1

The temperature dependence of χ_M (inset) and $\chi_M T$ (χ_M being the magnetic susceptibility for two Mn^{II} ions) for complex **1** is shown in Figure 8. The χ_M value (0.028

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

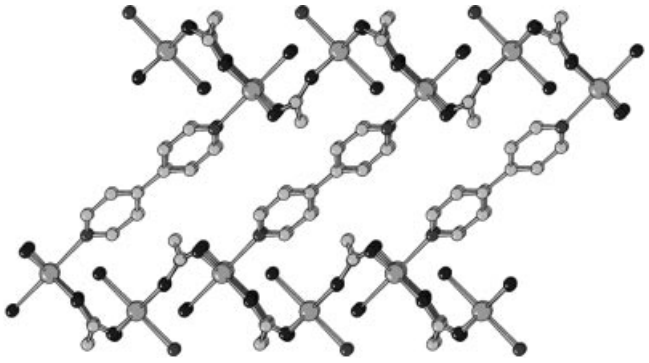

Figure 7. Crystal packing of $[Mn_2(mal)_2(4,4'\text{-bipy})(H_2O)_2]_n$ with layers connected by 4,4′-bipy ligands

cm^3mol^{-1} at 300 K) increases on decreasing the temperature. From room temp. to 100 K there is a smooth increase and from 100 K to 2 K the increase is more pronounced with a maximum at 4 K (χ_M = 0.717 cm^3mol^{-1}). Finally from 4 K to 2 K there is a slight decrease to 0.68 cm^3mol^{-1} at 2 K. χ_MT at 300 K is 8.42 $cm^3mol^{-1}K$, a value which is as expected for two "isolated" Mn^{II} ions. χ_MT is almost invariable up to 100 K and then gradually decreases while cooling to reach 1.36 $cm^3mol^{-1}K$ at 2 K. The shape of these curves is characteristic of the occurrence of weak antiferromagnetic interactions between the Mn^{II} centers.

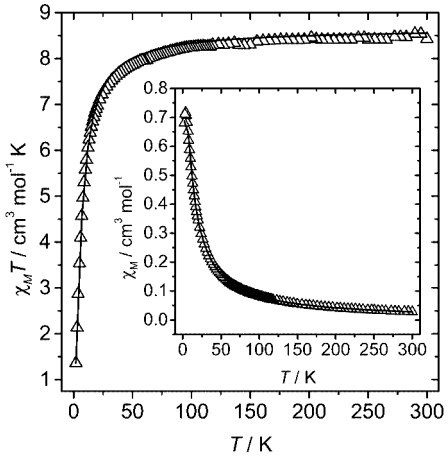

Figure 8. Temperature dependence (300−2 K) of χ_M (inset) and χ_MT (χ_M being the magnetic susceptibility for two Mn^{II} ions) for complex **1**; the solid line represents the best theoretical fit (see text for details)

The structure is one-dimensional, but from a magnetic point of view it can be considered as a dinuclear entity in which two Mn^{II} ions are linked by two distorted *syn-syn*-carboxylate bridges. These entities are linked together by an *m*-phthalate unit [monodentate to one Mn^{II} ion and chelated to the other], through a skeleton of five carbon atoms at distance of 7.276 Å. Thus, the only magnetic pathway is through Mn−O(4)−C(28)−O(3)−Mn in *syn-syn* conformation, which creates weak antiferromagnetic coupling (see below),[1b,14] although weak ferromagnetic coupling has also been reported in some cases.[2e]

Taking into account the pseudo-dinuclearity of **1**, the susceptibility data have been fitted applying the formula for a dinuclear complex of Mn^{II} (S = 5/2),[14] and the initial results were improved by adding a possible J' (intermolecular coupling) using the mean-field approach. The employed Hamiltonian was $H = -JS_1S_2 + g\beta S_zH - zJ'<S_z>S_z$.[1b] The best fit is given by the following parameters: $J = -0.88 \pm 0.02$ cm^{-1}, $J' = -0.1$ cm^{-1} and $g = 1.99 \pm 0.01$. The factor $R = \Sigma(\chi_mT_{obsd.} - \chi_mT_{calcd.})^2/\Sigma(\chi_mT_{calcd.})^2$ is 1.1×10^{-5} corroborating an excellent agreement between experiment and theory.

Complex 2

The temperature dependence of χ_M (inset) and χ_MT (χ_M being the magnetic susceptibility for one Mn^{II} ion) for complex **2** is shown in Figure 9. The χ_M value is 0.0144 cm^3mol^{-1} at 295 K. On decreasing the temperature the value of χ_M increases; from room temperature to 100 K there is a smooth increase and from 100 K to 2 K the increase is more pronounced (χ_M = 0.54 cm^3mol^{-1} at 2 K). In this case there is no maximum in the χ_M curve, as observed in complex **1**; only a tendency to a maximum is shown close to 2 K. χ_MT at 300 K is 4.24 $cm^3mol^{-1}K$, a value which is as expected for an "isolated" Mn^{II} ion. χ_MT is almost invariable up to 100 K (4.10 $cm^3mol^{-1}K$) and gradually decreases while cooling to reach 1.08 $cm^3mol^{-1}K$ at 2 K. The shape of these curves is characteristic of the occurrence of weak antiferromagnetic interactions between the Mn^{II} centers.

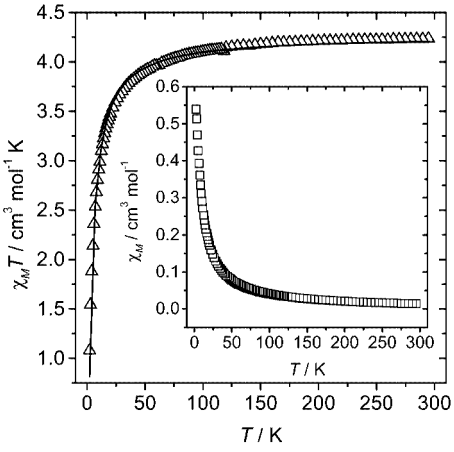

Figure 9. Temperature dependence (300−2 K) of χ_M (inset) and χ_MT (χ_M being the magnetic susceptibility for one Mn^{II} ion) for complex **2**; solid line represents their best theoretical fit (see text for details)

Taking into account that the structure is a three-dimensional network, it is impossible to fit the susceptibility data in order to find an appropriate J value. But, the structure can be considered as two-dimensional sub-lattices, consisting of Mn^{II} ions and malonate bridging ligands (Figure 4), which are linked to each other by hmt ligands. The Mn−N(1) distance [2.342(3) Å] is the longest in the distorted octahedral environment of Mn^{II}, which serves to simplify the calculations. The Mn−O(1) and Mn−O(2) distances [malonate bridge Mn−O(2)−C(1)−O(1)−Mn in *syn-anti* conformation] are shorter [2.154(2) and 2.163(2) Å, respectively]. Thus, owing to these differences in Mn−O/N

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

distances and the large Mn−Mn separation (8.029Å), we can assume that the magnetic coupling through hmt will be almost negligible. Thus, with the pseudo two-dimensional character of **2**, the susceptibility data have been fitted according to two approaches:

a) By the expansion series[15] of Line's equation for an $S = 5/2$ antiferromagnetic quadratic layer, based on the exchange Hamiltonian $H = -\Sigma_{nn} JS_iS_j$, where Σ_{nn} runs over all pairs of nearest-neighbor spins i and j [Equation (1)], where $\theta = kT/|J|S(S+1)$, $C_1 = 4$, $C_2 = 1.448$, $C_3 = 0.228$, $C_4 = 0.262$, $C_5 = 0.119$, $C_6 = 0.017$ and N, g and β have their usual meanings.

$$Ng^2\beta^2/\chi|J| = 3\theta + (\Sigma C_n/\theta^{n-1}) \quad (1)$$

The best fit is obtained with $J = -0.24 \pm 0.03$ cm^{-1} and $g = 1.99 \pm 0.01$. The factor $R = \Sigma(\chi_m T_{obsd.} - \chi_m T_{calcd.})^2/\Sigma(\chi_m T_{calcd.})^2$ is 1.57×10^{-4}, which actually corresponds to an excellent experiment-theory agreement.

b) By means of the analytical expression derived by Curély for an infinite 2D square lattice composed of classical spins ($S = 5/2$), isotropically coupled, and based on the exchange Hamiltonian $H = -\Sigma_{nn} JS_iS_j$, where S_{nn} runs over all pairs of nearest-neighbor spins i and j (Heisenberg couplings)[16] [Equation (2)], where N is the Avogadro number, β the Bohr magneton, k the Boltzmann constant, and u is the well-known Langevin function defined as $u = L[JS(S+1)/kT] = \coth[JS(S+1)/kT] - kT/JS(S+1)$.

$$\chi = [Ng^2\beta^2 S(S+1)(1+u)^2]/[3kT(1-u)^2] \quad (2)$$

The best fit leads to $J = -0.21 \pm 0.01$ cm^{-1}; $g = 1.99 \pm 0.01$. The factor $R = \Sigma(\chi_m T_{obsd.} - \chi_m T_{calcd.})^2/\Sigma(\chi_m T_{calcd.})^2$ is 1.46×10^{-4}, which gives excellent agreement between experimental and theory.

The J values obtained by Line's or Curély expressions are very close: -0.24 cm^{-1} and -0.21 cm^{-1}, respectively. Taking into account that the Curély formula is more accurate and is valid up to 0 K (the Line's formula is only valid up to the maximum of χ_M, approximately), the value of -0.21 cm^{-1} seems to be the most precise for **2**.

Conclusion

As indicated in recent papers on manganese carboxylate, the most common feature for carboxylate bridges is the *syn-syn* mode.[17] The *syn-anti* bridge appears to be rather uncommon for Mn^{II} complexes, and only in a few cases have the magnetic properties been reported to date.[11,17,18] Corbella et al. have recently demonstrated that magnetic interactions through a *syn-anti*-carboxylate bridge in manganese complexes should be very sensitive to small structural changes: Mn−O distances, the O_{anti}−Mn−O_{syn} angle, the planarity of the bridge, etc.[19] A complete Table of this kind of complexes, including the magnetic data, has recently been gathered by Durot et al.[17] In general, *syn-anti* bridges induce very small antiferromagnetic J values because of the mismatch in the orientation of magnetic orbitals. All reported exchange coupling constants are reported to be between 0 cm^{-1} (no coupling) and -2 cm^{-1}.

Thus, although both complexes **1** and **2** have the same kind of bridging ligand; carboxylate in a distorted *syn-syn* conformation for **1** and a *syn-anti* conformation for **2**, the more antiferromagnetic J value in **1** can be ascribed to the smaller Mn−O distances (2.113 and 2.114 Å) in comparison with those found in **2** (2.154 and 2.164 Å). Moreover, in complex **2**, the simultaneous presence of hmt, as the bridging ligand that is further away, allows us to attribute the weak antiferromagnetic coupling only to the carboxylate bridging group. A contribution from the hmt ligand (if any) should be partial and very small.

Experimental Section

Materials: High-purity 1,3-bis(4-pyridyl)propane (bpp) and hexamethylenetetramine (hmt, also known as urotropine) were purchased from Aldrich Chemical Company Inc. and E. Merck (India) Ltd., respectively, and used as received. All the other chemicals were of A.R. grade.

Physical Measurements: Elemental analyses (carbon, hydrogen and nitrogen) were performed using a Perkin−Elmer elemental analyzer. IR spectra (4000−600 cm^{-1}) were taken in KBr pellets using a Jasco FT-IR (model 300E). The magnetic measurements were carried out on polycrystalline samples with a Quantum Design MPMS SQUID magnetometer (applied field 0.1 T) working in the temperature range 300−2 K. Diamagnetic corrections were estimated from Pascal's tables.[1b]

X-ray Structure Determination: Diffraction data of both structures were collected at room temperature with a Nonius DIP-1030H system equipped with a graphite monochromator and Mo-K_α radiation ($\lambda = 0.71073$ Å). A total of 30 frames were collected, each with an exposure time of 20 min with a rotation angle of 6° about φ, the detector being at 90 mm from the crystal. Cell refinement, indexing and scaling for both the data sets were carried out using Mosflm[20] and Scala.[20] The structures were solved by Patterson and Fourier analyses[21] and refined by the full-matrix least-squares method based on F^2 with all observed reflections.[21] Hydrogen atoms were located in idealized geometries. All the calculations were performed by means of the WinGX System, Ver. 1.64.05.[22] The crystal data and structure refinements are given in Table 2. CCDC-231735 (**1**) and -231736 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of [(*m*-phth)Mn(bpp)$_2$]·0.5H$_2$O (1): An aqueous solution (5 mL) of bpp = 1,3-bis(4-pyridyl)propane (2 mmol, 0.369 g) was added dropwise to an aqueous solution (5 mL) of $MnCl_2 \cdot 4H_2O$ (1 mmol, 0.197 g) with constant stirring for 5 min until the mixture became turbid. To this resulting mixture an aqueous solution (5 mL) of disodium *m*-phthalate (1 mmol, 0.210 g) was added dropwise yielding a transparent solution. The reaction mixture was refluxed for 1 h and filtered, the filtrate was kept in a $CaCl_2$ desiccator. After a few days, colorless crystals suitable for X-ray analysis

were obtained. Yield 0.437 g (70%). $C_{34}H_{33}MnN_4O_{4.5}$ (624.58): calcd. C 65.38, H 5.29, N 8.97; found C 65.65, H 5.22, N 8.91. IR: $\tilde{\nu}$ = 3429 (w, v br.), 3071 (w), 2925 (w), 1610 (vs), 1570 (s), 1543 (s), 1447 (m), 1390 (vs), 1222 (w), 1023 (w), 752 (m) 716 (w), 512 (vw) cm^{-1}.

Synthesis of [(mal)$_2$(Mn)$_2$(H$_2$O)$_2$(hmt)] (2): An aqueous solution (5 mL) of hmt (0.5 mmol, 0.070 g) was added dropwise, with constant stirring, to a methanolic solution (5 mL) of $MnCl_2{\cdot}4H_2O$ (1 mmol, 0.197 g). An aqueous solution (5 mL) of disodium malonate (1 mmol, 0.148 g) was added to this solution yielding a colorless compound. The single crystals suitable for X-ray analysis were obtained by allowing a methanolic solution (10 mL) of $MnCl_2{\cdot}4H_2O$ to diffuse into an aqueous layer of disodium malonate and hmt (1:1 mixture) (10 mL) in a tube. The colorless crystals were found at the junction of the two solutions after three weeks. Yield 0.147 g (60%). $C_{12}H_{20}Mn_2N_4O_{10}$ (490.20): calcd. C 29.38, H 4.08, N 11.42; found C 29.65, H 3.97, N 11.61. IR: $\tilde{\nu}$ = 3436−3239 (s, v br.), 2980 (w), 1572 (vs), 1445 (m), 1357 (s), 1225 (m), 1025 (w), 992 (s), 691 (m), 577 (w) cm^{-1}.

Supporting Information: A figure showing the 2D sheet of complex **1** (formed by hydrogen bonding between the lattice water and uncoordinated bpp nitrogen atoms of the adjacent chains) and a table containing the H bond parameters [Å, °] for **1** and **2** have also been deposited.

Tetranuclear Copper(II) and Nickel(II) Complexes Incorporating a New Imidazole-Containing Ligand

Soumen Mukherjee,[a] Thomas Weyhermüller,[a] Eckhard Bill,[a] and Phalguni Chaudhuri*[a]

Keywords: Tetranuclear complexes / Imidazolate bridging / Copper / Nickel / Magnetic properties

The ligating properties of a new tridentate imidazole- and phenol-containing ligand H_3L towards nickel(II) and copper(II) ions have been studied. The ligand generates, in the presence of air and base, iminosemiquinone radical anions, which are not stable in the presence of the metal ions. The amine bond >C–NH– of the parent ligand becomes oxidized to >C=N– bonds upon coordination with Ni^{II} or Cu^{II}. The imidazole N atom becomes deprotonated and the resulting imidazolate group acts as a bridging ligand to generate tetranuclear complexes $[Cu^{II}{}_4L'_4]$ and $[Ni^{II}{}_4L'_4]$, where $[L']^{2-}$ is the dianionic new Schiff base formed after oxidation of the parent ligand. The square-planar tetranickel(II) complex is diamagnetic, as expected, whereas the four copper centres bridged by imidazolate anions in the complex $[Cu^{II}{}_4L'_4]$ are antiferromagnetically exchange coupled (J = –49 cm^{-1}), which has been supported by the EPR measurements. A simple magnetostructural correlation for the imidazolate-bridged copper(II) complexes is yet to emerge.

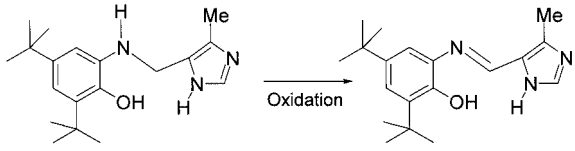
Introduction

Imidazole (ImH) occurs in proteins as part of the side chain of the amino acid histidine and constitutes all or part of the binding sites of various transition metal ions such as Ni^{2+}, Cu^{2+} or Zn^{2+} in a large number of metalloproteins.[1–4] Particularly, copper–imidazole interactions are widely known in biological systems. As for example, the conjugate base imidazolate ion (Im^-) is present as a bridging ligand between copper(II) and zinc(II) in superoxide dismutase,[5] which catalyses the disproportionation of the harmful superoxide radical anion.

In order to understand the unusual spectroscopic properties and the catalytic mechanisms of copper proteins, the development of relatively simple synthetic models of the active sites of copper proteins is of considerable interest. Since imidazole is present in many natural enzymes and proteins, we have been interested for some time in low molecular weight copper complexes with imidazole[6,7] and imidazolate-containing ligands which may serve as structural as well as spectroscopic models for the active site of copper proteins. As a continuation of this program, we report here a new tridentate ligand, 2,4-di-*tert*-butyl-6-[(5-methyl-3*H*-imidazol-4-ylmethyl)amino]phenol (H_3L) and its copper(II) and nickel(II) complexes.

This new ligand affords tetranuclear complexes, $[L'_4Ni^{II}_4]$ (**1**) and $[L'_4Cu^{II}_4(THF)_4]$ (**2**), where $[L']^{2-}$ is the dianionic Schiff-base form of the parent ligand H_3L after oxidation.



H_3L H_2L'

Complexes **1** and **2** have been characterised not only structurally but also by magnetic susceptibility measurements and EPR spectroscopy, in order to identify the exchange coupling for this tetracopper(II) complex **2** and hopefully to add a new brick to the construction of the correlation between structure and exchange coupling in imidazolate-bridged copper(II) complexes.

Results and Discussion

The ligand H_3L has been prepared in a two-step process involving first a Schiff-base condensation of 6-amino-2,4-di-*tert*-butylphenol with the appropriate 5-methyl-3*H*-imidazole-4-carbaldehyde and the subsequent reduction of the Schiff base by $NaBH_4$ in methanol. The ligand H_3L precipitates as a white solid in an aqueous medium. The ligand was fully characterised by ^1H, ^{13}C NMR, and IR spectroscopy, mass spectrometry and microanalysis together with its melting point determination (see Exp. Sect.). The IR bands due to ν(OH), ν(NH), ν(C–H of *tert*-butyl), ν(C=N), ν(C=C) and ν(C–O) are readily identified for the free H_3L which occur as strong peaks at ca. 3500, 3299, 2959, 1615, 1591 and 1233 cm^{-1}, respectively, and serve as a useful indication for complex formation. There is a distinct

[a] Max Planck Institute for Bioinorganic Chemistry, Stiftstraße 34–36, 45470 Mülheim an der Ruhr, E-mail: chaudh@mpi-muelheim.mpg.de

bathochromic shift typical for coordination of the deprotonated ligand to transition metal centres. The EI mass spectrometric molecular peak at m/z = 315 for H_3L is consistent with the elemental analysis.

A methanolic solution of the ligand, made basic by a few drops of triethylamine, is susceptible to aerial oxidation and forms a radical, presumably an iminosemiquinone, as evidenced by the EPR spectrum (Figure 1) at ambient temperature. A simulation of the spectrum yields the hyperfine coupling constants for the nitrogen atom and three protons to be a_N = 4.74 G, $a_{H(1)}$ = 9.30 G and $a_{H(2)}$ = 3.59 G. The simulated g value of 2.0049 clearly shows that the ligand is "noninnocent" and forms radicals in air. This ligand radical is not stable in the presence of a metal centre, which is shown by the X-ray crystal structures of **1** and **2**, confirming the ligand to be present in an iminophenolate form after complexation. The imine >C=N− character of the coordinated ligand $[L']^{2-}$ is also exhibited in the solid-state IR spectra for **1** and **2**; a sharp strong band appears at 1600 cm^{-1} for **1** and 1595cm^{-1} for **2**.

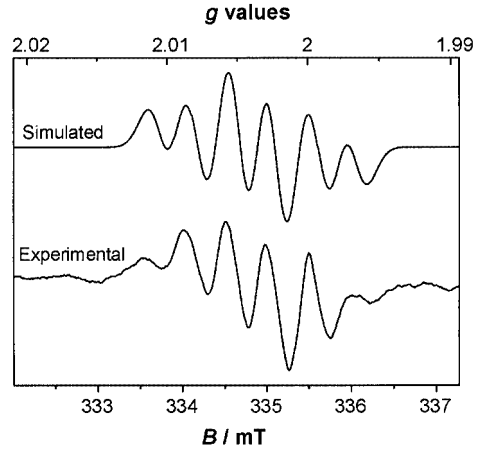


Figure 1. EPR spectrum of the ligand H_3L at room temperature in the presence of triethylamine in methanol

Mass spectrometry in the ESI positive mode (in CH_2Cl_2) is not very helpful in identifying the nuclearity of the nickel(II) complex **1**. The peak at m/z (%) = 683.4 (100) corresponds to the mononuclear species NiL'_2. But for **2**, the Cu^{II} complex, peaks at m/z = 374, 748, 1124 and 1496 with respective isotope distribution clearly show the tetranuclear nature of the copper complex.

Complex **1**, a tetrameric square-planar nickel(II) complex, is diamagnetic as expected, as is evidenced from the magnetic susceptibility as well as the ^1H NMR spectrum. In the ^1H NMR spectrum, the ratio of protons *tert*-butyl/*tert*-butyl/methyl/imine/aromatic/imidazole is 9:9:3:1:2:1, which is to be expected from the oxidized deprotonated ligand (see Exp. Sect.).

Molecular Structure of $[L'_4Ni_4]\cdot 9CH_2Cl_2$ (1)

From a dichloromethane/methanol (1:1) solvent mixture orange red X-ray quality crystals of **1** were obtained and they were subjected to diffractometric studies. The molecule consists of a neutral tetranuclear nickel complex along with 9 CH_2Cl_2 solvent molecules. The neutral molecule with its atom-labelling scheme is shown in Figure 2. Selected bond lengths and angles are listed in Table 1. Each of the nickel centres is in a distorted square-planar geometry with N_2O coordination from the deprotonated ligand and the fourth donor atom being the nitrogen atom of the imidazolate ring originating from the adjacent NiN_2O unit. Worth noting is the short C(8)−N(7) distance of 1.297(11) Å with a >C=N− character indicating oxidation of the >CH_2−NH− bond of the ancillary ligand H_3L. The average Ni−O (phenol), Ni−N (imine), Ni−N (imidazole) and Ni−N (adjacent imidazole) bond lengths of 1.856, 1.850, 1.891 and 1.850 Å, respectively, are similar to those in other square-planar Ni^{II} complexes.[8] The four nickel centres are arranged in the form of a "butterfly" with the Ni(1)−Ni(1A)−Ni(1B) and Ni(1C)−Ni(1A)−Ni(1B) planes forming the "wings" of the butterfly (see b in Figure 2).[9] The dihedral angle between these two planes is 107.7°. All the adjacent Ni···Ni distances are equal with a value of 5.851 Å.

Molecular Structure of $[L'_4Cu_4(THF)_4]$ (2)

Although the analytical data unambiguously show the presence of a CuL′ core as the smallest unit in **2**, the magnetic susceptibility data exhibit a strong temperature dependence with effective moments as 1.52 μ_B at 290 K and 0.09 μB at 2 K, refuting the mononuclear formulation. Hence, an X-ray analysis was undertaken to remove the doubts regarding connectivity. Unfortunately, crystals of **2** obtained from a THF/methanol mixture diffract X-rays very weakly.[10] In spite of the high R factor and large standard deviations due to the severity of the disorder and weakness of the data collected from a poorly diffracting small crystal, the crystal structure analysis of **2** confirmed its tetranuclear nature. Because of its unacceptable quality, we are unable to publish the crystal data in detail. It is not clear how many THF molecules are present in the unit cell. The structure consists of distinct $[L'_4Cu_4(THF)_4]$ molecules (Figure 3).

Selected interatomic distances and angles are given in Table 2. As observed in **1**, oxidation of the ligand occurs at the same position [C(8)−N(7) = 1.31 Å]. The structure consists of a distorted square-pyramidal tetranuclear neutral molecule with the Cu centres forming a "butterfly structure" (Figure 3). A THF molecule occupies the fifth position of the coordination site in each copper centre. The dihedral angle between the plane defined by connecting Cu(1)−Cu(2)−Cu(4) and Cu(3)−Cu(2)−Cu(4) is 150.1°. The average Cu−O (phenol), Cu−N (imine), Cu−N (imidazolate) and Cu−N (imidazolate of adjacent ligand) bond lengths are 1.942 Å, 1.942 Å, 1.992 Å and 1.948 Å, respectively, which are similar to other square-planar/pyramidal Cu^{II} complexes.[6,7,11] It is observed that the Cu(1)−N(10) bond is more elongated than it is for the other coordinating atoms. This tendency is the same for the other copper centres and is due to a Jahn−Teller effect which is present for d^9 systems thus making **2** less symmetric than **1**, a d^8

system; Cu(1) is displaced by 0.11 Å from the mean basal plane of the three nitrogen atoms [N(7), N(10), N(42)] and one oxygen atom [O(1)]. The dihedral angles between the plane N(42)O(1)N(7)N(10) containing the Cu(1) ion and the planes N(42)C(43)C(39)N(40)C(41) and N(10)-C(9)C(13)N(12)C(11) describing the two imidazolate bridging groups are 47.2° and 82.2°, respectively. It is interesting to note that the angle between the Cu(1)−N_{im}(42) and Cu(2)−N_{im}(40) vectors is 142.2° and that between the Cu(1)−N_{im}(10) and Cu(4)−N_{im}(12) vectors is 132.6°. The angle between the planes defined by Cu(1)O(1)N(7)N-(10)N(42) and Cu(2)O(31)N(37)N(40)N(72) is 139.1°.

Magnetochemistry and EPR Studies with 2

The magnetic susceptibility data for a polycrystalline sample of **2** was measured from 2 to 290 K in an applied magnetic field of 1 T to characterise the nature and magnitude of the exchange interaction propagated by the bridging ligands. The Heisenberg spin Hamiltonian used was in the form $\hat{H} = -2J \sum_{ij} \vec{S}_i \cdot \vec{S}_j$ for an isotropic exchange coupling. The experimental magnetic data were simulated using a least-squares fitting computer program[12] with a full-matrix diagonalisation of exchange coupling, Zeeman splitting,

and axial single-ion zero-field interactions $D\vec{S}_z^{\,2}$, if necessary. The susceptibility data were corrected for diamagnetism (Pascal corrections), temperature-independent paramagnetism (TIP) and the presence of paramagnetic monomer impurities (P) in the following way: $\chi_{calcd.} = (1 - P)\chi + \chi_{TIP} + P\chi_{mono}$.

The nature of the μ_{eff} vs. T plot for **2** (Figure 4) shows a behaviour typical for antiferromagnetic spin coupling. The effective moment μ_{eff} decreases monotonically with the decrease in temperature; the values of μ_{eff} are 3.051 μ_B at 290 K and 0.180 μ_B at 2 K. The magnetic data reveal an energetically well-isolated ground state of total spin $S_t = 0$, discernible from the decline of effective moments at temperatures below 100 K. The residual moment of 0.180 μ_B at 2 K is attributed to a monomeric ($S = 1/2$) impurity (2.0%). Monomeric species were also detected in weak abundance in the EPR spectra, as will be mentioned later. The susceptibility data could be simulated considering exchange coupling between adjacent Cu^{II} pairs with local spins ($S = 1/2$), as shown in the inset in Figure 4. The multiplets $|S_A S_B S_t>$ are labelled by the "pair spins", S_A ($\vec{S}_A = \vec{S}_1 + \vec{S}_3$) and S_B ($\vec{S}_B = \vec{S}_2 + \vec{S}_4$). The ground state is a singlet $|S_A S_B S_t> = |110>$ and the first excited state at energy $2J$ is a triplet $|111>$ (Figure 4). The states $|011>$, $|000>$ and $|101>$ are degenerate at energy $4J$ and the highest state at energy $6J$ is a quintuplet $|112>$. In zero field the multiplets remain degenerate in energy with pure magnetic quantum numbers,

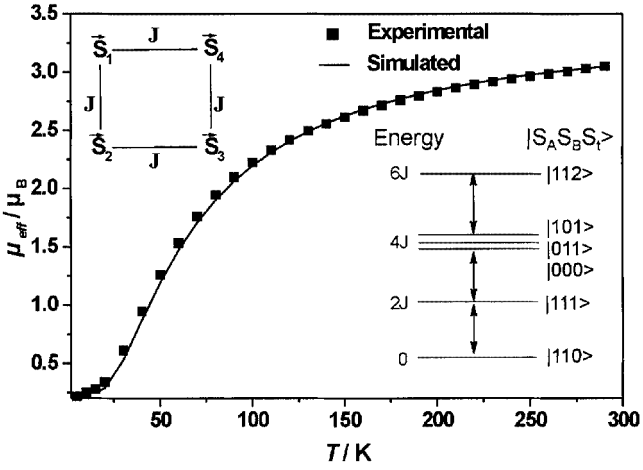

Figure 4. Plot of μ_{eff} vs. T for **2**; the solid line represents the simulated curve; insets: model used to simulate the spin coupling in **2** and corresponding spin states resulting from the spin Hamiltonian used (see text)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

according to their multiplicity. Projections of local spins S_i on the total spin S_t ($\vec{S}_t = \vec{S}_A + \vec{S}_B$)[13] reveal identical g_t values for all multiplets $S_t \neq 0$. The simulation of the experimental susceptibility data for the tetramer yielded an exchange coupling constant $J = -49$ cm^{-1}, $g = 2.022$, a paramagnetic impurity (P: $S = {}^1/_2$) of 2% and a temperature-independent paramagnetism (TIP) of 240×10^{-3} emu.

X-band EPR spectra for **2** in the solid state from 11.7 K to 62.1 K are dominated by a strong almost isotropic signal at $g = 2.08$ which shows the usual Curie behaviour, $I \sim 1/T$, for the given temperature range. Therefore, the strong derivative signal at $g \approx 2$ is attributed to the monomeric paramagnetic impurity (2%) present in the solid-state susceptibility measurements. In addition to the prominent line there are a number of weak signals in the measured field range extending from 50 to 600 mT. Their appearance is typical of integer spin manifolds arising for the exchange-coupled Cu^{II} tetramer, because competing Zeeman and zero-field splitting are expected due to dipolar coupling and anisotropic exchange. As a consequence, the resonances are widely spread over a large field range and the derivative signals appear to be weak (not the intensity). On increasing the temperature, changes in the relative intensities of these features are observed between 150 and 260 mT and between 380 and 600 mT (Figure 5), which is typical of integer spin signals from excited spin multiplets.

In order to elucidate the correlation between the EPR spectra and the spin multiplets of the coupled system, the change of intensity (I) of the derivative peak at 480 mT was scanned over the entire temperature (T) range. As the population of the excited state in the first order is dependent on the Boltzmann function of resonating levels, the product intensity·temperature, $I \cdot T$, was plotted versus temperature (Figure 5b). The fading below 10 K and the strong rise at elevated temperatures prove that the signals arise from excited states and that the ground state is diamagnetic and EPR-silent, in accordance with the susceptibility findings. For quantitative analysis, the experimental data were compared with the theoretical Boltzmann functions derived from the spin-coupling model (Figure 4). It is to be noted that values up to 40 K were taken as line broadening, which occurs above this temperature. The best agreement was obtained for $I_{111}T$, describing the thermal population of the first excited triplet state $|111>$, $I_{111}\ T \approx [\exp(2J/kT)]/Z$, where $Z = 1 + 3\exp(2J/kT) + 7\exp(6J/kT) + 5\exp(12J/kT)$. The solid line is a fit with $J = -42$ cm^{-1}, which is close to the exchange coupling constant of $J = -49$ cm^{-1} evaluated from the susceptibility measurements. Therefore, particular non-Kramers resonance at $B = 480$ mT, and probably the whole complex EPR spectrum in the field range 380−600 mT appears to arise from the first excited triplet state $|111>$ of the tetramer.

In an imidazolate-bridged system, there can be two pathways used to explain the magnetic interaction, viz. the σ- and the π-exchange pathways. Generally, it is agreed that the π orbitals are not involved in the coupling.[7,14] It has been stated that, since the magnetic orbitals are σ-antibonding for square-planar and square-pyramidal complexes, the relevant exchange pathway through the imidazolate bridge is of the σ-type. The imidazolate orbitals responsible for this sort of interaction are essentially parallel to the N−N′ (or C−C) direction.[7,11c]

Several studies have already been reported,[7,11c] in which structural data have been used to find correlations between structure and exchange coupling in imidazolate-bridged copper(II) complexes. Comparison of the numerical data shows that a simple magnetostructural correlation for imidazolate-bridged Cu complexes does not exist. However, as the values of J are independent of θ, the angle between the copper and imidazole coordination planes, a π-exchange pathway can be discarded. It has been concluded from EHMO calculations[11c] that the extent of anti-ferromagnetic coupling will increase when the N−N and other Cu−N bonds are parallel to the imidazolate carbon−carbon bond, thus favoring a σ-exchange pathway. Although the coupling constant for **2** is strong compared with the other complexes, the values of J cannot be strictly attributed to the values of α, the angle between the Cu−N and N−N vectors. This indicates that σ-superexchange cannot be the only mechanism for the exchange coupling for

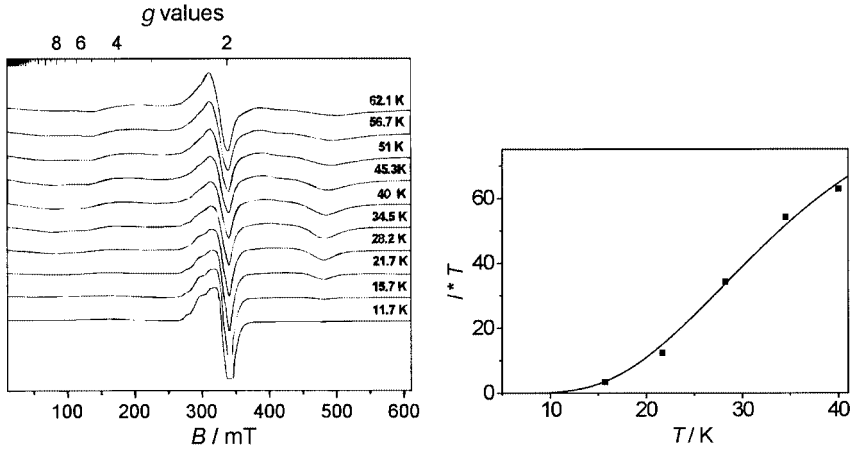

Figure 5. (a) EPR spectra of a powdered sample of **2** recorded as a function of temperature; (b) temperature dependence of the temperature-weighted intensity ($I \cdot T$) of the EPR subspectra; the solid line is the calculated Boltzmann function $I_{111} \cdot T$ with $J = -42$ cm^{-1}

this compound. The presence of ligand−ligand interactions may also play a part in this type of exchange coupling. Recently, a theoretical DFT study[15] on the magneto-structural correlation in imidazolate-bridged dicopper(II) complexes showed that the exchange coupling constant *J* mainly depends on the Cu−*N*−C(Im) bond angle and is insensitive to the variation of the Cu−N(Im) distance and the dihedral angle between the bridged imidazolate ring and copper coordination planes.

Concluding Remarks

The ligating properties of a new tridentate ligand, 2,4-di-*tert*-butyl-6-[(5-methyl-3*H*-imidazol-4-ylmethyl)amino]-phenol containing an imidazole N-donor atom together with a phenol O-donor and amine N-donors towards the nickel(II) and copper(II) centers are described. The imidazole N atom becomes deprotonated and the resulting imidazolate group serves as a bridging ligand to generate tetranuclear complexes of the said metal centres. Although the ligand generates the iminosemiquinone monoanion radical very easily in the presence of a base and air, as evidenced by EPR spectroscopy, the radical form could not be stabilized in the presence of the metal centres. The C−NH bonds from the parent ligand have been oxidized to C=N bonds upon coordination with the Ni^{II} or Cu^{II} centres. The realization that the present phenol as well as imidazole-containing ligand can generate polynuclear complexes highlights the prospect of designing a generic ligand system, which should form polynuclear species with other metal centres.

The imidazolate-bridged copper(II) complexes are, as expected, antiferromagnetically exchange-coupled yielding diamagnetic ground states. No simple magneto-structural correlation has yet emerged for these imidazolate-bridged complexes. The synthesis of more of these imidazolate-bridged copper(II) complexes would therefore be warranted in order to resolve this complex problem of magnetostructural correlation.

Experimental Section

Materials and Physical Measurements: Commercial grade chemicals were used for synthetic purposes, and solvents were distilled and dried before use. Fourier transform IR spectroscopy on KBr pellets was performed with a Perkin−Elmer 2000 FT-IR instrument. Mass spectra were recorded either in the EI or the ESI (in CH_2Cl_2) modes with a Finnigan MAT95 or 8200 spectrometer. Magnetic susceptibilities of the polycrystalline samples were recorded with a SQUID magnetometer (MPMS, Quantum Design) in the 2−290 K temperature range with an applied field of 1 T. Diamagnetic contributions were estimated for each compound by the use of Pascal's constants. ^1H and ^{13}C NMR spectra were recorded using a Bruker ARX 250, or DRX 400 spectrometer. The spectra are referenced to TMS, using the ^{13}C or residual ^1H signals of the deuterated solvents as internal standards. X-band EPR spectra were recorded with a Bruker ESP 300E spectrometer equipped with a helium flow cryostat (Oxford Instruments ESR 910), an NMR field probe (Bruker 035M) and a microwave frequency counter HP 5352B.

X-ray Crystallographic Data Collection and Refinement of the Structures: A single crystal of **1** was coated with perfluoropolyether, picked up with glass fibres, and mounted on a Nonius Kappa-CCD diffractometer equipped with a cryogenic nitrogen cold stream operating at 100(2) K. Graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used. Intensity data were corrected for Lorentz and polarisation effects. The intensity data set of **1** was corrected for absorption with the program SADABS[16] The Siemens SHELXTL software package[17] was used for solution, refinement, and artwork of the structure, and neutral atom scattering factors of the program were used. All structures were solved and refined by direct methods and difference Fourier techniques. Non-hydrogen atoms were refined anisotropically, and hydrogen atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters. Details of data collection and structure refinements are summarized in Table 3. CCDC-236872 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Ligand Synthesis

2,4-Di-*tert*-butyl-6-[(5-methyl-3*H*-imidazol-4-ylmethyl)amino]-phenol (H_3L): 2-Amino-4,6-di-*tert*-butylphenol (2.2 g, 10 mmol) and 5-methyl-3*H*-imidazole-4-carbaldehyde (1.1 g, 10 mmol) were added to deaerated methanol (50 mL) and the resulting solution was refluxed under argon for 2 h. The red solution was cooled and $NaBH_4$ was added portionwise until the solution turned a faint yellow. The precipitation of a white solid was initiated by dropwise addition of water. The white solid was collected by filtration and dried under vacuum. Yield: 2.8 g (89%). M.p. 186 °C. $C_{19}H_{29}N_3O$ (315.5): calcd. C 72.34, H 9.27, N 12.84; found C 71.0, H 9.2, N

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

12.8. ^{1}H NMR ([D$_6$]DMSO): δ = 1.21 (s, 9 H), 1.31 (s, 9 H), 2.15 (s, 3 H), 4.02 (s, 2 H), 6.5 (t, 2 H), 7.4 (s, 1 H) ppm. ^{13}C NMR ([D$_6$]DMSO): δ = 30.0 (s), 34.1 (s), 34.5 (s), 48.6 (s), 107.5 (s), 111.1 (s), 133.2 (s), 136.3 (s), 140.3 (s), 141.9 (s) ppm. IR (KBr): $\tilde{\nu}$ = 3299 s, 2959 s, 1615 s, 1591 s, 1233 s cm^{-1}. EI-MS: *m*/*z* = 315 [M$^+$].

Complex 1 [Ni$_4$L′$_4$]: The ligand H_3L (1 mmol, 0.315 g) was dissolved in 25 mL of deaerated methanol. Solid $Ni(ClO_4)_2 \cdot 6H_2O$ (1 mmol, 0.365 g) along with NEt_3 (0.15 mL) were added to the ligand solution. The resulting orange-red solution was refluxed under argon for 1 h and then stirred in air for 0.5 h, whereupon a microcrystalline orange-red solid precipitated. The solid was filtered, dried in air. Yield: 0.21 g (58%). $C_{76}H_{100}N_{12}Ni_4O_4$ (1480.5): calcd. C 61.66, H 6.81, N 11.35, Ni 1586; found C 58.8, H 5.8, N 10.7, Ni 15.5. IR (KBr): $\tilde{\nu}$ = 2952, 1600, 1474, 1399, 1253, 1130, 861 cm^{-1}. X-ray quality crystals for **1** $[Ni_4L_4] \cdot 9CH_2Cl_2$ were obtained from a mixture of dichloromethane/methanol (1:1).

Complex 2 [Cu$_4$L′$_4$]: The ligand H_3L was dissolved in 15 mL of methanol. Solid $Cu(CH_3COO)_2 \cdot 4H_2O$ (0.5 mmol, 0.10 g) was added to the ligand solution, and the whole solution was made basic by adding NEt_3 (0.15 mL). The resulting light orange-red solution was refluxed for 1 h and then cooled to room temperature, whereupon a red-orange microcrystalline solid precipitated. The microcrystalline solid separated by filtration was recrystallised from a tetrahydrofuran/methanol solvent mixture. Yield: 0.120 g (64%). $C_{76}H_{100}Cu_4N_{12}O_4$ (1499.9): calcd. C 60.86, H 6.72, Cu 16.95, N 11.21; found C 59.8, H 6.6, Cu 17.3, N 11.1. IR (KBr): $\tilde{\nu}$ = 2951, 1595, 1470, 1398, 1257, 1126, 857, 647 cm^{-1}.

NMR Observations of Interligand Interference in the Molecular Motion of Double-Stranded Dinuclear Helicates

Hirohiko Houjou,*[a][‡] Nathanaëlle Schneider,[b] Yoshinobu Nagawa,[a] Masatoshi Kanesato,[a] Romain Ruppert,[b] and Kazuhisa Hiratani[c]

Keywords: DNA / Helical structures / NMR spectroscopy / Palladium / Schiff-base ligands

Double-stranded dinuclear complexes with either twisted or parallel arrangements were obtained by reaction between Schiff-base ligands and Pd^{II} ions. Linear ligands mainly afforded twisted arrangements, while macrocyclic ligands forced the complex to adopt parallel arrangements. In these dinuclear complexes, one isomer could not be converted into the other even upon prolonged heating. The NMR spectra showed that the chemical shifts of the diastereotopic protons can be used as an indicator to distinguish between the arrangements. The NOE cross-peak characteristics of the complexes with twisted arrangements are interpreted with reference to the crystal structure of a Cu^{II} complex as an isostructural model of the Pd^{II} complex. Variable-temperature measurements revealed the rotational interference between the ligands of the counterpart strands, the first time that this has been observed for helically arranged complexes.

Introduction

The spontaneous assembly of coordination compounds is an important tool for the construction of such fascinating architectures as a nanoscale molecule with well-defined polyhedral shape, or an infinite coordination polymer with a regularly arranged cavity.[1−4] Amongst the various three-dimensional structures, the helix is an attractive one to investigate. Many studies on helically arranged complexes have so far served as the foundation of molecular design, synthetic strategy, thermodynamics, kinetics, stereochemistry, and molecular architectonics in metallo-supramolecular chemistry.[5−7] Recently, helical complexes have been studied not only as a subject in basic chemistry, but also as a useful building block for functional materials.[8−12]

There have been many attempts to prepare double- or triple-stranded helical complexes by using metal-directed self-assembly.[13−22] For the efficient construction of helical structures the design of the linker connecting the chelating units is quite important, because a ligand could afford either a homochiral complex (helicate) with twisted arrangement or a heterochiral complex (*meso*-helicate, mesocate, or side-by-side complex) with parallel arrangement depending on the linker's shape and symmetry (Figure 1).[13] Since the potential advantages of the helical structures originate in their chirality, much attention has been paid to the thermodynamics of the complexes. It is known, for example, that in some cases the helical and nonhelical forms are in equilibrium in solution, resulting in the racemization of the compound.[23−25] This kind of dynamic interconversion is an inevitable result of entropy-driven molecular aggregation.

Another possible process to construct the helical structures is enthalpy-driven molecular aggregation, which

would afford thermally stable products. However, this method has an intrinsic difficulty in controlling the products because the reaction is largely kinetically controlled. Thus, a desirable ligand should maintain a conformation suitable for the formation of a helix during the complexation. We have investigated a variety of Schiff bases containing a 2-methylenepropane-1,3-diyl (isobutenylene) chain as a linker, as a promising ligand that would fulfill this requirement.[26] We have succeeded in synthesizing dinuclear complexes of Ti^{IV}, Y^{III}, Ni^{II}, and Cu^{II}.[27–29] Among these complexes, we found that Ni^{II} and Cu^{II} species have a helical arrangement in which the coordination site adopts a square-planar geometry.[29] This finding suggested a possible access to an isostructural complex of Pd^{II}. Such complexes with diamagnetic properties could be studied by NMR techniques, leading to the understanding of their formation mechanisms as well as their structure in solution and thermodynamic behavior. In this article we describe the synthesis and characterization of Pd^{II} complexes of our Schiff-base ligands. We will highlight the difference in NMR features between the complexes with twisted and parallel arrangements. Those NMR results are successfully interpreted based on a comparative study of the crystal structures between the Pd^{II} and Cu^{II} complexes. In particular, interligand interference in molecular motion is observed for the first time for the complexes with a twisted arrangement.

Results and Discussion

Characterization of the Helical and Nonhelical Complexes

The reaction of the Schiff-base ligands (H_2L^1 to H_2L^3; see Figure 2) and palladium(II) acetate afforded yellowish orange solids. The major products show ESI-MS peaks corresponding to a 2:2 assembly of ligand and palladium ion. Based on the results of our previous studies,[29] the products were expected to be the double-stranded dinuclear palladium complexes $[Pd_2L^1_2]$, $[Pd_2L^2_2]$ and $[Pd_2L^3_2]$, as shown in Figure 2. Their NMR spectra and elemental analyses were also in agreement with the proposed structure.

The ^1H NMR spectrum of $[Pd_2L^1_2]$ shows a split pair of doublets at δ = 1.87 ppm (^2J = 14.2 Hz) and 2.34 ppm (^2J = 14.2 Hz), which were assigned to the benzylic methylene protons (Figure 2) of the isobutenylene linker. This AB-type geminal coupling suggests a constraint of molecular motion which makes the two protons diastereotopic. These benzylic protons and the *exo*-methylene protons (δ = 4.75 ppm) exhibit NOE cross-peaks, among which one peak (between δ = 1.87 and 4.75 ppm) is significantly stronger than the other one (between δ = 2.34 and 4.75 ppm). These biased cross-peaks suggested a difference in distance ($d_{H\cdots H}$) between the benzylic proton and the *exo*-methylene proton. In view of the possible rotamers of the isobutenylene group,[26c,26d,30] one benzylic proton should be located in the in-plane region ($d_{H\cdots H} \approx 2.3$ Å) with respect to the π-plane of the ethylene group, while the other should be located in the out-of-plane region ($d_{H\cdots H} \approx 3.3$ Å). Therefore, we assigned the signal at δ = 1.87 ppm to the in-plane proton, and the signal at δ = 2.34 ppm to the out-of-plane proton. The NMR spectra of $[Pd_2L^2_2]$ and $[Pd_2L^3_2]$ also show similar features. The chemical shifts of the in-plane and out-of-plane protons are summarized in Table 1.

The ^1H NMR spectrum of the crude precipitate obtained after the reaction between Pd^{II} and ligand L^1 indicates the presence of a by-product that gives a split pair of doublets at δ = 2.02 and 2.20 ppm in the region of the benzylic methylene protons (Table 1). After purification, we were able to obtain a by-product-rich sample and a major product-rich sample, for which the ratio of the two components did not change even after the sample was heated at 80 °C for several hours. This indicates that these components are kinetically controlled products, which are not thermally interconvertible. The mass spectra recorded before and after the purification show no significant change, suggesting that the major product and the by-product have the same molecular weight. This observation led to the assumption that the major and minor components are two isomers with twisted and parallel arrangements (see Figure 1).

Table 1. The chemical shift[a] (in ppm) of the benzylic methylene protons, and the presumed arrangement of the complexes

Compound	In-plane proton	Out-of-plane proton	$\Delta\delta$	Arrangement
$[Pd_2L^1{}_2]$	1.87 (14.2)	2.34 (14.2)	0.47	twisted
$[Pd_2L^1{}_2]$ (by-product)	2.02 (14)	2.20 (14)	0.18	parallel
$[Pd_2L^2{}_2]$	1.88 (14.1)	2.49 (14.1)	0.61	twisted
$[Pd_2L^3{}_2]$	1.84 (14.5)	2.40 (14.4)	0.56	twisted
$[Pd_2L^4{}_2]$	2.38 (14.1)	2.53 (14.5)	0.15	parallel
$[Pd_2L^5{}_2]$	2.32 (14.5)	2.59 (14.4)	0.27	parallel

[a] Every peak appears as a doublet. The coupling constants (^2J in Hz) are given in parentheses.

To clarify the difference between the two isomers — the twisted and parallel forms — we prepared similar dinuclear palladium complexes with the ligands H_2L^4 and H_2L^5 (Figure 2) that would not allow the helical arrangement owing to their macrocyclic structure. Figure 3 shows the crystal structure of $[Pd_2L^5{}_2]$. As expected, the ligand adopts a parallel arrangement around the two palladium atoms, to which two nitrogen atoms and two oxygen atoms are bound in a slightly distorted square-planar geometry with *trans* coordination. If only electronic factors are taken into account, the coordination geometry around the palladium(II) ion is expected to be *cis* for N−O chelating ligands.[31−33] In the present case, however, since the nitrogen atom is substituted by an aromatic group, the geometry around the palladium ion is defined by steric factors. Although the crystallographic symmetry of $[Pd_2L^5{}_2]$ is C_i, the NMR spectra show a C_{2h}-like behavior of the molecule, probably due to thermal fluctuations.

The ^{1}H NMR spectra of $[Pd_2L^4{}_2]$ and $[Pd_2L^5{}_2]$ show a split pair of doublets, which are again assigned to the benzylic protons (Table 1). The pattern of these signals is similar to that observed for $[Pd_2L^1{}_2]$ to $[Pd_2L^3{}_2]$, except that the resonances are significantly shifted downfield. Table 1 also lists the difference ($\Delta\delta$) of chemical shift between the out-of-plane and in-plane protons. It should be noticed that the $\Delta\delta$ values (0.15 and 0.27 ppm) measured for complexes $[Pd_2L^4{}_2]$ and $[Pd_2L^5{}_2]$, respectively, are much lower than those found for complexes $[Pd_2L^1{}_2]$ to $[Pd_2L^3{}_2]$ (0.47−0.61 ppm), and are very close to the $\Delta\delta$ value (0.18 ppm) measured for the by-product formed along with $[Pd_2L^1{}_2]$. These distinctive $\Delta\delta$ values may arise from differences in the chemical environment of the benzylic methylene groups in the twisted arrangement and in the parallel one. In other words, the $\Delta\delta$ value can be an indicator of the arrangement of the complexes. Based on the above results, we presume that $[Pd_2L^1{}_2]$ to $[Pd_2L^3{}_2]$ have a twisted arrangement, while $[Pd_2L^4{}_2]$, $[Pd_2L^5{}_2]$, and the by-product of $[Pd_2L^1{}_2]$ have a parallel arrangement (Table 1).

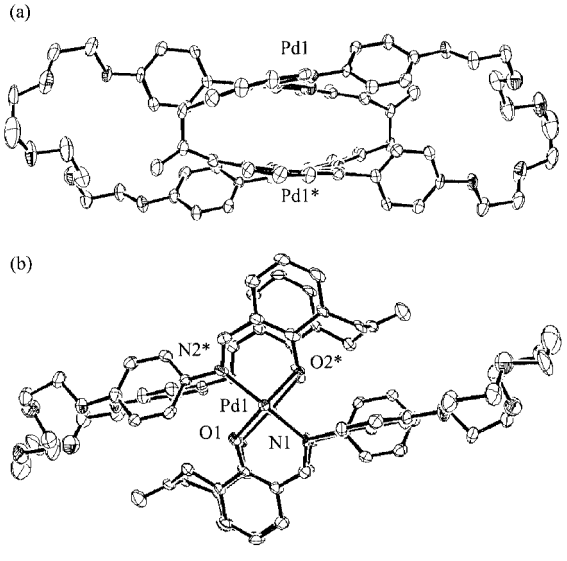

Figure 3. Crystal structure of $[Pd_2L^5{}_2]$: (a) view from the direction perpendicular to the Pd1···Pd1* line (pseudo-C_2 axis); (b) view nearly along the pseudo-C_2 axis; selected interatomic distances [Å] and bond angles [°]: O1−Pd1 1.995, O2*−Pd1 1.977, N1−Pd1 2.024, N2*−Pd1 2.042, Pd1−Pd1* 4.151; O1−Pd1−O2* 172.0, N1−Pd1−N2* 172.2; the hydrogen atoms have been omitted for clarity

NMR Features in Helical Complexes

An analysis of the crystal structures would provide helpful information to interpret the NMR spectra. Although the crystal structures of $[Pd_2L^1{}_2]$ to $[Pd_2L^4{}_2]$ have not been obtained, a comparison of the crystal structures between palladium and copper complexes confirms the assumption that these complexes have very similar structures. As shown in Figure 4, the crystal structure of $[Cu_2L^5{}_2]$ is highly reminiscent of that described above for $[Pd_2L^5{}_2]$ (see Figure 3). As expected, as copper is a first-row transition metal and palladium a second-row one, the main differences are found in the M−O and M−N distances; the other main interatomic distances in the two complexes are very close. For example, the distance between the two *exo*-methylene carbon atoms of $[Pd_2L^5{}_2]$ is 12.768 Å, while that of $[Cu_2L^5{}_2]$ is 12.685 Å, a difference of only 0.7%. Figure 5 shows the crystal structure of $[Cu_2L^2{}_2]$, which demonstrates the helical arrangement of the ligands around the two copper atoms.[12] In spite of the difference in arrangement, the geometry around each coordination site of $[Cu_2L^2{}_2]$ is quite similar to that of $[Cu_2L^5{}_2]$. From all these observations, it is reasonable to assume that the structure of $[Pd_2L^2{}_2]$ is also similar to that of $[Cu_2L^2{}_2]$.

The NOESY spectra of $[Pd_2L^1{}_2]$ to $[Pd_2L^3{}_2]$ show the characteristic cross-peaks that would be expected from a twisted arrangement. For $[Pd_2L^2{}_2]$, for example, we observed correlation peaks between the *tert*-butyl protons and the methoxy protons of the anisidine unit, and between the benzylic protons out of the plane of the ethylene group and

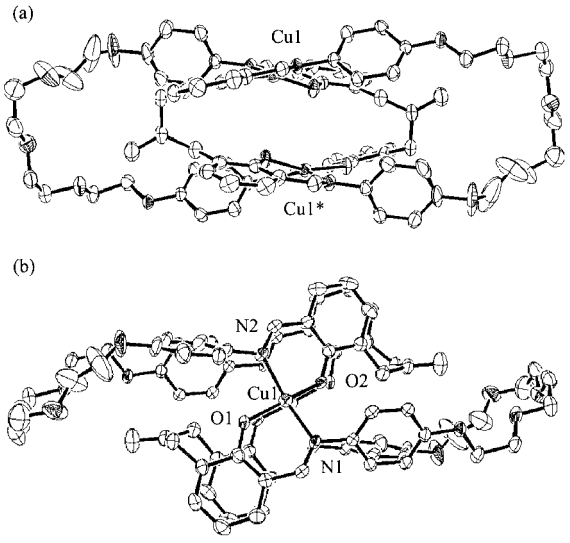

Figure 4. Crystal structure of $[Cu_2L^5_2]$: (a) view from the direction perpendicular to the Cu1···Cu1* line (pseudo-C_2 axis); (b) view nearly along the pseudo-C_2 axis; selected interatomic distances [Å] and bond angles [°]: O1−Cu1 1.881, O2−Cu1 1.892, N1−Cu1 2.002, N2−Cu1 1.999, Cu1−Cu1* 4.113; O1−Cu1−O2* 161.0, N1−Cu1−N2 158.6; the hydrogen atoms and the solvent of crystallization ($CHCl_3$) have been omitted for clarity

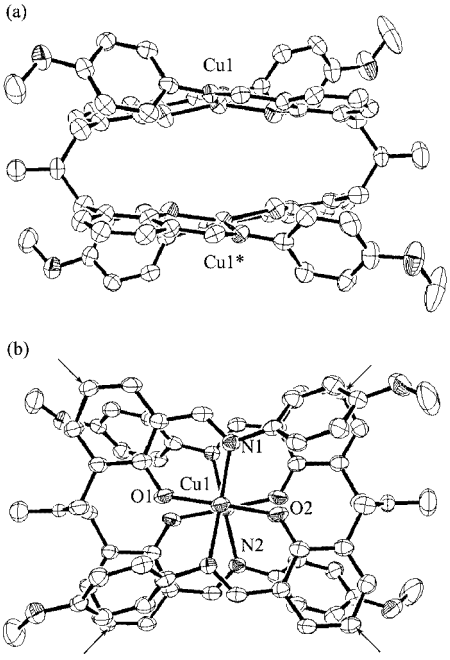

Figure 5. Crystal structure of $[Cu_2L^2_2]$: (a) view from the direction perpendicular to the Cu1···Cu1* line (pseudo-C_2 axis); (b) view nearly along the pseudo-C_2 axis; selected interatomic distances [Å] and bond angles [°]: O1−Cu1 1.880, O2−Cu1 1.864, N1−Cu1 1.984, N2−Cu1 1.991, Cu1−Cu1* 3.887; O1−Cu1−O2 159.2, N1−Cu1−N2 161.2; the hydrogen atoms and the solvent of crystallization (CH_2Cl_2) have been omitted for clarity; the *tert*-butyl groups have also been omitted for clarity, but the four carbon atoms to which they are attached are indicated by arrows in (b)

the aromatic protons (H_a and H_b, see Figure 2) of the anisidine unit. For a better understanding of these NOESY results, we analyzed the crystal structure of $[Cu_2L^2_2]$ as a model of $[Pd_2L^2_2]$. Figure 6 shows a partial structure of $[Cu_2L^2_2]$ in which the hydrogen atoms of interest are noted. The distances between the protons accurately account for the cross-peaks. First, the protons of the *tert*-butyl groups of the ligand are close to the methoxy group protons of the anisidine units of its counterpart (dashed lines A in Figure 6). This type of contact occurs only when the complex adopts a twisted arrangement. Secondly, the out-of-plane protons of the ligand are in close proximity to the anisidine units of its counterpart (dashed lines B and C in Figure 6). In addition, Figure 6 clearly shows the arrangement of the in-plane and out-of-plane benzylic protons (dashed lines D in Figure 6), which could cause the biased NOE cross-peak signals with the *exo*-methylene proton. Similarly, we were able to explain the NOE cross-peaks of the complexes with parallel arrangements — $[Pd_2L^4_2]$ and $[Pd_2L^5_2]$ — on the basis of the crystal structure of $[Pd_2L^5_2]$ (Figure 3).

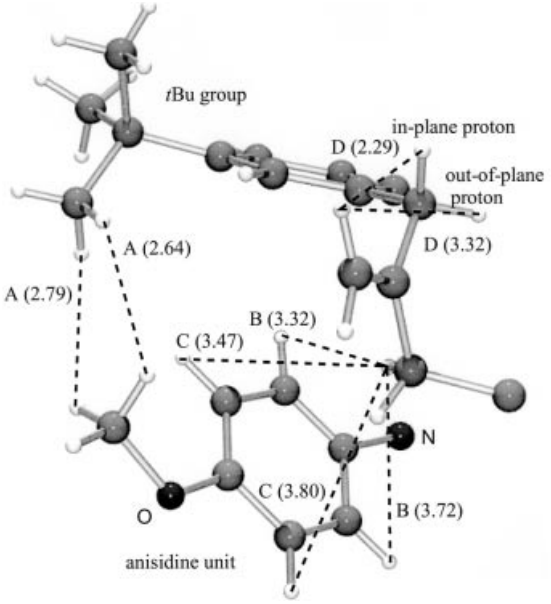

Figure 6. The crystal structure of $[Cu_2L^2_2]$ as a model of $[Pd_2L^2_2]$; notations A−D indicate a pair of protons in close proximity and their distance (in parentheses [Å])

Variable-temperature NMR measurements revealed a critical difference between the complexes with twisted and parallel arrangements. For $[Pd_2L^2_2]$, the H_a and H_b signals (anisidine protons denoted in Figure 2) appear as two doublets at $\delta = 6.56$ and 6.29 ppm, respectively, at 323 K, indicating that the anisidine ring freely rotates within the NMR timescale. At 213 K, as indicated by dashed lines in Figure 7, the H_a signal splits into two doublets at $\delta = 7.13$ and $\delta = 6.02$ ppm, while the H_b signal splits into two doublets at $\delta = 6.67$ and 5.81 ppm. The coalescence temperature is close to 253 K for both H_a and H_b. This spectral change suggests that the four protons become chemically inequivalent due to interference in the rotation of the anisidine moieties. Based on the temperature dependence of the line

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

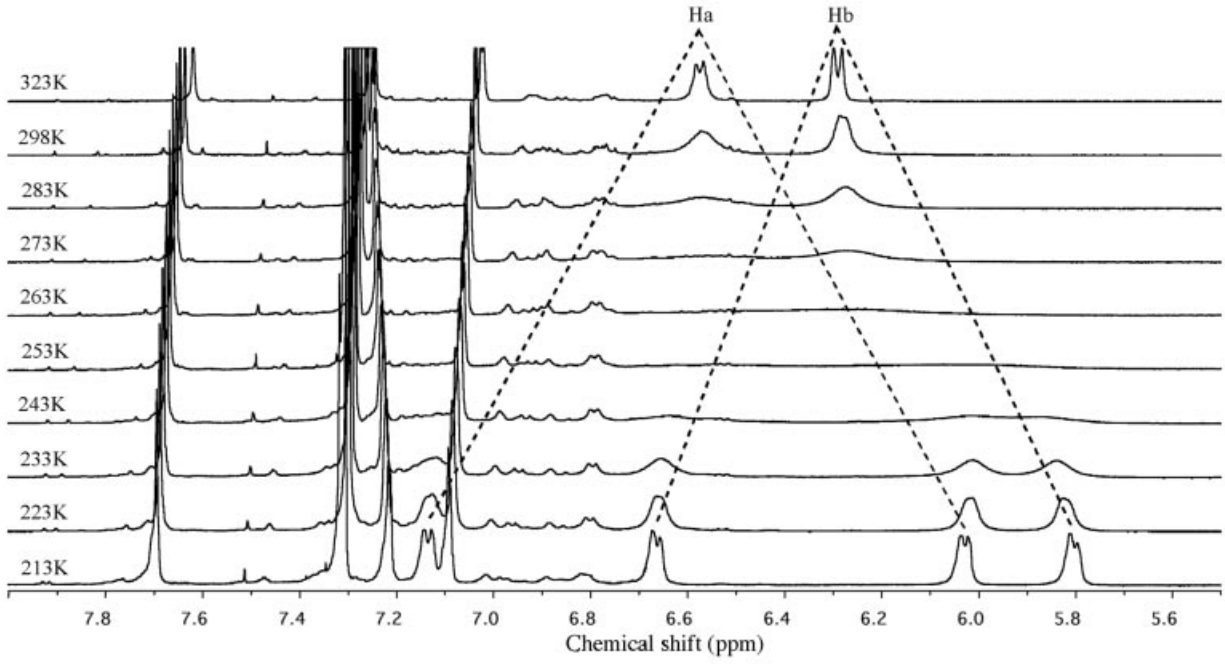

Figure 7. The temperature dependence of the ^{1}H NMR signals of the anisidine protons H_a and H_b

shape, the rotational barrier was estimated to be 47.8 kJ/mol. A similar temperature dependence was observed for $[Pd_2L^1_2]$, but with a lower coalescence temperature (243 K) and lower rotational barrier (45.4 kJ/mol). The difference in the barrier is attributable to the *tert*-butyl group on the phenolate, implying that the phenolate moiety acts as a hindrance to the rotating anisidine moiety. An influence due to contact with the benzylic methylene group is ruled out because a similar contact is also observed in the parallel complexes, which do not show interference in the anisidine rotation. To explain these phenomena, we need to assume a close contact between the anisidine moiety of one ligand and the phenolate moiety of the other, as shown in Figure 6, since the approach of these two moieties would be impossible in a single ligand molecule. Consequently, such an interligand steric hindrance is a phenomenon exclusively observed for the complexes with a twisted arrangement. On the other hand, the corresponding ^{1}H NMR signals of the complex with a parallel arrangement show little dependence on temperature. For example, the signals of H_a and H_b of $[Pd_2L^5_2]$ are observed as two doublets at δ = 7.20 and 6.87 ppm at 298 K, and they show only a slight shift to δ = 7.09 and 6.79 ppm, respectively, at 213 K.

Remarks on the Formation Mechanism

As described above, several characteristic NMR features enable us to distinguish the arrangement of the dinuclear Pd^{II} complexes. With the ligand H_2L^1, we obtained two isomers, namely the twisted form as a major product and the parallel form as a by-product. These isomers could not be interconverted, even after prolonged heating, demonstrating their thermodynamic stability. Similarly, for the other two linear ligands (H_2L^2 and H_2L^3), the major product of the reaction is the twisted isomer. By contrast, when the ligands have mechanical constraints due to their macrocyclic structures (H_2L^4 and H_2L^5), the parallel forms are the major reaction products. These results suggest that the acyclic ligands prefer a conformation that can induce a twisted arrangement in the dinuclear complexes. At this point it is worth mentioning the nature of the linker unit connecting the two chelating units in terms of symmetry. Albrecht et al. have introduced the "even-odd principle", which accounts for the relation between the arrangement and the ligand used to actively control the formation of helicates and *meso*-helicates.[34] Namely, an alkyl chain with an even number of methylene units has C_2 symmetry, which favors a helicate, whereas an alkyl chain with an odd number of methylene units has C_{2v} symmetry, which favors a *meso*-helicate. As for the present system, the isobutenylene chain can adopt several stable conformers with various symmetry such as skew-skew (C_2 symmetry), *syn-syn* (C_{2v} symmetry) and skew-skew′ (C_s symmetry). As already remarked in the previous paper, the isobutenylene chains have the skew-skew form in the helical Ni^{II} and Cu^{II} complexes. Since the helical Pd^{II} complexes are suggested to be isostructural to them, the chains should also adopt the skew-skew form. As for the nonhelical complexes, Figure 3 shows that the isobutenylene chains of $[Pd_2L^5_2]$ adopt the skew-skew′ form. According to an ab initio study (MP2/6-311**G//HF/6-311G** level of theory) of model compounds, the skew-skew form is more stable than the skew-skew′ form by 8.28 kJ/mol.[30] Although the calculated energy difference is rather small, it is suggested that the thermodynamic preference for the skew-skew conformation contributes to the efficient formation of the helical complexes to some extent.

Consequently, the present system is a good example of enthalpy-driven molecular aggregation during which the ligand component effectively controls the arrangement of the products.

Conclusion

We have described the synthesis and structure of several dinuclear palladium(II) complexes of double-stranded Schiff-base ligands with either twisted or parallel arrangements. In the present system the complexation is enthalpy driven, and the product is largely kinetically controlled. Due to this formation mechanism, the twisted and parallel isomers are thermodynamically inconvertible in solution, such that we can observe the characteristic NMR features of a given complex with a definite arrangement. To the best of our knowledge, this is the first work that clearly exhibits the interligand interactions exclusively brought into helically arranged complexes.

Experimental Section

Measurements: NMR measurements were performed using a Bruker AVANCE500 (500 MHz for ^{1}H nuclei) spectrometer. The temperature was set at 298 K unless otherwise noted. The samples were dissolved in $CDCl_3$, and TMS was used as an internal standard. The chemical shifts of ^{1}H and ^{13}C nuclei were assigned by using NOESY, ROESY, COSY, and DQF-COSY techniques. Variable-temperature measurements were performed for dynamic NMR spectroscopic analysis. Calculations for complete line-shape analyses were carried out with an IBM R-32 computer using the computer program g NMR version 4.1.[35] Theoretical spectra were calculated to obtain an optimum fit with the observed spectra by varying the exchange-rate constants. The activation parameters were obtained using the Eyring equation.[36]

For X-ray diffraction of a single crystal, the data were collected with a Rigaku RAXIS-RAPID Imaging Plate diffractometer, λ(Mo-K_α) = 0.7107 Å radiation. The structure was solved by direct methods and expanded using Fourier techniques. The nonhydrogen atoms' coordinates were refined anisotropically. Hydrogen atoms' coordinates were calculated. The final cycle of full-matrix least-squares refinement was based on the observed reflections with $I > 1.5\sigma(I)$ and variable parameters. The refinement converged with the unweighted and weighted agreement factors, R_1 and R_w. All the calculations were performed with RIGAKU Corporation's Crystal-Structure software package.[37] ORTEP drawings were created with ellipsoids of 50% probability by using the ORTEP-3 software package.[38]

Synthesis of the Pd^{II} Complexes: The Schiff-base ligands H_2L^1 to H_2L^5 (Figure 2) were prepared from the corresponding bis(hydroxybenzaldehyde) and aniline derivative according to reported methods.[26] For example, a stoichiometric amount (L^1/Pd = 1:1) of palladium(II) acetate and a few drops of methanol and acetonitrile were added to a solution of H_2L^1 (507 mg, 1.0 mmol) in chloroform (10 mL). The solution was stirred at 25 °C for several days. After confirming the disappearance of the starting material by TLC, a large quantity of methanol was added to precipitate a yellowish orange solid. Similarly, ligands H_2L^2 to H_2L^5 were allowed to react with the palladium salt. Since we found it difficult to elute the products from a silica gel column, we attempted the purification by reprecipitation from a diethyl ether/chloroform system.

[Pd$_2$L$^1_2$]: Yield: 61 mg (10%). ^{1}H NMR: δ = 1.87 (d, J = 14.2 Hz, 4 H, Ar−CH_2−), 2.34 (d, J = 14.2 Hz, 4 H, Ar−CH_2−), 3.64 (s, 12 H, −OCH_3), 4.73 [s, 4 H, −C(=CH_2)−], 6.31 (d, J = 8.0 Hz, 8 H, ArH−OCH$_3$), 6.60 (dd, J = 7.4 Hz, 7.3 Hz, 4 H, ArH−OPd), 6.61 (d, J = 7.4 Hz, 8 H, ArH−OCH$_3$), 7.09 (d, J = 7.3 Hz, 4 H, ArH−OPd), 7.11 (d, J = 7.6 Hz, 4 H, ArH−OPd), 7.61 (s, 4 H, −CH=N−) ppm. ^{13}C NMR (213 K): δ = 32.8, 55.7, 111.6, 113.1, 114.0, 114.4, 118.7, 124.7, 125.0, 131.8, 132.8, 134.3, 142.7, 149.9, 156.9, 162.6, 162.9 ppm. Synthesis, Structures and Reactivity of Mono- and Diborylacetylenes

Avijit Goswami,[a] Hans Pritzkow,[a] Frank Rominger,[b] and Walter Siebert*[a]

Dedicated to Professor Margot Becke on the occasion of her 90th birthday

Keywords: Alkynes / Boranes / Cobalt / Cyclooligomerization

The reaction of [bis(diisopropylamino)boryl]acetylene with 2 equiv. of HCl and 1 equiv. of dithiocatechol or 2-hydroxythiophenol yields the corresponding monoborylacetylenes **1** and **2**, respectively. Diborylacetylenes **3** and **4** are obtained from the reactions of bis(trimethylstannyl)acetylene with 2 equiv. of bromoboranes. Treatment of chlorobis(diisopropylamino)-borane with LiC≡C–EMe$_3$ (E = C, Si) leads to the corresponding element-substituted [bis(diisopropylamino)boryl]-acetylenes **5a**,**b**. The syntheses of monoborylacetylenes **6a**,**b**–**8a**,**b** are achieved by the reaction of **5a**,**b** with 2 equiv. of HCl and 1 equiv. of catechol, dithiocatechol or 2-hydroxythiophenol, respectively. Stoichiometric amounts of [CpCo(CO)$_2$] react with **1**–**4** in refluxing toluene to give the corresponding (η^4-cyclobutadiene)cobalt complexes **9**–**12**. Analogous isomeric mixtures of (η^4-cyclobutadiene)cobalt complexes **13a/13a′**–**15a/15a′** are obtained from 1-*tert*-butyl-2-borylacetylenes **6a**–**8a** and [CpCo(C$_2$H$_4$)$_2$], whereas isomeric mixtures of (η^4-cyclohexatriene)(η^5-cyclopentadienyl)-cobalt complexes **13b/13b′**–**15b/15b′** are formed with 1-boryl-2-silylacetylenes **6b**–**8b** under similar conditions. Hydrolysis of **13a**–**15a** yields the (η^4-1,3-di-*tert*-butylcyclobutadiene)cobalt complex **16**. Catalytic trimerizations of mono- (**1**, **2**) and diborylacetylenes (**3**, **4**) with Co$_2$(CO)$_8$ lead to isomeric mixtures of triboryl- (**17/17′**, **18/18′**) and hexaborylbenzene derivatives (**19**, **20**), respectively. The new compounds are characterized by NMR spectroscopy and mass spectrometry as well as by X-ray structure analyses for **1b**, **5b**, **6b**, **14a**, **15a** and **16**.

Introduction

Over the past three decades, cobalt-mediated cyclooligomerization reactions of acetylenes have been recognized as a powerful tool for the synthesis of various compounds.[1] In general, catalytic cyclotrimerizations of less bulky substituted acetylenes with [CpCoL$_2$] (L = CO, C$_2$H$_4$) lead to benzene derivatives,[2] whereas CpCo complexes of cyclobutadiene[3] and/or cyclopentadienone[4] (with benzene derivatives as side products) are obtained with stoichiometric amounts of [CpCoL$_2$] complexes.

Recently, we have reported the synthesis of oxygen- and sulfur-substituted monoborylacetylenes.[5] Surprisingly, it was found that oxygen-substituted borylacetylenes formed only benzene derivatives in catalytic as well as stoichiometric reactions with [CpCoL$_2$]. On the other hand, with sulfur-substituted borylacetylenes only (η^4-cyclobutadiene)cobalt complexes were achieved. This unique heteroatom effect in borylacetylenes encouraged us to perform further studies. The monoborylacetylenes **1** and **2** and the diborylacetylenes **3** and **4** were synthesized and found to follow the same reaction trend to undergo dimerization with [CpCoL$_2$] to furnish (η^4-cyclobutadiene)cobalt complexes **9**−**12**. This indicated that the aryl groups have less electronic or steric influences on the reactivity of previously reported 1-aryl-2-borylacetylenes.[5]

In order to shed further light on the influence of bulky substituents on the borylacetylenes, we have prepared 1-boryl-2-*tert*-butylacetylenes and 1-boryl-2-silylacetylenes **6**−**8**, in which two oxygen atoms (in **6**), two sulfur atoms (in **7**) and one oxygen and one sulfur atom (in **8**) are bound to the boron atom. It is expected that the bulky substituents have different steric and electronic effects on the reactivity of the acetylenes **6**−**8**. In this paper, we report on the syntheses, structures and reactivity of the above-mentioned acetylenes **1**−**4** and **6**−**8**.

Results and Discussion

Synthesis and Properties of Mono- and Diborylacetylenes

The preparation of sulfur-substituted borylacetylenes was achieved by treatment of [bis(diisopropylamino)boryl]-acetylene with 2 equiv. of HCl and 1 equiv. of dithiocatechol or 2-hydroxythiophenol in THF, to give the mono-

2	S	O	H

Scheme 1

In the ^{11}B NMR spectrum the signals at δ = 47 (**1a**), 48 (**1b**) and 38 (**2**) ppm indicate trigonal-planar boryl groups, which was confirmed by the solid-state structure of **1b** (Figure 1). The ^{1}H NMR spectra of **1a**,**b** and **2** exhibit a characteristic singlet for the acetylenic proton at δ = 3.71 (**1a**), 3.70 (**1b**) and 3.17 (**2**) ppm. In the ^{13}C NMR spectrum the signals for B−C_{sp} are not observed; the signals for H−C_{sp} (δ = 90−100 ppm) are shifted to lower field compared to those of alkylacetylenes (δ = 70−80 ppm).

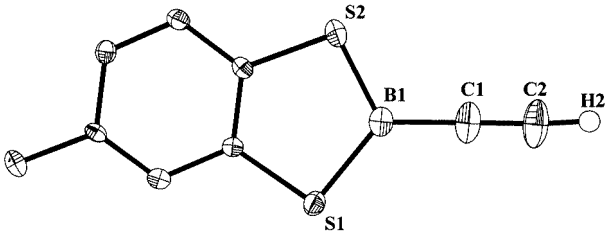

Figure 1. Molecular structure of **1b** in the solid state; selected bond lengths [Å] and bond angles [°]: B1−S1 1.849(3), B1−S2 1.728(3), B1−C1 1.521(2), C1−C2 1.188(3); C2−C1−B1 178.3(2), C1−C2−H2 175.9(2), C1−B1−S2 117.9(2), C1−B1−S1 128.4(2), S2−B1−S1 113.5(1)

Diborylacetylenes **3** and **4** were prepared by the reaction of bis(trimethylstannyl)acetylene with 2 equiv. of bromoboranes (Scheme 2). The colorless, air-sensitive solids formed are well soluble in chloroform and toluene, but less so in hexane and pentane. The ^{11}B NMR spectra show broad signals at δ = 47 (**3**) and 37 (**4**) ppm.

Scheme 2

The synthesis of the [bis(diisopropylamino)boryl]acetylenes **5a**,**b** was performed according to a literature procedure[6] by treating chlorobis(diisopropylamino)borane with LiC≡C−EMe_3 (E = C, Si). The products were isolated in almost quantitative yields (Scheme 3).

Scheme 3

The light-yellow acetylenes **5a**,**b** were characterized by ^{1}H, ^{11}B and ^{13}C NMR spectroscopy, and by mass spectrometry. The X-ray structure analysis of **5b** (Figure 2) reveals an almost linear B−C≡C−Si moiety; the C≡C distance (1.21 Å) is slightly longer than in other R−C≡C−R compounds (1.18 Å).[7]

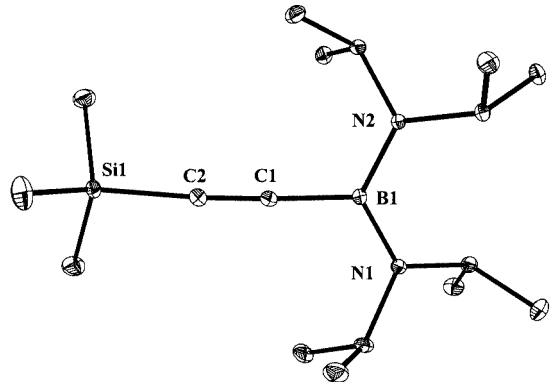

Figure 2. Molecular structure of **5b** in the solid state; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and bond angles [°]: B1−C1 1.564(1), C1−C2 1.214(1), Si1−C2 1.830(1), N1−B1 1.428(1), N2−B1 1.439(1); C2−C1−B1 177.3(1), C1−C2−Si1 174.54(9), N1−B1−N2 124.40(8), N2−B1−C1 117.46(8), N1−B1−C1 118.13(8)

The synthesis of compounds **6**−**8** was achieved by the reaction of the [(diisopropylamino)boryl]acetylenes **5a**,**b** with 2 equiv. of HCl and 1 equiv. of catechol, dithiocatechol or 2-hydroxythiophenol, respectively, in THF (Scheme 4). Compounds **7a** and **7b** are colorless solids, whereas **6a**,**b**[8] and **8a**,**b** are pale-yellow liquids, which are readily soluble in common organic solvents.

Scheme 4

The ^{11}B NMR spectra exhibit broad signals at δ = 24 (**6a**), 23 (**6b**), 48 (**7a**), 47 (**7b**), 38 (**8a**) and 37 (**8b**) ppm. In the ^{1}H NMR spectra of **6b**−**8b** and **6a**−**8a** singlets appear at δ = 0.2−0.3 ppm ($SiMe_3$) and 1.2−1.3 ppm (CMe_3). Single crystals of **6b** were obtained at −20 °C. The molecular structure of **6b** (Figure 3) indicates an almost linear B−C≡C−Si moiety with a slightly elongated C≡C bond. The boron atom is trigonal coordinated and the heterocycle is almost planar.

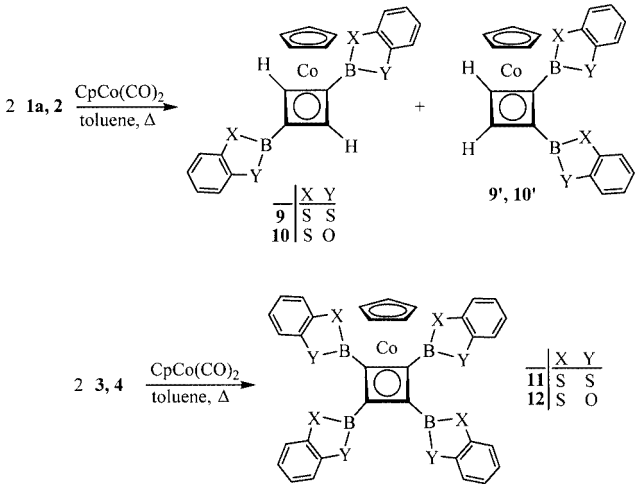
(η^4-Cyclobutadiene)cobalt Complexes 9−12

CpCo-mediated cyclodimerization has proved particularly efficient for tolerating the presence of varied functionalities on the alkyne.[9] As a result, the $[CpCoL_2]$ (L = CO, PR_3, olefin) complex family has been utilized for intensive studies, culminating in the isolation of numerous (η^4-cyclobutadiene)cobalt complexes. In refluxing toluene the mono- (**1a**, **2**) and diborylacetylenes (**3**, **4**) formed the (η^4-cyclobutadiene)cobalt complexes **9**−**12** in the presence of stoichiometric amounts of $[CpCo(CO)_2]$ (Scheme 5). Purification of complexes **9**−**12** was performed by repeated washing with hexane and toluene. The red-brown solids of **9**−**12** are partially soluble in chloroform; in methanol a fast reaction leads to the formation of $B(OMe)_3$.

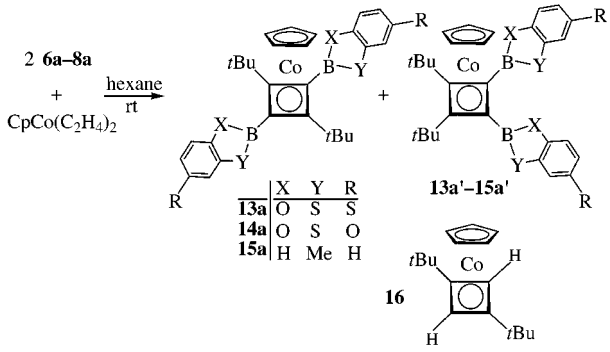


Scheme 5

Complexes **9**−**12** were characterized by ^1H, ^{11}B and ^{13}C NMR spectroscopy, and by mass spectrometry. The ^{11}B NMR spectra show broad signals at δ = 60 (**9**), 48 (**10**), 63 (**11**) and 50 (**12**) ppm. The ^1H NMR spectra of **9**−**12** exhibit multiplets in the region δ = 6.6−8.2 ppm for thr aromatic protons in addition to the Cp resonances (δ = 4.7−5.4 ppm). The *cis* isomers **9′**, **10′** could not be identified by NMR spectroscopy; however, analysis of the fragmentation patterns in the mass spectra in terms of the degradation of the cyclobutadiene ring clearly indicates the presence of trace amounts of *cis* isomers in the isomeric mixtures. It is worth mentioning that no benzene derivative was formed in the catalytic cyclotrimerization (thermal or photochemical) reactions of $[CpCo(CO)_2]$ with the borylacetylenes **1**−**4**.

Reactions of $[CpCo(C_2H_4)_2]$ with 6a−8a

The reaction of borylacetylenes **6a**−**8a** with stoichiometric amounts of $[CpCo(CO)_2]$ in refluxing toluene led only to 50−60% conversion of the starting acetylenes to an isomeric mixture of (η^4-cyclobutadiene)cobalt complexes **13a/13a′**, **14a/14a′** and **15a/15a′**, respectively. Using the more reactive complex $[CpCo(C_2H_4)_2]$[10] resulted in complete conversion of the borylacetylenes to the CpCo complexes **13a/13a′**−**15a/15a′** (Scheme 6).



Scheme 6

Attempts to separate the isomeric mixtures of the cobalt complexes **13a/13a′**−**15a/15a′** by column chromatography led to the known complex $[CpCo(\eta^4\text{-}C_4tBu_2H_2)]$ (**16**).[11] Compounds **13a/13a′**−**15a/15a′** and **16** are soluble in common organic solvents and were characterized by ^1H, ^{11}B and ^{13}C NMR spectroscopy, mass spectrometry as well as by X-ray analyses for **14a**, **15a** and **16**. The ^{11}B NMR spectra show broad signals at δ = 36 (**13a/13a′**), 63 (**14a/14a′**) and 50 (**15a/15a′**) ppm. The ^1H NMR spectra of **13a**−**15a** exhibit singlets in the region δ = 4.8−5.2 ppm for H_{Cp} in addition to the *tert*-butyl group resonances (δ = 1.2−1.4 ppm). The molecular-ion peaks of **13a**−**15a** were detected with the expected isotopic pattern by mass spectrometry. The presence of very small amounts of *cis* isomers (**13a′**, **14a′** and **15a′**) in the isomeric mixtures was confirmed by analyzing the major peaks in the mass spectra (analogous to **9′**, **10′**).

Complexes **14a** and **15a** were characterized by performing a single-crystal X-ray diffraction analysis (Figures 4 and 5), which revealed that the *tert*-butyl and boryl groups are in *trans* positions. Neither of the boron heterocycles of **14a** lies in the cyclobutadiene plane, whereas one of the boron heterocycles of **15a** is coplanar with the cyclobutadiene ring.

A solid-state structure analysis of **16** was carried out on a single crystal. This complex crystallizes with two independent molecules in the asymmetric unit with very similar distances and angles; only one structure is shown in Figure 6 and the average values are listed in the caption.

[CpCo(η⁴-cyclohexatriene)] Complexes 13b/13b′−15b/15b′

Reaction of **6b−8b** with $[CpCo(C_2H_4)_2]$[12] led to the [CpCo(η⁴-cyclohexatriene)] complexes **13b/13b′−15b/15b′**

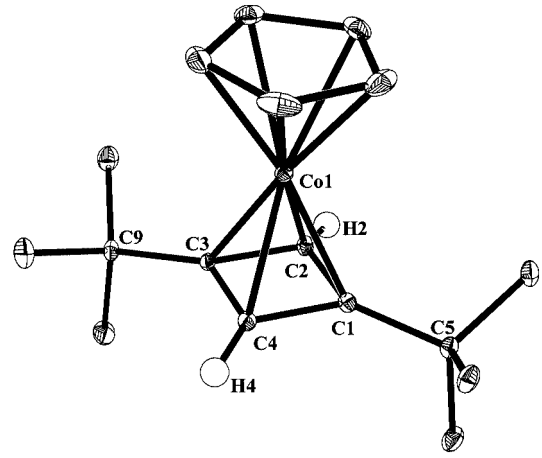

Figure 6. Molecular structure of **16** in the solid state; hydrogen atoms are omitted for clarity; selected bond lengths [A] and bond angles [°]: C1−C2 1.449(3), C1−C4 1.455(3), C2−C3 1.455(3), C3−C4 1.461(3); C2−C1−C4 89.8(2), C1−C2−C3 90.7(2), C2−C3−C4 89.3(2), C1−C4−C3 90.2(2)

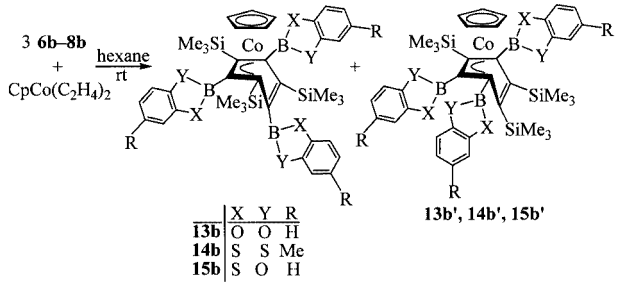


Scheme 7

in moderate yields (Scheme 7). They were purified by column chromatography on Florosil and isolated as reddish-brown oils, which were characterized by ^1H, ^{11}B, ^{13}C and ^{29}Si NMR spectroscopy, and by mass spectrometry.

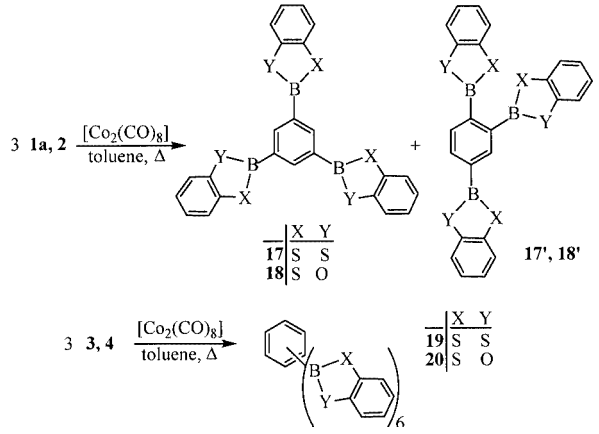
The ^{11}B NMR spectra show broad signals at $\delta = 32$ (**13b/13b′**), 60 (**14b/14b′**) and 49 (**15b/15b′**) ppm and the ^1H NMR spectra exhibit multiplets in the aromatic region of $\delta = 6.3-7.5$ ppm in addition to the Cp resonances ($\delta = 4.9-5.3$ ppm). The EI-MS data confirm the identity of complexes **13b−15b** by the appearance of the molecular-ion peaks with the correct isotopic pattern.

[$Co_2(CO)_8$]-Catalyzed Cyclotrimerization of 1−4

In refluxing toluene the mono- and diborylacetylenes **1−4** form the corresponding benzene derivatives **17−20** in the presence of a catalytic amount of $Co_2(CO)_8$ (Scheme 8).[13] The air-stable colorless solids **17−20** are not soluble in common organic solvents, although triborylbenzene derivatives **17** and **18** are partially soluble in chloroform. In general, for unsymmetrical acetylenes one can expect to achieve mixtures of both 1,3,5 and 1,2,4 isomers in variable ratios. Due to their low solubility, the mixtures of isomers **17/17′** and **18/18′** could not be separated by column chromatography.[14] Purification of the compounds was accomplished by repeated washing with hexane and toluene. Compounds **17** and **18** were characterized by ^1H, ^{11}B and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

^{13}C NMR spectroscopy, and by mass spectrometry. In the ^{13}C NMR spectra of **17** and **18** the signals for the central benzene rings are not observed. Therefore, one cannot rule out the possibility that the isomers **17**/**17′** and **18**/**18′** are present. The hexaborylbenzene derivatives **19** and **20** were identified by mass spectrometry by the appearance of molecular-ion peaks with the correct isotopic pattern. Owing to their very low solubility, NMR measurements were not possible for **19** and **20**.



Scheme 8

Under similar reaction conditions no triborylbenzene derivative was found from the reactions with 1-alkyl-2-borylacetylenes **6**−**8**.

Conclusions

The reaction of borylacetylenes with catalytic as well as stoichiometric amounts of $[CpCo(CO)_2]$, $[CpCo(C_2H_4)_2]$ and $[Co_2(CO)_8]$ have been studied. Benzene derivatives are not formed by [2+2+2] catalytic cyclotrimerization reactions of $[CpCoL_2]$ (L = CO, C_2H_4) with borylacetylenes **1**−**4** and **6**−**8**. The (η^4-cyclobutadiene)cobalt complexes **9**−**12** are, however, formed by the reaction of mono- (**1**, **2**) and diborylacetylenes (**3**, **4**) with stoichiometric amounts of $[CpCo(CO)_2]$. Analogous (η^4-cyclobutadiene)cobalt complexes **13a**−**15a** have been prepared by the reaction of the corresponding *tert*-butylborylacetylenes **6a**−**8a** in the presence of $[CpCo(C_2H_4)_2]$. The interaction of a sulfur atom with the cobalt atom in the coordinatively unsaturated cobaltacyclopentadiene derivative probably does not allow the approach of a third acetylene molecule to the cobalt center; therefore formation of benzene derivatives does not occur by [2+2+2] catalytic cycloaddition reactions of the monoboryl acetylenes **1**−**4**, **7a** and **8a**. As similar oxygen−cobalt interactions are not known, steric bulkiness may be the reason for obtaining only (η^4-cyclobutadiene)cobalt complexes from the reaction of **6a** with $[CpCo(C_2H_4)_2]$. In **7a** and **8a**, the presence of the bulky *tert*-butyl group obviously hinders the formation of benzene derivatives.

Surprisingly, such types of cyclobutadienylcobalt complexes are not found in the reactions of 1-boryl-2-silylacetylenes **6b**−**8b** under similar reaction conditions. On the other hand, treatment of **6b**−**8b** with $[CpCo(C_2H_4)_2]$ at ambient temperature led to the novel (η^4-cyclohexatriene)(η^5-cyclopentadienyl)cobalt complexes **13b**−**15b**. Reaction of mono- and diborylalkynes (**1**−**4**) with catalytic amounts of $[Co_2(CO)_8]$ gives rise to triboryl- (**17**/**17′** and **18**/**18′**) and hexaborylbenzene derivatives (**19** and **20**), respectively.

Experimental Section

General: All reactions were performed under nitrogen using standard Schlenk techniques. Solvents were dried with the appropriate drying agents and distilled under nitrogen. Glassware was dried with a heat gun under high vacuum. Column chromatography: Florosil® (Fluka), 100−200 mesh. ^1H, ^{11}B and ^{13}C NMR: Bruker AC 200 spectrometer; ^1H and ^{13}C spectra were referenced to $Si(CH_3)_4$; ^{11}B spectra to $F_3B{\cdot}OEt_2$. Mass spectra were obtained with Finnigan MAT 8230 plus spectrometers using the EI technique. Melting points (uncorrected) were obtained with a Büchi apparatus, using capillaries which were filled under nitrogen and sealed. (iPr$_2$N)$_2$BCl[15] and [bis(diisopropylamino)boryl]acetylene[16] were prepared according to literature procedures. Bromo(dithiocatechol)-borane and bromo-1,3,2-benzooxathiaborole, not previously reported in the literature, were prepared by the reactions of dithiocatechol and 2-hydroxythiophenol with excess of BBr_3. Catechol, dithiocatechol, 4-methyldithiocatechol, 2-mercaptophenol and bis(trimethylstannyl)acetylene were purchased from Aldrich.

(1,3,2-Benzodithiaborol-2-yl)acetylene (1a), (5-Methyl-1,3,2-benzodithiaborol-2-yl)acetylene (1b) and (1,3,2-Benzooxathiaborol-2-yl)-acetylene (2): $HCl{\cdot}OEt_2$ (2 M; 10.5 mL, 21 mmol) was added to a stirred solution of [bis(diisopropylamino)boryl]acetylene (2.40 g, 10.1 mmol) in 50 mL of THF at −78 °C within 15 min. Stirring was continued at room temp. for 2 h. Then, 10.1 mmol of the corresponding aromatic diol (**1a**: 1.43 g of dithiocatechol; **1b**: 1.57 g of 4-methyldithiophenol; **2**: 1.27 g of 2-hydroxythiophenol; in 15 mL of THF) was added to the white suspension and the reaction mixture was stirred overnight at room temp. After filtration, the solution was concentrated almost to dryness, and a crystalline solid was obtained.

1a: Yield: 0.98 g (55%), m.p. 62 °C (dec.). ^1H NMR (200.1 MHz, $CDCl_3$): δ = 3.71 (s, 1 H, C≡CH), 7.20, 7.80 (m, 4 H, C_6H_4) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 47 ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 94.10 (C≡*C*H), 126.0, 126.8, 140.8 (C_6H_4) ppm; C_{sp}−B signal not observed. MS (70 eV, EI): *m*/*z* (%) = 176 (20) [M^+]. MS (70 eV, HR-EI): *m*/*z* (%) = 175.9915 (13) [M^+; $^{12}C_8{}^1H_5{}^{32}S_2{}^{11}B$: 175.9926]; Δmmu = −1.1.

1b: Yield: 0.97 g (51%), m.p. 71 °C. ^1H NMR (200.1 MHz, $CDCl_3$): δ = 2.43 (s, 3 H, CH_3), 3.70 (s, 1 H, C≡CH), 7.20, 7.62 (m, 3 H, C_6H_3) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 48 ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 21.06 (CH_3), 96.24 (C≡*C*H), 126.2, 126.9, 127.3, 136.2, 137.6, 140.9 (C_6H_3) ppm; C_{sp}−B not observed.

2: Yield: 0.79 g (49%), m.p. 56 °C. ^1H NMR (200.1 MHz, $CDCl_3$): δ = 3.17 (s, 1 H, C≡CH), 7.1−7.7 (m, 4 H, C_6H_4) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 38 ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 97.23 (C≡*C*H), 115.1, 120.9, 124.1, 126.4, 127.8, 156.5 (C_6H_4) ppm; C_{sp}−B signal not observed. MS (70 eV, EI): *m*/*z* (%) = 160 (10) [M^+].

Isolation of an Intermediate during the Decomposition of a Tetragold-Phosphane Complex

Nermin Biricik,[a] Zhaofu Fei,[a] Rosario Scopelliti,[a] and Paul J. Dyson*[a]

Keywords: N,P Ligands / Diphosphanylamines / Gold complexes

Reaction of the diphosphanylamine 2,6-{$(Ph_2P)_2N$}$_2C_5H_3N$ with four equivalents of Au(tht)Cl (tht = tetrahydrothiophene) affords the tetragold complex 2,6-{$(ClAuPh_2P)_2N$}$_2C_5H_3N$ in high yield. Decomposition of the tetragold compound results in the formation of the digold complex 2,6-{$(ClAuPh_2P)HN$}$_2C_5H_3N$ and colloidal gold. A trigold intermediate, which contains a Au–Au interaction [2.9886(5) Å] has been isolated, and while ultimately unstable, it is thought to be partially stabilised by virtue of the aurophilic nature of gold.

Introduction

Gold(I)-phosphane complexes and clusters have been extensively studied over the years.[1] Apart from fundamental interest in these types of compounds, they exhibit a number of interesting properties which gives rise to a wide range of different applications. Gold(I) complexes display anticancer activity and are employed in clinics for the treatment of rheumatoid arthritis.[2] In addition, they exhibit interesting photophysical[3] and catalytic properties.[4] From the plethora of studies involving gold(I) complexes, interactions between linearly coordinated gold(I) centres have been found to be extremely common, leading to self-assembled suprastructures through Au−Au intermolecular contacts.[5] In many cases these suprastructures exhibit strong photo-luminescence.[6] The term used to describe the affinity of gold to form Au−Au interactions is "aurophilicity",[7] which was introduced in 1989, and theoretical studies have since placed the effect on a solid foundation.[8]

Many different phosphane ligands have been used to form complexes with gold, in particular heterodentate phosphanes, which tend to afford multi-nuclear complexes containing Au−Au interactions.[9] Such interactions have been shown to persist in solution.[10] Aurophilicity is especially favoured where several phosphorus centres are in close proximity, enabling intramolecular auration, for example, in calix[3]arene and calix[4]arene based phosphane systems.[11] Complexes with diphosphanylamine ligands are also known.[12] Diphosphanylamines comprise a P−N−P backbone and some of their gold(I) complexes are light/moisture sensitive,[13] presumably due to the instability of both the P−N and Au−P bonds, resulting in the formation of colloidal gold particles. Formation of gold colloids, typically denoted by the precipitation of a purple/black powder, is frequently observed in gold(I) chemistry, however, the intermediate species formed during the decomposition process and decomposition mechanism remain essentially unknown. In this paper we describe the synthesis of a tetragold-diphosphanylamine complex and its decomposition to a digold species in which an intermediate trigold compound is isolated and characterised, providing insight into the decomposition mechanism.

Results and Discussion

The diphosphanylamine ligand 2,6-{$(Ph_2P)_2N$}$_2C_5H_3N$ (**L_1**) has previously been shown to undergo a remarkable reaction with H^+ to form the iminobiphosphane 2,6-$(Ph_2P-Ph_2P=N)_2C_5H_3NH^+$.[14] Since H^+ and certain gold fragments are isolobal[15] we thought that it would be interesting to explore the reactivity of **L_1** towards gold. Thus, under an inert atmosphere, **L_1** was treated with four equivalents of Au(tht)Cl (tht = tetrahydrothiophene) in dichloromethane at room temperature yielding 2,6-{$(ClAuPh_2P)_2N$}$_2C_5H_3N$ (**1**) as the only product (Scheme 1). The ^{31}P NMR spectrum of the reaction solution exhibits a sharp singlet at $\delta = 84.0$ ppm indicating that all of the phosphorus atoms are equivalent. In addition, the electrospray ionisation mass spectrum of **1** in dichloromethane exhibits a parent peak at $m/z = 1775$ which corresponds to the protonated intact parent ion $[M + H]^+$. After removal of the solvent under reduced pressure **1** was obtained as a white powder.

Compound **1** is stable in the solid state, but decomposes slowly in solution on exposure to air/moisture. The decomposition reaction can be monitored by ^{31}P NMR spectroscopy. The ^{31}P NMR spectrum in dichloromethane exhi-

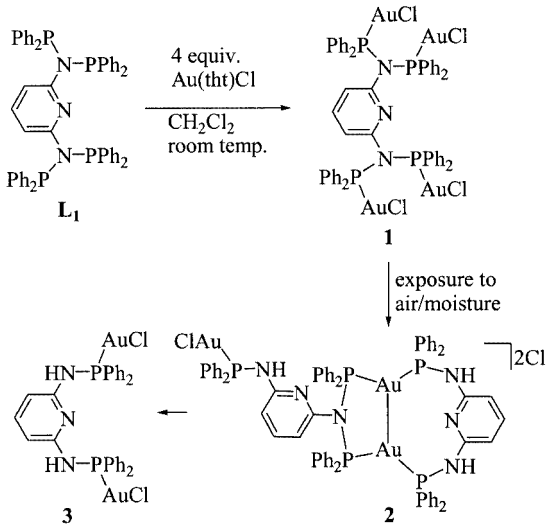

Scheme 1. Degradation of **1** and its decomposition to **3** via **2**, following exposure to air/light

bits, in the first instance, the signal at δ = 84.0 ppm corresponding to **1**, which decreases in intensity until it has completely disappeared after six hours. In its place three broad signals at 97.0, 68.9, 52.2 ppm (for which the P−P coupling could not be resolved) together with signals at δ = 35.6 ppm and −20.6 ppm ($J_{P\text{-}P}$ = 229.0 Hz) which are readily attributed to $Ph_2P(O)PPh_2$,[16] are observed. Simultaneously, the reaction mixture turns from colourless to purple, a characteristic colloid colouration, due to the formation of elemental gold. The three unidentified signals correspond to a new complex **2**, which by virtue of being a salt, precipitates from solution, on addition of diethyl ether. After filtration and removal of the solvent, the solid was washed with diethyl ether and obtained in its pure form and recrystallised from chloroform to afford crystals suitable for analysis by X-ray diffraction. The structure of the dication in **2** is shown in Figure 1 and key bond parameters are listed in the caption. Crystal data and details of the structure determination are listed in Table 1 and further details are given in the Experimental Section.

Compound **2** contains three gold centres and two different ligands, 2-{$(Ph_2P)_2N$}-6-{$(Ph_2P)HN$}-C_5H_3N (**L_2**) and 2,6-{$(Ph_2P)HN$}$_2C_5H_3N$ (**L_3**) (see Figure 2), both derived from the diphosphanylamine ligand **L_1** by substitution of one and two Ph_2P units by a proton, respectively. The Au−P and Au−Cl distances in **2** are similar to those observed in structurally related compounds;[17] whereas the Au−Au distance is 2.9886(5) Å, which is somewhat longer than those usually found in complexes containing Au−Au bonds within an "A"-frame structure involving a five-membered ring.[18] However, this distance is not long when compared to those observed in complexes where the gold centres are not orientated in such close proximity. The Au(1)−P(1) [2.301(2) Å], Au(1)−P(3) [2.312(2) Å], Au(2)−P(2) [2.303(2) Å] and Au(2)−P(4) [2.299(2) Å] distances are all similar, being slightly longer than the Au(3)−P(5) [2.219(3) Å] distance which involves the P−Au−Cl system. While the P(5)−Au(3)−Cl(1) fragment is nearly linear with an angle of 177.33(9)°, the P(1)−Au(1)−P(3) and P(2)−Au(2)−P(4) units form angles

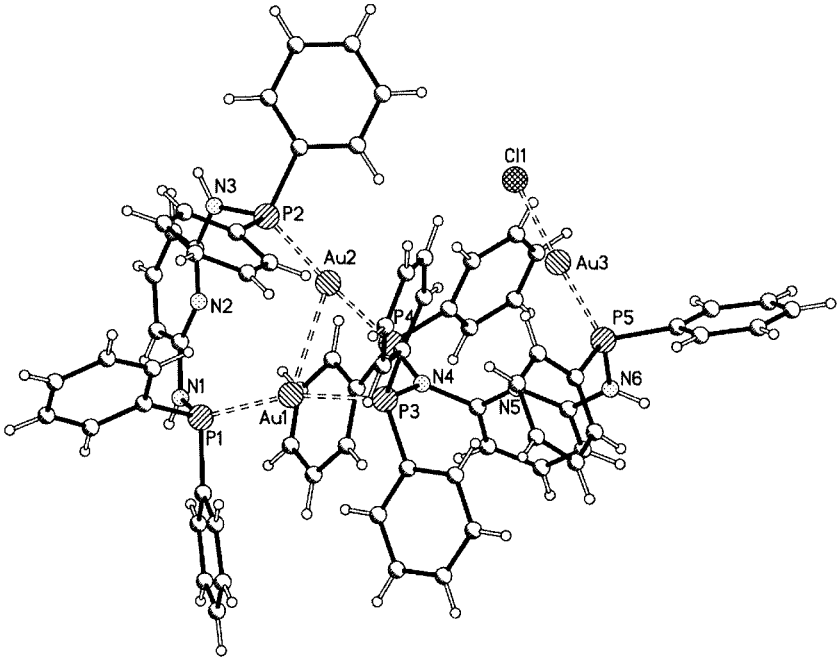

Figure 1. Molecular structure of **2** in the solid state (ball-and-stick representation showing just the cation with a partial labelling scheme, the Cl anions and all the solvent molecules have been omitted for clarity); key bond lengths (Å) and angles (°) include: Au(1)−P(1) 2.301(2), Au(1)−P(3) 2.312(2), Au(1)−Au(2) 2.9886(5), Au(2)−P(4) 2.299(2), Au(2)−P(2) 2.303(2), Au(3)−P(5) 2.219(3), Au(3)−Cl(1) 2.305(3), P(1)−N(1) 1.670(7), P(2)−N(3) 1.673(8), P(3)−N(4) 1.694(7), P(4)−N(4) 1.702(8), P(5)−N(6) 1.676(8), P(1)−Au(1)−P(3) 163.94(8), P(1)−Au(1)−Au(2) 112.58(6), P(3)−Au(1)−Au(2) 80.68(6), P(4)−Au(2)−P(2) 174.23(8), P(4)−Au(2)−Au(1) 78.00(6), P(2)−Au(2)−Au(1) 107.24(6), P(5)−Au(3)−Cl(1) 177.33(9)

to **2** steadily disappear, with the concomitant formation of a new singlet resonance at δ = 55.1 ppm. The peak at δ = 55.1 ppm has been assigned to **3**, which has been isolated in its pure form following the decomposition of **2** in dichloromethane on a preparative scale. In addition, **3** can be prepared directly from the reaction of Au(tht)Cl with 2,6-{$(Ph_2P)HN\}_2C_5H_3N$ (see below). The other components from the reaction, as denoted by ^{31}P NMR spectroscopy, have been tentatively assigned as $Ph_2P(O)PPh_2$ (see above), with lesser amounts of $Ph_2P(O)OH$ and Ph_2POH, as represented by signals of low relative intensity at δ = 35.5 and 24.0 ppm. A dark purple precipitate is observed which presumably corresponds to gold colloid. The structure of **3** has been established in the solid-state by single-crystal X-ray diffraction on crystals grown from a dichloromethane/diethyl ether solution at room temperature. The molecular structure of **3** is shown in Figure 3 and key bond parameters are listed in the caption.

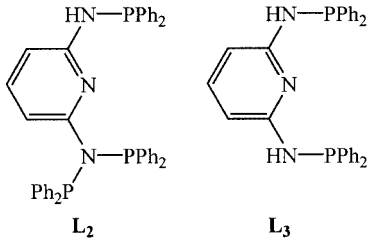

Figure 2. Ligands $\mathbf{L_2}$ and $\mathbf{L_3}$

of 163.94(8) and 174.23(8)°, respectively. The deviation from linearity is presumably due to the bulky ligands surrounding the Au−Au unit, which also results in the relatively long Au−Au contact.

Compound **2** is stable in the solid-state, but decomposes in solution on exposure to air/light. The decomposition reaction of complex **2** in dichloromethane was followed in situ by ^{31}P NMR spectroscopy. The peaks corresponding

Compound **3** is based on a $\mathbf{L_3}$-type ligand in which a Au−Cl fragment coordinates to each phosphorus(III) centre. The parameters in **3** are largely in accordance with the structurally similar compounds.[12,13] The Au(1)−P(1) [2.2377(14) Å] and Au(2)−P(2) [2.2359(15) Å] bond lengths are similar and somewhat longer than the related Au(3)−P(5) bond of 2.219(3) Å in **2**. The P(1)−Au(1)−Cl(1) and P(2)−Au(2)−Cl(2) units are essen-

Figure 3. tially linear with bond angles of 179.59(5) and 178.69(6)°, respectively.

The decomposition process **1** → **2** → **3** is worth some further comment since **2** cannot be prepared by a rational route. Complex **2** contains two different aminophosphane ligands, $\mathbf{L_2}$ and 2,6-{$(Ph_2P)HN$}$_2C_5H_3N$ ($\mathbf{L_3}$) which are derived from $\mathbf{L_1}$ by substitution of one and two Ph_2P units by a proton, respectively. Ligand $\mathbf{L_3}$ has been reported before,[19] and attempts to prepare $\mathbf{L_2}$ using a rational route, viz. reaction of one equivalent of 2,6-diaminopyridine with three equivalents of Ph_2PCl, are only partially successful. The main product from this reaction is $\mathbf{L_1}$ based on ^{31}P NMR spectroscopy and electrospray ionisation mass spectrometry. The formation of $\mathbf{L_2}$ was identified in the reaction mixture by electrospray ionisation mass spectrometry which contained peaks corresponding to $\mathbf{L_1}$ and $\mathbf{L_2}$, the peak at m/z = 662 corresponds to $[\mathbf{L_2}+H]^+$, but it has, as yet, not been possible to isolate $\mathbf{L_2}$ from the mixture, although attempts are ongoing.

Reaction of $\mathbf{L_3}$ with Au(tht)Cl in a 1:2 molar ratio gave complex **3** in quantitative yield, however, all attempts to prepare **2** from different combinations of $\mathbf{L_1}$ and $\mathbf{L_3}$ and Au(tht)Cl were unsuccessful. The reason that **2** is isolated at all is probably due to the lower solubility of **2** relative to **1** and **3** since it is a salt which facilitates precipitation from the reaction solution. However, this property alone does not fully explain the stability of **2** and we propose that the aurophilicity of gold, resulting in the Au−Au interaction, further stabilises the intermediate and facilitates its isolation. This property frequently results in structural diversity in gold(I) complexes.[20] However, we believe that compound **2** is especially pleasing as all researchers preparing novel gold complexes are frequently frustrated by decomposition to (or formation of) gold colloids, and in our system, we were fortunate enough to isolate a decomposition intermediate.

Experimental Section

The ligands 2,6-{$(Ph_2P)_2N$}$_2C_5H_3N$ ($\mathbf{L_1}$)[21] and 2,6-{$(Ph_2P)HN$}$_2C_5H_3N$ ($\mathbf{L_3}$)[19] and the complex Au(tht)Cl (tht = tetrahydrothiophene)[22] were prepared according to literature methods. Solvents were dried using appropriate reagents and distilled prior to use. NMR spectra were recorded in $CDCl_3$ at 20 °C with a Bruker DMX 200 instrument using $SiMe_4$ as the external standard for the ^1H NMR spectroscopy and 85% H_3PO_4 for the ^{31}P NMR spectroscopy. ESI-MS spectra were recorded on a ThermoFinnigan LCQ↗ Deca XP Plus quadrupole ion trap instrument using a literature method.[23] Samples were infused directly into the source at 5 μL min^{-1} using a syringe pump. The spray voltage was set at 5 kV and the capillary temperature at 50 °C. The MS detector was tuned automatically on the base peak, which optimised the remaining parameters. Elemental analyses was carried out at the Institute of Molecular and Biological Chemistry at the EPFL.

Synthesis of 1: Au(tht)Cl (256 mg, 0.80 mmol) was added to a solution of 2,6-{$(Ph_2P)_2N$}$_2C_5H_3N$ (170 mg, 0.20 mmol) in dichloromethane (10 mL) at 0 °C. The reaction mixture was allowed to warm to room temperature and stirred for 15 minutes. The solvent was removed under vacuum and the resulting white solid was washed with diethyl ether (2 × 2 mL) to give the product **1** as a white powder. Yield: 330 mg, 94%. ^1H NMR: δ = 6.5−8.20 (m, aromatic H) ppm. ^{31}P NMR: δ = 84.0 (s) ppm. ESI-MS$^+$ m/z: 1775 $[M + H]^+$. $C_{53}H_{43}Au_4Cl_4N_3P_4$ (1775.52): H 2.44, C 35.85, N 2.37; found H 2.47, C 35.89, N 2.34.

Synthesis of 2: A solution of **1** (300 mg, 0.17 mmol) in dichloromethane (10 mL) was stirred in air for 6 h at room temperature, after which time the ^{31}P NMR spectra showed the absence of the starting material **1**. The solvent was removed under reduced pressure and the remaining solid was washed with diethyl ether (3 × 10 mL) to give **2** as a white powder. Colourless crystals were obtained by slow evaporation of a solution in $CDCl_3$ at room temperature. Yield: 105 mg, 22%. M.p. 147 °C. ^1H NMR: δ = 6.5−8.20 (m, aromatic H); 6.30 (broad signal, NH) ppm. ^{31}P NMR: δ = 97.0 (broad signal), 68.9 (broad signal), 52.2 (broad signal) ppm. ESI-MS$^+$ m/z: 1765 [cation]$^+$. $C_{70}H_{59}Au_3Cl_3N_6P_5$ (1836.40): H 3.24, C 45.78, N 4.58; found H 3.31, C 45.89, N 4.60.

Synthesis of 3. Method A: A solution of **2** (190 mg, 0.10 mmol) in dichloromethane (10 mL) was stirred in air in for 24 hours at room temperature. The solvent was removed under reduced pressure and the remaining solid was washed with diethyl ether (3 × 10 mL). Colourless crystals were obtained by slow evaporation of a solution in dichloromethane at room temperature in two days. Yield: 40 mg, 41%.

Method B: Au(tht)Cl (64 mg, 0.20 mmol) was added to a solution of $\mathbf{L_3}$ (47 mg, 0.10 mmol) in dichloromethane (10 mL) at 0 °C. The reaction mixture was allowed to warm to room temperature and stirred for 30 minutes. The solvent was removed under vacuum and the resulting white solid was washed with diethyl ether (2 × 2 mL) to give the product **3** as a white powder. Yield: 90 mg, 95%. M.p. 163 °C (decmp.). ^1H NMR: δ = 6.5−8.20 (m, aromatic H); 6.50 (br., NH) ppm. ^{31}P NMR: δ = 55.1 (s) ppm. ESI-MS$^+$ m/z: 942 $[M + H]^+$. $C_{29}H_{25}Au_2Cl_2N_3P_2$ (942.32): H 2.67, C 36.96, N 4.46; found H 2.71, C 37.04, N 4.39.

X-ray Sructure Determination: Details about the crystals and their structure refinement are listed in Table 1, whereas relevant geometrical parameters, including bond lengths and angles are included in the figure captions. Data collections for both compounds were performed at 140 K on a 4-circle goniometer having kappa geometry and equipped with an Oxford Diffraction KM4 Sapphire CCD. Data reduction was carried out with CrysAlis RED, release 1.7.0.[24] Absorption corrections[25] have been applied to both data sets. Structure solution and refinement as well as molecular graphics and geometrical calculations were performed for both structures with the SHELXTL software package, release 5.1.[26] The structures were refined using the full-matrix least-squares on F^2 with all of the non-H atoms defined anisotropically. H atoms were placed in calculated positions using the "riding model".

CCDC-242559 (for **2**) and -242560 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Nonbridging and Monodentate Carboxylate Coordination of Calcium(2+) Through the Use of Intramolecular Hydrogen Bonding in a New Sterically Hindered Carboxylate Ligand

Jonathan D. Crane,*[a] David J. Moreton,[b] and Eleanor Rogerson[a]

Keywords: Calcium / Hydrogen bonds / Carboxylate ligands / Sterically hindered ligands

The sterically hindered carboxylate ligand 2,6-bis(2,2-dimethylpropionylamino)benzoic acid (**HL**) has been prepared. The two intramolecular hydrogen bonds in **HL** are exploited to restrict the corresponding carboxylate anion ($\mathbf{L}^-$) to nonbridging coordination and to preorganise its sterically bulky substituents proximal to the first and second coordination sphere of the bound metal ion. The crystal structures of the ligand anion as the ammonium salt $[NH_4][\mathbf{L}]$ and the distorted octahedral calcium complex $Ca\mathbf{L}_2(H_2O)_2$, in which $\mathbf{L}^-$ binds to the calcium(2+) ion in a monodentate, nonbridging mode, are described.

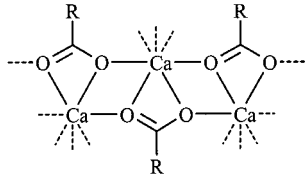
Introduction

Sterically hindered ligands are commonly used to control the coordination environment of metal ions, and hence their properties, through favouring lower coordination numbers and/or by preventing the unwanted formation of polynuclear species that often arise through ligand bridging.[1] This approach is particularly challenging for carboxylate ligands, nevertheless over recent years the application of this strategy has proven to be effective for the synthesis of some low molecular weight model compounds for transition metal ion sites in proteins, in which the role of the protein in providing a preorganised arrangement of carboxylate ligands at a metal ion binding site has been to some extent reproduced by the use of steric hindrance.[2] With sterically hindered carboxylate ligands the challenge is not primarily to limit coordination numbers, but rather to inhibit the strong natural tendency of the carboxylate group to bridge between two or more metal ions which results in the undesired formation of polymeric or highly polynuclear species. This is particularly problematic for the coordination chemistry of calcium(2+) which has an ionic radius of 0.99 Å, substantially larger than divalent transition metal ions [e.g., high-spin iron(2+), 0.78 Å], and as a consequence the triply bridging motif **I** and related structures are commonplace for simple carboxylate ligands.[3] In contrast, monodentate, nonbridging carboxylates are common ligands for calcium(2+) in proteins,[4] and although there are several examples of such calcium(2+) coordination for small molecules in the Cambridge Crystallographic Database,[5] these are all apparently serendipitous, arising unpredictably from the use of polydentate ligands and/or fortuitous packing arrangements.[6]



I

We wished to design a sterically hindered carboxylate ligand that specifically excludes the possibility of laterally bridging coordination to calcium(2+) or other metal ions. The sterically hindered 2,6-dialkyl- or 2,6-diarylbenzoic acid derivatives currently used for transition metal studies were not considered appropriate as the carboxylate group is free to rotate out of the plane of the aromatic ring and thus bridging is still allowed to occur.[2] The chosen design strategy was to use two intramolecular hydrogen bonds from adjacent amide groups to constrain the carboxylate group to be coplanar with the aromatic ring and therefore prevent lateral bridging to metal ions, whilst preorganising two sterically bulky groups proximal to the first and second coordination spheres of any bound metal ion. We herein report the synthesis of the *tert*-butyl-substituted ligand **HL**, the structure of its anion (as the ammonium salt) and its complexation with calcium(2+). Moreover, the straightforward synthesis of **HL** should allow the facile preparation of derivatives with a wide variety of R substituents, thus

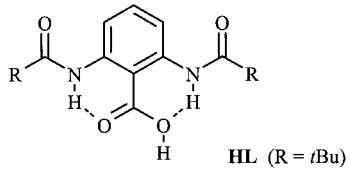
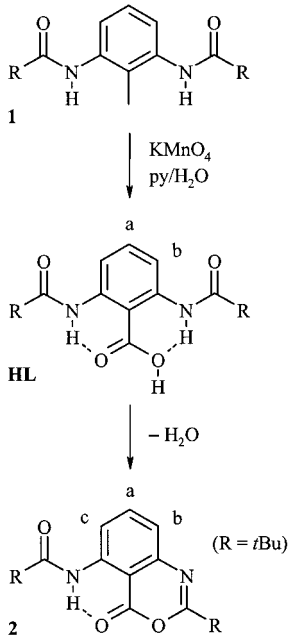
providing the opportunity for further control over the first and second coordination spheres of any metal ion and greater scope for the design of metallobiosite model complexes where restriction of the carboxylate coordination mode is required.



Results and Discussion

The carboxylic acid **HL** was readily prepared in 41% yield by the oxidation of the aromatic methyl group of diamide **1**[7] with potassium permanganate in aqueous pyridine at reflux (Scheme 1).[12] The two intramolecular hydrogen bonds in **HL** would be expected to stabilise the corresponding carboxylate anion, but less so than for 2,6-dihydroxybenzoic acid (vide supra).[13] In nonprotogenic solvents (e.g., chloroform) the carboxylic acid **HL** was found readily to eliminate water over several hours to form the benzoxazine **2**. ^{1}H and ^{13}C NMR spectroscopy showed that in chloroform an equilibrium (1:2) mixture of **HL/2** (and water) was formed after approximately 24 h. Pure **2** could be obtained in quantitative yield by the deliberate dehydration of a toluene solution of **HL** with excess acetic anhydride. Under mildly basic conditions in the presence of water both **HL** and **2** were found to rapidly reform the carboxylate anion $\mathbf{L}^{-}$.



Scheme 1

The structure of the carboxylate anion $\mathbf{L}^{-}$ is revealed by the single-crystal X-ray structure determination of the ammonium salt **3** (Figure 1). As expected, there are intramolecular hydrogen bonds between the two amide N−H groups and the carboxylate oxygen atoms. The X-ray diffraction data were of sufficient quality for the amide N−H hydrogen atoms to be located in the difference Fourier map and freely refined; the N−H bond lengths of 0.90(3) Å indicate that there is no significant lengthening of the N−H bonds compared with the expected value of 0.85−0.90 Å, as determined by X-ray diffraction.[5] In addition, the N(1)···O(1) and N(2)···O(2) distances of 2.564(3) and 2.571(3) Å are relatively long, and the N(1)−H(1)···O(1) and N(2)−H(2)···O(2) angles of 142(2) and 147(3)° are significantly more acute than the usual range of 160−180° for strong hydrogen bonds. Furthermore, the carboxylate and two amide groups are slightly twisted out of the plane of the central aromatic ring with torsional angles between the respective pairs of least-squares planes of 21.3(1), 10.6(1) and 18.7(1)°. All these structural parameters suggest that these hydrogen bonds are weaker than in the near-planar 2,6-dihydroxybenzoate anion (Table 1),[13] and indicate that **HL** should be a weaker acid than 2,6-dihydroxybenzoic acid. However, the most important effect of these hydrogen bonds is that they successfully preorganise the planar, *trans*-primary-amide groups and therefore position the bulky *tert*-butyl groups to restrict coordination to the carboxylate group. In the lattice of **3** the packing of the carboxylate anions leaves cavities that are each occupied by a pair of ammonium counterions, with an inter-ammonium cation (N···N) distance of 3.675(3) Å, which, although short, is typical for ammonium carboxylate structures.[14] This electrostatically unfavourable arrangement is compensated for by the formation of hydrogen bonds to all four of the ammonium N−H bonds, thus the two ammonium ions are imprisoned in a cage of eight appropriately positioned hydrogen bond acceptor oxygen atoms (Figure 2, Table 2).

The structure of **4** (Figure 3) shows that the carboxylate ligand is bound to the calcium ion in the desired monodentate and nonbridging manner, and that the calcium ion is restricted to six coordination and a distorted octahedral geometry. Indeed, the "average" coordination environment for calcium(2+) in proteins is octahedral, and moreover with a mixture of carboxylate, peptide carbonyl and water ligands,[4] coincidently very similar to the specific structure described here. The average Ca−O bond length is 2.359 Å, only slightly longer than the value of 2.337 Å found for the comparable, unhindered octahedral complex $Ca(acac)_2(H_2O)_2$.[15] The Ca−O(1) distance is the longest in the calcium coordination sphere in **4**, 2.3830(11) Å, presumably due to the steric congestion of the carboxylate group, and the carboxylate is clearly monodentate with a very long Ca(1)···O(2) distance of 3.7205(12) Å. It is particularly noteworthy that this coordination mode is preferred over a more symmetrical bidentate coordination, or the formation of simple second coordination sphere $[Ca(H_2O)_n]^{2+}$ hydrogen-bonded salts of the ligand anion. One possible reason for the stability of **4** is that the long Ca−O(1) bond is supported by a strong hydrogen bond between the adjacent water ligand and the nonbound carboxylate oxygen atom

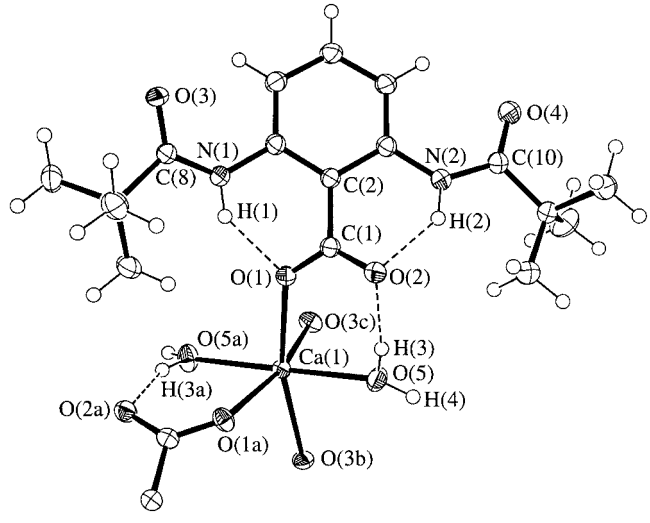

Figure 3. ORTEP[18] view of the structure of **4** with thermal ellipsoids shown at 50%; hydrogen bonds are denoted by dashed lines; for clarity only one ligand is shown in its entirety; selected bond lengths [Å] and angles [°]: Ca(1)−O(1) 2.3830(11), Ca(1)−O(5) 2.3378(11), Ca(1)−O(3b) 2.3560(11), C(8)−N(1) 1.349(2), C(8)−O(3) 1.241(2), C(10)−N(2) 1.362(2), C(10)−O(4) 1.232(2); O(1)−Ca(1)−O(5) 80.45(4), O(1)−Ca(1)−O(1a) 93.16(6), O(1)−Ca(1)−O(3b) 164.67(4), O(3b)−Ca(1)−O(3c) 90.37(6), O(3b)−Ca(1)−O(5) 84.29(4), O(5)−Ca(1)−O(5b) 177.44(7); symmetry transformations: a: 3 − *x*, *y*, 3/2 − *z*; b: 1/2 + *x*, 1/2 + *y*, *z*; c: 5/2 − *x*, 1/2 + *y*, 3/2 − *z*

O(2) (Table 1); thus the carboxylate group is effectively acting as a bidentate ligand to a $Ca-OH_2$ group. Indeed, several similar structural motifs have been described over recent years in the transition metal chemistry of sterically hindered carboxylate ligands,[2] and in calcium(2+) coordination chemistry.[16] The coordination sphere of the calcium ion is completed by one amide carbonyl group from each of two equivalent neighbouring molecules, and the Ca(1)−O(3a) bond length of 2.3560(11) Å and Ca(1)−O(3a)−C(8a) angle of 169.98(11)° are typical of a predominantly electrostatic interaction with the metal ion. This interaction also results in a slight perturbation of the amide group with a longer C(8)=O(3) distance of 1.241(2) Å and shorter C(8)−N(1) distance of 1.349(2) Å compared to 1.232(2) and 1.362(2) Å, respectively for the other, non-coordinated amide group. Similar to as described above for **3**, the carboxylate and two amide groups in **4** are twisted out of the plane of the central aromatic ring. The torsional angles between the respective pairs of least-squares planes of 33.6(1), 25.0(1) and 10.1(1)° show that the ligand in **4** has larger distortions from planarity than in **3**, particularly with regard to the carboxylate group. For **3** and **4** these variations in torsional angles probably primarily arise from different packing effects and bonding requirements of the ammonium and calcium(2+) ions, respectively.

In conclusion, the sterically hindered ligand **HL** designed for nonbridging coordination to metal ions has been successfully prepared and its desired mode of coordination structurally characterised for a mononuclear calcium(2+) complex. The coordination chemistry of **HL** and related ligands with transition metal and lanthanide ions is currently under investigation.[17]

Experimental Section

General: *N*-[3-(2,2-Dimethylpropionylamino)-2-methylphenyl]-2,2-dimethylpropionamide (**1**) was prepared from 2,6-diaminotoluene and trimethylacetyl chloride by a literature method.[7] Elemental analyses were obtained with a Fisons EA1108 CHNS analyser. IR spectra were recorded as KBr disks with a Perkin−Elmer Paragon-100 FT-IR spectrophotometer. NMR spectra were recorded using a Jeol JNM-LA400 spectrometer at room temperature (20 °C) and are reported relative to tetramethylsilane. Mass spectra were recorded with a Finnigan 1200 (EI) mass spectrometer.

2,6-Bis(2,2-dimethylpropionylamino)benzoic Acid (HL): Potassium permanganate (4.75 g, 30 mmol) and diamide **1** (4.35 g, 15 mmol) in pyridine/water (1:1, 150 mL) was heated at reflux with constant stirring for 2 h, or until the purple colour of the permanganate had disappeared. The reaction mixture was allowed to cool to room temperature, water (250 mL) added, then the solution filtered to remove the dark brown precipitate of hydrated manganese dioxide. The pale yellow filtrate was concentrated to near dryness under reduced pressure and water (150 mL) added. The insoluble residue of unchanged **1** was filtered off, concentrated hydrochloric acid (20 mL) added to the filtrate and the precipitate of **HL** extracted into dichloromethane (3 × 40 mL). The dichloromethane extracts were combined, dried ($MgSO_4$), filtered, and the solvents evaporated to dryness under reduced pressure. Yield: 2.55 g (53%). The product was sufficiently pure for subsequent use, but an analytically pure sample could not be obtained by recrystallisation due to the facile conversion of **HL** to ***N*-(2-*tert*-butyl-4-oxo-4*H*-benzo-[*d*][1,3]oxazin-5-yl)-2,2-dimethylpropionamide (2)**. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.32 (s, 18 H, CH_3), 7.20 (br. s, 1 H, CO_2H), 7.49 (t, ^3J = 8.3 Hz, 1 H, H^a), 8.26 (d, ^3J = 8.3 Hz, 2 H, H^b), 10.44 (s, 2 H, NH) ppm. ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 27.6, 40.3, 106.8, 117.1, 134.3, 140.9, 169.6, 177.5 ppm. IR (KBr): ṽ = 3407 (m), 2970 (m), 2874 (w), 1694 (s), 1636 (m), 1610 (m), 1582 (s), 1514 (s), 1464 (s), 1368 (m), 1294 (m), 1222 (s), 1163 (m), 1125 (w), 812 (m), 785 (m), 752 (m), 701 (w), 420 cm^{-1} (w). MS (EI): *m*/*z* (%) = 320 (14) [M^+], 302 (26) [$M^+ - H_2O$].

***N*-(2-*tert*-Butyl-4-oxo-4*H*-benzo[*d*][1,3]oxazin-5-yl)-2,2-dimethylpropionamide (2):** In nonaqueous solutions (e.g., chloroform) **HL** was found to eliminate water over a period of a few hours to give an equilibrium mixture of **HL**, the benzoxazine **2** and water. The deliberate dehydration of **HL** with excess acetic anhydride in toluene gave a near quantitative yield of pure **2**. A sample for analysis was recrystallised from petroleum ether (boiling range 60−80 °C) as colourless needles. $C_{17}H_{22}N_2O_3$ (302.37): calcd. C 67.53, H 7.33, N 9.26; found C 67.49, H 7.46, N 9.25. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.37 (s, 9 H, CH_3), 1.40 (s, 9 H, CH_3), 7.26 (d, ^3J = 8.2 Hz, 1 H, H^b), 7.75 (t, ^3J = 8.2 Hz, 1 H, H^a), 8.79 (d, ^3J = 8.2 Hz, 1 H, H^c), 11.39 (s, 1 H, NH) ppm. ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 27.5, 27.6, 37.8, 40.6, 103.9, 118.2, 120.8, 137.9, 141.6, 147.1, 162.5, 167.2, 178.5 ppm. IR (KBr): ṽ = 3298 (w), 2968 (m), 1716 (m), 1698 (s), 1645 (m), 1610 (m), 1580 (s), 1542 (m), 1475 (m), 1291 (m), 1182 (m), 1157 (s), 1049 (m), 914 (w), 817 (s), 715 (m), 690 (m), 556 cm^{-1} (w). MS (EI): *m*/*z* (%) = 302 (31) [M^+], 245 (100) [$M^+ - C_4H_9$].

Ammonium 2,6-Bis(2,2-dimethylpropionylamino)benzoate, [NH$_4$]L (3): Carboxylic acid **HL** (0.96 g, 3 mmol) and potassium hydroxide (0.16 g, 2.9 mmol) were dissolved in methanol/water (1:1, 40 mL). Concentrated aqueous ammonia (20 mL) was added, the solution filtered and allowed to concentrate slowly. Large, colourless, X-ray quality crystals of **3** were obtained after 2−3 d. Yield: 0.56 g (55%). $C_{17}H_{27}N_3O_4$ (337.42): calcd. C 60.51, H 8.07, N 12.45; found C 60.35, H 8.32, N 12.32. ^{1}H NMR (400 MHz, [D$_6$]DMSO): δ = 1.20 (s, 18 H, CH_3), 7.14 (t, ^3J = 8.2 Hz, 1 H, H^a), 7.24 (br. s, 4 H, NH_4^+), 8.21 (d, ^3J = 8.2 Hz, 2 H, H^b), 14.04 (br. s, 2 H, NH) ppm. ^{13}C NMR (100.6 MHz, [D$_6$]DMSO): δ = 27.5, 111.5, 113.1, 129.1, 141.6, 171.3, 176.3 (the *t*Bu peak at ca. 40 ppm is masked by the solvent peak). IR (KBr): ṽ = 3080 (m), 2970 (m), 2155 (w), 1943 (w), 1654 (m), 1611 (m), 1580 (s), 1473 (s), 1433 (s), 1362 (s), 1252 (m), 916 (w), 839 (m), 785 (m), 709 (w), 548 (w), 421 cm^{-1} (w).

Calcium Bis[2,6-bis(2,2-dimethylpropionylamino)benzoate] Dihydrate, CaL$_2$(H$_2$O)$_2$ (4): Carboxylic acid **HL** (0.96 g, 3 mmol) and potassium hydroxide (0.16 g, 2.9 mmol) were dissolved in water (45 mL). A solution of calcium acetate monohydrate (0.24 g, 1.5 mmol) in water (5 mL) was added and the resulting solution was filtered. Large, colourless, X-ray quality crystals of **4** were obtained after 3−4 d. Yield: 0.68 g (63%). $C_{34}H_{50}CaN_4O_{10}$ (714.87): calcd. C 57.13, H 7.05, N 7.84; found C 56.97, H 7.01, N 7.66. ^{1}H NMR (400 MHz, [D$_6$]DMSO): δ = 1.21 (s, 18 H, CH_3), 3.35 (br. s, 2 H, H_2O), 7.16 (t, ^3J = 8.3 Hz, 1 H, H^a), 8.22 (d, ^3J = 8.3 Hz, 1 H, H^b), 13.85 (br. s, 2 H, NH) ppm. ^{13}C NMR (100.6 MHz, [D$_6$]DMSO): δ = 27.5, 111.0, 113.2, 129.4, 141.7, 172.2, 176.3 (the *t*Bu peak at ca. 40 ppm is masked by the solvent peak). IR (KBr): ṽ = 3398 (m), 3133 (m), 2967 (m), 1652 (m), 1626 (m), 1591 (m), 1480 (s), 1441 (m), 1360 (s), 1306 (m), 1252 (m), 1172 (m), 991 (w), 917 (w), 831 (m), 783 (m), 747 (m), 640 (w), 549 (w), 416 cm^{-1} (w).

II image plate diffractometer. Space groups were determined by an examination of the systematic absences in the data, and their correct identification was confirmed by the successful solution and refinement of the structures. Solutions were provided by direct methods using SHELXS-97 and refined by full-matrix least squares on F^2 using SHELXL-97.[8] Numerical absorption corrections were applied to **4** using X-RED/X-SHAPE.[9] All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were placed in calculated positions with U_{iso} set at 1.2 times the U_{eq} of the parent atom, and methyl groups were allowed to rotate about their X−C bonds; the positions of all N−H and O−H groups were freely refined. The analysis of the structures was carried out with PLATON[10] and WinGX.[11] Details are given in Table 3. Supplementary data for **3** and **4** are available free of charge from the Cambridge Crystallographic Data Centre (CCDC), 12 Union Road, Cambridge, CB2 1EZ, UK [Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk], quoting the deposition numbers CCDC-239602 and -239601, respectively.

Synthesis, Structure, Optical Properties and Theoretical Studies of $Pt(P-P)(CN)_2$ with P−P = 1,2-Bis(diphenylphosphanyl)benzene and 2,2′-Bis(diphenylphosphanyl)-1,1′-binaphthyl − Luminescence from Metal-to-Ligand Charge Transfer and Intraligand States

Valeri Pawlowski,[a] Horst Kunkely,[a] Christian Lennartz,*[b] Karlheinz Böhn,[b] and Arnd Vogler*[a]

Keywords: Electronic spectra / Luminescence / Platinum complexes / Phosphane complexes / Quantumchemical calculations

The complexes $Pt^{II}(P–P)(CN)_2$ with P–P = 1,2-bis(diphenylphosphanyl)benzene (dppb) and 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl (binap) were synthesised and characterised by elemental analysis, ESI MS and electronic spectroscopy. The structure of $Pt(dppb)(CN)_2$ was resolved by single-crystal X-ray diffraction. This compound consists of mononuclear Pt^{II} complexes with an almost planar PtP_2C_2 coordination. While both complexes are not luminescent in solution, they show an emission in the solid state under ambient conditions. It is suggested that the luminescence of $Pt(dppb)(CN)_2$ originates from a (Pt^{II}→dppb) metal-to-ligand charge transfer (MLCT) triplet with some dppb intraligand (IL) contribution. This assignment is confirmed by calculations which provide further insight into the excited state properties of the complex. In solution the phosphorescence is absent because the MLCT/IL state is deactivated to a non-emissive ligand field (LF) triplet, which is located at rather low energies owing to its distortion towards a tetrahedral structure. In the solid state this distortion is hindered. In the case of solid $Pt(binap)(CN)_2$, the phosphorescence is apparently of the IL type as the ππ* triplet of the binaphthyl chromophore occurs at low energies. Again, in solution the phosphorescence is absent owing to the interference by a distorted LF state.

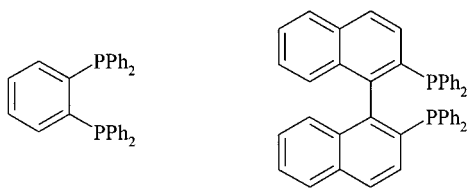
1. Introduction

A variety of square-planar Pt^{II} complexes has been shown to be luminescent under ambient conditions.[1−3] Diverse potential applications have stimulated interest in these compounds.[3] Generally, mononuclear Pt^{II} complexes emit from their lowest-energy triplet, which may be of the metal-to-ligand charge transfer (MLCT), ligand-to-ligand charge transfer (LLCT) or intraligand (IL) type. Pt^{II} complexes with low-energy ligand field (LF) triplets are not emissive at room temperature. The complex $Pt(1,2\text{-diimine})(CN)_2$ with 1,2-diimine = 4,7-diphenyl-1,10-phenanthroline is a typical example of a Pt^{II} complex which emits from an IL triplet.[4] This room temperature phosphorescence is facilitated by the low energy of the ππ* diimine IL states as well as by the strong LF strength of the cyanide ligands which push interfering LF states to rather high energies.[4] The number of emissive Pt^{II} complexes may be increased considerably if the diimines of $Pt(1,2\text{-diimine})(CN)_2$ are replaced by other strong-field ligands with low-energy excited states. Promising candidates are bidentate phosphanes that carry aromatic chromophores. We explored this possibility and selected the complex $Pt^{II}(P-P)(CN)_2$ with P−P = 1,2-bis(diphenylphosphanyl)benzene (dppb) and 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl (binap) for the present study (Scheme 1).



dppb binap

Scheme 1

The aromatic chromophores of these ligands were expected to serve as luminophores[5] of both complexes. In this context it should be mentioned that a few Pt^{II} phosphane complexes have been reported to display luminescence. However, these emissions do not originate from IL states. In some cases the phosphanes are only spectator

E-mail: arnd.vogler@chemie.uni-regensburg.de, christian.lennartz@basf-ag.de
[b] BASF AG, Computational Chemistry and Biology, GVC/C-A30, 67057 Ludwigshafen, Germany

ligands and are not directly involved in emission.[6−8] In other cases the luminescence is associated with metal−metal interactions in binuclear Pt^{II} complexes.[9,10] Our target compounds $Pt(P-P)(CN)_2$ were expected to be accessible by simple synthetic procedures.

2. Results and Discussion

Experimental Results

The complexes $Pt(dppb)(CN)_2$ and $Pt(binap)(CN)_2$ were obtained as white or slightly yellow solids by the reaction of $Pt(CN)_2$ with dppb and binap, respectively. The composition was confirmed by elemental analysis and mass spectroscopy. The positive ion electrospray mass spectrum (+ESI MS) of $[Pt(dppb)(CN)_2]$ in CH_3CN (+ 1% CH_3COOH) consists of peaks at m/z = 693, 694, 695, 696 and 697. The complex has apparently added one proton at the cyanide ligands. In addition, peaks at 1358, 1359, 1360, 1361, 1362, 1363 and 1364 indicate the presence of the dimer $Pt_2(dppb)_2(CN)_4$ which has lost one cyanide ligand. The +ESI MS spectrum of the binap complex shows an analogous pattern. The complex $Pt(binap)(CN)_2$ in its monoprotonated form displays peaks at 869, 870, 871, 872 and 873, while peaks of the cation $[Pt_2(binap)_2(CN)_4]^+$ appear at 1710, 1711, 1712, 1713, 1714, 1715, 1716 and 1717. In all cases there is a good agreement between the calculated and observed isotopic peak pattern.

The electronic spectrum of dppb in CH_3CN/CH_2Cl_2 (1:1) exhibits an absorption at λ_{max} = 276 nm (ε = 17 920 M^{-1} cm^{-1}). At room temperature, solutions of dppb are not emissive, but in ethanol glasses at 77 K a strong phosphorescence appears at λ_{max} = 502 nm. The absorption spectrum of $Pt(dppb)(CN)_2$ in CH_3CN (Figure 1) shows bands at λ_{max} = 295 (1420), 267 (12 940) and 225 nm (sh, 51 570). Solutions of the complex do not emit. However, at room temperature the solid compound shows a slightly structured luminescence (Figure 1) at λ_{max} = 502 nm with shoulders at approximately 480 and 540 nm. The absorption spectrum of $Pt(binap)(CN)_2$ in CH_3CN (Figure 2) contains bands at λ_{max} = 343 (3500) and shoulders at about 314 (5100), 290 (8500), 262 (33 500) and 220 nm (86 000). Again, in solution the complex does not emit, but the solid compound exhibits a luminescence at λ_{max} = 513 nm with distinct structural features at 470, 550, 600 and 640 nm (Figure 2).

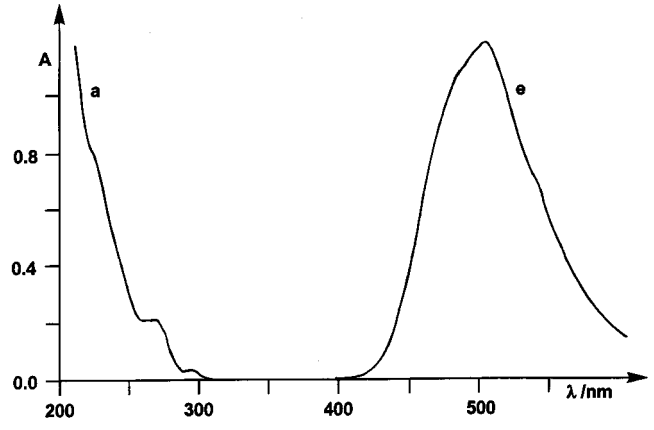

Figure 1. Electronic absorption (a) and emission (e) spectrum of $Pt(dppb)(CN)_2$ at room temperature; absorption: 1.54×10^{-5} M in CH_3CN, 1-cm cell; emission: solid, λ_{exc} = 300 nm, intensity in arbitrary units

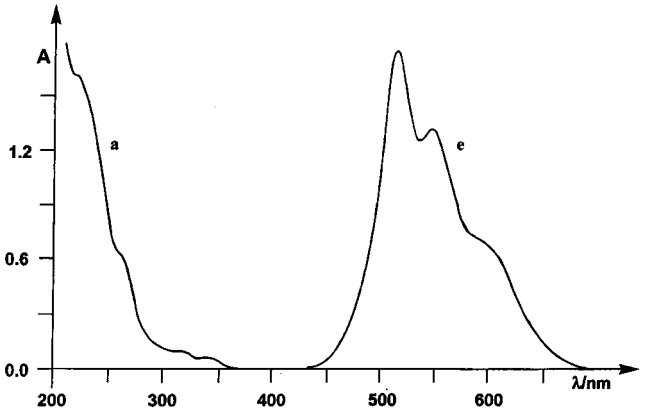

Figure 2. Electronic absorption (a) and emission (e) spectrum of $Pt(binap)(CN)_2$ at room temperature; absorption: 2.06×10^{-5} M in CH_3CN, 1-cm cell; emission: solid, λ_{exc} = 350 nm, intensity in arbitrary units

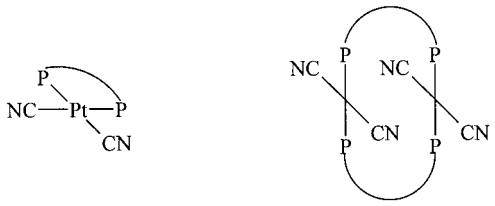
Interpretation

Complexes with the general composition $Pt^{II}(P-P)(CN)_2$ may be monomeric or dimeric[9,10] (Scheme 2).



Scheme 2

In the dimers the cyanide ligands occupy *trans* positions and both square-planar Pt^{II} complex moieties are connected by bridging phosphanes. With regard to the complexes $Pt(dppb)(CN)_2$ and $Pt(binap)(CN)_2$, our analytical data do not provide an unambiguous distinction. The MS spectra indicate the presence of monomers as well as dimers. However, the dimers $Pt_2(P-P)_2(CN)_4$ with P−P = bis(diphenylphosphanyl)methane, bis(dimethylphosphanyl)methane and bis(dicyclohexyl-phosphanyl)methane show an intense absorption ($\varepsilon > 10^4$) around 330 nm, which is associated with the Pt−Pt interaction.[9,10] These absorptions do not appear in the spectra of $Pt(dppb)(CN)_2$ and $Pt(binap)(CN)_2$. Accordingly, the latter complexes are either monomeric at least in solution, or dimeric but with large Pt−Pt distances that prevent any efficient metal−metal interaction.

For $Pt(dppb)(CN)_2$, the monomeric structure was confirmed by single-crystal X-ray diffraction (Figure 3). The complex is essentially planar with P−Pt−P and C−Pt−C bond angles of 86.6° and 89.3°, respectively. The average

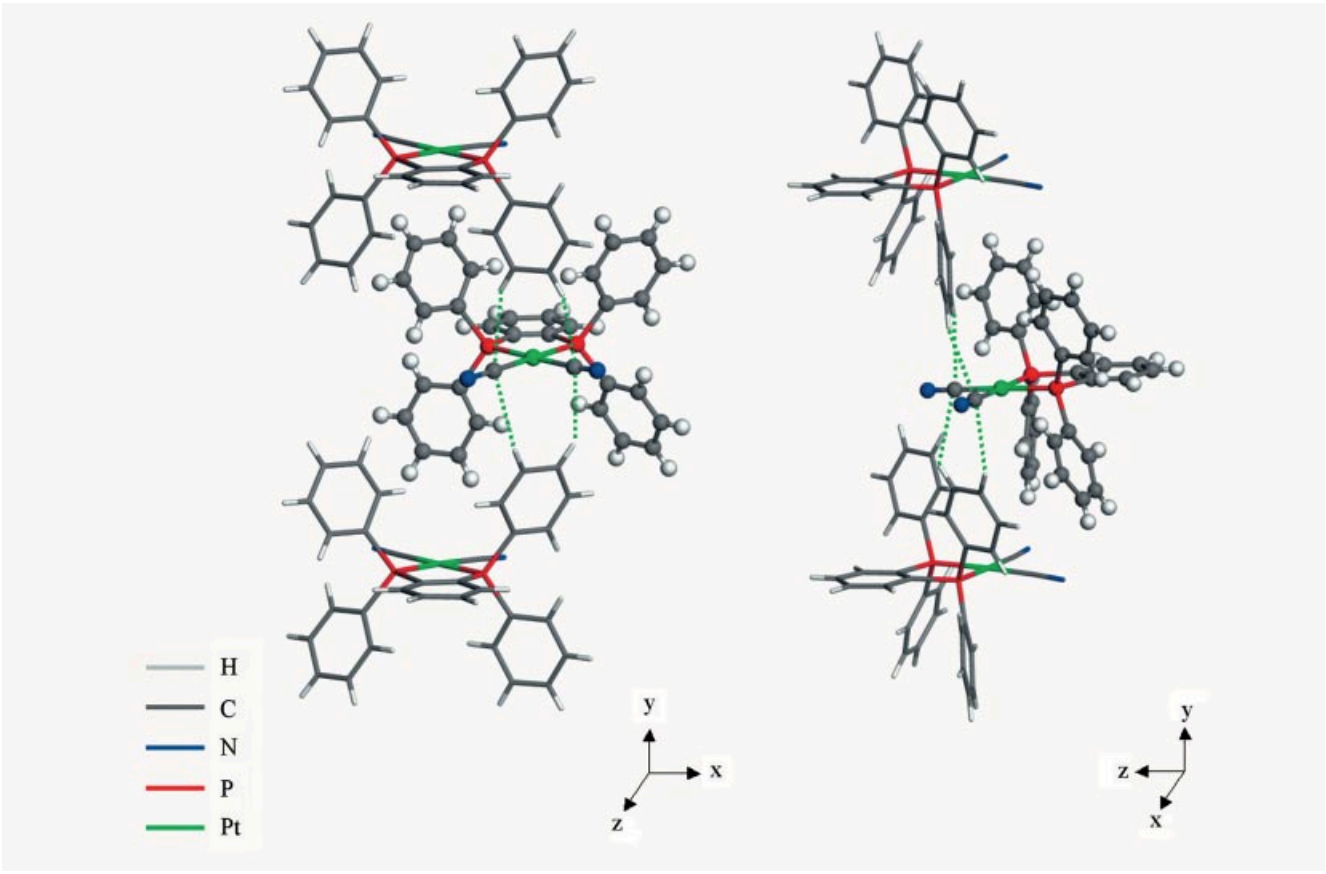

Figure 3. Crystal structure of monomeric Pt(dppb)$(CN)_2$: visualisation of the steric interactions between the Pt$(CN)_2$ fragment and two phenyl groups from neighbouring molecules

metal−ligand bond lengths are 2.26 Å for Pt−P and 1.98 Å for Pt−C. Cyanide is coordinated in a linear fashion.

The lowest-energy excited state of Pt(dppb)$(CN)_2$ seems to be of the IL type since the complex and the free ligand show this phosphorescence at the same wavelength (λ_{max} = 502 nm). However, the lowest-energy transitions of simple aromatic phosphanes are associated with the promotion of an electron from the lone pair (l) at the phosphorus atom to the π* orbitals of the aromatic substituents.[11] Upon coordination the lone pair is stabilised by σ-bonding. As a consequence, the l→π* transition of the phosphane becomes a σ→π* IL transition that should be shifted to higher energies.[11] This concept does not seem to apply to dppb and Pt(dppb)$(CN)_2$. Fortunately, theory provides a satisfactory explanation. According to density functional calculations, the emitting state of the complex is a MLCT state that contains a σ→π* IL contribution. The HOMO is essentially metal-based but also includes the Pt−P bonds, while the LUMO is largely restricted to the aromatic substituents (Figure 4).

To get further insight into the electronic structure and geometry of the excited state of the Pt(dppb)$(CN)_2$ molecule, additional density functional calculations were performed. Optimising the geometries of the singlet-ground state (S_0) and the first triplet state (T_1) results in a quadratic-planar coordination geometry with respect to Pt^{II} for

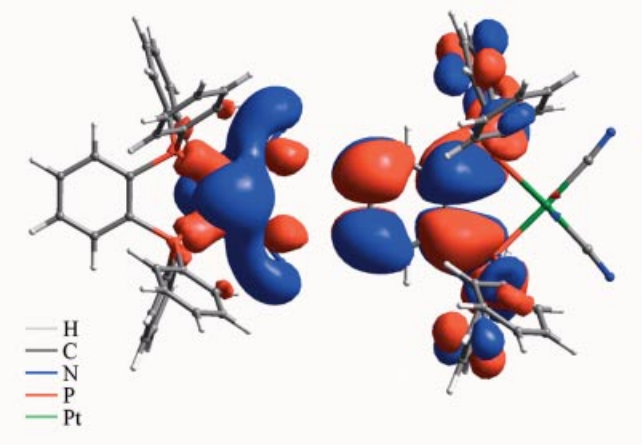

Figure 4. Frontier orbitals of the electronic transition at planar geometry: HOMO (left) and LUMO (right)

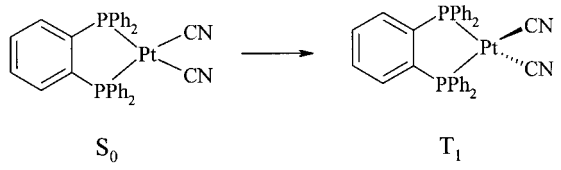
the ground state, while the geometry is heavily distorted in the triplet state yielding a deformed tetrahedral geometry as indicated in Scheme 3.

The angle between the cyanocarbons and Pt amounts to 160°, thus resembling more a linear coordination geometry regarding platinum and the two cyano groups than a true tetrahedron. Due to this distortion, the calculated energy gap between the triplet state and the ground state is reduced

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3

to 0.1 eV at the triplet geometry. Therefore energetic relaxation of the triplet state should be dominated by nonradiative vibrational relaxation, thereby explaining the nonemissive behaviour of the molecule in solution.

To understand the origin of this distortion an orbital correlation diagram was derived from the density functional calculations. A schematic version is shown in Figure 5. Starting on the left the excitation process promotes one electron from the HOMO to the LUMO and generates the S_1-state. The character of this transition is best described as MLCT, which can be seen in Figure 4, where the frontier orbitals are shown. If the geometry of the S_1-state is now slightly distorted in a tetrahedral way due to corresponding normal modes, then orbital 28a′′ will be substantially stabilised, while orbital 30a' will be destabilised, in such a way that these two orbitals now become the frontier orbitals and a net stabilisation energy for the whole system is gained. Spin-orbit coupling yields the final triplet state. The reason for this orbital behaviour can be seen from the schematic orbital pictures. While an antibonding interaction in orbital 28a′′ vanishes during the rotation, an antibonding character is introduced into orbital 30a′ resulting in a completely different frontier orbital structure for the triplet state. As can be seen from orbitals 22a′′ and 38a′, the electronic transition to the ground state is now basically of a d-d (LF) type.

The crystal structure of $Pt(dppb)(CN)_2$ (Figure 3) shows that, in contrast to the isolated molecule, the triplet distortion is hindered by intermolecular steric interactions between the $Pt(CN)_2$ fragment and two phenyl groups from neighbouring molecules. These groups are oriented perpendicular to the plane spanned by Pt and the two CN groups.

For the complex $Pt(binap)(CN)_2$, the situation could be different as the binaphthyl substituent is characterised by an extended π-electron system. Accordingly, the lowest-energy transition of binap may not be of the l→π* type but rather a ππ* transition of the binaphthyl moiety. This assumption is supported by a comparison of the absorption and emission spectra of $Pt(binap)(CN)_2$ and $Au_2Cl_2(binap)$.[12] For the latter complex it is quite clear that the lowest-energy transitions are of the binap IL type as gold(I) complexes do not have available metal-centred or MLCT excited states at low energies.[13] Indeed, the long-wavelength region of the absorption spectrum of $Pt(binap)(CN)_2$ between 270 and 400 nm (Figure 2) is very similar to that of $Au_2Cl_2(binap)$. Moreover, the emission spectra of both complexes are also rather similar and resemble the phosphorescence of the free binap ligand which, however, is only observed at low temperatures.[14] The IL assignment for the phosphorescence of $Pt(binap)(CN)_2$ is also supported by the fact that the emission shows a pronounced structure which is typical for the phosphorescence from IL states.[1,15] The phosphorescence of $Pt(binap)(CN)_2$ appears only in the solid state and is absent in solution. Again, it is suggested that a rigid structure of the solid compound prevents a distortion towards a tetrahedral structure of a low-energy LF state that does not emit in solution.

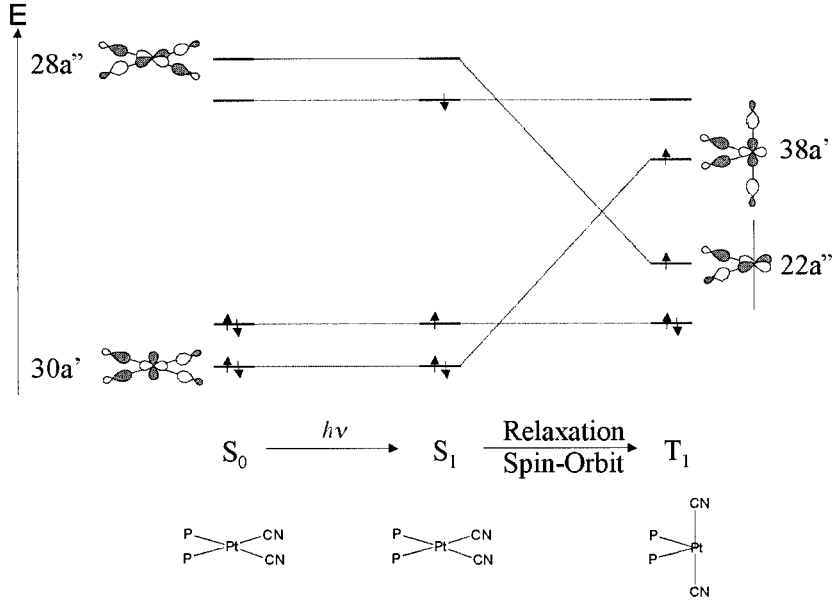


Figure 5. Schematic view of the orbital correlation diagram; only the orbitals responsible for the geometric rearrangement are shown

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In summary, solid compounds of the type $Pt(P-P)(CN)_2$ with bidentate phosphane ligands such as dppb and binap, which carry aromatic chromophores, are triplet emitters under ambient conditions. This phosphorescence originates from MLCT and/or IL states.

Experimental Section

Materials: All solvents used for spectroscopic measurements were of spectrograde quality. $Pt(CN)_2$, dppb and binap were commercially available (Aldrich and Strem) and used without further purification. The complexes $Pt(P-P)(CN)_2$ were obtained by the following procedures.

[Pt(dppb)(CN)$_2$]: A mixture of $Pt(CN)_2$ (0.76 g, 3 mmol) and dppb (1.38 g, 3 mmol) in dimethylformamide (70 mL) was refluxed for 6 h. A white powder slowly precipitated. It was collected by filtration, washed with diethyl ether and dried over silica gel under reduced pressure. The resulting white material was purified by recrystallisation from dichloroethane/ether yielding 0.92 g (43%). $C_{32}H_{24}N_2P_2Pt$ (693.58): calcd. C 55.42, H 3.49, N 4.04; found C 55.06, H 3.60, N 3.94.

[Pt(binap)(CN)$_2$] × H$_2$O: A mixture of $Pt(CN)_2$ (0.25 g, 1 mmol) and binap (0.63 g, 1 mmol) in dimethylformamide (40 mL) was refluxed for 20 h. After filtration, ether was added to the solution. A slightly yellow powder precipitated. It was collected by filtration, washed with diethyl ether and dried over silica gel under reduced pressure. The resulting slightly yellow material was recrystallised from dichloromethane/ether yielding 0.58 g (65%). $C_{46}H_{34}N_2OP_2Pt$ (887.82): calcd. C 62.23, H 3.86, N 3.16; found C 62.68, H 3.90, N 3.07.

X-ray Crystallographic Data for [Pt(dppb)(CN)$_2$]: $C_{32}H_{24}N_2P_2Pt$, M = 693.6; T = 203(2) K; monoclinic, $P2_1/n$ (no. 14); a = 10.031(2) Å, b = 14.885(7) Å, c = 18.812(5) Å, β = 98.138 (5); V = 2781(2) Å^3; Z = 4; Data from 2817 reflections, 2626 unique [R(int.) = 0.047], were collected with a Siemens P4 diffractometer by use of Cu-K_α radiation. The structure was refined by full-matrix least-squares refinement with the SHELXL-97 programmes. All non-H atoms were refined anisotropically, hydrogen atoms were included in riding mode with U_{iso}(H) = 1.2 U_{eq}(C) to give $R1$ = 0.051, $wR2$ = 0.137 [$I > 2\sigma(I)$] and $R1$ = 0.067, $wR2$ = 0.146 (all data).
CCDC-226785 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 IEZ, UK: Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Instrumentation: Absorption spectra were measured with a Shimadzu 2100 spectrophotometer. Emission spectra were recorded on a Hitachi 850 spectrofluorometer equipped with a Hamamatsu 928 photomultiplier for measurements up to 900 nm. The mass spectra were obtained using a TSQ 7000 Finnigan Thermoquest mass spectrometer.

Calculations: Geometries and energies were calculated with the use of density functional theory involving the BP86 functional,[16] in combination with a split-valence basis set with polarisation functions on all heavy atoms [SV(P)].[17] For platinum, an effective core potential with relativistic corrections (ecp-60-mwb: derived from a multielectron fit to the quasi-relativistic Wood−Boring total valence energies) was employed.[18] The corresponding valence part was of SVP quality.[19,20] Triplet states were optimised with the unrestricted KS approach. Resolution of identity techniques[19] was used throughout. All calculations were carried out with the TURBOMOLE software package.[21]
The orbital correlation diagram is based on the assumption that the relevant excitations are sufficiently described by one-electron transitions between orbitals. We performed additional TD-DFT calculations using the same functional and basis set as described above to check for the single excitation character of the corresponding transitions. The weight of the leading configuration amounts to more then 80% for all relevant singlet excitations. This is also true in the case of the lowest triplet excitation based on the same singlet ground state orbitals for nondistorted geometries. For the distorted triplet geometry the UKS orbitals closely resemble the corresponding RKS orbitals. Therefore the one-electron interpretation is justified.

Solid-State Reactions of AgAc with $TabHPF_6$ at Room Temperature − Isolation and Structural Characterisation of an Unusual Octadecanuclear Silver Thiolate Cluster $[Ag_9(Tab)_8(MeCN)_8]_2(PF_6)_{18}\cdot 4MeCN$ [Tab = 4-(trimethylammonio)benzenethiolate]

Jin-Xiang Chen,[a] Qing-Feng Xu,[a] Ying Xu,[a] Yong Zhang,[a] Zhong-Ning Chen,[b] and Jian-Ping Lang*[a]

Keywords: Solid-state reactions / Thiolates / Silver / Clusters

The room-temperature solid-state reaction of silver acetate with $TabHPF_6$ [Tab = 4-(trimethylammonio)benzenethiolate] followed by recrystallization from MeCN afforded a unique octadecanuclear silver thiolate complex $[Ag_9(Tab)_8(MeCN)_8]_2(PF_6)_{18}\cdot 4MeCN$ (**1**). An X-ray analysis of **1** revealed that the structure of $[Ag_9(Tab)_8(MeCN)_8]_2^{18+}$ contains an unprecedented tubular motif in which one central saddle-shaped Ag_6S_6 fragment and two identical Ag_5S_6 fragments are interconnected by a pair of Ag atoms and four Ag–S bonds. The solid-state product was assumed to be $[Ag_9(Tab)_8]_2(PF_6)_{18}$ and might have the $Ag_{18}S_{16}$ core structure of **1** based on elemental analysis, IR spectroscopy, ^1H NMR spectroscopy, luminescence spectra, XRD and TGA measurements.

Introduction

In recent years, silver thiolate complexes have been of intense interest due to their unique structures,[1−3] their relations to metallothioneins[4,5] and their potential applications in advanced materials [6−9] and antimicrobial drugs.[10] Usually, such complexes are prepared through routine solution reactions. Very few have been reported to have been prepared by solid-state reactions of silver salts with thiolates, especially at room temperature. On the other hand, we have been interested recently in the preparation of silver sulfide clusters from thiometallates with silver salts in the solid state.[11] In these reactions, the solid-state product must be extracted using certain solvents in order for structural characterisation to be carried out.[11a] One question may then arise: Does the solid-state product interact with solvent molecules when it is extracted? This is likely to be true because in the structure of the solid-state products, there are a number of metal atoms with vacant coordination sites which may be further coordinated by solvent molecules bearing donor atoms. However, isolation of such solvent-ligated products is difficult due to their instability arising from the weak coordination between the metal atoms and solvent molecules. In our continuing exploitation of solid-state syntheses of new metal thiolate clusters, we found that a zwitterionic thiolate $TabHPF_6$ [Tab = 4-(trimethylammonio)benzenethiolate][12] readily reacts with AgAc in the solid state at room temperature. When the resultant solid-state product was extracted with acentonitrile, an intriguing octadecanuclear silver thiolate cluster $[Ag_9(Tab)_8(MeCN)_8]_2(PF_6)_{18}\cdot 4MeCN$ (**1**) was formed in high yield. This represents an interesting example of the isolation of the solid-state product having solvent molecules coordinated and solvated. Herein we report its synthesis and structural characterisation.

Results and Discussion

Silver acetate (argenteous powder) and $TabHPF_6$ (white powder) were mixed in a molar ratio of 1:1 and firmly ground in an agate mortar at ambient temperature for about 0.5 h. During grinding, a strong smell of acetic acid was apparent while the colour of the mixture gradually became yellow. The liberation of the volatile acetic acid vapour might be the driving force for this solid-state reaction. The IR spectrum of the yellow powder showed the disappearance of the stretching vibration of the S−H group of $TabHPF_6$ at 2592 cm^{-1},[2f] implying completeness of the reaction. As shown in Scheme 1, the reaction yielded 1 equiv.

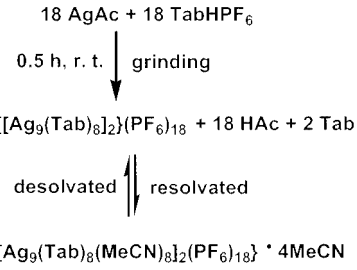
of acetic acid and 1/9th of an equivalent of the zwitterionic Tab ligand which is very soluble in methanol. Consequently, we thoroughly washed the powder with MeOH and Et_2O and then dried the product in vacuo for 1 h to form a yellow solid **1a**. Subsequent extraction of **1a** with MeCN, followed by diffusion of Et_2O into the extract gave rise to colourless crystals of $[Ag_9(Tab)_8(MeCN)_8]_2(PF_6)_{18}\cdot 4MeCN$ (**1**) in 95% yield; the elemental analysis of **1** corresponds to this formula. The IR spectrum of **1** shows a C=N stretching vibration for MeCN at 2262 cm^{-1} and two strong characteristic peaks arising from PF_6 at 841 and 559 cm^{-1}. The ^1H NMR spectrum of **1** in $[D_6]$DMSO exhibits a single signal at $\delta = 2.07$ ppm for protons of the MeCN molecules, a singlet at $\delta = 3.34$ ppm for the NMe_3 groups and multiplets in the $\delta = 7.43-7.48$ ppm region for the phenyl groups. The identity of **1** was finally confirmed by a single-crystal X-ray diffraction study.



Scheme 1

Compound **1** crystallises in the triclinic space group $P\bar{1}$ and the asymmetric unit contains one-half of the discrete $[Ag_9(Tab)_8(MeCN)_8]_2^{18+}$ cation, ten $[PF_6]^-$ anions (two of them having an occupancy of 0.5) and two MeCN solvate molecules. Figure 1 shows the packing diagram of **1** in the unit cell. The $[Ag_9(Tab)_8(MeCN)_8]_2^{18+}$ cations are parallel to each other along the *c* axis. The associated $[PF_6]^-$ anions are located between the two tubular octadecacations. Except for the electrostatic forces between the octadecacations and the $[PF_6]^-$ anions, there are no other apparent interactions between the MeCN solvent molecules and the octadecacations or the $[PF_6]^-$ anions.

Figure 2 shows a perspective view of the $[Ag_9(Tab)_8(MeCN)_8]_2^{18+}$ ion while Figure 3 represents a side-view of the tubular structure of the octadecacation of **1**. Table 1 lists selected bond lengths and angles of **1**. Being a crystallographic centre of symmetry on the midpoint of Ag(1) and Ag(1′), the octadecacation of **1** contains 18 Ag atoms, 16 Tab moieties and 16 coordinated MeCN molecules. The $Ag_{18}S_{16}$ core of the octadecacation may be visualised as a long tubular structure which is composed of one central saddle-shaped Ag_6S_6 fragment and two identical Ag_5S_6 fragments bridged by a pair of Ag [Ag(3) and Ag(3′)] atoms and four Ag−S bonds [Ag(5)−S(5), Ag(4)−S(2), Ag(5′)−S(5′) and Ag(4′)−S(2′)]. The Ag_6S_6 fragment consists of two six-membered Ag_3S_3 rings, Ag(5)S(1′)Ag(1′)S(2′)Ag(2′)S(4′) and Ag(5′)S(1)Ag(1)S(2)Ag(2)S(4), which are held together by the Ag(1)−S(4′) and Ag(1′)−S(4) bonds. Each Ag_5S_5 fragment is composed of one six-membered Ag(9)S(7)Ag(7)S(3′)Ag(8)S(8) [or Ag(9′)S(7′)Ag(7′)S(3)Ag(8′)S(8′)] ring and one eight-membered Ag(9)S(7)Ag(7)S(6)Ag(6)S(5)Ag(4)S(8) [or Ag(9′)S(7′)Ag(7′)S(6′)Ag(6′)S(5′)Ag(4′)S(8′)] ring, sharing a group of Ag(9), S(7), Ag(7) and S(8) [or Ag(9′), S(7′), Ag(7′) and S(8′)] atoms. It is noteworthy that the coordination geometry of the 18 Ag atoms can be classified into three groups: distorted tetrahedral [Ag(1), Ag(1′), Ag(4), Ag(4′), Ag(5) and Ag(5′)], pyramidalised Y-shape [Ag(8) and Ag(8)] and trigonal planar [Ag(2), Ag(2′), Ag(3), Ag(3′), Ag(6), Ag(6′), Ag(7) Ag(7′) Ag(9) and Ag(9′)]. As can be seen in Table 1, most Ag···Ag contacts [3.011(3)−3.426(3) Å] are similar to those found in $\{[Ag_3(Tab)_4](PF_6)_3\cdot 2DMF\}_n$ [3.207(2) Å],[2f] but shorter than the sum of the van der Waals radii of two Ag atoms (3.44 Å), implying the possible existence of the silver−silver interactions.[13] Other relatively longer Ag···Ag separations such as Ag(3)···Ag(7′) = 3.667(3) Å and Ag(2)···Ag(8) = 3.758(3) Å may constitute weak nonbonding interactions. The sixteen sulfur atoms show doubly bridging [S(6), S(6′), S(7), S(7′)] and triply bridging [S(1) to S(5), S(1′) to S(5′), S(8), S(8′)] modes. The observed trend in the Ag−S bond lengths varying from 2.397(5) to 2.654(5) Å correlates with the coordination geometries of the Ag centres. The average Ag−S bond length of 2.512 Å is not unusual when compared with structures containing three-coordinate Ag^I such as $\{[Ag_3(Tab)_4](PF_6)_3\cdot 2DMF\}_n$ (2.529 Å),[2f] $[PPh_4]_2[Ag_4(SCH_2C_6H_4CH_2S)_3]$ (2.505 Å)[14] and $[PPh_4]_3[Ag_9(SCH_2CH_2S)_6]$ (2.579 Å).[15] Interestingly, as shown in Figure 1, except for Ag(7) and Ag(7′), the other sixteen Ag atoms are coordinated by sixteen MeCN molecules in an ordered way: 5 each on the right or left side and 3 each behind or before the tubular structure. Judging from the Ag−N bond lengths listed in Table 1, however, the strengths of the interactions between the Ag atoms and the MeCN molecules vary significantly. The longest Ag(3)−N(11) bond of 2.49(1) Å is 0.22 Å longer than that of the shortest Ag(9)−N(16) bond. This implies that some MeCN molecules may coordinate weakly at silver centres and some may bind tightly to silver atoms. This fact is con-

Interestingly, when crystals of **1** were heated in vacuo at 150 °C for 1 h, a yellow solid **1b** was formed and the liberation of MeCN was apparent by collection in a cold trap. When **1b** was immersed in MeCN, colourless crystals of **1** (identified by X-ray crystallography) were formed again in almost quantitative yield. What are the identities of **1a** and **1b**? We made numerous attempts to grow crystals of **1a** and **1b** in other solvents such as acetone and DMSO but were unsuccessful. Elemental analyses of **1a** and **1b** are in agreement with the formula $[Ag_9(Tab)_8]_2(PF_6)_{18}$. The FT-IR spectra of **1a** and **1b** are almost identical and display two strong peaks for PF_6 at 856 and 559 cm^{-1} but no C=N vibration at around 2262 cm^{-1} for **1**. The ^1H NMR spectra of both **1a** and **1b** in $[D_6]$DMSO exhibit only singlets at

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

δ = 3.34 ppm for the NMe_3 groups and multiplets in the δ = 7.43−7.48 ppm region for phenyl groups but no resonances for the methyl groups of MeCN molecules in the region of δ = 2.07 ppm. Not surprisingly, the UV/Vis spectra of **1**, **1a** and **1b** in MeCN exhibit the same strong and broad absorbance band at 284 nm (see Supporting Information, for Supporting Informations see also the footnote on the first page of this article) which may overlap the possible absorption bands in the visible region for **1**, **1a** and **1b**.

Crystals of **1** quickly lose some of the solvated MeCN molecules as soon as they are taken out of the mother liquor at room temperature. The surfaces of the crystals were observed to crack within seconds under the microscope. As shown in Figure 2, the thermogravimetric analysis revealed that **1** underwent decomposition in three stages between 25 and 400 °C. As shown in Figure 4, the first stage caused a weight loss of 4.5% in the region of 25−90 °C which corresponds roughly to the loss of three solvate MeCN molecules and another six coordinated MeCN molecules. The second stage resulted in a weight loss of 5.1% in the region of 90−160 °C, consistent with the loss of the remaining ten MeCN molecules in **1**. In the first stage, one more solvate MeCN molecule may be missing during the sample preparation for TGA measurement. However, **1a** and **1b** were relatively stable in the range of 25−160 °C. On heating further to 250 °C, samples of **1**, **1a** and **1b** began to decompose with almost the same pattern.

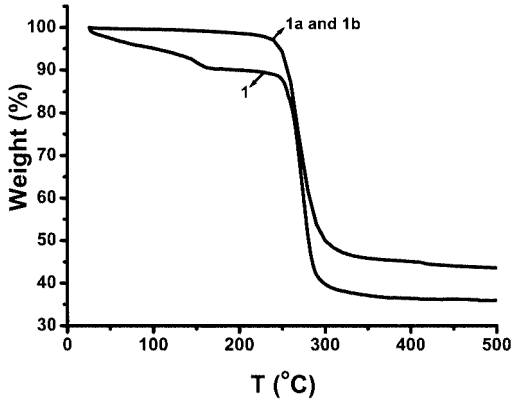

Figure 4. TGA curves for **1**, **1a** and **1b** under nitrogen

X-ray powder diffraction measurements for **1**, **1a** and **1b** gave data which was a little bit weak with a noisy baseline (see Supporting Information). However, the powder patterns of **1a** and **1b** resemble that of **1** which indicates that **1a** and **1b** may possess the $[Ag_{18}S_{16}]$ cluster core framework of **1**.

Compounds **1**, **1a** and **1b** exhibit luminescence in the solid state at ambient temperature. As shown in Figure 5, compound **1** exhibits an intense emission band at 625 nm (λ_{ex} = 450 and 507 nm) while **1a** and **1b** exhibit a similar emission band at 627 nm (λ_{ex} = 457 nm). As the free Tab ligand is not emissive in the solid state at ambient temperature, the possible origins of these emissions may be tentatively assumed to be MLCT from silver (4d) to the ligand (π^*) or an LC transition from S (nonbonding 3p) to the benzene ring (π^*) of the Tab ligands, though the metal-centred transition arising from the silver−silver contacts and transitions from surface S−Ar states cannot be ruled out.[2f,16]

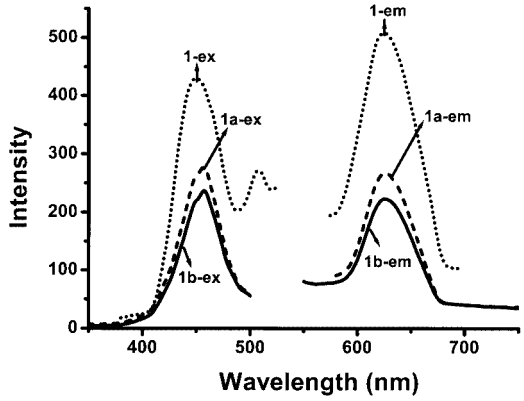

Figure 5. Excitation and emission spectra of **1**, **1a** and **1b** in the solid state at ambient temperature

Conclusions

In summary, we have successfully prepared a new silver thiolate complex from solid-state reactions between AgAc and $TabHPF_6$ at room temperature. When the solid-state product $[Ag_9(Tab)_8]_2(PF_6)_{18}$ was recrystallized from MeCN, it was solvated by MeCN molecules and some Ag atoms in its framework were coordinated by MeCN molecules, forming the unusual silver thiolate cluster **1**. The isolation of **1** provides convincing evidence that some solid-state products may have their structures altered, or at least experience changes in the coordination geometries of certain metal atoms in their structures when they are extracted with a solvent. The facile room-temperature solid-state synthesis reported in this paper is in accord with the current trend in green chemistry. Further investigation on the preparation of other metal/Tab complexes by this method is currently under way in our laboratory.

Experimental Section

General: $TabHPF_6$ was prepared according to a literature method.[12] Other chemicals and reagents were obtained from commercial sources and used as received. All solvents were pre-dried with activated molecular sieves and heated to reflux in the presence of appropriate drying agents under argon. IR spectra were recorded with a Nicolet MagNa-IR 550 instrument as KBr disk (4000−400 cm^{-1}). ^1H NMR spectra were recorded at ambient temperature with a Varian UNITYplus-400 spectrometer. ^1H NMR chemical shifts were referenced to the $[D_6]$DMSO signal. UV/Vis spectra were measured with a Hitachi U-2810 spectrophotometer. Elemental analyses for Ag and P were carried out by inductively coupled plasma atomic emission spectroscopy (Leeman PLA-SPECI ICP spectrophotometer). The elemental analyses for C, H and N were performed with an EA1110-CHNS elemental analyser. The thermal

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

analysis was performed with a Perkin−Elmer TGA-7 thermogravimetric analyser at a heating rate of 10 °C/min and a flow rate of 100 cm^3/min (N_2). XRD spectra were recorded with a Rigaku D/MAX-IIIC X-ray diffractometer.

Preparation of $[Ag_9(Tab)_8(MeCN)_8]_2(PF_6)_{18}$·4MeCN (1): A mixture of argenteous AgAc powder (0.33 g, 2 mmol) and white $TabHPF_6$ powder (0.63 g, 2 mmol) was placed in an open agate mortar and ground at room temperature for 0.5 h. During this time, the mixture gradually became yellow and a strong smell of acetic acid was apparent. The mixture was washed with CH_3OH/Et_2O (3:1) and dried in vacuo to form 0.78 g of a yellow solid (**1a**). $C_{144}H_{208}Ag_{18}F_{108}N_{16}S_{16}P_{18}$ (7227.2): calcd. C 23.93, H 2.90, Ag 26.87, N 3.10, P 7.71; found C 24.12, H 3.28, Ag, 26.23, N 3.55, P, 7.58. IR (KBr disc): $\tilde{\nu}$ = 1624 (w), 1489 (s), 1126 (s), 1010 (m), 856 (s), 744 (s), 559 (m) cm^{-1}. UV/Vis (MeCN): $\lambda_{max.}$ (ε [M^{-1}·cm^{-1}]) = 282 (220000) nm. ^1H NMR (400 MHz, [D_6]DMSO): δ = 7.43−7.48 (m, 4 H, Ph), 3.34 (s, 9 H, NMe_3) ppm. Into a glass beaker containing **1a** (0.78 g) was added MeCN (10 mL) immediately forming a yellow solution. Colourless crystals of $[Ag_9(Tab)_8(CH_3CN)_8]_2(PF_6)_{18}$·$4CH_3CN$ (**1**) were isolated by layering diethyl ether (10 mL) onto the solution for one week. The crystals were collected by filtration and washed with $MeOH/Et_2O$ (1:4) Yield: 0.85 g (95%). $C_{184}H_{268}Ag_{18}F_{108}N_{36}P_{18}S_{16}$ (8048.3): calcd. C 27.46, H 3.36, Ag 24.13, N 6.26, P 6.93; found C 27.89, H 3.28, Ag 23.85, N 6.65, P 6.73. IR (KBr disc): $\tilde{\nu}$ = 2262 (w), 1628 (w), 1489 (s), 1126 (w), 1010 (w), 841 (s), 744 (w), 559 (m) cm^{-1}. UV/Vis (MeCN): $\lambda_{max.}$ (ε [M^{-1}·cm^{-1}]) = 283 (180000) nm. ^1H NMR (400 MHz, [D_6]DMSO): δ = 7.43−7.48 (m, 16 H, Ph), 3.34 (s, 36 H, NMe_3), 2.07 (s, 12 H, MeCN) ppm. Crystals of **1** suitable for X-ray analysis were obtained by recrystallization from MeCN.

De-solvation and Re-solvation Experiments: Colourless crystals of **1** (0.805 g, 0.1 mmol) were placed in a Pyrex glass tube which was connected to a cold trap. The tube was heated to 150 °C and allowed to stand at that temperature for 10 h. During this period, the colour of **1** gradually turned from white to yellow. After it was cooled to room temperature, 0.72 g of yellow solid **1b** had formed. To a glass beaker containing **1b** (0.3 g) was added MeCN (5 mL) forming a yellow solution. Similar workup generated colourless crystals of **1** (confirmed by X-ray crystallography) in 98% yield. **1b:** $C_{144}H_{208}Ag_{18}F_{108}N_{16}S_{16}P_{18}$ (7227.2): calcd. C 23.93, H 2.90, Ag 26.87, N 3.10, P 7.71; found C 23.62, H 2.56, Ag 26.45, N 3.42, P 7.60. IR (KBr disc): $\tilde{\nu}$ = 1620 (w), 1493 (s), 1126 (m), 1010 (m), 856 (s), 744 (s), 559 (m) cm^{-1}. UV/Vis (MeCN): $\lambda_{max.}$ (ε [M^{-1}·cm^{-1}]) = 282 (240000) nm. ^1H NMR (400 MHz, [D_6]DMSO): δ = 7.43−7.48 (m, 4 H, Ph), 3.34 (s, 9 H, NMe_3) ppm.

X-ray Crystal Structure Determination of 1: All measurements were carried out with a Rigaku Mercury CCD X-ray diffractometer (3 kV, sealed tube) using graphite-monochromated Mo-K_α radiation (λ = 0.71070 Å). A colourless single-crystal of **1** with dimensions of 0.30 × 0.30 × 0.30 mm was mounted at the top of a glass fibre and cooled to 193 K in a stream of gaseous nitrogen. Diffraction data were collected in the ω mode with a detector-to-crystal distance of 35 mm. Indexing was performed from 6 images each of which resulted from a 15 s exposure. Cell parameters were refined using the program CrystalClear (Rigaku and MSc, Ver. 1.3, 2001) on all observed reflections with θ between 3.0° and 27.5°. A total of 720 oscillation images were collected in the range 1.96° < 2θ < 54.9°. The collected data were reduced using the program CrystalStructure (Rigaku and MSC, Ver. 3.16, 2003) and an absorption correction (Multi-Scan) was applied which resulted in transmission factors ranging from 0.498 to 0.648. The data were also corrected for Lorentz and polarization effects. The structure of **1** was solved by direct methods[17] and refined by full-matrix least squares on *F*.[18] Non-hydrogen atoms except P(5) to P(10), F(1) to F(6), N(16) to N(18), C(7) to C(9), C(34) to C(36), C(52) to C(54) and C(87) to C(92) were refined anisotropically. The two PF_6^- anions bearing P(8) and P(10) were refined using restrained parameters as rigid groups with occupancy factors of 0.5. All hydrogen atoms were placed in calculated positions and refined in the final structure-factor refinement. There may be more than two free acetonitrile solvent molecules in the asymmetric unit. However, attempts to locate other acetonitrile molecules were unsuccessful. Besides, the relatively high thermal parameters of the F atoms of the PF_6^- anions of P(5) to P(10) and some carbon atoms [C(7) to C(9), C(34) to C(36), C(52) to C(54) and C(87) to C(92)] of the NMe_3 groups showed signs of disorder, but attempts to model these disorders did not succeed. The relatively high *R* values may be due to the quality of the crystal and the possible disorder of the methyl groups, part of the PF_6^- anions and part of the acetonitrile molecules. Neutral atom-scattering factors were taken from Cromer and Waber.[19] Anomalous dispersion effects were included in $F_{calcd.}$.[20] All calculations were performed with a Dell workstation using the CrystalStructure crystallographic software package. Crystal and data collection parameters for **1** are summarised in Table 2. CCDC-229000 (**1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

A Novel Hybrid Supramolecular Network Assembled from Perfect π−π Stacking of an Anionic Inorganic Layer and a Cationic Hydronium-Ion-Mediated Organic Layer

Tzuoo-Tsair Luo,[a,b] Yen-Hsiang Liu,[b] Hui-Lien Tsai,[c] Chan-Cheng Su,[a] Chuen-Her Ueng,*[a] and Kuang-Lieh Lu*[b]

Keywords: Coordination polymers / Hydrogen bonds / Self-assembly / Stacking interactions

The synthesis and characterization of a three-dimensional inorganic-organic hybrid network $[\{Cu_2(CA)_3\}\{(H_3O)_2(phz)_3\}\cdot G]_n$ (**1**; H_2CA = chloranilic acid, phz = phenazine; G = $2CH_3COCH_3\cdot 2H_2O$) is described. The crystal structure of **1** shows that the 3D network assembly is based on a combination of two types of grid-building sub-units of (6,3) topology: an anionic metal-organic coordination honeycomb grid, and a cationic hydronium-ion-mediated organic honeycomb grid. The inorganic and organic honeycomb nets are perfectly π–π-stacked, creating an infinite number of open-end channels (channel size about 8 Å in diameter). The solid framework of **1** retains its rigidity upon removal of the guest molecules under high vacuum to form compound $[\{Cu_2(CA)_3\}\{(H_3O)_2(phz)_3\}]_n$ (**2**) as revealed by a single-crystal X-ray diffraction analysis. Compounds $[\{M_2(CA)_3\}\{(H_3O)_2(phz)_3\}\cdot G]_n$ (M = Cd, **3**; M = Zn, **4**; M = Co, **5**; G = $2CH_3COCH_3\cdot 2H_2O$) were also prepared and characterized as isostructures of **1** [crystal data for **1**: $Cu_2(CA)_3(H_3O)_2(phz)_3\cdot G$, trigonal, space group $P\bar{3}1m$, formula mass = 1478.86, a = 13.7593(2) Å, c = 9.1869(2) Å, V = 1506.22(5) Å^3, Z = 1; crystal data for **2**: $Cu_2(CA)_3(H_3O)_2(phz)_3$, trigonal, space group $P\bar{3}1m$, formula mass = 1326.62, a = 13.7565(4) Å, c = 9.1544(5) Å, V = 1500.3(1) Å^3, Z = 1]. The magnetic-exchange coupling between the copper centers for compound **1** was analyzed on the basis of the Curie–Weiss expression and a dinuclear magnetic model. The negative values of the Weiss constant and the magnetic-exchange coupling constant indicate an antiferromagnetic interaction between the copper centers.

Introduction

The use of noncovalent interactions, (e.g. metal−ligand coordination, hydrogen bonding, π−π stacking, etc.) to arrange molecular building blocks has evolved into one of the most useful and flexible strategies for the crystal-engineering design of extended networks that have versatile functions.[1−14] Successful examples of this method include highly porous metal-organic frameworks with controllable pore sizes and channel properties,[15−25] porous magnetic networks with guest-tunable magnetism,[26,27] chiral porous networks with enantioselective catalytic properties,[28−32] and guest-responsive dynamic frameworks.[33,34] Inorganic-organic hybrid materials that have potential hybrid properties are of great importance in crystal engineering design due to their possible applications.[35−37] Typically, however, it is difficult to prepare a crystalline material containing more than two components as the entropy effect may induce unpredictable crystal structures.[38] However, it is a route to the generation of materials that have novel properties which are not characteristic of the individual components.

It is known that the chloranilate (CA) ligand and its homologues, which contain two chelating coordination sites, are capable of bridging metal centers to form monomeric molecules, chains, sheets, or 3D structures.[37,39−47] Studies based on CA-containing magneto-networks have also been carried out with respect to the propagation of magnetic superexchange interactions between the paramagnetic metal centers through the CA bridges.[37,39−47] The benefits derived from the phenazine ligand are twofold. First, it contains two pyridine donor sites capable of participation in coordination and hydrogen-bonding interactions, and second, the three fused aromatic rings of the phenazine ligand facilitate π−π stacking interactions. As part of our continuous efforts in the design and synthesis of functional crystalline materials,[13,48−51] we report herein on new supramolecular extended networks, $[\{M_2(CA)_3\}\{(H_3O)_2(phz)_3\}]_n$ (M = Cu, Cd, Zn, and Co), assembled from the

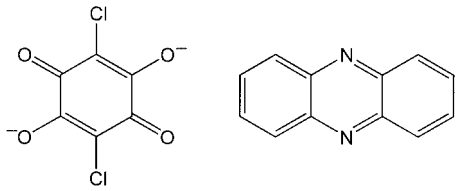
perfect π−π stacking of alternate inorganic and organic 2D hexagonal grid (6,3) nets.[11] The chloranilate and phenazine ligands play key roles in the formation of the inorganic and the organic honeycomb building subunits as well as in the construction of unusually robust ionic 3D networks which contain neutral nanoscale 1D channels.



CA phz

Results and Discussion

Synthesis

The ligand CA was chosen as a bridging ligand and phenazine as a π-stacking moiety. Compound **1** was obtained as dark-purple crystals in a mixed-solvent system at room temperature (Scheme 1) and formulated as $[\{Cu_2(CA)_3\}\{(H_3O)_2(phz)_3\}\cdot G]_n$ (**1**; G = $2CH_3COCH_3\cdot 2H_2O$) by elemental and TG analyses. The self-assembly of **1** was achieved by the combination of two types of grid-building sub-units of a (6,3) topology: an anionic metal-organic coordinated honeycomb grid, and a cationic hydronium-ion-mediated organic honeycomb grid. Compound **1** is insoluble in most common solvents such as water, ethanol, acetonitrile, THF, DMF, acetone, etc. $[\{Cu_2(CA)_3\}\{(H_3O)_2(phz)_3\}]_n$ (**2**) was obtained by removing the guest molecules from **1** under vacuum and identified by X-ray single-crystal diffraction techniques and TG analysis. According to a similar synthetic strategy, compounds $[\{M_2(CA)_3\}\{(H_3O)_2(phz)_3\}\cdot G]_n$ (M = Cd, **3**; M = Zn, **4**; M = Co, **5**; G = $2CH_3COCH_3\cdot 2H_2O$) were also synthesized from $Cd(NO_3)_2\cdot 4H_2O$, $Zn(ClO_4)_2\cdot 6H_2O$ and $Co(NO_3)_2\cdot 6H_2O$, respectively.

$$Cu(NO_3)_2\cdot 4H_2O + H_2CA + phz \longrightarrow [Cu_2(CA)_3][(H_3O)_2(phz)_3]\cdot G$$

1, G = $2CH_3COCH_3\cdot 2H_2O$

$$[Cu_2(CA)_3][(H_3O)_2(phz)_3]\cdot G \xrightarrow[24\ h]{vacuum} [Cu_2(CA)_3][(H_3O)_2(phz)_3]$$

1 **2**

Scheme 1

Structural Analysis

A single-crystal X-ray analysis reveals that **1** exists in a trigonal crystal lattice (space group $P\bar{3}1m1$) with a formula of $[Cu_2(CA)_3(H_3O)_2(phz)_3]\cdot G$ (G = $2CH_3COCH_3\cdot 2H_2O$). The results of the X-ray analysis of **2** were similar to those for **1** except for the absence of the guests. Crystals of compounds **3**−**5** were also grown and characterized by X-ray diffraction analysis. Selected interatomic bond lengths and angles for **1** and **2** are given in Table 1. An analysis of the local site symmetry reveals that each Cu^{II} center is positioned on a special symmetry site containing a mutually perpendicular threefold rotation axis and a twofold rotation axis. The Cu^{II} center is chelated by three CA ligands that are related by the site symmetry to form a propeller-like arrangement, resulting in an octahedral CuO_6 coordination environment (Figure 1).

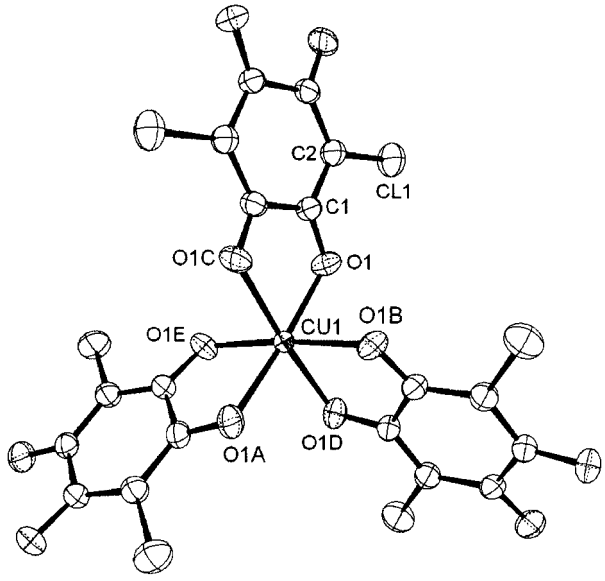

Figure 1. Coordination environment of the Cu^{II} center of compound **1** with atom numbering scheme

The oxygen atom of the hydronium ion also positioned at an identical type of symmetry site as the Cu^{II} ion, which is translated 4.593 Å (half the *c* axis) from the copper centers. The three hydrogen atoms of the hydronium ion are related by site symmetry, and form a strong O−H···N hydrogen-bonding interaction with three phz ligands [O···N distance of 2.583(3) Å, O−H distance of 0.921(0) Å and O−H···N angle of 180.0(1)°] (Figure 2). The short O···N distances between the hydronium ion and the phz ligands cause the phz ligands to assume a propeller-like arrangement.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

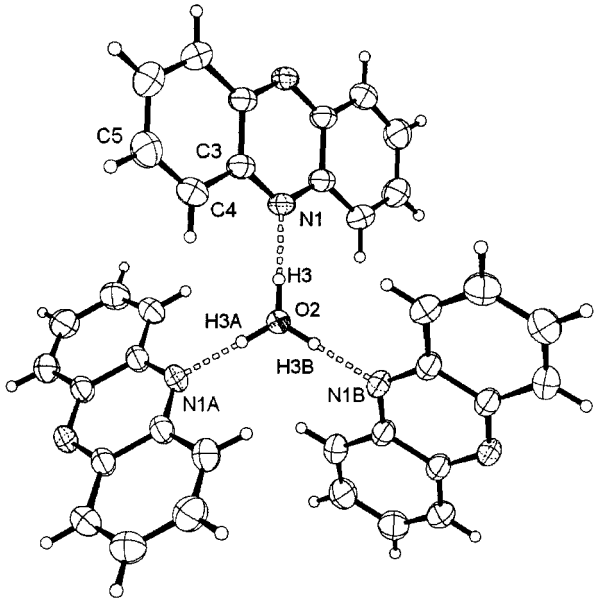

Figure 2. Propeller-like arrangement of hydronium ion and phenazine ligands of compound **1**

Based on the Cu−CA coordination and H_3O−phz hydrogen-bonding interactions, the self-assembly of the two types of two-dimensional grid building subunits with a (6,3) topology occurs. As shown in Figure 3a and 3b, a twelve-membered-ring pore is formed in both the anionic $[Cu_2(CA)_3]^{2-}$ metal-organic coordination layer and the cationic $[(H_3O)_2(phz)_3]^{2+}$ organic hydrogen-bonding layer. Infinite tubular channels with a pore diameter of about 8 Å are observed along the [001] direction (Figure 3c), which can be attributed to the alternate π−π stacking of the two types of grid-building subunits (Figure 3d) with a very short interplanar distance of 3.29 Å.[47] The propeller-like arrangement around the copper and hydronium ion centers is responsible for this perfect-layer π−π-stacking mechanism. The crystal-packing diagrams are shown in Figure 4. The results of an X-ray diffraction analysis of compounds **3**−**5**

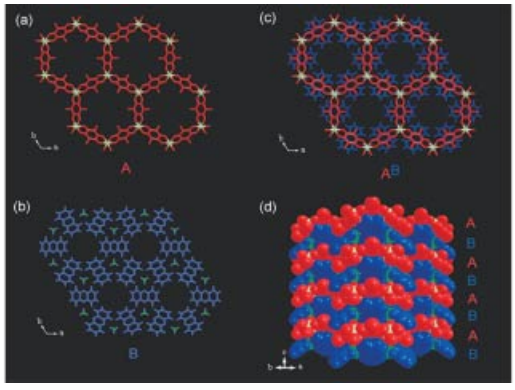

Figure 3. Perspective view of: (a) twelve-membered rings in the $[Cu_2(CA)_3]^{2-}$ metal-organic coordination layers; (b) twelve-membered rings in the $[(H_3O)_2(phz)_3]^{2+}$ organic hydrogen-bonding layers; (c) top-view and (d) side-view of the tubular channel formed by the alternate π−π stacking of the $[Cu_2(CA)_3]^{2-}$ (red) and $[(H_3O)_2(phz)_3]^{2+}$ (blue) grid-building subunits (channel size about 8 Å in diameter); the Cu^{II} ion is yellow, and the hydronium oxygen atom is green

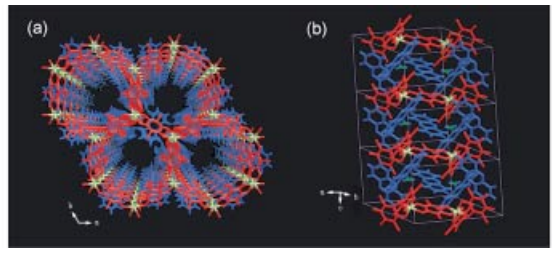

Figure 4. Crystal packing diagrams of **1** showing the perfect π−π stacking and (a) the honeycomb channels along the [001] direction and (b) the arrangement of Cu^{2+} (pale-yellow) and H_3O^+ (green)

reveal that these compounds are isomorphous with **1**. It is noteworthy that a considerable residual density of guest molecules is observed within the channels. However, attempts to resolve these disordered solvent molecules were not successful.

A weight loss of about 9.5%, corresponding to guest molecules, is observed in the TGA diagram of **1** (Figure 5). The alternating charged layers accommodate neutral guest molecules, which enter the extra-framework area in situ during the self-assembly of the framework. After the removal of the guest molecules from the channels under high vacuum for 24 h, the structural integrity of the guest-free network **2** was maintained (vide infra). We conclude that the size of the channels is sufficiently large to contain some diffused solvents, although the diffused portions of the crystal could not be determined clearly by X-ray diffraction analysis. The elemental analysis and thermogravimetric analysis support the assignment of the guest molecules as $2CH_3COCH_3{\cdot}2H_2O$. On the other hand, the acetone, water or THF content of the guests probably varies from crystal to crystal.

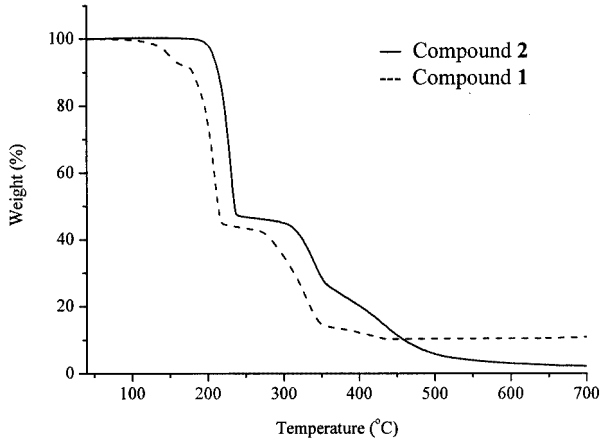

Figure 5. Thermogravimetric-analysis diagrams of **1** and **2**

Removal of Guests

Water, acetone or THF molecules occupy the one-dimensional channels of **1**, which have an estimated diameter of 8 Å (Figures 3 and 4). Attempts were made to remove the guests to form $[\{Cu_2(CA)_3\}\{(H_3O)_2(phz)_3\}]_n$ (**2**) by placing a single crystal of **1** under high vacuum for 24 h. The structure of **2** remained intact, even after the removal of the guest, as evidenced by the single-crystal X-ray analysis

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(Table 2). A TGA diagram of the desolvated compound **2** shows no weight loss until 190 °C (Figure 5), indicating that guest molecules can be removed under vacuum. Soaking crystals of **2** in benzene, chlorobenzene, *n*-hexane, or chloroform gave new inclusion compounds, which were characterized by single-crystal X-ray analysis. Surprisingly, the frameworks of these compounds are stable, but the issue of disordered guests remains unresolved.

Magnetic Studies

The magnetic susceptibility (χ_M) and effective moment (μ_B) per mol of copper for complex **1** are given in Figure 6. The effective moment per mol of copper is approximately 1.94 μ_B at 300 K and decreases slowly with decreasing temperature to 30 K. It then decreases sharply at temperatures below 20 K. This behavior indicates a typical weak antiferromagnetically coupled magnetic pair. As a first approximation, we applied the Curie−Weiss law [Equation (1)] to the magnetic-susceptibility data to measure the magnetic coupling interaction; N, g, β, and k_B have their usual meaning and J is the exchange interaction between metal ions.[52]

$$\chi = \frac{Ng^2\beta^2 S(S+1)}{3k_BT - 3JS(S+1)} = \frac{C_M}{T-\theta} \quad (1)$$

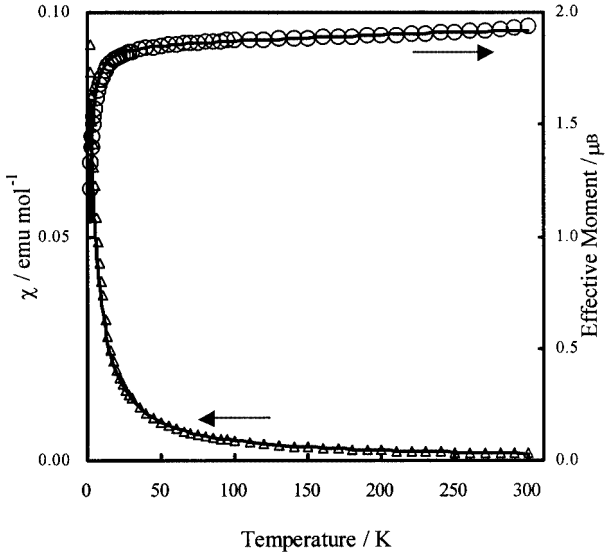

Figure 6. Plots of magnetic susceptibility (χ_M) and the effective magnetic moment (μ_B) per mol of copper versus temperature; the solid line of the magnetic susceptibility is from the fitting results of the Curie−Weiss law and the solid line of the effective magnetic moments is from the fitting results of the dinuclear magnetic equation

The temperature dependency of the magnetic susceptibility of complex **1** in the range 2.0−300 K was fit to the Curie−Weiss expression with a C_M value of 0.464 emu K/mol and a θ value of −3.80 K, which were determined by least-squares fitting in order to minimize the R agreement factor, defined as $R = \Sigma[(\chi_M)_i^{obs} - (\chi_M)_i^{calc}]^2/\Sigma[(\chi_M)_i^{obs}]^2$ (1.94×10^{-2}). The negative θ value is indicative of antiferromagnetic coupling between the metal sites. The effective moment $\mu_{eff} = (8 \times C_M)^{1/2}$ and exchange coupling constant $J/k_B = \theta/[S(S + 1)]$ were calculated to be 1.93 μ_B and −5.06 K, respectively, for complex **1**. The value of μ_{eff} is larger than the spin-only value of 1.73 μ_B; the corresponding g value of 2.22 commonly observed for Cu^{2+} centers is due to the spin-orbital coupling.[53] The magnetic coupling constant J/k_B is around −5.06 K, indicating a weak antiferromagnetic coupling between the copper centers via the CA ligands.

In order to analyze the magnetic exchange coupling interactions between the copper atoms, the susceptibility data of the complex were analyzed using the Bleaney−Bowers dinuclear magnetic equation [Equation (2)], with $H = -2JS_1 \cdot S_2$ as the Heisenberg exchange Hamiltonian,[54] where *TIP* is the temperature-independent paramagnetism of the Cu^{2+} ion.

$$\chi = \frac{2Ng^2\beta^2}{k_BT}\frac{1}{3+\exp(\frac{-2J}{k_BT})} + TIP \quad (2)$$

A reasonable fitting result for the magnetic susceptibility data with $TIP = 200 \times 10^{-6}$ emu/mol was found to be g = 2.14, J = −2.22 K (−1.58 cm^{-1}) for complex **1**, with an agreement factor R of 1.05×10^{-2}. The absolute value of J is much smaller than the value for $[Cu(CA)]_n$ ($J = -12.3\ cm^{-1}$), and is similar to the value for $[\{Cu(CA)(H_2O)\}(L)]_n$ (L = H_2O, dmpyz, phz).[41] Since this antiferromagnetic interaction is very weak, the maximum peak (T_N) of the magnetic susceptibility data would not be observed above 2.0 K. This very weak antiferromagnetic exchange interaction can be attributed to intrinsic structural aspects: because of the site symmetry (D_3) around the copper atom, the magnetic orbital is no longer pure $d_{x^2-y^2}$ and is mixed with the d_{z^2} orbital. This induces a reversal of 90° around the O−Cu−O axis of the magnetic orbital, and, consequently, reduces the extent of the antiferromagnetic interactions. Because of the weak antiferrromagnetic interactions within complex **1**, the Curie−Weiss law and the Bleaney−Bowers expression for the dimer both give reasonable fitting results. However, the values of the exchange coupling parameter J obtained from the two approximations are slightly different, which is due to the fact that both are not complete expressions of the honeycomb structure.

Conclusion

A novel robust supramolecular network $[\{Cu_2(CA)_3\}\{(H_3O)_2(phz)_3\}]_n$ has been synthesized and analyzed. The perfect π−π stacking of an alternating anionic inorganic layer and a cationic organic layer leads to an infinite number of one-dimensional, open-ended channels. The alternating charged layers are able to contain guests within the channels; these guests can be removed under high vacuum. This type of compound may have potential for use in vivo as guest adsorption/desorption and micro-reaction vessels for catalysts. The results of the magnetic study indicate the presence of an antiferromagnetic network.

Experimental Section

General Remarks: Chloranilic acid, phenazine and metal nitrate salts were purchased commercially and used as received without further purification. Thermogravimetric analyses were performed under nitrogen with a Perkin−Elmer TGA-7 analyzer. Powder-diffraction measurements were recorded with a Siemens D-5000 diffractometer at 40 kV (30 mA) with Cu-K_α radiation (λ = 1.5406 Å), with a step size of 0.02° in θ and a scan speed of 1 s per step size. Variable-temperature dc magnetic susceptibility data were collected for a polycrystalline sample of complex **1** in an applied field of 1.0 kG in the temperature range 2.0−300.0 K with a SQUID magnetometer (Quantum Design, MPMS-7). The sample was embedded in eicosane wax to prevent any torquing of the polycrystalline material in the magnetic field. Pascal's constants were used to estimate the diamagnetic corrections.[55]

$[\{Cu_2(CA)_3\}\{(H_3O)_2(phz)_3\}\cdot G]_n$ (1; G = $2CH_3COCH_3\cdot 2H_2O$): The synthesis of **1** was carried out at ambient temperature by carefully layering a solution of H_2CA (0.6 mmol) in acetone (6 mL) on top of a solution of phenazine (0.6 mmol) in THF (2 mL, middle), and a solution of $Cu(NO_3)_2\cdot 4H_2O$ (0.4 mmol) in H_2O (2.5 mL, bottom). After the solutions had been allowed to stand for about one week, dark-purple, hexagonal-shaped crystals were formed in 65% yield based on H_2CA, along with a black amorphous powder of unknown composition. The bulk product was washed with deionized water and ethanol, and separated by suction filtration. Hexagonal-shaped crystals, suitable for crystallographic analysis, were separated mechanically from the dark powder and dried in a desiccator at ambient temperature. A powder X-ray diffraction pattern of the isolated crystals was in good agreement with the pattern simulated from single-crystal data (vide infra). $[\{Cu_2(CA)_3\}\{(H_3O)_2(phz)_3\}\cdot 2CH_3COCH_3\cdot 2H_2O]_n$ = $C_{60}H_{46}Cl_6Cu_2N_6O_{18}$ (1478.81): calcd. C 48.73, H 3.14, N 5.68; found C 49.24, H 2.94, N 5.55.

$[\{Cu_2(CA)_3\}\{(H_3O)_2(phz)_3\}]_n$ (2): A single crystal of **2** was obtained by mounting a single crystal of **1** on a glass fiber and keeping it sealed in a Schlenk tube under vacuum (10^{-3} Torr) for 24 h. The resulting crystal was sealed to prevent contact with moisture from the air during the single-crystal X-ray diffraction analysis.

$[\{M_2(CA)_3\}\{(H_3O)_2(phz)_3\}\cdot G]_n$ (M = Cd, 3; M = Zn, 4; M = Co, 5; G = $2CH_3COCH_3\cdot 2H_2O$): Cd, Zn, and Co analogs of **1** were synthesized under similar reaction conditions using $Cd(NO_3)_2\cdot 4H_2O$, $Zn(ClO_4)_2\cdot 6H_2O$, and $Co(NO_3)_2\cdot 6H_2O$, respectively, as starting materials. These hexagonal-shaped crystals of the products were small and formed in low yield, along with a black amorphous powder of unknown composition. Crystals with good quality could be selected easily for single-crystal X-ray diffraction analysis. Nevertheless, we were not able to obtain sufficient amounts of pure products for other analyses.

X-ray Crystallographic Study: A hexagonal single crystal of **1** with dimensions of 0.38 × 0.38 × 0.18 mm was mounted on the tip of a glass fiber and placed onto the goniometer head for indexing and intensity data collection using a Bruker Smart CCD diffractometer (Mo-K_α = 0.71073 Å). The raw frame data for **1** were integrated into SHELX format reflection files and corrected for Lorentz and polarization effects with the Denzo program.[56] Corrections for incident- and diffracted-beam absorption effects were applied with the Multiscan method.[57] The structure of **1** was solved by direct methods and refined against F^2 by the full-matrix least-squares technique, using the WINGX,[58] PLATON,[59] and SHELX[60] software packages. The hydrogen atoms of the hydronium ion were located from the difference map and refined isotropically. The remaining hydrogen atoms were calculated and refined as riding atoms; all non-hydrogen atoms were refined with anisotropic displacement parameters. The minimum and maximum residual density of −0.45 and 1.25 e/Å^3 indicated that some guest molecules could be assigned from the difference maps. Nevertheless, attempts to resolve these disordered solvent molecules failed. No further attempts to resolve these diffusion regions were made. To analyze compound **2**, a newly selected crystal of good quality of **1** with dimensions of 0.28 × 0.28 × 0.18 mm was first held under a vacuum and then sealed. A crystallographic determination procedure similar to that described above was then performed. Crystallographic details for compounds **1** and **2** are given in Table 2 and selected bond lengths and angles are shown in Table 1. Compounds **3**, **4** and **5** were also characterized by single-crystal X-ray diffraction analysis and their crystallographic details are also given in Table 2. CCDC-235466 (**1**), -235467 (**2**), -235468 (**3**), -235469 (**4**) and -235470 (**5**) contain the supplementary crystallographic data

The (Chloromethyl)dihalosilanes X_2HSiCH_2Cl (X = F, Cl, Br, I): Synthesis, Multinuclear NMR Spectroscopy and Rotational Isomerism Examined by Raman Spectroscopy

Karl Hassler,*[a] Reinhard Hummeltenberg,[a] and Günter Tekautz[a]

Keywords: Infrared spectroscopy / NMR spectroscopy / Raman spectroscopy / Silanes / Synthesis

(Chloromethyl)diphenylsilane Ph_2HSiCH_2Cl (**1**) was prepared from Ph_2SiHCl and $LiCH_2Cl$, in situ, and was then treated with CF_3SO_3H/LiCl and CF_3SO_3H/LiBr to give the (chloromethyl)dihalosilanes Cl_2HSiCH_2Cl (**2**) and Br_2HSiCH_2Cl (**3**). I_2HSiCH_2Cl (**4**) was formed quantitatively in a protodearylation reaction between liquid hydrogen iodide and **1**. Fluorination of **4** with ZnF_2 gave F_2HSiCH_2Cl (**5**), albeit in low yields. Compounds **1**–**5** were characterised by multinuclear NMR spectroscopy (^{29}Si, ^{13}C, ^{19}F) and vibrational spectroscopy. The temperature-dependent vibrational Raman spectra of **2**, **3** and **4** prove that they are mixtures of *gauche* and *anti* rotamers in the liquid state. Enthalpy differences, ΔH ($H_{anti} - H_{gauche}$), were determined for the liquids by applying the van't Hoff relation, with the *gauche* rotamer being lower in energy for **3** and **4**, and the *anti* rotamer for **2**. The vibrational spectra were assigned with the help of ab initio calculations of equilibrium geometries and harmonic fundamental frequencies. Harmonic symmetry force constants and potential energy distributions were calculated from the ab initio Hessian matrices.

Introduction

α-(Halomethyl)silanes are versatile starting materials for the synthesis of organosilicon compounds such as silylmethyllithium derivatives or main-group derivatives $M\text{-}CH_nX_{2-n}SiR_3$, where X is a halogen.[1] However, only a handful of methods, each one with its own limitations, can be used for their preparation. These comprise the direct chlorination of methylsilanes, $MeSiR_3$ with Cl_2 [2] or Cl_2SO_2,[3] a method which does not tolerate silyl, vinyl or aryl groups as the R substituent. Another synthetic approach uses silyllithiums, $LiSiR_3$ as precursors, treating them with, for instance, CH_2Cl_2 to form CH_2ClSiR_3.[4] However, this method is not widely applicable due to a lack of suitable silyllithiums. A third method with a wider range of applications is the alkylation of chlorosilanes by a (halomethyl)lithium $X_nH_{3-n}CLi$ (n = 1, 2, 3; X = halogen), which is usually generated in situ. Pannell and co-workers have prepared a considerable number of (chloromethyl)silanes with this method that contain functionalities such as SiH, SiCl, SiSi, Si-vinyl, Si-allyl and Si-phenyl.[5] The introduction of these functional groups was a major step forward, as they can be replaced by other substituents without affecting the halomethyl functionality.

We are interested in the synthesis and spectroscopic properties of silaethanes, silapropanes and disilapropanes bearing no other substituents but hydrogen and halogen atoms. They can be considered as the link between halogenated hydrocarbons and their heavier analogues the halogenated disilanes and trisilanes. The chemical behaviour of both the Si−Si bond and the Si−C bond is strongly influenced by the substituents at the molecular skeleton. Numerous experimental investigations show a weakening of the Si−C bond of carbosilanes (a term coined by Fritz[6] for compounds in which the molecular framework is exclusively built up by Si−C bonds) upon chlorination at the carbon atom, whereas chlorination at the silicon atom has the opposite effect, causing a bond strengthening. Ab initio studies of chlorinated silaethanes confirm these effects.[7] For instance, the bond-dissociation energies of $SiCl_3CH_3$, SiH_3CH_3, and SiH_3CCl_3 were calculated as 392, 369 and 314 kJ/mol, respectively. With disilanes, the bond strengths decrease in the order $SiCl_3SiCl_3 > SiH_3SiCl_3, > SiH_3SiH_3$, which is supported by experimental and ab initio Si−Si force constants and $^{29}Si,^{29}Si$ coupling constants, for instance.[8] The effect of Si chlorination can be rationalised by Bent's rule,[9] which states that bonds to electronegative substituents possess more p-character, thereby increasing the s-character of the bonds to electropositive atoms; more s-character usually means a stronger bond. Upon *C*-chlorination, Bent's rule should also be at work, but the effect is overridden by the repulsive force between the positive charges at the Si and C atoms due to the short Si−C distance. Moreover, the steric repulsion between the chlorine atoms at carbon — the Cl···Cl distance is in fact considerably shorter than the van der Waals distance — is reduced

[a] Institute of Inorganic Chemistry, University of Technology, Stremayrgasse 16, 8010 Graz, Austria

in the free CCl_3 radical upon dissociation. This reduction of intramolecular repulsion energy certainly provides a further contribution to the weakening of the bond.

If chlorine is replaced by other halogens, the relative contributions of these two effects will certainly vary. Fluorine substitution is expected to increase the positive charge on the carbon atom, thereby also increasing the Si−C repulsion. Conversely, the nonbonding halogen−halogen repulsion will decrease. Substitution with bromine should decrease the positive charge and increase the nonbonding interactions, an effect which will be even more pronounced with iodine. For instance, no (triiodomethyl)silanes have been reported in the literature so far. C_2I_6 is also unstable and has not been prepared yet.

These properties of the Si−C bond should also influence the barriers to internal rotation and conformer stabilities. Our attention, therefore, is mainly focussed on silaethanes and silapropanes that can display rotational isomerism. The existence of at least two different conformers in silaethanes and silapropanes demands the presence of EH_2X or EHX_2 groups (X = halogen, E = C or Si) in the molecule. A literature search revealed that only a handful of these compounds have been prepared so far, such as ClH_2CSiCl_2H[10] and ClH_2CSiH_2X (X = F, Cl, Br);[11] no such compounds with iodine have been described. Moreover, the literature search revealed a complete absence of general procedures for the preparation of (halomethyl)silanes with SiH_2X or $SiHX_2$ groups. We have therefore set out to develop general synthetic methods suitable for the preparation of a wide range of (halomethyl)dihalosilanes.

Results and Discussion

Syntheses

Tetrachlorosilaethane, $CClH_2SiCl_3$, is readily obtained by direct chlorination of trichloromethylsilane with Cl_2.[12] However, it is difficult to transform it into $CClH_2SiCl_2H$ or $CClH_2SiClH_2$, as it is not easy to achieve a selective chlorination of the SiH_3 group. Recently, a two-step reaction sequence was reported[10] involving a reduction with $LiAlH_4$ and subsequent chlorination with $SnCl_4$.

$(ClH_2C)SiCl_3 + LiAlH_4 \rightarrow (ClH_2C)SiH_3$
$(ClH_2C)SiH_3 + SnCl_4 \rightarrow (ClH_2C)SiCl_2H$

Dichloro(chloromethyl)silane was prepared for vibrational spectroscopic purposes. No NMR shifts and physical data were reported, and the synthesis seems inappropriate for the preparation of larger quantities due to the volatility of $(ClH_2C)SiH_3$.

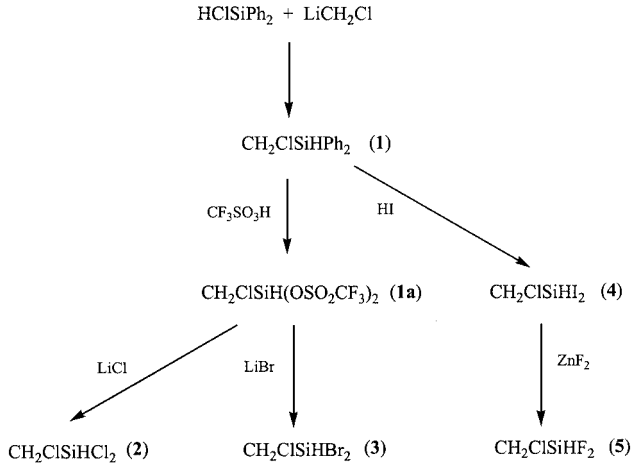
The introduction of aryl substituents into (chloromethyl)-silanes offers the possibility to replace them with Cl, Br or I by using either liquefied hydrogen halides HX or trifluoromethanesulfonic acid in combination with the lithium halides LiX. Both methods tolerate chloromethyl groups as well as Si−H and Si−Si functionalities, give good to excellent yields, and are widely applicable.

Si-aryl + HX → SiX + arylH (method 1)
Si-aryl + $CF_3SO_3H \rightarrow SiOSO_2CF_3$ + arylH
$SiOSO_2CF_3 + LiX \rightarrow SiX + Li^+[OSO_2CF_3]^-$ (method 2)

Method 1 usually gives better overall yields than 2.

From our experience with these two methods we expect that they can also be used successfully with (bromomethyl)-, (iodomethyl)- and even (fluoromethyl)silanes, though we have not yet tested them with these substrates.

The choice of which of the two methods to apply for a specific problem is dictated by practical considerations. If the desired carbosilane has a boiling point which is near that of the hydrocarbon arylH formed (which is the case for benzene and $CClH_2SiCl_2H$), purification becomes difficult. If one wishes to apply method 1 a larger aryl group can be introduced; for instance, phenyl groups can be replaced by tolyl or mesityl groups. Method 2 offers the advantage that phenyl groups still can be used as substituents, because benzene is easily separated from the trifluoromethanesulfonyloxysilane by evaporation in vacuo. Thus, commercially available phenylsilanes can be used as starting materials, reducing the time needed for the synthesis. As shown in Scheme 1, chlorodiphenylsilane was treated with CH_2ClLi, generated in situ from bromochloromethane and lithium at low temperatures,[13] forming (chloromethyl)diphenylsilane **1**. When a solution of **1** in toluene was treated with two equivalents of trifluoromethanesulfonic acid, the two phenyl groups were cleaved off, giving benzene and (chloromethyl)bis(trifluoromethanesulfonyloxy)silane (**1a**) without noticeable side reactions. Toluene and benzene were then removed by evaporation in vacuo, giving the pure (chloromethyl)sulfonyloxysilane as a colourless oily liquid. Upon addition of LiCl or LiBr, the (halomethyl)silanes **2** and **3** were formed in yields not exceeding 30%, presumably due to Si−C cleavage.



Scheme 1. Synthesis of (chloromethyl)dihalosilanes

Compound **4** was prepared by method 1, treating **1** with liquid HI. Dry gaseous hydrogen iodide was easily obtained from tetrahydronaphthalene and iodine as described in the literature,[14] and purified by trap-to-trap condensation. Scheme 1 summarises the syntheses of **1**−**5**. Fluorination

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of **4** with various fluorinating agents such as ZnF_2 turned out to be difficult due to extensive Si−C bond cleavage. The yields achieved were so small that only the NMR spectra of **5** could be obtained, albeit in good quality. We will therefore report on the fluorination of **5** in conjunction with the synthesis of (bromomethyl)halosilanes and (iodomethyl)halosilanes.

NMR Spectroscopy

Compounds **2**−**5** were characterised by multinuclear NMR spectroscopy (^{13}C, ^{19}F, ^{29}Si), and **1** by ^{29}Si NMR only. Table 1 summarises the chemical shifts and coupling constants that were obtained. In the proton-coupled ^{29}Si NMR spectra of **2**, **3** and **4**, the signal of the Si nucleus is split into a doublet of triplets due to one- and two-bond Si−H coupling. The ^{13}C NMR signal splits into a triplet of doublets. The ^{29}Si and ^{13}C NMR spectra of **5** are presented in Figure 1. The unusual appearance of the ^{29}Si NMR spectrum, which consists of two triplets and two quadruplets, results from the near equality of $^1J_{Si,H}$ and $^1J_{Si,F}$, the difference being almost equal to $^2J_{Si,H}$. Each quadruplet is therefore an overlap of two triplets. The ^{13}C NMR spectrum is composed of six triplets, as expected for a first-order spectrum.

Table 1. Chemical shifts[a] (ppm) and coupling constants (Hz) for the (chloromethyl)dihalosilanes **1**−**5**

	$\delta(^{29}Si)$	$\delta(^{13}C)$	$\delta(^{19}F)$	$^1J_{Si,H}$	$^2J_{Si,H}$	$^1J_{C,H}$	$^2J_{C,H}$	$^2J_{C,F}$	$^1J_{Si,F}$
1	−17.6			204.9	4.3				
1a	−30.3			335.6					
2	+0.9	29.9		300.0	4.3	144.0	16.0		
3	−13.4	29.6		299.0	4.3	146.0	15.0		
4	−85.2	28.1		292.0	4.3	146.0	11.0		
5	−29.1	23.8	−141.5	301.0	4.8	141.0	23.5	18.3	305.0

[a] $\delta(^{29}Si)$ and $\delta(^{13}C)$ are referenced against TMS; $\delta(^{19}F)$ is referenced against CCl_3F.

The ^{29}Si NMR chemical shifts of **1**−**5** do not follow a linear dependence on the electronegativities of the directly bonded halogens, which is not surprising, as it is known that ^{29}Si chemical shifts depend on the sum of the electronegativities of the substituents in a nonlinear manner.[15] The shift maximum for **2** can easily be explained on that basis.

One-bond Si−H coupling constants usually increase with increasing electronegativities (sum of the electronegativities) of the substituents, which can be interpreted in terms of isovalent hybridisation. Bonds to electronegative elements possess more p-character, which is balanced by more s-character in the Si−H bond. As the Fermi contact term dominates $^1J_{Si,H}$, the coupling constant increases. Interestingly, the values of $^1J_{Si,H}$ for **2**−**5** show only a slight increase by no more than 9 Hz with increasing electronegativity of the halogens. For the silanes H_2SiI_2 and H_2SiF_2, the difference is 7.4 Hz.[15]

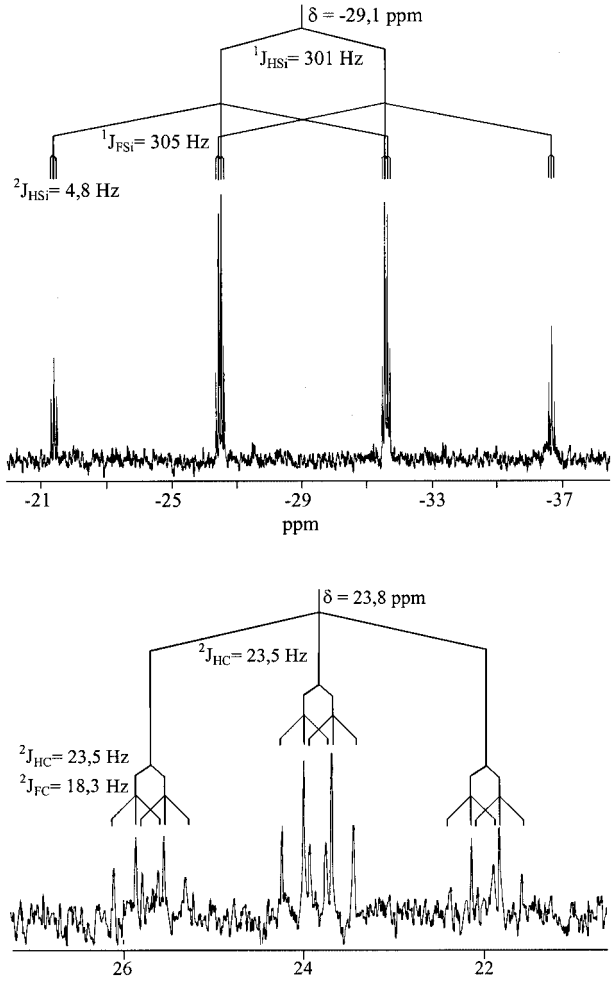


Figure 1. Splitting of the ^{29}Si (top) and the ^{13}C NMR signal (bottom) of CH_2ClSiF_2H due to indirect spin−spin coupling

Raman Spectroscopy and Rotational Isomerism

At ambient temperatures, the (chloromethyl)dihalosilanes **2**−**5** exist as mixtures of *gauche* [C_1 symmetry, ω(ClCSiH) ≈ 52°] and *anti* [C_s, ω(ClCSiH) = 180°] conformers, as illustrated in Figure 2 with the help of Newman projections.

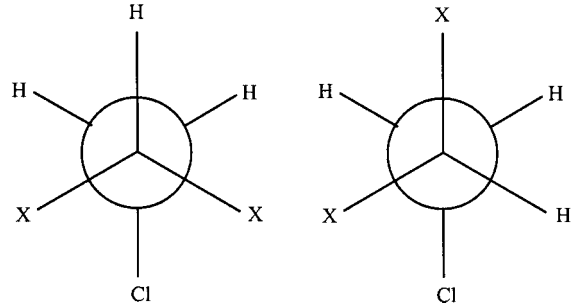

Figure 2. Newman projections of *anti* (left) and *gauche* (chloromethyl)dihalosilanes

As long as the barriers separating the two conformers are well above 2.5 kJ/mol (= RT at room temperature), they

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

behave as distinct vibrating entities and can be identified by their IR and Raman vibrational spectra. For Si−C and Si−Si bonds this condition is usually fulfilled. For assigning bands to individual rotamers, a normal coordinate analysis based upon ab initio calculations of vibrational frequencies and force constants is normally carried out for both conformers.

The rotational isomerism of dichloro(chloromethyl)silane has been investigated recently by FT-IR spectroscopy on solutions in liquid xenon, with the more stable form being the *gauche* conformer ($\Delta H_{exp.} = 4.34 \pm 0.48$ kJ/mol).[10] The result is consistent with ab initio calculations at the MP2/6-31G(d) level of theory, but is also reproduced correctly at the Hartree−Fock level. Values for ΔH obtained on solutions in noble gases are supposed to differ only slightly from values in the gas phase.

For the present study, we have recorded the Raman spectra for the liquids of **2**, **3** and **4**. Figure 3 presents the Raman spectrum of **3** at two temperatures, illustrating the variations that occur upon cooling. In all cases we only obtained glassy solids at low temperatures that contained both conformers at the temperature of liquid nitrogen. No crystallisation was observed.

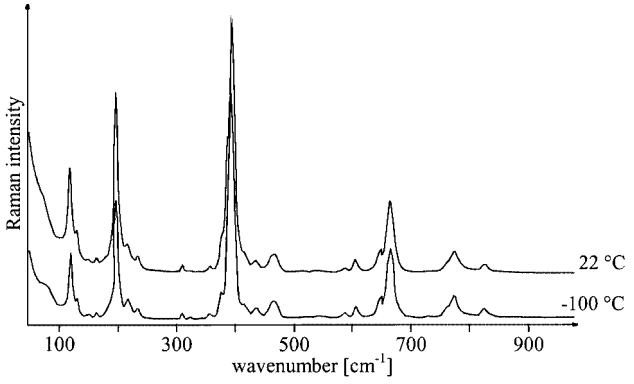

Figure 3. Raman spectrum of dibromo(chloromethyl)silane in the range 50−900 cm^{-1} at 22 °C and −100 °C.

To facilitate the identification of vibrational bands belonging to the various conformers, ab initio calculations of equilibrium geometries, harmonic frequencies and force constants (Hessian matrices) were performed at the Hartree−Fock level of theory for **2**−**5**. Inner filled electron shells were replaced by the electron core potentials (ECPs) reported by Stevens, Krauss and Basch.[16] A 6-31G** double-zeta basis set was used for the valence electrons. By use of the ECPs, relativistic corrections for the heavier halogens are taken into account. Table 2 summarises the most important geometric parameters for both conformers of **2**−**5** — *anti* and *gauche* — as well as the relative conformational energies predicted by the ab initio calculations. The Hessian matrices, which represent the force constants defined in Cartesian coordinates, were transformed into force fields defined with symmetry coordinates which are linear combinations of bond distortions and angle distortions. With the symmetry force fields, normal coordinate analyses were carried out which allow the description of the normal modes as group vibrations by use of the potential-energy distributions (PEDs). The program ASYM40[17] was used for these calculations. A factor of 0.92 was used to scale the calculated frequencies, and $(0.92)^2$ to scale the force constants. Table 3 and 4 summarise the wavenumbers in the Raman and IR spectra of **3** and **4**, the scaled and unscaled ab initio wavenumbers, and the descriptions of the modes as group vibrations based on calculated PEDs. The spectra of **2** are not repeated here as they have been reported previously.[10]

The value of the enthalpy difference can be determined from temperature-dependent vibrational spectra by applying the van't Hoff relationship, which is derived under the assumption that ΔH is independent of temperature

$$\ln(I_a/I_g) = -\Delta H/RT + \text{const.}$$

where I_a and I_g are the intensities of the Raman or IR bands for rotamer a and g, respectively. Plotting $\ln(I_a/I_g)$ versus $1/T$ thus results in a straight line whose slope is equal to $-\Delta H/R$. ΔH values were obtained by a least-squares fit from three line pairs for **2** and **3**, and from two pairs for **4**. As an example, two van't Hoff plots are presented in Figure 4.

Table 5 summarises the ΔH values together with the relevant band pairs and the statistical error. In these experiments, severe interference from overlapping with overtones or combination bands occur quite often. Fermi resonances between overtones and fundamentals are also encountered quite frequently. It is also a prerequisite of the method that the bands of the two conformers both have reasonably high intensity and are sitting on a flat baseline. These difficulties have been reviewed recently by Klaboe.[18]

The discrepancies between the experimental ΔH values obtained from the different band pairs can easily be explained on that basis. Average ΔH values of -0.57 ± 0.37, 0.21 ± 0.07 and 0.56 ± 0.50 were obtained for **2**, **3** and **4**, respectively, by neglecting the statistical uncertainties resulting from the least-squares fits. Due to the uncertainties mentioned above, the standard deviations are quite large.

Opposite to the gaseous state, the *anti* rotamer of $CH_2ClSiHCl_2$ is slightly more stable in the liquid. This can

be explained by considering the dipole moments of the two rotamers, as the conformer with the larger dipole moment is normally stabilized in a polar solvent. The predicted dipole moments for *gauche* and *anti* $CH_2ClSiHCl_2$ are 1.53 and 3.22 D, respectively, and the latter is therefore stabilized in the liquid. *anti* $CH_2ClSiHBr_2$ and *anti* $CH_2ClSiHI_2$ are also

stabilized, but due to the smaller dipole moments and the larger *gauche-anti* energy differences (Table 2) the stabilizing effect is not able to reverse the sign of ΔH.

It is also of some note that the SiC valence force constants calculated from the Hessian matrices by use of symmetry coordinates increase with increasing electronegativity of the halogen substituents. The calculated values for *gauche* **5**, **2**, **3** and **4** [N/cm, scaled by $(0.92)^2$] are: 2.87, 2.77, 2.73 and 2.67, respectively; the force constants for the *anti* conformers are smaller by 0.03−0.04 N/cm.

Experimental Section

General Remarks: All compounds except (chloromethyl)diphenylsilane are sensitive towards moisture; some of them, such as (chloromethyl)diiodosilane, are also sensitive towards oxygen. All syntheses and manipulations were therefore carried out under an atmosphere of dry, oxygen-free nitrogen using Schlenk techniques. Solvents were dried over sodium or potassium and distilled under N_2 prior to use.

Raman spectra were recorded with a Jobin−Yvon T64000 spectrometer equipped with a triple monochromator. A frequency-doubled Nd:YAG laser (20 mW) operating at 532 nm served as light source and a charge-coupled device (CCD) camera was used as detector. The samples were condensed into 1 mm capillary glass tubes that were sealed under nitrogen atmosphere. Variable-temperature Raman spectra were obtained by mounting the capillary on a copper block supplied with a heater and a thermocouple for temperature monitoring. Liquid nitrogen was used for cooling.

Infrared spectra in the range from 3000−250 cm^{-1} were measured with a Perkin−Elmer 883 spectrometer using a film of the pure liquid between CsBr plates

NMR spectra of **2**−**5** as solutions in $CDCl_3$ were obtained with a Bruker MSL 300 spectrometer.

(Chloromethyl)diphenylsilane (1): A solution of chlorodiphenylsilane (55.17 g, 250 mmol) and bromochloromethane (32.63 g, 250 mmol) in 500 mL of THF was cooled to −70 °C, and 138 mL of a 2 M solution of BuLi in pentane was added dropwise over a period of 2 h, whilst maintaining the temperature. After completion of the addition the mixture was stirred at −70 °C for another 2 h. It was then allowed to warm to room temperature and stirred overnight. After hydrolysis and extraction with n-hexane the organic layer was separated. Subsequently, the solvent is removed by evaporation in vacuo and the liquid residue was fractionated, giving 20.7 g (88.9 mmol, 35%) of **1** as a colourless liquid. $B.p._{0.1}$ = 125 °C. $C_{13}H_{13}ClSi$ (232.77): calcd. C 67.07, H 5.63; found C 66.98, H 5.6.

Dichloro(chloromethyl)silane (2): Triflic acid (6.46 g, 43.3 mmol) was added dropwise at a temperature of −30 °C to a solution of **1** (5.01 g, 21.5 mmol) in 20 mL of toluene. After completion the mixture was allowed to warm to room temperature and stirred for 5 h. The benzene formed in the reaction and the toluene were completely removed in vacuo, this process was controlled by IR spectroscopy. Diethyl ether and 3 g of LiCl (100% excess) were added and the mixture was then stirred at room temperature for 2 d. After this time all volatile substances were condensed off. The diethyl ether was removed very carefully from the mixture by distillation. The liquid residue was fractionated under slightly reduced pressure giving 0.9 g (6 mmol) of **2** (28.1%) as colourless liquid. $B.p._{200}$ = 42 °C. CH_3Cl_3Si (149.48).

Dibromo(chloromethyl)silane (3): Compound **3** was prepared using the same procedure as for **2**, except that LiBr was used instead of LiCl. The following amounts of starting materials were used: 5.67 g of **1** (24.36 mmol); 7.31 g of triflic acid and 5 g of LiBr. Fractionation in vacuo yielded**3** (1.4 g, 5.8 mmol; 24.1%) as a colourless liquid. $B.p._{20}$ = 43−45 °C. CH_3Br_2ClSi (238.38): calcd. Br 64.04; found Br 64.18.

(Chloromethyl)diiodosilane (4): Compound **1** (4.37 g) and an excess of HI were placed in a sealed glass tube and stored for one week at room temperature. After removal of the excess HI and the benzene formed during the reaction, the liquid residue was fractionated in vacuo to give 3.7 g (mmol) of **4** (59.3%) as a colourless liquid. $B.p._{0.1}$ = 33−35 °C. CH_3ClI_2Si (332.39): calcd. I 76.36; found I 76.15.

(Chloromethyl)difluorosilane (5): A solution of **4** (1.5 g, 4.5 mmol) in 15 mL of hexachlorobutadiene was added at a pressure of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

30 Torr to a suspension of 5.7 g of zinc fluoride (excess) in 60 mL of hexachlorobutadiene. The volatile products were continuously condensed into a flask cooled with liquid nitrogen. After completion of the addition the mixture was stirred at 90 °C for 5 h. The volatile products contained just a small amount of the desired product, as deduced from the NMR spectra. No further attempts to isolate these small quantities of CH_3F_2ClSi on a preparative scale were made.

The Effect of the Steric Bulk of the Ligand on the Geometry of the Species Self-Assembled from Co^{III} Bis(dioximates) and Boronic Acids

Renata Dreos,*[a] Giorgio Nardin,[a] Lucio Randaccio,*[a] Patrizia Siega,[a] Silvia Scagliola,[a] and Giovanni Tauzher[a]

Keywords: Boronic acid / Cobalt / Dioximes / Self-assembly / Solid-state structures

The synthesis and characterization of the products of the reactions between the bis(diphenylglyoximato)cobalt(III) complexes $[Co(CH_3)(dpgH)_2L]$ [L = py or H_2O; $dpgH_2$ = bis(diphenylglyoxime)] and 4-pyridinylboronic acid (**1**) and 3-aminophenylboronic acid (**2**) are described. The crystals of both **1** and **2** are built up by dimeric units arranged on a crystallographic symmetry center, so that the 4-pyridinyl (in **1**) or the 3-aminophenyl residue (in **2**) of one moiety coordinates to the Co atom of the symmetry-related unit. ^1H NMR spectra show that both **1** and **2** are stable in solution in aprotic solvents: they do not dissociate and are not in equilibrium with species having different nuclearity. The geometry of **1** is very similar to that of the species assembled from the corresponding bis(dimethylglyoximato)cobalt(III) complex and 4-pyridinylboronic acid. On the contrary, the replacement of the methyls by phenyls prevents the trimeric arrangement previously found in the supramolecular species assembled from methylcobaloxime and 3-aminophenylboronic acid and leads to the dimeric species **2**.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Organobis(dimethylglyoximato)cobalt(III) complexes $[Co(CH_3)(dmgH)_2L]$ [$dmgH_2$ = bis(dimethylglyoxime)], also known as organocobaloximes (Scheme 1), have been widely studied as vitamin B_{12} models.[1] Their derivatives with either one or both of the intramolecular O−H···O bridges replaced by organoboryl groups are well known and have recently been reviewed.[2] In the last few years organocobaloximes have also been shown to be good building blocks for the assembly of supramolecular systems by reaction with functionalised aromatic boronic acids.[3−5] The $B(OH)_2$ group of the boronic acid reacts with the oxime bridge of one cobaloxime molecule, with simultaneous coordination of the donor atom to the cobalt of another cobaloxime. Products of different nuclearity and geometry have been obtained depending on the boronic acid used as linker (Scheme 1). Thus, the reaction of methylcobaloxime with 4- and 3-pyridinylboronic acid (L^1 and L^2, respectively) gave a dinuclear "molecular box"[4] and a dinuclear "molecular parallelogram",[3] respectively, whereas reaction with 3-aminophenylboronic acid (L^3) gave a trinuclear molecular triangle (Scheme 2).[5]

The substitution of Co by Rh in the reaction with 3-aminophenylboronic acid produced a dramatic structural change, leading to an inorganic polymer (Scheme 3), although both the geometry and the coordination properties of the $[Rh(CH_3)(dmgH)_2L]$ and $[Co(CH_3)(dmgH)_2L]$ moieties are very similar. These results suggest that slight variations in the geometry of the building blocks can strongly affect the structure of the assembled polynuclear systems. Therefore, we decided to study the effect of the increase in steric hindrance of the metal complex by substituting either one or both of the methyl groups of the equatorial bis(dimethylglyoximato) ligand by a phenyl group (Scheme 1). The synthesis and characterization of the products of the reactions between the organobis(diphenylglyoximato)cobalt(III) complexes $[Co(CH_3)(dpgH)_2L]$ and L^1, L^2 and L^3 are discussed in this paper, whereas the results concerning the reactions of organobis(methylphenylglyoximato)cobalt(III) complexes $[Co(CH_3)(mpgH)_2L]$ will be reported elsewhere.

Results and Discussion

Synthesis

The starting complex for the synthesis of **1**, $[Co(CH_3)(dpgH)_2py]$, was synthesized as described previously.[6,7] In the synthesis of **2**, $[Co(CH_3)(dpgH)_2(H_2O)]$ was used instead of $[Co(CH_3)(dpgH)_2py]$ to facilitate the replacement of the axial ligand by the amine nitrogen of

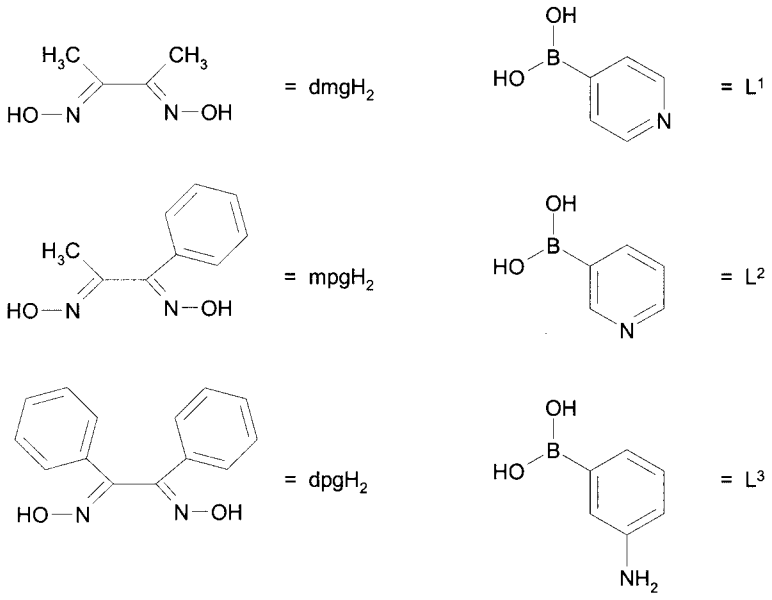
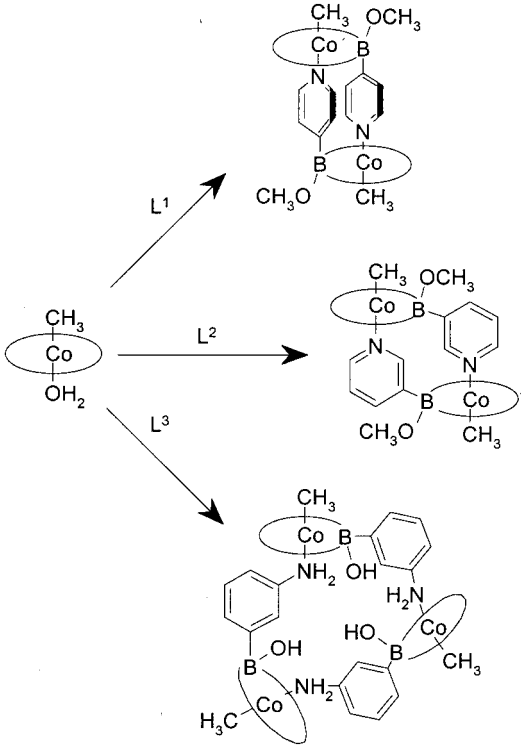
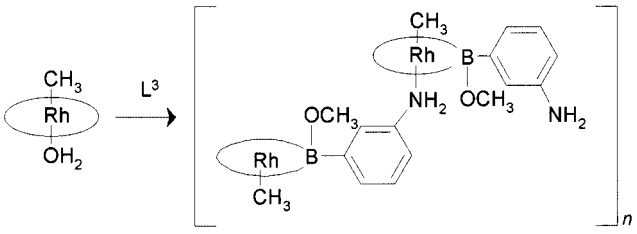


Scheme 1



Scheme 2

the boronic acid. It has previously been shown that the products of the reactions of methylcobaloxime with L^1, L^2 and L^3 are strongly pH dependent,[4,5] because the boronic acids are zwitterionic species.[8] Indeed, the formation of the supramolecular species occurs by reaction of the complex with either the neutral or the zwitterionic form of the boronic acid.[4] The macroscopic pK_a values of the first and the second deprotonation are, respectively, 3.83 and 8.2 for L^1,[4] 4.0 and 8.2 for L^2,[8] and 4.56 and 9.14 for L^3.[5]



Scheme 3

Therefore the reactions were carried out within these pH ranges also in the present case. X-ray quality crystals of **1** and **2** were obtained from the reaction with L^1 and L^3, after one week and after four days, respectively. Only complicated mixtures of products were obtained from the reaction with L^2, despite several attempts carried out at different pH values and in different solvents, and they were not further characterized.

It should be noted that the reaction time for the formation of **1** and **2** is substantially longer than that required for the assembly of the corresponding systems starting from cobaloximes. This effect may be due to both electronic and to steric effects. In fact, the electron-withdrawing power of the phenyls decreases the electron density on the oxime oxygens with respect to cobaloximes and hinders the electrophilic attack of the sp^2-hybridized B atom of the boronic acid. Furthermore, the steric hindrance of the phenyls may also make the approach of L both to the oxime bridge and to the axial coordination position more difficult.

X-ray Crystal Structures

The crystal structure of $[Co(CH_3)(dpgH)\{dpgB(OMe)(4\text{-}Py)\}]_2$ (**1**) is built up from dimeric units arranged on a crystallographic symmetry center in such way that the 4-pyridi-

nyl residue of one unit axially coordinates the Co atom of the symmetry-related unit (Figure 1). Four MeOH and two H_2O molecules were also located in the unit cell, all with half-occupancy factor. A series of H-bonds are formed between water and methanol [O1w···O7Me = 2.929 Å; O1w···O6Me = 2.422 Å] and between methanol and the B-methoxide residue [O6Me···O5 = 2.735 Å]. The dimer can be considered a rectangular box with the two equatorial moieties and the two pyridinyl groups as ideal sides. The Co···Co distance is 7.605(1) Å, whereas the Co···B distance is 3.240(4) Å, Co···B1 is 6.510(4) Å and the Co−B−Co′ and B−Co−B1 angles are 96.7(1)° and 82.9(9)°, respectively. The geometry of the dimer is very close to that found in $[Co(CH_3)(dmgH)\{dmgB(OMe)(4\text{-}Py)\}]_2$ (**1′**) in which the corresponding distances and angles are 7.592(3) Å, 3.20(1) Å, 6.51(1) Å, 97.1° and 82.9°, respectively (Scheme 4).[4] As in **1′**, the pyridinyl ligand is nearly perpendicular to the Co_2B_2 mean plane (85.4°) and oriented in such way as to nearly bisect the five-membered ring of the equatorial moiety. The two pyridinyl rings, related by a symmetry center, are nearly face to face at a distance of 3.38 Å (3.30 Å in **1′**).[4] The latter orientation of the axial planar ligand is typical of the iminocobaloximes (Costa's models)[1] and of bis(diphenylborylated) cobaloximes,[9−11] whereas the axial ligand is rotated by about 90° in the monomeric complexes $[CoR(dpgH)_2py]$ with R = CH_3,[6] CH_2SiMe_3,[7] CH_2CMe_3,[7] and CF_3,[7] where the pyridine ligand bisects the O···O vectors of the diphenylglyoximate ligands.

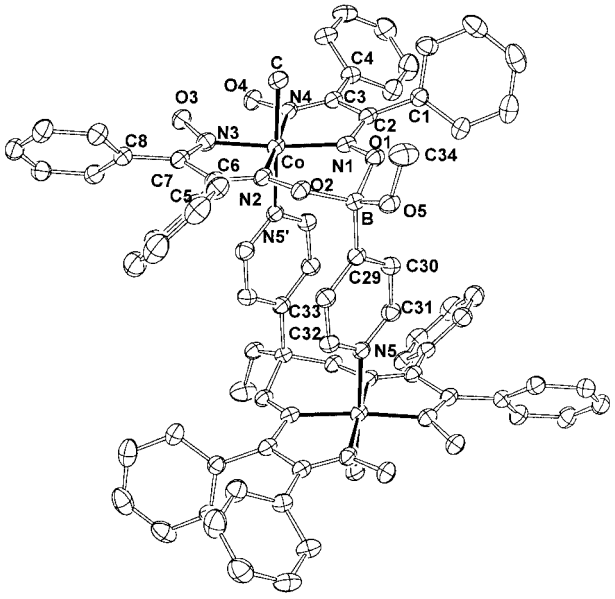

Figure 1. ORTEP drawing (thermal ellipsoids at 30% probability) and labeling scheme for the independent atoms in the dimer **1**; the crystallization solvent molecules have been removed

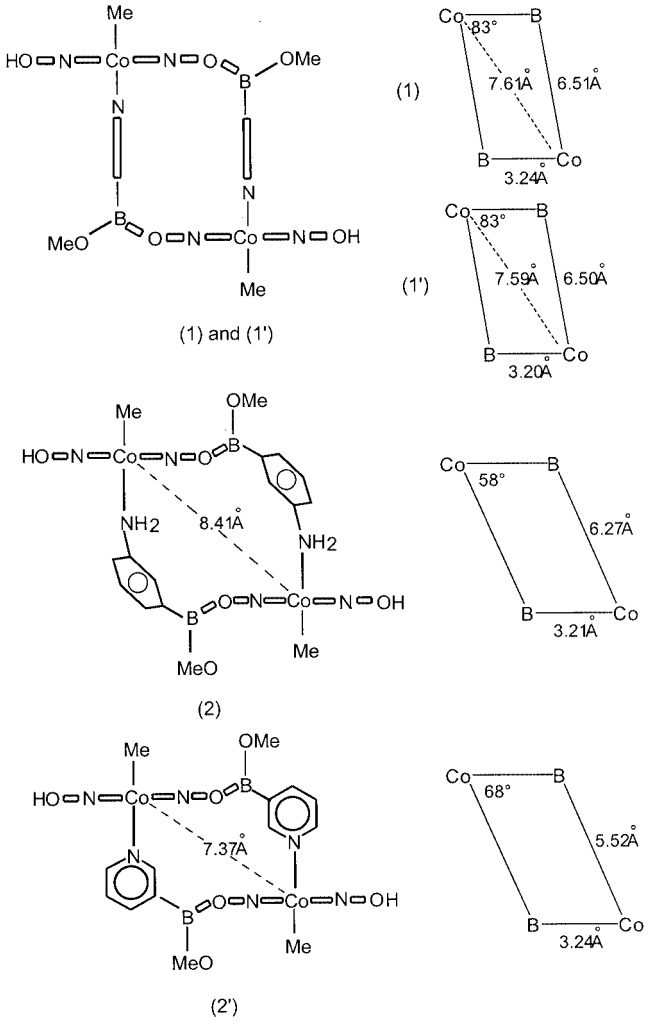
An ORTEP view of **2** is shown in Figure 2. The structure consists of dimeric units arranged around a crystallographic symmetry center so that the pendant 3-aminophenyl residue of one moiety coordinates the Co atom of the other unit in one axial position, as shown in Figure 2. The dimeric unit may be considered a molecular box, similar to that of **1**,



Scheme 4

but more distorted. In fact, the Co_2B_2 group, which forms a nearly regular rectangle in **1**, forms a distorted parallelogram in **2** (Scheme 4). This parallelogram is similar to that observed in $[Co(CH_3)(dmgH)\{dmgB(OMe)(3\text{-}Py)\}]_2$ (**2′**).[3] However, owing to the greater conformational freedom of the aminophenyl group with respect to that of the 3-pyridinyl one, a molecular box with the two phenyl groups oriented face to face is formed in **2**, whereas a "molecular parallelogram" is formed in **2′**.[3] In fact, in the latter the two pyridinyl residues are not faced but nearly coplanar. In **2**, the Co···Co distance of 8.410(2) Å is significantly longer than that observed in **2′** [7.365(4) Å]. The orientation of the axial aminophenyl residue with respect to the equatorial plane in **2** (dihedral angle Co′N5−C33C34 = 86.2°, interplanar angle 33.2°) is similar to that observed in the trimeric species $[Co(CH_3)(dmgH)\{dmgB(OH)(3\text{-}NH_2Ph)\}]_3$ (**3**; mean value 102.1°; interplanar mean angle 31.4°).[5] However, in the latter a trinuclear molecular triangle of cobalt atoms of about 9.47 Å side, was found. The difference between **2** and **3** can be ascribed to the replacement of the Me groups on the equatorial moiety by Ph groups. In fact, in **3** the closure of the Co triangle imposes the orientation of three methyl groups towards the centre of the Co tri-

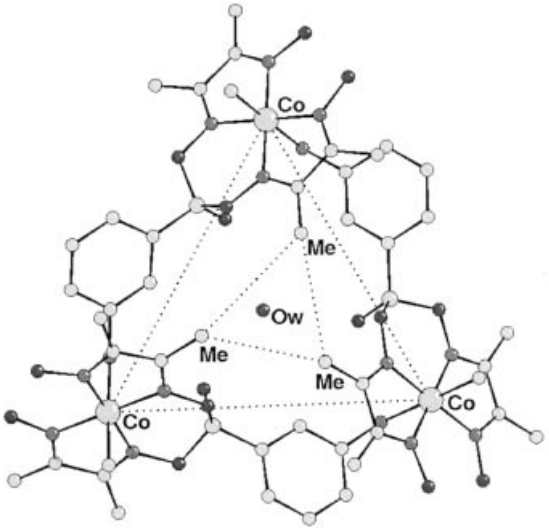
angle. Therefore the arrangement requires that the three C(Me) atoms are at about 3.89 Å (Scheme 5). When a phenyl group replaces the methyl group, the trimeric arrangement of **2** is prevented because of the steric hindrance between the phenyl groups.



Scheme 5. A view of the molecular triangle **3**; the dotted lines indicate the Co···Co (mean value 9.47 Å) and the C(Me)···C(Me) (mean value 3.9 Å) distances

The coordination bond lengths in **1** and **2** are given in Table 1 and compared with those in **1′**, **2′** and **3**. As expected, the Co−N5′ (sp^2) distances in **1**, **1′**, and **2′** are essentially identical and shorter than the corresponding Co−N5′ (sp^3) distances in **2** and **3**.

^{1}H NMR Spectra

The ^{1}H NMR spectrum of **1** in $CDCl_3$ shows a single set of signals because of the presence of a symmetry center in the molecule. The axial methyl resonates at δ = 1.59 ppm, deshielded with respect to $[Co(CH_3)(dpgH)_2py]$ (δ = 1.44 ppm),[7] probably due to the electron-withdrawing effect of the boryl bridge. The singlet at δ = 3.27 ppm is due to the $BOCH_3$ protons. The *ortho* protons of the pyridinyl residue, assigned from a ^{1}H-^{1}H COSY experiment, resonate at δ = 7.35 ppm and the *meta* protons at δ = 6.75 ppm, considerably upfield shifted relative to those of $[Co(CH_3)(dpgH)_2py]$ (δ = 8.92 and 7.44 ppm, respectively), due to the shielding effect of the two faced pyridinyl rings.[7] The phenyl protons give rise to a multiplet in the range δ = 7.18−7.43 ppm.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The ^1H NMR spectrum of **2** was recorded in C_6D_6 because the compound is almost insoluble in the most common deuterated solvents. The magnetic anisotropy of this solvent spreads the signals of the aromatic protons over a larger range, allowing an almost complete assignment. The axial methyl resonates at $\delta = 2.30$ ppm and the $BOCH_3$ group at $\delta = 3.20$ ppm. The NH_2 protons, which are diastereotopic as a consequence of the coordination, give rise to a doublet of doublets at $\delta = 3.32$ and 3.80 ppm. The protons of the four non-equivalent phenyls and the aminic protons resonate in the range $\delta = 6.20-8.01$ ppm.

These results are entirely consistent with the solid-state structures, suggesting that **1** and **2** are stable in solution in aprotic solvents: they do not dissociate and are not in equilibrium with species having different nuclearity.

Conclusion

The most interesting consequence of the increase of the steric hindrance in the equatorial ligand of the metal complex on going from bis(dimethylglyoximato) to bis(diphenylglyoximato), is the change in the nuclearity of the supramolecular species assembled from L^3. The molecular triangle **3** was obtained starting from bis(dimethylglyoximato) whereas the dimeric species **2** was obtained from bis(diphenylglyoximato). Assembly is still possible because of the conformational freedom of the boron bridge, which is directed toward the methyl group in **2**, whereas it is directed towards the opposite side in the triangle **3**; however, the trimeric arrangement is prevented because of the steric hindrance of the phenyl groups.

A further structural difference is the esterification of the B(OH) residual groups by methanol in **2**, which does not occur in **3**. In this case the esterification is probably hampered by the network of H-bonds between a water molecule lying approximately in the center of the triangle (Ow, Scheme 5) and the three boron OH groups.

Finally, both electronic and steric effects may be responsible for the longer time required for the assembly reaction in comparison with cobaloximes.

Experimental Section

General Remarks: NMR spectra were recorded on a Jeol EX-400 spectrometer with TMS as internal standard. Electrospray mass spectra were recorded in positive mode by using an API 1 mass spectrometer (Perkin−Elmer) at 60 V cone voltage. $[Co(CH_3)(dpgH)_2py]$ was prepared according to a literature procedure.[6,7] All other reagents were reagent grade and used without further purification.

Synthesis of $[Co(CH_3)(dpgH)_2(H_2O)]$: $[Co(CH_3)(dpgH)_2py]$ (0.10 g, 0.16 mmol) was dissolved in 10 mL of CH_2Cl_2 and 40 mL of CH_3OH. The solution was filtered to remove the undissolved residue and 0.30 g of the acidic cation exchange resin Dowex 50 W was added. The solution was heated at 50 °C for 2 h and then filtered and concentrated to half volume on a rotary evaporator. Red crystals of $[Co(CH_3)(dpgH)_2(H_2O)]$ were recovered from the solution after allowing it to stand. Yield: 63.7 mg (69%). $C_{29}H_{27}CoN_4O_5$ (570.48): calcd. C 61.06, H 4.77, N 9.82; found C 60.7, H 4.91, N

9.60. ESI-MS (60 V, CH_3OH; m/z^+): calcd. for $CH_3Co(dpgH)_2H_2O$ 570.482; found 553.1 (100%) [$CH_3Co(dpgH)_2H_2O - H_2O$]. ^1H NMR ($CDCl_3$, 400 MHz, TMS): δ = 1.23 (s, 3 H, CH_3 ax.), 7.26 (m, 20 H, equatorial phenyls) ppm.

Synthesis of [Co(CH$_3$)(dpgH){dpgB(OMe)(4-Py)}]$_2$ (1): 4-Pyridinylboronic acid (0.012 g, 0.1 mmol) was added whilst stirring to a solution of [Co(CH$_3$)(dpgH)$_2$py] (0.03 g, 0.05 mmol) in a mixture of methanol (10 mL) and CH_2Cl_2 (2 mL). The resulting mixture was filtered and the pH was adjusted to 5 by addition of $HClO_4$ (70% w/w). X-ray quality crystals formed from the solution in 1 week. Yield: 0.014 g (40%). $C_{70}H_{62}B_2Co_2N_{10}O_{10}$ (1342.8): calcd. C 62.00, H 4.65, N 10.43; found C 61.8, H 4.69, N 10.18. ESI-MS (60 V, CH_2Cl_2/HCOOH 1%; m/z^+): calcd. for **1** 1342.8; found 1343.2. (43%) [**1** + H^+]. ^1H NMR ($CDCl_3$, 400 MHz, TMS): δ = 1.59 (s, 6 H, CH_3 ax.), 3.27 (s, 6 H, OCH_3), 6.72 (d, $^3J_{H,H}$ = 6.4 Hz, 4 H, *meta* of py), 7.18−7.43 (m, 40 H, equatorial phenyls), 7.35 (d, $^3J_{H,H}$ = 6.4 Hz, 4 H, *ortho* of py), 18.24 (s, 2 H, O···H···O) ppm.

Synthesis of [Co(CH$_3$)(dpgH){dpgB(OMe)(3-NH$_2$Ph)}]$_2$ (2): 3-Aminophenylboronic acid monohydrate(0.03 g, 0.18 mmol) was added whilst stirring to a solution of [Co(CH$_3$)(dpgH)$_2$(H$_2$O)] (0.10 g, 0.18 mmol) in methanol (100 mL). The resulting solution was filtered and the pH was adjusted to 8 by addition of $HClO_4$ (70% w/w). X-ray quality crystals formed from the solution within 4 days. Yield: 0.037 g (30%). $C_{72}H_{66}B_2Co_2N_{10}O_{10}$ (1370.8): calcd. C 63.08, H 4.85, N 10.22; found C 62.7, H 5.02, N 10.2. ^1H NMR (C_6D_6, 400 MHz, TMS): δ = 2.3 (s, 6 H, CH_3 ax.), 3.20 (s, 6 H, OCH_3), 3.32 (d, 2 H, NH_2), 3.80 (d, 2 H, NH_2), 6.21 (d, $^3J_{H,H}$ = 8.3 Hz, 1 H, *ortho*-C_6H_4-NH_2), 6.29 (t, 4 H, *meta*-Ph^I), 6.37 (d, $^3J_{H,H}$ = 7.8 Hz, 4 H, *ortho*-Ph^I), 6.67 (m, 2 H, *para*-Ph^I); 6.75 (t, 4 H, *meta*-Ph^{II}), 6.82 (m, 2 H, *para*-Ph^{II}), 7.10 (d, $^3J_{H,H}$ = 7.8 Hz, 4 H, *ortho*-Ph^{II}), 6.92 (m, 2 H, *para*-Ph^{IV}), 7.10 (t, 4 H, *meta*-Ph^{IV}), 7.91 (d, $^3J_{H,H}$ = 7.3 Hz, 4 H, *ortho*-Ph^{IV}), 6.95−7.05 (m, 6 H, *meta*- and *para*-Ph^{III}), 7.56 (d, $^3J_{H,H}$ = 7.3 Hz, 4 H, *ortho*-Ph^{III}), 7.25 (m, 2 H, *meta* -C_6H_4-NH_2), 7.43 (s, 2 H, *ortho*-C_6H_4-NH_2), 8.01 (d, $^3J_{H,H}$ = 7.3 Hz, 2 H, *para*-C_6H_4-NH_2), 19.50 (s, 2 H, O···H···O) ppm.

X-ray Crystallographic Study: Single crystals suitable for X-ray data collection,were obtained as reported above. X-ray diffraction data were collected at 150 K, with a Nonius DIP 1030 H System, using graphite-monochromated Mo-K_α radiation. For all compounds a total of 30 frames were collected, using the Xpress program,[12] over a half of reciprocal space with rotation of 6° about the φ axis. A Mac Science Image Plate (diameter = 300 mm) was used and the crystal-to-plate distance was fixed at 90 mm. The determination of unit-cell parameters, integration of reflection intensities and data scaling were performed using MOSFLM and SCALA from the CCP4 program suite.[13] Reflections, which were measured on previous and following frames, were used to scale the frames with each other, a procedure that partially eliminated absorption effects, taking into account also any crystal decay. The structures were solved by direct methods,[14] followed by Fourier syntheses and refined by full-matrix least-squares (on F^2) cycles.[15] Compound **1** crystallized with one water and two independent methanol molecules (all with occupancy factor 0.5), while **2** co-crystallized with three methanol molecules (one with o.f. 0.5). The solvent molecules were refined isotropically. The H-atoms were included at calculated positions in the final refinements. A suite of programs[5] was also used in the geometrical and final calculation. Crystal and refinement data of interest are given in Table 2.

CCDC-236499 (for **1**) and -236500 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

The C_α-Deprotonated Iminophosphorane $Ph_2P(CH_2Py)(NSiMe_3)$ as an *N,N*-Chelating Ligand for Iron and Zinc

Alexander Murso[a] and Dietmar Stalke*[a]

Keywords: Chelates / Hypervalent compounds / Iminophosphoranes / Iron / N ligands

The iminophosphorane $Ph_2P(CH_2Py)(NSiMe_3)$ (Py = NC_5H_4) is deprotonated at the C_α-position in a reaction with $[M\{N(SiMe_3)_2\}_2]$ (M = Fe^{2+}, Zn^{2+}) to give metallaspirocycles in which the metal cations are *N,N*-chelated by the ring- and imino-nitrogen atoms of both monoanionic ligands. The molecular structures of $[M\{Ph_2P(CHPy)(NSiMe_3)\}_2]$ [M = Fe (**1**), Zn (**2**)] are discussed and general trends in the bonding of the $[Ph_2P(CHPy)(NSiMe_3)]^-$ anion on metal coordination are deduced.

Introduction

Iminophosphoranes of the general type R_3PNR' are valuable building blocks in organometallic and organic syntheses.[1] Their reactivity is mainly due to the inherent polarity of the phosphorus−nitrogen bond, which makes them reactive towards both electrophilic and nucleophilic reagents.[2] In silylated iminophosphoranes, $R_3PNSiMe_3$, the Si−N bond is cleaved in reactions with main-group[3] or transition-metal halides,[4] resulting in the $[R_3PN]^-$ building block, which has similar steric and electronic characteristics to the ubiquitous cyclopentadienyl ligand.[5] In addition, the incorporation of heteroaromatic substituents at the phosphorus centre instead of commonly used alkyl or phenyl groups alters and augments the reactivity and coordination modes of iminophosphoranes. In reactions of pyridyl-substituted iminophosphoranes and amino(imino)phosphoranes with organolithium compounds and lithium amides reduction of the phosphorus(V) centre by P−C or P−N bond cleavage is observed to give phosphanylamides or phosphanides.[6] Likewise, transiminations are observed when treating iminophosphoranes with imines.[7]

Additionally, *P*-alkyl-substituted iminophosphoranes can easily be deprotonated to give attractive building blocks for metallacycles.[8] The introduction of alkyl bridges between the phosphorus atom and the donating heterocycle in the ligand periphery of iminophosphoranes provides not only the opportunity of a higher geometrical adaptability by a wider bite but can also allow the formation of anionic species. Delocalisation of the carbanionic charge to the donating atoms would enable the ligand to respond to the various requirements of metal atoms with their different radii and polarisability. Recently, Leung et al. reported some main-group metal complexes of $iPr_2P(CH_2Py)(NSiMe_3)$ and [2,6-$(Me_3SiNPiPr_2CH_2)_2(cy\text{-}C_5H_3N)$], obtained by deprotonation with organolithium compounds, alkylmagnesium compounds or group-14 amides. Metathesis with group-14 halides gave 1,3-dimetallacyclobutanes (Scheme 1).[9,10]

In the literature the imino nitrogen atom is commonly described as a two-electron σ-donor with only minor π-acceptor properties.[1] However, we recently reported the syntheses and coordination modes of the iminophosphorane $Ph_2P(CH_2Py)(NSiMe_3)$ (Py = NC_5H_4) and its anion in alkali metal complexes and provided experimental evidence that the P=N bond in iminophosphoranes has to be regarded as a P^+-N^- single bond with high electrostatic contributions,[11] as already predicted from theoretical investigations.[12,13] Thus, we found both lone pairs at the sp^3-hybridized imino nitrogen atom in $[(Et_2O)Li\{Ph_2P(CHPy)(NSiMe_3)\}]$ to be directed towards the cation. Hence, the metal−imino nitrogen interactions cannot be regarded as simple 2e-donor bonds (Figure 1).

This bifurcated 4e-coordination pattern and the sidearm donation capability of the pyridyl nitrogen atom in the $[Ph_2P(CHPy)(NSiMe_3)]^-$ anion prompted us to investigate reactions of the iminophosphorane $Ph_2P(CH_2Py)(NSiMe_3)$ with transition metal amides $[M\{N(SiMe_3)_2\}_2]$. In this contribution we report the complexes of divalent iron and zinc (M = Fe, Zn).

Results and Discussion

Syntheses

The reaction of the iron(II) amide $[Fe\{N(SiMe_3)_2\}_2]_2$[14] with the iminophosphorane $Ph_2P(CH_2Py)(NSiMe_3)$[11] in a 1:2 ratio in polar solvents such as THF or Et_2O results, even at −78 °C, in dark-red to black solutions containing

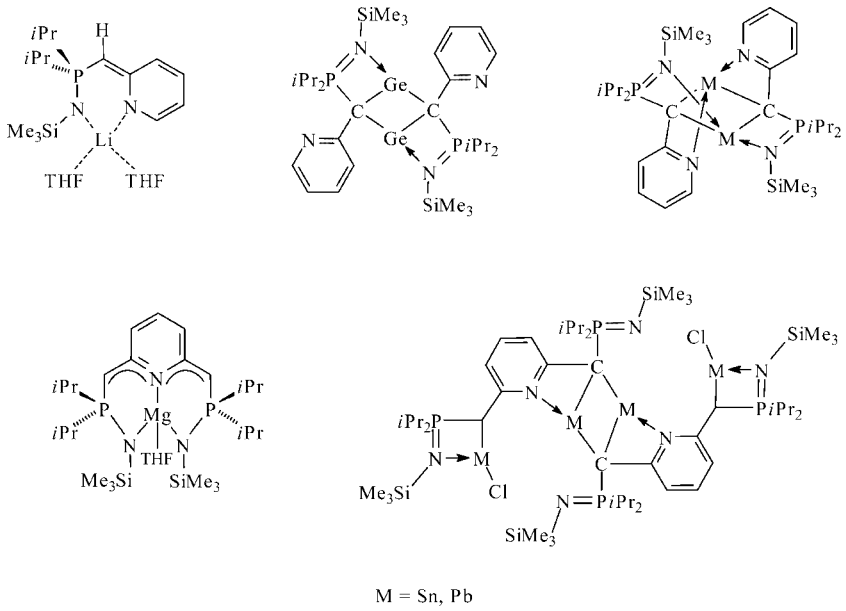

Scheme 1. Main-group metal complexes of $iPr_2P(CH_2Py)(NSiMe_3)$ (top) and $[2,6\text{-}(Me_3SiNPiPr_2CH_2)_2(cy\text{-}C_5H_3N)]$ (bottom)

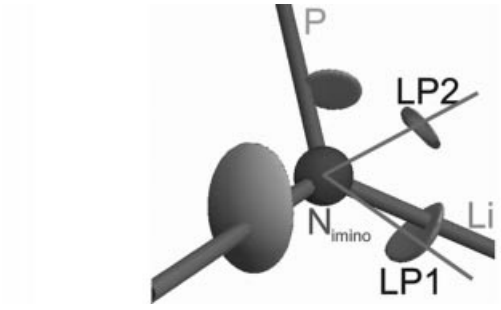

Figure 1. Bifurcated donation of the valence shell charge concentrations derived from experimental charge density studies of the imino nitrogen atom in $[(Et_2O)Li\{Ph_2P(CHPy)(NSiMe_3)\}]$

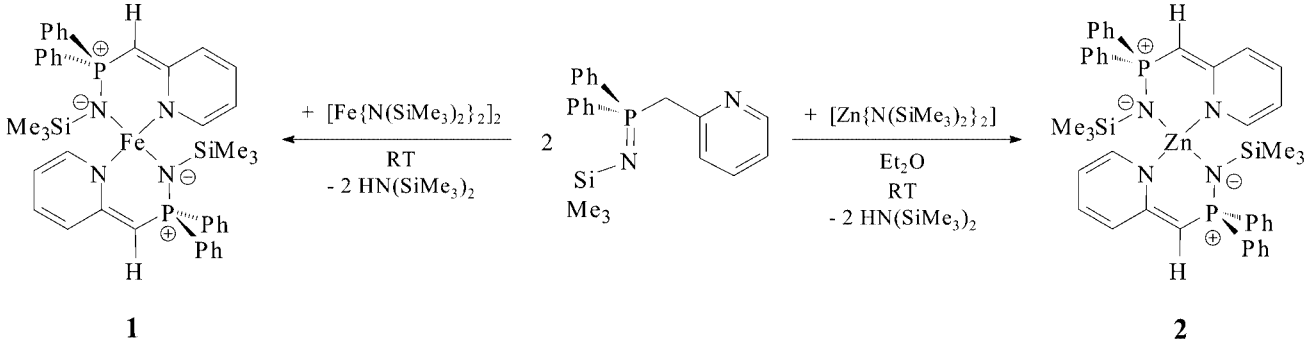
several products. In contrast, the addition of pure $[Fe\{N(SiMe_3)_2\}_2]_2$ to the solid iminophosphorane $Ph_2P(CH_2Py)(NSiMe_3)$ at room temperature gives immediately a red oily suspension of solid $[Fe\{Ph_2P(CHPy)(NSiMe_3)\}_2]$ (**1**) in liquid $HN(SiMe_3)_2$, formed by the C_α-deprotonation of the iminophosphorane (Scheme 2, left). A similar reaction of the iminophosphorane with $[Zn\{N(SiMe_3)_2\}_2]$[15] gives the isomorphous zinc derivative $[Zn\{Ph_2P(CHPy)(NSiMe_3)\}_2]$ (**2**; Scheme 2, right).

After workup, both complexes were isolated in high yields and their molecular structures determined by X-ray diffraction experiments. Both compounds **1** and **2** are insoluble in nonpolar solvents. The complexes were analysed by IR spectroscopy and elemental analysis. For the iron complex **1** no NMR spectroscopic data were available due to its paramagnetic nature. The NMR resonances for the zinc derivative **2** are given in the Exp. Sect.

Structure Discussion

The solid-state structure of **1** is depicted in Figure 2. The central iron(II) cation is chelated by the nitrogen atoms N1−N4 of the two ligands. The coordination sphere is best described as a distorted tetrahedron with the angles at the iron cation varying from 100.92(8) to 124.40(8)°. In the metallaspirocycle, the two six-membered FeN_2C_2P rings adopt a distorted boat conformation, each with the deprotonated carbon atoms C1 and C22 displaced by, on average, 45 pm



Scheme 2. Syntheses of $[Fe\{Ph_2P(CHPy)(NSiMe_3)\}_2]$ (**1**) and $[Zn\{Ph_2P(CHPy)(NSiMe_3)\}_2]$ (**2**) in the reaction of $Ph_2P(CH_2Py)(NSiMe_3)$ with the corresponding metal amide $[M\{N(SiMe_3)_2\}_2]_2$ (M = Fe, Zn)

from the respective best N−P−C−N plane (29 pm for the Fe^{2+} cation).

The Fe−N_{imino} distances (av. 204.4 pm) are equal within their estimated standard deviations (esds). They are in the range typically found for iron(II) complexes in which the cation is coordinated to imino functions, for example in [Fe{(*o*-C_6H_4)$Ph_2PNSiMe_3$}$_2$] (211.1 pm),[16] [Fe{2-(R*N*PPh_2)-6-R′(*c*-C_5H_3N)}Cl_2] (R = 2,6-Me_2-C_6H_3, 2,6-*i*Pr_2-C_6H_3; R′ = Ph, H_2CPh, $SiMe_3$; 204.8−206.7 pm)[17] or in the 12 VE iron(II) complex [Fe(H_2CPh)-{HC(CMeNAr)$_2$}] (198.2 pm).[18] The Fe−N_{imino} distances in **1** are about 24.4 pm shorter than in the dibromoiron(II) compound [{2,6-($Ph_2PNSiMe_3$)Py}$FeBr_2$], where the Fe−N contacts are on average 228.8 pm,[19] reflecting the pronounced amidic character of the Fe−N_{imino} bonds.

It seems remarkable that the Fe−N_{py} distances in **1** (av. 207.7 pm) are only 3.3 pm longer than the Fe−N_{imino} contacts. They are much shorter than in the donor base coordinated complexes [(H_2NCH_2Py)Fe][Br]$_2$ (Fe−N_{py}: av. 222.3 pm),[20] [(Hpy)$_2$(H_2O)$_4$Fe][$MeCO_2$]$_2$ (221.3 pm)[21] or [Fe{2-(R*N*PPh_2)-6-R′(*cy*-C_5H_3N)}Cl_2] (R = 2,6-Me_2-C_6H_3, 2,6-*i*Pr_2-C_6H_3; R′ = Ph, H_2CPh, $SiMe_3$; 218.4−222.9 pm),[17] but similar to those in [Fe{C(H)(Si*t*$BuMe_2$)Py}$_2$]$_2$ (209.7 and 218.9 pm),[22] where the pyridyl nitrogen atom acts as a side-arm donor, like in **1**.

The solid-state structure of the isomorphous zinc derivative [Zn{$Ph_2P(CHPy)(NSiMe_3)$}$_2$] (**2**) is shown in Figure 3.

The central zinc cation is fourfold coordinated by the nitrogen atoms N1−N4 of the two anionic ligands. The coordination polyhedron around the Zn^{2+} ion is a nearly ideal tetrahedron [the angles vary from 103.70(6) to 111.31(6)°]. Like in **1**, both monoanionic [$Ph_2P(CHPy)(NSiMe_3)$]$^-$ units act as bidentate *N*,*N*-chelates and the two six-membered rings of the metallaspirocycle each show a distorted boat conformation. The displacement of the deprotonated carbon atoms and the metal centre from the best plane of the ligand (av. 45 pm for C1/C22 and 21 pm for Fe) is similar to **1**.

In **2**, the distances between the zinc atom and the imino nitrogen atoms N1 and N3 (av. 201.43 pm) are equal within the esds. In general, Zn−N contacts span a wide range from 182 pm for covalently bonded zinc amides to 231 pm for donor-base complexed dimethylzinc;[23] in **2** they are similar to Zn−N_{imino} interactions in the related zinc bis(iminophosphorane)methanides [Zn{HC(Ph_2PNR}$_2$X] [R = Mes, $SiMe_3$; X = Me, N($SiMe_3$)$_2$, $OCPh_3$], where the contacts vary from 198.6 to 208.3 pm.[24] In the *ortho*-deprotonated [Zn(*o*-$C_6H_4PPh_2NSiMe_3$)$_2$] the Zn−N contacts are 14.4 pm longer (215.8 pm).[25] Thus, the Zn1−N1/3 contacts in **2** are in the range for covalently bonded zinc amides. The Zn−N_{py} distances are identical (Zn1−N3/4: av. 203.92 pm) and only 2.5 pm longer than the Zn−N_{imino} interactions. The average value quoted for Zn−N_{py} contacts is 208.3 pm.[26] To judge the covalent or dative character of the Zn−N_{py} bonds, complex **2** is best compared with the bis(1,4-dihydropyridin-1-yl)bis(pyridine)zinc system:[27] the Zn−N_{py} distances in **2** are 4.4 pm longer than the covalent bonds in bis(1,4-dihydropyridin-1-yl)bis(pyridine)zinc (197 pm), but 11.6 pm shorter than the dative ones (213 pm), clearly emphasising the amidic character of the Zn−N_{py} interactions in **2**.

The geometrical parameters of the anionic ligands of both complexes **1** and **2** are almost equal. Thus, in the following discussion the averages are given; the exact parameters are listed in the captions of Figures 1 and 2, respectively.

The P1−C1 and P2−C22 bonds in **1** and **2** (av. 172.5 pm) are about 12 pm shorter than formal P−C single bonds (185 pm);[28] they are in the range found for ylidic P^+−C^- interactions (163−173 pm).[12,29] In addition, the C1/22−C2/23 contacts (av. 139.6 pm) are 10 pm shorter than the corresponding bond length in the neutral starting material $Ph_2P(CH_2Py)(NSiMe_3)$ (182.57 pm).[11] As a consequence, the C2−N2 and C23−N4 bonds in the pyridyl substituents (average 137.6 pm) are 4.4 pm longer than in the starting material (133.17 pm).[11] The sum of the angles at the imino nitrogen atoms in both complexes is about 360°, illustrating a planar coordination sphere at these atoms. For the pyridyl nitrogen atoms N2 and N4, a marginal pyramidal environment is observed, with a mean sum of the angles of 355.5° in **1** and 356.3° in **2**. All these parameters are very similar to those found in the alkali metal derivatives

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[(Et_2O)Li\{Ph_2P(CHPy)(NSiMe_3)\}]$ and $[\{Ph_2P(CH_2Py)(NSiMe_3)\}M\{Ph_2P(CHPy)(NSiMe_3)\}]$ (M = Li, Na), containing the same anion,[11] and to the related $[(THF)Mg\{2,6\text{-}(Me_3SiNPiPr_2CH)_2(c\text{-}C_5H_3N)\}]$.[10] In the metallacyclobutanes $[\{2\text{-}[M\{C(iPr_2PNSiMe_3)\}]\text{-}6\text{-}[M\{HC(iPr_2PNSiMe_3)\}X]\}(c\text{-}C_5H_3N)]_2$ (M = Sn, X = Cl; M = Pb, X = $N(SiMe_3)_2$], which contain the mono- and dianionic derivative of $[2,6\text{-}(Me_3SiNPiPr_2CH_2)_2(c\text{-}C_5H_3N)]$, longer P−$C_\alpha$(H) (av. 178.6 pm) and C_α(H)−C_{Py} distances (av. 147.3 pm) are found than in **1** and **2** due to the observed [M]−C_α bonds in addition to the [M]−N contacts.[10] Whereas in the metallacyclobutanes the negative charge is accumulated at the deprotonated carbon centres, in **1** and **2** it is delocalised over the [HC−Py] backbone of the ligand, leading to a perturbation of the aromatic ring systems and charge accumulation at the pyridyl nitrogen atom. The increased electron density in the pyridyl substituents leads to a displacement of the metal cations from the ring plane towards the π-density of the pyridyl substituent, which explains the short M−N_{py} distances in **1** and **2**.

The P−N bonds in **1** and **2** are, on average, 161.2 pm long. They are at the upper end of the range found for P−N bonds in iminophosphoranes (147−162 pm)[30] and reflect the trend of P−N bond elongation on weakening the electrostatic P^+-N^- interaction because of the presence of the adjacent deprotonated C_α position and the additional *N*-metal coordination.[9,11,31] The Si−N distances in **1** and **2** are, on average, 173.6 pm long and are therefore about 5.5 pm longer than in the neutral iminophosphorane $Ph_2P(CH_2Py)(NSiMe_3)$ (168.08 pm).[11] Similar changes in Si−N bond lengths have been found in the alkali-metal derivatives of $Ph_2P(CH_2Py)(NSiMe_3)$[11] and in bis(iminophosphorane)methanides[32] with regard to the parent starting materials.[33] The long Si−N bonds found in **1** and **2** are a result of the strong interactions of the negatively charged imino nitrogen atoms with the doubly charged cations, reducing the electrostatic contributions in the Si−N interactions.

Spectroscopic Investigations

The IR spectra of **1** and **2** show signals at 1360 cm^{-1} for both complexes. These signals are in the range found for P−N stretching modes (1140−1370 cm^{-1}),[1,34] and are shifted 11 cm^{-1} to higher wavenumbers relative to the starting iminophosphorane (ν_{PN} = 1349 cm^{-1}). A similar shift to higher wavenumbers was detected unambiguously by DFT assignment earlier from the starting material $Ph_3PNSiMe_3$ (ν_{PN} = 1319 cm^{-1}) to the *ortho*-metallated $[(Et_2O)Li(o\text{-}C_6H_4PPh_2NSiMe_3)\}_2]$ (ν_{PN} = 1328 cm^{-1}).[35]

Due to the presence of a d^6 Fe^{II} centre in a tetrahedral coordination, no NMR spectroscopic data could be obtained for the paramagnetic iron complex **1**. In the ^{31}P NMR spectrum of **2**, the phosphorus nuclei resonate at δ = 26.4 ppm. Like for the alkali-metal derivatives of $Ph_2P(CH_2Py)(NSiMe_3)$,[11] deprotonation at the C_α atom results in a downfield shift from the resonance of the starting iminophosphorane (δ = −0.32 ppm). The negative charge and metal coordination at the *P*-bound nitrogen atom decrease the electron density at the phosphorus centre. The almost invariant ^{15}N NMR spectroscopic shift of the imino nitrogen atoms in **2** (δ = −348 ppm) and the iminophosphorane (δ = −343 ppm) indicate that the charge density at this nitrogen atom is less affected by the deprotonation. However, the ^{15}N NMR resonance for the pyridyl ring nitrogen atoms in the anionic ligands of **2** (δ = −182 ppm) differs remarkably from that of the parent iminophosphorane (δ = −61 ppm); it is considerably shifted to higher fields. This resonance is in the range observed earlier for the $[Ph_2P(CHPy)(NSiMe_3)]^-$ anion and is in accordance with charge accumulation at the pyridyl ring nitrogen atoms.[11]

Conclusion

Metal bis(trimethylsilyl)amides easily deprotonate the iminophosphorane $Ph_2P(CH_2Py)(NSiMe_3)$ at the methylene bridge to furnish *N*,*N*-chelating monoanionic ligands coordinating to the metal atom through the pyridyl and the imino nitrogen atoms. The negative charge is delocalised over the [HC−Py] backbone of the ligand, increasing the electron density in the pyridyl rings. Thus, the metal cations are shifted towards the π-density of the pyridyl rings. On metal coordination, the P−N and Si−N bonds in the ligands get simultaneously elongated, due to the decay of the electrostatic contributions in the P^+-N^- and Si^+-N^- bonds. Additionally, we found shorter M−N_{imino} contacts than expected for M←N donor bonds. These geometrical parameters show that the imino nitrogen atom cannot be regarded as a simple two-electron donor. The M−N_{imino} distances in complexes **1** and **2** reflect a high ionic contribution to the bonding. This leads to a description of the imino nitrogen atom between a monoanionic two- and four-electron donating centre.

Experimental Section

General Remarks: All manipulations were performed under dry N_2 with Schlenk techniques or in an argon-filled glovebox. All solvents were dried with Na/K alloy and distilled prior to use. IR spectroscopy was performed with a Bruker IFS 25 spectrometer. NMR spectra were recorded at room temperature with a Bruker DRX 300 spectrometer at 300.1 (^1H), 75.5 (^{13}C), 121.5 (^{31}P), 59.6 (^{29}Si) and 30.4 MHz (^1H,^{15}N HMBC). Chemical shifts are given as δ values relative to $[D_8]$toluene for ^1H, ^{13}C and to external formamide for ^1H,^{15}N HMBC NMR, H_3PO_4 (85%) for ^{31}P and to $SiMe_4$ for ^{29}Si NMR. Elemental analyses were performed by the Microanalytisches Labor der Universität Würzburg.

$[Fe\{Ph_2P(CHPy)NSiMe_3\}_2]$ (1): Pure, liquid $[Fe\{N(SiMe_3)_2\}_2]_2$ (0.26 g, 0.69 mmol) was added by syringe to solid $Ph_2P(CH_2Py)(NSiMe_3)$ (0.50 g, 1.37 mmol) in a drybox. The suspension turned red immediately. It was stirred at room temp. for 1 h, then 20 mL of hexane was added and the suspension was stirred for an additional 2 h. After evaporation of the solvent and formed $HN(SiMe_3)_2$ in vacuo, 0.99 g (1.27 mmol, 93%) of red solid **1** was isolated. To crystallise **1**, the red powder was dissolved in hexane/Et_2O (2:1). After 3 d, red blocks, suitable for an X-ray diffraction experiment, were obtained. IR: ν_{PN} = 1360 cm^{-1}. $C_{42}H_{48}FeN_4P_2Si_2$ (782.81): calcd.

C 64.44, H 6.18, N 7.16; found C 64.36, H 6.21, N 7.12. M.p. (DTA) 258 °C.

[Zn{$Ph_2P(CHPy)NSiMe_3$}$_2$] (2): [Zn{$N(SiMe_3)_2$}$_2$] (0.29 g, 0.75 mmol) was dissolved in 10 mL of Et_2O and added slowly to a solution of $Ph_2P(CH_2Py)(NSiMe_3)$ (0.50 g, 1.37 mmol) in 25 mL of Et_2O at room temp. After stirring of the yellow solution for 2 h, the volume of the solvent was reduced. Storage of the solution at 4 °C overnight yielded 0.54 g (0.68 mmol, 91%) of **2** as yellow plates. IR: ν_{PN} = 1360 cm^{-1}. ^1H NMR: δ = 0.17 (s, 18 H, $SiMe_3$), 3.32 (d, $^2J_{P,H}$ = 20.9 Hz, 2 H, 1-H), 5.53 (dd, $^3J_{5,6}$ = 5.6, $^3J_{5,4}$ = 6.6 Hz, 2 H, 5-H), 6.28 (d, $^3J_{3,4}$ = 8.8 Hz, 2 H, 3-H), 6.56 (dd, $^3J_{4,3}$ = 8.8, $^3J_{4,5}$ = 6.6 Hz, 2 H, 4-H), 7.12 (d, $^3J_{6,5}$ = 5.6 Hz, 2 H, 6-H), 7.01−7.06 (m, 12 H, *m*-, *p*-PhH), 7.73−7.91 (m, 8 H, *o*-PhH) ppm. ^{13}C NMR: δ = 4.7 (d, $^3J_{Si,C}$ = 3.8 Hz, $SiMe_3$), 59.2 (d, C-1), 106.5 (s, C-5), 120.2 (d, C-3), 134.8 (s, C-4), 146.9 (s, C-6), 166.6 (d, C-2), 128.5 (*m*-PhC), 131.0 (*p*-PhC), 133.1 and 133.4 (*o*-PhC), 138.2 (*i*-PhC) ppm. ^{29}Si NMR: δ = 1.32 (d, $^2J_{Si,P}$ = 1.8 Hz) ppm. $^1H,^{15}N$-HMBC NMR: δ = −348 ($NSiMe_3$), −182 (PyN) ppm. ^{31}P NMR: δ = 26.4 (s) ppm. $C_{42}H_{48}N_4P_2Si_2Zn$ (792.33): calcd. C 63.67, H 6.11, N 7.07; found C 63.72, H 6.14, N 6.96. M.p. (DTA) 176 °C (dec.).

X-ray Crystallographic Study: All data were collected at 100(2) K[36] using graphite-monochromated Mo-K_α radiation (λ = 71.073 pm) with a Bruker D8 goniometer platform, equipped with a Smart Apex CCD detector. Cell parameters were determined and refined using the SMART software.[37] A series of ω-scans was performed at several φ settings. Raw frame data were integrated using the SAINT program.[38] Empirical absorption correction was carried out with SADABS 2.05.[39] The structures were solved by direct methods and refined by full-matrix least squares on F^2 using SHELXL.[40] *R* values defined as $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{0.5}$, $w = [\sigma^2(F_o^2) + (g_1P)^2 + g_2P]^{-1}$, $P = 1/3[\max(F_o^2,0) + 2F_c^2]$. The positions of the hydrogen atoms H1 at C1 and H22 at C22 in **1** and **2** were taken from the difference Fourier map and refined freely. All other hydrogen atoms were refined using a riding model. The U_{iso} values for the hydrogen atoms of a CH_3 group were set to be 1.5 times and those of all other hydrogen atoms 1.2 times the U_{eq} values of the corresponding C atoms. All non-hydrogen atoms were refined anisotropically. The anisotropic displacement parameters (ADP) in the supplementary crystallographic data were drawn at the 50% probability level. **1:** $C_{42}H_{48}FeN_4P_2Si_2$, M_r = 782.81 g/mol, triclinic, space group $P\bar{1}$, a = 1028.83(6), b = 1081.12(6), c = 1836.20(11) pm, α = 85.8120(10), β = 81.1290(10), γ = 79.9010(10)°, V = 1.9845(2) nm^{-3}, Z = 2, $\rho_{calcd.}$ = 1.310 $Mg{\cdot}m^{-3}$, μ = 0.556 mm^{-1}, $F(000)$ = 824. Data were collected from θ = 2.03 to 25.35°. 30624 reflections measured, from which 7251 were unique, $R(int)$ = 0.0295, $wR2$(all data) = 0.1181, $R1[I > 2\sigma(I)]$ = 0.0414, for 7243 data and 474 parameters. **2:** $C_{42}H_{48}N_4P_2Si_2Zn$, M_r = 792.33 g/mol, triclinic, space group $P\bar{1}$, a = 1026.46(5), b = 1077.28(5), c = 1830.69(9) pm, α = 85.8180(10), β = 80.9470(10), γ = 79.7270(10)°, V = 1.96499(16) nm^{-3}, Z = 2, $\rho_{calcd.}$ = 1.339 $Mg{\cdot}m^{-3}$, μ = 0.803mm^{-1}, $F(000)$ = 832. Data were collected from θ = 2.04 to 26.44°. 42026 reflections measured, from which 8072 were unique, $R(int)$ = 0.0310, $wR2$(all data) = 0.0920, $R1[I > 2\sigma(I)]$ = 0.0347, for 8067 data and 474 parameters. CCDC-232887 (**1**) and -232888 (**2**) contain the supplementary crystallographic data for this paper. Structural Studies of Mono- and Dimetallic Mo^{VI} Complexes − A New Mechanistic Contribution in Catalytic Olefin Epoxidation Provided by Oxazoline Ligands

José A. Brito,[a] Montserrat Gómez,*[a] Guillermo Muller,[a] Helena Teruel,*[b] Jean-Claude Clinet,[c] Elisabet Duñach,[c] and Miguel A. Maestro[d]

Keywords: Molybdenum / Chiral oxazolines / Selective epoxidation / Oxo peroxo complexes / Catalysis

New seven-coordinate oxo(peroxo)molybdenum(VI) complexes with bidentate chiral oxazolines, anionic κ^2-*N*,*O* (**V**) and neutral κ^2-*N*,*N* (**VI**), have been prepared and fully characterised by NMR spectroscopy and single-crystal X-ray diffraction studies. Dimetallic dioxo(μ-oxo)molybdenum(VI) compounds containing oxazolinylpyridine ligands **II**–**IV** have also been synthesised. NMR studies showed the presence of several isomers (up to six species) due to the Mo–O–Mo bridge angle and the unsymmetrical nature of the N,N ligand. The roles of mono- (**I**, **V** and **VI**) and dimetallic (**II**) oxomolybdenum(VI) complexes in the catalytic epoxidation of cyclooctene, norbornene and (*R*)-limonene have been studied. The high activity of the oxomono(peroxo) precursor **V** containing the hemilabile oxazolinylphenolate, in contrast to the unexpected low activity for the oxobis(peroxo) species **VI**, could be justified by the inertness observed for the oxazolinylpyridine ligand. In addition, the dimetallic system **II** afforded high selectivity towards limonene epoxide formation (*trans*/*cis*-**10** ratio up to 9:1).

Introduction

High-valent oxometal species have demonstrated the ability to catalyse the oxidation of a variety of organic substrates by homogeneous as well as heterogeneous routes.[1,2] In particular, the Mo-catalysed alkene-to-epoxide conversion has received most attention due to its industrial interest. However, the oxygen transfer mechanism is still a controversial subject and three main hypotheses have dominated the discussion. Mimoun suggested that the olefin coordinates to the metal atom before subsequent insertion into the η^2-Mo−O_2 bond to form a five-membered alkyl peroxide metallacycle.[3,4] Coordination of the olefin to the metal centre makes the olefin electrophilic and thus ready for further reaction with a peroxo group acting as a nucleophile. On the other hand, Sharpless proposed a concerted reaction mechanism involving a direct attack by the olefin on the peroxo oxygen atom (with a three-membered ring intermediate).[5] In this case, the coordinated peroxo group is thought to have a sufficiently increased electrophilic character by decreasing the negative charge on the peroxo oxygen atoms. A "hybrid" mechanism was proposed by Jørgensen and Hoffman in which intramolecular slipping of the olefin after coordination to the metal atom, which depends on their relative orientation, was believed to form a three-membered metallacycle intermediate.[6,7]

In terms of the spectator part of the catalyst molecule, S-, N- and O-donor ligands have been mainly used because of their stability towards oxidation processes. However, under catalytic conditions, they frequently suffer partial decoordination.[8,9] This fact discourages their use as selective catalysts in certain organic processes.

Oxazolines have been used as stabilising agents for many transition metals based on their robustness under a variety of reaction conditions when coordinated.[10] Consequently, they have been frequently employed in asymmetric catalytic organic transformations.[11,12]

We have been carrying out research with dioxomolybdenum(VI) compounds (type-**I** complexes, Figure 1) and we herein describe the first examples of oxo(peroxo) and dioxodimetallic molybdenum complexes containing chiral bidentate oxazoline ligands (Figure 1). Both types of systems have been explored as catalytic precursors in olefin epoxid-

ation processes. Related structural studies, especially in solution, afforded new insight into the nature of the catalytic species involved.

Results and Discussion

Dimetallic Dioxomolybdenum Complexes II−IV

Dimetallic bis(oxazolinylpyridine)dioxo(μ-oxo)dimolybdenum(VI) complexes **II**−**IV** with oxazolinylpyridines of the general formula (μ-O)[MoO_2(NCS)(κ²-*N*,*N*-**L**)]₂ (**L** = **2**−**4**) were prepared according to the methodology previously described (Scheme 1, a).[13] A dichloromethane solution of the ligand **2**−**4** was added to an acidic aqueous solution of $Na_2MoO_4{\cdot}2H_2O$ and KSCN under phase-transfer conditions, affording the corresponding complexes in good yields (ca. 70%). Using the same conditions, the analogous complexes containing bis(oxazoline) ligands could not be isolated due to the oxazoline moiety decomposing to give amide derivatives. Modifications of the experimental conditions (higher pH values, different solution concentrations) were also unsuccessful.[14]

The IR spectra of **II**−**IV** show the characteristic functional group absorptions: a very strong band for NCS at ca. 2050 cm^{-1}, 1658 cm^{-1} for the oxazoline imine bond, two strong bands at 906 and 941 cm^{-1} for Mo=O as well as 772 cm^{-1} for the μ-oxo moiety (Mo−O−Mo). In the positive FAB-MS spectra, despite the absence of the parent ion, fragments such as $[Mo_2O_5(NCS)\mathbf{L}_2]^+$, $[Mo_2O_4(NCS)\mathbf{L}]^+$ and $[Mo_2O(NCS)\mathbf{L}]^+$ indicate the dimetallic nature of the complexes.

Efforts to grow single crystals were unsuccessful, probably due to the existence of some isomers (see below).

Studies in solution showed the presence of several species and the 2D NOESY spectra revealed exchange signals among them all. In the case of **II**, the signals were well enough separated to allow us to suggest the presence of at least six species (relative ratios 8.0:5.6:3.3:2.5:1.6:1) in $CDCl_3$. The most abundant isomer (ca. 40%) shows two equivalent oxazolinylpyridine fragments. The other isomers, however, show signals indicating that the two bidentate ligands are not chemically equivalent. In the case of symmetrical ligands, as in the 4,4′-disubstituted bipyridine compound (μ-O)[MoO_2(NCS)(4,4′-*tert*-butyl-2,2′-bpy)]₂, two isomers were formed depending on the Mo−O−Mo bridge angle (180° and ca. 156°, respectively, relative ratios 44:56).[13] The formation of more than two species would be expected for nonsymmetrical oxazolinylpyridines **2**−**4** and the major isomer exhibiting the symmetrical structure must correspond to the conformer with an Mo−O−Mo angle of 180°. In Figure 2, the arrangements of the three nonequivalent isomers are depicted with an Mo−O−Mo bridge angle of 180° and where the isocyanate ligand is opposite to the bridging oxygen atom. In addition, the corresponding isomers with an Mo−O−Mo angle less than 180°, could also be expected.

Monometallic Oxo(peroxo)molybdenum Complexes V, VI

New seven-coordinate monometallic oxo(peroxo)molybdenum(VI) complexes **V**, **VI** containing chiral oxazoline ligands were prepared by previously reported methods.[15] For the anion of **1**, an oxo(peroxo) compound with two bidentate N,O ligands, $[MoO(O_2)(\kappa^2\text{-}N,O\text{-}\mathbf{L})_2]$ (**V**), was isolated while for the oxazolinylpyridine **2**, the oxobis(peroxo)

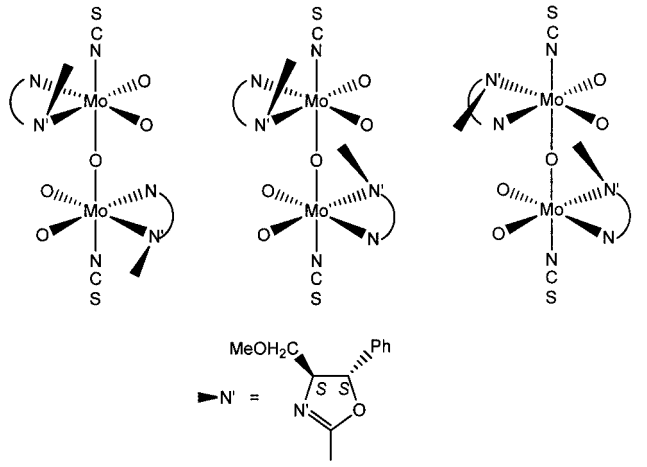

Figure 2. Isomers of dimetallic complex **II** containing the pure chiral oxazolinylpyridine ligand **2**, with an Mo−O−Mo angle of ca. 180°

complex $[MoO(O_2)_2(\kappa^2\text{-}N,N\text{-}\mathbf{2})]$ (**VI**) was produced (Scheme 1, b).

MoO_3 was dissolved in H_2O_2 (30%) to prepare an aqueous solution of $[Mo(O)(O_2)_2(H_2O)_2]$ (pH = 4). A methanol solution of the oxazoline **1**−**2** was then added and after addition of diethyl ether, **V** and **VI** were isolated as yellow solids, both stable in the solid state and in solution. No corresponding amide derivatives of the oxazolines were observed under these conditions. Attempts to isolate the oxo(peroxo) species **V** by perhydrolysis of **I** were unsuccessful.

In the solid state, the IR spectra of **V** and **VI** show two characteristic strong absorption bands at 962 (Mo=O) and 865−863 (O−O) cm^{-1}, as well as a very strong band at 1636−1630 (C=N) cm^{-1} corresponding to the oxazoline imine bond.

Single crystals of **V** and **VI** were obtained from dichloromethane/diethyl ether solutions (Figure 3). In Table 1, selected bond lengths and angles are collected. In **V**, the molybdenum atom is heptacoordinated by an oxo, a peroxo and two bidentate anionic phenolate oxazoline ligands. The geometry around the metal atom can be described as pseudo-pentagonal bipyramidal with the axial sites occupied by the oxo group O(1) and one of the phenolate oxygen atoms O(4). Thermal disorder is present around the Mo−oxo unit with high anisotropic parameters. The disorder was modelled with the two positions O(1A) and O(1B) having partial occupancies of 0.46(3) and 0.54(3), respectively. The peroxo bond O(2)−O(3) (1.3 Å) is shorter than usual (ca. 1.4−1.5 Å). This fact can be attributed to the relatively high thermal parameter for O(2) (anisotropic displacement parameter 0.148) compared with those of the phenolate and oxazolinyl oxygen atoms (0.05−0.07). Consequently, the distance is inaccurate. The remaining coordinating atoms are located in the equatorial plane in an almost coplanar arrangement, as indicated by the dihedral angles: N(1)−O(6)−N(2)−O(3) 4.60°, O(6)−N(2)−O(3)−O(2) 0.93°, N(2)−O(3)−O(2)−N(1) 5.43°, O(3)−O(2)−N(1)−O(6) 8.16° and O(2)−N(1)−O(6)−N(2) 6.11°. The other bond lengths and angles are similar to those in the only related published complex $[MoO(O_2)(8\text{-quinolate})_2]$.[16] In our case, the two nitrogen atoms are located almost opposite to each other [N(1)−Mo(1)−N(2) = 158.96°], while in the example reported in ref.[16], the two nitrogen atoms are vicinal (N−Mo−N = 81.91°).

In structure **VI**, the molybdenum atom is also heptacoordinated by an oxo group, two peroxo moieties and one bidentate oxazolinylpyridine **2** and the geometry around the metal atom can also be described as pseudo-pentagonal bipyramidal, with the axial sites occupied by the oxo group O(1) and the nitrogen atom from the pyridine moiety of the oxazoline ligand N(1). The remaining coordinating atoms are located in the equatorial plane in a nearly coplanar distribution, as indicated by the dihedral angles O(3)−O(2)−O(4)−O(5) 0.991°, N(2)−O(5)−O(4)−O(2) 1.596°, O(2)−O(3)−N(2)−O(5) 3.143° and O(3)−N(2)−O(5)−O(4) 2.460°. These angles are similar to other heptacoordinate oxobis(peroxo)molybdenum complexes containing bipyridine[17,18] and pyrazolylpyridine[19−21] derivatives. In the X-ray diffraction studies of the N,N-unsymmetrical ligands, the pyridine fragment is in an equatorial position while in **VI** it is axial. Intramolecular non-bonding O···H distances are longer than 3 Å.

The ^1H NMR spectrum of a freshly prepared solution of **V** in $CDCl_3$ revealed that the two anionic N,O-bidentate moieties are nonequivalent. A second set of signals appeared after approximately 12 h resulting in a relative ratio between the two molybdenum species of ca. 10:1. In deuterated acetone, the formation of the second species is favoured (relative ratio 4:1) and no changes were observed even after several days. This solvent dependence turned out to be similar to that observed for the analogous dioxomolybdenum complex **I** where partial decoordination of the oxazoline ligand takes place in coordinating solvents.[9]

For the major compound, important differences in the chemical shifts were observed. Compared with the free oxazoline [δ(H) = 4.10 ppm] the stereo-centre proton signal shifted remarkably downfield [δ(H) = 5.06 and 5.73 ppm]. This deshielding can be attributed to interaction with the oxo and peroxo groups, as shown by the average interatomic distances H(8A)···O=Mo and H(19A)···O_2−Mo from the crystallographic data, ca. 2.85 and 2.25 Å, respectively.

NMR studies of **VI** in solution clearly indicated only one compound in coordinating solvents. The chemical shifts of the oxazoline protons moved downfield (Δδ = 0.2−0.7 ppm) relative to those of the free oxazoline **2**. The coordination of the oxazolinylpyridine ligand is limited to the pyridine nitrogen atom located in an axial position opposite to the strong *trans*-directing oxo group in agreement with the X-ray study, although the thermodynamically favoured isomer should bear the poorer σ-donor moiety *trans* to the oxo group. In addition, the stereochemical behaviour is similar to that observed for oxobis(peroxo)molybdenum complexes with *N*,*N*-pyrazolylpyridines,[22] but oxazolinylpyridine dissociation was not observed.

Olefin Epoxidation Catalysed by Oxomolybdenum Complexes

The dioxo mono- and dimetallic complexes **I** and **II**, respectively, were tested as catalytic precursors for the epoxidation of cyclooctene (**5**), norbornene (**6**) and (*R*)-limonene (**7**), using *t*BuOOH in water as the oxidant at room temperature (Scheme 2). When reactions were performed using *t*BuOOH in decane, lower conversions were obtained. Catalytic reactions were carried out with and without solvent (toluene). Table 2 lists the catalytic results. In the case of **I**, activities were higher in the presence of solvent (Entries 1, 3, 5 and 6) but for **II** these differences were not significant (Entries 2, 4, 7 and 8). For both systems, cyclooctene oxide **8** and *exo*-norbornene oxide **9** were the only products obtained and the monometallic system **I** was more active (up to 57% conversion, Entry 3) than dimetallic **II** (Entries 1 and 3 versus 2 and 4). In the case of limonene oxidation, a mixture of products was detected, *trans*/*cis*-limonene oxide (**10**), the corresponding double epoxide (**11**) and alcohols (Scheme 2). Activity (substrate conversion) and chemoselectivity (ratio **10**/**11**) are almost the same for both catalytic systems (Entries 5−8). Ring epoxide opening to afford alcohols was lower for **I** than for **II** (alcohols/epoxide = 0−0.1 for **I** and 0.2−0.5 for **II**) (Entries 5 and 6 versus 7 and 8). An outstanding diastereoisomeric induction was observed for **10** when **II** was used (*trans*/*cis*-**10** up to 9:1 for 77% of olefin conversion, Entry 8) but no discrimination occurred with **I** (Entries 5 and 6).

The absence of exocyclic oxide formation suggests that the double epoxide **11** is probably produced by epoxidation of **10**. When *trans*/*cis*-**10** (ratio ca. 1:1) was used as the substrate and **II** as the catalyst, under the same experimental conditions, a 45% conversion to **11** and alcohols (**11**/alcohols ≈ 4:1) was obtained (Scheme 3). The remaining **10**, enriched in one of the diastereoisomers (relative ratio *trans*/*cis*-**10** > 98:2), indicates that *cis*-**10** reacts faster than *trans*-**10**. However, when monometallic complex **I** was used as a catalytic precursor, no kinetic resolution occurred.

Oxo(peroxo)molybdenum species are known key intermediates in epoxidation processes. The mono- and bis-

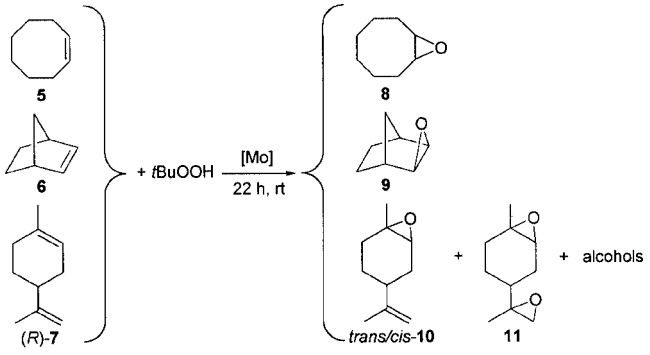
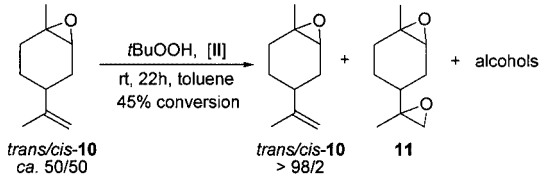
[a] Catalytic conditions: 0.025 mmol of Mo (complexes **I**, **II**, **V** and **VI**), 1 mmol olefin (**5**−**7**) and 1.5 mmol of *t*BuOOH (8 M in water) in 1 mL of toluene at room temp. for 22 h; 0.2−0.4 mmol of undecane (as external standard) was used to quantify the catalytic reaction. [b] Conversion percentage based on the substrate determined by GC; in parentheses is the conversion obtained without solvent; in italics the conversions obtained using *t*BuOOH in decane (5.5 M). [c] In parentheses, the ratio of *trans*/*cis* of endocyclic epoxide **10**. [d] Determined by GC. [e] Reaction carried out without solvent.



Scheme 2. Cyclooctene (**5**), norbornene (**6**) and (*R*)-limonene (**7**) epoxidation catalysed by **I**, **II**, **V** and **VI** using *t*BuOOH as an oxidant; olefin/*t*BuOOH/Mo = 40:60:1



Scheme 3. *trans*/*cis*-Limonene oxide (**10**) epoxidation catalysed by **II** using *t*BuOOH as an oxidant; olefin/*t*BuOOH/Mo = 40:60:1

(peroxo) complexes **V** and **VI** were tested for oxidation of **5** and (*R*)-**7**. It was found that **V** was the most active of all systems studied (Entries 9 and 11) achieving 95% cyclooctene conversion (Entry 9). The higher activities observed for oxo(peroxo) species **V** than for the dioxo compound **I** suggest that the former is the catalytically active species and **I** is its precursor. On the contrary, **VI** gave the lowest conversions (Entries 10 and 12). Similar to the dioxo monometallic complex **I**, diastereoisomeric induction of (*R*)-limonene did not take place for either **V** or **VI**.

Mechanistic Aspects of Olefin Epoxidation

The structural studies carried out provided evidence of a certain relationship between the lability of the molybdenum centre and catalytic olefin epoxidation. Despite heptacoordinated oxobis(peroxo)molybdenum complexes having been reported to be fairly good epoxidation catalysts, the unexpected low activity [in the oxidation of cyclooctene and (*R*)-limonene] observed for **VI** can be attributed to the nonlability of the oxazolinylpyridine ligand, as observed by NMR spectroscopy (see above). However, in the case of **V**, the high activity obtained is in accordance with partial decoordination of the *N*,*O*-oxazolinylphenolate ligand, already observed for its precursor **I**[9] and for oxobis(peroxo) Thiel-type complexes.[19−22] The ability to generate a coordination vacancy at the molybdenum atom can then be responsible for the differences in the catalytic behaviour of **V** and **VI**. Furthermore, the remarkably higher activity obtained with **II** compared with **VI**, with both systems containing the nonlabile bidentate ligand **2**, is due to the facile formation of a vacant site in **II** by isothiocyanate dissociation. Thus, metallic species with unsaturated coordination environments will favour either the olefin or the oxidant to approach the metal. With regards to the equimolar *trans*/*cis*-**10** mixture obtained in the epoxidation of (*R*)-limonene using monometallic catalysts, the species directly coordinated to the molybdenum centre is probably *t*BuOOH instead of the olefin.

Information derived from NMR experiments and catalytic reactivity patterns allows us to propose the mechanism shown in Scheme 4. The oxo(peroxo)molybdenum species **V** can easily form a vacant site due to the hemilabile nature of the oxazolinylphenolate ligand (**A**). Further coordination of *t*BuOOH (**B**) leads to the formation of a transition state (**TS**), in which the olefin approaches towards the *tert*-butyl peroxide fragment, producing the epoxide and concomitant elimination of *tert*-butyl alcohol, the active catalytic species **V** being regenerated.

On the other hand, the unexpected selectivity observed with the dimetallic catalytic system **II** in both oxidations, (*R*)-limonene (**7**) (Entries 7 and 8, Table 2) and limonene epoxide **10** (Scheme 3), can only just be explained by the

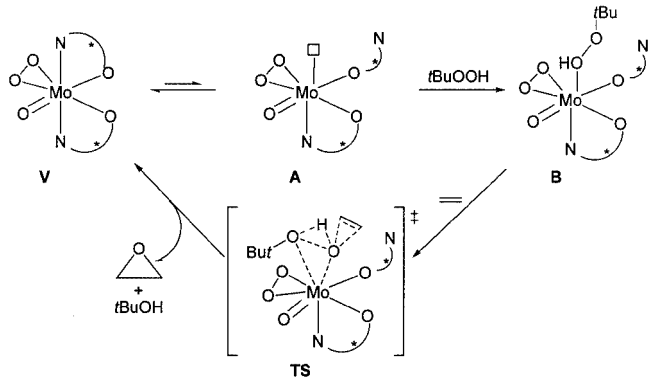

Scheme 4. Mechanistic proposal for olefin epoxidation catalysed by seven-coordinate molybdenum species containing hemilabile ligands

mechanism described. Nevertheless, as stated above, the nonlability of the oxazolinylpyridine ligand and the presence of a vacant site can favour the direct olefin coordination to the metal atom. Stereoselectivity control in the organic process is then possible.

Further reactivity studies with dimetallic molybdenum species involved in catalytic olefin epoxidations are in progress.

Experimental Section

General Remarks: Solvents were purified by standard procedures and distilled under nitrogen. $Na_2MoO_4{\cdot}2H_2O$ (Probus), MoO_3 (Strem), aqueous *t*BuOOH (8 M; Fluka), *t*BuOOH in decane solution (5.5 M; Fluka), cyclooctene (Fluka), norbornene (Aldrich) and (*R*)-limonene (Aldrich) were used as purchased. Ligands **1**,[23] **2**−**4**[24,25] and complex **I**[9] were prepared as described previously. NMR spectra (in $CDCl_3$) were recorded with Bruker Avance600, Varian XL-500, Varian Gemini or Bruker DRX 250 spectrometers. Chemical shifts are reported downfield from standards. IR spectra were recorded with a Nicolet 520 FT-IR or a Bruker IFS 55 FTIR spectrometer. FAB mass spectra were obtained with a Micromass VG-Quattro instrument. The GC-MS analyses were performed with a Hewlett−Packard 5890 Series II gas chromatograph (50 m Ultra 2 capillary column) interfaced with a Hewlett−Packard 5971 mass-selective detector. Elemental analyses were carried out by the Serveis Cientifico-Tècnics de la Universitat de Barcelona with an Eager 1108 microanalyser.

μ-Oxobis{[(3′*S*,4′*S*)-2-(3′,4′-dihydro-4′-methoxymethyl-2′-oxazolyl-3′-phenyl)pyridine-*N*,*N*](isothiocyanato)dioxomolybdenum(VI)} (II): HCl (1 M 1.7 mmol, 1.7 mL) was slowly added, with stirring, to a mixture of aqueous solutions (10 mL) of $Na_2MoO_4{\cdot}2H_2O$ (100 mg, 0.413 mmol) and KNCS (160 mg, 1.652 mmol). After 15 min, the oxazolinylpyridine **2** (110.8 mg, 0.413 mmol) in CH_2Cl_2 (20 mL) was added to the yellow solution and vigorously stirred for 45 min. The organic layer was extracted, washed with water (3 × 10 mL) and dried with Na_2SO_4. The solvent was removed under reduced pressure. The solid obtained was washed with diethyl ether (3 × 20 mL) and dried under vacuum. Yield: 0.161 g (77%). $C_{34}H_{32}Mo_2N_6O_9S_2$ (924.68): calcd. C 43.68, H 3.46, N 9.09, S 6.93; found C 43.62, H 3.29, N 8.90, S 6.84. MS (FAB positive): *m*/*z* = 867 [M − NCS]. IR (KBr): $\tilde{\nu}$ = 2045 (st, C=N_{NCS}), 1658 (st, C=N), 941 and 906 (Mo=O) cm^{-1}. ^1H NMR (600 MHz): δ_{major} = 8.87 (d, *J* = 4.8 Hz, 1 H), 8.18 (pt, *J* = 7.8 Hz, 1 H), 8.06 (d, *J* = 7.6 Hz, 1 H), 7.4−7.2 (m, 5 H), 6.02 (d, *J* = 7.0 Hz, 1 H), 4.45 (m, 1 H), 3.87 (m, 1 H), 3.78 (dd, *J* = 10.0, 3.4 Hz,1 H), 3.40 (s, 3 H) ppm.

μ-Oxobis{[(3′*S*,4′*S*)-2-(4′-acetoxymethyl-3′,4′-dihydro-2′-oxazolyl-3′-phenyl)pyridine-*N*,*N*](isothiocyanato)dioxomolybdenum(VI)} (III): An analogous procedure to that described for the preparation of **II** was used, replacing **2** with **3**.Yield: 0.443 g (75%). $C_{38}H_{36}Mo_2N_6O_{11}S_2$ (1008.37): calcd. C 44.02, H 3.48, N 8.11, S 6.18; found C 44.50, H 3.65, N 7.80, S 5.94. MS (FAB positive): *m*/*z* = 1010 [M], 922 [M − NCS − 2 O]. IR (KBr): $\tilde{\nu}$ = 2056 (st, C=N_{NCS}), 1658 (st, C=N) and, 940 and 910 (Mo=O) cm^{-1}.

μ-Oxobis{[(3′*S*,4′*S*)-2-(3′,4′-dihydro-2′-oxazolyl-3′-phenyl-4′-tritylmethyl)pyridine-*N*,*N*](isothiocyanato)dioxomolybdenum(VI)} (IV): An analogous procedure to that described for the preparation of **II** was used, replacing **2** with **4**. Yield: 0.302 g (68%). $C_{70}H_{56}Mo_2N_6O_9S_2$ (1381.26): calcd. C 60.87, H 4.06, N 6.09, S 4.64; found C 59.75, H 3.98, N 5.99, S 5.03. MS (FAB positive): *m*/*z* = 780 [M − NCS − 3 O − **4**]. IR (KBr): $\tilde{\nu}$ = 2043 (st, C=N_{NCS}), 1658 (st, C=N) and, 942 and 911 (Mo=O) cm^{-1}.

Bis[(4′*R*)-2-(4′-ethyl-3′,4′-dihydro-2′-oxazolyl)phenolato-*N*,*O*]oxo(peroxo)molybdenum(VI) (V): MoO_3 (0.285 g, 1.980 mmol) was added in portions to an aqueous H_2O_2 solution (30%, 5 mL) at room temperature. The mixture was stirred for 20 min and warmed to 40 °C for 40 min. The reaction mixture was filtered, the yellow solution was cooled to 10 °C and a solution of **1** (0.384 g, 2.00 mmol) in CH_3OH was added. The mixture was stirred at 20 °C for 30 min and then at 0 °C for 16 h. It was concentrated under reduced pressure to approximately 5 mL and diethyl ether was added (20 mL). The yellow precipitate obtained was filtered and recrystallized from CH_2Cl_2/diethyl ether (3:1). Yield: 0.405 g (39%). M.p. 197 °C. $C_{22}H_{24}MoN_2O_7$ (524.38): calcd. C 50.39, H 4.61, N 5.34; found C 50.34, H4.85, N 5.17. MS (FAB positive): *m*/*z* = 525. Molybdenum-Catalysed Olefin Epoxidation: The precursor (0.025 mmol of complex: 12.7 mg for **I**, 11.6 mg for **II**, 13.1 mg for **V** and 11.1 mg for **VI**) was dissolved in toluene (1 mL). The olefin (1 mmol, 110 mg for **5**, 94 mg for **6** and 139 mg for **7**) was added, followed by a *tert*-butyl hydroperoxide aqueous solution (8 M, 0.19 mL, 1.50 mmol). The mixture was stirred at room temperature for 22 h and then quenched by addition of ethyl acetate and filtered through silica. Undecane was added as an external standard (0.2−0.4 mmol). Analyses of organic products were performed by gas chromatography. Catalytic reactions were also performed without solvent according to the above mentioned experimental procedure.

X-ray Crystallographic Studies: Single crystals were grown by allowing diethyl ether to diffuse into a dichloromethane solution. The crystal data for **V** and **VI** were collected using a Bruker SMART CCD based diffractometer operating at room temperature. Intensities were collected with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) generated at 50 kV and 30 mA, using the ω/2θ scan technique. A total of 1271 frames of intensity data were collected over a hemisphere of the reciprocal space by combination of three exposure sets. Each frame covered 0.3° in ω and the first 50 frames were recollected at the end of data collection to monitor crystal decay. The crystals used for the diffraction studies showed no decomposition during data collection. The crystallographic data for **V** and **VI** are summarised in Table 3. Absorption corrections were applied using the SADABS programme.[26] The structures were solved using the Bruker SHELXTL-PC software by direct methods and refined by full-matrix least-squares methods on F^2.[27] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions and refined using the riding mode. CCDC-236207 (**V**) and -236208 (**VI**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Formation of VN from VCl_4 and $NH(SiMe_3)_2$ by APCVD − a Potential Solar Control Coating

Anne Newport,[a] Claire J. Carmalt,[a] Ivan P. Parkin,*[a] and Shane A. O'Neill[a]

Keywords: Chemical vapour deposition / Nitrides / Solar control coatings

Vanadium nitride thin films have been synthesised by the reaction of vanadium(IV) chloride with hexamethyldisilazane (HMDS) under atmospheric pressure (AP)CVD conditions at 300–550 °C. The films deposited have good optical characteristics and low electrical resistivities. These films were not scratched off the glass substrate by a steel stylus and were not degraded by immersion in a range of solvents. X-ray diffraction showed an NaCl-type cubic cell with a = 4.102(1)–4.127(1) Å, dependent on the sample. X-ray photoelectron spectroscopy shows that the films have a V/N ratio close to unity. For comparison, films were also deposited by the APCVD reaction of $VOCl_3$ with HMDS. These films consist of mixed phases of vanadium oxynitride and V_2O_3. The VN films show properties suitable for use as solar control coatings.

Introduction

Vanadium nitride is a hard refractory material with metallic properties.[1] In its purest form it has a gold colour. Like the other transition metal nitrides it has many uses especially when deposited as a thin film.[2,3] Vanadium nitride has good metallic conductivity and stability to heat that makes it suitable as a barrier coating for microelectronic devices.[4] It is resistant to chemical attack by most solvents and reagents apart from hydrofluoric acid and aqua regia. The mechanical hardness of VN films has found application in wear-resistant parts.

Vanadium nitride films have been deposited under atmospheric pressure chemical vapour deposition (APCVD) conditions by reaction of vanadium chloride with nitrogen/hydrogen or ammonia[5] and reactions of vanadium amides {$[V(NR_2)_4]$; R = Me, Et}.[6] The former method evolved hydrogen chloride gas that is undesirable in the synthesis of films for microelectronic devices due to its corrosive nature.[5] The latter method yielded polycrystalline films with pinhole defects as result of rapid gas phase nucleation. This method also produced organic by-products.[7,8] Other methods of producing VN thin films include: N_2/H_2 plasma processing,[9] ion beam assisted deposition,[10] magnetron sputtering,[11] molecular organic CVD,[12] and pulsed laser deposition.[13]

Single-source CVD methods to prepare VN have also been reported using $[V(NR)Cl_3]$ (R = Me, C_6H_4Me, *t*Bu).[14] Unfortunately, the use of single-source precursors have so far yielded films with significant carbon contamination.[14] The presence of carbon can affect the optical properties of the film, whereas low amounts of oxygen seemingly do not.[15] It should be noted that in the case of VN, films have been classified as vanadium nitride with over 40 atom% carbon and oxygen contents. The decomposition of $[V(N\textit{t}Bu)Cl_3]$ gave films at temperatures as low as 250 °C that were shown to be vanadium carbonitride upon analysis.[14] Related precursors, $[V(NMe)Cl_3]$ and $[V(NC_6H_4Me)Cl_3]$, gave films with higher nitrogen content but only at temperatures above of 900 °C.[14]

We report here the dual-source CVD of vanadium nitride from vanadium(IV) chloride and hexamethyldisilazane (HMDS) under atmospheric pressure which yielded high-quality gold-coloured films of vanadium nitride. The reason for exploring HMDS as a nitrogen source was to try and avoid the problems in the conventional reaction of VCl_4 and NH_3 − which invariably lead to non-uniform films due to rapid gas-phase nucleation. Hexamethyldisilazane offers an alternative pathway by elimination of Me_3SiCl. The steric crowding in HMDS would also afford reduced rates of gas-phase combination and potentially better quality films. The VN films grown in this study show interesting properties that have potential to be used in glazing products for solar control applications.

Results

Vanadium(IV) Chloride with Hexamethyldisilazane (HMDS)

Synthesis

Reactions of vanadium(IV) chloride with hexamethyldisilazane (HMDS) under APCVD conditions at 300−550 °C yielded coatings of vanadium nitride on SiO_2-coated stand-

300	0.02	0.05	1.0	amorphous	4000

ard float glass. The reaction could be expressed, in the idealised form, as shown in Equation (1). This idealised equation does not take into account the thermal stability of Me_3SiCl which would almost certainly decompose to other materials under the CVD conditions.

$$VCl_4 + 2\,(Me_3Si)_2NH \rightarrow VN + 4\,Me_3SiCl + 1/6\,N_2 + 2/3\,NH_3 \quad (1)$$

Flow rates of the precursor and plain nitrogen lines were varied. At total gas flow rates of 1.5 L min^{-1} or greater the films covered the whole substrate. However, at high carrier gas flow rates totalling over 3 L min^{-1} the deposition became non-uniform due to turbulence. For optimisation and coverage of all of the substrate in this particular APCVD setup, flow rates of 1 L min^{-1} for the plain nitrogen line and 0.3 L min^{-1} for the HMDS and 0.1 L min^{-1} for the VCl_4 line were used. This corresponds with molar flows of ca. 0.02 mol min^{-1} of VCl_4 and 0.05 mol min^{-1} of HMDS.

Characterisation

The films were analysed using glancing angle XRD, sheet resistance, SEM, EDAX, XPS, contact angle, Raman and UV/Vis reflectance and transmission measurements, selected data is given in Table 1. Film quality has been primarily correlated to deposition temperature and gas concentrations.

Films of uniform thickness were deposited over the entire substrate for a range of temperatures from 300 to 550 °C. The onset of deposition was noted at 300 °C as no film could be grown at 250 °C. The films were gold-coloured and free of pin-hole defects. The films could not be removed by rubbing with a tissue, soft cloth or scratched with a brass stylus or steel scalpel, indicating that they were extremely hard and typical of metal nitride films.[16] The vanadium nitride films were also unchanged by immersion in water, propan-2-ol, acetone, petroleum spirit and dilute (2 M) mineral acids for 48 h.

The glancing angle XRD analysis showed the presence of crystalline VN as the only detectable phase present in the films prepared at 450−550 °C.[17] The peaks were broad with the (2 0 0) peak being the most intense one, indicating a degree of preferred orientation. These films have a lattice constant from 4.09(2) to 4.13(2) Å (Table 1). This can be compared to the literature values where $VN_{1.00}$ films have a lattice constant recorded as a = 4.14(1) Å.[18] Bulk $VN_{0.92}O_{0.11}$ has an NaCl (*Fm3m*) structure and a lattice constant of a = 4.12 Å.[19] Previous work on the APCVD reaction of VCl_4 and NH_3 produced thin films of composition from $VN_{0.80}O_{0.18}$ to $VN_{0.68}O_{0.42}$ with lattice parameters of 4.078−4.072 Å. Notably in all of these studies the higher lattice constants were associated with the better nitrided products.

EDAX analysis confirmed the presence of vanadium and nitrogen in the films, although accurate quantitative data were not available due to the N peak being partially obscured by the vanadium. The EDAX measurements also showed breakthrough to the underlying substrate, thus making an accurate determination of any oxygen contaminant difficult. SEM analysis showed fine sub-micron spheroid particles of a uniform size distribution in the region of 250 nm (Figure 1). Growth rates as calculated from side-on SEM work were 175 nm min^{-1} at 450 °C and 250 nm min^{-1} at 550 °C.

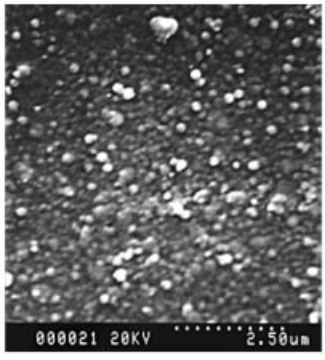

Figure 1. SEM of the films produced from the reaction of VCl_4 with HMDS at 550 °C

XPS analysis showed a small overlayer of oxide on all the VN samples, this was removed on Ar^+ etching. After the first few etchings the oxygen content was significantly reduced and the composition of the films prepared at 450, 500 and 550 °C had a V/N ratio of close to unity ($VN_{0.95(1)}$). This analysis also shows a surface N 1s binding energy shift at 396.9 eV and V 2p at 513.2 eV. These match previous measurements on VN.[20] the oxygen found in these films is a result of post CVD surface oxidation. This is because the oxygen content decreases with XPS sputtering depth and virtually disappears. This surface oxidation seems to be self-limiting as the VN films show no change in composition or in optical properties after storage in air for two years.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The VN films are highly reflective and the spectra show a strong reflection in the NIR beyond 600 nm. This is more pronounced for films laid down at the higher deposition temperatures. These VN coatings prepared at 500 and 550 °C show good heat-mirror properties and suggest that these films have potential application as solar control coatings where visible light is transmitted but IR radiation is reflected. At deposition temperatures below 450 °C the films show little reflectance in the NIR. Films deposited at this temperature and below had a matte appearance and were not as shiny. The morphology of the films was identical to that grown at higher temperatures − it would seem that it is the lack of crystallinity that accounts for the observed changes in the reflection properties of the films. The transmission spectra of the films prepared at 450−550 °C showed few features transmitting light across the majority of the visible spectrum, (Figure 2). Notably no pin-hole defects were detected by optical microscopy or SEM in these films.

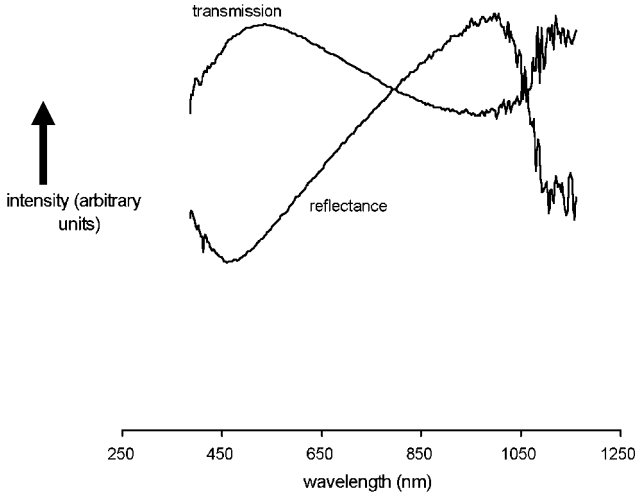

Figure 2. Transmission and reflectance spectra of films produced from the reaction of VCl_4 with HMDS at 550 °C

Raman analysis showed broad bands between 50 and 300 cm^{-1} that correspond to the region in which a powdered vanadium nitride standard gave a broad signal. Apart from this the Raman spectra were featureless. This indicates the absence of vanadium oxide phases (V_2O_5, VO_x, VO_2 and V_2O_3) and graphitic carbon in the films; as these are particularly strong Raman scatterers and would be expected to dominate the spectra even at low concentrations.

The electrical resistivity of the VN films was inversely proportional to the temperature of deposition. Post-treating the VN films with HMDS does not change the electrical resistivity of the film produced. The electrical resistivities of the films can be correlated with the powder XRD analysis − that is the resistance decreases with an increase in crystallite size (from amorphous at a deposition temperature of 300 °C to ca. 400 Å at 550 °C). The electrical resistivities measured of 380−4000 μΩ cm were similar to sputtered VN films (Table 1).[5]

The contact angles for water droplets of these films were calculated to be between 80 and 95° which indicates that the films were hydrophobic. The contact angle value for the silica-coated plain float glass was 75°.

Vanadium Oxychloride with Hexamethyldisilazane

Synthesis and Characterisation

Films produced from the reaction of vanadium(V) oxychloride with HMDS under APCVD conditions were dark-grey in colour. An idealised form of the reactions is given in Equation (2).

$$VOCl_3 + 2\,(Me_3Si)_2NH \rightarrow VN + 2\,Me_3SiCl + (Me_3Si)_2O + 1/2\,N_2 + HCl \quad (2)$$

Although some shiny areas were produced, the bulk of the films had a matte (lustreless) appearance. Substrate temperatures of 250−575 °C were employed in the deposition of these films in an attempt to improve uniformity of the surface and reduce the matte appearance. Despite this, most of the films were inhomogeneous and no correlations could be drawn as to what conditions favoured formation of the matte over shiny areas.

Powder XRD analysis of the films formed from $VOCl_3$ and HMDS showed slightly different data to the VCl_4 films. A cubic VN or oxynitride phase was identified and the measured lattice parameters *a* were from 4.07(9) to 4.08(0) Å. A second phase was also noted of V_2O_3.[21,22] This result is somewhat surprising as the analogous reaction of $VOCl_3$ and NH_3 yielded just a single-phase vanadium oxynitride material and not a biphasic mixture.

The XPS analysis gave a compositional ratio of $V_{3.0}N_{1.0}O_{4.0}$ for the film prepared from the reaction of $VOCl_3$ and HMDS at 600 °C which is consistent with the film consisting of two species V_2NO and V_2O_3. This correlates with the literature where treatment of V_2O_5 with ammonia at temperatures above 600 °C yielded a mixture of V_2NO and V_2O_3.[25] The V_2NO was reported to be black and have a cubic (*Fm3m*) structure which agrees with the XRD results.[23] Binding energy shifts for V 2p were at 513.5 eV, N 1s at 396.8 eV and O 1s at 530.7 eV which are in agreement with previous results.[17] The V 2p and O 1s peaks were much broader than that obtained for the XPS analysis of the films formed from VCl_4 and HMDS and was consistent with two environments (oxide and oxynitride).

The Raman spectra of the films formed from $VOCl_3$ and HMDS show a broad band at the lower wavenumbers similar to the samples produced from VCl_4 and HMDS. An additional broad band in the spectra was observed and assigned to the presence of a vanadium oxide phase reinforcing the XPS and XRD results (Figure 3). The additional Raman peaks associated with V_2O_3 were more defined in the matte area of the coatings.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

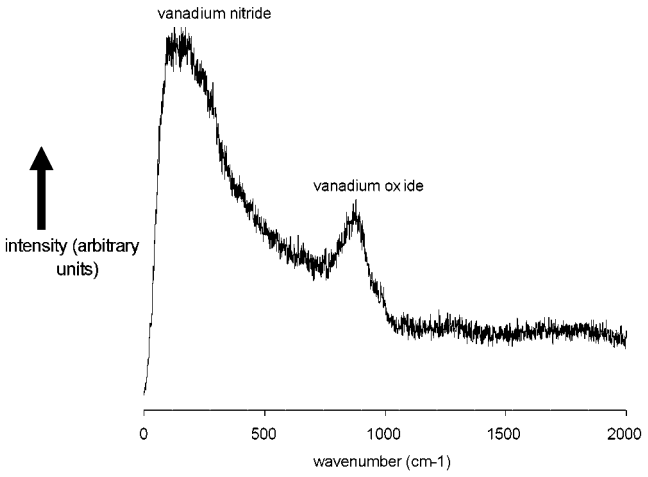

Figure 3. Raman spectrum of film produced from the reaction of $VOCl_3$ with HMDS

Reflectance spectra showed that certain of these samples reflect in the NIR although this extended across the visible as well. This was most apparent for the reflective areas of the films. The transmission spectra were noisy and, although they transmitted light across the visible, they also had transmission in the IR region showing that these films are not of sufficient quality for heat-mirror applications.

The majority of these films were conducting although their resistivity was an order of magnitude higher than the films formed from the reaction of VCl_4 with HMDS. There was difficulty in finding a correlation between deposition conditions and resistivity values of the film and few conclusions could be reached regarding the production of better quality deposition. The resistivity readings changed dependent on the area under analysis on the same film. Resistivity was noted to be greater on the matte regions of the film.

Contact angle measurements of these films for water droplets were contrasting depending on the area of film analysed. The shiny areas were measured in the region of 80° which is similar to that of the films from the reaction of VCl_4 with HMDS. However, values as low as 28° were recorded on the areas that were blackened, suggesting the presence of a vanadium oxide phase which has a lower contact angle. Measurements in these areas was not as simple as the shiny areas and open to error due to the presence of solid deposits on the surface of the films. Indeed, the irregular porous surface structure could be responsible for the lowered contact angle.

Discussion

Reaction of vanadium(IV) chloride with hexamethyldisilazane under APCVD conditions produced vanadium nitride films with good optical characteristics − free of pin-hole defects, reflecting in the NIR and transmitting in the visible. This demonstrates that these films have potential to be used as heat-mirror coatings on window glass. To be effective in this application the coating needs to have good transmission in the visible region whilst providing high reflectance in the IR.[24] This means that the heat mirror would enable a householder to see out of the window but not be subject to heat-gain from the IR part of the solar spectrum. Few materials have this combination of properties.

Less ideal reflectance and transmission spectra from the VN samples deposited at lower temperatures can be explained by lower crystallinity. This is confirmed by the resistivity measurements and the glancing angle XRD data, where samples deposited at temperatures above 450 °C gave an XRD pattern typical of a crystalline material and had considerably lower resistivity values. The SEM analysis shows that these films are composed of fine particles.

In comparison with films produced from the standard dual-source reaction of VCl_4 with ammonia, the films deposited from the APCVD reaction of VCl_4 with HMDS have superior qualities. In the former case, fast pre-reaction led to blockages of the pipework and gas-phase nucleation caused pin-hole defects in the films. Films formed from the dual-source reaction of VCl_4 with HMDS gave uniform coverage of the substrate and were free from pin-hole defects. These films were also gold-coloured whereas the VCl_4/NH_3 reaction under comparable conditions produced less reflective brown-yellow films. The reaction between VCl_4 and HMDS is probably less rapid than VCl_4 and NH_3 due to the size of the $SiMe_3$ groups. The absence of Si and C in these films suggests that the elimination of Me_3SiCl is facile, providing the driving force of the APCVD reaction [Equation (1)]. Notably a large excess of HMDS is not required to form VN films, just a slight excess over the gas-phase concentration of the vanadium tetrachloride (1:2.5). In nitride preparation from a metal halide and ammonia typically a hundredfold excess of ammonia would be used. The VN films formed in this work were superior in optical properties to those prepared from the analogous reaction with ammonia.

The films produced from the reaction of vanadium oxychloride and HMDS gave unexpected results. These were dark grey and, although the majority were conducting, the resistivity values were significantly higher than those of the samples produced from VCl_4. The reflectance and transmission spectra from these samples showed poorer heat-mirror properties and, although certain patches of these films were hard and adhered to the substrate, larger areas appeared to consist of powdery deposits and were more easily removed from the substrate. The Raman data shows that these films are contaminated with carbon and vanadium(III) oxide. This result was confirmed by XRD and by the compositional analysis by XPS. This suggests that significant amounts of oxygen remains bound with the vanadium from the vanadium oxychloride precursor during the reaction with HMDS. Interestingly, these results contrast with the reactions with $VOCl_3$ and NH_3 which formed a single-phase oxynitride product rather than a mixed-phase material.[15] This is probably a consequence of involv-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing the $SiMe_3$ as a leaving group in the reaction. However, further speculation is not warranted at this stage as to the detailed reaction mechanism.

Conclusion

Vanadium(IV) chloride reacts with hexamethyldisilazane under APCVD conditions to form uniform gold-coloured films that have optical properties suitable for heat-mirror applications. These films have a composition of $VN_{1.0}$. This has proved to be a novel and efficient method of producing VN films utilising existing technology. This method produces more uniform films free of pin-hole defects compared to the current method of treating VCl_4 with ammonia. It should also be noted that multi-precursor CVD normally requires a large excess of one of the reactants and by using hexamethyldisilazane as the nitrogen source this is overcome as a more complete reaction is occurring. Although a silicon-containing precursor is utilised in these depositions, no evidence of silicon is found in the resulting films.

The APCVD reaction of $VOCl_3$ with HMDS gave non-uniform grey-black films with a higher electrical resistivity than the gold-coloured VCl_4/HMDS films. These films consist of an oxynitride (V_2NO) and V_2O_3.

Experimental Section

Vanadium(IV) chloride, vanadium(V) oxychloride and 1,1,1,3,3,3-hexamethyldisilazane (HMDS) were purchased from Aldrich Chemical Company and used without further purification. The HMDS was loaded in one bubbler and the vanadium precursor was loaded into a second bubbler. Standard float glass with a silica diffusion barrier coating was used for the following deposition studies. The glass was cleaned thoroughly prior to use with water followed by propan-2-ol then dried at room temperature in a vertical position. Nitrogen (99.9% BOC) was used as the carrier gas after being passed through an oxygen removal column (CuH). The pipe assembly, bubbler and experimental setup are fully described elsewhere.[20,25] For this series of deposition experiments three independently controlled gas streams − the vanadium source, HMDS and nitrogen − are passed into a mixing chamber prior to entering the reaction chamber. The reactor is a cold-wall design similar to those reported by us previously.[18] The substrate is heated on a graphite-block containing a single Whatman cartridge-heater. The glass is coated in a horizontal position and has dimensions of 15 cm × 4 cm × 0.3 cm. The temperature of the glass substrate was recorded using an independent thermocouple and compared to the setting of the controlling thermocouple. It was found that there was a temperature variation across the surface of the glass substrate of ca. 40 °C. All temperatures recorded for the depositions in this report are those of the hottest central part of the glass substrate. Substrate temperatures ranged from 250 to 575 °C. All coatings were carried out at atmospheric pressure for 2 min. A range of flow rates for all three gas lines was used. Glancing angle X-ray diffraction analysis of the films was obtained using a Siemens D5000 diffractometer in the reflection mode (1.5° incidence) using Cu-K_α (1.5406 Å) radiation. SEM/EDAX was determined with a JEOL CR-37. XPS was performed with a VG ESCALAB 220i XL using focused (300 μm spot) monchromatic Al-K_α radiation at a pass energy of 20 eV. Scans were acquired with steps of 100 meV. A flood gun was used to control charging and the binding energies were referenced to an advantageous C 1s peak at 284.6 eV. Depth profiles were obtained by using an argon sputtering-gun. Reflectance and transmission spectra were recorded between 300 and 2600 nm with a U4000 spectrophotometer and between 300 and 1150 nm with a Zeiss miniture grating spectrometer. Raman spectra were obtained with a Renishaw 1000 spectrometer using an Ne excitation laser line. Contact angle measurements were determined by measuring the spread of a 1 μL^3 droplet of water. A powder sample of vanadium nitride (99%) was purchased from Aldrich Chemical Co. and used for comparison purposes for Raman spectroscopy.

Reactivity of a Thiolate-Bridged Dinuclear Ruthenium Complex with Nitrogenous Molecules: Spectroscopic Identification of a Labile Dinitrogen Complex[‡]

Dieter Sellmann,[a][†] Raju Prakash,*[a,b] and Frank W. Heinemann[a]

Dedicated to Prof. Dr. Joachim Sieler on the occasion of his 65th birthday

Keywords: N ligands / Nitrogenases / Nitrogen fixation / Ruthenium / S ligands

Reactions of the thiolate-bridged diruthenium complex $[Ru(py^{bu}S_4)]_2$ (**1**) {$py^{bu}S_4^{2-}$ = 2,6-bis[(3,5-di-*tert*-butyl-2-sulfanylphenyl)thiomethyl]pyridine(2–)} with small-molecule ligands L afforded the corresponding mononuclear complexes $[Ru(L)(py^{bu}S_4)]$ [L = H^- (**2**); CH_3CN (**3**); NH_3 (**4**); CO (**5**); N_2H_4 (**6**); PMe_3 (**7**); N_3^- (**8**)]. The molecular structures of **3**, **4**, and **5** exhibit pseudooctahedral geometry with two thiolate and two thioether donor atoms in a *trans* configuration. Complexes **2**–**8** exhibit a quasi-reversible, one-electron redox wave of the Ru^{II}/Ru^{III} couple in the region between $E_{1/2}$ = +0.214 and +0.460 V vs. NHE. Complex **1** reacts reversibly with N_2 (60 bar) at 40 °C to give the labile dinitrogen complex $[Ru(N_2)(py^{bu}S_4)]$ (**9**). Complex **9** can also be obtained from the reaction between **3** and N_2 (20 bar) at room temperature. Treatment of **4** with NO afforded the labile 19-valence-electron species $[Ru(NO)(py^{bu}S_4)]$ (**10**) in solution, which could subsequently be converted to **9** upon high-pressure reaction with N_2 (20 bar). In contrast, the analogous reaction of **4** with $NOBF_4$ results in the formation of the oxidized complex $[Ru(NH_3)(py^{bu}S_4)]BF_4$ (**11**), the structure of which was confirmed by X-ray structure analysis. The carbonyl complex $[Ru(CO)(py^{bu}S_4)]$ (**5**) could be reversibly protonated at the thiolate sulfur atom to give $[Ru(CO)(py^{bu}S_4H)]BF_4$ (**12**). UV irradiation of **5** and **12** under N_2 at –80 °C produced the short-lived species **9** and **13**, respectively, which were identified spectroscopically.

Introduction

Nitrogenases comprise sulfur-dominated polynuclear FeMo, FeV or FeFe cofactors as their active sites, which catalyze the transformation of dinitrogen to ammonia under mild conditions.[1] Coordination of N_2 to a sulfur-rich transition metal complex is thought to be an effective strategy towards nitrogen fixation.[2] Despite numerous intensive efforts,[3] metal−sulfur complexes that bind molecular nitrogen are very scarce.[4] However, it is believed that systematic in-depth studies on sulfur-rich transition metal complexes with biologically relevant molecules such as CO, NO, N_2H_2, N_2H_4, N_3^- etc. will shed light on this intriguing N_2 activation and its exploitation to produce ammonia under mild conditions. As part of our contribution in this field, we recently obtained the mononuclear and dinuclear dinitrogen complexes $[Ru(N_2)(PR_3)(N_2Me_2S_2)]$ and $[\mu\text{-}N_2\{Ru(PR_3)(N_2Me_2S_2)\}_2]$ [R = *i*Pr, Cy; $N_2Me_2S_2^{2-}$ = *N*,*N*′-dimethyl-1,2-ethanediamine-*N*,*N*′-bis(benzenethiolate)-(2−)] by direct reaction of $[Ru(CH_3CN)(PR_3)(N_2Me_2S_2)]$ with molecular nitrogen under very mild conditions.[5] However, attempts to reduce the coordinated N_2 in these complexes were unsuccessful due to decoordination of the N_2 ligand. Meanwhile, we developed the fragment $[M(pyS_4)]$ {M = Fe, Ru or Os; pyS_4^{2-} = 2,6-bis[(2-sulfanylphenyl)thiomethyl]pyridine(2−)}, which readily binds a number of small nitrogenase-relevant ligands. The resultant six-coordinate mononuclear complexes are redox-active and are formed diastereoselectively by maintaining the thiolate and thioether donors always *trans* to each other.[6] However, none of these metal fragments is capable of binding molecular nitrogen, even at elevated N_2 pressure (200 bar) and high temperature (100 °C).
