Growth and Change

The past year for EurJIC has been characterized by growth and change. Both are vital for life and therefore welcomed. There is no doubt that EurJIC consequently faces many challenges − another sign of vibrant life.

The first change took effect at the beginning of 2003 when the structure of the journal changed to be anal ogous with that of other journals of the European family. Simultaneously the first indication of burgeoning submissions became evident (see Figure 1). Following the trend, early in October 2003 EurJIC had already received the same number of submissions as in 2002. The excellent support from the Editorial Board members enabled the journal to cope with this exceptional development. We thank the Board members most sincerely for their invaluable suggestions and advice that has contributed significantly to the growth in quality and not just "quantity" of EurJIC.

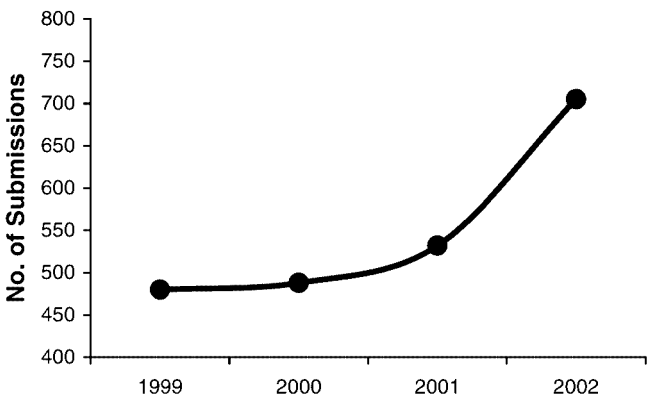

Figure 1. Number of submissions to EurJIC per year from 1999 to 2002

Invaluable support from Editorial Board

Readers will have noticed that the journal arrived twice a month, but the individual issueshardly diminished in size. We expanded the editorial office to accommodate this growth, but also introduced the publishing of articles in EarlyView to speed up the access to new publications. These EarlyView articles are fully citable by DOI, although they have not yet been assigned to an issue.

Publication times are falling as a result: even before EarlyView by DOI, the average time from submission to publication on the Web had dropped to less than five and a half months for full papers and three and a half months for the urgent Short Communications. Thus, speed of publication remains a priority, but speed is not everything. EurJIC will continue to allow peer reviewers sufficient time to comment soundly on a manuscript. Some of our referees invest a lot of time in communicating their impression of a paper in writing to the author. But the peer-review process does not stop there: many authors appreciate this new look at their work and undertake time-consuming experiments to test the ideas before submitting their revised version. All researchers profit from this process through more detailed papers, although the publication is delayed by this assiduity. Here we expressly thank each reviewer and author who exercises this dedication for the betterment of science.

The (publication) times, they are a-changin'

Peer review is a laborious process. In recognition of the load of some scientists, we attempt to keep the number of manuscripts for each reviewer down to well below one a month. With expanding submissions this is a difficult task and calls for innovative methods. We wish to thank all Editorial Board members, Advisory Board members, but also experts in fields not covered by the Boards, for their willing participation in experimentation for preselection of manuscripts. Your contribution is enormous. You keep the quality of the journal high, the work of fellow reviewers lower, and help prevent the fragmentation of our science literature into a collection of least publishable units.

Peer reviewers acknowledged

The drawbacks of modern technology also impinge on publishing. For speed, e-mail communication is preferred, but in general, partially as a result of Spam mails and stringent firewalls, about 5% of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mail is blocked without returning a warning to the sender. A confirmation of receipt is a two-edged sword: the reviewer receives even more mail. The alternative is not knowing whether the report has arrived in the Editorial Office. Our solution to this dilemma is to send our thanks in the topic line ending with EOM (end of message). Such a mail can be clicked away without opening.

E-mail attachments are often suspect. ManuscriptXpress, the new online submission of manuscripts in conjunction with the author/referee homepage system, precludes the necessity of sending manuscripts as WORD, RTF, or PDF attachments. Directly from their computers authors can upload a document, which the system then uses to generate a PDF file. This PDF file can be easily accessed by the referees through their personal homepages, who can then submit their reports online. Authors can also conveniently gain access to their own manuscripts at any stage of publication by the same means. "No more tedious copying!" said one of our authors who preferentially submits through ManuscriptXpress. For more information, please refer to our Guidelines for Authors on page A1. There are advantages for all. Referees can refer to their reports, which are archived together with the original PDF versions of the manuscript. This system, together with the reorganization of the editorial office, has helped to reduce our publication times, in spite of an increase of 30% in the pages published.

The combined editorial office of EurJIC and EurJOC are always ready to help if anything is unclear. Early in 2003 the system was still new to authors and referees. The secretarial staff and assistants at the challenging interface between editorial office and customer did all in their power to assist, from talking an author through submission to submitting the manuscript by proxy − at a time when their learning curve with ManuscriptXpress was steep and the workload was extreme. In spite of the pressure they kept cheerful. They have deservedly earned my admiration and thanks (editor, KJH). Try them − you'll receive friendly assistance.

Unusual mention of exceptional performance

The advantages of modern technology enable scientists to keep up with the literature almost automatically! Everyone, not only subscribers, can regularly receive the Table of Contents of an issue by e-mail when it is published ("**Content Alerts**"), as well as information tailored to specific research interests about titles and authors of current articles ("**Profiled Alerts**"). More information about this service can be found at http://www.interscience.wiley.com/alerts. If you have no access to the journal but need one of the articles for your research, the Pay-per-View system will provide it in a minimum of time.

Research the literature while you sleep!

Some of these advances have been initiated by a request from an author, reviewer, or reader. EurJIC takes your suggestions seriously and encourages you to keep up the contact.

We are proud of our journal, which is developing well, as witnessed by the constant increase in the Impact Factor. EurJIC is now a well-established journal for both organometallic and material chemists, although a lot remains to be done to attract more contributions from other important areas within the inorganic chemistry community, such as bioinorganic chemistry as well as technological applications of inorganic compounds. It will be our duty to attract more submissions from these important fields and to make EurJIC a really outstanding journal for the whole community of inorganic chemists.

On behalf of the Editorial Board and the Editorial Office, the Chairman of the Board and the Editor wish you all a happy and successful 2004.

Ivano Bertini — Chairman of the Editorial Board

Structure and Reactivity of Coordinatively Unsaturated Half-Sandwich Iron, Ruthenium and Osmium Complexes

Manuel Jiménez-Tenorio,[a] M. Carmen Puerta,[a] and Pedro Valerga*[a]

Keywords: Transition metals / Phosphane ligands / Electron-deficient compounds / Cyclopentadienyl ligands / Agostic interactions / Sandwich complexes

This review deals with the study of coordinatively unsaturated half-sandwich iron, ruthenium and osmium complexes, in particular those bearing bulky phosphane ligands. The synthesis, properties and structure of neutral complexes of the type $[(C_5R_5)MX(L)]$ and their cationic derivatives $[(C_5R_5)M(L)_2]^+$, are described here. We will also refer to related compounds containing hydrotris(pyrazolyl)borate (Tp) ligands, given the formal relationship existing between these and those containing cyclopentadienyl groups. In addition, we discuss the reactivity of these unsaturated species towards small molecules and alkynes.

1. Introduction

Organometallic derivatives that do not adhere to the 18-electron rule are also known as coordinatively unsaturated organometallics, and have been referred to as the interface between Werner-type complexes and 18-electron organometallic complexes.[1] Bulky ligands are known to play an important role in the stabilization of coordinatively unsaturated metal complexes, by the steric protection provided, against the entry of additional ligands which might eventually complete the electron count at the metal centre. Since such unsaturated compounds are potential catalysts, it is

Manuel Jiménez-Tenorio was born in Jerez (Cádiz), Spain in 1965. He obtained his graduate degree in 1987 from the University of Cádiz and his Doctorate in 1991 with Prof. G. Jeffery Leigh at the University of Sussex, United Kingdom. In 1991 he returned to the University of Cádiz to work in collaboration with Prof. M. Carmen Puerta and Dr. Pedro Valerga. He took a permanent lectureship position in 1996 at the University of Cádiz. His current research interests are centred on the activation of dihydrogen, dinitrogen and other small molecules at coordinatively unsaturated metal centres, as well as the development of nickel and ruthenium catalysts for olefin polymerisation and alkyne coupling reactions.

Maria del Carmen Puerta, was born in Constantina (Sevilla), Spain in 1952. She obtained her graduate degree in 1974 from the University of Sevilla and her Doctorate in 1979, also at the University of Sevilla. From 1979 to 1981 she worked as a postdoc with Prof. Dieter Sellman at Friedrich-Alexander Universität Erlangen-Nürnberg. She took a permanent lectureship position at the University of Cádiz in 1983 and became a Full Professor in 2000. Her current research interests include C-H, C−C and C−X bond activation mediated by ruthenium and nickel complexes, in order to obtain high added value chemicals starting from olefins and alkynes.

Pedro Valerga, was born in Sanlúcar de Barrameda (Cádiz), Spain in 1953. He obtained his graduate degree in 1975 from the University of Sevilla and his Doctorate in 1982 with Prof. Agustín Martín-Rodríguez at the University of Cádiz. From 1985 to 1987 he worked as a postdoc with Prof. Walter L. Roth at the State University of New York at Albany. In 1987 he took a permanent lectureship position at the University of Cádiz. He has authored about 90 publications in reviewed journals. His research interests have been focused on the structural features of inorganic compounds, with special emphasis on organometallic compounds of transition metals with applications to organic synthesis and catalysis.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

desirable to understand the parameters that correlate structure with stability and reactivity. Our research group has been studying the chemistry of transition metal complexes containing bulky phosphane ligands, particularly those with the strong electron-releasing phosphane 1,2-bis(diisopropylphosphano)ethane (dippe).[2−11] We have focused on the isolation of coordinatively unsaturated complexes and the study of their reactivity towards small molecules and alkynes. We initially worked with the 16-electron hydride complex $[RuH(dippe)_2][BPh_4]$.[2−4] Studies on the reactivity of this material led us to report the first example of dioxygen activation at a dihydrogen-binding site unequivocally supported by the X-ray structure analysis of the hydridodioxygen derivative *trans*-$[RuH(O_2)(dippe)_2][BPh_4]$.[2,3] Some of these results were extended later to osmium,[12,13] but we were already interested in the chemistry of half-sandwich complexes prior to that.[7−10] $[(C_5R_5)MX(L)_2]$ (R = H, Me; M = Fe, Ru, Os; X = monoanionic ligand; L = neutral ligand) derivatives constitute a very extensive class of 18-electron compounds.[14,15] Ligand dissociation from these materials gives rise to two possible types of 16-electron complexes: a) neutral complexes $[(C_5R_5)MX(L)]$ generated by dissociation of one of the neutral ligands, and b) cationic complexes $[(C_5R_5)M(L)_2]^+$ generated by dissociation of the monoanionic ligand. Both types of complexes are considered as intermediates in ligand-exchange reactions which follow a dissociative mechanism. In general, these complexes are short-lived, highly reactive transient species that are difficult to isolate. However, with a proper combination of the steric bulk and the electron-donating abilities of the ligands, the isolation of such coordinatively unsaturated species has been possible in a number of cases. These compounds are stable enough to be handled allowing their study and, in some instances, even characterisation by X-ray structure analysis. However, consistent with their coordinatively unsaturated nature, these 16-electron species remain very reactive towards a large number of substrates, including rather inert molecules such as dinitrogen. In this review we discuss the synthesis, structure and reactivity of these stable, yet reactive 16-electron half-sandwich complexes of iron, ruthenium and osmium, with emphasis on those bearing bulky phosphane ligands. We will also refer to related compounds containing hydrotris(pyrazolyl)borate (Tp) ligands, given the formal relationship existing between these and those containing cyclopentadienyl groups.[16]

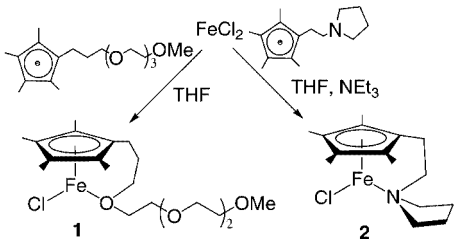
2 Neutral Complexes of the Type $[(C_5R_5)M(X)(L)]$

2.1 Iron Complexes

Compared to the heavier elements in its group, iron complexes that do not follow the 18-electron rule are in general more abundant since iron is a first-row transition metal.[1] However, 16-electron complexes of formula $[(C_5R_5)Fe(X)(L)]$ are rather scarce.

Based upon the magnetic properties the complex [Cp*Fe(acac)(PMe_3)] (Cp* = C_5Me_5) is likely to have a 16-electron, spin triplet configuration with a monodentate acac ligand, or is in equilibrium with a paramagnetic product of phosphane dissociation.[17]

The reaction of $FeCl_2$ with $Li[C_5Me_4(CH_2)_2N(C_4H_8)]$ in THF/NEt_3[18] or with $Li[C_5Me_4(CH_2)_3(OCH_2CH_2)_3OMe]$ in THF[19] at low temperature yields the corresponding neutral 16-electron complexes, which appear stabilised by intramolecular coordination of the pendant amine or glycol ether moiety to iron.



Whereas **1** appears to be stable only in solution, where it was characterised by derivatization reactions,[19] **2** has been isolated in the crystalline state.[18]

Notably, the diamagnetic 14-electron complex [Cp*Fe{$N(SiMe_3)_2$}] has been reported.[20] This compound, prepared by reaction of $FeCl_2$ with one equivalent of $K[N(SiMe_3)_2]$ in THF and subsequent addition of LiCp*, has a "pogo-stick" structure unprecedented in the chemistry of open shell organometallics (Figure 1).

In contrast with this unique compound, which contains Cp*, there is a small but growing number of 14-electron complexes of the type [Tp^RFeX] [Tp^R = hydrotris(3-*tert*-butylpyrazolyl)borate, hydrotris(3,5-diisopropylpyrazolyl)borate, hydrotris(3,4,5-trimethylpyrazolyl)borate; X = halide, alkyl, C≡CPh].[21,22] Several of these compounds have been structurally characterized by X-ray crystallography, and show a distorted tetrahedral geometry around the iron atom (Figure 2).

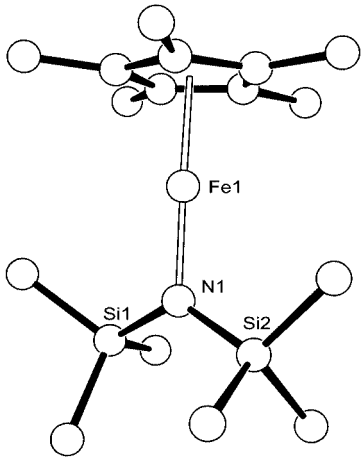


Figure 1. Molecular structure of [Cp*Fe{$N(SiMe_3)_2$}]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

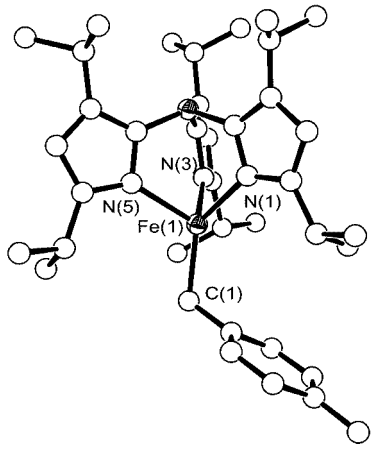

Figure 2. Molecular structure of the 14-electron complex [Tp*i*PrFeCH$_2$Tol]

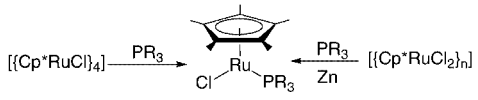
[Tp^{R}FeX] derivatives, and in particular alkyl complexes such as [Tp*i*PrFeCH$_2$CH$_3$] [Tp*i*Pr = hydrotris(3,5-diisopropylpyrazolyl)borate],[22] appear to be remarkably stable despite the coordinative unsaturation, and do not undergo a β-elimination reaction. Besides, the reactions of the alkyl complexes [Tp*i*PrFeR] towards unsaturated organic substrates (olefins, acetylene) tend to be slow. This stability is attributed to the high-spin electronic configuration where four out of five frontier orbitals are singly occupied, as suggested by extended Hückel molecular orbitals (EHMO) calculations.[22]

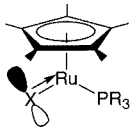
2.2 Ruthenium Complexes

Compounds of the type [Cp*RuCl(PR$_3$)] are well-established reactive intermediates in dissociative phosphane-exchange reactions.[23] If bulky phosphane ligands are used, the isolation of the 16-electron complexes [Cp*RuCl(PR$_3$)] becomes feasible. In 1988, Tilley and co-workers prepared the compounds [Cp*RuCl(PR$_3$)] (R = *i*Pr, Cy) by reaction of tetrameric, cubane-like [(Cp*RuCl)$_4$][24] with one equivalent of the corresponding phosphane in dichloromethane.[25] Almost simultaneously, Chaudret and co-workers also reported the synthesis of these compounds by reduction of the Ru^{III} precursors [Cp*RuCl$_2$(PR$_3$)] (R = *i*Pr, Cy, *t*Bu), usually generated in situ by reaction of [Cp*RuCl$_2$]$_n$ with the appropriate amounts of phosphane and Zn in a variety of solvents.[26]

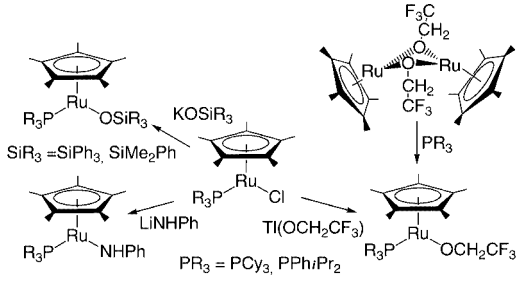


The complexes [Cp*RuCl(PMe*t*Bu$_2$)],[27] [Cp*RuCl(PPh*i*Pr$_2$)],[28] [Cp*RuCl(PMe*i*Pr$_2$)],[29] and [Cp*RuCl(η^1-(P)-PCy$_2$CH$_2$CH$_2$OMe)] (bearing a pendant ether group)[30] have also been synthesized by following any of the methods outlined above. Only bulky phosphanes with a sufficiently large cone angle allow the isolation of these 16-electron complexes. Smaller phosphanes, such as PMe$_3$ or PEt$_3$, readily form the corresponding 18-electron species [Cp*RuCl(PR$_3$)$_2$]. Furthermore, the reaction of [Cp*RuCl(PR$_3$)] (R = *i*Pr, Cy) with smaller cone angle phosphane ligands yielded complexes with filled coordination spheres. These reactions have been the subject of very detailed thermochemical investigations, which have shown that sterically demanding phosphane ligands exhibit the weakest Ru−PR$_3$ bonds.[31] There is an upper limit for the phosphane cone angle which allows the stabilization of [Cp*RuCl(PR$_3$)] species. If the cone angle is too large this results in an inefficient Ru−PR$_3$ interaction. Consistent with this, it has been noted that the reaction of [(Cp*RuCl)$_4$] with bulkier phosphanes such as PPh*t*Bu$_2$ or P(*o*-toly)$_3$ gave the unreacted starting material [(Cp*RuCl)$_4$] after 24 h at 25 °C in hexanes.[28] On the other hand, the phosphane PMe*i*Pr$_2$ defines a lower limit for the cone angle range, as both [Cp*RuCl(PMe*i*Pr$_2$)] and the 18-electron complex [Cp*RuCl(PMe*i*Pr$_2$)$_2$] are accesible depending on the phosphane to tetramer ratio.[29]

Another requirement for the stabilization of [Cp*RuX(PR$_3$)] complexes is the presence of π-electrons at the X ligand, since π-donation by lone pairs mitigates the coordinative unsaturation which would be present if the X ligand were a pure σ-donor. This is termed π-stabilized unsaturation. For this reason, these compounds have been referred to as *operationally* unsaturated, rather than *coordinatively* unsaturated.[28,32]



Following the initial report on the isolation of [Cp*RuCl(PR$_3$)] derivatives, the compounds of general formula [Cp*RuX(L)] (X = monoanionic ligand; L = neutral ligand) have become an important class of 16-electron complexes. Thus, alkoxo, siloxo and phenylimido complexes have been prepared. The alkoxo derivatives [Cp*Ru(OCH$_2$CF$_3$)(PR$_3$)] (PR$_3$ = PCy$_3$, PPh*i*Pr$_2$) were obtained either by reaction of the corresponding [Cp*RuCl(PR$_3$)] with Tl(OCH$_2$CF$_3$) in toluene or, alternatively, by addition of the appropriate amount of phosphane to the dimer [{Cp*Ru(μ-OCH$_2$CF$_3$)}$_2$].[28]

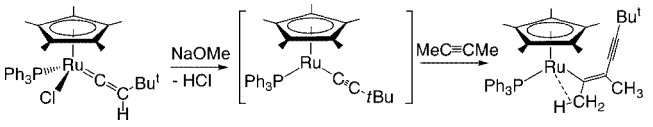


The siloxo derivatives [Cp*Ru(OSiPh$_3$)(PR$_3$)] and [Cp*Ru(OSiMe$_2$Ph)(PR$_3$)] (PR$_3$ = PCy$_3$, PPh*i*Pr$_2$) were prepared by reaction of [Cp*RuCl(PR$_3$)] with K[OSiPh$_3$] or K[OSiMe$_2$Ph] in toluene, whereas the phenylimido complexes [Cp*Ru(NHPh)(PR$_3$)] (PR$_3$ = PCy$_3$, PPh*i*Pr$_2$) were obtained in a similar fashion by reaction of [Cp*RuCl(PR$_3$)] with Li[NHPh].[28] All of these [Cp*RuX(PR$_3$)]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

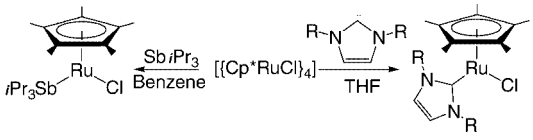
derivatives contain X ligands which bear electron lone pairs at the donor atom, and hence fall into the category of π-stabilized unsaturated complexes.

The complexes [Cp*Ru(C≡CR)(PPh_3)] (R = Ph, *t*Bu) are coordinatively unsaturated species considered to be key intermediates in the catalytic coupling of alkynes.[33,34] These intermediates are generated in situ by deprotonation of the corresponding neutral vinylidene complexes [Cp*-Ru=C=CHR(Cl)(PPh_3)], but they have never been isolated as such in stable form. However, the reaction of [Cp*Ru=C=CH*t*Bu(Cl)(PPh_3)] with MeC≡CMe and NaOMe in MeOH has made possible the isolation and characterization of the β-agostic enynyl complex [Cp*Ru{C(H-CH_2)=CMeC≡C*t*Bu}(PPh_3)].[33]

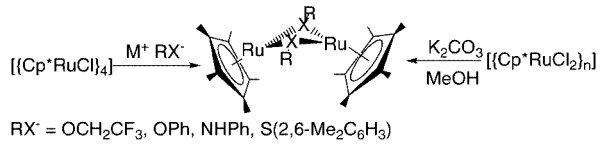


Whereas no stable compounds of the type [TpRu(X)(L)] are known, the involvement of 16-electron alkynyl species [TpRu(C≡CR)(PR_3)] in catalytic processes is well established.[35–37]

Non-phosphane ligands are also capable of stabilizing 16-electron complexes of the type [Cp*RuX(L)]. Thus, the triisopropylstibane complex [Cp*RuCl(Sb*i*Pr_3)] has been synthesized by reaction of [(Cp*RuCl)$_4$][24] with Sb*i*Pr_3 in benzene, or, alternatively, by reduction of [Cp*$RuCl_2$-(Sb*i*Pr_3)] with magnesium amalgam in THF albeit in poorer yields.[38] A series of carbene complexes of the type [Cp*RuCl(carbene)] {carbene = 1,3-R_2-imidazol-2-ylidene, R = mesityl (IMes), cyclohexyl (ICy), tolyl (ITol), 4-chlorophenyl (IpCl), adamantyl (IAd), diisopropylphenyl (IPr), (*R*)-(−)-1-cylohexylethyl [(−)ICMe], (1*S*,2*S*,3*S*,5*R*)-(+)-isopinocamphenyl [(+)I^{i}PCamp]; 1,3-dimesityl-4,5-dichloroimidazol-2-ylidene (IMesCl)} has been recently reported.[39–42] Many of these compounds have been structurally characterized, and all were prepared by reaction of the tetramer [{Cp*RuCl}$_4$][24] with the corresponding free carbene in THF.



Although they do not fall specifically within the scope of this review, we should mention here a number of binuclear 16-electron complexes of the type [(Cp*Ru)$_2$(μ-$RX)_2$] {RX = OMe,[43,44] OPh,[45] OCH_2CF_3,[28] PhNH,[46] S(2,6-$Me_2C_6H_3$)[47]}, which are useful precursors for the preparation of further unsaturated complexes. These compounds display "folded" structures in the solid state and have been prepared by reaction of [(Cp*RuCl)$_4$][24] with the corresponding M^+RX^- salts or, in the case of [(Cp*Ru)$_2$(μ-$OMe)_2$], by reaction of [(Cp*$RuCl_2)_n$] with K_2CO_3 in MeOH.[43]



All [Cp*RuX(L)] derivatives structurally characterized display two-legged piano-stool structures, like [Cp*RuCl-(P*i*Pr_3)][25] represented in Figure 3.

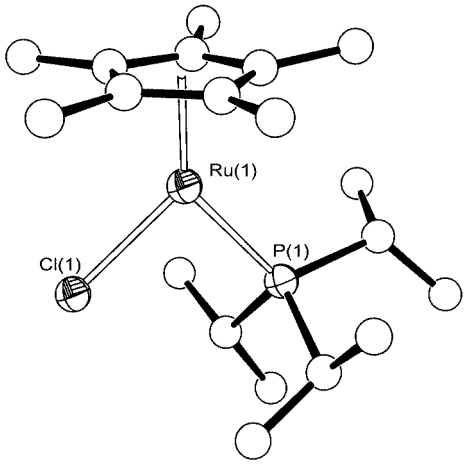


Figure 3. Molecular structure of [Cp*RuCl(P*i*Pr_3)]

Relevant bond lengths and angles for [Cp*MX(L)] (M = Ru, Os) compounds are summarized in Table 1.

The plane defined by the atoms X−Ru−L is almost perpendicular to the plane defined by the C_5 ring of Cp*. This is reflected in the pyramidalization angle α, which is the angle between the centroid of the Cp* ring, the metal atom and the centroid of the moiety X−M−L. The value of α is 170° or greater in most cases. EHMO calculations have shown the preference for a planar (non-pyramidalized, α = 180°) structure in the case of the model compounds [CpRuI-(PH_3)] and [CpRu(OH)(PH_3)], consistent with experimental data.[28] It can be said that the presence of a π-donor ligand increases the preference for a planar structure over a σ-donor ligand, whereas π-acceptor ligands favour a bent structure {α = 160° for $[CpRu(CO)_2]^+$}.[28]

In Table 1, we can see that the carbene complex [Cp*-RuCl(ICy)] has α = 143.1°. The reason for this is that this particular compound is an 18-electron chloride-bridged dimer, with a Ru−Ru separation of 3.968 Å, despite the fact that it was initially reported as a 16-electron monomer.[40] A packing diagram produced by ORTEP[48] (Figure 4) confirms the dimeric structure of [Cp*RuCl(ICy)].

A similar situation occurred for the complex [Cp*Ru-(acac)], which was initially reported as a monomer having a bent structure.[49] A packing diagram showed a 18-electron dimeric structure consisting of two independent molecules in the asymmetric unit, linked through an inversion centre, and each ruthenium bonded to the γ-carbon of the symmetry related acac group (Figure 5).[50]

Despite this, there is numerous spectral evidence in support of the coordinatively unsaturated nature of [Cp*Ru-(acac)] in solution.[51] Most likely [Cp*RuCl(ICy)] exists

[a] Pyramidalization angle α = C_5 ring (centroid)−M−X(L)(centroid). [b] Reported as a 16-electron monomeric complex, it is actually a 18-electron chloride-bridged complex. [c] Displays one agostic interaction with one of the hydrogen atoms of one adamantyl group. [d] 3D-coordinates not available for calculation in the CSD.

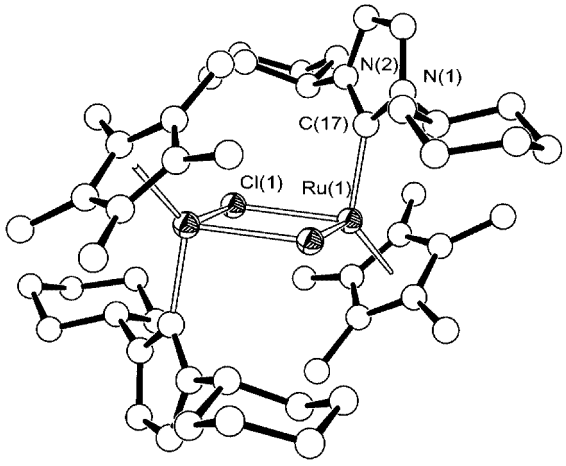

Figure 4. Molecular structure of the binuclear complex [{Cp*-Ru(ICy)}$_2$(μ-Cl)$_2$]

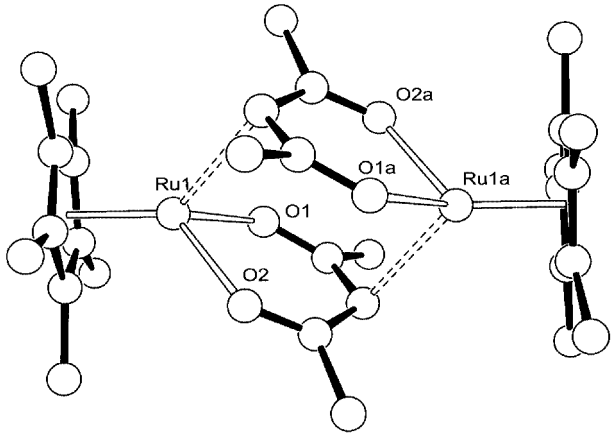

Figure 5. Molecular structure of the dimer [{Cp*Ru(acac)}$_2$]

also in solution as the monomeric species, presumably in equilibrium with its dimeric form, as has been observed for [Cp*RuCl(PMe*i*Pr$_2$)].[29]

The value of 166° found in the case of [Cp*RuCl(IAd)] is attributed to the presence of one agostic interaction with one hydrogen atom of one of the adamantyl groups (Figure 6).

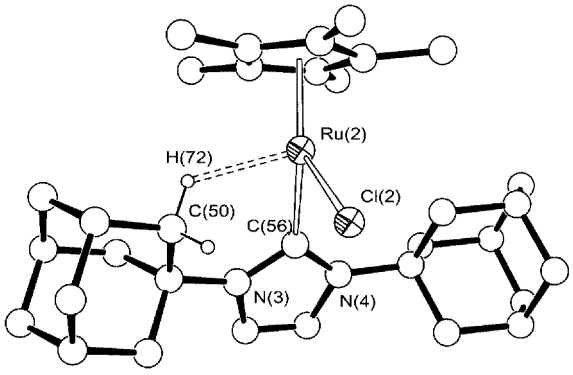

Figure 6. Molecular structure of the complex [Cp*RuCl(IAd)]; calculated average Ru···H^{agostic} 2.20 Å

The average Ru···C(H^{agostic}) distance of 2.89 Å (calculated average Ru···H^{agostic} 2.20 Å) compares well with the average value of 2.875 Å reported for the Ru···C separations in [RuPh(CO)(PMe*t*Bu$_2$)$_2$][BAr′$_4$], a complex which contains two strong agostic interactions with hydrogen atoms of the *t*Bu groups of the two phosphanes.[52]

Very recently, a series of π-stabilized complexes of the type [Cp*Ru{RC(NR′$_2$)}] (R = Me, Ph; R′ = *i*Pr, *t*Bu, Cy) has been reported.[53] In these compounds, the amidinate ligand is acting both as a σ- and π-donor to compensate coordinative unsaturation. The crystal structure of [Cp*-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

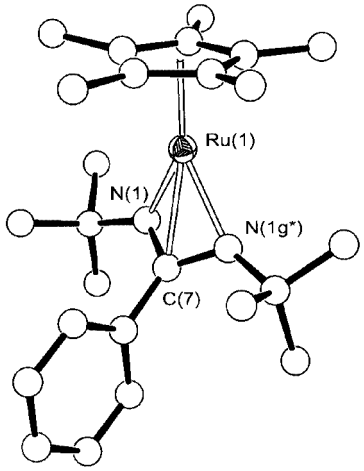

Figure 7. Molecular structure of the amidinate complex [Cp*-Ru{PhC(N*t*Bu)$_2$}]

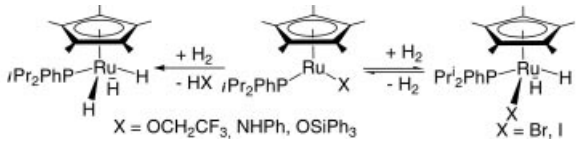
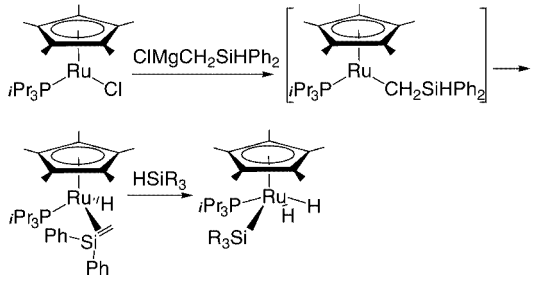
Ru{PhC(N*t*Bu)$_2$}] (Figure 7) shows an almost perfectly planar arrangement of the Cp* centroid and the RuN_2 moiety ($\alpha = 179°$), but the NCN plane appears "folded", with an angle of 48.9° and a Ru···C separation of 2.336 Å, in a fashion which resembles that of the allyl ligands.

All coordinatively unsaturated complexes of the type [Cp*Ru(X)(L)] are extremely air sensitive materials ranging in color from dark blue to purple. The blue or purple colour is actually very characteristic of these 16-electron systems, whereas complexes having filled coordination spheres tend to be yellow, orange or red. Consistent with their coordinatively unsaturated nature, and despite any partial electronic compensation coming from π-donor ligands, [Cp*-Ru(X)(L)] derivatives are very reactive, with a strong tendency to add one ligand L (L = CO, olefins, pyridine) to attain the 18-electron configuration.[25−28] However, they are unreactive towards N_2 and are very reluctant to react with hydrogen. Thus, [Cp*RuCl(PPh*i*Pr$_2$)] shows no evidence for reaction with 2 atm of H_2 at −80 °C in [D_8]toluene. However, within 5 min of exposure of [Cp*-Ru(X)(PPh*i*Pr$_2$)] (X = Br, I) to H_2 at 25 °C in [D_8]toluene, there is evidence for the formation of the labile adducts [Cp*RuH$_2$(X)(PPh*i*Pr$_2$)] in equilibrium with [Cp*-Ru(X)(PPh*i*Pr$_2$)]. A *cisoid* square pyramidal structure has been proposed for these Ru^{IV} species. The reaction of [Cp* Ru(X)(PPh*i*Pr$_2$)] (X = CF_3CH_2O, NHPh, $OSiPh_3$) with H_2 under similar conditions involves Ru−X bond cleavage leading to [Cp*RuH$_3$(PPh*i*Pr$_2$)] plus HX.[54]

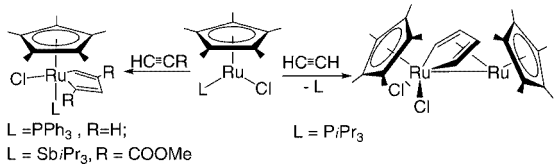


The reaction of [Cp*Ru(X)(PR$_3$)] derivatives with silicon-containing molecules has been thoroughly investigated. Intramolecular Si−H oxidative addition to ruthenium in [Cp*RuCH$_2$SiHPh$_2$(P*i*Pr$_3$)], generated by reaction of ClMgCH$_2$SiHPh$_2$ with [Cp*RuCl(P*i*Pr$_3$)], was used to produce the first isolated η^2-silene complex, [Cp*RuH(η^2-CH$_2$=SiPh$_2$)(P*i*Pr$_3$)].[55] The reaction of this compound with hydrosilanes occurs via 16-electron alkyl or silyl derivatives produced by migration of the hydride back to the silene ligand, leading to Ru^{IV} silyl hydride complexes of the types [Cp*RuH$_2$(SiR$_3$)(P*i*Pr$_3$)] and [Cp*RuH(SiR$_3$)$_2$-(P*i*Pr$_3$)].[56]

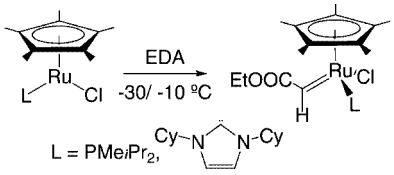


The derivatives [Cp*RuH$_2$(SiR$_3$)(PPh*i*Pr$_2$)] were generated by reaction of [Cp*Ru(OCH$_2$CF$_3$)(PPh*i*Pr$_2$)] with tertiary silanes $HSiR_3$ in pentane, whereas the reaction with the secondary silane SiH_2Ph_2 led to a mixture of [Cp*-RuH$_2$(SiHPh$_2$)(PPh*i*Pr$_2$)] and [Cp*RuH$_2${Si(OCH$_2$CF$_3$)-HPh$_2$}(PPh*i*Pr$_2$)].[54]

[Cp*RuCl(P*i*Pr$_3$)] reacts with acetylene to yield the binuclear ruthenacyclopentadiene [Cp*RuCl$_2${κ^2(*C*,*C*)-μ-C$_4$H$_4$}RuCp*],[57] whereas the reaction of the stibane homologue [Cp*RuCl(Sb*i*Pr$_3$)] with HC≡CCOOMe generates the mononuclear ruthenacyclopentadiene complex [Cp*RuCl{κ^2(*C*,*C*)-C(COOMe)=CHC(COOMe)=CH}-(Sb*i*Pr$_3$)].[38] The reaction of acetylene with [Cp*-RuCl(PPh$_3$)$_2$] also leads to the ruthenacyclopentadiene complex [Cp*RuCl{κ^2(*C*,*C*)-CH=CHCH=CH}(PPh$_3$)] by intermediacy of the 16-electron species [Cp*RuCl(PPh$_3$)] generated in situ.[58]



Diazo compounds add to [Cp*RuCl(PMe*i*Pr$_2$)] complexes furnishing the unstable carbene complexes [Cp*Ru=CHR(Cl)(PMe*i*Pr$_2$)] (R = COOEt, $SiMe_3$).[59] In analogous fashion, the bis(carbene) derivative [Cp*Ru=CHCOOEt-(Cl)(ICy)] is accesible by reaction of the corresponding unsaturated carbene complexes [Cp*RuCl(ICy)] with N_2CHCOOEt (EDA) in toluene at −10 °C.[60]



The unsaturated carbene complexes [Cp*RuCl(L)] (L = ICy, IMes) have been shown to be efficient catalysts for 1-alkyne dimerization. The conversion and selectivity of these

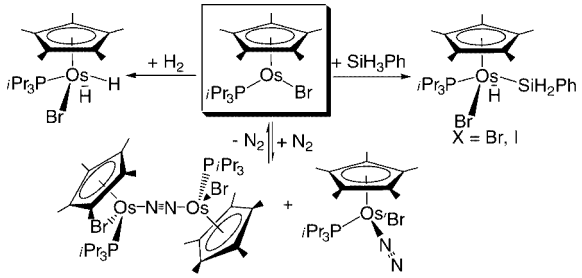
reactions are strongly dependent on the alkyne as well as the *N*-heterocyclic carbene substituents.[61]

[Cp*RuCl(PCy$_3$)] has recently shown to be an effective catalyst, in conjunction with Al(O*i*Pr)$_3$, for the living radical polymerization of methylmethacrylate. Although this is a versatile system which gives very narrow molecular weight distributions, the polymerizations are slow and need over 100 h for completion.[62]

2.3 Osmium Complexes

Whereas [Cp*RuCl(P*i*Pr$_3$)] was reported in 1988,[25−26] the osmium complex [Cp*OsBr(P*i*Pr$_3$)] has only been prepared very recently.[63] One possible reason for this is the unavailability of the complex [Cp*OsCl]$_4$, the homologue of [Cp*RuCl]$_4$,[24] which could serve as the starting material for the preparation of [Cp*OsCl(L)] derivatives as in the ruthenium case. Alternatively, Girolami and co-workers have described the synthesis and crystal structure of the Os^{III} dimeric complex [(Cp*OsBr)$_2$(μ-Br)$_2$],[64] providing a useful and versatile starting compound for the entry into Cp*Os chemistry. Hence, the Os^{III} phosphane complex [Cp*OsBr$_2$(P*i*Pr$_3$)] was obtained by reaction of [(Cp*-OsBr)$_2$(μ-Br)$_2$] with two equivalents of P*i*Pr$_3$ in CH_2Cl_2. Reduction of [Cp*OsBr$_2$(P*i*Pr$_3$)] with Na/Hg amalgam (0.3%, one equivalent) in THF followed by workup afforded purple-black crystals of the 16-electron complex [Cp*-OsBr(P*i*Pr$_3$)].[63] This is the only stable compound of the type [Cp*Os(X)(L)] isolated so far. X-ray crystallography showed a planar two-legged piano stool structure for this compound, just as its ruthenium congeners (Table 1).

[Cp*OsBr(P*i*Pr$_3$)] reversibly binds N_2 at low temperature to give the terminal and bridging dinitrogen complexes [Cp*OsBr(N$_2$)(P*i*Pr$_3$)] [ν(N$_2$) 2074 cm^{-1}] and [{Cp*-OsBr(P*i*Pr$_3$)}$_2$(μ-N$_2$)], which were characterized by ^{15}N NMR spectroscopy. Reaction with H_2 affords the Os^{IV} dihydrido complex [Cp*OsBrH$_2$(P*i*Pr$_3$)], whereas reaction with $PhSiH_3$ yielded the silylhydrido derivative [Cp*-OsHBr(SiH$_2$Ph)(P*i*Pr$_3$)].[63]

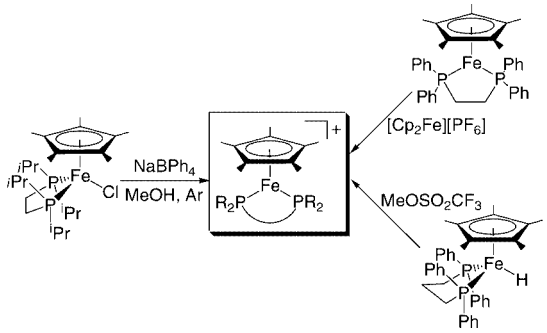


The complex [CpOsCl(P*i*Pr$_3$)$_2$] dissociates one P*i*Pr$_3$ ligand very easily in solution generating the unsaturated complex [CpOsCl(P*i*Pr$_3$)] in situ, which reacts rapidly with P(OMe)$_3$, olefins and internal alkynes furnishing 18-electron complexes of the type [CpOsCl(L)(P*i*Pr$_3$)] [L = P(OMe)$_3$, methylacrilate, bis(carboxymethyl)acetylene].[65] Besides, [CpOsCl(P*i*Pr$_3$)] is capable of H−X activation (X = H, C, Si, Ge, Sn).[66] In a similar fashion, thermolysis of the alkyl complexes [(C$_5$R$_5$)OsCH$_2$SiMe$_3$(PR$_3$)$_2$] (R = H, Me; PR$_3$ = PPh$_3$, PMe$_3$) also generates the corresponding highly reactive 16-electron complexes [(C$_5$R$_5$)OsCH$_2$SiMe$_3$(PR$_3$)] in situ, which easily undergo C−H activation processes leading to alkyl, silyl and hydridosilyl derivatives.[67]

3. Cationic Complexes of the Type [(C$_5$R$_5$)M(L)$_2$]$^+$

3.1 Iron Complexes

Although not strictly a half-sandwich complex, the 16-electron pentadienyl derivative [(η^5-pentadienyl)Fe(PEt$_3$)$_2$][PF$_6$] was reported in 1990. It was prepared by reaction of [Fe(η^5-pentadienyl)(η^3-pentadienyl)(PEt$_3$)] with Ag[PF$_6$] and PEt$_3$ in dichloromethane, or, alternatively, by addition of [HPEt$_3$][PF$_6$] to the former iron complex.[68] The first 16-electron half-sandwich complexes of iron isolated and unequivocally characterized were [(C$_5$R$_5$)Fe(dippe)][BPh$_4$] (R = H, Me).[7] These yellow-brown compounds were prepared by halide abstraction from the corresponding chloro complexes [(C$_5$R$_5$)FeCl(dippe)][6] in MeOH under argon, using NaBPh$_4$ as a chloride scavenger. The complex [Cp*Fe(dppe)][PF$_6$], prepared by oxidation of the 17-electron radical complex [Cp*Fe(dppe)] using [Cp$_2$Fe][PF$_6$], was reported shortly afterwards.[69] The related derivative [Cp*Fe(dppp)][CF$_3$SO$_3$] [dppp = 1,3-bis(diphenylphosphano)propane] has been described recently.[70] This compound was obtained by hydride abstraction from [Cp*-FeH(dppp)] using MeOSO$_2$CF$_3$ as a hydride scavenger.



All compounds [(C$_5$R$_5$)Fe(P)$_2$]$^+$ reported to date, as well as [(η^5-pentadienyl)Fe(PEt$_3$)$_2$]$^+$, are paramagnetic species with magnetic moments ranging from 2.93 to 3.8 μ$_B$. These values for the magnetic moment are consistent with the presence of two unpaired electrons, and hence have a triplet state electron configuration. The structure of these coordinatively unsaturated two-legged piano-stool complexes has been analyzed using both extended Hückel methodology[71] and density functional theory (DFT).[71−72] Detailed DFT calculations performed on the complex [Cp*Fe(dppe)]$^+$ found a triplet ground state with a small singlet-triplet separation. Geometry optimization has shown that the structure of the compounds [(C$_5$R$_5$)Fe(PR′$_2$CH$_2$CH$_2$PR′$_2$)]$^+$ (R = H, Me; R′ = H, Ph) is planar in the triplet state (α = 177° to 180°), whereas in the singlet state it is pyramidalized, with the angle α between 145° and 162°.[72] The

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

question of the spin state, geometry and structural dynamics of these systems has been explained in terms of the second-order Jahn−Teller instability of their planar (non-pyramidalized) geometry.[72] The through-space coupling (TSC) concept has also been applied to the study of the geometry of $[Cp'ML_2]$ systems (Cp′ = cyclopentadienyl or a derivative, M = Fe^{II}, Ru^{II}, L = P- or N-donor co-ligands). This concept is the molecular orbital representation of van der Waals-like repulsive-attractive forces between the ligands in addition to the interactions with the metal centre.[73] According to this, the combination of both determines whether a planar or a pyramidal structure is adopted and also whether the complex is diamagnetic or paramagnetic.[73]

The theoretical findings are supported by the experimental solid-state structures of [Cp*Fe(dippe)][BPh_4] (Figure 8),[7] [Cp*Fe(dppe)][PF_6],[69] and [Cp*Fe(dppp)]-[CF_3SO_3].[70] All of these compounds were determined by X-ray crystallography.

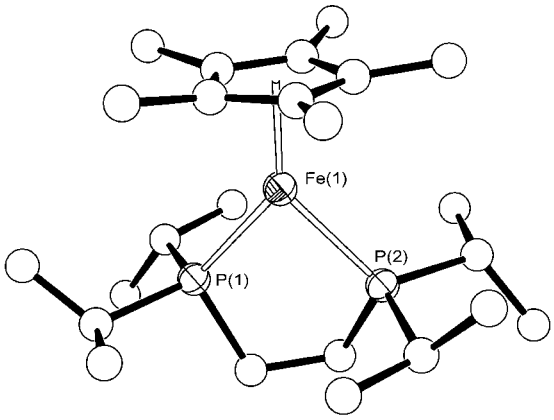


Figure 8. Molecular structure of the cation $[Cp^*Fe(dippe)]^+$

These compounds display planar two-legged piano-stool structures, and their most significant dimensions are summarized in Table 2.

There are two basic reactivity patterns for these $[(C_5R_5)Fe(P)_2]^+$ unsaturated complexes: a) addition of the ligand L to form the corresponding 18-electron complex $[(C_5R_5)Fe(L)(P)_2]^+$; and b) oxidation reactions to Fe^{III} complexes.

Complexes $[(C_5R_5)Fe(P)_2]^+$ react with a range of neutral donors such as H_2O, acetone, MeCN or CO affording the corresponding saturated complexes.[7,69,70] The resulting $[(C_5R_5)Fe(L)(P)_2]^+$ derivatives can be either diamagnetic or paramagnetic. In particular, those adducts containing oxygen-donor ligands such as acetone, H_2O or $[CF_3SO_3]^-$ in combination with Cp* as a co-ligand, all exhibit paramagnetic behaviour.[72] The complex $[Cp^*Fe(MeCN)(dippe)]^+$ is also paramagnetic at variance with its Cp counterpart, which is diamagnetic.[7] DFT has been used in an attempt to account for the unusual magnetic behaviour of these complexes.[72]

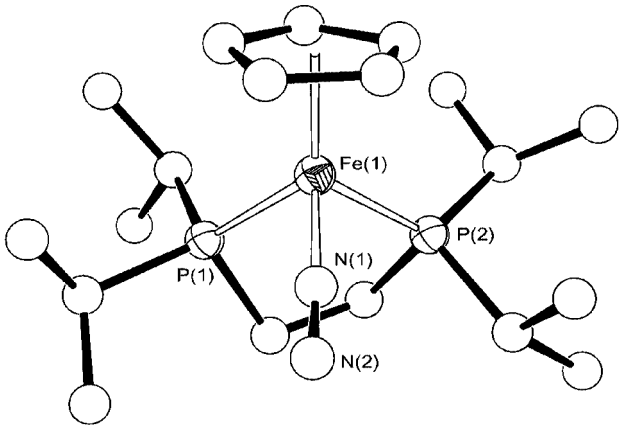

Figure 9. Molecular structure of the cationic dinitrogen complex $[CpFe(N_2)(dippe)]^+$

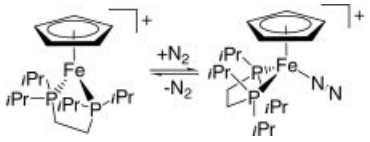
The complex [CpFe(dippe)][BPh_4] binds N_2 reversibly, furnishing the diamagnetic terminal dinitrogen complex [$CpFe(N_2)$(dippe)][BPh_4] [$\nu(N_2)$ 2112 cm^{-1}], which was structurally characterized (Figure 9).[7]

This dinitrogen complex exists in equilibrium with [CpFe(dippe)][BPh_4] in acetone under dinitrogen. The study of this equilibrium allowed the calculation of $\Delta H°$ and $\Delta S°$ for this process (18.2 ± 0.5 kJ·mol^{-1} and 68 ± 2 J·mol^{-1} K^{-1}, respectively).



Thus, the dissociation process is entropy driven and addition of N_2 may be favoured by lowering the temperature. Poli has pointed out that the actual strength of the $Fe-N_2$ bond in this complex is greater because part of the energy spent in breaking this bond is regained as a result of the spin-state change from singlet to triplet in [CpFe-(dippe)]$^+$.[1]

3.2 Ruthenium Complexes

Cationic complexes of the type $[(C_5R_5)Ru(P)_2]^+$ are readily generated in situ by reaction of the corresponding halide

Table 2. Relevant bond lengths (Å) and angles (°) for structurally characterized cationic complexes of the type $[Cp^*Fe(P)_2]^+$

Compound	M−L [Å]	M−L [Å]	M−Cp*(centroid) [Å]	X−M−L [°]	α [°][a]	Ref.

complex $[(C_5R_5)RuX(P)_2]$ (X = Cl, Br, I) with a suitable halide scavenger, such as Ag^+ or Tl^+ salts. However, the resulting unsaturated cations $[(C_5R_5)Ru(P)_2]^+$ are in most cases too reactive to be isolated, and react with any suitable donor molecule in the reaction mixture to give 18-electron complexes. The donor can be a solvent molecule, particularly if it is coordinating, or, alternatively, the counterion may also act as a ligand. Hence, reports claiming the synthesis of the supposedly 16-electron complexes such as $[CpRu(dcpe)][CF_3SO_3]$ [dcpe = 1,2-bis(dicyclohexylphosphano)ethane][74] or $[Cp^*Ru(dppe)][CF_3SO_3]$[75] as orange solids which were characterized by NMR spectroscopy and microanalysis, might actually correspond to the 18-electron species $[CpRu(\eta^1\text{-}(O)\text{-}CF_3SO_3)(dcpe)]$ or $[Cp^*Ru(\eta^1\text{-}(O)\text{-}CF_3SO_3)(dppe)]$, respectively. Even counterions such as $[BPh_4]^-$ are known to bind in an η^6-fashion to ruthenium.[10] The introduction of the bulky, non-coordinating anion $[BAr'_4]^-$ {Ar′ = 3,5-$[(CF_3)_2C_6H_3]$}[76] and its use as a halide scavenger opens up new possibilities to generate and stabilize cationic, highly electrophilic 16-electron species. Thus, halide abstraction from [Cp*RuCl(TMEDA)] (TMEDA = $Me_2NCH_2CH_2NMe_2$) using $NaBAr'_4$ in Et_2O affords the blue cationic 16-electron complex [Cp*Ru(TMEDA)][BAr′4] in 92% isolated yield.[77] In a similar fashion, the reaction of $[(Cp^*RuCl)_4]$ with the diamines $Me_2NCH_2CH_2NR_2$ [R_2 = *i*Bu$_2$, $(CH_2CH_2)_2O$] and $NaBAr'_4$ in Et_2O afforded the corresponding unsaturated cationic complexes $[Cp^*Ru(Me_2NCH_2CH_2NR_2)][BAr'_4]$ in high yields. However, when the diamine $Me_2NCH_2CH_2NMePh$ was used, the 18-electron η^6-arene complex $[Cp^*Ru\{\eta^6\text{-}C_6H_5N(Me)CH_2CH_2NMe_2\}][BAr'_4]$ was obtained.[78] The complex [CpRu(TMEDA)][BAr′4] has also been synthesized following a a similar procedure, and structurally characterized (Figure 10).[79]

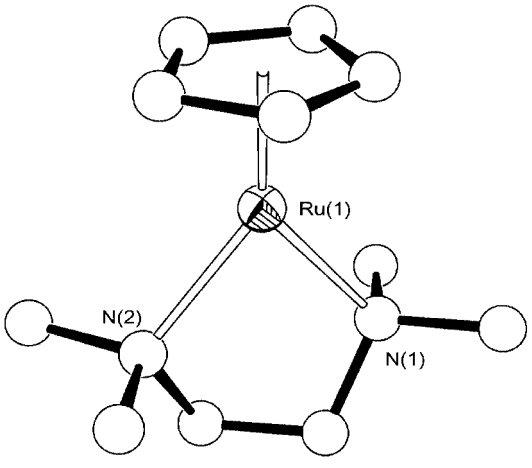

Figure 10. Molecular structure of the cation $[CpRu(TMEDA)]^+$

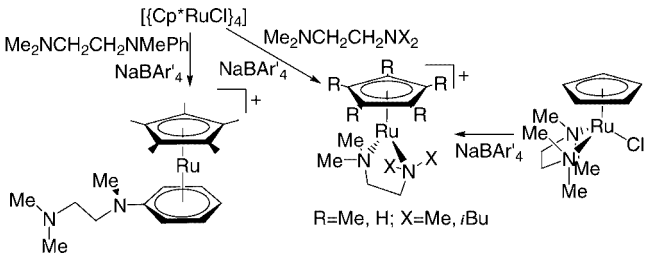
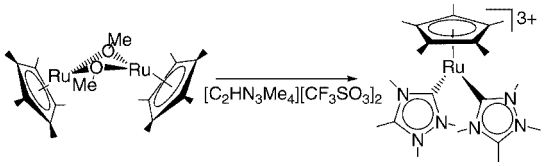


By addition of one equivalent of the dicationic carbene precursor 1,2,3,4-tetramethyl-1,2,4-triazolium bis(triflate) $[C_2HN_3Me_4][CF_3SO_3]_2$ to the dimer $[\{Cp^*Ru\}_2(\mu\text{-}OMe)_2]$,[43] the remarkably stable tricationic bis(carbene) complex $[Cp^*Ru(C_2N_3Me_4)_2][CF_3SO_3]_3$ was isolated in moderate yield.[80]



The rather long Ru−C(carbene) bond lengths in this complex (Figure 11) are in agreement with two datively bound carbenes acting as two-electron donors, and therefore the cation $[Cp^*Ru(C_2N_3Me_4)_2]^{3+}$ should be considered as a 16-electron species.

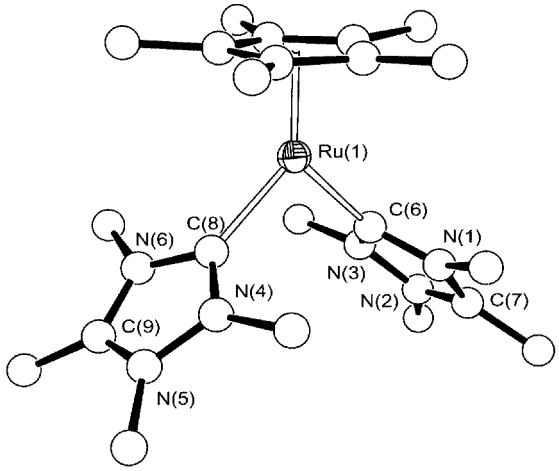


Figure 11. Molecular structure of the tricationic complex $[Cp^*Ru(C_2N_3Me_4)_2]^{3+}$

The first stable compounds of the type $[Cp^*Ru(P)_2]^+$ were unequivocally characterized and recently reported by our research group.[81,82] The complex [Cp*Ru(PMe*i*Pr$_2$)$_2$][BAr′4] (Figure 12) was prepared by reaction of [Cp*RuCl(PMe*i*Pr$_2$)][29] with $NaBAr'_4$ in fluorobenzene under argon in the presence of PMe*i*Pr$_2$, whereas the derivatives [Cp*Ru(dippe)][BAr′4] (Figure 13) and $[Cp^*Ru(PEt_3)_2]$-[BAr′4] were similarly obtained by chloride abstraction from either [Cp*RuCl(dippe)][9] or $[Cp^*RuCl(PEt_3)_2]$[83] using $NaBAr'_4$ in fluorobenzene under argon.

Although this seems to be a general reaction for the preparation of cationic 16-electron half-sandwich ruthenium complexes, the range of stable compounds of this type amenable to isolation is in fact very limited. Scheme 1 summarizes the variety of products which may result from the halide abstraction reaction of $[(C_5R_5)RuCl(P)_2]$ complexes using $NaBAr'_4$ in fluorobenzene under argon.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

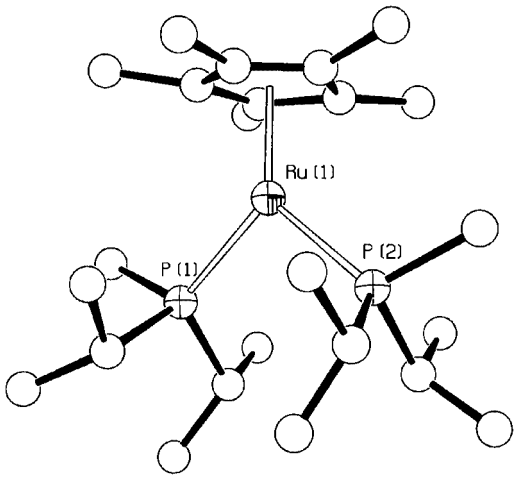

Figure 12. Molecular structure of the cation $[Cp^*Ru(PMe{\it i}Pr_2)_2]^+$

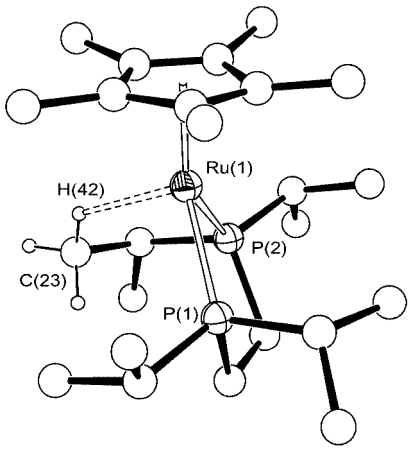

Figure 13. Molecular structure of the cation $[Cp^*Ru(dippe)]^+$; calculated $Ru\cdots H^{agostic}$ 2.262 Å

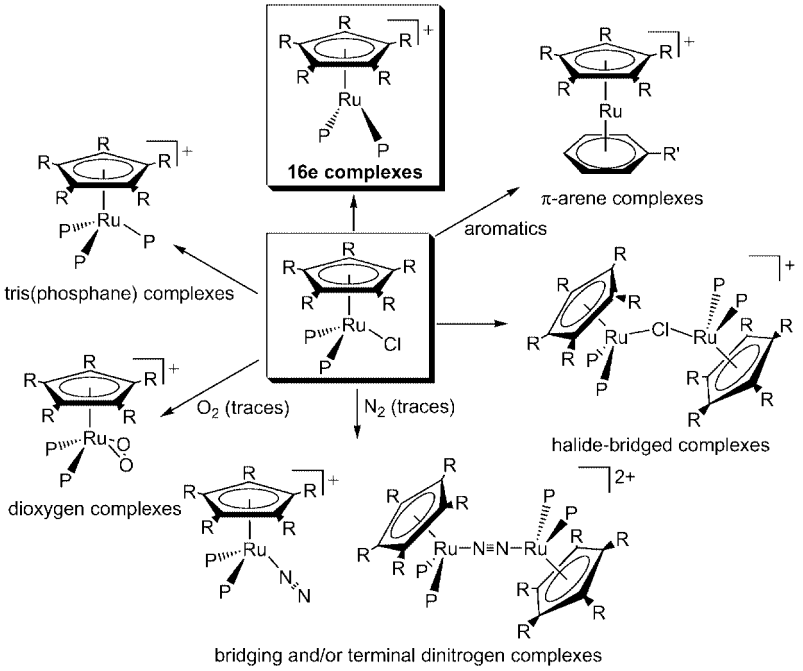
Thus, with phosphanes other than $PMe{\it i}Pr_2$, dippe or PEt_3, a variety of 18-electron compounds have been isolated. Even a non-coordinating solvent such as fluorobenzene might become a good ligand under these conditions, and hence the sandwich complex $[Cp^*Ru(\eta^6\text{-FPh})][BAr'_4]$ has been isolated from the reactions of $[Cp^*RuCl(PR_3)]$ (PR_3 = P*i*Pr$_3$, PCy_3) with $NaBAr'_4$ in fluorobenzene under argon in the presence of PR_3 in an attempt to prepare the corresponding unsaturated complexes.[82] Halide abstraction from $[Cp^*RuCl(PMe_3)_2]$ in fluorobenzene results in ligand redistribution and a mixture of $[Cp^*Ru(\eta^6\text{-FPh})][BAr'_4]$ and the tris(phosphane) complex $[Cp^*Ru(PMe_3)_3][BAr'_4]$ is obtained. If aromatic substituents are present on the phosphane ligand, the ultimate product from the halide abstraction reaction is usually the corresponding sandwich derivative $[Cp^*Ru(\eta^6\text{-}C_6H_5PR_2)][BAr'_4]$ (R = *i*Pr, Ph).[82] Another way to attain the 18-electron configuration for these systems is the formation of halide bridges. When the halide ligand is abstracted and the 16-electron fragment is generated, it can react with the remaining halo complex furnishing a cationic 18-electron halide-bridged binuclear complex. This happens in the course of the reaction of [Cp*-RuCl(dppm)] with $NaBAr'_4$ in fluorobenzene under argon, and the resulting binuclear compound undergoes phosphane rearrangement yielding $[\{Cp^*Ru\}_2(\mu\text{-Cl})(\mu\text{-dppm})_2][BAr'_4]$.[84] In a similar fashion, halide abstraction from $[Cp^*RuCl(CO)(PR_3)]$ (PR_3 = PEt_3, P*i*Pr$_2$) also leads to halide-bridged binuclear complexes $[\{Cp^*Ru(CO)(PR_3)\}_2(\mu\text{-Cl})][BAr'_4]$.[85]

The use of Cp* instead of Cp as the co-ligand is also very important for the stabilization of cationic half-sandwich 16-electron species of the type $[(C_5R_5)Ru(P)_2]^+$. Thus, when halide abstraction from $[CpRuCl(P)_2]$ [$(P)_2$ = dippe, PEt_3, P*i*Pr$_2$] using $NaBAr'_4$ in fluorobenzene under argon was



Scheme 1. Variety of products which may result from the halide abstraction reaction of $[(C_5R_5)RuCl(P)_2]$ using $NaBAr'_4$/FPh

attempted, the resulting 16-electron species generated in this way are potentially so reactive that they scavenge trace amounts of dinitrogen present even in high-purity argon, giving dinitrogen-bridged complexes $[\{CpRu(P)_2\}_2(\mu\text{-}N_2)][BAr'_4]_2$ (Figure 14).[86]

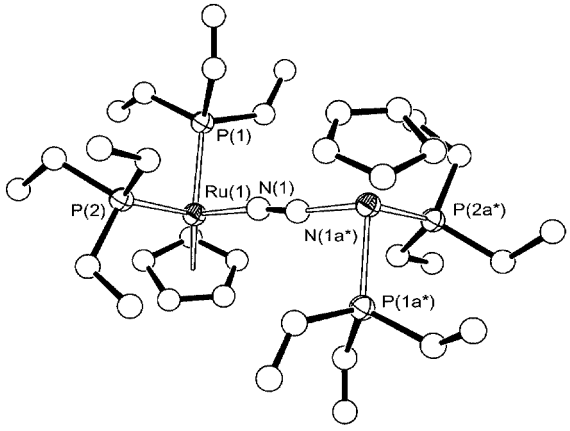

Figure 14. Molecular structure of the dicationic dinitrogen-bridged complex $[\{CpRu(PEt_3)_2\}_2(\mu\text{-}N_2)]^{2+}$

Chloride abstraction from $[CpRuCl(PMe\textit{i}Pr_2)(PPh_3)]$ under argon afforded a compound of formula $[CpRu(PMe\textit{i}Pr_2)(PPh_3)][BAr'_4]$. However, this compound is not a genuine 16-electron species, since the vacant coordination position is occupied by one of the C=C bonds of a phenyl substituent of the PPh_3 ligand (Figure 15). Hence in this case, the PPh_3 ligand adopts a very rare η^3-coordination mode[87] and the system attains the 18-electron configuration in this way.[86]

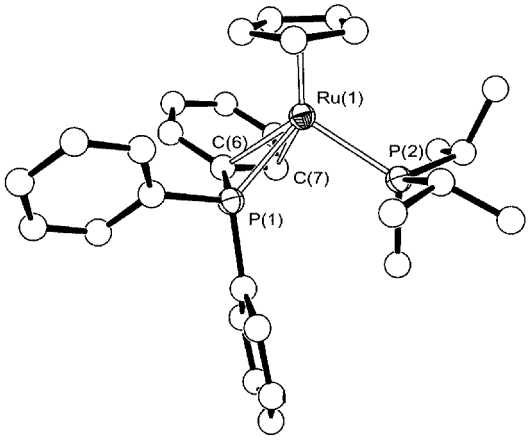

Figure 15. Molecular structure of the cation $[CpRu(\eta^3\text{-}PPh_3)(PMe\textit{i}Pr_2)]^+$

In a similar fashion, the complexes $[CpRu\{(R)\text{-}(BINAP)\}][CF_3SO_3]$[88,89] [BINAP = 2,2′-bis(diphenylphosphano)-1,1′-binaphthyl] and $[CpRu(MeO\text{-}BIPHEP)][BF_4]$[89] {MeO-BIPHEP = (6,6′-dimethoxybiphenyl-2,2′-diyl)bis[bis(3,5-di-*tert*-butylphenyl)phosphane]} contain chelating phosphane ligands acting as six-electron donors through coordination of one of the biaryl double bonds to ruthenium, also attaining the 18-electron configuration (Figure 16).

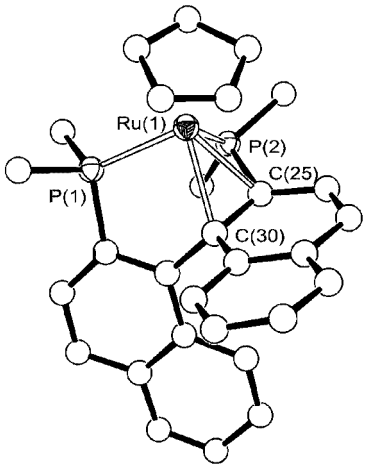

Figure 16. Molecular structure of the cation $[CpRu[(R)\text{-BINAP})]^+$; only the *ipso*-carbon atoms of the phenyl rings of the BINAP ligand are represented

All cationic compounds $[(C_5R_5)Ru(L)_2]^+$ structurally characterized display two-legged piano-stool structures (Table 3). The pyramidalization angle α falls between 170° and 180° in most cases, indicative of non-pyramidalized structures.

The angle of 160° found for $[Cp^*Ru(dippe)]^+$ is due to the presence of an agostic interaction with one of the hydrogen atoms of an isopropyl group [Figure 13; $Ru\cdots C(H^{agostic})$ distance of 2.953(4) Å, calculated $Ru\cdots H^{agostic}$ 2.262 Å].[81,82] Complexes stabilized by bonding to C=C bonds of either aryl or biarylphosphane group (Figure 15 and 16) display pyramidalization angles of 155−157°, consistent with their coordinatively saturated character. Extended Hückel[73,78,79] and DFT[73,82] calculations have been performed on several model systems $[CpRu(L)_2]^+$ $[(L)_2 = (NH_3)_2, NH_2CH_2CH_2NH_2, (PH_3)_2, PH_2CH_2CH_2PH_2]$ (Figure 17). The TSC concept has also been applied recently to the MO analysis of $[CpRu(L)_2]^+$ complexes.[73]

The calculated ground-state structure of the model phosphane complexes is strongly pyramidalized ($\alpha = 149-152°$), with an energy difference of ca. 6 kcal mol^{-1} between the ideally planar ($\alpha = 180°$) and the pyramidal geometry. In contrast, the model amine complexes adopt essentially planar structures ($\alpha = 171-179°$), with an almost flat inversion barrier.[82] It must be noted, however, that bending is hampered by bulky L_2 ligands, and the reactivity of the fragment is modified accordingly. Amine ligands participate much less than phosphane ligands in the LUMO, and this participation is further increased on bending. This is reflected in the observed agostic interaction in $[Cp^*Ru(dippe)]^+$.

Complexes $[(C_5R_5)Ru(L)_2]^+$ are highly electrophilic, as expected, although their reactivity depends strongly on the nature of both the C_5R_5 and L ligands. Thus, Cp complexes are more reactive than their Cp* homologues. For example, $[CpRu(TMEDA)]^+$ adds dihydrogen affording $[CpRu(H_2)(TMEDA)]^+$, whereas $[Cp^*Ru(TMEDA)]^+$ is unreactive

[a] Pyramidalization angle α = C_5 ring (centroid)−M−X(L)(centroid). [b] Contains one agostic interaction with a hydrogen atom of an isopropyl group. [c] Attains 18-electron configuration by coordination of one C=C bond of a Ph substituent of the PPh_3 ligand. [d] Attains 18-electron configuration by coordination of one of the biaryl bonds.

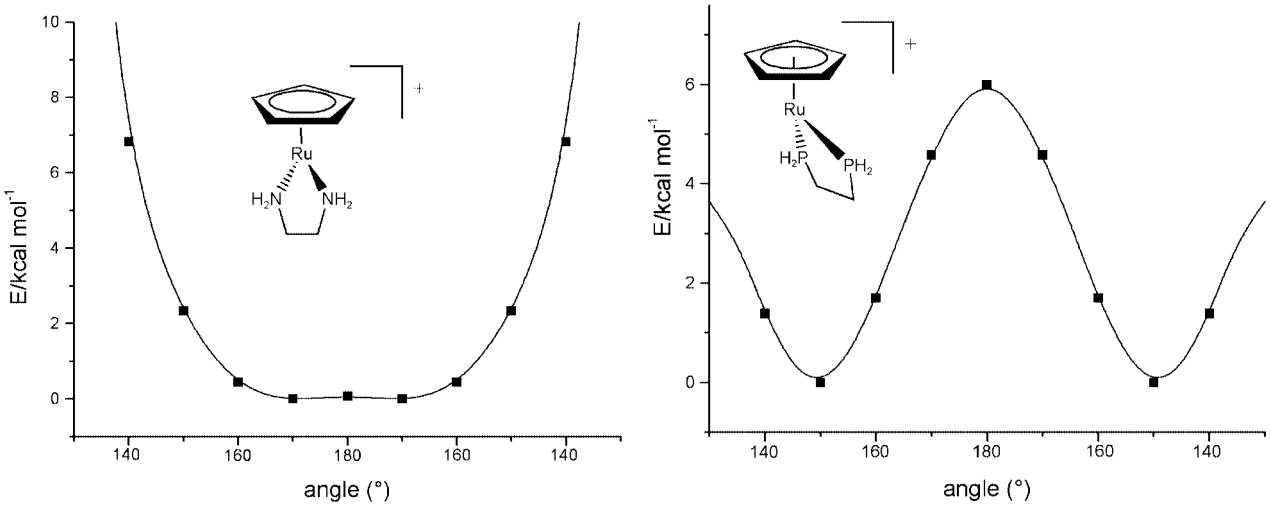

Figure 17. Energies of optimized $[CpRu(NH_2CH_2CH_2NH_2)]^+$ and $[CpRu(PH_2CH_2CH_2PH_2)]^+$ as a function of the pyramidalization angle α (°)

towards H_2.[79] In general, the transformation into the 18-electron configuration can be attained in three different ways, namely (a) direct ligand addition, (b) oxidative addition, and (c) degradation to other stable 18-electron species, such as the $[(C_5R_5)Ru(\eta^6\text{-arene})]^+$ complexes. The general reactivity patterns of $[(C_5R_5)Ru(L)_2]^+$ are summarized in Scheme 2.

All compounds $[(C_5R_5)Ru(L)_2]^+$ exhibit different degrees of affinity for an additional ligand. Whereas some compounds scavenge traces of N_2 present in argon to yield dinitrogen-bridged complexes such as $[\{CpRu(P)_2\}_2(\mu\text{-}N_2)][BAr'_4]_2$,[86] other systems {i.e. $[Cp^*Ru(TMEDA)]^+$ and $[Cp^*Ru(PMe{\it i}Pr_2)_2]^+$} are unreactive towards dinitrogen. However, most of them form terminal dinitrogen complexes $[(C_5R_5)Ru(N_2)(L)_2]^+$ {R = H, $(L)_2$ = TMEDA,[79] dippe, $(PMe{\it i}Pr_2)_2$, $(PMe{\it i}Pr_2)(PPh_3)$;[86] R = Me, $(L)_2$ = dippe,[10] dppe, dppm,[84] $(PEt_3)_2$[29]}. The reaction with oxygen often leads to the formation of stable dioxygen complexes $[(C_5R_5)Ru(O_2)(L)_2]^+$ {R = H, $(L)_2$ = TMEDA;[79] R = Me, $(L)_2$ = dppe,[75] dippe,[9] dppm,[90] $(PEt_3)_2$[29]}. All compounds of the type $[(C_5R_5)Ru(P)_2]^+$ add H_2 oxidatively furnishing the corresponding Ru^{IV} dihydride complexes $[(C_5R_5)RuH_2(P)_2]^+$. In many cases, the corresponding dihydrogen $[(C_5R_5)Ru(H_2)(P)_2]^+$ complexes have also been characterized in solution at low temperatures by NMR spectroscopy.[10,29,82]

With the exception of the reaction with HCl, the amine complexes $[(C_5R_5)Ru(TMEDA)][BAr'_4]$ (R = H, Me) are reluctant to undergo oxidative addition reactions, at variance with $[Cp^*Ru(P)_2]^+$ [$(P)_2$ = dippe, PEt_3, $PMe{\it i}Pr_2$] derivatives. One particular case is the chelate-assisted methyl C−H activation that takes place in the course of the reaction of $[Cp^*RuCl(PPh_2CH_2CH_2NMe_2)]$ with $NaBPh_4$ in CH_2Cl_2 to yield the unstable hydrido complex $[Cp^*RuH\{\kappa^3(P,N,C)\text{-}PPh_2CH_2CH_2N(=CH_2)Me\}]^+$, which is readily converted into $[Cp^*RuCl\{\kappa^3(P,N,C)\text{-}PPh_2CH_2CH_2N(=CH_2)Me\}]^+$.[91]

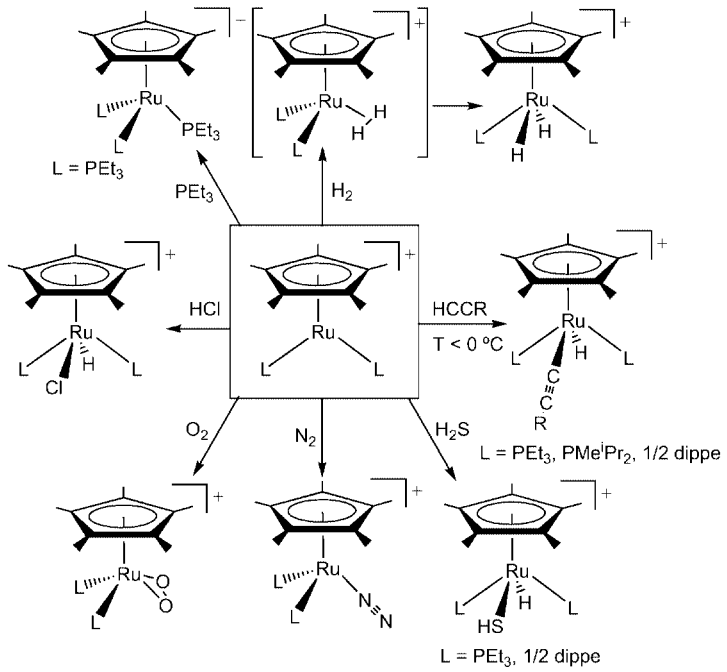
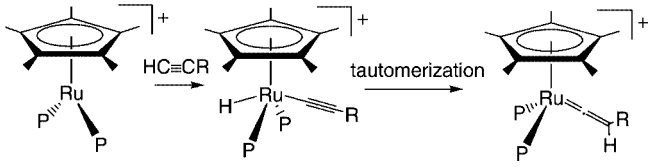


Scheme 2. General reactivity patterns of $[(C_5R_5)Ru(L)_2]^+$ complexes $[(L)_2$ = set of (NN) or (PP) ligands]

The Ru^{IV} hydridometallothiol complexes $[Cp^*RuH(SH)(P)_2]^+$ $[(P)_2$ = dippe, $PEt_3]$[83,92] result from the oxidative addition of H_2S to either $[Cp^*Ru(dippe)]^+$ or $[Cp^*Ru(PEt_3)_2]^+$. Interestingly, the addition of thiophenol yields the thiol adduct $[Cp^*Ru(HSPh)(dippe)]^+$ rather than the oxidative addition product.[92]

One of our research group contributions has been the isolation and characterization of the metastable Ru^{IV} alkynyl and hydroxyalkynyl hydrido complexes $[Cp^*RuH(C{\equiv}CR)(P)_2]^+$ $[(P)_2$ = dippe, PEt_3, $PMeiPr_2]$[8,93–97] as intermediates in the alkyne to vinylidene tautomerization process. This process takes place both in solution and in the solid state.[98]



Since the initial EHMO calculations by Silvestre and Hoffmann on the alkyne to vinylidene rearrangement,[99] most theoretical studies had concluded that the intermediacy of alkynyl hydrido complexes generated by oxidative addition of the alkyne to a d^6 metal centre is too high in energy, and an alternative reaction pathway, namely a 1,2-H shift, is preferred. Recent DFT studies performed on $[CpRu(HC{\equiv}CH)(PMe_3)_2]^+$ have shown that in this particular case the energy barriers for the 1,2-H shift and the oxidative addition are almost similar, so that the latter process might become competitive.[100] Further theoretical support for the involvement of alkynyl hydrido complexes in the alkyne to vinylidene tautomerization process has been found recently, when Cp* instead of Cp is introduced in the model system for computation using a combination of DFT and quantum mechanics/molecular mechanics calculations.[97]

Whereas the solid-state structures determined by X-ray crystallography for several alkynyl hydrido complexes show a *transoid* disposition of alkynyl and hydrido ligands (Figure 18), we have spectral evidence in the case of the complexes $[Cp^*RuH(C{\equiv}CR)(PMeiPr_2)_2]^+$ [R = Ph, COOMe, *t*Bu, $CH_2(OH)$, CMeH(OH), $CMe_2(OH)$, CMePh(OH), CHPh(OH), $CPh_2(OH)$, CCy(OH)] are consistent with the occurrence of a rapid equilibrium between the *cisoid* and *transoid* isomers in solution.[96]

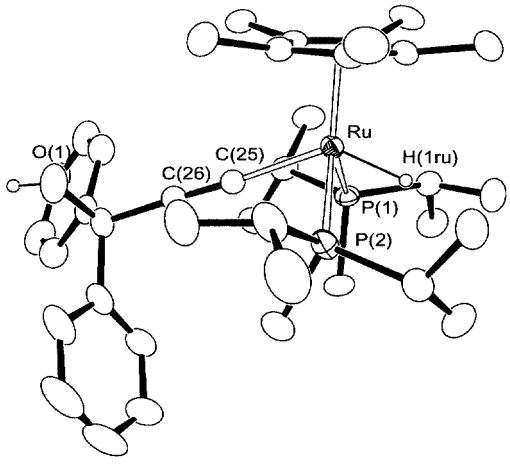


Figure 18. Molecular structure of the hydroxyalkynyl hydrido complex $[Cp^*RuH(C{\equiv}CC(OH)Ph_2(PMeiPr_2)_2]^+$

The halide abstraction reactions from hydridotris(pyrazolyl)borate $[TpRuX(L)_2]$ (L = PPh_3, dppe, dippe, PEt_3, $PMeiPr_2$, $PPh_2CH_2CH_2NMe_2$) has so far not allowed the isolation of stable 16-electron species formally analogous to their Cp*Ru counterparts.[101−105] The resulting coordinatively unsaturated fragments $[TpRu(L)_2]^+$ are extremely reactive, being trapped by any donor molecule L′ (i.e. counterion, solvent, N_2, H_2O) present in the reaction mixture to give the corresponding 18-electron complexes $[TpRu(L')(L)_2]^+$. Aquo complexes $[TpRu(H_2O)(L)_2]^+$ are often the final products isolated from halide abstraction reactions.[101,104,105] In the case of $[TpiPrRu(H_2O)(dppe)][CF_3SO_3]$, the H_2O ligand is labile and can be removed by means of molecular sieves (4 Å) affording the coordinatively unsaturated species $[TpiPrRu(dppe)][CF_3SO_3]$. This compound is stabilized by means of an agostic interaction with a hydrogen atom of one of the isopropyl groups of the Tp*i*Pr ligand, as revealed by X-ray crystallography [Figure 19; Ru···C($H^{agostic}$) 2.627(6) Å, Ru···$H^{agostic}$ 1.83(6) Å].[106] There is spectral evidence for the formation of analogous species in the cases of $[TpiPrRu(dppm)]^+$ and $[TpiPrRu(Ph_2PCH{=}CHPPh_2)]^+$, but these are too unstable to be isolated.[106]

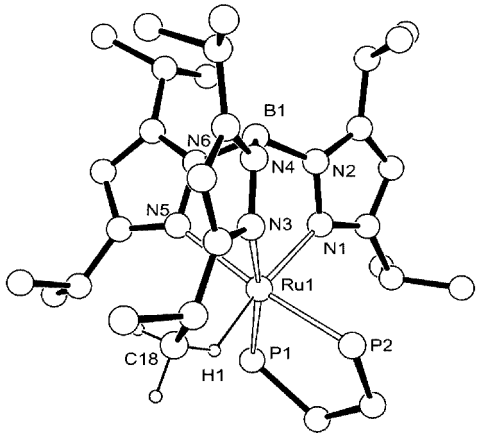

Figure 19. Molecular structure of the cationic complex $[TpiPrRu(dppe)]^+$; the phenyl rings of the dppe ligand have been omitted; the distance Ru···H^{agosti} is 1.83(6) A.

3.3 Osmium Complexes

To date, no stable compound of the type $[(C_5R_5)Os(L)_2]^+$ has been reported. Phosphane complexes $[(C_5R_5)Os(P)_2]^+$ can be generated in situ, but these are extremely reactive and easily undergo metallation reactions furnishing 18-electron organoosmium(IV) species. Thus, $[CpOsCl(PiPr_3)(PR_3)]$ (PR_3 = $PiPr_3$, PPh_3) dissociates its chloride ligand in methanol or acetone, and the resulting unsaturated metallic

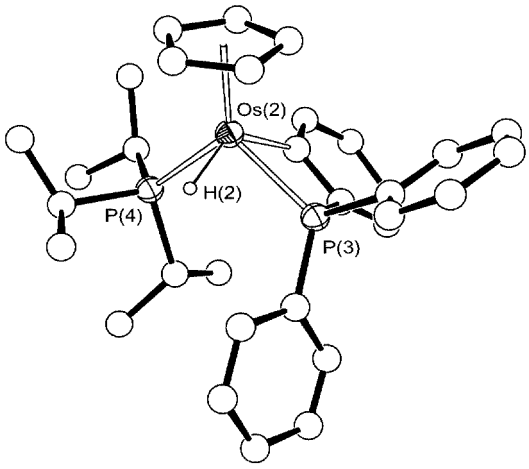

Figure 20. Molecular structure of the Os^{IV} metallated complex $[CpOsH(C_6H_4PPh_2)(PiPr_3)]^+$

fragment is capable of activating a methyl or phenyl C−H bond of a phosphane ligand to afford either $[CpOsH\{CH_2CH(CH_3)PiPr_2\}(PiPr_3)]^+$,[65] or $[CpOsH\{(C_6H_4)PPh_2\}(PiPr_3)]^+$.[107] The X-ray crystal structure of $[CpOsH\{(C_6H_4)PPh_2\}(PiPr_3)][PF_6]$ has been determined (Figure 20).[107]

In a similar fashion, the labile triflate complex $[CpOs(\eta^1\text{-}(O)\text{-}CF_3SO_3)(PPh_3)_2]$, generated by reaction of $[CpOsBr(PPh_3)_2]$ with $AgCF_3SO_3$ in toluene, undergoes spontaneous metallation both in solution and in the solid state furnishing the Os^{IV} derivative $[CpOsH\{(C_6H_4)PPh_2\}(PPh_3)][CF_3SO_3]$.[67]

Further proof of the extreme reactivity of the moieties $[(C_5R_5)Os(P)_2]^+$ comes from the fact that the fragment $\{[Cp^*Os(dmpm)]^+\}$ [dmpm = 1,2-bis(dimethylphosphano)-methane], generated in situ, has been shown to bind CH_4. The authors claimed a σ-bound methane molecule as an intermediate for hydrogen scrambling of the hydride into the methyl group in $[Cp^*OsH(CH_3)(dmpm)]^+$.[108]

Given the strong tendency displayed by the fragments $\{[(C_5R_5)Os(P)_2]^+\}$ to undergo oxidative addition reactions, the formation of Os^{IV} alkynylhydrido complexes is much easier than in ruthenium complexes. Thus, the reaction of $[CpOsCl(PiPr_3)_2]$ with $TlPF_6$ and the appropriate alkyne or alkynol in acetone/dichloromethane yields the alkynylhydrido derivatives $[CpOsH(C{\equiv}CR)(PiPr_3)_2][PF_6]$ [R = Ph, Cy, C(OH)MePh, $C(OH)Ph_2$].[109] However, at variance with their ruthenium homologues, these Os^{IV} alkynylhydrido complexes are stable species which do not rearrange into their vinylidene isomers.

4. Conclusion

Coordinatively unsaturated half-sandwich complexes of Fe, Ru and Os are very reactive species. However, with the proper combination of electron donating capabilities and steric protection of the co-ligands, the isolation of 16-electron complexes of type $[(C_5R_5)MX(L)]$ or $[(C_5R_5)M(L)_2]^+$ is possible in some cases. These species display two-legged

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

piano-stool structures which exhibit different degrees of pyramidalization. These structures have been rationalised by means of several theoretical approaches, namely EHMO, TSC and DFT. The reactivity patterns of the unsaturated complexes change steadily from iron to osmium through ruthenium, with an increase in the tendency to undergo oxidative addition reactions to attain 18-electron configuration. From the knowledge of the correlations structure-reactivity of these species it should be possible in the future to develop new catalytic applications in C−C bond formation reactions such as alkyne oligomerisation or olefin polymerisation.

Functionalization of Polyoxometalates by a Negatively Charged Bridging Ligand: The Dimeric $[(SiW_{11}O_{39}Ln)_2(\mu\text{-}CH_3COO)_2]^{12-}$ (Ln = Gd^{III}, Yb^{III}) Complexes

Pierre Mialane,*[a] Anne Dolbecq,[a] Eric Rivière,[b] Jérôme Marrot,[a] and Francis Sécheresse[a]

Keywords: Coordination chemistry / Lanthanides / Magnetic properties / Polyoxometalates

The possibility of coupling lacunary polyoxometalates through a cationic center present in the vacancy by negatively charged organic ligands is demonstrated for the first time by single-crystal X-ray diffraction. The structure of the dimeric $K_{12}[\{Yb(\alpha\text{-}SiW_{11}O_{39})(H_2O)\}_2(\mu\text{-}CH_3COO)_2]\cdot 38H_2O$ complex, where two acetato ligands connect the ytterbium centers in a (η^2, μ-1,1) fashion, is reported. Using gadolinium instead of ytterbium, both the isostructural dimeric compound $K_{12}[\{Gd(\alpha\text{-}SiW_{11}O_{39})(H_2O)\}_2(\mu\text{-}CH_3COO)_2]\cdot 38H_2O$ and the mononuclear sandwich complex $[Gd(SiW_{11}O_{39})_2]^{13-}$ can be selectively isolated, depending on the synthetic conditions. The magnetic properties of the dimeric gadolinium complex are presented. The influence of the nature of the rare-earth metal on the final compound is further highlighted by the fact that when praseodymium is used as the rare-earth element, only the sandwich compound can be obtained.

Introduction

Polyoxometalates (POMs) have definite sizes and shapes and resemble discrete fragments of metal-oxide structures.[1] They are especially valuable for studies in diverse areas of current interest, which include medicine, catalysis and magnetism.[2] Among the wide variety of POMs, the Keggin series has been the most studied. These complexes have the general formula $\{XM_{12}O_{40}\}$, where X is the central atom (X = Si^{4+}, P^{5+}, As^{5+}, etc.) and M is a metal in a high oxidation state (M = $W^{5+/6+}$, $Mo^{5+/6+}$, $V^{4+/5+}$, etc.). They are usually synthesized in acidic aqueous media. The mono-, di- and trivacant species, corresponding to the formal removal of one, two or three metal centers, respectively, are successively obtained when the pH of the solution is increased. The resulting vacancies can be filled by addition of rare-earth or transition-metal cations. The vacant POM acts, for each atom incorporated in the vacancies, as a tetradentate ligand for rare-earth metals or a pentadentate ligand for transition metals. While the coupling of transition-metal or rare-earth centers coordinated to polydentate organic ligands through negatively charged bridging species (such as acetate, oxalate, squarate, phenolate, etc.) has been widely explored and has led to one of the largest family of inorganic compounds, analogous connection through either Ln^{3+} or transition-metal cations$^{2+/3+}$ present in the vacancies of POMs has not been observed. Polymeric polyoxometalate complexes have then been mainly obtained by acid-base condensation.[3] More recently, connections of the tetracapped $[\varepsilon\text{-}H_4PMo_{12}O_{40}\{La(H_2O)_4\}_4]^{5+}$ polyoxocations by carboxylates, affording multidimensional materials, have been made successfully.[4]

This lack of reactivity of polyoxoanions toward negatively charged organic ligands is mainly due to the following three characteristics of these species: (1) rare-earth- or transition-metal- substituted POMs are generally highly negatively charged, and then connection to bridging anionic ligands is not favored; (2) when a transition metal is used, as the POM acts as a pentadentate ligand, only one coordination site is available, preventing reactivity with chelating ligands; (3) due to the steric hindrance of POMs, bridging of subunits by relatively large ligands is unlikely. Nevertheless, we have developed a synthetic approach which has allowed us to overcome these difficulties. First, as the negative charge of a POM decreases with the number of vacancies, we have started our study considering a monovacant POM. Secondly, rare-earth cations have been preferred to transition-metal cations. Indeed, considering that the lanthanides have higher coordination numbers than transition metal cations, linkage to organic ligands must be facilitated. Finally, acetate has been chosen as the bridging agent, considering both its small size and its high affinity for rare-earth centers. We present here the structural characterization of compound $K_{12}[\{Yb(\alpha\text{-}SiW_{11}O_{39})(H_2O)\}_2(\mu\text{-}$

$CH_3COO)_2]\cdot 38H_2O$, a unique di-μ-acetato polyoxometalate complex. The influence of the size of the rare-earth metal and of the nature of the synthetic media is discussed. Magnetic properties of the isostructural $K_{12}[\{Gd(\alpha\text{-}SiW_{11}O_{39})(H_2O)\}_2(\mu\text{-}CH_3COO)_2]\cdot 38H_2O$ complex are presented.

Results and Discussion

It has been shown recently that $[\alpha\text{-}SiW_{11}O_{39}]^{8-}$ {written below as $[SiW_{11}O_{39}]^{8-}$} reacts with rare-earth metals to afford solid-state one- or two-dimensional compounds.[5] These compounds dissociate in water leading to molecular species, of general formula $[Ln(SiW_{11}O_{39})(H_2O)_x]^{5-}$. Dissolution with heating of the precursor $K_5[Yb(SiW_{11}O_{39})(H_2O)_2]\cdot 24H_2O$ in 2 M acetate buffer has afforded crystals of the dimeric complex $K_{12}[\{Yb(SiW_{11}O_{39})(H_2O)\}_2(\mu\text{-}CH_3COO)_2]\cdot 38H_2O$ (**1**; Figure 1). In **1**, each ytterbium ion is eight-coordinate, adopting a distorted Archimedean antiprism geometry (pseudo-D_{4d}), with one $[SiW_{11}O_{39}]^{8-}$ entity acting as a tetradentate ligand and with a terminal water molecule. The remaining three coordination sites are occupied by two oxygen atoms of the bidentate-bridging acetate and one acetato-oxygen atom from the other $\{(Yb(SiW_{11}O_{39})(H_2O))(\mu\text{-}CH_3COO)_2\}$ subunits. The ytterbium ions are therefore doubly bridged by two (η^2, μ-1,1)-acetate ligands, separated by a distance of 4.085(18) Å. This connection mode has been previously encountered for two ytterbium dimers where each rare-earth center is coordinated to two cyclopentadienyl ligands, with intramolecular Yb−Yb lengths similar to that found in **1** (d_{Yb-Yb} = 3.905 and 3.930 Å).[6] The Yb−O lengths are divided into three groups, corresponding to the three different types of oxygen atoms present in the coordination sphere of the rare-earth metal [$d_{Yb-O(POM)}$ = 2.255(2)−2.289(1) Å; d_{Yb-OH_2} = 2.342(14) Å; $d_{Yb-O(Ac)}$ = 2.420(7)−2.448(4) Å]. The structure of complex **1** can be compared to the two previously reported dimeric Dawson polyoxometalates $[Ln^{III}(\alpha\text{-}n\text{-}P_2W_{17}O_{61})]^{7-}$ (Ln = Ce, n = 1; Ln = Eu, n = 2).[7] In both cases, the absence of exogenous ligands provokes the connection of each lanthanide center to the two $[P_2W_{17}O_{61}]$ subunits. Moreover, the rare-earth cations are not directly bridged with long Ln−Ln lengths [d_{Ce-Ce} = 6.0803(4) and d_{Eu-Eu} = 6.600(1) Å].

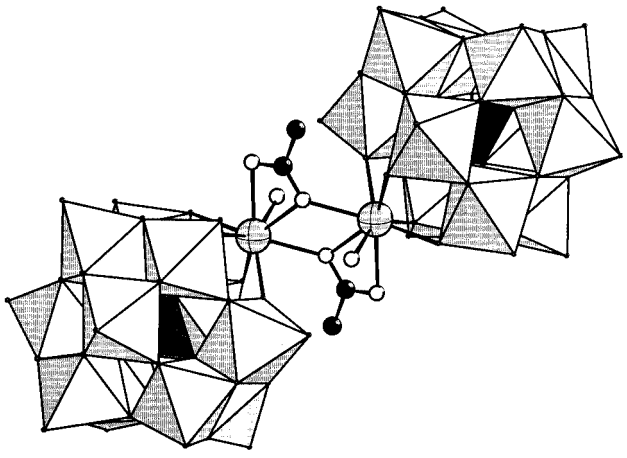

Figure 1. Polyhedral representation of complex $[\{Yb(\alpha\text{-}SiW_{11}O_{39})(H_2O)\}_2(\mu\text{-}CH_3COO)_2]^{12-}$ in **1**; grey crosshatched circles, Yb; white circles, O; light gray octahedra, $\{WO_6\}$; black tetrahedra, $\{SiO_4\}$

Syntheses in similar conditions have been performed replacing the ytterbium precursor by the related praseodymium complex **2a**. The IR spectrum of the obtained compound **2b** indicates the absence of an acetato ligand. A single-crystal X-ray diffraction study revealed that compound **2b** is the sandwich complex $K_{13}[Pr(SiW_{11}O_{39})_2]\cdot 35H_2O$, which structure has been previously postulated by Blasse et al.[8] by analogy with the known structure of $Cs_{12}[U(GeW_{11}O_{39})_2]$.[9] In **2b**, the Pr^{3+} cation is in an antiprismatic environment, coordinated to four oxygen atoms of each $[SiW_{11}O_{39}]^{8-}$ subunit [$d_{Pr-O(POM)}$ = 2.421(1)−2.518(2) Å]. Analogously, anion $[Gd(SiW_{11}O_{39})_2]^{13-}$ was obtained from heating a solution of $K_5[Gd(SiW_{11}O_{39})]\cdot 25H_2O$ in a 2 M acetate buffer. An alternative synthetic pathway was conducted to obtain the gadolinium acetato species. A concentrated acetate buffering solution was added to a solution of the gadolinium precursor dissolved in hot water and cooled to room temperature, until a 1 M acetate buffer solution was obtained. A microcrystalline compound **3** containing acetato ligands as shown by IR spectroscopy was isolated after slow evaporation. Comparison of the simulated diffraction powder pattern of **1** with the experimental X-ray diffraction powder pattern of **3** showed that **1** and **3** are isostructural. If the buffer concentration is adjusted to 2 M, the sandwich gadolinium complex $[Gd(SiW_{11}O_{39})_2]^{13-}$ is recovered. It must be noted that it has not been possible to isolate the praseodymium dimeric compound, while the ytterbium sandwich complex has never been obtained even in highly concentrated buffer solutions. It can then be concluded that as the atomic radius of the rare-earth metal decreases, the dimeric $[\{Ln(SiW_{11}O_{39})\}_2(\mu\text{-}CH_3COO)_2]^{12-}$ is preferentially formed, while an increase of the acetato buffer concentration favors the formation of the sandwich $[Ln(SiW_{11}O_{39})_2]^{13-}$ complex. It is not possible at this stage to rationalize the two observed tendencies, but clearly, this indicates that considerations on the affinity of rare-earth cations for carboxylato ligands, which increases when the size of the lanthanide decreases, are not sufficient to elucidate the reaction pathway.

The magnetic properties of $K_{12}[\{Gd(\alpha\text{-}SiW_{11}O_{39})(H_2O)\}_2(\mu\text{-}CH_3COO)_2]\cdot 38H_2O$ have been studied. The thermal dependence (χ_{MT}) of **3** is shown in Figure 2. The $\chi_M T$ curve follows a Curie law from 300 K ($\chi_M T$ = 16.2 $cm^3\cdot mol^{-1}\cdot K$) to 50 K, and then decreases from 50 K to 2 K ($\chi_M T$ = 14.6 $cm^3\cdot mol^{-1}\cdot K$). This behavior is characteristic of an antiferromagnetic coupling, in agreement with the previously reported homopolynuclear gadolinium complexes, with the exception of the dimeric Gd^{3+} salicylic complex reported by Costes et al., where the lanthanide centers were found to be ferromagnetically coupled.[10] As Gd^{3+} has an $^8S_{7/2}$ ground state, the $\chi_M T = f(T)$ curve can be fitted considering the HDVV isotropic spin Hamiltonian

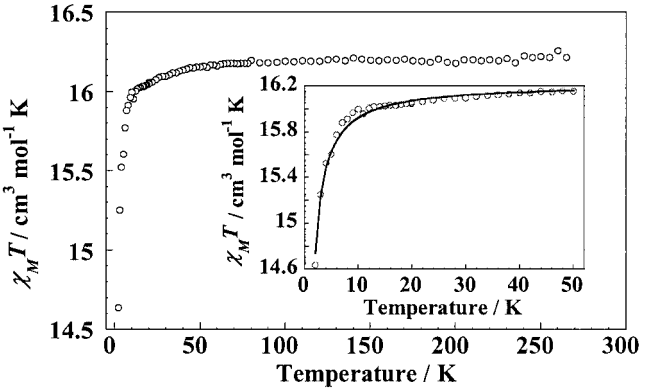

Figure 2. $\chi_M T$ per mol of compound $K_{12}[\{Gd(\alpha\text{-}SiW_{11}O_{39})(H_2O)\}_2(\mu\text{-}CH_3COO)_2]\cdot 38H_2O$ (**2**) as a function of temperature between 300 and 2 K; inset: $\chi_M T = f(T)$ between 300 and 2 K; the solid line was generated from the best fit parameters given in the text

$H = -JS_{Gd1}\cdot S_{Gd2}$, with $S_{Gd1} = S_{Gd2} = 7/2$. An excellent fit is found (Figure 2) for $J = -0.02\ cm^{-1}$ and $g = 2.02$, with an agreement factor R equal to 2.0×10^{-6} $\{R = [\Sigma(\chi_M T_{calcd.} - \chi_M T_{obsd.})^2/\Sigma(\chi_M T_{obsd.})^2]\}$. This J value is close but slightly lower than for the two previously reported dinuclear gadolinium complexes ($J = -0.05$ and $-0.21\ cm^{-1}$).[11] Nevertheless, due to the lack of structural and magnetic data, it is not possible to propose magneto-structural correlations at the moment.

Connection through Ln^{3+} or transition-metal cations$^{2+/3+}$ located in the POM vacancies has therefore been achieved. It should be noted that such dimeric lanthanide polyoxometalate compounds allow a highly accurate determination of the magnetic exchange parameters, as the Ln_2 cores are well isolated from each other due to the steric hindrance of the diamagnetic POM ligands. The magnetic study of dimeric analogous lanthanide complexes with rare-earth metals possessing a ground state with first-order orbital momentum must be performed. The reactivity of $[Ln(\alpha\text{-}SiW_{11}O_{39})(H_2O)_2]^{5-}$ ($Ln = Gd^{3+}$, Yb^{3+}) precursors with more sophisticated negatively charged organic ligands is under investigation.

Experimental Section

Synthesis: Compounds $K_5[Yb(SiW_{11}O_{39})(H_2O)_2]\cdot 24H_2O$ and $K_5[Gd(SiW_{11}O_{39})]\cdot 25H_2O$ have been prepared as described previously, for the preparation of the cesium salt[5b] but using KCl instead of CsCl. $K_5[Pr(SiW_{11}O_{39})]\cdot 26H_2O$ **2a** was prepared following the procedure described for the ytterbium compound, but using $PrCl_3\cdot 6H_2O$ instead of $YbCl_3\cdot 6H_2O$. The degree of hydration for the three precursors was determined by TGA.

$K_{12}[\{Yb(SiW_{11}O_{39})(H_2O)\}_2(\mu\text{-}CH_3COO)_2]\cdot 38H_2O$ (1): $K_5[Yb(SiW_{11}O_{39})(H_2O)_2]\cdot 24H_2O$ (350 mg, 0.1 mmol) is dissolved in potassium acetate buffer (10 mL, 2 M) and stirred at 60 °C for 1 h. After cooling to room temperature, the solution was left to evaporate. After a few days, colorless parallelopipedes of **1** were obtained. Yield: 220 mg (68 %). $C_4H_{86}K_{12}O_{122}Si_2W_{22}Yb_2$ (7002.16): calcd. Yb 4.94, W 57.76, K 6.70, C 0.68; found Yb 4.95, W 57.78, K 6.90, C 0.86. IR: $\tilde{\nu}$ = 1618 cm^{-1} (m), 1537 (m), 1453 (m), 1007 (m), 951 (s), 915 (s), 884 (s), 820 (s), 790 (s), 703 (s), 681 (s), 541 (m), 523 (m).

$K_{13}[Pr(SiW_{11}O_{39})_2]\cdot 35H_2O$ (2b): Compound **2b** was synthesized following the procedure described for **1** but with $K_5[Pr(SiW_{11}O_{39})]\cdot 26H_2O$ instead of $K_5[Yb(SiW_{11}O_{39})(H_2O)_2]\cdot 24H_2O$. After a few days, large pale green parallelepipedes of **2b** were obtained. Yield: 130 mg. $H_{70}K_{13}O_{113}PrSi_2W_{22}$ (6628.09): calcd. Pr 2.11, W 60.69, K 7.63; found Pr 1.90, W 60.77, K 7.53. IR: $\tilde{\nu}$ = 1619 cm^{-1} (m), 1005 (m), 948 (s), 906 (s), 891 (s), 827 (s), 765 (s), 720 (s), 545 (m), 526 (m), 482 (m).

$K_{12}[\{Gd(SiW_{11}O_{39})(H_2O)\}_2(\mu\text{-}CH_3COO)_2]\cdot 38H_2O$ (3): $K_5[Gd(SiW_{11}O_{39})(H_2O)_2]\cdot 24H_2O$ (350 mg, 0.1 mmol) was dissolved in water (5 mL) and heated to 60 °C. The resulting solution was cooled to room temperature. Potassium acetate buffer (5 mL, 2 M) was added and the solution left to evaporate. After a few days, colorless parallelepipedes of **3** were obtained. Yield: 170 mg (52 %). $C_4H_{86}Gd_2K_{12}O_{83}W_{22}$ (6290.40): calcd. Gd 4.50, W 57.90, K 6.72, C 0.69; found Gd 4.48, W 57.38, K 7.23, C 0.90. IR: $\tilde{\nu}$ = 1624 cm^{-1} (m), 1530 (m), 1453 (m), 999 (m), 955 (s), 906 (s), 889 (s), 812 (s), 790 (s), 755 (m), 703 (m), 693 (m), 678 (m), 543 (m), 523 (m).

The Role of Spacers between Carboxylate Groups in Self-Assembly Process: Syntheses and Characterizations of Two Novel Cadmium(II) Complexes Derived from Mixed Ligands

Ruihu Wang,[a] Maochun Hong,*[a] Daqiang Yuan,[a] Yanqiong Sun,[a] Lijin Xu,[b] Junhua Luo,[a] Rong Cao,[a] and Albert S. C. Chan[b]

Keywords: Cadmium / Bridging ligands / X-ray diffraction / Polymers / Self assembly

Two novel cadmium(II) coordination polymers, $[Cd_2(bpda)_2(dpe)]_n$ (**1**) and $[Cd_2\{(R)\text{-Hdmpa}\}_2\{(S)\text{-Hdmpa}\}_2(dpe)_3]_n$ (**2**), [H_2bpda = 1,1′-biphenyl-3,3′-dicarboxylic acid, H_2dmpa = 6,6′-dimethyl-1,1′-biphenyl-2,2′-dicarboxylic acid, and dpe = 1,2-di(4-pyridyl)ethylene] have been prepared by hydrothermal reactions of both $Cd(NO_3)_2{\cdot}4H_2O$ and dpe with H_2bpda and H_2dmpa, respectively. **1** is a threefold interpenetrating three-dimensional coordination network composed of paddle-wheel tetracarboxylate dicadmium(II) units bridged by dpe. **2** affords an example of ligand self-discrimination in an assembly process, in which dpe connects the [Cd{(*R*)-Hdmpa}{(*S*)-Hdmpa}] building units to generate a one-dimensional ladder structure.

Introduction

The prospect of generating new materials with interesting structures and technologically useful functions provides significant motivation for the recent surge of research interest in organic-inorganic supramolecular frameworks.[1,2] The construction of metal−organic polymeric networks has achieved considerable progress in supramolecular chemistry and material science due to their intriguing structural diversities and potential applications in molecular adsorption, ion exchange, molecular recognition and heterogeneous catalysis.[2−5] Molecular self-assembly based on the principle of crystal engineering has proved to be efficient for the formation of these architectures. Some structural motifs with specific topologies and functions can, to a certain extent, be predicted through dominating the assembly and orientation of individual building blocks. For example, the groups of Yaghi,[3] Zaworotko,[4] and others[5] have developed a strategy to construct extended porous structures using rigid dicarboxylate ligands with different spacers and metal clusters of known geometries. However, the mechanism of molecular self-assembly is still unclear, and predictability and tinability of the exact structures of the assembly products are difficult. Thus, understanding the factors that govern the assembly process is crucial to technological development. Such factors include: the role of spacers between coordination sites in organic bridging ligands and the coordination geometry of metal ions;[6] the formation and role of the reaction precursors;[7] the formation of interpenetration and/or interdigitation lattices vs. the inclusion of solvent or guest molecules;[8] and the formation of the convergent products and the divergent products.[9]

It is well-known that the design and synthesis of bridging ligands containing appropriate coordination sites linked by spacers with specific orientations are especially crucial to the construction of desirable frameworks. By closely controlling the properties of the spacers, such as the shape, functionality, flexibility, length, and symmetry, a remarkable class of materials containing diverse architectures and functions can be obtained.[2−6] The coordination of multipyridine and multi-carboxylate ligands to metal centers has proved to be an excellent tool in the assembly process and has been highly influenced by the structural characterizations of linker groups. Moreover, as the length of organic spacer increases, interpenetration and/or interdigitation has been commonly adopted by nature in order to avoid the formation of large open channels or cavities.[10] The combination of metal ions and mixed bridging ligands containing carboxylate and pyridyl groups can allow for the formation of coordination networks possessing different structures and functional properties.[11,12] The exo-bidentate pyridyl

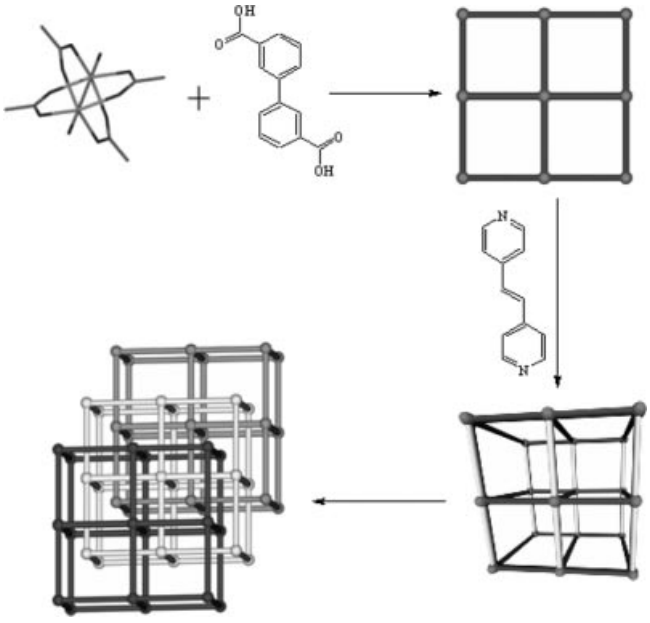
derivative, *trans*-1,2-di(4-pyridyl)ethylene (dpe), possesses several peculiar characteristics when used in the construction of the extended networks: 1) the double bond in the ligand can result in conformational rigidity;[13] 2) the delocalized π-system can be applied as potential electron propagating components;[14] 3) the long spacer between coordination sites can result in interpenetration and/or interdigitation;[14,15] and 4) this ligand may be used as a reaction precursor.[7a,16] However, supramolecular architectures constructed by dpe, and ligands with di- or multi-carboxylate groups, have seldom been reported to date.[16,17] Very recently, we have reported a three-dimensional pillared compound consisting of dodecanuclear cadmium(II) macrocycles $[\{Cd_2(dpa)(pya)\}_6(pya)_6(dpe)_3]_n$ (H_2dpa = diphenic acid and Hpya = isonicotinic acid),[16] in which dpe not only serves as a μ-bridge, but also acts as the precursor of pya. To systematically investigate the effects of the steric hindrance of the spacers between the carboxylate coordination sites on dpe and the assembly products, we have designed two new ligands, 1,1′-biphenyl-3,3′-dicarboxylic acid (H_2bpda) and 6,6′-dimethyl-1,1′-biphenyl-2,2′-dicarboxylic acid (H_2dmpa). The steric hinderance between the two carboxylate groups of Bpda is smaller than for H_2dpa, and this provides a greater degree of freedom for the twisting of the two phenyl rings in Bpda relative to that in H_2dpa can be more freely twisted than H_2dpa. However, not only is the steric hinderance between the two carboxylate groups of racemic dmpa greater than for H_2dpa, but dmpa can also formproducts of ligand self-discrimination or self-recognition. Herein, we wish to report the syntheses and characterizations two novel cadmium(II) complexes, $[Cd_2(bpda)_2(dpe)]_n$ (**1**), and $[Cd_2\{(R)\text{-Hdmpa}\}_2\{(S)\text{-Hdmpa}\}_2(dpe)_3]_n$ (**2**).

Result and Discussion

Synthesis and Characterization

Diphenic acid (H_2dpa) is an excellent bridging ligand for the construction of metallomacrocyclic and helical frameworks[16,18] owing to the steric hindrance between the 2,2′-positioned carboxylate groups in the assembly process, which results in a great distortion of the two phenyl rings about the central bond in dpa. Bpda and dmpa are dicarboxylate ligands that are similar to dpa. In bpda, the two carboxylate groups in the 3,3′-positions have a smaller effect on the distortion of the diphenyl spacer about the central bond in the assembly process. Dmpa is an axially chiral ligand, in which two phenyl rings cannot freely rotate about the central bond and therefore can produce two different conformations, (*R*)-dmpa and (*S*)-dmpa. Hence, it is interesting to investigate the assembly process of H_2bpda or H_2dmpa with dpe and $Cd(NO_3)_2{\cdot}4H_2O$ under the same reaction conditions as those used in the formation of $[\{Cd_2(dpa)(pya)\}_6(pya)_6(dpe)_3]_n$.[16]

The hydrothermal reaction of H_2bpda, dpe, $Cd(NO_3)_2{\cdot}4H_2O$, and NaOH, with a molar ratio of 2:2:2:3, in H_2O at 180 °C for 3 days, produced a threefold interpenetrating three-dimensional coordination polymer consisting of the dimeric cadmium−tetracarboxylate secondary building units (SBUs) bridged by dpe. Dpe has not been hydrolyzed and only serves as the axis linkers of the SBUs so as to extend the two-dimensional $[Cd_2(bpda)_2]_n$ layer into a three-dimensional framework (Scheme 1). The hydrothermal reaction of dpe, the racemic mixture of (*R*)-H_2dmpa and (*S*)-H_2dmpa, and $Cd(NO_3)_2{\cdot}4H_2O$ under the same conditions as those used in the preparation of **1** afforded the colorless crystals of **2**, in which Hdmpa undergoes ligand self-discrimination and acts as a chelating mono-bidentate ligand in the formation of the building units of [Cd{(*R*)-Hdmpa}{(*S*)-Hdmpa}].



Scheme 1. Construction of the threefold interpenetrating three-dimensional framework in **1**

Thermogravimetric analysis (TGA) was performed on polycrystalline samples under a nitrogen atmosphere. No chemical decomposition was observed up to 390°C and 300 °C for **1** and **2**, respectively. The two most significant weight losses occurred between 440 and 730 °C for **1**, and between 350 and 430 °C for **2**, and are attributed to the complete decomposition of the samples to cadmium(II) oxide. Considering the formation of stoichiometric amounts of CdO, this conclusion is supported by 29.7% (above 820 °C) and 13.2% (above 540 °C) of the residues for **1** and **2**, respectively, which are in accordance with the expected values (28.9% for **1** and 13.9% for **2**).

Structural Description

$[Cd_2(bpda)_2(dpe)]_n$ (1)

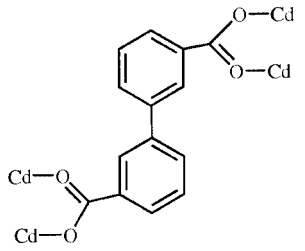
space group $P2_1/c$. As shown in Figure 1(a), the geometry around the Cd^{II} center is square-pyramidal and the metal center is coordinated by four oxygen atoms from different bpda ligands in the equatorial plane and a nitrogen atom from dpe at the axial position. Four carboxylate groups from different bpda ligands form a bridge between the two cadmium(II) centers in a *syn-syn* bidentate mode, forming a paddle-wheel secondary building unit (SBU). The Cd−Cd distance of 3.0428(14) Å suggests that there is no significant Cd^{II}−Cd^{II} interaction in the SBU (the sum of the van der Waals radii of Cd^{II} is 3.04 Å[19]); however, this distance is significantly shorter than those in discrete dimeric cadmium−tetracarboxylate complexes (3.278−3.452 Å).[20]



Scheme 2. Coordination mode of bpda in **1**

Bpda acts as a bis-bidentate bridging ligand by coordinating to four different Cd^{II} centers (Scheme 2). The dihedral angle between the two phenyl rings in bpda is 34.8°. The

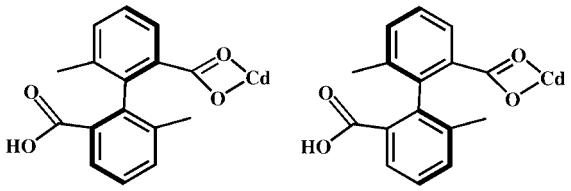
dihedral angles of 3.6 and 14.5° between the carboxylate groups and the linking phenyl rings allow for the formation of paddle-wheel SBUs.[21] The SBUs are inter-connected by bpda forming a two-dimensional layer with a Cd···Cd separation across bpda of 13.481 Å. To the best of our knowledge, this is the first extended structure constructed from cadmium−tetracarboxylate SBUs. The dpe ligands are *trans*-coordinated to the SBUs and form axis linkers with a Cd−N distance of 2.237(9) Å and Cd−Cd−N angle of 178.0(3)°. Thus, dpe can serve as a pillar between two adjacent two-dimensional layers thus generating a three-dimensional open framework (Figure 1,b). The Cd···Cd separation across dpe is 13.809 Å. It should be emphasized that there is a large void within the cuboidal units owing to the longer spacers between the coordination sites in dpe and bpda, but no enclathration of solvent or guest molecules is observed within the larger units. Thus, two identical frameworks fill the void in another framework, which results in the formation of a threefold interpenetrating framework (Figure 1, c).

It is worthy noting that the cuboidal units in **1** are not regular due to the fact that the coordination sites are off-axis in dpe and bpda. Klinowski et al.[11a] has recently reported a threefold interpenetrating three-dimensional modular coordination network using the more flexible biphenyl-4,4′-dicarboxylate and 1,2-bis(4-pyridyl)ethane mixed ligands, in which the cuboidal units are highly distorted owing to the high flexibility of spacers between the coordination sites. However, Chen et al.[11b] has reported a twofold interpenetrating three-dimensional structure using the mixed ligands 4,4′-bipyridine and terephthalate, in which the cuboidal units are regular due to the rigidity of the bridging ligands. This shows that the spacers between coordination sites have an important effect on the construction of the structural framework.

$[Cd_2\{(R)\text{-Hdmpa}\}_2\{(S)\text{-Hdmpa}\}_2(dpe)_3]_n$ (2)

Compound **2** is a one-dimensional ladder structure and crystallizes in the monoclinic space group $P2_1/c$. As shown in Figure 2(a), the Cd^{II} center has a distorted pentagonal bipyramidal geometry, and is coordinated by two chelating carboxylate groups from different conformational Hdmpa and three nitrogen atoms from different dpe ligands. The ligands (*R*)-Hdmpa and a (*S*)-Hdmpa are coordinated by the Cd^{II} center, which suggests an assembly process of ligand self-discrimination, therefore, no optical activity is expected in this structure. Three dpe ligands form a slightly distorted T-shaped arrangement at the seven-coordinate Cd^{II} center [N(1)−Cd−N(3) 85.0(2)°; N(2A)−Cd−N(3) 96.4(2)°; N(1)−Cd−N(2A) 177.5(2)°], in which two nitrogen atoms (N1 and N2) stand at the apical positions, the remaining nitrogen atom (N3) and four carboxylate oxygen atoms (O31, O32, O51, and O52) occupy the equatorial positions. The Cd^{II} center lies in the plane defined by the equatorial atoms, with a deviation of 0.0155 Å. Hdmpa



(*R*)-Hdmpa (*S*)-Hdmpa

Scheme 3. Coordination modes of (*R*)-Hdmpa and (*S*)-Hdmpa in **2**

(Scheme 3) serves as a chelating mono-bidentate ligand which is coordinated through the carboxylate group to the Cd^{II} center; carboxylic groups do not take part in coordination and do not interact with the metal centers or other ligands, therefore, this is an unusual feature of di- or multicarboxylic ligands. The dihedral angles between the two phenyl rings in (*R*)-Hdmpa and (*S*)-Hdmpa are 85.6 and 85.1°, respectively, and hence they are approximately perpendicular to each other. However, the dihedral angles between the carboxylate groups and the linking phenyl rings in (*R*)-Hdmpa and (*S*)-Hdmpa are 58.8 and 59.4°, and 29.2 and 56.1°, respectively, which are significantly larger than those in **1** and are unfavorable for the formation of the paddle-wheel SBU.[21] Dpe acts as a *trans* exo-bidentate ligand and links the [Cd{(*R*)-Hdmpa}{(*S*)-Hdmpa}] building units to form an infinite ladder structure (Figure 2, b). The methyl groups in Hdmpa prevent the formation of an extended motif. The adjacent Cd···Cd distances along the side dpe and the inner dpe are 14.069 and 13.893 Å, respectively. Owing to a longer spacer in the dpe ligand, there is a large void within the rhombohedral grids, which have been effectively filled by interdigitation of Hdmpa from the adjacent one-dimensional ladders in the *ac* plane (Figure 2, c).

Conclusions

The hydrothermal reactions of $Cd(NO_3)_2{\cdot}4H_2O$ and 1,2-di(4-pyridyl)ethylene (dpe) with dicarboxylic ligands with different steric properties, 1,1′-biphenyl-3,3′-dicarboxylic acid (H_2bpda) and 6,6′-dimethyl-1,1′-biphenyl-2,2′-dicarboxylic acid (H_2dmpa), under the same reaction conditions, produced two novel cadmium(II) coordination polymers $[Cd_2(bpda)_2(dpe)]_n$ (**1**) and $[Cd_2\{(R)\text{-Hdmpa}\}_2\{(S)\text{-Hdmpa}\}_2(dpe)_3]_n$ (**2**), respectively. In **1**, bpda and dpe link the dimeric cadmium−tetracarboxylate secondary building units (SBUs) to form a threefold interpenetrating three-dimensional coordination network. **2** is a one-dimensional ladder structure constructed from [Cd{(*R*)-Hdmpa}{(*S*)-Hdmpa}] building units and dpe bridges, and exhibits a ligand self-discrimination in an assembly process. The large void in **1** and **2** has been efficiently filled through the inter-interpenetration and inter-interdigitation of adjacent frameworks, respectively. The results show that the steric hindrance of spacers between the carboxylate coordination sites has an important effect on the coordination modes of the carboxylate groups, and different spacers between the carboxylate coordination sites can result in supramolecular architectures with different structures and functions.

Experimental Section

1,1′-Biphenyl-3,3′-dicarboxylic acid and 6,6′-dimethyl-1,1′-biphenyl-2,2′-dicarboxylic acid were synthesized according to literature methods, using 3-aminobenzoic acid and 2-amino-3-methylbenzoic acid, respectively, as staring materials.[22] 1,2-di(4-pyridyl)ethylene and 2-amino-3-methylbenzoic acid were purchased from Aldrich and used without further purification, all the other reagents were commercially available and used as purchased. The IR spectra as KBr discs were recorded on a Magna 750 FT-IR spectrophotometer. C, H, and N elemental analyses were determined on an Elementary Vario ELIII elemental analyzer. Thermal analyzes were performed using a Thermal Analyst 2100 TA Instrument and a SDT 2960 Simultaneous TGA-DTA Instrument.

Synthesis of $[Cd_2(bpda)_2(dpe)]_n$ (1): A mixture of H_2bpda (0.12 g, 0.5 mmol), dpe (0.09 g, 0.5 mmol), $Cd(NO_3)_2{\cdot}4H_2O$ (0.15 g, 0.5 mmol) and NaOH (0.03 g, 0.75 mmol), with a molar ratio of about 2:2:2:3 in H_2O (15.0 mL), was placed in a Parr Teflon-lined stainless steel vessel and heated to 180 °C for 72 h. The reaction system was then cooled at room temperature for 24 hours. A large amount of colorless crystals were obtained and collected by filtration, washed with water and dried in air. Yield: 0.06 g (54%). Elementary analysis: calcd. for $C_{20}H_{13}CdNO_4$ (444.71): calcd. C 54.13, H 2.93, N 3.16; found C 54.07, H 2.89, N 3.18%. IR (KBr pellet): $\tilde{\nu}$ = 3469 cm^{-1} (w), 3057 (w), 1686 (w), 1622 (s), 1610 (s), 1593 (s), 1568 (s), 1433 (m), 1408 (s), 1385 (s), 1301 (vw), 1263 (w), 1169 (vw), 1024 (w), 835 (w), 758 (s), 690 (m), 623 (vw), 552 (w).

Synthesis of $\{Cd_2[(R)\text{-Hdmpa}]_2[(S)\text{-Hdmpa}]_2(dpe)_3\}_n$ (2): The procedure was similar to the synthesis of compound **1**, except that H_2dmpa (0.13 g, 0.5 mmol) was used instead of H_2bpda. Yield: 0.05 g (43% based on H_2dmpa). Elementary analysis: calcd. for $C_{50}H_{39}CdN_3O_8$ (922.24): calcd. C 65.11, H 4.23, N 4.55; found C 65.05, H 4.18, N 4.57%. IR (KBr pellet): $\tilde{\nu}$ =3051 cm^{-1} (vw), 2922 (vw), 2872 (vw), 1738 (m), 1722 (m), 1606 (s), 1560 (s), 1504 (w), 1421 (s), 1406 (s), 1389 (s), 1375 (m), 1290 (w), 1142 (vw), 1070 (vw), 1012 (w), 835 (w), 775 (w), 721 (w), 554 (w).

X-ray Crystallographic Study: Intensity data for **1** and **2** were measured on a Siemens Smart CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at room temperature. All empirical absorption corrections were applied using the SADABS program.[23] The structures were solved by direct methods and refined on F^2 by full-matrix least-squares using the SHELXL-97 program package.[24] The positions of the H atoms were generated geometrically (C−H bond fixed at 0.96 Å), assigned isotropic thermal parameters, and allowed to ride on their parent carbon atoms before the final cycle of refinement. The summary of the crystal data and structure determination for **1** and **2** are listed in the Table 1. The selected bond lengths and angles for **1** and **2** are listed in the Table 2.

Crystallographic data (excluding structure factors) for the two structures have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication CCDC-212589 and -212590. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Formation and Reactivity of Gaseous Iron-Sulfur Clusters

Konrad Koszinowski,[a] Detlef Schröder,[a] and Helmut Schwarz*[a]

Dedicated to Professor Heinz Georg Wagner on the occasion of his 75th birthday

Keywords: Cluster compounds / Electron transfer / Gas-phase reactions / Iron / Sulfur

The gas-phase reactions of Fe_n^+ clusters, n = 1–6, with COS and CS_2 have been investigated by means of Fourier-transform ion-cyclotron resonance mass spectrometry. Whereas CS_2 predominantly substitutes one Fe atom, COS exclusively affords multiple sulfur transfer and thus opens a synthetic route to gaseous $Fe_nS_x^+$ clusters. In the final products such as $Fe_2S_2^+$, $Fe_3S_2^+$, and $Fe_4S_4^+$, the sulfur atoms appear to occupy multiple coordination sites much like in the analogous biogeneous iron-sulfur clusters. Bracketing experiments find $IE(Fe_2S_2)$ = 7.2±0.3 eV besides providing upper limits for $IE(Fe_3S_2)$ and $IE(Fe_4S_4)$. In accordance with the low $IE(Fe_2S_2)$, $Fe_2S_2^+$ does not activate H_2 or small hydrocarbons and only exhibits rather limited reactivity towards more reactive substrates.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Among the many functions of iron in biological systems, its involvement in redox processes is particularly important. Inter alia, electron-transfer (ET) reactions associated with photosynthesis, respiration, and nitrogen fixation rely heavily upon this transition metal. A common feature of the different enzymes mediating these processes is that their catalytically active centers are not comprised of a single iron atom but consist of several Fe atoms bound to sulfur.[1−4] The [4Fe-4S] core with its hetero-cubane structure is an especially famous example of such clusters.

Various strategies have been pursued in order to elucidate the chemical relationship between the remarkable structures of the iron-sulfur clusters and their outstanding reactivity in terms of ET. To probe the intrinsic properties of these systems, exclusion of environmental effects is warranted. This approach can be rigorously achieved by gas-phase techniques that allow a thorough investigation of the object of interest. For instance, anionic clusters of the type $Fe_nS_x^-$ have been examined by means of photoelectron spectroscopy.[5,6] In the case of their cationic counterparts, however, experiments so far have mainly centered around mononuclear systems FeS_x^+.[6−12] In a joint study with the group of Armentrout, we have recently derived thermochemical data with respect to polynuclear clusters $Fe_nS_x^+$, $n \leq 5$ and $x \leq 2$, from the kinetic energy dependences of the reactions of Fe_n^+ with COS and CS_2.[13] Although these studies provide evidence for multiple sulfur transfer, the guided-ion beam (GIB) technique applied is not the method of choice for the detailed investigation of such processes. Instead, the longer time-scale of Fourier-transform ion-cyclotron resonance mass spectrometry (FT-ICR MS) and its supreme suitability for MS^n experiments make this technique particularly adequate for the elucidation of multi-step reactions. Since it cannot compete with the GIB approach for the determination of thermochemical quantities, however, both methods are complementary. Taking advantage of this situation, the present FT-ICR study focuses on the primary and consecutive reactions between Fe_n^+ clusters, $n \leq 6$, with COS as well as CS_2. Particular attention has been paid to possible structural assignments of the evolving $Fe_nS_x^+$ ions. Moreover, the reactivity of the cluster ions $Fe_2S_2^+$, $Fe_3S_2^+$, and $Fe_4S_4^+$ has been explored briefly, with an emphasis on ET reactions and a comparison with the analogous iron-oxide clusters.

Results

Reactions with COS and CS_2

The reactions of Fe_n^+ with COS lead to stepwise sulfur transfer to the metal cluster, as shown in the reaction according to Equation (1).

$$Fe_n^+ + x\,COS \rightarrow Fe_nS^+ + CO + (x-1)\,COS \rightarrow \rightarrow Fe_nS_x^+ + x\,CO \quad (1)$$

As was established previously, mononuclear iron only accepts a single sulfur atom with an appreciable efficiency.[10] In contrast, the second sulfur transfer for Fe_2^+ is significantly faster than the first and no further reaction can be observed. Similarly, the reaction apparently stops after transfer of two S atoms in the case of Fe_3^+. For n =

[a] Institut für Chemie der Technischen Universität Berlin, Straße des 17. Juni 135, 10623 Berlin, Germany

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200300480

4 and 6, addition of four S atoms occurs whereas even $x = 5$ is reached for Fe_5^+. Although the maximum sulfur contents observed do not necessarily correspond to the ultimate level at infinite reaction times, they nevertheless imply that any possible further reactions proceed significantly less efficiently.

A more detailed analysis required a quantitative treatment. To this end, the experimental temporal ion abundances were fitted to the kinetic model defined by reaction (1). Note that the validity of this model, postulating a stepwise sulfur transfer, can safely be assumed because no termolecular reactions are feasible at the low pressures maintained. However, a minor complication arose from side reactions with contaminants in the cases of Fe_4^+ and Fe_5^+. In order to monitor the whole series of consecutive processes, reaction times up to 30 s were necessary. Thus, continuous reactions with background oxygen and water led to the accumulation of products formed by oxidative cluster degradation and hydrolysis (for $n = 4$, species such as $Fe_2O_2^+$, $Fe_3S_2^+$, and $Fe_4S_2O^+$ are indicative of such processes). To a first approximation, similar degradation or hydrolysis probabilities may be assumed for all intermediates $Fe_nS_x^+$ within a reaction series such that the neglect of the by-products should not affect the rate constants derived for the sulfur-transfer reactions themselves. Given the relatively low amounts of the by-products resulting from contamination ($\leq 30\%$ and 15% of the total ion intensity for $n = 4$ and 5, respectively), this approach indeed appears reasonable.

The results of the kinetic modeling show uniformly high efficiencies for the reactions of the clusters with $n \geq 3$ (Table 1). In these cases, the operation of substantial enthalpic or kinetic restrictions can obviously be excluded. This finding suggests lower limits for the binding energies of the iron-sulfur clusters according to $D_{298}(Fe_nS_{x-1}^+-S) \geq D_{298}(OC-S) = 308\ kJ{\cdot}mol^{-1}$, $n = 3-6$.[14]

The reactions of Fe_n^+ with CS_2 do not afford efficient sulfur transfer but are included in the present work for comparison with the GIB data. Mononuclear Fe^+ does not react with CS_2 at thermal energies.[10,11] Similarly, the reaction of Fe_2^+ exhibits a low efficiency of $\varphi = 0.01$ with simple adduct formation as the main reaction (80% branching ratio, b.r.). Doubling of the pressure (from 1 to $2{\cdot}10^{-7}$ mbar) does not change the rate constant for this process within the relative uncertainty of 10% such that irradiative rather than termolecular stabilization seems to account for the association.[15] A second reaction channel yields $Fe_2S_2^+$ (10% b.r.). Presumably, this process involves Fe_2S^+ as an intermediate that does not build up in substantial concentrations because of a rapid second sulfur transfer. See reaction in Equation (2) with $n = 2$.

$$Fe_n^+ + 2\,CS_2 \rightarrow Fe_nS^+ + CS + CS_2 \rightarrow Fe_nS_2^+ + 2\,CS \quad (2)$$

The occurrence of CS_2^+ as a third product (10% b.r.) might point to the presence of residual amounts of electronically excited Fe_2^+ because charge transfer from ground-state Fe_2^+ to CS_2 would be strongly endothermic [$IE(Fe_2) = 6.30\pm0.01$ vs. $IE(CS_2) = 10.07\pm0.01$ eV).[16,17] Note, however, that the reaction of Fe_2^+ with CS_2 is the only case where there is a possible indication of the involvement of electronically excited states. Moreover, for the presence of large amounts of excited Fe_n^+ one would not expect the observed exponential decrease of the reactant Fe_n^+ ions as is evident from linear slopes in semi-logarithmic plots. Therefore, the formation of CS_2^+ in the reaction of Fe_2^+ is rather ascribed to the presence of small amounts of an unobserved reactive intermediate. Because of the low efficiency of this reaction channel ($\varphi = 10^{-3}$), involvement of a contaminant such as O_2 cannot be excluded either.[18]

The larger clusters react much more efficiently with CS_2 ($\varphi = 0.5-0.8$). Here, the main process corresponds to substitution of one Fe atom by CS_2 [Equation (3)]. Only for Fe_3^+, reaction (2) still takes place (25% b.r.). Obviously, CS_2 binds quite strongly to the larger Fe_n^+ clusters.

$$Fe_n^+ + CS_2 \rightarrow Fe_{n-1}CS_2^+ + Fe \quad (3)$$

The same conclusion can be drawn from the consecutive reactions that efficiently lead to the mere association of one or even two further CS_2 molecules for $n \geq 4$. Since the pressures applied for the larger cluster ions were more than an order of magnitude lower than in the case of Fe_2^+, the tendency towards termolecular stabilization should be even more reduced and, therefore, cannot account for the effective relaxation. Instead, a deep potential well of the ion-molecule complex is supposed to increase the lifetime of the collision complexes, thereby facilitating their relaxation. In comparison with Fe_2^+, the higher numbers of internal degrees of freedom in the $Fe_{n-1}CS_2^+$ clusters, $n = 4-6$, also allow a faster redistribution of the energy released upon complexation and thereby raise the lifetimes of the energetic encounter complexes as well. Such phenomena are quite

Table 1. Bimolecular rate constants k and efficiencies for the reactions of Fe_n^+ with COS derived from kinetic modeling

common for the reactions of cluster ions in the highly diluted gas phase.[19]

Reactivity of $Fe_2S_2^+$

The reactivity of the smallest iron-sulfur cluster, i.e. $Fe_2S_2^+$, was investigated in some detail. Focusing on this cluster is advantageous for practical reasons because it can easily be generated in high abundance. Moreover, a comparison with the analogous $Fe_nO_x^+$ ions promised to be most revealing for the dinuclear systems because $Fe_2O_2^+$ has been studied extensively.[20,21]

$Fe_2S_2^+$ does not react with the inorganic substrates H_2, N_2, O_2, CO, CO_2, and H_2O ($\varphi < 10^{-3}$). Upon exposure to NH_3, $Fe_2S_2^+$ slowly binds up to three molecules of the neutral reagent. The determined rate constant $k = 3.8 \cdot 10^{-11}$ $cm^3 \cdot s^{-1}$ ($\varphi = 0.019$) does not show any dependence on the pressure [$p(NH_3)$ between 1 and $3 \cdot 10^{-7}$ mbar], thus again suggesting radiative rather than termolecular relaxation of the association complexes. Compared with H_2O, the enhanced reactivity of NH_3 reflects its higher basicity that leads to a stronger dative binding which in turn raises the lifetime of the energetic ion-molecule complexes, see above. Similarly, Nakajima et al. found association of NH_3 to be much more efficient than H_2O addition for larger $Fe_nS_x^+$ clusters. However, a comparison with these data should take into account that they refer to differently produced clusters such that the structural identities of the $Fe_nS_x^+$ species are not necessarily given.[6]

In view of the low reactivity of $Fe_2S_2^+$ towards inorganic molecules, one also does not expect it to readily activate hydrocarbons. Therefore, the reactions of $Fe_2S_2^+$ with alkanes were not investigated but its reactivity toward alkenes was addressed right away. Whereas exposure to 1-butene only afforded rather slow adduct formation ($\varphi = 0.04$), 1,4-cyclohexadiene was efficiently activated by $Fe_2S_2^+$ ($k = 6.3 \cdot 10^{-10}$ $cm^3 \cdot s^{-1}$, $\varphi = 0.61$). The reactivity of 1,4-cyclohexadiene is governed by its tendency towards H_2 elimination which meets expectation because the presumably concomitant formation of benzene provides a strong thermodynamic driving-force for this process. Consequently, loss of C_6H_6 constitutes the main reaction channel [reaction (4), 80% b.r.]. Note that this process corresponds to a formal reduction of the iron cluster-core. The second reaction channel (20%) results in hydro-desulfuration[22] [reaction (5)] and thus highlights the redox character of the reactions in an even more pronounced manner. It remains unclear whether the ionic product contains an intact benzene molecule or if further bond activation involving the remaining S atom has occurred.

$$Fe_2S_2^+ + C_6H_8 \rightarrow [Fe_2,S_2,H_2]^+ + C_6H_6 \quad (4)$$

$$Fe_2S_2^+ + C_6H_8 \rightarrow [Fe_2,S,C_6,H_6]^+ + H_2S \quad (5)$$

The primary products undergo efficient consecutive reactions. Whereas both $[Fe_2,S,C_6,H_6]^+$ and $[Fe_2,S_2,H_2]^+$ add one more 1,4-cyclohexadiene molecule under dehydrogenation [reactions (6) and (7)], the latter also loses two molecules of H_2 upon reaction with C_6H_8 [reaction (8), 70% b.r.]. Formally, this process regenerates the $Fe_2S_2^+$ cluster core with one added benzene ligand and thus corresponds to the reverse of the reduction in reaction 4. Apparently, the dinuclear cluster can easily switch from one oxidation state to another.

$$[Fe_2,S,C_6,H_6]^+ + C_6H_8 \rightarrow [Fe_2,S,C_{12},H_{12}]^+ + H_2 \quad (6)$$

$$[Fe_2,S_2,H_2]^+ + C_6H_8 \rightarrow [Fe_2,S_2,C_6,H_8]^+ + H_2 \quad (7)$$

$$[Fe_2,S_2,H_2]^+ + C_6H_8 \rightarrow [Fe_2,S_2,C_6,H_6]^+ + 2\,H_2 \quad (8)$$

ET Reactions

Given the well-known activity of biogeneous Fe_nS_x clusters in terms of ET, the respective behavior of their gaseous counterparts also deserves attention. Although the reactivity observed for $Fe_2S_2^+$ already provides some first indications with regard to its redox activity, further efforts are necessary to address this issue explicitly. Within FT-ICR mass spectrometry, a straightforward determination of *IE*s can be achieved by bracketing experiments. To this end, the ion of interest A^+ is exposed to substrates B with known *IE*s. Occurrence of ET indicates $IE(A) \geq IE(B)$, whereas in the absence of ET, the opposite relation should hold true as long as no kinetic barriers are associated with the ET process. The latter assumption is valid if the structure of the substrate B is not strongly changed upon ionization, i.e., in the case of favorable Franck−Condon factors that are usually observed for (substituted) arenes.

The bracketing method can be refined by consideration of the efficiency of the ET process instead of the only qualitative distinction between occurrence and nonoccurrence.[23] In the present case, however, major difficulties arose from the apparently rather low *IE*s of the Fe_nS_x clusters. In order to observe ET, substrates with similarly small *IE*s such as amino- or methoxy-substituted arenes were required. The low vapor pressures and the unfavorable pumping characteristics of these compounds severely complicate their handling in high-vacuum devices and prevent the determination of accurate absolute rate constants. Moreover, the appreciable basicity of aniline and its derivatives results in strong interactions between these reagents and the ionic clusters, thereby favoring mere association compared with ET. For larger clusters, adduct formation becomes even more important because of lifetime effects (see above) such that ET may no longer compete although it is still feasible thermochemically. Hence, the investigations with regard to ET had to be restricted to the smaller clusters $Fe_2S_2^+$, $Fe_3S_2^+$, and $Fe_4S_4^+$. Instead of the impractical measurement of absolute rate constants, the ratio between the rates of ET and adduct formation, as evidenced from the product distribution, was considered. For the stepwise decrease of the substrates' *IE*s, one expects the ratio k_{ET}/k_{add} to rise steeply from its low background level as soon as the *IE* of the substrate matches that of the Fe_nS_x cluster and the ET process becomes thermodynamically accessible. Indeed, this situation was found in the case of $Fe_2S_2^+$ where k_{ET}/k_{add} increases by more than one order of magnitude when changing the substrate from 1,4-dimeth-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

oxybenzene (IE = 7.56 eV)[17] to *N*-methylaniline (IE = 7.32 eV)[17] and then to *N*,*N*-dimethylaniline (IE = 7.12 eV, Figure 1).[17] This progression roughly suggests $IE(Fe_2S_2)$ = 7.2±0.3 eV. In the reaction with *N*,*N*-dimethylaniline, hydride transfer from the substrate to the $Fe_2S_2^+$ cluster occurs with approximately equal efficiency as ET [reaction (9)]. Like reaction (4) with 1,4-cyclohexadiene, this process demonstrates the ready uptake of two reduction equivalents by $Fe_2S_2^+$. Similarly, the hydro-desulfuration observed with *N*-methylaniline [reaction (10)] has its counterpart in reaction (5) for $Fe_2S_2^+$ with 1,4-cyclohexadiene.

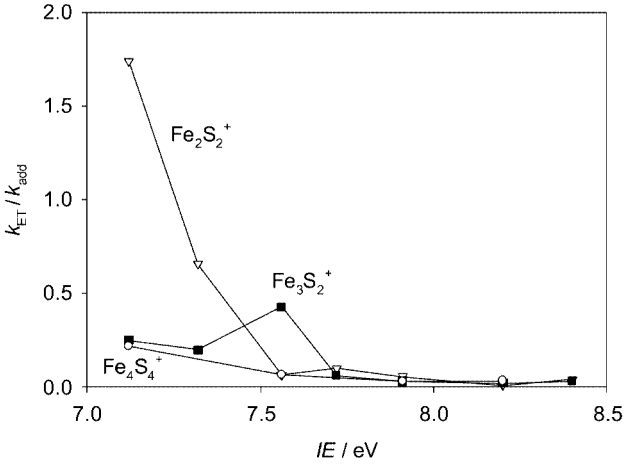

Figure 1. Ratio of ET versus addition processes for the reactions of $Fe_nS_x^+$ clusters with several substrates, B, as a function of IE(B). Specifically, the substrates applied were (in the order of increasing IE): *N*,*N*-dimethylaniline, *N*-methylaniline, 1,4-dimethoxybenzene, aniline, 2-methylnaphthalene, anisole, and mesitylene.

$$Fe_2S_2^+ + C_6H_5N(CH_3)_2 \rightarrow C_6H_5N(CH_3)CH_2^+ + [Fe_2,S_2,H] \quad (9)$$

$$Fe_2S_2^+ + C_6H_5NHCH_3 \rightarrow [Fe_2,S,C_7,H_7,N]^+ + H_2S \quad (10)$$

In the case of $Fe_3S_2^+$, the situation is more complex. The ratio k_{ET}/k_{add} substantially increases for the change from aniline (IE = 7.72 eV)[17] to 1,4-dimethoxybenzene (IE = 7.56 eV),[17] but drops again for *N*-methylaniline (IE = 7.32 eV).[17] This non-monotonic behavior might possibly result from differences between the substrates' tendencies towards adduct formation. Considering the ratio k_{ET}/k_{add} rather than the absolute rate constant k_{ET} as a criterion for ET relies on the assumption that k_{add} does not strongly change for the differently substituted arenes. However, it cannot be excluded that the small differences between the various substrates already give rise to significantly distinct lifetime effects that might account for the non-monotonic progression of k_{ET}/k_{add}. Nonetheless, it is not clear why the reaction between 1,4-dimethoxybenzene and $Fe_2S_2^+$ does not exhibit a similar anomaly.

For $Fe_4S_4^+$, low k_{ET}/k_{add} ratios were observed without exception. From the present experiments, one cannot judge whether this finding merely reflects a higher tendency towards association for the larger cluster or if a further decrease of the substrates' IEs were necessary to induce efficient ET. Note that probing the latter is far from trivial because of the low vapor pressures of the respective compounds. Hence, only upper limits for the IEs of Fe_3S_2 and Fe_4S_4 can be derived for the time being: $IE(Fe_3S_2) \leq 7.6$ and $IE(Fe_4S_4) \leq 7.6$ eV.

Discussion

Comparison between FT-ICR and GIB Data

First, the present results regarding the reactivity of Fe_n^+ clusters toward COS and CS_2 are compared with the previous GIB data.[13] With regard to the reactions with COS, both methods find sulfur transfer according to reaction (1) as the exclusive process taking place at thermal energies. Whereas the primary reactions are quite efficient for clusters sizes $n \geq 3$, a significantly decreased reactivity is consistently observed in the case of Fe_2^+ (Table 1). Since this reaction is strongly exothermic (Δ_rH° = −104±5 kJ·mol^{-1}),[13] kinetic rather than energetic restrictions must account for its low efficiency. A possible explanation suggested previously centers on the formally forbidden spin-inversion associated with the dissociation of COS ($^1\Sigma$ ground state) into CO ($^1\Sigma$) and S (^{3}P).[11,13,24] For the larger metal clusters, the presence of numerous energetically accessible electronic states mixing with the wave functions of COS is likely to weaken this restriction. In the case of the dinuclear system, however, the smaller number of electronic states appears to be insufficient for suspending spin selection-rules. This line of argument is supported by the high efficiency (φ = 0.66) observed for the consecutive reaction of Fe_2S^+ with a further COS molecule. Apparently, symmetry breaking by the sulfide ligand effectively releases spin restrictions. In addition, occurrence of the consecutive reactions for $n \geq 2$ implies negative reaction enthalpies associated with these processes. These conclusions are in full agreement with the thermochemical data derived for $Fe_2S_2^+$ and $Fe_3S_2^+$ from the GIB experiments.[13]

The agreement between the FT-ICR and GIB data also continues for the reactions of Fe_n^+ with CS_2. Here, substitution of one iron atom by CS_2 is the predominant process for $n \geq 3$ [reaction (2)] and largely suppresses sulfur transfer despite its thermochemical feasibility. In comparison with COS, the stronger binding of CS_2 presumably results from both its enhanced π-donor and π-acceptor properties. Similarly, CS is commonly known to bind to transition metals more strongly than CO.[25] Again, Fe_2^+ behaves differently from the larger clusters and does not undergo reaction 2 as both the FT-ICR and GIB approach demonstrate.[13] The CS_2 ligand probably interacts with more than one iron center such that expulsion of the second Fe atom is disfavored and instead the adduct $Fe_2CS_2^+$ is formed for n = 2. A further comment is also warranted with respect to reaction (2). Whereas the first sulfur transfer from CS_2 to Fe_2^+ is slightly endothermic (Δ_rH° = 27±6 kJ·mol^{-1}) according to the GIB method,[13] the observation of the consecutive

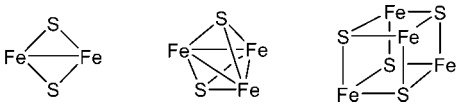
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$Fe_2S_2^+$ product in the present work implies feasibility of the primary reaction under FT-ICR conditions. However, its low efficiency $\varphi = 10^{-3}$ also points to the operation of energetic or kinetic restrictions. On the basis of a simple Arrhenius approach, one finds an activation energy $E_A = -RT \ln\varphi = 17$ kJ·mol^{-1} which is in reasonable agreement with the $\Delta_r H°$ value determined by the GIB method.

Structural Assignments

A principal problem of mass-spectrometric studies results from the difficulty of structural assignments because these have to rely on indirect evidence only. In the case of the $Fe_nS_x^+$ clusters, previous studies primarily focused on the mononuclear FeS_x^+ ions.[8,10,12] Upon reaction with ethylene sulfide, Fe^+ adds to up to six sulfur atoms. Ligand-exchange, photodissociation, and collision-induced dissociation experiments point to the formation of S_2 or larger S_y units in these systems.[8] Similarly, FeS_2^+ generated from the reaction of Fe^+ with COS contains an S_2 ligand as well.[10] In contrast, the GIB study provided indications for separated S atoms in $Fe_2S_2^+$ and $Fe_3S_2^+$. In particular, the high bond-dissociation energies $D_0(SFe_n^+-S)$ and $D_0(Fe_n^+-S) > 400$ kJ·mol^{-1} derived for $n \geq 2$ suggest the occupation of multiple coordination sites by sulfur.[13] The interaction with more than a single metal center should saturate the open valencies of sulfur and thus diminish its tendency towards oligomerization.

The present findings further support the presence of separate S atoms in $Fe_2S_2^+$ and $Fe_3S_2^+$. Unlike FeS_2^+, they do not undergo ligand exchange with arenes as one would expect for $Fe_n(S_2)^+$ structures. The observed saturation at $x = 2$ in the reaction of Fe_2^+ with COS is consistent with rhombic $Fe_2S_2^+$ (Scheme 1). This geometry is also known for biogeneous [2Fe-2S] clusters.[1−4] In the case of $n = 3$, saturation after the addition of two S atoms is compatible with coordination to both faces of a triangle. Such a structure would correspond to the maximum number of binding interactions between each sulfur atom and the iron centers. For Fe_4^+, the metal cluster takes up four sulfur atoms that do not undergo exchange with arenes and therefore are not assumed to combine to form S_2 or even larger units. Given that the iron core in $Fe_4S_4^+$ adopts a tetrahedral structure as in the unperturbed Fe_4^+ system,[26] the maximum coordination possible would position each of the four S atoms above one triangular face. This geometry corresponds to the hetero-cubane structure known from biological systems.[1−4] In the cases of $n = 5$ and 6, the $Fe_5S_5^+$ and $Fe_6S_4^+$ clusters resulting from sulfur transfer were not exposed to further substrates such that the questions of ligand exchange and eventual sulfur oligomerization cannot be answered. However, in analogy to their smaller homologues, multifold coordination by separate sulfur atoms appears probable for these species. Similar conclusions have been drawn by Nakajima et al. for neutral Fe_nS_x clusters produced by laser vaporization of a solid iron-sulfur mixture.[6]



Scheme 1

Reactivity of $Fe_nS_x^+$ Clusters

The overall rather low reactivity found for $Fe_2S_2^+$ reflects the high thermochemical stability of this cluster as already inferred from the previous GIB experiments.[13] Presumably, the absence of hydrolysis and ammonolysis reactions results not only from the strength of the iron−sulfur bonds but also from the lower stability (in comparison with H_2O or NH_3) of H_2S which is the neutral by-product formed in hydrolysis or ammonolysis of $Fe_2S_2^+$. With regard to the reverse process, $Fe_2O_2^+$ indeed is known to react with two equivalents of H_2S to yield $Fe_2S_2^+$.[21] This observation indicates that hydrolysis of $Fe_2S_2^+$ is prohibited for thermochemical reasons. Compared with $Fe_2S_2^+$, the higher reactivity of $Fe_2O_2^+$ is also evident from its ability to attack non-activated hydrocarbons such as *n*-butane.[20,21] Obviously, the metal core cannot fully compensate for the electron deficiency of the O atoms such that the latter exhibit a high affinity for oxidation reactions. For $Fe_2S_2^+$, the lower electronegativity of sulfur leads to a better balanced electronic structure in this cluster and a significantly reduced oxidative power. The role of $Fe_2S_2^+$ as a mild oxidant becomes clearly visible in its reaction with 1,4-cyclohexadiene which apparently affords a reversible H_2 transfer. Moreover, this process points to the possibility of catalytic redox reactions of $Fe_2S_2^+$ which could be considered as gas-phase models for the active sites of the corresponding enyzmes.

The distinct behavior of $Fe_2S_2^+$ and $Fe_2O_2^+$ in terms of redox chemistry should also be reflected in the quantitative data derived for these systems. In comparison with $IE(Fe_2O_2) = 8.4\pm0.3$ eV,[21] $IE(Fe_2S_2) = 7.2\pm0.3$ eV is substantially lower, consistent with the arguments raised above. The present value obtained for $IE(Fe_2S_2)$ is somewhat larger than that inferred from the GIB approach, $IE_{GIB}(Fe_2S_2) = 6.64\pm0.35$ eV,[13] but both agree within the combined error margins. Note that one a priori might expect the present method to yield a slightly too high *IE* because the thermal energies of the reactants are not explicitly accounted for while they should decrease the energetic threshold of the ET reactions compared with those at $T = 0$ K. Nonetheless, the newly determined value indicates that the theoretical prediction $IE_{theo}(Fe_2S_2) = 7.76$ eV[27] does not lie as far from experiment as the comparison with $IE_{GIB}(Fe_2S_2)$ alone suggests. In the cases of Fe_3S_2 and Fe_4S_4, only upper limits could be derived for their *IE*s. Apparently, the *IE*s of these clusters are also quite low.

Conclusions

FT-ICR mass spectrometry has been used to study the formation and reactivity of cationic iron-sulfur clusters.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$Fe_nS_x^+$ clusters can be generated by the reaction of Fe_n^+ with COS whereas exposure of Fe_n^+ to CS_2 mainly leads to substitution of one Fe atom by CS_2. These findings are fully consistent with previous results obtained by means of guided-ion beam techniques.[13] For the final products of sulfur transfer such as $Fe_2S_2^+$, $Fe_3S_2^+$, and $Fe_4S_4^+$, the absence of ligand exchange provides evidence against the presence of S_2 or larger S_y units which have been proven in the case of mononuclear FeS_x^+. This difference can be rationalized by the involvement of multiple bridging bonds between the Fe core and the sulfur atoms that are only possible for the cluster ions. The interaction with more than a single metal center saturates the open valencies of the sulfur atoms thereby preventing oligomerization. Thus, the structures of the gaseous $Fe_nS_x^+$ ions appear to strongly resemble those of biogeneous iron-sulfur clusters.

Moreover, the formation of multifold bonds substantially stabilizes the $Fe_nS_x^+$ clusters and diminishes their reactivity as demonstrated for $Fe_2S_2^+$. The low reactivity of the latter becomes particularly evident in the comparison with the analogous oxide species $Fe_2O_2^+$. Thus, the lower electronegativity of sulfur results in a well-adjusted electronic balance for $Fe_2S_2^+$ such that it does not exhibit an increased tendency towards oxidation reactions. Hence, iron-sulfur clusters seem to be intrinsically well suited for the participation in reversible redox reactions and catalytic ET processes.

Experimental Section

Experiments were performed using a Spectrospin CMS 47X FT-ICR mass spectrometer[28,29] that has recently[30] been equipped with a Smalley-type[31] cluster-ion source developed by Bondybey, Niedner-Schatteburg, and co-workers.[32] Briefly, the fundamental of a pulsed Nd:YAG laser (λ = 1064 nm, Spectron Systems) is focused onto a rotating iron target to generate a hot metal plasma. Cluster formation occurs by synchronization of a helium pulse and subsequent supersonic expansion. After passing a skimmer, the ionic components of the molecular beam are transferred into the analyzer cell where they are trapped in the field of a 7.05 T superconducting magnet. The distribution of cluster ions thus produced can be somewhat controlled by varying the delays between helium pulse, laser shot, and subsequent inlet into the analyzer cell. Whereas the abundances achieved for Fe^+ and Fe_2^+ were quite high, those for the larger clusters were significantly lower, thereby complicating the experiments in such cases. After mass-selection of a specific cluster size and removal of peaks resulting from the ^{54}Fe and ^{57}Fe isotopes by means of the FERETS ion-ejection protocol,[33] the Fe_n^+ ions were thermalyzed by an argon pulse.

Ion-molecule reactions between Fe_n^+ and COS and CS_2, respectively, were then studied by leaking-in the neutral substrate at $p \approx 5 \cdot 10^{-9}$ to $2 \cdot 10^{-7}$ mbar and recording the decline of the reactant Fe_n^+ clusters and the evolution of the products. Bimolecular rate constants k ($\pm$30% uncertainty)[34] were derived on the basis of the pseudo-first-order approximation, and the corresponding reaction efficiencies $\varphi \equiv k/k_{cap}$ were calculated according to capture theory.[35] Consecutive reactions were analyzed using numerical routines.[36,37] For the reactivity studies of the $Fe_nS_x^+$ clusters, the reactant ions were prepared by pulsing-in COS to mass-selected Fe_n^+. After further mass selection, the reactions with the permanently leaked-in substrates were recorded similarly to the way described above.

Lanthanide Homobimetallic Triple-Stranded Helicates: Insight into the Self-Assembly Mechanism

Mourad Elhabiri,[a] Josef Hamacek,[a] Jean-Claude G. Bünzli,[b] and Anne-Marie Albrecht-Gary*[a]

Keywords: Europium / Helicates / Mechanisms / Self-assembly / Supramolecular chemistry

The self-assembly mechanism leading to the exclusive formation of a triple-stranded bimetallic helicate upon reaction of Eu^{III} with a ditopic hexadentate ligand L bearing two carboxylate moieties has been fully elucidated in water for a wide range of $[Eu]_{tot}/[L]_{tot}$ ratios. Using a fruitful combination of electrospray mass spectrometry, potentiometry, UV/Vis spectrophotometry, luminescence, and ^1H NMR spectroscopy, the final product Eu_2L_3 and the intermediate species EuL_2 and Eu_2L_2 have been characterised. The presence of terminal carboxylates in L significantly reduces the electrostatic repulsions of the coordination sites in Eu_2L_2 and Eu_2L_3 compared with the corresponding complexes formed with analogous neutral ligands and thus increases the stability of the L-europium(III) complexes. Kinetic investigations carried out with an excess of L and with an excess of Eu^{III}, show that the self-assembly proceeds through either EuL_2 or Eu_2L intermediates depending on the experimental conditions and leads to a pre-organized Eu_2L_2 complex by either a "braiding" or a "keystone" mechanism. In the last step, a fast and efficient wrapping of the third ligand strand leads to the target Eu_2L_3 helicate. The overall process is mainly governed by electrostatic interactions and proceeds via a key double stranded intermediate helicate Eu_2L_2. To the best of our knowledge, as a result of the fine-tuning of the coordination properties of L, we present one of the most efficient and cooperative metal/ligand systems for the spontaneous organization of a bimetallic triple-stranded structure.

Introduction

The self-assembly of supramolecular edifices, which was inspired from one of the basic principles in biology,[1] is an appealing approach to the design of novel nanomaterials with predetermined and specific properties.[2] In particular, combining the toolbox of non-covalent interactions with the intriguing chemical and physicochemical properties of transition metal ions allows one to build functional supramolecular architectures via metal-ion assisted self-assembly.[3] This strategy has successfully generated fascinating two and three-dimensional edifices from polytopic ligands, which include rods,[4] grids,[5] cages,[6] helices,[7] ladders,[8] and rings.[9] Initial studies of metallo-supramolecular helicates have mainly involved double- or triple-stranded structures containing cations such as Cu^I, Ag^I, Cu^{II}, Ni^{II}, Ga^{III}, or Fe^{III} and ligands derived from bipyridine, terpyridine, or catechol frameworks.[10,11] The specific magnetic and luminescent[12−14] properties of the trivalent lanthanide cations[15] are increasingly being taken advantage of in medical diagnoses[16,17] and therapy[18] as well as in the catalytic cleavage of DNA and RNA.[19] In this context, the synthesis of elaborate polymetallic lanthanide helicates, which are potentially chiral, may contribute to the development of such applications. However, the poor stereochemical preferences and the variable coordination numbers adopted by Ln^{III} ions render difficult a reliable molecular programming in solution. In spite of this difficulty, we have demonstrated that a careful ligand design based on the induced fit principle[20] leads to the strict self-assembly of lanthanide-containing triple-stranded helicates in organic media.[21,22] Ditopic pentadentate, hexadentate or nonadentate ligands derived from 2-pyridin-2-yl-1*H*-benzimidazole are indeed versatile building blocks and can be used to prepare bimetallic 3d−4f and 4f−4f assemblies,[23] as well as trimetallic 4f−4f−4f edifices.[24] Recently, we have also shown that grafting different substituents at the end of the hexadentate ligands results in ditopic hosts able to specifically recognize a pair of lanthanide ions in solution.[25] Bioanalytical and medical applications require water-soluble probes, so that the ditopic ligand L with two terminal carboxylate moieties was synthesized (Figure 1) and was found to yield highly stable bimetallic helicates

Ln_2L_3 in water, despite the large hydration enthalpy of the metal ions.[26]

The numerous helicates reported so far[10] have been essentially characterised by their molecular structures and, sometimes, by their thermodynamic parameters. Kinetic data, which are essential for deciphering the self-assembly mechanism and, therefore for understanding the recognition process, are extremely scarce.[27–30] As part of our ongoing kinetic investigations of supramolecular edifices with polytopic ligands, dealing with either copper(I) trimetallic double-stranded[29] or lanthanide(III) bimetallic triple-stranded[30] helicates in acetonitrile, we present here a detailed physicochemical study of the Eu_2L_3 helicate in aqueous solution. The work is focused on getting a better understanding of the key steps of the self-assembly process. An original combination of potentiometry, absorption and emission spectrophotometry, ES mass spectrometry, and stopped-flow techniques, allowed us to determine both the thermodynamic and kinetic parameters characterising the formation of the bimetallic europium(III) triple-stranded helicate in water.

Results and Discussion

Ligand Properties

Detailed interpretation of thermodynamic and kinetic data requires knowledge of the ligand pK_a values, at least in the pH range in which the data are collected. Indeed, pK_a values of the carboxylic acid functions are difficult to determine in view of the extremely poor solubility of the ligand below pH 6 and its precipitation at pH 4. We have therefore investigated the acid-base properties of the ligand in the sole pH range 10.5–5.8 by various techniques. Potentiometric titrations of ca. 10^{-3} M solutions (Figure S1 in the Supporting Information; see also the footnote on the first page of this article) followed by a statistical treatment of the data[31] yielded the three protonation constants listed in Table 1. The corresponding distribution diagram is presented in Figure S2 (see Supporting Information).

Table 1. Successive protonation constants of ligand L; solvent: water; T = 25.0±0.2 °C; I = 0.1 M ($NEt_4{\cdot}ClO_4$); for the sake of simplicity charges have been omitted

Equilibrium			log K_{LH_n} ± 3σ
L + H	$\xrightarrow{K_{LH}}$ $\xleftarrow{}$	LH	10.1 ± 0.1
LH + H	$\xrightarrow{K_{LH_2}}$ $\xleftarrow{}$	LH_2	9.5 ± 0.2
LH_2 + H	$\xrightarrow{K_{LH_3}}$ $\xleftarrow{}$	LH_3	6.0 ± 0.2

In order to confirm the first pK_a, UV/Visible absorption spectra of the free ligand (see Supporting Information, Figure S3) were recorded in the range 7.38 < p[H] < 11.59 and a single cumulative protonation constant logβ_{LH_2} = 19.8±0.6 could be extracted using statistical methods[31] compared with 19.6 obtained by potentiometry.

$$L + n\,H \xrightarrow{\beta_{LH_n}} LH_n \qquad \text{with } n = 2 \tag{1}$$

We have also taken advantage of the fluorescent properties of the benzimidazole derivatives.[32,33] Decreasing the p[H] from 11.43 to 7.59 resulted in a drastic quenching of the ligand-centered fluorescence (Figure 2) and statistical treatment[31] of the data leads to the following protonation constants: logK_{LH} = 10.9±0.7 and logK_{LH_2} = 8.7±0.5. The re-calculated spectra for L, LH and LH_2 are presented in Figure S4 (see Supporting Information).

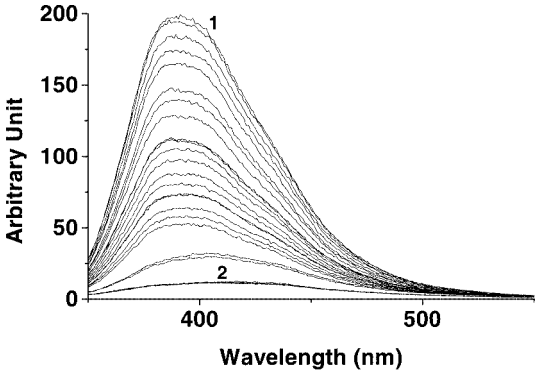

Figure 2. Corrected fluorescence spectra of L as a function of p[H]. Solvent: water; $T = 25.0 \pm 0.2$ °C; $I = 0.1$ M (NEt_4ClO_4); $l = 1$ cm; $\lambda_{exc} = 308$ nm. $[L]_{tot} = 3.56 \times 10^{-6}$ M; (**1**) p[H] 11.43; (**2**) p[H] 7.59. Spectra are not corrected for dilution

Finally, the assignment of the pK_a values was made on the basis of structural information extracted from ^{1}H and ^{13}C NMR spectra recorded at various p[D] values. These data clearly point to both monoprotonated LH and diprotonated LH_2 species retaining C_2 symmetry in the p[D] range 13.00−7.10, indicating that no intramolecular interaction occurs between the two identical subunits of the ditopic strand (Figure 1). This lack of interaction can be further confirmed by the difference between logK_{LH} and logK_{LH_2} ($\Delta \log K = 0.6$, Table 1), which is in excellent agreement with a statistical evaluation.[34] NOE effects are consistent with a *transoid* conformation for the ligand at p[D] = 13.[26] When the p[D] was decreased from 13.00 to 7.10, small but significant variations in the chemical shifts of the aromatic protons of the benzimidazole moiety ($H^{4'}$, $H^{6'}$, and $H^{7'}$) were observed whereas the ^{13}C chemical shifts related to the terminal carboxylates did not vary (Table 2). These NMR spectroscopic data strongly suggest that the first two protonation processes occur at the imidazolyl groups, an assumption confirmed by the absence of a red shift in the absorption and emission spectra in the p[H] range 11.4−7.4 (Figure 2 and Figure S3 in the Supporting Information). Such a shift would be expected if the *N*-pyridyl groups were protonated.[35,36]

In spite of the converging of the information provided by our measurements, one has to be aware that intra- and intermolecular hydrogen bonding may occur which could modify the above reasoning. For instance, in the case of 2-(2′-pyridyl)benzimidazole in hydrochloric acid, ^{15}N NMR spectroscopic measurements result in only two resonances and are consistent with the presence of fast exchanging resonance structures, one of which having a proton linked to two nitrogen atoms.[37] A similar situation is met for 1,10-phenanthroline which displays one ^{15}N signal regardless of the solvent, also pointing to the formation of bifurcated hydrogen bonds involving both nitrogen atoms.[38] In our case, formation of a hydrogen bond between the imidazolyl and the pyridine nitrogen atom is feasible and could affect the pyridyl protons, especially H^5 (Table 2 and Scheme 1).

Table 2. ^{1}H- and ^{13}C-chemical shifts δ (ppm vs. TMS) as a function of p[H]; p[H] values were determined by using p[H] = p[D] − 0.40;[88] solvent: D_2O; $[L]_{tot} = 10^{-2}$ M; $T = 25 \pm 1$ °C

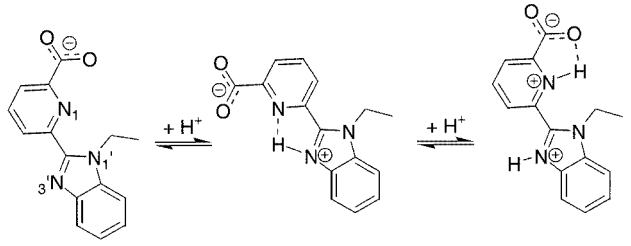

Scheme 1. Potential hydrogen bonding in two protonated subunits of L

The protonation constants logK_{LH} and logK_{LH_2} are at least 4−5 orders of magnitude larger than those reported for benzimidazole (log$K$ = 5.58)[39,40] or 2-(2′-pyridyl)benzimidazole (log$K$ = 4.41),[36] but less than two orders of magnitude smaller than the first protonation constant determined for 1,10-phenanthroline-2,9-dicarboxylic acid in water ($\log K_1 = 11.77 \pm 0.08$).[41] Carboxylic functions in positions 2 and 9 of the phenanthroline indeed induce a drastic increase in the basicity of the *N*-pyridyl atoms compared with phenanthroline ($\log K_1 = 4.77$).[42] A similar trend can be observed for the ditopic ligand L, and we note that intramolecular hydrogen bonds between N(3′) and N(1) would also contribute to increasing logK_{LH} and logK_{LH_2} (Scheme 1). If the third protonation were to take place at N(1), a large decrease in K_{LH_3} could be expected, due to both statistical effects and hydrogen bonding. The value of K_{LH_3} is about four orders of magnitude lower than K_{LH_2} and could therefore reflect these contributions and be satisfactorily compared with the constant relative to the second protonation of 1,10-phenanthroline-2,9-dicarboxylic acid ($\log K_2 = 9.04 \pm 0.14$).[41] Solubility problems below p[H] 5.89 prevented the determination of K_{LH_4}, K_{LH_5}, and K_{LH_6}. In fact, K_{LH_4} is related to K_{LH_3} in terms of symmetry (L adopting C_2 symmetry) and statistically should be smaller than the latter by approximately 0.6.[34] Much lower values of K_{LH_5} and K_{LH_6} are expected according to data available in the literature for picolinic ($\log K_2 \approx 1$)[43,44] and 1,10-phenanthroline-2,9-dicarboxylic acids ($\log K_3 = 2.37 \pm 0.21$[41]).[45] In 1.5 M $HClO_4$, slow and irreversible

degradation of ligand L via a potential de-carboxylation reactions was observed by UV/Visible spectrophotometry (see Supporting Information, Figure S5).

Stoichiometry and Stability of Europium(III) Complexes with L

The use of electrospray mass spectrometry (ES-MS) to characterize the stoichiometry of metallic complexes in solution is well documented,[10,46] and has been employed by us for this purpose on previous occasions.[21,27−30,47−49] ES-MS measurements were carried out at two different $[Eu]_{tot}/[L]_{tot}$ ratios (Figure 3) and the corresponding spectra clearly indicate the formation of three europium(III) complexes, Eu_2L_3, Eu_2L_2, and EuL_2 (see Supporting Information, Table S1). The peaks of the triple-stranded Eu_2L_3 helicate dominate the spectra, even with an excess of Eu^{III}. The inner coordination spheres of the minor species Eu_2L_2 and EuL_2 are completed with water molecules. Since lanthanide cations possess large solvation energies,[47,48] the ES-MS responses[50] will be drastically decreased for the latter complexes compared with that of the Eu_2L_3 helicate. Loss of neutral CO_2 was also observed, as previously reported for amino acid- or peptide-metal complexes in positive[51,52] and in negative modes.[53]

To quantify the interaction between L and Eu^{III}, we titrated the ligand in water at p[H] 6.15±0.05 with europium(III) and monitored the changes occurring in solution using both absorption (Figure 4a, and Figure S6 in the Supporting Information) and gated luminescence spectroscopy (Figure 4b).

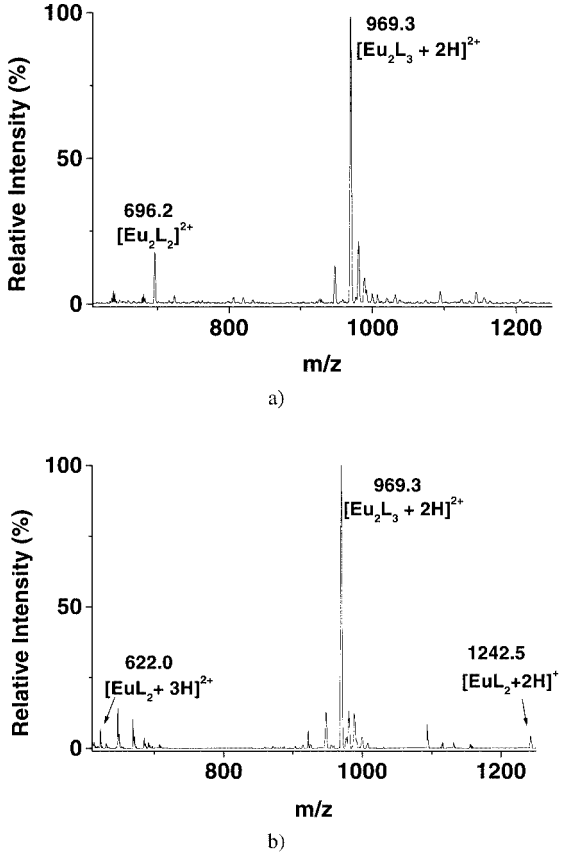

Figure 3. Electrospray mass spectra (a) $[Eu]_{tot} = 7.96 \times 10^{-4}$ M. $[L]_{tot} = 4.04 \times 10^{-4}$ M; (b) $[Eu]_{tot} = 2.05 \times 10^{-4}$ M. $[L]_{tot} = 7.96 \times 10^{-4}$ M. Solvent: CH_3OH / H_2O (80 / 20 by weight); positive mode; $V_c = 120$ V

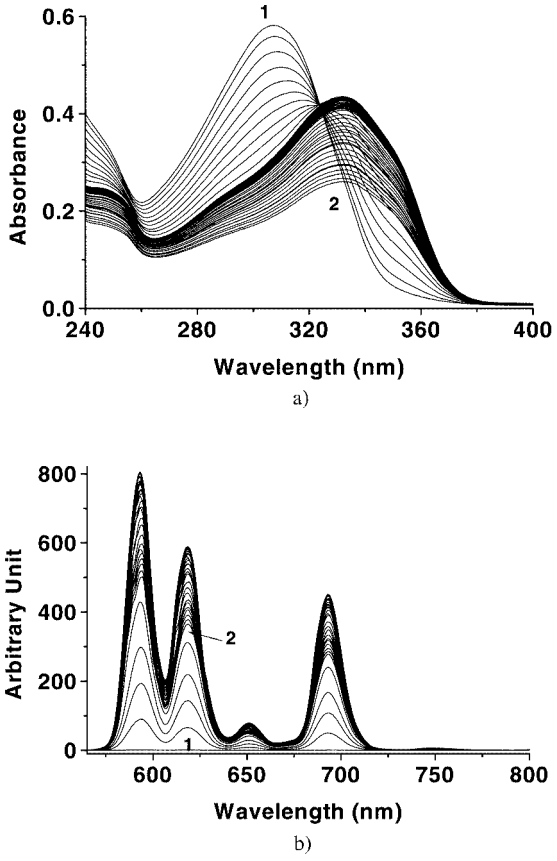

Figure 4. Spectrophotometric titrations of L versus Eu^{III} concentrations. (a) Absorption spectra: $l = 2$ cm. $[L]_{tot} = 8.22 \times 10^{-6}$ M; (1) $[Eu]_{tot}/[L]_{tot} = 0$; (2) $[Eu]_{tot}/[L]_{tot} = 23.36$. (b) Gated luminescence spectra; $\lambda_{exc} = 308$ nm; $t_d = 0.05$ ms; gate time = 1 ms; cycle time = 200 ms. $[L]_{tot} = 1.64 \times 10^{-6}$ M; (1) $[Eu]_{tot}/[L]_{tot} = 0$, (2) $[Eu]_{tot}/[L]_{tot} = 15.37$. Solvent: water; buffer MES (0.1 M); p[H] = 6.15±0.05; $T = 25.0 \pm 0.2$ °C

The formation of the helicate induces a significant red shift to 332 nm in the ligand π→π* transition band centered at 308 nm (Figure 4a). Moreover, L was reported to be a fair luminescence sensitizer for europium(III),[26] the absolute quantum yield of the metal-centered luminescence reaching 1.3% at p[H] ≈ 7.0 with a lifetime of 2.13(2) ms. Data were satisfactorily fitted to the simple model represented by Equation (2) and both experiments yielded very similar values (Table 3), in agreement with the previously

reported one obtained via ^{1}H NMR competitive titrations with various concentrations of DOTA (1,4,7,10-tetraazacyclodecane-*N*,*N*′,*N*′′,*N*′′′-tetraacetic acid) in D_2O.[26]

$$3\,L + 2\,Eu \underset{\longleftarrow}{\xrightarrow{\beta_{Eu_2L_3}}} Eu_2L_3 \quad (2)$$

Spectrophotometric (absorption and luminescence) and NMR spectroscopic data clearly demonstrate that the major species in aqueous solution at pH 6.15 and in a large range of $[Eu]_{tot}/[L]_{tot}$ ratios is the triple-stranded helicate Eu_2L_3. In addition to this main species ES-MS, which is by far a more sensitive method, indicated the presence of small amounts of Eu_2L_2 with an excess of Eu^{III}, and of EuL_2 with an excess of L. The triple stranded helicate is with no doubt a thermodynamic product and its structure in aqueous solution is the same as that determined by single-crystal X-ray diffraction.[26] Although the Eu_2L_2 species is not seen in the spectrophotometric titrations, 2:2 species have been observed with similar ligands.[21,22] In particular, $[Eu_2(L^B)_2]^{6+}$ (L^B: R^1 = C(O)NEt_2 and R^2 = CH_3, see Figure 1) adopts a box-like structure in the solid state, in which the ligand strands are arranged "side-by-side" and the two metal are ions connected via hydrogen bonds produced by four water molecules.[22] Therefore, the 2:2 species may also be considered to be a thermodynamic product. The presence of the terminal carboxylate functions of L could be expected to significantly reduce the electrostatic repulsions of the coordination sites in Eu_2L_2 and Eu_2L_3 by comparison with the corresponding complexes with L^A (R^1 = 1-(3,5-dimethoxybenzyl)-1*H*-benzimidazole and R^2 = CH_3, see Figure 1) and L^B and thus to increase the stability of the L-europium(III) complexes.[54]

Formation Kinetics in Excess of Ligand

Two series of experiments carried out with two different metal concentrations, $[Eu]_{tot} = 1.06 \times 10^{-6}$ M and 2.73×10^{-6} M, allowed us to observe two rate-limiting steps in the second and minute time spans, respectively (see Supporting Information, Figure S7). The corresponding spectrophotometric signals recorded at 350 nm undergo an increase in absorbance followed by a decrease. The variation of the two corresponding pseudo-first-order rate constants $k_{2,obs}$ and $k_{3,obs}$ (s^{-1}) versus $[L]_{tot}$ (see Supporting Information, Tables S2 and S3) is presented in Figure 5.

The variation of $k_{2,obs}$ is in good agreement with a fast pre-equilibrium for the formation of EuL, followed by a slower binding of L to EuL:

$$Eu + L \underset{\text{fast}}{\overset{K_{EuL}}{\rightleftharpoons}} EuL \quad (3)$$

$$EuL + L \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} EuL_2 \quad (4)$$

The rate law corresponding to the equilibrium according to Equation (4) is expressed by the following Equation (5).

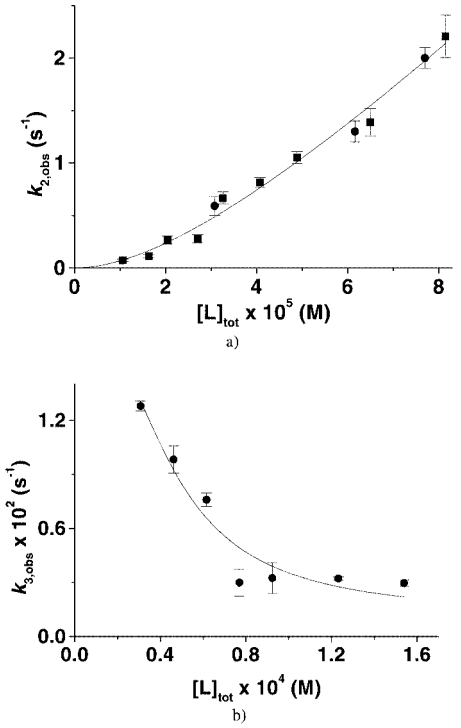

Figure 5. Variation of the pseudo-first order constants $k_{2,obs}$ (a) and $k_{3,obs}$ (b) for the formation of L-europium(III) complexes versus $[L]_{tot}$. Solvent: water; T = 25.0±0.2 °C; p[H] = 6.15±0.05 (MES buffer 0.1 M); ■ $[Eu]_{tot} = 1.06 \times 10^{-6}$ M; • $[Eu]_{tot} = 2.73 \times 10^{-6}$ M

$$d[EuL_2]/dt = k_2 \times [EuL] \times [L]_{tot} - k_{-2} \times [EuL_2] \quad (5)$$

and leads to Equation (6).[55]

$$k_{2,obs} = \frac{k_2 \times K_{EuL} \times [L]_{tot}^2}{1 + K_{EuL} \times [L]_{tot}} + k_{-2} \quad (6)$$

The rate constant k_2 and the stability constant K_{EuL} were determined by a non-linear least-squares method[56] (Table 4) but k_{-2} could not be obtained under our experimental conditions.

On the other hand, the variation of $k_{3,obs}$ versus $[L]_{tot}$ suggests the coordination of a second Eu^{III} cation to EuL_2:

$$EuL_2 + Eu \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} Eu_2L_2 \quad (7)$$

The corresponding rate law can be written:

$$d[Eu_2L_2]/dt = k_3 \times [EuL_2] \times [Eu] - k_{-3} \times [Eu_2L_2] \quad (8)$$

Resolution of the differential Equation (8)[55] leads to the following reduced expression, under our experimental conditions:

$$k_{3,obs} = \frac{4 \times k_3 \times \beta_{EuL_2} \times [L]_{tot}^2 \times [Eu]_{tot}}{(1 + K_{EuL} \times [L]_{tot} + \beta_{EuL_2} \times [L]_{tot}^2)^2} + k_{-3} \quad (9)$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 4. Formation mechanism of Eu_2L_3 with an excess of L; solvent: water; T = 25.0 ± 0.2 °C; p[H] = 6.15±0.05 (MES buffer 0.1 M); the errors are given as standard errors[56]

Steps			Experimental values	Calculated values
Eu + L	$\overset{K_{EuL}}{\rightleftharpoons}$	EuL	$K_{EuL} = (1.9 \pm 0.8) \times 10^4$ M^{-1}	
EuL + L	$\overset{k_2}{\underset{k_{-2}}{\rightleftharpoons}}$	EuL_2	$k_2 = (4.4 \pm 0.9) \times 10^4$ M^{-1}s^{-1} $\beta_{EuL2} = (2.0 \pm 0.7) \times 10^9$ M^{-2}	$k_{-2} = \frac{k_2 \times K_{EuL}}{\beta_{EuL_2}} = 0.4 \pm 0.3$ s^{-1}
EuL_2 + Eu	$\overset{k_3}{\underset{k_{-3}}{\rightleftharpoons}}$	Eu_2L_2	$k_3 = (7.0 \pm 0.6) \times 10^3$ M^{-1}s^{-1} $k_{-3} = (1.1 \pm 0.8) \times 10^{-3}$ s^{-1}	$K_{Eu2L2} = \frac{k_3}{k_{-3}} = (6.4 \pm 4.7) \times 10^6$ M^{-1} $\beta_{Eu2L2} = \beta_{EuL2} \times K_{Eu2L2} = (1.3 \pm 1.0) \times 10^{16}$ M^{-3}
Eu_2L_2 + L	$\overset{k_4}{\underset{k_{-4}}{\rightleftharpoons}}$	Eu_2L_3	not determined	

The corresponding rate constants k_3, k_{-3} are given in Table 4.

The absorbance at 350 nm at the end of the third step (Figure S7 in the Supporting Information) is in good agreement, within experimental error, with the sum of the absorption of the excess of free ligand and of the bimetallic triple-stranded helicate ($[Eu_2L_3]_\infty$ = 1/2$[Eu]_{tot}$). This result constitutes a good indication that the last step is faster than the formation of the Eu_2L_2 precursor and that the final step in the formation of Eu_2L_3 involves the addition of a third ligand to Eu_2L_2, in a "braiding" mechanism, as opposed to a "keystone" mechanism in which the second metal ion is added to a pre-organized EuL_3 complex.[57]

Formation Kinetics with an Excess of Europium(III)

Kinetic measurements were carried out under pseudo-first order conditions. Two exponential signals were recorded at 332 nm in the second time range using a stopped-flow technique, whereas an exponential signal was measured in the hour time range on a classical spectrophotometer (Figure 6).

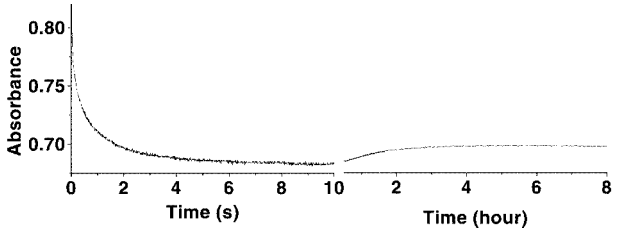

Figure 6. Variation of the absorbance at 332 nm versus time. Solvent: water; T = 25.0±0.2 °C; p[H] = 6.15±0.05 (MES buffer 0.1 M); l = 1 cm. $[L]_{tot} = 2.55 \times 10^{-5}$ M, $[Eu]_{tot} = 1.80 \times 10^{-3}$ M

Three corresponding pseudo-first-order rate constants $k'_{2,obs}$, $k'_{3,obs}$, and $k'_{4,obs}$ (s^{-1}) extracted from these data are reported in Table 5 (see also Figure S8 in the Supporting Information).

Table 5. Variation of $k'_{2,obs}$, $k'_{3,obs}$, and $k'_{4,obs}$ for the formation of L-europium(III) complexes versus $[Eu]_{tot}$; solvent: water; T = 25.0±0.2 °C; p[H] = 6.15±0.05 (MES buffer 0.1 M); $[L]_{tot} = 2.55 \times 10^{-5}$ M; reported errors are ±3σ

$[Eu]_{tot} \times 10^4$ [M]	$k'_{2,obs}$ [s^{-1}]	$k'_{3,obs}$ [s^{-1}]	$k'_{4,obs} \times 10^4$ [s^{-1}]
2.57	12.9±2.2	0.99±0.01	5.3±0.6
5.15	15.9±2.5	1.07±0.03	2.5±0.3
7.70	16.1±1.2	1.07±0.04	2.7±0.3
10.30	15.1±2.5	1.08±0.04	8.2±0.9
12.80	16.5±3.6	0.98±0.02	6.2±0.9
15.40	16.8±3.7	0.96±0.02	1.4±0.3
18.00	16.2±2.4	0.86±0.02	2.4±0.6

The pseudo-first-order rate constant $k'_{2,obs}$ increased slightly, but significantly as $[Eu]_{tot}$ was increased. A large increase of the spectrophotometric absorption occurred during the dead-time (≈ 3 ms) of the stopped-flow device and could be attributed to the initial and fast formation of EuL [Equation (3)]. The following equilibria are in satisfactory agreement with these experimental data:

$$EuL + Eu \underset{k'_{-2}}{\overset{k'_2}{\rightleftharpoons}} Eu_2L \quad (10)$$

The rate law corresponding to equilibrium (10) is expressed by:

$$d[Eu_2L]/dt = k'_2 \times [EuL] \times [Eu]_{tot} - k'_{-2} \times [Eu_2L] \quad (11)$$

and leads to Equation (12):[55]

$$k'_{2,obs} = \frac{k'_2 \times K_{EuL} \times [Eu]^2_{tot}}{1 + K_{EuL} \times [Eu]_{tot}} + k'_{-2} \quad (12)$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 6. Formation mechanism of the Eu_2L_3 helicate with an excess of Eu^{III}; solvent: water; $T = 25.0 \pm 0.2$ °C; p[H] = 6.15±0.05 (MES buffer 0.1 M); the errors are given as standard errors[56]

Steps		Experimental values	Calculated values	
$Eu + L \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} EuL$		$K_{EuL} = (1.9 \pm 0.5) \times 10^4\ M^{-1}$		
$EuL + Eu \underset{k'_{-2}}{\overset{k'_2}{\rightleftharpoons}} Eu_2L$		$k'_2 = (1.7 \pm 0.8) \times 10^3\ M^{-1}\ s^{-1}$ $k'_{-2} = 13.8 \pm 0.9\ s^{-1}$	$K_{Eu2L} = \frac{k'_2}{k'_{-2}}$	$= (1.2 \pm 0.6) \times 10^2\ M$ $\beta_{Eu2L} = K_{Eu2L} \times K_{EuL}$ $= (2.3 \pm 1.3) \times 10^6\ M^{-2}$
$Eu_2L + L \underset{k'_{-3}}{\overset{k'_3}{\rightleftharpoons}} Eu_2L_2$		$k'_3 = (2.2 \pm 0.3) \times 10^6\ M^{-1}\ s^{-1}$	$k'_{-3} = \frac{k'_3 \times \beta_{Eu_2L}}{\beta_{Eu_2L_2}}$	$= (3.9 \pm 3.8) \times 10^{-4}\ s^{-1}$
$Eu_2L_2 + L \underset{k'_{-4}}{\overset{k'_4}{\rightleftharpoons}} Eu_2L_3$		$k'_4 = (4 \pm 1) \times 10^{-4}\ s^{-1}$	$k'_4 = \frac{k_{-4} \times \beta_{Eu_2L_3}}{\beta_{Eu_2L_2}}$	$= (6.1 \pm 4.9) \times 10^7\ M^{-1}\ s^{-1}$

If we consider that under our experimental conditions $K_{EuL} \times [Eu]_{tot} >> 1$:

$$k'_{2,obs} = k'_2 \times [Eu]_{tot} + k'_{-2} \tag{13}$$

The values of the rate constants k'_2 and k'_{-2} were calculated by a least-squares method[56] and are reported in Table 6.

When $[Eu]_{tot}$ is increased, $k'_{3,obs}$ is decreases (Table 5 and Figure S8b in the Supporting Information), which suggests that the coordination of a second ligand strand to Eu_2L takes place and leads to the bimetallic double-stranded species Eu_2L_2:

$$Eu_2L + L \underset{k'_{-3}}{\overset{k'_3}{\rightleftharpoons}} Eu_2L_2 \tag{14}$$

The rate law is then expressed by:

$$d[Eu_2L_2]/dt = k'_3 \times [Eu_2L] \times [L] - k'_{-3} \times [Eu_2L_2] \tag{15}$$

If we assume that equilibrium is reached at the end of the previous steps, we can use the corresponding stability constants to solve the mass balance equation and evaluate [L]:

$$[L] = \frac{[L]_{tot} - 2 \times [Eu_2L_2]}{1 + K_{EuL} \times [Eu]_{tot} + \beta_{Eu_2L} \times [Eu]^2_{tot}} \tag{16}$$

The new expression of the rate law becomes:

$$\frac{d[Eu_2L_2]}{dt} = \frac{k'_3 \times \beta_{Eu_2L} \times [Eu]^2_{tot} \times ([L]_{tot} - 2[Eu_2L_2])^2}{(1 + K_{EuL} \times [Eu]_{tot} + \beta_{Eu_2L} \times [Eu]^2_{tot})^2} - k'_{-3} \times [Eu_2L_2] \tag{17}$$

The resolution of this differential equation,[55] taking our experimental conditions into account, gives the reduced equation:

$$k'_{3,obs} = \frac{4 \times k'_3 \times \beta_{Eu_2L} \times [L]_{tot} \times [Eu]^2_{tot}}{(1 + K_{EuL} \times [Eu]_{tot} + \beta_{Eu_2L} \times [Eu]^2_{tot})^2} + k'_{-3} \tag{18}$$

Statistical processing[56] of the kinetic data allows estimation of k'_3, K_{EuL} and β_{Eu_2L} (Table 6), but not of k'_{-3}. It is noteworthy that the absorbance at the end of this step (Figure 6) corresponds to the absorption at 332 nm of the bimetallic triple-stranded helicate Eu_2L_3 (see Supporting Information, Figure S6). This is a sound indication that the formation of Eu_2L_2 is followed by the fast addition of a third ligand strand leading to the final thermodynamically stable helicate Eu_2L_3:

$$Eu_2L_2 + L \xrightarrow[\text{fast}]{k'_4} Eu_2L_3 \tag{19}$$

A decrease of more than four orders of magnitude was observed for $k'_{4,obs}$ compared with $k'_{3,obs}$ (Table 5), but $k'_{4,obs}$ did not vary significantly with $[Eu]_{tot}$ (see Supporting Information, Figure S8c). These data strongly suggest a slow release of L from Eu_2L_3 which was rapidly formed in the previous step:

$$Eu_2L_3 \xrightarrow{k'_{-4}} Eu_2L_2 + L \tag{20}$$

The corresponding rate law can now be expressed by the following relationship:

$$-d[Eu_2L_3]/dt = k'_{-4} \times [Eu_2L_3] \tag{21}$$

with:

$$k'_{4,obs} = k'_{-4} \tag{22}$$

We will now discuss the overall self-assembly mechanism of the bimetallic triple-stranded helicate Eu_2L_3 presented in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

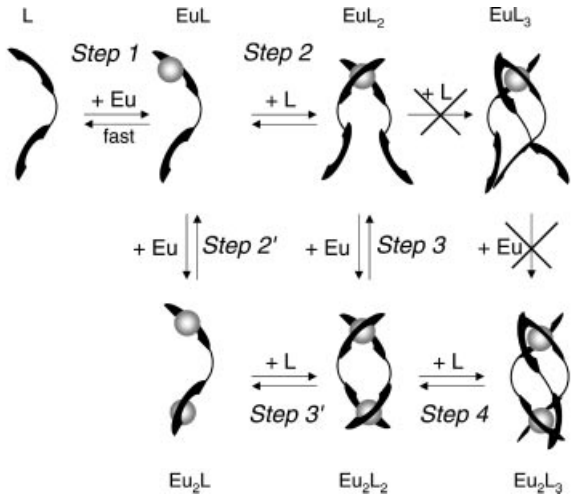

Figure 7. Schematic representation of the self-assembly mechanism of Eu_2L_3

Figure 7. The initial and final steps are independent of the stoichiometric ratio $[Eu]_{tot}/[L]_{tot}$. In contrast, the intermediate steps depend on whether the kinetics were measured in the presence of an excess of ligand or metal.

Since the water exchange rates of Ln^{III} ions are large,[58] slow complex formation is related to the ligand properties.[59–61] The ditopic molecule L was designed for the fine-tuning of the Ln^{III} coordination sphere, with a short methylenic spacer to prevent self-folding. At p[H] = 6.15, LH_2, the major species, possesses one proton on each imidazolyl group. If they are stabilized by hydrogen bonds as shown in Scheme 1, the tridentate subunits of L adopt a *cisoid* conformation (Scheme 1) which is preferable to a coordination of Eu^{III} limited by the exchange rate of the first water molecule on the lanthanide cation.[58,62] Using the water exchange rate constant k_{ex} determined by ^{17}O NMR spectroscopy for Eu^{III} (5×10^8 s^{-1}),[58,62] we calculated an outer-sphere stability constant[63,64] $K_{os} = 0.16$ M^{-1} for a triple charged cation/neutral ligand system. Under these conditions, the formation rate constant for EuL can be estimated[65] as $k_1 = K_{os} \times k_{ex} = 8 \times 10^7$ $M^{-1} \times s^{-1}$. This value is similar to the literature data reported for the formation of anthranilate-Eu^{III} (1.05×10^8 $M^{-1} \times s^{-1}$),[66,67] picolinate-La^{III} (4.9×10^8 $M^{-1} \times s^{-1}$) or picolinate-Dy^{III} (1.5×10^8 $M^{-1} \times s^{-1}$)[68,69] complexes at various temperatures and ionic strengths in water. The formation mechanism of EuL is at odds with the one determined for the EuL^A analogue, for which conformational changes lead to a slower binding rate constant and to an increased inertness.[30] The stability constant $K_{EuL} = (1.8 \pm 0.9) \times 10^4$ M^{-1}, calculated from the variation of the initial absorbance A_0 versus $[Eu]_{tot}$ in the experiments with an excess of metal (Figure 6 and Figure S9 in the Supporting Information), is in excellent agreement with the values given in Tables 4 and 6. Comparing this constant with the one obtained for the complex with the bidentate picolinate ligand ($K_1 = 1.06 \times 10^4$ M^{-1})[70] gives a good indication of a partial binding to Eu^{III} by one of the tridentate subunits in L. The dissociation rate constant $k_{-1} = k_1/K_{EuL}$ can then be estimated to be ca. 4×10^3 s^{-1}. EuL is indeed a labile species as was observed, for instance, for the anthranilate-Eu^{III} complex (3.3×10^4 s^{-1}).[66,67] Step 1 can therefore be considered as being a fast pre-equilibrium in the formation process of the target Eu_2L_3.

With an excess of L, Step 2 implies the binding of a second ligand strand to EuL, leading to the more stable complex EuL_2. The bimolecular rate constant k_2 (Table 4) is about four orders of magnitude lower than k_1. The electrostatic repulsions between the terminal carboxylate groups of the ligands probably induce conformational rearrangements which drastically slow down the coordination of L to EuL. The strong negative interactions between the ligands will prevent even more efficiently the formation of EuL_3. The addition of a second Eu^{III} cation to EuL_2 proceeds in Step 3 and leads to a very inert complex Eu_2L_2 for which either the release of a ligand ($k_{-3} \approx 10^{-3}$ s^{-1}) or of a cation ($k'_{-3} \approx 10^{-4}$ s^{-1}) is dramatically slow. Since Eu_2L_2 is a minor species, detected by ES-MS but neither by spectrophotometry nor by ^1H NMR, its stability constant could only be calculated from the rate constants (Table 4).

With an excess of Eu^{III}, the binding of a second cation (Step 2′) leads to the formation of Eu_2L. Assuming a dissociative Eigen–Wilkins[65] mechanism and using the Fuoss equation,[63] a formation rate constant equal to 5×10^3 $M^{-1} \times s^{-1}$ can be calculated, in excellent agreement with the measured rate constant k'_2 (Table 6). Therefore, the binding of a second Eu^{III} cation does not involve any structural rearrangement, but is mainly governed by the de-solvation of the entering cation and by intramolecular electrostatic repulsions. The latter induce a sizeable negative cooperative effect[27,34] as demonstrated by the ratio $K_{Eu_2L}/K_{EuL} \approx 10^{-2}-10^{-3}$. Step 3′ is related to the formation of a double-stranded bimetallic "pre-helicate" from Eu_2L. The approach of a second ligand is favored because coordination of the first ligand strand labilises the solvation sphere of the two cations and reduces the charge on the two binding sites. The estimation, via $\beta_{Eu_2L_2}$ (Tables 4 and 6), of k'_{-3} ($\approx 10^{-4}$ s^{-1}) provides information on the inertness of Eu_2L_2. A "side-by-side" arrangement, as already reported in the solid state for a closely related ligand[22] with two europium(III) cations, cannot explain an inert edifice in which the interactions between the two lanthanide ions are drastically reduced, perhaps by a "braided" structure (Figure S10, see Supporting Information).

Step 4 corresponds to the fast wrapping of the third strand around Eu_2L_2. The kinetic behavior in Step 4 is dominated by the slow solvolysis of the bimetallic triple-stranded helicate. The rate constant k_{-4} listed in Table 6 is within the range of data reported for the dissociation of various Ln^{III}-polyaminocarboxylate complexes (10^{-6} $s^{-1} < k < 10^{-3}$ s^{-1}).[71] This could also be in line with the X-ray structure of Eu_2L_3, in which two slightly different types of molecules were found, showing that an increase in the solvation of the carboxylates induces a lengthening of Eu^{III}–O distances.[26] It is noteworthy that the self-assembly mechanism of Eu_2L_3 does not exhibit any slow rearrangement from a precursor species, as previously reported by us for

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a tri-cuprous double-stranded helicate.[29] The situation is summarized in Figure 8 which displays the calculated time-dependences of the concentrations of the various Eu^{III}-containing species formed during the self-assembly process for a stoichiometric $[Eu]_{tot}/[L]_{tot}$ ratio of 0.67. The formation of the unique species Eu_2L_3 clearly occurs via the "braiding" of two ligand stands around the first Eu^{III} cation followed by the "keystone" addition of a second Eu^{III} ion and a fast wrapping of the third ligand around Eu_2L_2, the latter never being significantly accumulated.

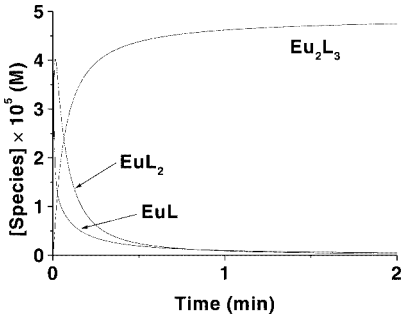

Figure 8. Calculated time dependence of the concentrations of the Eu^{III} complexes formed using the rate constants given in Tables 4 and 6.[31] Solvent: water; $T = 25.0 \pm 0.2$ °C; p[H] = 6.15±0.05 (MES buffer 0.1 M). $[L]_{tot} = 1.5 \times 10^{-4}$ M; $[Eu]_{tot}/[L]_{tot} = 0.67$

Conclusion

A fruitful combination of potentiometry, absorption and emission spectrophotometry, ^1H and ^{13}C NMR spectroscopy, and electrospray mass spectrometry allowed us to fully characterize the formation mechanism of a europium-containing triple-stranded Eu_2L_3 helicate with a hexadentate ditopic ligand. The self-assembly process implies a key bimetallic double-stranded species Eu_2L_2. This species is very inert towards the release of either a ligand or a cation, but reacts very rapidly with an additional ligand strand to yield the final triple-stranded helicate. This kinetic behavior points to the Eu_2L_2 intermediate probably adopting a structure different from the "side-by-side" arrangement observed for $Eu_2(L^B)_2$ in the solid state.[22] Indeed the formation of a 2:2 helical structure at this stage will decrease the steric hindrance and, moreover, the presence of negatively charged terminal carboxylate groups obviously contributes to prevent the formation a labile "side-by-side"[30,57] species. This is in contrast to the formation mechanism of $Eu_2(L^A)_3$ for which we propose the formation of a labile intermediate $Eu_2(L^A)_2$.[30] As far as we can tell, the increased inertness of the key intermediate is the main reason why the rate constant of the last step in the self-assembly process of Eu_2L_3 is 10^5 times larger than $Eu_2(L^A)_3$. Moreover, the addition of the successive ligand strands leads to a strong diminishing of the electrostatic interactions between the two coordination sites. These two features, which are reflected by the very low equilibrium concentrations of the intermediates, are probably of importance to "cooperatively" drive a fast and efficient self-assembly of the target triple-stranded di-europium(III) helicate.

In conclusion, the hexadentate ditopic ligand L leads to one of the most efficient cation/ligand systems for the self-assembly of a bimetallic triple-stranded helicate in water. This is mainly due to the simultaneous presence of a short spacer and of the one negative charge borne by each extremity.

Experimental Section

Starting Materials and Solvents: L was synthesized according to a previously published procedure.[26] $Eu(ClO_4)_3{\cdot}nH_2O$ was prepared from the oxide (Rhône−Poulenc, 99.99%) in the usual way.[72]

CAUTION! *Perchlorate salts combined with organic ligands are potentially explosive and should be handled in small quantities and with adequate precautions.*[73]

Distilled water was further purified by passing through a mixed bed of ion-exchanger (Bioblock Scientific R3-83002, M3-83006) and activated carbon (Bioblock Scientific ORC-83005). Spectrophotometric grade methanol (Merck, p.a.) and water were de-oxygenated using CO_2- and O_2-free argon (Sigma Oxiclear cartridge). All stock solutions were prepared using an AG 245 Mettler Toledo analytical balance (precision 0.01 mg).

Electrospray Mass Spectrometric Measurements: ES mass spectra were recorded on an HP 1100 mass spectrometer (Agilent Technologies, Palo Alto, CA, USA, formerly Hewlett−Packard Company Analytical Products Group). ES-MS was conducted in the positive ion mode. Scanning was performed from $m/z = 200$ to 1500 and the sampling cone voltage (V_c) was set at 120 V. For electrospray ionization, the drying gas was heated at 250 °C and its flow set at 3 L/min, the nebuliser pressure was 10 p.s.i. and the capillary voltage 4 kV. Solutions containing ligand L (7.96×10^{-4}, 4.04×10^{-4}, 2.02×10^{-5} M) and various equivalents of Eu^{III} were prepared in CH_3OH/H_2O (80:20 by weight). They were injected into the mass spectrometer source with a syringe pump (Harvard type PHD 2000, Harvard Apparatus Inc., South Natick, MA, USA) at a flow rate of 2 μL/min.

Potentiometric Titrations: The potentiometric titration of L ($1.036 \cdot 10^{-3}$ M) was performed using an automatic titrator system DMS 716 Titrino (Metrohm) with a combined glass electrode (Metrohm 6.0234.500, Long Life) filled with 0.1 M aqueous NaCl and connected to a microcomputer. The ionic strength was fixed at $I =$ 0.1 M with tetraethylammonium perchlorate (Fluka, puriss.). The combined glass electrode was calibrated as a hydrogen concentration probe by titrating known amounts of $HClO_4$ (9.997×10^{-2} M) with CO_2-free NMe_4OH solutions (1.040×10^{-1} M).[74] The cell was thermostatted at 25.0±0.2 °C by the flow of a Haake FJ thermostat. A stream of argon, pre-saturated with water vapour was passed over the surface of the solution. The potentiometric data (about 160 points collected over the pH range 5.9−11.0) were refined with the Hyperquad 2000[75] program which uses non-linear least-squares methods.[76] Potentiometric data points were weighted by a formula allowing greater pH errors in the region of an end-point than elsewhere. The weighting factor W_i is defined as the reciprocal of the estimated variance of measurements: $W_i = 1/\sigma_i^2 = 1/[\sigma_E^2 + (\delta E/\delta V)^2\sigma_V^2]$ where σ_E^2 and σ_V^2 are the estimated variances of the potential and volume readings, respectively. The con-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

stants were refined by minimizing the error-square sum, U, of the potentials shown below:

$$U = \sum_{i}^{N} W_i (E_{obs,i} - E_{cal,i})^2$$

Three titrations were treated either as single sets or as separated entities, for each system, without significant variation in the values of the determined constants. The quality of fit was judged by the values of the sample standard deviation, S, and the goodness of fit, χ^2, (Pearson's test). At σ_E = 0.1 mV (0.0023 σ_{pH}) and σ_V = 0.005 mL, the values of S in different sets of titrations were between 0.9 and 1.1, and χ^2 was below 12.6. The scatter of residuals versus pH was reasonably random, without any significant systematic trends, thus indicating a good fit of the experimental data. The successive protonation constants were calculated from the cumulative constants determined with the program. The uncertainties in the log K values correspond to the added standard deviations in the cumulative constants. The distribution curves of the protonated species of L as a function of pH (Figure S2, see Supporting Information) were calculated using the Haltafall program.[77]

Potentiometric and UV/Visible Titrations: A stock solution of L (8.91×10^{-5} M) was prepared by quantitative dissolution of a solid sample in deionised water and the ionic strength was adjusted to 0.1 M with NEt_4ClO_4 (Fluka, puriss). 100 mL of this solution were introduced into a jacketed cell (Metrohm) maintained at 25.0±0.2 °C (Haake FJ thermostat). The free hydrogen ion concentration was measured with a combined glass electrode (Metrohm 6.0234.500, Long Life) and a Tacussel Isis 20,000 millivoltmeter. The Ag/AgCl reference electrode was filled with NaCl (0.01 M, Fluka, p.a.) and $NaClO_4$ (0.09 M, Fluka, p.a). Standardization of the millivoltmeter and verification of the linearity (3.00 < p[H] < 9.00) of the electrode were performed using commercial buffers (Merck, Titrisol) according to classical methods.[78] The initial p[H] was adjusted to 11.59 with NMe_4OH (Merck, 10 wt.% solution in water), and the titration of the free ligand (7.38 < p[H] < 11.59) was then carried out by addition of known volumes of 1.69×10^{-2} M perchloric acid (Prolabo, normapur, 70% min) with an Eppendorf microburette. $HClO_4$ solution (Prolabo, normapur, 70% min) was titrated with NaOH (10^{-1} M, Carlo Erba, Titrisol Normex) using phenolphthalein (Prolabo, purum) as an indicator and prepared just before use. An aliquot (1 mL) was taken after each addition of acid, and simultaneous p[H] and UV/Visible spectra (230−400 nm) were recorded. Spectrophotometric measurements were made using Hellma quartz optical cells (0.2 cm) on a Kontron Uvikon 941 spectrophotometer maintained at 25.0±0.2 °C (Haake NB 22 thermostat).

UV/Visible Titrations: To probe the coordination properties of L with Eu^{III}, a solution of ligand L (8.22×10^{-6} M) at p[H] = 6.15±0.05 [0.1 M, 2-morpholinoethanesulfonic acid (MES), Fluka, microselect, 99.5%] was prepared. Europium(III) solutions were prepared immediately before use from deionised water saturated with argon. The solutions were acidified to p[H] < 4 with H_2SO_4 (Carlo Erba Reagenti, 96%) before complexometric titration to avoid hydroxide precipitation. Standardized Na_2H_2EDTA solution (Titriplex® III, Merck) in ammonium acetate (Prolabo, rectapur) buffered medium was used with xylene orange as an indicator.[79] The spectrophotometric titration of L with Eu^{III} was carried out in a Hellma quartz optical cell (2 cm). Microvolumes of a concentrated buffered (0.1 M MES, p[H] = 6.15±0.05) solution of europium(III) (4.24×10^{-4} M) were added to 4 mL of the stock ligand solution (the $[Eu]_{tot}/[L]_{tot}$ ratio varied from 0 to 23.36). Special care was taken to ensure that complete equilibration was attained. The corresponding UV/Visible spectra were recorded from 230 nm to 500 nm on a Kontron Uvikon 941 spectrophotometer maintained at 25.0±0.2 °C by the flow of a Haake NB 22 thermostat.

Potentiometric and Fluorescence Titrations: A stock solution of L (3.56×10^{-6} M, I = 0.1 M NEt_4ClO_4, Fluka, puriss) was prepared by quantitative dissolution of a solid sample and 100 mL were introduced into a jacketed cell (Metrohm) maintained at 25.0±0.2 °C by the flow of a Haake FJ thermostat. The initial p[H] was adjusted to 11.43 with NMe_4OH (Merck, 10 wt.% solution in water), and the titration of L (7.59 < p[H] < 11.43) was carried out by addition of known volumes of 1.69×10^{-2} M perchloric acid (Prolabo, normapur, 70% min) with an Eppendorf microburette. An aliquot (2 mL) was taken after each addition of acid, and simultaneous p[H] and fluorescence emission spectra were recorded (350−550 nm) with Hellma quartz optical cells (1 cm) on a Perkin−Elmer LS-50B instrument maintained at 25.0±0.2 °C by the flow of a Haake FJ thermostat. The excitation wavelength was 308±1 nm and the slit width was set at 4 nm for both excitation and emission. The source was a pulsed xenon flash lamp with a pulse width at half peak height < 10 μs and power equivalent to 20 kW.

Luminescence Titrations: Luminescence titrations were carried out on solutions with an absorbance less than 0.1 at wavelengths $\geq \lambda_{exc}$ in order to avoid any errors due to the inner filter effect. The p[H] was maintained at 6.15±0.05 by the use of 0.1 M MES (Fluka, microselect, 99.5%) and perchloric acid (Prolabo, normapur, 70% min). The titration of L (1.64×10^{-6} M) was carried out in a 1 cm Hellma quartz optical cell by addition of known microvolumes of a buffered solution of Eu^{III} (6.55×10^{-5} M) with an Eppendorf multipette® plus microburette. The $[Eu]_{tot}/[L]_{tot}$ ratio was varied from 0 to 15.37. Metal-centered luminescence spectra were recorded from 550 nm to 800 nm on a Perkin−Elmer LS-50B instrument at 25.0±0.2 °C. Gated spectra were obtained using phosphorimeter acquisition, with a delay time of 0.05 ms, a 200 ms sample window, 1 ms per flash and 1 flash per point. The slit width was 12.5 nm for both excitation and emission.

Analysis and Processing of the Spectroscopic Data: The spectrophotometric data were analyzed with both the Letagrop−Spefo[80−82] and Specfit[31] programs which adjust the absorptivities and the stability constants of the species formed at equilibrium. The Letagrop-Spefo program uses the Newton−Raphson algorithm to solve mass balance equations and a pit-mapping method to minimize the errors and determine the best parameter values. Specfit uses factor analysis to reduce the absorbance matrix and to extract the eigenvalues prior to the multiwavelength fit of the reduced data set according to the Marquardt algorithm.[83,84]

Kinetics of Formation: All kinetic measurements were performed in water at p[H] = 6.15±0.05 (0.1 M MES buffer) using a stopped-flow spectrophotometer (Applied Photophysic SX-18MV) equipped with a diode array device. The reactants were thermostatted at 25.0±0.2 °C (Lauda M12 thermostat) and mixed in a 1 cm optical cell. The data sets, averaged out of at least three replications, were recorded and analyzed with the commercial software Biokine.[85] This program fits up to three exponential functions to the experimental curves with the Simplex algorithm[86] after initialization with the Padé−Laplace method.[87]

The reaction of L with Eu^{III} in excess was followed at 332 nm. Ligand L concentration was equal to 2.55×10^{-5} M and Eu^{III} concentrations were varied from 2.57×10^{-4} M to 2.57×10^{-3} M. The reaction of Eu^{III} with ligand L in excess was followed at 350 nm.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Two sets of experiments were carried out. Eu^{III} concentration was equal to 1.06×10^{-6} M or, 2.73×10^{-6} M and L concentrations were varied from 1.06×10^{-5} M to 8.15×10^{-5} M or from 3.08×10^{-5} M to 1.54×10^{-4} M.

Acknowledgments

This work was supported by the Centre National de la Recherche Scientifique (CNRS, UMR 7509), by the faculty of Chemistry (Université Louis Pasteur, Strasbourg, France) and the Swiss National Science Foundation. J. Hamacek thanks the European Community for granting him a Marie Curie fellowship. The authors thank Dr. S. Blanc (Université de Pau et des pays de l'Adour, Laboratoire de Chimie Structurale, Pau, France) for stimulating and helpful discussions, Dr A.-S. Chauvin for her help in acquiring the ^{13}C NMR spectroscopic data and Mr. R. Hueber for his skilful assistance in the ES-MS measurements.

[45] In reference 26b, pK_a data are incorrect. In fact the reported figures (4.42 and 7.7) are pK_b values and not pK_a values. Recalculating these data in terms of pK_a values gives 9.6 and 6.3, two values in good agreement with those reported in Table 1, given the slightly different experimental conditions.

Supramolecular Chemistry Based on $[W_3S_4(H_2O)_6Cl_3]^+$ – A Versatile Building Block

Maxim N. Sokolov,*[a] Olga A. Gerasko,[a] Danil N. Dybtsev,[a] Elena V. Chubarova,[a] Alexander V. Virovets,[a] Cristian Vicent,[b] Rosa Llusar,[b] Dieter Fenske,[c] and Vladimir P. Fedin[a]

Keywords: Cluster compounds / Tungsten / Antimony / Cucurbituril / Supramolecular chemistry

The cluster $[W_3S_4(H_2O)_6Cl_3]^+$ (which is present in solutions of $[W_3S_4(H_2O)_9]^{4+}$ in 1–4 M HCl) reacts with the macrocyclic cavitand cucurbituril ($C_{36}H_{36}N_{24}O_{12}$) to form supramolecular adducts of 2:1 cluster/cucurbituril stoichiometry, where two portals of cucurbituril (which contains a water molecule in its cavity) are closed by two cluster cations. These aggregates are bound together in the solid by complementary hydrogen bonds between coordinated Cl^- and the cations $H_9O_4^+$ to give chains. Thus, a supramolecular architecture is achieved from three different but complementary building blocks. The packing of the chains affords a honeycomb structure (hexagonal symmetry) with channels (about 5.2 Å in diameter). The overall stoichiometry is $(H_9O_4)\{[W_3S_4(H_2O)_6Cl_3]_2(C_{36}H_{36}N_{24}O_{12})\}Cl_3\cdot 16.15H_2O$ (**1**). $[W_3S_4(H_2O)_6Cl_3]^+$ reacts with $SbCl_3$ in 6 M HCl to give cuboidal $[W_3(SbCl_3)S_4(H_2O)_6Cl_3]^+$, which forms with the macrocyclic cavitand cucurbituril a 2:1 cluster/cucurbituril adduct – a discrete supramolecule consisting of five independent molecular units. In the solid it crystallizes as a salt of very rare anion $[SbCl_6]^{3-}$ with the stoichiometry $\{[W_3(SbCl_3)S_4(H_2O)_6Cl_3]_2(C_{36}H_{36}N_{24}O_{12})\}(SbCl_6)_{2/3}\cdot 12H_2O$ (**2**).

Introduction

Building supramolecular aggregates relies heavily upon complementary hydrogen bond formation. Much has been done in the field of pure organic supramolecular assemblies and this new branch of organic synthesis has been aptly termed "noncovalent synthesis".[1] Though the potential of hydrogen bonds for noncovalent binding in the so-called second coordination sphere was recognized about 20 years ago and a review summarizing binding of transition metal complexes (mostly ammino complexes) to crown ethers and related macrocycles (through N–H···O bonding) appeared as early as in 1983,[2] most of the spectacular success in the field of supramolecular chemistry in the last decennium was due to the skillful use of possibilities of classical coordination chemistry.[3,4] A reason for this may well be the lesser degree of liberty with which inorganic compounds containing H-bond donors (or acceptors) can be tailored to suit the requirements of complementarity. However, if we take an aqua complex in solution of an acid whose anion is only a moderate or even a weak donor, an array of mixed complexes would form, and each individual complex will have its particular geometrical arrangement of coordinated water molecules. This can be regarded as a combinatorial library and, if the interconversion between different species within the library is rapid enough, we will have a dynamic combinatorial library.[5] By introducing an organic H-bond acceptor with a purposefully chosen geometry, we could then selectively "recognize" any single desired component, making isolation of active species in equilibrium with its chemically closely congeners simple. Our previous work suggests that triangular cluster aqua ions of the general formula $[M_3Q_4Cl_x(H_2O)_{9-x}]^{4-x}$ (M = Mo, W; Q = S, Se; x = 1–5) can be regarded as components of one such library.[6–10] Specific requirements of complementarity between six-coordinated water molecules in $[M_3Q_4Cl_x(H_2O)_{9-x}]^{4-x}$ (H-bond donors) and six oxygen atoms of C=O groups of a macrocyclic cavitand cucurbituril lead to the isolation of supramolecular adducts when x = 1–3, i.e., the specific recognition of only a part of the library components, and moreover, in each case only of one of all possible isomers.[7–11]

In the present study we show, in one case – $(H_9O_4)\{[W_3S_4(H_2O)_6Cl_3]_2(C_{36}H_{36}N_{24}O_{12})\}Cl_3\cdot 16.15H_2O$ (**1**) – how the complementarity towards $[W_3S_4Cl_3(H_2O)_6]^+$ may be reinforced through introducing "guanidinium-like"

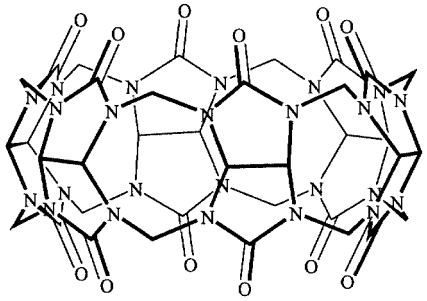
$H_9O_4^+$ which also acts as structure-directing building block making the formation of a honeycomb-like structure possible, and, in another case – $\{[W_3(SbCl_3)S_4(H_2O)_6Cl_3]_2(C_{36}H_{36}N_{24}O_{12})\}(SbCl_6)_{2/3}\cdot 12H_2O$ (**2**) – how weak interactions other than hydrogen bonds may be exploited to build a nanosized supramolecular aggregate containing five units of three different building blocks, each of which is known as independent chemical species.

Results and Discussion

Although Cl^- coordination to $[M_3Q_4(H_2O)_9]^{4+}$ (M = Mo, W; Q = S, Se) in aqueous solutions is fairly weak {for the formation of $[Mo_3S_4(H_2O)_8Cl]^{3+}$ K is only 3.0 M^{-1}}, and no fully substituted species $[M_3Q_4Cl_9]^{5-}$ (or of other halides) have been isolated, some equilibration to the extent at least of $[M_3Q_4(H_2O)_4Cl_5]^-$ does take place in 1–6 M HCl.



Cucurbituril

Using cucurbituril as a second coordination sphere ligand (Cuc, $C_{36}H_{36}N_{24}O_{12}$) to promote crystallization through formation of complementary associates based on hydrogen bonds between the carbonyl groups of Cuc and water molecules *cis* to the μ_3-Q ligand of the cluster it was possible to isolate the following compounds and to determine their X-ray structures: (i) monosubstituted $\{[W_3S_4(H_2O)_8Cl](pyH\subset Cuc)\}Cl_4\cdot 15.5H_2O$,[8] $\{[W_3Se_4(H_2O)_8Cl]_2(Cuc)\}Cl_6\cdot 12H_2O$[11] and $\{[Mo_3Se_4(H_2O)_8Cl]_2(Cuc)\}Cl_6\cdot 16H_2O$;[9] (ii) disubstituted $\{[W_3S_4(H_2O)_7Cl_2](Cuc)\}Cl_2\cdot 10H_2O$;[7] (iii) trisubstituted $\{[Mo_3S_4(H_2O)_6Cl_3][Mo_3S_4(H_2O)_7Cl_2](pyH\subset Cuc)\}Cl_4\cdot 17H_2O$,[7] $(H_3O)_2[Mo_3S_4(H_2O)_6Cl_3](Cuc)Cl_3\cdot 9H_2O$[10] and $\{[W_3Se_4(H_2O)_6Cl_3](pyH\subset Cuc)\}_2Cl_3\cdot 18H_2O$.[12] In all these structures the barrel-shaped cucurbituril molecule is effectively closed by one or two cluster "lids"; in some cases a small molecule (pyridinium cation) is included and retained inside the cucurbituril inner cavity.[7,8,12,13] The chloride substitution is always at the *trans* positions to the μ_3-chalcogen atom, other H_2O ligands are retained and used for complementary hydrogen bonding with Cuc. When more (5 Cl^-) enter into the cluster, as in $(H_3O)_2\{[Mo_3Se_4(H_2O)_4Cl_5]_2(Cuc)\}\cdot 15H_2O$, the complementarity is lost.[9] In all cases the $[M_3Q_4(H_2O)_6Cl_3]^+$ species are present as the most symmetrical isomers (with a threefold axis). Comparison of the geometrical parameters of $\{W_3S_4\}$ cluster cores in the aqua complexes is given in Table 1. We can see that W–W bond lengths are only slightly affected by the environment of tungsten atoms.

Formation and Structure of 1

The structure of the cluster cation $[W_3S_4(H_2O)_6Cl_3]^+$ in compounds **1** is shown in Figure 1. Main bond lengths of $\{W_3S_4\}$ cluster core are similar to that found in the tungsten aqua complexes (Table 1). Six water molecules in *cis* position to the core μ_3-S atom form hydrogen bonds with portal oxygen atoms of cucurbituril (O···O, 2.76–2.94 Å), and a complementary cationic associate $\{[W_3S_4(H_2O)_6Cl_3](Cuc)[W_3S_4(H_2O)_6Cl_3]\}^{2+}$ ("two lids on the barrel" type) is formed. It has a very high crystallo-

graphic symmetry, 6bar*m*2 (D_{3h}). This associate has an ellipsoidal egg-like shape of about 19.5 Å height and 14.4 Å in diameter. The associates are arranged according to the ideal hexagonal close packing (h.c.p.) motif (Figure 2). The space group of **1** is $P6_3/mmc$ − quite common for the h.c.p. structure type (e.g. Mg metal structure). It must be stressed that the associates do not contact each other in the hexagonal layer because the distances between them (16.47 Å) are longer than the van der Waals "diameter" of the associate. It means that we have not exactly close packing, but only an h.c.p.-like motif. From this point of view, the $H_9O_4^+$ cations occupy exactly one half of the tetrahedral voids. They are planar, the central oxygen atom is surrounded by three other ones at the distance of 2.59 Å which is typical for hydroxonium cations.[15] The disordered Cl^- anions and water molecules lie in the octahedral voids playing the role of a layer between the positively charged associates. The macrocyclic cavitand cucurbituril contains a water molecule in its cavity.

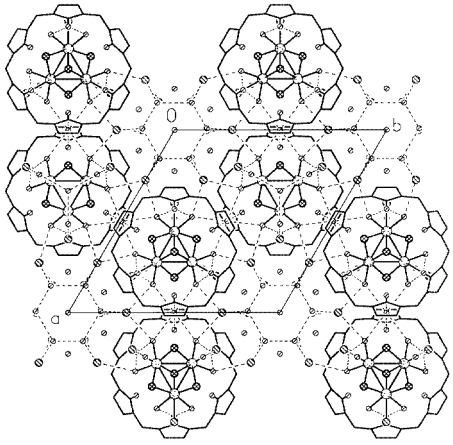

Figure 2. Crystal packing in compound **1** (projection on *a*,*b* plane); hydrogen bonds are shown as dashed lines

Once the discrete "lid-on-the-barrel" complexes between Cuc and $[M_3Q_4Cl_x(H_2O)_{9-x}]^{4-x}$ ($x = 1-3$) are formed, their further aggregation in the solid state can take place. First, through noncovalent Q···Q interactions between bridging μ_2-Q atoms (which seem to be more important when Q = Se) polymeric chains may form. This is the case for $\{[W_3Se_4(H_2O)_8Cl]_2(Cuc)\}Cl_6\cdot 12H_2O$,[11] $\{[Mo_3Se_4(H_2O)_8Cl]_2(Cuc)\}Cl_6\cdot 16H_2O$,[9] $\{[Mo_3S_4(H_2O)_6Cl_3][Mo_3S_4(H_2O)_7Cl_2](pyH\subset Cuc)\}Cl_4\cdot 17H_2O$,[7] $\{[W_3Se_4(H_2O)_6Cl_3](pyH\subset Cuc)\}_2Cl_3\cdot 18H_2O$.[12] The reluctance of the $\{W_3S_4\}$ unit to dimerise through S···S interactions is apparent here. Instead of this kind of association, in the structure of **1** the $H_9O_4^+$ cations lie between cluster−cucurbituril associates. They form hydrogen bonds with three terminal chlorine ligands of two cluster cations, Cl···O being of 3.11 Å. The guanidinium-like structure of $H_9O_4^+$ makes it suitable for complementary O−H···Cl hydrogen bonding with $[W_3S_4(H_2O)_6Cl_3]^+$. The resulting chains run along the *c* axis (Figure 3). They are shifted in such a way that each $H_9O_4^+$ cation is surrounded by four associates.

In structure **1** there are also channels along the *c* axis filled with disordered Cl^- anions and water molecules. The diameter of the channels is 5.2 Å, taking the values 1.70, 1.15, 1.40 and 1.36 Å as van der Waals radii of C, H, N and O, respectively.[16] These channels, from the h.c.p.'s point of view, are nothing else than the columns of octahedral voids. The porous frameworks built on relatively strong noncovalent interactions, like H-bonds, are of certain interest since they can be more easily disassembled than ones based on stronger covalent bonding. Kim and co-workers recently reported another cucurbituril-based honeycomb structure in $\{[Rb_2(OH)_2(CH_3OH)_2(H_2O)_2](Cuc)\}\cdot 17H_2O$ where the channels have a mean diameter of about 8.9 Å.[17]

Formation and Structure of 2

The complementarity for hydrogen bonding with cucurbituril is not lost when cuboidal chalcogen-bridged aqua complexes are dealt with since they retain the unit $\{M_3Q_4(H_2O)_6\}$. One of the most interesting properties of the triangular clusters with $\{M_3Q_4\}$ cores is their ability to incorporate a low-valent metal M′ with the formation of a cuboidal cluster $\{M_3M'Q_4\}$. In the case of $Mo_3S_4^{4+}$, some 20 transition and post-transition metals have been incorporated. It seems that all metals having $d^{10}s^2$ configuration [e.g. those of group 12 (Cd^0, Hg^0), 13 (Ga^I, In^I, Tl^I), 14 (Ge^{II}, Sn^{II}, Pb^{II}), 15 (As^{III}, Sb^{III}, Bi^{III}), and possibly group 16] can react in this way. Reactions are generally fast but in some cases (Tl^I, Pb^{II}, As^{III}, Bi^{III}) reaction does not take place in aqueous solution and/or with aqua ions, but proceed smoothly in organic solvents and with different coordination environment.[18] Antimony seems to be a border case. We observed characteristic color changes on addition of $SbCl_3$ to solutions of $[M_3Q_4(H_2O)_9]^{4+}$ in HCl, but it turned out to be difficult to characterize the reaction products.

$$[M_3Q_4(H_2O)_9]^{4+} + SbCl_3 \rightarrow [M_3(SbCl_3)Q_4(H_2O)_9]^{4+}$$

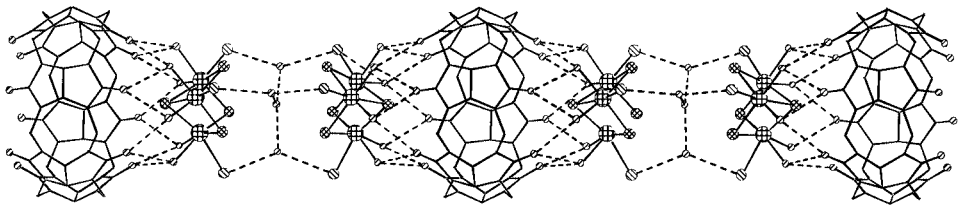

Figure 3. Fragment of the supramolecular chain in compound **1**; hydrogen bonds are shown as dashed lines

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Column purification, which is a standard procedure in this kind of chemistry, cannot be applied since (i) this equilibrium is shifted very much to the left, (ii) lowering $[H^+]$ destroys $SbCl_3$ to give oxochlorides or eventually $Sb(OH)_3$. Solutions of such cuboidal clusters in HCl are notoriously difficult to crystallize, and using Hpts (*p*-toluenesulfonic acid) for crystallization is excluded by the absence of soluble Sb^{III} cationic species in this media for the range of concentration involved (1−4 M Hpts). Therefore crystallization with cucurbituril was attempted and allowed us to isolate a cuboidal cluster $[W_3(SbCl_3)S_4(H_2O)_6Cl_3]^+$ as $\{[W_3(SbCl_3)S_4(H_2O)_6Cl_3]_2(C_{36}H_{36}N_{24}O_{12})\}(SbCl_6)_{2/3}\cdot 12H_2O$ (**2**).

The structure of the cluster cation $[W_3(SbCl_3)S_4(H_2O)_6Cl_3]^+$ in **2** is shown in Figure 4. The only other known cuboidal cluster with the $W_3SbS_4^{7+}$ core is found in $[W_3(SbI_3)S_4(OAc)(dtp)_3(DMF)]$ (dtp = diethyl dithiophosphate).[19] Also several derivatives of the $Mo_3SbS_4^{7+}$ core have been reported; they all contain dtp ligands at Mo and 3 X (X = Cl, Br, I) at Sb (Table 2).[20−22] We can see that in the case of tungsten complexes the Sb−S bond lengths are notably longer than in Mo_3SbS_4 clusters. At the same time the M−M and M−S bonds are not affected by the nature of M.

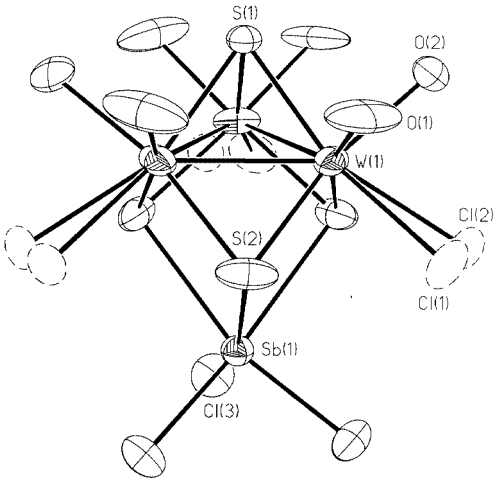

Figure 4. Cluster cation $[W_3(SbCl_3)S_4(H_2O)_6Cl_3]^+$ in the compound **2** (50% probability ellipsoids); disordered terminal chlorine ligands are shown by dashed ellipsoids, site occupancies being equal to 0.5; main bond lengths [Å]: W(1)−W(1)#1 2.7100(12), W(1)−W(1)#2 2.7100(12), W(1)−S(1) 2.349(5), W(1)−S(2) 2.300(5), W(1)···Sb(1) 3.8660(12), W(1)−Cl(1) 2.502(10), W(1)−Cl(2) 2.503(10), W(1)−O(1) 2.133(13), W(1)−O(2) 2.143(13), Sb(1)−S(2)#2 2.845(4), Sb(1)−Cl(3) 2.404(4); symmetry transformations used to generate equivalent atoms: #1: $-z+1$, $x-1/2$, $-y+1/2$; #2: $y+1/2$, $-z+1/2$, $-x+1$

In the cluster cation $[W_3(SbCl_3)S_4(H_2O)_6Cl_3]^+$ main bond lengths of $\{W_3S_4\}$ cluster core are similar to that found in the tungsten aqua complexes (Table 1). Along with the large distances W···Sb (3.87 Å) and Sb−S (2.85 Å) it makes a strong case for regarding the $[W_3(SbCl_3)S_4(H_2O)_6Cl_3]^+$ in **2** as a rather weakly bound associate of $[W_3S_4(H_2O)_6Cl_3]^+$ and $SbCl_3$. There are also a few complexes of $SbCl_3$ with thioethers [1,4,7-trithiacyclononane, 1,4,7,10,13,16-hexathiacyclooctadecane, 1,2-bis-(methylthio)ethane]. A general feature is that all of them have very long Sb−S distances, no shorter than 2.97 Å.[23,24] That in our case as well as in the other $M_3SbS_4^{7+}$ clusters the Sb−S bonds are shorter may be regarded as the result of a partial charge transfer from Sb onto M_3S_4 unit, diminishing the electron density on Sb and increasing it on S − a synergetic effect, as has been put forward to explain similar structural features of $W_3SnS_4^{6+}$.[25]

In the case of compound **2** the complementary associate cluster−cucurbituril−cluster ("two lids on the barrel" type) is also formed (Figure 5), O···O being of 2.77−2.83 Å. Thus, a nanosized supramolecular aggregate containing five units of three different building blocks, each of which is known as independent chemical species ($[W_3S_4(H_2O)_6Cl_3]^+$, $SbCl_3$ and Cuc), is formed. The largest distance between outermost chlorine atoms in this aggregate is 26.7 Å. In structure **2** associates are located on the non-intersecting

threefold axes of $Pa\bar{3}$ space group, forming crystal packing similar to solid CO_2.

An interesting feature of this structure is the occurrence of the rare octahedron $[SbCl_6]^{3-}$ as counterion. The Sb−Cl distance is 2.678 Å, which is in agreement with the range 2.675−2.765 Å, reported for hexachloroantimonate(3−).[26,27] On the contrary, in $SbCl_6^-$ the Sb−Cl bonds are much shorter − about 2.37 Å.[28] To the best of our knowledge, there are only two other reports on $[SbCl_6]^{3-}$: in $[Co(NH_3)_6][SbCl_6]$[26] and in 2-aminoguanidinium 2-ammonioguanidinium hexachloroantimonate(III) $(CH_8N_4)(CHN_4)[SbCl_6]$.[27] In all three structures the lone pair in $[SbCl_6]^{3-}$ does not occupy a coordination site, but rather is a spherically symmetric *s* orbital.

Experimental Section

General: All reactions were carried out in air. Stock solutions of $[W_3S_4(H_2O)_9]^{4+}$ in 2 M HCl were prepared by a published procedure[29] and made up to the required $[H^+]$ concentration with 12 M HCl. Cucurbituril was synthesized by a published procedure.[30] $SbCl_3$ was of commercial quality (Aldrich). Elemental analyses were carried out in the Laboratory of Microanalysis, Institute of Organic Chemistry, Novosibirsk.

$(H_9O_4)\{[W_3S_4(H_2O)_6Cl_3]_2(C_{36}H_{36}N_{24}O_{12})\}Cl_3\cdot 16.15H_2O$ (1): A cucurbituril solution (0.3 mL, 20 mM) in 4 M HCl was added to a $[W_3S_4(H_2O)_9]^{4+}$ solution (1.5 mL, 10 mM) in 10 M HCl. The reaction mixture was stirred and left in a closed vial at room temperature for 5 d. Dark violet hexagonal crystals of **1** were collected by filtration and dried in air. Yield: 7 mg (20%). $C_{36}H_{101.3}Cl_9N_{24}O_{44.15}S_8W_6$ (3255.74): calcd. C 13.29, H 3.13, Cl 9.81, N 10.33, S 7.89; found C 13.98, H 2.59, Cl 9.00, N 10.74, S 7.94.

$\{[W_3(SbCl_3)S_4(H_2O)_6Cl_3]_2(C_{36}H_{36}N_{24}O_{12})\}(SbCl_6)_{2/3}\cdot 12H_2O$ (2): A cucurbituril solution (0.3 mL, 20 mM) in 6 M HCl was added to a mixture of a $[W_3S_4(H_2O)_9]^{4+}$ solution (1.5 mL, 10 mM) in 6 M HCl, containing 10 mg of $SbCl_3$. The reaction mixture was stirred and left in a closed vial at room temperature for 2 d. Red crystals of **2** were collected by filtration and dried in air. Yield: 8 mg (32%). $C_{36}H_{84}Cl_{16}N_{24}O_{36}S_8Sb_{2.67}W_6$ (3680.52): calcd. C 11.62, H 2.28, N 9.03; found C 11.79, H. 2.91, N 9.15.

X-ray Crystal Structure Determinations: Structures of both **1** and **2** were determined by X-ray analysis on single crystals in essentially a routine manner. **1:** $C_{36}H_{101.3}Cl_9N_{24}O_{44.15}S_8W_6$, formula mass 3255.74, hexagonal, space group $P6_3/mmc$, $Z = 2$, $a = 16.474(3)$, $c = 21.307(3)$ Å, $\gamma = 120°$, $V = 5008.0(12)$ Å^3, $D_{calcd.} = 2.159$ g·cm^{-3}, μ(Mo-K_α) = 7.362 mm^{-1}. Experimental data were measured at $T = 203$ K from a dark-violet crystal of 0.20 × 0.18 × 0.16 mm size by the standard technique with a STOE STADI4 four-cycle diffractometer using Mo-K_α radiation ($\lambda = 0.7107$ Å). A total of 6236 reflections was measured up to $2\theta_{max} = 50°$, of which 1701 are unique, $R_{int} = 0.1134$. Absorption correction was applied by measuring 3 azimuthal scans, transmission factors were from 0.7094 to 0.9965. The structure was solved by direct methods and refined by full-matrix methods for all non-hydrogen atoms using SHELX-97 program set.[31] Solvent water molecules and chlorine anions were seriously disordered. Their site occupancy factors were refined taking into account the chemical analysis data, electroneutrality and refined values of atomic thermal parameters, leading to the resulting formula that is in a good agreement with other data. $R_1 = 0.0512$ for 1089 $F \geq 4\sigma(F)$, $wR_2 = 0.1339$, $GooF = 1.142$ for all unique data. **2:** $C_{36}H_{84}Cl_{16}N_{24}O_{36}S_8Sb_{2.67}W_6$, formula mass 3680.52, cubic, space group $Pa\bar{3}$, $Z = 8$, $a = 21.788(3)$ Å, $V = 10344(2)$ Å^3, $D_{calcd.} = 2.363$ g·cm^{-3}, μ(Mo-K_α) = 7.984 mm^{-1}. Experimental data were measured at $T = 293$ K from a red crystal of 0.1 × 0.08 × 0.08 mm size by the standard technique with a Bruker SMART CCD diffractometer using Mo-K_α radiation ($\lambda = 0.7107$ Å). A total of 48756 reflections was measured up to $2\theta_{max} = 46.5°$, of which 2491 were unique, $R_{int} = 0.1968$. Absorption correction was applied empirically using the SADABS program, the ratio between minimum and maximum transmission factors was 0.8622. The structure was solved by direct methods and refined by full-matrix methods for all non-hydrogen atoms using the SHELXTL program set.[32] All non-hydrogen atoms were refined anisotropically. The Sb(1) atom was found in a special position (on a threefold axis) coordinated to three symmetry-related equivalent chlorine atoms Cl(3) and to three symmetry-related sulfur atoms S(2) (Figure 4). The hexachloroantimonate(3−) anion was found in a special position and refined as partially occupied in order to balance the overall charge of the cluster. Attempts to refine the $[SbCl_6]^{3-}$ anion with full occupancy resulted in high equivalent isotropic displacement parameters for both antimony (120 Å^2) and chlorine (240 Å^2) and a electron density hole of −3 e$^-$Å^{-3} near the antimony position. The equivalent isotropic displacement parameters in our partially occupied model were 70 Å^2 for antimony and 150 Å^2 for chlorine while the electron density hole near antimony decreased to 1.56 e$^-$Å^{-3} (highest peak is 1.30 e$^-$Å^{-3}). Based on this we decided to balance our cluster charge refining the antimony anion with partial occupancy instead of assuming the protonation of one of the crystallization water molecules. One tungsten atom per asymmetric unit was found in a general position and was coordinated to two O atoms from water molecules *cis* to μ_3-S−(W_3) [O(1) and O(2)] and to one Cl atom. The anisotropic thermal parameters of this Cl atom suggested a splitting of the electron density in two positions Cl(1) and Cl(2). The positions of all cucurbituril hydrogen atoms were generated geometrically, assigned isotropic thermal parameters and allowed to ride on the respective parent carbon atoms. Water hydrogen atoms were not refined. The five highest peaks left on the electron density map were assigned to partially occupied crystallization water molecules and refined isotropically. Convergence was reached at residuals of $R_1 = 0.0551$ and $wR_2 = 0.1348$ with a goodness-of-fit parameter of 1.041. CCDC-201934 and -201935 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Structure-Dependent Electrochemical Behavior of Thienylplatinum(II) Complexes of N,N-Heterocycles

Feng Zhao,[a] Xingling Xu,[a] Soo Beng Khoo,*[a] and T. S. Andy Hor*[a]

Keywords: Platinum / N ligands / Cyclic voltammetry / Thin films / Heterocycles

trans-[Pt(MeCN)(PPh_3)$_2$(2-thienyl)]BF_4 (**1**) serves as a convenient precursor to bifunctional mononuclear *trans*-[Pt(PPh_3)$_2$(η^1-*N*-*N*)(2-thienyl)]BF_4 [*N*-*N* = pyrazine (**2**); 2-chloropyrazine, (**3**)] and dinuclear *trans,trans*-[Pt_2(PPh_3)$_4$(μ-*N*-*N*)(2-thienyl)$_2$](BF_4)$_2$ [(*N*-*N* = 4,4′-bipyridine (**4**); 4,4′-vinylenedipyridine (**5**)] complexes. The nuclear selectivity is conveniently controlled by the choice of the heterocyclic ligands or spacers. Both structural types **3** and **5** were confirmed by single-crystal X-ray crystallographic analyses. Their solution identities were established by positive-ion Electrospray Mass Spectrometry (ESMS). The electroactivities of these complexes were studied by cyclic voltammetry (CV). Continuous CV scans of **4** and **5** revealed variations in the redox waves with the number of scans. While the initial oxidative scan exhibited only a broad, irreversible wave, further cycling showed the growth of two additional redox couples up to about the tenth cycle. The peak currents of these redox couples began to decay with prolonged potential cycling beyond the tenth cycle. These findings are consistent with the formation of electroactive oligomers/polymers, and this conclusion is supported by visible thin film formation on the electrodes. In contrast, the mononuclear complexes (**2** and **3**) do not show such behavior. The films formed were further studied by repetitive potential cycling and XPS.

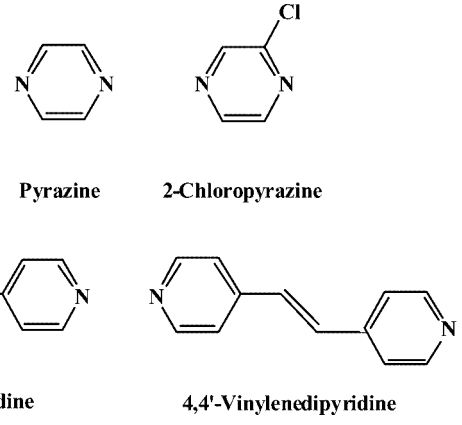
Introduction

The preparation of macro- and supramolecular assemblies with functionalised properties is currently a major challenge in synthetic chemistry.[1] A careful selection of a transition metal and a conjugated ligand could result in not only targeted molecular sizes and shapes,[2] but also expected electrochemical, magnetic and optical properties. Incorporation of transition metals into the conjugated backbone enhances metal dπ-pπ* back-bonding, which is expected to contribute significantly to the π-electron delocalization.[3] The combination of conjugated ligands, electron-rich metal centers, and the high degree of covalence inherent in soft-soft bonding can promote low-energy electronic interactions between the metal and the ligand. Our recent interest has been focused on novel electroactive metal-organic complexes.[4] Our current interest in d^8 thienyl complexes[5] stems from their geometric directionality and conductive potential[6] upon polymerization. Recently, we have extended this study to the construction of N- and P-bridged transition metal thienyl complexes. The simplest way to achieve this is through the introduction of a bridging co-ligand, or spacer. A non-thienyl spacer would bring an extra dimension of functionality to the complex. This paper describes a combined use of thienyl and nitrogen-containing heterocyclic ligands (depicted below) in the assembly of multimeric bifunctional d^8 networks based on a readily synthesized precursor. Introduction of different N-ligands, viz. pyridine or pyrazine-based heterocycles enables us to tune the spatial and structural features that have a direct impact on the electrochemical responses.



Results and Discussion

(1) Synthesis

The reaction in acetonitrile solution between equimolar *trans*-[PtBr(PPh_3)$_2$(2-thienyl)][7,8] and $AgBF_4$, gives *trans*-[Pt(MeCN)(PPh_3)$_2$(2-thienyl)]BF_4, (**1**). Its quantitative yield

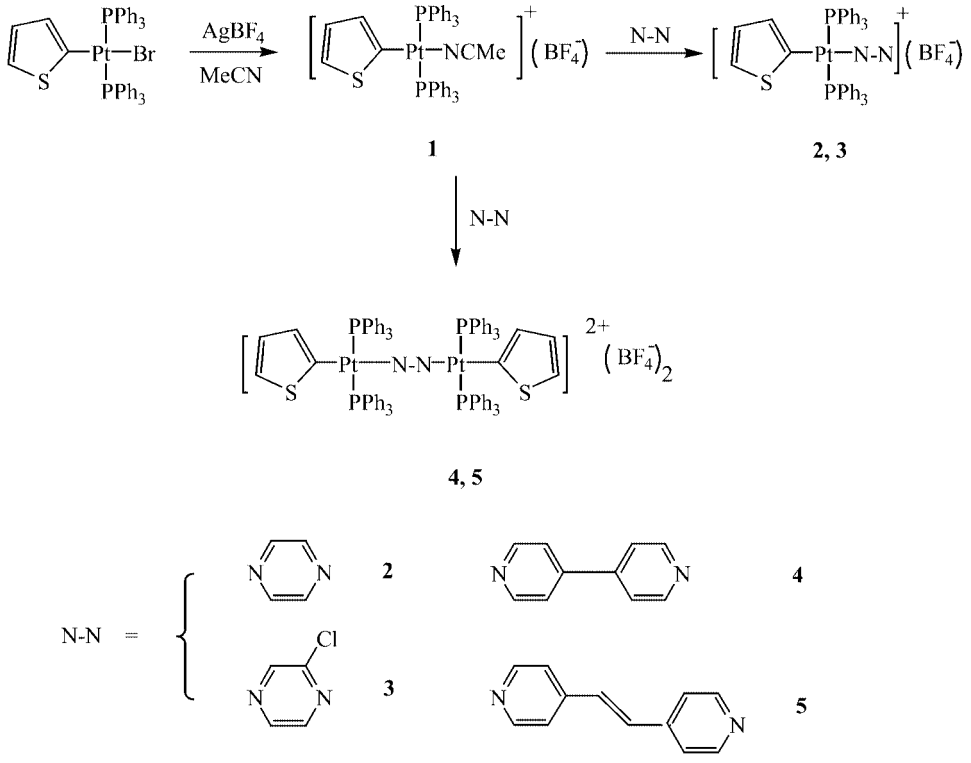

Scheme 1. Formation pathway of complexes **1**−**5**

and the presence of a labile MeCN solvent molecule make it a suitable precursor to bifunctional complexes. Although **1** can be isolated, it is more convenient to use it in situ. Upon removal of AgBr by filtration from the product mixture, addition of 4,4′-bipyridine or 4,4′-vinylenedipyridine gives dinuclear *trans,trans*-$[Pt_2(PPh_3)_4(\mu\text{-}N\text{-}N)(2\text{-thienyl})_2][BF_4]_2$ [*N*-*N* = 4,4′-bipyridine (**4**), 4,4′-vinylenedipyridine (**5**)] respectively. However, use of pyrazine and 2-chloropyrazine as substrates gives only mononuclear *trans*-$[Pt(PPh_3)_2(\eta^1\text{-}N\text{-}N)(2\text{-thienyl})][BF_4]$ [*N*-*N* = pyrazine, (**2**), 2-chloropyrazine, (**3**)] as yellow solids in high yields, despite the presence of a *trans*-disposed N-functionality (Scheme 1).

These illustrate an effective nuclear selectivity through a simple control of the N-spacer. Heterocycles in which charge delocalization is efficient, such as **2** and **3**, would have a lower nucleophilicity of the second nitrogen to an extent that it prefers to be pendant rather than bridging. The presence of the bulky PPh_3 ligand could also impede the approach of the neighboring Pt^{II} moiety towards a less protruded heterocyclic arm. Construction of cationic metal-based molecular boxes have met with a similar fate.[9,10] NMR analysis suggested that these cationic complexes are nonlabile. The ^1H coordination shifts (upfield) of the α- and β- pyrazine or pyridine hydrogen atoms (possibly due to shielding by the PPh_3 ligand) are indicative of coordinative nonlability. The α- and β-pyridine hydrogen atoms of **2** are similarly shifted upfield to δ = 8.21, 7.96 ppm, relative to free pyrazine (δ_H = 8.58), and, similarly for **5**, to δ = 7.81, 7.06 ppm, relative to free 4,4′-vinylenedipyridine (H_α δ = 8.62, H_β δ = 8.39 ppm). The ^{31}P NMR spectra of all the complexes showed the expected *trans*-phosphanes [typically $^1J_{Pt\text{-}P}$ (ca. 3480 Hz)] that are equivalent. As expected, both the shifts and couplings are fairly insensitive to subtle electronic changes in the *cis* N-ligands.

(2) Solid State Structures

Complexes **3** (Figure 1) and **5** (Figure 2) were chosen as models for X-ray crystallographic elucidation of the solid-state structures. The refinement data and bond/angle parameters are collected in Table 1 and Table 2, respectively. Complex **3** is mononuclear, comprising two *trans*-oriented phosphanes [P(2)−Pt(1)−P(2) 176.28(6)°] and a thienyl

group opposite the chloropyrazine ring [N(1)−Pt(1)−C(1) 179.4(5)°]. The nitrogen atom meta to the chloro functionality is preferentially coordinated whereas the ortho counterpart is pendant. The thienyl and chloropyrazine rings are tilted at an angle of 29.5° to each other. The proximity of the phenyl rings makes the pendant nitrogen atom less susceptible to attack. Complex **5** is dinuclear with a 4,4′-vinylenedipyridine group bridging two Pt^{II} centers, opposite two thienyl terminal ligands [N(1)−Pt(1)−C(1) 168.9(2)°]. The two pyridyl rings are strictly coplanar (θ, 0°).

Complex **3** has a noncrystallographic twofold symmetry along the N(1)−Pt(1)−C(1) axis. Both substituents at the Pt(1) center, namely thienyl and 2-chloropyrazine groups are disordered along this axis. Complex **5** has a center of inversion between the methylene carbon atoms of the 4,4′-vinylenedipyridine bridging ligand, and the thienyl groups are disordered.

All Pt−N[11] [2.082(4)-2.107(4) Å] and Pt−P[10] lengths [2.3212(19)-2.323(3) Å] are normal although the Pt−N bonds of **5** are somewhat longer (in 1.2%) than in **3**. There is no evidence of perturbance to the olefinic [C(10)−C(10A) 1.352 Å] moiety at the center of the bridge.

(3) ESMS Characterization

The development of electrospray mass spectrometry (ESMS) by Fenn[12] and others[13] has provided a powerful soft technique to study multiply-charged ions, primarily large biomolecules, in solution. Recently, we have extended this development as a combinatorial-like technique to probe the chemistry of $[Pt_2(\mu\text{-}X)_2(PPh_3)_4]$ (X = S, Se).[14] In this paper we use ESMS to investigate the fragmentation of the

parent ions in solution. Analysis of the mononuclear complexes in CH_2Cl_2 in the positive ion mode gave a $[M(N\text{-}N)]^+$ peak for **2** (m/z = 881.7) and **3** (m/z = 915.7) [M = $Pt(PPh_3)_2$(2-thienyl); *N*-*N* = pyrazine, (**2**), 2-chloropyrazine, (**3**)]. In these complexes, there is a common peak associated with the replacement of the pyrazine ligand by MeCN viz. $[M(MeCN)]^+$ (m/z = 843.8), which was observed as the main peak for complex **1**. These data suggested that the solid-state identity of these complexes is maintained in solution.

The positive-ion ES mass spectrum of complex **5** dissolved in CH_2Cl_2 is shown in Figure 3. A possible fragmentation pathway is illustrated in Scheme 2. The presence of the intact, doubly charged molecular ion Peak A (m/z = 892.7, 100%), $[M_2(4,4'\text{-vinylenedipyridine})]^{2+}$ lends support to the suggestion that the solution and solid state structures are in agreement. Fragmentation peaks B (m/z = 802.0, 10%), D (m/z = 843.8, 4%), and C (m/z = 983.8, 32%) were also detected, corresponding to M^+, $[M(MeCN)]^+$ and $[M(4,4'\text{-vinylenedipyridine})]^+$, respectively. Similarly, in the positive-ion ES mass spectrum of complex **4**, the intact, doubly charged molecular ion peak at m/z = 880.1 was observed, together with the fragmental molecular ion peaks at m/z = 957.0 {$[M(4,4'\text{-bipyridine})]^+$}, 802.0 and 843.8.

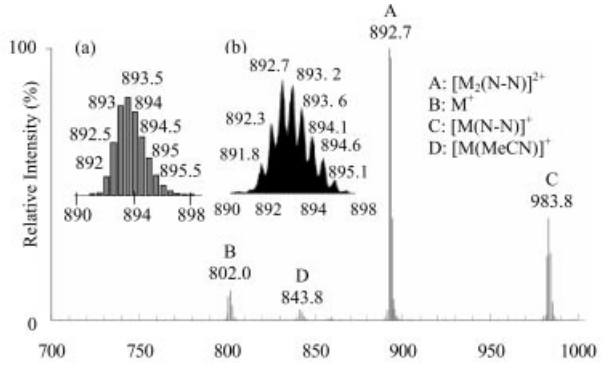

Figure 3. Positive-ion ES mass spectrum of **5** in CH_2Cl_2 solvent. The insets show the (a) calculated and (b) observed isotope distribution pattern for the intact dinuclear parent ion

Their formation can be explained by bridge cleavage by the residual MeCN molecule, thereby generating two cationic mononuclear complexes in which one bears a pendant heterocyclic ligand and the other captures the solvent ligand (Scheme 2). The ligand replacement or bridge cleavage by the strong coordination solvent MeCN has been reported before.[15] However, we should add that this takes place only when voltage is applied under spectrometric conditions. The cleavage invariably occurs at the heterocyclic junction, indicating that this is the weakest link in this series of bifunctional networks. The strong σ-donating and π-accepting character of the phosphanes as well as the anionic nature of thienyl, which electrostatically strengthens the M−C bond, make them relatively immune to such attack.

(4) Electrochemical Behavior

Cyclic voltammetric (CV) studies were performed on complexes **2**, **3**, **4** and **5** (1 mM) in CH_2Cl_2 by using Bu_4NBF_4 (0.10 M) as the supporting electrolyte. All complexes show one irreversible oxidation wave in the first scan. Complexes **4** and **5** show different electrochemical behavior from that of **2** and **3**. The repetitive cycling profiles for **5** are illustrated in Figure 4.

During the first cycle, the forward (anodic) scan gave a complex oxidation wave $\mathbf{O_1}$, which could be assigned to thiophene oxidation,[16] with at least two unresolved peaks. On reversing the scan, the reduction peaks $\mathbf{R_3}$ and $\mathbf{R_2}$ were observed. During the second cycle, new oxidation peaks $\mathbf{O_2}$ and $\mathbf{O_3}$ emerged, which were not observed on the first scan. Associated with these, the earlier oxidation wave $\mathbf{O_1}$ dropped significantly in the second anodic scan, and disappeared completely in subsequent cycles. Conversely, peaks $\mathbf{O_2/R_2}$ and $\mathbf{O_3/R_3}$ continued to increase in size to the tenth cycle, after which they began to decay with further cycles. This behavior is consistent with the formation of electroactive or conductive polymers or high oligomers.[17] Since these species are less readily soluble in the analyte solution, their formation would alter the redox pattern of the sample, and eventually render the analyte featureless in the CV scans. Polymerization is likely to take place at the thienyl site since electropolymerization of thiophene, bithiophene and substituted thiophenes is common.[18] When the electrode was removed from solution at the conclusion of the scanning experiments, rinsed with CH_2Cl_2 and dried, a greenish thin film was visible on the electrode surface. The

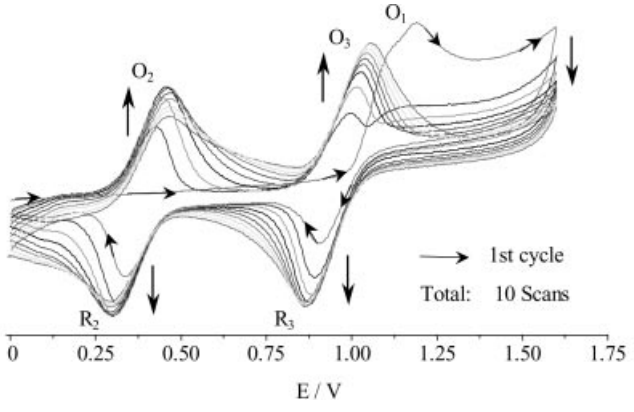

Figure 4. Continuous cyclic scanning between 0.00 to +1.60 V of **5** (0.1 mol·dm^{-3}) supported by Bu_4NBF_4 in CH_2Cl_2

material properties of this film are under investigation in our laboratory.

Cycling experiments on **4** revealed a similar decay phenomenon, with slightly different redox potentials. This suggests that the CV behavior is structurally related, and the redox potentials are sensitive to the bridging ligands. Accordingly, **2** and **3**, which are isostructural, show similar initial oxidative behavior to that of **4** and **5** (i.e. only a broad, irreversible oxidation wave) but no corresponding film formation is observed with continuous cycling. Cycling of these two analyte solutions resulted in the decrease of the oxidation wave $\mathbf{O_1}$ with no other obvious peak formation. The relevant electrochemical parameters for the complexes are summarized in Table 3. The CV profiles thus serve as supporting finger-printing diagnosis for these complexes.

In an attempt to understand this disparity, we carried out further electrochemical investigations of the films. After film formation (typically 10 scans), the potential cycling in the complex solution was terminated, and the film-coated electrode was washed with CH_2Cl_2. The electrode was then re-immersed in the blank electrolyte solution and cycled again between +0.00 V and +1.60 V. The peak heights decreased slowly with repetitive potential cycling, suggesting that the films formed from **4** and **5** are not electrochemically stable. The CV responses of these films upon treatment are also different from those seen in the $\mathbf{O_2/R_2}$ and $\mathbf{O_3/R_3}$ couples when the films were first formed. As seen in Table 3, after the tenth cycle, the anodic peak current in $\mathbf{O_2}$ is 2.79 $\times$ 10^{-5} A (i_{pc}^{R2}/i_{pa}^{O2} = 0.96 in this cycle) while that in $\mathbf{O_3}$ is 3.68 $\times$ 10^{-5} A (i_{pc}^{R3}/i_{pa}^{O3} = 1.02). This gives an $\mathbf{O_2/O_3}$ peak height ratio of 0.76. Similar analysis of the isolated film (Figure 5) shows 9.57 $\times$ 10^{-6} A for the anodic peak current in $\mathbf{O_2}$ and 1.58 $\times$ 10^{-5} A for that in $\mathbf{O_3}$, thus yielding a ratio of 0.60 (i_{pc}^{R2}/i_{pa}^{O2} = 0.86 and i_{pc}^{R3}/i_{pa}^{O3} = 0.73). The current after film formation and isolation is unusual but can be understood. Firstly, the electrogenerated cation could be a very reactive electrophilic Pt^{III}, which is

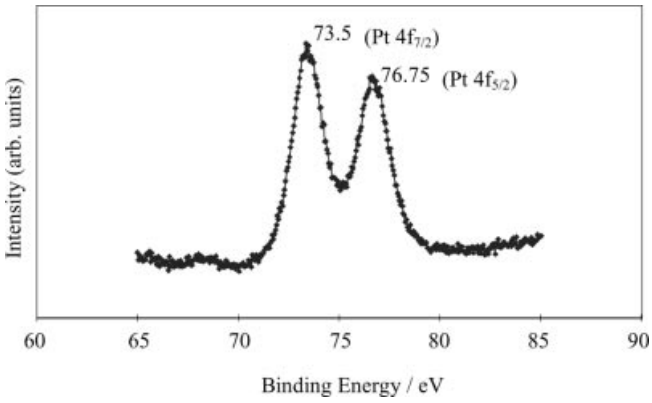

Figure 6. The XPS spectra of the film formed from **5**

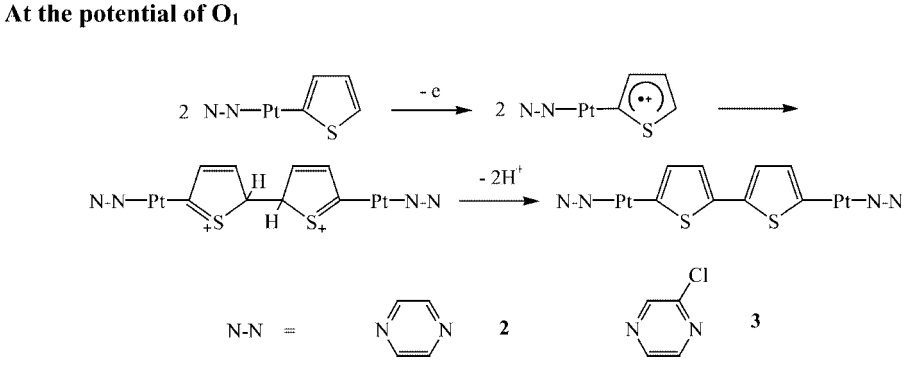
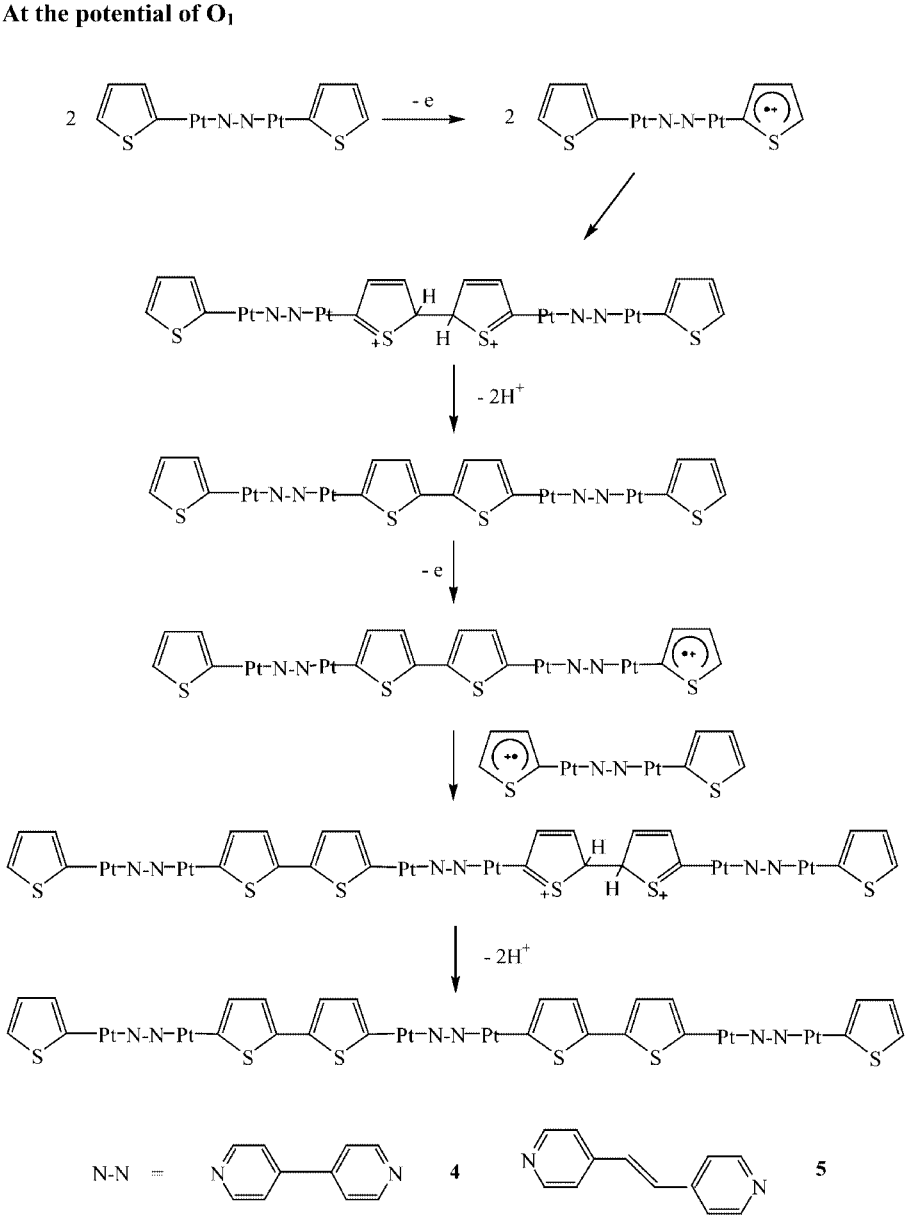
bound to decay rapidly at room temperature.[19] Secondly, the stability of the film at the potentials at which it is formed could be poor, which is known as the "thiophene paradox"[20] in the synthesis of polythiophene conducting polymers via electrooxidation.

To gain some understanding of the elemental composition of the film, we carried out an XPS analysis[21] of the film formed from **5**. This film was formed typically after about 10 scans. When the potential cycling of the complex solution was terminated, the film-coated electrode was retrieved and washed with CH_2Cl_2, and the film analyzed by XPS, the Pt(4f) spectrum showed the spin-orbit components separated by 3.25 eV (Figure 6). The Pt(4f) binding energies, which compare well with those of phosphane-bearing platinum,[22] are indicative of Pt^{II}. Further S(2p), N(1s) and P(2p) spectral analyses revealed fairly typical spectra for thienyl, bipyridyl and phosphane complexes. Further studies of the film properties and characteristics, which are outside the present scope, will be a subject of our future reports.



Scheme 3. Possible dimerization pathway for the mononuclear species **2** and **3** under applied potential in CV experiments

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 4. Possible polymerization process for **4** and **5** that leads to film formation on the surface of the electrode from continuous scanning

It is not our primary interest to study the details of the electropolymerization mechanism, but we can propose a reasonable pathway, involving repetitive electrogeneration of a cation radical, followed by α-α coupling, that is grounded in the literature[23−25] and allows us to explain the different behavior of the mono- (Scheme 3) and dinuclear complexes (Scheme 4). At the first cycle of electropromoted coupling, the dinuclear precursors **4** and **5** yield bithiophene-bridged Pt_4 complexes that have two free ends of α-thienyl group. The latter could undergo further coupling using the free α functionality by a similar mechanism as above. This would transform a Pt_4 into a Pt_6 chain, and so on. As there is no facile chain-termination step, a film would be the obvious product on ending the electropolymerization cycles. However, for mononuclear complexes **2** and **3**, dimerization would lead to a Pt_2 complex bridged through bithiophenyl groups and with terminal N−N groups. There is no α-thienyl end and hence no further thienyl−thienyl coupling. These electrogenerated dinuclear complexes are soluble and they do not lead to further polymerization or film formation.

Conclusion

Using ESMS as a guide, we have successfully constructed novel mononuclear and dinuclear thienylplatinum complexes with different bridging coligands. The nuclear selectivity can be easily controlled by the choice of the N-spacer. The electrochemical experiments led to promising metal-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

containing thin films from electrocycling of dinuclear complexes with a thiophene function at either end. The potential for film formation from structurally characterizable materials and the possibility for adjusting the film properties through the use of different spacers would add a new dimension to our current research.

Experimental Section

All reactions were routinely performed under purified nitrogen using standard Schlenk techniques. Solvents used were of reagent grade and were freshly distilled and degassed under purified nitrogen before use. Elemental analyses were carried out in the Chemistry Department of National University of Singapore (NUS). ^{1}H and ^{31}P NMR spectra were recorded on a Bruker ACF 300 MHz spectrometer at ca. 300 K. ^{1}H and ^{31}P NMR chemical shifts are quoted in ppm downfield of Me_4Si and externally referenced to 85% H_3PO_4, respectively.

Electrospray Mass Spectrometry (ESMS): The electrospray mass spectra were recorded in positive-ion mode on a Finningan LCQ spectrometer. The spray voltage was 4.5 kV, and the capillary temperature was 40 °C. The peaks in the ESMS are identified by the most intense *m*/*z* value within the isotopic mass distribution. Isotope patterns were recorded under high-resolution conditions for all major ions and compared with theoretical patterns obtained using the Isotope program.[26] In all cases there was good agreement between the experimental and calculated isotopic mass distributions.

Cyclic Voltammetry (CV): Containers (glassware, polyethylene bottles, etc.) were soaked overnight in 10% HNO_3 prior to use. Electrochemical experiments were performed with an Autolab PGSTAT 30 electrochemical system (Eco Chemie, Netherlands). A locally made three-electrode glass cell of approximately 5 mL capacity was used for all electrochemical experiments. The reference electrode (Ag|$AgNO_3$, 0.01 M in MeCN) was placed in a compartment containing the supporting electrolyte solution separated from the working electrode compartment by a 4 mm diameter Vycor frit. Working electrodes were 3 mm diameter glassy carbon disks.

***trans*-[Pt(PPh$_3$)$_2$(pyrazine)(2-thienyl)][BF$_4$] (2):** To a stirred solution of $AgBF_4$ (19.5 mg, 0.1 mmol) in MeCN (2 mL) was added a solution of [*trans*-PtBr(PPh$_3$)$_2$(2-thienyl)] [88.3 mg, 0.1 mmol in CH_2Cl_2 (10 mL)]. The mixture was stirred, shielded from light, for 1 h and AgBr was removed by filtration. A solution of pyrazine (8.0 g, 0.1 mmol) in CH_2Cl_2 (2 mL) was then added to the colorless filtrate. The mixture was stirred at room temperature for 4 h. The clear pale yellow solution was condensed to about 2 mL under vacuum, and the pale yellow solid residue of complex **2** (92.0 mg, 95%) was collected by adding Et_2O. The product was purified by recrystallization from CH_2Cl_2/hexane to give pale yellow crystals. $C_{44}H_{37}BF_4N_2P_2PtS$ (969.69): calcd. C 54.5, H 3.85, N 2.89, S 3.30; found C 54.38, H 3.59, N 2.85, S 3.51. ^{1}H NMR ($CDCl_3$): δ = 7.2−7.5 (m, 60 H, phenyl), 8.21 (d, 1 H, pyrazine), 7.96 (d, 1 H, pyrazine), 6.93 (d, 1 H, thiophene), 6.37 (t, 1 H, thienyl), 5.94 (d, 1 H, thienyl) ppm. ^{31}P NMR ($CDCl_3$): δ = 18.34 (s) ppm.

***trans*-[Pt(2-chloropyrazine)(PPh$_3$)$_2$(2-thienyl)][BF$_4$] (3):** The synthesis follows that of **2**. 2-Chloropyrazine (11.5 mg, 0.1 mmol) and [*trans*-PtBr(2-thienyl)(PPh$_3$)$_2$] (88 mg, 0.1 mmol) gave a light yellow powder of complex **3** (98.8 mg, 94%). Recrystallization from CH_2Cl_2/Et_2O gave light yellow crystals. $C_{44}H_{36}BClF_4N_2P_2PtS$ (1004.13): calcd. C 52.63, H 3.61, N 2.79, S 3.19; found C 52.28, H 3.12, N 2.55, S 3.58. ^{1}H NMR ($CDCl_3$): δ = 7.2−7.5 (m, 60 H, phenyl), 8.69 (d, 1 H, pyrazine), 7.93 (d, 1 H, pyrazine), 7.61 (s, 1 H, pyrazine), 6.94 (d, 1 H, thiophene), 6.39 (t, 1 H, thiophene), 5.96 (d, 1 H, thiophene) ppm. ^{31}P NMR ($CDCl_3$): δ = 18.12 (s) ppm.

***trans,trans*-[Pt$_2$(μ-4,4′-bipyridine)(PPh$_3$)$_4$(2-thienyl)$_2$][BF$_4$]$_2$ (4):** The synthetic procedure is similar to that of **2**. 4,4′-Bipyridine (7.8 mg, 0.05 mmol) and complex [*trans*-PtBr(2-thienyl)(PPh$_3$)$_2$] (88 mg, 0.1 mmol) gave a pale yellow solid residue of complex **4** (78.5 mg, 80%). $C_{90}H_{74}B_2F_8N_2P_4Pt_2S_2$ (1935.38): calcd. C 55.85, H 3.85, N 1.45, S 3.31; found C 55.40, H 3.79, N 1.38, S 3.83. ^{1}H NMR (MeCN): δ = 7.2−7.5 (m, 60 H, phenyl), 8.48 (d, 4 H, pyridine), 6.89 (d, 4 H, pyridine), 7.03 (d, 2 H, thiophene), 6.35 (t, 2 H, thiophene), 5.37 (d, 2 H, thiophene) ppm. ^{31}P NMR (MeCN): δ = 18.46 (s) ppm.

***trans,trans*-[Pt$_2$(PPh$_3$)$_4$(2-thienyl)$_2$(μ-4,4′-vinylenedipyridine)][BF$_4$]$_2$ (5):** The procedure is similar to that of **2**. 4,4′-Vinylenedipyridine (9.1 mg, 0.05 mmol) and complex [*trans*-PtBr(2-thienyl)(PPh$_3$)$_2$] (88 mg, 0.1 mmol) gave a yellow solid residue of complex **5** (80.3 mg, 82%). Recrystallization from CH_2Cl_2/hexane gave pale yellow crystals. $C_{92}H_{76}B_2F_8N_2P_4Pt_2S_2$ (1961.42): calcd. C 56.34, H 3.91, N 1.43, S 3.27; found C 56.49, H 3.65, N 1.50, S 3.16. ^{1}H NMR ($CDCl_3$): δ = 7.2−7.5 (m, 60 H, phenyl), 7.81 (d, 4 H, pyridine), 7.06 (d, 4 H, pyridine), 7.07 (s, 2 H, pyridine), 6.96 (d, 2 H, thiophene), 6.41 (t, 2 H, thiophene), 5.97 (d, 2 H, thiophene) ppm. ^{31}P NMR ($CDCl_3$): δ = 18.59 (s) ppm.

Crystallography: The diffraction experiments for complexes **3** and **5** were carried out on a Bruker AXS CCD diffractometer with a Mo-K_α sealed tube. The software SMART[27] was used for collecting frames of data, indexing reflections, and determination of lattice parameters, SAINT[27] for integration of intensity of reflections and scaling, SADABS[28] for empirical absorption correction, and SHELXTL[29] for space group and structure determination, refinements, graphics, and structure reporting. In the crystal structures of **3** and **5**, the thienyl groups were disordered. Two independent models were refined in each case. The chlorine atom of the chloropyrazine ligand in **3** was also found to be disordered. The asymmetric unit in **5** has half a dichloromethane solvate molecule and 1.5 mol of disordered water molecules. The positive residual electron densities in **5** were associated with the Pt atom. A summary of crystallographic parameters for the data collections and refinements is given in Table 1. CCDC-182455 and CCDC-182456 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The authors acknowledge the National University of Singapore (NUS) for financial support and the technical staff for supporting services, in particular, J. J. Vittal and G. K. Tan for the valuable help in crystallographic analysis and interest in the project, L. J. Chen for spectroscopic assistance, and H. Xu for XPS (NUS Physics) assistance. F. Z. thanks NUS for the research scholarship. X. Xu thanks NUS for a postdoctoral fellowship. We also thank W. Henderson (Waikato) for helpful discussions and advice, and P. Teo for some experimental assistance.

Synthesis and Crystal Structure of $\{[HNEt_3]_{2n}[Ag_8Ag_{4/2}(SC_6H_4tBu\text{-}4)_{12}]_n \cdot nC_2H_5OH\}$ and Its Reaction Product with CS_2

Kaluo Tang,[a] Xiangjin Xie,[a] Liang Zhao,[a] Yaohua Zhang,[a] and Xianglin Jin*[a]

Keywords: Silver / Polymers / Sulfur / Clusters

By using an arylthiolate ligand with a substituent in the *para*-position, 4-$tBuC_6H_4S^-$, the yellow silver-thiolate complex $\{[HNEt_3]_{2n}[Ag_8Ag_{4/2}(SC_6H_4tBu\text{-}4)_{12}]_n \cdot nC_2H_5OH\}$ (**1**) has been synthesized and structurally characterized. Complex **1** is ionic composed of $[HNEt_3]^+$ cations and a polymeric $[Ag_8Ag_{4/2}(SC_6H_4tBu\text{-}4)_{12}]_n^{2n-}$ anion. Complex **1** reacts with CS_2 in acetone to give a red pentaconta-nuclear silver anionic cluster complex $\{[HNEt_3]_4[Ag_{50}S_7(SC_6H_4tBu\text{-}4)_{40}] \cdot 2CS_2 \cdot 6C_3H_6O\}$ (**2**). The core of the anionic cluster of **2** consists of fifty silver atoms and forty seven sulfur atoms, shaped like a discus with a diameter of ca. 2.0 nm. The factors influencing the structure and the formation mechanism of the large cluster are discussed.

Introduction

Investigations of syntheses, structures, and properties of large metal clusters, especially nano-sized cluster complexes, continues to attract increasing interest because of their potential use as new materials with unique properties.[1] Recently Müller et al.[2] reported the largest known derivative of a heteropolyacid namely $Na_{48}[H_xMo_{368}O_{1032}(H_2O)_{240}(SO_4)_{48}] \cdot nH_2O$ ($x = 16$: $n = 1000$), with a diameter of ca. 6 nm. An important part of these investigations includes the remarkably large number of reported transition metal mega-clusters with chalcogenide or chalcogenolate ligands.[3] Using the reaction of transition-metal salts with group 16 silyl derivatives $E(SiMe_3)_2$ or $RESiMe_3$ (R = alkyl or aryl; E = S, Se, Te) and tertiary phosphanes, Fenske and co-workers have successfully synthesized a series of transition metal giant clusters,[4] for instance $[Cu_{146}Se_{73}(PPh_3)_{30}]$, $[Ag_{172}Se_{40}(Se\textit{n}Bu)_{92}(dppp)_4]$, $[Ag_{38}Te_{13}(Te\textit{t}Bu)_{12}(dppe)_6]$, $[Au_{18}Se_8(dppe)_6]Cl_2$, and $[Zn_{16}Te_{13}(TePh)_6(tmeda)_5]$. In addition to these huge M−Se and M−Te clusters, two new large Ag−S cluster complexes, $[Ag_{70}S_{16}(SPh)_{34}(PhCO_2)_4$ (triphos)$_4]$ and $[Ag_{188}S_{94}(PR_3)_{30}]$ were recently synthesized by the same route.[5]

Over the last few years one of our major fields of research interest has been the synthesis of transition metal clusters with sulfur or selenium containing ligands.[6,7] We studied the insertion reaction of CS_2 into M−S bonds (M = Ag, Cu, Cd) and applied it to the synthesis of clusters.[8] It was found that the mononuclear insertion products $(PPh_3)_2M(S_2CSR)$ (M = Ag or Cu, R = alkyl or aryl) react easily with various solvents to give a series large cluster complexes, such as $[Ag_{14}(\mu_6\text{-}S)(SPh)_{12}(PPh_3)_8] \cdot 4CH_3OH \cdot 13H_2O$[9] and $[Cu_{14}(\mu_2\text{-}S)(SPh)_{12}(PPh_3)_6]$[10] etc. When cadmium thiolates were reacted with CS_2 in solvents in the absence of PPh_3, several large Cd−S cluster complexes, for example $[S_4Cd_{17}(SPh)_{24}(CH_3OCS_2)_{4/2}]_n \cdot nCH_3OH$[11] and $(Me_4N)_2[Cd_8S(SPh)_{12}Cl_4]$,[12] were obtained. In order to synthesize high-nuclearity clusters, we changed the size and the position of the substituents on the arylthiolate to affect steric control of the ligand and increase solubility. The silver complex $[AgSC_6H_2iPr_3\text{-}2,4,6]_n$ with the bulky sterically hindered arylthiolate ligand reacted with CS_2 in $CHCl_3/C_2H_5OH$ to give a deca-nuclear silver cluster complex $[Ag(SC_6H_2iPr_3\text{-}2,4,6)]_{10} \cdot 2CHCl_3 \cdot C_2H_5OH$.[13] However, the less sterically hindered 4-*tert*-butylthiophenolate containing silver anionic polymeric complex $\{[HNEt_3]_{2n}[Ag_8Ag_{4/2}(SC_6H_4tBu\text{-}4)_{12}]_n \cdot nC_2H_5OH\}$ (**1**) reacted with CS_2 in acetone to give a very large pentaconta-nuclear silver cluster complex. Here we present the syntheses and the X-ray crystal structures of the silver anionic polymeric complex **1** and its reaction product with CS_2, $[HNEt_3]_4[Ag_{50}S_7(SC_6H_4tBu\text{-}4)_{40}] \cdot 2CS_2 \cdot 6C_3H_6O$ (**2**). The latter compound has been reported as a communication.[14]

Results and Discussion

Structure of Complex 1

The X-ray crystal structure determination indicates that complex **1** is ionic and composed of $[HNEt_3]^+$ cations and a polymeric anion $[Ag_8Ag_{4/2}(SC_6H_4tBu\text{-}4)_{12}]_n^{2n-}$, the structure of which is displayed in Figure 1. Selected bond lengths and angles of **1** are presented in Table 1. One structural unit of the polymeric anion is $[Ag_8Ag_{4/2}(SC_6H_4tBu\text{-}4)_{12}]^{2-}$ (Fig-

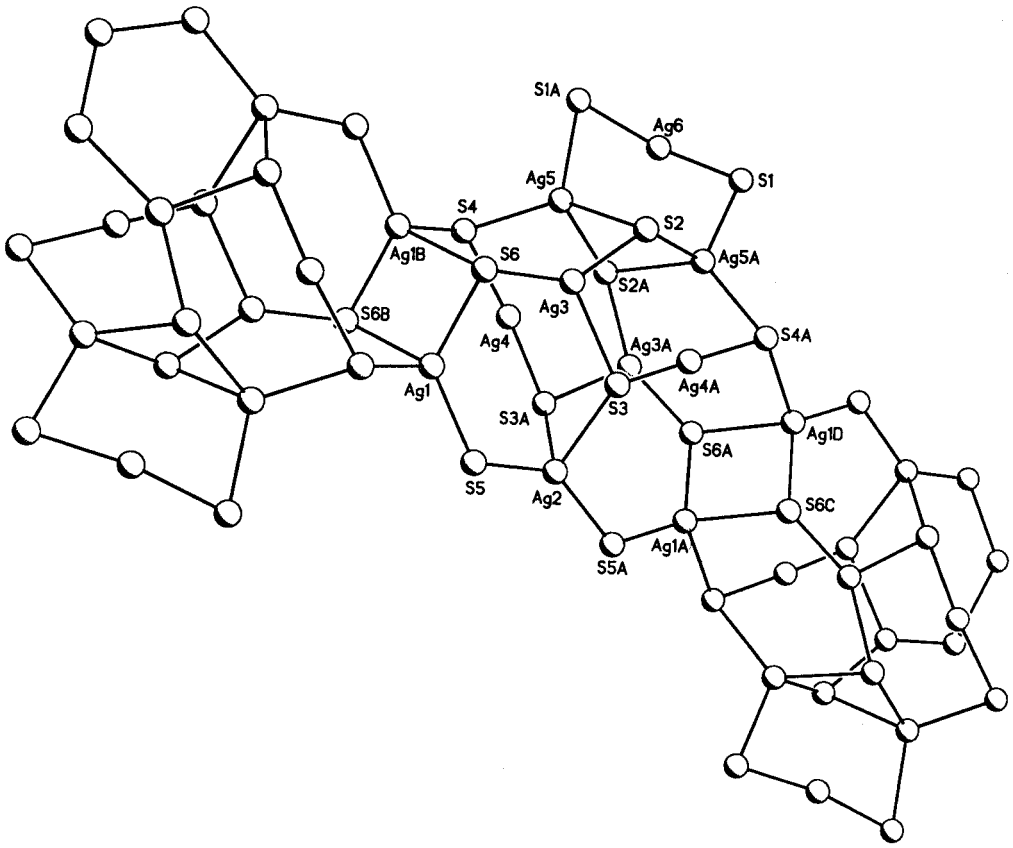

Figure 3. Structure of the $(Ag_8Ag_{4/2}S_{12})_n$ core of the polymeric anion $[Ag_8Ag_{4/2}(SC_6H_4tBu\text{-}4)_{12}]_n^{2n-}$ in **1**

at the center of the Ag_2S_2 monocycle (Ag1 S6 Ag1B S6B). Repeating the inversion symmetry operation produces a one-dimensional polymeric structure. The structure of the core of the polymeric anion of **1** is presented in Figure 3.

In the polymeric anion of **1**, all S atoms are derived from the aryl-thiolate ligands 4-tBuC$_6$H$_4$S$^-$. They are the μ_2-S (S1 and S5) and the μ_3-S (S2, S3, S4, S6) bridges to the Ag atoms. The S1 atom bridges Ag6 and Ag5A, and the angle Ag6−S1−Ag5A is 76.14 (5)°. The bond distances Ag6−S1 and Ag5A−S1 which are 2.383(2) and 2.606(2) Å, respectively are significantly different. The S5 atom bridges Ag1 and Ag2, and the angle Ag1−S5−Ag2 is 122.42(6)°. The bond distances Ag1−S5 and Ag2−S5 which are 2.546(2) and 2.550(2) Å, respectively are similar. With regards to the mean distances of the μ_3-S bridges to the Ag atoms, one is short [av. 2.449 Å (2.385−2.4845 Å)], and two are longer [av. 2.639 Å (2.556−2.735 Å)].

There are three coordination modes observed between all silver atoms and the sulfur donors: the linear, diagonally coordinated silver centers (Ag4, Ag6) exhibit an average Ag−S distance of 2.380 Å (2.383−2.369 Å), the trigonally coordinated silver centers (Ag3) exhibit an average Ag−S distance of 2.538 Å (2.444−2.686 Å) and the tetrahedrally coordinated silver centers (Ag1, Ag2, Ag5) exhibit an average Ag−S distance of 2.624 Å (2.546−2.672 Å). There are Ag−Ag interactions among the Ag atoms (Ag3, Ag4, Ag5, Ag6 Ag3A, Ag4A, Ag5A) in the unit of the polymeric anion of **1**. The Ag−Ag contacts which vary between 2.964−3.292 Å are shorter than the sum of the van der Waals radii of two Ag atoms (3.44 Å), and longer than the Ag−Ag distance in metallic Ag (2.886 Å). This may suggest they are related by so-called agentophilicity.[19] The Ag···Ag distances among those Ag atoms (Ag1, Ag2, Ag1A) are longer than 3.44 Å, which indicates that they are non-bonding and involved in very weak interactions.

Structure of Complex 2

An X-ray crystal structure determination revealed that **2** is an ionic complex composed of four $[HNEt_3]^+$ cations and an anionic cluster $[Ag_{50}S_7(SC_6H_4tBu\text{-}4)_{40}]^{4-}$. The selected bond lengths of **2** are presented in Table 2. The structure of the anionic cluster, which possesses a two-fold axis through Ag8 and Ag26, is shown in Figures 4 and . The core of the anionic cluster consists of fifty silver atoms and forty seven sulfur atoms. The shape of the core is discus-like, the inner part of which is the thickest. There is a pseudo five-fold axis at the core. The fifty Ag atoms are organized into three parts, as shown in Figure 5. In the inner part exists an Ag_{15} pentagonal prismatic unit, consisting of three overlapping Ag_5 pentagonal planar layers. The Ag−Ag distances are between 2.950 and 3.458 Å (mean 3.174 Å) in the pentagons and between 3.164 and 3.257 Å (mean 3.214 Å) between the layers. There are twenty Ag atoms in the intermediate part forming a distorted flat Ag_{20} decagonal prism, of which the

[a] Symmetry transformations used to generate equivalent atoms: #1 $-x, -y + 1, -z + 1$; #2 $-x, y, -z + 1/2$; #3 $-x, -y, -z + 1$. Ag20, Ag21, and Ag23 (Figure 5) are disordered, corresponding to Ag2A, Ag2B, Ag2C, Ag2D, Ag2E, and Ag2F in Table 2.

five Ag_4 rectangle fragments cap the five Ag_6 side faces of the inner pentagonal prism. Each vertex of the rectangle is connected two Ag atoms on the Ag_6 face. The Ag−Ag distances are between 2.994 and 3.424 Å (mean 3.173 Å) in these rectangles and range from 2.946 to 4.137 Å (mean 3.486 Å) between the rectangles and the pentagonal prism. For the fifteen peripheral Ag centers, two out of three Ag atoms are located at the two opposite sides of a rectangle of the intermediate part. The mean Ag−Ag distance from

these peripheral Ag atoms to the vertices of the rectangles is 3.313 Å (3.102−3.522 Å), and the distances between two peripheral Ag atoms lie in the range of 3.010−3.747 Å.

Of the forty seven S atoms, forty of them are derived from the arylthiolate ligands 4-*t*BuC$_6$H$_4$S$^-$, and seven constitute the S^{2-} ligands. The coordination modes of these S atoms to the Ag atoms fall into several categories, as shown in Figure 6. The arrangement of the fortyfive S atoms is similar to the fifty silver atoms. In the inner region, a S_{15} pentagonal prism is located between the Ag_{15} pentagonal prism and the Ag_{20} decagonal prism, and the S_{15} pentagonal prism is staggered relative to the Ag_{15} pentagonal prism. The ten S atoms at the two outer pentagonal layers of the S_{15} unit are from the arylthiolate ligands, each of which coordinates to four silver atoms. Two of the four Ag−S distances are short (2.394−2.552Å, mean 2.452 Å) and the other two are longer (2.606−3.119Å, mean 2.842 Å). However, the five S atoms in the middle layer of the S_{15} unit exist as S^{2-} ligands, each of which bonds six Ag atoms. The mean distance of the μ_6-S bridging ligands to the silver atoms is 2.545 Å (2.430−2.678 Å). The S_{20} decagonal prism in the intermediate region is larger than the Ag_{20} decagonal prism, and also staggered relative to the Ag_{20} polyhedron. All twenty S atoms are from the arylthiolates, which coordinate to the peripheral Ag atoms and the Ag centers of the Ag_{20} unit. Ten S atoms of the S_{20} unit are μ_4-S bridges and another ten S atoms are μ_3-S bridges. With regards to the mean distance of the μ_3-S bridging ligands to the silver atoms, one is short (2.404−2.449 Å, mean 2.422 Å), and two are longer (2.605−2.730 Å, mean 2.677 Å). The μ_4-S bridging ligands exhibit two short (2.470−2.668 Å, mean 2.554 Å) and two long (2.686−3.131 Å, mean 2.796 Å) distances to the silver atoms. Finally, the peripheral ten S atoms of the arylthiolates μ_2- bridge the fifteen peripheral Ag atoms three of which have two μ_2-S bridges. The mean μ_2-S−Ag distance is 2.459 Å (2.400−2.597 Å). Additionally, there are two S^{2-} ligands in the inner Ag_{15} pentagonal prism, which are located between the pentagonal layers (Figure 6). The distances between each S^{2-} ligand and the Ag atoms are different, since the Ag20, Ag21 and Ag23 atoms are disordered. The observed Ag−S distances lie in the range of 2.449−3.781 Å. Within the S polyhedra, all the S−S distances are larger than 3.414 Å.

The core of the discus-shaped cluster, which is a nanocluster, has a diameter of ca. 2.0 nm. The core of the Ag−S cluster is surrounded by 4-*tert*-butylthiophenolate ligands leading to a diameter of ca. 2.9 nm and a maximum depth of ca. 2.2 nm. Two CS_2 solvent molecules fill in the channel-like cavities formed by the thiophenolates (Figure 7). The six acetone solvent molecules and four [HNEt$_3$]$^+$ cations are located in the bigger cavities formed by the clusters. The solvent molecules are easy to remove so that the unsolvated compound was used for elemental analysis.

It is of note that in the formation of the cluster complex **2**, the S^{2-} ligands were not added via a reagent. However, the S^{2-} ligands are essential for the formation of large clusters, since they bind the metal ions together. We have also found that in our previously reported large complexes, $[Ag_{14}(\mu_6\text{-}S)(SPh)_{12}(PPh_3)_8]\cdot 4CH_3OH\cdot 13H_2O$,[9] $[Cu_{14}(\mu_2\text{-}S)(SPh)_{12}(PPh_3)_6]$,[10] and $[S_4Cd_{17}(SPh)_{24}(CH_3OCS_2)_{4/2}]_n\cdot$

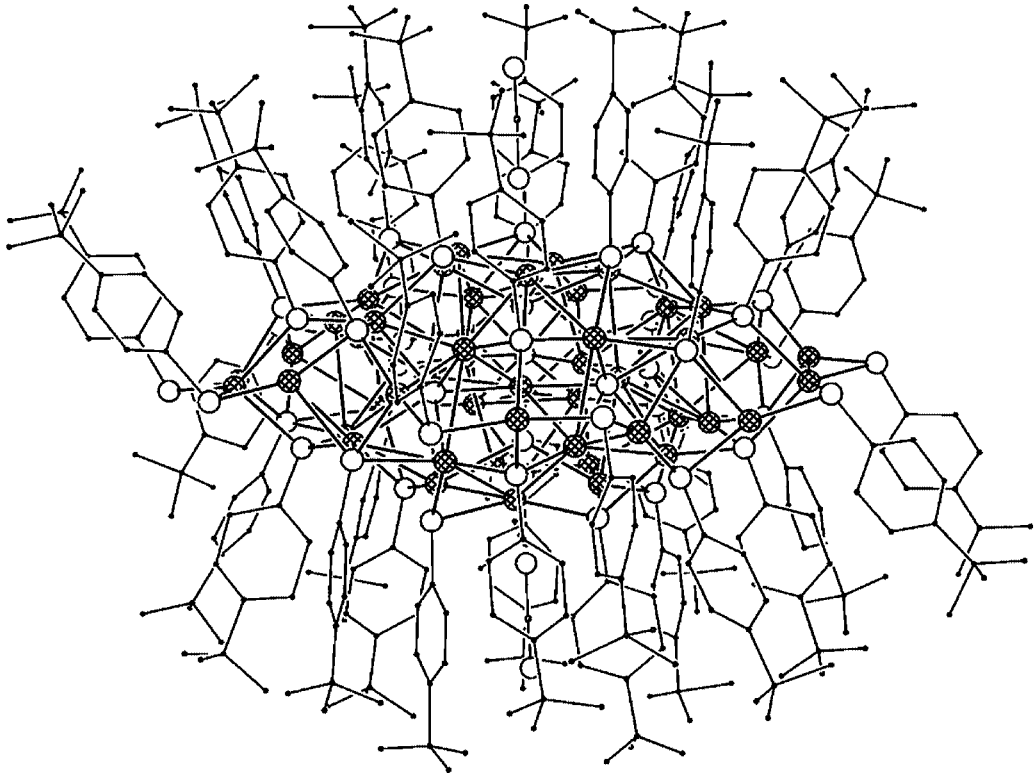

Figure 7. Structure of anionic cluster $[Ag_{50}S_7(SC_6H_4t\text{Bu-}4)_{40}]^{4-}$ in **2** with CS_2 solvent molecules in the channel-like cavities formed by the thiophenolates

$n$$CH_3OH$[11] etc., the S^{2-} ligands are formed from the reaction of CS_2 with RS^- in solution. We suggest that when the metal thiolate compound is dissolved, the solvent causes it to dissociate into various "active fragments", including RS^-, which reacts with CS_2 resulting in the formation of S^{2-} ions, as shown in Equation (1).[8]

$$RS^- + CS_2 \longrightarrow RS\text{-}CSS \overset{RS^-}{\rightleftharpoons} RS\text{-}CS\text{-}SR + S^{2-} \quad (1)$$

The new product is formed by the optimum "self-assembly" of these active fragments and then crystallizes from the solution. This new method for the synthesis of large M-S clusters has many advantages compared with other methods. The S^{2-} anions result from the equilibrium reaction. When large clusters are formed, the S^{2-} anions are used and the position of equilibrium shifts to right and the formation of S^{2-} is slow. However, the direct addition of reagents such as Na_2S, S, NaHS, or $S(SiMe_3)_2$ may cause M_xS_y precipitation because the reaction is rapid and difficult to control. In the formation of the **2**, the reaction conditions are mild (room temperature) and easy to control and a moderate yield of 67% was observed. This result suggests that this is a promising method although further investigations are needed.

We have found that silver thiolate complexes, $(AgSR)_n$, such as $(AgS$*t*$Bu)_n$, $(AgSC_6H_5)_n$, or $(AgSC_6H_2Me_3$-2,4,6$)_n$ with less bulky substituents hardly react with CS_2 and are insoluble in inert solvents. However, by increasing the size of the substituents, the polymeric complex $(AgSC_6H_2$*i*Pr_3-2,4,6$)_n$ with sterically hindered arylthiolate ligands reacts readily with CS_2 in solution to give a decanuclear silver cluster complex $[Ag(SC_6H_2$*i*Pr_3-2,4,6$)]_{10}$.[13] The arylthiolates with bulky substituents in the *ortho*-positions are more sterically congested than those with substituents in the *para*-position and this limits the cluster size. In this study, by the use of an arylthiolate ligand, 4-*t*$BuC_6H_4S^-$, with a substituent in the *para*-position, we obtained a large pentaconta-nuclear silver cluster complex **2**. However, using the arylthiolate ligand, 4-*i*$PrC_6H_4S^-$, with a less bulky substituent in the *para*-position, a larger hexaconta-nuclear silver cluster complex $[HNEt_3]_4[Ag_{60}S_7(SC_6H_4$*i*$Pr-4)_{50}]$ (**3**) has been recently synthesized by the same method.[20] Complex **3** is also ionic composed of four $[HNEt_3]^+$ cations and an anionic cluster $[Ag_{60}S_7(SC_6H_4$*i*Pr-4$)_{50}]^{4-}$, the structure of which is very similar to that of $[Ag_{50}S_7(SC_6H_4$*t*Bu-4$)_{40}]^{4-}$, as shown in Figure 8. The core of the anionic cluster **3** consists of sixty silver atoms and fifty seven sulfur atoms. The shape of the core is discus-like, the inner part of which is the thickest. This fact once again demonstrates the rule we have observed that the less bulky the R group in $(AgSR)_n$, the more the degree of the association, n.[6] Clearly, however, the factors influencing the formation and structures of large clusters need to be further investigated.

Experimental Section

Reactions were carried out under a nitrogen atmosphere using standard Schlenk techniques. Solvents were dried and distilled under nitrogen. Infrared spectra were recorded in KBr discs with a Nicolet-550 spectrometer. Elemental analyses were carried out using an Elemantar Vario EL analyzer. Melting points were measured with an X_6 microscopic melting point apparatus.

Complex 1: A solution of 4-*t*BuC_6H_2SH[15] (0.38 cm^3, 2.3 mmol) and Et_3N (0.32 cm^3, 2.3 mmol) in C_2H_5OH (8 cm^3) was added dropwise with stirring to a solution of $AgNO_3$ (274 mg, 1.6 mmol) in CH_3CN (5 cm^3). After stirring overnight at room temperature under a nitrogen atmosphere, the solvents were removed. The residue was dried in vacuo and then recrystallized from ethanol to afford a yellow powder (470 mg, yield 89.1%). Yellow crystals of **1** suitable for X-ray diffraction analysis were obtained by slow evaporation of the solvent from the ethanol solution of the crude product at room temperature over two days. m.p. 244.2−246.1 °C. $\{[HNEt_3]_{2n}[Ag_8Ag_{4/2}(SC_6H_4$*t*$Bu-4)_{12}]_n \cdot n C_2H_5OH\}$: calcd. C 48.64, H 6.00, N 0.833; found C 48.40, H 5.676, N 0.790%. IR: $\tilde{\nu}$ = 3057 w, 3019 vw, 2958 vs, 2915 m, 2869 m, 2789 w, 2656 w, 2468 w, 1900 w, 1629 m, 1560 vw, 1483 s, 1465 m, 1393 m, 1361 m, 1268 m, 1190 w, 1159 w, 1118 s, 1080 w, 1018 m, 821 s, 732 w, 588 w, 546 m, 465 w cm^{-1}.

Complex 2: Carbon disulfide (4 cm^3) was added to a yellow-green solution of **1** (20 mg) in acetone (4 cm^3). The solution became golden-yellow and was then filtered. The filtrate gradually became red upon standing. Red block crystals of **2** (yield 67%) suitable for X-ray diffraction analysis were obtained by evaporating the filtrate at room temperature over several days. The crystals of **2** break into pieces and desolvate in a few minutes upon removal of the mother liquor and become black very easily when exposed to light. This necessitates storage with the mother liquor and with the exclusion of light. $Ag_{50}S_{47}C_{424}H_{584}N_4$ (unsolvated): calcd. C 40.30, H 4.66, N 0.443; found C 39.89, H 4.76, N 0.399%. IR: $\tilde{\nu}$ = 3049 w, 2946 vs, 2869 s, 2789 w, 2671 w, 2472 w, 1888 w, 1621 w, 1589 w, 1485

X-ray Crystal Structure Determination of Complexes 1 and 2: Crystallographic measurements of complexes **1** and **2** were made on a Rigaku R-AXIS RAPID Image Plate diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) operating at 50Kv and 40 mA. Absorption corrections were applied by correction of symmetry-equivalent reflections using the ABSCOR program.[16] The structures were solved by direct methods and successive difference map (SHELXS-97)[17] and refined using full-matrix least-squares on F^2 for all unique data (SHELXL-97).[18] For complex **1**, all non-hydrogen atoms except the C and O atoms in the solvent molecule C_2H_5OH were refined anisotropically. The hydrogen atoms in the benzene groups and the three ordered *t*Bu groups were included in their calculated positions with the rigid model. Other hydrogen atoms were excluded from the refinement. The carbon atoms of the three *t*Bu groups are disordered. The occupancy of the solvent molecules C_2H_5OH were fixed at 0.7. For complex **2**, the Ag, S, and 72 C atoms are anisotropic whilst the N, O, and 150 C atoms are isotropic. Three Ag atoms and six C atoms are disordered. No hydrogen 3atoms were included in the refinement. There are 20 residual peaks (1.00−3.10 e·Å^{-3}) near the Ag atoms.

CCDC-199451 (for **1**) and -178360 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]. Crystal data and structure refinements for **1** and **2** are presented in Table 3.

Syntheses, Crystal Structures and Optical Limiting Properties of Three Novel Organometallic Tungsten-Copper-Sulfur Clusters: $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3(CuCN)_2]$, $[(\eta^5\text{-}C_5Me_5)WS_3Cu_2(PPh_3)(\mu\text{-}CN)]_2$ and $[PPh_4][\{(\eta^5\text{-}C_5Me_5)WS_3Cu_2(CN)(Py)\}_2(\mu\text{-}CN)]$

Jian-Ping Lang,*[a,b] Qing-Feng Xu,[a] Wei Ji,[c] Hendry Izaac Elim,[c] and Kazuyuki Tatsumi[d]

Keywords: Copper / Tungsten / Sulfur / Cluster compounds

Reactions of $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3]$ with two equivalents of CuCN in MeCN produced a novel trinuclear butterfly-shaped cluster $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3(CuCN)_2]$ (**1**) in a 70% yield. Treatment of **1** with excess PPh_3 or Py gave rise to two different hexanuclear clusters $[(\eta^5\text{-}C_5Me_5)WS_3Cu_2(PPh_3)(\mu\text{-}CN)]_2$ (**2**) and $[PPh_4][\{(\eta^5\text{-}C_5Me_5)WS_3Cu_2(CN)(Py)\}_2(\mu\text{-}CN)]$ (**3**), respectively. Compounds **1**–**3** were fully characterized by spectroscopy and X-ray crystallography. The structure of the cluster anion of **1** contains a butterfly-like WS_3Cu_2 fragment in which each Cu atom is coordinated to one μ-S atom, one μ_3-S atom, and one terminal CN group. The neutral compound **2** has a double butterfly-shaped structure in which two WS_3Cu_2 fragments are interconnected by two Cu–μ-CN–Cu bridges. The anion of **3** adopts another type of double butterfly-shaped structure in which the two WS_3Cu_2 fragments are linked by a single Cu–μ-CN–Cu bridge. Compared with C_{60} in terms of the optical limiting (OL) properties measured under identical conditions, **1** and **2** exhibit a relatively good OL performance, whereas the OL effect is not observed for **3**.

Introduction

The reactions of thiomolybdates and thiotungstates $[MO_{4-n}S_n]^{2-}$ (M = Mo, W) with various transition metal halides has been extensively investigated as a result of their rich chemistry.[1−4] Their relation to industrial catalysis,[2] biological systems,[3] and electro/photonic materials has also been demonstrated.[4−5] However, only a few reactions have been reported that are involved in the utilization of metal cyanides such as CuCN and AgCN.[6] So far, a dozen Mo(W)/Cu(Ag)/S clusters containing either a terminal or bridging cyano group around their cluster framework have been prepared.[6−7] Among them, the polymeric clusters $\{[Et_4N]_2[MS_4Cu_4(CN)_4]\}_\infty$ (M = Mo, W) were reported to exhibit large optical limiting (OL) effects in DMF.[7b]

We have recently reported on a series of mixed-metal clusters prepared from the reactions of the organometallic trisulfido complex anions $[(\eta^5\text{-}C_5Me_5)MS_3]^-$ (M = Mo,[8a] W[8b]) with metal halides.[9] Intriguingly, when $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3]$ was treated with AgCN, a cyano-bridged helical polymer $\{[(\eta^5\text{-}C_5Me_5)WS_3]_2Ag_3(CN)\}_\infty$ was produced.[10] In order to extend the chemistry of $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3]$, we carried out the reaction of $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3]$ with CuCN. A discrete trinuclear anionic cluster $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3(CuCN)_2]$ (**1**) was the only product that was isolated. As discussed later in this paper, the anion of **1** contains two three-coordinate Cu atoms and two terminal CN groups. The coordination geometry around the Cu atoms may be completed, substitution of the CN groups may take place, and the formation of new clusters may be anticipated if suitable donor ligands are used. In this context, the reactions of **1** with excess PPh_3 or Py were performed, and two novel hexanuclear cyano-bridged clusters $[(\eta^5\text{-}C_5Me_5)WS_3Cu_2(PPh_3)(\mu\text{-}CN)]_2$ (**2**) and $[PPh_4][\{(\eta^5\text{-}C_5Me_5)WS_3Cu_2(CN)(Py)\}_2(\mu\text{-}CN)]$ (**3**) were obtained. Furthermore, in our continued efforts to search for good OL materials,[5a−5c] we have also examined the OL properties of **1**−**3** in solution with 7-ns laser pulses at 532 nm. Herein we report on the syntheses and crystal structures of **1**−**3**, along with their OL properties in solution.

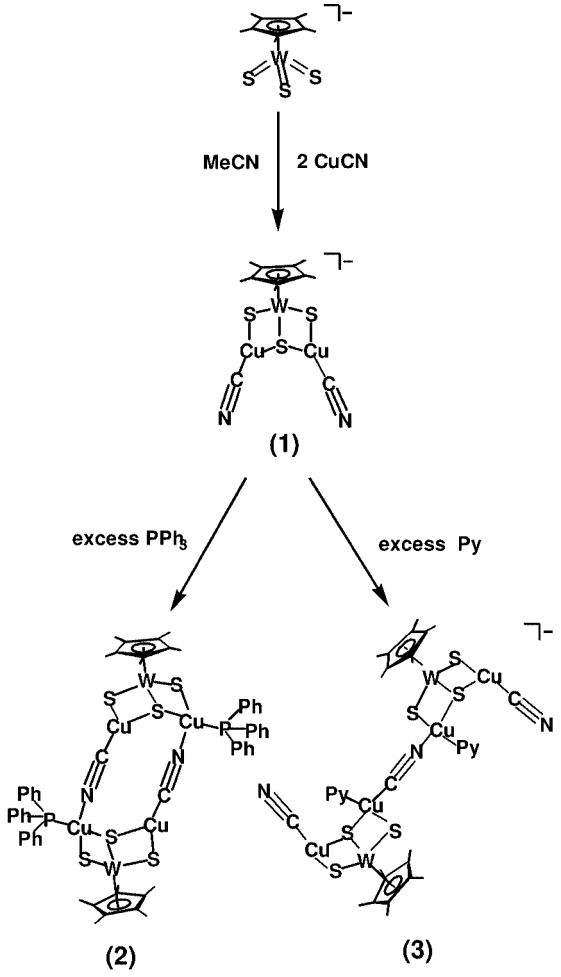
Results and Discussion

Synthesis and Spectral Characterization

As depicted in Scheme 1, addition of 2 equiv. of CuCN to a red solution of $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3]$ in MeCN generated a darkened solution, which was stirred for 1 h and filtered. The filtrate was layered with Et_2O, affording $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3(CuCN)_2]$ (**1**) as red crystals in a 70% yield. Treatment of **1** in MeCN with excess PPh_3 or Py resulted in a homogeneous solution. Subsequent standard workups produced two new clusters, $[(\eta^5\text{-}C_5Me_5)WS_3Cu_2(\mu\text{-}CN)(PPh_3)]_2$ (**2**) as red plates, and $[PPh_4][\{(\eta^5\text{-}C_5Me_5)WS_3Cu_2(CN)(Py)\}_2(\mu\text{-}CN)]$ (**3**) as orange-red needles, respectively. Compounds **1**−**3** are relatively air and moisture stable in the solid state. Compounds **1** and **3** are soluble in DMF and slightly soluble in MeCN. Both **1** and **3** are insoluble in CH_2Cl_2 and $CHCl_3$. Compound **2** dissolves in CH_2Cl_2 and $CHCl_3$, and not in MeCN and DMF.



Scheme 1

The FT-IR spectra of **1**−**3** display bands assigned to the W−S_{br} stretching vibrations at 433/410 (**1**), 434/417/409 (**2**) and 445/430/413 (**3**) cm^{-1}, respectively. The IR spectrum of **1** shows a strong terminal C≡N stretching vibration at 2119 cm^{-1}, while that of **2** shows a bridging C≡N stretching vibration at 2139 cm^{-1}. Compound **3** exhibits both a terminal C≡N stretching vibration at 2053 cm^{-1} and a bridging C≡N stretching vibration at 2130 cm^{-1}. The ^1H NMR spectra of **1** and **3** in CD_3CN and of **2** in $CDCl_3$ at ambient temperature display a single resonance assigned to the $\eta^5\text{-}C_5Me_5$ group at 2.05 (**1**), 2.05 (**2**), and 2.08 (**3**) ppm, respectively. The UV/Vis spectra of **1** in MeCN and of **3** in DMF are characterized by three bands at 435, 390, and 214 nm (**1**), 452, 393, and 321 nm (**3**), while that of **2** in CH_2Cl_2 exhibits only one absorbance band at 394 nm. As the electronic spectrum of $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3]$ in MeCN shows a strong absorbance band at 381 nm,[8b] the bands at 390 (**1**), 394 (**2**), and 393 (**3**) nm observed in the UV/Vis spectra of **1**, **2**, and **3** are red-shifted (Figure 1), and they are probably dominated by the S→W^{VI} charge-transfer transitions of the $(\eta^5\text{-}C_5Me_5)WS_3$ moiety.[9c] The crystal structures of **1**−**3** were further confirmed by single crystal X-ray analysis.

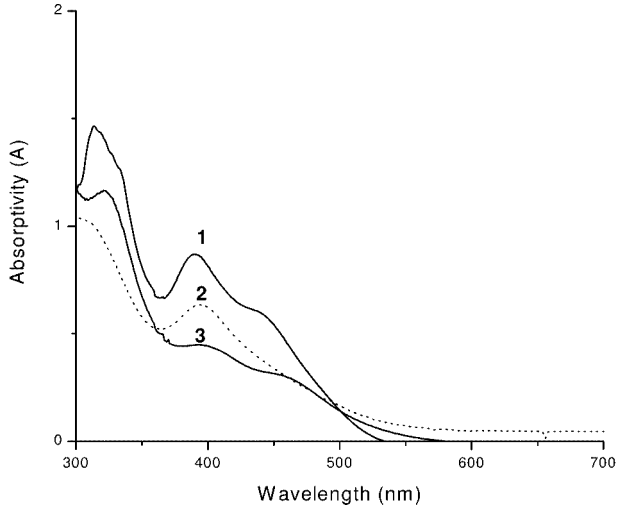


Figure 1. Absorbance spectra of **1** in MeCN, **2** in CH_2Cl_2, and **3** in DMF with a 1-mm optical length

Crystal Structure of $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3(CuCN)_2]$ (1)

Compound **1**·MeCN crystallizes in the orthorhombic space group $Pna2_1$ and the asymmetric unit contains one discrete anion $[(\eta^5\text{-}C_5Me_5)WS_3(CuCN)_2]^-$, one $[PPh_4]^+$ cation, and one MeCN solvated molecule. The $[PPh_4]^+$ cation does not interact with the cluster anion and all the bond lengths and angles related to this cation are typical. Therefore, Figure 2 only shows the structure of the cluster anion of **1**, and Table 1 lists the selected bond lengths and angles of the cluster anion of **1**. The cluster anion of **1** consists of a $(\eta^5\text{-}C_5Me_5)WS_3$ unit bound to two CuCN groups via one μ_3-S and two μ-S atoms. Alternatively, the anion of **1** may be described as containing a butterfly-shaped WS_3Cu_2 fragment, which has previously been observed in $[MoOS_3(CuSPh)_2]^{2-}$,[6a] $[(\eta^5\text{-}C_5Me_5)WS_3Cu_2(PPh_3)_2Br]$,[9d] $[MoOS_3M'_2(PPh_3)_3]$ (M = W, Mo; M′ = Cu^I, Ag^I),[11a,11b] and $[WS_4Cu_2(dppm)_3]$.[11c] The $(\eta^5\text{-}C_5Me_5)WS_3$ unit of **1** has a slightly distorted three-legged piano stool structure. The mean W−μ-S and W−μ_3-S bond lengths, 2.237 Å and 2.308 Å, are elongated by 0.05 Å and 0.12 Å, respectively,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

relative to that of $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3]$,[8b] due to the coordination of the sulfur atoms to the Cu atoms. Each Cu atom adopts a trigonal planar geometry, coordinated by one μ-S atom, one μ_3-S atom, and one terminal CN group. The mean W···Cu distance of 2.660 Å is similar to those found in the three-coordinate Cu clusters such as $[PPh_4]_2[(\eta^5\text{-}C_5Me_5)WS_3Cu_3Br_3]_2$ (2.661 Å)[9a] and $[PPh_4][\{(\eta^5\text{-}C_5Me_5)WS_3Cu_2\}_2S_2]_2$ (2.677 Å).[12] The average Cu−S length of 2.230 Å is similar to those of $[PPh_4]_2[(\eta^5\text{-}C_5Me_5)WS_3Cu_3Br_3]_2$ (2.234 Å) and $[PPh_4][\{(\eta^5\text{-}C_5Me_5)WS_3Cu_2\}_2S_2]_2$ (2.222 Å). The average terminal Cu−C length (1.892 Å) in **1** compares with those found in $[n\text{-}Pr_4N]_2[MoS_4(CuCN)]$ (1.880 Å) and $[AsPh_4]_2[MoS_4(\text{-}CuCN)_2]$ (1.886 Å).[6c]

Crystal Structures of $[(\eta^5\text{-}C_5Me_5)WS_3Cu_2(PPh_3)(\mu\text{-}CN)]_2$ (2) and $[PPh_4][\{(\eta^5\text{-}C_5Me_5)WS_3Cu_2(CN)(Py)\}_2(\mu\text{-}CN)]$ (3)

Compound **2** crystallizes in the monoclinic space group $P2_1/n$ and the asymmetric unit contains half a molecule of $[(\eta^5\text{-}C_5Me_5)WS_3Cu_2(PPh_3)(\mu\text{-}CN)]_2$; **3**·1.25Py crystallizes in the triclinic space group $P\bar{1}$ and the asymmetric unit consists of one discrete $[\{(\eta^5\text{-}C_5Me_5)WS_3Cu_2(CN)(Py)\}_2(\mu\text{-}CN)]^-$ anion, one $[PPh_4]^+$ cation, and 1.25 molecules of pyridine as solvated molecules. The refinements of the structures of **2** and **3** showed that the bridging cyanide groups between the Cu atoms have two orientations (i.e. the bridging cyanide groups are either coordinated through the C atoms, or through the N atoms). All the relevant C and N atoms were refined with a 50% probability of being C or N over each orientation. The derived Cu−C and Cu−N distances at the same site [e.g. Cu(1)−C(1) and Cu(1)−N(1a) in **2**, and Cu(1)−N(2) and Cu(1)−C(26a) in **3**] are identical and really express the average value. It is not known whether the distances in an ordered system would be equal. Therefore, Figure 3 shows the structure of **2** with the orientation of the bridging cyanide containing C(1) and N(1), while Figure 4 depicts the perspective view of the $[\{(\eta^5\text{-}C_5Me_5)WS_3Cu_2(CN)(Py)\}_2(\mu\text{-}CN)]^-$ anion of **3** with

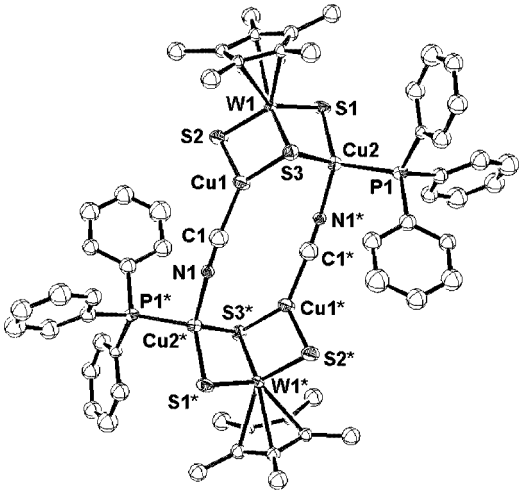

Figure 3. The perspective view of the molecular structure of **2** with 50% thermal ellipsoids. The C and N atoms of the bridging cyanide are disordered and only one orientation [C(1) and N(1)] is shown, and the hydrogen atoms are omitted for clarity.

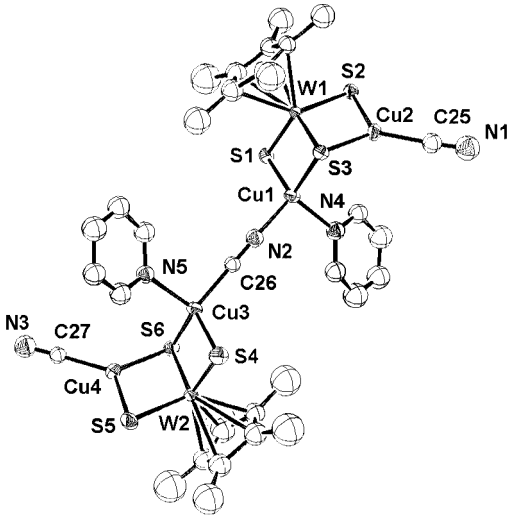

Figure 4. The perspective view of the anion of **3** with 50% thermal ellipsoids. The C and N atoms of the bridging cyanide are disordered and only one orientation [C(26) and N(2)] is shown, and the hydrogen atoms are omitted for clarity.

the orientation of the bridging cyanide containing C(26) and N(2). Tables 2 and 3 list the selected bond lengths and angles for **2** and **3** with the orientation of the bridging cyanide consisting of C(1) and N(1) in **2**, and C(26) and N(2) in **3**, respectively. The molecular structure of **2** can be viewed as a double butterfly-shaped structure in which two [(η^5-C_5Me_5)WS_3Cu_2] fragments are interconnected by a pair of Cu−μ-CN−Cu bridges. Meanwhile, the anion of **3** presents another type of double butterfly-shaped structure in which two [(η^5-C_5Me_5)WS_3Cu_2] fragments are linked by a single Cu−μ-CN−Cu bridge. To the best of our knowledge, the two structures are unprecedented in the tetrathiometallates. In both structures, each [(η^5-C_5Me_5)WS_3Cu_2] fragment shows a very similar structure to that of **1**. However, the two Cu atoms in each [(η^5-C_5Me_5)WS_3Cu_2] fragment of **2** and **3** exhibit a somewhat different coordination geometry from that of **1**. One Cu atom adopts a similar trigonal planar geometry, while the other Cu atom is coordinated by two S atoms, one CN group and one PPh_3 (**2**) or Py (**3**) group, thus exhibiting a distorted tetrahedral coordination geometry. Therefore, the different coordination geometries around the Cu atoms results in different W···Cu distances within the same [(η^5-C_5Me_5)WS_3Cu_2] fragment. The mean W···Cu distances for the three-coordinate Cu atom [2.657(2) Å in **2** and 2.661(2) Å in **3**] are similar to that of **1**. However, the mean W···Cu distance for the four-coordinate Cu atom in **2** [2.768(2) Å] is similar to those of [WS_4Cu_4(dppm)$_4$](PF_6)$_2$ (2.760 Å),[11c] but longer than those found in **3** [2.714(2) Å] and other clusters containing tetrahedral Cu atoms such as [(η^5-C_5Me_5)WS_3-Cu_2(PPh_3)$_2$Br] (2.704 Å),[9d] [Et_4N]$_2$[WS_4Cu_4(NCS)$_4$] (2.691 Å),[13a] [Et_4N]$_4$[$WS_4Cu_4I_6$] (2.692 Å),[13b] and [WS_4Cu_4(γ-MePy)$_8$][W_6O_{19}] (2.686 Å).[13c] The mean Cu−μ_3-S−Cu angle of 97.1(2)° in **3** is similar to that of **1**; however, it is about 10° smaller than that in **2**. The reason may be ascribed to the larger steric bulk of the two PPh_3 ligands coordinated at Cu(2) and Cu(2*) in **2**. The effect is also reflected in the linearity of the Cu−μ-CN−Cu bridges of **2** and **3**. The Cu−μ-CN−Cu portion in **2** is slightly bent, with Cu(1)−C(1)−N(1) and C(1)−N(1)−Cu(2*) angles of 170.9(8)° and 160.7(7)°, respectively. However, the Cu−μ-CN−Cu bridge in **3** is practically linear, with Cu(1)−N(2)−C(26) and Cu(3)−C(26)−N(2) angles of 179.0(6)° and 179.4(7)°, respectively. The Cu−C/N and Cu−N/C distances of the bridging cyanide groups in **2** and **3** range from 1.910(6) Å to 2.048(14) Å, which are similar to those found in [Cu(4-CNPy)(μ-CN)] [Cu−N/C = 1.907(2) Å and Cu−C/N = 1.999(2) Å].[13d] The mean Cu−P length of 2.251(5) Å in **2** is similar to those found in [(η^5-C_5Me_5)WS_3Cu_3(PPh_3)$_2$Br$_2$] (2.247 Å) and [PPh_4][(η^5-C_5Me_5)$WS_3Cu_3Br_3$(dppm)] (2.270 Å).[9c] The mean Cu−N(Py) length of 2.138 Å in **3** is longer than those found in [WS_4Cu_4(γ-MePy)$_8$][W_6O_{19}] (2.02 Å)[13c] and [Cu(Py)$_4$]-ClO_4 (2.046 Å).[14] The mean W−μ-S, W−μ_3-S, and Cu−S distances in both **2** and **3** compare with those found in **1**.

Optical Limiting (OL) Properties of 1−3

As shown in Figure 1, compounds **1**−**3** have a low absorbance at 532 nm. This promises low intensity loss and small temperature changes by photon absorption when the laser pulse propagates in these materials. The fluence-dependent transmission measurements of **1**−**3** are depicted in Figure 5. For **1**, the light energy transmitted begins to deviate from normal linear behavior as soon as the input light fluence reaches about 0.4 J/cm^2, and the material becomes increasingly less transparent as the light fluence rises. We define the limiting threshold as the incident fluence at which the sample transmittance falls to 50% of the corresponding linear transmittance. The limiting threshold of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

compound **1** is 7.5 J/cm^2. For **2**, when the input light fluence reaches about 2.6 J/cm^2, the light energy transmitted begins show less than linear behavior. The limiting threshold for compound **2** is larger than 10 J/cm^2. Unfortunately, no OL effects are observed for compound **3**. Although the concentration of C_{60} ($9.02\cdot10^{-4}$ M) is higher than the concentrations of **1** ($3.57\cdot10^{-4}$ M) and **2** ($1.20\cdot10^{-4}$ M), the OL performance of **1** is about 3 times better than that of C_{60} measured under identical conditions, while the OL performance of compound **2** is similar to C_{60}. The poor solubility of compounds **1** and **2** prohibits higher concentrations to be attained, and hence limits their OL performance. Better OL effects would be expected for higher concentrations of these compounds.

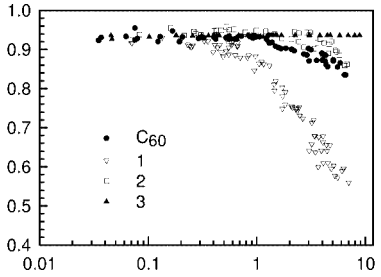

Figure 5. Optical limiting responses to 7-ns, 532 nm laser pulses, of **1** in MeCN, **2** in CH_2Cl_2, **3** in DMF, and C_{60} in toluene. Solutions with 92% transmittance at 532 nm correspond to $3.57\cdot10^{-4}$ M (**1**), $1.20\cdot10^{-4}$ M (**2**), $1.69\cdot10^{-4}$ M (**3**), and $9.02\cdot10^{-4}$ M (C_{60}), respectively

Conclusion

We demonstrated the facile synthesis of **1** and its reactivity towards PPh_3 and Py. The successful isolation of **2** and **3** shows that compound **1** can be a useful precursor for the construction of new W−Cu−S clusters in the presence of suitable donor ligands. The structures of **1**−**3** have been fully characterized by spectroscopy and X-ray analysis. Compounds **2** and **3** exhibit two types of double butterfly-shaped structures, which have not previously been observed in the chemistry of the corresponding tetrathiometallates. The OL properties of **1**−**3** in solution have been measured, and **1** and **2** exhibit relatively good OL performances when compared with C_{60}. As some preformed clusters may be assembled into supramolecular compounds via the bridging ligands such as 4,4′-bipy, and their NLO performances may be improved,[15] it is still worth screening more compounds formed from the reactions of **1** with hooking ligands such as the one mentioned above. We are currently investigating this.

Experimental Section

General: All manipulations were carried out under argon using standard Schlenk-techniques. $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3]$ was prepared as reported previously.[8b] Other chemicals were obtained from commercial sources and used as received. All solvents were predried over activated molecular sieves and refluxed over the appropriate drying agents under argon. The IR spectra were recorded on a Nicolet MagNa-IR500 FT-IR spectrometer (4000−400 cm^{-1}). ^{1}H NMR spectra were recorded at ambient temperature on a Varian UNITYplus-400 spectrometer. UV/Vis spectra were measured on a Hitachi UV-3410 spectrophotometer. The elemental analyses for C, H, and N were performed on a Carlo−Erba CHNO-S microanalyzer.

Reaction of $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3]$ with CuCN: CuCN (0.023 g, 0.26 mmol) was added to a red solution of $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3]$ (0.10 g, 0.13 mmol) in MeCN (10 mL). The solution quickly turned dark red and the mixture was stirred at room temperature for 1 h and then filtered. Diethyl ether (20 mL) was carefully layered onto the filtrate, forming red prisms of $[PPh_4][(\eta^5\text{-}C_5Me_5)WS_3(CuCN)_2]\cdot$MeCN (**1**·MeCN), which were isolated by filtration, washed with Et_2O, and dried in vacuo. Yield: 0.085 g (70%). $C_{36}H_{35}Cu_2N_2PS_3W$: calcd. C 47.02, H 4.51, N 4.49; found C 46.78, H 3.90, N 4.31%. UV/Vis (MeCN) [λ_{max}/nm (ε/M^{-1}cm^{-1})]: 435 (1700), 390 (6300), 314 (8600). IR (KBr disk): $\tilde{\nu}$ = 2119 (s), 1586 (s), 1483 (s), 1439 (vs), 1377 (m), 1318 (w), 1186 (w), 1109 (vs), 1025 (m), 995 (m), 754 (s), 724 (vs), 692 (s), 531 (s), 433 (w), 410 (m) cm^{-1}. ^{1}H NMR (CD_3CN, 400 MHz, 25 °C): δ = 7.26−7.89 (m, 20 H, PPh_4^+), 2.05 (s, 5 H, $\eta^5\text{-}C_5Me_5$) ppm.

Reaction of 1 with PPh_3: Treatment of a solution of **1** (0.042 g, 0.05 mmol) in MeCN (5 mL) with PPh_3 (0.026 g, 0.1 mmol) gave rise to a homogeneous solution, which was allowed to stir for 30 min. Diethyl ether (5 mL) was carefully layered onto the filtrate, forming red plates of $[(\eta^5\text{-}C_5Me_5)WS_3Cu_2(\mu\text{-}CN)(PPh_3)]_2$ (**2**), which were isolated by filtration, washed with Et_2O, and dried in vacuo. Yield: 0.071 g (85%). $C_{29}H_{30}Cu_2NPS_3W$: calcd. C 41.53, H 4.01, N 1.75; found C 41.89, H 3.90, N 1.68%. IR (KBr disk): $\tilde{\nu}$ = 2139 (s), 1480 (m), 1435 (s), 1376 (m), 1097 (m), 1027 (m), 747 (s), 723 (w), 695 (vs), 518 (s), 434 (m), 417 (w), 409 (w) cm^{-1}. UV/Vis (CH_2Cl_2) [λ_{max}/nm (ε/M^{-1}cm^{-1})]: 394 (5600). ^{1}H NMR ($CDCl_3$, 400 MHz, 25 °C): δ = 7.27−7.89 (m, 15 H, PPh_3), 2.05 (s, 5 H, $\eta^5\text{-}C_5Me_5$) ppm.

Reaction of 1 with Py: Compound **1** (0.042 g, 0.05 mmol) was dissolved in 1.5 mL of pyridine. The mixture was stirred at room temperature for 30 min, giving a clear solution. Diethyl ether (5 mL) was carefully layered onto the filtrate to form orange-red needles of $[PPh_4][\{(\eta^5\text{-}C_5Me_5)WS_3Cu_2(CN)(Py)\}_2(\mu\text{-}CN)]\cdot1.25$Py (**3**·1.25Py), which were isolated by filtration, washed with Et_2O, and dried in vacuo. Yield: 0.063 g (80%). $C_{29}H_{30}Cu_2NPS_3W$: calcd. C 48.42, H 4.50, N 4.12; found C 48.18, H 4.21, N 3.97%. IR (KBr disk): $\tilde{\nu}$ = 2130 (m), 2053 (m), 1483 (m), 1436 (s), 1376 (m), 1108 (vs), 996 (m), 753 (m), 724 (vs), 690 (vs), 527 (vs), 445 (w), 430 (w), 413 (w) cm^{-1}. UV/Vis (DMF) [λ_{max}/nm (ε/M^{-1}cm^{-1})]: 452 (20200), 393 (7700), 321 (5400). ^{1}H NMR ($CDCl_3$, 400 MHz, 25 °C): δ = 8.62 (br. s, 2 H, Py), 7.64−7.90 (m, 28 H, Py+PPh_4^+), 2.08 (s, 5 H, $\eta^5\text{-}C_5Me_5$) ppm.

X-ray Diffraction Crystallography: All measurements were performed on a Rigaku Mercury CCD X-ray diffractometer (3 kV, sealed tube) at −80 °C, using graphite monochromated Mo-*Kα* (λ = 0.71070 Å). A red chip of **1**·MeCN with dimensions 0.60 × 0.40 × 0.20 mm, a red prism of **2** with dimensions 0.10 × 0.05 × 0.05 mm, and a red platelet of **3**·1.25Py with dimensions 0.55 × 0.15 × 0.05 mm, were mounted at the top of a glass fiber. Diffraction data were collected at ω mode with a detector distance of 55 mm (**1**·MeCN and **2**) or 35 mm (**3**·1.25Py) to the crystal. Indexing was performed from 6 images, each of which was exposed for 15 s. A total of 1080 (**1**·MeCN) or 720 (**2** and **3**·1.25Py) oscillation images were collected in the range $1.95° < 2\theta < 54.96°$ for

[a] $R = \Sigma F_o| - |F_c\|/\Sigma|F_o|$. [b] $R_w = \{w\Sigma(|F_o| - |F_c|)^2/\Sigma w|F_o|^2\}^{1/2}$. [c] GOF $= \{\Sigma w(|F_o| - |F_c|)^2/(M - N)\}^{1/2}$, where M is the number of reflections and N is the number of parameters.

1·MeCN, $1.97° < 2\theta < 50.04°$ for **2**, and $1.60° < 2\theta < 61.86°$ for **3**·1.25Py. The collected data were reduced by using the program CrystalClear (Rigaku and MSC, Ver. 1.3, 2001), and an empirical absorption correction was applied which resulted in transmission factors ranging from 0.266 to 0.433 for **1**·MeCN, from 0.610 to 0.759 for **2**, and from 0.623 to 0.852 for **3**·1.25Py. The reflection data were also corrected for Lorentz and polarization effects.

The structures of **1**·MeCN and **2** were solved by direct methods[16a] while that of **3**·1.25Py by heavy-atom Patterson methods,[16b] and expanded using Fourier techniques.[16c] For **1**·MeCN, all non-hydrogen atoms except those of the MeCN crystal solvent molecule were refined anisotropically. For **2**, W, Cu, S, and P atoms were refined anisotropically, while C and N atoms were refined isotropically. In both cases, all hydrogen atoms were introduced at the calculated positions and included in the structure-factor calculations. Crystal **3**·1.25Py contains 1.25 Py solvated molecules in an asymmetric unit. One Py solvent molecule is refined isotropically. The other is located on a center of symmetry and is refined with one-quarter occupancy. All non-H atoms except those of CN, Py, and η^5-C_5Me_5 were refined anisotropically. Hydrogen atoms except those of the two Py solvent molecules were placed on the idealized positions and included in the final structure-factor refinements. In the structure of **2** or **3**·1.25Py, the orientation of the bridging cyanide group was found to be disordered, and the C and N atoms were refined with a 50% probability of being C or N, i.e. C(1)/N(1a) = 0.5:0.5 and N(1)/C(1a) = 0.5:0.5 (**2**), C(26)/N(2a) = 0.5:0.5, and N(2)/C(26a) = 0.5:0.5 (**3**·1.25Py). Neutral atom scattering factors were taken from Cromer and Waber.[17a] Anomalous dispersion effects were included in $F_{calcd.}$.[17b] All calculations were performed on a Dell workstation using the CrystalStructure crystallographic software package (Rigaku and MSC, Ver. 3.0, 2002). A summary of the key crystallographic information for **1**·MeCN, **2**, and **3**·1.25Py is given in Table 4. CCDC-202420 (**1**), 202421 (**2**), and 202422 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at http://www.ccdc.cam.ac.uk/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Optical Limiting Measurements: Samples were dissolved in MeCN (**1**), CH_2Cl_2 (**2**), and DMF (**3**). The solutions with concentrations of $3.57\cdot10^{-4}$ M (**1**), $1.20\cdot10^{-4}$ M (**2**), and $1.69\cdot10^{-4}$ M (**3**) were contained in a 1-mm-thick quartz cuvette. Optical limiting experiments were performed with a Q-switched, frequency-doubled Nd:YAG laser (λ = 532 nm) with linearly polarized 7-ns pulses. The interval between the laser pulses was set at 10 s so that every pulse of light was assured to meet fresh molecules in the sample to eliminate the influence of any photo-degradation. The optical limiting phenomenon was demonstrated by measuring fluence-dependent transmissions. The laser pulses were focused on to the sample using a focusing mirror of 25-cm focal length. The spot radius of the laser pulses at the cuvette was measured to be of 35±5 μm (half width of $1/e^2$ maximum in irradiance). Both incident and transmitted laser pulses were monitored simultaneously using a calibrated beam splitter and two energy detectors (from Laser Precision, Rjp-735 energy probes). The detectors were linked to a computer by an IEEE interface. The linear (low-intensity) transmittance of all the samples was adjusted to 92%. Fullerene (C_{60}) dissolved in toluene ($9.02\cdot10^{-4}$ M) was used as a standard sample since its optical limiting performance had been well-documented.[18]

Investigation of the Thermal Properties of $[Cu_{20}Se_{13}(PEt_3)_{12}]$

Andreas Eichhöfer,*[a] Dieter Fenske,[b] and Petra Scheer[a]

Keywords: Cluster compounds / Mixed-valent compounds / Thermogravimetry / Copper / Selenium

The mixed-valence cluster $[Cu_{20}Se_{13}(PEt_3)_{12}]$ has been synthesized by the reaction of CuCl and PEt_3 with $Se(SiMe_3)_2$. A powder-diffraction pattern has revealed its crystalline purity and UV/Vis reflectance spectra display an intervalence band around 1200 nm. The solid-state conversion of the cluster upon heating yields, even at moderate temperatures of around 100 °C, α-Cu_2Se and not a Cu_3Se_2 phase that should be favoured in terms of the Cu/Se ratio of 3.1:2 in the cluster complex. This thermogravimetric analysis, coupled with mass spectrometry, shows that in addition to the labile phosphane ligands selenium atoms are cleaved as $SePEt_3$ during the consolidation process.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Cluster molecules of semiconductor materials, composed of tens of atoms with bonding resembling that in the solid state, are interesting molecular models for the bulk.[1] Various cluster molecules of different sizes and structures, composed of elements of either groups 11 and 16 or groups 12 and 16, have been synthesized and characterized by single-crystal XRD.[2−4] Remarkable examples include $[Cd_{32}S_{14}(SPh)_{36}(dmf)_4]$ (dmf = *N*,*N*-dimethylformamide),[5] $[Cu_{146}Se_{73}(PPh_3)_{30}]$,[6] $[Ag_{172}Se_{40}(n\text{BuSe})_{92}(dppp)_4]$ [dppp = bis(diphenylphosphanyl)propane][7] and $[Ag_{188}S_{94}(P\text{n}Pr_3)_{30}]$[8] with cluster core sizes up to 3 nm. Farneth et al. have found that the thermal properties of group 12/16 cluster molecules with the general formula $(R_4N)_4[M_{10}S_4(SPh)_{16}]$ (R = Me, Et; M = Cd, Zn) can give valuable insight into the mechanism of their solid-state conversion upon heating.[9] Investigations on $[Cu_{70}Se_{35}(PEt_2Ph)_{24}]$ reveal that the phosphane ligand shell can be cleaved at moderate temperatures (145 °C) in vacuo in a one-step process that produces nanocrystalline copper selenide.[10] Powder-diffraction measurements show that the cleavage of this ligand molecule is accompanied by an aggregation of the copper selenide cluster cores, in agreement with X-ray photoelectron spectroscopy (XPS) findings on a series of copper selenide clusters.[11] In addition, Corrigan et al. have recently investigated the mechanism of cluster condensation of the copper chalcogenolate $[Cu_6(TePh)_6(PPh_2Et)_5]$ in hexagonally ordered mesoporous MCM-41.[12]

Herein we report the thermal properties of the mixed-valence copper chalcogenide cluster $[Cu_{20}Se_{13}(PEt_3)_{12}]$ and the characterization of its thermolysis products.

Results and Discussion

The reaction of CuCl and PEt_3 with $Se(SiMe_3)_2$ in diethyl ether affords $[Cu_{70}Se_{35}(PEt_3)_{22}]$[13] while only in one experiment a small amount of $[Cu_{20}Se_{13}(PEt_3)_{12}]$ (**1**) crystals were also found. During our investigations it turned out that the use of PTFE gaskets for the stoppers, instead of grease, in combination with evacuation of the flask containing the reaction solution before refrigeration leads to the crystallization of pure **1** (Scheme 1). Obviously, the gaskets were not totally closed, allowing small amounts of oxygen and moisture to enter the flask which could affect an in situ partial oxidation of Se^{2-} to Se^{1-} or Cu^{1+} to Cu^{2+}, respectively. However, attempts to synthesize **1** by the use of an appropriate amount of $CuCl_2$ or $Cu(OOCCH_3)_2$ failed.

$$\begin{array}{l} \text{CuCl + 3 PEt}_3 \\ \text{Et}_2\text{O / −10 °C} \quad \Big| \quad \text{+ 0.5 Se(SiMe}_3)_2 \text{ / } n\text{O}_2 \\ \\ [Cu_{20}Se_{13}(PEt_3)_{12}] \quad \textbf{(1)} \end{array}$$

Scheme 1

The lattice constants of the black octahedral crystals of **1** correspond to those published[13] and the powder-diffraction pattern agrees well with the calculated values, suggesting a high crystalline purity with respect to the formation of other crystalline clusters namely $[Cu_{70}Se_{35}(PEt_3)_{22}]$

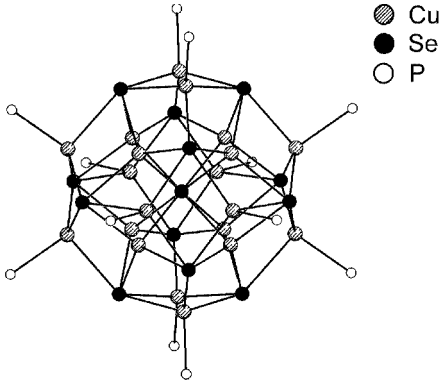

Figure 1. Molecular structure of $[Cu_{20}Se_{13}(PEt_3)_{12}]$ (**1**);[13] copper−copper contacts and carbon and hydrogen atoms omitted for clarity

(Table 1). In the molecular structure of **1** (Figure 1) 13 selenium atoms form a distorted, centered icosahedron (nonbonding Se−Se distances: 4.001−4.143 Å). Twelve of the 20 Se_3 faces are bridged by copper−phosphane units, whereas eight more copper atoms are below the remaining faces, all tetrahedrally surrounded due to an additional Cu−Se bond to the central selenium atom. Assuming a formal charge of 2− for the selenium atoms, one can assign 14 Cu^+ centers and six Cu^{2+} centers. However, the coexistence of Cu^{2+} and Se^{2-} is thermodynamically unlikely because of an electron-transfer process from the reducing Se^{2-} ligand to the oxidizing Cu^{2+} center. Additionally, the electron deficiency has to be assumed to be delocalised as there is no structural reason for it to be localised on either six of the copper atoms or on six of the selenium atoms. The compound should therefore better be described in terms of a "pure" Cu^+ substructure ligated by selenium atoms with an average charge of −1.54.

Compounds containing metal atoms in formally different oxidation states generally exhibit interesting spectroscopic behaviour. Depending on the degree of charge delocalisation in the molecular framework, one may detect additional bands in the near IR. The UV/Vis reflectance spectrum of **1** (Figure 2) shows several bands between 700 and 300 nm. The band with a maximum at 550 nm and a shoulder at 592 nm is responsible for the dark purple colour of the compound while the absorption peak at 262 nm originates most probably from charge-transfer transitions of the PEt_3 ligands. However, the broad, intense peak centered around 1200 nm can be assigned as an intervalence band, in agreement with observations made for similar copper telluride clusters.[14] According to the classification of Robin and Day,[15] which describes the different amounts of electron delocalisation between the metal atoms, **1** belongs to class IIIa (metal clusters). In this class, metal centers with different valencies cannot be distinguished, and total delocalisation of the charge is achieved.

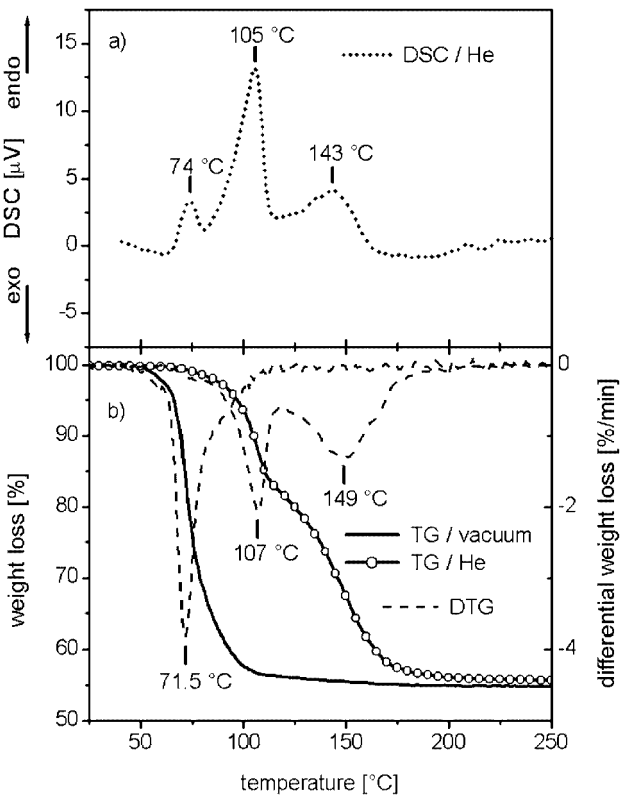

Figure 3. (a) Differential scanning calorimetry of **1**; (b) thermogravimetric analysis of $[Cu_{20}Se_{13}(PEt_3)_{12}]$ (**1**) in vacuo (straight line) and with helium flow (line with circles), the corresponding differential thermogravimetric curves are drawn as dashed lines

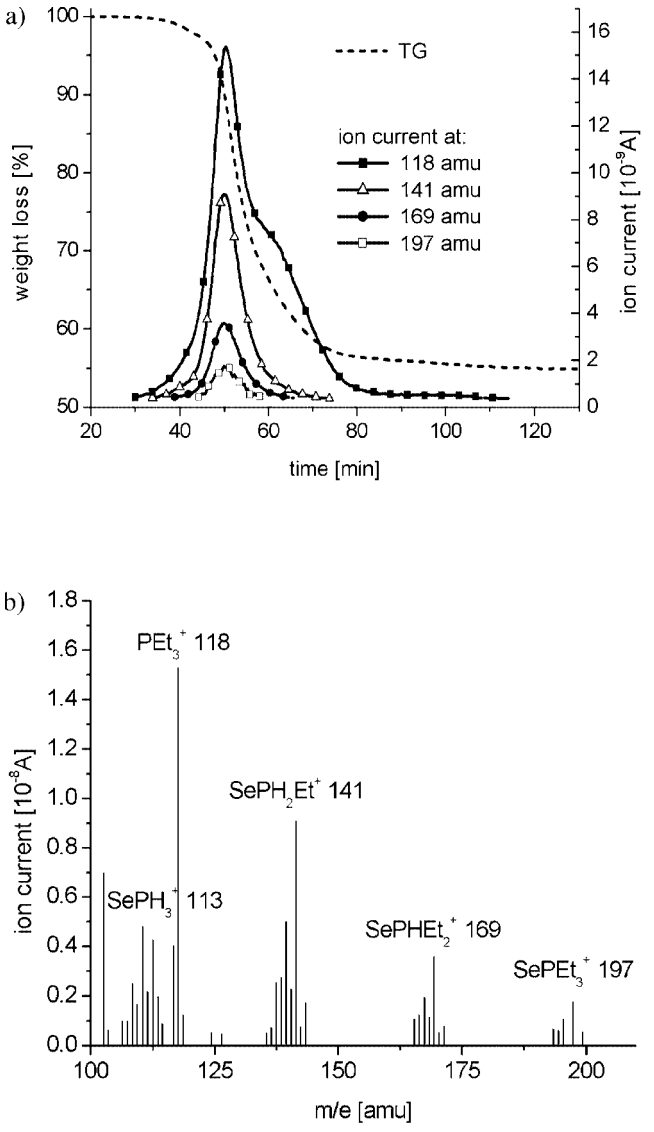

Figure 4. (a) Thermogravimetric analysis of $[Cu_{20}Se_{13}(PEt_3)_{12}]$ (**1**) in vacuo (dashed line) and ion current versus measuring time at 118, 141, 169 and 197 amu; (b) simultaneously recorded mass spectrum of the cleavage products from the thermogravimetry of **1** at cycle 131 (ca. 50 min measuring time)

a theoretical weight loss of 38.2% there appears to be additional elimination of selenium. This was confirmed by simultaneously recorded mass spectra that show peaks attributable to $SePEt_3$ and its fragmentation products (Figure 4, b). The course of the ion current caused by these species (Figure 4, a) indicates that they are formed at an early stage of the cleavage process. In contrast, the ion current for PEt_3 is spread over the whole cleavage process. Theoretical cleavage of three selenium atoms and twelve PEt_3 molecules would lead to a weight loss of 44.5%, which is close to the experimental value. Further evidence for this assumption comes from elemental analysis of the black residue obtained from the TGA, in which the Cu/Se ratio was found to be 1.97:1, in contrast to 3.1:2 in the cluster complex. The analysis further yields C 0.55%, H 0.12%, P $<$ 0.1%.

Thermogravimetric analysis of **1** in a dynamic helium gas flow showed that the thermal decomposition occurs in two successive steps, with maxima in the DTG curve at 107 and 149 °C and weight losses of approximately 17 and 27.4% (Figure 3, b). Here, the change of atmosphere increases the mean cleavage temperature, as has been observed previously for $[Cu_{70}Se_{35}(PEt_2Ph)_{24}]$.[10] The simultaneously recorded mass spectra of the volatile products show only the appropriate peaks for PEt_3 from the beginning of the first step but not for $SePEt_3$ at any stage of the cleavage process. This originates from the use of a TG-MS skimmer coupling system under normal pressure, which reduces the amount of substances reaching the detector and thus the intensity of the signal in comparison with measurements in vacuo. However, the formation of $SePEt_3$ in this case was proven by ^{31}P NMR in C_6D_6 [δ = 44.55 (m) ppm][16] and GC-MS of the collected cleavage products from a cold trap.

A more detailed investigation of the two cleavage steps suggests that in the first step only PEt_3 is cleaved and no $SePEt_3$, due to the different boiling points of the two compounds. In agreement, elemental analysis of the product at approximately 17% mass loss shows C 14.7% and H 3.1%, corresponding to the theoretical cleavage of five PEt_3 molecules (16% weight loss) which would lead to $Cu_{20}Se_{13}(PEt_3)_7$ (C 16.14%, H 3.4%) while the cleavage of three $SePEt_3$ molecules (15.6% weight loss) would give $Cu_{20}Se_{10}(PEt_3)_9$ (C 20.8%, H 4.4%). Furthermore, the cleavage of

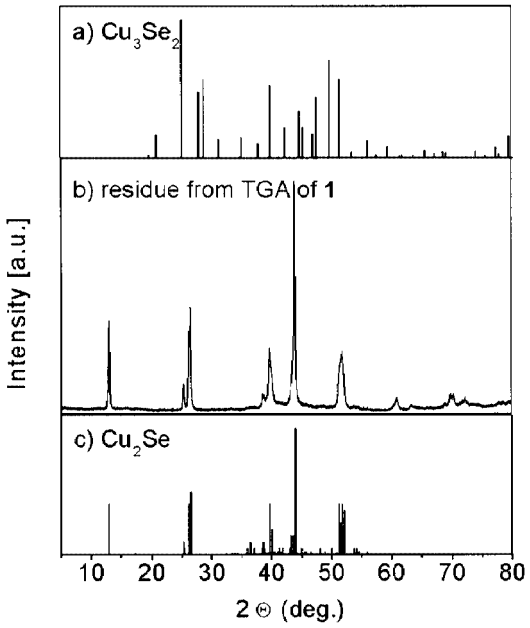

Figure 5. Room-temperature powder-diffraction patterns of (a) Cu_3Se_2;[19] (b) residue of the thermogravimetric analysis of $[Cu_{20}Se_{13}(PEt_3)_{12}]$ (**1**) in vacuo and (c) monoclinic α-Cu_2Se from ref.[18]

$SePEt_3$ in the second step can just be observed by eye upon careful stepwise heating of **1** in a glass flask and is indicated by the sudden formation of white needles on the flask walls above 100 °C. In the powder-diffraction pattern of the intermediate product (heated to 120 °C, 17% mass loss) we found no reflections due to the reported structure of Cu_3Se_2[17] but rather broad reflections pointing to the formation of Cu_2Se[18] (see discussion of powder-diffraction patterns below). Additionally, we found sharp peaks that agree with the calculated pattern of $SePEt_3$.[19] Thus, at almost below 100 °C, phosphane selenide is formed, in agreement with the vacuum TGA, but due to its higher boiling point under normal pressure it escapes from the crucible in the second step.

The differential scanning calorimetry (DSC) curve displays three separated peaks that correspond to three endothermal events in the sample under normal pressure in a dynamic helium gas flow. While the peaks at 105 and 143 °C agree with the two weight-loss steps in thermogravimetry the first endothermal reaction, centered around 74 °C, is more complicated. As the determination of the melting point of the sample gives no evidence for a related process of **1** at this temperature we suggest that the onset of the DSC signal (64 °C) depicts the limit of the thermal stability of **1**. Further heating leads to a decomposition of **1** induced by the formation of $SePEt_3$, a process that is thus clearly separated from the mass loss generated by the escape of PEt_3 and $SePEt_3$ from the crucible.

The powder-diffraction pattern of the thermogravimetric residues of **1** after heating to 250 °C are similar for measurements both in vacuo and in a helium gas flow. The peak positions (Figure 5) agree well with those reported for monoclinic α-Cu_2Se.[18] Furthermore no formation of a Cu_3Se_2 phase[19] was observed although it should be more favoured according to the Cu/Se ratio of 3.1:2 in the cluster complex. This corresponds, on the one hand, to the composition $Cu_{1.97}Se$ determined by elemental analysis and, on the other hand, to the observed mass reduction in thermogravimetry, which strongly suggests the cleavage of three selenium atoms in addition to the triethylphosphane ligands. Stevels has reported that Cu_3Se_2 disproportionates between 120 and 135 °C to form $Cu_{1.8}Se$ and CuSe.[20] In our case, vacuum conditions and the phosphanes, which allows the formation of volatile $SePEt_3$, obviously further reduces the stability of the Cu_3Se_2 phase, leading to the formation of α-Cu_2Se.

Experimental Section

General: Standard Schlenk techniques were employed throughout the syntheses using a double manifold vacuum line with high-purity dry nitrogen. Diethyl ether was dried with sodium/benzophenone and distilled under nitrogen. Anhydrous CuCl (Fluka) was purified from traces of $CuCl_2$ by subsequent washing with dilute HCl, methanol and diethyl ether followed by drying in vacuo. $Se(SiMe_3)_2$ [21] and PEt_3 [22] were prepared according to standard literature procedures. ^{31}P NMR spectra were recorded with a Bruker DPX Avance 300 with 85% H_3PO_4 as an external standard. The solid-state reflectance spectra were measured with a Varian Cary 500 spectrophotometer as micron-sized crystalline powders between quartz plates with a Labsphere integrating sphere.

$[Cu_{20}Se_{13}(PEt_3)_{12}]$ (1): PEt_3 (1.43 mL, 9.7 mmol) was added to a suspension of CuCl (0.32 g, 3.23 mmol) in diethyl ether (40 mL) and stirred for 1 h to give a clear solution. $Se(SiMe_3)_2$ (0.36 mL, 1.62 mmol) was then added at −40 °C and the flask with the PTFE gaskets as stoppers was evacuated before storage at −20 °C. A successful reaction is indicated by the formation of a violet solution. Then, after warming up to −10 °C, black octahedral crystals of **1** appeared within a few days with a final total yield of 20%. $C_{72}H_{180}Cu_{20}P_{12}Se_{13}$ (3715.3): calcd. C 23.28, H 4.88; found C 23.03, H 4.72.

X-ray Crystallography: Crystals suitable for single-crystal X-ray diffraction were obtained directly from the reaction solutions of the compound and then selected in perfluoroalkyl ether oil. Single-crystal X-ray diffraction data for determination of the cell constants of **1** were collected using graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å) with a STOE IPDS II (Imaging Plate Diffraction System). For more details concerning the crystallographic data of **1**, see ref.[13] The molecular diagram was prepared using the program SCHAKAL 97.[23] X-ray powder-diffraction (XRD) patterns were measured with a STOE STADI P diffractometer (Cu-K_α radiation, germanium monochromator, Debye−Scherrer geometry) in sealed glass capillaries. Theoretical powder-diffraction patterns for **1** were calculated on the basis of the atom coordinates obtained from single-crystal X-ray analysis by using the program package STOE WinXPOW.[24]

Thermogravimetric Analysis: Thermogravimetric analyses were run with a thermobalance STA 409 from Netzsch either in vacuo or with a dynamic helium gas flow (70 mL/min) (heating rate 2 K/min). The balance is coupled with a quadrupole mass spectrometer QMG 422 (Balzers) that includes a skimmer system for measurements under normal pressure.

Crystal Field Strengths, Nephelauxetic Effects, and Experimentally Based Molecular Orbital Schemes (in the f Range) of Selected Cyclopentadienyl Complexes of Samarium(III)[‡]

Hanns-Dieter Amberger,*[a] Hauke Reddmann,[a] Stefan Jank,[a] Maria Irene Lopes,[b] and Noémia Marques[b]

Keywords: Lanthanides / Cyclopentadienyl ligands / Optical spectra / Crystal field analysis / Molecular orbital schemes

The absorption and luminescence spectra of pseudo (ψ) trigonal planar [Sm(η^5-C_5H_4tBu)$_3$] (**1**), low symmetric [Sm(η^5-Cp)(η^3-Tp^{Me_2})(η^2-Tp^{Me_2})] (Cp = η^5-cyclopentadienyl; Tp^{Me_2} = hydrotris(3,5-dimethylpyrazolyl)borato) (**2**) as well as ψ trigonal pyramidal [Sm(η^5-C_5H_4tBu)$_3$(THF)] (**3**), [Sm(η^5-Cp)$_3$(THF)] (**4**) and [Sm(η^5-Cp)$_3$(CNC_6H_{11})] (**5**) have been measured at room and low temperatures. From the spectra obtained, truncated crystal field (CF) splitting patterns of these compounds could be derived, and simulated by fitting the parameters of a phenomenological Hamiltonian. On the basis of the CF parameters used, the global CF strengths experienced by the Sm^{3+} central ions of complexes **1**–**5**, as well as the individual CF strength associated with one C_5H_4tBu$^-$ ligand are estimated. The obtained Slater parameters F^2 and the spin-orbit coupling parameters ζ_{4f} allow the insertion of compounds **1**–**5** into truncated nephelauxetic and relativistic nephelauxetic series. Besides, the experimentally based non-relativistic and relativistic molecular orbital schemes (in the f range) of complexes **1** and, partly, **3** are set up and compared with the results of quantum chemical model calculations.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

After a successful parametric analysis of the experimentally derived crystal field (CF) splitting pattern, the global CF strength [$N_v/(4\pi)^{1/2}$] experienced by the central ion of a lanthanide [Ln(III)] compound may be calculated by the relation[2]

$$N_v / \sqrt{4\pi} = \sum_{k,q} \sqrt{\frac{(B_q^k)^2}{2k+1}}$$

where the B_q^k's represent the phenomenological CF parameters used in the fit.[3–6] The individual CF strength associated with one single ligand L^- of homoleptic neutral LnL_3 or anionic $[LnL_p]^{3-p}$ complexes is obtained by dividing $N_v/(4\pi)^{1/2}$ by three or the number of ligands (p), respectively (method A).

Alternatively, the individual CF strength of the ligand L^- of neutral $LnLL'_2$ or anionic $[LnLL'_q]^{2-q}$ complexes is nearly equal to the global CF strength if the CF strength associated with the ligands L'^- may be safely neglected (method B).

In recent years, we have parametrized the CF splitting patterns of a number of monomeric homoleptic LnL_3 [L = $C_5H_4SiMe_3^-$,[7] $N(SiMe_3)_2^-$,[8–10] $CH(SiMe_3)_2^-$,[11,12] OC_6H_3tBu$_2$-2,6$^-$[13]] complexes and — using method A — we found enormous individual CF strengths. By combining these ligands L with those producing weak CF strengths, the individual CF strength of the ligand L may also be estimated by means of method B.

Some years ago, we compared the absorption spectra of [Nd(COT)(Tp^{Me_2})] [COT = η^8-cyclooctatetraenyl; Tp^{Me_2} = hydrotris(3,5-dimethylpyrazolyl)borato] and [Nd(COT)(I)(THF)$_3$] and observed only minor differences.[14] As the CF strengths of I^- and THF are relatively small,[15] we concluded that this holds also for the Tp^{Me_2} ligand. Applying method B, the large global CF strengths found for [Ln(COT)(Tp^{Me_2})] (Ln = Pr, Nd, Sm)[16–19] were considered to be approximately equal to the individual CF strength of the COT ligand.

Up to now, the results of both methods (with the central Ln^{3+} ion as well as the ligand L^- fixed) have not been cross-checked. Because of the existence of Sm^{III} and Sm^{II} precursors, the variety of organosamarium(III) complexes is

extremely well developed. In the framework of the present and some following estimations of the CF strengths of the strong ligands L adopting methods A and B, respectively, we will focus on the combination of the Sm^{3+} ion and (substituted) η^5-cyclopentadienyl (Cp) ligands. In this first study, we select from the series of hitherto described homoleptic $[SmCp'_3]$ [$Cp' = C_5H_4tBu^-$, $C_5H_3(1,3\text{-}SiMe_3)_2^-$, $C_5Me_5^-$, $C_5HMe_4^-$, $C_5Me_4Et^-$, $C_5H_4SiEt_3^-$, $C_5H_4CH(SiMe_3)_2^-$][20–27] and monomeric $[SmCp'L'_2]$ ($Cp' = Cp^-$, $C_5H_4tBu^-$, $C_5H_4Me^-$, $C_5Me_5^-$, $C_5H_4SiMe_3^-$, $C_5Me_4CH_2Ph^-$; $L' = Cl^-$, acac$^-$, I^-, Tp^{Me_2})[28–32] complexes the combination $[Sm(C_5H_4tBu)_3]$ (**1**)/ $[Sm(Cp)(Tp^{Me_2})_2]$ (**2**).

For the purpose of demonstrating that the CF strengths associated with the $C_5H_4tBu^-$ and Cp ligand, respectively, are comparable, it is planned to additionally analyze the absorption spectra of $[Sm(C_5H_4tBu)_3(THF)]$ (**3**) and $[Sm(Cp)_3(THF)]$ (**4**). In order to study spectroscopic and nephelauxetic effects associated with the isocyanide and nitrile ligand, respectively, we wish to compare the result of a CF analysis on $[Sm(Cp)_3(CNC_6H_{11})]$ (**5**) with that of a previous one on $[Sm(Cp)_3(NCCH_3)]$.

Organometallic π complexes of f elements usually have poor crystallizing properties, and additionally the principal rotation axes of the individual molecules in the unit cell are frequently not aligned. Even if they were aligned as in the case of low symmetric crystal systems, it is difficult to orientate these rotation axes with respect to outer homogeneous or vector fields. For this reason, the optical properties of organo-f element complexes are usually studied in solution or as pellets, thus missing the additional information obtainable from optical polarization measurements. A way out of these difficulties would be to extract a first rough set of parameters from the results of quantum chemical calculations on the compound of interest.

In order to check the predictions of previous model calculations on model pseudo (ψ) trigonal planar $[Ln(\eta^5\text{-}Cp)_3]$ (Ln = Sm, Pr, Ce)[33–35] as well as of real ψ trigonal pyramidal $[Pr(\eta^5\text{-}Cp)_3(B)]$ (B = THF, CNC_6H_{11})[35] and $[Gd(\eta^5\text{-}Cp)_3(THF)]$,[36] we wish to compare the calculated non-relativistic and relativistic molecular orbital (MO) schemes (in the f range) of these compounds with our experimentally based results.

Results and Discussion

General Symmetry Considerations, Selection Rules and the Phenomenological Hamiltonian

The crystal and molecular structure of compound **1** is unknown, however, the optical spectra of this complex exhibits the same features as those of $[Sm(C_5Me_5)_3]$ or $[Sm(C_5HMe_4)_3]$,[37] where the three Cp centroids describe a trigonal planar geometry around the Sm^{3+} ion.[23,24] Thus for **1**, we assume an effective CF of D_{3h} symmetry.

A single-crystal X-ray study of complex **2** revealed a symmetrical η^5-bonding of the Cp ring and an η^3- as well as an η^2-bonding mode of the two Tp^{Me_2} ligands[32] (Figure 1).

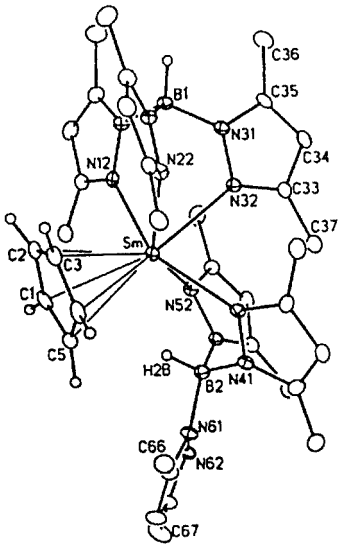

Figure 1. Molecular structure of $[Sm(\eta^5\text{-}Cp)(\eta^3\text{-}Tp^{Me_2})(\eta^2\text{-}Tp^{Me_2})]$ from a single-crystal analysis[32]

In order to simplify the parametrization of the experimentally derived energy level scheme of this low symmetric compound, we adopt the following two approaches: in analogy with our previous treatments of the CF splitting patterns of $[Ln(COT)(Tp^{Me_2})]$ (Ln = Pr, Nd, Sm)[16–19] we only consider the influence of the Cp ligand, which leads to C_{5v} symmetry. Alternatively, we approximate the real molecular geometry by a pentagonal sandwich complex (D_{5h} symmetry of the effective CF).

The electrostatic potentials of seven- and higher-membered aromatic ring ligands, experienced by f electrons, are equivalent to circles,[38] thus the effective CFs of $[Ln(COT)]^+$ fragments[16–19] are of $C_{\infty v}$ symmetry. Theoretically, in the case of lower membered aromatic ligands such as Cp, the actual C_{5v} symmetry of the $[Sm(Cp)]^{2+}$ moiety has to be considered. However, a number of previous studies of ψ trigonal pyramidal[39] and ψ trigonal bipyramidal[40] Cp complexes of rare earths showed that the five-membered Cp rings disturb the pseudo symmetry only weakly. Therefore, in the framework of this approach instead of the actual molecular C_{5v} the higher $C_{\infty v}$ symmetry is assumed. Effective CFs of D_{5h} and $C_{\infty v}$ symmetry have the same CF Hamiltonians (vide infra), thus both approaches are equivalent from the aspect of CF theory.

Single-crystal X-ray analyses of numerous mono base adducts of the type $[Ln(Cp')_3(B)]$ ($Cp' = Cp$, alkylated or silylated Cp, B = THF, CNC_6H_{11}, $NCCH_3$) revealed a ψ trigonal pyramidal structure,[20] suggesting an effective CF of C_{3v} symmetry for adducts **3–5**.

The free Sm^{3+} ion gives rise to multiplets $^{2S+1}L_J$ with $1/2 \leq J \leq 21/2$.[41] If the Sm^{3+} ion is placed into CFs of D_{3h}, $D_{5h}/C_{\infty v}$ or C_{3v} symmetry, respectively, these multiplets are split into various CF levels.[6] The wavefunctions of these levels are described to first order by $\pm M_J$ for $D_{5h}/C_{\infty v}$ symmetry, whereas different $\pm M_J$ functions with $\Delta M_J = 6$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mix for D_{3h}, and $\Delta M_J = 3$ for C_{3v} symmetry. Table 3 of ref.[42] lists the composition of the CF eigenvectors of f^n systems (with an odd number of f electrons) exposed to a CF of D_{3h} symmetry, and correlates them with the irreducible representations (irreps) Γ_7, Γ_8 and Γ_9 of the D_{3h}' double group. In this table the convention of Koster et al.[43] is used. The convention suggested by Hüfner[44] interchanges Γ_7 and Γ_8.

In the case of $D_{5h}/C_{\infty v}$ symmetry, the CF states are sufficiently characterized by their M_J quantum numbers, and in the case of C_{3v} symmetry, the CF states transform like the irreps Γ_4 and $\Gamma_{5/6}$.

The electric dipole selection rules (odd number of f electrons) for powdered or dissolved species with an effective CF of D_{3h} symmetry are given in Table A 5.2. of ref.[6] This table shows that the only forbidden transitions for adduct **1** are of the type $\Gamma_7 \rightarrow \Gamma_7$ and $\Gamma_8 \rightarrow \Gamma_8$, respectively.

In the case of compound **2**, the ideal $D_{5h}/C_{\infty v}$ symmetry is noticeably distorted, thus we expect that each $^{2S+1}L_J$ multiplet splits into J + 1/2 levels, and all transitions are allowed. According to Table A 5.3. of ref.[6], all transitions in C_{3v} symmetry are allowed for dissolved and powdered adducts **3**−**5**.

The energy levels within f^n configuration in D_{3h}, $D_{5h}/C_{\infty v}$ and C_{3v} symmetry can be written in terms of the atomic free ion (H_{FI}) and crystal field (H_{CF}) Hamiltonians as follows:

$H = H_{FI} + H_{CF}$, where

$$H_{FI} = \sum_{k=0,2,4,6} f_k F^k(nf,nf) + a_{so}\zeta_{4f} + \alpha L(L+1) + \beta G(G_2) + \gamma G(R_7) + \sum_{i=2,3,4,6,7,8} t_i T^i + \sum_{k=0,2,4} m_k M^k + \sum_{k=2,4,6} p_k P^k \text{ [4]}, \text{ and}$$

$$H_{CF}(D_{3h}) = B_0^2 C_0^{(2)} + B_0^4 C_0^{(4)} + B_0^6 C_0^{(6)} + B_6^6 (C_{-6}^{(6)} + C_6^{(6)}) \text{ (Ref.[6], p. 242).}$$

$$H_{CF}(D_{5h}/C_{\infty v}) = B_0^2 C_0^{(2)} + B_0^4 C_0^{(4)} + B_0^6 C_0^{(6)} \text{ (Ref.[6], p. 242/245).}$$

$$H_{CF}(C_{3v}) = B_0^2 C_0^{(2)} + B_0^4 C_0^{(4)} + B_3^4 (C_{-3}^{(4)} - C_3^{(4)}) + B_0^6 C_0^{(6)} + B_3^6 (C_{-3}^{(6)} - C_3^{(6)}) + B_6^6 (C_{-6}^{(6)} + C_6^{(6)}) \text{ (Ref.[6], p. 245).}$$

The $F^k(nf,nf)$'s and ζ_{4f} terms represent, respectively, the radial parts of the electrostatic and spin-orbit interactions between f electrons, while f_k and a_{so} are the angular parts of these interactions. α, β and γ are the parameters associated with the two-body effective operators of configuration interaction, and the T^i's are the corresponding three-body effective operators. The M^k parameters represent the spin-spin, and spin-other-orbit interactions, while the P^k parameters arise from electrostatic spin-orbit interactions with higher configurations.[4] The CF interaction for the above symmetries is represented by the B_q^k parameters and the tensor operators $C_q^{(k)}$.[3]

Optical Spectra of [Sm(C$_5$H$_4$*t*Bu)$_3$]

Homoleptic base-free SmL_3 complexes with alkylated or silylated ligands are usually deeply colored[20−27] because of an energetically low-lying charge-transfer transition of the type $Sm^{III}(L^-)_3 \rightarrow Sm^{II}(L_3)^{2-}$. Thus these compounds show either no or a few luminescence transitions (on the basis of which the CF splitting patterns of Sm^{III} compounds in the low energy range < 5000 cm^{-1} are usually derived).[45] For this reason the energies of the low-lying levels of compound **1** have to be extracted mainly from "hot" transitions and IR/NIR spectra, where, however, fundamental vibrations as well as binary and ternary C−H combination vibrations and overtones are severely disturbing.

In order to partly separate stronger bands of f-f transitions from weaker vibrational signals, we also recorded the absorption spectrum of "optically empty" [La(C$_5$H$_4$*t*Bu)$_3$] in the IR/NIR range. As the NIR spectrum of this compound was poorly resolved, we also used [La(C$_5$H$_4$SiMe$_3$)$_3$] (oil at room temperature) for the above purpose.

Comparing the low-temperature IR spectra of **1** and the corresponding La compound, we could not detect any differences, thus the energies of low-lying levels have to be concluded from "hot" transitions in the UV/Vis/NIR range and the rare transitions of the luminescence spectrum. In the low temperature Vis/NIR spectrum of complex **1** some "hot" signals (with $\Delta E \approx 486$ cm^{-1} from the corresponding "cold" bands) that appear in the room temperature spectrum are missing, thus indicating an excited level at about 486 cm^{-1}.

Luminescence transitions of organometallic Sm^{III} compounds usually initiate at the lowest CF level of $^4G_{5/2}$,[45,46] which is found at 17489 cm^{-1} in the room temperature absorption spectrum of complex **1** dissolved in methylcyclohexane. In the luminescence spectrum of solid **1**, we could not detect a single luminescence transition, but a methylcyclohexane solution showed a signal at 16591 cm^{-1} (using the exciting line at 476.5 nm) which suggests the existence of a CF level at 898 cm^{-1}.

In the range 4000−4650 cm^{-1} of the IR/NIR spectrum (pellet) the expected transitions $^6H_{5/2} \rightarrow {}^6H_{11/2}$ are partially obscured by strong C−H combination vibrations and overtones, but in the remaining part of this spectrum a number of f-f transitions could be clearly identified (Figure 2, Table 1).

The UV/Vis part of the low temperature absorption spectrum is dominated by a strong broad charge-transfer band. On the low-energy side of this band one strong (17486 cm^{-1}) and three diffuse signals at approximately 18282, 19245 and 19485 cm^{-1} appeared (Table 1).

Optical Spectra of [Sm(Cp)(Tp^{Me_2})$_2$]

In order to separate bands of f-f and vibrational origin in the absorption spectrum of compound **2**, we could not make use of the corresponding "optically empty" La, Gd,

[a] Dominating Russell-Saunders multiplet $^{2S+1}L_J$. [b] Largest eigenvector component $\pm M_J$. [c] From luminescence measurements. [d] From absorption measurements.

Y, Lu compounds as these don't exist at this point, but as a proxy we used the combined vibrational energies of NaCp and KTp^{Me_2}. The wavenumbers of the thus separated signals of presumable f-f origin in the Vis/NIR spectrum are given in Table 2 (Figure 3).

By using all of the exciting lines of an Ar^+ laser, the best signal-to-noise ratio in the luminescence spectrum of compound **2** was observed by applying the line at 476.5 nm. Using this line, the vibrational Raman signals are well separated from the luminescence transitions.[45,46] The observed

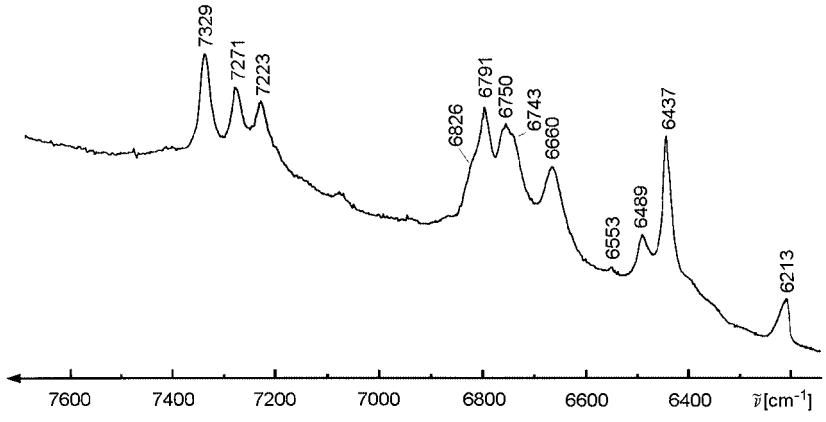

Figure 3. Absorption spectrum of $[Sm(Cp)(Tp^{Me_2})_2]$ in the range 6150−7700 cm^{-1}, pellet, ca. 80 K

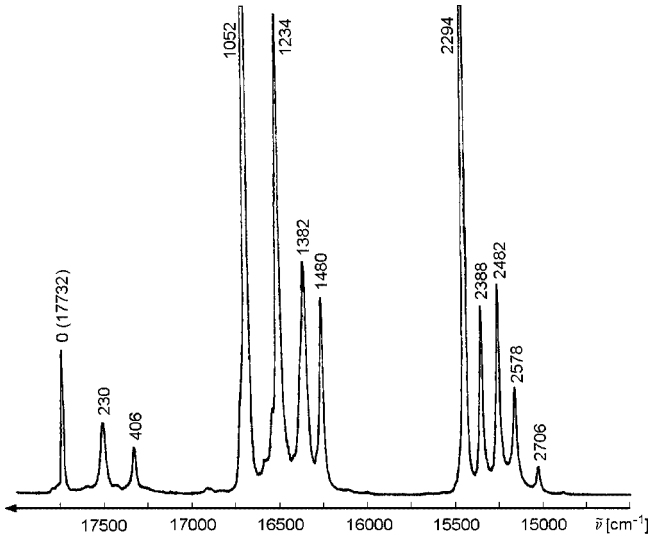

Figure 4. Luminescence spectrum of $[Sm(Cp)(Tp^{Me_2})_2]$ in the range 14500−18000 cm^{-1}, powder, ca. 90 K; the value in brackets denotes the absolute wavenumber of the fluorescing level, and those without brackets the derived CF energies.

low temperature luminescence spectrum (Figure 4) can be rationalized by identifying the fluorescing level at 17732 cm^{-1} with the lowest CF state of the multiplet $^4G_{5/2}$, and the terminal levels arising from the multiplets ^6H_J (J = 5/2, 7/2, 9/2, 11/2, 13/2, 15/2) and $^4F_{1/2}$. On this basis, the CF splitting pattern of **2** in the low-energy range could be derived (Table 2). In the overlapping region, the CF energies directly observed in the absorption spectrum and concluded from the luminescence spectrum, agree nicely (cf. Table 2).

Using the exciting line at 457.9 nm two "negative bands" with minima at 19927 cm^{-1} and 20041 cm^{-1} appeared. The existence of these signals may be explained by an absorption process from background radiation.[17] The former peak corresponds to a broad asymmetric band with the maximum at ca. 19930 cm^{-1} in the "ordinary" absorption spectrum of a pellet.

Absorption Spectra of $[Sm(C_5H_4tBu)_3(THF)]$, $[Sm(Cp)_3(THF)]$ and $[Sm(Cp)_3(CNC_6H_{11})]$

The low temperature absorption spectra of dissolved adducts **3**−**5** and previously analyzed solid $[Sm(Cp)_3(NCCH_3)]$[45] are nearly identical. The same holds for the luminescence spectra of adducts **4** and **5** and for that of $[Sm(Cp)_3(NCCH_3)]$[45] For this reason we do not present figures of the recorded spectra and refer the reader to ref.[45] Because of the deep purple color of a glassy frozen solution of compound **3**, we didn't try to record its luminescence spectrum.

CF Analyses

Because of the missing optical polarization measurements of oriented single crystals, and the principle impossi-

bility to interpret magnetic circular dichroism measurements of dissolved systems with an odd number of f electrons,[47] the derived sequences of CF levels of compounds **1**−**5** cannot be assigned on an experimental but only on a calculational (**1**, **2**) or comparative (**3**−**5**) basis.

In order to get a first idea of the signs and magnitudes of the CF parameters of complexes **1** and **2**, we adopted the CF parameter set of ψ trigonal planar $[Pr(C_5H_4SiMe_3)_3]$[7] for **1**, and for **2**, we divided the CF parameters B_0^2, B_0^4 and B_0^6 of this compound by three. Because of the similarity of the optical spectra of $[Sm(Cp)_3(NCCH_3)]$[45] and those of adducts **3**−**5**, we used the unchanged CF parameters of $[Sm(Cp)_3(NCCH_3)]$[45] as a starting set for the latter complexes.

Together with the unchanged free-ion parameters of $LaCl_3:Sm^{3+}$ [41] for compound **2**, those of $[Sm(Cp)_3(NCCH_3)]$[45] for adducts **3**−**5** and compound **1** (however, because of presumably increased covalency the Slater parameter F^2 of the latter compound was reduced by 3%), the above mentioned sets of CF parameters were inserted into the energy matrices of the f^5 system exposed to the CFs of D_{3h}, $D_{5h}/C_{\infty v}$ and C_{3v} symmetry, respectively. Diagonalizing these matrices we calculated eigenvalues which were not too different from the experimental energies of CF states, which were thus assigned. On this basis in the framework of subsequent fitting procedures, the parameters of $H_{FI} + H_{CF}$ were fitted to the experimental CF splitting patterns. In order to reduce the number of free parameters, α, β, γ, the T^i, M^k and P^k parameters[4] were fixed at the values used in the CF analyses of $[LaCl_3:Sm^{3+}]$[41] and $[Sm(Cp)_3(NCCH_3)]$.[45] The remaining parameters were allowed to vary. For 25, 59, 25, 51 and 59 assignments, the reduced r.m.s. deviations (σ, cf. ref.[6] p.182) for compounds **1**−**5** were 17.5, 35.0, 30.8, 30.4 and 25.2 cm^{-1}, respectively.

Table 3 gives the final values of the CF and free-ion parameters for compounds **1**−**5**. For comparison purposes, the parameters of $[Sm(Cp)_3(NCCH_3)]$ and $[La_{0.8}Sm_{0.2}(Cp)_3(NCCH_3)_2]$ are also listed. In Table 1 and 2, experimental and calculated CF splitting patterns of complexes **1** and **2** are compared. Those of adducts **3**−**5** are not given because of the close similarity of the CF splitting patterns of these compounds and $[Sm(Cp)_3(NCCH_3)]$.[45]

Inserting the CF parameters of compounds **1**−**5** into the relation below[2] one ends up with $N_v/(4\pi)^{1/2}$ values of 1749, 522, 1371, 1378 and 1373 cm^{-1}, respectively.

$$N_v / \sqrt{4\pi} = \sum_{k,q} \sqrt{\frac{(B_q^k)^2}{2k+1}}$$

The above mentioned global CF strength of 1749 cm^{-1} for base-free compound **1** is the highest global CF strength ever found for a lanthanide compound. This is in agreement with the results of previous and current CF analyses of ψ trigonal planar complexes such as $[Pr(C_5H_4SiMe_3)_3]$, $[Pr(C_5H_4tBu)_3]$, $[Nd(C_5H_4SiMe_3)_3]$ and $[Nd(C_5H_4tBu)_3]$ where $N_v/(4\pi)^{1/2}$ values of 1429, 1497, 1662 and 1651 cm^{-1} were found,[7,48] which are the highest hitherto concluded for Pr^{III} and Nd^{III} compounds.

The CF strengths experienced by the Sm^{3+} central ions decrease from base-free compound **1** via mono adducts **3**−**5** to the bis adduct $[La_{0.8}Sm_{0.2}(Cp)_3(NCCH_3)_2]$ (Table 3) which is mainly due to the decreasing absolute value of B_0^2 within this series. The results[49] of basic model calculations in the framework of the angular overlap model[50−52] are consistent with the found trend for the above mentioned compounds (Table 3). The enormous decrease of CF strength going from base-free compound **1** to the mono adduct **3** is paralleled by the pair of compounds $[Sm(C_5H_4SiEt_3)_3]$/$[Sm(C_5H_4SiEt_3)_3(NCCH_3)]$ (where the former complex has a comparable CF splitting pattern as compound **1**) which have preliminary $N_v/(4\pi)^{1/2}$ values of 1721 and 1375 cm^{-1}.[53]

Applying method A on compound **1** and method B on complex **2**, $C_5H_4tBu^-$ and unsubstituted Cp produce CF strengths of 583 and 522 cm^{-1}, respectively. Comparing both values, the agreement is not too bad.

The most obvious reason for the discrepancy found would be that it is not allowed to neglect the CF strengths of the two Tp^{Me_2} ligands. Usually, nine-coordinate Ln^{3+} central ions experience low CF strengths.[54] For this reason, it was originally assumed that this also holds for homoleptic nine-coordinate $[Ln(\eta^3\text{-}Tp)_3]$ (Ln = La−Tb)[55,56] and $[Ln(COT)(\eta^3\text{-}Tp^{Me_2})]$ (Ln = Pr, Nd, Sm),[16−19] where the N atoms of the Tp^{Me_2} ligands have only somewhat shorter distances from the Ln central ions[57] as in $[Ln(Tp)_3]$.[55,56] Thus, we neglected the contribution of the Tp^{Me_2} ligand to the global CF strength and identified (adopting method B) the global CF strength of $[Ln(COT)(Tp^{Me_2})]$ (approximately 1250 cm^{-1})[16−19] with the individual CF strength of the COT ligand.

In order to examine the above assumption of a low CF strength of the Tp^{Me_2} or Tp ligand, we recently analyzed the optical spectra of homoleptic $[Ln(\eta^3\text{-}Tp)_3]$ (Ln = Eu, Pr)[56,58] and found averaged CF strengths of 149 cm^{-1} [56] and 194 cm^{-1},[58] respectively, per Tp ligand. In view of the global CF strength of approximately 1250 cm^{-1} of $[Ln(COT)(Tp^{Me_2})]$ complexes it is a somewhat rough but reasonable approximation to neglect the contribution of the Tp^{Me_2} ligand to the global CF strength.

By means of compound **1** and applying method A, the individual CF strength of the $C_5H_4tBu^-$ ligand was estimated to be 583 cm^{-1} (vide supra). This value is approximately three times greater than that of the Tp ligand and thus the contribution of the η^3- and η^2-coordinated Tp^{Me_2} ligands to the global CF strength of complex **1** cannot be neglected. In view of these facts, it is rather surprising that methods A and B, when applied to compounds **1** and **2**, lead to comparable values of the CF strength of η^5-coordinated (substituted) Cp ligands (vide supra). The most simple explanation for this finding would be that opposite effects cancel out in the case of compound **2**, thus giving almost the same individual CF strength of the Cp ligand as found for the substituted Cp ligand of compound **1**.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

If one accepts the above rough approximation for [Ln(COT)(Tp^{Me_2})], the individual CF strength of COT ligand is (with about 1250 cm^{-1}) by a factor of 2.1 greater than that which we derived for the $C_5H_4tBu^-$ ligand of compound **1** adopting method A. If one refers to the ligand field strength produced by one coordinated C atom of both ring ligands, one arrives at 156 cm^{-1} (COT) and 116 cm^{-1} (Cp).

The optical spectra of [Sm{$CH(SiMe_3)_2$}$_3$] have not been analyzed at this point, but in the case of the corresponding Nd compound we found an individual CF strength of 348 cm^{-1} for the essentially σ bonded $CH(SiMe_3)_2^-$ ligand,[12] which is considerably greater than those associated with one carbon atom of π bonded COT or Cp ligands. These findings may be partly explained by the considerably reduced average Sm−C distance of [Sm{$CH(SiMe_3)_2$}$_3$] (2.33 Å)[59] as compared to [Sm(COT)(Tp^{Me_2})] (2.622 Å)[57] and (as a proxy for compound **1**) [Sm(C_5H_3(1,3-$SiMe_3$)$_2$)$_3$] (2.76 Å).[22]

The CF parameters B_0^4 and B_0^6 of complex **2** have unusual low absolute values as compared to the remaining Cp compounds of Table 3, a fact which contributes mainly to the low global CF strength of this compound. In contrast to B_0^2, which is caused mainly by electrostatic effects the CF parameter B_0^6 is dominated by covalency effects (ref.[44] p.71). Possibly, the low covalency of complex **2** (vide infra) may be partly responsible for the low absolute values of B_0^4 and B_0^6 of this compound.

The Slater parameter F^2 and the spin-orbit coupling parameter of the gaseous Sm^{3+} ion are unknown, thus the nephelauxetic parameter beta = F^2(complex)/F^2(free ion), the relativistic nephelauxetic parameter beta′ = ζ_{4f}(complex)/ζ_{4f}(free ion), and the covalency √b [defined as √b = √(1-beta)/2 [60]] cannot be calculated. Furthermore, the Slater parameters of Sm^{III} compounds are frequently not well defined due to the limited number of $^{2S+1}$L terms (with different L or S) considered in the fits. Anyway, the insertion of compounds **1**−**5** into truncated empiric nephelauxetic and relativistic nephelauxetic series can be seen from Table 4. Evidently, the truncated nephelauxetic series for Sm^{III} compounds in Table 4 is only partly paralleled by the trend of ζ_{4f} values, and thus the relativistic nephelauxetic series.

Obviously, complex **1** has the lowest F^2 value and thus is the most covalent Sm^{III} compound hitherto analyzed, F^2 of adducts **3**−**5** moves within the typical range of mono adducts, whereas **2** has a relatively low covalency. The observed trends within compounds **1** and **3**−**5** are paralleled by the corresponding Pr and Nd complexes.[48]

Comparing the found F^2 and $N_v/(4\pi)^{1/2}$ values of adduct **5** and [Sm($Cp)_3$($NCCH_3$)] (Table 3), one has to conclude that covalency and global CF strength are more pronounced for the isocyanide than for the nitrile adduct.

The eigenvalues of an energy matrix of the spin-free f^1 system, into which the CF parameters of a parametric analysis of the compound of interest had been inserted, were defined in ref.[49] as the experimentally based non-relativistic MO scheme of this compound in the f range. Likewise, the eigenvalues of an energy matrix of the real f^1 system, into which the spin-orbit coupling as well as the CF parameters had been inserted, were defined as the experimentally based relativistic MO scheme of this compound in the f range.[66]

In Figure 5, the experimentally based non-relativistic MO schemes (in the f range) of complex **1** and [Pr(η^5-$C_5H_4SiMe_3$)$_3$][52] are compared with the non-relativistic MO scheme of fictive ψ trigonal planar [Sm(η^5-Cp)$_3$] calculated in the framework of the SW-Xα approximation.[33]

Obviously, the calculated splitting of f orbitals is considerably greater than the experimentally based ones. Moreover, the experimentally based sequences of f orbitals are roughly comparable for **1** and [Pr(η^5-$C_5H_4SiMe_3$)$_3$] (only the close-lying orbitals f_{z^3} and $f_{z(x^2-y^2)}$/f_{xyz} are interchanged) but at the first glance considerably different from the calculated one for fictive trigonal planar[Sm($Cp)_3$]. Fitting the free parameters of the phenomenological Hamiltonian of

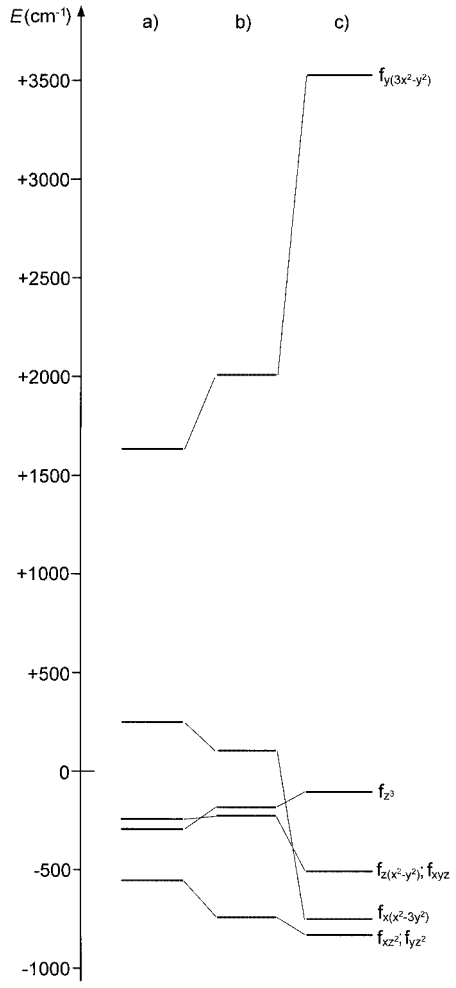

Figure 5. Experimentally based and calculated non-relativistic MO schemes of: a) $[Pr(C_5H_4SiEt_3)_3]$ (exp., from ref.[7]); b) $[Sm(C_5H_4tBu)_3]$ (exp.); c) fictive ψ trigonal planar $[Sm(Cp)_3]$ (calcd. from ref.[33])

the spin-free f^1 system to the calculated energies of f orbitals of the latter complex one arrives at $B_0^2 = -3443\ cm^{-1}$, $B_0^4 = 2817\ cm^{-1}$, $B_0^6 = 1296\ cm^{-1}$ and $B_6^6 = -6033\ cm^{-1}$. Comparing these values with those of compound **1** (Table 4), it becomes evident that first of all the CF parameters B_6^6 (which considers the interactions between the orbitals $f_{x(x^2-3y^2)}$ and $f_{y(3x^2-y^2)}$ within the framework of CF theory) but also B_0^4 are heavily overestimated by the model calculation. If one reduces B_6^6 to a quarter, not only the correct sequence of levels but also the correct total splitting of f orbitals would result. From the aspect of MO theory the required reduction of B_6^6 means that the interaction of $f_{y(3x^2-y^2)}$ with the corresponding symmetry adapted linear combination of ligand orbitals is overestimated and that of $f_{x(x^2-3y^2)}$ is underestimated by the model calculation.

The electronic structure of fictive ψ trigonal planar $[Pr(Cp)_3]$ was calculated by means of the SW-Xα[33] as well as the INDO/1[35] approximation. The SW-Xα calculation yielded a comparable MO scheme (in the f range) as for $[Sm(Cp)_3]$[33] and the more basic INDO/1 calculation led, astonishingly, to the same energetic sequence[35] as we had concluded for $[Pr(\eta^5\text{-}C_5H_4SiMe_3)_3]$ (Figure 5). However, in the case of the INDO/1 approximation the calculated total splitting of f orbitals ($1545\ cm^{-1}$ [35]) is noticeably smaller than the experimentally based one ($2189\ cm^{-1}$ [7]).

The result of a recent non-relativistic discrete variational (DV)-Xα calculation on ψ trigonal planar $[Ce(Cp)_3]$[34] is similar to that of the SW-Xα approximation.[33]

In Figure 6, the result of a previous relativistic DV-Xα calculation on fictive ψ trigonal planar $[Ce(Cp)_3]$[34] is compared with the experimentally based relativistic MO schemes of compound **1** and that of a model compound, the CF splitting pattern of which was calculated adopting the spin-orbit coupling parameter used for $[Ce(Cp)_3(NCCH_3)_2]$ ($610\ cm^{-1}$)[67] and the CF parameters of complex **1**. Obviously, the same sequences of levels exist, but the DV-Xα calculation predicts a total splitting of f levels which is a factor of 1.75 greater than that of the above characterized model compound. This is mainly due to an overestimated spin-orbit coupling parameter of the DV-Xα calculation, which is approximately twice as great ($1300\ cm^{-1}$) as those found in the framework of previous CF analyses of Ce^{III} compounds (cf. ref.[6] p. 127).

To the best of our knowledge, results of model calculations on mono adducts of the $Sm(Cp)_3$ moiety have not been published up to now. However, $[Ln(Cp)_3(THF)]$ (Ln = Pr,[35] Gd[36]) and $[Pr(Cp)_3(CNC_6H_{11})]$[35] have been the subject of INDO/1 calculations. In the case of $[Pr(Cp)_3(B)]$ ($B = CNC_6H_{11}$, THF), these calculations led to the same

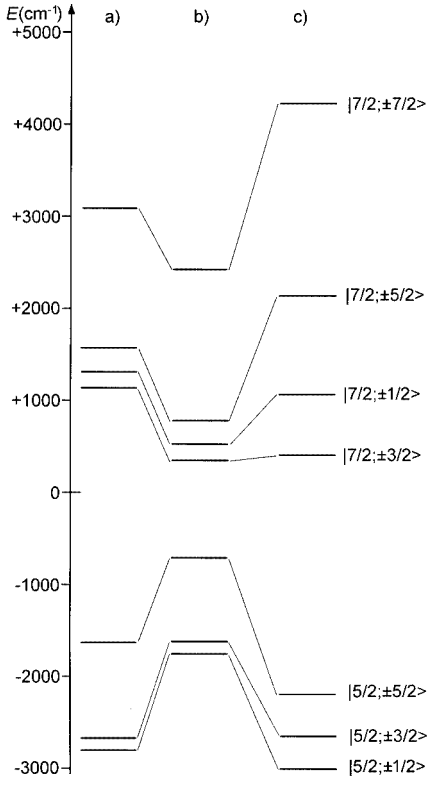

Figure 6. Experimentally based and calculated relativistic MO schemes of: a) $[Sm(C_5H_4tBu)_3]$ (exp.); b) calculated, adopting CF parameters of $[Sm(C_5H_4tBu)_3]$ and $\zeta_{4f} = 610\ cm^{-1}$; c) ψ trigonal planar $[Ce(Cp)_3]$ (calcd., from ref.[34])

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

energetic sequence of f orbitals as we found on an experimental basis for these compounds[68] as well as for $[Sm(Cp)_3(NCCH_3)]$[69] and adducts **3**–**5**. However, the calculated total splitting of f orbitals of $[Pr(Cp)_3(B)]$ is with 742 cm^{-1} (B = CNC_6H_{11}) and 997 cm^{-1} (B = THF) considerably smaller than the experimentally based ones of $[Pr(Cp)_3(CNC_6H_{11})]$ (1978 cm^{-1}),[68] $[Pr(Cp)_3(THF)]$ (1722 cm^{-1} [68]), $[Sm(Cp)_3(NCCH_3)]$ (1989 cm^{-1} [69]) and compounds **3** (2043 cm^{-1}), **4** (2007 cm^{-1}) and **5** (1988 cm^{-1}).

The above-mentioned INDO calculation for $[Gd(Cp)_3(THF)]$ led to the following energetic sequence of f orbitals: $f_{z^3} < f_{xz^2}/f_{yz^2} < f_{z(x^2-3y^2)}/f_{xyz} < f_{x(x^2-3y^2)} < f_{y(3x^2-y^2)}$ (with a total splitting of f orbitals of 230 cm^{-1} [36]) which differs considerably from the experimentally based ones for mono adducts of the $[Ln(Cp)_3]$ moiety (Figure 7).

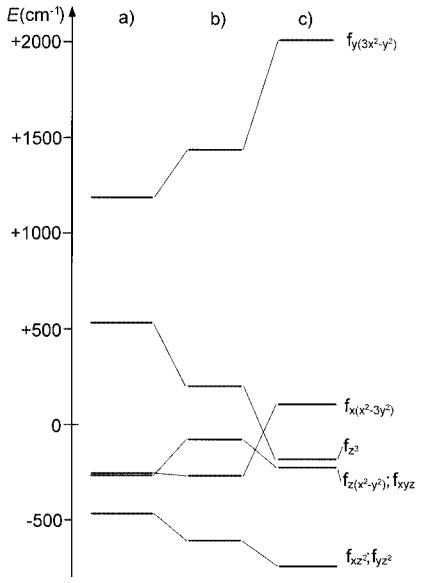

Figure 7. Experimentally based non-relativistic MO schemes of: a) $[La_{0.8}Sm_{0.2}(Cp)_3(NCCH_3)_2]$; b) $[Sm(C_5H_4tBu)_3(THF)]$; c) $[Sm(C_5H_4tBu)_3]$

To the best of our knowledge model calculations on bis adducts of the $[Ln(Cp)_3]$ moiety have not been performed, thus no calculated counterpart of the experimentally derived MO scheme of $[La_{0.8}Sm_{0.2}(Cp)_3(NCCH_3)_2]$ exists.

Going from the fictive base-free trigonal planar $[Ln(Cp)_3]$ complex via a trigonal pyramidal mono to a trigonal bipyramidal bis base adduct, the axially f_{z^3} orbital should be increasingly energetically destabilized adopting the approximation of the angular overlap model.[49] This is nicely demonstrated by the series of compounds **1**, **3** and $[La_{0.8}Sm_{0.2}(Cp)_3(NCCH_3)_2]$ (Figure 7).

Conclusion

The CF strengths of $C_5H_4tBu^-$ and Cp ligands estimated by applying method A on compound **1**, and applying method B to **2** differ by some 10%. The main reason for this discrepancy is that it is not justified to neglect the CF strength associated with the Tp^{Me_2} ligand in the case of complex **2**. This finding suggests to apply method B to other $[Sm(Cp)(L')_2]$ compounds such as $[Sm(Cp)(acac)_2]$ and $[Sm(Cp)(I)_2]$ where the CF strengths produced by the $acac^-$ and I^- ligands are probably weaker than in the case of Tp^{Me_2}.

In this work, the experimentally based MO schemes of compound **1** and the corresponding THF adduct are compared with the results of previous model calculations of different degrees of sophistication. Astonishingly, and perhaps accidentally, basic model calculations in the framework of the INDO/1 approximation on $[Pr(Cp)_3]$ and $[Pr(Cp)_3(B)]$ (B = THF, CNC_6H_{11}) would have led to correct signs but to noticeably reduced absolute values of the CF parameters as compared to those of the sets $[Pr(C_5H_4SiMe_3)_3]$/(**1**) and $[Pr(Cp)_3(B)]$/(**3**–**5**) (B = THF, CNC_6H_{11}).

Besides, applying the relativistic DV/Xα approximation to fictive ψ trigonal planar $[Ce(Cp)_3]$ a sequence of CF levels was calculated which is in agreement with the experimentally based relativistic MO scheme of complex **1**. However, this approximation seriously overestimated mainly the spin-orbit coupling parameter.

It seems that the present approximations of quantum chemistry have to be refined somewhat until they are really helpful for interpreting optical spectra of f element organyls.

Experimental Section

Compounds **1, 2**, **4** and **5** as well as the "optical empty" reference compounds $[La(C_5H_4SiMe_3)_3]$ and $[La(C_5H_4tBu)_3(THF)]$ were synthesized by adopting the procedures of Wayda,[21] Lopes et al.,[32] Birmingham et al.,[70] Fischer et al.[71] and Stults et al.[72] The absorption spectra of compounds **1** and **2** were recorded by means of KBr pellets, and those of adducts **3** and **4** (dissolved in a mixture of MeTHF/THF in the ratio 3:1) as well as those of complex **5** (dissolved in a mixture of methylcyclohexane/toluene in the ratio 3:1) as glassy frozen solutions, making use of a Cary 5e instrument. The luminescence spectra of compounds **1, 2**, **4** and **5** were run as powders (and that of **1** additionally as methylcyclohexane solution) by means of a Raman spectrometer (Jobin–Yvon, model U 1000) equipped with an Ar^+ laser (Coherent model Innova 70). In all optical low temperature measurements the samples were immersed in liquid nitrogen. Using liquid He as coolant didn't change the appearance of the spectra but worsened the signal-to-noise ratio.

The room temperature absorption spectrum of complex **1** dissolved in a mixture of glassy freezing 2-MeTHF and THF in the ratio 3:1 was identical with the data recorded by means of a KBr pellet of **1**. At 77 K, however, the absorption spectrum resembled those of $[Sm(Cp)_3(B)]$ (B = THF, $NCCH_3$, CNC_6H_{11}), thus we assume that the mono THF adduct of complex **1** (i.e. **3**) is formed quantitatively.

In order to confirm the results of the fit of compound **2**, we calculated the temperature dependence of μ^2_{eff} of this complex on the basis of calculated wavefunctions and eigenvalues, and planned to compare these data with the corresponding experimental values.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Unfortunately, compound **2** lost weight in the framework of the susceptibility measurements,[73] thus leading to less reliable experimental μ^2_{eff} values. Nevertheless, the calculated temperature dependence of μ^2_{eff} in the range $77\ K < T < 280\ K$ was within the experimental array of curves.

Acknowledgments

H.-D. A. acknowledges D. Powietzka (ITC, Forschungszentrum Karlsruhe) for the efforts to record the temperature dependence of the paramagnetic susceptibility of $[Sm(Cp)(Tp^{Me_2})_2]$, Dr. B. Nissen-Sobocinska as well as Dr. J. Ren for communicating the results of their quantum chemical model calculations. Besides, the generous financial support of the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie (H.-D. A.) as well as the NATO (N. M.) is gratefully acknowledged.

Synthesis, Spectroscopy, and Magnetic Properties of Fe^{II} and Co^{II} Quinoline-2-carboxylates − Crystal Structure of *trans*-Bis(quinoline-2-carboxylato)bis(propanol)iron(II)

Danuta Dobrzyńska,*[a] Marek Duczmal,[a] Lucjan B. Jerzykiewicz,[b] Jolanta Warchulska,[c] and Krzysztof Drabent[b]

Keywords: Vibrational spectroscopy / Magnetic properties / Iron / Cobalt / Quinoline-2-carboxylates

The new coordination compounds, $[Fe(quin\text{-}2\text{-}c)_2(EtOH)_2]$ (**1**), $[Co(quin\text{-}2\text{-}c)_2(EtOH)_2]$ (**2**), and $[Fe(quin\text{-}2\text{-}c)_2(PrOH)_2]$ (**3**) (where quin-2-c = quinoline-2-carboxylate) have been synthesized and investigated by ligand field, IR, Raman, and Mössbauer spectroscopy and by magnetic measurements. The X-ray analysis of the structure of **3** has been performed and refined to an *R* factor of 0.0377. The compound crystallizes in the monoclinic space group $P2_1/n$ with a = 6.104(1), b = 10.515(2), c = 19.339(4) Å, β = 92.57(3)°. The *trans* N_2O_4 environment around the Fe^{II} ion has a distorted octahedral geometry and the quin-2-c ion coordinates to iron in the equatorial plane in a chelating mode. The axial positions are occupied by propan-1-ol molecules. The spectral studies indicate the same molecular structure for all three compounds. The magnetic susceptibility and the magnetization of **2** were calculated for Co^{2+} ions in an octahedral crystal field with a rhombic zero field distortion ($|D|$ = 34 cm^{-1}, $E \approx 0$, g_{iso} = 2.35 and $N = 6.9 \cdot 10^{-4}$ emu·mol^{-1}).
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Carboxylate ligands are ubiquitous in biological materials and common in systems of catalytic utility. The carboxylate group offers a variety of coordination modes and many types of complexes are known.[1] Many of them, with interesting magnetic properties, have been obtained and characterized.[2]

Quinoline-2-carboxylic acid is a strong chelating agent and has been used as a reagent for the gravimetric determination of copper, cadmium, zinc and palladium.[3,4] In complexes with Rh^{I},[5−8] Rh^{III},[9] Mn^{II},[10,11] Cu^{II},[12] Ga^{III},[13] and Zn^{II}.[14] X-ray studies have revealed an N,O coordination mode of the quinoline-2-carboxylate ion. In chlorotriphenyl(quinolinium-2-carboxylato-*O*)tin(IV) monohydrate a quinoline-2-carboxylic acid binds to tin in its zwitterionic form.[15] The neutral acid molecule is demonstrated in the structure of bis(quinoline-2-carboxylic acid)tetrabromogold(III) monohydrate.[16] In the $Nd_2L_6{\cdot}3H_2O$ dimer, the coordinated quinoline-2-carboxylate ions display three modes of bonding: a bidentate carboxylate bridge, an O,O and an N,O chelating mode.[17]

It is interesting that the carboxylate group in the position *ortho* to the quinoline nitrogen, present in quin-2-c, is essential for binding Ca^{2+} and Fe^{2+} in PQQ (pyrroloquinilnequinone) which is involved as co-factor in enzymes of the quinoprotein group.[18]

In this paper, we describe the synthesis, spectroscopic and magnetic studies of low molecular weight, neutral complexes of iron(II) and cobalt(II) with the quionoline-2-carboxylate ion. The crystal structure of the ferrous compound is also presented.

Results and Discussion

Description of the Structure

The molecular geometry of $[Fe(quin\text{-}2\text{-}c)_2(PrOH)_2]$ (**3**) is shown in Figure 1, and Figure 2 (a) shows the crystal packing. Table 1 lists selected bond lengths and angles.

In the molecule of **3**, the iron(II) is six-coordinate with an O_4N_2 donor set. The coordination sphere can be described as distorted ocahedral. Two quin-2-c ligands coordinate to iron in the O,N chelating mode in the equatorial plane. The axial positions are occupied by the propanol molecules. The complex has an inversion center at the Fe^{II} ion. The Fe−O(1) bond length of 2.033(2) Å is short in comparison with the data found for iron(II) dipicolinates,[19−21] picolin-

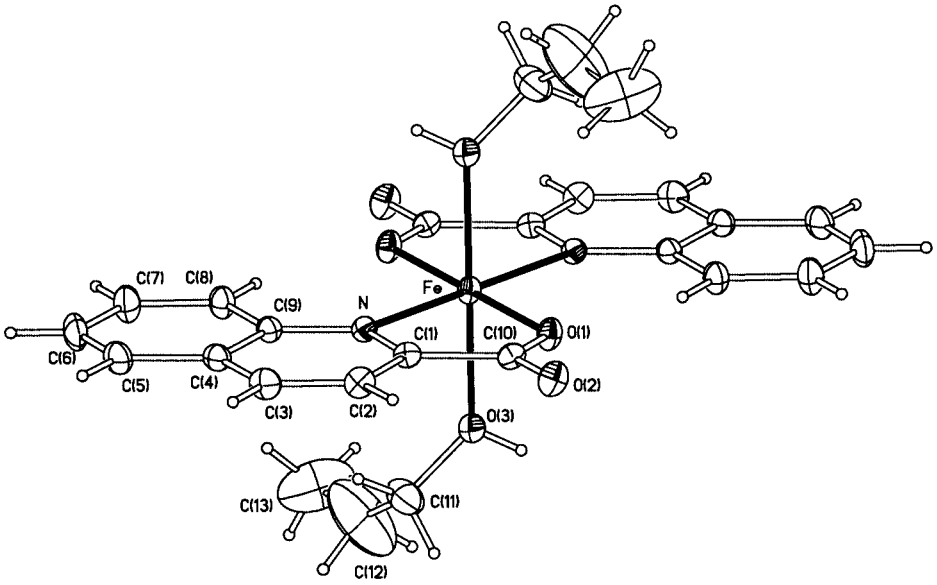

Figure 1. The molecular structure of $[Fe(quin\text{-}2\text{-}c)_2(PrOH)_2]$ with atom numbering scheme; the displacement ellipsoids are drawn at the 50% probability level

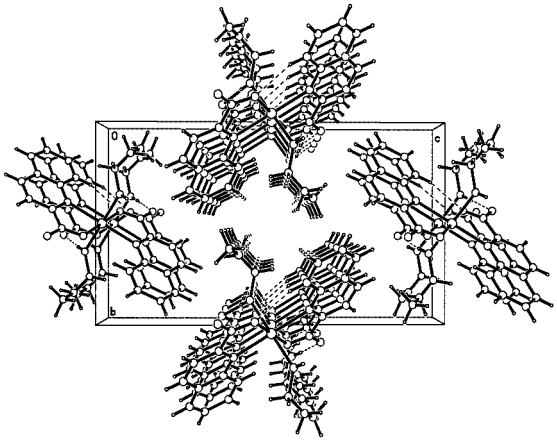
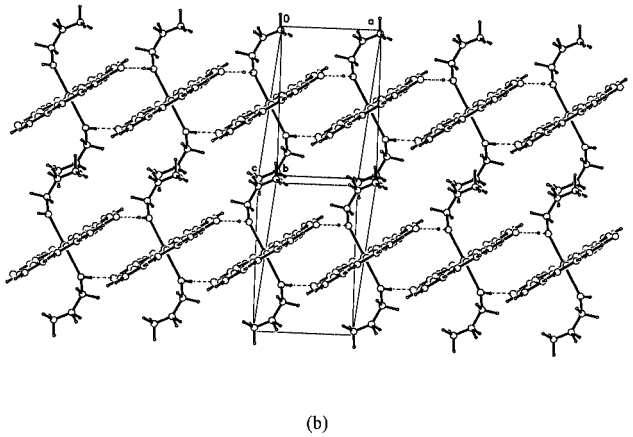


(a)



(b)

Figure 2. (a) The crystal packing of **3** viewed down the *a* axis; (b) the 1D-chains of $[Fe(quin\text{-}2\text{-}c)_2(PrOH)_2]$ molecules connected through the $O(2)^{ii}\cdots H(3O)-O(3)$ hydrogen bonds (indicated by the dashed lines)

ates,[22] and *bis*(isonicotinato)iron(II),[23] which cover the range 2.05(1)−2.37(1) Å. The Fe−N distance of 2.246(2) Å is similar to those found in ferrous dipicolinates[21] and picolinates[22] and is characteristic of high-spin Fe^{II} complexes.[24] The Fe−O(3) bond length is 2.170(3) Å. This distance is slightly shorter than the Fe^{II}−O(H)Me bond in iron(II) alkoxide cubes [2.24(2) and 2.208(2) Å][25] and in $[Fe(Pic)_2(MeOH)_2]$ [2.208(1) Å].[22]

The quinoline rings are coplanar with the equatorial chelate rings. This plane of the complex is stabilized by the weak C−H···O type intramolecular interaction [the $C(8)\cdots O(1)^{i}$ distance is 3.179(4) Å, the $C(8)-H(8)\cdots O(1)^{i}$ angle is 154(1)°, i = $-x$, $-y$, $-z$ + 1, Table 2]. Each carbonyl oxygen of the carboxylate group acts as an acceptor, resulting in a strong hydrogen bond with the hydroxyl group of the coordinated propanol molecule of an adjacent complex [the $O(2)^{ii}\cdots O(3)$ distance is 2.659(4) Å, the $O(2)^{ii}\cdots H(3O)-O(3)$ angle is 177(5)°, ii = $-x$ + 1, $-y$, $-z$ + 1]. This intermolecular interaction links the molecules into an infinite 1D-chain along the *a* axis (Figure 2, b). The Fe···Fe distance in the chain is 6.104(1) Å. In the crystal, interactions occur between the aromatic rings of the quinoline units (3.5 Å separation in stack).

Vibrational Spectra

The bands observed in the IR spectra of $[Fe(quin\text{-}2\text{-}c)_2(EtOH)_2]$ (**1**), $[Co(quin\text{-}2\text{-}c)_2(EtOH)_2]$ (**2**), and $[Fe(quin\text{-}2\text{-}c)_2(PrOH)_2]$ (**3**) and in the Raman spectrum of **2** as well as tentative assignments of these bands are given in Table 3. The IR spectra of $[Fe(quin\text{-}2\text{-}c)_2(EtOH)_2]$ and $[Co(quin\text{-}2\text{-}c)_2(EtOH)_2]$ are very similar in terms of the frequency, intensity and shape of the bands over the whole frequency region. The spectra are dominated by strong bands resulting from quinoline-2-carboxylate oscillations, but sev-

eral bands characteristic of vibrations due to ethanol are also observed. Differences between these two spectra are observed in the low frequency region and are related to the bands generated by the vibrations of metal−ligand bonds.

The IR spectrum of $[Fe(quin\text{-}2\text{-}c)_2(PrOH)_2]$ is in very good agreement with the spectrum of $[Fe(quin\text{-}2\text{-}c)_2(EtOH)_2]$ in terms of the bands resulting from vibrations of the quin-2-c ion and vibrations of the coordination bonds. In particular, the bands found in the regions 1630−1150 cm^{-1} and 900−750 cm^{-1} have the same positions, intensities and shapes. The bands related to the propan-1-ol vibrations are easily found in the spectrum of **3** (Table 3).

The features which make the spectra of **1** and **2** distinct from that of **3**, apart from the previously mentioned alcohol and coordination modes, are two weak and broad bands observed near 3400 cm^{-1} and 700 cm^{-1} seen only for the ethanolic adducts. We have attributed these bands to the vibrations of trace amounts of water, $\nu(H_2O)$ and $\rho_w(H_2O)$, respectively. The positions and shapes of these bands are characteristic of coordinated water molecules.[26,27] The lower quality crystals of **1** and **2** compared with those of **3** may result from disorder in the crystals caused by the trace amounts of water. The absence of the above mentioned bands near 3400 cm^{-1} and 700 cm^{-1} in the IR spectrum of the propanol adduct **3**, the structure of which is presented here, supports our assignment.

The bands generated by the ν(OH) vibrations of alcohols are expected over a wide frequency range (3400−2500 cm^{-1}) with the frequencies considerably dependent on hydrogen bonding.[28] In the crystal of **3** the hydroxyl group of the coordinated propan-1-ol molecule forms a strong hydrogen bond with the carbonyl oxygen atom from the carboxylate group of neighbouring molecule. On this basis we have assigned the vibrations of the hydrogen bond in **3** to the medium bands observed at 2686 and 2574 cm^{-1} in its IR spectrum. The hydrogen bonding modes may also contribute to the group of strong and closely spaced bands at higher frequencies (3200−2800 cm^{-1}), but as a result of overlapping with the $\nu(C-H)_{aliph}$ and $\nu(C-H)_{arom}$ absorptions, their frequencies cannot be resolved. In the spectra of **1** and **2,** in the region 2750−2500 cm^{-1}, two doublets can be observed repeating the intensity pattern seen in the spectrum of **3** (see Table 2). These can be attributed to hydrogen bonding involving the OH group from the ethanol molecule.

The characteristic bands due to the vibrations of alcohols [with exception of the ν(OH) mode] are observed in the regions of 3100−2800 cm^{-1} [$\nu(CH_3)$ and $\nu(CH_2)$] 1100−900 cm^{-1} [ν(CO) and CH_3, CH_2 deformations] and 500−400 cm^{-1} (deformations of the C−C−O fragment) in the IR spectra of all complexes.

Inspection of the IR region 1630−1300 cm^{-1} indicates that the carboxylate group coordination mode is the same for all complexes. The values of $\Delta\nu(CO_2) = \nu_{as}(CO_2) - \nu_s(CO_2)$ are equal to 232, 225, and 234 cm^{-1} for **1**, **2**, and **3**, respectively, and indicate that the carboxylate group binds in a monodentate fashion.[29]

The energies of the stretching vibrations of the iron(II)-aromatic nitrogen are indicative of the spin state of the ferrous ion. The ν(Fe−N) vibrations can be observed in the range 250−220 cm^{-1} for high-spin and 530−370 cm^{-1} for low spin complexes.[30,31] In the IR spectra of **1** and **3** the ν(Fe−N) mode generates the bands located at 239 cm^{-1} and 238 cm^{-1}, respectively. The positions of the bands due to the metal-oxygen bond vibrations according to Nakamoto[27] are listed in the Table 3.

Comparison of the IR and Raman spectra of **1** and **2** with that of **3** leads to the conclusion that the molecular structures of the three complexes are very similar. Two quin-2-c ions occupy the equatorial positions and coordinate to the metal in a chelating mode via the carboxylate group and the aromatic nitrogen atom. The axial positions are occupied by two propan-1-ol molecules in **3** and by molecules of ethanol and trace amounts of water in **1** and **2**.

Electronic Spectra and Magnetic Properties

The maximum observed in the ligand field spectrum of $[Fe(quin\text{-}2\text{-}c)_2(EtOH)_2]$ at $9.5\cdot10^3$ cm^{-1} is characteristic of high spin iron(II) octahedral complexes.[32] This absorption can be attributed to the spin allowed $^5E_g \leftarrow {}^5T_{2g}(D)$ transition. A strong band, centered at $18.0\cdot10^3$ cm^{-1}, arises from an iron→ligand CT absorption. The ligand field absorption bands in the cobalt complex are found at about 8.41, 18.6, 20.9, and $22.3\cdot10^3$ cm^{-1}. These bands are commonly observed for six coordinate high-spin Co^{II} complexes.[32]

The structure of the framework of magnetic ions in $[Fe(quin\text{-}2\text{-}c)_2(PrOH)_2]$ consists of linear chains of Fe^{2+} ions along the *a* axis [Figure 2 (b)]. The M−M distance of 6.104(1) Å is rather long, precluding any direct magnetic exchange interactions. However the strong hydrogen bonds between the molecules in the chain [O(3)−H(3O)···O(2)^{ii}] make indirect interactions possible. The distance between the neighbouring chains is larger than 10 Å and the spatial arrangement of the ligands seems to rule out an effective pathway for inter-chain magnetic exchange.

The magnetic susceptibilities of $[Fe(quin-2\text{-}c)_2(EtOH)_2]$ and $[Fe(quin\text{-}2\text{-}c)_2(PrOH)_2]$ obey the Curie−Weiss law above ca. 50 K with the positive Weiss constants (+2.6 K and +7.0 K for **1** and **3**, respectively) and large magnetic moments (5.22 μ_B and 5.22 μ_B, calculated from the Curie−Weiss formula) characteristic of high-spin iron(II) complexes [Figure 3 shows the results for $[Fe(quin\text{-}2\text{-}c)_2(PrOH)_2]$. The results for $[Fe(quin\text{-}2\text{-}c)_2(EtOH)_2]$ are quite similar].

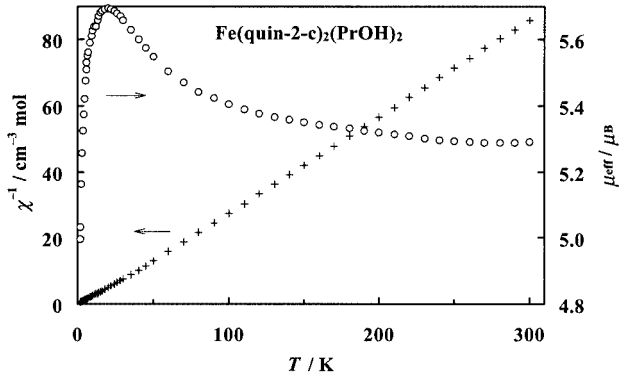

Figure 3. Temperature dependence of reciprocal susceptibility (+) and the effective magnetic moment (o) for the polycrystalline sample of $[Fe(quin\text{-}2\text{-}c)_2(PrOH)_2]$ (H = 5000 Oe)

The effective magnetic moments of the iron compounds increase with desreasing temperature, reach broad maxima at 23 K (**1**) and 20 K (**3**), then decreases quickly below T_{max}. Such behaviour is characteristic of complexes with ferro- or ferrimagnetic exchange interactions.[33] The field dependence of the magnetizations is also interesting (Figure 4). Both compounds show hysteresis at 1.9 K with the zero magnetic remanence. Similar curves have been observed for metamagnetic compounds, for example $Fe(N_2H_5)_2(SO_4)_2$.[34]

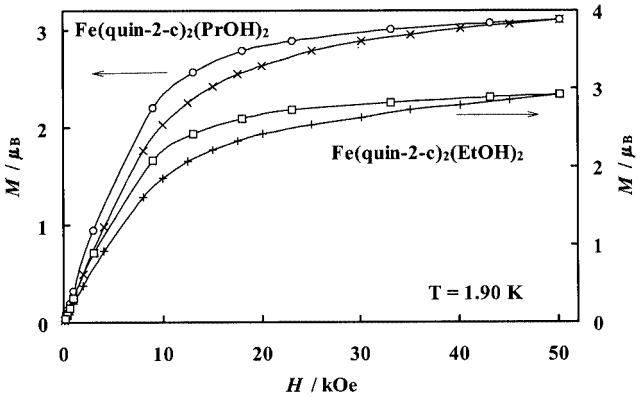

Figure 4. Field dependence of magnetization at 1.90 K for $[Fe(quin\text{-}2\text{-}c)_2(PrOH)_2]$ and $[Fe(quin\text{-}2\text{-}c)_2(EtOH)_2]$; crosses − increasing field, circles and squares − decreasing field

The magnetic properties of the iron complexes do not have a satisfactory explanation. A long-range order, which may be considered as an explanation of the behaviour of isothermal magnetization (Figure 4), is not possible in a pure one-dimensional network. However, it is not easy to see any obvious pathway for the interchain magnetic exchange. A more detailed analysis of the magnetic data is beyond the scope of this article and will be presented elsewhere.

The magnetic properties of the cobalt compound are different from those of the iron complexes. The properties of $[Co(quin\text{-}2\text{-}c)_2(EtOH)_2]$ are rather typical. The magnetic susceptibility obeys the Curie−Weiss law down to about 30 K (Figure 5). The parameters of the C−W equation depend on the Van Vleck temperature-independent paramagnetism ($N\alpha$), which is usually strong for high-spin Co^{2+} compounds.[35,36] If we assume $N\alpha = 6.9\cdot10^{-4}$ emu mol^{-1}, obtained from the fitting of the calculated and the experimental μ_{eff} (see below), the values μ = 4.57 μ_B and θ = −3.0 K are obtained (μ = 4.84 μ_B and θ = −15.6 K are found for the uncorrected susceptibility). The effective magnetic moment decreases monotonically between room temperature and 1.9 K, changing from 4.75 to 3.62 μ_B. The field dependence of magnetization shows no hysteresis and the

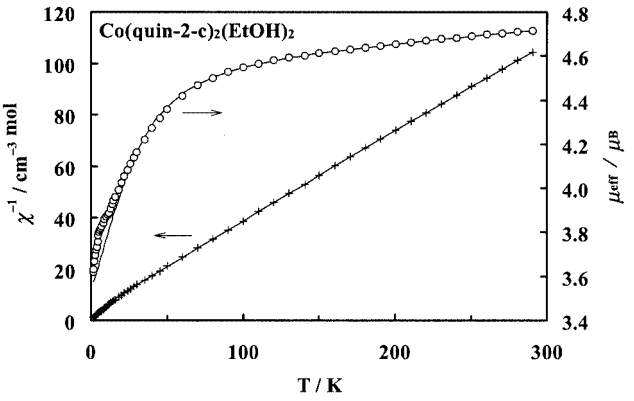

Figure 5. Temperature dependence of reciprocal susceptibility (+) and the effective magnetic moment (o) for the polycrystalline sample of $[Co(quin\text{-}2\text{-}c)_2(EtOH)_2]$ (H = 5000 Oe); the lines were calculated for S = 3/2 with the ZFS parameter $|D|$ = 34 cm^{-1}, g = 2.35 and $N\alpha = 6.9\cdot10^{-4}$ $cm^3\cdot mol^{-1}$

magnetization is almost saturated at 1.9 K in a field of 50 kOe, reaching a value of 2.2 μ_B (Figure 6).

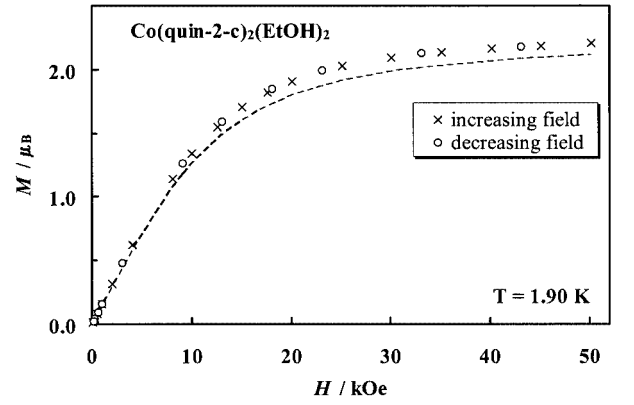

Figure 6. Field dependence of magnetization at 1.90 K for $[Co(quin\text{-}2\text{-}c)_2(EtOH)_2]$; the dashed line represents the ZFS magnetization with $|D|$ = 34 cm^{-1}, $E \approx 0$, $g_z = g_x = g_y$ = 2.35 and the Van Vleck contribution $N\alpha = 6.9\cdot10^{-4}$ $cm^3\cdot mol^{-1}$

In contrast to the iron compounds, magnetic exchange interactions are not well pronounced in the experimental results for $[Co(quin\text{-}2\text{-}c)_2(EtOH)_2]$. We therefore tried to apply the model of isolated Co^{2+} ions in the octahedral crystal field deformed by the rhombic zero field distortion. Taking into account only the second-order crystal field parameters, the spin Hamiltonian can be written as [Equation(1)], where S = 3/2.

$$H = g_z\cdot\beta\cdot H\cdot S_z + D\cdot[S_z^2 - 1/3\cdot S\cdot(S+1)] + E\cdot(S_x^2 - S_y^2) \quad (1)$$

The appropriate matrix elements and the relations between the parameters of the Hamiltonians with the different field directions were given by Abragam and Bleaney.[37] The least-squares refinement of the temperature dependence of μ_{eff} yielded $|D|$ = 34 cm^{-1}, $E \approx 0$, $g_z = g_x = g_y$ = 2.35 and the Van Vleck contribution $N\alpha = 6.9\cdot10^{-4}$ $emu\cdot mol^{-1}$. The calculated curve fits the experimental points well at higher temperatures. Below 30 K the calculated points deviate slightly from the experimental ones (Figure 5).

Moreover, the field dependence of magnetization is fairly well described by this set of parameters (Figure 6). There are at least two possible reasons of the low-temperature discrepancies: neglecting the fourth-order crystal-field parameters[38,39] and the appearance of weak magnetic exchange effects in the lowest temperature range. The large value of the axial ZFS parameter D is not unusual for Co^{2+} complexes. For example, in $Cd_2P_2S_6:Co^{2+}$ with trigonally distorted CoS_6 octahedra D = 63 cm^{-1} and it reaches a value of 84 cm^{-1} for the more covalent $Cd_2P_2Se_6:Co^{2+}$.[40,41]

The Mössbauer spectrum of $[Fe(quin\text{-}2\text{-}c)_2(EtOH)_2]$ recorded at 293 K consists of an unsymmetrical quadrupole split doublet, Figure 7.

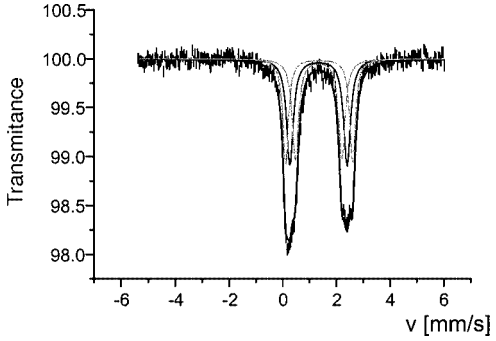

Figure 7. Room temperature Mössbauer spectrum of $[Fe(quin\text{-}2\text{-}c)_2(EtOH)_2]$

The observed asymmetry of the Mössbauer doublet cannot be attributed to the metal−metal interaction because the magnetic susceptibility data indicate that the ferrous ions are isolated. However the crystal structure of **1** is not known, although we can expect that the Fe−Fe distance in **1** is similar to that found in **3** [6.104(1) Å]. According to the least squares fitting with Lorenz curves, the Mössbauer spectrum of $[Fe(quin\text{-}2\text{-}c)_2(EtOH)_2]$ was resolved into three quadrupole doublets with *IS*, *QS*, and Γ parameters (Table 4) being very close to each other. This indicates that in the studied sample, three complexes of Fe^{II} are present having the same donor set and the same geometry. The parameters of the three components of the quadrupole split doublet are characteristic of high-spin iron(II) in an N_2O_4 octahedral environment.[18,19−21,23] The results of the Mössbauer study are consistent with the IR data and demonstrate that three compounds appear in the crystal of **1**, namely $[Fe(quin\text{-}2\text{-})_2(EtOH)_2]$, $[Fe(quin\text{-}2\text{-}c)_2(H_2O)_2]$, and $[Fe(quin\text{-}2\text{-}c)_2(EtOH)(H_2O)]$.

Experimental Section

Safety Note: Perchlorates are potentially explosive. Although we have experienced no accidents so far, all compounds containing perchlorate should be handled with care and in small quantities.

***trans*-Bis(quinoline-2-carboxylato)bis(ethanol)iron(II) (1):** A solution of $Fe(ClO_4)_2 \cdot 6H_2O$ (0.100 g; 0.275 mmol) in ethanol (50 cm^3) was added to a solution of quinoline-2-carboxylic acid (0.095 g, 0.55 mmol) in ethanol (100 cm^3) at room temperature under aerobic conditions. The resultant deep red solution was allowed to stand for two days. During this period crystals of [Fe(quin-2-c)$_2$(EtOH)$_2$] appeared. The dark violet crystals were filtered, washed with ethanol and left to dry in air. Attempts to obtain X-ray quality crystals of this compound were unsuccessful. $C_{24}H_{24}FeN_2O_6$: calcd. C 58.55, H 4.89, N 5.69, Fe 11.34; found C 58.74, H 5.04, N 5.80, Fe 11.03.

***trans*-Bis(quinoline-2-carboxylato)bis(ethanol)cobalt(II) (2):** [Co(quin-2-c)$_2$(EtOH)$_2$] was obtained by a modification of the method reported for Co(quin-2-c)$_2 \cdot 1/2H_2O$.[13] A solution of $CoCl_2 \cdot 6H_2O$ (0.065 g, 0.275 mmol) in ethanol (50 cm^3) was added to a solution of quinoline-2-carboxylic acid (0.095 g, 0.55 mmol) in ethanol (100 cm^3) at room temperature. After two days pink-yellow crystals appeared. The crystals were filtered, washed with water and left to dry in air. Attempts to obtain X-ray quality crystals of this compound were unsuccessful. $C_{24}H_{24}CoN_2O_6$: calcd. C 58.19, H 4.88, N 5.65, Co 11.90; found C 58.01, H 5.20, N 5.65, Co 11.44.

***trans*-Bis(quinoline-2-carboxylato)bis(propanol)iron(II) (3):** A solution of $Fe(ClO_4)_2 \cdot 6H_2O$ (0.100 g; 0.275 mmol) in propanol (50 cm^3) was added to a solution of quinoline-2-carboxylic acid (0.095 g, 0.55 mmol) in propanol (100 cm^3) at room temperature under aerobic conditions. The resultant deep red solution was allowed to stand for two days. During this period crystals of [Fe(quin-2-c)$_2$(PrOH)$_2$] appeared. The dark violet, X-ray quality crystals were filtered, washed with propanol and left to dry in air. $C_{26}H_{28}FeN_2O_6$: calcd. C 60.01, H 5.42, N 5.38, Fe 10.73; found C 60.49, H 5.22, N 5.68, Fe 11.01.

Physical Measurements

Elemental Analyses were performed in the Analytical Laboratory, Department of Chemistry, Wrocław University of Technology.

Magnetic susceptibility down to 1.9 K and magnetization up to 50 kOe were measured with a Quantum Design SQUID magnetometer. Diamagnetic corrections were calculated using Pascal's constants[42] and were found to be $-283 \cdot 10^{-6}$ emu·mol^{-1}, $-282 \cdot 10^{-6}$ emu·mol^{-1}, and $-306 \cdot 10^{-6}$ emu·mol^{-1} for **1**, **2**, and **3**, respectively.

IR spectra were recorded in KBr pellets or nujol mulls using Perkin−Elmer FTIR-2000 and Perkin−Elmer FTIR-1600 spectrophotometers in the frequency range 50−4000 cm^{-1}. The Raman spectra of solid samples were recorded in the range 0−3600 cm^{-1} with a Bruker FIS-88 TRA-10G-Raman instrument. The excitation was provided by a diode pumped neodymium laser at 1064 nm (150 mV Nd:YAG).

Solid state UV/Vis spectra of the powdered samples were measured in the diffuse reflectance mode on a Carry 500 Scan (Varian) UV/Vis/NIR spectrophotometer.

The Mössbauer spectra of a powdered sample of [Fe(quin-2-c)$_2$(EtOH)$_2$] were recorded on a Mössbauer 2330 spectrophotometer (Polon, Poland). The isomer shift values were referenced to a sodium nitroprusside (SNP) standard. ^{57}Co in the Rh matrix of 10 mCi activity was used as the source. The spectra were processed numerically by distribution into Lorenz curves.

X-ray crystallographic Study: Crystal data collection and refinement are summarized in Table 5. Preliminary examination and intensity data collections were carried out on a KUMA KM-4 κ-axis diffractometer with graphite-monochromated Mo-K_α radiation. All data were corrected for Lorentz and polarization effects. Data reduction and analysis were carried out with the Kuma Diffraction programs.[43] The structures were solved by direct methods[44] and refined by the full-matrix least-squares method on all F^2 data using the SHELXL-97 software.[45] After refinement with isotropic displacement parameters for all atoms, an absorption correction was also applied. Carbon-bonded hydrogen atoms were included in calculated positions and refined in the riding mode using the SHELXL-97 default parameters. Other hydrogen atoms were located in a difference map and refined freely. All non-hydrogen atoms were refined with anisotropic displacement parameters.

CCDC-210965 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge

Study of the Reaction of Tridentate Ligands with Ferrocenyl Boronic Acid

Victor Barba,*[a] Rubí Xochipa,[b] Rosa Santillan,[b] and Norberto Farfán[b]

Keywords: Cyclizations / Boron / Tridentate ligands / Ferrocene

Evaluation of the reactivity of eight tridentate ligands derived from amino alcohols and salicylaldehyde, 2-hydroxyacetophenone, or 2-hydroxybenzophenone with ferrocenyl boronic acid has shown that the reaction leads to both monomeric and dimeric ferrocenyl boronates. A coordinative N–B bond is essential to give the tetrahedral boron atoms that are responsible for the formation of heterobicyclic structures containing six, seven and ten members. The purity and identity of all compounds were unequivocally established by analytical and multinuclear (^{1}H, ^{11}B, ^{13}C) magnetic resonance spectroscopic data. Furthermore, the structures of the dimeric (**2a**) and monomeric (**5b**) boron complexes were established by X-ray diffraction analyses. The dimeric compound contains a ten-membered ring in a *boat–chair–boat* conformation, while the monomeric compound has a seven-membered ring with a *chair* conformation.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The synthesis and study of ferrocenyl boron derivatives has generated considerable interest due to their interesting properties and potential applications.[1−6] The boryl group attached to the Cp fragment exerts an interesting influence, attributed to $p_\pi-p_\pi$ interactions between the cyclopentadienyl system and the boron p_z orbital. Additionally, the through-space Fe−B interaction seen in (dibromoboryl)ferrocenes and (bispentafluorophenyl)boryl ferrocenes is favored because the occupied d orbitals on the iron center have the appropriate symmetry to interact with the empty p orbital of the boron center.[6b,7] Borylated ferrocenes are isoelectronic with stable ferrocenyl carbocations.[7,8] Due to possible applications of their unusual properties to electronic materials, boron compounds containing ferrocenyl units have recently been examined as charge-transfer complexes.[9−12]

Moreover, boronic acids are potentially useful for selective recognition of sugars as they can form strong boronic acid−diol interactions.[10,13,14] In addition, the complexation of boronic acids with sugars affords a fluorescence intensity that is affected by complexation.[15] Ferrocenyl boronic acid derivatives have also been used in the electrochemical detection of saccharides[13,14] and the selective recognition of fluoride, whereby the boron atom acts as a hard acid and fluoride as the hard base.[16]

Recently, ferrocenyl boron macrocycles have been prepared by the reaction of 1,1′ diborylated ferrocene [1,1′-{C_5H_4[B(R)Br]}$_2$] with tetrafunctional Lewis bases such as 2,5-di(pyrazol-1-yl)hydroquinone and quaterpyridine.[17,18] Here, formation of the dative N−B bond facilitates cyclization leading to cyclic oligomers. However, the reaction of difunctional Lewis bases such as pyrazine or 4,4′-bipyridine with 1,1-diborylated ferrocene led to polymeric materials only.[19]

Relatively few detailed studies have been performed on the coordination chemistry of ferrocenyl boronic acid. Previously, we reported the synthesis of monomeric,[20,21] dimeric,[21,22] trimeric,[23] and tetrameric[24] boron compounds by reaction of boronic acids with Schiff bases where the formation of dative N−B bonds is very important in their cyclization.[25] Here we describe the reactivity of ferrocenyl boronic acids with different tridentate ligands using simple condensation reactions.

Results and Discussion

We have investigated the reaction of boronic acids with different ligands to establish the factors involved in the formation of macrocyclic structures. To further evaluate electronic and steric factors we selected $CpFeC_5H_4B(OH)_2$, as the ferrocenyl group is bulkier and more electrophilic than a phenyl group.[22] Thus, we discuss here the reactivity of various tridentate ligands with ferrocenyl boronic acid in order to prepare new macrocyclic boron compounds.

The reaction of tridentate ligand **1a** derived from salicylaldehyde and ethanolamine with ferrocenyl boronic acid was carried out under reflux of THF to yield, after 60 min, a red solid that is stable to air (Scheme 1). The EI mass

Scheme 1. Dimeric boron compounds from tridentate ligands

spectrum has a highest peak at m/z = 718, establishing the dimeric composition of compound **2a**.

To determine if a larger substituent could influence the imine bond and alter the course of the reaction, we prepared ligands derived from 2-hydroxyacetophenone (**1b**) and 2-hydroxybenzophenone (**1c**); however, these ligands react with ferrocenyl boronic acid to give dimeric boronates **2b** and **2c** in moderate yields (Scheme 1).

The dimeric composition of these compounds was established by spectroscopic analyses whereby the EI mass spectra have highest peaks at m/z = 746 and 870, which correspond to the molecular weight of **2b** and **2c**, respectively. In all cases, the base peak corresponds to the loss of one ferrocenyl moiety. NMR analyses of **2a** and **2c** could not be obtained due the compounds' insolubility in common solvents. In the NMR spectra of **2b** only a single set of signals is observed, owing to the C_2 fold axis present in the molecule. The ^{11}B NMR spectrum of **2b** shows a singlet at δ = 7.8 ppm, which is in the range expected for tetracoordinate boron atoms containing a dative N−B bond.[26]

The stretching band for the C=N group in the IR spectra is shifted to 1640, 1610, and 1606 cm^{-1} for **2a**, **2b**, and **2c**, respectively. The lower shift showed by **2b** and **2c** can be attributed to electronic and inductive effects of the methyl and phenyl groups present.

The crystal structure of **2a** confirms the dimeric nature of this compound (Figure 1). Crystallographic data and selected distances and bonds are listed in Tables 1 and 2, respectively. In analogy to the dimeric compounds previously described,[22,24,25] the structure has an inversion center at the center of the ten-membered ring. Ferrocenyl substituents on each boron atom are *trans* disposed with regard to the ten-membered macrocycle, which may be attributed to the bulkiness of the ferrocenyl moieties. A dative N−B bond, together with the required tetrahedral geometry of the boron atoms, is responsible for the dimeric form of these compounds.

Thus, B(1)−N(1) [1.632(5) Å] in **2a** is very similar to that of the boron-phenyl derivative [1.624(3) Å[24]] and accords with analogous systems.[27] The C(10)−B(1) [1.595(6) Å] is slightly shorter than in the phenyl derivative [1.601(3) Å] because the ferrocenyl group is a stronger electron donor than the phenyl group.

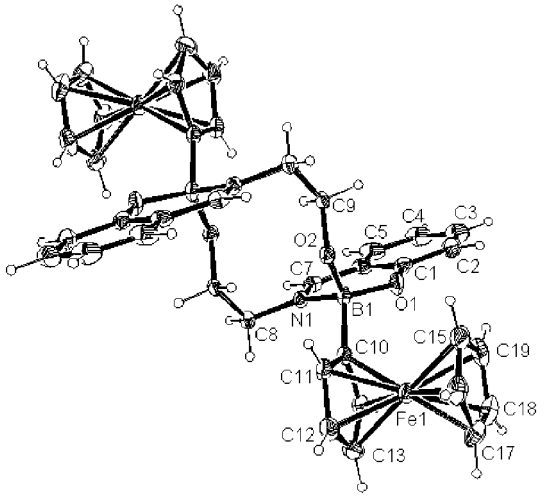

Figure 1. Molecular structure of solid-state **2a**

The tetrahedral geometry for the boron atom is evident from the bond angles, which are in the range 106.9(3)−111.5(3)°, the largest being O(1)−B(1)−C(10), which in the boron-phenyl derivative[24] is 109.4(2)°. This difference in bond angles may be attributed to the steric effect of the bulkier ferrocene unit, compared to the phenyl group. As expected, the inverse effect is observed on comparing the N(1)−(B1)−(C10) angle, which is slightly smaller [107.0(3)°] in the ferrocene derivative than in the phenyl [108.1(2)°] one.[24] The six-membered heterocycle is nearly planar, as evidenced by the O(1)−B(1)−N(1)−C(7) torsion angle (10.2°). The ten-membered heterocycle presents a *boat−chair−boat* conformation. The structure shows a relatively short transannular H···O interaction (2.47 Å) between the oxygen atom on one side of the ring with a hydrogen atom from the CH_2 group on the opposite side.

In contrast, the reaction of ligands **1d** and **1e**, obtained from salicylaldehyde and 1-aminomethylcyclohexanol, with two equivalents of ferrocenyl boronic acid provided exclusively complexes **3a** and **3b** (Scheme 2). The different reactivity, compared to **1a** and **1c** ligands, may be attributed to the cyclohexyl group at the β position relative to the nitrogen

atom in ligands **1d** and **1e**, which could cause strong intramolecular interactions upon formation of either a dimeric structure or a monomeric compound containing five- and six-membered rings. Consequently, bicyclic structures are preferred. The six- and seven-membered rings contain two boron atoms, one tetrahedral and the other tricoordinate. When only one equivalent of ferrocenyl boronic acid is used, **3a** and **3b** are also formed, but in lower yields. Attempts to form the dimeric compound from this ligand by using different reaction conditions as well as other boronic acids were unsuccessful.

Bicyclic structures for **3a** and **3b** were established by MS, where the molecular peaks appear at m/z = 639 and 653, respectively. ^{11}B NMR spectra show two signals at δ = 34.8 and 8.2 ppm for **3a** and 38.3 and 7.2 ppm for **3b**, corresponding to trigonal and tetrahedral boron atoms, respectively. ^{1}H NMR shows an AB system for the NCH_2C group, due to the formation of the seven-membered heterocycle.

We then examined the ligand containing three carbon atoms between the OH and C=N groups to evaluate the effect upon ring closure. **1f** reacted with ferrocenyl boronic acid under reflux in THF (40 min) to yield a red solid that was characterized as monomeric compound **4** (Scheme 3). In accordance with previous reports,[20,28] the six-membered ring is favored (monomer) over a twelve-membered ring (dimer) in this type of ligands. The ^{11}B NMR spectrum shows a signal significantly up-field (δ = 5.0 ppm) with respect to ferrocenyl boronic acid, due to the formation of a tetrahedral boron atom. In ^{1}H NMR, an AB system appears at δ = 4.82 and 4.89 ppm, corresponding to the CH_2 group. The iminic proton is shifted to down field (9.21 ppm) in comparison with the ligand (8.57 ppm) due to formation of the dative N−B bond. All boron compounds described herein shown diastereotopic signals for the C_5H_4 moiety attached to the boron atoms, in accordance with the literature data.[2]

We also prepared ligands **1g** and **1h** from 4-aminobutanol and salicylaldehyde or 2-hydroxyacetophenone, respectively. **1g** and **1h** reacted with ferrocenyl boronic acid to give the

Scheme 3. Monomeric boron compound from an aromatic tridentate ligand

monomeric compounds **5a** and **5b** with six- and seven-membered-rings (Scheme 4). Only a monomeric product was isolated, in contrast to using phenylboronic acid,[30] where both monomeric and dimeric compounds were isolated; a possible explanation is that the bulky ferrocenyl group prevents formation of the dimeric compound. Tetracoordination of the boron atom is evident in the ^{11}B NMR spectra, with signals at $\delta = 9.6$ ppm and 8.7 ppm for **5a** and **5b**, respectively, as a result of dative N−B bond formation.

Compound **5b** was characterized by X-ray crystal structure analysis (Figure 2). Selected bond lengths and angles are summarized in Table 2. The corresponding bond lengths and angles in the six-membered rings of **2a** and **5b** are indistinguishable within experimental error. Insignificant variations were found in the dative bond, for **5b** N−B bond is 1.641(3) Å and is very similar to **2a** [1.632(5) Å]. In **5b**, B−O is longer in the six-membered [1.481(4) Å] than in the seven-membered [1.426(4) Å] heterocycle, and the O−B−N bond angle is smaller in the six-membered [105.0(2)°] than in the seven-membered ring [107.8(2)°] as a result of the annular tension and planarity of the ring. The seven-membered ring has a chair conformation in the solid state (Figure 2).

Conclusions

Ferrocenyl boronic acid reacts with different tridentate ONO ligands to provide, in one step, novel dimeric and monomeric structures depending on the ligand used. Neither different groups in the imine position nor a bulky group such as ferrocenyl influence the formation of the structure. The new chemistry reported here may be useful in macrocyclic syntheses, and ferrocene derivatives could find interesting applications for molecular recognition. Current work in our laboratory involves the reactivity of analogous compounds.

Experimental Section

Materials and Methods: All reagents were purchased from Aldrich and were used without further purification. NMR spectra were recorded at room temperature using the following spectrometers: Jeol GSX 270, Bruker 300, and Jeol eclipse+400. Chemical shifts are given in ppm. Infrared spectra were recorded on a Perkin−Elmer 16F-PC FT-IR spectrophotometer. Mass spectra were obtained with a HP 5989-A mass spectrometer operating in electron impact mode. Melting points were determined with a Gallenkamp MFB-595 apparatus. Elemental microanalyses were performed by Oneida Research Services (Whitesboro, NY. 13492).

Crystal Structure Determination: Single Crystals of **2a** suitable for X-ray diffraction were obtained when the reaction was performed in THF at 25 °C without stirring; crystals of **5b** suitable for X-ray structure analysis were grown by slow evaporation of a THF/CH_2Cl_2 solution of the complex. Intensity data were collected at 293 K with an Enraf−Nonius CAD4 diffractometer for compound **2a** and a Bruker-AXS APEX diffractometer with a CCD area detector for **5b**; Mo-*K*α-radiation, λ = 0.71073 Å, graphite monochromator, ω = 2θ scan. Empirical absorption corrections (DIFABS) were applied. The structures were solved by direct methods (SHELXS-86)[30] and refined using SHLXS-97.[31] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in geometrically calculated positions using a riding model. Crystallographic data for the structures have been deposited at the Cambridge Crystallographic Data Center as supplementary material No. 211441 for complex **2a** and 210542 for **5b**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK. E-mail: deposit@ccdc.cam.ac.uk.

General Method for the Preparation of Tridentate Ligands 1a−1h: The ligands were obtained by condensation of an aldehyde or ketone with the corresponding amino alcohol under reflux in methanol for 45 min. The water formed and part of the solvent was removed using a Dean−Stark trap and the product was then dried under high vacuum. Ligands **1a**,[24] **1b**,[29] **1f**,[20] and **1g**[30] have been described previously.

General Syntheses for Boron Complexes: An equimolar solution of **1a−1h** and ferrocenyl boronic acid in THF (60 mL) was prepared and then boiled under reflux for 60 min (two equivalents of the boronic acid were used to prepare **3a** and **3b** complexes). Part of the solvent was then removed with a Dean−Stark trap so as to favor precipitation. The product was then filtered off and washed with small amounts of the same solvent.

Complex 2a: Compound **2a** was prepared from **1a** (0.50 g, 3.02 mmol) and ferrocenyl boronic acid (0.70 g, 3.02 mmol). A red solid was obtained, in 72% yield (0.78 g, 1.08 mmol), that is insoluble in all common solvents, m.p. 280−282 °C. IR ṽ = (KBr): 3412, 2930, 2850, 1640 (C=N), 1608, 1560, 1480, 1438, 1316, 1308, 1234, 1214, 1148, 1126, 1110, 1104, 1054, 1044, 1026, 1010, 970, 794, 752 cm^{-1}. EM (15 eV): *m*/*z* (%) = 718 (1) [M^+] 570 (2), 361 (25), 359 (100), 358 (35), 357 (10), 356 (3), 334 (4), 333 (2), 330 (2), 294 (6), 293 (6), 292 (4), 291 (8), 290 (3), 255 (3), 187 (7), 186 (51), 184 (4), 175 (7), 174 (50), 173 (20), 121 (2). $C_{38}H_{36}B_2Fe_2N_2O_4$: calcd. C 63.06, H 4.97, N 3.87; found C 63.38, H 5.33, N 3.84 (%).

Complex 2b: Compound **2b** was prepared from **1b** (0.50 g, 2.79 mmol) and ferrocenyl boronic acid (0.64 g, 2.79 mmol) as an orange solid, in 77% yield (0.80 g, 1.06 mmol) that is slightly soluble in chloroform, m.p. 204−206 °C. IR ṽ = (KBr): 2918, 2850, 1610 (C=N), 1550, 1456, 1444, 1332, 1276, 1214, 1144, 1134, 1118, 1106, 1004, 814, 758 cm^{-1}. MS (15 eV): *m*/*z* (%) = 746 (5) [M^+], 745 (2), 585 (3), 584 (1), 399 (3), 398 (2), 375 (3), 374 (18), 373 (74), 372 (20), 371 (5), 370 (2), 359 (2), 358 (9), 357 (2), 308 (2), 296 (2), 212 (1), 189 (11), 188 (100), 187 (43), 186 (75), 185 (5), 184 (4), 174 (5), 121 (2), 72 (4), 71 (5), 43 (3), 42 (11), 41 (4). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.84 (s, 3 H, Me), 4.10−3.93 (m, 4 H, 8-, 9-H), 4.22 (s, 5 H, Cp-H), 4.36 (m, 2 H, 12-, 13-H), 4.44 (m, 2 H, 11-, 14-H), 6.92 (t, *J* = 7.7 Hz, 1 H, 5-H), 7.08 (d, *J* = 7.7 Hz, 1 H, 3-H), 7.54 (t, *J* = 7.7 Hz, 1 H, 4-H), 7.76 (d, *J* = 7.7 Hz, 1 H, 6-H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 16.7 (Me), 51.1 (C-8), 61.4 (C-9), 71.9 (C-Cp), 77.2 (C-11, 14), 77.6 (C-12, 13), 118.7 (C-1, 5), 120.5 (C-3), 128.5 (C-6), 136.7 (C-4), 161.4 (C-2), 175.3 (C-7) ppm. ^{11}B NMR (96 MHz, $CDCl_3$): δ = 7.8 ppm ($h_{1/2}$ = 228 Hz). $C_{40}H_{40}B_2Fe_2N_2O_4$: calcd. C 63.91, H 5.32, N 3.72; found C 63.96, H 5.78, N 3.54 (%).

Complex 2c: 2c was prepared from **1c** (0.50 g, 2.07 mmol) and ferrocenyl boronic acid (0.48 g, 2.07 mmol). A red solid was obtained, in 83% yield (0.74 g, 0.84 mmol), that is insoluble in all common solvents, m.p. 288−298 °C. IR ṽ = (KBr): 3094, 3066, 2934, 2916, 1606 (C=N), 1548, 1474, 1456, 1444, 1338, 1214, 1148, 1118, 1112, 1102, 1026, 1012, 1002, 802, 752 cm^{-1}. MS (15 eV): *m*/*z* (%) = 870 (15) [M^+], 435 (24), 311 (17), 239 (13), 368 (20), 296 (16), 250 (100), 236 (24), 186 (21), 148 (15), 98 (27), 84 (32), 44 (79). $C_{50}H_{44}B_2Fe_2N_2O_4$: calcd. C 68.56, H 5.02, N 3.20; found C 68.89, H 5.29; N 3.20 (%).

Complex 3a: 3a was prepared from **1d** (0.30 g, 1.28 mmol) and ferrocenyl boronic acid (0.30 g, 1.28 mmol) as a red solid, in 73% yield (0.60 g, 0.93 mmol), that is slightly soluble in chloroform, m.p. 228 °C. IR ṽ = (KBr): 3504, 2928, 2850, 1638 (C=N), 1552, 1474, 1458, 1446, 1406, 1390, 1382, 1270, 1260, 1214, 1176, 1148, 766 cm^{-1}. Hydrothermal Syntheses, Crystal Structures and Photoluminescent Properties of Three Metal-Cluster Based Coordination Polymers Containing Mixed Organic Ligands

Jun Tao,*[a] Xin Yin,[a] Zan-Bin Wei,[a] Rong-Bin Huang,[a] and Lan-Sun Zheng[a]

Keywords: Coordination polymers / Zinc / Cadmium / 5-Sulfoisophthalate / 5-Nitroisophthalate

Three novel metal-cluster based coordination polymers (MCCPs) with formulae $[Zn_4(\mu_3\text{-}OH)_2(H_2O)_2(sip)_2(4,4'\text{-}bpy)_2]\cdot 3H_2O$ (MCCP-4), $[Cd_4(\mu_3\text{-}OH)_2(H_2O)_2(sip)_2(4,4'\text{-}bpy)_4]\cdot H_2O$ (MCCP-5) and $[Cd_6(\mu_3\text{-}OH)_4(\mu_2\text{-}OH_2)_2(OH_2)_2(nip)_4(4,4'\text{-}bpy)_3]\cdot 3H_2O$ (MCCP-6) [H_2sip = 5-sulfoisophthalic acid, H_2nip = 5-nitroisophthalic acid and 4,4′-bpy = 4,4′-bipyridyl] were hydrothermally synthesized and characterized by single-crystal X-ray diffraction studies. MCCP-4 crystallizes in the triclinic space group $P\bar{1}$ with a = 10.106(2), b = 10.851(2), c = 11.125(2) Å, α = 105.66(3), β = 112.63(3), γ = 98.18(3)°, V = 1041.8(4) Å^3, and Z = 2. MCCP-5 crystallizes in the monoclinic space group $C2/c$ with a = 25.602(1), b = 16.571(1), c = 13.322(1) Å, β = 92.524(1)°, V = 5646.4(2) Å^3, and Z = 4. MCCP-4 and -5 consist of similar $[M_4(\mu_3\text{-}OH)_2]^{6+}$ tetranuclear building units that are joined through sip and 4,4′-bpy ligands to generate a two-dimensional structure (MCCP-4) and a three-dimensional structure (MCCP-5), respectively. MCCP-6 crystallizes in the triclinic space group $P\bar{1}$ with a = 14.295(2), b = 14.472(2), c = 20.204(3) Å, α = 73.362(3), β = 82.200(3), γ = 62.769(2)°, V = 3560.9(10) Å^3, and Z = 2. MCCP-6 contains unprecedented $[Cd_6(\mu_3\text{-}OH)_4(\mu_2\text{-}OH_2)_2]^{8+}$ hexanuclear building units which are linked through nip and 4,4′-bpy ligands to afford a two-dimensional structure. The infrared spectroscopy, thermal stability and photoluminescence of the three complexes were studied.

Introduction

Coordination polymers have attracted considerable attention in recent years due to their interesting properties and promising applications in the areas of catalysis, gas storage, magnetism and optics.[1] Concurrent with these studies has been the development of highly ordered multi-dimensional frameworks based primarily on combining organic and inorganic units through the assembly of metal centers with di- or multitopic organic ligands.[2] To date, the structures and properties of the vast majority of reported coordination polymers have been finely tuned by closely controlling the molecular properties of the organic ligands such as size, shape, functionality, flexibility and symmetry. One current challenge involves the preparation of coordination polymers in which the inorganic components display different physical properties or have different structural influences. This goal has been recently illustrated by metal-cluster based coordination polymers (MCCPs),[3] whose dimensions, geometries and properties can be controlled by the choice of metal clusters. Metal clusters can be very versatile in terms of coordination properties and rigidity as well as displaying intriguing physical properties in comparison with mono- or dinuclear species. Thus, coordination polymers constructed with metal clusters are usually more stable and promising in terms of potential applications. At present, in addition to utilizing H_2O_2 or excess base to facilitate the formation of metal clusters,[4,5] they can also be obtained from hydrothermal reactions involving in situ hydrolysis of metal ions with or without template ligands. In our group, we have focused our attention on metal-cluster based coordination polymers (particularly of Zn^{II} and Cd^{II}) with respect to their optical properties and we have found that in the presence of mixed organic ligands, metal clusters can form under hydrothermal conditions[6] e.g., $[Zn_4O(ip)_3(4,4'\text{-}bpy)]$ (MCCP-1, where ip = isophthalate), $[Zn_4(OH)_2(fa)_3(4,4'\text{-}bpy)_2]$ (MCCP-2, where fa = fumarate), $[Zn_3(OH)_2(4,4'\text{-}bpy)_{0.5}(4,4'\text{-}oba)_2]\cdot 0.5H_2O$ [MCCP-3, where 4,4′-oba = 4,4′-oxybis(benzoate)]. Based on our experience in this area and with the long-term goal of classifying the factors affecting the formation of metal clusters and metal-cluster based coordination polymers, we have started to synthesize new coordination polymers with metal clusters.

Our previous work on $[Zn_4O(ip)_3(4,4'\text{-}bpy)]$ (MCCP-1)[6a] has led us to consider whether ligands derived from isophthalate can produce similar structures, especially the 5-substituted forms of isophthalate. We selected 5-sul-

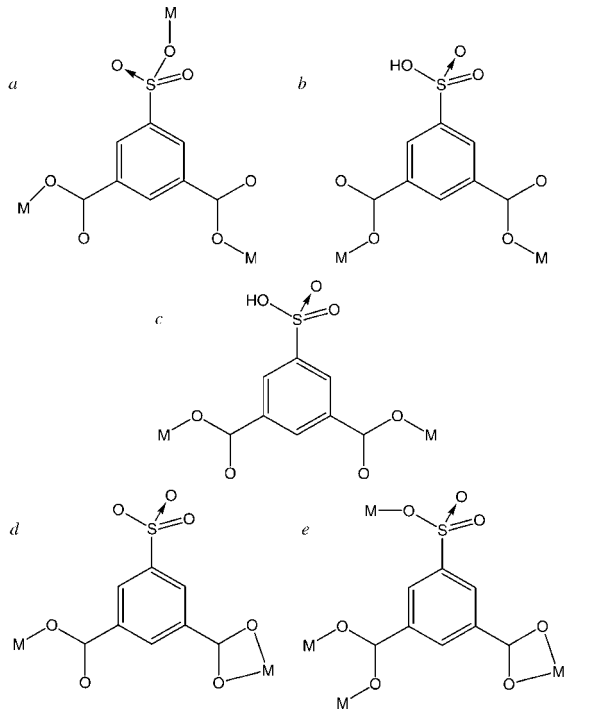
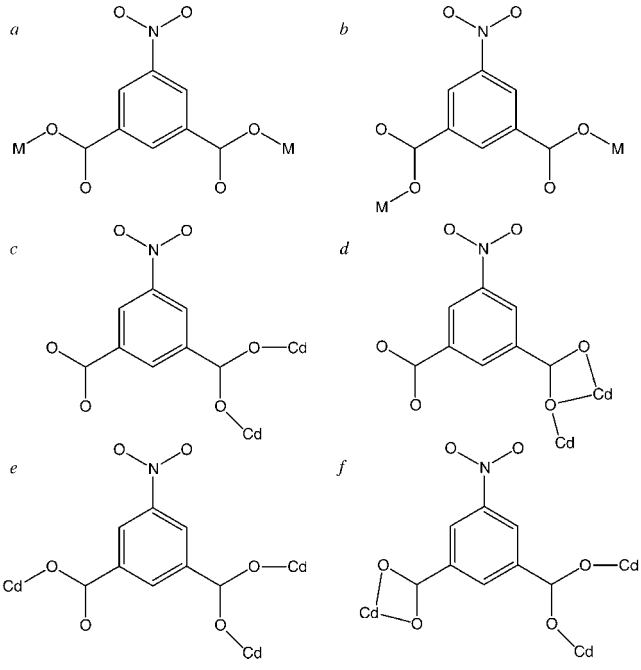
foisophthalate (sip) and 5-nitroisophthalate (nip) as ligands in which the sulfonate group shows weak coordination strength towards transition metals[7] and both sulfonate and nitro groups are suitable H-bonding acceptors.[8] As such they may be helpful for stabilizing these complexes. Herein we report three novel coordination polymers constructed from zinc and cadmium clusters and mixed organic ligands: $[Zn_4(\mu_3\text{-}OH)_2(H_2O)_2(sip)_2(4,4'\text{-}bpy)_2]\cdot 3H_2O$ (MCCP-4), $[Cd_4(\mu_3\text{-}OH)_2(H_2O)_2(sip)_2(4,4'\text{-}bpy)_4]\cdot H_2O$ (MCCP-5) and $[Cd_6(\mu_3\text{-}OH)_4(\mu_2\text{-}OH_2)_2(OH_2)_2(nip)_4(4,4'\text{-}bpy)_3]\cdot 3H_2O$ (MCCP-6).

The sip ligand was studied recently as a building block for extended frameworks. Shimizu[9] has reported a pseudo-honeycomb coordination polymer $\{[Cu_{1.5}(sip)(py)_5]\cdot(py)\cdot(H_2O)_{6.76}\}_n$, and Cao[10] reported two zeolite-like supramolecular complexes $\{[Cu(H_2O)_2(Hsip)]\cdot(H_2O)_2\cdot(pip)_{0.5}\}_n$ and $\{[Cu(H_2O)_3(Hsip)]\cdot(H_2O)_6\cdot(hmt)_{0.5}\}_n$ (pip = piperazine, hmt = hexamethylenetetramine). To date the above three Cu(sip) coordination complexes are the only transition metal sip complexes reported. In these three complexes, the sip ligands exhibit three different coordination modes, henceforth denoted as *a*-sip, *b*-sip and *c*-sip and depicted in Scheme 1. The sip ligands reported here (MCCP-4 and -5) coordinate to metal atoms in different coordination modes, namely as *d*-sip in MCCP-4 and *e*-sip in MCCP-5, respectively. With regards to the nip ligand, the only other metal-(nip) complexes which have been prepared are two Cu(nip) supramolecular isomers[11] and two Zn(nip) supramolecular structures, namely $\{[Zn(nip)(py)(H_2O)]\cdot(H_2O)\}_n$ and $\{[Zn(nip)(4,4'\text{-}bpy)_{0.5}(H_2O)_2]\cdot(H_2O)\}_n$. In the two zinc complexes that have been reported by our group,[8c,8d] the nip ligand displays two slightly different coordination modes, namely *a*-nip and *b*-nip as illustrated in Scheme 2. Interestingly, the nip ligand in MCCP-6 exhibits four different coordination modes, viz. *c*-nip, *d*-nip, *e*-nip, and *f*-nip as shown in Scheme 2.



Scheme 1. The five different coordination modes of the sip ligand in refs.[9,10] (*a*, *b*, *c*), MCCP-4 (*d*) and MCCP-5 (*e*)



Scheme 2. The six different coordination modes of the nip ligand in refs.[8c,8d,11a] (*a*, *b*) and MCCP-6 (*c*−*f*)

Results and Discussion

Syntheses and Characterization

The hydrothermal method has been proven to be very effective for the synthesis of zeolites, nanomaterials and more recently coordination polymers. It is well known that small changes in one or more of the hydrothermal parameters, such as temperature, reaction time, pH value, and molar ratios of reactants may exert a profound influence on the final reaction products. During the past few years, we have explored the synthesis of MCCPs containing mixed organic ligands under typical hydrothermal conditions (i.e., 120−180 °C for 2−7 d), and found that a pH of 7−8 and the existence of 4,4′-bpy are most suitable in forming metal clusters as well as MCCPs. These conditions have been used directly to prepare MCCP-4, -5 and -6, where it is believed that the formation of metal clusters can be attributed to the hydrolysis of metal ions in neutral systems under hydrothermal conditions.

The FT-IR spectra of MCCP-4, -5 and -6 show no bands in the region 1690−1730 cm^{-1}, indicating complete deprotonation of the carboxyl groups. The spectra exhibit broad absorption bands in the range of 3260−3570 cm^{-1} due to the ν(OH) vibrations of coordinated water molecules. The absorptions in the region 1000−1230 cm^{-1} for MCCP-4 and -5 are typical for a sulfonate group,[12] and those at

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1360−1460 cm^{-1} for MCCP-6 characterize the asymmetric and symmetric vibrations of the nitro group.[13] The strong bands at 1360−1610 cm^{-1} for all MCCPs are characteristic of a carboxylate group. In MCCP-6 these bands probably overlap partially with those of the nitro group.

The thermogravimetric analyses (TGA) of MCCP-4 and -6 showed the occurrence of three consecutive processes, namely dehydration, ligand pyrolysis (or volatilization) and inorganic residue formation. The TGA for MCCP-4 showed the complete loss of five water molecules at ca. 135 °C (found 7.61%; calcd. 8.68%). The dehydrated compound remained stable up to ca. 360 °C without any weight loss, however, MCCP-4 decomposed when heated to 140 °C at 0.05 Torr for 12 h as evidenced by the diffraction lines observed in its X-ray powder diffraction pattern (see Supporting Information) and at a temperature range of 360−580 °C the pyrolysis (or volatilization) of both sip and 4,4′-bpy ligands occurred leaving residual ZnO (remaining weight: found 26.60%; calcd. 4ZnO: $[Zn_4(\mu_3\text{-}OH)_2(H_2O)_2(sip)_2(4,4'\text{-}bpy)_2]\cdot 3H_2O$ 27.48%). The TGA for MCCP-6 showed an initial weight loss of 3.06% from 180 to 215 °C corresponding to the removal of three lattice water molecules per formula unit (calcd. 2.49%), followed by another weight loss of 60.98% from 307 °C for elimination of the nip ligands and 4,4′-bpy pillars from the framework, the remaining residue was probably $Cd(OH)_2$. (as calcd. 6$Cd(OH)_2$: $[Cd_6(\mu_3\text{-}OH)_4(\mu_2\text{-}OH_2)_2(OH_2)_2(nip)_4(4,4'\text{-}bpy)_3]\cdot 3H_2O$ 40.42%). The TGA curve of MCCP-5 was somewhat different from those of MCCP-4 and -6. MCCP-5 remained stable under nitrogen up to 186 °C before it suffered a weight loss of 22.24% of the total weight between 186 and 335 °C. This can be assigned to the evaporation of one lattice water molecule, two-coordinated water molecules and two one-end-bound 4,4′-bpy ligands per formula (calcd. 22.22%). The second distinct weight loss appeared in the temperature range 335−550 °C and was caused by the pyrolysis (or volatilization) of the sip and μ_2-4,4′-bpy ligands resulting in a residue of $Cd(OH)_2$ (found 35.81%; calcd. 35.52%).

Description of Crystal Structures

Single-crystal X-ray diffraction analysis has revealed that MCCP-4 is a 2D-framework constructed from $[Zn_4(\mu_3\text{-}OH)_2]^{6+}$ clusters and two organic ligands. The structure contains a crystallographic inversion center located at the center of the $[Zn_4(\mu_3\text{-}OH)_2]^{6+}$ cluster with the two crystallographically nonequivalent zinc atoms assuming two different coordination geometries. Zn1 is in a distorted trigonal-bipyramidal environment and is coordinated in the equatorial plane to one μ_3-OH group, one 4,4′-bpy nitrogen atom and one oxygen atom from the monodentate carboxylate group of a *d*-sip ligand (Scheme 1). In the axial positions it is also coordinated to one μ_3-OH group and one oxygen atom from the bidentate carboxylate group of another *d*-sip ligand, as shown in Figure 1. However, the Zn1···O4B distance of 2.826(2) Å suggests a nonnegligible interaction with the uncoordinated oxygen atom of the monodentate carboxylate group of a *d*-sip ligand, which may be described as a semichelating coordination mode.[14] Hence, Zn1 may also be regarded as being in a pseudooctahedral environment. Selected bond lengths and angles are given in Table 1. Zn2 is tetrahedrally surrounded by one μ_3-OH group, one bpy nitrogen atom, one water molecule and one oxygen atom from the bidentate carboxylate group of a *d*-sip ligand. The average bond lengths around Zn2 (1.976 Å) are somewhat shorter than those of Zn1 (2.077 Å) and this is consistent with the fact that bond lengths in a tetrahedral geometry are generally shorter than those in other geometries. Two pairs of symmetry-related zinc atoms are then joined by two triply bridging μ_3-OH groups to generate the basic structural building unit $[Zn_4(\mu_3\text{-}OH)_2]^{6+}$ and the Zn−O(hydroxo) distances [1.962(2)−2.172(2) Å] are in the range of those previously reported in the literature.[4,6,15]

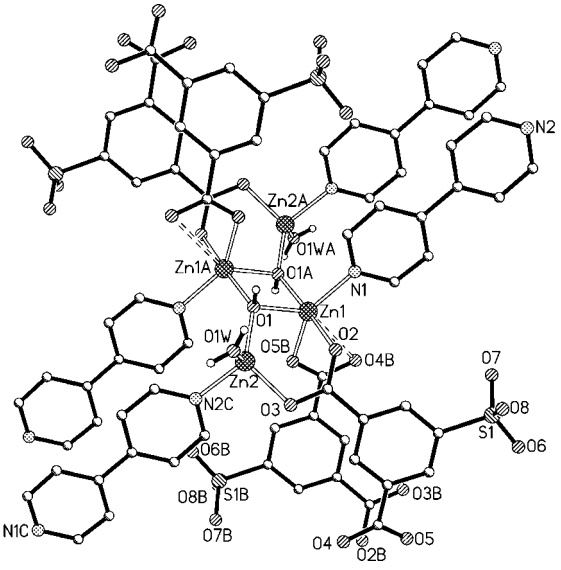


Figure 1. Perspective view of the coordination environments of zinc atoms in MCCP-4; lattice water molecules have been omitted for clarity

Table 1. Selected bond lengths [Å] and angles [°] for MCCP-4; symmetry codes A: $-x+1, -y+1, -z+1$; B: $-x+2, -y+1, -z+2$, C: $x, y+1, z+1$

Zn1−O1	2.029(2)	Zn1−O2	2.220(2)
Zn1−O1A	2.172(2)	Zn1−O5B	1.959(2)
Zn1−N1	2.005(2)	Zn1···O4B	2.826(2)
Zn2−O1	1.962(2)	Zn2−O3	1.963(2)
Zn2−O1W	1.955(2)	Zn2−N2	2.025(2)
O1−Zn1−N1	119.5(1)	O1−Zn1−O2	88.9(1)
O1−Zn1−O5B	95.6(1)	O1−Zn1−O1A	85.2(1)
N1−Zn1−O5B	144.6(1)	O1A−Zn1−O2	173.8(1)
O1−Zn2−O3	119.2(1)	O1−Zn2−O1W	109.1(1)
O3−Zn2−O1W	106.6(1)	O3−Zn2−N2C	97.8(1)

It is interesting that the $[Zn_4(\mu_3\text{-}OH)_2]^{6+}$ clusters are interlinked by the carboxylate groups of *d*-sip in mono- and bidentate fashions, resulting in one-dimensional $[Zn_4(\mu_3\text{-}OH)_2(H_2O)_2(sip)_2]_n$ chains, which are further bridged

through μ-4,4′-bpy ligands to generate an infinite two-dimensional sheet, with uncoordinated sulfonate groups deviating from the plane and orientated on both sides (Figure 2). The distances S1−O6, S1−O7 and S1−O8 are 1.429(2), 1.462(2) and 1.442(2) Å, respectively, and all fall within the typical range of S−O bond lengths in a sulfonate anion (1.40−1.49 Å).[16] Two oxygen atoms of the sulfonate group are involved in hydrogen bonding with the μ_3-OH group and zinc-bound water molecule [O8···O1 2.703(3) Å and O7···O1 W 2.713(3) Å] on the adjacent sheets, and these hydrogen bonds serve to increase the order of the structure of MCCP-4 from two to three-dimensional.

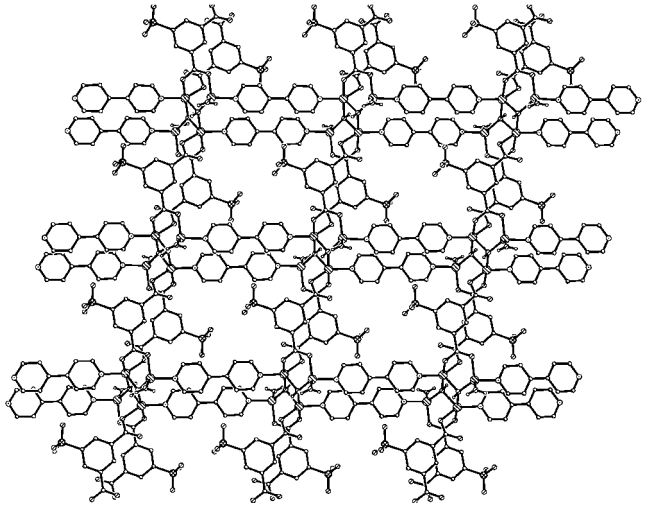

Figure 2. Perspective view of the two-dimensional sheet of MCCP-4; lattice water molecules and hydrogen bonds have been omitted for clarity

The structure of MCCP-5 is constructed from $[Cd_4(\mu_3\text{-}OH)_2]^{6+}$ clusters similar to that of MCCP-4, and also contains a crystallographic inversion center located at the center of the $[Cd_4(\mu_3\text{-}OH)_2]^{6+}$ cluster but its coordination environment around the Cd atoms is somewhat different from that of the Zn centers in MCCP-4. Selected bond lengths and angles are given in Table 2. The octahedral Cd1 atom is bound to one 4,4′-bpy nitrogen atom, three oxygen atoms from the bidentate and chelating carboxylate groups of two different *e*-sip ligands, respectively (Scheme 1). The remaining two coordination sites of the octahedron are filled by one μ_3-OH group and a sulfonate oxygen of an *e*-sip ligand (Figure 3). Cd2 adopts a slightly distorted octahedral geometry and is coordinated to two μ_3-OH groups, one 4,4′-bpy nitrogen atom and one carboxylate oxygen atom of an *e*-sip ligand in the equatorial plane, and to one water molecule and one 4,4′-bpy nitrogen atom in the axial positions. It is noteworthy that the latter 4,4′-bpy ligand uses only one nitrogen atom (N3) to coordinate to Cd2 leaving the other nitrogen (N4) free, as found in $[Zn(C_4H_4O_4)(4,4'\text{-bpy})]$ and the Co-4,4′-bpy molecular railroad.[17]

Table 2. Selected bond lengths [Å] and angles [°] for MCCP-5; symmetry codes A: $-x + 1/2, -y + 1/2, -z + 1$; B: $x, -y, -z + 1$, C $-x + 1/2, -y + 1/2, -z + 3/2$; D: $-x + 2, y + 1/2, -z + 1/2$; E: $-x, -y, -z + 1$

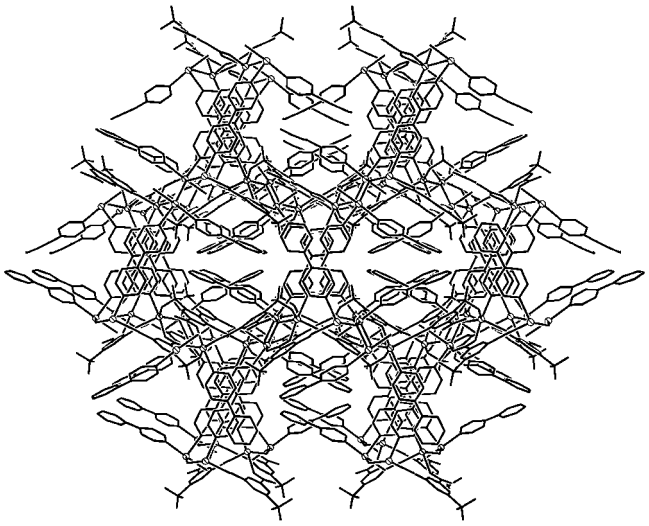

Figure 5. Perspective view of the three-dimensional structure of MCCP-5; lattice water molecules have been omitted for clarity

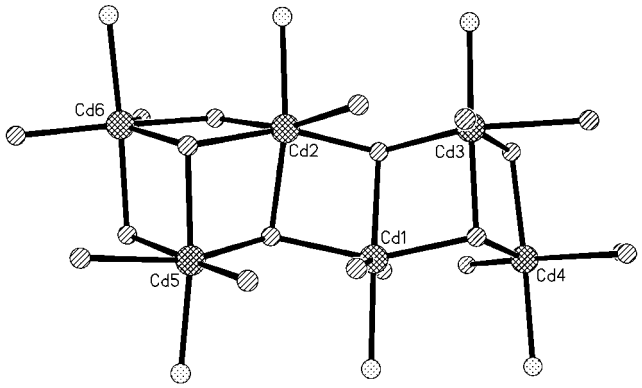

Figure 6. Perspective view of the hexanuclear cadmium cluster in MCCP-6

The most striking feature in MCCP-5 is the connection of all $[Cd_4(\mu_3\text{-}OH)_2]^{6+}$ clusters through *e*-sip ligands using their bridging bidentate carboxylate and sulfonate groups and 4,4′-bpy ligands to form an infinite two-dimensional sheet. The remaining chelating carboxylate groups orientate themselves up and down, as shown in the small circle in Figure 4. The two *e*-sip ligands drawn in open line are indeed symmetrically related (x, $-y$ +2, z − 1/2), and the chelating carboxylate group (small circle) and the *e*-sip ligand (large circle) are further coordinated to the nearest $[Cd_4(\mu_3\text{-}OH)_2]^{6+}$ cluster in the adjacent sheet which is intersected with the first one. Similarly, the two *e*-sip ligands drawn with a dashed line also are coordinated likewise. Thus, the intersected two-dimensional sheet is inter-linked through the chelating carboxylate groups of *e*-sip ligands to form an actual three-dimensional structure containing nearly hexagonal channels that are occupied by pendant 4,4′-bpy ligands and lattice water molecules, as illustrated in Figure 5. To the best of our knowledge, whereas three basic cadmium clusters have been found,[18] this is the first example of a coordination polymer constructed from $Cd_4(\mu_3\text{-}OH)_2$ clusters.

The basic building unit in MCCP-6 is the $[Cd_6(OH)_4(OH_2)_4]^{8+}$ cluster (Figure 6), which is constructed from hexameric units composed of six octahedral Cd^{II} centers in which four nip ligands doubly bridge the six cadmium clusters in *e* and *f* modes, and two nip ligands are doubly bound to four cadmium atoms in terminal *c* and *d* modes (Figure 7 and Scheme 2). Selected bond lengths and angles are listed in Table 3. Cd1 is coordinated to three μ_3-OH groups (O1, O2 and O3) and one 4,4′-bpy nitrogen

atom in the equatorial plane, and to two oxygen atoms from the bridging bidentate carboxylate group of a *c*-nip ligand (O11) and the bridging bidentate carboxylate group of an *f*-nip ligand (O19B) in the axial positions. Cd2 has a similar coordination environment and is bound to three μ_3-OH groups (O2, O3 and O4) and one nitrogen atom from the 4,4′-bpy ligand. The remaining two coordination sites of the octahedron are filled by two oxygen atoms from the bidentate carboxylate group (O6) of an *e*-nip ligand and the chelating/bridging carboxylate group (O23) of a *d*-nip ligand. Cd3 lies in the center of a distorted octahedron and is coordinated to one μ_3-OH group (O2), one μ_2-bridging water molecule (O1W), one terminal water molecule (O3W) and one oxygen atom from the bidentate carboxylate group (O5) of an *e*-nip ligand in the equatorial plane. The coordination sphere is completed by one μ_3-OH group (O1) and one nitrogen atom from the 4,4′-bpy ligand in the axial positions. Cd4 is octahedrally coordinated by one μ_3-OH group (O1), one oxygen atom from the bridging bidentate carboxylate group (O12) of a *c*-nip ligand, two oxygen atoms from the chelating carboxylate group (O17, O18) of an *f*-nip ligand, one μ_2-bridging water molecule (O1W) and one 4,4′-bpy nitrogen atom. The coordination environments around Cd5 and Cd6 are somewhat similar to those of Cd3 and Cd4, respectively, except for the different coordination modes of the nip ligands. It is noteworthy that the six cadmium atoms are interlinked through four triply bridging μ_3-OH groups to form four basic $Cd_3(OH)$ subunits, in which the Cd−O distances of between 2.211 and 2.368 Å are consistent with those of other μ_3-OH-bridged cadmium motifs.[18,19] The assignment of μ_3-OH groups was based on the near tetrahedral angles around the central O atoms with average angles between 101.1 and 106.9°, which are a little larger than those found in the $(F_5C_5CdOH)_4$ cubane.[19]

The most striking feature of MCCP-6, however, is the connection of all $[Cd_6(\mu_3\text{-}OH)_4(\mu_2\text{-}OH_2)_2(OH_2)_2]^{8+}$ building blocks through linking *e*- and *f*-nip ligands to form a slightly corrugated, infinite 1D-chain with the formula $[Cd_6(\mu_3\text{-}OH)_4(\mu_2\text{-}OH_2)_2(OH_2)_2(nip)_4]_n$ (Figure 8), in which pairs of *c*- and *d*-nip ligands are located on both sides. Obviously, the large bulk combined with short nip links does not allow for high coordination of the hexanuclear cluster because of the steric hindrance. Their links by *e*- and *f*-nip ligands are made to bind in a pairwise manner to two hexanuclear cluster as observed for ip in MOF-49.[20] As shown in Figure 7, each hexanuclear cluster is coordinated to six nitrogen atoms from six μ_2-4,4′-bpy ligands up and down, thus the adjacent 1D-chains are further interlinked through these μ_2-4,4′-bpy ligands to generate an infinite undulating 2D-sheet (Figure 9).

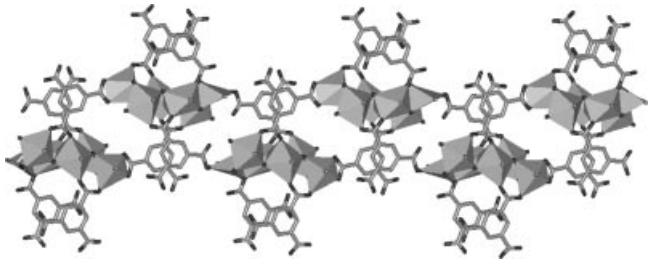

Figure 8. Perspective view of the one-dimensional chain constructed with hexanuclear cadmium clusters and nip ligands; coordinated 4,4′-bpy ligands have been omitted for clarity

Photoluminescent Properties

As we and others previously reported, coordination polymers containing zinc or cadmium oxide or hydroxide motifs exhibit photoluminescent properties[6,18b] and in this study we also investigated the photoluminescent properties of MCCP-4, -5 and -6 (Figure 10). In the solid state, the maximum of the emission bands of MCCP-4 is located at

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

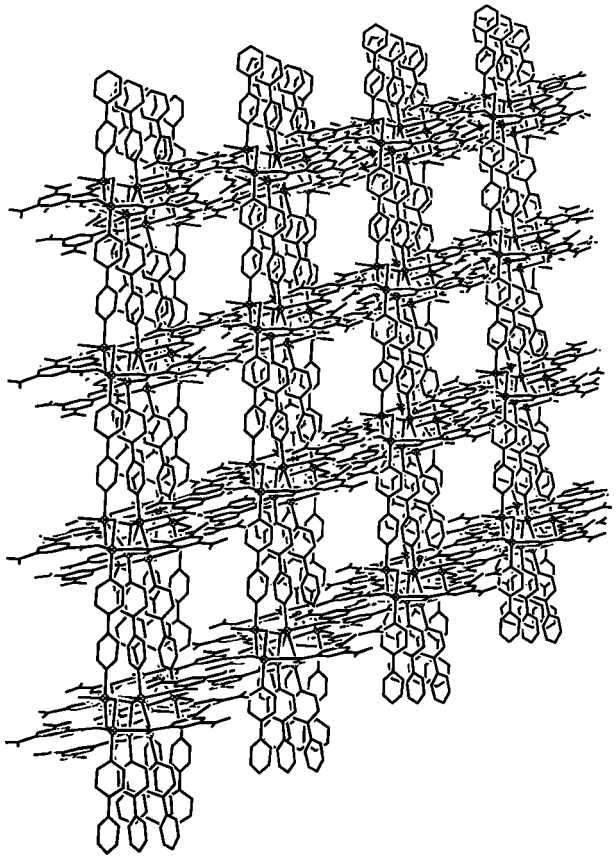

Figure 9. Perspective view of the two-dimensional structure of MCCP-6

562 nm (λ_{ex} = 505 nm), while MCCP-5 shows two emission bands at 370 nm and 468 nm (λ_{ex} = 340 nm), respectively. Since free H_2sip exhibits photoluminescence emission at 355 nm, the emission band at 370 nm of MCCP-5 may be due to the ligand donation, while the emission bands at 562 nm and 468 nm of MCCP-4 and -5 might be attributable to the formation of $[M_4(\mu_3\text{-}OH)_2]^{6+}$ (M = Zn^{II}, Cd^{II}) clusters and/or to ligand-to-metal charge transfer (LMCT).[6,21] MCCP-6 also exhibits intense photoluminescence with the maximum at 470 nm. Because the free H_2nip ligand does not emit any luminescence in the range 400−800 nm, the emission of MCCP-6 might also be assigned to the formation of $[Cd_6(\mu_3\text{-}OH)_4]^{8+}$ clusters and/or to ligand-to-metal charge transfer (LMCT).[6,21]

In conclusion, we have synthesized three novel metal-cluster-based coordination polymers, in which the sip and nip ligands show versatile coordination modes. The sulfonate groups in MCCP-4 and -5 are uncoordinated and monodentate, respectively. Furthermore, the sulfonate and nitro groups are involved in extensive inter-framework hydrogen bonding, which thus leads to extended structures with a higher order of dimensions.

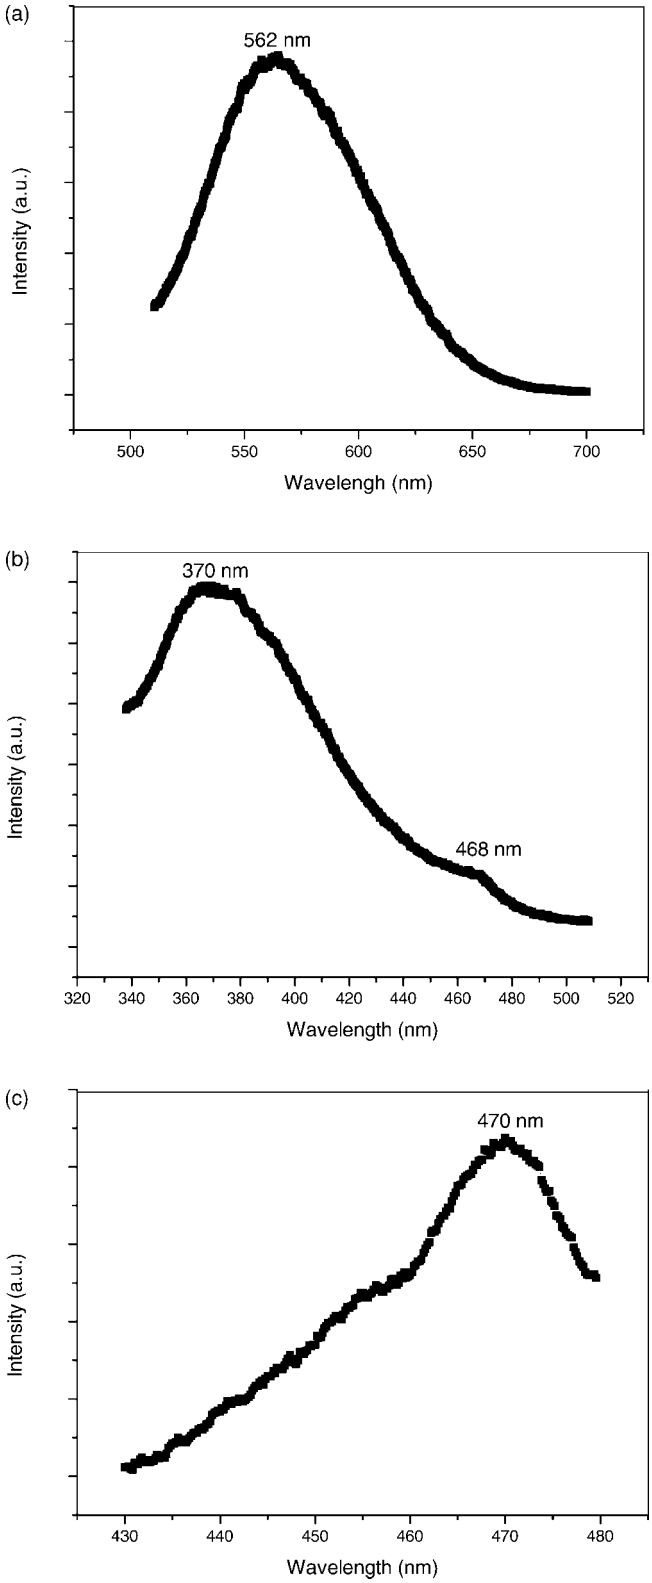

Figure 10. The solid-state photoluminescent spectra of MCCP-4 (a), -5 (b) and -6 (c) at room temperature

Experimental Section

General Remarks: All reagents were purchased from commercial sources and used without further purification. Elemental analyses

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$.

were performed with a CE EA 1110 elemental analyzer. IR spectra were recorded from 4000 to 400 cm^{-1} with a Nicolet AVATAR FT-IR360 instrument. The thermal gravimetric analyses (TGA) were carried out under nitrogen with a NETZSCH STA 449C differential thermal analyzer with a rate of 10 °C/min.

Synthesis of MCCP-4: An aqueous solution (5 mL) of H_2sip (0.134 g, 0.50 mmol) was adjusted to pH = 7 with 1 M NaOH, and transferred into a Parr Teflon-lined stainless steel vessel (23 mL) containing $Zn(NO_3)_2{\cdot}6H_2O$ (0.158 g, 0.50 mmol) and 4,4′-bpy (0.078 g, 0.50 mmol). To the resultant mixture was added an additional 3 mL of water. The vessel was then sealed and heated to 180 °C for 3 d, followed by cooling at 2.5 °C/h to room temperature. Colorless block-like crystals were collected by hand, washed with distilled water and dried in air at ambient temperature [yield: ca. 75% based on $Zn(NO_3)_2$]. $C_{18}H_{17}N_2O_{10.5}SZn_2$ (592.14): calcd. C 36.51, H 2.89, N 4.73; found C 36.30, H 2.75, N 4.80. IR (KBr): $\tilde{\nu}$ = 3416 m, 3269 m, 3019 m, 3022 m, 1610 vs, 1560 vs, 1498 m, 1441 s, 1372 s, 1255 s, 1228 m, 1205 m, 1171 m, 1104 m, 1077 m, 1038 s, 1016 w, 912 w, 876 w, 822 m, 772 m, 731 m, 678 w, 643 m, 625 m, 593 w, 548 w, 453 w cm^{-1}.

Synthesis of MCCP-5: The synthesis of MCCP-5 was similar to the above description for MCCP-4 except that zinc nitrate hexahydrate was replaced by cadmium nitrate tetrahydrate. Yield: ca. 60% based on $Cd(NO_3)_2$. $C_{56}H_{46}Cd_4N_8O_{19}S_2$ (1648.73): calcd. C 40.79, H 2.81, N 6.80; found C 40.40, H 2.90, N 6.66. IR (KBr): $\tilde{\nu}$ = 3569 w, 3367 w, 3104 w, 3073 w, 3042 w, 3017 w, 1600 s, 1560 s, 1534 s, 1492 m, 1430 m, 1415 m, 1367 s, 1223 m, 1202 m, 1166 m, 1101 m, 1067 m, 1035 s, 996 m, 934 w, 877 w, 859 w, 821 m, 775 s, 728 s, 676 m, 619 vs, 576 m, 516 w, 464 m, 441 m cm^{-1}.

Synthesis of MCCP-6: An aqueous solution (5 mL) of H_2nip (0.106 g, 0.50 mmol) was adjusted to pH = 7 with 1 M NaOH, and transferred into a Parr Teflon-lined stainless steel vessel (23 mL) containing $Cd(NO_3)_2{\cdot}4H_2O$ (0.154 g, 0.50 mmol) and 4,4′-bpy (0.078 g, 0.50 mmol). To the resultant mixture was added an additional 3 mL of water and the vessel was then sealed and heated to 140 °C for 3 d, followed by cooling at 5 °C/h to room temperature. Colorless block-like crystals were collected by hand, washed with distilled water, and dried in air at ambient temperature [yield: ca. 40% based on $Cd(NO_3)_2$]. $C_{62}H_{54}Cd_6N_{10}O_{35}$ (2173.55): calcd. C 34.26, H 2.50, N 6.44; found C 34.10, H 2.55, N 6.15. IR (KBr): $\tilde{\nu}$ = 3410 m, 3094 m, 2914 m, 1610 vs, 1566 s, 1529 m, 1455 m, 1418 m, 1365 vs, 1219 w, 1076 w, 1009 w, 927 w, 809 m, 731 s, 630 m cm^{-1}.

Crystallographic Analyses: Diffraction data were collected with an Enraf Nonius CAD-4 diffractometer for MCCP-4 and with a Bruker APEX CCD diffractometer for MCCP-5 and MCCP-6 with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The three structures were solved by direct methods and refined anisotropically by full-matrix least squares based on F^2 using the SHELXTL crystallographic software package.[22] Non-hydrogen atoms in all structures were refined with anisotropic displacement parameters. Hydrogen atoms attached to carbon atoms were calculated and included as riding atoms. In the final difference Fourier map of MCCP-6 was a peak larger than 1 e·Å^{-3}. The unit cell, however, contains no residual Solvent Accessible Area as calculated by PLATON.[23] Crystal parameters and details of the data collection and refinement for the structures of MCCP-4, -5 and -6 are listed in Table 4. CCDC-201032 (MCCP-4), -201033 (MCCP-5) and -202206 (MCCP-6) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Reaction of $[Cp^*RhCl_2]_2$ (**1**) with bis(diphenylphosphanylmethyl)phenylphosphane (dpmp) in the presence of KPF_6 generated the mono- or bi-nuclear complexes $[(Cp^*RhCl)(dpmp\text{-}P,P,P)(RhCl_2Cp^*)](PF_6)$ (**2**) or $[Cp^*RhCl(dpmp\text{-}P,P)](PF_6)$ (**3**), depending on the reaction conditions. These complexes have two chiral centers at Rh and the central P atoms, and the diastereomers were separated by successive recrystallization. The structures of **2(B)** with an $R_{Rh}S_P/S_{Rh}R_P$ pair and **3(A)** with an $R_{Rh}S_P/S_{Rh}R_P$ pair were elucidated by X-ray analyses. Reaction of **1** with an excess of dpmp in the presence of Ag(OTf) generated a hetero-tetranuclear complex $[\{Cp^*RhCl_2(dpmp\text{-}P,P,P)Ag\}_2](OTf)_2$ (**4**). An X-ray analysis revealed that each Cp^*RhCl_2 moiety is connected by a terminal P^1 atom of the dpmp ligand and each Ag atom is two-coordinate and is surrounded by another terminal P^3 atom, and a central P^{*2} atom of the other dpmp ligand. A mixture of **1** and dpmp was treated with $Au(SC_4H_8)$ or CuCl in the presence of KPF_6, generating the hetero-tetranuclear complexes $[\{Cp^*RhCl_2(dpmp\text{-}P,P,P)M\}_2](PF_6)_2$ (**7**: M = Au; **8**: M = Cu), in which the structures, except for the Cl-bridged structure of **8**, are fundamentally similar to that of **4**. These complexes were also prepared by the reactions of **3** with $Au(SC_4H_8)$ or CuCl. Complex **3** reacted with AgOTf to afford $[Cp^*Rh(dpmp\text{-}P,P,P)](OTf)_2$ (**5**). Treatment of **3(A)** (a diastereomer with an $R_{Rh}S_{P2}/S_{Rh}R_{P2}$ pair) with **1**, $[(p\text{-cymene})RuCl_2]_2$ or $PdCl_2(cod)$ gave $[Cp^*RhCl(dpmp\text{-}P,P,P)RhCl_2Cp^*](PF_6)$ (**2**) or $[Cp^*RhCl(dpmp\text{-}P,P,P)RuCl_2(p\text{-cymene})](PF_6)$ (**6**), respectively. These addition reactions proceeded stereoselectively.

Introduction

Triphosphanes, especially bis(diphenylphosphanylmethyl)-phenylphosphane (dpmp), play an important role as the backbone in the construction of polynuclear clusters. The chemistry of rhodium, iridium, and gold has been sited by Balch.[1] We have developed systematic syntheses of homo- and hetero-bimetallic and -trimetallic platinum and palladium clusters with tridentate phosphane and isocyanide ligands.[2] These complexes are constructed fundamentally of a square planar framework and contain dpmp, carbon monoxide, halogens and isocyanides as ligands. Octahedral complexes can lead to compounds with diverse dimensionality, in comparison with square-planar complexes.

Recently, we reported the preparation of supramolecular complexes based on quasi-octahedral geometries of rhodium(III) and iridium(III) bearing a pentamethylcyclopentadienyl or arene ruthenium(II) moiety. Thus, the reactions of $[Cp^*MCl_2(\mu\text{-}1,4\text{-}(CN)_2\text{-}2,3,5,6\text{-}Me_4C_6)MCl_2Cp^*]$ (M = Rh, Ir; $Cp^* = C_5Me_5$) with bidentate ligands such as pyrazine, bipyridine and di-isocyanide in the presence of AgOTf ($OTf = CF_3SO_3$) generated tetranuclear complexes with a square core.[3–5] Recently, self-assembled supramolecules with the pentamethylcyclopentadienyl or cyclopentadienyl groups in which the CN group has been generally used as a binary ligand have been reported by several researchers.[6–9]

We are interested in the chemistry of the interaction between quasi-octahedral complexes and dpmp containing three potential coordination sites because of expectation of various coordination modes and polynuclear complexes. We adopted binuclear complexes of rhodium(III), iridium(III) or ruthenium(II) containing pentamethylcyclopentadienyl or arene groups as quasi-octahedral complexes, for which the chemistry has not yet been developed. Here we report the preparation and stereochemistry of mononuclear, binuclear and polynuclear complexes of rhodium(III) bearing dpmp and pentamethylcyclopentadienyl ligands. Part of this work has already been briefly reported.[10]

Results and Discussion

Reactions of $[Cp^*RhCl_2]_2$ (1) with dpmp in the Presence of KPF_6 or AgOTf

When $[Cp^*RhCl_2]_2$ (**1**) ($Cp^* = C_5Me_5$) was treated with an equivalent of dpmp in the presence of KPF_6 at room temperature, two kinds of complexes [**2(A)** and **2(B)**] with the empirical formula of $[Cp^*_2Rh_2Cl_3(dpmp\text{-}P,P,P)](PF_6)$ were isolated by successive recrystallization (Scheme 1). The IR spectrum of **2** showed a peak at ca. 845 cm^{-1} consistent with the presence of a PF_6 anion. The ^1H NMR spectrum of the reaction mixture indicated a ratio of 1.1:1.0 for **2(A):2(B)**. The Cp* protons appeared at δ = 1.28 (d) and 1.55 (t) for **2(A)** and at δ = 1.27 (d) and 1.73 (t) for **2(B)**, respectively. The chemical shift of the Cp* protons in the chelate ring moiety appeared at a lower magnetic field than those of the other Cp* protons since the Rh atom in a chelate ring is sufficiently electron-deficient for the transfer electron density from the Cp* ligand to the rhodium center. The X-ray analysis of **2(B)** revealed that a Rh atom is connected by the terminal and the central P atoms, and another Rh atom is coordinated to another terminal P atom.[10]

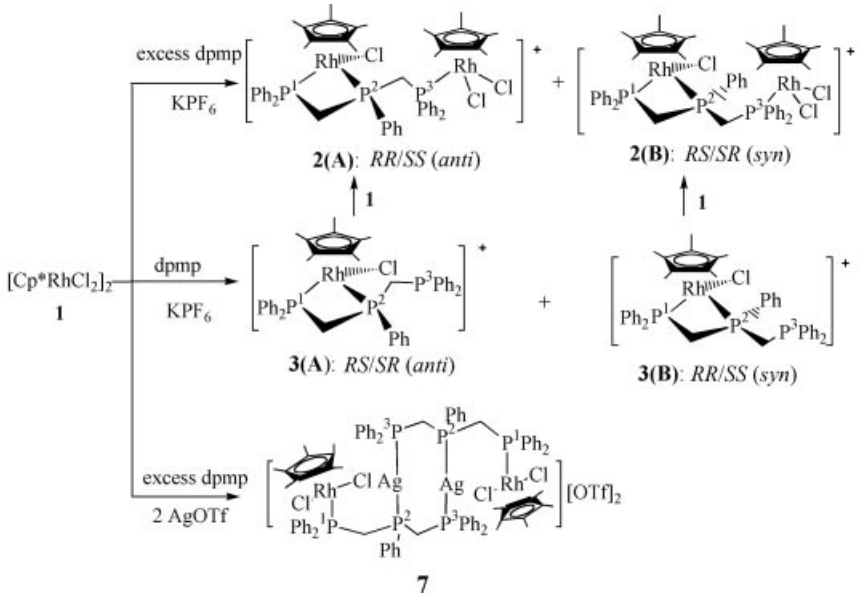
The molecule has two chiral centers namely the Rh and the central P^2 atom. Based on the priority order of the ligands around the two chiral centers,[10] compound **2(B)** was identified as the diastereomer with an $R_{Rh}S_P/S_{Rh}R_P$ pair. Thus **2(A)** is the diastereomer with an $R_{Rh}R_P/S_{Rh}S_P$ pair. The stereochemical difference is that the Cl atom and the P-substituted Ph group occupy the opposite side in **2(A)** and the same side in **2(B)**, where the structure of a **2(A)** type is designated as an *anti*-form and that of a **2(B)** type as a *syn*-form.

The reaction of **1** with an excess of dpmp in the presence of KPF_6 afforded yellow crystals of $[Cp^*RhCl(dpmp)](PF_6)$ (**3**). The ^1H NMR spectrum of the reaction mixture consists of two sets of isomers, **3(A)** and **3(B)**, with an intensity ratio of 2:1, which were separated by successive recrystallization. The X-ray study of **3(A)** revealed its stereochemistry to be that of the diastereomer with an $R_{Rh}S_P/S_{Rh}R_P$ pair (*anti*-form), based on the priority order of the ligands.[10] Thus **3(B)** is assumed to be the $R_{Rh}R_P/S_{Rh}S_P$ pair (*syn*-form). The geometries around the Rh and P^2 centers were found to be similar for **2(A)** and **3(A)**, and for **2(B)** and **3(B)**. In the ^1H NMR spectra, the Cp* protons appeared at δ = 1.74(t) for **3(A)** and at δ = 1.78 for **3(B)**. In the $^{31}P\{^1H\}$ NMR spectrum of **3**, the chemical shifts (δ = −24 ≈ −30) of the free P nuclei appeared at the higher magnetic fields by ca. 10 ≈ 20 ppm than those found for the coordinated P nuclei.[11]

Complex **3(A)** or **3(B)** was treated with **1** at room temperature, exclusively generating **2(A)** or **2(B)**, respectively. The reactions proceeded stereospecifically. Complex **2(A)** was treated with dpmp at room temperature, affording a mixture of **3(A)** and **3(B)** consisting of an approximately 5:1 molar ratio. A similar reaction of **2(B)** gave a mixture of **3(A)** and **3(B)** consisting of an approximately 1:2 molar ratio (Scheme 2). The ratios are reasonable on the basis of the formation ratio in the original reaction of **1** with dpmp. In these reactions the conversion from **2(B)** to **3** and its reverse reaction are slower than inter-conversion between **2(A)** and **3**.

Isomerization from **2(A)** [or, **3(A)**] to **2(B)** [or, **3(B)**] and its reverse reaction did not occur on standing for a long period of time (>100 h) at room temperature. When compound **2(A)** was treated with xylyl isocyanide in acetone at reflux, cleavage of the $Rh-P^3$ bond occurred, generating **3(A)** and $Cp^*RhCl_2(XylNC)$ (Scheme 2). This reaction suggests a greater bond strength in the chelate ring.

A similar reaction of **1** with dpmp was carried out in the presence of two equivalents of Ag(OTf) which afforded an orange-yellow complex **4**, formulated as $[\{Cp^*RhCl_2\text{-}(dpmp\text{-}P,P,P)Ag\}_2](OTf)_2$ (Scheme 1). The structure was



Scheme 1. Reactions of $[Cp^*RhCl_2]_2$ **1** with dpmp in the presence of KPF_6 or Ag(OTf)

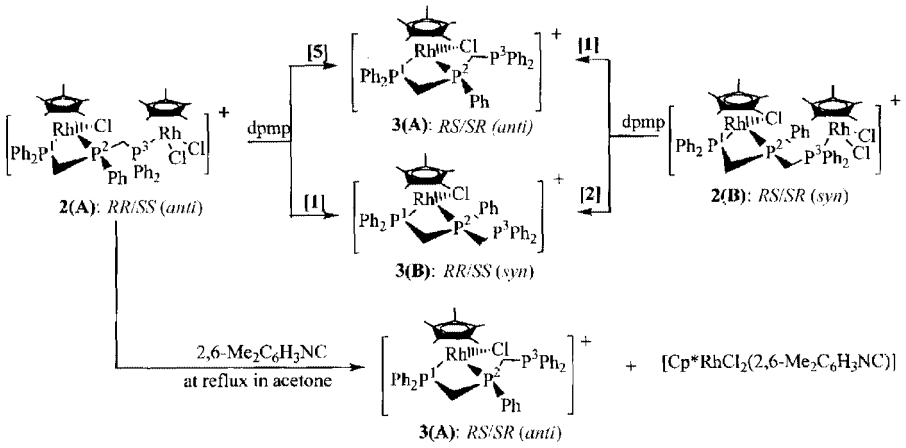

Scheme 2. Reactions of **2** with dpmp or xylyl isocyanide, where the PF_6 anion has been omitted for clarity. The formation ratio of **3(A)** and **3(B)** is designated in the bracket [].

subsequently confirmed by X-ray analysis (Figure 1). Each Cp^*RhCl_2 moiety is connected by a terminal P^1 atom of the dpmp ligand. Each Ag atom is two-coordinate and is surrounded by another terminal P^3 atom and a central P^{*2} atom of the other dpmp ligand. It is interesting to note that **4** was isolated as an addition product without the abstraction of Cl anions by Ag(OTf).

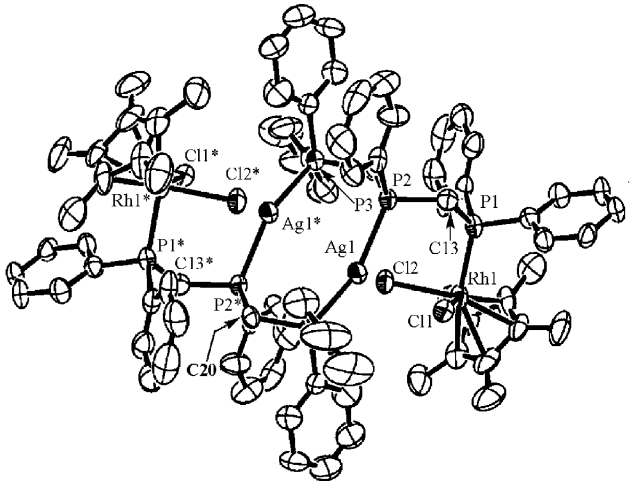

Figure 1. Molecular structure of $4{\cdot}H_2O$; the OTf anion and H_2O have been omitted for clarity and thermal ellipsoids have been drawn at the 50% probability level.

In the ^1H NMR spectrum, the Cp* protons appeared at $\delta = 1.25$ as a doublet, suggesting a symmetric structure. The $^{31}P\{^1H\}$ NMR spectrum showed a double doublet at $\delta = 28.6$ ($J_{PRh} = 146$, $J_{P,P} = 12.9$ Hz) due to the P^1 nucleus coordinated to the rhodium atom and the unresolved signals around $\delta = 2.6$ are due to the other P nuclei.

Reactions of [Cp*RhCl(dpmp-*P,P*)](PF$_6$) and [Cp*$_2$Rh$_2$Cl$_3$-(dpmp-*P,P,P*)](PF$_6$)

The mononuclear complex **3** was anticipated as being a potential precursor to hetero- or homo-multiple nuclear complexes. The reactions of **3** are depicted in Scheme 3.

In order to try to extract a Cl anion, **3** was treated with an excess of KPF_6, but only the starting material could be recovered. A similar reaction with AgOTf, however, gave the yellow η^3-complex [Cp*Rh(dpmp-*P,P,P*)](OTf)$_2$ (**5**) bearing a tridentate ligand as evidenced by the presence of a quadruplet for the Cp* protons in the ^1H NMR spectrum. The X-ray analysis was in agreement with the proposed structure (Figure 2).

When **3(A)** was treated with [(*p*-cymene)$RuCl_2]_2$ at room temperature, a reaction readily occurred, generating a brown complex **6(A)** established from elemental analysis and FAB mass spectrometry as [Cp*RhCl(dpmp-*P,P,P*)$RuCl_2$(*p*-cymene)](PF$_6$). In the ^1H NMR spectrum, the Cp* protons appeared at δ 1.52 as a triplet and the methyl protons of the isopropyl group showed two doublets at $\delta = 0.52$ and 1.00, due to nonequivalence arising from the chiral centers. The $^{31}P\{^1H\}$ NMR spectrum showed three resonances at $\delta = -12.0$ (dt, $^1J_{RhP2} = {}^2J_{P2P1} = 97.0$, $^2J_{P2P3} = 55.5$ Hz, P^2), -1.41 (t, $^1J_{P1Rh} = {}^2J_{P1P2} = 97.0$ Hz, P^1) and 23.7 (d, $^2J_{P3P2} = 55.5$ Hz, P^3) for the dpmp ligand. The stereochemistry with the *anti*-form ($R_{Rh}R_{P2}/S_{Rh}S_{P2}$) of the starting complex is assumed to be retained. Complex **6** was also prepared from the reaction of **1** with [(*p*-cymene)$RuCl_2]_2$ in a 1:1 molar ratio in the presence of KPF_6. Crystallization of the reaction mixture gave two diastereomers in a 52% yield, consisting of a 1:2 molar ratio of **6(A)** and **6(B)**, suggesting that a chelating formation including a Rh atom is preferable to one with a Ru atom. In the ^1H NMR spectrum of **6(B)**, the Cp* protons appeared at $\delta = 1.73$ and two doublets for the isopropyl protons resulted in magnetic non-equivalence. The $^{31}P\{^1H\}$ NMR

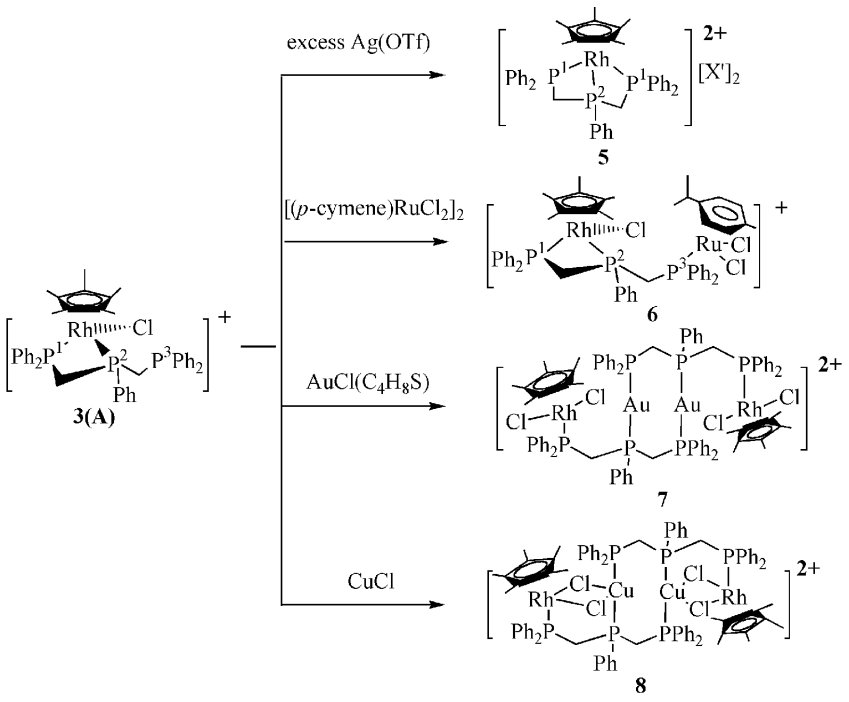

Scheme 3. Reactions of **3(A)**, where the PF_6 anions have been omitted for clarity.

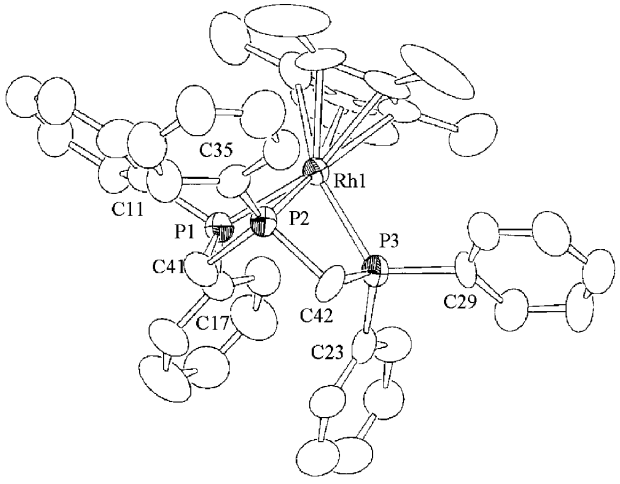

Figure 2. Molecular structure of the cation of **5**; the OTf anions have been omitted for clarity and thermal ellipsoids have been drawn at the 50% probability level.

spectrum showed three resonances at δ = −13.8 (dt, $^1J_{RhP2}$ = $^2J_{P2P1}$ = 105, $^2J_{P2P3}$ = 55.0 Hz, P^2), −10.2 (t, $^1J_{P1Rh}$ = $^2J_{P1P2}$ = 109.0 Hz, P^1) and 26.6 (d, $^2J_{P3P2}$ = 55.0 Hz, P^3) for the dpmp ligand.

Complex **3(A)** reacted readily with $AuCl(SC_4H_8)$ at room temperature, giving the reddish brown complex **7** [{Cp*$RhCl_2$(dpmp-*P,P,P*)Au}$_2$]$(OTf)_2$. X-ray analysis confirmed that the molecular structure is fundamentally similar to that of **4**.[10] Complex **7** was directly generated from **1**, $AuCl(SC_4H_8)$ and dpmp in the presence of KPF_6.

Copper(I) chloride reacted with **3(A)** at room temperature, generating the orange complex [{Cp*$RhCl_2$(dpmp-*P,P,P*)Cu}$_2$]$(PF_6)_2$ (**8**). The ^{1}H NMR spectrum showed two doublets at δ = 1.08 and 1.20 ppm with an intensity ratio of 1:2 due to the Cp* protons, suggesting the presence of diastereomers arising from two chiral centers (the central P atom of dpmp). Crystals of **8(A)** were suitable for X-ray analysis. The structure, except for the presence of two Cl bridges, is essentially similar to those of **4** and **7**. The stereochemistry was confirmed as an $R_{P2}S_{P2*}/S_{P2}R_{P2*}$ pair (Figure 3). Thus complex **8(B)**, with the chemical shift of δ = 1.08, is assumed to be a diastereomer with an $R_{P2}R_{P2*}/S_{P2}S_{P2*}$ pair.

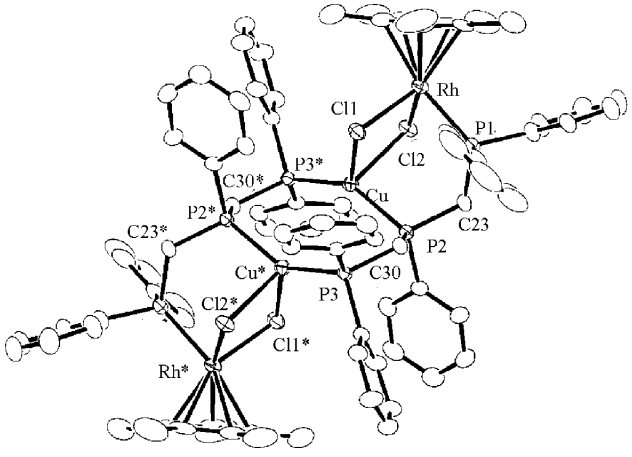

Figure 3. Molecular structure of **8**·$2CH_2Cl_2$; the OTf anions and CH_2Cl_2 molecules have been omitted for clarity and thermal ellipsoids have been drawn at the 50% probability level.

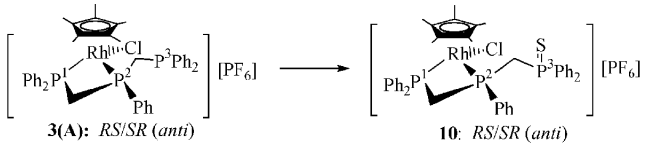
A one-pot synthesis from **1**, an excess of dpmp and CuCl in the presence of KPF_6 can also be used to prepare a mixture of the diastereomers of **8**. The BF_4 anion complex was obtained from the reaction of **1** with dpmp in the presence of $[Cu(MeCN)_4](BF_4)$.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Complex **3(A)** was treated with S_8 at room temperature, affording an orange compound formulated from elemental analysis and FAB mass spectrometry as [Cp*RhCl(dpmp-*P,P,P*)S](PF_6) **9** (Scheme 4). The molecular structure is assumed to be consistent with addition of a S atom to the free terminal P^3 atom. This reaction is similar to the usual reaction of tertiary phosphanes with sulfur.



3(A): *RS/SR* (*anti*) **10**: *RS/SR* (*anti*)

Scheme 4. Reactions of **3(A)** with sulfur

The substitution reaction of **2(A)** with xylyl isocyanide (XylNC) in the presence of KPF_6 was unsuccessful, leading only to recovery of the starting materials. The reaction in the presence of Ag(OTf), however, gave [(Cp*RhCl)$_2$(dpmp-*P,P,P*)(XylNC)](OTf)$_2$ (**10**) (Scheme 5). The presence of a terminal isocyanide ligand was confirmed by appearance of a ν(N≡C) band at 2168 cm^{-1} and disappearance of a PF_6 band at ca. 850 cm^{-1}. The ^1H NMR spectrum exhibited two resonances at δ = 1.48(t) and 2.00(d) for the Cp* protons. The $^{31}P\{^1H\}$ NMR spectrum showed three resonances at δ = −15.5(ddd), −2.76(dd) and 28.6(dd) due to the P^2, P^1 and P^3 nuclei, respectively. These spectroscopic data suggest the structure depicted in Scheme 5. Since this complex has three chiral centers namely the two Rh centers and a P^2 atom, formation of two diastereomers was expected. However, no isomers were detected in the ^1H NMR spectrum. The stereochemistry for the chelating group in **10** was maintained, but the geometry around the other Rh center remains unknown.

Possible Pathway

A possible route to a hetero-nuclear complex from **1** consists of the initial formation of [Cp*RhCl(dpmp-*P,P*)]Cl **A**, followed by substitution of a Cl anion with the PF_6 or OTf anions to form **B** and AgCl (or KPF_6) (Scheme 6). This proposal was confirmed by the fact that in separate experiments, complex **A** was prepared by the reaction of **1** with an excess of dpmp, and subsequently treated with KPF_6, generating **3**. The next process is the coordination of the resultant AgCl to the free P atom of **3**, generating an intermediate **C**.

This type of species has been isolated as [Cp*IrCl(dpmp-*P,P,P*)AuCl](PF$_6$)[12] or [(C$_6$Me$_6$)Ru(dpmp-*P,P,P*)AuCl](PF$_6$)[10] by the reactions of [Cp*IrCl(dpmp-*P,P*)](PF$_6$) or [(C$_6$Me$_6$)Ru(dpmp-*P,P*](PF$_6$) with AuCl(SC$_4$H$_8$). Finally, dimerization of **D** resulting in a nucleophilic attack of the Cl anion to the Rh atom led to formation of tetranuclear complexes.

Molecular Structures

P−Rh−P bite angle has a typical value of 70.9°, except for the P(1)−Rh−P(3) bite angle of 95.2°. The latter wide angle is a result of an unrestrained angle by a methylene chain. The Rh(1)−P(3) length of 2.369(4) Å is longer by ca. 0.05 Å than the average value of other Rh−P bonds.

Structures of 4·H_2O and 8·2CH_2Cl_2: Perspective drawings of **4** and **8** with the atomic numbering scheme are given in Figure 1 and Figure 3, and selected bond lengths and angles are listed in Table 2 and Table 3. Complexes **4** and **8** contain one H_2O and two CH_2Cl_2 solvate molecules, respectively.

Complexes **4** and **8** both have a crystallographically imposed inversion center in the middle of the Ag···Ag* and Cu···Cu vectors like that in the Au···Au vector in **7**.[10] The eight $M_2P_4C_2$ rings (M = Ag, Au, Cu) adopt a chair form to relieve the steric repulsion of the phenyl groups. Each Cp*$RhCl_2$ moiety is connected by a terminal P^1 atom of the dpmp ligand. These compounds have two chiral centers (P^2 and P^{2*}). The priority order of the ligands is M > Ph > C^2 > C^1 for the central P^2 and P^{2*}atoms, where C^1 represents the methylene carbons between the P^1 and P^2 atoms and C^2 is another methylene carbon atom. Complexes **4** and **8** have been identified as the $R_{P2}S_{P2*}/S_{P2}R_{P2*}$ pairs, similarly to **7**.[10]

An Au···Au separation of 3.203(2) Å in **7** suggests the presence of a weak interaction between the two Au centers.[10] However, the measured Ag···Ag separation of 3.385 Å in **4** suggests the absence of a metal−metal bond, since the Ag^I−Ag^I separations of 3.162−3.223 Å in [Ag_3{HC(PPh_2)$_3$}] have also suggested the absence of metal-metal bonds.[14] In comparison, [Ag_2(dpmp)$_2$](NO_3)$_2$, which is considered to have an Ag−Ag bond has an Ag−Ag separation of 3.085(1) Å.[15] A Cu···Cu separation of 3.566 Å in **8** is indicative of the absence of a metal-metal bond.

Since the M···Cl separations of 2.709 and 2.911 Å in **4** [M = Ag], and of 3.05 and 3.15 Å in **7** [M = Au] are longer than those found in each of the M−Cl-bridged bonds,[16] the Ag atoms are two-coordinate and are surrounded by two P atoms (a terminal P^{3*} atom from a dpmp ligand and a central P^2 atom from another dpmp). The P(2)−M−P(3)* angles are 150.3(1)° for **4** and 164.6(1)° for **7**, bent from the linear array to the reverse side against another Ag atom. The Cu···Cl(1) separation of 2.443 Å can be compared with the bridged Cu−Cl bond lengths of 2.448(3) Å in [$Ir_2(H)_4Cu(CO)_2$(μ-Cl)Cl(μ-dpma)$_2$]$^+$ [17] and another Cu···Cl(2) separation of 2.568 Å can be assumed to be a weak interaction, although it is somewhat longer. These Cu···Cl interaction cause the P(2)−Cu−P(3)* angle [145.77(7)°] to be more acute than those found in other complexes.

The M−P lengths increase with M in the order Cu, Au and Ag in accordance with the atomic radii of the metals. The Cl(1)−Rh−Cl(2) and Cl−Rh−P(1) angles which are in the range 87.3−92.7°are nearly perpendicular as a result of the octahedral core. The Rh−Cl bond lengths in the range 2.417−2.440 Å are typical.

Conclusion

The chemistry of dpmp has been limited to square-planar complexes of palladium, platinum and rhodium as well as two coordinate complexes of silver and gold. In this paper the chemistry of dpmp has been extended to the octahedral geometry. Pentamethylcyclopentadienyl rhodium(III) complexes bearing a dpmp ligand may be useful in the strategic synthesis of hetero-polynuclear compounds, where the cluster core could be tuned by the choice of the additional metal complex.

Experimental Section

All procedures were carried out under a nitrogen atmosphere. Dichloromethane was distilled from CaH_2 and diethyl ether was distilled from $LiAlH_4$. Isocyanides,[18] $(Ph_2PCH_2)_2PPh$,[19] $[Cp^*RhCl_2]_2$,[20] and $[Cu(MeCN)_4](BF_4)$[21] were prepared according to the literature. Infrared and electronic absorption spectra were recorded on FT/IR-5300 and U-best30 instruments, respectively. NMR spectra were recorded on a JEOL JNM-ECL-400 spectrometer. ^1H NMR spectra were measured at 400 MHz and $^{31}P\{^1H\}$ NMR spectra were measured at 161 MHz using 85% H_3PO_4 as an external reference.

Preparation of [{Cp*RhCl$_2$(dpmp-*P,P,P*)Ag}$_2$](OTf) (4): A mixture of **1** (52.8 mg, 0.085 mmol), dpmp (107.5 mg, 0.212 mmol) and Ag(OTf) (61.4 mg, 0.239 mmol) was stirred in CH_2Cl_2 (15 mL) and acetone (10 mL) at room temperature. After 4 h the solvent was removed and the solids were washed with diethyl ether and the residue was extracted with CH_2Cl_2. The CH_2Cl_2 solution was concentrated, and diethyl ether was added to give reddish orange crystals (124.0 mg, 67.5%). UV/Vis (CH_2Cl_2): λ_{max} = 392 nm. ^1H NMR ($CDCl_3$): δ = 1.25 (d, $J_{H,P}$ = 3.5 Hz, Cp*), 1.90, 2.82, 3.13, 3.48 (m, CH_2), 5.32 (s, CH_2Cl_2), 6.8−8.2 (m, Ph). The $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 28.6 (J_{PRh} = 146, $J_{P,P}$ = 12.9 Hz, P1), 2.6 (m, the other P nuclei), −143.6 (sept, J_{PF} = 707.5 Hz, PF_6).

Preparation of [Cp*Rh(dpmp-*P,P,P*)](OTf)$_2$ (5): A mixture of **3** (50 mg, 0.054 mmol) and AgOTf (75.4 mg, 0.293 mmol) in CH_2Cl_2 (15 mL) and acetone (5 mL) was stirred at room temperature. After 3 h, the solvent was removed and the residue was extracted with CH_2Cl_2. The solution was concentrated and diethyl ether was added to form orange crystals (41.8 mg, 72.4%). IR (nujol): $\tilde{\nu}$ = 1255, 1153, 1028 cm^{-1} (OTf). UV/Vis (CH_2Cl_2): λ_{max} = 335, 270 nm. ^1H NMR [$(CD_3)_2CO$]: δ = 1.66 (q, J_{PH} = 4.5 Hz, Cp*, 15 H), 5.49 (c, CH_2, 4 H), 7.3−8.4 (c, Ph, 25 H). $^{31}P\{^1H\}$ NMR [$(CD_3)_2CO$]: δ = −18.2 (dt, J_{P1P2} = J_{P1Rh} = 97.2 Hz, P^1), −47.4 (q, J_{P2P1} = J_{P2Rh} = 97.2 Hz, P^2), −143.6 (sept, J_{PF} = 707.5 Hz, PF_6). $C_{44}H_{44}F_6O_6P_3RhS_2$ (1042.8): calcd. C 50.68, H 4.25; found C 50.99, H 4.38.

Preparation of [Cp*RhCl(dpmp-*P,P,P*)RuCl$_2$(*p*-cymene)](PF$_6$) (6)

(1) From 3(A) and [(*p*-Cymene)RuCl$_2$]$_2$: A mixture of **3(A)** (50.4 mg, 0.054 mmol) and [(*p*-cymene)$RuCl_2$]$_2$ (19.3 mg, 0.032 mmol) was stirred in CH_2Cl_2 (10 mL) at room temperature for 5 h. The solution was concentrated to ca. 3 mL and diethyl ether was added, affording the yellow complex **6(A)** (43.6 mg, 65.6%). UV/Vis (CH_2Cl_2): λ_{max} = 361 nm. IR (nujol): $\tilde{\nu}$ = 837 cm^{-1}. FAB MS: *m*/*z* = 1085 ($[M]^+$). ^1H NMR ($CDCl_3$): δ = 0.53 (d, $J_{H,H}$ = 7.0 Hz, *i*Pr, 3 H), 1.00 (d, $J_{H,H}$ = 7.0 Hz, *i*Pr, 3 H), 1.52 (t, $J_{H,H}$ = 3.5 Hz, Cp*, 15 H), 1.75 (s, *p*-Me, 3 H), 2.41 (sept, $J_{H,H}$ = 7.0 Hz, *i*Pr, 1 H), 4.06 (c, CH_2, 2 H), 3.72 (c, CH_2, 1 H), 4.92 (c, CH_2, 1 H), 5.33, 5.44 (AB system, $J_{H,H}$ = 6.0 Hz, *p*-cymene), 6.8−8.4 (m, ph, 25 H). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −12.0 (dt, $^1J_{RhP2}$ = $^2J_{P2P1}$ = 97.0, $^2J_{P2P3}$ = 55.5 Hz, P^2), −1.41 (t, $^1J_{P1Rh}$ = $^2J_{P1P2}$ = 97.0 Hz, P^1) and 23.7 (d, $^2J_{P3P2}$ = 55.5 Hz, P^3), −143.5 (sept, J_{PF} = 707.5 Hz, PF_6).

(2) Direct Reaction: A mixture of $[Cp^*RhCl_2]_2$ (50.0 mg, 0.081 mmol), [(*p*-cymene)$RuCl_2$]$_2$ (50.9 mg, 0.083 mmol), dpmp (94.4 mg, 0.186 mmol) and KPF_6 (43.1 mg, 0.234 mmol) was stirred in CH_2Cl_2 (10 mL) and acetone (10 mL) at room temperature. After 20 h, the solution was evaporated to dryness and the residue extracted with CH_2Cl_2. The CH_2Cl_2 solution was concentrated to ca. 2 mL and diethyl ether was added, affording orange crystals (45.8 mg, 52.1%). The crystals were mainly isolated as the diastereomer **6(B)** based on the NMR spectrum. The ratio of **6(A)** to **6(B)** was 1:2.

6(B): ^1H NMR ($CDCl_3$): δ = 0.52 (d, $J_{H,H}$ = 7.0 Hz, *i*Pr, 3 H), 1.05 (d, $J_{H,H}$ = 7.0 Hz, *i*Pr, 3 H), 1.73 (t, $J_{H,H}$ = 4.0 Hz, Cp*, 15 H), 1.80 (s, *p*-Me, 3 H), 2.33(sept, $J_{H,H}$ = 7.0 Hz, *i*Pr, 1 H), 2.69 (dt, $J_{H,H}$ = 16.0, J_{PH} = J_{PH} = 12.0 Hz, CH_2, 1 H), 3.67 (dt, $J_{H,H}$ = 16.0, J_{PH} = J_{PH} = 12.0 Hz, CH_2, 1 H), 4.01 (ddd, $J_{H,H}$ = 16.0, J_{PH} = 7.0, $J_{P'H}$ = 4.0 Hz, CH_2, 1 H), 4.30 (ddd, $J_{H,H}$ = 16.0, J_{PH} = 7.0, J_{PH} = 4.0 Hz, CH_2, 1 H), 4.68, 5.20 (AB system, $J_{H,H}$ = 5.5 Hz, *p*-cymene), 7.0−8.5 (m, ph, 25 H). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −13.8 (dt, $^1J_{RhP2}$ = $^2J_{P2P1}$ = 105, $^2J_{P2P3}$ = 55.0 Hz, P^2), −10.2 (t, $^1J_{P1Rh}$ = $^2J_{P1P2}$ = 109.0 Hz, P^1) and 26.6 (d, $^2J_{P3P2}$ = 55.0 Hz, P^3), −143.5 (sept, J_{PF} = 707.5 Hz, PF_6).

Preparation of [{Cp*Rh(μ-Cl)$_2$(dpmp-*P,P,P*)Cu}$_2$](PF$_6$)$_2$ (8)

(1) One-Pot Synthesis: A mixture of **1** (32.9 mg, 0.053 mmol), dpmp (60.8 mg, 0.12 mmol) and CuCl (56.1 mg, 0.175 mmol) was stirred in CH_2Cl_2 (5 mL) and acetone (5 mL) for 24 h. The solvent was then removed and the residue extracted with CH_2Cl_2. The solution was concentrated to ca. 3 mL and diethyl ether was added, affording red crystals (47.6 mg, 43.7%).

(2) From 3: Complex **8** (16.9%) was prepared from **3(A)** and CuCl. UV/Vis (CH_2Cl_2): λ_{max} = 387, 235 nm. IR (nujol): $\tilde{\nu}$ = 835 cm^{-1}.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

^{1}H NMR (CD_2Cl_2): δ = 1.10 (d, $J_{H,P}$ = 3.5 Hz), 1.26 (d, J_{PH} = 3.5 Hz, Cp*), 2.1−3.3 (m, CH_2), 6.9−8.05 (c, Ph). $C_{84}H_{88}Cl_4Cu_2F_{12}P_8Rh_2$·1/2$CH_2Cl_2$ (2090.6): calcd. C 48.55, H 4.29; found C 48.52, H 4.25.

Preparation of [{Cp*Rh(μ-Cl)$_2$(dpmp-*P,P,P*)Cu}$_2$](BF$_4$)$_2$: The BF_4 anion complex (11.1%) was prepared from **1** (0.051 mmol), dpmp (0.011 mmol) and [Cu(MeCN)$_4$](BF_4) (0.13 mmol). The complex was established as a BF_4 anion analog of **8** by comparison with the ^{1}H NMR spectrum of **8**.

Preparation of [Cp*RhCl(dpmp=S)](PF$_6$) (9): A mixture of **3(A)** (50.9 mg, 0.055 mmol) and S_8 (7.8 mg, 0.030 mmol) was stirred in CH_2Cl_2 (5 mL) at room temperature. After 51 h, the solvent was removed under reduced pressure. After the residue was extracted with CH_2Cl_2, the solution was concentrated to ca. 2 mL, and diethyl ether was added, affording a yellow powder (16.7 mg, 31.7%). UV/Vis (CH_2Cl_2): λ_{max} = 359, 260 (sh) nm. IR (nujol): $\tilde{\nu}$ = 837 cm^{-1} (PF_6). FAB MS: *m*/*z* = 811 ([M]$^+$). ^{1}H NMR ($CDCl_3$): δ = 1.64 (t, $J_{H,P1}$ = J_{HP2} = 4.0 Hz, Cp*, 15 H), 4.3−4.9 (m, CH_2, 2 H), 6.8−8.1 (c, Ph, 25 H). ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 35.6 (d, J_{P3P2} = 31.5 Hz, P^3), 0.92 (dd, J_{P1Rh} = 114.0, J_{P1P2} = 94.0 Hz, P1), −15.5 (ddd, J_{RhP2} = 114.0, J_{P2P3} = 31.5, J_{P2P1} = 94.0 Hz, P2), −143.6 (sept, J_{PF} = 707.5 Hz, PF_6). $C_{42}H_{44}ClF_6P_4RhS$ (957.1): calcd. C 49.56, H 4.45; found C 49.71, H 4.53.

Preparation of [{Cp*RhCl}(dpmp-*P,P,P*){RhCl(XylNC)Cp*}](OTf)$_2$ (10): To a mixture of **3(A)** (50.6 mg, 0.045 mmol) and Ag(OTf) (27.4 mg, 0.167 mmol) in CH_2Cl_2 (10 mL) and acetone (5 mL) was added XylNC (13.9 mg, 0.107 mmol) at room temperature. After the reaction mixture was stirred for 24 h usual workup of the mixture gave orange crystals of **10** (35.2 mg, 52.3%). IR (nujol): $\tilde{\nu}$ = 2168 cm^{-1} (N≡C). UV/Vis (CH_2Cl_2): λ_{max} = 342 nm. ^{1}H NMR ($CDCl_3$): δ = 1.48 (t, J_{PH} = 4.0 Hz, Cp*, 15 H), 1.56 (d, $^2J_{PH}$ = 3.8 Hz, Cp*, 15 H), 2.00 (s, *o*-Me, 6 H), 4.10 (m, CH_2, 1 H), 4.51 (m, CH_2, 1 H), 4.90 (m, CH_2, 2 H), 6.8−8.0 (c, 25 H). ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 28.6 (dd, $^1J_{RhP3}$ = 122.2, $^2J_{P3P2}$ = 50.1 Hz, Rh(CNR)−P, P^3), −2.76 (dd, $^1J_{RhP1}$ = 113.1, $^2J_{P2P1}$ = 98.0 Hz, RhCl−P, P^1), −15.3 (ddd, $^1J_{RhP2}$ = 111.1, $^2J_{P2P1}$ = 98.0, $^2J_{P2P3}$ = 50.1 Hz, RhCl−P, P^2). $C_{63}H_{68}Cl_2F_6NO_6P_3Rh_2S_2$ (1483.0): calcd. C 50.02, H 4.62, N 0.94; found C 50.11, H 4.71, N 1.13.

Preparation of [(Cp*RhCl)(dpmp-*P,P*)]Cl (A): A mixture of [Cp*$RhCl_2$]$_2$ (30.5 mg, 0.049 mmol) and dpmp (55.2 mg, 0.109 mmol) in CH_2Cl_2 (10 mL) was stirred at room temperature for 24 h. After the removal of the solvent, the residue was washed with diethyl ether and crystallized from CH_2Cl_2 and diethyl ether to give orange crystals (28.8 mg, 36.0%). FAB MS: *m*/*z* = 780 [M$^+$]. UV/Vis (CH_2Cl_2): λ_{max} = 356, ca. 270 (sh) nm. ^{1}H NMR ($CDCl_3$): δ = 1.81 (t, *J* = 3.8 Hz, Cp*, 15 H), 3.47 (m, CH_2, 2 H), 4.24 (m, CH_2, 1 H), 5.30 (s, CH_2Cl_2), 5.49 (m, CH_2, 1 H), 7.0−7.7 (c, 25 H). ^{31}P{^{1}H} NMR ($CDCl_3$): δ = −5.10 ppm (dd, J_{P3Rh} = 115.6, J_{P2P3} = 99.0 Hz, RhCl−P, P^3), −11.0 (ddd, J_{P2Rh} = 114.1, J_{P2P3} = 99.0, J_{P2P1} = 46.5 Hz, RhCl−P, P^2), −29.4 (d, J_{P1P2} = 46.5 Hz, CH_2P, P^1). $C_{42}H_{44}Cl_2P_3Rh$·3/4CH_2Cl_2 (879.2): calcd. C 58.40, H 5.22; found C 58.03, H 5.47. The structure is assumed to be similar to that of **3(B)**, based on the ^{1}H NMR spectrum.

Reaction of 2(A) with Xylyl Isocyanide: A mixture of **2(A)** (50 mg, 0.041 mmol) and xylyl isocyanide (26.9 mg, 0.205 mmol) was heated to reflux in acetone (15 mL). After 5 h, the solvent was removed and the residue was extracted with CH_2Cl_2. The solution was concentrated and diethyl ether was added, affording a dark brown solid of [Cp*$RhCl_2$(XylNC)] (30 mg, 78%). Workup of the mother liquor gave **3(A)** (10.3 mg, 57.2%).

X-ray Data Collection: All complexes were recrystallized from CH_2Cl_2/diethyl ether. The cell constants for **5** were determined from 20 reflections on a Rigaku four-circle automated diffractometer AFC5S. Data collection was carried out using a Rigaku AFC5S diffractometer. Intensities were measured by the 2θ−ω scan method using Mo-K_α radiation (λ = 0.71069).

Table 4. [{Cp*$RhCl_2$(dpmp-*P,P,P*)Ag}$_2$](OTf)$_2$·H_2O (**4**·H_2O), [Cp*Rh(dpmp-*P,P,P*)](OTf)$_2$ (**5**), and [{Cp*$RhCl_2$(dpmp-*P,P,P*)-Cu}$_2$](OTf)$_2$·2CH_2Cl_2 (**8**)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Throughout the data collection the intensities of the three standard reflections were measured after every 200 reflections as a check of the stability of the crystals and no decay was observed. Absorption corrections were made using the ψ scan methods.

The measurements for **4**·H_2O and **8**·$2CH_2Cl_2$ were made on an MSC/ADSC Quantum CCD/Rigaku AFC7 diffractometer, using Mo-K_α radiation at 0 °C under a cold nitrogen stream. Four preliminary data frames were measured at 0.5° increments of ω in order to assess the crystal quality and preliminary unit cell parameters were calculated. The cell parameters were refined using all reflections measured in the range $2.8° < 2\theta < 40°$. The intensity images were measured at 0.5° intervals of ω for a duration of 20 s. The frame data were integrated using the d*TREK program package, and the data sets were corrected for absorption using the REQAB program.

The crystal parameters along with the details of the data collections are summarized in Table 4. Intensities were corrected for Lorentz and polarization effects. Atomic scattering factors were taken from the usual tabulation of Cromer and Waber.[22] Anomalous dispersion effects were included in F_{calcd};[23] the values of $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley.[24] All calculations were performed using the teXsan crystallographic software package.[25]

Determination of the Structures: All complexes were solved by direct methods (SIR92) except **7** which was solved by Patterson methods (DIRDIF94 PATTY) . The non-hydrogen atoms of all complexes were refined anisotropically using full-matrix least-squares based on F^2 or F values. All hydrogen atoms were calculated in ideal positions with a C−H distance of 0.95 Å. The crystal data are listed in Table 4.

CCDC-190355 for **4**·H_2O, -213525 for **5** and -190357 for **8**·$2CH_2Cl_2$ contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The authors would like to thank Professor Shigetoshi Takahashi and Dr Fumie Takei of The Institute of Scientific and Industrial Research, Osaka University for performing the FAB mass spectrometry measurements. This work was partially supported by a Grant-in Aid for Scientific Research from the Ministry of Education, Science, Culture and Sports, Japan.

A Theoretical Study of the Exchange Coupling in Hydroxo- and Alkoxo-Bridged Dinuclear Oxovanadium(IV) Compounds

Antonio Rodríguez-Fortea,*[a,c] Pere Alemany,[b,c] Santiago Alvarez,[a,c] and Eliseo Ruiz[a,c]

Keywords: Exchange coupling / Density functional calculations / Magnetic properties / Magneto-structural correlations / Vanadium

A density functional study of exchange coupling in hydroxo- and alkoxo-bridged dinuclear oxovanadium(IV) compounds is presented. Coupling constants calculated for full unmodeled structures are in good agreement with experimentally reported values, confirming the ability of the computational strategy used in this work to predict the exchange coupling in dinuclear V^{IV} compounds. The influence of the configuration of the $[VO(\mu\text{-}OR)_2VO]^{2+}$ core in compounds with two edge-sharing octahedrally coordinated oxovanadium(IV) centers, of the nature of the terminal ligands and of structural distortions on the coupling constant have been analyzed through model calculations. The results indicate that the coupling constant is less affected by these factors than for hydroxo- and alkoxo-bridged Cu^{II} compounds. The calculations support the orbital models usually employed in qualitative interpretations of magneto-structural correlations, showing good correlations between the calculated coupling constants and the overlap between the two magnetic orbitals or the square of the orbital gap.

Introduction

The phenomenon of exchange coupling between the spins of unpaired electrons located at different metal atoms in polynuclear complexes leads to magnetic behaviors that differ completely from the one predicted for independent paramagnetic entities. Antiferromagnetic coupling results when the ground state presents an antiparallel alignment of the spins, whereas ferromagnetic coupling is a consequence of the alignment of the electron spins in a parallel manner. Since the discovery of intramolecular antiferromagnetic coupling in copper(II) acetate monohydrate in 1951,[1] much experimental and theoretical work has been carried out to elucidate the mechanism of exchange coupling in polynuclear complexes. This work has led to the now well-established field of molecular magnetism, that is, the synthesis and the study of the magnetic properties of materials based on molecular entities.[2−7]

Dinuclear systems have been the most studied compounds because of their relative simplicity, especially the family of Cu^{II} compounds. This ion, with a d^9 electronic configuration, presents only one unpaired electron per metal atom, and is therefore the simplest case for the analysis of magnetic properties. A large number of compounds with different bridges have been studied and interesting relationships between the magnetic properties and the structural parameters of the bridge have been established, especially for dihydroxo-bridged compounds.[8−12] Such magneto-structural correlations are very useful for predicting magnetic properties of new compounds.

Vanadium(IV) dinuclear complexes constitute another interesting family of compounds for the study of intramolecular exchange coupling since the electronic configuration of V^{IV} is d^1, thus having one unpaired electron per metal center as in Cu^{II} compounds. A considerable number of oxovanadium(IV) dimers have been characterized, since they play an important role in biological processes[13−21] and are also relevant in solid-state chemistry,[22−28] but the established magneto-structural correlations are much fewer than for dinuclear Cu^{II} complexes.

The main difference between the Cu^{II} and V^{IV} cations is in the orbitals in which the unpaired electron is placed. In octahedral or square-planar Cu^{II} systems the unpaired electron is occupying an orbital of the e_g set, with a large contribution of the $d_{x^2-y^2}$ metal orbital, whereas for V^{IV} the only occupied orbital is of t_{2g} symmetry, mainly a d_{xy} metal orbital, if the ligands are placed along the x and y axis and the oxygen atom of the vanadyl group along the z axis. As a consequence, the exchange mechanism in dinuclear Cu^{II} and in dinuclear V^{IV} compounds is expected to be different,

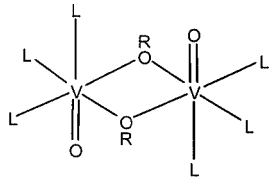
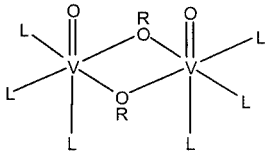
since the $d_{x^2-y^2}$ metal orbital is pointing directly towards the orbitals of the bridging ligands, thus favoring a superexchange mechanism, whereas the d_{xy} metal orbital does not point to orbital ligands, but to the other d_{xy} metal orbital, leading to direct σ overlap between them and resulting in a direct through-space exchange mechanism, as suggested by Ginsberg[29] and other authors.[16,30−33]

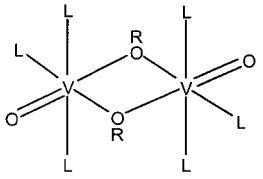
The aforementioned direct exchange mechanism is, however, not effective in all dinuclear V^{IV} compounds, since specific geometric arrangements exist in which a direct overlap between the orbitals that bear the unpaired electron (the so called magnetic orbitals) is not possible. A useful classification of the geometries of the $[VO(\mu\text{-}OR)_2VO]^{2+}$ cores in compounds built from two edge-sharing octahedrally coordinated oxovanadium(IV) centers has been given by Plass.[34] The arrangements are classified (i) according to the orientation of the V=O groups with respect to the bridging plane, that is the plane formed by the two vanadium centers and the two oxo bridging atoms (orthogonal, coplanar or twisted), and (ii) the relative orientation of the two V=O groups (*syn* or *anti*), as shown in **1**−**5**.



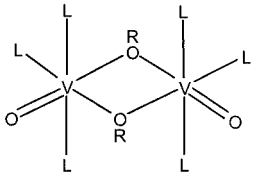
anti-orthogonal (**1**)



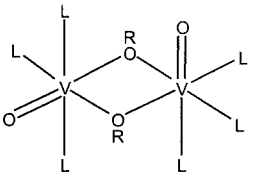
syn-orthogonal (**2**)



anti-coplanar (**3**)



syn-coplanar (**4**)



twisted (**5**)

Many dinuclear V^{IV} complexes have been reported in the two orthogonal[17,32,33,35−38] and the *anti*-coplanar configurations,[34,39−44] but the *syn*-coplanar[44,45] and the twisted arrangements[34,44] are not so frequent. There are also dinuclear V^{IV} complexes in which the metallic centers are five-coordinate in a square-pyramidal environment with the apical position occupied by the oxo group. In such a family of compounds, the classification of Plass can also be applied, the orthogonal geometries being the only possible ones.[16,20,36]

As far as the nature of the exchange coupling is concerned, it has been found that compounds with *anti*-orthogonal, *syn*-orthogonal or *syn*-coplanar configurations (**1**, **2** and **4**) present strong to moderate antiferromagnetic coupling, whereas compounds with *anti*-coplanar and twisted arrangements (**3** and **5**) show weak ferromagnetic coupling (Table 1). These experimental results have been interpreted in a qualitative way regarding the interaction between the magnetic orbitals of each center:[34] for the orthogonal configurations the direct (through-space) exchange mechanism is more effective than the superexchange pathway, and is the predominant mechanism of the exchange interaction. For *syn*-coplanar compounds, the direct exchange mechanism is not as effective as in orthogonal configurations and antiferromagnetic coupling can be qualitatively justified by considering the superexchange mechanism to be operative. For *anti*-coplanar and twisted configurations the situation is, however, different since neither mechanism seems to be effective in mediating the exchange interaction, resulting in a weak ferromagnetic coupling.[34]

Despite the large amount of experimental data for hydroxo- and alkoxo-bridged oxovanadium(IV) dinuclear complexes reported so far, theoretical studies of their magnetic properties are still rare.[34,46−49] Computation of exchange coupling constants for some structures within the density functional theory (DFT) framework has been reported by Plass, reproducing the nature of the coupling for *anti*-orthogonal (antiferromagnetic), *anti*-coplanar and twisted configurations (both ferromagnetic). Other DFT studies of the exchange interaction for hydroxo- and alkoxo-bridged oxovanadium(IV) dinuclear systems exist: (i) an analysis of the effects of the bridging V−O distance, the bridging V−O−V angle and the protonation of the bridging ligands on the coupling constant for a *syn*-coplanar core configuration,[47] and (ii) a study of the exchange interaction in the three phases of vanadyl pyrophosphate, by means of modelization with dinuclear molecular fragments.[48,49]

The aim of this contribution is to examine the exchange coupling phenomenon for hydroxo- and alkoxo-bridged oxovanadium(IV) dinuclear systems by applying a recently developed computational strategy that is able to quantitatively reproduce the coupling constants for a large variety of compounds with different bridging ligands and/or paramagnetic centers.[50−60] We will report first calculations of the exchange coupling constant for a variety of full nonmodeled structures to compare them directly with the experimental data. We will then extensively study the exchange coupling in hydroxo-bridged compounds by analyzing the influence of the $[VO(\mu\text{-}OH)_2VO]^{2+}$ core geometry on the coupling constant and studying magneto-structural correlations for distortions found in these systems. We will also study the effect of the nature of the terminal ligands on the coupling constant. Finally, we will analyze the effect that some of the aforementioned factors have on the coupling constant in the related alkoxo-bridged compounds.

[a] One metal ion is six-coordinate and the other one is five-coordinate. [b] The metal ions are five-coordinate. [c] The V−O−V, τ and σ angles are averages of the two different values found in each of these compounds. [d] The position of the H atoms has not been determined in the crystal structure. [e] The values for the structural parameters correspond to the bridge that is not in *trans* position with respect to the oxo ligand. [f] The σ angle is not defined for coplanar configurations. [g] Average of the two significantly different V−O−V (100.1 and 108.0°) and τ (44.1 and 13.8°) angles.

Computational Methodology

Since a detailed description of the computational strategy adopted in this work can be found elsewhere,[51,53,55,59] we will only briefly sketch its most relevant aspects here. Using a phenomenological Heisenberg Hamiltonian $\hat{H} = -J\hat{S}_1 \bullet \hat{S}_2$ to describe the exchange coupling in a dinuclear compound, where J is the coupling constant, and S_1 and S_2 the local spins on centers 1 and 2, respectively, the coupling constant J can be related to the energy difference between states with different spin multiplicity. For the case in which $S_1 = S_2$, the coupling constant may be obtained by using Equation (1), where E_{HS} is the energy of the state with the highest total spin, E_{LS} that of the lowest total spin state ($S = 0$ when $S_1 = S_2$), and S_i are the local spins on each metal atom.

$$E_{HS} - E_{LS} = -2JS_i(S_i + 1/2) \quad (1)$$

It has been found that, when using DFT-based wavefunctions, a reasonable estimate of the energy corresponding to the low spin state, E_{LS}, can be obtained directly from the energy of a broken-symmetry solution, E_{BS}.[53,61] In this case, introducing $S_i = 1/2$ in Equation (1), we arrive at the following expression for J:

$$J \approx E_{BS} - E_{HS} \quad (2)$$

Experience has shown that the use of this equation leads to a good agreement with experimental data for a large variety of compounds with exchange-coupled electrons.[50−60] The inclusion of an unspecified amount of non-dynamic correlation energy in the broken symmetry solution by means of the commonly used functionals is probably responsible for such a good agreement, as pointed out recently by Polo et al.[62]

The hybrid, DFT-based B3LYP method[63] has been used in all calculations as implemented in Gaussian-98,[64] mixing the exact Hartree−Fock exchange with Becke's expression for the exchange functional[65] and using the Lee−Yang−Parr correlation functional.[66] Double-ζ quality basis sets[67] have been employed for all atoms except for the metal ones, for which a triple-ζ basis set[68] with two extra *p* orbitals (polarization functions) has been used. Due to the small magnitude of the exchange coupling constants all energy calculations must be performed including the *SCF=Tight* option of Gaussian to ensure sufficiently well converged values for the state energies.

Results and Discussion

1. Calculations for Full Structures: In order to check the accuracy of the computational procedure employed in this work for the family of hydroxo- and alkoxo-bridged dinuclear V^{IV} complexes, we have performed calculations for several full non-modeled structures with hydroxo and alkoxo bridging ligands in which the metal atom presents distorted square-pyramidal or octahedral coordination environments (Figure 1). We note that the experimental magnetic susceptibility used to obtain the coupling constant is measured from solid samples in which packing forces can induce small deviations from the minimum energy geometry of the individual molecules. In order to be able to compare our computed coupling constants for full structures, we have used in our calculations the molecular structure as determined experimentally by X-ray diffraction rather than an optimized one, in which small changes with respect to the experimental structure could result in significant deviations of the calculated coupling constant.

The results (Table 2) show that there is a fair agreement between calculated and experimental coupling constants, reproducing the sign of the coupling constant in all cases, but obtaining rougher estimations than for other systems studied previously.[55] However, considering that the coupling constants are obtained as energy differences that are

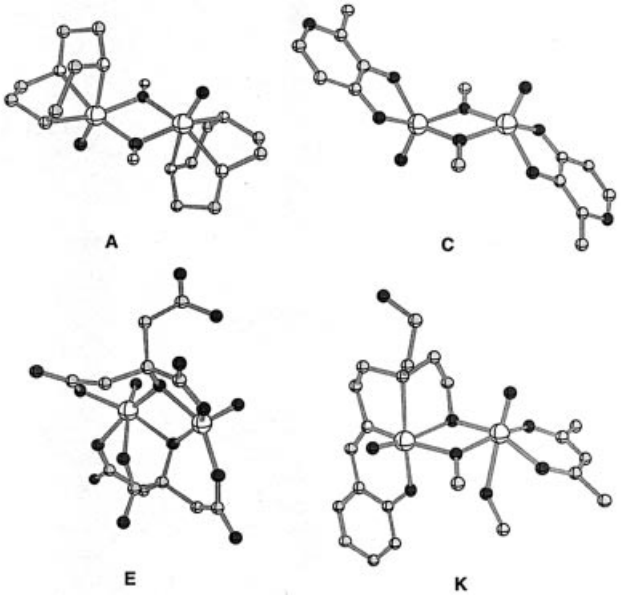

Figure 1. Crystal structures of hydroxo- and alkoxo-bridged dinuclear V^{IV} compounds whose coupling constants have been computed; large white spheres represent V atoms, medium white spheres N atoms, small white spheres H atoms, grey spheres C atoms, and dark spheres O atoms; H atoms of terminal ligands have been omitted for clarity; the labels **A**, **C**, **E** and **K** refer to Entries in Tables 1 and 2

calculated from total energy values eight or nine orders of magnitude larger, these deviations can be considered as acceptable.

2. Exchange Coupling in μ-Hydroxo Compounds: After verifying the agreement between calculated and experimental values of *J* for full non-modeled structures, we study now the effects of different factors on the coupling constant by performing calculations on a model system. In this model system, the terminal ligands present in experimental structures have been replaced by ammonia molecules (L = NH_3) and idealized structures have been considered. The bond lengths and angles used in the model system are averages of experimental values (see the Appendix). First of all, we analyze the dependence of the exchange coupling on the configuration of the $[VO(\mu\text{-}OH)_2VO]^{2+}$ core (**1**−**5**), studying then some magneto-structural correlations for distortions found in this family of compounds. Finally, we have looked at the influence of the terminal ligands on the coupling constant as well.

(a) Influence of the Configurations of the $[VO(\mu\text{-}OH)_2VO]^{2+}$ Core on the Exchange Coupling: Five different configurations of the $[VO(\mu\text{-}OH)_2VO]^{2+}$ core in complexes consisting of two edge-sharing octahedrally coordinated V^{IV} centers have been experimentally characterized (**1**−**5**). All the structural parameters are kept the same in the five models in order to study which is the effect of the core

configuration on the coupling constant. For each core configuration the V−O−V bridging angle has been varied between 100 and 108°. The calculated coupling constant *J*, together with the overlap between the broken-symmetry occupied magnetic spin orbitals (BS-OMSOs)[69] S_{ab} and the relative energy of each configuration, are shown in Table 3.

In the orthogonal configurations (**1** and **2**), the calculated coupling constant experiences a significant variation with the V−O−V angle (more than 200 cm^{-1}), becoming more negative — enhanced antiferromagnetic coupling — for smaller values of the V−O−V bridging angle and correspondingly shorter V···V distances. The calculated values for configurations **1** and **2** are very similar, showing the small influence on the coupling constant of the orientation of the V=O groups in orthogonal configurations. These effects can be understood considering that the orbital that bears the unpaired electron is on the basal plane of the axially distorted octahedron, and its mixing with the orbitals of the ligands in the apical positions is very small for symmetry reasons. It is worth noting that the coupling constant for a model compound consisting of two edge-sharing square-pyramidally coordinated V^{IV} centers in an *anti*-orthogonal configuration with a V−O−V angle of 104° is −19.7 cm^{-1}, a value that is also in agreement with such an orbital explanation.

On the other hand, there is a much smaller variation of the coupling constant (about 50 cm^{-1}) in the model with *syn*-coplanar configuration (**4**) when the V−O−V angle is varied. Moreover, the angular dependence is opposite to that presented by orthogonal configurations, **1** and **2**, since in **4** the antiferromagnetic coupling decreases when the V−O−V angle becomes smaller. These results are consistent with the existence of different exchange mechanisms between the unpaired electrons located at the metal centers in the orthogonal and the *syn*-coplanar configurations, as suggested previously by other authors.[16,29,31−34,46] The predominant mechanism in orthogonal configurations (**1** and **2**) is direct through-space exchange, because of the important σ overlap between the d_{xy} metal orbitals (Figure 2, a) that becomes larger when the V−O−V angle and the V···V distance decrease. On the other hand, in the *syn*-coplanar configuration (**4**), the direct exchange is not so effective because the overlap between the metal orbitals that bear the unpaired electron is poor due to their relative orientation. In this case, the superexchange mechanism becomes more important since the orbitals of the bridging ligand overlap with the metal orbitals (Figure 2, b). Finally, in the *anti*-coplanar (**3**) and twisted configurations (**5**) the coupling constant is relatively small regardless of the V−O−V angle considered, showing that neither a direct exchange nor a superexchange pathway are important. It is interesting to note, though, that a weak ferromagnetic coupling is predicted for the *anti*-coplanar configuration **3**, whereas for the twisted configuration **5** weak antiferromagnetic coupling is calculated. The expectation of antiferromagnetic coupling contrasts with the experimental finding of ferromagnetic behavior for the twisted configuration **5**.[34,46] In our results we see that although the overlap between BS-OMSOs is small in the twisted configuration, it is non-zero (i.e. the orbitals are not strictly orthogonal), and the antiferromagnetic contribution to the coupling constant is larger than the ferromagnetic one, obtaining as a result a weak antiferromagnetic coupling. This result is, however, consistent with the experimental data because we use an undistorted model structure in our calculations. Distortions of the structure or the effect of terminal ligands can be at the origin of the ferromagnetic behavior shown by compound **K**,[34] whose experimental coupling constant is also well reproduced by our computational method, as shown above (Table 2).

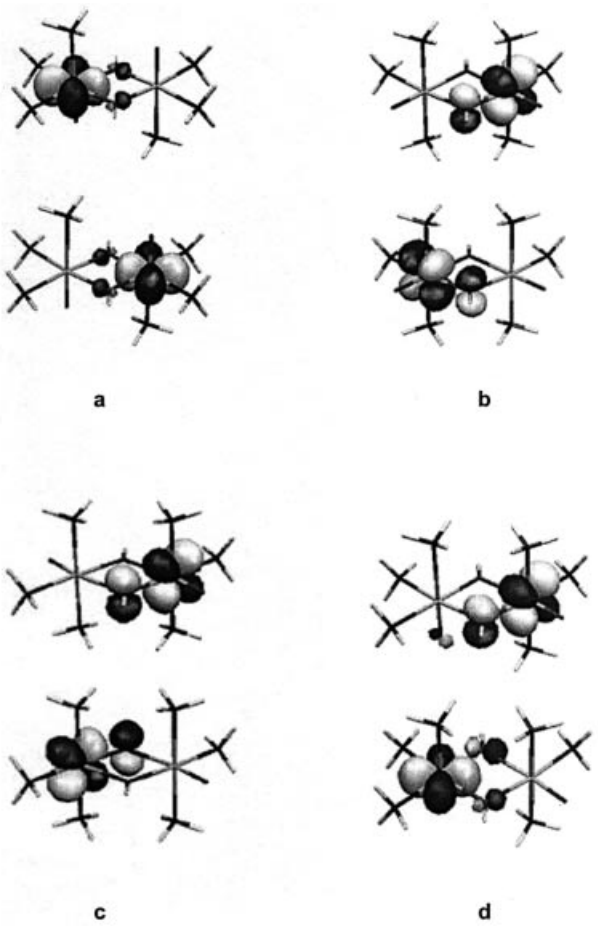

Figure 2. Computed magnetic orbitals (BS-OMSOs) for the *anti*-orthogonal (a), *syn*-coplanar (b), *anti*-coplanar (c) and twisted (d) $[VO(\mu\text{-}OH)_2VO]^{2+}$ core configurations

Together with the topology of the BS-OMSOs, two additional results support the prevalence of a direct exchange mechanism in orthogonal configurations and of a superexchange mechanism in the coplanar ones. First, a correlation between the type of core arrangement and the V···V distance exists in experimental hydroxo- and alkoxo-bridged oxovanadium(IV) dinuclear compounds: orthogonal configurations present V···V distances up to 3.20 Å, whereas in coplanar and twisted configurations the distance is larger (up to 3.45 Å), hinting to the existence of a through-space interaction in orthogonal configurations that keeps the two

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

metal atoms closer than in the coplanar ones. The other result is related to the sign of the spin population in the high-spin state: in the *syn*-coplanar configuration the spin density at the oxygen atom of the only effective bridge presents the same sign as in the vanadium atoms, showing that the delocalization of the spin density is more important than the spin polarization mechanism and confirming the primacy of superexchange over the direct exchange mechanism in that core configuration. On the other hand, spin polarization predominates at the oxygen atoms of the bridge in orthogonal configurations showing that delocalization through the bridging atoms (i.e. superexchange) is not so effective in this case.

From Table 3 (last column, $E_{rel.}$), it can also be seen that the type of distortion considered here is possible from the energetic point of view for each of the five configurations studied, since only a few kcal/mol are needed to produce such a distortion. This result is in good agreement with the fact that the experimental structures of hydroxo- and alkoxo-bridged six-coordinate oxovanadium(IV) dinuclear compounds present values for the V−O−V angle over a wide range (Table 1). It is also important to note that the minimum energy for each of the configurations corresponds to a V−O−V angle of 108°, except for the orthogonal configurations in which the minimum energy corresponds to smaller angles.

The dependence of the coupling constant on the core configuration can be rationalized within the framework of the qualitative model proposed by Kahn and coworkers[3,70−76] that results in an expression for the coupling constant dependent on the overlap between non-orthogonal localized magnetic orbitals [Equation (3)].

$$J \approx 2K_{ab} + 4\beta S_{ab} \quad (3)$$

Here K_{ab} is the exchange integral involving non-orthogonal magnetic orbitals *a* and *b*, β the transfer integral and S_{ab} the overlap between the magnetic orbitals as well. The first term in Equation (3) ($2K_{ab}$) is positive and can be interpreted as a ferromagnetic contribution (J_F) to the exchange coupling constant, responsible for the stability of the triplet state, whereas the second one ($4\beta S_{ab}$) is negative and represents an antiferromagnetic term (J_{AF}) favoring the singlet state. Since within the Wolfsberg−Helmholtz approximation the transfer integral is proportional to the overlap, $\beta \propto S_{ab}$, then the antiferromagnetic contribution to the coupling constant should be proportional to the square of the overlap between magnetic orbitals, $J_{AF} \propto S_{ab}^2$.

Although Equation (3) has been obtained within the framework of the wave function based theory, it has been shown that Kohn−Shan orbitals obtained from density functional calculations are physically sound and suitable for qualitative molecular orbital theory.[77,78] In Figure 3, the values of the coupling constant corresponding to the five core configurations and three different V···V distances (Table 2) are plotted as a function of the square of the overlap between the broken-symmetry occupied magnetic spin-orbitals (BS-OMSOs).[69] We have used BS-OMSOs because they are the most suitable orbitals to represent the so-called *magnetic orbitals* for d^1 centers, since they form a non-orthogonal basis set (a must in Kahn and Briat's model) and are very similar to the localized natural orbitals as well.[79,80] From the linear fittings in Figure 3 we can find estimates for the value of the exchange integral K_{ab} by comparison with Equation (3). The estimated K_{ab} values for the five core configurations are +18.1, +15.1, +4.7, −6.9 and +1.8 cm^{-1} for the *anti*-orthogonal, *syn*-orthogonal, *anti*-coplanar, *syn*-coplanar and twisted configurations (**1**−**5**), respectively. These values are rather small compared to that found for hydroxo-bridged dinuclear Cu^{II} compounds (+412 cm^{-1}),[51] showing the low ability of hydroxo-bridged dinuclear oxovanadium(IV) compounds to propagate ferromagnetic interactions. It should be noted that although the predicted K_{ab} sign for the *syn*-coplanar configuration is wrong (−6.9 cm^{-1}, whereas K_{ab} must be positive), its value is very small, thus indicating that it must also be a small positive value as has been found for the other configurations.

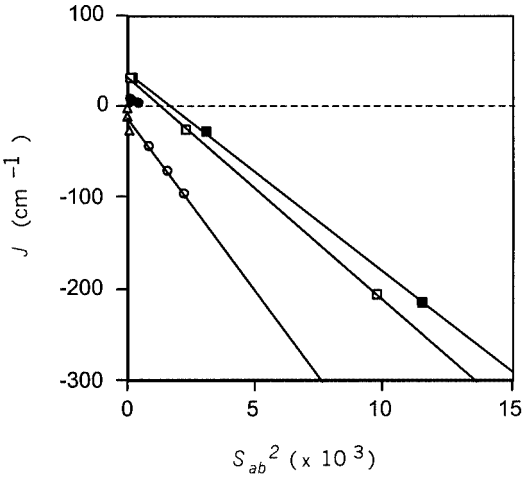

Figure 3. Dependence of the coupling constant *J* on the square of the overlap integral S_{ab}^2 (×1000) between BS-OMSOs for the different $[VO(\mu\text{-}OH)_2VO]^{2+}$ core configurations (three different V···V distances have been considered for each configuration): *anti*-orthogonal (**1**, solid squares), *syn*-orthogonal (**2**, squares), *anti*-coplanar (**3**, solid circles), *syn*-coplanar (**4**, circles) and twisted (**5**, triangles); linear fittings for the *anti*-coplanar and twisted configurations have been omitted for clarity

(b) Magnetostructural Correlations: The experimental structures for hydroxo- and alkoxo-bridged dinuclear oxovanadium(IV) compounds often deviate from the idealized geometries adopted in our model compounds. In this section we analyze the effect of the most common distortions on the coupling constant.

Effect of the V−O−V Bridging Angle (or the V···V Distance): We have studied exhaustively the dependence of the coupling constant on the V−O−V angle (or what is the same, on the V···V distance, since the V−O distance has been kept frozen), but in this section we consider only the orthogonal configurations **1** and **2**. We have checked that the variation of *J* with the V−O−V angle for each of the orthogonal configurations is almost identical, in good

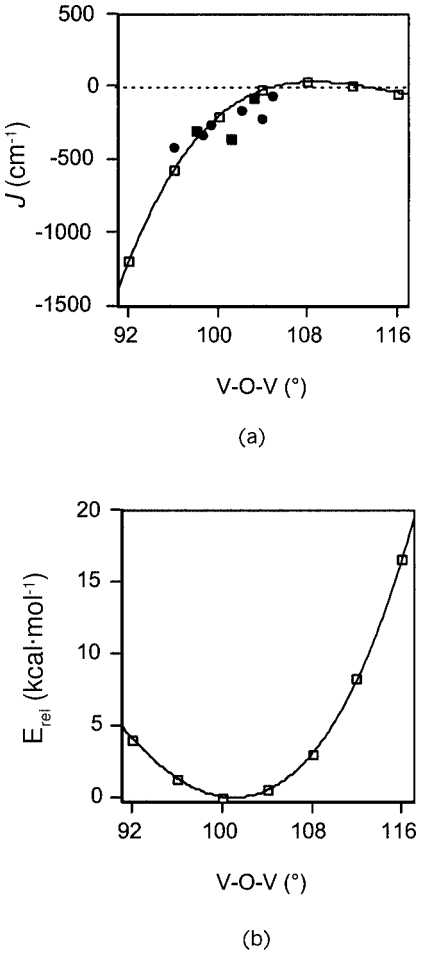

Figure 4. (a) Dependence of the calculated coupling constant J (solid line) on the bridging V−O−V angle for the model compound with an *anti*-orthogonal core configuration (**1**); black squares and circles correspond to experimental values for hydroxo- and alkoxo-bridged compounds, respectively; (b) relative energy of the ground state as a function of the V−O−V bridging angle

agreement with the simple two electrons—two orbitals approximation. In Figure 4 the results corresponding to the *anti*-orthogonal configuration are presented. From Figure 4 (a) it can be seen that strong antiferromagnetic coupling appears at small V−O−V angles (i.e. short V···V distances), as a consequence of the increased through-space overlap between the metal orbitals. This strong antiferromagnetic coupling drops sharply and becomes weakly ferromagnetic at V−O−V angles between 104° and 110° (i.e. V···V distances between 3.12 and 3.20 Å) reaching a maximum at about 108° (3.20 Å). The ferromagnetic coupling appears at much larger V−O−V angles than in the case of hydroxo-bridged dinuclear copper(II) compounds (at about 98°).[9,51] The experimental values of the coupling constant for hydroxo- and alkoxo-bridged compounds fit very well with our theoretical prediction (Figure 4a). As can be seen in Figure 4 (b), the minimum energy corresponds to the structure with a V−O−V angle of 100°. Structures with V−O−V angles ranging from 92° to 110° (V···V distances from 2.85 to 3.24 Å) are however possible (less than 5 kcal/mol), in good agreement with the fact that experimental structures present V···V distances within this range of values, as can be seen in Table 1 (configuration **1** and **2**).

The dependence of the coupling constant on the V−O−V angle for orthogonal configurations has also been analyzed by means of the qualitative model proposed by Hay, Thibeault and Hoffmann (HTH).[81] These authors obtained an approximate expression for the coupling constant of a homodinuclear complex with two unpaired electrons that predicts that the antiferromagnetic contribution to the coupling constant depends on the square of the orbital gap according to Equation (4), where K_{ab}, J_{aa}, and J_{ab} are the exchange and Coulomb integrals involving orthogonal localized orbitals a and b, and ε_1 and ε_2 are the energies of the two SOMOs of the complex.

$$E_S - E_T = J = 2K_{ab} - \frac{(\varepsilon_1 - \varepsilon_2)^2}{J_{aa} - J_{ab}} \quad (4)$$

A plot of J versus the square of the orbital gap for the *anti*-orthogonal configuration **1** is shown in Figure 5. It can be seen that the linear relation predicted by HTH holds for the hydroxo-bridged oxovanadium(IV) models studied here if the occupied magnetic spin orbitals (OMSOs)[69] are considered. An almost identical behavior is found when the *syn*-orthogonal configuration **2** is considered (not shown in Figure 5). The estimated values for K_{ab} are +13.9 and +14.7 cm^{-1} for **1** and **2**, respectively. These values are very similar to the ones predicted in Kahn and Briat's model for these core configurations (+18.1 and +15.1 cm^{-1} for **1** and **2**, respectively). Within the HTH model, it is also possible to estimate the value of $(J_{aa} - J_{ab})$ — 6.5×10^4 and 6.3×10^4 cm^{-1} for **1** and **2**, respectively — which are similar to that found for hydroxo-bridged dinuclear Cu^{II} compounds (7.2×10^4 cm^{-1}).[51,58]

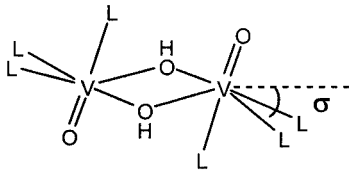
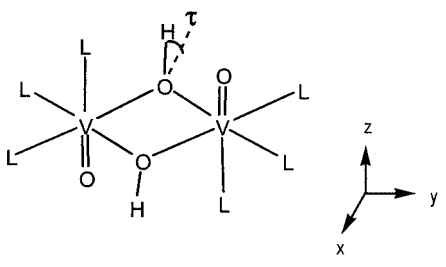
Effect of Bending of the Terminal Ligands: The experimental structures of some compounds with orthogonal core configurations are distorted with respect to the idealized model in the way shown in **6**.



6

To study the effect of the angle σ on the coupling constant, we have performed calculations using model compounds that present an *anti*-orthogonal core configuration (**1**), keeping other structural parameters constant (a value of 104° has been taken for the V−O−V bridging angle). An increase of the antiferromagnetic coupling constant is found when σ changes from 0° (−23.8 cm^{-1}) to 30° (−86.4 cm^{-1}). This result can be rationalized by means of the HTH model since an increase in the orbital gap between OMSOs appears when the structure is distorted in this way. It is also seen that the most stable structure corresponds to that with a σ angle between 10° and 20°, in good agreement with most of the experimental structures, which present values for the σ angle of approximately 20° (Table 1). It is, however, very difficult to check the accuracy of the theoretically predicted dependence of the coupling constant on σ because *J* also depends on other structural parameters (especially on the V−O−V angle or the equivalent V···V distance) that change significantly from one structure to another.

Effect of the Orientation of the Bridge: We have also studied the dependence of the coupling constant on the displacement of hydrogen atoms out of the V_2O_2 plane for structures with an *anti*-orthogonal configuration (**1**). This type of distortion, commonly found for this family of compounds, can be represented by the structural parameter τ (**7**). The other structural parameters have been kept constant (V−O−V = 104°). A change in the nature of the magnetic coupling is found at an angle of about 20° (Figure 6), reaching a maximum of $J \approx +60$ cm^{-1}, a small value in good agreement with the predictions of qualitative models. This type of distortion is energetically possible since less than 5 kcal/mol are required to reach a τ angle of 50°, in good agreement with experimental data, where it is possible to find τ angles ranging from about 0° to 40° (Table 1).



7

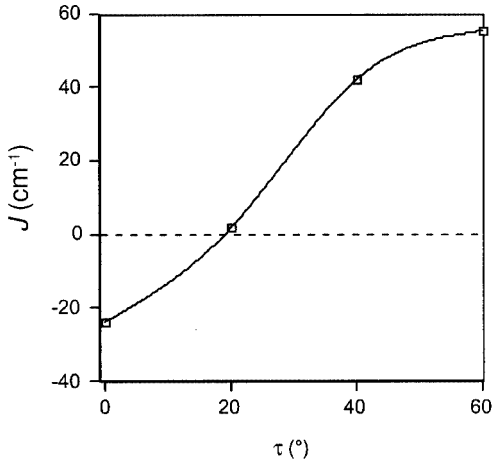


Figure 6. Dependence of the coupling constant *J* on the τ angle for the model compound with an *anti*-orthogonal core configuration (**7**)

(c) Influence of the Terminal Ligands on the Exchange Coupling Constant: The effect of changing the terminal ligands has been previously studied for several families of dinuclear Cu^{II} compounds.[50,57,59] To explain the observed shifts in the coupling constant, a detailed analysis of the magnetic orbitals for each particular case is needed and no general rules can be established.

We have studied this effect on the coupling constant of dinuclear oxovanadium(IV) compounds for two different core configurations, *anti*-orthogonal (**1**) and *syn*-coplanar (**4**). Ammonia (NH_3) and aqua (H_2O) terminal ligands have been used for the present analysis since most of the known experimental structures present N-donor and/or O-donor ligands. A value of 104° for the V−O−V angle has been employed in the model compounds. A rather small influence on the coupling constant is observed, the antiferromagnetic coupling decreasing in the *anti*-orthogonal configuration (from −23.8 to −10.0 cm^{-1}) and increasing in the *syn*-coplanar one (from −71.0 to −80.1 cm^{-1}) when ammonia is replaced by aqua ligands. This minute effect of the terminal ligands can be rationalized by the small contribution of the donor (N or O) atomic orbitals to the OMSOs: both ammonia and aqua ligands are σ-donor ligands whereas the metal orbitals that contribute to the OMSOs are of a π nature.

3. Exchange Coupling in μ-Alkoxo Compounds: Finally, we have also studied how the exchange coupling is affected by the replacement of the hydroxo bridges by alkoxo groups. We have modeled the alkoxo bridging ligands by methoxy groups (see Appendix), maintaining for the rest of the structural parameters the same values as those used in hydroxo-bridged models.

The results (Table 4) show that no significant differences appear when the hydroxo bridging ligands are replaced by methoxy groups, in contrast to the behavior found for dinuclear Cu^{II} compounds, in which an important enhancement of the antiferromagnetic coupling occurs.[51] The most

Table 4. Computed coupling constants, together with the relative energy of the antiferromagnetic state for methoxo-bridged model structures **1**−**5** (R = Me) presenting different V−O−V angles (and the related V···V distances)

Configuration	V−O−V (°)	V···V (Å)	J (cm^{-1})	$E_{rel.}$ (kcal/mol)
anti-Orthogonal (**1**)	100	3.03	−196	0.0
	104	3.12	−13.9	0.7
	108	3.20	+34.4	3.3
syn-Orthogonal (**2**)	100	3.03	−208	0.8
	104	3.12	−17.6	0.0
	108	3.20	+34.9	1.4
anti-Coplanar (**3**)	100	3.24	+8.8	4.9
	104	3.33	+11.4	1.2
	108	3.42	+12.0	0.0
syn-Coplanar (**4**)	100	3.03	−72.9	10.7
	104	3.12	−109	4.2
	108	3.20	−137	0.0
Twisted (**5**)	100	3.03	−24.0	5.1
	104	3.12	−11.3	1.6
	108	3.20	−4.1	0.0

notable changes, even though not very significant, correspond to structures with *syn*-coplanar configurations, which show a moderate increase in the antiferromagnetic coupling constant, and the *anti*-coplanar ones, in which a slight increase of the ferromagnetic coupling is found. In orthogonal configurations, the results are almost identical to those found for hydroxo-bridged systems (the experimental alkoxo-bridged compounds fit well in the predicted dependence of J on the V−O−V angle for hydroxo-bridged model compounds, Figure 4a). The coupling constant for a model compound consisting of two edge-sharing square-pyramidally coordinated V^{IV} centers in an *anti*-orthogonal configuration, with a V−O−V angle of 104°, has been predicted to be -7.5 cm^{-1}, a value that is also similar to that in hydroxo-bridged compounds (-19.7 cm^{-1}), if somewhat smaller. Consistently, no significant differences in the experimental coupling constants are found when replacing the bridging hydroxo by alkoxo groups, and the structural parameters that play an important role in the magnetic coupling of the complexes are not very different (Table 1).

The different behavior of dinuclear V^{IV} complexes compared to that of the Cu^{II} ones is related to the predominant mechanism of exchange interaction for each family of compounds. In Cu^{II} complexes superexchange is the main mechanism and, as a consequence, the larger the orbital delocalization through the bridging ligands, the stronger the antiferromagnetic coupling. This explains the considerable enhancement of antiferromagnetic coupling when hydroxo bridging ligands are replaced by methoxo ones.[51] For V^{IV} complexes with orthogonal core configurations, the direct through-space interaction between metal orbitals is the prevalent mechanism, thus making the nature of the bridging ligands much less important. For V^{IV} complexes with *syn*-coplanar configurations, superexchange is more important than in orthogonal configurations, but still much less than in Cu^{II} complexes, thus having an intermediate behavior: a moderate enhancement of the antiferromagnetic coupling when the hydroxo bridging ligands are replaced by alkoxo ligands.

As far as the energetic cost of the V−O−V angle distortion is concerned, we obtain similar results to those found for hydroxo-bridged compounds (Table 4): (i) a few kcal/mol are needed to perform such a distortion, and (ii) the minimum energy structures present smaller V−O−V angles for orthogonal configurations **1** and **2**.

The magneto-structural correlation for the distortion corresponding to a displacement of the R group of the alkoxo bridges out of the bridging plane (**7**) has also been studied for a model structure with an *anti*-orthogonal core configuration (with an V−O−V angle of 104°). An almost identical behavior as for hydroxo-bridged compounds has been found: a change in the nature of the coupling, becoming ferromagnetic at a τ angle of about 10° and reaching a maximum of $+56$ cm^{-1} at $\tau = 40°$. It has been seen that this type of distortion is energetically possible as well: the most stable structures are the ones with τ angles about 20°, and less than 7 kcal/mol are needed to reach τ values of 40°.

Conclusions

The present contribution confirms that the computational strategy — based on density functional theory — employed to investigate the exchange coupling in hydroxo- and alkoxo-bridged dinuclear oxovanadium(IV) compounds provides fair estimates of their experimental coupling constants. With its moderate demand for computer time, it also permits us to investigate separately the effect on the coupling constant of the different types of core arrangements that exist in $[VO(\mu\text{-}OH)_2VO]^{2+}$ compounds, as well as the influence of the nature of terminal and bridging ligands and the magneto-structural correlations corresponding to the most common distortions for this family of compounds. The results confirm that different exchange mechanisms predominate in orthogonal (through-space mechanism) and coplanar configurations (superexchange mechanism). This is a consequence of the dissimilar topology of the OMSOs in each geometrical configuration. Qualitative orbital models (Kahn−Briat and Hay−Thibeault−Hoffmann) are seen to be useful in analyzing the results, giving estimates for the ferromagnetic contribution to the exchange coupling in this family of compounds. A minute influence of the nature of the terminal ligand on the coupling constant has been found, a consequence of the σ-donor character of N- and O-donor ligands considered, opposed to the π nature of the interacting electrons.

Regarding the magneto-structural correlations, a very strong antiferromagnetic coupling is found for structures that present short V···V distances when orthogonal configurations are considered, a result related to the important overlap between BS-OMSOs in such configurations. Another interesting finding is the small effect of the displacement of the hydrogen atom of the bridge out of the plane on the coupling constant, that induces a change in the nat-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ure of the coupling (from antiferromagnetic to ferromagnetic), but that is not as important as in the case of hydroxo-bridged dinuclear Cu^{II} compounds. Finally, it is worth mentioning that important changes in the coupling are not found when the hydroxo bridging ligands are replaced by alkoxo groups, a result that differs from the behavior shown by dinuclear Cu^{II} compounds, in which an important increase in the antiferromagnetic coupling occurs.

Appendix

The bond lengths and angles used for model compounds are: 1.59 Å for the V=O bond; 1.98 Å for V−O (2.24 Å when the O bridging atom is in the *trans* position with respect to the oxo O-atom); 2.11 Å for V−N (2.34 Å when the N atom is *trans* with respect to the oxo O-atom); 0.85 Å for O−H; a value of 104° for the V−O−V bridging angle; and 91.5° for N−V−N. The N−H distance within the ammonia ligands is 1.02 Å and the H−N−H angle is 109°. For alkoxo-bridged compounds: 1.43 and 0.98 Å for O−C and C−H distances, respectively and 109° for the H−C−O angle.

In Quest of the Double Rotaxane Formation of the Bis(coronand) (1,5),(2,4)-Durenetetrayl-bis(18-crown-5) with Organomagnesium Compounds

Gerard P. M. van Klink,[a] Tateo Nomoto,[b] Martin Lutz,[c] Anthony L. Spek,[c] Otto S. Akkerman,[d] and Friedrich Bickelhaupt*[d]

Keywords: Magnesium / Mercury / Chelates / Crown compounds

The interaction between the title compound, bis(coronand) **8**, and the diarylmagnesium compounds Ph_2Mg and $(p\text{-}tBuC_6H_4)_2Mg$ in diethyl ether leads to the formation of 1:2 complexes (**9** and **10**, respectively), irrespective of the initial ratio of the components. In [D_8]toluene, the three complex types can be discerned by ^1H NMR spectroscopy: double side-on (**9a**, **10a)**, side-on/rotaxane (**9b**, **10b)**, and, to a very minor extent, double rotaxane (**9c**, **10c**). In the case of **10a** and **10b**, the temperature dependence showed that rotaxane formation is enthalpically favored at the expense of a more negative entropy. As crystals suitable for structure determination could not be obtained from **9** and **10**, the interaction of **8** with the sterically less demanding $Hg(SCN)_2$ was studied. In this case, analogous pseudorotaxanes are formed exclusively, and both the 1:2 complex [**8**·{$Hg(SCN)_2$}$_2$] (**11**) and its 1:1 analogue **12** were observed. The double rotaxane structure of **11** was confirmed by X-ray crystal structure determination.

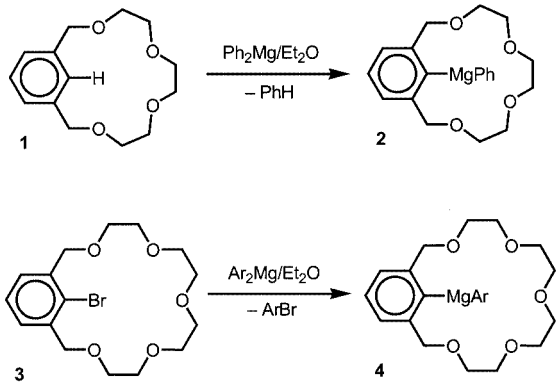
Introduction

In most respects, crown ethers derived from *m*-xylene behave as normal ligands toward organomagnesium compounds. For instance, side-on complexes involving two crown ether oxygen atoms are formed, allowing magnesium to achieve its usual coordination number of four.[1] However, a number of aspects unusual in the chemistry of organomagnesium compounds have also been encountered.[1,2] An illustration is the high organolithium-like reactivity demonstrated by intra-annular metalation of **1** to **2** (Scheme 1),[3] by metal−halogen exchange as in **3** to furnish **4**,[3,4] and by several ether cleavage reactions of substrates which are normally inert toward organomagnesium reagents.[2,5,6]



Scheme 1. Ar = Ph, *p*-$tBuC_6H_4$

Another challenging aspect is the formation of organometallic rotaxanes[7,8] such as **6**,[1,2,9,10] and even catenanes **7**[11] from **5** (Scheme 2). They are of interest not only in view of their remarkable structures, but also because of their mode of formation. The problem is that the crown ether cavity is too small to permit direct penetration by a benzene ring, so multistep processes that involve reversible ionic cleavage of a carbon-magnesium bond have to be postulated.[9−11]

In spite of the extensive literature on rotaxanes and catenanes in general,[12,13] derivatives of organometallic compounds with multiple threading have not been reported yet. On the basis of the results briefly indicated above, it seemed of interest to extend our investigations to double rotaxanes or catenanes of organomagnesium compounds for two re-

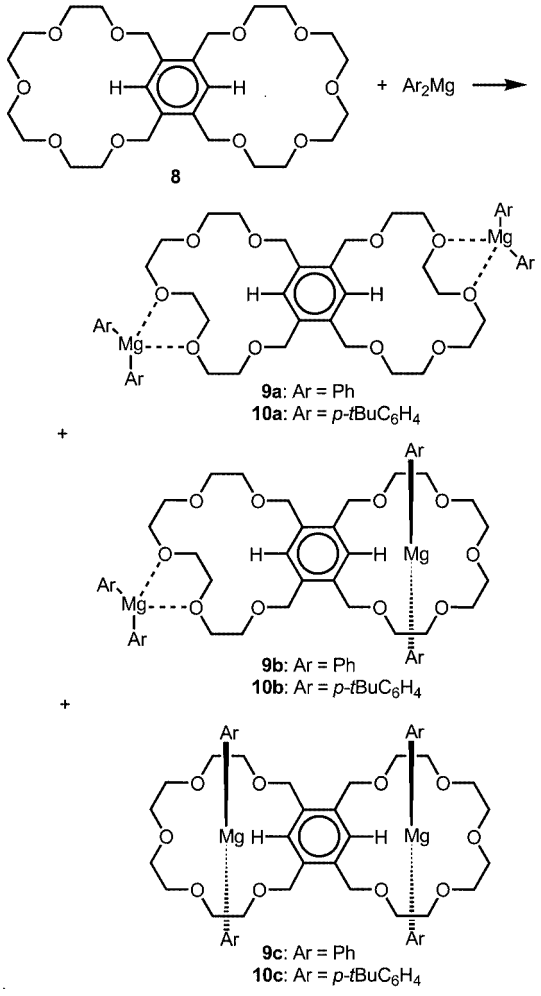
asons: firstly, it was attractive to explore the transmission of conformational information between the different complexation sites, the so-called allosteric effect;[14−17] and secondly, it was conceivable that one could construct higher-order assemblies of these complex types. A good starting point for such investigations appeared to be the title compound, the bis(coronand) **8** (Scheme 3), the synthesis of which has been described.[18]



Scheme 3

Results and Discussion

Complexation of 8 with Diarylmagnesium Compounds

To study the interaction between **8** and diphenylmagnesium, diethyl ether solutions of the two compounds were mixed at room temperature in a molar ratio of 1:2. A homogeneous yellow solution resulted, but after a few minutes, a white precipitate formed. The supernatant solution was removed and hydrolyzed; it contained 10% diphenylmagnesium [according to the titration for Mg^{2+} and OH^- (acid/base and EDTA)][19] and no **8** (^{1}H NMR spectroscopy). From the precipitate, residual diethyl ether was removed by pumping under high vacuum; the resulting pale brown residue dissolved almost completely in [D$_8$]toluene. Hydrolysis of a sample followed by titration as mentioned above revealed the presence of **8** and of diphenylmagnesium in a ratio of 1:2. The ^{1}H NMR spectrum (400 MHz) in [D$_8$]toluene was rather complex. It showed, amongst others, crown

ether signals at about δ = 4.2 and 4.09 ppm (Ar′CH_2) and at δ = 8.6 ppm (Ar′H; Table 1).

These Ar′CH_2 protons are shielded by about 0.4 ppm and the corresponding crown ether methylene protons (see Exp. Sect.) by 0.4−0.5 ppm are similar to those within **8**. Interestingly, the intra-annular aromatic xylylene protons Ar′H are deshielded by 0.4 ppm. This is reminiscent of analogous behavior of aryl protons inside the cavity of small metacyclophanes;[20,21] it has been ascribed to the van der Waals effect caused by steric congestion.[22] As similar changes have also been observed for **6**[9] and **7**,[11] these phenomena are indicative of the rotaxane-type threading of a diarylmagnesium into a *m*-xylylene crown ether cavity. In view of the 1:2 ratio of the two components, three structures are conceivable: the double side-on complex **9a**, the side-on/rotaxane complex **9b**, and the double rotaxane complex **9c** (Scheme 3).

Due to the complicated pattern and to partial overlap, it was difficult to assign all of the signals for the three complexes. However, based on the Ar′CH_2 signals at δ = 4.50, 4.47, 4.20, and 4.09 ppm with a relative intensity of 56:21:22:1, a tentative assignment was possible, which was supported by the intensities of the Ar′H signals at δ = 7.83, 7.74, 8.60, and 8.56 ppm, the ratio of which is Ar′CH_2/Ar′H = 4:1. As the values of δ = 4.50 and 7.83 ppm are very close to those of free **8** (δ = 4.57 and 7.93 ppm), they must be assigned to **9a**. Two other pairs of shifts at δ = 4.47 and 7.74 ppm and δ = 4.20 and 8.60 ppm have equal intensities which is in line with **9b**; this is further supported by the observation that the shifts of the first pair correspond to those of **9a** indicating side-on coordination, while those for the second pair are typical for a rotaxane structure.[9,11] The least certain assignment is that of the pair at δ = 4.09 and 8.56 ppm due to the low intensity; it cannot be excluded that these signals are caused by impurities, but on the other hand, the 4:1 ratio and the typical "rotaxane shift range" support the tentative assignment to **9c**.

An attempt to change the ratios of the three isomers by mixing **8** and diphenylmagnesium in diethyl ether in a 1:1 ratio was not successful. Again, a precipitate was formed. Analysis of the supernatant by titration and ^{1}H NMR spectroscopy (vide supra) showed it to contain only **8**. The precipitate was dissolved in [D_8]toluene; the ^{1}H NMR spectrum was practically identical to that described above, i.e. a 1:2 ratio for the components **8** and diphenylmagnesium, and the same isomer pattern as for **9**. This is remarkable insofar as the 1:2 complexes are apparently preferred even in the presence of an excess of the bis(coronand) **8**. It is unlikely that this is due to an allosteric effect; more likely, the low solubility of **9** shifts the equilibrium in its favor.

This low solubility also hampered the spectral analysis of **9**. In an attempt to obtain more soluble complexes, we performed analogous experiments by mixing **8** with di(*p*-*tert*-butylphenyl)magnesium in diethyl ether, but in this case, too, precipitation occurred. After evaporation of the diethyl ether and dissolution in [D_8]toluene, ^{1}H NMR analysis (Table 1) revealed the presence of the double side-on complex **10a** and of the side-on/rotaxane complex **10b**; the double rotaxane **10c** could not be reliably identified, but a faint signal at δ = 4.08 ppm might be due to its ArCH_2 protons. It is not surprising to find that the equilibrium between the two types of complexes is not strongly influenced by the remote *tert*-butyl group in **10**; at 298 K, the **a**/**b** ratios are 56:43 for **9** and 64.5:35.5 for **10**. According to the X-ray crystal structure of **6**,[9] one of the aryl rings is probably located partly above the aromatic ring of the crown ether; this could lead to increased steric hindrance in **10b** as compared to **9b** which explains the slightly higher preference for **10a**.

As the solubility of **10** was somewhat higher than that of **9**, we were able to check the temperature dependence of the ^{1}H NMR spectrum and its influence on the equilibrium between **10a** and **10b**. The results (Table 2) are not very reliable because a precipitate formed slowly in the NMR tube, especially at higher temperatures.

Table 2. Temperature dependence of isomer ratios **10a**:**10b**

T [K]	298	328	344	355	365
10a[a][b]	64.5	70.7	73.5	82.1	88.9
10b[a][b]	35.5	29.3	26.5	17.9	11.1

[a] In [D_8]toluene. [b] In %.

Raising the temperature shifts the equilibrium in favor of the major component **10a**. On cooling down, this process is (slowly!) reversible. In view of the precipitate formation and the few data points, it is problematic to derive quantitative values for ΔH and ΔS. However, at least a qualitative indication can be obtained if one neglects two dubious points (with more precipitate) at higher temperature. For the transformation **10a** → **10b**, the three lower points give a very good linear correlation [Equation (1)], from which ΔH = −7.8 kJ·mol^{-1} and ΔS = −31 J·mol^{-1}·K^{-1} are obtained; inclusion of all 5 temperatures would lead to ΔH = −19 kJ·mol^{-1} and ΔS = −66 J·mol^{-1}·K^{-1} (R = 0.820).

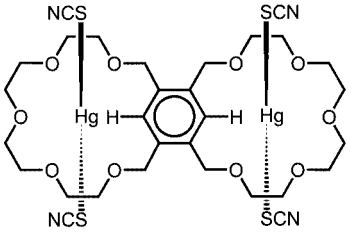
$$\Delta G = -7791 + 31.1 \cdot T \; (R = 1.000) \qquad (1)$$

With appropriate caution, one may conclude that the transformation of a side-on complex to a rotaxane in the reaction **10a** → **10b** is slightly exothermic. This is reasonable if one considers that in **10a**, the magnesium atom is coordinated to two oxygen atoms only, whereas the magnesium atom in the rotaxane cavity of **10b** weakly interacts with additional oxygens as indicated by the X-ray structures of **6** and analogous rotaxanes.[1,7−11] As expected, the reaction entropy ΔS is negative because the rotaxane is conformationally more rigid than the side-on complex. Apparently, this additional rigidity overcompensates the gain in enthalpy in the transformation of the mono rotaxanes **b** to the double rotaxanes **c**; consequently, **9c** and **10c** are minor components only.

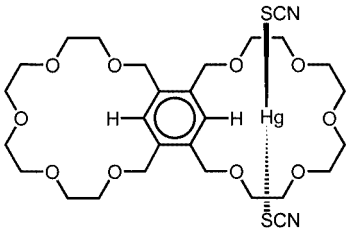
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Complexation of 8 with $Hg(SCN)_2$

As the double rotaxane formation between **8** and diarylmagnesium compounds turned out to be unfavorable, we investigated the interaction of **8** with $Hg(SCN)_2$; the latter has served to study pseudorotaxane formation and allosteric effects in several crown ether systems.[17,23,24] When solutions of **8** and of $Hg(SCN)_2$ in acetone were mixed, a colorless precipitate was obtained. It was filtered off, dissolved in $CDCl_3$, and analyzed by ^1H NMR spectroscopy (Table 1), which revealed the formation of a single symmetrical complex. The most conspicuous signal was at δ = 8.05 ppm; the deshielding of this proton relative to its counterpart in **8** (δ = 7.69 ppm; $\Delta\delta$ = −0.36 ppm) is indicative of the intra-annular Ar*H* of a rotaxane structure (vide supra). The structural assignment of **11** (Scheme 4) is further supported by the equivalence of the two Ar*H* protons and the eight $ArCH_2$ protons. Finally, the identity of **11** was proven by an X-ray crystal structure determination (Figure 1). As the crystals were obtained directly from the reaction mixture and could not be recrystallized due to decomposition, the quality of this determination was not high ($R1$ = 0.0740); nevertheless, it unambiguously established the double pseudorotaxane threading of $Hg(SCN)_2$ through **8**.



11



12

Scheme 4

Solutions of **11** in $CDCl_3$ deteriorated on standing as evidenced by the appearance of several new signals in the ^1H NMR spectra. When **8** and $Hg(SCN)_2$ were mixed in a 1:1 ratio, four Ar*H* signals were observed at δ = 7.69, 7.77, 7.79, and 8.05 ppm. Those at 7.69 and 8.05 ppm stem from free **8** and **11**, respectively. The two remaining signals are assigned to the mono pseudorotaxane **12**. From the signal intensities, the following ratios were derived: **8**:**12**:**11** = 20:72:8, again showing a small bias against formation of the double pseudorotaxane (**11**) which, however, is less dramatic than in the case of **9c** and **10c**. This may be ascribed to the fact that the linear $Hg(SCN)_2$ causes fewer steric interactions inside the crown ether than the aryl groups of Ar_2Mg.

Conclusion

The interaction between the title bis(coronand) **8** and the diarylmagnesium compounds Ph_2Mg and $(p\text{-}t\text{Bu}C_6H_4)_2Mg$ in diethyl ether results in the formation of 1:2 complexes (**9** and **10**, respectively), irrespective of the initial ratio of the components; presumably, this is caused by the low solubility of **9** and **10**. In [D_8]toluene, three types of complexes can be discerned by ^1H NMR spectroscopy: double side-on (**9a**, **10a**), side-on/rotaxane (**9b**, **10b**), and, to a very minor extent, double rotaxane (**9c**, **10c**); the latter two occur in approximately 1% yield only and are the first examples of organometallic double rotaxanes. In the case of **10a** and **10b**, the temperature dependence showed that rotaxane formation is enthalpically favored at the expense of a more negative entropy. Presumably, the formation of the double rotaxanes **9c** and **10c** is counteracted by interaction of the magnesium bound aryl groups across the central aromatic ring.

Due to the low solubility of **9** and **10**, crystals suitable for structure determination could not be obtained. For this reason, the interaction of **8** with the sterically less demanding $Hg(SCN)_2$ was studied. In this case, pseudorotaxanes are formed exclusively, and both the 1:2 complex [**8**·{$Hg(SCN)_2$}$_2$] (**11**) and its 1:1 analogue **12** were observed by ^1H NMR spectroscopy. The double pseudorotaxane structure of **11** was confirmed by an X-ray crystal structure determination.

Experimental Section

General: All manipulations involving organomagnesium compounds were carried out in completely sealed glassware using standard high vacuum techniques.[19] Amounts of ′total base′ and magnesium in organomagnesium samples were determined, after hydrolysis of a sample, by titration with HCl (OH^-) and EDTA (Mg^{2+}), respectively.[19] Solvents were dried by distillation from $LiAlH_4$ after pre-drying over NaOH. NMR spectra were recorded on

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a Bruker AC 200 spectrometer (^{1}H NMR: δ = 200.1 MHz; ^{13}C NMR: δ = 50.32 MHz) or on a Bruker MSL 400 spectrometer (^{1}H NMR: δ = 400.1 MHz; ^{13}C NMR: δ = 100.6 MHz). HRMS measurements were performed on a Finnigan MAT 90 spectrometer (direct inlet). **Caution:** Organomercury compounds are poisonous!

Diphenylmagnesium: Diphenylmercury (6.39 g, 18 mmol) was stirred with doubly sublimed magnesium (4.37 g, 180 mmol) in diethyl ether (180 mL) in a fully sealed glass system for three weeks. After the magnesium amalgam had settled, the clear solution was decanted into a second vessel, and an aliquot of known volume was hydrolyzed and titrated (OH^- and Mg^{2+})[19] to establish the concentration of diphenylmagnesium.

Bis(*p*-*tert*-butylphenyl)magnesium: In a fully sealed glass system, bis(*p*-*tert*-butylphenyl)mercury (9.34 g, 20 mmol) was stirred with doubly sublimed magnesium (4.86 g, 200 mmol) in diethyl ether (200 mL) for three weeks. After settling of the magnesium amalgam, the clear solution was decanted into a second vessel, and an aliquot of known volume was hydrolyzed and titrated (OH^- and Mg^{2+})[19] to establish the concentration of bis(*p*-*tert*-butylphenyl)magnesium.

Reaction of 8 with Two Molar Equivalents of Diphenylmagnesium: Solutions of **8**[18] [7.55 mg, 0.0147 mmol in diethyl ether (2 mL)] and of diphenylmagnesium [0.03 mmol in diethyl ether (8 mL)] were combined in a fully sealed glass system. Within 15 min, the clear yellow solution decolorized, and a white precipitate was formed. After heating at 40 °C for 2 h, the clear supernatant was carefully decanted. The diethyl ether mother liquor was hydrolyzed, and the aqueous phase was titrated (OH^- and Mg^{2+}).[19] This indicated that more than 90% of the Ph_2Mg was contained in the precipitate. This titration sample was carefully extracted with benzene. The organic layers were combined, dried ($MgSO_4$), filtered, and the solvents evaporated to dryness. ^{1}H NMR spectroscopy revealed no signals that could be ascribed to starting material **8**. The solid reaction product obtained by decantation was dried by pumping under high vacuum, and toluene (10 mL) was then added, upon which most of the solid dissolved. From the supernatant, a sample was taken for characterization by ^{1}H NMR spectroscopy in [D_8]toluene. To quantify the effects of complexation on the chemical shifts of the crown ether, a reference spectrum of pure **8** was measured under identical conditions. ^{1}H NMR spectroscopy revealed that signals of the free crown ether **8** were absent. Assignment of all signals was not possible due to overlap and the complexity of the spectrum. Integration of the benzylic proton signals was used to determine the following relative yields: **9a** (55.9%), **9b** (43.2%), and **9c** (0.9%).
8: ^{1}H NMR {[D_8]toluene, 200.1 MHz, ref. $C_6D_5CD_2H$: δ = 2.03 ppm}: δ = 3.43−3.51 (br. s, 32 H, CH_2), 4.57 (s, 8 H, $ArCH_2$), 7.93 (s, 2 H, ArH) ppm. ^{13}C NMR {[D_8]toluene, 50.32 MHz, ref. $C_6D_5CD_3$: δ = 20.40 ppm}: δ = 69.61 (tt, ^1J = 139.9, ^2J = 4.2 Hz, 4C, CH_2O), 71.00 (t, ^1J = 141.9 Hz, 4C, CH_2O), 71.05 (t, ^1J = 139.9 Hz, 4C, CH_2O), 71.18 (td, ^1J = 140.4, ^3J = 3.8 Hz, 4C, $ArCH_2$), 71.46 (tt, ^1J = 140.0, ^2J = 2.5 Hz, 4C, CH_2O), 128.22 (d, ^1J = 163.8 Hz, 2C, aryl-CH), 135.50 (d, ^2J = 3.5 Hz, 2C, aryl-C) ppm.
9a: ^{1}H NMR {[D_8]toluene, 200.1 MHz, ref. $C_6D_5CD_2H$: δ = 2.03 ppm}: δ = 3.38 (s br., 16 H, CH_2), 3.41 (m, 16 H, CH_2), 4.50 (s, 8 H, $ArCH_2$), 7.24−7.26 [m, ArH(4)], 7.34 [t br., J = 6.9 Hz, ArH(3.5)], 7.83 (s, 2 H, xylyl-H), 8.11 [d br., ^3J = 6.2 Hz, ArH(2.6)] ppm.
9b: ^{1}H NMR {[D_8]toluene, 200.1 MHz, ref. $C_6D_5CD_2H$: δ = 2.03 ppm}: δ = 2.94−3.01 (m, 4 H, CH_2), 3.12−3.16 (m, 4 H, CH_2), 3.30−3.34 (m, 4 H, CH_2), 4.20 [s, 4 H, $ArCH_2$ (rotaxane)], 4.47 [s, 4 H, $ArCH_2$ (side-on)], 7.10−7.14 [m, ArH(4) (rotaxane)], 7.22 [t, J = 7.1 Hz, ArH(3.5)], 7.80 [d, ^3J = 6.4 Hz, ArH(2.6)], 7.74 [s, 1 H, xylyl-H (side-on)], 8.60 [s, 1 H, xylyl-H (rotaxane)] ppm. The other signals coincide with those of **9a**.
9c: ^{1}H NMR {[D_8]toluene, 200.1 MHz, ref. $C_6D_5CD_2H$: δ = 2.03 ppm}: δ = 4.09 (s, 8 H, $ArCH_2$), 8.56 (s, 2 H, xylyl-H) ppm. The other signals coincide with those of **9a** and **9b**.

Reaction of 8 with One Molar Equivalent of Diphenylmagnesium: Solutions of **8** (7.55 mg, 0.0147 mmol) in diethyl ether (2 mL) and of diphenylmagnesium [0.015 mmol in diethyl ether (4 mL)] were combined in a fully sealed glass system. After formation of a white suspension, the diethyl ether was distilled off and replaced by toluene (10 mL). The clear supernatant was decanted and analyzed by titration and by ^{1}H NMR spectroscopy in [D_8]toluene, which showed that only the starting material **8** was present. The pale brown precipitate was dissolved in [D_8]toluene and showed essentially the same ^{1}H NMR spectrum as that obtained in the reaction of **8** with two equivalents of Ph_2Mg, but with the products **9a** and **9b** in a ratio of 55:45. ^{1}H NMR signals of **9c** were not detected.

Reaction of 8 with Two Molar Equivalents of (p-tBuC_6H_4)$_2$Mg: A solution of (p-tBuC_6H_4)$_2$Mg (0.085 mmol) in diethyl ether (1 mL) was added to **8** (0.02167 g, 0.0421 mmol) in a fully sealed glass system, to give a clear yellow solution. After 10 min, a finely divided powder started to precipitate. After 2.5 h, the diethyl ether was distilled off, and toluene (10 mL) was added to the residue. The mixture was heated, but a clear solution was not obtained. Several attempts to crystallize the white residue in order to obtain suitable crystals for an X-ray crystal structure determination were unsuccessful. A sample was analyzed by ^{1}H NMR spectroscopy in [D_8]toluene. Assignment of all signals was not possible due to the complex nature of the spectrum. The two complexes in a mixture of **10a** and **10b** were present in a ratio of 64.5:35.5. In this case, only a faint signal of the double rotaxane complex **10c** was discernible at δ = 4.08 ppm.
10a: ^{1}H NMR {[D_8]toluene, 400.1 MHz, ref. $C_6D_5CD_2H$: δ = 2.03 ppm}: δ = 1.36 (s, 36 H, tBu), 3.37−3.45 (m, 32 H, CH_2), 4.52 (s, 8 H, $ArCH_2$), 7.45 [d, AB, ^3J = 8 Hz, 8 H, ArH(3.5)], 7.89 (s, 2 H, xylyl-H), 8.11 [d, BA, ^3J = 8 Hz, 8 H, ArH(2.6)].
10b: ^{1}H NMR {[D_8]toluene, 400.1 MHz, ref. $C_6D_5CD_2H$: δ = 2.03 ppm}: δ = 1.39 (s, 18 H, tBu) 2.93−2.99 (m, 4 H, CH_2), 3.11−3.12 (m, 4 H, CH_2), 3.17−3.23 (m, 4 H, CH_2), 3.32−3.36 (m, 4 H, CH_2), 4.23 [s, 4 H, $ArCH_2$ (rotaxane)], 4.49 [s, 4 H, $ArCH_2$ (side-on)], 7.27 [d, AB, ^3J = 7.9 Hz, 4 H, ArH(3.5)], 7.77 [d, BA, ^3J = 7.9 Hz, 4 H, ArH(2.6)], 7.89 [s, 1 H, xylyl-H (side-on)], 8.67 [s, 1 H, xylyl-H (rotaxane)] ppm. The other signals overlap with those of **10a**.

Reaction of 8 with Two Molar Equivalents of Hg(SCN)$_2$: A solution of $Hg(SCN)_2$ (0.06335 g, 0.200 mmol) in acetone (2 mL) was added to a solution of **8** (0.05143 g, 0.100 mmol) in acetone (2 mL). Within a few minutes, a white precipitate formed, which was separated by filtration and characterized by ^{1}H NMR spectroscopy as [**8**·{$Hg(SCN)_2$}$_2$] (**11**); this assignment was confirmed by the X-ray crystal structure determination.
11: ^{1}H NMR ($CDCl_3$, 200.1 MHz, ref. $CHCl_3$: δ = 7.27 ppm): δ = 3.67 (s br., 24 H, CH_2), 3.82 (m, 8 H, CH_2), 4.78 (s, 8 H, $ArCH_2$), 8.05 (s, 2 H, ArH) ppm. ^{13}C NMR ($CDCl_3$, 100.6 MHz, ref. $CDCl_3$: δ = 77.00 ppm): δ = 69.20 (t, ^1J = 145.6 Hz, 4C, CH_2), 69.42 (t, ^1J = 139.7 Hz, 4C, CH_2), 69.74 (t, ^1J = 142.7 Hz, 4C, CH_2), 69.84 (t, ^1J = 141.9 Hz, 4C, CH_2), 71.06 (t, ^1J = 140.3 Hz, 4C, $ArCH_2$), 135.72 (d, ^2J = 44.8 Hz, 2C, aryl-CH), 137.69 (br. s, 4C, aryl-C) ppm. Contrary to **12** (vide infra), **11** was not volatile under DCI conditions.

Reaction of 8 with One Molar Equivalent of $Hg(SCN)_2$: A solution of $Hg(SCN)_2$ (0.03168 g, 0.100 mmol) in acetone (2 mL) was added to a solution of **8** (0.05143 g, 0.100 mmol) in acetone (2 mL). The mixture slowly became turbid and after one hour, the organic solvent was evaporated to dryness. The residue was dissolved in $CDCl_3$ and analyzed by ^1H NMR spectroscopy: **8** (21%), **11** (8%), and **12** (72%).

12: ^1H NMR ($CDCl_3$, 200.1 MHz, ref. $CHCl_3$: δ = 7.27 ppm): δ = 3.65 (s br., 12 H, CH_2), 3.72−3.77 (m, 20 H, CH_2), 4.59 [s, 4 H, $ArCH_2$ (rotaxane)], 4.79 [s, 4 H, $ArCH_2$ (free)], 7.77 (s, 1 H, ArH), 7.79 (s, 1 H, ArH) ppm. MS (DCI, NH_3): *m/z* (%) = 850 (10) [M + NH_4]$^+$, 791 (7) [M + NH_4-HSCN]$^+$, 632 (14), 591 (100).

X-ray Crystallographic Study: $C_{30}H_{42}Hg_2N_4O_{10}S_4$, (1148.10), colorless needles, 0.38 × 0.15 × 0.05 mm^3, triclinic, $P\bar{1}$ (no. 2), a = 7.3747(4), b = 10.0516(16), c = 14.593(3) Å, α = 89.817(15), β = 78.769(10), γ = 77.999(9)°, V = 1037.0(3) Å^3, Z = 1, ρ_x = 1.838 gcm^{-3}, 4716 measured reflections, 3633 unique reflections (R_{int} = 0.044). 161 refined parameters, R (obsd. refl.): $R1$ = 0.0740, $wR2$ = 0.2058. R (all data): $R1$ = 0.0868, $wR2$ = 0.2188, GooF = 1.055. Intensities were measured on a Enraf−Nonius CAD4T diffractometer with a rotating anode (Mo-K_α, λ = 0.71073 Å) at a temperature of 150 K. Reflection profiles for the best available crystal were structured, indicating a low quality crystal. An absorption correction was applied (program PLATON,[25] routine DELABS, μ = 7.647 mm^{-1}, 0.27−0.69 transmission). The structure was solved with Patterson methods using the program DIRDIF97,[26] and refined with the program SHELXL-97[27] against F^2 of all reflections up to a resolution of $(\sin/\lambda)_{max}$ = 0.59 Å^{-1}. Hg and O atoms and the SCN ligand were refined freely with anisotropic displacement parameters; all other carbon atoms were refined with isotropic displacement parameters. Hydrogen atoms were refined as rigid groups. The drawings, structure calculations, and checking for higher symmetry were performed with the program PLATON.[25]

1D-Polyoxometalate-Based Composite Compounds − Design, Synthesis, Crystal Structures, and Properties of $[\{Ln(NMP)_6\}(PMo_{12}O_{40})]_n$ (Ln = La, Ce, Pr; NMP = *N*-methyl-2-pyrrolidone)

Jing-Yang Niu,*[a] Mei-Lin Wei,[a] Jing-Ping Wang,*[a] and Dong-Bin Dang[b]

Keywords: Polyoxometalates / Oxo ligands / Lanthanides / Structure elucidation / Zig-zag chain

The structures of three 1:1 composite compounds prepared with the polyoxometalate (POM) $[PMo_{12}O_{40}]^{3-}$ and the cations $[Ln(NMP)_6]^{3+}$ [Ln = La (**1**), Ce (**3**), Pr (**2**); NMP = *N*-methyl-2-pyrrolidone] exhibit two types of zig-zag chains with alternating cations and anions through Mo–O_t–Ln–O_t–Mo links in the crystal. The compounds were characterized by IR, UV, and ESR spectroscopy, single-crystal X-ray structural analysis, and by a study of their thermal properties. In all the compounds, the La^{3+}, Pr^{3+}, and Ce^{3+} centers are eight-coordinate with the oxygen atoms in bicapped trigonal-prismatic geometries. The variation of the average Ln–O separations along the La, Ce, and Pr series is consistent with the effects of the lanthanide contraction. The results of the single-crystal X-ray diffraction analyses and the IR spectroscopic studies are in agreement and both show the metal cation units are coordinatively bonded to the Keggin clusters. The UV spectra of the title compounds suggest that their structures are entirely disrupted in dilute solution. Low-temperature ESR spectra indicate that thermal electron delocalization occurs among the Mo atoms in the three compounds. The results of cyclic voltammetry (CV) show that compounds **1**, **2**, and **3** all undergo five two-electron reversible reductions and that the $[PMo_{12}O_{40}]^{3-}$ anions are the active centers for electrochemical redox reactions in solution, while the corresponding cations have only a small effect on the electrochemical properties. Studies of magnetic properties show that **1** is diamagnetic, while **2**and **3** exhibit antiferromagnetic Pr–Pr or Ce–Ce exchange interactions. In addition to the results of CV, the average bond lengths and the magnetic properties of compound **3** indicate that the oxidation state of cerium is iii in the compound of formula $[\{Ce(NMP)_6\}(PMo_{12}O_{40})]_n$.

Introduction

As a rich and diverse class of inorganic cluster systems, the polyoxometalate ions formed by the early transition metals are noted for their fascinating structural, electrochemical, catalytic, magnetic, medicinal, and photophysical properties.[1] In the field of designing and assembling molecular-based materials[2−10] with structures based on the so-called anion-cation salts or host-guest solids, polyoxometalates have been found to be extremely versatile inorganic building blocks due to their ability to accept electrons.[11] So far, many intermolecular complexes based on polyoxometalates have been synthesized and reported.[11−23] Through electron transfer between organic units and polyanions, some are able to enhance the SHG (second harmonic generation) nonlinear optical response[12] while others enhance electric or magnetic properties.[13−18] The interactions existing in the structures of organic substrates and heteropoly acids or salts are mainly facilitated by hydrogen bonds, van der Waals forces, and electrostatic forces. However, infinitely extended chains based on Keggin- or Dawson-type anions and joined together by W(Mo)−O_t−M[19] links are relatively rare. Structurally characterized notable examples include $[ET]_8[PMnW_{11}O_{39}]\cdot 2H_2O$ [ET = bis(ethylenedithio)tetrathiafulvalene],[20] $[NEt_3H]_5[XCoW_{11}O_{39}]\times 3H_2O$ (X = P or As),[21] $[Cu(en)_2(OH_2)]_2[H_2en][\{Cu(en)_2\}\text{-}P_2CuW_{17}O_{61}]\times 5H_2O$ (en = ethylenediamine), $[Cu(en)_2(OH_2)]_2[Cu(en)]_{0.5}\text{-}[H_2en]_{0.5}[\{Cu(en)_2\}P_2CuW_{17}O_{61}]\times 5H_2O$,[22] $[\{Ba(DMSO)_5\text{-}(H_2O)\}_2(SiMo_{12}O_{40})]$, $[\{Ba(DMSO)_3(H_2O)_3\}\{Ba(DMSO)_5\text{-}(H_2O)GeMo_{12}O_{40}\}]$,[11] and $[\{Ca(DMF)_5\}_2SiMo_{12}O_{40}]_n$.[23]

In polyoxometalate chemistry, one of the major challenges is the "rational" synthesis of new compounds. The development of rational methods for the modification and functionalization of polyoxometalate systems may provide the means to fully exploit the desirable attributes mentioned above. From the standpoint of molecular design, we attempted to use traditional synthesis to realize such molecular assemblies. Firstly, we introduced metal ions into the framework formed by polyanions and organic units, so that

the combination of polyanions and organic units through metal ions could be achieved. Here, we chose lanthanide(III) metal ions, which have potential uses in bioinorganic chemistry and materials science.[24−26] Secondly, we chose NMP molecules as electron donors, since polyoxometalate anions are good electron acceptors, thus, they can interact leading to electron transfer. In this paper, we report the synthesis and single-crystal X-ray structural analyses of three infinitely extended polyoxometalate-based composites: $[\{Ln(NMP)_6\}(PMo_{12}O_{40})]_n$ (Ln = La, Ce, Pr; NMP = *N*-methyl-2-pyrrolidone). In the structures of these composites, the rare-earth ions are firstly coordinated by six NMP and polyanionic ligands to form a structural unit. These structural units are then connected through $Mo-O_t-Ln-O_t-Mo$[19] links to form one-dimensional chain-like structures. To the best of our knowledge, the types of structure exhibited by these compounds have not been previously reported. This paper reports studies of the magnetic and electrochemical properties as well as solid-state structural aspects of three organic-inorganic complexes with novel structures, in which infinite stacking assemblies between polyanions and cationic units have been achieved.

Results and Discussion

Experiments demonstrated that selection of a suitable solvent was crucial for growing crystals of the title compounds. Stable crystals of compounds **1**, **2**, and **3** were obtained from acetonitrile/water mixtures at room temperature. Compounds **1**, **2**, and **3** are all soluble in CH_3CN and its mixtures with water. When **1**, **2**, and **3** were dissolved in pure CH_3CN, irregular crystals were obtained because of rapid loss of solvent, therefore necessitating control of the concentration rate of the solution. This problem was overcome by simply adding water to the acetonitrile solutions. Using this method, crystals suitable for X-ray diffraction were eventually obtained. In addition, exposure of the solutions to sunlight was avoided as a result of the photosensitivity of the crystals, the reasons for which have been mentioned above.

The structures of the three composite compounds constructed from $[PMo_{12}O_{40}]^{3-}$ and the cations $[Ln(NMP)_6]^{3+}$ (Ln = La, Ce, Pr) exhibit two types of zig-zag chains with alternating cations and anions through $Mo-O_t-Ln-O_t-Mo$ links in the crystal. The novelty of these composite compounds is based on the fact that the alternating chains now contain only one cation per anion instead of two[11,23] (which is the usual case observed in other POM-cation chains). $[\{La(NMP)_6\}(PMo_{12}O_{40})]_n$ and $[\{Pr(NMP)_6\}(PMo_{12}O_{40})]_n$ show the same zig-zag chains (Figure 1). Representative molecular structural units and the coordination environment of compound **1** are shown in Figures 2 and 3(a). However, $[\{Ce(NMP)_6\}(PMo_{12}O_{40})]_n$ forms different zig-zag chains (Figure 4) from **1** and **2**, with molecular structural units and the coordination environments shown

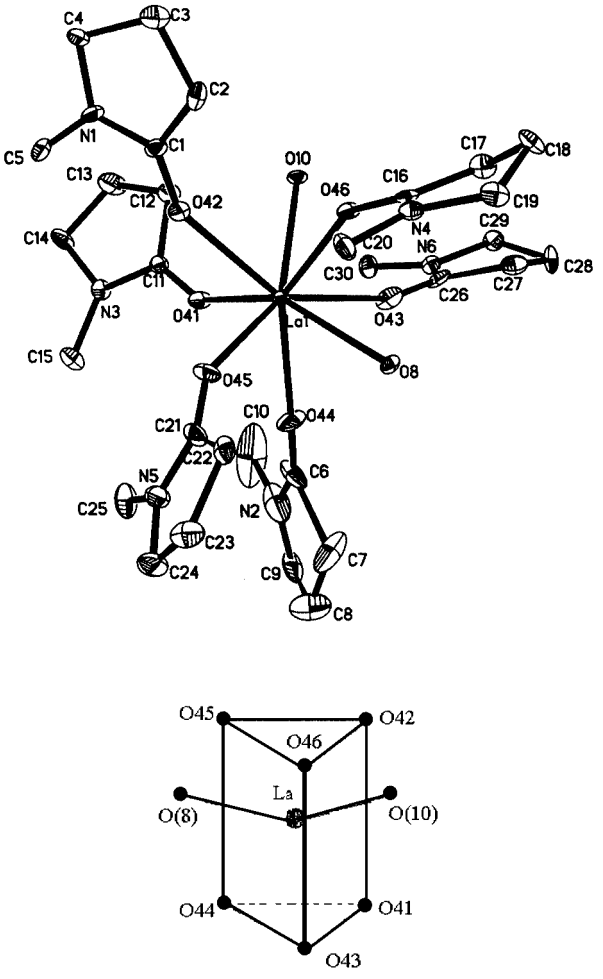

Figure 3. (a; top) Coordination environment of La^{3+} in **1**, hydrogen atoms are omitted for clarity; (b; bottom) coordination polyhedron around La^{3+} in **1**

in Figures 5 and 6. The coordination numbers of the La^{3+}, Pr^{3+} and Ce^{3+} ions are all 8 (six O atoms from the NMP ligands, and the remaining two O atoms from two adjacent heteropolyanions). The coordination environments of the La^{3+}, Pr^{3+}, and Ce^{3+} ions can be described as bicapped trigonal-prismatic, an example being that of La^{3+} shown in Figure 3(b). This is one of the common coordination geometries for complexes with a coordination number of 8.[27] In the three compounds each La^{3+}, Pr^{3+}, and Ce^{3+} ion has six O atoms from six NMP molecules forming two trigonal planes, and two terminal oxygen atoms from the polyanions occupying the caps due to the steric hindrance of the polyanions. These factors all contribute towards the stability of the title compounds. In addition, the O(10)#1−La(1)−O(8) bond angle is 124.27(15)°, the O(10)#1−Pr(1)−O(8) bond angle is 124.8 (3)°, and the O(6)#1−Ce(1)−O(6) bond angle is 122.4(3)° resulting in the formation of zig-zag chains. Comparing **3** with **1** and **2**, the striking difference lies in the type of zig-zag chains observed. In **1** and **2**, for each $[PMo_{12}O_{40}]^{3-}$ unit, there are two terminal coordinating oxygen atoms, O(10) and O(8) are almost at 90° in the Keggin-type cage while in **3**, O(6) and O(6)#1 are almost in a *para* position.

The La−O, Pr−O, and Ce−O bond lengths range from 2.397 to 2.660 Å, from 2.347 to 2.592 Å, and from 2.388 to 2.649 Å, respectively. The average bond length for all La−O bonds is 2.474 Å, which is 0.028 Å longer than the La−O1A bond length (2.446 Å) in $[La^{III}(NITBzImH)_4](ClO_4)_3\times2THF\times2H_2O$ (NITBzImH = nitronyl nitroxide radicals),[27] in which the coordination number is 8 and the coordination polyhedron around the La^{3+} ion is distorted from dodecahedral toward a square-antiprismatic geometry. This bond is 0.006 Å shorter than the La−O1A bond (2.48 Å) in $[La^{III}(NITMeBzImH)_4](ClO_4)_3\times2THF\times1H_2O$ (NITMeBzImH = nitronyl nitroxide radicals),[27] in which the coordination number of the La^{3+} ion is 8 and the coordination polyhedron around the La^{3+} ion is a distorted cube. The average bond length for all Pr−O bonds is 2.429 Å, which is 0.099 Å longer than the mean Pr(1)−O bond length (2.393 Å) of $[Pr_2(bbpen)_2(NO_3)(H_2O)]NO_3\times CH_3OH$,[28] in which the coordination number of the Pr^{3+} ion is 8 and the coordination polyhedron around the Pr^{3+} ion is a distorted cube. The average bond length for all Ce−O bonds is 2.47 Å, which is 0.064 Å shorter than the mean Ce(1)−O bond length of 2.53 Å in $[(THF)_3Ce(SC_6F_5)_3]_2$,[29] in which the coordination number of the $Ce^{3+}(1)$ ion is 8. The variation of the Ln−O average bond separations along the La, Ce, and Pr series (La−O > Ce−O > Pr−O) is consistent with the effects of the lanthanide contraction (ionic radius: $La^{3+} > Ce^{3+} > Pr^{3+}$). The fact that the mean La−O(NMOP), Pr−O(NMP), and Ce−O(NMP) bond lengths of 2.361, 2.387, and 2.405 Å, respectively, are 0.257, 0.169, and 0.244 Å shorter than the corresponding La−O_t, Pr−O_t, and Ce−O_t distances of 2.618, 2.556, and 2.649 Å indicates that the Ln−O(NMP) bonds are more stable than the Ln−O_t bonds. This is probably because the charge density at the oxygen atom of C=O is larger than that of O_t, resulting from the electron-donating effect of the methyl groups through the N atoms in the NMP molecules and the electron-withdrawing effect of the polyanions.

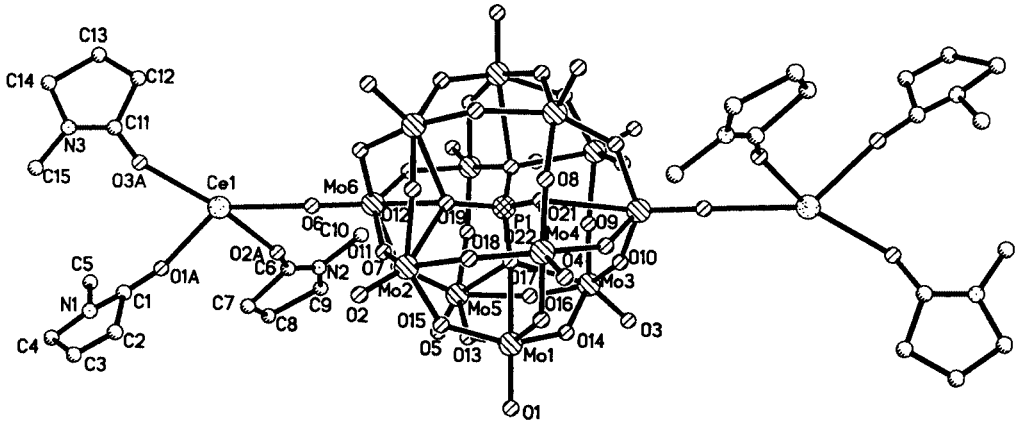

Figure 5. Molecular structural unit with atomic labeling of **3**; ellipsoids are shown at the 30% probability level; hydrogen atoms are omitted for clarity

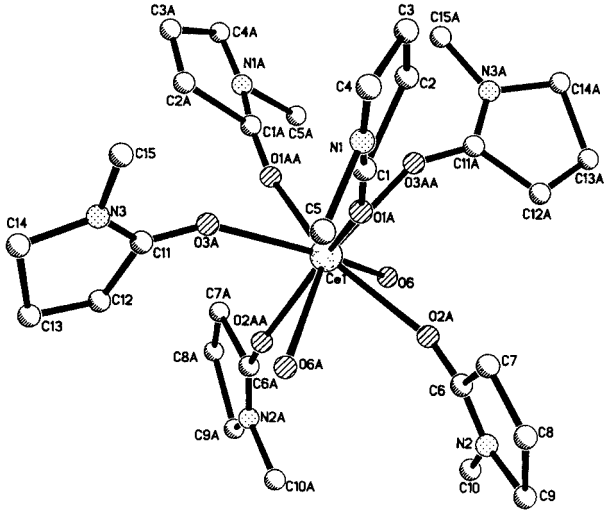

Figure 6. Coordination environment of Ce^{3+} in **3**; hydrogen atoms are omitted for clarity

The P−O bond lengths range from 1.521 to 1.546 Å for **1**, from 1.523 to 1.550 Å for **2**, and from 1.438 to 1.604 Å for **3**, respectively, with the O−P−O bond angles ranging from 108.4 to 109.9° for **1**, from 108.3 to 110.5° for **2**, and from 103.7 to 116.5° for **3**, respectively, indicating that the PO_4 tetrahedrons are distorted to a different extent in each case. The $Mo-O_t$ bond lengths range from 1.663 to 1.689 Å (av. 1.676 Å) for **1**, from 1.651 to 1.697 Å (av. 1.674 Å) for **2**, and from 1.633 to 1.664 Å (av. 1.650 Å) for **3** while the $Mo-O_a$[19] bond lengths range from 2.380 to 2.452 Å (av. 2.416 Å) for **1**, from 2.394 to 2.462 Å (av. 2.428 Å) for **2**, and from 2.384 to 2.483 Å (av. 2.427Å) for **3**. Finally, the $Mo-O_{b,c}$[19] bond lengths range from 1.804 to 2.023 Å for **1**, from 1.776 to 2.041 Å for **2**, and from 1.688 to 2.178 Å for **3**. These observations show that the MoO_6 octahedra of the polyanions in the title compounds are severely distorted because of the influence of the outer coordinating cations. Clearly, although the La^{3+}, Pr^{3+}, and Ce^{3+} ions in the title compounds have the same coordination number and coordination polyhedra, the Ce^{3+} ions distort the $[PMo_{12}O_{40}]^{3-}$ units to a larger extent than do the La^{3+} and Pr^{3+} ions. Moreover, the $Mo-O_t-Ln-O_t-Mo$ (Ln = La, Ce, Pr) links are important, firstly because polyoxometalates as ligands are electron acceptors which, in some cases, can be reduced by one or more electrons, giving rise to mixed-valence clusters. Secondly, because rare-earth atoms with magnetic properties have been introduced into the structures of compounds **1**, **2**, and **3**, they may have the potential to become novel solid-state materials in which delocalized electrons coexist with localized magnetic moments, thus affording the opportunity for the investigation of molecular systems combining magnetic and conducting properties.

There are four characteristic asymmetric vibrations resulting from heteropolyanions with the Keggin structure, namely $\nu_{as}(Mo=O_t)$, $\nu_{as}(Mo-O_b)$, $\nu_{as}(Mo-O_c)$, and $\nu_{as}(P-O_a)$. Upon comparison of the IR spectra of the title compounds with those of α-$H_3PMo_{12}O_{40}\times nH_2O$[30] the vibrational bands of the $Mo=O_t$ bonds exhibit red shifts from 975 to 961 cm^{-1} in **1**, from 975 to 959 cm^{-1} in **2** and from 975 to 961 cm^{-1} in **3**. The peaks due to the $Mo-O_c$ bonds show red shifts from 810 to 804 cm^{-1} in **1**, from 810 to 801 cm^{-1} in **2** and from 810 to 803 cm^{-1} in **3**. Lastly, the $P-O_a$ bond vibrations show red shifts from 1067 to 1063 cm^{-1} for **1**, **2**, and **3**, while the vibrational bands of the $Mo-O_b$ bonds exhibit blue shifts from 870 to 881 cm^{-1}in **1** and **3**, and from 870 to 878 cm^{-1} in **2**. These results indicate that the polyanions in the title compounds still retain the basic Keggin structure, but are distorted due to the effects of coordination. This is in agreement with the results of the single-crystal X-ray diffraction studies. In addition, there are three characteristic asymmetric vibrations resulting from NMP molecules, namely $\nu_{as}(C=O)$ (1666.1 cm^{-1}), $\nu_{as}(C-N)$ (1506 cm^{-1}), and $\nu_{as}(N-CH_3)$ (1114 cm^{-1}).[31] Upon comparison of the IR spectra of the title compounds with those of NMP molecules,[31] $\nu_{as}(C=O)$ is lower by 25.3 cm^{-1} (from 1666.1 to 1640.8 cm^{-1}) in **1**, 28.2 cm^{-1} (from 1666.1 to 1637.9 cm^{-1}) in **2**, and 27.1 cm^{-1} (from 1666.1 to 1639 cm^{-1}) in **3**, confirming that the NMP ligands are coordinated to the rare-earth ions by means of their oxygen atoms. The $\nu_{as}(C-N)$ and $\nu_{as}(N-CH_3)$ frequencies in the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

three compounds rise slightly by 8 cm^{-1} and 2−6 cm^{-1}, respectively. This can be explained by the fact that the charge density at the oxygen and carbon centers is decreased due to the O atoms of the C=O bonds being coordinated to the rare-earth ions, leading to an increase in the electron-donating effect of the methyl groups through the N atoms. The IR spectroscopic studies show that there are strong interactions between the polyanions and the organic groups in the solid state.

The UV spectra of compounds **1**, **2**, and **3** measured in aqueous solution are similar to that of α-$H_3PMo_{12}O_{40}\times nH_2O$ in the same solution. There are absorption peaks at approximately 205 nm, which can be assigned to the $O_t\rightarrow Mo$ charge-transfer bands which are also strong due to the absorption of NMP molecules at the same wavelength.[31] This suggests that although the compounds exist in polymeric form in the solid state, the polymeric chains are entirely disrupted in dilute solution. This has been observed in a previous study.[12]

The three complexes are strongly photosensitive towards irradiation with sunlight, resulting in charge-transfer by oxidation of the NMP moieties and reduction of the $[PMo_{12}O_{40}]^{3-}$ groups. ESR spectra of powders of the title compounds after exposure to sunshine are typical of molybdenum(v).[32−33] At 110 K, $g = 1.949$ for **1**, $g = 1.947$ for **2**, and $g = 1.948$ for **3**. Observation of an intense, relatively narrow ESR signal from about 3460 to 3500 G (40 G peak to peak) for **1**, **2**, and **3** at 110 K indicates that intramolecular electron transfer is relatively slow on the ESR timescale, and that the electron is delocalized.

Table 1. Cathodic peak potentials (E_{cp}) and anodic (E_{ap}) and potential differences for α-$H_3PMo_{12}O_{40}\times nH_2O$ and compounds **1** and **2** (in a mixture of 50% 1,4-dioxane and 50% H_2O containing 0.5 mol/L H_2SO_4 as the supporting electrolyte, sensitivity 10 μA, $v = 50$ mV·s^{-1}, SCE as the reference electrode)

Table 1 summarizes the cathodic and anionic peak potentials [V], the half-wave potentials $E_{1/2}$ [V], as well as the difference potentials for α-$H_3PMo_{12}O_{40}\times nH_2O$ and compounds **1**, **2**, and **3** (in a mixture of 50% 1,4-dioxane and 50% H_2O containing 0.5 mol/L H_2SO_4 as the supporting electrolyte, sensitivity 10 μA, $v = 50$ mV·s^{-1}, SCE as the reference electrode). Figure 7 shows the CVs for α-$H_3PMo_{12}O_{40}\times nH_2O$ and compounds **1**, **2**, and **3** carried out at a sensitivity of 10 μA. For phospho-polyoxomolybdate it is difficult to obtain well-defined redox waves in cyclic voltammetry in aqueous electrolytes due to the ease of hydrolysis of $[PMo_{12}O_{40}]^{3-}$. However, it can be stabilized by addition of comparatively large amounts of organic solvents. Thus, cyclic voltammetry was measured in organic/aqueous solvent mixtures (50% 1,4-dioxane and 50% redistilled H_2O) containing 0.5 mol/L H_2SO_4 as the supporting electrolyte. α-$H_3PMo_{12}O_{40}\times nH_2O$ as well as compounds **1**, **2**, and **3** all undergo five two-electron reversible reductions. The reversibility criterion used was $\Delta E_p = E_{ap} - E_{cp} = 59/n$ mV (n = number of electrons). The small difference in $E_{1/2}$ [V] of the three compounds shows that the $[PMo_{12}O_{40}]^{3-}$ anions are the active centers for electrochemical redox activity in the solutions, while the corresponding cations have only a small effect on the electrochemical redox behavior. Upon comparison of the results of the CVs of the three compounds, it was found that the effect of $[Ce(NMP)_6]^{3+}$ on the electrochemical redox behavior of $[PMo_{12}O_{40}]^{3-}$ is stronger than that of $[La(NMP)_6]^{3+}$ or $[Pr(NMP)_6]^{3+}$.

In aqueous solution, cerium has two accessible oxidation states namely III and IV. Only strong oxidants such as permanganate and peroxodisulfate can oxidize Ce^{III}. In general, the determination of the oxidation state of cerium is frequently a difficult problem. Previous work has shown that selected heteropolyoxotungstates can significantly influence the behavior of complex f-ions. In 1971, Peacock and Weakley reported that heteropolyoxotungstates could stabilize tetravalent cerium.[34] This stabilization was apparent from the ease of oxidation of Ce^{IV} in $[Ce(PW_{11}O_{39})_2]$, $[Ce(SiW_{11}O_{39})_2]$ and $[Ce(P_2W_{17}O_{61})_2]$. In aqueous solution, these oxidations were found to occur at +0.6 to +0.9 V vs. Ag/AgCl, which is less than the standard reduction potential of Ce^{IV}. More recently, Haraguchi et al.[35] have confirmed the shifts of the Ce^{III}/Ce^{IV} redox potentials in these heteropolyoxotungstates. The implication of their work is that the oxidation of Ce^{III} is possible with the use of only mild oxidants.[36] In contrast, the shifts of the Ce^{III}/Ce^{IV} redox potentials in heteropolymolybdates have not been reported and consequently we have examined the shift of the Ce^{III}/Ce^{IV} redox potential in $[\{Ce(NMP)_6\}(PMo_{12}O_{40})]_n$.

Figure 8 (A and B) shows the CVs of α-$H_3PMo_{12}O_{40}\times nH_2O$ (1 mmol/L) and compound **3** (1 mmol/L) in a mixture of 50% 1,4-dioxane and 50% H_2O containing 0.5 mol/L H_2SO_4 as the supporting electrolyte with Ag/AgCl as the reference electrode. Figure 8 (C) depicts the CV of compound **3** (1 mmol/L) in a mixture of 50% 1,4-dioxane and 50% H_2O containing 1.0 mol/L $HClO_4$ as the supporting electrolyte with Ag/AgCl as the reference electrode. In contrast, it was found that Ce^{III} in $[\{Ce(NMP)_6\}(PMo_{12}O_{40})]_n$ cannot be oxidized to Ce^{IV} even

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

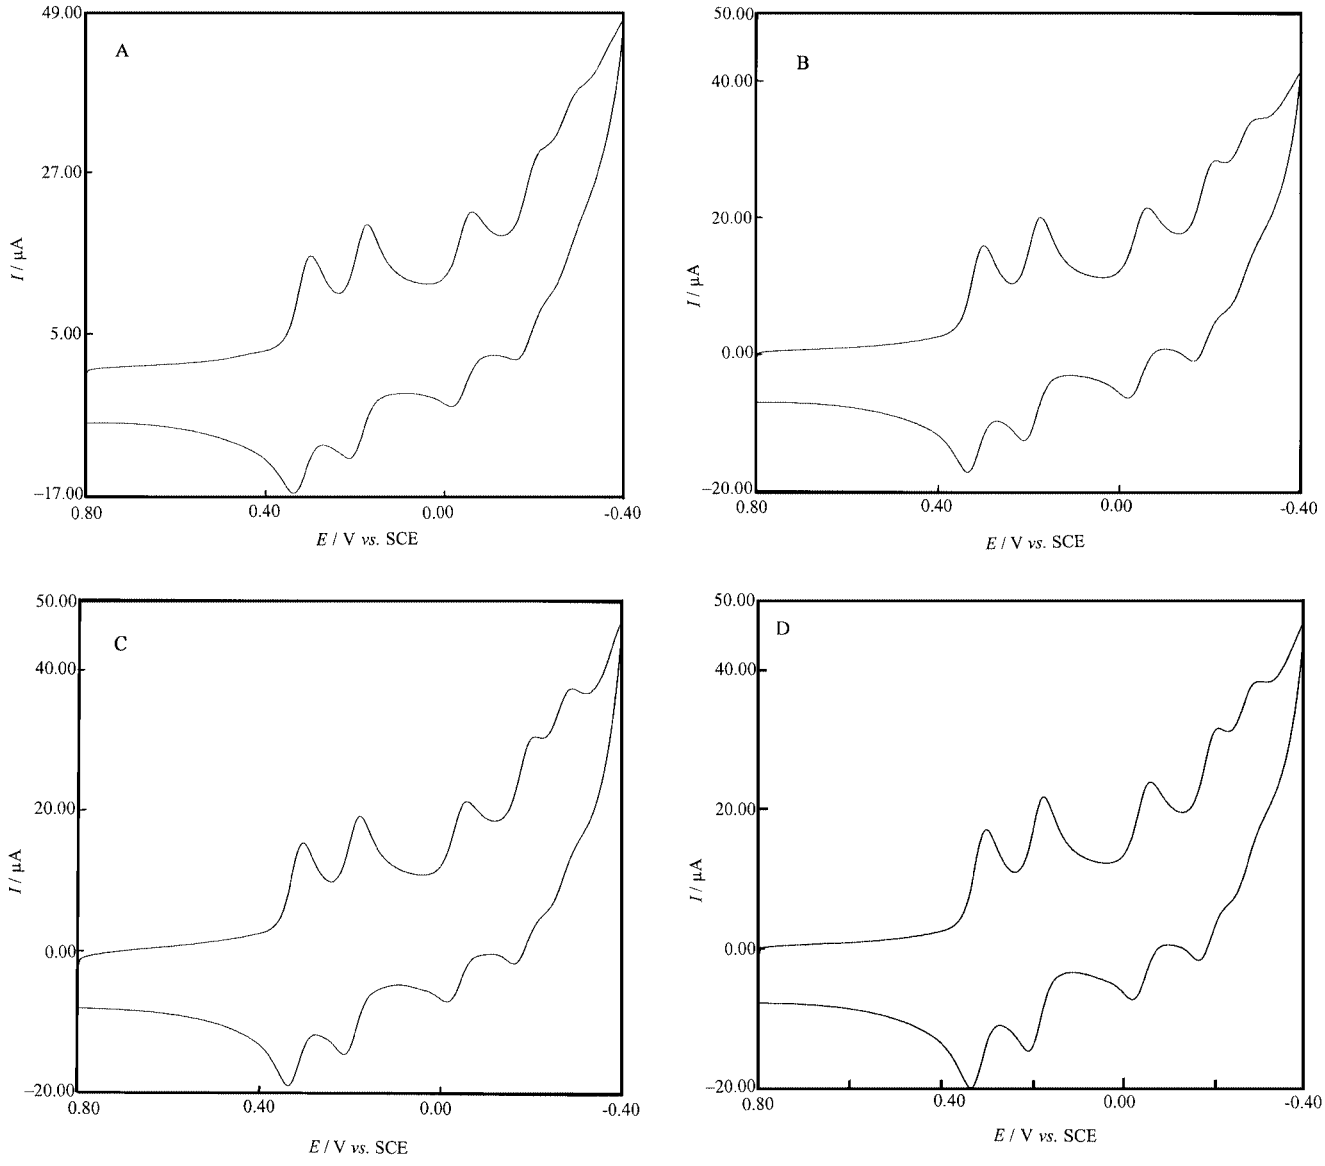

Figure 7. (A) CV of α-$H_3PMo_{12}O_{40}\times nH_2O$(1 mmol/L) in a mixture of 50% 1,4-dioxane and 50% H_2O containing 0.5 mol/L H_2SO_4 as the supporting electrolyte, sensitivity 10 μA, v = 50 mV·s^{-1}, SCE as the reference electrode; (B) CV of compound **1** (1 mmol/L) in a mixture of 50% 1,4-dioxane and 50% H_2O containing 0.5 mol/L H_2SO_4 as the supporting electrolyte, sensitivity 10 μA, v = 50 mV·s^{-1}, SCE as the reference electrode; (C) CV of compound **2** (1 mmol/L) in a mixture of 50% 1,4-dioxane and 50% H_2O containing 0.5 mol/L H_2SO_4 as the supporting electrolyte, sensitivity 10 μA, v = 50 mV s^{-1}, SCE as the reference electrode; (D) CV of compound **3** (1 mmol/L) in a mixture of 50% 1,4-dioxane and 50% H_2O containing 0.5 mol/L H_2SO_4 as the supporting electrolyte, sensitivity 10 μA, v = 50 mV s^{-1}, SCE as the reference electrode

under rigorous conditions (+1.5 V vs. Ag/AgCl; electrolyte 1 mol/L $HClO_4$ purged with O_2). These conditions are sufficient to oxidize the noncomplexed Ce^{III} aqua ion. The Ce^{III} ion in compound **3** is not oxidized at potentials higher than would be required for its oxidation in noncomplexing media, indicating a stabilization of Ce^{III} in this case. In addition, the solution chemistry of cerium(III) is similar to that of Zr, Hf and, particularly, tetravalent actinides. Thus, Ce^{III} gives phosphates insoluble in 4 mol/L HNO_3 and iodates insoluble in 6 mol/L HNO_3, as well as an insoluble oxalate. Upon addition of 5 mL of 4 mol/L NaOH to 20 mL of an aqueous solution of 1 mmol of $[\{Ce(NMP)_6\}(PMo_{12}O_{40})]_n$, which dissociates into small molecules, white deposited material can be observed. Filtration of the mixture to recover the solid, which is soluble in 5 mL of dilute HCl (0.5 mol/L), followed by the addition of two drops of concentrated phosphoric acid to the resultant solution produces a white precipitate which is soluble in 4 mol/L HNO_3.

Finally, the average $Ce^{III}-O$ distance in compound **3** is 2.47 Å, which is essentially the same as the sum of the Ce and O ionic radii of 2.49 Å for eight-coordinate Ce and two-coordinate O centers.[36]

Thus, based on the results of CV, the solution chemistry, the average bond lengths and the following magnetic susceptibilities, we can conclude that $[\{Ce(NMP)_6\}(PMo_{12}O_{40})]_n$ contains a tervalent cerium center.

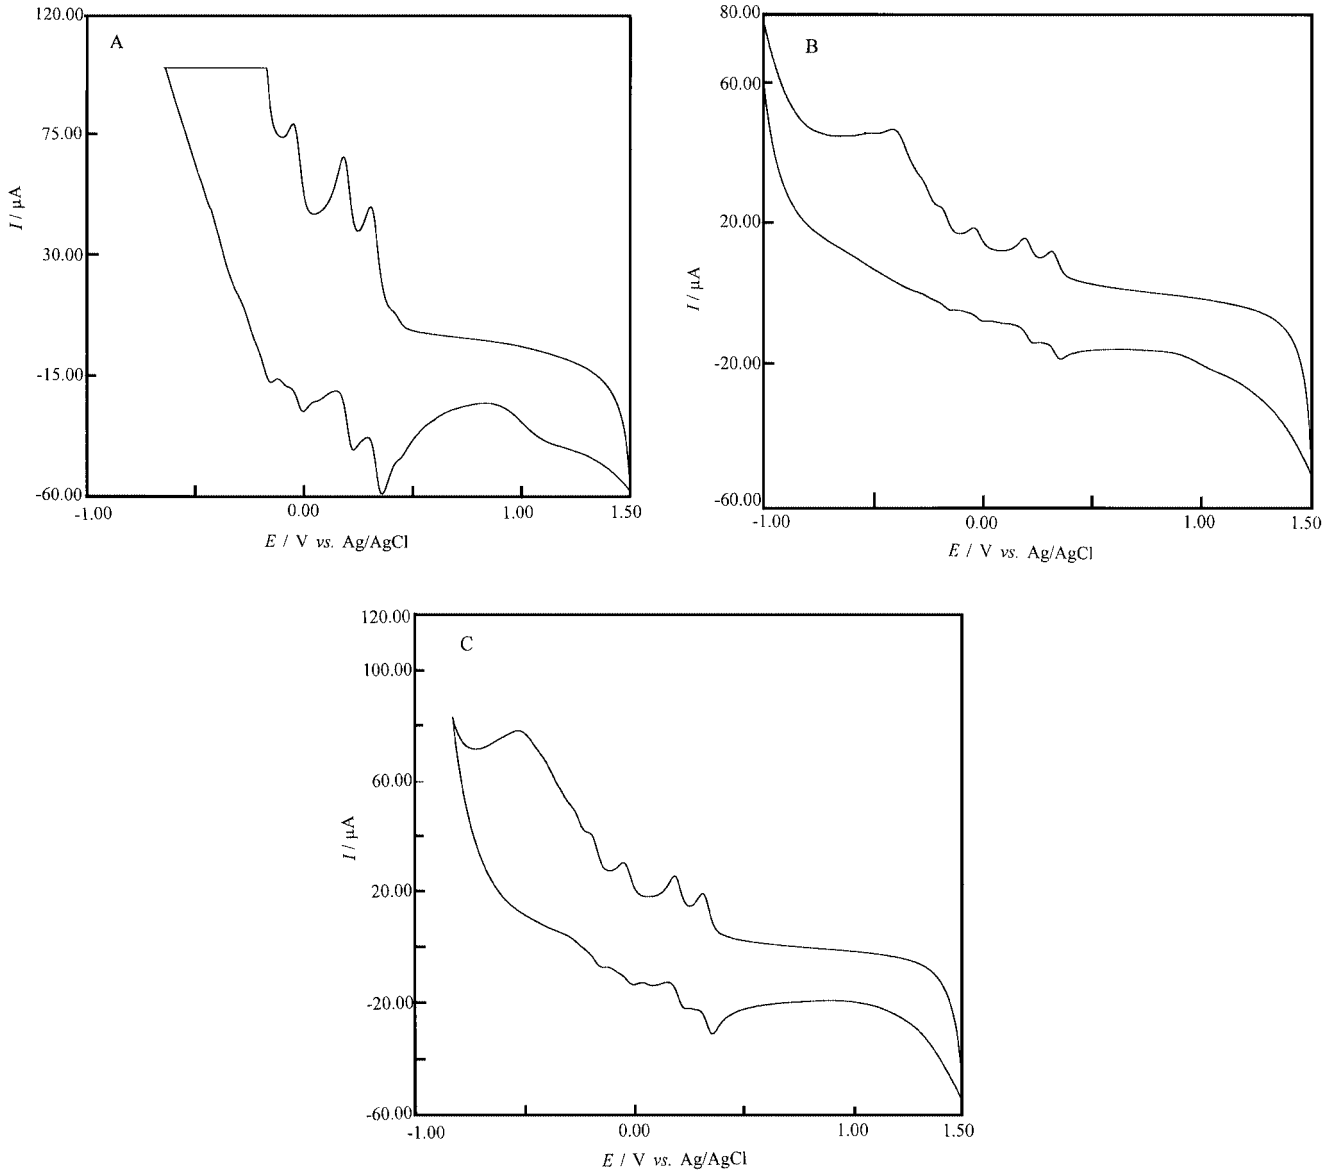

Figure 8. (A) CV of α-$H_3PMo_{12}O_{40}\times nH_2O$ (1 mmol/L) in a mixture of 50% 1,4-dioxane and 50% H_2O containing 0.5 mol/L H_2SO_4 as the supporting electrolyte, sensitivity 10 μA, v = 50 mV·s^{-1}, Ag/AgCl as the reference electrode; (B) CV of compound **3** (1 mmol/L) in a mixture of 50% 1,4-dioxane and 50% H_2O containing 0.5 mol/L H_2SO_4 as the supporting electrolyte, sensitivity 10 μA, v = 50 mV·s^{-1}, Ag/AgCl as the reference electrode; (C) CV of compound **3** (1 mmol/L) in a mixture of 50% 1,4-dioxane and 50% H_2O containing 1.0 mol/L $HClO_4$ as the supporting electrolyte, sensitivity 10 μA, v = 50 mV s^{-1}, Ag/AgCl as the reference electrode

The variable-temperature magnetic susceptibilities of polycrystalline powders of the three compounds were measured with a Cahn-2000 magnetometer between 75 and 300 K. The studies of magnetic properties show that compound **1** is diamagnetic, while compounds **2**and **3** exhibit antiferromagnetic Pr−Pr or Ce−Ce exchange interactions. The results are displayed in the form of $1/\chi_M$ (the molar magnetic susceptibility per formula unit) vs. absolute temperature in Figures 9 and 10 for compounds **2** and **3**. The mean molar magnetic susceptibility of $[\{La(NMP)_6\}(PMo_{12}O_{40})]_n$ (**1**) (−0.00018 cm^3·mol^{-1}) was used as a diamagnetic correction for the molar magnetic susceptibilities of **2** and **3**. The magnetic data for compounds **2** and **3** have been fitted to the Curie−Weiss law $\chi_M = C/(T - \theta)$ and $\chi_M = Ng^2\beta s\ (s + 1)/3k(T - \theta)$ (s_{Ce} = 1/2; s_{Pr} = 1). The Weiss constants $\theta_{Pr} = -58.88$ and $\theta_{Ce} = -108.78$ show that there are strong antiferromagnetic Pr−Pr or Ce−Ce exchange interactions in **2** and **3**.

Conclusions

Three one-dimensional composite compounds have been prepared based on the polyoxometalate anion $[PMo_{12}O_{40}]^{3-}$ and the cations $[LnNMP]_6]^{3+}$ (Ln = La, Ce, Pr). Single-crystal X-ray diffraction studies showed that the three compounds exhibit two types of zig-zag chains with alternating cations and anions through Mo−O_t−Ln−

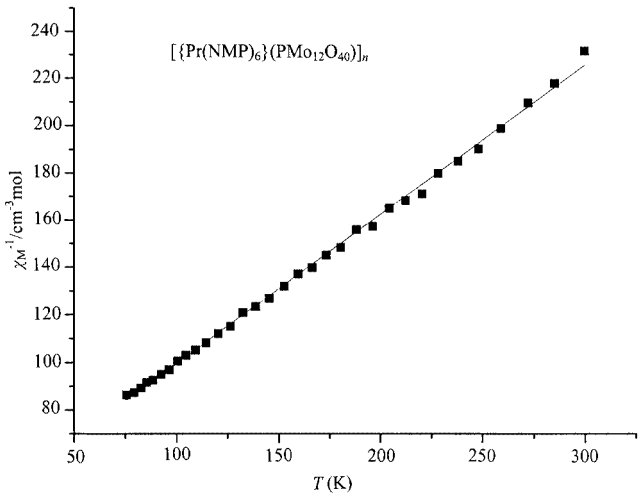

Figure 9. Plot of inverse molar susceptibility vs. absolute temperature for compound **2** (black squares); the solid line represents the best fit of the data with value in the text

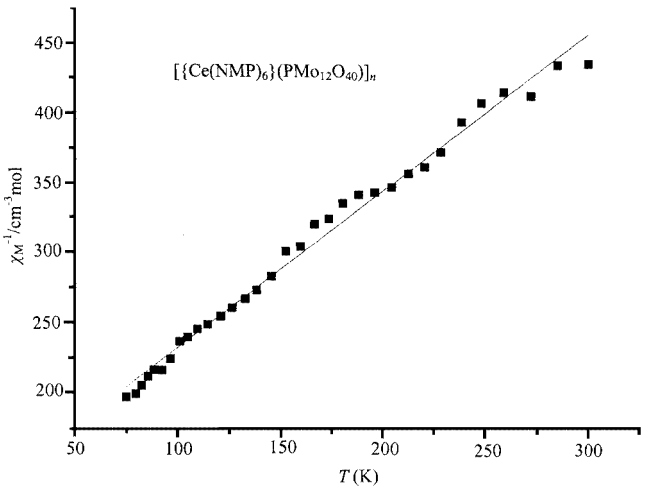

Figure 10. Plot of molar susceptibility vs. absolute temperature for compound **3** (black squares); the solid line represents the best fit of the data with value in the text

O_t−Mo links in the crystal. The variation of the Ln−O average bond separations along the La, Ce, and Pr series is consistent with the effects of the lanthanide contraction (ionic radius: $La^{3+} > Ce^{3+} > Pr^{3+}$) and the polyanions in the title compounds are severely distorted as a result of the influence of the outer coordinating cations. The polymeric structures of the compounds are entirely disrupted in dilute solution, and the cyclic voltammograms measured show that the three compounds all undergo five two-electron reversible reductions. The studies of magnetic properties indicate that **1** is diamagnetic while **2** and **3** exhibit antiferromagnetic Pr−Pr or Ce−Ce exchange interactions.

Experimental Section

Materials: All organic solvents and materials used for synthesis were of reagent grade and used without further purification. α-$H_3PMo_{12}O_{40}\times nH_2O$ was prepared according to a literature method.[30] The metal chlorides $LnCl_3$ (Ln = La, Ce, Pr) were prepared by addition of concentrated HCl to Ln_2O_3 (99.9%).

Syntheses

$[\{La(NMP)_6\}(PMo_{12}O_{40})]_n$ (1), $[\{Pr(NMP)_6\}(PMo_{12}O_{40})]_n$ (2), and $[\{Ce(NMP)_6\}(PMo_{12}O_{40})]_n$ (3): The formation of heteropolyacid lanthanide salts was accomplished by neutralization of the acids. α-$H_3PMo_{12}O_{40} \times nH_2O$ (3.8 g, 2 mmol) and $LnCl_3$ (2 mmol) were dissolved in water (15 mL) and the solution was heated to dryness at 80 °C in a water bath. NMP (2 mL) was then added to the resultant dry solid (2 g) with stirring until the mixture became a paste. After standing for ca. 15 min, the paste was dissolved in a minimum of an acetonitrile/water mixture (3:2, v/v). Finally, the solution was filtered and left standing to concentrated at room temperature. After 1−2 d, yellow crystals suitable for X-ray diffraction were obtained; yield based on α-$H_3PMo_{12}O_{40} \times nH_2O$ ca. 80%. $C_{30}H_{54}LaMo_{12}N_6O_{46}P$ (**1**) (2555.95): calcd. [a] Symmetry transformation used to generate equivalent atoms: #1: $-x$, y, $-z + 1/2$; #2: $-x - 1/2$, $-y - 1/2$, $-z$.

in aqueous solution with a UV-250 spectrometer in the range of 190−400 nm. Thermogravimetric analyses (TG/DTA) were performed in air with a Perkin−Elmer-7 instrument with a heating rate of 10 °C/min from room temperature to 600 °C. ESR spectra of powdered samples of the title compounds after exposure to sunshine were recorded with a Bruker ER-200-D-SRC spectrometer in the X-band frequency at 110 K. Cyclic voltammograms were obtained with an LK98BII electrochemical analyzer at 25 °C. A glass-carbon (diameter = 3 mm) electrode was employed as the working electrode. The electrode was subjected to ultrasonic washing for 5 min followed by washing with water and acetone prior to every measurement. A platinum rod (diameter = 2 mm) was used as the counter electrode. The reference electrode was an SCE or an Ag/AgCl electrode. A Cahn-2000 magnetometer was used to measure the temperature dependence of the magnetic susceptibilities of three compounds in the 75−300 K temperature range. The crystal structures of **1**, **2**, and **3** were determined from single-crystal X-ray diffraction data. Intensity data were collected with a Rigaku RAXIS-IV image plate area detector with Mo-K_α (λ = 0.71073 Å) radiation at 293(2) K. The structures were solved by direct methods and refined using full-matrix least-squares calculations with anisotropic displacement parameters for all non-hydrogen atoms. All hydrogen atoms were geometrically fixed to allow riding on the parent atoms to which they are attached and refined with individual isotropic displacement parameters. All calculations were performed using the SHELXTL-97 program.[37] A summary of the X-ray crystal data for the three compounds is shown in Table 2. Selected bond lengths and bond angles are listed in Tables 3, 4, and 5. CCDC-201822 (**1**), -201823 (**2**), and -201821 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Deposition of II-VI Thin Films by LP-MOCVD Using Novel Single-Source Precursors

Mohammad Afzaal,[a] David Crouch,[a] Mohmmad A. Malik,[a] Majid Motevalli,[b] Paul O'Brien,*[a] Jin-Ho Park,[a] and J. Derek Woollins[c]

Keywords: Chemical vapour deposition / Chalcogens / Zinc / Cadmium

Thin films of several zinc or cadmium chalcogenides have been deposited on glass substrates by low pressure metal-organic chemical vapour deposition (LP-MOCVD) using single-source precursors, $[M\{(EP\textit{i}Pr_2)_2N\}_2]$ (M = Cd^{II}, Zn^{II} and E = S, Se). X-ray single crystal structures show that $[Zn\{(EP\textit{i}Pr_2)_2N\}_2]$ (E = S or Se) and $[Zn\{(SePPh_2)_2N\}_2]$ are tetrahedrally distorted. TGA analyses showed that the precursors are volatile, making them suitable for MOCVD studies. As-deposited films were polycrystalline as confirmed by X-ray powder diffraction (XRPD) and their morphologies were studied by scanning electron microscope (SEM).

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The direct nature of band gaps in II-VI materials makes them suitable for use in devices, such as blue/blue-green laser diodes,[1−3] which could lead to high-density optical storage systems.[4−6] Cadmium chalcogenides are also useful materials in solid-state solar cells, photoconductors, field effect transistors, sensors and tranducers.[7,8]

Single-source precursors have several potential advantages over conventional MOCVD which uses dual-sources. These include limited premature reactions and good quality homogeneous films.[1] The solid-state chemistry of cadmium and zinc with the chalcogens is typified by the formation of polymeric structures with tetrahedral metal ions,[1] the admantyl structures of many thiolates with zinc and cadmium provide well-characterised examples of such behaviour,[2−4] as do the polymeric chain complexes formed by pyridinethione and 2,3-mercaptobenzothiazole with cadmium and zinc.[5,6] Bochmann et al. have extended such chemistry by producing a range of precursors based on 2,4,6-tri-*tert*-butylphenylchalcogenolate, which have been used to deposit thin films of the metal sulfides and selenides in low-pressure growth experiments.[7−9] In related work, Arnold and co-workers have also deposited a range of chalcogenides using silicon-based ligands, i.e. $[\{MESi(SiCH_3)_3\}_2]$ (M = Zn^{II}, Cd^{II}, Hg^{II} and E = S, Se or Te).[10,11]

Other classes of molecules, which have proved useful for the deposition of thin films include coordination complexes such as dialkyl dichalcogenocarbamates or dithiophosphinates.[12−16] Various groups have studied simple $[M(S_2CNEt_2)_2]$ (M = Cd^{II}, Zn^{II}) complexes and deposited CdS or ZnS films by different deposition techniques.[13−15] However, the use of metal diethyldiselenocarbamates to deposit ZnSe and CdSe on glass substrates resulted in the deposition of elemental selenium.[16] Asymmetrical alkyl substituents as in $[M(E_2CNMeHex)_2]$ (M = Cd^{II}, Zn^{II} and E = S, Se) which were originally introduced in order to increase volatility and have been successfully used to deposit II−VI films (including ZnSe and CdSe) by low pressure metal-organic chemical vapour deposition (LP-MOCVD). An investigation into decomposition mechanisms by gas chromatography mass spectroscopy (GC-MS) and electron impact mass spectroscopy (EI-MS) showed that the deposition of selenium during growth is inhibited in such compounds.[16]

We have recently identified a new class of metal-organic single-source precursors based on bis(diphenylphosphanyl-amine) e.g., $[NH(SePPh_2)_2]$ ligands (an analogue of the β-diketonates) a system pioneered by Woollins, $[M\{(SePPh_2)_2N\}_2]$ (M = Cd^{II}, Zn^{II}) complexes which have been used as precursors for zinc/cadmium selenide films by LP-MOCVD.[17] In this paper, we report crystal structures of $[Zn\{(EP\textit{i}Pr_2)_2N\}_2]$ (E = S or Se) and $[Zn\{(SePPh_2)_2N\}_2]$. We also report the deposition and characterisation of metal chalcogenide films on glass substrates from

$[M\{(EP{i}Pr_2)_2N\}_2]$ (M = Cd^{II}, Zn^{II} and E = S, Se) complexes **1**−**4**) by low-pressure MOCVD.

Results and Discussion

The syntheses of ligands $[NH(EP{i}Pr_2)_2]$ (E = S or Se) were carried out according to previously reported methods.[18,19] The synthesis of the precursor involves deprotonation of the N−H moiety, using sodium methoxide, to form anionic chelate complexes which is subsequently reacted with the metal chloride (Scheme 1). These reactions have some advantages over the routes via metal carbonates and higher yields are obtained particularly for the selenium complexes. The reactions occur efficiently and cleanly at room temperature in anhydrous methanol. All the compounds are soluble in organic solvents and are air-stable.

$$NH(SiMe_3)_2 + 2\ {}^{i}Pr_2PCl \xrightarrow[\text{stirring (3 hours)}]{50\text{–}70\ ^{\circ}C} NH(P{}^{i}Pr_2)_2 + 2\ ClSiMe_3 \quad \text{(Eq. 1)}$$

$$NH(SiMe_3)_2 \xrightarrow[\text{reflux}]{E = S,\ Se} NH(EP{}^{i}Pr_2)_2 \quad \text{(Eq. 2)}$$

$$2\ NH(EP{}^{i}Pr_2)_2 + MCl_2 \xrightarrow[MeOH]{NaOMe} M[(EP{}^{i}Pr_2)_2N]_2 + 2\ NaCl \quad \text{(Eq. 3)}$$

Scheme 1

X-ray Structures

Crystals of $[Zn\{(SePPh_2)_2N\}_2]$ suitable for X-ray diffraction studies were obtained by slow diffusion of hexane into a chloroform solution of the complex. During attempts to synthesise the mixed-alkylzinc complexes by comproportionation reactions between dimetylzinc and $[Zn\{(EP{i}Pr_2)_2N\}_2]$ (E = S or Se), the serendipitous formation of $[Zn\{(EP{i}Pr_2)_2N\}_2]$ (E = S or Se) crystals from toluene solutions occurred. The molecular structures of the compounds are shown in Figures 1−3.

X-ray single crystallographic studies carried out on $[Zn\{(EP{i}Pr_2)_2N\}_2]$ (E = S or Se) and $[Zn\{(SePPh_2)_2N\}_2]$ reveal that the complexes are tetrahedrally coordinated by two ligands. The structure of $[Zn\{(SeP{i}Pr_2)_2N\}_2]$ illustrated in Figure 1 is isostructural with its sulfur analogue (Figure 2). The Zn−Se bond lengths are in the range of 2.458(9) to 2.467(9) Å which are slightly larger than Zn−S bond lengths [2.350(11) to 2.359(11) Å]. Similarly, the Se−Zn−Se bite angles are also increased from the bite angles of S−Zn−S [111.84(4)−112.81(4)°] (Tables 2 and 3). Shortening of the P−N bonds to 1.583(3)−1.592(4) Å and

the subsequent extension of the P−Se bonds 2.177(13)−2.183(13) Å relative to the free ligand, indicates an increase in delocalization within the architecture due to deprotonation.[19] Crystalline $[Zn\{(SPiPr_2)_2N\}_2]$ as reported by Woollins et al. exhibits completely different unit cell parameters.[18] The unit cell described here contains two independent monomeric molecules versus four reported in the earlier paper.[18]

The zinc atom in $[Zn\{(SePPh_2)_2N\}_2]$ is also coordinated to the selenium atoms through two bidentate ligands forming six-membered chelate rings. The tetrahedral geometry around the zinc atom is distorted which is reflected in the Se−Zn−Se angles which range from 103.85(9) to 115.93(6)° (Table 4). There is no significant difference in the Zn−Se bond lengths of $[Zn\{(SePR_2)_2N\}_2]$ (R = Ph or *i*Pr). The ZnE_2P_2N (E = S or Se) rings have puckered geometries with a distorted boat conformation. This conformation appears to be the most commonly adopted for complexes containing $[R_2P(E)NP(E)R_2]^-$ (E = S or Se) ligands, although other conformations also have been reported with selenium or sulfur and phosphorous atoms at the apices.[29,30]

Deposition Studies: In this study, metal chalcogenide thin films have been deposited using air-stable single-source precursors, $[M[(EPiPr_2)_2N\}_2]$ (M = Cd^{II}, Zn^{II} and E = S, Se). The suitability of the precursors were determined by thermogravimetric analysis (TGA) at atmospheric pressure, and all show clean sublimation without any residues, as desirable in precursors for MOCVD studies (Table 5). Deposition of thin films was attempted over a range of substrate temperatures (400 to 500 °C) on glass substrates for one hour with ca. 200 mg of precursor used for each growth experiment.

Table 5. TGA data for compounds **1**−**4**

Compound	T_s (°C)[a]	T_f (°C)[b]
$[Cd\{(SPiPr_2)_2N\}_2]$	237	355

$[Zn\{(SePiPr_2)_2N\}_2]$	240	366

[a] T_s = sublimation temp. [b] T_f = decomposition temp.

Cadmium Sulfide: CdS films were grown from $[Cd\{(SPiPr_2)_2N\}_2]$ at growth temperatures of 425 and 450 °C with a precursor temperature of 250 °C. Deposited films were yellow, transparent and well-adherent to the glass sur-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

face. At higher growth temperature (475 °C), slightly dark yellow-brown film was observed after one hour of growth. As-deposited cadmium sulfide films were analysed by XRPD, which indicated that the hexagonal CdS films (Table 6) have been deposited with a preferred orientation along the (002) plane (Figure 4). SEM studies indicate that the morphology of film deposited at 450 °C consists of randomly oriented domains of compacted thin acicular crystallites with ca. 1.75 μm in thickness (Figure 5). Similar morphology was also observed for the film deposited at 425 °C. On the basis of EDAX analyses, the films were found to be slightly cadmium rich with 52%, sulfur (46%) and phosphorous (2%).

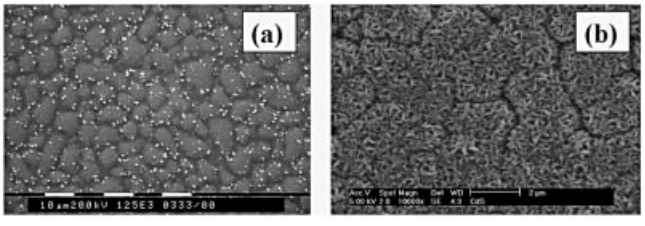

Figure 5. SEM images of CdS films from $[Cd\{(SPiPr_2)_2N\}_2]$ deposited at (a) 425 °C and 450 °C

Cadmium Selenide: Deposition of CdSe films was attempted at substrate temperatures of 425−500 °C, with the precursor temperature set at 325 °C using $[Cd\{(SePiPr_2)_2N\}_2]$. Little or no deposition was observed below 450 °C. At higher growth temperatures, 475 and 500 °C, deposited films were black and adherent to the surface. XRPD studies of the deposited films indicate that polycrystalline hexagonal CdSe films (Table 7) have been deposited with a preferred orientation along the (100) plane (Figure 6). Film deposited at 500 °C was slightly more ordered than the film grown at 475 °C indicated by the absence of (002) plane at 25.5Θ 2θ. Films grown from $[Cd\{(SePPh_2)_2N\}_2]$ also resulted in hexagonal CdSe at 500 and 525 °C but show different preferred orientations (002) and (101) respectively.[17]

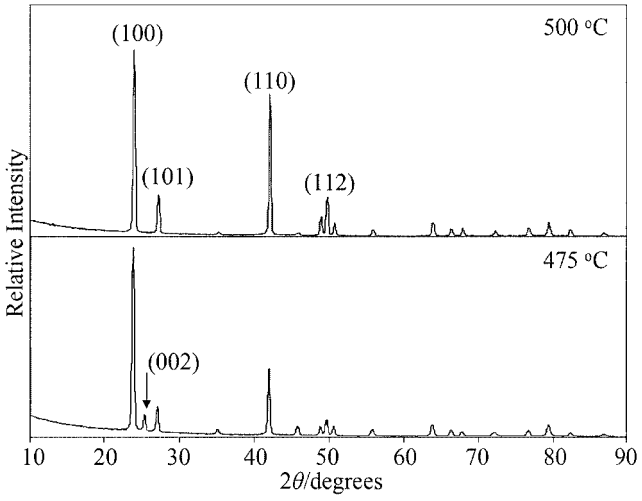

Figure 6. XRPD patterns of CdSe films deposited from $[Cd\{(SePiPr_2)_2N\}_2]$ by LP-MOCVD

SEM studies indicate that the morphology of the film grown at 500 °C consists of randomly orientated platelets (ca. 1 μm in size) (Figure 7b) with a growth rate of ca. 3 μm h^{-1}. At lower growth temperature (475 °C), film morphology consists of clusters of thin particles (Figure 7a). The surface morphology can also be compared with pre-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

vious attempts to deposit CdSe films from $[Cd\{(SePPh_2)_2N\}_2]$, which exhibited low degree of crystallinity and growth rate was also significantly lower (1 μm h^{-1}).[17] The EDAX spectrum of the film deposited at 500 °C from $[Cd\{(SeP\textit{i}Pr_2)_2N\}_2]$ shows the presence of cadmium (54%) and selenium (46%). No phosphorous contamination was detected in the films.

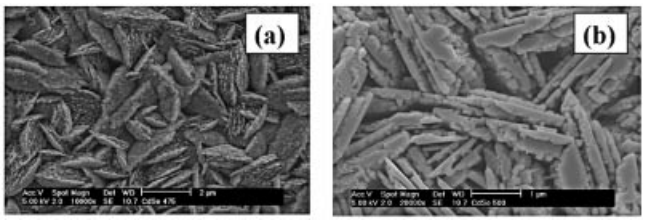

Figure 7. SEM images of CdSe films from $[Cd\{(SeP\textit{i}Pr_2)_2N\}_2]$ deposited at (a) 475 °C and 500 °C

Zinc Sulfide: Non-adherent, brown films were deposited at 450 and 475 °C maintaining precursor temperature at 250 °C using $[Zn\{(SP\textit{i}Pr_2)_2N\}_2]$. Zinc sulfide is known to exist in two phases, at low-temperature cubic polymorph (zinc blende) and at high temperature hexagonal phase (wurtzite).[31] XRPD pattern for the film deposited at 475 °C is shown in (Figure 8) and is consistent with the formation of hexagonal ZnS (JCPDS 36−1450) with a preferred orientation along the (100) plane. At higher growth temperatures (500 °C), deposited film was found to be amorphous indicated by XRPD.

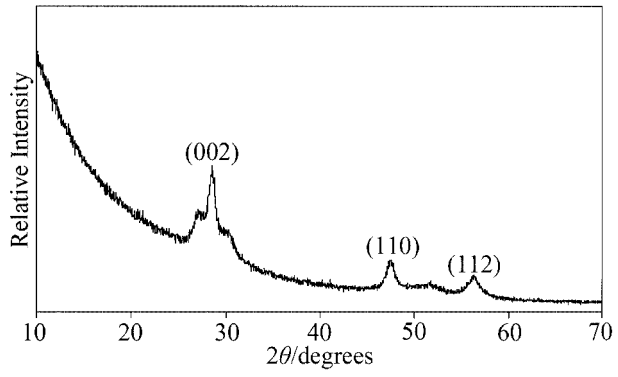

Figure 8. XRPD pattern of ZnS film deposited on glass from $[Zn\{(SP\textit{i}Pr_2)_2N\}_2]$ by LP-MOCVD

SEM micrographs for the film deposited at 475 °C shows that the film surface consists of globules ranging in size 0.25−1.25 μm. Cross-sectional SEM image of the film indicates columnar growth for ZnS and the growth rate is found to be ca. 1 μm h^{-1} (Figure 9). Similar surface morphology also has been observed for the growth of ZnS from previously studied single-source precursors by MOCVD e.g. zinc bis(diisobutyldithiophosphinate)[32] and zinc diethyldithiocarbamate.[33] EDAX indicates the presence of zinc and sulfur, however, 3% of phosphorous was also detected which is incorporated during the decomposition of precursor.

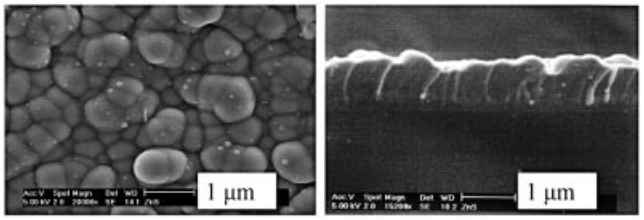

Figure 9. SEM images of ZnS films deposited at 475 °C from $[Zn\{[SP\textit{i}Pr_2)_2N\}_2]$ by LP-MOCVD

Zinc Selenide: ZnSe films were grown over a range of substrate temperatures (400−500 °C) using $[Zn\{(SeP\textit{i}Pr_2)_2N\}_2]$ but the optimum growth temperature appears to be between 425−450 °C with the precursor temperature at 275 °C. As-deposited films were orange-yellow, adherent and specular on the glass substrates. XRPD patterns indicate that the films grown at 425 and 450 °C on glass substrates showed only single-phase hexagonal ZnSe (Table 8, Figure 10). $[Zn\{(SePPh_2)_2N\}_2]$ also deposited hexagonal films at comparatively higher deposition temperatures (500 and 525 °C).[17] At higher growth temperatures

(450 °C), the crystallinity of deposited film is significantly improved. However, at lower growth temperatures (425 °C), the XRPD pattern was weak indicating a less crystalline film.

SEM micrographs for the film deposited at 450 °C on glass consists of well-defined, randomly orientated particles, with an average size of ca. 0.5 μm (Figure 11). In 1 hour growth, film with ca. 2 μm thickness has been deposited. In contrast, films deposited at 425 °C had platelike morphologies with the plates laid down horizontally with respect to the glass surface. EDAX confirms that the film is close to stoichiometric ZnSe with a small amount of phosphorous (ca. 2%).

The optical properties of the films were measured by UV/Vis spectroscopy. The bandgap values extrapolated for CdS, CdSe, ZnS and ZnSe thin films are 2.30, 1.71, 3.64 and 2.63 eV, respectively. The bandgap values are all close to the literature values of 2.53 (CdS), 1.74 (CdSe), 3.8 (ZnS) and 2.58 eV (ZnSe).[34]

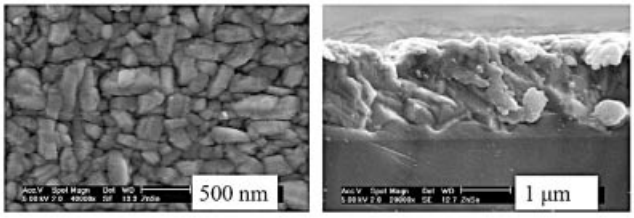

Figure 11. SEM images of ZnSe films deposited at 450 °C from $[Zn\{(SeP\textit{i}Pr_2)_2N\}_2]$ by LP-MOCVD

Conclusion

The air-stable single-source precursors $[M\{(EP\textit{i}Pr_2)_2N\}_2]$ (M = Cd^{II}, Zn^{II} and E = S, Se) have been prepared and characterised by various analytical techniques and utilised as single-source precursors for the deposition of metal chalcogenide thin films by LP-MOCVD. X-ray single crystal structures of zinc compounds indicate distorted tetrahedral geometry at the metal centres. Clean volatilisation of precursors studied by TGA makes them useful for MOCVD studies. XRPD patterns of as-deposited films show that only hexagonal phase of metal sulfide/selenide have been prepared at different growth temperatures.

Experimental Section

Precursor Synthesis: All compounds were prepared by a modified method to that reported in the literature.[18,19] The ligands $[NH(EP\textit{i}Pr_2)_2N]$ (E = S, Se) were sythesised by the reported method.[18,19]

$[Cd\{(SP\textit{i}Pr_2)_2N\}_2]$ (1):[18] In a typical preparation sodium methoxide (1.09 g, 19.7 mmol) was added to a stirred solution of $[NH(SP\textit{i}Pr_2)_2N]$ (6.00 g, 19.2 mmol) in anhydrous methanol (100 cm^3) and stirred for 10 minutes at room temperature. On addition of cadmium chloride (1.76 g, 9.5 mmol) to the resulting solution a white precipitate was formed which was furthur stirred for 2−3 hours, filtered and dried under vacuum. Recrystallisation from dichloromethane/petroleum ether (40−65 °C) yielded 6.2 g (89%) product as white solid. FT-IR: $\tilde{\nu}$ = 1224, 767 (ν P-*N*−P) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.3 (m, 48 H, 16 CH_3-R), 2.1 (m, 8 H, 8 R-CH) ppm. ^{31}P NMR ($CDCl_3$): δ = 62.59 ppm. MS (FAB): *m*/*z* = 737 $[M + H^+]$. $C_{24}H_{56}CdN_2P_4S_4$: calcd. C 39.12, H 7.60, N 3.80, P, 16.81; found C 39.30, H 7.80, N 3.74, P 17.11.

$[Cd\{(SeP\textit{i}Pr_2)_2N\}_2]$ (2):[19] Recrystallisation of the white solid product from chloroform/methanol gave white crystals, yield 4.51 g (99%). FT-IR: $\tilde{\nu}$ = 1226, 763 (ν P-*N*−P), 425 (ν P-Se) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.15 (m, 48 H, 16 CH_3-R), 2.1 (m, 8 H, 8 R-CH) ppm. ^{31}P NMR ($CDCl_3$): δ = 57.101 ppm. MS (FAB): *m*/*z* = 926 $[M + H^+]$. $C_{24}H_{56}CdN_2P_4Se_4$: calcd. C 31.16, H 6.10, N 3.03, P 13.39; found C 31.33, H 6.15, N 2.98, P 13.53.

$[Zn\{(SP\textit{i}Pr_2)_2N\}_2]$ (3):[18] Recrystallisation from dichloromethane/petroleum ether (40−65 °C) gave a white powder, yield 69%. FT-IR: $\tilde{\nu}$ = 1226, 773 (ν P-*N*−P) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.3 (m, 48 H, 16 CH_3-R), 2.1 (m, 8 H, 8 R-CH) ppm. ^{31}P NMR ($CDCl_3$): δ = 63.99 ppm. MS (FAB): *m*/*z* = 689 $[M + H^+]$. $C_{24}H_{56}N_2P_4S_4Zn$: calcd. C 41.79, H 8.55, N 4.06, P 17.96; found C 41.83, H 8.56, N 4.03, P 18.64.

$[Zn\{(SeP\textit{i}Pr_2)_2N\}_2]$ (4):[19] Recrystallisation from chloroform/methanol gave white crystals, yield 4.21 g (98%) white crystals. FT-IR: $\tilde{\nu}$ = 1228, 762 (ν P-*N*−P), 427 (ν P-Se) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.2 (m, 48 H, 16 CH_3-R), 2.0 (m, 8 H, 8 R-CH) ppm. ^{31}P NMR ($CDCl_3$): δ = 57.101 ppm. MS (FAB): *m*/*z* = 878 $[M + H^+]$. $C_{24}H_{56}N_2P_4Se_4Zn$: calcd. C 32.83, H 6.43, N 3.19, P 14.11; found C 33.02, H 6.61, N 3.12, P 14.18.

Characterisation Techniques: Unless otherwise stated, all reactions were performed under dry nitrogen using standard Schlenk techniques. All solvents and reagents were purchased from Sigma−Aldrich chemical company and used as received. In addition, toluene was distilled from over sodium under nitrogen. ^1H and ^{31}P NMR studies were carried out with a Bruker AC300 FT NMR Spectrometer. Mass spectra were recorded with a Kratos concept 1S instrument. Infrared spectra were recorded with a Specac single reflectance ATR instrument.

Growth Experiments: Low Pressure Metal-Organic Chemical Vapour Deposition (LP-MOCVD): Thin films of metal chalcogenides were grown on borosilicate glass in a low pressure (≈ 10^{-2} Torr) MOCVD reactor tube which has been described elsewhere.[21] A graphite susceptor holds the substrate dimensions (10 mm × 15 mm) which was heated by a tungsten halogen lamp.

Film Characterisations: X-ray powder diffraction studies were carried out using Philips X'Pert MPD diffractometer by using monochromated Cu-K_α radiation. The samples were mounted flat and scanned from 10° to 90° in a step size of 0.04° with a count rate of 2.5 s. Samples were carbon-coated using Edward's coating system E306A before SEM and EDAX analyses. SEM was carried out by using Philip XL30 FEG and EDAX was preformed with DX4. TGA measurements were carried out by a Seiko SSC/S200 model with a heating rate of 10 °C min^{-1} under nitrogen. Electronic absorption spectra were recorded with Helios-Beta Thermospectronic spectrophotometer.

X-ray Crystallographic Study: Single-crystal X-ray diffraction data for the compounds were collected with a CAD-4 diffractometer and Mo-K_α radiation (λ = 0.71069 Å) using ω-2θ scan. The unit cell parameters were determined by least-squares refinement on diffractometer angles (9.99° ≤ θ ≤ 12.51°) for 25 automatically centred reflections.[22] All data were corrected for absorption by empirical methods (ψ scan)[23] and for Lorentz-polarization effects

by XCAD4.[24] The structures were solved by heavy-atom method using DIRDIF-99[25] programs, refined anisotropically(non-hydrogen atoms) by full-matrix least-squares on F^2 using SHELXL-97[26] program. The H atoms were calculated geometrically and refined with a riding model. In the final stage of refinement data were correct for absorption by DIFABS.[27] The program ORTEP-3[28] was used for drawing the molecules. Crystallographic details and selected interatomic distances and angles are given in Tables 1−4.

CCDC-204283−204285 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Structure, and Properties of Biimidazole-Chelated Arylruthenium Complexes

Bikash Kumar Panda,[a] Suman Sengupta,[a] and Animesh Chakravorty*[a,b]

Keywords: Ruthenium / Fluorescence / Marcocyclic ligands / Hydrogen bonding

By reacting Ru(η^2-RL)(PPh_3)$_2$(CO)Cl (**1**) with excess 4,5-dimethyl-2,2′-biimidazole (dmbi), organometallics of the type [Ru(η^1-RL)(PPh_3)$_2$(CO)(dmbi)](PF_6) (**2**) have been isolated in excellent yield (η^2-RL is C_6H_2O-2-CHNHC_6H_4R(*p*)-3-Me-5, η^1-RL is C_6H_2OH-2-CHNC_6H_4R(*p*)-3-Me-5 and R is Me, OMe and Cl). In this process the dmbi ligand undergoes five-membered chelation, the iminium-phenolato function tautomerizes to the imine-phenol function and the Schiff base performs a large rotation around the Ru–C bond. The crystal and molecular structure of [Ru(η^1-MeL)(PPh_3)$_2$(CO)(dmbi)](PF_6)·CH_2Cl_2 is reported. For steric reasons the carbon monoxide ligand is located *syn* to the phenolic oxygen atom as opposed to *anti* in the precursor **1**. In the hydrogen bonded imine-phenol function the O–H, H···N, and N···O distances are 0.83(8), 1.77(8), and 2.552(6) Å, respectively, the O–H···N angle being 156(2)°. The Ru(dmbi) chelate along with the metallated carbon atom and the CO ligand define an equatorial plane from which the metallated aldimine fragment is rotated by 34.5° due to interligand repulsion. This results in two unequal [2.348(2) and 2.411(2) Å] Ru–P bonds and an apparent suppression of the *trans* influence of the metallated carbanionic site. The cation and anion in the complex are engaged in N–H···F and C–H···F hydrogen bonding, generating a centrosymmetric dimer in the lattice. One of the hydrogen bonds, characterized by H···F, 2.03(8) Å and N–H···F, 166(2)°, is particularly strong. Solutions of **2** absorb near 400 nm and emit near 460 nm with quantum yields and lifetimes of ca. 10^{-3} and ≤ 20 ns, respectively. The emission, which probably involves the ^{3}MLCT state incorporating a π^*(dmbi) contribution, is peculiar to the coligation of η^1-RL and dmbi to bivalent ruthenium. In dichloromethane solution **2** displays a quasireversible $\mathbf{2}^+/\mathbf{2}$ couple near 0.70 V vs. SCE [$\mathbf{2}^+$ is the ruthenium(III) analogue of **2**]. Coulometrically generated solutions of $\mathbf{2}^+$ display a strong absorption near 400 nm and rhombic EPR spectra with *g* values near 2.55, 2.15, and 1.83.

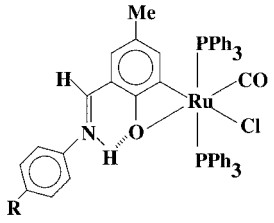
Introduction

New orthometallated ruthenium compounds are of current interest in terms of synthesis[1−3] reactivity[1,4−9] and photophysical properties.[10,11]

The decarbonylative metallation of 4-methyl-2,6-diformylphenol by $Ru(PPh_3)_3Cl_2$ in the presence of primary aromatic amines ($RC_6H_4NH_2$) furnishes organoruthenium species of the type Ru(η^2-RL)(PPh_3)$_2$(CO)Cl, (**1**), incorporating a four-membered chelate ring adjacent to a hydrogen-bonded iminium-phenolato ring.[12−14] The reactivity of **1** is under our scrutiny. Alkynes and isocyanides promote metallacycle expansion[5,6,8,15,16] but bidentate monoanionic σ-donor reagents such as carboxylates, nitrate, nitrite, xanthate, and pyridine-2-thiolate invariably form a four-membered chelate ring.[17−20]



1

The richness of this reaction chemistry prompted us to explore the treatment of **1** with an electroneutral heterocyclic ligand suited for five-membered *N*,*N*-chelation − with the result that 4,5-dimethyl-2,2′-biimidazole (dmbi) has been used to afford a crystalline organoruthenium system, characterized by hydrogen bonding interactions within itself and with anions in the lattice. This is accompanied by changes in the rotameric and tautomeric states of the Schiff base ligand. The structure and properties of the new organometallics, which are also luminescent in the visible region, are scrutinized here.

Results and Discussion

Reaction of 1 with dmbi: Chelation and Tautomerization

Addition of excess dmbi to a violet solution of Ru(η^2-RL)(PPh_3)$_2$(CO)Cl (**1**) in boiling $MeOH/CH_2Cl_2$ solution

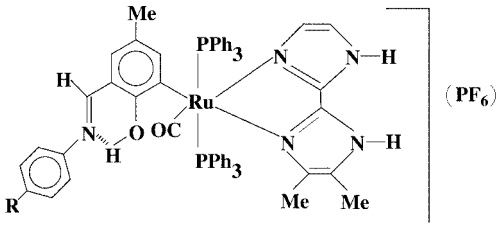
in the presence of NH_4PF_6 afforded the yellow salt [Ru(η^1-RL)(PPh_3)$_2$(CO)(dmbi)](PF_6) (**2**) according to Equation (1).

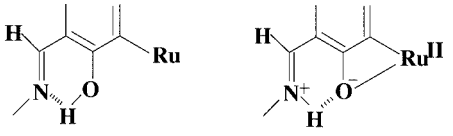
$$\mathbf{1} + \text{dmbi} + PF_6^- \rightarrow \mathbf{2} + Cl^- \quad (1)$$

In this work R = Me, OMe, and Cl, and specific compounds are identified with R in parenthesis, e.g. for **2** (Me) R = Me. Ruthenium complexes of biimidazoles have received some attention[21−25] but organoruthenium species incorporating chelation by such ligands as in **2** appear to be unprecedented. The salt **2** has been uniformly isolated in pure form in >80% yield. An isomer (the coordinating nitrogen atoms interchanged) of **2** is possible in principle but it has never been observed. Careful examination of ^{1}H NMR spectra of crude samples (before recrystallization) did not reveal any extra methyl or other signals apart from those characterizing **2** (see Exp. Sect.).



2

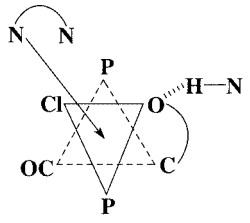
In Equation (1) the Ru−Cl and Ru−O (phenolato) bonds are displaced by the chelating dmbi ligand. With the liberation of the phenolato oxygen, the Schiff base fragment assumes the imine-phenol tautomeric form **3**, as opposed to the zwitterionic iminium-phenolato form **4** present in **1**.[12] This has been proven by structure determination (vide infra) and is fully consistent with spectroscopic data.



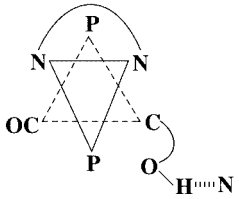
3 **4**

Thus the C=N stretching frequency in **2** is significantly lower at ca. 1600 cm^{-1} than that in **1** (ca. 1620 cm^{-1}), as expected.[26,27] Also, the aldimine CH signal in ^{1}H NMR in **2** is at a lower field, ca. 8.0 ppm as compared to ca. 7.5 ppm in **1**. The O−H resonance in **2** is a relatively sharp signal near 13 ppm, having a half-height width of ca. 30 Hz. In contrast the iminium N−H resonance in **1** is broad (width, ca. 150 Hz) due to the quadrupole moment of the nitrogen atom.[12] The prototropic transformation between **1** and **2** has certain similarities with the imine−iminium tautomerization in rhodopsins.[26]

Equation (1) is believed to proceed[17,28] via *cis* attack of chloride/O(phenolato) by dmbi as stylized in **5**. The anchored ligand can then displace both chloride and phenolato oxygen atom to achieve chelation as in **6** with concomitant prototropic and rotameric (vide infra) changes.



5



6

Characterization

Type **2** organometallics are diamagnetic (Ru^{II}, idealized t_{2g}^6) and behave as 1:1 electrolytes in acetone solution (Λ, 133−138 Ω^{-1} cm^2 mol^{-1}). The C≡O stretching frequency (ca. 1940 cm^{-1}) in **2** is indicative of dπ(Ru)−pπ(dmbi) back-bonding. In **1** as well as in the acetate and other derivatives this stretch lies systematically at lower frequencies, near 1920 cm^{-1}.[12,17−20]

In the ^{1}H NMR spectra the 3-H and 5-H proton signals of the metallated ring are sharp singlets near 6.5 ppm. The C(4)-Me signals near δ = 1.8 ppm are subject to shielding by phosphane phenyl rings.[12,17,29] The same applies to the C(22)-Me signal near 1.7 ppm; the C(21)-Me resonance is near 2.0 ppm. The PPh_3, Schiff base (C_6H_4R), and the biimidazole aromatic proton signals form a complex multiplet in the region 6.8−7.4 ppm. The dmbi N−H protons resonate near 10.2 ppm. The chemical shifts of the imine-phenol protons are considered above. The photophysical and redox properties of the complexes are examined below.

Structure: Nonbonded Interactions, Rotameric Change, and Hydrogen Bonding

The dichloromethane solvate [Ru(η^1-MeL)(PPh_3)$_2$(CO)-(dmbi)](PF_6)·CH_2Cl_2, afforded crystals suitable for structure determination. A view of the cation (Figure 1) and

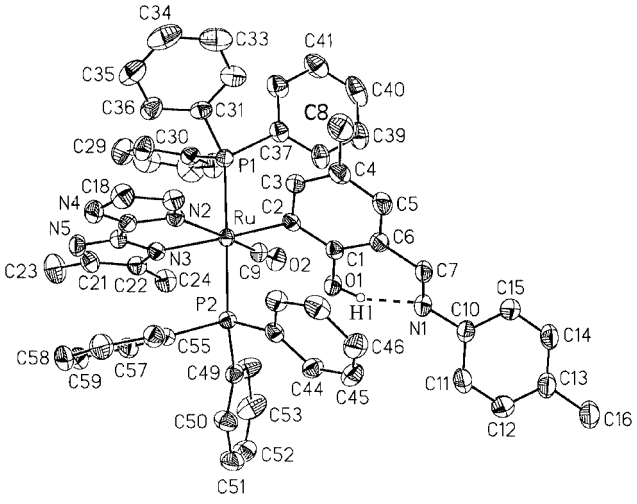


Figure 1. Perspective view and atom labeling scheme for the cation of **2**(Me)·CH_2Cl_2. All non-hydrogen atoms are represented by 30% thermal probability ellipsoids.

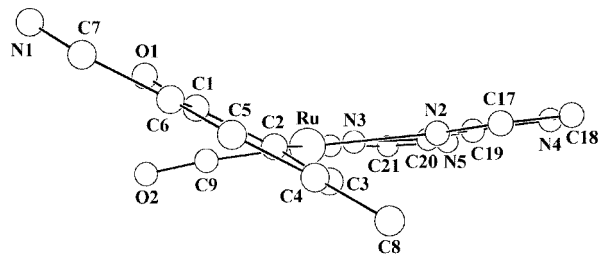
Table 1. Selected bond lengths (Å) and angles (°) for complex **2**(Me)·CH_2Cl_2

Bond lengths			
Ru−P(1)	2.348(2)	Ru−N(3)	2.157(4)
Ru−P(2)	2.411(2)	C(9)−O(2)	1.152(6)
Ru−C(2)	2.068(5)	C(7)−N(1)	1.259(7)
Ru−C(9)	1.791(5)	C(1)−O(1)	1.347(6)
Ru−N(2)	2.166(4)	N(1)···O(1)	2.552(6)
Angles			
P(1)−Ru−P(2)	175.7(1)	P(2)−Ru−C(2)	87.9(1)
P(1)−Ru−N(2)	91.0(1)	Ru−C(9)−O(2)	174.8(5)
P(1)−Ru−N(3)	90.8(1)	C(2)−Ru−N(2)	95.4(2)
P(1)−Ru−C(9)	87.0(2)	C(9)−Ru−N(3)	96.5(2)
P(1)−Ru−C(2)	90.5(1)	C(9)−Ru−N(2)	172.4(2)
P(2)−Ru−N(2)	85.2(1)	N(2)−Ru−N(3)	76.3(2)
P(2)−Ru−N(3)	90.3(1)	C(9)−Ru−C(2)	91.9(2)
P(2)−Ru−C(9)	97.1(2)		

selected bond parameters (Table 1) are given here. All the hydrogen atoms in the structure, except those of CH_2Cl_2, were directly observable in difference Fourier maps, which helped in characterizing the hydrogen bonds, vide infra. In Figure 1 only the phenolic hydrogen is explicitly shown. The solvent of crystallization CH_2Cl_2 displays a nonbonded Cl···Cl interaction [3.576(4) Å] with another symmetry related CH_2Cl_2 molecule, the two forming a centrosymmetric pair in the lattice.

The $RuC_2P_2N_2$ coordination sphere has a severely distorted octahedral geometry. The angles subtended by *cis* and *trans* pairs of ligands span the ranges 76−98° and 171−176°, respectively. On the basis of covalent radii, the idealized Ru^{II}−C(sp^2) bond length is estimated to be 2.06 Å.[17,30] The observed Ru−C(2) is 2.068(5) Å. The Ru−N(3) bond is not lengthened by the *trans* influence of the carbanionic C(2) site due to certain repulsive interactions in the structure, see below.

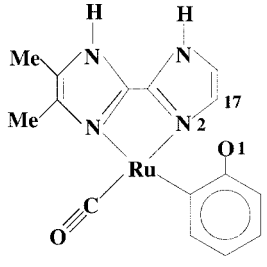
The Ru(dmbi) chelate fragment (excluding the methyl groups) along with the metallated carbon atom C(2) and the carbon monoxide ligand constitute a satisfactory plane of mean deviation 0.03 Å (plane A). Another relevant plane (plane B) is the metallated aldimine ring defined by Ru, C(1) to C(8), N(1), O(1) (mean deviation 0.03 Å). The two planes are noncoplanar as highlighted in **7**, the dihedral angle between them is 34.5°. As a result the environment is more crowded around P(2), and Ru−P(2) [2.411(2) Å] is significantly longer than Ru−P(1) [2.348(2) Å]. In the precursor complex **1** the Schiff base lies on the equatorial plane and the two Ru−P lengths are both 2.387(2) Å.[12]



7

The noncoplanarity of A and B planes arise from the repulsive nonbonded interactions between the dmbi and Schiff base ligands. Thus C(17)···C(3) [3.298(7) Å] is less than the sum (3.40 Å) of the van der Waals (vdW) radii of the two carbon atoms.[31] The distance would have been even lower, further augmenting the repulsion, if the A and B planes were coplanar. The repulsive interaction is also expressed in an effective lengthening of the Ru−N(2) bond. The *trans* influence of the carbanionic C(2) site should normally make the Ru−N(3) bond longer than the Ru−N(2) bond although the electron-donating methyl group adjacent to N(3) may marginally counter this effect. In practice the two bond lengths − 2.157(4) and 2.166(4) Å, respectively − are equal within experimental error, primarily due to the nonbonded repulsion noted above.

The conversion of **1** into **2** is attended by a large rotation of the Schiff base fragment around the Ru−C(2) bond. The carbon monoxide ligand lies *syn* to the metallated carbon atom in both **1** and **2** but it is respectively *syn* and *anti* to the phenolic C−O function in **2** and **1**.[12] The O(1)−C(1)···C(9)−O(2) torsion angle in **2**(Me)·CH_2Cl_2 is 46.7°. The computer-generated hypothetical *anti* configuration of dmbi fragment is shown in **8** where the estimated C(17)···O(1) and N(2)···O(1) are 2.416(5) Å and 2.621(6) Å, respectively, are far below the respective sums of the vdW radii (3.20 and 3.05 Å).[31] The *anti* configuration is thus unstable and the above-noted conformational change occurs to relieve the strain. The observed C(17)···O(1) and N(2)···O(1) distances in the *syn*-configured complex are 5.660(5) and 4.930(6) Å, respectively.



8

Within the imine-phenol fragment of **8**, O−H, H···N, and N···O are 0.83(8), 1.77(8), and 2.552(6) Å respectively, the O−H···N is 156(2)°. The hydrogen bonding is thus very unsymmetrical. In the iminium-phenolato fragment **4** of the precursor **1** the relevant bond lengths and angle are: N−H, 0.99(6) Å, H···O, 1.75(5) Å, N···O, 2.665(12) Å, and N−H···O, 144(1)°.[12] In effect, the hydrogen bonding is stronger (shorter N···O distance) in the imine-phenol species.

The dmbi ligand in the cation and the PF_6^- anion are engaged in N−H···F and C−H···F hydrogen bonding. The

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

centrosymmetric dimer thus generated is shown in Figure 2 along with approximate bond parameters. In organometallic hexafluorophosphate salts, H···F distances <2.6 Å, along with X−H···F (X = C, N, O) angles >90°, generally indicate significant hydrogen bonding.[32] Of the three hydrogen bond types in Figure 3 the, N(5)−H···F(1) bond is particularly strong [H···F, 2.03(8) Å; N−H···F, 166(2)°].

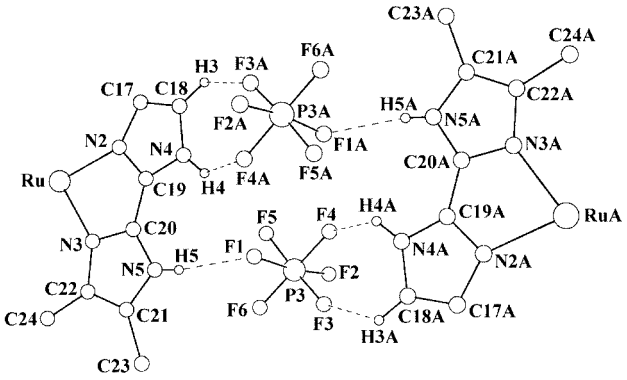


Figure 2. Hydrogen bonding in crystals of **2**(Me)·CH_2Cl_2. Relevant bond lengths (Å) and angles (°) are N(5)···F(1), 2.775(5); H(5)···F(1), 2.03(8); N(4)···F(4), 2.945(5); H(4)···F(4), 2.31(9); C(18)···F(3), 3.144(6); H(18)···F(3), 2.54(7). N(5)−H(5)···F(1), 166(2); N(4)−H(4)···F(4), 131(3); C(18)−H(18)···F(3), 123(1)

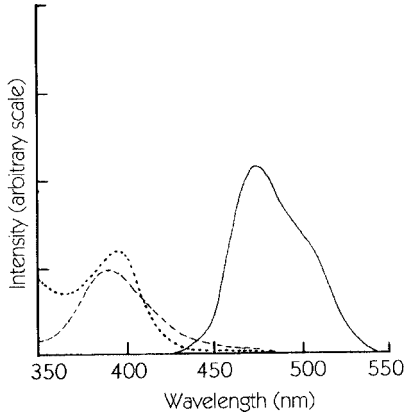

Figure 3. Absorption (···) fluorescence (——) and excitation (− − −) spectra of **2**(Cl) in dichloromethane solution.

Photophysical Properties

Type **2** complexes display two allowed transitions near 320 and 400 nm (Table 2). The later band is weaker in intensity and is believed to have significant dπ(Ru)−π*(dmbi) MLCT character. Dichloromethane solutions of **2** are fluorescent at room temperature, the emission peak lying near 460 nm. The quantum yields (φ_r) are nearly one order of magnitude lower than that of the $[Ru(bpy)_3]^{2+}$ standard[33] (Table 2).

Excitation spectral studies have revealed that the emission is associated with the absorption band near 400 nm. A representative case is shown in Figure 3. Assuming that the band has MLCT character, as suggested above, the possible involvement of the ^{3}MLCT state incorporating a π*(dmbi) contribution is implicated in the emission process. However, tris-biimidazole complexes of bivalent ruthenium are nonemitters at room temperature.[21,34] Further the parent type **1** organometallics also do not emit in the visible region. Thus the observed emission in **2** is a property peculiar to the coligation of η^1-RL and dmbi to bivalent ruthenium. Lifetime studies revealed single-exponential decay with $\tau_0 \leq 20$ ns, which is shorter than the usual (10^2-10^3 ns) lifetimes of fluorescent ruthenium(II) complexes of conjugated nitrogenous ligands.[21,23]

Electrochemistry: Metal Oxidation

In dichloromethane solution **2** displays a quasireversible (peak-to-peak separation, ca. 100 mV) cyclic voltammetric response assigned to the couple of Equation (2) where $\mathbf{2}^+$ represents the ruthenium(III) analogue of **2**.

$$\mathbf{2}^+ + e \rightarrow \mathbf{2} \quad (2)$$

The reduction potentials ($E_{1/2}$) lie near 0.70 V vs. SCE and become more positive as the electron-withdrawing power of the R group increases (OMe < Me < Cl), see Table 2. The one-electron nature of the couple is consistent with current height data, as compared to those of the one-electron standard $[Ru(bpy)_3]^{2+}$. More importantly exhaustive coulometric oxidation at 0.9 V afforded a coulomb count corresponding to a one-electron transfer (Table 2).

The trivalent organometallics $\mathbf{2}^+$, generated coulometrically, have been examined in solution. Their cyclic voltammograms (initial scan cathodic) are virtually superimposable on those of **2** (initial scan anodic), showing that $\mathbf{2}^+$ retains the gross structure of **2**. Orange-red solutions of $\mathbf{2}^+$ are characterized by an intense band near 400 nm, associ-

ated with a shoulder near 520 nm (Table 3). The solutions are EPR-active when frozen into the glassy state (dichloromethane/toluene, 77 K), giving rise to well-resolved rhombic spectra that are consistent with a low-spin $4d^5$ configuration in a nonaxial geometry.[35,36] A representative spectrum (Figure 4) and the g values (Table 3) are given here.

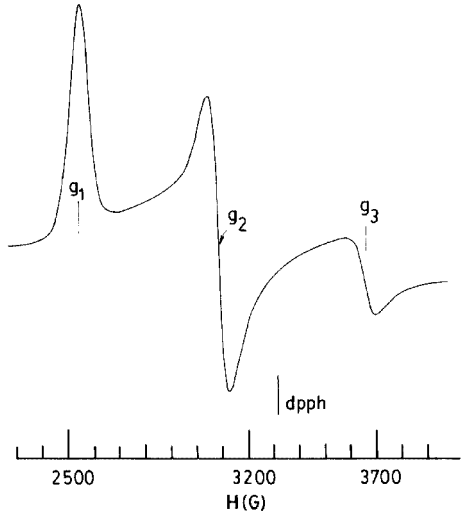

Figure 4. X-band EPR spectrum of electrogenerated $\mathbf{2}(OMe)^+$ in dichloromethane/toluene glass at 77 K. Instrument settings: power, 30 dB; modulation, 100 kHz; sweep centre, 3200 G.

Conclusions

Organometallics of type **1** are transformed into salts of type **2** upon reacting with dmbi. The conversion is attended by five-membered dmbi chelation, iminium-phenolato → imine-phenol prototropic shift and rotameric isomerization (*anti*→ *syn*) of the phenolic function with respect to the carbon monoxide ligand. The metallated aromatic ring is turned away from the dmbi chelate plane due to steric repulsion, resulting in significant inequality of the two Ru−P bonds. Also, the carbanionic *trans* influence is apparently suppressed. In solution **2** is emissive in the visible region and is electrooxidizable to its ruthenium(III) analogue $\mathbf{2}^+$, which is characterized by rhombic EPR spectra.

Experimental Section

Materials: $Ru(PPh_3)_3Cl_2$ [37] and $Ru(\eta^2\text{-RL})(PPh_3)_2(CO)Cl$[12] were prepared by reported methods, and 4,5-dimethyl-2,2′-biimidazole was obtained from Aldrich. Dichloromethane was purified for electrochemical work as described before.[35,38] All other chemicals and solvents were of analytical grade and were used as received.

Physical Measurements: Electronic and IR spectra were recorded with a Shimadzu UV-1601 PC spectrophotometer and a Nicolet Magna IR series II spectrometer respectively. ^1H NMR spectra were obtained using a Bruker 300 MHz FT NMR spectrometer. The numbering scheme used for ^1H NMR is the same as in the crystallography. Spin−spin structures are abbreviated as: s, singlet; d, doublet; t, triplet; m, multiplet. EPR spectra were recorded on a Varian E-109C X-band spectrometer fitted with a quartz dewar. Microanalyses (C, H, N) were performed using a Perkin−Elmer 240C elemental analyzer. Solution electrical conductivity was measured in acetone with a Phillips PR 9500 bridge by using a platinized electrode (cell constant of 1.05). The electrochemical measurements were performed at a platinum electrode under a nitrogen atmosphere in dichloromethane solution by using a model 620A electrochemical analyzer of CH Instruments. The supporting electrolyte was tetraethylammonium perchlorate and potentials are referenced to the saturated calomel electrode (SCE). For EPR studies $\mathbf{2}^+$ was generated coulometrically in dichloromethane solution to which dry toluene was added before freezing into the glassy state.

Fluorescence and quantum yields (using $[Ru(bpy)_3]^{2+}$ as standard,[33] $\varphi = 0.042$) were recorded with a Perkin−Elmer model LS 55 luminescence spectrometer. Luminescence lifetimes were measured in an Applied Photophysics SP-70 nanosecond fluorescence spectrometer based on a time-correlated single-photon counting technique. The decay curves were deconvoluted using the Global Fluorescence Analysis version 1.2 software of Photon Technology International.

Synthesis of Complexes: The $[Ru(\eta^1\text{-RL})(PPh_3)_2(CO)(dmbi)](PF_6)$ (**2**) complexes were synthesized in excellent yield (ca. 85%) by reacting $Ru(\eta^2\text{-RL})(PPh_3)_2(CO)Cl$ (**1**) with excess 4,5-dimethyl-2,2′-biimidazole. Details of a representative case are given below. The other compounds were prepared analogously.

2(Me): dmbi (89 mg, 0.549 mmol) was added to a hot solution of **1**(Me) (100 mg, 0.109 mmol) in a mixture of methanol (20 mL) and dichloromethane (10 mL). On subsequent heating to reflux for 3 h, the mixture changed from violet to yellow. NH_4PF_6 (30 mg, 0.184 mmol) was then added and the resultant solution was further boiled under reflux for 20 min. The solvent was then evaporated under reduced pressure and the yellow solid thus obtained was washed thoroughly with water (for removal of excess NH_4PF_6), dried, and then dissolved in dichloromethane (excess dmbi remains insoluble). The filtered solution was then stripped of solvent under reduced pressure and the residue was recrystallized from a dichloromethane/hexane (1:3) mixture followed by drying in vacuo to furnish the complex in nonsolvated form. Yield: 110 mg (85%). $C_{60}H_{54}F_6N_5O_2P_3Ru$ (1185.10): calcd. C 60.81, H 4.59, N 5.91; found C 60.75, H 4.63, N 5.85. IR (KBr): $\tilde{\nu}$ = 1939 cm^{-1}(ν_{CO}), 1591 ($\nu_{C=N}$), 847 (ν_{PF6}). ^1H NMR (300 MHz, $CDCl_3$, 298 K): δ = 12.96 (s, 1 H, O−H), 10.30 (s, 1 H, N−H), 10.20 (s, 1 H, N−H), 7.96 (s, 1 H, H7), 6.59 (s, 1 H, H5), 6.52 (s, 1 H, H3), 2.37 (s, 3 H, 13-Me), 2.02 (s, 3 H, 21-Me), 1.84 (s, 3 H, 4-Me), 1.72 (s, 3 H, 22-Me), 6.90−7.25 (m, 36 H, $2PPh_3$, H11, H12, H14, H15, H17, H18). Λ_M = 133 $\Omega^{-1}cm^2mol^{-1}$.

2(OMe): **1**(OMe) (100 mg, 0.107 mmol) and dmbi (87 mg, 0.536 mmol) were employed. Yield: 106 mg (82%). $C_{60}H_{54}F_6N_5O_3P_3Ru$ (1201.10): calcd. C 60.00, H 4.53, N 5.83; found C 60.05, H 4.58, N 5.77. IR (KBr): $\tilde{\nu}$ = 1938 cm^{-1} (ν_{CO}), 1611 ($\nu_{C=N}$), 846 (ν_{PF6}). ^1H NMR (300 MHz, $CDCl_3$, 298 K): δ = 12.99 (s, 1 H,

2(Cl): **1**(Cl) (100 mg, 0.107 mmol) and dmbi (87 mg, 0.536 mmol) were used. Yield: 107 mg (83%). $C_{59}H_{51}ClF_6N_5O_2P_3Ru$ (1205.52): calcd. C 58.78, H 4.26, N 5.81; found C 58.82, H 4.29, N 5.76. IR (KBr): $\tilde{\nu}$ = 1940 cm^{-1} (ν_{CO}), 1605 ($\nu_{C=N}$), 848 (ν_{PF6}). ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 12.69 (s, 1 H, O-H), 10.19 (s, 1 H, N−H), 10.09 (s, 1 H, N−H), 7.95 (s, 1 H, H7), 6.62 (s, 1 H, H5), 6.54 (s, 1 H, H3), 2.02 (s, 3 H, 21-Me), 1.83 (s, 3 H, 4-Me), 1.75 (s, 3 H, 22-Me), 6.90−7.34 (m, 36 H, 2 PPh_3, H11, H12, H14, H15, H17, H18). Λ_M = 138 Ω^{-1} cm^2 mol^{-1}.

X-ray Crystallography: Bright yellow single crystals of [Ru(η^1-MeL)$(PPh_3)_2$(CO)(dmbi)](PF_6)·CH_2Cl_2 (2(Me)·CH_2Cl_2) (0.40 × 0.30 × 0.25 mm^3) were grown by slow diffusion of hexane into dichloromethane solutions at room temperature. Cell parameters were determined by a least-squares fit of 30 machine-centered reflections (2θ range 14−28°) on a Siemens R3m/V four-circle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073). Two check reflections measured after every 198 reflections showed no significant intensity reduction. All data were corrected for Lorentz polarization effects and an empirical absorption correction[39] was performed on the basis of an azimuthal scan of six reflections for the crystals. The metal atom was located from Patterson maps and the rest of the non-hydrogen atoms and all the hydrogen atoms except those of CH_2Cl_2 emerged from successive Fourier syntheses. The structure was refined by a full-matrix least-squares procedure. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were refined isotropically with a fixed *U* = 0.08 Å^2. Calculations were performed using the SHELXTL, version 5.03[40] package. Crystal data are listed in Table 4. CCDC-210733 contains the supplementary crystallographic data for **2** (Me)·CH_2Cl_2. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computer Generation of Motif 5: The relative positions of CO and the dmbi chelate were retained as in the structure of [Ru(η^1-MeL)$(PPh_3)_2$(CO)(dmbi)](PF_6)·CH_2Cl_2 but the phenolic oxygen O(1) was shifted so as to correspond to the relative position in **1** (Me), the C−O length being set at 1.347(6) Å. The same software as noted above was used.

Novel Supramolecular Frameworks Self-Assembled from One-Dimensional Polymeric Coordination Chains

Xin Shi,[a] Guangshan Zhu,*[a] Qianrong Fang,[a] Gang Wu,[a] Ge Tian,[a] Renwei Wang,[a] Daliang Zhang,[a] Ming Xue,[a] and Shilun Qiu*[a]

Keywords: Supramolecular chemistry / Coordination modes / Fluorescence / Polymers

The novel supramolecular frameworks $[Cd(BDC)(phen)(H_2O)]_n$ (**2**) and $[Cd_2(HBTC)_2(phen)_2]_{2n}\cdot nCd(HBTC)(phen)_2$ (**3**) have been synthesized by reaction of the metal source $Cd(phen)_2(NO_3)_2$ (**1**) with benzene-1,4-dicarboxylic acid (H_2BDC) and benzene-1,3,5-tricarboxylic acid (H_3BTC), respectively in a mixed solution of $DMF/C_2H_5OH/H_2O$. The three-dimensional supramolecular structure of **2** is constructed through hydrogen-bond and aromatic π–π interactions between adjacent metal-organic polymeric coordination chains. Conversely, interestingly, the supramolecular architecture **3** is formed by extending 1-D metal-organic polymeric coordination chains into a 3-D framework by hydrogen-bond interactions between polymeric coordination chains and metal-organic coordination complexes instead of by interchain hydrogen-bond interactions. Additionally, these three compounds exhibit strong fluorescence at room temperature in the solid state.

Introduction

Metal-organic coordination frameworks with various intriguing topologies have been extensively studied for their versatile chemical and physical properties and potential applications in functional materials.[1−8] With the development of supramolecular chemistry, self-assembly based on molecules has become an effective approach to construct functional coordination frameworks. Hydrogen bonds provide an ideal synthetic example for the rational design of an organic crystalline framework.[9] Recently, attempts have been made to combine metal−ligand coordination and hydrogen bond interactions to self-assemble multidimensional metal-organic supramolecular frameworks.[10−12] Some 3-D supramolecular frameworks have been self-assembled from one-dimensional polymeric coordination chains, which are generated by transition metal ions and multidentate units, through hydrogen bonding and π−π interactions.[11,12]

Metal-organic coordination compounds as reactants provide not only transition metal ions but also segmental organic ligands in synthesis systems. Hence novel topologies and, particularly, chemical and physical properties may be obtained if metal-organic coordination compounds are used as the metal source to prepare supramolecular frameworks; however, we could not find any reported examples.

We report here the two novel fluorescent supramolecular frameworks $[Cd(BDC)(phen)(H_2O)]_n$ (**2**) and $[Cd_2(HBTC)_2(phen)_2]_{2n}\cdot nCd(HBTC)(phen)_2$ (**3**), which are self-assembled from metal-organic coordination compound $Cd(phen)_2(NO_3)_2$ (**1**) with benzene-1,4-dicarboxylic acid (H_2BDC) and benzene-1,3,5-tricarboxylic acid (H_3BTC), respectively.

Results and Discussion

Description of Crystal Structure

Cd(phen)$_2$(NO$_3$)$_2$ (1)

In the asymmetric unit of coordination compound **1** (Figure 1) the seven-coordinate cadmium center is chelated by four nitrogen atoms (N1, N2; N3, N4) of two chelating

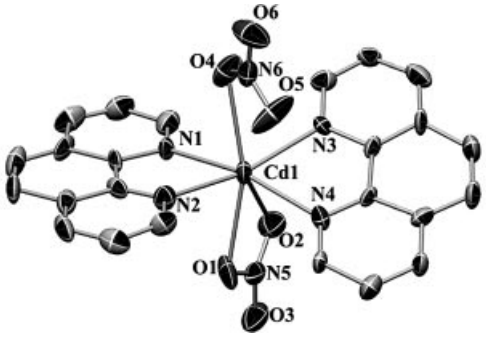

Figure 1. Asymmetry unit of **1**; thermal ellipsoids are drawn at the 50% probability level; all hydrogen atoms are omitted for clarity

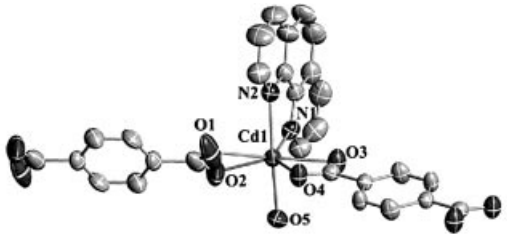
 DOI: 10.1002/ejic.200300390 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

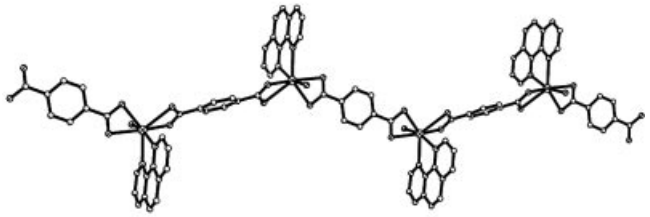
phen ligands and three oxygen atoms (O1, O2; O4) of two NO_3^- anions in different ways.

[Cd(BDC)(phen)(H$_2$O)]$_n$ (2)

A single-crystal X-ray analysis revealed that **2** is self-assembled from 1-D zig-zag polymeric coordination chains. In the asymmetric unit of **2**, there are one Cd atom, one BDC ligand, one phen ligand and one coordinated H_2O molecule. [Figure 2 (a)] The cadmium atom is seven-coordinate through coordination to five oxygen atoms (O1, O2; O3, O4; O5) of two chelating carboxylate groups of two BDC ligands, one water molecule and two nitrogen atoms (N1, N2) of one chelating phen ligand. The bond lengths of Cd1−O2 and Cd1−O3 are 2.567 and 2.401 Å, which are longer than those in other cadmium carboxylate coordination polymers.[13a] The distortion of the Cd−O bond may be due to the severe steric hindrance caused by the bulky phen group.



(a)



(b)

Figure 2. (a) Perspective view of the coordination environment of the cadmium atom in **2**; thermal ellipsoids are drawn at the 50% probability level; all hydrogen atoms are omitted for clarity; (b) 1-D zig-zag polymeric chain

Each BDC ligand bridges two cadmium atoms in bis(bidentate) fashion to form a 1-D infinite zig-zag chain [Figure 2(b)]. The coordinated H_2O molecules of the polymeric chains are well positioned to form interchain hydrogen bonds with the carboxylate oxygen atoms. The oxygen atoms of coordinated H_2O molecules and carboxylate oxygen atoms of BDC ligands from adjacent chains form strong hydrogen bonds (O2···O5 2.704 Å), which combine the 1-D zig-zag chains into 2-D undulating layers. Between neighboring 2-D undulating layers, C atoms with hydrogen atoms of phen ligands and carboxylate oxygen atoms of BDC ligands from neighboring layers form interlayer C−H···O hydrogen bonds (C9−H9···O4). The C9···O4 in C9−H9···O4 hydrogen bond is 3.219 Å long and the C9−H9···O4 angle is 147.20°, which are acceptable according to recent studies.[12b,14] There are also aromatic π−π stacking interactions between neighboring undulating layers. The plane−plane distance between adjacent two phen ligands of two neighboring layers is 3.517 Å, which is reasonable.[12b,15] All lateral phen ligands from neighboring undulating layers are intercalated in a zipper-like manner, which is similar to some previous examples.[12b,12c] Thus, the C−H···O hydrogen bonds along with aromatic π−π interactions further extend the 2-D undulating layers into a 3-D supramolecular framework (Figure 3).

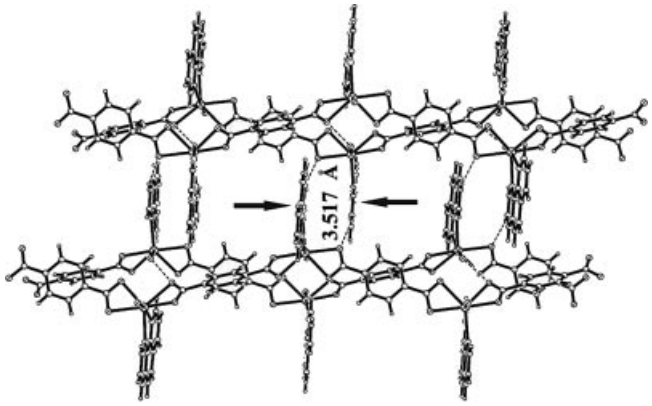


Figure 3. 3-D supramolecular framework along the [010] direction; neighboring undulating 2-D layers are intercalated in a zipper-like manner through C−H···O hydrogen bonds and π−π interactions

[Cd$_2$(HBTC)$_2$(phen)$_2$]$_{2n}$·nCd(HBTC)(phen)$_2$ (3)

X-ray crystallography reveals that **3** consists of 1-D polymeric coordination chains $[Cd_2(HBTC)_2(phen)_2]_n$ and metal-organic coordination complexes nCd(HBTC)(phen)$_2$. There are three six-coordinate cadmium centers in each asymmetric unit of **3**. Cd1 adopts a distorted octahedral geometry by coordinating to four nitrogen atoms (N1, N2; N3, N4) of two chelating phen ligands and two oxygen atoms (O14; O17) of two monodentate carboxylate groups from two H_3BTC ligands.

Two carboxylate groups from each of two crystallographically equivalent H_3BTC ligands bridge two cadmium atoms (Cd1 and Cd1A) to form a metal-organic coordination complex but the third carboxy group is uncoordinated. From the difference in bond lengths between C57−O15 [1.209(9) Å] and C57−O16 [1.326(9) Å] in the uncoordinated carboxy group, C57−O15 can be assigned to a double bond and C57−O16 to a single bond, and the hydrogen atom H16 should be linked to O16 [Figure 4 (a)].

Cd2 also adopts a distorted octahedral geometry by coordinating to four oxygen atoms (O1, O2; O5, O8) of one chelating carboxylate group of one H_3BTC ligand, two bis(monodentate) carboxylate groups of two different H_3BTC ligands and two nitrogen atoms (N5, N6) of one chelating phen ligand. The coordination environment of Cd3 is same

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

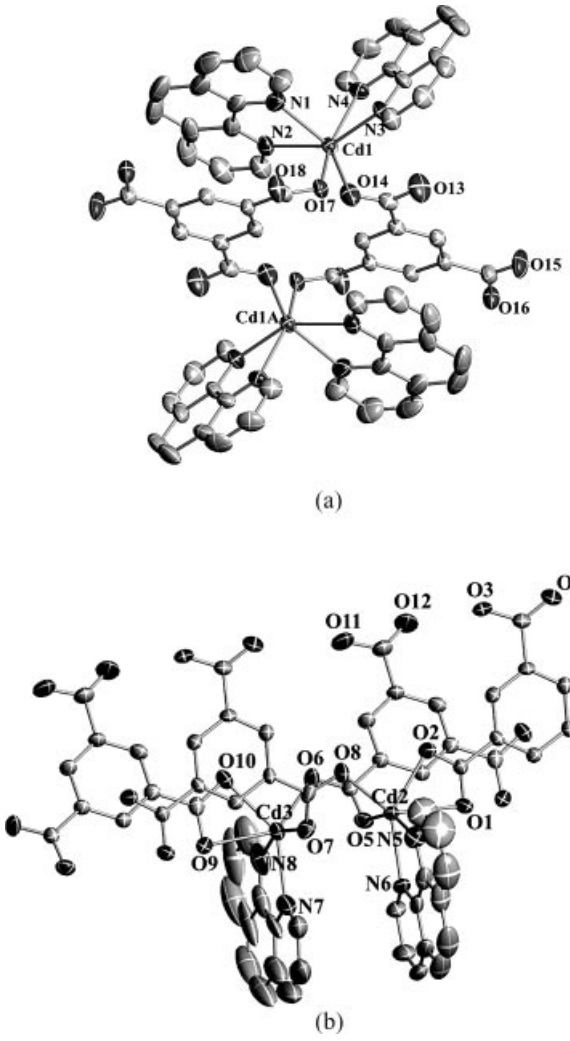

Figure 4. Perspective view of (a) the coordination environment of Cd1 in **3** and (b) the coordination environment of Cd2 and Cd3 in **3**; thermal ellipsoids are drawn at the 50% probability level; all hydrogen atoms are omitted for clarity

as that of Cd2 [Figure 4 (b)]. The bond lengths and angles of Cd−O are similar to those of cadmium trimesate polymers.[13b]

The coordinated H_3BTC ligands have two unchelated carboxy groups. The C−O bonds [C5−O3 1.298(9) Å, C40−O11 1.303(10) Å] are much longer than C=O [C5−O4 1.203(9) Å, C40−O12 1.195(10) Å] in the carboxy groups, so C5−O4 and C40−O12 can be assigned as double bonds and C5−O3 and C40−O11 as single bonds, with H3 and H11 linked to O3 and O11. The IR spectrum of **3** exhibits a broad band at ca. 3200 cm^{-1}, which is typical of the O−H vibration of a carboxy group. This shows that deprotonation of the H_3BTC ligands is incomplete, which is in good agreement with the uncoordinated carboxy groups in the structure of **3**.

Incompletely deprotonated H_3BTC ligands using the carboxylate functionality link Cd2 and Cd3 to form 1-D infinite polymeric chains $[Cd_2(HBTC)_2(phen)_2]_n$. Two adjacent 1-D chains are intercalated in a zipper-like manner[12b,12c] to form a double polymeric chain $[Cd_2(HBTC)_2(phen)_2]_{2n}$

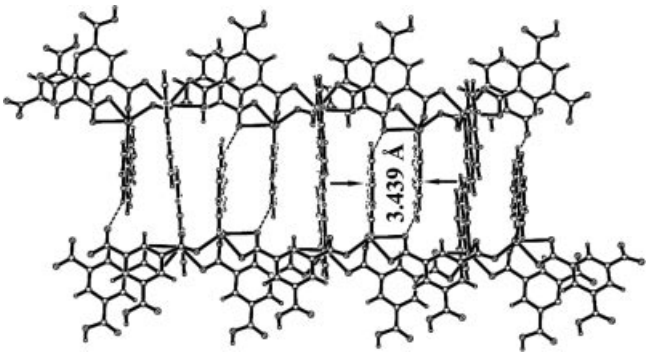

Figure 5. Double chain formed by intercalating two adjacent 1-D chains in a zipper-like manner through hydrogen bonds and π−π interactions

through C−H···O hydrogen bonds (C17···O1 2.217 Å, C17−H17···O1 154.77°)[14] and aromatic π−π stacking interactions (plane−plane distance 3.439 Å)[15] (Figure 5).

Each double polymeric chain is surrounded by metal-organic coordination complexes (Figure 6). Uncoordinated

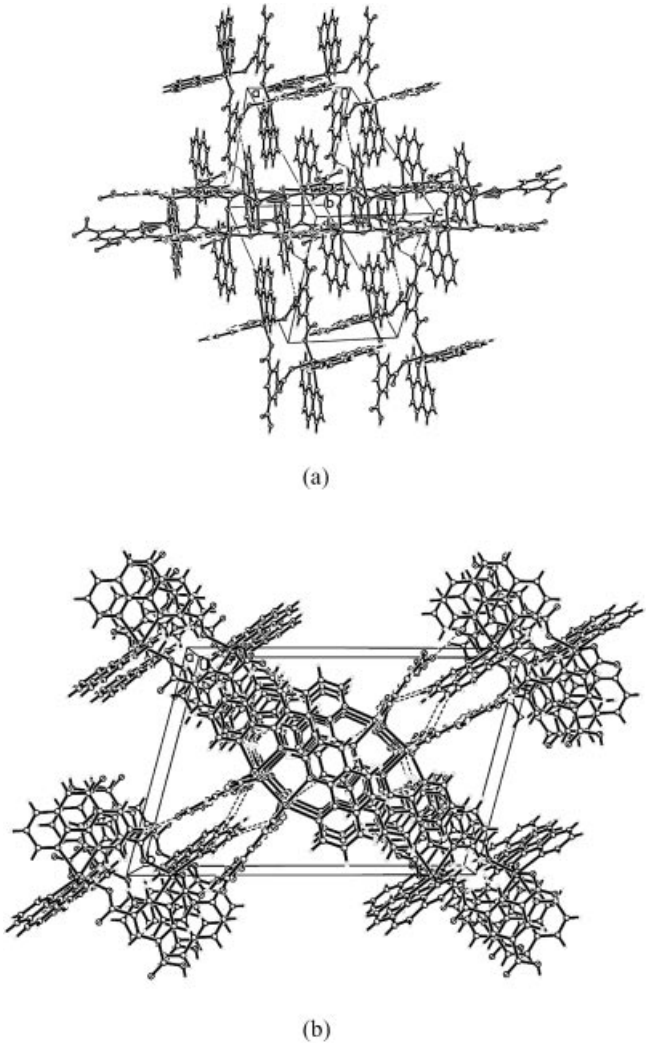

Figure 6. Perspective view of hydrogen bonds between 1-D double polymeric chains and metal-organic coordination complexes from different directions

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

carboxy oxygen atoms (O3−H3 and O11−H11) of H_3BTC ligands from the double polymeric chains point outward to form hydrogen bonds (O3−H3···O18, O11−H11···O13) with the carboxylate oxygen atoms (O18 and O13) from surrounding metal-organic coordination complexes. At the same time, uncoordinated carboxy oxygen atoms (O16−H16) from the metal-organic coordination complexes are well positioned to form hydrogen bonds (O16−H16···O9) with carboxylate oxygen atoms (O9) from the double polymeric chains. The O···O distances and O−H···O angles are listed in Table 1.

Table 1. O−O distances [Å] and O−H···O angles [°] of O···O hydrogen bonds in **3** (symmetry transformations used to generate equivalent atoms: #1: $x - 1, y, z$; #2: $-x + 1, -y + 1, -z$)

D−H···A	*d*(D−H)	*d*(H···A)	*d*(D···A)	<(DHA)
O(3)−H(3)···O(18)	0.82	1.73	2.532(7)	166.6
O(11)−H(11)···O(13)#1	0.82	1.77	2.551(8)	158.9
O(16)−H(16)···O(9)#2	0.82	1.82	2.617(7)	163.4

In addition to O···O hydrogen bonds, C−H···O hydrogen bonds exist between double polymeric chains and metal-organic coordination complexes. Double polymeric chains and their surrounding metal-organic coordination complexes intercalate so as to form hydrogen bonds between them. C atoms with hydrogen atoms (C10−H10 and C16−H16a) of a phen ligand from double polymeric chains form C−H···O hydrogen bonds (C10−H10···O18 and C16−H16a···O16) with carboxylate oxygen atoms (O18 and O16) from coordination complexes. Simultaneously, C atoms with hydrogen atoms (C42−H42, C49−H49 and C72−H72) of a phen ligands from coordination complexes also form C−H···O hydrogen bonds (C42−H42···O2, C49−H49···O10 and C72−H72···O12) with carboxylate oxygen atoms (O2, O10 and O12) from double polymeric chains. The C···O distances (2.438−2.546 Å) of C−H···O hydrogen bonds (C10−H10···O18, C16−H16a···O16, C42−H42···O2, C49−H49···O10, C72−H72···O12) and the C−H···O angles (148.22−159.34°) are both within acceptable ranges.[14] Thus, two kinds of complementary hydrogen bonds form multi-linked hydrogen-bond interactions between double polymeric chains and metal-organic coordination complexes, which ultimately extend one-dimensional double polymeric chains into a three-dimensional supramolecular framework along [011] and [0−11] (Figure 7).

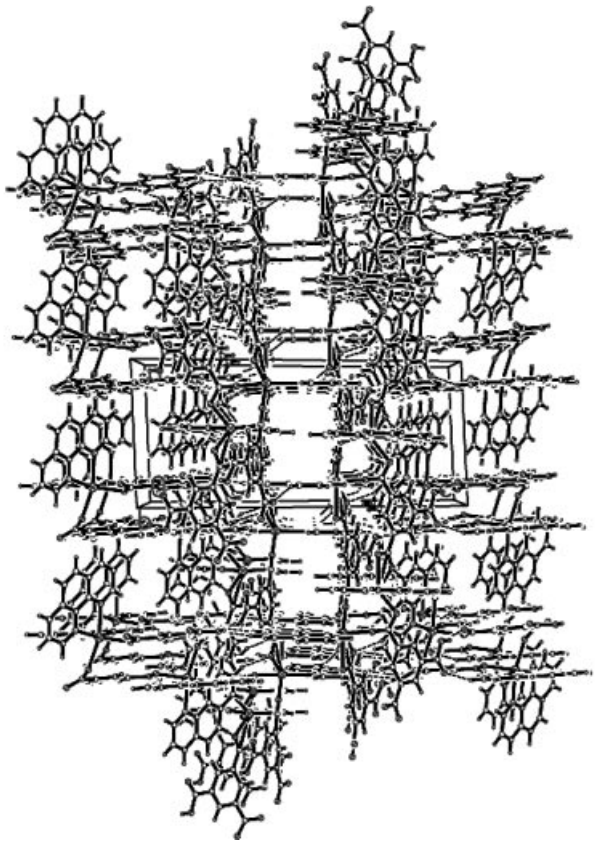

Figure 7. 3-D supramolecular architecture of **3** along [010] direction

Fluorescent Properties

Solid-state **1**, **2** and **3** exhibit strong fluorescence at room temperature. The free phen·H_2O also fluoresces in the solid state. The emission bands for free phen·H_2O are at 365 and 388 nm ($\lambda_{exc.}$ = 310 nm), which may be attributed to the $\pi^* \rightarrow \pi$ transition [Figure 8 (a)]. Of the emission bands for **1** at 366, 389 and 410 nm ($\lambda_{exc.}$ = 384 nm) [Figure 8 (b)] the first two are obviously due to intraligand charge transfer of coordinated phen ligands, similarly to the emission of free phen·H_2O. The band at 410 nm for **1** is neither LMCT (ligand-to-metal charge transfer) nor MLCT (metal-to-ligand charge transfer) in nature, and tentatively can be assigned to the intraligand fluorescent emission of coordinated phen ligands due to the planar configuration of excimeric phen molecules maintained by the cadmium ion.[16] The emission bands for **2**, at 367, 385 and 404 nm ($\lambda_{exc.}$ = 332 nm), can be assigned like those of **1** [Figure 8 (c)].[16] It is reported that free H_2BDC and free H_3BTC show fluorescence emission in the solid state. Their emission bands are mainly located at about 390 nm, with a shoulder at 370 nm for free H_3BTC (H_2BDC: $\lambda_{exc.}$ = 350 nm; H_3BTC: $\lambda_{exc.}$ = 334 nm) and are attributed to a $\pi^* \rightarrow$ n transition.[17] For **2**, the H_2BDC ligands show almost no contribution to the fluorescent emission, due to very weak fluorescent emission, resulting from a $\pi^* \rightarrow$ n transition of H_2BDC, compared with the $\pi^* \rightarrow \pi$ transition of phen and/or fluorescence quenching of carboxy groups of H_2BDC (which are strong electron-withdrawing groups). Interestingly, **3** has a single broad emission band at 380 nm ($\lambda_{exc.}$ = 330 nm), which is obviously different from the multi-bands of **2**, and may tentatively be assigned to intraligand charge transfer of coordinated phen ligands [Figure 8 (d)]. Here H_3BTC ligands also show almost no contribution to the fluorescent emission of **3**, as with **2**. The large difference between the emission bands of **2** and **3**, although they are both mixed-ligand systems, may be due to the uniquely complicated structure of **3**, with attachment of the dicadmium complex to the 1-D polymeric chain through hydrogen bonds. This complicated structure

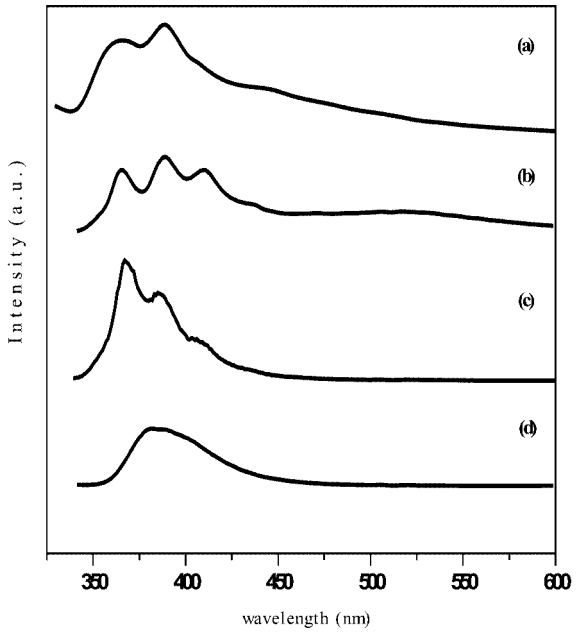

Figure 8. Solid-state fluorescent emission spectra of (a) free phen·H_2O, (b) $Cd(phen)_2(NO_3)_2$, (c) $[Cd(BDC)(phen)(H_2O)]_n$ and (d) $[Cd_2(HBTC)_2(phen)_2]_{2n}$·$n$Cd(HBTC)$(phen)_2$ at room temperature

causes multiple charge-transfer with close transition energies, which might ultimately result in a single broad emission band.

Conclusions

Two 3-D supramolecular frameworks have been synthesized by using a metal-organic coordination compound as the metal source under mild conditions. Notably for **3**, it is the hydrogen-bonding interactions between polymeric coordination chains and coordination complexes that extend the 1-D double chains into a 3-D supramolecular framework – in contrast to previously reported supramolecular structures constructed through interchain hydrogen bonds. Moreover, these compounds exhibit strong fluorescence at room temperature in the solid state.

Experimental Section

General Remarks: Elemental analyes were performed with a Perkin–Elmer 2400 element analyzer, and inductively couple plasma (ICP) analysis with a Perkin–Elmer Optima 3300DV ICP spectrometer. IR spectra were obtained with a Nicolet Impact 410 FTIR spectrometer. Fluorescence spectra were obtained with a LS 55 fluorescence/phosphorescence spectrophotometer at room temperature.

Preparation

Metal Source $Cd(phen)_2(NO_3)_2$ (1): Synthesis under hydrothermal conditions. The reaction of $Cd(NO_3)_2$·$6H_2O$ (0.308 g, 1.0 mmol) with 1,10-phenanthroline monohydrate (0.257 g, 1.3 mmol) in a solution of NaOH (10^{-3} mol/L, 10 mL) at 160 °C for 6 d produced large yellow block crystals in 86% yield (0.513 g). $C_{24}H_{16}CdN_6O_6$ (596.83): calcd. C 48.30, H 2.680, Cd 18.83, N 14.08; found C 48.36, H 2.675, Cd 18.73, N 14.12. IR (KBr): $\tilde{\nu}$ = 3066, 1600, 1588, 1495, 980, 880 cm^{-1}.

Compound 2: Preparation under mild conditions by allowing $Cd(phen)_2(NO_3)_2$ (0.158 g, 0.25 mmol) and H_2BDC (0.041 g, 0.25 mmol) to react in a solution of *N*,*N*′-dimethylformamide (DMF) (10.0 mL), absolute ethanol (2.0 mL), and distilled water (3.0 mL) at 55 °C for 4 d to produce large yellow block crystals in 59% yield (0.070 g). $C_{20}H_{14}CdN_2O_5$ (474.73): calcd. C 50.60, H 2.949, Cd 23.67, N 5.900; found C 50.52, H 2.941, Cd 23.72, N 5.884. IR (KBr): $\tilde{\nu}$ = 3325, 3079, 1625, 1606, 1541, 1418, 1012, 780 cm^{-1}.

Compound 3: Synthesis by allowing $Cd(phen)_2(NO_3)_2$ (0.158 g, 0.25 mmol) and H_3BTC (0.053 g, 0.25 mmol) to react in a solution of *N*,*N*′-dimethylformamide (DMF) (10.0 mL), absolute ethanol (2.0 mL), and distilled water (3.0 mL) at 55 °C for 6 d. The result-

ant colorless block crystals were filtered off, washed with absolute ethanol and dried at room temperature. The yield was about 46% (0.064 g). $C_{75}H_{44}Cd_3N_8O_{18}$ (1682.38): calcd. C 53.54, H 2.615, Cd 20.04, N 6.660; found C 53.58, H 2.620, Cd 20.07, N 6.652. IR (KBr): $\tilde{\nu}$ = 3200, 3058, 1598, 1568, 1409, 998, 860, 676 cm^{-1}.

Single-Crystal Structure Determination: Crystallographic data for **1** and **3** were collected at 293(2) K with a Rigaku R-AXIS RAPIC IP diffractometer with Mo-K_α (λ = 0.71073 Å). Crystallographic data for **2** were collected at 293(2) K with a Bruker-AXS Smart CCD diffractometer with Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods[18] and refined by full-matrix least-squares method against F^2 (SHELXL-97).[19] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms of organic ligands were located geometrically. The crystallographic data for **1**−**3** are listed in Table 2, and selected bond lengths and angles for **2** and **3** are presented in Tables 3 and 4, respectively. CCDC-216289 for $[Cd(phen)_2(NO_3)_2]$, -216290 for [Cd(BDC)(phen)(H_2O)] and -216291 for $[Cd_2(HBTC)_2(phen)_2{\cdot}Cd(HBTC)(phen)_2]$ contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

COVER PICTURE

The cover picture shows the structure of the cation $[ReO(cyclen\text{-}H)I]^+$. This complex and the analogous $[ReO(cyclen\text{-}H)Cl]^+$ are the first examples of d transition metal oxo complexes anchored by a monoanionic cyclen ligand. The deprotonation of cyclen can be accounted by the enhanced Lewis acidity of the d^2 rhenium center. Although the geometric contraints of *cis*-octahedral cyclen could impose the *cis*-ReO_2 unit, the resulting *cis*-dioxo complex, *cis*-$[ReO_2(cyclen)]^+$, is very reactive, being readily converted into $[ReO(cyclen\text{-}H)X]^+$. Details are discussed in the article by I. Santos et al. on p. 243 ff.

The "Rebound Controversy": An Overview and Theoretical Modeling of the Rebound Step in C−H Hydroxylation by Cytochrome P450

Sason Shaik,*[a] Shimrit Cohen,[a] Samuël P. de Visser,[a] Pankaz K. Sharma,[a] Devesh Kumar,[a] Sebastian Kozuch,[a] François Ogliaro,[a] and David Danovich[a]

Dedicated to H. F. (Fritz) Schaefer, a friend and a great scientist, on the occasion of his 60th birthday

Keywords: Alkanes / Cytochrome P450 / Density functional calculations / Enzyme catalysis / Free radicals / C−H hydroxylation

C–H hydroxylation by the enzyme cytochrome P450 is one of Nature's important and most ubiquitous processes. There is strong evidence that the mechanism proceeds by initial hydrogen abstraction, from the alkane, by the high-valent iron–oxo species of the enzyme, followed by a rebound of the alkyl radical to form the ferric–alcohol product complex (the Groves "rebound" mechanism). Nevertheless, the "rebound" mechanism is still controversial due to the ultrashort radical lifetimes deduced from radical-clock experiments. This review describes the main elements of the controversy and its updated resolution by theory, with an emphasis on the controversial rebound step. The theoretically derived model for alkane hydroxylation is found to involve two-state reactivity (TSR). In TSR, radicals are produced on two different spin-state surfaces, and thereafter they react differently; on the low-spin surface, the rebound proceeds with no product rearrangement and the lifetime of the radicals is ultrashort (or zero), while on the high-spin surface the barrier for rebound is substantial and the lifetime of the radical is sufficiently long that rearrangement may compete with product formation by rebound. A new valence-bond model is developed to model the rebound barrier on the high-spin surface and conceptualize its dependence on the nature of the alkyl radical. The possible intermediacy of carbocationic intermediates alongside radicals is discussed. It is shown that the TSR scenario provides a satisfactory rationale for the controversial findings in the field, and makes verifiable predictions. One of the predictions of TSR is that the ratio of unrearranged to rearranged products, [*U*/*R*], will be subject to an intrinsic isotope effect that is substrate-dependent. This prediction and its possible verification by experiment are discussed.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Cytochrome P450, one of Nature's most potent monooxygenating enzymes in aerobic organisms,[1] has an oxidizing domain that consists of an iron−protoporphyrin complex, Figure 1, held by the protein through salt bridges to the propionate substituents and via a cysteinate (CysS) axial ligand — the "proximal ligand" — which is part of the encapsulating protein. Entrance of a substrate, RH, triggers a succession of events, which include dioxygen uptake, reduction and protonation, all of which activate the oxidase domain and convert the iron−porphyrin complex into the active species of the enzyme, the high-valent iron−oxo species called Compound I (Cpd I; Figure 1). Some of the most important functions of the enzyme involve the hydroxylation of alkanes to alcohols. As stated in the title, this paper focuses on the recent controversy that surrounds the rebound mechanism of alkane hydroxylation, and in particular on the key step of this mechanism, the rebound step itself.

In 1976 Groves and McClusky[2] suggested that alkane (Alk−H) hydroxylation by P450 proceeds by a rebound mechanism (Scheme 1). The first step in this mechanism involves hydrogen abstraction from the alkane by Cpd I. Subsequently, the alkyl radical is partitioned between two competing processes. It can either instantly rebound to form an alcohol complex, where the alcohol is unrearranged (*U*),

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

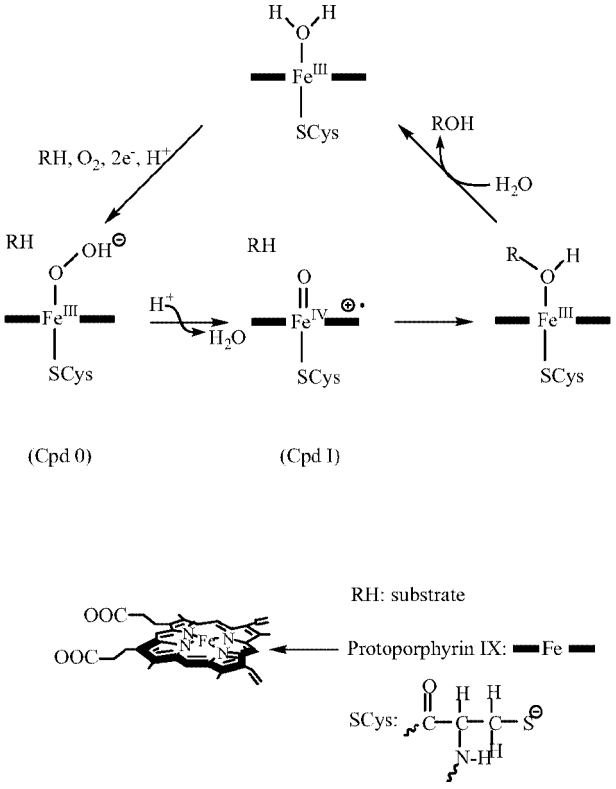

Figure 1. A truncated catalytic cycle of the enzyme cytochrome P450, showing the resting state, the active species Cpd I, its precursor, Cpd 0, and the initial product of alkane hydroxylation, the alcohol complex

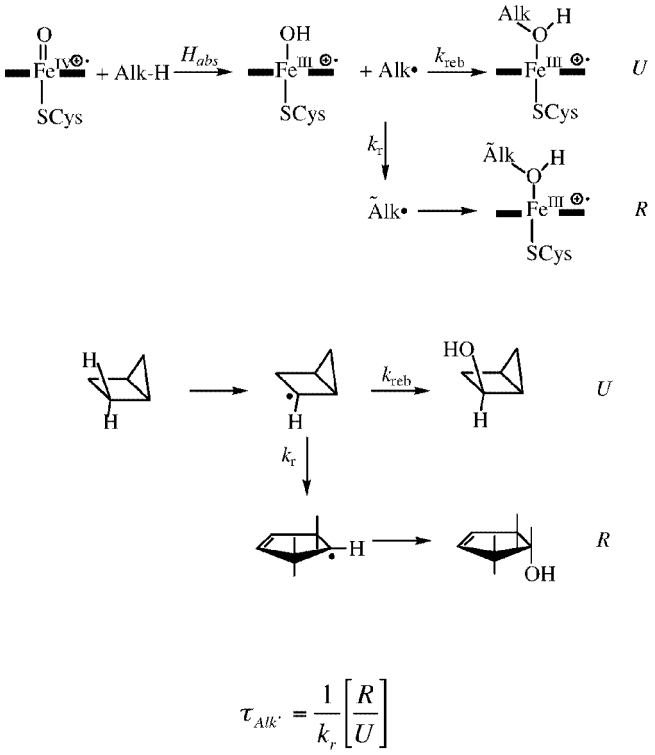


Scheme 1. The rebound mechanism, and the results of hydroxylation of bicyclo[2.1.0]pentane (ref.[12])

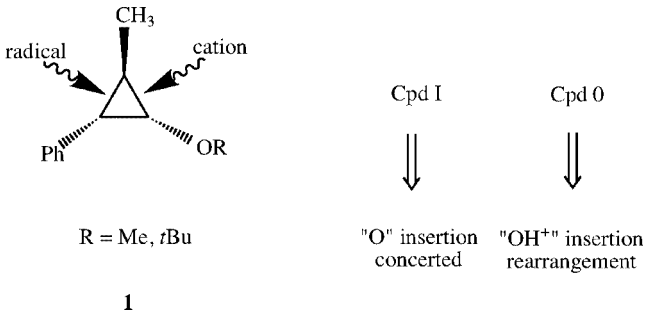
keeping the original stereochemical information possessed by the alkane, or it can first undergo skeletal rearrangement and then rebound to give a rearranged (*R*) alcohol product. The rebound mechanism accounts for the partial loss of stereochemistry and geometrical rearrangement data,[3] as well as for the large kinetic isotope effect (KIE) observed[4−10] when the hydrogen atom of the scissible C−H bond is replaced by a deuterium atom. However, the large degree of stereoselectivity (> 90%) and the sometimes completely stereospecific[8,11] hydroxylation suggested that the radicals are rather short-lived.

The Research Group in The Hebrew University: This Microreview summarizes the story of six years of intensive scientific discourse in the attempt to resolve the "rebound controversy" in the C−H hydroxylation chemistry by cytochrome P450. Our group entered the research on heme enzymes through the crack provided by the tiny FeO^+ diatomic that mimics the ability of cytochrome P450 to hydroxylate C−H bonds. This small diatomic posed some very enticing puzzles: the reaction with hydrocarbons was highly exothermic, apparently spin-allowed, and certainly orbitally allowed. Despite these rosy prospects, the efficiency of the reaction was extremely poor! The solution of this puzzle, together with Helmut Schwarz and Detlef Schröder, led to the development of the idea of two-state reactivity, TSR (ref.[26]), which is gaining increasing popularity in the community. Already then there was something in the air of P450 literature that spelled TSR. The "rebound controversy" was reminiscent of some TSR features, the intellectual dilemma it posed was challenging, and the chance for a scientific discourse was appealing. Our foray into the field was rather modest (ref.[33]). The three postdocs who started us off, Michael Filatov (now in Goteborg), Nathan Harris (now with Chemical Abstracts), and François Ogliaro (now in Kings College, London) were soon joined by other coworkers who are still in the group in Jerusalem, Sam de Visser (a Dutch postdoc from Amsterdam), Pankaz K. Sharma (an Indian postdoc from Hyderabad), Devesh Kumar (an Indian postdoc from Gorakhpur), Shimrit Cohen (a Ph.D. student from Jerusalem), Sebastian Kozuch (a Ph.D. student, a new immigrant from Argentina, now an M.Sc. student in Jerusalem), and David Danovich (a senior research associate, in the group since 1992). At present, the group has grown by three more postdocs and one graduate student.

The field of P450 is a vast ocean of many waters. Besides its being an intellectual arena full with enticing puzzles waiting to be solved, it is also an interdisciplinary field that is nestled in the crossroads between chemistry, biology, physics and medicine. Being active in such a field requires maintenance of many dialogues, and our group has been fortunate to enjoy and benefit from useful discussions with chemists and biologists of variegated expertise; Bernard Meunier, John Dawson, Joe Dinnocenzo, Sunichi Fukuzumi, Mike Green, Zeev Gross, Jay Groves, Fred Guengrich, Danni Harris, Jeff Jones, Isao Morishima, Marty Newcomb, Paul Ortiz de Montellano, Tom Poulos, Steve Sligar, Yoshi Watanabe, Wolf-D. Woggon, Kazunari Yoshizawa, Hendrik Zipse, and others in the heme enzyme community. As a group of theoretical chemistry, we have initially used only quantum mechanics (QM). Some controversies in the description of the active species of the enzyme by different QM modeling methods led us to the development of the concept of chameleon oxidants (ref.[27]), and very quickly it was evident that we must master also hybrid quantum mechanics/molecular mechanics (QM/MM) calculation since they enable to account for the effect of the protein environment. This is done in a fruitful and ongoing collaboration (ref.[46]) with Walter Thiel and his group members, Jan Schöneboom and Natalie Reuter (from the Max Planck Institute in Mülheim). We are even beginning to enjoy some docking calculations, and appreciate the importance of the protein motions that Judith Klinman talks about. Indeed, the field of heme enzymes has offered much more than initially expected in the fall of 1997, when I (S. S.) drew the active species of P450 for the first time and attempted to figure it out.

The first experiment to determine the lifetime of the radical was done by Ortiz de Montellano and Stearns,[3,12] using bicyclo[2.1.0]pentane (Scheme 1). Using the percentage of rearrangement [*U*/*R*] and the free-radical rearrangement rate constant, k_r, enabled them to quantitate the lifetime of the radical as 50 ps. However, since the products were exclusively the *endo* isomers, it was further concluded that the radical can rearrange but its reorientation, from the *endo* to the *exo* face, is restricted within the pocket of the protein. A similar conclusion was reached by Sligar et al.[6] for the C−H hydroxylation of camphor by P450cam, by Jones et al.[13] for C−H hydroxylation of *para*-xylene, and so on.[3] By contrast, an NMR study by Ortiz de Montellano[14] showed that a substrate like adamantane is mobile within the timescale of the enzymatic turnover within the pocket. It appears, therefore, that the restricted mobility of the radical is anisotropic. Other studies of radical clocks followed, and generated a variety of lifetime data, which indicated that the radicals are short-lived and somewhat restricted in their motions.[3]

The support for the rebound mechanism looked solid until Newcomb et al.[15−18] began their investigation of ultrafast radical clocks and carbocationic clocks. Thus, Newcomb has shown that the quantity [*U*/*R*] for a series of radical clocks does not correlate with the known lifetimes of the putative free-radical clocks.[15] Some rearrangement patterns of clocks like **1**, depicted in Scheme 2, were shown to correspond to carbocationic species.[16,18−20] Subtraction of these carbocationic rearrangements from the overall product mixture resulted in lifetimes as short as 70 fs;[16,18] durations much too short to qualify as lifetimes of a real intermediate species. These unrealistic lifetimes and the rearranged products derived from carbocations have led Newcomb and co-workers[15] to suggest that radical intermediates are not present during the reaction, and that alkane hydroxylation proceeds by two competing mechanisms nascent from two oxidant species of the enzyme, Cpd I and its precursor ferric peroxide species, so called Cpd 0 (Figure 1). As shown in Scheme 2, one mechanism involves a concerted [O] insertion from Cpd I into the C−H bond, while the second one involves hydroxonium ion (OH^+) insertion from Cpd 0 into the C−H bond. This latter process generates a protonated alcohol, which subsequently rearranges in a manner typical of a carbocation, with no intermediary of free carbocations. Newcomb's work has cast the rebound mechanism into doubt and started what is dubbed in the title of this work, as "*the rebound controversy*", which is still ongoing.[20−22]



1

Scheme 2. The two-oxidant hypothesis using Cpd I and Cpd 0, and a probe substrate (**1**) that can open differently depending on whether it leads to a radical or a cationic intermediate (ref.[15])

The "rebound controversy" touches the limits of chemistry's capabilities to pinpoint complex reaction mechanisms. Its importance derives from these limits, because it forces us to grapple with the state-of-the art of our understanding of molecular processes. An eventual resolution of this controversy will no doubt come from the interplay of theory and experiment. Theory has already offered a resolution of the main elements in the controversy.[23−26] Since then, a few more theoretical studies were performed by the Jerusalem group,[27,28] and by Yoshizawa et al.[29−31] Also relevant is the molecular dynamics simulations by Gualar et al.[32] which described the rebound step in the enzyme methyl monooxygenase (MMO), and which is interesting to compare to the rebound in P450. These studies cover a range of systems and pose an opportunity to give an overview intended to refine our current understanding of the controversy, with a focus on the rebound step that appears to be the origin of the intriguing controversy.

Results and Discussion

Background: Theoretical Calculations of Alkane Hydroxylation and Key Points of Contention and Focus

In 1998, Shaik et al.[23,33] offered a possible reconciliation of the controversy based on the two-state reactivity (TSR) paradigm. Subsequently, the Jerusalem group[23,24,26,27] used density functional theory (DFT) to compute model alkane hydroxylation reactions between Cpd I (HS^- as a proximal ligand) with methane and propene. As shown in the energy profiles in Figure 2, the computations reveal that alkane hydroxylation proceeds via two states, one is a high-spin (**HS**) quartet state and the other is a low-spin (**LS**) doublet state. These two states originate in the ground state of Cpd I that possesses three unpaired electrons, which give rise to two closely lying **HS** and **LS** states, separated in energy by a few wavenumbers.[34−36] The reaction path involves a C−H activation phase, which looks like a hydrogen-abstraction process, leading to a radical, loosely coordinated to the iron−hydroxo intermediate by a C···HO hydrogen bond, followed by a reorientation phase in which the radical rotates away from the OH bond to form a direct C···O contact, and finally a rebound phase in which the radical attacks the oxygen atom to form the C−O bond of the alcohol.

The **HS** and **LS** profiles are close in energy, all the way to the PorFeOH/Alk˙ cluster, and subsequently they bifurcate. In the **LS** manifold, once the radical snaps out of the C···HO hydrogen interaction with the iron−hydroxo species, the ensuing **LS** rebound phase is barrierless.[23,24,27] By contrast, the **HS** rebound has a significant barrier to rebound, with a real transition state that has clear structural and spin density features, indicative of the source of activation. As such, the radical intermediate will have a suffic-

iently long lifetime on the **HS** manifold. By contrast, the lifetime of the **LS** intermediate will be shorter than the **HS** and its upper limit will be set by the frequency of rotational modes, which establish a rebound position. Thus, the "lifetime of the radical" in this scenario is a two-state information content with an ultrashort component and a "normal" longer component.

Extending this picture to a clock experiment (Scheme 1) means that the amount of rearranged product *R* originates mainly in the **HS** state, while the unrearranged product *U* is contributed by both **HS** and **LS** states, although mostly by the **LS** state. Thus, the apparent radical lifetime, which is quantified from the ratio [*U*/*R*], is not a true lifetime, since it reflects the relative yields of the **HS** and **LS** processes. At the limiting case when rearrangement occurs only on the **HS** manifold, the [*U*/*R*] quantity will be equal to the percentage of the **LS** and **HS** processes in the total product yield. As a rule, within the two-state picture, the quantity [*U*/*R*] will yield apparent lifetimes that are shorter than the real ones. Ultrashort apparent lifetimes will result whenever the contribution of **HS** processes to the total hydroxylation reaction is very small. This TSR explanation[23,26] provided a reasonable solution of the controversy and revealed a scenario that, on the one hand, accommodated the KIE evidence, indicating a hydrogen-abstraction-like transition in the bond activation, and, on the other hand, demonstrated the reason for the controversial apparent lifetimes, which are determined assuming that the [*U*/*R*] quantity is a result of a single radical intermediate that is partitioned between instant rebound and rearrangement followed by rebound, as in Scheme 1.

Recent results of Newcomb et al.[37,38] indicate that the ratio [*U*/*R*] is subject to an isotope effect when the hydrogen atom is replaced by a deuterium atom in the scissile C−H bond. This finding of a product isotope effect rules out a single pathway or a single intermediate that is partitioned between rebound and rearrangement pathways. The observed product isotope effect can therefore indicate the operation of either TSR or two-oxidant (Scheme 2) scenarios. However, recent calculations by the Jerusalem group showed that Cpd 0 has a very high barrier for olefin epoxidation (its marker reaction), much higher than that which is calculated with Cpd I as an oxidant.[39] More recent DFT calculations[40] show the same trend for sulfoxidations, for which the barrier is much higher than with Cpd I, even when Cpd 0 is assisted by a powerful proton source. Thus, *DFT calculations rule out the possibility that Cpd 0 can compete with Cpd I as an oxidant*. Furthermore, the cryogenic EPR and ENDOR experiments of Davydov et al.[41] for camphor hydroxylation support oxidation by Cpd I, but not by Cpd 0. Even the most recent experimental evidence, which implies that Cpd 0 can indeed epoxidize olefins, shows that the putative reaction is sluggish compared with that of Cpd I and occurs only in the absence of Cpd I.[42] Similarly, radical-derived rearrangements were produced from model systems which involve only Cpd I as an electrophilic oxidant.[43,44] Thus, while one cannot rule out the presence of another oxidant, in the absence of Cpd I, at this stage of the research, the balance seems to favor the TSR scenario with only Cpd I as a plausible mechanism of hydroxylation by P450.[3]

Two DFT studies of ethane hydroxylation were performed by Yoshizawa et al.[29,30] using a model Cpd I with MeS^- as a proximal ligand. Their two studies indeed revealed TSR with bond-activation transition states that look like hydrogen-abstraction species. However, there were conflicting results and differences with the results of Ogliaro et al.[23,45] Thus, the study with the better basis set[29] reveals an **HS** profile that is ca. 6 kcal·mol^{-1} lower than the **LS** profile, while with a smaller basis set,[30] the **HS**−**LS** energy differences are small (0.6−3.2 kcal·mol^{-1}), but the **HS** profile is higher than the **LS**, in agreement with the results of Ogliaro et al.[23] The most recent study of camphor hydroxylation, by Kamachi and Yoshizawa,[31] which used a large

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

basis set, gave a difference of 2.2 kcal·mol^{-1} between **HS** and **LS** barriers, in somewhat better agreement with Ogliaro et al.[23,45] but still the lower profile is that of the **HS** process. We think that these switches in the results originate in the choice of the thiolate ligand to model the cysteinate ligand within the protein pocket. In a recent quantum mechanical/molecular mechanical (QM/MM) study, Schöneboom et al.[46] showed that Cpd I, with MeS^- as a proximal ligand, exhibits a greater sensitivity to basis set and environmental effects, than with the model HS^- as a proximal ligand. Furthermore, it was shown that with HS^-, the gas-phase calculation of Cpd I is closer to its final state in the protein pocket.

As far as the rebound step is concerned, the earlier results of the Yoshizawa group[29,30] were in conflict with those of Ogliaro et al.,[23] although the most recent ones appear to be in good agreement. Thus, the DFT calculations of camphor hydroxylation by Kamachi and Yoshizawa,[31] with a good-quality basis set, led to a picture similar to that which was obtained by Ogliaro et al.,[23] with an **LS** rebound that has a very tiny barrier, 0.7 kcal·mol^{-1}, and an **HS** rebound that has a substantial barrier of more than 3 kcal·mol^{-1}. Even though the remaining disagreements are minimal, nevertheless these apparently conflicting results highlight both the complexity of the rebound process as well as *the need for a fundamental theoretical understanding of the rebound problem*, rather than over-reliance on computations alone. Thus, since there is an experimental and theoretical consensus about the nature of the bond-activation step, the remaining doubts concern the rebound step. As such, the major questions, which are addressed in this Microreview are the following: *What is the origin of the **HS** rebound barrier? Why does the **LS** process have a tiny rebound barrier, if at all? Will the **LS** rebound barrier always be tiny*?

There are several issues within these questions. One issue concerns the electromeric identity of the iron−hydroxo intermediate, which can either be a ferric, $Por^{\cdot+}Fe^{III}OH$, species or a ferryl, $PorFe^{IV}OH$, one. In an early paper[47] the Jerusalem group argued that in the protein pocket the ground states of the iron−hydroxo complex will be the $Por^{\cdot+}Fe^{III}OH$ species. Accordingly, the studies of Harris et al.[24] and Ogliaro et al.[23] described the rebound processes for $Por^{\cdot+}Fe^{III}OH/Alk^{\cdot}$, but pointed out that smaller barriers are expected for $PorFe^{IV}OH/Alk^{\cdot}$ ($Alk^{\cdot}$ = methyl, allyl). Recent EXAFS studies of the iron−hydroxo species of the enzyme chloroperoxidase indicate that the ground state is $PorFe^{IV}OH$,[48] and similar results were obtained computationally.[27,47,49] However, the results of Groves et al.[50] and Gross et al.[51] show that in model systems in solution, both electromers may coexist. Therefore, in the following sections, we address the question of the ground state of the iron−hydroxo species, and the respective rebound barriers of the ferric and ferryl states.

The second issue is the behavior of the **HS** vis-à-vis the **LS** rebound step. We now have data on rebound processes in methane,[23] camphor[31,52] and propene[27,49] hydroxylations, and in epoxidations of ethene[25] and propene,[27,49] as well as in methane hydroxylation by a ruthenium analog of Cpd I.[28] Based on this insight, we shall present a valence-bond model for the rebound process on the **HS** and **LS** states. Using this model we shall attempt to pattern the existing experimental data of radical scrambling during alkane hydroxylation. Finally, we shall assess the possible sources of carbocations, which are implicated by the studies of Newcomb and co-workers[15,20] and the recent studies of Ortiz de Montellano and Groves et al.[21]

Electromeric States of the Iron−Hydroxo Species and the Iron−Hydroxo/Alk$^{\cdot}$ Cluster Intermediate

The iron−hydroxo intermediate formed in the hydrogen abstraction step of Figure 2 possesses three low-lying states, shown in Scheme 3, using the d-block and other key orbitals. These are the π*-orbitals [antibonding $d_{xz,yz}$(Fe)-$p_{x,y}$(O) combinations], and the a_{2u} orbital [an antibonding a_{2u}(Por)-p_z(S) combination]. Other orbitals are the δ-orbital on the iron atom, which is always doubly occupied, and the $d_{z^2}(\sigma^*_{z^2})$ orbital, which becomes populated during the HS rebound process. The ferryl state involves two singly occupied π*-orbitals, which, together with the doubly occupied δ-orbital, correspond to a d^4 metal configuration, and hence to the $^3PorFe^{IV}OH$ electromer. The other two states involve singly occupied π^*_{yz} and a_{2u}, which, together with

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the double occupancy of δ and π^*_{xz} correspond to a d^5 metal configuration and a radical cation situation formally on the porphyrin, hence the $^{1,3}Por^{\cdot+}Fe^{III}OH$ electromer states. Addition now of the alkyl radical gives rise to five different states of the iron−hydroxo/Alk$^{\cdot}$ cluster, labeled as $^{2,4}C_I(IV)$, $^{2,4}C_I(III)$ and $^{2}C_I(III')$.

The geometries and spin densities of the ferryl and ferric varieties are depicted in Figure 3a for the simple model with porphine and HS^- as proximal ligand. All values in parentheses refer to a polarizing environment, characterized by a dielectric constant, ε, of 5.7. The ferric species exhibits greater sensitivity to the polarizing environment. Thus, reminiscent of our findings for Cpd I,[46,52,53] the $Por^{\cdot+}Fe^{III}OH$ species undergoes Fe−S bond shortening and charge transfer from the porphyrin to the sulfur atom. By contrast, the ferryl species, $PorFe^{IV}OH$, is less sensitive to the environmental effect. The relative ordering of the ferric and ferryl species depends on a few variables (see detailed data in the Supporting Information) and can be described as follows. With the double-zeta LACVP(6-31G) basis set, the ground state of the bare system is the ferryl species. A larger basis set, LACV3P+*(6-311+G*), increases this preference to 5.2 kcal·mol^{-1}. Medium polarization and geometry optimization, however, stabilize the ferric states relative to the ferryl ones and decrease the difference to 3.14 kcal·mol^{-1}, as indicated in Figure 3a.

A more extensive model is the species with octamethylporphyrin and the full cysteinato ligand, shown in Figure 3b, with LACVP(6-31G) geometric values, alongside the energy differences obtained by single-point calculations with the triple-zeta LACV3P basis set and with inclusion of medium polarization. The energy difference of 1.72 kcal·mol^{-1} in favor of the ferryl situation is the highest limit of this difference. An estimate of the energy difference due to the effect of geometry optimization leads to a smaller difference of less than 0.7 kcal·mol^{-1} (values in parentheses). One can further expect that the real protoporphyrin substituents, two vinyl groups and two propionate anions, may tip the balance.[47]

Bringing in the alkyl radicals will give rise to the five states of the PorFeOH/Alk$^{\cdot}$ intermediate en route to the rebound step (see Scheme 3). The interaction of the alkyl group with the iron−hydroxo is by means of an H···C hydrogen-bonding interaction of the FeOH···C(Alk$^{\cdot}$) type, which leads to the intermediates $^{2,4}C_I$ in Scheme 3. Since the carbon atom of the alkyl group is slightly negative and the hydrogen atom of the hydroxo group is slightly positive, this hydrogen-bonding interaction will further modulate the energy differences between the ferric and ferryl states. The calculations show that the ferryl complex has a slightly larger positive charge on the hydrogen atom than in the ferric state, and therefore one might expect that the preference for the ferryl intermediate will be slightly larger in the presence of the radical, as is indeed borne out by all the calculations. However, this interaction is expected to be undermined in the presence of the screening effect of the

protein pocket. The resulting clusters from our most recent QM/MM study of camphor hydroxylation by P450cam are depicted in Figure 4. The group spin densities clearly illustrate that, under a realistic representation of the protein environment, the ferric electromers are the ground states, but the ferryl states lie very close in energy,[52] as is indeed shown by experiment for model systems in chlorinated solvents.[50,51] Since, for realistic alkanes, all the five intermediate states will lie below the hydrogen abstraction transition states, $^{2,4}TS_H$ (Figure 2), in principle, they will all be accessible for rebound, and may further complicate the TSR picture into a multi-state scenario, where both spin and oxidation states are variable.

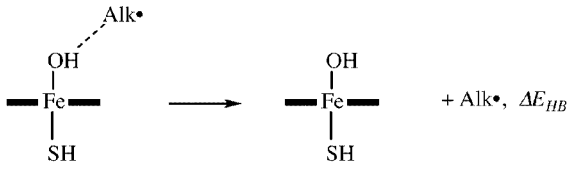
Is the Radical Free, Bound or a "Guided Radical"?

The computational data in Scheme 4 show that the strength of the FeOH···C(Alk˙) hydrogen bond in C_I is of the order of 1.9−2.7 kcal·mol^{-1}, and is marginally dependent on the radical, methyl vis-à-vis allyl. The weakness of this interaction is manifested in the presence of six-to-nine modes of very low frequencies, less than 100 cm^{-1}, and a few others with less than 200 cm^{-1}, which describe the relative movement of the alkyl radical with respect to the iron−hydroxo species, for example, ω = 81.9 cm^{-1} for the stretching mode of the hydrogen bond, H···CH_3. These frequencies are collected in the Supporting Information for the cases of methyl and allyl radicals in the ferryl states. Some of these modes are internal rotations of the radical, while others involve what may look like a stretching mode of the H···C hydrogen bond, and still others look like reorientation modes, which converts the C_I cluster to a C_H cluster held by a C−H···OFe hydrogen bond, as well as swing and flip modes. For example, a swing motion that changes the terminal of the allyl radical that is coordinated by the FeOH···C hydrogen bond, will be responsible for allylic scrambling. Likewise, a flip of the radical (self rotation), which changes the face that is coordinated to the iron−hydroxo species, will be responsible for inversion of configuration of the radical. Clearly, therefore, the radical is loosely coordinated and has a great deal of freedom at a small energy expense.



Alk	Fe	ΔE_{HB} (kcal mol^{-1})
CH_3	Fe(III)	1.9 (HS); 2.1 (LS)
CH_3	Fe(IV)	2.6 (HS); 2.7 (LS)
C_3H_5	Fe(III)	not available
C_3H_5	Fe(IV)	2.3 (HS); 2.7 (LS)

Scheme 4. OH···C hydrogen bonding energies (ΔE_{HB}) calculated at the B3LYP/LACVP level

Is the radical "bound" or is it a free radical? Since the interaction is rather small and since coordination causes the fragments to lose their individual rotational entropies ($T\Delta S \approx -6$ kcal·mol^{-1}), on the free-energy scale the separated fragments are more abundant than the FeOH···C(Alk˙) cluster, i.e., *there are more radicals that are not bound to the iron−hydroxo complex than radicals that are*. The portion of the bound species[32,54,55] will perform a periodic motion along the C···H hydrogen-bonding coordinate, as recently described in the semi-classical trajectory study of the rebound step in the enzyme MMO.[32] However, all this may be less relevant since a major consideration should be given to the situation in the protein pocket. Substrate binding by the protein is different for different P450 isozymes.[21] For example, in the enzyme $P450_{cam}$, the side chain Tyr96 holds the camphor by a hydrogen bond, C=O···HO−Tyr, to its carbonyl group.[56] This hydrogen-bonding interaction is quite exergonic, in part because it is *entropically driven* by the release of a few water molecules. Thus, this interaction appears to be more important than the weak FeOH···C(Alk˙) hydrogen bond between the alkyl group and the iron−hydroxo species. This hydrogen bonding to Tyr96 continues to hold the camphoryl radical and may even serve to reorient it towards a favorable rebound position. Thus, *we might be dealing with a "guided radical" that is conveniently oriented to the rebound position by the protein*. These protein-binding modes must be taken into account in a molecular dynamics study, and these may over-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

shadow the weak interaction found in the gas-phase calculations. Until such time when a molecular dynamics study within the protein can be conducted, we limit the analysis of the rebound step to a few essential features, which depend on clear electronic factors.

The Reorientation and Rebound Phases

Among the low-frequency vibrations of $^{2,4}C_I$, a unique mode is the one that involves either rotation of the alkyl group around the O···C axis, or the one in which the rotation of the radical is coupled to the O−H rotation around the Fe−O axis. Both movements bring the radical to the backside of the H−O bond to the rebound position (see Figure 2). This motion, which leads to the release of the radical from the FeOH···C(Alk˙) hydrogen bond, involves an energy rise of the order of 1−1.5 kcal·mol^{-1}. Both the **HS** and **LS** FeOH···C(Alk˙) species possess this feature.[23] However, once the radical snaps out of this interaction and maintains a "rebound position" with a direct O···C orientation, the **LS** and **HS** rebound processes differ in a fundamental manner. The **HS** rebound has an additional "chemical" barrier to surmount with a distinct transition state,[23,24,27] whereas the **LS** rebound is barrier-free. This, at least, is the situation in the alkyl radicals tested so far.

Table 1 collects the **HS** rebound barriers, $\Delta E^{\ddagger}_{reb}$, for the various systems studied in our group and others, including for epoxidation. These barriers are seen to be significant and to depend on the oxidation state of the iron atom in the iron−hydroxo complex [$\Delta E^{\ddagger}_{reb}$(III) > $\Delta E^{\ddagger}_{reb}$(IV)], on the identity of the transition metal [$\Delta E^{\ddagger}_{reb}$(Fe) << $\Delta E^{\ddagger}_{reb}$(Ru)], as well as on the proximal ligand [$\Delta E^{\ddagger}_{reb}$($SH^-$) > $\Delta E^{\ddagger}_{reb}$($MeSO_3^-$) ≥ $\Delta E^{\ddagger}_{reb}$(ImH)]. A polarizing field (mimicked by a dielectric constant, ε, of 5.7) raises the barrier for the Fe^{III} electromer by a significant amount, ca. 4−5 kcal·mol^{-1}, but the effect on the Fe^{IV} electromer is small and is counteracted by the effect of NH···S hydrogen bonding and further lowered by inclusion of zero-point energy effect (ZPE). As such, for the Fe^{IV} electromer, the calculated gas-phase barrier is a good approximation for the barrier that includes all these effects, while for the Fe^{III} electromer the barrier is significantly raised by the polarity of the medium.

A few rebound transition states, $^4TS_{reb}$, are depicted in Figure 5, along with a typical example of the reaction vector (the mode with imaginary frequency), which shows a clear rebound mode. The geometries of the $^4TS_{reb}$ species exhibit Fe−S and Fe−O bond elongation vis-à-vis their corresponding ^4C_I clusters. Finally, all the $^4TS_{reb}$ species exhibit reduction of the spin density on the radical and increase of the spin densities on iron, while the $^4TS_{reb}$-III species exhibit, in addition, depletion of the spin density on the porphine. Thus, both geometric as well as electronic changes accompany the **HS** rebound process.

In contrast to the **HS** rebound, once the radical in the **LS** intermediate assumes a rebound position, the ensuing rebound proceeds in a barrierless fashion for both ferryl and ferric states (Figure 2).[24,27] An illustrative example of the **LS** rebound is the behavior of $^2PorFe^{IV}OH$/allyl˙ shown in Figure 6. During the C···O shortening, the allyl radical swings around the Fe−O bond to a rebound position, the energy rises by about 1.5 kcal·mol^{-1} and then falls abruptly to the product complex, ^2P. The top structure of the potential energy profile always falls back into ^2C_I(IV) upon transition-state-optimization procedures. A frequency calcu-

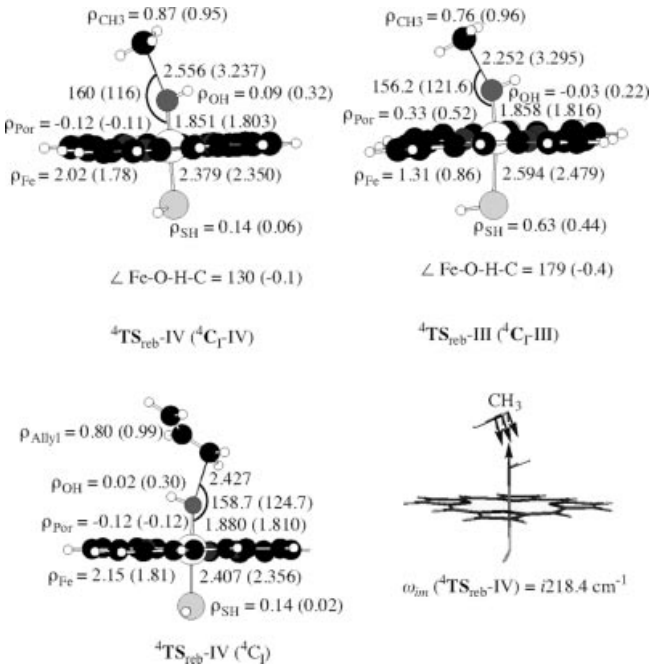

Figure 5. Rebound transition states for the **HS** process, $^4TS_{reb}$, with key geometric values and spin densities (ρ); the right-hand bottom drawing exemplifies the reaction vector (imaginary mode) for the methyl rebound $^4TS_{reb}$ species of the Fe^{IV} electromer

lation on this top structure revealed the imaginary mode displayed in the figure. It can be seen that this mode has no rebound component and is a pure rotational motion that connects the OH···C-coordinated ^2C_I(IV) conformer to the rebound conformer by a direct C···O contact. Since the latter conformer is not a real minimum, nor a saddle point, it falls abruptly to the alcohol complex product. Such rotational structures were found also for the ^2C_I(IV) intermediate of methyl radical where the imaginary rotational mode ($\omega = i92.4$ cm^{-1}) involved coupled rotation of the OH group and the methyl radical (see Supporting Information). Similar results were reported by Kamachi and Yoshizawa,[31] who located an **LS** rebound transition state with a purely rotational reaction vector ($\omega = i29.4$ cm^{-1}). The orientational nature of these structures is further evident by noting that they involve very little, if any, change in structure and spin-density distribution compared to the ^2C_I(IV) intermediate (see ρ and bond lengths in Figure 6). All the ^2C_I(III) intermediates for both allyl and methyl radicals either fell down to the corresponding alcohol products, or exhibited featureless rotational profiles en route to the products, ^2P, with structures having two or three imaginary modes corresponding to internal rotations within the cluster. Qualitatively identical results were found in our QM/MM study of the rebound process.[52]

It follows that the weak FeOH···C(Alk˙) hydrogen bond forms a flat rotational ridge that separates the **LS** iron−hydroxo/(Alk˙) intermediate and the product alcohol complex. Once the alkyl radical snaps out of this interaction, the rebound itself is a continuous downhill process. These orientational barriers amount to 0.3−1.5 kcal·mol^{-1}

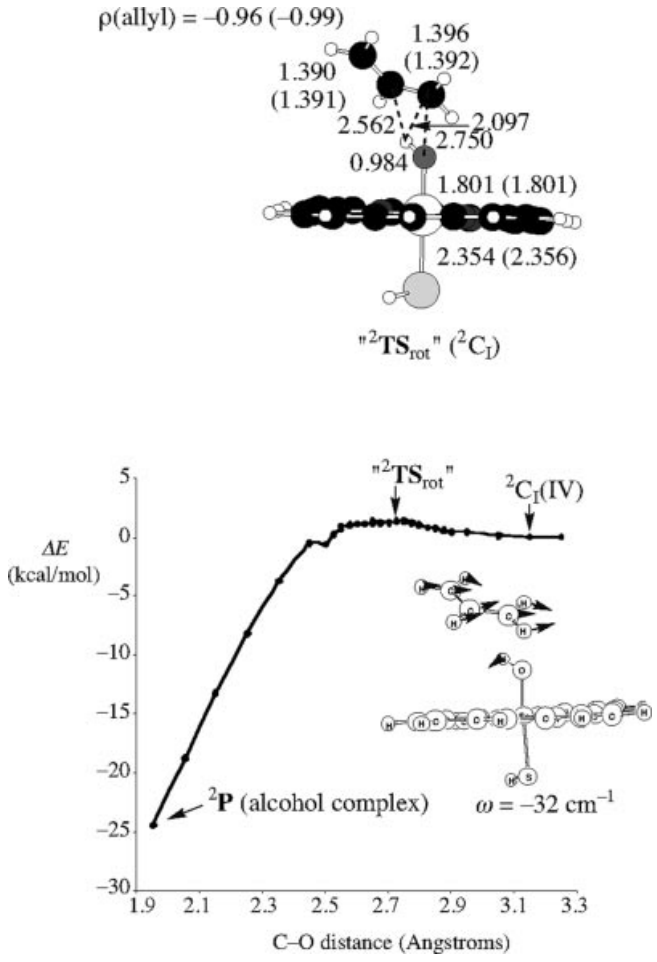

Figure 6. Illustration of the energy profile for an **LS** rebound process of the allyl radical; the topmost structure, "$^2TS_{rot}$", corresponds to a coupled rotation of the allyl radical and the OH group to assume a rebound position with a direct C···O contact; the arrows indicating the imaginary mode of "$^2TS_{rot}$" illustrate this coupled rotation; the structures on top correspond to the "$^2TS_{rot}$" species and to its precursor cluster, ^2C_I; note the virtual identity in the geometric features, and in the spin densities (ρ) of "$^2TS_{rot}$" and ^2C_I

for the various systems studied in our group. This analysis of the **LS** rebound is supported nicely by the results of the **LS** rebound in olefin epoxidation, where *the radicals are not coordinated by hydrogen bonding* to the iron−oxo complex and have barrierless rebound processes.[25,27] In conclusion, therefore, the barriers for **HS** rebound will be significantly higher than those for the **LS** rebound. Accordingly, we may expect that the lifetime of the radical on the **LS** surface will be much shorter than on the **HS** surface, and be limited by the rotational mode that the alkyl group (or OH) has to perform to establish rebound position.

The question is: Will the radical on the **LS** surface have sufficient lifetime to rearrange, or will the entire **LS** hydroxylation process be effectively concerted, while all the rearranged products will be originating in the **HS** process? In P450 hydroxylation, the rebound barriers on the **HS** surface are of the order of ≥ 4 kcal·mol^{-1} (Table 1), and are larger for the ferric states, ^4C_I(III), and within a polarizing en-

vironment. These **HS** rebound barriers are larger than, or of the order of, the barriers for skeletal rearrangements of radicals,[57] for face-flip modes leading to inversion of chirality in the product, and for a heme alkylation process.[58] By contrast, these barriers are much larger than the ones for positional swing modes, such as migration of allylic groups that leads to allylic scrambling.[27,59] *As such, we may anticipate that the **HS** pathway will give rise to anisotropical scrambling of the stereochemical information*, in a manner that depends on the barriers for the various rearrangement modes vis-à-vis the rebound barrier, as well as on the protein environment, which restricts some modes more than others. By contrast, the reorientational barriers on the **LS** surface, about 0.3−1.5 kcal·mol^{-1}, are smaller than the barriers for skeletal rearrangement in typical clocks. In this sense, the **LS** rebound will be effectively concerted. The only rearrangement modes that may compete with the **LS** rebound are softer ones (e.g., swing), which radical clocks may be able to perform, provided no restrictions exist in the protein pocket (see ref.[21] for a similar discussion).

Finally, any quantitation of the rearrangement problem is based on the assumption that the rate of radical rearrangement in the clusters, ^4C_I, is roughly the same as that of the free radicals. Recent B3LYP/LANL2DZ(6-31G*) results by Clark[60] show that the barrier for rearrangement of the cyclopropylcarbinyl radical complexed to metal ions is about 1 kcal·mol^{-1} higher than the barrier for the free-radical rearrangement. Our own results for *trans*-phenylcyclopropylcarbinyl radical show that the rearrangements for the free radical have slightly (0.6 kcal·mol^{-1}) higher barriers than the coordinated ones.[61] These results indicate that the coordination of the radical does not dramatically change its rearrangement rate. What may change it, however, are the constraints within the protein pocket. But as yet there is no such hard evidence that can contest the assumption behind the clock experiments, namely, that the rate of rearrangement of the clock can be approximated by those of the free-radical rearrangement data.[15−19]

Origins of the Differences between LS and HS Rebounds

The difference between the **HS** and **LS** rebound processes has a fundamental origin. This can be appreciated by appeal to Figure 7, which depicts in part (a) the electronic structural changes attending the rebound processes of the ferryl $^{4,2}C_{reb}$(IV) species to the respective alcohol complexes, ^{4,2}P. During these transformations, the iron center is enriched by one electron, $Fe^{IV} \rightarrow Fe^{III}$. At the same time the Alk(C)···O linkage loses one electron and becomes a standard two-electron C−O bond. Starting from $^{4,2}C_{reb}$(III) in part (b), the porphyrin radical cation gains the electron that is lost from the C···O linkage. Thus, during rebound, *the C−O bond formation is attended by a single electron shift formally from the alkyl radical to the heme moiety.* This is common to both **LS** and **HS**. However, while in the **LS** process the electron is shifted to the low-lying orbitals (π^*_{xz} and a_{2u}), in the **HS** rebound the electron is shifted to the high-lying $\sigma^*(d_z^2)$ orbital in order to conserve the quartet spin.

As illustrative examples, we show in Figure 8 the spin-density variation along the methyl rebound path of the ferric cluster for the **HS** and **LS** states. In both states, the free spins on the methyl and porphyrin moiety diminish; however, while in the **LS** state the spin on the iron atom does not vary much, in the **HS** state the spin on the iron atom increases from an initial value of unity to about 2.5 at the end of the rebound. Therefore, relative to the **LS** rebound, the **HS** process involves an additional electronic

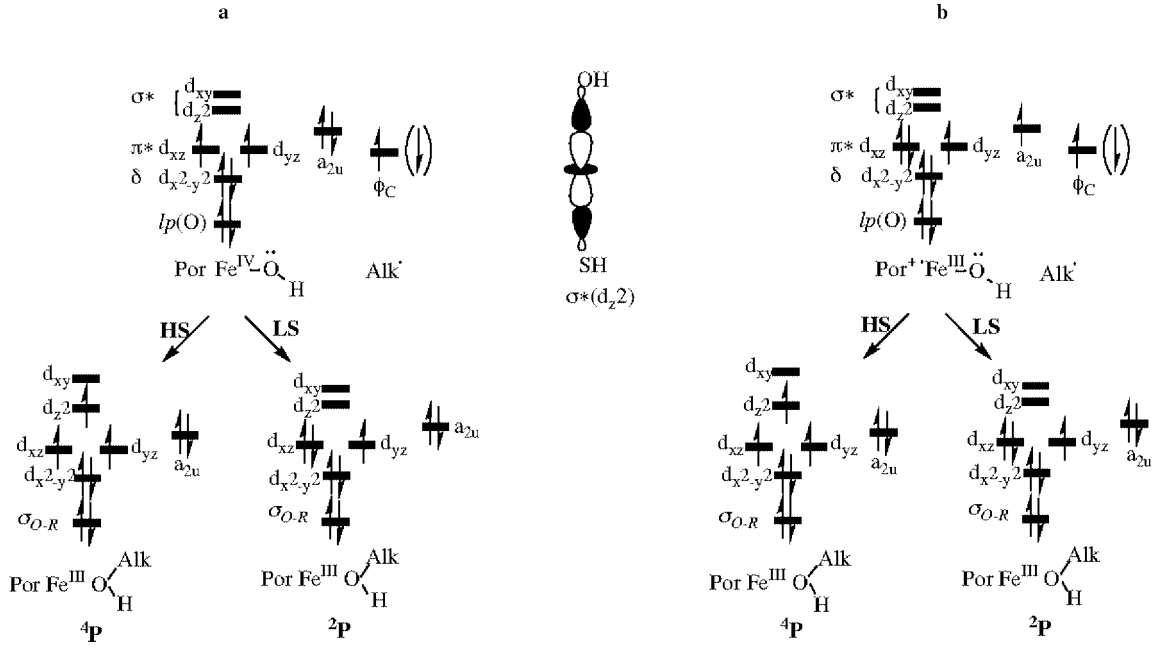

Figure 7. Orbital diagrams showing the electronic changes during rebound: (a) for the ferryl species, $^{4,2}C_I$(IV), and (b) for the ferric species, $^{4,2}C_I$(III); the $\sigma^*(d_z^2)$ orbital is drawn in between the diagrams

excitation within the d-block orbital.[23−25] This additional promotion to the σ*(d_z^2) orbital, which is antibonding in the S−Fe−O axis (Figure 7), is responsible for the lengthening of both Fe−S and Fe−O bonds in the $^4TS_{reb}$ species in Figure 5, and for the increase of the spin density on the iron atom and its decrease on the porphyrin in Figure 8. In turn, the lengthening of the Fe−O and Fe−S bonds is responsible for the **HS** rebound barrier. The role of the d_z^2(σ*) orbital is apparent by looking at the angle ∠FeO-C(Alk) in the $^4TS_{reb}$ species (Figure 5). This angle is very wide, ca. 156−160°, compared with the much smaller angle in the corresponding clusters, and it thereby indicates that the accepting orbital is σ*(d_z^2) that lies along the Fe−O axis (see orbital depiction in Figure 7).

In contrast with the **HS** process, the **LS** rebound does not require this electronic promotion. As such, during the **LS** rebound the Fe−S undergoes shortening and becomes strengthened; for example, in the case of allyl radical **LS** rebound, the Fe−S bond is shortened by about 0.2 Å for the various ^2C_I(III,IV) situations.[23,27] Part of this bond shortening is no doubt responsible for the fact that the **LS** rebound is considerably more exothermic (Figure 2) than the **HS** rebound, by ca. 7 kcal·mol^{-1} (for methyl) and 13 kcal·mol^{-1} (for allyl). Thus, the Fe−S bond shortening mitigates the energy rise due to the Fe−O bond lengthening and evidently eliminates altogether the rebound barrier in the **LS** manifold.

A Valence Bond (VB) Modeling of the Barrier for the Rebound Process

To outline a systematic structure-reactivity relationship for the rebound process, we present here a valence bond (VB) analysis of the origins of the barrier in the rebound step.[62] The oxidation-state changes, discussed above, which attend the rebound process correspond to an avoided crossing of the characteristic VB structures that possess these oxidation states. A typical VB diagram is shown in Figure 9, along a ''reaction coordinate'' that converts the ferryl rebound cluster (at the left hand extreme) to a ferric−alcohol complex (at the right hand extreme). A similar diagram will correspond to the conversion of the ferric intermediate, C_I(III), to the ferric−alcohol product. These valence-bond crossing patterns were recently verified computationally by creating the vertical states of the diagram and subsequently monitoring their crossover through the changes in charge and spin density on the alkyl group during the **HS** and **LS** rebound pathways for the substrate *trans*-1-isopropyl-2-phenylcyclopropane.[63]

The ground state, on the left-hand side, corresponds to a ferryl, C(IV), cluster. The excited state involves *an ion-pair* that corresponds to the vertical state in which the electron from the alkyl radical has been shifted to the iron−hydroxo moiety, to an orbital that depends on the spin state and oxidation state of the iron−hydroxo species, as discussed above in Figure 7. The vertical excited state correlates directly to the ground state of the alcohol complex product, on the left-hand side, since they possess essentially the same electronic structure. On the other hand, the ground state on the left-hand side correlates to an excited state of the alcohol product complex, in which one electron is excited from the π*(d_{xz}) orbital into the σ*(C−O) orbital. Since the two VB states have the same symmetry properties, they can mix with each other and avoid the crossing leading to an adiabatic state, which is lower by an amount *B* than the crossing point, and which corresponds to the transition state for rebound.

The rebound barrier is given by the following equation:[62]

$$\Delta E^{\ddagger}_{reb} = fG - B; f < 1 \quad (1)$$

Here, *G* is the vertical gap between the VB structures at the onset of the diagram, and *f* is the fraction of this excitation gap that enters under the crossing point of the VB

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

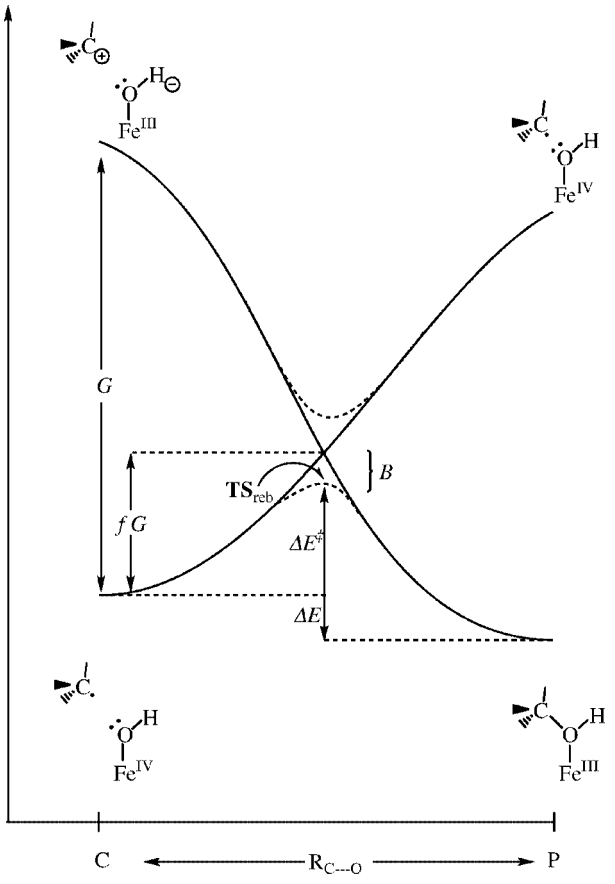

Figure 9. A valence-bond diagram (see ref.[62]) showing the origin of the rebound barrier; *G* is the vertical energy gap between the ground state of the rebound cluster, exemplified by C(IV) and the excited state where an electron was shifted to the iron d orbital; in the **LS** process the electron is shifted to the low-lying π* orbital (on the FeO moiety), while in the **HS** rebound the electron is shifted to the high-lying σ*(d_z^2) orbital; the quantity *fG* corresponds to the height of the crossing point, *B* to the quantum mechanical resonance energy due to the mixing of the valence bond forms, and Δ*E* to the energy difference between the cluster and the alcohol complex product

state curves. Finally, *B* is the VB mixing energy at the crossing point.

The vertical gap, *G*, depends on the spin state and is given by the following expression:

$$G_{\mathbf{HS}} = IP_{\mathrm{Alk.}} - EA_{\mathrm{FeOH}} + E_{\mathrm{el}} + \Delta E_{\pi^*\rightarrow\sigma^*} \quad (2a)$$

$$G_{\mathbf{LS}} = IP_{\mathrm{Alk.}} - EA_{\mathrm{FeOH}} + E_{\mathrm{el}} \quad (2b)$$

where *IP* is the ionization potential, *EA* the electron affinity, and E_{el} the electrostatic energy in the ion pair. The **HS** gap is seen to involve the additional excitation energy term, $\Delta E_{\pi^*\rightarrow\sigma^*}$, to the $d_z^2(\sigma^*)$ orbital. Calculated at the LACVP(6-31G) level, this quantity is ca. 24 kcal·mol^{-1}. The second factor, *f*, depends, inter alia, on the thermodynamic driving force of the rebound step, Δ*E*, and becomes smaller the more exothermic the rebound is.[62] Since the **LS** rebound is considerably more exothermic (Figure 2) than the **HS** rebound (e.g. by 13 kcal·mol^{-1} for allyl rebound), the *f* factor will depend on the spin state such that:

$$f_{\mathbf{LS}} < f_{\mathbf{HS}} \quad (3)$$

Therefore the height of the crossing point for the **LS** rebound will be considerably smaller than that for the **HS** rebound:

$$f_{\mathbf{LS}}G_{\mathbf{LS}} << f_{\mathbf{HS}}G_{\mathbf{HS}} \quad (4)$$

The calculated gas-phase electron affinity of the iron−hydroxo species is quite large, 63 kcal·mol^{-1} at the LACVP(6-31G) level, and in a polarizing medium (ε = 5.7) it goes up to about 100 kcal·mol^{-1}. The *IP* of radicals like allyl or cyclopropylcarbinyl is 180 kcal·mol^{-1}, and it goes down further in a polarizing medium [for allyl radical *IP*(ε = 5.7) = 131 kcal·mol^{-1}]. Thus, after inclusion of the electrostatic interaction, E_{el}, between the cation and the anion, the gap factor for the **LS** process of typical radicals (allyl, cyclopropylcarbinyl, etc.) would be rather small — $G \approx 60$ kcal·mol^{-1}. Using a typical value of $f = 0.25$, the *fG* term will be rather small, approximately 15 kcal·mol^{-1}. Since VB mixing further lowers the state by an amount *B*, which itself is of the order of 15 kcal·mol^{-1},[62] the **LS** rebound barrier will have an exceedingly small value or be virtually eliminated, as indicated by the DFT calculations. By contrast, the barrier for the **HS** rebound will persist and be significant, due to the additional excitation to the $d_z^2(\sigma^*)$ orbital and the poorer exothermicity factors. Using the computed values of the **HS** excitation energy, $\Delta E_{\pi^*\rightarrow\sigma^*}$, and a typical value for *f* ($f = 0.25$)[62] predicts that the **HS** barrier will be 6 kcal·mol^{-1} higher than the **LS** process. This is not too far from the DFT-computed difference.

The role of the excitation term to the $d_z^2(\sigma^*)$ orbital is further illustrated by the dependence of the barrier on the identity of the proximal ligand (Table 1). Thus, for thiolate, which interacts strongly with the iron atom, the $d_z^2(\sigma^*)$ orbital is high and the rebound barrier is significant. By contrast, imidazole (ImH) and methyl sulfonate ($MeSO_3^-$) proximal ligands, which are much poorer σ-binders, have much lower $d_z^2(\sigma^*)$ orbitals,[64] and consequently their rebound barriers decrease and virtually disappear, as seen in Table 1 (Entries 8 and 9).

A more striking effect is caused by changing the transition metal, i.e., when iron is replaced by ruthenium (Table 1). The 4d orbitals of ruthenium overlap much better with the 2p orbitals of the oxygen atom than the 3d orbitals of the iron atom.[28,65] Consequently, the $\sigma^*(d_z^2)$ orbital of the ruthenium−hydroxo species is much higher than the corresponding orbital of the iron−hydroxo one. This is the reason why the rebound barrier for ruthenium is almost four times larger than the corresponding barrier for iron.

The dependence of the **HS** rebound barrier on the oxidation state of the iron atom in the iron−hydroxo species can be understood by consideration of the term *B* in Equa-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion (1), by appeal to Figure 7. This term can be viewed as the C···O bonding energy in the transition state and along the rebound path. In the ferryl(IV) situation, the electron is shifted from the radical center directly to the $d_z^2(\sigma^*)$ orbital, and hence *B*(IV) is simply proportional to the overlap of these two orbitals, namely, $<\varphi_C|d_z^2(\sigma^*)>$. By contrast, in the ferric(III) situation, the electron cannot be shifted directly to $d_z^2(\sigma^*)$ due to spin frustration. Instead, while the spin-up electron in the φ_C orbital shifts into $d_z^2(\sigma^*)$, the spin-down electron in π^*_{xz} has to shift to a_{2u} to fill this orbital. Due to this higher order reorganization of the electronic structure, the factor *B*(III) is proportional to a product of orbital overlaps of the orbitals which participate in this electronic reshuffle, $<\varphi_C|d_z^2(\sigma^*)><\pi^*_{xz}|a_{2u}>$, and is hence smaller, namely:

$$B(\mathrm{IV}) > B(\mathrm{III}) \quad (5)$$

Since the two **HS** rebounds have approximately the same *G* and *f* factors, the stronger VB mixing for the ferryl situation will give rise to a smaller rebound barrier, as is indeed reflected by the data in Table 1.

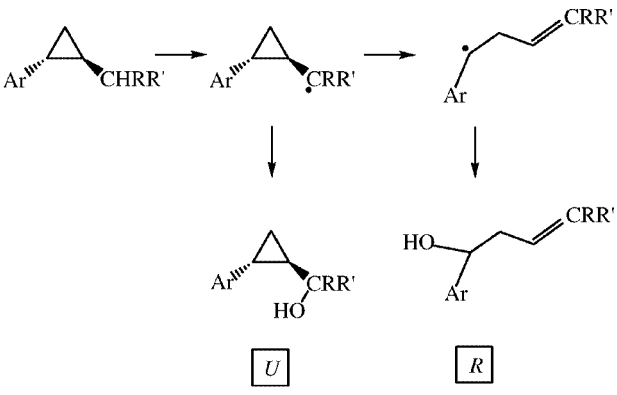
Finally, further consideration of the term *B* shows that the rebound trajectory of the **LS** and **HS** processes must be quite different. In the **HS** rebound the electron shifts from the radical center to the $d_z^2(\sigma^*)$ orbital. Hence, to maximize the bonding term, *B*, the $^4TS_{reb}$ species must assume a structure with a large ∠FeOC angle, as is indeed shown in Figure 5 (∠FeOC ≈ 160°). By contrast, since the **LS** rebound [in the C(IV) electromer] involves a shift of the electron from the alkyl radical to the π^*_{xz} orbital, maximization of the O···C bonding along the rebound pathway requires an ∠FeOC angle of ≥ 90°. When one of these angular requirements cannot be met due to steric constraints, the corresponding barrier will increase. Such a case was recently encountered[63] in the rebound of aryl radicals, which resulted in rebound barriers in both **HS** and **LS** manifolds, since the required ∠FeOC angle of ≥ 90° for the **LS** path was barred by steric effects. These cases will not be discussed any further in the present Microreview.

Rearrangement Patterns of Radical Clocks

Clearly, the VB model in Figure 9 provides a consistent framework for analyzing and predicting trends in the rebound process. Let us now consider a series of probe substrates, which can form radicals that can undergo skeletal rearrangement, so that the unrearranged (*U*) and rearranged (*R*) forms of the radical can rebound and give rise to corresponding alcohol products, *U* and *R*, like the clock probes used by Newcomb et al.[15] The negative results of the slow clocks cannot be analyzed, but they enable us at least to bracket the barrier of the **HS** rebound to be smaller than the barrier for a slow probe like cyclopropyl carbinyl radical, which has a rearrangement barrier of approximately 6.9 kcal·mol^{-1}.[57] There are, however, [*U*/*R*] data that can be analyzed, and the question is: What can we predict for the measurable quantity [*U*/*R*], in a clock experiment?

For simplicity, we must consider a case where the only competing processes are the radical rearrangement and the **HS** and **LS** rebounds. Assuming that the **LS** rebound is effectively concerted, giving rise to only *U* products, and that the radicals on the **HS** manifold can give rise to both *U* and *R*, we can then make some predictions about the behavior of the quantity, $[U/R]_{HS}$, that arises from the **HS** rebound. A clear prediction can be made when the series meets the following conditions: (i) the rearrangement rate of the radicals is constant or quasi constant, (ii) the thermodynamics of the **HS** rebound does not vary in an adverse manner to the gap, and (iii) the rearrangement of the radical is irreversible, such that all rearranged radicals end up as rearranged alcohols.

The VB model (Figure 9) and the equation for the barrier [Equations (1) and (2)] tell us that when the above conditions hold true, the rebound barrier, $\Delta E^{\ddagger}_{reb}$, will depend on a single factor, the IP_{Alk} of the radical (within the protein pocket). The smaller the IP_{Alk} quantity, the lower the rebound barrier will be, and the shorter will be the radical lifetime on the **HS** manifold. Thus, for the above conditions, we expect that the $[U/R]_{HS}$ quantity, as well as the total [*U*/*R*], will increase as the IP_{Alk} decreases, i.e., as the radical becomes a better electron donor. Such a series was investigated by Newcomb et al.[15,17] who used clocks that are structurally related and have virtually identical rearrangement rate constants of ca. 10^{11} s^{-1}. These clocks are arranged in Scheme 5, in order of donor ability of the corresponding radical, and along with the measured [*U*/*R*] quantities. It can be seen that, in this series, which meets



probe	Ar	R,R'	IP_{Alk}	[*U*/*R*]
2	*p*CF_3	H, H	highest	4
3	*p*H	H, H	⇑	4.3
4	*p*CF_3	H, CH_3		12
5	*p*H	H, CH_3		25
6	*p*H	CH_3, CH_3	lowest	> 100

Scheme 5. A rebound/rearrangement scheme for probe substrates (ref.[15]) and the variation of their [*U*/*R*] quantities with the ionization potentials of the corresponding alkyl radicals

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

approximately the requirements stated above, the [*U*/*R*] quantity increases rapidly, with decrease of IP_{Alk}, from 4 to more than 100, as predicted by the above simple consideration. Our most recent calculations of the best donor substrate, **6**, in this series shows that, indeed, the **HS** rebound barrier vanishes, and as such both the **LS** and **HS** processes become effectively concerted.[63]

Interestingly, Newcomb, Lippard et al,[20,57] found that for MMO hydroxylation the probe substrate **3** gave no rearrangement at all, as opposed to the approximately 25% of rearranged alcohol observed during P450 hydroxylation of the same probe. This can be understood by recognizing that the electron affinity of the iron−hydroxo form of the enzyme MMO is significantly larger than that of the iron−hydroxo species of P450. As such, the energy gap factor, *G* [Equation (2)], for MMO rebound processes will generally be smaller than the same gap in P450 rebounds, leading to less rearranged products.

An interesting trend that can be predicted from the VB model refers to the effect of the strength of Fe−S binding on the **HS** rebound barrier. Weak binding will lower the energy of the $d_z^2(\sigma^*)$ orbital, and will therefore decrease the **HS** rebound barrier. Since rebound and rearrangement compete with one another, enhancement of the rebound rate will, in turn, decrease the amount of observed rearranged product. The polarity and acidity of the protein pocket affect the strength of the Fe−S bonding,[46,64,66,67] and one might therefore expect to find that the [*U*/*R*] quantity is different for different P450 isozymes. This conclusion means that [*U*/*R*] is not a pure property of the clock probe. Furthermore, studies by Newcomb et al.[38,68] and by Ortiz de Montellano and Groves et al.[21] show dependencies of the [*U*/*R*] quantity on the P450 isozyme. While we cannot rationalize the precise trends we can at least point out that the VB model predicts such behavior as the result of the variation of the Fe−S bonding with the identity of the isozyme. Presumably, this kind of information on the Fe−S bonding can ultimately be obtained by crystallography and spectroscopy.[66,69] Such a dependence of the [*U*/*R*] quantity on the identity of the isozyme is a clear demonstration that [*U*/*R*] does not measure intrinsic lifetimes of the radicals. Therefore one does not expect to find a correlation between this quantity and the rate of free-radical rearrangement, as indeed demonstrated in the study of Newcomb et al.[15]

What Does the [*U*/*R*] Quantity Actually Measure?

The above discussion considers the $[U/R]_{\mathbf{HS}}$ quantity that arises from the **HS** rebounds. However, the rebound also involves an **LS** component, and hence the total [*U*/*R*] quantity is a two-state information that must also be associated with the relative **LS/HS** yields, and not only with lifetimes as such. The question we wish to address here is: What mechanistic information is provided by the measured [*U*/*R*] quantity? One apparent aspect of the "rebound controversy" is that while the slow clocks do not lead to rearranged products, with the notable exceptions of norcarane and bicyclo[2.1.0]pentane,[20,21] the fast clocks undergo rearrangement, but lead to apparent lifetimes that are too short, sometimes as short as 70 fs.[15] Using the two-state approach enables us to understand this aspect, by appeal to Figure 2, and assuming that the **LS** pathway is effectively concerted (or leading to a negligible amount of rearranged products).

At the limit of independent **LS** and **HS** pathways with initial fractions *n* and (1 − *n*), respectively, the actual rate of rebound on the **HS** manifold is given by:[23,26]

$$k_{reb}^{(\mathbf{HS})} = k_r\{[U/R]_{tot} - F_{\mathbf{LS/HS}}\}/\{1 + F_{\mathbf{LS/HS}}\};\quad F_{\mathbf{LS/HS}} = [n/(1-n)]k_{\mathbf{LS}}/k_{\mathbf{HS}} \tag{6}$$

Here, $k_{\mathbf{LS}}$ and $k_{\mathbf{HS}}$ correspond to the rate constants for C−H bond activation for the **LS** and **HS** states, respectively, while $[U/R]_{tot}$ is the total ratio of unrearranged to rearranged products obtained from the two states:

$$[U/R]_{tot} = [(U_{\mathbf{HS}} + U_{\mathbf{LS}})/R_{\mathbf{HS}}] \tag{7}$$

The apparent rebound rate, which is quantified simply from the measured $[U/R]_{tot}$ quantity, is given on the other hand by:

$$k_{reb}^{(app)} = k_r[U/R]_{tot} \tag{8}$$

The lifetimes are inversely related to the rate constant of the rebound, and hence the ratio of the actual lifetime of the radical, on the **HS** manifold, to the apparent lifetime will be given by:

$$\tau^{(\mathbf{HS})}/\tau^{(app)} = \{[U/R]_{tot}(1 + F_{\mathbf{LS/HS}})\}/\{[U/R]_{tot} - F_{\mathbf{LS/HS}})\} > 1 \tag{9}$$

Clearly, the apparent lifetime is shorter than the actual one. The difference may be small if the relative yield quantity, $F_{\mathbf{LS/HS}}$, is close to unity. In such a case, the apparent lifetime is a reasonable approximation to the actual lifetime of the radical in the **HS** manifold. If, however, $k_{\mathbf{LS}}$ is significantly larger than $k_{\mathbf{HS}}$ and/or $n >> (1 - n)$, the result is that $F_{\mathbf{LS/HS}} >> 1$. In such a situation, the apparent lifetime will be much shorter than the actual one, leading to absurdly short lifetimes. Our recent computations of allylic hydroxylation show that under conditions that mimic the polarity and hydrogen bonding in the protein pocket, $k_{\mathbf{LS}}/k_{\mathbf{HS}}$ is approximately 10.[27,49] With such values of $F_{\mathbf{LS/HS}} \approx 10$, the apparent lifetime [Equation (8)] will be absurdly short.

In the general situation, $F_{\mathbf{LS/HS}}$ is predicted to increase[23] with the improved donor ability of the alkane, and hence to vary as the measured $[U/R]_{tot}$ quantity itself. Thus, in a series such as the Newcomb clocks in Scheme 5, the value of $F_{\mathbf{LS/HS}}$ will vary; its meaningful variation is limited by the requirement to produce only positive lifetimes. For example, with the probe **3** (Scheme 5), for which $[U/R]_{tot} \approx 4$, $F_{\mathbf{LS/HS}}$ should be < 4 (to yield a positive lifetime), while with the best donor probe, **6**, where $[U/R]_{tot} > 100$, $F_{\mathbf{LS/HS}}$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is much larger since in this case both **HS** and **LS** processes rebound in a barrierless fashion,[63] such that, in fact, $[U/R]_{tot} \rightarrow \infty$. In any event, the actual lifetime will be longer than the apparent one by a factor N:

$$\tau^{(HS)} = N \cdot \tau^{(app)};\ N > 1 \quad (10)$$

For example, taking N to be equal to 10, the values of $F_{LS/HS}$ that will yield positive lifetimes must vary from < 3 to 9 in the Newcomb series in Scheme 5, while for $N = 5$, $F_{LS/HS}$ varies between < 2 and 4. This range of $F_{LS/HS}$ variation is reasonable, as can be judged from the DFT calculations that indicate preponderance of the **LS** process. Thus, we may bracket the value of N in Equation (10) between 5 and 10. With such N values in Equation (10), the radicals in the Newcomb series will possess real lifetimes of the order of picoseconds, which are reasonable lifetimes. Clearly, since the $[U/R]_{tot}$ quantity is a two-state information content, it does not measure the actual lifetime of the intermediate *but depends strongly on the relative yields of **HS** and **LS** reaction fluxes for a given total yield of products.*

There exist alternative scenarios, which can potentially reconcile the ''rebound controversy''. The common element to all the alternative models is that the apparent lifetime reflects the interplay of effects not present in a single state rearrangement of the ''free radical''. Let us mention three such alternative scenarios.

One possibility that has been proposed[3,10,60] is that, inside the protein, radical clocks rearrange much slower than the corresponding ''free radicals'', due to stereoelectronic constraints. This alternative has never been tested seriously, and merits evaluation. It will not, however, rule out the concomitant validity of the two-state picture.

The second scenario is the two-oxidant hypothesis[15] (Scheme 2), in which the second oxidant inserts hydroxonium ion and leads to rearrangements by anchimeric assistance typical to carbocations without having free carbocation intermediates. The problem with this otherwise perfectly legitimate hypothesis is the unknown nature of the second electrophilic oxidant. Ferric hydroperoxide, Cpd 0 (Figure 1), was tested and found to possess huge barriers for epoxidation[39,70] and sulfoxidation[40] compared with the same processes with Cpd I. This at least rules out the reactivity of Cpd 0 in the presence of Cpd I. Moreover, the sulfoxidation study[40] shows that the barrier would still be high even if the reaction of Cpd 0 were to be catalyzed by a potent proton source like H_3O^+ coordinated by a single water molecule. Thus, Cpd 0 appears to be a poor electrophile, which is expected to react only in the absence of Cpd I. Recent evidence shows that in mutants of P450, where the primary machinery of proton delivery that converts Cpd 0 to Cpd I is disrupted, the enzyme can still perform epoxidation but very sluggishly, and *it loses completely its hydroxylation capability.*[42] Thus, even if Cpd 0 functions as an oxidant, it is still doubtful, at least at the present state of experimental and theoretical understanding, that Cpd 0 can play a role in the hydroxylation mechanism.

The third alternative emerges from a recent study of a semiclassical molecular dynamics simulation of ethane hydroxylation by the enzyme MMO.[32] Applying this scenario to P450 requires a single intermediate species, which is the ^4C_I intermediate, FeOH···C(Alk), generated by a hydrogen-abstraction step. Since the hydrogen-abstraction transition state lies above the rebound transition state, part of the total reaction flux can bypass the intermediate and proceed in an effectively concerted process. In this process, the fast energy transfer of the excess energy to the OH rotational mode that is active in the rebound can carry the hydrogen-abstraction transition state directly to the final hydroxylation product, without residing in the well of the OH···C(Alk) intermediate. This concerted process results in alcohol products that conserve the stereochemical identity of the alkane. The other part of the reaction flux will pass through the well of the OH···C(Alk) intermediate, and be partitioned between rebound and rearrangement modes giving rise to a mixture of unrearranged and rearranged products. Thus, here too the $[U/R]_{tot}$ quantity reflects the interplay of two processes, one effectively concerted and the other stepwise, precisely as described above for the two-state scenario. Moreover, using the VB model (Figure 9) coupled to the dynamic scenario for analyzing the trends in the barrier of the stepwise component can, in principle, rationalize the behavior of the Newcomb probe series (Scheme 5). However, to be considered equally valid for the P450 enzyme, the dynamic scenario must fulfil the following two requirements. Firstly, the dynamics[32] have to be done within the protein environment, where fast dissipation of the excess energy to the protein modes may minimize the concerted component. Secondly, a proper dynamic study should prove or disprove the two-state scenario by including this aspect of the problem. Should such a study be carried out, and *should it indeed rule out the participation of two states*, this would then favor an original Groves mechanism,[59] within the formulation of a ''bound radical''.[32,54,55] Still, however, any mechanistic model of alkane hydroxylation must meet the challenge described in the following section.

The Product Isotope Effect and Its Mechanistic Significance in TSR

A product isotope effect (PIE) in the context of alkane hydroxylation means that when the hydrogen atom that is transferred from the alkane to the iron−oxo moiety is replaced by a deuterium atom, the product ratio $[U/R]$ will exhibit an isotope effect. *The observation of such an isotope effect means necessarily that the products U and R cannot be generated from a single intermediate or pathway and must be mediated by two pathways or from two sources.* The two-state scenario predicts that there should, in principle, be a product isotope effect (PIE) on the $[U/R]$ quantity, since U and R are produced from two pathways.[45]

To derive a simplified expression for the PIE, we assume that the rearranged alcohol is generated only on the **HS** process, and this leads to the following equation for the isotope effect on the $[U/R]$ quantity:

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$[U/R]_H/[U/R]_D = \mathrm{PIE}[U/R] = [(k^H_{LS}/k^D_{LS})/(k^H_{HS}/k^D_{HS})]\{(k^D_r/k^H_r)[(k^H_r/k^D_{reb} + k^H_{reb}/k^D_{reb})/(1 + k^D_r/k^D_{reb})]\} = (IE_{LS}/IE_{HS})\{(1/IE_r)[(k^H_r/k^D_{reb} + IE_{reb})/(1 + k^D_r/k^D_{reb})]\} \quad (11)$$

Thus, the PIE[*U*/*R*] should depend on the ratio of intrinsic isotope effects (IEs) of the **HS** and **LS** hydrogen-abstraction steps (i.e. IE_{LS}/IE_{HS}), the isotope effect of rearrangement process (i.e. IE_r), and that of the rebound process (i.e. IE_{reb}). In the events that the rearrangement and rebound processes do not exhibit isotope effect, the expression becomes very simple, and depends only on the intrinsic IE ratio of the **LS** and **HS** hydrogen-abstraction steps, namely:

$$\mathrm{PIE}[U/R]_{TSR} \approx IE_{LS}/IE_{HS} \quad (12)$$

As such, for those systems where rearrangement and rebound processes are not subject to an isotope effect, the PIE[*U*/*R*] quantity can be predicted by straightforward DFT calculations of IE_{LS} and IE_{HS}. Using this equation, it is easily apparent that the two-state scenario would predict a product isotope effect, namely PIE[*U*/*R*] $\neq$ 1 unless the **HS** and **LS** transition states (TSs) happen to have accidentally identical structures, which they usually do not. Furthermore, the two-state mechanism predicts a substrate-dependent PIE[*U*/*R*], and this dependency can be understood by recalling,[5] that the maximal IE value is expected when the hydrogen-abstraction TS is "central" (i.e., having identical C···H and H···O bond orders/lengths), while smaller values are expected for TSs that are either "early" or "late". Thus, *the direction of the intrinsic PIE[U/R] (< 1 or > 1) quantity will generally reflect the relative positions of the hydrogen-abstraction transition states along the reaction coordinate, for the **HS** and **LS** processes.*

The ratios IE_{LS}/IE_{HS} were computed for the hydroxylation of methane,[45] propene,[27] ethane,[29,30] camphor,[31] and *trans*-1-methyl-2-phenylcyclopropane.[61] In the cases of methane, ethane and propene, the ratios are < 1, of the order of 0.7−0.8, while for camphor,[31] these ratios are either > 1 or close to 1, depending on the pattern of isotopic substitution, and on whether the IEs are inter- or intramolecular. Finally, for *trans*-[D_2]-1-methyl-2-phenylcyclopropane, the computed[61] intramolecular PIE[*U*/*R*] is 1.083−1.223, where the larger values include the effect of tunneling. Similarly, calculation of this quantity[61] for the intermolecular isotope effect (i.e., *trans*-1-methyl-2-phenylcyclopropane vs. *trans*-[D_3]-1-methyl-2-phenylcyclopropane) led to PIE[*U*/*R*] values of 0.943−1.123 where, again, the larger values involve strong tunneling correction. Other cases we studied,[63] show that the ratio of IE_{LS}/IE_{HS} can deviate from unity by as much as 40%, depending on the substrate.

Earlier experimental data by Newcomb and Ingold[37] for the two enantiomers of *trans*-1-methyl-2-phenylcyclopropane revealed ambiguous results, with values both smaller and larger than unity, PIE[*U*/*R*] $\approx$ 0.6−1.09, for the intermolecular isotope effect (i.e., *trans*-1-methyl-2-phenylcyclopropane vs. *trans*-[D_3]-1-methyl-2-phenylcyclopropane). By contrast, more recent data of Newcomb et al.[38] led to values larger than unity (e.g., the average PIE[*U*/*R*] $\approx$ 1.143) for the intramolecular isotope effect (using *trans*-[D_2]-1-methyl-2-phenylcyclopropane); the corresponding computed values using the TSR scenario[61] are 1.083−1.223. Despite this good agreement between theory[61] and the latter experimental results,[38] some qualification is in order. The experimental results are sensitive to very small changes in the percentages of the products, and gas chromatographic analysis of product distribution is subject to errors of 1−2%.[5] As such, without a proper error analysis, the recent experimental study[38] only shows that the [*U*/*R*] product ratio is likely to exhibit an isotope effect. Such an isotope effect means that the products *U* and *R* are generated by two pathways or from two sources. In this sense, the experimental results suggest the operation of TSR in alkane hydroxylation. However, should the experimental values[38] prove to be accurate, then the match between experiment and TSR theory will be a proof of principle for the operation of TSR in alkane hydroxylation.

Are There Carbocation Intermediates in P450 Hydroxylation?

Newcomb et al. have devised probes that can distinguish between cationic and radical rearrangements. One of these probes, **1** in Scheme 2, opens at the C−C bond that has an alkoxy substituent, which is the rearrangement mode expected for a carbocation intermediate. Similarly, Ortiz de Montellano, Groves et al.[21] and Newcomb et al.[20] have observed rearrangement products of norcarane that can be associated with a carbocationic rearrangement. However, Newcomb et al.[15] do not actually invoke free carbocations, but rather describe this typical rearrangement mode as being due to the presence of a protonated alcohol (nascent from OH^+ insertion, Scheme 2). By contrast, Ortiz de Montellano, Groves et al.[21] ascribe the small yield of these products to the presence of free carbocations generated by electron transfer (ET):

$$Alk^{\cdot} + \mathrm{PorFeOH} \rightarrow Alk^+ + \mathrm{PorFeOH}^-; \quad \Delta E_{ET} = IP_{Alk\cdot} - EA_{FeOH} \quad (13)$$

Right from the outset, it should be apparent that the ET process bears a resemblance to the rebound step, in the sense that in both cases the same two VB structures intersect (Figure 9). However, while during the rebound process this intersection occurs along a bond-making trajectory with a large VB mixing term *B*, and favorable exothermicity, in the ET process this will have to occur in an outer-sphere manner, with $B \rightarrow 0$, along a trajectory that avoids bond making and is thermodynamically less favorable. This typical competition between related bond-making and ET processes is well known,[62] and the bond-making process prevails unless bonding is blocked.

To assess the feasibility of ET, we calculated the energy change, ΔE_{ET}, of the reaction for a variety of alkyl radicals, using the ionization potential data in Table 2. The electron

[a] Calculated with the Green's function technique as described in refs.[74,75]

affinity of the iron−hydroxo species is 63 kcal·mol^{-1} in the gas phase, and 100 kcal·mol^{-1} in a polarizing medium with $\varepsilon = 5.7$. As we showed recently,[64] the thiolate ligand hampers the electron-acceptor properties of iron−porphyrin species, relative to non-thiolated alternatives, by as much as 30 kcal·mol^{-1} in a polarizing medium (and much more, 50−100 kcal·mol^{-1}, in the gas phase). Thus, with MMO, where the electron affinity of the diiron−hydroxo species is expected to be larger than the P450-derived iron−hydroxo one, the incursion of a carbocation species would be very much more feasible than in P450. Therefore, evidence of the presence of carbocations in MMO hydroxylations cannot constitute a proof for their existence also in the P450 reaction, unless the radical is a very good electron donor. For a radical like allyl, with calculated $IP_{allyl} = 186$ kcal·mol^{-1} (131 kcal·mol^{-1} in $\varepsilon = 5.7$) the electron-transfer reaction in Equation (13) is endothermic by 31 kcal·mol^{-1}. Even after inclusion of electrostatic interactions of ca. 14 kcal·mol^{-1} (for an ion-pair at 3 Å in an effective dielectric constant of a protein), the ET reaction is still endothermic. This should be the case for all the radicals in Table 2. However, for probes with $IP_{Alk\cdot} < 160$ kcal·mol^{-1} (< 106 kcal·mol^{-1} in $\varepsilon = 5.7$), one might anticipate an exothermic ET reaction with diffusive cationic species.

A bound carbocation that is coordinated to an iron−hydroxo anion is more likely to exist than a diffusive one. For example, in our recent study of benzene hydroxylation, we located an oxopentadienyl carbocation intermediate coordinated to the heme anion.[71] This carbocationic intermediate becomes more stable (by 4.9 kcal·mol^{-1}) than the corresponding radical in a polarizing medium ($\varepsilon = 5.7$). However, as shown in Figure 10a, the charge on the phenyl group (Q_{Ph}) is significantly less than unity. The species is therefore an intimate ion-pair with a significant degree of electronic conjugation between the radical and the iron−hydroxo moieties. To test the situation with a typical Newcomb probe system, we calculated[61] the putative cationic intermediate that can derive from *trans*-1-methyl-2-phenylcyclopropane, shown in Figure 10b. This is done by shifting the electron from the radical center on the organic moiety to the heme singly occupied orbital (π^* or a_{2u} orbital), and then letting the resulting species optimize its

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

electronic structure. From the charges on the alkyl moiety (0.18−0.27), it is apparent that this species is not an ion-pair; the charge on the organic moiety is simply too small, as might be expected from its relatively high *IP* (Entry 4a in Table 2). A natural orbital analysis indicates that the species behaves as a mixed-valent state, where the electron resides partly on the radical and partly on the porphyrin in the a_{2u} orbital. This feature is depicted in Scheme 6, alongside the drawing of the natural orbitals that contain the population of 1.5 and 0.5 e^-. These orbitals are the bonding and anti-bonding combinations of the radical orbital, φ_C, and the a_{2u} orbital (the mixing is mediated by the π* orbitals of the FeO moiety). As such, this species is mostly the $Fe^{III}Por^{\cdot+}(R^{\cdot})$ species with a minor contribution from an intimate ion-pair form, $Fe^{III}Por(R^+)$. Even the best electron-donor radical in the Newcomb series (Table 2, Entry 6a) has an *IP* value close to benzene-derived pentadienyl radical (Entry 3). As such, this radical, too, generates a mixed species with a charge of +0.6 on the alkyl moiety.[63] It is doubtful that these species, even in the cases where they possess a large carbocationic character, will behave like free carbocations.

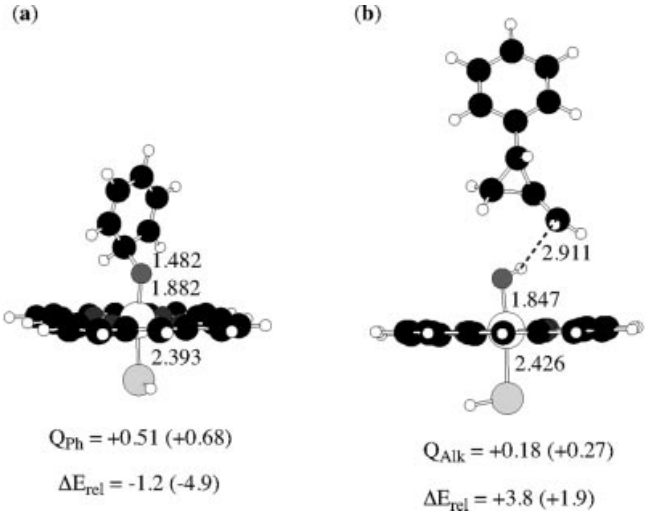

Figure 10. The geometric structures of (a) the ion-pair intermediate in benzene hydroxylation and (b) an analogous species in *trans*-1-methyl-2-phenylcyclopropane hydroxylation; below each structure we indicate the group charge of the organic moiety (*Q*) and the relative energy (ΔE_{rel}) to the radical intermediate (C_I) in vacuo (out of parentheses) and in a dielectric constant, ε = 5.7 (in parentheses)

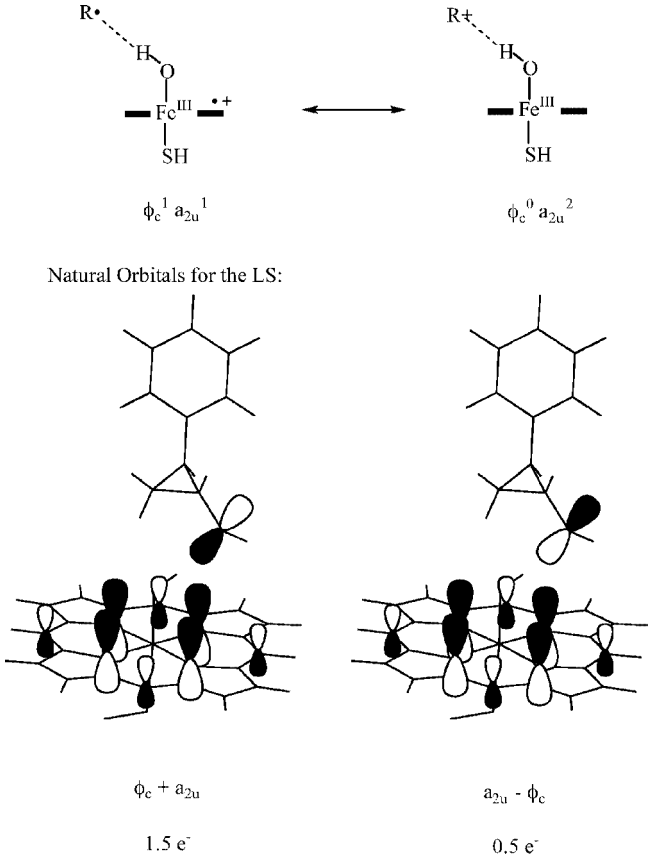
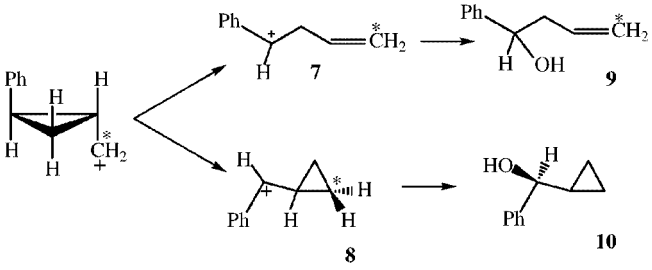


Scheme 6. The resonance structures that describe the "intimate ion-pair" species; the drawing below corresponds to the natural orbitals, which are mixtures of the radical orbital, φ_C, and the a_{2u} orbital, for the "intimate ion-pair" species derived from *trans*-1-methyl-2-phenylcyclopropane depicted in Figure 10b



Scheme 7. The rearrangement patterns of "free" *trans*-2-phenylcyclopropylcarbinyl cation and the expected hydroxylation products

Our calculations of the rearrangement patterns of the free cation derived from *trans*-1-methyl-2-phenylcyclopropane reveals that the free cation would rearrange in a completely different manner than the corresponding radical, as summarized in Scheme 7. Alongside the "normal" rearrangement process to give **7**, the carbocation rearranges also to species **8**, in which the carbocation center is stabilized by both phenyl and cyclopropyl groups. The presence of **8** would have led to the hydroxylation product **10**, which, to the best of our knowledge, has never been reported.[15] We may therefore conclude that free carbocations are not present in the chemistry of these particular probes.

We cannot, however, rule out the presence of cations in other probes. Such cations can escape the intimate ion-pairing and be stabilized by the protein environment, subsequently undergoing typical rearrangements. How much of the carbocationic products does one expect? A direct ET to produce diffusive carbocations will always be less efficient than rebound or radical rearrangement (recall that the radical clocks rearrange very fast, e.g., $k_r \approx 10^{11}$ s^{-1}). This, in turn, would require that the amount of carbocation-derived products be smaller than the amount of radical-derived rearrangement. While some P450 hydroxylation data[16,21] indeed show that the amount of cation-derived rearranged

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

product is marginally smaller than the amount of radical-derived products, other data[18,20] show the opposite trend. Alternatively, a carbocation intermediate of the intimate ion-pair type can arise directly from the C−H bond-activation phase by a hydride-abstraction process that competes with the radical-type hydrogen-abstraction process. This mechanism has not been observed yet and needs to be proven. Clearly the appearance of carbocation-derived products remains enigmatic and there is place for future experimental and theoretical studies of this issue.

Conclusion

The rebound controversy touches the limits of experimental capabilities to pinpoint complex reaction mechanisms. In such cases, theory can complement experiment by suggesting new alternatives. The two-state reactivity (TSR) scenario, which is supported by theory, provides such a paradigm. In TSR, radicals are produced on two different spin-state surfaces, and thereafter they react differently; on the low-spin surface rebound is barrierless, and hence the lifetime of the radicals is far too short to produce any rearranged products, while on the high-spin surface there is a substantial barrier for rebound, and hence the lifetime of the radical is sufficiently long so that rearrangement may compete with product formation by rebound. This paradigm provides a satisfactory rationale for the controversial findings in the field, and makes some verifiable predictions. Is this success merely accidental? This will have to be answered by future articulations of the concept.

One of the predictions of TSR is that the ratio of unrearranged to rearranged products, [*U*/*R*], is subject to an isotope effect that is substrate-dependent. Further complications in the TSR picture are caused by the presence of different electromeric states of the iron−hydroxo intermediates (Figure 2), and possibly of an intimate ion-pair carbocation, which has a mixed valent character, $PorFeOH^{-}\cdots Alk^{+} \rightleftarrows PorFeOH\cdots Alk^{\cdot}$. Finally, for sterically demanding rebound processes, as in the case of benzyl radicals for example, one may expect TSR with rebound barriers on both **HS** and **LS** manifolds. These aspects, as well as the spin crossover between the two spin states, still await a future treatment.

Theoretical Section

General Remarks: DFT calculations with the hybrid functional B3LYP were routinely used and are described in great detail in our work.[23,25,27,39,67] The calculations were carried out with JAGUAR 4.1[72] and GAUSSIAN 98 packages.[73] The standard basis involves a double zeta basis set which is called LACVP(6-31G), involving, on the iron atom, a Friesner basis set matched to an effective core potential, and a Pople 6-31G basis set on all other atoms. For some specified species, we also used more extended basis sets: one with polarization and diffuse functions on all heavy atoms, LACVP+*(6-31+G*), a fully polarized basis, LACVP**/6-31G**, and two triple zeta basis sets without and with polarization functions, LACV3P(6-311G) and LACV3P*(6-311G*). All species were characterized by geometry optimization and subsequent frequency calculations. Calculations of the species with a polarizing electric field were done with the solvent model in JAGUAR 4.1 (based on the Poisson−Boltzmann model) using a dielectric constant of $\varepsilon = 5.7$ and a probe radius, for the solvent, of 2.72 Å. Vertical ionization potentials were calculated using the outer valence Green's function (OVGF) technique, written by one of us (D. D.) and implemented in AMPAC.[74,75]

Solid-State Models of Ion Solvation: Crystal Structures of Dimethyl Sulfoxide Solvates of Alkaline Earth Cations

Jack M. Harrowfield,[a] William R. Richmond,[b] Brian W. Skelton,[a] and Allan H. White*[a]

Keywords: Alkaline earth metals / Dimethyl sulfoxide solvates / Solid state structures / Solvent effects

Structural studies of the dimethyl sulfoxide solvates of the perchlorates of Mg, Sr and Ba show the presence of a variety of complex ion species indicative of the forms possible in solution. While $Mg(ClO_4)_2$·6dmso contains the expected $[Mg(dmso)_6]^{2+}$ cation, the crystallised strontium species contains a mononuclear $[Sr(dmso)_6]^{2+}$ cation and two dinuclear species, the complex $[(dmso\text{-}O)_5Sr(\mu\text{-}dmso\text{-}O)_3Sr(OH_2)(dmso\text{-}O)_3]^{4+}$ containing both seven- and eight-coordinate Sr metal centres, and $[\{(dmso\text{-}O)_5Sr(\mu\text{-}dmso\text{-}O)\}_2]^{4+}$ containing seven-coordinate Sr metal centres. The barium complex, of empirical formula $Ba(ClO_4)_2$·5dmso, contains a centrosymmetric dimer, $[Ba_2(dmso\text{-}O)_6(\mu\text{-}dmso\text{-}O)_4(O_2ClO_2)_2]^{2+}$, involving an unsymmetrically chelating perchlorate and a nine-coordinate Ba metal centre.

Introduction

In the sense that they are the end products of solvent removal from solutions, crystals and the species they contain may provide an indication of the species dominant in the most concentrated of solutions. In many instances, there is good evidence that the species characterised in crystalline solids are those predominant in relatively dilute solutions, though there is also evidence to the contrary.[1] At the very least nonetheless, species found in the solid state illustrate possible forms for solution species and, especially for elements which are either spectroscopically silent or inconveniently studied by spectroscopic methods, single-crystal X-ray diffraction measurements can provide by far the most efficient means of precisely defining the nature of the forms that dissolved solutes may take. This is particularly true for many metal derivatives, Sc^{III} providing an intriguing example,[2] and the case of $Pb(ClO_4)_2$ solvation by dimethyl sulfoxide (dmso) providing an example[3] of how seemingly simple stoichiometry may disguise some quite surprising coordination chemistry. In conducting an extensive structural study of solvated metal salts, we have found that dmso solvates of the alkaline earth cations provide remarkable examples of how complicated the nature of such solvates may prove to be.

Results and Discussion

Analytical characterisation of the recrystallised dmso solvates of the perchlorates of the alkaline earth metals is close to consistent with their formulations as $Be(ClO_4)_2$·4dmso[4] $Mg(ClO_4)_2$·6dmso, $Ca(ClO_4)_2$·6dmso, $Sr(ClO_4)_2$·6dmso and $Ba(ClO_4)_2$·5dmso. Given the knowledge that in numerous complexes of quite diverse ligands, the coordination number of Ba^{II} invariably equals or exceeds that of Sr^{II} in its direct analogue,[5] this fact alone indicates that some of these formulae may be oversimplified representations. In fact, this is not so for the Mg complex, for which the structure determination (Figure 1) provides a justification for its description as $[Mg(dmso\text{-}O)_6][ClO_4]_2$.

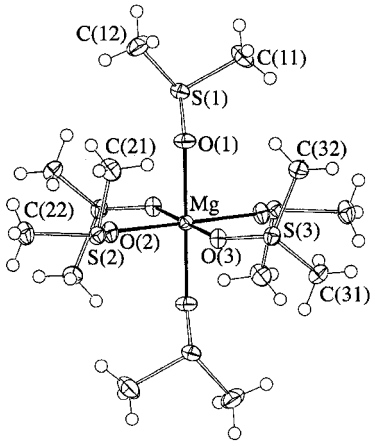

Figure 1. Projection of the centrosymmetric $[Mg(dmso\text{-}O)_6]^{2+}$ cation present in solid $Mg(ClO_4)_2$·6dmso; Mg−O(1,2,3) are 2.063(1), 2.084(1), 2.0512(9) Å, the maximum angular excursion from orthogonality being 88.60(4)°; Mg−O−S angles are 130.18(5), 127.51(7), 139.80(7)°

Although our numerous efforts to obtain crystals of both the Be and Ca complexes suitable for a structure determination have proved fruitless, so that strictly speaking the nature of the solid perchlorate species must be considered unknown, there would appear to be little doubt that the Be compound should contain tetrahedral $[Be(dmso\text{-}O)_4]^{2+}$ [4,6] while the octahedral $[Ca(dmso\text{-}O)_6]^{2+}$ species has been structurally characterised in association with two different anions.[7] The remaining two members of the alkaline earth series, however, provide some surprises. The Ba compound, which proves to have the "simpler" solid-state structure, is best formulated as the dimer $[Ba_2(dmso\text{-}O)_6(\mu\text{-}dmso\text{-}O)_4(O_2ClO_2)_2][ClO_4]_2$ and is related in structure to mixed-neutral-ligand species involving dmso[8] and dma (dimethylacetamide).[9] The dimer in the simple perchlorate (Figure 2) is centrosymmetric, with the (nine-) coordination geometry of the Ba atoms rendered somewhat irregular by the fact that four of the dmso-*O* donor atoms are bridging and one of the terminal sites on each Ba atom is occupied by unsymmetrically bidentate perchlorate [Ba−O 2.917(3), 3.056(3) Å]. If the perchlorate ligand is regarded as occupying a single coordination site, however, the geometry around the Ba metal centre is close to square antiprismatic. The perchlorate entities not found in the metal ion's primary coordination sphere appear to be involved in CH···O interactions with the dmso methyl groups (C···O approx. 3.3 Å), a mode of association which could presumably persist in solution. All the dmso molecules are coordinated and all by way of oxygen.

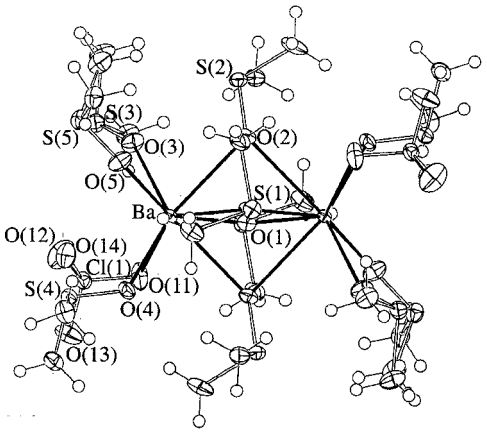

Figure 2. Projection of the centrosymmetric dinuclear cation $[(dmso\text{-}O)_3(O_2ClO_2)Ba(\mu\text{-}dmso\text{-}O)_2]_2^{4+}$; Ba−O($ClO_4$) are 2.917(3), 3.055(3); Ba−O(dmso) 2.663(3)−2.710(2), Ba-(μ-dmso-*O*) 2.797(3), 2.827(2) Å; Ba···Ba is 3.9406(4) Å; only partial atom labelling is shown for clarity

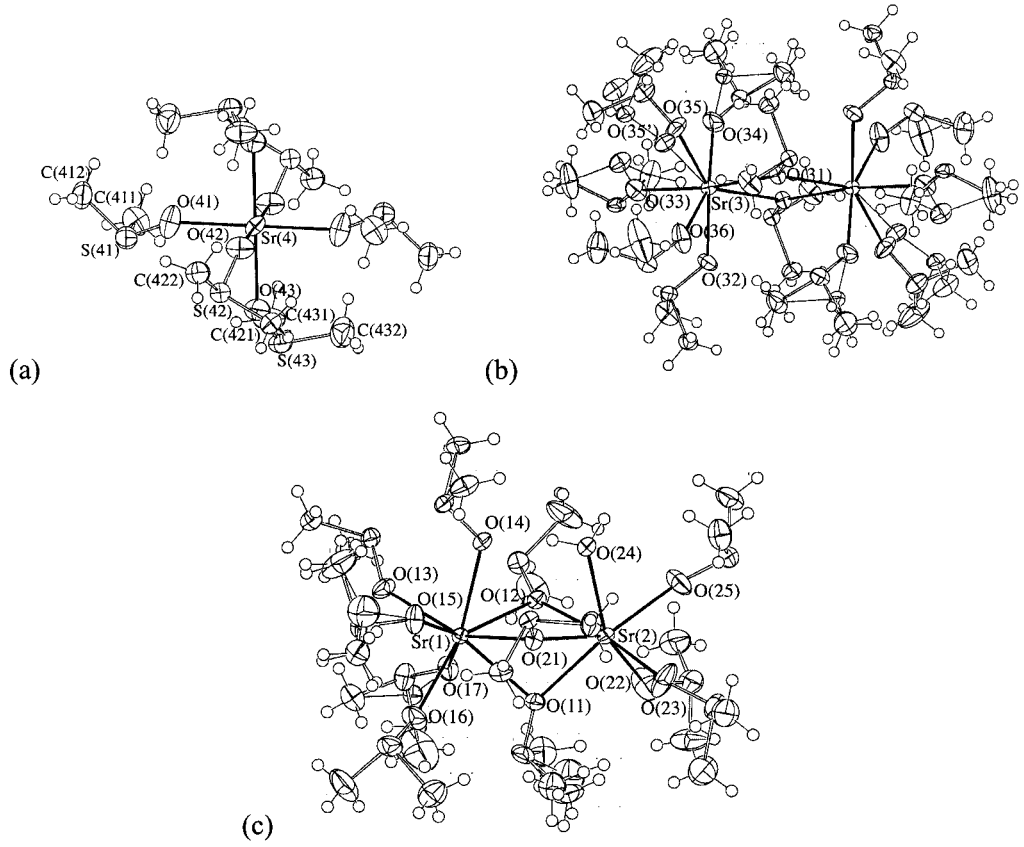

Figure 3. Projections of the cationic species in $Sr_7(ClO_4)_{14}\cdot 40dmso\cdot 2H_2O$; (a) the centrosymmetric $[Sr(dmso\text{-}O)_6]^{2+}$ cation, the maximum angular excursion from orthogonality being 91.6(2)°; Sr(4)−O(41,42,43) are 2.418(4), 2.452(5), 2.463(4) Å, corresponding Sr−O−S angles being 150.9(3), 133.0(2), 142.7(3)°; (b) the centrosymmetric $[(dmso\text{-}O)_5Sr(\mu\text{-}dmso\text{-}O)_2Sr(dmso\text{-}O)_5]_2^{4+}$ cation; Sr(3)−O(31,31′) are 2.548(3), 2.692(4), while Sr−O(unidentate dmso) range between 2.473(10) and 2.524(3) Å; (c) the $[(dmso\text{-}O)_5Sr(\mu\text{-}dmso\text{-}O)_3Sr(OH_2)(dmso\text{-}O)_3]_2^{4+}$ cation; Sr(2)−O(11,12,21) are 2.582(4), 2.490(3), 2.584(3) Å; Sr(1)−O(11,12,21) 2.659(3), 2.634(4), 2.623(3) Å, with Sr−O−Sr 94.2(1), 97.04(9), 95.01(9)°, and O(11)···O(12, 21), O(12)···O(21) 2.864(5), 2.724(5), 3.326(4) Å; Sr−O(unidentate) about Sr(2) are 2.451(4)−2.491(5) (dmso), 2.636(4) (OH_2) and about Sr(1) 2.507(5)−2.641(4) Å

The complete coordination of dmso as an *O*-bound species is perhaps the only obvious common characteristic of both the Ba and Sr compounds. The structure determined for the Sr compound (Figure 3) shows that dmso is not the only solvent present and that the formula $Sr(ClO_4)_2$·6dmso is imprecise, a better representation being $[Sr_7(dmso)_{40}(OH_2)_2][ClO_4]_{14}$ or, better still, $[(dmso\text{-}O)_5Sr(\mu\text{-}dmso\text{-}O)_3Sr(OH_2)(dmso\text{-}O)_3]_2[\{(dmso\text{-}O)_5Sr(\mu\text{-}dmso\text{-}O)\}_2][Sr(dmso\text{-}O)_6][ClO_4]_{14}$. The presence of a water ligand may simply reflect the use of solvents which were not completely dried and may mean that different species could be obtained under different crystallisation conditions, but the particular phase presently obtained is nonetheless of interest, even if it only exemplifies possible structures. (It may also be noted that in some related systems,[8] only certain mixed solvent species are readily crystallised.) Extraordinarily, the lattice contains three distinct strontium-containing species, two of them dinuclear, in which none of them is perchlorate coordinated. Sr^{II} is found in five different coordination environments: close to regular octahedral six-coordination in the mononuclear $[Sr(dmso\text{-}O)_6]^{2+}$; irregular seven-coordination, as $[(O\text{-dmso})_5Sr(\mu\text{-}O\text{-dmso})_{(2/2)}]$, in the centrosymmetric dinuclear species, as well as in the partially aquated moiety of the unsymmetrical dinuclear species $[(dmso\text{-}O)_3(H_2O)Sr(\mu\text{-dmso-}O)_3]$; and irregular eight-coordination in the "homoleptic" component of the latter, $[(dmso\text{-}O)_5Sr(\mu\text{-dmso-}O)_3]$. The bridging units of the dinuclear arrays contain fewer (three and two) μ-dmso-*O* units than that of the above dinuclear barium species, where there are four. The mononuclear species [Figure 3(a)] is a very rare example of a homoleptic, six-coordinate Sr^{II} complex with neutral ligands, the homoleptic aqua complex, for example, being a $[Sr(OH_2)_8]^{2+}$ species.[10] There is considerable divergence in the Sr−O−S angles, but only a loose correlation between those values and their associated Sr−O distances. In the centrosymmetric dinuclear cation, [Figure 3(b)], the two Sr−O distances of the obligate planar central four-membered ring are similar and longer than the closely ranged unidentate donor distances. The stereochemistry is irregular; there is one outstandingly large angle [O(31)−Sr(3)−O(33) 171.3(1)°], but the remaining five donor atoms do not constitute an acceptable equatorial plane. All Sr−O distances are longer than those found in the six-coordinate array. Three of the unidentate dmso moieties in this array are affected by disorder; in two, this is resolvable only in the sulfur atom, distributed over positions corresponding to inversion, but in dmso (35) it is more widespread, affecting the coordinating oxygen. In the unsymmetrical aquated dinuclear cation, there are now three μ-dmso-*O* moieties, of an irregular disposition most obvious in the variation of their O···O distances, Sr−O for the eight-coordinate Sr^{I} being longer than those to the seven-coordinate Sr^{II} metal centre; the unidentate dmso-O−Sr distances follow a similar pattern, with Sr(2)−O(24) (OH_2) longer than Sr(2)−O(22,23,25).

Within the group of alkaline earth elements, the coordination chemistry of Sr^{II} generally shows closer similarities to that of Ca^{II} than Ba^{II}.[5,11] Thus, the detection of several species within crystalline solvated $Sr(ClO_4)_2$ salt can be seen as being consistent with the extensive evidence for the co-existence of various solvated forms of Ca^{II},[12] though a comparison in the particular case of dmso solvates cannot yet be made [except that the elemental analysis indicates the Ca^{II} solvate to have the composition $Ca(ClO_4)_2$·6dmso]. The higher coordination number (9) presently observed for Ba^{II} than the mean for Sr^{II} is associated with bidentate coordination of perchlorate, consistent with a rather general tendency for oxyanion coordination, especially through unsymmetrical chelation, to be prominent with very heavy metals.[13] Possibly significantly, however, is the eight-coordination for Sr^{II}, accompanied by anion coordination, is seen in solid $[Sr(dmso\text{-}O)_2(CF_3SO_3)_2]$.[14] The exploration of such subtleties by structural work can therefore be seen as providing an important contribution to the development of more sophisticated molecular models for electrolyte solutions. Following the suggestion of a referee, we note that one particular use of single-crystal data is to provide a coordination number associated with a given mean metal−donor atom distance, since solution X-ray measurements (LAXS, XAFS, EXAFS) frequently provide precise values for the latter but imprecise values for the former.[10b,12,14] Mean values for Sr−O (unidentate dmso) obtained from the present structures for six-, seven- and eight-coordination are 2.45(2), 2.50(2) and 2.56(3) Å, respectively, the value for seven-coordination being slightly less than that determined for $[Sr(dmso)_7]^{2+}$ in solution, although neither of the presently observed species containing seven-coordinate Sr is mononuclear.

Experimental Section

Synthesis and Crystal Growth

$Be(ClO_4)_2$·4dmso: Attempts to grow diffraction quality crystals of this known compound were unsuccessful.

$Mg(ClO_4)_2$·6dmso: Anhydrous $Mg(ClO_4)_2$ (1.0 g) was dissolved in ethanol (25 mL), dimethyl sulfoxide (5 mL) was added, followed by diethyl ether (25 mL) and the mixture was allowed to stand for 10 min as colourless crystals (1.90 g, 60 %) were deposited on the sides of the flask. These were recrystallised using the mixture of solvents, dmso/ethanol/diethyl ether, before crystals suitable for structural work were obtained by vapour diffusion of diethyl ether into a solution in dmso/ethanol (1:2). $C_{12}H_{36}Cl_2MgO_{14}S_6$ (692.0): calcd. C 20.83, H 5.24, S 27.80; found C 20.4, H 5.0, S (28.2).

"$Sr(ClO_4)_2$·6dmso": Concentrated perchloric acid (72 %) was added drop by drop to $SrCO_3$ (0.50 g) until most of the solid had dissolved. The mixture was transferred to a steam bath and heated. Acid addition was continued until a clear viscous solution had formed. This was heated for a further 2 min to ensure complete evolution of CO_2, then cooled to room temperature and dissolved in ethanol (40 mL). Dimethyl sulfoxide (10 mL) was added to this solution, followed by diethyl ether (50 mL). The mixture was cooled on ice to give a white, crystalline deposit (1.9 g, 75 %), which was then recrystallised twice from dmso/ethanol/diethyl ether. For elemental analysis, portion was dried by vacuum desiccation over silica gel. $C_{12}H_{36}Cl_2O_{14}S_6Sr$ (757.9): calcd. C 19.08, H 4.80, S 25.47; found C 18.9, H 4.4, S 25.1. $[Sr_7(ClO_4)_{14}$·40dmso·H_2O;

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

calcd. C 18.66, H 4.74, S 24.91.] Crystals suitable for structure determination were obtained by vapour diffusion of diethyl ether into a solution of the recrystallised material in dmso/ethanol (1:2).

(The Ca analogue was prepared in the same way from $CaCO_3$. $Ca(ClO_4)_2{\cdot}6dmso = C_{12}H_{36}CaCl_2O_{14}S_6$ (708.1): calcd. C 20.4, H 5.15, Cl 10.0, S 27.2; found C 20.1, H 4.95, Cl 10.2, S 27.0. Large crystals of the complex could be obtained as for the Sr complex but they proved too fragile and too unstable for diffraction measurements to be possible.)

$Ba(ClO_4)_2{\cdot}5dmso$: $Ba(ClO_4)_2{\cdot}3H_2O$ was dissolved in dmso, ethanol and diethyl ether were added to give a white precipitate in quantitative yield. This was then twice recrystallised from dmso by addition of ethanol and diethyl ether. For analysis, the compound was dried by vacuum desiccation over silica gel. $C_{10}H_{30}BaCl_2O_{13}S_5$ (726.99): C 16.5, H 4.16, Cl 9.75; found C 16.9, H 4.22, Cl 10.0.

Structure Determinations (T ca. 153 K; monochromatic Mo-K_α radiation, $\lambda = 0.71073$ Å; Bruker AXS CCD instrument).

$Mg(ClO_4)_2{\cdot}6dmso$, $[Mg(dmso\text{-}O)_6][ClO_4]_2$: $C_{12}H_{36}Cl_2MgO_{14}S_6$ (692.0). Triclinic, $P\bar{1}$, $Z = 1$, $a = 7.6918(5)$, $b = 10.6220(7)$, $c = 10.6308(7)$ Å, $\alpha = 61.082(1)$, $\beta = 83.724(2)$, $\gamma = 84.696(2)°$, $V = 754.9$ Å^3. $D_c = 1.522$ g·cm^{-3}. $R = 0.037$, $R_w = 0.042$ for $N_o = 7706$ reflections [$F > 4\sigma(F)$] ($\theta_{max} = 60°$).

"$Ba(ClO_4)_2{\cdot}5dmso$", $[(dmso\text{-}O)_3(O_2ClO_2)Ba(\mu\text{-}dmso\text{-}O)_2]_2[ClO_4]_2$: $C_{20}H_{60}Ba_2Cl_4O_{26}S_{10}$ (1453.8). Monoclinic, $P2_1/c$, $Z = 2$ dinuclear f.u., $a = 12.046(1)$, $b = 20.560(2)$, $c = 11.5985(9)$ Å, $\beta = 110.140(2)°$, $V = 2697$ Å^3. $D_c = 1.790$ g·cm^{-3}. $R = 0.031$, $R_w = 0.040$ for $N_o = 6020$ ($\theta_{max} = 60°$). All anion and solvent species were fully ordered in the refinement, as was also true of the Mg adduct.

$Sr_7(ClO_4)_{14}{\cdot}40dmso{\cdot}2H_2O \equiv [(dmso\text{-}O)_5Sr(\mu\text{-}dmso\text{-}O)_3Sr(OH_2)(dmso\text{-}O)_3]_2[\{(dmso\text{-}O)_5Sr(\mu\text{-}dmso\text{-}O)\}_2][Sr(dmso\text{-}O)_6][ClO_4]_{14}$: $C_{80}H_{242}Cl_{14}O_{97}S_{40}Sr_7$ (5167). Triclinic, $P\bar{1}$, $Z = 1$ f.u., $a = 13.1158(6)$, $b = 19.651(1)$, $c = 23.224(1)$ Å, $\alpha = 67.478(1)$, $\beta = 75.279(1)$, $\gamma = 89.144(1)°$, $V = 5339$ Å^3. $D_c = 1.607$ g·cm^{-3}. $R_1 = 0.057$, $wR_2 = 0.072$ for No = 20926 (2θmax = 60°). Various anion and solvent components were modelled as disordered over pairs of sites, disordered fragment site occupancies refining to x, $1-x$ (minor components with isotropic displacement parameter forms), much seemingly concerted; thus for C(111, 112); S(15); S(172), C(172); S(34); O(60n); O(702−4), $x = 0.727(1)$, while for S(dmso 35); O(50n); $x = 0.5$. This affects the coordination sphere of Sr(3) where O(35)···O(35′) is 0.62(1) Å.

In the figures, non-hydrogen atoms are shown with 50 % probability amplitude displacement ellipsoids, hydrogen atoms having arbitrary radii of 0.1 Å. CCDC-14741, -214742 and -214743 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The Construction of $(N_2S_2)Ni-Pd$ Clusters: A Slant-Chair, a Basket and a C_4-Paddlewheel Structure

Melissa L. Golden,[a] Stephen P. Jeffery,[a] Matthew L. Miller,[a] Joseph H. Reibenspies,[a] and Marcetta Y. Darensbourg*[a]

Keywords: Metallothiolate ligands / Phosphane mimics / Nickel / Palladium / Cluster compounds

In pursuit of an analogy between bidentate diphosphane ligands and *cis*-dithiolato nickel complexes, the easily prepared [bis(mercaptoethane)diazacycloheptane]nickel complex, **Ni-1′**, has been treated with Pd^{II} and Ni^{II} sources. With the latter, trinickel species are observed with typical slant-chair structures; for palladium(ii) chloride, a basket-type structure is realized in which the floor of the basket is a PdS_4 unit and the sides are N_2S_2 units. One chloride atom is held within the basket at a Pd···Cl distance of 3.26 Å. With $Pd(NO_3)_2$ as a palladium source, a hexanuclear aggregate in the form of a C_4-paddlewheel structure is obtained. In this structure, the N_2S_2Ni complex serves as a bidentate ligand which bridges two Pd^{2+} cations at a distance of 3.132 Å.

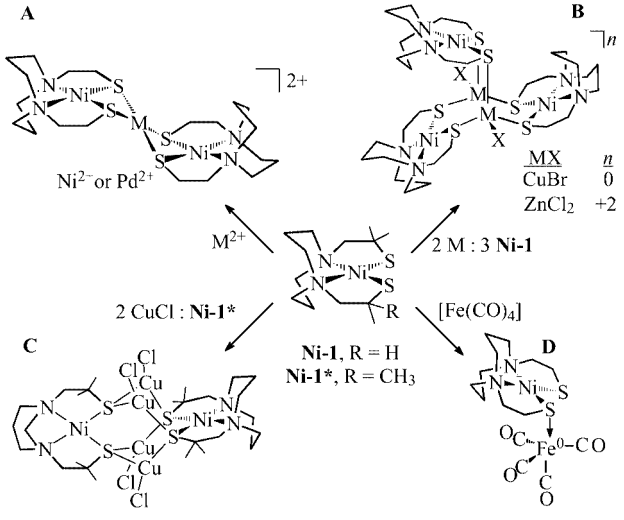
Introduction

The scope of polyheterometallic cluster complexes with thiolates as bridging ligands traverses the periodic table,[1,2] and there is extensive literature of N_2S_2Ni complexes as metallothiolate ligands to nickel and palladium.[2−7] The most common composition is a trimetallic cluster complex with a slant-chair structure made of two square-planar N_2S_2Ni complexes, which flank a central planar S_4Ni unit. This form (**A**, Scheme 1) is highlighted by [bis(mercaptoethane)-diazacyclooctane]nickel, [(bme-daco)Ni^{II}], or **Ni-1**, and is known to readily capture excess Ni^{II} or Pd^{II} metal ions.[8,9] A 2:3 ratio of $ZnCl_2$ or CuBr to **Ni-1** results in a C_3-paddlewheel cluster with three **Ni-1** units performing as bidentate-bridging ligands, placing either Zn^{II} or Cu^{I} atoms in tetrahedral S_3X coordination geometry (**B**, Scheme 1).[10,11] With an excess of $Cu^{I}Cl$, an adamantane-like Ni_2Cu_4 cluster **C** results; four CuCl units bridge two (bme*-daco)Ni^{II} moieties [**Ni-1***, bme*-daco = *N*,*N*′-bis(2-mercapto-2-methylpropyl)-1,5-diazacyclooctane], engaging all available lone pairs on all sulfurs for coordinating to the soft Cu^{I} metal centers.[12] At the other extreme, the **Ni-1** moiety uses a single lone pair and binds as a monodentate ligand to iron(0) in [(**Ni-1**)$Fe(CO)_4$], D.[13]



Scheme 1

The success of **Ni-1** and **Ni-1*** as metallothiolate ligands to other metals may be ascribed to the strong chelate effect of bme- and bme*-daco to Ni^{II}, as well as the generally excellent crystallinity and typical air stability of its derivatives. These features are attributed to the optimal 90° bite angles of the N−Ni−N and S−Ni−S moieties within the square-planar **Ni-1** and **Ni-1*** complexes, as well as the fused six-membered nickel-diazacyclohexane rings which adopt classic and stable chair-boat configurations.[14] Points of modification have thus far been limited to the attachment of different pendant arms to the diazacycle framework.[15−17] The readily procured seven-membered ring diazacycloheptane may be substituted for the daco ligand, generating [(bme-dach)Ni] or **Ni-1′**, whose S-based reactivity towards electrophiles such as O_2 and RX differs subtly as compared to **Ni-1**.[18] Electronic effects arising from disparities in Ni−S orbital overlap account for the differences observed. The use of **Ni-1′** as a metallothiolate ligand has not yet been explored.

It is increasingly apparent that N_2S_2Ni complexes behave toward other metals as ligands with donor abilities which are similar to phosphane ligands.[11,13,19,20] Steric and electronic modifications should lead to a class of ligands whose properties might be controlled similarly to the exceedingly versatile and technically important phosphane ligands. We report on the preparation of Ni−Pd polymetallic complexes based on **Ni-1′** as a metallothiolate ligand.

Results and Discussion

Consistent with reactions of **Ni-1** that led to structural type **A** (Scheme 1), metallation of **Ni-1′** with palladium(II) chloride produced a trimetallic species, which was discovered to be (**Ni-1′**)$_2$PdCl$_2$. X-ray diffraction studies revealed a molecular structure which is unlike any so far reported for such formulations. Rather than the slant-chair arrangement of the three d^8 square-planar conformations, the N_2S_2Ni planes emanate from the same side of the S_4Pd plane with dihedral angles of 132−134°, and Pd−Ni and Ni−Ni distances of 3.13 and 5.97 Å, respectively. As shown in Figure 1, the basket-like structure shows the 2-carbon N−N linker in both **Ni-1′** units facing inward towards an entrained chloride ion, which is located 3.26 Å above the Pd^{II} metal center. Although this distance is about 0.4 Å longer than expected for a Pd−Cl bond in square-pyramidal coordination,[21] conductivity measurements (vide infra) indicate that ion association is maintained in solution. The extended crystal packing diagram shows the second chloride ion to be located at interstitial positions throughout the crystal lattice.

While the N- and S-atom mean deviations from the best N_2S_2 and S_4 planes of [(**Ni-1′**)$_2$PdCl][Cl] are no more than 0.014 Å, the palladium atom is displaced by 0.157 Å from the S_4 plane towards the chloride ion (Table 1). The Ni^{II} cations are displaced, by 0.224 and 0.167 Å out of the S(1)−S(2)−N(1)−N(2) and N(3)−N(4)−S(3)−S(4) planes, respectively. This moves the nickel ions away from the chloride ion and into a less sterically encumbered position with respect to the hydrocarbon N to S and N to N linkages (Figure 1). The S−Ni−S angles are approximately 90°, and the bite angle imposed by the S−Ni−S metallothiolate ligand on the Pd metal center, i.e. the S−Pd−S angle, is considerably less, mean 81.4°.

Although the Ni:Pd ratio in the complex, which is derived from treating **Ni-1′** and Pd(NO$_3$)$_2$ in a 2:1 ratio, is the same as that of the chloride analogue, the composition of the isolated complex is a discrete hexanuclear cluster cation [(**Ni-1′**)$_4$Pd$_2$]$^{4+}$ with four nitrate counterions within the crystal lattice. The form of the Ni_4Pd_2 cluster (Figure 2) is that of a C_4-paddlewheel structure, which contains a Pd−Pd axis and four **Ni-1′** paddles in which S−Ni−S units

span the palladium atoms that are 3.13 Å apart. In addition to the two rather perfect S_4Pd and four N_2S_2Ni square planes, two other planes are comprised of S_4Pd_2 units. The nitrate counterions appear to have directional long-range interactions with O−Ni and O−Pd average distances of 3.42 and 3.55 Å, respectively. This is not the first structure of its kind.[6,22] A similar C_4-paddlewheel structure, which comprise bis(aminoethanethiolate)nickel [$(H_2NCH_2CH_2S)_2$-Ni or aet_2Ni] as a metallothiolate ligand to palladium, has been reported with parallel S_4Pd planes separated by 3.02 Å.[6] The isostructural compound $[(aet_2Pd)_4Pd_2]^{4+}[Br_4]^{4-}$ has a Pd···Pd distance of 3.19 Å.[6]

A recently reported hexanickel complex was derived from the aggregation of two $Ni(BF_4)_2$ moieties with four N_2S_2Ni complexes based on the $[^-S(CH_2)_2N(Me)(CH_2)_3N$-$(Me)(CH_2)_2S^-]$ ligand.[22] The flexibility of this open-chain ligand generated torsionally distorted or twisted NiS_4 units, in contrast to the highly regular structural features of the cationic complex $[(\mathbf{Ni\text{-}1'})_4Pd_2]^{4+}$.

In order to determine the interplay of the mesocycle and counterion effects on the basket, the paddlewheel, and the slant-chair structural forms of the Ni−Pd polymetallic complexes, **Ni-1** was exposed to $Pd(NO_3)_2$ under the reaction conditions which produced the C_4-paddlewheel structure. However, the slant-chair trimetallic molecular structure was evident in the isolated crystalline material; it had no significant differences in metric parameters from those found for the chloride salt of $[(\mathbf{Ni\text{-}1})_2Pd]^{2+}$ (Scheme 1).[9]

Likewise, the **Ni-1′** moiety was treated with $NiCl_2$, which resulted in a trimetallic complex of composition [(**Ni-1′**)$_2$NiCl][Cl]. As shown in Figure 3, this trimetallic complex does not adopt the basket form of the palladium analogue $[(\mathbf{Ni\text{-}1'})_2PdCl][Cl]$, but is rather a modified slant-chair structure with a chloride ion strongly bound to a the pentacoordinate square-pyramidal nickel central atom of the S_4NiCl unit. The Ni−Cl distance is 2.304 Å, and Ni is displaced by 0.52 Å from the S_4 plane towards the apical chloride ligand. The Ni−S distances in the pentacoordinate $ClNiS_4$ unit are on average 0.27 Å longer than the Ni−S distances in the four-coordinate nickel atom within the N_2S_2Ni plane. The orientation of the chloride ligand generates distinctly different environments for Ni(3) and Ni(1). Ni(3) is displaced from its N_2S_2 ligand plane by 0.194 Å and shifts away from the chloride ligand; Ni(1) lies within the N_2S_2 plane (displacement of 0.053 Å). The closest Cl···Ni(1) and Cl···Ni(3) distances are 4.712 Å and 3.539 Å, respectively. Another consequence of this asymmetric structure is the difference in S−Ni−S angles of the N_2S_2Ni sites: the terminal S−Ni−S angles are 5° smaller than the parent N_2S_2Ni complex [90.5° and 90.46° for S(2)−Ni(3)−S(2a) and S(1)−Ni(1)−S(1a), respectively]. The central nickel atom (NiS_4) has bite angles to the N_2S_2Ni ligands of 79.2° and 77.7°.

Two other structures were determined as references for counterion interactions. The trimetallic complex prepared from the reaction of **Ni-1′** with $NiBr_2$ showed the common slant-chair arrangement, with no anion interaction with the central S_4Ni unit (Figure 4). However, the product of combining $PdBr_2$ and **Ni-1′** produced another hexanuclear, Ni_4Pd_2 C_4-paddlewheel complex with four bromide anions, as in the nitrate salt.

Solution Characterization

The colors, electronic spectral, and electrochemical features of the heterometallic complexes are ascribed to a combination of the central NiS_4 or PdS_4 units and the S-modified (bme-dach)Ni moieties. The basket and the C_4-paddlewheel palladium structures are paprika-red in color and have similar electronic spectral features. The intense L→M charge-transfer band of tan-colored **Ni-1′** at 280 nm is red-shifted on formation of the Pd derivatives to approximately 320 nm, and a broad band of lower intensity covers the 370−480 nm range. The latter has been assigned to PdS_4 coordination.[7] In contrast the trinickel slant-chair species are an intense red-black. The absorptions of the CT bands that tail off into the range of 400−500 nm have ε values of approximately 2000 $Lmol^{-1}cm^{-1}$. These values are again consistent with previous assignments to a NiS_4 chromophore.[7]

The results of molar conductivity measurements determined on CH_3OH solutions at 25 °C are listed in Table 2. The molar conductance values for the trinickel species are well within the range of three ions in CH_3OH (reported as 160−220 $cm^{-1}mol^{-1}\Omega^{-1}$),[23] indicating ion dissociation and a di-uni-uni electrolyte system. In contrast, for the [(**Ni-1′**)$_2$PdCl]Cl "basket" compound, a lower value of Λ_M = 83 $cm^{-1}mol^{-1}\Omega^{-1}$ is indicative of a uni-uni electrolyte which has a range in CH_3OH of 80−115 $cm^{-1}mol^{-1}\Omega^{-1}$.[23] From this, we conclude that the Pd−Cl interaction implied for the entrained chloride in the solid-state molecular structure remains intact in CH_3OH. The C_4-paddlewheel structure has a value of Λ_M = 136 $cm^{-1}mol^{-1}\Omega^{-1}$, which is between the two- and three-ion range in CH_3OH, and indicates that at least some of the long-range nitrate associations with the 4+ cation that was observed in the solid-state structure are maintained in solution, generating $[\{(\textbf{Ni-1}')_4Pd_2\}(NO_3)_2]^{2+}$ and two free nitrate ions.

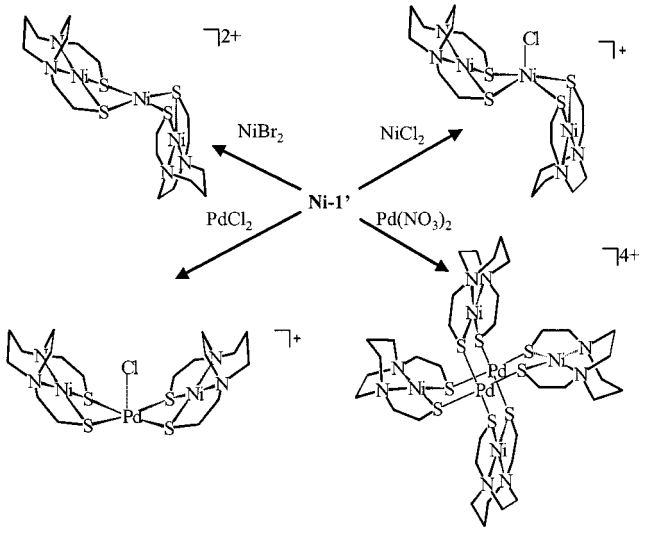
Table 2. Molar conductivities in MeOH at 25 °C

Compound	Λ_M at 10^{-3} M ($cm^{-1}mol^{-1}\Omega^{-1}$)
[(**Ni-1**)$_2$Ni][Br]$_2$	191
[(**Ni-1′**)$_2$NiCl][Cl]	168
[(**Ni-1′**)$_2$Ni][Br]$_2$	166
[(**Ni-1′**)$_2$PdCl][Cl]	83
[(**Ni-1′**)$_4$Pd$_2$][NO$_3$]$_4$	136

Electron-spray ionization mass spectral results for the new cluster compounds were consistent with the solid-state formulations, including observation of a group of signals centered at 1508 m/z with correct isotopomer ratios computed for the intact hexanuclear cluster complex with three nitrates attached, $[\{(\textbf{Ni-1}')_4Pd_2\}^{4+}(NO_3)_3]^+$. The dicationic complex $[(\textbf{Ni-1}')_2M]^{2+}$ is a prominent species in this and all other compounds studied.

Conclusion

The graphical summary of the polymetallics based on **Ni-1′** (Scheme 2) shows the N_2S_2Ni metallothiolate ligand maintains its structural integrity whether it serves as a bidentate bridging ligand spanning two metal centers or as a that bidentate ligand to a single metal center. As can be seen in Figure 5, when **Ni-1′** is a bidentate ligand to a single metal center, the S−Ni−S angle is smaller then in its parent complex, but as a bridging bidentate ligand there is no change. Both binding modes generate stable complexes which are related to diphosphane derivatives. Analogy of **Ni-1′** in its bidentate bridging capability is towards the diphenylphosphinomethane (dppm) ligand, whose small bite angle is well-known to facilitate the formation of "A-frame" bimetallic clusters. The structure of a heptanuclear Ni_3Cu_4



Scheme 2

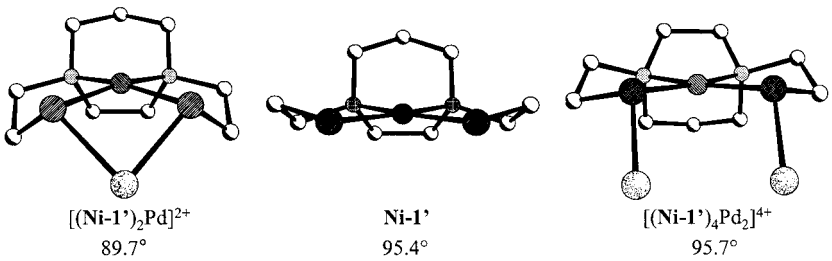


Figure 5. Comparison of the N_2S_2Ni unit as a bidentate ligand, its parent complex, and as a bidentate bridging ligand; values given are S−Ni−S angles

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cluster with a mixed set of dppm and aet_2Ni ligands support this analogy.[24] Nevertheless, dppm has also been used in the preparation of mononuclear $[M(dppm)][BF_4]_2$ salts, M = Pd, Ni;[25] these cations are analogous to our trimetallic cations.

The minor structural change from the eight-membered daco ring to the seven-membered dach framework for N_2S_2 ligand complexes resulted in structural diversity heretofore not observed in the polymetallic species. Notably, in contrast to the daco analogue, the loss of one methylene unit in the dach framework resulted in a different folding pattern as evidenced by the basket case, a different nuclearity as seen in the paddlewheel structure, and an enhanced capability to bind counterions as noted in the chloride-bound slant-chair structure. These differences appear to derive from a lesser steric requirement of the dach mesocyclic framework.

Experimental Section

General Remarks: Where anaerobic conditions were required, standard Schlenk techniques with argon and an argon glovebox were used. Solvents were dried and distilled using standard methods.[26] (bme-daco)Ni,[27] (bme-dach)Ni,[18] and [(bme-daco)$_2$Ni$_3$][Cl$_2$] [8] were synthesized according to published procedures. Anhydrous nickel(II) bromide (Strem), nickel(II) chloride hexahydrate (J.T. Baker), palladium(II) nitrate hydrate (Strem), and palladium(II) chloride (Johnson Matthey) were used as received. UV/Vis spectra were recorded on a Hewlett−Packard 8453 diode array spectrometer using quartz cells (1.00 cm path length). Elemental analyses were performed by Canadian Microanalytical Services Ltd., Delta, British Columbia, Canada. Electrospray Ionization mass spectra were recorded using a MDS-Series QStar Pulsar with a spray voltage of 5 KeV at the Laboratory for Biological Mass Spectroscopy at Texas A&M University. Conductance measurements were made using an Orion 160 conductivity meter.

[{(bme-dach)Ni}$_2$PdCl]$^+$[Cl]$^-$: Palladium chloride (0.087 g, 0.49 mmol) was refluxed under argon in CH_3CN (25 mL) until dissolved and then added to (bme-dach)Ni (0.272 g, 0.982 mmol) in CH_3CN (15 mL) to produce an orange-red precipitate. The solid was collected, redissolved in a minimum of CH_3OH, filtered and dried in vacuo. Yield: 0.336 g, 94 %. Single crystals of X-ray quality were grown from slow diffusion of diethyl ether into an CH_3CN solution. UV/Vis (CH_3OH) λ_{max} in nm (ε): 230 (22 500), 266 (19 000), 308 (20 000), 386 (6600), 420 (5700). $C_{18}H_{36}Cl_2N_4Ni_2PdS_4$ (731.5): calcd. C 29.56, N 7.66, H 4.96; found C 27.7, N 7.05, H 5.32. Mass spectrum (*m*/*z*): 330 [{(bme-dach)Ni}$_2$Pd]$^{2+}$; 696 [{(bme-dach)Ni}$_2$PdCl]$^+$.

[{(bme-dach)Ni}$_4$Pd$_2$][NO$_3$]$_4$: (bme-dach)Ni (0.116 g, 0.419 mmol) was made into a slurry with CH_3CN (25 mL). Palladium nitrate hydrate (0.049 g, 0.212 mmol) was dissolved in CH_3CN (25 mL) and transferred by cannula to the (bme-dach)Ni solution which immediately began to turn orange red. After about 10 minutes, the reaction mixture was filtered in air leaving some unchanged (bme-dach)Ni, which was washed with CH_3CN. The solution was layered with *n*-hexane and put in the refrigerator to give dark red blocks of product. Yield: 0.105 g, 64 %. UV-Vis (CH_3OH), λ_{max} in nm (ε): 230 (53 000), 266 (39 000), 308 (43 000), 386 (15 000), 420 (12 000). $C_{36}H_{72}N_{12}Ni_4O_{12}Pd_2S_8$ (1569.2): calcd. C 27.55, N 10.71, H 4.62; found C 27.36, N 10.77, H 4.73. Mass spectrum (*m*/*z*): 330 [{(bme-dach)Ni}$_2$Pd]$^{2+}$; 722 [{(bme-dach)Ni}$_2$(PdNO$_3$)]$^+$, 1507 [{(bme-dach)Ni}$_4${Pd$_2$(NO$_3$)$_3$}]$^+$, 461 [{(bme-dach)Ni}$_4$(Pd$_2$NO$_3$)]$^{3+}$.

[{(bme-daco)Ni}$_2$Pd][NO$_3$]$_2$: (bme-daco)Ni (0.230 g, 0.791 mmol) was dissolved in CH_3CN (15 mL). The yellow-brown sample of palladium nitrate hydrate (0.091 g, 0.394 mmol) was dissolved in CH_3CN (15 mL) and transferred by cannula to the purple (bme-daco)Ni solution which immediately began to turn dark red, forming a precipitate. The reaction mixture was stirred overnight and then placed in an ice-water bath. The precipitate was collected on a Büchner funnel and washed with ice cold CH_3CN. Yield: 0.178 g, 58 %. Single crystals of X-ray quality were grown from slow diffusion of diethyl ether vapor into a CH_3OH solution in the refrigerator. UV-Vis (CH_3OH), λ_{max} in nm (ε): 286 (17 700), 250 (16 000), 328 (13 000), 408 (4000), 524 (3000). $C_{20}H_{40}N_6Ni_2PdO_6S_4$ (812.6): calcd. C 29.56, N 10.34, H 4.96; found C 29.18, N 10.10, H 4.98. Mass spectrum (*m*/*z*): 343 [{(bme-daco)Ni}$_2$Pd]$^{2+}$.

[(bme-dach)$_2$Ni$_3$][Br]$_2$: A slurry containing $NiBr_2$ (0.374 g, 1.71 mmol) in 50 mL of distilled CH_3OH was added to a slurry of (bme-dach)Ni (0.535 g, 1.93 mmol) in CH_3OH (20 mL). The development of a dark red color was immediate. The solution was stirred overnight. The solvent was removed, the residue dissolved in CH_3CN, and filtered through a medium porosity frit under air. The solvent was removed in vacuo yielding a dark red solid. Yield: 0.084 g, 11%. Single crystals of X-ray quality were grown from slow evaporation of a CH_3OH solution. UV-Vis (CH_3OH), λ_{max} in nm (ε): 482 (1880), 406 (2520), 278 (16 600), 227 (19 700). $C_{18}H_{36}Br_2N_4Ni_3S_4$ (772.7): calcd. C 27.98, N 7.25, H 4.70; found C 26.83, N 7.00, H 4.73. Mass spectrum (*m*/*z*): 306 [(bme-dach)$_2$Ni$_3$]$^{2+}$; 693 [(bme-dach)$_2$Ni$_3$]$^{2+}$Br$^-$.

[(bme-dach)$_2$Ni$_3$Cl]$^+$[Cl]$^-$: [(bme-dach)$_2$Ni$_3$Cl]$^+$Cl$^-$ was synthesized in a similar fashion to [(bme-dach)$_2$Ni$_3$][Br]$_2$, using $NiCl_2{\cdot}6H_2O$ as an exogenous nickel source. Yield: 0.150 g, 60 %. $C_{18}H_{36}Cl_2N_4Ni_3S_4$ (683.8): calcd. C 29.67, N 8.19, H 5.31; found C 31.62, N 7.65, H 5.29. Mass spectrum (*m*/*z*): 306 [(bme-dach)$_2$Ni$_3$]$^{2+}$; 647 [(bme-dach)$_2$Ni$_3$Cl]$^+$.

X-ray Crystallographic Study: Low temperature X-ray diffraction data were collected on a Bruker SMART CCD-based diffractometer (Mo-K_α radiation, λ = 0.71073 Å) and covered a hemisphere of space upon combining three sets of exposures. The space groups were determined based on systematic absences and intensity statistics using the SMART[28] program for data collection and cell refinement. Raw data frame integration was performed with SAINT+.[29] Other programs used include SHELXS-86 (Sheldrick)[30] for structure solution, SHELXL-97 (Sheldrick)[31] for structure refinement and SHELXTL-Plus, version 5.1 or later (Bruker),[32] for molecular graphics and preparation of material for publication. The structures were solved by direct methods. Anisotropic displacement parameters were determined for all non-hydrogen atoms. Hydrogen atoms were added at idealized positions and refined with fixed isotropic displacement parameters equal to 1.2 (1.5 for methyl protons) times the isotropic displacement parameters of the atoms to which they were attached. Collection and refinement summaries are shown in Table 3. SADABS[31] and Wingx[33] were used on the palladium clusters. CCDC-215014 [{(**Ni-1′**)$_2$Ni}Br$_2$], CCDC-215016 [{(**Ni-1′**)$_2$NiCl}Cl], CCDC-215015 [{(**Ni-1′**)$_4$Pd$_2$}(NO$_3$)$_4$], and CCDC-215013 [{(**Ni-1′**)$_2$PdCl}Cl] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge

Novel Room Temperature Inorganic Ionic Liquids

Liyi Dai,[a] Shuyuan Yu,[a] Yongkui Shan,*[a] and Mingyuan He[a]

Keywords: Inorganic ionic liquids / Ionic liquids / Polyoxometalates / Transition metals / Green chemistry

New inorganic ionic liquids (IIL) consisting of an inorganic polyoxometalate anion with the Keggin structure and a sodium cation, that is $Na_{13}[Ln(TiW_{11}O_{39})_2]\cdot xH_2O$ [where Ln = lanthanide (type 1)], $Na_5[MTiW_{11}O_{39}]\cdot xH_2O$ and $Na_6[MTiW_{11}O_{39}]\cdot xH_2O$ [where M = transition metal (type 2)], were prepared and their physicochemical properties were investigated. These ionic liquids were characterized by NMR and IR spectroscopy and by elemental analysis. Their melting point, viscosity, conductivity, thermal stability, and miscibility with water and organic solvents were determined. When the temperature is below ambient temperature (about 298 K) these ionic liquids are almost immiscible with water. When the temperature is raised, the solubility of the new ionic liquids increases sharply. The influence of the size and of the charge density of both the cations and anions on these properties was examined. The most remarkable feature of IILs is that water is their indispensable component. The role of the water molecule in ionic liquids is similar to that of crystalline water in hydrated compounds.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Ionic liquids constitute a large, fundamental class of fluid materials that in recent years have aroused increasing interest because of their relevance to separation technologies, manufacturing processes and catalysis in green chemistry. Their properties, in fact, are low melting point, a wide liquid range, negligible vapor pressure, good solubility characteristics, relatively low viscosity, nonflammability, a wide electrochemical window, tolerance to strong acids, and excellent thermal and chemical stability.[1−10] Since the discovery of the first ionic liquid (ethylammonium nitrate) in 1914,[11] many classes of ionic liquids have been investigated. According to the current definition, ionic liquids should become liquid at or below 373 K[1] or 423 K[4]. They are typically composed of organic cations with a variety of substituents such as quaternary ammonium cations,[12,13] heterocyclic aromatic compounds,[14] pyrrolidinium cations,[15] derivatives of natural products,[16] phosphonium,[17−18] sulfonium,[19] guanidinium[20] and some more exotic cations,[21,22] and a variety of anions such as Cl^-, Br^-, NO_3^-, I^-, BF_4^-, $AlCl_4^-$, PF_6^- and others. Such ionic liquids are commonly referred to as organic−inorganic ionic liquids.[4] Only few ionic liquids comprising organic cations and organic anions (organic ionic liquids) have been investigated.[4,23−25] However, with the exception of the supercooled ionic liquid, $[Ca(NO_3)_2]_{0.4}$-$(KNO_3)_{0.6}$, reported by Moom and Jeong,[26] ionic liquids consisting of inorganic cations and inorganic anions (inorganic ionic liquids) have not yet appeared in the literature. Although their rapid emergence as environmentally benign solvents and catalysts has lead to a growing number of applications, the basic understanding and study of their physical and chemical properties has lagged behind. A significant barrier to the widespread use of ionic liquids is the lack of understanding of such properties and of the suitable manufacturing processes. It is very important to accumulate a substantial body of scientific and technological data for these fascinating fluid materials, so that their true potential as solvents and catalysts in chemical synthesis and separation processes can be realized. Here, we report the synthesis and characterization of several new inorganic ionic liquids consisting of an inorganic polyoxometalate anion with the Keggin structure and a sodium cation, that is $Na_{13}[Ln(TiW_{11}O_{39})_2]\cdot xH_2O$ [where Ln = lanthanide(type 1)], $Na_5[MTiW_{11}O_{39}]\cdot xH_2O$ and $Na_6[MTiW_{11}O_{39}]\cdot xH_2O$ [where M = transition metal (type 2)]. These materials have allowed us to further explore the formation mechanism of ionic liquids with lower melting points and to reveal the relationship between the structural features of an ionic liquid and its useful properties. Their incorporation into ionic liquids may expand the utility of ionic liquids and open up a new field of ionic liquid chemistry.

Results and Discussion

The syntheses of the novel inorganic ionic liquids were carried out in a mixture comprising an aqueous solution of sodium tungstate, tetrachlorotitanium and the related transition-metal salts (or lanthanide nitrate) at 333 K.[27] The

[a] Center for the Chemistry of Ionic Liquids, East China Normal University,

E-mail: ykshan@chem.ecnu.edu.cn

ionic liquids synthesized have high solubility in water at high temperatures but they are almost immiscible below ambient temperature; we were therefore able to separate the water from the synthetic mixture at low temperatures. These ionic liquids can change into amorphous powders when they are mixed with anhydrous acetone or ethanol, due to the loss of constituent water from the ionic liquids to the organic solvent. The molar ratios of the constituent elements in the investigated ionic liquids, Na:Ti:Ln:W = 13:2:1:22 (type 1), Na:Ti:M:W = 5:1:1:11 (when M = Fe, or Cr), Na:Ti:M:W = 6:1:1:11 [when M = Mn, Zn(type 2)], were determined by inductively coupled plasma-emission spectrometry. The Keggin structure characteristic of the anions was evidenced by IR spectroscopy. These results illustrate that the anion of type 1 is twice as large as that of type 2, but the charge density on the surface of the anion has no significant difference.

The most remarkable trait of IILs is that water is their indispensable component. The water content of the new ionic liquids was estimated by Karl Fischer analysis and is showed in Table 1. Although various amounts of water were also present in previously known ionic liquid systems,[4] in our IILs system water is a necessary component. Upon heating in air and in the absence of organic solvents, such ionic liquids could change into mudlike solids after loss of constituent water. This phenomenon is reminiscent of the dehydration process in crystalline solids containing crystallization water. The difference between the two phenomenona is that ionic liquids change into mudlike solids while crystals change into amorphous powders.

Table 1. Water content of the inorganic ionic liquids

Compound	H_2O (wt.-%)	x
$Na_{13}[La(TiW_{11}O_{39})_2]\cdot xH_2O$	11.18	40.0
$Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot xH_2O$	9.16	32.6
$Na_{13}[Pr(TiW_{11}O_{39})_2]\cdot xH_2O$	10.08	36.3
$Na_{13}[Sm(TiW_{11}O_{39})_2]\cdot xH_2O$	10.92	39.8
$Na_{13}[Gd(TiW_{11}O_{39})_2]\cdot xH_2O$	7.72	27.1
$Na_{13}[Dy(TiW_{11}O_{39})_2]\cdot xH_2O$	8.22	29.1
$Na_{13}[Er(TiW_{11}O_{39})_2]\cdot xH_2O$	10.76	39.2
$Na_{13}[Tm(TiW_{11}O_{39})_2]\cdot xH_2O$	9.26	33.2
$Na_{13}[Yb(TiW_{11}O_{39})_2]\cdot xH_2O$	11.83	43.7
$Na_5[CrTiW_{11}O_{39}]\cdot xH_2O$	15.95	30.2
$Na_6[MnTiW_{11}O_{39}]\cdot xH_2O$	15.75	30.0
$Na_5[FeTiW_{11}O_{39}]\cdot xH_2O$	17.62	34.0
$Na_6[ZnTiW_{11}O_{39}]\cdot xH_2O$	14.70	27.2

One of the most important criteria for the evaluation of an ionic liquid is its melting point. The solid−liquid phase transition of the new inorganic ionic liquids was examined with a PerkinElmer DSC and a YAN-1 melting point apparatus and the results are summarized in Table 2. The DSC curve for $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 33H_2O$, at a heating rate of 10 K/min, is shown in Figure 1. The DSC measurements show two distinct peaks, which demonstrate that two liquid phases, an aqueous phase and an ionic liquid phase, can be formed when the solid melts.[28] The presence of little free-water in the sample is indeed confirmed by a small

Table 2. Melting point (T_m) of the inorganic ionic liquids

Compound	T_m (K)	Compound	T_m (K)
$Na_{13}[La(TiW_{11}O_{39})_2]$	253.0	$Na_{13}[Tm(TiW_{11}O_{39})_2]$	260.2
$Na_{13}[Ce(TiW_{11}O_{39})_2]$	263.0	$Na_{13}[Yb(TiW_{11}O_{39})_2]$	267.2
$Na_{13}[Pr(TiW_{11}O_{39})_2]$	253.0	$Na_5[CrTiW_{11}O_{39}]$	261.5
$Na_{13}[Sm(TiW_{11}O_{39})_2]$	256.0	$Na_5[MnTiW_{11}O_{39}]$	253.0
$Na_{13}[Gd(TiW_{11}O_{39})_2]$	265.1	$Na_5[FeTiW_{11}O_{39}]$	257.6
$Na_{13}[Dy(TiW_{11}O_{39})_2]$	265.2	$Na_6[ZnTiW_{11}O_{39}]$	257.4
$Na_{13}[Er(TiW_{11}O_{39})_2]$	261.0		

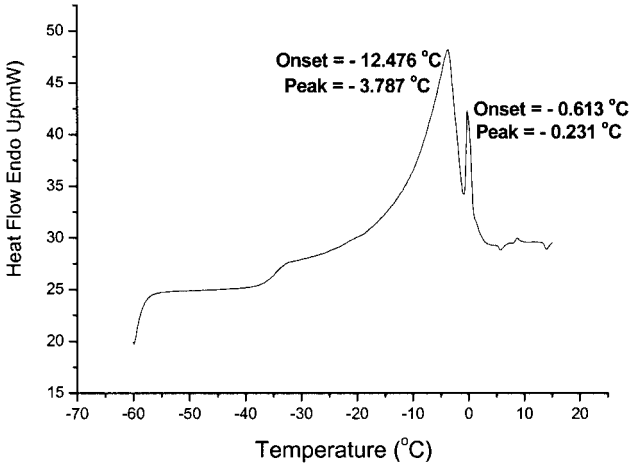

Figure 1. DSC analysis curve of $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 33H_2O$

shoulder peak at 272.4 K. However, the main peak at 260.5 K shows that the highly hydrated inorganic ionic liquid of $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 33H_2O$ exists in a pure phase. The results in Table 2 illustrate that all the ionic liquids possess a very low melting point and are liquid below room temperature. In general, the melting point of an ionic liquid is correlated with the symmetry, size and charge density of the component ion.[4] Hydrogen bonding and Van Der Waals interactions have also a slight influence on the melting point.[2] The low melting point of the new ionic liquids (shown in Table 2) is ascribed to the absence of hydrogen bonding between the anions and the cations and to the lower charge density on the surface of the anions.

The viscosity measurement of the new inorganic ionic liquids was carried out with an NEX-11 rotational viscosimeter. The lower viscosity (42.5−82.5 cps at 298 K) found in these ionic liquids is similar to that of [emim][BF_4](43 cps at 293 K)[29] and [bmim][CF_3SO_3](90 cps at 293 K).[30] It appears from the examination of a number of organic ionic liquids that the viscosity of the corresponding ionic liquids is related to the structure and the size of the component ions, to their tendency to form hydrogen bonding and to the strength of their van der Waals interactions.[1,31] In the inorganic ionic liquids the structures of all the component ions are very simple. For example, the cation is sodium Na^+ or hydrated sodium $Na^+(H_2O)_x$, the anion is the spherical ion with the Keggin structure $[MTiW_{11}O_{39}]^{5-}$ or $[MTiW_{11}O_{39}]^{6-}$ (where M = Cr, Mn, Fe, Zn) or the dumbbell complex ion with a double lacunary Keggin structure

Table 3. Specific conductivity of measurable samples at 298 K

Compound	σ (×10⁴μS/cm)	Compound	σ (×10⁴μS/cm)
$Na_{13}[La(TiW_{11}O_{39})_2]$	1.10	$Na_5[CrTiW_{11}O_{39}]$	1.62
$Na_{13}[Ce(TiW_{11}O_{39})_2]$	2.02	$Na_6[MnTiW_{11}O_{39}]$	1.80
$Na_{13}[Pr(TiW_{11}O_{39})_2]$	1.85	$Na_5[FeTiW_{11}O_{39}]$	2.66
$Na_{13}[Sm(TiW_{11}O_{39})_2]$	2.24	$Na_{13}[Tm(TiW_{11}O_{39})_2]$	1.59
$Na_{13}[Er(TiW_{11}O_{39})_2]$	1.68	$Na_{13}[Yb(TiW_{11}O_{39})_2]$	1.77
$Na_{13}[Gd(TiW_{11}O_{39})_2]$	2.30	$Na_6[ZnTiW_{11}O_{39}]$	2.01
$Na_{13}[Dy(TiW_{11}O_{39})_2]$	1.92		

$[Ln(TiW_{11}O_{39})_2]^{13-}$, which has the largest ionic radius and the lowest charge density on it. The tendency to form hydrogen bonds between the cations and the anions of ionic liquids may be completely suppressed. Therefore, the viscosity in these inorganic ionic liquids is simply governed by a weak electrostatic interaction force.

The conductivity of an ionic liquid can been described by the equation below:[31]

$$\sigma = yF^2d(6\pi N_A FW\eta)[(\zeta_a r_a)^{-1} + (\zeta_{ac} r_c)^{-1}] \quad (1)$$

and can be related to its viscosity (η), formula weight (FW), density (*d*), ion radii (r_a and r_c) and to the specific interactions between the mobile ions (ζ_a and ζ_c) in an ionic liquid. The conductivity of the new inorganic ionic liquids was measured with a DDS-11 conductivitimeter and the results are shown in Table 3. Following on from the equation above, the ionic liquid containing the smallest ion should provide the highest conductivity but in our results (see Table 3) both type 1 and type 2 have some conductivity around 2×10^4 μS/cm. This phenomenon can be attributed to the similar charge density on the anionic surface of the type 1 and type 2 ionic liquids and it illustrates that one must not only focus on viscosity, molecular weight, or density, but also keep in mind the importance of the charge density on the iron when searching for highly conducting ionic liquids.

The thermal stability of the new ionic liquids in air or nitrogen was examined by Mettler Toledo thermogravimetric analysis at a heating rate of 2 K/min. Figure 2 shows the TG and SDTA data for $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 32.6H_2O$. It is important to note that this ionic liquid is only stable up to 308 K in N_2. The two steps of water-loss and the accompanying endothermal process were observed in the TG and SDTA curves in the temperature range 291−673 K. In order to clarify the thermal behavior, the conductivity of $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 32.6H_2O$ was measured at various temperatures after heating for 1 h in air. The experimental results are shown in Figure 3. The conductivity of this ionic liquid is almost constant in the temperature range 308−328 K and it decreases rapidly as the temperature increases, which leads to loss of constituent water. This result shows that the new ionic liquid is much less stable and possesses a liquid range of about 65 K with a melting point of around 263 K (see Table 2).

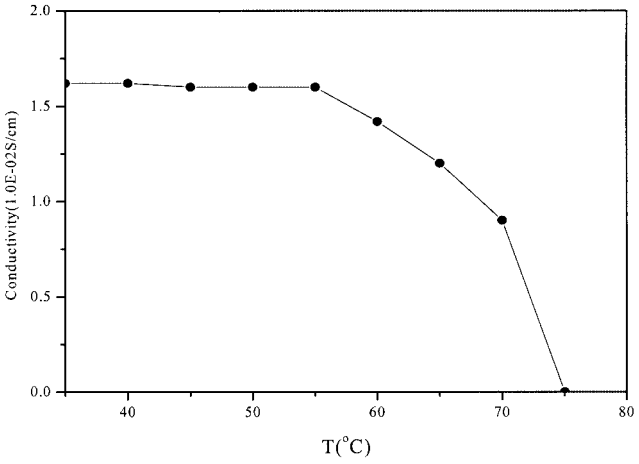

Figure 3. Specific conductivity of $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 32.6H_2O$ at different temperatures after heating for 1h

All the investigated ionic liquids are immiscible with organic solvents having low, medium and high dielectric constants (ε): cyclohexane (ε = 2.02), benzene (ε = 2.284), carbon tetrachloride (ε = 2.238), toluene (ε = 2.379), diethyl ether (ε = 4.22), chloroform (ε = 4.724), ethyl acetate (ε = 6.02), ethanol (ε = 25.2), methanol (ε = 32.63)and acetonitrile (ε = 37.4), and so forth. They are only miscible with water but their solubility in water varies drastically depending on the temperature. When the temperature is below ambient temperature (about 293 K) these ionic liquids are almost immiscible with water. However, if the tempera-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ture is raised , the solubility of the new ionic liquids in water increases. Most of the known ionic liquids are miscible with common organic solvents and with water, which leads us to believe that these ionic liquids may play an unexpected role in some fields such as separation and biphasic catalysis.

In order to determine the structure of the anion, the ^{183}W NMR and IR spectra of the new ionic liquids were recorded on a Bruker DRX400 nuclear magnetic resonance spectrometer, and on a Nicolet NEXUS 670 FT-IR spectrometer. The ^{183}W NMR and IR spectra of $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 32.6H_2O$ and $Na_6(ZnTiW_{11}O_{39})\cdot 27.2H_2O$ are shown in Figures 4 and 5. The ^{183}W NMR (Figure 4) and IR (Figure 5) spectra of $Na_6(ZnTiW_{11}O_{39})\cdot 27.2H_2O$ reveal six very strong, well-resolved resonance lines and four infrared bands in the $400-1200cm^{-1}$ range, in accordance with eleven tungsten atoms involved in the expected Keggin structure (C_s symmetry) with a lacunary site.[32] The infrared spectra of $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 32.6H_2O$ is virtually identical to that of $Na_6(ZnTiW_{11}O_{39})\cdot 27.2H_2O$, which proves that the ligand with a mono-vacant Keggin structure $(TiW_{11}O_{39})^{8-}$ consists of the new ionic liquid $Na_6(ZnTiW_{11}O_{39})\cdot 27.2H_2O$ and $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 32.6H_2O$. However, there is a marked difference between the ^{183}W NMR spectra of $Na_6(ZnTiW_{11}O_{39})\cdot 27.2H_2O$ and that of $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 32.6H_2O$ (see Figure 4). Ten stronger well-resolved resonance lines and some weaker resonance lines were observed in the ^{183}W NMR spectra of $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 32.6H_2O$. This phenomenon may be due to the presence of the paramagnetic center Ce^{III} and of the isomer with a different configuration[33] or to the small magnitude of the other anionic component in the ionic liquid $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 32.6H_2O$, as was observed in [emim]Cl-$AlCl_3$[34–36] ionic liquids.

In summary, a new series of inorganic ionic liquids consisting of an inorganic polyoxometalate anion with the Keggin structure and a sodium cation were prepared and investigated. They are the first examples of inorganic ionic liquids containing only one kind of inorganic compound and possessing different physicochemical properties from those of the known organic-inorganic ionic liquids or organic ionic liquids. Some of the characteristics of these new ionic liquids are not so desirable but they can enrich the

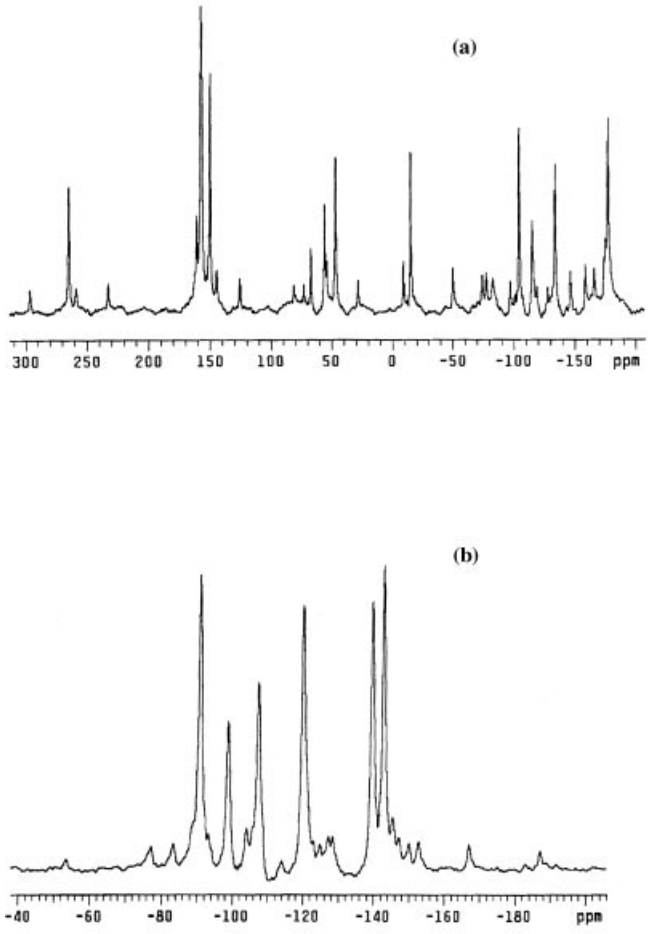

Figure 4. ^{183}W NMR spectra of $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 32.6H_2O$ (a) and $Na_6(ZnTiW_{11}O_{39})\cdot 27.2H_2O$ (b)

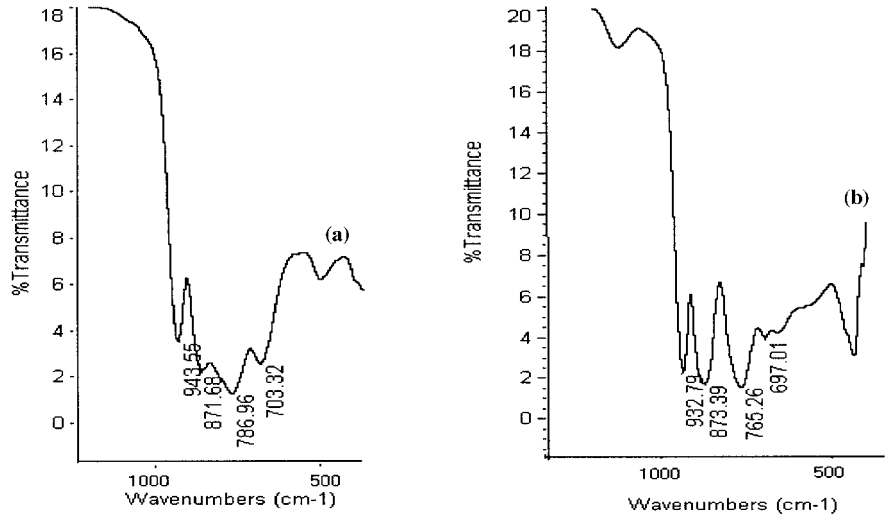

Figure 5. IR spectra of $Na_{13}[Ce(TiW_{11}O_{39})_2]\cdot 32.6H_2O$(a) and $Na_6(ZnTiW_{11}O_{39})\cdot 27.2H_2O$(b)

chemistry of ionic liquids and open up new opportunities for further research in this field. It is extremely important to be able to access tailor-made ionic liquids for biphasic catalysis and novel separation techniques.

Experimental Section

Preparation of the Inorganic Ionic Liquids: $Na_{13}[Ln(TiW_{11}O_{39})_2]\cdot xH_2O$ (Ln = lanthanide) were prepared by dissolving sodium tungstate (36.3 g, 0.11 mol) in water (200 mL). $TiCl_4$ (1.099 mL, 0.01 mol) was added to the solution with stirring violently. The pH was adjusted to 6 with glacial acetic acid. The mixture was refluxed at 333 K for half an hour, then about 5 mL of a solution containing 0.005 mol of $Ln(NO_3)_3$ was added to the hot mixture. After stirring for 2.5 h at 333 K, the mixture was filtered and the filtrate was cooled to room temperature in a beaker. Anhydrous ethanol (50 mL) was added to the cool filtrate. The product, a colored oil, was collected at the bottom of the beaker.

The method of preparation of $Na_5[MTiW_{11}O_{39}]\cdot xH_2O$ and $Na_6[MTiW_{11}O_{39}]\cdot xH_2O$, (M = transition metal; type 2) is similar to that of type 1. The difference between the two is only the amount of metal salt used as a starting material. In the case of a transition metal, the amount of salt added is 0.01 mol, rather than 0.005 mol of the lanthanide salt.

Synthesis and Structural Studies of Rhenium(v) Complexes Stabilized by a Monoanionic Cyclen Ligand

Catarina Xavier,[a] António Paulo,[a] Angela Domingos,[a] and Isabel Santos*[a]

Keywords: Rhenium / Oxo ligands / Macrocycles / N ligands

The novel cationic (oxo)Re^{V} complexes [ReO(cyclen-H)Cl]X [X = Cl (**3a**), BPh_4 (**3b**)] and [ReO(cyclen-H)I]I (**4**) have been prepared by treating cyclen (1,4,7,10-tetrazacyclododecane) with $(Bu_4N)[ReOCl_4]$ (**1**) and *cis*-$[ReO_2I(PPh_3)_2]$ (**2**), respectively. The X-ray structural analyses of **3a** and **4**, as well as ^1H NMR spectroscopy, showed that the macrocyclic ligand is coordinated in the unprecedented monoanionic form. ^1H and ^{13}C NMR spectroscopy also demonstrated that **3a**,**b** and **4** exist in solution as single isomers. To the best of our knowledge, **3a** and **4** are the first examples of structurally characterized oxo complexes of d transition elements with cyclen bound to the metal atom through one amido and three amine groups. In both complexes, the geometry around the Re^{V} center is best described as distorted octahedral. The terminal oxo and halo ligands are coordinated in relative *cis* positions, and the amido and three amino nitrogen atoms from cyclen occupy the four remaining coordination positions. The Re–N(amido) bonds [1.894(9) Å in **3a** and 1.888(12) Å in **4**] are *trans* to the halo ligands and, as expected, are considerably shorter than the Re–N(amine) bonds, which span from 2.110(6) to 2.246(8) Å and from 2.124(8) to 2.268(10) Å for cations the cations of **3a** and **4**, respectively.

Introduction

Macrocyclic polyamines, especially those based on cyclen (1,4,7,10-tetrazacyclododecane) or cyclam (1,4,8,11-tetrazacyclotetradecane) frameworks are widely used in the coordination chemistry of the d and f elements in search of applications in a wide variety of areas such as catalysis, biomimicry and medicine.[1] The coordination chemistry explored with macrocyclic polyamines for rhenium has involved only cyclam[2−4] and tacn (1,4,7-triazacyclononane)[5−11] type ligands. In the case of cyclam, part of this research work has been pursued due to the relevance of rhenium complexes in the development of diagnostic or therapeutic radiopharmaceuticals.[3,4] In fact, the β-emitters ^{186}Re and ^{188}Re are potentially useful as therapeutic radionuclides, and rhenium complexes are adequate surrogates of complexes of radioactive ^{99m}Tc, which is the most widely used radionuclide in diagnostic nuclear medicine.[12−14]

The (cyclam)rhenium chemistry so far reported is restricted almost to the cationic *trans*-$[ReO_2(cyclam)]^+$ species, which contains the macrocycle coordinated in a neutral, tetradentate and equatorial fashion.[2−4] The strong tendency of cyclam to form complexes with the *trans*-$[ReO_2]^+$ core is well illustrated by the fact that *trans*-$[ReO_2(cyclam)]^+$ can be prepared using rhenium starting materials as diverse as $[ReOCl_3(PPh_3)_2]$, $[ReNCl_2(PPh_3)_2]$, or even $[ReCl_3(CH_3CN)(PPh_3)_2]$.[3] In contrast, for tacn type ligands a much more diverse rhenium chemistry has been developed. These neutral, facial and tridentate ligands allowed the stabilization of a plethora of rhenium complexes, with the metal atom in oxidation states spanning from I to VII.[5−11]

Until now, research on rhenium chemistry with cyclen, also a potentially tetradentate macrocycle like cyclam but displaying a smaller cavity size, has remained completely unexplored. Aiming to widen the scope of the chemistry of Re^{V} oxides with cyclic tetradentate polyamines, and taking into account that cyclen tends to form mainly *cis*-octahedral complexes,[15] we decided to evaluate the possibility of using cyclen as an anchor to stabilize complexes with $[Re{=}O]^{3+}$ or *cis*-$[ReO_2]^+$ cores. In this contribution we describe reactions of cyclen with the Re^{V} starting materials $(Bu_4N)[ReOCl_4]$ (**1**) and *cis*-$[ReO_2I(PPh_3)_2]$ (**2**), which led to the formation of [ReO(cyclen-H)Cl]Cl (**3a**) and [ReO(cyclen-H)I]I (**4**), respectively. Herein, we also discuss the mechanism involved in the formation of complex **4**, which most probably proceeds through the intermediate *cis*-$[ReO_2(cyclen)]^+$, as indicated by ^1H and ^{13}C NMR spectroscopic studies.

Results and Discussion

While there is an extensive literature[16] on mono(oxo)Re^{V} complexes, namely with chelating N-donor ligands, complexes with the *cis*-$[ReO_2]^+$ core are scarce. To the best of our knowledge, the latter class of compounds

[a] Departamento de Quimica, ITN

Fax: (internat.) + 351-219941455
E-mail: isantos@itn.mces.pt

is comprised of only the five-coordinate *cis*-[$ReO_2I(PPh_3)_2$] (**2**)[17] and the six-coordinate *cis*-[$ReO_2(bipy)(py)_2$] (bipy = 2,2′-bipyridine)[18] and *cis*-[$ReO_2(OH_2)(Me_3tacn)]^+$ (Me_3-tacn = 1,4,7-trimethyl-1,4,7-triazacyclononane)[11]. For the synthesis of mono(oxo)Re^V complexes, several methodologies are available, namely oxygen abstraction reactions of Re^{VII} compounds already containing the ancillary ligands, reduction of perrhenate in the presence of the incoming ligands or metathesis reactions of (halo)(oxo)Re^V complexes, such as (Bu_4N)[$ReOCl_4$] (**1**) or [$ReOCl_3(PPh_3)_2$].[16,19–21] In contrast, there are no well-established synthetic methods for preparing *cis*-dioxorhenium(V) complexes.

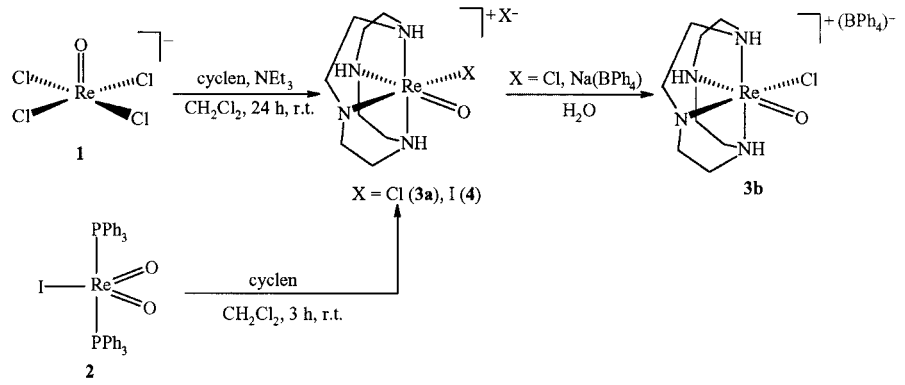
To enter into the chemistry of mono(oxo)Re^V complexes with cyclen we decided to start from (Bu_4N)[$ReOCl_4$] (**1**),[22] while for preparing cyclen complexes with the *cis*-$[ReO_2]^+$ core we selected *cis*-[$ReOI_2(PPh_3)_2$] (**2**)[17] as the more convenient starting material. As depicted in Scheme 1, compound **1** reacts smoothly with cyclen in dichloromethane giving [ReO(cyclen-H)Cl]Cl (**3a**) in moderate yield (57%). Compound **3a** slowly precipitates from the reaction mixture as a grey-green microcrystalline solid. ^1H NMR analysis of the precipitate showed the presence of **3a** contaminated with a small amount of protonated cyclen, due to release of HCl which is scavenged by the cyclen still present in solution. To suppress the formation of protonated cyclen, we have studied the reaction of **1** with cyclen in the presence of Et_3N. However, even under these conditions **3a** co-precipitates with protonated cyclen, which was removed by successive washings with methanol. An alternative for purification of $[ReO(cyclen\text{-}H)Cl]^+$ is the replacement of the counterion in **3a** by the larger anion BPh_4^- (Scheme 1). Treatment of an aqueous solution of crude **3a** with $NaBPh_4$ was accompanied by the precipitation of [ReO(cyclen-H)Cl](BPh_4) (**3b**), which was recovered analytically pure in 65% yield, after washing with water and methanol.

The reaction of *cis*-[$ReO_2I(PPh_3)_2$] (**2**) with cyclen in dichloromethane is quite fast, resulting in a brown solution from which a red solid precipitates almost immediately. During the course of the reaction, this insoluble red solid slowly vanishes and, meanwhile, a green microcrystalline solid starts to precipitate. This green material, recovered after a reaction time of 3 h, was identified as [ReO(cyclen-H)I]I (**4**), the iodo analogue of **3** (Scheme 1). Compound **4** was obtained in approximately 40% yield after purification by successive washings with warm water to remove some protonated cyclen and perrhenate, which were formed during the reaction.

Compounds [ReO(cyclen-H)Cl]X [X = Cl (**3a**), BPh_4 (**3b**)] and [ReO(cyclen-H)I]I (**4**) were unambiguously identified by the common analytical techniques which included X-ray crystallographic analysis in the case of **3a** and **4**.

The analysis of compounds **3a**, **3b** and **4** by ^1H and ^{13}C NMR spectroscopy demonstrated that the respective complex cations exist in solution as single isomers. In fact, the ^{13}C NMR spectra of these compounds in [D_6]DMSO showed four resonances for the methylene carbon atoms of cyclen in the range δ = 49.8−71.9 ppm, and three additional resonances for the aromatic carbon atoms of the counterion in the case of **3b**. These ^{13}C NMR spectra are consistent with the solid-state structures found for **3a** and **4**, and can be accounted for by the presence of a horizontal mirror plane which bisects the macrocycle and makes each pair of chelate rings magnetically equivalent.

The ^1H NMR spectra of **3a**,**b** and **4** should display eight resonances for the 16 diastereotopic methylene protons of the monodeprotonated cyclen, one resonance for the two equivalent apical N*H* protons and one resonance for the equatorial N*H* proton. Using [D_6]DMSO as the solvent, all the expected NH resonances were observed but some signals of the methylene protons of cyclen overlapped with the signal from residual water. In **3a**,**b** and **4**, the two apical N*H* resonances appear between δ = 9.64 and 9.84 ppm, and are considerably deshielded in comparison with the equatorial NH proton which resonates between δ = 4.25 and 4.52 ppm. All spectra display four poorly resolved multiplets in the range δ = 3.50−4.00 ppm, integrating for 8 CH_2 protons, and two high-field-shifted multiplets between δ = 2.4 and 2.8 ppm, integrating each for 2 CH_2 protons. For complex **3a** there is one CH_2 resonance very close to the residual water signal, appearing at δ = 3.52 ppm, and another under the water signal as demonstrated by 2D COSY and 2D HETCOR experiments. In fact, in the COSY spectrum of **3a** three correlations were found between the water signal and three of the CH_2 resonances, while in the HETCOR spectrum one correlation was observed between the water signal and the carbon atom reson-



Scheme 1

ating at δ = 64.1 ppm. In the spectra of compounds **3b** and **4**, two resonances are missing for the cyclen methylene protons. By analogy with the spectrum of 3**a**, these resonances must be under the signal of residual water, which appears at δ ≈ 3 ppm.

X-ray quality crystals of **3a** and **4** were obtained from methanol or water solutions, respectively, in the presence of air. Compound **3a** crystallized as $[ReO(cyclen\text{-}H)Cl]Cl_{0.67}(ReO_4)_{0.33}$, most probably due to partial oxidation of **3a** during the recrystallization process. Noticeably, for compound **4** no partial oxidation or hydrolysis of the rhenium−iodo bond was observed during its recrystallization from water, as evidenced by the crystal structure being consistent with intact [ReO(cyclen-H)I]I (**4**).

The crystallographic analyses showed that the complex cations **3a** and **4** are monomeric with approximately octahedral coordination geometries. ORTEP views of the structures are shown in Figures 1 and 2, and selected bond lengths and angles are listed in Tables 1 and 2, respectively.

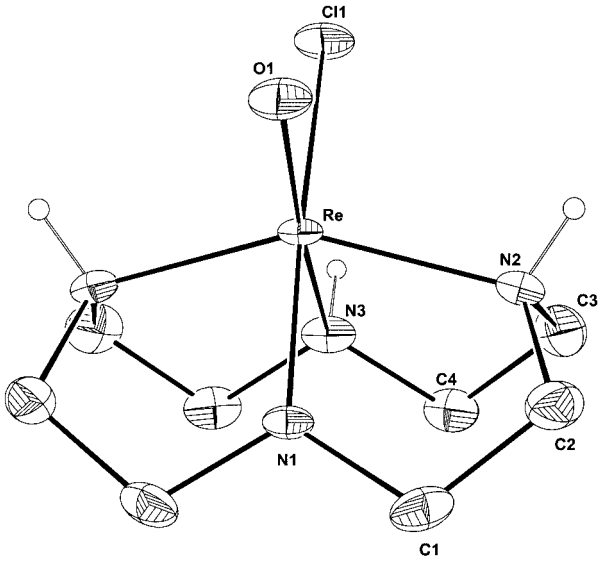

Figure 1. ORTEP view of the cationic complex **3a**; thermal ellipsoids are drawn at the 30% probability level

To the best of our knowledge, **3a** and **4** are the first reported structurally characterized examples of oxo complexes of d transition metals stabilized by a cyclen ligand. The presence of a monodeprotonated cyclen ligand is another unique feature of the structures of **3a** and **4**. In all reported structures of cyclen complexes the macrocycle is coordinated as a neutral ligand.[23−25] In both complexes, the rhenium center is coordinated by the one amido and three amine groups from cyclen, an oxo ligand and a halo ligand. The oxo and halo ligands are in *cis*-positions, as imposed by the *cis*-octahedral coordination of the tetradentate cyclen which occupies the remaining four coordination sites.

The presence of the rhenium−amido bonds is confirmed by their short lengths [Re−N(1) 1.894(9) Å in **3a**; Re−N(1) 1.888(12) Å in **4**], and by the almost planar sp^2-hybridized

N(1) atom. The Re−N(1) bond lengths in **3a** and **4** are similar to the Re−amido bond lengths recently reported for cationic (oxo)Re^V complexes with an acyclic tetradentate N-donor ligand.[16] As expected, these Re−N(1) bonds are considerably shorter than the three Re−N(amine) bonds, which span from 2.110(6) to 2.246(8) Å and from 2.124(8) to 2.268(10) Å for **3a** and **4**, respectively. Among the Re−N(amine) bonds, the longest are those corresponding to the nitrogen atom coordinated *trans* to the oxo ligand

[Re−N(3) 2.246(8) Å in **3a**; Re−N(3) 2.268(10) Å in **4**], reflecting the *trans* effect of this multiply bound ligand. The Re=O bond lengths [1.704(8) Å in **3a**; 1.715(9) Å in **4**] are within the expected range for octahedral mono(oxo)Re^{V} complexes but the Re−Cl [2.525(3) Å in **3a**] and the Re−I [2.8791(10) Å in **4**] bonds are longer than the values usually observed in (halo)(oxo)Re^{V} complexes.[16,17]. The lengthening of the Re−X (X = Cl, I) bonds can probably be accounted for by the presence of intramolecular hydrogen bonds involving the halo ligands and the equatorial N−H hydrogen atoms [Cl···N(3) 2.968 Å in **3a**; I···N(3) 3.262 Å in **4**].

In the structures of cations **3a** and **4**, the cyclen ligands adopt a folded and butterfly-like configuration, defining four chelate rings. There is a crystallographic mirror plane which contains the Re, O, N(1), N(3) and halide atoms, bisecting the coordinated macrocycle and resulting in two pairs of crystallographically equivalent five-membered chelate rings. The crystallographically equivalent chelate rings containing the deprotonated N(1) atom {[Re, N(1), C(1), C(2), N(2)] and [Re, N(1), C(1*), C(2*), N(2*)]} adopt an envelope conformation, while the other two equivalent five-membered chelate rings {[Re, N(2), C(3), C(4), N(3)] and ([Re, N(2*), C(3*), C(4*), N(3)]} assume a twisted conformation. The small cavity size of cyclen imparts a significant angular strain on the folded ring, as clearly indicated by the axial N(2)−Re−N(2*) bond angles of 147.5(3)° in **3a** and 147.4(4)° in **4**, which bend away the macrocycle from the oxo and halo ligands coordinated in the equatorial positions. This bending is more pronounced than that usually observed in *cis*-octahedral complexes containing neutral and tetradentate cyclen, where the axial angles usually lie between 160 and 170°.[23−25] The increased bending of the macrocycle in **3a** and **4** most probably reflects the presence of the Re−N(amido) bonds, which introduce additional steric constraints in the *cis*-octahedral coordination of the small sized cyclen.

For complexes **3a** and **4**, two isomeric forms could exist, depending on the *syn* or *anti* orientation of the equatorial N−H hydrogen atoms (see Figure 3), but only one isomeric form was detected, both in solid state and in solution. In the solid-state structures found for **3a** and **4**, the two apical NH hydrogen atoms and the equatorial NH hydrogen atom are directed towards the oxo and halo ligands, corresponding to the *syn*(X) (X = Cl, I) form. The establishment of the above-mentioned intramolecular hydrogen bonds X···H

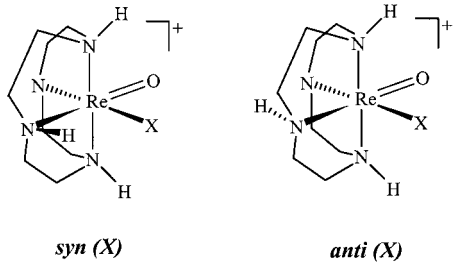

Figure 3. Schematic representation of the two possible isomers for cations $[ReO(cyclen\text{-}H)X]^{+}$ [X = Cl (**3**), I (**4**)]

[X = Cl (**3a**), I (**4**)], involving the equatorial N−H hydrogen atoms, certainly contribute to the formation of the single *syn* isomers.

Interestingly, the solid-state structures of **3a** and **4** give some support to the conjugate base catalyzed dissociative mechanism (D_{cb}), generally accepted for substitution reactions of (cyclen)Co^{III} complexes. Such mechanism involves intermediate Co^{III} complexes containing a monodeprotonated cyclen, but these intermediates were never isolated.[25]

In order to have a better insight into the nature of the intermediates involved in the formation of green [ReO(cyclen-H)I]I (**4**), we tried to identify the red solid which was formed almost immediately when *cis*-$[ReO_2I(PPh_3)_2]$ (**2**) was treated with cyclen. After a short reaction time of 30 min, the red insoluble solid was separated and washed with dichloromethane. After drying under vacuum, the recovered red and microcrystalline material was analyzed by ^{1}H and ^{13}C NMR spectroscopy. As will be discussed below, the collected NMR spectroscopic data indicated that we must have isolated the cationic complex "*cis*-$[ReO_2(cyclen)]^{+}$" (**I_1**). However, complex **I_1** was never obtained analytically pure, being always contaminated with $cyclenH^{+}$ and perrhenate. All attempts to purify **I_1** were unsuccessful because of its tendency to be transformed into [ReO(cyclen-H)I]I (**4**), even under strictly anhydrous and anaerobic conditions.

The ^{13}C NMR spectrum in [D_6]DMSO of the intermediate *cis*-$[ReO_2(cyclen)]^{+}$ (**I_1**) is even simpler than those of **3** and **4**, displaying only two methylene resonances at δ = 63.6 and 58.1 ppm for the coordinated cyclen. This pattern is consistent with the formulation proposed for **I_1**, since all the chelate rings are expected to be magnetically equivalent, due to the higher symmetry of this complex, which displays one horizontal mirror plane containing the metal atom, the oxo ligands and the equatorial nitrogen atoms, and one vertical mirror plane passing through the apical nitrogen atoms and the metal atom. Consistent with this, the ^{1}H NMR spectrum of **I_1** shows two broad resonances, centered at δ = 9.38 and 6.18 ppm and integrating for 2 protons each, which we have attributed to the two equivalent apical N*H* protons and to the two equivalent equatorial N*H* protons, by comparison with the ^{1}H NMR spectroscopic data of compounds **3a**,**b** and **4**, which have been unambiguously identified. Based on the formulation proposed for complex **I_1**, four resonances were expected for the CH_2 protons of cyclen with relative intensities of 4:4:4:4. In [D_6]DMSO, the ^{1}H NMR spectrum of **I_1** displays three resonances at δ = 3.01, 3.19 and 3.74 ppm, integrating each for 4 protons. The missing resonance also probably overlapped with the signal of residual water, as discussed above for complexes **3a**,**b** and **4**. Hence, the NMR spectroscopic properties of **I_1** seem to be in accord with its formulation as a *cis*-dioxo complex containing a tetradentate and neutral cyclen ligand.

In spite of the occurrence of parallel oxidation processes, we believe that formation of compound **4** involves **I_1** as an intermediate, as proposed in Scheme 2. The observed *cis*-dioxo intermediate **I_1** most probably rearranges into the (hydroxo)(oxo)Re^{V} derivative **I_2**, following an intramolecu-

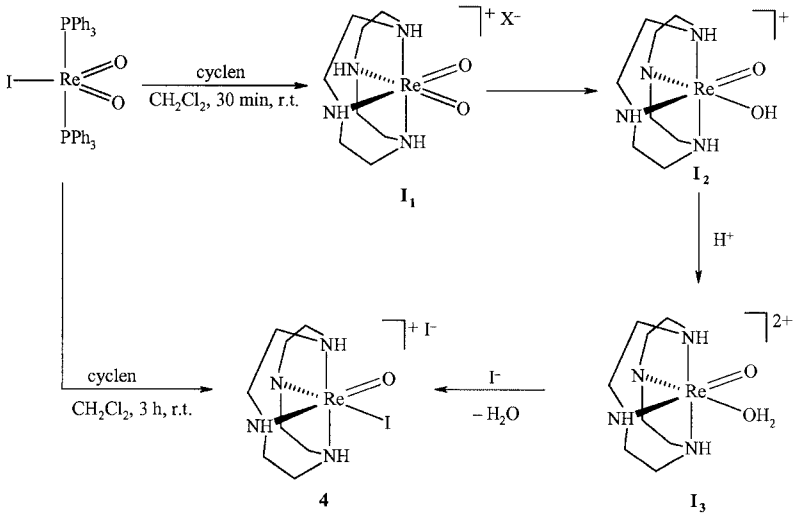

Scheme 2

lar proton transfer from cyclen to one of the oxo ligands. Further protonation of the hydroxo ligand, eventually by adventitious water, gives the intermediate aqua complex $\mathbf{I_3}$, which is finally transformed into the (iodo)(oxo) complex **4** upon replacement of the water molecule by the halide anion. The driving force for the transformation of $\mathbf{I_1}$ into **4** is certainly the basicity of the oxo ligands associated with the unstable *cis* configuration of the $[ReO_2]^+$ unit, due to the antibonding interactions between the metal d orbitals and the oxygen lone pairs.[26] In fact, the scarcity of *cis*-dioxorhenium(v) complexes has been attributed to electronic factors, the *trans* arrangement of the MO_2 unit being the most stable in octahedral dioxo transition metal complexes with a d^2 configuration.[26]

Conclusions

The novel cationic [ReO(cyclen-H)Cl]X [X = Cl (**3a**), BPh_4 (**3b**)] and [ReO(cyclen-H)I]I (**4**) were prepared in moderate yields using $(Bu_4N)[ReOCl_4]$ (**1**) or *cis*-$[ReO_2I(PPh_3)_2]$ (**2**), respectively, as the starting materials. The cations of compounds **3** and **4** are the first examples of d transition metal oxo complexes anchored to a monoanionic cyclen ligand. In the case of **3a** and **4**, the unprecedented coordination mode of the macrocycle was confirmed by X-ray crystallography, and the deprotonation of cyclen is certainly justified due to the enhanced Lewis acidity of the d^2 rhenium center. Apparently, the geometrical constraints of *cis*-octahedral cyclen could impose the *cis* geometry on the ReO_2 unit, but the resultant reactive *cis*-dioxo complex, *cis*-$[ReO_2(cyclen)]^+$, is readily converted into compound **4**. This transformation more than likely involves deprotonation of one amine group from cyclen, protonation of one of the oxo ligands from the *cis*-ReO_2 unit, and coordination of the incoming halide ion. A possible strategy for the efficient trapping of cyclen *cis*-dioxorhenium(v) derivatives could be the use of tetrasubstituted *N*-alkylated cyclen ligands, which are unable to undergo deprotonation.

Remarkably, in complexes **3** and **4** the cyclen ligand remains deprotonated even under aqueous conditions, indicating that cations **3** and **4** exhibit considerable stability in water and under aerobic conditions. These features may offer the possibility of applying such systems in the development of ^{99m}Tc or $^{186/188}Re$ radiopharmaceuticals, which is nowadays one of the most relevant areas for the application of rhenium coordination compounds.

Although not yet explored, a diverse derivative chemistry can be anticipated for complexes **3** and **4**, based on oxygen transfer or metathesis reactions, allowing an interesting comparison with the chemistry reported so far for the related macrocyclic cations $[ReO(tacn)Cl_2]^+$ and $[ReO(Me_3tacn)Cl_2]^+$.[7]

Experimental Section

General: The syntheses of the complexes were carried under nitrogen, using standard Schlenk techniques and dry CH_2Cl_2, while the workup procedures were performed under air. The starting materials $[Bu_4N][ReOCl_4]$ (**1**) and *cis*-$[ReO_2I(PPh_3)_2]$ (**2**) were prepared according to literature methods.[17,22] Other chemicals were used as purchased. ^1H and ^{13}C NMR spectra were recorded with a Varian Unity 300 MHz spectrometer. ^1H and ^{13}C chemical shifts are given in ppm and were referenced to the residual solvent resonances relative to Me_4Si. IR spectra were recorded as KBr pellets with a Perkin−Elmer 577 spectrometer. C, H and N analyses were performed with an EA 110 CE Instruments automatic analyzer.

[ReOCl(cyclen)]Cl (3a): To a solution of $[Bu_4N][ReOCl_4]$ (**1**) (200 mg, 0.34 mmol) in CH_2Cl_2 (15 mL) was added a solution of cyclen (58 mg, 0.34 mmol) and triethylamine (0.36 mmol, 50 mL) in CH_2Cl_2 (5 mL) at room temperature. The initially yellow solution became dark brown after complete addition of the ligand. The reaction mixture was stirred for 24 h and, after this time, a red

supernatant and an insoluble gray-green solid were obtained. This solid, which was recovered using a centrifuge, was washed with methanol and formulated as **3a**. Yield: 86 mg (0.19 mmol, 57%). $C_8H_{19}Cl_2N_4ORe$ (444.38): calcd. C 21.61, H 4.27, N 12.60; found C 21.36, H 4.15, N 12.33. IR: $\tilde{\nu}$ = 940 [ν(Re=O)] cm^{-1}. ^1H NMR (300 MHz, [D$_6$]DMSO): δ = 2.49 (br., 2 H, CH_2), 2.70−2.82 (m, 2 H, CH_2), 3.40−3.52 (m, 2 H, CH_2), 3.75−4.15 (m, 8 H, CH_2), 4.24 (br., 1 H, NH), 9.84 (br., 2 H, NH) ppm. ^{13}C NMR (300 MHz, [D$_6$]DMSO): δ = 50.5, 60.9, 64.6, 71.1 ppm.

[ReOCl(cyclen)]BPh$_4$: A solution of $NaBPh_4$ (77 mg, 0.23 mmol) in distilled water (10 mL) was added to a solution of **3a** (50 mg, 0.13 mmol) in water (10 mL), causing the immediate formation of **3b** as a yellow-green microcrystalline solid. Compound **3b** was recovered using a centrifuge, followed by successive washings with methanol. Yield: 60 mg (0.085 mmol, 65%). $C_{32}H_{39}BClN_4ORe$ (728.16): calcd. C 52.78, H 5.40, N 7.69; found C 53.18, H 5.73, N 7.72. IR : $\tilde{\nu}$ = 940 [ν(Re=O)] cm^{-1}. ^1H NMR (300 MHz, [D$_6$]DMSO): δ = 2.49 (br., 2 H, CH_2), 2.72 (m, 2 H, CH_2), 3.72−4.15 (m, 8 H, CH_2), 4.24 (br.,1 H, NH), 6.78 (m, 4 H, Ar), 6.91(m, 8 H, Ar), 7.16 (m, 8 H, Ar), 9.84 (br., 2 H, NH) ppm. ^{13}C NMR (300 MHz, [D$_6$]DMSO): δ = 50.5, 60.9, 64.6, 71.1, 121.5, 125.3, 135.5 ppm.

[ReOI(cyclen)]I (4): To a solution of *cis*-[$ReO_2I(PPh_3)_2$] (130 mg, 0.15 mmol) in CH_2Cl_2 (15 mL) was added a solution of cyclen (28 mg, 0.16 mmol) in CH_2Cl_2 (5 mL). The initially purple solution became brown, and a red solid started to precipitate almost immediately. During the course of the reaction, the red solid vanished and, meanwhile, a green microcrystalline solid started to precipitate. After 3 h, the green solid, which was formulated as **4**, was recovered using a centrifuge, washed with CH_2Cl_2 and warm water, and dried under vacuum. Further purification of **4** was achieved by recrystallization from distilled water. Yield: 38 mg (0.06 mmol, 40%). $C_8H_{19}I_2N_4ORe$ (627.28): calcd. C 15.30, H 3.03, N 8.93; found C 15.65, H 2.96, N 8.79. IR: $\tilde{\nu}$ = 940 [ν(Re=O)] cm^{-1}. ^1H NMR (300 MHz, [D$_6$]DMSO): δ = 2.49−2.60 (m, 2 H,CH_2), 2.78−2.83 (m, 2 H, CH_2), 3.83−3.98 (m, 6 H, CH_2), 4.07−4.15 (m, 2 H, CH_2), 4.52 (br.,1 H, NH), 9.64 (br., 2 H, NH) ppm. ^{13}C NMR (300 MHz, [D$_6$]DMSO): δ = 51.2, 61.1, 63.4, 71.9 ppm.

X-ray Crystallographic Analysis: Crystals were obtained by recrystallization from a saturated methanol solution (**3a**) or from a saturated aqueous solution (**4**) and mounted in thin-walled glass capillaries. Data were collected at room temperature with an Enraf−Nonius CAD-4 diffractometer with graphite-monochromated Mo-K_α radiation, using an ω-2θ scan mode. The crystal data are summarized in Table 3. The data were corrected[27] for Lorentz and polarization effects, and empirically for absorption by Ψ-scans. The heavy-atom positions were located by Patterson methods using SHELXS-97.[28] The remaining atoms were located in successive Fourier difference maps and refined by least-squares refinements on F^2 using SHELXL-97.[29] All non-hydrogen atoms were refined anisotropically; the contributions of the hydrogen atoms were included in calculated positions, constrained to ride on their carbon atoms with group U_{iso} values assigned. Atomic scattering factors and anomalous dispersion terms were as in SHELXL-97.[29] The drawings were made with ORTEP-3.[30] Crystallographic data for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-215009 (**3a**) and -215010 (**4**). Copies of the data can be obtained free of charge on applicaton to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

A New Alternating Ferro-Antiferromagnetic One-Dimensional Azido-Bridged (Arylazoimidazole)manganese(II), $[Mn(TaiEt)(N_3)_2]_n$ [TaiEt = 1-Ethyl-2-(*p*-tolylazo)imidazole], Exhibiting Bulk Weak Ferromagnetic Long-Range Ordering

Keywords: Magnetic properties / Manganese / N ligands / Polymers

1-Ethyl-2-(*p*-tolylazo)imidazole [*p*-Me–C_6H_4–N=N–$C_3H_2N_2$–Et-1; TaiEt], an unsymmetrical N,N′-blocker, and azide (N_3^-), a versatile intermediary, coordinate to manganese(II) forming an alternating chain with the formula $[Mn(TaiEt)(N_3)_2]_n$ (**1**). The compound crystallizes in the triclinic $P\bar{1}$ space group with a = 7.9297(7) Å, b = 9.5883(9) Å, c = 11.8366(11) Å, α = 103.555(2)°, β = 105.811(2)°, γ = 104.280(2)°, and Z = 2. The structure consists of neutral chains in which each manganese(II) center is alternately bridged by two end-on and two end-to-end azide ligands. The unsymmetrical arylazo heterocycle chelator creates a strong distortion around the metal center [N–Mn–N′ bite 67.7°; Mn–N′(azo) distance 2.562 Å]. The magnetic properties of **1** have been investigated over the temperature range 2–300 K. Magnetic data are analyzed on the basis of an alternating ferro- and antiferromagnetic Heisenberg chain of the manganese(II) ions, described by the spin Hamiltonian $H = -J_1\Sigma S_{2i}S_{2i+1} - J_2\Sigma S_{2i+1}S_{2i+2}$. The J exchange parameters are 2.65 ± 0.12 cm^{-1} and −14.5 ± 0.15 cm^{-1}, respectively. Magnetic studies at low temperatures indicate long-range ordering (canting) with a remnant magnetism that vanishes above 40 K. The canting phenomenon has been studied by various techniques including an EPR spectroscopic investigation at different temperatures and appears to be due to the local distortion around each metal center and the π-π stacking in the 3-D network.

Introduction

The preparation of inorganic-organic hybrid functional materials based on covalent bonds with malleable coordination spheres and non-covalent forces involving hydrogen-bonding X−H···π and π···π interactions is a field of current interest in coordination chemistry.[1−6] Self-assembly[7] is the most efficient approach in this regard. Covalent systems are particularly useful in magnetochemistry as they can provide high magnetic ordering and afford different varieties of magnetic materials.[1,2] A judicious choice of a suitable transition metal template, appropriate organic blocker and efficient magnetic coupler can lead to different molecular architectures with tunable magnetic properties. The pseudohalides, especially azide,[8] are versatile bridging ligands and allow μ-1,1 (end-on, EO), μ-1,3 (end-to-end, EE),[9] μ-1,1,3[10] and other[11,12] modes of interactions. It is established that the μ-1,1 (EO) mode gives ferromagnetic (F) and μ-1,3 (EE) gives antiferromagnetic (AF) interactions[9−12] with few exceptions.[13−16] Different combinations of azide-bridging modes have resulted in some unusual structures which consequently changes the magnetism.[9−30]

To date the maximum number of reports on azide-bridging coordination polymers with various organic blockers and investigations of their structure and magnetism have appeared for copper(II) and nickel(II).[9−21] In this regard, analogues studies of other 3d ions like manganese, iron, cobalt are less familiar. The manganese−azido system is currently attracting the attention of magnetochemists, since it enables work to be done with a greater local spin value.[9] The use of different heterocyclic N-donor ligands such as pyridine, polypyridine and their substituted derivatives, pyridine Schiff bases, are well documented.[9,22−30] But no such work has been initiated with unsymmetrical ligands having azo-N and heterocyclic-N donor centers. Arylazo heterocycles with the azoimine (−N=N−C=N−) function are unsymmetrical *N*,*N*′-end-capping chelators. For the last few years our group has been engaged[31−34] in exploring

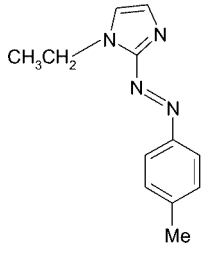
the chemistry of such ligand systems with transition and non-transition metal ions. Ligands have been anchored on a surface to synthesize a solid-phase extractant[34] that has been used in the separation of different d^n ions from ores, alloys, medicinal samples, etc.

With this background we are interested in preparing and characterizing new polynuclear azidomanganese(II) complexes with a bidentate azoimidazole ligand, 1-ethyl-2-(*p*-tolylazo)imidazole (TaiEt). The ligand system plays a substantial role in chemistry[31−33] involving stabilizing low oxidation states of transition metal ions. We have used metal/bidentate ligands in 1:1 ratios in such a way that the four coordination vacancies around the six-coordinate manganese(II) ion should be completed by the excess azide ligands. According to this principle, we are able to prepare a new alternating double-bridged μ-1,1 (EO) and μ-1,3 (EE) azidomanganese(II) complex of TaiEt with a one-dimensional (1-D) chain along with noncovalent C−H···π and *p*···π inter-chain interactions leading to a 3-D geometry, which has been characterized by X-ray diffraction and spectroscopic studies. Magnetic measurements indicate global AF behavior with the presence of a weak F component intrinsic to the sample. The most interesting feature is the weak long-range ferromagnetic ordering likely to occur due to a canting phenomenon originating from the local distortion around the manganese(II) centers and the π-π stacking in the 3-D network.



Results and Discussion

Synthesis and Formulation

The preparation of **1** can be achieved in high yield by the reaction of $Mn(OAc)_2{\cdot}4H_2O$ with TaiEt and NaN_3 in dry MeOH at room temperature. The procedure is summarized in Equation (1).

The organic blocker belongs to the unsymmetrical *N*,*N*′-chelating ligand, where N and N′ are the N(imidazole) and N(azo) donor centers, respectively. The air-stable moisture-insensitive red-brown compound is insoluble in common organic solvents. In the IR spectrum the asymmetrical azido stretch, $\nu_{assym}(N_3)$ appears as strong bands between 2095 and 2050 cm^{-1} which suggests the simultaneous existence of EE and EO bridging modes in the complex.[9,35] The azide symmetric stretch $\nu_{sym}(N_3)$ corresponding to the EO bridging mode can be observed as a band of medium intensity at 1330 cm^{-1}. This mode is not active for the symmetrical EE coordination. Finally, the band assignable to the deformation mode of the azido group, $\delta(N_3)$, found at 610, 600 cm^{-1}, is in good agreement with that observed for all polynuclear azido compounds.[9,35] Furthermore, the pertinent bands characteristic of the bound TaiEt ligand appear at 1590 [ν(C=N)] and 1395 [ν(N=N)] cm^{-1}. The diffused reflectance spectrum of $[Mn(TaiEt)(N_3)_2]_n$ exhibits an intraligand charge transfer transition at 380 nm and weak spin-forbidden *d*-*d* bands at 525 (sh) and 455 nm corresponding to an octahedral symmetry.[36]

Description of the Structure

The structure of $[Mn(TaiEt)(N_3)_2]_n$ was revealed by a single-crystal X-ray diffraction study [Figure 1, (a) and (b)]. Selected bond lengths and angles are given in Table 1. Each manganese center exhibits a distorted octahedral MnN_6 coordination sphere linked by two EO and two EE azide groups as well as two N-centers from *N*,*N*′-chelator (TaiEt), respectively, forming four-membered, eight-membered and five-membered loops around each metal center. The chelate angle =N−Mn−N′ is 67.7(1)° which is smaller than those reported values for other transition metal arylazo complexes[31−33,37,38] [76.5° for a ruthenium(II) complex[37] and 77.8° for an osmium(II) compound].[38] This may have a major influence on distortion from idealized O_h symmetry. The Mn−N(azo) bond [Mn−N(1), 2.562(2) Å] is elongated by 0.34 Å compared to the Mn−N(imidazole) distance [Mn−N(3), 2.221(2) Å]; however, it is well below the sum of the van der Waals radii of Mn^{II} and N(azo).[39] The N=N bond [N(1)−N(2), 1.267(3) Å] is longer than that of the free ligand [1.252(1) Å].[40] This increment may refer to a dπ(Mn)→π*(azo) charge transition.[32]

The atomic arrangements Mn, N1, N2, C8, N3 constitute a plane (mean deviation < 0.07 Å) and the pendant phenyl ring makes a dihedral 16.83(2)° with the plane. The manganese(II) ions are alternately linked by two EO [Mn−N(8) 2.217(2) Å, Mn−N(8a) 2.214(3) Å] and two EE [Mn−N(5) 2.204(3) Å, Mn−N(7b) 2.215(3) Å] azido bridges. The Mn−N(8)−Mn(a) angle in the EO mode is 103.53(9)° and lies within the range (100−105°)[9] for this kind of bridge. The bridging arrangement Mn−N(8)−Mn(a)−N(8a) is planar but the azide ligands do not reside within the plane. The Mn−N(5)−N(6) and Mn−N(7b)−N(6b) angles are 135.3(2)° and 130.1(2)°, respectively. The dihedral angle between the mean plane of Mn−N(5)−N(6)−N(7) and Mn−N(7b)−N(6b)−N(5b) with a chair configuration is 3.5°. The dihedral angle between the least-squares plane formed by the six N atoms of the EE double-bridging azide ligands and the N(5)−Mn−N(7b) system is 1.82(13)°. The

N−N distances of the azide ligand ranges from 1.144(4) to 1.194(3) Å and reflects typical double-bond character. In the EO mode, the N−N distance of terminal and bridging types exhibit usual distortion (ca. 0.05 Å) compared to the symmetrical bond lengths in the EE motif; but the results show that in the EE motif the azide ligand is slightly distorted from linearity [N(5)−N(6)−N(7) 177.1(3)°] compared to the EO azide form [N(8)−N(9)−N(10) 179.4(4)°]. 165.16(9)°. The imidazole N center [N(3)] of TaiEt is *trans* to the EO azide N atom [N(8)] while the azo N atom [N(1)] is *trans* to the EE azide N atom [N(7b)]. This reveals a 1-D chain structure of the molecule, which is being supported by EO and EE Mn−N_3 motifs.

The C−H···π and π···π interactions are two noncovalent forces operating among the molecules to generate a three-dimensional network.[41−43] Each molecular unit shows two C−H···π bonding interactions [C(7)−H(7C)···C_g(1) and C(11)−H(11b)···C_g(2)] with imidazole [C_g(1)] (−x, 1 − y, 1 − z) and *p*-tolyl [C_g(2)] (1 − x, 1 − y, 1 − z) rings of neighboring molecules [Table 1, Figure 1 (b)]. The C(7)−H(7c) bond is from the methyl group of (C_6H_4)−CH_3 (*p*), and C(11)−H(11b) is part of the methylene moiety of the N(4)−CH_2−(CH_3) group. Their interactions with C_g(1) and C_g(2), respectively, may provide inter-chain rigidity and is the operating force of a 3-D network. The *p*···π interactions C_g(1)···C_g(1) [3.416(2) Å], C_g(1)···C_g (2) [3.525(2) Å], C_g(1)···C_g(2) [3.136(2) Å] and C_g(2)···C_g(2) [3.545(2) Å] enhance the inter-chain networking strength. These noncovalent interactions among 1-D parallel units are ideal in forming a 3-D supramolecular continuum.

Magnetic Properties

The temperature dependence of the magnetic susceptibility is shown in Figure 2. The χ_M value is 0.0123 $cm^3 \cdot mol^{-1}$ at 300 K and increases smoothly with decreasing

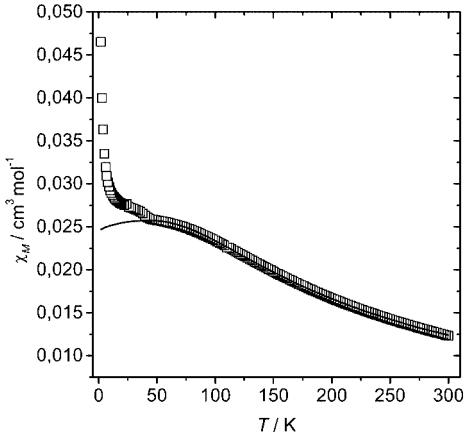

Figure 2. Plots of χ_M vs. T for **1**; the solid line represents the best fit (see text for the parameters calculated)

temperature (0.025 $cm^3 \cdot mol^{-1}$ at 50 K), and finally increases abruptly to a maximum value of 0.0465 $cm^3 \cdot mol^{-1}$ at 1.95 K. This reflects global antiferromagnetic coupling with the presence of a weak ferromagnetic long-range ordering down to 40 K presumably due to a canting phenomenon.[44] Thus, unusual χ_M values at low temperatures restrict us in fitting all of the magnetic data: it is only possible to fit the data to the temperature where the canting arises (40 K) (see below). To avoid any misleading interpretation we have carried out the fitting from 300−50 K.

(a) High-Temperature Zone (300−50 K) − Calculation of the Coupling Parameters

The structural findings demand an alternating chain of exchange interactions with nearest neighbors that have been described by the spin Hamiltonian where J_1 and J_2 stand for the alternating exchange constants, and "classical" spin operators are expressed by S are.

$$H = -J_1\Sigma S_{2i}S_{2i+1} - J_2\Sigma S_{2i+1}S_{2i+2}$$

This approximation is justified for manganese(II) ion, which exhibits a large spin ($S = 5/2$). The fit of experimental data for such a manganese(II) 1-D system has been carried out using the reported relation[26] derived from the above Hamiltonian, in Equation (2), in which $u_1 = \coth(J_1/kT) - kT/J_1$, $u_2 = \coth(J_2/kT) - kT/J_2$ with the scaling factors $J_i = J_{i'}S(S + 1)$ and $g_i = g_{i'}[S(S + 1)]^{1/2}$.[26]

$$\chi = \frac{Ng^2\beta^2}{3kT}\left(\frac{1+u_1+u_2+u_1u_2}{1-u_1u_2}\right) \quad (2)$$

The best J parameters obtained are: 2.7 ± 0.10 cm^{-1} and -14.6 ± 0.15 cm^{-1}, $g = 2.01$ and $R = 2.56 \times 10^{-9}$. If g is kept at 2.00, which is the expected value for Mn^{II}, J_1 and J_2 do not differ significantly: 2.65 ± 0.12 cm^{-1} and -14.5 ± 0.15 cm^{-1} and $R = 1.75 \times 10^{-8}$. A negative J value (AF) can be attributed to the EE azido bridge whereas the positive J value (F) corresponds to the EO mode.[9] The main structural and magnetic parameters of the reported alternating manganese(II) 1-D azido systems along with **1** are collected in Table 2 for a comparison of the magnetic behavior. Assuming that the Mn−N distances do not vary considerably, the main factor controlling the intensity of the ferromagnetic interactions in the EO bridge appears to be the bridging Mn−N(azido)−Mn angle (θ). Density functional calculations[45,46] on some model compounds of manganese(II) show a parabolic dependence of J on this bridging angle (θ): for θ lower than 98°, AF coupling is expected; for θ greater than 98°, F coupling should result.[45] A crossover from F to AF is predicted at θ = 98°. The angles (see Table 2) are close to 100° and J values vary from 9.6 to 1.8 cm^{-1}. **1** has a very large angle (θ = 103.5°); thus, its J value should be one of the largest. However, it is one of the lowest J values (2.65 cm^{-1}) indicating that the correlation of J with θ may be complicated and a more accurate pragmatic theory is needed to systematize this behavior.

Now assuming that the Mn−N distances do not vary considerably, the most useful structural parameter for examining the magnitude of the AF coupling via EE bridges

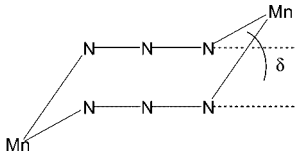
Table 2. [a] θ corresponds to the Mn−N(azido)−Mn angle. [b] δ is defined in Scheme 1. [c] The J values reported in refs.[24,27] have been simulated by us because they seemed to be too large. Effectively, the simulation using the same formula indicated in the text (ref.[26]) does not agree at all with the figures of χ_M vs. T. On the contrary, dividing by $S(S + 1) = 5/2 \times 7/2 = 8.75$ the recalculated J values (indicated in parentheses in bold) perfectly agree with the figures given in refs.[24,27] This error may be due to the meaning of J given in ref.[24]; the scaling factor is $J_i = J_{i'}S(S + 1)$ used by us, which has not been used in these two papers.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is the dihedral angle (δ) (Scheme 1). EHMO calculations[24,26] show that the AF coupling should decrease for larger values indicating that the loss of overlap due to the increase in the torsion angle becomes the driving parameter controlling the magnitude of the exchange interaction. For **1**, the δ value is the lowest reported so far (1.82°) (Table 2). Thus, the AF coupling should be greater. In fact, it is the highest $|J|$ value (14.5 cm^{-1}) reported to date. At this stage it is very difficult to draw a general conclusion. Other complexes with high δ values (close to 30°, for example, in the two complexes[22,23] with a *trans* blocker) have similar J values (Table 2) when, theoretically, this should be very small. So new compounds and more accurate calculations are necessary to systematize these kinds of magnetostructural correlations in the manganese(II) systems.



Scheme 1

(b) Low-Temperature Zone (50−2 K) − Origin of the Weak Ferromagnetism

The increase in susceptibility down to ca. 45−50 K indicates the presence of a weak intrinsic ferromagnetic contribution, possibly due to a spin canting effect.[44] A cursory report of a similar feature is found in only one of the alternating EE and EO azido-bridged 1-D manganese complexes (Table 2).[24] In the present case, extensive experiments have been performed to substantiate the long-range ordering as pointed below.

(1) An abrupt break in χ_M and $\chi_M T$ occurs at 40 K when lower fields are employed (Figure 3). This transition at 40 K, when the magnetic field changes, is indicative of the onset of long-range magnetic ordering.[47]

(2) The field-cooled magnetization (FCM) obtained on cooling within the field (50 Oe) shows the typical feature [Figure 4 (a)] of a ferromagnetic transition, i.e. a rapid increase in χ_M occurs when T decreases below 40 K and, then, appears at the beginning of saturation. If the field is switched off below 40 K, a remnant magnetization is observed. The zero-field-cooled magnetization (ZFCM) is obtained by cooling in zero-field and then applying the field and heating. At any temperature below T_c the ZFCM is smaller than the FCM, due to the fact that in this temperature range the applied field is too weak to move the domain walls. The remnant magnetization (RM) [Figure 4 (b)] indicates the presence of magnetization from 2 to 40 K. Thus, the critical temperature for the long-range magnetic ordering is 40 K.

(3) The magnetization study (from −5 T to +5 T at 2 K) shows (Figure 5) the $M/N\beta$ value to be 0.3 e^-, which is clearly indicative of the global antiferromagnetic interaction. An isolated manganese(II) ion would give 5 e^-. At the

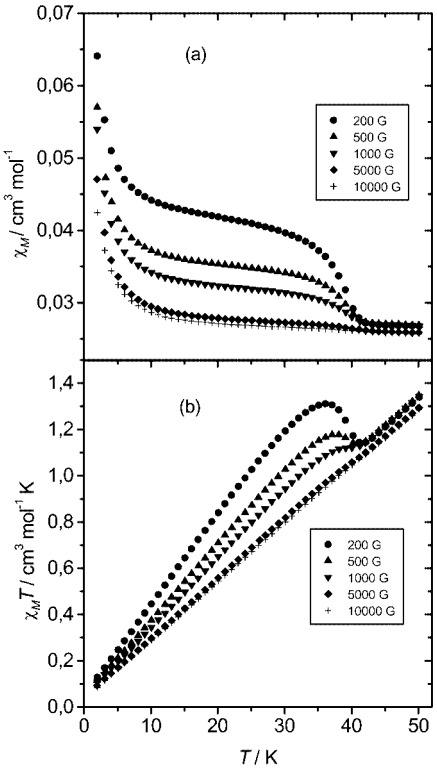


Figure 3. Plots of (a) χ_M vs. T and (b) $\chi_M T$ vs. T at different fields in the temperature range (2−50 K); at lower fields abrupt breaks are seen (see text)

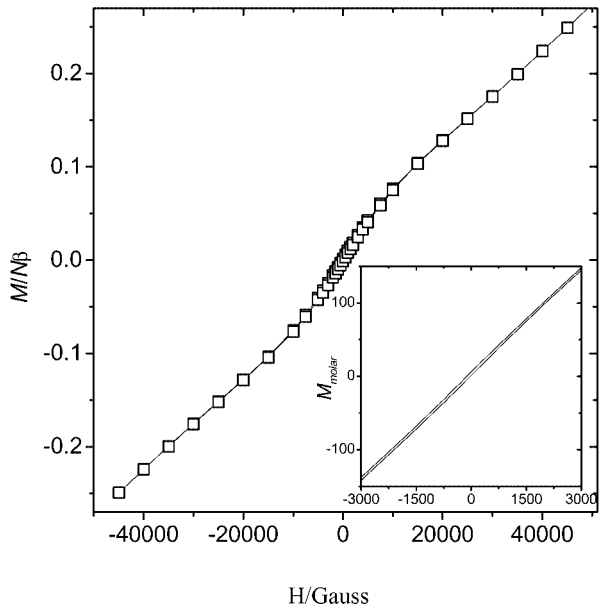

Figure 5. Reduced magnetization curve for **1**, at 2 K; (inset) central part of the magnetization curve for **1**, showing a very small hysteresis loop

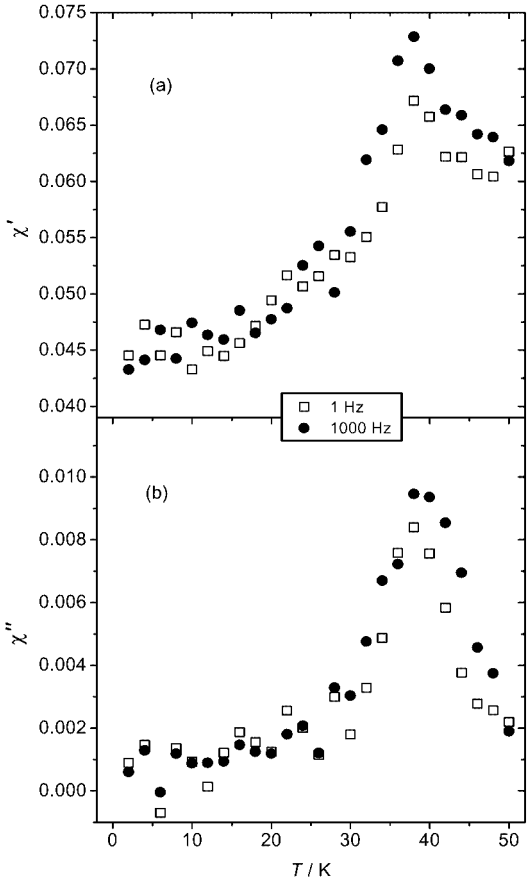

Figure 6. *In-phase* (a) and *out-of-phase* (imaginary) (b) parts of the *ac* susceptibility curves for **1** at two different frequencies (1 and 1000 Hertz)

bottom of the figure (from −0.5 T to +0.5 T) a weak hysteresis loop is seen. The coercive field is difficult to calculate, as it is too large, but the remnant magnetization at 0 K is 6.7 cm^3 Gauss·mol^{-1}, which is typical of a soft ferromagnet.

(4) The *ac* susceptibility measurements are definitely the best proof of the long-range order. The real part of the *ac* magnetic susceptibility (χ_{ac}') has a maximum at ca. 40 K, accompanied by the occurrence of non-zero field-independent χ_{ac}'' (Figure 6) suggesting that the T_c of **1** is close to 40 K. The small χ values indicate weak ferromagnetic character (in accordance with the hysteresis loop values).

(5) EPR spectroscopic measurements at room temperature (298 K) show a very intense isotropic signal centered at $g = 2.00$ (without hyperfine splitting) which is typical for the manganese(II) ion. The peak-to-peak band-width increases on lowering the temperature (at 298 K and 77 K it is ca. 150 Gauss; at 40 K it is ca. 400 Gauss) (Figure 7) and its intensity strongly diminishes. Finally, at 4 K the peak-to-peak band-width is > 2000 Gauss and 1600 times less intense than that at room temperature, which is in accordance with the behavior of long-range ordered compounds at low temperature.[48] It is worth mentioning that this feature in the EPR spectra indicates that the magnetic ordering cannot be attributed to ferromagnetic impurities and the canting phenomenon must be inherent to the sample. Canted one-dimensional (1-D)[49−51] and/or discrete[52] systems are reported in the literature though very scarce. Instead, canting is more frequent in two-dimensional (2-D) and three-dimensional (3-D) systems[53] because the canting, per se, is a three-dimensional long-range ordering. To interpret this behavior in 1-D, it is necessary to have some linkages in **1**, though weak, resulting in a 3-D network. This may be attributed to the π···π stacking (Figure 1, b) and other weak interactions. The spin canted structure is *not compatible* with the crystal structure of **1** because of the presence of an inversion center (space group $P\bar{1}$). Thus, the existence of the possible canting effect must be due to a distortion in the crystal net at low temperatures, that suppresses the inversion center. It is well known that two mechanisms lead to spin canting: (i) magnetic anisotropy (D and E) and (ii) antisymmetric exchange, $\boldsymbol{d}_{ij}[S_i \times S_j]$.[44,54] In both cases, the total energy is minimized through a compromise in which the spins are tilted away from the antiparallel towards a position in which they are perpendicular (Scheme 2). The D parameter is, in principle, non-zero because the ground state is $S = 5/2$ and there is a great distortion in the manganese(II) ion as is evident from the N−Mn−N′ angle of 67.7° created by the chelator and from lengthening of the Mn−N(azo) bond (2.56 Å) over the other five Mn−N bonds (ca. 2.2 Å). The Mn−N(azo) distance is anomalously long creating greater distortion and anisotropy. Such a coordination environment plays a major role for the canting behavior in this case and as also found in some manganese(III)[55,56] ($S = 2$) and nickel(II)[50,57] ($S = 1$) systems. The other possible origin of the canting, the antisymmetric part of the spin Hamiltonian, is proportional to $[(g - 2)/g]J$, where the intermolecular coupling, J is an average between −14.5 and 2.65 cm^{-1}. The average g value

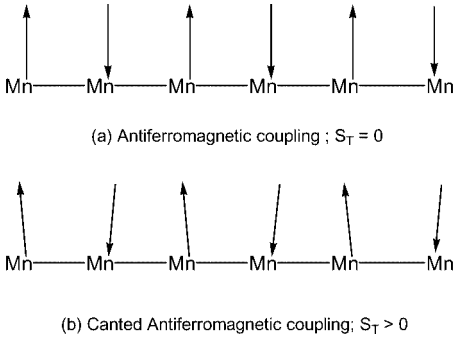

Scheme 2

is close to 2.00. Thus, although very small, this term could not be nullified. Such an explanation is found in the literature for several non-distorted iron(III),[58] manganese(II)[59,60] and copper(II) canted complexes.[61,62] In the present case, the magnetization curve allows us to calculate the (possible) canting angle. According to the literature, there are several approaches to calculate the canting angle.[22,44] The most useful is $\sin^{-1}(\mu_{RM}/\mu_{satd.})$ or $\sin^{-1}(M_{RM}/M_{satd.})$ being $\mu_{sat} = 5$ for manganese(II) ions. In complex **1**, M_{RM} is 0.3, thus the angle is very small (0.34°) and results in a very small ferromagnetic ordering.

Conclusion

We have presented here the synthesis, single-crystal X-ray structure, and magneto-structural correlation of a new 1-D azido-bridged manganese(II) coordination polymer. The structural characterization shows an alternating bis(-bridged) EE and EO azido network with a very unsymmetrical organic blocker as a *cis* chelate. The presence of C−H···π and π···π interactions leads to the generation of a three-dimensional network. From the magnetic point of view the complex shows a long-range magnetic order arising due to a canting phenomenon originated most likely from the distortion created by the low bite of the chelator resulting a very strong distortion in the Mn−N(azo) distance (2.56 Å) and 3-D structural evolution. The use of an arylazo heterocycle ligand system over pyridine or polypyridine systems[22−30] provides ample scope for such long-range magnetic ordering. We are currently working with this azo heterocycle having varied substituents on its network to prepare different molecular architectures with other 3d transition metal ions using pseudohalide intermediaries and to study their magnetic behavior towards the preparation of molecule-based magnets.

Experimental Section

Materials: Manganese(II) acetate tetrahydrate (SRL, India) and sodium azide (SRL, India) were purchased and used without further purification. 1-Ethyl-2-(*p*-tolylazo)imidazole (TaiEt) was prepared according to a reported procedure.[31] All other chemicals and solvents for preparative and spectroscopic work were of reagent grade and were used as received.

CAUTION! Azido complexes of transition metal ions containing organic ligands are potentially explosive. Only a small amount of material should be prepared, and it should be handled with care.

Physical Measurements: IR spectra (KBr discs, 4000−300 cm^{-1}) were recorded with a JASCO FTIR model 420 spectrophotometer. Microanalyses (C, H and N) were done with a Perkin−Elmer 2400 CHNS/O elemental analyzer. The diffuse reflectance spectrum was run at room temperature with a JASCO UV/Vis/NIR V-570 spectrophotometer in the 200−1000 nm range. A Bruker ES 200 spectrometer (X-band frequency) was used to record the EPR of polycrystalline samples at room (298 K) and low temperatures (77 K, 30 K, 4 K). Magnetic measurements on powdered samples were performed over the temperature range 2−300 K using a Quantum Design MPMS-7 SQUID magnetometer in a magnetic field of 0.1 T. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal tables).

Synthesis of the Complex $[Mn(TaiEt)(N_3)_2]_n$ (1): 1 was synthesized from $Mn(OAc)_2{\cdot}4H_2O$ (0.100 g, 0.408 mmol), TaiEt (0.087 g, 0.408 mmol) and NaN_3 (0.053 g, 0.816 mmol) in dry methanol solution (25 mL). The resulting intense red solution was filtered and left to stand at room temperature. After several days, prismatic dark-red single crystals were obtained. They were separated by filtration, washed with Et_2O and dried in vacuo over indicator silica gel. Yield: 0.124 g (75%). $C_{12}H_{14}MnN_{10}$ (353.27): calcd. C 40.8, H 4.0, N 39.7; found C 40.6, H 3.9, N 39.5.

X-ray Structure Determination: A suitable single crystal of the title complex for X-ray analysis was mounted on a Siemens SMART CCD diffractometer equipped with a graphite monochromator and Mo-K_α (λ = 0.71073 Å) radiation. Data were collected at 295 K. The crystal size was 0.08 × 0.10 × 0.18 mm. The intensity data were corrected for Lorentz and polarization effects and an empirical absorption correction was also employed using the SAINT[63] program. A summary of the crystallographic data and structure refinement parameters is given in Table 3. A total of 7947 reflections (unique reflections, 3546, R_{int} = 0.029) were collected in the range 1.9° < θ < 28.1° and 2683 were assumed applying the condition $I > 2\sigma(I)$. The structure was solved by the Patterson method using SHELXS-97[64] followed by Fourier and difference Fourier synthesis. Full-matrix least-squares refinements on F^2 were carried out using SHELXL-97 with anisotropic displacement parameters for all non-hydrogen atoms. The hydrogen atoms were fixed geometrically and refined using a riding model. In the final difference Fourier map the residual maxima and minima were 0.52 and −0.38 e·Å^{-3}. All calculations were carried out using the SHELXL-97, ORTEP-32[65], PLATON[66] programs. CCDC-193975 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

New Complexes of Niobium(V) and Tantalum(V) with Monoanionic NNO Heteroscorpionate Ligands

Antonio Otero,*[a] Juan Fernández-Baeza,[a] Antonio Antiñolo,[a] Juan Tejeda,[a] Agustín Lara-Sánchez,[a] Luis Sánchez-Barba,[a] and Ana M. Rodríguez[a]

Keywords: Niobium / Tantalum / Tripodal ligands / Oxo ligands / Alkoxide ligands

A new synthetic route based on bis(3,5-dimethylpyrazol-1-yl)acetic acid (Hbdmpza) (**1**) has afforded the alcohol 2,2-bis(3,5-dimethylpyrazol-1-yl)ethanol (Hbdmpze) in good yield. This alcohol and the related lithium compound $[\{Li(bdmpza)(H_2O)\}_4]$ are excellent precursors for introducing these scorpionate ligands into transition metal complexes. For example, the lithium compound and Hbdmpze (the latter after prior addition of *n*BuLi) react with a solution of MCl_5 (M = Nb, Ta) in THF to give, after stirring for 12 h at –70 °C, a solution from which the complexes $[MCl_4(\kappa^3\text{-bdmpzx})]$ (*x* = *a*, M = Nb **2**, Ta **3**; *x* = *e*, M = Nb **4**, Ta **5**) have been isolated. When solutions of **2**–**5** in THF were stirred at ca. 20 °C for 48 h, the oxo complexes $[MCl_2(O)(\kappa^3\text{-bdmpzx})]$ (*x* = *a*, M = Nb **6**, Ta **7**; *x* = *e*, M = Nb **8**, Ta **9**) were isolated. The structures of these complexes have been determined by spectroscopic methods and the X-ray crystal structure of **8** has been established. Finally, a new class of heteroscorpionate-metal complexes containing an alkoxide ligand has been prepared. Direct reaction of the complexes $[MCl_4(\kappa^3\text{-bdmpza})]$ (M = Nb **2**, Ta **3**) with several alcohols gave the complexes $[MCl_3(\kappa^3\text{-bdmpza})(OR)]$ (M = Nb, R = Me **10**, Et **11**, *i*Pr **12**, *t*Bu **13**; M = Ta, R = Me **14**, Et **15**, *i*Pr **16**, *t*Bu **17**) after the appropriate workup.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Several classes of poly(pyrazol-1-yl)borato niobium complexes containing halide, alkoxide, alkyl, imido, oxo, or alkyne ancillary ligands have been prepared.[1] We have reported the preparation of several complexes of the type $TpNb(Cl)_2(RC{\equiv}CR')$ or Tp*Nb(O)(Cl)(OR) [Tp = hydridotris(pyrazol-1-yl)borate and Tp* = hydridotris(3,5-dimethylpyrazol-1-yl)borate],[2] and have recently examined the synthesis of new "heteroscorpionate" ligands[3] that incorporate pyrazole rings. The target compounds are related to the tris(pyrazol-1-yl)methane system,[4] where one pyrazole group is replaced by a carboxylate, dithiocarboxylate or ethoxide group; i.e. bis(3,5-dimethylpyrazol-1-yl)acetate (bdmpza), bis(3,5-dimethylpyrazol-1-yl)dithioacetate (bdmpzdta) and 2,2-bis(3,5-dimethylpyrazol-1-yl)ethoxide (bdmpze). The aim is to provide a small degree of steric hindrance and considerable coordinative flexibility in the ligand. These compounds are excellent reagents for the introduction of scorpionate ligands into niobium complexes and a series of alkyne-containing niobium(III) complexes has been isolated and characterized.[5] More recently, we extended the range of complexes to include group 4 metals.[6]

In continuing such research we have further studied the synthesis of heteroscorpionate-containing niobium(V) and tantalum(V) species, where any compounds have been reported in the literature. We describe here the synthesis and characterization of new classes of heteroscorpionate-niobium and -tantalum complexes containing halide, oxo and alkoxide ancillary ligands.

Results and Discussion

The alcohol 2,2-bis(3,5-dimethylpyrazol-1-yl)ethanol (Hbdmpze) was obtained by reduction of the lithium compound $[\{Li(bdmpza)(H_2O)\}_4]$ with a 2.0 M solution of $(CH_3)_2S{\cdot}BH_3$ (borane-methyl sulfide complex) in THF at reflux in a 1:1 molar ratio (Scheme 1).[5] However, to increase the low yield (46%) of this method we proposed a new route based on the use of bis(3,5-dimethylpyrazol-1-yl)acetic acid (Hbdmpza) (**1**), which was also synthesized and characterized in this work. The lithium compound $[\{Li(bdmpza)(H_2O)\}_4]$ reacted at room temperature in a 1:1 molar ratio (Scheme 1) with hydrochloric acid to give, after appropriate workup, the acid **1** (97% yield). Reduction of this acid with a 2.0 M solution of $(CH_3)_2S{\cdot}BH_3$ gave the alcohol 2,2-bis(3,5-dimethylpyrazol-1-yl)ethanol (Hbdmpze) in 84% yield (Scheme 1). The mass spectrum (FAB) of **1** indicates a mononuclear formulation (Exp. Sect.). The IR spectrum shows two strong bands at 1578 and 1414 cm^{-1}, which are assigned to $\nu_{as}(CO_2^-)$ and

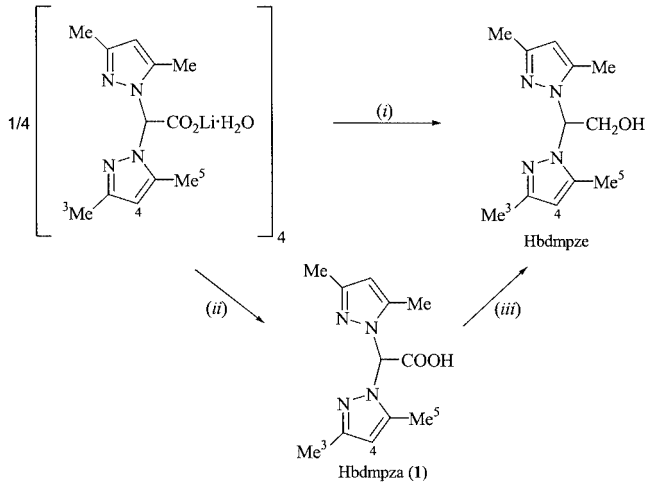
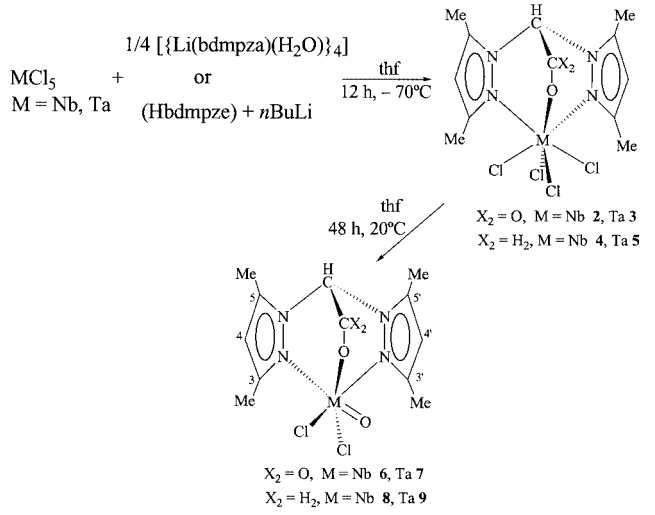


Scheme 1. Summary of reactions leading to compound **1**. Reagents and conditions: (i) $(CH_3)_2S{\cdot}BH_3$, THF, reflux, 12 h under an atmosphere of dry nitrogen, yield 46%; (ii) HCl, THF, 1 h, 20 °C, yield 97%; (iii) $(CH_3)_2S{\cdot}BH_3$, THF, reflux, 12 h under an atmosphere of dry nitrogen, yield 84%.

$\nu_s(CO_2^-)$, respectively. The ^1H NMR spectrum shows a set of resonances for H^4, Me^3 and Me^5, indicating that both pyrazole rings are equivalent in solution. In addition, all the resonances are shifted to lower fields than those for the lithium compound [{Li(bdmpza)(H_2O)}$_4$]. The $^{13}C\{^1H\}$ NMR spectra exhibit the corresponding signals for CH, C^3, C^4, C^5, Me^3, Me^5 and CO_2^- (Exp. Sect.).

[{Li(bdmpza)(H_2O)}$_4$] and (Hbdmpze) were used in the complexation of some niobium and tantalum fragments, initially with MCl_5 (M = Nb, Ta). Thus, [{Li(bdmpza)(H_2O)}$_4$] and (Hbdmpze) (the latter with prior addition of *n*BuLi) reacted with a solution of MCl_5 (Scheme 2) in THF to give, after stirring for 12 h at −70 °C, a solution from which the complexes [$MCl_4(\kappa^3$-bdmpzx)] (x = *a*, M = Nb **2**, Ta **3**; x = *e*, M = Nb **4**, Ta **5**) were isolated as red, (**2**) yellow (**3, 4**) and white (**5**) solids after the appropriate workup. When solutions of **2**−**5** in THF were stirred at ca. 20 °C for 48 h, the oxo complexes [$MCl_2(O)(\kappa^3$-bdmpzx)] (x = *a*, M = Nb **6**, Ta **7**; x = *e*, M = Nb **8**, Ta **9**) were isolated as white solids after the appropriate workup (Scheme 2). Although rigorously anhydrous experimental conditions were used, hydrolysis still occurred.



Scheme 2. Syntheses of complexes [$MCl_4(\kappa^3$-bdmpzx)] (**2**−**5**) and [$MCl_2(O)(\kappa^3$-bdmpzx)] (**6**−**9**)

The complexes were characterised spectroscopically. The mass spectra of **2**−**9** indicate a mononuclear formulation (Exp. Sect.). The ir spectra of **2**−**3** and **6**−**7** show two strong bands at ca. 1750 and 1500 cm^{-1}, which are assigned to $\nu_{as}(CO_2^-)$ and $\nu_s(CO_2^-)$, respectively. In the lithium compound [{Li(bdmpza)(H_2O)}$_4$], $\Delta\nu_{as\text{-}s}$ [$\nu_{as}(CO_2^-) - \nu_s(CO_2^-)$] is 180 cm^{-1}, and the carboxylate forms a coordinating bridge between two lithium atoms. IR spectroscopy is a good indicator of the bonding mode of carboxylate ligands:[7] bonding through the two oxygen atoms (chelate mode) leads to a decrease in $\Delta\nu_{as\text{-}s}$ in comparison to the absorptions of a bridge mode, and bonding through the single oxygen atom leads to an increase in $\Delta\nu_{as\text{-}s}$, again in comparison to a bridging mode. The $\Delta\tilde{\nu}_{as\text{-}s}$ (ca. 235 cm^{-1}) for these compounds accords with an *O*-coordination (monodentate) mode. The IR spectra of **4**, **5**, **8** and **9** contain a strong band at ca. 570 cm^{-1} that is assigned to ν(M−O). Complexes **2**−**9** show other bands of interest at ca. 420 and 315 cm^{-1}, which are assigned to ν(M−Cl) of the terminal group for a mononuclear disposition, with a seven-coordinate model or octahedral environment for each niobium atom. The ^1H and $^{13}C\{^1H\}$ NMR spectra of **2**−**5** show a single set of resonances for the pyrazole rings, indicating that the pyrazoles are equivalent. These data confirm a seven-coordinate model (Scheme 2), with κ^3-NNO coordination for the bdmpza or bdmpze.

The ^1H NMR spectra of **6**−**9** exhibit two resonances for each H^4, Me^3 and Me^5 pyrazole protons, indicating that the two pyrazole rings are non-equivalent (Exp. Sect.). These results are consistent with a proposed octahedral disposition in which the two pyrazole rings are located in *cis* and *trans* positions with respect to the oxo ligand (Scheme 2). Homonuclear NOE (nuclear Overhauser enhancement) difference spectroscopy confirmed these assignments for each pyrazole ring. In addition, the $^{13}C\{^1H\}$ NMR spectra of complexes **6**−**9** exhibit two resonances for the different pyrazole carbon atoms C^3, C^4, C^5, Me^3, Me^5 which have been assigned on the basis of $^1H-^{13}C$ HETCOR correlation experiments (Exp. Sect.). The chiral centre of the metal atom in these complexes was confirmed by the presence in solution of the two enantiomers upon addition of the chiral shift reagent (*R*)-(−)-(9-anthryl)-2,2,2-trifluoroethanol. This process gave rise to two signals for each proton in the ^1H NMR spectra, resulting from the two diastereoisomers of the corresponding two enantiomers (Figure 1).

The molecular structure of complex **8** was determined by X-ray diffraction. It crystallizes in the orthorhombic space group *Pbca* with eight molecules per unit cell, and consists of a monomeric unit with a heteroscorpionate ligand bonded to the niobium atom through the two nitrogen atoms and the oxygen from the alkoxide group (Figure 2).

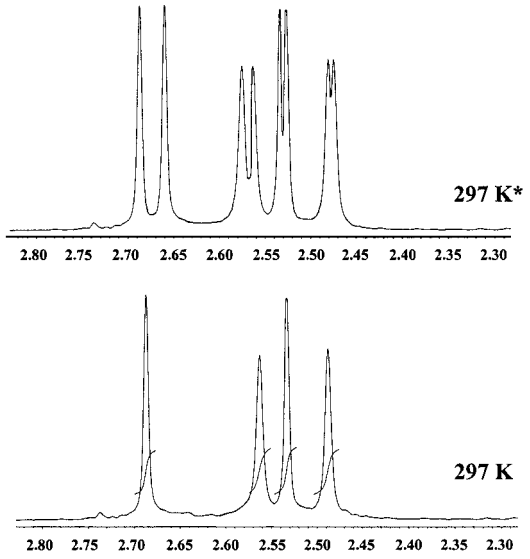

Figure 1. ^{1}H. NMR spectra in the region of the Me group of the complex [$NbCl_2(O)(\kappa^3$-bdmpza)] (**6**); *with chiral shift reagent

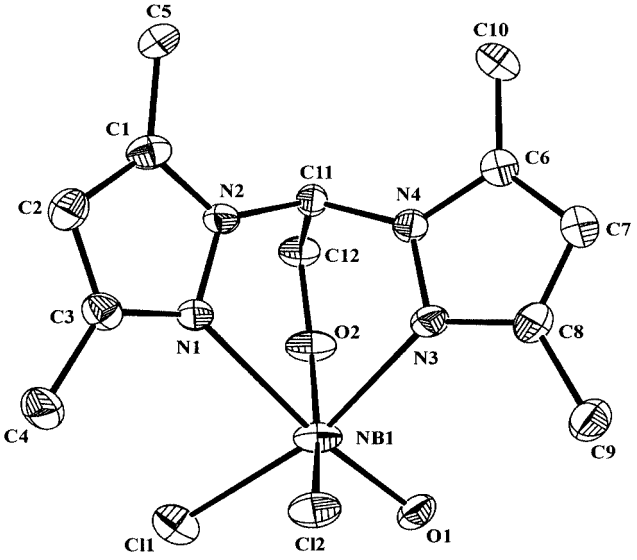

Figure 2. ORTEP drawing of the complex [$NbCl_2(O)(\kappa^3$-bdmpze)] (**8**)

In addition, the niobium centre is coordinated to two chloride atoms and one oxygen, rendering the niobium atom a chiral centre. In the solid state, due to the centrosymmetric space group, both enantiomers are present and one, *OC*−6−43(C), is depicted in Figure 2.

This complex has a pseudooctahedral geometry with an equatorial plane defined by the N1, N3, O1 and Cl1 atoms and two apical positions defined by O2 and Cl2. The major distortion appears in the O2−Nb1−Cl2 angle [157.7(2)°, Table 1]. The Nb1−N3 bond length [2.263(6) Å] is as expect for an Nb pyrazolyl complex[2] but the elongated Nb1−N1 [2.456(5) Å] indicates that O1 exerts a strong *trans* influence. The Nb1−O1 [1.796(5) Å] is as expected for a double bond.[8]

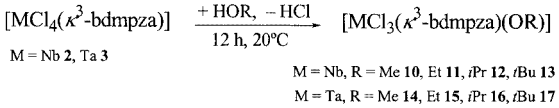
To extend the range of alkoxide-containing niobium and tantalum species we prepared a new class of heteroscorpionate-metal complex, which contains an alkoxide ancillary ligand. Direct reaction of complexes [$MCl_4(\kappa^3$-bdmpza)] (M = Nb **2**, Ta **3**) with several alcohols (Scheme 3) gave, after appropriate workup, the complexes [$MCl_3(\kappa^3$-bdmpza)(OR)] (M = Nb, R = Me **10**, Et **11**, *iPr* **12**, *t*Bu **13**; M = Ta, R = Me **14**, Et **15**, *iPr* **16**, *t*Bu **17**), which were isolated as yellow solids. The mass spectra of complexes **10**−**17** indicate a mononuclear formulation (Exp. Sect.). In the IR spectra $\Delta\tilde{\nu}_{as\text{-}s}$ is ca. 225 cm^{-1}, which accords with coordination by a single oxygen. Three strong bands are also observed at ca. 550, 370 and 300 cm^{-1}, and the first of these was assigned to ν(M−OR) and the latter two to ν(M−Cl). The ^{1}H NMR spectra of these complexes exhibit a single set of resonances for H^4, Me^3 and Me^5, indicating that the pyrazole rings are equivalent. These results are consistent with the proposed seven-coordinate disposition in which the alkoxide and chloride ligands bisect the plane of the scorpionate ligand (Figure 3). In addition, the $^{13}C\{^1H\}$ NMR spectra show the corresponding signals for C^3, C^4, C^5, Me^3 and Me^5 and the different carbon atoms of the corresponding alkoxide ligand (Exp. Sect.).



Scheme 3. Synthesis of complexes [$MCl_3(\kappa^3$-bdmpza)(OR)] **10**−**17**

Conclusion

A new synthetic route has provided the alcohol 2,2-bis(3,5-dimethylpyrazol-1-yl)ethanol (Hbdmpze) in good yield. Both this alcohol and the related lithium compound

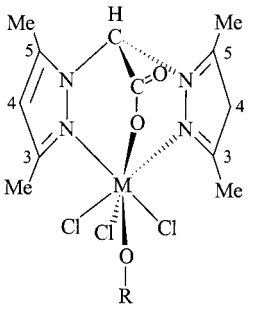

Figure 3. Proposed structure for complexes **10−17**

[{Li(bdmpza)(H_2O)}$_4$] are excellent precursors for introducing these scorpionate ligands into transition metal complexes, as confirmed by the preparation of different niobium and tantalum complexes. New classes of heteroscorpionte-niobium(v) and tantalum(v) complexes, containing halide, oxo and alkoxide ancillary ligands have also been isolated.

Experimental Section

All reactions were performed using standard Schlenk-tube techniques under an atmosphere of dry nitrogen. Solvents were distilled from appropriate drying agents and degassed before use. Microanalyses were carried out with a Perkin−Elmer 2400 CHN analyser. Mass spectra were recorded on a VG Autospec instrument using the FAB technique and 3-nitrobenzyl alcohol as matrix. Infrared spectra were recorded in the region 4000−200 cm^{-1} using a Perkin−Elmer 883 spectrophotometer. ^1H and ^{13}C NMR spectra were registered on a Varian Unity FT-300 and 200 spectrometers referenced to the residual deuterated solvent. The NOE difference spectra were recorded with the acquisition parameters: spectrum width 5000 Hz, acquisition time 3.27 s, pulse width 90°, relaxation delay 4 s, irradiation power 5−10 dB, number of scans 120. Two-dimensional NMR spectra were acquired using standard VARIANT-FT software and processed using an IPC-Sun computer.

The complexes $NbCl_5$ and $TaCl_5$ were purchased from Aldrich. The compounds [{Li(bdmpza)(H_2O)}$_4$] and Hbdmpze were prepared as reported previously.[3,5]

Preparations

Hbdmpza (1): A 10% solution of HCl (4.50 mL, 11.02 mmol) in water was added to [Li(bdmpza)(H_2O)}$_4$] (3.00 g, 11.02 mmol) dissolved in dry THF (30 mL) in a Schlenk tube (250 mL), and the resultant reaction mixture was stirred for 1 h at room temperature. The mixture was then separated and the organic layer dried with $MgSO_4$ and subsequently concentrated to afford the white solid **1**, which was washed with hexane and crystallized from a mixture of THF/hexane. Yield 97%. $C_{12}H_{16}N_4O_2$ (248.3): calcd. C 58.05, H 6.49, N 22.56; found C 58.12, H 6.65, N 22.31. ^1H NMR ($CDCl_3$, 297 K): δ = 6.89 (s, 1 H, CH), 5.91 (s, 2 H, H^4), 2.15 (s, 6 H, Me^3), 2.30 (s, 6 H, Me^5) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 69.3 (CH), 149.6, 142.6 (C^3 or C^5), 106.9 (C^4), 13.5 (Me^3), 11.1 (Me^5), 168.2 (CO_2^-) ppm. IR (Nujol): $\tilde{\nu}$ = 1562 ν(C=N), 1578 $\nu_{as}(CO_2^-)$, 1414 $\nu_s(CO_2^-)$ cm^{-1}. Mass spectrum (*m*/*z* assignment, % intensity): 248 $[Hbdmpza]^+$, 100.

[$NbCl_4$(κ^3-bdmpza)] (2): An equimolar quantity of [{Li(bdmpza)(H_2O)}$_4$] (1.01 g, 0.92 mmol) was added dropwise to a THF (100 mL) solution of $NbCl_5$ (1.00 g, 3.70 mmol). The resultant solution was then stirred for 12 h at −70 °C, and the solvent then removed under vacuum to give a solid that was extracted with CH_2Cl_2. The solvent was then removed to give a red solid. Yield 92%. $C_{12}H_{15}Cl_4N_4NbO_2$ (482.0): calcd. C 29.90, H 3.13, N 11.66; found C 30.02, H 3.13, N 11.72. ^1H NMR ($CDCl_3$, 297 K), δ = 6.85 (s, 1 H, CH), 6.18 (s, 2 H, H^4), 2.55 (s, 6 H, Me^3), 2.70 (s, 6 H, Me^5) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 72.1 (CH), 149.2, 142.3 (C^3 or C^5), 106.5 (C^4), 12.1 (Me^3), 11.6 (Me^5), 168.3 (CO_2^-) ppm. IR (Nujol): $\tilde{\nu}$ = 1575 ν(C=N), 1760 $\nu_{as}(CO_2^-)$, 1525 $\nu_s(CO_2^-)$, 429, 304 ν(Nb−Cl) cm^{-1}. Mass spectrum (*m*/*z* assignment, % intensity): 446 [M − Cl], 100.

[$TaCl_4$(κ^3-bdmpza)] (3): The synthetic procedure was the same as for complex **2**, using $TaCl_5$ (1.00 g, 2.79 mmol) and [{Li(bdmpza)(H_2O)}$_4$] (0.76 g, 0.70 mmol). The solution was stirred for 12 h at −70 °C, and the solvent was then removed under vacuum and the solid extracted with CH_2Cl_2. The latter solvent was then removed to give a yellow solid. Yield 91%. $C_{12}H_{15}Cl_4N_4O_2Ta$ (570.0): calcd. C 25.31, H 2.61, N 9.82; found C 25.34, H 2.65, N 9.86. ^1H NMR ($CDCl_3$, 297 K): δ = 7.83 (s, 1 H, CH), 6.01 (s, 2 H, H^4), 2.33 (s, 6 H, Me^3), 2.42 (s, 6 H, Me^5) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 73.4 (CH), 148.7, 141.2 (C^3 or C^5), 105.8 (C^4), 12.3 (Me^3), 11.1 (Me^5), 168.7 (CO_2^-) ppm. IR (Nujol): $\tilde{\nu}$ = 1572 ν(C=N), 1712 $\nu_{as}(CO_2^-)$, 1498 $\nu_s(CO_2^-)$, 405, 315 ν(Ta−Cl) cm^{-1}. Mass spectrum (*m*/*z* assignment, % intensity): 534 [M − Cl], 100.

[$NbCl_4$(κ^3-bdmpze)] (4): A 1.6 M solution of *n*BuLi in hexane (2.3 mL, 3.70 mmol) was added to a cooled (−70 °C) solution of Hbdmpze (0.87 g, 3.70 mmol) in dry THF (100 mL). After 30 min a solution of $NbCl_5$ (1.00 g, 3.70 mmol) in THF (50 mL) was added and the reaction mixture was stirred for 12 h at −70 °C. The so obtained product was then extracted into CH_2Cl_2 (50 mL) and the solvent removed under vacuum to give a yellow solid. This solid was then crystallised from a mixture of THF/hexane. Yield 90%. $C_{12}H_{17}Cl_4N_4NbO$ (468.0): calcd. C 30.73, H 3.63, N 11.91; found C 30.83, H 3.92, N 12.12. ^1H NMR ($CDCl_3$, 297 K): δ = 7.29 (t, $^3J_{H,H}$ = 5.4 Hz, 1 H, CH), 4.50 (d, $^3J_{H,H}$ = 5.4 Hz, 2 H, CH_2O), 6.04 (s, 2 H, H^4), 2.17 (s, 6 H, Me^3), 2.36 (s, 6 H, Me^5) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 71.7 (CH), 62.8 (CH_2O), 149.1, 141.1 (C^3 or C^5), 108.4 (C^4), 12.4 (Me^3), 11.2 (Me^5) ppm. IR (Nujol): $\tilde{\nu}$ = 1574 ν(C=N), 585 ν(Nb−O), 425, 325 ν(Nb−Cl) cm^{-1}. Mass spectrum (*m*/*z* assignment, % intensity): 432 [M − Cl], 100.

[$TaCl_4$(κ^3-bdmpze)] (5): The synthetic procedure was the same as for complex **4**, using $TaCl_5$ (1.00 g, 2.79 mmol), Hbdmpze (0.65 g, 2.79 mmol) and *n*BuLi (1.7 mL, 2.79 mmol), to give **5** as a white solid (85% yield). $C_{12}H_{17}Cl_4N_4OTa$ (556.1): calcd. C 25.92, H 3.18, N 10.08; found C 25.92, H 3.22, N 10.12. ^1H NMR ($CDCl_3$, 297 K): δ = 7.59 (t, $^3J_{H,H}$ = 4.4 Hz, 1 H, CH), 4.55 (d, $^3J_{H,H}$ = 4.4 Hz, 2 H, CH_2O), 6.06 (s, 2 H, H^4), 2.14 (s, 6 H, Me^3), 2.38 (s, 6 H, Me^5) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 71.3 (CH), 63.1 (CH_2O), 149.3, 141.8 (C^3 or C^5), 106.1 (C^4), 12.3 (Me^3), 11.2 (Me^5) ppm. IR (Nujol): $\tilde{\nu}$ = 1570 ν(C=N), 564 ν(Ta−O), 409, 312 ν(Ta−Cl) cm^{-1}. Mass spectrum (*m*/*z* assignment, % intensity): 520 [M − Cl], 100.

[$NbCl_2$(O)(κ^3-bdmpza)] (6): A THF (100 mL) solution of [$NbCl_4$(κ^3-bdmpza)] (**2**) (0.50 g, 1.03 mmol) was stirred for 48 h at 20 °C. The solvent was then removed under vacuum to give a white solid, which was crystallised from a mixture of THF/hexane. Yield 92%. $C_{12}H_{15}Cl_2N_4NbO_3$ (427.1): calcd. C 33.72, H 3.51, N 13.13; found C 33.72, H 3.51, N 13.13. ^1H NMR ($CDCl_3$, 297 K): δ = 6.74 (s, 1 H, CH), 6.18, 6.04 (s, 2 H, H^4 or $H^{4'}$), 2.70, 2.55 (s, 6 H, Me^3 or $Me^{3'}$), 2.54, 2.49 (s, 6 H, Me^5 or $Me^{5'}$) ppm. $^{13}C\{^1H\}$ NMR

Mass spectrum (*m*/*z* assignment, % intensity): 572 [M − Cl], 100.

Crystal Data for 8: Single crystals suitable for X-ray diffraction were obtained by slow evaporation of the solvent from a solution of **8** in dichloromethane. The crystals were mounted on fine glass fibres with epoxy cement. The diffractions were measured on a four-circle diffractometer (Nonius-MACH3) at 200 K using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) and a ω/2θ scan. Two standard diffractions were monitored every hour and showed no significant intensity variation. The lattice parameters were refined by least-squares fitting from 25 automatically centred diffractions. An empirical absorption correction was made. The structure was solved by direct methods[9] yielding the positions of all non-hydrogen atoms. Refinement on F^2 was carried out by full-matrix least-squares techniques.[10] All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in calculated positions and were refined isotropically (Table 2). CCDC-208238 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Table 2. Crystal data and structure refinement for **8**

Empirical formula	$C_{12}H_{17}Cl_2N_4NbO_2$
Molecular weight	413.11
Temperature	200(2) K
Wavelength	0.71073 Å
Crystal system	orthorhombic
Space group	*Pbca*
Unit cell dimensions	
	a = 13.106(1) Å
	b = 16.463(3) Å
	c = 14.650(2) Å
Volume	3160.8(8) $Å^3$
Z	8
Density (calculated)	1.736 g/cm^3
Absorption coefficient	11.08 cm^{-1}
F(000)	1664
Crystal size	0.3 × 0.2 × 0.2 mm^3
Index ranges	$0 \le h \le 17$, $0 \le k \le 21$, $0 \le l \le 19$
Reflections collected	3787
Independent reflections	3787 [R(int) = 0.0000]
Data/restraints/parameters	3787/0/191
Goodness-of-fit on F^2	1.045
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0758, $wR2$ = 0.1973
R indices (all data)	$R1$ = 0.0931, $wR2$ = 0.2062
Extinction coefficient	0.0001(2)
Largest diff. peak and hole	3.711 and −2.442 e·$Å^{-3}$

Syntheses and Crystal Structures of Tetrakis(arylamidine)nickel(II) Chloride and Bis[2,4-dipyridyl-1,3,5-triazapentadienato]nickel(II)

Jianping Guo,[a] Wai-Kwok Wong,*[a] and Wai-Yeung Wong[a]

Keywords: Hydrogen bonds / Nickel / N ligands / Magnetic properties / Macrocyclic ligands

The reaction of $LiN(SiMe_3)_2$ with arylnitrile, followed by the addition of anhydrous $NiCl_2$ gives ionic complexes of the general formula $[Ni\{H_2NC(Ar)=NH\}_4]Cl_2$ (Ar = Ph **1**, *p*-tolyl **2**). When the above reaction is carried out with cyanopyridine instead of arylnitrile under the same reaction conditions, neutral complexes of the general formula [{HN=C(Py)N=C(Py)NH}$_2$Ni] (Py = 4-pyridyl, **3**; 3-pyridyl, **4**] are obtained. Compound **1** undergoes a metathesis reaction with sodium benzoate to give the neutral complex $[(PhCO_2)_2Ni\{H_2NC(Ph)=NH\}_4]$ (**5**). Magnetic susceptibility measurements show that **1**–**4** are diamagnetic and that **5** is paramagnetic with two unpaired electrons. These results suggest that **1**–**4** are d^8 square-planar complexes and **5** is an octahedral complex. The solid state structures of compounds **1**–**5** were determined by X-ray crystallography. Structural analyses reveal that **1** and **2** form a one-dimensional network through charge-assisted hydrogen bonds; whereas **5** forms a one-dimensional network through hydrogen bonds only. In complexes **3** and **4**, the 2,4-dipyridyl-1,3,5-triazapentadienyl ligand behaves as a bidentate ligand forming a six-membered ring with the metal ion.

Introduction

Lithium amidinates, which can be readily generated in situ through the reaction of lithium amide with α-hydrogen-free nitriles RCN,[1] are very versatile reagents for organic and organometallic syntheses. They are the preferred bases for the formation of ketone enolates,[2] generating low steady-state concentrations of some relatively unstable carbanions,[3] and for the preparation of dithiadiazole heterocycles[4] and π-electron rich phosphorus-nitrogen hetero-donor ligands.[5] Amidinates possess a very diverse and rich coordination chemistry. As anionic ligands, they can behave as mono- and bidentate ligands when coordinated by a single metal atom, and as bridging bidentate ligands when coordinated by two metal atoms. Amidinates form coordination compounds with virtually every metal in the periodic table, ranging across the main group and transition metal series, and into the lanthanides.[6] There is a growing interest in the coordination of amidinate ligands by first-row transition metals, with the goal of creating new catalysts that have industrial use.[7] Usually these compounds were prepared by the reaction of the corresponding lithium amidinates, generated in situ, with metal halides. Metal complexes with bulky,[8] asymmetrical[9] or pendant substituents[10] on amidinato ligands, bridged amidinato ligands[11] or oxalic amidinato ligands[12] have also been synthesized. Recently, the coordination chemistry of related β-diketiminato ligands has also received increasing attention;[13] however, there are very few reports on the isoelectronic 1,3,5-triazapentadienato ligands. Herein we report on the reaction of anhydrous nickel(II) chloride with lithium *N*,*N*′-bis(trimethylsilyl)arylamidinate, $[(Me_3Si)N(Li)C(Ar)-N(SiMe_3)]$ (Ar = phenyl, tolyl, 4-pyridyl, 3-pyridyl), generated in situ from the reaction of $LiN(SiMe_3)_2$ with either benzonitrile, *p*-tolunitrile, 4-cyanopyridine or 3-cyanopyridine. Depending on the nature of the aryl group, the reactions gave either tetrakis(arylamidine)nickel(II) chloride $[Ni\{H_2NC(Ar)=NH\}_4]Cl_2$ (Ar = Ph 1, *p*-tolyl 2) or bis[2,4-dipyridyl-1,3,5-triazapentadienato]nickel(II) [{HN=C(Py)-N=C−(Py)NH}$_2$Ni] (Py = 4-pyridyl, **3**; 3-pyridyl, **4**) complexes (Scheme 1). This is in contrast to the reaction of $NiCl_2{\cdot}0.3C_4H_{10}O_2$ and $[MCl_2(PhCN)_2]$ (M = Pd or Pt) with lithium *N*,*N*′-diphenylbenzamidinate, [PhN(Li)-C(Ph)NPh], which gave the dimeric and monomeric bis(amidinato) complexes, $[Ni_2\{PhNC(Ph)NPh\}_4]$[14a] and $[M\{PhNC(Ph)NPh\}_2]$ (M = Pd, Pt),[14a,14b] respectively, in the solid state.

Results and Discussion

Synthesis and Structural Characterization

Yellow crystals of tetrakis(arylamidine)nickel(II) chloride $[Ni\{H_2NC(Ar)=NH\}_4]Cl_2$ (Ar = Ph, **1**; *p*-tolyl, **2**) were obtained in good yields (67 and 76%, respectively) when $LiN(SiMe_3)_2$ was reacted with one equivalent of benzonitrile or tolunitrile in THF, followed by the addition of half an

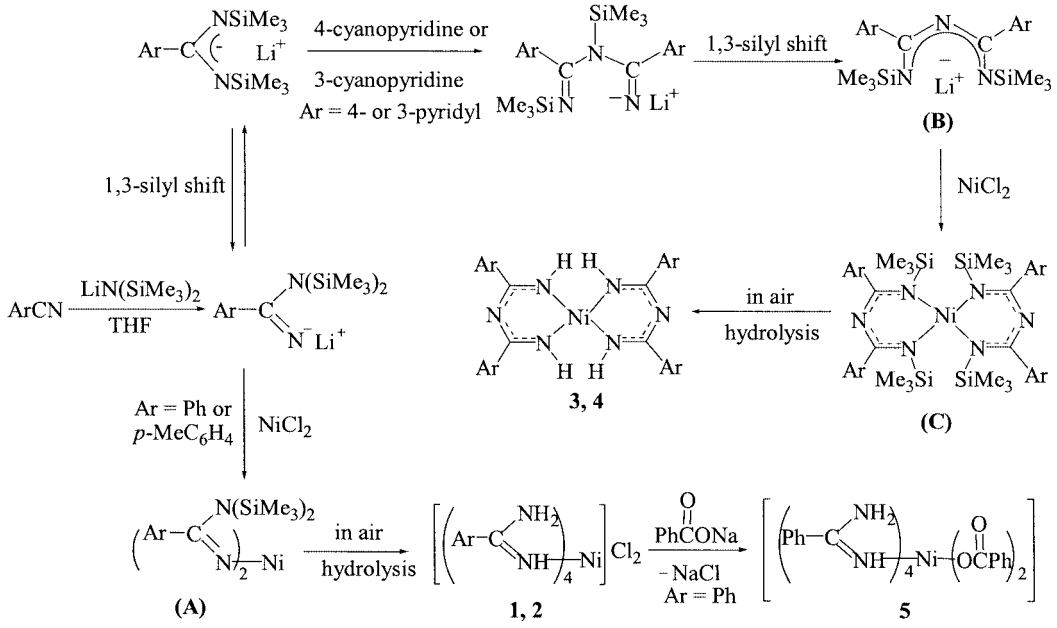

Scheme 1

equivalent of anhydrous nickel chloride and workup in air. However, when two equivalents of 4-cyanopyridine or 3-cyanopyridine were used instead of benzonitrile in the above reaction, yellow crystals of bis[2,4-dipyridyl-1,3,5-triazapentadienato]nickel(II) [{HN=C(Py)N=C(Py)NH}$_2$Ni] (Py = 4-pyridyl, **3**; 3-pyridyl, **4**), with 30 and 28% yields, respectively were obtained. Magnetic susceptibility measurements show that compounds **1**−**4** are all diamagnetic. This suggests that compounds **1**−**4** are d^8 square-planar Ni^{II} complexes. The solid state structures of these four compounds were determined by X-ray crystallography. Perspective drawings of compounds **1**−**4** are shown in Figure 1, 3, 5 and 6, respectively. Selected bond lengths and angles are given in Table 1.2

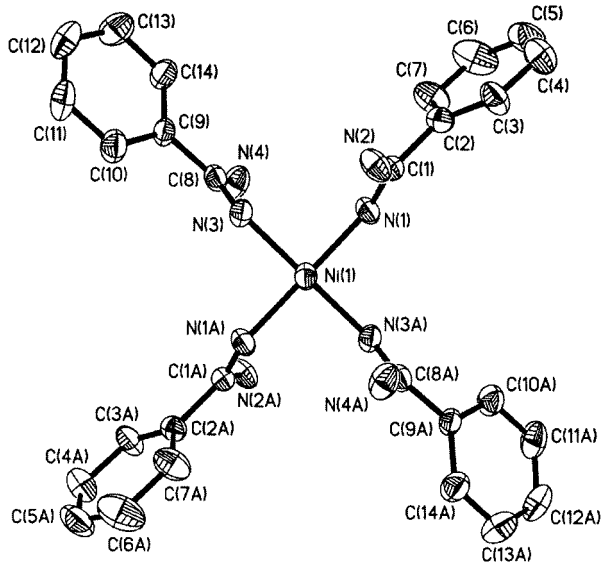

Figure 1. A perspective view of the cation of compound **1**; hydrogen atoms are omitted for clarity

The crystal structure of **1**, shown in Figure 1, reveals that the dication is centrosymmetric and that the nickel center has a square-planar geometry, the N(1)−Ni(1)−N(3) angle is 90.49(18)° and the Ni−N(coordinated) distances are 1.895(4) [Ni(1)−N(1)] and 1.885(4) Å [Ni(1)−N(3)]. The C(1)−N(1) [1.276(6) Å] and C(1)−N(2) [1.337(6) Å] distances of the N−C−N framework indicate that N(1) and N(2) are imino and amino nitrogens, respectively. The C(1)−N(2) distance, which is intermediate between a C−N single (1.47 Å) and double (1.30 Å) bond length, reflects some degree of delocalization within the N−C−N framework. The N(1)C(1)N(2) and N(3)C(8)N(4) planes form dihedral angles of 36.9 and 40.2° with the C(2)- and C(9)-phenyl planes, respectively. The distance between Ni(1B) and Cl(1A) is 3.271 Å, which is longer than the sum of the ionic radii of the Ni^{II} cation and chloride anion. This indicates that the Ni(1B) and Cl(1A) ions are held together by electrostatic attractive forces and that complex **1** is a d^8 square-planar complex. The fact that **1** is diamagnetic further supports this. The distance between Cl(1A) and N(2A) is 3.225 Å and is similar to that of the N···Cl distance of 3.332(5) Å between a NH group and a Cl^- anion involved in H-bonding.[15] The distance between Cl(1A) and the hydrogen atom bonded to N(2A) is 2.416 Å, which is the same as that between Cl(1D) and the hydrogen atom bonded to N(2AB), and is within the range (2.2−2.6 Å) observed for M−Cl···H−N distances.[16] This indicates that there is a hydrogen-bonding interaction between the chloride ion and the amino group of the benzamidine ligand. It is evident that each chloride ion interacts with one cation through electrostatic forces and with another through hydrogen−bonding. Through these interactions, the com-

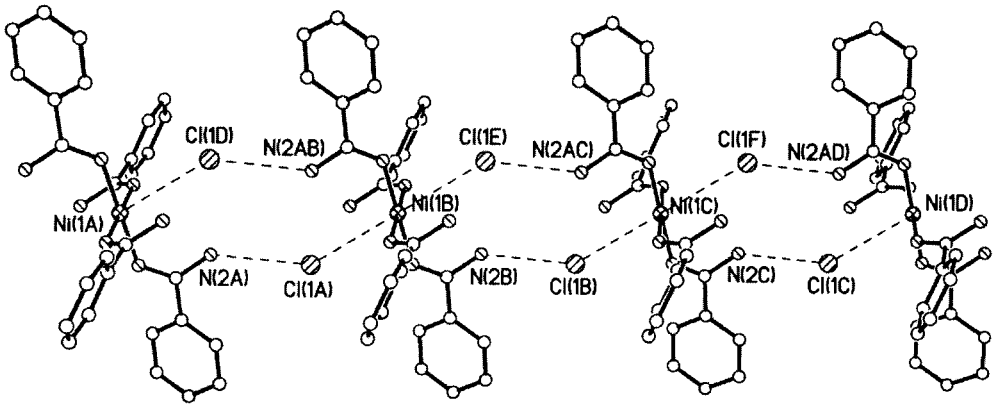

Figure 2. Crystal packing diagram for **1** showing the electrostatic and hydrogen-bonding interactions in a one-dimensional network

plex cations and chloride anions are arranged in a regular manner to form a one-dimensional network structure (Figure 2).

The solid state structure of **2** is very similar to that of **1** (Figure 3). There is centrosymmetry about the Ni center and the dication adopts a square-planar geometry with a N(1)−Ni(1)−N(3) angle of 90.18(17)°. The bond lengths between the nickel center and the coordinated nitrogen atoms are 1.861(4) [Ni(1)−N(1)] and 1.867(4) Å [Ni(1)−N(3)]. The C−N distances for the N(1)−C(1)−N(2) framework are 1.307(6) [C(1)−N(1)] and 1.337(6) Å [C(1)−N(2)], and for the N(3)−C(9)−N(4) framework are 1.297(6) [C(9)−N(3)] and 1.335(6) Å [C(9)−N(4)]. These distances again indicate some degree of delocalization within the N−C−N framework. The N(1)C(1)N(2) and N(3)C(9)N(4) planes form dihedral angles of 38.2 and 34.4° with the C(2)- and C(10)-phenyl planes, respectively. As is the case for **1**, the distance between the nickel center and the chloride atom is 3.287 Å, implying that there is an electrostatic interaction between the two ions. The N···Cl distance between Cl(1A) and N(2AB) is 3.225 Å, and the Cl···H−N distance between Cl(1A) and the hydrogen atom bonded to N(2AB), which is the same as that between

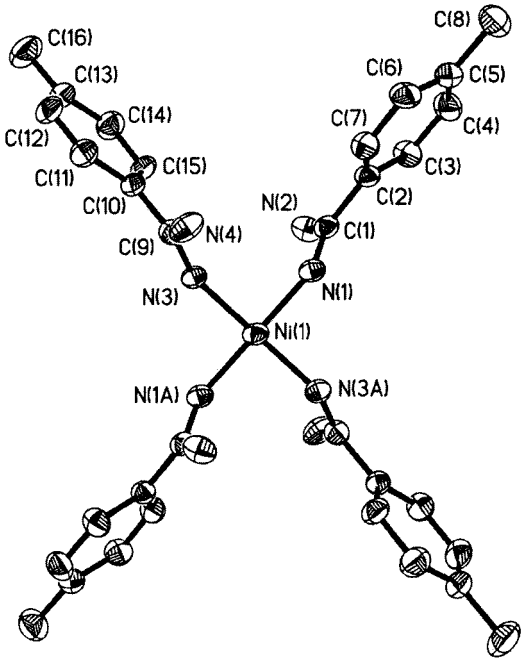

Figure 3. A perspective view of the cation of compound **2**; hydrogen atoms are omitted for clarity

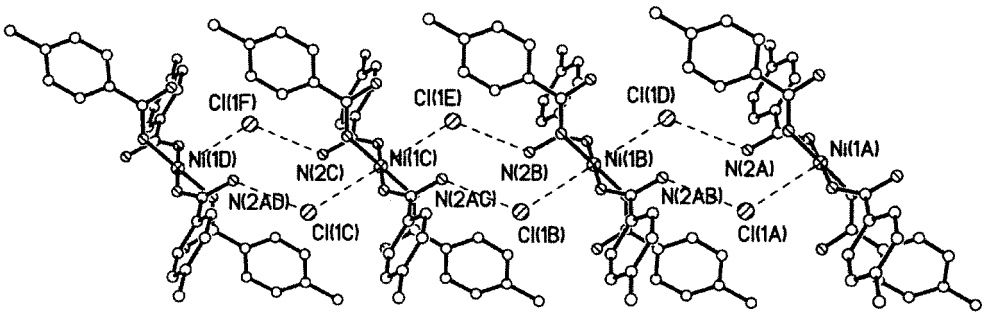

Figure 4. Crystal packing diagram for **2** showing the electrostatic and hydrogen-bonding interactions in a one-dimensional network

Cl(1D) and N(2A), is 2.505 Å. These distances indicate that there is a hydrogen-bonding interaction between the chloride ion and the nitrogen atom of the amino group. Likewise, the complex cations and chloride anions in **2** are arranged in a regular manner through charge-assisted hydrogen bonds to form a one-dimensional network structure (Figure 4).

What is perhaps remarkable in the solid state structures of **1** and **2** is the presence of both electrostatic interactions and hydrogen bonds, which link the cations and anions together to form a loose one-dimensional polymeric structure. Schröder and co-workers have also reported similar weak electrostatic forces and hydrogen-bonding interactions in a palladium complex ligated by a urea-functionalized thioether macrocycle.[15] These types of hydrogen bonds are regarded as medium-strong in strength.[17] Recently, there has been a growing interest in the use of charge-assisted hydrogen bonds for the generation of H-bonded molecular networks.[18]

The solid state structures of **3** and **4** are very similar. Structural analyses reveal that both **3** and **4** are centrosymmetric with the nickel(II) ion adopting a square-planar geometry. In complex **3**, shown in Figure 5, the nickel(II) ion is located at the center of the plane defined by the four nitrogen atoms of the two bidentate 1,3,5-triazapentadienyl ligands, $[HN{=}C(4\text{-}Py){-}N{=}C(4\text{-}Py){-}NH]^-$, with Ni−N distances of 1.876(3) [Ni−N(1)] and 1.856(3) Å [Ni−N(2)], and a N(1)−Ni(1)−N(2) angle of 89.12(13)°. Each bidentate 1,3,5-triazapentadienyl ligand forms a six-membered ring with the metal ion. The six-membered ring is almost planar, with a mean deviation of 0.0035 Å from the plane. Within the 1,3,5-triazapentadienyl ligand, the C(1)−N(1) (1.309(4) Å), C(1)−N(3) (1.348(4) Å), C(7)−N(3) (1.338(4) Å) and C(7)−N(2) (1.322(5) Å) distances are very similar, indicating complete delocalization within the N−C−N−C−N framework. The plane of the six-membered ring forms dihedral angles of 3.0 and 44.7° with the N(4)- and N(5)-pyridyl planes, respectively. Solid state packing effects presumably account for such a large difference in the above-mentioned angles.

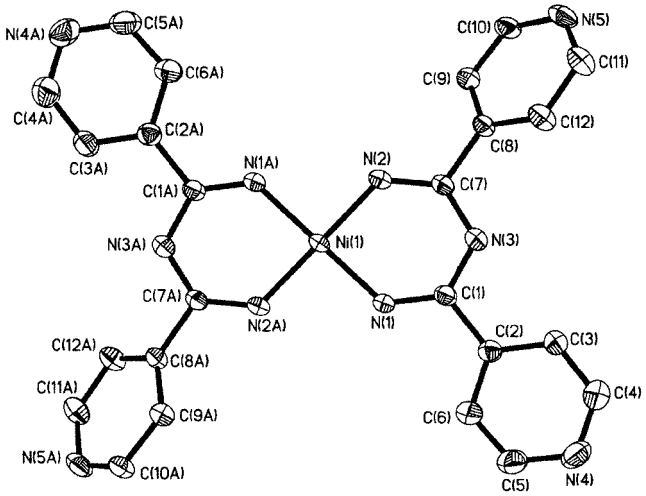

Figure 5. A perspective view of compound **3**. Hydrogen atoms are omitted for clarity

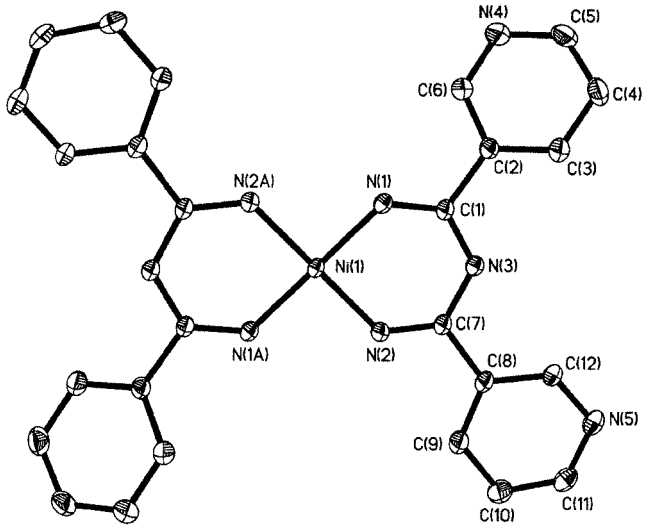

Figure 6. A perspective view of compound **4**; hydrogen atoms are omitted for clarity

Figure 6 shows the nickel(II) ion of **4** positioned at the center of the N(1)N(2)N(1A)N(2A) plane, with Ni−N distances of 1.847(2) [Ni(1)−N(1)] and 1.855(2) Å [Ni(1)−N(2)], and a N(1)−Ni(1)−N(2) angle of 89.14(9)°. Each bidentate 1,3,5-triazapentadienyl ligand forms a six-membered ring with the metal ion. The six-membered ring is almost planar, with a mean deviation of 0.0583 Å from the plane. Within the 1,3,5-triazapentadienyl ligand, the similarity between the C(1)−N(1) [1.307(3) Å], C(1)−N(3) [1.341(3) Å], C(7)−N(3) [1.354(3) Å] and C(7)−N(2)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

[1.307(3) Å] distances shows complete delocalization within the N−C−N−C−N framework. The plane of the six-membered ring forms dihedral angles of 33.8 and 9.9° with the N(4)- and N(5)-pyridyl planes, respectively.

In the literature, Lappert and co-workers reported on the formation of metal β-diketiminate complexes by the nucleophilic addition reaction of PhCN with $LiCHR_2$ or LiCHRR′.[19] The typical character of these complexes is that the ligands $[N(R^1)=C(R^2)-C(R^3)=C(R^4)-N(R^5)]^-$ form six-membered chelate rings with the metal cations. Many similar diimine ligands and complexes are also known.[20] However, there are only a few examples of transition metal complexes with the anionic 1,3,5-triazapentadienyl ligand $[HN=C(R)-N=C(R)-NH]^-$. One complex is formed by the evaporation of a methanol solution of nickel chloride hexahydrate and acetamidine,[21] the second from reacting acetonitrile with a dinuclear nickel complex $[Ni_2(\mu\text{-}OH)_2(tpa)_2](ClO_4)_2$ [tpa = tris(2-pyridylmethyl)amine],[22] and the third from reacting triazine with copper acetate.[23] The synthetic route in this paper provides a new and convenient method for the preparation of complexes with 1,3,5-triazapentadienyl ligands.

A plausible mechanism for the formation of the compounds **1**−**4** is depicted in Scheme 1. The nitrile is first attacked by $LiN(SiMe_3)_2$, giving a lithium ketimide. Reaction with benzonitrile or tolunitrile and $NiCl_2$ gives a nickel ketimide intermediate, **A**, which hydrolyzes during workup in air to give **1** or **2**, respectively. However, if 4-cyanopyridine or 3-cyanopyridine is used instead of benzonitrile or tolunitrile, the resulting lithium ketimide undergoes a rapid 1,3-silyl shift, giving a lithium *N*-silylated amidinate, which then attacks another 4-cyanopyridine. This is followed by a 1,3-silyl shift to produce the 1,3,5-triazapentadienyllithium intermediate, **B**, which then reacts with $NiCl_2$ to give the intermediate **C**, which hydrolyzes during workup in air to give **3** or **4**. We also found that varying the ratio of $LiN(SiMe_3)_2$ to the organic nitrile did not alter the results. For example, when the ratio of $LiN(SiMe_3)_2$ to benzonitrile was changed to 1:2 and that of $LiN(SiMe_3)_2$ to 4-cyanopyridine to 1:1, **1** and **3** were the only isolable products from the respective reactions. No other nickel complexes were isolated. This suggests that the resultant ketimide-amidinate $[(4\text{-}Py)C(NSiMe_3)_2]^-$ from 4-cyanopyridine reacts rapidly with another molecule of 4-cyanopyridine, thus producing the 1,3,5-triazapentadienyl anion $[(SiMe_3)NC(4\text{-}Py)NC(4\text{-}Py)N(SiMe_3)]^-$; whereas the resultant ketimide-amidinate $[PhC(NSiMe_3)_2]^-$ from benzonitrile does not react further with benzonitrile. To further support this, we also examined the hydrolysis reaction of the intermediate formed between $LiN(SiMe_3)_2$ and the organic nitriles. The $[M + 1]^+$ peak corresponding to the phenyl amidine $[PhC(=NH)NH_2]$ and the 2,4-dipyridyl-1,3,5-triazapentadiene $[HN=C(4\text{-}Py)-N=C(4\text{-}Py)-NH_2]$ was observed in the positive ESI mass spectra of the hydrolysis products obtained from the hydrolysis reaction of the intermediate derived from benzonitrile and 4-cyanopyridine, respectively. This is in agreement with the fact that the pyridyl group is a stronger electron-withdrawing substituent than the phenyl group. Therefore, the nitrile carbon atom is activated to a greater degree by the pyridyl group than the corresponding phenyl group, thus rendering it more susceptible to nucleophilic attack.

Compound **1** undergoes a metathesis reaction with sodium benzoate to give bis(benzoato)tetrakis(benzamidine)nickel(II) $[(PhCO_2)_2Ni\{H_2NC(Ph)=NH\}_4]$ (**5**) in a moderate yield (Scheme 1). Unlike **1**, which is diamagnetic, **5** is paramagnetic and has an effective magnetic moment (μ_{eff}) of 2.64 μ_B, which corresponds to two unpaired electrons. This suggests that **5** is a d^8 octahedral Ni^{II} complex. This is confirmed by the solid state X-ray structure of **5**. A perspective drawing of **5** is shown in Figure 7. Selected bond lengths and angles are given in Table 2. **5** has a distorted octahedral geometry, the two benzoato ligands are in a *trans* disposition, with N−Ni−N angles of 91.73(12) [N(1)−Ni(1)−N(3)], 176.10(12) [N(1)−Ni(1)−N(5)] and 89.39(12)° [N(1)−Ni(1)−N(7)], and a O(1)−Ni−O(3) angle of 177.51(10)°. The bond lengths between the nickel center and the coordinated nitrogen atoms are 2.075(3) [Ni(1)−N(1)], 2.073(3) [Ni(1)−N(3)], 2.096(3) [Ni(1)−N(5)] and 2.077(3) Å [Ni(1)−N(7)], and those between the nickel center and the coordinated oxygen atoms are 2.153(3) [Ni(1)−O(1)] and 2.195(3) Å [Ni(1)−O(3)]. Similar to **1** and **2**, the C(1)−N(1) (1.277(5) Å) and C(1)−N(2) (1.338(5) Å) bond lengths of the benzamidine ligand are indicative of a carbon−nitrogen double bond and single bond, respectively. The C(8)−N(3) (1.286(4) Å) and C(8)−N(4) (1.332(4) Å), C(15)−N(5) (1.270(5) Å) and C(15)−N(6) (1.338(5) Å), and C(22)−N(7) (1.284(4) Å) and C(22)−N(8) (1.338(4) Å) bond lengths also indicate that they are double and single bonds, respectively. The N(1)C(1)N(2), N(3)C(8)N(4), N(5)C(15)N(6) and N(7)C(22)N(8) planes form dihedral angles of 27.2, 36.0, 26.7 and 38.1° with the C(2)-, C(9)-, C(16)- and C(23)-phenyl planes, respectively. The benzoato ligands are almost

planar. The dihedral angle between the O(1)C(29)O(2) plane and the C(30)-phenyl plane is 7.7°, and that between the O(3)C(36)O(4) plane and the C(37)-phenyl plane is 2.5°. Figure 8 shows one entity selected from its packing diagram. It is evident that the non-coordinating oxygen atoms of the two carbonyl groups of the benzoato ligands of one molecule interact with the non-coordinating nitrogen atoms of the amino group of two neighboring molecules through hydrogen bonds to form a one-dimensional infinite network. The distance between O(2A) and N(8B) is 2.891 Å, and that between O(2A) and the hydrogen atom bonded to N(8B) is 2.156 Å. The distance between O(4B) and N(4A) is 2.886 Å, and that between O(4B) and the hydrogen atom bonded to N(4A) is 2.070 Å.

Spectroscopic Properties of Compounds 1−5

The peaks in the ^{1}H NMR spectra of compounds **1** and **2** are very broad, although they are diamagnetic. This is probably due to the presence of free amidine ligands, which arise as a result of the dissociation of the complexes.[24] We were unable to locate the resonances for the NH protons of the amino and imino groups in the ^{1}H NMR spectra. However, the IR spectra of **1** and **2** exhibit strong multiple absorptions in the region between 3100−3500 cm^{-1} which are assigned to antisymmetric and symmetric NH and NH_2 stretching, and a strong absorption at 1645 cm^{-1} assigned to C=N stretching of the amidine ligands.[25] The medium strong bands around 1460 cm^{-1} can be assigned to the C−N single bond stretching. Both compounds do not show the molecular ion in their mass spectra. The LRMS (positive FAB) spectrum of **1** exhibits a peak at *m*/*z* = 453 corresponding to the $[NiL_3Cl]^+$ [L = PhC(=NH)NH_2] fragment for ^{35}Cl, and that of **2** shows a peak at *m*/*z* = 325 corresponding to the $[NiL^1(L^1-H)]^+$ [L^1 = *p*-$CH_3C_6H_4C$(=NH)NH_2; (L^1 − H) = *p*-$CH_3C_6H_4C(NH)_2^-$] fragment.

The protons at the terminal nitrogen atoms in compounds **3** and **4** are chemically equivalent, thus they have similar chemical shifts in the ^{1}H NMR spectra of **3** and **4** and appear as a singlet at δ = 7.56 for **3** and δ = 7.37 ppm for **4**. The pyridyl groups are each attached to the 1,3,5-triazapentadiento unit via a single bond, therefore, the four pyridyl rings, which are free to rotate in solution, are chemically equivalent and have similar chemical shifts. In the spectrum of **3**, the resonances for the 4-pyridyl protons appear as two doublets at δ = 8.73 (d, *J* = 4.4 Hz, 8 H) and 7.94 (d, *J* = 4.4 Hz, 8 H) ppm; whereas in the spectrum of **4**, the resonances for the 3-pyridyl protons appear as a singlet, two doublets and a doublet of doublets at δ = 9.17 (s, 4 H), 8.69 (d, *J* = 4.4 Hz, 4 H), 8.34 (d, *J* = 8.0 Hz, 4 H) and 7.51 (dd, *J* = 8.0, 4.4 Hz, 4 H) ppm, respectively. In their IR spectra, both compounds exhibit strong multiple absorptions, assigned to NH stretchings, in the region 3100−3500 cm^{-1}. Furthermore, there are other two strong absorption bands in their IR spectra. A strong broad multiple absorption band is seen between 1400−1500 cm^{-1}, and a strong single peak is seen around 1300 cm^{-1}. These can be assigned to the skeleton vibrations of the 1,3,5-triazapentadienyl ligand. The molecular ion peaks $[M + H]^+$ of

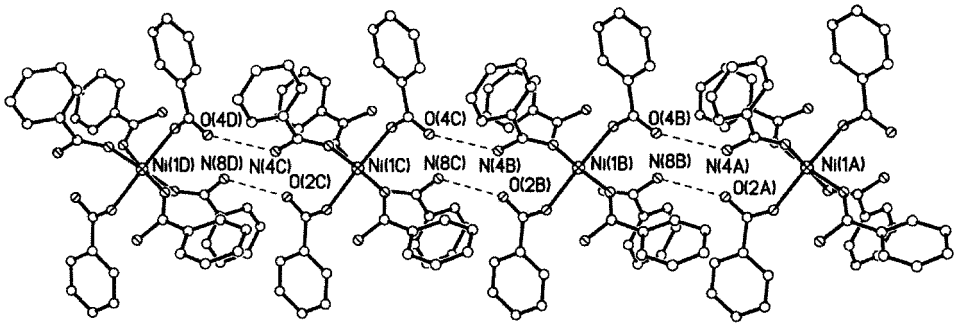

Figure 8. Crystal packing diagram for **5** showing the hydrogen-bonding in a one-dimensional network

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

both **3** and **4** are exhibited at m/z = 507 in their LRMS (positive FAB) spectra.

Due to the paramagnetic nature of compound **5**, we were unable to obtain an interpretable ^{1}H NMR spectrum. In the IR spectrum, in addition to the characteristic absorption bands of the benzamidine ligands, **5** also exhibits strong absorptions at 1680 and 1136 cm^{-1}, corresponding to the C=O and C−O stretches of the benzoato ligands, respectively. No molecular ion was observed in the mass spectrum of **5**. The highest mass peak observed in the LRMS (FAB+) of **5** was at m/z = 339, which corresponds to the $[(PhCOO)_2Ni + K]^+$ fragment.

Concluding Remarks

We have developed a convenient synthetic method for some new nickel(II) complexes containing the arylamidinato and 1,3,5-triazapentadienyl ligands. The formation of one-dimensional network structures in the solid state through charge-assisted hydrogen bonds is observed for **1** and **2**; while only hydrogen-bonding interactions are apparent in the crystal lattice of **5**. We have also investigated in detail the factors that control the type of product formed, and we observed that the products obtained depend on the nature of the aryl groups used in the starting arylnitrile.

Experimental Section

General Procedures: All reactions were carried out under nitrogen in flamed Schlenk-type glassware on a dual manifold Schlenk line, unless otherwise stated. Solvents were pre-dried by standard procedures. All chemicals used were of reagent grade, obtained from Aldrich or Fisher Scientific Chemical Company. The IR spectra (KBr pellets) were recorded with a Perkin−Elmer Paragon 1000PC or Nicolet Nagan-IR 550 Series II FTIR spectrometer, and NMR spectra with a Varian INOVA 400 spectrometer. Chemical shifts for the ^{1}H NMR spectra were referenced to internal deuterated solvents and then recalculated to TMS (δ = 0.00 ppm). Fast atom bombardment (FAB) low-resolution mass spectra were obtained with a Finnigan MAT SSQ-710 spectrometer in positive mode and reported as m/z. Magnetic susceptibilities were measured with a MSB-AUTO magnetic susceptibility balance. Elemental analyses were performed by the Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences.

Tetrakis(benzamidine)nickel(II) Chloride (1): Benzonitrile (0.515 mL, 5.0 mmol) and $LiN(SiMe_3)_2$ (0.837 g, 5.0 mmol) were placed in THF (20 mL) at 0 °C. The resultant yellow solution was warmed to room temperature and stirred for an additional 2 h before cooling down to −78 °C. Anhydrous $NiCl_2$ (0.324 g, 2.5 mmol) was then added to the reaction mixture, after which it was stirred at −78 °C for 1 h before warming up to room temperature. The mixture was reacted overnight. The solvent was removed in vacuo and the residue was extracted with CH_2Cl_2 (2 × 10 mL) and the solution was filtered. Removal of the solvent in vacuo gave a dark red oily product. The product was dissolved in THF (20 mL) and the solvent was evaporated slowly to give yellow crystals of **1**. Yield: 0.512 g, 67%; m.p. 174−176 °C. IR (KBr): ṽ = 3335 s, 3179 s, 1645 vs, 1606 m, 1571 s, 1457 m, 1245 w, 1127 w, 781 w and 701 s cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 7.14 (br. s, 4 H, Ph), 8.02 (br. s, 8 H, Ph) and 8.41 (br. s, 8 H, Ph) ppm; we were unable to locate the resonance due to imino NH and amino NH_2 protons. LRMS (+FAB): m/z = 453 $[(NiL_3Cl)^+$, L = PhC(=NH)NH_2] for ^{35}Cl. $C_{28}H_{32}Cl_2N_8Ni{\cdot}C_4H_8O{\cdot}0.5H_2O$ (691.33): calcd. C 55.60, H 5.98, N 16.21; found C 55.92, H 6.13, N 15.88.

Tetrakis(tolueneamidine)nickel(II) Chloride (2): Compound **2** was produced under the same reaction conditions and using the same procedures as for **1**; however, *p*-tolunitrile (0.586 g, 5.0 mmol) was used instead of benzonitrile. Yield: 0.635 g, 76%; m.p. 181−182 °C. IR (KBr): ṽ = 3326 s, 3188 s, 1645 s, 1612 s, 1565 m, 1519 w, 1460 m, 1262 w, 1133 w, 831 m, 734 m, 684 w cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 2.67 (br. m, 12 H, Me), 7.73 and 7.83 (br. m, 16 H, C_6H_4) ppm. LRMS (+FAB): m/z = 325 $\{[NiL^1(L^1-H)]^+$; L^1 = [*p*-$CH_3C_6H_4C(=NH)NH_2$], (L^1-H) = [*p*-$CH_3C_6H_4C(NH)_2^-$]. $C_{32}H_{40}Cl_2N_8Ni{\cdot}1.5H_2O{\cdot}0.4C_4H_8O$ (722.19): calcd. C 55.88, H 6.45, N 15.51; found C 55.86, H 6.37, N 15.26.

Bis[2,4-di(4-pyridyl)-1,3,5-triazapentadienato]nickel(II) (3): The procedure was similar to that of **1**. 4-Cyanopyridine (0.520 g, 5.0 mmol), $LiN(SiMe_3)_2$ (0.418 g, 2.5 mmol) and anhydrous $NiCl_2$ (0.162 g, 1.3 mmol) were used. The residue was extracted with methanol (2 × 10 mL) and the solution was filtered. Slow evaporation of the methanol solution gave yellow crystals of **3**. Yield: 0.201 g, 30%; m.p. > 300 °C. IR (KBr): ṽ = 3658 m, 3291 s, 3270 s, 3184 bw, 1601 m, 1577 m, 1533 vs, 1446 vs, 1411 s, 1315 s, 1063 m, 1003 w, 848 m, 759 s, 718 w and 595 w cm^{-1}. ^{1}H NMR ([D$_6$]DMSO): δ = 7.56 (s, 4 H, NH), 7.94 (d, J = 4.4 Hz, 8 H, pyridyl) and 8.73 (d, J = 4.4 Hz, 8 H, pyridyl) ppm. MS (+FAB): m/z = 507 [M + 1]$^+$. $C_{24}H_{20}N_{10}Ni{\cdot}0.25CH_3OH{\cdot}H_2O$ (533.21): calcd. C 54.63, H 4.35, N 26.27; found C 54.59, H 4.24, N 26.29.

Bis[2,4-di(3-pyridyl)-1,3,5-triazapentadienato]nickel(II) (4): Compound **4** was produced under the same reaction conditions and using the same procedures as for **1**. 3-Cyanopyridine (0.312 g, 3.0 mmol), $LiN(SiMe_3)_2$ (0.250 g, 1.5 mmol) and anhydrous $NiCl_2$ (0.973 g, 0.75 mmol) were used. Yield: 0.112 g, 28%; m.p. > 300 °C. IR (KBr): ṽ = 3449 m, 3305 m, 3170 m, 1643 s, 1594 s, 1548 s, 1536 s, 1480 m, 1426 m, 1303 s, 1203 m, 1023 m, 815 m, 726 s, 704 m cm^{-1}. ^{1}H NMR ([D$_6$]DMSO): δ = 7.37 (s, 4 H, NH), 7.51 (dd, J = 8.0, 4.4 Hz, 4 H, pyridyl), 8.34 (d, J = 8.0 Hz, 4 H, pyridyl), 8.69 (d, J = 4.4 Hz, 4 H, pyridyl) and 9.17 (s, 4 H, pyridyl) ppm. LRMS (+FAB): m/z = 507 [M + 1]$^+$. $C_{24}H_{20}N_{10}Ni{\cdot}CH_3OH{\cdot}1.5H_2O$ (566.25): calcd. C 53.03, H 4.81, N 24.74; found C 53.06, H 4.72, N 24.65.

Bis(benzoato)tetrakis(benzamidine)nickel(II) (5): After the preparation of **1** from benzonitrile (0.25 mL, 2.40 mmol), sodium benzoate (0.173 g, 1.20 mmol) was added to the THF mixture, and stirring was continued at room temperature for 48 h. The solvent was then removed in vacuo and dichloromethane (20 mL) was added to the residue and the solution was filtered. The solvent of the filtrate was removed in vacuo, a red oily product was obtained. The product was dissolved in THF (20 mL) and the solvent was evaporated slowly, giving pale yellow crystals of **5**. Yield: 0.261 g, 56%; m.p. > 300 °C. IR (KBr): ṽ = 3184 s, 3061 s, 1680 m, 1645 m, 1605 m, 1563 m, 1518 w, 1484 w, 1391 vs, 1136 vs, 721 w, 696 m cm^{-1}. LRMS (+FAB): m/z = 339 $[(C_6H_5COO)_2Ni + K]^+$. $C_{42}H_{42}N_8NiO_4$ (781.55): calcd. C 64.55, H 5.42, N 14.33; found C 64.38, H 5.50, N 14.25.

X-ray Crystallography: Crystals of **1**·C_4H_8O, **2**·2C_4H_8O, **3**·2CH_3OH, **4**·2CH_3OH and **5** suitable for X-ray diffraction were grown by slow evaporation of a solution of **1**, **2**, **5** in THF and **3**, **4** in CH_3OH, in air. The intensity data were collected with a Bruker

AXS SMART 1000 CCD area-detector diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 293 K. The collected frames were processed with proprietary software SAINT[26] and an absorption correction was applied (SADABS[27]) to the collected reflections. The structures of these molecules were solved by direct methods and expanded by standard difference Fourier syntheses using the software SHELXTL.[28] Structure refinements were made on F^2 using the full-matrix least-squares technique. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were placed in their idealized positions and allowed to ride on the respective carbon atoms. Pertinent crystallographic data and other experimental details are summarized in Table 3. CCDC-200431 (**1**), -215047 (**2**), -200430 (**3**), -215048 (**4**) and -215049 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EW, UK [Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Characterization and Electrochemistry of the Novel Dawson-Type Tungstophosphate $[H_4PW_{18}O_{62}]^{7-}$ and First Transition Metal Ions Derivatives

Israel-Martyr Mbomekalle,[a] Bineta Keita,[a] Yu Wei Lu,[a] Louis Nadjo,*[a] Roland Contant,[b] Nebebech Belai,[c] and Michael T. Pope[c]

Keywords: Polyoxometalates / Tungsten / Heteropolyanions / Electrochemistry / Electrocatalysis

Following the synthesis of pure $[H_4PW_{18}O_{62}]^{7-}$ (PW_{18}), its derivatives monosubstituted with M (M = Mo^{VI}, V^{IV}, V^{V}, Mn^{II}, Fe^{III}, Co^{II}, Ni^{II} Cu^{II} and Zn^{II}) were obtained. All compounds were characterized by elemental analysis, IR, UV/visible and ^{31}P NMR spectroscopy. Their cyclic voltammetry properties were studied as a function of pH and systematically compared with those of their analogs derived from the symmetrical species, $[P_2W_{18}O_{62}]^{6-}$(P_2W_{18}). Comparison of the two unsubstituted precursors revealed that the merging of the first two waves of the monophosphate occurred in a less acidic medium than for the diphosphate. The observations point to the higher basicity of the reduced forms of PW_{18} compared with those of P_2W_{18}. The fingerprint pattern observed for α_2-$P_2W_{17}M$ derivatives in media of pH = 3 consisted of the splitting of the third W redox system into two one-electron closely spaced waves which is in contrast to the same system in α_1-$P_2W_{17}M$. This peculiarity was also obtained for several of the present α_2-$PW_{17}M$ systems in media of pH = 3 and confirmed that α_2-substituted derivatives were indeed formed. The absence of this peculiar behavior in some other derivatives is consistent with smooth variations of acid-base properties from one derivative to the next. The electrocatalytic properties of all the compounds are illustrated by the reduction of nitrite by reduced PW_{18} and of nitrate by reduced α_2-$PW_{17}Cu$.

Introduction

Heteropolyanions constitute a unique class of molecular metal-oxygen clusters which are remarkable in several respects: the variety of their properties based on their sizes, shapes, charge densities and reversible redox potentials and the enormous diversity of their structures.[1,2] Therefore, they appear as good candidates for applications in a wide range of areas, including catalysis, electrocatalysis, medicine, materials science, photochemistry, analytical chemistry and magnetochemistry.[3−6] Even though complete rationalization of the build-up of these structures is not available at present, very many of them might be recognized as being derived, at least partly, from lacunary Keggin and Dawson-type fragments. Keeping with the basic structures themselves, a formal direct relationship can be found between the Dawson structure and a tri-vacant Keggin structure. The appropriate Keggin fragment, A-$X^{V}W_9O_{34}$, is derived from the saturated $[XW_{12}O_{40}]^{n-}$ species by the removal of three MO_6 octahedra belonging to three different M_3O_{13} moieties. The Dawson structure is constructed from two half anions A-$X^{V}W_9O_{34}$, (with X = P^{V} or As^{V}).[7,8] Such "dimerization" mostly gives species in which the same heteroatom is present in the two halves. We were interested in the possibility of obtaining such "dimers" with two different central heteroatoms, with the complementary aim of studying the consequences of such asymmetry on the electrochemical and electrocatalytic properties of these heteropolyanions. To the best of our knowledge, the only example with two different heteroatoms in the +v oxidation state is an 18-tungsto monoarsenic monophosphoric acid, which was not fully characterized however.[9] In contrast, even though scarce, several examples of well-characterized heteropolyanions with two different heteroatoms and X atoms in the +III oxidation state have been reported namely $[H_nX^{III}W_{18}O_{60}]^{(9-n)-}$ (X = As or Sb, n = 2; X = Bi, n = 2).[10−12] Their X-ray crystal structures revealed them to be composed of two half-anions, B-XW_9O_{33}, connected by six oxygen atoms. For example, the two halves of $[H_2AsW_{18}O_{60}]^{7-}$ contain a trivalent As atom in one half and two hydrogen atoms in the other.[10] The two compounds $[H_2AsW_{18}O_{60}]^{7-}$ and $[H_2SbW_{18}O_{60}]^{7-}$ were found to differ only by the connectivity of their two halves.[11] In contrast, only recently has the description of $Na_7[H_2BiW_{18}O_{60}]$ confirmed the possibility that the Bi^{III} analog

might contain two hydrogen atoms[12] instead of the three previously invoked in $(Me_4N)_6[H_3BiW_{18}O_{60}]$.[13] Finally, the present status of these asymmetric derivatives is that they are constructed from a B-XW_9O_{33} anion and a B-$H_2W_9O_{33}$ anion. To this family of asymmetric derivatives belongs the series of novel Sn^{II} substituted compounds reported recently by Krebs and co-workers.[14]

In contrast to this general situation, one of the present authors recently reported the synthesis of the novel Dawson-type tungstophosphate $[H_4PW_{18}O_{62}]^{7-}$ and its lacunary and zinc-substituted derivatives, $[H_4PW_{17}O_{62}]^{11-}$ and $[Zn(H_2O)(H_4PW_{18}O_{61})]^{9-}$, in which the two anionic halves are of the A-type with only one of them containing a central heteroatom in the +v oxidation state.[15] This pioneering report stimulated further work and, soon afterwards, our group confirmed the feasibility of this synthesis for the As^V -containing analog of the corresponding trivacant lacunary species and the synthesis of two sandwich-type derivatives, $[Zn_4(H_2O)_2(H_4AsW_{15}O_{56})_2]^{18-}$ and $[Cu_4(H_2O)_2(H_4AsW_{15}O_{56})_2]^{18-}$.[16] Finally, we have established the best experimental conditions for the synthesis of $[H_4AsW_{18}O_{62}]^{7-}$ and demonstrated that these conditions differ substantially from those necessary to obtain the well-known symmetric species $[As_2W_{18}O_{62}]^{6-}$.[17]

All of these exploratory results support the following conclusions: the putative or realized possibility of manipulating the compositions and, presumably, the acid−base and redox properties of heteropolyanions has been illustrated once more; a new family of Dawson-type heteropolyanions has been unambiguously established.

Herein we report the synthesis, characterization and electrochemistry of the hitherto unknown first-row transition metal cation-substituted heteropolyanions derived from $[H_4PW_{18}O_{62}]^{7-}$. Their electrochemistry reveals differences with the corresponding symmetric heteropolyanions. This study is completed by an evaluation of their electrocatalytic properties for the reduction of nitrate and nitrite.

Results and Discussion

All the polyanions in the present study are primarily derived from α-$[H_4PW_{18}O_{62}]^{7-}$ (abbreviated hereafter as PW_{18}) and their formulae will be written as $PW_{17}M$, with omission of oxygen atoms and overall charges when no confusion is likely to arise. M represents the substituent metal cation. The main PW_{18} isomer of interest in the following is that obtained after prolonged heating of the reaction mixture. Scheme 1 illustrates the α-structure proposed for this isomer in analogy with that of α-$[P_2W_{18}O_{62}]^{6-}$ (P_2W_{18}), an assumption based on the close resemblance of the ^{183}W NMRspectra of the two compounds.[15] In line with the numbering of tungsten atoms in α-P_2W_{18}, the IUPAC recommendations have also been followed for α-PW18. A detailed discussion[15] then shows how the results of electrochemistry, ^{31}P NMR and IR spectroscopy were combined, in this preliminary work on PW_{18}, PW_{17} and $PW_{17}Zn$, to demonstrate that the mild alkaline degradation of PW_{18} resulted in the removal of a W atom from the "cap" in the half of this molecule containing the single P atom, thus creating the first vacancy in one of the so-called α_2 positions.

Syntheses

A number of slight modifications were introduced into the pioneering synthesis of $K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$.[15] The heating duration was prolonged to at least 96 h because we found that after the formerly proposed 60 h, the reaction mixture still contained α-$K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$ as the major but not the exclusive species. Even so heating at 80 °C was ultimately necessary to obtain pure α-$K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$. It is worth noting that the present procedure was essential to obtain the desired product pure and in good yield (> 65% in all preparations). Also, it must be pointed out that the optimal reagent ratios were the same as those determined previously in our synthesis of α-$K_7[H_4AsW_{18}O_{62}]\cdot 18H_2O$.[17]

The mono-lacunary derivative was obtained under mild conditions and resulted, as indicated previously, in the creation of a vacancy in a α_2-position in the half of the molecule containing the P atom. All the metal cation-substituted species were elaborated under the same conditions as the Zn^{II}-substituted compound, sometimes with slight modifications as described in the Exp. Sect. The mild conditions of the procedure leads to isomerically pure products.

UV/Visible and IR Spectroscopic Characterization

As usual, UV/Vis spectra of these compounds cannot be considered as specific fingerprints for the polyoxoanions in this series. However, the stability of the complexes in the series as a function of pH and time was studied by monitoring the UV/Vis spectra over periods of at least 24 h. The spectra were recorded between 1300 nm and 210 nm, with the maximum absorptions being located between 240 nm and 300 nm, depending on the heteropolyanion in question. The duration of observation is larger than necessary for electrochemical characterization of the complexes but was retained in order to eventually open the way for long-lasting or preparative scale catalytic or electrocatalytic processes. For this study, in addition to the mono-vacant species itself, two groups of substituted derivatives were considered. The substituted compounds are represented by α_2-$ML(PW_{17}O_{61})$, with M representing the substituent metal cation, the ligand L = O^{2-} for M = Mo^{6+}, V^{5+} and V^{4+}, while L = H_2O for all other metal cations in this work.[1,18−20] The difference between these two groups is important in that the behavior of several of these derivatives suggests only the Mo- and V-substituted compounds fea-

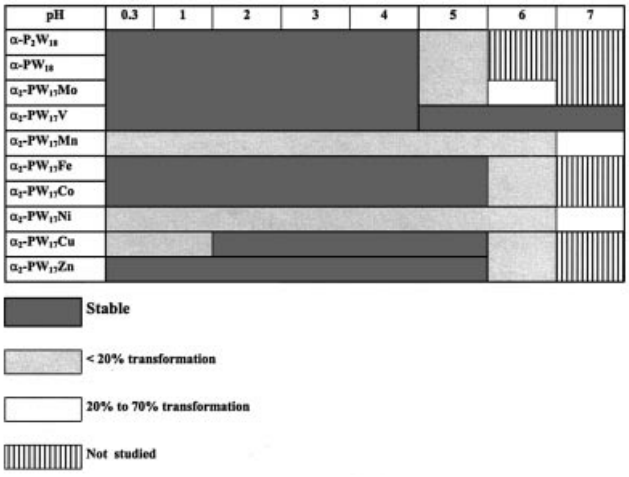
ture really "saturated" substituted species while the others are close to the lacunary precursor complex. Following this classification, PW_{17} was found to be unstable regardless of the pH and to undergo fast transformation. For pH < 4, such a transformation was observed in less than one hour and the lower the pH, the faster the transformation gradually giving the saturated species PW_{18}. This behavior parallels that observed for P_2W_{17}.[1] The so-called saturated substituted compounds show stabilities close to those of unsubstituted ones: all of them were found to be stable between pH 0.3 and pH 4, with decomposition occurring to an extent of less than 20% at pH 5 and comprising between 20% and 70% at pH 6. In contrast to these results, $PW_{17}V$ remains stable up to at least pH 8. The stability domains for the other substituted complexes are shown in Table 1. Dark grey indicates the domain in which a particular derivative is stable; plain grey corresponds to a decomposition less than or equal to 20%; finally, clear grey indicates a decomposition of between 20% and 70%. Obviously, the Mn and Ni derivatives are the less stable species in the series, even though their decomposition does not reach 20% for a pH between 0.3 and 5. In contrast, Fe-, Co- and Zn-substituted complexes are stable from pH 0.3 to 5. Their transformation does not reach 20% at pH 6 and is even in the range of 6% for $PW_{17}Zn$. The case of $PW_{17}Cu$ deserves emphasis since it was observed to be stable between pH 2 and 5.

Table 1. Stability, monitored by UV/visible spectroscopy over 24 h, of α-P_2W_{18}, α-PW_{18} and the α_2-$PW_{17}M$ derivatives of the latter complex, as a function of pH. For further details, see text



The most characteristic IR band shifts in tungstophosphates are observed between 1200 and 1000 cm^{-1} and correspond to P−O vibrations. They allow a characterization of lacunary species relative to the saturated precursor. When a substituent metal cation is introduced into the vacancy, the whole symmetry of the saturated complex tends to be restored, at least as far as the IR spectra are concerned. Table 2 lists the main IR band energies for the complexes in the present study. The complex PW_{18} is characterized by two bands observed at 1066 and 1032 cm^{-1} respectively. In contrast, they are replaced mainly by a single band located at 1033 cm^{-1} in PW_{17}. Provisionally, this modification supports the location of the vacancy in the α_2 position in the half of the molecule containing the P atom. Examination of Table 2 indicates that two kinds of spectra were obtained through the series of substituted derivatives. Complexes substituted with Mo^{VI}, V^{V}, Fe^{III}, Co^{II}, Ni^{II} and Cu^{II} behave like PW_{18} itself and show two IR bands between 1200 and 1000 cm^{-1}.Complexes containing V^{IV}, Mn^{II} or Zn^{II} have only one IR band in the same energy region. These observations reflect the alteration of symmetry around the central PO_4 moiety.[21−23] This alteration clearly appears to be a function of the substituent cation. It has also been claimed that the nature of the counter-cation seems to influence the degree of restoration of symmetry in the polyanion[24] but a study and discussion of these phenomena are beyond the scope of this work. It should be noted that, in each group, the IR spectra are very similar to one another thus preventing any reliable identification of a given anion by this spectroscopic method.

^{31}P NMR Spectroscopy

Table 3 shows the ^{31}P NMR shifts and line widths for the novel Dawson-type tungsto-monophosphates and their first row transition metal ion derivatives. At least two remarks can be made regarding these results: i) as expected, the spectrum of each of these molecules displays a unique signal ii) the shifts and line widths comply with expectations from the knowledge of shifts observed for the phosphorus atom nearer to the substituent in α_2-$P_2W_{17}M$ derivatives. Further comparison of the actual shifts among the two series and also with the corresponding α_1-$P_2W_{17}M$ derivatives[25] confirms that substitution occurs in the PW_9 moiety of PW_{18} and in the α_2-position. In several instances, larger shifts were observed in the α_2-$PW_{17}M$ compounds than in the α_2-$P_2W_{17}M$ series. Further comments on this trend are, however, beyond the scope of this paper. To the best of our knowledge, Jorris et al.[26] were the first to study the NMR of paramagnetic element-containing HPA's on P_2W_{17} derivatives. Even though their syntheses resulted in mixtures of α_1 and α_2 isomers, their pioneering work constitutes a valuable basis for the interpretation of the present observations. In these complexes, it is convenient to designate the phosphorus atom nearer to the eventually paramagnetic substituent ion as P(1) and the phosphorus atom far from this element as P(2). Observations of the ^{31}P NMR spectra of several Dawson structures substituted in the α_2 position have established that the chemical shift of P(2) is practically unaffected by the nature of the substituent element. As expected, the resonance assigned to the P atom nearest to the substitution site is considerably shifted downfield in the presence of paramagnetic cations and the shift is larger for α_1 derivatives. The ^{31}P NMR line widths depend on the particular nature of the substituent atom and especially on its electronic ground state configuration. As expected[25,26] and shown in Table 3, contrasting situations are encountered for the P(1) line with respect to its line width. The signal might be narrow or relatively narrow, or become ex-

[a] Ref.[15]

ceedingly broadened as exemplified by the case of the Mn^{II} derivative, the ground state of which is orbitally non-degenerate. Finally, it can be considered that a satisfactory agreement with the qualitative results from the observations of Jorris et al.[26] and other literature results[25] has been obtained in the present work. The same line of reasoning can also be applied to the interpretation of the spectra of the Zn^{II} and Cu^{II}-substituted derivatives. From the electronic configuration of Zn^{II}, no dramatic chemical shift is expected for the P atom compared with those observed with other diamagnetic substituents. The results in Table 3 validate this reasoning. In contrast, Cu^{II} is a paramagnetic d^9 ion that has a dramatic effect on the observed chemical shift, as expected.

Electrochemistry

Evidence for the Influence of the Asymmetry on the Voltammetric Behavior of PW_{18}: Comparison with P_2W_{18}

A comparison of the voltammetric characteristics of PW_{18} and P_2W_{18} is probably useful in highlighting the peculiarities of the former complex. Figure 1 shows the cyclic voltammograms (CV's) of the two complexes in a pH 0.3 sulfate medium superimposed on each other. The potential region was selected to avoid any deleterious derivatization of the electrode surface.[27] Furthermore, such an area is the most useful for the elucidation of electrocatalytic processes. Here, the voltammetric pattern is restricted to the first three waves observed for PW_{18} in this medium. Under the same conditions, the voltammetry of P_2W_{18} is known[28] and consists of two one-electron waves followed by two two-electron waves. These waves feature reversible diffusion-controlled processes. The comparison of the CV's of the two heteropolyanions (HPA's) is shown in Figure 1 (A) and is enlightening. The first wave of PW_{18} represents unambiguously a two-electron chemically reversible process. This point was checked by controlled potential coulometry. The two subsequent waves also feature two-electron processes. In short, the pattern for PW_{18} is composed of a set of three reversible diffusion-controlled waves. This observation was expanded by a brief study of the pattern as a function of pH. Figure 1 (B) illustrates this point and shows, in superimposition, the CV's of PW_{18} at pH 0.3 and 4. With the increase in pH, the formerly two-electron wave splits into

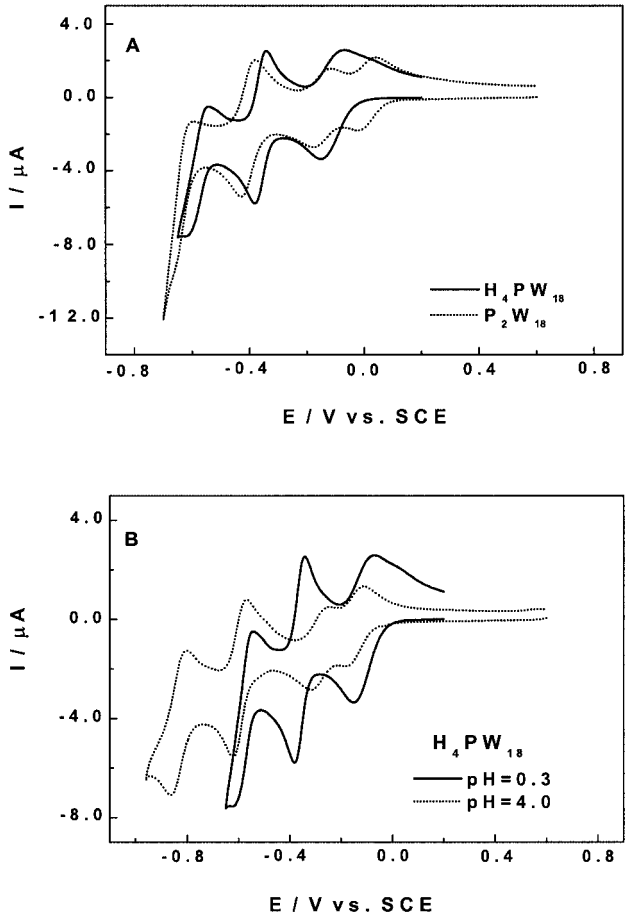

Figure 1. Cyclic voltammograms (CV's) recorded on 5×10^{-4} M solutions of the relevant polyoxometalates; scan rate: 10 $mV \cdot s^{-1}$; working electrode: glassy carbon; reference electrode: SCE; A: Comparison of the CV's observed in a pH 3 medium (0.2 M Na_2SO_4 + H_2SO_4) for the two unsubstituted tungstophosphates: PW_{18} and P_2W_{18}; B: pH Effect on the CV of PW_{18}. For further details, see text

two apparently one-electron processes. No attempt was made to ascertain quantitatively that the splitting was complete at pH 4. Turning more specifically to the comparison of the voltammetric behavior of the two HPA's, all the observations point to the higher basicity of the reduced forms of PW_{18} compared with those of P_2W_{18}. The results are consistent with the deductions which could have been forecast from their structures. Formally, PW_{18} is composed of two A-type half-anions which can be formulated as H_4W_9 and PW_9 respectively. A loose analogy might prompt us to point out the similarity between the hydrogenated fragment of PW_{18} and $[H_2W_{12}O_{40}]^{6-}$ (H_2W_{12}). This analogy should be expressed in terms of the comparable basicity between PW_{18} and P_2W_{18}, with reference to the known basicity influence in the reduction of H_2W_{12} compared with those of the corresponding species of classical Keggin-type HPA's.[28−30] In fact, polarograms (and voltammograms) of H_2W_{12} at pH < 3.5, show three waves of 2, 2 and ca. 10 electrons each,[29,30] under conditions in which the first two reductions of its analogs $[PW_{12}O_{40}]^{3-}$ and $[SiW_{12}O_{40}]^{4-}$ and even the Dawson-type P_2W_{18}, are one electron pH-independent processes. Therefore, the pH-dependent voltammetric behavior observed for PW_{18} in comparison with that of P_2W_{18} can be compared with that of H_2W_{12} vis à vis $[PW_{12}O_{40}]^{3-}$ and $[SiW_{12}O_{40}]^{4-}$. It must be concluded that PW_{18} and its first several reduced species show greater basicity compared with the corresponding P_2W_{18} species. Provisionally it is worth mentioning, in contrast, that a roughly 6 M HCl solution was necessary to make the first two waves of P_2W_{18} merge[28] and the concentration of acid reaches 7−8 M HCl in the case of $[SiW_{12}O_{40}]^{4-}$. Such merging could not be achieved for $[PW_{12}O_{40}]^{3-}$ in solution[28] and was only achieved inside polymer matrices.[31] This observation is rewarding and represents a good step in our continuous search for ways to accumulate electrons on the first or the first several waves of HPA's under mild conditions. To the best of our knowledge, this series of compounds represents the first examples in which a two-electron W-wave in a saturated species is found to appear at a relatively less negative potential and milder acidity than generally obtained in classical Dawson HPAs. This constitutes one of the favorable conditions for eventual electrocatalytic processes.

Electrochemistry of Substituted Derivatives

The lacunary precursor species PW_{17} is unstable whatever the pH of the medium which precludes a comparison of its electrochemical behavior with that of its substituted derivatives and with that of P_2W_{17}. In the study of a related series of derivatives, experimental evidence had enabled separation of the compounds into two main groups, in agreement with the discussion set down earlier in this paper.[1,18−20] Such a separation and its formerly studied electrochemical consequences should also be valid here. Following this line, the first group is composed of those derivatives that can be considered as truly saturated and include the Mo and V^V (or V^{IV})-substituted compounds; their voltammetric behavior is expected to parallel that of PW_{18} itself, in addition to the redox activity of the substituents. The second group consists of all the other derivatives and they should behave more or less like the electrochemically unknown lacunary precursor PW_{17}. Actually, we suggest that the overall electrochemical trends should be similar to those observed previously in a systematic study of α_2-$P_2W_{17}M$ derivatives[32] and should guide us toward a direct comparison of the corresponding results. The pH = 3 experiments were selected for this comparison. Figure 2 (A through C) shows representative examples of superimposed CV's. For this comparison, it is worth recalling the presence of a distinctive fingerprint for α_2-$P_2W_{17}M$ compared with α_1-$P_2W_{17}M$ at pH = 3: this peculiarity appeared in the third W-waves where a single two-electron reversible wave for the α_1 complex was replaced by two, closely spaced, presumably one-electron waves for the α_2 isomer.[32] The case of the Fe-substituted derivatives is represented in Figure 2 (A). The substituent cation is reduced within the complex more positively than the W-centers. The gross feature is that the fingerprint is present with the two one-electron waves which are more closely spaced in α_2-$PW_{17}Fe$ than in α_2-$P_2W_{17}Fe$. The presence of the fingerprint was also observed

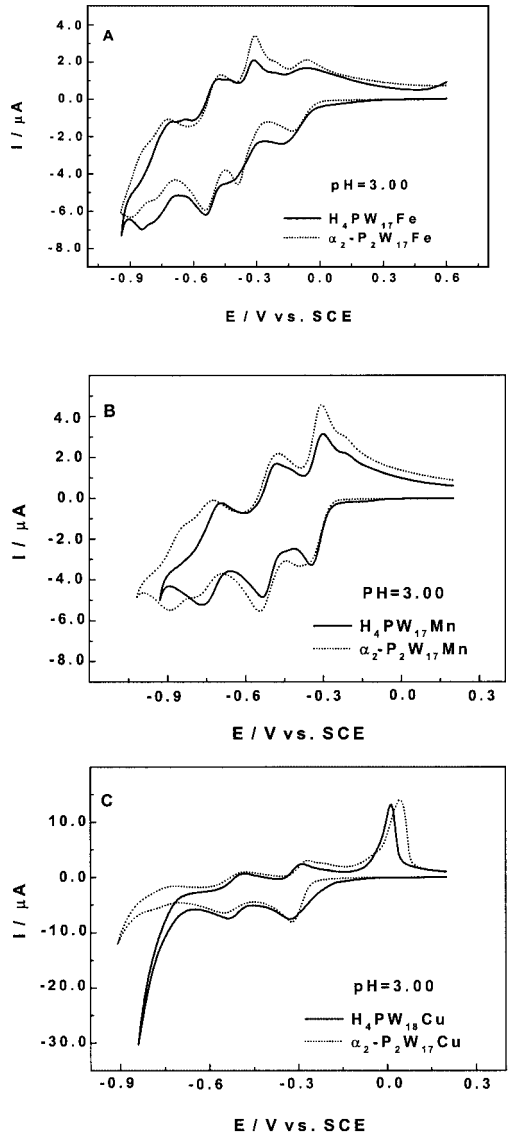

Figure 2. Comparison of the CV's observed in a pH 3 medium (0.2 M Na_2SO_4 + H_2SO_4) for representative examples of 5×10^{-4} M substituted tungstophosphates: α_2-$PW_{17}M$ and α_2-$P_2W_{17}M$; scan rate: 10 $mV.s^{-1}$; working electrode: glassy carbon; reference electrode: SCE. A: α_2-$PW_{17}Fe$ and α_2-$P_2W_{17}Fe$; B: α_2-$PW_{17}Mn$ and α_2-$P_2W_{17}Mn$; C: α_2-$PW_{17}Cu$ and α_2-$P_2W_{17}Cu$

with the V^{IV}- and Co-substituted complexes, with an almost complete merging of the waves in the latter case. In the potential region explored in Figure 2 (B), the Mn wave is not shown. The first two W-waves were observed roughly at the same potentials as the corresponding waves in α_2-$P_2W_{17}Mn$. However, the third redox system of α_2-$PW_{17}Mn$ features a single, slightly broad wave. In short, the presence of this substituent drives the third redox system in the positive potential direction and makes the fingerprint disappear. It must be pointed out that α_2-$PW_{17}Mn$ could be considered as fairly stable in the timescale of CV and the same phenomenon was seen for α_2-$PW_{17}Ni$ and α_2-$PW_{17}Zn$. Finally, the deposition of copper in Figure 2 (C) and the initiation of a probably catalytic hydrogen evolution reaction after the second W-wave precludes the observation of any possible fingerprint. In short, whatever the case, the third redox system is located at a more positive potential for α_2-$PW_{17}M$ than for α_2-$P_2W_{17}M$. Furthermore, when the fingerprint is present, the corresponding waves are more closely spaced in the former complex than in the latter. Thus, the formation of a single third W-wave is obtained through a positive move and a merging of the fingerprint waves. Such a smooth variation has not been previously observed.[32] On increasing the pH from 3 to 5, the fingerprint in the CV of α_2-$PW_{17}Fe$ becomes hardly visible. A consideration of these observations suggests that the difference in basicity between the α_2-$PW_{17}M$ and α_2-$P_2W_{17}M$ reduced forms is the basis for the splitting or otherwise of the third W-redox systems in the CV's. Such a difference in basicity is expected as a parallel to that observed between α-PW_{18} and α-P_2W_{18}. However, its intensity seems to depend critically on the substituent cations. Another outcome of this comparison is the confirmation that α_2-substituted derivatives were indeed formed.

The main other voltammetric characteristics of α_2-$PW_{17}M$ are gathered for pH 3 and pH 5 values in Table 4 for the potential locations of the first two W-waves and in Table 5 for those of the electroactive substituent cations. The values in Table 5 speak for themselves and do not call for particular comments. Even though subtle differences exist from one substituent cation to the next, a rough conclusion can be drawn from Table 4. The nature of the cation seems to induce a uniform influence on the potential locations of the two W-waves, except for the remarkable examples of Mo and Cu. The small differences are more pronounced at pH 3 than at pH 5 and more on the first wave than on the second. A combined Cu and W-wave is observed for α_2-$PW_{17}Cu$. No net separation of these two processes was obtained on going from pH 3 to 5. Controlled potential coulometry just past the peak location of this composite wave consumes four electrons per molecule for complete reduction at pH 3. Electrolysis conducted at half wave potential indicates, by spectroelectrochemistry or even by simple inspection of the solution color, that the two-electron reduction of the Cu^{2+} centre is completed before that of the W^{6+}-centres begins.

Electrocatalytic Reductions of Nitrite and Nitrate

Complexes were selected on the basis of their stability as a function of pH. Their behavior towards the electrocatalytic reductions of nitrite and nitrate in cyclic voltammetry was examined. In the potential regions explored, no direct reduction of nitrite or nitrate on the glassy carbon electrode surface could be observed.[33,34] The catalytic current intensity enhancement on the first wave or the first several waves of each HPA is preferable, with the aim of saving energy and to avoid derivatization of the electrode surface.[27] Conclusions from our previous work[16,34] are confirmed here which indicate only Cu and Ni-substituted species catalyze the reduction of nitrate, while most derivatives catalyze the reduction of nitrite. Therefore, two representative examples were selected. Figure 3 (A) illustrates the voltammetric behavior of PW_{18} towards the reduction of nitrite. For this

experiment, a medium of pH 1 was selected to obtain a complete merging of the first two waves of PW_{18}. Addition of NO_2^- [35] induced a large current intensity enhancement. No anodic trace was observed on potential reversal, even for small values of the excess parameter γ ($\gamma = C_{NO2}^-/C_{HPA}$). Increasing the concentration of nitrite still enhanced the cathodic current. It must be concluded that an efficient catalysis of the reduction of nitrite[35] can be achieved during the reduction of PW_{18}. It is worth pointing out that the catalytic process is carried out on a two-electron first wave obtained under mild conditions in the tungsten series. Provisionally, similar observations were made with the first wave of P_2W_{18}, except that this wave features a one-electron process in the medium of pH 1.

While electrocatalysis by PW_{18} is triggered by reduced W centers within the HPA, a multi-step process must be considered in the case of $PW_{17}Cu$. The phenomena will be described in terms of the example of electrocatalytic reduction of nitrate which is not common among substituted HPA's.[16,34] For example, electrocatalytic reduction of nitrate was not expected and was not observed with PW_{18}. In contrast, Figure 3 (B) shows the electrocatalytic reduction of nitrate by $PW_{17}Cu$ at pH 3. The composite nature of the first wave of $PW_{17}Cu$, described above, combines the reduction of Cu^{2+} within the complex and the first reduction of the W centers. Upon addition of increasing amounts of nitrate, a high intensity catalytic wave was observed starting just negative of the peak potential of the combined first wave. For a selected potential in the catalytic wave domain, increasing the concentration of nitrate still enhanced the cathodic wave. In the present case, electrocatalysis of nitrate was triggered by the electrodeposited copper as well as the reduced W centers. The electrocatalysis remains efficient at pH 5. Whatever the pH, the electrocatalysis of nitrate was observed at more negative potentials than for nitrite. Furthermore, in order to observe catalytic activity, larger values of the excess parameter were necessary for the former substrate than for the latter.

Conclusions

First-row transition metal cations were introduced as mono-substituents in the framework of the novel Dawson-

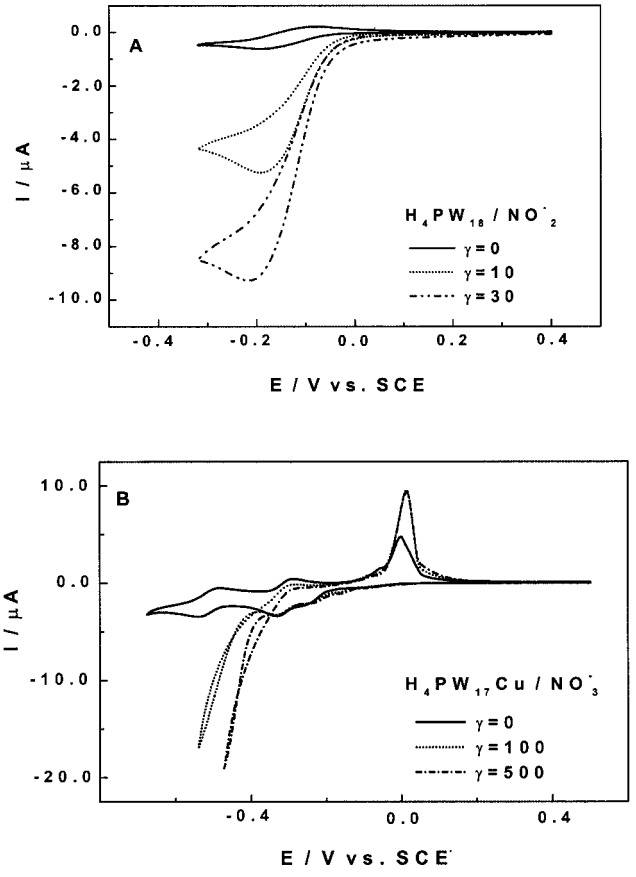

Figure 3. Cyclic voltammograms showing the catalytic activity of PW_{18} towards nitrite and α_2-$PW_{17}Cu$ towards nitrate respectively. Scan rate: 2 $mV \cdot s^{-1}$; working electrode: glassy carbon; reference electrode: SCE; A: Cyclic voltammograms at pH 1 (0.2 M Na_2SO_4 + H_2SO_4) of 2×10^{-4} M PW_{18} in the presence of increasing amounts of nitrite; the excess parameter $\gamma = C_{NO2}^{-}/C_{HPA}$ is indicated in the figure; B: Cyclic voltammograms at pH 3 (0.2 M Na_2SO_4 + H_2SO_4) of 5×10^{-4} M α_2-$PW_{17}Cu$ in the presence of increasing amounts of nitrate; the excess parameter $\gamma = C_{NO3}^{-}/C_{HPA}$ is indicated in the figure

type tungstomonophosphate PW_{18}. During this work, more prolonged heating times than used previously proved helpful in obtaining pure PW_{18} as a starting material. Comparison of the CV properties of PW_{18} and P_2W_{18} as a function of pH shows that the first two W-waves merge in less acidic solution in the former than in the latter complex. This observation leads to the conclusion that the first reduced forms of PW_{18} are more basic than the corresponding forms of P_2W_{18}. The result is interesting in at least two respects: the merging of the W-waves was obtained here through the manipulation of the acid base properties of the molecule by assembling two different building blocks; the association of such "putative" building blocks might constitute an important step in designing polyoxometalates with pre-selected properties. Another aspect of the observed basicity of PW_{18} deserves emphasis i.e. the facile formation of a two-electron first W-wave in mildly acidic media is uncommon in the classical saturated Dawson HPAs and might constitute a favorable first step in electrocatalytic processes that require several electrons in order to be effective. Concerning monosubstituted derivatives, several lines of experimental evidence converge to indicate that the substitution occurs in the α_2 position. Among them, the splitting of the third W redox system in pH 3 media was observed in several substituted derivatives. It deserves particular attention because it confirms that α_2-substituted derivatives were formed. Indeed the extent of splitting also varies smoothly from one derivative to the next, thus suggesting a simple explanation based on small basicity variations for this phenomenon.

Experimental Section

Preparations: All chemicals were of reagent grade and were used as received. The yields of finally isolated pure products ranged constantly from 60 to 95% in all the preparations.

$K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$: The literature method was followed[15] with slight modifications. A sample of $Na_2WO_4\cdot 2H_2O$ (240 g, 0.73 mol) was dissolved in Millipore water (300 mL). The solution was acidified under vigorous stirring by 4 M HCl (160 mL). A mixture of 1 M H_3PO_4 (38 mL) and 4 M HCl (100 mL) was then added. The pH was adjusted to a value slightly less than 2, and the solution was heated to reflux for at least 96 h. After cooling, the solution was treated with solid KCl (100 g). The precipitate was redissolved in H_2O (150 mL) and heated at 80 °C for at least 48 h. After cooling, the clear solution was treated with solid KCl (30 g) to give a fine yellow crystalline powder. $K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$ (4934.2): calcd. K 5.55, P 0.63, W 67.07; found K 5.96, P 0.63, W 66.62.

$K_{11}[H_4PW_{17}O_{61}]\cdot 18H_2O$: A sample of $K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$ (8 g, 1.62 mmol) was dissolved in Millipore water (20 mL) with stirring. To the clear solution, was added a 1 M $KHCO_3$ solution (17 mL) and a white precipitate formed. Stirring was continued for roughly one more hour. The solid was then left to settle and was filtered, washed twice with ethyl alcohol, twice with diethyl ether and was air-dried by suction through a flask with a water pump. $K_{11}[H_4PW_{17}O_{61}]\cdot 18H_2O$ (4890.6): calcd. K 8.76, P 0.63, W 63.67; found K 9.66, P 0.63, W 62.80.

$K_9[H_4Zn(H_2O)PW_{17}O_{61}]\cdot 19H_2O$ (abbreviated as $PW_{17}Zn$): A sample of $Zn(NO_3)_2\cdot 6H_2O$ (0.30 g, ≈ 1 mmol) was dissolved in Millipore water (45 mL) and $K_{11}[H_4PW_{17}O_{61}]\cdot 18H_2O$ (4 g, 0.82 mmol) was added. The mixture was filtered while hot and the clear filtrate left in a beaker. A white crystalline material appeared during cooling. This material was filtered and left to dry in the open air. $K_9[H_4Zn(H_2O)PW_{17}O_{61}]\cdot 19H_2O$ (4913.8): calcd. K 7.16, P 0.63, W 63.61, Zn 1.33; found K 8.88, P 0.62, W 63.54, Zn (1.52). ^{183}W NMR: δ = −98 (2 W), −135 (2 W), −147 (2 W), −176 (2 W), −195 (2 W), −200 (2 W), −205 (2 W), −208 (2 W), −222 (1 W) ppm.

$K_9[H_4Cu(H_2O)PW_{17}O_{61}]\cdot 17H_2O$ (abbreviated as $PW_{17}Cu$): A sample of $Cu(NO_3)_2\cdot 3H_2O$ (0.25 g, ≈ 1 mmol) was dissolved in Millipore water (45 mL) and $K_{11}[H_4PW_{17}O_{61}]\cdot 18H_2O$ (4 g, 0.82 mmol) was added in small portions while heating the mixture on a water bath (≈ 60 °C). After half an hour, the mixture was filtered hot and the green clear filtrate left in a beaker. A pale green crystalline material appeared during cooling. This material was filtered and left to dry in the open air. $K_9[H_4Cu(H_2O)PW_{17}O_{61}]\cdot 17H_2O$ (4875.9): calcd. K 7.22, P 0.64, W 64.10, Cu 1.30; found K 7.11, P 0.62, W 63.42, Cu 1.44.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$K_9[H_4Ni(H_2O)PW_{17}O_{61}]\cdot 20H_2O$ (abbreviated as $PW_{17}Ni$): A sample of $Ni(NO_3)_2\cdot 6H_2O$ (0.30 g, ≈ 1 mmol) was dissolved in Millipore water (45 mL) and $K_{11}[H_4PW_{17}O_{61}]\cdot 18H_2O$ (4 g, 0.82 mmol) was added in small portions while heating the mixture on a water bath (≈ 60 °C). After half an hour, the mixture was filtered hot and the green clear filtrate left in a beaker. A pale green yellow crystalline material appeared during cooling. This material was filtered and left to dry in the open air. $K_9[H_4Ni(H_2O)PW_{17}O_{61}]\cdot 20H_2O$ (4925): calcd. K 7.15, P 0.63, W 63.46, Ni 1.19; found K 7.40, P 0.63, W 64.11, Ni 1.29. W NMR: δ = +468 (2 W), +386 (2 W), −140 (2 W), −164 (2 W), −167 (2 W), −187 (2 W), −245 (1 W) ppm.

$K_9[H_4Co(H_2O)PW_{17}O_{61}]\cdot 20H_2O$ (abbreviated as $PW_{17}Co$): A sample of $Co(NO_3)_2\cdot 6H_2O$ (0.30 g, ≈ 1 mmol) was dissolved in Millipore water (45 mL) and $K_{11}[H_4PW_{17}O_{61}]\cdot 18H_2O$ (4 g, 0.82 mmol) was added in small portions while heating the mixture on a water bath (≈ 60 °C). After half an hour, the mixture was filtered hot and the clear dark red filtrate left in a beaker. A "terre claire'' crystalline material appeared during cooling. This material was filtered and left to dry in the open air. $K_9[H_4Co(H_2O)PW_{17}O_{61}]\cdot 20H_2O$ (4925.3): calcd. K 7.14, P 0.63, W 63.46, Co 1.20; found K 7.39, P 0.65, W 63.94, Co 1.34.

$K_8[H_4Fe(H_2O)PW_{17}O_{61}]\cdot 19H_2O$ (abbreviated as $PW_{17}Fe$): A sample of $Fe(NO_3)_3\cdot 9H_2O$ (0.40 g, ≈ 1 mmol) was dissolved in Millipore water (45 mL) and $K_{11}[H_4PW_{17}O_{61}]\cdot 18H_2O$ (4 gm, 0.82 mmol) was added in small portions while heating the mixture on a water bath (≈ 60 °C). After half an hour, the mixture was filtered hot and the yellow clear filtrate transferred to a beaker. Upon treatment of this filtrate with KCl (10 g), a pale yellow crystalline material appeared. This material was filtered and left to dry in the open air. $K_8[H_4Fe(H_2O)PW_{17}O_{61}]\cdot 19H_2O$ (4865): calcd. K 6.43, P 0.64, W 64.24, Fe 1.15; found K 6.79, P 0.64, W 63.96, Fe 1.34.

$K_9[H_4Mn(H_2O)PW_{17}O_{61}]\cdot 20H_2O$ (abbreviated as $PW_{17}Mn$): A sample of $Mn(NO_3)_2\cdot 4H_2O$ (0.25 g, ≈ 1 mmol) was dissolved in Millipore water (45 mL) and $K_{11}[H_4PW_{17}O_{61}]\cdot 18H_2O$ (4 g, 0.82 mmol) was added in small portions while heating the mixture on a water bath (≈ 60 °C). After half an hour, the mixture was filtered hot and the dark beige clear filtrate left in a beaker. A chestnut colored crystalline material appeared during cooling. This material was filtered and left to dry in the open air. $K_9[H_4Mn(H_2O)PW_{17}O_{61}]\cdot 20H_2O$ (4921.3): calcd. K 7.15, P 0.63, W 63.51, Mn 1.12; found K 7.22, P 0.62, W 65.90, Mn 1.08.

$K_9[H_4PV^{(4+)}W_{17}O_{62}]\cdot 18H_2O$ [abbreviated as $PW_{17}V^{(4+)}$]: A sample of $VOSO_4\cdot 5H_2O$ (0.42 g, 1.7 mmol) was dissolved in Millipore water (90 mL) and acidified with 4 M HCl (8.5 mL). $K_{11}[H_4PW_{17}O_{61}].18H_2O$ (8 g, 1.64 mmol) was then added in small portions with stirring. The black solution was stirred for roughly half an hour and then, treated with KCl (10 g). The grey black precipitate that resulted was recrystallized from a minimum of acidified water (HCl solution pH < 1). $K_9[H_4PV^{(4+)}W_{17}O_{62}]\cdot 18H_2O$ (4879.3): calcd. K 7.21, P 0.64, W 64.06, V 1.04; found K 7.13, P 0.62, W 64.7, V 1.05.

$K_8[H_4PV^{(5+)}W_{17}O_{62}]\cdot 18H_2O$ [abbreviated as $PW_{17}V^{(5+)}$]: To Millipore water (90 mL) was added a solution of 0.5 M HVO_4^{2-} (3.5 mL) with 4 M HCl (8.5 mL). $K_{11}[H_4PW_{17}O_{61}]\cdot 18H_2O$ (8 g, 1.64 mmol) was then added in small portions whilst stirring. The yellow solution was stirred for roughly half an hour, filtered and then treated with KCl (10 g). The yellow precipitate that resulted was recrystallized from a minimum of acidified water (HCl solution pH < 1). $K_8[H_4PV^{(5+)}W_{17}O_{62}]\cdot 18H_2O$ (4840.2): calcd. K 6.46, P 0.64, W 64.57, V 1.05; found K 5.95, P 0.63, W 65.10, V 0.95.

$K_7[H_4PMoW_{17}O_{62}]\cdot 18H_2O$ (abbreviated as $PW_{17}Mo$): A sample of $Na_2MoO_4\cdot 2H_2O$ (0.40 g, 1.7 mmol) was dissolved in Millipore water (90 mL) and acidified with 4 M HCl (8.5 mL). $K_{11}[H_4PW_{17}O_{61}]\cdot 18H_2O$ (8 g, 1.64 mmol) was then added in small portions with stirring. The clear yellow solution was stirred for roughly half an hour and then filtered and treated with KCl (10 g). The fine yellow precipitate that resulted was recrystallized from a minimum of acidified water (HCl solution pH < 1). $K_7[H_4PMoW_{17}O_{62}]\cdot 18H_2O$ (4846.1): calcd. K 5.65, P 0.64, W 64.49, Mo 1.98; found K 5.76, P 0.66, W 64.51, Mo 2.01.

General Methods and Materials: Pure water was used throughout and was obtained by passing through an RiOs 8 unit followed by a Millipore-Q Academic purification set. All reagents were of high-purity grade and were used as purchased. Elemental analyses were performed by Kanti Labs Ltd. in Mississauga, Canada. The IR spectra were recorded in KBr pellets with a Perkin−Elmer Spectrum One FT-IR spectrophotometer. The UV/Vis spectra were recorded with a Perkin−Elmer Lambda 19 spectrophotometer on 2.5 × 10^{-5} M solutions of the relevant polyanion. Matched 1.000-cm optical path quartz cuvettes were used. The compositions of the various media were as follows: for pH 0.33: 0.5 M H_2SO_4; for pH 1 to 3: 0.2 M Na_2SO_4 + H_2SO_4; for pH 4 and 5: 0.4 M CH_3COONa + CH_3COOH; for pH 6 and 7: 0.4 M NaH_2PO_4 + NaOH.

Electrochemical Experiments: The same media used for UV/visible spectroscopy were also used for electrochemistry except that the polyanion concentration was 5 × 10^{-4} M. All cyclic voltammograms were recorded at a scan rate of 10 mV·s^{-1} unless otherwise stated.

The solutions were de-oxygenated thoroughly for at least 30 min with pure argon and kept under a positive pressure of this gas during the experiments. The source, mounting and polishing of the glassy carbon electrodes (GC, Tokai, Japan) has been described.[36] The glassy carbon samples had a diameter of 3 mm. The electrochemical set-up was an EG & G 273 A system controlled by a PC with M270 software. Potentials are quoted relative to the saturated calomel electrode (SCE). The counter electrode was a platinum gauze of large surface area. All experiments were performed at room temperature.

Synthesis, Spectroscopic Properties, and Structure of [Tetrakis(2,4-dimethyl-3-pentyloxy)phthalocyaninato]metal Complexes

Wei Liu,[a] Chi-Hang Lee,[a] Hoi-Shan Chan,[a] Thomas C. W. Mak,[a] and Dennis K. P. Ng*[a]

Keywords: Macrocyclic compounds / Inclusion compounds / N ligands

A series of highly soluble [tetrakis(2,4-dimethyl-3-pentyloxy)phthalocyaninato]metal complexes [$MPc(OC_7H_{15})_4$] (M = Zn, Pd, Co) were prepared by cyclic tetramerization of 3-(2,4-dimethyl-3-pentyloxy)phthalonitrile (**2**) in the presence of the corresponding metal salts and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in *n*-pentanol. For M = Zn and Pd, two major isomers with a C_{4h} and C_{2v} symmetry were isolated by column chromatography and characterized with various spectroscopic methods, while the cobalt analogue showed only the C_{4h} isomer. The (phthalocyaninato)manganese complex [$MnClPc(OC_7H_{15})_4$] was also synthesized by metallation of the metal-free phthalocyanine $H_2Pc(OC_7H_{15})_4$ formed by treating **2** with $CeCl_3$ and DBU in *n*-pentanol. The structures of the C_{4h} isomers of the (phthalocyaninato)zinc and -cobalt complexes and the C_4 isomer of the manganese analogue were also established by X-ray diffraction analyses. The palladium counterpart formed a novel 1:1 inclusion complex with oxalic acid, the crystal structure of which was also determined.

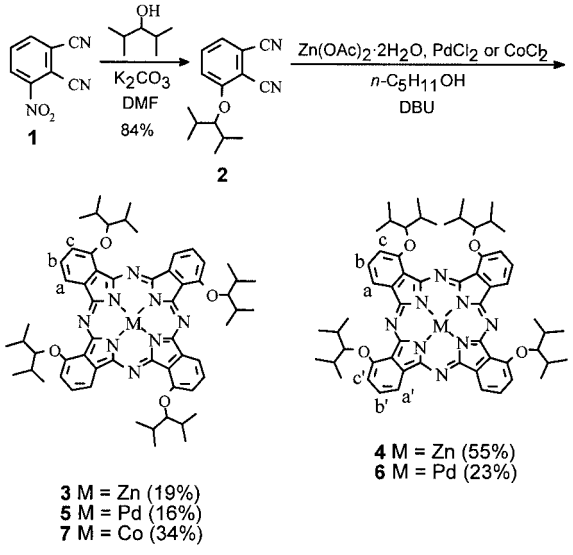
Introduction

Phthalocyanines are traditional pigments that were discovered almost a century ago. They are a unique class of macrocyclic compounds, with intriguing physical and chemical properties that allow their use in many disciplines.[1] Their well-documented functions as molecular opto-electronic materials,[2] photosensitizers for photodynamic therapy,[3] and catalysts for oxidative degradation of pollutants[4] are still being actively exploited. For some of these applications, highly soluble and non-aggregated phthalocyanines are desirable. The former property facilitates the purification and the fabrication processes, while the latter assists in characterization and allows these materials to function properly; many properties of phthalocyanines change upon aggregation.[5] As a result, a substantial number of phthalocyanines with sterically demanding substituents have been reported.[6] We describe herein a series of (phthalocyaninato)metal complexes substituted with four 2,4-dimethyl-3-pentyloxy groups. These bulky and hydrophobic substituents not only enhance the solubility of phthalocyanines in organic solvents and reduce their tendency to aggregate, but also facilitate the separation of the isomers of tetra-α-substituted phthalocyanines. Phthalocyanines containing these substituents have been briefly reported for use as optical recording materials.[7]

Results and Discussion

Synthetic Studies

In the synthesis of these (phthalocyaninato)metal complexes (Scheme 1) 3-nitrophthalonitrile (**1**) is treated with



Scheme 1. Preparation of [tetrakis(2,4-dimethyl-3-pentyloxy)-phthalocyaninato]zinc, -palladium, and -cobalt complexes

2,4-dimethyl-3-pentanol in the presence of K_2CO_3 in DMF to afford 3-(2,4-dimethyl-3-pentyloxy)phthalonitrile (**2**). Cyclization of **2** with zinc(II) acetate or palladium(II) chloride in the presence of DBU in *n*-pentanol then furnishes the corresponding (phthalocyaninato)metal complexes. Only the C_{4h} and C_{2v} isomers could be isolated by column chromatography, while the D_{2h} and C_s isomers were not detected. For the (phthalocyaninato)zinc complexes, the C_{4h} isomer **3** was eluted first followed by the C_{2v} isomer **4**. Interestingly, this order was reversed for the palladium analogues **5** and **6**. These isomers are usually separated by medium- or high-pressure liquid chromatography,[8] but their facile separation here may be attributed to the bulky 2,4-dimethyl-3-pentyloxy substituents at the α-positions. It is also noteworthy that for both the zinc and palladium analogues the C_{2v} isomer is produced in higher yield than the C_{4h} counterpart, which is supposed to be thermodynamically more stable. This cannot be explained by the alkoxide-induced sequential nucleophilic attack of phthalonitriles[9] and the "template" mechanism proposed by Hanack et al.,[8b] which will give predominantly the C_{4h} and C_s isomers, respectively. The reaction mechanism remains elusive but, as reported earlier,[8b] the isomer distribution of tetra-α-substituted (phthalocyaninato)metal complexes depends on many factors, including the nature of the substituent, reaction conditions, and metal center. Further investigation is clearly required.

The cobalt counterpart **7**, prepared similarly using $CoCl_2$ as the metal salt, was unstable on silica gel: the blue color faded gradually during chromatography. Preliminary purification could, however, be achieved by flash chromatography through a short column packed with neutral alumina. Further purification by recrystallization led to the pure C_{4h} isomer **7**, which was confirmed by single-crystal X-ray analysis. Other constitutional isomers, which were probably also formed during the reaction, could neither be isolated nor detected by ^{1}H NMR spectroscopy due to the paramagnetic cobalt(II) center.

Our recently reported cerium-promoted method to prepare metal-free phthalocyanines afforded high yields of 1,8,15,22-tetrakis(2,4-dimethyl-3-pentyloxy)phthalocyanine (**8**),[10] which can be used to prepare (phthalocyaninato)metal complexes. Thus, while treatment of the dinitrile **2** with $Mn(OAc)_2{\cdot}2H_2O$ and DBU in *n*-pentanol yielded a dark brown solution which did not show the typical phthalocyanines' Q-band absorption, compound **8** could be metallated with $Mn(OAc)_2{\cdot}2H_2O$ in DMF to give the (phthalocyaninato)manganese(III) complex **9** in 88% yield (Scheme 2). The manganese(II) ion was oxidized during the reaction and the axial chloro ligand came from the brine used during the workup procedure. Similar results were also observed during the preparation of (chloro)(porphyrazinato)manganese(III) complexes.[11]

Scheme 2. Preparation of (phthalocyaninato)manganese complex **9**

Spectroscopic Properties

The C_{4h} and C_{2v} isomers of the (phthalocyaninato)zinc and -palladium complexes could be distinguished readily by ^{1}H NMR spectroscopy. The rather broad signals for the zinc analogues **3** and **4** in $CDCl_3$ were sharpened upon addition of a drop of [D_5]pyridine to give well-resolved spectra, due to the relief of aggregation by the axial coordination of the zinc(II) center by pyridine.[12] The spectra for the palladium analogues **5** and **6** were well resolved even in the absence of [D_5]pyridine. Figure 1 (b) shows the ^{1}H NMR spectrum of **5** in $CDCl_3$, in which all the signals can be assigned unambiguously. The spectrum shows a doublet at δ = 9.05 ppm, an overlapping doublet of doublets (or virtual triplet) at δ = 8.03 ppm, and a doublet at δ = 7.68 ppm for the three sets of ring protons. The four equivalent 2,4-dimethyl-3-pentyloxy groups resonate at δ = 4.67 (t, OCH), 2.54−2.64 (m, CH), 1.48 (d, Me), and 1.19 ppm (d, Me). All these signals are split for compound **6** [Figure 1 (a)], which clearly confirms its C_{2v} symmetry.

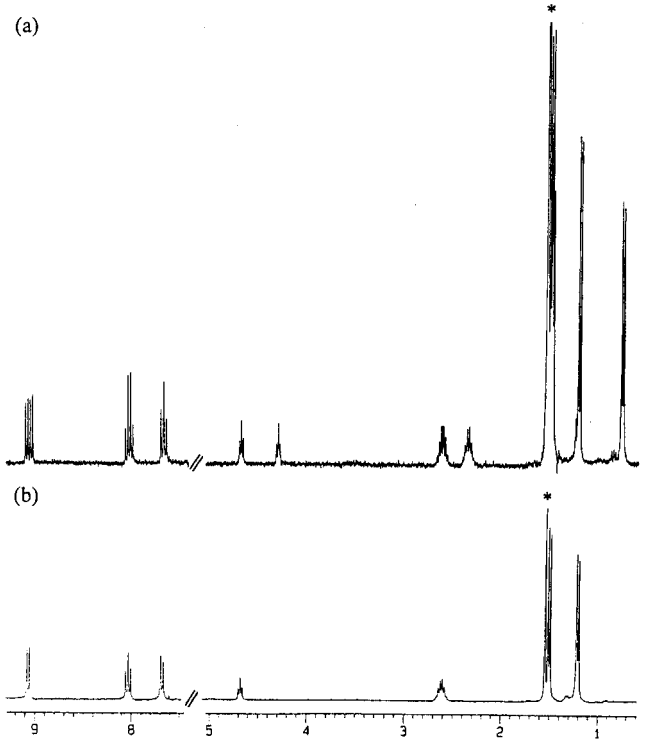

Figure 1. ^{1}H NMR spectra of **6** (a) and **5** (b) in $CDCl_3$; * water signal

The (phthalocyaninato)metal complexes **3**−**7** and **9** gave typical UV/Vis absorptions of phthalocyanines (Table 1). The absorption data of the C_{4h} and C_{2v} isomers of the (phthalocyaninato)zinc and -palladium complexes do not

Table 1. UV/Vis data for (phthalocyaninato)metal complexes **3**−**7** and **9** in $CHCl_3$

Compound	λ_{max} [nm] (log ε)				
	B-band	LMCT	Vibronic band(s)		Q-band
$Zn[Pc(OC_7H_{15})_4]$ (**3**)	322 (4.54)	−	638 (4.37)	−	711 (5.13)
$Zn[Pc(OC_7H_{15})_4]$ (**4**)	323 (4.59)	−	638 (4.41)	−	709 (5.14)
$Pd[Pc(OC_7H_{15})_4]$ (**5**)	314 (4.31)	−	623 (4.36)	664 (4.08)	694 (5.10)
$Pd[Pc(OC_7H_{15})_4]$ (**6**)	314 (4.44)	−	625 (4.46)	671 (4.44)	696 (5.19)
$Co[Pc(OC_7H_{15})_4]$ (**7**)	313 (3.86)	−	631 (3.66)	−	702 (4.31)
$MnCl[Pc(OC_7H_{15})_4]$ (**9**)	337 (4.18)	550 (3.85)	693 (3.93)	−	775 (4.67)

show significant differences. The Q-band position, however, is highly dependent on the metal center in the order $Pd^{II} < Co^{II} < Zn^{II} << Mn^{III}$. The (phthalocyaninato)manganese complex **9** is brown instead of the characteristic blue-green as a result of the very long Q-band absorption (775 nm), which appears to be the longest wavelength recorded for (phthalocyaninato)metal complexes. This remarkably large red-shift may be attributed to the effects of metal center and the electron-donating alkoxy substituents introduced at the α-positions. A characteristic ligand-to-metal charge-transfer (LMCT) band at 550 nm was also seen for **9**.[13]

Having four bulky 2,4-dimethyl-3-pentyloxy substituents, these phthalocyanines are expected to be relatively non-aggregated in solutions. This was confirmed by variable-concentration UV/Vis studies of compounds **3**, **5**, and **9** in $CHCl_3$. For these three compounds, plots of the Q-band absorbance versus concentration (from 2×10^{-7} to 3×10^{-5} mol·dm^{-3}) gave perfect straight lines, showing that the compounds strictly follow the Lambert−Beer law. This indicates that the compounds exist mainly in monomeric form under the conditions employed. The zinc complexes **3** and **4**, however, are slightly aggregated at higher concentrations (ca. 10^{-3} mol·dm^{-3}) as shown by NMR studies (see above).

Structural Studies

Both the zinc and cobalt phthalocyanines **3** and **7** co-crystallize with a water molecule, which may come from the solvents used for recrystallization. In the molecular structure of **3** the zinc atom is disordered about the inversion center relating the two halves of the molecule (Figure 2). The oxygen atom of water occupies a site with half occupancy, giving the shortest Zn−O distance at 2.034 Å, which may be regarded as axial ligation.[14] The corresponding Co−O distance in **7** (2.494 Å), however, is significantly longer than typical $Co-OH_2$ bonds in (aquo)cobalt(II) complexes (ca. 2.1−2.2 Å).[15]

Both **3** and **7** crystallize in the monoclinic system with two molecules per unit cell. The phthalocyanine rings are arranged in a herringbone manner[16] along the crystallographic *b* axis with a stacking angle of 54.1 (**3**) or 59.7° (**7**) and an interplanar distance of 6.98 (**3**) or 7.40 Å (**7**) (Figure 3). This arrangement is similar to that of the metal-free analogue **8**[10a] and the unsubstituted phthalocyanine.[17] Due to the bulky 2,4-dimethyl-3-pentyloxy substituents, which act as spacers, the interplanar distances for these substituted phthalocyanines are much larger than that of the unsubstituted counterpart (3.31 Å).

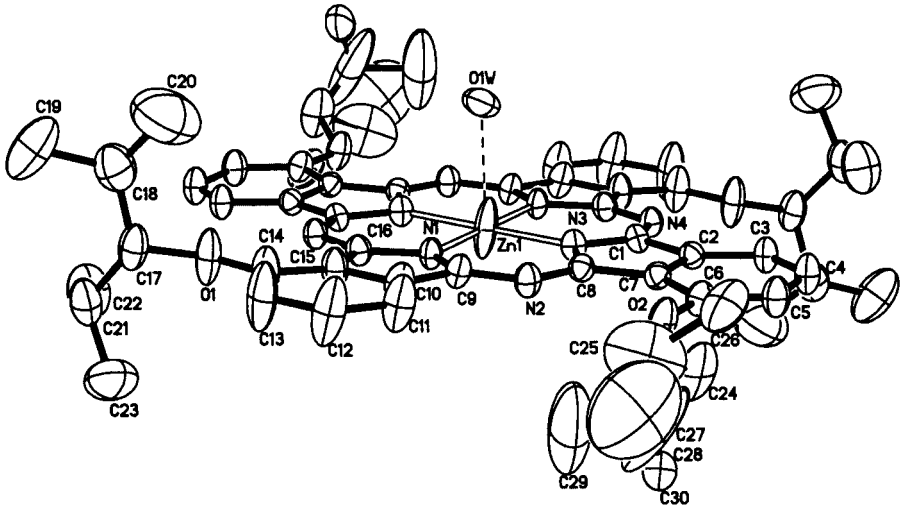

Figure 2. Molecular structure of **3** showing the 30% probability thermal ellipsoids for all non-hydrogen atoms; the zinc atom is disordered with the shortest $Zn-OH_2$ distance at 2.034 Å

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

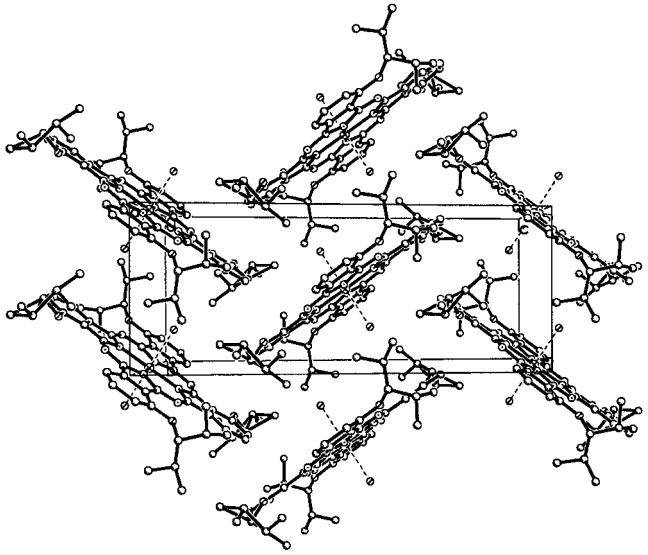

Figure 3. Packing of **3**·H_2O viewed along the *a* axis; all hydrogen atoms omitted for clarity

In the (phthalocyaninato)manganese complex **9** the manganese center is coordinated by four isoindole nitrogen atoms of the phthalocyanine ring and one terminal chloro ligand, forming a slightly distorted square pyramid (Figure 4). In contrast to the zinc and cobalt analogues, in which the metal center lies in the isoindole N_4 plane, the manganese atom is displaced 0.291 Å above the N_4 plane towards the apical chloro ligand. The displacement is similar to that in [Mn(OESTAP)Cl] [0.291 Å; OESTAP = 2,3,7,8,12,13,17,18-octakis(ethylsulfanyl)-*meso*-tetraazaporphyrinate],[18] but is 0.03 Å longer than that in [Mn(TPP)Cl] (TPP = *meso*-tetraphenylporphyrinate).[19] The average Mn−N(isoindole) distance (1.960 Å) is also similar to the average Mn−N(pyrrole) distance of [Mn(OESTAP)Cl] (1.951 Å), but shorter than that in [Mn(TPP)Cl] (2.02 Å). This is in agreement with the larger central cavity of the TPP ring. The Mn−Cl distance in **9** (2.343 A) is significantly shorter than that in [Mn(OESTAP)Cl] (2.394 Å) and [Mn(TPP)Cl] (2.37 Å). Due to the square-pyramidal structure and the C_4 disposition of the substituents, compound **9** can exhibit chirality. That the compound crystallizes in the orthorhombic system with a $P2_12_12_1$ space group shows that the crystal contains only one of the enantiomers, although a racemic mixture is expected to form during the reaction. This compound is thus a rare example of a structurally characterized manganese complex[20] and phthalocyanine with a planar asymmetry.[21]

We have recently reported a novel 1:1 inclusion complex of the metal-free phthalocyanine **8** and oxalic acid generated unexpectedly in a cerium-promoted cyclization reaction.[10a] The crystal structure shows that the oxalic acid molecules are intercalated between the phthalocyanine rings and not be hydrogen-bonded in any conventional or unconventional manner. This is very unusual for molecules, such as oxalic acid, which have good hydrogen-bonding functionalities.[22] To further explore this novel class of inclusion complexes, the (phthalocyaninato)palladium complex **5** was recrystallized in the presence of 1 equiv. of oxalic acid, giving the 1:1 inclusion complex **5**·$C_2H_2O_4$. The IR spectrum of **5**·$C_2H_2O_4$ (KBr) showed a strong band at 1671 cm^{-1} and a medium band at ca. 3400 cm^{-1}, which can be ascribed to the C=O and O−H stretches, respectively, of the oxalic acid. Figure 5 depicts the packing of molecules in the lattice viewed along the crystallographic *a* and *b* axes, which shows that the guest species are not hydrogen-bonded and simply hang between the phthalocyanine rings. The polar oxalic acid preferentially resides in the more polar cavity between the phthalocyanine rings rather than in bulk $CHCl_3$. The stacking angle is 54.3° and the interplanar distance is 7.13 Å, which are similar to those of **3** and **7**. The oxalic acid

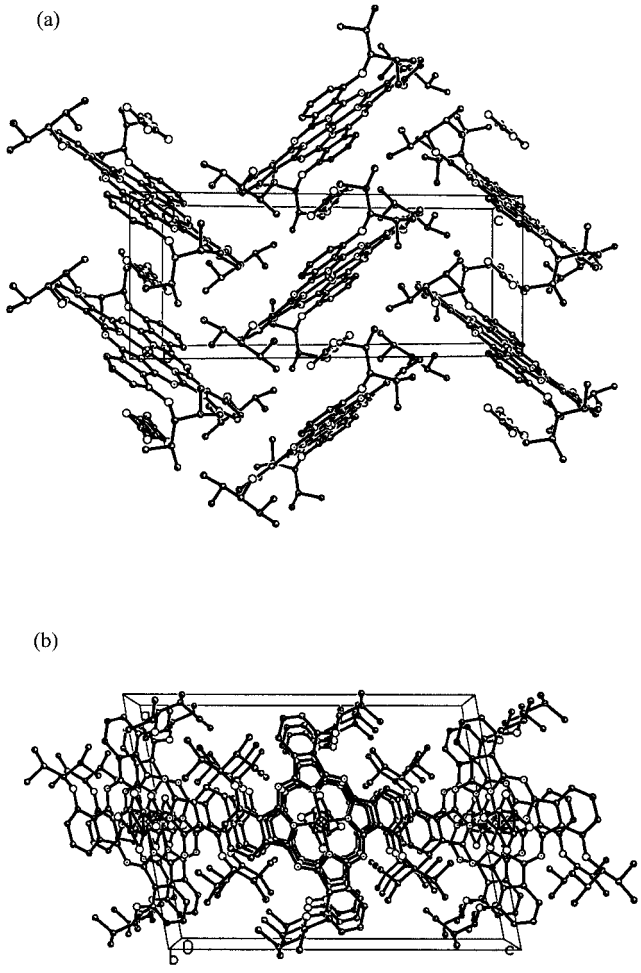

Figure 5. Crystal structure of $5 \cdot C_2H_2O_4$: views along the *a* (a) and *b* axis (b); all hydrogen atoms omitted for clarity

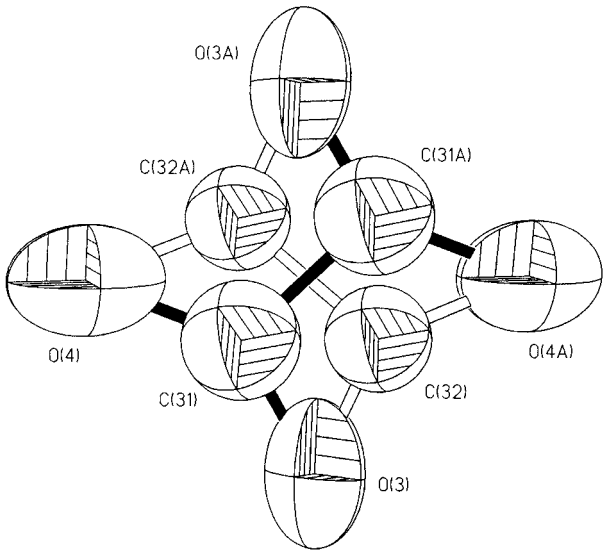

Figure 6. Molecular structure of the disordered oxalic acid in $5 \cdot C_2H_2O_4$; selected bond lengths [Å] and angles [°]: C(31)−C(31A) 1.566(10), C(31)−O(4) 1.142(16), C(31)−O(3) 1.204(18), C(32)−C(32A) 1.572(10), C(32)−O(4A) 1.176(16), C(32)−O(3) 1.229(18); O(4)−C(31)−O(3) 140.7(13), O(4)−C(31)−C(31A) 129(2), O(3)−C(31)−C(31A) 89.7(17), O(4A)−C(32)−O(3) 147.5(13), O(4A)−C(32)−C(32A) 125(2), O(3)−C(32)−C(32A) 87.7(16)

molecule is disordered (Figure 6). The average C−C, C=O, and C−O bond lengths are 1.569, 1.159, and 1.217 Å, respectively. The latter two are significantly shorter than the corresponding values for hydrogen-bonded oxalic acid (ca. 1.20 and 1.31 Å).[23]

Conclusion

We have prepared and characterized a series of (phthalocyaninato)metal complexes substituted with four bulky 2,4-dimethyl-3-pentyloxy groups. The C_{4h} isomers of the (phthalocyaninato)zinc and -cobalt complexes and the C_4 isomer of the manganese analogue have been structurally characterized. The palladium counterpart forms a rare 1:1 inclusion complex, with oxalic acid, the structure of which has also been determined.

Experimental Section

General Remarks: Reactions were performed under nitrogen. *n*-Pentanol and THF were distilled from sodium and sodium/benzophenone ketyl, respectively. DMF was predried with barium oxide and distilled under reduced pressure. Chromatographic purifications were performed on silica gel columns (Macherey−Nagel, 70−230 mesh) with the indicated eluents unless otherwise stated. Hexane used in chromatography was distilled from anhydrous $CaCl_2$. All other reagents and solvents were of reagent grade and used as received. The preparation of the metal-free phthalocyanine **8** has been reported previously.[10] ^{1}H and ^{13}C NMR spectra were recorded with a Bruker DPX 300 spectrometer (^{1}H: 300 MHz; ^{13}C: 75.4 MHz) in $CDCl_3$ solutions unless otherwise stated. Chemical shifts are relative to internal $SiMe_4$ (δ = 0 ppm). IR spectra were measured with a Nicolet Magna 550 FT-IR spectrometer as KBr pellets. UV/Vis spectra were taken with a Cary 5G UV/Vis/NIR spectrophotometer. Liquid secondary-ion (LSI) mass spectra were recorded with a Bruker APEX 47e Fourier transform ion cyclotron resonance (FTICR) mass spectrometer with a 3-nitrobenzyl alcohol matrix. Elemental analyses were performed by Medac Ltd., Brunel Science Centre, UK.

3-(2,4-Dimethyl-3-pentyloxy)phthalonitrile (2):[24] A mixture of 3-nitrophthalonitrile (**1**) (2.0 g, 12 mmol), 2,4-dimethyl-3-pentanol (4.8 g, 41 mmol), and K_2CO_3 (12.6 g, 91 mmol) in DMF (20 mL) was heated at 65 °C for 2 d. The mixture was then poured into ice-cold water (200 mL) to give a light brown solid, which was filtered off and dissolved in $CHCl_3$ (20 mL). The resultant solution was dried with anhydrous $MgSO_4$ and then concentrated in vacuo. The residue was chromatographed with $CHCl_3$ as eluent to give the product as a white solid. Further purification was achieved by recrystallization with hexane to afford white shiny needles (2.4 g, 84%), m.p. 82−83 °C. $C_{15}H_{18}N_2O$ (242.3): calcd. C 74.34, H 7.49, N 11.57; found C 74.43, H 7.28, N 11.62. ^{1}H NMR: δ = 7.50−7.55 (m, 1 H, ArH), 7.21−7.24 (m, 2 H, ArH), 4.00 (t, *J* = 6.0 Hz, 1 H, OCH), 2.02−2.11 (m, 2 H, CH), 0.94 (d, *J* = 6.9 Hz, 6 H, Me), 0.88 (d, *J* = 6.9 Hz, 6 H, Me) ppm. ^{13}C{^{1}H} NMR: δ = 163.3, 134.3, 124.5, 117.8, 117.1, 115.4, 113.3, 105.0, 90.9, 30.5, 19.8, 17.4 ppm. IR (KBr): $\tilde{\nu}$ = 2225 m cm^{-1} (C≡N). HRMS (EI): *m*/*z* calcd. for $C_{15}H_{18}N_2O$ [M$^+$] 242.1419, found 242.1435.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

[Tetrakis(2,4-dimethyl-3-pentyloxy)phthalocyaninato]zinc(II) (3 and 4): A mixture of the dinitrile **2** (100 mg, 0.41 mmol), $Zn(OAc)_2{\cdot}2H_2O$ (32 mg, 0.15 mmol), and DBU (0.2 mL) in *n*-pentanol (3 mL) was heated at 160 °C for 8 h. The volatiles were then removed in vacuo and the residue was chromatographed with hexane/ethyl acetate (2:1) as eluent. A green band was collected and the solvents were evaporated to give a crude isomeric mixture of $[ZnPc(OC_7H_{15})_4]$, which was further purified by chromatography using $CHCl_3$/ethyl acetate (10:1) as eluent. Two green bands were then developed which were collected separately to give the C_{4h} isomer **3** (20 mg, 19%) and the C_{2v} isomer **4** (59 mg, 55%), respectively. **3:** ^{1}H NMR ($CDCl_3$ with a drop of $[D_5]$pyridine): δ = 9.06 (d, *J* = 7.5 Hz, 4 H, Pc-H_a), 7.95 (t, *J* = 7.5 Hz, 4 H, Pc-H_b), 7.61 (d, *J* = 7.5 Hz, 4 H, Pc-H_c), 4.61 (t, *J* = 5.7 Hz, 4 H, OCH), 2.50−2.60 (m, 8 H, CH), 1.47 (d, *J* = 6.6 Hz, 24 H, Me), 1.14 (d, *J* = 6.6 Hz, 24 H, Me) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$ with a drop of $[D_5]$pyridine): δ = 158.7, 153.8, 143.9, 142.0, 129.8, 125.8, 114.7, 113.6, 89.7, 31.2, 20.2, 18.4 ppm. HRMS (LSI): *m*/*z* calcd. for $C_{60}H_{73}N_8O_4Zn$ $[MH^+]$ 1033.5046, found 1033.5182. **4:** ^{1}H NMR ($CDCl_3$ with a drop of $[D_5]$pyridine): δ = 9.03−9.11 (m, 4 H, Pc-H_a and Pc-$H_{a'}$), 7.93−8.04 (m, 4 H, Pc-H_b and Pc-$H_{b'}$), 7.59−7.68 (m, 4 H, Pc-H_c and Pc-$H_{c'}$), 4.66 (t, *J* = 6.0 Hz, 2 H, OCH), 4.27 (t, *J* = 6.0 Hz, 2 H, OCH), 2.52−2.64 (m, 4 H, CH), 2.28−2.39 (m, 4 H, CH), 1.49−1.53 (m, 24 H, Me), 1.17 (d, *J* = 6.6 Hz, 12 H, Me), 0.73 (d, *J* = 6.6 Hz, 12 H, Me) ppm. HRMS (LSI): *m*/*z* calcd. for $C_{60}H_{73}N_8O_4Zn$ $[MH^+]$ 1033.5046, found 1033.5181.

[Tetrakis(2,4-dimethyl-3-pentyloxy)phthalocyaninato]palladium(II) (5 and 6): A mixture of the dinitrile **2** (100 mg, 0.41 mmol), $PdCl_2$ (21 mg, 0.12 mmol), and DBU (0.2 mL) in *n*-pentanol (3 mL) was heated at 140 °C for 18 h. The volatiles were then removed in vacuo and the residue was subjected to chromatography using $CHCl_3$ as eluent. The crude product was chromatographed again with hexane/$CHCl_3$ (2:1) as eluent to develop two green bands, which were collected and the solvents evaporated. The first band was found to be the C_{2v} isomer **6** (26 mg, 23%), while the second band was the C_{4h} isomer **5** (18 mg, 16%), which could be further purified by recrystallization from $CHCl_3$/MeOH. **5:** $C_{61}H_{73}Cl_3N_8O_4Pd$ (**5**·$CHCl_3$): calcd. C 61.39, H 6.17, N 9.40; found C 60.34, H 6.32, N 9.24. ^{1}H NMR: δ = 9.05 (d, *J* = 7.5 Hz, 4 H, Pc-H_a), 8.03 (dd, *J* = 7.5, 8.1 Hz, 4 H, Pc-H_b), 7.68 (d, *J* = 8.1 Hz, 4 H, Pc-H_c), 4.67 (t, *J* = 5.7 Hz, 4 H, OCH), 2.54−2.64 (m, 8 H, CH), 1.48 (d, *J* = 6.6 Hz, 24 H, Me), 1.19 (d, *J* = 6.6 Hz, 24 H, Me) ppm. $^{13}C\{^1H\}$ NMR: δ = 158.6, 154.7, 143.1, 141.4, 130.6, 124.2, 114.7, 113.7, 89.5, 31.4, 20.4, 18.5. HRMS (LSI): *m*/*z* calcd. for $C_{60}H_{73}N_8O_4Pd$ $[MH^+]$ 1075.4783, found 1075.4870. **6:** ^{1}H NMR: δ = 9.09 (d, *J* = 7.5 Hz, 2 H, Pc-H_a or Pc-$H_{a'}$), 9.03 (d, *J* = 7.5 Hz, 2 H, Pc-H_a or Pc-$H_{a'}$), 7.98−8.06 (m, 4 H, Pc-H_b and Pc-$H_{b'}$), 7.64−7.69 (m, 4 H, Pc-H_c and Pc-$H_{c'}$), 4.69 (t, *J* = 5.7 Hz, 2 H, OCH), 4.31 (t, *J* = 5.7 Hz, 2 H, OCH), 2.57−2.68 (m, 4 H, CH), 2.30−2.41 (m, 4 H, CH), 1.49−1.52 (m, 24 H, Me), 1.22 (d, *J* = 6.6 Hz, 12 H, Me), 0.77 (d, *J* = 6.6 Hz, 12 H, Me). $^{13}C\{^1H\}$ NMR: δ = 160.0, 158.6, 154.0, 152.0, 143.2, 143.0, 140.0 (2 overlapping signals), 130.6, 130.4, 124.2 (2 overlapping signals), 117.0, 115.0, 114.4, 113.9, 94.2, 89.4, 31.4, 29.7, 20.4, 19.9, 18.4, 18.3 ppm. HRMS (LSI): *m*/*z* calcd. for $C_{60}H_{73}N_8O_4Pd$ $[MH^+]$ 1075.4783, found 1075.5037.

[1,8,15,22-Tetrakis(2,4-dimethyl-3-pentyloxy)phthalocyaninato]-cobalt(II) (7): A mixture of the dinitrile **2** (100 mg, 0.41 mmol), anhydrous $CoCl_2$ (13 mg, 0.10 mmol), and DBU (0.2 mL) in *n*-pentanol (3 mL) was heated under reflux overnight. The volatiles were then removed in vacuo and the residue was subjected to flash chromatography on neutral alumina using hexane/ethyl acetate (1:4) as eluent. The crude product obtained was further purified by chromatography again using the same eluent to develop two blue bands. The first band was collected and the solvents were evaporated to give the C_{4h} isomer **7** as a green solid (35 mg, 34%), which could be recrystallized by layering MeOH onto a $CHCl_3$ solution. The second band contained about 5 mg of material, which could not be further purified by recrystallization because of its instability in solutions. HRMS (LSI): *m*/*z* calcd. for $C_{60}H_{72}CoN_8O_4$ $[M^+]$ 1027.5008, found 1027.4739.

Chloro[1,8,15,22-tetrakis(2,4-dimethyl-3-pentyloxy)phthalocyaninato]manganese(III) (9): A mixture of the metal-free phthalocyanine **8** (50 mg, 0.05 mmol) and $Mn(OAc)_2{\cdot}2H_2O$ (10 mg, 0.05 mmol) in DMF (3 mL) was heated at 60 °C for 4 h. Water (10 mL) was then added and the resulting mixture was washed with hexane (3 × 15 mL) to remove unchanged **8**. The obtained brown aqueous layer was mixed with saturated brine (5 mL), and the mixture was then extracted with $CHCl_3$ (3 × 15 mL). The combined reddish-brown extracts were dried with anhydrous $MgSO_4$ and the solvents evaporated in vacuo to give a brown residue, which was purified by column chromatography on neutral alumina using hexane/ethyl acetate (4:1) as eluent. The crude product was further purified by recrystallization from hexane/THF to give brown needles (48 mg, 88%). $C_{64}H_{80}ClMnN_8O_5$ (**9**·THF): calcd. C 67.93, H 7.13, N 9.91; found C 67.84, H 7.03, N 9.77. HRMS (LSI): *m*/*z* calcd. for $C_{60}H_{72}MnN_8O_4$ $[M^+ - Cl]$ 1023.5057, found 1023.4670.

X-ray Crystallographic Analyses of 3·H_2O, 5·$C_2H_2O_4$, 7·H_2O and 9·H_2O·THF: Single crystals of **3**·H_2O and **7**·H_2O were obtained by layering MeOH onto a $CHCl_3$ solution of **3** or **7**. By adding oxalic acid in the MeOH layer, single crystals of **5**·$C_2H_2O_4$ were obtained similarly. Single crystals of **9**·H_2O·THF were obtained by layering hexane onto a THF solution of **9**. Crystal data and details of data collection and structure refinement are given in Table 2. Data collection for all these compounds was performed with a Bruker SMART CCD diffractometer with Mo-K_α radiation (λ = 0.71073 Å) in a sealed tube at 293 K, using an ω-scan mode with an increment of 0.3°. Preliminary unit cell parameters were obtained from 45 frames. Final unit cell parameters were derived by global refinements of reflections obtained from integration of all of the frame data. The collected frames were integrated by using the preliminary cell-orientation matrix. The following software was employed: SMART to collect frames of data, index reflections, and determine the lattice constants; SAINT-PLUS to integrate the intensity of reflections and for scaling;[25] SADABS for absorption correction;[26] and SHELXL for space group and structure determination, refinements, graphics, and structure reporting.[27] CCDC-212501 to -212504 contain the supplementary crystallographic data for **3**·H_2O, **5**·$C_2H_2O_4$, **7**·H_2O and **9**·H_2O·THF, respectively. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

η^1-P_{basal} Coordination of P_4X_3 (X = S, Se) Molecules toward 16e Ruthenium Fragments

Massimo Di Vaira,[a] Isaac de los Rios,[a] Fabrizio Mani,[a] Maurizio Peruzzini,[b] and Piero Stoppioni*[a]

Keywords: Ruthenium / Cyclopentadienyl ligands / Bidentate ligands / Density functional calculations

Ruthenium(II) pentamethylcyclopentadienyl complexes [Ru(η^5-C_5Me_5)Cl(L–L)] [L–L = 1,2-bis(diphenylphosphanyl)-ethane, dppe (**1**), bis(diphenylphosphanyl)methane, dppm, *cis*-1,2-bis(diphenylphosphanyl)ethylene, dppet, and (1-diphenylarsanyl-2-diphenylphosphanyl)ethane, dpadppe] treated with a stoichiometric amount of P_4X_3 (X = S, Se) in THF have yielded the compounds [Ru(η^5-C_5Me_5)(L–L)-(P_4X_3)]BPh_4 (X = S, Se). In the P_4Se_3 derivatives the heptatomic cage is bound to the metal through a basal phosphorus atom. The P_4S_3 derivatives have been obtained as pairs of coordination isomers, with the cage linked either through the apical or through one of the basal P atoms, the latter form predominating (95% abundance), irrespective of the L–L ligand. The monometal complex [Ru(η^5-C_5Me_5)(dppe)(η^1-P_{basal}-P_4Se_3)]BPh_4 reacts with **1** to afford the dimetal compound [{Ru(η^5-C_5Me_5)(dppe)}$_2$(μ,$\eta^{1:1}$-P_{basal}-P_{apical}-P_4Se_3)]-(BPh_4)$_2$, where the cage exhibits both modes of bonding. The compounds have been characterized by NMR spectra (^{1}H, ^{13}C and ^{31}P) and elemental analyses. A theoretical analysis of the bonding properties of the two coordination isomer types is also presented.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The mixed cage molecules E_4X_3 (E = P, As; X = S, Se) (Scheme 1, **I**) possess a unique structure exhibiting a pseudo-tetrahedral array of pnicogen atoms, where a homocyclic E_3 unit is connected via three bridging chalcogen atoms to a single pnicogen in the apical position.[1] Their behaviour towards transition metal fragments has been widely studied and various compounds containing E_mX_n units, which originate from the disruptive fragmentation of the heptatomic cages, particularly P_4S_3 and As_4S_3, have been described.[2−6] Although such units, stabilized by the metal moieties, are considered to form through stepwise disruption and/or formation of E−E bonds following the initial interaction of the intact E_4X_3 cage with the metal fragment, primary complexation of the cages has been accomplished only in few instances, e.g. with Lewis acidic metal fragments which, upon coordination, yield electronically saturated compounds having either octahedral, e.g. [$M(CO)_{5-x}(\eta^1$-$P_4S_3)_{1+x}$] [Scheme 1: M = Mo, W; x = 0

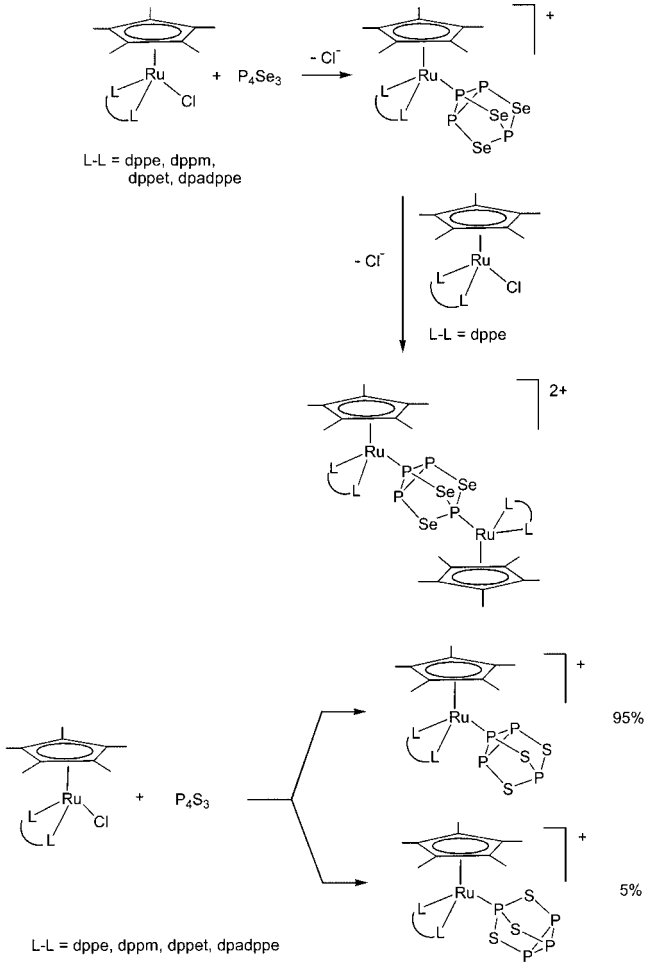
(**II**);[7] M = Cr, Mo, W; $x = 1$, (**III**);[8] M = Cr, Mo; $x = 2$ (**IV**)[8]], or tetrahedral geometry in the presence of sterically protecting groups on the coligand, e.g. $[(NP_3)M(\eta^1\text{-}P_4X_3)]$, **V** [$NP_3$ = tris(diphenylphosphanylethyl)amine; M = Ni,[9] Pd;[10] X = S, Se].

All of the above compounds, characterized by either X-ray diffraction analysis or ^{31}P NMR spectroscopy, contain the cage bound to the metal through the apical phosphorus atom, which, accordingly, has been considered a better donor than a basal phosphorus atom. Recently the 16e $[(triphos)Re(CO)_2]^+$ fragment[11] [triphos = 1,1,1-tris(diphenylphosphanylmethyl)ethane] has yielded, in the presence of P_4X_3 (X = S, Se), a mixture of Re-η^1-P_{apical} and Re-η^1-P_{basal} complexes, the latter being predominant (ca. 87%). Both, apical and basal P_4X_3 complexes with the Lewis acids BBr_3, BI_3 and $NbCl_5$ have been reported.[12] Conversely, P_4X_3 weak complexes with the silver ion have been reported in which the intact cage interacts with the metal through one sulfur and both the apical and one basal P atoms.[13]

We report here on the synthesis and characterization of the family of novel η^1-tetraphosphorus trichalcogenide complexes $[Ru(\eta^5\text{-}C_5Me_5)(L{-}L)(\eta^1\text{-}P_4X_3)]BPh_4$ [L−L = 1,2-bis(diphenylphosphanyl)ethane, dppe, bis(diphenylphosphanyl)methane, dppm, *cis*-1,2-bis(diphenylphosphanyl)ethylene, dppet, and (1-diphenylarsanyl-2-diphenylphosphanyl)ethane, dpadppe; X = S, Se]. In the P_4Se_3 derivatives the intact cage is bound to the metal fragment through a basal P atom. The P_4S_3 compounds present a mixture of Ru-η^1-P_{apical} and Ru-η^1-P_{basal} coordination isomers. All compounds have been characterized by NMR measurements. L−L ligands with different electronic and geometric requirements do not affect the binding properties of the metal fragments, which are highly specific for a basal phosphorus atom of the cage. The monometal complex $[Ru(\eta^5\text{-}C_5Me_5)(dppe)(\eta^1\text{-}P_{basal}\text{-}P_4Se_3)]BPh_4$ yields, in the presence of $[Ru(\eta^5\text{-}C_5Me_5)Cl(dppe)]$, the dinuclear compound $[\{Ru(\eta^5\text{-}C_5Me_5)(dppe)\}_2(P_4Se_3)](BPh_4)_2$ which combines the Ru-η^1-P_{apical} and Ru-η^1-P_{basal} coordination modes. Repeated attempts to obtain the compounds in crystalline form, suitable for X-ray investigations, failed. Their structures and bonding were then investigated by computational methods.

Results and Discussion

The pseudo-octahedral complexes $[Ru(\eta^5\text{-}C_5Me_5)Cl(L{-}L)]$ [L−L = ddpe (**1**), dppm (**2**), dppet (**3**), dpadppe (**4**)], which easily dissociate the chloride in solution,[14−16] react in THF with one equivalent of P_4X_3 (X = S, Se) to form a brick-red solution. Upon addition of $NaBPh_4$ and after workup the compounds $[Ru(\eta^5\text{-}C_5Me_5)(L{-}L)(\eta^1\text{-}P_4X_3)]BPh_4$ are isolated as microcrystalline solids in fairly good yield. The solids are soluble in CH_2Cl_2, THF and $(CH_3)_2CO$; they are stable under an inert atmosphere and may be handled in air for a limited time. Elemental analysis of the products confirms the formation of 1:1 adducts between the $[Ru(\eta^5\text{-}C_5Me_5)(L{-}L)]^+$ synthon and the P_4X_3 molecule. The formation of the P_4X_3 derivatives is sketched in Scheme 2.



Scheme 2

The compounds have been characterized by ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR measurements. The intensity ratios of the $^{31}P\{^1H\}$ signals accord with the proposed formulae; the NMR spectroscopic data of the uncoordinated and the coordinated P_4X_3 cages, and the labelling scheme used for the different phosphorus nuclei, are shown in Table 1.

Characterization of the P_4Se_3 Coordination Compounds

The P_4Se_3 derivatives $[Ru(\eta^5\text{-}C_5Me_5)(L{-}L)(P_4Se_3)]BPh_4$ [L−L = dppe (**5**), dppm (**6**) and dppet (**7**)] exhibit in their $^{31}P\{^1H\}$ NMR spectra an A_2FM_2Q spin system which is consistent with the P_4Se_3 cage molecule being bound to the metal through one basal phosphorus atom. The diphosphane ligand P atoms (P_A) of each compound yield a doublet due to coupling with the P_Q atom of the cage bound to the metal; both the chemical shifts and coupling constants have values expected for ruthenium(II) half-sandwich compounds.[10,14,17] The heptatomic cage yields the FM_2Q part of the spin system (Table 1). The two equivalent uncoordinated basal P_M atoms yield a doublet of doublets in the

[a] NMR spectra were recorded at room temperature with a Varian Gemini g300bb spectrometer. Key: d = doublet, t = triplet, q = quadruplet, m = multiplet. [b] P_M atoms of compounds with the phosphars ligands **8** and **13** (major isomer) are diastereotopic. [c] Spectrum recorded in CD_2Cl_2. [d] Spectrum recorded in $(CD_3)_2CO$. [e] Only one P_A atom present.

spectra of **5, 6** and **7**, characterized by a small coupling with P_F and a large one to P_Q (ca. 240 Hz). The dpadppe compound **8** exhibits an AFMM′Q spin system in which the two basal uncoordinated phosphorus atoms of the cage are diastereotopic for L−L ligands of different donors (one P and one As) which make the ruthenium atom chiral. The resonance of P_M atoms is moderately shielded with respect to the three equivalent basal P atoms of the free cage (Table 1), whereas the P_Q resonance is shifted notably downfield. The uncoordinated P_F apical atom of the cage in **5−8** yields a doublet of triplets which is slightly downfield shifted with respect to the free ligand. The spectra of compounds **5**, **6** and **7** do not change from −60 to +50 °C (^{31}P NMR experiment in a sealed tube). Due to the limited solubility of the compounds ^{77}Se NMR spectra were not recorded.

The monometal compound [Ru(η^5-C_5Me_5)(dppe)(P_4Se_3)]BPh_4 (**5**) dissolved in THF reacts with the chloride labile **1** to form, after workup, the dimetal species [{Ru(η^5-C_5Me_5)(dppe)}$_2$(P_4Se_3)]$(BPh_4)_2$ (**9**). The ^{31}P NMR spectrum of the compound (Table 1) yields an $A_2A'_2FM_2Q$ spin system, consistent with double metallation of the P_4Se_3 molecule, which holds the two non-equivalent [{Ru(η^5-C_5Me_5)(dppe)] metal units together and is responsible for the FM_2Q part of the spin system. The coupling constants of the two resolved multiplets due to the cage phosphorus atoms (the apical and a basal one) bound to the metal fragments are particularly useful to assign the signals of the dppe ligands in the two ruthenium fragments, occurring in a narrow region (71.1 and 72.0 ppm). The apical phosphorus atom of P_4Se_3 bound to the metal undergoes a significant downfield shift upon coordination; the same trend, although less pronounced, occurs for the [(triphos)Re(CO)$_2$(P_4Se_3)]$^+$ cation.[11] Although polymetallic cluster compounds containing two[18] or three[19] bridging P_4S_3 units, formed through activation of a P−P bond, and tetrametallic compounds containing the P_4Se_3 unit, resulting from the cleavage of P−P and P−Se bonds,[6] have been described, the present dimetal species exhibits the intact P_4Se_3 molecule in a bridging position between two transition metal fragments, in analogy with the very recently reported P_4S_3 silver adducts.[13]

Characterization of the P_4S_3 Coordination Compounds

The $^{31}P\{^1H\}$ NMR spectra of the [Ru(η^5-C_5Me_5)(L-L)(P_4S_3)]BPh_4 compounds [L−L = dppe (**10**), dppm (**11**), dppet (**12**) and dpadppe (**13**)] indicate a pair of coordination isomers, present in a ratio of ca. 19:1, that differ in the bonding mode of the P_4S_3 molecule to the metal fragment: either through the apical P or through one of the

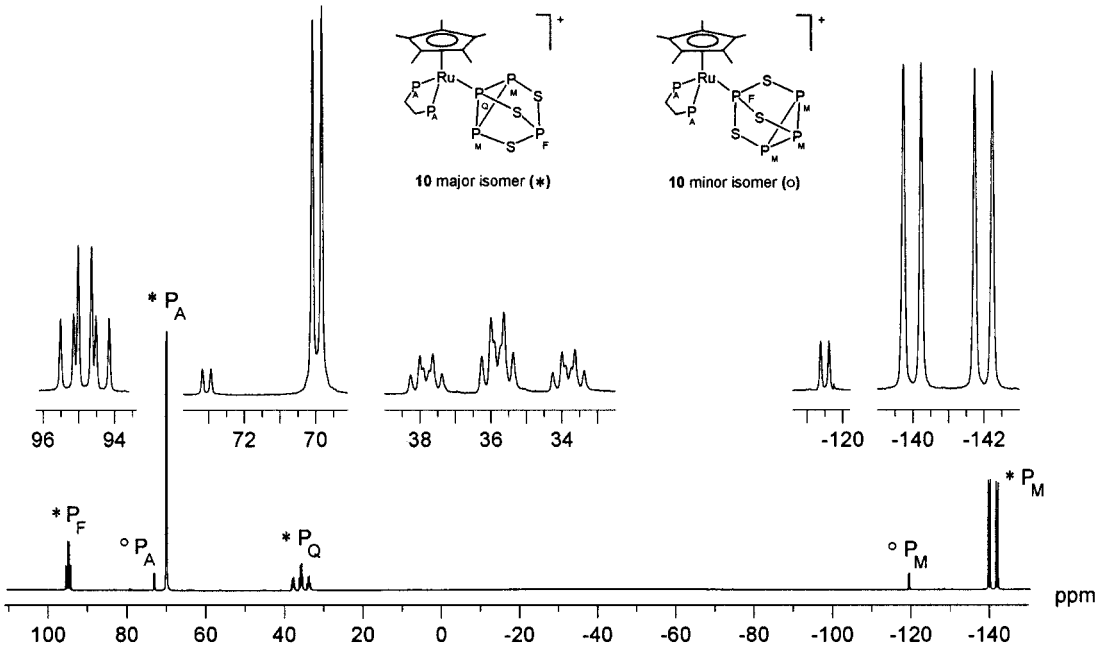

Figure 1. $^{31}P\{^{1}H\}$ NMR spectrum of $[Ru(\eta^5\text{-}C_5Me_5)(dppe)(P_4S_3)]BPh_4$ in CD_2Cl_2. The multiplet due to P_F of the minor isomer, a weak, broad signal at $\delta = 150.6$ ppm, is not reported.

basal P atoms (Scheme 2). This is supported by the $^{31}P,^{31}P$-2D COSY NMR spectra of **10** and **11**, which show two sets of correlated peaks. The $^{31}P\{^{1}H\}$ spectrum of $[Ru(\eta^5\text{-}C_5Me_5)(dppe)(P_4S_3)]BPh_4$ (**10**) is shown in Figure 1.

The major isomers of **10**, **11** and **12** exhibit an A_2FM_2Q spin system (Table 1), indicative of coordination by the cage through a basal P atom. The spectral features parallel those of the P_4Se_3 derivatives, with the cage accounting for the FM_2Q part of the spin system. The P_M signal is split, with unequal P_M-P_Q and P_M-P_F coupling constants, as found for **5**−**7** and the related rhenium compound $[(triphos)Re(CO)_2(P_4S_3)]^+$.[11] The downfield shift of the P_Q signal is larger than that of the rhenium analog.[11] As discussed above for **8**, the major isomer of the dpadppe derivative **13** exhibits an AFMM′Q spin system due to the chirality of the metal atom. The chemical shifts and coupling constants are similar to those of the major isomers of **10**−**12**.

The minor isomers of **10**, **11** and **12** exhibit an A_2FM_3 spin system (Table 1), consistent with coordination of the intact cage to the metal via the apical P_F atom. The L−L ligand P_A atoms yield a doublet at the expected field. The FM_3 part of the splitting pattern, due to the cage, exhibits chemical shifts and coupling constants in agreement with those of the corresponding coordination isomer of the rhenium compound previously described.[11] The signals of the P_4S_3 phosphorus atoms do not significantly depend on the ancillary L−L ligand (Table 1). Notably, the ruthenium-bonded P_F atom resonance occurs at low field (142−155 ppm) as a complex multiplet due to coupling with P_A and P_M; the P_F-P_M coupling constant is smaller than for the free cage (Table 1) and approaches that with the phosphane P_A. In keeping with the proposed structure, the three basal P_M atoms afford a doublet due to coupling with P_F. The minor isomer of the dpadppe derivative, **13**, yields an AFM_3 spin system, as expected, due to the presence of only one magnetically active P atom in the dpadppe ligand. The $^{31}P\{^{1}H\}$ NMR spectra of **10**, **11** and **13**, obtained in the temperatures range −60 to +50 °C (experiment in a sealed tube), do not show any dynamic process and the relative amounts of the two isomers do not change. This rules out an equilibrium between the two species which, therefore, should form through independent interactions of the basal and the apical phosphorus atoms of the cage.

Quantum-Mechanical Calculations

In the absence of crystallographic structural data on the compounds quantum-mechanical calculations were undertaken to gain information on the geometries, the relative energies of isomers and to possibly rationalize structural preferences. As described in the Exp. Sect., building on results from preliminary calculations performed on models at various levels of accuracy, the geometry of the lowest-energy conformer found for each of the coordination modes of the cage molecule in the $[Ru(\eta^5\text{-}C_5Me_5)(dppe)(P_4S_3)]^+$ cation (i.e., coordination through the apical phosphorus atom, P_{apc} hereafter, or through a basal one, P_{bas}), was optimized at the B3LYP/6−31G(d) level, with metal atom ECP functions.[20] These two models will be referred to as **10**apc and **10**bas, respectively. After Se for S substitution in the former models and subsequent optimizations, models **5**apc and **5**bas for the $[Ru(\eta^5\text{-}C_5Me_5)(dppe)(P_4Se_3)]^+$ cation were obtained. Representations of the **10**apc and **10**bas isomers are shown in Figure 2; those of the **5**apc and **5**bas models are similar and are given, with more details, with the Sup-

[c] Bond lengths (Å) within the free cage molecules (possessing threefold symmetry), from calculations at the B3LYP/6−31G(d) level, are [averages of experimental values from ref.[21] (P_4S_3) and refs.[10,19,22] (P_4Se_3) in parentheses]: P_4S_3, P_{apc}−S = 2.150 (2.06), P_{bas}−S = 2.139 (2.09), P_{bas}−P_{bas} = 2.276 (2.23); P_4Se_3, P_{apc}−Se = 2.276 (2.25), P_{bas}−Se = 2.264 (2.23), P_{bas}−P_{bas} = 2.270 (2.24).

porting Information (S.I.). Relative energy values within isomer pairs and essential data on geometries are presented in Table 2.

For both pairs of isomers the calculations yielded the species with the cage bound through the base as being slightly more stable than the "apical" isomer, with increasing energy separation between the isomers on going from the models of the P_4S_3 derivative to those of P_4Se_3. Although this trend qualitatively agrees with the NMR spectroscopic data, it is difficult to rationalize in terms of a restricted number of factors, due to the complexity of the systems and to the fine balance in energies. However, the following considerations may shed some light on the preferences for the two coordination modes of these cage molecules with respect to the $Ru(\eta^5\text{-}C_5Me_5)(dppe)$ metal−ligand system.

From calculations at the consistent B3LYP/6−31G(d) level on the isolated P_4S_3 and P_4Se_3 molecules, the (twofold degenerate) HOMO for both systems has important contributions from the P_{bas} atoms. An MO with dominant P_{apc} contribution lies 69.0 kJ·mol^{-1} (P_4S_3) and 89.9 kJ·mol^{-1} (P_4Se_3) below the HOMO; the situation is not substantially altered if calculations on the cages are performed at a better level, such as the B3LYP/6−31++G(2d). This suggests that, based only on these energy differences, a P_{bas} atom should be a better donor than P_{apc}, particularly for the P_4Se_3 cage, towards empty metal orbitals. Conversely, according to the localized orbital picture of the NBO approach, the lone pair (lp) of a P_{bas} atom lies at lower energy than the P_{apc} lp; however, the gap between the two decreases (from 66.9 to 26.3 kJ·mol^{-1}) on going from P_4S_3 to P_4Se_3.

The NBO analysis generally describes, at second-order perturbation theory level, the interaction between the cage and the metal as mostly consisting of donation from the P_{bas} (or P_{apc}) lp into a lobe of an antibonding orbital of the metal−ligand moiety. The **5**bas model, however, is peculiar since (a) the P_{bas} lp is involved in more than one fractional interaction of the above type, (b) Ru empty orbitals, rather than Ru-based antibonding acceptor MOs, are involved in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

such interactions and (c) no significant repulsive interactions of the P_{bas} lp with bonding (filled) orbitals of the metal moiety are detected, contrary to the other three models. These features, pointing to a comparatively higher strength of the P_{bas}−Ru interaction in the **5**bas system, result from several small changes in MO compositions and energies, and are difficult to analyse in deeper detail. Overall, the cage molecules transfer electron density to the metal moiety, with apparently negligible back-donation, according to the NBO perturbation treatment (but see below: changes in antibonding orbital populations). The amount of transferred charge (q, a.u.) increases from apical to basal coordination and, for a given coordination mode, increases on going from P_4S_3 to P_4Se_3. The, perhaps slightly overestimated, $|q|$ are: 0.196 **10**apc, 0.214 **10**bas, 0.199 **5**apc and 0.228 **5**bas.

The cage molecules undergo only small changes in geometry upon coordination, although some trends are evident. The most significant of these may be rationalized by considering the variations in the populations of the bonding and (to a greater extent) antibonding localized orbitals, according to the NBO picture. In particular, the 0.02 Å (P_4S_3) or 0.04 Å (P_4Se_3) elongation of the P_{apc}−S/Se bonds upon coordination in the apical mode (Table 2, including footnote c for the free cage molecules) can be accounted for by the modest decrease (1%) in the P_{apc}−S/Se bonding populations and considerable increase in the antibonding ones (e.g., from 0.137 to an average 0.205 a.u. for **10**apc) for both cages. Similarly, for basal coordination by P_4S_3 (**10**bas; trends are strictly similar for the Se analog **5**bas) where the P(2)−S(1) bond elongates by 0.012 Å and the S(1)−P(1) bond shortens by 0.021 Å with respect to the computed free cage values, the corresponding antibonding orbital NBO populations increase (from 0.080 to 0.153 a.u.) and, respectively, decrease (from 0.137 to 0.103 a.u.). Such trends, predominantly indicative of back donation, may be reconciled with the overall flow of negative charge *towards* the metal moiety considering that complex charge redistributions are allowed by the topology of the cage molecules.

As noted for the P_4S_3 molecule in a related study,[11] calculated bond lengths for both cage molecules here, whether coordinated or uncoordinated (Table 2), are slightly larger than the experimental values;[10,21−23] this could be due in part to effects of thermal motion causing an apparent shortening of the bonds in the diffraction experiments on the free cage molecules. The calculated Ru-P(dppe) distances (Table 2) are longer than generally found for dppe ruthenium complexes with a similar environment, although the experimental values span a large range, e.g., from 2.28 [24] to 2.41 Å.[25] Also, the calculated Ru−C are longer than the experimental ranges for η^5-C_5Me_5 (2.20−2.26 Å,[26] 2.25−2.34 Å[25]). These results may reflect the limitations of the present approach (nature of the particular DFT potential[27−29] and of the metal ECP[20] used), but may be caused by overcrowding around the metal atom in the present systems. A theoretical study on the adducts of the present cage molecules with BX_3 (X = Br, I) and $NbCl_5$ Lewis acids[12] has reached quite similar conclusions for the energetics, although more detailed comparisons are prevented by differences between the systems.

Conclusions

$[Ru(\eta^5\text{-}C_5Me_5)(L\text{-}L)]^+$ metal fragments are rather specific for basal coordination by the P_4X_3 cage molecules, independently of moderate changes in the L−L ligand. Combined with previous results for $[(triphos)Re(CO)_2(P_4X_3)]CF_3SO_3$ compounds,[11] the present ones suggest that the coordination mode of the P_4X_3 molecules through one of the basal phosphorus atoms is competitive with the apical mode and the balance between the two coordination isomers may be set by subtle properties of the metal fragments and by minor features of their interactions with the cage molecules.

Experimental Section

All reactions and manipulations were performed under an atmosphere of dry oxygen-free argon. THF was freshly distilled from sodium; dichloromethane, *n*-hexane, methanol and ethanol were degassed and flushed with argon prior to use. The ^1H, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR spectra were measured on a Varian Gemini g300bb spectrometer, equipped with a variable-temperature unit, operating at 300 MHz (^1H), 121.46 MHz (^{31}P) and 75.46 MHz (^{13}C). Chemical shifts are relative to tetramethylsilane and to H_3PO_4 85% as external standards at δ = 0.00 ppm; coupling constants are given in Hertz. Analytical data for carbon, hydrogen and sulfur were obtained from the Microanalytical Laboratory of the Department of Chemistry of the University of Firenze. The ligands 1,2-bis(diphenylphosphanyl)ethane (Aldrich), dppe, bis(diphenylphosphanyl)methane (Aldrich), dppm, *cis*-1,2-bis(diphenylphosphanyl)ethylene (Aldrich), dppet, and (1-diphenylarsanyl-2-diphenylphosphanyl)ethane (Pressure Chemical Company), dpadppe, were used as purchased. P_4S_3 was purchased from Fluka AG. and recrystallized from toluene before use. P_4Se_3 was synthesized from red phosphorus and grey selenium as described previously.[30] The complexes $[Ru(\eta^5\text{-}C_5Me_5)Cl(L\text{-}L)]$ [L−L = dppe (**1**) and dppm (**2**)] were synthesized according to the literature method.[14] The complexes $[Ru(\eta^5\text{-}C_5Me_5)Cl(L\text{-}L)]$ [L−L = dppet (**3**) and dpadppe (**4**)] are new and were synthesized by the same procedure reported for **1** and **2**.[14] The ^1H, and $^{13}C\{^1H\}$ NMR spectroscopic data of the compounds, together with the $^{31}P\{^1H\}$ NMR data of the phosphane ligands are reported here. For the minor isomers of **10**−**13** the weak ^1H resonances of the L−L ligand aliphatic protons and the ^{13}C signals were not observed. The uninformative ^1H and $^{13}C\{^1H\}$ signals of phenyl groups of the L−L ligands and of the tetraphenylborate anion, occurring in the expected regions of 6.8−7.5 and 133.5−130.0 ppm, respectively, are not reported.

C 64.7, H 5.6; found C 64.5, H 5.8. ^1H NMR ($CDCl_3$, 298 K): δ = 2.01 [s, 15 H, br, $C_5(CH_3)_5$] and 7.85 (s, 2 H, br, PC*H*). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 298 K): δ = 6.2 [br. s, $C_5(CH_3)_5$], 94.5 [br. s, $C_5(CH_3)_5$] and 137.5 (br. s, P*C*H). $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ = 94.5 (s).

$[Ru(\eta^5\text{-}C_5Me_5)Cl(dpadppe)]$ (4): Yellowish orange microcrystals, yield 82%. $C_{36}H_{39}AsClPRu$ (714.1): calcd. C 60.6, H 5.5; found C

60.4, H 5.6. ^{1}H NMR (C_6D_6, 298 K): δ = 1.67 [s, 15 H, br, $C_5(CH_3)_5$], 2.40 (s, 2 H, br, $AsCH_2$) and 2.76 (s, 2 H, br, PCH_2). $^{13}C\{^1H\}$ NMR (C_6D_6, 298 K): δ = 10.1 [br. s, $C_5(CH_3)_5$], 24.1 (br. s, $AsCH_2$), 28.7 (br. s, PCH_2) and 87.6 [br. s, $C_5(CH_3)_5$]. $^{31}P\{^1H\}$ NMR (C_6D_6, 298 K): δ = 76.4 (s).

[Ru(η^5-C_5Me_5)(dppe)(P_4Se_3)]BPh_4 (5): P_4Se_3 (175 mg, 0.5 mmol) dissolved in THF (30 mL) at 40 °C was added to a THF solution (15 mL) of (**1**) (335 mg, 0.5 mmol); neat $NaBPh_4$ (250 mg, 0.7 mmol) was then added. The resulting solution was stirred at room temperature for 2 h. An ethanol/light petroleum (1:1) solution (15 mL) was then slowly added, and orange microcrystals were obtained by slowly evaporating the resulting solution. Yield 60%. $C_{60}H_{59}BP_6RuSe_3$ (1314.7): calcd. C 54.8, H 4.5; found C 54.5, H 4.7. ^{1}H NMR (CD_2Cl_2, 298 K): δ = 1.56 [dt, 15 H, $^4J(H-P_Q)$ = 3.0, $^4J(H-P_A)$ = 1.8 Hz, $C_5(CH_3)_5$], 2.38, 2.82 (m, 4 H, PCH_2). $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 10.8 [s, $C_5(CH_3)_5$], 27.3 [t, $^1J(C-P_A)$ = 22.6 Hz, PCH_2], 98.5 [s, $C_5(CH_3)_5$]. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 72.2 [2 P, d, $^2J(P_A-P_Q)$ = 27.5 Hz].

The compounds [Ru(η^5-C_5Me_5)(L-L)(P_4Se_3)]BPh_4 [L−L = dppm (**6**), dppet (**7**) and dpadppe (**8**)] were prepared by the same procedure as for **5**.

[Ru(η^5-C_5Me_5)(dppm)(P_4Se_3)]BPh_4 (6): Yield 62%. $C_{59}H_{57}BP_6RuSe_3$ (1300.7): calcd. C 54.5, H 4.4; found C 54.8, H 4.3. ^{1}H NMR [$(CD_3)_2CO$, 298 K]: δ = 1.79 [dt, 15 H, $^4J(H-P_Q)$ = 3.0, $^4J(H-P_A)$ = 2.1 Hz, $C_5(CH_3)_5$], 3.91, 4.72 (1 H each, m, PCH). $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 11.7 [s, $C_5(CH_3)_5$], 46.1 [t, $^1J(C-P_A)$ = 24.0 Hz, PCH_2], 98.6 [s, $C_5(CH_3)_5$]. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 2.4 [2P, d, $^2J(P_A-P_Q)$ = 29.7 Hz].

[Ru(η^5-C_5Me_5)(dppet)(P_4Se_3)]BPh_4 (7): Yield 60%. $C_{60}H_{57}BP_6RuSe_3$ (1312.7): calcd. C 58.9, H 4.4; found C 58.6, H 4.4. ^{1}H NMR (CD_2Cl_2, 298 K): δ = 1.59 [dt, 15 H, $^4J(H-P_Q)$ = 2.7, $^4J(H-P_A)$ = 1.8 Hz, $C_5(CH_3)_5$]; the ^{1}H and ^{13}C signals of the ligand CH group were masked by the aromatic resonances. $^{13}C\{^1H\}$ NMR [$(CD_3)_2CO$, 298 K]: δ = 11.6 [s, $C_5(CH_3)_5$], 98.6 [s, $C_5(CH_3)_5$], 130.9 [vt, $^1J(C-P_A)$ = 5.8 Hz, PCH)]. $^{31}P\{^1H\}$ NMR [$(CD_3)_2CO$, 298 K]: δ = 76.7 [2P, d, $^2J(P_A-P_Q)$ = 31.9 Hz].

[Ru(η^5-C_5Me_5)(dpadppe)(P_4Se_3)]BPh_4 (8): Yield 63%. $C_{60}H_{59}AsBP_5RuSe_3$ (1358.7): calcd. C 53.0, H 4.4; found C 53.1, H 4.3. ^{1}H NMR [$(CD_3)_2CO$, 298 K]: δ = 1.66 [dd, 15 H, $^4J(H-P_Q)$ = 2.7, $^4J(H-P_A)$ = 1.8 Hz, $C_5(CH_3)_5$], 2.38 (s, 2 H, br, $AsCH_2$), 2.78 (s, 2 H, br, PCH_2). $^{31}P\{^1H\}$ NMR [$(CD_3)_2CO$, 298 K]: δ = 74.4 [1P, dd, $^2J(P_A-P_Q)$], 33.5 [$^3J(P_A-P_M)$ = 6.0 Hz].

[{Ru(η^5-C_5Me_5)(dppe)}$_2$(P_4Se_3)]$(BPh_4)_2$ (9): [Ru(η^5-C_5Me_5)Cl(dppe)] (**1**) (170 mg, 0.25 mmol) dissolved in THF (15 mL) was added to **5** (263 mg, 0.20 mmol) in THF (20 mL). The resulting solution was stirred at room temperature for 1 h; neat $NaBPh_4$ (96 mg, 0.28 mmol) was then added. Orange microcrystals were subsequently obtained by adding an ethanol/light petroleum (1:1) mixture (15 mL) and by concentrating the solution. Yield 50%. $C_{120}H_{118}B_2P_8Ru_2Se_3$ (2268.7): calcd. C 63.5, H 5.2; found C 63.3, H 5.2. ^{1}H NMR (CD_2Cl_2, 298 K): δ = 1.48 [30 H, br, $C_5(CH_3)_5$], 2.43, 2.86 (s, 8 H, br, PCH_2). $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 11.2, 11.5 [s, $C_5(CH_3)_5$], 28.5, 29.7 [d, $^1J(C-P_A)$ = 24.0 Hz, (PCH_2)], 99.1, 101.1 [s, $C_5(CH_3)_5$]. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 71.1 [2P, d, P_A, $^2J(P_A-P_Q)$ = 30.4 Hz], 72.0 [2P, d, $P_{A'}$, $^2J(P_A-P_F)$ = 25.5 Hz].

[Ru(η^5-C_5Me_5)(dppe)(P_4S_3)]BPh_4 (10): A THF solution (15 mL) of **1** (335 mg, 0.5 mmol) was added to P_4S_3 (110 mg, 0.5 mmol) dissolved in THF (15 mL); neat $NaBPh_4$ (250 mg, 0.7 mmol) was then added. The resulting solution was stirred at room temperature for 2 h. An ethanol/light petroleum ether (1:1) solution (15 mL) was then slowly added, and yellow microcrystals were obtained by slowly evaporating the resulting solution. Yield 65%. $C_{60}H_{59}BP_6RuS_3$ (1174.0): calcd. C 61.4, H 5.1, S 8.2; found C 60.9, H 5.2, S 8.0. Major isomer: ^{1}H NMR (CD_2Cl_2, 298 K): δ = 1.52 [dt, 15 H, $^4J(H-P_Q)$ = 3.3, $^4J(H-P_A)$ = 1.5 Hz, $C_5(CH_3)_5$], 2.40, 2.80 (m, 4 H, PCH_2). $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 10.8 [s, $C_5(CH_3)_5$], 27.4 [t, $^1J(C-P_A)$ = 22.4, PCH_2], 98.6 [s, $C_5(CH_3)_5$]. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 69.3 [2 P, d, $^2J(P_A-P_Q)$ = 31.4]. Minor isomer: ^{1}H NMR (CD_2Cl_2, 298 K): δ = 1.62 [dt, 15 H, $^4J(H-P_F)$ = 2.7, $^4J(H-P_A)$ = 1.5 Hz, $C_5(CH_3)_5$]. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 67.0 [2 P, d, $^2J(P_A-P_F)$ = 28.7 Hz].

The compounds [Ru(η^5-C_5Me_5)(L−L)(P_4S_3)]BPh_4 [L−L = dppm (**11**), dppet (**12**) and dpadppe (**13**)] were prepared by the same procedure as for **10**.

[Ru(η^5-C_5Me_5)(dppm)(P_4S_3)]BPh_4 (11): Yield 65%. $C_{59}H_{57}BP_6RuS_3$ (1160.0): calcd. C 61.4, H 5.1; found C 60.9, H 5.2. [Ru(η^5-C_5Me_5)(dpadppe)(P_4S_3)]BPh_4 (13): Yield 70%. $C_{60}H_{59}AsBP_5RuS_3$ (1218.0): calcd. C 59.2, H 4.9; found C 59.1, H 4.8. Major isomer: ^{1}H NMR (CD_2Cl_2, 298 K): δ = 1.58 [dd, 15 H, $^4J(H-P_Q)$ = 3.3, $^4J(H-P_A)$ = 1.8 Hz, $C_5(CH_3)_5$], 2.44 (s, 2 H, br, $AsCH_2$), 2.78 (s, 2 H, br, PCH_2). $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 10.8 [s, $C_5(CH_3)_5$], 20.9 [d, $^2J(C-P_A)$ = 11.0 Hz, $AsCH_2$], 30.1 [dd, $^1J(C-P)$ = 32.7, $^3J(C-P_Q)$ = 5.4 Hz, PCH_2], 97.3 [s, $C_5(CH_3)_5$]. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 73.1 [1 P, dd, $^2J(P_A-P_Q)$ = 36.0, $^3J(P_A-P_M)$ = 7.0]. Minor isomer: ^{1}H NMR (CD_2Cl_2, 298 K): δ = 1.58 [dd, 15 H, $^4J(H-P_Q)$ = 3.3, $^4J(H-P_A)$ = 1.8 Hz, $C_5(CH_3)_5$]. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 76.1 [1 P, d, $^2J(P_A-P_F)$ = 27.4 Hz].

Computational Procedures

Calculations were performed on models of the [Ru(η^5-C_5Me_5)(dppe)(P_4S_3)]$^+$ and [Ru(η^5-C_5Me_5)(dppe)(P_4Se_3)]$^+$ cations with the GAUSSIAN 98 suite of programs,[31] using the hybrid HF-DFT B3LYP method.[27−29] Preliminary geometry optimizations (not reported), were performed (a) on simplified models of the P_4S_3 derivative, where the methyl and phenyl groups were replaced by hydrogen atoms, using the 6−31G(d,p) basis set[32] for the non-metal atoms and the LANL2DZ valence functions and effective core potential (ECP)[20] for ruthenium and (b) on "complete" models, with no simplifying replacements of methyl and phenyl groups using, however, the lower quality 3−21G (C, H) and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3−21G* (P, S)[33,34] basis sets for the non-metal atoms. In these preliminary calculations coordination by the P_4S_3 cage molecule through the apical phosphorus atom, and through one of its basal P atoms, was considered, no symmetry was imposed. Overall, these calculations revealed a delicate energy balance between geometrical isomers differing in the mode of coordination by the cage. Moreover, for each mode the calculations on the "complete" models revealed the existence of several energy minima, characterized by small differences in the corresponding geometries. This was probably due to the effects of numerous non-bonded interactions between the bulky groups surrounding the metal atom. Computationally demanding geometry optimizations on the "complete" models at the better B3LYP/6−31G(d) level (with LANL2DZ Ru functions as above) were then performed, starting from the lowest-energy arrangement detected in the preliminary search for each of the P_4S_3 coordination modes of the $[Ru(\eta^5\text{-}C_5Me_5)(dppe)(P_4S_3)]^+$ system. The two corresponding models for the $[Ru(\eta^5\text{-}C_5Me_5)(dppe)(P_4Se_3)]^+$ cation were obtained by substitution of Se for S in the former P_4S_3 optimized models and underwent optimization in turn. Frequency calculations were performed for the four final models [a small negative (imaginary) frequency of -11 cm^{-1} for the system with apically bound P_4Se_3, at the verge of significance for residual rotational motion of CH_3 groups, was confidently ignored] and unscaled zero-point energy corrections were applied. The interpretation of results was aided by natural bond orbital (NBO) analyses.[35,36] For graphics MOLDEN[37] and ORTEP[38,39] were employed.

Spectroscopic Characterization of an Fe^{IV} Intermediate Generated by Reaction of XO^- (X = Cl, Br) with an Fe^{II} Complex Bearing a Pentadentate Non-Porphyrinic Ligand − Hydroxylation and Epoxidation Activity

Véronique Balland,[a] Marie-France Charlot,[b] Frédéric Banse,*[b] Jean-Jacques Girerd,*[b] Tony A. Mattioli,[a] Eckhard Bill,[c] Jean-François Bartoli,[d] Pierrette Battioni,[d] and Daniel Mansuy[d]

Keywords: Iron / Oxo ligands / Bioinorganic chemistry / Epoxidation / Hydroxylation

Mononuclear Fe^{IV} intermediates have been generated in MeOH upon reaction of sodium hypochlorite or hypobromite with a ferrous complex bearing the pentadentate ligands *N*-methyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)ethane-1,2-diamine (L_5^2) or *N*-methyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)propane-1,3-diamine (L_5^3). These highly unstable green complexes are characterized by an absorption band at ca. 750 nm. Mössbauer data indicate that the iron center is low spin (S = 1) with an axial electronic structure, allowing identification of the mononuclear Fe^{IV} complexes as $[L_5Fe^{IV}O]^{2+}$ or $[L_5Fe^{IV}OCH_3]^{3+}$. In acetonitrile/dichloromethane solutions, the $L_5^3Fe^{IV}$ system exhibits very selective activities toward hydroxylation of cyclohexane or epoxidation of cyclooctene and *cis*-stilbene. Computational studies performed on $[L_5Fe^{IV}O]^{2+}$ and on the model compound $[(NH_3)_5Fe^{IV}O]^{2+}$ reveal that the ground state possesses two unpaired electrons in the two π^* orbitals, as known for O_2. Electronic spectra computed by time-dependent DFT exhibit only one band in the visible region that is essentially due to d-d transitions.

Introduction

Porphyrinic Fe^{IV}−oxo species have been detected by spectroscopy in several heme enzymes[1−7] and their chemical models.[8−11] With respect to non-heme enzymes, studies of Fe^{IV} species are more recent and thus less advanced. Dinuclear $Fe^{III}Fe^{IV}$ or $Fe^{IV}Fe^{IV}$ species have been identified in enzymes[12,13] as well as having been chemically modeled.[14−18] The mononuclear non-heme Fe^{IV}−oxo entity has frequently been postulated in the catalytic cycle of enzymes[19,20] but to date has not been characterized. From reactivity studies of chemical models, Que et al. have postulated mononuclear Fe^{IV}−oxo intermediates.[21] Using macrocyclic tetraamido ligands, mononuclear Fe^{IV}−Cl and Fe^{IV}−CN species have been prepared and studied by Collins et al.[22,23] To the best of our knowledge, the first spectroscopic study of a non-heme mononuclear Fe^{IV}−oxo species was reported by Grapperhauser et al.[24] This complex was obtained with the macrocyclic tetraamino ligand cyclam-acetato. With the ligand tetramethylcyclam (TMC), Rohde et al. very recently obtained the complex $[Fe^{IV}(O)(TMC)(NCCH_3)]^{2+}$ after reaction of iodosylbenzene or H_2O_2 with a ferrous precursor in CH_3CN at −40 °C.[25] Moreover, they were able to obtain its X-ray crystallographic structure, since the species is stable at −40 °C in CH_3CN for at least one month. With the tetradentate tripodal ligand TPA [tris(2-pyridylmethyl)amine)], the same authors obtained the intermediate $[Fe^{IV}(O)(TPA)]^{2+}$.[26] Owing to its relative instability, the latter complex is a more efficient oxygen-atom transfer agent than $[Fe^{IV}(O)(TMC)(NCCH_3)]^{2+}$.

In this paper, we report the preparation and spectroscopic characterization of an Fe^{IV}−oxo (or methoxo) species in methanol with a non-porphyrinic nonmacrocyclic ligand as well as the preliminary study of the reactivity of the Fe^{IV}−oxo form in acetonitrile/dichloromethane.

Our strategy was to use a pentadentate ligand leaving one vacant site on the Fe center which could potentially be occupied by an oxygen species. This allowed us, and others in the past, to obtain low-spin $Fe^{III}OOH$ species.[27−34] For

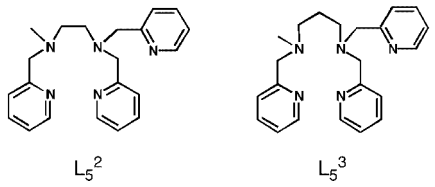
instance, the $Fe^{III}OOH$ species was obtained by addition of an excess of H_2O_2 to $[L_5{}^2Fe^{II}Cl]^+$.[27,30,31,35]

In the same manner, we prepared a low-spin $Fe^{III}OOH$ species with $L_5{}^3$.[36]

In order to generate an $Fe^{IV}O$ entity we adopted the strategy of studying the reaction of the oxygen atom donors ClO^- or BrO^- with $[L_5{}^3Fe^{II}Cl]^+$ and $[L_5{}^2Fe^{II}Cl]^+$ (Scheme 1).



Scheme 1. Pentadentate ligands used in this study

Results and Discussion

UV/Vis Spectroscopy

The reaction of $[L_5{}^3Fe^{II}Cl]PF_6$ at −50 °C in CH_3OH with 2 equiv. of ClO^- was monitored by UV/Vis spectroscopy. Visually, a transient orange color first appeared which quickly changed to green. The green solution exhibited a band at 742 nm which persisted for about 5 min. In Mössbauer samples, this green species correspond to almost 70% of the total Fe. Taking into account the loss of this unstable species upon transfer to the Mössbauer cell, one can assume that in the solution used for UV/Vis spectroscopy, the conversion is almost quantitative. The extinction coefficient is thus $\varepsilon \approx 300\ M^{-1}cm^{-1}$.

The reaction in CH_3OH at 0 °C between $[L_5{}^3Fe^{II}Cl]PF_6$ and 100 equiv. of ClO^- was monitored by stopped-flow UV/Vis spectroscopy (Figure 1).

The maximum intensity of the band at 742 nm was obtained after 100 ms. It completely disappeared under these conditions after 2.5 s. The absorption maximum for the initial orange species was detected at 430 nm and at 0 °C it disappeared in 50 ms.

The same reaction was studied starting from $[L_5{}^2Fe^{II}Cl]PF_6$ and the series of spectra for the first 200 ms is shown in Figure 1. Even though the spectral features are very similar, some differences between the $L_5{}^2$ and $L_5{}^3$ complexes can be noted. The initial absorption band, corresponding to the orange complex, lies at 440 nm. This complex is less fleeting than its $L_5{}^3$ analog since the 440-nm band was still observable as a shoulder after 200 ms. This orange species evolved to the green complex as a clear isobestic point was observed at 503 nm. The green species was characterized by a band at 756 nm with a maximum absorbance weaker than the one observed for the $L_5{}^3$ analog, suggesting a lower conversion into the green species for the $L_5{}^2$ system. This last observation is consistent with the fact that the orange and green complexes coexist in solution in the $L_5{}^2$ system. Finally, the reactivities of $[L_5{}^3Fe^{II}Cl]PF_6$ and $[L_5{}^2Fe^{II}Cl]PF_6$ in the presence of ClO^- are similar but the stabilities of the green and orange species are different.

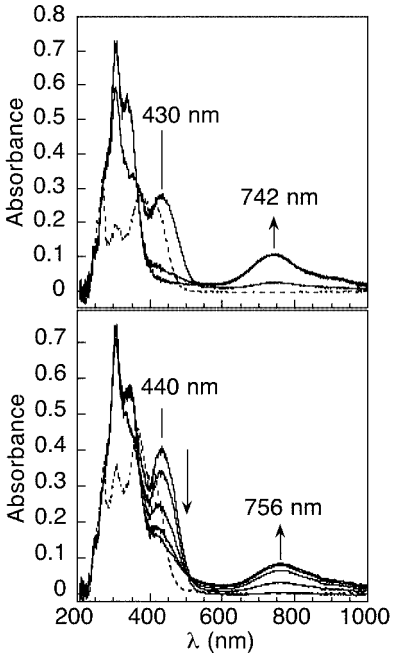


Figure 1. Evolution of the reaction between 0.5 mM $[L_5{}^3Fe^{II}Cl]PF_6$ (top) or $[L_5{}^2Fe^{II}Cl]PF_6$ (bottom) and 100 equiv. of ClO^- monitored in CH_3OH at 0 °C by stopped-flow absorption spectroscopy; the evolutions are shown between 0 and 100 ms for $L_5{}^3$ and 0 and 200 ms for $L_5{}^2$; the spectra in dashed lines are relative to the Fe^{II} starting complexes (0.5 mM)

By ozonolysis of a ferric complex with the ligand cyclamacetato, Grapperhauser obtained an $Fe^{IV}=O$ complex, characterized by a green colour (λ_{max} = 676 nm).[24] The complex $[Fe^{IV}(O)(TMC)(NCCH_3)]^{2+}$ reported by Rohde et al.[25] was also characterized by a pale green colour, with an absorption maximum at 820 nm and an extinction coefficient of 400 $M^{-1}cm^{-1}$. By using the ligand TPA, Lim and co-workers[26] were able to prepare an $Fe^{IV}=O$ complex in CH_3CN at −40 °C. This pale green intermediate exhibited a band at 724 nm with an extinction coefficient of ca. 300 $M^{-1}.cm^{-1}$. These characteristics are similar to the ones observed in the present study.

Mössbauer Spectroscopy

For Mössbauer studies a sample was prepared from $[L_5{}^3Fe^{II}Cl]PF_6$ labeled with 50% ^{57}Fe. The complex was oxidized with 2 equiv. of ClO^- at −60 °C and the green solution thus obtained was quickly frozen to 77 K.

In the absence of an applied magnetic field, the oxidation product exhibited an asymmetric quadrupole doublet at 80 K that could be deconvoluted in two symmetric subspectra. The isomer shift and quadrupole splitting of the minor species [$\delta(2) = 0.35\ mm{\cdot}s^{-1}$, $\Delta E_Q(2) = 0.88\ mm{\cdot}s^{-1}$] indicate the presence of some oxidized Fe^{III} contaminant,[37] whereas the major sub-spectrum (1) can be assigned to the green oxidation product (68% relative abundance, determined from the magnetic spectra given below). The parameters $\delta(1) = 0.02\ mm{\cdot}s^{-1}$ and $\Delta E_Q(1) = 1.20\ mm{\cdot}s^{-1}$ are indicative of low-spin Fe^{IV} species.[38]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Applied field measurements show that the major component (1) in fact possesses integer spin. Weak fields (1 T) at 4.2 K induce only weak magnetic splittings due to the nuclear Zeeman effect resulting from the applied field (Figure 2, top), but the internal fields are vanishingly small according to dominating strong zero-field splittings (zfs) and an $M_S = 0$ ground level without significant level mixing. Sizeable internal fields were detected only at strong fields (7 T) and higher temperatures. In contrast, the contaminating species sub-spectrum (2) shows a wide magnetically split hyperfine pattern due to half-integer spin or even magnetic ordering. The large splittings attenuate the absorptions of this minor contribution to an almost vanishing baseline distortion.

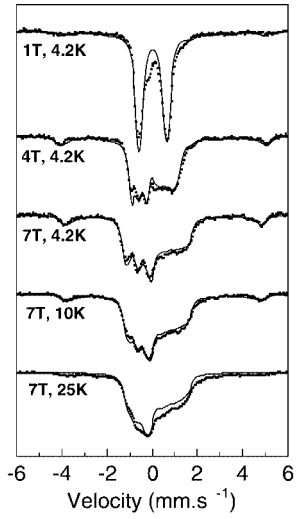

Figure 2. Mössbauer spectra of ^{57}Fe-enriched $[L_5{}^3Fe^{II}Cl]PF_6$ + 2 equiv. of ClO^- recorded at variable fields and temperatures; simulations of the spectra, made by considering a low-spin mononuclear Fe^{IV} complex, are represented by solid lines; the contamination background [sub-spectrum (2), 32% relative intensity] was taken into account by a simulation based on the equation given in the text for $S = 5/2$, $\delta = 0.4$ mm·s^{-1}, $\Delta E_Q = 0.7$ mm·s^{-1}, $D = 1$ cm^{-1}, $E/D = 0.33$, $A'_{iso}/g_N\beta_N = -19$ T

The field and temperature dependence of the magnetic Mössbauer spectra of the green oxidation product could be well simulated using the usual spin Hamiltonian

$$H = D\,[S_z{}^2 - 2/3 + E/D\,(S_x{}^2 - S_y{}^2)] + \mu_B\,\mathbf{B}\,g\,\boldsymbol{S} + H_N$$

for an electronic spin $S = 1$, where D and E/D are the zfs parameters, and H_N is the usual nuclear Hamiltonian for the ^{57}Fe nucleus.[39] The values of the spin Hamiltonian and hyperfine parameters are summarized in Table 1. We mention that alternative fits with $S = 2$ required magnetic hyperfine coupling constants with a small isotropic contribution $A'_{iso}/g_N\beta_N = -6.5$ T which is unreasonable and far below the values for known high-spin Fe^{IV}, $S = 2$, compounds.[22,40,41] This implies that the green oxidation product is an $S = 1$ species like the known oxo−ferryl compounds.

The values obtained for the green complex generated by reaction of $[L_5{}^3FeCl]^+$ with 2 equiv. of ClO^- compare well with those reported for the complexes obtained with the non-heme ligands of the cyclam family[24,25] or the amine/pyridine ligand TPA[26] (see Table 1). The Mössbauer parameters are also similar to those reported for the compound I analogue $S = 1$ Fe^{IV}=O derivative of Fe−porpholactone $[Fe^{IV}$=O**2**$]^+$.[10] For Horse Radish Peroxidase compound II, it was found that $\delta = 0.03$ mm/s and $\Delta E_Q = 1.61$ mm/s.[3] The Mössbauer analysis for the $S = 1$ porphyrinic dimethoxy complex $[Fe^{IV}(TMP)(OCH_3)_2]$ gave $\delta = -0.025$ mm/s and $\Delta E_Q = 2.1$ mm/s.[42,43] The $Fe^{IV}{}_2O_2$ diamond-core complex involving two $S = 1$ metal centers recently characterized by the group of Que yielded corresponding values for δ (0.1 mm/s) and ΔE_Q (1.75 mm/s).[18] These comparisons demonstrate that the parameters obtained from Mössbauer analysis are similar for all the Fe^{IV} species with oxygenated ligands and are independent of the nuclearity of the moieties and of the environment(s) of the metal ion(s). In contrast, low-spin $Fe^{IV}-CN$[23] and $Fe^{IV}(CN\,tBu)_2$[44] species have much larger ΔE_Q values (4.35 mm/s and 3.38 mm/s) although the δ values are similar. This strongly suggests that the $L_5{}^3Fe^{IV}$ complex has an oxygenated group as an axial ligand. The small E/D value observed here is also consistent with an axial electronic structure. This is confirmed a contrario by the larger E/D value (0.15) found by Que et al. for the dinuclear $Fe^{IV}{}_2O_2$ complex. We propose, therefore, that the green species in MeOH can be formulated as an oxo species $[L_5{}^3Fe^{IV}O]^{2+}$ or its methoxo derivative $[L_5{}^3Fe^{IV}OCH_3]^{3+}$.

We suggest that the orange species, which absorbs at 430 nm, could be the ClO^- adduct. This complex then ev-

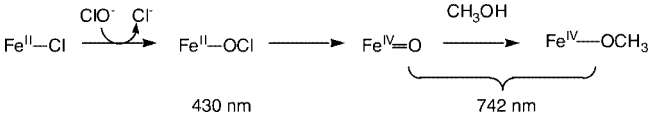
olves to the high-valent iron complex characterized by an absorption band at 742 nm. The observed events can thus be summarized as shown in Scheme 2.



Scheme 2. Mechanism proposed for the formation of mononuclear Fe^{IV} complexes from ClO^- and $[L_5{}^3Fe^{II}Cl]^+$ or $[L_5{}^2Fe^{II}Cl]^+$

Resonance Raman Spectroscopy

We recorded resonance Raman spectra of the green species (prepared with either $Br^{16}O^-$ or $Br^{18}O^-$ in a 25 mM solution of the complex in MeOH/acetone, 2:1) using excitation at 752.5 nm and acetone was used in order to increase the solubility of the complex. In both cases, the green species was characterized by the same UV/Vis spectrum as the one observed using ClO^-. The Raman spectrum is shown in Figure 3 and the band at 752 cm^{-1} is a good candidate for the $Fe^{IV}-$oxygen vibration. Indeed, its frequency is similar to the ones reported for several ferryl−oxo heme proteins.[45] Moreover, this is the only band of the spectrum that vanishes when the green colour disappears. However, no shift was observed upon ^{18}O labelling. It is possible that either a fast exchange between $[L_5{}^3Fe^{IV}O]^{2+}$ and unlabelled H_2O occurred as reported for the intermediate ES of cytochrome c peroxidase[46,47] or that the green intermediate in the presence of methanol is an $Fe^{IV}OCH_3$ species.[48]

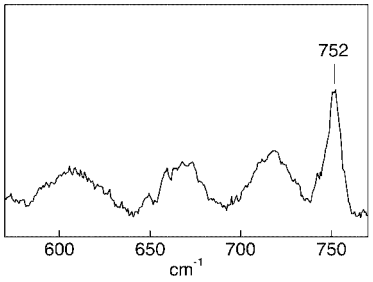


Figure 3. Resonance Raman spectrum at 10 K of the Fe^{IV} green complex prepared with a 25 mM solution of $[L_5{}^3Fe^{II}Cl]PF_6$ in presence of BrO^-; the laser wavelength used was 752.5 nm

In the case of the complex $[Fe^{IV}(O)(TMC)(NCCH_3)]^{2+}$,[25] no $Fe^{IV}=O$ vibration could be detected by Raman spectroscopy using laser excitation at 752.5 nm. However, this vibration was detected at 834 cm^{-1} by Fourier transform IR spectroscopy. With porphyrinic ligands, the $Fe^{IV}-$oxo vibration frequencies are greater than 800 cm^{-1}.[49,50] Complementary studies are therefore necessary to unambiguously assign the 752 cm^{-1} vibration observed here.

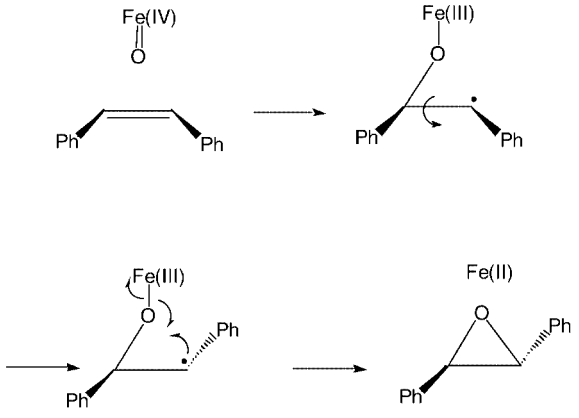
Reactivity

Reactivity studies were conducted at −20 °C with 2 equiv. of ClO^- in a mixture of acetonitrile/dichloromethane, 1:1, under aerobic conditions for cyclohexane and cyclooctene and under argon for *cis*-stilbene. The solution was stirred for 3 h and the products analyzed (Table 2).

Table 2. Yields (%/ClO^-) obtained at −20 °C for the oxidation reactions of different substrates by $[L_5{}^3FeCl]PF_6$ + 2 equiv. of ClO^- (Bzl = benzaldehyde, 800 equiv. of substrate)

Cyclohexan-		-cyclooctene		-Stilbene	
-ol	-one	Epoxy-	*cis*-	*trans*-	Bzl
10	0	15	0	10	0

The $[L_5{}^3FeCl]PF_6/ClO^-$ mixture is able to hydroxylate cyclohexane in 10% yield relative to the oxidant. Remarkably no ketone was formed. This high selectivity towards hydroxylation indicates the absence of free radical chemistry since the oxidation is performed under aerobic conditions.[51] Cyclooctene was epoxidized in a 15% yield, which is comparable to the yield of 30% reported for the intermediate $[Fe^{IV}(O)(TPA)]^{2+}$.[26] Epoxidation of *cis*-stilbene occurred with a 10% conversion but with a complete isomerization to the *trans*-epoxide. Such an isomerization has been attributed to a long-lived radical as observed with heme $Fe^{IV}=O$ species.[52] This is illustrated in Scheme 3.



Scheme 3

With the different substrates, the same experiments performed at 20 °C did not lead to any oxidation products even in the presence of a higher ClO^- concentration. This indicates that ClO^- is not directly responsible for these oxidations. This remark is important since hypochlorite may exhibit an oxidation activity in the presence of Lewis-acidic species.[53] Moreover, at room temperature, the solution became rapidly colorless and a reddish solid precipitated which is very likely to be iron oxide as suggested by Mössbauer spectroscopy (see above). On the contrary, after 2 h at −20 °C, the solution was still yellow and only a small amount of solid was observed.

This reactivity in acetonitrile/dichloromethane strongly supports the presence of a $[L_5{}^3Fe^{IV}O]^{2+}$ species.

As pointed out by Lim et al.,[26] the reactivity of $Fe^{IV}=O$ species appears to correlate strongly with their stability:

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the less stable the species, the stronger the oxidant. The complex $[Fe^{IV}(O)(TMC)(NCCH_3)]^{2+}$, which is stable for at least one month at −40 °C, is capable of oxidizing PPh_3 but not olefins.[25] The TPA complex[26] and the porphyrin analog $[Fe^{IV}(O)(TMP)]$,[52] which are less stable than the former, are able to epoxidize olefins. The $L_5{}^3$ complex, which is much more unstable than the above complexes, is also much more reactive since it is even able to hydroxylate unactivated C−H bonds.

Quantum Calculations

The value of the molar extinction coefficient (300 $M^{-1}\cdot cm^{-1}$) of the band observed at 742 nm in methanol seems low when compared with the intense bands which have been recently detected in the 500−900-nm region for the low-spin $Fe^{IV}{}_2O_2$ model system described by Costas et al.[18] On the contrary it agrees well with the value of 400 $M^{-1}\cdot cm^{-1}$ observed at 820 nm for the X-ray characterized non-heme complex $[Fe^{IV}(O)(TMC)(NCCH_3)]^{2+}$.[25]

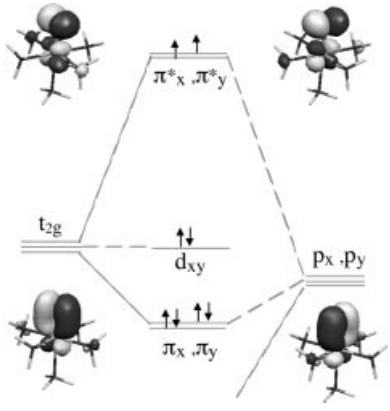
Spin-unrestricted DFT calculations were performed on the model compounds $[(NH_3)_5Fe^{IV}O]^{2+}$ and $[(NH_3)_5Fe^{IV}OCH_3]^{3+}$ as well as on the real complex $[L_5{}^3Fe^{IV}O]^{2+}$ using the Gaussian98 program package[54] with Becke's three parameter hybrid functional[55] and the correlation functional of Lee, Yang and Parr (B3LYP).[56] For both models, atomic distances were optimized in the two $S = 1$ and $S = 2$ spin states leading to the conclusion that the low-spin state is the more stable. The geometry of the real complex was fully optimized only in the $S = 1$ spin state. For the oxo model, the Fe−O bond length was found to be 1.635 Å, consistent with the value reported by Lehnert et al.[57,58]

The electronic absorption spectrum of the model compound $[(NH_3)_5Fe^{IV}O]^{2+}$ in the low-spin state ($S = 1$) was computed by time-dependent DFT (TDDFT) (see Exp. Sect.). It shows in the visible region only one weak band at 600 nm (oscillator strength $f = 0.0015$) (see Supporting Information). In C_{4v} symmetry (z being the Fe−O axis) this band corresponds to two degenerate transitions. The first one, with y polarization, consists of approximately equal amounts of an α excitation from the antibonding $d_{yz} - p_y$ orbital to a $d_{x^2-y^2}$-type orbital and of a β excitation from a d_{xy}-type orbital to the antibonding $d_{xz} - p_x$ orbital. The second one is the corresponding x-polarized transition involving excitation from the α-antibonding $d_{xz} - p_x$ orbitals to $d_{x^2-y^2}$ and β excitation from d_{xy} to the antibonding $d_{yz} - p_y$ orbital. These two transitions have therefore both MLCT and LMCT character. As a consequence, no appreciable charge transfer occurs and the observed band is essentially a weak-intensity d−d transition. This calculation then confirms the explanation proposed by Rohde et al. to interpret the observed low intensity.[25] The expected oxo-to-Fe^{IV} LMCT band was found at 360 nm with z polarization and involves β transitions from bonding $d_{xz} + p_x$ to antibonding $d_{xz} - p_x$ orbitals and from bonding $d_{yz} + p_y$ to antibonding $d_{yz} - p_y$ orbitals (see Supporting Information).

These conclusions can be compared with those we obtained for the Fe^{IV}−methoxo system $[(NH_3)_5Fe^{IV}OCH_3]^{3+}$. The geometry optimization led to a linear Fe−O−CH_3 motif with a short Fe−O distance of 1.709 Å, only slightly larger than the value of 1.635 Å found for the oxo model. In this case, however, the MOs containing the p_x and p_y contributions of oxygen delocalized on the CH_3 group and two essentially d−d transitions were calculated at 550 (d_{xz} or d_{yz} to d_{z^2}) and 450 nm (d_{xz} or d_{yz} to $d_{x^2-y^2}$) ($f \approx 0.0015$). The former had a zero intensity in the oxo model (see Supporting Information). The full geometry optimization of the real complex $[L_5{}^3Fe^{IV}O]^{2+}$ in the $S = 1$ state gave an Fe−O distance of 1.646 Å. In the visible region (see Supporting Information), the computed spectrum exhibits a band at 530 nm ($\varepsilon = 500\ M^{-1}.cm^{-1}$) which results from nondegenerate transitions essentially from d_{xz}- or d_{yz}-type orbitals to a $d_{x^2-y^2}$-type orbital. The LMCT transition from bonding $d + p_O$ to antibonding $d - p_O$ orbitals was calculated at 382 nm. We stress the fact that most of the informations relative to the calculated spectrum of the real complex were present in the simple model and that all orbitals of concern are strikingly similar, except for a small delocalization on the ligand $L_5{}^3$.

Finally, these calculations indicate that the weak band observed at 742 nm in MeOH for this low-spin Fe^{IV} mononuclear species has predominantly d−d character.

We would like to finish this part with some simple theoretical considerations. Is the Fe^{IV}=O notation the most accurate for a ferryl species? As is well known, the basic theoretical description of an $S = 1$ low-spin Fe^{IV}=O motif implies MOs combining the "t_{2g}" d orbitals with the p_x and p_y O orbitals to give occupied π-bonding orbitals and semi-occupied π*-antibonding orbitals with $\pi_x^* = \lambda\ d_{xz} + \mu\ p_x$ and $\pi_y^* = \lambda\ d_{yz} + \mu\ p_y$ as illustrated in Scheme 4.



Scheme 4

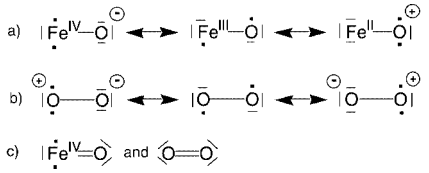
This MO description enables us to understand both the delocalized spin triplet character and the double bond composed of a σ bond (not shown) and two half π bonds.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

It is instructive to examine the electronic structure of $Fe^{IV}O$ from a Valence Bond point of view. The triplet state is represented by the following Slater determinant:

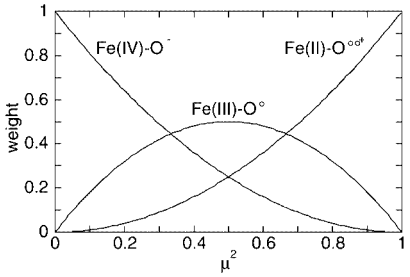
$$|\pi_x^*\ \pi_y^*| = \lambda^2\,|d_{xz}\ d_{yz}| + \lambda\mu\,|d_{xz}\ p_y| + \lambda\mu\,|p_x\ d_{yz}| + \mu^2\,|p_x\ p_y|$$

The determinant $|d_{xz}\ d_{yz}|$ describes a spin triplet localized on Fe in an $Fe^{IV}{}_{LS}-O^-$ pair, the $|d_{xz}\ p_y|$ and $|p_x\ d_{yz}|$ ones describe spin triplets equally shared between Fe and O in an $Fe^{III}{}_{LS}-O^\circ$ pair and the $|p_x\ p_y|$ one describes a spin triplet localized on O in an $Fe^{II}{}_{LS}-O^{\circ\circ+}$ pair. The electron distributions related to these mesomeric forms in the ground state are represented in part a) of Scheme 5.



Scheme 5. In a) all forms have an actual charge of +2; the formal oxidation states are reported for Fe and the formal charges for O

Making the simplifying assumption of zero overlap between the d and p orbitals for this qualitative discussion, we deduced from the wave function $|\pi_x^*\ \pi_y^*|$ that the weight is λ^4 for the $Fe^{IV}-O^-$ form, μ^4 for the $Fe^{II}{}_{LS}-O^{\circ\circ+}$ and $2\lambda^2\mu^2$ for the $Fe^{III}{}_{LS}-O^\circ$ form, with $\lambda^2 + \mu^2 = 1$ arising from the normalization conditions of π_x^* and π_y^*. Within the same assumption of zero overlap, the spin densities are $\rho_{Fe} = 2\,\lambda^2$ and $\rho_O = 2\,\mu^2$. Scheme 6 represents the weight of each different mesomeric form as a function of μ^2.



Scheme 6

The DFT calculations showed that the spin density is in fact almost equally shared between iron and oxygen, as shown in Figure 4. Within our simple hypothesis, this would imply $\lambda^2 \approx \mu^2$. When $\lambda^2 = \mu^2 = 0.5$, the $Fe^{IV}-O^-$ form amounts to 25%, the $Fe^{III}{}_{LS}-O^\circ$ form to 50% and the $Fe^{II}{}_{LS}-O^{\circ\circ+}$ form to 25%. When μ^2 decreases slightly from 0.5, the amount of $Fe^{II}{}_{LS}-O^{\circ\circ}$ evidently decreases whereas the amount of the $Fe^{IV}-O^-$ form increases. The Fe^{IV} orbitals are lowered so much in energy that they become close to the oxygen p orbitals which themselves are destabilized in O^{2-}. These AOs interact strongly and the MOs are delocalized on both Fe and O as reflected in the short Fe−O distance. The simple model of zero overlap no longer holds, but it allows us to conclude that the system has gained a significant $Fe^{III}{}_{LS}-O^\circ$ character and even $Fe^{II}{}_{LS}-O^{\circ\circ}$ character.

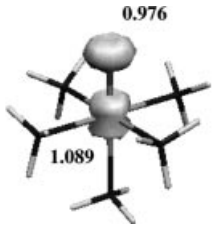


Figure 4. Spin densities calculated for the model compound $[(NH_3)_5Fe^{IV}O]^{2+}$

The description of the "$Fe^{IV}O$" species simultaneously as a diradical and a double bond system is in fact reminiscent of the electronic structure of the dioxygen molecule. It has also to be noted that, for the compound I of cytochrome P-450, the iron−oxo moiety possesses a triplet pair of electrons in π* orbitals.[59] For dioxygen the different forms are represented in part b) of Scheme 5. It is evident from symmetry that the spin is equally distributed on both oxygen atoms in triplet dioxygen. As explained by Valence Bond theory,[60] the double-bond character of O_2 arises from one σ bond, half a π_x bond and half a π_y bond and is fully compatible with a triplet state.

As represented in part c) of Scheme 5, the double-bond notation is unsatisfying both for $Fe^{IV}O$ and O_2 since this notation masks the spin density on the oxygen atom(s).

At this stage we stress that the $Fe^{III}{}_{LS}-O^\circ$ mesomeric form is dominant in the low spin ferryl system and, as for O_2, the strong radical character on O may explain the reactivity observed (see above).

We went beyond the monodeterminantal representation of the $S = 1$ ferryl ground state. We have performed a self consistent field computation (SCF) with full Configuration Interaction (CI) involving the subset of π and π* orbitals (complete active-space multi configuration SCF/CASSCF) together with localization of these orbitals into orthogonal orbitals with predominant p_x, p_y, d_{xz} and d_{yz} character. This procedure gave us the following contributions for each form: $Fe^{III}{}_{LS}-O^\circ \approx 94.5\%$, $Fe^{II}{}_{LS}-O^{\circ\circ+} \approx 5\%$ and $Fe^{IV}-O^-$ only $\approx 0.5\%$. This enrichment in $Fe^{III}{}_{LS}-O^\circ$ form is related to the removal of charge fluctuation by CI.[61] Basically, in the $Fe^{III}{}_{LS}-O^\circ$ form the monocenter electron−electron repulsion is weakened. Similarly, CI for O_2 leads to more than 80% diradical form.[62]

Conclusion

In MeOH at low temperature, we have obtained green intermediates, after reaction of XO^- (X = Cl, Br) and Fe^{II} complexes bearing the pentadentate amine/pyridine ligands $L_5{}^3$ or $L_5{}^2$. These green complexes have been assigned as Fe^{IV} entities, i.e. $[LFe^{IV}O]^{2+}$ or possibly $[LFe^{IV}OCH_3]^{3+}$ if the former reacts with MeOH. To date, $[LFe^{IV}O]^{2+}$ or $[L_5{}^3Fe^{IV}OCH_3]^{3+}$ complexes are among the first non-heme Fe^{IV} mononuclear species characterized. Spectroscopic

studies are underway to determine which of the two possible formulations of the species is occurring in MeOH.

The reactivity, performed in acetonitrile/dichloromethane solution showed that the $ClO^-/L_5{}^3$ system is able to oxidize cyclohexane to cyclohexanol as well as cyclooctene and *cis*-stilbene to the corresponding epoxides although in the last case with a complete isomerization to the *trans* form. These very specific oxidations are consistent with the mediation of a ferryl intermediate. Moreover, we have performed DFT calculations and obtained the electronic description of the ground state for the triplet "$Fe^{IV}O$" complex. As for the triplet dioxygen molecule, the ferryl−oxo complex is actually better described as the diradical $Fe^{III}-O^{\circ}$ form. This strong radical character on the oxygen atom must be at the origin of the hydroxylation and epoxidation reactivity, in particular the isomerization observed during oxidation of the *cis*-stilbene.

Experimental Section

Materials: Starting materials were purchased from Acros. Solvents were purchased from Merck and used without further purification.

Syntheses

Ligand *N*-Methyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)ethane-1,2-diamine ($L_5{}^2$): This ligand was synthesized according to the method reported by Bernal et al.[27]

Ligand *N*-Methyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)propane-1,3-diamine ($L_5{}^3$): This ligand was obtained according to the method reported by Bernal et al.[27] using *N*-methylpropane-1,3-diamine as the starting material. The crude product obtained after evaporation of $CHCl_3$ was a dark oil purified by chromatography on Al_2O_3 (eluent $CHCl_3$/EtOH, 20:1).

Complex $[L_5{}^2Fe^{II}Cl]PF_6$: This complex was obtained as described previously.[27]

Complex $[L_5{}^3Fe^{II}Cl]PF_6$: The method described by Balland et al.[36] has been reproduced here.

^{18}O-Labelled BrO^-: ^{18}O-labelled BrO^- was prepared using $H_2{}^{18}O$ (purchased from Eurisotop, isotopic enrichment 95%) according to the method reported by Bortolini et al.[63]

Reactivity Experiments: Reactivity experiments were performed at −20 °C in CH_3CN/CH_2Cl_2, 1:1, under vigorous stirring. The amounts of reactants were: 10^{-3} mmol of Fe complex; 2 equiv. of ClO^-, and 800 equiv. of substrate. The oxidation products were analyzed by GC. The conversion of *cis*-stilbene into the *trans*-epoxide was determined by NMR spectroscopy.

Physical Measurements: UV/Vis spectra were recorded with a Varian Cary 5E spectrophotometer equipped with a Dewar fitted with quartz windows for low-temperature measurements. Stopped-flow experiments were performed with a Biologic SFM-300 instrument equipped with a Julabo F 30C cryostat. Spectra were recorded in the 200−1022-nm range with a 0.5-cm optical path and a 50-μL cuvette. The delay after mixing was 3 ms. Mössbauer data were recorded with an alternating constant-acceleration spectrometer. The minimum experimental line width was 0.24 mm·s^{-1} (full width at half-height). The sample temperature was maintained at a constant value either with an Oxford Instruments Variox or an Oxford Instruments Mössbauer-Spectromag cryostat. The latter is a split-pair superconducting magnet system for applied fields up to 8 T where the temperature of the sample can be varied in the range of 1.5−250 K. The field at the sample is perpendicular to the γ-beam. The ^{57}Co/Rh source (1.8 GBq) was positioned at room temperature inside the gap of the magnet system at a zero-field position. Isomer shifts are quoted relative to iron metal at 300 K. Samples were doped at 50% with ^{57}Fe. The solutions were prepared at −60 °C in MeOH (5.5 mM in Fe) and were studied at 77 K. Resonance Raman spectra were recorded using a Jobin Yvon spectrometer equipped with a 900 lines/mm grating and a liquid-nitrogen cooled CCD camera. The 752.5-nm line of a Kr^+ laser was used for excitation with a power of 50 mW. The samples (1.5 mM in iron) were prepared at −80 °C in CH_3OH/acetone, 2:1, then frozen and studied at 10 K.

Computational Details: Spin-unrestricted DFT calculations were performed on the model compounds $[(NH_3)_5Fe^{IV}O]^{2+}$ and $[(NH_3)_5Fe^{IV}OCH_3]^{3+}$ as well as on the real complex $[L_5{}^3Fe^{IV}O]^{2+}$ using the Gaussian98 program package[54] with Becke's three parameter hybrid functional[55] and the correlation functional of Lee, Yang and Parr (B3LYP).[56] The double zeta basis set (SV) of Ahlrichs et al.[64] was employed for all atoms. For both models the distances were optimized in the two $S = 1$ and $S = 2$ spin states leading to the conclusion that the low-spin state is the more stable and the geometry of the complex was fully optimized in the $S = 1$ spin state. The energy of the excited states and oscillator strengths, *f*, were calculated by the Time Dependent DFT (TDDFT) formalism as implemented in the Gaussian98 program.[65] The theoretical electronic spectra were then simulated using Gaussian line shapes with a bandwidth at half-height of 2000 cm^{-1}, a value which usually gives molar extinction coefficients consistent with experimental values. For the configuration interaction calculations, Slater-type orbitals (STO-3G) were used.[66]

Supporting Information: Energy diagram and contour plot of the molecular orbitals calculated by DFT for the model complex $[(NH_3)_5Fe^{IV}O]^{2+}$ in the $S = 1$ state (Figure S1). Theoretical UV/Vis spectra of the models $[(NH_3)_5Fe^{IV}O]^{2+}$ and $[(NH_3)_5Fe^{IV}OCH_3]^{+}$ and of the real complex $[L_5{}^3Fe^{IV}O]^{2+}$ (Figures S2, S3, S4, respectively).

Phenylcyanamido Ligand Building Molecular, 1-D, and 2-D Systems − Syntheses, Crystal Structures and Magnetic Properties

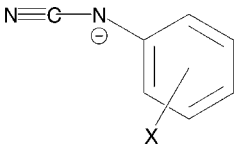
Albert Escuer,[a] Núria Sanz,[a] Franz A. Mautner,[b] and Ramon Vicente*[a]

Keywords: Manganese / Magnetic properties / Phenylcyanamido ligands / Bridging ligands

Several Mn^{II} compounds have been synthesised with the phenylcyanamido ligand, C_6H_5–NCN^-, and characterised by means of single crystal X-ray structure determination. The reported compounds show a wide variety of nuclearity: mononuclear, dinuclear, 1-D, and 2-D compounds are present in which the phenylcyanamido anion ($pcyd^-$) acts as a bridging ligand. The mononuclear compound $[Mn(pcyd)_2(phen)_2]$ (**1**) crystallises in the orthorhombic system, *Pbcn* space group; dinuclear compound $[\{Mn(pcyd)(phen)(MeOH)\}_2(\mu_{1,3}\text{-}pcyd)_2]$ (**2**) crystallises in the monoclinic system, *C*2/*c* space group; 1-D chain $[Mn(4\text{-}bzpy)_2(\mu_{1,3}\text{-}pcyd)_2]_n$·MeOH (**3**·MeOH) crystallises in the triclinic system, $P\bar{1}$ space group; 2-D network $[Mn(\mu_{1,3}\text{-}pcyd)_2(\mu\text{-}4,4'\text{-}bpy)]_n$·MeOH (**4**·MeOH) crystallises in the monoclinic system, C2 space group. Susceptibility measurements on compounds **2**–**4** reveal moderate AF coupling in all cases.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

In the last few years, a wide variety of bridging ligands have been used to promote the magnetic interaction between transition metal ions in polynuclear systems. In this sense, the anions azido[1] and dicyanamido[2] have generated a plethora of new polynuclear compounds ranging from dinuclear to 3D with different architectures. The study of the magnetic behaviour of these compounds has made for fast growth in the field molecular magnetism. However, the X-phenylcyanamido ligands (X-$pcyd^-$), Scheme 1, have practically been forgotten[3,4] as superexchange mediators in spite of the similarities with the azido or dicyanamido ligands. The $XPh-NCN^-$ group is electronically similar to the azido ligand (N_3^-), and it is reasonable to expect similar coordination modes. On the other hand, the nitrile group approaches the coordination properties of those observed for the dicyanamido ligand (mainly for M−N−C and M−N bond parameters).[2,5]



Scheme 1

With the aim of exploring the magnetic and synthetic possibilities of the R-phenylcyanamido ligands, we have recently published[5] the syntheses and structural characterisation of several representative Mn^{II} derivatives: the mononuclear compound $[Mn(3\text{-}Clpcyd)_2(H_2O)_2(4\text{-}bzpy)_2]$; the dinuclear ones $[\{Mn(3\text{-}Clpcyd)(2,2'\text{-}bpy)(S)\}_2(\mu_{1,3}\text{-}3\text{-}Clpcyd)_2]$, S = MeOH or EtOH; the 1-D $[Mn(2,2'\text{-}bpy)(\mu_{1,3}\text{-}4\text{-}Clpcyd)_2]_n$ and the 2-D $[Mn(\mu_{1,3}\text{-}3\text{-}Fpcyd)_2(\mu\text{-}4,4'\text{-}bpy)]_n$, in which 4-bzpy is 4-benzoylpyridine, 2,2′-bpy and 4,4′-bpy corresponds to the 2,2′- and 4,4′-bipyridyls. This series of compounds was obtained by using different X-phenylcyanamido derivatives: 3-$Clpcyd^-$, 4-$Clpcyd^-$ and 3-$Fpcyd^-$ are the 3-chloro-, 4-chloro-, or 3-fluorophenylcyanamido ligands, respectively. Magnetic measurements on the polynuclear $\mu_{1,3}$-X-$pcyd^-$ compounds revealed moderate AF coupling for all of them. This coupling lies in an intermediate position between the typical magnitude of the coupling induced by $\mu_{1,3}$ azido and $\mu_{1,5}$ dicyanamido bridges. MO calculations have evaluated the influence of the chair distortion of the $Mn-(NCN)_2-Mn$ unit, the effect of the halo substituent in the *para* position and the torsion effect of the phenyl rings on the superexchange interaction, and the theoretical results have been correlated with the experimental data.

In this paper, bearing in mind that the number of compounds is still low, we extend the study to the coordination compounds derived from the X-phenylcyanamido ligands by reporting the use of *only* the phenylcyanamido anion ($pcyd^-$), to synthesise a new series of $[Mn(pcyd)_2(L)_n]$ derivatives which show different nuclearities and dimensionalities. Successful syntheses and structural characterisation have been carried out for several representative complexes,

with formulae $[Mn(pcyd)_2(phen)_2]$ (**1**), $[\{Mn(pcyd)(phen)(MeOH)\}_2(\mu_{1,3}\text{-pcyd})_2]$ (**2**), $[Mn(4\text{-bzpy})_2(\mu_{1,3}\text{-pcyd})_2]\cdot MeOH$ (**3**·MeOH) and $[Mn(\mu_{1,3}\text{-pcyd})_2(\mu\text{-}4,4'\text{-bpy})]_n\cdot MeOH$ (**4**·MeOH) where 4-bzpy is 4-benzoylpyridine, 4,4′-bpy corresponds to 4,4′-bipyridyl and phen is 1,10-phenanthroline. These compounds were obtained by reaction in alcoholic media of manganese salts with the corresponding pyridinic or bipyridinic ligands and the deprotonated phenylcyanamide. The X-ray crystal structure determination reveals a wide variety of topologies and supramolecular arrangements: compound **1** is a mononuclear complex; compounds **2** a dinuclear complex bridged by double phenylcyanamido ligands, giving a supramolecular 1-D system by means of hydrogen bonds; compound **3**·MeOH is a chain of manganese atoms linked by double phenylcyanamido bridges. Finally, compound **4**·MeOH is a 2-D system formed by the crossing of phenylcyanamido and 4,4′-bpy chains. This paper gives the second structural set of data for polynuclear phenylcyanamide bridged derivatives with Mn^{II} as the central atom, together with a set of new experimental variable temperature susceptibility data for the $\mu_{1,3}$-X-pcyd$^-$ superexchange mediator.

Magnetic measurements for compounds **2**−**4** reveal a moderate AF coupling which lies in an intermediate position between the typical values of the coupling induced by $\mu_{1,3}$-azido and $\mu_{1,5}$-dicyanamido bridges. The obtained coupling constants are in accordance with the general rules for the $\mu_{1,3}$ coordination mode of pcyd$^-$ ligands discussed in the previous paper.[5]

Results and Discussion

Infrared Spectra: Neutral pcydH shows a characteristic IR ν(NCN) stretching absorption over a short wavenumber range (2225−2249 cm^{-1}), which shifts down to ca. 2120 cm^{-1} for deprotonated pcyd$^-$, suggesting a lower contribution of the resonance form containing the nitrile fragment. *N*-nitrile-coordinated X-pcyd$^-$ ligands, exhibit intermediate positions (always lower than 2200 cm^{-1}), with a dependence on the nature of the metallic centre and the number of halo groups.[3] For pcyd$^-$, the signal appears at 2108 cm^{-1} for **1** (only *N*-nitrile-coordinated pcyd$^-$ ligand), at 2168−2136 cm^{-1} for **2** (containing the two $\mu_{1,3}$-pcyd and *N*-nitrile pcyd$^-$ coordination modes) and at 2164 and 2133 cm^{-1} for **3** and **4,** respectively (containing the two $\mu_{1,3}$-X-pcyd$^-$ coordination modes). The structurally characterised $\mu_{1,3}$ copper dimer $[\{Cu(pcyd)(2,2'\text{-bpy})\}_2(\mu_{1,3}\text{-pcyd})_2]$[6] is in reasonable agreement with this assignment: it exhibits two similar absorptions at 2175 and 2103 cm^{-1}. In the mononuclear compound with the 3-Clpcyd$^-$ ligand $[Mn(3\text{-Clpcyd})_2(H_2O)_2(4\text{-bzpy})_2]$ the signal appears at 2108 cm^{-1} (only *N*-nitrile-coordinated pcyd$^-$ ligand) and at 2155−2132 cm^{-1} and 2159−2133 cm^{-1} in the dinuclear ones $[\{Mn(3\text{-Clpcyd})(2,2'\text{-bpy})(S)\}_2(\mu_{1,3}\text{-3-Clpcyd})_2]$, S = MeOH or EtOH, respectively (containing the two $\mu_{1,3}$-pcyd$^-$ and *N*-nitrile pcyd$^-$ coordination modes).[5] The wavenumber sequence for the ν(NCN) stretching absorption seems then to be pcydH > $\mu_{1,3}$-X-pcyd > *N*-nitrile coordination or anionic X-pcyd$^-$. The limited data for Mn^{II} derivatives suggest the above order, but further experimental data are required to obtain a general assignment.

Description of the Structure of $[Mn(pcyd)_2(phen)_2]$ (1): This compound consists of monomeric units in which the terminal pcyd$^-$ ligands adopt a *cis* arrangement around the central Mn^{II} ion (Figure 1). Selected bond parameters are given in Table 1.

[a] Symmetry codes: _a: $-x, y, -z + 1/2$

The Mn^{2+} ion shows a strongly distorted octahedral environment imposed by the rigidity of the 1,10-phenantroline ligands. The pcyd$^-$ ligands are coordinated to the Mn atom by the nitrile N atoms. There are two kinds of bond Mn−N distances: a short distance of 2.131(3) Å between the Mn^{II} ion and the nitrile N atoms, and longer distances to the N(phen) atoms: Mn(1)−N(3) 2.312(2) Å and Mn(1)−N(4) 2.314(2) Å. The most distorted bond angles around the Mn atom are N(3)−Mn−N(4), 71.3(1)°, N(1)−Mn−N(1_a), 100.4(1)° and N(4)−Mn−N(4_a), 84.1(1)°. The coordination of the monodentate phenylcyanamido ligand to the manganese atom is not linear with a Mn(1)−N(1)−C(1) bond angle of 158.8(5)°.

The NCN unit is practically linear with a N(1)−C(1)−N(2) angle of 171.5°. NCN is asymmetric, with bond lengths of N(1)−C(1) = 1.154(5) Å and C(1)−N(2) =

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1.299(6) Å. The cyanamido unit is practically coplanar with the phenyl group of the pcyd$^-$ ligand and shows a C(1)−N(2)−C(2) bond angle of 121.7(4)°.

Description of the Structure of [{Mn(pcyd)(phen)(MeOH)}$_2$($\mu_{1,3}$-pcyd)$_2$] (2): The structure consists of centrosymmetric dinuclear Mn units linked by double end-to-end phenylcyanamido bridges (Figure 2). Selected bond parameters are given in Table 2.

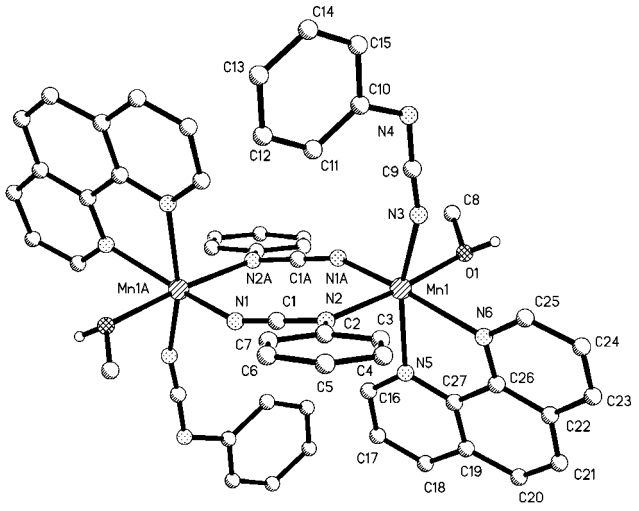

Figure 2. Labelled plot of [{Mn(pcyd)(phen)(MeOH)}$_2$($\mu_{1,3}$-pcyd)$_2$] (**2**)

[a] Symmetry codes: (A) $-x$, $-y$, $-z+1$.

The six coordination sites around the Mn atoms are occupied by the two N atoms of one phen ligand, one nitrile N atom of the terminal pcyd$^-$ ligand, one nitrile and one amido nitrogen atoms of the two bridging cyanamido ligands and one O atom of the solvent molecule (methanol). The linked phen and the variety of ligands distorts the coordination polyhedron of the Mn atom: bond angles ranging between 72.1(1)° for N(5)−Mn(1)−N(6) and 105.5(1)° for N(2)−Mn(1)−N(6) are found. The different nature of the N atoms of the phenylcyanamido ligand also induces different bond parameters in the bridging region: Mn(1)−N(1) takes the value of 2.278(2) Å whereas Mn(1)−N(1A) is only 2.166(2) Å. Mn−*N*−C bond angles are also different, being Mn(1A)−N(1)−C(1) 156.2(2)° in contrast with Mn(1)−N(2)−C(1), which takes the value of 113.2(1)°. As occurs in **1**, the monodentate phenylcyanamido ligands coordinate to the manganese atom in a quasi-linear arrangement, with a Mn(1)−N(3)−C(9) bond angle of 160.3(1)°.

The C−N−C angles between the cyanamido and the phenyl groups are similar for the terminal and the bridging ligands: 117.2(2)° and 117.0(2)°, respectively. The Mn−(NCN)$_2$−Mn subunit shows a chair distortion similar to those often found in similar systems with double azido bridges.[1] This means that the two −NCN− groups are in the same plane with the manganese atoms placed 0.403(1) Å out of the main plane. The torsion angle between the plane determined by the two −NCN− groups and the N(2)−Mn(1)−N(1A) plane is 14.7(1)°. The pcyd$^-$ ligand is practically planar with a minor torsion of 4.1(2)° between the bond direction N(2)−C(2) and the (NCN)$_2$ plane. The phenylcyanamido ligand is placed out of the main (NCN)$_2$ plane, which forms an acute angle of 15.7(1)° with the N(2)−C(2) bond direction. The Mn···Mn intradimer distance is 5.479(1) Å.

The dinuclear units generate a supramolecular one-dimensional H-bonded system by means of the OH group of the coordinated methanol molecules, O(1) atom, and the N(4) atoms of the terminal pcyd$^-$ ligands. Two of these H bonds appear between each dinuclear unit, giving a structurally alternating 1-D system (Figure 3). The N(4)−O(1) distance is 2.727(2) Å and the bond angle O(1)−H(1)−N(4) has a value of 178(3)°.

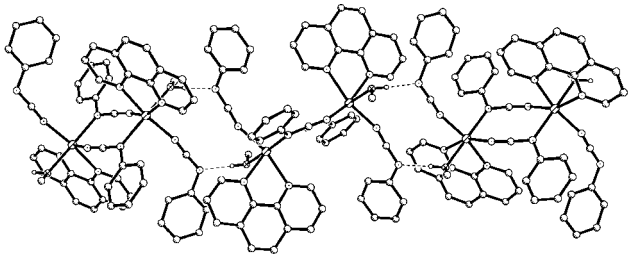

Figure 3. Hydrogen bond chain in compound **2**

Description of the Structure of [Mn(4-bzpy)$_2$($\mu_{1,3}$-pcyd)$_2$]·MeOH (3·MeOH): Selected bond parameters are given in Table 3. The structure consists of a one-dimensional Mn system where the coordination environment around the Mn atoms includes two N atoms of *trans*-4-bzpy ligands and four N atoms of bridging pcyd$^-$ ligands. The compound crystallizes with one MeOH molecule per formula unit.

[a] Symmetry codes: _a: $-x, -y, -z + 1$; _b: $-x + 1, -y, -z + 1$.

Double cyanamido bridges link the Mn atoms, giving a *trans* chain (Figure 4). The bond parameters in the bridging region show different bond lengths for the Mn−N(nitrile) and the Mn−N(amide) unions: Mn(1)−N(1), 2.168(2) Å and Mn(1)−N(3), 2.195(2) Å; Mn(1)−N(2), 2.305(3) Å, and Mn(1)−N(4), 2.272(3) Å. The bond angle Mn(1_a)−N(2_a)−C(1), 109.0(2)° is clearly smaller than Mn(1)−N(1)−C(1), 142.3(2)°. The Mn−$(NCN)_2$−Mn subunits show an important chair distortion: for the Mn(1)−[N(1)−C(1)−N(2)]$_2$−Mn(1_a) ring the Mn atoms are placed 0.979(1) Å out of the $(NCN)_2$ main plane and there is a dihedral angle of 37.0(1)° between the N(1)−Mn(1)−N(2) plane and the main $(NCN)_2$ plane. In this case the deviation of the phenyl groups, given by the acute angle between the bond directions N(2)−C(2) or N(4)−C(9) and the $(NCN)_2$ plane are only 9.6(2) and 7.2(2)°, respectively. The Mn atoms are placed 0.048 Å out of the $(NCN)_2$ plane in the Mn(1_b)−[N(3)−C(8)−N(4)]$_2$−Mn(1) dinuclear unit. The dihedral angle between N(3)−Mn(1)−N(4) and the main $(NCN)_2$ plane is 36.1°. The Mn···Mn intrachain distance is 5.328(1) Å, whereas the minimum interchain Mn···Mn distance is 8.520(1) Å.

Description of the Structure of $[Mn(\mu_{1,3}\text{-pcyd})_2(\mu\text{-}4,4'\text{-bpy})]_n\cdot MeOH$ (4·MeOH): The use of 4,4′-bpy determines a *trans*-octahedral arrangement around the Mn atoms (Figure 5). Selected bond parameters are given in Table 4.

The compound crystallises with a MeOH molecule per formula unit. The coordination sites around the manganese atom are occupied by two *trans* N atoms of two bridging 4,4′-bpy ligands and by four bridging $pcyd^-$ ligands. The structure may then be described as a two-dimensional sys-

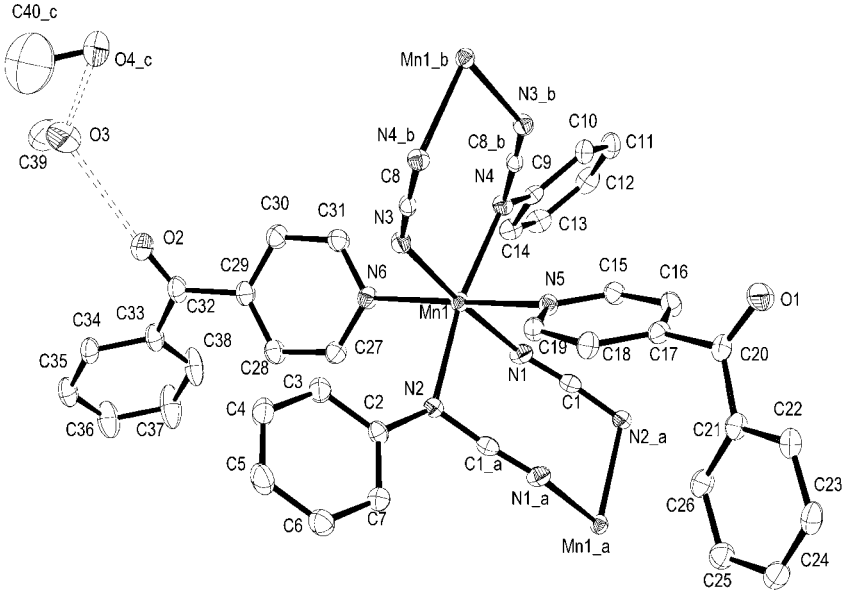

Figure 4. ORTEP plot of $[Mn(4\text{-bzpy})_2(\mu_{1,3}\text{-pcyd})_2]\cdot MeOH$ (**3**·MeOH) with thermal ellipsoids at the 40% probability level

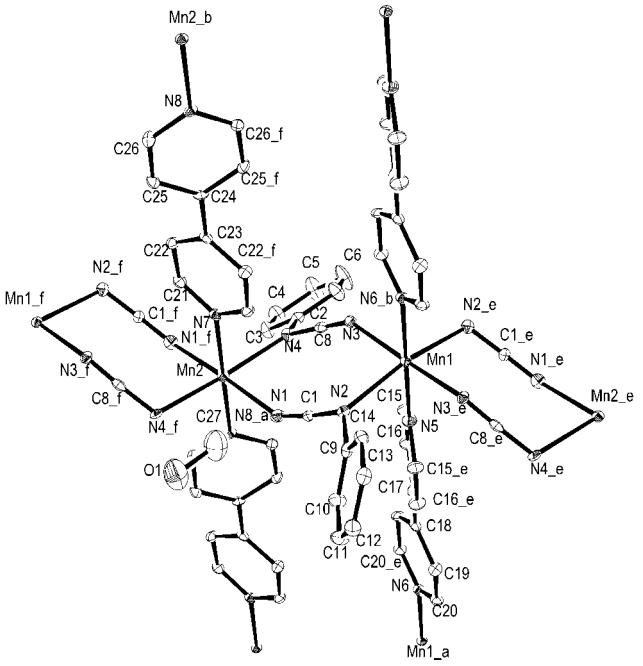

Figure 5. ORTEP plot of the basic unit of $[Mn(\mu_{1,3}\text{-pcyd})_2(\mu\text{-}4,4'\text{-bpy})]_n\cdot$MeOH (**4**·MeOH) with thermal ellipsoids at the 50% probability level

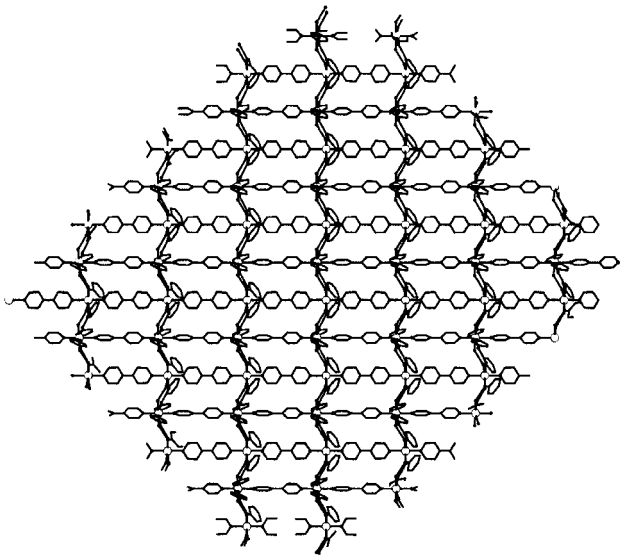

Figure 6. View of the 2-D arrangement of **4**·MeOH by means of the pcyd and 4,4′-bipy bridging ligands

tem with 4,4′-bpy-Mn chains crossed by Mn-pcyd chains (Figure 6).

The bond lengths in the bridging region again show a clear difference between nitrile and amide N atoms of the ligand: bond lengths for Mn(1)−N(3) and Mn(2)−N(1) are 2.187(4) Å and 2.173(3) Å whereas Mn(1)−N(2) and Mn(2)−N(4) are 2.315(4) Å and 2.327(4) Å, respectively. Bond angles related to the nitrile N atom Mn(1)−N(3)−C(8), 148.9(5)° and Mn(2)−N(1)−C(1), 142.3(4)° are larger than the angles related to the amide N atom Mn(1)−N(2)−C(1), 111.7(3)° and Mn(2)−N(4)−C(8), 111.2(3)°. As occurs for the above compounds, Mn−$(NCN)_2$−Mn subunits show a clear chair distortion with the Mn atoms placed 0.808(1)−0.942(1) Å out of the cyanamido plane. A dihedral angle of 30.6(2)−34.3(2)° is found between the $(NCN)_2$ planes and N(1)−Mn(2)−N(4)

or N(3)−Mn(1)−N(2) planes. Bridging phenylcyanamido ligands are far from planar, showing torsion angles for N(3)−N(4)−C(2)−C(3) of 38.7(4)° and N(1)−N(2)−C(9)−C(10) of 7.7(3)°.

In this case, a small deviation of the phenyl groups is evidenced by the 26.5(3)° or 0.8(3)° acute angles between the bond directions N(2)−C(9) or N(4)−C(2) with the reference $(NCN)_2$ plane. The Mn···Mn distance through the cyanamido unit is 5.407(1) Å, through the 4,4′-bpy bridge 11.712(1) Å, and the minimum interplane Mn···Mn distance is 10.289(1) Å.

Magnetic Measurements and Coupling Constant Calculations: Magnetic measurements were performed for compounds **2**−**4** in the 300−4 K temperature range on powdered crystalline samples, (see Exp. Sect.). The overall interaction is moderately antiferromagnetic in all cases.

The susceptibility plots increase gradually on cooling for compound **2** (Figure 7), but don't reach a maximum because at low temperatures a low quantity of impurities produce a sudden increase in the susceptibility value. The experimental data were analysed with the analytical expression for an isotropic $S = 5/2$ dinuclear compound by using the analytical expression derived from the isotropic Hamiltonian $H = -JS_1 \cdot S_2$, including an impurity term. The best fit parameters were $J = -3.5(1)$ cm^{-1}, $g = 2.01(1)$, $\rho = 0.030$.

Magnetic susceptibilities for compounds **3** and **4** also increase on cooling, reaching a broad maximum at 16 K in compound **4** (Figure 7). For compound **3** a sudden increase is also observed in the susceptibility values due to paramagnetic impurities. The coupling through the 4,4′-bpy bridges is negligible, so 2-D compound **4** should be assumed to be magnetically one-dimensional through the phenylcyanamido bridges. The experimental data were analysed with the analytical expression for an isotropic $S = 5/2$ chain system[7] derived by Fisher from the Hamiltonian $H = \Sigma -JS_i \cdot S_{i+1}$, including an impurity term for **3**. The best fit parameters were $J = -2.7(1)$ cm^{-1}, $g = 2.00(1)$, $\rho = 0.027$ and $J = -2.1(1)$ cm^{-1}, $g = 2.00(1)$ for **3** and **4,** respectively.

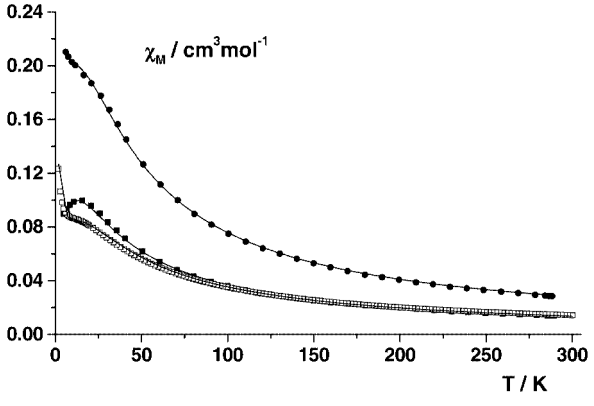

Figure 7. Plot of χ_M vs T for compounds [{Mn(pcyd)(phen)(MeOH)}$_2$($\mu_{1,3}$-pcyd)$_2$] (**2**) (solid circles) [Mn(4-bzpy)$_2$($\mu_{1,3}$-pcyd)$_2$]$_n$ (**3**) (open squares) and [Mn($\mu_{1,3}$-pcyd)$_2$(μ-4,4′-bpy)]$_n$ (**4**) (solid squares). Solid line shows the best fit of the data (see text)

EPR spectra for compound **1** show an isotropic broad band with a peak-to-peak increment (Δ_{pp}) of 674 G at room temperature, centred at $g = 2.00$. At 4 K the spectrum exhibits the main signal centred at $g = 2.00$ and a second weaker half-field band displaced at $g = 4.21$. Compound **2** shows one isotropic broad band at room temperature and 77 K, centred at room temperature at $g = 2.01$ with Δpp of 286 G. At 4 K the spectrum exhibits two main signals centred at $g = 2.01$ and 10.27 with Δpp of 438 G and 595 G, respectively, and several signals with minor intensities, which indicate some anisotropic effect at very low temperatures. Spectra of compounds **3** and **4** correspond nicely to that expected for one-dimensional systems with moderate antiferromagnetic coupling and weak dipolar interactions (Mn···Mn distances around 5.5 Å).[8] Between room temperature and 77 K the isotropic signals centered at $g = 2.01$ show a Δpp of 94 G and 92 G, respectively. Analogous Mn^{II} doubly bridged chains with end-to-end azido ligands with similar Mn···Mn intrachain distances have J values that typically lie around -10 cm^{-1}, the peak-to-peak linewidth being only 35 G due to the greater superexchange narrowing.[9] Instead, for weaker coupling, doubly dca bridged Mn^{II} chains, the peak-to-peak linewidth is much greater reaching values around 100−120 G[6] that show dipolar broadening on cooling down to 4 K.

The efficiency in transmitting the superexchange interactions is in the order $N_3^- > X\text{-pcyd}^- >> N(CN)_2^-$ [5] with typical values of the J parameter in the 1-D systems being around $-7/-15$ cm^{-1} (azido), $-1/-3$ cm^{-1} (X-pcyd$^-$) and weaker than -0.5 cm^{-1} for dicyanamide. The new series of J values reported here for the polynuclear phenylcyanamide bridged derivatives with Mn^{II} as the central atom confirms the assumption.

Conclusion

The ability of the X-phenylcyanamido ligands to act as bridging ligands has been newly confirmed by using the phenylcyanamido anion (pcyd$^-$) to synthesise a new series of formula [Mn(pcyd)$_2$(L)$_n$], L = phen, 4-bzpy and 2,2′-bpy, which show different nuclearities and dimensionalities. The coordination mode of the bridging pcyd$^-$ ligands is $\mu_{1,3}$. The magnetic measurements indicate AF coupling. The obtained coupling constant values are intermediate between the equivalent values for azido and dicianamido bridging ligands.

Experimental Section

Physical Methods: Magnetic susceptibility measurements were carried out on polycrystalline samples with a DSM8 pendulum susceptometer working in the range 4−300 K under magnetic fields of approximately 1 T. Diamagnetic corrections were estimated from Pascal tables. The infrared spectra (4000−400 cm^{-1}) were recorded from KBr pellets with a Nicolet 520 FTIR spectrophotometer. EPR spectra were recorded with a Bruker ES200 spectrometer at X-band frequency.

Synthesis: Neutral phenylcyanamide (pcydH) was prepared by desulfurisation of the phenylthiourea with lead acetate, following the described general synthetic procedure.[11]

Compound 1: 1 was prepared by reaction of a solution of manganese nitrate hexahydrate (1 mmol) and 1,10-phenanthroline (2 mmol) in 40 mL of methanol with a solution of pcydH (2 mmol) in 10 mL of NaOH (0.2 M) to deprotonate the ligand. After the reagents were mixed, the resulting clear solution was evaporated, giving a yellow crystalline compound suitable for X-ray measurements in a few days. Yield 21%. $C_{38}H_{26}MnN_8$ (649.6): calcd. C 70.3, H 4.0, N 17.2; found C 69.8, H 4.0, N 17.5.

Compound 2: 2 was prepared by reaction of a solution of manganese nitrate hexahydrate (1 mmol) and 1,10-phenanthroline (1 mmol) in 40 mL of methanol with a solution of pcydH (2 mmol) in 5 mL of NaOH (0.2 M) to deprotonate the ligand. After the reagents were mixed, the resulting clear solution was evaporated, giving a yellow crystalline compound suitable for X-ray measurements in three days. Yield 44%. $C_{54}H_{44}Mn_2N_{12}O_2$ (1002.9): calcd. C 64.7, H 4.4, N 16.8; found C 63.7, H 4.2, N 16.7.

Compounds 3 and 4: The method was the same as that for compound **2**, using 4-benzoylpyridine (2 mmol) for **3** and 4,4′-bipyridine (1 mmol) for **4** instead of phenanthroline (1 mmol). Yield of the corresponding yellow products, was 13% and 34%, respectively. Elemental analyses were performed on **3** and **4** in powdered samples three weeks after their preparation. **Compound 3:** $C_{38}H_{28}MnN_6O_2$ (655.6): calcd. C 69.6, H 4.3, N 12.8; found C 68.5, H 4.4, N 12.8. **Compound 4:** $C_{24}H_{18}MnN_6$ (445.4): calcd. C 64.7, H 4.1, N 18.9; found C 64.4, H 4.2, N 18.9. The elemental analysis for **3** and **4** indicates the absence of crystallisation of MeOH molecules in the powdered samples. To avoid errors in the magnetic measurements, the corresponding samples of **2** were freshly extracted from the mother solutions, dried and powdered just prior to performing the measurements. Moreover, the samples of **3** and **4** were dried and powdered some days before performing the magnetic measurements.

X-ray Crystallographic Study: Crystal data and details of the structure determinations are presented in Table 5. Data were collected on a modified STOE 4-circle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) and the ω-scan technique. Data of **1**−**4**·MeOH were collected at room temperature, −185(2) °C, −173(2) °C and −185(2) °C, respectively, and processed in the usual way. The structures were solved by direct methods using the SHELXS-86 computer program,[12] and refined by full-matrix least-squares methods on F^2, using the SHELXL-93 program[13] incorporated in the SHELXTL/PC V 5.03 program library[14] and the graphics program PLUTON.[15] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms bonded to donor atoms were located from difference Fourier maps, and the remaining ones were located on calculated positions by using the HFIX utility of the SHELXL-93 program. Selected bond parameters are given in Table 1−4 for compounds **1**−**4**·MeOH, respectively. CCDC-201204 (**1**), -201205 (**2**), -201206 (**3**·MeOH) and -201207 (**4**·MeOH) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Reactivity of $[Cp_2Ti(CO)_2]$ towards Nitrile and Water Adducts of $B(C_6F_5)_3$: Formation of $[Cp_2Ti(\eta^2\text{-}F_3CC_6H_4CN)\cdot B(C_6F_5)_3]$ and $[Cp_2Ti][HOB(C_6F_5)_3]$ with a Ti···F Interaction

Robert Choukroun,*[a] Christian Lorber,[a] and Laure Vendier[a]

Keywords: Titanium / Boranes / N ligands / Structure elucidation / Hydrolysis

The reaction of $[Cp_2Ti(CO)_2]$ with borane adducts $CF_3C_6H_4CN\cdot B(C_6F_5)_3$ and $[H_2O\cdot B(C_6F_5)_3]$ has afforded the titanaazirine $[Cp_2Ti(\eta^2\text{-}C,N\text{-}F_3CC_6H_4CN)\cdot B(C_6F_5)_3]$ (**1**) and the Ti^{III} salt $[Cp_2Ti][HOB(C_6F_5)_3]$ (**2**), respectively. In both cases, a Ti···F interaction between the titanium centre and an *ortho*-fluorine atom of the tris(perfluorophenyl)borane is observed in the X-ray structure determination.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

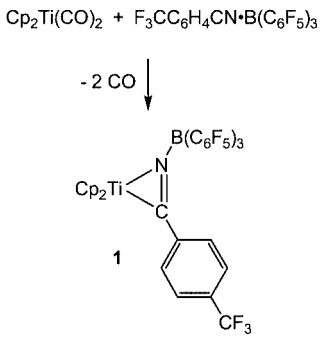
Introduction

The reactivity of the Lewis acid $B(C_6F_5)_3$ with organometallic complexes has been the subject of much literature, mainly concerning Ziegler−Natta catalysts in relation to the cationic group-4 complexes.[1−3] Novel aspects of the reactivity of $B(C_6F_5)_3$ recently investigated by our group on the vanadium(V) complex $[VO(OCH_2CF_3)_3]$[4] and the titanocene $[Cp_2Ti(CO)_2]$[5] led to the unexpected formation of the organometallic complex $[VO(C_6F_5)(\mu\text{-}OCH_2CF_3)(OCH_2CF_3)]_2$ and to the acylborane $[Cp_2Ti(CO)\{\eta^2\text{-}OCB(C_6F_5)_3\}]$, respectively. Addition of a Lewis acid to a nitrile allows the activation of the C−N nitrile bond; reaction with the vanadocene $[VCp_2]$ gives the vanada(IV)azirine complex $[Cp_2V\{\eta^2\text{-}RC{=}N\cdot B(C_6F_5)_3\}]$ (R = CH_3, $CF_3C_6H_4$).[6]

To prepare the titanium analogue to the vanada(IV)azirine series, we extended our findings on the reactivity of a nitrile bond activated with the Lewis acid $B(C_6F_5)_3$ toward the vanadocene[6] to the titanocene $[Cp_2Ti(CO)_2]$. In addition, a titanium(III) complex has been obtained by a controlled hydrolytic reaction with the $[H_2O\cdot B(C_6F_5)_3]$ adduct.

Results and Discussion

$[Cp_2Ti(CO)_2]$ reacts with a stoichiometric mixture of $CF_3C_6H_4CN$ and $B(C_6F_5)_3$ at 50 °C in toluene to give a red-orange crystalline complex of the titanaazirine $[Cp_2Ti(\eta^2\text{-}C,N\text{-}F_3CC_6H_4CN)\cdot B(C_6F_5)_3]$ (**1**), which has been isolated and characterized by an X-ray structure determination (Scheme 1, Figure 1).



Scheme 1. Synthesis of $[Cp_2Ti(\eta^2\text{-}C,N\text{-}F_3CC_6H_4CN\cdot B(C_6F_5)_3]$ (**1**)

This is reminiscent of our recent work based on the vanadocene $[VCp_2]$ and the so-called "activated" nitrile $RCN\cdot B(C_6F_5)_3$.[6] The well-known formation of adducts between nitrile and a Lewis acid is associated with an increase in the ν(CN) frequency in the IR spectrum and an increase of the electron density on the C≡N triple bond.[3a,7]

The C−N nitrile bond is attached to the titanium atom through two σ-type Ti−C and Ti−N bonds of 2.075(2) and 2.0940(18) Å. These values are expected for such bonds, by comparison with those of the iminoacyl complex $[Ti(OAr\text{-}2,6\text{-}iPr_2)_2(\eta^2\text{-}t\text{BuNCCH}_2\text{Ph})(CH_2Ph)]$ [Ti−C 2.086(6), Ti−N 2.025(5) Å] and $[Cp_2Ti(\eta^2\text{-x,yNCPh})]$ [xy = 2,6-$(CH_3)_2C_6H_3$] [Ti−C 2.096(4), Ti−N 2.149(4) Å].[8] The carbon−nitrogen distance [1.243(3) Å] is typical of a carbon−nitrogen double bond. There are small differences between the distances and angles in the organic framework $F_3CC_6H_4CN\cdot B(C_6F_5)_3$ of **1** and those in the previously published vanadium(IV) analogue complex $[Cp_2V(\eta^2\text{-}C,N\text{-}F_3CC_6H_4CN)\cdot B(C_6F_5)_3]$.[6] The molecular geometry of **1** is

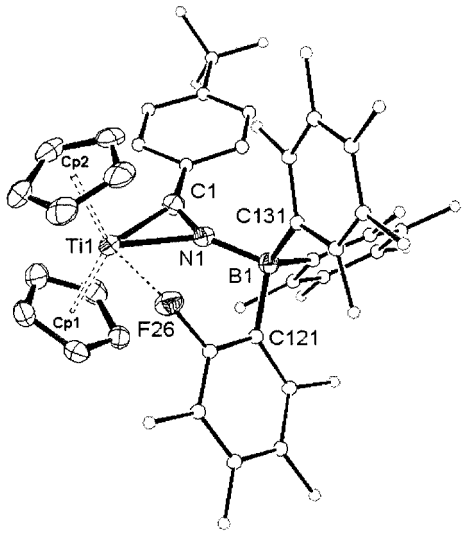

Figure 1. Molecular structure of **1**; hydrogen atoms and some labeled atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Ti(1)−C(1) 2.075(2), Ti(1)−N(1) 2.0940(18), C(1)−N(1) 1.243(3), N(1)−B(1) 1.575(3), C(1)−Ti(1)−N(1) 34.69(3), C(1)−N(1)−B(1) 147.19(9), Ti(1)−N(1)−C(1) 140.84(14)

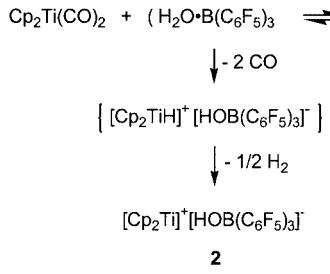
similar to vanadium(IV) except for a C−F···Ti interaction in the solid state between an *ortho*-fluorine atom of the borane adduct and the titanium atom. The Ti···F distance (2.453 Å) is notably less than the sum of the Ti and F van der Walls radii (1.45 and 1.47 Å, respectively). This is similar to that found in $[(C_5Me_5)Ti\{C_5Me_4CH_2B(C_6F_5)_3\}]$ [Ti−*ortho*-fluorine atom = 2.406(3) Å].[9] A small but significant lengthening of the C−F(···Ti) bond [1.378(2) Å] relative to other C−F bonds (average 1.346 Å) of the perfluorophenyl groups of the borane is observed. In the ^{13}C NMR spectrum, the characteristic carbon resonance at δ = 225.6 ppm of the η²-*C,N* carbon atom is found and the corresponding ν(C=N) band appears in the IR spectrum at 1725 cm^{-1}. ^{19}F NMR obtained in $[D_8]$THF (the only solvent in which **3** is soluble) does not show a peak attributable to a Ti···F interaction at room temperature, but at 233 K the five fluorine substituents of one pentafluorophenyl group become inequivalent. This splitting exhibits a high-field ^{19}F resonance at δ = −128.1 ppm, which is characteristic for a bridging fluorine atom, in agreement with the fluorine-bridged solid-state structure. The C−F···V interaction was not observed in the vanadium analogue in the solid state but is demonstrated in solution by EPR.[6] Complex **1** can also be obtained directly by addition of a toluene solution of $CF_3C_6H_4CN$ on insoluble $[Cp_2Ti(CO)\{\eta^2\text{-}OCB(C_6F_5)_3\}]$[5] in toluene with evolution of CO.

Additionally, accidental hydrolysis during the crystallization procedure of **1** yielded a few large crystals of a blue complex. This hydrolysis was confirmed by treating the $[H_2O{\cdot}B(C_6F_5)_3]$ adduct, prepared in situ,[10] with $[Cp_2Ti(CO)_2]$ in pentane, which gave a blue complex after at least 4 d. Although an X-ray structure determination allowed us to characterize this product as the titanoxyborane $[Cp_2TiOB(C_6F_5)_3]$, careful investigation of the crystals by IR and NMR spectroscopy revealed the salt structure $[Cp_2Ti][HOB(C_6F_5)_3]$ (**2**) for the blue Ti^{III} paramagnetic crystals (vide infra) (Scheme 2). This ambiguous situation has been clarified by preparing the deuterated analogue $[Cp_2Ti][DOB(C_6F_5)_3]$ from $D_2O{\cdot}B(C_6F_5)_3$ and $[Cp_2Ti(CO)_2]$. The ν_{OH} and ν_{OD} IR frequencies (3645 and 2680 cm^{-1}, respectively) confirm chemically the formulation of the counter-anion as $[HOB(C_6F_5)_3]$; unfortunately, the hydrogen atom bound to the oxygen atom could not be located in the X-ray structure determination. Although the paramagnetic $[Cp_2Ti]^+$ fragment is NMR-silent, ^1H and ^2H NMR spectra of the diamagnetic anion show a peak at δ = 3 ppm ($\Delta\nu_{1/2}$ = 36 Hz) which could be due to a hydrogen atom in a BOH moiety. The Ti−O bond [2.1456(18) Å] is longer than a σ(Ti−O) distance,[11] which excludes the titanoxyborane formulation (Figure 2). This distance is quite similar to other Ti−O bond lengths of a coordinated alcohol on a titanium centre: $[Ti(OC_6F_5)_3(OiPr)(HOiPr)]$ 2.128(7) Å, $[Ti\{OCH(CF_3)_2\}_2(OEt)_2(HOEt)]$ 2.187(9) Å,[12] $[TiCl_2(OiPr)(HOiPr)(\mu\text{-}Cl)]_2$ 2.087(4) Å, and $[TiCl_2(O\text{-}iPr)(HOiPr)(\mu\text{-}OiPr)]_2$ 2.093(2).[13] The B−O bond [1.519(3) Å] is longer than in the anion $[(C_6F_5)_3BOH]^-$ [1.487(3) Å] [1.597(2) Å in $H_2O{\cdot}B(C_6F_5)_3$[14]]. A C−F···Ti interaction between the titanium atom and one *ortho*-fluorine atom of



Scheme 2. Suggested hydrolytic pathway leading to $[Cp_2Ti][HOB(C_6F_5)_3]$ (**2**)

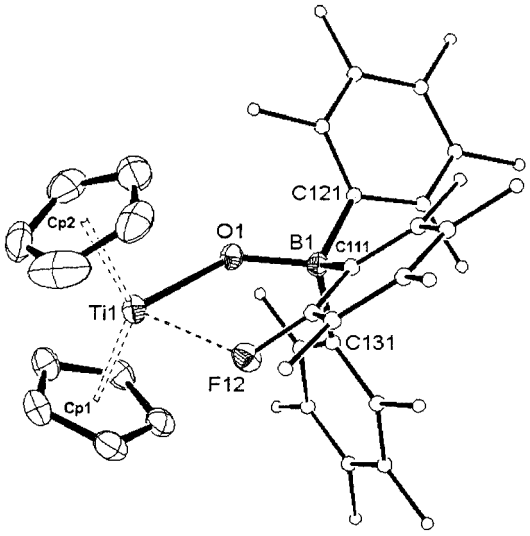


Figure 2. Molecular structure of **2**; hydrogen atoms and some labeled atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Ti(1)−O(1) 2.1456(18), O(1)−B(1) 1.519(3), Ti(1)−F(12) 2.2841(17); Ti(1)−O(1)−B(1) 137.78(14), O(1)−Ti(1)−F(12) 73.37(6)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the $B(C_6F_5)_3$ moiety occurs in the solid-state structure. The Ti···F distance [2.2841(17) Å] is still shorter than in complex **1** and there is a lengthening of the C−F(···Ti) bond [1.375(3) Å] relative to other C−F bonds (average 1.340 Å) of the perfluorophenyl groups of the borane. A similar Ti^{III} complex as [*rac*-(ebthi)Ti][$HOB(C_6F_5)_3$] [ebthi = 1,2-ethylene-1,1′-bis(η^5-tetrahydroindenyl)], formed due to adventitious water, has been recently fully characterized by an X-ray structure analysis; the hydrogen atom attached to the oxygen atom could not be localized [*d*(Ti−O) = 2.097(3) Å; *d*(B−O) = 1.482(4) Å; *d*(Ti···F) = 2.365(2) Å].[15] Similar Ti···F distances between the titanium centre and *ortho*-fluorine atoms in zwitterionic Ti^{III} structures have also been observed {[CpTi{$C_5H_4B(C_6F_5)_3$}]: 2.248(2), 2.223(3) Å; [(*i*PrC_5H_4)Ti{*i*Pr$C_5H_3B(C_6F_5)_3$}]: 2.64(2), 2.256(2) Å}.[16,17]

Our result differs slightly from those of Green and colleagues with $[MCp_2]$ (M = Cr, Fe, Co) yielding cationic $[MCp_2]^+$ with a counter-anion such as $[(C_6F_5)_3B(\mu\text{-}OH)B(C_6F_5)_3]^-$ or $[(C_6F_5)_3BOH\cdots H_2OB(C_6F_5)_3]^-$.[14] In their case the observed difference in the anion part is due to their synthetic procedure {2 equiv. of $H_2O{\cdot}B(C_6F_5)_3$ or an equimolecular mixture of $H_2O{\cdot}B(C_6F_5)_3/B(C_6F_5)_3$ are implied in the reaction with $[MCp_2]$}. Their proposed pathway contains the suggested intermediate $[Cp_2M][HOB(C_6F_5)_3]$, which is corroborated here {Scheme 2; the first intermediate $[Cp_2TiH][HOB(C_6F_5)_3]$ is assumed only}. Complex **2** is blue, and its magnetic susceptibility (1.76 μB) and EPR spectrum in THF (g = 1.974) confirm that it is a paramagnetic Ti^{III} complex. The single line in the EPR spectrum implies that there is no interaction between the Ti atom and the *ortho*-fluorine atom (I = 1/2) in THF solution, suggesting that the solvent occupies a coordination position on the metal atom, thus releasing the Ti···F interaction. The EPR solution spectrum is unchanged at −100 °C.

In conclusion, the reactivity of the borane adducts $[RCN{\cdot}B(C_6F_5)_3]$ and $[H_2O{\cdot}B(C_6F_5)_3]$ is described with $[Cp_2Ti(CO)_2]$. As expected, the formation of the titana(IV)-azirine complex **1** confirms the role of the tris(perfluorophenyl)borane in activating a nitrile bond, as already observed in the vanadium chemistry. The formation of **2** can be controlled and derives from an hydrolytic decomposition pathway.

Experimental Section

General: All manipulations were carried out using standard Schlenk line or dry-box techniques under argon. Solvents were boiled under reflux, dried with appropriate agents under argon, collected by distillation, and then stored in a dry-box over activated molecular sieves (4 Å). Deuterated solvents were degassed and dried over activated molecular sieves (4 Å). NMR spectroscopic data were recorded using Bruker AMX-400, DPX-300, and AC-200 spectrometers, and referenced internally to residual protio solvent (^{1}H) resonances, and are reported relative to tetramethylsilane (δ = 0 ppm). ^{19}F NMR (188.298 MHz) spectra were recorded with a Bruker AC-200 spectrometer (reference CF_3CO_2H). EPR spectra were obtained by using a Bruker ESP300E spectrometer. Elemental analyses (C, H, N) were performed at the Laboratoire de Chimie de Coordination (Toulouse, France). $B(C_6F_5)_3$ was prepared according to the literature.[18]

$[Cp_2Ti(\eta^2\text{-}F_3CC_6H_4CN){\cdot}B(C_6F_5)_3]$ (1): A freshly prepared toluene (3 mL) solution of $B(C_6F_5)_3$ (51 mg, 0.01 mmol) and $CF_3C_6H_4CN$ (17 mg, 0.01 mmol) was added to $[Cp_2Ti(CO)_2]$ (23 mg, 0.01 mmol) in toluene (3 mL). The resulting red solution was heated to 50 °C for 12 h. Red crystals of **1** were formed at room temperature (15 mg). The filtrate was left for 2 d to give a further crop of microcrystalline **1** (35 mg). Yield: 58%. $C_{36}H_{14}BF_{18}NTi$ (861.19): calcd. C 50.21, H 1.64, N 1.63; found: C 50.3, H 1.58, N 1.61. IR: $\tilde{\nu}$ = 1725 [ν(C≡N)] cm^{-1}. ^{1}H NMR ([D$_8$]THF): δ = 6.18 (s, Cp), 7.85, 7.21 (d, $^1J_{C,H}$ = 8.3 Hz, C_6H_4) ppm. ^{11}B NMR ([D$_8$]THF): δ = −9.60 ppm. ^{13}C NMR ([D$_8$]THF): δ = 114.3 (d, $^1J_{C,H}$ = 174 Hz, Cp), 121 [br., $\Delta\nu_{1/2}$ = 190 Hz, *ipso*-C, $B(C_6F_5)$], 125.2 (q, $^1J_{C,F}$ = 253 Hz, *C*F$_3$), 126.8 (d, $^1J_{C,H}$ = 168 Hz, C_6H_4), 133.7, (d, $^1J_{C,H}$ = 164 Hz, C_6H_4), 134.2 (q, $^3J_{C,F}$ = 33 Hz, *C*CF$_3$), 136.1 (s, *ipso*-C, C_6H_4), 138.8 (d, $^1J_{C,F}$ = 253 Hz, C_6F_5), 141.3 (d, $^1J_{C,F}$ = 250 Hz, C_6F_5), 150.0 (d, $^1J_{C,F}$ = 237 Hz, C_6F_5), 225.6 (s, *C*=N) ppm. ^{19}F NMR (376.41 MHz, 298 K, [D$_8$]THF): δ = 13.3 (s, C*F*$_3$), −56.9 (br., 6 *o*-F, C_6F_5), −82.5 (t, 3 *p*-F, C_6F_5), −88.6 (br., 6 *m*-F, C_6F_5); (233 K): δ = 12.7 (s, C*F*$_3$), −56.8 (d, 1 *o*-F, C_6F_5), −57.2 (d, 4 *o*-F, C_6F_5), −82.2 (t, 1 *p*-F, C_6F_5), −87.5 (t, 4 *p*-F C_6F_5), −85.4 (t, 1 *m*-F, C_6F_5), −87.9 (1 *m*-F, C_6F_5), −88.5 (t, 4 *m*-F, C_6F_5), −128.1 (d, 1 *o*-F, C_6F_5) ppm.

$[Cp_2Ti][HOB(C_6F_5)_3]$ (2): $[Cp_2Ti(CO)_2]$ (23 mg, 0.01 mmol) in pentane (3 mL) was added to a pentane suspension of $B(C_6F_5)_3$ (51 mg, 0.01 mmol) in the presence of H_2O (or D_2O) (1.8 μmol). After leaving the resultant red solution for one week, blue crystalline **2** was obtained in 35% yield (25 mg). Another synthesis from a mixture of $[Cp_2Ti(CO)_2]$ (23 mg, 0.01 mmol) and $B(C_6F_5)_3$ (51 mg, 0.01 mmol) in pentane (5 mL), passed several times through undried deoxygenated Celite and left for one week, afforded large blue crystals of **2** that were suitable for X-ray analysis. $C_{28}H_{10}BF_{15}OTi$ (706.07): calcd. C 47.63, H 1.43; found: C 47.24, H 1.33. EPR: g = 1.974, a(^{49}Ti) = 11.0 G (a single line with low intensity satellites due to the interaction of d^1 electron with ^{49}Ti and ^{47}Ti isotopes (5.51% abundant, I = 7/2 and 7.75% abundant, I = 5/2, respectively), the six inner components of the ^{49}Ti octuplet exactly superimpose on the sextuplet from ^{47}Ti). μ_{eff} = 1.76 μB. ^{1}H NMR ([D$_8$]THF): δ = 3 (br., $\Delta\nu_{1/2}$ = 36 Hz, BO*H*) ppm.

Crystallographic Data for 1 and 2: For structures **1** and **2** (Table 1) data were collected using a Stoe Imaging Plate Diffraction System (IPDS). The final unit cell parameters were obtained by least-squares refinement of a set of 5000 reflections, and crystal decay was monitored by measuring 200 reflections by image. No fluctuations of the intensity were observed over the course of the data collection. A semiempirical absorption correction[19] was applied to the data. The structure was solved by direct methods using SIR92[20] and refined by least-squares procedures on F^2 with the aid of SHELXL-97[21] which is included in WinGX (version 1.63).[22] The atomic scattering factors were taken from International Tables for X-ray crystallography.[23] All hydrogen atoms were located on a difference Fourier map. All the remaining non-hydrogen atoms were anisotropically refined and in the last refinement cycles a weighting scheme was used where weights were calculated from $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, where $P = (F_o^2 + 2F_c^2)/3$. The molecules were drawn using the program ORTEP32.[24] The criteria for a satisfactory complete analysis were the ratio of rms shift to standard deviation being less than 0.1 and no significant features in final difference maps. CCDC-212614 (**1**) and -212615 (**2**) contain the supplementary crystallographic data for this paper.

New Vanadium(V) Complexes with Salicylaldehyde Semicarbazone Derivatives: Synthesis, Characterization, and in vitro Insulin-Mimetic Activity − Crystal Structure of [$V^{V}O_2$(salicylaldehyde semicarbazone)]

Pabla Noblía,[a] Enrique J. Baran,[b] Lucía Otero,[a] Patricia Draper,[c] Hugo Cerecetto,[c] Mercedes González,[c] Oscar E. Piro,[d] Eduardo E. Castellano,[e] Toshifumi Inohara,[f] Yusuke Adachi,[f] Hiromu Sakurai,[f] and Dinorah Gambino*[a]

Keywords: Vanadium / Tridentate ligands / N,O,O ligands / Insulin-mimetic agents

The new dioxo(semicarbazone)vanadium(V) complexes *cis*-VO_2L, where L = salicylaldehyde semicarbazone (L^1), salicylaldehyde 4-*n*-butylsemicarbazone (L^2), or salicylaldehyde 4-(2-naphthyl)semicarbazone (L^3), have been synthesized, characterized by ^1H and ^{13}C NMR and FTIR spectroscopy and tested for bioactivity as potential insulin-mimetic agents. All dioxovanadium(V) complexes exhibited essentially no in vitro insulin-mimetic activity, but the VO_2L^2 complex developed activity in the presence of ascorbic acid, similar to that of vanadyl sulfate. The molecular structure of the novel complex VO_2L^1 has been solved by X-ray diffraction methods. It crystallizes in the tetragonal space group $P4_2/n$ with a = 12.7674(7), c = 11.5308(5) Å, and Z = 8. The vanadium atom is in a distorted square-pyramidal coordination, with L^1 acting as a tridentate ligand through its azomethyne nitrogen atom, carbonyl oxygen atom and deprotonated phenol oxygen atom. The coordination sphere is completed by two oxo ligands at *cis* positions.

Introduction

The interaction of simple vanadium species with ligand groups bearing pharmacological activity, particularly those with antitumoral and insulin-mimetic properties, is of growing interest. A more detailed physicochemical characterization of vanadium compounds with pharmacologically interesting ligands will help in furthering the inorganic pharmacology of vanadium.[1]

In particular, the discovery of the insulin-like in vitro and in vivo activity of oxovanadates(V) and oxovanadium(IV) compounds such as vanadyl sulfate has stimulated research on vanadium compounds that may have promising application in the treatment of non-insulin-dependent type-2 diabetes mellitus.[2−9] Different approaches have been attempted to develop more potent and orally active vanadium-containing insulin enhancing agents.[10] Some vanadium complexes, such as bis(alkylmaltolato)oxovanadium(IV) ones, are promising candidates as oral complements for insulin in the treatment of diabetes. Although such complexes have shown pharmacological advantages (better gastrointestinal absorption, higher potency and less toxicity) compared to the uncomplexed $VOSO_4$, further improvement in ligand design is needed, focusing on identifying new vanadium compounds with increased potency and decreased toxicity.[11]

Semicarbazones and thiosemicarbazones (Figure 1) show a wide range of biological activities.[12−15] Although some (thiosemicarbazone)vanadium complexes have been synthesized and characterized, there are very few examples of the analogous semicarbazone ligands.[12] To further discern the chelating behaviour of semicarbazones of pharmacological

Figure 1. General formula of semicarbazones (X = O) and thiosemicarbazones (X = S)

interest,[16−18] a more detailed physicochemical characterization of their vanadium complexes has been made, involving the synthesis, characterization and in vitro biological evaluation as potential insulin-mimetic agents of a series of novel (semicarbazone)VO_2^+ complexes with the general formula *cis*-V^VO_2L. Selected ligands L are salicylaldehyde semicarbazone derivatives bearing moieties with different lipophilicity − a physicochemical property that determines an adequate bioresponse of drugs, and is related to their absorption, distribution, metabolism, elimination and toxicity.[19] The ligands L (Figure 2) are salicylaldehyde semicarbazone (L^1), salicylaldehyde 4-*n*-butylsemicarbazone (L^2) and salicylaldehyde 4-(2-naphthyl)semicarbazone (L^3).

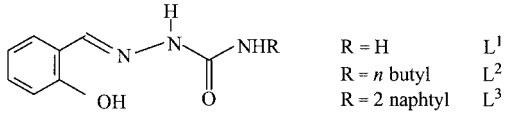

Figure 2. Selected ligands: salicylaldehyde semicarbazone (L^1), salicylaldehyde 4-*n*-butylsemicarbazone (L^2) and salicylaldehyde 4-(2-naphthyl)semicarbazone (L^3)

Although almost no $V^VO_2^+$ complex has shown good insulin-enhancing properties, V^V complexes may be reduced in vivo to form potentially bioactive $V^{IV}O^{2+}$ complexes.[20] In particular, vanadium(v) dipicolinate is an effective oral agent in live animals.[21] Thus, it seemed interesting to test the insulin-mimetic activity of the three novel complexes reported here.

Results and Discussion

Three novel V^V semicarbazone complexes have been synthesized and characterized. Complexes with the formula V^VO_2L, where L = salicylaldehyde semicarbazone (L^1), salicylaldehyde 4-*n*-butylsemicarbazone (L^2) or salicylaldehyde 4-(2-naphthyl)semicarbazone (L^3), were prepared in good yields and high purity. The analytical data agree with the proposed formulae.

In contrast to $V^{IV}O^{2+}$ complexes, those of VO_2L do not show electronic d−d transitions in the visible region due to the absence of d-electrons. Thus, the yellow color of the V^V complexes arises from intense absorption tailing-in from the UV region, originating in O→V charge transfer transitions.[22]

Selected vibration bands of the free ligands and their vanadium complexes, which are useful for determining the ligand's mode of coordination, are given in Table 1. The shifts in the ν(C=O) and the ν(C=N) bands upon coordination are consistent with bidentate coordination of the semicarbazone portion of the ligand through the carbonyl oxygen atom and azomethine nitrogen atom.[17,18] The third coordination position is the deprotonated phenol oxygen; thus the O−H stretching band is not in the spectrum of the complexes. In addition, the typical strong bands owing to asymmetric and symmetric stretching modes of the *cis*-VO_2 moiety are observed.[22]

Table 1. Selected vibration bands of the ligands L and the V^VO_2L complexes (cm^{-1}); ν: stretching; as: asymmetric, s: symmetric

Compound	ν(C=O)	ν(C=N)	ν(C−O)	ν(O−H)	$\nu_{as}(VO_2^+)$	$\nu_s(VO_2^+)$
VO_2L^1	1661	1606	1557	−	908	933
L^1	1683	1598	1522	3422	−	−
VO_2L^2	1645	1577	1473	−	933	912
L^2	1651	1573	1488	3300	−	−
VO_2L^3	1601	1560	1508	−	907	889
L^3	1647	1566	1508	3307	−	−

NMR Studies

The NMR spectra show narrow signals typical of V^V diamagnetic complexes. HETCOR experiments allowed us to assign all of signals for the studied complexes. The ^1H NMR chemical shifts along with the chemical shift differences between each complex and the corresponding ligand, expressed as Δδ, are listed in Table 2. The formula in the table shows the numbering scheme of the free ligands. The ^1H NMR integrations and signal multiplicities agree with the proposed formula. The three complexes show similar ^1H and ^{13}C chemical shifts for the salicylaldehyde semicarbazone common portion. When the ligand is coordinated, the deshielding effect of the metal atom is apparent in some protons, causing a downfield shift of the corresponding ^1H NMR peaks. Upfield shifts in the ^1H NMR spectra of the signals of 4- and 6-H of the complexes could be the result of ligand deprotonation upon coordination, due to the lack of 7-H (Table 2).[18] The upfield shift of the signal of 3-H could be due to the decreasing azomethine anisotropic effect in the coordinated form of L. When L is coordinated, the azomethine moiety is fixed by the vanadium core in an opposite spatial distribution to 3-H. Thus, after coordination, this proton is less affected by the magnetic anisotropy of the C=N double bond than in the free ligand.[23]

Structural Results

Intramolecular bond lengths and angles around the metal ion in VO_2L^1 (Table 3) and an ORTEP[24] drawing of the molecule (Figure 3) are shown here.

The X-ray diffraction study shows that the complex VO_2L^1 consists of a discrete monomeric molecule. The vanadium(v) ion is in a distorted square-pyramidal environ-

ment, coordinated at the pyramid basis to a salicylaldehyde semicarbazone molecule that acts as a tridentate ligand through its azomethine nitrogen atom [d(V−N) = 2.154(5) Å], and its carbonyl and deprotonated phenol oxygen atoms [V−O distances of 1.998(4) and 1.894(4) Å, respectively], and to an oxo ligand [d(V−O) = 1.641(4) Å]. The fivefold coordination is completed by another oxo ligand at the pyramid apex [d(V−O) = 1.622(4) Å]. Both oxo ligands are in *cis* positions. The average V−O bond length and O−V−O angle are quite similar to those previously reported for the *cis*-VO_2 moiety in other complexes.[25] The *trans*-ligand−V−ligand angles are O1−V−O2 147.9(2)° and N3−V−O12 148.7(2)° and the *cis*-ligand−V−ligand angles vary from 74.2(2) to 108.1(2)°.

The nitrogen atom and the three coordinated oxygen atoms at the pyramid base are nearly in a plane (rms deviation of NO_3 atoms from the least-squares plane is 0.017 Å) with the metal ion 0.401 Å apart from this plane, towards the axial oxo ligand.

The salicylaldehyde semicarbazone molecule is also nearly planar (rms deviation of ligand atoms from the least-squares plane is 0.065 Å) and subtends an angle of 5.8(1)° with the NO_3 plane. Of the possible isomeric forms for the ligand, the (*E*) isomer is preferred. The crystal is further stabilized by a net of medium-to-strong intermolecular N−H···O bonds, involving the terminal NH_2 group of a given ligand molecule and the phenol oxygen atom [d(N1···O2′) = 2.972 Å, N1−H1A···O2 = 174.9°] and the equatorial oxo ligand [d(N1···O12″) = 2.870 Å, N1−H1B···O12″ = 171.4°] of neighboring ligand molecules, and also the N−H group in an N−H···O bond with the axial oxo ligand [d(N2···O11″) = 2.723 Å, N2−H2···O11″ = 153.2°].

Figure 4. Inhibitory effects of $VOSO_4$ and dioxovanadium(v) complexes with or without 1 mM ascorbic acid on FFA release from isolated rat adipocytes treated with epinephrine

Biological Activity of the Complexes

In vitro insulin-mimetic activities of the three dioxovanadium(v) complexes were examined, with or without 1 mM ascorbic acid, with regard to inhibition of FFA release from isolated rat adipocytes treated with epinephrine (Figure 4). Ascorbic acid exhibited essentially no inhibitory effect on FFA release under the experimental conditions. The inhibitory effects of dioxovanadium(v) complexes were compared with those of $VOSO_4$ as a positive control (IC_{50} = 1.00 ± 0.27 mM). In the absence of ascorbic acid, all dioxovanadium(v) complexes exhibited scarcely any inhibitory effects at concentrations of 10^{-4}, 5×10^{-4} and 10^{-3} M. The in vitro insulin-mimetic activities of the three dioxovanadium(v) complexes were lower than that of $VOSO_4$. However, the addition of 1 mM ascorbic acid to $VOSO_4$ or VO_2L^2 complex ($VOSO_4$-asc and VO_2L^2-asc) significantly enhanced the inhibitory effect of FFA release (Table 4, $VOSO_4$-asc: 0.34 ± 0.15 mM, VO_2L^2-asc: 0.73 ± 0.27 mM). Thus, the in vitro insulin-mimetic activity of VO_2L^2 was improved by the addition of the reducing agent ascorbic acid, even though it remained lower than that of pure $VOSO_4$ under the same conditions.

Upon addition of $VOSO_4$ to the adipocytes under air, the vanadyl state was found to be oxidized during the 3 h of incubation (unpublished results). Therefore, the addition of ascorbic acid was thought to maintain the vanadyl state during incubation, which in turn enhances the insulin-mimetic activity of $VOSO_4$. Interestingly, of the tested dioxovanadium(v) complexes only VO_2L^2 exhibited insulin-mi-

metic activity in the presence of ascorbic acid, although spectroscopic experiments showed that all three complexes were reduced by the addition of ascorbic acid, as described below. These results suggest the importance of the interaction between the reduced forms of the complexes and the adipocytes, and that this interaction strongly depends on the chemical nature of the ligands.

Reaction of V^VO_2L with Ascorbic Acid

The reaction of $V^VO_2L^2$ with ascorbic acid was monitored by ^1H NMR spectroscopy at 303 K in [D_6]DMSO/D_2O. Immediately after the addition of ascorbic acid, the solution changed from yellow to dark-green and the narrow signals characteristic of the V^V diamagnetic complex were converted into broad ones. This strongly suggests that during the reaction the $V^VO_2L^2$ complex is reduced by the ascorbic acid to a paramagnetic V^{IV} species. Signals of free L^2 were not detected, indicating that the ligand remained coordinated to the central atom in the V^{IV} species.

Similar conclusions arise from the spectrophotometric study of the reduction with ascorbic acid of $V^VO_2L^2$ and $V^VO_2L^3$, as previously reported for (maltol)- and (ethylmaltol)vanadium(v) complexes.[25] In each case, after addition of the reducing agent a new band in the visible region near 670 nm was detected, which is attributable to a d−d transition of the resulting V^{IV} species.[22] After keeping the solution under air for 8 h, the new band disappeared gradually and finally the initial spectrum was obtained (Figure 5).

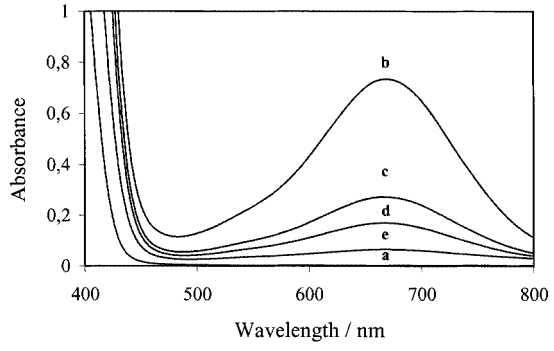

Figure 5. Electronic spectra (400−800 nm) of a 9.5×10^{-4} M DMSO solution of $V^VO_2L^2$ (a) before and (b) immediately after the addition of ascorbic acid, and (c) 20, (d) 60 and (e) 300 min after the addition

With $V^VO_2L^1$ re-oxidation of the V^{IV} species occurred almost immediately under the experimental conditions tested.

Thus, NMR and spectrophotometric experiments strongly indicate that ascorbic acid reduces V^VO_2L to a $V^{IV}O^{2+}L$ complex.

In particular, the reduction of the $V^VO_2L^2$ complex could explain the enhancement in insulin-mimetic activity of this complex in the presence of ascorbic acid.

These results, together with those of the biological tests in the presence of ascorbic acid, encouraged us to try to synthesize and isolate the $V^{IV}L^2$ complex, which could show the desirable in vitro and/or in vivo insulin-mimetic activity. We are thus extending our research to examine the structure-activity relationship of these complexes − involving redox potentials, partition coefficients, stability constants, molecular sizes and the elucidation of the chemical structure of the reduced forms. The emerging results will be the subject of a future publication.

Experimental Section

Materials: All common laboratory chemicals were purchased from commercial sources and used without further purification. 4-*n*-Butylsemicarbazide, 4-(2-naphthyl)semicarbazide and $V^{IV}O(acac)_2$, where acac = acetylacetonate, were prepared according to well-established literature procedures.[27−29] Vanadyl sulfate ($VOSO_4 \cdot 2.8H_2O$) and (+)-L-ascorbic acid were purchased from Wako Pure Chemical (Osaka, Japan). The purity of $VOSO_4 \cdot 2.8H_2O$ was determined by chelatometry using Cu-Pan [Cu-1-(2-pyridylazo-2-naphthol)]. Collagenase (Type II), bovine serum albumin (BSA; fraction V) and (±)-epinephrine hydrochloride (adrenaline) were obtained from Sigma Chemical (St. Louis, MO, USA). (+)-D-Glucose was purchased from Nacalai Tesque, Inc. (Kyoto, Japan). Other reagents were of the highest purity commercially available.

Physicochemical Characterization: C, H, N analyses were performed with a Carlo Erba Model EA1108 elemental analyzer. FTIR spectra (4000−400 cm^{-1}) were measured as KBr pellets with a Bomen M102 instrument. Electronic spectra were recorded with a Spectronic 3000 spectrophotometer. ^1H and ^{13}C NMR spectra of the free ligands and of the complexes were recorded with a Bruker DPX-400 instrument (at 400 and 100 MHz, respectively). Experiments were performed at 303 K in [D_6]DMSO/D_2O (8:2) (stability of the complexes in this medium had been tested previously). Heteronuclear correlation experiments (2D-HETCOR), HMQC (multiple quantum) and HMBC (multiple bond) were performed with the same instrument. MS experiments of the free ligands were obtained in the mass range 40−500 amu using a Shimadzu MSQP 1100 EX spectrometer with EI at 70 eV and a direct insertion probe.

Syntheses of the Ligands: All reactions were carried out under nitrogen. An equimolar mixture of 2-hydroxybenzaldehyde (salicylaldehyde) and the corresponding semicarbazide was stirred with *p*-TsOH (catalytic amounts) in dry toluene as solvent at room temperature until no more carbonyl compound was detected (SiO_2, 1% MeOH in CH_2Cl_2). For L^1 and L^2 the resulting solid was collected by filtration. For L^3 the solution was concentrated in vacuo and the solid was filtered off. The ligands were characterized by ^1H and ^{13}C NMR, IR and MS.

Syntheses of the Complexes: The $V^{V}O_2L$ complexes were prepared by boiling under reflux $V^{IV}O(acac)_2$ (100 mg, 0.375 mmol, acac = acetylacetonate) with L (0.375 mmol) in ethanol (10 mL) for 10 h.

$V^{V}O_2L^1$: $V^{V}O_2L^1$ was filtered off from the hot solution as a yellow-greenish solid. Yield 69 mg, 70%. Single yellow-greenish crystals, suitable for X ray diffraction, were obtained by slow concentration of an ethanolic solution at room temperature. $C_8H_8N_3O_4V$ (261.1): calcd. C 36.8, H 3.09, N 16.1; found C 37.1, H 3.41, N 15.8. UV/Vis (MeOH): λ_{max} = 237, 278, 315 nm. ^{1}H NMR: δ = 6.79 (m, 2 H), 7.37 (t, 1 H), 7.48 (d, 1 H), 7.96 (br. s, 2 H), 8.58 (br. s, 1 H), 12.50 (br. s, 2 H) ppm. ^{13}C NMR: δ = 118.20, 119.30, 120.00, 133.00, 134.30, 150.0, 161.4, 164.20 ppm.

$V^{V}O_2L^2$: $V^{V}O_2L^2$ was obtained as a microcrystalline powder by slow concentration of the reaction mixture at room temperature. Yield 47 mg, 40%. $C_{12}H_{16}N_3O_4V$ (317.2): calcd. C 45.4, H 5.08, N 13.2; found C 45.1, H 5.31, N 13.1. UV/Vis (MeOH): λ_{max} = 244, 287, 359 nm. ^{1}H NMR: δ = 0.90 (t, 3 H), 1.33 (m, 2 H), 1.49 (m, 2 H), 3.20 (m, 2 H), 6.80 (d, 1 H), 6.85 (t, 1 H), 7.39 (t, 1 H), 7.51 (d, 1 H), 8.35 (br. s, 1 H), 8.63 (br. s, 1 H) ppm. ^{13}C NMR: δ = 14.40, 20.18, 31.86, 41.03, 118.66, 119.77, 120.31, 133.39, 134.65, 150.22, 160.59, 164.58 ppm.

$V^{V}O_2L^3$: $V^{V}O_2L^3$ was obtained as a yellow solid by slow concentration of the reaction mixture at room temperature, after filtering off the unreacted ligand from the hot solution. Yield 73 mg, 50%. $C_{18}H_{14}N_3O_4V$ (387.3): calcd. C 55.8, H 3.64, N 10.8; found C 55.5, H 3.90, N 10.6. UV/Vis (MeOH): λ_{max} = 242, 283, 330 nm. ^{1}H NMR: δ = 6.80 (br. t, 1 H), 6.85 (br. d, 1 H), 7.30−7.90 (m, 7 H), 8.06 (m, 1 H), 8.42 (br. s, 1 H), 8.69 (br. s, 1 H), 9.82 (br. s, 1 H), 9.93 (br. s, 1 H) ppm. ^{13}C NMR: δ = 116.90, 119.00, 120.10, 121.00, 121.75, 125.17, 127.29, 127.88, 128.34, 128.82, 129.26, 131.48, 134.28, 134.69, 137.59, 150.00, 159.66, 163.79 ppm.

X-Ray Diffraction Data and Crystal Structure Determination and Refinement: Crystal data, the data collection procedure, structure determination methods and refinement results for $V^{V}O_2L^1$ are summarized in Table 5. The hydrogen atoms were included in the molecular model at stereochemical positions and refined with the riding model. CCDC-213179 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Animals: Male Wistar rats (7 weeks old) weighing 200−250 g were obtained from the Shimizu Experimental Material Co. (Kyoto, Japan). Animals were maintained on a 12 h light/dark cycle in a central animal facility. All animals were allowed free access to solid food (MF, Oriental Yeast Co. Tokyo, Japan) and tap water. All animal experiments were approved by the Experimental Animal Research Committee of Kyoto Pharmaceutical University (KPU) and were performed according to the Guidelines for Animal Experimentation of KPU.

Inhibitory Effects of $VOSO_4$ and Dioxovanadium(v) Complexes on Free Fatty Acid (FFA) Release from Isolated Rat Adipocytes Treated with Epinephrine:[4,7] Epididymal fat pads, excised from male Wistar rats (7−8 weeks) anesthetized with ether, were cut into appropriate pieces and incubated in type-II collagenase digestion in a Krebs−Ringer hydrogen carbonate (KRB) buffer (120 mM NaCl, 1.27 mM $CaCl_2$, 1.2 mM $MgSO_4$, 4.75 mM KCl, 1.2 mM KH_2PO_4 and 24 mM $NaHCO_3$; pH = 7.4) containing 2% BSA and 5 mM glucose at 37 °C with gentle shaking at 100 cycles/min for 1 h. The prepared cells were filtered through sterilized cotton gauze and were then washed with KRB buffer. Isolated rat adipocytes cells ($1.0-2.0 \times 10^6$ cells/mL) were preincubated at 37 °C for 30 min with various concentrations ($10^{-4}-10^{-3}$ M) of $VOSO_4$ or dioxovanadate complexes in KRB buffer containing 2% dimethyl sulfoxide (DMSO) with or without 1 mM (+)-L-ascorbic acid. The reaction mixtures were then incubated at 37 °C for 3 h after the addition of epinephrine (10^{-5} M, adrenaline). The reactions were stopped by soaking in ice/water and the resultant mixtures were centrifuged at 3000 rpm at 4 °C for 10 min. For the outer solution of the cells, the FFA levels were determined with an FFA kit (NEFA C-test Wako, Wako Pure Chemicals). In vitro insulin-mimetic effects of the dioxovanadate complexes were evaluated by the apparent IC_{50} value (50% inhibitory concentration of the FFA released in each system).

Reaction of $V^{V}O_2L$ with Ascorbic Acid: The reduction of $V^{V}O_2L$ by ascorbic acid was studied by electronic spectroscopy in DMSO solution. Ascorbic acid (0.047 mmol, 8.3 mg) was added to a $V^{V}O_2L$ solution (9.5×10^{-4} M, 5.0 mL) ($V^{V}O_2L$/ascorbic acid, molar ratio 1:10). The spectrum of the resultant solution was measured in the range 400−800 nm both before and after the addition and monitored with time until no bands were detected. The reaction of $V^{V}O_2L^2$ with ascorbic acid was also monitored by ^{1}H NMR at 303 K, by first dissolving $V^{V}O_2L^2$ (0.032 mmol) in [D_6]DMSO/D_2O (8:2) in an NMR tube. After purging the solution with nitrogen for 5 min, the ^{1}H NMR spectrum was measured. The ascorbic acid (0.032 mmol) was then added in one portion, and the ^{1}H NMR spectrum measured again after keeping the mixture under nitrogen for 30 min.

X-ray Crystallographic Study of Copper(II), Cobalt(II) and Silver(I) Complexes of Ligands Containing Two Oxine Subunits Linked by Xylylene Spacer Groups

Muna R. A. Al-Mandhary[a] and Peter J. Steel*[b]

Keywords: N,O ligands / Copper / Cobalt / Silver / Bridging ligands

X-ray crystal structures are reported for six transition-metal complexes of the ligands 1,2-bis(8-quinolyloxymethyl)benzene (**3**) and 1,3-bis(8-quinolyloxymethyl)benzene (**4**). In three mononuclear copper(II) and cobalt(II) complexes, **3** acts as a chelating ligand with either *N*,*O*,*N*′-tridentate or *N*,*O*,*O*′,*N*′-tetradentate coordination. A novel dinuclear silver(I) complex of **3** is shown to be stabilised by a number of weak metal–ligand contacts and multiple intramolecular π–π stacking interactions. In two dinuclear copper(II) nitrate complexes of **4**, the ligand adopts very different bridging modes of coordination.

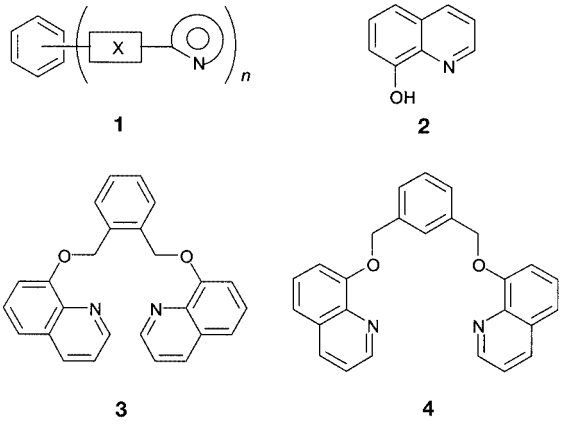
Introduction

Studies of combinations of organic ligands and metal-ion precursors for the controlled self-assembly of metallosupramolecular species have been the subject of a number of recent reviews.[1] Whereas rigid components are most commonly used for the rational construction of various molecular architectures, we have adopted a different approach of using flexible building blocks in order to gain access to topologies not accessible from more rigid precursors. In this context, we have recently[2] been synthesising a class of ligands represented by the general structure **1** (Scheme 1). Each of these ligands consists of a number of heterocyclic donor groups linked by flexible spacers (X) to a central arene core. This simple representation disguises the complexity of a large library of compounds that we are currently investigating. By systematically varying the number of arms, the specific heterocycle, the nature of the linking groups and the type of arene core, we can prepare ligands with a diverse range of properties.

We have found xylylene derivatives to be particularly useful components for the construction of various interesting new supramolecular architectures. For example, we have prepared new ligands consisting of *ortho*-, *meta*- and *para*-xylylene groups connected to pyrazolyl,[3] 2-pyridyloxy,[4] 2-pyridylsulfanyl[5] and benzotriazolyl[6] moieties and used them in reactions with various metals to produce metallosupramolecular species of diverse dimensionalities. In such compounds, additional stability can be imparted to the metal complexes by incorporating chelating binding domains into the ligand design. Although bridging ligands containing multiple 2,2′-bipyridine binding sites are by far the most well studied,[7] we,[8] and others,[9] have found the 3-(2-pyridyl)pyrazol-1-yl substituent to be a useful *N*,*N*′-chelating structural subunit and have attached this moiety to xylylene spacers.



1 **2** **3** **4**

Scheme 1

Recently, we have embarked on the synthesis of a range of ligands that contain *N*,*O*-chelating moieties and have chosen 8-hydroxyquinoline (oxine; **2**) as a common starting material. Although oxine itself has a long history as a versatile bidentate ligand,[10] it has not commonly been incorporated into larger multidentate ligands. Recently, Albrecht and co-workers have reported the use of a number of ligands containing two oxine groups linked through the carbon atoms of the quinoline ring in order to prepare various complexes.[11] However, our approach has been to join the oxine subunits through the oxygen atoms.[12,13]

We herein describe the syntheses and X-ray crystal structures of a number of transition-metal complexes with ligands **3** and **4**, which consist of two oxine groups attached to the *ortho*- and *meta*-xylylene cores, respectively. Recently, we have communicated the intriguing ability of **4** to form a compact trinuclear circular helicate upon reaction with silver triflate.[14]

Results and Discussion

The ligands 1,2-bis(8-quinolyloxymethyl)benzene (**3**) and 1,3-bis(8-quinolyloxymethyl)benzene (**4**) are known compounds that were prepared by literature procedures.[15,16] We also prepared the corresponding para-isomer,[16] but were unable to form any crystalline complexes with it. Related podands, including **3**, have previously been shown to form stable complexes with alkali and alkaline earth metals.[17] Ligands **3** and **4** were treated with a variety of transition-metal salts under various reaction conditions and stoichiometric ratios. Six such reactions produced crystalline products suitable for X-ray crystal structure analysis, the structures of which we describe below. These two ligands might be expected to adopt a variety of coordination modes depending on which of the donor atoms are involved. The ligands could act as bidentate *N*,*N*′-donors in chelating or bridging modes, or as tetradentate ligands with involvement of the weaker ether oxygen donors.

Reactions of **3** with copper(II) chloride, copper(II) nitrate and cobalt(II) bromide all furnished crystalline products in good yields. Each of these complexes crystallise in the triclinic space group $P\bar{1}$ and is mononuclear with 1:1 L:MX_2 stoichiometry. Figure 1−3 show perspective views, with selected interatomic distances and angles, of the three structures in similar orientations. Although the three structures appear very similar, there are some intriguing, subtle differences. In all three structures ligand **3** adopts a very similar conformation, wherein the plane of each quinoline ring is almost orthogonal to the plane of the attached xylylene group (range of angles between planes ca. 86.3−88.8°).

Figure 1. Figure 3. Perspective view of the X-ray crystal structure of **7**; selected interatomic distances (Å) and angles (????): Co−N11 2.153(2), Co−N21 2.157(2), Co−O1 2.211(2), Co−O2 2.282(2), Co−Br2 2.490(1), Co−Br1 2.496(1); N11−Co−N21 169.93(8), N11−Co−O1 73.76(7), N21−Co−O1 99.18(7), N11−Co−O2 97.68(8), N21−Co−O2 73.06(8), O1−Co−O2 72.54(7), N11−Co−Br2 92.36(6), N21−Co−Br2 94.86(6), O1−Co−Br2 90.15(5), O2−Co−Br2 156.49(5), N11−Co−Br1 94.97(6), N21−Co−Br1 89.45(6), O1−Co−Br1 159.18(5), O2−Co−Br1 92.22(5), Br2−Co−Br1 108.09(2)

However, the structures differ in the extent of interaction of the ether oxygens with the metal centre. This, in turn, is reflected in different bonding geometries at the metal centre. In the copper(II) chloride complex **5** the metal has approximately square-pyramidal five-coordinate geometry, as

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

defined by a τ value of 0.19.[18] In this arrangement the atoms N11, N21, O2 and Cl1 define the basal plane and Cl2 occupies the apical position and, accordingly, has a longer bond length to the copper atom. This geometry allows for a weak interaction [2.466(2) Å] between the metal and the formally noncoordinated ether oxygen O1 (shown as a dashed line in Figure 1). However, in the copper(II) nitrate complex **6**, the geometry is intermediate between square-pyramidal and trigonal-bipyramidal with a τ value of 0.47. Once again, this geometry permits a weak interaction [2.457(3) Å] between the copper atom and O2.

In contrast, the greater requirement for six-coordination of cobalt results in the distorted octahedral geometry of complex **7** in which ligand **3** employs all of its four donor atoms. This results in two five-membered *N*,*O*-chelate rings being fused to a central seven-membered *O*,*O*′-chelate ring. The distortions from idealised octahedral geometry result from the bite angles of the chelate rings (ca. 73°) and the Br1−Co−Br2 bond angle [108.09(2)°]. Thus, in these three complexes, ligand **3** acts as a chelating ligand with either *N*,*O*,*N*′-tridentate or *N*,*O*,*O*′,*N*′-tetradentate coordination.

Previously,[14] we have described the reaction of **4** with silver triflate to produce a novel trinuclear circular helicate. The analogous reaction of **3** with silver triflate produced a very different result. The crystalline product **8** obtained from this reaction crystallises in the monoclinic space group $P2_1/c$; the asymmetric unit comprises a M_2L_3 unit, two triflate counterions and a diethyl ether solvate molecule. Figure 4 show a perspective view of the dinuclear dication, along with selected interatomic distances and angles. The nearly symmetrical structure consists of a central molecule of **3** that bridges two silver atoms, each of which is further coordinated to another molecule of **3**. The structure of **8** is interesting for a number of reasons. Each silver atom is coordinated to two quinoline nitrogen atoms with near-linear geometry. However, the bond lengths (> 2.2 Å) are somewhat long for two-coordinate silver centres.[19] The reason for this is the involvement of other donor substituents with the d^{10} silver centres.

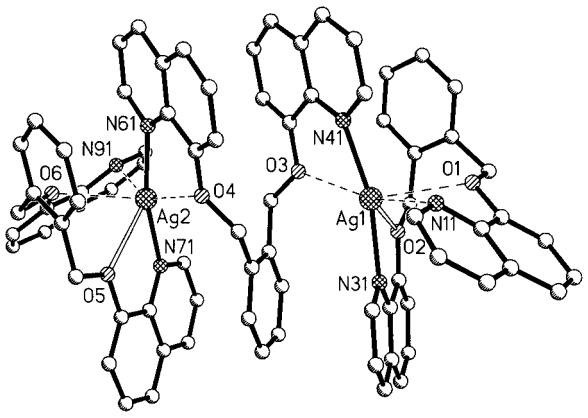

Figure 4. Perspective view of the X-ray crystal structure of **8**, hydrogen atoms, the triflate counterions and the diethyl ether solvate molecule are all omitted for clarity; selected interatomic distances (Å) and angles (°): Ag1−N41 2.213(2), Ag1−N31 2.229(2), Ag1−O2 2.595(2), Ag1−O1 2.714(2), Ag1−N11 2.714(2), Ag1−O3 2.656(2), Ag2−N61 2.230(2), Ag2−N71 2.261(2), Ag2−O5 2.575(2), Ag2−O4 2.722(2), Ag2−N91 2.722(2), Ag2−O6 2.725(2); N41−Ag1−N31 163.74(8), N41−Ag1−O2 125.39(7), N31−Ag1−O2 66.56(7), N61−Ag2−N71 167.94(8), N61−Ag2−O5 122.13(8), N71−Ag2−O5 66.53(8)

The oxygen atoms attached to the externally coordinated quinoline rings are involved in weak chelation (ca. 2.58 Å) with the silver atoms (hollow bonds in Figure 4). A notable feature of the structure is the unusual and symmetrical conformations of three molecules of **3** in this complex. We believe that each of these ligands contorts itself into the observed conformations in order to bring the remaining six potential donors into proximity with the silver atoms. Although each of these interactions (dashed bonds in Figure 4) is undoubtedly weak (ca. 2.7 Å), the combined forces of all six such interactions is likely to have a significantly stabilising influence. There is also a further stabilising factor operating in this complex, the intramolecular π−π stacking interactions between the various aromatic ring systems. Specifically, the central benzene ring of the bridging ligand is stacked between the two chelating quinolines. Additionally, the two quinoline rings of the central bridging ligand are stacked on top of one another and between the benzene rings of the outer two ligands. All of these interactions involve coplanar rings (angles between planes < 5°) separated by about 3.4 Å. Once again, although these are weak interactions, the combined influence of all five stacking interactions is likely to be significant.

Having demonstrated that ligand **3** is capable of acting as both a chelating and bridging ligand, we turned our attention to the *meta*-isomer **4**, where a chelating mode of coordination would appear less likely. Ligand **4** was treated with copper(II) nitrate in a variety of different solvents. In two cases this provided crystalline products, which were shown to be structurally very different. Reaction in methanol produced complex **9**, which crystallises in the monoclinic space group $P2_1/n$. Figure 5 shows a perspective view of **9**, with selected interatomic distances and angles.

This complex consists of a dinuclear copper pair bridged by two methoxide anions and ligand **4**. Monodentate nitrate anions complete the coordination environment of the two square-planar copper atoms. Once again the bridging ligand **4** adopts an unusual conformation, which we believe occurs in order to bring the noncoordinated ether oxygens into the coordination sphere of the copper atoms (dashed bonds in Figure 5). Relatively few dinuclear methoxide-bridged copper complexes of this type are known.[20] The Cu1−Cu2 interatomic distance [3.029(1) Å] is similar to that found in related examples.[20]

In contrast to this result, reaction of **4** with copper(II) nitrate in acetonitrile led to complex **10** which has very different architecture. It crystallises in the triclinic space group $P\bar{1}$ and has the structure shown in Figure 6. In this complex the ligand **4** acts as a more conventional bridging ligand separating two copper atoms at a distance of 10.526(1) Å. The copper atoms have square-pyramidal geometry (τ values 0.08 and 0.02 for Cu1 and Cu2, respectively) and are further coordinated to two monodentate nitrates, a water molecule and, with considerably longer bonds, to ether oxy-

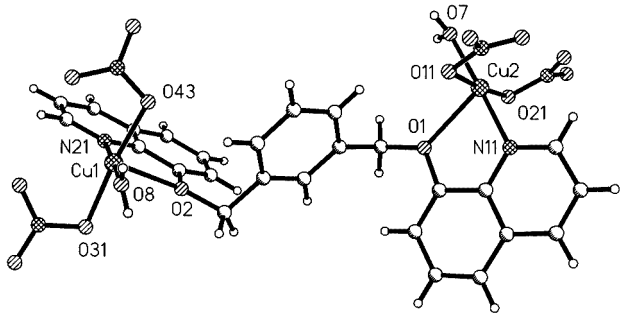

Figure 6. Perspective view of the X-ray crystal structure of **10**; diethyl ether and acetonitrile solvate molecules are not shown; selected interatomic distances (Å) and angles (°): Cu1−O8 1.935(2), Cu1−N21 1.985(2), Cu1−O43 1.987(2), Cu1−O31 1.990(2), Cu1−O2 2.391(2), Cu2−O7 1.937(2), Cu2−N11 1.975(2), Cu2−O11 1.987(2), Cu2−O21 2.010(2), Cu2−O1 2.395(2); O8−Cu1−N21 177.78(9), O8−Cu1−O43 87.87(9), N21−Cu1−O43 91.59(8), O8−Cu1−O31 86.74(9), N21−Cu1−O31 93.96(8), O43−Cu1−O31 172.91(7), O8−Cu1−O2 107.48(9), N21−Cu1−O2 74.68(7), O43−Cu1−O2 90.45(7), O31−Cu1−O2 86.78(7), O7−Cu2−N11 175.81(10), O7−Cu2−O11 88.90(9), N11−Cu2−O11 94.01(9), O7−Cu2−O21 86.22(9), N11−Cu2−O21 90.98(9), O11−Cu2−O21 174.68(8), O7−Cu2−O1 102.09(9), N11−Cu2−O1 74.76(8), O11−Cu2−O1 93.34(8), O21−Cu2−O1 89.74(8)

gens in the apical positions. Surprisingly, a search of the Cambridge Crystallographic Database revealed that this is an unprecedented geometry for a copper atom with this donor set.

Thus, ligand **4** acts as a bridging ligand in each of these two copper complexes, but in doing so, produces dinuclear complexes with very different topologies. As mentioned above, we have previously reported a novel trinuclear circular helicate resulting from reaction of **4** with silver triflate. We have since treated **4** with silver nitrate and found that this leads to a similar circular helicate, but we were unable to refine its X-ray crystal structure to a level that we consider to be acceptable (currently $R_1 = 6.5$ %). Nevertheless, this result shows that the formation of such circular helicates occurs independently of the counterion, thereby suggesting that the self-assembly process does not involve anion templation.[21]

Conclusion

In this study, we have shown that ligands comprising two oxine subunits separated by xylylene spacer groups represent useful substrates for the construction of a diverse range of interesting new complexes of varying nuclearity. These ligands have been shown to be capable of both chelating and bridging modes of coordination. Presently, we are extending this design concept to related ligands containing a greater number of oxine substructures, thereby providing access to more complex multinuclear species.

Experimental Section

Ligands **3**[15] and **4**[16] were prepared by literature procedures. Solvents were purified according to literature procedures. Other reagents were obtained from commercial sources and used as supplied. Melting points were determined using an Electrothermal melting point apparatus and are uncorrected. Elemental analyses were performed by the Campbell Microanalytical laboratory at the University of Otago.

Complex 5: $CuCl_2·2H_2O$ (8.7 mg, 0.051 mmol) dissolved in MeCN (1 mL) was layered onto a solution of ligand **3** (20 mg, 0.051 mmol) in CH_2Cl_2 (1 mL) to produce orange crystals suitable for X-ray analysis. M.p. 168 °C. Yield 21 mg (78 %). $C_{26}H_{20}Cl_2CuN_2O_2$ (526.90): C 59.27, H 3.83, N 5.32; found C 59.25, H 4.00, N 5.41.

Complex 6: $Cu(NO_3)_2·3H_2O$ (12 mg, 0.050 mmol) dissolved in MeCN (1 mL) was layered onto a solution of ligand **3** (20 mg, 0.051 mmol) in CH_2Cl_2 (1 mL) to produce yellow crystals suitable for X-ray analysis. M.p. 140−142 °C. Yield 24 mg (71 %). $C_{26}H_{20}CuN_4O_8Cu·CH_2Cl_2$ (664.94): C 48.77, H 3.33, N 8.43; found C 49.13, H 3.13, N 8.41.

Complex 7: $CoBr_2$ (22 mg, 0.10 mmol) dissolved in MeOH (1 mL) was layered onto a solution of ligand **3** (20 mg, 0.051 mmol) in CH_2Cl_2 (1 mL) to give purple crystals suitable for X-ray analysis. M.p. 240 °C (decomp.). Yield 22 mg (71 %). $C_{26}H_{20}Br_2CoN_2O_2$ (611.19) C 51.09, H 3.30, N 4.58; found C 51.17, H 3.19, N 4.67.

Complex 8: AgOTf (8.7 mg, 0.034 mmol) dissolved in MeCN (1 mL) was added to a solution of ligand **3** (20 mg, 0.051 mmol) dissolved in MeCN (1 mL). Diethyl ether (1 mL) was then added to this solution. Slow evaporation of this mixture provided colourless crystals suitable for X-ray analysis. M.p. 226−229 °C. Yield 20 mg (70 %). $C_{80}H_{60}Ag_2F_6N_6O_{12}S_2$ (1691.22): C 56.81, H 3.58, N 4.97; found C 56.63, H 3.54, N 4.91.

Complex 9: $Cu(NO_3)_2·3H_2O$ (25.6 mg, 0.102 mmol) dissolved in MeOH (1 mL) was layered onto a solution of ligand **4** (20 mg, 0.051 mmol) in CH_2Cl_2 (1 mL) to give dark green crystals suitable for X-ray analysis. M.p. 205 °C (decomp.). Yield 11 mg (31 %). $C_{28}H_{26}Cu_2N_4O_{10}$ (705.62): C 47.66, H 3.71, N 7.94; found C 47.69, H 3.85, N 7.91.

Complex 10: $Cu(NO_3)_2{\cdot}3H_2O$ (12 mg, 0.051 mmol) dissolved in MeCN (1 mL) was layered onto a solution of ligand **4** (10 mg, 0.025 mmol) in CH_2Cl_2 (1 mL) to give a green solution. Diffusion of diethyl ether into this solution gave green crystals suitable for X-ray analysis. M.p. 118 °C (decomp.). Yield 14 mg (58 %). $C_{32}H_{37}Cu_2N_7O_{17}{\cdot}Cu_2{\cdot}1/2(CH_2Cl_2)$ (961.23): C 41.61, H 3.98, N 10.21; found C 41.27, H 3.68, N 10.34.

X-ray Crystallography: The crystal data and details of the data collections and refinements for all six structures are listed in Table 1. Measurements were made with a SMART CCD area detector using graphite-monochromatized Mo-K_α (λ = 0.71073Å) radiation. The structures were solved by direct methods using SHELXS[22] and refined on F^2 using all data by full-matrix least-squares procedures with SHELXL-97.[23] All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were included in calculated positions with isotropic displacement parameters 1.2 times the isotropic equivalent of their carrier atoms. The functions minimised were $\Sigma w (F_o^2 - F_c^2)$, with $w = [\sigma^2(F_o^2) + aP^2 + bP]^{-1}$, where $P = [\max F_o^2 + 2F_c^2]/3$. Full tables of atom coordinates, thermal parameters, bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre. CCDC-194259−194264 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank the Royal Society of New Zealand Marsden Fund for financial support and Sultan Qaboos University for sabbatical leave to M. Al-Mandhary. We also thank Chris Fitchett and John Cannon for important contributions to the crystallography.

Syntheses, Structures, and Magnetic Properties of Copper(II) Complexes with 1,3-[Bis(2-pyridylmethyl)amino]benzene (1,3-tpbd) as Ligand

Simon P. Foxon,[a] Gemma Romualdo Torres,[a] Olaf Walter,[b] Jens Zacho Pedersen,[c] Hans Toftlund,[c] Martina Hüber,[d] Karsten Falk,[d] Wolfgang Haase,[d] Joan Cano,[e] Francesc Lloret,[e] Miguel Julve,*[e] and Siegfried Schindler*[a]

Keywords: Copper / Magnetic properties / EPR spectroscopy / Spin polarisation / Dinuclear complexes

The dinuclear copper(II) complexes $\{[Cu_2(1,3\text{-tpbd})(H_2O)(OAc)_2](ClO_4)_2\}_{0.23}\{[Cu_2(1,3\text{-tpbd})(H_2O)_2(OAc)](ClO_4)_3\}_{0.77}\cdot 0.77H_2O$ (**1**), $[Cu_2(1,3\text{-tpbd})(H_2O)_2(OAc)_2](ClO_4)_2\cdot 2H_2O$ (**2**), and the tetranuclear copper(II) complex $[Cu_4(1,3\text{-tpbd})_2(H_2O)_2(SO_4)_4]\cdot 8H_2O$ (**3**) {1,3-tpbd = 1,3-bis[bis(2-pyridylmethyl)amino]benzene} were synthesised and structurally characterised by X-ray diffraction. Variable-temperature (2.0–290 K) magnetic susceptibility measurements on these complexes as well as on the dinuclear copper(II) complex $[Cu_2(1,3\text{-tpbd})(H_2O)_2(ClO_4)_3]ClO_4$ (**4**) (whose structure was published earlier) were performed. In contrast to **2** and **3**, significant ferromagnetic coupling with $J = +9.3$ cm^{-1} was observed for **4** (the Hamiltonian being defined as $\hat{H} = -J\,\hat{S}_1\cdot\hat{S}_2$). Density functional theory (DFT) calculations were used successfully for the interpretation of the ferromagnetic coupling observed in **4**.

Introduction

Continuing interest in the synthesis and characterisation of polynuclear copper(II) complexes derives from the efforts to understand the factors that are responsible for the magnetic exchange interactions between coupled metal centres. Attention has been focused on the magnetostructural correlations and the exchange mechanism involving different bridging groups.[1−7]

The symmetry and energy of the SOMOs ("magnetic orbitals": the molecular orbitals which define each unpaired electron of a paramagnetic centre) and the molecular orbitals of the bridging ligands are important for the understanding of the magnetic exchange phenomena in polynuclear complexes.[3,8−10] The most common situation for magnetic coupling through extended bridges is the antiferromagnetic interaction: the larger the overlap integral between the SOMOs involved, the larger the antiferromagnetic coupling. However, ferromagnetic coupling is observed when the interacting SOMOs are orthogonal to one another: the larger the overlap density between orthogonal SOMOs, the larger the ferromagnetic coupling. Orthogonality can be achieved by either geometrical or topological symmetry; geometrical symmetry has been successfully applied to bimetallic compounds[3] and metal−radical systems.[11] Topological symmetry is being used extensively in designing high-spin organic polyradical species; the intramolecular spin alignment can be explained in terms of the spin polarisation mechanism.[12,13] This mechanism describes how an unpaired electron on one atom polarizes the electron cloud on the adjacent atom in the opposite sense.

Although the spin polarisation mechanism was shown to be valid for some oxygen or nitrogen perturbed systems[14,15] as well as for some organic radical-paramagnetic transition metal ion type systems,[16] the limits of its application are unclear, especially for coordination compounds containing transition metal ions as the only spin sources. In fact, polymeric transition metal complexes containing pyrimidine bridges have been designed as an approach to molecule-based ferromagnets.[17−22] Ward and co-workers provided examples of antiferromagnetic/ferromagnetic coupling between transition metal ions connected by conjugated bridges with an even/odd number of atoms.[19,20]

Some of us have investigated dinuclear copper complexes with ligands derived from 1,3-phenylenediamine which can be regarded as model compounds for copper proteins.[23,24] However, only a few ligands are described in the literature that are based on a 1,3-phenylenediamine unit.[21,25−30]

We have synthesised and characterised dinuclear copper(I) and copper(II) complexes with the ligand 1,3-bis[bis(2-pyridylmethyl)amino]benzene (1,3-tpbd).[23] A schematic representation of the cation of the copper(II) complex $[Cu_2(1,3\text{-tpbd})(H_2O)_2(ClO_4)_3]ClO_4$ characterised by single-crystal X-ray diffraction is shown below in Figure 1.

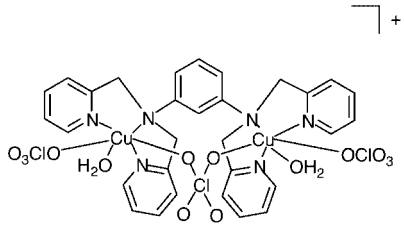

Figure 1. Schematic representation of the molecular structure of the cation of $[Cu_2(1,3\text{-tpbd})(H_2O)_2(ClO_4)_3]ClO_4$ (**4**)

To investigate the effect of substituting the perchlorate bridge in $[Cu_2(1,3\text{-tpbd})(H_2O)_2(ClO_4)_3]ClO_4$ with other anions we synthesised and structurally characterised the dinuclear copper(II) complexes $\{[Cu_2(1,3\text{-tpbd})(H_2O)(OAc)_2](ClO_4)_2\}_{0.23}\{[Cu_2(1,3\text{-tpbd})(H_2O)_2(OAc)](ClO_4)_3\}_{0.77}\cdot 0.77H_2O$ (**1**), $[Cu_2(1,3\text{-tpbd})(H_2O)_2(OAc)_2](ClO_4)_2\cdot 2H_2O$ (**2**), and the tetranuclear copper(II) complex $[Cu_4(1,3\text{-tpbd})_2(H_2O)_2(SO_4)_4]\cdot 8H_2O$ (**3**) and furthermore investigated their magnetic behaviour in comparison with $[Cu_2(1,3\text{-tpbd})(H_2O)_2(ClO_4)_3]ClO_4$ (**4**).

Results and Discussion

Synthesis and Crystal Structures

$[Cu_2(1,3\text{-tpbd})(H_2O)_2(ClO_4)_3](ClO_4)$ (**4**) was prepared and characterised as described previously.[23] Dinuclear cop-

per(II) complexes with acetate or sulfate as additional anionic ligands in place of perchlorate were obtained by mixing the appropriate copper(II) salts with 1,3-tpbd in methanol/water mixtures.

Acetate can display varying modes of coordination in its copper(II) complexes: bridging, bidentate and monodentate coordination modes of this ligand are well-known and for the sake of brevity only a few examples are given in the cited references.[31−37] Our first attempt of reacting together 1,3-tpbd, copper(II) perchlorate and copper(II) acetate resulted in a mixture of blue and green crystals. The molecular structure of both compounds was solved by single-crystal X-ray diffraction; the blue crystals showed disorder at one copper(II) ion indicating that in the unit cell there were two different complexes present, denoted **1a** and **1b**, which were found in a 23 to 77 ratio respectively. The contents of the unit cell can be represented as $\{[Cu_2(1,3\text{-tpbd})(H_2O)(OAc)_2](ClO_4)_2\}_{0.23}\{[Cu_2(1,3\text{-tpbd})(H_2O)_2(OAc)](ClO_4)_3\}_{0.77}\cdot 0.77H_2O$ ($\mathbf{1a}_{0.23}\mathbf{1b}_{0.77}\cdot 0.77H_2O$). In **1a** the copper(II) ion Cu(1) is tetra-coordinated to three N-donor atoms of the 1,3-tpbd ligand and one O atom of an acetate, the ligands forming a distorted square planar environment around the copper(II) ion (Figure 2 and Table 1 and 2). The coordination geometry around the copper(II) ion Cu(2) is square pyramidal; Cu(2) is bound to three N-donor atoms of the 1,3-tpbd ligand, one O atom of an acetate ion [O(4) in Figure 2] and one O-donor atom of a coordinated water molecule.

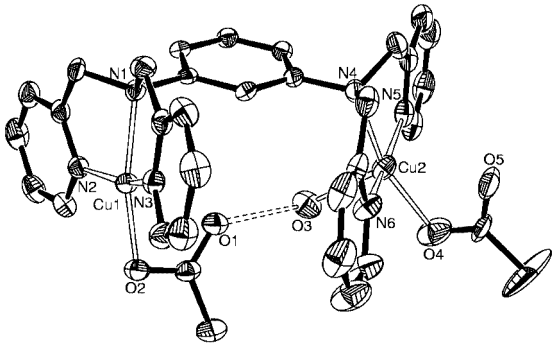

Figure 2. ORTEP representation (30% probability displacement ellipsoids) of the cation of **1a** (hydrogen atoms are omitted for clarity)

The copper(II) coordination environments in **1a** and **1b** differ; one of the coordinated acetate anions in **1a** [O(4) in Figure 2] is replaced by a water solvent molecule and an additional perchlorate anion is found in the unit cell.

An intramolecular hydrogen bond formed by the water solvent molecule O(3), which is always coordinated to Cu(2), and the non-coordinated O atom O(1) of the acetate ligand bound to the other copper ion Cu(1) leads to further stabilisation (Table 2).

The dark green crystals were characterised as $[Cu_2(1,3\text{-tpbd})(H_2O)_2(OAc)_2](ClO_4)_2\cdot 2H_2O$ (**2**) and the molecular

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structure of the cation of **2** is shown in Figure 3 (Table 1 and 2). Each copper(II) centre is five-coordinate and their coordination geometries are best described as square pyramidal.

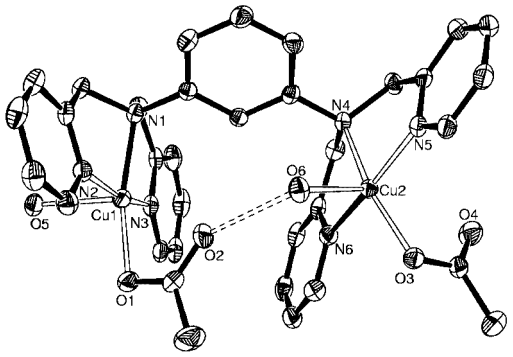

Figure 3. ORTEP representation (30% probability displacement ellipsoids) of the cation of **2** (hydrogen atoms are omitted for clarity)

2 was obtained in a pure form by mixing 1,3-tpbd and copper(II) acetate stoichiometrically (1:2) in methanol/water with an excess of sodium perchlorate. Only large green crystals of **2** were grown from that solution. An excess of acetate ions in solution is necessary to avoid substitution of the acetate ligands by water molecules.

In contrast to **4**, where a perchlorate ion bridges the two copper(II) ions in the solid state, the acetate ions in **1a**, **1b** and **2** coordinate only in a monodentate fashion. The Cu−O bond lengths in **1a**, **1b** and **2** (Table 2) are similar to those found in other monodentate acetate-containing copper(II) complexes and the $Cu-N_{pyridine}$ bonds are shorter than the $Cu-N_{amine}$ bonds.[35,37] In the cases where the copper(II) ion is coordinated by an axial ligand, the bond lengths of Cu−O are clearly longer than those in the equatorial positions. Bond lengths and angles of **1** and **2** compare well with **4**. The Cu···Cu distances in **1** (6.06 Å) and **2** (5.85 Å) are similar to **4** (5.87 Å)[23] even though the two copper(II) ions are not bridged by acetate.

Sulfate was also chosen to replace the perchlorate bridge in **4**. There are numerous examples of structurally characterised transition metal complexes with sulfate as a bridging ligand (a limited number of examples are given in the references).[38−43] Mixing stoichiometric amounts of copper(II) sulfate and 1,3-tpbd (2:1) in water lead to the formation of dark blue crystals after slow evaporation at room temperature. The molecular structure revealed that the tetranuclear complex $[Cu_4(1,3\text{-tpbd})_2(H_2O)_2(SO_4)_4]\cdot 8H_2O$ (**3**) formed (Figure 4 and Table 1 and 2) with the sulfate ion acting as both a terminal ligand and as a bridging ligand.

Each copper(II) ion in **3** is five-coordinate and their coordination geometries are best described as distorted square pyramidal. The two sulfate-bridged copper(II) ions are separated by 3.316 Å. The sulfate anions exhibit an unusual one atom bridging mode which is reflected in the different S−O bond lengths of 1.515(2) Å (coordinated oxygen) and 1.461(2) Å (mean value, uncoordinated oxygens). The Cu···Cu distances through the bridging 1,3-tpbd units (7.20 Å) in **3** are much longer than in **1**, **2** or **4**. We are aware of only one other example of a bis-sulfate bridged copper(II) complex $[Cu(HL)(SO_4)]_2$ (HL = 2-formylpyridine thiosemicarbazone) which has been structurally characterised.[39] The geometry of the coordination sphere around the copper(II) ions in $[Cu(HL)(SO_4)]_2$ is distorted square-pyramidal, with bond lengths and angles for $[Cu(HL)(SO_4)]_2$ similar to those observed in **3**.

Magnetic Properties of 2, 3 and 4

The temperature dependence of $\chi_M T$ for **4** (χ_M is the magnetic susceptibility per two copper(II) ions) is shown in Figure 5.

At room temperature, $\chi_M T$ is equal to 0.85 $cm^3\cdot K\cdot mol^{-1}$, the expected value for two magnetically isolated spin doublets. Upon cooling, the value of $\chi_M T$ increases, attaining a maximum at 3.5 K and then decreasing slightly further. This behaviour is typical of a ferromagnetically coupled dinuclear copper(II) complex, the small decrease of $\chi_M T$ in the low temperature range being due to weak intermolecular magnetic interactions.

The susceptibility data of **4** were analysed through a simple Bleaney−Bowers expression[44] for two magnetically interacting local spin doublets derived from the Hamiltonian $\hat{H} = -J\,\hat{S}_1\cdot\hat{S}_2$ ($\hat{S}_1 = \hat{S}_2 = 1/2$) with the inclusion of a θ parameter to account for the intermolecular interactions. Least-squares best-fit results are: $J = +9.3\ cm^{-1}$, $g = 2.12$, $\theta = -0.08$ K and $R = 1.8 \times 10^{-6}$ (R is the agreement factor defined as $\Sigma_i[(\chi_M T)_{obsd.}(i) - (\chi_M T)_{calcd.}(i)]^2/$

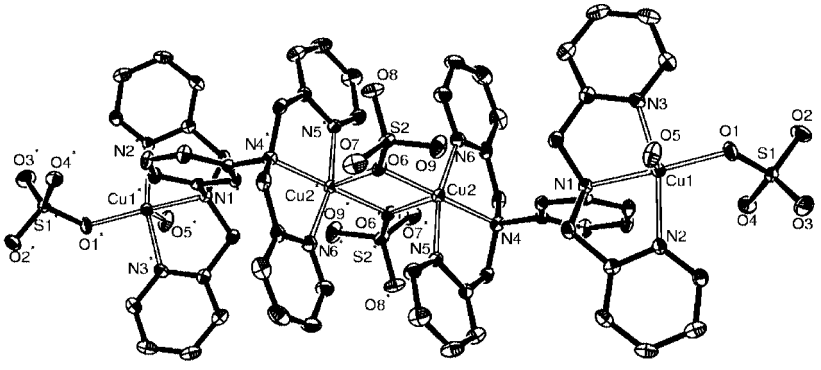

Figure 4. ORTEP representation (30% probability displacement ellipsoids) of **3** (hydrogen atoms are omitted for clarity)

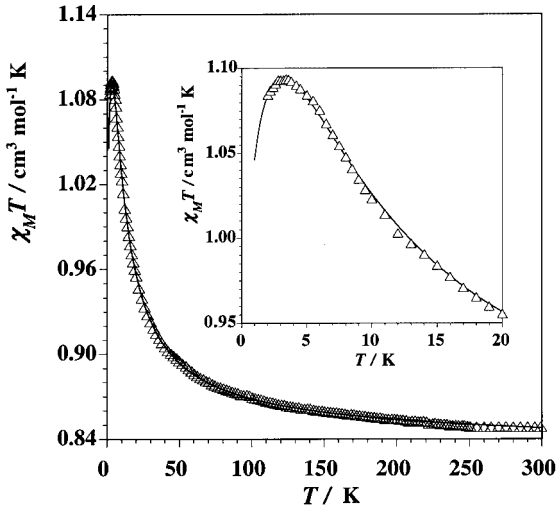

Figure 5. Thermal variation of $\chi_M T$ for **4**: (△) experimental data; (−) best fit (see text). The inset shows the maximum of $\chi_M T$ in the low-temperature region (applied magnetic field of 0.1 T)

$\Sigma_i[(\chi_M T)_{obsd.}(i)]^2$). The theoretical curve (solid line in Figure 5) fits the experimental data well as indicated by the low value of the agreement factor. The magnetisation versus H plot up to 5 T (maximum available magnetic field with our SQUID) at 2 K (Figure 6) tends to a saturation value of ca. 2.1 BM as expected for a $S = 1$ spin state with $g = 2.12$.

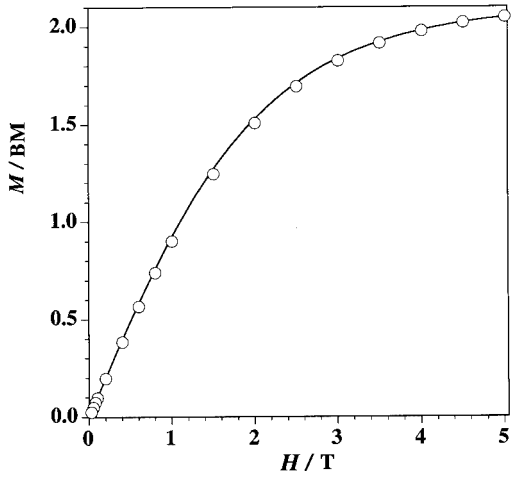

Figure 6. M versus H plot at 2 K for **4**: (o) experimental data; (–) Brillouin function for an $S = 1$ spin state with $g = 2.12$

The EPR spectrum of **4** in methanol (Figure 7) was recorded at X-band frequency at 100 K to elucidate further the nature of the magnetic coupling. The spectrum shows a seven line splitting pattern in the $g_{||}$ region, with the 1:2:3:4:3:2:1 intensity pattern characteristic of a coupled dinuclear Cu^{II} system. A similar signal, but with much lower intensity, due to the forbidden $\Delta M = \pm 2$ state was observed around 1500 G. The observed half-field signal confirms the presence of a $Cu^{II}-Cu^{II}$ triplet state. No changes in the positions of the signals were observed in this spectrum when working at 5 K.

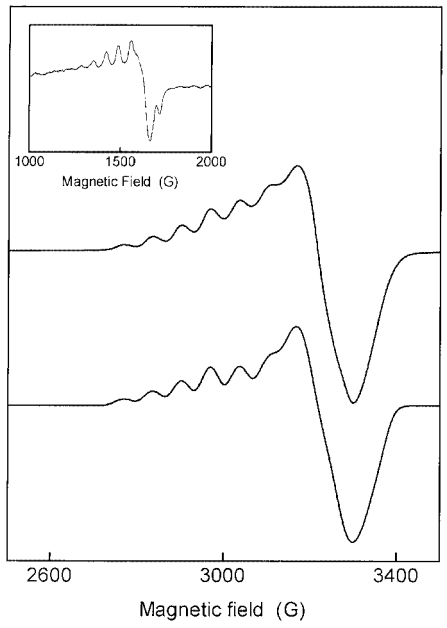

Figure 7. Top: Measured EPR spectrum of **4** in methanol/water; Bottom: Simulated spectrum. The inset shows the measured EPR spectrum at half-field

Magnetic susceptibility measurements of **2** were problematic. A large crystal, which was taken out of the mother liquor, was investigated immediately and no magnetic coupling could be detected during the magnetic measurements. This behaviour changed when the crystal became dry with a ferromagnetic coupling of ca. $J = +9.1$ cm^{-1} observed. Ferromagnetic coupling was observed when smaller crystals were used which seemed to loose water molecules when a vacuum was applied during the magnetic measurements. Most likely, carboxylate-assisted water loss occurs and the structural change associated with this process [carboxylate bridge between Cu(1) and Cu(2)] would lead to a 1,3-tbpd-bridged dicopper(II) fragment very close in nature to that observed for **4**, the magnetic coupling of the anhydrous phase of **2** being essentially identical to that of **4**.

EPR measurements of **2** were unsuccessful in providing a complete description of the magnetic behaviour. The EPR spectrum of the pure green crystals dissolved in methanol demonstrated that at least a mixture of three species exists under these conditions. This is similar to our findings during the structural characterisation of the complexes, where from one solution three different complexes were obtained. Clear changes in the EPR spectra were observed by adding sodium perchlorate or sodium acetate indicating the presence of equilibria in solution. Even though no "clean" EPR spectrum could be measured for **2**, we observed that no triplet state at half field was detected under the same conditions as for **4**, in agreement with the magnetic susceptibility measurements of the large crystal. Therefore, it is clear that none of the acetate complexes in methanolic solutions [most likely species consisting of differing amounts of acetate and water molecules coordinated to the copper(II)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ions as shown in Figure 2 and 3] provide a magnetic exchange pathway for ferromagnetic coupling.

Magnetic susceptibility measurements of **3** failed to provide any information that magnetic coupling between the copper(II) ions in this complex takes place. **3** showed typical normal magnetic behaviour of four magnetically isolated copper(II) ions and the data followed a Curie law. This finding is the same as the findings obtained for $[Cu(HL)(SO_4)]_2$ where no magnetic exchange phenomena were detected.[39] EPR spectra of **3** could not be obtained because the complex is insoluble in methanol and those performed in water or methanol/water mixtures were not well resolved.

The number of ferromagnetically coupled dinuclear copper(II) complexes is small when compared to that of antiferromagnetically coupled ones.[1,3,32,34,45–52] Herein, different bridging groups were found to provide a magnetic exchange pathway for ferromagnetic coupling in dinuclear copper(II) complexes. However, in all these cases (with the exception of a related complex reported recently[21]) the distance between the two copper(II) ions is much less than 5.87 Å as in **4**. Moreover, magnetic exchange coupling over large distances is often weak and antiferromagnetic.[3,6,53,54]

Examining the structure of **4** (Figure 1), two possible exchange pathways could be operative, one involving the phenylenediamine unit and the other involving the perchlorate bridge. The latter pathway is ruled out taking into account that the perchlorate oxygen is axially coordinated to the copper(II) ion [2.39 Å for Cu–O(perchlorate)].[23] As the unpaired electron of the copper(II) ion is delocalised only in the four short equatorial bonds, it is clear that the spin density on the perchlorate oxygen should be very small. A similar conclusion was reached by Murray and coworkers for the perchlorate bridged complex $[Cu_2L^1(ClO_4)_2]\cdot 2H_2O$ [L^1 = *N*-(2-pyridinyl)acetoacetamide].[55] Furthermore, from the X-ray structure data of **4** the intermolecular exchange interaction can be excluded: the shortest intermolecular copper–copper distance is 8.67 Å, with no ligand present which could provide a possible exchange pathway. Consequently, the exchange pathway involved in the ferromagnetic coupling observed in **4** is operating through the *meta*-phenylenediamine bridge. In contrast to **4**, complexes with either a *para*-phenylenediamine (pd) bridge as in $[(tren)Cu(pd)Cu(tren)]^{4+}$[56,57] [tren = tris(2-aminoethyl)amine], or the dinuclear copper(II) complex of the *para* homologue of 1,3-tpbd, $[Cu_2(1,4\text{-tpbd})(H_2O)_4](S_2O_6)_2$ ($J = -15.56$ cm^{-1}),[58] show weak antiferromagnetic coupling.

The relatively weak exchange coupling of the unpaired electrons of the copper(II) ions in **4** is expected since the superexchange pathway, attributed to magnetic exchange coupling interactions, is most often described as operating via the sigma bond framework. In the case of $[Cu_2(1,4\text{-tpbd})(H_2O)_4](S_2O_6)_2$ the pathway is seven bonds long. A comparison of the magnetic coupling observed in $[Cu_2(1,4\text{-tpbd})(H_2O)_4](S_2O_6)_2$ with the magnetic coupling observed in **4** provides a demonstration of the spin-polarisation mechanism between paramagnetic ions via an aromatic organic bridging group. Ferromagnetism is predicted in cases where there is an odd number of bridging atoms and antiferromagnetic exchange coupling with an even number of bridging atoms. With five atoms between the copper(II) ions in **4**, the σ framework is one bond shorter than that in $[Cu_2(1,4\text{-tpbd})(H_2O)_4](S_2O_6)_2$. The two SOMOs involved in **4** are almost perpendicular to the phenyl ring and the unpaired electrons in the $d_{x^2-y^2}$ orbitals of both copper(II) ions can interact via this pathway. Thus the nature of the exchange coupling observed in these two complexes (ferro- in **4** and antiferromagnetic in $[Cu_2(1,4\text{-tpbd})(H_2O)_4](S_2O_6)_2$] is expected using this model.

In order to interpret the ferromagnetic interaction present in **4**, DFT calculations were performed (see paragraph of Computational Methodology in the Exp. Sect.)[23] on the model systems depicted in Figure 8 (**I**–**IV**), where the donor nitrogen atoms of 1,3-tpbd have been replaced by ammonia molecules (model **IV** corresponds to the complex **4**).

In the four models, the unpaired electron on each copper(II) ion (that is the SOMO) lies in the basal plane of the

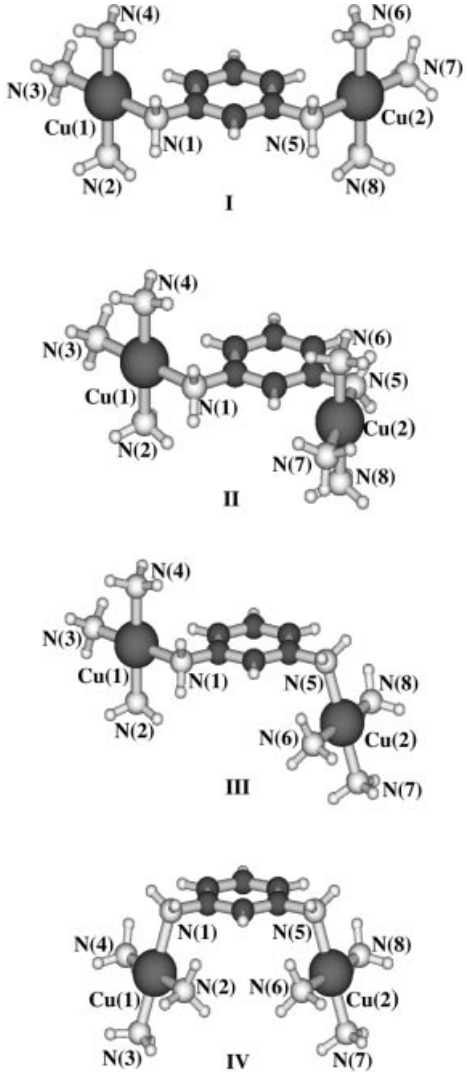

Figure 8. Model systems (**I**–**IV**) of dinuclear copper(II) complexes which were used to carry out the DFT type calculations (see text)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

metal ion [comprising of atoms N(1), N(2), N(3), and N(4) for Cu(1) and N(5), N(6), N(7), and N(8) for Cu(2)]. The orientation of the two SOMOs with respect to the phenylenediamine plane is gradually varied in **I**−**IV** in such a manner that the exchange interaction is transmitted through either pure σ (**I** and **II**) or π (**IV**) pathways, whereas **III** is a mixed σ-π type. The calculated values of *J* for models **I**−**IV** are −1.7, −0.1, +0.6 and +7 cm^{-1}, respectively.

The analysis of the trend for the observed *J* values shows that the magnetic interaction is weak and antiferromagnetic in **I** and **II**, with that of **I** being somewhat larger. The SOMOs in these models are perpendicular to the plane of the phenylenediamine plane, but they differ in their conformation: *anti-anti* in **I** versus *anti-syn* in **II**. The σ in-plane overlap between the SOMOs of Cu(1) and Cu(2), through the long pathway Cu(1)−N(1)−C−C−C−N(5)−Cu(2) in both models, is expected to be weak and poorer in the case of **II** because of its *anti-syn* configuration. Since the antiferromagnetic interaction in a dinuclear copper(II) complex is proportional to the square of the overlap integral between the SOMOs,[56,57] the value of the antiferromagnetic coupling in **I** and **II** is expected to be very small and weaker for **II**. In the case of **III** the SOMO of Cu(2) lies below the plane of the phenylenediamine plane, whereas that of Cu(1) remains unchanged. In this situation, although the set of atoms involved in the exchange pathway is the same as in **I** and **II** [Cu(1)−N(1)−C−C−C−N(5)−Cu(2)], the spin density on N(1) is of a σ type whereas that on N(5) is of a π type. Consequently, a zero overlap between the SOMOs will result (case of accidental orthogonality) and a ferromagnetic coupling interaction is expected. This coupling has to be small because of the extended bridging pathway involved.[56,57] In the case of model **IV** the two SOMOs, being perpendicular to the phenylenediamine plane, lie below this plane. The spin density on the N(1) and N(5) amine nitrogens is of the π type. The DFT calculations for this model indicate a ground triplet spin state lying below the excited singlet spin state. The calculated value of *J* for **IV** (+7 cm^{-1}) agrees well with the experimental value obtained for **4** from the fit of the susceptibility data ($J = +9.3\ cm^{-1}$). To qualitatively understand this result, a focus on the nature of the singly occupied molecular orbitals (SOMOs) depicted in Figure 9 (a) is helpful.

The SOMOs are composed of the in-phase and out-of-phase combinations of the 3d orbitals of the copper(II) ions with two π-type nonbonding molecular orbitals of appropriate symmetry of the *meta*-phenylenediamine unit. In these SOMOs there is an antibonding interaction between the $d_{x^2-y^2}$ orbital of the copper(II) ion and the p_z atomic orbital of the nitrogen atoms of the bridging ligand. This interaction involves: i) an energy gap between the two SOMOs following the rules formulated by Kanamori and Goodenough or Kahn's model.[3,8−10] Since the orbitals of the ligands involved in the building of these SOMOs are of a non-bonding character and, consequently, similar energies, and since the electronic densities on the nitrogen atoms are also similar in both orbitals, the two resultant SOMOs

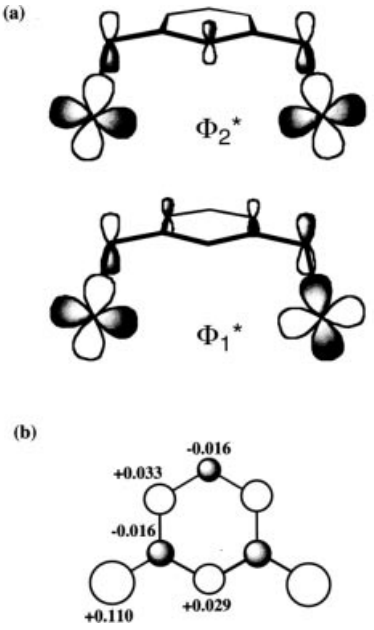

Figure 9. Schematic representation of (a) the two SOMOs and (b) the spin density distribution on the bridge region for **4** on the basis of DFT calculations. Empty and full contours represent positive and negative spin densities, respectively. Calculated average atomic spin densities are presented

(φ_1* and φ_2*) are practically degenerate, with a small energy gap of 347 cm^{-1}; ii) a spin delocalisation from the copper(II) ion to the nitrogen atom of the π system of the bridging skeleton, that accounts for the transmission of the exchange. Thus, the direct overlap between the $d_{x^2-y^2}$ orbital of the metal ion and the π system of the pyridyl ligand allows the unpaired spin of the metal to induce a polarisation of spin on the bridging skeleton (see Figure 9), as occurs in similar compounds described by Ung et al.[20] These systems constitute very interesting cases because of the strong competition between spin delocalisation and spin polarisation, prevailing the alternating spin rule in our case, as shown by experimental data and theoretical calculations.

Conclusion

Complex **4** is an example of a dinuclear copper(II) complex showing ferromagnetic exchange coupling over quite a long distance. The ferromagnetic coupling in **4** is due to the non-coplanarity of the metal coordination planes, leading to a folded structure, placing the two SOMOs in **4** practically perpendicular to the phenyl ring. The symmetry in **4** breaks down if the bridging perchlorate ion is substituted by a non-bridging acetate ion as in **2** and the magnetic interaction vanishes. The magnetic coupling in the dehydrated phase of **2** is essentially identical to that of **4**. Such a fact suggests that the carboxylate-assisted loss of the coordinated water molecule in **2** leads to a carboxylato-bridged species where the carboxylato group mimics the perchlorato group in **4**, leading to a very similar structure. The relative arrangement of the SOMOs of the copper(II) ions, with re-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

spect to the *meta*-phenylenediamine plane, and the fact that the sulfate-oxygen occupies an equatorial position of one copper(II) ion [Cu(2A)] and the axial one at the adjacent copper(II) ion [Cu(2)] account for the lack of magnetic coupling in the tetrameric complex **3**.

Experimental Section

General Remarks: Reagents and solvents used were of commercially available reagent grade quality. 1,3-tpbd and **4** were synthesised as described previously.[23] Electron spin resonance measurements at X-band frequency were obtained using a Bruker EMX-113 spectrometer. Samples in methanol or methanol water (9:1) mixtures were measured at 100 K. Simulation of all EPR spectra was made with the Bruker SimFonia program. Magnetic susceptibility data were collected: a) Over the temperature range 4.2−295 K at an applied magnetic field of 0.56−1.5 T. The measurements were performed using a Faraday-type magnetic balance, equipped with a Cahn D-200 microbalance and a Bruker B-MN 200/60 electromagnet.[59] The sample constituted of microcrystals contained in a quartz basket which was calibrated independently, using $HgCo(SCN)_4$ as calibrant. The diamagnetic correction of the magnetic susceptibility was calculated using Pascal's constants. b) Over the temperature range 2.0−290 K with a Quantum Design SQUID susceptometer and using an applied magnetic field of 0.1 T (compounds **2** and **4**). The susceptometer was calibrated with $(NH_4)_2Mn(SO_4)_2{\cdot}12H_2O$.

Computational Methods: The computational strategy used in the present work has been fully described elsewhere,[60] and it is briefly outlined here. For the evaluation of the coupling constant for each model compound (**I**−**IV**, Figure 8), two separate calculations were carried out using DFT, one for the triplet state and another one for the low-spin, broken symmetry state. The hybrid B3LYP method[61] was been used in the calculations as implemented in GAUSSIAN 98,[61] with all-electron double-ζ basis proposed by Ahlrichs and co-workers except for copper where we have used a triple-ζ basis.[62] Ammonia molecules were used as peripheral ligands in **I**−**IV** and the bond lengths and angles are those of the average values of the real structures. The complete dimeric structures were used in the calculations to estimate the values of *J*.

Caution! *Perchlorate salts are potentially explosive and should be handled with great care. Our preparations were carried out on mmol scale and heating was avoided.*

Mixture of $[Cu_2(1,3\text{-tpbd})(H_2O)(OAc)_2](ClO_4)_2$/$[Cu_2(1,3\text{-tpbd})(H_2O)_2(OAc)](ClO_4)_3$ (1a/1b) and $[Cu_2(1,3\text{-tpbd})(H_2O)_2(OAc)_2](ClO_4)_2$ (2): To a suspension of 1,3-tpbd (250 mg, 0.5 mmol) in methanol (15 mL) was added a solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (195 mg, 0.525 mmol) and $Cu(OAc)_2{\cdot}H_2O$ (104 mg, 0.525 mmol) in water (20 mL). The green solution was stirred for a few minutes, filtered and crystals suitable for X-ray analysis formed after a few days.

$[Cu_2(1,3\text{-tpbd})(H_2O)_2(OAc)_2](ClO_4)_2{\cdot}2H_2O$ (2): To a suspension of 1,3-tpbd (250 mg, 0.5 mmol) in methanol (15 mL) was added a solution of $Cu(OAc)_2{\cdot}H_2O$ (208 mg, 1.05 mmol) in 20 mL of water. After an excess of solid $NaClO_4$ was added to the green solution it was stirred for a few minutes, filtered and left on the shelf. Crystals suitable for X-ray analysis formed after a few days. Yield 267 mg (54%). $C_{34}H_{42}Cl_2Cu_2N_6O_{16}$ (988.7): calcd. C 41.30, H 4.28, N 8.50; found C 40.94, H 4.06, N 8.48.

$[Cu_4(1,3\text{-tpbd})_2(H_2O)_2(SO_4)_4]{\cdot}8H_2O$ (3): To a suspension of 1,3-tpbd (300 mg, 0.63 mmol) in methanol (15 mL) was added a solution of $Cu(SO_4)_2{\cdot}6H_2O$ (315 mg, 1.26 mmol) in water (20 mL). The deep green solution was stirred for a few minutes, filtered and blue crystals suitable for X-ray analysis formed after a few days. Yield 220 mg (40%). $C_{60}H_{76}Cu_4N_{12}O_{26}S_4$ (1763.7): calcd. C 40.86, H 4.34, N 9.53; found C 40.86, H 4.58, N 9.40.

X-ray Crystallographic Study: Crystal data and experimental conditions are listed in Table 2. The molecular structures are illustrated in Figures 2−4. Selected bond lengths and bond angles with standard deviations in parentheses are presented in Table 1. Intensity data were collected on a Siemens SMART 5000 CCD-Diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). The collected reflections were corrected for Lorentz, polarisation and absorption effects.[63] The structures were solved by direct methods and refined by full-matrix-least-squares methods on F^2.[64,65] CCDC-204112, -204113, and -204114 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

S. S. and W. H. gratefully acknowledge financial support from the Volkswagen-Stiftung and the Deutsche Forschungsgemeinschaft. Furthermore, we thank Dr. Achim Elvers and Prof. Dr. Ulrich Zenneck (University of Erlangen-Nürnberg) for their assistance with the first EPR measurements and helpful discussions. S. S. furthermore thanks Prof. Dr. Rudi van Eldik (University of Erlangen-Nürnberg) for his support of this work. Financial support from the Spanish Ministry of Science and Technology through Project BQ2001−2928 is also acknowledged.

Tuning the Magnetic Properties of a Dinuclear Copper Complex: From Ferromagnetic to Antiferromagnetic Coupling

Simon P. Foxon,[a] Olaf Walter,[b] Robert Koch,[c] Holger Rupp,[c] Paul Müller,[c] and Siegfried Schindler*[a]

Keywords: Magnetism / Copper / Azides / Dinuclear complexes

A novel structural motif in oxalate bridged copper(II) complexes has been prepared namely a metallamacrocyclic compound of the dinucleating ligand 1,3-bis[bis(2-pyridylmethyl)-amino]benzene (= 1,3-tpbd). It could be demonstrated that the magnetic properties of copper(II) complexes of the 1,3-tpbd ligand can be adjusted from weakly ferromagnetic (J = +9.3 cm^{-1}) to strongly antiferromagnetic [J = –366(9) cm^{-1}] by variation of the additional ligands (e.g. perchlorate, azide, oxalate etc.).

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

We have previously demonstrated that the ligand 1,3-tpbd {tpbd = 1,3-bis[bis(2-pyridylmethyl)amino]benzene}, a derivative of 1,3-phenylenediamine, provides a rigid structural framework in which two copper(I) or copper(II) ions can bind in close proximity to one another.[1] A magnetic study on the structurally characterised perchlorate bridged dinuclear copper(II) complex $[Cu_2(1,3\text{-tpbd})(H_2O)_2(ClO_4)_3](ClO_4)$ (**1**, Figure 1) showed that a significant ferromagnetic coupling (J = +9.3 cm^{-1}, the Hamiltonian being defined as $\mathbf{H} = -J\mathbf{S}_1\cdot\mathbf{S}_2$) mediated by the phenylenediamine unit could be observed[2] and the intramolecular Cu···Cu distance is 5.873(1) Å.[1] Ferromagnetic coupling has also been reported recently for a related dinuclear complex.[3] The ferromagnetic coupling following the spin polarisation mechanism was successfully interpreted for both complexes using density functional theory (DFT) calculations.[2,3]

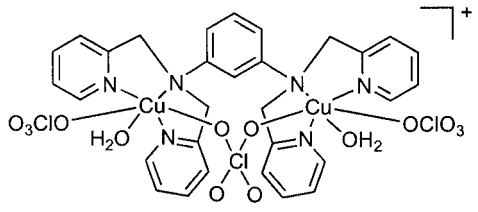

Figure 1. Schematic representation of the cation of **1**

In contrast, no magnetic exchange coupling was observed when the perchlorate group in **1** was substituted with acetate {which did not bridge the two copper(II) ions} or sulfate {the sulfate ion acting as both a terminal ligand and a one-atom bridging ligand in the tetranuclear complex $[Cu_4(1,3\text{-tpbd})_2(H_2O)_2(SO_4)_4]$}.[2]

Besides acetate, azide, and oxalate are typical multidentate ligands employed in copper(II) chemistry in order to achieve strong magnetic coupling between two metal centres.[4] Polynuclear copper(II) complexes with bridging azide ligands have received much attention due to the diverse range of their structural and magnetic properties.[4] Interest originates from the variety of coordination modes the azide anion can exhibit. It can act either as a terminal ligand or as a bridging ligand. For the latter case, three different types of structure may be observed: N_3^- can bridge through just one of the terminal nitrogen atoms (μ-1,1)[5–16] or through both terminal nitrogen atoms (μ-1,3) either symmetrically or asymmetrically.[5,17–23] The magnetic behaviour of the respective modes of coordination has been well established. The μ-1,1 mode mediates strong ferromagnetic exchange interactions and the symmetric μ-1,3 mode mediates strong antiferromagnetic exchange interactions.

During the last 20 years extensive theoretical and experimental studies by Kahn[9,24,25] and others[26,27] have been carried out in order to understand the exceptional ability of the oxalate bridge in mediating very weak to quite strong antiferromagnetic coupling between copper(II) centres separated by more than 5.5 Å. Kahn et al. elegantly demonstrated that in a series of dinuclear copper(II) μ-oxalate

complexes it was possible to "tune" the singlet-triplet energy gap (2J) over a wide range ($0 < 2J < 400$ cm^{-1}) by keeping the [Cu(μ-oxalate)Cu]$^{2+}$ core constant and varying only the nature of the amine ligands.[28]

We decided to exploit the fact that the ligand 1,3-tpbd is capable of binding two metal ions at a fixed distance in order to prepare a novel dinuclear copper(II) bridging oxalate complex. It was envisaged that the 1,3-tpbd backbone would "fix" the [Cu(μ-oxalate)Cu]$^{2+}$ core in a rigid planar conformation leading to a strong antiferromagnetic interaction between the two copper(II) centres mediated by the oxalate bridge. Herein, we report the synthesis, structural characterisation, and magnetic behaviour of 1,3-tpbd copper(II) complexes with azide and oxalate as co-ligands.

Results and Discussion

Crystal Structure of [Cu_2(1,3-tpbd)(N_3)$_4$] (2)

The mode of azide binding which would occur in the copper(II) complex of 1,3-tpbd [Cu_2(1,3-tpbd)(N_3)$_4$] (**2**) was not at all predictable. We assumed the azide ligands would most likely adopt an intra- or intermolecular bridging mode (the common case). A structural determination of **2** revealed, however, two terminal azide anions coordinated to each copper(II) ion (the less common case). An ORTEP[29] representation of the crystal structure of **2** is shown below in Figure 2. Crystallographic data for **2** are presented in Table 2 with selected bond lengths and angles in Table 1.

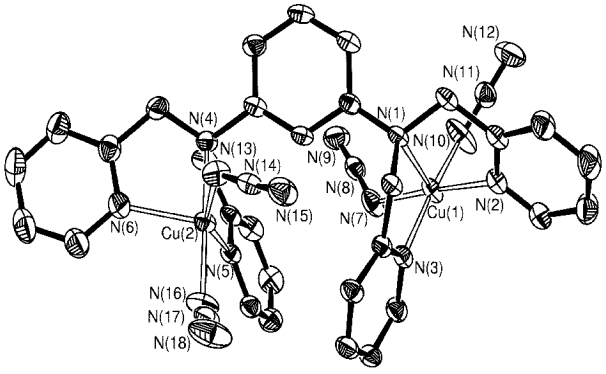

Figure 2. ORTEP[29] representation (50% probability displacement ellipsoids) of **2**. Hydrogen atoms omitted for clarity

Each copper(II) ion in **2** is five-coordinate [intramolecular separation Cu(1)···Cu(2) = 6.160(2) Å] being ligated by five nitrogen donor atoms, three nitrogen atoms from the 1,3-tpbd ligand and two azide ions. The coordination geometry around Cu(1) and Cu(2) is best described as distorted square-based pyramidal, with Cu(1) adopting a closer to ideal square-based pyramidal geometry than Cu(2). For Cu(1) the trigonality index parameter[30] $\tau = 0.06$ [where $\tau = (\beta - \alpha)/60$, with α and β being the two largest coordination angles around the metal centre. For ideal square-pyramidal geometry $\tau = 0$, while for perfect trigonal-bipyramidal geometry $\tau = 1$]. The equatorial plane around Cu(1) consists of the pyridyl donor atoms N(2) and N(3) of the ligand and the azide donor atoms N(7) and N(10) [Cu(1)−N(2) = 2.036(2) Å, Cu(1)−N(3) = 2.044(2) Å, Cu(1)−N(7) = 1.955(2) Å, Cu(1)−N(10) = 1.975(2) Å]. Occupying the apical coordination site is the tertiary amine atom N(1) of the ligand [Cu(1)−N(1) = 2.474(2) Å]. Around Cu(2) the coordination geometry is significantly distorted from square pyramidal towards trigonal bipyramidal (τ[30] = 0.36). The apical coordination site of Cu(2) however is occupied by the pyridyl donor atom N(6) of the ligand [Cu(2)−N(6) = 2.176(2) Å] and not by the tertiary amine atom N(4), which is in contrast to what is evident for Cu(1). The equatorial plane around Cu(2) consists of

the tertiary amine atom N(4) and the pyridyl donor atom N(5) of the ligand and the donor atoms N(13) and N(16) of the two azide ligands [Cu(2)−N(4) = 2.138(2) Å, Cu(2)−N(5) = 2.029(2) Å, Cu(2)−N(13) = 1.979(2) Å, Cu(2)−N(16) = 1.959(2) Å]. Cu(2) deviates from the mean plane of the square pyramid towards the apical N(6) by ca. 0.22 Å.

Asymmetric azide stretching vibrations generally occur above 2000 cm^{-1}, and the appearance of more than one band is a good indication that more than one type of azide ligand is present. In the solid state the N_3^- stretching frequency in **2** appears as a sharp band at 2048 cm^{-1}, a value which is in agreement with other structurally and spectroscopically characterised dinuclear copper(II) complexes containing terminal azide ligands.[11,31]

$[Cu_2(1,3\text{-tpbd})(C_2O_4)(DMF)_2](ClO_4)_2\cdot DMF$ (3)

Reacting sodium oxalate with **1** led to the initial isolation of a turquoise coloured precipitate. Recrystallisation of the precipitate by slow diffusion of diethyl ether into a DMF containing solution led to the formation of the dinuclear complex $[Cu_2(1,3\text{-tpbd})(C_2O_4)(DMF)_2](ClO_4)_2\cdot DMF$ (**3**). An ORTEP[29] representation of the crystal structure of the cation of **3** is shown below in Figure 3. Crystallographic data for **3** are presented in Table 2 and selected bond lengths and angles are in Table 1.

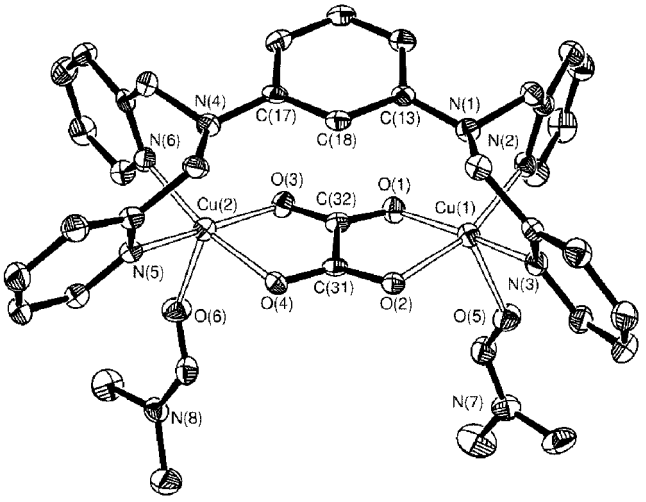

Figure 3. ORTEP[29] representation (50% probability displacement ellipsoids) of **3**. Hydrogen atoms and one DMF solvent molecule omitted for clarity

The cation of **3** consists of two copper(II) ions [intramolecular separation Cu(1)···Cu(2) = 5.188(2) Å] with the copper(II) ions being bridged by the bis-bidentate oxalate ion. Both the copper(II) centres are best described as having a "4+1" square pyramidal coordination geometry and the geometrical parameters around each copper(II) centre do not differ significantly from one another. The basal plane around Cu(1) consists of the two pyridine nitrogen atoms of the ligand [Cu(1)−N(2) = 2.026(3) Å and Cu(1)−N(3) = 2.027(3) Å] and two oxygen atoms of the oxalate anion [Cu(1)−O(1) = 2.013(2) Å and Cu(1)−O(2) = 1.996(2) Å]. A DMF solvent molecule occupying the apical site [Cu(1)−O(5) = 2.242(2) Å] completes the coordination environment around Cu(1). The tertiary amine nitrogen N(1) forms a very weak interaction with Cu(1) [Cu(1)···N(1) = 2.509(2) Å]. This is most likely the reason for the much smaller distance between the copper(II) ions in **3** compared with **1** or **2**. The dimensions of the oxalate anion show no abnormalities and are typical of those found in other structurally characterised copper(II) complexes. The basal planes around Cu(1) and Cu(2) do not lie perfectly coplanar with the plane containing the oxalate bridge: the oxalate bridge is slightly "puckered", giving rise to a "boat type" conformation.[27] The oxalate anion and the central aromatic ring of the 1,3-tpbd moiety are not coplanar with one another and, moreover, the oxalate anion does not lie directly beneath the aromatic ring. However, the central aromatic ring carbon atoms C(13), C(17), and C(18) make several close contacts with the oxalate anion: [C(13)···O(1) = 3.333 Å, C(18)···C(31) = 3.018 Å, C(18)···C(32) = 3.171 Å, and C(17)···O(3) = 3.262 Å].

Many structurally characterised oxalate bridged complexes are known: a search of the Cambridge Structural Database[32] for dinuclear copper(II) complexes of amine ligands containing a bridging bis-bidentate oxalate unit reveals there to be between 40 and 50 such structures.[28,33−37]

However, in contrast to these compounds, complex **3** presents a novel structural motif in which the two copper(II) ions are furthermore bridged by the dinucleating 1,3-tpbd ligand, thus leading to a metallamacrocyclic complex when oxalate is coordinated. There are only two other examples of structurally characterised dinuclear copper(II) complexes that use oxalate only as an additional bridging ligand.[38,39] However, these complexes contain macrocyclic ligands prior to their binding to oxalate and the magnetic properties of these complexes have not been described.

Magnetic Measurements

Measurements of the magnetic properties on powder samples of **2** and **3** were performed. A plot of $m\cdot T/B$ vs. temperature for **2** at a magnetic field of 5.5 T showed no maximum which is characteristic of antiferromagnetic coupling and is shown below in Figure 4.

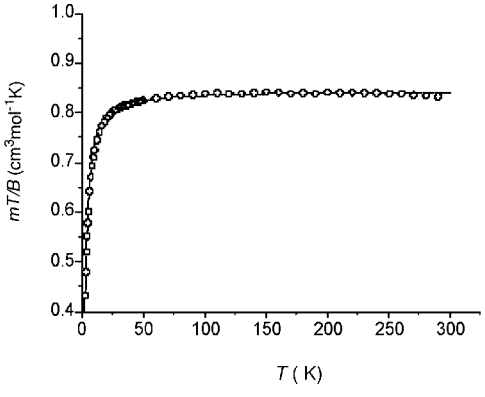

Figure 4. $m\cdot T/B$ vs. temperature of **2**. Circles represent experimental data, the solid line represents the fit

For $T > 50$ K the system behaves like an uncoupled dimer as the signal is constant at a value of 0.8 $cm^3 \cdot mol^{-1} \cdot K$. At low temperatures, the signal decreases with temperature, an indication that the value of $|J|$ is small. Quantitative analysis of the data using the Hamiltonian $H = -J\, \boldsymbol{S}_1 \cdot \boldsymbol{S}_2 + \mu_B g \boldsymbol{S} \cdot \boldsymbol{B}$, where J denotes the exchange coupling parameter, g the Zeeman factor, $\boldsymbol{S}_1$, $\boldsymbol{S}_2$, and $\mathbf{S}$ the Spin Operators for each copper(II) ion and for the coupled system] revealed as a best fit the following parameters: $J = -2.1(4)$ cm^{-1}, $g = 2.10(8)$ with $R = 1.25 \cdot 10^{-5}$ ($R = \{\Sigma[(\chi_m T)_{exp} - (\chi_m T)_{calc}]^2\}/[\Sigma(\chi_m T)^2_{exp}]\}$. As the azide anions do not act as bridging ligands, no suitable magnetic exchange pathway is available between the unpaired electrons of each copper(II) ion. Ferromagnetic coupling is no longer possible because one of the amine nitrogen donor atoms N(1) occupies the axial site of Cu(1) and is no longer in an equatorial position of the complex.

The magnetic behaviour of **3** is shown in Figure 5 as a plot of $\chi_m \cdot T$ vs. temperature, where χ_m denotes the molar susceptibility. The signal decreases with temperature down to 100 K. At lower temperatures the signal vanishes indicating an antiferromagnetic $\mathbf{S} = 0$ ground state. For theoretical analysis the same spin Hamiltonian as above was employed. At 300 K the signal is well below the value expected for two isolated copper(II) ions (0.8 $cm^3 \cdot mol^{-1} \cdot K$) indicating a huge value for $|J|$. The parameters obtained from a best fit obtained from a least-squares analysis are: $J = -366(9)$ cm^{-1}, $g = 2.18(2)$ and $R = 7.3 \cdot 10^{-6}$. The theoretical curve using the above parameters is shown in Figure 5.

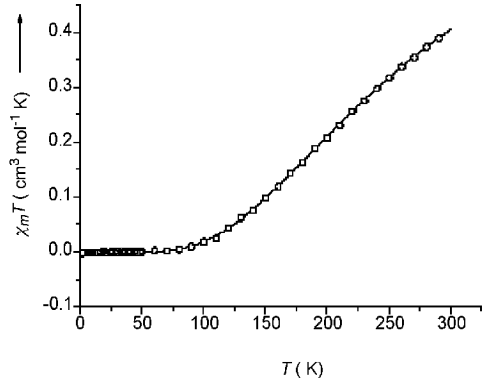

Figure 5. $\chi_m \cdot T$ vs. temperature of **3**. Circles represent experimental data, the solid line represents the fit

In contrast to **1**, ferromagnetic coupling in **3** via a spin polarisation pathway through the phenylenediamine backbone is completely excluded because the tertiary amine nitrogen atoms N(1) and N(4) of the ligand (see Figure 3 above) are not coordinated to the copper(II) ions. However, in contrast to **2**, the bridging oxalate ligand in **3** offers a pathway for strong antiferromagnetic coupling. The J value lies in the expected range for a square pyramidal copper(II) centre, albeit towards the strongest coupling observed for a Cu(ox)Cu complex containing only nitrogen donor ligands. The antiferromagnetic coupling is only slightly smaller than that found in the $[tmen(H_2O)Cu(\mu\text{-}C_2O_4)Cu(H_2O)tmen]^{2+}$ cation ($J = -384.5$ cm^{-1}).[4]

Conclusion

From the results presented herein together with an earlier report we have clearly demonstrated that the magnetic properties of copper(II) complexes of the 1,3-tpbd ligand can be adjusted from weakly ferromagnetic to strongly antiferromagnetic. However normal magnetic behaviour of magnetically isolated copper(II) ions (data following the Curie Law) as well as very weak antiferromagnetic behaviour can also be achieved. Often changes in the magnetic properties of dinuclear copper(II) complexes can be achieved by varying the nature of the ligand, and not the magnetic coupling unit e.g. azide or oxalate.

Experimental Section

General Remarks: The ligand 1,3-tpbd was synthesised as described previously.[1] Reagents and solvents were of commercially available reagent grade quality and were used without further purification. Magnetic susceptibility data for **2** and **3** were collected in the temperature range of 1.8−300 K on a Quantum Design MPMS-7 SQUID magnetometer. Two samples of each compound were investigated. The powder samples (typically 0.5 mg) were mixed with apiezon grease and fixed on a plastic straw. The signal of the grease could be subtracted from the experimental measurements, whereas the signal due to the straw was negligible.

Caution! *The syntheses and procedures described below involve compounds that contain perchlorate and azide ions, which can detonate explosively and without warning. Although we have not encountered any problems with the compounds used in this study, they should be handled with extreme caution.*

$[Cu_2(1,3\text{-tpbd})(N_3)_2]$ (2): 1,3-tpbd (0.100 g, 0.21 mmol) was suspended in acetonitrile (3 cm^3). To this suspension was added $Cu(OAc)_2 \cdot H_2O$ (0.085 g, 0.42 mmol) in water (2 cm^3). The green coloured solution was stirred for a few minutes and sodium azide (0.055 g, 0.84 mmol) in water (2 cm^3) was added dropwise. The solution became dark green. Within the period of a few hours a precipitate had formed which was removed and discarded. The remaining dark green coloured solution was allowed to evaporate slowly at room temperature. Within one week small dark green coloured needles of **2** appeared which were suitable for a single-crystal X-ray structural determination; found C 46.64, H 3.75, N 33.00. $C_{30}H_{28}Cu_2N_{18}$ (767.770) requires C, 46.93, H 3.68, N 32.84%.

$[Cu_2(1,3\text{-tpbd})(C_2O_4)(DMF)_2](ClO_4)_2 \cdot DMF$ (3): 1,3-tpbd (0.100 g, 0.21 mmol) was suspended in methanol (3 cm^3). To this suspension was added $Cu(ClO_4)_2 \cdot 6H_2O$ (0.157 g, 0.42 mmol) in water (2 cm^3). The dark green coloured solution was stirred for a few minutes and sodium oxalate (0.0284 g, 0.21 mmol) in water (2 cm^3) was added dropwise. A turquoise coloured precipitate appeared immediately. The precipitate was filtered, washed with a little water and diethyl ether, and dried (0.178 g, 0.19 mmol, 91%). The blue coloured powder was dissolved in dimethylformamide (2 cm^3). Diethyl ether was allowed to slowly diffuse into the solution and within the period of a few days small light green coloured crystals appeared which were suitable for a single-crystal X-ray structural determination; found C 44.62, H 4.74, N 11.14. $C_{41}H_{49}Cl_2Cu_2N_9O_{15}$ (1105.897) requires C 44.53, H 4.47, N 11.40%. IR (KBr disc): $\tilde{\nu}/cm^{-1}$: 1661 ($\tilde{\nu}_{asym}$OCO oxalate); 1348, 1306 ($\tilde{\nu}_{sym}$OCO oxalate); 774 (δ_{sym}OCO oxalate).

X-ray Crystallographic Studies: The details of structure solution and refinement are given in Table 2. Cell dimensions and intensity data for **2** and **3** were measured at 200(2) K on a Siemens SMART 1000 CCD diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). The collected reflections were corrected for Lorentz, polarisation, and absorption effects. The structures were solved by direct methods and refined by full-matrix least-squares procedures on F^2.[40−42] Anisotropic displacement parameters were refined for all non-hydrogen atoms, and isotropic hydrogen atoms were included with riding model constraints.

CCDC-207005 for **2** and -207004 for **3** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Mercury−Chalcogenide Clusters: Synthesis and Structure of $[Hg_{10}Te_4(SePh)_{12}(PPhnPr_2)_4]$, $[Hg_{10}Te_4(TePh)_{12}(PPhnPr_2)_4]$ and $[Hg_{34}Te_{16}(SePh)_{36}(PPhnPr_2)_4]$

Andreas Eichhöfer*[a] and Peter Deglmann[b]

Keywords: Cluster compounds / Mercury / Tellurium / Selenium / DFT calculations

The reaction of $HgCl_2$ with $PPhnPr_2$, $Te(SinBu_3)_2$ and $PhESiMe_3$ (E = Se, Te) in DME at –30 °C results in the formation of yellow octahedral crystals of $[Hg_{10}Te_4(SePh)_{12}(PPhnPr_2)_4]$ and $[Hg_{10}Te_4(TePh)_{12}(PPhnPr_2)_4]$ respectively. The molecular structures of the clusters are similar to those of other $[M_{10}Se_4(SePh)_{12}(PR_3)_4]$ (M = Cd, Zn; R = org. group) cluster compounds, but are the first of this type with tellurium as the group 16 metal atom. Dissolution of $[Hg_{10}Te_4(SePh)_{12}(PPhnPr_2)_4]$ in benzene/toluene at 5 °C leads to the formation of the larger cluster $[Hg_{34}Te_{16}(SePh)_{36}(PPhnPr_2)_4]$ which displays a new structure type for group 12–16 cluster molecules. The "$Hg_{34}Te_{16}Se_{36}$" cluster core can be considered as an idealized tetrahedral fragment, 15 Å in diameter, of the cubic sphalerite lattice with a vacancy in the center. Theoretical investigations on the basis of density functional theory (DFT) reproduce the structural data and the measured electronic spectra for this cluster. Additionally we found that formal occupation of the vacancy by a mercury ion would lead to an ionic cluster $[Hg_{35}Te_{16}(SeMe)_{36}(PMe_3)_4]^{2+}$ which should be stable according to the results of the calculations. This suggests that the formation of the vacancy is probably driven by the absence of an appropriate counterion in the reaction which might stabilize such an ionic cluster molecule.

Introduction

Systematic studies of the size dependent optical and electronic properties of CdSe cluster-molecules show that the quantum confinement effect common with larger CdSe nanocrystals also occurs in these small molecular systems.[1] Synthesis and structural characterization of group 12−16 cluster molecules has mostly focused on ZnS,[2] ZnSe,[3] ZnTe[4] and CdS.[5,6] Chalcogenide cluster compounds with mercury are still rare even though these materials possess interesting properties as bulk- or nano-materials. The alloy $Cd_{1-x}Hg_xTe$ is a well known material in long-wavelength IR detector technologies for example, and HgTe nanoparticles have been proposed as potential amplifiers operating at wavelengths of 1.3 μm and 1.55 μm in telecommunication devices.[7,8] Recent investigations on mercury selenide clusters reveal that the smaller cluster $[Hg_{10}Se_4(SePh)_{12}(PPh_2nPr)_4]$ is converted in benzene to a larger cluster $[Hg_{32}Se_{14}(SePh)_{36}]$.[9,10] In order to extend optical investigations on group 12−16 cluster molecules and to study further the mechanism of structural growth of nanoclusters in this size regime we investigated the synthesis and crystallization of mercury selenide and mercury telluride cluster molecules.

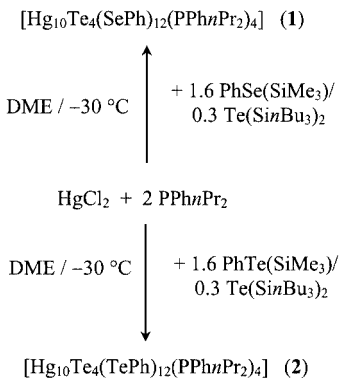
Results and Discussion

Synthesis and Structure

The reaction of $HgCl_2$ with $PPhnPr_2$, $Te(SinBu_3)_2$ and $PhESiMe_3$ (E = Se, Te) in DME at −30 °C results in the formation of yellow octahedral crystals of $[Hg_{10}Te_4(SePh)_{12}(PPhnPr_2)_4]$ (**1**) and $[Hg_{10}Te_4(TePh)_{12}(PPhnPr_2)_4]$ (**2**), respectively (Scheme 1).



Scheme 1

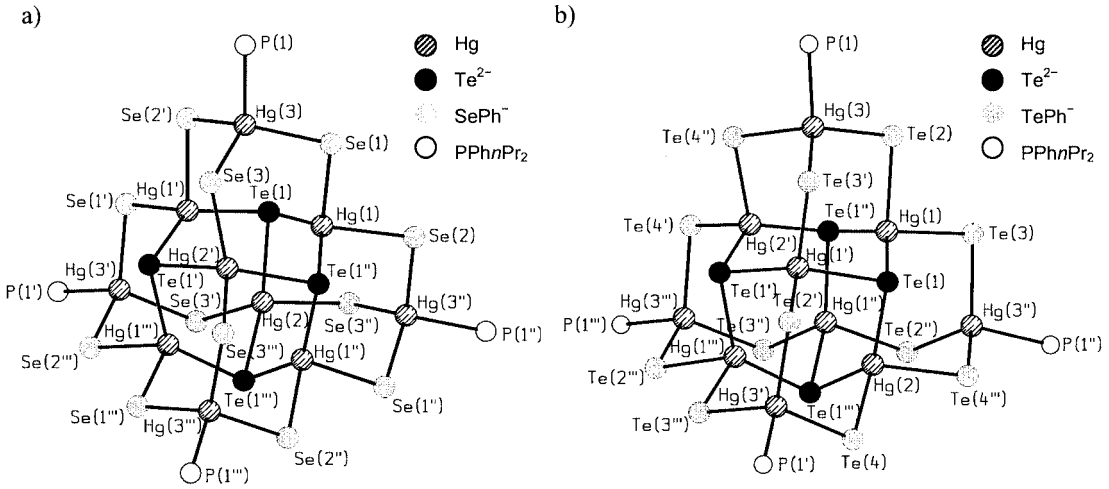


Figure 1. a) The $Hg_{10}Te_4Se_{12}P_4$ cluster core as a section of the molecular structure of $[Hg_{10}Te_4(SePh)_{12}(PPhnPr_2)_4]$ (**1**) (symmetry transformations for generating equivalent atoms: $-y + 1/4$, $x + 1/4$, $-z + 1/4$; $y - 1/4$, $-x + 1/4$, $-z + 1/4$; $-x$, $-y + 1/2$, z; $-x$, $-y + 1$, $-z + 1$). b) The $Hg_{10}Te_{16}P_4$ cluster core as a section of the molecular structure of $[Hg_{10}Te_4(TePh)_{12}(PPhnPr_2)_4]$ (**2**) (symmetry transformations for generating equivalent atoms: $y - 1/4$, $-x + 1/4$, $-z + 1/4$; $-y + 1/4$, $x + 1/4$, $-z + 1/4$; $-x$, $-y + 1/2$, z). C and H atoms are omitted for clarity.

Figure 1(a) shows the molecular structure of the $[Hg_{10}Te_4Se_{12}P_4]$ cluster core of **1** determined by single-crystal X-ray diffraction (see also Table 3). The compound crystallizes in the tetragonal space group $I4_1/a$ (4bar site symmetry). The cluster core, which is comprised of four adamantane cages each of which is formed by three tellurium, three selenium and four mercury atoms, is a macrotetrahedral fragment of the sphalerite structure, which is also found in HgSe and HgTe.[11] The resultant tetrahedron, with the four phosphane atoms in the apex positions, has edge lengths of 1240.6−1284.2 pm and has a diameter of 820 pm (from the mercury atom at the vertex of the tetrahedron to the center of the opposite tetrahedral face).

The mercury atoms Hg1−Hg3 have distorted tetrahedral environments, coordinated by the selenium atoms of the μ_2-$SePh^-$ ligands (Se1, Se2, Se3) and the μ_3-Te^{2-} ligands (Te1) as well as the phosphorus atoms of the $PPhnPr_2$ ligands (P1) (bond angles are: Se−Hg−Se 96.59−112.26(3); Se−Hg−Te 92.17−113.73(3); Te−Hg−Te 134.47−137.15(4); P−Hg−Se 104.76−108.22(11)°]. The Hg−SePh bond lengths which range from 263.44−278.09(10) pm are similar to those found in $[Hg_{10}Se_4(SePh)_{12}(PPh_2nPr)_4]$[10] while the Hg−Te bond lengths between 270.92−274.13(7) pm are shorter than those in HgTe (279 pm).[12] The Hg−P1 bond length of the four outer Hg3 atoms coordinated by the $PPhnPr_2$ ligands is 256.9(3) pm.

Figure 1(b) shows the molecular structure of the $[Hg_{10}Te_{16}P_4]$ cluster core of **2** determined by single-crystal X-ray diffraction which is isostructural with **1**. Due to the larger covalent radii of the tellurium atoms the cluster core is slightly larger in comparison with **1** as indicated by edge lengths of 1289.3−1298.7 pm of the tetrahedron formed by the four phosphane atoms and a diameter of 840 pm taken from the mercury atom at the vertex of the tetrahedron to the center of the opposite tetrahedral face. The Hg−TePh bond lengths range from 278.02−291.11(11) pm corresponding to values found in $[Hg_6(\mu\text{-}Br_2)Br_2(\mu\text{-}TePh)_8(py)_2]$[13] and the Hg−Te bond lengths from

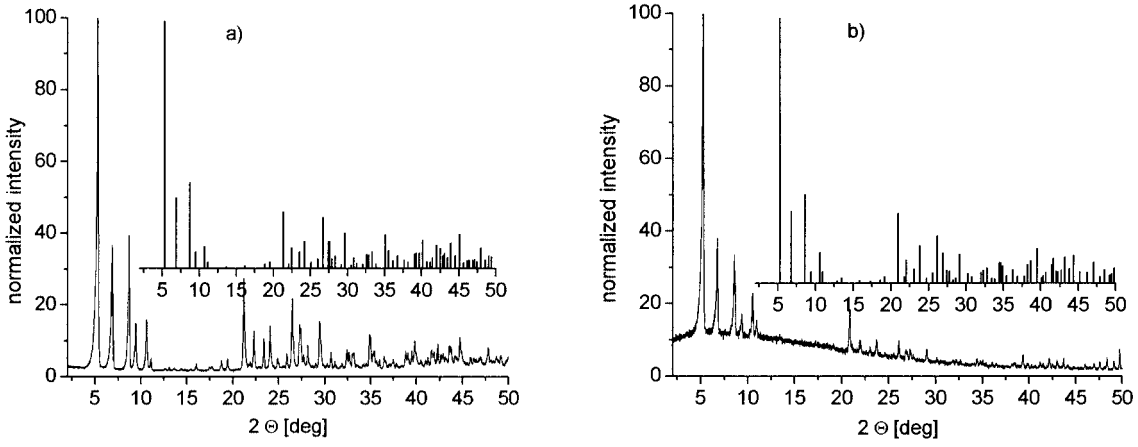

Figure 2. Measured X-ray powder pattern and calculated peak pattern for a) $[Hg_{10}Te_4(SePh)_{12}(PPhnPr_2)_4]$ (**1**) and b) $[Hg_{10}Te_4(TePh)_{12}(PPhnPr_2)_4]$ (**2**).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

272.39−275.74(10) pm are similar to those in **1**. The value of the Hg−P1 bond length for the four outer Hg3 atoms coordinated by the PPh*n*Pr$_2$ ligands is 261.1(4) pm.

Filtration of **1** and **2** at −30 °C and subsequent drying in vacuo resulted in yellow powders which are stable under nitrogen at room temperature. Powder diffraction patterns of the two compounds show their crystalline purity (Figure 2). If **2** is dissolved in benzene/toluene at 5 °C the formation of an orange solution can be observed from which **3** crystallizes within a few days (Scheme 2).

$$4\ [Hg_{10}Te_4(SePh)_{12}(PPh\mathit{n}Pr_2)_4]\ \ (\mathbf{1})$$

$$\xrightarrow[5\ ^\circ C]{C_6H_6/\text{toluene}}$$

$$[Hg_{34}Te_{16}(SePh)_{36}(PPh\mathit{n}Pr_2)_4]\ \ (\mathbf{3})$$
$$+$$
$$6\ Hg(SePh)_2\ +\ 12\ PPh\mathit{n}Pr_2$$

Scheme 2

The compound crystallizes in the triclinic space group $P\bar{1}$ (see also Table 3). The $Hg_{34}Te_{16}Se_{36}$ cluster framework is formed from four fused $Hg_{10}Te_4Se_{12}$ cluster cores and thus 16 $Hg_6Te_3Se_3$ adamantane like cages with a tetrahedral hole in the center of the molecule (Figure 3).

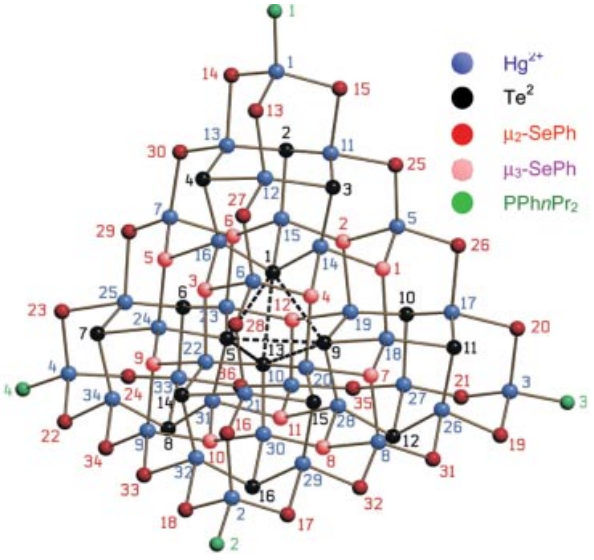

Figure 3. The $Hg_{34}Te_{16}Se_{36}P_4$ cluster core as a section of the molecular structure of $[Hg_{34}Te_{16}(SePh)_{36}(PPh\mathit{n}Pr_2)_4]$ (**3**). Atoms are labeled with numbers only. Nonbonding Te−Te distances (dashed line): Te1−Te9: 376.4 ; Te5−Te13: 385.5 pm. C and H atoms are omitted for clarity.

Thus one could formally explain the formation of **3** in terms of a direct condensation reaction of four "$Hg_{10}Te_4(SePh)_{12}$" cluster cores accompanied by the formal cleavage of six "$(PPhnPr_2)_2Hg(SePh)_2$" units (Scheme 2). In agreement with this, small amounts of $Hg(SePh)_2$ could be crystallized upon layering supernatant reaction solutions of **3** during which the formation of HgTe was not observed. Formal occupation of the tetrahedral hole by a mercury atom would lead to an ideal tetrahedral fragment of the cubic sphalerite structure. The diameter of the cluster core taken as the distance from the Hg atom at the vertex of the tetrahedron to the center of the opposite tetrahedral face is about 1500 pm.

Whereas the known cluster $[Hg_{32}Se_{14}(SePh)_{36}]$[10,11] is, according to theoretical considerations, a larger homolog of the cluster $[Hg_{17}Se_4(SePh)_{28}]^{2-}$, compound **3** is in fact a larger homolog of the cluster $[Hg_{10}Te_4(SePh)_{12}(PPhnPr_2)_4]$.[14] In contrast to the predicted formula by Dance et al. for such a group 12−16 metal chalcogenide cluster $[M_{35}E_{28}(ER)_{24}(PR_3)_4]^{10-}$ (M = Zn, Cd, Hg; E = S, Se, Te) we observed in **3**, a formal exchange of E^{2-} ions by additional ER^- ligands resulting in an overall zero charge. These 12 additional $SePh^-$ ligands are therefore each bridging three mercury atoms in contrast to the other 24 μ_2-$SePh^-$ ligands, a bonding mode which had not been observed before for $SePh^-$ ligands in group 12−16 cluster molecules. Although all mercury atoms Hg1−Hg34 have distorted tetrahedral coordination geometries, three different atomic environments coexist. The atoms Hg1−Hg4 are each coordinated by one phosphorous atom (P1−P4) of the PPh*n*Pr$_2$ ligands and three selenium atoms of the μ_2-$SePh^-$ ligands (Se13−Se24) (for selected bond length and angles see Table 1). Six of the mercury atoms namely Hg5−Hg10 are each bonded to four selenium atoms, two of them belonging to the remaining μ_2-$SePh^-$ ligands (Se25−Se36) and two of them to the μ_3-$SePh^-$ ligands (Se1−Se12). The remaining 24 mercury atoms (Hg11−Hg34) are each surrounded by two selenium atoms from either the two μ_2-$SePh^-$ ligands or the two μ_3-$SePh^-$ ligands and two tellurium atoms from the μ_3-Te^{2-} ligands (Te1−Te16). The Hg−SePh bond lengths and the Hg−Te bond lengths which range from 262.1−293.3(4) pm and 268.4−279.3(3) pm respectively correspond to those found in **1** but show a broader range due to larger distortions of the ideal tetrahedral cluster molecule.

Interestingly a similar cluster core structure was predicted by Spanhel et al. for a group 12−16 cluster of the formal composition $[Cd_{34}Se_{19}(COOCH_3)_{25}(OH)(P\mathit{n}Bu_3)_{7.5}]$ on the basis of a powder X-ray pattern, SAXS, chemical elemental analysis and FTIR spectroscopy.[15] They derived this structure from similar cage like tetrahedral pyramids (Koch pyramids) which are well known from fractal geometry.[16] According to this, the cluster structure "$Hg_{34}Te_{16}(SePh)_{36}$" corresponds to the third hierarchical level of self-similar Koch pyramids with a fractal dimension 2.

UV/Vis Spectroscopy

To investigate the electronic structure of the cluster-molecules, we measured the UV/Vis reflectance spectra of **1**−**3** as nujol mulls. The spectra are shown in Figure 4. A systematic behavior is seen for the absorption onsets reflecting the position of the first optically allowed transition. The onset shows a small shift to lower energy upon substitution of the atom in the E′ position from Se to Te in

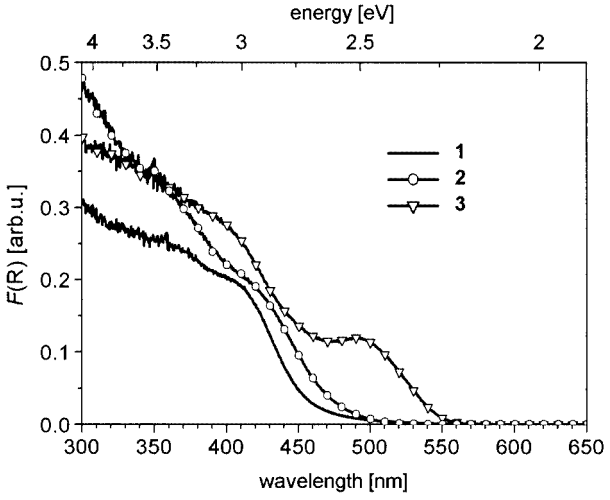

Figure 4. Reflectance spectra of $[Hg_{10}Te_4(SePh)_{12}(PPhnPr_2)_4]$ (**1**), $[Hg_{10}Te_4(TePh)_{12}(PPhnPr_2)_4]$ (**2**) and $[Hg_{34}Te_{16}(SePh)_{36}(PPhnPr_2)_4]$ (**3**) as microcrystalline powders in oil between two quartz plates.

$[Hg_{10}Te_4(E'Ph)_{12}(PPhnPr_2)_4]$ (**1**, **2**). This is consistent with the known dependence of the band gap in the corresponding bulk semiconductors HgTe and HgSe. An increase of cluster size in **3** is accompanied by a shift of the band gap to lower energies of about 0.5 eV compared with **1**. This can be interpreted in terms of the quantum confinement effect observed in larger group 12−16 nanocrystals. For **1** and **2** the spectra display two weakly resolved absorption shoulders at 400/355 nm and 410/355 nm respectively, a pattern which was also observed for $[Hg_{10}Se_4(SePh)_{12}(PPh_2nPr)_4]$ and $[Cd_{10}E_4(E'Ph)_{12}(PR_3)_4]$ (E = Se, Te; E′ = S, Se, Te).[10,17] Cluster **3** shows one well resolved absorption maximum at 493 nm followed by a further broad shoulder extending to 300 nm which shows no distinct maximum. The spectrum of **3** is therefore different from those of $[Cd_{32}Se_{14}(SePh)_{36}(PPh_3)_4]$ and $[Hg_{32}Se_{14}(SePh)_{36}]$ which both show two distinct absorption maxima in the low energy region of the spectra.[1,10] Furthermore the first electronic transition for $[Hg_{32}Se_{14}(SePh)_{36}]$ lies 50 nm lower in energy at 550 nm compared with **3** although the latter contains two additional mercury atoms and 16 tellurium atoms instead of the selenium atoms. These absorption features are therefore most probably related to the difference in the structure of the cluster core in particular the mercury vacancy in the center of **3**. The dissolution of **3** in THF at −25 °C followed by careful warming to room temperature resulted in a clear orange solution which showed an absorption spectrum similar to that of the crystalline powder as a mull in oil. This is also evidence for the stability of **3** in solution at room temperature.

Compound **2** dissolved in THF at −25 °C to yield a clear red orange solution from which a deep red microcrystalline powder precipitated upon warming to room temperature. The X-ray powder diffraction pattern shows in the low 2 theta region (2θ = 2−7 deg.) several well resolved peaks suggesting crystallization of cluster molecules. Furthermore, this red powder displays an absorption onset at 650 nm with a shoulder at about 530 nm. The elemental analysis (found C 18.69, H 1.46%) shows unusually good agreement with the calculated values for the formula $[Hg_{34}Te_{16}(TePh)_{36}](PPhnPr_2)_4]$ (calcd. C 18.64, H 1.52%).

Theory

Density functional investigations have been carried out to elucidate certain features of **3**. All calculations were performed with the RI-DFT modules[18] (RI means the "resolution of the identity", i.e. an auxiliary basis set expansion is used, to process Coulomb-energy contributions more efficiently) of the TURBOMOLE[19] program system employing the BP86-functional,[20] which is a rather reliable functional for treatment of transition metal compounds, and (if not mentioned otherwise) a "split valence plus polarization" basis set − SV(P)[21] − where the brackets indicate that the polarization functions were omitted for H.

The first point of interest concerns the hole in the center of **3**. A condensation of **1** might also be expected to lead to a "real cubic sphalerite cluster" with one further mercury atom in the vacancy (and perhaps two phosphane ligands being replaced by μ_1-$SePh^-$ to maintain the overall zero charge). Thus we performed geometry optimizations of the model clusters $[Hg_{34}Te_{16}(SeMe)_{36}(PMe_3)_4]$, $[Hg_{35}Te_{16}(SeMe)_{36}(PMe_3)_4]^{2+}$ (both *T*-symmetry) and $[Hg_{35}Te_{16}(Se-$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$Me)_{38}(PMe_3)_2]$ (*C*2-symmetry). A drastic lowering of the HOMO−LUMO gap was observed upon introducing μ_1-SeR^- ligands (from 1.52 eV for $[Hg_{34}Te_{16}(SeMe)_{36}(PMe_3)_4]$ and 1.17 eV in $[Hg_{35}Te_{16}(SeMe)_{36}(PMe_3)_4]^{2+}$ to only 0.23 eV for $[Hg_{35}Te_{16}(SeMe)_{38}(PMe_3)_2]$), which indicates that this kind of coordination should be unfavorable. Another way of obtaining a neutral cluster with 35 Hg atoms might be substitution of two μ_3-SeR^- ligands by Te^{2-}, but in the observed condensation reaction all Te^{2-} available from **1** is already incorporated in the structure with the central hole, so if there is no other source of chalcogenide dianions, the loss of electroneutrality might be one reason for the formation of **3**. However, geometrical reasons also seem at a first glance to prevent a "filled" cluster core because the vacancy is simply not large enough to be occupied by Hg^{2+}. The computed Te−Te distances of 398.7 pm for $[Hg_{34}Te_{16}(SeMe)_{36}(PMe_3)_4]$ in the central Te_4-unit would lead to Hg−Te distances of 244.1 pm for a mercury atom in the center of this Te_4-tetrahedron while the Te−Te distances found in the X-ray structure of **3** are even shorter (376.4−385.5 pm). It seems as if the $PhSe^-$-ligands on the edges of this mixed chalcogenide cluster are responsible for this, because the predicted value for a hypothetical $[Hg_{34}Te_{16}(TeMe)_{36}(PMe_3)_4]$ cluster is 434.2 pm which is only slightly shorter than the observed Te−Te distance (456 pm) and the Hg−Te bond length (279 pm) in bulk HgTe.[13] The insertion of a central Hg^{2+} in **3**, leading to $[Hg_{35}Te_{16}(SeMe)_{36}(PMe_3)_4]^{2+}$, resulted in a significant increase of the predicted Te−Te distances with values of 470.7 pm which might cause high tension and reduced stability for the latter system. Interestingly however, the size of the tetrahedron of the outer Hg-atoms (Hg1−Hg4 in Figure 3) only increased from 1722.5 pm to 1754.7 pm when going from $[Hg_{34}Te_{16}(SeMe)_{36}(PMe_3)_4]$ to $[Hg_{35}Te_{16}(SeMe)_{36}(PMe_3)_4]^{2+}$ and all other bond lengths did not change by more than 7 pm. The tension caused by the stretching of the central Te_4 tetrahedra is rather compensated for by a deformation of the bond angles which is of course mostly significant for the four tellurium atoms in the center (Te1, Te5, Te9, Te13) changing from μ_3-bridging (Hg−Te−Hg: 92.86°) to a distorted tetrahedral coordination (Hg−Te−Hg: 104.73−113.87°) while all the other bond angles did not change by more than 4.3°. These findings suggest that from the theoretical point of view such an ionic cluster molecule could be stable but its formation is not favored in the present reaction due to the absence of an appropriate counterion.

$[Hg_{32}Se_{14}(SePh)_{36}]$ and **3** are obviously different in their coordination behavior towards phosphane ligands. Although both clusters are synthesized starting from phosphane-coordinated "Hg_{10}" cluster molecules, **3** appears with all four Hg corners saturated by $PPhnPr_2$ whereas in the cluster with 32 mercury atoms all four mercury atoms at the corners are only trigonally coordinated by three $SePh^-$ ligands. Since a comparison of the influence of the phosphane ligands on the electronic structure of $[Hg_{34}Te_{16}(SeMe)_{36}(PMe_3)_4]$ and $[Hg_{32}Se_{14}(SeMe)_{36}(PMe_3)_4]$ showed no real differences between these two model compounds, we performed further geometry optimizations of the more realistic systems $[Hg_{34}Te_{16}(SePh)_{36}(PMe_3)_4]$, $[Hg_{34}Te_{16}(SePh)_{36}(PPh_3)_4]$, $[Hg_{32}Se_{14}(SePh)_{36}(PMe_3)_4]$, and $[Hg_{32}Se_{14}(SePh)_{36}(PPh_3)_4]$. This however was only possible using two different small basis sets (single zeta quality) for the organic ligands, which are specially optimized for the description of phenyl- and methyl-substituents (available as "SZ.benzene" and "sz.methane" in TURBOMOLE). The energies for the detachment of the PMe_3 ligands from $[Hg_{34}Te_{16}(SePh)_{36}(PMe_3)_4]$ and $[Hg_{32}Se_{14}(SePh)_{36}(PMe_3)_4]$ are quite similar (+44.6 kJ/mol and +43.8 kJ/mol per ligand, respectively). In contrast to this, the corresponding Hg−P bond strengths are clearly lower in the case of PPh_3 (+23.2 kJ/mol in $[Hg_{34}Te_{16}(SePh)_{36}(PPh_3)_4]$ and only +7.8 kJ/mol in $[Hg_{32}Se_{14}(SePh)_{36}(PPh_3)_4]$), which can be explained by the higher steric demands of the phenyl substituent. Especially in the $[Hg_{32}Se_{14}(SePh)_{36}]$ cluster core the μ_2-$SePh^-$ groups near the terminal Hg-atoms protrude so much that repulsion effects prevent a stronger metal-ligand interaction. The nuclear arrangement in the clusters with 34 Hg-atoms, i.e. in a $[Hg_{34}Te_{16}(SePh)_{36}]$ cluster core, is more favorable for the uptake of bulky ligands, and additionally, the experiments leading to **3** were carried out with $PPhnPr_2$. The steric properties of the latter phosphane should be somewhere in between those of PMe_3 and PPh_3. This clearly accounts for the experimental findings.

The differences between the UV/Vis spectra of **3** and $[Hg_{32}Se_{14}(SePh)_{36}]$ are also in line with theoretical results obtained by time dependent DFT as shown in Table 2. Electronic excitations were calculated using the TURBOMOLE module "ESCF".[22,23] The experimental absorbance maximum of **3** appears at 493 nm, which means an excitation energy of 2.51 eV, whereas two distinct maxima in $[Hg_{32}Se_{14}(SePh)_{36}]$ are located at 2.27 eV and 2.47 eV. Once again, for the model compounds $[Hg_{34}Te_{16}(SeMe)_{36}(PMe_3)_4]$ and $[Hg_{32}Se_{14}(SeMe)_{36}]$, we calculated the energies of the twenty lowest singlet transitions in the dipole-allowed irreducible representation *t*. The red-shift of time dependent DFT[24] was taken into account by adding a systematic offset of 0.8 eV. As a result, there are two strong low energy

Table 2. Comparison of experimental and calculated (TDDFT) spectra of $[Hg_{32}Se_{14}(SePh)_{36}]$ and $[Hg_{34}Te_{16}(SeMe)_{36}(PMe_3)_4]$.

	Transition energy (exp.) in eV	Transition energy (TDDFT) in eV	Oscillator strength (TDDFT)
$Hg_{32}Se_{14}(SePh)_{36}$	2.27	2.221	0.30
	2.47	2.353	0.05
$Hg_{34}Te_{16}(SeMe)_{36}(PMe_3)_4$	2.51	2.411	0.25
		2.495	0.10

transitions in the predicted spectrum of $[Hg_{34}Te_{16}(SeMe)_{36}(PMe_3)_4]$ at 2.41 eV and 2.49 eV − the experimental procedure might not be able to resolve this small energetic separation which would explain the solitary maximum at 2.51 eV in the spectrum of **3**. For $[Hg_{32}Se_{14}(SeMe)_{36}]$, apart from transitions with negligibly small oscillator strengths, one also finds two important excitations at 2.22 eV and 2.35 eV, which closely resemble the measured values in the spectrum of the corresponding phenyl cluster (it should be noted, that the calculated oscillator strength of the second transition is smaller than for the first excitation, which is also the case in the experimental spectrum, though however not to this extent).

Conclusions

We have shown that reactions of $HgCl_2$ with $PPhnPr_2$, $Te(SinBu_3)_2$ and $PhESiMe_3$ (E = Se, Te) in DME result in the formation of $[Hg_{10}Te_4(EPh)_{12}(PPhnPr_2)_4]$ (E = Se **1,** E = Te **2**). Investigations in solution reveal that the cluster $[Hg_{10}Te_4(SePh)_{12}(PPh_2nPr)_4]$ (**1**) is a metastable compound which is converted in benzene/toluene at room temperature to $[Hg_{34}Te_{16}(SePh)_{36}(PPhnPr_2)_4]$ (**3**). The "$Hg_{34}Te_{16}Se_{36}$" cluster core of **3** consists of four tetrahedral "$Hg_{10}Te_4(SePh)_{12}$" cages each sharing three "$Hg(SePh)_3$" edges, a cage structure well known in fractal geometry as a "Koch pyramid". Thus the structure can be described as an ideal tetrahedral fragment, 1500 pm in diameter, of the cubic sphalerite lattice with one mercury vacancy in the center. The molecular structure of **3** with mixed chalcogen atoms is therefore different from that of $[Hg_{32}Se_{14}(SePh)_{36}]$ which is a product of the recrystallization of the pure selenide cluster $[Hg_{10}Se_4(SePh)_{12}(PPh_2nPr)_4]$.[10] DFT calculations reveal that an ionic cluster $[Hg_{35}Te_{16}(SeMe)_{36}(PMe_3)_4]^{2+}$ in which the vacancy is filled by a mercury ion could also be stable. This suggests that the formation of the vacancy is probably mostly driven by the absence of an appropriate counterion in the reaction which would stabilize such an ionic cluster molecule. This peculiarity of the structure has also a distinct influence on the electronic structure of **3** in comparison with $[Hg_{32}Se_{14}(SePh)_{36}]$ as can be seen from the UV/Vis reflectance spectra. In future we will target the development of conditions for further controlled cluster growth of these molecules.

Experimental Section

Standard Schlenk techniques were employed throughout the syntheses using a double manifold vacuum line with high purity dry nitrogen. The solvents tetrahydrofuran (THF), dimethylethylene glycol (DME) and benzene were dried over sodium-benzophenone and toluene over $LiAlH_4$, and distilled under nitrogen. Anhydrous $HgCl_2$ was purchased from Aldrich. $PhSeSiMe_3$,[24] $Se(SiMe_3)_2$ [25] and $PhTeSiMe_3$ [26] were prepared according to standard literature procedures. $Te(SinBu_3)_2$ was prepared accordingly to the synthesis of $Se(SiMe_3)_2$ by the use of $ClSinBu_3$ instead of $ClSiMe_3$.

UV/Vis absorption spectra of cluster molecules in solution were measured on a Varian Cary 500 spectrophotometer in quartz corvettes. Solid state reflection spectra were measured as micron sized crystalline powders between quartz plates with a Labsphere integrating sphere.

1: $HgCl_2$ (0.27 g, 0.99 mmol) was dissolved in DME (40 mL) with the addition of $PPhnPr_2$ (0.42 mL, 1.99 mmol). $PhSeSiMe_3$ (0.34 mL, 1.79 mmol) was then added at 0 °C and the resultant clear yellow solution stirred for half an hour. Addition of $Te(SinBu_3)_2$ (0.14 mL, 0.3 mmol) at −40 °C led to the formation of a pale yellow solution from which $[Hg_{10}Se_4(TePh)_{12}(PPhnPr_2)_4]$ (**1**) could be crystallized at −30 °C (60% yield). $C_{120}H_{136}Hg_{10}P_4Se_{12}Te_4$ (5166.11): calcd. C 27.89, H 2.65; found C 27.79, H 2.72.

2: $HgCl_2$ (0.23 g, 0.85 mmol) was dissolved in DME (35 mL) with the addition of $PPhnPr_2$ (0.36 mL, 1.69 mmol). $PhTeSiMe_3$ (0.31 mL, 1.36 mmol) was then added at 0 °C and the resultant clear yellow solution stirred for an hour. Addition of $Te(SinBu_3)_2$ (0.12 mL, 0.25 mmol) at −40 °C led to the formation of a pale yellow solution from which $[Hg_{10}Te_4(TePh)_{12}(PPhnPr_2)_4]$ (**2**) could be crystallized at −30 °C (63% yield). $C_{120}H_{136}Hg_{10}P_4Te_{16}$ (5749.79): calcd. C 25.06, H 2.38; found C 24.95, H 2.26.

3: Compound **1** (0.11 g, 0.019 mmol) was dissolved in a mixture of benzene (4 mL) and toluene (16 mL) at 5 °C giving an orange solution. The solution was then gradually allowed to warm up in the cooling bath and over the period of one week orange crystals of $[Hg_{34}Te_{16}(SePh)_{36}(PPhnPr_2)_4]$ (**3**) were formed (yield 70% calculated for Scheme 2). $C_{264}H_{256}Hg_{34}P_4Se_{36}Te_{16}$ (15257.05): calcd. C 20.78, H 1.69; found C 20.41, H 1.60.

Crystals suitable for single-crystal X-ray diffraction were obtained directly from the reaction solutions of the compounds and then selected in perfluoroalkyl ether oil.

Single-crystal X-ray diffraction data were collected using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) on a STOE IPDS II (Imaging Plate Diffraction System). The structures were solved with the direct methods program SHELXS[27] of the SHELXTL PC suite of programs and were refined with the use of the full-matrix least-squares program SHELXL.[28] Molecular diagrams were prepared using the program SCHAKAL 97[28] and DIAMOND.[29]

All Hg, Te, Se and P atoms were refined with anisotropic displacement parameters. In **2** the C atoms were also refined anisotropically. The C atoms in **1** were refined isotropically while the C atoms of the phenyl groups in **3** were refined isotropically as rigid groups. H atoms of the SePh groups were included in calculated positions for **2**. C_6H_6 solvent molecules in **3** were refined as rigid groups with half occupancy. Residual electron density in the difference Fourier map of **3** indicates the existence of additional disordered solvent molecules in the crystal lattice which could not be refined successfully (see Table 3).

Numerical absorption corrections were applied to the data of **2** and **3**.

CCDC-205710 (**1**), -205711 (**2**), and -205712 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk).

[a] $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$.

X-ray powder diffraction patterns (XRD) were measured on a STOE STADI P diffractometer (Cu-K_α radiation, Germanium monochromator, Debye−Scherrer geometry) in sealed glass capillaries. Theoretical powder diffraction patterns for **1** and **2** were calculated on the basis of the atom coordinates obtained from single-crystal X-ray analysis by using the program package STOE WinXPOW.[30]

Acknowledgments

This work was supported by the Deutsch-Israelisches Programm (DIP) and the Deutsche Forschungsgemeinschaft (Center for Functional Nanostructures CFN). A. E. is grateful to Prof. D. Fenske for helpful discussions and for providing excellent working conditions, E. Tröster for her invaluable assistance in the practical work and Dr. Susan Anson for careful revision of the manuscript.

Pyridine-2-sulfonates as Versatile Ligands for the Synthesis of Novel Coordinative and Hydrogen-Bonded Supramolecules

Tarlok S. Lobana,*[a,b] Isamu Kinoshita,*[a] Kentaro Kimura,[a] Takanori Nishioka,[a] Daisuke Shiomi,[a] and Kiyoshi Isobe[a]

Keywords: Coordination polymers / Hydrogen bonds / Supramolecular chemistry / Magnetic properties / Stacking interactions

The reactions of 3-methylpyridine-2-sulfonic acid (3-mpSO$_3$H) with Cu^{II} and 4-methylpyridine-2-sulfonic acid (4-mpSO$_3$H) with Zn^{II} in water formed one-dimensional infinite coordination polymers, [Cu(3-mpSO$_3$)$_2$]$_n$ (**1**) and [Zn(4-mpSO$_3$)$_2$]$_n$ (**2**). Similarly, two-dimensional hydrogen-bonded supramolecules of stoichiometries, [ML$_2$(H$_2$O)$_2$] [L = 3-methylpyridine-2-sulfonate (3-mpSO$_3$), M = Mn (**3**), Fe (**4**), Co (**5**), Zn (**6**); L = 5-methylpyridine-2-sulfonate (5-mpSO$_3$), M = Zn (**7**); L = pyridine-2-sulfonate (PySO$_3$), M = Zn (**8**); L = 4-mpSO$_3$, M = Co (**9**)], [Ni(3-mpSO$_3$)$_2$(H$_2$O)$_2$]·H$_2$O (**10**) and the one-dimensional hydrogen-bonded network [VO(acac)(3-mpSO$_3$)(H$_2$O)] (**11**) (acac = acetylacetonate) have been prepared. The ligands are tridentate [*N*,*O*-chelating-Cu-μ-*O*-bridging] in **1** and **2**, while in all the other compounds the N,O-chelating and uncoordinated O atoms are engaged in intermolecular hydrogen bonding leading to the formation of hydrogen-bonded networks. The geometry around each metal center is octahedral (**9**) or distorted octahedral (**1**–**8**, **10** and **11**). The compounds **3**–**8**, and **10** showed novel π–π stacking interactions, not shown by **9** and **11**. The magnetic behavior of **3** and **11** indicates lack of any intermolecular magnetic interactions. The position of the substituents in the pyridyl ring and Jahn–Teller effect (Cu^{II}) appear to determine the stacking interactions as well as the density of ligands with regard to the formation of coordinative and hydrogen-bonded supramolecules.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The hydrogen bonding and coordinative bond are the two main principles involved in the synthesis of supramolecules.[1−4] The intrinsic magnetic, optical, catalytic and structural properties of the metal ions are the prerequisites, in the field of crystal engineering, for non-linear optic, ferromagnetic, superconducting and gas-occlusion materials. The self-assembled metal complexes having one-, two-, or three-dimensional solid state networks are expected to play vital roles in the specific functions of materials.[5−8]

Pyridine-2-thione, the simplest prototype of heterocyclic thioamides, has shown its versatility in the formation of a wide range of mononuclear through to polynuclear compounds with interesting structural novelties, magnetic, electrochemical, spectral and conduction properties.[9−14] A remarkable observation is that it can bind one to four metals giving rise to polymetallic materials.[9,12] This unusual property of pyridine-2-thiolates prompted us to investigate pyridine-2-sulfonates, which are extensions of pyridine-2-thiones involving oxidation of sulfur at the 2-position of the pyridine rings. These pyridine-2-sulfonates possess one N and three O atoms (N, 3O donor set) which could provide several possibilities for coordinative and other types of bonding interactions. It may be mentioned here that only the limited coordination chemistry of pyridine-2-sulfonates is known.[15,16]

The aerobic oxidation of sulfur in 2,2′-bis(3-methylpyridine) disulfide in the presence of copper(II) bromide in methanol generated 3-methylpyridine-2-sulfonic acid, which subsequently formed an infinite one-dimensional polymer, [Cu(3-mpSO$_3$)$_2$]$_n$. A direct reaction of 3-methylpyridine-2-sulfonic acid (3-mpSO$_3$H) with Zn^{II} bromide also formed a two-dimensional hydrogen-bonded polymer, [Zn(3-mpSO$_3$)$_2$(H$_2$O)$_2$].[17] These observations stimulated our interest to systematically investigate the coordination behavior of pyridine-2-sulfonic acids. The oxidation of sulfur by the metal ions and C−S bond cleavage reactions mimic the metabolism of organic sulfur in mammals.[17,18]

In this paper, we report on novel coordination polymers and hydrogen-bonded supramolecules prepared using pyri-

dine-2-sulfonic acid, 3-, 4- and 5-methylpyridine-2-sulfonic acids (Scheme 1) and divalent cations/oxocations, viz. VO^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+} and Zn^{2+}. These ligands might act as multidentate ones involving *N*,*O*−chelation, *N*,*O*−chelation-Cu-μ-*O*-bridging, hydrogen bonding and π−π (pyridine ring based) interactions. All these compounds are characterized using analytical data, IR and NMR spectroscopy, X-ray crystallography and magnetic moment studies.

Results and Discussion

Compounds **1**−**11** were prepared by the reactions of divalent cations/oxocations with neutral pyridine/substituted pyridine-2-sulfonic acids or their sodium salts. The reactions may be labeled as metathetical ones with the exchange of an anion with a metal salt by the RSO_3 anion (R = Py, x-Py, x = 3-Me, 4-Me, 5-Me) of a pyridine sulfonic acid. Allowing the reaction mixture to stand at room temperature gave crystals suitable for X-ray crystallography in many cases, while in some other cases the volume of the reaction mixture was reduced to obtain the crystals. The complexes are soluble in water as well as in alcoholic solvents such as ethanol, methanol etc. On the basis of stoichiometry, as revealed by the elemental analyses, and later confirmed by X-ray crystallography (vide infra), the complexes are grouped into four types: (a) $[ML_2]_n$ [L, M: 3-mpSO_3, Cu (**1**), 4-mpSO_3, Zn (**2**)]; (b) $[ML_2(H_2O)_2]$ [L, M: 3-mpSO_3, Mn (**3**), Fe (**4**), Co (**5**), Zn (**6**); 5-mpSO_3, Zn (**7**); $PySO_3$, Zn (**8**); 4-mpSO_3, Co (**9**)]; (c) $[Ni(3\text{-mpSO}_3)_2(H_2O)_2]\cdot H_2O$ (**10**) and (d) [VO(acac)(3-mpSO_3)(H_2O)] (**11**) (Hacac = acetylacetone). *Type a* compounds (**1**, **2**) are found to be one-dimensional covalently bonded infinite polymers, while *types b*−*d* are hydrogen-bonded (noncovalent) one- or two-dimensional (**3**−**11**) infinite polymers. Table 3 contains the crystal data and Table 1 contains bond lengths and bond angles of the compounds **1**−**11**.

The major IR spectral bands of the compounds **1**−**11** and those of the ligands are listed in the Exp. Sect. The presence of water is clearly identified by the well-defined, strong bands of the ν(O−H) and δ(O−H) stretching vibrations. The compounds **3**−**6** and **10** show three ν(O−H) peaks each, while **7**−**9** and **11** show only two such bands; however, all show one δ(O−H) stretching vibration. The splitting of the ν(O−H) peaks shows an unequivalent chemical environment in the vicinity of the O−H groups which are modulated by the hydrogen bonding; the compounds **1** and **2** show no water peaks. The peaks due to the pyridine ring are relatively strong versus those due to the methyl group. The sulfonate group RSO_3^- shows strong bands due to ν(S−O) vibrations generally found in the region 1300−1055 cm^{-1}. The ν(C−S) peak of free 3-mpSO_3H at 1035 cm^{-1} shifts to the low energy region, and were thus found in the region 1015−1031 cm^{-1}; **1** showed the largest shift.[19] Other ligands also show shifts in the ν(C−S) peaks to lower energies in their complexes. A characteristic peak due to the rocking mode of the methyl group, δ(C−CH_3) is assigned in the region 800−850 cm^{-1}. The absorption due to the vanadyl group, ν(V−O), is observed at 974 cm^{-1} as a strong peak.

Table 1−3 give a summary of important highlights of compounds **1**−**11**, bond parameters and crystal data, respectively.

Coordination Polymers

Type a compounds (**1**, **2**) belong to this category and have one-dimensional polymeric structures. The reaction of copper(II) bromide with 3-mpSO_3H in a methanol/water mixture formed monoclinic green crystals of empirical formula, Cu(3-mpSO_3)$_2$ and X-ray crystallography has shown that it exists as a one-dimensional covalently bonded polymer, $[Cu(3\text{-mpSO}_3)_2]_n$ (**1**). It is interesting to note that the aerial oxidation of 2,2′-bis(3-methylpyridine) disulfide in the presence of copper(II) bromide in methanol formed triclinic green crystals with the same crystal structure as **1**.[17] The different crystal modifications may be the consequence of the reaction conditions involved in the two cases (Table 2 and 3).

The reaction of 3-mpSO_3H with zinc(II) bromide in water did not form a polymer similar to **1**, but rather a complex with the stoichiometry, $[Zn(3\text{-mpSO}_3)_2(H_2O)_2]$ (**6**, vide infra) was formed. However, the related ligand, 4-mpSO_3H with zinc(II) bromide formed a complex of stoichiometry, Zn(4-mpSO_3)$_2$ which is also an one-dimensional coordination polymer **2**.

Figure 1 and 2 show the polymers along the *c* axis and *a* axis, respectively, with the numbering schemes (3 metal atoms shown in each case). The formation of **1** is believed to take place by initially forming the moiety, *trans*-Cu(3-mpSO_3)$_2$ (A) in which 3-mpSO_3 forms five-membered rings. This moiety (repeat unit) combines with another unit via free oxygen atoms along the axial side forming the dimer with eight-membered rings [$Cu_2O_4S_2$ core] and this process continues to finally form the one-dimensional infinite polymer. In this polymer each Cu atom is bonded to 2 N and 4 O atoms; two N and two O atoms occupy *trans* positions of the square plane of the CuN_2O_2 core and the geometry around each Cu center is elongated octahedral. The axial Cu−O [2.438(10) Å] bonds are longer than the equatorial Cu−O bonds [1.989(8) Å] by ca. 0.45 Å. Further, the equatorial Cu−O and Cu−N [1.97(10) Å] bond lengths are close to the sum of the covalent radii of Cu and O (1.93 Å) or Cu and N (1.95 Å), respectively. The longer Cu−O axial bonds lead to shorter S(1)−O(3) bonds and the free S(1)−O(2) bond length is in between the two extremes. These S−O distances are much less than the sum of the

covalent radii of S and O atoms (1.75 Å).[20] It shows partial double bond character of the S−O bonds. The S(1)−C(1) distance is close to that of a single covalent bond length (1.79 Å) (Table 1).

The formation of polymer **2** can be viewed in a manner similar to that of **1**; however the axial Zn−O [2.182(1) Å] and equatorial Zn−O [2.111(1) Å] bond lengths are comparable and coupled with the bond angles, the geometry around each zinc(II) center is close to an ideal octahedron. It may be noted that the variations in coordinated bond lengths are controlled by the metal-oxygen interactions. The stronger M−O bonds lead to long S−O bonds and vice

versa. The S(1)−O(2) bonds of the RSO_3 groups, which are not involved in bonding to the metals in polymers **1** and **2** are also marginally affected by the change of the metal (Table 1). The OMN bite angle is 86.1(4)° in the Cu polymer and 82.85(5)° in the zinc polymer and this is probably linked with the size of the metal center. The angles at O(1), S(1), C(1) and N(1) are also affected by the bite angles. The large bite angle at the Cu^{I} center is accompanied by a relatively large angle at O(1) and smaller angles at S(1), C(1), and N(1), while the reverse trend is shown by the zinc polymer. Thus in compounds **1** and **2**, $3\text{-}mpSO_3^-$ and $4\text{-}mpSO_3^-$ ligands act as N,O,O donor sets with one free S−O bond in each case.

Structures of Mononuclear Units (*Types b*−*d*)

Compounds **3**−**9** (*type b*) have the same structural formula, $[ML_2(H_2O)_2]$ and the differences lie in the nature of the metal, presence of a methyl substituent in the pyridyl ring and the position of the water ligands. Thus the compounds, **3**−**6** have $3\text{-}mpSO_3^-$ while **7**−**9** have $5\text{-}mpSO_3^-$, $PySO_3^-$ and $4\text{-}mpSO_3^-$, respectively, as the anionic ligands. Further, H_2O molecules occupy *cis* positions of the octahedral compounds **3**−**8** (Figure 3) and *trans* positions in compound **9** (Figure 4).

Compounds **3**−**8** are monoclinic with space groups, $C2/c$, **9** has triclinic crystals with space group $P\bar{1}$, and **3**−**6** are isomorphic. It shows that the position of water in the octahedron and not the substituent of the pyridyl ring most probably determines the crystal system (Table 2 and 3). Figure 3 (only structure of compound **3** shown) and Figure 4 (compound **9**) show the numbering schemes of the complexes. The molecular structure of each of compounds **3**−**9** consists of two N,O-chelating RSO_3^- (R = Py, x-Py) ligands and two water molecules; the divalent metal center, Co^{II} is located on the crystallographic inversion center in compound **9**.

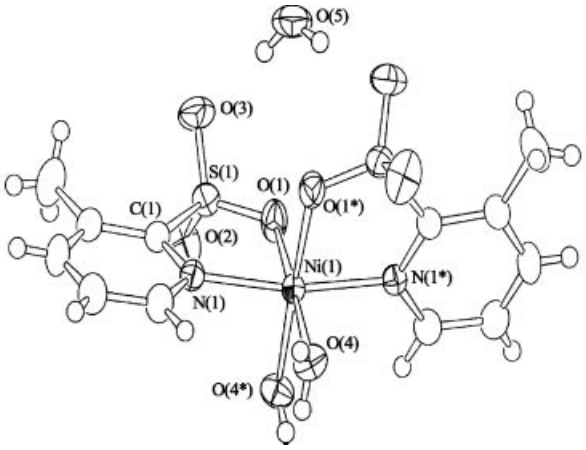

Figure 5. ORTEP view of *cis*-[Ni(3-mpSO$_3$)$_2$(H$_2$O)$_2$]·H$_2$O (**10**)

A discussion on the differences in the bond parameters of **3**−**9** now follows. In these compounds, M(1)−O(1), O(1*), N(1) and N(1*) bonds are related to the RSO$_3^-$ moiety and M−O(4), O(4*) bonds refer to the coordinated H$_2$O molecules. The oxygen atoms of S−O(2) and S−O(3) bonds are free and engage in the intermolecular hydrogen bonding (vide infra). In compound **3**, the M(1)−O(1) bond length, 2.187(2) Å, is close to the sum of the covalent radii of Mn and O (2.12 Å).[20] The Mn(1)−O(4) bond length, 2.164(2) Å, is less than the Mn(1)−O(1) bond length and it shows that water is relatively more tightly bonded to Mn(1). The Mn(1)−N(1) bond length, 2.242(2) Å, is also close to the sum of the covalent radii of Mn and N (2.14 Å).[20] The trend in M(1)−O(1), O(4), N(1) bond lengths for compounds **4**−**9** is similar. The metal−ligand bond lengths clearly vary with the size of the central metal atom: Mn > Fe > Co > Ni. The coordinated S(1)−O(1) bond is only marginally longer than the uncoordinated S(1)−O(2), O(3) bonds in all these compounds (Table 1). All these S−O bond lengths are less than the sum of the covalent radii of S and O atoms (1.75Å).[20] Finally, S(1)−C(1) distances lie in the narrow range ca.1.783−1.802 Å and close to the single covalent bond length (1.79 Å).

Each of compounds **3**−**8** have a distorted octahedral geometry and the *trans* N(1)−M−N(1*) bond angles are in the range, ca. 155−165°; however, compound **9** has a perfect octahedral geometry. The bite angle, O(1)−M(1)−N(1) of the pyridine-2-sulfonates lie in the range, ca. 76−81° in compounds **3**−**9** and these bite angles are less than those shown by **1** (ca. 86°) and **2** (ca. 83°). Thus compound **1** showed the largest bite angle among complexes **1**−**9**. The coordinated H$_2$O molecules are *trans* in compound **9** and cause the O(4)−M−O(4*) bond angles to be ca. 82−86° in complexes **3**−**8**. The trend of bond angles at O(1), S(1), C(1) and N(1) atoms is similar to that observed in compounds **1** and **2** (Table 1).

Figure 5 and 6 show molecular structures with numbering schemes of compounds **10** (*type c*) and **11** (*type d*), respectively. Compound **10** has two chelating 3-mpSO$_3^-$ ligands, two coordinated water molecules and one lattice water molecule. It also crystallizes in the *C*-centered monoclinic space group *C*2/*c* (Table 2 and 3) and it has a molecular structure similar to that of **3** (Figure 3). The bond parameters are also similar to those of compounds 3−9 except that Ni(1)−O(1) and Ni(1)−(4) (coordinated H$_2$O) have the same bond lengths. Finally compound **11** formed monoclinic crystals with space group, $P2_1/c$ and in this compound the VO^{2+} ion is coordinated by a water molecule and two different chelating ligands, acac$^-$ and 3-mpSO$_3^-$(Table 3). The geometry around the vanadium(IV) center is distorted octahedral. The equatorial plane of the vanadyl is occupied by the O atom of the water molecule, N atom of 3-mpSO$_3^-$ and two O atoms of acac. One oxygen atom of 3-mpSO$_3$ occupies a position *trans* to the V=O group. The bond angles and lengths show trends similar to those of compounds **3**−**10**; the V=O bond as expected, is the shortest bond [V(1)−O(6) = 1.588(2) Å]. The acac$^-$ ion forms bonds stronger than those formed by the oxygen atom of 3-mpSO$_3^-$ or it may be the *trans* effect of V=O bond which lengthens V(1)−O(1) bond vis-à-vis V(1)−O(4), O(5) bonds which are short.

of the two-dimensional (**3**−**10**) and one-dimensional (**11**) supramolecules. Compounds **3**−**8** and **10** showed additional noncovalent π−π interactions, not shown by compounds **9** and **11**. The uncoordinated sulfonato oxygen atoms and coordinated water molecules of compounds **3**−**6** containing 3-mpSO_3^- ligands connect each mononuclear

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

unit via the intermolecular hydrogen bonds, O(2)··· H-O(4) and O(3)··· H−O(4) (Table 1) to form two-dimensional hydrogen-bonded networks parallel to the *bc* plane. For example, Figure 7 shows the H bonded network of compound **3** parallel to the *bc* plane. In the two-dimensional network, the adjacent molecules along the *b* axis have the same orientation, while the neighboring molecules along the *c* axis have inverted structures of the original molecule and are in the opposite orientation to the original. All of the pyridine rings of the 3-mpSO$_3^-$ ligands are stacked by relatively strong π−π interactions (ca. 3.47Å) as shown for the crystal packing of **3** in Figure 8. Compounds **4**−**6** have the same hydrogen and π−π stacking patterns and their intermolecular parameters are listed in Table 1.

The hydrogen bonding in compound **8** containing the pySO$_3^-$ ligand forms a two-dimensional network parallel to the *ab* plane (Figure 9). The two dimensional hydrogen-bonded sheets are stacked over each other by π−π interactions (ca. 3.70 Å) of the pyridine rings in an offset geometry as shown in Figure 10.

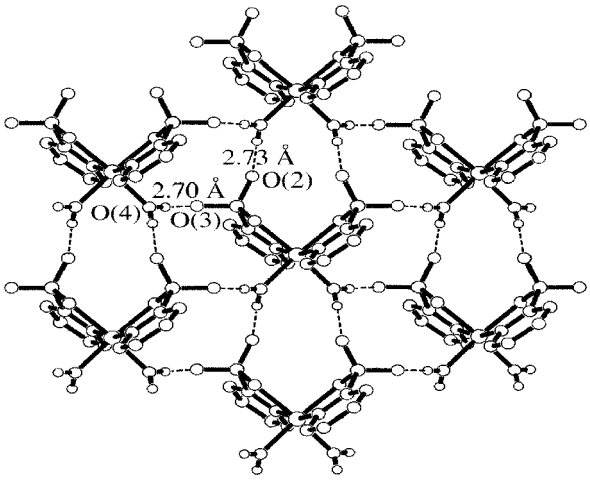

Figure 9. H bonded network of [Zn(PySO$_3$)$_2$(H$_2$O)$_2$] (**8**) parallel to the *ab* plane

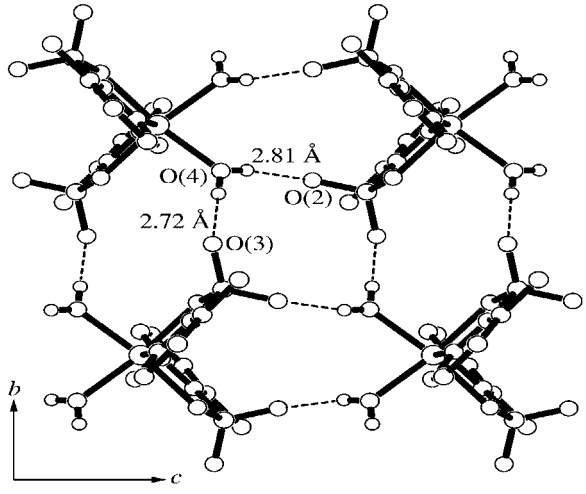

Figure 7. H bonded network of [Mn(3-mpSO$_3$)$_2$(H$_2$O)$_2$] (**3**) parallel to the *bc* plane

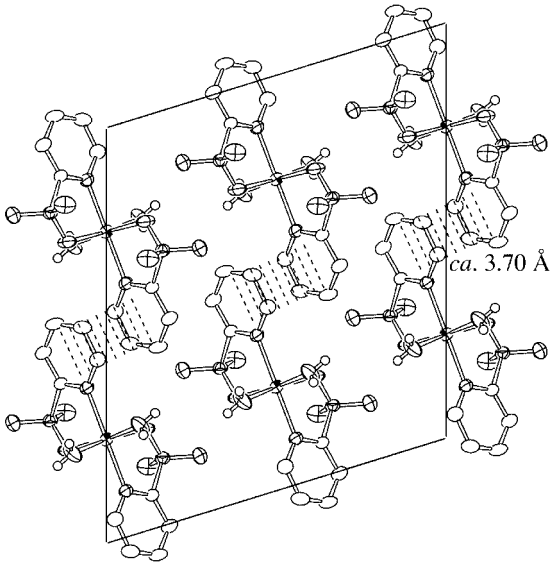

Figure 10. Crystal packing of [Zn(PySO$_3$)$_2$(H$_2$O)$_2$] (**8**) when viewed along the *b* axis

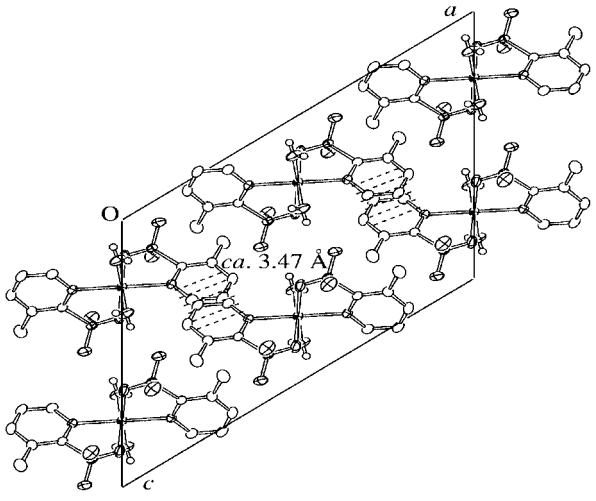

Figure 8. Crystal packing of [Mn(3-mpSO$_3$)$_2$(H$_2$O)$_2$] (**3**) when viewed along the *b* axis

The hydrogen-bonded network of compound **7** containing the 5-mpSO$_3^-$ ligand is also similar to that of **8.** Figure 11 shows that the pyridine rings of the 5-mpSO$_3^-$ ligands are most weakly stacked over each other (ca. 3.96 Å), as compared to the aromatic stacking in the crystals of **3**−**6**, **8** and **10**. Therefore, the calculated density for **7** (1.775 g·cm^{-3}) is clearly less than that for compound **6** (1.821 g·cm^{-3}) even though the two zinc complexes have a common chemical formula. It may be further noted that the

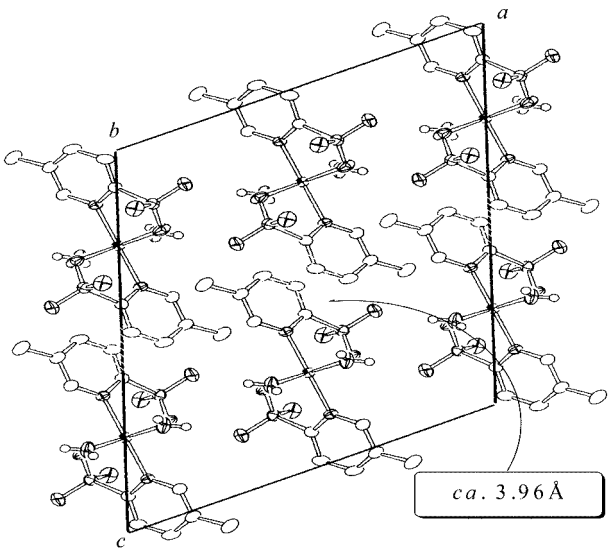

Figure 11. Crystal packing of $[Zn(5\text{-}mpSO_3)_2(H_2O)_2]$ (**7**) when viewed along the *b* axis, geometry as shown in Figure 10

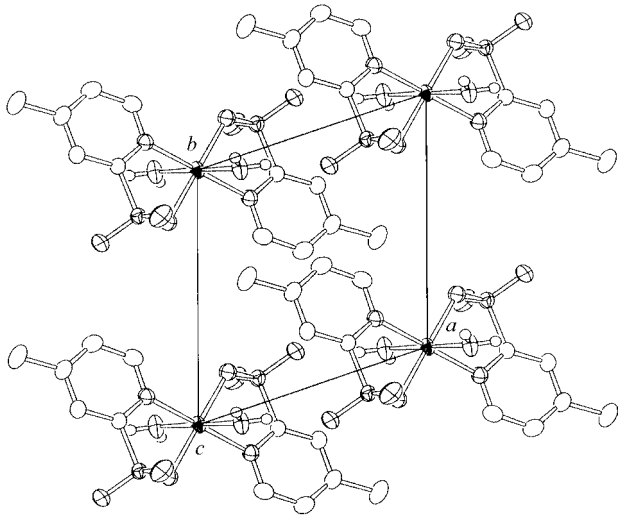

Figure 13. Crystal packing of $[Co(4\text{-}mpSO_3)_2(H_2O)_2]$ (**9**) when viewed along the *c* axis

stacking interaction in compound **6** (ca. 3.50 Å) is stronger than that in compound **8** (above).

It may be interesting to add here that the stoichiometry of zinc(II) complexes **6**−**8** is different from that of **2** which is a one-dimensional polymer as described earlier. The exceptional behavior can be ascribed to the steric effect of the methyl group at the 4-position in the pyridine ring of the 4-$mpSO_3^-$ ligand in **2**. The methyl group sticking out along the Zn(1)-N(1)···C(3) line is probably unfavorable for the formation of hydrogen-bonded networks similar to those of complexes **6**−**8**.

In compound **9**, the hydrogen-bonded network is spread out parallel to the *ac* plane (Figure 12) and it does not show any π−π interaction in the crystal structure (Figure 13) unlike that shown by compound **5**. The methyl group at the 4-position in the 4-$mpSO_3^-$ ligand elongates the structure of **9** along the Co(1)-N(1)···C(3) line and this structural elongation may be the main factor for the absence of π−π interactions in its crystal structure. In compound **10**, two uncoordinated oxygen atoms of 3-$mpSO_3^-$ [O(2), O(3)] participate in intermolecular hydrogen bonds with the coordinated and lattice water molecules leading to the formation of two-dimensional hydrogen-bonded networks (Figure 14). The H bonded sheets are stacked by the π−π interactions of the pyridyl rings in an offset geometry (Figure 15). Finally for compound **11**, the self-assembly of the mononuclear complexes results in the formation of a one-dimensional supramolecular structure along the crystallographic *b* axis (Figure 16).

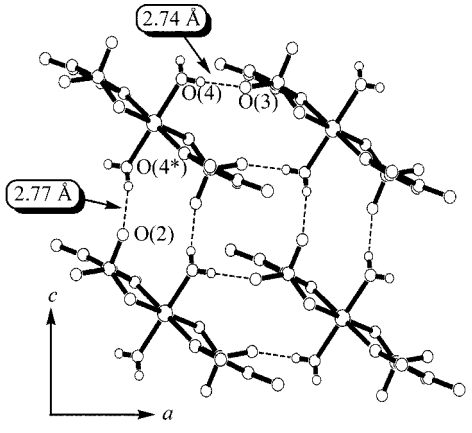

Figure 12. H bonded network of $[Co(4\text{-}mpSO_3)_2(H_2O)_2]$ (**9**) parallel to the *ac* plane

Magnetic Properties

The magnetic measurement studies of compounds **3** and **11** were carried out in order to check for possible magnetic exchange interactions, if any, between adjacent metal centers of the hydrogen-bonded networks. The variable temperature magnetic susceptibility studies revealed that these compounds are typical paramagnetic compounds with ground spin-states of $S = 5/2$ for **3** and $S = 1/2$ for **11**. The

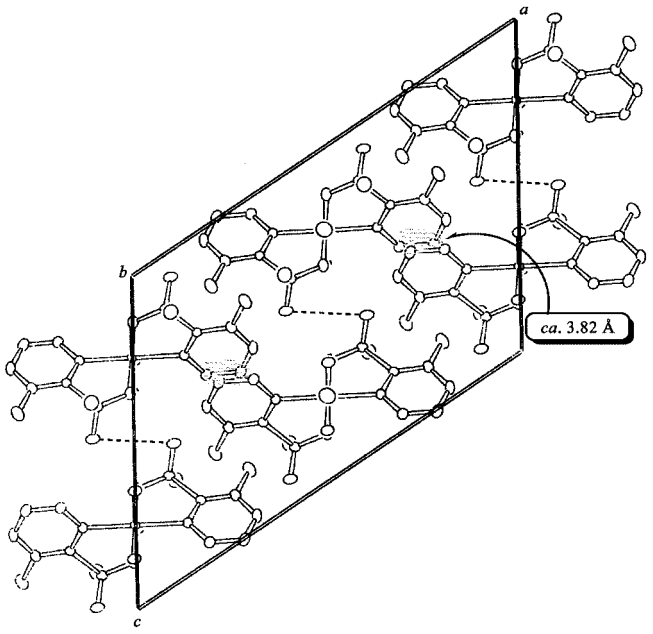

Figure 15. Crystal packing of $[Ni(3\text{-}mpSO_3)_2(H_2O)_2]\cdot H_2O$ (**10**) when viewed along the *b* axis

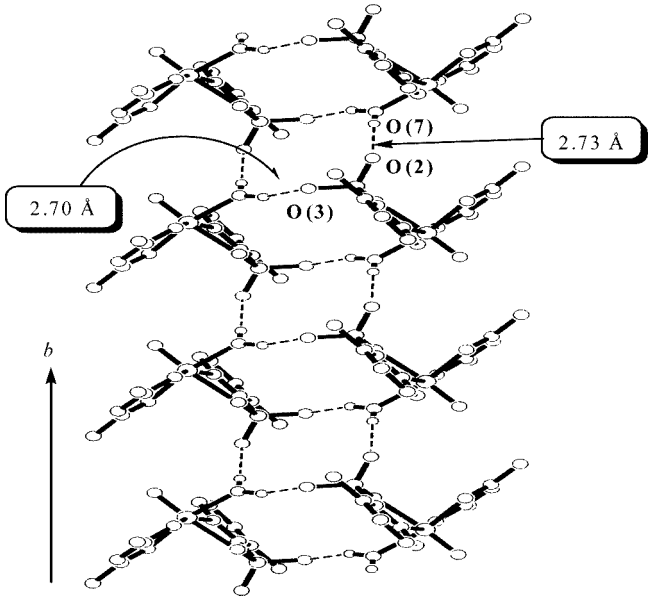

Figure 16. One-dimensional hydrogen-bonded network of complex **11**

magnetic behavior indicates that the intermetallic distances (7.11−7.47 Å) in these network structures are too long to cause any intermolecular magnetic interactions. Other complexes (**1**, **4**, **5**, **9** and **10**) also showed typical paramagnetic behavior.

Solution Phase Behavior

The NMR spectroscopic data of the ligands and zinc(II) complexes recorded in CD_3OD solvent are listed in the Exp. Sect. The ligand spectra are broad as well as partially resolved in view of the exchange of a proton between a N atom and sulfonate SO_3 groups and after the deprotonation of the complexes, the spectra generally become sharp as well as better resolved indicating metal−ligand interaction. Consider first $PySO_3$ and its compound **8**, three pyridyl ring protons show a high-field shift and the magnitude of the shift varies as follows: H(4) > H(5) > H(3). The H(6) proton close to the N coordinating center can be considered as essentially unchanged. The same trend is shown by the compounds **2**, **6** and **7**. The methyl group of $3\text{-}mpSO_3^-$ in compound **6** shows a low-field shift, but the 4-and 5-methyl groups of compounds **2** and **7** show high-field shifts. This difference is understandable in view of the deshielding influence of the sulfonate group, which exerts the largest effect on the methyl group at the 3-position. This is in line with the relatively low up-field shift of H(3) protons of compounds **2**, **7** and **8** which are close to the SO_3 group. NMR spectroscopic studies reveal one very interesting observation that electron density of pyridyl rings is highly polarized and the H(4) (or, 4-Me) and H(5) (or, 5-Me) protons experience high diamagnetic shielding. The NMR spectrum of compound **6** shows that the group $3\text{-}mpSO_3^-$ has distinctly different behavior, which was also reflected in the solid state (compounds **3**−**6**, vide supra).

Conclusions

The location of methyl substituents at the 3-position of the pyridyl ring ($3\text{-}mpSO_3$ ligand) appears to be most suited to induce close π−π stacking interactions (3.47−3.50 Å), a prerequisite for possible electrical conductivity properties. $PySO_3^-$ in compound **8** showed π−π stacking interactions of medium strength (3.70 Å) and the 5-methyl substituent in compound **7** appears to disfavor such interactions leading to a very weak interaction, ca. 3.96 Å. The stacking in $[Ni(3\text{-}mpSO_3)_2(H_2O)_2]\cdot H_2O$ (**10**) is weakened by the presence of water of hydration which increases π−π stacking distance to 3.82 Å compared to other $3\text{-}mpSO_3$ analogs (compounds **3**−**6**). Interestingly the methyl substituent at the 4-position totally disfavors the π−π stacking interactions as for example in compound, $[Co(4\text{-}mpSO_3)_2(H_2O)_2]$ (**9**), because of elongation of the structure along the Co(1)-N(1)···C(3) line. Compound **11** has a columnar one-dimensional structure, which is not suited for such stacking interactions. An analysis of metal−oxygen and metal−nitrogen bond lengths (Table 1) reveals that (i) along the axial side Cu−O bond is weakest, while the Cu−N bonds are shortest and (ii) that water forms very strong metal−oxygen bonds in all the water ligated compounds (**3**−**11**). The longer Cu−O axial bonds are due to Jahn−Teller distortion. Thus copper(II) water ligation appears to be energetically less favored over copper(II) polymer formation as in compound **1**. The factors for the formation of the coordination polymer $[\{Zn(4\text{-}mpSO_3)_2\}_n]$ (**2**), unlike hydrogen-bonded compound of type **9**, are not well understood. However, the compact polymeric structure as in **2** appears energetically more favored.

Experimental Section

Materials and Physical Measurements: All chemicals were purchased from Aldrich, Nacharai Tesque, and Wako Pure Chemical. All reagents and solvents were used without further purification. Infrared spectra in the range 4000−400 cm^{-1} were recorded on KBr discs with a JASCO FTIR 420 spectrophotometer. The ^1H NMR spectra were measured with a JEOL Lambda 400 spectrometer. The magnetic susceptibilities were measured with a Quantum Design SQUID magnetometer MPMS. Elemental analyses were carried out by the Analytical Center of Graduate School of Science in Osaka City University.

Synthesis of Ligands: Pyridine-2-sulfonic acid and its methyl-substituted analogs were prepared by the oxidation of the corresponding pyridine-2-thiones as reported in the literature.[21] The substituted pyridine-2-thiones, namely, 1-H-*x*-methylpyridine-2-thiones (*x* = 3, 4, 5) were synthesized via sulfhydrylation of their corresponding 2-bromopyridines.[22] 1-H-*x*-methylpyridine-2-thione (2.25 g, 0.018mol) was dissolved in 40 mL of glacial acetic acid and then 6.5 mL (0.058 mol) of 30% hydrogen peroxide was added to the mixture. The reaction mixture was heated to 80 °C with stirring until the color of the thione completely disappeared. After removal of the solvent by evaporation under a reduced pressure, the resulting residue was recrystallized from water/methanol (1:1, by volume) to afford colorless crystal of *x*-methylpyridine-2-sulfonic acids.

Caution! *The mixture of acetic acid and hydrogen peroxide produces potentially explosive materials. It is preferable that only limited amounts are prepared at a time, while the temperature is maintained with care. Stirring of the reaction mixture should also be well controlled.*

Pyridine-2-sulfonic Acid ($PySO_3H$): Yield 1.77 g (55%). $C_5H_5NO_3S$ (159.17): calcd. C 37.73, H 3.17, N 8.80; found C 37.72, H 3.09, N 8.77. IR: $\tilde{\nu}$ = ν(N−H) + ν(O−H) 3445 (br. w), 3198 (m), 3132 (s) cm^{-1}; ν(C−H) 3110−2931 (w); δ(N−H) + δ(O−H) 1618 (s); ν(C−N) 1600 (s); ν(C−C) 1520 (s); δ(C−H) 1459 (s), 1417 (w), 1359 (w); ν(S−O) 1303 (s), 1269 (vs), 1247 (vs), 1206 (vs), 1166 (s), 1148 (vs), 1090 (s); ν(C−S) 1041 (vs) cm^{-1}. ^1H NMR (400 MHz, [D_4]methanol, 22 °C): δ = 8.76 (br. s, 1 H, 6-H), 8.69 (t, $J_{H,H}$ = 10.3 Hz, 1 H, 4-H), 8.36 (br. s, 1 H, 5-H), 8.10 (br. s, 1 H, 3-H) ppm.

3-Methylpyridine-2-sulfonic Acid (3-$mpSO_3H$): Yield 1.75 g (50%). $C_6H_7NO_3S$ (173.2): calcd. C 41.61, H 4.07, N 8.09; found C 41.52, H 4.04, N 8.08. IR: $\tilde{\nu}$ = ν(N−H) + ν(O−H) 3210 (m), 3165 (s) cm^{-1}; ν(PyC−H) 3106 (s), 3055 (s); δ(N−H) + δ(O−H) 1614 (m); ν(C−N) 1594 (w); ν(C−C) 1511 (s); δ(C−H) 1459 (m),1446 (m), 1388 (m); ν(S−O) 1316 (m), 1292 (m), 1269 (vs), 1251 (vs), 1237 (s), 1217 (vs), 1210 (sh), 1186 (s), 1158 (s), 1146 (m), 1112 (m); ν(C−S) 1035 (vs); δ(C−CH_3) 816 (m), 802 (m). ^1H NMR (400 MHz, [D_4]methanol, 22 °C): δ = 8.53 (d, $J_{H,H}$ = 6.7 Hz, 2 H, 4-H, 6-H), 7.99 (t, $J_{H,H}$ = 6.7 Hz, 1 H, 5-H); 3.27 (s, 3 H, CH_3) ppm.

4-Methylpyridine-2-sulfonic Acid (4-$mpSO_3H$): Yield 1.93 g (55%). $C_6H_7NO_3S$ (173.2): calcd. C 41.61, H 4.07, N 8.09; found C 41.51, H 4.22, N 8.06. IR: $\tilde{\nu}$ = ν(N−H) + ν(O−H) 3532 (br. vs), 3466 (br. vs), 3363 (m), 3238 (m) cm^{-1}; ν(PyC−H) 3091 (m), 3064 (w); ν(MeC−H) 3008−2858 (w); δ(N−H) + δ(O−H) 1626 (s); ν(C−N) 1602 (m); ν(C−C) 1516 (m); δ(C−H) 1463 (br. s), 1367 (w); ν(S−O) 1297 (m), 1271 (vs), 1245 (vs), 1225 (s), 1200 (m), 1133 (m), 1112 (m); ν(C−S) 1054 (vs); δ(C−CH_3) 836 (vs). ^1H NMR (400 MHz, [D_4]methanol, 22 °C): δ = 8.57 (d, $J_{H,H}$ = 5.9 Hz, 1 H, 6-H), 8.20 (s, 3-H, 1 H), 7.92 (d, $J_{H,H}$ = 5.9 Hz, 1 H, 5-H), 3.24 (s, 3 H, CH_3) ppm.

5-Methylpyridine-2-sulfonic Acid (5-$mpSO_3H$): Yield 1.75 g (50%). $C_6H_7NO_3S$ (173.2): calcd. C 41.61, H 4.07, N 8.09; found C 41.57, H 4.09, N 8.08. IR: $\tilde{\nu}$ = ν(N−H) + ν(O−H) 3475 (br. vs), 3417 (br. vs), 3250 (sh), 3175(sh) cm^{-1}; ν(PyC−H) 3101(m); ν(MeC−H) 3000−2800 (w); δ(N−H) + δ(O−H) 1634 (s); ν(C−N) 1620 (m); ν(C−C) 1556 (m); δ(C−H) 1458 (m), 1436 (m); ν(S−O) 1301 (m), 1267 (vs), 1218 (vs), 1153 (s), 1137 (m); ν(C−S) 1048 (vs); δ(C−CH_3) 849 (s). ^1H NMR (400 MHz, [D_4]methanol, 22 °C): δ = 8.60 (s, 1 H, 6-H), 8.52 (d, $J_{H,H}$ = 7.7 Hz, 1 H, 4-H), 8.23 (d, $J_{H,H}$ = 7.7 Hz, 1 H, 3-H); 3.60 (s, CH_3, 3 H) ppm.

Syntheses of Compounds 1−11

[{Cu(3-$mpSO_3$)$_2$}$_n$] (1): A solution of copper(II) bromide (0.20 g, 0.90 mmol) in 3 mL of water was placed at the bottom of an H-shaped cell, and a solution of 3-$mpSO_3H$ (0.31 g, 1.8 mmol) in 3 mL of water was settled at the other bottom of the cell. The bridging part of the cell was slowly immersed with a methanol/water mixture (1:1 by volume), and the cell was kept steady for 2 weeks. Pale blue crystals of **1** were formed at the bridging part of the cell. Yield 0.140 g (38%). $C_{12}H_{12}CuN_2O_6S_2$ (407.90): calcd. C 35.30, H 2.94, N 6.86; found C 35.28, H 2.92, N 6.76. IR: $\tilde{\nu}$ = ν(PyC−H) 3086 (m) cm^{-1}; ν(MeC−H) 3015−2828 (w); ν(C−N) 1589 (m); ν(C−C) 1580 (w); δ(C−H) 1451 (s), 1374 (w); ν(S−O) 1280 (vs), 1208 (m), 1170 (vs), 1147 (vs), 1075 (m); ν(C−S) 1041 (w), 1015 (s); δ(C−CH_3) 847 (m), 813 (s).

[{Zn(4-$mpSO_3$)$_2$}$_n$] (2): An aqueous solution of 4-$mpSO_3H$ (0.14 g, 0.80 mmol) was neutralized with a diluted aqueous sodium hydroxide solution, and the solvent was evaporated to dryness under reduced pressure. The residue was dissolved in 3 mL of water. The resulting solution was mixed with a solution of zinc(II) bromide (0.091 g, 0.40 mmol) in 1 mL of water. The mixture was stirred for 10 minutes. and subsequently allowed to stand for 1 month at room temperature to obtain colorless crystals of **2**. Yield 0.038 g (23%). $C_{12}H_{12}N_2O_6S_2Zn$ (409.74): calcd. C 35.14, H 2.93, N 6.83; found C 35.15, H 2.90, N 6.73. IR: $\tilde{\nu}$ = ν(PyC−H) 3087 (m) cm^{-1}; ν(MeC−H) 2900−3070 (vw); ν(C−N) 1612 (s); ν(C−C) 1551 (w); δ(C−H) 1437 (m), 1401 (m), 1376 (m); ν(S−O) 1285 (sh), 1277 (vs), 1240 (s), 1172 (vs), 1137 (s), 1114 (s); ν(C−S) 1042 (s), 1024 (s) (νC−S); δ(C−CH_3) 849(s).). ^1H NMR (400 MHz, [D_4]methanol, 22 °C)(ppm): δ = 8.52 (br. d, 1 H, 6-H), 7.90 (s, 1 H, 3-H), 7.50 (s, br., 1 H, 5-H), 2.73 (s, 3 H, CH_3) ppm. Compounds **7** and **9** were prepared similarly.

[Mn(3-$mpSO_3$)$_2$(H_2O)$_2$] (3): A solution of manganese(II) acetate (0.10 g, 0.58 mmol) in 2 mL of water was added to a solution of 3-$mpSO_3H$ (0.20 g, 1.2 mmol) in 4 mL of water and the mixture was stirred for 10 minutes. The solution was kept steady for a week to yield colorless crystals of **3**. Yield 0.096 g (38%). $C_{12}H_{16}MnN_2O_8S_2$ (435.32): calcd. C 33.08, H 3.68, N 6.43; found C 33.17, H 3.67, N 6.43. IR: $\tilde{\nu}$ = ν(O−H) 3409 (br. vs), 3352 (br. vs), 3253 (br. s) cm^{-1}; ν(PyC−H) 3090 (w); ν(MeC−H) 3050−2800 (vw); δ(O−H) 1657 (s); ν(C−N) + ν(C−C) 1583 (m); δ(C−H) 1455 (m), 1415 (w), 1392 (w); ν(S−O) 1238 (vs), 1217 (s), 1191 (vs), 1154 (s), 1123 (w), 1076 (m); ν(C−S) 1029 (vs); δ(C−CH_3) 839 (m), 804 (s). Compounds **8** and **10** were prepared similarly.

[Fe(3-$mpSO_3$)$_2$(H_2O)$_2$] (4): A vial containing iron(II) chloride tetrahydrate (0.16 g, 0.80 mmol) was placed under argon to displace the air, and then 2 mL of degassed water was added to the vial to dissolve the salt. A solution of 3-$mpSO_3H$ (0.28 g, 1.6 mmol) in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

5 mL of degassed water was added dropwise to the metal-containing solution by a syringe. The mixture was allowed to stand for 2 days, yielding yellow crystals of **4**, stable in air and moisture. Yield 0.069 g (20%). $C_{12}H_{16}FeN_2O_8S_2$ (436.23): calcd. C 33.01, H 3.67, N 6.42; found C 33.04, H 3.68, N 6.46. IR: $\tilde{\nu}$ = ν(O−H) 3417 (br. vs), 3349 (br. vs), 3253 (br. s) cm^{-1}; ν(PyC−H) 3092 (w), 3064 (w); ν(MeC−H) 3020−2881 (w); δ(O−H) 1658 (s); ν(C−N) + ν(C−C) 1581 (m); δ(C−H) 1456 (m), 1416 (w), 1391 (w); ν(S−O) 1238 (vs), 1217 (w), 1194 (s), 1154 (s), 1125 (w), 1076 (m); ν(C−S) 1027 (s); δ(C−CH_3) 840 (m), 804 (s).

[Co(3-mpSO$_3$)$_2$(H$_2$O)$_2$] (5): A solution of cobalt(II) bromide hexahydrate (0.10 g, 0.31 mmol) in 2 mL of water was added to a solution of 3-mpSO$_3$H (0.11 g, 0.62 mmol) in 5 mL of water and the mixture was stirred for 10 minutes. The solution was concentrated slowly to ca. 3 mL in a dessicator under water vapor pressure, yielding reddish purple crystals of **5**. Yield 0.049 g (36%). $C_{12}H_{16}CoN_2O_8S_2$ (439.32): calcd. C 32.78, H 3.64, N 6.37; found C 32.73, H 3.64, N 6.37. IR: $\tilde{\nu}$ = ν(O−H) 3433 (br. vs), 3358 (br. vs), 3260 (br. s) cm^{-1}; ν(PyC−H) 3092 (w), 3065 (w); ν(MeC−H) 3000−2827 (vw); δ(O−H) 1657 (s); ν(C−N) + ν(C−C) 1586 (m); δ(C−H) 1458 (s), 1391 (w); ν(S−O) 1241 (vs), 1219 (m), 1186 (vs), 1152 (s), 1127 (m), 1076 (m); ν(C−S) 1027 (vs);); δ(C−CH_3) 841 (m), 805 (s).

[Zn(3-mpSO$_3$)$_2$(H$_2$O)$_2$] (6): A solution of zinc(II) bromide (0.091 g, 0.40 mmol) in 2 mL of water was added to a solution of 3-mpSO$_3$H (0.14 g, 0.80 mmol) in 5 mL of water, and the mixture was stirred for 10 minutes. The solution was left for two weeks to yield colorless crystals of **6**. Yield 0.040 g (22%). $C_{12}H_{16}N_2O_8S_2Zn$ (445.77): calcd. C 32.30, H 3.59, N 6.28; found C 32.30, H 3.58, N 6.26. IR: $\tilde{\nu}$ = ν(O−H) 3424 (br. vs), 3356 (vs), 3255 (vs) cm^{-1}; ν(PyC−H) 3093 (m), 3066 (m); ν(MeC−H) 3025−2856 (w); δ(O−H) 1655 (s); ν(C−N) 1587 (s); ν(C−C) 1541 (w); δ(C−H) 1454 (s), 1419 (w), 1391 (m); ν(S−O) 1282 (m), 1237 (vs), 1197 (vs), 1157 (vs), 1127 (s), 1078 (s); ν(C−S) 1031 (vs); δ(C−CH_3) 842 (m), 806 (s). ^{1}H NMR (400 MHz, [D$_4$]methanol, 22 °C): δ = 8.60 (d, $J_{H,H}$ = 4.9 Hz, 1 H, 6-H), 7.99 (d, $J_{H,H}$ = 7.7 Hz, 1 H, 4-H); 7.59 (dd, $J_{H,H}$ = 4.9, 7.7 Hz, 1 H, 5-H), 3.41 (s, 3 H, CH_3) ppm.

[Zn(5-mpSO$_3$)$_2$(H$_2$O)$_2$] (7): Yield 0.068 g (34%). $C_{12}H_{16}N_2O_8S_2Zn$ (445.77): calcd. C 32.30, H 3.59, N 6.28; found C 32.43, H 3.58, N 6.20. IR: $\tilde{\nu}$ = ν(O−H) 3359 (vs), 3245 (s) cm^{-1}; ν(PyC−H) + ν(MeC−H) 3100−2900 (vw); δ(O−H) 1649 (s); ν(C−N) 1598(m); ν(C−C) 1577 (w); δ(C−H) 1473 (m), 1378 (m); ν(S−O) 1298 (m), 1233 (vs), 1207 (vs), 1157 (s), 1125 (s); ν(C−S) 1030 (vs); δ(C−CH_3) 835 (s). ^{1}H NMR (400 MHz, [D$_4$]methanol, 22 °C): δ = 8.58 (s, 1 H, 6-H), 8.02 (d, $J_{H,H}$ = 8.2 Hz, 1 H, 4-H), 7.95 (d, $J_{H,H}$ = 8.2 Hz, 1 H, 3-H); 3.05 (s, 3 H, CH_3) ppm.

[Zn(PySO$_3$)$_2$(H$_2$O)$_2$] (8): Yield 0.016 g (31%). $C_{10}H_{12}N_2O_8S_2Zn$ (417.71): calcd. C 28.73, H 2.87, N 6.70; found C 28.84, H 2.82, N 6.70. IR: $\tilde{\nu}$ = ν(O−H) 3335 (br. vs), 3240 (s) cm^{-1}; ν(PyC−H) 3107(m); δ(O−H) 1650 (s); ν(C−N) 1596 (s); ν(C−C) 1568 (w); δ(C−H) 1470 (m), 1436 (s); ν(S−O) 1300 (m), 1235 (vs), 1205 (vs), 1170 (s), 1159 (s), 1101 (m), 1056 (m); ν(C−S) 1032 (vs). ^{1}H NMR (400 MHz, [D$_4$]methanol, 22 °C): δ = 8.72 (d, $J_{H,H}$ = 5.1 Hz, 1 H, 6-H), 8.18 (t, $J_{H,H}$ = 7.8 Hz, 1 H, 4-H), 8.08 (d, $J_{H,H}$ = 7.8 Hz, 1 H, 3-H), 7.69 (t, $J_{H,H}$ = 6.2 Hz, 1 H, 5-H) ppm.

[Co(4-mpSO$_3$)$_2$(H$_2$O)$_2$] (9): Yield 0.130 g (38%). $C_{12}H_{16}CoN_2O_8S_2$ (439.32): calcd. C 32.78, H 3.64, N 6.37; found C 32.94, H 3.64, N 6.42. IR: $\tilde{\nu}$ = ν(O−H) 3375 (br. vs), 3260 (br. s) cm^{-1}; ν(PyC−H) 3081 (m); ν(MeC−H) 2964−2834 (w); δ(O−H) 1654 (s); ν(C−N) 1611 (s); ν(C−C) 1555 (w); δ(C−H) 1473 (m), 1438 (m), 1405 (m), 1376 (m); ν(S−O) 1240 (vs), 1188 (vs), 1141 (s), 1113 (s), 1036 (s); ν(C−S) 1018 (vs); δ(C−CH_3) 847 (s).

[Ni(3-mpSO$_3$)$_2$(H$_2$O)$_2$].H$_2$O (10): Yield 0.12 g (66%). $C_{12}H_{18}N_2NiO_9S_2$ (457.10): calcd. C 31.50, H 3.94, N 6.13; found C 31.78, H 3.90, N 6.23. IR: $\tilde{\nu}$ = ν(O−H) 3453 (br. vs), 3366 (br. vs), 3266 (br. s) cm^{-1}; ν(PyC−H) 3094 (m), 3066 (m); ν(MeC−H) 3000−2800 (vw); δ(O−H) 1655 (s); ν(C−N) + ν(C−C) 1588 (m); δ(C−H) 1457 (s), 1391 (m); ν(S−O) 1243 (vs), 1186 (vs), 1155 (vs), 1077 (s); ν(C−S) 1026 (vs); δ(C−CH_3) 843 (s), 807 (s).

[VO(acac)(3-mpSO$_3$)(H$_2$O)] (11): A solution of bis(acetylacetonato)vanadium(IV) oxide (0.11 g, 0.40 mmol) in 2 mL of methanol was added to a solution of 3-mpSO$_3$H (0.14 g, 0.80 mmol) in 5 mL of water. The navy blue mixture was stirred for 5 minutes and left at room temperature for 2 days to afford navy blue crystals of **11**. Yield 0.098 g (68%). $C_{11}H_{15}NO_7SV$ (356.24): calcd. C 37.05, H 4.24, N 3.93; found C 37.17, H 4.27, N 3.96. IR: $\tilde{\nu}$ = ν(O−H) 3324 (br. vs), 3222 (br. vs) cm^{-1}; ν(PyC−H) 3092 (w); ν(MeC−H) 3001−2884 (w); δ(O−H) 1648 (s); ν(C−N) + ν(C−C) + ν(C−O) 1578 (vs), 1525 (vs); δ(C−H) + ν(CH=C) 1452 (m), 1430 (m), 1366 (vs); ν(S−O) 1284 (s), 1259 (vs), 1192 (vs), 1156 (s), 1077 (m); ν(C−S) 1031 (vs); ν(V−O) 974 (vs); δ(C−CH_3) 841 (m), 811 (s).

X-ray Crystallography: For all crystals intensity data were collected on a Rigaku AFC-7S diffractometer with a graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) at 296 K using the ω−2θ scan technique to a maximum 2θ value of 60.° Three standard reflections monitored after every 150 reflections were used for the crystal decay corrections. The observed reflections [$I > 3\sigma(I)$] were extracted from the unique reflections, and the data were corrected for Lorentz and polarization effects. An absorption correction was applied using the empirical ψ-scan method. All crystallographic calculations were carried out using teXsan programs.[23] The structure was solved by the direct methods (SIR92),[24] and refined with full-matrix least-squares techniques,[25] with anisotropic displacement parameters for the non-hydrogen atoms. Some hydrogen atoms were located on difference Fourier maps and refined isotropically, the rest were located in calculated positions and included in the refinement. Table 3 contains crystal data for complexes **1**−**11**. CCDC-205227 to -205236 for complexes **1**−**5**, **7**−**11**, respectively, and -116650 for complex **6** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk]

Heterometallic Molecular Squares and Polymers Based On Self-Assembly Reactions of Multiply Bonded Dirhenium Complexes

Jitendra K. Bera,[a] John Bacsa,[a] Bradley W. Smucker,[a] and Kim R. Dunbar*[a]

Keywords: Self-assembly / Polymers / Supramolecular chemistry / Rhenium / Multiple bonds

Self-assembly reactions of the triply-bonded dirhenium complex *cis*-$[Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2]$ with *cis*-protected Pt^{II} and Zn^{II} precursors have produced heterometallic squares. Analogous reactions with $Ag(O_3SCF_3)$, *cis*-$[Re_2Cl_4(O_2CCH_3)_2(H_2O)_2]$ and $[Rh_2(O_2CCH_3)_4]$ have yielded mixed-metal polymeric structures. These results demonstrate that the isonicotinate ligand is useful for accessing heterometallic structures involving metal–metal bonded complexes.

Introduction

The assembly of metal-based units into supramolecular structures may furnish interesting conducting,[1] magnetic,[2] optical,[3] or catalytic properties.[4] Among the complexes that have been synthesized in this vein are dimetal (M_2) "lantern" complexes as building blocks for homometallic supramolecular assemblies, efforts that have largely focused on the use of dicarboxylic acids.[5] In addition, edge-sharing bi-octahedral dirhenium units can be linked by cyanide and thiocyanate to yield mixed metal Re_4Pd_2, Re_2Ag, Re_2W, Re_2Pt, and Re_2Rh complexes.[6] Recently, we reported a new type of self-assembly reaction that affords molecules with both M_2 and M′ units. The isonicotinate ligand was used as it binds to three metals (Scheme 1). Specifically, the precursor molecule *cis*-$[Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2]$ (**1**) was synthesized and treated with *cis*-$[Pt(dbbpy)(Otf)_2]$ (dbbpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine; Otf = O_3SCF_3) to yield a molecular square composed of alternating dirhenium and platinum corners.[7] Herein we report further reactions of **1** with various metal complexes to yield a new heterometallic molecular square with alternating Re_2 and Zn corners and three open-chain polymers consisting of 1:1 Re_2/Ag, Re_2/Re_2, and Re_2/Rh_2 units.

Results and Discussion

The molecular structure of complex **1** involves orthogonally disposed isonicotinate groups with two dangling nitrogen donors available for further coordination. Reactions of **1** with *cis* and *trans* accessible transition metal precursors can, in principle, generate various cyclic and open-frame oligomers as well as polymers (Scheme 2). Self-assembly reactions typically yield one major product in a high yield as dictated by a combination of enthalpic and entropic contributions. Here, various building blocks have been employed in reactions of **1**, including $[Pt(dbbpy)(O_3SCF_3)_2]$, $ZnCl_2$, $Ag(O_3SCF_3)$, *cis*-$[Re_2Cl_4(O_2CCH_3)_2(H_2O)_2]$, and $[Rh_2(O_2CCH_3)_4]$, all of which have at least two positions available for facile substitution, but differ in the geometry and disposition of the available metal binding sites. *Hybrid* molecular squares $[\{cis\text{-}Re_2(O_3SCF_3)_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}\{Pt(dbbpy)\}]_2(O_3SCF_3)_4$ (**2**) and $[\{cis\text{-}Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}\{ZnCl_2\}]_2$ (**3**), composed of alternating $Re_2^{II,II}$ and M^{II} (M = Pt and Zn) corners, have been isolated from the reactions of **1** with $[Pt(dbbpy)(O_3SCF_3)_2]$[7] and $ZnCl_2$, respectively. In contrast, the reactions of **1** with $Ag(O_3SCF_3)$, *cis*-$[Re_2Cl_4(O_2CCH_3)_2(H_2O)_2]$ and $[Rh_2(O_2CCH_3)_4]$ yield open-chain polymeric structures $[\{cis\text{-}Re_2(OReO_3)_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}\{Ag{\cdot}ReO_4\}]_\infty$ (**4**), $[\{cis\text{-}Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}\{cis\text{-}Re_2Cl_4(O_2CCH_3)_2\}]_\infty$ (**5**), and $[\{cis\text{-}Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}\{Rh_2(O_2CCH_3)_4\}]_\infty$ (**6**), respectively. These reactions are essentially instantaneous as judged by the rapid formation of insoluble solids. Crystals of complexes **3**–**6** were obtained by slow diffusion. Regardless of the ratio of complex **1** and the metal precursors, the isolated products are essentially the same. The new compounds **3**–**6** are insoluble in common organic solvents, which prevents measurements of their physical properties in solution.

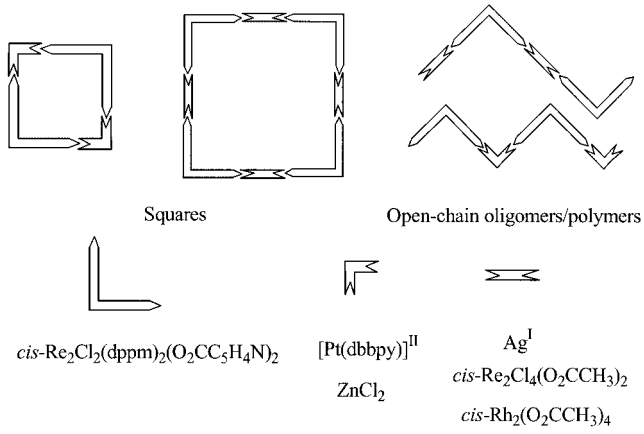

Scheme 2

Complex **3**·10($C_2H_4Cl_2$)·11(CH_3OH)·(H_2O) is a molecular square consisting of alternating $(dppm)_2Re_2^{II}$ and $Zn^{II}Cl_2$ units at the vertices and isonicotinate ligands along the edges (Figure 1). Selected bond lengths and angles are provided in Table 1. The square is considerably distorted, as evidenced by the Zn···Zn diagonal distance of 11.881(5) Å whereas the diagonal defined by the midpoints of the two Re_2 units is 13.608(3) Å. These distances are strikingly similar to the corresponding values in complex **2** (11.971(3) and 13.263(3) Å], the structure of which is identical to complex **3** except that the $ZnCl_2$ corners are replaced by Pt(dbbpy) units (Figure 2). The Re−Re [2.318(1) Å] and the Re−P [2.387(4)−2.412(3) Å], Re−O [2.133(8)−2.160(9) Å], and Re−Cl distances [2.513(3) and 2.523(3) Å] are similar to the corresponding distances in the precursor complex **1**. The vertex angle subtended by the Re_2 units is less than the ideal 90° [O1−Re2−O3 80.6(3)° and O2−Re1−O4 80.0(3)°]. The coordination environment around Zn is best described as distorted tetrahedral. The N1−Zn1−N2 vertex angle is 101.0(5)° while Cl3−Zn1−Cl4 is significantly larger [122.8(2)°], presumably due to non-bonded repulsions between the adjacent chlorine atoms.

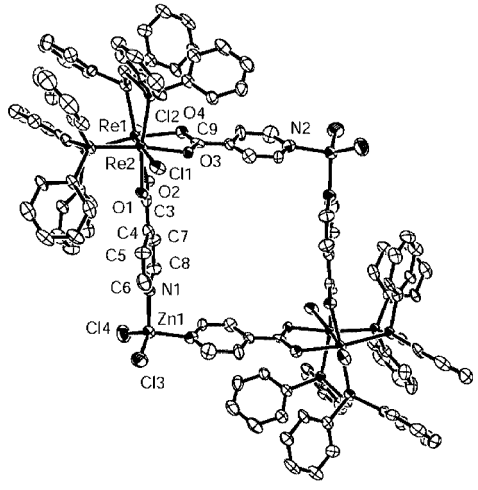

Figure 1. ORTEP representation of the neutral molecular square [{*cis*-$Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2$}{$ZnCl_2$}]$_2$ in **3**·10($C_2H_4Cl_2$)·11(CH_3OH)·(H_2O) with important atoms labeled. Thermal ellipsoids are at the 50% probability level; hydrogen atoms have been omitted for clarity

Table 1. Selected bond lengths [Å] and angles [deg] for **3**

Bond lengths

P4−Re1−P2	94.12(12)	Cl4−Zn1−Cl3	122.8(2)

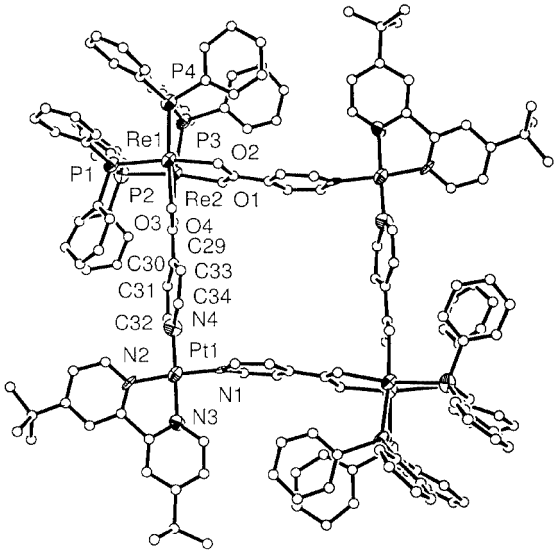

Figure 2. ORTEP representation of the molecular square [*cis*-$Re_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2Pt(dbbpy)]_2$ with important atoms labeled. Thermal ellipsoids are at the 50% level except for the carbon and oxygen atoms which are represented as circles of arbitrary radius. Note that the C, O, F, and S atoms of the triflate anions are axially coordinated, and the hydrogen atoms are removed for clarity

A cyclic voltammetric study of **2** in a 0.1 M nBu_4NPF_6/CH_2Cl_2 solution reveals weak electronic coupling between the dirhenium units through the Pt centers ($\Delta E_{1/2}$ = 130 mV; K_c = 158). The extent of coupling is similar to that estimated for complexes in which dirhenium units are connected by terephthalate ligands.[5]

In complex **4**, the structure of which has been confirmed by X-ray diffraction, the axial chloride ligands have, surprisingly, been replaced by $[ReO_4]^-$ ions. Moreover, it does not contain an outer-sphere triflate anion, rather a second $[ReO_4]^-$ unit is located in the interstices. The $[ReO_4]^-$ anion is a result of oxidative decomposition of **1**, which also explains the relatively low yield of complex **4**. The intense IR

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

resonances seen between 890 and 950 cm^{-1} indicate ν(Re−O) stretches.

The cationic $[\{cis\text{-}Re_2(OReO_3)_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}\{Ag\}]^+$ repeat unit in the crystal structure of **4**·1.5($C_2H_4Cl_2$)·2(CH_3OH) (Figure 3) and selected distances and angles (Table 2) are given here. Each of the $\{Re_2(OReO_3)_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}$ units is connected by Ag^I ions.[8] The *anti* orientation of one set of the isonicotinate ligands in adjacent dirhenium units results in a zig-zag pattern for the polymeric structure (see Figure 4, a). The axial positions of the Re_2 unit in complex **4** are occupied by the $[ReO_4]^-$ anion (instead of the original Cl^- ion in **1**) which leads to a slightly shorter Re−Re distance [2.2850(13) Å] as compared to **1** [2.3271(4) Å]. All metrical parameters involving the dirhenium units are typical of other dirhenium−diphosphane complexes.[9] The two-coordinate Ag^I ion is in a nearly linear geometry (N6−Ag1−N18 172.3(8)°] with Ag1−N6 and Ag1−N18 distances of 2.130(18) and 2.128(18) Å, respectively.

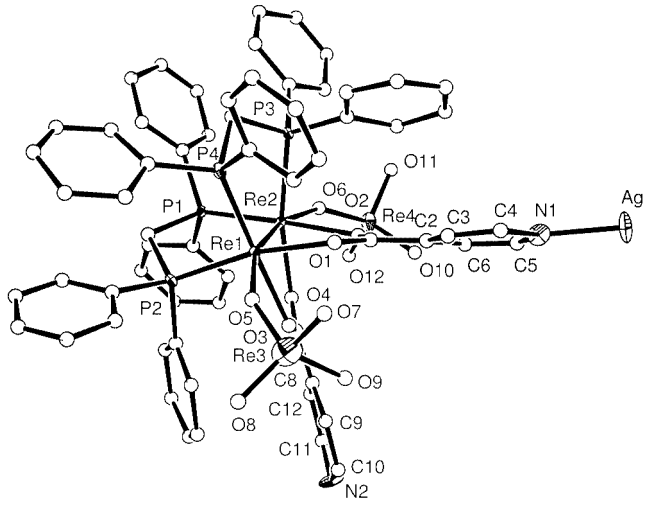

Figure 3. ORTEP representation of the repetitive cationic fragment $[\{cis\text{-}Re_2(OReO_3)_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}\{Ag\}]^+$ in **4**·1.5($C_2H_4Cl_2$)·2(CH_3OH) with important atoms labeled. Thermal ellipsoids are at the 40% level except for the carbon and oxygen atoms which are represented as circles of arbitrary radius. Hydrogen atoms have been omitted for clarity

As the complexes *cis*-$[Re_2Cl_4(O_2CCH_3)_2(H_2O)_2]$[10] and $[Rh_2(O_2CCH_3)_4]$[11] engage in axial interactions, they were used here as linkers for complex **1**. Although structurally similar, the difference in the lengths of the quadruple bond in the dirhenium complex [2.224(5) Å] and the single bond in the dirhodium compound [2.403(2) Å] allowed us to vary the linker length. The axial water ligands in *cis*-$[Re_2Cl_4(O_2CCH_3)_2(H_2O)_2]$ are readily replaced by the nitrogen atoms of the isonicotinate ligands in complex **1**. Each of the $\{cis\text{-}Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}$ moieties is coordinated to two different $\{cis\text{-}Re_2Cl_4(O_2CCH_3)_2\}$ units. The isonicotinate ligands of neighboring $\{cis\text{-}Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}$ units are *anti*, leading to a zig-zag chain structure with alternating triply bonded $Re_2^{II,II}$ and quadruply bonded $Re_2^{III,III}$ units (Figure 4, b). A portion of the polymer, namely the $[\{cis\text{-}Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}\{cis\text{-}Re_2Cl_4(O_2CCH_3)_2\}]$ unit, is depicted in Figure 5. Selected bond lengths and angles are provided in Table 3. The Re−Re of 2.3143(9) Å, Re−P [2.371(4)−2.410(4) Å], Re−Cl [2.530(4), and 2.538(4) Å] are all typical of triply bonded dirhenium complexes with similar ligands.

Table 2. Selected bond lengths [Å] and angles [deg] for **4**

Bond lengths			
Re2−Re1	2.2850(13)	Re1−O3	2.133(14)
Ag1−N6	2.13(2)	Re1−O5	2.22(2)
Ag1−N18	2.128(18)	Re2−P1	2.401(5)
Re2−O2	2.120(13)	Re2−P3	2.419(5)
Re2−O4	2.147(13)	Re1−P2	2.405(6)
Re2−O9	2.230(14)	Re1−P4	2.408(6)
Re1−O1	2.133(13)		
Bond angles			
N6−Ag1−N18	172.3(8)	O1−Re1−O3	79.4(5)
O2−Re2−O4	79.4(5)	O1−Re1−O5	78.4(6)
O2−Re2−O9	80.9(5)	O3−Re1−O5	77.9(6)
O4−Re2−O9	80.2(5)	O1−Re1−P2	168.9(4)
O2−Re2−P1	169.5(4)	O3−Re1−P2	90.1(4)
O4−Re2−P1	94.1(4)	O5−Re1−P2	96.0(5)
O9−Re2−P1	90.0(4)	O1−Re1−P4	95.6(4)
O2−Re2−P3	89.9(4)	O3−Re1−P4	171.2(4)
O4−Re2−P3	168.7(4)	O5−Re1−P4	94.0(5)
O9−Re2−P3	94.4(4)	P2−Re1−P4	94.4(2)
P1−Re2−P3	95.83(18)		

The Re(1)−Re(2) [2.244(1) Å] in the $\{Re_2Cl_4(O_2CCH_3)_2\}$ unit is characteristic of a Re−Re quadruple bond, and is slightly longer than the Re−Re bond [2.224(5) Å] in *cis*-$[Re_2(O_2CCH_3)_2Cl_4(H_2O)_2]$. The Re−O and Re−Cl distances are typical of values reported for similar complexes,[12] and the Re−Re−O angles [89.3(3)−90.3(3)°] are close to 90°. The corresponding angles involving the equatorial Cl^- ligands [103.6(1)−104.4(1)°] are much wider. This "bending back" of the chloride ligands away from the Re−Re bond and towards the axial sites leads to a marked non-linearity of the Re−Re−N (axial) units as evidenced by the Re4−Re3−N2 and Re3−Re4−N1 angles of 163.2(3) and 163.6(4)°, respectively.

Reaction of $[Rh_2(O_2CCH_3)_4]$ with **1** also produced crystals of a zig-zag polymeric chain compound with alternating triply bonded $Re_2^{III,III}$ and singly bonded $Rh_2^{II,II}$ units (Figure 4, c). A diagram of the unit $[\{cis\text{-}Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2\}\{Rh_2(O_2CCH_3)_4\}]$ is shown in Figure 6. Selected bond lengths and angles are provided in Table 4. The metrical parameters involving the triply bonded dirhenium units are similar to those observed in analogous complexes. The two sets of Rh−Rh distances [2.417(6) and 2.392(5) Å] observed in the crystal structure are both typical of singly bonded Rh_2^{4+} units with axial nitrogen donor ligands.[11] The axial Rh−N distances are 2.27(4) and 2.22(2) Å. The Rh1−Rh1′−N1 and Rh2−Rh2′−N2 angles are much closer to linearity at 177.6(7) and 176.3(7)° in complex **6** while the corresponding angles in complex **5** are significantly smaller.

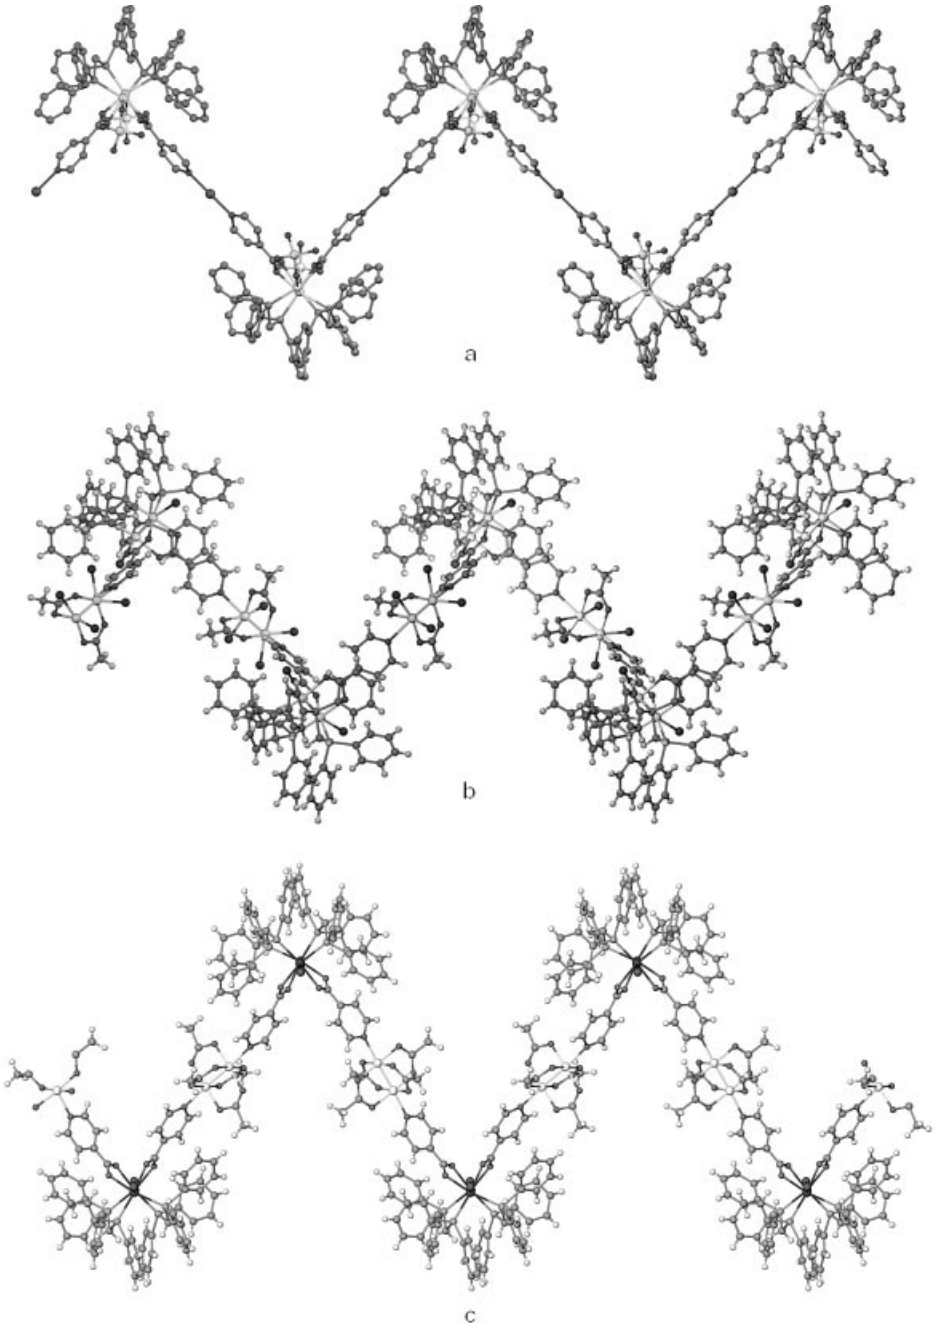

Figure 4. Graphical representation of the zig-zag patterns of the polymeric structures of complexes **4** (a), **5** (b), and **6** (c)

The crystal packing of compounds **2**−**6** share a common interesting feature, namely the phenyl groups of the dppm ligands from the neighboring molecules are engaged in close phenyl−phenyl contacts.[13] A representative example of the packing of Re_2/Zn squares in complex **3** is shown in Figure 7. Such arrangements create a cavity in the crystal lattice in which several solvent molecules are trapped during crystallization.

As documented here, self-assembly the reactions of **1** with *cis* and *trans* disposed linkers can yield discrete cyclic structures or polymers. The rationale for the formation of low-nuclearity species is based solely on the entropy factor. There is also a slight favorable enthalpic contribution for the stabilization of the cyclic structures versus the open-frame oligomers, as the former involves more metal−ligand interactions. Finally, the formation of the heterometallic squares **2** and **3** as the major products, rather than smaller or larger sized rings, is presumably a consequence of the ring-strain of the metallacyclophane. Having stated these points, why do the reactions of $Ag(O_3SCF_3)$, *cis*-$[Re_2Cl_4(O_2CCH_3)_2(H_2O)_2]$, and $[Rh_2(O_2CCH_3)_4]$ react with **1** to yield polymers instead of squares of larger dimensions? A common explanation is the role of concentration in the self-assembly reactions. Dilute solutions typically lead to cyclic

products whereas concentrated solutions produce polymers. However, we found no evidence of lower nuclearity products, regardless of the concentrations of the precursors. Polymer formation may occur because squares of larger dimensions would require many solvent molecules to crystallize in the void space. Close-packed polymers also contain solvent molecules, but the packing of larger squares is expected to be much less efficient.

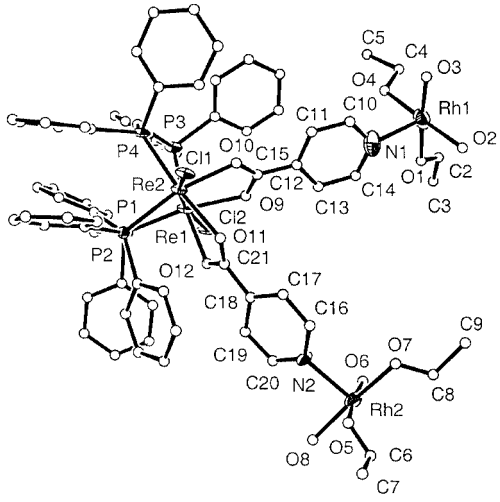

Figure 6. ORTEP representation of the repetitive neutral fragment [{*cis*-$Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2$}{$Rh_2(O_2CCH_3)_4$}] in **6**·1.5($C_3H_6O$)·2($CH_2Cl_2$)·$H_2O$ with important atoms labeled. Thermal ellipsoids are at the 40% level except for the carbon and oxygen atoms which are represented as circles of arbitrary radius. Hydrogen atoms have been omitted for clarity

Concluding Remarks

The results of this study demonstrate the feasibility of preparing both discrete cyclic products and open-chain polymers based on the self-assembly of triply-bonded dirhenium units with various inorganic precursors. Dirhodium

Figure 7. Packing diagram of the Re_2/Zn molecular squares in the crystal structure of complex **3**

complexes with isonicotinate ligands as well as 4-cyanobenzoate groups have been prepared recently and it appears that this will be a generally useful method for preparing mixed-metal clusters.[14] The title compound **1** provides access to different types of heterometallic structures, and its reactions illustrate the usefulness of such molecules for incorporating electron-rich metal−metal bonded complexes into cyclic and acyclic architectures that contain a second type of metal site.[15]

Experimental Section

Solvents were dried by conventional methods, distilled from over nitrogen and deoxygenated prior to use. The starting materials *cis*-$[Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2]$,[7] *cis*-$[Re_2Cl_4(O_2CCH_3)_2(H_2O)_2]$,[16] $[Rh_2(O_2CCH_3)_4]$[17] were synthesized by literature methods. Silver triflate and zinc chloride were purchased from Aldrich and used without further purification. Infrared spectra were recorded in the range 400−4000 cm^{-1} using a Nicolet 470 FT-IR spectrometer as Nujol mull samples suspended between KBr plates. Elemental microanalyses were performed by Dr. H. D. Lee of the Purdue University Microanalytical Laboratory.

Synthesis of [{*cis*-$Re_2(O_3SCF_3)_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2$}{Pt(dbbpy)}]$_2(O_3SCF_3)_4$ (2): A mixture of *cis*-$[Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2]$ (0.095 g, 0.07 mmol) and 0.052 g (0.07 mmol) of $[Pt(dbbpy)(O_3SCF_3)_2]$ was stirred in CH_2Cl_2 for 8−10 h. The resultant red solution was then concentrated and treated with diethyl ether to yield a solid that was collected by filtration, washed with fresh diethyl ether (3 × 5 mL) and dried in vacuo. Single crystals were grown by slow diffusion of Et_2O into a solution of **2** in CH_2Cl_2. Yield: 34 mg (42%). ^1H NMR (δ in $CDCl_3$): 5.05 and 6.50 (m, 4 H, -CH_2- of dppm); 6.8−7.2, 7.42, 7.60 (m, 40 H, Ph of dppm); 8.01 and 8.80 (m, 8 H, isonicotinate), 8.19, 8.28, 9.42 (m, 6 H, aromatic, dbbpy), 1.45 (m, 18 H, CH_3 of dbbpy) ppm. $^{31}P\{^1H\}$ NMR (δ in $CDCl_3$): −9.88 ppm.

Synthesis of [{*cis*-$Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2$}{$ZnCl_2$}]$_2$ (3): A CH_3OH solution (10 mL) of $ZnCl_2$ (5 mg, 0.04 mmol) was carefully layered over a solution of 1,2-dichloroethane (10 mL) that contained *cis*-$Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2$ (50 mg, 0.03 mmol). After 7 days, a crop of bright-red crystals was collected by filtration, washed with methanol (3 × 5 mL) followed by dichloromethane (3 × 5 mL) and dried in vacuo. Yield: 48 mg (87%). $C_{67}H_{64}Cl_8N_2O_5P_4Re_2Zn$ (i.e. **2**·$2C_2H_4Cl_2$·CH_3OH): calcd. (%) C 44.15, N 1.54, H 3.54, Cl 15.56; found C 44.01; N 1.52, H 3.51, 15.07.

Synthesis of [{*cis*-$Re_2(OReO_3)_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2$}{Ag·$ReO_4$}] (4): A CH_3OH solution of AgO_3SCF_3 (10 mg, 0.04 mmol) was layered over a solution of *cis*-$[Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2]$ (50 mg, 0.03 mmol) in 1,2-dichloroethane (10 mL). The Schlenk-tube was then wrapped with foil to avoid light and stored in a refrigerator. After 7 days, a small quantity of block-shaped crystals of **2** had formed along with a gray precipitate. The crystals were separated from the solid, washed with methanol (3 × 5 mL) followed by dichloromethane (3 × 5 mL) and dried in vacuo. Yield: 16 mg (21%). $C_{62}H_{52}AgN_2O_{16}P_4Re_5$: calcd. C 33.19, N 1.25, H 2.34; found C 32.92; N 1.28, H 2.32.

Synthesis of [{*cis*-$Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2$}{*cis*-$Re_2Cl_4(O_2CCH_3)_2$}] (5): An acetone solution (10 mL) of *cis*-$[Re_2Cl_4(O_2CCH_3)_2(H_2O)_2]$ (25 mg, 0.04 mmol) was carefully layered over a dichloromethane solution of *cis*-$[Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2]$ (50 mg, 0.03 mmol). After 2 days, the dark blue crystals that had formed were collected by filtration, washed with acetone (3 × 5 mL) followed by dichloromethane (3 × 5 mL) and dried in vacuo. Yield: 66 mg (92%). $C_{66}H_{58}Cl_6N_2O_8P_4Re_4$: calcd. (%) C 37.95, N 1.34, H 2.80; Cl 10.18; found C 37.65; N 1.31, H 2.73, Cl 10.03.

Synthesis of [{*cis*-$Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2$}{$Rh_2(O_2CCH_3)_4$}] (6): An acetone solution (10 mL) of $[Rh_2(O_2CCH_3)_4]$ (17 mg, 0.04 mmol) was carefully layered over a dichloromethane solution of *cis*-$[Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2]$ (50 mg, 0.03 mmol). After 7 days, the resultant red crystals were collected by filtration, washed with acetone (3 × 5 mL) and dichloromethane (3 × 5 mL), and dried in vacuo. Yield: 56 mg (86%). $C_{70}H_{64}Cl_2N_2O_{12}P_4Re_2Rh_2$: calcd. (%) C 44.29, N 1.48, H 3.40; found C 44.11; N 1.56, H 3.27.

X-ray Crystallography: Crystals of **3**−**6** were harvested directly from the slow diffusion reactions as described in the synthesis section. Single-crystal X-ray intensities were collected at 110(2) K on a Bruker SMART CCD based X-ray diffractometer with 1.5 kW graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). Data reduction, cell-refinement, and corrections for Lorentz and polarization effects were carried out with the program SAINT.[18] Semi-empirical absorption corrections were carried out with the program SADABS.[19] The structures were solved and refined using X-SEED,[20] a graphical interface to SHELX.[21] Additional crystallographic calculations were performed by the programs PLATON[22] and PARST.[23] The hydrogen atoms were refined in a riding mode with values of U_{eq} that were 1.2 times the U_{eq} for the heavy atoms to which they are bonded. Experimental details and pertinent crystallographic data for complexes **3**−**6** are summarized in Table 5.

[{*cis*-$Re_2Cl_2(dppm)_2(O_2CC_5H_4N\text{-}4)_2$}{$ZnCl_2$}]$_2$·10($C_2H_4Cl_2$)·11($CH_3OH$)·($H_2O$) [3·10($C_2H_4Cl_2$)·11($CH_3OH$)·($H_2O$)]: The data were collected using ω-scans in the range $1.67 < \theta < 27.82°$. The detector to crystal distance was set at 60 mm. Exposure times of 20 s per frame and scan widths of 0.3° were used throughout the data collection. The fact that the beta angle is close to 90° combined with the large R-merge value indicated possible pseudo-

[a] $R1 = \Sigma||F_o| - |F_c||/\Sigma F_o$ with $F_o^2 > 2\sigma(F_o^2)$. [b] $wR_2 = [\Sigma w(|F_o^2| - |F_c^2|)^2/\Sigma|F_o^2|^2]^{1/2}$.

merohedral twinning of the crystal. A search for possible twin laws was carried out, but none of them reduced the *R*-factor appreciably. As the final discrepancy indices of both R_1 and R_{int} were small for a potentially twinned data set, we surmised that the major contribution to the integrated data was from one component of the twin and therefore a twin correction would not improve the model significantly. Disordered solvent molecules with fractional site occupancies were modeled with restraints. All non-hydrogen atoms except the carbon and oxygen atoms of the methanol and water molecules were refined anisotropically.

[{*cis*-$Re_2(OReO_3)_2(dppm)_2(O_2CC_5H_4N$-4)$_2$}{Ag·$ReO_4$}]·1.5($C_2H_4Cl_2$)·2-($CH_3OH$) [4·1.5($C_2H_4Cl_2$)·2($CH_3OH$)]: Exposure times of 25 s per frame and scan widths of 0.3° were used throughout the data collection. The data were collected using ω-scans in the θ range 1.53 to 25.35°. The numerous heavy metal atoms resulted in the crystal exhibiting a large absorption coefficient. Unfortunately, the weak nature of the diffraction prevented the use of very small crystal that would minimize the effects of absorption. The isolated $[ReO_4]^-$ ions are disordered over two positions and were modeled using two components with restraints on the Re−O and O···O distances and site occupancies. All the non-hydrogen atoms except the carbon and oxygen atoms were refined anisotropically.

[{*cis*-$Re_2Cl_2(dppm)_2(O_2CC_5H_4N$-4)$_2$}{*cis*-$Re_2Cl_4(O_2CCH_3)_2$}]·3-($C_3H_6O$)·2($CH_2Cl_2$) [5·3($C_3H_6O$)·2($CH_2Cl_2$)]: The data were collected using ω-scans in the range $1.22 < \theta < 23.34°$. The diffraction patterns were indexed using a primitive orthorhombic cell, and the structure was solved and refined in the space group *Pbcn*. A disordered dichloromethane solvent molecule was modeled using two components with restraints on the C−Cl and Cl···Cl distances and site occupancies for the two fragments set to 0.5 each. In the final cycles of refinement, all non-hydrogen atoms, except those belonging to solvent molecules, were refined anisotropically.

[{*cis*-$Re_2Cl_2(dppm)_2(O_2CC_5H_4N$-4)$_2$}{$Rh_2(O_2CCH_3)_4$}]·1.5-($C_3H_6O$)·2($CH_2Cl_2$)·$H_2O$ [6·1.5(C_3H_6O)·2(CH_2Cl_2)·H_2O]: The crystal selected for data collection was removed from the solvent and quickly placed in a cold-stream to prevent decay. The detector-to-crystal distance was set at 60 mm. Exposure times of 40 s per frame and scan widths of 0.3° were used throughout the data collection. The data were collected using ω-scans in the θ range 1.57 to 23.14°. The diffraction patterns were indexed using a primitive monoclinic cell. The space group $P2_1/n$ was chosen on the basis of the systematic absences in the diffraction pattern. In the final cycles of refinement the Re, Cl, P, and O atoms belonging to the coordination polymer were refined anisotropically. Anisotropic refinement of carbon atoms and the atoms belonging to guest molecules resulted in these atoms having non-positive definite displacement parameters.

Synthesis and X-ray Crystal Structures of Cobalt and Copper Complexes of 1,3-Bis(benzotriazolyl)propanes

Philip Børsting[a] and Peter J. Steel*[a]

Keywords: Copper / Cobalt / Cluster compounds / Bridging ligands / N ligands

Two propylene-bridged bis-benzotriazole ligands, **1** and **2**, were used to obtain three novel coordination polymers with cobalt(II), copper(II) and copper(I). The complexes were structurally characterised by X-ray crystallography. The complex $[Co(1)Cl_2]_n$, **3**, possesses a helical zigzag chain structure in which tetrahedral $CoCl_2$ centres are bridged by molecules of **1** having an extended conformation. The complex $[Cu(1)Cl_2]_n$, **4**, exhibits a more complex supramolecular architecture, which extends in two dimensions, with bridging through Cu_2Cl_4 dimeric units in one direction and through the organic ligand in an orthogonal direction. The complex $[Cu(2)Cl]_n$, **6**, has a one-dimensional polymeric structure involving 16-membered M_2L_2 rings bridged by Cu_2Cl_2 units.

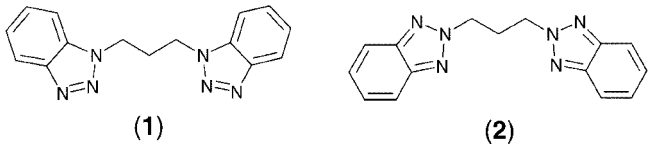
Introduction

The use of linear and angular components for the controlled self-assembly of two- and three-dimensional metallosupramolecular species has been the subject of considerable study in recent years.[1] The most commonly employed organic-connecting components are rigid, linear, bridging heterocyclic ligands, such as pyrazine and 4,4′-bipyridine. More recently, flexible ligands have been employed in order to gain access to topologies not available from logical combination of rigid building blocks. The simplest way to introduce flexibility into ligand design is by incorporation of alkyl chain spacer groups. For example, symmetrical ligands containing propylene spacer groups between 4-pyridyl,[2] 8-quinolyloxy,[3] 1-pyrazolyl,[4] 1-triazolyl,[5] and 2-benzimidazolyl[6] donor groups have recently been used for the construction of interesting new supramolecular architectures.

For some years now we have been involved in the synthesis and study of ligands containing less commonly studied heterocyclic ring systems.[7] One such heterocycle is benzotriazole, which is extensively used as a synthetic auxiliary in organic chemistry[8] but has been largely ignored by coordination chemists. The parent heterocycle can coordinate up to three metals in its deprotonated form.[9] Particular emphasis has been placed on copper complexes, due to the importance of benzotriazole as a corrosion inhibitor.[10] We have recently reported the incorporation of benzotriazole groups into a number of chelating ligands[11] and into a bidentate bridging ligand that forms a triple stranded helicate.[12] We now describe complexes of two symmetrical, isomeric ligands, **1** and **2**, which contain benzotriazole groups separated by flexible propylene spacer units (see Figure 1).



(1) (2)

Figure 1. Structural formulae of ligands **1** and **2**

Results and Discussion

The ligands **1** and **2** were prepared by reaction of benzotriazole with 1,3-dibromopropane in the presence of sodium hydroxide in DMSO solution, as described previously by Katritzky et al.[13] This reaction produces a mixture of the symmetrical 1,1′- and 2,2′-isomers **1** and **2**, along with the unsymmetrical 1,2′-isomer. The three isomers were separated by column chromatography on silica gel and recrystallized from absolute ethanol, and their properties were in agreement with those described previously.[13] However, ligand **1** has recently been described by other workers,[14] who reported a ^1H NMR spectrum that we believe to be that of isomer **2**. In order to resolve this discrepancy unambiguously, we carried out an X-ray crystal structure determination of the compound we identified as **2**.

Figure 2 shows a perspective view of the structure of this ligand, which is indeed the 2,2′-isomer, in agreement with the NMR assignment of Katritzky et al.[13] The compound crystallizes in the orthorhombic space group $P2_12_12_1$ with

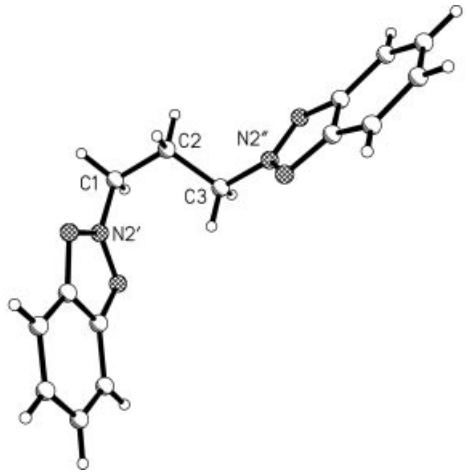

Figure 2. Perspective view of the X-ray molecular crystal structure of ligand **2**

a complete molecule in the asymmetric unit. The bonding geometry of the benzotriazole rings is similar to that in other 2-alkylbenzotriazoles.[13,15] In the solid state it adopts an unsymmetrical conformation about the central propylene spacer group. Specifically, one of the benzotriazole rings exists in a *gauche* conformation [N2′−C1−C2−C3 torsional angle = 59.0(2)°], while the other ring has the expected *anti* conformation [C1−C2−C3−N2′′ torsional angle = 172.2(1)°]. This unusual shape undoubtedly results from a complex system of intermolecular forces, comprising face-to-face and edge-to-face aromatic interactions,[16] as well as C−H···N interactions,[17] all of which are now well-known to contribute significantly to the solid-state structures of heteroaromatic compounds.

Having unambiguously established the structures of the ligands, we proceeded to study their coordination chemistry. All three ligands were treated with a variety of first row transition metal salts. Complexes of the unsymmetrical 1,2′-isomer failed to assemble into any crystalline product. However, reactions of **1** and **2** with both cobalt(II) chloride and copper(II) chloride furnished single crystals suitable for X-ray structure determination.

Reaction of cobalt(II) chloride with **1** formed $[Co(1)Cl_2]_n$, **3**, which is a one-dimensional coordination polymer. Figure 3 shows a perspective view of a section of the extended

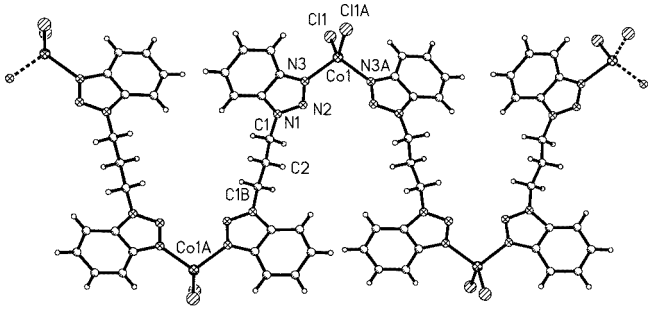

Figure 3. Perspective view, with selected atom labelling, of the one-dimensional coordination polymer $[Co(1)Cl_2]_n$, **3**; selected bond lengths (Å) and angles (°): Co1−N3 2.011(2); Co-Cl1 2.2235(6); N3−Co1−N3A 108.2(1); N3−Co1−Cl1 104.33(5); N3−Co1−Cl1A 112.02(5)

structure with selected atom labelling. The complex crystallizes in the orthorhombic space group *Pnna*, with half the ligand and half a $CoCl_2$ in the asymmetric unit. Thus, the distorted tetrahedral cobalt atom and the central carbon of the propylene group (C2) each lie on different two-fold rotation axes. The resulting polymer chains extend into a helical zigzag pattern, in which the bridging ligand adopts the most extended possible form, with *anti* conformations of the propylene spacer [N1−C1−C2−C1B torsional angle = 179.6(2)°] and coordination by the less sterically hindered N3 nitrogen atoms, as was observed for the $CuCl_2$ complex of the related ligand with a methylene spacer group.[11] As a result, the ligand bridges the cobalt atoms, which are separated by 12.462(1) Å. The polymer chains stack on each other by face-to-face interactions between the benzotriazole groups in such a way that each chain stacks with four other chains.

An analogous reaction of **1** with copper(II) chloride led to a complex, $[Cu(1)Cl_2]_n$, **4**, with a more complex supramolecular architecture. The compound crystallizes in the monoclinic space group $P2_1/n$ with a dichlorocopper(II) unit and a whole bridging ligand in the asymmetric unit. Figure 4 shows a perspective view of the contents of the asymmetric unit and the symmetry-related connecting atoms. The benzotriazole rings are both coordinated through the N3 nitrogen atoms in preference to the more sterically congested N2 nitrogen atoms. Within complex **4** the bridging ligand exists in a more compact conformation than was observed in **3**. In particular, the propylene bridge folds into a *gauche-gauche* conformation [N1"−C1−C2−C3 torsional angle = 57.2(3)° and C1−C2−C3−N1′ torsional angle = 68.0(3)°], which is similar to that observed in a zinc(II) thiocyanate complex of the same ligand.[14] As a consequence, copper atoms bridged by ligand **1** are separated by only 9.157(1) Å, much less than the metal−metal separation in **3**.

The copper atom is five-coordinate, being bonded to two molecules of **1** that are related by a crystallographic glide plane, a terminal chlorine atom and two bridging chlorines that are related by a centre of inversion. The geometry of the copper is square pyramidal with a τ value[18] of 0.088; one of the bridging chlorines occupies the axial site. The terminal chlorine has a bond length of 2.283(1) Å and the two bridging chlorine atoms have bond lengths of 2.324(1) and 2.644(1) Å, giving the Cu_2Cl_2 unit a parallelogram-like shape, which, by virtue of the crystallographic centre of inversion, is strictly planar. The Cu1···Cu1A interatomic distance across the parallelogram is 3.509(1) Å. These distances are within the range of other known di-μ-chlorocopper(II) complexes.[7,10b,19]

The bridging nature of the heterocyclic ligand serves to extend the structure in one dimension. Further bridging by the chlorine atoms results in an orthogonal extension of the structure that produces a complicated two-dimensional network. Large 44-membered fused metallacyclic ring-systems exist within this network as M_6L_4 units, one of which is shown in Figure 5. A stabilising influence within this structure appears to come from π−π stacking between the benzotriazole rings separated by the Cu_2Cl_2 units. These rings lie perpendicular to the Cu_2Cl_2 plane and are separated by approximately 3.5 Å, although they are offset such that the centroids of the benzo rings are separated by ca. 4.18 Å.

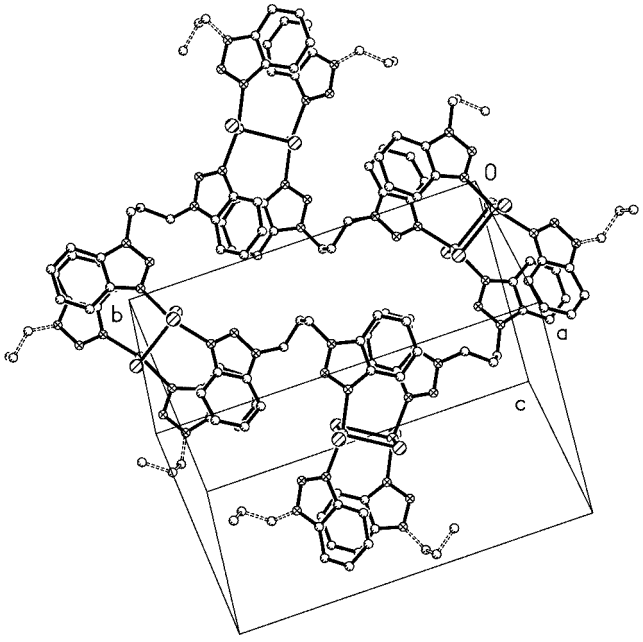

Figure 5. Perspective view of a section of the extended two-dimensional polymeric structure of **4**; the unit cell is indicated

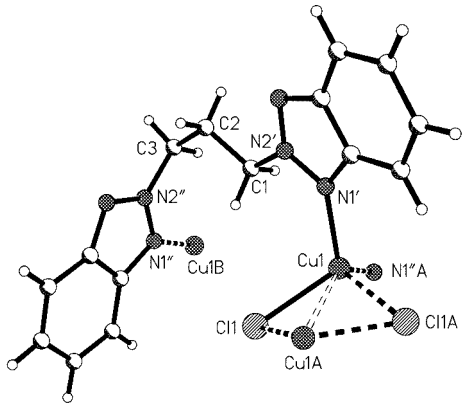

Figure 6. Perspective view showing the contents of the asymmetric unit and the connected atoms (dashed bonds), with selected atom labelling, in the crystal structure of $[Cu(2)Cl]_n$, **6**; selected bond lengths (Å) and angles (°): Cu1−N1′ 2.011(3); Cu1−N1′′A 2.015(3); Cu1−Cl1 2.3724(9); Cu1−Cl1A 2.4287(9); N1′−Cu1−N1′′A 115.3(1); N1′−Cu1−Cl1 112.29(8); N1′′A−Cu1−Cl1 111.19(8); N1′−Cu1−Cl1A 108.30(8); N1′′A−Cu1−Cl1A 107.59(8); Cl1−Cu1−Cl1A 101.01(3)

Reaction of **2** with cobalt(II) chloride gave a $[Co(2)Cl_2]_n$ complex, **5**, as a light blue solid, which failed to produce any crystals suitable for X-ray crystallography. In contrast, reaction of **2** with copper(II) chloride in methanol gave, quite unexpectedly, a copper(I) species as lemon-coloured crystals. This surprising result proved to be quite reproducible, although the identity of the metal reductant remains undetermined. The resulting polymeric $[Cu(2)Cl]_n$ complex, **6**, crystallizes in the monoclinic space group *C*2/*c*, with a copper(I) chloride unit and a whole bridging ligand in the asymmetric unit. Figure 6 shows a perspective view of the contents of the asymmetric unit and the symmetry-related connecting atoms.

Within the complex the ligand adopts a conformation quite similar to that found in the structure of the free ligand **2**, in which one benzotriazole group adopts a *gauche* conformation to the propylene linker [C1−C2−C3−N2′′ torsional angle = 64.9(4)°] and the other group an *anti* conformation [N2′−C1−C2−C3 torsional angle = 177.8(3)°].

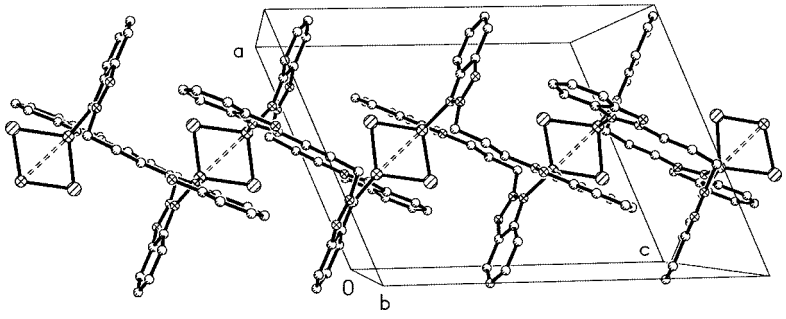

Figure 7. Perspective view of a section of the extended one-dimensional polymeric structure of **6**; the unit cell is indicated

This results in a relatively short intermetallic separation across the ligand bridge [Cu1···Cu1B = 6.010(1) Å]. The copper(I) atom has tetrahedral geometry with coordination to two bridging chlorine atoms, related by a twofold rotation axis, and two nitrogen atoms of different ligands, related by a centre of inversion. The Cu−Cl bond lengths are relatively symmetric [2.372(1) and 2.429(1) Å] and are in the range of other known binuclear Cu_2Cl_2 complexes.[20] The Cu_2Cl_2 unit is nonplanar with a rather short Cu···Cu contact [Cu1···Cu1A = 2.8093(8) Å]. The Cu−N1 distances are also within the range of similar known binuclear Cu_2Cl_2 complexes.[20] Two molecules of ligand **2** bridge two copper atoms, thereby generating a 16-membered M_2L_2 ring structure about a crystallographic centre of inversion. As shown in Figure 7, these rings further extend into a one-dimensional polymeric structure through the chloro bridges. Once again, the extended structure appears to be stabilised by π−π stacking interactions across the Cu_2Cl_2 units between adjacent benzotriazole systems, whose mean planes are separated by ca. 3.5 Å.

Conclusion

The present study has shown that benzotriazole is a useful heterocyclic ring system for incorporation into bridging ligands. The bidentate ligands **1** and **2**, having flexible propylene linkers, generate one- and two-dimensional coordination polymer networks with copper and cobalt chlorides.

Experimental Section

General Procedures and Ligand Syntheses: NMR spectra were recorded on a Varian Unity 300 spectrometer with a 3 mm probe and operating at 300 MHz and 75 MHz for ^1H and ^{13}C, respectively. Melting points were determined using an electrothermal melting point apparatus and are uncorrected. Elemental analyses were performed by the Campbell Microanalytical laboratory at the University of Otago.

The ligands were prepared according to the procedure of Katritzky et al.[13] This gave a mixture of **1** [m.p. 139−139.5 °C (ref.[13] 119−121 °C)], **2** [119−121 °C (ref.[13] 116−118 °C)] and the unsymmetrical 1,2′-disubstituted isomer [80−81 °C (ref.[13] 83−83.5 °C)], which were separated by chromatography on silica gel and recrystallized from ethanol.

Preparation of Complexes

Cobalt(II) Chloride Complex of 1, viz. 3: 1,3-Bis(benzotriazolyl)propane (10 mg, 0.036 mmol) was dissolved in boiling MeOH (1 mL) and added to a solution of $CoCl_2·6H_2O$ (8.5 mg, 0.036 mmol) in MeOH (1 mL). After 20 days blue plate crystals suitable for X-ray crystallography had formed. The crystals were removed and washed with MeOH. Yield: 8.5 mg (58%), m.p. 322 °C. $C_{15}H_{14}Cl_2CoN_6$ (408.15): calcd. C 44.14, H 3.46, N 20.59 %; found: C 44.28, H 3.27, N 20.48 %.

Copper(II) Chloride Complex of 1, viz. 4: $CuCl_2·2H_2O$ (6.0 mg, 0.035 mmol) was dissolved in MeOH (3 mL) and added to a solution of 1,3-bis(benzotriazolyl)propane (10 mg, 0.036 mmol) dissolved in hot MeOH (3 mL). The light green mixture was mixed well and left standing at room temperature. After a few minutes blue crystals began to form and after 1 hour the solution was colourless. The blue block-shaped crystals are stable in air and suitable for X-ray diffraction. Yield: 11.9 mg (82%), m.p. 274 °C. $C_{15}H_{14}Cl_2CuN_6$ (412.76): calcd. C 43.65, H 3.42, N 20.36 %; found: C 43.76, H 3.37, N 20.15 %.

Cobalt(II) Chloride Complex of 2, viz. 5: 1,3-Bis(benzotriazol-2-yl)-propane (32.4 mg, 0.116 mmol) and $CoCl_2·6H_2O$ (25.2 mg, 0.106 mmol) were stirred and refluxed in MeOH (8 mL) for 16 h, which resulted in a blue solution. The blue solution was evaporated

in vacuo, the resulting solid was redissolved in $CHCl_3$ (2 mL) and the solution was subjected to slow evaporation, which gave a light blue solid. Yield: 39 mg (90%), m.p. 265−266 °C. $C_{15}H_{14}Cl_2CoN_6$ (408.15): calcd. C 44.14, H 3.46, N 20.59 %; found: C 43.89, H 4.07, N 20.29 %.

Copper(I) Chloride Complex of 2, viz. 6: 1,3-Bis(benzotriazol-2-yl)-propane (10 mg, 0.036 mmol) was dissolved in boiling MeOH (1 mL), and $CuCl_2{\cdot}2H_2O$ (6.0 mg, 0.036 mmol) dissolved in MeOH (1 mL) was added. The pale green solution was mixed well. After a few days, lemon-coloured crystals suitable for X-ray crystallography had formed. The crystals were filtered off and washed with MeOH. Yield: 4.9 mg (36%), m.p. 199 °C. $C_{15}H_{14}ClCuN_6$ (377.31): calcd. C 47.64, H 3.73, N 22.22 %; found: C 47.69, H 3.58, N 22.06.

X-ray Crystallography: Crystal data and experimental details of the data collections and structure refinements are listed in Table 1. Data were collected with a Siemens SMART CCD area detector, using graphite monochromatised Mo-K_α radiation (λ = 0.71073 Å). Almost complete spheres of data were collected. The structures were solved by direct methods using SHELXS,[21] and refined on F^2 using all data by full-matrix least-squares procedures with SHELXL-97.[22] Hydrogen atoms were included in calculated positions with isotropic displacement parameters 1.3 times the isotropic equivalent of their carrier atoms. The function minimised was $\Sigma w(F_o^2 - F_c^2)^2$, with $w = [\sigma^2(F_o^2) + (aP)^2 + bP]^{-1}$, where $P = [\max(F_o,0)^2 + 2F_c^2]/3$. CCDC-207061 (for **3**), -207062 (for **4**), -207063 (for **2**), -207064 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk.

Role of the 2,6-Bis(trifluoromethyl)phenyl Group on the Acidity of the Corresponding Phosphane[‡]

Karinne Miqueu,[a] Jean-Marc Sotiropoulos,[a] Geneviève Pfister-Guillouzo,*[a] Valentyn Rudzevich,[b] Vadim Romanenko,[b] and Guy Bertrand[b]

Keywords: Photoelectron spectroscopy / DFT calculations / Phosphanide anions / Phosphanes

The proton affinities of $PhPH^-$ (**1**) and Ar_fPH^- (**2**) were calculated using the B3LYP hybrid functional and the 6-31+G(d,p) basis set. For both anions a net difference was observed. The study of the structural and electronic properties of the anionic species and the corresponding phosphanes $PhPH_2$ (**3**) and Ar_fPH_2 (**4**) allowed us to unsderstand this results and point out the specific role of the 2,6-bis(trifluoromethyl)phenyl (Ar_f) substituent.

Introduction

During the last two decades the 2,6-bis(trifluoromethyl)-phenyl (Ar_f) and 2,4,6-tris(trifluoromethyl)phenyl substituents have been widely used in main-group element chemistry,[2] because they feature a unique combination of steric and electronic properties. The steric effects of perfluoroalkylated aryl groups are well established and highlighted by the synthesis of a wide range of the kinetically stabilized low-coordinated main-group element derivatives, such as phosphaalkenes,[3] diphosphenes,[4] iminoarsanes[5] and their transition metal derivatives. The electronic effects of Ar_f groups are less studied and represent a more recent and developing area.[6]

In a preliminary communication[7] we reported the synthesis and molecular structure of the ion-separated salt $[P(H)Ar_f][K(benzo\text{-}15\text{-}crown\text{-}5)_2]$ representing the first structurally characterized example of a dicoordinated monoorganylphosphanide anion. The use of other bulky substituents (without fluorinated groups) does not allow for the isolation and characterization of such anionic species. Therefore, it was of interest to rationalize this experimental observation and to understand the electronic effects of the Ar_f group. Moreover, information about specific behavior of this latter can be obtained by calculation of the proton affinities of $PhPH^-$ (**1**) and Ar_fPH^- (**2**). This involves naturally the theoretical study of the anions, performed here for the first time, but also the knowledge of the neutral species. The coupling between UV photoelectron spectroscopy and calculations allows us to obtain structural and electronic properties of the phosphanes $PhPH_2$ (**3**) and Ar_fPH_2 (**4**).

For the neutral species, previous works[8] on the basic properties of arylphosphanes had shown that the orientation of the phosphorus lone pair relative to the aromatic ring was an important factor. However, reinvestigating the photoelectron spectrum of $PhPH_2$ (**3**) Veszpremi et al. concluded that the conjugative interaction between the phosphorus lone pair and the phenyl ring is of minor importance in agreement with other spectroscopic and quantum chemical results (MNDO and HF/MP2).[9] The rotational barrier of the phenyl group in **3** has been found to be rather low.

No experimental and theoretical data exist concerning the [2,6-bis(trifluoromethyl)phenyl]phosphane (**4**). Considering the importance of electron correlation for the geometry optimization of compounds having a flat potential energy surface, we investigated the rotational barriers for $PhPH_2$ (**3**) and Ar_fPH_2 (**4**) using the density functional theory. Moreover, the He-I photoelectron spectra of **3** and **4** were carried out and the data compared with the theoretical results. Such an approach would allow to determine if neutral species show notable differences.

First, we are going to present the theoretical results concerning the anionic species and then the PE spectra as well as the calculations of the corresponding phosphanes.

Results and Discussion

Anionic Species

The geometrical parameters for the anionic species **1** and **2** are summarized in Table 1. For the two systems $PhPH^-$ (**1**) and Ar_fPH^- (**2**), the lowest energetic form (form **1A** and **2A**, respectively) is planar. The C^1-P-H angle is 95.8° for **1** and 97.5° for **2**. Such a structure presents a lone pair in the C^1PH plane with a strong s character and a pure p orthogonal lone pair. The transition states corresponding to the rotation around the C^1-P bond (form **1B** and **2B**; PH perpendicular to the phenyl ring) are calculated to be 8.76 and 15.52 kcal/mol (ZPE correction) for $PhPH^-$ and Ar_fPH^-, respectively, higher than their minima.

Table 1. Selected bond lengths [Å] and bond angles [°] for the privileged structures and the transition states of $PhPH^-$ (**1**) and Ar_fPH^- (**2**) calculated with the B3LYP hybrid functional and the basis set 6-31+G(d,p)

The stabilization of the planar structure can be explained by the interaction between the π phosphorus lone pair (p character) and the π^*_{b1} orbital of the ring, localized on the C^1 (and C^4) atoms (Figure 1). In fact, for the two minima **1A** and **2A** the HOMO is stabilized by about 0.27 eV for **1** and 0.53 eV for **2**, compared to the transition states **1B** and **2B** (HOMO: n_P^{π}). In contrast, for the transition states **1B** and **2B** we notice a strong destabilizing of the HOMO-1 (around 0.5 eV), compared to **1A** and **2A** due to an interaction between the s lone pair and the b_1 orbital.

For the fluorinated compound **2**, the inductive effect of the CF_3 groups stabilizes the b_1, a_2, a_2^*, and b^*_1 orbitals of the phenyl ring. In this case the destabilizing interaction between the π phosphorus lone pair and the b_1 orbital does not exist and only the stabilizing interaction occurs with the b^*_1. So, the π stabilizing interaction between n_P^{π} and π^*_{b1} is more important for **2** than for **1** as displayed Figure 1.

For the privileged forms **1A** and **2A**, we observe a shortening of the $P-C^1$ bond and a lengthening of the C^1-C^2 and C^1-C^6 bonds compared to the neutral species

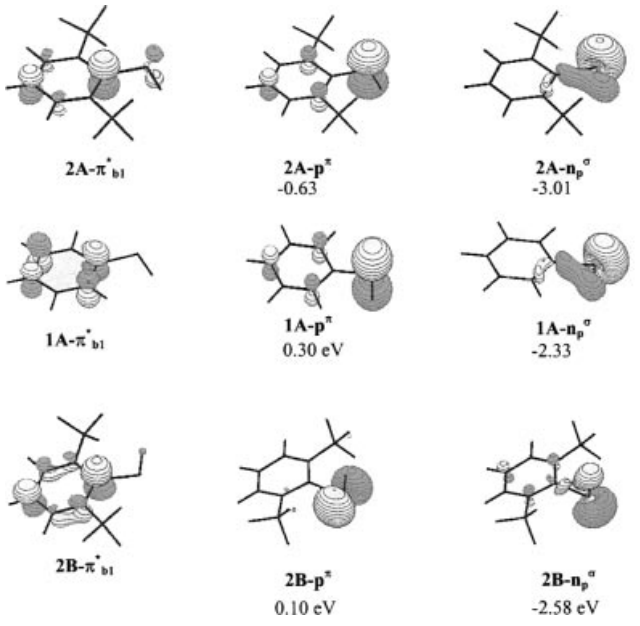

Figure 1. Plot of the molecular orbitals for the minima of $PhPH^-$ (**1A**) and Ar_fPH^- (**2A**) and the corresponding transition states **1B** and **2B**

(Table 2). This effect is more pronounced for **2** than **1** (**2**: $P-C^1$: 1.787 Å, C^1-C^2: 1.459 Å, C^1-C^6: 1.457 Å; **1**: $P-C^1$: 1.811 Å, C^1-C^2: 1.428 Å and C^1-C^6: 1.427 Å). These geometrical changes are due to the stabilizing interaction $n_P^{\pi} \rightarrow \pi^*_{b1}$. For the anion **2**, these calculated geometric parameters are in particularly good agreement with the X-ray values[7] ($P-C^1$: 1.795 Å, C^1-C^2: 1.453 Å, and C^1-C^6: 1.452 Å). The delocalization of the negative charge (NBO analysis) to the aryl group is well described by the electronic distribution (Table 3). Noteworthy is the π-electronic trans-

fer of about 0.7 π e^- from the phosphorus lone pair to the π system of the phenyl ring (**1**: 0.62 π e^-; **2**: 0.76 π e^-).[10]

Table 3. NBO charges computed at the B3LYP/6-31G(d,p) level for $PhPH^-$ (**1**) and Ar_fPH^- (**2**)

	$PhPH^-$ (**1A**)	Ar_fPH^- (**2A**)
P	−0.26	−0.09
C^1	−0.32	−0.32
C^2	−0.27	−0.22
C^3	−0.25	−0.20
C^4	−0.33	−0.34
C^5	−0.25	−0.20
C^6	−0.28	−0.23
H^1	−0.08	−0.06

For the transition states **1B** and **2B**, the calculated P−C bonds (1.886 and 1.884 Å, respectively) are longer than those for **1A** and **2A**. The C^1-C^2 and C^1-C^6 bond lengths (ca. 1.427 Å) for **2B** also agree with a weak delocalization of the phosphorus lone pair, with an s character, in the ring as shown in Figure 1.

Thus, considering the charges and the geometric parameters it appears that the phenyl ring substituted by CF_3 groups acts as an electron acceptor by the π^*_{b1} orbital and contributes to the stability of the Ar_fPH^- anion (**2**) which features a quinoid structure.

However, the stabilization of the anion **2** is not the only factor that explains the isolation of such species from the phosphane Ar_fPH_2 precursor **4**. A second reason can be proposed: the presence of the CF_3 groups must induce destabilizing interactions into the neutral molecule. In order to check such a hypothesis, we theoretically determined the stationary points (minima and saddle points) corresponding to the rotation process of the two phosphanes **3** and **4**. In addition, the photoelectron spectra were recorded to determine the possibility of a favored orientation between the aryl group and the phosphorus lone pair. The agreement between theoretical data and PE experiments allow us to determine the importance of interactions between the π system of this aryl group and the n_p phosphorus lone pair.

Phenylphosphane (3)

For the phenylphosphane the energetically privileged rotamer **3A** presents a *gauche* orientation of the phenyl ring ($H^1-P-C^1-C^2$: −112.7°, $H^2-P-C^1-C^2$: 152.9°; Lp $P-C^1-C^2$: 10.5°). In this case, there is a very weak interaction between the π-system of the phenyl ring and the phosphorus lone pair. During the rotation process, two transition states (**3B**; Lp $P-C^1-C^2$: 90°) and (**3C**; Lp $P-C^1-C^2$: 0°) have been found on the potential energy surface. For **3B**, there is a maximal interaction between the phosphorus lone pair and the π system of the phenyl ring, whereas **3C** presents no interaction. The geometrical parameters are described in Table 2. The energy difference between the different transition states (**3B** or **3C**) and the minimum **3A** is very weak (calculated at 0.6 kcal/mol for **3B**) or negligible (for **3C**). It means that a free rotation of the phenyl group in the gas phase can occur. This result is in agreement with the one reported by Veszpremi et al. (HF/MP2 calculations).[9a]

For these different structures the electronic and nuclear repulsion energies are summarized in Table 4. We can note that the lowest energy structure corresponds to a form where the electronic and nuclear repulsion energies are intermediate between those of the two transition states. For **3B**, the electronic and the repulsion energies are strongest, this latter being predominating.

Table 4. Electronic and nuclear repulsion energies [hartrees] for the different structures of $PhPH_2$ (**3**) and Ar_fPH_2 (**4**)

	E_{elec}	E_{rep}
$PhPH_2$ (**3A**) min	−893.013421	318.800771
$PhPH_2$ (**3B**)	−893.206339	318.994787
$PhPH_2$ (**3C**)	−892.953020	318.740385
Ar_fPH_2 (**4A**) min	−2453.638501	1205.321897
Ar_fPH_2 (**4B**)	−2450.487236	1202.174381

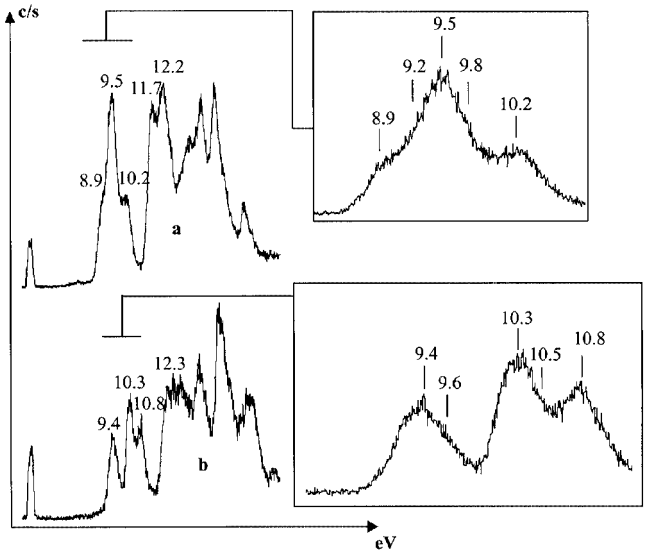

Figure 2. **a**: He-I spectrum of $PhPH_2$ (**3**); **b**: He-I spectrum of Ar_fPH_2 (**4**)

For compound **3**, the PE spectrum (Figure 2) presents, at low energies, three bands of different intensities at 8.9, 9.5 and 10.2 eV, the second one being the most intense.

For the lowest energy structure **3A**, the three first Kohn−Sham (K-S) orbitals are energetically close (Table 5: $\pi_{b1} - n_P$: −6.92; π_{a2}: −7.17; $\pi_{b1} + n_P$: −7.43 eV). Thus, the PE spectrum would present three bands with the same intensities, each separated by about 0.25 eV, or a unique broad band. The experimental spectrum cannot correspond to **3A** since, experimentally, the separation between the first and the third band is about 1.2 eV and the second band is more intense than the first and third ones. This observation suggests the presence of other rotamers. In fact, this PE

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

spectrum would be a superposition of all rotamers' ionizations (Figure 3), as previously observed.[9a]

Table 5. Kohn−Sham energies and ΔSCF values for $PhPH_2$ (minimum **3A** and transition states **3B** and **3C**) and Ar_fPH_2 (minimum **4A** and transition state **4B**) calculated with the B3LYP hybrid functional and the basis set 6-31+G(d,p)

Kohn−Sham energies [eV] (Δ*SCF values*)				
$PhPH_2$ (**3A**)	$PhPH_2$ (**3B**)	$PhPH_2$ (**3C**)	Ar_fPH_2 (**4A**)	Ar_fPH_2 (**4B**)
−6.92	−6.47	−7.13	−7.22	−7.57
$\pi_{b1} - n_P$ (*8.86 eV*)	$\pi_{b1} - n_P$ (*8.41 eV*)	π_{a2} (*9.10 eV*)	$\pi_{b1} - n_P$ (*9.14 eV*)	n_P (*9.86 eV*)
−7.17	−7.14	−7.19	−8.25	−8.08
π_{a2}	π_{a2}	π_{b1}	π_{a2}	π_{a2}
−7.43	−7.94	−7.19	−8.67	−8.28
$\pi_{b1} + n_P$	$\pi_{b1} + n_P$	n_p	$\pi_{b1} + n_P$	π_{b1}

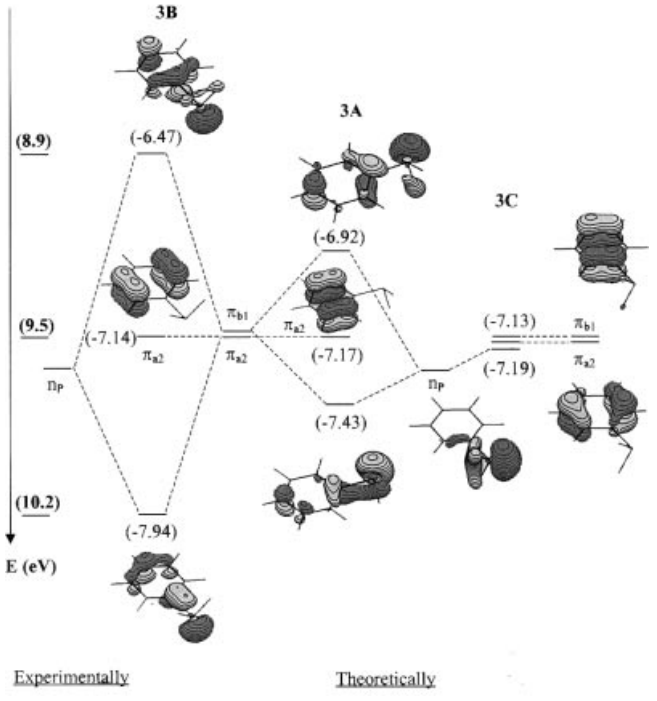

Figure 3. Experimental ionization potentials, molecular orbitals and Kohn−Sham values of $PhPH_2$ (minimum **3A** and transition states **3B** and **3C**)

For **3C** the K-S energies (−7.13: π_{a2}; −7.19 eV: π_{b1} and n_P) of the first three orbitals are almost identical (Table 5). These three ionizations would appear in a unique band, like for **3A**. Taking into account the similar K-S energies for **3A** and **3C** as well as the π_{a2} and π_{b1} ionization potentials of the phenyl ring,[11] the first three ionizations of these two rotamers will be at the same energy (9.5 eV). Thus, the second band can be assigned to the removal of an electron from the $\pi_{b1} - n_P$, π_{a1}, $\pi_{b1} + n_P$ orbitals of **3A** as well as the π_{a2}, π_{b1}, and n_P orbitals of all rotamers around **3C**. This rotamer population explains the intensity of this latter in the PE spectrum.

For **3B**, the first three Kohn−Sham energies (Table 5) are calculated at −6.47: $\pi_{b1} - n_P$; −7.14: π_{a2}; −7.94 eV: $\pi_{b1} + n_P$, respectively. Only the presence of rotamers population with a structure close to **3B** allows the assignment of the complete experimental spectrum. Like for **3A** and **3C**, the second ionization π_{a2} corresponds to the experimental band centered at 9.5 eV. Taking into account the theoretical difference between the first and second ionization (0.67 eV) the band at 8.9 eV corresponds to the removal of an electron from the $\pi_{b1} - n_P$ orbital. Moreover, the comparison between the experimental (1.3 eV) and theoretical (1.4 eV) energetic gap between the first and third band allows us to associate the third ionization to the band at 10.2 eV.

These assignments are consistent with the expanded spectra (Figure 2) where we observe an intense band centered at 9.5 eV with a shoulder between 8.6 and 9.0 eV and a broad shoulder between 9.8 and 10.3 eV.

[2,6-Bis(trifluoromethyl)phenyl]phosphane (4)

For **4**, one minimum is found on the potential energy surface (Table 2). This lowest energy structure (**4A**) corresponds to a maximal interaction between the phosphorus lone pair and the π system. A comparison between **4A** and **3B** (phenyl ring with the same orientation) shows a slight lengthening of the P−C^1 bond length (1.876 Å for **4A** and 1.855 Å for **3B**) and a phosphorus pyramidalization more pronounced for **4** (ΣP angle: 287.13° for **4A**, 288.26° for **3B**). An explanation is found considering the strong interatomic and electronic repulsions between the phosphorus lone pair and the CF_3 substituents. For **4A**, the theoretical H−F and P−F distances (2.46 and 2.92 Å, respectively) correspond to a van der Waals contact (2.55 and 3.25 Å, respectively). However, there is a compensation between these high steric repulsions, which destabilize the system and an electronic delocalization between the phosphorus lone pair and the aromatic system, which is stabilizing.

The ring system of the transition state **4B** has similar orientation than **3C** [no interaction between n_P and $\pi_{C=C}$]. It is found to be 1.99 kcal/mol higher in energy than the minimum. As for $PhPH_2$, a free rotation can also be proposed in this case. A lengthening of the P−C^1 bond is noteworthy when we compared the calculated geometric parameters of **4B** and **3C** (Table 2).

For these two structures **4A** and **4B** the electronic and nuclear repulsion energies are summarized Table 4. The lowest energy structure **4A** corresponds to the form where the electronic energy is the more important. The presence of σ-attractor CF_3 groups involves an electronic delocalization between the phosphorus lone pair and the aromatic system (π^*_{b1}) which stabilizes the system and counterbalances the high steric interactions (Figure 4). For **4** the photoelectron spectrum (Figure 2) shows three well-separated first bands which appear at 9.4, 10.3, and 10.8 eV, respectively.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

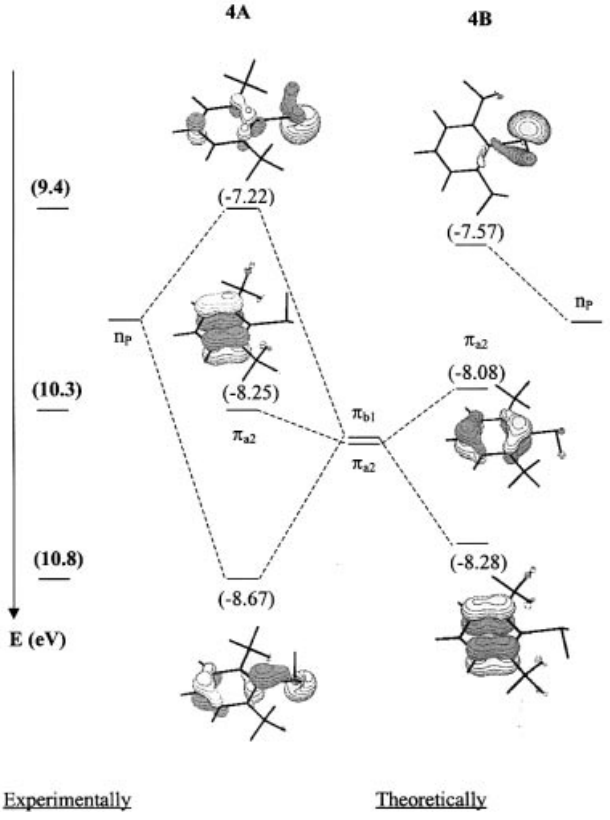

Figure 4. Experimental ionization potentials, molecular orbitals and Kohn−Shan values of Ar_fPH_2 (minimum **4A** and T.S. **4B**)

For the lowest energy structure (**4A**) the three K-S energies (Table 5) are calculated at −7.22: $\pi_{b1} - n_P$; −8.25: π_{a2}; −8.67 eV: $\pi_{b1} + n_P$, respectively. In the PE spectrum the second band, centered at 10.3 eV is associated with the ionization of the π_{a2} orbital.[12] The experimental separation between the first and the third band is about 1.4 eV. Taking into account the calculated energetic gap between the first and third ionizations (1.45 eV), we assign the first band (9.4 eV) to the ionization from the $\pi_{b1} - n_P$ orbital and the third band (10.8 eV) to the $\pi_{b1} + n_P$ orbital.

The weak energy difference between the two rotamers **4A** and **4B**, as previously observed in the case of **1**, involves the existence of a free rotation process. It means that the ionizations of **4B** are going to also appear in the experimental spectrum. For **4B** the K-S energies are the following: −7.57: n_P; −8.08: π_{a2}; −8.28 eV: π_{b1} (Table 5). Thus, for this rotamer, the ionization of the phosphorus lone pair is located in the shoulder of the first band (9.4 eV) and the π_{a2} and π_{b1}' ionizations in the second band centered at 10.3 eV, which explains its intensity. The expanded spectrum allows us to check the existence of a shoulder (9.6 eV) in the first band and the presence of several ionizations near 10.3 eV.

The photoelectron study shows that for these neutral species, the ring orientation is of minor importance.

Proton Affinity

Considering the previous results on the phosphanides and corresponding phosphanes, it was of interest to focus our attention on the proton affinity (PA) of the anion (or the acidity of the phosphane).

Taking into account the equation $A^- + H^+ \rightarrow HA$, PA is the result of the energiy difference between the neutral and the anion species. A net difference is observed between the two anions since PA is calculated at 352.93 kcal/mol for $PhPH^-$ (**1**) and 337.37 kcal/mol for Ar_fPH^- (**2**). Such results are coherent with the existence of the naked phosphanide **2**, both in the solid state and in solution. In fact the Ar_f substituent involves a stabilization of the anion species (interaction $p^{\pi} \rightarrow \pi^*_{b1}$) but also a destabilization of the corresponding phosphane (important steric repulsion between the phosphorus and fluorine lone pairs). These two factors lead to a peculiar gas-phase acidity for the Ar_fPH_2 compound. It is noteworthy that the gas-phase acidity of **4** is stronger than the one of PH_3 (expt. 370.8 kcal/mol; calcd. 364.7 kcal/mol) and close to the one of HCOOH (found 345 kcal/mol; calcd. 335.5 kcal/mol).

The calculation of the proton affinity can also be performed by the isodesmic reaction $NH_4^+ + Ar_fPH^- \rightarrow Ar_fPH_2 + NH_3$. In this case the PA can reliably be anchored on the experimental value of NH_3 (202.3 kcal/mol[13]). Noteworthy that the PA values resulting from the isodesmic reaction are calculated at 352.0 kcal/mol for **1** and 336.44 kcal/mol for **2**. These latter are very close to the previous ones which result from the energies difference between the neutral and the anion species.

Conclusion

The stabilization of the fluorinated anion Ar_fPH^- (**2**) as well as the presence of destabilizing interactions into the corresponding neutral molecule Ar_fPH_2 (**4**) allow us to explain the difference observed in the calculated proton affinities for **1** and **2**. For the anionic species we theoretically showed that favored form is planar because of stabilizing interaction between the π phosphorus lone pair (p character) and the π^*_{b1} orbital. This latter seems to be more important for the fluorinated compound **2** compared to **1** since the inductive effect of the CF_3 groups involves a stabilization of the a_2, b_1, a^*_2, and b^*_1 orbitals of the aryl group, and decreases the $p^{\pi} \rightarrow \pi^*_{b1}$ energetic gap. In this case Ar_f is an electron acceptor by its LUMO orbital and contributes to the observed stability of the corresponding anion.

With regard to neutral species, the coupling of UV Photoelectron Spectroscopy and DFT calculations, showed that a free rotation of the aryl group occurs in the gas phase. However, the phosphanes **3** and **4** exhibit different favored forms: the phosphorus lone pair is in maximal interaction with the π system of the ring for **4**, while almost no interaction exists for **3**. For the bulky compound **4**, the orientation of the phenyl ring allows a compensation between two competitive factors: high steric repulsions (between phosphorus and fluorine lone pairs) which destabilize

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the system and an electronic delocalization between the phosphorus lone pair and the aromatic system, which is stabilizing.

Computational Details

Calculations were performed with the Gaussian 98 program[14,15] using the density functional theory.[16] The various structures were fully optimized at the B3LYP level.[17] This functional is built with Becke's three-parameter exchange functional[17a] and the Lee−Yang−Parr correlation functional.[17c] Kass et al.[18] have shown, with 35 different anionic species, that the density functional theory provides reasonable results concerning acidities compared to the experimental data. Thus, calculations for the anions $PhPH^-$ (**1**) and Ar_fPH^- (**2**) have been carried out using the B3LYP hybrid functional and the 6-31+G(d,p) basis set, with polarization functions on all the atoms and diffuse functions on all non-hydrogen atoms. Moreover, the use of density functional theory (DFT) within its Kohn−Sham (K-S) presents many advantages. First, the cost of a K-S DFT calculation is at most of the same order of magnitude as a Hartree−Fock one whereas most of the description of electron correlation is taken into account. Thus, it is substantially less expensive than traditional correlated techniques. The basis set used for all calculations is the 6-31G+(d,p) set which is augmented with polarisation functions on all the atoms and diffuse functions on all non-hydrogen atoms since the inclusion of polarization is necessary for the obtention of accurate energies. The structures were optimized and the second derivatives were calculated in order to determine if a minimum or a transition state (one negative eigenvalue) existed for the resulting geometry. All total energies have been zero-point energy (ZPE) and temperature corrected using unscaled density functional frequencies. For the large molecules, association between ionization potential and Kohn−Sham (K-S) energies calculated with common functionals (Koopmans' theorem like) has been discussed in depth. Arduengo and co-workers[19] first used DFT calculations at the nonlocal level to assign their photoelectron spectra. They applied a uniform shift to the orbital energies considering the difference between the calculated and experimental molecular ionization potential. The aim was to directly compare the K-S energies to the experimental energies. Moreover, Werstiuk and Rademacher[20] have developed and successfully applied a routine for the interpretation of PE spectra based on B3LYP theory. This routine requires the calculation of the molecule's first vertical ionization potential IP_v. Calculated orbital energies $-\varepsilon$ are then shifted uniformly so that the HOMO energy equals that of the IP_v, giving the higher IPs. More recently, Hoffmann[21] underlined that the K-S orbitals are a good basis for a qualitative interpretation of molecular orbitals. He concludes that if we want to go a step beyond a qualitative interpretation and look at orbital energies as rough ionization potentials and if the DFT calculations are done with commonly used potentials, then it appears we must take the absolute constant and linear orbital energy shift into account by applying a suitable $ax + b$ scaling. In the case of large molecules, the ordering of levels found using the DFT calculations, seems to be qualitatively well translated as well by using HF methods. This fact, despite the evident limits of correlation, gives a good base to discuss the ionizations assignments which cannot be reached by a direct calculation. The "natural population analysis" (NBO calculations) at the given optimized geometries, allowing to calculate orbital populations of molecular wave functions, was carried out according to the Weinhold−Reed partitioning scheme.[22]

Photoelectron Spectra: The photoelectron spectra were recorded with a Helectros 0078 instrument equipped with 127° cylindrical analyser and monitored by a microcomputer supplemented with a digital/analog (D/A) converter. The spectra were calibrated with the known auto-ionisation of helium at 4.98 eV [He-II(He)] and nitrogen ionisation at 15.59 eV.

Reduction of 1,2-Bis[(2,6-diisopropylphenyl)imino]acenaphthene (dpp-bian) with Alkali Metals − A Study of the Solution Behaviour of (dpp-bian)$^{n-}$[M$^+$]$_n$ (M = Li, Na; n = 1−4) with UV/Vis, ESR and ^{1}H NMR Spectroscopy

Igor L. Fedushkin,*[a] Alexandra A. Skatova,[a] Valentina A. Chudakova,[a] Vladimir K. Cherkasov,[a] Georgy K. Fukin,[a] and Mikhail A. Lopatin[a]

Keywords: Lithium / Sodium / Bis(imino)acenaphthene / Polyanions

An excess of lithium or sodium in diethyl ether consistently reduces 1,2-bis[(2,6-diisopropylphenyl)imino]acenaphthene (dpp-bian) to the mono-, di-, tri- and tetraanion, (dpp-bian)$^{n-}$[M$^+$]$_n$ (M = Li, Na; n = 1–4). The process of reduction is easily observed by the change in colour of the solution, on going from the neutral ligand (yellow) to the monoanion (red), the dianion (green for Na or Li in Et_2O; dark blue, followed by green, for Li in TMEDA), the trianion (brown) and the tetraanion (red-brown). In each reduction the maximum of the absorption, caused by electron transition from the HOMO of the respective form (dpp-bian)$^{n-}$ (n = 1–4), is shifted to the long-wavelength region in comparison to the previously reduced state. The disproportionation reactions (dpp-bian)$^{1-}$ → (dpp-bian)^0 + (dpp-bian)$^{2-}$ and (dpp-bian)$^{2-}$ → (dpp-bian)$^{1-}$ + (dpp-bian)$^{3-}$ take place in solution along with the reduction process, thus causing the presence of three reduced forms of the ligand at the same time in the first and second stages of the reduction. Paramagnetic (dpp-bian)$^{1-}$ and (dpp-bian)$^{3-}$ are characterised by ESR spectroscopy. For the diamagnetic forms (dpp-bian)$^{2-}$ and (dpp-bian)$^{4-}$ ^{1}H NMR spectra were recorded. The complex [Li$^+$(dpp-bian)(TMEDA)] (**1**), which formed from the initial stage of the reduction of dpp-bian with lithium metal in TMEDA, was isolated in a crystalline form and its molecular structure was determined by single-crystal X-ray diffraction.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Within the last few years 1,2-bis[(2,6-diisopropylphenyl)imino]acenaphthene (dpp-bian) began to be used widely in coordination chemistry of transition metals.[1] Several interesting chemical reactions of metal complexes based on this ligand were reported. Until recently only complexes of transition metals and only with the neutral dpp-bian ligand were studied. These complexes are active as catalysts in alkyne hydrogenation[2a], C−C[2b] and C−Sn[2c] bond formation, and especially in olefin polymerisation.[3] We have reported on the synthesis, isolation of crystals and detailed characterisation of the magnesium and calcium complexes with the dpp-bian dianion, (dpp-bian)$^{2-}$M^{2+}(L)$_n$ (M = Mg, L = THF, n = 2, 3 and L = Py, n = 3; M = Ca, L = THF, n = 3, 4).[4] These Mg and Ca complexes are easy to synthesise by direct reduction of the ligand with metallic magnesium or calcium. The use of sodium metal has allowed the reduction of dpp-bian leading to the formation of the dianion and also the tetraanion. Thus, sodium salts of mono-, di-, tri- and tetraanions of the ligand, [Na$^+$(dpp-bian)$^-$]$_2$, [Na$^+_2$(Et$_2$O)$_3$(dpp-bian)$^{2-}$], [Na$^+_3$(Et$_2$O)$_2$(dpp-bian)$^{3-}$]$_2$, [Na$^+_4$(THF)$_4$(dpp-bian)$^{4-}$]$_2$, were isolated in crystalline form and characterised by single-crystal X-ray diffraction.[5] Thus, for the first time four anionic forms of a single ligand were isolated on a preparative scale and characterised by single-crystal X-ray structure analysis. At present one of our objectives is to use these sodium salts for synthesis of other non-transition metal complexes, which in turn, can be used as reducing agents of various classes of organic substrates, working over a wide range of the redox potentials.

To find an optimal synthetic approach to other metal complexes by metathetical reactions using the sodium salts (dpp-bian)$^{n-}$(Na$^+$)$_n$ (n = 1−4), more insight into their solution behaviour is needed. Therefore, we started the UV/Vis and ESR spectroscopic study of (dpp-bian)$^{n-}$(Na$^+$)$_n$ (n = 1−4) in solution. We also report here on the solution behavior of the lithium salts (dpp-bian)$^{n-}$(Li$^+$)$_n$ (n = 1−4) prepared in situ in both diethyl ether and TMEDA as well as the solid-state molecular structure of the TMEDA adduct [Li$^+$(dpp-bian)$^-$(TMEDA)] (**1**).

Results and Discussion

Reduction of dpp-bian with Sodium and Lithium − The Solution UV/Vis Spectroscopy

In general, a solution of the dpp-bian ligand was added into an ampoule which contained the appropriate alkali metal and was connected to the spectroscopic cell. Then the ampoule was sealed off under vacuum. On shaking the ampoule for several hours, a colour change was observed and monitored by UV/Vis spectroscopy. Figure 1 represents the electronic absorption spectra of $[Na^+_n(dpp\text{-}bian)^{n-}]$ (n = 1−4) obtained by reduction of dpp-bian with sodium metal in diethyl ether. The curves 1−9 reflect the change of spectra in a chronological sequence. The reduction is completed within 6 h upon intense shaking at room temperature. The neutral ligand exhibits an absorption at 420 nm, which corresponds to a yellow solution. Over the course of reduction the colour of the solution becomes darker, the band of absorption of the initial ligand gradually disappears, and the absorption of the radical anion $(dpp\text{-}bian)^-$ (435, 460 and 495 nm) (Figure 1, a, spectrum 1) becomes visible. As the reduction proceeds, the absorption band of $(dpp\text{-}bian)^-$ is lowered again and the absorption of the dianion (640 nm) is enhanced (Figure 1, a, spectrum 2). Spectrum 3 (Figure 1, a) shows the absorption of the dianion (640 nm) becoming more intensive and indicates the prevalence of the dianion in solution. The compound $[Na_2(Et_2O)_3(dpp\text{-}bian)]$, isolated in crystalline form,[5] exhibits the same spectrum. Figure 1 (b) reflects changes on going from $(dpp\text{-}bian)^{2-}$ to $(dpp\text{-}bian)^{3-}$. The absorption at 840 nm indicates the formation of the trianion $[Na^+_3(dpp\text{-}bian)^{3-}]$. As seen from Figure 1 (a and b), three reduced forms of the ligand are present at the same time in solution. This may be explained by the disproportionation: $(dpp\text{-}bian)^{1-} \rightarrow (dpp\text{-}bian)^0 + (dpp\text{-}bian)^{2-}$ and $(dpp\text{-}bian)^{2-} \rightarrow (dpp\text{-}bian)^{1-} + (dpp\text{-}bian)^{3-}$. Upon further reduction of $(dpp\text{-}bian)^{3-}$ with sodium the absorption of the trianion (840 nm) disappears (Figure 1, c). Spectrum 9 in Figure 1 (c) indicates the complete reduction of the ligand to the tetraanion. The tri- and tetraanions of the ligand show similar absorbance in the wavelength region (400−600 nm), but differ in the region of 700−1100 nm. It should be noted that this difference cannot be visually observed. Therefore, it is difficult to distinguish the colour of solutions of the tri- and tetraanions. Taking into account the observation that the absorption of every next reduced form has a lower absorption compared to that of the previous form, one can suggest that the absorption of the tetraanion, which originates from the electron transfer from the HOMO, is shifted into the near IR region. Although there is no isosbestic point in spectra 7−9, one can conclude that the disproportionation process $(dpp\text{-}bian)^{3-} \rightarrow (dpp\text{-}bian)^{2-} + (dpp\text{-}bian)^{4-}$ does not take place because of the absence of the absorption of the dianion (Figure 1, c).

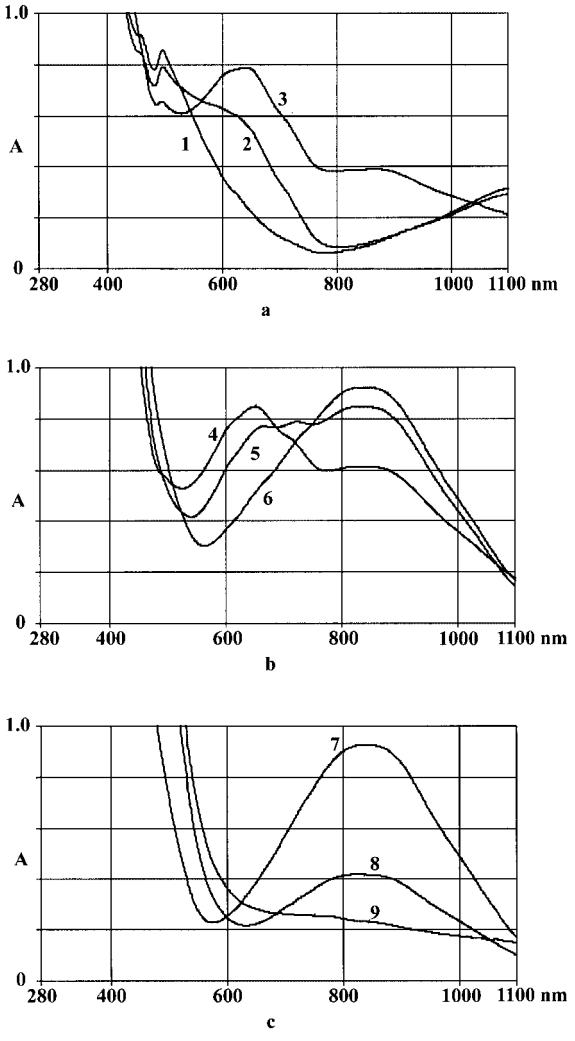

Figure 1. UV/Vis spectra of $(dpp\text{-}bian)^{n-}Na^+_n$ (n = 1−4) in Et_2O (10^{-3} mol/L) in the Pyrex cell (3.5 mm): (a) $(dpp\text{-}bian) \rightarrow (dpp\text{-}bian)^-$, (b) $(dpp\text{-}bian)^- \rightarrow (dpp\text{-}bian)^{2-} \rightarrow (dpp\text{-}bian)^{3-}$, (c) $(dpp\text{-}bian)^{3-} \rightarrow (dpp\text{-}bian)^{4-}$; the curves **1−9** reflect the change of spectra in a chronological sequence

The process of the reduction of the dpp-bian ligand with lithium metal was also investigated by electron absorption spectroscopy. The spectra, which correspond to the intermediate reduced forms of the ligand, are presented in Figure 2. Spectra 1−3 indicate the consecutive transformation of the radical anion $(dpp\text{-}bian)^-$ to the dianion $(dpp\text{-}bian)^{2-}$ (432, 468, 503 nm and 595, 650 nm, respectively). In spectrum 2 the simultaneous presence of the three forms in solution is clearly visible. The trianion $(dpp\text{-}bian)^{3-}$ has a maximum at 718 nm, which confirms the dissproportionation of the dianion to the radical anion and trianion. Figure 2 (b) reflects a gradual transition of $(dpp\text{-}bian)^{2-}$ into $(dpp\text{-}bian)^{3-}$ (718 and 780 nm). Spectrum 6 corresponds to a solution in which the $(dpp\text{-}bian)^{3-}$ form is dominant. Figure 2 (c) shows changes in solution on going from the trianion to the tetraanion. The existence of the isosbestic point in spectra 7−9 indicates that the trianion is completely converted by lithium under electron transfer into the tetranion without any side reactions (disproportionation etc.).

Upon reduction of dpp-bian with lithium in a diluted diethyl ether solution, we observed at the initial stages an appearance of an intense blue colour on cooling to about

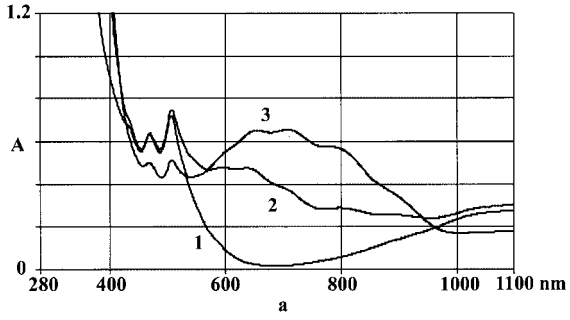

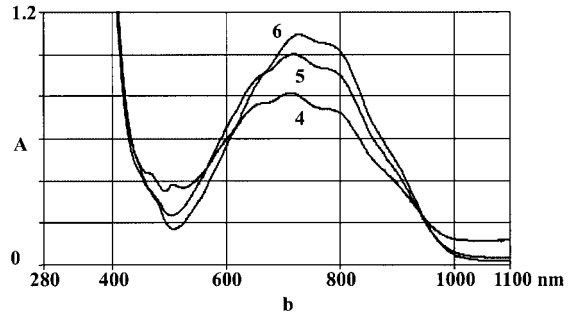

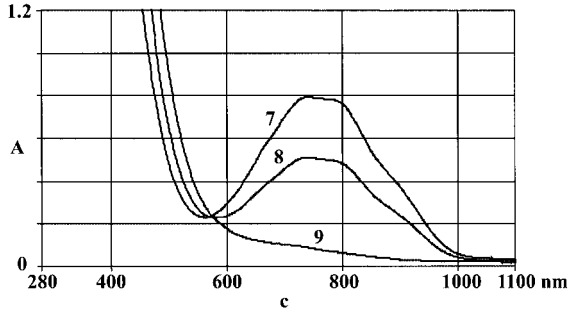

Figure 2. UV/Vis spectra of $(dpp\text{-}bian)^{n-}Li^{+}_{n}$ ($n = 1-4$) in Et_2O (10^{-3} mol/L) in the Pyrex cell (3.5 mm): (a) (dpp-bian) → (dpp-bian)$^{-}$, (b) (dpp-bian)$^{-}$ → (dpp-bian)$^{2-}$ → (dpp-bian)$^{3-}$, (c) (dpp-bian)$^{3-}$ → (dpp-bian)$^{4-}$; the curves **1**−**9** reflect the change of spectra in a chronological sequence

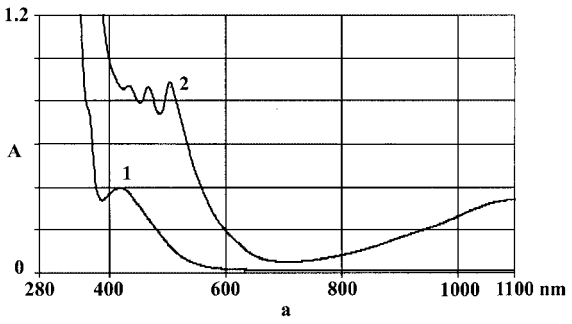

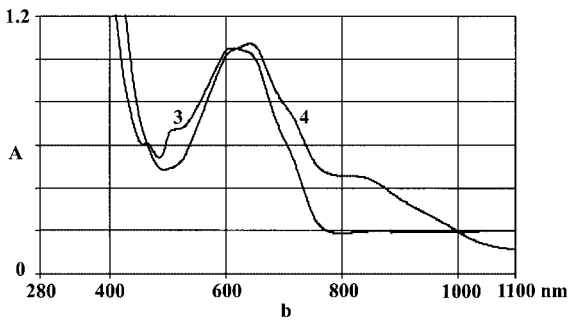

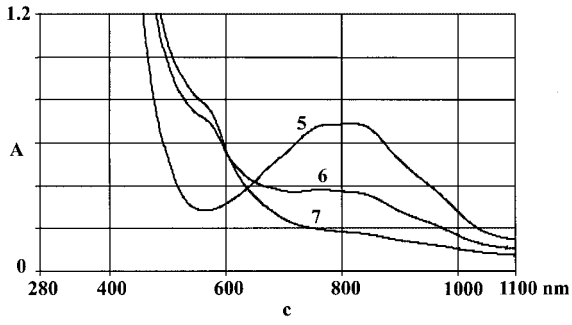

Figure 3. UV/Vis spectra of $(dpp\text{-}bian)^{n-}Li^{+}_{n}$ ($n = 1-4$) in TMEDA (10^{-3} mol/L) in a Pyrex cell (3.5 mm): (a) (dpp-bian) → (dpp-bian)$^{-}$, (b) (dpp-bian)$^{-}$ → (dpp-bian)$^{2-}$ → (dpp-bian)$^{3-}$, (c) (dpp-bian)$^{3-}$ → (dpp-bian)$^{4-}$; the curves **1**−**7** reflect the change of spectra in a chronological sequence

−50 °C. It was neither observed in the case of sodium nor at higher concentrations of the ligand in the case of lithium. Thawing of the ether solution leads to a colour change from blue to green. A similar colour has been observed earlier for THF solutions of lanthanide complexes with the naphthalene dianion {575 nm for $[EuI(THF)_4]_2(\mu\text{-}C_{10}H_8)$ and 604 nm for $[LaI_2(THF)_3]_2(\mu\text{-}C_{10}H_8)$}.[6] One can suggest that in the diluted Et_2O solution, at different temperatures, the mutual transition of two electronic isomers of the ligand takes place. In one of these forms the negative charge is, presumably, located mainly on the diimine function of the ligand (green) and in the second form on the naphthalene rings (deep blue). The latter form of the dpp-bian ligand may be considered as a dianion of the 1,8-disubstituted naphthalene. We suppose that transformation of the green dianion to the blue dianion is forced by the separation of the cation from the dianion by the solvent.

In order to find an experimental confirmation for this assumption we have tried to stabilise the dark blue form of $(dpp\text{-}bian)^{2-}$ using TMEDA as a solvent. Earlier, TMEDA was successfully used for the stabilisation of the lithium complex with the naphthalene dianion $[Li(TMEDA)]_2(\mu\text{-}C_{10}H_8)$.[7] The electronic absorption spectra of the reduction of dpp-bian with lithium in TMEDA are given in Figure 3. For the transition from $(dpp\text{-}bian)^{-}$ [432, 465 and 502 nm; Figure 3 (a), spectrum 2] to $(dpp\text{-}bian)^{2-}$ [Figure 3 (b), spectrum 3] the absorption that reflects the dianion formation, has a maximum at 612 nm and a shoulder at 645 nm. This spectrum corresponds to a dark blue colour of the solution. Further, this dark blue colour changes to a blue-green colour (spectrum 4). At that moment the absorption at 645 nm becomes most intense, and the maximum at 612 nm becomes a shoulder. We believe, that at the initial stages of the dianion formation, when its concentration is still very small, $Li^{+}_{2}(dpp\text{-}bian)^{2-}$ exists in solution as a solvent-separated ion pair. The negative charge of the dianion is located mostly on the naphthalene part of the molecule. Figure 3 (c) presents the transition from (dpp-

bian)$^{3-}$ to (dpp-bian)$^{4-}$. The absorption of the trianion (760 and 837 nm) gradually disappears in the sequence 5 → 6 → 7. We have not had an opportunity to record the spectrum of (dpp-bian)$^{4-}$ in the region of 1100−2000 nm, but we suggest that the absorption of (dpp-bian)$^{4-}$, which corresponds to the excitation of an electron from the HOMO of the tetraanion, shifts to the long-wavelength region (> 1100 nm).

Molecular Structure of [Li$^+$(dpp-bian)$^-$(TMEDA)] (1)

Suitable crystals of **1** were obtained for X-ray structure determination by concentration of the TMEDA solution of **1**. The lithium atom in **1** has a distorted tetrahedral environment (Figure 4). The bite angles N(1)−Li(1)−N(2) and N(3)−Li(1)−N(4) are 87.03 and 83.90°, respectively. The lithium−dpp-bian bonds [Li(1)−N(1) 2.0365(18) and Li(1)−N(2) 2.0603(18) Å] are notably shorter than the lithium−TMEDA bonds [Li(1)−N(3) 2.1201(19) and Li(1)−N(4) 2.1701(19) Å]. The anionic character of the radical of the dpp-bian ligand in **1** is evident from the elongation of the C−N bond of the diimine moiety [C(1)−N(1) 1.3295(11) Å and C(11)−N(2) 1.3303(11) Å], compared with that of the neutral related ligand *p*-tol-bian [1.267(3) Å],[1b] the four-coordinate Pd^{II} complex [(dpp-bian)PdCl(CH$_3$)][1b] (1.287 Å) and the five-coordinate Cu^{II} complex [(dpp-bian)CuCl$_2$(AcOH)][8] (1.287 Å). On the other hand, the bonds C(1)−N(1) and C(11)−N(2) are very close to the respective bonds in [Na$^+$(dpp-bian)$^-$]$_2$ [1.3239(18) Å and 1.3326(19) Å][5] and substantially shorter than in the sodium complex with the dpp-bian dianion [Na$^+_2$(Et$_2$O)$_3$(dpp-bian)$^{2-}$] [1.387(4) and 1.386(4) Å].[5]

ESR Spectroscopy of (dpp-bian)$^{n-}$[M$^+$]$_n$ (M = Li, Na; *n* = 1 or 3)

The mono- and trianions of dpp-bian consist of an unpaired electron making them detectable by ESR spectroscopy. Figures 5 and 6 represent the ESR spectra of (dpp-bian)$^-$ and (dpp-bian)$^{3-}$, respectively (upper spectra − observed; lower spectra − simulated). In a toluene solution [Na$^+$(dpp-bian)$^-$] reveals an ESR signal of six lines (g = 2.0025) due to the coupling of the unpaired electron to two ^{14}N nuclei (I = 1, natural abundance 99.6%) and

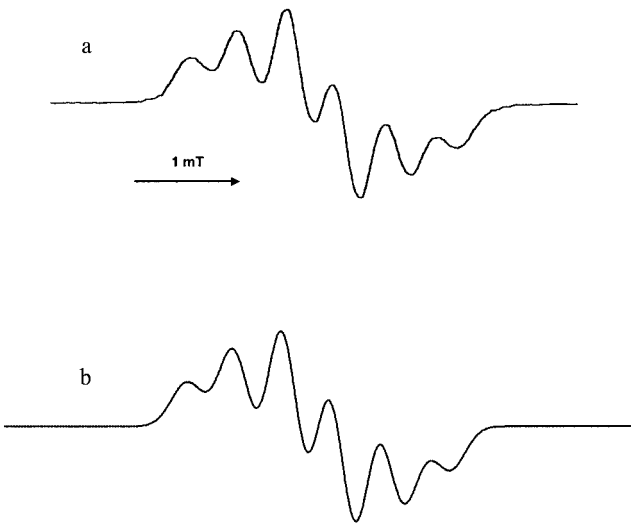

Figure 5. X-band ESR spectrum of [Na$^+$(dpp-bian)$^-$] in toluene at 285 K: (a) experimental; (b) simulated [A_N = 0.46 (2 N), A_{Na} = 017 (1 Na) mT, line width −0.31 mT)]

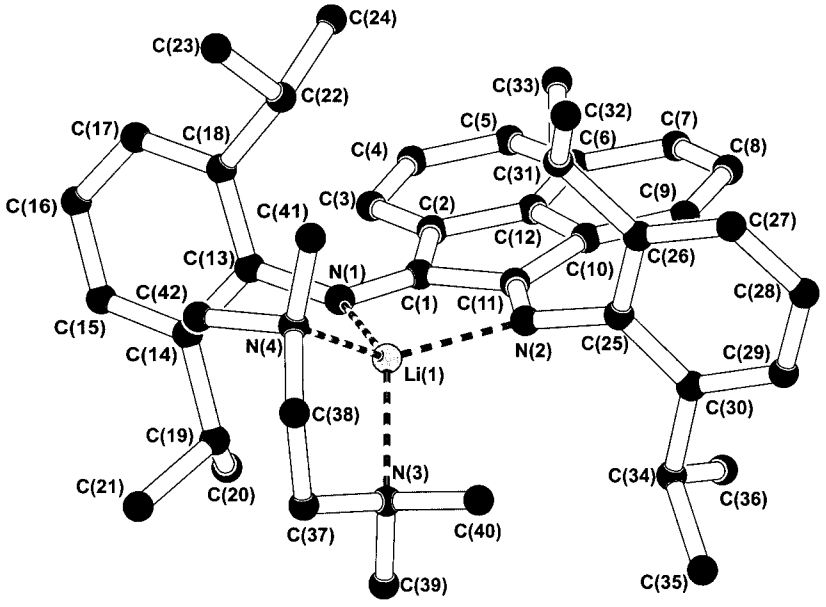

Figure 4. PLATON plot of the molecular structure of complex **1**; hydrogen atoms are omitted; selected bond lengths [Å] and angles [°]: Li(1)−N(1) 2.0365(18), Li(1)−N(2) 2.0603(18), Li(1)−N(3) 2.1201(19), Li(1)−N(4) 2.1701(19), N(1)−C(1) 1.3295(11), N(2)−C(11) 1.3303(11), N(1)−C(13) 1.4231(11), N(2)−C(25) 1.4206(11), C(1)−C(11) 1.4538(12), C(1)−C(2) 1.4768(12), C(2)−C(3) 1.3821(12), C(4)−C(5) 1.3766(15), C(2)−C(12) 1.4218(12), C(3)−C(4) 1.4216(13), C(5)−C(6) 1.4217(14), C(6)−C(7) 1.4263(14), C(6)−C(12) 1.3949(12), C(7)−C(8) 1.3747(15), C(8)−C(9) 1.4222(13), C(10)−C(12) 1.4219(12), C(9)−C(10) 1.3859(13), C(10)−C(11) 1.4793(12); N(1)−Li(1)−N(2) 87.03(7), N(3)−Li(1)−N(4) 83.90(7), N(2)−Li(1)−N(3) 110.21(9), N(1)−Li(1)−N(4) 113.44(9), N(2)−Li(1)−N(4) 135.97(9), N(1)−Li(1)−N(3) 133.90(9)

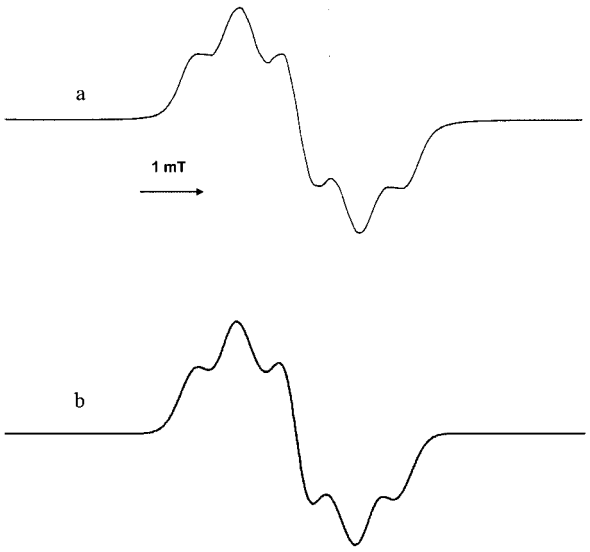

Figure 6. X-band ESR spectrum of $[Na^+{}_3(dpp\text{-}bian)^{3-}]$ in THF at 293 K: (a) experimental; (b) simulated [A_H = 0.027 (2 H), 0.39 (2 H), 0.66 (2 H) mT, line width −0.42 mT)]

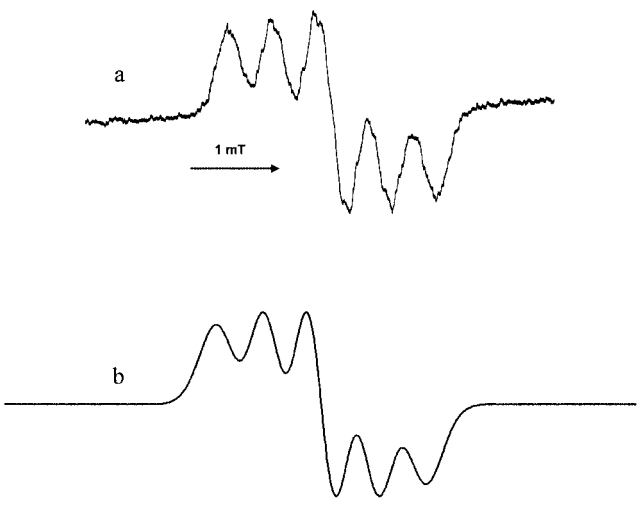

Figure 7. X-band ESR spectrum of $[Li^+(dpp\text{-}bian)^-]$ in TMEDA at 280 K: (a) experimental; (b) simulated [A_N = 0.46 (2 N) mT, line width −0.42 mT)]

the ^{23}Na nucleus (I = 3/2, natural abundance 100%). The hyperfine coupling constants [A_N = 0.46 (2 N) and A_{Na} = 0.17 (1 Na) mT)] of this signal indicate that: (i) the unpaired electron is mainly localized over the diimine part of the dpp-bian molecule and (ii) the complex exists in THF solution as a contact ion pair with the sodium atom being coordinated by two nitrogen atoms of the ligand. In contrast, the ESR signal of the trianion $[Na^+{}_3(dpp\text{-}bian)^{3-}]$ (g = 2.0023) exhibits a hyperfine structure due to the coupling of the unpaired electron to three different pairs of ^1H nuclei [A_H = 0.027 (2 H), A_H = 0.39 (2 H) and A_H = 0.66 (2 H) mT] (Figure 6). As there is no coupling to ^{14}N nuclei in the ESR signal of the trianion, we conclude that in $(dpp\text{-}bian)^{3-}$ the unpaired electron is delocalised over the naphthalene part of the dpp-bian ligand. These findings are in good agreement with the solid-state structures of $[Na^+(dpp\text{-}bian)^-]_2$ and $[Na^+{}_3(Et_2O)_2(dpp\text{-}bian)^{3-}]_2$.[5] In contrast to the sodium salt of the monoanion $(dpp\text{-}bian)^-$ the lithium derivative $[Li^+(dpp\text{-}bian)^-(TMEDA)]$ in TMEDA shows the ESR signal of five components (Figure 7). The hyperfine structure of this signal [g = 2.0021, A_N = 0.46 (2 N) mT] is caused by the coupling of the unpaired electron to only two ^{14}N nuclei, thus indicating that in TMEDA complex **1** exists as a solvent-separated ion pair. The ESR signal of $[Na^+(dpp\text{-}bian)^-]$ in THF is similar to that of complex **1** in TMEDA. However, in this spectrum there is a line of low intensity, which appears exactly in the middle of the quintuplet. The observed spectrum may be attributed to two overlapped signals of five and six lines. These signals correspond to the contact and solvent-separated ion pairs $[Na^+(dpp\text{-}bian)^-]$ (quintuplet) and $[Na(THF)_n]^+[dpp\text{-}bian]^-$ (sextuplet).

^1H NMR Spectroscopy of $(dpp\text{-}bian)^{n-}[M^+]_n$ (M = Na, n = 2 or 4)

As anticipated, complexes $[Na^+{}_2(Et_2O)_3(dpp\text{-}bian)^{2-}]$ and $[Na^+{}_4(THF)_4(dpp\text{-}bian)^{4-}]_2$ are diamagnetic and therefore are detectable by NMR spectroscopy. The signals of the paramagnetic mono- and trianionic species, which appear in the solution due to disproportionation of $[Na^+{}_2(Et_2O)_3(dpp\text{-}bian)^{2-}]$, are not visible in the ^1H NMR spectrum because of their broadening. In the ^1H NMR solution spectrum in C_6D_6 the methyl groups of the isopropyl group appear as two doublets centred at δ = 1.41 ppm and for $[Na^+{}_2(Et_2O)_3(dpp\text{-}bian)^{2-}]$, due to hindered rotation about the aryl carbon−nitrogen bond, at δ = 1.33 ppm (^3J = 8.0 Hz for both doublets). The signal for the four $H-C(CH_3)_2$ protons appears as a septuplet at δ = 3.85 ppm (^3J = 8.0 Hz). The signals of the twelve aromatic protons are found in a relatively narrow region (δ = 7.32−6.51 ppm). Despite the extreme sensitivity of complex $[Na^+{}_4(THF)_4(dpp\text{-}bian)^{4-}]_2$ towards air and moisture, attempts to obtain its ^1H NMR spectrum were undertaken. The spectrum obtained in $[D_8]$THF revealed the presence of some impurities amounting to about 10%. These narrow signals are attributable to those observed for $[Na^+{}_2(Et_2O)_3(dpp\text{-}bian)^{2-}]$ in C_6D_6. The dominant signals in the spectrum are noticeably broadened, high-field shifted, and probably belong to the aromatic protons of the tetraanion (δ = 6.56, 6.45, 5.83, 4.64, 3.93, 2.83 ppm). The signal corresponding to the $H-C(CH_3)_2$ proton appears to be partly overlapping with the THF signal at δ = 3.60 ppm. The methyl protons of the isopropyl groups are observed as a broad single signal at δ = 0.91 ppm.

Conclusion

Based on the UV/Vis spectroscopy data for $(dpp\text{-}bian)^{n-}[M^+]_n$ (M = Li, Na; n = 1−4), we have established that in solution $(dpp\text{-}bian)^-$ and $(dpp\text{-}bian)^{2-}$ undergo disproportionation to species which can be oxidised and reduced by one electron. Nevertheless, as reported recently,[5] every reduced form of $(dpp\text{-}bian)^{n-}$ (n = 1−4) may be isolated from solution in the individual state. The ESR spec-

troscopy data for lithium and sodium salts of the monoanion $(dpp\text{-}bian)^-$ show that these salts may exist in solution either as solvent-separated or contact ion pairs.

Experimental Section

General Remarks: All manipulations were carried out under vacuum using Schlenk ampoules. Prior to use THF, toluene and diethyl ether were distilled from sodium/benzophenone. TMEDA was dried with lithium and condensed prior to use. 1,2-Bis[(2,6-diisopropylphenyl)imino]acenaphthene (dpp-bian) was prepared according to a published procedure.[8] The UV/Vis spectra were recorded with a Perkin−Elmer Lambda 25 spectrometer. Into the ampoule for UV/Vis spectroscopy, which contained sodium or lithium metal (10- to 20-fold excess calculated on the ligand), the solution of dpp-bian (20 mg, 0.04 mmol) in diethyl ether (40 mL) or in TMEDA (40 mL) was added. This ampoule was then sealed off under vacuum. The ESR spectra were recorded with a Bruker ER 200D-SRC spectrometer. The ESR signals were referenced to the signal of diphenylpicrylhydrazyl (DPPH, $g = 2.0037$).

[Li(dpp-bian)(TMEDA)] (1): A suspension of dpp-bian (0.5 g, 1.0 mmol) in TMEDA (30 mL) was added into a Schlenk ampoule, which contained lithium (1.0 g, 0.14 mmol). The mixture was stirred for 1 h. While stirring, the solution turned cherry-red. The solution was decanted from the lithium metal and then concentrated to 15 mL by evaporation of the solvent in vacuo on heating affording 0.34 g (55%) of **1** as dark red crystals. M.p. 199−201 °C. $C_{42}H_{56}LiN_4$ (623.85): calcd. C 80.72, H 9.11; found C 80.86, H 9.05.

Single-Crystal X-ray Structure Determination of 1: The data were collected with a SMART APEX diffractometer (graphite-monochromated, Mo-K_α radiation, ω- and ψ-scan technique, $\lambda = 0.71073$ Å). The structures were solved by direct methods using SHELXS-97[9] and were refined on F^2 using SHELXL-97[10]. All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were placed in calculated positions and assigned to an isotropic displacement parameter of 0.08 Å^2. SADABS[11] was used to perform area-detector scaling and absorption corrections (max./min. transmission 0.9811/0.9688). The geometrical aspects of the structure were analysed using PLATON.[12] Data collection: crystal dimensions 0.50 × 0.40 × 0.30 mm, triclinic, $P\bar{1}$, $a = 10.5011(9)$ Å, $b = 13.2585(12)$ Å, $c = 14.0911(12)$ Å, $\alpha = 98.926(2)°$, $\beta = 104.293(2)°$, $\gamma = 91.076(2)°$, $V = 1874.8(3)$ Å^3, $Z = 2$, $\rho_{calcd.} = 1.105 \times 10^3$ kg m^{-3}, $\mu = 0.064$ mm^{-1}, $F(000) = 678$, $1.98° \le \theta \le 29.00°$, $-14 \le h \le 14$, $-18 \le k \le 17$, $-19 \le l \le 19$, 19549 data collected, 9690 unique data ($R_{int} = 0.0223$), 648 refined parameters, GOF(F^2) = 1.030, final R indices $\{R_1 = \Sigma F_o - F_c/\Sigma F_o$, $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}\}$ $R_1 = 0.0515$, $wR_2 = 0.1204$, max./min. residual electron density 0.422/−0.210 e·Å^{-3}. Synthesis, Crystal Structures, and Magnetic Properties of a Mono- and a Dinuclear Copper(II) Complex of the 2,4,6-Tris(2-pyridyl)-1,3,5-triazine Ligand

Thorsten Glaser,*[a] Thomas Lügger,[a] and Roland Fröhlich[b]

Keywords: Magnetic properties / Copper / N ligands / Coordination chemistry

The reaction of 2,4,6-tris(2-pyridyl)-1,3,5-triazine (tptz) with $Cu(BF_4)_2 \cdot 3H_2O$ and *N*,*N*-bis(3-aminopropyl)methylamine (Medpt) yielded the monomeric complex $[(tptz)Cu^{II}(Medpt)](BF_4)_2 \cdot 2MeOH$ (**1**) whereas reaction of tptz with $CuCl_2 \cdot 2H_2O$ yielded the dinuclear complex $[\{Cu^{II}Cl_2\}(tptz)\{Cu^{II}Cl_2(MeOH)\}]$ (**2**). The molecular structures of **1** and **2** were established by single-crystal X-ray diffraction studies. The copper ion in complex **1** is elongated octahedral with the nitrogen atoms of Medpt and the triazine nitrogen atom of tptz in the equatorial positions, and the two pyridyl nitrogen atoms of tptz in axial positions. The two Cu^{II} ions in complex **2** are bridged by tptz, coordinating to Cu1 in a terpyridine-like fashion and to Cu2 in a bipyridine-like coordination mode. The triazine nitrogen atom bound to Cu1 is coordinated in an equatorial position whereas the triazine nitrogen atom bound to Cu2 is situated in the apical position. The equatorial plane of Cu1 is coplanar with the 1,3,5-triazine plane whereas the equatorial plane of Cu2 is perpendicular to the 1,3,5-triazine plane. Intermolecular interactions in the solid state result in both compounds in "dimeric units" due to hydrogen bonding. Both complexes were investigated by variable-temperature magnetic susceptibility measurements. Through-space dipolar couplings and/or weak through-bond interactions in complex **1** result in a small intermolecular antiferromagnetic interaction ($J = -0.09$ cm^{-1}). The intramolecular exchange coupling in the dinuclear complex **2** is antiferromagnetic ($J = -2.5$ cm^{-1}). This antiferromagnetic interaction was analyzed in view of the molecular structure considering spin-polarization, superexchange and orbital-orthogonality. A spin-polarization pathway seems to be the leading contribution which does not involve the 1,3 bridging pathway.

Introduction

The rational design of polynuclear complexes with ferromagnetic interactions between the paramagnetic centers is central to the development of new classes of molecule-based magnets.[1] One strategy for synthesizing materials with ferromagnetic interactions is provided by the *meta*-phenylene linkage of organic radicals and carbenes utilizing the spin-polarization mechanism.[2] This concept has been applied to binuclear transition metal complexes bridged in a *meta*-phenylene arrangement using a variety of bridging ligands.[3] Some of these compounds do indeed exhibit ferromagnetic interactions between the transition metal ions.[4−7] However, many complexes with the same kinds of bridging ligands exhibit antiferromagnetic interactions between the transition metal ions.[8] Several theoretical investigations have been performed in order to obtain an insight into the question of why the concept of spin-polarization cannot be applied in a straightforward manner to transition metal complexes. Bencini et al. showed on resorcinol- and hydrochinone-bridged dinuclear Mo^V complexes that for both bridging units not only is the spin-polarization mechanism active but also the superexchange interaction.[9] The orientation of the magnetic orbital on each metal site relative to the plane of the bridging benzene ring was found to be crucial for a ferromagnetic or an antiferromagnetic contribution of the superexchange interaction as well as of the spin-polarization mechanism. Takano et al. investigated dinuclear Cu^{II} and Mn^{II} complexes with a bridging pyrimidine ligand using DFT and post-Hartree−Fock methods.[10] They concluded that superexchange interactions leading to antiferromagnetic interactions are more important in *meta*-phenylene bridged transition metal complexes compared with *meta*-phenylene bridged organic carbenes and radicals. Finally, ferromagnetic interactions were proposed in pyrimidine-bridged dinuclear Cu^{II} complexes when the pyrimidine-nitrogen donor of one Cu^{II} center is coordinated equatorially and the pyrimidine-nitrogen donor of the other Cu^{II} center is coordinated axially. Antiferromagnetic interactions were proposed when both nitrogen atoms are coordinated equatorially.[8a,11]

Recently, we reported the use of modified 1,3,5-trihydroxybenzene (phloroglucinol) ligands to bridge three

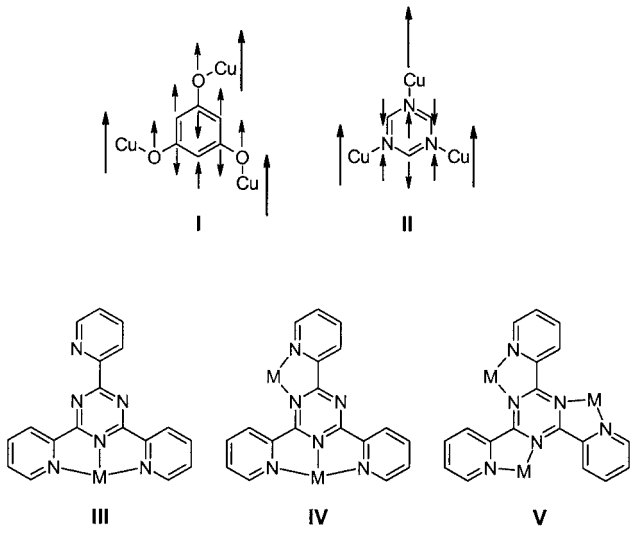
Cu^{II} ions in a *meta*-phenylene linkage.[12] These complexes exhibit ferromagnetic interactions between the three $S_i = {}^1/_2$ sites to result in a $S_t = {}^3/_2$ spin ground state due to the spin-polarization mechanism (**I** in Scheme 1). In an extended version of these ligands, we incorporated salen-like coordination environments because salen-like ligands form stable complexes with most metal ions.[13] Just as phloroglucinol is the triangularly topological extension of resorcinol, the triangularly topological extension of pyrimidine is 1,3,5-triazine. We wanted to investigate whether modified 1,3,5-triazine-ligands may be used for the synthesis of trinuclear transition metal complexes with ferromagnetic interactions between the paramagnetic centers based on the spin-polarization mechanism (**II** in Scheme 1).



Scheme 1

Hendrickson and co-workers reported a series of trinuclear Ti^{III} complexes using the tri-anions of cyanuric acid and trithiocyanuric acid as bridging ligands.[14] While the Ti^{III} centers in the cyanuric bridged complex are antiferromagnetically coupled, a ferromagnetically coupled system was found in the trithiocyanuric system. Recently, Dunbar and co-workers used 1,3,5-triazine-2,4,6-tricarboxyclic acid for the synthesis of a one-dimensional chain compound with Fe^{II} ions. However, no exchange interactions between the Fe^{II} centers were observed and this was attributed to the large distance between the paramagnetic centers in the chain. The ferrous ions are not bridged by coordination to one 1,3,5-triazine ring. The ligand bridges the Fe^{II} ions by use of one 1,3,5-triazine nitrogen donor at one site and by a carboxylic group at the other site.[15] Gamez, Reedijk and co-workers reported an interesting copper coordination polymer using 2,4,6-tris(dipyridin-2-ylamino)-1,3,5-triazine which demonstrated the use of modified 1,3,5-triazine ligands for the construction of higher-dimensional assemblies.[16]

The modified 1,3,5-triazine ligand 2,4,6-tris(2-pyridyl)-1,3,5-triazine (tptz)[17] has been used in the spectrophotometric determination of transition metal ions[18] and as a solvent extraction reagent.[19] Several transition-metal complexes using the ligand tptz have been reported.[20−22] The predominant coordination mode of tptz is tri-dentate terpyridine-like (**III** in Scheme 1). However, tptz is also capable of bridging two metal centers in one terpyridine- and one bipyridine-like coordination mode (**IV** in Scheme 1) but no magnetic properties were reported. Several reports have described that coordination of one metal ion, especially Cu^{II}, to tptz induces the hydrolysis of tptz to form bis(2-pyridylcarbonyl)amine and its complexes.[22,23]

In order to use tptz as a ferromagnetic coupler between three transition metal ions we investigated whether complexes with tptz as a bridging ligand between three metal ions in bipyridine-like sites would be accessible (**V** in Scheme 1). Herein we report the reaction of tptz with an excess of Cu^{II} ions. In the presence of *N*,*N*-bis(3-aminopropyl)methylamine (Medpt), only the mononuclear complex $[(tptz)Cu^{II}(Medpt)](BF_4)_2{\cdot}2MeOH$ (**1**) was isolated. In contrast, reaction of tptz with an excess of $CuCl_2{\cdot}2H_2O$ resulted in the dinuclear complex $[\{Cu^{II}Cl_2\}(tptz)\{Cu^{II}Cl_2(MeOH)\}]$ (**2**). No indications of hydrolysis of tptz were observed. Both complexes were fully characterized by single-crystal X-ray diffraction studies and magnetic measurements. To the best of our knowledge complex **2** is the first dinuclear copper complex of tptz and this is the first determination of exchange interactions mediated by the tptz ligand.

Results and Discussion

Synthesis and Spectroscopy

In order to synthesize a trinuclear Cu^{II} complex of type **V** (Scheme 1) with three bipyridine-like coordination sites, additional ligands for complexation of the Cu^{II} centers have to be provided. Since the preferred coordination number of Cu^{II} ions is five, we used an additional tridendate ligand (Medpt). The reaction of tptz with three equivalents of $Cu(BF_4)_2{\cdot}3H_2O$ and three equivalents of Medpt in methanol resulted in a blue solution from which green crystals of **1** separated upon diffusion of diethyl ether into the solution. The FTIR spectrum of **1** confirmed the presence of the tptz ligand by the absorptions in the 400 to 1600 cm^{-1} region. Two intense N−H bands at 3173 and 3077 cm^{-1} and C−H bands of aliphatic groups between 2800 and 3000 cm^{-1} demonstrate the presence of the Medpt ligand. Additionally, the typical bands of BF_4^- show the cationic nature of the complex. The electrospray mass spectrum of **1** exhibits a prominent ion at a mass-to-charge ratio (*m*/*z*) of 259.9, with mass and isotopic distribution patterns corresponding to $[(tptz)Cu(Medpt)]^{2+}$ (calculated *m*/*z* of 260.1). The elemental analysis combined with these data are in accordance with the formulation of **1** as $[(tptz)Cu^{II}(Medpt)](BF_4)_2{\cdot}2CH_3OH$ which was corroborated by an X-ray diffraction study.

The reaction of tptz with 15 equivalents of $CuCl_2{\cdot}2H_2O$ in MeOH resulted in a green solid. Elemental analysis gave a tptz/Cu/Cl ratio of 1:2:4 corresponding to a dinuclear complex and not the 1:3:6 ratio expected for a trinuclear

complex. Diffusion of methanolic solutions of tptz and an excess of $CuCl_2 \cdot 2H_2O$ yielded green needles suitable for single-crystal X-ray diffraction. The FTIR spectrum of **2** exhibits a broad absorption between 2500 and 3200 cm^{-1} indicating the presence of hydrogen bonded O−H groups. The spectrum shows the main signals of the free tptz ligand which are slightly shifted and in most cases split. Structural characterization by a single-crystal X-ray diffraction study enabled the formulation of **2** as [{$Cu^{II}Cl_2$}(tptz)-{$Cu^{II}Cl_2$(MeOH)}].

Crystal Structures

Figure 1a shows the molecular structure of the dication $[(tptz)Cu^{II}(Medpt)]^{2+}$ in **1** and the labeling scheme used. The asymmetric unit consists of the dication, two BF_4^- anions and two methanol molecules. Selected interatomic distances and angles are listed in Table 1. The copper ion is coordinated by six nitrogen donors (N1, N4, N5 of tptz; N7, N8, N9 of Medpt). The distance between Cu and the triazine nitrogen donor N1 is 2.15 Å whereas the distances with the two pyridyl nitrogen donors N4 and N5 are long at 2.41 Å and 2.50 Å, respectively. The central tertiary amine donor N9 of Medpt is coordinated trans to the triazine nitrogen donor with a bond length of 2.13 Å whereas the primary amine donors N7 and N8 form short bonds of 1.99 Å and 2.00 Å, respectively. The coordination environment of the Cu^{II} ion is best described as an axially elongated octahedron with severe distortion. The equatorial plane consists of N1, N7, N8, and N9 and is orientated perpendicular to the 1,3,5-triazine plane. The angle of 142° subtended by the two axial donors N4 and N5 and the copper center deviates strongly from the ideal N−Cu−N angle of 180°. However, this decreased angle is typical for a Cu^{II} ion in a terpyridine-like environment with the two pyridyl donors in axial positions.

The two di-cations are organized in pairs as "dimers" held together by hydrogen bonds with the methanol solvate molecules (Figure 1b). One methanol forms a hydrogen bond with the uncoordinated pyridyl nitrogen atom (N6−O31′ and N6‴−O31″ 2.80 Å). This methanol forms an additional hydrogen bond to a second methanol (O31′−O30″ and O31″−O30′ 2.73 Å) while this second methanol forms a hydrogen bond with a coordinated primary amine of a second di-cation (O30″−N7‴ and O30′−N7 3.03 Å). The Cu−Cu‴ distance is 11.5 Å. However, the shortest Cu−Cu distance in **1** is 7.77 Å. The packing is governed mainly by weak interactions, *viz.* long N−H···F, C−H···F, π-π interactions (there are no strong π-π interactions in **1**) etc.

Figure 2a shows the molecular structure of the dinuclear complex [{$Cu^{II}Cl_2$}(tptz){$Cu^{II}Cl_2$(MeOH)}] (**2**) and the labeling scheme used. Selected interatomic distances and angles are listed in Table 2. Cu1 is coordinated by tptz in a terpyridine-like coordination mode (**III** in Scheme 1) with two additional chloride donors resulting in five-fold coordination. The Cu1−N1 distance of the triazine nitrogen donor is 1.94 Å and the distances with the two pyridyl donors N26 and N66 of tztp are both 2.07 Å. The chloride Cl12 is coordinated trans to the triazine nitrogen donor N1 at a distance of 2.22 Å whereas chloride Cl11 forms a long bond of 2.51 Å. The coordination geometry of Cu1 may best be described as distorted square pyramidal with N1, N26, N66, and Cl12 forming the equatorial plane and Cl11 occupying the apical position. This equatorial plane is almost coplanar with the 1,3,5-triazine plane. The N26−Cu1−N66 angle of 154° of the terpyridine-like unit is significantly larger compared with the analogous

N4−Cu−N5 angle in **1**. This increase originates from the decreased Cu1−N1 bond length of 1.94 Å compared with 2.15 Å in **1** and the different coordination mode of the two pyridyl rings. In **2**, the pyridyl rings are in the equatorial plane (short bonds, 2.07 Å) which is in contrast to **1** where the pyridyl rings occupy axial positions (long bonds, 2.41 and 2.50 Å).

Cu2 is coordinated by tptz in a bipyridine-like coordination mode (**IV** in Scheme 1) with two additional chloride donors and one methanol ligand resulting in a five-fold coordination. The Cu2−N3 bond length of the triazine nitrogen donor at 2.45 Å is the longest found in the two complexes. Conversely, the pyridyl nitrogen donor of tztp N46 forms the shortest pyridyl nitrogen−copper bond at 2.02 Å. Chloride Cl22 is coordinated trans to the pyridyl nitrogen donor at a distance of 2.22 Å and chloride Cl21 is coordinated cis to the pyridyl nitrogen donor at a distance of 2.24 Å. The Cu2−O71 bond length of the coordinated methanol ligand is 2.05 Å. The coordination geometry of Cu2 may also best be described as distorted square pyramidal but in contrast to Cu1 the 1,3,5-triazine nitrogen donor occupies the axial position and the equatorial plane formed by N46, Cl21, Cl22, and O71 is oriented perpendicular to the 1,3,5-triazine plane. With implications for the magnetic properties it is interesting to note that the axial ligand N3 is tilted from a perfect axial position as indicated by the acute N3−Cu2−N46 angle of 75°.

Two molecules of **2** form dimers as a result of two hydrogen bonds which are symmetry related (Figure 2b). The chloride ligand coordinated in the axial position of Cu1 in one molecule forms a hydrogen bond with the coordinated methanol ligand of Cu2 of the other molecule at a distance of 3.01 Å.

Magnetic Properties

The magnetic susceptibilities of **1** and **2** were measured in the temperature range 2−300 K. The raw data were corrected for underlying diamagnetism by using tabulated Pascal's constants and for temperature-independent paramagnetism, χ_{TIP}, which was obtained as a fit parameter. The magnetic properties were analyzed by using the spin Hamiltonian in Equation (1) including the isotropic Heisenberg−Dirac−van Vleck (HDvV) exchange Hamiltonian and the single-ion Zeeman interaction by using a full-matrix diagonalization approach.

$$H = -2J\mathbf{S}_1\mathbf{S}_2 + \sum_i [\mu_B g_i \mathbf{S}_i \mathbf{B}] \quad (1)$$

The effective magnetic moment, μ_{eff}, of complex **1** has a temperature-independent value of 1.84 μ_B in the range 300−30 K and decreases below 30 K to a value of 1.53 μ_B at 2 K (not shown). These data were simulated by using the spin-Hamiltonian for an isolated $S_i = {}^1/_2$ system with $g = 2.123$ and $\chi_{TIP} = 33 \cdot 10^{-6}$ cm^3·mol^{-1}. However, the decrease below 30 K could not be well reproduced although saturation effects were already taken into account. Thus, the decrease in μ_{eff} reflects intermolecular antiferromagnetic

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

interactions. We tried to simulate this decrease by introducing a Weiss temperature Θ. The simulation using Θ = −0.14 K resulted in a better agreement, but the simulation was still not satisfactory in the low temperature region. We tried to simulate the magnetic data of **1** using spin Hamiltonian in Equation (1) for a weak exchange coupled dimer. Figure 3 (top) shows the temperature dependence of μ_{eff} calculated for the "dimer $\mathbf{1}_2$". This model, using the same *g*-value and χ_{TIP} per site as for the monomeric model described above, gave a satisfactory agreement between experimental and simulated data even in the low temperature range with $J = -0.09$ cm^{-1}. It was not possible to assign the origin of this weak intermolecular antiferromagnetic interaction. Through-space dipolar couplings (closest Cu−Cu distance 7.77 Å) and/or through-bond interactions may account for this weak intermolecular interaction.

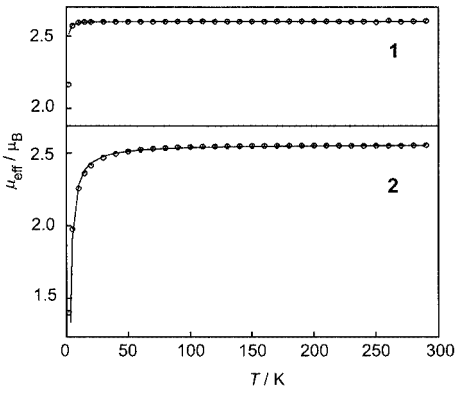

Figure 3. Top: Temperature dependence of the effective magnetic moment, μ_{eff}, calculated for the "dimeric unit" of complex **1** at 1 T. The solid line is a fit of the experimental data using the spin Hamiltonian in Equation (1) with $S_1 = S_2 = 1/2$, $g_1 = g_2 = 2.123$, $\chi_{TIP} = 66{\cdot}10^{-6}$ cm^3·mol^{-1} for the "dimer", and $J = -0.09$ cm^{-1}. Bottom: Temperature dependence of the effective magnetic moment, μ_{eff}, of complex **2** at 1 T. The solid line is a fit of the experimental data using the spin Hamiltonian (1) with $S_1 = S_2 = 1/2$, $g_1 = g_2 = 2.090$, $\chi_{TIP} = 180{\cdot}10^{-6}$ cm^3·mol^{-1}, and $J = -2.5$ cm^{-1}.

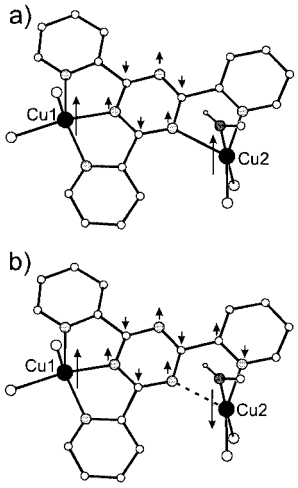
The effective magnetic moment, μ_{eff}, of the dinuclear complex **2** has a temperature-independent value of 2.55 μ_B in the range 300−110 K and decreases below 110 K to a value of 1.40 μ_B at 2 K (Figure 3 bottom). This is typical behavior for an antiferromagnetically coupled Cu^{II} dimer. The simulation using the spin Hamiltonian in Equation (1) with $g = 2.090$, $\chi_{TIP} = 180{\cdot}10^{-6}$ cm^3·mol^{-1}, and $J = -2.5$ cm^{-1} nicely reproduces the experimental data. Thus, there is a sizeable exchange coupling through the tptz ligand which is antiferromagnetic in nature.

To the best of our knowledge, the determination of the exchange coupling in **2** is the first established for the tptz ligand. The antiferromagnetic interaction is, at a first glance, counterintuitive to the spin-polarization mechanism mediated by the *meta*-phenylene arrangement of the two copper centers. The spin-polarization should result in a ferromagnetic coupling as depicted in Scheme 2a. However, a close inspection of the molecular structure of **2** results in a deeper understanding of the exchange coupling in **2**. The magnetic orbitals $d_{x^2-y^2}$ of square-pyramidal-coordinated Cu^{II} ions are located in the equatorial plane. The equatorial plane of Cu1 is orientated parallel to the 1,3,5-triazine ring consisting of N1, N26, N66, and Cl12. In contrast, the equatorial plane of Cu2 is oriented perpendicular to the 1,3,5-triazine ring and consists of N46, Cl12, Cl22, and O71. The $d_{x^2-y^2}$ orbital of Cu1 is delocalized to N1 in a σ-type pathway. There is no delocalization of the $d_{x^2-y^2}$ orbital of Cu2 to N3. First, the Cu2−N3 distance of 2.45 Å is too long for significant delocalization and secondly, the $d_{x^2-y^2}$ orbital of Cu2 is of δ-type symmetry with respect to the Cu2−N3 bond. There is however a strong delocalization of the $d_{x^2-y^2}$ of Cu2 to N46 (Cu2−N46 2.02 Å) in a σ-type pathway. Thus, the spin-polarization mechanism is not operative through the pathway depicted in Scheme 2a but it is operative through a pathway incorporating the pyridyl ring of N46. This pathway for the spin-polarization leads to an antiferromagnetic coupling between the two copper centers (Scheme 2b) and is consistent with the experimental data. The ability of polypyridyl type bridging ligands to mediate spin-polarization over long distances of a ferro- and antiferromagnetic nature depending on the relative arrangement of the pyridyl rings has been demonstrated by McCleverty, Ward, and co-workers.[3,7]



Scheme 2

As indicated in the introduction, not only the spin-polarization contribution to the exchange coupling but also the superexchange contribution seems to be effective. The orientation of the equatorial planes of the two copper centers is orthogonal. Thus, the magnetic orbitals of Cu1 and Cu2 are orthogonal to each other. This orbital orthogonality was used to understand the ferromagnetic interactions observed in pyrimidine bridged dinuclear Cu^{II} complexes with an equatorial-axial ligation of the pyrimidine bridging ligand.[8a,11] However, the deviation of the axial triazine nitrogen donor N3 of Cu2 from perfect axial ligation (vide supra) removes the strict orthogonality of the magnetic orbitals and some positive overlap of the $d_{x^2-y^2}$ orbital of Cu2 with the *p*-orbitals of N3 might occur. Due

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to the long bond length, this overlap is weak and gives a small further contribution to the observed antiferromagnetic exchange interaction.

Experimental Section

General Methods and Materials: Infrared spectra (400−4000 cm^{-1}) of solid samples were recorded on a Bruker Vector 22 spectrometer as KBr disks. ESI mass spectra were recorded on a Micromass Quattro LC mass spectrometer. All starting materials were obtained commercially and used without further purification. Temperature-dependent magnetic susceptibilities of finely ground crystals were measured using a SQUID magnetometer (Quantum Design) at 1.0 T (2.0−300 K). For calculations of the molar magnetic susceptibility, χ_M, the measured susceptibilities were corrected for the underlying diamagnetism of the sample using tabulated Pascal's constants. The JULIUS routine was used for spin Hamiltonian simulations using a full-matrix diagonalization approach of the data.[24]

[(tptz)Cu^{II}(Medpt)]$(BF_4)_2$·2MeOH (1): A solution of Medpt (84 mg, 0.57 mmol) in methanol (5 mL) was added dropwise to a green solution of tptz (60 mg, 0.19 mmol) and $Cu(BF_4)_2$·$3H_2O$ (168 mg, 0.57 mmol) in methanol (15 mL). The resultant blue solution was stirred for 3 hours. Diffusion of diethyl ether into this solution afforded green crystals. Yield: 95 mg (65%). ESI-MS (positive ion mode): m/z = 260 $[(tptz)Cu(Medpt)]^{2+}$. IR (KBr): $\tilde{\nu}$/cm^{-1} = 3315 w, 3173 m, 3077 m, 2956 w, 2883 w, 2081 w, 1660 m, 1590 w, 1562 w, 1522 m, 1523 s, 1486 w, 1470 w, 1434 w, 1401 w, 1385 s, 1377 s, 1294 w, 1264 m, 1215 w, 1181 w, 1084 s, 1032 s, 1001 w, 929 w, 862 w, 763 s, 738 w, 675 m, 667 m, 628 w, 620 w, 533 m, 522 m; elemental analysis calcd. (%) for [(tptz)Cu^{II}(Medpt)]$(BF_4)_2$·2MeOH $C_{27}H_{39}B_2CuF_8N_9O_2$ (758.83): calcd. C 42.74, H 5.18, N 16.61; found C 42.40, H 4.88, N 16.59.

[{$Cu^{II}Cl_2$}(tptz){$Cu^{II}Cl_2$(MeOH)}] (2): Solid tptz (10 mg, 0.032 mmol) and solid $CuCl_2$·$2H_2O$ (50 mg, 0.29 mmol) were each placed in one arm of an H-shaped tube. The tube was filled carefully with methanol allowing for diffusion of the two solutions between the two arms. During the course of 7 days, green needles appeared. Yield: 19 mg (97%). IR (KBr): $\tilde{\nu}$/cm^{-1} = 3417 m, 3137 m, 3093 m, 3042 m, 1608 w, 1578 s, 1563 m, 1544 s, 1494 m, 1475 m, 1445 w, 1408 m, 1396 w, 1377 s, 1308 w, 1264 m, 1154 w, 1097 w, 1039 w, 1016 m, 773 s, 687 m, 668 m, 661 m, 641 w; elemental analysis calcd. (%) for [{$Cu^{II}Cl_2$}(tptz){$Cu^{II}Cl_2$(MeOH)}] $C_{19}H_{16}Cl_4Cu_2N_6O$ (613.26): calcd. C 37.21, H 2.63, N 13.70; found C 36.88, H 2.65, N 13.50.

X-ray Crystal Structure Analysis of [(tptz)Cu^{II}(Medpt)]$(BF_4)_2$·2MeOH (1): Formula $C_{27}H_{39}B_2CuF_8N_9O_2$, M = 758.83 g·mol^{-1}, green crystal 0.45 × 0.29 × 0.12 mm, a = 11.857(2), b = 12.370(2), c = 13.033(2) Å, α = 103.01(1), β = 109.01(1), γ = 103.13(1)°, V = 1664.6(4) $Å^3$, $\rho_{calcd.}$ = 1.514 g·cm^{-3}, μ = 7.43 cm^{-1}, empirical absorption correction (0.731 ≤ T ≤ 0.916), Z = 2, triclinic, space group $P\bar{1}$ (No. 2), λ = 0.71073 Å, T = 153 K, ω and φ scans, 16469 reflections collected (±h, ±k, ±l), [(sinθ)/λ] = 0.65 $Å^{-1}$, 7635 independent (R_{int} = 0.027) and 6466 observed reflections [$I \geq 2\ \sigma(I)$], 621 refined parameters, R = 0.040, wR^2 = 0.098, max. residual electron density 0.51 (−0.47) e·$Å^{-3}$, hydrogens calculated and refined as riding atoms.

X-ray Crystal Structure Analysis of [{$Cu^{II}Cl_2$}(tptz){$Cu^{II}Cl_2$(MeOH)}] (2): formula $C_{19}H_{16}Cl_4Cu_2N_6O$, M = 613.26 g·mol^{-1}, green crystal 0.60 × 0.10 × 0.03 mm, a = 8.332(1), b = 26.006(1), c = 10.496(1) Å, β = 99.09(1)°, V = 2245.7(4) $Å^3$, $\rho_{calcd.}$ = 1.814 g·cm^{-3}, μ = 23.96 cm^{-1}, empirical absorption correction (0.327 ≤ T ≤ 0.932), Z = 4, monoclinic, space group $P2_1/c$ (No. 14), λ = 0.71073 Å, T = 198 K, ω and φ scans, 8930 reflections collected (±h, ±k, ±l), [(sinθ)/λ] = 0.66 $Å^{-1}$, 5113 independent (R_{int} = 0.040) and 3665 observed reflections [$I \geq 2\ \sigma(I)$], 293 refined parameters, R = 0.043, wR^2 = 0.094, max. residual electron density 0.89 (−0.59) e·$Å^{-3}$, hydrogens calculated and refined as riding atoms.

Data sets were collected with Bruker AXS APEX and Nonius Kappa CCD diffractometers, equipped with rotating anode generators. Programs used: data collection SMART[25] and COLLECT,[26] data reduction SAINT[25] and Denzo-SMN,[27] absorption correction SADABS[25] and SORTAV,[28] structure solution SHELXS-97,[29] structure refinement SHELXL-97.[30]

CCDC-211262 and -211263 contain the supplementary crystallographic data for this paper. Cyano-Bridged Dimetallic Polynuclear Cu_6Cr, Cu_6Cr_6, Cu_2W, and CuW Arrays: Synthesis, Crystal Structure, and Magnetism

Hui-Zhong Kou,*[a] Bei Chuan Zhou,[a] Shu-Feng Si,[a] and Ru-Ji Wang[a]

Keywords: Cyano bridges / Magnetic properties / Tungsten / Copper / Chromium

The synthesis, structure, and properties of the dimetallic complexes $[CuLCr(CN)_6]_6\cdot[\{CuL(H_2O)\}_6Cr(CN)_6](ClO_4)_3\cdot 16H_2O$ (**1**), $[CuLCr(CN)_5(NO)]_6\cdot[\{CuL(H_2O)\}_6Cr(CN)_5(NO)](ClO_4)_3\cdot 16H_2O$ (**2**) and $[CuL]_3[W(CN)_8]_2\cdot 4H_2O$ (**3**) {L = 3,7-bis(2-aminoethyl)-1,3,5,7-tetraazabicyclo[3.3.2]decane} are presented. The structures of **1** and **2** are isomorphous and consist of novel cyano-bridged $[CuL(\mu\text{-}CN)_2Cr(CN)_4]_6$ dodecanuclear units and $[CuL(H_2O)(\mu\text{-}CN)]_6Cr$ heptanuclear moieties. Every cyclic dodecanuclear Cu_6Cr_6 group embeds a ClO_4^- anion. The heptanuclear and the dodecanuclear units are connected through hydrogen bonds to generate a vacant hole, in which another ClO_4^- anion is accommodated. Complex **3** contains cyano-bridged Cu_2W trimers and CuW dimers. Magnetic studies have shown that the three complexes display ferromagnetic coupling across the Cr–CN–Cu or W–CN–Cu linkages. The best fit to the magnetic data gave for complex **1** $J_{CuCr} = +2.40\ cm^{-1}$, $g_{Cr} = 1.99$, $g_{Cu} = 2.09$, and an intermolecular coupling constant $\theta = +0.23$ K while for complex **2** $J_{CuCr} = +12\ cm^{-1}$, $g = 2.13$, and $\theta = -0.49$ K. Ferromagnetic Cu^{II}-W^{V} coupling is operative in complex **3**.

Introduction

The magnetic properties of cyano-bridged dimetallic assemblies have been actively researched.[1−55] Exciting findings include the design and synthesis of cyano-bridged room-temperature molecule-based magnets[1] and magnetically tunable materials.[2−5] In particular, cyano-bridged polynuclear species can be used to elucidate the strength of intermetallic coupling through the bridges and to search for single-molecule magnets.[10−21] Until now, cyano-bridged star-like heptanuclear complexes $\{[ML^1]_6[M'(CN)_6]\}^{n+}$ (M = Cu^{II}, Ni^{II}, or $Mn^{II/III}$; L^1 = organic ligands; M′ = Fe^{III}, Cr^{III}) have been synthesized,[21−29] some of which have been structurally characterized. The magnetism of cyano-bridged tri-, tetra-, penta-, and pentadecanuclear complexes has also been reported.[34−50] These studies show that the coupling constants of Ni^{II}-Fe^{III}, Mn^{II}-Fe^{III}, Ni^{II}-Cr^{III}, Mn^{II}-Cr^{III}, and Cu^{II}-Cr^{III} through the cyano bridges are generally less than 20 cm^{-1} (absolute values). Very recently, a cyano-bridged Mo_6Mn complex has been found to exhibit interesting single-molecule magnet behavior.[20] Our interest in low-dimensional cyano-bridged dimetallic complexes[41,46] has suggested that treating the Cu^{II} building block $[CuL](ClO_4)_2$ {L = 3,7-bis(2-aminoethyl)-1,3,5,7-tetraazabicyclo[3.3.2]decane} with $[Cr(CN)_6]^{3-}$, $[Cr(CN)_5(NO)]^{3-}$ or $[W(CN)_8]^{3-}$ will generate cyano-bridged species since the cyano nitrogen atoms can replace the weakly coordinated ClO_4^- oxygen atoms around the Cu^{II} atom.[56] Three novel polynuclear dimetallic complexes have been obtained and investigated for their magnetic properties. We report our findings here.

Results and Discussion

Synthesis and Physical Characterization

$[Cr(CN)_6]^{3-}$/$[Cr(CN)_5(NO)]^{3-}$ and $[CuL](ClO_4)_2$ react to form the new complexes **1** and **2** irrespective of the molar ratios of two precursors. Usually, di- or trinuclear and 1D chain complexes are produced by the reactions of hexacyanometallate with Cu^{II} complexes.[30,43−45,47−49] Thus, the formation of cyano-bridged dodecanuclear Cu_6Cr_6 and heptanuclear Cu_6Cr moieties is unexpected. Similarly, an attempt to synthesize Cu_6Fe complexes led to the cocrystallisation of heptanuclear and pentanuclear moieties.[23]

Similar to the reaction of $[Cu(en)_2]^{2+}$ with $[W(CN)_8]^{3-}$, $[CuL]^{2+}$ with $[W(CN)_8]^{3-}$ affords a cyano-bridged polynuclear Cu_3W_2 complex (**3**). Although a cyano-bridged 3D molecular structure is assumed for $Cu(en)_2-W(CN)_8$, it may be best regarded as polynuclear owing to its considerably weak $Cu-N_{cyano}$ coordination bonds.[52]

The three strong IR bands at 2129, 2119, and 2112 cm^{-1} for complex **1**, and 2115, 2110, 2098 cm^{-1} for complex **2** are attributed to C≡N stretching modes. The splitting of $\nu_{C\equiv N}$ indicates the presence of both bridging and nonbridging cyano ligands, which is consistent with the X-ray structural results (vide infra). The strong band centred at 1089 cm^{-1} (ν_{Cl-O}) indicates the existence of ClO_4^- anions. The

 DOI: 10.1002/ejic.200300500 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

very strong band at 1664 cm^{-1} ($\nu_{O=N}$) shows the presence of NO^+ groups in complex **2**.[55,57,58]

The solution electronic spectrum of complex **1** shows a weak broad band centred at 530 nm due to the d−d transition of Cu^{II}.[56] The d−d transition of Cr^{III} may be masked by that of Cu^{II}.

The powder X-band EPR spectrum of **1** at room temperature shows a broad, nearly isotropic signal that affords a g_{iso} value of 2.02. No half-field transition was observed. The broad isotropic signal differs from that of an axial $S = 1/2$ Cu^{II} complex. With the presence of nearly isolated Cu^{II} moieties in the complex, the EPR spectrum can be tentatively explained as the superimposition of the transitions for $S = 3/2$ (Cr^{III}), $S = 1/2$ (Cu^{II}) and the ferromagnetically coupled ground state $S = 2$ for $Cu^{II}Cr^{III}$ (vide infra).

Crystal Structures

The structures of complexes **1** and **2** are shown in Figures 1, 2, and 3. Figure 4 shows the Cu_6Cr_6 dodecanuclear unit of both complexes. The cell packing plots of three complexes are shown in the Supporting Information. The structure of the polynuclear units for complex **3** is shown in Figure 6. Selected bond lengths and angles are listed in Tables 1 and 2.

Complex **1** is isostructural to complex **2**. The structure of both complexes confirms the cocrystallization of heptanuclear Cu_6Cr^{9+} cations, cyclic $Cu_6Cr_6^{6-}$ anions, and ClO_4^- counter-anions. The molar ratio of the constituents is 1:1:3.

The $Cu_6Cr_6^{6-}$ anion consists of six $[CuL]^{2+}$ moieties and six $[Cr(CN)_6]^{3-}$ (**1**) or $[Cr(CN)_5(NO)]^{3-}$ (**2**), which are alternatively connected by the cyano ligands. The coordination environment of Cu^{II} is distorted octahedral (4 + 1 + 1) with the N_{cyano} atom at the axial position [Cu(1)−N(2) and Cu(1)−N(4A) bond lengths are 2.506(5) and 3.072(6) Å for **1**, and 2.378(5) and 3.082(6) Å for **2**].

[a] Symmetry operation: #1: $2/3 + x - y$, $1/3 + x$, $1/3 - z$.

The Cu^{II} ion is equatorially coordinated by four nitrogen atoms from the L ligand. The cyano ligand coordinates to the Cu^{II} ion in a bent fashion with Cu−N−C angles of 142.7(6) and 114.1(5)° for **1**, and 144.8(5)° and 112.2(5)° for **2**. In **2**, the bridging cyano ligands are *cis* or *trans* to the NO^+ ligand (Figure 2). The Cr···Cu distances through the cyano bridge are 5.427(1), 5.248(1) Å for **1** and 5.333(1), 5.225(1) Å for **2**. Within the cyclic Cu_6Cr_6 group, a perchlorate anion [Cl(1)] is embedded, which is disordered over two sets of positions (Figure 3).

C(47)−N(47)−Cu(3)	147.5(4)		

The $[Cr(CN)_6]^{3-}$ anion is nearly octahedral: the *cis*- and *trans*-C−Cr−C angles are close to 90° and 180°, respectively. The Cr−C−N linkages show only a slight deviation from linearity. The $[Cr(CN)_5(NO)]^{3-}$ anion has a distorted octahedral environment (C_{4v} symmetry): the Cr−*N*−O and Cr−C−N linkages are nearly linear, and the N−Cr−C *cis* angles are > 90° due to the greater electronegativity (EN) of the nitrosyl group with respect to the cyanide groups. This agrees with the EN calculations of Huheey ($NO^+ > CN^- > H_2O$).[59] The Cr−C bonds range from 1.985(8) to 2.099(7) Å, while the Cr−N distance is 1.886(8) Å. These data are in good agreement with complexes incorporating $[Cr(CN)_5(NO)]^{3-}$.[55,58]

In the heptanuclear cation (Figure 4), $[Cr(CN)_6]^{3-}$ (**1**) or $[Cr(CN)_5(NO)]^{3-}$ (**2**) is encapsulated by six $[CuL(H_2O)]^{2+}$ units through the weak $Cu-N_{cyano}$ coordination bonds [Cu−N = 3.021(5) Å for **1** and 2.950(7) Å for **2**], forming an almost spherical cluster. The Cu(2) coordination geometry is elongated octahedral with four nitrogen atoms of L at the equatorial plane, and the oxygen atom [O(2)] of one water molecule and one nitrogen atom of the bridging CN^- ligand at the axial positions [Cu(2)−O(2) = 2.463(5) Å for **1** and 2.464(7) Å for **2**]. The disorder of NO^+ over six positions in **2** precludes an accurate determination of the Cu−O(NO^+) bond length. However, the encapsulation of the $[CuL(H_2O)]^{2+}$ group reveals an NO^+ bridge.

The Cu−N≡C angles in the heptanuclear cations [129.1(5)° for **1** and 129.8(5)° for **2**] show a greater deviation from linearity. The axial O(2)−Cu(1)−N(1) angles also deviate from linearity [154.9(2)° for **1** and 155.6(2)° for **2**]. The Cr···Cu distances through the cyano bridge are 5.591(1) Å (**1**) and 5.489(1) Å (**2**).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Cl(1) and Cr(1) lie in special positions, viz. at the $\bar{3}$ rotation axis along the *c* axis, resulting in the disorder of the ClO_4^- anion. Also, the heptanuclear and the dodecanuclear units pack along the *c* axis (Figure 5), and are connected through hydrogen bonds [O(2)···N(3A)] (Figure 6). A ClO_4^- anion is accommodated between the two polynuclear units, and is hydrogen-bonded to the nitrogen atoms [N(8)] of L.

The structure of **3** consists of two cyano-bridged trimeric Cu_2W and dimeric CuW moieties (Figure 6). In the Cu_2W trimer, $[W(CN)_8]^{3-}$ uses two cyano ligands to connect two $[CuL]^{2+}$ groups, giving rise to a "V"-shaped structure. The Cu^{II} ions are five-coordinate with four nitrogen atoms of the L ligand occupying the equatorial plane and one cyano nitrogen atom at the apical position. The $Cu-N_{cyano}$ bond lengths are 2.300(5) Å for Cu(1)−N(1) and 2.210(5) Å for Cu(2)−N(6). The cyano bridging ligands coordinate to the copper ions with bond angles of 161.0(5)° for Cu(1)−N(1)−C(1) and 169.3(8)° for Cu(2)−N(6)−C(6). The CuW dimer differs from the trimer in that it contains only one cyano bridge linking two metal ions. The cyano bridging ligand coordinates to the copper ion [Cu(3)−N(47) = 2.368(4) Å] with a bond angle of 147.5(4)°. Based on the $Cu-N_{cyano}$ bond lengths and the corresponding Cu−N−C bond angles, the shorter the $Cu-N_{cyano}$ bond lengths the larger are the Cu−N−C bond angles. The corresponding metal−metal separations are 5.535 Å for Cu(1)−W(2), 5.458 Å for Cu(2)−W(2) and 5.436 Å for W(1)−Cu(3). In the cell, two polynuclear moieties are linked through weak intermolecular contacts ($Cu-N_{cyano} > 3.16$ Å) giving rise to a 3D network (see Supporting Information). Water molecules within the network are hydrogen-bonded to the primary amine nitrogen atoms and the nonbridging cyano nitrogen atoms.

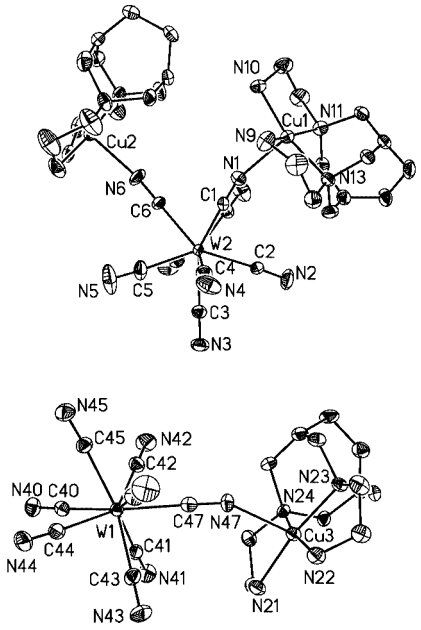

Figure 6. Structure of complex **3**, showing the discrete trimeric and dimeric units

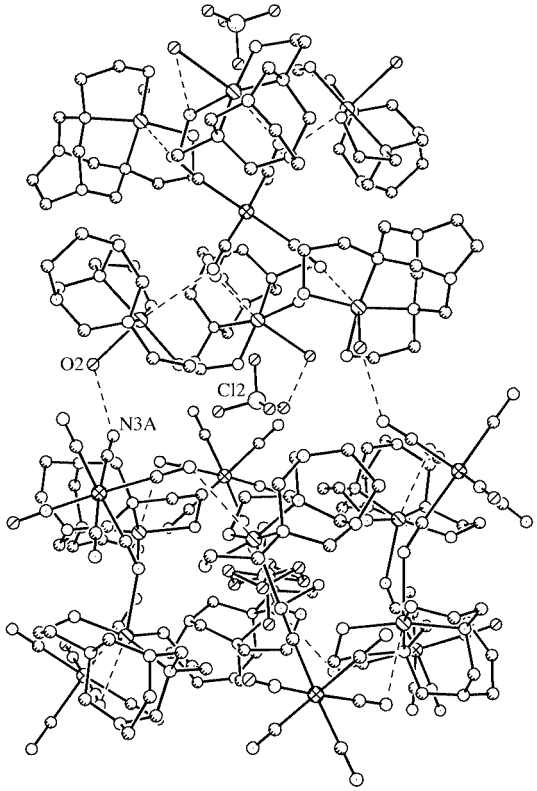

Figure 5. Hydrogen-bonded cyclic Cu_6Cr_6 and spherical Cu_6Cr units of **1** and **2** showing the encapsulation of the ClO_4^- anion (Cl2)

Magnetic Properties

The magnetic susceptibilities of the three complexes have been measured, and plots of $\chi_m T$ vs. T are shown in Figures 7, 8, and 9, where χ_m is the magnetic susceptibility per $Cu_{12}Cr_7$ unit or per Cu_3W_2 unit.

With decreasing temperature, $\chi_m T$ of **1** increases slowly until ca. 30 K and then sharply reaches a maximum of 23.0 emu·K·mol^{-1} at 4 K. The magnetic susceptibilities obey the Curie−Weiss law with a positive Weiss constant of +2.1 K and a Curie constant of 17.9 emu·K·mol^{-1} (calculated

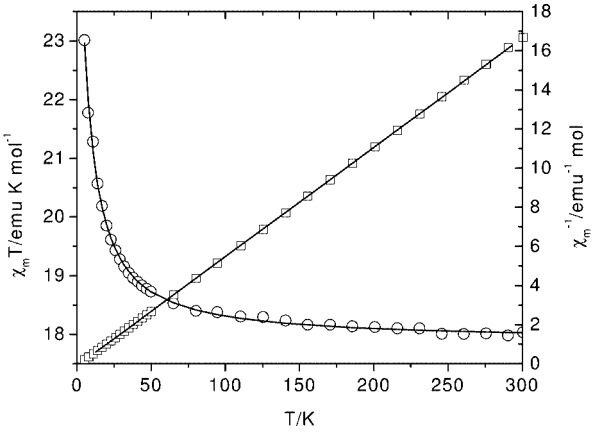

Figure 7. Temperature dependence of $\chi_m T$ and χ_m for **1**; the solid line is the best fit with the parameters in the text

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

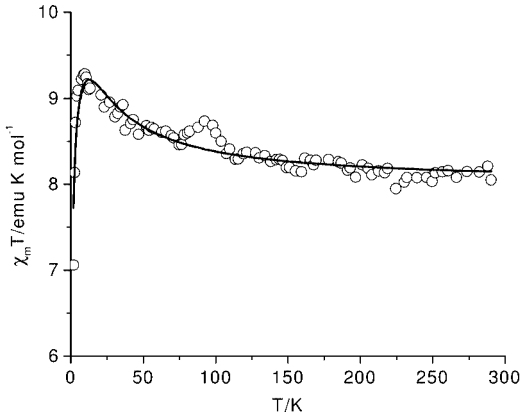

Figure 8. Temperature dependence of $\chi_m T$ for **2**; the solid line is the fit to the Curie−Weiss law

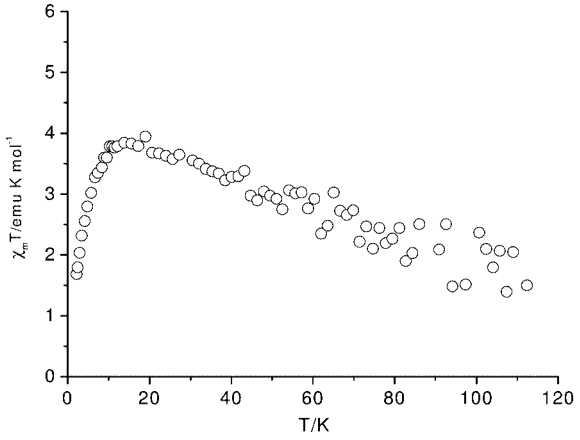

Figure 9. Temperature dependence of $\chi_m T$ for **3**

value is 17.75 emu·K·mol^{-1} assuming $g = 2$). This magnetic behaviour reveals ferromagnetic coupling between the $Cu^{II}-Cr^{III}$ ions through the cyanide bridges. The ferromagnetic interaction between the Cr^{III} and Cu^{II} ions is due to the orthogonality of the magnetic orbitals of Cr^{III} (t_{2g}^3) and Cu^{II} (e_g^3).

From the structural information of **1**, the system can be treated as six strongly interacting CuCr dimers [$Cu-N_{cyano}$ = 2.506(5) Å] between which a weak interaction is present [$Cu-N_{cyano}$ = 3.072(6) Å] and weakly interacting Cu_6Cr clusters [$Cu-N_{cyano}$ = 3.021(6) Å]. The weak interactions are negligibly small and can be included in the intermolecular field term during the fit. Hence, the magnetic susceptibilities can be simulated by Equations (1) and (2) based on the isotropic spin Hamiltonian $\hat{H} = -2J_d S_{Cr} S_{Cu}$ for the strongly interacting $Cu^{II}Cr^{III}$ dimer, where g_1 and g_2 are the g factors for the total spin states of $S_T = 1$ and 2, respectively, and θ accounts for the interdimeric coupling. The g_1 and g_2 factors are related to g_{Cu} and g_{Cr}, viz. $g_1 = 3/4g_{Cr} - 1/4g_{Cu}$ and $g_2 = 3/4g_{Cr} + 1/4g_{Cu}$ according to the literature method.[61−63]

$$\chi_d = \frac{Ng^2\beta^2}{k(T-\theta)} \cdot \frac{2g_1^2 + 10g_2^2 \exp(4J_d/kT)}{3 + 5\exp(4J_d/kT)} \quad (1)$$

$$\chi_m = 6\times\chi_d + 6\times\frac{Ng_{Cu}^2\beta^2}{3kT} S_{Cu}(S_{Cu}+1) + \frac{Ng_{Cr}^2\beta^2}{3kT} S_{Cr}(S_{Cr}+1) \quad (2)$$

The best fit to the magnetization data gives g_{Cu} = 2.09, g_{Cr} = 1.99, J_d = +2.40 cm^{-1} and θ = +0.23 K (Figure 7). To approximate the $Cu^{II}-Cr^{III}$ coupling in the Cu_6Cr moieties we used an identical θ, giving rise to a similar result with g_{Cu} = 2.09, g_{Cr} = 1.99, J_d = +2.37 cm^{-1} and θ = +0.17 K. The positive θ indicates weak intermolecular ferromagnetic interactions. Of course, this θ includes two effects: the $Cu^{II}-Cr^{III}$ magnetic coupling through the weak bridging cyano ligands and the intercluster magnetic exchange. The $Cu^{II}-Cr^{III}$ coupling constant is similar to those reported for the cyano-bridged 1D CuCr complexes $\{[Cu(L^2)][Cu(L^2)Cr(CN)_6]ClO_4\cdot 2H_2O\}_n$ (L^2 = *meso*-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane) (J = +4.82 cm^{-1}) and $[Cu(cyclam)]_3[Cr(CN)_6]_2\cdot 4H_2O$ (J = +4.33 cm^{-1}),[64,30] and is lower than that of the cyano-bridged Cu_3Cr complex $[Cu(edma)]_3Cr(CN)_6$ ($edma^-$ = ethylenediaminemonoacetate) (J = +9.16 cm^{-1}).[44]

A Cu^{II} ion in elongated octahedral surroundings has a magnetic orbital built from a $d_{x^2-y^2}$ orbital (x and y axes are taken along the $Cu-N_{equatorial}$ directions) with little contribution from the d_z^2 orbital and localized in the equatorial plane. A weak magnetic interaction is anticipated due to the little delocalization of the magnetic orbital towards the axial position by the bridging cyano atom for complex **1** and $\{[Cu(L^2)][Cu(L^2)Cr(CN)_6]ClO_4\cdot 2H_2O\}_n$.[64] That the strongest Cu···Cr coupling is present in the Cu_3Cr complex is understandable because the bridging cyano atom is situated within the coordination plane (xy plane).

The magnetic behaviour of complex **2** is similar to that of complex **1** (Figure 8); $\chi_m T$ increases smoothly as the temperature is lowered to ca. 9.6 K, reaching a maximum of 9.3 cm^3·K·mol^{-1}, and then decreases. The anomaly at ca. 90 K is due to experimental errors. Such magnetic behaviour is characteristic of an unambiguous local ferromagnetic interaction. The magnetic susceptibility in the range 10−300 K has been fitted by the Curie−Weiss expression that is usually used to describe weakly coupled systems. The positive Weiss constant obtained (+4.0 K) suggests a ferromagnetic interaction. The Curie constant C (8.0 emu·K·mol^{-1}) is consistent with the theoretical value of 8.00 emu·K·mol^{-1} with g = 2.12.

The fit to the magnetic data of **2** with a model similar to complex **1** affords g = 2.13, J_d = +12 cm^{-1}, and θ = −0.49 K. The $Cu^{II}-Cr^{I}$ magnetic coupling constant (J_d) is positive, indicating a ferromagnetic interaction between the metal ions.

Complex **2** is the first example incorporating Cu^{II} and low-spin Cr^{I} ions. Analogously, the ferromagnetic nature of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the $Cu^{II}-Cr^{I}$ coupling can be interpreted by the orthogonality of the magnetic orbitals of the low-spin Cr^{I} [$3d^5$, $(d_{xy})^1$] and Cu^{II} [$3d^9$, $(d_{x^2-y^2})^1$] ions.[55]

The comparatively large Weiss constant and J_d compared to that of complex **1** may be partially due to the shorter Cu(1)−N(2) bond length in complex **2**, which favours a stronger Cu···Cr coupling through the cyano bridge.

The magnetic behavior of complex **3** indicates a ferromagnetic nature (Figure 9), which is consistent with the reported analogous cyano-bridged $Cu^{II}-W^{V}$ complexes, in which ferromagnetic $Cu^{II}-W^{V}$ coupling is always observed.[50,52] The decrease of $\chi_m T$ below 18 K may be due to intermolecular antiferromagnetic interaction through the weak cyano contacts and the field saturation effect.

Conclusion

The self-assembly of the $[CuL]^{2+}$ precursor, and $K_3[Cr(CN)_6]$, $K_3[Cr(CN)_5(NO)]$, or $K_3[W(CN)_8]$ affords a series of cyano-bridged polynuclear complexes. X-ray diffraction analysis shows that they consist of novel polynuclear star-like Cu_6Cr and cyclic Cu_6Cr_6 moieties, and that the CuW complex has a cyano-bridged dinuclear and trinuclear structure. Variable-temperature magnetic susceptibility measurements show that the three complexes exhibit ferromagnetic coupling between neighbouring metal ions.

Experimental Section

General Remarks: Elemental analyses of carbon, hydrogen, and nitrogen were carried out with an Elementar Vario EL. Infrared spectroscopy was performed with a Magna-IR 750 spectrophotometer in the 4000−650 cm^{-1} region. The electronic spectrum of **1** was measured with a Perkin−Elmer Hitachi-240 spectrophotometer in water. The room-temperature EPR powder spectrum of **1** was recorded at the X-band with a Bruker ER 200B spectrometer. Variable-temperature magnetic susceptibility measurements of **1** were performed with a Quantum Design MPMS SQUID magnetometer, while those of **2** and **3** were carried out with a MagLab 2000 magnetometer. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal's Tables) and the sample holder (gelatine capsule). All chemicals and solvents used in the synthesis were of reagent grade. $[CuL](ClO_4)_2$, $K_3[Cr(CN)_6]$, $K_3[Cr(CN)_5(NO)]$, and $K_3[W(CN)_8]$ were prepared according to literature methods.[56,57,60,65] ***Caution!*** Perchlorate salts of metal complexes are potentially explosive; only a small amount of material should be prepared, and it should be handled with care.

$[CuLCr(CN)_6]_6[\{CuL(H_2O)\}_6Cr(CN)_6](ClO_4)_3\cdot 16H_2O$ (1): Cubic red single crystals were obtained by slow concentration of an aqueous solution (15 mL) of $[CuL](ClO_4)_2$ (0.1 mmol) and $K_3[Cr(CN)_6]$ (0.1 mmol) in a molar ratio of 1:1. Yield: 23 mg, 40% (based on Cu). IR: $\tilde{\nu}$ = 2129 s, 2119 s, 2112 s ($\nu_{C\equiv N}$); 1086 br (ν_{Cl-O}) cm^{-1}. UV/Vis: λ = 530 nm.

$[CuLCr(CN)_5(NO)]_6\cdot[\{CuL(H_2O)\}_6Cr(CN)_5(NO)](ClO_4)_3\cdot 16H_2O$ (2): Red single crystals of **2** were prepared by a procedure similar to that for **1**, using $K_3[Cr(CN)_5(NO)]$ instead of $K_3[Cr(CN)_6]$. Yield: 24 mg, 50% (based on Cu). IR: 2115 s, 2110 s, 2098 sh ($\nu_{C\equiv N}$); 1664 vs ($\nu_{O=N}$); 1089 vs (ν_{Cl-O}) cm^{-1}.

$[CuL]_3[W(CN)_8]_2\cdot 4H_2O$ (3): Violet single crystals were obtained by slow concentration of an aqueous solution (10 mL) of $[CuL](ClO_4)_2$ (0.1 mmol) and $K_3[W(CN)_8]$ (0.1 mmol) in a molar ratio of 1:1. Yield: 11 mg, 20% (based on Cu). IR: 2142 s, 2105 sh ($\nu_{C\equiv N}$) cm^{-1}.

X-ray Crystallographic Study: The data collections of **1**, **3**, and **2** were made with a Bruker Siemens P4 and a Rigaku R-Axis RIPID IP diffractometer at 293 K, respectively. The structures were solved by direct methods (SHELXS-97) and refined by full-matrix least squares (SHELEXL-97) on F^2.[66] Anisotropic thermal parameters were used for the non-hydrogen atoms and isotropic parameters for the hydrogen atoms. Hydrogen atoms were added geometrically and refined by using a riding model. Weighted R factors wR and goodness of fit values (S) are based on F^2, conventional R factors are based on F, with F set to zero for negative F^2. Crystal data are summarized in Table 3. During the solution of the crystal structure of complex **2**, it was found that the atoms (five C and one N) lie from 1.886(8) to 2.099(7) Å away from Cr. Considering that the usual Cr−C bond length is approximately 2.0 Å and that the Cr−N bond length is ca. 1.8 Å,[55,58] the N atom was unambiguously assigned a Cr−N distance of 1.886(8) Å. CCDC-207494 (**1**), -207495 (**2**), -215992 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge

(Neocuproin)zinc Thiolates: Attempts at Modeling Cobalamin-Independent Methionine Synthase

Jan Seebacher,[a] Mian Ji,[a] and Heinrich Vahrenkamp*[a]

Keywords: Zinc / Metal complexes / Thiolates / Bioinorganic chemistry

Several new complexes [(neo)Zn(SR)$_2$] [neo = neocuproin (2,9-dimethylphenanthroline)] have been synthesized and structurally characterised. They react in a stepwise fashion with the alkylating agents CH_3I and $(CH_3)_2SO_4$ to afford the thioethers CH_3SR and first the mixed complexes [(neo)Zn(SR)X] (X = I, CH_3SO_4) and then [(neo)ZnX$_2$]. Similar alkylations occur with benzyl iodide, but not with trimethyl phosphate in nonpolar media. Under these conditions, thiolate exchange with [PPN]SR does not occur which indicates that the alkylations take place at the zinc-bound thiolates. In polar solvents (methanol, DMSO), thiolate exchange occurs readily, and at higher temperatures $(CH_3)_3PO_4$ also acts as an alkylating agent which indicates that under these conditions free thiolate is available in solution. Qualitative kinetic data support the associative alkylation mechanism in nonpolar media and the change of mechanism in polar media.

Introduction

In recent years the well-investigated classes of zinc enzymes, i.e. those for hydrolytic reactions and those of the alcoholdehydrogenase family, have been accompanied by a new class responsible for thiolate alkylations. Their most prominent function is the synthesis of methionine from homocysteine.[1,2] Other thiolate-alkylating enzymes include betain:homocysteine *S*-methyltransferase,[3] protein prenyltransferases[4−6] like farnesyl transferase,[7] methanol:CoM methyltransferase,[8] and the Ada repair protein.[9,10] It is believed that all these enzymes activate the thiol by attaching it to zinc as a thiolate.[5,11] We were able to show that this correlates with the ability of low-coordinate zinc to lower the pK_a of zinc-bound water to 7 or below, thereby generating Zn−OH species under physiological conditions which react with thiols to produce Zn−SR species and water.[12]

In cobalamin-independent methionine synthase[13] and several of the related enzymes,[14] zinc is attached to the protein by one histidine and two cysteinate residues and bears a labile ligand, typically water. Thereby its coordination in the resting state is $ZnNS_2O$, and after substrate attachment it is $ZnNS_3$. Several compounds modeling methionine synthase with zinc complexes have approximated this coordination. Darensbourg[15] alkylated ZnN_2S_2 species, Carrano[16−18] various ZnN_2SX and ZnN_2S_2 species, Parkin[19] a ZnS_4 complex, Riordan prepared $ZnNS_3$ and ZnS_4 complexes[20] and studied the alkylation of an NiN_4S complex,[21] and very recently Darbre[22] found that the ZnN_2S_2 complex [Zn(MEPA)$_2$] previously reported by us[23] can be methylated with trimethyl phosphate. So far the alkylation of a close model complex, i.e. one with $ZnNS_3$ coordination, has not been studied. In the cases where mechanistic investigations were undertaken, they indicated that the thiolates are alkylated in the zinc-bound state and the resultant thioethers are subsequently released. Only in the alkylation of anionic $[Zn(SR)_4]^{2-}$, which was studied as a model for the Ada repair protein, was it observed that the thiolate dissociates from zinc prior to being attacked by the alkylating agent.[24]

Our own contributions to this field have so far consisted of the investigation of (pyrazolylborato)zinc thiolate (Tp* Zn−SR) complexes, i.e. ZnN_3S systems. During the synthetic studies[25−28] it was found that such complexes are easily formed in neutral solutions from TpZn−OH and the corresponding thiol, i.e. their formation does not require a base. Detailed mechanistic studies[29,30] then revealed that the alkylation of their thiolates occurs intramolecularly and that the zinc−sulfur bond is broken after the formation of the thioether. The drawback of the model chemistry using TpZn−SR complexes is that their zinc coordination is different from that in the enzyme ($ZnNS_3$) and that they are not reactive toward the biological alkylating agents *N*-methyltetrahydrofolate or organic phosphates nor analogues thereof in the form of alkylammonium salts or trimethyl phosphate.

With the hope of increasing the reactivity of the zinc thiolates and to approximate the natural binding situation of zinc we therefore set out to investigate zinc thiolates with

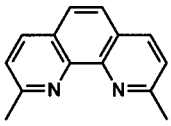
a more sulfur-rich ligand environment. This paper describes the chemistry of ZnN_2S_2 systems and work on $ZnNS_3$ and ZnS_4 systems is in progress. Ideally one would have taken a pyrazolylborate-derived tripodal N_2S ligand to study $(N_2S)Zn-SR$ complexes for this purpose. Since such a ligand is not available as yet, however, we resorted to an appropriate chelating N_2 ligand and the corresponding $(N_2)Zn(SR)_2$ complexes. Based on previous favourable experience with such complexes[31–34] we opted for neocuproin (neo, 2,9-dimethylphenanthroline). This paper reports the syntheses and structures of some new $[(neo)Zn(SR)_2]$ complexes and reactivity studies related to the stepwise removal of their thiolate ligands as thioethers by means of alkylation with various alkylating agents under a variety of conditions.



neocuproin (neo)

Results and Discussion

(Neocuproin)zinc Bis(thiolate) Complexes

The neocuproin ligand is favourable for stable and tetrahedral zinc complexes. It has already been observed that this is also true for bis(thiolate) complexes.[31–34] For the simple bis(thiolates), the benzenethiolate,[34] and the phenylethanethiolate[31] have also been structurally characterized and we now contribute the bis(thiolates) **1a**–**h**. Their preparation can be achieved with comparable yields by two alternative methods. The first of these consists of the successive treatment of sodium methoxide with the thiol, hydrated zinc perchlorate and then neocuproin. The other uses zinc bis[bis(trimethylsilyl)]amide as the base and the zinc precursor, which is added to a mixture of the thiol and neocuproin.

R	C_2H_5	$CH_2C_6H_5$	*p*-$CH_3C_6H_4$	*p*-$NO_2C_6H_4$	2,6-$(C_6H_5)_2C_6H_3$

R'	C_2H_4	*o*-$CH_2C_6H_4CH_2$	*o*-$CH_2C_6H_4$
	1f	**1g**	**1h**

In complexes **1a**–**e**, the monodentate thiolates were varied so as to have aliphatic, benzylic, and aromatic substituents, and among the aromatic substituents the electron density and the steric bulk were varied. The same aliphatic/benzylic/aromatic variation was the reason for the choice of the three bidentate thiolate ligands in **1f**–**h**. Specifically in **1h** the thiolate ligand is benzylic at one sulfur atom and aromatic at the other, and it was hoped that this would be reflected in the reactivity of the two thiolate functions.

All complexes **1** are yellow crystalline solids. Their IR spectra are not diagnostic since there are hardly any band shifts for the ligands upon coordination to zinc. Similarly the ^1H NMR spectra are characteristic only for the thiolate ligands (see Exp. Sect.), while the neocuproin resonances [typical values in $CDCl_3$: δ = 3.1 (s, CH_3), 7.5 (d, J = 8.4 Hz, 4-H), 7.9 (s, 5-H), 8.3 (d, J = 8.4 Hz, 3-H) ppm] show only very small shifts upon coordination.

Four of the eight bis(thiolate) complexes were subjected to structural determinations. One typical example of each of the monodentate (**1c**) and bidentate thiolates (**1h**) are presented as Figures 1 and 2. A summary of selected bond

lengths and angles for all four structures is given in Table 1. The table shows {as does the comparison with previously reported [(neo)Zn(SR)] complexes[31,33,34]} that the Zn−N and Zn−S bond lengths are rather constant, irrespective of the electronic nature of the thiolate ligands. Likewise the N−Zn−N angle is fixed to its low value due to the steric constraints of the neocuproin ligand. The only variable quantities are the S−Zn−S and N−Zn−S angles. While the chelating bis(thiolate) in **1h** fixes the S−Zn−S angle near the tetrahedral value, it can extend to almost 140° in the absence of any restraints, as in **1c**. The average size of the N−Zn−N angle which is large for **1h** and small for **1c** is a mere consequence of the size of the S−Zn−S angles.

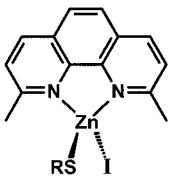
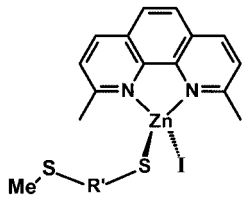
Alkylation Reactions

As before,[30] the most convenient reagent for alkylation of the zinc-bound thiolates was methyl iodide. With the exception of **1e** all thiolates **1** were treated with 1 mol-equiv. of CH_3I in chloroform. Clean reactions occurred with the bis(thiolates) **1a−c** resulting in the liberation of the thioether CH_3SR and isolation of the iodide thiolate complexes **2a−c**. Complex **1d** reacted too slowly at room temperature, but yielded decomposition products at elevated temperatures which prevented the isolation of pure **2d**. Of the chelating bis(thiolates), **1f** and **1g** underwent clean release of one thiolate function, producing **2f** and **2g** with thioether thiolate ligands. The asymmetric chelating bis(thiolate) **1h** was found by NMR observation to be, as expected, more reactive at the benzylthiolate than at the phenylthiolate function, yet the methylation of the benzylthiolate unit did not go to completion before methylation of the phenylthiolate began. As a result the thioether thiolate complex **2h**, like **2d**, could only be identified by its NMR spectroscopic data.

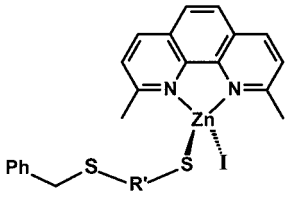


R	C_2H_5	$CH_2C_6H_5$	*p*-$CH_3C_6H_4$	*p*-$NO_2C_6H_4$
	2a	**2b**	**2c**	**2d**



R'	C_2H_4	*o*-$CH_2C_6H_4CH_2$	*o*-$CH_2C_6H_4$
	2f	**2g**	**2h**

Alkylations with benzyl iodide were performed with the chelate complexes **1f** and **1g**. They were slightly faster than the methyl iodide reactions and yielded the thioether thiolate complexes **3f** and **3g**.



R'	C_2H_4	*o*-$CH_2C_6H_4CH_2$
	3f	**3g**

Crystals of **3g** suitable for an X-ray analysis were obtained. Figure 3 shows the molecular shape which is an indication of the intramolecular nature of the alkylation reactions. The coordination of zinc in **3g** largely resembles that in the bis(thiolate) complexes **1**. Notably the N−Zn−S angles are spread over a range of 14°, and the S−Zn−I angle is close to the tetrahedral value.

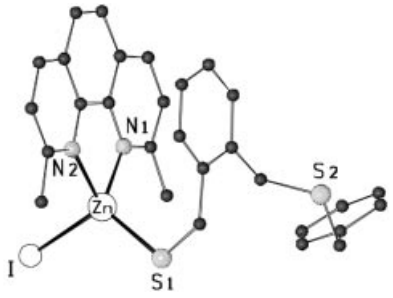


Figure 3. Molecular structure of **3g**; selected bond lengths [Å] and angles [°]: Zn−I 2.580(1), Zn−S 2.244(2), Zn−N1 2.082(5), Zn−N2 2.074(5); S−Zn−I 111.87(6), N1−Zn−N2 80.8(2), N1−Zn−S 118.2(2), N2−Zn−S 122.6(2), N1−Zn−I 110.6(1), N2−Zn−I 109.0(1)

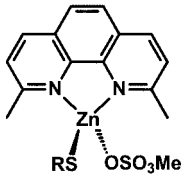
When 2 equiv. of methyl iodide were allowed to react with **1a−c**, **1f**, and **1g**, complete removal of the thiolate ligands occurred and the resultant methyl thioethers could be identified by their ^1H NMR spectra. The remaining zinc complex (neo)ZnI_2 was isolated from the reactions of **1c** and **1f** and characterised and its crystal structure deter-

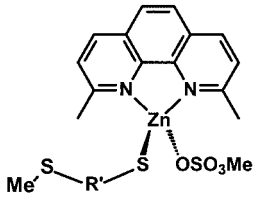
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mined (see Exp. Sect.). It was observed that the second step of the alkylations is not significantly slower than the first step. This also means that even with 1 equiv. of methyl iodide part of the starting materials **1** are converted into (neo)ZnI_2 and 2 equiv. of the thioether, which in some cases hampered the isolation of the mixed complexes **2**.

We have previously observed[30] that dimethyl sulfate is as good as methyl iodide for the alkylation of zinc-bound thiolates, but that the low stability of the resultant zinc−(methyl sulfate) complexes creates preparative problems. This was not so pronounced in the present study. Complexes **1a**, **b**, **f**, and **g** were chosen for the dimethyl sulfate reactions, representing two cases each of monodentate and chelating bidentate thiolates. Treatment with 1 equiv. of dimethyl sulfate produced the corresponding methyl thioethers, as evidenced by ^1H NMR spectroscopy. The resultant zinc complexes **4**, of which **4f** and **g** still contain the thioether as a ligand, were isolated in good yields. They are methyl sulfate complexes which are stable at room temperature. Yet both their NMR spectra and their elemental analyses showed that they were not pure, and attempts at purifying them by recrystallisation only increased their impurity content.



R	Et	Bn
	4a	**4b**



R'	C_2H_4	*o*-$CH_2C_6H_4CH_2$
	4f	**4g**

Treatment of **4a**, **b**, **f**, or **g** with an excess of dimethyl sulfate resulted in complete release of the corresponding methyl thioethers just as in the methyl iodide reactions, but the fate of the remaining zinc species is unclear. No evidence for the formation of [(neo)$Zn(OSO_3CH_3)_2$] was obtained. Only in one case could a small amount of a crystalline product be isolated from the reaction of **1f**. A structural determination, the result of which is shown in Figure 4, identified this product as complex **5**.

5: [$(neo)_2Zn-OSO_3Me$](OSO_3Me)

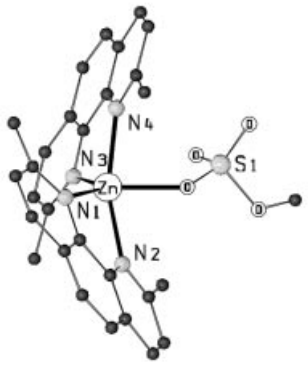


Figure 4. Molecular structure of **5**; selected distances [Å] and angles [°] in the complex cation: Zn−O 2.138(2), Zn−N1 2.093(2), Zn−N2 2.130(2), Zn−N3 2.059(2), Zn−N4 2.135(2), (Zn)O−S 1.465(2), S=O 1.435(2) and 1.437(2), S−O(C) 1.592(2); N2−Zn−N4 161.9(1), O1−Zn−N1 119.5(1), O1−Zn−N3 119.8(1), N1−Zn−N3 120.7(1); in the methyl sulfate anion: S=O 1.394(3), 1.430(5) and 1.420(7), S−O(C) 1.589(10)

The major piece of information from the structure of **5** is the demonstration of the existence of zinc−(alkyl sulfate) binding. The coordination of the zinc ion in **5** is somewhere between square-pyramidal and trigonal-bipyramidal. The suggested square-pyramidal coordination is impossible because the four methyl groups of the neocuproin ligands prevent a symmetric basal arrangement. The alternative trigonal-bipyramidal coordination is impossible because of the small intra-chelate-ligand N−Zn−N angles. The molecular shape of **5** and its bonding parameters closely resemble those in the corresponding nitrate complex.[35] The S=O bond lengths in the ligated and the free methyl sulfate groups do not differ significantly. This holds specifically for the S−O(Zn) bond which is much closer in length to the S=O bonds than to the real single bonds S−O(C). This situation resembles that in the zinc−(organyl phosphate) complexes[36,37] and, just as for the latter, indicates that there is a considerable amount of ionic character in the Zn−O bond.

A more "biological" alkylating agent is trimethyl phosphate, since the Ada repair protein dealkylates alkyl phosphates by transferring the alkyl groups from phosphate to thiolate.[9,10] As before,[30] we also found here that trimethyl phosphate does not alkylate the thiolate ligands of complexes **1** in nonpolar media. It has, however, been reported in the literature[22,24] that in strongly polar solvents and at elevated temperatures the alkylation does take place. This could be reproduced by us using complex **1c**. Heating equimolar amounts of **1c** and $PO(OMe)_3$ in DMSO to 80 °C for 2 weeks produced an almost quantitative formation (by NMR) of $MeSC_6H_4$-*p*-CH_3 and a good isolated yield of the phosphate complex **6**. Likewise with a fivefold amount of $PO(OMe)_3$ nearly quantitative formation of the bis(phosphate) complex **7** took place. The harsh reaction conditions required due to the low alkylating strength of trimethyl phosphate most probably involve a change in the mechanism of the alkylation. As suggested before,[22,24] we con-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

clude (see below) that in these cases free thiolate is liberated and alkylated without the involvement of zinc.

6: [(neo)Zn(S−*p*-Tol)OPO(OMe)$_2$]

7: [(neo)Zn{OPO(OMe)$_2$}$_2$]

The biological alkylating agent in cobalamin-independent methionine synthase is N^5-methyltetrahydrofolic acid, a methylammonium salt. Two synthetic analogues, *N*,*N*,*N*-trimethylanilinium iodide and *N*-methyltetrahydroquinoxalinium iodide, were found to be good mimics,[38] yet they showed no methylating tendency even towards **1b**, the most reactive of the thiolates investigated here even at elevated temperatures.

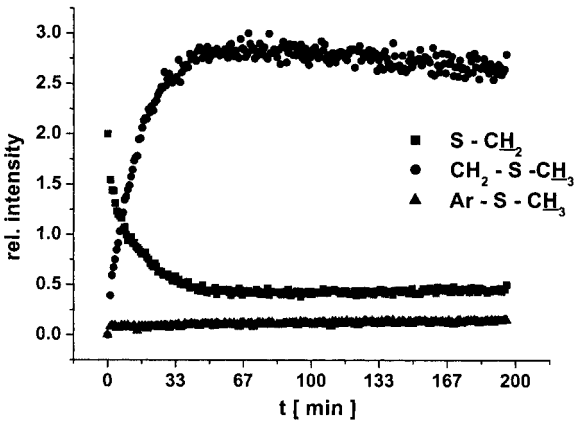

Figure 5. Kinetic traces (by ^{1}H NMR) for the reaction of **1h** (0.005 M) with a four-fold excess of CH_3I in chloroform at 300 K

Mechanistic Considerations

The question of whether the alkylation occurs at the zinc-bound or at the free anionic thiolates was addressed with the same procedures as used in our preceding work.[30] Both thiolate exchange experiments and kinetic investigations led to the conclusion that the [(neo)Zn(SR)$_2$] complexes just like the Tp*Zn−SR complexes undergo intramolecular alkylation, i.e. they do not dissociate in nonpolar media.

The thiolate exchange experiments were monitored by ^{1}H NMR spectroscopy. In no case could a replacement of SR in [(neo)Zn(SR)$_2$] by SR′ from [PPN]SR be observed in chloroform. In methanol, however, fast exchange between [(neo)Zn(SBn)$_2$] (**1b**) and NaSEt took place. Starting with a 1:1 mixture of the reagents, an equilibrium was reached in which [(neo)Zn(SBn)$_2$] and [(neo)Zn(SEt)$_2$] exist in a 10:1 ratio. When treating [(neo)Zn(SBn)$_2$] with the chelating thiolate $Na_2(SCH_2-C_6H_4-CH_2S)$, a quantitative conversion into the chelating dithiolate complex **1g** and NaSBn occurred within minutes. The driving force for this reaction is the precipitation of **1g** from the methanolic solution.

Kinetic data were accumulated for several of the alkylation reactions under pseudo-first-order conditions. Yet in no case could they be fitted cleanly by assuming first-order behaviour. The reasons for this are mainly due to the early onset of the second alkylation step and precipitation of some of the mixed iodide thiolate complexes **2**. A characteristic plot is displayed in Figure 5 which shows in the trace at the bottom the formation of the doubly alkylated bis(thiolate) and in the trace at the top the appearance and subsequent disappearance of the monoalkylated species **2h**.

A qualitative estimate of the second-order rate constant could be obtained for the reaction of **1g** with an excess of methyl iodide. By comparing initial rates at identical concentrations with those of the previously reported Tp*Zn−SR/MeI reaction[30] a value of k'' of the order of 10^{-4} $M^{-1}s^{-1}$ was obtained. This is considerably slower than for [Tp*Zn−SR] complexes, but compares favourably with the k'' value obtained by Carrano[18] for the MeI methylation of an [(N_2O)Zn−SPh] complex. There still exist too few second-order rate constants for such alkylations to allow a meaningful discussion, however.

Finally, another argument in favour of a dissociative alkylation process in polar media (i.e. a nondissociative process in chloroform) was found in the comparison of reaction speeds: in methanol the reaction between **1b** and methyl iodide is roughly one order of magnitude faster than in chloroform. As for the thiolate exchange reactions and for the alkylations with trimethyl phosphate (see above) the simplest explanation for this is the existence of free anionic thiolate in the polar medium.

Conclusions

The present work represents the second step in our investigations on modeling biological thiolate alkylations with tetrahedral zinc complexes. After the ZnN_3S situation in (pyrazolylborato)zinc thiolates the ZnN_2S_2 situation in (neocuproin)zinc thiolates was addressed. Again, the accumulated evidence indicates that the thiolates are alkylated in the zinc-bound state. Furthermore, while the coordination environment of zinc in the enzymes could be approximated, the alkylating agents had to be much stronger than the naturally occuring *N*-methyltetrahydrofolate.

It was found that both thiolate ligands in the [(neo)Zn(SR)$_2$] complexes are alkylated in a stepwise fashion. When, as in complex **1h**, both an aromatic and a benzylic thiolate are offered, the benzylic one as expected reacts first, although not significantly faster than the aromatic one. Compared with the [Tp*Zn−SR] complexes the [(neo)Zn(SR)$_2$] complexes are more reactive due to their more electron-rich ZnN_2S_2 situation.

Unlike the pyrazolylborate ligands the neocuproin ligand cannot encapsulate the zinc ion, thereby approximating its enzymatic environment. This would call for tripodal N_2S ligands, possibly derived from the pyrazolylborates. The synthesis of such ligands is still a challenge. Similar tripodal ligands of the NS_2 and S_3 type exist, however,[39,40] and we are investigating thiolate alkylations of [L·Zn−SR] complexes derived from them.

Experimental Section

General: For general working and measuring procedures, see ref.[41] Starting materials were obtained commercially, except for $Zn[N(SiMe_3)_2]_2$,[42] *o*-(mercaptomethyl)thiophenol,[43] and *o*-bis-(mercaptomethyl)benzene.[44] The methyl thioethers resulting from the methylations have been described[45−48] and were identified by their ^1H NMR spectra. The PPN salts of the thiols were prepared by cation exchange as described.[49]

Elemental Analyses: All new compounds were characterized by elemental analyses which were satisfactory in most cases. Yet, as mentioned in the text, several of the alkylation reactions yielded product mixtures, from which the expected products could not be isolated in a fully pure form. For these products four elements were analyzed, giving an overall satisfactory picture for **1b**, **1e**, **1g**, **4a**, **4b**, and **4g**. Only for **2f**, **3f**, and **4f** was the purity obviously insufficient.

Complex 1a: A solution of $Zn[N(SiMe_3)_2]_2$ (1.71 g, 4.42 mmol) in toluene (50 mL) was added slowly with stirring to a solution of neo·H_2O (1.00 g, 4.42 mmol) and ethanethiol (0.66 mL, 550 mg, 8.8 mmol) in toluene (100 mL) over a period of 2 h. A light yellow precipitate resulted which was filtered and washed two times each with toluene (3 mL) and diethyl ether (3 mL). **1a** (1.50 g, 86%) remained as a light yellow powder, m.p. 250 °C (dec.). $C_{18}H_{22}N_2S_2Zn$ (395.91): calcd. C 54.61, H 5.60, N 7.08, Zn 16.52; found C 53.02, H 5.64, N 6.75, Zn 15.89. ^1H NMR ($CDCl_3$): δ = 1.16 [t, *J* = 7.4 Hz, 6 H, CH_3(Et)], 2.46 [q, *J* = 7.4 Hz, 4 H, CH_2(Et)] ppm.

Complex 1b: Similar procedure to that for **1a** from $Zn[N(SiMe_3)_2]_2$ (1.71 g, 4.42 mmol), neo·H_2O (1.00 g, 4.42 mmol), and benzylmercaptan (1.10 g, 8.84 mmol). Yield 2.10 g (91%) of **1b** as light yellow powder, m.p. 148 °C. $C_{28}H_{26}N_2S_2Zn$ (520.05): calcd. C 64.67, H 5.04, N 5.39, Zn 12.57; found C 65.98, H 5.27, N 4.87, Zn 11.49. ^1H NMR ($CDCl_3$): δ = 3.54 [s, 4 H, CH_2(Bn)], 6.65−6.71 (m, 6 H, Bn), 6.86−6.91 (m, 4 H, Bn) ppm.

Complex 1c: A solution of $Zn(ClO_4)_2·6H_2O$ (0.372 g, 1.00 mmol) in methanol (80 mL) was added very slowly with stirring to a solution of *p*-thiocresol (0.248 g, 2.00 mmol) and NaOMe (0.108 g, 2.00 mmol) in methanol (100 mL) over a period of 3 h; neo·H_2O (0.208 g, 1.00 mmol) in methanol (15 mL) was then added and the mixture stirred overnight. The volume was reduced to 30 mL in vacuo, the precipitate filtered, dried in vacuo, and recrystallized from hot methanol; **1c** (0.41 g, 79%) resulted as yellow crystals, m.p. 207 °C. $C_{28}H_{26}N_2S_2Zn$ (520.05): calcd. C 64.67, H 5.04, N 5.39, S 12.33; found C 64.54, H 5.53, N 5.59, S 12.25. ^1H NMR ([D_6]DMSO): δ = 1.89 [s, 6 H, CH_3(Tol)], 6.28 (d, *J* = 8.0 Hz, 4 H, Tol), 6.64 (d, *J* = 8.0 Hz, 4 H, Tol) ppm.

Complex 1d: Similar to **1a** from $Zn[N(SiMe_3)_2]_2$ (1.46 g, 3.77 mmol), neo·H_2O (0.785 g, 3.77 mmol), and *p*-nitrothiophenol (1.17 g, 7.54 mmol). Recrystallization from toluene yielded **1d** as dark yellow crystals (1.05 g, 48%), m.p. 213 °C. $C_{26}H_{20}N_4O_4S_2Zn$ (581.99): calcd. C 53.66, H 3.46, N 9.63, S 11.02; found C 53.45, H 3.53, N 9.78, S 10.76. ^1H NMR ($CDCl_3$): δ = 7.20 (d, *J* = 8.0 Hz, 4 H, Ar), 7.54 (d, *J* = 8.0 Hz, 4 H, Ar) ppm.

Complex 1e: Like **1c** from $Zn(ClO_4)_2·6H_2O$ (0.093 g, 0.25 mmol), 2,6-diphenylthiophenol (0.131 g, 0.50 mmol), NaOMe (0.027 g, 0.50 mmol), and neo·H_2O (0.052 g, 0.25 mmol). Yield 0.114 g (57%) of **1e** as yellow crystals, m.p. 260 °C (dec.). $C_{50}H_{38}N_2S_2Zn$ (796.39): calcd. C 75.41, H 4.81, N 3.52, S 8.05; found C 74.35, H 4.95, N 3.45, S 7.97. ^1H NMR ($CDCl_3$): δ = 6.74−6.92 (m, 18 H, Ar), 7.11−7.16 (m, 8 H, Ar) ppm.

Complex 1f: Like **1a** from $Zn[N(SiMe_3)_2]_2$ (1.71 g, 4.42 mmol), neo·H_2O (1.00 g, 4.42 mmol) and ethanedithiol (0.41 g, 4.4 mmol). Yield 1.12 g (69%) of **1f** as a yellow solid, m.p. 270 °C (dec.). $C_{16}H_{16}N_2S_2Zn$ (365.84): calcd. C 52.53, H 4.41, N 7.66, S 17.87; found C 52.59, H 4.44, N 7.59, S 17.10. ^1H NMR ($CDCl_3$): δ = 3.03 (s, 4 H, CH_2) ppm.

Complex 1g: Like **1c** from $Zn(ClO_4)_2·6H_2O$ (0.447 g, 1.20 mmol), *o*-bis(mercaptomethyl)benzene (0.204 g, 1.20 mmol), NaOMe (2.45 mmol of a 0.25 M solution), and neo·H_2O (0.272 g, 1.20 mmol). Yield 0.240 g of **1g** as a light yellow powder and, after reducing the volume of the filtrate and cooling, 0.030 g of **1g** as yellow crystals. Total yield 0.270 g (51%) of **1g**, m.p. 270 °C (dec.). $C_{22}H_{20}N_2S_2Zn$ (441.94): calcd. C 59.79, H 4.56, N 6.34, Zn 14.80; found C 58.14, H 4.45, N 6.01, Zn 13.70. ^1H NMR ($CDCl_3$): δ = 4.03 (s, 4 H, CH_2), 7.12−7.18 (m, 2 H, Ph), 7.35−7.39 (m, 2 H, Ph) ppm.

Complex 1h: Like **1c** from $Zn(ClO_4)_2·6H_2O$ (2.62 g, 7.04 mmol), *o*-(mercaptomethyl)thiophenol (1.10 g, 7.04 mmol), NaOMe (0.807 g, 14.9 mmol), and neo·H_2O (1.59 g, 7.04 mmol). Yield 1.56 g of **1h** as a yellow powder and, after reducing the volume of the filtrate and cooling, 0.16 g of **1h** as yellow crystals. Total yield 1.72 g (58%) of **1h**, m.p. 265 °C (dec.). $C_{21}H_{18}N_2S_2Zn$ (427.91): calcd. C 58.95, H 4.24, N 6.55, S 14.99; found C 58.49, H 3.78, N 6.02, S 14.34. ^1H NMR (CD_3OD): δ = 3.97 (s, 2 H, CH_2), 6.95−7.07 (m, 2 H, Ar), 7.27−7.32 (m, 1 H, Ar), 7.46−7.55 (m, 1 H, Ar) ppm.

Alkylations with Methyl Iodide

2a: Complex **1a** (500 mg, 1.26 mmol) and MeI (79 μL, 180 mg, 1.26 mmol) in chloroform (40 mL) were stirred for 2 d. Reduction of the volume in vacuo to 20 mL and layering with diethyl ether (10 mL) yielded **2a** (17 mg, 3%) as a colourless powder, m.p. 300 °C (dec.). $C_{16}H_{17}IN_2SZn$ (461.68): calcd. C 41.63, H 3.71, N 6.07, Zn 14.16; found C 41.00, H 3.58, N 5.86, Zn 14.63. ^1H NMR ($CDCl_3$): δ = 1.33 [t, *J* = 7.3 Hz, 3 H, CH_3(Et)], 2.73 [q, *J* = 7.3 Hz, 2 H, CH_2(Et)] ppm.

2b: Complex **1b** (100 mg, 0.19 mmol) and MeI (12 μL, 27.3 mg, 0.19 mmol) in chloroform (25 mL) were stirred for 2 d. The volume was reduced to 1 mL in vacuo. The precipitate was filtered and washed three times with cold chloroform (1 mL) leaving behind **2b** (90 mg, 89%) as a colourless solid, m.p. 270 °C (dec.) which was not analytically pure. $C_{21}H_{19}IN_2SZn$ (523.75): EI MS: *m/z* (%) = 399.2 (100) [$M^+ - C_6H_5CH_2S$], 314.2 (30) [$C_6H_5CH_2SZnI$]. ^1H NMR ($CDCl_3$): δ = 3.54 (s, 2 H, CH_2), 7.02−7.12 (m, 5 H, Ph) ppm.

2c: Like **1b** with **1c** (133 mg, 0.26 mmol) and MeI (36 mg, 0.26 mmol) for one week. Yield 56 mg (40%) of **2c** as a light yellow solid, m.p. 200 °C. $C_{21}H_{19}IN_2SZn$ (523.75): calcd. C 48.16, H 3.66, N 5.35, S 6.12; found C 48.00, H 3.99, N 5.42, S. 5.75. ^1H NMR ([D_6]DMSO): δ = 1.89 [s, 3 H, Me(Tol)], 6.29 (d, *J* = 7.8 Hz, 2 H, Tol), 6.64 (d, *J* = 7.8 Hz, 2 H, Tol) ppm.

2f: Like **1a** with **1f** (250 mg, 0.68 mmol) and MeI (97 mg, 0.68 mmol). Yield 167 mg (48%) of **2f** as light yellow crystals, m.p. 210 °C (dec.). $C_{17}H_{19}IN_2S_2Zn$ (507.78): calcd. C 40.21, H 3.77, N 5.52, Zn 12.88; found C 36.29, H 3.08, N 5.10, Zn 12.40. ^1H NMR ($CDCl_3$): δ = 2.16 (s, 3 H, SCH_3), 2.77−2.89 (m, 2 H, CH_2), 2.91−3.02 (m, 2 H, CH_2) ppm.

2g: Complex **1g** (500 mg, 1.13 mmol) and MeI (161 mg, 1.13 mmol) in chloroform (40 mL) were stirred for 1 d. The resultant precipitate was filtered, washed with diethyl ether, and dried in vacuo, leaving behind **2g** (302 mg, 47%) as a colourless powder, m.p. 220

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

°C (dec.). $C_{23}H_{23}IN_2S_2Zn$ (583.87): calcd. C 47.31, H 3.97, N 4.80, Zn 11.20; found C 47.16, H 3.89, N 4.67, Zn 12.50. ^{1}H NMR ($CDCl_3$): δ = 2.02 (s, 3 H, SMe), 3.90 [s, 2 H, CH_2(Ar)], 3.96 [s, 2 H, CH_2(Ar)], 6.57−6.70 (m, 1 H, Ar), 6.72−6.84 (m, 1 H, Ar), 6.87−6.95 (m, 1 H, Ar), 6.97−7.05 (m, 1 H, Ar) ppm.

Alkylations with Benzyl Iodide

3f: Complex **1f** (250 mg, 0.68 mmol) and benzyl iodide (149 mg, 0.68 mmol) in chloroform (50 mL) were stirred for 1 d. Layering with hexane yielded **3f** (323 mg, 81%) as a colourless powder, m.p. 330 °C (dec.) which was filtered and dried in vacuo. $C_{23}H_{23}IN_2S_2Zn$ (583.87): calcd. C 47.31, H 3.97, N 4.80, S 10.98; found C 48.61, H 4.33, N 4.52, S 10.14. ^{1}H NMR ($CDCl_3$): δ = 2.79−2.85 (m, 2 H, CH_2), 2.91−2.99 (m, 2 H, CH_2), 3.79 [s, 2 H, CH_2(Bn)], 7.23−7.40 (m, 5 H, Ph) ppm.

3g: Like **1f** with **1g** (567 mg, 1.28 mmol) and benzyl iodide (279 mg, 1.28 mmol). Yield 228 mg (27%) of **3g** as colourless crystals, m.p. 220 °C (dec.). $C_{29}H_{27}IN_2S_2Zn{\cdot}0.5CHCl_3$ (659.97 + 119.38): calcd. C 49.23, H 3.85, N 3.98; found C 49.68, H 3.79, N 4.18. ^{1}H NMR ($CDCl_3$): δ = 3.64 [s, 2 H, CH_2(Ph)], 3.81 [s, 2 H, CH_2(Ph)], 3.91 [s, 2 H, CH_2(Ph)], 6.54−6.62 (m, 1 H, Ar), 6.68−6.75 (m, 1 H, Ar), 6.84 (d, *J* = 7.6 Hz, 1 H, Ar), 7.00 (d, *J* = 7.6 Hz, 1 H, Ar), 7.05−7.30 (m, 5 H, Ar) ppm.

Twofold Methylations

With 1c: Complex **1c** (103 mg, 0.20 mmol) and CH_3I (450 mg, 3.2 mmol) in chloroform (25 mL) were stirred for 2 d. All volatiles were then removed in vacuo and the residue washed with diethyl ether (2 mL) and dichloromethane (2 mL), leaving behind (neo)ZnI_2 (48 mg, 46%) as a colourless powder, m.p. 320 °C (dec.). Crystals for the structure determination were obtained by recrystallization from chloroform. $C_{14}H_{12}I_2N_2Zn$ (527.46): calcd. C 31.88, H 2.29, N 5.31; found C 31.67, H 2.41, N 5.04. ^{1}H NMR ($CDCl_3$): δ = 3.25 (s, 6 H, CH_3), 7.78 (d, *J* = 8.4 Hz, 2 H, H_B), 7.95 (s, 2 H, H_C), 8.47 (d, *J* = 8.4 Hz, 2 H, H_A).

With 1f: Complex **1f** (50 mg, 0.14 mmol) and CH_3I (2.27 g, 16.0 mmol) in chloroform (25 mL) were stirred for 1 week. Workup as above yielded (neo)ZnI_2 (12 mg, 17%).

Methylations with Dimethyl Sulfate

4a: Complex **1a** (281 mg, 0.71 mmol) and $(MeO)_2SO_2$ (67 μL, 89 mg, 0.71 mmol) in chloroform (40 mL) were stirred for 2 d. Reduction of the volume to 20 mL in vacuo and layering with diethyl ether yielded a precipitate which was filtered and washed twice with diethyl ether (5 mL), leaving behind **4a** (285 mg, 90%) as a colourless powder, m.p. 300 °C (dec.). $C_{17}H_{20}N_2O_4S_2Zn$ (445.88): calcd. C 45.79, H 4.52, N 6.28, Zn 14.67; found C 43.48, H 4.15, N 6.07, Zn 14.26. ^{1}H NMR ($CDCl_3$): δ = 1.34 [t, *J* = 7.3 Hz, 3 H, CH_3(Et)], 2.58 [q, *J* = 7.3 Hz, 2 H, CH_2(Et)], 3.68 (s, 3 H, OMe) ppm.

4b: Like **1a** with **1b** (150 mg, 0.29 mmol) and $(MeO)_2SO_2$ (27 μL, 36 mg, 0.29 mmol), yielded **4b** (146 mg, 99%) as a colourless powder, m.p. 150 °C. $C_{22}H_{22}N_2O_4S_2Zn$ (507.95): calcd. C 52.02, H 4.37, N 5.52, Zn 12.87; found C 48.70, H 4.42, N 5.25, Zn 11.57. ^{1}H NMR ($CDCl_3$): δ = 3.66 (s, 3 H, OMe), 3.72 (s, 2 H, CH_2), 6.36−6.51 (m, 3 H, Ph), 6.76−6.85 (m, 2 H, Ph) ppm.

4f: Complex **1f** (160 mg, 0.44 mmol) and $(MeO)_2SO_2$ (45 μL, 60 mg, 0.48 mmol) in chloroform (20 mL) were stirred for 2 d. Layering with hexane (30 mL) yielded, within one week, a mixture of a colourless powder and colourless crystals, which was filtered, washed with diethyl ether, and dried in vacuo. Manual removal of the crystals left behind **4f** (25 mg, 12%), m.p. 270 °C (dec.). $C_{18}H_{22}N_2O_4S_3Zn$ (491.97): calcd. C 43.95, H 4.51, N 5.69, Zn 13.29; found C 42.15, H 3.84, N 6.22, Zn 13.62. ^{1}H NMR ($CDCl_3$, ppm): δ = 2.06 (s, 3 H, SMe), 2.72−2.85 (m, 2 H, CH_2), 2.91−3.01 (m, 2 H, CH_2), 3.69 (s, 3 H, OMe) ppm. The crystals amounted to 5 mg (2%) of **5**, m.p. 254 °C, which was identified by the structural determination.

4g: Like **1f** with **1g** (500 mg, 1.13 mmol) and $(MeO)_2SO_2$ (107 μL, 143 mg, 1.13 mmol), yield **4g** (520 mg, 81%) as a colourless powder, m.p. 160 °C. $C_{24}H_{26}N_2O_4S_3Zn$ (568.07): calcd. C 50.74, H 4.61, N 4.93, Zn 11.50; found C 48.82, H 4.34, N 4.96, Zn 11.47. ^{1}H NMR ($CDCl_3$): δ = 1.89 (s, 3 H, SMe), 3.70 (s, 3 H, OMe), 3.76 (s, 2 H, CH_2), 3.83 (s, 2 H, CH_2), 6.02−6.17 (m, 1 H, C_6H_4), 6.30−6.45 (m, 1 H, C_6H_4), 6.47−6.63 (m, 2 H, C_6H_4).

Methylations of 1c with Trimethyl Phosphate

With 1 Equiv.: Complex **1c** (200 mg, 0.38 mmol) and $PO(OMe)_3$ (54 mg, 0.38 mmol) in DMSO (10 mL) were stirred at 80 °C for 2 weeks. All volatiles were then removed in vacuo at 80 °C. The residue was washed with diethyl ether and dried in vacuo, leaving behind **6** (135 mg, 67%) as a light yellow powder, m.p. 148 °C. $C_{23}H_{25}N_2O_4PSZn$ (521.89): calcd. C 52.93, H 4.83, N 5.37, S 6.14; found C 53.56, H 4.92, N 6.32, S 7.08. ^{1}H NMR ([D$_6$]DMSO): δ = 1.91 [s, 3 H, CH_3(Tol)], 3.30 (d, *J* = 5.2 Hz, 6 H, OMe), 6.34 (d, *J* = 7.0 Hz, 2 H, Tol), 6.70 (d, *J* = 7.2 Hz, 2 H, Tol) ppm.

With 2 Equiv.: As above with **1c** (100 mg, 0.19 mmol) and $PO(OMe)_3$ (133 mg, 0.95 mmol), yielded **7** (85 mg, 85%) as a light yellow powder, m.p. 142 °C. $C_{18}H_{24}N_2O_8P_2Zn{\cdot}H_2O$ (523.73 + 18.02): calcd. C 39.91, H 4.84, N 5.17; found C 39.89, H 5.02, N 4.69. ^{1}H NMR ($CDCl_3$): δ = 1.50 (s, 2 H, H_2O), 3.59 (d, *J* = 10.9 Hz, 12 H, OMe) ppm.

NMR Experiments: For all alkylation reactions described above, from which zinc complexes were isolated, the resultant alkyl thioethers which are known compounds[45−48] were identified by ^{1}H NMR spectroscopy, specifically by their characteristic *S*-methyl resonances. The NMR spectroscopic data showed that none of the reactions were clean, i.e. decomposition reactions and subsequent alkylations set in before the first alkylation step was complete. In those cases where the resultant zinc complexes could not be isolated, i.e. in the CH_3I methylations of **1d** and **1h** and the double methylations with CH_3I and $(CH_3O)_2SO_2$, the information on the reaction course rests on the NMR spectroscopic data alone. Likewise the qualitative determinations of reaction rates were done by ^{1}H NMR spectroscopy. This concerns the rates for methylations versus benzylations, for single versus double methylations and for methylations in chloroform versus methanol.

Thiolate Exchange: 1. A mixture of **1b** (9.9 mg, 19.0 μmol) and NaSEt (1.6 mg, 19.0 μmol) in CD_3OD (0.5 mL) reached equilibrium within 1 h. The intensity ratio of the benzyl CH_2 singlets for **1b** vs. NaSBn was 10:1. 2. **1b** (12.3 mg, 23.8 μmol) and $Na_2[SCH_2-C_6H_4-CH_2S]$ (5.1 mg, 23.8 μmol) in CD_3OD (0.25 mL) immediately produced a light yellow precipitate of **1g**. ^{1}H NMR of the solution showed that no more **1b** remaind and the major organic component was NaSBn.

Kinetic Measurements: The measurements were performed on 0.005−0.02 M $CDCl_3$ solutions of the zinc complex. Kinetic traces were recorded at 10-min intervals for reaction mixtures containing 4−10 mol-equiv. of CH_3I. The intensities of isolated ^{1}H NMR resonances were recorded. In all cases it was observed that the second alkylation sets in before the first half-life of the first alkylation is

reached. This virtually prevented the determination of rate constants. Detailed investigations were made for the CH_3I methylation of **1g** and **1h**. Taking the data for the first hour of the methylation of **1g** (ca. 40% conversion), pseudo-first-order rate constants could be obtained which were roughly 100 times smaller than those for the methylation of $Tp^{Ph,Me}Zn-SBn$ under similar conditions.[30] The methylation of **1h**, for which the kinetic traces are displayed in Figure 5, is about one order of magnitude faster.

Structural Determiantions:[50] Crystals were obtained as described in the Exp. Sect. Diffraction data were recorded at room temp. [**1g**, **1h**, **3g**, (neo)ZnI_2, **5**] and at −90 °C (**1c**, **1d**) with a Nonius CAD4 (**5**) or a Bruker Smart CCD diffractometer [**1c**, **1d**, **1g**, **1h**, **3g**, (neo)ZnI_2]. Empirical absorption corrections were applied for **1c**, **1d**, **1g**, **1h**, **3g**, and (neo)ZnI_2. The structures were solved with direct methods and refined anisotropically using the SHELX[51] program suite. Hydrogen atoms were included at fixed distances and isotropic temperature factors 1.2 times those of the atoms to which they are attached. Parameters were refined against F^2. Drawings were produced with SCHAKAL.[52] Table 2 lists the crystallographic data.

Access to 3-Methyl-4-methylene-*N*-tosylpyrrolidine and 3,4-Dimethyl-*N*-tosylpyrroline by Ruthenium-Catalyzed Cascade Cycloisomerization/Isomerization Reactions

Ismail Özdemir,[a] Engin Çetinkaya,[b] Bekir Çetinkaya,*[b] Metin Çiçek,[a] David Sémeril,[c] Christian Bruneau,*[c] and Pierre H. Dixneuf[c]

Keywords: Ruthenium / Benzimidazole / Homogeneous catalysis / Olefination

New $RuCl_2$(benzimidazole)(arene) complexes have been prepared. Upon reaction with 1,1-diphenylprop-2-ynol they generate catalyst precursors which perform the cycloisomerization of diallyltosylamide into 3-methyl-4-methylene-*N*-tosylpyrrolidine. The presence of *N*-(2,4,6-trimethylbenzyl)benzimidazole as ligand leads to a subsequent isomerization and gives the 3,4-dimethyl-*N*-tosylpyrroline.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Transition metal complexes with nitrogen-containing ligands have recently shown their potential to perform selective catalytic transformations of molecules with atom economy.[1] Especially, a variety of RuX_2(arene)(L) complexes promoting catalytic reactions such as nucleophilic addition to triple bonds to form furans (L = imidazoline, tetrahydropyrimidine,[2] benzimidazole[3]), hydrogen transfer (L = amino acid,[4] amino alcohol,[5] diamine[6]), cyclopropanation (L = diamine[7]), or Diels−Alder cycloaddition and Claisen rearrangement [L = bis(oxazoline)[8,9]]. It is also well established that $RuCl_2$(arene)(L) complexes can easily be transformed by activation of propargylic alcohols into cationic ruthenium(allenylidene) complexes, which have shown catalytic properties in olefin metathesis.[10]

We now report (i) the straightforward preparation of new $RuCl_2$(η^6-arene)(L) complexes with an *N*-coordinated benzimidazole ligand and (ii) their in situ transformation into efficient catalyst precursors for cycloisomerization of diallyltosylamide into 3-methy-4-methylene-*N*-tosylpyrrolidine followed, when a suitable benzimidazole is used (R = mesityl-CH_2), by double bond isomerization to form a pyrroline derivative. This study reveals a very efficient ruthenium catalyst for isomerization of the exocyclic C=CH_2 double bond of 3-methyl-4-methylenepyrrolidine into the tetrasubstituted C=C bond of 3,4-dimethylpyrrolidine derivatives (Scheme 1).

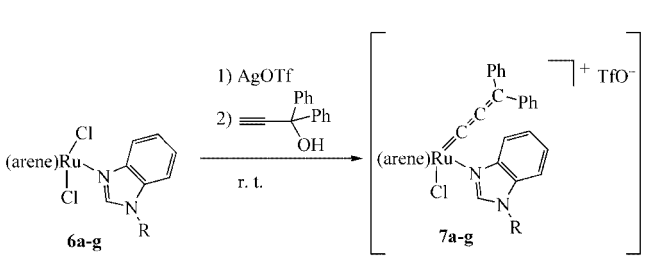
plexes proceeded smoothly in refluxing toluene to give the $RuCl_2$(benzimidazole)(arene) complexes **6a**−**g** as crystalline solids in 82−90% yields (Scheme 2, Table 1).

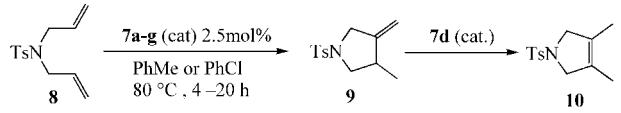
Complexes **6a**−**g**, which are very stable in the solid state have been characterized by analytical and spectroscopic techniques (Table 1). The IR data show the presence of a C=N bond with a ν(C=N) vibration at 1506−1616 cm^{-1}, and the ^{1}H NMR spectra clearly exhibit a singlet at δ = 7.70−8.44 ppm typical of the N=CH−N fragment. In the ^{13}C NMR spectrum, the chemical shift of the corresponding C-2 atom was detected in the region δ = 142.96−146.18 ppm with a $^{1}J_{C,H}$ coupling constant close to 200 Hz. These new complexes show typical spectroscopic signatures which are in line with those recently reported for other $RuCl_2$(arene)(benzimidazole) complexes with R = Me, Et, $(CH_2)_2NEt_2$, $(CH_2)_2CO_2Et$.[3]

In contrast with the related (arene)$RuCl_2$(phosphane),[11] (arene)$RuCl_2$(diaminocarbene) complexes,[12,13a] **6** presented no metathesis catalytic activity for the transformation of *N*,*N*-diallyltosylamide (**8**). The known catalytic activities of [RuCl(=C=C=CPh_2)(arene)(L)][X] (L = PCy_3,[10] diaminocarbene[13]) to perform the ring-closing metathesis of dienes and ring-opening metathesis polymerization of cyclic olefins, provided impetus to prepare the corresponding cationic ruthenium(allenylidene)(benzimidazole) complexes according to the reaction depicted in Scheme 3. Indeed, purple complexes were prepared in dichloromethane but they were not stable enough to be cleanly isolated and characterized. Based on previous results obtained with more stable ruthenium(allenylidene) complexes from analogous precursors,[10,13] we assumed that the new organometallic species **7a**−**g** (Scheme 3) contained the $[RuCl(arene)(benzimidazole)(allenylidene)]^+$ cation. In order to circumvent this instability problem, they were generated in situ from complexes **6a**−**g** just before use, by abstraction of chloride with silver triflate followed by addition of 1,1-diphenylprop-2-ynol at room temperature in the selected solvent (Scheme 3).



Scheme 3

The catalytic performances of these in situ generated precursors were evaluated in the transformation of *N*,*N*-diallyltosylamide (**8**) at 80 °C in various solvents (Scheme 4, Table 2).



Scheme 4

Table 2. Catalytic transformation of *N*,*N*-diallyltosylamide (**8**)

Catalyst	Solvent	Time [h]	Conversion [%]	**9** [%]	**10** [%]
7a	PhCl	18	100	100	
7b	PhMe	13	76	76	
7b	PhCl	10	100	100	
7c	PhMe	12	37	37	
7c	PhCl	10	82	82	
7d	PhMe	4	100	100	
7d	PhMe	10	100		100
7d	PhCl	6	98	60	38
7d	PhCl	10	100		100
7e	PhCl	18	65	65	
7f	PhMe	10	58	58	
7f	PhCl	20	100	100	
7g	PhCl	20	79	40	39

Thus, the catalyst was first generated by successive additions of silver triflate (0.0125 mmol) and HC≡$CCPh_2OH$ (0.0125 mmol) to a solution of **6** (0.0125 mmol, 2.5 mol %) in 2.5 mL of solvent and stirred at room temperature for 20 min. The diene **8** (0.5 mmol) was then added and the solution was heated at 80 °C for 4−20 h. The catalytic precursors thus prepared in situ showed catalytic activity for the transformation of the 1,6-diene **8** into the cycloisomerization compounds **9** or **10**. According to this procedure, the presence of the diene **8** added just after the preparation of **7** might stabilize organometallic intermediates and generate catalyst precursors with long-lasting activity.

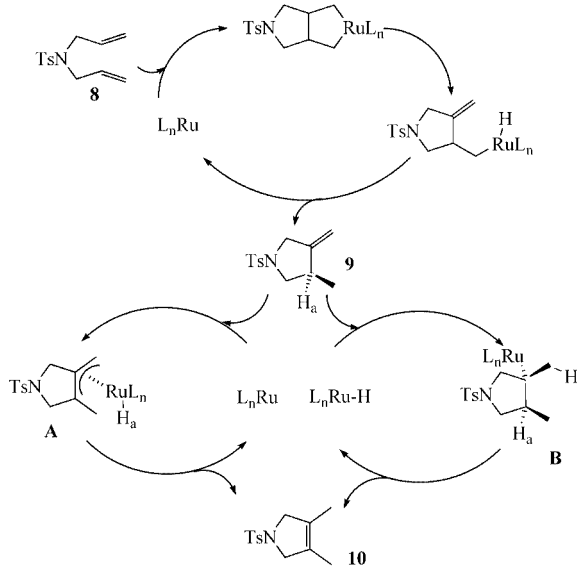
In contrast with the catalyst arising from the allenylidene complex [RuCl(=C=C=CPh_2)(PCy_3)(*p*-cymene)][OTf],[10]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

no trace of *N*-tosyl-2,5-dihydropyrrole was detected, which indicated that no metathesis reaction took place with precursors **7**.

The catalysts resulting from **6a**−**c** and **6e**−**f**, which bear an aliphatic R group as substituent of the benzimidazole ligand led to the formation of the 3-methyl-4-methylene heterocycle **9**. The reaction was faster in chlorobenzene than in toluene and the total conversion of the starting substrate could be achieved in 10 h with the precatalyst **7b** and within 18−20 h with **7a** and **7f**.

The catalytic species generated from **7d** containing the *N*-(2,4,6-trimethylbenzyl)-substituted benzimidazole ligand **5** was much more efficient and the complete conversion of **8** to **9** was carried out in toluene in less than 4 h. Under the reaction conditions, a subsequent isomerization took place which led to 3,4-dimethyl-*N*-tosylpyrroline (**10**) bearing a tetrasubstituted endocyclic double bond in quantitative yield at 80 °C after 10 h, whatever the solvent. Apparently, in toluene, as the formation of **10** starts only after complete conversion of **8**, the presence of the starting diene inhibits the isomerization of **9** to **10**. The analogous catalytic system **7g** resulting from the C_6Me_6-containing precursor was less active at 80 °C after 20 h, as the conversion reached only 79 % and a 1:1 mixture of **9** and **10** was obtained. This observation is consistent with the hypothesis of the initial displacement of the arene ligand to generate the catalytic species (Scheme 5).[13b,14,15] During the catalytic process, the formation of indenylidene complexes by rearrangement of the allenylidene ligand, cannot be ruled out.[16]



Scheme 5

From a separate experiment, it was possible to show that **10** resulted from the catalytic isomerization of **9** in the presence of **7d** as catalyst. Thus, by using the catalytic system prepared in situ from 2.5 mol % of the ruthenium precursor **6d**, AgOTf (2.5 mol %) and HC≡CCPh$_2$OH (2.5 mol %) in 2.5 mL of toluene, **9** (0.5 mmol) was completely converted into **10** at 80 °C after 4 h. Two possible mechanisms could account for this isomerization: (i) allylic C−H activation and H migration via an (allyl)(hydrido)ruthenium intermediate **A** or (ii) if a Ru−H species is formed, by insertion of the exocyclic double bond into a Ru−H bond followed by β-elimination (Scheme 5). Both processes should be stereoselective as the coordination of the Ru atom should preferentially take place on the less hindered face of **9**. Thus, β-elimination from **B** should be favored with H_a in the *syn* position, as well as the (allyl)ruthenium formation by coordination to **9** on the sterically less hindered face.

Transition-metal-catalyzed cycloisomerization reactions from α,ω-dienes is a topic of current interest.[17] The formation of 3-methyl-4-methylene cyclic derivatives of type **9** has already been observed with several metal catalysts including palladium,[18,19] nickel,[19] rhodium[20] and titanium.[21] Other efficient catalytic systems based on ruthenium precursors such as $[Ru(cod)Cl_2]_n$ or Cp*Ru(cod)Cl in protic solvents,[22] or generated in situ from $[RuCl_2(p\text{-cymene})]_2$, an imidazolinium salt and a base,[15] have been reported.

A few examples of cycloisomerization of 1,6-diene into 1,2-dimethylcyclopentene derivatives involve palladium catalysts in the presence of silane[23] or rhodium catalysts,[20] and most of the substrates which lead to these cycloisomerization products are 2,2-diallylmalonate derivatives. In the present ruthenium-catalyzed isomerization of **8** to **10**, the role of the 2,4,6-trimethylbenzyl ligand in **7d** appears to be crucial. It might result from temporary interaction of the mesityl group with the metal center as its coordination operates with closely related diaminocarbene ligands.[13b,14]

Conclusion

New ruthenium species generated in situ from $RuCl_2$(arene)(benzimidazole) complexes in the presence of 1,1-diphenylprop-2-ynol are active catalysts to perform the cycloisomerization of *N*,*N*-diallyltosylamide to the *N*-tosylpyrrolidine **9** featuring an exocyclic methylene group under neutral and mild conditions. The catalyst containing the benzimidazole **5** (R = 2,4,6-$Me_3C_6H_2CH_2$) exhibits specific catalytic properties. It leads to the fastest cycloisomerization reaction and in addition offers the first example of ruthenium-catalyzed isomerization of 3-methyl-4-methylene-*N*-tosylpyrrolidine (**9**) to 3,4-dimethyl-*N*-tosylpyrroline (**10**).

Experimental Section

General: Manipulations were carried out with standard Schlenk techniques under nitrogen with previously dried solvents. The complexes $[RuCl_2(arene)]_2$ were prepared according to known methods.[24] 1-Substituted benzimidazoles **2**−**5** were prepared by alkylation of the potassium salt of benzimidazole. Infrared spectra were recorded as KBr pellets in the range 400−4000 cm^{-1} with an ATI UNICAM 2000 spectrometer. ^{1}H NMR (300 MHz) and ^{13}C NMR (75.5 MHz) were recorded with a Bruker AM 300 WB FT spectrometer with chemical shifts referenced to residual solvent $CDCl_3$. Microanalyses were performed by the TÜBITAK analyses centre.

Preparation of the Ruthenium(benzimidazole) Complexes 6a−g: A solution of the *N*-substituted benzimidazole **2**−**5** (1.05 mmol) and $[RuCl_2(p\text{-cymene})]_2$ or $[RuCl_2(hexamethylbenzene)]_2$ (0.5 mmol) in toluene (15 mL) were heated under reflux for 2 h. Upon cooling to room temperature, orange crystals of **6a**−**g** were obtained. The crystals were filtered, washes with diethyl ether (3 × 10 mL) and dried under vacuum.

$RuCl_2$(*p*-cymene)(*N*-isopropylbenzimidazole) (6a): ^{1}H NMR (300 MHz, $CDCl_3$): δ = 8.44 (s, 1 H, N=C*H*), 7.33 (m, 4 H, C_6H_4), 5.42 and 5.32 [2 × d, *J* = 6.00 Hz, 4 H, $(CH_3)_2CHC_6H_4CH_3$], 4.58 [sept, *J* = 6.70 Hz, 1 H, C*H*$(CH_3)_2$], 2.06 [s, 3 H, $(CH_3)_2CHC_6H_4CH_3$], 1.83 [sept, *J* = 7.00 Hz, 1 H, $(CH_3)_2CHC_6H_4CH_3$], 1.49 [d, *J* = 6.70 Hz, 6 H, CH$(CH_3)_2$], 1.18 [d, *J* = 7.00 Hz, 6 H, $(CH_3)_2CHC_6H_4CH_3$] ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 142.9 (N=*C*H), 142.2, 133.2, 123.8, 123.5, 120.7, 111.5 (m, C_6H_4), 102.4, 97.9, 82.8, 81.2 $[(CH_3)_2CHC_6H_4CH_3]$, 49.0 [*C*H$(CH_3)_2$], 30.7 $[(CH_3)_2CHC_6H_4CH_3]$, 22.5 [CH$(CH_3)_2$], 22.3 $[(CH_3)_2CHC_6H_4CH_3]$, 18.5 $[(CH_3)_2CHC_6H_4CH_3]$ ppm. Gold and Silver Complexes with the Ligands *N*-[Bis(isopropoxy)-thiophosphoryl]thiobenzamide and *N*-[Bis(isopropoxy)thiophosphoryl]-*N′*-phenylthiourea

Olga Crespo,[a,b] Vasiliy V. Brusko,[c] M. Concepción Gimeno,[a] M. Loreto Tornil,[b] Antonio Laguna,*[a] and Nail G. Zabirov[c]

Keywords: Gold / Silver / Sulfur / Thiourea / Thioamide

Gold and silver complexes with the *N*-[bis(isopropoxy)-thiophosphoryl]thiobenzamide (HL^1) and *N*-[bis(isopropoxy)-thiophosphoryl]-*N′*-phenylthiourea (HL^2) ligands are reported. The compounds $[M(HL)(PPh_3)]TfO$, $[Ag(HL)(TfO)]$ and $[Ag(HL)(PPh_3)_2]TfO$ were obtained by the reaction of both ligands with the corresponding trifluoromethanesulfonate salts. The (acetylacetonato)gold and -silver materials $[M(acac)(PPh_3)]$ or $[Au(acac)(C_6F_5)_2]$ cause deprotonation of the ligands and afford $[ML(PPh_3)]$ or $[AuL(C_6F_5)_2]$, whereas the reaction of $[Au(TfO)(PPh_3)]$ with HL^1 in a 2:1 molar ratio in KOH/MeOH affords $[Au_2(L^1)(PPh_3)_2]TfO$. The first homoleptic anionic metal compounds $[Au^IL_2]^-$ are also reported.

Introduction

The chemistry of chelating ligands attached to metal centers through sulfur atoms has been extensively investigated. Unusual coordination at the metal centers and interesting stereochemistries of the chelate rings have been found. Among them, the coordination chemistry of *N*-(thiophosphoryl)thioamides or *N*-(thiophosphoryl)thioureas has been studied and extraction of metals using *N*-[bis(isopropoxy)thiophosphoryl]thiobenzamide has been reported[1] as well as a liquid ion-selective electrode for Hg^{2+} determination.[2] Different $R^1C(X)NHP(Y)R^2R^3$ ligands have been reported[3−10] (R^1 = R-NH or NX_2 X = H, alkyl or aryl group; R^2, R^3 = alkyl, aryl, alkoxy or aryloxy group, X = O, S; Y = O, S, Se) and despite the tautomeric forms in which they can exist, infrared studies on some of them support the presence of structures in which two double bonds C=S and P=S are present[7] although delocalization of the C−NH−P unit has been found as more representative of the bonding in the crystal structures[11] of $PhC(S)NHP(S)(OR)_2$ (R = *i*Pr, Et). The species consisting on one 1,10-diaza-18-crown-6 with two "$(O\textit{i}Pr)_2P(S)NHC(S)$" units bonded to the nitrogen atoms has also been described.[8]

A brief overview of the chemistry with representative elements includes the potassium derivatives in which the metal atom is bonded to the sulfur atoms of "$(O\textit{i}Pr)_2P(S)NHC(S)Ph$". The potassium atom can be in the center of a diaza-18-crown-6 cycle, or as part of a more complicated structure.[12,13] Other examples of coordination to representative elements include the mononuclear hexacoordinate compounds prepared from the reactions of different ligands with $SnCl_4$ although the geometries were not confirmed by X-ray studies,[14] and the lead derivatives $[Pb\{(O\textit{i}Pr)_2P(X)NC(S)Ph\}_2]$.[15] The $[M^{2+}L_2]$ stoichiometry is the most common among the transition metal complexes described so far (M = Ni, Co, Pt, Pd, Zn, Cd)[6,7,16−22] which have been confirmed in many cases by single-crystal X-ray diffraction studies.

Among the reported complexes, those containing the coinage metals are however scarcely represented. The synthesis of $[Cu\{PhNHC(S)NP(S)(O\textit{i}Pr)_2\}]$[5] and also the reduction of Cu^{II} to Cu^I with other ligands[23] such us $PhNHC(S)NHP(S)Ph_2$, $Me_2NC(S)NHP(S)Ph_2$, or $Et_2NC(S)NHP(S)(OPh)_2$ have been described. For the latter, the crystal structure[24] consists on a trinuclear derivative of formula $[Cu\{Et_2NC(S)NP(S)(OPh)_2\}]_3$. The three-coordinate environment of the copper atom in $[Cu\{PhC(O)NP(S)Ph_2\}(PPh_3)]$[7] has also been described. To the best of our knowledge the only such silver complex reported is the tetranuclear derivative $[Ag\{PhC(S)NP(S)(O\textit{i}Pr)_2\}]_4$,[25] but no related gold complexes have been described. In this paper we report the synthesis and characterization of gold and silver complexes with the *N*-[bis(isopropoxy)thiophosphoryl]thiobenzamide

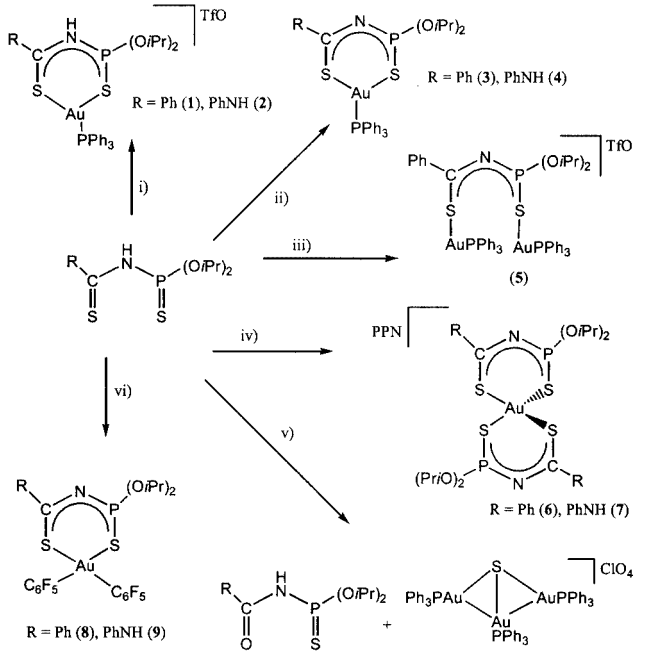
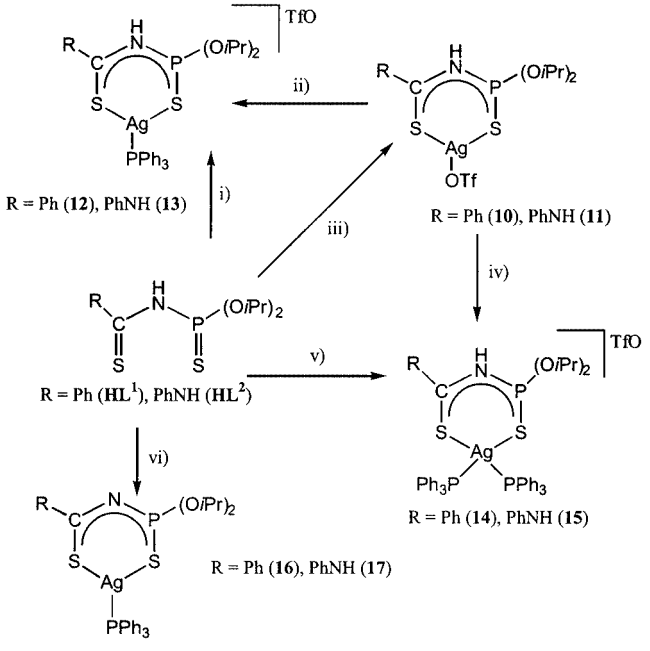
[PhC(S)NHP(S)(O*i*Pr)$_2$, HL^1) and *N*-[bis(isopropoxy)-thiophosphoryl]-*N*′-phenylthiourea (PhNHC(S)NHP(S)-(O*i*Pr)$_2$, HL^2) ligands (see Schemes 1 and 2). The first homoleptic anionic metal compounds [Au^{I}L$_2$]$^-$ are also reported. The previously reported derivatives are neutral (the metal oxidation state is +II) and different stoichiometries were obtained when the oxidation state was +I. In many of the derivatives shown here, coordination of the ligand takes place without any previous deprotonation of the ligands.



Scheme 1. i) [Au(TfO)(PPh$_3$)]/CH$_2$Cl$_2$, ii) [Au(TfO)(PPh$_3$)]/KOH, MeOH, iii) 2 [Au(TfO)(PPh$_3$)]/KOH, MeOH, iv) 1/2 PPN[Au(acac)$_2$]/CH$_2$Cl$_2$, 1/2 PPN[AuCl$_2$]/KOH, MeOH, v) [O{Au(PPh$_3$)}$_3$]ClO$_4$/CH$_2$Cl$_2$, vi) [Au(C$_6$F$_5$)$_2$(acac)]/CH$_2$Cl$_2$, NBu$_4$[Au(C$_6$F$_5$)$_2$]/KOH, MeOH



Scheme 2. i) [Ag(TfO)(PPh$_3$)]/CH$_2$Cl$_2$, ii) PPh$_3$, iii) AgTfO/CH$_2$Cl$_2$, iv) 2 PPh$_3$, v) [Ag(TfO)(PPh$_3$)$_2$]/CH$_2$Cl$_2$, vi) [Ag(TfO)(PPh$_3$)]/KOH, MeOH, [Ag(acac)(PPh$_3$)]/CH$_2$Cl$_2$

Results and Discussion

All the complexes described below are air and moisture stable. The behavior of their acetone solutions corresponds to their proposed neutral or ionic structures (Tables 1 and 2 show the conductivity values, yields, elemental analyses for C, H, N and S, NMR and mass spectral data for all the complexes presented). Characteristic absorptions are present in the IR spectra of the ligands.

Thus, in HL^1 the ν(NH) vibration appears at 3240 cm^{-1} and the ν(P=S) at 648. In HL^2 the ν(P=S) vibration appears at 640 cm^{-1}. Two ν(NH) vibrations appear at 3200 (Ph−NH) and 3063 cm^{-1} (C−NH−P), the second being observed as a shoulder of the nujol band in the spectrum of HL^2. In the discussion we will comment on the modification of the first band and the other band always appears as a shoulder on the nujol band in the complexes in which the ligand HL^2 has not been deprotonated. The shifts of the ν(P=S) IR band and the ^{31}P{^{1}H} NMR resonance due to the phosphorus atom of the ligand from those in the free ligands point to the involvement of the sulfur atom of the PS unit in the formation of the complexes. The shift of the ν(NH) vibration in the SCN(H)PS unit in the complexes which contain ligands which have not been deprotonated could point to the formation of a six-membered chelating ring. This is a reasonable proposal since tendency of the ligands to coordinate in a chelating form has already been shown in the literature and has also been confirmed by the X-ray structures of two of the compounds described herein.

Gold Complexes

The displacement of the labile trifluoromethanesulfonate ligand in [Au(TfO)(PPh$_3$)] affords the complexes [Au(HL^1)(PPh$_3$)]TfO (**1**) and [Au(HL^2)(PPh$_3$)]TfO (**2**). The vibrations corresponding to the anionic TfO groups are present in their IR spectra [$\nu_{asym}(SO_3)$ 1270, $\nu_{sym}(CF_3)$ 1225, $\nu_{asym}(CF_3)$ 1151, $\nu_{sym}(SO_3)$ 1033 cm^{-1}].[26] In **1** the ν(NH) absorption appears at 3242 cm^{-1} and the ν(P=S) at 579. In **2** they appear at 3205 and 580 cm^{-1}, respectively. In their ^{1}H NMR spectra the isopropyl hydrogen atoms appear at approximately δ = 1.3 (CH$_3$) and 5.0 (CH) ppm. The NH hydrogen atoms of the amido-thiophosphoryl groups appear at around δ = 10 (**1**) or 11 (**2**) ppm. The values in each case are at lower fields than in the corresponding ligands (δ = 8.05 ppm HL^1; 9.61 ppm HL^2). In the spectrum of **2** the shift of the other NH hydrogen atom (δ = 9.69 ppm) also appears downfield of the corresponding shift in HL^2 (δ = 7.01 ppm).

The ^{31}P{^{1}H} NMR spectra show two resonances, as expected, for the two nonequivalent phosphorous atoms. Those observed near δ = 50 ppm can be assigned to the phosphorous atoms of the HL^1 or HL^2 coordinated fragments. In **1** the signal is δ = 2.6 ppm upfield from that in

the free ligand and in **2** it is shifted δ = 2.1 ppm downfield of that in free HL^2. The signal in the higher field region can be assigned to the triphenylphosphane ligand. In the Liquid Secondary Ion Mass Spectra (LSIMS +) of **2** the cation molecular peak can be observed at *m*/*z* = 792 (13 % intensity), although the most intense peak corresponds to the species [Au(PPh$_3$)]$^+$ (*m*/*z* = 459). The cationic molecular peak was not observed in the spectrum of **1** and the most intense peak corresponds to the species [Au(PPh$_3$)]$^+$ in this case also. An observation of note is the presence in both spectra of the peak corresponding to [Au$_2$L(PPh$_3$)$_2$]$^+$ which indicates the important stability of these species. This observation led us to specifically investigate the synthesis of complexes of higher nuclearity. The starting compound [O{Au(PPh$_3$)}$_3$]$^+$ is a good deprotonating agent which can also be used to introduce between one and three "Au(PPh$_3$)" fragments. The results of such reactions with both ligands in a 1:1 molar ratio are shown in Scheme 1. In both cases, the cleavage of the C=S bond and the formation of the corresponding *N*-[bis(isopropoxy)thiophosphoryl]-benzamide [^{31}P{^{1}H} NMR: δ = 58.7(s)ppm] or *N*-[bis(isopropoxy)thiophosphoryl]-*N*′-phenylurea [^{31}P{^{1}H} NMR: δ = 58.2(s) ppm] and the gold complex [S{Au(PPh$_3$)}$_3$]$^+$ (^{31}P{^{1}H} NMR: δ: s, 33.4 ppm) were observed. Deprotonation of the ligands and coordination of only one "Au(PPh$_3$)" fragment is possible by using the starting compound [Au(acac)(PPh$_3$)] (acac = acetylacetonate). This reaction afforded [AuL^1(PPh$_3$)] (**3**) and [AuL^2(PPh$_3$)] (**4**). In the IR spectra of the latter complexes, the ν(P=S) vibrations appear at 584 and 577 cm^{-1}, respectively. The ν(NH) vibrations due to the "CN(H)P" fragments were not observed and in the spectrum of **4** the ν(NH) vibration corresponding to the "PhNH" unit appears at 3293 cm^{-1}. The ^{1}H NMR spectra also corroborate the observed deprotonation of the ligands since no signal corresponding to the "CN(H)P" fragment could be observed. In the spectrum of **4** the signal corresponding to the "PhNH" hydrogen atom overlaps with the broad signal arising from the protons of the PPh$_3$ group. The ^{31}P{^{1}H} NMR spectra of **3** and **4** show similar patterns to those observed in the spectra of **1** and **2**. It is of note that the chemical shifts observed for the thiophosphoryl phosphorous atoms are less significant compared with those of the analogous nondeprotonated complexes **1** and **2**. The signals corresponding to the triphenylphosphane ligands are shifted about 1 ppm downfield in both cases. In the LSIMS + the molecular peaks

[a] Theoretical values in brackets. [b] $\Omega^{-1}cm^2mol^{-1}$. [c] δ in ppm. [d] v.m. means more than one multiplet.

appear at *m*/*z* = 776 (16 %) (**3**) and 791 (8 %) (**4**). The reaction of HL^1 or HL^2 with [Au(TfO)(PPh$_3$)] in a 1:1 molar ratio in MeOH with a stoichiometric amount of KOH affords **3** or **4**. The reaction in a 1:2 molar ratio of HL^1 with [Au(TfO)(PPh$_3$)] in KOH/MeOH affords [Au$_2$L^1(PPh$_3$)$_2$]TfO (**5**). In the IR spectrum of **5** the vibrations corresponding to the anionic trifluoromethanesulfonate are observed and the ν(P=S) band appears at 579 cm^{-1}. The ligand deprotonation is confirmed by the absence of the NH vibration in the IR spectrum and an analysis of the ^{1}H NMR spectrum in which only those absorptions corresponding to the isopropyl and phenyl groups are observed. The ^{31}P{^{1}H} NMR spectrum display two signals, that at δ = 49.9 ppm can be assigned to the phosphorus atom of the thiophosphoryl group with the other (a broad signal) corresponding to the triphenylphosphane ligands. The cationic molecular peak is present in the LSIMS + (*m*/*z* = 1234, 52 %). The same reaction with HL^2 affords a solid, the ^{31}P{^{1}H} NMR spectrum of which displays five signals. The most intense resonance corresponds to the [S{Au(PPh$_3$)}$_3$]$^+$ cation and two of the signals which appear with very weak intensities at 54.9 and 37.0 ppm possibly correspond to the analog of **5** i.e. [Au$_2$L^2(PPh$_3$)$_2$]TfO. In fact, the LSIMS + shows a peak corresponding to the species [Au$_2$L^2(PPh$_3$)$_2$] (*m*/*z* = 1249, 28 %) and the proposed structure is shown in Scheme 1.

We have also investigated the reactivity of these ligands towards PPN[Au(acac)$_2$] in a molar ratio of 2:1. The resultant compounds PPN[Au(L^1)$_2$] (**6**) and PPN[Au(L^2)$_2$] (**7**) show ν(P=S) bands at 610 and 578 cm^{-1}, respectively. In **7** the ν(NH) vibration appears at 3302 cm^{-1}. The ^{1}H NMR spectra show the phenyl and isopropyl protons and in the case of compound **7** the NH hydrogen atom appears at δ = 8.52 ppm. Two signals are present in their ^{31}P{^{1}H} NMR spectra. The resonance at approximately δ = 63 ppm can be assigned to the thiophosphoryl group which shows a very significant downfield shift from the signals of the ligands. The other signal at δ = 21.2 ppm corresponds to the PPN cation. The anionic molecular peak of compound **6** is present in the LSIMS − (*m*/*z* = 829, 85 %). Although no structural confirmation has been obtained by X-ray crystallography, a homoleptic mononuclear derivative has been proposed. More complicated arrangements consisting of more that one "[AuL$_2$]$^+$" unit could give rise to the same conductivity and elemental analysis values but are considered to be much less probable. Based on the probable chelate mode

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the ligand and the results of similar studies with other metals we are inclined to favor a tetra-coordinated arrangement as the most likely structure.

The syntheses of gold(III) complexes derived from [Au(acac)(C_6F_5)$_2$] have also been carried out. The resultant products, [Au(C_6F_5)$_2$(L^1)] (**8**) and [Au(C_6F_5)$_2$(L^2)] (**9**), show ν(P=S) vibrations at 567 and 591 cm^{-1}, respectively, and in **9** the ν(NH) vibration appears at 3403 cm^{-1}. The vibrations corresponding to the pentafluorophenyl rings are also present at around 1508, 964 and 784 cm^{-1}. In both derivatives the deprotonation of the ligands is evident from the ^{1}H NMR spectra. Very notable high field shifts from the values in the free ligands were observed in the ^{31}P{^{1}H} spectra for both complexes (see Table 1). The ^{19}F spectra show the presence of two nonequivalent pentafluorophenyl rings, five signals were observed in the ratio of 1(F_p):1(F_p):2(F_o):2(F_o):4(F_m). The signal at approximately δ = −160 ppm corresponds to the *meta* fluorine atoms. The fluorine atoms in the *para*- and *ortho*-positions give rise to two triplets at around δ = −158 ppm and two multiplets at approximately δ = −121 ppm, respectively. The molecular peaks are present in the LSIMS + at *m*/*z* = 848 (24 %) (**8**) and 863 (42 %; **9**).

Silver Complexes

The reaction of AgTfO with both ligands in a molar ratio of 1:1 afforded the complexes [Ag(TfO)(HL^1)] (**10**) and [Ag(TfO)(HL^2)] (**11**). Their conductivity values in acetone solution are between those described for the presence of no electrolyte and a 1:1 electrolytic species. This is due to the lability of the trifluoromethanesulfonate anion. In their IR spectra the vibrations corresponding to the presence of covalent TfO[26] groups are present [$\nu_{asym}(SO_3)$ 1283 and 1240, $\nu_{sym}(CF_3)$ 1220, $\nu_{asym}(CF_3)$ 1180, $\nu_{sym}(SO_3)$ 1030 cm^{-1}]. The ν(NH) and ν(P=S) vibrations appear at 3290, 575 (**10**) or 3270, 598 (**11**) cm^{-1}. In the ^{1}H NMR spectrum of **10** the NH hydrogen atom bonded to the thiophosphoryl group is coincidental with the multiplet which corresponds to the phenyl protons whereas in **11**, it appears at δ = 10.65 ppm. The other NH proton in **11** shows a resonance at δ = 9.58 ppm. Their ^{31}P{^{1}H} NMR spectra both display one singlet near δ = 50 ppm. These resonances are shifted upfield by δ = 5.5 ppm in (**10**) and downfield by δ = 1.2 ppm in (**11**) from those of the free ligands. The LSIMS + of complex **11** shows the cationic molecular peak [Ag(HL^2)]$^+$ at *m*/*z* = 441 (47 %).

Displacement of the trifluoromethanesulfonate anion and deprotonation in **10** and **11** allows the synthesis of different complexes. Thus, the reaction with triphenylphosphane in a 1:1 or 1:2 molar ratio affords the three-coordinate [Ag(HL^1)(PPh_3)]TfO (**12**), [Ag(HL^2)(PPh_3)]TfO (**13**) or four-coordinate [Ag(HL^1)(PPh_3)$_2$]TfO (**14**) and [Ag(HL^2)(PPh_3)$_2$]TfO (**15**) complexes. Compounds **12** and **13** can also be obtained by reaction of the ligands with [Ag(TfO)(PPh_3)] in a 1:1 molar ratio. In their IR spectra the vibrations corresponding to the TfO$^-$ anion are present and those due to ν(P=S) appear at 575 (**12**) and 574 cm^{-1} (**13**). The NH bands appear at 3260 (**12**) or 3220 (**13**) cm^{-1}. In the ^{1}H NMR spectra, resonances arising from the hydrogen atoms of the NH groups bonded to the thiophosphoryl groups are shifted to low field from those of the free ligands. An additional signal is present in **13** at δ = 9.61 ppm due to the hydrogen atom of the NH urea unit. In the ^{31}P{^{1}H} NMR spectra the two nonequivalent phosphorus atoms display resonances with different shapes. One of them, assigned to the thiophosphoryl group, is a narrow resonance which appears at about δ = 54 ppm while the other is broad and corresponds to the triphenylphosphane ligand. When the spectra were recorded at −55 °C the broad resonances split into two doublets as a consequence of the phosphorus atom coupling to the two silver isotopes, ^{107}Ag and ^{109}Ag. The LSIMS + show the cationic molecular peaks in both cases [*m*/*z* = 686, 28 % (**12**); 704, 31 % (**13**)].

Like **12** and **13**, complexes **14** and **15** can also be obtained by reaction of the ligands with [Ag(TfO)(PPh_3)$_2$] in a 1:1 molar ratio. In their IR spectra the ν(P=S) vibrations appear at 571 (**14**) and 573 (**15**) cm^{-1}, and those arising from the NH groups come at 3280 (**14**) and 3220 (**15**) cm^{-1}. In the ^{1}H NMR spectra of **15** both the NH resonances can be observed whereas in **14** the resonance of the hydrogen atom of the NH group is obscured by the phenyl hydrogen resonances. The ^{31}P{^{1}H} NMR spectra show the same patterns observed for **12** and **13** but only in the case of **15** the broad signal becomes split at low temperature (even at −85 °C). For these four-coordinate complexes the resonances due to the triphenylphosphane ligands appear near δ = 7 ppm which is upfield of those in the three-coordinate analogs. The structure of both complexes have been analyzed by X-ray studies which reveal the expected four-coordination (tetrahedral geometry) around the silver center (Figure 1, Figure 2). In compound **14** the ring defined by Ag(1), S(1), P(1), N(1), C(1) and S(2) adopts a boat conformation in which the angle between the planes defined by S(1), P(1), Ag(1), S(2) and P(1), N(1), C(1), S(2) is 53.7°. Compound **15** shows a twist boat conformation in which the atoms S(1), Ag(1), S(2) and C(1) lie in the same plane. Similar Ag−P bond lengths (Tables 2 and 3) can be observed in both complexes which vary from 2.4712(8) to 2.4909(7) Å. The shortest values of those found in [Ag(dppe)$_2$]NO_3 [2.488(3)−2.527(3) Å][27] are very close to those in **14** and **15** and also those found in [Ag(phen){(PPh_2)$_2$$C_2B_{10}H_{10}$}]$ClO_4$ [2.463(2), 2.479(2) Å].[28] Longer values have been found in [Ag{($SPPh_2$)$_2$$CH_2$}{($PPh_2$)$_2$$C_2B_{10}H_{10}$}]$ClO_4$ [2.526(2), 2.532(2) Å][28] and in [Ag(PPh_3)$_4$]ClO_4 (1 × 2.650(2), 3 × 2.668(5) Å].[29] Two different Ag−S bond lengths are present in each complex, the distances to the sulfur atoms of the thiophosphoryl groups are longer [2.6952(8) Å (**14**), 2.6648(8) (**15**) Å] than the other Ag-S distances [2.5892(2) Å (**14**), 2.5379(8) (**15**) Å] in both complexes (Table 4). These values can be compared with those found in other tetrahedral silver complexes such as [AgBr(18S_6)] (18S_6 = 1,4,7,10,13,16-hexathiacyclooctadecane) [2.514(1)−2.636(1) Å],[30] [Ag{($SPPh_2$)$_2$$CH_2$}{($PPh_2$)$_2$$C_2B_{10}H_{10}$}]$ClO_4$ [2.540(2), 2.588(2) Å],[28] [Ag{$S_2C_2(CN)_2$}(PPh_3)$_4$][31]

The syntheses of deprotonated derivatives have been carried out by two synthetic routes just as for the gold complexes. The first is the use of $(acac)^-$ as a deprotonating agent, the other using methanol and KOH. The reactions afford $[AgL^1(PPh_3)]$ (**16**) or $[AgL^2(PPh_3)]$ (**17**). In the IR spectrum of **17** the ν(P=S) vibration appears at 575 cm^{-1} and the ν(NH) at 3203 cm^{-1}. Due to a poor mixture between **16** and Nujol, no satisfactory IR spectrum for **16** could be recorded. The deprotonation of the ligands is evident from the ^1H NMR spectra. Moreover, two resonances are present in the $^{31}P\{^1H\}$ NMR spectra and only in the case of compound **16**, the broad signal is split into two doublets.

Conclusions

The reactions studied indicate that a great variety of coordination types and complexes can be prepared (Schemes 1 and 2). Some notable points are a) The use of acetylacetonate as a suitable deprotonating agent. This is a new synthetic pathway that allows the use of solvents other than alcohols. The mixture MeOH/KOH, widely described in the literature, may not be the best since some metallic fragments may not be soluble in alcohol. b) The [Ag(HL)(TfO)] compounds synthesized are interesting starting materials which allow the incorporation of the "Ag(HL)" unit (also deprotonated) into more complicated structures. c) Cleavage of the C=S bond occurs upon the reaction of the oxonium salt $[O\{Au(PPh_3)\}_3]$ with the ligands.

Experimental Section

Reagents: AgTfO and PPh_3 were purchased from Aldrich and were used as received. The ligands (HL^1)[4] and (HL^2)[5] and the starting materials $[Au(acac)(PPh_3)]$,[33] $[O\{Au(PPh_3)\}_3]ClO_4$,[34] $[Au(acac)(C_6F_5)_2]$,[35] $PPN[Au(acac)_2]$,[33,36] $[Ag(TfO)(PPh_3)]$,[37] $[Ag(TfO)(PPh_3)_2]$[37] were synthesized according to literature methods. $[Au(TfO)(PPh_3)]$ was synthesized from $[AuCl(PPh_3)]$[38] and AgTfO in dichloromethane.

General Procedures: Infrared spectra were recorded on a Perkin−Elmer FT-IR Spectrum 1000 spectrophotometer in the range 4000−400 cm^{-1} using Nujol mulls between polyethylene sheets. Conductivities were measured in (ca. 5×10^{-4}) M acetone solutions with a Jenway 4010 conductimeter. Elemental analyses of C, H, N and S were carried out with a Perkin−Elmer 240C microanalyzer. Mass spectra were recorded on a VG Autospec instrument using the LSIMS (+, −) techniques and nitrobenzyl alcohol as a matrix and on an HP59987 A ELECTROSPRAY. ^{1}H, ^{19}F and ^{31}P NMR spectra were recorded on a Bruker ARX 300 spectrometer in $CDCl_3$ or $(CD_3)_2CO$. Chemical shifts are quoted relative to external $SiMe_4$ (^{1}H), $CFCl_3$ (^{19}F) or 85 % H_3PO_4 (^{31}P).

Syntheses: [Au(HL)(PPh$_3$)]TfO [L = L^1(1), L^2(2)]: HL^1 (0.1 mmol, 0.032 g) or HL^2 (0.1 mmol, 0.033 g) was added to a dichloromethane solution (20 mL) of [Au(TfO)(PPh_3)] (0.1 mmol, 0.0610 g). After stirring for 15 min the solvent was reduced to about 5 mL. Addition of *n*-hexane (20 mL) led to precipitation of an orange (**1**) or white (**2**) solid. Recrystallization from dichloromethane/hexane afforded the pure compounds.

[Au(L)(PPh$_3$)] [L = L^1(3), L^2(4)] Method a: KOH (0.1 mmol, 0.006 g) and then HL^1 (0.1 mmol, 0.032 g) or HL^2 (0.1 mmol, 0.033 g) was added to a solution of [Au(TfO)(PPh_3)] (0.1 mmol, 0.0610 g) in methanol (20 mL). After stirring for 15 min the solvent was reduced to about 5 mL. Addition of *n*-hexane (20 mL) led to precipitation of a yellow (**3**) or white (**4**) solid.

Method b: HL^1 (0.1 mmol, 0.032 g) or HL^2 (0.1 mmol, 0.033 g) was added to a solution of [Au(acac)(PPh_3)] (0.1 mmol, 0.056 g) in dichloromethane. After stirring for 15 min the solution was filtered through celite and the filtrate concentrated to about 5 mL. Addition of *n*-hexane (20 mL) led to precipitation of a yellow (**3**) or white (**4**) solid**.** Recrystallization from dichloromethane/hexane afforded the pure compounds.

[Au$_2$(L^1)(PPh$_3$)$_2$]TfO (5): KOH (0.1 mmol, 0.006 g) and HL^1 (0.1 mmol, 0.032 g) were added to a solution of [Au(TfO)(PPh_3)] (0.2 mmol, 0.121 g) in methanol (20 mL). After stirring for 15 min the solvent was concentrated to about 5 mL. Addition of *n*-hexane (20 mL) led to precipitation of a yellow solid (**5**). Recrystallization from dichloromethane/hexane afforded the pure compound.

PPN[Au(L)$_2$] [L = L^1(6), L^2 (7)]: HL^1 (0.2 mmol, 0.064 g) or HL^2 (0.2 mmol, 0.066 g) was added to a solution of PPN[Au(acac)$_2$] (0.1 mmol, 0.093 g) in dichloromethane (20 mL). After stirring for 15 min the solution was filtered through celite and the filtrate concentrated to about 5 mL. Addition of *n*-hexane (20 mL) led to precipitation of a pale yellow (**6**) or brown (**7**) solid. Recrystallization from dichloromethane/hexane afforded the pure compounds.

[Au(C$_6$F$_5$)$_2$(L)] [L = L^1 (8), L^2 (9)]: HL^1 (0.1 mmol, 0.032 g) or HL^2 (0.1 mmol, 0.033 g) was added to a solution of [Au(C_6F_5)$_2$(acac)] (0.1 mmol, 0.063 g) in dichloromethane (20 mL). The stirred solution was filtered through celite and the filtrate concentrated to about 5 mL. Addition of *n*-hexane (20 mL) led to precipitation of a yellow solid (**8** or **9**). Recrystallization from dichloromethane/hexane afforded the pure compounds. ^{19}F NMR for **8**: δ = −160 (m, *m*-F, 4F), 156 (t, *p*-F, ^{3}J(FF) 20.0 Hz), 155.7 (t, *p*-F, ^{3}J(FF) 19.8 Hz), −121.9 (m, *o*-F, 2F), −121.7 (m, *o*-F, 2F) ppm. ^{19}F NMR for **9**: δ = −161.8 (m, *m*-F, 4F), 157.2 (t, *p*-F, ^{3}J(FF) 20.0 Hz), 156.8 (t, *p*-F, ^{3}J(FF) 19.6 Hz), −122.4 (m, *o*-F, 2F), −122.1 (m, *o*-F, 2F).

[Ag(HL)(TfO)] [L = L^1 (10), L^2 (11)]: HL^1 (0.1 mmol, 0.032 g) or HL^2 (0.1 mmol, 0.033 g) was added to a dichloromethane solution (20 mL) of Ag(TfO) (0.1 mmol, 0.026 g). After stirring for 4 hours the solvent was reduced to about 5 mL. Addition of *n*-pentane (20 mL) led to precipitation of a yellow (**10**) or white (**11**) solid. Recrystallization from dichloromethane/pentane afforded the pure compounds.

[Ag(HL)(PPh$_3$)]TfO [L = L^1 (12), L^2 (13)] Method a: PPh_3 (0.1 mmol, 0.026 g) was added to a solution of [Ag(HL)(TfO)] (0.1 mmol; L^1 0.057 g, L^2 0.058 g) in dichloromethane (20 mL). After stirring for 15 min the solvent was concentrated to about 5 mL. Addition of *n*-hexane (20 mL) led to precipitation of a yellow (**12**) or white (**13**) solid.

Method b: HL^1 (0.1 mmol, 0.032 g) or HL^2 (0.1 mmol, 0.033 g) was added to a solution of [Ag(TfO)(PPh_3)] (0.1 mmol, 0.052 g) in dichloromethane (20 mL). The stirred solution was concentrated to about 5 mL. Addition of *n*-hexane (20 mL) led to precipitation of a yellow (**12**) or white (**13**) solid. Recrystallization from dichloromethane/hexane afforded the pure compounds.

[Ag(HL)(PPh$_3$)$_2$]TfO [L = L^1 (14), L^2 (15)] Method a: PPh_3 (0.2 mmol, 0.053 g) was added to a solution of [Ag(HL)(TfO)] (0.1 mmol; L^1 0.057 g, L^2 0.058 g) in dichloromethane (20 mL). After stirring for 15 min the solvent was concentrated to about 5 mL. Addition of *n*-hexane (20 mL) led to precipitation of a yellow (**14**) or white (**15**) solid.

Method b: HL^1 (0.1 mmol, 0.032 g) or HL^2 (0.1 mmol, 0.033 g) was added to a solution of $[Ag(TfO)(PPh_3)_2]$ (0.1 mmol, 0.078 g) in dichloromethane (20 mL). The stirred solution was concentrated to about 5 mL. Addition of *n*-hexane (20 mL) led to precipitation of a yellow (**14**) or white (**15**) solid. Recrystallization from dichloromethane/hexane afforded the pure compounds.

$[Ag(L)(PH_3)]$ [L = L^1 (16), L^2 (17)] Method a: KOH (0.1 mmol, 0.006 g) and HL^1 (0.1 mmol, 0.032 g) or HL^2 (0.1 mmol, 0.033 g) were added to a solution of $[Ag(TfO)(PPh_3)]$ (0.1 mmol, 0.052 g) in methanol (20 mL). After stirring for 15 min the solvent was concentrated to about 5 mL. Addition of *n*-hexane (20 mL) led to precipitation of a pale yellow (**16**) or white (**17**) solid.
Method b: HL^1 (0.1 mmol, 0.032 g) or HL^2 (0.1 mmol, 0.033 g) was added to a solution of $[Ag(acac)(PPh_3)]$ (0.1 mmol, 0.047 g) in dichloromethane. The stirred solution was filtered through celite and the filtrate concentrated to about 5 mL. Addition of *n*-hexane (20 mL) led to precipitation of a pale yellow (**16**) or white (**17**) solid. Recrystallization from dichloromethane/hexane afforded the pure compounds.

X-ray Crystallographic Study: The crystals were mounted in inert oil on a glass fiber and transferred to the cold gas stream of a Bruker SMART APEX CCD system diffractometer. Data were collected using monochromated Mo-K_α radiation (λ = 0.71073 Å). Absorption corrections were based on multiple scans (program SADABS). The structures were refined on F^2 using the program SHELXL-97.[39] All non-hydrogen atoms were refined anisotropically. CCDC 203107 and 203108 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

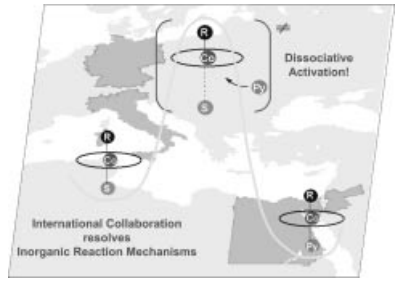
COVER PICTURE

The cover picture shows the dissociative character of the displacement of a coordinated solvent molecule *trans* to the alkyl group in cobalt(III) complexes. Details are discussed in the article by R. van Eldik et al. on p. 653ff. The work has benefited greatly from an international collaboration.



MICROREVIEW

Contents

445 **M. Gielen,* M. Biesemans, R. Willem, E. R. T. Tiekink**

Diorganotin Salicylaldoximate Clusters: Their Fascinating Chemistry and Structures

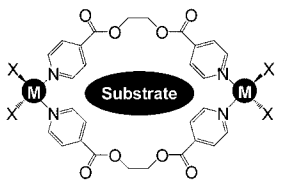
Keywords: Cluster compounds / NMR spectroscopy / Substitution reactions / Tin / X-ray diffraction

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

SHORT COMMUNICATIONS

453 **P. Grosshans, A. Jouaiti, V. Bulach, J.-M. Planeix, M. W. Hosseini,* N. Kyritsakas**

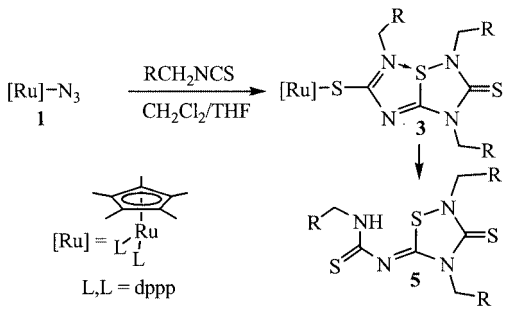
Design and Structural Analysis of Metallamacrocycles Based on a Combination of Ethylene Glycol Bearing Pyridine Units with Zinc, Cobalt and Mercury



Keywords: Glycol / Pyridine / Zinc / Cobalt / Mercury / Metallamacrocycle

459 **S.-C. Hsu, Y.-C. Lin,* S.-L. Huang, Y.-H. Liu, Y. Wang, H. Liu**

Novel Thiotetraazapentalene Complexes from the Reaction of Ruthenium Azide Complex with Alkyl Isothiocyanates

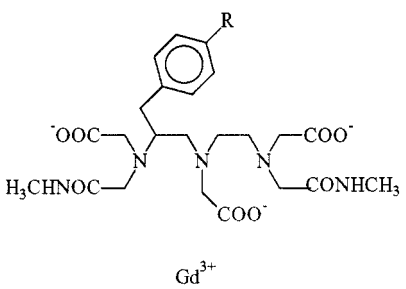


Keywords: Ruthenium / Azides / Isothiocyanates / Thiotetraazapentalene

FULL PAPERS

463 **S. Laurent, F. Botteman, L. Vander Elst, R. N. Muller***

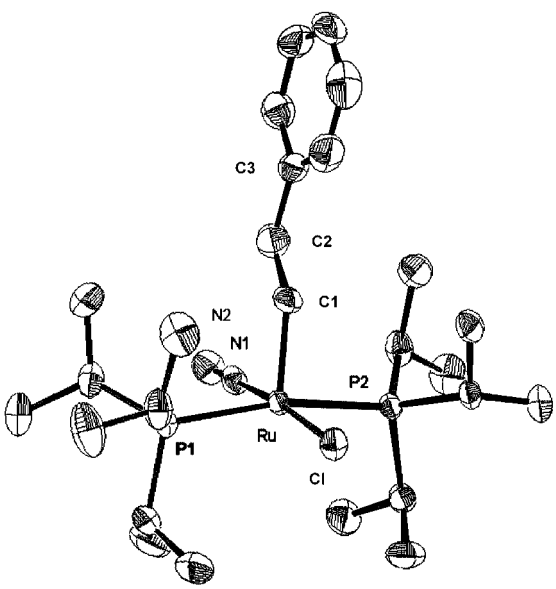
New Bifunctional Contrast Agents: Bis-Amide Derivatives of *C*-Substituted Gd-DTPA



Keywords: Gadolinium / Zinc / Metallation / Amides

469 **S. Jung, K. Ilg, C. D. Brandt, J. Wolf, H. Werner***

A Series of Vinylidene-, Vinyl-, Carbene- and Carbyneruthenium(II) Complexes with $[Ru(PCy_3)_2]$ and $[Ru(PiPr_3)_2]$ as Molecular Building Blocks



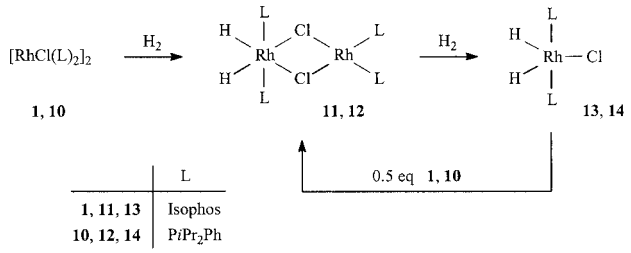
Keywords: Carbene complexes / Carbyne complexes / Ruthenium / Vinyl complexes / Vinylidene complexes

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

481 **P. Krüger, H. Werner***

Mono- and Dinuclear Rhodium and Iridium Complexes with Chiral Phospholanes as Ligands

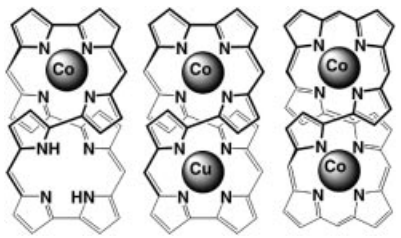
Keywords: Allyl ligands / Carbonyl ligands / Hydrido complexes / Phospholanes / Rhodium



492 **J. Bley-Escrich, J.-P. Gisselbrecht,* M. Michels, L. Zander, E. Vogel, M. Gross***

Electrochemical and Spectroelectrochemical Investigations of Mono- and Binuclear Cobalt(II) Complexes of "Figure-Eight" Octapyrrolic Macrocycles

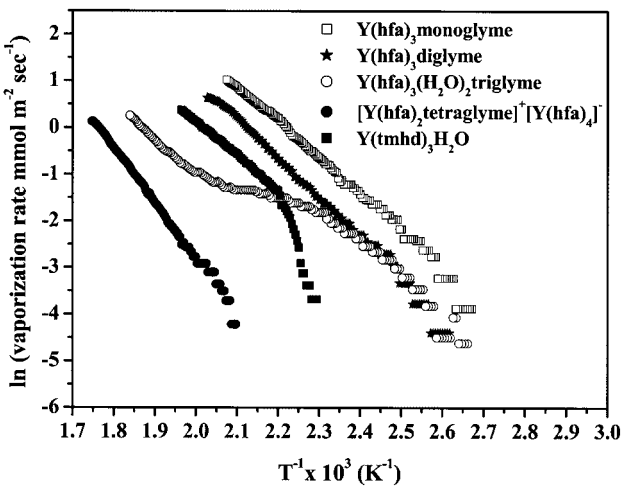
Keywords: Macrocyclic ligands / Cobalt / Cluster complexes / Electrochemistry



500 **G. Malandrino, R. Lo Nigro, I. L. Fragalà,* C. Benelli**

Yttrium β-Diketonate Glyme MOCVD Precursors: Effects of the Polyether Length on Stabilities, Mass Transport Properties and Coordination Spheres

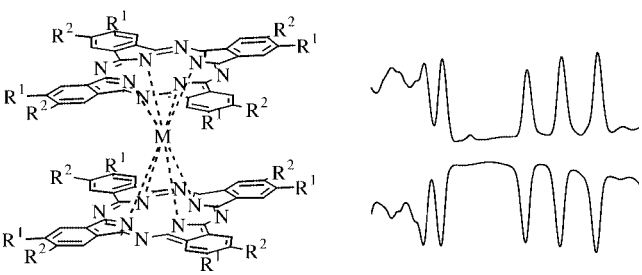
Keywords: Yttrium / Thermogravimetry / Superconductors



510 **P. Zhu, F. Lu, N. Pan, D. P. Arnold,* S. Zhang, J. Jiang***

Comparative Electrochemical Study of Unsubstituted and Substituted Bis(phthalocyaninato) Rare Earth(III) Complexes

Keywords: Phthalocyanines / Sandwich complexes / Rare earths / Electrochemistry



518 **P. Zhu, N. Pan, C. Ma, X. Sun, D. P. Arnold,* J. Jiang***

Electrochemistry of Heteroleptic Tris(phthalocyaninato) Rare Earth(III) Complexes

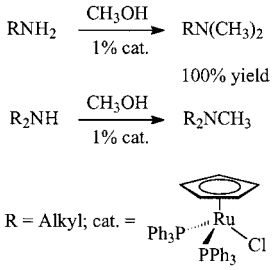
Keywords: Phthalocyanines / Sandwich complexes / Rare earths / Electrochemistry

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

524 **A. Del Zotto,* W. Baratta, M. Sandri, G. Verardo, P. Rigo**

Cyclopentadienyl Ru^{II} Complexes as Highly Efficient Catalysts for the *N*-Methylation of Alkylamines by Methanol

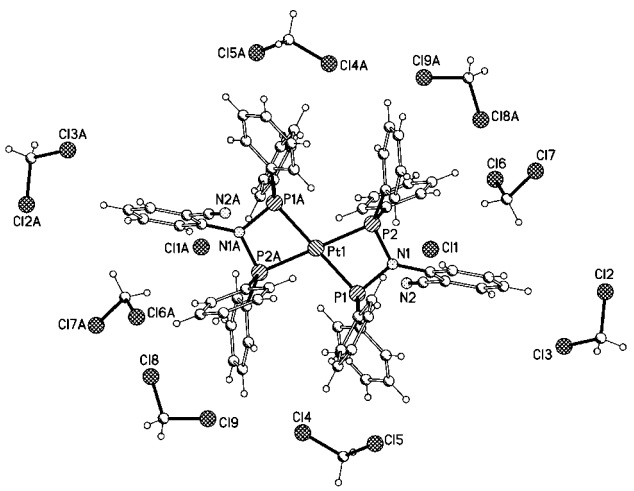
Keywords: Homogeneous catalysis / Ruthenium / Amines / *N*-methylation / Imines



530 **Z. Fei, R. Scopelliti, P. J. Dyson***

On the Reactivity of the Iminodiphosphane $C_6H_4(o\text{-}CN)N{=}PPh_2{-}PPh_2$: Fragmentation Versus Isomerisation

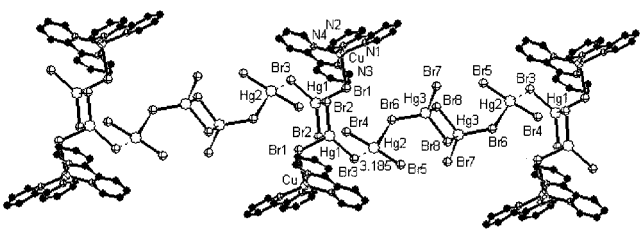
Keywords: N,P ligands / Palladium / Platinum / Reaction mechanisms / Structure elucidation



538 **J.-L. Song, J.-G. Mao,* H.-Y. Zeng, Z.-C. Dong**

Syntheses, Crystal Structures and Magnetic Properties of Four Cu^{II}-Hg^{II} Mixed-Metal Halide Oligomers

Keywords: Copper / Mercury / Magnetic properties / Cluster compounds



544 **X.-M. Zhang***

A Microporous Zinc Phosphonocarboxylate with a Zeolite ABW Framework via the Trialkyl Phosphonocarboxylate Route: In situ Synthesis and Characterization of $Na[Zn(O_3PC_2H_4CO_2)]\cdot H_2O$

Keywords: Microporous materials / Organic-inorganic hybrid / Zeolites / Zinc
