Diorganotin Salicylaldoximate Clusters: Their Fascinating Chemistry and Structures

Marcel Gielen,*[a] Monique Biesemans,[a] Rudolph Willem,[a] and Edward R. T. Tiekink[b]

Keywords: Cluster compounds / NMR spectroscopy / Substitution reactions / Tin / X-ray diffraction

A large variety of small oxotin clusters, characterised as stable crystalline products or solution transients, has been obtained by the reaction of various diorganotin oxides and salicylaldoxime. The structures were investigated by high resolution multinuclear NMR methods and X-ray crystallography. The predominant trinuclear clusters contain one seven- and two five-coordinate tin atoms and undergo a series of reversible substitution reactions, including those leading to clusters of differing nuclearity, in solution at room temperature. Such a variety of structures is rather unusual in organotin chemistry.

Introduction

An interesting review paper by White, Tasker and Smith[1] gives an overview of the crystal structural chemistry of phenolic oximes and their metal complexes. This review underlines that for both the free ligand and its metal complexes, hydrogen bonds between the oximic proton and

Marcel Gielen was born in Brussels in 1938. He received his PhD at the Université Libre de Bruxelles in 1963 with Professor Jacques Nasielski, in the field of the kinetics and mechanisms of the bimolecular electrophilic aliphatic substitutions. He was a fellow of the Fonds National de la Recherche Scientifique until he received a position of lecturer at the newly created Vrije Universiteit Brussel in 1966, where he became full professor in 1972. His main research interests were, and still are, the stereochemistry at carbon of S_E2 reactions at a saturated carbon atom, the fluxionality of inorganic and organometallic complexes, the stereochemistry of S_N2 reactions at tetrahedrally substituted atoms and the development of metal-based drugs. He is the author of 300 papers devoted to organometallic chemistry, devoted for instance to the synthesis, characterization and antitumour activities of organotin compounds. He has been the editor of several books and journals and is now, with Edward Tiekink, Narayan Hosmane and Rudolph Willem, the coordinating editor of the section "Main Group Metal Compounds" of Applied Organometallic Chemistry. He is, with Rudi Willem and Bernd Wrackmeyer, the editor of the series "Physical Organometallic Chemistry" published by Wiley; the fourth volume, Fluxional Organometallic Compounds, is in press. He is also, with Edward Tiekink, the editor of another book published by Wiley entitled "Metallotherapeutic Agents" that appears in 2004.

Monique Biesemans received her PhD in Organic Chemistry in 1978 at the Vrije Universiteit Brussel (VUB), where she studied the interaction between proteins and organic substrates by NMR spectroscopy under the supervision of Prof. Georges Van Binst. She worked since 1969 as assistant, and later as Doctor-Assistant at the VUB, under the leadership of Prof. Louis Van Hove, a specialist in steroid chemistry. In 1990, she joined the group of Prof. Marcel Gielen, where she directed her research to advanced structure determinations by multinuclear NMR spectroscopy, focussing on applied organotin chemistry, and more recently on organotin interface chemistry. She is the author or co-author of over 140 peer-reviewed publications on these subjects.

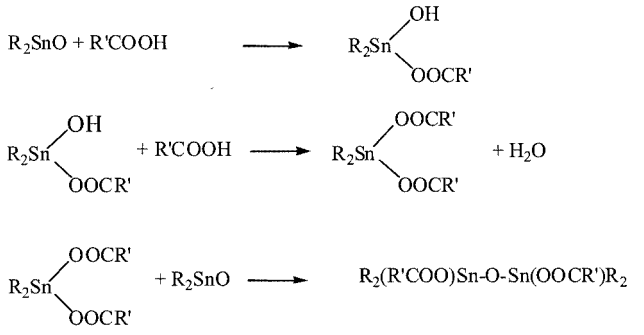
Rudolph Willem was born in 1948 and received his PhD in Theoretical Chemistry at the Université Libre de Bruxelles in 1975, active in group theoretical modelling of stereochemically dynamic processes under the supervision of Prof. Jean Brocas. He became assistant, and later Doctor-Assistant at the Vrije Universiteit Brussel (VUB) from 1972, under the leadership of Prof. Marcel Gielen. He is known as an active researcher in the field of experimental NMR applications on dynamic stereochemistry and in cellular NMR during a post-doctoral stay in the Max Planck Institute for Physiology in Dortmund, Germany, under the supervision of Prof. R. Kinne in 1987. He became an Associate Professor at the Engineering Science Faculty of the VUB from 1988, and the head of the NMR Department of the VUB from 1989. He received the titles Professor of Chemistry in 1997 and Full Professor and Vice-Dean of the Faculty in 2002. He is the author or coauthor of over 240 peer-reviewed publications on structural chemistry and advanced NMR applications to structure determinations, with focus on applied organotin chemistry, and more recently on organotin interface chemistry and tin NMR spectroscopy.

Edward R. T. Tiekink is a Ph.D. (1985) graduate of The University of Melbourne. After moving to The University of Adelaide, first as a Research Associate and later as a member of the academic staff, he made the move to the National University of Singapore (2001) where he pursues research interests in crystal engineering, nanoparticles generation of main group element sulfides, and the development of metal-based drugs. His research has resulted in over 850 publications and currently he serves on the editorial boards of "Zeitschrift für Kristallographie" (Co-Editor), "Acta Crystallographica E" (founding Co-Editor), "Applied Organometallic Chemistry" (Section Co-Editor), and "Bioinorganic Chemistry & Applications".

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

phenolic oxygen atom play a fundamental role in the structural chemistry of these compounds. Whereas this review focuses on structures obtained from X-ray crystallography, the present review will be devoted, in the main, to the solution chemistry of tin salicylaldoximate clusters and will outline more particularly the existence of transient species generated upon dissolution (chloroform) of pure single crystals of these clusters. The use of 2D heteronuclear NMR techniques involving the ^{119}Sn nucleus is revealed as the optimal tool to investigate the structural chemistry of this system.

Many series of diorganotin carboxylates have been synthesized, either for investigating their solid state or solution structure,[2] or for assessing their performance as PVC stabilizers,[3] biocides,[4] anti-tumour agents,[5] anion-recognition agents,[6] and catalysts for polyurethane foams,[7] for room temperature vulcanisation of silicon rubbers,[8] for transesterifications,[9] for acetylations of alcohols,[10] and for dehydrations of alcohols to ethers.[11] They can be synthesized by condensing diorganotin oxides with carboxylic acids.[5] Two types of structures can be obtained, depending basically on the diorganotin oxide/carboxylic acid molar ratio. When a 1:1 ratio is used, dimeric dicarboxylatotetraorganodistannoxanes are generally generated through a diorganotin carboxylate hydroxide intermediate:



The latter compound dimerises as follows:

$$2\,[R_2(R'COO)Sn-O-Sn(OOCR')R_2] \rightarrow [R_2(R'COO)Sn-O-Sn(OOCR')R_2]_2$$

Moreover, a distannoxane unit can react with 2 equiv. of carboxylic acid to yield the diorganotin dicarboxylate:

$$R_2(R'COO)Sn-O-Sn(OOCR')R_2 + 2\,R'COOH \rightarrow H_2O + 2\,(R'COO)_2SnR_2$$

The dimeric centrosymmetric distannoxane is characterized by an Sn_2O_2 four-membered ring with two endocyclic five-coordinate tin atoms (quite common in organotin chemistry) that is linked, by the bridging oxygen atoms, to two exocyclic five-coordinate diorganotin moieties (Figure 1) so that the structure contains two μ_3-oxo functionalities.

When salicylaldoxime, represented hereafter as HOZNOH (see Scheme 1) rather than a carboxylic acid, is involved in condensation reactions with a diorganotin oxide,[12] a totally different coordination chemistry takes

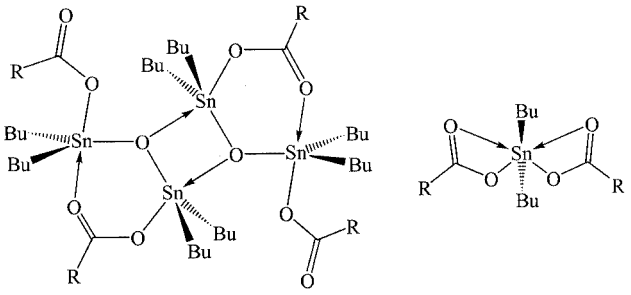


Figure 1. Structures of dimeric dicarboxylatotetraorganodistannoxanes and diorganotin dicarboxylates

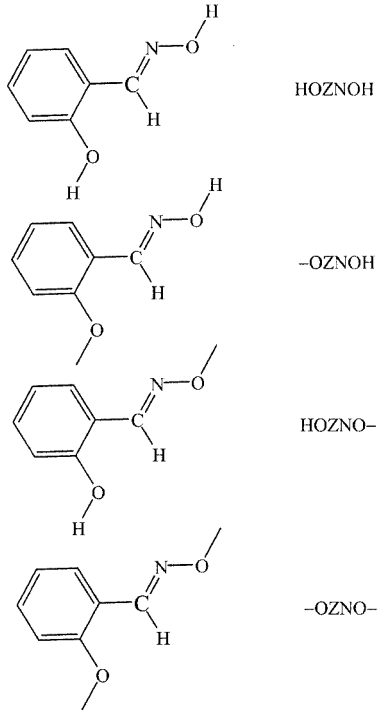
place at the tin atom. This paper provides a review of the syntheses, structures and solution chemistry of tin salicylaldoximates, as investigated over the last decade or so.



Scheme 1

Structures and Chemistry of Diorganotin Salicylaldoximates

One of the reasons for the difference in the organotin chemistry of salicylaldoxime is the presence of two constitutionally different hydroxylic protons that can potentially be substituted by a metal atom. Reaction of salicylaldoxime with di-*n*-butyltin oxide gives rise to a cluster,[13–15] the structure[16] of which was determined by X-ray crystallography (see Figure 2) and investigated in solution by 1D and 2D multinuclear (^{1}H, ^{13}C, ^{119}Sn) NMR techniques.[16]

This complex is generated irrespective of the starting ratio between nBu$_2$SnO and HOZNOH, and can be formulated as [(Bu$_2$Sn)(Bu$_2$SnO)(Bu$_2$SnOH)(OZNO)(OZNOH)] (**1**). It contains a protonated distannoxane unit with two

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

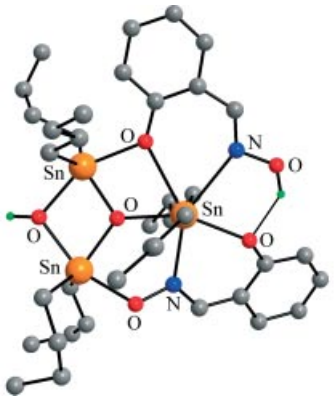


Figure 2. Structure of the crystalline organotin cluster $[(Bu_2Sn)(Bu_2SnO)(Bu_2SnOH)(OZNO)(OZNOH)]$ (**1**); in this diagram and in subsequent molecular structures, drawn with DIAMOND™, only the acidic hydrogen atoms are shown for reasons of clarity; colour code for all molecular structures in this review: orange, tin; red, oxygen; blue, nitrogen; turquoise, halide; grey, carbon; and green, hydrogen

five-coordinate tin atoms, which are in turn connected through a three-coordinate oxygen atom to a third, seven-coordinate tin atom, also coordinated by two differently bonded salicylaldoximate ligands. Another form (**1′**) related to cluster **1** arises from proton transfer from the SnOH moiety in the Sn_2O_2 group to the oxygen of the NO function of the OZNO ligand, as evidenced by ^{1}H NMR spectroscopy. The formula of **1′** is best represented as $[(Bu_2Sn)(Bu_2SnO)_2(OZNOH)_2]$ (see Figure 3).

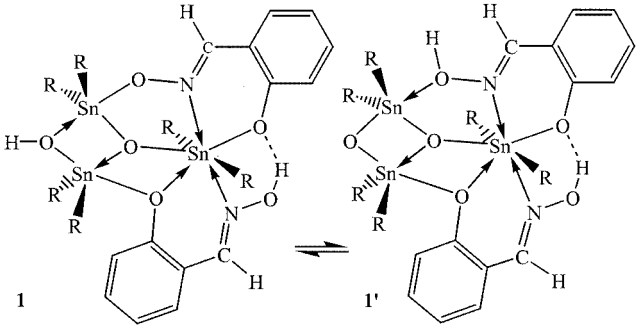

Figure 3. Structures in solution for the organotin cluster $[(Bu_2Sn)(Bu_2SnO)(Bu_2SnOH)(OZNO)(OZNOH)]$ (**1**) as found in the crystalline state, in equilibrium with a proton transfer isomer $[(Bu_2SnO)_2(Bu_2Sn)(OZNOH)_2]$ (**1′**)

In the latter formulation, a cyclodimer of diorganotin oxide is interacting with the one salicylaldoximate ligand through a PhO→Sn interaction and with the other one by a C=NO→Sn coordination, and an $(nBu_2Sn)_2O$→Sn contact from one oxygen atom of the four-membered Sn_2O_2 ring to the seven-coordinate tin atom. This suggests that the soluble cluster could act as an in situ reservoir of soluble diorganotin oxide, although this remains to be proven.[17,18]

Upon dissolution of monocrystalline **1** in $CDCl_3$, intense ^{119}Sn NMR resonances are observed for cluster **1**, together with other minor resonances that were assigned to other species as discussed below. Thus, a set of three minor, equally intense ^{119}Sn resonances were assigned to another cluster, **2**, that was subsequently synthesized independently from the reaction:

$$3\ HOZNOH + 3/n\ (R_2SnO)_n \rightarrow 2\ H_2O + [(R_2SnO)(R_2Sn)_2(HOZNO)(ZNOH)(OZNO)]\ (\mathbf{2})$$

Cluster **2** has three constitutionally different salicylaldoximate ligands. Its structural formula is shown in Figure 4, together with a crystal structure for the case when R = Me. Attempts to recrystallise **2** often failed for R = Me or provided crystals of **1** from undried solvents for R = *n*Bu. It was only under very carefully controlled crystallization conditions[19] that crystals of **2** could eventually be obtained for R = Me.

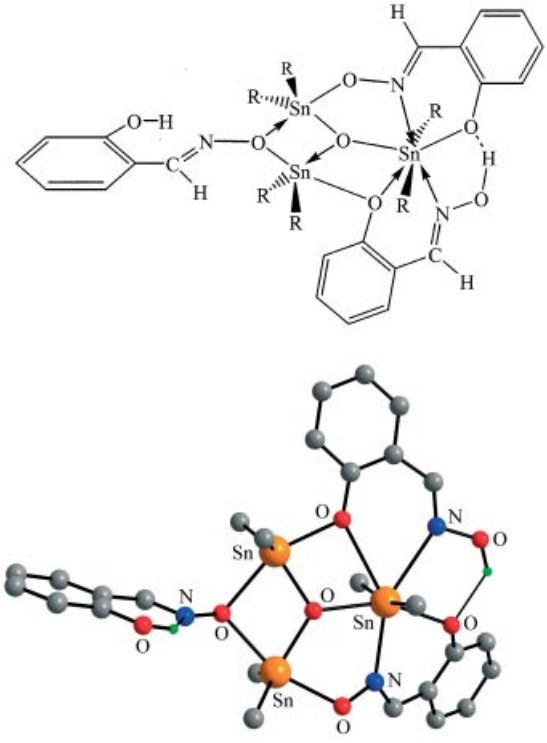

Figure 4. Lewis formula (top) and molecular structure (bottom) of the organotin cluster $[(R_2SnO)(R_2Sn)_2(HOZNO)(OZNOH)(OZNO)]$ (**2**; R = Me)

The μ_2-salicylaldoximate ligand of **2** is oriented in an approximately perpendicular position with respect to the almost planar trinuclear cluster. This yields a chiral skeleton in the solid state where the three tin atoms are inequivalent. The consequences of this chirality observed in the crystal are not observable in solution, suggesting a fast inversion of the skeletal chirality on the NMR timescale.[20]

The water generated in the synthesis of **2** is available in situ to convert **2** into **1**, which, at least for R = *n*Bu, explains the formation of the crystalline cluster **1** (Figure 2):

$$[(Bu_2SnO)(Bu_2Sn)_2(HOZNO)(OZNOH)(OZNO)] + H_2O \rightarrow [(Bu_2SnO)(Bu_2Sn)(Bu_2SnOH)(OZNOH)(OZNO)] + HOZNOH$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The water converts the μ^2-bridging HOZNO ligand into the good nucleophilic leaving group HOZNOH in such a way so that the substitution reaction of the HOZNO ligand by HO can occur because it is catalysed through electrophilic assistance by a hydroxylic proton available in the medium (e.g. from water generated in situ and/or present in undried solvents).

The structures of **1** and **2** are quite similar, as can be deduced from the similarity of their tin NMR spectra as well as their crystalline structures. Both are unsymmetrical networks of tin−oxygen and tin−nitrogen bonds with one seven-coordinate tin atom and two five-coordinate tin atoms.

Another series of weak ^{119}Sn resonances arising upon dissolution of crystalline **1** originate from another totally different tin cluster, **3**, the structure of which, determined by multinuclear NMR spectroscopy, is shown in Figure 5. It contains two six- and two five-coordinate tin atoms and two salicylaldoximate moieties.

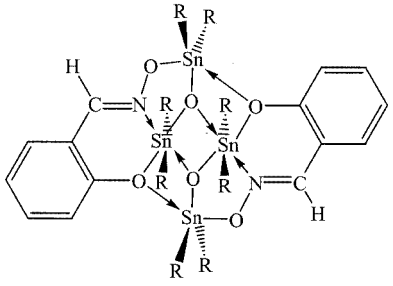

Figure 5. Structure of the organotin cluster $[(R_2Sn)_2(R_2SnO)_2(OZNO)_2]$ (**3**)

Lastly, a single ^{119}Sn resonance arises from a third very symmetrical cluster, **4** (Figure 6), containing four six-coordinate tin atoms and four salicylaldoximate ligands, as deduced from the relative intensities of $^2J(^{119}SnO\text{-}^{117}Sn)$ coupling satellites with respect to their parent signal.

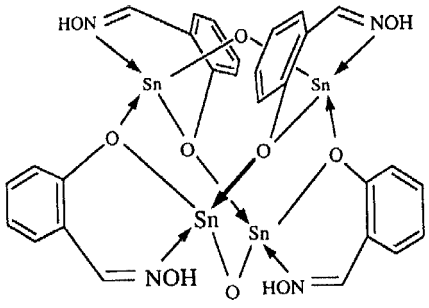

Figure 6. Structure of the organotin cluster $[(R_2Sn)_2(R_2SnO)_2(OZNOH)_4]$ (**4**); the tin-bound R groups have been omitted for clarity

An explanation for the formation of the first of the two minor species, $[(R_2Sn)_2(R_2SnO)_2(OZNO)_2]$ (**3**), observed in the solution generated from crystalline **1**, is shown in Figure 7:

$$2[(R_2SnO)(R_2Sn)(R_2SnOH)(OZNO)(OZNOH)] \rightarrow [(R_2Sn)(R_2SnO)(OZNOH)_2] + H_2O + 2[(R_2Sn)(R_2SnO)(OZNO)]$$

followed by

$$2[(R_2Sn)(R_2SnO)(OZNO)] \rightarrow [(R_2Sn)_2(R_2SnO)_2(OZNO)_2] \quad (3)$$

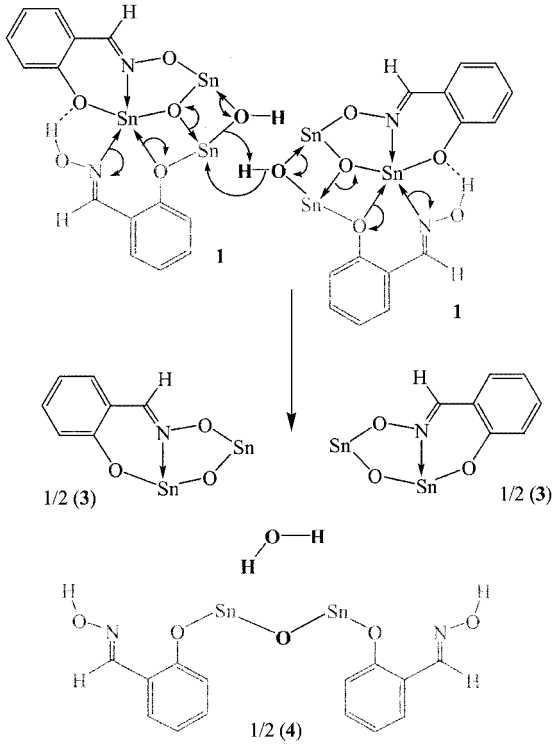

Figure 7. Reaction of two cluster units **1** yielding water, two identical molecules that, upon aggregation, provide **3**, as well as a distannoxane, the dimer of which is cluster **4**; the tin-bound R groups have been omitted for clarity

The second minor species, $[(R_2Sn)_2(R_2SnO)_2(OZNOH)_4]$ (**4**), is then formed by the dimerisation of $[(R_2Sn)(R_2SnO)(OZNOH)_2]$ generated by the reaction shown in Figure 7.

Another relatively straightforward reaction explains the presence of the latter minor compound **4**:

$$[(R_2Sn)(R_2SnO)(R_2SnOH)(OZNO)(OZNOH)] \rightarrow R_2SnO + [(R_2Sn)(R_2SnO)(OZNOH)_2]$$

which is again the monomeric precursor of **4**, R_2SnO precipitating in its usual polymeric form $(R_2SnO)_n$, in agreement with the experimental observation of precipitate formation.

Another reaction consistent with the presence of the minor species is given in Figure 8. Compound **1** can react with $[(R_2Sn)(R_2SnO)(OZNOH)_2]$ to yield $[(R_2SnO)(R_2Sn)_2(HOZNO)(OZNOH)(OZNO)]$ (**2**), H_2O

and $[(R_2Sn)(R_2SnO)(OZNO)]$, the monomeric precursor of **3**, already described above.

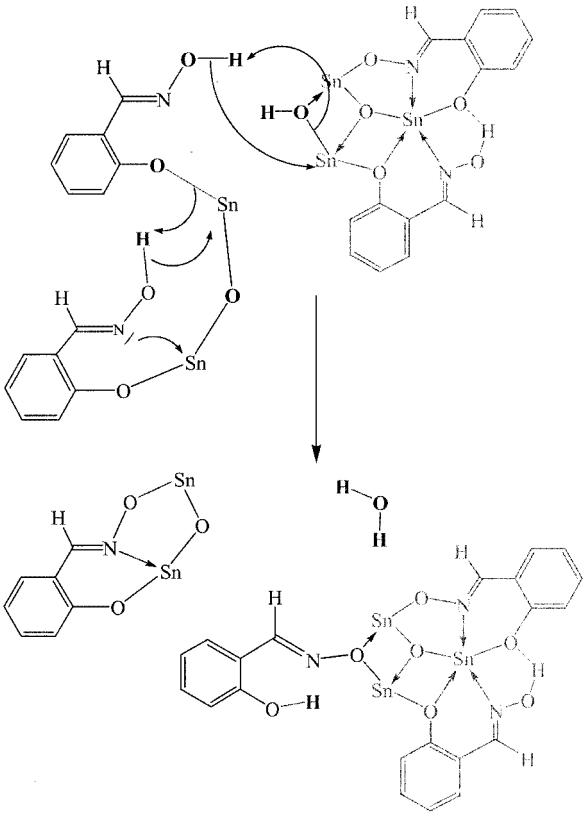

Figure 8. Reaction of cluster **1** with $[(R_2Sn)(R_2SnO)(OZNOH)_2]$, yielding water, cluster **2** and a distannoxane, the dimer of which is cluster **3**; the tin-bound R groups have been omitted for clarity

When both organic substituents on the tin atom are methyl groups, the dimethyl analogue of **1** can no longer be obtained in crystalline form. When alcohols R′OH are used for the crystallization, the crystals formed arise from novel structures containing an R′O group bridging the two five-coordinate tin atoms, instead of the OH group present in **1** (Figure 9),[21,22] i.e. $[(R_2Sn)(R_2SnO)(R_2SnOR')(OZNO)(OZNOH)]$ (see Table 1).

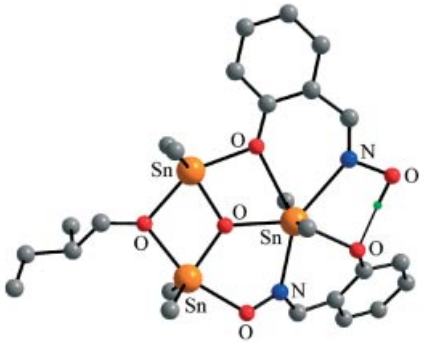

Figure 9. Structure of the organotin cluster $[(Me_2Sn)(Me_2SnO)(Me_2SnOCH_2CHMeEt)(OZNO)(OZNOH)]$ (**9**)

A mechanism similar to the one described for the transformation of **2** into **1** by the action of water remains applicable for the generation of **3** and **5**−**9** from **4**. This consists of protonation of the oximic oxygen atom of (HOZNO) in **4**, utilizing the proton from the entering R′OH to promote substitution with HOZNOH, which is the stable leaving group.

Table 1. Compounds obtained by treating di-*n*-butyl or dimethyltin oxide with salicylaldoxime; in the case when R = Me, compound **3** was observed solely as a transient, **4** was obtained as a crystalline solid, and compounds **5**−**9** were isolated from solutions in the corresponding alcohol R′OH

Compd.	R′O	R
1	HO	*n*Bu
2	*o*-HOZNO	*n*Bu
3	HO	Me
4	*o*-HOZNO	Me
5	MeO	Me
6	EtO	Me
7	PrO	Me
8	*i*PrO	Me
9	(*R*)-2-methylbutoxy	Me

More sterically hindered alcohols did not yield the corresponding alkoxy-bridged clusters. It should also be mentioned that the alkoxy-bridged compounds **5**−**9** are somewhat unstable since, upon ageing, their benzene solutions reveal the appearance of **4** and **3** as transients.

Because an electrophilic assistance by the proton of the entering R′OH appeared necessary in all these reactions to allow for the substitution of YO (YO = HOZNO or HO) by R′O, it was assessed whether other nucleophiles possessing a transferable proton are suitable for a similar substitution reaction. It appears that the MeO group of **5** can, indeed, be substituted for the PhCH=NO group (Figure 10),[22] yielding cluster **10**.

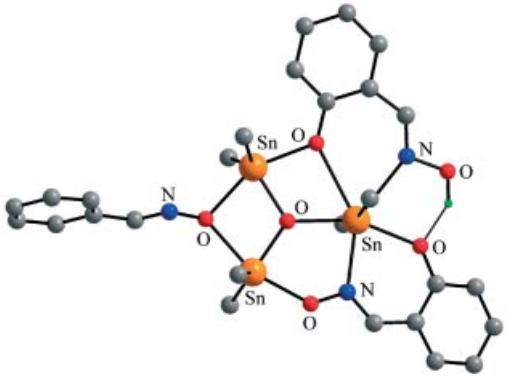

Figure 10. Structure of the organotin cluster $[(Me_2Sn)(Me_2SnO)(Me_2SnON{=}CHPh)(OZNO)(OZNOH)]$ (**10**)

Table 2 shows that phenols, ArOH, are also capable of inducing such reactions (Figure 11).[22]

Steric hindrance likewise hampers the substitution reaction in aryloxy cluster formation, as for the alkoxy cluster analogues, since 2,6-dimethylphenol, with a pK_a similar to the 3,5 analogue, is not capable of converting the methoxy

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

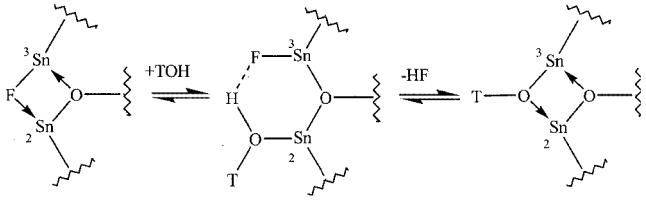
cluster into the corresponding 2,6-dimethylphenolate in pure form, as is the case with the 3,5 compound, **15**.

When treated with **5**, phenols with a pK_a slightly lower than 8.0, like *p*-cyanophenol (pK_a = 7.95) or *p*-nitrophenol (pK_a = 7.16), do not yield any substitution products that could be isolated as pure compounds, being observed solely as unstable transients. The threshold pK_a above which a substitution converts **5** into its aryloxy-substituted analogue in a way amenable to isolation and purification, lies in the range 8.0−8.4. Very acidic phenols, such as 2,4-dinitrophenol, completely destroy the cluster structure.

The acidity of carboxylic acids is also sufficient to destroy the cluster skeleton, yielding the usual carboxylatodistannoxane dimers discussed in the Introduction. However, the low acidity of the nucleophile is not sufficient to allow for a smooth substitution, since the weakly acidic acetylacetone (acacH) converts **5** into [$Me_2Sn(acac)_2$]. When **5** is treated with ethylene glycol, 2,2-dimethyl-1,3-dioxa-2-stannacyclopentane is generated.

A special case is provided by cluster **16** (Figure 12)[23] where the nucleophile bridging both five-coordinate tin atoms is simply a fluoride ion. Cluster **16** was obtained by reaction of **4** with NH_4F, showing that the necessary acidic reaction activation is ensured by a proton of the ammonium cation being transferred to the bridging HOZNO ligand to be substituted as HOZNOH. The mechanism of the substitution reaction of fluoride towards **4** or **5** was completely elucidated, taking advantage of the benefits of ^{19}F and ^{119}Sn NMR spectroscopy, in particular the associated spectral patterns arising from $^1J(^{19}F\text{-}^{119/117}Sn)$ scalar couplings. It was unambiguously established that the substitution occurs through an addition/elimination reaction mechanism, involving an intermediate where the entering and leaving nucleophiles are part of a motif where the transferred proton acts as a hydrogen bond connecting them (see Scheme 2).

Figure 12. Structure of the organotin cluster [(Me_2Sn)(Me_2SnO)-(Me_2SnF)(OZNO)(OZNOH)] (**16**)



Scheme 2

Conclusion

It can be stated that a large variety of small clusters can be obtained as stable crystalline products or solution transients upon reaction between diorganotin oxides and salicylaldoxime. The basic coordination pattern consists of one seven- and two five-coordinate tin atoms. In solution, such clusters undergo readily reversible substitution reactions under very mild conditions revealing a very broad panel of novel clusters. This variety is rather unusual in organotin chemistry.

Design and Structural Analysis of Metallamacrocycles Based on a Combination of Ethylene Glycol Bearing Pyridine Units with Zinc, Cobalt and Mercury

Philippe Grosshans,[a] Abdelaziz Jouaiti,[a] Véronique Bulach,[a] Jean-Marc Planeix,[a] Mir Wais Hosseini,*[a] and Nathalie Kyritsakas[b]

Keywords: Glycol / Pyridine / Zinc / Cobalt / Mercury / Metallamacrocycle

In the presence of MX_2 salts, ligand **1** (in a M/L ratio of 2:2, M = Zn, Hg, Co, X = Cl or I), based on the ethylene glycol fragment bearing two pyridine units as monodentate coordination sites, leads to isostructural square-shaped neutral metallamacrocycles as demonstrated by X-ray diffraction on single crystals. For all dinuclear complexes generated, the dicationic metal centre adopts a distorted tetrahedral coordination geometry and its coordination sphere is composed of the X_2N_2 set of coordinating atoms. For all complexes, the parallel packing of the cyclic structures generates channels which are occupied by solvent molecules. The solvent molecules, which behave as substrates, are positioned within the cavity of the metallamacrocycles. Control of the dimension of the macrocycles, by varying the size of the connecting metal centre, has also been demonstrated.

Introduction

Metallamacrocycles are finite entities composed of organic fragments and endocyclic metal centres.[1−11] These species may be described as cyclic structures either resulting from the bridging of metal centres by organic ligands that possess at least two coordinating sites or from the interconnection of organic ligands by the metal centres. For the design of metallamacrocycles, one must take into account the characteristics of the organic ligand (shape, rigidity, number and disposition of the coordinating sites) as well as the stereochemical requirements of the metal centre (oxidation state, geometry, number and disposition of free coordination sites).[3]

The majority of metallamacrocycles reported to date are based on the combination of *cis*-protected cationic square-planar metal units such as diphosphane or ethylenediamine complexes of Pd^{II} and Pt^{II} and often bis(pyridine) neutral ligands.[2−4] For these cases, due to the neutral nature of the ligands used, the metallamacrocycles formed are cationic in nature and thus are associated with anions for charge neutrality purposes. In order to generate uncharged metallamacrocycles, one may consider a combination of neutral metal complexes and organic ligands. This has been previously demonstrated with metal halide complexes.[11,12] Indeed, in that case, the coordinating halide centres not only neutralise the cationic charge of the metal cation, but also, by occupying some of the coordination sites within the first coordination sphere around the metal, allow the disposition of the remaining unoccupied sites to be controlled. This aspect has been demonstrated by us both in the case of discrete metallamacrocycles[12] and for coordination networks.[13−20]

Another important issue associated with the metallamacrocycles is the control of the nuclearity (i.e. the metal to ligand ratio). Indeed, depending on the nature of the bis(monodentate) ligand (rigidity, positioning of the coordinating sites) and the metal cation used (number and disposition of coordination sites), different cyclic structures such as [1.1] I, [2.2] II, [3.3] III, [4.4] IV etc. may be expected (Figure 1).[3,21]

Here, in the continuation of our investigations on the design of metallamacrocycles,[12,21−27] we describe the formation of four new neutral metallamacrocycles based on the use of the bis(monodentate) ligand **1** and neutral metal halide complexes (MX_2: M = Zn, Hg, Co; X = Cl or I).

Results and Discussion

The design of ligand **1** (Scheme 1) is based on the ethylene glycol fragment **2** as a spacer connecting two monodentate pyridine derivatives. The connection between the two

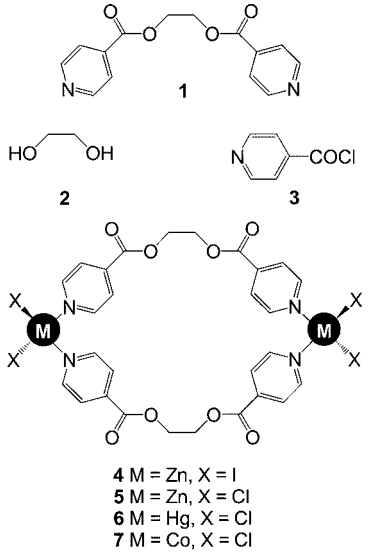

Scheme 1

units is achieved through an ester group at the 4-position of the pyridine ring. Although the straight forward synthesis of **1** has been reported,[28] we used our own methodology consisting of the condensation of ethylene glycol **2** with **3** in dry THF and in the presence of Et_3N (see Exp. Sect.).

Compound **1**, which is of the bis(monodentate) type, may either behave as a ligand and thus lead to metallamacrocyclic complexes or act as a tecton and generate coordination networks in the presence of appropriate metal centres.[29,30] We have previously demonstrated the latter case using analogous oligoethylene glycol based tectons, which lead to the formation of double-helical infinite networks when combined with silver cations.[31,32] Ligand **1** has also been used for the formation of 1D coordination networks in the presence of copper bromide.[33] The formation of coordination networks based on an analogous compound for which the ethylene glycol unit is replaced by an ethylene diamine fragment has also been reported.[34]

For the generation of metallamacrocycles under self-assembly processes, the choice of the coordinating heteroatoms and the cationic metal centre is crucial. Indeed, the self-assembly phenomena requires reversible coordination bond formation. Since ligand **1** contains two pyridine units as coordinating sites, zinc(II), mercury(II) and cobalt(II) halides have been chosen because the binding of pyridine to these metals in the oxidation state II is reversible. Thus, although many different species may be formed in solution, the selection of a metallamacrocycle with a given nuclearity may be achieved by the crystallisation process. In the present investigation, zinc(II), mercury(II) and cobalt(II) halides were combined with ligand **1** under crystallisation conditions leading exclusively to four new metallamacrocycles **4**−**7**, which were characterised by elemental analysis and X-ray diffraction on single crystals (Table 1). All four metallamacrocycles were found to be insoluble in common solvents such as CH_2Cl_2, $CHCl_3$, MeOH, EtOH, THF, CH_3CN and dioxane and for that reason they could not be characterised by NMR spectroscopy. The metallamacrocycles **4**−**7** were slightly soluble in DMF and readily soluble in DMSO. However, the ^1H NMR solution study in DMSO revealed that the chemical shifts observed for all signals were identical to those observed for the free ligand in the same solvent, probably implying that the metallamacrocycles are degraded in DMSO.

Treatment of ligand **1** with ZnI_2, produced slightly yellowish single crystals upon slow diffusion of a solution of ZnI_2 in EtOH into a solution of **1** in $CHCl_3$. The X-ray diffraction study of **4** (Table 1) revealed that the crystal (triclinic, $P\bar{1}$) is composed of one ZnI_2 dinuclear [2.2] complex **4** (Type II; Figure 1) and one disordered $CHCl_3$ solvent molecule. The solvent molecule is located within the cavity of the metallamacrocycle of the cyclophane (there are four edges, each defined by one pyridine unit), which leads to an inclusive complex in the crystalline phase (Figure 2).

The shape of the metallamacrocycle is a very slightly distorted square (8.65 Å × 8.72 Å) with the two ZnI_2 units occupying diagonal corners (Zn···Zn distance 12.25 Å). For ligand **1**, the ethylene glycol fragment adopts a gauche conformation with the O−C−C−O dihedral angles of −80.2° and +80.3°. The plane of the two ester groups (average C−O and C=O distances are approximately 1.32 Å and 1.19 Å, respectively; the O−C−O angle lies between 123.6° and 125.0°) is slightly tilted with respect to the connected pyridine unit (C−C−C−O dihedral angles of 2.3° and 6.2°). The coordination sphere around the metal is composed of two I^- anions and two N atoms belonging to two pyridine units of two different ligands (**1**) with average Zn−N and Zn−I bond lengths of approximately 2.06 Å and 2.54 Å, respectively (Figure 2). The metal centre adopts a distorted tetrahedral coordination geometry with N−Zn−N and I−Zn−I angles of 102.8° and 121.0°, respectively. The N−Zn−I angle varies between 106.4° and 107.4°. The slightly distorted square metallamacrocycles are packed in a parallel fashion thus generating channels occupied by solvent molecules. In one direction of space, the metallamacrocycles probably interact through stacking be-

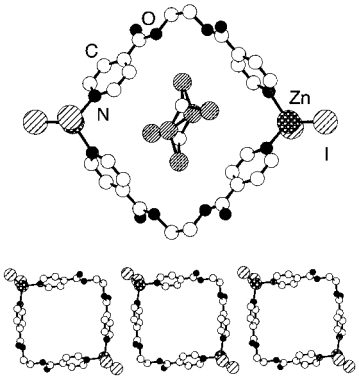

Figure 2. Solid-state structure of the dinuclear zinc metallamacrocycle **4** obtained upon reacting ligand **1** with ZnI_2; the cavity of the square macrocycle is occupied by a disordered $CHCl_3$ molecule (top) and in one direction of space; the metallamacrocycles interact through stacking between pyridine units (bottom); H atoms are not represented for clarity; for bond lengths and angles see text

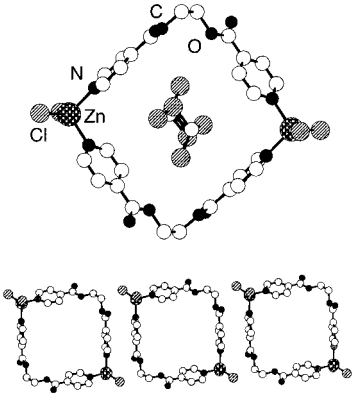

Figure 3. The solid-state structure of the dinuclear zinc metallamacrocycle **5** (top) obtained upon reacting ligand **1** with $ZnCl_2$; the square macrocycle forms an inclusive complex with a $CHCl_3$ molecule (disordered) and the packing of consecutive units (bottom); H atoms are not represented for clarity; for bond lengths and angles see text

tween pyridine units disposed in an anti-parallel manner (shortest distance between carbon atoms of two pyridines belonging to two consecutive metallamacrocycles is ca. 3.80 Å).

As expected, when ZnI_2 was replaced by $ZnCl_2$ under the same conditions, the X-ray diffraction study (Table 1) again revealed a similar metallamacrocycle **5** (Figure 3). The crystal structure (monoclinic, $P2_1/c$) is again composed of one $ZnCl_2$ dinuclear complex **5** and one disordered $CHCl_3$ solvent molecule. The latter, as mentioned above, is located within the cavity of the metallamacrocycle (Figure 3). The metallamacrocycle adopts a similarly distorted square form as above with almost identical dimensions (8.64 Å × 8.73 Å, Zn···Zn distance is 12.36 Å). Ligand **1** presents the same characteristics as those observed for the ZnI_2 complex **4**, that is, gauche conformation of the ethylene glycol fragment (O−C−C−O dihedral angles −77.2° and +77.2°). The plane of the two ester groups (average C−O and C=O distances are ca. 1.32 Å and 1.19 Å, respectively; the O−C−O angle lies between 124.6° and 125.2°) is again slightly tilted with respect to the connected pyridine unit (C−C−C−O dihedral angles of −0.8° and +10.2°). The coordination sphere around the metal centre is composed of two Cl^- anions and two N atoms belonging to two pyridine units of two different ligands (**1**) with Zn−N and Zn−Cl average bond lengths of approximately 2.05 Å and 2.21 Å, respectively (Figure 2). The metal centre adopts a distorted tetrahedral coordination geometry with N−Zn−N and Cl−Zn−Cl angles of 101.6° and 121.5°, respectively. The

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

N−Zn−Cl angle varies between 105.9° and 111.4°. Again, as for the previous case mentioned above, the square metallamacrocycles are packed in a parallel fashion generating channels. Also, in one direction of space, the metallamacrocycles probably interacts through stacking between pyridine units disposed in an anti-parallel fashion (shortest distance between carbon atoms of two pyridines belonging to two consecutive metallamacrocycles is ca. 3.67 Å). Comparison of structures **4** and **5** shows that changing the steric demand of the halogen atoms coordinated to the metal centre has almost no effect on the size of the metallamacrocycle.

In order to increase the dimensions of the metallamacrocycle, that is, the size of the endocyclic cavity, it may be possible to increase the size of the metal centre. For that reason, ligand **1** was treated with $HgCl_2$. Upon slow diffusion of a solution of $HgCl_2$ in EtOH into a solution of **1** in $C_2H_2Cl_4$, colourless crystals were obtained (Table 1). The crystal structure (monoclinic, $P2_1/c$) is composed of one neutral metallamacrocycle **6** and one tetrachloroethane solvent molecule. The solvent molecule is again located within the cavity of the metallamacrocycle **6** (Figure 4). The structure again adopts a slightly distorted square form with larger dimensions, as expected (8.98 Å × 9.05 Å, the Hg···Hg distance is 13.29 Å). Ligand **1** presents the same characteristics as those observed for the dinuclear metallamacrocycles **4** and **5** obtained with zinc, that is, gauche conformation of the ethylene glycol fragment (O−C−C−O dihedral angles −81.8° and +81.8°). The plane of the two ester groups (average C−O and C=O distances are ca 1.33 Å and 1.19 Å, respectively, the O−C−O angle lies between 123.6° and 123.8°) is again slightly tilted with respect to the connected pyridine unit (C−C−C−O dihedral angles of −1.2° and −8.9°). The coordination sphere around the Hg^{2+} cation is composed of two Cl^- anions and two N atoms belonging to two pyridine units of two different ligands (**1**) with Hg−N and Hg−Cl average bond lengths of approximately 2.39 Å and 2.36 Å, respectively. The metal centre adopts a distorted tetrahedral coordination geometry with N−Hg−N and Cl−Hg−Cl angles of 97.0° and 141.7°, respectively. The N−Hg−Cl angle varies between 97.0° and 104.7°. As for the previous cases mentioned above, the square metallamacrocycles are packed in a parallel fashion with stacking interactions (shortest distance between carbon atoms of two pyridines belonging to two consecutive metallamacrocycles ca. 3.60 Å) in one direction of space between consecutive metallamacrocycles **6** (Figure 4).

Finally, ligand **1** was allowed to react with $CoCl_2$ under crystallisation conditions. The slow diffusion of a solution of $CoCl_2{\cdot}6H_2O$ in EtOH into a solution of **1** in $C_2H_2Cl_4$ afforded blue crystals (Table 1). The crystal structure (monoclinic, $P2_1/c$) is composed of one $CoCl_2$ dinuclear complex **7** and one tetrachloroethane solvent molecule. Again the solvent molecule is located within the cavity of the metallamacrocycle **7** (Figure 5), which adopts a slightly distorted square shape with similar dimensions (8.63 Å × 8.71 Å, Co···Co distance is ca. 12.22 Å) close to those observed for the Zn complexes **4** and **5**. Ligand **1** presents the same characteristics as those observed for the dinuclear metallamacrocycles **4**−**6** which were obtained with zinc and mercury, that is, gauche conformation of the ethylene glycol fragment (O−C−C−O dihedral angles −77.8° and +77.9°). The plane of the two ester groups (average C−O and C=O distances are ca. 1.33 Å and 1.19 Å, respectively; O−C−O angles lie between 124.2° and 125.0°) is again tilted with respect to the connected pyridine unit (C−C−C−O dihedral angles of −1.5° and +9.9°). Interestingly, the coordination sphere around the Co^{2+} cation is only composed of two Cl^- anions and two N atoms belonging to two pyridine units of two different ligands (**1**) with Co−N and Co−Cl average bond lengths of approximately 2.04 Å and 2.22 Å, respectively. The metal centre adopts a distorted tetrahedral coordination geometry with N−Co−N and Cl−Co−Cl angles of 105.7° and 120.4°, respectively. The N−Co−Cl angle varies between 105.4° and 110.2°. This coordination geometry around Co^{II} with the (X_2N_2) set of coordinating centres differs from the previously observed octahedral geometry with the same type of donor sites (pyridine and Cl^-).[13−18] Once again, as for

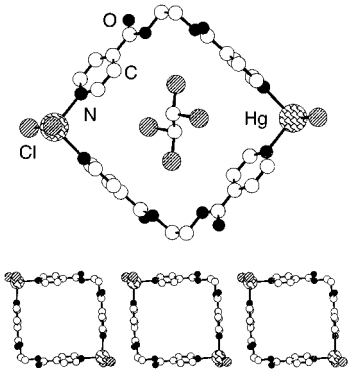

Figure 4. The solid-state structure of the dinuclear mercury metallamacrocycle **6** (top) obtained upon reacting ligand **1** with $HgCl_2$; the square macrocycle forms an inclusive complex with tetrachloroethane molecule; the packing of consecutive units generates channels (bottom); H atoms are not represented for clarity; for bond lengths and angles see text

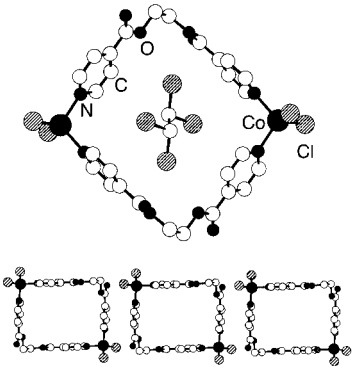

Figure 5. The solid-state structure of the dinuclear cobalt metallamacrocycle **7** (top) obtained upon reacting ligand **1** with $CoCl_2$; the Co^{II} centre adopts a distorted tetrahedral coordination geometry; the square macrocycle forms an inclusive complex with tetrachloroethane molecule; the packing of consecutive units generates channels (bottom); H atoms are not represented for clarity; for bond lengths and angles see text

the previous cases mentioned above, the slightly distorted square metallamacrocycles are packed in a parallel fashion with stacking interactions (shortest distance between carbon atoms of two pyridines belonging to two consecutive metallamacrocycles is ca. 3.60 Å) are in one direction of space between consecutive metallamacrocycles of **7**.

In summary, the rather simple ligand **1**, composed of an ethylene glycol unit bearing two pyridines as monodentate coordination sites, leads in the presence of metal halides (MX_2: M = Zn, Hg, Co; X = Cl or I) in a M/L ratio of 2:2 to isostructural square-shape neutral metallamacrocycles. The metallamacrocyclic structures offer rather large cavities of the cyclophane type which are occupied by solvent molecules. In the crystal, the square-cyclic units are packed in a parallel fashion, thus generating channels occupied by solvent molecules. In one direction of space, the metallamacrocycles probably interact with each other through stacking of the pyridine units belonging to consecutive units and are disposed in an anti-parallel manner. Since the solvent molecules included in the cavity of the metallamacrocycles may play a template role and thus define the nuclearity of the complex, we are currently evaluating this aspect. The formation of other types of finite metallamacrocycles using ligand **1**, other metal centres and the generation of infinite coordination networks are currently under investigation. The ability of the analogous ligand for which the pyridine units are connected at the 3-position to generate metallamacrocycles and/or coordination networks with a variety of metal complexes is also currently being investigated.

Experimental Section

General: All commercially available reagents were purchased and used without further purification. ^1H and ^{13}C NMR spectra were recorded on Bruker spectrometers at 400 and 300 MHz and at 50 MHz, respectively. Microanalyses were performed by the Service de Microanalyses de la Fédération de Recherche Chimie, Université Louis Pasteur, Strasbourg.

Synthesis of Ligand 1: A solution of **3** as its hydrochloride salt (2.15 g, 12 mmol) in dry THF (30 mL) was added to ethylene glycol **2** (0.3 g, 4.8 mmol) under argon. The mixture was stirred before Et_3N (5 mL) was added and stirred at room temperature for a further 12 hours. The brownish solution was evaporated to dryness under reduced pressure. A saturated aqueous hydrogenocarbonate solution (50 mL) was added to the residue and the mixture was extracted with CH_2Cl_2 (3 × 50 mL). The organic solvent was removed and the residue purified by column chromatography (SiO_2, CH_2Cl_2-0-2 % MeOH) affording the pure compound **1** (0.66 g, 51 %) as a slightly yellowish oil. $C_{14}H_{12}N_2O_4$ (272.26): calcd. C 61.76, H 4.44, N 10.29; found C 61.59, H 4.53, N 9.96. ^1H NMR ($CDCl_3$, 300 MHz, 25 °C): δ = 4.71 (s, 4 H, CH_2O), 7.84 (dd, 4 H, J = 1.65 and 4.41 Hz), 8.79 (dd, J = 1.6, 4.4 Hz, 4 H) ppm. ^{13}C NMR ($CDCl_3$; 300 MHz; 25 °C): δ = 63.2, 122.8, 136.7, 150.7, 164.9 ppm.

Synthesis of Metallamacrocycles 4−7: Single crystals of suitable quality for X-ray diffraction investigations were obtained within 2−4 days at room temperature, upon slow diffusion of a $CHCl_3$ or $C_2H_2Cl_4$ solution (1 mL) of **1** (5 mg) into a EtOH (2 mL) solution of ZnI_2, $ZnCl_2$, $HgCl_2$ or $CoCl_2·6H_2O$ (1.5 mg); **4**: $C_{14}H_{12}O_4N_2·ZnI_2$ (591.45): calcd. C 28.43, H 2.05, N 4.74; found C 28.38, H 2.12, N 4.68; **5**: $C_{14}H_{12}N_2O_4·ZnCl_2$ (408.55): calcd. C 41.16, H 2.96, N 6.86; found C 41.33, H 3.08, N 6.90; **6**: $C_{14}H_{12}N_2O_4·HgCl_2$ (543.76): calcd. C 30.92, H 2.22, N 5.15; found C 30.89, H 2.32, N 5.46; **7**: $C_{14}H_{12}N_2O_4·CoCl_2$ (410.10): calcd. C 41.82, H 3.10, N 6.97; found C 41.88, H 3.06, N 6.99.

Crystal Structure Characterisation: X-ray diffraction data was carried out on a Kappa CCD diffractometer equipped with an Oxford Cryosystem liquid N_2 device, with graphite-monochromated Mo-K_α radiation (Table 1). In the case of **6**, diffraction data were corrected for absorption and analysed using the OpenMolen package,[35] whereas for the other three metallamacrocycles **4**, **5** and **7**, Nonius−Maxus Package 4.3 was used. All non-H atoms were refined anisotropically. CCDC-216069 to -216071 and -216073 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk.

Novel Thiotetraazapentalene Complexes from the Reaction of a Ruthenium Azide Complex with Alkyl Isothiocyanates

Sheng-Chin Hsu,[a,b] Ying-Chih Lin,*[a] Shou-Ling Huang,[a] Yi-Hung Liu,[a] Yu Wang,[a] and Hwang Liu[b]

Keywords: Ruthenium / Azides / Isothiocyanates / Thiotetraazapentalene

Reactions of the ruthenium azide complex **1** with alkyl isothiocyanates give novel ruthenium thiotetraazapentalenedithione complexes **3a–c** containing a hypervalent sulfur atom. The ligand, bound through one sulfur atom, is derived from three isothiocyanate molecules and one nitrogen atom from an azide ion. The synthesis and structural determination of **3a–c**, as well as a possible mechanism for their formation is described.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Isothiocyanates are known to undergo reactions with unsaturated substrates (including Diels−Alder reactions and nucleophilic additions) to provide heterocyclic derivatives.[1] The pathways for these conversions are controlled by the character of the substrates as well as by the type of reagent.[2−4] For example, addition to the C=S or C=N bond of the heteroallene moiety can occur, leading to polymerization,[5,6] whereas the reactions of acyl/thioacyl isothiocyanates often lead to the formation of 1,4-cycloadducts.[7] The organic chemistry of these isothiocyanate heteroallenes has been described in several reviews,[8,9] but reactions of isothiocyanates with metal complexes have not yet been comprehensively investigated. We reported previously the reactions of ruthenium acetylide complexes with isothiocyanate, which yielded ligands containing four- and six-membered heterocyclic rings.[10,11] Because the reaction of arylsulfonyl isothiocyanates with alkyl azides is known[12] to give 4-alkyl-5-arylsulfonylimino-1,2,3,4-thiatriazolines we were interested in studying the reactions of ruthenium azide complexes with isothiocyanates. Surprisingly, these reactions give ruthenium thiotetraazapentalene[13,14] complexes containing a hypervalent sulfur atom. It is known that thiotetraazapentalene can be prepared from the reaction of thiourea with isothiocyanate,[15,16] but metal-coordinated species are relatively rare. The synthesis and structural characterization of these novel thiotetraazapentalene ruthenium complexes **3a−c** are described below. The isolation of several minor products led to the elucidation of a possible mechanism.

Results and Discussion

The reaction of $[Ru]N_3$ (**1**, [Ru] = (η^5-C_5Me_5)(dppp)Ru, dppp = 1,3-bis(diphenylphosphanyl)propane) with a fivefold excess of $PhCH_2NCS$ in THF under nitrogen for one day gave **3a** in 40 % yield. This compound was identified as a ruthenium thiotetraazapentalene complex by single-crystal X-ray diffraction analysis. About 35 % of the unchanged azide was also isolated. Interestingly, the reaction of **1** with a tenfold excess of $PhCH_2NCS$ in THF gave $\{[Ru]NCS[Ru]\}^+NCS^-$ (**2**) as the major product in 55 % yield and complex **3a** in only 20 % yield (Scheme 1). Following removal of **2** and **3a**, two minor products, [Ru]SC(=NH)$NHCH_2Ph$ (**4**) and **5** (Scheme 2) could be separated from the reaction mixture by fractional crystallization in 5 % and 6 % yield respectively (based on **1**). The reaction of **1** with other alkyl isothiocyanates (EtNCS and MeNCS) in a fivefold excess resulted in the formation of the analogous ruthenium thiotetraazapentalene complexes **3b** and **3c** (Scheme 1) in comparable yields.

Varying the relative amounts of the reactants gave similar yields of the product, however no attempt was made to isolate the compounds analogous to **4** and **5** because of their low yields. Interestingly, the reaction of **1** with phenyl isothiocyanate yielded the monomeric complex [Ru]NCS (**6**) as the only isolable product.

The IR spectrum of **3a** displays absorption bands at 1174 and 699 cm^{-1}, assignable to the $\nu_{C=S}$ and ν_{C-S} stretches respectively.[17,18] In the ^1H NMR spectrum of **3a** at room

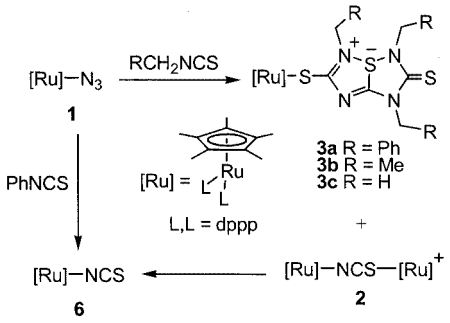
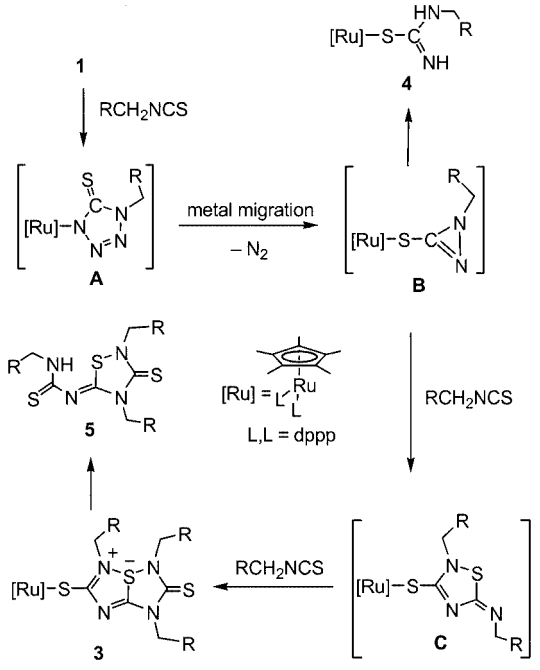


Scheme 1



Scheme 2

temperature (in addition to the singlet at δ = 1.51 ppm due to Cp*), there is a very broad resonance at δ = 5.07 ppm and two sharp singlet resonances at δ = 4.86 and 4.72 ppm, which are assignable to the three methylene groups. At 233 K, these resonances resolve into two AX patterns at δ = 5.57 and 3.93 ppm ($J_{H,H}$ = 16.09 Hz) and δ = 5.16 and 4.67 ppm ($J_{H,H}$ = 14.39 Hz), and an AB pattern at δ = 5.13 and 5.07 ppm ($J_{H,H}$ = 17.02 Hz). The ^{31}P NMR spectrum at room temperature displays a broad singlet resonance at δ = 37.54 ppm, which splits into two doublets at δ = 40.51 and 34.81 ppm with $J_{P,P}$ = 51.7 Hz at 233 K. This is possibly because of the hindered rotation of the Ru−S bond at low temperature.[12,19,20] Consistent with this structure, the FAB mass spectrum shows a parent peak at *m*/*z* = 1110.1. Single crystals of **3a** readily formed in a mixture of hexane and THF, enabling the structure of **3a** to be unambiguously determined by single-crystal X-ray diffraction analysis (Figure 1).

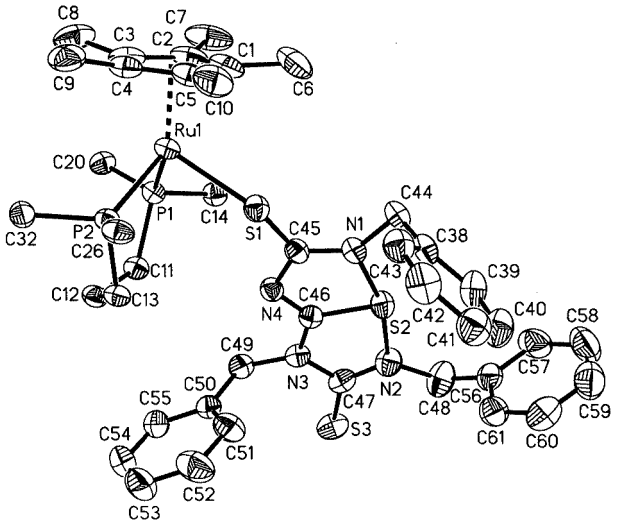


Figure 1. X-ray crystal structure of **3a** with thermal ellipsoids at the 30 % probability level; the four dppp phenyl groups and all of the hydrogen atoms have been omitted for clarity; selected bond lengths (Å): Ru(1)−S(1) 2.4427(8), S(1)−C(45) 1.739(3), C(45)−N(1) 1.305(4), C(45)−N(4) 1.370(4), C(47)−N(2) 1.296(5), C(47)−N(3) 1.406(4), C(46)−N(3) 1.370(4), C(46)−N(4) 1.314(4), S(2)−N(1) 1.884(3), S(2)−N(2) 1.969(3), C(46)−S(2) 1.722(3), C(47)−S(3) 1.683(3); selected bond angles (deg): C(45)−S(1)−Ru(1) 126.56(10), N(1)−S(2)−C(46) 81.80(14), S(2)−C(46)−N(4) 120.4(2), N(3)−C(46)−S(2) 116.6(2), C(46)−N(4)−C(45) 110.9(3), C(45)−N(1)−S(2) 113.1(2), N(2)−C(47)−N(3) 109.8(3), C(46)−N(3)−C(47) 116.1(3), C(46)−S(2)−N(2) 82.79(14), S(2)−N(2)−C(47) 114.7(2), N(1)−C(45)−S(1) 122.4(2), N(4)−C(45)−S(1) 123.7(2), N(2)−C(47)−S(3) 128.2(3), N(3)−C(47)−S(3) 122.1(3)

Thiatetraazapentalenes have been prepared from cyclic thioureas and two equivalents of RNCS.[15,16] A bis(thiatetraazapentalenedithione)copper(I) complex has also been reported, in which four sulfur atoms in the thiocarbonyl groups coordinate tetrahedrally to the copper atom, to form a one-dimensional coordination polymer.[21]

Even though complexes **2** and **6** have the same empirical formula, their spectra are quite distinctive. For example, in **2**, there are two singlets (with equal intensities) at δ = 37.93 and 35.38 ppm in the ^{31}P NMR spectrum and likewise at δ = 1.31 and 1.29 ppm in the ^{1}H NMR spectrum, attributable to the two Cp* groups. In contrast, there is a singlet at δ = 37.86 ppm in the ^{31}P NMR spectrum of **6** and a singlet at δ = 1.29 ppm in the ^{1}H NMR spectrum. The FAB mass spectrum of **2** also displays parent peaks at *m*/*z* = 1356.3, consistent with its formula. Generally, ruthenium isothiocyanate complexes form N-bound linkage isomers,[22−26] but many S-bound isothiocyanate ruthenium complexes are also known, one of which was recently characterized by single-crystal X-ray diffraction analysis.[27] Dinuclear Ru complexes bridged by isothiocyanate ligands are also known in the literature.[28,29]

Complex **4** was characterized by spectroscopic as well as elemental analysis. In the IR spectrum of **4**, two absorption bands at 1617 and 699 cm^{-1} (assignable to the $\nu_{C=N}$ and ν_{C-S} stretches respectively) were observed, with the $\nu_{C=S}$

being absent. In the ^{1}H NMR spectrum, the Cp* ligand appeared as a singlet at δ = 1.22 ppm, a broad resonance at δ = 6.01 ppm was attributed to the amine proton, and a broad resonance at δ = 4.08 ppm was identified as belonging to the methylene protons of the benzyl group. These last two resonances showed $^3J_{H,H}$ coupling in the COSY spectrum. In addition, the broad resonance at δ = 4.32 ppm was assigned to the =NH proton of the imine group. The room temperature ^{31}P NMR spectrum of **4** displays a singlet at δ = 37.09 ppm. The crystal structure of **4** indicates that the isothiourea ligand is bound to the ruthenium metal through the sulfur atom (Figure 2).

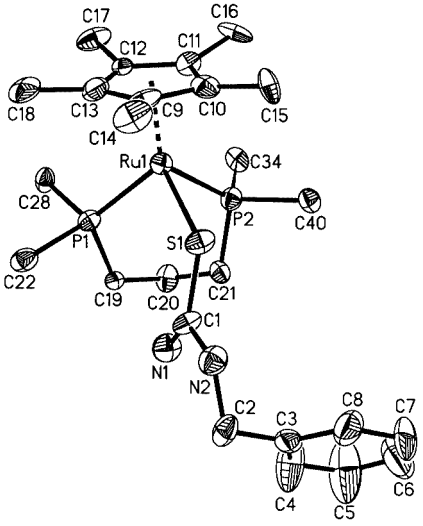

Figure 2. Structural drawing of **4** with thermal ellipsoids at the 30 % probability level; the four dppp phenyl groups and all of the hydrogen atoms have been omitted for clarity; selected bond lengths (Å): Ru(1)−S(1) 2.415(3), S(1)−C(1) 1.726(12), C(1)−N(1) 1.22(2), C(1)−N(2) 1.371(13); selected bond angles (deg): Ru(1)−S(1)−C(1) 126.0(4), S(1)−C(1)−N(1) 126.8(10), S(1)−C(1)−N(2) 112.4(9), N(1)−C(1)−N(2) 120.1(12)

The product **5** was identified by spectroscopic methods as being a five-membered 5-imino-1,2,4-thiadiazolidin-3-thione (Scheme 2).

In the IR spectrum of **5**, absorption bands at 1617, 1184 and 698 cm^{-1} were assigned to $\nu_{C=N}$, $\nu_{C=S}$ and ν_{C-S} stretches, respectively. The high resolution FAB mass spectrum of **5** has a parent peak at *m*/*z* = 463.1807, consistent with the molecular formula. Two isomers (*E* and *Z* forms) in a ratio of 3:2 were apparent from the NMR spectrum of **5**. The fact that the five-membered ring had opened was clear from the presence of a doublet at δ = 4.62 ppm, assigned to one of the methylene groups from its coupling to the NH proton. The resonances for the other two methylene groups at δ = 5.18 and 5.70 ppm remain as singlets. This indicates that the formation of **5** could result from cleavage of the dative N−S bond of **3a**, followed by cleavage of the Ru−S bond. Non metal-containing compounds with similar structures have been reported in the literature;[30] (*E*) and (*Z*) isomers arising from the imine bond are also known.

As mentioned in the literature,[12] it is common to observe the [3+2] cycloaddition of organic azides with the C=N bond of isothiocyanates. However, the thiatetraazapentalenes **3** incorporate three isothiocyanate molecules and only one nitrogen atom from the azide ligand. A possible mechanism for the formation of **3** is depicted in Scheme 2. Cycloaddition of the azide ligand of complex **1** with the C=N bond of the isothiocyanate to form **A** is followed by loss of nitrogen and migration of the ruthenium metal from nitrogen to sulfur to give **B**, which could provide the S-metalated isothiourea complex **4** as a minor product. Complex **B** could then undergo two successive [3+2] cycloadditions; the first with the C=S bond[31,32] of isothiocyanate (to give **C**), and the second with the C=N bond[33] of isothiocyanate, to afford **3**. Formation of **5** (R = Ph) might then be accounted for by loss of the metal from **3a**.

Conclusion

In summary, a novel metallated thiatetraazapentalene has been isolated from the reaction of a ruthenium azide with alkyl thioisocyanates. Formation of this product may proceed through a tandem process that involves three consecutive [3+2] cycloadditions with an alkyl thioisocyanate, a new method for the preparation of this type of compound. Isolation of the S-metalated isothiourea complex **4** and the 5-imino-[1,2,4]thiadiazolidine-3-thione **5** as minor products provides insight into a mechanism for the formation of **3**. Detailed mechanistic studies (including the use of ^{15}N-labeled azide as the starting material) are currently underway.

Experimental Section

Synthesis of 3a: A mixture of [Ru]N_3 **1** (0.45 g, 0.65 mmol) and $PhCH_2NCS$ (0.90 mL, 10.3 mmol) in THF (30 mL) was heated at reflux for one day under nitrogen. The solvent was evaporated under reduced pressure and enough *n*-hexane added to cause precipitation of a yellow solid, which was isolated by filtration and washed with *n*-hexane to give {[Ru]NCS[Ru]}$^+$NCS$^-$ **2** (0.13 g, 14 %). (Upon recrystallization, only the monomeric complex [Ru]NCS **6** was obtained.) Red crystals formed in the filtrate, which were isolated by filtration, washed with diethyl ether and *n*-hexane and dried under vacuum. This product was identified as **3a** (0.29 g, 40 %). Orange crystals formed in the remaining filtrate, which were isolated by filtration to provide **4** (0.03 g, 5 %). Finally, a white compound crystallized from the residual solution, identified as **5** (0.02 g, 6 %), in both the (*E*) and (*Z*) forms.

Data for 3a: $C_{61}H_{62}N_4P_2RuS_3$ (1110.27): calcd. C 65.98, H 5.63, N 5.05, S 8.66; found C 66.04, H 5.70, N 4.98, S 8.70. MS (FAB, ^{102}Ru): *m*/*z* = 1110.1 [M]$^+$, 649.1 [M − N($PhCH_2NCS)_3$]$^+$. IR (KBr): $\tilde{\nu}$ = 1174 (C=S), 699 (C−S) cm^{-1}. ^{1}H NMR ([D_8]THF): δ = 7.46−6.89 (m, 20 H, Ph), 5.07 (br. s, 2 H, CH_2), 4.86 (s, 2 H, CH_2), 4.72 (s, 2 H, CH_2), 2.83−1.35 (m, 6 H, CH_2), 1.51 (s, 15 H, Cp*-CH_3) ppm. ^{31}P NMR ([D_8]THF): δ = 37.54 (br. s) ppm.

X-ray Crystallographic Studies: Data was collected at room temperature from epoxy-coated crystals mounted on a glass fiber. All measurements were made on a CCD Smart diffractometer with

New Bifunctional Contrast Agents: Bis-Amide Derivatives of *C*-Substituted Gd-DTPA

Sophie Laurent,[a] François Botteman,[a] Luce Vander Elst,[a] and Robert N. Muller*[a]

Keywords: Gadolinium / Zinc / Metallation / Amides

In order to expand upon and confirm previous observations on the positive and adverse roles played by the functionalization and substitution of the parent MRI contrast agent Gd-DTPA, two new bi-functionalized contrast agents namely Gd-(*S*)-EOB-DTPA-BMA and Gd-(*S*)-C_4Bz-DTPA-BMA have been synthesized, purified, and characterized by multinuclear NMR studies. Water ^{1}H nuclear magnetic relaxation dispersion profiles were recorded at several temperatures. τ_R was determined by ^{2}H NMR on the diamagnetic lanthanum complex. τ_M, the water residence time, was obtained by ^{17}O NMR measurements and the stability versus transmetallation by zinc was evaluated by proton relaxometry. The residence time of water molecules in the first coordination sphere of the Gd complexes has confirmed the antagonistic effects of amide functions and C-4 substitution on the reduction of the water residence time, a critical parameter of relaxivity. This C-4 position is thus particularly appropriate for the substitution required by the design of new contrast agents covalently bound to macromolecules or carrying specific vectors.

Introduction

The efficacy of the gadolinium complexes currently used as contrast agents in Magnetic Resonance Imaging results partly from the presence of water molecules in the first coordination sphere of the ion and from the exchange of these coordinated molecules with the bulk. An exchange rate which is too slow or too fast limits the efficacy of the contrast agent. In a previous report,[1] we have shown that Gd-DTPA derivatives carrying benzyl groups are characterized by water exchange rates which differ according to the position of the group: the complex *C*-substituted on an ethylenic carbon i.e. [Gd-(*S*)-C_4Bz-DTPA] has a faster water exchange rate and an higher relaxivity, the bis(benzylamide) (Gd-DTPA-BBzA) has a slightly higher proton relaxivity at 37 °C than the parent compound but the longer residence time of its coordinated water molecules (τ_M) clearly limits the relaxivity at low temperatures and, finally, the bis-ester derivative (Gd-DTPA-BBzE) behaves like Gd-DTPA. Another *C*-substituted derivative, Gd-(*S*)-EOB-DTPA, was also shown to be characterized by an increased water exchange rate compared with the parent compound.[2] On the contrary, amide derivatives of Gd-DTPA or Gd-DOTA are known to be characterized by slower water exchange rates than those of their parent structures.[3−5]

In this work, the influence of the *C*-substitution on the behavior of bis-amide derivatives was thus studied on two compounds, both substituted on the ethylenic C-4 carbon. Gd-(*S*)-EOB-DTPA-BMA (**1**) and Gd-(*S*)-C_4Bz-DTPA-BMA (**2**) (Figure 1) were synthesized and their gadolinium complexes were characterized by: i) proton relaxation rate measurements between 0.5 mT and 7.05 T (NMRD profiles), ii) estimation of their rotational correlation times through the analysis of the deuterium relaxation rates of their specifically labeled La-analogues, and iii) determination of the water residence times of their coordinated water molecules through the analysis of the temperature dependence of the ^{17}O transverse relaxation rates of water. Their stability versus transmetallation by Zn^{2+}, an important endogenous ion, was also studied. Finally, all these parameters, compared with those of parent and analogous compounds, are discussed in the context of the structure−relaxivity relationship.

Results and Discussion

The bis-amide complexes **1** and **2** (Figure 1) were synthesized by the classical method starting from the reaction of the pentacarboxylated ligands with acetic anhydride in the presence of pyridine to produce *C*-functionalized DTPA bis-anhydrides. The subsequent amination was carried out with an excess of methylamine.

NMRD profiles recorded at 310 K show that, in general, the relaxivities (r_1) of all the *C*-substituted derivatives are higher than those of Gd-DTPA and Gd-DTPA-BMA (Figure 2). At low magnetic fields, the relaxivities of the bis-amide derivatives of the *C*-substituted complexes are slightly lower than those of their carboxylate analogues. At higher fields, however, the relaxivities of the bis-amides **1** and **2** are similar to those of their parent compounds Gd-(*S*)-EOB-DTPA (**5**) or Gd-(*S*)-C_4Bz-DTPA (**6**) but still markedly higher than those of the unsubstituted structures Gd-DTPA (**3**) or Gd-DTPA-BMA (**4**). At 0.47 T (20 MHz) and 310 K, the relaxivity values of Gd-(*S*)-EOB-DTPA (**5**), Gd-(*S*)-EOB-DTPA-BMA (**1**), Gd-(*S*)-C_4Bz-DTPA (**6**), Gd-(*S*)-C_4Bz-DTPA-BMA (**2**), Gd-DTPA (**3**), and Gd-DTPA-BMA (**4**) are 5.5, 5.0, 4.8, 4.7, 3.9, and 3.8 $s^{-1}\cdot mM^{-1}$ respectively.

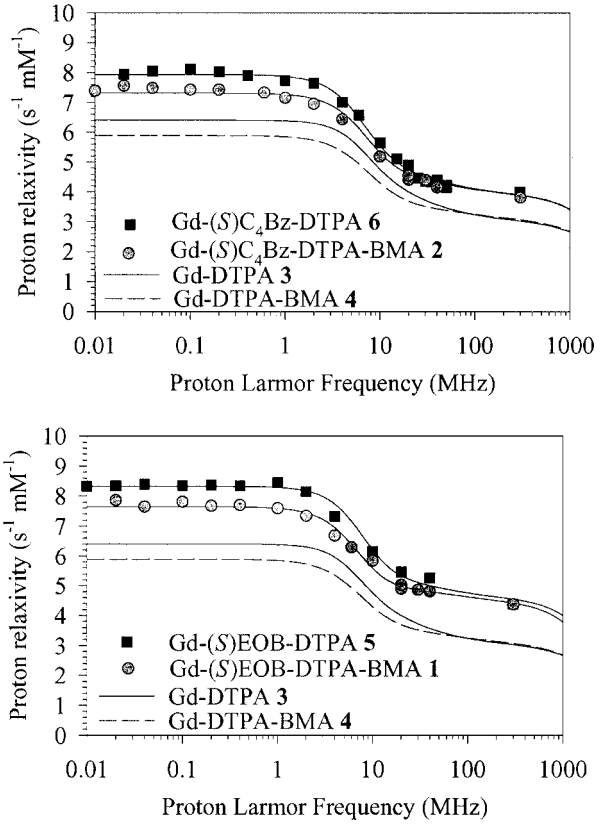

Figure 2. ^{1}H NMRD relaxivity profiles of Gd-(*S*)-C_4Bz-DTPA-BMA (**2**) and Gd-(*S*)-C_4Bz-DTPA (**6**) in water at 310 K ([Gd complex] = 1 mM) (top graph) and of Gd-(*S*)-EOB-DTPA-BMA (**1**) and Gd-(*S*)-EOB-DTPA (**5**) in water at 310 K ([Gd complex] = 1 mM) (bottom graph). The fittings of the NMRD profiles of Gd-DTPA (**3**) and Gd-DTPA-BMA (**4**) are shown for comparison. The lines correspond to the theoretical fittings of the data points.

The longitudinal relaxivity, r_1, arises from both short (inner sphere) and long (outer sphere) distance magnetic interactions. The inner sphere contribution can be described by the Solomon−Bloembergen equations,[6−7] while the outer sphere contribution can be accounted for by the Freed model[8] (see ref.[2] for the description of the models). A rather large number of structural parameters is included in those models: q the number of water molecules in the first coordination sphere, τ_M the residence time describing the exchange between coordinated and bulk water, r the distance between coordinated water protons and the unpaired electron spin, d the distance of closest approach, D the relative diffusion constant, τ_R the rotational correlation time of the hydrated complex and $\tau_{s1,2}$ the longitudinal and transverse relaxation times of the electron. These latter parameters are field dependent with τ_{SO} being the value of $\tau_{s1,2}$ at zero field and τ_v the correlation time modulating the interaction responsible of the electronic relaxation.

Therefore, the analysis of the proton NMRD curves by a multi-parametric fitting procedure takes advantage of the knowledge of some of the parameters.[2,9] In previous studies,[2,4,9−12] it has been shown that q, τ_R, and τ_M could be evaluated by specific NMR techniques and reduce the ambiguity of the analysis of the proton NMRD curves. By analogy with similar complexes [Gd-(*S*)-EOB-DTPA (**5**), Gd-DTPA-BMA (**4**) or Gd-DTPA (**3**)], q was assumed to be equal to one and d and D^{310} were set to 0.36 nm and 3.3 $\times 10^{-9}$ $m^2\cdot s^{-1}$ respectively.

The determination of τ_R was performed at five temperatures (from 278 K to 318 K) on the diamagnetic lanthanum complexes deuterated at the α positions of the carbonyl groups[13] through the analysis of the deuterium longitudinal rates.[2] At 310 K, the values of τ_R are fairly close {τ_R [La-(*S*)-[D_8]EOB-DTPA-BMA] = 63 ± 7 ps; τ_R [La-(*S*)-[D_{10}]EOB-DTPA] = 66 ± 7 ps; τ_R [La-(*S*)-[D_8]C_4Bz-DTPA-BMA] = 60 ± 6 ps; τ_R [La-(*S*)-[D_{10}]C_4Bz-DTPA] = 65 ± 7 ps; τ_R [La-[D_8]DTPA-BMA] = 67 ± 7 ps; and τ_R [La-[D_{10}]DTPA] = 60 ± 6 ps}. The activation energies for the rotations calculated from the evolutions of τ_R with temperature are comparable for all the complexes (E_R = 20 −24 kJ/mol).

Among the two relaxation mechanisms, i.e. the outer sphere and the inner sphere contributions, only the latter is influenced by the water residence time and can thus be quenched at low temperatures while the former always increases when the temperature is lowered. Therefore, as long as the water residence time is not limiting the propagation of the relaxation ($\tau_M < T_{1M}$ where T_{1M} is the relaxation time of the protons of the coordinated water molecule), the global relaxivity increases when temperature decreases. If this condition is not fulfilled, the global relaxivity may reach a plateau or even decrease at low temperatures. The possible influence of τ_M on the proton relaxivity was evaluated at 0.47 T over a range of temperatures between 278 K and 318 K (Figure 3). Like Gd-DTPA itself, its *C*-functionalized derivatives exhibit a continuous increase in r_1 when the temperature is lowered, revealing that τ_M does not limit the relaxation rate. On the contrary, the bis-amide

complexes Gd-DTPA-BMA **4**, Gd-(*S*)-C_4Bz-DTPA-BMA **2**, and Gd-(*S*)-EOB-DTPA-BMA **1** show a clear limitation of their relaxivity by the water exchange below 310 K.

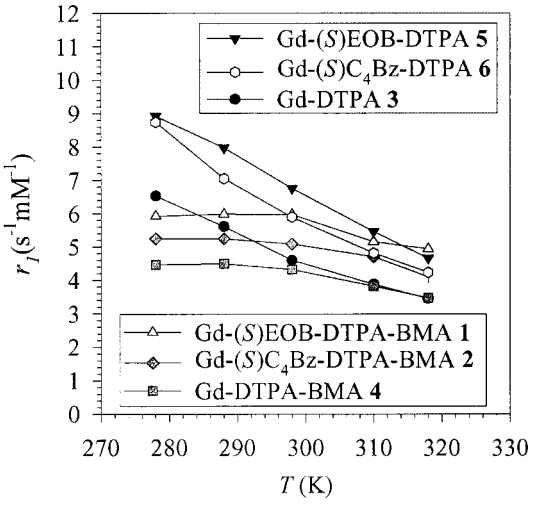

Figure 3. Temperature dependence of the proton relaxivities of the various Gd complexes at 0.47 T.

A quantitative estimation of the residence times of water molecules in the first coordination spheres of the gadolinium complexes (τ_M) was obtained from the analysis of the temperature dependence of the ^{17}O transverse relaxation rates of solutions containing 13−50 mM of the gadolinium complexes. Various parameters are involved in the theoretical fitting of the ^{17}O data: $A/\hbar$, the hyperfine coupling constant between the oxygen nucleus of bound water molecules and the Gd^{3+} ion; τ_V, the correlation time modulating the electronic relaxation of Gd^{3+}; E_v, the activation energy related to τ_V; Δ^2, the mean-square zero field splitting energy (Δ^2 is related to τ_{SO} by $\tau_{SO} = [12\ \Delta^2\tau_V]^{-1}$); and $\Delta H^{\#}$ and $\Delta S^{\#}$, the enthalpy and entropy of the water exchange process. The theoretical fitting of the transverse relaxation rates obtained over a temperature range from 280 K to 350 K gives values of τ_M^{310} for Gd-(*S*)-EOB-DTPA-BMA (**1**) and Gd-(*S*)-C_4Bz-DTPA-BMA (**2**) of 472 ± 38 ns and 429±23 ns, respectively. These values are between those reported for pentacarboxylate complexes {τ_M^{310} [Gd-DTPA (**3**)] = 143±25 ns; τ_M^{310} [Gd-(*S*)-EOB-DTPA (**5**)] = 82 ± 21 ns; τ_M^{310} [Gd-(*S*)-C_4Bz-DTPA (**6**)] = 86 ± 8 ns} and the bis-amide parent structure (τ_M^{310} [Gd-DTPA-BMA (**4**)] = 967±36 ns) (Table 1). These results are in good agreement with the temperature dependence of r_1 at 0.47 T and they confirm that the presence of amide functions on the structure of the DTPA ligand considerably decreases the exchange rate and that a conformational or steric effect, induced by substitution on the C_4 of the ligand, counteracts this unfavorable effect.

The fittings of the proton NMRD profiles were performed with the distance *r* fixed to the usual value of 0.31 nm for Gd-DTPA (**3**) and Gd-DTPA-BMA (**4**). For the *C*-functionalized complexes, such a distance results in τ_R values significantly larger than those obtained by deuterium relaxometry (τ_R^{310}= 112 ps, 91 ps, 109 ps, and 84 ps for complexes **1**, **2**, **5**, and **6** respectively). Shorter effective distances (0.291 nm and 0.3 nm) were therefore used to fit the data (Table 2). For complexes **1** and **5**, τ_R values obtained for the distance r equal to 0.291 nm are in better agreement with the values obtained by deuterium relaxometry, whereas for complexes **2** and **6**, both distances (0.291 nm and 0.3 nm) can account for the experimental results. The fitted values of τ_{SO} and τ_V (Table 2) are in the same range for all the complexes and agree with those obtained by the fitting of the ^{17}O data (Table 1). At low magnetic fields, the lower relaxivity of the bis-amide *C*-substituted complexes **1** and **2**, compared with their parent complexes **5** and **6**, can be related to their longer τ_M values which result in a more marked limitation of the relaxivity at low rather than at high fields.

The NMRD profiles of Gd-(*S*)-EOB-DTPA-BMA (**1**) and Gd-(*S*)-C_4Bz-DTPA-BMA (**2**) at 298 K and 310 K are shown in Figure 4. The data recorded at 298 K are only slightly greater than those obtained at 310 K, confirming that τ_M is indeed limiting the relaxivity. The parameters obtained from the theoretical fitting are shown in Table 2.

Finally, the transmetallation of the gadolinium complex by Zn^{2+} has been assessed. In a phosphate buffer (pH = 7), a precipitation of gadolinium ions expelled from the complex by Zn^{2+} occurs resulting in a decrease of the proton paramagnetic relaxation rate of the solution. The time evolution of the proton relaxation rate was monitored at 0.47 T and 310 K. Previous results showed that, on the one hand, the *C*-functionalized carboxylate complexes are kinetically and thermodynamically more stable than the parent compound Gd-DTPA and, on the other hand, that bis-amide derivatives are less stable.[14] For the bis-amide *C*-substituted compounds, the C-substitution and the bis-amide functions have opposite effects. The "kinetic index", which is the time required to reach 80 percent of the initial R_1^P value, and the "thermodynamic index", which is the R_1^P (t)/R_1^P (0) value measured after 3 days, indeed show a faster and more extensive transmetallation of Gd-(*S*)-EOB-

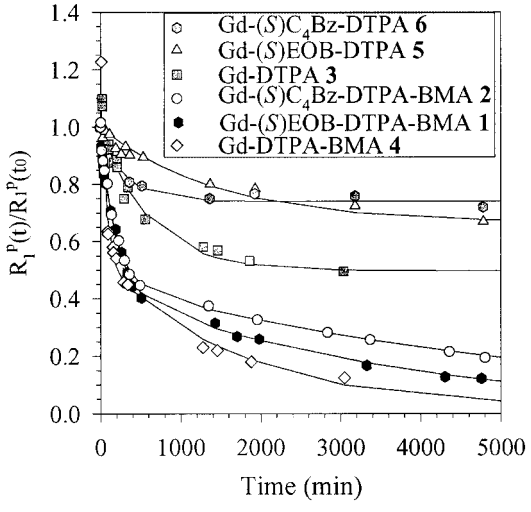

Figure 5. Evolution of the R_1^p (t)/ R_1^p (t = 0) ratio as a function of time for Gd-(*S*)-C_4Bz-DTPA (**6**), Gd-(*S*)-EOB-DTPA (**5**), Gd-DTPA (**3**), Gd-(*S*)-C_4Bz-DTPA-BMA (**2**), Gd-(*S*)-EOB-DTPA-BMA(**1**), and Gd-DTPA-BMA (**4**) (concentrations of Gd complexes and $ZnCl_2$ are 2.5 mM in a phosphate buffer of pH = 7, T = 310 K, B_0 = 0.47 T)

Table 3. Values of the kinetic and thermodynamic indexes obtained during the transmetallation process

	Kinetic index (min)[a]	Thermodynamic index (%)[b]
Gd-(*S*)-EOB-DTPA-BMA (**1**)	70	13
Gd-(*S*)-C_4Bz-DTPA-BMA (**2**)	80	22
Gd-DTPA (**3**)[c]	260−280	49
Gd-DTPA-BMA (**4**) [c]	50−60	9
Gd-(*S*)-EOB-DTPA (**5**) [c]	1500	69
Gd-(*S*)-C_4Bz-DTPA (**6**) [c]	300	73

[a] The kinetic index is defined here as the time required to attain 80 % of the initial value of R_1^P. [b] The thermodynamic index is defined here as the ratio between R_1^P at 4320 min and the initial R_1^P. [c] From ref.[14].

DTPA-BMA (**1**) and Gd-(*S*)-C_4Bz-DTPA-BMA (**2**) than that observed for the parent compound Gd-DTPA (**3**). Only a slight stabilization was observed with respect to the unsubstituted bis-amide derivative (Figure 5 and Table 3).

Conclusion

Two new bi-functionalized compounds, Gd-(*S*)-EOB-DTPA-BMA (**1**) and Gd-(*S*)-C_4Bz-DTPA-BMA (**2**), have been successfully synthesized. The τ_M values obtained by ^{17}O NMR spectroscopy confirm the lengthening and adverse effect of the amide functions and demonstrate the beneficial effect of a C-4 substitution on the reduction of the water residence time. As assessed by the Zn^{2+} transmetallation process, the two new bis-amides are less stable than Gd-DTPA and slightly more stable than Gd-DTPA-BMA (**4**). In conclusion, although more difficult to synthesize, C-4-substituted DTPA complexes are better suited for the covalent binding to macromolecules or to specific vectors in the context of the design of new specific contrast agents for molecular imaging.

Experimental Section

General

Chemicals: Gd-DTPA (**3**), Gd-(*S*)-EOB-DTPA (**5**), and the ligand EOB-DTPA were provided by Schering AG (Berlin, Germany). The ligand (*S*)-C_4Bz-DTPA and the corresponding gadolinium complex were obtained as described earlier.[1] The organic reactants and intermediates were purchased from Aldrich (Bornem, Belgium). NMR Spectroscopy: ^1H and ^{13}C NMR spectra were recorded with a Bruker AMX-300 instrument (Bruker, Karlsruhe, Germany). Chemical shifts (in ppm) are referred to the solvent peak. For ^{13}C NMR, the methyl signal of *tert*-butanol was used as reference (δ = 31.2 ppm). Mass Spectrometry: Mass spectra (LSIMS) were obtained with a VG AUTOSPEC mass spectrometer (VG Analytical, Manchester, UK). Samples were dissolved in water and deposited in a glycerol matrix. Chromatography: High-performance liquid chromatography (HPLC) was performed with a Waters 600 multisolvent delivery system equipped with a Rheodyne injection valve (20μL loop) and controlled by the Millenium software (Waters, Milford, USA). A Novapak C18 column (4.56 mm × 150 mm) was used. Elution was performed with a linear gradient of pure 0.05 M triethylammonium acetate (pH = 6) to 100 % methanol at a flow rate of 1 mL/min for 20 min. A fluorescence detector was used to monitor the elution of the gadolinium complex. Relaxometry: Proton Nuclear Magnetic Relaxation Dispersion (NMRD) profiles were recorded with a Field Cycling Relaxometer working between 0.02 and 50 MHz. Additional points at 20 and 300 MHz respectively were obtained on a Bruker Minispec PC-20 thermostatically controlled by a tetrachloroethylene flow and with a Bruker AMX 300 spectrometer. Fitting of the ^1H NMRD curves was performed with previously described software using minimization routines (Minuit, CERN Library).[15,16] The deuterium and ^{17}O measurements were carried out with 2 mL samples contained in 10-mm o.d. tubes with a Bruker AMX-300 spectrometer equipped with a broadband probe. The field homogeneity was optimized on the proton free induction decay using the decoupling coil. The temperature was regulated by air or nitrogen flow (Bruker BVT-2000 unit). Deuterium longitudinal relaxation rates were measured using an inversion recovery Fourier transform sequence on solutions containing the labeled diamagnetic lanthanum complex dissolved in deuterium depleted water (Aldrich, Bornem, Belgium). The experimental data were fitted with a three-parameter minimization routine. Diamagnetic transverse relaxation times of ^{17}O water (pH ≈ 6.5) were measured at natural abundance using a Carr−Purcell−Meiboom−Gill sequence and a two-parameter fit of the data. ^{17}O transverse relaxation times of water (natural abundance) in solutions containing paramagnetic complexes were calculated directly from the linewidth. All ^{17}O NMR spectra were proton decoupled. The theoretical fitting of the data was performed as described previously.[1,2,9]

Synthesis of Ligands

3,6,9-Tris(carboxymethyl)-4-ethoxybenzyl-1,11-bis(methylamino)-3,6,9-triazaundeca-1,11-dione [(*S*)-EOB-DTPA-BMA (1)]: A mixture of (*S*)-EOB-DTPA (0.4 g), acetic anhydride (0.6 mL), and pyridine (0.5 mL) was heated at 70 °C for 24 h. The suspension was cooled, a 2 M methylamine (methanol solution) was added (3 mL) and the mixture was stirred for around 24 h. After addition of methanol (50 mL), the mixture was filtered. The filtrate was evaporated to dryness under reduced pressure. Water (5 mL) was then added and the pH was adjusted to 2 with 2 N HCl. The solution was passed through a DOWEX AG 50 W-X8 (H^+ form) cation-exchange resin which was first eluted with water and the product was recovered from the resin by elution with 2 N aqueous ammonia. The residue obtained after evaporation of the solution was dissolved in acetic acid and precipitated with ethyl acetate. The crude product was recovered by filtration. Yield: 0.16 g (38 %). ^1H NMR (D_2O): δ = 6.9−6.7 (4 H, AA′BB′, Ph), 3.8 (q, 2 H, CH_2), 3.6−2.8 (m, 19 H, 8 × CH_2, CH), 2.5 (s, 3 H, CH_3), 2.45 (s, 3 H, CH_3), 1.1 (t, 3 H, CH_3) ppm. ^{13}C NMR (D_2O): δ = 178.1, 171.8, 171.2, 170.6, 170.4, 166.1, 114.2, 128.9, 130.4, 65.1, 62.5, 61.1, 58.9,

57.3, 57.2, 56.5, 55.1, 53.7, 52.3, 51.8, 26.4, 26.3, 14.3 ppm. LSIMS: $[M + 1]^+$: 554^+. HPLC: 13.3 min.

4-Benzyl-3,6,9-tris(carboxymethyl)-1,11-bis(methylamino)-3,6,9-triazaundeca-1,11-dione [(*S*)-C_4Bz-DTPA-BMA (2)]: This compound was obtained from (*S*)-C_4Bz-DTPA[1] as described for (*S*)-EOB-DTPA-BMA above. Yield: 0.142 g (32 %). ^{1}H NMR (D_2O): δ = 7.3−7.0 (m, 5 H, Ph), 3.45−2.6 (m, 19 H, 9 × CH_2, CH), 2.5 (s, 3 H, CH_3), 2.45 (s, 3 H, CH_3) ppm. ^{13}C NMR (D_2O): δ = 177.9, 171.9, 171.3, 170.6, 170.3, 138.8, 128.6, 128.3, 125.8, 62.4, 61.0, 58.8, 57.2, 57.1, 56.6, 55.2, 53.6, 52.4, 51.7, 26.4, 26.3 ppm. LSIMS: $[M + 1]^+$: 536^+. HPLC: 12.5 min.

Complexation: The La^{III} or Gd^{III} complexes were prepared by mixing aqueous solutions of equimolar amounts of hydrated $LaCl_3$ or $GdCl_3$ and the ligand. The pH was adjusted to between 6.5 and 7. The absence of free La or Gd ions was checked with xylenol orange indicator. The complexes were passed through a Sep-Pak column (Waters, Accell Plus QMA Cartridges) and the eluted solutions were freeze-dried. The purities of the chelates were verified by HPLC and their masses confirmed by LSIMS.

Deuteration: Deuteration of the ligands [(*S*)-EOB-DTPA-BMA and (*S*)-C_4Bz-DTPA-BMA] or of the lanthanum complexes at the α position of the carbonylic groups was performed by the procedure described by Wheeler and Legg.[13] The ligand or complex (4 mmol) was dissolved in D_2O (40 mL), the pD was adjusted to 10.6 by addition of K_2CO_3 and the mixture was heated to reflux for 24 h with stirring. The pD was then adjusted to 2 (ligand solution) or 6 (lanthanum complex solution) with concentrated hydrochloric acid, the solution was evaporated to a final volume of 10 mL and the solid KCl was removed by filtration. Acetone was added to induce precipitation of the deuterated compounds, which were recovered by filtration, dissolved in H_2O and isolated after lyophilization. The deuteration (> 95 %) was confirmed by ^{1}H NMR spectroscopy.

(*S*)-[D_8]EOB-DTPA-BMA: NMR (D_2O, pH = 10): δ = 6.9−6.7 (4 H, AA′BB′, Ph), 3.8 (q, 2 H, CH_2), 3.6−2.8 (m, 11 H, 5 × CH_2, CH), 2.5 (s, 3 H, CH_3), 2.45 (s, 3 H, CH_3), 1.1 (t, 3 H, CH_3) ppm.

(*S*)-[D_8]C_4Bz-DTPA-BMA: NMR (D_2O, pH = 10): δ = 7.4−7.1 (m, 5 H, Ph), 3.45−3.0 (m, 5 H, 2 × CH_2, CH), 2.9−2.6 (m, 6 H, 3 × CH_2), 2.5 (s, 3 H, CH_3), 2.45(s, 3 H, CH_3) ppm.

Kinetics of the Transmetallation: The technique is based on the evolution of the paramagnetic proton longitudinal relaxation rate (R_1^p) of a phosphate buffer solution (pH, 7, $[H_2PO_4^-]$ + $[HPO_4^{2-}]$ + $[PO_4^{3-}]$ = 67 mM) containing 2.5 mM of gadolinium complex and 2.5 mM of $ZnCl_2$.[14] The measurements were performed with a Bruker Minispec PC 120 (20 MHz) spin analyzer at 310 K.

A Series of Vinylidene-, Vinyl-, Carbene- and Carbyneruthenium(II) Complexes with $[Ru(PCy_3)_2]$ and $[Ru(P\mathit{i}Pr_3)_2]$ as Molecular Building Blocks

Stefan Jung,[a] Kerstin Ilg,[a] Carsten D. Brandt,[a] Justin Wolf,[a] and Helmut Werner*[a]

Dedicated to Professor Michael F. Lappert on the occasion of his 75th birthday

Keywords: Carbene complexes / Carbyne complexes / Ruthenium / Vinyl complexes / Vinylidene complexes

The hydrido(vinylidene) complexes $[RuHCl(=C=CHR)(L)_2]$ (R = H, *t*Bu, Ph; L = PCy_3, $P\mathit{i}Pr_3$) undergo metathesis reactions in the presence of KX (X = I, NCO, OPh, CH_3CO_2, CF_3CO_2) to give the substitution products $[RuHX(=C=CHR)(L)_2]$ (**6**–**15**) in good to excellent yields. Treatment of $[RuHX(=C=CHR)(L)_2]$ with HBF_4 in diethyl ether affords the cationic carbyneruthenium(II) derivatives $[RuHX(\equiv CCH_2R)(OEt_2)(L)_2]BF_4$ (**17**, **18**, **20**, **21**) and $[RuH(\kappa^2\text{-}O_2CCH_3)(\equiv CCH_2R)(L)_2]BF_4$ (**19**, **22**). The reactions of $[RuHCl(=C=CHR)(L)_2]$ with MX [X = BF_4, PF_6, BPh_4, $B(Ar_f)_4$] in acetonitrile lead to the formation of cationic five- and six-coordinate vinylruthenium(II) compounds **26a**–**d** and **27a**–**d** of which $[Ru(CH=CH_2)(CH_3CN)_2(PCy_3)_2]BPh_4$ (**26c**) has been characterized by X-ray crystallography. The starting material $[RuHCl(=C=CHPh)(P\mathit{i}Pr_3)_2]$ reacts with CO to give $[RuCl(CH=CHPh)(CO)_2(P\mathit{i}Pr_3)_2]$ (**28**) and with N_2 to produce $[RuCl(CH=CHPh)(N_2)(P\mathit{i}Pr_3)_2]$ (**29**). The molecular structure of **29** has been determined. Protonation of $[Ru(CH=CH_2)(CH_3CN)_2(PCy_3)_2]X$ and $[Ru(CH=CHPh)(CH_3CN)_3(P\mathit{i}Pr_3)_2]X$ with HBF_4 and $HB(Ar_f)_4$ yields the dicationic carbeneruthenium(II) complexes $[Ru(=CHCH_3)(CH_3CN)_2(PCy_3)_2]X_2$ (**30a**,**b**) and $[Ru(=CHCH_2Ph)(CH_3CN)_3(P\mathit{i}Pr_3)_2][B(Ar_f)_4]_2$ (**31**), the latter of which eliminates styrene to give $[Ru(CH_3CN)_3(P\mathit{i}Pr_3)_2][B(Ar_f)_4]_2$ (**32**).

Introduction

In the context of our investigations on the preparation and reactivity of vinylideneruthenium(II) complexes,[1] we recently reported that the reaction of the five-coordinate hydrido(vinylidene) compound $[RuHCl(=C=CH_2)(PCy_3)_2]$ with acids HA, containing an anion that does *not* coordinate to the metal center, in diethyl ether affords the cationic carbyne(hydrido) complex $[RuHCl(\equiv CCH_3)(PCy_3)_2(OEt_2)]^+$ instead of the anticipated isomeric carbene derivative $[RuCl(=CHCH_3)(PCy_3)_2(OEt_2)]^+$.[2] This cation, as well as the corresponding cations with coordinated water or dimethylaniline instead of diethyl ether, turned out to be a highly efficient catalyst for olefin metathesis, including the cross-olefin metathesis of cyclopentene with methylacrylate to afford multiply unsaturated esters $CH_2(C_5H_8)_nCHCO_2Me$ (n = 1−3). The cations $[RuHCl(\equiv CCH_3)(PCy_3)_2(S)]^+$, however, in the absence of excess HA are rather labile and decompose in solution within 20 min at room temperature. For this reason, we set out to prepare more stable ruthenium carbynes by modifying the coordination sphere and using different ruthenium vinylidenes as the precursors.

In this paper we report the synthesis of a series of new hydrido(vinylidene) complexes $[RuHX(=C=CHR)(PCy_3)_2]$ and $[RuHX(=C=CHPh)(P\mathit{i}Pr_3)_2]$, their conversion into the corresponding cationic ruthenium carbynes and into neutral as well as cationic vinylruthenium compounds, and also the formation of dicationic, five-coordinate ruthenium carbenes. Some preliminary results have already been communicated.[3]

Results and Discussion

The hydrido(dihydrogen) complex $[RuHCl(H_2)(PCy_3)_2]$ (**1**), which can be prepared from $RuCl_3{\cdot}3H_2O$ in high yield,[2,4] is not only an appropriate starting material for $[RuHCl(=C=CH_2)(PCy_3)_2]$ (**3**) and $[RuHCl(=C=CHPh)(PCy_3)_2]$ (**4**) but also for the *tert*-butylvinylidene counterpart **2** [see Equation (1)]. Treatment of a solution of **1** in CH_2Cl_2 with two equivalents of tBuC≡CH at −78 °C leads to the formation of **2** which, after removal of the solvent, was isolated as a brown air-sensitive solid in 72% yield. In contrast to **3** and **4**, compound **2** decomposes slowly in solution even at low temperatures and thus only ^1H and ^{31}P NMR spectroscopic data could be obtained. The ^1H NMR spectrum displays the signal for the vinylidene proton as a triplet at δ = 2.87 ppm and the resonance for the hydride, also as a triplet, at δ = −13.89 ppm.

$$[RuHCl(H_2)(PCy_3)_2] \xrightarrow[-CH_2=CHtBu]{2HC\equiv CtBu} [RuHCl(=C=CHtBu)(PCy_3)_2] \quad (1)$$

1 **2**

While attempts to replace the chloro ligand in **2** by iodide or isocyanate led to a mixture of products that could not be separated by fractional crystallization, a clean reaction occurs between **2** and excess CH_3CO_2K that affords the acetato derivative **6** in virtually quantitative yield. The characteristic signals for the =CH and the RuH protons appear in the ^1H NMR spectrum at $\delta = 2.12$ and -12.48 ppm, respectively, and are split into triplets due to ^1H-^{31}P coupling. The IR spectrum of **6** shows two bands for the asymmetric and symmetric OCO stretching modes at 1635 and 1448 cm^{-1}, respectively, which, in agreement with literature data,[5] indicate a chelating coordination of the acetate unit.

The reactions of compounds **3** and **4**, being significantly more stable than **2**, with both KOCN and CH_3CO_2K in THF proceed cleanly and give the substitution products **7**−**10** in good to excellent yields. Apart from the elemental analyses, the spectroscopic data support the proposed structure shown in Scheme 1. Since the IR spectra of **7** and **9** display the symmetric ν(NCO) stretch at 1446 cm^{-1}, we assume that the NCO ligand is *N*-bonded. In case of an *O*-coordination, the corresponding absorption is expected to appear below 1200 cm^{-1}.[6]

Both the hydrido(vinylidene) complex **5**, containing two triisopropylphosphane ligands, and the compounds **11**−**15** obtained by salt metathesis with KX in THF (Scheme 1) are considerably more stable than their PCy_3 counterparts. In solution (C_6H_6 or CH_2Cl_2) they do not decompose even after 24 h. In the ^1H NMR spectra of **11**−**15**, the vinylidene =CH proton resonates at between $\delta = 4.25$ and 4.40 ppm and the RuH proton at between $\delta = -9.3$ and -13.6. In the low-field region the ^{13}C NMR spectra of **11**−**15** display two triplets, one between $\delta = 327$ and 338 ppm and the other between $\delta = 108$ and 110 ppm, which are assigned to the α- and β-carbon atoms of the vinylidene ligand. For the Ru(NCO) compound **12** and the Ru(κ^2-O_2CCR_3) de-

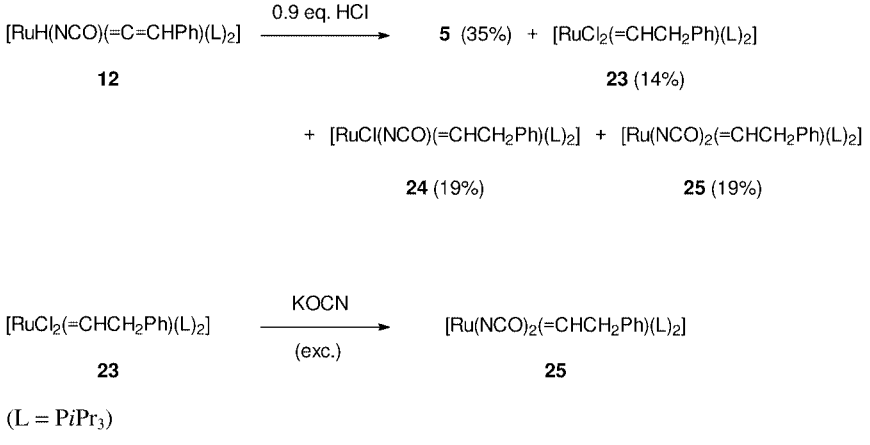
rivatives **14** and **15** the positions of the ligand vibrations in the IR spectra are quite similar to those of **7** and **9** and **8** and **10**, respectively, and thus an *N*-linkage for the NCO^- anion and a chelating coordination mode for the carboxylate unit can be assumed.

The ruthenium vinylidenes **4**, **5**, **7**, **8**, **14** and **16** are readily protonated with a solution of HBF_4 in diethyl ether at low temperatures to give the six-coordinate cationic carbyne complexes **17**−**22** in 55−73% yield. The products were isolated as light yellow, moderately air-sensitive solids by precipitation with diethyl ether. While solutions of the acetato derivatives **19** and **22** (see Scheme 2) are stable for about one hour, the related compounds **17**, **18** and **20**, **21** decompose more readily, for example in dichloromethane in ca. 30 min even at 0 °C. Conductivity measurements (in nitromethane) confirm the presence of 1:1 electrolytes. The ^1H NMR spectra of **17** and **18** show a singlet for the methyl protons of the carbyne ligand at δ = 2.51 (**17**) and 2.23 ppm (**18**), while the spectra of **20**−**22** display the resonance (also a singlet) for the CH_2Ph protons at δ = 3.66−4.03 ppm. The hydride signal appears between δ = −6.41 and −7.46 ppm and is thus shifted downfield by ca. 3−6 ppm compared with the hydrido(vinylidene) precursors. The ^1H NMR spectra of **17**, **18** and **20**, **21** also confirm the coordination of one molecule of diethyl ether which is noteworthy insofar as in the five-coordinate carbyneruthenium complexes $[RuCl_2(\equiv CCH_2R)(PR'_3)_2]^+$ (R = Ph, *t*Bu; R′ = Cy, *i*Pr) the position *trans* to the carbyne ligand is not occupied by a solvent molecule.[7]

Similarly to the chloro derivative $[RuHCl(\equiv CCH_3)(PCy_3)_2(OEt_2)]BF_4$,[2] the cationic carbyne(hydrido) compounds **17** and **18** also catalyze the ring opening metathesis polymerization (ROMP) of cyclooctene. While for **18**, the rate, the yield of the polymer and the ratio of the *trans*- and *cis*-oriented carbon-carbon double bonds of the polymer are almost identical to the data obtained with the Grubbs catalyst $[RuCl_2(=CHPh)(PCy_3)_2]$, for **17** the results are less good. Under the same conditions (CH_2Cl_2, room temperature, ratio cyclooctene to ruthenium complex = 500:1), the acetato compound **19** is nearly inert in the ROMP of cyclooctene, which is probably due to the coordination number of six at ruthenium(II). The entering olefin can thus not bind to the metal center and can also not initiate the conversion of the $RuH(\equiv CCH_3)$ to the active $Ru(=CHCH_3)$ moiety.

Taking into consideration the fact that hydrido(vinylidene)ruthenium compounds $[RuHCl(=C=CHR)(PR'_3)_2]$ react with one equivalent of HCl to give the Grubbs-type carbene complexes $[RuCl_2(=CHCH_2R)(PR'_3)_2]$,[4] we also attempted to convert the relatively stable isocyanato derivative **12** into the corresponding metal carbene. However, while the dichloro compound **23** was exclusively formed with two equivalents of HCl, the reaction of **12** with HCl in the molar ratio 1:0.9 gave a mixture of four products. Apart from the hydrido(vinylidene) complex **5** three carbene derivatives could be detected, which in the ^{31}P NMR spectrum give rise to three singlets at δ = 45.2, 47.0 and 48.3 ppm. The ^1H NMR spectrum of the mixture equally shows three resonances for the carbene Ru=CH proton at δ = 19.06, 19.50 and 19.95 ppm, which are split into triplets due to ^1H-^{31}P coupling. While the signals at δ = 45.2 (^{31}P) and 19.95 ppm (^1H) belong to the dichloro compound **23**,[1d,1e] the corresponding resonances at δ = 48.3 (^{31}P) and 19.06 ppm (^1H) are assigned to the bis(isocyanato) counterpart **25**, which was prepared from **23** and excess KOCN in THF (see Scheme 3). The mixed ligand RuCl(NCO) species **24** is thus characterized by the signals at δ = 47.0 (^{31}P) and 19.50 ppm (^1H). To explain the formation of the unexpected products **23** and **25** in the reaction of **12** with HCl, we assume that the acid attacks both the C=C bond of the vinylidene and the metal, leading to an NCO/Cl exchange and formation of both **5** and HNCO. The starting material **12** can therefore react either with HCl to give **24** or with HNCO to afford **25**. Analogously, the reaction of **5** (generated from **12** and HCl) furnishes **23** (with HCl) and **24** (with HNCO). All attempts to separate the reaction mixture consisting of **5**, **23**, **24** and **25** by fractional crystallization or low-temperature column chromatography failed.

Since the Ru−Cl bond of the hydrido(vinylidene) complexes is quite labile, we were tempted to replace the chloride not only by other anions but also by a neutral Lewis



Scheme 3

base such as acetonitrile. Treatment of a solution of **3** in CH_2Cl_2 with MeCN led, indeed, to a quick change of color from deep red to brown-yellow but afforded, after conventional workup, the cationic vinyl compound [Ru(CH=CH_2)$(NCMe)_2(PCy_3)_2$]Cl instead of a vinylidene complex. Because this compound, even as a solid, is rather unstable, the reaction was repeated in the presence of $NaBF_4$ or KPF_6 and gave the more stable complexes **26a** and **26b** in about 90% yield (Scheme 4). Salt metathesis with $NaBPh_4$ and $NaB(Ar_f)_4$ [Ar_f = 3,5-$C_6H_3(CF_3)_2$] in methanol led to the formation of **26c** and **26d**, respectively. Compounds **26a**−**d** are red-brown or orange-red, only slightly air-sensitive solids, which, in contrast to the analogous chloride, can be stored under argon at room temperature for weeks without decomposition. The composition of **26a**−**d** has been confirmed by elemental analysis and conductivity measurements. Typical spectroscopic features of **26a**−**d** are the three resonances for the vinyl protons which, taking **26a** as an example, appear at δ = 7.38, 4.84 and 4.70 ppm. The signal at lowest field is a doublet of doublets with a large *trans*-^{1}H-^{1}H and a smaller *cis*-^{1}H-^{1}H coupling and is assigned to the C*H*=CH_2 proton. The two other signals are doublets and belong to the methylene protons. The ^{31}P NMR spectra of **26a**−**d** display a single resonance confirming that the two phosphane ligands are stereochemically equivalent.

The result of the X-ray crystal structure analysis of **26c** is shown in Figure 1. The coordination geometry around the metal center of the cation corresponds to that of a square pyramid with the two phosphanes and the two acetonitriles *trans*-disposed. The atoms C(5) and C(6) of the vinyl ligand (which occupies the apical position) lie in the same plane as the nitrogen and carbon atoms of the MeCN units. In contrast to the nearly linear N(1)−Ru−N(2) axis, the P(1)−Ru−P(2) axis is slightly bent, with the phosphorus atoms pointing away from the CH=CH_2 moiety.

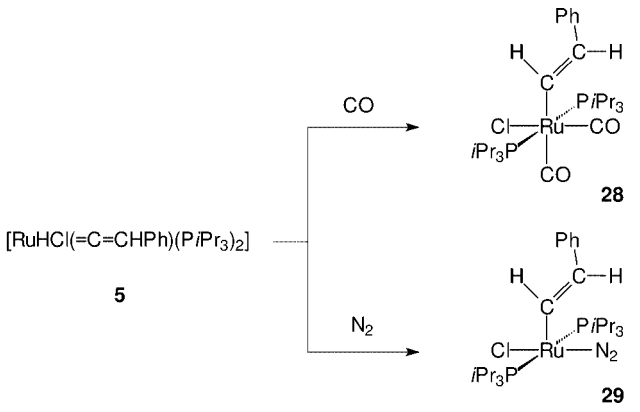
The distance Ru−C(6) of 2.001(5) Å is relatively short but similar to that in other ruthenium compounds with a Ru−C(sp^2) bond.[8] The Ru−P bond lengths of 2.3975(13) and 2.3979(12) Å lie in the expected range and are nearly identical to those found in five-coordinate carbeneruthenium(II) complexes containing a [Ru(PCy_3)$_2$] fragment.[9,10]

The bis(triisopropylphosphane) compound **5** behaves similarly to **3** and reacts with acetonitrile in CH_2Cl_2 to give **27a** (Scheme 4). In the presence of KPF_6, the hexafluorophosphate **27b** is formed, which, upon salt metathesis, affords **27c** and **27d**. The elemental analyses as well as the spectroscopic data of the vinyl complexes **27a**−**d** confirm that, in contrast to **26a**−**d**, *three* acetonitrile ligands are coordinated to the metal center. The smaller cone angle of P*i*Pr$_3$ (160°) compared to PCy_3 (170°)[11] probably favors the increase of the coordination number from five to six in the [Ru(P*i*Pr$_3$)$_2$] derivatives. An uncharged six-coordinate ruthenium compound of composition [$RuCl_2$(NCMe)$_2$(P*i*Pr$_3$)$_2$] has recently been prepared by Katayama and Ozawa from [(*p*-cymene)$RuCl_2$]$_2$ and P*i*Pr$_3$ in toluene/acetonitrile.[12] Moreover, Caulton et al. have found that the hydrido(iodo) complex [RuHI(=C=CHSiMe$_3$)(P*t*Bu$_2$Me)$_2$] reacts with excess methyl isocyanide to give the substituted vinylruthenium(II) derivative [Ru(CH=CHSiMe$_3$)(CNMe)$_3$(P*t*Bu$_2$Me)$_2$]I.[13]

An intramolecular migration of the hydride to the α-carbon atom of the vinylidene ligand also occurs upon treatment of compound **5** with carbon monoxide. This reaction is accompanied by a quick change of color from olive-green to red and then to pale yellow. The final product is the six-coordinate dicarbonyl complex **28** (Scheme 5), which is probably formed via the corresponding red, monocarbonyl complex [RuCl{(*E*)-CH=CHPh)}(CO)(P*i*Pr$_3$)$_2$]. This monocarbonyl compound was previously prepared in our laboratory from [RuHCl(CO)(P*i*Pr$_3$)$_2$] and phenylacetylene and shown to react readily with CO to give **28**.[14]



Scheme 5

Quite unexpectedly, the hydride shift to afford a RuCH=CHPh unit can also be initiated by N_2. Stirring a solution of **5** in pentane under an atmosphere of dinitrogen leads to a smooth change of color from olive-green to red-brown and gives, after low-temperature crystallization and drying the precipitate in a stream of N_2, the insertion product **29** in 92% isolated yield. In the IR spectrum of **29**, the $\nu(N_2)$ stretching mode appears at 2067 cm^{-1} and thus at a similar position as for a [Ru(N_2)(P*i*Pr$_3$)] complex with a tetradentate *N*,*S*,*S*,*N*-bonded chelate ligand.[15] The ^{1}H NMR spectrum of **29** displays the two signals for the vinyl protons at δ = 9.50 (RuCH) and 6.37 ppm (=CH) while the resonances for the corresponding carbon atoms appear at δ = 147.5 (RuC) and 130.2 ppm (C=*C*), respectively.

The formation of **29** from **5** is reversible. If a solution of **29** in benzene is stored at room temperature for ca. 2 h, the ^{1}H NMR spectrum reveals the presence of **5** and **29** in the ratio of 2:3. After evaporation of the solvent in vacuo, only the hydrido(vinylidene) complex can be detected. The elimination of N_2, accompanied by an α-shift of the RuCH proton from carbon to the metal, also takes place in the thermal reaction of **29**, which has been studied by differential thermal analysis (DTA). The ^{1}H NMR spectrum of the remaining product is identical to that of **5**. An analogous reversible formation of a vinylmetal compound has also been observed by Bercaw et al. who reacted [(η^5-C_5Me_5)$_2$TaH(=C=CH_2)] with CO to give [(η^5-C_5Me_5)$_2$Ta(CH=CH_2)(CO)] and regenerated the hydrido(vinylidene) precursor photochemically.[16]

The proposed structure of the dinitrogen complex **29** has been confirmed crystallographically (see Figure 2). As in the cationic vinyl compound **26c**, the coordination geometry around the metal center is square-pyramidal with the vinyl ligand in the apical position. The bending of the P(1)−Ru−P(2) axis [168.74(3)°] is somewhat more pronounced than in **26c** [171.04(4)°], which could be due to a slightly stronger steric repulsion between the phenyl and the

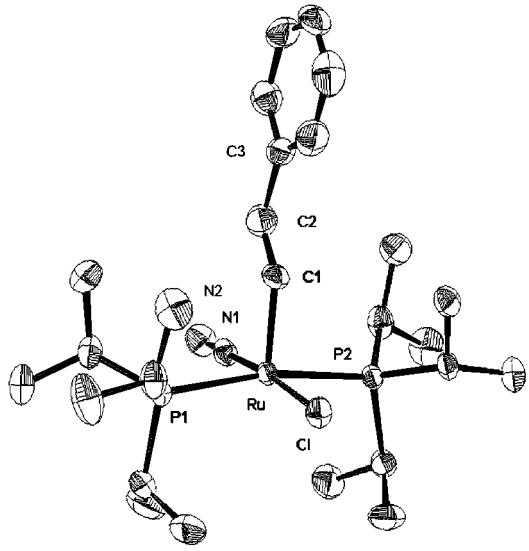


Figure 2. Molecular structure of **29** (hydrogen atoms are omitted for clarity); selected bond lengths [Å] and angles [°]: Ru−P(1) 2.4021(7), Ru−P(2) 2.4005(7), Ru−N(1) 1.869(5), Ru−Cl 2.3959(19), Ru−C(1) 1.973(3), C(1)−C(2) 1.296(5), N(1)−N(2) 1.088(8); P(1)−Ru−P(2) 168.74(3), N(1)−Ru−Cl 174.13(17), P(1)−Ru−Cl 98.15(9), P(2)−Ru−Cl 93.12(9), N(1)−Ru−P(1) 89.42(17), N(1)−Ru−P(2) 90.59(17), Cl−Ru−P(1) 89.33(4), Cl−Ru−P(2) 89.52(4), Cl−Ru−N(1) 90.63(19), Cl−Ru−C(1) 95.23(11), Ru−N(1)−N(2) 179.2(7), Ru−C(1)−C(2) 135.0(3), C(1)−C(2)−C(3) 125.1(3)

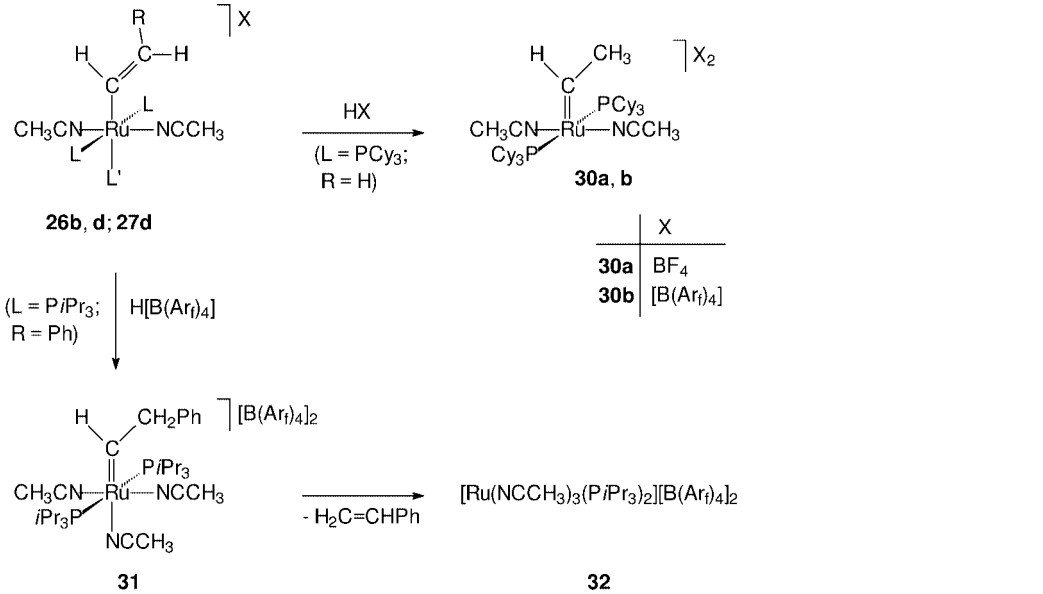
isopropyl groups. The Ru−N(1)−N(2) axis is perfectly linear while in the related complex $[RuHCl(N_2)(P\mathit{i}Pr_3)_2]$ the bond angle Ru−*N*−N is 175(2)°.[17] The bond lengths Ru−N(1) and N(1)−N(2) are, respectively, 1.869(5) and 1.088(8) Å and thus quite similar to those in $[RuHCl(N_2)(P\mathit{i}Pr_3)_2]$.

The reactions of the vinyl complexes $[Ru(CH{=}CHR)(NCMe)_n(L)_2]X$ (L = PCy_3: *n* = 2; L = $P\mathit{i}Pr_3$: *n* = 3) with strong acids lead to a conversion of the vinyl ligand into a coordinated carbene. While the protonation of **26a** or **26c** with excess HBF_4 in diethyl ether gives a salt-like product with $[Ru(=CHCH_3)(NCMe)_2(PCy_3)_2]^{2+}$ as the cation and different ratios of, respectively, PF_6^-/BF_4^- and BPh_4^-/BF_4^- as the anion, the reaction of **26b** with HBF_4 affords the bis(tetrafluoroborate) **30a** cleanly in 75% yield (Scheme 6). In a similar way, compound **30b** was prepared on treatment of **26d** with Brookhart's acid $[H(OEt_2)_2][B(Ar_f)_4]$.[18] Both **30a** and **30b** are yellow, moderately air-stable solids, the conductivity of which (in nitromethane) corresponds to that of 1:2 electrolytes. Regarding the spectroscopic data, the most typical features are the signal for the carbene =CH proton at δ = 17.70 (**30a**) and 17.20 ppm (**30b**) in the ^1H NMR spectra and the multiplet for the carbene carbon atom at δ = 335.1 ppm (**30b**) in the ^{13}C NMR spectrum. The single resonance for the phosphorus nuclei in the ^{31}P NMR spectra of **30a** and **30b** suggests that the phosphane ligands are stereochemically equivalent and thus in a *trans* disposition. Attempts to generate the dication $[Ru(=CHCH_3)(NCMe)_2(PCy_3)_2]^{2+}$ from $[RuCl_2(=CHCH_3)(PCy_3)_2]$ by substitution of the chloro ligands for acetonitrile failed.

In contrast to **26d**, the related bis(triisopropylphosphane) compound **27d** reacts with an equimolar amount of $[H(OEt_2)_2][B(Ar_f)_4]$ in CH_2Cl_2 at 0 °C to give a 1:1 mixture of the dicationic complexes **31** and **32**. Since both compounds are readily soluble in dichloromethane but insoluble in benzene or pentane, they could not be separated by fractional crystallization. The ^1H NMR spectrum of the mixture displays a triplet at δ = 17.32 ppm, assigned to the =CH proton, and a multiplet, which becomes a doublet in off-resonance, at δ = 4.22 ppm for the CH_2Ph protons of the carbene ligand of **31**. In the ^{31}P NMR spectrum, a single resonance for the ^{31}P nuclei of **31** is observed.

Stirring the solution of **31** and **32** for 2 h at room temperature leads to a complete conversion of **31** into the carbene-free complex **32**, which was isolated as a green, moderately air-stable solid in 90% yield. As a by-product, styrene was detected both by ^1H NMR spectroscopy and GC/MS analysis. Since both the ^1H and ^{13}C NMR spectra of **32** show a single set of signals for the protons and carbon atoms of the CH_3CN ligands and since the molecule is diamagnetic, instead of a trigonal-bipyramidal structure a fluxional square-pyramidal geometry is more likely. With regard to the mechanism of the conversion of **31** to **32**, we assume, in agreement with results recently reported by Carmona[19] and Gimeno[20] and their co-workers, that the carbene ligand $CHCH_2Ph$ rearranges by an intramolecular 1,2-H shift to styrene. As the bonding of an olefin to a twofold positively charged metal center is, in general, considered to be weak, styrene is eliminated from the intermediate and the five-coordinate complex **32** is formed.

The formation of a metal carbene from a metal vinyl precursor is not without precedence. Casey[21] and Helquist[22] et al. showed already in 1982 that neutral cyclopentadienyliron compounds with $Fe-CR{=}CH_2$ as a linkage can be converted with HBF_4 into the corresponding cationic carbene derivatives. Similar transformations of neutral vinyl to monocationic carbene complexes by attack of an electrophile at the β-carbon atom of the vinyl ligand have since been carried by various research groups[23] including ours.[24] However, we note that: (1) as far we know there is no report about the preparation of a *dicationic* metal



Scheme 6

carbene from a *monocationic* vinylmetal precursor by protonation, and (2) to the best of our knowledge **30a** and **30b** are the first dicationic five-coordinate carbeneruthenium complexes described as yet.

Experimental Section

All operations were carried out under argon using Schlenk techniques. The starting materials **1**,[4,25] **3**−**5**,1d][1e,25] **16**,[4,25] and **23**[1d,1e] were prepared as described in the literature. IR spectra were recorded on a Bruker IFS 25 FT-IR infrared spectrometer, and NMR spectra were recorded at room temperature on Bruker AC 200 and AMX 400 instruments, unless otherwise stated. The molar conductivity Λ_M was determined in nitromethane. Melting points were measured by differential thermal analysis (DTA) with a Thermoanalyzer Du Pont 9000. Abbreviations used: s, singlet; d, doublet; t, triplet; q, quadruplet; sept, septet; m, multiplet; vt, virtual triplet; br, broadened signal; $N = {}^3J_{P,H} + {}^5J_{P,H}$ or ${}^1J_{P,C} + {}^3J_{P,C}$.

Preparation of [RuHCl(=C=CH*t*Bu)(PCy$_3$)$_2$] (2): A solution of **1** (177 mg, 0.25 mmol) in CH_2Cl_2 (15 mL) was treated at −78 °C with *tert*-butylacetylene (0.1 mL, 0.82 mmol). After stirring the reaction mixture for 30 s, the solvent was removed in vacuo. A brown solid was obtained, which was washed at −78 °C with pentane (6 mL) and dried in vacuo; yield 143 mg (72%); m.p. 80 °C (decomp). IR (KBr): ν(RuH) = 2106, ν(C=C) = 1637 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 2.87 (t, $J_{P,H}$ = 3.7 Hz, 1 H, Ru=C=CH), 2.61−1.20 (m, 66 H, C_6H_{11}), 1.27 (s, 9 H, CCH_3), −13.89 (t, $J_{P,H}$ = 17.8 Hz, 1 H, RuH) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 39.0 (s) ppm. $C_{42}H_{77}ClP_2Ru$ (780.5): calcd. C 64.63, H 9.94; found C 63.95, H 9.72.

Preparation of [RuH(κ^2-O$_2$CCH$_3$)(=C=CH*t*Bu)(PCy$_3$)$_2$] (6): A solution of **2** (97 mg, 0.12 mmol) in THF (8 mL) was treated with finely divided potassium acetate (280 mg, 2.85 mmol) and stirred for 20 min at room temperature. The solvent was evaporated in vacuo and the residue was extracted with benzene (10 mL). The extract was dried in vacuo, and the remaining off-white solid was washed twice with pentane (3 mL each) and dried; yield 93 mg (96%); m.p. 50 °C (decomp). IR (KBr): ν(RuH) = 2053, ν($OCO_{asym.}$) = 1635, ν(C=C) = 1546, ν($OCO_{sym.}$) = 1448 cm^{-1}. ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 2.12 (t, $J_{P,H}$ = 3.3 Hz, 1 H, Ru=C=CH), 1.97−0.87 (m, 66 H, C_6H_{11}), 1.43 (s, 3 H, CH_3CO_2), 0.73 (s, 9 H, CCH_3), −12.48 (t, $J_{P,H}$ = 19.6 Hz, 1 H, RuH) ppm. ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 180.3 (s, CH_3CO_2), 114.8 (s, Ru=C=*C*H), 33.4 (vt, *N* = 17.8 Hz, C1 of C_6H_{11}), 32.4 (s, *C*CH_3), 30.1 (s, C3 or C5 of C_6H_{11}), 29.4 (s, C3 or C5 of C_6H_{11}), 28.2, 28.0 (both vt, *N* = 10.2 Hz, C2,6 of C_6H_{11}), 26.9 (s, C4 of C_6H_{11}), 24.4 (s, *C*H_3CO_2) ppm; the signal of the Ru=C carbon atom could not be located exactly. ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 38.0 (s) ppm. $C_{44}H_{80}O_2P_2Ru$ (804.1): calcd. C 65.72, H 10.03; found C 65.62, H 10.19.

Preparation of [RuH(NCO)(=C=CH$_2$)(PCy$_3$)$_2$] (7): A solution of **3** (80 mg, 0.11 mmol) in THF (8 mL) was treated with an excess of finely divided KOCN (400 mg, 4.93 mmol) and stirred for 30 min at room temperature. A gradual change of color from red-brown to brown occurred. The solvent was evaporated in vacuo, the residue was extracted with benzene (10 mL), and the extract was again dried in vacuo. After the oily residue was layered with pentane (5 mL), a brown solid precipitated which was separated from the mother liquor and dried; yield 63 mg (78%); m.p. 42 °C (decomp). IR (KBr): ν($NCO_{asym.}$) = 2219, ν(RuH) = 2072, ν(C=C) = 1612, ν($NCO_{sym.}$) = 1446 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 2.66 (t, $J_{P,H}$ = 3.7 Hz, 2 H, Ru=C=CH_2), 2.47−0.81 (m, 66 H, C_6H_{11}), −18.30 (t, $J_{P,H}$ = 18.3 Hz, 1 H, RuH) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 43.9 (s) ppm. $C_{39}H_{69}NOP_2Ru$ (731.0): calcd. C 64.08, H 9.51, N. 1.92; found C 63.16, H 9.41, N. 2.07.

Preparation of [RuH(κ^2-O$_2$CCH$_3$)(=C=CH$_2$)(PCy$_3$)$_2$] (8): This compound was prepared as described for **6**, with **3** (74 mg, 0.10 mmol) and potassium acetate (250 mg, 2.55 mmol) as starting materials. Pale brown solid; yield 70 mg (94%); m.p. 50 °C (decomp). IR (KBr): ν(RuH) = 2064, ν($OCO_{asym.}$) = 1601, ν(C=C) = 1549, ν($OCO_{sym.}$) = 1447 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 2.74 (t, $J_{P,H}$ = 3.3 Hz, 2 H, Ru=C=CH_2), 2.44−1.07 (m, 66 H, C_6H_{11}), 1.94 (s, 3 H, CH_3CO_2), −11.84 (t, $J_{P,H}$ = 19.1 Hz, 1 H, RuH) ppm. ^{13}C NMR (100.6 MHz, C_6D_6): δ = 330.0 (t, $J_{P,C}$ = 15.3 Hz, Ru=*C*=CH_2), 197.7 (s, CH_3CO_2), 84.6 (t, $J_{P,C}$ = 3.8 Hz, Ru=C=*C*H_2), 33.1 (vt, *N* = 17.8 Hz, C1 of C_6H_{11}), 29.5, 28.9 (both s, C3,5 of C_6H_{11}), 27.6, 27.4 (both vt, *N* = 10.2 Hz, C2,6 of C_6H_{11}), 26.2 (s, C4 of C_6H_{11}), 23.8 (s, *C*H_3CO_2) ppm. ^{31}P NMR (162.0 MHz, C_6D_6): δ = 39.4 (s) ppm. $C_{40}H_{72}O_2P_2Ru$ (748.0): calcd. C 64.23, H 9.70, Ru 13.51; found C 63.70, H 9.00, Ru 13.63.

Preparation of [RuH(NCO)(=C=CHPh)(PCy$_3$)$_2$] (9): This compound was prepared as described for **7**, with **4** (133 mg, 0.17 mmol) and KOCN (300 mg, 3.70 mmol) as starting materials. Olive-green solid; yield 92 mg (67%); m.p. 50 °C (decomp). IR (KBr): ν($NCO_{asym.}$) = 2205, ν(RuH) = 2071, ν(C=C) = 1615, ν($NCO_{sym.}$) = 1446 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 7.15−6.76 (m, 5 H, C_6H_5), 4.34 (t, $J_{P,H}$ = 3.9 Hz, 1 H, Ru=C=CH), 2.37−1.17 (m, 66 H, C_6H_{11}), −14.42 (t, $J_{P,H}$ = 17.2 Hz, 1 H, RuH) ppm. ^{31}P NMR (C_6D_6, 81.0 MHz): δ = 43.1 (s) ppm. $C_{45}H_{73}NOP_2Ru$ (807.1): calcd. C 66.97, H 9.12, N 1.74; found C 66.80, H 8.89, N 2.07.

Preparation of [RuH(κ^2-O$_2$CCH$_3$)(=C=CHPh)(PCy$_3$)$_2$] (10): This compound was prepared as described for **6**, with **4** (81 mg, 0.10 mmol) and potassium acetate (230 mg, 2.34 mmol) as starting materials. Pale brown solid; yield 68 mg (83%); m.p. 42 °C (dec.). IR (KBr): ν(RuH) = 2099, ν(C=C) = 1610, ν($OCO_{asym.}$) = 1588, ν($OCO_{sym.}$) = 1446 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 7.29−6.92 (m, 5 H, C_6H_5), 4.35 (t, $J_{P,H}$ = 3.3 Hz, 1 H, Ru=C=CH), 2.31−1.07 (m, 66 H, C_6H_{11}), 1.95 (s, 3 H, CH_3CO_2), −10.66 (t, $J_{P,H}$ = 19.1 Hz, 1 H, RuH) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 40.1 (s) ppm. $C_{46}H_{76}O_2P_2Ru$ (824.1): calcd. C 67.04, H 9.29; found C 66.20, H 9.25.

Preparation of [RuHI(=C=CHPh)(P*i*Pr$_3$)$_2$] (11): A solution of **5** (73 mg, 0.13 mmol) in THF (7 mL) was treated with an excess of finely divided KI (250 mg, 1.51 mmol) and stirred for 20 min at room temperature. The solvent was evaporated in vacuo, the residue was extracted with benzene (8 mL), and the extract was again dried in vacuo. After the residue was layered with pentane (5 mL) and the solution stored at −78 °C, a brown solid formed which was washed with small quantities of pentane and dried; yield 71 mg (84%); m.p. 36 °C (decomp). IR (KBr): ν(RuH) = 2075, ν(C=C) = 1609 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 7.54−6.83 (m, 5 H, C_6H_5), 4.33 (t, $J_{P,H}$ = 3.3 Hz, 1 H, Ru=C=CH), 2.56 (m, 6 H, PC*H*CH_3), 1.21 (m, 36 H, PCHC*H*$_3$), −9.32 (t, $J_{P,H}$ = 18.0 Hz, 1 H, RuH) ppm. ^{13}C NMR (50.3 MHz, C_6D_6): δ = 326.8 (t, $J_{P,C}$ = 15.3 Hz, Ru=*C*=CHPh), 132.8 (s, *ipso*-C of C_6H_5), 128.3, 127.8, 123.9 (all s, C_6H_5), 109.1 (t, $J_{P,C}$ = 4.4 Hz, Ru=C=*C*HPh), 25.7 (vt, *N* = 20.4 Hz, P*C*HCH$_3$), 20.4, 20.3 (both s, PCH*C*H$_3$) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 51.6 (s) ppm. $C_{26}H_{49}IP_2Ru$ (651.6): calcd. C 47.93, H 7.58, Ru 15.51; found C 47.75, H 7.30, Ru 15.46.

Preparation of [RuH(κ^2-O$_2$CCH$_3$)(=C=CHPh)(P*i*Pr$_3$)$_2$] (14): This compound was prepared as described for **11**, with **5** (67 mg, 0.12 mmol) and potassium acetate (250 mg, 2.55 mmol) as starting materials; reaction time 10 min. Orange-red solid; yield 65 mg (92%); m.p. 62 °C (decomp). IR (KBr): ν(RuH) = 2021, ν(C=C) = 1603, ν(OCO$_{asym.}$) = 1586, ν(OCO$_{sym.}$) = 1449 cm^{-1}. ^{1}H NMR (400 MHz, C_6D_6): δ = 7.25−6.84 (m, 5 H, C_6H_5), 4.31 (t, $J_{P,H}$ = 3.5 Hz, 1 H, Ru=C=CH), 2.39 (m, in ^{1}H{^{31}P} sept, $J_{H,H}$ = 7.0 Hz, 6 H, PC*H*CH$_3$), 1.82 (s, 3 H, CH_3CO_2), 1.28, 1.25 (both m, in ^{1}H{^{31}P} both d, $J_{H,H}$ = 7.0 Hz, 18 H each, PCHC*H*$_3$), −10.58 (t, $J_{P,H}$ = 18.7 Hz, 1 H, RuH) ppm. ^{13}C NMR (100.6 MHz, C_6D_6): δ = 335.2 (t, $J_{P,C}$ = 15.3 Hz, Ru=*C*=CHPh), 181.3 (s, CH_3CO_2), 134.9 (s, *ipso*-C of C_6H_5), 128.3, 123.8, 123.0 (all s, C_6H_5), 108.6 (t, $J_{P,C}$ = 3.8 Hz, Ru=C=*C*HPh), 24.6 (s, CH_3CO_2), 24.4 (vt, *N* = 19.0 Hz, P*C*HCH$_3$), 20.1, 19.5 (both s, PCH*C*H$_3$) ppm. ^{31}P NMR (162.0 MHz, C_6D_6): δ = 49.1 (s) ppm. $C_{28}H_{52}O_2P_2Ru$ (583.7): calcd. C 57.61, H 8.98, Ru 17.31; found C 57.99, H 8.73, Ru 17.84.

Preparation of [RuH(κ^2-O$_2$CCF$_3$)(=C=CHPh)(P*i*Pr$_3$)$_2$] (15): This compound was prepared as described for **11**, with **5** (153 mg, 0.27 mmol) and CF_3CO_2K (400 mg, 2.63 mmol) as starting materials. The residue was extracted with toluene (9 mL); reaction time 10 min. Red solid; yield 157 mg (91%); m.p. 54 °C (decomp). IR (KBr): ν(RuH) = 2044, ν(C=C) = 1628, ν(OCO$_{asym.}$) = 1588, ν(OCO$_{sym.}$) = 1444 cm^{-1}. ^{1}H NMR (400 MHz, C_6D_6): δ = 7.22−6.85 (m, 5 H, C_6H_5), 4.24 (t, $J_{P,H}$ = 3.5 Hz, 1 H, Ru=C=CH), 2.29 (m, in ^{1}H{^{31}P} sept, $J_{H,H}$ = 7.0 Hz, 6 H, PC*H*CH$_3$), 1.19, 1.16 (both m, in ^{1}H{^{31}P} both d, $J_{H,H}$ = 7.0 Hz, 18 H each, PCHC*H*$_3$), −11.51 (t, $J_{P,H}$ = 18.4 Hz, 1 H, RuH) ppm. ^{13}C NMR (100.6 MHz, C_6D_6): δ = 338.1 (t, $J_{P,C}$ = 15.3 Hz, Ru=*C*=CHPh), 163.4 (q, $J_{F,C}$ = 36.9 Hz, CF_3CO_2), 133.4 (s, *ipso*-C of C_6H_5), 128.5, 124.0, 123.7 (all s, C_6H_5), 115.2 (q, $J_{F,C}$ = 287.3 Hz, *C*F$_3$CO$_2$), 108.9 (t, $J_{P,C}$ = 3.8 Hz, Ru=C=*C*HPh), 24.5 (vt, *N* = 20.4 Hz, P*C*HCH$_3$), 20.0, 19.5 (both s, PCH*C*H$_3$) ppm. ^{19}F NMR (376.5 MHz, C_6D_6): δ = −75.2 (s) ppm. ^{31}P NMR (162.0 MHz, C_6D_6): δ = 48.2 (s) ppm. $C_{28}H_{49}F_3O_2P_2Ru$ (637.7): calcd. C 52.74, H 7.74, Ru 15.85; found C 52.60, H 7.50, Ru 16.80.

Preparation of [RuHI(≡CCH$_3$)(OEt$_2$)(PCy$_3$)$_2$]BF$_4$ (17): A solution of **16** (123 mg, 0.15 mmol) in a 1:1 mixture of CH_2Cl_2 (5 mL) and diethyl ether (5 mL) was treated at −78 °C with a 1.6 M solution of HBF_4 in diethyl ether (0.15 mL, 0.24 mmol). After warming the solution to 0 °C the solvent was evaporated in vacuo and the residue was layered with diethyl ether (5 mL). A light yellow solid precipitated, which was filtered, washed with pentane (5 mL) and dried; yield 86 mg (59%); m.p. 45 °C (decomp). Λ_M (Ω^{-1}cm^{2}mol^{-1}) = 54. ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 3.42 (q, $J_{H,H}$ = 7.3 Hz, 4 H, OC*H*$_2$CH$_3$), 2.51 (s, 3 H, Ru≡CCH$_3$), 2.37−1.32 (m, 66 H, C_6H_{11}), 1.15 (t, $J_{H,H}$ = 7.3 Hz, 6 H, OCH$_2$C*H*$_3$), −6.87 (t, $J_{P,H}$ = 15.3 Hz, 1 H, RuH) ppm. ^{31}P NMR (81.0 MHz, CD_2Cl_2): δ = 55.7 (s) ppm. $C_{42}H_{80}BF_4IOP_2Ru$ (977.8): calcd. C 51.59, H 8.25; found C 51.45, H 7.98.

Preparation of [RuH(NCO)(≡CCH$_3$)(OEt$_2$)(PCy$_3$)$_2$]BF$_4$ (18): This compound was prepared as described for **17**, from **7** (45 mg, 0.06 mmol) and a 1.6 M solution of HBF_4 in diethyl ether (0.3 mL, 0.48 mmol). Light yellow solid; yield 39 mg (73%); m.p. 69 °C (decomp). Λ_M (Ω^{-1}cm^{2}mol^{-1}) = 95. IR (KBr): ν(NCO$_{asym.}$) = 2229, ν(RuH) = 1973, ν(NCO$_{sym.}$) = 1448 cm^{-1}. ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 3.42 (q, $J_{H,H}$ = 7.3 Hz, 4 H, OC*H*$_2$CH$_3$), 2.23 (s, 3 H, Ru≡CCH$_3$), 2.30−1.31 (m, 66 H, C_6H_{11}), 1.15 (t, $J_{H,H}$ = 7.3 Hz, 6 H, OCH$_2$C*H*$_3$), −7.46 (t, $J_{P,H}$ = 16.3 Hz, 1 H, RuH) ppm. ^{31}P NMR (81.0 MHz, CD_2Cl_2): δ = 46.8 (s) ppm.

Preparation of [RuH(κ^2-O$_2$CCH$_3$)(≡CCH$_3$)(PCy$_3$)$_2$]BF$_4$ (19): A solution of **8** (81 mg, 0.11 mmol) in toluene (5 mL) was treated at 0 °C with a 1.6 M solution of HBF_4 in diethyl ether (0.3 mL, 0.48 mmol) and stirred for 15 min at 0 C. The solvent was evaporated in vacuo, the remaining light yellow resisue was washed with pentane (5 mL) and dried; yield 61 mg (66%); m.p. 60 °C (decomp). Λ_M (Ω^{-1}cm^{2}mol^{-1}) = 113. IR (KBr): ν(RuH) = 2066, ν(OCO$_{asym.}$) = 1629, ν(OCO$_{sym.}$) = 1448 cm^{-1}. ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 2.50−1.30 (m, 72 H, C_6H_{11}, Ru≡CCH$_3$ and CH_3CO_2), −7.31 (t, $J_{P,H}$ = 17.0 Hz, 1 H, RuH) ppm. ^{31}P NMR (81.0 MHz, CD_2Cl_2): δ = 48.7 (s) ppm.

Preparation of [RuHCl(≡CCH$_2$Ph)(OEt$_2$)(PCy$_3$)$_2$]BF$_4$ (20): This compound was prepared as described for **17**, from **4** (93 mg, 0.12 mmol) and a 1.6 M solution of HBF_4 in diethyl ether (0.2 mL, 0.32 mmol). Light yellow solid; yield 75 mg (65%); m.p. 55 °C (decomp). Λ_M (Ω^{-1}cm^{2}mol^{-1}) = 61. ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 7.42−6.69 (m, 5 H, C_6H_5), 4.03 (s, 2 H, Ru≡CC*H*$_2$Ph), 3.44 (q, $J_{H,H}$ = 7.3 Hz, 4 H, OC*H*$_2$CH$_3$), 2.83−1.26 (m, 66 H, C_6H_{11}), 1.15 (t, $J_{H,H}$ = 7.3 Hz, 6 H, OCH$_2$C*H*$_3$), −6.41 (br. s, 1 H, RuH) ppm. ^{31}P NMR (81.0 MHz, CD_2Cl_2): δ = 56.0 (s) ppm. $C_{48}H_{84}BClF_4OP_2Ru$ (962.5): calcd. C 59.90, H 8.80; found C 58.91, H 8.50.

Preparation of [RuHCl(≡CCH$_2$Ph)(OEt$_2$)(P*i*Pr$_3$)$_2$]BF$_4$ (21): A solution of **5** (56 mg, 0.10 mmol) in a 1:1 mixture of CH_2Cl_2 (3 mL) and diethyl ether (3 mL) was treated at −78 °C with a 1.6 M solution of HBF_4 in diethyl ether (0.2 mL, 0.32 mmol). After warming the solution to 0 °C, the solvent was evaporated in vacuo, and the residue was treated with diethyl ether (10 mL). The suspension was stirred for 15 min at 0 °C which led to the precipitation of a light yellow solid. This was separated from the mother liquor, washed with diethyl ether (5 mL) and dried; yield 40 mg (55%); m.p. 60 °C (decomp). Λ_M (Ω^{-1}cm^{2}mol^{-1}) = 61. ^{1}H NMR (200 MHz,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

CD_2Cl_2): δ = 7.41−7.27 (m, 5 H, C_6H_5), 3.95 (s, 2 H, Ru≡CCH_2Ph), 3.43 (q, $J_{H,H}$ = 7.3 Hz, 4 H, OCH_2CH$_3$), 2.76 (m, 6 H, PCHCH$_3$), 1.31 (m, 36 H, PCHCH_3), 1.14 (t, $J_{H,H}$ = 7.3 Hz, 6 H, OCH$_2$CH_3), −6.73 (br. s, 1 H, RuH) ppm. ^{31}P NMR (81.0 MHz, CD_2Cl_2): δ = 63.6 (s) ppm.

Preparation of [RuH(κ^2-O$_2$CCH$_3$)(≡CCH$_2$Ph)(P*i*Pr$_3$)$_2$]BF$_4$ (22): A solution of **14** (67 mg, 0.11 mmol) in toluene (7 mL) was treated at 0 °C with a 1.6 M solution of HBF_4 in diethyl ether (0.4 mL, 0.64 mmol) and stirred for 15 min at 0 °C. The solution was warmed to room temperature and then concentrated to ca. 1 mL in vacuo. A light yellow solid precipitated, which was separated from the mother liquor, washed with pentane (5 mL, 0 °C) and dried; yield 43 mg (55%); m.p. 48 °C (decomp). Λ_M (Ω^{-1}cm^{2}mol^{-1}) = 96. IR (KBr): ν(RuH) = 2072, ν(OCO$_{asym.}$) = 1587, ν(OCO$_{sym.}$) = 1465 cm^{-1}. ^{1}H NMR (200 MHz, CD_2Cl_2, 295 K): δ = 7.40−7.18 (m, 5 H, C_6H_5), 3.90 (s, 2 H, Ru≡CCH_2Ph), 2.34 (s, 3 H, CH_3CO_2), 2.33 (m, 6 H, PCHCH$_3$), 1.34 (m, 36 H, PCHCH_3), −6.90 (br. s, 1 H, RuH) ppm. ^{1}H NMR (200 MHz, CD_2Cl_2, 263 K): δ = −6.75 (t, $J_{P,H}$ = 17.4 Hz, 1 H, RuH) ppm. ^{31}P NMR (81.0 MHz, CD_2Cl_2, 295 K): δ = 59.1 (br. s) ppm. ^{31}P NMR (81.0 MHz, CD_2Cl_2, 263 K): δ = 59.0 (s) ppm. $C_{28}H_{53}BF_4O_2P_2Ru$ (671.5): calcd. C 50.08, H 7.95; found C 49.73, H 7.75.

Reaction of 12 with HCl: A solution of **12** (87 mg, 0.16 mmol) in benzene (10 mL) was treated with a 0.42 M solution of HCl in benzene (0.33 mL, 0.14 mmol) and stirred for 10 min at room temperature. The solvent was evaporated in vacuo and the red-brown residue was dissolved in C_6D_6 (0.5 mL). The NMR spectra indicated that besides the starting material **12** (13%) a mixture of four products was formed, of which **5** (35%) and [RuCl$_2$(=CHCH$_2$Ph)(P*i*Pr$_3$)$_2$] (**23**, 14%) were identified by comparison with authentic samples.[1d,1e] The other two products were assumed to be [RuCl(NCO)(=CHCH$_2$Ph)(P*i*Pr$_3$)$_2$] (**24**, 19%) and [Ru(NCO)$_2$(=CHCH$_2$Ph)(P*i*Pr$_3$)$_2$] (**25**, 19%). Characteristic data for **24**: ^{1}H NMR (200 MHz, C_6D_6): δ = 19.50 (t, $J_{H,H}$ = 5.1 Hz, Ru=CH), 4.15 (d, $J_{H,H}$ = 5.1 Hz, CH_2Ph).

Preparation of [Ru(NCO)$_2$(=CHCH$_2$Ph)(P*i*Pr$_3$)$_2$] (25): A solution of **23** (102 mg, 0.17 mmol) in a mixture of THF (10 mL) and CH_2Cl_2 (3 mL) was treated with finely divided KOCN (150 mg, 1.85 mmol) and stirred for 24 h at room temperature. After evaporation of the solvent in vacuo, the residue was extracted twice with benzene (9 mL each). The combined extracts were dried in vacuo, the remaining violet solid was washed three times with pentane (5 mL each) and dried; yield 98 mg (94%); m.p. 82 °C (decomp). IR (KBr): ν(NCO$_{asym.}$) = 2230, ν(NCO$_{sym.}$) = 1450 cm^{-1}. ^{1}H NMR (400 MHz, C_6D_6): δ = 19.06 (t, $J_{H,H}$ = 5.2 Hz, 1 H, Ru=CH), 7.24−7.04 (m, 5 H, C_6H_5), 3.99 (d, $J_{H,H}$ = 5.2 Hz, 2 H, CH_2Ph), 2.14 (m; in ^{1}H{^{31}P} sept, $J_{H,H}$ = 7.0 Hz, 6 H, PCHCH$_3$), 0.98 (dvt, N = 14.0, $J_{H,H}$ = 7.0 Hz, 36 H, PCHCH_3) ppm. ^{13}C NMR (100.6 MHz, C_6D_6): δ = 319.5 (br. s, Ru=CH), 139.9 (s, NCO), 136.6 (s, *ipso*-C of C_6H_5), 127.9, 127.3, 125.9 (all s, C_6H_5), 64.3 (s, CH$_2$Ph), 22.4 (vt, N = 20.4 Hz, PCHCH$_3$), 18.1 (s, PCHCH$_3$) ppm. ^{31}P NMR (162.0 MHz, C_6D_6): δ = 48.3 (s) ppm. $C_{28}H_{50}N_2O_2P_2Ru$ (609.7): calcd. C 55.16, H 8.26, N 4.59; found C 54.69, H 8.24, N 4.44.

Preparation of [Ru(CH=CH$_2$)(NCCH$_3$)$_2$(PCy$_3$)$_2$]PF$_6$ (26a): A solution of **3** (270 mg, 0.39 mmol) in a 1:1 mixture of CH_2Cl_2 and acetonitrile (30 mL) was treated with KPF_6 (250 mg, 1.36 mmol) and stirred for 35 min at room temperature. A gradual change of color from red-brown to light brown occurred. The solvent was evaporated in vacuo and the residue was extracted twice with CH_2Cl_2 (10 mL each). The combined extracts were dried in vacuo, the remaining brown solid was washed twice with pentane (8 mL each) and dried; yield 307 mg (87%); m.p. 55 °C (dec.). Λ_M (Ω^{-1}cm^{2}mol^{-1}) = 69. IR (KBr): ν(CN) = 2253 cm^{-1}. ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 7.38 (dd, $J_{H,H}$ = 15.8, $J_{H,H}$ = 7.9 Hz, 1 H, CH=CH$_2$), 4.84 (d, $J_{H,H}$ = 7.9 Hz, 1 H, *cis*-H of CH=CH_2), 4.70 (d, $J_{H,H}$ = 15.8 Hz, 1 H, *trans*-H of CH=CH_2), 2.49 (s, 6 H, CH_3CN), 2.24−1.22 (m, 66 H, C_6H_{11}) ppm. ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 150.2 (br. s, RuCH), 125.5 (s, CN), 117.3 (s, CH=CH$_2$), 34.3 (vt, N = 16.2 Hz, C1 of C_6H_{11}), 29.7 (s, C3,5 of C_6H_{11}), 28.1 (vt, N = 10.2 Hz, C2,6 of C_6H_{11}), 26.5 (s, C4 of C_6H_{11}), 5.0 (s, CH$_3$CN) ppm. ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 22.4 (s, PCy$_3$), −144.0 (sept, $J_{F,P}$ = 709.4 Hz, PF_6) ppm. $C_{42}H_{75}F_6N_2P_3Ru$ (916.0): calcd. C 55.07, H 8.25, N 3.06, Ru 11.03; found C 54.89, H 7.81, N 3.06, Ru 10.76.

Preparation of [Ru(CH=CH$_2$)(NCCH$_3$)$_2$(PCy$_3$)$_2$]BF$_4$ (26b): This compound was prepared as described for **26a**, from **3** (101 mg, 0.14 mmol) and $NaBF_4$ (250 mg, 2.28 mmol) in a 2:1 mixture of CH_2Cl_2 and acetonitrile (15 mL). Orange-red solid; yield 109 mg (91%); m.p. 52 °C (decomp). Λ_M (Ω^{-1}cm^{2}mol^{-1}) = 58. IR (KBr): ν(CN) = 2254 cm^{-1}. ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 7.21 (dd, $J_{H,H}$ = 15.6, $J_{H,H}$ = 7.7 Hz, 1 H, CH=CH$_2$), 4.62 (d, $J_{H,H}$ = 7.7 Hz, 1 H, *cis*-H of CH=CH_2), 4.54 (d, $J_{H,H}$ = 15.6 Hz, 1 H, *trans*-H of CH=CH_2), 2.39 (s, 6 H, CH_3CN), 2.25−1.10 (m, 66 H, C_6H_{11}) ppm. ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 148.7 (br. s, RuCH), 125.6 (s, CN), 117.1 (s, CH=CH$_2$), 34.2 (vt, N = 16.2 Hz, C1 of C_6H_{11}), 29.7 (s, C3,5 of C_6H_{11}), 28.0 (vt, N = 9.5 Hz, C2,6 of C_6H_{11}), 26.5 (s, C4 of C_6H_{11}), 5.0 (s, CH$_3$CN) ppm. ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 22.5 (s) ppm. $C_{42}H_{75}BF_4N_2P_2Ru$ (857.9): calcd. C 58.80, H 8.81, N 3.27; found C 58.55, H 8.54, N 3.36.

Preparation of [Ru(CH=CH$_2$)(NCCH$_3$)$_2$(PCy$_3$)$_2$]BPh$_4$ (26c): A solution of **26a** (450 mg, 0.49 mmol) in methanol (20 mL) was treated with $NaBPh_4$ (200 mg, 0.58 mmol) and stirred for 15 min at room temperature. An orange-red solid precipitated, which was separated from the mother liquor, washed three times with methanol (10 mL each) and dried in vacuo; yield 416 mg (78%); m.p. 100 °C (decomp). Λ_M (Ω^{-1}cm^{2}mol^{-1}) = 63. IR (KBr): ν(CN) = 2244 cm^{-1}. ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 7.33−6.86 (m, 21 H, CH=CH$_2$ and BC$_6$H$_5$), 4.70 (d, $J_{H,H}$ = 7.3 Hz, 1 H, *cis*-H of CH=CH_2), 4.63 (d, $J_{H,H}$ = 15.2 Hz, 1 H, *trans*-H of CH=CH_2), 2.33 (s, 6 H, CH_3CN), 2.24−1.24 (m, 66 H, C_6H_{11}) ppm. ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 164.1 (q, $J_{B,C}$ = 49.6 Hz, *ipso*-C of BC$_6$H$_5$), 147.2 (br. s, RuCH), 136.0 (s, CH of BC$_6$H$_5$), 125.7 (q, $J_{B,C}$ = 3.2 Hz, *ortho*-C of BC$_6$H$_5$), 121.7 (s, BC$_6$H$_5$), 117.2 (s, CH=CH$_2$), 34.3 (vt, N = 16.5 Hz, C1 of C_6H_{11}), 29.8 (s, C3,5 of C_6H_{11}), 28.1 (vt, N = 10.2 Hz, C2,6 of C_6H_{11}), 26.5 (s, C4 of C_6H_{11}), 4.8 (s, CH$_3$CN) ppm; the signal of the CN carbon atom could not be located exactly. ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 23.0 (s) ppm. $C_{66}H_{95}BN_2P_2Ru$ (1090.3): calcd. Generation of [RuCl{(*E*)-CH=CHPh}(CO)$_2$(P*i*Pr$_3$)$_2$] (28): In an NMR tube, a solution of **5** (28 mg, 0.05 mmol) in C_6D_6 (0.5 mL) was cooled to −78 °C. The tube was evacuated in vacuo and then filled with CO. Upon warming to room temperature, a change of color from olive-green to red and finally to pale yellow occurred. The ^1H and ^{31}P NMR spectra of the solution revealed that compound **28** was formed in quantitative yield. It was identified by comparison of the NMR spectroscopic data with those of an authentic sample.[14]

Preparation of [RuCl{(*E*)-CH=CHPh}(N$_2$)(P*i*Pr$_3$)$_2$] (29): A solution of **5** (68 mg, 0.12 mmol) in pentane (8 mL) was stirred under a nitrogen atmosphere for 2 h at room temperature. A change of color from olive-green to brown occurred and a red-brown solid precipitated. After storing the solution for 12 h at −20 °C, the mother liquor was separated and the remaining red-brown solid dried in a stream of N_2; yield 65 mg (92%); m.p. 34 °C (decomp). IR (KBr): ν(N_2) = 2067 cm^{-1}. ^1H NMR (400 MHz, C_6D_6): δ = 9.50 (dt, $J_{H,H}$ = 16.6, $J_{P,H}$ = 1.5 Hz, 1 H, C*H*=CHPh), 7.39−6.86 (m, 5 H, C_6H_5), 6.37 (dt, $J_{H,H}$ = 16.6, $J_{P,H}$ = 1.9 Hz, 1 H, CH=C*H*Ph), 2.62 (m; in $^1H\{^{31}P\}$ sept, $J_{H,H}$ = 7.2 Hz, 6 H, PC*H*CH_3), 1.17, 1.15 (both m; in $^1H\{^{31}P\}$ both d, $J_{H,H}$ = 7.2 Hz, 18 H each, PCHC*H*$_3$) ppm. ^{13}C NMR (100.6 MHz, C_6D_6): δ = 147.5 (t, $J_{P,C}$ = 10.8 Hz, RuCH), 138.0 (s, *ipso*-C of C_6H_5), 130.2 (t, $J_{P,C}$ = 3.2 Hz, CH=*C*HPh), 127.9, 123.2, 123.1 (all s, C_6H_5), 22.5 (vt, *N* = 17.8 Hz, P*C*HCH$_3$), 18.8, 18.7 (both s, PCH*C*H$_3$) ppm. ^{31}P NMR (162.0 MHz, C_6D_6): δ = 33.3 (s) ppm. $C_{26}H_{49}ClN_2P_2Ru$ (588.2): calcd. C 53.10, H 8.40, N 4.76; found C 53.24, H 8.30, N 3.86.

Preparation of [Ru(=CHCH$_3$)(NCCH$_3$)$_2$(PCy$_3$)$_2$](BF$_4$)$_2$ (30a): A solution of **26b** (275 mg, 0.32 mmol) in CH_2Cl_2 (8 mL) was treated with a 1.6 M solution of HBF_4 in diethyl ether (1.0 mL, 1.60 mmol) at room temperature. A change of color from red to yellow-orange

occurred. The solvent was evaporated in vacuo, the remaining yellow solid was washed three times with pentane (5 mL each) and dried; yield 225 mg (75%); m.p. 55 °C (decomp). Λ ($\Omega^{-1}cm^2mol^{-1}$) = 99. IR (KBr): ν(CN) = 2275 cm^{-1}. ^1H NMR (200 MHz CD_2Cl_2): δ = 17.70 (m, 1 H, =C*H*CH_3), 2.96 (br.s, 3 H, =CHC*H*$_3$), 2.79 (s, 6 H, CH_3CN), 2.53−1.31 (m, 66 H, C_6H_{11}) ppm. ^{31}P NMR (81.0 MHz, CD_2Cl_2): δ = 38.0 (s) ppm. $C_{42}H_{76}B_2F_8N_2P_2Ru$ (945.7): calcd. C 53.34, H 8.10, N. 2.96; found C 53.01, H 7.73, N 3.42.

Preparation of [Ru(=CHCH$_3$)(NCCH$_3$)$_2$(PCy$_3$)$_2$][B(Ar$_f$)$_4$]$_2$ (30b): A solution of **26d** (94 mg, 0.06 mmol) in CH_2Cl_2 (8 mL) was treated at 0 °C with a solution of $[H(OEt_2)_2][B(Ar_f)_4]$ (58 mg, 0.06 mmol) in CH_2Cl_2 (4 mL). A change of color from red to yellow occurred. After warming the solution to room temperature, the solvent was evaporated in vacuo, and the remaining yellow solid was washed three times with pentane (5 mL each) and dried; yield 130 mg (87%); m.p. 130 °C (decomp). Λ_M ($\Omega^{-1}cm^2mol^{-1}$) = 139. ^1H NMR (400 MHz, CD_2Cl_2): δ = 17.20 (q, $J_{H,H}$ = 5.9 Hz, 1 H, =C*H*CH_3), 7.72 [br. s, 16 H, *ortho*-H of $B(Ar_f)_4$], 7.57 [br. s, 8 H, *para*-H of $B(Ar_f)_4$], 2.87 (d, $J_{H,H}$ = 5.9 Hz, 3 H, =CHC*H*$_3$), 2.75 (s, 6 H, CH_3CN), 2.17−1.23 (m, 66 H, C_6H_{11}) ppm. ^{13}C NMR (100.6 MHz, [D$_6$]acetone): δ = 335.1 (m, Ru=C), 163.0 [q, $J_{B,C}$ = 49.6 Hz, *ipso*-C of $B(Ar_f)_4$], 135.9 [br. s, *ortho*-C of $B(Ar_f)_4$], 130.4 [br. q, $J_{F,C}$ = 31.8 Hz, *meta*-C of $B(Ar_f)_4$], 125.7 (q, $J_{F,C}$ = 272.1 Hz, CF_3), 118.8 [m, *para*-C of $B(Ar_f)_4$], 48.5 (s, =CH*C*H$_3$), 35.3 (vt, *N* = 19.1 Hz, C1 of C_6H_{11}), 30.8 (s, C3, 5 of C_6H_{11}), 28.5 (vt, *N* = 10.2 Hz, C2, 6 of C_6H_{11}), 26.1 (s, C4 of C_6H_{11}), 5.7 (s, *C*H$_3$CN) ppm. The signal of the CN carbon atom could not be located exactly. ^{19}F NMR (376.5 MHz, [D$_6$]acetone): δ = −62.9 (s) ppm. ^{31}P NMR (162.0 MHz, [D$_6$]acetone): δ = 41.0 (s) ppm. $C_{106}H_{100}B_2F_{48}N_2P_2Ru$ (2498.5): calcd. C 50.96, H 4.03, N 1.12; found C 50.72, H 3.77, N 1.13.

Generation of [Ru(=CHCH$_2$Ph)(NCCH$_3$)$_3$(P*i*Pr$_3$)$_2$][B(Ar$_f$)$_4$]$_2$ (31): A solution of **27d** (48 mg, 0.03 mmol) in CH_2Cl_2 (5 mL) was treated at 0 °C with a solution of $[H(OEt_2)_2][B(Ar_f)_4]$ (32 mg, 0.03 mmol) in CH_2Cl_2 (3 mL). A change of color from red to light green occurred. After stirring the solution for 2 min, it was filtered and the filtrate was dried in vacuo. The ^1H and ^{31}P NMR spectra of the light green residue revealed that it consisted of equal amounts of **31** and **32**. Data for **31**: ^1H NMR (400 MHz, CD_2Cl_2): δ = 17.32 (t, $J_{H,H}$ = 5.1 Hz, 1 H, =C*H*CH_3), 4.42 (m; in $^1H\{^{31}P\}$ d, $J_{H,H}$ = 5.1 Hz, 2 H, C*H*$_2$Ph) ppm. ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 51.5 (s) ppm.

Preparation of [Ru(NCCH$_3$)$_3$(P*i*Pr$_3$)$_2$][B(Ar$_f$)$_4$]$_2$ (32): A solution of **27d** (80 mg, 0.05 mmol) in CH_2Cl_2 (6 mL) was treated with a solution of $[H(OEt_2)_2][B(Ar_f)_4]$ (53 mg, 0.05 mmol) in CH_2Cl_2 (4 mL) and stirred for 2 h at room temperature. The solution was filtered, and the filtrate was dried in vacuo. The remaining green solid was washed twice with pentane (5 mL each) and dried; yield 102 mg (90%); m.p. 68 °C (decomp). Λ_M ($\Omega^{-1}cm^2mol^{-1}$) = 153. IR (KBr): ν(CN) = 2288 cm^{-1}. ^1H NMR (400 MHz, CD_2Cl_2): δ = 7.72 [br. s, 16 H, *ortho*-H of $B(Ar_f)_4$], 7.57 [br. s, 8 H, *para*-H of $B(Ar_f)_4$], 2.48 (m; in $^1H\{^{31}P\}$ sept, $J_{H,H}$ = 7.2 Hz, 6 H, PC*H*CH_3), 2.40 (s, 9 H, CH_3CN), 1.32, 1.31 (both dvt, *N* = 13.5, $J_{H,H}$ = 7.2 Hz, 18 H each, PCHC*H*$_3$) ppm. ^{13}C NMR (100.6 MHz, C_6D_6): δ = 161.8 [q, $J_{B,C}$ = 49.8 Hz, *ipso*-C of $B(Ar_f)_4$], 134.9 [br. s, *ortho*-C of $B(Ar_f)_4$], 128.9 [br. q, $J_{F,C}$ = 31.8 Hz, *meta*-C of $B(Ar_f)_4$], 127.5 (s, CN), 124.7 (q, $J_{F,C}$ = 272.7 Hz, CF_3), 117.6 [m, *para*-C of $B(Ar_f)_4$], 24.0 (vt, *N* = 19.1 Hz, P*C*HCH$_3$), 19.0 (s, PCH*C*H$_3$), 4.7 (s, *C*H$_3$CN) ppm. ^{19}F NMR (376.5 MHz, CD_2Cl_2): δ = −62.8 (s) ppm. ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 27.9 (s) ppm. $C_{88}H_{75}B_2F_{48}N_3P_2Ru$ (2271.1): calcd. C 46.54, H 3.33, N 1.85; found C 46.65, H 3.35, N 2.31.

X-ray Structure Determination of Compounds 26c and 29: Single crystals of **26c** were grown from CH_2Cl_2 at −20 °C and those of **29** from pentane at −78 °C. Crystal data collection parameters for these structures are presented in Table 1. The data were collected on a Stoe IPDS diffractometer (**26c**) and a Bruker Smart Apex diffractometer (**29**) using monochromated Mo-K_α radiation (λ = 0.71073 Å). Intensity data were corrected for Lorentz and polarization effects and an empirical absorption correction was applied (SADABS2.0). The structures were solved by direct methods (SHELXS-97).[26] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by the full-matrix least-squares method on F^2 using SHELXL-97.[27] The asymmetric unit of **26c** includes a molecule of dichloromethane, the chloro atoms of which are disordered (ratio of occupancy factors Cl1/Cl2:Cl1′/Cl2′ = 82:18). The hydrogen atoms of the vinyl ligand were found in a difference-Fourier synthesis and refined without restraints. The positions of all other hydrogen atoms were calculated according to the ideal geometry and refined by the riding method. The chloro and the nitrogen ligands of **29** are disordered and could be refined anisotropically without restraints (occupancy factor 80:20).

Ref. code MIKMUO (**26c**) and CCDC-215082 (**29**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Mono- and Dinuclear Rhodium and Iridium Complexes with Chiral Phospholanes as Ligands

Peter Krüger[a] and Helmut Werner*[a]

Dedicated to Professor Christoph Elschenbroich on the occasion of his 65th birthday

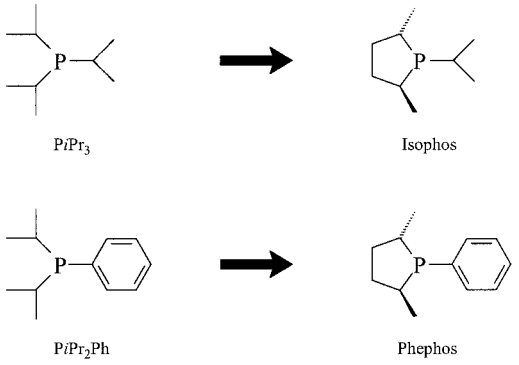
Keywords: Allyl ligands / Carbonyl ligands / Hydrido complexes / Phospholanes / Rhodium

The dinuclear complexes $[RhCl(L)_2]_2$ (**1**, **2**) with L = 1-isopropyl-(2*S*,5*S*)-2,5-dimethylphospholane (Isophos) and (2*S*,5*S*)-2,5-dimethyl-1-phenylphospholane (Phephos), respectively, prepared from $[RhCl(C_8H_{14})_2]_2$ and four equivalents of L, react with Lewis bases such as L, CO, ethene and diphenylacetylene by cleavage of the chloride bridges. Mononuclear compounds of the general composition $[RhCl(L)_3]$ (**3**, **4**) and *trans*-$[RhCl(L')(L)_2]$ (**5**–**9**; L′ = CO, C_2H_4, C_2Ph_2) were obtained, of which **4** (L = Phephos) and **8** (L′ = C_2H_4; L = Phephos) are in equilibrium with the precursors. Oxidative addition of H_2 to **1** (L = Isophos) and $[RhCl(PiPr_2Ph)_2]_2$ (**10**) affords the mononuclear dihydrido complexes $[RhH_2Cl(L)_2]$ (**13**) and $[RhH_2Cl(PiPr_2Ph)_2]$ (**14**), respectively, via the unsymmetrical compounds $[RhH_2(L)_2(\mu\text{-}Cl)_2Rh(L)_2]$ (**11**) and $[RhH_2(PiPr_2Ph)_2(\mu\text{-}Cl)_2Rh(PiPr_2Ph)_2]$ (**12**) as intermediates. These intermediates can be isolated by treatment of **13** and **14** with one half equivalent of **1** or **10**, respectively. The hydrogenation of the η^3-allyl and η^3-benzyl complexes $[(\eta^3\text{-}2\text{-}RC_3H_4)Rh(L)_2]$ (**16**–**18**) and $[(\eta^3\text{-}CH_2Ph)Rh(L)_2]$ (**19**, **20**), which were prepared from **1** or **2** and the corresponding Grignard reagent, leads to the dinuclear $Rh^{III}Rh^{I}$ products $[RhH_2(L)_2(\mu\text{-}H)_2Rh(L)_2]$ (**21**, **22**), which are structurally related to the dichloro(dihydrido) derivatives **11** and **12**. Compound **21** (L = Isophos) reacts with CO to give *trans*-$[RhH(CO)(L)_2]$ (**23**). While treatment of **1** with phenylacetylene yields the vinylidene complex *trans*-$[RhCl(=C=CHPh)(Isophos)_2]$ (**26**), via η^2-alkyne and alkynyl(hydrido) intermediates, the reaction of **2** with PhC≡CH affords the labile enyne compound *trans*-$[RhCl\{\eta^2\text{-}(E)\text{-}PhC{\equiv}CCH{=}CHPh\}(Phephos)_2]$ (**27**). Reaction of **27** with CO gives **6** and the free enyne. The carbene complexes *trans*-$[RhCl(=CPh_2)(L)_2]$ (**30**, **31**), obtained from *trans*-$[RhCl(=CPh_2)(SbiPr_3)_2]$ (**29**) and L, react with ethene not by olefin metathesis but by formation of the isomeric olefins $Ph_2C{=}CHCH_3$ (**32**) and $CH_2{=}CHCHPh_2$ (**33**) in different ratios. With iridium as the metal center, carbonyl, dihydrido, and dihydrido(carbonyl) compounds with $[IrCl(Isophos)_2]$ as the building block have been prepared.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

In the context of our investigations on low-valent organorhodium compounds containing bulky tertiary phosphanes as supporting ligands,[1] we recently observed that even an apparently minor change in the size of the phosphane upon going from $PiPr_3$ to $PiPr_2Ph$ causes a difference in the reactivity of the corresponding complexes.[2] A striking example is the behavior of the acetato derivatives $[Rh(\kappa^2\text{-}O_2CCH_3)(PiPr_3)_2]$ and $[Rh(\kappa^2\text{-}O_2CCH_3)(PiPr_2Ph)_2]$, of which the first reacts with two equivalents of phenylacetylene to give a vinylrhodium(III) compound containing a Rh(CH=CHPh) unit,[3] while under the same conditions the second affords a product with $Rh(CPh{=}CH_2)$ as a molecular fragment.[2]

Taking these results into consideration, we started a systematic study of the reactivity of rhodium (and some iridium) complexes with 1-isopropyl-(2*S*,5*S*)-2,5-dimethylphospholane (abbreviated as Isophos) and (2*S*,5*S*)-2,5-dimethyl-1-phenylphospholane (abbreviated as Phephos) as ligands. As depicted in Scheme 1, these phospholanes are similar in size to $PiPr_3$ and $PiPr_2Ph$, but in contrast to these tertiary phosphanes are chiral, which for catalytic purposes



Scheme 1

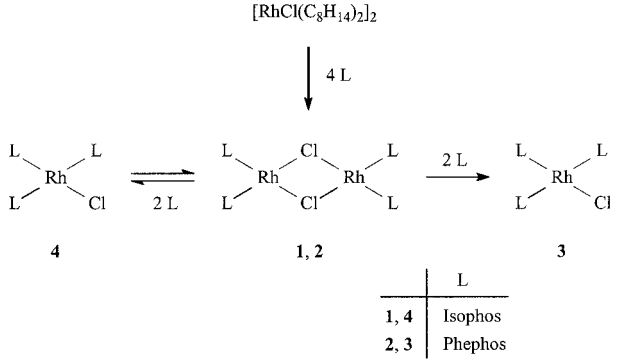
could be an important factor. In this paper we report the preparation of the starting materials $[RhCl(Isophos)_2]_2$ (**1**) and $[RhCl(Prephos)_2]_2$ (**2**), the reactivity of these compounds toward H_2, CO, ethene, internal and terminal alkynes, and the conversion of **1** and **2** to η^3-allyl- and η^3-benzylrhodium(I) complexes, and discuss very briefly some exploratory experiments regarding the synthesis and reactivity of iridium compounds with Isophos as ligand.

Results and Discussion

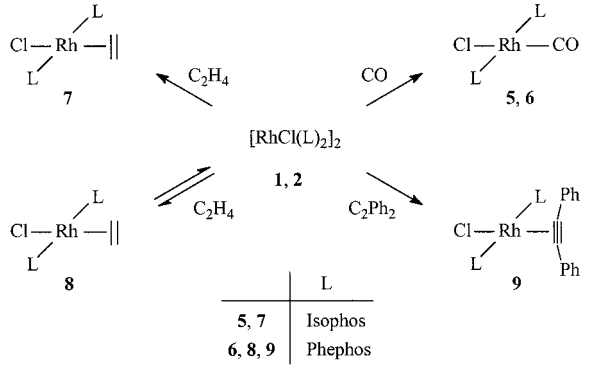
The method previously used by us for the preparation of $[RhCl(P\mathit{i}Pr_3)_2]_2$ [4] could also be applied to the synthesis of **1** and **2** (Scheme 2). Treatment of a suspension of the bis(cyclooctene) derivative $[RhCl(C_8H_{14})_2]_2$ with four equivalents of Isophos[5] or Phephos[6] in acetone or benzene gives the required products in 92% (**1**) and 75% (**2**) isolated yields. Both **1** and **2** are red or orange-red solids, which, like $[RhCl(P\mathit{i}Pr_3)_2]_2$, are thermally not very stable, but in contrast to their $P\mathit{i}Pr_3$ counterpart are less air-sensitive. The ^{31}P NMR spectra of **1** and **2** display a sharp doublet with a large $^1J_{Rh,P}$ coupling constant of 196.2 Hz (**1**) and 198.0 Hz (**2**) that is characteristic for a $Rh(PR_3)_2$ moiety with the P-donors in a *cis* arrangement.[4,7] The ^1H NMR spectra of **1** and **2** show two signals for the protons of the different methyl groups of the phospholane units but are otherwise quite complicated due to the overlap of the resonances for the CH_2 and CH protons of the five-membered ring. Similar observations have also been made for the other Isophos and Phephos complexes described in this paper and thus the corresponding ^1H NMR spectroscopic data will not be discussed.



Scheme 2

Treating a suspension of $[RhCl(C_8H_{14})_2]_2$ with eight instead of four equivalents of Isophos or Phephos leads to the formation of the mononuclear compounds **3** and **4**, respectively (see Scheme 2). However, while **3** could be isolated as an analytically pure product, the analogue **4** is in equilibrium with **1** and free Isophos. The equilibrium lies completely on the side of **4** only in the presence of excess Isophos and thus all attempts to obtain **4** without Isophos as a by-product failed. The ^{31}P NMR spectrum of **3** at room temperature displays, apart from a sharp doublet of triplets for the ^{31}P nuclei *trans* to chloride, a broad signal that becomes a doublet of doublets at 330 K owing to an increase in the rate of the exchange process for the phospholanes. The $^1J_{Rh,P}$ and $^2J_{P,P}$ coupling constants for **3** are very similar to those of the Wilkinson complex $[RhCl(PPh_3)_3]$.[8]

The reactions of compounds **1** and **2** with CO, ethene and diphenylacetylene, that all lead to cleavage of the chloro bridges, are summarized in Scheme 3. The carbonyl complexes **5** and **6** are formed almost instantaneously and were isolated as yellow, moderately air-sensitive solids in ca. 90% yields. Compound **5** is also accessible from **7** and CO and compound **6** similarly from **3** and carbon monoxide by ligand exchange. In contrast to the behavior of **1** and **2** toward an excess of Isophos or Phephos, the reaction of **2** (with Phephos as ligand) with ethene approaches an equilibrium, while the corresponding reaction of **1** (with Isophos as ligand) affords the mononuclear complex **7** nearly quantitatively. Treatment of **2** with diphenylacetylene does not lead to an equilibrium but gives compound **9** as a yellow solid in 72% yield. The ^{31}P NMR spectra of **5**−**9** all display one sharp doublet, indicating that in each case the two phospholane ligands are *trans*-disposed. The wavenumbers for the ν(CO) stretching mode in the IR spectra of **5** and **6** (1947 and 1961 cm^{-1}) are nearly identical to those of their phosphane counterparts *trans*-$[RhCl(CO)(P\mathit{i}Pr_3)_2]$ (1943 cm^{-1})[9] and *trans*-$[RhCl(CO)(P\mathit{i}Pr_2Ph)_2]$ (1960 cm^{-1})[10] which suggests that the coordinative capabilities of $P\mathit{i}Pr_3$ and $P\mathit{i}Pr_2Ph$ on one hand and those of the phospholanes on the other are similar. With regard to the lability of **8** we note that the bis(triphenylphosphane) complex *trans*-$[RhCl(C_2H_4)(PPh_3)_2]$ also loses the ethene ligand in the absence of an excess of C_2H_4 and rearranges to $[RhCl(PPh_3)_2]_2$.[11]

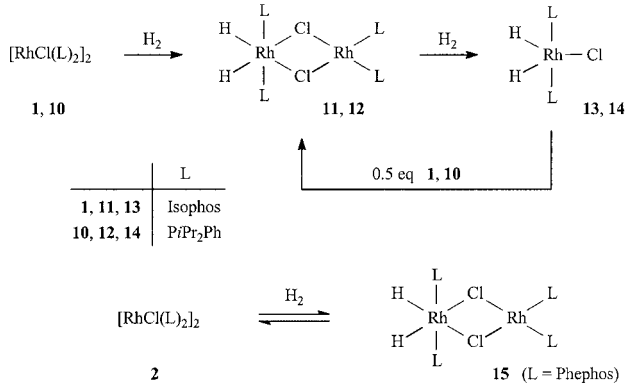


Scheme 3

The course of the oxidative addition of H_2 to the metal centers of **1**, **2** and the related compound $[RhCl(P\mathit{i}Pr_2Ph)_2]_2$ (**10**)[2] is also dependent on the type of phosphorus donor. Passing a slow stream of dry dihydrogen through a solution of **1** or **10** in toluene or pentane at low temperatures leads, after warming to 20 °C, to the formation of the dihydrido complexes **13** and **14** in 76−87% isolated yields. In contrast, the reaction of **2** with H_2 generates an equilibrium which, even after stirring the solution for 12 h under a dihydrogen

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

atmosphere, could not be completely shifted to the side of product **15** (Scheme 4). In the absence of H_2, **15** is reconverted into **2**. The fact that **15** is not an analogue of **13** and **14** is confirmed by the ^{31}P NMR spectrum, which displays two resonances (both doublets) at $\delta = 69.9$ and 52.2 ppm, respectively. Since the signal at lower field shows a large $^1J_{Rh,P}$ coupling constant of 195.8 Hz, it is assigned to the *cis*-oriented phospholanes at the lower coordinated rhodium center. The chemical shift and the coupling constant (118.4 Hz) for the signal at higher field are very similar to those of **14** ($\delta = 53.7$ ppm; $^1J_{Rh,P} = 119.1$ Hz) with P*i*Pr$_2$Ph as ligand. The ^{31}P NMR spectra of **13** and **14** (which are both yellow solids that can be stored under argon for weeks) show only one resonance, confirming that the two P-donors are in the *trans* positions. In the ^1H NMR spectra of **13** and **14** there is also only one set of signals (doublet of triplets) at $\delta = -22.00$ and -21.24 ppm for the hydride ligands, which is in agreement with the proposed structure shown in Scheme 4. An X-ray crystal structure analysis of [RhH$_2$Cl(P*i*Pr$_3$)$_2$] has been carried out, and this proved that the coordination geometry is trigonal bipyramidal with the phosphanes in the apical positions.[12]



Scheme 4

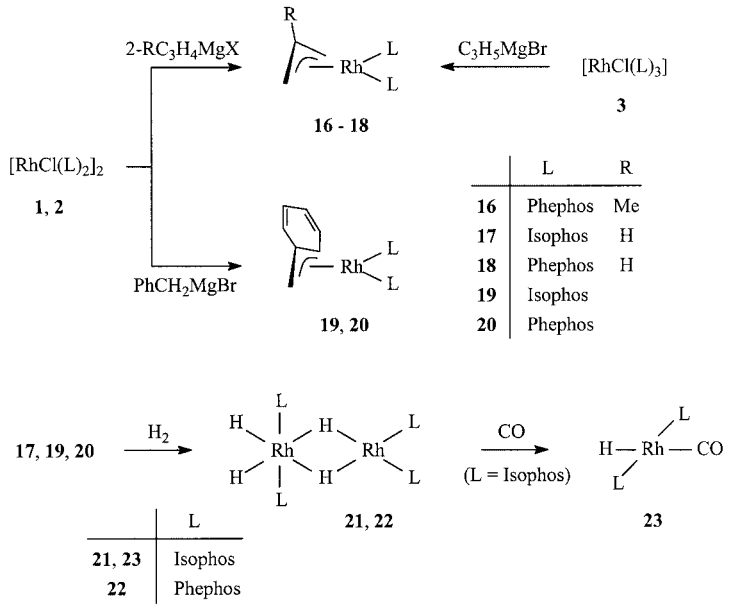
The plausible assumption that compounds **13** and **14** are formed via **11** and **12** as intermediates was confirmed by the reactions of **13** and **14** with one half equivalent of **1** or **10**, respectively. The conversion is relatively slow (3 h at 20 °C in C_6D_6) and was monitored by NMR spectroscopy. The ^1H and ^{31}P NMR spectra of **11** and **12** are similar to those of **15** and also to those of [RhH$_2$(PPh$_3$)$_2$(μ-Cl)$_2$Rh(PPh$_3$)$_2$], which is the first compound of this structural type reported in the literature.[8] It should be mentioned that dimer **1**, with Isophos as ligand, reacts in C_6D_6 at 60 °C with a tenfold excess of cyclooctane to give **11** and cyclooctene. However, this dehydrogenation is a stoichiometric reaction and all attempts to convert C_8H_{16} into C_8H_{14} catalytically using **1** as the catalyst failed.

In analogy to the preparation of [Rh(η^3-C$_3$H$_5$)(PR$_3$)$_2$] (PR$_3$ = P*i*Pr$_3$,[7,13] P*i*Pr$_2$Ph[2]), the starting materials **1** and **2**, both generated in situ from [RhCl(C$_8$H$_{14}$)$_2$]$_2$ and the corresponding phospholane, react with a solution of the Grignard reagent 2-RC$_3$H$_4$MgBr in diethyl ether to give the η^3-allyl complexes **16**−**18** in 72−82% isolated yield (Scheme 5). The Phephos derivative **18** is equally accessible from **3** and C$_3$H$_5$MgBr in the molar ratio of 1:4. Similarly to the related P*i*Pr$_3$ and P*i*Pr$_2$Ph compounds, **16**−**18** are orange-yellow solids that are not only air sensitive but also thermally quite labile. In contrast to the ^{31}P NMR spectra of [Rh(η^3-C$_3$H$_5$)(PR$_3$)$_2$] (PR$_3$ = P*i*Pr$_3$, P*i*Pr$_2$Ph) and [Rh(η^3-2-MeC$_3$H$_4$)(P*i*Pr$_3$)$_2$],[2,13] which display a sharp doublet, the ^{31}P NMR spectra of **16**−**18** exhibit the AB part of an ABX system, which reflects the non-equivalence of the chiral phospholane ligands. Owing to this non-equivalence, the ^1H NMR spectra of **16**−**18** show two signals for the *anti*- and two for the *syn*-protons of the terminal allylic CH$_2$ units, with a significant difference in the chemical shifts. Since the spectrum of **16** remains unchanged in the temperature range between 278 and 330 K, there is no doubt that in solution the Rh(η^3-2-MeC$_3$H$_4$) moiety is rigid on the NMR timescale and does not undergo an η^3-η^1-η^3 rearrangement.[14]

Under similar conditions as used for the preparation of **16**−**18**, the in situ generated dimers **1** and **2** also react with the benzyl Grignard reagent PhCH$_2$MgBr to give the η^3-benzylrhodium(I) compounds **19** and **20** in about 80% yield. The red air-sensitive solids are thermally even less stable than their Rh(η^3-C$_3$H$_5$) counterparts **17** and **18** and under argon slowly decompose at room temperature. In benzene, **19** and **20** are stable for ca. 1 h, while in CHCl$_3$ and CH$_2$Cl$_2$ they decompose almost instantaneously. The ^1H NMR spectrum of **19** shows, apart from a triplet for the CH$_2$ protons of the benzylic group, five distinct resonances for the six-membered ring protons H^3 − H^7, which, as for **16**−**18**, indicates that the bonding between the C$_6$H$_5$CH$_2$ ligand and the metal is rigid on the NMR timescale. As expected, the ^{31}P NMR spectra of **19** and **20** display two doublets of doublets of which those at lower fields ($\delta = 76.0$ ppm for **19** and $\delta = 65.2$ ppm for **20**), owing to their larger $^1J_{Rh,P}$ coupling constant of ca. 260 Hz, are assigned to the ^{31}P nuclei *trans* to the ring and those at higher fields ($\delta = 64.9$ ppm for **19** and $\delta = 58.1$ ppm for **20**), with a $^1J_{Rh,P}$ coupling constant of ca. 180 Hz, to the ^{31}P nuclei *trans* to the benzylic CH$_2$ unit.

The η^3-allyl and η^3-benzyl complexes **17**, **19** and **20** react smoothly with H_2 at a pressure of 1 bar to give the Rh$_2$H$_4$ derivatives **21** and **22**, respectively (see Scheme 5). Compounds of the general composition [Rh$_2$H$_4$(L)$_4$] with L = P*i*Pr$_3$,[15] P(OR)$_3$,[16] P(NMe$_2$)$_3$,[17] and L$_2$ = *i*Pr$_2$P(CH$_2$)$_n$-P*i*Pr$_2$ (n = 2, 3)[18] are well-known, but in most cases are rather labile and can be handled only under a hydrogen atmosphere. The X-ray crystal structure analysis of the stable complex [Rh$_2$H$_4$\{P(NMe$_2$)$_3$\}$_4$] revealed that the two rhodium centers, which are bridged by two hydride ligands, have a different coordination geometry, one being octahedral and the other square planar.[17] According to the spectroscopic data, we assume that the phospholane complexes **21** and **22** are structurally related to their P(NMe$_2$)$_3$ counterpart. The ^1H NMR spectrum of **21** (which is a dark green, extremely air-sensitive solid) displays two resonances at $\delta = -10.20$ and -17.50 ppm in the high-field region, of which the first is split into a triplet of quintets due to ^{103}Rh-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

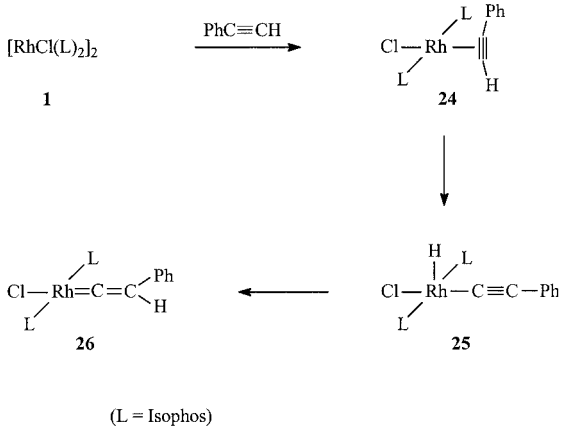


Scheme 5

^{1}H and ^{31}P-^{1}H couplings. Therefore, this signal is assigned to the bridging hydrides. The second resonance is a doublet of triplets and belongs to the terminal hydrides at the Rh^{III} center. The ^{1}H NMR spectrum of **22** also shows two hydride signals (with similar chemical shifts as for **21**), but these signals are rather broad, possibly due to a slow intramolecular rearrangement process as found for $[Rh_2H_4\{P(O\textit{i}Pr)_3\}_4]$.[19] In agreement with the proposed structure, the ^{31}P NMR spectra of **21** and **22** display two doublets at δ = 77.8 and 72.1 ppm (**21**) and δ = 73.8 and 65.4 ppm (**22**) with similar intensities, confirming that the four phospholane units are pairwise equivalent. Owing to the significant difference in the coupling constants, the signals at lower field are assigned to the *trans*-disposed P-donors at the Rh^{III} centers and the signals at higher field to the *cis*-disposed P-donors at the Rh^{I} centers of the molecules.

The Isophos complex **21** reacts quite rapidly with CO by cleavage of the hydride bridges and elimination of H_2 to afford the mononuclear carbonyl(hydrido)rhodium(I) compound **23** in nearly quantitative yield (see Scheme 5). Typical spectroscopic features of **23** (which is a yellow air-sensitive solid for which a correct elemental analysis has been obtained) are the sharp doublet at δ = 64.7 ppm in the ^{31}P NMR spectrum, confirming the equivalence of the phospholane ligands, the doublet of triplets at δ = −10.36 ppm for the hydride in the ^{1}H NMR spectrum, and the ν(CO) and ν(RhH) stretching modes at 1965 and 2065 cm^{-1} in the IR spectrum. Whereas the triisopropylphosphane derivative $[Rh_2H_4(P\textit{i}Pr_3)_4]$ reacts smoothly with CO to give $[Rh(CO)_3(P\textit{i}Pr_3)]_2$,[15b] a similar conversion of **23** to $[Rh(CO)_3(Isophos)]_2$ was not observed, even if the carbonyl(hydrido) compound is stored for 12 h under a CO atmosphere.

The reactivity of the Isophos complex **1** toward phenylacetylene is quite similar to that of the phosphane analogue $[RhCl(P\textit{i}Pr_3)_2]_2$.[20] Treatment of a solution of **1** in benzene with two equivalents of PhC≡CH at room temperature leads to a quick change of color from brick-red to yellow. If the reaction is carried out in C_6D_6 and monitored by ^{1}H NMR spectroscopy, after a few minutes a doublet is observed at δ = 4.11 ppm, which we assign to the alkyne proton of the η^2-alkyne intermediate **24** (Scheme 6). The ^{31}P NMR spectrum of **24** exhibits the AB part of an ABX spin system indicating that the rotation of the alkyne around the metal-alkyne axis is slow on the NMR timescale.



Scheme 6

Only 10 min after the signals of **24** have appeared, a subsequent rearrangement takes place which generates the alkynyl(hydrido)rhodium(III) species **25**. Noteworthy spectroscopic data of this intermediate are the hydride signal in the ^{1}H NMR spectrum at δ = −19.38 ppm, which is split by the ^{103}Rh and ^{31}P nuclei into a doublet of triplets, and the doublet at δ = 50.1 ppm in the ^{31}P NMR spectrum. The $^1J_{Rh,P}$ coupling constant of 99.2 Hz is consistent with a *trans* disposition of the two phospholanes, and thus a

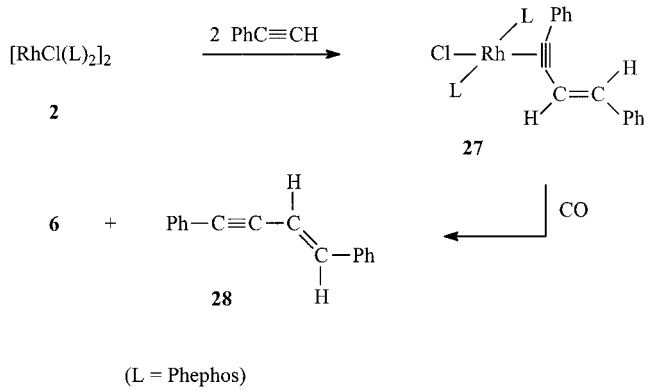
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

square-pyramidal structure for the five-coordinate compound can be proposed.

The final conversion of **25** to the stable isomer **26** proceeds upon warming the solution to 80 °C and affords, after chromatographic workup, the vinylidene complex in 84% isolated yield. In contrast to yellow **24** (which we failed to isolate), **26** is a violet, moderately air-stable solid, which is soluble in all common organic solvents apart from pentane and hexane. The ^{13}C NMR spectrum of **26** shows two resonances (both doublets of triplets) in the low-field region at δ = 296.3 and 112.3 ppm, which are characteristic for a Rh=C=CHR unit.[20,21] With regard to the course of the conversion of **25** to **26**, we note that owing to recent ab inito MO calculations both a mononuclear as well as a bimolecular mechanism seems possible.[22] In contrast to the related ruthenium system,[23] the alkynyl(hydrido)rhodium(III) species lies in a relative energy minimum, which is in agreement with the results presented in Scheme 6.

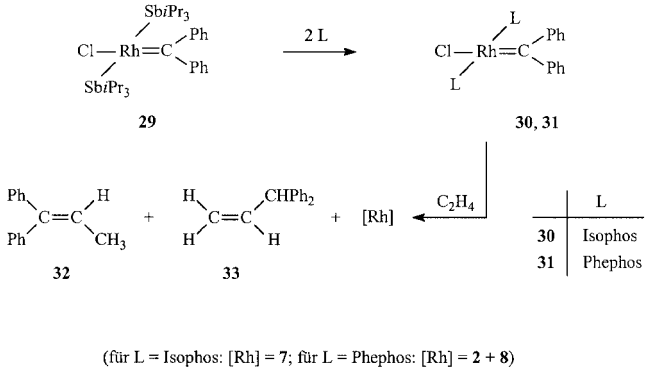
Compared with its Isophos counterpart **1**, the Phephos complex **2** behaves differently toward PhC≡CH. Instead of a vinylidene compound, the square-planar enynerhodium(I) complex **27** is generated which, however, is quite labile and could not be isolated in an analytically pure state. The ^1H NMR spectrum of **27** displays two signals for the olefinic protons at δ = 6.88 and 7.36 ppm, which, as indicated by the large $^3J_{H,H}$ coupling constant of 15.4 Hz, are *trans*-disposed at the C=C double bond. Other spectroscopic data are similar to those of *trans*-[RhCl{η^2-(*E*)-PhC≡CCH=CHPh}($P i Pr_3$)$_2$], which is obtained from the alkynyl(vinylidene) derivative *trans*-[Rh(C≡CPh)(=C=CHPh)($P i Pr_3$)$_2$] and protic acids.[3,24]

Upon passing a slow stream of CO through a solution containing **27**, a gradual change of color from yellow to pale yellow occurs and the formation of the carbonyl complex **6** and free (*E*)-PhC≡CCH=CHPh (**28**) can be detected (Scheme 7). It should be mentioned that the reaction of [RhCl(PMe_3)$_2$]$_2$ with excess phenylacetylene leads to PhC≡CC(Ph)=CH_2, which means that in this case the head-to-tail instead of the head-to-head dimerization is preferred.[25]



Scheme 7

Square-planar rhodium carbenes of the general composition *trans*-[RhCl(=CPh_2)(L)$_2$] could be obtained with both Isophos and Phephos as ligands L. The reaction of the starting material **29** with two equivalents of the corresponding phospholane proceeds under mild conditions and affords the required products **30** and **31** in 79−93% isolated yield (Scheme 8). The carbene complexes are green air-sensitive solids that decompose slowly in benzene and acetone but rapidly in $CHCl_3$ solution. Since the ^{31}P NMR spectra of **30** and **31** show a single resonance (doublet), there is no doubt that the two phospholane ligands are coordinated in the *trans* positions.



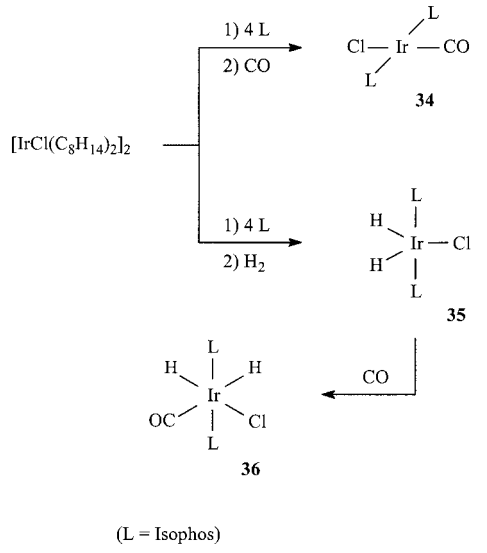
Scheme 8

Similarly to **29** and the phosphane analogues *trans*-[RhCl(=CPh_2)(PR_3)$_2$] (PR_3 = $P i Pr_3$, $P i Pr_2 Ph$, $P i PrPh_2$, PPh_3),[26] the related phospholane derivatives **30** and **31** are catalytically inactive in olefin metathesis. However, they do react with ethene relatively fast (10 min in C_6D_6 at room temperature) to give, apart from the ethene complexes **7** and **8** (and the dimer **2** in the case of Phephos as ligand), a mixture of two olefins **32** and **33** (see Scheme 8). With **30** as the precursor, the ratio of **32**:**33** is 94:6, while with **31** as precursor the ratio is 86:14. In our previous work we have already postulated that the major isomer **32** is probably generated via a rhodiacyclobutane, which, following a β-H shift, affords a RhH(η^3-CH_2CHCPh_2) intermediate. This reacts, in the presence of ethene, by reductive elimination to give the trisubstituted olefin.[3] The route to the minor isomer is not clear as yet, but possibly also proceeds via a rhodiacyclobutane as an intermediate.[27] For comparison it should be mentioned that by using *trans*-[RhCl(=CPh_2)($P i Pr_3$)$_2$] as the precursor, the ratio of **32**:**33** is 90:10 and with *trans*-[RhCl(=CPh_2)($P i Pr_2 Ph$)$_2$] it is 81:19.[27]

Some preliminary results regarding the preparation of iridium complexes with Isophos as ligand are summarized in Scheme 9. In contrast to [RhCl(C_8H_{14})$_2$]$_2$, the iridium counterpart reacts with four equivalents of Isophos to give a product which, even after storing for 12 h in vacuo, contains some cyclooctene. A similar situation results if [IrCl(C_8H_{14})$_2$]$_2$ is treated with $P i Pr_3$ in a 1:4 molar ratio.[28] Attempts to crystallize the crude product, obtained from [IrCl(C_8H_{14})$_2$]$_2$ and Isophos, from acetone led partly to the carbonyl derivative **34**. This complex is more conveniently prepared if a slow stream of CO is passed through the solution generated from [IrCl(C_8H_{14})$_2$]$_2$ and Isophos. The IR spectrum of the yellow solid displays a ν(CO) stretch at

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1937 cm^{-1} which is nearly identical to the value (1935 cm^{-1}) reported for *trans*-[IrCl(CO)(P*i*Pr$_3$)$_2$].[29]



Scheme 9

If instead of CO a stream of H_2 is passed through the solution obtained from [IrCl(C_8H_{14})$_2$]$_2$ and Isophos, the dihydridoiridium(III) compound **35** is generated. Similarly to the rhodium analogue **13**, it is a yellow air-sensitive solid which is readily soluble in all common organic solvents. Since there is only one resonance (triplet) for the hydrides at $\delta = -26.98$ ppm in the ^{1}H NMR spectrum and only one singlet (triplet in off-resonance) for the ^{31}P nuclei at $\delta = 51.2$ ppm in the ^{31}P NMR spectrum, we assume that the coordination geometry around the iridium center corresponds to a trigonal bipyramid with the P-donors in the apical positions. This geometry has been confirmed crystallographically for [IrH$_2$Cl(*t*Bu$_2$PCH$_2$CMe$_3$)$_2$].[30] As expected, the five-coordinate dihydrido complex **35** adds one molecule of CO to give the octahedral compound **36**, which, in contrast to the precursor, is only slightly air sensitive. The ^{1}H NMR spectrum of **36** displays two signals in the high-field region at $\delta = -8.57$ ppm and $\delta = -19.97$ ppm, which is consistent with the assumption that one of the hydrido ligands is *trans* to CO and the other *trans* to chloride. The triisopropylphosphane counterpart [IrH$_2$Cl(CO)(P*i*Pr$_3$)$_2$] is also known and shows the hydride resonances in the ^{1}H NMR spectrum at $\delta = -8.64$ ppm and $\delta = -20.20$ ppm, respectively.[31]

In conclusion, the work described in this paper illustrates that a series of rhodium and iridium complexes with the phospholanes Isophos and Phephos is accessible following similar preparative routes to those used for the synthesis of the P*i*Pr$_3$ and P*i*Pr$_2$Ph analogues. Owing to the similar size of the phosphanes and the phospholanes (see Scheme 1) and owing to the related donor/acceptor capabilities, it is also not surprising that both the chemical properties and the spectroscopic data of the M(P*i*Pr$_3$)$_2$ and the M(Isophos)$_2$ as well as those of the Rh(P*i*Pr$_2$Ph)$_2$ and the Rh(Phephos)$_2$ complexes are similar. Some preliminary results from catalytic studies reveal that in the hydrogenation of styrene (toluene, 60 °C, ratio catalyst to substrate = 1:100) the Isophos derivative **1** is significantly less active (TOF = 46.6 h^{-1}) than the Wilkinson complex [RhCl(PPh$_3$)$_3$] (TOF = 1250 h^{-1}). Moreover, the optical yield in the hydrogenation of PhCH=C(CO$_2$R)NHC(O)Me (R = H, Me) with **1** as the catalyst under similar conditions is rather low (14% *ee*) and could only be improved slightly in the presence of excess Isophos. Therefore, the aim for the future is to modify the coordination sphere around rhodium (and possibly iridium) in such a way that the phospholanes also become attractive ligands for catalysis, not necessarily only for hydrogenation reactions.

Experimental Section

All operations were carried out under argon using standard Schlenk techniques. The starting materials [RhCl(C_8H_{14})$_2$]$_2$,[32] [RhCl(P*i*Pr$_2$Ph)$_2$]$_2$ (**10**),[2] *trans*-[RhCl(=CPh$_2$)(Sb*i*Pr$_3$)$_2$] (**29**),[26] and [IrCl(C_8H_{14})$_2$]$_2$ [33] were prepared as described in the literature. NMR spectra were recorded at room temperature (if not otherwise stated) on Bruker AC 200 and AMX 400 instruments and IR spectra on a Perkin−Elmer 1420 infrared spectrophotometer. Abbreviations used: s = singlet; d = doublet; t = triplet; q = quadruplet; quin = quintet; m = multiplet; vt = virtual triplet; br = broadened signal, $N = {}^3J_{P,H} + {}^5J_{P,H}$ or ${}^1J_{P,C} + {}^3J_{P,C}$. Melting points were measured by differential thermal analysis (DTA).

Preparation of [RhCl(Isophos)$_2$]$_2$ (1): A suspension of [RhCl(C_8H_{14})$_2$]$_2$ (176 mg, 0.25 mmol) in acetone (2 mL) was treated with Isophos (166 mg, 1.05 mmol) and stirred for 10 min at room temperature. A brick-red solid precipitated which was filtered, washed three times with 1 mL portions of pentane (0 °C) and dried; yield 209 mg (92%); m.p. 54 °C (dec.). ^{1}H NMR (200 MHz, C_6D_6): δ = 2.20 [m, 8 H, CH(ring)], 2.01 [m, 4 H, CH(*i*Pr)], 1.85 [m, 12 H, CH$_3$(*i*Pr)], 1.81 [dvt, $N = 23.3$, $J_{H,H} = 6.9$ Hz, 8 H, CH$_2$(ring)], 1.70 [dvt, $J_{P,H} = 20.8$, $J_{H,H} = 7.3$ Hz, 12 H, CH$_3$(*i*Pr)], 1.40 [m, 8 H, CH$_2$(ring)], 1.38 [dvt, $N = 19.9$, $J_{H,H} = 7.1$ Hz, 12 H, CH$_3$(ring)], 1.17 [dvt, $N = 19.0$, $J_{H,H} = 7.3$ Hz, 12 H, CH$_3$(ring)] ppm. ^{13}C NMR (50.3 MHz, C_6D_6): δ = 37.1 [dt, $J_{Rh,C} = 11.1$, $J_{P,C} = 3.7$ Hz, CH$_2$(ring)], 36.2, 35.0 [both s, CH(ring)], 34.8 [t, $J_{Rh,C} = 12.0$ Hz, CH$_2$(ring)], 28.7 [vt, $N = 18.6$ Hz, CH(*i*Pr)], 22.9 [d, $J_{Rh,C} = 29.6$ Hz, CH$_3$(ring)], 22.4, 17.3 [both s, CH$_3$(*i*Pr)], 14.9 [s, CH$_3$(ring)] ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 75.8 (d, $J_{Rh,P} = 196.2$ Hz) ppm. $C_{36}H_{76}Cl_2P_4Rh_2$ (909.6): calcd. C 47.54, H 8.42; found C 47.43, H 8.18.

Preparation of [RhCl(Phephos)$_2$]$_2$ (2): A suspension of [RhCl(C_8H_{14})$_2$]$_2$ (116 mg, 0.16 mmol) in benzene (2 mL) was treated with Phephos (127 mg, 0.66 mmol) and stirred for 10 min at room temperature. A clear orange-red solution was generated which, after stirring for 2 h, was dried in vacuo. The remaining orange-red solid was washed three times with 1 mL portions of pentane (−78 °C) and dried; yield 125 mg (75%); m.p. 60 °C (dec.). ^{1}H NMR (200 MHz, C_6D_6): δ = 7.74−6.84 (m, 20 H, C_6H_5), 1.62−0.75 [m, 24 H, CH(ring) and CH$_2$(ring)], 1.19, 0.67 [both m, 12 H each, CH$_3$(ring)] ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 71.1 (d, $J_{Rh,P} = 198.0$ Hz) ppm. $C_{48}H_{68}Cl_2P_4Rh_2$ (1045.7): calcd. C 55.13, H 6.55; found C 54.59, H 7.22.

Preparation of [RhCl(Phephos)$_3$] (3): This compound was prepared as described for **2**, with [RhCl(C_8H_{14})$_2$]$_2$ (120 mg, 0.17 mmol) and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Prephos (257 mg, 1.34 mmol) in acetone (2 mL) as starting materials. Orange solid; yield 204 mg (84%); m.p. 59 °C (dec.). ^{1}H NMR (200 MHz, C_6D_6, 295 K): δ = 7.86−6.90 (m, 15 H, C_6H_5), 3.20−0.02 (m, 36 H, ring protons) ppm. ^{13}C NMR (50.3 MHz, C_6D_6, 295 K): δ = 137.9 (br. d, $J_{P,C}$ = 26.8 Hz, *ipso*-C of PC_6H_5), 136.8 (vt, *N* = 26.9 Hz, *ipso*-C of PC_6H_5), 134.0 (vt, *N* = 9.2 Hz, *ortho*-C of PC_6H_5), 133.5 (d, $J_{P,C}$ = 8.3 Hz, *ortho*-C of PC_6H_5), 130.4, 128.7 (both s, *para*-C of PC_6H_5), 126.9 (vt, *N* = 9.2 Hz, *meta*-C of PC_6H_5), 126.8 (d, $J_{P,C}$ = 8.3 Hz, *meta*-C of PC_6H_5), 38.0 (br. dvt, *N* = 23.1 Hz, CH), 34.6, 34.4, 34.3, 34.2 (all br. s, CH_2), 33.7 (br. s, CH), 31.9 (d, $J_{P,C}$ = 25.9 Hz, CH), 23.7 [d, $J_{P,C}$ = 12.0 Hz, CH_3(ring)], 23.3 [vt, *N* = 12.0 Hz, CH_3(ring)], 16.6, 15.9 [both s, CH_3(ring)] ppm. ^{31}P NMR (81.0 MHz, C_6D_6, 295 K): δ = 69.1 (dt, $J_{Rh,P}$ = 145.2, $J_{P,P}$ = 39.6 Hz, Phephos *trans* to Cl), 49.4 (br. s, Phephos *cis* to Cl) ppm. ^{31}P NMR (81.0 MHz, C_6D_6, 330 K): δ = 69.4 (dt, $J_{Rh,P}$ = 185.1, $J_{P,P}$ = 39.2 Hz, Phephos *trans* to Cl), 49.9 (dd, $J_{Rh,P}$ = 137.9, $J_{P,P}$ = 39.2 Hz, Phephos *cis* to Cl) ppm. $C_{36}H_{51}ClP_3Rh$ (715.1): calcd. C 60.47, H 7.19; found C 60.34, H 7.08.

Generation of [RhCl(Isophos)$_3$] (4): A solution of $[RhCl(C_8H_{14})_2]_2$ (70 mg, 0.10 mmol) in [D_8]toluene (0.5 mL) was treated with Isophos (127 mg, 0.80 mmol) and stirred for 10 min at room temperature. The ^{31}P NMR spectrum revealed that a mixture of **1** and **4** in the ratio of 1:9 was formed. Attempts to separate **4** from the by-product failed. Data for **4**: ^{31}P NMR (81.0 MHz, [D_8]toluene): δ = 84.2 (dt, $J_{Rh,P}$ = 190.7, $J_{P,P}$ = 41.2 Hz, Isophos *trans* to Cl), 59.0 (br. s, Isophos *cis* to Cl].

Preparation of *trans*-[RhCl(CO)(Isophos)$_2$] (5): A slow stream of CO was passed through a solution of either **1** (120 mg, 0.13 mmol) or **7** (24 mg, 0.05 mmol) in benzene (5 mL) for 30 s at room temperature. A change of color from brick-red to pale yellow occurred. The solvent was evaporated in vacuo and, after recrystallization of the residue from pentane at −78 °C, a pale yellow solid was isolated; yield 111 mg (88%) from **1** or 22 mg (92%) from **7**; m.p. 174 °C (dec.). IR (benzene): ν(CO) = 1947 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 2.10−1.60 [m, 10 H, CH(ring), CH(*i*Pr), CH_2(ring)], 1.55 [dvt, *N* = 24.3, $J_{H,H}$ = 7.1 Hz, 6 H, CH_3(*i*Pr)], 1.40 [m, 4 H, CH_2(ring)], 1.31 [dvt, *N* = 23.0, $J_{H,H}$ = 7.1 Hz, 6 H, CH_3(*i*Pr)], 1.19 [dvt, *N* = 21.2, $J_{H,H}$ = 7.0 Hz, 6 H, CH_3(ring)], 1.18 [dvt, *N* = 21.6, $J_{H,H}$ = 7.1 Hz, 6 H, CH_3(ring)] ppm. ^{13}C NMR (50.3 MHz, C_6D_6): δ = 189.3 (dt, $J_{Rh,C}$ = 73.7, $J_{P,C}$ = 15.3 Hz, RhCO), 36.5 [vt, *N* = 28.1 Hz, CH(ring)], 36.0, 35.8 [both s, CH_2(ring)], 34.8 [vt, *N* = 24.1 Hz, CH(ring)], 25.0 [vt, *N* = 20.0 Hz, CH(ring)], 21.3 [s, CH_3(ring)], 20.5 [vt, *N* = 9.0 Hz, CH_3(ring)], 18.9, 15.4 [both s, CH_3(ring)] ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 53.1 (d, $J_{Rh,P}$ = 118.2 Hz) ppm. $C_{19}H_{38}ClOP_2Rh$ (482.82): calcd. C 47.27, H 7.93; found C 47.30, H 8.02.

Preparation of *trans*-[RhCl(CO)(Phephos)$_2$] (6): A slow stream of CO was passed through a solution of either **2** (120 mg, 0.12 mmol) or **3** (50 mg, 0.07 mmol) in benzene (5 mL) for 30 s at room temperature. The solution was then worked-up as described for **5**. Pale yellow solid; yield 111 mg (88%) from **2** or 36 mg (94%) from **3**; m.p. 131 °C (dec.). IR (benzene): ν(CO) = 1961 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 7.96 (m, 4 H, *ortho*-H of C_6H_5), 7.10 (m, 6 H, *meta*-, *para*-H of C_6H_5), 3.39−0.75 [m, 12 H, CH(ring), CH_2(ring)], 1.72, 0.86 [both m, 6 H each, CH_3(ring)] ppm. ^{13}C NMR (50.3 MHz, C_6D_6): δ = 186.5 (dt, $J_{Rh,C}$ = 74.0, $J_{P,C}$ = 16.2 Hz, RhCO), 134.1 (vt, *N* = 12.0 Hz, *ortho*-C of C_6H_5), 132.5 (vt, *N* = 32.4 Hz, *ipso*-C of C_6H_5), 129.7 (s, *para*-C of C_6H_5), 127.6 (vt, *N* = 9.2 Hz, *meta*-C of C_6H_5), 35.1 [d, $J_{P,C}$ = 25.0 Hz, CH(ring)], 34.3 [d, $J_{P,C}$ = 13.9 Hz, CH(ring)], 33.6 [vt, *N* = 13.0 Hz, CH_2(ring)], 21.3 [vt, *N* = 12.0 Hz, CH_3(ring)], 14.9 [s, CH_3(ring)] ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 48.6 (d, $J_{Rh,P}$ = 123.9 Hz) ppm. $C_{25}H_{34}ClOP_2Rh$ (550.85): calcd. C 54.51, H 6.22; found C 54.37, H 6.27.

Preparation of *trans*-[RhCl(C_2H_4)(Isophos)$_2$] (7): A slow stream of ethene was passed through a solution of **1** (120 mg, 0.13 mmol) in benzene (5 mL) for 2 min at room temperature. A change of color from brick-red to pale yellow occurred. The solution was worked up as described for **5**. Pale yellow solid; yield 110 mg (88%); m.p. 72 °C. IR (hexane): ν(C=C) = 1510 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 2.52, 2.28 (both m, 2 H each, C_2H_4), 2.12−1.80 [m, 10 H, CH(ring), CH(*i*Pr), CH_2(ring)], 1.78 [dd, $J_{P,H}$ = 16.0, $J_{H,H}$ = 8.7 Hz, 6 H, CH_3(*i*Pr)], 1.63 [dd, $J_{P,H}$ = 14.6, $J_{H,H}$ = 7.3 Hz, 6 H, CH_3(*i*Pr)], 1.33 [m, 4 H, CH_2(ring)], 1.26 [dd, $J_{P,H}$ = 14.7, $J_{H,H}$ = 7.3 Hz, 6 H, CH_3(ring)], 1.02 [dd, $J_{P,H}$ = 13.9, $J_{H,H}$ = 6.9 Hz, 6 H, CH_3(ring)] ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 46.7 (d, $J_{Rh,P}$ = 121.4 Hz) ppm. $C_{20}H_{42}ClP_2Rh$ (482.87): calcd. C 49.75, H 8.77; found C 49.30, H 8.72.

Generation of *trans*-[RhCl(C_2H_4)(Phephos)$_2$] (8): A slow stream of ethene was passed through a solution of **2** (50 mg, 0.05 mmol) in C_6D_6 (0.5 mL) for 5 min at room temperature. The ^{31}P NMR spectrum revealed that **2** and **8** were present in equal amounts. If the ethene atmosphere was replaced by argon, the starting material was regenerated. Attempts to separate the two compounds failed. Data for **8**: ^{31}P NMR (81.0 MHz, C_6D_6): δ = 48.8 (d, $J_{Rh,P}$ = 125.5 Hz) ppm.

Preparation of *trans*-[RhCl(PhC≡CPh)(Phephos)$_2$] (9): A solution of $[RhCl(C_8H_{14})_2]_2$ (85 mg, 0.12 mmol) in benzene (10 mL) was treated dropwise with a solution of Phephos (102 mg, 0.53 mmol) in benzene (2 mL) at room temperature. After stirring the solution for 30 min, a solution of diphenylacetylene (21 mg, 0.12 mmol) in benzene (2 mL) was added. The reaction mixture was stirred for 4 h and then the solvent was evaporated in vacuo. The residue was dissolved in acetone (1 mL), the solution was layered with pentane (5 mL) and stored for 12 h at −78 °C. Orange-yellow crystals precipitated which were filtered, washed twice with 2 mL portions of pentane (0 °C) and dried; yield 109 mg (72%); m.p. 81 °C (dec.). ^{1}H NMR (200 MHz, C_6D_6): δ = 8.25, 7.86 (both m, 4 H each, C_6H_5), 7.65 (m, 2 H, C_6H_5), 7.24 (m, 10 H, C_6H_5), 2.78−1.05 [m, 6 H, CH(ring), CH_2(ring)], 2.22 [br. vt, *N* = 24.0 Hz, 6 H, CH_3(ring)], 0.68 [br. vt, *N* = 19.3 Hz, 6 H, CH_3(ring)] ppm. ^{13}C NMR (50.3 MHz, C_6D_6): δ = 135.0 (vt, *N* = 10.8 Hz, *ortho*-C of PC_6H_5), 132.7 (vt, *N* = 28.0 Hz, *ipso*-C of PC_6H_5), 132.0, 129.2, 128.7, 128.3 (all s, C_6H_5), 127.4 (vt, *N* = 8.2 Hz, *meta*-C of PC_6H_5), 88.2 (dt, $J_{Rh,C}$ = 15.7, $J_{P,C}$ = 2.8 Hz, Ph*C*≡*C*Ph), 37.1 [vt, *N* = 24.4 Hz, CH(ring)], 35.8, 35.5 [both s, CH_2(ring)], 31.9 [vt, *N* = 23.0 Hz, CH(ring)], 21.0 [vt, *N* = 11.6 Hz, CH_3(ring)], 15.7 [s, CH_3(ring)] ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 41.9 (d, $J_{Rh,P}$ = 121.3 Hz) ppm. $C_{38}H_{44}ClP_2Rh$ (701.1): calcd. C 65.10, H 6.33; found C 64.85, H 6.09.

Generation of [RhH_2(Isophos)$_2$(μ-Cl)$_2$Rh(Isophos)$_2$] (11): A solution of **1** (45 mg, 0.05 mmol) and **13** (45 mg, 0.10 mmol) in C_6D_6 (0.5 mL) was stirred for 3 h at room temperature. The ^{1}H and ^{31}P NMR spectra revealed that compound **11** was generated. Attempts to isolate **11** failed. Characteristic data for **11**: ^{1}H NMR (200 MHz, C_6D_6): δ = −21.50 (dt, $J_{Rh,H}$ = 24.7, $J_{P,H}$ = 14.5 Hz) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 74.5 [d, $J_{Rh,P}$ = 193.3 Hz, *cis*-Rh(Isophos)$_2$], 64.0 [d, $J_{Rh,P}$ = 114.4 Hz, *trans*-Rh(Isophos)$_2$] ppm.

Generation of [RhH_2(P*i*Pr_2Ph)$_2$(μ-Cl)$_2$Rh(P*i*Pr_2Ph)$_2$] (12): A solution of **10** (21 mg, 0.02 mmol) and **14** (21 mg, 0.04 mmol) in C_6D_6 (0.5 mL) was stirred for 3 h at room temperature. The ^{1}H and ^{31}P NMR spectra revealed that compound **12** had formed. Attempts

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to isolate **12** failed. Characteristic data for **12**: ^{1}H NMR (200 MHz, C_6D_6): δ = −21.46 (dt, $J_{Rh,H}$ = 22.8, $J_{P,H}$ = 16.0 Hz) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 55.7 [d, $J_{Rh,P}$ = 196.2 Hz, *cis*-Rh(P*i*Pr$_2$Ph)$_2$], 48.5 [d, $J_{Rh,P}$ = 117.1 Hz, *trans*-Rh(P*i*Pr$_2$Ph)$_2$] ppm.

Preparation of [RhClH$_2$(Isophos)$_2$] (13): A solution of **1** (120 mg, 0.13 mmol) in toluene (5 mL) was stirred for 5 min at −78 °C under a H_2 atmosphere. Upon warming the solution slowly to room temperature, a change of color from brick-red to yellow occurred. After stirring for 15 min, the solvent was evaporated in vacuo and the residue was extracted with pentane (10 mL). The extract was dried in vacuo to give a yellow solid; yield 90 mg (76%); m.p. 64 °C (dec.). IR (KBr): ν(RhH) = 2155 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 2.04−1.84 [m, 10 H, CH(ring), CH(*i*Pr), CH$_2$(ring)], 1.83 [dd, $J_{P,H}$ = 16.3, $J_{H,H}$ = 6.9 Hz, 6 H, CH$_3$(*i*Pr)], 1.46 [dd, $J_{P,H}$ = 13.6, $J_{H,H}$ = 7.0 Hz, 6 H, CH$_3$(*i*Pr)], 1.32 [m, 4 H, CH$_2$(ring)], 1.30 [dd, $J_{P,H}$ = 13.9, $J_{H,H}$ = 6.9 Hz, 6 H, CH$_3$(ring)], 1.10 [dd, $J_{P,H}$ = 13.6, $J_{H,H}$ = 6.8 Hz, 6 H, CH$_3$(ring)], −22.00 (dt, $J_{Rh,H}$ = 26.0, $J_{P,H}$ = 14.6 Hz, 2 H, RhH) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 64.0 (d, $J_{Rh,P}$ = 113.1 Hz) ppm. $C_{18}H_{40}ClP_2Rh$ (456.8): calcd. C 47.33, H 8.83; found C 47.30, H 8.82.

Preparation of [RhClH$_2$(P*i*Pr$_2$Ph)$_2$] (14): A suspension of **10** (100 mg, 0.095 mmol) in pentane (2 mL) was stirred for 5 min at −50 °C under a H_2 atmosphere. The suspension was slowly warmed to room temperature, which led to a smooth change of color from dark violet to yellow. After stirring for 1 h at 20 °C, the yellow solution was concentrated in vacuo to ca. 1 mL and stored for 3 h at 0 °C. A yellow solid precipitated, which was separated from the mother liquor and dried; yield 88 mg (87%); m.p. 67 °C (dec.). IR (KBr): ν(RhH) = 2164 cm^{-1}. ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 7.85 (m, 4 H, *ortho*-H of C_6H_5), 7.12 (m, 6 H, *meta*- and *para*-H of C_6H_5), 2.63 (m, 4 H, PC*H*CH$_3$), 1.29 (dvt, *N* = 15.0, $J_{H,H}$ = 7.1 Hz, 12 H, PCHC*H*$_3$), 1.01 (dvt, *N* = 14.3, $J_{H,H}$ = 7.0 Hz, 12 H, PCHC*H*$_3$), −21.24 (dt, $J_{Rh,H}$ = 24.8, $J_{P,H}$ = 14.4 Hz, 2 H, RhH$_2$) ppm. ^{13}C NMR (50.3 MHz, C_6D_6): δ = 134.8 (vt, *N* = 11.6 Hz, *ortho*-C of C_6H_5), 129.9 (s, *para*-C of C_6H_5), 127.9 (vt, *N* = 9.1 Hz, *meta*-C of C_6H_5), 127.7 (d, $J_{P,C}$ = 18.5 Hz, *ipso*-C of C_6H_5), 24.3 (vt, *N* = 24.6 Hz, P*C*HCH$_3$), 19.4, 18.9 (both s, PCH*C*H$_3$) ppm. ^{31}P NMR (81.0 MHz, CD_2Cl_2): δ = 53.7 (d, $J_{Rh,P}$ = 119.1 Hz) ppm. $C_{24}H_{40}ClP_2Rh$ (528.9): calcd. C 54.50, H 7.62; found C 54.24, H 7.49.

Generation of [RhH$_2$(Phephos)$_2$(μ−Cl)$_2$Rh(Phephos)$_2$] (15): A slow stream of H_2 was passed for 20 s through a solution of **2** (50 mg, 0.05 mmol) in C_6D_6 (0.5 mL) at room temperature. The ^{1}H and ^{31}P NMR spectra revealed that an equilibrium between **2** and **15** was established which, even after repeated addition of H_2, could not be completed shifted to the side of the dinuclear complex. If the hydrogen atmosphere was replaced by argon, compound **15** was reconverted into **2**. Characteristic data for **15**: ^{1}H NMR (200 MHz, C_6D_6): δ = −20.77 (dt, $J_{Rh,H}$ = 24.7, $J_{P,H}$ = 14.5 Hz) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 69.9 [d, $J_{Rh,P}$ = 195.8 Hz, *cis*-Rh(Phephos)$_2$], 52.2 [d, $J_{Rh,P}$ = 118.4 Hz, *trans*-Rh(Phephos)$_2$] ppm.

Preparation of [Rh(η^3-2-MeC$_3$H$_4$)(Phephos)$_2$] (16): A suspension of [RhCl(C$_8$H$_{14}$)$_2$]$_2$ (82 mg, 0.11 mmol) in diethyl ether (2 mL) was treated at 0 °C with Phephos (88 mg, 0.46 mmol) and stirred for 30 min at 0 °C. A clear orange-red solution was formed to which a 0.8 M solution of 2-MeC$_3$H$_4$MgCl in THF (0.58 mL, 0.46 mmol) was added dropwise. A change of color from orange-red to yellow occurred. After stirring the reaction mixture for 30 min at room temperature, the solvent was removed in vacuo and the residue was extracted with pentane (20 mL). The extract was dried in vacuo, the remaining orange-yellow air-sensitive solid was washed three times with 1 mL portions of acetone (0 °C) and dried; yield 98 mg (82%); m.p. 55 °C (dec.). ^{1}H NMR (200 MHz, 278 K, C_6D_6): δ = 7.52 (m, 6 H, *meta*-, *para*-H of C_6H_5), 7.20 (m, 4 H, *ortho*-H of C_6H_5), 2.92−0.72 [m, 12 H, CH(ring), CH$_2$(ring)], 2.84 (d, $J_{P,H}$ = 3.3 Hz, 1 H, allyl-H$_{syn}$), 2.64 (d, $J_{P,H}$ = 2.9 Hz, 1 H, allyl-H$_{syn}$), 2.18 (d, $J_{P,H}$ = 6.2 Hz, 1 H, allyl-H$_{anti}$), 1.78 (d, $J_{P,H}$ = 5.8 Hz, 1 H, allyl-H$_{anti}$), 1.66 (d, $J_{Rh,H}$ = 2.2 Hz, 3 H, allyl-CH$_3$), 1.31 [dd, $J_{P,H}$ = 15.4, $J_{H,H}$ = 7.3 Hz, 3 H, CH$_3$(ring)], 1.22 [dd, $J_{P,H}$ = 15.4, $J_{H,H}$ = 6.9 Hz, 3 H, CH$_3$(ring)], 0.49 [dd, $J_{P,H}$ = 13.2, $J_{H,H}$ = 6.9 Hz, 3 H, CH$_3$(ring)], 0.35 [dd, $J_{P,H}$ = 13.5, $J_{H,H}$ = 6.9 Hz, 3 H, CH$_3$(ring)] ppm. ^{13}C NMR (50.3 MHz, C_6D_6): δ = 139.9 (d, $J_{P,C}$ = 21.3 Hz, *ipso*-C of C_6H_5), 139.4 (d, $J_{P,C}$ = 22.2 Hz, *ipso*-C of C_6H_5), 134.1 (d, $J_{P,C}$ = 2.8 Hz, *ortho*-C of C_6H_5), 133.8 (d, $J_{P,C}$ = 1.9 Hz, *ortho*-C of C_6H_5), 128.8, 128.7 (both s, *para*-C of C_6H_5), 127.5, 127.4 (both d, $J_{P,C}$ = 3.7 Hz, *meta*-C of C_6H_5), 117.0 [d, $J_{Rh,C}$ = 6.5 Hz, CH$_2$*C*(CH$_3$)CH$_2$], 51.6, 51.2 [both ddd, $J_{P,C}$ = 12.0 and 7.4, $J_{Rh,C}$ = 1.9 Hz, *C*H$_2$C(CH$_3$)CH$_2$], 40.9 [ddd, $J_{P,C}$ = 41.6 and 19.5, $J_{Rh,C}$ = 3.7 Hz, CH(ring)], 35.4 [s, CH$_2$(ring)], 33.2 [t, $J_{P,C}$ = 19.0 Hz, CH(ring)], 26.4 [s, CH$_3$(ring)], 23.5 [d, $J_{P,C}$ = 16.1 Hz, CH$_2$C(*C*H$_3$)CH$_2$], 14.7 [s, CH$_3$(ring)] ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ$_A$ = 62.1, δ$_B$= 62.9 (AB part of ABX spectrum; A, B = P, X = Rh; $J_{A,B}$ = 27.8, $J_{A,X}$ = 195.0, $J_{B,X}$ = 195.7 Hz) ppm. $C_{28}H_{41}P_2Rh$ (542.5): calcd. C 61.99, H 7.62; found C 62.06; H 7.58.

Preparation of [Rh(η^3-C$_3$H$_5$)(Isophos)$_2$] (17): This compound was prepared as described for **16**, with [RhCl(C$_8$H$_{14}$)$_2$]$_2$ (169 mg, 0.24 mmol), Isophos (168 mg, 1.06 mmol) and a 0.56 M solution of C$_3$H$_5$MgBr in diethyl ether (0.42 mL, 0.48 mmol) as starting materials. Orange-yellow air-sensitive solid; yield 159 mg (72%); m.p. 71 °C (dec.). ^{1}H NMR (200 MHz, C_6D_6): δ = 4.76 (m, 1 H, CH$_2$C*H*CH$_2$), 3.55, 3.42 (both m, 1 H each, allyl-H$_{syn}$), 2.31−1.62 [m, 12 H, CH(ring), CH(*i*Pr), CH$_2$(ring), allyl-H$_{anti}$], 1.35 [m, 4 H, CH$_2$(ring)], 1.24 [dd, $J_{H,H}$ = 7.6, $J_{P,H}$ = 3.3 Hz, 6 H, CH$_3$(*i*Pr)], 1.20 [dd, $J_{P,H}$ = 11.0, $J_{H,H}$ = 7.1 Hz, 6 H, CH$_3$(*i*Pr)], 1.15 [dd, $J_{P,H}$ = 11.0, $J_{H,H}$ = 7.1 Hz, 6 H, CH$_3$(ring)], 1.07 [dd, $J_{H,H}$ = 7.1, $J_{P,H}$ = 5.1 Hz, 6 H, CH$_3$(ring)] ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ$_A$ = 65.7, δ$_B$= 67.7 (AB part of ABX spectrum; A, B = P, X = Rh; $J_{A,B}$ = 24.7, $J_{A,X}$ = 206.4, $J_{B,X}$ = 206.0 Hz) ppm. $C_{21}H_{43}P_2Rh$ (460.4): calcd. C 54.78, H 9.41; found C 55.23, H 9.78.

Preparation of [Rh(η^3-C$_3$H$_5$)(Phephos)$_2$] (18): a) This procedure was analogous to that described for **16**, with [RhCl(C$_8$H$_{14}$)$_2$]$_2$ (67 mg, 0.09 mmol), Phephos (72 mg, 0.37 mmol) and a 0.74 M solution of C$_3$H$_5$MgBr in diethyl ether (0.5 mL, 0.37 mmol) as starting materials. Orange-yellow air-sensitive solid; yield 70 mg (74%). b) A suspension of **3** (100 mg, 0.14 mmol) in benzene (5 mL) was treated with a 0.70 M solution of C$_3$H$_5$MgBr in diethyl ether (0.8 mL, 0.56 mmol) at room temperature. A quick change of color from orange to yellow occurred. After stirring the reaction mixture for 30 min, the solvent was evaporated in vacuo, the residue was extracted with pentane (5 mL) and the extract was dried in vacuo. The residue was recrystallized from acetone (1 mL) at −78 °C to give an orange-yellow air-sensitive solid; yield 55 mg (75%), m.p. 49 °C (dec.). ^{1}H NMR (200 MHz, 278 K, C_6D_6): δ = 7.61−7.48 (m, 6 H, *meta*-, *para*-H of C_6H_5), 7.06 (m, 4 H, *ortho*-H of C_6H_5), 5.11 (m, 1 H, CH$_2$C*H*CH$_2$), 3.50, 3.29 (both m, 1 H, allyl-H$_{syn}$), 2.66−1.11 [m, 14 H, CH(ring), CH$_2$(ring), allyl-H$_{anti}$], 1.34, 1.31 [both dd, $J_{P,H}$ = 15.0, $J_{H,H}$ = 7.5 Hz, 3 H each, CH$_3$(ring)], 0.69, 0.47 [both dd, $J_{P,H}$ = 13.4, $J_{H,H}$ = 6.9 Hz, 3 H each, CH$_3$(ring)] ppm. ^{13}C NMR (50.3 MHz, C_6D_6): δ = 139.5, 139.3 (both d, $J_{P,C}$ = 19.5 Hz, *ipso*-C of C_6H_5), 133.7 (d, $J_{P,C}$ = 4.6 Hz, *ortho*-C of C_6H_5), 133.5 (d, $J_{P,C}$ = 3.7 Hz, *ortho*-C of C_6H_5), 128.3, 128.2

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(both s, *para*-C of C_6H_5), 127.1, 127.0 (both d, $J_{P,C}$ = 2.8 Hz, *meta*-C of C_6H_5), 105.9 (d, $J_{P,C}$ = 5.9 Hz, CH_2CHCH_2), 52.4 (ddd, $J_{P,C}$ = 25.0 and 7.4, $J_{Rh,C}$ = 1.9 Hz, CH_2CHCH_2), 51.2 (ddd, $J_{P,C}$ = 25.0 and 7.4, $J_{Rh,C}$ = 2.8 Hz, CH_2CHCH_2), 40.9 [ddd, $J_{P,C}$ = 41.6, $J_{P,C}$ = 19.5, $J_{Rh,C}$ = 3.7 Hz, CH(ring)], 35.4 [d, $J_{P,C}$ = 11.9 Hz, CH_2(ring)], 35.2 [s, CH_2(ring)], 34.3 [d, $J_{P,C}$ = 21.1 Hz, CH(ring)], 33.3 [d, $J_{P,C}$ = 20.5 Hz, CH(ring)], 23.0 [d, $J_{P,C}$ = 15.7 Hz, CH_3(ring)], 22.6 [d, $J_{P,C}$ = 17.6 Hz, CH_3(ring)], 14.6, 14.5 [both s, CH_3(*i*Pr)] ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ_A = 58.5, δ_B = 61.0 (AB part of ABX spectrum; A, B = P, X = Rh; $J_{A,B}$ = 27.9, $J_{A,X}$ = 116.2, $J_{B,X}$ = 116.9 Hz) ppm. $C_{27}H_{39}P_2Rh$ (528.5): calcd. C 61.37, H 7.44; found C 61.41, H 7.38.

Preparation of [Rh(η^3-$CH_2C_6H_5$)(Isophos)$_2$] (19): A suspension of **1** (90 mg, 0.10 mmol) in diethyl ether (10 mL) was treated dropwise at 0 °C with a 0.86 M solution of $C_6H_5CH_2MgBr$ in diethyl ether (0.23 mL, 0.20 mmol). A gradual change of color from brick-red to deep red occurred. After stirring the reaction mixture for 30 min, it was warmed to room temperature, and then the solvent was evaporated in vacuo. The residue was extracted with pentane (20 mL) and the extract was dried in vacuo. The remaining deep red, air-sensitive solid was washed three times with 1 mL portions of acetone (0 °C) and dried; yield 83 mg (82%). ^{1}H NMR (200 MHz, [D$_8$]toluene): δ = 7.17 (t, $J_{H,H}$ = 8.2 Hz, 1 H, H^3), 7.07 (t, $J_{H,H}$ = 6.9 Hz, 1 H, H^4), 6.72 (t, $J_{H,H}$ = 6.9 Hz, 1 H, H^2), 6.16 (d, $J_{H,H}$ = 6.2 Hz, 1 H, H^1), 5.79 (d, $J_{H,H}$ = 6.2, 1 H, H^5), 2.11 (t, $J_{P,H}$ = 2.4 Hz, 2 H, CH_2), 2.30−0.23 (m, 38 H, Isophos protons) ppm; the phenyl protons are numbered clockwise beginning at the position next to the carbon atom carrying the CH_2 group. ^{31}P NMR (81.0 MHz, [D$_8$]toluene): δ = 76.0 (dd, $J_{Rh,P}$ = 260.8, $J_{P,P}$ = 24.0 Hz), 64.9 (dd, $J_{Rh,P}$ = 177.7, $J_{P,P}$ = 24.4 Hz) ppm. $C_{25}H_{45}P_2Rh$ (510.5): calcd. Rh 20.16; found Rh 20.08.

Preparation of [Rh(η^3-$CH_2C_6H_5$)(Phephos)$_2$] (20): This compound was prepared as described for **16**, with $[RhCl(C_8H_{14})_2]_2$ (120 mg, 0.17 mmol), Phephos (135 mg, 0.70 mmol) and a 0.86 M solution of $C_6H_5CH_2MgBr$ in diethyl ether (0.39 mL, 0.34 mmol) as starting materials. Deep red, air-sensitive solid; yield 156 mg (80%). ^{1}H NMR (200 MHz, C_6D_6): δ = 7.73−6.90 (m, 10 H, C_6H_5), 6.60 (t, $J_{H,H}$ = 7.3 Hz, 1 H, H^2), 6.11 (d, $J_{H,H}$ = 7.3 Hz, 1 H, H^1), 6.04 (d, $J_{H,H}$ = 7.7 Hz, 1 H, H^5), 2.74−0.23 [m, 12 H, CH(ring), CH_2(ring)], 0.78 [dd, $J_{P,H}$ = 14.3, $J_{H,H}$ = 7.3 Hz, 6 H, CH_3(ring)], 0.66 [dd, $J_{P,H}$ = 15.7, $J_{H,H}$ = 7.3 Hz, 3 H, CH_3(ring)], 0.46 (dd, $J_{P,H}$ = 13.2, $J_{H,H}$ = 7.0 Hz, 3 H, CH_3(ring)] ppm; the phenyl protons are numbered clockwise beginning at the position next to the carbon atom carrying the CH_2 group; signal for benzylic CH_2 protons partially covered by signals of H^1 and H^2, signals of H^3 and H^4 probably covered by that of the C_6H_5 protons. ^{13}C NMR (50.3 MHz, C_6D_6): δ = 139.1 (d, $J_{P,C}$ = 23.1 Hz, *ipso*-C of C_6H_5), 137.8 (d, $J_{P,C}$ = 19.4 Hz, *ipso*-C of C_6H_5), 133.1 (d, $J_{P,C}$ = 4.6 Hz, *ortho*-C of C_6H_5), 132.9 (d, $J_{P,C}$ = 2.8 Hz, *ortho*-C of C_6H_5), 132.1 (s, C^{2,4}), 129.3, 128.8 (both s, *para*-C of C_6H_5), 126.9, 126.7 (both d, $J_{P,C}$ = 2.8 Hz, *meta*-C of C_6H_5), 120.5 (s, CCH_2), 115.8 (s, C^3), 105.8 (d, $J_{P,C}$ = 7.4 Hz, C^{1,3}), 39.0 [br. d, $J_{P,C}$ = 25.0 Hz, CH(ring)], 37.8 [d, $J_{P,C}$ = 25.6 Hz, CH(ring)], 36.1 [d, $J_{P,C}$ = 17.6 Hz, CH(ring)], 34.5, 32.5 [both m, CH_2(ring)], 31.6 [d, $J_{P,C}$ = 19.4 Hz, CH(ring)], 23.6 [d, $J_{P,C}$ = 14.8 Hz, CH_3(ring)], 22.5 [d, $J_{P,C}$ = 16.7 Hz, CH_3(ring)], 14.6, 13.1 [both d, $J_{P,C}$ = 2.8 Hz, CH_3(ring)] ppm; signal of benzylic CH_2 carbon atom not located exactly. ^{31}P NMR (81.0 MHz, C_6H_6): δ = 65.2 (dd, $J_{Rh,P}$ = 256.8, $J_{P,P}$ = 28.0 Hz), 58.10 (dd, $J_{Rh,P}$ = 180.6, $J_{P,P}$ = 30.5 Hz) ppm. $C_{31}H_{41}P_2Rh$ (578.5): calcd. Rh 17.79; found Rh 18.21.

Preparation of [Rh_2H_4(Isophos)$_4$] (21): A solution of **17** (150 mg, 0.33 mmol) in pentane (10 mL) was stirred at −78 °C for 5 min under a H_2 atmosphere. The solution was then slowly warmed to room temperature, which led to a change of color from yellow dark green. After stirring for 15 min, the solvent was evaporated in vacuo, the remaining dark green, extremely air-sensitive solid was washed three times with 2 mL portions of acetone (−78 °C) and dried; yield 128 mg (92%). IR (hexane): ν(RhH) = 2001 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 2.76−0.18 (m, 76 H, Isophos protons), −10.20 (tquint, $J_{P,H}$ = 27.6, $J_{Rh,H}$ = 8.2 Hz, 2 H, RhH_2Rh), −17.50 (dt, $J_{P,H}$ = 16.7, $J_{Rh,H}$ = 1.5 Hz, 2 H, RhH_2) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 77.8 [d, $J_{Rh,P}$ = 109.0 Hz, *trans*-Rh(Isophos)$_2$], 72.1 [d, $J_{Rh,P}$ = 161.3 Hz, *cis*-Rh(Isophos)$_2$] ppm. Alternatively, instead of **17** compound **19** could be used as starting material; the yield of **21** (determined by NMR spectroscopy) was quantitative.

Generation of [Rh_2H_4(Prephos)$_4$] (22): A slow stream of H_2 was passed through a solution of **20** (50 mg, 0.09 mmol) in C_6D_6 (0.5 mL) at room temperature. A change of color from deep red to black occurred. Removal of the solvent in vacuo led to quick decomposition. Therefore, the product was characterized by ^{1}H and ^{31}P NMR spectroscopy in the presence of hydrogen. Data for **22**: ^{1}H NMR (200 MHz, C_6D_6): δ = −11.2 (br. m), −18.1 (br. m) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 73.8 [d, $J_{Rh,P}$ = 111.9 Hz, *trans*-Rh(Prephos)$_2$], 65.4 [d, $J_{Rh,P}$ = 157.7 Hz, *cis*-Rh(Prephos)$_2$].

Preparation of *trans*-[RhH(CO)(Isophos)$_2$] (23): A slow stream of CO was passed through a solution of **21** (130 mg, 0.15 mmol) in hexane (10 mL) for 30 s at room temperature. A quick change of color from dark green to yellow occurred. The solvent was evaporated in vacuo, the residue was dissolved in pentane (3 mL) and the solution was stored for 12 h at −78 °C. Yellow air-sensitive crystals precipitated which were separated from the mother liquor and dried; yield 126 mg (94%); m.p. 64 °C. IR (hexane): ν(RhH) = 2065, ν(CO) 1965 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 2.15 [m, 2 H, CH(*i*Pr)], 2.00−1.43 [m, 12 H, CH(ring), CH_2(ring)], 1.24 [dvt, *N* = 23.6, $J_{H,H}$ = 6.9 Hz, 6 H, CH_3(*i*Pr)], 1.10 [dvt, *N* = 23.7, $J_{H,H}$ = 7.9 Hz, 6 H, CH_3(*i*Pr)], 1.09 [dvt, *N* = 21.7, $J_{H,H}$ = 6.9 Hz, 6 H, CH_3(ring)], 0.88 [dvt, *N* = 21.7, $J_{H,H}$ = 6.9 Hz, 6 H, CH_3(ring)], −10.36 (dt, $J_{P,H}$ = 6.9, $J_{Rh,H}$ = 4.9 Hz, 1 H, RhH) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 35.8 (d, $J_{Rh,P}$ = 136.6 Hz) ppm. $C_{19}H_{39}OP_2Rh$ (448.4): calcd. C 50.90, H 8.77; found C 51.04, H 8.79.

Generation of *trans*-[RhCl(PhC≡CH)(Isophos)$_2$] (24) and [RhHCl-(C≡CPh)(Isophos)$_2$] (25): A solution of **1** (15 mg, 0.02 mmol) in C_6D_6 (0.5 mL) was treated dropwise with phenylacetylene (11 μL, 10 mg, 0.10 mmol) at room temperature. A quick change of color from brick-red to yellow occurred. The ^{1}H and ^{31}P NMR spectra indicated that compound **24** had formed. If the solution was stored for 10 min, new signals appeared in the NMR spectra which were assigned to intermediate **25** and the final product **26**. Attempts to isolate **24** or to separate **25** from **26** failed. Characteristic data for **24**: ^{1}H NMR (200 MHz, C_6D_6): δ = 4.11 (d, $J_{Rh,H}$ = 2.9 Hz, ≡CH), 1.88 (m, 6 H, CH_3), 1.59 (m, 6 H, CH_3), 1.30 (m, 6 H, CH_3), 0.90 (m, 3 H, CH_3), 0.60 (m, 3 H, CH_3) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ_A = 44.8, δ_B = 44.0 (AB part of ABX spectrum; A, B = P, X = Rh; $J_{A,B}$ = 36.0, $J_{A,X}$ = 116.2, $J_{B,X}$ = 117.0 Hz) ppm. Characteristic data for **25**: ^{1}H NMR (200 MHz, C_6D_6): δ = −19.38 (dt, $J_{Rh,H}$ = 21.8, $J_{P,H}$ = 11.6 Hz) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 50.1 (d, $J_{Rh,P}$ = 99.2 Hz) ppm.

Preparation of [RhCl(=C=CHPh)(Isophos)$_2$]$_2$ (26): A solution of **1** (80 mg, 0.09 mmol) in benzene (5 mL) was treated dropwise with a solution of phenylacetylene (24 μL, 22 mg, 0.22 mmol in benzene (2 mL) at room temperature. A quick change of color from brick-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

red to yellow occurred. After the solution was stirred for 3 h at 90 °C, a subsequent change of color from yellow to violet took place. The solution was cooled to room temperature, the solvent was evaporated in vacuo, the residue was dissolved in benzene (2 mL) and the solution was chromatographed on Al_2O_3 (neutral, activity grade III, length of column 5 cm). With benzene (20 mL) a colorless fraction was eluted which was discarded. With a mixture of benzene/acetone (10:1), a violet fraction was eluted which was dried in vacuo. The remaining violet solid was washed three times with 2 mL portions of pentane (0 °C) and dried; yield 47 mg (84%); m.p. 118 °C (dec.). ^{1}H NMR (200 MHz, C_6D_6): δ = 7.32−6.83 (m, 5 H, C_6H_5), 3.20−0.84 [m, 14 H, CH(ring), CH(*i*Pr), CH_2(ring)], 1.87 (dt, $J_{P,H}$ = 3.3, $J_{Rh,H}$ = 1.2 Hz, 1 H, =C*H*Ph), 1.61 (m, 6 H, CH_3), 1.34 (m, 12 H, CH_3), 1.17 (m, 6 H, CH_3) ppm. ^{13}C NMR (50.30 MHz, C_6D_6): δ = 296.3 (dt, $J_{Rh,C}$ = 58.5, $J_{P,C}$ = 17.2 Hz, Rh=*C*=C), 128.9, 128.4, 125.4, 125.1 (all s, C_6H_5), 112.3 (dt, $J_{Rh,C}$ = 15.3, $J_{P,C}$ = 7.0 Hz, Rh=C=*C*), 35.6 (s, CH_2), 34.8 [vt, *N* = 23.0 Hz, CH(ring)], 34.4, 34.3 (both vt, *N* = 23.2 Hz, P*C*HCH$_3$), 24.7 [vt, *N* = 17.6 Hz, CH(ring)], 21.5, 21.4 [both s, CH_3(ring)], 19.9, 15.0 (both s, PCH*C*H$_3$) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 47.7 (d, $J_{Rh,P}$ = 134.8 Hz) ppm. $C_{26}H_{44}ClP_2Rh$ (556.9): calcd. C 56.07, H 7.96; found C 55.76, H 7.92.

Generation of *trans*-[RhCl(η^2-(*E*)-PhC≡CCH=CHPh)(Phephos)$_2$] (27): A solution of **2** (100 mg, 0.19 mmol) in C_6D_6 (0.5 mL) was treated dropwise with phenylacetylene (0.12 mL, 1.14 mmol) at room temperature. A gradual change of color from orange-red to deep red occurred. The reaction was monitored by NMR spectroscopy. After 1 h, the starting material had been consumed and the signals of a new compound were observed. Typical data for **27**: ^{1}H NMR (200 MHz, C_6D_6): δ = 7.36, 6.88 (both d, $J_{H,H}$ = 15.4 Hz, CH=CH *trans*-disposed) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 43.4 (d, $J_{Rh,P}$ = 136.2 Hz) ppm.

Reaction of Compound 27 with CO: A slow stream of CO was passed through a solution of **27**, generated as described above, for 20 s at room temperature. The ^{1}H NMR spectrum revealed that besides **6** the enyne (*E*)-PhC≡CCH=CHPh (**28**) was formed which was identified by comparison of the NMR spectroscopic data with those of an authentic sample.[3]

Preparation of *trans*-[RhCl(=CPh$_2$)(Isophos)$_2$] (30): A suspension of **29** (50 mg, 0.06 mmol) in pentane (10 mL) was treated at −78 °C with a solution of Isophos (20 mg, 0.12 mmol) in pentane (5 mL) and, after warming to room temperature, stirred for 1 h. The solvent was evaporated in vacuo, the residue was dissolved in hexane (2 mL) and the solution was chromatographed on Al_2O_3 (neutral, activity grade III, length of column 3.0 cm). With diethyl ether a green fraction was eluted, which was dried in vacuo. The remaining green solid was washed twice with 2 mL portions of hexane (0 °C) and dried; yield 30 mg (79%); m.p. 65 °C (dec.). ^{1}H NMR (200 MHz, C_6D_6): δ = 7.99 (m, 2 H, *ortho*-H of C_6H_5), 7.30 (m, 1 H, *para*-H of C_6H_5), 6.98 (m, 2 H, *meta*-H of C_6H_5), 2.37−0.69 [m, 12 H, CH(ring), CH(*i*Pr), CH_2(ring)], 1.90 [dvt, *N* = 16.9, $J_{H,H}$ = 7.2 Hz, 6 H, CH_3(ring)], 1.44 [dvt, *N* = 13.5, $J_{H,H}$ = 7.0 Hz, 6 H, CH_3(*i*Pr)], 1.09 [dvt, *N* = 14.2, $J_{H,H}$ = 7.2 Hz, 6 H, CH_3(*i*Pr)], 0.74 [dvt, *N* = 12.3, $J_{H,H}$ = 7.0 Hz, 6 H, CH_3(ring)] ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 29.5 (d, $J_{Rh,P}$ = 166.9 Hz) ppm. $C_{31}H_{48}ClP_2Rh$ (621.0): calcd. C 59.96, H 7.79, Rh 16.57; found C 60.87, H 7.43, Rh 16.48.

Preparation of *trans*-[RhCl(=CPh$_2$)(Phephos)$_2$] (31): A solution of **29** (112 mg, 0.14 mmol) in pentane (10 mL) was treated at −78 °C with a solution of Phephos (56 mg, 0.29 mmol) in pentane (2 mL) and, after warming to room temperature, stirred for 1 h. The solution was concentrated to ca. 1 mL in vacuo and stored for 2 h. A green microcrystalline solid precipitated, which was separated from the mother liquor, washed twice with 2 mL portions of pentane (0 °C) and dried; yield 90 mg (93%); m.p. 70 °C. ^{1}H NMR (200 MHz, C_6D_6): δ = 7.38−6.64 (m, 20 H, C_6H_5), 3.31−1.10 [m, 12 H, CH(ring), CH_2(ring)], 2.09, 0.85 [both m, 6 H each, CH_3(ring)] ppm. ^{13}C NMR (50.3 MHz, C_6D_6): δ = 162.2 (vt, *N* = 7.6 Hz, *ipso*-C of C_6H_5), 134.5 (s, *ortho*-C of C_6H_5), 133.2 (vt, *N* = 11.1 Hz, *ortho*-C of C_6H_5), 128.3, 127.5 (both s, *para*-C of C_6H_5), 126.8 (vt, *N* = 7.6 Hz, *meta*-C of C_6H_5), 126.7 (s, *meta*-C of C_6H_5), 34.9, 34.0 [both s, CH_2(ring)], 33.9, 32.0 [both vt, *N* = 22.8 Hz, CH(ring)], 22.5 [vt, *N* = 10.2 Hz, CH_3(ring)], 15.21 [s, CH_3(ring)] ppm; signal of carbene carbon atom could not be exactly located. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 37.3 (d, $J_{Rh,P}$ = 172.5 Hz) ppm. $C_{37}H_{44}ClP_2Rh$ (689.1): calcd. C 64.49, H 6.44, Rh 14.93; found C 64.56, H 6.43, Rh 15.12.

Preparation of *trans*-[IrCl(CO)(Isophos)$_2$] (34): A suspension of $[IrCl(C_8H_{14})_2]_2$ (140 mg, 0.16 mmol) in pentane (10 mL) was treated with Isophos (99 mg, 0.62 mmol) and stirred for 5 min at room temperature. A slow stream of CO was then passed through the solution for 10 min. A yellow solid precipitated which was filtered and recrystallized from a mixture of pentane/THF (10:1). Yellow air-stable crystals were isolated; yield 148 mg (81%); m.p. 232 °C (dec.). IR (CH_2Cl_2): ν(CO) = 1937 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 2.00−1.54 [m, 10 H, CH(ring), CH(*i*Pr), CH_2(ring)], 1.46 [dvt, *N* = 22.8, $J_{H,H}$ = 7.0 Hz, 6 H, CH_3(*i*Pr)], 1.38 [m, 4 H, CH_2(ring)], 1.29 [dvt, *N* = 23.2, $J_{H,H}$ = 7.0 Hz, 6 H, CH_3(*i*Pr)], 1.18 [dvt, *N* = 21.5, $J_{H,H}$ = 7.1 Hz, 6 H, CH_3(ring)], 1.11 [dvt, *N* = 21.4, $J_{H,H}$ = 6.9 Hz, 6 H, CH_3(ring)] ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 7.3 (s) ppm. $C_{19}H_{38}ClIrOP_2$ (572.1): calcd. C 39.89, H 6.70; found C 39.47, H 6.70.

Preparation of [IrClH$_2$(Isophos)$_2$] (35): A suspension of $[IrCl(C_8H_{14})_2]_2$ (140 mg, 0.16 mmol) in hexane (10 mL) was treated with Isophos (99 mg, 0.62 mmol) and stirred for 5 min at room temperature. A slow stream of H_2 was then passed through the solution for 10 min. The solvent was evaporated in vacuo, the residue was dissolved in pentane (3 mL) and the solution was stored for 12 h at −78 °C. Pale yellow air-sensitive crystals precipitated which were filtered, washed twice with 0.5 mL portions of pentane (−20 °C) and dried; yield 133 mg (76%); m.p. 98 °C (dec.). IR (KBr): ν(IrH) = 2290 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 2.10−1.70 [m, 10 H, CH(ring), CH(*i*Pr), CH_2(ring)], 1.78 [dvt, *N* = 22.3, $J_{H,H}$ = 6.9 Hz, 6 H, CH_3(*i*Pr)], 1.44 [dvt, *N* = 21.2, $J_{H,H}$ = 7.0 Hz, 6 H, CH_3(*i*Pr)], 1.34 [m, 4 H, CH_2(ring)], 1.28 [dvt, *N* = 20.7, $J_{H,H}$ = 6.9 Hz, 6 H, CH_3(ring)], 1.08 [dvt, *N* = 21.1, $J_{H,H}$ = 6.9 Hz, 6 H, CH_3(ring)], −26.98 [t, $J_{P,H}$ = 14.2 Hz, 2 H, IrH] ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 51.2 (br. s, t in off-resonance) ppm. $C_{18}H_{40}ClIrP_2$ (546.1): calcd. C 39.59, H 7.38; found C 39.43, H 7.38.

Preparation of [IrClH$_2$(CO)(Isophos)$_2$] (36): A slow stream of CO was passed through a solution of **35** (120 mg, 0.22 mmol) in pentane (5 mL) for 10 min at room temperature. A pale yellow solid precipitated which was filtered and then dissolved in methanol (10 mL). The solution was concentrated to ca. 2 mL in vacuo and stored for 6 h at −78 °C. Pale yellow, moderately air-sensitive crystals precipitated which were washed twice with 0.5 mL portions of methanol (−20 °C) and dried; yield 99 mg (78%); m.p. 185 °C (dec.). IR (KBr): ν(IrH) = 2210, 2005, ν(CO) 1975 cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 2.10−1.60 [m, 10 H, CH(ring), CH(*i*Pr), CH_2(ring)], 1.54 [dvt, *N* = 22.7, $J_{H,H}$ = 6.9 Hz, 6 H, CH_3(*i*Pr)], 1.48 [dvt, *N* = 21.2, $J_{H,H}$ = 7.0 Hz, 6 H, CH_3(*i*Pr)], 1.28 [m, 4 H,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

CH_2(ring)], 1.24 [dvt, N = 21.2, $J_{H,H}$ = 7.0 Hz, 6 H, CH_3(ring)], 0.94 [dvt, N = 19.7, $J_{H,H}$ = 6.9 Hz, 6 H, CH_3(ring)], −8.57 (dt, $J_{P,H}$ = 18.9, $J_{H,H}$ = 5.8 Hz, 1 H, IrH *trans* to CO), −19.97 (dt, $J_{P,H}$ = 11.6, $J_{H,H}$ = 5.8 Hz, 1 H, IrH *trans* to Cl) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 36.1 (s, t in off-resonance) ppm. $C_{19}H_{40}ClIrOP_2$ (574.1): calcd. C 39.75, H 7.02; found C 39.70, H 7.01.

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft (SFB, 347) and the Fonds der Chemischen Industrie. We thank Mrs. R. Schedl and Mr. C. P. Kneis for elemental analysis and DTA measurements and Mrs. M.-L. Schäfer and Dr. W. Buchner for NMR spectra.

Electrochemical and Spectroelectrochemical Investigations of Mono- and Binuclear Cobalt(II) Complexes of "Figure-Eight" Octapyrrolic Macrocycles

Jordi Bley-Escrich,[a] Jean-Paul Gisselbrecht,*[a] Martin Michels,[b] Lars Zander,[b] Emanuel Vogel,[b] and Maurice Gross*[a]

Keywords: Macrocyclic ligands / Cobalt / Cluster complexes / Electrochemistry

In this paper, electrochemical investigations of a set of three cyclooctaphyrin complexes containing divalent cobalt are reported. These complexes are the homodinuclear cobalt-cobalt complex Co_2L_1 with the ligand H_4L_1, the mononuclear cobalt complex CoH_2L_2 and the heterodinuclear copper(II)-cobalt complex $CoCuL_2$ with the ligand H_4L_2. All of these species undergo two reduction and three oxidation processes, all of which are reversible one-electron transfers. The two reduction and first two oxidation steps are ligand-centered, as confirmed by spectroelectrochemical investigations. In contrast, the third oxidation corresponds to a metal-centered reversible one-electron transfer. The metal-centered oxidation steps occur at lower potentials than the third oxidation steps of the free bases. UV/Visible spectral changes observed during oxidation confirm a metal-centered oxidation generating a cobalt(III) cation, which is rather unusual when compared with cobalt porphyrin complexes, in which the oxidation of the metal usually occurs before the oxidation of the ligand.

Introduction

The chemical and biological properties of vitamin B12 and its derivatives have generated considerable interest in the chemical investigation of cobalt complexes.[1]

Since functional mimics of multielectronic redox enzymes may involve two or more metal centers, numerous cofacial metalloporphyrins have been synthesized and cofacial cobalt porphyrins have been studied to evaluate their ability to carry out the tetraelectronic electrocatalytic reduction of O_2 to H_2O.[2]

Cobalt porphyrins are well-known systems and their redox behavior has been extensively studied;[3] however, cobalt complexes of larger polypyrrolic macrocycles have not yet been investigated. Although numerous macrocyclic polypyrrolic ligands have been synthesized,[4−10] their complexation properties with transition metals remain scarce in the literature[11−13] and only a few cobalt complexes have been characterized.[14,15]

Cyclooctapyrrolic ring systems have recently been synthesized.[16−18] They possess a "figure-eight" conformation delimiting two tetrapyrrolic complexation sites that are able to accommodate up to two divalent cations as shown in crystallographic structures.[19−21] However, due to their twisted geometry, the two tetrapyrrolic sites do not share the same plane. They are separated by a dihedral angle of approximately 60°. These cyclooctaphyrins (COP) have allowed the preparation and characterization of several cobalt complexes: Co_2L_1 with the ligand H_4L_1 [[34]COP(1.1.1.0.1.1.1.0)] as well as CoH_2L_2 and $CoCuL_2$ with the ligand H_4L_2 [[32]COP(1.0.1.0.1.0.1.0)] (Figure 1).

The aim of the present electrochemical investigation was to determine whether or not cyclooctaphyrins are able to stabilize cobalt(I) and/or cobalt(III), as is usually observed in porphyrins.[23−25] In order to study the solvent effects, electrochemical investigations were performed using rotating disk and cyclic voltammetry in two media differing in their solvation properties: benzonitrile (PhCN) and dichloromethane (CH_2Cl_2). Spectroelectrochemistry was used to identify the electron transfer sites (ligand versus metal).

The present results on cobalt cyclooctaphyrins can then be compared with our previous studies on three series of cyclooctaphyrin metallocomplexes for which only ligand-centered electron transfers were observed.[26,27]

Results and Discussion

Electrochemical Studies

The redox behavior of the three cobalt cyclooctaphyrin complexes were determined by cyclic voltammetry (CV) and rotating disk voltammetry (RDV) in dry PhCN + 0.1 M $TBAPF_6$ solutions at room temperature (25 °C).

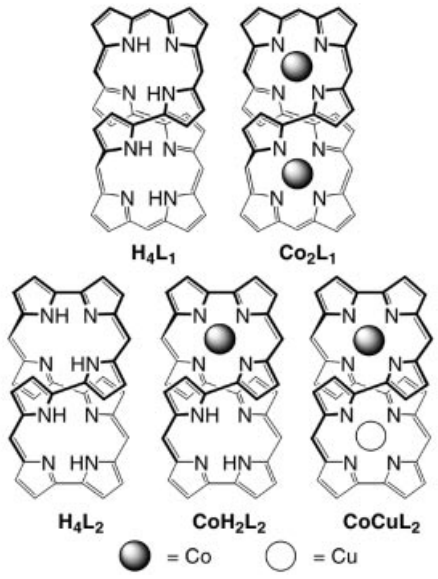

Figure 1. Free bases and complexes studied in the two cyclooctaphyrin series; the ethyl groups on the pyrroles are omitted for clarity; the compounds are named [−]COP(-.-.-.-.-.-.-) after the nomenclature proposed by Franck for polypyrrolic macrocycles[22]

RDV on Co_2L_1 presents two reduction (−1.96 and −1.33 V/Fc) and four oxidation waves (−0.42, 0.06, 0.30 and 0.63 V/Fc) (Figure 2). All waves are of similar amplitude and wave analysis using Tomeš criteria[28] give slopes close to 56.4 mV, the expected value for reversible one-electron processes, for the two reduction and the first three oxidation steps, whereas the fourth oxidation step has a slope of 90 mV (Table 1).

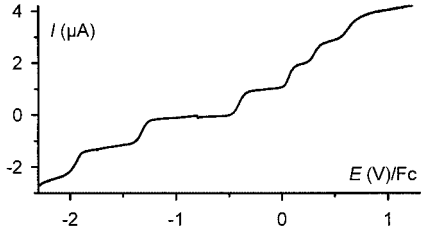

Figure 2. Rotating disk voltammetry on Co_2L_1 (≈10^{-4} M) in PhCN +0.1 M Bu_4NPF_6, at a Pt working electrode; scan rate: 0.05 V/s. N = 2000 rpm

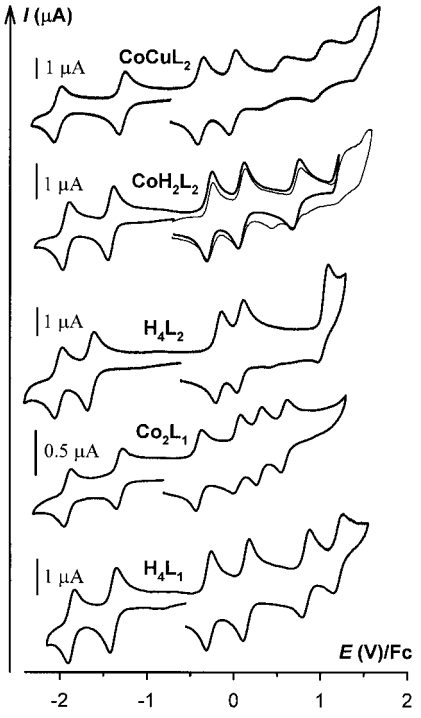

Figure 3. Cyclic voltammetry on H_4L_1, Co_2L_1, H_4L_2, CoH_2L_2 and $CoCuL_2$ in PhCN +0.1 M Bu_4NPF_6, at a Pt working electrode; scan rate: 1 V/s for H_4L_2 and 0.05 V/s for H_4L_1, Co_2L_1, CoH_2L_2 and $CoCuL_2$. c ≈10^{-4} M.

The results from the cyclic voltammetric study of Co_2L_1 (Figure 3) confirms the reversibility of each of the two one-electron reduction processes, as well as the first three one-electron oxidation steps. In contrast with the results from the rotating disk voltammetric study, the fourth oxidation step is also reversible. This reversibility was confirmed by monitoring the peak current (I_p) and the peak potentials (E_p) with increasing scan rates: E_p remained invariant with ν for sweep rates up to 5 V/s, the peak current ratio remained close to unity for all ν, and the peak potential difference ($\Delta E = E_{pc} - E_{pa}$) was approximately 60 mV.

A particular behavior is observed for the second oxidation step when the vertex potential is fixed after the third or fourth oxidation steps with sweep rates higher than 0.1 V/s. As shown in Figure 4 (a) the reverse peak of step II disappears on increasing the sweep rates and a new peak is observed at −0.11 V/Fc. Such behavior may be due to slow

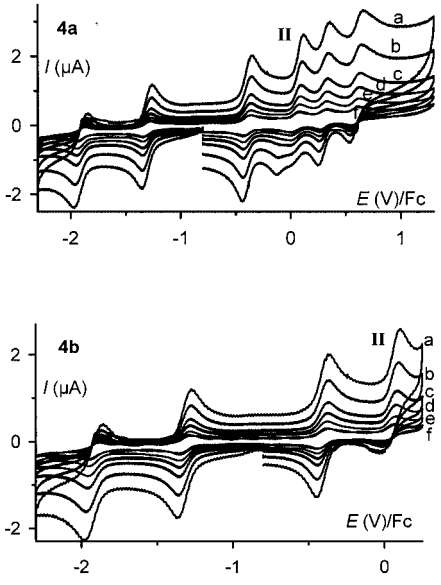

Figure 4. Series of cyclic voltammograms of Co_2L_1 ($\approx 10^{-4}$ M) with different scan rates in PhCN +0.1 M Bu_4NPF_6, performed at a Pt working electrode; scan rates for: a) 1 V/s; b) 0.5 V/s; c) 0.2 V/s; d) 0.1 V/s; e) 0.05 V/s; f) 0.02 V/s; for 4a potential range from −2.30 V to +1.30 V/Fc, and for 4b potential range from −2.30 V to +0.25 V/Fc.

geometric rearrangements occurring during the third oxidation process, preventing the molecule from returning to its initial structure again in the CV time scale ($\nu > 0.1$ V/s). The fact that the disappearance of a peak and the appearance of a new peak is not observed when the third oxidation has not been reached [Figure 4 (b)], confirms that these geometric rearrangements occur in the tricationic species.

It should be mentioned that the third and the fourth oxidation processes observed for Co_2L_1 using CV (Table 2) and rotating disk voltammetry (Table 1) occur at potentials that are less positive by 400 mV relative to those of the free bases, and by 200 mV relative to those of complexes with non-electroactive metals. This could be an indication of metal-centered electron transfers, which would explain the above hypothesis concerning the geometric changes that occur during the third oxidation process.

The two reduction and first two oxidation steps of the other two cobalt complexes, CoH_2L_2 and $CoCuL_2$, are similar to those of the free base H_4L_2.[26,27] After the second oxidation step, the complexes have a distinct behavior. When using RDV and CV, CoH_2L_2 presents a third one-electron oxidation that occurs at 0.73 V/Fc, which is 280 mV less positive than the third oxidation of the free base (Table 2). A fourth one-electron oxidation step is observed at +1.27 V/Fc (Figure 3). These data are in agreement with a metal-centered oxidation process for the third oxidation step of CoH_2L_2.

The complex $CoCuL_2$ presents three additional one-electron oxidation steps after the second oxidation. The third oxidation occurs at +0.57 V/Fc, 440 mV less positive than that of the free base (Table 2). This is consistent with the third oxidation process occurring at the cobalt center. The fourth and fifth oxidation steps are observed at +1.08 and +1.47 V/Fc (Figure 3).

It has been shown that in cobalt porphyrin complexes, the redox potential of the $Co^{III/II}$ couple is dependent on both the solvent and the supporting electrolyte. Indeed, strong coordinating solvents facilitate the oxidation of the metal, whereas in non-bonding solvents the redox potential is shifted towards positive potentials.[23−25,29−31] On the other hand, the redox potentials of ligand-centered electron transfers are less sensitive to solvation changes than metal-centered processes. For these reasons, a new set of measurements in non-coordinating CH_2Cl_2 was performed to study the solvent effects on the redox potentials when going from benzonitrile to dichloromethane.

In CH_2Cl_2, the reduction and first two oxidation steps of Co_2L_1 are similar to that described previously in PhCN. The third oxidation step is shifted to more positive potentials by 300 mV, while the fourth oxidation step is no longer observed under these experimental conditions. The addition of a strong axial ligand in dichloromethane is expected to shift the redox potential of a metal-centered electron transfer.[23−25] Therefore, pyridine was added to confirm that the third oxidation process is metal-centered. After the addition of pyridine, the third oxidation step shifts cathodically towards the value observed in PhCN (Figure 5). The

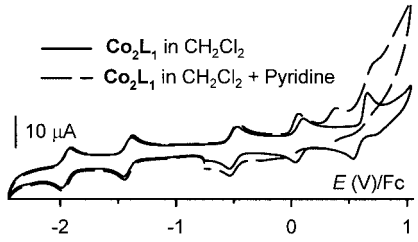

Figure 5. Cyclic voltammetry on Co_2L_1 ($5 \cdot 10^{-4}$ M) (solid line) and on Co_2L_1 +12 equivalents of pyridine (dashed line) in CH_2Cl_2 +0.1 M Bu_4NPF_6, at a Pt working electrode (scan rate: 0.1 V/s)

redox potentials determined are presented in Table 2. All of the above results demonstrate that the third oxidation step corresponds to the oxidation of Co^{II} to Co^{III}.

Under the same experimental conditions, a large potential shift (170 mV) is observed for the third oxidation step of $CoCuL_2$, and only a small shift (50 mV) is observed for CoH_2L_2 (Table 2). Such a small shift is characteristic of poor axial coordination by the cobalt ion. This can be explained in the following way: as this is a mononuclear complex of the smallest cyclooctaphyrin, it is possible that the ligand is more tightly wrapped around the cobalt cation, thus hindering the access for axial coordination to a greater extent relative to $CoCuL_2$.

Spectroelectrochemistry

In order to determine the electron transfer sites, spectroelectrochemical studies were carried out. Comparison of the spectral changes during electrolysis of the cobalt complexes with the spectra of the parent compounds (free base and complexes with non-electroactive metals) allowed us, in most cases, to assign the electron transfer sites in the cobalt complexes.

For each cobalt complex, the reduction processes produce spectral evolutions with well-defined isosbestic points. The spectra obtained after electrolysis revert quantitatively to the initial spectrum by stepwise electrochemical restoration of the starting cyclooctaphyrin. This result indicates that the two electroreduced species are stable in the time scale of the spectroelectrochemical experiments, i.e. about 30 min, which is a good indication of the high stability of the electrogenerated species under these experimental conditions. Spectral changes seen for the cobalt complexes are similar to those observed for the parent compounds [a blue shift for Co_2L_1; Figure 6 (a) and red shifts for CoH_2L_2 and $CoCuL_2$; Figure 6 (c and e)], which confirms that the reductions are ligand-centered. For complexes CoH_2L_2 and $CoCuL_2$, the presence of an intense and sharp absorption band (Soret-like) is observed after the second reduction process, as seen previously for metallocomplexes of cyclooctaphyrins with the same ligand.[27]

The three oxidation steps also produce spectral evolutions with well-defined isosbestic points, even for $CoCuL_2$ [Figure 6 (f)], for which the third oxidation process is quasi-reversible when using CV. The initial spectra could be quantitatively recovered by stepwise reduction of the electrogenerated species, which indicates the high stability of the generated species.

The fourth and further oxidations could not be studied for CoH_2L_2 and $CoCuL_2$ since their oxidation steps occur too close to the electrolyte discharge.

Spectral evolutions for the two first oxidations are similar to those of the free bases (blue shift for Co_2L_1 [Figure 6 (b)] and red shift for CoH_2L_2 and $CoCuL_2$ [Figure 6 (d and f)], which are characteristic of ligand-centered oxidations, thus generating the corresponding dications. Spectral evolutions for the third oxidation step differ for each complex studied.

For Co_2L_1 and CoH_2L_2, the spectral evolutions for the third oxidation step are quite different from those observed for the free base. The intensity of the band changes, while no changes are observed in the absorption wavelength. This is a good indication of a metal-centered oxidation process.

For $CoCuL_2$, the changes involving the third oxidation step are more significant; indeed the absorption bands at 388 and 646 nm decrease in intensity, whereas new bands appear at 331 and 424 nm.

The Unexpected Synthesis of the Radical Cation $CoH_2L_2^+$

As only a few cobalt complexes were available, we considered the possibility of the insertion of a second cobalt cation in the mononuclear complex by in situ complexation. As no spectroscopic data were available for the dinuclear cobalt complex of the ligand H_4L_2, in situ complexation in a mixture of methanol/dichloromethane (1:1) was tested with copper since the UV/Visible spectra of the mononuclear copper complex and the homodinuclear copper complex are already available. In situ complexation of copper to the ligand H_4L_2 confirmed the formation of the mononuclear complex [for 1 equiv. of $Cu(CF_3SO_3)_2$] and the dinuclear complex [for 2 equiv. of $Cu(CF_3SO_3)_2$]. The spectra shift to the red when going from the free base to the mono- and dinuclear copper complex, as shown in Figure 7 (a).

The same experiment was carried out with the cobalt salts $Co(CF_3SO_3)_2$ and $Co(OH)_2$. The first observation was that the complexation kinetics are much slower for cobalt than for copper. The characteristic spectrum of the mononuclear complex was observed eight hours after the introduction of the cobalt salt for a stoichiometric mixture. Further spectral changes were observed only when a large excess (saturated solution) of the cobalt(II) salt was added to the mononuclear complex. The observed spectrum indicated the presence of a new species X in solution [Figure 7 (b)]. Compound X was prepared by dissolving the free base H_4L_2 (5.3 mg) in 30 mL of a mixture of methanol/dichloromethane (1:1). 3000 equivalents of $Co(OH)_2$ were added to the solution, and the suspension was stirred overnight. The excess solid was removed by filtration. The solution was dried over $MgSO_4$ and then filtered. Finally, the solvent was removed under vacuum. A dark blue powder was obtained. The UV/Visible spectrum of X is identical to the spectrum observed when using spectroelectrochemistry after the first oxidation process of CoH_2L_2; this implies that the radical cation $CoH_2L_2^{\bullet+}$ is formed. Rotating disk voltammetry on the prepared compound shows potentials that are similar

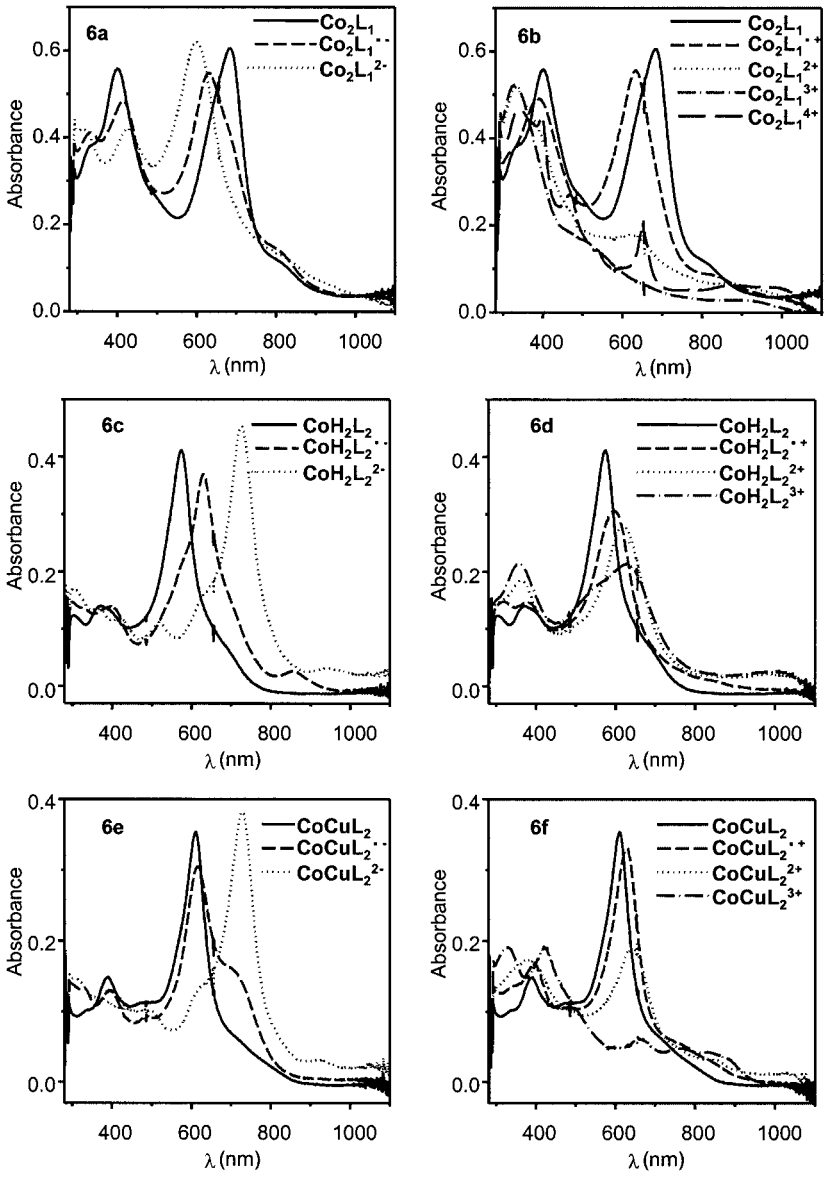

Figure 6. Spectroelectrochemistry on Co_2L_1, CoH_2L_2 and $CoCuL_2$, in PhCN +0.1 M Bu_4NPF_6; reduction [Figure 6 (a)] and oxidation processes [Figure 6 (b)] of Co_2L_1. Reduction [Figure 6 (c)] and oxidation processes [Figure 6 (d)] of CoH_2L_2; reduction [Figure 6 (e)] and oxidation processes [Figure 6 (f)] of $CoCuL_2$; $c \approx 10^{-5}$ M

to those observed for the complex CoH_2L_2; however, instead of an oxidation at −0.28 V/Fc, a reduction current is observed (Figure 8). The spectroelectrochemical reduction of X at −0.4 V/Fc produces spectral evolutions with well-defined isosbestic points that lead to the spectrum of neutral CoH_2L_2.

All these observations confirm that the prepared species X is in fact the radical cation of the complex CoH_2L_2. Mass spectrometry also confirms that X is a mononuclear cobalt complex (m/z = 537 $[M + H]^{2+}$, expected mass for $C_{68}H_{86}CoN_8$: 1073). In situ complexation did not allow us to prepare a new homodinuclear complex to extend our electrochemical studies. No explanation about the formation of this radical has been established. However, since the first oxidation step of the complex CoH_2L_2 occurs at a very low potential, the possible presence of an oxidizing agent as an impurity in the cobalt salt (3000 equiv.) used in excess or oxygen (even our experimental conditions are not suitable for this kind of reaction),[32] could be responsible for the chemical reaction generating the radical cation.

Discussion

The main difference between the free bases and the cobalt complexes (see Tables 1 and 2) that belong to the same COP ligand series involves the redox potentials beyond the second oxidation process. The third oxidations for the cobalt complexes occur at potentials much less positive than those observed for the free bases, and correspond to the oxidation of Co^{II} to Co^{III}. The redox potential of the latter step is solvent-dependent, as expected for metal-centered electron

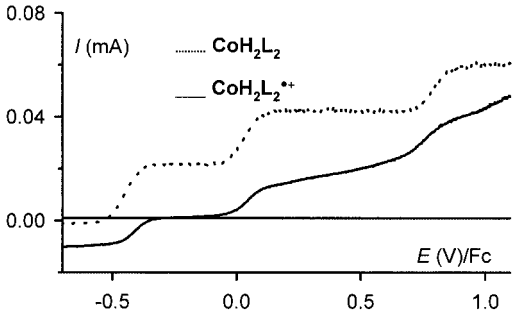

Figure 8. Rotating disk voltammetry on CoH_2L_2 and $CoH_2L_2^+$ in CH_2Cl_2 + 0.1 M Bu_4NPF_6, at a Glassy Carbon (GC) working electrode; scan rate: 0.01 V/s. N = 2000 rpm; $c \approx 10^{-4}$ M

transfers and as observed previously for porphyrins.[23,24] This behavior is due to the conversion of a preferred square-planar coordination for the Co^{II} to an octahedral coordination for the Co^{III} ion. Thus, a coordinating solvent like PhCN will be axially coordinated by metals, thus stabilizing the Co^{III} ion. This stabilization will facilitate the generation of Co^{III}, such that the potential will be cathodically shifted relative to the values determined in CH_2Cl_2.

All the studies undertaken confirm that COP do not stabilize the Co^{I} species at all. This is not the case for previously studied cobalt complexes.[24] COP behave like corrphycenes[33] and porphycenes,[34] and differ vastly from porphyrins, which usually stabilize cobalt(I) in the tetrapyrrolic ring system. The observed $Co^{II/III}$ redox potentials in COP are much more positive than those observed previously in tetrapyrrolic ring systems (−0.07 V/Fc for corrphycene,[33] +0.195 V/Fc for porphycene[34] and +0.30 V/Fc for porphyrins[35]). Such positive potentials are in agreement with the fact that cyclooctaphyrins destabilize Co^{III} in the corresponding "tetrapyrrolic" coordination site of COP. Within the COP series, Co_2L_1 stabilizes the cobalt(III) atom to a greater extent than other COP complexes such as CoH_2L_2 and $CoCuL_2$. Comparison with previously studied cobalt tetrapyrrolic macrocyclic complexes was not possible since the oxidation of the cobalt ion occurs before ring oxidation for these complexes. For the COP complexes, the oxidation of the cobalt ion occurs after the generation of the dication.

Spectral changes for the free base and the cobalt complex are similar during the two reduction and first two oxidation steps, indicating that these four redox steps occur on the ligand, generating the radical anion and the dianion during reduction, and the radical cation and the dication during oxidation. The free base presents a non-reversible behavior for the second reduction step for prolonged electrolysis: the spectral changes are similar to those observed for metal complexes for at least the first ten minutes. Thus, we can conclude that this electron transfer is also ligand-centered.

The third oxidation presents different spectral changes for the free base and the metal complex, which is consistent with a metal-centered electron transfer process. The spectral changes during this third oxidation for the cobalt complex mainly involve the intensity of the absorption bands. This type of behavior is also characteristic of a metal-centered electron transfer process, as generally it induces smaller geometric or topographic changes in the molecule.

For the other cobalt complexes similar conclusions are obtained from the spectroelectrochemical results. In addition, their behavior in two different solvents provides confirmation of the nature of the electron transfers.

Conclusion

All cyclooctaphyrin cobalt complexes undergo two reduction processes and a first and a second oxidation process, all one-electron, reversible and ligand-centered. Beyond the second oxidation, the redox behavior is different for each complex. They all possess a third one-electron reversible oxidation process centered at the metal ($Co^{2+} \rightarrow Co^{3+}$). The homodinuclear cobalt complex also undergoes a fourth oxidation step that is one-electron and reversible, and centered at the second cobalt cation; no further oxidations are observed. For the monocobalt complex, another oxidation is observed (ligand-centered), as well as two other oxidation steps observed in the case of the heterodinuclear cobalt-copper complex. Spectroelectrochemistry confirms the nature of the electron transfers. The metal-centered steps are affected by the solvent coordi-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nation properties. A shift towards cathodic potentials is observed for these steps in PhCN, except in the case of the monocobalt complex. An attempt to obtain the homodinuclear cobalt complex of the COP(1.0.1.0.1.0.1.0) series[32] led to the formation of the monocobalt complex radical cation. Under our experimental conditions, no cobalt-centered reductions are observed.

Experimental Section

General Remarks: In most of the cases the electrochemical measurements were carried out in a glove box (less than 3 ppm of H_2O and less than 2 ppm of O_2) at room temperature (25 ± 2 °C) in PhCN containing 0.1 M $TBAPF_6$ in a classical three electrode cell, connected to a PAR (model 273) potentiostat, interfaced with a PC computer. The working electrode was a platinum (Pt) disk electrode (diameter: 2 mm), used either motionless as in cyclic voltammetry (v = 20 mV/s to 5 V/s) or as a rotating disk electrode. The auxiliary and the pseudo-reference electrodes were platinum wires. PhCN (Aldrich, 99 %) was dried for two days over $CaCl_2$ (anhydrous, Fluka, 97 %), and distilled on P_2O_5 (Prolabo) under reduced pressure in an inert atmosphere (Argon). Bu_4NPF_6 was dried in an oven (65 °C) under vacuum for two days. Bu_4NPF_6 was dissolved in PhCN inside the glove box and the solution was then percolated over activated alumina. The available potentials at a platinum working electrode ranged from −2.5 to +1.8 V/Fc.

Some measurements were carried out under classical conditions out of the glove box, in CH_2Cl_2 containing 0.1 M $TBAPF_6$ in a three electrode cell. The electrochemical cell was connected to a computerized multipurpose electrochemical device (Autolab PGSTAT T20) controlled by GPSE software. The working electrode was a glassy carbon (GC) disk electrode (diameter: 3 mm), used either motionless as in cyclic voltammetry (v = 20 mV/s to 5 V/s) or as a rotating disk electrode. The auxiliary electrode was a platinum wire, and the reference electrode was Ag/AgCl/KCl (sat.) electrode. All potentials are referred to the ferrocene/ferrocenium (Fc/Fc^+) couple used as internal standard.

Spectroelectrochemical measurements were carried out in PhCN in a home-made quartz cell, having an optical pathway of 1 mm. The working electrode was a platinum grid (1000 mesh) placed in the optical pathway. The reference and the auxiliary electrodes were platinum wires separated by cotton from the solution in individual compartments. The cell was filled in the glove box, and hermetically closed, then it was placed in a diode array spectrophotometer (Hewlett−Packard 8453), and the spectra were recorded during electrolysis.

2,3,7,8,12,13,16,17,21,22,26,27,31,32,35,36-Hexadecaethyloctaphyrin-(1.1.1.0.1.1.1.0)ato-dicobalt(II) (Co_2L_1): The dinuclear cobalt(II) complex Co_2L_1 was prepared by dissolving the free base H_4L_1 (52 mg, 0.05 mmol) in 50 mL of absolute DMF, by gently heating the solution under argon. A solution of cobalt(II) acetate tetrahydrate (125 mg, 0.5 mmol) dissolved in 15 mL of DMF was added to the ligand and the solution was refluxed for three hours. After cooling to room temperature, 50 mL of toluene was added to the solution as well as 150 mL of ice water. The organic layer was washed several times with water, dried over Na_2SO_4 and finally the solvent was removed under vacuum. Recrystallization under argon in a mixture of acetonitrile/t-butylmethyl ether (4:1) gave Co_2L_1 as a black powder. Yield 36 mg (65 %). MS (FAB): m/z = 1156 $[M^+]$ (100 %). $C_{70}H_{86}Co_2N_8$ (1157.4): calcd. C 72.64, H 7.49, N 9.68; found C 72.36, H: 7.49, N: 9.42. IR (CsI): $\tilde{\nu}$ = 2962, 2930, 2869, 1663, 1577, 1492, 1464, 1450, 1371, 1314, 1275, 1205, 1170, 1141, 1110, 1055, 1029, 1018, 986, 960, 925, 848, 835, 809, 746, 679 cm^{-1}. UV/Vis (CH_2Cl_2) λ_{max} (ε) = 347 sh (34400), 401 (51500), 682 nm (55600 M cm^{-1}). M.p. >300 °C.

2,3,6,7,11,12,15,16,20,21,24,25,29,30,33,34-Hexadecaethyloctaphyrin-(1.01.0.1.0.1.0)atocobalt(II) (CoH_2L_2): The mononuclear cobalt(II) complex CoH_2L_2 was prepared by dissolving the free base H_4L_2 (102 mg, 0.1 mmol) in a mixture of 30 mL of dichloromethane and 1 mL of triethylamine under an inert atmosphere. $Co(OAc)_2$ $4H_2O$ (55 mg, 0.22 mmol) in 15 mL of methanol was added to the solution. The mixture was stirred at room temperature for six hours and the solvent removed under vacuum. At all times the solution temperature was maintained below 25 °C. The remaining compound was chromatographically filtered through aluminum oxide (5 × 2 cm column) with a hexane/dichloromethane mixture (1:3) and finally recrystallized from an acetonitrile/dichloromethane/methanol mixture (1:1:1). CoH_2L_2 was obtained as green crystals. Yield 86 mg (80 %). MS (FAB): m/z = 1073 (100 %) $[M]^+$. $C_{68}H_{86}CoN_8$ (1074.4): calcd. C 76.02, H: 8.07, N 10.43; found C 76.07, H 8.10, N 10.40. Yttrium β-Diketonate Glyme MOCVD Precursors: Effects of the Polyether Length on Stabilities, Mass Transport Properties and Coordination Spheres

Graziella Malandrino,[a] Raffaella Lo Nigro,[b] Ignazio L. Fragalà,*[a] and Cristiano Benelli[c]

Keywords: Yttrium / Thermogravimetry / Superconductors

The glyme adducts of trishexafluoroacetylacetonato yttrium, [Y(hfa)$_3$·monoglyme], [Y(hfa)$_3$·diglyme], [Y(hfa)$_3$·(H$_2$O)$_2$·triglyme] and [Y(hfa)$_2$·tetraglyme]$^+$[Y(hfa)$_4$]$^-$ {CH$_3$(OCH$_2$CH$_2$)$_n$-OCH$_3$, n = 1 monoglyme, 2 diglyme, 3 triglyme and 4 tetraglyme}, were synthesized and characterized by elemental analysis, mass spectrometry, and IR, ^{1}H and ^{13}C NMR spectroscopy. Additionally, [Y(hfa)$_3$·monoglyme] and [Y(hfa)$_3$·diglyme] were characterized by single-crystal X-ray diffraction studies. The mass-transport properties of these adducts were investigated by thermogravimetric analysis, differential scanning calorimetry, evaporation-rate measurements and chemical vapour-deposition experiments. There is evidence of high volatility and very good thermal stabilities with a residue lower than 2–4 %. Vaporization-rate experiments proved that all adducts are well-suited for metal-organic chemical vapour-deposition experiments. The [Y(hfa)$_3$·monoglyme] complex was successfully applied in the low-pressure MOCVD process of YBaCuO HTc superconductor using a multimetal molten single source.

Introduction

New lanthanide β-diketonate adducts with polyethers[1−13] have recently attracted particular attention because they have better properties than their parent β-diketonate precursors for MOCVD, in terms of thermal stability and volatility.

Although yttrium is not a 4f element, its chemistry resembles that of lanthanides and, in particular, similarities are observed either with neodymium and samarium or with holmium and erbium ions, depending on whether the nature of the bonds is predominantly covalent or ionic.[14] Yttrium ions are present in a wide variety of materials, ranging from yttria (Y_2O_3) and yttria-stabilized zirconia (YSZ), to optoelectronic materials such as yttrium aluminium or indium garnet (YGA and YIG respectively), or from yttrium aluminate ($YAlO_3$) to the superconducting metal oxide $YBa_2Cu_3O_{7-\delta}$ (YBCO). The synthesis of these materials in the form of thin films, using a friendly and low-cost technique, represents a great challenge. In this context, the Metal-Organic Chemical Vapour Deposition (MOCVD) technique offers a softer approach for all these applications, with lower processing temperatures and greater throwing power (versatility and adaptability) than other alternative methodologies.[15]

To date, the conventional yttrium precursors, such as Y(tmhd)$_3$ (Htmhd = 2,2,6,6-tetramethyl-3,5-heptandione), have had several drawbacks, most notably the high quantity of residue left in commercial evaporators/bubblers and their poor stability in the atmosphere.[16,17]

In this scenario, novel monomeric, thermally stable, volatile and water-free yttrium complexes are of strategic relevance due to the lack of MOCVD precursors with suitable mass-transport properties. This consideration prompted investigations on new, suitable, highly chelated molecular architectures that inhibit oligomerization and water-coordination processes and improve the thermal stability, volatility and mass-transport properties.

It has been already demonstrated that the combined use of fluorinated β-diketonates and of ancillary-coordinated polyethers provides monomeric, volatile and thermally stable precursors of a large variety of metal ions including rare-earth metals.[1−7,12,13,18] The same strategy was adopted for the yttrium ion, and the tailoring of the molecular architecture of the ligand framework yielded novel, very promising second-generation yttrium precursors.[19,20] However, there is no information on the thermal and mass-transport properties of all these adducts.

In this paper we report the synthesis and transport properties of the four yttrium adducts [Y(hfa)$_3$·L] [where

Hhfa = 1,1,1,5,5,5-hexafluoroacetylacetone, L = CH_3O-$(CH_2CH_2O)_nCH_3$ with n = 1 monoglyme (1,2-dimethoxyethane), 2 diglyme [bis(2-methoxyethyl)ether), [$Y(hfa)_3$·$(H_2O)_2$·triglyme] [triglyme = (2,5,8,11-tetraoxadodecane)], and [$Y(hfa)_2$·tetraglyme]$^+$[$Y(hfa)_4$]$^-$, [tetraglyme = (2,5,8,11,14-pentaoxatetradecane)]. The X-ray single crystal structure of [$Y(hfa)_3$·monoglyme] is reported and the current X-ray data of [$Y(hfa)_3$·diglyme] are compared with those previously reported. Thermal stabilities and volatilities of all the adducts were evaluated and compared with those of the first-generation yttrium precursors. The use of [$Y(hfa)_3$·monoglyme] in the deposition of YBCO thin films was also addressed in detail, and, finally, the effects of the polyether length on the coordination/structure, thermal stability, volatility and coordination sphere of the $Y(hfa)_3$ moiety are discussed.

The aim of the present study is, therefore, the functional validation of these "second-generation" yttrium precursors, in the perspective of MOCVD applications, also in terms of a multimetal molten single source.

Results

Synthesis

The adducts of $Y(hfa)_3$ with four different glymes were prepared through one-pot reactions from yttrium hydroxide, hexafluoroacetylacetone and polyether in hexane [see Equation (1)]:

$$Y(OH)_3{\cdot}nH_2O + 3Hhfa + L \rightarrow [Y(hfa)_3{\cdot}L] + (n+3)H_2O$$
$$\text{or } [Y(hfa)_3{\cdot}(H_2O)_2{\cdot}L'] \quad \text{or } [Y(hfa)_2{\cdot}L'']^+[Y(hfa)_4]^-$$
(L = monoglyme, diglyme; L' = triglyme; L'' = tetraglyme) (1)

A slight excess of yttrium hydroxide favours the isolation of the product, since the insoluble excess of $Y(OH)_3{\cdot}nH_2O$ can be easily filtered off. The present syntheses can be efficiently carried out in hexane with good yields thus avoiding the use of carcinogenic benzene or toluene, as in the alternative syntheses already reported.[19,20]

The adducts synthesised are very soluble in common organic solvents such as ethanol, chloroform, acetone, pentane, and toluene, and slightly soluble in cyclohexane. Adducts **1−3** have low melting points and evaporate quantitatively at low temperature under vacuum. They are nonhygroscopic and can be handled in air.

X-ray Single Crystal Structures of [$Y(hfa)_3$·monoglyme] and [$Y(hfa)_3$·diglyme]

The ORTEP drawing of the asymmetric unit [$Y(hfa)_3$·monoglyme] is shown in Figure 1. Selected bond lengths and angles are reported in Table 1. The crystal structure consists of monomeric units of molecules where an yttrium ion is in an eight coordination sphere formed by the six oxygen atoms of three hfa ligands and by two oxygen atoms of the monoglyme ligand. The coordination polyhedron around the yttrium atom is highly distorted and far from any idealized polyhedron. The average Y−O(hfa) distance is 2.34 Å, similar to the bond lengths observed in other $Y(hfa)_3$ derivatives.

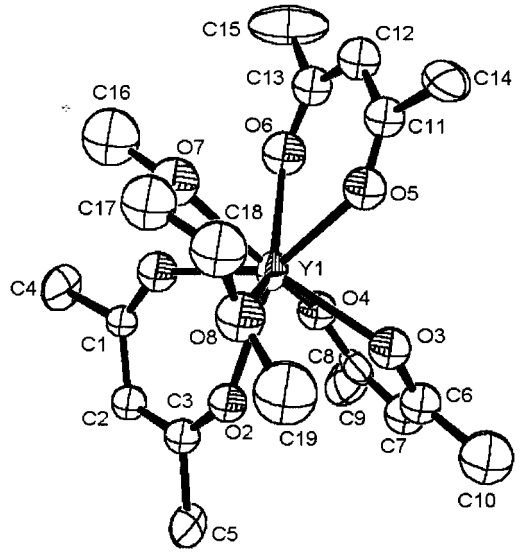

Figure 1. ORTEP drawing of the asymmetric unit of complex [$Y(hfa)_3$·monoglyme]; CF_3 groups have been omitted for clarity; probability of thermal ellipsoids is 50 %

The ORTEP drawing of the asymmetric unit [$Y(hfa)_3$·diglyme] is shown in Figure 2. Selected bond lengths and angles are reported in Table 2. The crystal structure consists of monomeric units of molecules where an yttrium ion is in a nine coordination sphere formed by the six oxygen atoms of three hfa ligands and by three oxygen atoms of the diglyme ligand. The [$Y(hfa)_3$·diglyme] complex possesses an orthorhombic structure. It should be noted that the structure of [$Y(hfa)_3$·diglyme] has been previously published by Pollard et al,[19] but in a monoclinic habit. The average Y−O(hfa) distance, observed in the current, more symmetrical structure, is 2.361 Å, 0.015 Å longer than the bond lengths observed in the monoclinic derivative (2.346 Å). Analogously, the average lenght of the Y−O(diglyme) bonds presently observed (2.510 Å) is 0.015 Å greater than that previously reported (2.495 Å).

It is interesting to compare the structures of these adducts with those of the analogous La,[1,4] Gd,[2] and Ho[20] derivatives. The average Y−O lenghts observed are similar to those reported for the Gd and Ho adducts. Moreover a large difference (0.150 Å) is observed between the average Y−O(diglyme) and the average Y−O(hfa) lenghts in the [$Y(hfa)_3$·diglyme], which is exactly the same as that observed for the Gd derivative and much larger than that reported (0.014 Å) for the La analogue. These data may be interpreted by considering the ionic radius values of the La^{3+} (1.13 Å), Gd^{3+} (1.02 Å), Y^{3+} (0.93 Å), and Ho^{3+} (0.97 Å) ions.

NMR Spectra

^1H and ^{13}C NMR spectra (see Table 3) were recorded in $CDCl_3$ for adducts **1−3**. In the case of adduct **4**, the lower

solubility in $CDCl_3$ required $(CD_3)_2CO$ and C_6D_6 for ^1H and ^{13}C NMR spectroscopy, respectively. The ^1H NMR spectra always show a singlet around 6.0 ppm associated with the alkene proton of the hfa ligand. Different resonances are associated with the polyether framework and the related values are reported in Table 3. The spectrum of **3** contains a resonance (δ = 3.94 ppm) associated with the coordinated H_2O. The intensities of pertinent resonances point to a 3:2:1 (hfa:H_2O:triglyme) ratio.

The evaluation of the relative intensities of hfa and tetraglyme resonances of adduct **4** points to a 6:1 (hfa:tetraglyme) ratio. This observation may be accounted for by considering an ionic structure [Y(hfa)$_2$·tetraglyme]$^+$-[Y(hfa)$_4$]$^-$, as previously proposed by Pollard et al.[19]

The ^{13}C NMR ($CDCl_3$) spectra can be assigned by comparison with the data of related lanthanum complexes.[1,3,4] Details of associated resonances are reported in Table 3.

Mass Spectra

The FAB$^+$ spectra of the adducts **1**−**4** are reported in Table 4. The spectra show fragment peaks due to fragmentation of both the hfa and polyether ligands. In addition, there is evidence of the characteristic fluorine-transfer process, already observed in the spectra of the analogous alkaline-earth[18,21] and lanthanide (La, Gd, Eu) adducts.[2,4,6] The fluorine-transfer process preludes a fluoride phase formation that could contaminate the deposited films, unless appropriate conditions are used. No molecular ion peaks or peaks at higher mass were observed for the adducts. The major peak of all the adducts corresponds to the ion [Y(hfa)$_2$·L]$^+$. At lower mass values, the more abundant peaks correspond to the fragments [Y(hfa)·L + F]$^+$, [Y·L + 2F]$^+$, [Y(hfa)$_2$]$^+$, [Y(hfa) + F]$^+$.

Infrared Spectra

The IR spectra of the raw and sublimed adducts are identical. The absence of any bands around 3300−3600 cm^{-1} in the spectrum of **1**, **2** and **4** is indicative of H_2O-free species. In contrast, the broad bands at 3380 cm^{-1} and 3260 cm^{-1} in the spectrum of **3** are associated with coordinated water (see below). In addition all the spectra show the characteristic peaks at 1660 cm^{-1} and 1500−1550 cm^{-1} associated with C=O and C=C stretching, respectively. The characteristic trend of peaks at 1255, 1210, 1140 and 1100 cm^{-1} arises from the overlap of the band due to C−F stretching and those associated with C−O stretching. The peaks between 800 and 1050 cm^{-1} may be considered fingerprints of the glyme coordination to the yttrium hexafluoroacetylacetonate moiety.

sis, differential scanning calorimetry (DSC) and atmospheric pressure TG vaporization-rate experiments.[22] The TG curves of **1−4** are reported in Figure 3. Single sublimation steps are observed for the monoglyme, diglyme and tetraglyme adducts. The monoglyme adduct shows a 96 % weight loss in the 79−220 °C range with a 4 % residue left at 275 °C. Adducts **2** and **4** show a weight loss in the 90−260 °C (residue = 2 % to 300 °C) and 170−330 °C (residue = 4 % to 400 °C) temperature ranges, respectively. The triglyme adduct shows two distinct sublimation steps corresponding to weight losses of 29 % in the temperature range 80−230 °C and 60 % in the temperature range 230−300 °C. The first step is probably due to the loss of the triglyme and coordinated H_2O molecules, whose corresponding weight loss is about 22 %.

When TG atmospheric-pressure vaporization rates of adducts **1−4** are compared to the data of [Y(tmhd)$_3$·H_2O] in Figure 4, it becomes evident that adducts **1** and **2** are more volatile than the "first-generation" [Y(tmhd)$_3$·H_2O] precursor, and in particular, vaporize approximately four and two times faster than [Y(tmhd)$_3$·H_2O], respectively. Adduct **3** shows a nonlinear behaviour of the vaporization rate confirming that partial decomposition may occur during vaporization. The low volatility of adduct **4** is probably due to its ionic structure: [Y(hfa)$_2$tetraglyme]$^+$ [Y(hfa)$_4$]$^-$.

The DSC data (see Figure 5) of these adducts show some interesting features in addition to the melting and evaporation processes. The DSC curve of the monoglyme adduct shows two endothermic peaks at 75.7 °C associated with the melting of the product and at approximately 175 °C due to evaporation. Similarly the DSC curve of adduct **2** shows two endothermic peaks associated with melting (62.2 °C) and evaporation processes (about 150 °C), respectively. Moreover, there is evidence at 220 °C of an exothermic peak that is observed in the freshly prepared as well as in the aged (over 4 months) samples.

The DSC data of adduct **3** show an unusually broad endothermic peak at 53.8 °C, which can be mainly associated with the melting of the product. Nevertheless, it is likely that another kind of process, that is, a solid-phase transition peak, may be hidden under the same peak. A second endothermic peak (at around 250 °C) is associated with the evaporation of the adduct. Similarly to adduct **2**, an exothermic peak is observed at 235 °C.

Adduct **4** shows two endothermic peaks at 176.9 °C, associated with the melting process, and at approximately 275 °C, due to evaporation. An exothermic peak was also found at 248.6 °C.

MOCVD YBCO Deposition From a Molten Multimetal Single Source

The [Y(hfa)$_3$·monoglyme] adduct was successfully employed in a novel, strategic approach to grow $YBa_2Cu_3O_{7-\delta}$ (YBCO) films on $LaAlO_3$ (100) substrates by MOCVD.

The synthesis of any multielement oxide film always introduces complications in the growth process due to the different physico-chemical properties of each single precursor that, of course, requires specific optimization. Recently we reported a new, very simple, low-cost route to high quality $LaAlO_3$ (100) films on $SrTiO_3$ (100) substrates adopting a multimetal molten single source.[23] The novelty of the approach relies upon the use of the [La(hfa)$_3$·diglyme] complex as a solvent for the aluminum precursor Al(acac)$_3$ (Hacac = acetylacetone), thus affording a two-component molten source. The same approach was adopted in the current study and the [Y(hfa)$_3$·monoglyme] complex was used as a solvent for the Ba and Cu precursors. Deposition parameters were, therefore, optimized for the single multimetal source.

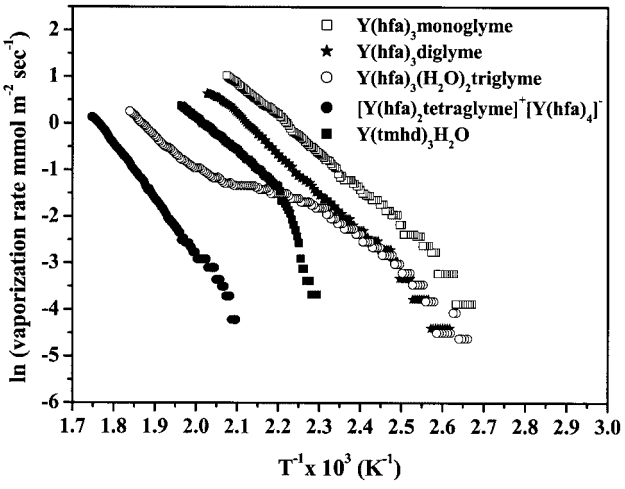

Figure 4. Atmospheric-pressure TG vaporization-rate data of adducts **1−4**

Systematic studies were carried out by changing operational parameters governing both deposition and cooling−annealing processes. The best operative parameters for the growth of high quality YBCO films are the following: i) a single molten multimetal source consisting of a mixture of [Y(hfa)$_3$·monoglyme], [Ba(hfa)$_2$·tetraglyme] and Cu(tmhd)$_2$ complexes (where Htmhd = 2,2,6,6-tetramethyl-3,5-heptanedione) in the 1:2:0.5 Y:Ba:Cu ratio; ii) argon carrier gas (300 sccm); iii) 200 sccm flow of water-saturated oxygen as a reaction gas; iv) deposition temperature of 800 °C; v) deposition time of 3 hours, and vi) annealing at 500 °C in oxygen ambient for 12 hours.

In Figure 6 the DSC curve of the 1:2:0.5 (Y:Ba:Cu) mixture is compared with the curves of each individual precur-

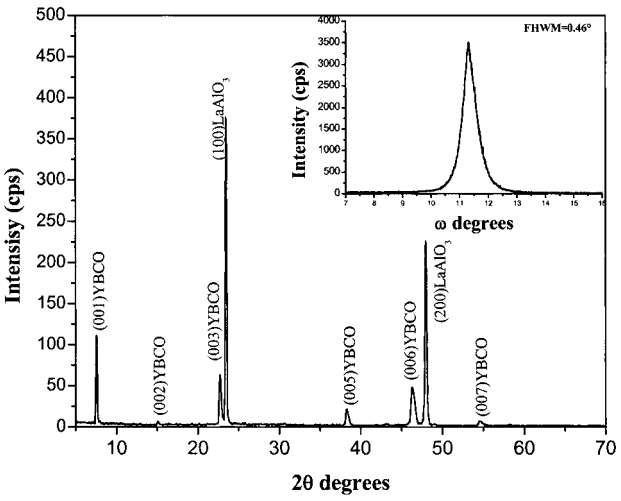

Figure 7. X-ray diffraction pattern of an MOCVD grown YBCO film on an $LaAlO_3$ (100) substrate; the inset shows the rocking curve of the YBCO (003) reflection

sor. The DSC scans of the single [Y(hfa)$_3$·monoglyme], [Ba(hfa)$_2$·tetraglyme] and Cu(tmhd)$_2$ precursors show evidence of the endothermic peaks due to melting {75.7 °C for [Y(hfa)$_3$·monoglyme], 153.6 °C for [Ba(hfa)$_2$·tetraglyme], and 196.3 °C for Cu(tmhd)$_2$} and to evaporation from the melts in the 150−190 °C, 260−290 °C, and 210−260 °C temperature ranges, respectively. The DSC scan of the multicomponent precursor mixture shows a lower temperature peak (73.5 °C) representing the melting of the [Y(hfa)$_3$·monoglyme] component. The following endothermic broad peak in the 110−160 °C temperature range clearly represents dissolution of [Ba(hfa)$_2$·tetraglyme] and Cu(tmhd)$_2$. Finally the endothermic process at the highest temperature (190−270 °C) is associated with the evaporation of the melted mixture. In this context the endothermic peaks expected for [Ba(hfa)$_2$·tetraglyme] and Cu(tmhd)$_2$ melting, at 153.6 °C and 196.3 °C, respectively, are not observed.

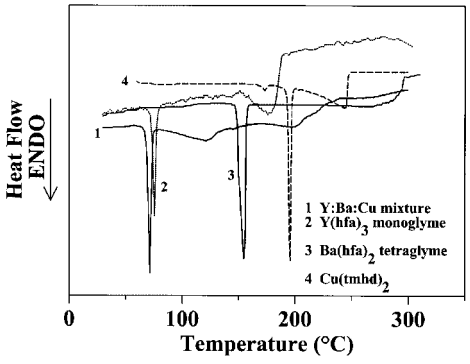

Figure 6. DSC curve of the 1:2:0.5 (Y:Ba:Cu) multimetal single source mixture compared with data of individual precursors [Y(hfa)$_3$·monoglyme], [Ba(hfa)$_2$·tetraglyme], and Cu(tmhd)$_2$

Great attention was devoted to the oxygen partial pressure during the cooling−annealing process, because of its influence on the phase transition from the tetrahedral to the orthorhombic phase. Thus, YBCO films were slowly cooled (3 °C/min) under low pressure (10 Torr) and then maintained at 500 °C under oxygen flow for 12 hours. The chemical composition of the YBCO samples, determined with a windowless EDX detector, indicates the correct 1:2:3 Y:Ba:Cu ratio. No fluorine atoms were detected. The X-ray diffraction pattern of a typical YBCO film deposited on $LaAlO_3$(100) substrates is shown in Figure 7. All the reflections are indexed as (00*l*) peaks, thus indicating that the films are strongly *c*-axis aligned. The degree of *c*-axis alignment was determined by ω-scans (rocking curve) of the (003) YBCO peak. The FWHM value of 0.46° indicates a high degree of texturing. The in-plane (*a*-and *b*-axes) alignment was established by recording the (103) pole figure. The intense four poles at $\Psi = 46°$ observed every 90° of φ in the (103) pole figure indicate a good in-plane orientation of the YBCO films on the $LaAlO_3$ (100) substrate.

Finally, the surface morphology of the YBCO films was observed by scanning electron microscopy. All the prepared samples show smooth surfaces with "platelike" grains. Preliminary measurements of electrical transport properties give a critical temperature (T_c) value of 83 K and a critical current density (J_c) of 10^5 A/cm.[2]

Discussion

The present syntheses reinforce our earlier assertion that this one-pot route is a "general" strategy for the preparation of alkaline-earth (M = Ba, Sr, and Ca)[18] and rare-earth[1−6] volatile and thermally stable metal adducts suitable for MOCVD applications. This synthetic procedure involves open-bench manipulations and yields, reproducibly, the water-free products **1**, **2** and **4**, despite Y(OH)$_3$·*n*H$_2$O being the reagent. Therefore, polyethers act as hard Lewis bases, which encapsulate the metal ion and favourably compete with H$_2$O in saturating the coordination sphere around the metal. Only in the case of the triglyme adduct, some H$_2$O molecules were found to be coordinated to the yttrium centre as indicated by the presence of the band at about 3600 cm^{-1} in the IR spectrum. The related X-ray single

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

crystal structure (see Exp. Sect.) points to an outer-sphere complex [Y(hfa)$_3$·(H$_2$O)$_2$·triglyme]. In addition, the ^{1}H NMR integration is indicative of a 3:2:1 (hfa:H$_2$O:triglyme) ratio and the fingerprint region of the IR spectrum points to a different and probably weaker coordination. It is interesting to observe that the outer-sphere complex is immediately formed with the current synthetic strategy, while it is originated by sublimation from the ionic structure [Y(hfa)$_2$·triglyme]$^+$[Y(hfa)$_4$]$^-$ obtained by Pollard et al.[19]

The vaporization behaviour of adduct **3**, which depends on the coordinated H$_2$O, deserves some further comments. It was already mentioned (see above) that the triglyme adduct shows two thermogravimetric step losses, thus indicating evaporation accompanied by a partial decomposition of the precursor. This behaviour has already been observed in other hydrated compounds. Therefore, H$_2$O is not an "innocent" or "spectator" ligand, but it plays a key role in the chemistry of this MOCVD precursor, similarly to the previous behaviour reported by Luten et al. for [Y(tmhd)$_3$·H$_2$O]$_2$.[16]

The polyether length also plays a crucial role on the coordination sphere around the yttrium ion and, hence, on the thermal properties of the related adducts. In fact, there is evidence of an intriguing interplay between the polyether chain length and the yttrium ionic radius in determining the volatility of these adducts (see Figure 3). Therefore, small polyethers, such as the monoglyme or diglyme, form more volatile precursors. The longer triglyme and tetraglyme parent adducts have more complex coordination spheres and form the less volatile adducts **3** and **4**, which are not so thermally stable. The coordinated H$_2$O molecules in **3** are responsible for the two-step decomposition−evaporation, while the proposed ionic structure of **4** accounts for the higher melting point and consequent low volatility.

In this context, it becomes interesting to compare the measured melting points with those reported by Pollard et al.[19] The observed data indicate that only the melting point of adduct **4** is quite similar. The data of **3** cannot be compared, since its melting point was not reported in ref.[19] However, our melting point of **1** is about 20 °C higher while that of **2** is about 20 °C lower. It is important to note that adduct **2** has a slightly different X-ray single crystal structure but no explanation for the discrepancy observed in the case of **1** can be proposed. In any case, it is noteworthy that the melting point data were obtained by DSC measurement-curves and agree quite well with the Koeffler data.

Structural analogies between the yttrium adducts and those of the previously reported lanthanide homologues deserve further comments. This series of complexes is analogous to that observed for Eu[6] and Gd[2] but is different from that observed for La ions.[1,4] In fact, in the case of La, completely different coordination spheres were found for adducts **1**, **3** and **4**. This indicates that in these compounds yttrium behaves like a smaller ionic radio lanthanon.

Close analogies with the diglyme La homologous precursor were found for [Y(hfa)$_3$·monoglyme] in terms of its ability to act as a solvent for other precursors, thus forming a multimetal liquid single MOCVD source. In particular, it dissolves the [Ba(hfa)$_2$·tetraglyme] and Cu(tmhd)$_2$ precursors and the formed melt represents a suitable source for the growth of YBCO thin films. The resulting in-situ growth of YBCO films using a single molten multimetal source is an important result. The multimetal mixture can be easily and cleanly evaporated from the melt with constant mass-transport rates. On the contrary the sublimation of solid precursors suffers several drawbacks associated with sintering and surface passivation upon sublimation, which, in turn, render transport processes largely irreproducible.

Even more important, the use of precursors in a single liquid phase implies simpler reactor design and control of deposition parameters, since the interplay of control of different sublimation−evaporation parameters and carrier gas flows are no longer required.

In summary, the present procedure yields quantitatively nonhygroscopic adducts through a viable low-cost route. This represents an important issue for materials used in CVD applications, where low-cost chemicals that can be manipulated on open benches are an important objective.[24] Furthermore the obtained raw materials are pure and the final products (no impurities are introduced in the one-pot synthesis) do not require further sublimation steps.

Conclusions

The present one-pot synthetic strategy has proven an efficient route for the preparation of thermally stable and volatile yttrium second-generation adducts from commercially available products. Thermogravimetric and vaporization-rate experiments indicate that they can be used in MOCVD deposition at temperatures lower than 200 °C, with better mass-transport properties and thermal behaviour than conventional rare-earth metal CVD precursors. Furthermore because of their low melting points they can be used as thermally stable precursors in the liquid phase, hence under constant vaporization and mass-transport rates.

The effect of the polyether framework was widely investigated and the results emphasise the key role of the polyether length on the coordination sphere, which, in turn, affects the thermal stability and volatility of the adducts.

Finally, adduct **1** was tested as a solvent for a variety of precursors for YBCO deposition complexes, thus providing liquid single-sources, which simultaneously deliver all the metal components in the required stoichiometry. In the present work, the monoglyme yttrium adduct was used as a solvent for [Ba(hfa)$_2$·tetraglyme] and Cu(tmhd)$_2$. The resulting multimetal, molten single-source was employed for the growth of highly textured YBCO films having good surface morphologies.

The present approach, which adopts a monocomponent, simple and low-cost MOCVD reactor, is an attractive alternative to the classical multicomponent MOCVD processes.

Experimental Section

Reagents: Hhfa, monoglyme, diglyme, triglyme and tetraglyme (Aldrich) were used without any further purification. Yttrium nitrate $[Y(NO_3)_3{\cdot}5H_2O]$ was purchased from Aldrich.

General Procedures: Elemental microanalyses were performed in the Analytical Laboratories of the University of Catania. ^{1}H NMR spectra were recorded on a Varian Inova 500 spectrometer. Infrared data were collected on a 684 Perkin−Elmer spectrometer as nujol mulls between NaCl plates. Thermal measurements were made using a Mettler 3000 system equipped with a TG 50 thermobalance, a TC 10 processor and DSC 30 calorimeter. The weights of the samples were between 10−15 mg (TGA) and 4−8 mg (DSC). Analyses were carried out under prepurified nitrogen using a 5 °C/min heating rate. FAB^+ mass spectra were obtained with a Kratos MS 50 spectrometer.

Synthesis of $Y(OH)_3{\cdot}nH_2O$: $Y(OH)_3{\cdot}nH_2O$ was precipitated from an aqueous solution of yttrium nitrate on addition of sodium hydroxide. The gelatinous precipitate was filtered and dried under vacuum over P_4O_{10}.

Synthesis of [Y(hfa)$_3$·monoglyme] (1): $Y(OH)_3{\cdot}nH_2O$ (1.482 g, 10.59 mmol) was first suspended in hexane (150 mL). Monoglyme (0.849 g, 9.42 mmol) was added to the suspension. Hhfa (5.881 g, 28.27 mmol) was added under vigorous stirring after 10 min and the mixture was refluxed whilst stirring for 1 hour. The excess of yttrium hydroxide was filtered off from the hot solution. White crystals precipitated after partial evaporation of the solvent. The colourless crystals were collected by filtration and dried under vacuum. The yield is 81 %. The melting point of the crude product is 74−77 °C. $C_{19}H_{13}F_{18}O_8Y$ (800.2): calcd. C 28.54, H 1.62; found C 28.24, H 1.56 %. The adduct sublimes quantitatively at 75−80 °C/10^{-3} Torr. IR (nujol or hexachlorobutadiene): $\tilde{\nu}$ = 2930 (vs), 1660 (s), 1610 (w), 1570 (m), 1540 (m), 1505 (m), 1455 (s), 1380 (m), 1250 (s), 1200 (s), 1150 (s), 1100 (m), 1040 (s), 1020 (m), 950 (w), 870 (m), 830 (vw), 800 (m), 770 (w), 740 (m), 660 (s), 600 (s), 530 (m) cm^{-1}. The NMR, MS and IR data of the raw and sublimed adduct are identical.

Synthesis of [Y(hfa)$_3$·diglyme] (2): Prepared as described for the monoglyme adduct from $Y(OH)_3{\cdot}nH_2O$ (1.152 g, 8.23 mmol), Hhfa (4.411 g, 21.21 mmol) and diglyme (0.948 g, 7.07 mmol). Yield 78 %. The melting point of the crude product was 60−63 °C. $C_{21}H_{17}F_{18}O_9Y$ (844.2): calcd. C 29.88, H 2.03; found C 29.25, H 2.25 %. The adduct sublimes quantitatively at 80−85 °C/10^{-3} Torr. IR (nujol or hexachlorobutadiene): $\tilde{\nu}$ = 2930 (s), 1660 (vs), 1605 (w), 1560 (w), 1530 (m), 1505 (s), 1460 (s), 1380 (m), 1260 (s), 1205 (s), 1140 (s), 1090 (s), 1055 (m), 1045 (s), 1010 (m), 950 (w), 870 (m), 835 (w), 800 (m), 770 (w), 740 (m), 660 (s), 600 (s), 535 (w) cm^{-1}. The NMR, MS and IR data of the raw and sublimed adduct are identical.

Synthesis of [Y(hfa)$_3$·(H$_2$O)$_2$·triglyme] (3): Prepared as described for the monoglyme adduct from $Y(OH)_3{\cdot}nH_2O$ (1.613 g, 11.52 mmol), Hhfa (6.615 g, 31.80 mmol) and triglyme (1.890 g, 10.60 mmol). Yield 88 %. Melting point of the crude product 52−55 °C. $C_{23}H_{25}F_{18}O_{12}Y$ (924.3): calcd. C 29.86, H 2.70; found: C 29.25, H 2.57 %. The adduct sublimes quantitatively at 95−105 °C/10^{-3} Torr. IR (nujol or hexachlorobutadiene): $\tilde{\nu}$ = 3370 (m), 3260 (m), 2930 (s), 1660 (s), 1560 (m), 1530 (m), 1505 (m), 1460 (s), 1370 (m), 1350 (w), 1255 (s), 1210(s), 1140 (s), 1100 (s), 1020 (w), 1005 (w), 940 (w), 840 (w), 800 (m), 740 (w), 720 (vw), 660 (m), 600 (m), 535 (w) cm^{-1}. The NMR, MS and IR data of the raw and sublimed adduct are identical.

Synthesis of [Y(hfa)$_2$·tetraglyme]$^+$[Y(hfa)$_4$]$^-$ (4): Prepared as described for the monoglyme adduct from $Y(OH)_3{\cdot}nH_2O$ (1.153 g, 8.24 mmol), Hhfa (4.410 g, 21.20 mmol) and tetraglyme(1.570 g, 7.067 mmol). Dichloromethane was used instead of hexane. Yield 65 %. The melting point of the crude product is 175−178 °C. $C_{40}H_{28}F_{36}O_{17}Y$ (1553.5): calcd. C 30.9, H 1.81; C 28.83, H 1.89 %. The adduct sublimes quantitatively at 130−140 °C/10^{-3} Torr. IR

Table 5. Crystal data and structure refinement for [Y(hfa)$_3$·monoglyme] and [Y(hfa)$_3$·diglyme]

Identification code	Y(hfa)$_3$Monoglyme	Y(hfa)$_3$Diglyme
Empirical formula	$C_{19}H_{13}F_{18}O_8Y$	$C_{21}H_{17}F_{18}O_9Y$
Molecular mass	800.20	844.26
Temperature	120(2) K	120(2) K
Wavelength	1.54052 Å	1.54184 Å
Crystal system	Orthorombic	Orthorombic
Space group	Pcab	$Pc2_1n$
Unit cell dimensions	a = 16.095(5) Å; α = 90.00(5)°	a = 11.151(5) Å; α = 90.00(5)°
	b = 17.983(5) Å; β = 90.00(5)°	b = 12.371(5) Å; β = 90.00(5)°
	c = 20.753(5) Å; γ = 90.00(5)°	c = 22.251(5) Å; γ = 90.00(5)°
Volume	6007(3) Å^3	3070 (2) Å^3
Z	8	4
Density (calculated)	1.770 Mg/m^3	1.827 Mg/m^3
Absorption coefficient	4.184 mm^{-1}	4.157 mm^{-1}
F(000)	3136	1664
Crystal size	0.385 × 0.502 × 0.235 mm	0.432 × 0.416 × 0.181 mm
Theta range for data collection	4.91 to 54.07°	4.44 to 58.03°
Index ranges	$0 \le h \le 16$, $0 \le k \le 18$, $0 \le l \le 21$	$-1 \le h \le 12$, $-1 \le k \le 19$, $-22 \le l \le 22$
Reflections collected	2906	8389
Independent reflections	2788 [R(int) = 0.0988]	3724 [R(int) = 0.0594]
Refinement method	Full-matrix least-squares on F^2	Full-matrix least-squares on F^2
Data/restraints/parameters	2788/18/312	3723/19/294
Goodness-of-fit on F^2	1.005	1.058
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.1152, $wR2$ = 0.2896	$R1$ = 0.0731, $wR2$ = 0.1919
R indices (all data)	$R1$ = 0.1700, $wR2$ = 0.3258	$R1$ = 0.0775, $wR2$ = 0.1992
Largest diff. peak and hole	1.307 and −1.626 eA^{-3}	2.192 and −1.737 eA^{-3}

(nujol or hexachlorobutadiene): $\tilde{\nu}$ = 2930 (s), 1650 (vs), 1605 (w), 1565 (m), 1540 (m), 1515 (m), 1495 (w), 1460 (s), 1380 (m), 1350 (w), 1260 (s), 1220 (s), 1200 (s), 1140 (s), 1100 (m), 1060 (m), 1035 (m), 950 (m), 930 (w), 850 (m), 830 (vw), 800 (m), 770 (w), 740 (m), 720 (vw), 660 (s), 600 (s), 535 (m) cm^{-1}. The NMR, MS and IR data of the raw and sublimed adduct are identical.

X-ray Structure Determination:[25] Single crystal X-ray diffraction patterns of mono-, di-, and triglyme adducts were obtained at room temperature using an ENRAF NONIUS CAD 4 four-circle diffractometer equipped with Mo-K_α radiation (λ = 0.71069 Å). The triglyme derivative was found to be isomorphous with the outer-sphere complex already reported by K. D. Pollard et al.,[19] and, therefore, it was not analysed further. Diffraction data for the diglyme derivative were collected at 120 K using the same diffractometer and the unit-cell parameters were derived from least-squares refinements of setting angles of 25 reflections in the 9−15° range. Data are reported in Table 5 with other experimental parameters. No crystals were found to be isomorphous to the previously reported crystal structure. The new data for the monoglyme derivative single crystal were collected at 100 K using a diffractometer equipped with a CCD SMART 1 K area detector (Bruker) and a Cu rotating anode. Six series of ω scans were collected using the SMART software,[26] each one of 0.3° width and 10 s exposure time. The data were reduced using the software package SAINT.[27] Completeness of unique data to 54.2 θ were 97.4 % with 0.97 redundancy and 98.3 % with 3.31 redundancy for the mono- and diglyme derivatives, respectively. Cell parameters were determined from a nonlinear least square fit of the peaks collected in the first 620 frames.

Corrections were applied for Lorentz and polarization effects. The intensities of the diglyme adduct were corrected for absorption (ψ scan) while for the monoglyme derivative attempts to account for absorption were performed by using the DIFABS package without improvement in the refinements. The reflections were processed by the direct method program SIR97[28] which provided satisfactory sets of atomic parameters for yttrium and oxygen atoms. The other atomic parameters were determined by conventional Fourier difference synthesis by using the SHELX93 package[29] up to the final results. The conventional agreement factor for the monoglyme adduct remained not satisfactory and therefore several crystals from different batches were examined. The data reported in Table 5 represent parameters with the lowest *R* values. A residual thermal disorder prevented a better refinement of the data. Anisotropic displacement parameters were introduced for several non hydrogen atoms trying to maintain a good parameters/observable factor. The hydrogen atoms were included as idealized atoms riding on the respective carbon atoms with C−H bond lengths appropriate to the carbon atom hybridization. The isotropic displacement parameters for each H atom were fixed 1.5 times the equivalent values of the bound carbon.

MOCVD Experiments: Low pressure MOCVD deposition of pure (00*l*)-oriented YBCO films was carried out from the metal precursors [Y(hfa)$_3$·monoglyme], [Ba(hfa)$_2$·tetraglyme], and Cu(tmhd)$_2$ using a horizontal hot-wall reactor. In each experiment a suitable mixture (see below) of yttrium, barium and copper precursors was used. The volatile liquid mixture was contained in a resistively heated alumina boat at 120 °C and was transported to the deposition zone by a 300 sccm argon flow. YBCO thin films were deposited on $LaAlO_3$ (100) substrates heated at 800 °C. Water saturated O_2 flow (200 sccm) was used as the reaction gas and introduced near to the substrate. The water bubbler was maintained at room temperature. The mass flows were controlled with 1160 MKS flowmeters using an MKS 147 electronic control unit. The total pressure was maintained at 5 Torr during the growth process. The depositions were carried out for 180 minutes. YBCO thin films were slowly cooled to 500 °C at a low total pressure of 10 Torr (P_{O2} = 4 Torr). The annealing step at 500 °C was performed at atmospheric pressure in oxygen ambient for 12 hours.

X-ray diffraction θ-2θ scans of thin films were recorded with a Bruker-AXS D 5005 θ-θ X-ray diffractometer using Cu-K_α radiation operating at 40 kV/30 mA. The pole figures were recorded on a Bruker-AXS D-5005 Texture X-ray diffractometer using Cu-K_α radiation operating at 40 kV/30 mA.

The atomic composition of the films was analyzed by energy dispersive X-ray analysis (EDX) using an IXRF detector. The surface morphology was examined with a Leo Iridium 1450 scanning electron microscope (SEM).

Comparative Electrochemical Study of Unsubstituted and Substituted Bis(phthalocyaninato) Rare Earth(III) Complexes

Peihua Zhu,[a] Fanli Lu,[a] Na Pan,[a] Dennis P. Arnold,*[b] Shuyong Zhang,[a] and Jianzhuang Jiang*[a,c]

Keywords: Phthalocyanines / Sandwich complexes / Rare earths / Electrochemistry

The electrochemistry of homoleptic substituted phthalocyaninato rare earth double-decker complexes $M(TBPc)_2$ and $M(OOPc)_2$ [M = Y, La...Lu except Pm; H_2TBPc = 3(4),12(13),21(22),30(31)-tetra-*tert*-butylphthalocyanine, H_2OOPc = 3,4,12,13,21,22,30,31-octakis(octyloxy)phthalocyanine] has been comparatively studied by cyclic voltammetry (CV) and differential pulse voltammetry (DPV) in CH_2Cl_2 containing 0.1 M tetra-*n*-butylammonium perchlorate (TBAP). Two quasi-reversible one-electron oxidations and three or four quasi-reversible one-electron reductions have been revealed for these neutral double-deckers of two series of substituted complexes, respectively. For comparison, unsubstituted bis(phthalocyaninato) rare earth analogues $M(Pc)_2$ (M = Y, La...Lu except Pm; H_2Pc = phthalocyanine) have also been electrochemically investigated. Two quasi-reversible one-electron oxidations and up to five quasi-reversible one-electron reductions have been revealed for these neutral double-decker compounds. The three bis(phthalocyaninato)cerium compounds display one cerium-centered redox wave between the first ligand-based oxidation and reduction. The half-wave potentials of the first and second oxidations and first reduction for double-deckers of the tervalent rare earths depend on the size of the metal center. The difference between the redox potentials of the second and third reductions for $M^{III}(Pc)_2$, which represents the potential difference between the first oxidation and first reduction of $[M^{III}(Pc)_2]^-$, lies in the range 1.08–1.37 V and also gradually diminishes along with the lanthanide contraction, indicating enhanced π–π interactions in the double-deckers connected by the smaller, lanthanides. This corresponds well with the red-shift of the lowest energy band observed in the electronic absorption spectra of reduced double-decker $[M^{III}(Pc')_2]^-$ (Pc' = Pc, TBPc, OOPc).

Introduction

Bis(phthalocyaninato) rare earth compounds have been extensively studied due to their potential applications for electronic devices.[1,2] Their electrochemical properties, especially those of lutetium compounds, have been intensively investigated in solutions or in aqueous $LiClO_4$, $KClO_4$, or KCl in cast, Langmuir–Blodgett, or spin-coated films by several research groups. These data are relevant to the use in electrochromic displays and molecular electronics of $Lu(Pc)_2$.[1–5] As noted by Simon and co-workers,[6] the gap between the first oxidation and first reduction processes of molecules is a good estimate of the thermal activation energy for the conduction of electric charges in the solid-state materials derived from these molecular precursors.

The spectroscopic properties, namely IR,[7] Raman,[8] and electronic absorption spectra,[9] of these sandwich-type (tetrapyrrole)metal compounds depend on the strong electronic interaction between the macrocycles, which in turn depends on the ring-to-ring distances in the molecules. Therefore it is worth studying systematically the electrochemical properties of the sandwich compounds of the complete series of rare earths for various ligands. So far, we have studied the molecular structures, NMR and vibrational spectroscopic characteristics of several series of tetrapyrrole compounds with the whole series of lanthanides from La to Lu.[7–10] The groups of Konami,[11] Iwase[12] and Homborg[13] have reported the NMR, electrochemical and electronic absorption properties of reduced double-deckers of the lanthanide series, namely $[Bu_4N][M(Pc)_2]$, $Li[M(Pc)_2]$ and $[N(C_nH_{2n+1})_4][M(Pc)_2]$, respectively. However, there is still no report on electrochemical investigations over the whole lanthanide series for the neutral bis(phthalocyaninato) species. The literature on any solution properties of the neutral unsubstituted bis-

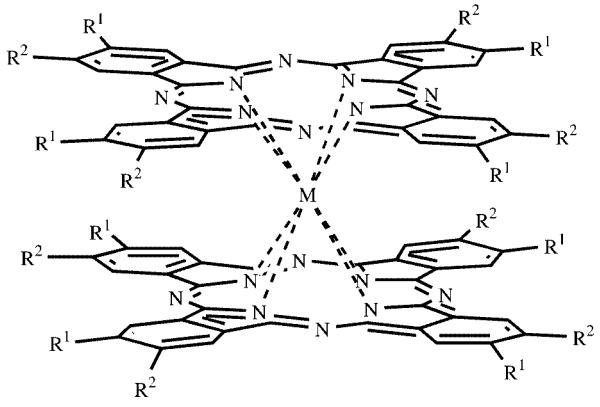
(phthalocyaninato) rare earth complexes is not rich due to the limited solubility of $M(Pc)_2$ in common organic solvents such as CH_2Cl_2. Investigations of the electrochemical properties of substituted bis(phthalocyaninato) rare earth compounds are also scarce, being limited to $M(OPPc)_2$ (M = Eu, Gd),[14] $M(OHPc)_2$ (M = Eu, Gd),[14] $M(OBPc)_2$ (M = Yb, Lu)[4d] and $Lu(TBPc)_2$.[4c] The ligand abbreviations are given in Table 1.

Table 1. Abbreviations for ligands

Abbreviation	Ligand
H_2Por	general porphyrin
H_2TBPP	5,10,15,20-tetrakis(4-*tert*-butylphenyl)porphyrin
H_2OEP	2,3,7,8,12,13,17,18-octaethylporphyrin
H_2Pc	phthalocyanine
H_2TBPc	2(3),9(10),16(17),24(25)-tetra-*tert*-butylphthalocyanine
H_2OOPc	2,3,9,10,16,17,24,25-octakis(octyloxy)phthalocyanine
H_2OPPc	2,3,9,10,16,17,24,25-octakis(pentyloxy)phthalocyanine
H_2OHPc	2,3,9,10,16,17,24,25-octakis(heptyl)phthalocyanine
H_2OBPc	2,3,9,10,16,17,24,25-octakis(butyloxy)phthalocyanine
$H_2(2,3\text{-Nc})$	2,3-naphthalocyanine (linearly annulated tetrabenzophthalocyanine)
$H_2(2,3\text{-TBNc})$	3(4),12(13),21(22),30(31)-tetra-*tert*-butyl-2,3-naphthalocyanine

We report here on two series of substituted bis(phthalocyaninato)lanthanide compounds, $M(OOPc)_2$ and $M(TBPc)_2$, whose solubility in CH_2Cl_2 is significantly improved due to the introduction of extended or bulky substituents onto the Pc rings (Scheme 1). The electrochemical characterization of these substituted bis(phthalocyaninato) compounds of the whole series of lanthanides has been achieved using a glassy carbon disk working electrode. For comparison, the corresponding unsubstituted analogues $M(Pc)_2$ have also been prepared and investigated electrochemically. These unsubstituted counterparts also show recognizable and reproducible electrochemical features under the present conditions although the cyclic and differential pulse voltammograms are not resolved as clearly as those of the substituted analogues $M(TBPc)_2$ and $M(OOPc)_2$. By comparison between the electrochemical characteristics of unsubstituted and substituted bis(phthalocyaninato) compounds of the whole series of lanthanides, the effects of ionic radius of the rare earth metal and substituents (*tert*-butyl and octyloxy groups) on the electrochemical properties of double-decker compounds have been studied.



Scheme 1. Bis(phthalocyaninato) rare earth complexes $R^1 = R^2 = H$, $M(Pc)_2$ (**A**); $R^1 \neq R^2 = H$, *tert*-C_4H_9, $M(TBPc)_2$ (**B**); $R^1 = R^2 = OC_8H_{17}$, $M(OOPc)_2$ (**C**)

More redox couples can be revealed by using the glassy carbon disk due to the decreased interaction or affinity between the highly charged electrochemically generated complexes and the electrode.[12b,15] The same methodology has been applied here to render possible the first observation by DPV of the fifth one-electron reduction of $M(Pc)_2$ in solution.[15]

Results and Discussion

Electrochemical Characteristics of Bis(phthalocyaninato) Rare Earth Complexes $M(Pc)_2$ (M = Y, La...Lu except Pm)

The electrochemical behavior of all the double-decker sandwich complexes $M(Pc)_2$ was first investigated by cyclic voltammetry (CV) and then differential pulse voltammetry (DPV) in CH_2Cl_2. The half-wave redox potentials vs. SCE are summarized in Table 2. Figure 1 shows the cyclic voltammograms and differential pulse voltammograms of $Y(Pc)_2$ as a typical representative of this series of rare earth compounds. The cyclic voltammograms of other compounds in the same series are similar. Within the electrochemical window of CH_2Cl_2 and according to the CV and DPV results, all the double-decker compounds of tervalent rare earths except Lu undergo two quasi-reversible one-electron oxidations and up to five quasi-reversible one-electron reductions under the present conditions. The separation of the reduction and oxidation peak potentials for each process is 60−95 mV. Since the oxidation state of the central tervalent rare earth ion does not change (except for M = Ce), these processes are due to successive removal or addition of electrons from or to the ligand-based orbitals that are represented by the redox states illustrated in Scheme 2, where oxidations are labeled as Oxd_1 and Oxd_2 and the reductions as Red_1 to Red_5.

The electrochemistry of the unsubstituted double-deckers in CH_2Cl_2 seen here differs from that previously reported. For instance, only three or at most four reductions were observed for $Lu(Pc)_2$ in CH_2Cl_2 or benzonitrile (PhCN) containing $TBAPF_6$.[4] However, under our experimental conditions, the neutral bis(phthalocyaninato) compounds of tervalent rare earths undergo up to five one-electron reductions according to both the CV and, more clearly, the DPV results.

The effect of rare earth ion size is clearly demonstrated by the slight shift in the negative direction of the half-wave potentials of the first oxidation and first reduction of $M^{III}(Pc)_2$ with decreasing rare earth ion radius. Moreover, a linear correlation exists between the potentials of the first oxidation and first reduction and the tervalent rare earth ionic radii (Figure 2). The half-wave potentials of the second oxidation also depend on the ionic radius of the central rare earth metal (Figure 2). However, the slope of this

[a] $\Delta E^\circ_{1/2}$ is the energy required to put a second electron in the semi-occupied HOMO of the neutral double-decker radical $M(Pc)_2$ or to remove one electron of the two from the HOMO of the reduced double-decker species $[M(Pc)_2]^-$: $\Delta E^\circ_{1/2} = Oxd_1 - Red_1$. [b] $\Delta E^{\circ\prime}_{1/2}$ is the potential difference between the first oxidation and first reduction processes, i.e. the HOMO−LUMO gap of $[M(Pc)_2]^-$: $\Delta E^{\circ\prime}_{1/2} = Red_1 - Red_2$. [c] Recorded by DPV. [d] This process involves an intermediate cerium Ce*X* species, where X is between III and IV. [e] Involves a cerium-centered redox process. [f] Involves a Ce^{III} species. [g] For $Ce(Pc)_2$: $\Delta E^\circ_{1/2} = Oxd_2 - Oxd_1$.

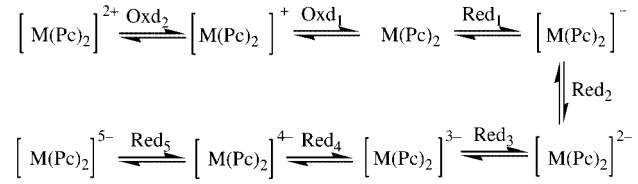

Scheme 2. The one-electron redox processes of $M(Pc)_2$

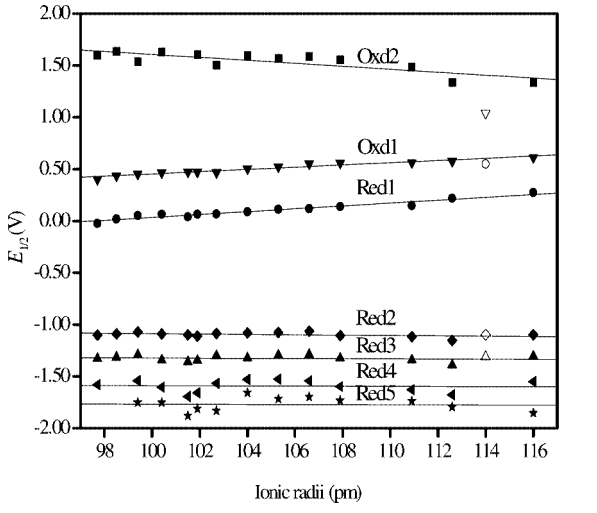

Figure 2. Half-wave potentials of redox processes of $M(Pc)_2$ as a function of the ionic radius of M^{III}

line is opposite to those of the first oxidation and first reduction waves (see below). The half-wave potentials of the second, third and fourth reductions for $M(Pc)_2$ are independent of the size of the central rare earth ions. This is also true for the half-wave potentials of the fifth reduction of $M^{III}(Pc)_2$ revealed here by DPV.

The potential difference between the first oxidation and first reduction process, $\Delta E^\circ_{1/2}$, for all double-decker compounds $M(Pc)_2$ spans a relatively narrow range, 0.34−0.43 V, which accords well with previously reported results for bis(phthalocyaninato)lutetium compounds.[4] This potential

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

difference is important for molecular materials because it predicts electrical properties such as the thermal activation energy for conduction in the condensed phases derived from these molecular precursors.[6] As with $Lu(Pc)_2$, the unsubstituted bis(phthalocyaninato) rare earth compounds should be good molecular semi-conductors based on the small potential difference between their first oxidation and first reduction.

X-ray crystallographic studies of bis(phthalocyaninato) rare earth compounds show that the two isoindole N_4 planes are very close to each other (2.68−3.11 Å).[1a] This proximity of the two conjugated π-systems in a face-to-face configuration causes the monomer molecular orbitals to split, which can be demonstrated by studying the redox behavior and the optical properties (UV/Vis, near-IR and MCD spectra). Figure 3 shows a qualitative scheme for the frontier orbitals of $M(Pc)_2$ derived from the highest occupied and lowest unoccupied molecular orbitals (HOMO and LUMO) of $M(Pc)_2$.[16,17] The LUMO of mono(metallophthalocyanines) is doubly degenerate (e_g) and can accept up to four electrons; this is also true for the LUMO of the bis(phthalocyaninato) rare earth compounds. The HOMO of the homoleptic phthalocyaninato double-deckers results from a splitting of the $4a_u$ π-HOMO of the mono(phthalocyanines) due to the interactions between the rings. Thus, in the neutral complexes consisting of a tervalent metal ion sandwiched between (formally) a dianion and an anion radical, the HOMO is semi-occupied. These neutral bis(phthalocyaninato) compounds of tervalent rare earths are thus expected to be reducible by a total of five electrons as confirmed by the above-described electrochemical measurements. This orbital proposal is well supported by the optical properties, especially in the near-IR range of $M(Pc)_2$.[18] The bis(phthalocyaninato) tervalent rare earth complexes

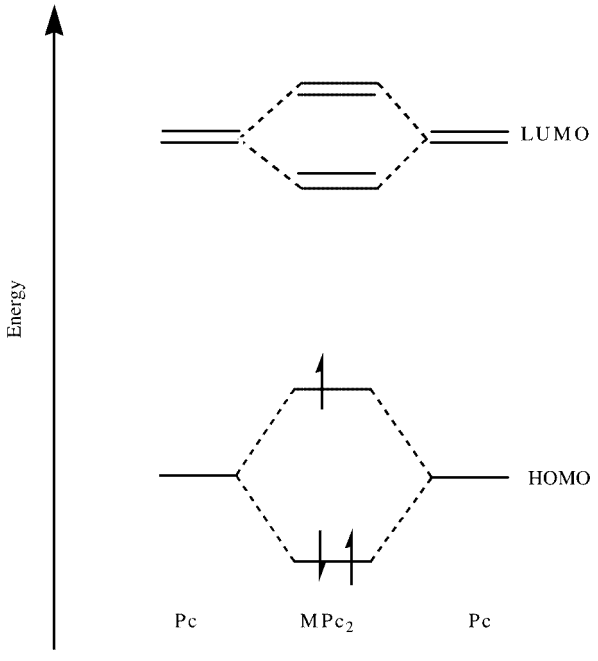

Figure 3. Frontier orbitals of $M(Pc)_2$

are known to be neutral radicals, the HOMO being semi-occupied. The absorption band at ca. 920 nm in the electronic spectrum, which shows an *A*-Faraday-type band in the MCD spectrum, is attributed to the electronic transition from the semi-occupied HOMO to the degenerate LUMO. The absorption to even lower energy at ca. 1400 nm is due to the transition from the second HOMO to the semi-occupied HOMO.[18] This energy represents the extent of electronic coupling between the macrocycles, since the electron correlation energy term vanishes due to the semi-occupation of the HOMO. This absorption band becomes increasingly blue-shifted with the lanthanide contraction, indicating that decreasing rare earth ionic size induces increasing ring-to-ring interaction and more profound splitting between the HOMO and second HOMO of double-deckers (Figure 3), and thus there is an increase in the energy of the HOMO and a decrease in that of the second HOMO. This is why the half-wave potentials of the second oxidation (Oxd_2) are shifted slightly in a more positive direction with decreasing rare earth ion radius, whereas those for the first oxidation and first reduction of $M^{III}(Pc)_2$, Oxd_1 and Red_1, are shifted slightly in the negative direction in the same order.

According to the orbital scheme depicted in Figure 3, $\Delta E^\circ_{1/2}$ (0.34−0.43 V) represents the energy for putting a second electron in the semi-occupied HOMO of the neutral double-decker radical $M(Pc)_2$ or to remove one electron of the two from the HOMO of the reduced double-decker species $[M(Pc)_2]^-$. In other words, it is the energy for pairing the two electrons in the HOMO of $[M(Pc)_2]^-$, and it remains almost unchanged for the whole series of lanthanides. The corresponding energy for removing one electron of the two from the HOMO of $Ce(Pc)_2$, 0.49 V, is slightly higher compared to that for $[M(Pc)_2]^-$ because of the smaller ionic size of the intermediate valence state of cerium and, thus, the more intense ring−ring interaction in $Ce(Pc)_2$. This is also true for substituted bis(phthalocyaninato)cerium complexes (Tables 3 and 4).

Furthermore, the difference of the redox potentials of Red_2 and Red_3 for $M(Pc)_2$ actually corresponds to the potential difference between the first oxidation and first reduction of $[M(Pc)_2]^-$, $\Delta E^{\circ\prime}_{1/2}$. The values range from 1.08 to 1.37 V across the series, and gradually diminish along with decreasing rare earth ion radius, clearly showing a size effect and indicating the enhanced π−π interactions in the double-deckers with smaller lanthanides compared with those connected by larger lanthanides (Table 2). The same general trend is also found for the substituted bis(phthalocyaninato) rare earth analogues $M(TBPc)_2$ and $M(OOPc)_2$ (see Table 4). As the first oxidation step and first reduction step, respectively, involve the HOMO and the LUMO of the molecule, the energy difference between these two redox processes for $[M(Pc)_2]^-$ corresponds to its electrochemical molecular band gap. Thus $\Delta E^{\circ\prime}_{1/2}$ should reflect the energy necessary for the transition of an electron from the HOMO to the LUMO of $[M(Pc)_2]^-$ and therefore should correlate with the lowest energy optical transition in the electronic absorption spectrum of $[M(Pc)_2]^-$. In fact, the diminished

[a] $\Delta E^\circ_{1/2}$ is the energy needed to put a second electron in the semi-occupied HOMO of the neutral double-decker radical $M(OOPc)_2$ or to remove one electron of the two from the HOMO of the reduced double-decker species $[M(OOPc)_2]^-$: $\Delta E^\circ_{1/2} = Oxd_1 - Red_1$. [b] $\Delta E^{\circ\prime}_{1/2}$ is the potential difference between the first oxidation and first reduction processes, i.e. the HOMO−LUMO gap of $[M(OOPc)_2]^-$: $\Delta E^{\circ\prime}_{1/2} = Red_1 - Red_2$. [c] This process involves an intermediate cerium Ce*X* species, where X is between III and IV. [d] Involves a cerium-centered redox process. [e] For $Ce(OOPc)_2$: $\Delta E^\circ_{1/2} = Oxd_2 - Oxd_1$. [f] Recorded by DPV.

trend observed for $\Delta E^{\circ\prime}_{1/2}$ of bis(phthalocyaninato)metal complexes along with the rare earth contraction is in good agreement with the red-shift of the lowest electronic absorption band of $[M(Pc)_2]^-$, 682 nm for M = Sm to 705 nm for M = Lu, along with the same order.

The cerium double-decker is particularly interesting because of its anomalous electrochemical and spectroscopic properties. As indicated by electronic absorption, Raman and ^1H NMR studies, both phthalocyanine rings seem to exist as dianions in bis(phthalocyaninato)cerium, $Ce(Pc^{2-})_2$, while the valence state of the cerium ion appears to be intermediate between III and IV from XNAFS data. This anomaly is due to the strong hybridization of the 4f orbital of cerium with the π orbitals of conjugated phthalocyanine ligands.[19] The CV and DPV studies of $Ce(Pc^{2-})_2$ show five distinct redox waves that represent quasi-reversible single-electron processes. The second and third reduction peaks at −1.10 and −1.31 V, respectively, are related to the successive addition of electrons to the ligand-based orbitals that are represented by the redox states $[Ce(Pc)_2]^-/[Ce(Pc)_2]^{2-}$ and $[Ce(Pc)_2]^{2-}/[Ce(Pc)_2]^{3-}$, in which the cerium ion seems to be tervalent, because both potentials correspond with those of the rest of the series $M^{III}(Pc)_2$ [M ≠ Ce] (Table 2 and Figure 2). The anomalous reduction wave at +0.09 V thus appears to be metal-centered: $[Ce^{III}(Pc^{2-})_2]^-/[Ce^X(Pc^{n-})_2]$, where X is between III and IV, and *n* is an average formal charge such as to maintain the required net charge.[19] The anomalous (with respect to the other lanthanides) electronic structure of cerium and the strong hybridization of the 4f orbitals with the ligand orbitals make the metal-centered redox process (here either the addition, or the removal, of one electron to, or from, a 4f orbital of the cerium ion) dependent on the nature of the phthalocyanine rings. Therefore, the half-wave potential of the cerium-based redox process for $Ce(Pc)_2$ differs from that for $Ce(TBPc)_2$ and $Ce(OOPc)_2$ [Tables 3 and 4 (see below)], following the logical order 0.09, −0.03, −0.18 as the ligands become more electron-donating and thus the metal centre becomes harder to reduce. The first and second oxidation processes at +0.55 and +1.04 V for $Ce(Pc)_2$ involve successive removal of electrons from the ligand-based HOMO that are represented by the redox states: $[Ce^X(Pc)_2]/[Ce^X(Pc)_2]^+$ and $[Ce^X(Pc)_2]^+/[Ce^X(Pc)_2]^{2+}$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(in which again a fractional average formal charge must be assigned to the ligands to maintain the overall charge). The cerium ion in these redox states has the same formal charge as in $[Ce(Pc)_2]^0$ because both potentials deviate significantly from the linear relationship established between the potentials of corresponding redox processes, actually the first reduction and first oxidation of $M^{III}(Pc)_2$, and the rare earth ion radii (Table 2 and Figure 2).

Electrochemical Characteristics of Bis[3(4),12(13),21(22),30(31)-tetra-*tert*-butylphthalocyaninato] Rare Earth Complexes $M(TBPc)_2$ (M = Y, La...Lu except Pm)

The bis[3(4),12(13),21(22),30(31)-tetra-*tert*-butylphthalocyaninato] rare earth complexes $M(TBPc)_2$, which are substituted by four *tert*-butyl groups on the periphery of each phthalocyanine macrocycle, are actually a mixture of isomers, all of which seem to have the same electrochemical properties. This has been confirmed by the electrochemical behavior of other bis(phthalocyaninato)lutetium or bis(naphthalocyaninato) rare earth compounds, tetrasubstituted on the periphery of each (na)phthalocyanine ring.[4c,9c]

Similar to the unsubstituted analogues, CV and DPV have revealed two ligand-centered quasi-reversible one-electron oxidations and up to four ligand-centered quasi-reversible one-electron reductions for $M^{III}(TBPc)_2$. The incorporation of the four electron-donating *tert*-butyl groups onto each phthalocyanine ring makes the compounds easier to oxidize and harder to reduce. This is well demonstrated by the lower oxidation and reduction half-wave potentials of the corresponding redox processes of $M(TBPc)_2$ compared with those of $M(Pc)_2$ (Table 3 and Figure 4). The cathodic shift of all the processes means that only four reductions were observed for $M(TBPc)_2$. The fifth reduction process observed for $M(Pc)_2$ under the same experimental conditions could not be seen. This is also the case for $M(OOPc)_2$ as discussed below. Moreover, since these *tert*-butyl-substituted bis(phthalocyaninato) rare earth complexes are more soluble in alkyl halides such as CH_2Cl_2 compared with $M(Pc)_2$, the measurement of their properties in solution is more favorable. This is verified by the improved resolution of the redox couples in most of the voltammograms. Figure 4 displays the CV and DPV diagrams of $Ce(TBPc)_2$, in which the sensitivity is seen to be better than for $M(Pc)_2$.

The dependence of the half-wave potentials of the redox processes on the ionic size of the central rare earth ion is similar for $M(TBPc)_2$ to that for $M(Pc)_2$ (Table 3). While the half-wave potentials of the second, third and fourth reductions of $M(TBPc)_2$ are independent of the size of the central rare earth ions, the potentials for the second and first oxidations and first reduction are size-sensitive, but the opposite slope is observed for the first process compared with the other two.

The small electron-pairing energy for $M(TBPc)_2$, $\Delta E^\circ_{1/2}$ (0.38−0.46 V), which corresponds well with those of corresponding $M(Pc)_2$ and $M(OOPc)_2$ (see below), indicates that

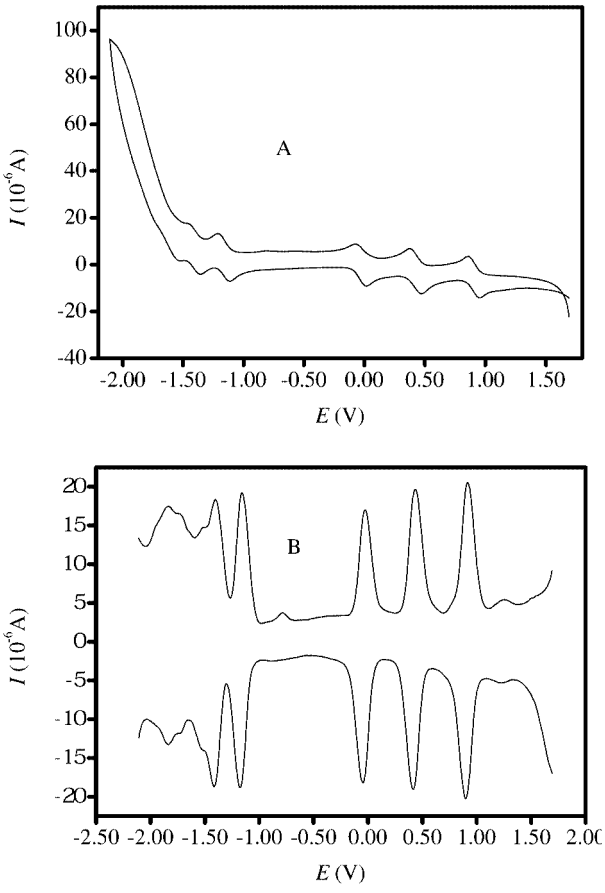

Figure 4. CV (A) and DPV (B) of $Ce(TBPc)_2$ in CH_2Cl_2 containing 0.1 M $[Bu_4N][ClO_4]$ at scan rates 20 and 10 mV s^{-1}, respectively

these substituted bis(phthalocyaninato) rare earth compounds should be good potential molecular semi-conductors, as expected for their unsubstituted analogues. Due to their increased solubility in common organic solvents, by virtue of the *tert*-butyl groups, these compounds would be more easily fabricated into electronic devices by solution fabrication methods. The similar $\Delta E^\circ_{1/2}$ values for $M(TBPc)_2$ to those of the unsubstituted counterparts indicates that the pairing energy in the HOMO of $[M(TBPc)_2]^-$ is quite similar to that for the HOMO of $[Mc(Pc)_2]^-$ although the redox potentials of the first oxidation and first reduction processes of $M(TBPc)_2$ shift cathodically due to the introduction of electron-donating *tert*-butyl groups. This is also true for $M(OOPc)_2$.

Furthermore, according to the decreasing $\Delta E^{\circ\prime}_{1/2}$ value of $M(TBPc)_2$ with decreasing rare earth ionic radius (Table 3), a red-shift in the lowest energy band of reduced tetra-*tert*-butyl-substituted bis(phthalocyaninato) rare earth compounds $[M(TBPc)_2]^-$ (M = Sm...Lu) should be expected to follow in the same order. In fact, the lowest energy band for $[M(TBPc)_2]^-$ shifts from 688 nm for M = Sm to 714 nm for M = Lu. This is also true for $[M(OOPc)_2]^-$.[9d]

As clearly shown in the CV and DPV spectra of $Ce(TBPc)_2$ (Figure 4) and on the basis of comparison between the electrochemical data of $Ce(TBPc)_2$ and those of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$M^{III}(TBPc)_2$ (Table 3), the same Ce redox states apply here as for $Ce(Pc)_2$ [and also for $Ce(OOPc)_2$ (Table 4)].

Electrochemical Characteristics of Bis[3,4,12,13,21,22,30,31-octakis(octyloxy)phthalocyaninato] Rare Earth Complexes $M(OOPc)_2$ (M = Y, La...Lu Except Pm)

Very similar electrochemical behavior to that of $M(Pc)_2$ and $M(TBPc)_2$ has been revealed by CV and DPV methods for bis[3,4,12,13,21,22,30,31-octakis(octyloxy)phthalocyaninato] rare earth complexes $M(OOPc)_2$ (Table 4). The introduction of eight octyloxy groups, which are more electron-donating than the four *tert*-butyl groups, means that the double-deckers $M(OOPc)_2$ become easier to oxidize and harder to reduce, therefore showing lower first and second oxidation potentials and more negative first, second and third reduction potentials than the corresponding analogues $M(TBPc)_2$. Due to the additional shift of corresponding redox processes of $M(OOPc)_2$ to a more negative direction than those of $M(TBPc)_2$, only three reduction processes were observed within the electrochemical window of CH_2Cl_2 for the former. Under similar experimental conditions, only one one-electron oxidation and two one-electron reductions were observed by Takahashi[4d] for the butyloxy-substituted bis(phthalocyaninato) rare earth analogues $M(OBPc)_2$ (M = Yb, Lu).

As can be seen from Table 4, discussion for $Ce(OOPc)_2$ is prevented due to the failure to record the half-wave potential for the second reduction process by either CV or DPV.

Conclusions

The five quasi-reversible one-electron reductions observed within the electrochemical window of CH_2Cl_2 for the unsubstituted bis(phthalocyaninato) rare earth complexes $M^{III}(Pc)_2$ (M ≠ Ce, Pm, Yb, Lu) demonstrate again that the LUMO of bis(phthalocyaninato) rare earth compounds is doubly degenerate and can accept up to four electrons, while the HOMO of the bis(phthalocyaninato) tervalent rare earth complexes is semi-occupied and can accept one electron. However, only three and four quasi-reversible one-electron reductions were observed for $M^{III}(OOPc)_2$ and $M^{III}(TBPc)_2$, respectively, under the same experimental conditions, due to the shift of corresponding redox potentials in a negative direction induced by the introduction of electron-donating octyloxy or *tert*-butyl groups. As usual, the Ce complexes are exceptional due to the unique oxidation state of the central metal ion. One cerium-centered redox wave could easily be distinguished from the CV and DPV diagrams of these three bis(phthalocyaninato)cerium compounds. Systematic studies of the electrochemical characteristics of unsubstituted, tetra-*tert*-butyl- and octakis-(octyloxy)-substituted bis(phthalocyaninato) complexes of the whole tervalent lanthanide series clearly indicate that the half-wave potentials, in particular the first oxidation and first reduction processes, are all metal-ion-size-dependent. The change in the half-wave potentials of these redox processes is apparently due to stronger inter-ligand interactions and generally tighter bonding as the metal ion radius contracts across the series. In the next paper in this series the corresponding data for heteroleptic tris(phthalocyaninato) rare earth(III) triple-deckers are reported and analyzed.[20]

Experimental Section

Homoleptic bis(phthalocyaninato) rare earth double-decker compounds $M(Pc)_2$, $M(OOPc)_2$ and $M(TBPc)_2$ were prepared according to published procedures.[9d,14,21] CV and DPV measurements were carried out with a BAS CV-50 W voltammetric analyzer. The cell consists of inlets for a glassy carbon disk working electrode (2.0 mm diameter) and a silver-wire counter electrode. The reference electrode was Ag/Ag^+ connected to the solution by a Luggin capillary whose tip was placed close to the working electrode. Results are corrected for junction potentials by being referenced internally to the ferrocenium/ferrocene (Fe^+/Fe) couple [$E_{1/2}(Fe^+/Fe) = +0.50$ V vs. SCE]. The potentials in this paper are referenced to the SCE. Typically, a 0.1 M solution of $[Bu_4N][ClO_4]$ in CH_2Cl_2 containing 0.5 mM sample was purged with nitrogen for 10 min; the voltammograms were then recorded at ambient temperature with scan rates of 20 and 10 mV/s for CV and DPV, respectively.

Electrochemistry of Heteroleptic Tris(phthalocyaninato) Rare Earth(III) Complexes

Peihua Zhu,[a] Na Pan,[a] Changqin Ma,[a] Xuan Sun,[a] Dennis P. Arnold,*[b] and Jianzhuang Jiang*[a,c]

Keywords: Phthalocyanines / Sandwich complexes / Rare earths / Electrochemistry

The electrochemical characteristics of a series of heteroleptic tris(phthalocyaninato) complexes with identical rare earths or mixed rare earths (Pc)M(OOPc)M(OOPc) [M = Eu...Lu, Y; H_2Pc = unsubstituted phthalocyanine, H_2(OOPc) = 3,4,12,13,21,22,30,31-octakis(octyloxy)phthalocyanine] and (Pc)Eu(OOPc)Er(OOPc) have been recorded and studied comparatively by cyclic voltammetry (CV) and differential pulse voltammetry (DPV) in CH_2Cl_2 containing 0.1 M tetrabutylammonium perchlorate (TBAP). Up to five quasi-reversible one-electron oxidations and four one-electron reductions have been revealed. The half-wave potentials of the first, second and fifth oxidations depend on the size of the metal center, but the fifth changes in the opposite direction to that of the first two. Moreover, the difference in redox potentials of the first oxidation and first reduction for (Pc)M(OOPc)M(OOPc), 0.85–0.98 V, also decreases linearly along with decreasing rare earth ion radius, clearly showing the rare earth ion size effect and indicating enhanced π–π interactions in the triple-deckers connected by smaller lanthanides. This order follows the red-shift seen in the lowest energy band of triple-decker compounds. The electronic differences between the lanthanides and yttrium are more apparent for triple-decker sandwich complexes than for the analogous double-deckers. By comparing triple-decker, double-decker and mononuclear [Zn^{II}] complexes containing the OOPc ligand, the HOMO–LUMO gap has been shown to contract approximately linearly with the number of stacked phthalocyanine ligands.

Introduction

Bis(phthalocyaninato) rare earth sandwich complexes have been extensively studied for potential applications in electronic devices.[1,2] The electrochemical properties of bis(phthalocyaninato) rare earth compounds have been systematically investigated from the viewpoint of electrochromic displays and to understand the nature of π−π interactions in the molecules.[3−5] Recently, triple-decker (na)phthalocyaninato rare earth analogues have aroused interest for the same reasons.[6−9] The expected relatively weaker electronic interaction in triple-deckers, which have a larger ring-to-ring separation than the double-decker analogues, has been revealed by spectroscopic studies. In 1986, Kasuga isolated traces of $Y_2(Pc)_3$ as a side-product in preparing double-decker $Y(Pc)_2$ and confirmed its triple-decker nature by mass spectrometry.[7a] Since 1993, Takahashi developed a new synthetic route for preparing homoleptic substituted tris(phthalocyaninato) rare earth compounds $M_2(OBPc)_3$ (M = La, Dy, Yb, Lu) using the reaction between free base phthalocyanine H_2(OBPc) and rare earth salt $M(OAc)_3{\cdot}nH_2O$[7b,7c] (for abbreviations of ligands, see Table 1). L'Her has detailed the synthesis, characterization, and electrochemical behavior of the tris(1,2-naphthalocyaninato)dilutetium compound $Lu_2(1,2\text{-Nc})_3$.[8] Ishikawa and co-workers have prepared homoleptic and heteroleptic

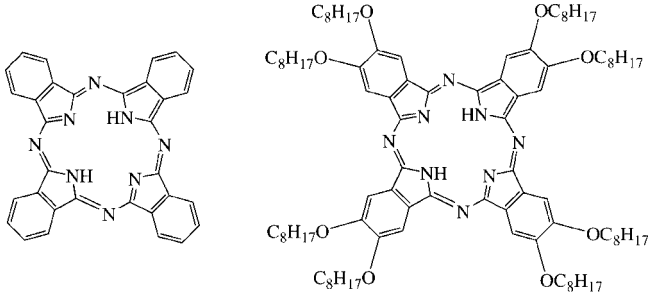
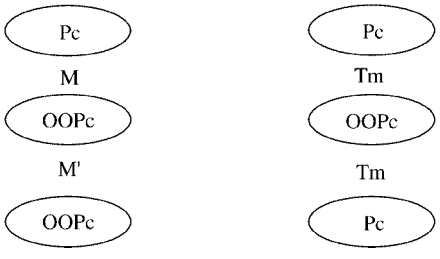
phthalocyaninato triple-decker complexes $Lu_2(Pc)_3$ and (Pc)Lu[Pc(15C5)$_4$]Lu(Pc) and studied their electronic absorption and MCD spectra.[9] Our group have reported a novel, versatile route for preparing a series of heteroleptic phthalocyaninato rare earth triple-deckers containing unsubstituted phthalocyaninato and 2,3,9,10,16,17,23,24-octakis(octyloxy)phthalocyaninato (OOPc) ligands[6a] and have systematically studied their NMR properties.[6b] Using a similar synthetic methodology, Ishikawa has prepared a series of similar heteroleptic tris(phthalocyaninato) rare earth compounds (Pc)M(Pc)M′(OBPc) (M =/≠ M′ = Tb, Dy, Ho, Er, Tm, Yb, Y) and studied the interaction between the f-electronic systems and phthalocyanine ligands in the dinuclear complexes of paramagnetic tervalent lanthanide ions as well as the f−f interactions between the metal ions by magnetic measurements.[10a,10b] However, of the reported triple-decker tris[(na)phthalocyaninato] rare earth compounds only five, $M_2(OBPc)_3$ (M = La, Dy, Yb, Lu)[7b,7c] and $Lu_2(1,2\text{-}Nc)_3$,[8b] have been investigated by electrochemical methods. The ring-to-ring interaction in these triple-decker molecules is worthy of systematic study from both theoretical and experimental viewpoints. We report here the electrochemical properties of a series of heteroleptic phthalocyaninato rare earth triple-decker complexes (Pc)M(OOPc)M(OOPc) (M = Eu...Lu, Y) and (Pc)Tm(OOPc)Tm(Pc) (Scheme 1) by cyclic voltammetry (CV) and differential pulse voltammetry (DPV). For comparison, the electrochemistry of the substituted (phthalocyaninato)zinc complex Zn(OOPc) and double-decker rare earth compounds $M(Pc)_2$ and $M(OOPc)_2$ are also discussed. The latter two series and the analogues $M(TBPc)_2$ feature in our previous paper.[5]





Scheme 1. Phthalocyanine ligands and schematic diagram of heteroleptic tris(phthalocyaninato) rare earth complexes (Pc)M(OOPc)M′(OOPc) (M = M′ = Eu...Lu, Y; M = Eu, M′ = Er) and (Pc)Tm(OOPc)Tm(Pc)

Results and Discussion

The electrochemical behavior of the triple-decker complexes together with monomeric Zn(OOPc) was investigated by cyclic voltammetry (CV) and differential pulse voltammetry (DPV) in CH_2Cl_2. While the monomeric compound Zn(OOPc) undergoes two reversible to quasi-reversible one-electron oxidations and two reversible to quasi-reversible one-electron reductions, the triple-decker compounds display up to five one-electron oxidations and up to four one-electron reductions within the electrochemical window of CH_2Cl_2 under the conditions employed. The reduction and oxidation peak potentials for each process are 60−90 mV apart. Since the oxidation state of the central zinc and tervalent rare earth ions in monomeric and triple-decker complexes, respectively, do not change, these processes are attributed to the successive removal, or addition, of one electron from, or to, the ligand-based orbitals of the redox states (Scheme 2). Oxidations are labeled Oxd_1 to Oxd_5 and the reductions Red_1 to Red_4. The half-wave redox potentials vs. SCE are summarized in Table 2. Representative cyclic voltammograms and differential pulse voltammograms for (Pc)Tm(OOPc)Tm(OOPc) are displayed in Figure 1. The observation of up to five cationic states for these triple-deckers supports the proposal of Lindsey that they are potential molecular materials for information storage.[11]

Our observations of the electrochemistry of these heteroleptic triple-deckers in CH_2Cl_2 differ slightly from those reported for homoleptic tris(phthalocyaninato) rare earth analogues.[7b,7c] For instance, up to four oxidation and three reduction processes were observed for $M_2(OBPc)_3$ in CH_2Cl_2 containing $TBAPF_6$.[7b,7c] However, under our experimental conditions, we observed two more oxidation states in some cases, particularly by DPV. Figure 2 shows the variation of the redox potentials of (Pc)M(OOPc)M(OOPc) with the ionic radius of the rare earth metal center. While the half-wave potentials of the third and fourth oxidations of (Pc)M(OOPc)M(OOPc) remain virtually unchanged, the half-wave potentials of the first, second and fifth oxidations of these triple-deckers correlate linearly with the ionic size of the rare earth metal center (Figure 2 and Table 2). The half-wave potentials of the first and second oxidations shift slightly in the cathodic direction with decreasing rare earth ion radius, while those of the fifth oxidation shift in the opposite direction.

As with bis(phthalocyaninato) rare earth compounds,[5] in the tris(phthalocyaninato) rare earth triple-decker molecules the close proximity of the three conjugated π-systems in a face-to-face configuration splits the doubly degenerate LUMO (e_g) and HOMO ($4a_u$) molecular orbitals derived from monophthalocyanines. This results in three pairs of doubly degenerate unoccupied frontier molecular orbitals (the bonding LUMO, second non-bonding LUMO and third anti-bonding LUMO) and three non-degenerate occupied frontier orbitals (the third bonding HOMO, second non-bonding HOMO and first anti-bonding HOMO) in the triple-deckers. The splitting of the filled MOs, actually the splitting between the first HOMO and second HOMO as

[a] $\Delta E°_{1/2}$ is the potential difference between the first oxidation and first reduction processes, i.e. the HOMO−LUMO gap of corresponding molecules, namely (Pc)M(OOPc)M(OOPc), (Pc)Tm(OOPc)Tm(Pc) and Zn(OOPc). [b] Recorded by DPV. [c] (Pc)Eu(OOPc)Er(OOPc). [d] (Pc)Tm(OOPc)Tm(Pc). [e] Zn(OOPc).

well as the second HOMO and third HOMO of triple-decker, increases with the lanthanide contraction due to the increase in the ring-to-ring interaction. Therefore, there is an increase in the energy of the anti-bonding HOMO and a corresponding decrease in the energy of the third bonding HOMO in the same order, but no change in the energy of the non-bonding second HOMO. This is why the half-wave potentials of the first and second oxidations (Oxd_1 and Oxd_2) dealing with the first anti-bonding HOMO are shifted slightly to a more negative direction with decreasing rare earth radius, and those for the fifth oxidation of (Pc)M(OOPc)M(OOPc) (Oxd_5) involving the third bonding HOMO are shifted slightly in the positive direction, in the same order. Conversely, those for the third and fourth oxidations, which are related to the second non-bonding HOMO, are essentially unchanged. This proposal is also well supported by the optical properties of (Pc)M(OOPc)M(OOPc). Previous studies have revealed that the lowest energy electronic absorption band at 683−714 nm in the electronic spectra of triple-decker tris(phthalocyaninato) rare earth complexes (Pc)M(OOPc)M(OOPc) (M = Pr...Tm), which involves the electronic transition from the HOMO to the degenerate LUMO, is red-shifted with decreasing rare earth ionic size.[5] It is noteworthy that the first and second oxidation (HOMO-related) potentials of tris(phthalocyaninato) rare earth compounds depend in a similar way on the rare earth ionic size as do the first reduction and first oxidation (also involving the HOMO) of their double-decker counterparts. However, the sensitivity to ionic size is significantly less for the triple-deckers due to their larger inter-ring distances.[3−5]

The half-wave potentials of all the *reductions* for (Pc)M(OOPc)M(OOPc) appear to reveal no systematic trends with ionic size. These results also correspond well with those obtained for the bis(phthalocyaninato) rare earth double-deckers.[3−5]

The redox behavior of the heterodinuclear compound (Pc)Eu(OOPc)Er(OOPc) was also examined by CV and DPV, and parallels those of its counterparts with two identical metals (Table 2). The redox potentials, especially those involving the HOMO and LUMO of (Pc)Eu(OOPc)-Er(OOPc), i.e. the first and second oxidations and the first and second reductions, fit the linear correlation seen between the redox potentials and ionic radii for complexes with identical metals if the mean ionic radius of Eu and Er is employed. This corresponds well with the results of Weiss and co-workers on the electrochemistry of mixed (phthalocyaninato)(porphyrinato) rare earth triple-decker complexes containing mixed or identical rare earth metals, clearly indi-

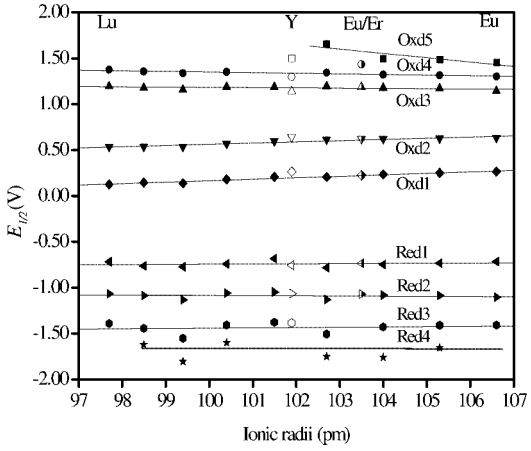

Figure 2. Half-wave potentials of redox processes of (Pc)M(OOPc)M(OOPc) (M = Eu...Lu) as a function of the ionic radius of M^{III}

cating the involvement of all three phthalocyanine rings in the frontier molecular orbitals of heteroleptic tris(phthalocyaninato) rare earth compounds.[12]

The potential difference between the first oxidation and first reduction, $\Delta E^\circ_{1/2}$, for all these triple-decker compounds (Pc)M(OOPc)M(OOPc) (M = Eu...Lu) spans the relatively narrow range 0.85−0.99 V, which corresponds well with results for $M_2(OBPc)_3$ (M = Dy, Yb, Lu)

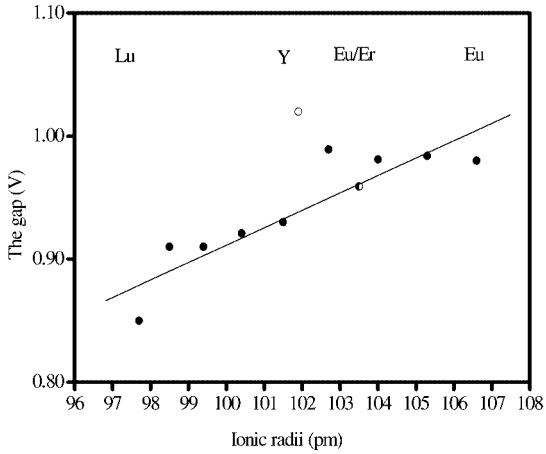

Figure 3. HOMO−LUMO gap between the half-wave potentials of the first oxidation and first reduction of (Pc)M(OOPc)M(OOPc) as a function of the ionic radius of M^{III}

(0.98−1.09 V)[7b,7c] and $Lu_2(1,2\text{-Nc})_3$[8b] (0.86 V). Figure 3 shows this potential gap for (Pc)M(OOPc)M(OOPc) as a function of the tervalent rare earth ionic radii. Clearly, the difference between the first oxidation and first reduction processes for (Pc)M(OOPc)M(OOPc) decreases more or less linearly with decreasing rare earth ion size. The clear outlier (Pc)Y(OOPc)Y(OOPc) is not unexpected as yttrium is not an f-series lanthanide, and so its interaction with the π orbitals of conjugated tetrapyrrole ligands is fundamentally different. Electrochemical investigations of a series of rare earth *double-decker* compounds with different tetrapyrrole ligands in either neutral or reduced form, namely $[M(Pc)_2]^-$ [3,4] and $M(Pc')_2$ (Pc′ = Pc, TBPc, OOPc),[5] $M(TBNc)_2$,[13] M(TPP)(Pc)[14] M(OEP)(Nc),[15] and $M(OEP)_2$,[16] have found that the gap between the first oxidation and the first reduction potentials of the monoanionic reduced form of all these tetrapyrrole double-deckers decreases linearly with the lanthanide contraction. The deviation for yttrium double-decker compounds $[Y(Pc')_2]^-$ (Pc′ = Pc, TBPc, OOPc) is not so obvious as in the triple-decker series studied here. This is due to the magnifying effects of the f−f interaction between the metal centers in the lanthanide triple-deckers. Of course, such interaction is absent for yttrium, so a large deviation is not unexpected.

As $\Delta E^\circ_{1/2}$ (Oxd_1 − Red_1), representing the electrochemical HOMO−LUMO gap, reflects the interactions among the tetrapyrrole rings in the sandwich molecules, the decrease in $\Delta E^\circ_{1/2}$ (Oxd_1 − Red_1) with the lanthanide contraction clearly suggests enhanced ring−ring interactions in the same order. This view is strongly supported as the HOMO−LUMO gap for the mixed-metal complex (Pc)Eu(OOPc)Er(OOPc) lies between those of the compounds with two identical metals (Pc)Eu(OOPc)Eu(OOPc) and (Pc)Er(OOPc)Er(OOPc) (Table 2 and Figure 3).

Furthermore, the electrochemical data for triple-deckers (Pc)M(OOPc)M(OOPc) and the mononuclear compound Zn(OOPc), together with those of the double-deckers $M(Pc)_2$ and $M(OOPc)_2$ obtained previously, render it pos-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sible to compare the effect of the extension of the π-networks along an axis perpendicular to the phthalocyanine plane. It must be pointed out that in the neutral double-decker species $M(Pc')_2$ (Pc′ = Pc, OOPc), one of the two Pc′ rings is a monoanion radical ($Pc'^{\cdot -}$), therefore the reduced double-decker species $[M(Pc')_2]^-$ (Pc′ = Pc, OOPc) should be considered for comparison with the monomeric Zn(OOPc) and triple-decker (Pc)M(OOPc)M(OOPc), so that all the phthalocyanine rings are in the dianionic form Pc'^{2-}.[8b] Comparison of the HOMO−LUMO gap for (Pc)M(OOPc)M(OOPc) (M = Eu...Lu), 0.85−0.98 V, with that of 1.08−1.37 V for $[M(Pc)_2]^-$ (M = La...Lu) or 1.13−1.40 V for $[M(OOPc)_2]^-$ (La...Lu) from our previous work[5] and 1.64 V for Zn(OOPc) makes it clear that the extension of the bonding over more phthalocyanine rings has an obvious effect on the MO levels. Zn(OOPc) is used as a comparable representative mononuclear complex as its gap is the same as that for Lu(1,2-Nc)(OAc);[8b] likewise the gap for $[Lu(1,2\text{-}Nc)_2]^-$ lies in the range for our double-decker anions, and that for $Lu_2(1,2\text{-}Nc)_3$ is in the range for our triple-deckers.[8b] For a qualitative comparison, it therefore seems appropriate to use the Zn complex, and thus avoid recording the full series of mononuclear rare earth complexes. The increase in the number of macrocycles in the face-to-face stack from monomer to triple-decker via double-decker induces important modifications in the orbital systems of these complexes, manifested in the decrease in the HOMO−LUMO gap (Figure 4). Further axial extension of delocalization of the stacked π-conjugated molecules is therefore predicted to lead to corresponding molecular materials with narrower HOMO−LUMO gaps. According to Simon,[17] the potential difference between the first oxidation and first reduction processes, $\Delta E^\circ_{1/2}$, allows the prediction of electrical properties such as the thermal activation energy for the conduction process of the condensed phases derived from the corresponding molecular precursors. Therefore one can reasonably expect further improved electrical properties of stacked π-conjugated phthalocyanine-derived molecular systems, i.e. sandwich-type

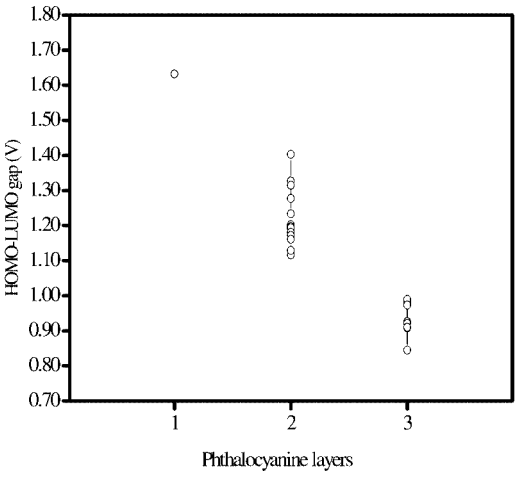

Figure 4. HOMO−LUMO gap of Zn(OOPc), $[M(OOPc)_2]^-$ (M = La...Lu; OOPc) and (Pc)M(OOPc)M(OOPc) (M = Eu...Lu) as a function of the number of phthalocyanine layers

(phthalocyaninato)metal oligomers or polymers, compared with those of double- and triple-deckers. So far no higher oligomers linked by metal ion connectors have been isolated, only systems linked by various axial ligands.[18]

CV and DPV studies revealed that (Pc)Tm(OOPc)-Tm(Pc), which is a representative of a series of more symmetrical heteroleptic tris(phthalocyaninato) rare earth compounds, also undergo five quasi-reversible one-electron oxidations and four quasi-reversible one-electron reductions (Table 2). In comparison with (Pc)Tm(OOPc)Tm(OOPc), the symmetrical compound clearly undergoes oxidations less readily, as shown by the higher oxidation potentials, whereas the reductions occur more readily, both effects being due to the incorporation of only one electron-rich OOPc ring in the molecule. However, the difference between the first oxidation and first reduction potentials of (Pc)Tm(OOPc)Tm(Pc), 0.97 V, is very similar to the 0.91 V for (Pc)Tm(OOPc)Tm(OOPc) and still lies in the range for the (Pc)M(OOPc)M(OOPc) series, indicating similar π−π interactions in the two series. Similar results have also been observed for heteroleptic and homoleptic bis(phthalocyaninato) rare earth compounds containing substituted phthalocyanine ring(s), namely M(Pc)(Pc*)[19] and $M(Pc^*)_2$ (Pc* = TBPc,[5,19a] OOPc,[5] OPPc,[19b] OHPc[19b]) when compared with the electrochemical properties of $M(Pc)_2$.[3−5]

Conclusions

Systematic studies of the electrochemical characteristics of heteroleptic tris(phthalocyaninato) rare earth complexes (Pc)M(OOPc)M(OOPc) have revealed that these compounds can undergo up to five quasi-reversible one-electron oxidations and up to four quasi-reversible one-electron reductions within the electrochemical window of CH_2Cl_2. The half-wave potentials of the first and second oxidations for these tervalent rare earth triple-deckers are metal-ion-size-dependent; the oxidations become easier with decreasing lanthanide ion size. Comparison among triple-deckers (Pc)M(OOPc)M(OOPc), reduced double-deckers $[M(Pc')_2]^-$ (Pc′ = Pc, OOPc)[5] and mononuclear Zn(OOPc) shows that the HOMO−LUMO gap is decreased by extension of the delocalized bonding along the axis perpendicular to the macrocycle plane.

Experimental

The monomeric (phthalocyaninato)zinc compound Zn(OOPc)[20] and heteroleptic phthalocyaninato rare earth triple-decker complexes (Pc)M(OOPc)M(OOPc) (M = Eu...Lu, Y), (Pc)Eu(OOPc)Er(OOPc), and (Pc)Tm-(OOPc)Tm(Pc) were prepared according to published procedures.[6a] Cyclic voltammetry (CV) and differential pulse voltammetry (DPV) were carried out with a BAS CV-50 W voltammetric analyzer. The cell consists of inlets for a glassy carbon disk working electrode (2.0 mm in diameter)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and a silver-wire counter electrode. The Ag/Ag^+ reference electrode was connected to the solution by a Luggin capillary whose tip was placed close to the working electrode. Results were corrected for junction potentials by being referenced internally to the ferrocenium/ferrocene (Fe^+/Fe) couple [$E_{1/2}(Fe^+/Fe)$ = 0.50 V vs. SCE]. Potentials in this paper are referenced to the SCE. Typically, a 0.1 M solution of $[Bu_4N][ClO_4]$ in CH_2Cl_2 containing 0.5 mM of sample was purged with nitrogen for 10 min, and then the voltammograms were recorded at ambient temperature. The scan rate was 20 and 10 $mV \cdot s^{-1}$ for CV and DPV, respectively.

Cyclopentadienyl Ru^{II} Complexes as Highly Efficient Catalysts for the *N*-Methylation of Alkylamines by Methanol

Alessandro Del Zotto,*[a] Walter Baratta,[a] Mauro Sandri,[a] Giancarlo Verardo,[a] and Pierluigi Rigo[a]

Keywords: Homogeneous catalysis / Ruthenium / Amines / *N*-methylation / Imines

The ruthenium(II) half-sandwich complex [RuCl(η^5-C_5H_5)(PPh_3)$_2$] (**1**) catalyses the reaction between methanol and alkylamines RNH_2 or R^1R^2NH to afford $RN(CH_3)_2$ and $R^1R^2NCH_3$ products, respectively. The reaction is quantitative and generally fast, at the methanol reflux temperature, for a wide spectrum of substrates. Starting from primary amines, the stepwise formation of $RN{=}CH_2$, $RNHCH_3$, and $RN(CH_3)_2$ has been observed. Both PPh_3 and Cl^- dissociation from **1** are key-steps in forming the effective catalytic species. The catalytic activity of several half-sandwich neutral or cationic complexes (**2**–**15**) related to **1** is also discussed.

Introduction

The efficient *N*-alkylation of primary or secondary amines by alcohols is an important synthetic route, the main advantage of which is that water is the only side-product. Thus, the reaction between amines and alcohols has been investigated in detail, particularly using homogeneous catalysts based on late transition metals;[1−12] those based on ruthenium have been the most widely investigated, including the ruthenium(II) complexes [$RuCl_2(PPh_3)_3$],[1,3,5−12] [$RuH_2(PPh_3)_4$],[2,4,5−7] [$RuHCl(CO)(PPh_3)_3$],[5,11] [$RuBr_2(PPh_3)_3$],[6] [$RuHCl(PPh_3)_3$],[6] [$RuH_2\{P(OEt)_3\}_4$],[7] [$RuCl_2(CO)_2(PPh_3)_2$],[8] [$RuCl_2(P{-}N)_2$],[8] (P−N = *o*-diphenylphosphanyl-*N*,*N*-dimethylaniline) [$RuH_2(CO)(PPh_3)_3$],[11] [$\{RuCl_2(\eta^5\text{-}C_5Me_5)\}_2$],[11] as well as those bearing terdentate NPN or NN′N type ligands,[12] the ruthenium(0) derivatives [$Ru(CO)_3(PPh_3)_2$],[5] [$Ru_3(CO)_{12}$],[11] and [Ru(cot)(cod)],[11] and, finally, "in situ" generated systems [$RuCl_3$/phosphane[6,7] or $RuCl_3/P(OR)_3$[6,7]] exhibit catalytic activity in the *N*-alkylation of amines by alcohols. Although the reaction is commonly performed in an autoclave at 120−215 °C, long reaction times are often required to obtain high yields of products.

During our studies[13−18] on the catalytic potential of the half-sandwich ruthenium(II) complex [RuCl(η^5-C_5H_5)(PPh_3)$_2$] (**1**), we found evidence that this readily available compound efficiently catalyses the *N*-methylation of both primary and secondary alkylamines by methanol, under milder conditions than previously reported for other ruthenium systems. Owing to the promising preliminary results obtained with **1**, we extended the investigation to a broad spectrum of half-sandwich ruthenium(II) complexes. In addition, as the *N*-alkylation of amines by alcohols is thought to proceed via an imine intermediate, which is then reduced to amine by a transfer hydrogenation process, useful information on the reduction of the C=N bond by transfer hydrogenation, a process of considerable importance, could also be obtained. The reduction of an imine intermediate is also a key-step in the reductive amination of aldehydes.

The results reported here demonstrate that complex **1** is the most active catalyst so far for the *N*-methylation of alkylamines by methanol.

Results and Discussion

N-Methylation of Amines

The amines employed in this work are shown in Table 1. When a primary (RNH_2) or secondary (R_2NH) alkylamine was refluxed in methanol in the absence of any catalyst, no *N*-methyl derivatives were observed. By contrast, when complex **1** was added to the boiling reaction mixture, the products $RN(CH_3)_2$ and R_2NCH_3, respectively, were quantitatively formed with rates that strongly depend on the nature of the R group. The reactions were carried out, under an argon atmosphere, with 1 mol % catalyst based on amine charged and methanol as solvent at reflux (oil bath 100 °C), with a methanol/amine molar ratio of ca. 100. Under the same experimental conditions, arylamines did not react over a 24 h period. Also, 1,2-ethylendiamine did not react with methanol, most probably owing to its chelation to the metal centre with formation of a catalytically inactive complex.

[a] For each substrate the yield is quantitative. Reaction conditions: T = 100 °C, 1 mol % complex **1**, solvent/amine molar ratio ≥ 100. [b] $t_{1/2}$ indicates the time necessary for the consumption of half of the starting amine.

To compare the reactivity of the various substrates, we chose the time needed to consume half of the starting amine ($t_{1/2}$) as a suitable parameter for both primary and secondary amines. The $t_{1/2}$s (Table 1) indicate that both basicity and steric crowding of the starting amine have an important influence on the reaction rate. No clear general trend was found, but the reaction rate usually increases on increasing the basicity of the substrate. For instance, the reaction rate decreased along the series piperidine (2.88), *N*-methylpiperazine (4.15), and morpholine (5.67) (the pK_bs in water solution are in parentheses). Furthermore, benzylamine, which has the highest pK_b (4.67) of the primary alkylamines examined here, shows the highest $t_{1/2}$. Within the series of *n*-alkyl primary amines ($C_xH_{2x+1}NH_2$; x = 4, 6, 8), whose pK_bs are 3.23, 3.44, 3.35 respectively, $t_{1/2}$ increases considerably on going from *n*-butyl- to *n*-octylamine.

To study in detail the *N*-methylation process promoted by **1**, the reaction between methanol and cyclohexylamine (**I**), chosen as a convenient substrate model, has been monitored by GC-MS (Figure 1). Apparently, the reaction proceeds stepwise (Scheme 1), the starting amine **I** being initially transformed into the imine *cyclo*-$C_6H_{11}-N=CH_2$ (**II**), whose concentration remains rather low (ca. 5 %) and almost constant throughout the reaction. A successive hydrogenation process converts **II** into the *N*-monomethyl derivative **III**, which is in turn transformed into the *N*,*N*-dimethyl product **IV**. For this final step, no intermediates could be detected in solution by GC-MS. The total conversion of **I** into **IV** is quantitative within ca. 6.5 h. The subsequent addition of **I** (100-fold excess with respect to **1**) to the reaction mixture requires about 7 h for its complete conversion into **IV**, indicating that the catalytic efficiency of **1** is maintained.

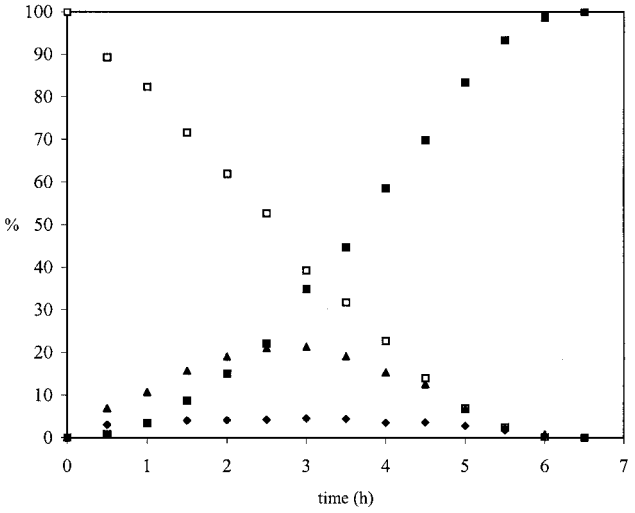

Figure 1. Variation in *cyclo*-$C_6H_{11}NH_2$ **I** (□), *cyclo*-$C_6H_{11}N=CH_2$ **II** (◆), *cyclo*-$C_6H_{11}NHCH_3$ **III** (▲), and *cyclo*-$C_6H_{11}NH(CH_3)_2$ **IV** (■) in the reaction between **I** and CH_3OH, at 100 °C with 1 mol % **1**

The rate of decay of **I** is virtually constant throughout the reaction, and several runs at different initial concentrations of **I** showed that the reaction is zero order for the amine, as reported by Watanabe and co-workers for the reaction between aniline and benzyl alcohol.[5] The effect of reaction time on the methylation of **I** (Figure 1) is similar

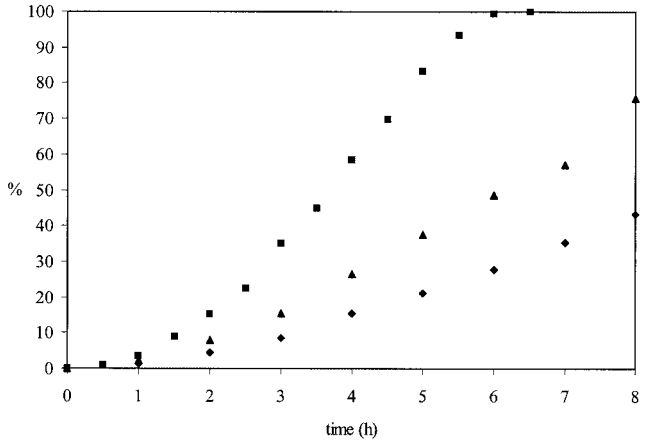

Figure 2. Amount of the product *cyclo*-$C_6H_{11}NH(CH_3)_2$ **IV** in the reaction between *cyclo*-$C_6H_{11}NH_2$ **I** and CH_3OH at 100 °C: with 1 mol % **1** (■); 1 mol % **1** and 5 mol % PPh_3 (▲); 1 mol % **1** and 20 mol % LiCl (◆)

to that reported for the alkylation of aminoarenes with alcohols in the presence of the complexes $[RuCl_2(PPh_3)_3]$[11] and $[RuCl_2(NN'N)(PPh_3)]$[12] {NN′N = $C_5H_3N[CH_2N(CH_3)_2]$-2,6}, for which no imine intermediates were detected in the reaction mixtures.

The reaction has also been carried out in the presence of 0.5 and 2 mol % catalyst, but at higher values complex **1** was not completely soluble in the reaction mixture. With 2 mol % **1**, **I** was converted completely into **IV** within 3.5 h. For the same reaction time 44.7 and 5.9 % of the product **IV** was obtained using 1 and 0.5 mol % catalyst, respectively. A nearly first-order dependence on the initial concentration of **1** was observed. In experiments at 20, 60, 70, and 80 °C, no catalytic activity was shown by **1** at 20 °C, while at 60 °C the reaction proceeded very slowly. At 80 °C the reaction rate was nearly the same as at 100 °C. At 70 °C no appreciable increase of the reaction rate with respect to 60 °C was observed.

Catalytic runs in the presence of different amounts of PPh_3 or Cl^- ions (LiCl) showed that both reagents strongly inhibit the reaction rate. Several experiments were run with PPh_3/**1** or LiCl/**1** molar ratios increasing from 1:1 to 20:1. In Figure 2 are reported the results obtained using a five-fold excess of PPh_3 and a 20-fold excess of LiCl, and, for comparison, that obtained with the catalyst only.

Catalytic Activity of Half-sandwich Complexes

To find the most efficient catalyst, several other half-sandwich ruthenium(II) complexes related to **1** (Table 2) were tested in the model reaction between cyclohexylamine and methanol. The aim was also to better understand the influence of both steric and electronic properties of the ancillary ligands on the catalytic activity of the complexes, and to get more information on the nature of the key-steps occurring at the metal centre.

The composition of the reaction mixtures after 6 h (100 °C, 1 mol % catalyst) (Table 2) clearly show that only complex **10**, bearing two P(*m*-Tolyl)$_3$ ligands, exhibits a catalytic activity similar to that of **1**. Complexes **9**, **12**, and **13**, containing the low sterically demanding ligands $PMePh_2$, $PHPh_2$ and CO, and **11** and **14**, bearing bidentate chelating ligands, are much less active than **1**, probably owing to a high activation barrier to neutral ligand dissociation. As regards the effect of the anionic ligand (X), the activity of the complexes decreases in the order **1** (Cl) > **2** (H) > **3** (I) > **4** (N_3) > **5** ($SnCl_3$). This trend apparently depends on both the size of X^- and the strength of the Ru−X bond, which can affect the tendency of half-sandwich ruthenium(II) complexes to dissociate a neutral ligand or the X^- ion to give a coordinatively unsaturated intermediate. Cationic complexes **6**−**8** show a catalytic activity that strongly decreases on increasing the number of coordinated acetonitrile ligands. The very low catalytic activity shown by the indenyl complex **15** is noteworthy since in the redox isomerisation of allyl alcohols to ketones[19b] complex **15** exhibits a higher catalytic activity than **1**, most probably due to the opening of a coordination site on the metal by haptotropic shift (from η^5 to η^3) of the indenyl ligand. Apparently, an analogous behaviour of complex **15** in the *N*-alkylation of amines is not operative.

NMR Measurements and Mechanistic Insights

The transition-metal-catalyzed *N*-alkylation reaction of primary amines with alcohols is generally thought to involve the hydrogenation of an imine intermediate, which results from the condensation of the starting amine with the aldehyde formed by deydrogenation of the alcohol.[1,5,8,11,12] The hydrogen produced in the dehydrogenation process is then transferred to the imine to give the alkylated secondary amine. With secondary amines, the condensation reaction with the aldehyde should give a transient immonium ion.

In the currently accepted mechanism, the ruthenium complex reacts with an alcohol molecule to give, via β-hydride elimination, a Ru−H(aldehyde) intermediate.[1,5,8,11,12] In a second step the condensation product of the aldehyde with the primary amine is hydrogenated by a Ru−H/Ru−H_2 system to the secondary amine. This product can re-enter the catalytic cycle to be converted into a

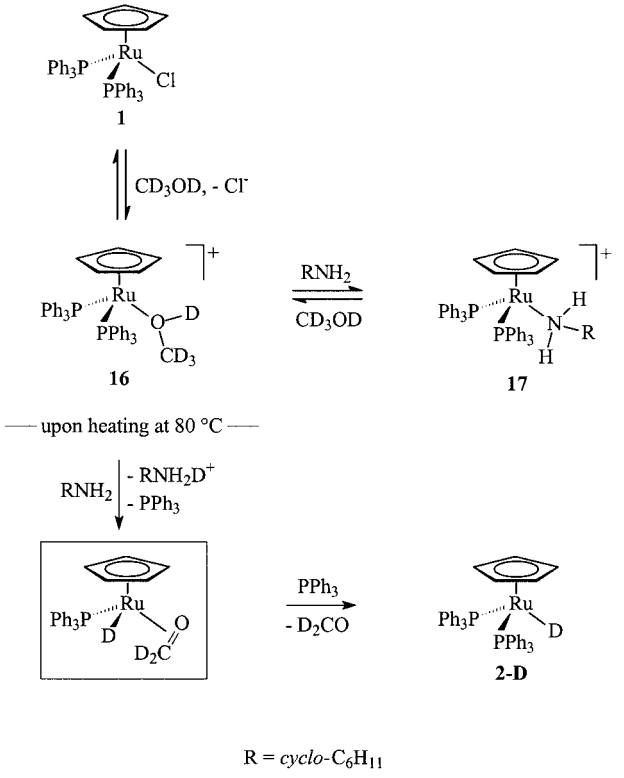
[a] Cp = η^5-C_5H_5. [b] dppe = 1,2-(diphenylphosphanyl)ethane. [c] dipy = 2,2′-dipyridyl.

tertiary amine. We tentatively propose that a similar mechanism also operates for the *N*-methylation catalysed by **1**.

$^{31}P\{^1H\}$ NMR studies indicate that the dissolution of **1** in CD_3OD occurs with Cl^- dissociation and formation of the cationic solvent complex [Ru(η^5-C_5H_5)(CD_3OD)(PPh_3)$_2$]$^+$ (**16**) (δ = 33.7 ppm). The analogous species containing CH_3OH has been isolated in low yield as the tetraphenylborate salt.[20] Addition of an excess of cyclohexylamine results in the formation of an equilibrium mixture of complexes **1**, **16**, and [Ru(η^5-C_5H_5)(*c*-$C_6H_{11}NH_2$)(PPh_3)$_2$]$^+$ (**17**) (δ = 45.4 ppm). No free PPh_3 is present in solution. Heating at 80 °C causes the catalytic formation of the imine **II** and the amines **III** and **IV**, while free PPh_3 appears in the reaction mixture. At this stage, the formation of the almost catalytically inactive [RuD(η^5-C_5H_5)(PPh_3)$_2$]$^+$ (**2-D**) [1:1:1 triplet, δ = 68.6, $J(^{31}P\text{-}^2H)$ = 4.9 Hz] is also observed (Scheme 2). Complex **17** has been isolated in the solid state in good yield as the perchlorate salt by treatment of complex **1** in THF with a slight excess of $AgClO_4$ in the presence of a tenfold excess of cyclohexylamine. Ru^{II} amino complexes analogous to **17** have been reported previously.[21] The $^{31}P\{^1H\}$ NMR chemical shift of complex **17** agrees with those found in related species with coordinated NH_3 and CH_3NH_2 (δ = 45.9 and 43.7 ppm, respectively).[21b] Prolonged heating of a CD_3OD solution of complex **17** results in its almost complete conversion into **16**.

The RuH(formaldehyde) intermediate, which is most probably the key-species of the catalytic cycle, might reasonably arise from complex **16** via PPh_3 dissociation that



Scheme 2. Complexes detected in solution in CD_3OD on treatment of **1** with excess cyclohexylamine. The species in the square (spectroscopically not detectable) is assumed to be the key-intermediate that initiates the catalytic cycle. Most of **1** is converted into **2-D**, which has a low catalytic activity

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

provides a vacant coordination site on the metal centre. This hypothesis agrees with the observed decrease in reaction rate in the presence of both free phosphane and chloride ions. In addition, the dissociation of both one PPh_3 and Cl^- from **1** has been previously proposed by Trost to account for the catalytic activity of this complex in other organic transformations.[19]

Finally, we found appreciable amounts of free imine in the reaction mixtures, unlike previous observations in which the imine is formed at the metal centre, by condensation between coordinated amine and aldehyde, and then, without decoordination, immediately hydrogenated to the corresponding amine.[1,5,8,11,12]

Conclusions

Complex **1** is confirmed as a homogeneous catalyst in several organic processes. The results indicate that it, as well as its P(*m*-Tolyl)$_3$ analogue **10**, exhibits the highest reported catalytic activity of ruthenium complexes for the *N*-methylation of primary and secondary alkylamines. Comparison of the literature data on the methylation of different alkylamines by methanol in the presence of Ru-based catalysts with those obtained here (Table 3) shows that **1** promotes a remarkably fast, quantitative conversion, under non-forcing conditions, of the starting amines into *N*-permethylated products. Such good results seem to indicate that complex **1** may also catalyze other organic processes that involve appropriate transformations of alkylamines or imines, such as the hydrogen transfer reduction of the latter.

Experimental Section

Caution! *Perchlorate salts of metal complexes with organic ligands are potentially explosive. These compounds must be handled with caution and should be prepared on a very small scale.*

Instrumentation and Analyses: The NMR spectra (^1H at 200.13, ^{13}C at 50.32, and ^{31}P at 81.02 MHz) in CD_3OD or CD_2Cl_2 solutions were run on a Bruker AC 200 F QNP spectrometer equipped with a variable-temperature probe. The chemical shifts were referenced to internal $SiMe_4$ for ^1H, residual $CHDCl_2$ for ^{13}C, and external 85 % H_3PO_4 for ^{31}P. High temperatures were calibrated with ethylene glycol 80 % in [D_6]DMSO. The GC-MS analyses were carried out with a Fisons TRIO 2000 gas chromatograph-mass spectrometer working in the positive ion 70 eV electron impact mode. The injector was kept at 250 °C and the column (Supelco® SE-54, 30 m long, 0.25 mm i.d., coated with a 0.5 μm phenyl methyl silicone film) was temperature programmed from 50 to 310 °C at 10 °C/min. GC analyses were run on a Fisons GC 8000 Series gas chromatograph equipped with a Supelco® PTA-5 column [30 m long, 0.53 mm i.d., coated with a 3.0 μm poly(5 % diphenyl/95 % dimethylsiloxane) film]; injector and column temperatures as indicated above.

Reagents and Catalysts: All amines (97−99.5 % purity) were purchased from Aldrich and used without further purification. Commercial methanol (Riedel) was purified on CaH_2 according to a standard method[22] and freshly distilled before use. However, the use of untreated solvent resulted in a negligible lowering of the reaction rate. The complexes [RuCl(η^5-C_5H_5)(PPh_3)$_2$] (**1**),[23] [RuH(η^5-C_5H_5)(PPh_3)$_2$] (**2**),[24] [RuI(η^5-C_5H_5)(PPh_3)$_2$] (**3**),[25] [RuN_3(η^5-C_5H_5)(PPh_3)$_2$] (**4**),[25] [Ru($SnCl_3$)(η^5-C_5H_5)(PPh_3)$_2$] (**5**),[26] [Ru(η^5-C_5H_5)(CH_3CN)(PPh_3)$_2$]PF_6 (**6**),[26] [Ru(η^5-C_5H_5)(CH_3CN)$_2$(PPh_3)]PF_6 (**7**),[27] [Ru(η^5-C_5H_5)(CH_3CN)$_3$]PF_6 (**8**),[28] [RuCl(η^5-C_5H_5)($PMePh_2$)$_2$] (**9**),[29] [RuCl(η^5-C_5H_5){P(*m*-Tolyl)$_3$}$_2$] (**10**),[15] [RuCl(η^5-C_5H_5)(dppe)] (**11**),[30] [RuCl(η^5-C_5H_5)($PHPh_2$)(PPh_3)] (**12**),[31] [RuCl(η^5-C_5H_5)(CO)(PPh_3)] (**13**),[32] [Ru(η^5-C_5H_5)(2,2′-dipyridyl)]Cl (**14**),[33] and [RuCl(Indenyl)(PPh_3)$_2$] (**15**)[34] were synthesised according to literature procedures.

Synthesis of Complex [Ru(η^5-C_5H_5)(*c*-$C_6H_{11}NH_2$)(PPh_3)$_2$]ClO_4 (17): Under an argon atmosphere, a mixture of complex **1** (181 mg, 0.25 mmol), $AgClO_4$ (62 mg, 0.30 mmol) and cyclohexylamine (248 mg, 2.5 mmol) was stirred in anhydrous THF (15 mL) for 30 min at room temperature. The resultant mixture was filtered through a glass-frit and then through a Celite® bed to eliminate traces of silver and silver compounds. *n*-Hexane (20 mL) was subsequently added to the solution and the THF pumped off. A yellow−green gum was obtained, which was slowly converted into a yellow solid by vigorous stirring in an ice-bath. The solid was recrystallised from THF/*n*-hexane in 73 % yield (162 mg).

Table 3. *N*-methylation of amines by methanol catalysed by ruthenium-based compounds. Comparison between literature data and the results herein reported[a]

Catalyst (mol %)	Starting amine	Product	Temperature	Time (h)	Yield (%)	Ref.

$C_{47}H_{48}ClNO_4PRu$ (889.37): calcd. (%) C 63.47, H 5.44, N 1.57; found C 63.11, H 5.35, N 1.49 %. $^{31}P\{^1H\}$ NMR (CD_3OD): δ = 45.4 (s); $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 43.9 (s) ppm. ^1H NMR (CD_2Cl_2): δ = 0.60−2.32 (m, 11 H, *c*-C_6H_{11}), 4.39 (s, 5 H, C_5H_5), 6.88−7.71 (m, 30 H, C_6H_5) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 24.4 (s), 25.2 (s), 34.9 (s), 61.4(t) J(^{13}C-^{31}P) = 2.3 Hz (*c*-C_6H_{11}), 80.6 (t) J(^{13}C-^{31}P) = 2.0 Hz (C_5H_5), 129.3 (*pseudo*-t), 131.0 (s), 133.7 (*pseudo*-t), 135.3 (*pseudo*-quintet) (C_6H_5) ppm.

General Procedure for the Catalytic *N*-Methylation of Amines: A 3-necked round-bottom flask (50 mL), equipped with a condenser and a rubber septum, was charged with catalyst (18.1 mg, $2.5 \cdot 10^{-2}$ mmol). Under an argon atmosphere, amine (2.5 mmol) and CH_3OH (10 mL, ca. 0.25 mol) were then added. After placing the flask in an oil-bath at a controlled temperature (60−100 °C) the initial orange mixture immediately turned into a clean yellow solution. Samples were extracted through the rubber septum with a syringe, diluted with diethyl ether and analysed by GC or GC-MS.

On the Reactivity of the Iminodiphosphane $C_6H_4(o\text{-}CN)N{=}PPh_2{-}PPh_2$: Fragmentation Versus Isomerisation

Zhaofu Fei,[a] Rosario Scopelliti,[a] and Paul J. Dyson*[a]

Keywords: N,P ligands / Palladium / Platinum / Reaction mechanisms / Structure elucidation

The reactivity of the iminodiphosphane $C_6H_4(o\text{-}CN)N{=}PPh_2{-}PPh_2$, which contains an N=P–P unit, has been investigated. Reaction with small molecules, [viz. H_2O/O_2, H_2O_2, CH_3OH, $C_6H_4(o\text{-}CN)NH_2$] and elemental sulfur result in cleavage of the P–P bond to give aminophosphane-derivatised compounds. The products from these reactions have been characterized spectroscopically, including two by single-crystal X-ray diffraction. The reactivity of the iminodiphosphane towards the transition metal complexes $[M(cod)Cl_2]$ (M = Pd or Pt) has also been investigated. In the reactions, the iminodiphosphane rearranges to form the more common diphosphonylamine (P–N–P) unit which chelates to the metal centres. Three different compounds were isolated from these reactions and they have all been fully characterised by spectroscopy and single-crystal X-ray diffraction.

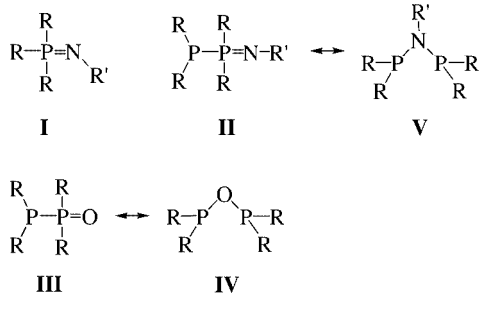
Introduction

Iminophosphorus compounds such as iminophosphoranes $R_3P{=}NR'$ (I in Scheme 1) act as monodentate ligands using the lone pair at the N-centre.[1] Because the phosphorus centre is formally in the +5 oxidation state, it is rarely involved in coordination to transition metal centres, although the P=N unit has been observed to act as a π-donor.[2] Iminodiphosphanes with $PR_2{-}PR_2{=}NR'$(**II**) backbones are isoelectronic to oxodiphosphanes with $PR_2{-}PR_2{=}O$ (**III**) skeletons. Oxodiphosphanes are useful compounds, since they can rearrange on coordination to transition metals to give diphosphoxanes $PR_2{-}O{-}PR_2$ (**IV**), which act as bidentate ligands.[3] Diphosphoxanes are otherwise difficult to produce due to the Arbuzov rearrangement and their instability towards disproportionation. Iminodiphosphanes are the unstable isomers of diphosphonylamines, which have a $PR_2{-}NR'{-}PR_2$ (**V**) skeleton. Diphosphonylamines are widely used as ligands,[4] with the ability to chelate to various transition metal centres,[5] and such compounds have been reviewed in detail.[6] Some diphosphonylamine complexes have been evaluated as catalysts in, for example, asymmetric hydrogenation and hydroformylation reactions,[7] and much of the recent research has focused on either chiral ligands[8] or functionalized diphosphonylamines with additional donor centres.[9]



Scheme 1

Although iminodiphosphanes have been known for many decades,[10] they have not been studied to the same extent as oxodiphosphanes or diphosphonylamines. This could be because they are generally less stable than these other compounds; some iminodiphosphanes are pyrophoric.[11] Reactivity studies on iminodiphosphanes are essentially concerned with the rearrangement from N=P−P to P−N−P that takes place in the presence of organic bases.[12] Compared to a large number of reports on coordination chemistry of P−O−P and P−N−P ligands, we are not aware of any related studies with iminodiphosphanes, although one could envisage that the phorphorus(III) centre should enable a rich coordination chemistry. Following our recent report on the synthesis of the iminodiphosphane $C_6H_4(o\text{-}CN)N{=}PPh_2{-}PPh_2$ (**1**),[13] which was formed as the major product instead of the diphosphonylamine $C_6H_4(o\text{-}CN)N(PPh_2)_2$, we report herein on the reactivity of **1** towards different reagents ranging from small molecules to transition metal complexes, which lead to very different outcomes as those which we expected.

Results and Discussion

The reaction of **1** with small molecules and transition metal complexes leads to two different outcomes. In all re-

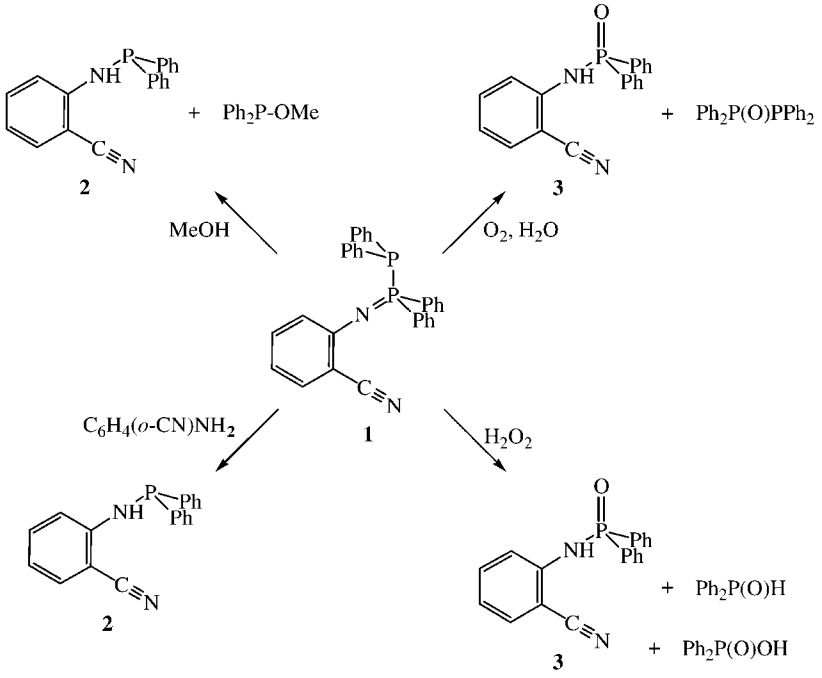
actions cleavage of the P−P bond takes place, but in the reactions with transition metal complexes P−P bond cleavage is accompanied by the formation of a new N−P bond.

Reactions of $C_6H_4(o\text{-CN})N{=}PPh_2{-}PPh_2$ (1) with Small Molecules

The iminodiphosphane **1** is stable in the solid state, but in solution it decomposes rapidly on exposure to air or moisture. In methanol, **1** decomposes immediately to form the aminophosphane precursor **2** and $Ph_2P{-}OMe$, as indicated by ^{31}P NMR spectroscopy which exhibits characteristic resonances at δ = 29.5 and 117.6 ppm, respectively.[14] Over a prolonged period, the only remaining phosphorus containing compound that is observed is $Ph_2P{-}OMe$ (Scheme 2). If a sample of **1** in CH_2Cl_2 is exposed to air or moisture, it slowly hydrolyses to the aminophosphane **2**, which reacts further to form the oxide [$C_6H_4(o$-CN)$NHPPh_2(O)$] (**3**). The other product observed in the reaction is $Ph_2P(O)PPh_2$, as evidenced by ^{31}P NMR spectroscopy, which exhibits two doublets centred at δ = −21.1 and 36.0 ppm ($^1J_{P,P}$ = 225 Hz).[14] The reaction of **1** with H_2O_2 is somewhat more complicated. In addition to the aminophosphane **2** and the oxide **3**, the ^{31}P NMR spectrum shows the presence of $Ph_2P(O)H$ and $Ph_2P(O)OH$ as indicated by signals at δ = 20 and 34 ppm, respectively.[14] Compound **1** also reacts with $C_6H_4(o\text{-CN})NH_2$ in $CDCl_3$ to form the aminophosphane **2** in quantitative yield; in this case, traces of HCl from the solvent may serve as catalysts leading to the cleavage of the P−P bond; a similar reaction has been previously reported.[12]

The reaction of **1** with elemental sulfur gave mixtures of several products. Attempts to isolate a pure product afforded [$C_6H_4(o$-CN)$NHPPh_2(S)$] (**6**; Scheme 3). Since it has previously been reported that treatment of iminodiphosphanes with elemental sulfur give N=P−P=S derivatives,[10] it is not unreasonable to assume that **6** and $Ph_2P(O)PPh_2$ could form via intermediates **4** or **5** (Scheme 3) by hydrolysis. The reaction was monitored by ^{31}P NMR spectroscopy over 24 hours. At the start of the reaction, two doublets at δ = 6.0 and 32.5 ppm ($^1J_{P,P}$ = 73.5 Hz) are observed. The coupling value is between that of an N=P−P=S intermediate similar to **4**, (ca. 30 Hz),[10] and that of type **5** compounds (ca. 100 Hz).[15] Few examples of related compounds are known[16] and it is therefore difficult to interpret the NMR spectroscopic data more fully. The intermediate could not be isolated. We must therefore speculate that while both could be involved, analogues of **5** are quite stable, and hence, **4** is more likely. It is worth noting that both **3** and **6** can be obtained in quantitative yield by reaction of **2** with H_2O_2 or elemental sulfur, respectively, using literature methods.[17]

The solid-state structures of **3** and **6** have been established by single-crystal X-ray diffraction and details of the structure determination are given in Table 1. Crystals of **3** were grown from diethyl ether and crystals of **6** were grown from dichloromethane/diethyl ether by slow evaporation. The structures of **3** and **6** are illustrated in Figures 1 and 2,



Scheme 2. Reaction of **1** with MeOH, O_2/H_2O, H_2O_2 and $C_6H_4(o\text{-CN})NH_2$

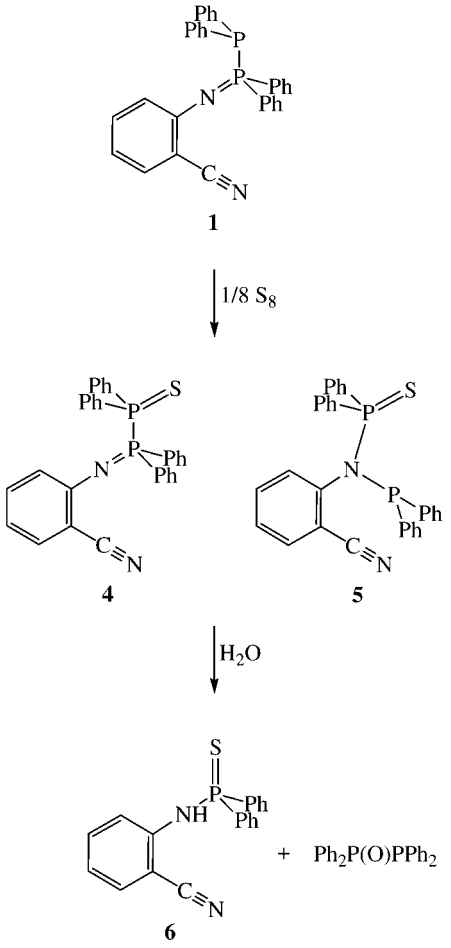

Scheme 3. Reaction of **1** with elemental sulfur showing the possible intermediates

respectively, and key bond parameters are given in the captions.

There are two independent molecules in the asymmetric unit of **3**. The P−N distances average 1.652(6) and 1.6773(15) Å in **3** and **6**, respectively, which is within the range usually found in related compounds.[18] The O-atom forms strong intermolecular N−H···O hydrogen bonds [N1A···O1B 2.788(7), N1B···O1AA 2.804(8) Å; N1A−H1A···O1B 161°, N1B−H1B···O1AA 152°], which, by symmetry, gives a polymeric one-dimensional chain along the base vector [1 0 1]. Interestingly, the N-atom of the CN group in **3** forms weak hydrogen bonds with the hydrogen atoms of a phenyl ring. In **6**, the hydrogen bond network similar to that observed in compound **2** (previously reported),[13] leads to a dimeric structure obtained through N−H···NC interactions [N···N, 3.098(2) Å; N−H···N, 151°]. The CN triple bond lengths in **3** and **6** are the same [1.140(10) versus 1.149(2) Å], and not significantly different from the free aminophosphane **2** [1.152(2) Å].

Reactions of C_6H_4(*o*-CN)N=PPh_2−PPh_2 (1) with Transition Metal Complexes

The reaction of **1** with [M(cod)Cl_2] (M = Pd or Pt, cod = cycloocta-1,5-diene) in equimolar quantities affords [M{C_6H_4(*o*-CN)N(PPh_2)$_2$}Cl_2], M = Pd (**7**), M = Pt (**8**), as the main products (Scheme 4). The synthesis of compounds **7** and **8** was followed by ^{31}P NMR spectroscopy, and in the reaction of **1** with [Pd(cod)Cl_2] in dichloromethane, for example, besides the main signal at δ = 39 ppm, another signal at δ = 64.2 ppm with low intensity was also observed. This peak probably corresponds to the free diphosphonylamine C_6H_4(*o*-CN)N(PPh_2)$_2$ (cf. the chemical shift of C_6H_4(*o*-OCH_3)N(PPh_2)$_2$ is δ = 65.6 ppm,[15] and C_6H_5N(PPh_2)$_2$ is δ = 67.7 ppm[19]). The ^{31}P NMR spectrum of **8** exhibits a signal at δ = 27.0 ppm ($^1J_{P,Pt}$ = 3377 Hz) typical of similar compounds, and there does not appear to be a significant influence on the chemical shift by virtue of the CN group.[20] The reaction of [M(cod)Cl_2] (M = Pd or Pt) with a series of iminodiphosphanes with electron-withdrawing groups[13b] have been followed by ^{31}P NMR spectroscopy. In one case, in the reaction between [Pt(cod)Cl_2] and C_6H_4(*o*-CF_3)N=PPh_2−PPh_2, the rate is sufficiently slow to reveal two doublets centred at δ = 65.0 ($J_{P\text{-}P}$ = 68 Hz) and 30.5 ($J_{P\text{-}P}$ = 68 Hz) ppm, which are tentatively ascribed to an intermediate in which the intact iminodiphosphane coordinates to the platinum. This assignment is based on the low value of the $J_{P\text{-}P}$ coupling constant and the short liftime, presumably because the coordinated iminodiphosphane rapidly rearranges to the diphosphonylamine, which initially coordinates through just one phosphorus centre before yielding the final product. Efforts to quench the reaction in order to analyse the intermediates in more detail failed. After 24 hours at room temperature the signals of the starting material and the two doublets at δ = 65.0 ppm and 30.5 ppm disappeared and only one main signal at δ = 25.5 ppm corresponding to the diphosphonylamine product remained.

The reaction of [Pt(cod)Cl_2] with two equivalents of **1** affords the cationic complex [Pt{C_6H_4(*o*-CN)N(PPh_2)$_2$}$_2$]Cl_2 (**9**) in high yield. ^{31}P NMR spectroscopy suggests that in the reaction complex, **8** forms initially, and reacts with further ligand to form **9**. The $^1J_{P\text{-}Pt}$ value of **9** is much lower than that of **8** and other mono-chelated platinum complexes, but is in keeping with structurally related bis-chelated compounds.[21] In the reaction mixture, low intensity signals at δ = 27.0 and 29.0 ppm are present, which correspond to **8** and the aminophosphane **2**. An additional signal at δ = 82.0 ppm with very low intensity is present, and possibly corresponds to Ph_2PCl. This would suggest that $Ph_2P^{\cdot}$ radicals are formed, which can be treated with [Pt(cod)Cl_2] starting material or CH_2Cl_2 solvent. The source of the chloride is more likely from [Pt(cod)Cl_2] as Ph_2PCl is also observed when the reaction is carried out in THF. The analogous reaction of **1** with [Pd(cod)Cl_2] does not give an analogous compound to **9**, possibly due to the smaller size of the palladium metal ion or the weaker Pd−P bond relative to platinum. Although we speculate that complexes **7**−**9** could be formed through the N=P−P−Pd or N=P−P−Pt intermediate, we were unable to obtain any evidence for their formation, even when the reactions were carried out at −20 °C.

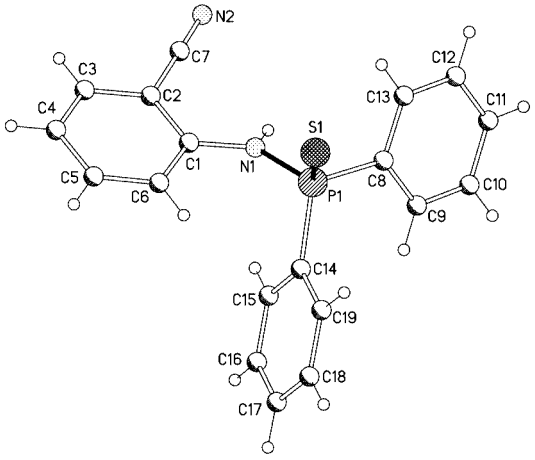

Figure 2. Molecular structure of **6** in the solid-state; key bond lengths (Å) and angles (°) include: S1−P1 1.9390(7), P1−N1 1.6773(15), N1−C1 1.399(2), N2−C7 1.149(2); N1−P1−S1 115.08(6), C1−N1−P1 126.84(13)

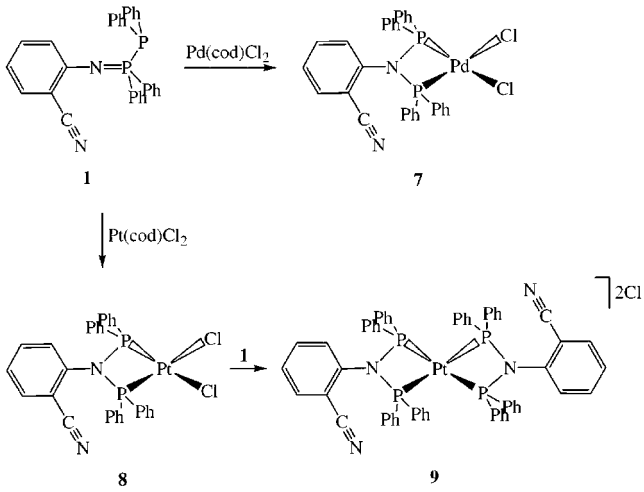

Scheme 4. Reaction of **1** with $[M(cod)Cl_2]$ (M = Pd or Pt)

Complex **7** forms good quality crystals suitable for X-ray determination from dichloromethane/thf solution at 0 °C. Crystals of complex **8** were obtained from dichloromethane/diethyl ether solution at 0 °C. Though the two structures could be isotypical, they have different space groups due to the cocrystallisation of different solvents with **7**. Two independent molecules lie within the asymmetric unit of **8**. There are close similarities between **7** and **8** shown in Figures 3 and 4, respectively. Both structures have a *cis*-chelating $C_6H_4(o\text{-}CN)N(PPh_2)_2$ ligand and two chloride ligands around the metal centres. The Pd−Cl/Pt−Cl and Pd−P/Pt−P bond lengths are all normal,[15,18,20] and the P1−N1−P2, and P1−Pd1−P2 angles as well as the P1···P2 distance in the palladium complex **7** compare very well with those found for **8** (see captions for details) and they are all within the range usually found in the related complexes.[15,18,20]

Compound **9** crystallises within a few minutes in a solvent mixture of dichloromethane and diethyl ether at −22 °C. The crystal architecture is composed of the dication, two chloride anions and eight dichloromethane molecules which form a *pseudo*-crown topology around the cation (Figure 5). The Pt metal centre lies on the inversion centre and this, in turn, imposes exact planar geometry at the metal centre although the bite angle of 71.51(3)° required by the chelating diphosphonylamine ligands causes a slight deviation from the idealised geometry. The phosphorus centres within each ligand are also close, the P1···P2 distance being 2.6919(11) Å, significantly longer than in **7** and **8**. The Pt−P bond lengths in **9** are equivalent with an aver-

ing interactions in a number of related platinum and palladium phosphane complexes have been reported previously.[22]

Concluding Remarks

In conclusion, we have examined the reactivity of $C_6H_4(o\text{-CN})N{=}PPh_2{-}PPh_2$ (**1**) towards small molecules and transition metal complexes. All the reactions carried out show that the P−P bond is easily cleaved. The reactions with small molecules give products with a P−NH backbone. In the presence of transition metals, rearrangements forming a P−N−P skeleton take place, a new type of reaction in this intensively explored field.

Experimental Section

All manipulations were performed under an inert atmosphere of dry nitrogen using standard Schlenk techniques. The iminodiphosphane $C_6H_4(o\text{-CN})N{=}PPh_2{-}PPh_2$ (**1**) and $C_6H_4(o\text{-CF}_3)N{=}PPh_2{-}PPh_2$ were prepared by the literature methods[13] and all other reagents were purchased from Aldrich and used as received. Solvents were dried using the appropriate reagents and distilled prior to use. NMR spectra were obtained at 20 °C on a Bruker DMX 200 instrument using $SiMe_4$ for ^1H and 85% H_3PO_4 for ^{31}P, as external standards. ESI-MS spectra were recorded on a Thermo-Finnigan LCQ™ Deca XP Plus quadrupole ion-trap instrument using literature methods[23] with samples infused directly into the source at 5 μL min^{-1} with a syringe pump. The spray voltage was set at 5 kV and the capillary temperature at 50 °C. Elemental analysis was carried out by the Institute of Molecular and Biological Chemistry (EPFL).

Reaction of 1 with MeOH: 1 (58 mg, 0.12 mmol) was added to MeOH (2.0 mL) at room temp. The ^{31}P NMR spectrum of the solution immediately showed the presence of two signals at δ = 29.5 and 117.6 ppm with equal intensity, corresponding to **2** and $Ph_2P{-}OMe$. After 24 h the signal at δ = 29.5 ppm disappeared leaving only the signal at δ = 117.6 ppm.

Reaction of 1 with O_2/H_2O: A sample containing **1** (195 mg, 0.40 mmol) in CH_2Cl_2 (5.0 mL) was exposed to air for two days. The resulting solid was then washed with diethyl ether (2 × 5.0 mL). The filtrates were collected and solvent was removed in vacuo. The remaining solid was washed with diethyl ether (2 × 2.0 mL). After slow evaporation of solvent, crystals of **3** were obtained, which were suitable for X-ray structure analysis. Yield 21 mg, 18 %. M.p. 168 °C. ^1H NMR (ppm in $CDCl_3$): δ = 6.70−8.15 (m, aromatic H), 5.50 (1 H, broad signal, NH) ppm. ^{31}P NMR (ppm in $CDCl_3$): δ = 20.5 (s) ppm. ESI-MS: *m/z*: 319 $[M + H]^+$. $C_{19}H_{15}N_2OP$ (318.3): calcd. C 71.69, H 4.75, N 8.80; found C 71.63, H 4.87, N 8.79.

Reaction of 1 with H_2O_2: An excess of H_2O_2 (0.20 mL, 30 %) was added at 0 °C to a solution of **1** (195 mg, 0.40 mmol) in CH_2Cl_2 (5.0 mL). The solvent was then removed and the resulting solid was recrystallised from dichloromethane and diethyl ether to give **3**. Yield 25.0 mg, 20 %.

Reaction of 1 with C_6H_4(o-CN)NH_2: A solution of **1** (486 mg, 1.0 mmol) and C_6H_4(o-CN)NH_2 (118 mg, 1.0 mmol) in $CDCl_3$ (5.0 mL) was stirred at room temp for 24 h. The ^{31}P NMR spectrum shows the full conversion of **1** into **2**. The solvent was removed in vacuo to give **2**. Yield 602 mg, 99 %. Spectroscopic data were in excellent agreement with that reported in ref.[13a]

Reaction of 1 with S_8: A sample containing **1** (195 mg, 0.40 mmol) and elemental sulfur (13 mg, 0.40 mmol) in CH_2Cl_2 (5.0 mL) was stirred at room temp for 24 h and then exposed to the air for 24 h. The resulting oily product was washed with diethyl ether (2 × 5.0 mL) to give a colourless solid. Recrystallisation from dichloromethane and diethyl ether gave compound **6** as colourless crystals suitable for X-ray analysis. Yield 50.0 mg, 15 %. M.p. 201 °C. ^1H NMR ($CDCl_3$): δ = 6.60−8.10 (m, aromatic H), 5.5 (1 H, broad signal, NH) ppm. ^{31}P NMR ($CDCl_3$): δ = 53.9 (s) ppm. ESI-MS: *m/z*: 335 $[M + H]^+$. $C_{19}H_{15}N_2PS$ (334.4): calcd. C 68.25, H 4.52, N 8.38; found C 68.63, H 4.57, N 8.29.

Reaction of 1 with [Pd(cod)Cl_2] in 1:1 Ratio: Pd(cod)Cl_2 (14.3 mg, 0.05 mmol) was added to a solution of **1** (24.3 mg, 0.05 mmol) in dichloromethane (5.0 mL) at room temp and stirred for 30 minutes. Thf (2.0 mL) was added and the sample was placed in a freezer at 0 °C. Crystals of **7** were collected by filtration. Yield 23.5 mg, 72 %. M.p. > 285 °C (decomp.). ^1H NMR ($CDCl_3$): δ = 6.65−8.15 (m, aromatic H) ppm. ^{31}P NMR ($CDCl_3$): δ = 39.0 (s) ppm. ESI-MS: *m/z*: 664 $[M - H + Li]^+$, $C_{31}H_{24}Cl_2N_2P_2Pd$ (663.8): calcd. C 56.09, H 3.64, N 4.22; found C 56.63, H 3.69, N 4.11.

An analogous procedure was used with $C_6H_4(o\text{-CF}_3)N{=}PPh_2{-}PPh_2$. Yield 68%. M.p. 220 °C. ^1H NMR (CD_3CN): δ = 6.65−8.15 (m, aromatic H) ppm. ^{31}P NMR (CD_3CN): δ = 44.80 (s) ppm. ESI-MS: *m/z*: $[M + H]^+$. $C_{31}H_{24}Cl_2F_3NP_2Pd$ (706.8): calcd. C 52.68, H 3.42, N 1.98; found C 52.73, H 3.49, N 2.00.

Reaction of 1 with [Pt(cod)Cl_2] in 1:1 Ratio: Pt(cod)Cl_2 (17.2 mg, 0.05 mmol) was added to a solution of **1** (24.3 mg, 0.05 mmol) in dichloromethane (5.0 mL) at room temp and stirred for 30 minutes. Thf (2.0 mL) was added and the sample was placed in a freezer at 0 °C. Crystals of **8** were collected by filtration. Yield 29.3 mg, 78 %. M.p. > 285 °C (decomp.). ^1H NMR ($CDCl_3$): δ = 6.60−8.10 (m, aromatic H) ppm. ^{31}P NMR $CDCl_3$): δ = 27.0 (s, ^1J(PPt) = 3377 Hz) ppm. ESI-MS: *m/z*: 754 $[M - H + Li]^+$. $C_{31}H_{24}Cl_2N_2P_2Pt$ (752.5): calcd. C 49.48, H 3.21, N 3.72; found H C 49.63, 3.30, N 3.68.

An analogous procedure was used with $C_6H_4(o\text{-CF}_3)N{=}PPh_2{-}PPh_2$. Yield 78 %. M.p. > 285 °C. ^1H NMR ($CDCl_3$): δ = 6.65−8.15 (several multiples, aromatic H) ppm. ^{31}P NMR ($CDCl_3$): δ = 25.43 (s, ^1J(PPt) = 3350.0 Hz) ppm. ESI-MS: *m/z*: 793 $[M + H]^+$. $C_{31}H_{24}Cl_2F_3NP_2Pt$ (795.5): calcd. C 46.81, H 3.04, N 1.76; found C 46.92, H 3.08, N 1.73.

Reaction of 1 with [Pt(cod)Cl_2] in 2:1 Ratio: Pt(cod)Cl_2 (18.7 mg, 0.05 mmol) was added to a solution of **1** (48.6 mg, 0.10 mmol) in dichloromethane (5.0 mL)and stirred for 30 min at room temp. Diethyl ether (2.0 mL) was added and the reaction mixture was placed in a freezer at −22 °C. X-ray suitable crystals of **9** were obtained within a few minutes. The crystals were collected by filtration. Yield 81.0 mg, 86 %. ^1H NMR ($CDCl_3$): δ = 6.60−8.10 (m, aromatic H), 5.32 (s, CH_2Cl_2) ppm. ^{31}P NMR ($CDCl_3$): δ = 39.5 (s, $^1J_{P,Pt}$ = 2399 Hz) ppm. ESI-MS^+ *m/z* = 1167 $[M]^+$. $C_{70}H_{64}Cl_{18}N_4P_4Pt$ (1918.4): calcd. C 43.83, H 3.36, N 2.92; found H 3.40, C 43.94, N 2.89.

An analogous procedure was used with $C_6H_4(o\text{-CF}_3)N{=}PPh_2{-}PPh_2$. Yield 51 %. M.p. 260 °C. ^1H NMR ($CDCl_3$): δ = 6.65−8.15 (m, aromatic H) ppm. ^{31}P NMR ($CDCl_3$): δ = 44.0 (s, ^1J(PPt) = 2400.0 Hz) ppm. ESI-MS: *m/z*: 1252 $[M]^+$. $C_{62}H_{48}Cl_2F_6N_2P_4Pt$ (1325.0): calcd. C 56.20, H 3.65, N 2.11; found C 56.32, H 3.68, N 2.13.

X-ray Characterization: X-ray measurements were performed on a 4-circle kappa goniometer equipped with an Oxford Diffraction KM4 Sapphire CCD (**3**, **6**, **9**) and on a marresearch mar345 IPDS (**7**, **8**) at 140 K; **7** was collected at room temp. A summary of the crystallographic data and the structure refinements is listed in Table 1 and relevant geometrical parameters, including bond lengths and angles are included into the figure captions. Data reduction was carried out with CrysAlis RED, release 1.6.9.[24] Absorption correction[25] was applied to all data sets but **6**. Structure solutions of **3**, **8** and **9** by SIR92,[26] **6** by SHELXS-97[27] and **7** by SIR97.[28] Structure refinement as well as molecular graphics and geometrical calculations were performed for all structures with the SHELXTL software package, release 5.1.[29] The structures were refined using the full-matrix least-squares on F^2 with all non-H atoms anisotropically defined. H atoms were placed in calculated positions using the "riding model'. Some disorder problems were encountered during the refinement of **7** and **8**. In the case of **7**, THF molecules were disordered over the inversion centre with 50 % occupation and in order to get reasonable parameters some geometrical restraints were employed, whereas for **8** the whole structure has undergone "rigid bond'' restraints. CCDC-201872 (**9**) and -209134 ... -209137 (**3**, **6**, **7**, **8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033: E-mail: deposit@ccdc.cam.ac.uk].

Syntheses, Crystal Structures and Magnetic Properties of Four Cu^{II}-Hg^{II} Mixed-Metal Halide Oligomers

Jun-Ling Song,[a] Jiang-Gao Mao,*[a] Hui-Yi Zeng,[a] and Zhen-Chao Dong[b]

Keywords: Copper / Mercury / Magnetic properties / Cluster compounds

Four heteronuclear Cu^{II}–Hg^{II} halides containing 2,2-bipyridine (bipy) ligands have been synthesized and structurally characterised by single-crystal X-ray diffraction studies. The dinuclear complex $[Cu(bipy)_2HgCl_2Br_2]$ (**1**) contains a five-coordinate copper(II) ion and a four-coordinate Hg^{II} ion, in which the two different types of metal ions are bridged by a pair of chloride anions. $[Cu_2(bipy)_4HgBr_4][Hg_2Br_6]$ (**2**) contains a trinuclear $[Cu_2(bipy)_4HgBr_4]^{2+}$ cation in which the two copper(II) ions are bridged by an $[HgBr_4]^{2-}$ tetrahedron via two Cu–Br bonds, and an edge-sharing tetrahedral $[Hg_2Br_6]^{2-}$ anion. The structure of $[Cu_2(bipy)_4Hg_2Br_6]$-$[Hg_4Br_{10}]$ (**3**) features a 1-D chain along the diagonal of the *a* and *c* axes constructed from tetranuclear $[Cu_2(bipy)_4Hg_2Br_6]^{2+}$ cations interconnected by $[Hg_4Br_{10}]^{2-}$ tetramers via elongated Hg–Br contacts (3.185 Å). Within the tetranuclear cationic unit, two $[Cu(bipy)_2]^{2+}$ units are bridged by an edge-sharing dimeric tetrahedral $[Hg_2Br_6]^{2-}$ anion. In the trinuclear complex $[Cu(bipy)_2Hg_2Cl_6]$ (**4**), each $[Hg_2Cl_6]^{2-}$ dimer bridges with a $[Cu(bipy)_2]^{2+}$ ion to form a trinuclear $[Cu(bipy)_2Hg_2Cl_6]$ unit, and each pair of such units is bridged by a pair of elongated Hg–Cl bonds [3.043(5) Å] to form a dimeric unit. The magnetic properties of **1**, **2**, and **4** have also been investigated.

Introduction

For several decades there has been considerable interest in polynuclear transition-metal complexes with linear-chain structures due to their unusual optical, electronic, and magnetic properties.[1] Such compounds are also ideal systems for the study of metal−metal interactions and in the search for molecular metal wires.[2] Low dimensional metal−organic halide networks have received considerable research attention in recent years due to their potential applications as electronic materials and catalysts.[3] Extensive studies on copper complexes are largely driven by their photochemical and photophysical properties. To date, numerous mononuclear metal coordination polymers with interesting structural motifs have been successfully synthesized. In contrast, the chemistry of bimetallic coordination polymers has received considerably less attention. Bimetallic coordination polymers have the potential to exhibit interesting physical properties such as electronic conductivity or magnetic ordering that result from interactions between two distinct metal centers connected by a suitable linker.[4] Homonuclear oligomers and chains of copper or mercury halogen compounds with polyamine ligands have been reported in the literature.[5−7] Their structures can be viewed as being built from polyamine (such as bipy) coordinated copper(II) moieties connected to copper(I) or copper(II) halides. Heteronuclear metal halides can exhibit not only new structural motifs that are unseen in homo-metallic systems, but also new or enhanced physical or chemical properties. However reports on heteronuclear metal halide compounds are relatively rare.[8−10] Several copper−zinc and copper−zirconium chlorides have been reported by the Martin group and[8] a series of nickel organoamine-halocadmates were reported by Zubieta and co-workers.[9] One, two, and three-dimensional mixed metal coordination polymers have been found in the Cu(prazinecarboxylate)$_2$/$CdCl_2$ system[10] and several Cu−Hg halides have been reported.[11] $[Cu(2\text{-pyrazinecarboxylato})_2HgI_2]\cdot HgI_2$ consists of an open framework constructed from Cu(2-pyrazinecarboxylato)$_2$ and HgI_2 building blocks, the other linear HgI_2 molecule is encapsulated in the cavity of the framework as a guest molecule.[11a] In $[Cu(en)_2][Hg_2Cl_6]$, the $[Cu(en)_2]^{2+}$ cations are bridged by dimeric Hg_2Cl_6 anions into a 1-D chain, whereas in $[Cu(en)_2][Hg_2Br_6]$, the $[Hg_2Br_6]^{2-}$ anions are interconnected through Hg−Br bonds to form an infinite chain and such chains are further bridged by $[Cu(en)_2]^{2+}$ cations into a 2-D layer. $[Cu(en)_2][HgBr_4]$ has a different chain structure in which the $[Cu(en)_2]^{2+}$ moieties are bridged by $[HgBr_4]$ tetrahedra.[11b] In $[Cu(bipy)_3]$-$[Hg_2I_6]$, the anions remain isolated due to the presence of a third chelating bipy ligand at the copper(II) ion.[11c]

We utilized the 2,2′-bipyridine ligand as a template to form the $[Cu(2,2'\text{-pyridine})_2]^{2+}$ cation. Reactions of the latter with Hg^{II} halides under different conditions (such as

different Cu/Hg ratios and solvents) led to four new $Cu^{II}-Hg^{II}$ mixed-metal oligomers, namely binuclear $[Cu(bipy)_2HgCl_2Br_2]$ (**1**), $[Cu_2(bipy)_4HgBr_4][Hg_2Br_6]$ (**2**) containing a trinuclear $[Cu_2(bipy)_4HgBr_4]^{2+}$ cation and an isolated $[Hg_2Br_6]^{2-}$ anion, $[Cu_2(bipy)_4Hg_2Br_6][Hg_4Br_{10}]$ (**3**) featuring a 1-D chain built from tetranuclear $[Cu_2(bipy)_4Hg_2Br_6]^{2+}$ cations interconnected by $[Hg_4Br_{10}]^{2-}$ tetramers and the trinuclear $[Cu(bipy)_2Hg_2Cl_6]$ (**4**), in which two $[Cu(bipy)_2]^{2+}$ cations are bridged by an $[Hg_4Cl_{12}]^{2-}$ tetramer. Herein we report their syntheses, crystal structures, and characterization.

Results and Discussion

The structures of **1**−**4** feature linear heteronuclear $Cu^{II}-Hg^{II}$ halogen oligomers in which the two different types of metal ions are bridged by the halide anions.

As shown in Figure 1, the Hg^{II} ion in dinuclear $[Cu(bipy)_2HgCl_2Br_2]$ (**1**) is tetrahedrally coordinated by two chloride anions and two bromide anions, whereas the copper(II) ion is six-coordinate with two bidentate chelating bipy ligands and two chloride anions in a distorted octahedral geometry. The Cu−N distances range from 2.00(1) to 2.08(1) Å. The Hg−Cl, Hg−Br, and Cu−Cl distances are 2.670(3), 2.488(2), and 2.750(4) Å, respectively and these bond lengths are similar to those reported in other copper(II) and Hg^{II} halogen complexes.[5,6,11] Unlike in $[Cu(en)_2]HgBr_4$,[11b] the Cu^{II} and Hg^{II} ions in **1** are bridged by a pair of μ^2-chloride anions to form a dinuclear molecular unit. $[Cu(en)_2]HgBr_4$ has a 1-D chain structure in which the two metal centers are bridged by only one bromide anion.[11b] We suggest that the difference is mainly due to the much larger steric hindrance of the bipy ligand than that of ethylene diamine. The structure of **1** is also significantly different from that of binuclear $[Ni(bipy)_2CdCl_2I_2]$ in that the cadmium(II) ion has a square planar coordination geometry instead of a tetrahedral one for the Hg^{II} ion.[9]

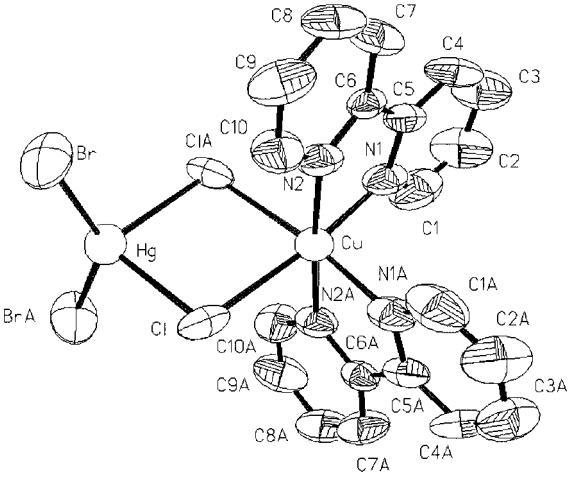

Figure 1. ORTEP representation of the asymmetric unit of $[Cu(bipy)_2HgCl_2Br_2]$ (**1**). Thermal ellipsoids are drawn at the 50% probability level. Symmetry code for the generated atoms: $1-x$, y, $3/2-z$

The Cu···Hg separation is 3.881(1) Å, indicating that there is no metal−metal bonding between the two metal centers.

These dinuclear molecular units in **1** are further interlinked via weak π-π interactions between neighboring pyridine rings to form a 1-D chain along the diagonal of the *a* and *c* axes (Figure 2). The distance between the centers of two such rings is 3.949 Å, and the dihedral angle between the two rings is 4.4°. Similar π-π interactions between pyridine rings have been reported in many phen-containing copper(II) complexes.[12] Such chains are held together via weak van der Waals forces.

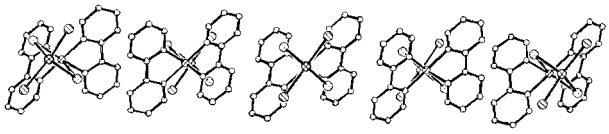

Figure 2. A 1-D chain formed from molecular units of complex **1** via π-π interactions between the pyridine rings

The copper(II) ions in **2**, **3**, and **4** are five-coordinate with two chelating bipy ligands and a halide anion. The coordination geometries around the Cu^{II} ions can be described as a slightly distorted square pyramidal with the square plane formed by 4 N atoms and the halogen atom occupying the axial position.

The structure of $[Cu_2(bipy)_4HgBr_4][Hg_2Br_6]$ (**2**) contains a trinuclear $[Cu_2(bipy)_4HgBr_4]^{2+}$ cation and a $[Hg_2Br_6]^{2-}$ anion (Figure 3). Within the trinuclear cationic unit, a pair of $[Cu(bipy)_2]^{2+}$ cations are bridged by an $HgBr_4$ tetrahedron. Hg(2) in the $[Hg_2Br_6]^{2-}$ anion is also four-coordinate and two $HgBr_4$ tetrahedra share an edge (Br5−Br5A) to form a dimeric unit. Such an $[Hg_2Br_6]^{2-}$ anion has been reported in other Hg^{II} bromide complexes.[11] The Cu−N, Cu−Br, and Hg−Br distances are similar to those in **1** (Table 1). The shortest Hg−Hg and Hg−Cu distances are 3.838(1) and 4.698(1) Å, respectively, thus there is no metal−metal interaction. The distance from Cu(1) in $[Cu_2(bipy)_4HgBr_4]^{2+}$ to the bromide of the nearest $[Hg_2Br_6]^{2-}$ anion is 3.838(2) Å, indicating that there are only electrostatic interactions between the two different building units. Similar to **1**, the neighboring $[HgCu_2(bipy)_4Br_4]^{2+}$ cations are further interlinked via weak π-π interactions between pyridine rings to form a 1-D double chain along the diagonal of the *a* and *c* axes. The

distance between the centers of two such rings is 3.771 Å, and the dihedral angle between the two rings is 6.2°.

The structure of $[Cu_2(bipy)_4Hg_2Br_6][Hg_4Br_{10}]$ (**3**) features a novel one-dimensional chain along the diagonal of the *a* and *c* axes (Figure 4). The chain is built from tetranuclear $[Cu_2Hg_2(bipy)_4Br_6]^{2+}$ cations interconnected by $[Hg_4Br_{10}]^{2-}$ tetramers via elongated Hg−Br bonds [3.185(2) Å]. Within the tetranuclear $[Cu_2Hg_2(bipy)_4Br_6]^{2+}$ cation, the edge-sharing tetrahedral dimeric $Hg(1)_2Br_6$ unit bridges with two $[Cu(bipy)_2]^{2+}$ units via two Br(1) atoms. The $[Hg_4Br_{10}]^{2-}$ tetramer is composed of an edge-sharing $Hg(3)_2Br_6$ dimeric unit and two $Hg(2)Br_2$ units [Br−Hg−Br 160.7(1)°] that are interconnected via Hg−Br bonds [Hg(2)−Br(6) 3.043(3) Å]. The coordination geometries around Hg(1) and Hg(3) can be described as slightly distorted tetrahedral. The distortion of the $Hg(2)Br_4$ tetrahedron is even more severe, two of the Hg-Br distances are longer than the remaining two Hg−Br bonds by more than 0.64 Å (Table 1). Similar to the situation in **1** and **2**, there is no metal−metal bonding between the metal centers, the shortest Hg−Cu and Hg−Hg distances are 4.435(2) and 3.823(2) Å, respectively. The 1-D chains of $[Cu_2(bipy)_4Hg_2Br_6][Hg_4Br_{10}]$ (**3**) are further interconnected via weak π-π interactions between neighboring pyridine rings to form a <010> 2-D layer (Figure 5). The distance between the centers of two such rings is 4.153 Å, and the dihedral angle between the two rings is 1.9°.

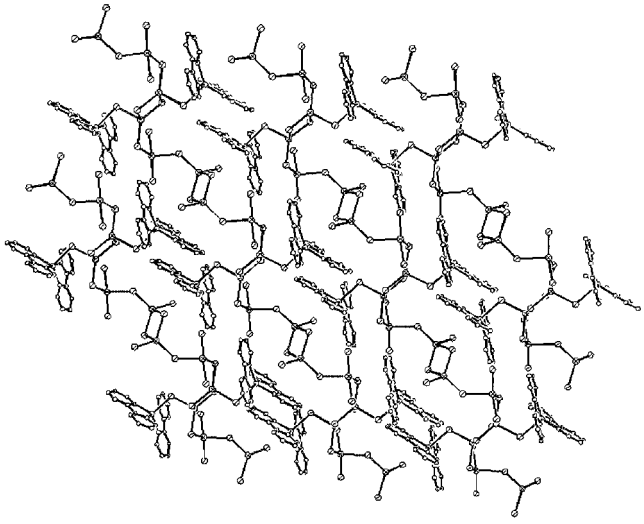

Figure 5. A <0 1 0> layer formed by 1-D chains of complex **3** through π-π interactions between the pyridine rings

In $[Cu(bipy)_2Hg_2Cl_6]$ (**4**), each $[Hg_2Cl_6]^{2-}$ dimeric unit bridges with a $[Cu(bipy)_2]^{2+}$ cation to form a trinuclear

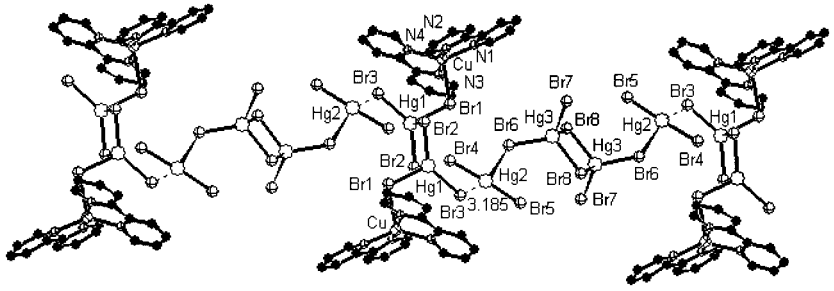

Figure 4. 1-D chain of $[Cu_2(bipy)_4Hg_2Br_6][Hg_4Br_{10}]$ (**3**) along the diagonal axis of *a* and *c*. Longer Hg−Br contacts are represented by dotted lines

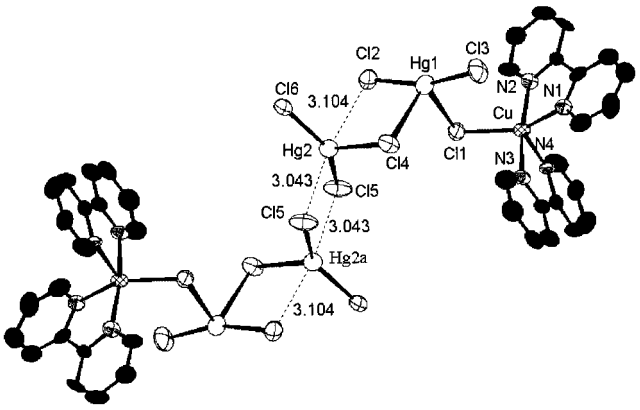

Figure 6. ORTEP representation of the structure of $[Cu(bipy)_2Hg_2Cl_6]_2$ (**4**). Thermal ellipsoids are drawn at the 50% probability level. Longer Hg−Cl contacts are represented by dotted lines. Symmetry code for the generated atoms: $1 - x, 2 - y, -z$

$[Cu(bipy)_2Hg_2Cl_6]$ unit (Figure 6). Two such neighboring units are interconnected by a pair of weak Hg−Cl bonds [Hg(2)−Cl(5) Å] into a hexanuclear $[Cu(bipy)_2Hg_2Cl_6]_2$ unit. The Hg(2)−Cl(2) distance of 3.104 Å is also much longer than the remaining Hg−Cl distance (Table 1). With all Hg−Cl bonds included, the coordination geometry around Hg(2) can be described as distorted trigonal bipyramidal with the two axial Hg−Cl bonds elongated. The coordination geometry of the Hg(1) center is severely distorted tetrahedral. The shortest Cu−Hg and Hg−Hg contacts are 4.053(1) and 4.0699(1) Å, respectively. The shortest Hg−Cl distance between two neighboring $[Hg_2Cu(bipy)_2Cl_6]_2$ units is more than 3.582(5) Å, thus these dimeric units are not further condensed. The structure of **4** is different from those of $[Cu(en)_2][Hg_2Cl_6]$ and $[Cu(en)_2][Hg_2Br_6]$ although they have a similar structural formula.[11b] In $[Cu(en)_2][Hg_2Cl_6]$, each $[Hg_2Cl_6]$ anion bridges with two $[Cu(en)_2]^{2+}$ cations to form a 1-D chain, and the Cu^{II} ion has a Jahn−Teller distorted octahedral coordination geometry. In $[Cu(en)_2][Hg_2Br_6]$, the copper(II) ion is also octahedrally coordinated, however the $[Hg_2Br_6]^{2-}$ anions are interconnected into a 1-D chain, and all Hg^{II} ions are five-coordinate with trigonal bipyramidal geometries. The anionic chains of $[Hg_2Br_6]^{2-}$ are cross-linked by bridging $[Cu(en)_2]^{2+}$ cations into a 1-D layer.[11b] Again we suggest the steric effect of the bipy group plays an important role in determining the structures of the so formed Cu^{II}−Hg^{II} halide compounds. Strong steric hindrance of two bipy ligands makes the octahedral coordination geometry unfavorable for the Cu^{II} ion.

The formula units of **4** are packed via π-π interactions between the pyridine rings to form a 1-D chain along the diagonal of the *a* and *c* axes. The distance from the pyridine ring center formed by N(3), C(11), C(12), C(13), C(14), and C(15) to that formed by N(4), C(16), C(17), C(18), C(19), and C(20) in neighboring formula units is 3.888 Å. The dihedral angle between these two pyridine rings is only 5.2°.

Results of magnetic measurements for **1**, **2**, and **4** indicate that the three compounds contain one, two, and one isolated single-spin d^9 Cu^{II} ion, respectively. Magnetic measurements for **3** were not performed due to an insufficient amount of samples. The measured μ_{eff} values are 1.766(3), 2.494(2), and 1.764(1) μ_B, respectively for **1**, **2**, and **4**. These values decrease very slightly with decreasing temperature and non-linear fitting of the data according to the Cuie−Weiss law [$\chi_M = C/(T - \theta) + \chi_0$] in the temperature range of 6−300 K gives θ vlues of −0.24(3), −0.27(1), and −0.15(6), and χ_0 values of $3.1(2)\cdot10^{-4}$, $-6.5(2)\cdot10^{-4}$, and $-3.9(2)\cdot10^{-4}$ emu/mol, for **1**, **2**, and **4** respectively. Thus there is little magnetic interaction between neighboring Cu^{II} ions, which is in good agreement with results from the X-ray structural analyses in which the nearest Cu···Cu separations are 8.112(2), 7.431(2), and 7.386(2) Å, for **1**, **2**, and **4** respectively.

Experimental Section

Materials and Methods: $CuCl_2\cdot2H_2O$, $CuBr_2$, $HgBr_2$, and 2,2′-bipyridine were purchased from the Fourth Factory of Shanghai Reagent and NH_4PF_6 was obtained from Acros. All chemicals and solvents were of reagent grade and used without further purification. Elemental analyses were performed on a Vario EL III elemental analyzer. IR spectra were recorded on a Magna 750 FT-IR spectrometer as KBr pellets in the 4000−400 cm^{-1}. Magnetic susceptibility measurements on polycrystalline samples were performed with a Quantum Design SQUID magnetometer at a field of 1 T over the range of 6 to 300 K. Raw data were corrected for the susceptibility of the container.

Synthesis of $[Cu(bipy)_2HgCl_2Br_2]$ (1): $CuCl_2\cdot2H_2O$ (0.09 g, 0.5 mmol), NH_4PF_6 (0.16 g,1.0 mmol, used for adjusting pH value of the solution), and 2,2′-bipyridine (0.16 g, 1.0 mmol) were dissolved in a solvent mixture of acetone (10.0 mL), ethanol (10.0 mL), and acetonitrile (10.0 mL) whilst stirring at room temperature. After 10 min, $HgBr_2$ (0.16 g, 0.5 mmol) was added and the solution was stirred for 20 hours. The resultant solution with a pH value close to 6.0 was filtered and allowed to evaporate slowly at room temperature. Blue crystals of **1** were obtained after five days in a yield of 40.2% (0.16 g). IR (KBr cm^{-1}): $\tilde{\nu}$ = 1601 m, 1570 w, 1495 m, 1444 s, 1317 m, 839 vs, 768 vs, 731 m, 557 m. $C_{20}H_{16}Br_2Cl_2CuHgN_4$ (807.22): found C 29.81, H 2.48, N 6.95%; calcd. C 29.76, H 2.00, N 6.94%.

Synthesis of $[Cu_2(bipy)_4HgBr_4][Hg_2Br_6]$ (2): $CuBr_2$ (0.16 g, 0.5 mmol), NH_4PF_6 (0.16 g, 1.0 mmol), and 2,2′-bipyridine (0.16 g, 1.0 mmol) were dissolved in a solvent mixture of acetone (10.0 mL), ethanol (10.0 mL), and acetonitrile (10.0 mL) at room temperature and stirred for 30 min. $HgBr_2$ (0.36 g, 1.0 mmol) was then added and the reaction was allowed to continue for a further 20 hours. The resultant solution with a pH value of 6.0 was filtered and the filtrate was allowed to evaporate slowly at room temperature. Green-blue crystals of **2** were obtained after one day in a yield of 78.1% (0.42 g). IR data (KBr cm^{-1}): $\tilde{\nu}$ = 1601s, 1495 m, 1473 s, 1444 vs, 1317 m, 1252 m, 1159 m, 1034 m, 764 vs, 732 s, 663 w. $C_{40}H_{32}Br_{10}Cu_2Hg_3N_8$ (2152.69): found C 22.54, H 3.20, N 5.12, Cu 6.26%. calcd. C 22.32, H 1.50, N 5.21, Cu 5.9%.

Synthesis of $[Cu_2(bipy)_4Hg_2Br_6][Hg_4Br_{10}]$ (3): A mixture of $CuBr_2$ (0.16 g, 0.5 mmol), NH_4PF_6 (0.08 g, 0.5 mmol), and 2,2′-bipyridine (0.16 g, 1.0 mmol) was dissolved in a solvent mixture of acetonitrile (5 mL) and methanol (5 mL) which was placed in one side of an H-shaped tube (total volume 35 mL). $HgBr_2$ (0.18 g, 0.5 mmol) dis-

solved in acetonitrile (10 mL) was added to the other side of the H-shaped tube. A solvent mixture of CH_2Cl_2 (5 mL) and hexane (5 mL) was then layered on the top of both ends of the H-shaped tube. The tube was sealed and the reaction allowed to proceed through diffusion of the two solutions over a period of six days. Air-stable green-blue crystals of **3** were collected from the $HgBr_2$-containing side of the H-tube in a very low yield of 5.6% (0.045 g). IR (KBr cm^{-1}): $\tilde{\nu}$ = 1601 s, 1568 m, 1477 m, 1444 vs, 1317 m, 1159 m, 1034 m, 764 vs, 729 s, 663 m. $C_{40}H_{32}Br_{16}Cu_2Hg_6N_8$ (3233.92): found C 14.92, H 2.60, N 3.34%; calcd. C 14.86, H 2.30, N 3.47%.

Synthesis of $[Cu(bipy)_2Hg_2Cl_6]_2$ (4): Compound **4** was synthesized by a similar procedure to that of **1** by reacting $CuCl_2{\cdot}2H_2O$ (0.09 g, 0.5 mmol), NH_4PF_6 (0.16 g, 1.0 mmol), 2,2′-bipyridine (0.16 g, 1.0 mmol), and $HgBr_2$ (0.27 g, 1.0 mmol) in a solvent mixture of acetone (10.0 mL) and methanol (10.0 mL) at room temperature. Yield 50.0%. IR (KBr): $\tilde{\nu}$ = 1599 cm^{-1} s, 1493 m, 1473 s, 1443 vs, 1317 m, 1250 m, 1157 m, 1028 m, 769 vs, 729 s, 650 w. $C_{20}H_{16}Cl_6CuHg_2N_4$ (989.79): found C 24.36, H 1.06, N 5.52%; calcd. C 24.25, H 1.62, N 5.65%.

Crystallography: Single crystals of **1**, **2**, and **4** were mounted on a Siemens Smart CCD diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Intensity data were collected by the narrow frame method at 293 K. The data sets were corrected for Lorentz polarization as well as for absorption using the SADABS program.[13] Data collection for **3** was performed on an Enraf−Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 298 K using ω-2θ scan methods. The data set for **3** was corrected for Lorentz polarization and an empirical absorption correction was applied based on the ψ scan technique. All four structures were solved by direct methods and refined by full-matrix least-squares fitting on F^2 using SHELX-97.[13] All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were located in geometrically calculated positions. Crystallographic data and structural refinements for **1** to **4** are summarized in Table 2. Important bond lengths and angles are listed in Table 1.

CCDC-209447 to -209450 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

A Microporous Zinc Phosphonocarboxylate with a Zeolite ABW Framework via the Trialkyl Phosphonocarboxylate Route: In situ Synthesis and Characterization of $Na[Zn(O_3PC_2H_4CO_2)]\cdot H_2O$

Xian-Ming Zhang[a]

Keywords: Microporous materials / Organic-inorganic hybrid / Zeolites / Zinc

A new zinc phosphonocarboxylate $Na[Zn(O_3PC_2H_4CO_2)]\cdot H_2O$ (**1**) has been hydrothermally synthesized by base-catalyzed hydrolysis of trimethyl 3-phosphonopropionate. An X-ray crystallographic study revealed that **1** consists of parallel stacked inorganic hexagonal sheets which are connected by organic –C–C–C–O– pillars forming a three-dimensional framework with the same topology as ABW-type zeolites. The accessible channel of **1** consisting of 22 atoms is larger than those of ABW-type zeolites and the metal phosphonates $Zn(O_3PC_2H_4NH_2)$ and $Zn(O_3PC_2H_4CO_2H)\cdot 1.5H_2O$. TGA shows the trapped water molecules in **1** can be thermally removed without damage to the framework. Furthermore, dehydrated **1** is stable up to 340 °C.

Introduction

Zeolites are microporous aluminosilicates and have widespread applications as absorbents, for separations, as catalysts and for ion-exchange.[1–5] The desire to develop new microporous materials has led to increasing interest in the synthesis of metal phosphonate materials in recent years.[6–7] Metal phosphonates are organic-inorganic hybrid materials in which the nature of the organic phosphonic acid, H_2O_3P-R-Z, can be designed to confer specific properties to this class of solids.[8–10] The dimensionality of metal phosphonates can be directly influenced by the Z terminal functional and the R group. Thus, it is possible to manipulate the metal phosphonate framework by choosing a system with or without a Z terminal function and by changing the R group. In the absence of the Z function, metal phosphonates usually have layered or tubular structures[11–17]with an arrangement that strongly depends upon the nature and oxidation state of the metal. One of the exceptions is β-$Cu(CH_3PO_3)$ which exhibits a three-dimensional structure with a channel-type arrangement.[18] If the terminal Z functional is the -PO_3H_2 group which has three potential binding sites, the resultant metal phosphonates often show three-dimensional pillared layered structures.[19–25] If the Z functional end is the $-CO_2H$,[26–33] $-C(NH_2)CO_2H$,[34–36] or NH_2[37] group, the dimensionality of the metal phosphonates often relies on the length of the R group.

Although some progress has been made in the construction of microporous metal phosphonate materials as mentioned above, less progress has been achieved in the synthesis of microporous metal phosphonates with the topology of zeolites. One requirement for metal phosphonates with such a topology is that all metal ions and phosphonic acids must be rigidly 4-connected. This results in a structure like the (4;2) connected topology of zeolites.[38] To the best of our knowledge, only two metal phosphonates with the topology of zeolites have been reported namely $Zn(O_3PC_2H_4CO_2H)\cdot 1.5H_2O$[33] and $Zn(O_3PC_2H_4NH_2)$.[37] Therefore, the generation of metal phosphonates with the zeolite topology poses a significant synthetic challenge due to the high coordination tendency and flexibility of organic phosphonic acids. Another problem in metal phosphonate chemistry is that many metal phosphonates formed by traditional methods (direct reaction of phosphonic acid with metal source by the hydrothermal method, by heating to reflux appropriate solutions, or by making metal salts contact with molten phosphonic acid) are formed too rapidly to allow growth of crystals sufficiently large to enable single crystal structural determinations to be carried out.[19] In this paper we report the crystal structure and thermal behavior of a new microporous zinc phosphonocarboxylate $Na[Zn(O_3PC_2H_4CO_2)]\cdot H_2O$ (**1**) which has an open framework with the same topology as ABW-type zeolites.

Results and Discussion

Both the selection of trimethyl 3-phosphonopropionate as the 3-phosphonopropionic acid source and the maintaining of strongly basic conditions are very critical for the

formation of single crystals of **1**. For example, one similar reaction (keeping all other conditions unchanged except for 3-phosphonopropionic acid in place of trimethyl 3-phosphonopropionate) did not result in single crystals of **1** but instead, a colorless powder. The synthesis of metal phosphonocarboxylates directly from the relevant trialkyl phosphonocarboxylate appears to be an extremely productive adaptation of the traditional hydrothermal methods employed in the syntheses of these materials. The initial pH in the synthesis of **1** must be strongly basic in order to promote in situ hydrolysis of the trialkyl phosphonocarboxylate to the phosphonocarboxylic acid. Although some metal phosphonates have been prepared by acid-catalyzed hydrolysis of dialkyl phosphonates,[39−40] no metal phosphonate has been synthesized by base-catalyzed hydrolysis of trialkyl phosphonocarboxylate. The synthetic method in this work has two benefits 1) the use of the trialkyl phosphonocarboxylate rather than the phosphonocarboxylic acid removes the need to synthesize the acid because trialkyl phosphonocarboxylates are often far easier to purify (this can often be achieved simply by distillation) than the corresponding phosphonocarboxylic acids and 2) the slow in situ formation of phosphonocarboxylic acid by base-catalyzed hydrolysis of trimethyl 3-phosphonopropionate will ensure the growth of single crystals sufficiently large to allow a single crystal X-ray structural determination.

The IR spectrum of **1** shows one broad band centered at 3451 cm^{-1} confirming the presence of crystal lattice water. The coordination of the carboxylate is represented by strong bands at 1641 and 1562 cm^{-1} which arise from the asymmetric and symmetric stretching modes of the C−O bonds of the carboxylate group. The set of intense bands from 900 to 1100 cm^{-1} is due to the stretching vibrations of the tetrahedral CPO_3 group.

A single-crystal X-ray diffraction study revealed that **1** crystallizes in the monoclinic space group $P2_1/n$ and the asymmetric unit consists of one crystallographically independent zinc atom, one 3-phosphonopropionate unit, one sodium ion and one crystal lattice water molecule as shown in Figure 1. The Zn(1) site is tetrahedral, being coordinated by three PO_3 oxygen atoms originating from three different 3-phosphonopropionate ligands and one carboxylate oxygen atom from an additional 3-phosphonopropionate ligand. Each of the three oxygen atoms of the PO_3 group coordinates to only one zinc atom. The coordination mode of the PO_3 group in **1** is referred as a (1,1,1) connection[41] which in combination with one additional carboxylate oxygen furnishes a μ_4:η^1:η^1:η^1:η^1 coordination mode for the 3-phosphonopropionate unit which is also observed in $Zn(O_3PC_2H_4CO_2H)\cdot 1.5H_2O$.[33] The Zn(1)−O and P(1)−O bond lengths are in the ranges of 1.926(3)−1.947(3) Å and 1.519(3)−1.529(3) Å, respectively. The O−Zn(1)−O angles are in the range of 101.05(13)−114.59(12)° which shows some deviation from ideal angle of 109.5°.

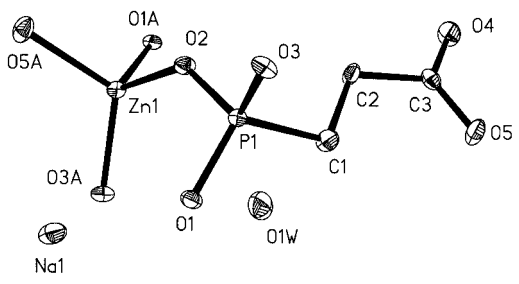

Figure 1. View of the coordination environment of the zinc atom in **1**

Within the *ac* plane, the corner-sharing connections of the CPO_3 and ZnO_4 tetrahedra result in a two-dimensional hexagonal sheet with a (6^3) topology as shown in Figure 2. The parallel stacking 2-D hexagonal sheets are held together by organic −C−C−C−O− pillars to form a 3-D pillared layered open framework (Figure 3). In each hexagonal sheet, one free corner of each tetrahedral atom can point up (U) or down (D) from the layer. The hexagonal sheets in **1** are arranged such that three adjacent tetrahedral

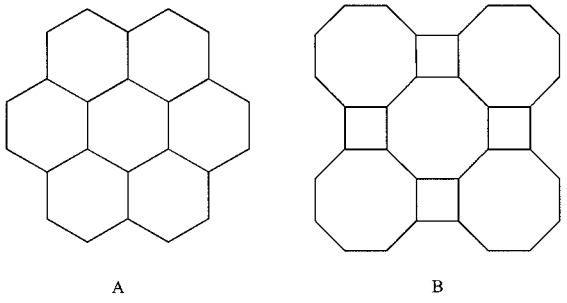
atoms all are directed up while the other adjacent three are directed down (UUUDDD),[38,42] which indicates that **1** has the topology of ABW-type zeolites. The Zn and P centers occupy 4-connected vertices of the ABW-type zeolite framework and the two-connected connectors are the O atoms and the C−C−C−O pillars. There are two types of channel along the *a* axis direction as shown in Figure 3. The larger one, sized ca. 3.4−7.2 Å, has roughly a dumbbell shape which is enclosed by 22 atoms with the sequence O−P−C−C−C−O−Zn−O−P−O−Zn−O−P−C−C−C−O−Zn−O−P−O−Zn. The guest sodium ions and water molecules are trapped in the channels in **1**. The smaller channel enclosed by 14 atoms is too small to contain guest molecules.

It is interesting to compare the structure of **1** with some ABW-type aluminosilicate and metal phosphate zeolites. Zeolite ABW structures can be viewed as being built from the stacking of hexagonal sheets. The unit cell of **1** was chosen so that the stacking direction is along the *b* axis, just as in hydrated ABW-type zeolites. The hexagonal layers in **1** and other ABW-type zeolites are similar because their repeat units in two directions within the hexagonal layers are close [8.797 Å and 5.462 Å in NH_4CoPO_4-ABW; 8.883 Å and 5.222 Å in **1**]. The repeat units along the hexagonal layer stacking direction in **1** is 15.519 Å which is significantly larger than those in hydrated ABW-type aluminosilicate and metal phosphate zeolites (10.313 Å for $LiAlSiO_4{\cdot}H_2O$ and 8.797 Å for NH_4CoPO_4-ABW).[42,43] The accessible channel along the layer stacking direction in zeolite ABW is composed of 16 atoms (8 corner-shared TO_4 tetrahedra, Scheme 1, B) but the accessible channel in **1** consists of 22 atoms. The accessible channel in **1** is also larger than those of the only other known metal phosphonates with the topology of zeolites i.e. $Zn(O_3PC_2H_4CO_2H){\cdot}1.5H_2O$[33] and $Zn(O_3PC_2H_4NH_2)$[37] in which the accessible channels also consist of 16 atoms with sizes close to those of ABW-type zeolites. Compared with ABW-type zeolites, the larger repeat unit along the hexagonal layer stacking direction and the larger channel size in **1** result from the longer connector. The connectors along the hexagonal layer stacking direction in ABW-type zeolites and **1** are O atoms and C−C−C−O groups, respectively. Compared with the only other known metal phosphonates with the topology of zeolites, $Zn(O_3PC_2H_4CO_2H){\cdot}1.5H_2O$ and $Zn(O_3PC_2H_4NH_2)$, the larger channel size in **1** mainly results from its unique architecture. Unlike $Zn(O_3PC_2H_4CO_2H){\cdot}1.5H_2O$ and $Zn(O_3PC_2H_4NH_2)$ which have inorganic (4.8^2) layers (Scheme 1, B), **1** is constructed from inorganic hexagonal (6^3) layers connected by organic pillars into a 3-D framework.

The TGA trace of **1** shows an initial mass loss of 7.5 % below 185 °C, attributable to loss of the trapped water molecules within the channels (Figure 4). The second mass loss starting at around 340 °C is thought to be due to the oxidation of the hydrocarbon part of the phosphonocarboxylate group. The total mass loss is 29.3 % upon heating to 600 °C in flowing air, which is consistent with the loss of the organic part of the material (calculated mass loss is 28.7 %). This value is also consistent with the CHN analysis. Control experiments confirm that the framework of **1** is maintained upon heating and removal of the trapped water molecules but it does not undergo exchange of the Na^+ ions by protons.



Scheme 1. Schematic view of 2-D (4.8^2) (A) and (6^3) (B) nets in zeolite ABW. For clarity, the oxygen atoms are represented by straight lines

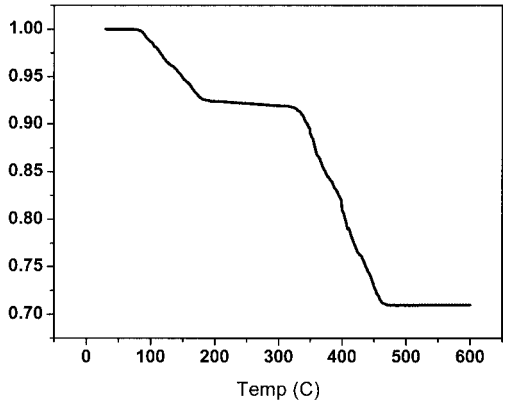


Figure 4. The TGA curve of **1**

In conclusion, we have synthesized a new microporous zinc phosphonocarboxylate with a zeolite ABW-type topology by base-catalyzed hydrolysis of trimethyl 3-phosphonopropionate. The use of the trialkyl phosphonocarboxylate as the phosphonocarboxylic acid source simplifies the traditional methods for metal phosphonocarboxylates and the in situ formation of phosphonocarboxylic acid guarantees the growth of single crystals of sufficient size for X-ray diffraction. The accessible channel in ABW-type zeolites consists of 16 atoms but partial replacement of O atoms with C−C−C−O groups as connectors in **1** generates same topological structure with a larger accessible channel consisting of 22 atoms.

Experimental Section

General Remarks The synthesis was carried out in a 15 mL volume Teflon-lined reactor under autogenous pressure with a filling capacity of 50 %. The CHN microanalysis was performed on a Perkin-Elmer 240 elemental analyzer. The FT-IR spectra were recorded in KBr pellets in the range of 4000−400 cm^{-1} on a Nicolet 5DX spectrometer. Thermal gravimetric analyses (TGA) were per-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

formed under a static air atmosphere from 30−600 °C using a Perkin-Elmer 7 thermogravimetric analyzer with a heating rate of 10 °C·min^{-1}.

Synthesis of Na[Zn($O_3PC_2H_4CO_2$)]·H_2O (1): A mixture of $Zn(MeCO_2)\cdot 2H_2O$ (0.220 g, 1 mmol), trimethyl 3-phosphonopropionate (0.228 g, 1 mmol), NaOH (0.18 g, 4.5 mmol), and H_2O (7 mL) in the molar ratio of 1:1:4.5:400 was stirred in air for 20 min (pH > 14) and transferred into a 15 mL Teflon-lined stainless steel reactor which was heated to 160 °C for 120 h. After cooling to room temperature, colorless needles **1** (65 %) in a single phase were recovered. The pH decreased to ca. 12 during the reaction. Elemental analysis for **1**: $C_3H_6O_6ZnNa$: calcd. C 14.00, H 2.35; found C 13.94, H 2.39. IR (KBr): $\tilde{\nu}$ = 3603 w cm^{-1}, 3451 br., 3088 w, 2968 w, 2927 w, 1641 s, 1608 m, 1562 s, 1454 m, 1418 m, 1257 m, 1124 m, 1094 s, 1011 s, 958 s, 832 m, 764 w, 721 w.

X-ray Crystallographic Study: Data collection was performed at 293 K on a Bruker Apex diffractometer (Mo-K_α, λ = 0.71073 Å). Lorentz-polarization and absorption corrections were applied. The structure was solved by direct methods and refined with the full-matrix least-squares technique (SHELX-97).[44] Analytical expressions of neutral-atom scattering factors were employed and anomalous dispersion corrections were incorporated. In all cases, all non-hydrogen atoms were refined anisotropically. Hydrogen atoms of organic ligands were geometrically placed. Hydrogen atoms of water were located from a difference Fourier map and refined with isotropic temperature factors. The crystallographic data for **1** are listed in Table 1 and selected bond lengths and bond angles are given in Table 2.

CCDC-216687 contains the supplementary crystallographic data for this paper. Apparent Allyl Rotation in New Allylpalladium(II) Complexes with Pyrazolyl *N*-Donor Ligands

Ana Guerrero,[a] Félix A. Jalón,[a] Blanca R. Manzano,*[a] Ana Rodríguez,[a] Rosa María Claramunt,*[b] Pilar Cornago,[b] Viktor Milata,[c] and José Elguero[d]

Keywords: Fluxionality / N ligands / Allyl ligands / Palladium

The ligands 2,4,6-tris(pyrazol-1-yl)-1,3,5-triazine (TPzT), 2,4,6-tris(3,5-dimethyl-pyrazol-1-yl)-1,3,5-triazine (Me_2-TPzT), and 2,4,6-tris(3,4,5-trimethylpyrazol-1-yl)-1,3,5-triazine (Me_3-TPzT) have been synthesised and their reaction with $[Pd(\eta^3\text{-}C_4H_7)(THF)_2]X$ was explored. The reaction in a 1:3 molar ratio (ligand/solvate) leads to the new derivatives $[\{Pd(\eta^3\text{-}C_4H_7)\}_2(BPz'TO)]X$ (Pz′ = pyrazole, X = BF_4, **2a**; Pz′ = 3,5-dimethylpyrazole, X = PF_6, **2c**; Pz′ = 3,4,5-trimethylpyrazole, X = PF_6, **2d**) in which the N-donor ligand has been partially hydrolysed. The complexes exist in the form of two isomers, a *meso* form and a *d,l* pair. An apparent allyl rotation process leads to a *syn-syn/anti-anti* interconversion and also to an interchange between the two isomers. The values of $\Delta G_c^{\ddagger}$ at the coalescence temperature have been calculated. The results, which have also been compared with those previously obtained for the complex with the 4-methylpyrazole ligand, indicate that the activation barrier for the process is not affected by the change in the pyrazole group. Appreciable effects were not observed on changing the concentration or on the addition of water to the acetone solutions of **2c**. However, the influence of the solvent (acetone versus chloroform) is worth noting. A negative activation entropy has been found and a mechanistic proposal for the process is included. The molecular structure of **2c** has been determined by X-ray diffraction. The *meso* isomer, in which the two C–Me axes of the allylic groups are oriented in the same direction, is found in the solid state.

Introduction

The chemistry of (η^3-allyl)palladium complexes has been widely studied due to them acting as precursors or intermediates in different catalytic processes.[1] The fluxional behaviour of these systems, either directly related to the allyl group or to the ancillary ligands, has also attracted much attention.[2] Apart from the fundamental interest of these studies, the dynamics of the allylpalladium derivatives have important implications in a variety of catalytic processes, especially those involving nucleophilic attack on (η^3-allyl)palladium intermediates in enantioselective synthesis.[3] One process that the allyl group frequently undergoes is a mutual exchange of *syn* and *anti* groups, which can lead to isomer interconversions.[4−12] This interchange is normally believed to occur through an η^3-η^1-η^3 pathway that in some cases is selective[13−15] due to steric or electronic factors (a high *trans* influence of a group favours the opening of the allylic carbon atom situated in the *trans* position). Theoretical calculations concerning the mechanism of the η^3-η^1-η^3 isomerisation in (η^3-allyl)palladium complexes have led to the conclusion that the process involves tetracoordinate (η^1-allyl)palladium intermediates with coordination of a solvent molecule or an ancillary ligand.[16] A second dynamic process that is frequently observed in complexes with N-donor ligands is the apparent rotation of the allyl group.[17−27] In certain examples both of the aforementioned processes have been observed.[28−34] Depending on the molecular symmetry, the apparent rotation is observed as a *syn-syn*/*anti-anti* exchange and/or an isomerisation process. Different mechanisms have been proposed for the apparent allyl rotation and these may be classified into two groups: i) associative mechanisms[19,27,28,31,32] that involve pentacoordinate intermediates with coordination of the solvent, the anion or other molecules, ii) dissociative mechanisms[17,18,20−22,24,25,30,33] that involve formation of

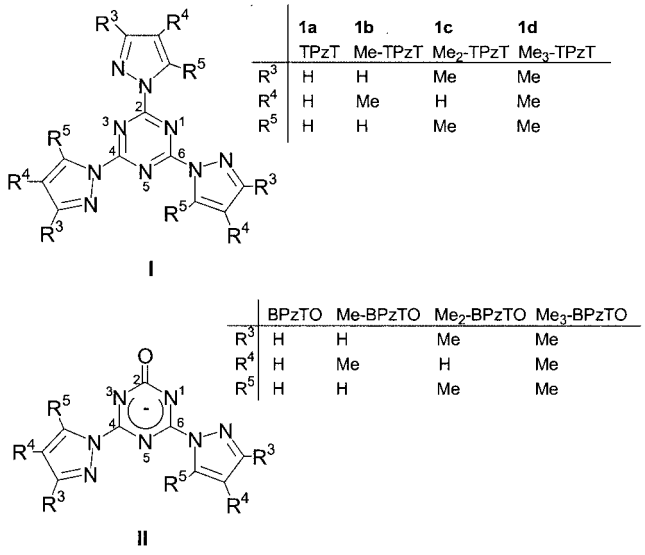
T-shaped three-coordinate intermediates after partial dissociation of a bidentate ligand, usually through Pd−N bond rupture. In some cases it has been reported that a ligand of higher basicity makes the apparent rotation more difficult,[20] while increased steric hindrance of the N-donor ligand facilitates the process.[19,28] In recent years we have been interested in the synthesis, structural characterisation and dynamic behaviour of (allyl)Pd^{II} complexes with N-donor ligands containing pyrazolyl substituents.[22−27,35] In most cases the process of apparent allyl rotation was observed and led to isomer interconversion. When the (allyl)-palladium fragment was treated with ligands of type **I** [2,4,6-tris(4-R-pyrazol-1-yl)-1,3,5-triazines; see Scheme 1; $R^3 = R^5 = H$, R^4 = Me, Br] it was found that during the course of the reaction one of the pyrazolyl residues was lost and, ultimately, the complexes formed were derived from the 4,6-bis(4-R-pyrazol-1-yl)-1,3,5-triazin-2-olate anion **II**[24] (see Scheme 1). The $\Delta G_c^{\ddagger}$ data led us to conclude that the main driving force of the hydrolysis process was the formation of a better coordinating ligand. In the work described here, we decided to explore the behaviour of similar ligands containing differently substituted pyrazolyl groups. In this way it was possible to analyse the influence (steric or electronic) of the pyrazolyl ring on the energy barrier of the apparent rotation process. We also decided to study the effect of concentration, the addition of water and a change in the solvent. Another aim was to determine whether the hydrolysis process was affected by differing basicity and consequently, the different leaving group character of the pyrazole moiety.



Scheme 1

The ligands used in this work were **1a**, **1c**, and **1d** (see Scheme 1). The ligand **1b**[24] is also included for the sake of comparison. The introduction of methyl substituents in positions 3 and 5 of the pyrazole rings increases the basicity and the steric hindrance, while the same substitution in position 4 would only be expected to cause an electronic change.

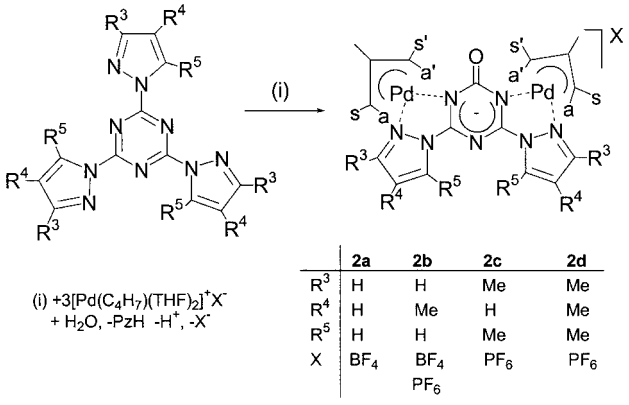
Results and Discussion

Synthesis of Ligands 1a−1d

Ligand **1a**,[36,37] ligand **1b** and its reaction with (allyl)palladium fragments,[24] and ligand **1c** and its X-ray molecular structure[38] have all been reported previously. The synthesis of **1d** is reported for the first time in this paper.

Synthesis of the Allyl Complexes

Reaction of the $[Pd(\eta^3\text{-}C_4H_7)(THF)_2]X$, X = BF_4^-, PF_6^- {obtained by mixing $[Pd(\eta^3\text{-}C_4H_7)(\mu\text{-}Cl)]_2$ and $AgBF_4$ or $AgPF_6$ in THF} with the ligands **1a**, **1c**, or **1d** gave complexes **2a**, **2c**, and **2d**, respectively, containing the hydrolysed ligand (see Scheme 2 and Exp. Sect.). Compounds **2b**·BF_4, **2b**·PF_6 and complexes with other anions have been described previously.[24]



Scheme 2

We tried unsuccessfully to isolate the intermediate $[Pd(\eta^3\text{-}C_4H_7)_2\cdot\mathbf{1}]X$ but, although the work was carried out under anhydrous N_2 and with freshly distilled (under N_2) solvents, hydrolysis to **2** always took place. Indeed, the hydrolysed products **2** were isolated even when the reaction was carried out at low temperature. The water necessary for the hydrolysis must arise from the silver salts and also perhaps from traces in the solvent. It was attempted to completely remove all water from $AgPF_6$ but this unfortunately proved impossible, even after drying the salt over P_2O_5 with a vacuum lower than 10^{-2} Torr for 5 d. Similar problems have been reported previously.[39] Given that the more basic the pyrazole the worse it is as a leaving group, ligand **1d** was selected (pK_a values: pyrazole 2.48, 4-methylpyrazole 3.04, 3,5-dimethylpyrazole 4.06, 3,4,5-trimethylpyrazole 4.56)[40] but, in this case, the same result was obtained. This observation is in accordance with our previous results[24] where it was found that the methoxy group, which is a poorer leaving group than pyrazole, also underwent the hydrolysis process. This result also supports our previously reported conclusion that the hydrolysis of the R-TPzT ligands, in the presence of the allylpalladium fragment, may have its origin in the bond reinforcement of the triazin-2-olate anion with the palladium centres. Complexes **2** are soluble in acetone, THF and dichloromethane but insoluble

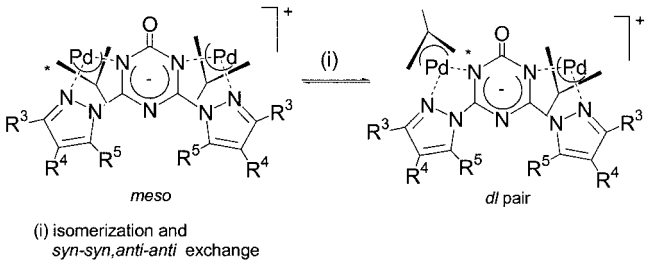
in diethyl ether, pentane and hexane. This solubility behaviour was used to obtain crystals of **2c**.

Structural Characterisation of Complexes 2a, 2c, and 2d

The IR spectra of the complexes contain a ν(C=O) band at 1696 (**2a**), [1685 (**2b**)],[24] 1691 (**2c**), or 1687 cm^{-1} (**2d**). The most characteristic peak in the FAB^+/MS corresponds to $[M - X]^+$ and this appears at 552 (**2a**), [580 (**2b**)],[24] 608 (**2c**), or 636 Da (**2d**). These peaks are due to the loss of the counterion from the molecular mass of the ionic complex. Secondary peaks that correspond to the loss of one or two allyl groups are also observed.

The data from the ^1H NMR spectra are compiled in Table 1. The signals of the complexes were assigned by comparison with the data for the corresponding ligands and considering the information obtained from NOE studies. For example, ligand **1d** and complex **2d** exhibit an NOE between Me^4 and Me^3/Me^5. The resonance for Me^3 also showed NOEs with H_{anti} and H_{syn} signals. A shift towards higher energies is observed in the resonances of the complexes with respect to the non-coordinated N-donor ligands.

At room temperature, **2a** showed only one broad signal for the H_{syn} or H_{anti} protons while the corresponding spectra for **2c** and **2d** contained two signals for each kind of protons. In all cases, signals corresponding to one type of pyrazole group were observed at this temperature. When the ^1H NMR spectra of the complexes were registered at low temperature, splitting of the signals was detected. Evidence was seen for two types of pyrazole groups in different ratios along with four H_{anti} and four H_{syn} (two types of intensities) protons. If we consider these data and the information deduced for the similar complex **2b**,[24] the situation observed must be due to the presence of two isomers − a *d*,*l* pair and a *meso* form − that differ in the relative orientation of the two allyl groups (see Scheme 3). Each isomer contains two equivalent pyrazole rings and two asymmetric and equivalent allylic groups. In the case of complex **2d**, where the allylic signals at low temperature are more differentiated than in the other complexes, we performed NOE studies at 213 K. It can be seen from the data in Table 1 that it was possible to identify, from the NOEs observed with the Me^3 signal, the resonances due to the allylic group *cis* to the pyrazole ring in each isomer. The H_{syn} and H_{anti} atoms of the same allylic carbon atom also showed a mutual NOE.



Scheme 3

The NOE studies at room temperature (and also in some cases at low temperature) showed a transfer of magnetisation within an allyl group between the two H_{syn} atoms on the one hand, and the two H_{anti} atoms on the other. This information, together with the observation of two isomers at low temperature that are seen as a single form at room temperature, is a clear indication of fluxional behaviour in the complexes. This possibility was further investigated by means of variable-temperature ^1H NMR spectroscopy studies and the results will be discussed in a separate section.

The $^{13}C\{^1H\}$ NMR spectroscopic data of the ligands and complexes at room temperature are reported in Table 2. The asymmetry of the 2-methylallyl group is apparent from the signals of the terminal carbon atoms at δ ≈ 60 ppm, one

close to the C=O and the other to the pyrazole. A number of the allyl signals are broad, indicating the existence of the afore-mentioned fluxional process. Complexation produces small effects on the signals of the ligands. HMQC experiments, relating ^1H and ^{13}C signals, proved particularly useful in assigning the methyl groups of the pyrazole rings.

X-ray Structure of 2c

The molecular structure of **2c** was determined by X-ray diffraction. The molecular structure consists of a dinuclear Pd monocation and a PF_6 counteranion. The ORTEP plot of the cation is shown in Figure 1, the crystallographic data are given in Table 6 and a selected list of bond lengths and angles is reported in Table 3. The N-donor ligand adopts a practically planar conformation with three coplanar heterocycles. The Pd centres are also practically coplanar with the azolylazine molecule. The bite angle of this ligand is ca. 76° in both coordination positions. The Pd−N bond lengths are also almost identical [2.076(6) and 2.102(5) Å], with the distance being slightly longer for the Pd−N(triazinolate) than for the Pd−N(pyrazole) bonds. The Pd−C bond lengths with the allyl groups are in the range expected for these types of complexes,[24] with the longer distance measured for the Pd−C(central) than for the Pd−C(terminal) bonds. The dihedral angle between the allylic plane and the palladium coordination plane is ca. 114°, with the C(central)-to-CH_3 vector pointing away from the metal centre. If we define a plane containing the Pd centre and the corresponding N-donor atoms (coordination plane), the terminal allylic carbon atoms are practically in the plane and the central carbon atom is clearly above it. The C(7)−O(1) bond length is 1.207(8) Å, which is indicative of a certain degree of double-bond character. The triazinolate ring C−N distances at C(7) are typical single-bond values (ca. 1.39 Å), and the remaining four C−N distances are narrowly spread in the double-bond range [between 1.319(8) and 1.334(9) Å]. If one also considers the planarity of the heterocycle, this situation points to a pentadienide delocalization bonding of the five atoms N(1)−C(5)−N(2)−C(6)−N(3).

Fluxional Behaviour of the Allyl Complexes

Variable-temperature ^1H NMR studies in [D_6]acetone were performed for **2a**, **2c**, and **2d** in the temperature range 183−323 K. As stated previously, low-temperature ^1H NMR spectra contain resonances corresponding to the presence of two isomers in a different ratio (a *d*,*l* pair, a *meso* form; see Scheme 3 and Table 1). Several coalescences were observed on increasing the temperature: the two signals due to each pyrazole proton and also the allylic methyl groups simplified to give one resonance and the four lines for the H_{syn} protons coalesced consecutively until finally only one resonance was observed (the same was seen for the H_{anti} signals). Consequently, a process was observed that involved an apparent allyl rotation that simultaneously

leads to an isomerisation and to a *syn-syn/anti-anti* interchange. Interconversion between H_{anti} and H_{syn} protons was not seen in these studies. It is possible that the absence of a ligand of high *trans* influence increases the energy of this process. Free energies of activation were calculated from the coalescence temperatures and the δν values between the coalescing signals. The corresponding data are shown in Table 4 and in each case the interchanging groups are indicated. The data for complex **2b**[24] have also been included for the sake of comparison. When the free energy of activation values are plotted against the coalescence temperatures for **2a**−**2d** (see Figure 2), it can be seen that the values do not differ significantly from one complex to another. Consequently, the process of apparent allyl rotation is not markedly affected by a change in the basicity or steric hindrance of the pyrazolyl fragment.

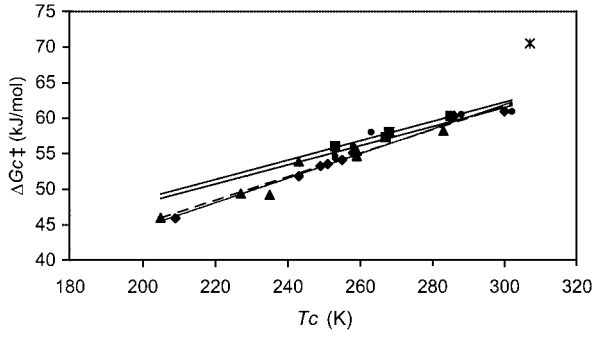

Figure 2. Linear plot of $\Delta G_c^{\ddagger}$ [kJ/mol] versus T_c [K] for complexes **2a**−**2d** in [D_6]acetone (see Table 4): **2a** (diamonds, -----), **2b** (dots, ——), **2c** (squares, ——), **2d** (triangles, ——), **2d** (star) in $CDCl_3$

In the case of complex **2d** a variable-temperature ^1H NMR spectroscopy study was also performed in $CDCl_3$. At low temperature (213 K) a splitting of the allylic methyl signal is observed. This enables the calculation of the corresponding free energy of activation (see Table 4). When the value obtained is compared with those calculated for complex **2d** in [D_6]acetone (see Figure 2), it is evident that in this poorly coordinating solvent the process of allyl rotation is clearly hindered. We must take into account that the anions in our complexes are also of low coordinating ability.

In the case of complex **2c**, variable-temperature studies were performed at different concentrations and also after the addition of water for one of the experiments. In this way, we tried to evaluate whether the presence of water in the deuterated solvent could influence the dynamic process. The $\Delta G_c^{\ddagger}$ values are collected in Table 5 and the appropriate plot is shown in Figure 3. The two lines corresponding to the studies with and without additional water are extremely similar. This means that in [D_6]acetone the addition of water does not affect the interconversion process. Moreover, the effect of the concentration, at least in the range studied, is also of minor importance.

It can be deduced unambiguously from Figures 2 and 3 that the value for the entropy of activation is negative. Con-

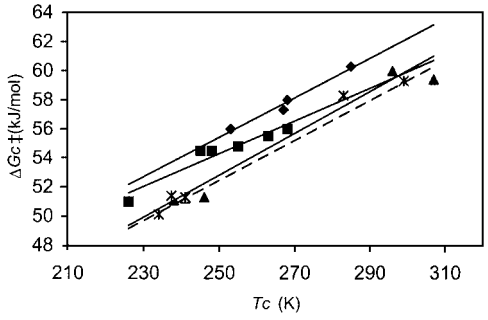

Figure 3. Linear plot of $\Delta G_c^{\ddagger}$ [kJ/mol] versus T_c [K] for complex **2c** in [D_6]acetone (see Tables 4 and 5): $7.94\cdot10^{-3}$ (diamonds, ——), $4.18\cdot10^{-3}$ (squares, ——); $2.10\cdot10^{-3}$ (triangles, -----); $2.10\cdot10^{-3}$ (stars, ——) with 15 μL of H_2O in 0.5 mL of solution

[a] With the addition of 15 μL of H_2O in 0.5 mL of solution.

sidering all these data, we propose an associative mechanism involving the coordination of acetone. Such a situation is in accordance with the negative sign of the entropy and the effect of the solvent. Even in the more concentrated solutions, it is assumed that acetone coordination takes place without difficulty and that the concentration does not significantly influence the process. After coordination of the acetone molecule, the system could evolve through pseudorotation of the allyl group.[2a,28] We cannot rule out the participation of the bond breaking of Pd−N(triazine) in this process. However, there is evidence that the Pd−N(pyrazole) bond rupture does not influence this process because ligands with pyrazole groups that differ substantially in their electronic (and steric) characteristics practically have the same energetic barrier.

Experimental Section

General Comments: All manipulations were carried out under dry oxygen-free nitrogen using standard Schlenk techniques. Solvents were distilled from the appropriate drying agents and degassed before use. The derivative [Pd(η^3-C_4H_7)(μ-Cl)]$_2$[41] and ligands **1a**,[36,37] **1b**,[24] and **1c**[38] were prepared according to literature procedures. Elemental analyses were performed with a Perkin−Elmer 240 B microanalyser. IR spectra where recorded as nujol mulls with a Perkin−Elmer PE 883 IR spectrometer. Mass spectra (position of the peaks in Da) were recorded with a VG Autospec spectrometer (University of Zaragoza) using the FAB$^+$ technique and *m*-nitrobenzylic alcohol as matrix, and HPLC1100-MSD (Quadrupole analyzer) for the electrospray technique. ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded with a Varian Unity 300 spectrometer using, unless specified, $(CD_3)_2CO$ as solvent and the chemical shifts are given in ppm. Standard experimental conditions were employed.[24,25] The ^{15}N NMR spectrum of compound **1d** was registered with a Bruker DRX 400 instrument with the chemical shifts in ppm, obtained by the heteronuclear-shift-correlation-spectra gs-HMQC and gs-HMBC with the standard pulse sequences[42] and referenced to an external sample of nitromethane. (^{1}H-^{1}H) COSY spectra: standard pulse sequence with an acquisition time of 0.214 s, pulse width 10 ms, relaxation delay 1 s, number of scans 16, number of increments 512. The NOE difference spectra were recorded with the following acquisition parameters: spectral width 5000 Hz, acquisition time 3.27 s, pulse width 18 ms, relaxation delay 4 s, irradiation power 5−10 dB, number of scans 240. For variable-temperature spectra the probe temperature (±1 K) was controlled by a standard unit calibrated with a methanol reference. Free energies of activation (kJ·mol^{-1}) were calculated[43] from the coalescence temperature (T_c) and the frequency difference between the coalescing signals (extrapolated at the coalescence temperature) with the formula $\Delta G_c^{\ddagger} = a\cdot T\cdot[9.972 + \log(T/\delta\nu)]$, $a = 1.914\cdot10^{-2}$. The estimated error in the calculated free energies of activation is ±1.1 kJ·mol^{-1}. *M* and *m* refer to the major or minor isomers, respectively.

Preparation of Compounds

(a) 2,4,6-Tris(3,4,5-trimethylpyrazol-1-yl)-1,3,5-triazine (1d): NaH (55.6 mg of 95 %, 2.2 mmol) was added to a solution of 3,4,5-trimethylpyrazole[44] (237 mg, 2.15 mmol) in freshly distilled dry THF (20 mL). After 1 h at 90 °C, the solution was cooled and 2,4,6-trichlorotriazine (cyanuric chloride) (99 % purity, Aldrich C9,550-1) (126.1 mg, 0.62 mmol) was added. The solution was heated at 90 °C for 10 h and at 70 °C for 18 h. The solvent was evaporated and the residue chromatographed on silica using $CHCl_3/CH_3OH$ (2:1) as eluent. Compound **1d** [R_f ($CHCl_3/CH_3OH$, 2:1) = 0.23], m.p. 295−297 °C, yield 49 % (135.7 mg). $C_{21}H_{27}N_9$ (405.24): calcd. C 62.20, H 6.71, N 31.09; found C 62.18, H 6.99, N 30.87. MS (FAB$^+$): *m*/*z* = 406.2 Da; (electrospray): *m*/*z* = 406.2 Da. ^{15}N NMR (40.56 MHz, $CDCl_3$, 25 °C): δ = −168.4 (N-1, pyrazole), −87.4 (N-2, pyrazole), −168.4 (N-triazine) ppm.

(b) [{Pd(η^3-C_4H_7)}$_2$(BPzTO)]BF_4 (2a): $AgBF_4$ (52.2 mg, 0.26 mmol) was added to a solution of [Pd(η^3-C_4H_7)(μ-Cl)]$_2$ (52.8 mg, 0.13 mmol) in THF (20 mL). The mixture was stirred for 2 h and protected from light. The solution was filtered through Celite to eliminate AgCl. The ligand TPzT (24.3 mg, 0.087 mol) was added and the mixture was stirred for 4 h. The solvent was evaporated to dryness and the pale yellow residue was washed with diethyl ether. The solid was crystallised in acetone/diethyl ether to obtain white crystals of **2a**. Yield: 36 % (20 mg). $C_{17}H_{20}BF_4N_7OPd_2$ (638.00): calcd. C 32.00, H 3.16, N 15.36; found C 31.75, H 3.28, N 15.24.

(c) [{Pd(η^3-C_4H_7)}$_2$(Me_2-BPzTO)]PF_6 (2c): A similar procedure to that used for **2a** was applied for **2c**. Amounts were as follows: $AgPF_6$ (145.6 mg, 0.58 mmol), [Pd(η^3-C_4H_7)(μ-Cl)]$_2$ (113.4 mg, 0.29 mmol), Me_2-TPzT (69.8 mg, 0.19 mmol). The solid was pale yellow in colour. Yield: 35 % (50 mg). $C_{21}H_{28}F_6N_7OPPd_2$ (752.27): calcd. C 33.53, H 3.75, N 13.03; found C 33.43, H 3.63, N 12.99.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(d) [{Pd(η^3-C_4H_7)}$_2$(Me_3-BPzTO)]PF_6 (2d): A similar procedure to that used for **2a** was applied for **2d**. Amounts were as follows: $AgPF_6$ (60.7 mg, 0.24 mmol), [Pd(η^3-C_4H_7)(μ-Cl)]$_2$ (48.0 mg, 0.12 mmol), Me_3-TPzT (32.4 mg, 0.08 mmol). The solid was pale yellow in colour. Yield: 30 % (19 mg). $C_{24}H_{32}F_6N_7OPPd_2$ (792.34): calcd. C 36.38, H 4.07, N 12.37; found C 36.02, H 4.33, N 12.59.

Preparation of NMR Spectroscopic Samples of 2: Samples for the studies found in Table 4. The corresponding amount of the complexes (**2a**: 2.53 mg; **2c**: 2.99 mg; **2d**: 3.14 mg) was dissolved in 0.5 mL of the deuterated solvent. Samples for the studies found in Table 5. Complex **2c** (3.14 mg) was dissolved in 1 mL of [D_6]acetone. After recording the NMR spectra, 0.25 mL of this solution was mixed with 0.25 mL of [D_6]acetone and the spectra were recorded. Finally, 15 μL of H_2O was added.

X-ray Data Collection, Structure Determination, and Refinement of Complex 2c: The crystallographic data and experimental details are given in Table 6. Crystals of complex **2c** suitable for X-ray diffraction were obtained by slow diffusion of pentane into a saturated solution of the complex in acetone. Accurate unit cell parameters were determined by least-squares refinement of the setting angles of 25 randomly distributed and carefully centred reflections. The data collection was performed with a Nonius-Mach3 diffractometer equipped with a graphite monochromator [Mo-K_α radiation (λ = 0.71073 Å)] using an $\omega/2\theta$ scan technique to a maximum value of 56°. Data were corrected for Lorentz and polarisation effects. The structures were solved by direct methods (SIR92)[45] and refined first isotropically by full-matrix least squares using the SHELXL-97[46] program and then anisotropically by blocked full-matrix least squares for all the non-hydrogen atoms. The hydrogen atoms were included in calculated positions and refined "riding" on their parent carbon atoms. CCDC-212257 (**2c**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Table 6. Crystal data and structure refinement for **2c**

Empirical formula	$C_{21}H_{28}N_7OPd_2{\cdot}PF_6$
Formula mass	752.27 Da
Temperature	293(2) K
Wavelength	0.71073 Å
Crystal system, space group	triclinic, $P\bar{1}$
Unit cell dimensions	a = 8.815(5) Å, α = 106.560(5)°
	b = 12.936(5) Å, β = 102.890(5)°
	c = 13.074(5) Å, γ = 99.190(5)°
Volume	1352.6(11) Å^3
Z, calculated density	2, 1.847 g/cm^3
Absorption coefficient	14.59 cm^{-1}
F(000)	744
Crystal size	0.3 × 0.2 × 0.2 mm
Limiting indices	$-11 \le h \le 11$, $-17 \le k \le 16$,
	$0 \le l \le 17$
Reflections collected/unique	6808/6525 [R(int) = 0.0510]
Data/restraints/parameters	6525/37/398
Goodness-of-fit on F^2	0.951
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0559, $wR2$ = 0.1100
R indices (all data)	$R1$ = 0.1814, $wR2$ = 0.1444
Largest diff. peak and hole	0.502 and −0.652 e·Å^{-3}

Formation of Cubic GaN Nanocrystals: A Study of the Thermal Stability of GaP Nanocrystals under Nitrogen

Shanmin Gao,[a] Liying Zhu,[a] Yi Xie,*[a] and Xiaobo Qian[a]

Keywords: Gallium / Phosphorus / Nitrides / Nanostructures / Thermochemistry

Cubic GaN nanoparticles and nanorods have been successfully synthesized from the nitridation of nanocrystalline GaP at 500 °C for 30 min, by manipulating different heating rates in nitrogen. The results of the thermal stability studies of nanocrystalline GaP under N_2 at different heating rates support the idea that cubic GaN can form from GaP via a N–P metathesis mechanism. The morphology of the cubic GaN can be controlled by variation of the external synthetic parameters such as the rate of heating. This work shows that it is very simple to synthesize cubic GaN nanoparticles or nanorods and opens a wide route towards detailed studies of the fundamental properties and potential applications of semiconductor nanocrystals.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Nanostructures have potential for unique applications in electronics, optoelectronics and catalysis due to their high surface-to-volume ratios, quantum confinement effects and high fraction of chemically similar surface sites.[1,2] Wide band-gap semiconductor compound nanomaterials of the 13−15 group, such as GaN, GaP and GaAs are important in fundamental physics and are widely used for high-speed digital circuits, electronic and optoelectronic devices.[3] Over the past several years, considerable efforts have been made to explore new and simple synthetic routes to group 13−15 semiconductor nanocrystals.[4−7]

Of this group of semiconductors, the properties of GaN nanocrystals have received the least attention due to the difficulty involved in their preparation. Of the limited studies on GaN nanocrystals which have been reported, most have focused on hexagonal GaN with the wurtzite structure.[8−12] In comparison, cubic GaN nanocrystals have generally been studied in the form of thin films.[13−15] A recent report of cubic GaN powder synthesis via ammonolysis under thermal conditions required over 2700 atm of NH_3 pressure for over 24 h and the resultant product was generally found to be mixed with hexagonal phase GaN.[16] Moreover, cubic GaN has advantageous physical properties compared with those of the hexagonal phase, such as easier *p*-type doping, easier cleaving for laser facets, and a narrower energy band gap which means it is easier to reach the blue and green region.[17] Studies of the synthesis of cubic GaN nanocrystals is therefore of great importance.

Low-dimensional crystal structures, geometries such as wires, rods, and thin films are currently the focus of much attention due to their special properties.[18−20] These fascinating systems are expected to exhibit remarkable mechanical, electrical, optical and magnetic properties. Such low-dimensional crystalline materials have potential applications in molecular based electronic devices such as optical memory and in switches, displays and data records. Several approaches have been successfully developed for the fabrication of such nanowires and nanorods and their morphologies, microstructures and growth mechanisms have been studied.[21−25]

The synthesis, optical properties and catalytic reactivity of GaP nanocrystals have been studied in detail by our group.[26−28] The growth process and stability of GaP nanocrystals under thermal conditions in benzene have also been studied and a method for controlling the reaction process and uniformity of GaP grains has been reported.[29]

As is already known, the application of semiconductors depends on the change in the environmental conditions, so studying the influence of such conditions on the properties of semiconductor nanomaterials is also important. In this study, the thermal stability of GaP nanocrystals under a nitrogen atmosphere was investigated in detail and resulted in the establishment of a new preparative route to cubic GaN nanoparticles and nanorods.

Results and Discussion

XRD patterns were used to examine the crystal structures and phase purities of the products which were obtained by heating GaP nanoparticles at 500 °C for 30 min.

XRD patterns of (A) the starting GaP nanocrystals (B) the pure cubic GaN sample prepared from the heat treatment of GaP nanocrystals at 500 °C for 30 min with a heating rate of 5 °C/min and 10 °C/min (C) the cubic GaN sample prepared from the heat treatment of GaP nanocrystals at 500 °C for 30 min with a heating rate of 20 °C/min, the note * labels the residual elemental Ga

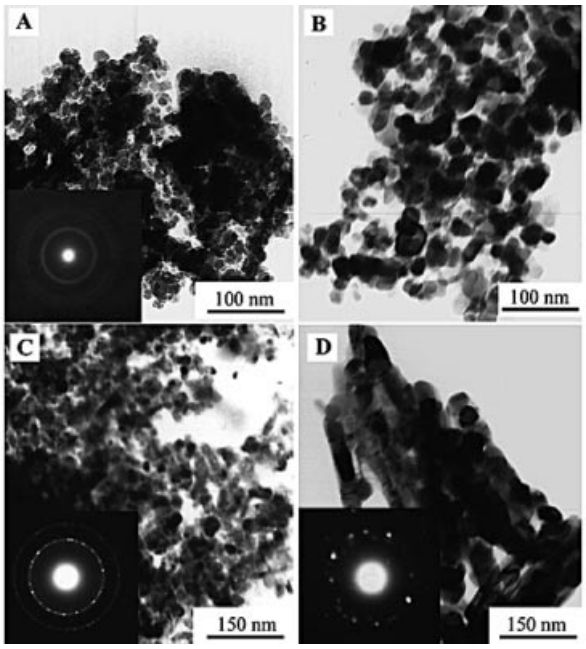

Figure 2. (A) TEM image of the starting GaP nanocrystals (B), (C) and (D) TEM images of cubic GaN obtained from heat treatment of GaP nanocrystals in N_2 at 500 °C for 30 min at heating rates of 5 °C/min, 10 °C/min and 20 °C/min, respectively; the picture insets are the SAED patterns of the corresponding materials

Figure 1 (A) displays the XRD pattern of the starting GaP nanocrystals. Pure cubic GaN was obtained from GaP nanocrystals at a low heating rate (≤10 °C/min) under N_2 at 500 °C for 30 min and the corresponding XRD pattern is shown in Figure 1 (B). All the reflections at $2\theta = 35.5$, 40.5, 58 and 68.5°, were indexed to the (111), (200), (220) and (311) lattice planes of cubic GaN, respectively. The calculated lattice parameter of cubic GaN using a computer simulation is $a_0 = 4.502 \pm 0.004$ Å, which is good agreement with the reported value.[17]

Figure 1 (C) shows the XRD pattern of the product prepared from the heat treatment of GaP nanocrystals under N_2 at 500 °C for 30 min at a heating rate of 20 °C/min, indicating that the product is cubic GaN coexisting with a minor amount elemental Ga (denoted as *, JC,PDF File, No. 31-0539). The minor elemental Ga can be easily removed by treatment using 1 N hydrochloric acid and pure cubic GaN can be obtained and its identity confirmed by its XRD pattern which is similar to that in Figure 1 (B). The XRD patterns of all the products are quite different from that of the starting GaP nanoparticles. The above results show that cubic GaN is formed by the heat treatment GaP nanocrystals under N_2 via a P−N metathesis reaction.

The morphology and structure of the prepared cubic GaN nanocrystallites were further characterized using transmission electron microscopy (TEM). Figure 2 (A) shows that the starting GaP nanocrystals are uniform spherical particles with a diameter of 8 ± 2 nm. Figure 2 (B and C) show that the cubic GaN obtained under N_2 at 500 °C for 30 min are uniform spherical particles with a diameter of 16 ± 2 nm for the product obtained with a heating rate of 5 °C/min and 22 ± 3 nm for the product obtained with a heating rate of 10 °C/min, in good agreement with the XRD result in which the average size can be calculated by employing the Scherrer equation. They exhibit the same morphology as the starting GaP nanocrystallites, the only difference being that the resultant GaN nanocrystals are larger than the starting GaP nanocrystallites due to the heat treatment at 500 °C. The SAED pattern [inset of Figure 2 (C)] shows diffraction rings consistent with the (111), (200), and (220) lattice plane of the cubic GaN phase. Except for the cubic GaN obtained at 500 °C for 30 min with a heating rate of 20 °C/min, the morphologies of the products [Figure 2 (D)] are different from the product obtained at 500 °C for 30 min with a heating rate of 10 °C/min in which nanorods are formed with diameters of 25 −30 nm and lengths of 200 −500 nm.

X-ray photoelectron spectroscopy (XPS) was used to investigate the elemental composition of the starting GaP nanocrystals and the above prepared GaN nanocrystals. The XPS results can provide evidence for the formation of GaN. Higher resolution spectra were taken of the Ga_{3d} and N_{1s} regions. The XPS spectra are shown in Figure 3. The binding energy values of the Ga_{3d} and N_{1s} core levels agree well with their chemical environments in cubic GaN. This clearly indicates that the N_2 molecules must be chemically bonded to Ga atoms, presumably forming N−Ga bonds.

The above results indicate that the P−N metathesis reaction occurred regardless of the heating rates used in our experiments . The replacement of P by N atoms is facilitated by the fact that P is more volatile than Ga and tends to escape from GaP upon thermal annealing. Traditionally, nitridation reactions using N_2 need high temperature (>1000 °C), since N_2 is very inert and stable. Small GaN crystals have been synthesized from molten gallium and N_2 at 700 °C in an alkali metal flux[30,31] and nanorod architectures have been prepared from catalyzed reactions between

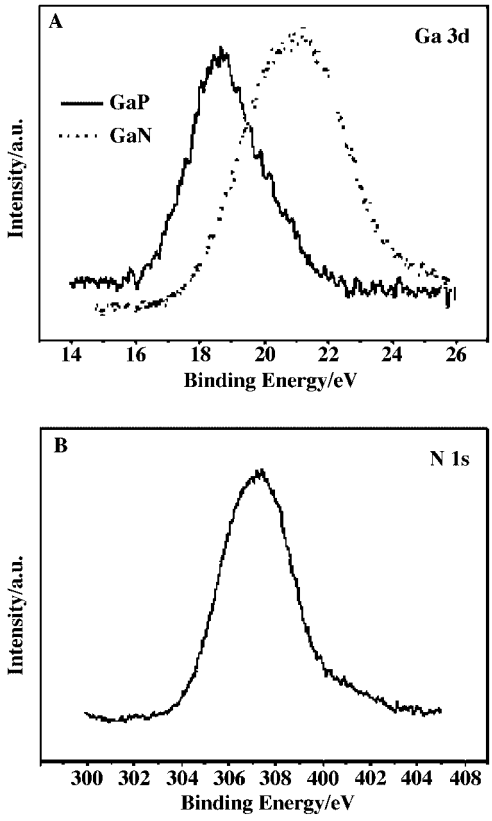

Figure 3. XPS spectra of the Ga_{3d} (A) and N_{1s} (B) core levels; the solid line represents the raw material GaP nanocrystals and the broken line represents the prepared cubic GaN obtained by heat treatment of GaP nanocrystals in N_2 at 500 °C for 30 min with a heating rate of 10 °C/min

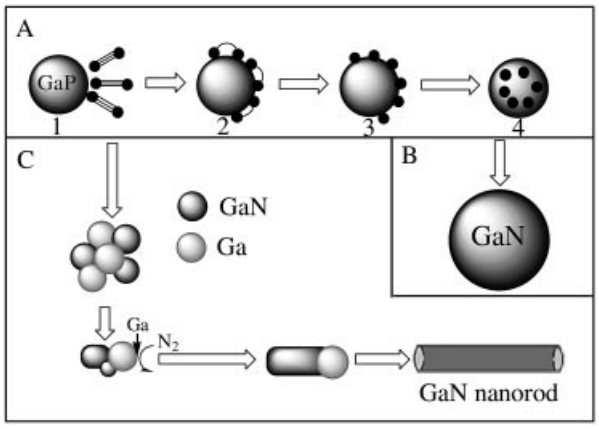
gallium and NH_3 above 900 °C.[32,33] Our experiments indicate that cubic GaN can form at lower temperatures and shorter reaction times, an observation which is based on the high surface-to-volume ratio of nanocrystalline raw materials of GaP which can remarkably reduce the difficulty of nitridation. The GaP particles sizes significantly affect the nitridation reaction. The nitridation process may become more difficult or even incomplete and when the particle sizes reach the micron dimension, XRD results indicate that no GaN forms at all. Furthemore, at different heating rates the synthesized GaN exhibits different nanoscale morphologies, which leads us to believe that different heating rates cause different reaction mechanisms. The mechanisms of the surface adsorption reaction on GaP nanocrystals, and the formation of cubic GaN nanoparticles and nanorods are shown schematically in Scheme 1.

Regardless of the heating rates used in our experiments, the initial process involves the desorption of P atoms from the starting GaP nanocrystallites, adsorption of N atoms on the GaP surface and the further nitridation reaction [Scheme 1 (A)]. As is known, the surface area of nanocrystals is much larger than the bulk materials and there exist many vacancies and dangling bonds on the surface. In our experiments, the N_2 molecules are adsorbed onto the surface of the starting GaP nanocrystals during the initial stage of heating [Scheme 1 (A1)]. Firstly N_2 is adsorbed on



Scheme 1. The proposed mechanism for the formation of cubic GaN nanocrystals; (A) the surface adsorption reaction of N_2 on GaP nanocrystals and the nucleation of GaN; (B) the growth of GaN nanoparticles at lower heating rates; (C) step growth of GaN nanorods at higher heating rates

to the surface of the GaP nanocrystals (adsorbent), the physical adsorption depending on the van der Waals force. The vacancies and dangling bonds on the surface of the GaP nanocrystals provide a favorable environment for N_2 molecules to form bonds. Upon elevating the temperature, chemical bonding of N and Ga results, producing the activated adsorption. As a result, the N_2 molecules can be activated on the surface of GaP nanocrystals at a rather low temperature, remarkably weakening the strength of the N≡N bond on the surface of the GaP nanocrystals [Scheme 1 (A2)]. After the activated N atoms have formed [Scheme 1 (A3)] the N−P metathesis reaction can take place [Scheme 1 (A4)]. Since the metathesis reaction involves conversion of one zinc blende structure to another zinc blende structure this reaction can therefore be called a topotactic transformation.

At a lower heating rate (≤10 °C/min), the desorption of P, absorption of N and nitridation of GaP is a synchronous process on the GaP nanocrystals with no formation of excess Ga droplets, an observation which has been validated by the XRD pattern [as shown in Figure 1 (B)]. Thus GaN gradually forms on the surface of the GaP nanoparticles during this process. The total reaction can be described as in Equation (1).

$$GaP + N_2 \rightarrow GaN + P \quad (1)$$

The high surface area and reactivity of nanocrystalline GaP directly result in the formation of cubic GaN at lower temperature, lower pressure and shorter reaction times [Scheme 1 (B)]. The resultant GaN nanoparticles inherit the GaP matrixes in terms of structure and morphology which explains the similarity between the structures and morphologies of the resultant GaN and the starting GaP.

When the heating rate is higher (≥20 °C/min), however, the reaction is complicated and the initial chemical reaction is the desorption of P from the GaP nanocrystals, as described in Equation (2).

$$GaP \rightarrow Ga + P \quad (2)$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The desorption chemical reaction is dominant and rapid and so the newly formed gallium has high activity and can react with N_2 to produce GaN nuclei, Equation (3).

$$Ga + N_2 \rightarrow GaN \quad (3)$$

A higher heating rate also promotes gallium coalescence along with its nitridation resulting in the appearance of smaller droplets of Ga. GaN nuclei start to aggregate and act as the nucleation seeds, then, stepwise growth proceeds with Ga droplets being pushed outward by the descending GaN [Scheme 1 (C)]. The Ga droplets play a crucial role in the growth of GaN nanorods based on the vapor-solid (VS) mechanism which is widely used to explain the growth of fiber-like semiconductors.[34] VS growth is apparently supported by the large Ga surface area and high reactivity which increases the effective steady-state Ga vapor pressure. The system is not in equilibrium because the Ga vapor reacts to form GaN. The increased rate of evaporation afforded by the large surface area of Ga more than likely produces a larger *steady-state* vapor pressure than is present over larger and coarser Ga particles. Scheme 1 (C) schematically depicts the mechanism of the formation of cubic GaN nanorods. More evidence has been provided by the supplementary experiments undertaken with a heating rate of 50 °C/min. The crystal structures and phase purities of the products are shown in Figure 4 (A) and the morphologies of the nanocrystalline GaN samples are shown in Figure 4 (B). The XRD pattern of the product prepared from the heat treatment of GaP nanocrystals under N_2 at 500 °C for 30 min with a heating rate of 50 °C/min indicates that the product is cubic GaN coexisting with a minor amount of elemental Ga (denoted as *) supporting that idea that cubic GaN nanorods can be obtained at the higher heating rate and the growth of GaN nanorods is based on the vapor-solid (VS) mechanism.

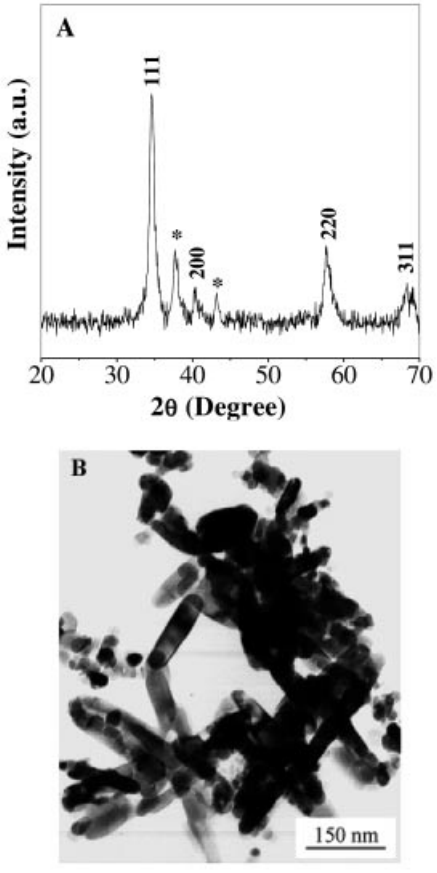


Figure 4. XRD pattern (A) and TEM image (B) of cubic GaN obtained from heat treatment of GaP nanocrystals at 500 °C for 30 min in N_2 with a heating rate of 50 °C/min

The above mechanism showing that cubic GaN can form in GaP via P−N metathesis is directly supported by the thermal stability study of GaP nanocrystals under nitrogen. At a lower heating rate, the desorption of P and nitridation are synchronous processes and, accordingly, the weight loss should be slow. At a higher heating rate, however, the desorption of P is preferential, so the weight loss should be rapid. In order to validate this, the thermogravimetric analysis (TGA) technique was used to analyze the thermal behavior of the GaP nanoparticles under N_2 at different heating rates. A typical TGA profile is shown in Figure 5, and the results are completely in accord with the above conclusion.

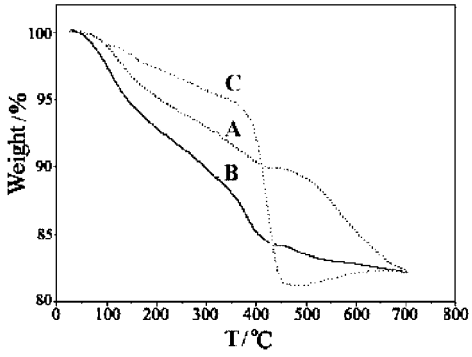

Figure 5. Thermogravimetric analyses of GaP nanocrystals in an N_2 flow at different heating rates; (A) 5 °C/min, (B) 10 °C/min, (C) 20 °C/min

One can see that at a heating rate of 5 °C/min [Figure 5 (A)], the weight loss is gradual, i.e. reaction (1) takes place during this process. The N and Ga atoms can be rendered miscible by an oxidation process since the N and Ga atoms can form a stable electrovalent bond, resulting in the final formation of GaN nanoparticles. At a heating rate of 10 °C/min, the weight loss is quicker than with a heating rate of 5 °C/min [Figure 5 (B)]. A precipitate line is obtained at a heating rate of 20 °C/min [Figure 5 (C)], indicating that the weight loss is much quicker than at the heating rates of 5 °C/min and 10 °C/min, namely, that reaction (2) takes place first followed by reaction (3) so the weight increases again later. The thermal stability results of GaP nanocrystalline under N_2 at different heating rates support the proposed mechanism that cubic GaN can form in GaP via a N−P metathesis mechanism.

Conclusion

In conclusion, a convenient, low-temperature technique has been established for the synthesis of cubic GaN nano-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

crystals based on the fact that the small size effect of the starting GaP can remarkably reduce the difficulty of nitridation. Cubic GaN nanoparticles and nanorods have been successfully synthesized from the nitridation of nanocrystalline GaP at 500 °C for 30 min using a range of different heating rates. The thermal stability results of GaP nanocrystalline under N_2 at different heating rates support the proposal that cubic GaN can form in GaP via a N−P metathesis mechanism.

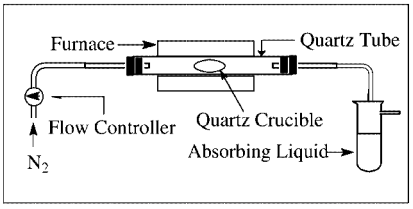

Figure 6. Schematic experimental setup for the formation of cubic GaN nanocrystals; GaP nanocrystals were placed in the quartz crucible

Experimental Section

Synthesis of Cubic GaN Nanocrystals: The starting GaP nanocrystals used in the present study were synthesized in the benzene-thermal route using Na_3P and $GaCl_3$ as the raw materials which has been described in detail elsewhere.[26] In a typical experiment, the starting GaP nanocrystals were loaded into a quartz crucible which was then horizontally placed in the quartz tube of a tubular furnace. The experimental setup for the formation of cubic GaN nanocrystals is described schematically in Figure 6. Firstly, the quartz tube was evacuated for 20 min. After this, the quartz tube was ventilated with high purity (99.999%) N_2 at a flow of about 20 sccm (standard cubic centimeters per minute) for several minutes, a unit mass flow controller was used to regulate the flow velocity of N_2 gas. The system was heated to 500 °C using different heating rates and then maintained at this temperature for 30 min. The samples were then allowed to cool to room temperature and were subsequently sealed in glass tubes for further characterization.

Characterization: Powder X-ray diffraction (XRD) patterns were obtained at room temperature using a Rigaku D/max-γA model X-ray diffractometer with Ni-filtered Cu-K_α radiation. TEM images of the samples were obtained from a Hitachi H800 transmission electron microscope using an accelerating voltage of 200 kV. Samples for TEM investigations were briefly ultra-sonicated in ethanol, and then a drop of suspension was placed on a holey copper grid with carbon film. X-ray photoelectron spectra (XPS) were measured on a VGESCALAB 220i-XL X-ray photo spectrometer with Al-K_α (1186.6 eV) radiation as the exciting source with measurements performed at pressures lower than 1×10^{-8} Torr. Thermogravimetric analyses (TGA) were performed on a Perkin−Elmer DC/2C type TG-DTA apparatus under a N_2 atmosphere at different heating rates. Fourier transform infrared spectra (FT-IR) of pellets of the samples mixed with KBr were recorded on a Nicolet Magna-IR 750 FTIR spectrometer at a resolution of 4 cm^{-1}.

Multi-Dimensional Systems Built from Dichromate Anions − Syntheses, Crystal Structures, and Magnetic Properties

Xiao-Yan Chen,[a] Bin Zhao,[a] Peng Cheng,*[a] Bin Ding,[a] Dai-Zheng Liao,[a] Shi-Pin Yan,[a] and Zong-Hui Jiang[a]

Keywords: Chromium / Magnetic properties / N ligands / Self-assembly

Three novel compounds with bridging dichromate anions with the formulae $[Fe(4,4'\text{-bpy})_2Cr_2O_7]_n$ (**1**), $[Co(4,4'\text{-bpy})_2Cr_2O_7]_n$ (**2**), and $[Ni(dpa)_2Cr_2O_7]\cdot H_2O$ (**3**) (4,4′-bpy = 4,4′-bipyridine, dpa = 2,2′-dipyridylamine) have been synthesized and characterized. The isostructural compounds **1** and **2** belong to the monoclinic space group *C*2/*c* and have been shown to be three-dimensional polymers in which the dichromate anions connect neighboring layers formed by $[M(4,4'\text{-bpy})_2]^{2+}$ (M = Fe, Co) units. Compound **3** is a metallacrown type compound, crystallizing in the monoclinic space group $P2_1/n$. Two chromate anions link two Ni^{II} centers forming a dinuclear entity. The uncoordinated oxygen atom of the dichromate anion forms a hydrogen bond with the N–H unit of dpa resulting in a two-dimensional network. Measurements of magnetic susceptibilities indicate the presence of antiferromagnetic interactions in **1** and **2** whereas the exchange coupling between the Ni^{II} ions in **3** is ferromagnetic. The IR and UV/Vis spectra of the above complexes have also been investigated.

Introduction

Investigations of novel inorganic-organic hybrid framework assemblies constitute one of the most active areas of material science and chemical research. The intense interest in these materials has been driven, to a large extent, by their interesting properties such as electrical conductivity, magnetism, photo-mechanistic behavior, and shape specificity as well as their potential applications in areas such as catalysis.[1−3] Many important properties of supramolecular systems depend largely on their structures and topologies. Rational design and construction of new materials with specific networks has therefore become a particularly important and topical subject.[4,5]

The chromate ion has long been known to bridge metal centers forming oligomeric and polymeric systems and many chromate bridged polynuclear complexes have been characterized.[6−9] On the other hand we know that between the physiologically accessible pH values of 2−6 the $HCrO_4^-$ and $Cr_2O_7^{2-}$ ions are in equilibrium.[10] Whereas many structural studies of simple or double "inorganic" dichromates have been reported,[11] the use of the dichromate anion as a bridging ligand forming multi-dimensional networks needs to be explored more deeply.[12,13]

We started to design hybrid complexes with dichromate anions and the typical polypyridine system which is well-known to act as a rigid, rod-like organic building block. In this paper we report the synthesis and structural characterization of three dichromate polymers, $[Fe(4,4'\text{-bipy})_2Cr_2O_7]_n$ (**1**), $[Co(4,4'\text{-bipy})_2Cr_2O_7]_n$ (**2**), and $[Ni(dpa)_2Cr_2O_7]\cdot H_2O$ (**3**) (4,4′-bpy = 4,4′-bipyridine, dpa = 2,2′-dipyridylamine). Furthermore, their magnetic and spectroscopic properties have also been studied.

Results and Discussion

Crystal Structure of $[Fe(4,4'\text{-bpy})_2Cr_2O_7]_n$ (1)

The molecular structure of **1** is shown in Figure 1. The iron atom is in an octahedral environment. Besides the two coordinated *trans*-oxygen atoms of the dichromate [Fe1−O1, 2.137(4); Fe1−O4, 2.132(4) Å] with the O1−Fe1−O4 angle of 173.65(13)°, there are four coordinated nitrogen atoms from the 4,4′-bipyridine ligands [Fe1−N1, 2.122(3); Fe1−N2, 2.277(4); Fe1−N3, 2.135(4); Fe1−N4, 2.264(4) Å]. Compared with $[Fe(C_2O_4)$(4,4′-bipyridine)] and $[FeCl_2$(4,4′-bipyridine)], the Fe−O and Fe−N bond lengths are in the normal range.[14,15] The non-bridging Cr−O distances are shorter than those of the bridging Cr−O distances. The Cr^{VI} ion adopts an almost regular tetrahedral geometry with an average O−Cr−O bond angle 109.46° for each $[Cr_2O_7]^{2-}$ unit. The Cr−O−Cr bond angle deviates significantly from 180° and is 128.5(2)° in **1**. Surprisingly, there is a 22.4° difference in the two Fe−O−Cr angles [157.9(2)° at O1 vs. 135.5(2)° at O4], although the Fe−O bond lengths are not significantly differ-

ent (Table 1). As a result there are two distinct Fe···Cr distances of 3.702(7) and 3.497(5) Å, which are similar to those of some rare examples of Fe−Cr systems.[10,16]

The structure of **1** contains 2-D parallelogram sheets built upon $[Fe(4,4'\text{-bpy})_2]^{2+}$ building blocks which are cross-linked by dichromate anions like the pillars in clays to form a 3-D structure with two types of channels perpendicular to the (010) and (101) planes, respectively. The rhombic channels with dimensions of 8.859 × 11.472 Å (defined by neighboring Fe···Fe distances) perpendicular to the (010) plane are shown in Figure 2(a), and the square channels with dimensions of 11.436 × 11.472 Å perpendicular to the (101) plane are shown in Figure 2(b).

$[Co(4,4'\text{-bpy})_2Cr_2O_7]_n$ (2)

The structures of **1** and **2** are isostructural except that Fe atoms are replaced by Co atoms. Owing to the difference of the atomic radius, the coordination geometry around the Co^{II} ion is slightly different. The Co^{II} ion is also in an octahedral environment with two *trans*-oxygen atoms of the two dichromate anions in the apical position and four nitrogen atoms of the 4,4′-bpy ligand in the equatorial plane. Similarly, the bridging Cr−O bond lengths [average Cr−O: 1.711(5)Å] are longer than the non-bridging Cr−O bond lengths [average Cr−O: 1.598(5) Å]. The angle O−Co−O is 175.31(14)°. The Cr^{VI} also adopts an almost regular tetrahedral geometry with an average O−Cr−O bond angle of 109.46° for each $[Cr_2O_7]^{2-}$ unit and the Cr−O−Cr bond angle of 128.7(2)° in **2** is similar to that in **1**. There is a 17.6° difference in the two Co−O−Cr angles [157.7(2)° and 140.1(2)°] which is smaller than that observed in compound **1**. Consequently there are also two distinct Co···Cr distances of 3.623(5) and 3.480(4) Å.

In compound **2**, the Co^{II} ions are linked by 4,4′-bpy units in two orthogonal directions and dichromate ions in the third direction thus forming a 3-D structure with two types of channels, similar to **1**. The dimensions of the channels are slightly different: the rhombic channels perpendicular to the (010) plane are 8.790 × 11.436 Å, and the square channels are 11.383 × 11.436 Å perpendicular to the (101) plane.

$[Ni(dpa)_2Cr_2O_7]\cdot H_2O$ (3)

The structure of **3** contains a center of inversion with two $\mu_{1,5}$-dichromate bridges between the two nickel atoms forming a metalla-crown type compound. There has been considerable interest in metalla-crown chemistry owing to its potential applications in chemically modified electrodes, anion-selective separation agents, liquid-crystal precursors and magnetic materials.[17−21]

The Ni···Ni separation of 6.642(5) Å is relatively large, e.g. the Ni···Ni separation in $[Py_2Ni_2(HOOCCMe_3)_2(OOCCMe_3)_2(\mu\text{-}OOCCMe_2)(\mu\text{-}OH_2)]$ is 3.456(2) Å,[22] and two terminal dpa ligands on each nickel complete the ligation (Figure 3). The coordination geometry around the nickel atom is octahedral, the equatorial positions being occupied by three nitrogen atoms from two dpa ligands and one oxygen atom from one bridging dichromate anion [Ni1−O1, 2.071(3) Å]. The axial positions are occupied by the other nitrogen atom of the dpa ligand and one oxygen atom from the other dichromate anion [Ni1−O7A, 2.064(3) Å]. The Ni−N distances ranging from 2.054(4) to 2.075(3) Å are similar to those found in [(oxa)Ni(dpa)] [2.029(2) −2.062(2) Å].[23] Each dpa pyridyl ring is essentially planar and the dihedral angle between the two rings is 35.0°, which is clearly different from other dpa complexes, e.g. in com-

plex $[Cu(dpa)(dca)_2]_n$ the dihedral angle between two pyridine rings of 27.2° is very close to that of free dpa (23°).[24] One nickel atom is coordinated to two dpa units and the large twist serves to relieve the steric hindrance within the ligand.

Despite the fact that the Cr^{VI} adopts an almost regular tetrahedral geometry with an average O−Cr−O bond angle 109.46°, the geometric conformation of the $[Cr_2O_7]^{2-}$ unit in **3** is somewhat different: the Cr−O−Cr bond angle [134.39(19)°] is large compared with those seen in **1** and

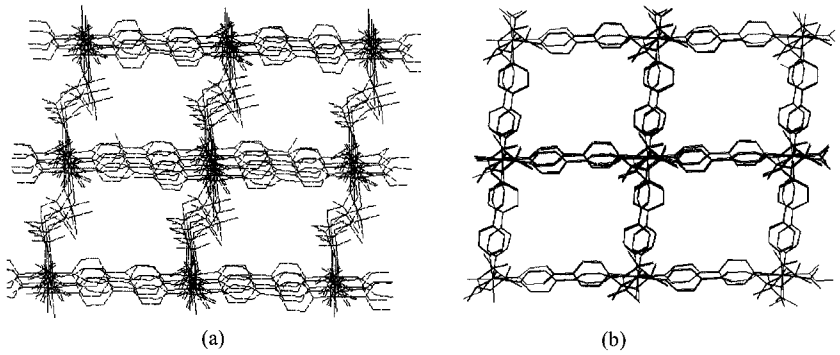

Figure 2. (a) Views of the structure of **1** perpendicular to the (010) plane, showing the rhombic channels; (b) views of the structure of **1** perpendicular to the (101) plane, showing the square channels

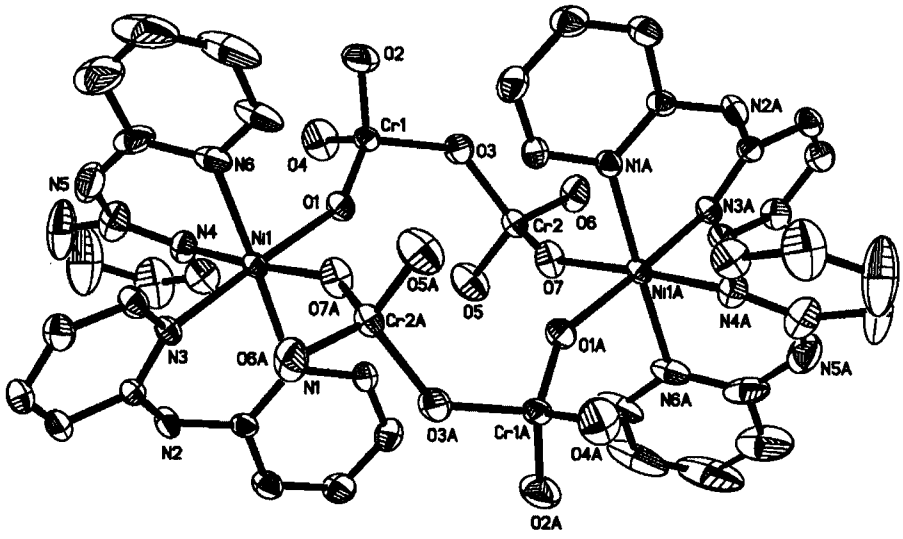

Figure 3. ORTEP diagram of $[Ni(dpa)_2Cr_2O_7]\cdot H_2O$ (**3**), the hydrogen atoms and water molecule have been omitted for clarity

2, and the Ni−O−Cr angles are equal to 151.59(18)°. The widening of the angle at the oxo center may be due to the steric requirements of forming this unusual 12-membered ring. Consequently the Ni···Cr distances are equal to 3.578(5) Å.

The hydrogen atoms of the water molecule in **3** form hydrogen bonds with the nitrogen atoms of neighboring dpa ligands [−H···N, 2.859(3) Å] and uncoordinated oxygen atoms of the bridging dichromate anions [O−H···O, 2.857(8) Å] leading to a 2-D network.

Spectroscopic Properties

The IR spectra of all the complexes show the stretching and bending frequencies of C−C and C−N bonds in the ranges of ca. 1650−1400 cm^{-1} and 1250−650 cm^{-1}, respectively. The ν_{Cr-O} stretching frequencies can be observed at 930−950 cm^{-1} which are in good agreement with those reported for $K_2Cr_2O_7$.[25]

The UV/Vis spectra are also similar. In the UV range, strong absorptions appears at ca. 270−285 nm, which can be assigned to ligand transitions. In the visible region weak absorptions can be observed at ca. 490 nm (spin-forbidden transitions $^5T_{2g}\rightarrow{}^3T_{1g}$, $^3T_{2g}$, ^3E_g) and a relatively stronger absorption at 880 nm ($^5T_{2g}\rightarrow{}^5E_g$) for high-spin Fe^{II} ion can be observed in the spectrum of **1**. A broad strong band centered at ca. 520 nm in the spectrum of **2** can be observed and may be attributed to the d-d transitions of Co^{II} ions in an octahedral environment [$^4T_{1g}\rightarrow{}^4A_{2g}$ and $^4T_{1g}\rightarrow{}^4T_{1g}(P)$]. For complex **3**, the electronic spectrum in the visible range contains a strong absorption band at 630 nm and a weaker one at 475 nm, which are characteristic of an octahedrally coordinated Ni^{II} ion and can be assigned to $^3A_{2g}\rightarrow{}^3T_{1g}$ and $^3A_{2g}\rightarrow{}^3T_{1g}(P)$ transitions, respectively.

Magnetic Properties

The molar magnetic susceptibilities χ_M were measured in the temperature range of 2 to 300 K in a field of 5 KOe for **1**, and 10 KOe for **2** and **3** (Figures 4−7).

As shown in Figure 4, the value of $\chi_M T$ for **1** at 300 K is 2.99 $cm^3\cdot K\cdot mol^{-1}$ (4.89 μ_B) which is close to that of an isolated high-spin Fe^{II} ion ($S = 2$). As the temperature is decreased, the value of $\chi_M T$ decreases gradually and then decreases rapidly in the lower temperature region indicating that a weak antiferromagnetic coupling exists between the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Fe^{II} ions. In **1**, two exchange pathways are available: one is the inter-chain coupling (via 4,4′-bpy) and the other is the intra-chain interaction (via the dichromate anion). The system was therefore treated using a one-dimensional approach. The Heisenberg exchange theory was utilized, where the Hamiltonian in Equation (1) was employed. The molar magnetic susceptibility per ion is given by the polynomial expression in Equation (2).[26]

$$H = -2J\sum_{i=1}^{N-1} S_i \cdot S_{i+1} \quad (1)$$

$$\chi_{chain} = (Ng^2\mu_B^2)(kT)^{-1}[(A(s) + [B(s)]\,x^2) \times (1 + [C(s)]x + [D(s)]x^3)^{-1}] \quad (2)$$

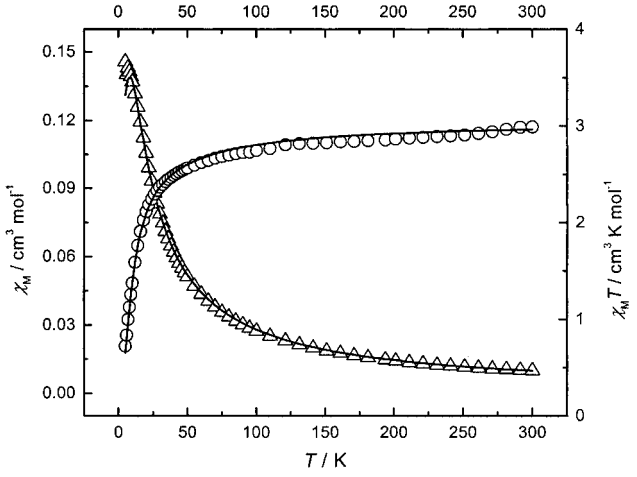

Figure 4. Plots of χ_M (Δ) and $\chi_M T$ (O) versus temperature for **1**; the solid line represents the theoretical curve with the best fit parameters

A molecular field approximation, Equation (3), was then used to modify the inter-chain interaction (zJ') giving the final susceptibility equations of the systems.[27] For the case of the $S = 2$ linear chain, $A = 2.000$, $B = 71.938$, $C = 10.428$, $D = 955.56$, and $x = J / kT$. The best fit of the magnetic susceptibility data yielded $J = -0.74$ cm^{-1}, $zJ' = -0.045$ cm^{-1} and $g = 2.02$. The agreement factor R is 3.65×10^{-4} $\{R = \Sigma[(\chi_M)^{obs} - (\chi_M)^{calc}]^2/[(\chi_M)^{obs}]^2\}$. This result indicates that there are weak antiferromagnetic interactions between the Fe^{II} ions within the chain which may be due to the large Fe···Fe distance and there also exist weak inter-chain antiferromagnetic interactions.

$$\chi_M = \chi_{chain} / [1 - \chi_{chain}(2zJ' / Ng^2\beta^2)] \quad (3)$$

For compound **2**, the high-spin octahedral Co^{II} ion has a $^4T_{1g}$ ground state and, as a consequence, exhibits unquenched spin-orbit coupling in addition to zero-field splitting, which dominates in the low-temperature region.[28]

Unfortunately, no expressions account for both factors simultaneously. Therefore, the data for **2** were fit using the expression in Equation (4) (with $x = \lambda/kT$) for spin-orbit coupling. The molecular field approximation which was further considered for the magnetic interactions between cobalt(II) ions and the magnetic susceptibilities is illustrated in Equation (5). The best fit (as shown in Figure 5) was obtained with values of $A = 1.5$, $\lambda = -170.8$ cm^{-1}, $g = 2.19$ and $zJ' = -0.09$ cm^{-1}, where A is a crystal field parameter ($A = 1.5$ is the weak-field limit), λ is the spin-orbit coupling constant ($\lambda = -176.0$ cm^{-1} is the free-ion value). The agreement factor $R = 4.71 \times 10^{-5}$. These are very similar to the published values for the related compound $[Ph_4P][Co\{N(CN)_2\}_3]$ (A = 1.5, $\lambda = -170.0$ cm^{-1}).[28] Thus, the fit suggests the presence of cobalt ions with slightly distorted octahedral geometries which is consistent with the crystal structure. The room-temperature magnetic moment of 5.13 μ_B is close to that expected for a weak-field ion (5.20 μ_B), with the slightly lower value indicative of the small perturbation from the ideal octahedral geometry as can be observed in the structure. The value of zJ' indicates a very weak antiferromagnetic exchange interaction between the Co^{II} ions.

$$\chi_M = \frac{N\beta^2}{3kT}\frac{\left[\frac{7(3-A)^2x}{5} + \frac{12(A+2)^2}{25A} + \left\{\frac{2(11-2A)^2x}{45} + \frac{176(A+2)^2}{675A}\right\}\exp\left(-\frac{5Ax}{2}\right) + \left\{\frac{(A+5)^2x}{9} - \frac{20(A+2)^2}{27A}\right\}\exp(-4Ax)\right]}{\frac{x}{3}\left[3 + 2\exp\left(-\frac{5Ax}{2}\right) + \exp(-4Ax)\right]} \quad (4)$$

$$\chi_M = \chi_{Co} / [1 - \chi_{Co}(2zJ' / Ng^2\beta^2)] \quad (5)$$

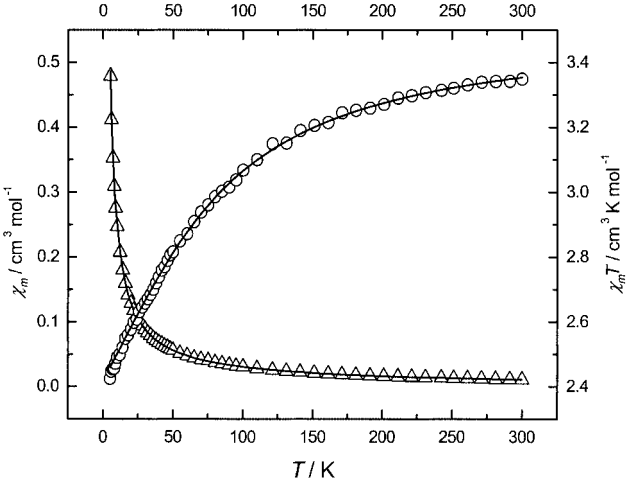

Figure 5. Plots of χ_M (Δ) and $\chi_M T$ (O) versus the temperature for **2**; the solid line represents the theoretical curve with the best fit parameters

The temperature dependence of $\chi_M T$ of **3** is shown in Figure 6. At room temperature $\chi_M T$ is 2.074 cm^3·K·mol^{-1} which is as expected for a spin-only Ni^{II} ion. It continuously increases upon cooling and reaches a maximum value of 2.172 cm^3·K·mol^{-1} at 24 K and further rapidly decreases to 1.85 cm^3·K·mol^{-1} at 2 K. This curve is in agreement with a significant ferromagnetic coupling between the nickel ions whereas in the published literature, most of the dimers with Ni^{II} (d^8) centers have been described as antiferromagnetic.[29–31] Zero-field splitting (D) and inter-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

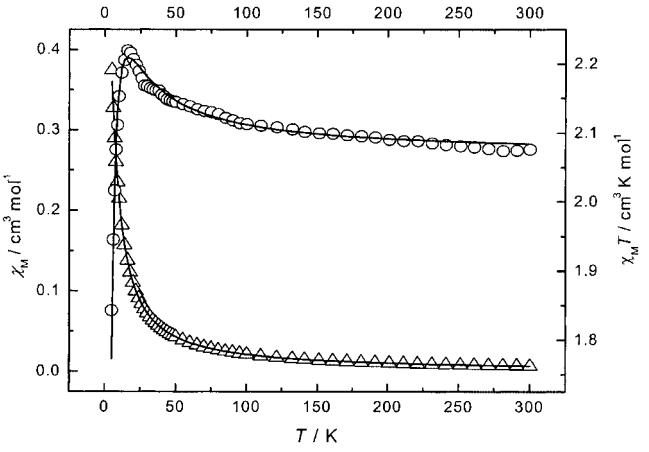

Figure 6. Plots of χ_M (Δ) and $\chi_M T$ (O) versus temperature for **3**; the solid line represents the theoretical curve with the best fit parameters

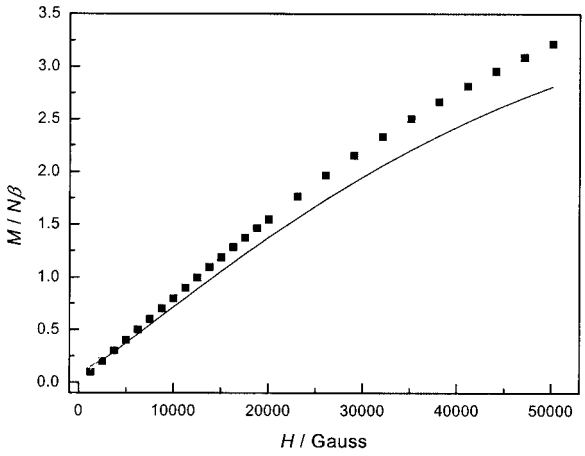

Figure 7. Magnetization curve of **3** (black squares) at 5 K; solid line: Brillouin function corresponding to two uncoupled Ni ions measured at 5 K supports the ferromagnetic interaction in this compound; the experimental values are higher than those calculated by Brillouin functions for two isolated centers with $S = 1$, which confirms the weak ferromagnetic correlation between the two Ni^{II} ions;[35] the effects of single-ion zero-field splitting and inter-dimer interactions cause the rapid low-temperature decrease in $\chi_M T$

molecular interactions could account for the decrease of $\chi_M T$ in the lower temperature region.

The nickel dimers contain "octahedrally" coordinated divalent nickel. Since the single-ion ground state is an orbital singlet state, it is appropriate to use the isotropic spin-coupling Hamiltonian [Equation (6)][32] where $\hat{H}_o$ is the Hamiltonian without considering the zero-field splitting and inter-dimer interactions, J is the exchange integral for the intra-dimer interaction between nickel atoms with spin operators $\hat{s}_1$ and $\hat{s}_2$. Since divalent nickel can have a large zero-field splitting parameter, it is necessary to evaluate the effect of single-ion zero-field splitting on the susceptibility. Allowing an external magnetic field H to be applied, the Hamiltonian can be described as shown in Equation (7).[33]

$$\hat{H}_o = -2J\hat{S}_1 \cdot \hat{S}_2 \quad (6)$$

$$\hat{H} = -2J\hat{S}_1 \cdot \hat{S}_2 - D(\hat{S}_{1z}^2 + \hat{S}_{2z}^2) - g\beta H\hat{S} \quad (7)$$

Taking $g_x = g_z = g$ (a very good approximation for Ni^{2+}), the temperature dependence of the magnetic susceptibilities was calculated using the equation derived from the above Hamiltonian operator.[33,34]

A temperature independent susceptibility term ($N\alpha$) was also include and was set as 2.0×10^{-4} cm^3·mol^{-1}.

A good fit, shown in Figure 6, was obtained for the following parameter set: $g = 2.04$, $J = 1.68$ cm^{-1}, $D = -2.86$ cm^{-1} and $R = 8.96 \times 10^{-5}$. Also the magnetization curve is shown in Figure 7 (0−50 kOe).

According to the above results, the two nickel(II) ions are weakly ferromagnetically coupled through the dichromate anions joining them [Ni···Ni, 6.642(5) Å].

Conclusion

The combined use of the polypyridine system and dichromate anion as ligands towards M^{II} ions [M = Fe (**1**), Co (**2**), Ni (**3**)] allowed us (i) to obtain three new dichromate bridged polymers with the dichromate exhibiting a $\mu_{1,5}$ bridging mode (ii) to study their spectroscopic properties, and (iii) to investigate the efficiency of this mode in mediating exchange interactions between the M^{II} ions. In conclusion, using the dichromate anion to form multi-dimensional systems is quite a useful method for building up multi-dimensional structures. It promises to open a new route for the formation of coordination polymers, which may exhibit interesting topologies and potential properties such as magnetic ordering and spectroscopic or electrical conductivity.

Experimental Section

General Remarks C, H, and N analyses were obtained at the Institute of Elemental Organic Chemistry, Nankai University. IR spectra were recorded in KBr disks on a Shimadzu IR-408 infrared spectrophotometer in the 4000−600 cm^{-1} region. UV/Vis spectra in DMF were recorded on a Shimadzu UV-2101 PC UV/Vis scanning spectrophotometer. Variable-temperature magnetic susceptibilities were measured on a Quantum Design MPMS-7 SQUID magnetometer. Diamagnetic corrections were made with Pascal's constants for all the constituent atoms.

Preparation of $[Fe(4,4'\text{-bipy})_2Cr_2O_7]_n$ (1): An aqueous solution of $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$ (78.4 mg, 0.2 mmol) and 4,4′-bipyridine (62.5 mg, 0.4 mmol) was heated to reflux for a few minutes. $K_2Cr_2O_7$ (58.8 mg, 0.2 mmol) dissolved in water (5 mL) was then added. The resultant mixture was heated to reflux for 2 h and was then filtered. The filtrate was evaporated at room temperature. Red crystals suitable for X-ray analysis were obtained after a week. Yield: 40%. $C_{20}H_{16}Cr_2FeN_4O_7$: calcd. C 41.12, H 2.76, N 9.59; found C 41.45, H 2.72, N 9.43.

$[Co(4,4'\text{-bipy})_2Cr_2O_7]_n$ (2): The synthetic method here was similar to that used for the preparation of **1** except that

$(NH_4)_2Fe(SO_4)_2{\cdot}6H_2O$ was replaced with $Co(ClO_4)_2{\cdot}6H_2O$. After several days, wine-colored crystals suitable for X-ray analysis were obtained. Yield: 55%. $C_{20}H_{16}CoCr_2N_4O_7$: calc. C 40.90, H 2.75, N 9.54; found C 40.76, H 2.67, N, 9.45.

$[Ni(dpa)_2Cr_2O_7]{\cdot}H_2O$ (3): The synthetic method here was similar to that used for the preparation of **1** except that $(NH_4)_2Fe(SO_4)_2{\cdot}6H_2O$ and 4,4′-bipyrydine were replaced by $Ni(ClO_4)_2{\cdot}6H_2O$ and dpa, respectively. Dark green crystals suitable for X-ray analysis were obtained after a week. Yield: 62%. $C_{20}H_{20}Cr_2N_6NiO_8$: calcd. C 37.82, H 3.17, N 13.23; found C 38.04, H 3.35, N 13.14.

Crystallographic Studies: Crystals of **1**, **2**, and **3** having the approximate dimensions of 0.30 mm × 0.25 mm × 0.20 mm were mounted on glass fibers. Determinations of the unit cells and data collection were performed with Mo-*Kα* radiation (λ = 0.71073 Å) on a Bruker SMART 1000 diffractometer equipped with a CCD camera. The ω − 2θ scan technique was employed. Crystal parameters and structural refinements for **1**, **2** and **3** are summarized in Table 2. Selected bond lengths and angles are listed in Table 1.

The structures were solved primarily by direct method and secondly by Fourier difference techniques and refined by the full-matrix least-squares method. Computations were performed with the SHELXL-97 program.[36,37] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were set in calculated positions and refined as riding atoms with a common fixed isotropic thermal parameter.

CCDC-194478 (for **1**), -187395 (for **2**), and -200551 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; or E-mail: deposit@ccdc.cam.ac.uk).

Intercalation of γ-Butyrolactone into Vanadyl Phosphate and Niobyl Arsenate

Vítězslav Zima,*[a] Klára Melánová,[a] Ludvík Beneš,[a] Miroslava Trchová,[b] and Jiří Dybal[b]

Keywords: Intercalations / Powder X-ray diffraction / Vibrational spectroscopy / ab initio calculations

Intercalation compounds of vanadyl phosphate and isostructural niobyl arsenate with γ-butyrolactone, $VOPO_4{\cdot}C_4H_6O_2$ and $NbOAsO_4{\cdot}C_4H_6O_2$, respectively, were prepared from corresponding propanol intercalates by molecular exchange in a microwave field. The prepared intercalates were characterized using powder X-ray diffraction, density measurements, and thermogravimetric analysis. Infrared and Raman spectra indicate a coordination of the carbonyl oxygen atom of the γ-butyrolactone molecule to the vanadium or niobium atom of the host structure. Quantum mechanical calculations at the ab initio level confirm the proposed structure in which the γ-butyrolactone guest molecules are arranged with the plane of the ring perpendicular to the host layers and are anchored to the layers through the carbonyl oxygen atom coordinated to the transition metal atom of the host.

Introduction

Vanadyl phosphate dihydrate $VOPO_4{\cdot}2H_2O$ and other isostructural layered compounds are able to accommodate some types of organic molecules in the interlayer space.[1] Aliphatic alcohols and diols,[2−4] amines,[5] carboxylic acids,[6] carboxamides[7] and aliphatic nitriles[8] belong to the compounds which can be intercalated in such a way. Great attention has been devoted to the intercalation of heterocyclic N- and S-donors.[9−13] Recently, the intercalation of ketones,[14,15] aldehydes,[16] poly(ethylene glycol)s,[17,18] and heterocycles with O-donors[18−20] into vanadyl phosphates has been described. These guests are anchored to the host layers by donor−acceptor bonds of their carbonyl or ether oxygen atoms to the vanadium atoms. These intercalates, except aliphatic aldehyde intercalates, are generally very stable in air and the guest molecules are released at relatively high temperatures (for example, the tetrahydrofuran intercalate decomposes at about 160 °C[19]). It indicates that the host−guest interaction is very strong. The aliphatic aldehyde intercalates are unstable and the guests undergo aldol condensation and oxidation. On the other hand, aromatic aldehyde intercalates do not decompose in this way.[16] Some of these intercalates are crystalline solids and their diffractograms show, besides a series of sharp (00*l*) reflections, a number of (*hkl*) diffraction lines giving evidence for a regular structure.

This paper reports the results of the intercalation of γ-butyrolactone into vanadyl phosphate and isostructural niobyl arsenate.

Results and Discussion

γ-Butyrolactone cannot be intercalated directly in anhydrous vanadyl phosphate and replacement of water molecules in $VOPO_4{\cdot}2H_2O$ does not lead to an intercalation. The intercalate had to be prepared by replacing 1-propanol or 2-propanol in the corresponding $VOPO_4$ intercalate with the desired guest. The prepared intercalate was a yellow crystalline solid indicating that vanadium(v) had not been significantly reduced. Similarly, white niobyl arsenate intercalated with γ-butyrolactone was prepared from $NbOAsO_4{\cdot}2C_3H_7OH$. As follows from the results of elemental analyses, both intercalates contain one molecule of the guest per formula unit.

The diffractograms (see Figure 1) of both intercalates show a series of sharp (00*l*) reflections and also contain a number of (*hkl*) diffraction lines (Tables 1 and 2) giving evidence of a regular structure. The lattice parameters of the tetragonal structure are $a = 6.2163(8)$ Å and $c = 9.6681(9)$ Å for the $VOPO_4$ intercalate and $a = 6.6557(8)$ Å and $c = 9.805(3)$ Å for the $NbOAsO_4$ intercalate. The calculated density of 2.205 g/cm^3 for $VOPO_4{\cdot}C_4H_6O_2$ is in a good agreement with the experimental value of 2.21 g/cm^3. A new diffraction line with $d = 11.100$ Å was observed in the diffractogram of the $VOPO_4$ intercalate, measured using synchrotron radiation. This diffractogram can be in-

dexed in the triclinic space group $P\bar{1}$ using a fourfold cell with shifted layers. Butyrolactone molecules form a superstructure in the interlayer space.[21]

Both intercalates are stable in air (at a relative humidity of ca. 50%) as are tetrahydrofuran or tetrahydropyran intercalates.[19]

The thermal stability of the $VOPO_4$ intercalate was monitored by X-ray diffraction and thermogravimetry. The position and the intensity of the diffraction lines did not change up to 160 °C. Above this temperature, the intensity of the

diffraction lines decreases and the sample becomes green which means that vanadium(v) is reduced and butyrolactone starts to decompose as follows from the thermogravimetry. The total weight loss (34.8%) corresponds to the formula $VOPO_4{\cdot}C_4H_6O_2$. The $NbOAsO_4{\cdot}C_4H_6O_2$ intercalate was not monitored by thermogravimetry, because the host is decomposed at ca. 500 °C.

The character of the bonding between the guest and the host layers in the butyrolactone intercalates was studied by IR and Raman spectroscopy. The IR spectrum of liquid butyrolactone, its intercalates in $VOPO_4$ and $NbOAsO_4$ and the spectra of corresponding hosts in the region from 4000

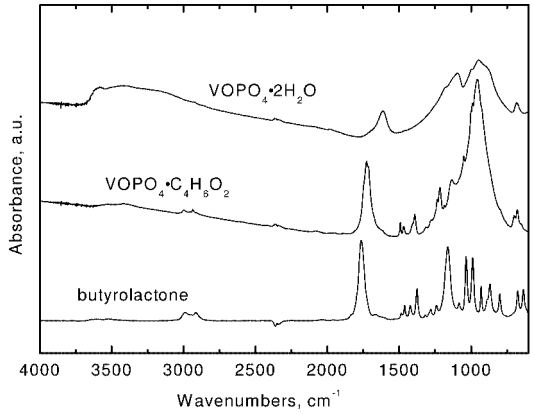

Figure 2. FT IR spectra of liquid butyrolactone (ATR on ZnSe crystal), vanadyl phosphate intercalated with butyrolactone and vanadyl phosphate dihydrate (in KBr pellets)

to 650 cm^{-1} are given in Figures 2 and 3. The Raman spectra of these compounds are given in Figures 4 and 5. The observed bands of the host compounds can be assigned properly, based on the previous studies of the $MOXO_4$ compounds.[22] The spectra have been interpreted in terms of the vibrations of the PO_4^{3-} and AsO_4^{3-} tetrahedrons. Positions of all of the arsenate bands are shifted to lower wavenumbers due to the mass effect of the As atom compared to the P atom.

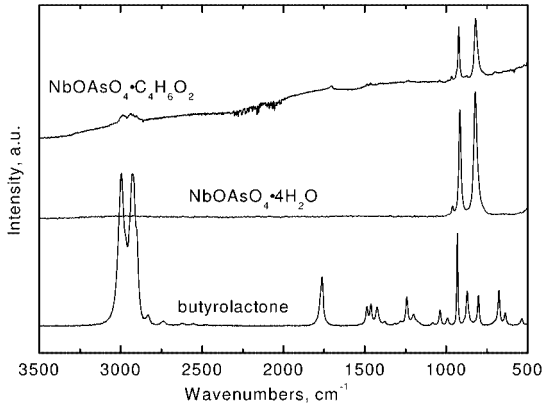

Figure 5. Raman spectra of liquid butyrolactone, niobyl arsenate intercalated with butyrolactone and niobyl arsenate tetrahydrate

The positions of the main spectral bands of the host structures in the vibration spectra of $VOPO_4$ and $NbOAsO_4$ intercalated with butyrolactone differ only slightly from those of vanadyl phosphate and niobyl arsenate hydrates. It confirms that the structures of the original $VOPO_4$ and $NbOAsO_4$ layers remain unchanged after the intercalation reaction. This conclusion is extremely important for the strategy of modeling.

The intense band at 937 cm^{-1} in the Raman spectrum of the $VOPO_4$ intercalate (see Figure 4) corresponds to the symmetric $\nu(PO_4)$ stretching vibration of the phosphate tetrahedron in the $(VOPO_4)_\infty$ layers and it is observed at 957 cm^{-1} in the IR spectrum of the intercalate (see Figure 2). Analogously the intense band at 820 cm^{-1} in the Raman spectrum of the $NbOAsO_4$ intercalate (see Figure 5) corresponds to the symmetric $\nu(AsO_4)$ stretching vibration of the arsenate tetrahedron in the $(NbOAsO_4)_\infty$ layers and it is observed at 817 cm^{-1} in the IR spectrum of the intercalate (see Figure 3). The positions of the V=O and Nb=O stretching vibrations appear to be especially sensitive to atoms coordinated to the vanadium atom within an octahedral arrangement in the host lattice structure. For instance, when water molecules are intercalated into $VOPO_4$, the position of this band at 1035 cm^{-1} in the IR spectrum of the anhydrous form of vanadyl phosphate changes to 995 cm^{-1} typical of mono- and dihydrates.[23] In the Raman spectrum of the vanadyl phosphate we can observe the V=O stretching vibration at 989 cm^{-1} corresponding to the hydrate form and also the vibration at 1035 cm^{-1} corresponding to the anhydrous form of vanadyl phosphate (see Figure 4). It is a result of the partial escape of the water molecules which occurs during the measurements due to the laser beam. In the Raman spectrum of niobyl arsenate, the Nb=O stretching vibration of the hydrate form is observed at 919 cm^{-1} and for the anhydrous form it is situated at 961 cm^{-1} (Figure 5). In the Raman spectrum of the vanadyl phosphate intercalate, the peak at 1000 cm^{-1} corresponds most probably to the V=O stretching vibration with an oxygen atom of butyrolactone coordinated to the vanadium atom (see Figure 4). Analogously, the peak at 924 cm^{-1} in the Raman spectrum of niobyl arsenate corresponds to the Nb=O stretching vibration with an oxygen atom of butyrolactone coordinated to the niobyl atom (see Figure 5). In the IR spectra of the intercalates these bands are overlapped by the spectrum of butyrolactone.

Comparing the positions of the stretching vibration bands of the C=O and C−O groups in the IR and Raman spectra of the pristine butyrolactone with these bands in the spectra of $VOPO_4$ and $NbOAsO_4$ intercalates we observed some shifts which indicate an interaction between the butyrolactone molecules and the host structure. The C=O stretching vibration observed at 1764 cm^{-1} in the IR spectrum of pure liquid butyrolactone is shifted to 1727 cm^{-1} in the IR spectrum of the $VOPO_4$ intercalate and to 1721 cm^{-1} in the IR spectrum of the $NbOAsO_4$ intercalate. In addition, a shoulder is clearly visible on the lower wavenumber side of the C=O stretch peak in the IR spectra. Its position changes from 1762 cm^{-1} in the Raman spectrum of pure butyrolactone to a small peak at 1726 cm^{-1} in the Raman spectrum of the $VOPO_4$ intercalate and at 1707 cm^{-1} of the $NbOAsO_4$ intercalate. The band due to the C−O stretching ring vibration of butyrolactone, observed at 1161 cm^{-1} in its IR spectrum is most probably shifted to the higher wavenumbers; to 1217 cm^{-1} in the IR spectrum

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the vanadyl phosphate intercalate (see Figure 2) and to 1244 cm^{-1} in the IR spectrum of the niobyl arsenate intercalate (see Figure 3). In the Raman spectra, these peaks are very small.

When the carbonyl oxygen atom of an ester is the donor, a weakening of the C=O bond can be expected together with a strengthening of the adjacent C−O bond as a secondary effect. When forming adducts with Lewis acids in which the metal ion is hexacoordinated by the ester molecule, esters show a negative shift in their carbonyl stretching frequency and a positive shift in their C−O stretching frequency.[24] It was shown[25] that the lithium ions are bound through the oxygen atom of the carbonyl group of butyrolactone in $LiClO_4$/butyrolactone solution. Both the C−C and C=O stretch vibrations are sensitive to an interaction between the Li^+ ion and the butyrolactone molecule. The shifts observed in the spectra of the butyrolactone intercalates indicate a coordination of the O_{guest} of the C=O group of butyrolactone to the vanadium and niobium atoms of the hosts.

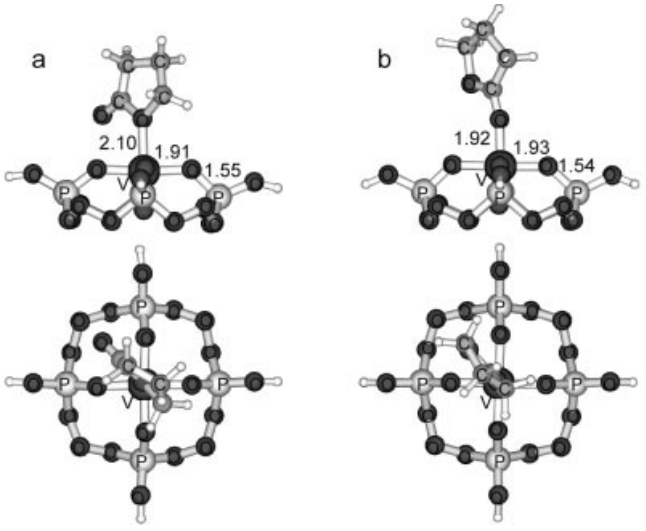

Figure 6. Two optimized HF/TZV structures of the molecular segment modeling the vanadyl phosphate−butyrolactone interaction with indicated bond lengths [A]

Figure 6 shows ab initio (HF/TZV) optimized structures of the molecular segment representing local interactions of vanadyl phosphate with butyrolactone. In order to preserve the overall planar structure of the segment during full geometry optimizations and at the same time make the electronic structure in the segment close to the conditions appearing in the intercalates, an oxygen atom had to be inserted between two neighboring PO_4 groups. Free terminal oxygen atoms have been replaced by OH groups and the total charge of the model compound was set to +3. It was found that all geometry optimizations with various starting orientations of butyrolactone with respect to the vanadyl group lead to the structures displayed in Figure 6 (a and b), which indicates that both C=O→V and C−O(−C)→V bonds can be formed. However, the structure shown in Figure 6 (b) is energetically more favorable by 22.7 kcal/mol and thus only the structure with the C=O→V bond is expected to be formed in the intercalates. This is also confirmed by the results of calculations of vibrational frequencies. While the calculated frequency of the C=O stretching vibration in the structure at Figure 6 (a) is shifted to higher wavenumbers compared to free butyrolactone, the C=O stretching vibration of the structure with the C=O→V bond [Figure 6 (b)] is shifted to lower wavenumbers as observed in the IR and Raman spectra.

Experimental Section

Preparation: The propanol intercalates were prepared by suspending microcrystalline $VOPO_4{\cdot}2H_2O$ or $NbOAsO_4{\cdot}4H_2O$ in dry propanol and monitored by a short exposure to a microwave field. The intercalation compounds were obtained by displacing propanol in $VOPO_4{\cdot}2C_3H_7OH$ or $NbOAsO_4{\cdot}2C_3H_7OH$ by γ-butyrolactone. The propanol intercalate (0.5 g) was dispersed in 15 mL of γ-butyrolactone and exposed to a microwave field for 5 min. The intercalates were filtered off, washed with diethyl ether, and dried in nitrogen. The composition of the intercalate was determined by elemental analyses. $C_4H_6O_7PV$ (248.0): calcd. C 19.37, H 2.44; found C 19.61 H 2.39. $C_4H_6AsNbO_7$ (333.9): calcd. C 14.39, H 1.81; found C 14.25, H 1.87.

XRD: Powder data were obtained with a D8-Advance diffractometer (Bruker AXE, Germany) using Cu-K_α radiation with a secondary graphite monochromator. Diffraction angles were measured from 7 to 80° (2θ).

Density: Density of the $VOPO_4$ intercalate was measured with an automated helium pycnometer (AutoPycnometer 1320, Micromeritics, USA) to 0.01 $g{\cdot}cm^{-3}$ accuracy.

Thermogravimetry: The TG analyses were performed using a Netzsch STA 449C instrument. The measurements were carried out in air between 30 and 800 °C at a heating rate of 5 $°C{\cdot}min^{-1}$.

IR Spectroscopy: IR measurements in the range 400−4000 cm^{-1} were made with a fully computerized Bruker IFS 55 EQUINOX FTIR spectrometer with DLATGS detector (256 scans per spectrum at 4 cm^{-1} resolution). Measurements of the intercalates were performed ex situ in the transmission mode using KBr pellets. The spectrum of the corresponding liquid butyrolactone was measured by the ATR technique on a ZnSe crystal. The spectra were corrected for the content of H_2O and CO_2 in the optical path.

Raman Spectroscopy: FT Raman spectra were collected using a Bruker IFS 55 EQUINOX FTIR spectrometer equipped with an FT Raman module FRA 106/S with diode-pumped, temperature-stabilized Nd YAG laser, and InGaAs detector (128 interferograms were co-added per spectrum in the range 4000 to −1000 cm^{-1} at 4 cm^{-1} resolution).

Calculations: Quantum chemical calculations were carried out at the ab initio level of theory employing the Gaussian 98[26] program package. Local interactions and structures in intercalates of vanadyl phosphate with the nitrile group were studied at the HF level using a TZV basis set.[27]

Copper(I)-Assembled Pseudorotaxanes Bearing Bis(nitrile) Ligands: Selective Formation of Large Chelate Rings

Efstathia G. Sakellariou,[a] Jean-Paul Collin,*[a] Christiane O. Dietrich-Bucheker,[a] and Jean-Pierre Sauvage*[a]

Keywords: Copper / N ligands / Macrocycles / Chelates

The syntheses of two novel Cu^{I}-bis(benzonitrile) complexes of the type $[Cu(dCN_n)_2][PF_6]$ {where dCN_n = $NCPhO(CH_2)_n$-OPhCN, n = 3, 4} are described. Both compounds have been characterized by X-ray crystallography. To our surprise, and although the two complexes were quite similar, two very distinct structures were obtained. For the $[Cu(dCN_4)_2][PF_6]$ complex, a tetrahedral geometry was observed whereas for $[Cu(dCN_3)_2][PF_6]$, a polymeric assembly was formed. A further extension of this work involved the syntheses of two threaded species bearing the M30 macrocycle, Cu metal and a dCN_n ligand. The formation of the desired complexes was confirmed by means of mass spectrometry as well as 1-D and 2-D ^1H NMR spectroscopy. Finally, the cyclic voltammograms of all 4 new species were recorded giving rise to redox potentials ranging from +0.88 to +1.25 V. These new threaded complexes are of particular interest since they can form the basis of novel rotaxane structures.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

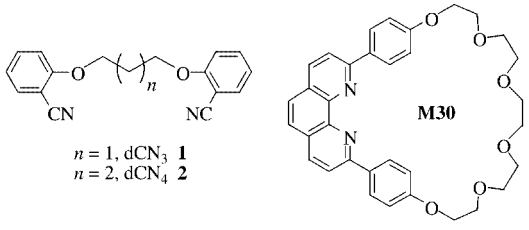
Introduction

Nowadays rotaxanes and catenanes constitute an important class of compounds[1] exhibiting interesting properties such as photoinduced electron transfer[2] and controlled molecular motion.[3] Due to the various synthetic strategies developed during the course of the last 20 years, interest in these multi-component systems has experienced a spectacular revival. However, as some of the synthetic approaches employed for their preparation are based on a metal-templated strategy,[4] the metallic species involved should be carefully chosen as it plays an essential role in the actual assembling of such complex structures. In addition, the electronic properties of the metal in question are important in order to control intramolecular electron transfer processes, in relation to the modeling of the photosynthetic reaction center, or to trigger electrochemically driven motions in artificial molecular machines and motors.[5] Traditionally, tetrahedral copper(I) has been the metal of choice in order to induce the formation of entangled structures from two coordinating molecular threads or to drive the formation of a pseudo-rotaxane from a ring and a molecular string.[4] Moreover, the use of octahedrally coordinated metal centers in order to assemble and pre-organize the various organic fragments to be incorporated in the desired catenanes and rotaxanes has also been described.[6,7] A further extension of this work involved the use of a five-coordinate Zn^{2+} center bearing terpyridine and phenanthroline as the coordinating ligands thus giving rise to novel catenane structures.[8]

Although the bidentate chelate of choice has mainly been the 1,10-phenanthroline (phen) unit and its derivatives, other ligands can be envisaged which should also lead to intertwined or threaded species, precursors of the catenanes and rotaxanes to be synthesized. Since copper(I) forms relatively stable complexes with π-accepting ligands and, in particular, with acetonitrile, the possibility of using bidentate chelates consisting of two terminal benzonitrile groups has been explored. In the present article the coordination chemistry between copper(I) and the aforementioned ligands as well as the formation of threaded complexes containing the traditional phen-incorporating 30-membered ring (M30),[9] copper(I) and a bis(nitrile) ligand is described.

Results and Discussion

The bis-nitrile ligands, as well as the 30-membered ring (M30) used in the preparation of the threaded complexes are represented in Scheme 1.



Scheme 1

E-mail: sauvage@chimie.u-strasbg.fr

Surprisingly, chelates consisting of two or more nitrile groups as coordinating sites have been very scarcely used. Angelici and co-workers synthesized a series of interesting complexes with various metal centers in conjunction with such ligands or their isocyanide analogues.[10] Recently, our group also described the synthesis of ruthenium(II) benzonitrile complexes in relation to light-driven molecular machines and motors.[11]

1. Synthesis of $[Cu(dCN_n)_2][PF_6]$ (n = 3, 4) Complexes

The synthesis of the two novel copper(I)−bis(benzonitrile) complexes is depicted in Equation (1).

$$[Cu(CH_3CN)_4][PF_6] \xrightarrow{2\ dCN_n} [Cu(dCN_n)_2][PF_6] + 4\ CH_3CN \quad (1)$$

$n = 3$, $[Cu(dCN_3)_2][PF_6]$ **3**

$n = 4$, $[Cu(dCN_4)_2][PF_6]$ **4**

Reaction of $Cu(CH_3CN)_4{\cdot}PF_6$ with two equivalents of the corresponding dCN_n (n = 3, 4) ligand in dichloromethane results in the quantitative formation of compounds **3** and **4**. The novel complexes were obtained as solids and were characterized by mass spectrometry and ^1H NMR spectroscopy. Moreover, reversible cyclic voltammograms were recorded for both Cu−dCN_n complexes. In particular, $[Cu(dCN_3)_2]^{2+/+}$ showed a remarkably high redox potential of E° = +1.20 V vs. the SCE in CH_2Cl_2, similar to that of the tetrahedral complex $[Cu(dCN_4)_2]^{2+/+}$ (E° = +1.25 V vs. SCE) in the same solvent.

X-ray Structural Studies

In both cases, single crystals suitable for X-ray analysis were obtained by slow diffusion of *n*-hexane (for compound **3**) or diisopropyl ether (for compound **4**) into a degassed solution of the corresponding complex in dichloromethane. Although the only difference between the two Cu−dCN_n complexes resides in the number of carbon atoms incorporated in the chain connecting the two benzonitrile rings, it is sufficient to give rise to two distinct structures as shown in Figures 1 and 2. Thus, although for the $Cu(dCN_3)_2{\cdot}PF_6$ complex a polymeric structure was obtained, for the $Cu(dCN_4)_2{\cdot}PF_6$ compound a monomeric tetrahedral structure was quantitatively formed. In the latter case, a bis-macrocyclization was achieved resulting in the formation of two 15-membered rings assembled around the copper center. The stability of this complex is remarkable confirming the preference of Cu^I in a tetra-coordinated geometry, as well as the "chelate" effect that the two dCN_4 ligands are exerting on the metal atom. Moreover, the high yielding reaction leading to this complex shows that very large metallacycles can be strongly stabilized over ill-defined oligomers or polymers. This is consistent with the observation that cyclic assemblies are very often formed quantitatively from multisite ligands and appropriate metal centers, one of the archetypical examples being that of Fujita's squares consisting of 4 Pd^{II} atoms at the corners and four 4,4′-bipyridine units as edges.[12]

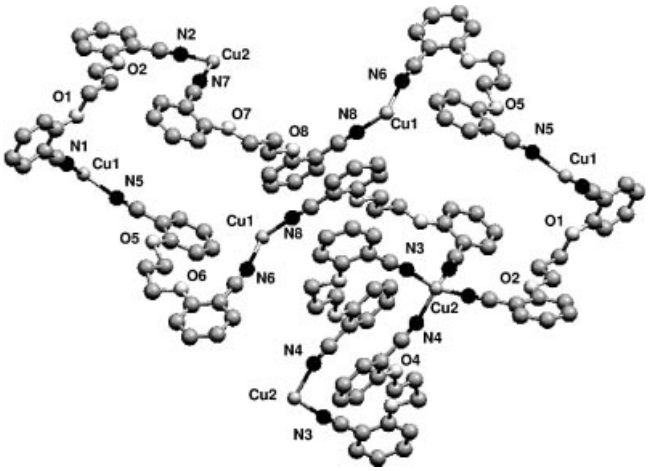

Figure 1. Repeating unit of the polymeric structure obtained for $[Cu(dCN_3)_2][PF_6]$. The assembly consists of 2 types of macrocycles of different size. Hence, the small cycle (28-membered ring) contains two Cu centers connected via two dCN_3 ligands whereas the larger cycle (84-membered ring) bears six Cu centers and the same number of dCN_3 ligands connected to each other in an alternating fashion (Cu-dCN_3−Cu-dCN_3···)

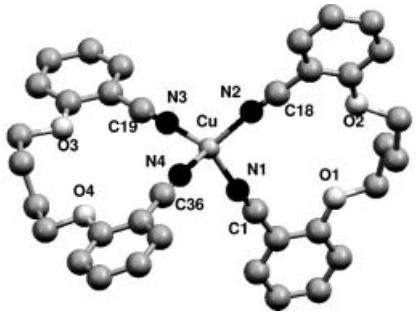

Figure 2. Crystal structure of $[Cu(dCN_4)_2][PF_6]$. A tetrahedral geometry around the Cu-center can be observed with the average Cu−N distances being 1.97 Å. Hydrogen atoms are omitted for clarity. The average N−Cu−N bond angle is 109.4 deg

It should be noted, however, that in the case of the polymeric structure **3** the average Cu^I−N bond length was found to be 1.99 Å which is not significantly different from that of the monomeric complex **4** (1.97 Å) and of the same order of magnitude as the average bond length found in $[Cu(CH_3CN)_4][PF_6]$ (1.99 Å).[13] On the other hand, a slightly longer Cu^I−N distance was measured in the tetrakis benzonitrile Cu^I complex $[Cu(PhCN)_4][SbCl_6]$ (2.05 Å).[14] Selected bond lengths and bond angles are given for both complexes in Tables 1 and 2.

2. Synthesis of $[Cu(M30)(dCN_n)][PF_6]$ (n = 3, 4) Threaded Complexes

Having successfully synthesized the two new Cu-dCN_n complexes, the threading reaction incorporating a ring, namely M30, the Cu metal and a dCN_n ligand was also attempted in order to see if the synthesis of pseudo-rotaxane structures based on such benzonitrile ligands was feasible.

Based on CPK models, the dCN ligand was found to fit comfortably within the cavity of the M30 ring which was therefore chosen as the macrocycle for the threading reac-

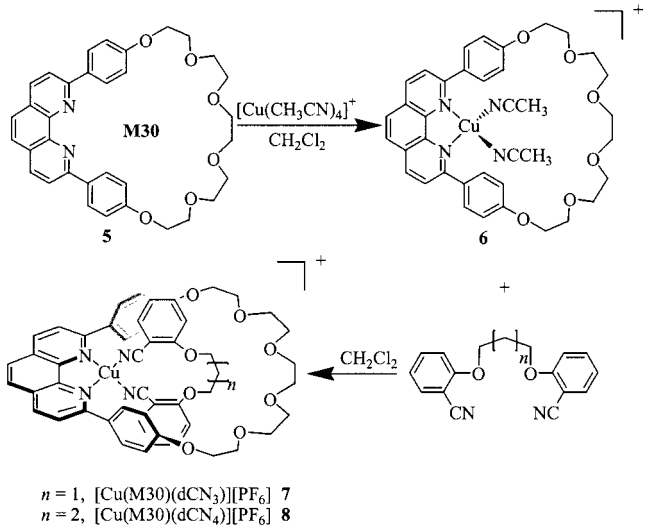
tion. The synthetic strategy employed in order to prepare the desired threaded species is shown in Scheme 2.



Scheme 2. Synthesis of the threaded complexes **7** and **8**

Thus, to a degassed solution of M30 in dichloromethane, a solution of the $Cu(CH_3CN)_4{\cdot}PF_6$ salt in the same solvent was added. Upon addition, a drastic change in color was observed from yellow to orange confirming the formation of complex **6**. To this complex, a solution of the corresponding dCN_n ligand was added and the reaction stirred overnight at ambient temperature under argon. The formation of the desired complexes **7** and **8** was confirmed by means of mass spectrometry and 1-D and 2-D ^{1}H NMR spectroscopy. In particular the 2-D NMR spectra were very informative, well-resolved and corresponded to the desired compounds. As shown in Figure 3, ^{1}H NMR spectroscopy confirmed the threaded structure of **8** and the entwining of the phen and dCN_4 units around the metal center. A similar spectrum was also obtained for compound **7**.

Hence, due to the intense ring current effect of the C_6H_4CN units, the resonance signals corresponding to the H_o and H_m protons of the phenoxy moieties in the threaded complex move to higher field compared with the free ligand M30. The same pattern was also observed for the $H_{1'}$ protons of the dCN_4 ligand which, upon threading, experience the ring current of the macrocycle and thus move to lower ppm values. This NMR behavior is in accord with previously described systems.[15] 2-D ^{1}H NMR spectroscopy was also employed in order to further elucidate both structures. The ROESY spectrum of complex **8** is given as a representative example in Figure 4. As expected, signals in the aromatic region showing the through space coupling of protons $H_{5,6}$ with $H_{4,7}$ and H_o with $H_{3,8}$ were observed. Moreover, interactions between the H_α protons of the dCN_4 ligand with $H_{4'}$ as well as coupling of the H_a protons of the M30 chain with H_m were present.

However, the threading reaction was mainly confirmed by the ROESY signals such as those between the $H_{4'}$ protons of dCN_4 and the $H_{b,c,d}$ protons of the M30 ring, as well as the signals between the H_α and H_β protons of dCN_4 and the H_a and $H_{b,c,d}$ protons of the macrocyclic chain. Two equally important signals stem from the interactions of both H_α and H_β protons of the dCN_4 ligand with the H_m protons of the phenoxy rings. All these observations are consistent with the interactions predicted based on the CPK model of the threaded structure in question.

Finally, the cyclic voltammograms of the pseudorotaxane structures **7** and **8** were also obtained. Hence, for the threaded complexes the $E°$ values were found to be +0.95 V and +0.88 V for $[Cu(M30)(dCN_3)]^{2+/+}$ and $[Cu(M30)(dCN_4)]^{2+/+}$, respectively. The less positive $E°$ values of compounds **7** and **8**, when compared with the $E°$ values of **3** and **4**, indicate a slight destabilization of the Cu^I oxidation state versus Cu^{II} upon formation of the pseudorotaxane structures. Unfortunately, all attempts to grow crystals suitable for X-ray analysis were unsuccessful for either of the two complexes.

However, both compounds are of particular interest since they could form the basis of novel rotaxane structures. Forming derivatives of the benzene rings could be envisaged in order to attach "stoppers" at each of the dCN fragments thus leading to the final rotaxanes.

Experimental Section

General: ^{1}H NMR spectra were acquired on either a Bruker AM 300 (300 MHz) or a Bruker AM 400 (400 MHz) spectrometer using the deuterated solvent as the lock and the residual solvent as the internal reference. Mass spectra were obtained using a VG ZAB-HF (FAB) spectrometer or a VG-BIOQ triple quadrupole, positive mode (ES-MS). Electrochemical experiments were performed using an EG&G PAR model 273A potentiostat with a standard three-

electrode configuration. Cyclic voltammetry was carried out in CH_2Cl_2, using as supporting electrolyte a Pt working electrode, a Pt counter-electrode, and an SCE as the reference electrode. The typical sweep rate was 100 mV/s, and the window used was from −2.0 V to +1.4 V. The following chemicals were prepared according to literature procedures: M30,[9] dCN_3,[11] dCN_4.[11] CH_2Cl_2 was dried by heating to reflux over CaH_2 followed by distillation.

[Cu(dCN$_3$)$_2$][PF$_6$] (3): To a degassed solution of $Cu(CH_3CN)_4{\cdot}PF_6$ (36.2 mg, 0.09 mmol) in CH_2Cl_2 (4 mL) was added a solution of dCN_3 (54.3 mg, 0.19 mmol) in the same solvent (4 mL) and the resultant reaction mixture was left stirring at 20 °C under argon for 24 h. Evaporation of the solvent gave complex **3** as a yellowish solid (69 mg). ^{1}H NMR (300 MHz, CD_2Cl_2, 25 °C): δ = 7.73−7.60 (m, 4 H), 7.18−7.06 (m, 4 H), 4.38 (t, J = 5.5 Hz, 4 H), 2.45 (q, J = 5.5 Hz, 2 H) ppm. MS: (ES-MS): m/z (%) = 619 (100) [M − H − PF_6^-], 341 (100) [M − dCN_3 − H − PF_6^-]. Redox potential (V vs. SCE): $E°$ ($Cu^{II/I}$) = 1.20 V.

[Cu(dCN$_4$)$_2$][PF$_6$] (4): To a degassed solution of $Cu(CH_3CN)_4{\cdot}PF_6$ (88.9 mg, 0.24 mmol) in CH_2Cl_2 (10 mL) was added a solution of dCN_4 (0.14 g, 0.48 mmol) in the same solvent (10 mL) and the resultant reaction mixture was left stirring at 20 °C under argon for 12 h. Evaporation of the solvent gave complex **4** as a white solid (187 mg, 98%). ^{1}H NMR (300 MHz, CD_2Cl_2, 25 °C): δ = 7.71−7.59 (m, 4 H), 7.11−7.01 (m, 4 H), 4.18 (br. s, 4 H), 2.13 (br. s, 4 H) ppm. MS: (ES-MS): m/z (%) = 647 (86) [M − H − PF_6^-], 355 (100) [M − dCN_4 − H − PF_6^-]. Redox potential (V vs. SCE): $E°$ ($Cu^{II/I}$) = 1.25 V.

[Cu(M30)(dCN$_3$)][PF$_6$] (7): A solution of $Cu(CH_3CN)_4{\cdot}PF_6$ (17 mg, 0.04 mmol) in degassed CH_2Cl_2 (6 mL) was added under argon and

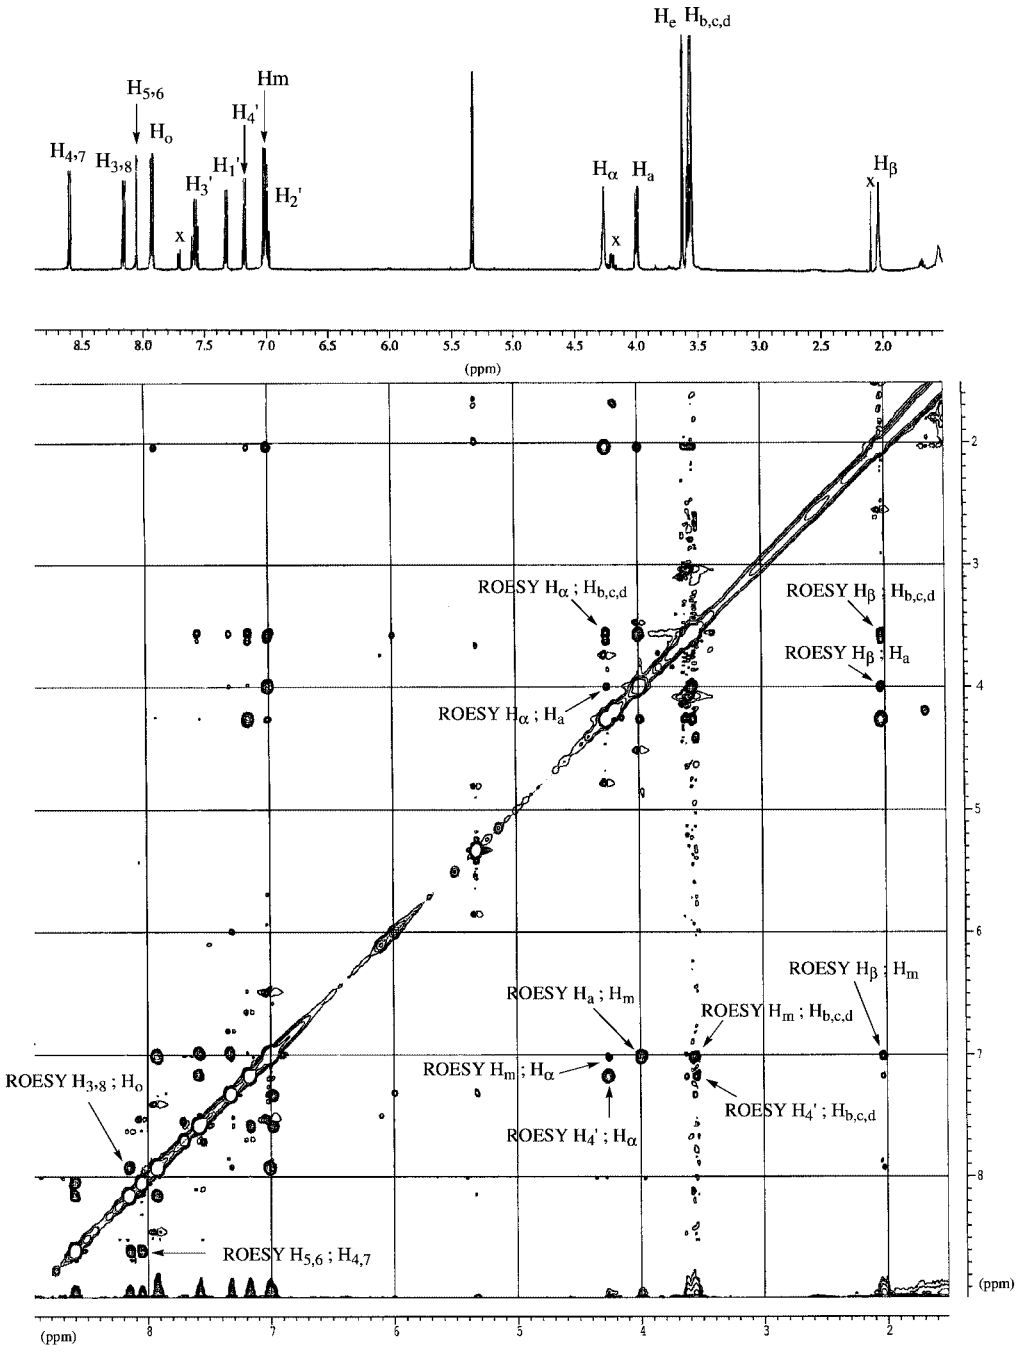

Figure 4. ROESY spectrum of the threaded complex **8** in CD_2Cl_2, (X denotes a small amount of impurity)

at 20 °C to a stirred degassed solution of M30 (25.8 mg, 0.04 mmol) in CH_2Cl_2 (5 mL) via a cannula. The instantaneous appearance of a deep orange color was ascribed to the formation of **6**. After 1 h at room temperature a solution of dCN_3 (12.7 mg, 0.04 mmol) in CH_2Cl_2 (5 mL) was added to **6**. The resultant reaction mixture was stirred for a further 2.5 h under argon. Evaporation of the solvent gave **7** as a brown solid (47 mg, 99.2%). ^{1}H NMR (400 MHz, CD_2Cl_2, 25 °C): δ = 8.63 (d, *J* = 8.2 Hz, 2 H), 8.19 (d, *J* = 8.4 Hz, 2 H), 8.07 (s, 2 H), 7.92 (d, *J* = 8.5 Hz, 4 H), 7.56 (ddd, *J* = 8.0, *J* = 1.7, *J* = 1.4 Hz, 2 H), 7.47 (dd, *J* = 7.8, *J* = 1.7 Hz, 2 H), 7.11 (d, *J* = 8.5 Hz, 2 H), 7.05 (d, *J* = 7.8 Hz, 4 H), 7.03 (dt, *J* = 7.5, *J* = 0.7 Hz, 2 H), 4.34 (t, *J* = 5.8 Hz, 4 H), 4.06 (t, *J* = 5.6 Hz, 4 H), 3.62 (t, *J* = 5.6 Hz, 8 H), 3.59 (s, 4 H), 3.54 (s, 4 H), 2.36 (q, *J* = 5.8 Hz, 2 H) ppm. MS: (ES-MS): *m/z* (%) = 907 (79) [M − H − PF_6^-], 629 (74) [M − dCN_3 − PF_6^-]. Redox potential (V vs. SCE): E° ($Cu^{II/I}$) 0.95 V.

[Cu(M30)(dCN$_4$)][PF$_6$] (8): A solution of $Cu(CH_3CN)_4{\cdot}PF_6$ (62.9 mg, 0.17 mmol) in degassed CH_2Cl_2 (15 mL) was added under argon and at 20 °C to a stirred degassed solution of M30 (96.1 mg, 0.17 mmol) in CH_2Cl_2 (15 mL) via a cannula. The instantaneous appearance of a deep orange color was ascribed to the formation of **6**. After 1 h at room temperature a solution of dCN_4 (49.6 mg, 0.17 mmol) in CH_2Cl_2 (10 mL) was added to **6**. The resultant reaction mixture was stirred for a further 2.5 h under argon. Evaporation of the solvent gave **8** as a brown solid (176 mg, 99%).

New Pentadentate Carboxylate-Derivatized Sulfur Ligands Affording Water Soluble Iron Complexes with [Fe(NS_4)] Cores that Bind Small Molecules (CO, NO, PMe_3) as Co-Ligands[‡]

Dieter Sellmann,[†][a] Kai P. Peters,*[a] and Frank W. Heinemann[a]

Keywords: Iron / Nickel / S ligands / P ligands / Water solubility

In the search for polydentate sulfur ligands that are able to form water-soluble iron complexes which can bind nitrogenase relevant molecules, the new pentadentate ligands py$CO_2Me$$S_4$–$H_2$ [2,6-bis[2-mercapto-3-(methoxycarbonyl)-phenylthio]dimethylpyridine] (**1**) and py$CO_2H$$S_4$–$H_2$ [2,6-bis(2-mercapto-3-carboxyphenylthio)dimethylpyridine] (**2**) having NS_4 donor atom sets and terminal thiolate donors have been synthesized. The starting material was $CO_2Me$$S_2$–$H_2$ (2,3-dimercapto benzoic acid methyl ester) which was alkylated with 2,6-bis[(tosyloxy)methyl]pyridine. The problem of specifically achieving regioselective monoalkylation of this 1,2-benzene-dithiol derivative was solved by carrying out the alkylation of $CO_2Me$$S_2$–$H_2$ at –78 °C in the presence of stoichiometric amounts of a base. Saponification of **1** afforded the carboxylic acid derivative. Coordination of py$CO_2Me$$S_4^{2-}$ to Fe^{II} in the presence of co-ligands (L = CO, PMe_3) yielded the complexes [Fe(L)(py$CO_2Me$$S_4$)] where L = CO (**5**) or PMe_3 (**4**). Upon treatment with $NOBF_4$, complex **5** afforded [Fe(NO)(py$CO_2Me$$S_4$)]$BF_4$ (**7**) which could be subsequently converted to the isolable 19 valence electron species [Fe(NO)(py$CO_2Me$$S_4$)] (**8**) upon reduction with N_2H_4. In the absence of potential co-ligands, coordination of py$CO_2Me$$S_4^{2-}$ to Fe^{II} afforded the dinuclear complex [Fe(py$CO_2Me$$S_4$)]$_2$ (**6**) whilst coordination to Ni^{II} gave [Ni(py$CO_2Me$$S_4$)]$_x$ (**3**). Solubility of these complexes in water could be achieved by replacing the CO_2Me groups with CO_2H substituents. The ligand py$CO_2H$$S_4^{2-}$ afforded the iron complexes [Fe(L)(py$CO_2H$$S_4$)] [L = CO (**10**) and PMe_3 (**12**)] and [Fe(NO)(py$CO_2H$$S_4$)]$BF_4$ (**11**). Both **10** and **12** could be reversibly deprotonated to give the corresponding water-soluble salts $(NMe_4)_2$[Fe(L)(*py*$CO_2$$S_4$)] with L = CO {$(NMe_4)_2$ [**9**]} and PMe_3 {$(NMe_4)_2$ [**13**]}. The complexes were characterized by elemental analysis, spectroscopic methods and X-ray structural determinations. The molecular structure of [Fe(PMe_3)(py$CO_2H$$S_4$)] (**12**) was found to exhibit inter- and intramolecular O–H···O and O–H···S hydrogen bonds which serve as models for proton transfer steps from external sources to the active sites of metal sulfur enzymes.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Iron atoms in sulfur dominated coordination spheres constitute the active sites of numerous metal enzymes.[1] In the search for low-molecular weight complexes which are capable of modeling characteristic features of the active sites of FeMo, FeV or FeFe nitrogenases such as the sulfur environment of the iron centers, binding of small molecules, and redox-activity, we have recently discovered the [Fe(pyS_4)] fragment (see Figure 1).[2]

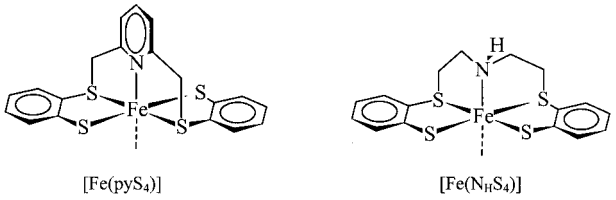

Figure 1. Schematic structure of [Fe(pyS_4)] and [Fe(N_HS_4)] fragments

This fragment binds small molecules, e.g. CO, N_2H_2, N_2H_4, NH_3.[3] The resultant complexes are redox-active and are formed diastereoselectively, always exhibiting the thiolate and thioether donors in *trans* positions. In contrast with related [Fe(L)(N_HS_4)][4] complexes of the pentadentate ligand $N_HS_4^{2-}$ [= dianion of 2,2′-bis(2-mercapto-phenylthio)diethylamine] which may contain low- or high-spin Fe^{II} depending on the σ or σ-π character of the ligand L, all 18 valence electron [Fe(L)(pyS_4)] complexes are diamagnetic. This was demonstrated, for example, by [Fe(CO)-

(pyS_4)] and [Fe(N_2H_4)(pyS_4)] which are both diamagnetic.[3] [Fe(L)(pyS_4)] complexes are, however, usually soluble only in non-aqueous solvents thus preventing any investigations in water which is clearly the important solvent in biological systems. In order to resolve this problem and to obtain water-soluble complexes, we attempted to introduce carboxylic acid substituents into the pyS_4^{2-} ligand. This required new ligands, the design and synthesis of which are reported here together with some related iron and nickel complexes.

Results and Discussion

Ligand Synthesis

Figure 2 summarizes starting materials, notations and the target ligands **1** and **2**.

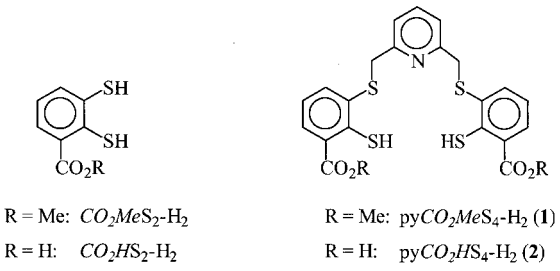

Figure 2. Starting materials, notations and the target ligands **1** and **2**

The notations $CO_2MeS_2{-}H_2$, $pyCO_2MeS_4{-}H_2$, $pyCO_2HS_4{-}H_2$, etc. have been used throughout in order to facilitate legibility and designation of the degrees of protonation/deprotonation of the individual ligands.

The starting material for the pentadentate target ligand **1** was $CO_2MeS_2{-}H_2$, and the major problem was to connect two of these molecules with 2,6-bis[(tosyloxy)methyl]-pyridine such that only one of the two SH functions in $CO_2MeS_2{-}H_2$ would be regioselectively alkylated.

All attempts to achieve a regioselective mono-alkylation using [$Fe^{II}(CO)_2$] or [Ni^{II}] complex fragments as templates remained unsuccessful, although such template reactions have afforded very good results in previous preparations of related ligands.[5] Analogous attempts with the acid derivative $CO_2HS_2{-}H_2$ also failed, as did direct alkylations of $CO_2MeS_2{-}H_2$ under ambient conditions in the absence of templates. In all cases an inseparable mixture of the three regioisomers **1**, **1a**, and **1b** was obtained (Figure 3).

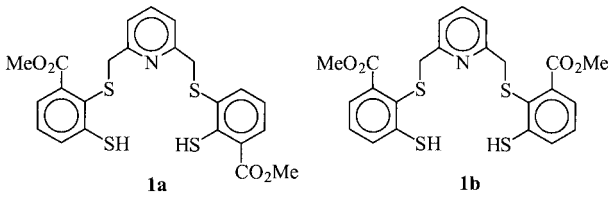

Figure 3. Isomers of $pyCO_2MeS_4{-}H_2$ (**1**)

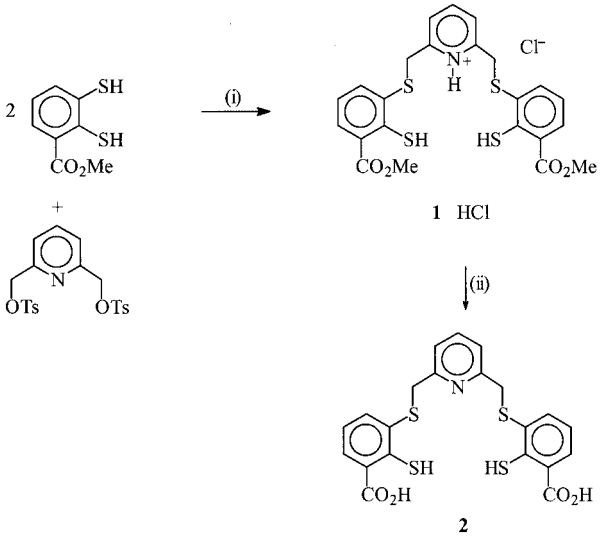
After a number of laborious experiments, it was finally found that alkylation of $CO_2MeS_2{-}H_2$ in the presence of one equivalent of NMe_4OH at −78 °C afforded the target molecule **1** as the major product. Even then however, a purification step via the nickel complex [Ni($pyCO_2MeS_4$)]$_x$ was necessary. Acidic hydrolysis of [Ni($pyCO_2MeS_4$)]$_x$ afforded **1** as its HCl salt in isomeric purity after recrystallization. Saponification of the ester functions of **1** gave the acid derivative $pyCO_2HS_4{-}H_2$ (**2**) (Scheme 1).



Scheme 1. Synthesis of the target ligands **1** and **2**: (i) 1) +2 NMe_4OH, −78 °C, THF/MeOH, 15 h; 2) $HCl_{aq.}$, CH_2Cl_2; 3) +2 LiOMe, + $Ni(OAc)_2{\cdot}4H_2O$, MeOH; 4) $HCl_{aq.}$, CH_2Cl_2. (ii) 1) +10 $NaOH_{aq.}$, THF, 72 h; 2) $HCl_{aq.}$, CH_2Cl_2

Neither ^1H nor ^{13}C NMR spectroscopy enabled us to unambiguous distinguish the target ligand **1** from its symmetrical regioisomer **1b**. This was possible only by an X-ray structural determination (vide infra).

Syntheses of Iron and Nickel Complexes

Straightforward coordination of the anion $pyCO_2MeS_4^{2-}$ to Fe^{II} and Ni^{II} afforded a series of complexes which are shown in Scheme 2.

Reaction of **1**·HCl with $Ni(OAc)_2{\cdot}4H_2O$ in the presence of three equivalents of LiOMe (for deprotonation of the pyridinium NH and thiol SH functions) afforded yellow-brown [Ni($pyCO_2MeS_4$)]$_x$ (**3**) which is presumably dinuclear like the analogous [Ni(pyS_4)]$_2$.[2] Complex **3** is moderately soluble in DMF and DMSO but only sparingly soluble in all other common solvents. Analogous reactions of **1**·HCl with $FeCl_2{\cdot}4H_2O$ in the presence of PMe_3 or CO gave red [Fe(PMe_3)($pyCO_2MeS_4$)] (**4**) and red [Fe(CO)($pyCO_2MeS_4$)] (**5**), respectively, with **5** showing a ν(CO) band at 1952 cm^{-1} in KBr. In the absence of potential co-ligands, dinuclear violet-red [Fe($pyCO_2MeS_4$)]$_2$ (**6**) was formed instead. Complex **6** is almost insoluble in all common solvents although THF suspensions of **6** react with gaseous CO to give **5** indicating that **6** partially dissociates into coordinatively unsaturated [Fe($pyCO_2MeS_4$)] monomers. Treatment of the carbonyl complex [Fe(CO)($pyCO_2MeS_4$)]

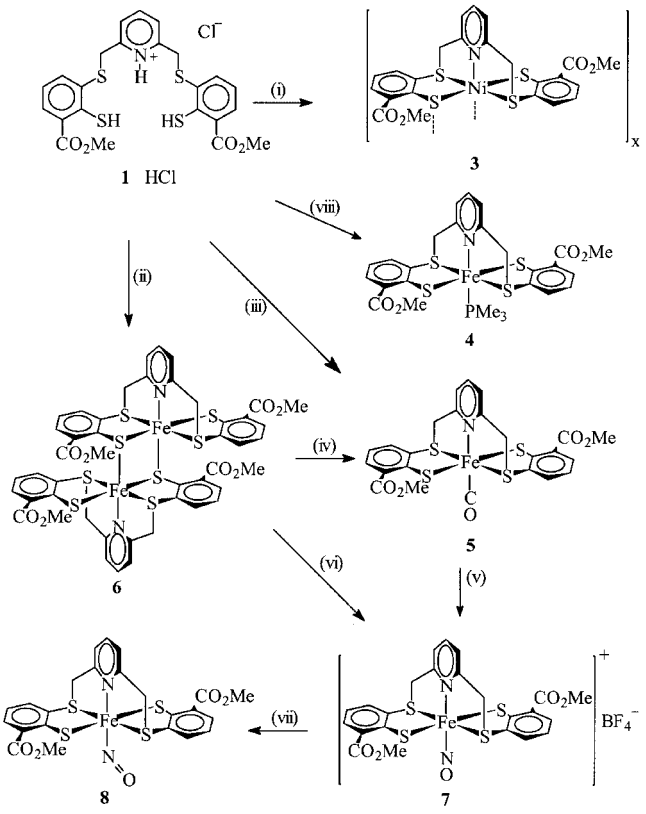
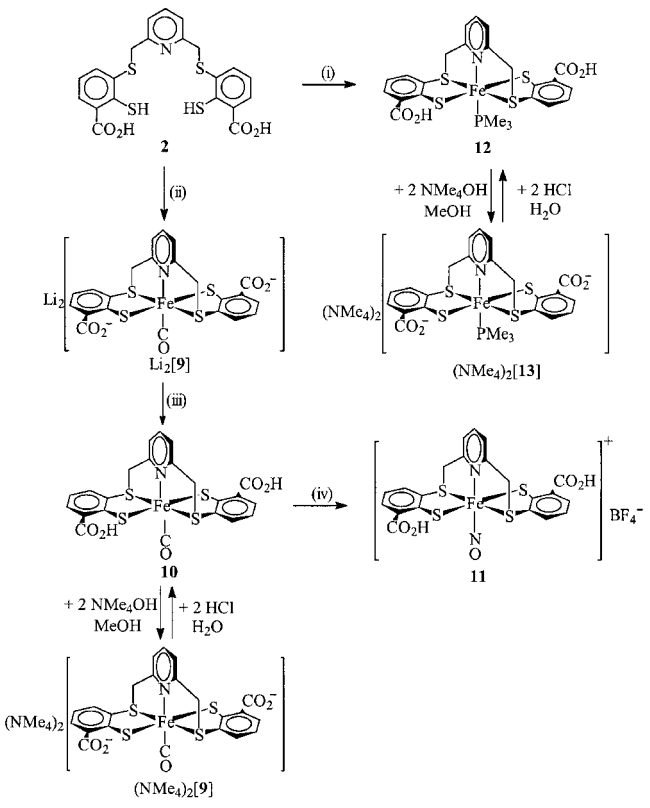


Scheme 2. Fe and Ni complexes with [M(pyCO_2MeS$_4$)] fragments: (i) +3 LiOMe, + $Ni(OAc)_2{\cdot}4H_2O$, MeOH; (ii) +3 LiOMe, + $FeCl_2{\cdot}4H_2O$, MeOH; (iii) +3 LiOMe, + $FeCl_2{\cdot}4H_2O$, + exc. CO, MeOH; (iv) + exc. CO, THF; (v) + $NOBF_4$, CH_2Cl_2; (vi) +2 $NOBF_4$, CH_2Cl_2; (vii) + exc. H_2N_4, MeOH; (viii) +3 LiOMe, + $FeCl_2{\cdot}4H_2O$, + exc. PMe_3, MeOH



Scheme 3. Synthesis of acidic [Fe(L)(pyCO_2HS$_4$)] complexes and corresponding salts with [Fe(L)(pyCO_2S$_4$)]$^{2-}$ anions: (i) + $FeCl_2{\cdot}4H_2O$, + exc. PMe_3, MeOH; (ii) +4 LiOMe, + $FeCl_2{\cdot}4H_2O$, + exc. CO, MeOH; (iii) +2 HCl, H_2O (iv) + $NOBF_4$, CH_2Cl_2

(**5**) with $NOBF_4$ led to CO substitution and formation of the brown 18 valence electron nitrosyl derivative [Fe(NO)(pyCO_2MeS$_4$)]BF_4 (**7**) having a ν(NO) band at 1881 cm^{-1}. Complex **7** also formed when dinuclear **6** was treated with an excess of $NOBF_4$. Reduction of **7** with hydrazine gave the neutral red-brown [Fe(NO)(pyCO_2MeS$_4$)] (**8**) having a ν(NO) band at 1617 cm^{-1}.

Preparation of complexes with the acid derivative pyCO_2HS$_4$−H_2 (**2**) or its fully deprotonated anion pyCO_2S$_4^{4-}$ were generally achieved in the same way (Scheme 3). The resultant complexes enabled studies of the reversible deprotonations and the electronic influence of carboxylic acid vs. carboxylate functions. It proved difficult to obtain analytically pure samples of salts containing [Fe(pyCO_2S$_4$)]$^{2-}$ anions. Recrystallization attempts of these salts always afforded powders and, in fact, single crystals suitable for an X-ray diffraction study could not be obtained.

Reaction of pyCO_2HS$_4$−H_2 (**2**) with four equivalents of LiOMe and subsequent treatment with $FeCl_2{\cdot}4H_2O$ and CO afforded Li_2[Fe(pyCO_2S$_4$)] (Li_2[**9**]). This compound tenaciously retained varying amounts of LiCl, H_2O, and MeOH. Its identity, however, was confirmed by IR and NMR spectroscopy and by its reaction with aqueous HCl which afforded the neutral complex [Fe(CO)(pyCO_2HS$_4$)] (**10**). Complex **10** could be reversibly deprotonated with NMe_4OH to give $(NMe_4)_2$[Fe(CO)(pyCO_2S$_4$)] {$(NMe_4)_2$[**9**]} and treatment of **10** with $NOBF_4$ afforded the corresponding nitrosyl complex [Fe(NO)(pyCO_2HS$_4$)](BF_4) (**11**) (ν(NO): 1900 cm^{-1} in KBr). Complex **11** could not be isolated in an analytically pure form but its identity was established from a combination of NMR and IR spectroscopy. Surprisingly, the PMe_3 complex [Fe(PMe_3)(pyCO_2HS$_4$)] (**12**) formed directly from neutral pyCO_2HS$_4$−H_2 and $FeCl_2{\cdot}4H_2O$ in the presence of an excess of PMe_3. The excess PMe_3 presumably acts as base giving PMe_3H^+ cations which result in the appropriate proton concentration needed for formation of neutral **12**. Deprotonation of **12** with NMe_4OH gave the salt $(NMe_4)_2$[Fe(PMe_3)(pyCO_2S$_4$)] {$(NMe_4)_2$[**13**]}.

X-ray Structural Determinations

X-ray structural determinations were indispensable for confirming the regioselectivity of the alkylation reactions (vide supra). Figure 4 shows the molecular structures of pyCO_2MeS$_4$−H_2·HCl (**1**·HCl), [Fe(CO)(pyCO_2MeS$_4$)] (**5**), [Fe(pyCO_2MeS$_4$)]$_2{\cdot}H_2O{\cdot}$THF (**6**·H_2O·THF) and [Fe(PMe_3)(pyCO_2HS$_4$)]·0.25MeOH (**12**·0.25MeOH). Table 1 lists selected distances and angles.

The ligand **1**·HCl exhibits C_2 symmetry in the solid state. The carboxylic acid methyl ester substituents are located in positions *ortho* to the thiol functions. The Cl^- counterion

forms a hydrogen bond to the protonated pyridine N atom.

The metal centers of all the complexes are six-coordinate and exhibit pseudo octahedral geometries. The thiolate and thioether donors always adopt *trans* positions to each other with the pyridine N donors in apical positions such that square pyramidal [MNS$_4$] cores result. This indicates that the rigid bis-methylene-pyridine bridge connecting the 1,2-benzene-dithiol fragments exerts a stereochemical directing influence. The sixth positions of the pseudo-octahedral metal centers are occupied either by the co-ligand L (CO, PMe$_3$) or a thiolate donor of another [MNS$_4$] core. Dinuclear [Fe(pyCO_2MeS$_4$)]$_2$ possesses a crystallographically imposed inversion center and contains both enantiomers of the chiral [Fe(pyCO_2MeS$_4$)] fragment. **5** crystallizes in the chiral space group $P2_1$ and contains only one enantiomer.

Distances and angles show no anomalies and lie in the range observed for the parent complex [Fe(CO)(pyS$_4$)].[2] The Fe−N(pyridine) distances range from 197. 8(3) to 201.2(6) pm in **6** and **7** respectively. Fe−S(thioether) distances (≈221 pm) are always shorter than Fe−S(thiolate) distances (≈228 pm) within the [FeNS$_4$] cores. The Fe−S distances to the bridging thiolate donors in dinuclear **6** are distinctly longer (≈234 pm) indicating the tendency of **6** to dissociate into mononuclear [Fe(pyCO_2MeS$_4$)] fragments.

The structure of [Fe(PMe$_3$)(pyCO_2HS$_4$)] (**12**) deserves special interest because the crystal lattice contains chains of [Fe(PMe$_3$)(pyCO_2HS$_4$)] molecules which are connected by intermolecular O−H···O hydrogen bonds. Each [Fe(PMe$_3$)-(pyCO_2HS$_4$)] molecule exhibits an additional intramolecular O−H···S(thiolate) hydrogen bond. Figure 5 shows part

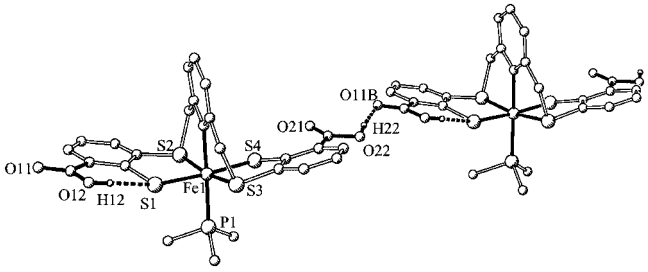

Figure 5. Intra- and intermolecular hydrogen bonds of [Fe(PMe$_3$)-(pyCO_2HS$_4$)] (**12**)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the crystal lattice consisting of chains that each contain only homochiral molecules.

The presence of intermolecular hydrogen bonds can be inferred from the distances *d*(O22−H22) = 82 pm, *d*(H22···O11B) = 193 pm, *d*(O22···O11b) = 274.1(4) pm and the angle [O22−H22···O11B] = 170.8°. The intramolecular O−H···S hydrogen bonds are indicated by the distances *d*(O12−H12) = 82 pm, *d*(H12···S1) = 211 pm, *d*(O12···S1) = 289.0(3) pm and the angle [O12−H12···S1] = 159.4°. In particular, the *d*(H12···S1) distance is considerably shorter than the sum of van der Waals radii of sulfur and hydrogen (r_H = 100 pm, r_S = 180 pm)[7] and suggests a strong S···H interaction. Such a strong S···H interaction is also indicated by an IR band in **12** at 2612 cm^{-1} (in KBr). This band can be assigned to a ν(OH) vibration strongly lowered in energy by hydrogen-bonding or alternatively to a ν(SH) vibration indicating protonation of the thiolate donor. The two types of hydrogen bonds in which the carboxylic acid groups are involved make these groups vibrationally inequivalent such that two different $\nu(CO)_{COOH}$ bands can be observed in the IR (KBr) spectrum of **12** at 1701 and 1668 cm^{-1}.

Inter- and intramolecular hydrogen bonds like those observed in **12** are of interest because they can serve as models for the transport of protons in metal sulfur enzyme proteins. Protons from an external source first bind to carboxylic acid/carboxylate side chains of the protein, migrate from there to Brønsted-basic sulfur sites and, if needed in an [H^+/e^-] coupled enzyme reaction, to a substrate molecule coordinated to a metal center.

General Properties and Spectroscopic Characterization of Complexes

A major goal of this work was to achieve water solubility of specific complexes by the rational design of ligands. This objective was successfully accomplished with lithium and ammonium salts of the anions $[Fe(CO)(py\mathit{CO_2}S_4)]^{2-}$ (**9**) and $[Fe(PMe_3)(py\mathit{CO_2}S_4)]^{2-}$ (**13**). The salts Li_2[**9**], $(NMe_4)_2$[**9**], and $(NMe_4)_2$[**13**] are soluble in H_2O and water-like solvents such as MeOH. All the other complexes are sparingly soluble or insoluble in H_2O or MeOH. The low solubility of neutral $[Fe(CO)(py\mathit{CO_2H}S_4)]$ (**5**) or $[Fe(PMe_3)(py\mathit{CO_2H}S_4)]$ (**12**) in H_2O corresponds to the insolubility in water of higher aliphatic or aromatic carboxylic acids.

All complexes were characterized by elemental analysis and common spectroscopic methods. The IR (KBr) spectra of the CO complexes exhibit characteristic ν(CO) bands in the region 1970−1949 cm^{-1} and those of the 18 VE nitrosyl complexes $[Fe(NO)(py\mathit{CO_2R}S_4)](BF_4)$ [R = Me (**7**), R = H (**11**)] display ν(NO) bands at 1881 and 1900 cm^{-1}. The ν(NO) band of the neutral 19 valence electron species appears at 1617 cm^{-1}, indicating that the unpaired electron occupies an antibonding orbital. As shown by DFT calculations for the related parent complex $[Fe(NO)(pyS_4)]$, this molecular orbital is antibonding with respect to all Fe−ligand interactions and has a large contribution from a π* type NO orbital.[8]

^{1}H NMR spectroscopy proved to be particularly suitable for quickly checking the purity and symmetry of the ligands and complexes. The ^{1}H and ^{13}C NMR spectra show typical signals for pyS_4 cores corroborating the two-fold symmetry for all compounds. Like $[Fe(PR_3)(pyS_4)]$ (R = PMe_3, $PnPr_3$), the PMe_3 complexes **4**, **12**, and $(NMe_4)_2$[**13**] show sharp ^{1}H NMR signals only in the presence of an excess of PMe_3. This has been previously explained by suggesting the occurrence of a reversible dissociation of the phosphane ligands in solution.[3]

Electronic Influence of Benzene Ring Substituents

CO_2R (R = alkyl, H) substituents are generally considered to withdraw electron density from benzene rings by inductive or mesomeric effects. It was therefore of interest to examine whether such an electron-withdrawing effect of the CO_2R substituents would reach beyond the thioether and thiolate donors and be detectable at the metal centers of the homologous complexes. This question was probed by examining the ν(CO) frequencies of the iron complexes listed in Table 2.

Table 2. ν(CO) Frequencies of iron carbonyl complexes with $[Fe(pyS_4)]$ cores [cm^{-1}]

Complex	In KBr	In solution
$[Fe(CO)(pyS_4)]$	1963	1974 (THF)[9]
$[Fe(CO)(pyS_4)]\cdot MeOH$	1955[2]	–
$[Fe(CO)(py\mathit{CO_2Me}S_4)]$	1952	1974 (THF)
$[Fe(CO)(py\mathit{CO_2H}S_4)]$	1962	1963 (DMF)
$Li_2[Fe(CO)(py\mathit{CO_2}S_4)]\cdot H_2O\cdot 3MeOH\cdot LiCl$	1969	1973 (MeOH)
$(NMe_4)_2[Fe(CO)(py\mathit{CO_2}S_4)]\cdot 2H_2O$	1949	1973 (MeOH)
$[Fe(CO)(py^{\mathit{bu}}S_4)]$	1969	1969 (THF)[9]

Table 2 demonstrates that all CO complexes show very similar or almost identical ν(CO) frequencies in solution indicating that different benzene ring substituents have practically no influence upon the electron density at the iron centers. In the solid state (KBr), the ν(CO) frequencies, although lying in the same range, show larger differences. As evidenced by both $[Fe(CO)(pyS_4)]$[9] and $[Fe(CO)(pyS_4)]\cdot MeOH$,[2] however, the presence of a lattice MeOH molecule can cause a wavenumber shift of 8 cm^{-1}. Conversely, $[Fe(CO)(py\mathit{CO_2H}S_4)]$ and $[Fe(CO)(py^{\mathit{bu}}S_4)]$[9] show practically identical ν(CO) frequencies in KBr, although two electron-withdrawing CO_2H substituents have been replaced by four electron donating tertiary butyl substituents. In conclusion, the results indicate that the benzene ring substituents have no significant influence upon the electron density at the metal center but, rather, the ν(CO) shifts observed are due to solvation or crystal packing effects. This conclusion is supported by cyclic voltammetry (CV) studies. The isoelectronic iron carbonyl complexes $[Fe(CO)(pyS_4)]$,[9] $[Fe(CO)(py\mathit{CO_2Me}S_4)]$, and $[Fe(CO)(py\mathit{CO_2H}S_4)]$ each show a reversible redox wave in the anodic region.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 3 lists the redox potentials of the three complexes in either CH_2Cl_2 or DMF.

Table 3. Redox potentials of carbonyl complexes with [Fe(pyS_4)] cores [mV]

Complex	CH_2Cl_2	DMF
[Fe(CO)(pyS_4)]	460	468
[Fe(CO)(pyCO_2MeS_4)]	514	539
[Fe(CO)(pyCO_2HS_4)]	–	490

The potentials (Table 3) indicate that CO_2R substituents render complexes with [Fe(pyS_4)] cores more difficult to oxidize. Conversely, when changing from CO_2Me to CO_2H, the trend in redox potentials is reversed. In addition the overall shifts of the redox potentials in the range of 22−71 mV (in DMF) are small. Taking into account also the fact that redox potentials in solution are sensitive towards the nature of the solvent and solvation effects (cf. the values in CH_2Cl_2 and DMF), it can safely be assumed that the ν(CO) frequencies listed in Table 2 indeed confirm that CO_2R substituents do not have a significant influence upon the electron density at the metal centers or [Fe(L)(NS_4)] cores.

Concluding Discussion

Two new pentadentate ligands containing NS_4 donor atom sets and terminal thiolate donors have been synthesized and coordinated to Fe^{II} and Ni^{II} centers affording a series of new iron and nickel complexes. The general problem of achieving a regioselective and specific mono-alkylation of the nearly equivalent thiol functions in the 1,2-benzenedithiol derivative $CO_2MeS_2-H_2$ could be solved by carrying out the alkylation at low temperature in the presence of limited amounts of a base (1 NMe_4OH:1 $CO_2MeS_2-H_2$) affording the target ligand py$CO_2MeS_4-H_2$ (**1**). Saponification of py$CO_2MeS_4-H_2$ (**1**) gave the acid derivative py$CO_2HS_4-H_2$ (**2**) that enabled synthesis of [Fe(L)(pyCO_2HS_4)] complexes (L = CO, PMe_3). These complexes become water-soluble upon deprotonation of the CO_2H substituents and form salts of the type (cation)$_2$[Fe(L)(pyCO_2S_4)] which had been the primary goal of this work.

Spectroscopic, electrochemical and X-ray structural results indicate that introducing CO_2Me or CO_2H substituents into the benzene rings of [Fe(L)(pyS_4)] complexes does not change the electron density at the Fe centers significantly. This is important for further investigations since achieving water solubility of the [Fe(L)(pyS_4)] complexes was the major goal but without changing the coordination properties of the iron centers that bind a considerable number of small molecules relevant to nitrogenase.

The X-ray structure of [Fe(PMe_3)(pyCO_2HS_4)] (**12**) further revealed that such complexes can form inter- and intramolecular O−H···O and O−H···S(thiolate) bonds. These hydrogen bonds may serve as models for the transport of protons from external sources to the metal centers of enzymes when small molecules binding to these centers are reduced by coupled [H^+/e^-] transfer steps.

Experimental Section

General Methods: Unless noted otherwise, all procedures were carried out under nitrogen using standard Schlenk techniques at room temperature with stirring. Solvents were dried and distilled before use. As far as possible, reactions were monitored by IR or NMR spectroscopy. Spectra were recorded on the following instruments: IR (KBr discs or CaF_2 cuvettes, solvent bands were compensated): Perkin−Elmer 16PC FTIR. NMR: Jeol-JNM-GX 270, JNM-EX 270 and JNM-LA 400 with the residual signals of the deuterated solvent used as an internal reference. Spectra were recorded at 25 °C. Mass spectra: JEOL MSTATION 700 spectrometer. Elemental analysis: Carlo Erba EA 1106 or 1108 analyzer. Magnetic susceptibility: Johnson Matthey susceptibility balance. Cyclic voltammetry was performed with a Radiometer Copenhagen IMT 102 electrochemical interface using a three-electrode cell with a glassy carbon (Radiometer Copenhagen EDI) working electrode and Pt reference and counter electrodes. Solutions were 10^{-3} M; $NBu_4[PF_6]$ (10^{-1} M) was used as the supporting electrolyte. Potentials were referenced to the normal hydrogen electrode (NHE) using Fc/Fc^+ as an internal standard (E_{Fc/Fc^+} = 0.4 V vs. NHE).[11] "S_2"-H_2 (1,2-benzene-dithiol),[12] $CO_2MeS_2-H_2$ (2,3-dimercapto benzoic acid methyl ester),[13] and 2,6-bis[(tosyloxy)methyl]pyridine[14] were prepared as described in the literature.

py$CO_2MeS_4-H_2$ (1): A yellow solution of $CO_2MeS_2-H_2$ (17.38 mmol, 3.48 g) and NMe_4OH (17.38 mmol, 7.36 mL of a 25% solution in MeOH) in THF (100 mL) was combined with a solution of 2,6-bis[(tosyloxy)methyl]pyridine (3.89 g, 8.69 mmol) in THF (130 mL) at −78 °C. After 2 h at −78 °C and 15 h at room temperature the resultant white precipitate was separated by filtration and washed with THF (35 mL). The combined filtrates were evaporated and the remaining residue was dissolved in CH_2Cl_2 (100 mL). Concentrated hydrochloric acid (20 mL) was added and the resultant mixture was stirred vigorously for 5 min. The CH_2Cl_2 phase was separated from the aqueous phase, washed with water (5 × 25 mL) until a pH of 7 was attained, dried over Na_2SO_4 and the solvents evaporated. The resultant almost colorless solid foam was suspended in MeOH (75 mL), and LiOMe (17.33 mmol, 17.33 mL of a 1 M solution in MeOH) was added. The resultant solution was filtered and combined with a solution of $Ni(OAc)_2{\cdot}4H_2O$ (2.16 g, 8.68 mmol) in MeOH (40 mL). The yellow-brown precipitate thus obtained was separated by filtration after 1 h, washed with MeOH (30 mL), dried in vacuo and suspended in CH_2Cl_2 (120 mL). Concentrated hydrochloric acid (30 mL) was added and the mixture was stirred vigorously for 20 min. The CH_2Cl_2 phase was separated from the acidic green aqueous phase, dried over Na_2SO_4 and the solvents evaporated. The resultant yellow solid foam was recrystallized from CH_2Cl_2/*n*-hexane to give green-yellow crystals. Yield: 2.33 g py$CO_2MeS_4-H_2{\cdot}$HCl (**1**·HCl) (61%).^{1}H NMR ($CDCl_3$, 269.60 MHz): δ = 18.2 (br., 2 H, N*H*), 7.97 (vdd, 2 H, C_6H_3), 7.80 (vt, 1 H, H_γ, pyridine), 7.59 (vdd, 2 H, C_6H_3), 7.17 (vd, 2 H, H_β, pyridine), 7.06 (vt, 2 H, C_6H_3), 6.58 (s, 2 H, S*H*), 4.65 (s, 4 H, CH_2), 3.87 (s, 6 H, CO_2CH_3) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 67.83 MHz): δ = 167.3 (CO_2CH_3), 154.2, 143.6, 139.4, 132.4, 132.3, 131.7, 127.2, 124.3 [*C*(aryl)], 52.6 (CO_2CH_3), 36.3 (CH_2) ppm. IR (KBr): $\tilde{\nu}$ = 2486 (br. m, N−H + S−H), 1714 cm^{-1} (s, C=O). MS (FD^+, CH_2Cl_2): *m*/*z* = 504 [py$CO_2MeS_4-H_3]^+$.

IR (KBr): $\tilde{\nu}$ = 1718 (s, C=O), 948 (m, P−C−H) cm^{-1}. $C_{26}H_{28}FeNO_4PS_4$ (633.60): calcd. C 49.29, H 4.45, N 2.21, S 20.24; found C 49.10, H 4.67, N 2.21, S 19.99.

[Fe(CO)(pyCO_2MeS$_4$)] (5)

(a) from 6: A suspension of **6**·H_2O·THF (0.070 g, 0.06 mmol) in THF (20 mL) was saturated with CO gas for 3 h and kept under a CO atmosphere for a further 24 h. The resultant red solution was filtered and reduced to one third of its volume. After addition of MeOH (5 mL) the red precipitate which formed was separated by filtration, washed with MeOH (5 mL) and dried in vacuo. Yield: 0.060 g [Fe(CO)(pyCO_2MeS$_4$)] (**5**) (82%).

(b) from 1: A solution of $FeCl_2$·4H_2O (0.083 g, 0.42 mmol) in MeOH (15 mL) was added to a solution of **1**·HCl (0.225 g, 0.42 mmol) and LiOMe (1.25 mmol, 1.25 mL of a 1 M solution in MeOH) in THF (15 mL) under an atmosphere of CO. The mixture was kept under CO gas for a further 2 h. The resultant red precipitate was separated by filtration, washed with MeOH (10 mL) and Et_2O (10 mL) and dried in vacuo. Recrystallization from CH_2Cl_2/Et_2O afforded fine red needles. Yield: 0.174 g [Fe(CO)(pyCO_2MeS$_4$)] (**5**) (71%).^{1}H NMR ($CDCl_3$, 269.60 MHz): δ = 7.67 (m, 4 H, C_6H_3), 7.32 (vt, 1 H, H_γ, pyridine), 7.11 (vd, 2 H, H_β, pyridine), 6.91 (vt, 2 H, C_6H_3), 5.12 (d, 2 H, CH*H*), 4.48 (d, 2 H, C*H*H), 3.84 (s, 6 H, CO_2CH_3) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 67.70 MHz): δ = 214.7 (*C*O), 167.5 (*C*O$_2$CH$_3$), 160.2, 157.3, 136.7, 135.6, 135.3, 132.2, 132.1, 121.6, 121.2 [C(aryl)], 56.6 (*C*H$_2$), 51.9 (CO$_2$*C*H$_3$) ppm. IR (KBr): $\tilde{\nu}$ = 1967 (sh, CO), 1952 (s, CO), 1718 (s, C=O) cm^{-1}. IR (THF): $\tilde{\nu}$ = 1974 (s, CO) cm^{-1}. MS (FD$^+$, CH_2Cl_2): *m*/*z* = 585 [Fe(CO)(pyCO_2MeS$_4$)]$^+$, 557 [Fe(pyCO_2MeS$_4$)]$^+$. C_{24} $H_{19}FeNO_5S_4$ (585.52): calcd. C 49.23, H 3.27, N 2.39, S 21.91; found C 49.46, H 3.21, N 2.37, S 21.66.

[Fe(pyCO_2MeS$_4$)]$_2$ (6): A solution of $FeCl_2$·4H_2O (0.320 g, 1.61 mmol) in MeOH (55 mL) was added dropwise to a solution of **1**·HCl (0.950 g, 1.76 mmol), LiOMe (5.28 mmol, 5.28 mL of a 1 M solution in MeOH) and a small amount of NaBH4 in THF (50 mL) over the course of 3 h. The violet microcrystalline solid which formed was separated by filtration after 45 min, washed with THF (40 mL), MeOH (25 mL) and again with THF (15 mL) and dried in vacuo. Yield: 0.925 g [Fe(pyCO_2MeS$_4$)]$_2$·H_2O·THF (**6**·H_2O·THF) (87%). IR (KBr): $\tilde{\nu}$ = 1711 (s, CO) cm^{-1}. MS (FD$^+$, DMF): *m*/*z* = 557 [Fe(pyCO_2MeS$_4$)]$^+$. Magnetic susceptibility (296 K): μ_{eff} = 0 μ_B. $C_{50}H_{48}Fe_2N_2O_{10}S_8$ (1205.16): calcd. C 49.83, H 4.01, N 2.32, S 21.29; found C 49.59, H 3.85, N 2.34, S 21.37.

[Fe(NO)(pyCO_2MeS$_4$)]BF$_4$ (7)

(a) from 6: $NOBF_4$ (0.023 g, 0.20 mmol) and **6**·H_2O·THF (0.119 g, 0.10 mmol) were suspended in CH_2Cl_2 (15 mL) for 2.5 h. The resultant brown precipitate was separated using a centrifuge, washed with CH_2Cl_2 (5 mL), and recrystallized from acetone. Yield: 0.070 g [Fe(NO)(pyCO_2MeS$_4$)]BF$_4$·0.5 acetone (**7**·0.5 acetone) (50%). $C_{24.5}H_{22}BF_4FeN_2O_{5.5}S_4$ (703.37): calcd. C 41.84, H 3.15, N 3.98, S 18.23; found C 41.95, H 2.93, N 3.96, S 18.18.

(b) from 5: Solid $NOBF_4$ (0.020 g, 0.17 mmol) was added to a solution of **5** (0.100 g, 0.17 mmol) in CH_2Cl_2 (40 mL). The resultant brown precipitate was separated by filtration after 18 h, washed with CH_2Cl_2 (15 mL) and dried in vacuo. Yield: 0.110 g [Fe(NO)(pyCO_2MeS$_4$)]BF$_4$·0.25CH_2Cl_2 (**7**) (93%). ^{1}H NMR (CD_3CN, 269.73 MHz): δ = 7.97 (m, 4 H, C_6H_3), 7.72 (vt, 1 H, H_γ, pyridine), 7.42 (vd, 2 H, H_β, pyridine), 7.39 (vt, 2 H, C_6H_3), 5.49 (d, 2 H, CH*H*), 4.95 (d, 2 H, C*H*H), 3.84 (s, 6 H, CO_2CH_3) ppm. ^{13}C{^{1}H} NMR (CD_3CN,, 67.83 MHz): δ = 166.8 (*C*O-OCH$_3$), 159.0, 154.1, 140.6, 137.1, 134.9, 133.7, 132.0, 127.2, 125.6 [C(aryl)], 56.2 (*C*H$_2$), 53.0 (CO$_2$*C*H$_3$) ppm. IR (KBr): $\tilde{\nu}$ = 1881 (s, NO), 1712 (s, C=O) cm^{-1}. MS (FD$^+$, CH_3CN): *m*/*z* = 557 [Fe(pyCO_2MeS$_4$)]$^+$. $C_{23.25}H_{19.5}BCl_{0.5}F_4FeN_2O_5S_4$ (695.56): calcd. C 40.15, H 2.82, N 4.03, S 18.44; found C 40.45, H 2.77, N 3.83, S 18.44.

[Fe(NO)(pyCO_2MeS$_4$)] (8): Hydrazine (0.02 mL, 0.66 mmol) was added to a brown solution of **7**·0.25CH_2Cl_2 (0.050 g, 0.07 mmol) in MeOH (15 mL). A red-brown precipitate formed which was separated using a centrifuge after 15 h, washed with MeOH (10 mL) and dried in vacuo. Yield: 0.025 g [Fe(NO)(pyCO_2MeS$_4$)] (**8**) (61%). IR (KBr): $\tilde{\nu}$ = 1720 (s, C=O), 1617 (s, NO) cm^{-1}. MS (FD$^+$, DMF): *m*/*z* = 557 [Fe(pyCO_2MeS$_4$)]$^+$. $C_{23}H_{19}FeN_2O_5S_4$ (587.53): calcd. X-ray Structural Determinations of pyCO_2MeS_4−H_2·HCl (1·HCl), [Fe(CO)(pyCO_2MeS_4)] (5), [Fe(pyCO_2MeS_4)]$_2$·H_2O·THF (6·H_2O·THF) and [Fe(PMe_3)(pyCO_2HS_4)]·0.25 MeOH (12·0.25MeOH): Green-yellow single crystals of **1**·HCl were grown by layering a solution of the ligand (0.560 g, 1.04 mmol) in CH_2Cl_2 (40 mL) with *n*-hexane (70 mL) over one week. Red plates of **6**·H_2O·THF were obtained by layering a solution of $FeCl_2{\cdot}4H_2O$ (0.021 g, 0.11 mmol) in H_2O (20 mL) successively with a solution of **1**·HCl (0.058 g, 0.11 mmol) in THF (20 mL), a layer of THF (8 mL), a layer of MeOH (20 mL) and 0.32 mL of a 1 M solution of LiOMe in MeOH. Orange prisms of **5** formed within one week from a saturated CH_2Cl_2 solution which had been layered with the same amount of MeOH. Red blocks of **12**·0.25MeOH were obtained by layering a solution of **1a**·HCl (0.080 g, 0.17) in THF (5 mL) with a solution of $FeCl_2{\cdot}4H_2O$ (0.033 g, 0.17 mmol) and PMe_3 (0.1 mL, 0.1 mmol) in MeOH (3 mL).

Suitable single crystals were embedded either in protective perfluoro polyalkyl ether oil or sealed in a glass capillary under N_2. Intensity data were collected using graphite monochromated Mo-K_α radiation (λ = 71.073 pm) on a Nonius−KappaCCD diffractometer (**6**, **5**) or a Siemens P4 diffractometer (**1**·HCl, **12**·0.25MeOH). Intensity data have been corrected for absorption

effects using either Psi-scans (**1**·HCl, **12**·0.25MeOH), multiple scans of equivalent reflections (SADABS,[15] **6**·H_2O·THF) or a numerical Gaussian integration (**5**). The structures were solved by direct methods, and full-matrix least-squares refinements were carried out on F^2 (SHELXTL NT 5.10[16] for **5**, **12** or SHELXTL NT 6.12[17] for **1**, **6**). All non hydrogen atoms were refined anisotropically. Ligand **1** crystallizes as an HCl adduct and the complexes **6** and **12** crystallize with solvent molecules (**6**·H_2O·THF, **12**·0.25MeOH). The MeOH solvate molecule in **12**·0.25MeOH is disordered on a crystallographic inversion center, as is the THF molecule in **6**·H_2O·THF, with two alternative sites for the O atom of the THF molecule. No hydrogen atoms have been taken into account for the structural model of the disordered MeOH of **12**·0.25MeOH and the solvent water of **6**·H_2O·THF. The PMe_3 group in **12** is disordered with two different sites having occupancies of 62(1)% and 38(1)%, respectively. The hydrogen atoms in **1**·HCl, **6**·H_2O·THF and **12**·0.25MeOH were geometrically positioned with isotropic displacement parameters fixed at 1.2 or 1.5 times the U(eq) of the corresponding carbon atom. The positions of the hydrogen atoms in **5** were taken from a difference Fourier synthesis. Their positional parameters were refined with a fixed common isotropic displacement parameter. Table 4 summarizes selected crystallographic data.[19]

Unusual Cu^{II} and Mn^{II} Complexes of Phenol-Based Ligands Containing Amine, Pyridine and Formyl Functions: Unexpected Structural Features and Solution Studies

Iryna A. Koval,[a] Mieke Huisman,[a] Arno F. Stassen,[a] Patrick Gamez,[a] Martin Lutz,[b] Anthony L. Spek,[b] and Jan Reedijk*[a]

Keywords: Copper / Manganese / Magnetic properties / EPR spectroscopy / Cyclic voltammetry

The phenol-based ligand Hpy2ald containing formyl, amine and pyridine functions reacts with copper(II) nitrate, copper(II) bromide and manganese(II) chloride to yield complexes with unexpected structures. In contrast to previously reported coordination compounds with similar ligands, the carbonyl group of the ligand in all complexes does not coordinate to the metal ions. The metal-to-ligand ratio is 2:1 in the case of the copper(II) nitrate complex and 1:1 in the case of the copper(II) bromide and manganese(II) chloride complexes. The copper(II) nitrate complex exhibits both donor-atom and coordination number asymmetry, as one copper ion is pentacoordinate with an N_3O_2 donor set, and the other one is hexacoordinate with an O_6 donor set. In the latter two complexes, the phenol group of the ligand remains protonated and fails to bridge the two metal ions; instead it is semi-coordinated to only one metal ion. This results in the formation of mononuclear complexes in which copper(II) or manganese(II) ions have a distorted square-pyramidal surrounding. All complexes were structurally, spectroscopically and magnetically investigated.

Introduction

Dinucleating phenol-based ligands, which are able to bind two metal ions simultaneously, have attracted significant attention from scientists in the past few years.[1−5] Interest in this topic is due partly to the presence of a dinuclear metal core in many proteins and enzymes. A large number of complexes with phenol-based ligands have been synthesized to mimic dimetallic biosites.[6−8] In addition, interest in this type of complex is also driven by their attractive catalytic[9,10] and magnetic[11−13] properties.

The recognition of the asymmetric nature of many dinuclear biosites has led to the synthesis of a variety of dinucleating ligands bearing adjacent, but dissimilar, donor sets. These ligands have been collectively termed "compartmental". Some time ago, Adams et al. reported an unexpected nickel-induced hydrolysis of unsymmetrical Schiff base compartmental ligands,[2,14] which resulted in the transformation of the imino group of the ligands into a formyl moiety. As this hydrolysis only occurred when nickel(II) salts with non- or weakly coordinating anions were used, it was suggested that the presence of such anions, as well as nickel ions, is crucial.[14]

All the dinuclear complexes obtained with these in situ generated ligands were found to have very similar crystal structures, comprising a dimetallic core with two bridging phenolato groups from two ligands. In all cases the metal-to-ligand ratio was found to be 2:2. The coordination environment around each metal ion was completed by three nitrogen donor atoms from an amino arm of the ligand and an oxygen atom of the formyl group, formed by hydrolysis, to give a distorted octahedron.

In the present study, three novel complexes of the phenol-based compartmental ligand Hpy2ald (Figure 1), containing formyl, amino and pyridine functions, with copper(II) nitrate and bromide, and manganese(II) chloride are reported. The ligand Hpy2ald was prepared as an intermedi-

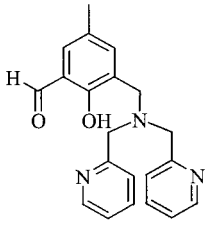

Figure 1. The phenol-based ligand Hpy2ald, containing the tridentate arm in the 2-position and the carbonyl group in the 6-position of the aromatic ring

ate in the synthesis of asymmetric dinucleating ligands.[15] In contrast to the coordination compounds reported by Adams et al.,[2,14] the present complexes do not possess dinuclear cores comprised of two metal ions and two ligands. In all complexes, the carbonyl group of the ligand does not coordinate to the metal ions, which partly originates from the presence of a stronger nitrate, bromide or chloride donor anion. The metal-to-ligand ratio was found to be 2:1 for the nitrate complex and 1:1 for the bromide and chloride complexes. The crystal structures, spectroscopic and magnetic properties of all three complexes are reported.

Results and Discussion

General

The phenol-based ligand Hpy2ald contains a tridentate arm in the 6′-position, and a carbonyl group in the 2′-position of the phenol ring. Quite similar ligands and their Ni^{II} coordination compounds were previously described by Adams et al.[2] In the overwhelming majority of cases, the ligands reported by Adams were formed in situ by the hydrolysis of an imino arm of the initially dinucleating phenol-based ligands.[2] The structures of the previously described complexes with this type of ligand include dinuclear metal cores, where two metals are doubly bridged by two phenolato groups. In all cases, the C=O group of the ligand is coordinated to the metal ion.[2]

In the present study, three new copper(II) and manganese(II) complexes with the ligand Hpy2ald are reported, each possessing quite different structures. The reaction of Hpy2ald with copper(II) nitrate yields the asymmetric dinuclear complex $[Cu_2(py2ald)(\mu\text{-}NO_3)(NO_3)_2]\cdot CH_3CN$ (Figure 2), in which the two metal ions are doubly bridged by a deprotonated cresolate anion and a didentate nitrate anion. The metal-to-ligand ratio in this complex is 2:1, and the octahedral coordination environment of one of the copper ions is completed by chelating nitrate anions. The aldehyde group of the ligand remains non-coordinated.

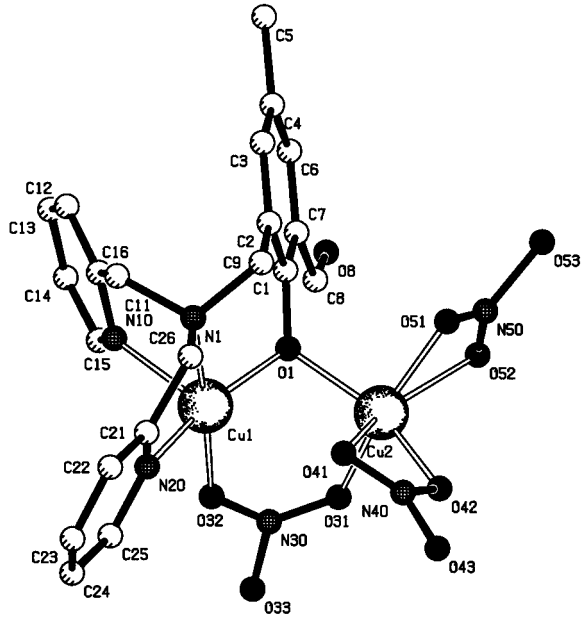

Figure 2. Platon[33] projection of the crystal structure of $[Cu_2(py2ald)(\mu\text{-}NO_3)(NO_3)_2]\cdot CH_3CN$; hydrogen atoms are omitted for clarity

The reaction of Hpy2ald with $CuBr_2$ yields a mononuclear complex with the formal composition $[Cu(Hpy2ald)Br_2]\cdot 0.5H_2O$. In the crystal, the copper complexes form dimers by hydrogen bonding with the lattice water molecules as hydrogen bond donors and the coordinated bromides as acceptors (Figure 3). The metal to ligand ratio within a mononuclear fragment is 1:1. In this complex, the phenol group of the ligand remains protonated, failing to bridge two metal ions and instead being only semi-coordinated to one metal. As in the case of the nitrate complex, the aldehyde group is not coordinated, but instead is hydrogen-bonded to the protonated phenol. The octahedral coordination environment around the metal ion is completed by nitrogen donor atoms of the tridentate arm from the ligand and two bromide anions.

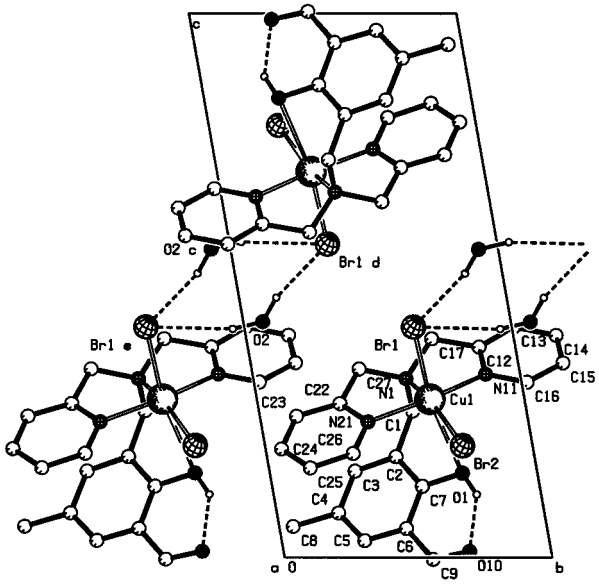

Figure 3. Platon[33] projection of the crystal structure of $[Cu(Hpy2ald)Br_2]\cdot 0.5H_2O$; the occupancy factor of each water molecule is 0.50; only the hydrogen atoms participating in hydrogen bonding are shown

Finally, the reaction of Hpy2ald with manganese(II) chloride yields the complex $[Mn(Hpy2ald)Cl]_2$. The molecular structure of this complex is very similar to the structure of the copper(II) bromide complex with intramolecular hydrogen bonding, but in the crystal lattice no intermolecular hydrogen bonding is present.

These unusual structural features of the three complexes open the possibility to speculate that the structure of complexes with carbonyl-containing phenol-based ligands is largely determined by the donor properties of the anion. Due to the presence of a very weak donor carbonyl group in the ligand, the counterions present in the solution may compete with the oxygen atom of the carbonyl group for a place in the coordination sphere of the metal ion. Thus, a dinuclear

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

core comprised of two metal ions and two ligands, in which the carbonyl group is coordinated to the metal ions, can only be formed if non-coordinating, or very weakly coordinating, anions are present in the solution. This hypothesis is supported by the fact that reaction of Hpy2ald with perchlorate or tetrafluoroborate metal salts yields complexes with structures[16] very similar to those described by Adams.[2] At the same time, stronger donors, such as nitrate and halogen anions, prevent a weaker donor — the carbonyl group — from coordinating to the metal ion. In addition, in all cases, changing the initial ratio of the reactants did not influence the structure of the formed complexes.

Crystal Structure Descriptions

[Cu_2(py2ald)(μ-NO_3-O,O′)(NO_3-O,O′)$_2$]·CH_3CN (1)

A molecular plot of [Cu_2(py2ald)(μ-NO_3)(NO_3)$_2$]·CH_3CN is shown in Figure 2. Selected bond lengths and angles are given in Table 1. The dinuclear core consists of two copper ions [Cu···Cu distance 3.0652(6) Å], bridged on one side by an endogenous (μ-phenoxo) bridge and on the other side by an exogenous didentate nitrate anion. The complex shows both coordination-number and donor-atom asymmetry. Cu1 is five-coordinate with an almost ideal square-pyramidal geometry (the parameter τ, which is used to describe the percentage of trigonal distortion from a square-pyramidal geometry, is 0.07 for the Cu1 ion; τ is zero for an ideal square pyramid and one for an ideal trigonal bipyramid),[17] and an N_3O_2 donor set. The basal plane contains two *cis*-located oxygen atoms, O1 from the deprotonated cresolate and O32 from the bridging nitrate anion, and two *cis*-located nitrogen atoms, N1 of the tertiary amine group and N20 of the pyridine ring. The nitrogen atom N10 from the other pyridine ring occupies the apical position. The interior angles of the basal plane vary between 82.07(9)° and 93.06(8)°. The distance Cu1···O41 is 3.031(3) Å and is thus too long to consider the O41 atom as the sixth ligand for the Cu1 ion.

The Cu2 ion is six-coordinate with a very distorted octahedral geometry and an O_6 donor set. Only one of the oxygen atoms belongs to the ligand: the other five are from three different nitrate anions. Two oxygen atoms (O41 and O52) from the two didentate chelating nitrate ions occupy the axial positions, with long Cu−O bonds of 2.585(3) Å and 2.479(3) Å, respectively. The O41−Cu2−O52 angle is only 149.42(9)°, indicating a very large distortion from the regular octahedral geometry, apparently imposed by the small bite angle of the nitrate anions. The oxygen atoms (O42 and O51) of two didentate chelating nitrate anions, the oxygen atom (O1) of the deprotonated cresolate and the oxygen atom (O31) of the didentate bridging nitrate anion lie in the equatorial plane, with Cu−O distances of 1.945(2)−1.978(2) Å. The interior angles of the equatorial plane are somewhat larger than 90°, viz. 90.26(10)−95.55(10)°. One non-coordinated molecule of acetonitrile is present in the crystal lattice.

[Cu(Hpy2ald)Br_2]·0.5H_2O (2)

A molecular plot of the complex is shown in Figure 3. Selected bond lengths and angles are presented in Table 2. As can be evidenced from the picture, the unit cell contains two mononuclear formula units and one water molecule, which appears to be disordered over two positions with an occupancy factor of 0.50. These uncoordinated water molecules act as hydrogen bond donors with coordinated bromide anions as acceptors (see Table 3), thus resulting in the formation of centrosymmetric dimers with the formal composition [Cu(Hpy2ald)Br_2]$_2$·H_2O.

The coordination environment around the copper(II) ion can best be described as either a very distorted octahedron with a Br_2N_3O donor set, or a square pyramid with a Br_2N_3 donor set and a loosely bound phenol group. The phenol group of the cresol ring remains protonated, which prevents it from forming a bridge between the two copper ions. This, in turn, results in the formation of a mononuclear complex. The oxygen atom (O1) from the phenol group can thus be best regarded as being only semi-coordinated to the Cu1 ion, with a very long Cu−O distance of 2.932(2) Å. It lies in one of the apical positions of an imaginary octahedron, with the second apical position being occupied by one of the bromide anions at a Cu1−Br1 distance of 2.7278(4) Å. The O1−Cu1−Br1 angle is 170.75(4)°. The equatorial plane is formed by the second bromide anion (Br2), the nitrogen atom (N1) from the tertiary amine group, and two nitrogen atoms (N11 and N21) from the pyridine rings. The pyridine rings are located on either side of the ligand plane, and are thus *trans* to each other. The interior angles N1−Cu1−N11 and N1−Cu1−N21 are smaller than 90° [81.03(8)° and 81.05(8)°, respectively], due to the constraints imposed by the three-bond ligand-bite.

Besides the intermolecular hydrogen bonding, an intramolecular hydrogen bond is realized between the cresolic proton and the oxygen atom from the formyl group (the O1···O10 distance is 2.645 Å, see also Table 4).

[Mn(Hpy2ald)Cl_2] (3)

A molecular plot of the complex is shown in Figure 4. Selected bond lengths and angles are presented in Table 3. The structure of the complex is very similar to that of complex **2**. However, in this case no intermolecular hydrogen bonding is present between the formula units. The coordination environment around the Mn1 ion can best be described as a very distorted octahedron. The chloride anion (Cl2) and the oxygen atom (O31) from the cresol group occupy the axial positions. Although the Mn1−O31 distance of 2.793(2) Å is shorter than the respective distance in complex **2** [2.932(2) Å], the oxygen atom can still be best regarded as being only semi-coordinated to the manganese ion. Similarly to the copper(II) bromide complex, the OH group of the cresolic moiety remains protonated. The Cl2−Mn1−O31 angle is 175.64(5)°. The basal plane of the octahedron is formed by two nitrogen atoms (N11 and N21) from two pyridine rings, the nitrogen atom (N1) from the tertiary amine group and the chloride anion (Cl1). The

Mn−N distances vary in the range 2.217(2)−2.360(2) Å, and the Mn1−Cl1 distance is 2.3737(9) Å. An intramolecular hydrogen bond is realized between the hydrogen atom of the cresolic group and the oxygen atom from the formyl group, with an O31···O40 distance of 2.660 Å (Table 4).

Physical Characterization

Mass Spectroscopy

The mass spectra (ESI-MS) of $[Cu(Hpy2ald)Br_2]\cdot H_2O$ and $[Mn(Hpy2ald)Cl_2]$, both recorded in methanol, are characterized by one major peak corresponding to the moiety $[M(Hpy2ald)X]^+$ (m/z = 491 for $[Cu(Hpy2ald)Br]^+$ and m/z = 437 for $[Mn(Hpy2ald)Cl]^+$). These results are as expected and indicate that the solid-state structures of both complexes are retained in solution. However, if the mass spectrum of $[Mn(Hpy2ald)Cl_2]$ is recorded again after one week in solution, two new peaks appear in the spectrum, at the expense of the original ones, at m/z = 362 and m/z = 451. The first of them was tentatively assigned to the product of an oxidation of the formyl group of the ligand to the respective carboxylate group. The theoretically calculated isotope pattern for the formula $C_{21}H_{20}N_3O_3$ (corresponding to the ligand with the carboxylic group instead of a formyl moiety) is in a good agreement with the experimentally observed one. Assuming the first assumption is correct, the peak at m/z = 451 should correspond to the complex of composition $[MnL'Cl]^+$, where L′ is the oxidized ligand. Interestingly, the oxidation of the ligand was only observed for the manganese complex, but not for the copper complexes.

The mass spectra of $[Cu_2(py2ald)(\mu\text{-}NO_3)(NO_3)_2]$ were recorded for comparison in two different solvents (acetonitrile and methanol). The spectrum of the complex in acetonitrile solution shows two major peaks. The most intense one, at m/z = 596, corresponds to the fragment $[Cu_2(py2ald)(NO_3)_2]^+$, in agreement with the solid-state structure of the complex. However, the second peak in the spectrum, whose intensity is only slightly lower (relative abundance 95%) at m/z = 472, corresponds to the mononuclear fragment $[Cu(Hpy2ald)NO_3]^+$. The discrimination between mononuclear and dinuclear fragments is unambiguous from the difference in observed isotopic patterns, caused by the presence of one or two copper ions. The structure of the latter complex can be expected to look similar to the structure of the copper bromide complex, with the phenol group of the ligand being still protonated. When the spectrum of the complex is recorded in methanol solution, the peak corresponding to the mononuclear fragment $[Cu(Hpy2ald)(NO_3)(CH_3OH)_2]^+$ becomes the most intense, while the intensity of the peak corresponding to the dinuclear moiety diminishes significantly (relative abundance 60%). The results of mass spectroscopy prompted us to suggest that, in solution, the dinuclear complex with the deprotonated ligand exists in equilibrium with the mononuclear complex with the protonated ligand, and this equilibrium is shifted towards the mononuclear complex in a methanol solution.

Ligand-Field Spectroscopy

Ligand-field spectra of all complexes were recorded in the solid state, as well as in solution (methanol for complexes **2** and **3** and acetonitrile and methanol for complex **1**). The ligand-field spectrum of complex **1** in the solid state (diffuse reflectance) is characterized by two major peaks. The first one, at 418 nm, corresponds to the LMCT transition of the phenolate group to the copper ions.[6] The second peak, at 640 nm, is in a normal range for d-d transitions of Cu^{II} ions.[18] In the diffuse reflectance spectrum of complex **2**, a fairly broad peak corresponding to a d-d transition is observed at 750 nm, with a shoulder around 940 nm. As shown previously, such spectroscopic behavior (high-energy absorption band in the visible region with a low-energy shoulder) is typical for square-pyramidal copper(II) complexes.[19] Thus the coordination sphere around the metal center can indeed be best described as square pyramidal. Another intense band is observed at 378 nm. Taking into account that the OH group of the ligand is only semi-coordinated to the copper ion, and thus the LMCT band from the OH group to the metal ions is unlikely to be visible, we were forced to assign this band to the charge transfer from the bromide anions to the copper ions. Similarly, in the diffuse reflectance spectrum of complex **3** a band is observed at 356 nm, which was assigned to the charge-transfer band from the chloride anions to the manganese ions. The d-d transition band in octahedrally surrounded Mn^{II} is known to be very weak, and must be hidden by the tail of the LMCT band, which is not uncommon.[18]

When the spectrum of complex **1** in acetonitrile solution is recorded, the position of the d-d transition band shifts only slightly to 672 nm. However, when the spectrum is recorded in methanol, this band shifts significantly (from 640 nm to 719 nm) towards higher wavelengths (“red shift”). These results suggest the change of the coordination sphere around the copper(II) ions in solution, presumably towards a square-pyramidal geometry.[20] This observation appears to be in agreement with the results of mass-spectroscopic measurements, which suggest the presence of significant amounts of mononuclear copper(II) species in methanol solution. The position of the d-d band in the spectrum of complex **1** in methanol solution is quite close to the position of the d-d band in complex **2**, which can be regarded as additional evidence for the presence of a mononuclear species similar in structure to complex **2**.

When the spectrum of complex **2** is taken in methanol solution, the position of the d-d band shifts somewhat towards the UV region (ca. 700 nm). Possible reasons for this shift are the solvation of the copper ions or partial exchange of the bromide anions with methanol molecules. The spectrum of $[Mn(Hpy2ald)Cl_2]$ remains unchanged if recorded in methanol. However, after a prolonged time in solution a shift of the LMCT band (ca. 100 nm) towards

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the IR region is observed, suggesting the oxidation of the ligand, as evidenced by mass-spectroscopic measurements.

EPR Spectroscopy

The EPR spectrum of complex **1**, recorded in the solid state at room temperature, exhibits one fairly broad isotropic signal with $g = 2.15$. No hyperfine splitting is resolved and no triplet signal is detected. The resolution does not improve upon cooling to liquid nitrogen temperature. A very similar spectrum is observed when the measurement is performed on a frozen acetonitrile solution. These data suggest an interaction between two copper(II) centers at relatively close positions, leading to exchange narrowing. However, when the spectrum is recorded in a methanol glass, it becomes much more complicated (Figure 5a). The spectrum obviously indicates the presence of two different species in solution, and can be best regarded as an overlapping superposition of two rhombic spectra. For both species, a ^{63,65}Cu hyperfine splitting can be observed in the g_z region, although some lines are partially hidden either due to the overlapping of two spectra with each other, or in $g_{x,y}$ region. The resulting spectrum was satisfactory simulated[21] (Figure 5b) considering two non-interacting Cu^{II}-containing species in an approximate 1:1 ratio. For the species X, the simulating parameters are $g_x \approx g_y = 2.10$, $g_z = 2.44$, $A_x = 1.1$ mT (11×10^{-4} cm^{-1}), $A_y = 0$, $A_z = 10.9$ mT (124×10^{-4} cm^{-1}), and for the species Y, $g_x \approx g_y = 2.14$, $g_z = 2.26$, $A_x = 0$, $A_y = 0.43$ mT (4×10^{-4} cm^{-1}), and $A_z = 17.2$ mT (182×10^{-4} cm^{-1}). Although the exact interpretation proved to be difficult, these parameters suggest a $d_{x^2-y^2}$ ground state for both species X and species Y. The simulation parameters for species X are characteristic for elongated rhombic octahedral CuO_6 chromophores,[20] and are very close to the values typical for Cu^{II} ions in a methanol glass. The origin of this species could be Cu^{II} ions coordinated by the nitrate anions and/or, at least partially, by methanol molecules. The simulation parameters for the species Y are close to those for square-planar CuN_2O_2 chromophores. Thus, these results are in good agreement with the presence in solution of a mononuclear species $[Cu(Hpy2ald)NO_3]^+$, as suggested by mass spectrometry and ligand-field spectroscopy. However, it should be noticed that neither EPR nor ligand-field measurements provide any direct evidence confirming the presence of dinuclear species in solution as well. Thus, although the presence of dinuclear species was evidenced during the mass-spectroscopic measurements, it cannot be directly deduced from other spectroscopic techniques. Therefore we cannot exclude another possibility — the complete dissociation of the dinuclear complex into mononuclear units of composition $[Cu(Hpy2ald)NO_3]^+$ in methanol solution.

The EPR spectrum of complex **2** in the solid state has a rhombic character, with $g_x = 2.05$, $g_y = 2.10$ and $g_z = 2.25$, suggesting a $d_{x^2-y^2}$ ground state. When the spectrum is recorded in a methanol glass, hyperfine splitting becomes obvious. Three of four lines are easily observed (Figure 6a), whereas the fourth is partially hidden in the $g_{x,y}$ region. The spectrum was simulated[21] (Figure 6b) using the parameters $g_x = 2.04$, $g_y = 2.06$, $g_z = 2.24$, $A_x \approx A_y \approx 0$ and $A_z = 18.4$ mT (192×10^{-4} cm^{-1}). These data suggest a distorted square-pyramidal environment for the Cu^{II} ions,[22] in agreement with the crystal structure of the complex.

One can also notice an additional peak at high field (approximately 330 mT), with a g-value below 2, in the spectrum of the complex. The appearance of this signal may indicate the presence of a small amount of dinuclear copper(II) species in solution. Although the solid-state structure of the complex is essentially mononuclear, the partial formation of dinuclear species in solution due to the presence of potentially bridging bromide anions can be imagined. In this case, this absorption should originate from a $\Delta M_s = \pm 1$ transition of the triplet spectrum.[6] No signal corresponding to a $\Delta M_s = \pm 2$ transition could be detected. As the structure of these presumably dinuclear species is unknown, the presence of this high-field signal was neglected during the simulation of the spectrum.

Table 5. Calculated equivalent conductances (ohm^{-1} cm^2 mol^{-1}) of the complexes, measured for 1 mM solutions in acetonitrile (**1**) and in methanol (**1**, **2** and **3**)

	$[Cu_2(py2ald)(NO_3)_3]\cdot CH_3CN$	$[Cu(Hpy2ald)Br_2]\cdot 0.5H_2O$	$[Mn(Hpy2ald)Cl_2]$
Acetonitrile	117	–	–
Methanol	160	73	78

The X-band EPR spectrum of the manganese complex **3** in the solid state shows a very broad pattern in the range 0−800 mT. The resolution does not improve upon cooling to 77 K. Such behavior of manganese complexes is not unusual and is caused by zero-field splitting effects.[23] No hyperfine splitting can be observed in the solid-state spectrum, due to dipole-dipole interactions between closely located manganese(II) ions. The spectrum recorded in a frozen methanol solution is much better resolved and shows the usual ^{55}Mn six-line pattern (A = 9.3 mT).

Conductivity Measurements

The specific conductivity of 1 mM solutions of the complexes was measured in acetonitrile and methanol for complex **1**, and in methanol for complexes **2** and **3**. The calculated values of equivalent conductances of all three complexes are presented in Table 5. As can be seen, the value of the equivalent conductance for complex **1** in acetonitrile (117 ohm^{-1} cm^2 mol^{-1}) suggests that the complex exists as a 1:1 electrolyte in acetonitrile solution.[24] However, in methanol solution the equivalent conductivity value of 160 ohm^{-1} cm^2 mol^{-1} falls in the range observed for 2:1 electrolytes.[24] These results seem to support the hypothesis about the complete dissociation of the dinuclear complex **1** into mononuclear units in methanol solution, as one would expect the resulting $[Cu(Hpy2ald)(NO_3)_2]$ complex to behave as a 1:2 electrolyte, due to relatively weak bonds between the copper ions and the nitrate groups. The values of the equivalent conductivities obtained for complexes **2** and **3** are very close (Table 5) and suggest that both complexes are 1:1 electrolytes.[24]

Cyclic Voltammetry

The cyclic voltammogram of complex **1**, recorded in an acetonitrile solution while scanning towards the negative region of potentials, is characterized by one quasi-reversible wave ($E_{1/2}$ = -0.31 V, ΔE = 0.19 V, v = 0.1 V), which was tentatively assigned to the $Cu^{II,II}/Cu^{II,I}$ redox couple, and one completely irreversible wave at E_{pc} = −0.60 V. On the reverse scan, a sharp stripping peak, caused by the redissolution of the copper metal deposited on the electrode, is present. It can therefore be concluded that the second metal-centered reduction is accompanied by the destruction of the complex. This is not surprising, as the coordination of three nitrate anions to the Cu^{I} ion is unlikely to be possible in this case. In the positive range of potentials, a reversible oxidation wave ($E_{1/2}$ = 0.81 V) is observed, corresponding to the one-electron oxidation of the ligand.[6] The cyclic voltammogram recorded in a methanol solution in the negative range of potentials is characterized as well by two successive partially overlapping electrochemical waves. However, they are shifted significantly towards the positive range of potentials and are completely irreversible (E_{pc} = −0.19 V and E_{pc} = −0.28 V). Similarly to the previous case, the reduction of the copper(II) ions to the copper(I) state is accompanied by the decomposition of the complex and the deposition of the metal on the electrode surface. The positive potential range does not change significantly when recording the voltammogram in a methanol solution.

The cyclic voltammogram of complex **2**, recorded in a methanol solution while scanning towards the negative range of potentials, is characterized by one fully reversible one-electron electrochemical wave, corresponding to the Cu^{II}/Cu^{I} complexed couple ($E_{1/2}$ = −0.12 V, ΔE = 0.18 V, v = 0.1 V/s). In the positive range of potentials, one irreversible electrochemical wave at E_{pa} = 1.17 V is observed, assigned to the ligand oxidation.

The cyclic voltammogram of complex **3** is characterized by only one irreversible oxidation wave at E_{pa} = 1.20 V. By comparing the results with the cyclic voltammogram of complex **2**, this electrochemical wave was assigned to the ligand oxidation. No metal-centered electrochemical waves can be observed up to +1.5 V vs. Ag/AgCl electrode, suggesting a very significant stability of the Mn^{II} oxidation state in the complex.

Magnetic Susceptibility

Magnetic susceptibility measurements have been performed on powdered crystals of **1** (m = 29.11 mg), **2** (m = 50.20 mg) and **3** (19. 04 mg) at 0.1 Tesla. Values for χ in the copper(II) complexes have been calculated for dinuclear species.

At 300 K, the χT value for complex **2** is 0.84 $cm^3\cdot K\cdot mol^{-1}$. This value remains almost constant, as the compound shows Curie−Weiss behavior over the entire temperature region. The Curie constant C_2 is 0.42 $cm^3\cdot K\cdot mol^{-1}$, indicating a g value of 2.12. The Curie temperature θ_2 is 0 K, as expected. Thus no magnetic coupling is present between two mononuclear fragments coupled by the disordered water molecule.

For complex **3**, χT is 4.40 $cm^3\cdot K\cdot mol^{-1}$ at 300 K, corresponding to a magnetic moment of 5.93 μ_B. This value is in perfect agreement with the theoretically expected value for a high-spin Mn^{II} ion (S = 5/2). It remains unchanged over the entire temperature range, indicating the paramagnetic behavior of the complex, as could be predicted from the structure of the complex. The Curie temperature θ is 0 K, as expected.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

A plot of χ^{-1} and χT vs. temperature for complex **1** between 5 and 150 K (with χ being the magnetization per dinuclear complex) is shown in Figure 7. From the increase of the magnetic susceptibility at low temperature (from $\chi_1 T$ = 0.89 $cm^3 \cdot K \cdot mol^{-1}$ at 150 K to $\chi_1 T$ = 1.05 $cm^3 \cdot K \cdot mol^{-1}$ at 5 K) ferromagnetic behavior is evidenced. By linear regression, the Curie constant has been determined to be 0.45 $cm^3 \cdot K \cdot mol^{-1}$, which results in a g value of 2.18. This value is in very good agreement with that determined from EPR measurements in the solid state (g = 2.15).

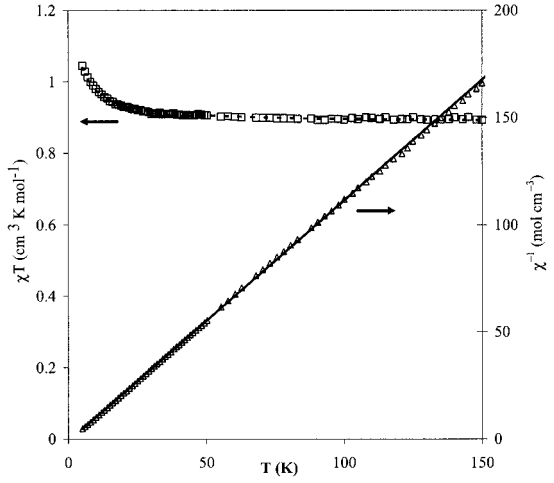

Figure 7. $\chi_1 T$ vs. T (Δ) and χ_1^{-1} vs. T curves ($\square$) of **1**; the solid line represents the linear fitting according to the Curie−Weiss law and the dashed line represents the calculated lines for the parameters J = 3.2 cm^{-1}, g = 2.17 and $R = 1.24 \times 10^{-5}$

A ferromagnetic interaction is usually observed when the magnetic orbitals of two metal ions have a negligible overlap, whereas an antiferromagnetic exchange is found when the magnetic orbitals are pointing towards each other in such a way that the overlap integral is reasonably large.[25,26] In complex **1**, two unpaired electrons of the Cu1 and Cu2 ions are both occupying $d_{x^2-y^2}$ orbitals. In a symmetrical complex, a bridging phenoxo group with an angle of 101.75(9)° between the copper centers would normally result in an antiferromagnetic interaction. However, due to the asymmetry of the penta- and hexacoordinate copper(II) ions, induced by the ligand Hpy2ald and the nitrate anions, an overlapping of two $d_{x^2-y^2}$ orbitals can be expected to be insignificant. In this case, a weak ferromagnetic exchange can be expected.

The magnetic behavior has been simulated using the Bleaney−Bowers equation[27,28] [see Equation (1)], in which $-J$ is the magnetic exchange parameter and all constants have their usual value.[27]

$$\chi = \frac{2Ng^2\beta^2}{kT[3 + \exp(-J/kT)]} \quad (1)$$

The best simulation is obtained with the values J = 3.2 cm^{-1} and g = 2.17. The reliability factor, defined as $R = n^{-1}[\Sigma(\chi_{obs} - \chi_{cal})^2/(\chi_{cal})^2]$ (n = number of data points) is 1.24×10^{-5}.

Conclusion

In the present study, three new complexes of copper(II) nitrate, copper(II) bromide and manganese(II) chloride with a phenol-based ligand containing a formyl group in the *ortho* position of the phenol ring have been prepared and structurally characterized. The structures of all compounds are very different from previously reported ones with similar ligands. In all cases, the carbonyl group of the ligand does not coordinate to the metal ions. The reaction of copper(II) nitrate with the ligand yields a dinuclear complex $[Cu_2(py2ald)(\mu\text{-}NO_3)(NO_3)_2]$, which possesses both donor-atom asymmetry and coordination-number asymmetry, whereas both copper(II) bromide and manganese(II) chloride form mononuclear complexes of formula [M(Hpy2-ald)X_2] (X = Cl or Br). The behavior of the complexes in the solid state and in solution was characterized by means of ligand field and EPR spectroscopy, mass spectrometry, conductivity measurements, cyclic voltammetry and magnetic susceptibility studies. Whereas the coordination environments of the metal ions for the mononuclear complexes appear to be mostly retained upon dissolution, we were able to observe the dissociation of the dinuclear nitrate complex in methanol. Although the results of mass-spectroscopic measurements suggest the existence of mononuclear, as well as dinuclear, species at equilibrium, other spectroscopic techniques, as well as conductivity measurements, do not offer direct evidence for the presence of an initial dinuclear complex in methanol solution. Therefore, the complete dissociation of the initial dinuclear complex into mononuclear units of composition $[Cu(Hpy2ald)(NO_3)_2]$, whose structure is expected to be similar to the copper(II) bromide and manganese(II) chloride complexes, can also be suggested. The magnetic susceptibility measurements indicate a ferromagnetic behavior for the nitrate complex and paramagnetic behavior for both the copper chloride and manganese bromide complexes.

Experimental Section

Materials and Methods: All starting materials are commercially available and were used as purchased. The ligand Hpy2ald was synthesized as described previously.[15] The infrared spectra of the complexes in the 4000−300 cm^{-1} range were recorded on a Bruker 330V IR spectrophotometer equipped with a Golden Gate Diamond. The ligand-field spectra of the solids (300−2000 cm^{-1}, diffuse reflectance) and in solution were taken on a Perkin−Elmer 330 spectrophotometer equipped with a data station. Electrospray mass spectra (ESI-MS) in acetonitrile or methanol solution were recorded on a Thermo Finnigan AQA apparatus. X-band electron paramagnetic resonance (EPR) measurements were performed at room temperature and at 77 K in the solid state, or at 77 K as frozen methanol solutions on a Jeol RE2x electron spin resonance spectrometer, using DPPH (g = 2.0036) as a standard. The conductivity measurements were performed using a Philips PW9526 digital

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

conductivity meter and PW 9552/60 measuring cell with 1 mM solutions of the complexes in acetonitrile and/or methanol. Cyclic voltammetry measurements were performed with an Autolab PGSTAT 10 cyclic voltammeter, using a Pt working electrode and a Ag/AgCl reference electrode in acetonitrile or methanol (10^{-3} M), with tetrabutylammonium perchlorate as supporting electrolyte, at a scan rate of 0.1 mV/s. Bulk magnetizations of polycrystalline samples were measured in the range 5−300 K with a Quantum Design MPMS-5S SQUID magnetometer, in a 1 kG applied field. The data were corrected for the experimentally determined contribution of the sample holder. Corrections for the diamagnetic responses of the complexes, as estimated from Pascal's constants, were applied.[29]

The solution studies were performed with either acetonitrile or methanol as solvent in the case of complex **1**, and methanol for complexes **2** and **3**, due to the fact that neither of the two latter complexes is soluble in acetonitrile.

$[Cu_2(py2ald)(\mu\text{-}NO_3)(NO_3)_2]\cdot CH_3CN$ (1): 20 mL of an acetonitrile solution of the ligand (56 mg, 0.16 mmol) were added to an equal volume of a copper(II) nitrate solution (77 mg, 32 mmol) in acetonitrile. Slow evaporation of the solvent led to the appearance of green rectangular crystals, which were of sufficient quality for X-ray structure determination. The crystals were found to deteriorate rapidly when taken out of the mother liquor, due to the loss of an acetonitrile molecule. $C_{21}H_{20}Cu_2N_6O_{11}$ (659.5): calcd. C 38.2, H 3.1, N 12.7; found C 37.9, H 3.4, N 12.8. IR: 3047 cm^{-1} (C−H stretching), 1610 (C=O stretching), 1550 (C=C arom., C=N arom.), 1436 (chelating didentate NO_3^-, N=O stretching), 1283 [bridging didentate NO_3^-, $\nu_a(NO_2)$], 998 [bridging didentate NO_3^-, $\nu_s(NO_2)$].

$[Cu(Hpy2ald)Br_2]\cdot 0.5H_2O$ (2): 20 mL of a methanol solution of the ligand (56 mg, 0.16 mmol) were added to an equal volume of a copper(II) bromide solution (72 mg, 0.32 mmol). Green rectangular crystals appeared when the solvent was almost completely evaporated. Their quality was found to be suitable for X-ray diffraction analysis. $C_{42}H_{44}Br_4Cu_2N_6O_5$:calcd. C 43.5, H 3.8, N 7.3; found C 43.9, H 3.8, N 7.5. IR: ca. 3600 cm^{-1}, broad band (H_2O, asymmetric and symmetric OH stretching), 2980 (C−H stretching), 1654 (C=O stretching), 1608 (C=C arom., C=N arom.).

$[Mn(Hpy2ald)Cl_2]$ (3): 20 mL of a methanol solution containing manganese(II) chloride dihydrate (129 mg, 0.8 mmol) were added to an equal volume of a methanol solution of the ligand (56 mg, 0.16 mmol). Slow evaporation of the resulting bright-yellow solution gave colorless crystals of the product. These crystals were found to be of sufficient quality for X-ray crystal structure determination. $C_{21}H_{21}Cl_2MnN_3O_2$: calcd. C 53.3, H 4.5, N 8.9; found C 52.9, H 4.9, N 8.9. IR: 2968 cm^{-1} (C−H stretching), 1655 (C=O stretching), 1604 (C=C arom., C=N arom.)

X-ray Crystallographic Study: X-ray intensities were collected on a Nonius−KappaCCD diffractometer with rotating anode (λ = 0.71073 Å, graphite monochromator) at a temperature of 150(2)K up to a resolution of $(\sin\theta/\lambda)_{max}$ = 0.65 $Å^{-1}$. The structures were solved by direct methods (SHELXS-97,[30] compound **1**) or automated Patterson methods (DIRDIF99,[31] compounds **2** and **3**) and refined with SHELXL-97[32] against F^2 of all reflections. Non-hydrogen atoms were refined freely with anisotropic displacement parameters. The phenolic hydrogen atoms of compounds **2** and **3** were located in the difference Fourier map and refined freely with isotropic displacement parameters. The water hydrogen atoms of compound **2** were located in the difference Fourier map and kept fixed in these positions. All other hydrogen atoms were refined as rigid groups. Illustrations, structure calculations, and structure checking were performed with the PLATON software package.[33] Further crystallographic details are given in Table 6.
CCDC-216684 (**1**), -216685 (**2**), and -216686 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Group 13 Complexes of 5-Methyl-1,3,5-dithiazinane[‡]

Juan Carlos Gálvez-Ruiz,[a] Carlos Guadarrama-Pérez,[a] Heinrich Nöth,[b] and Angelina Flores-Parra*[a]

Keywords: Aluminum / Halides / Indium / Conformational analysis

The synthesis of mono-N adducts of 5-methyl-1,3,5-dithiazinane (**1**) with $Al(CH_3)_3$, $Al(CH_3)_2Cl$, $AlCl_3$, $AlBr_3$ (**5**–**8**), a bis-N adduct with $InCl_3$ (**9**), and the corresponding dithiazinanium salts with the anions $AlBr_4^-$, $AlCl_4^-$, $GaCl_4^-$ and BCl_4^- (**10**–**14**) are reported. Compounds **5**–**7** adopt a preferred conformation in solution at room temperature and **8** at –10 °C. $\Delta G^{\neq}$ values for the ring inversion were calculated for **5**–**8**. Compounds **6**–**14** were studied by single-crystal X-ray diffraction. The solution and solid-state analyses showed that the rings are present in all cases in a chair conformation. In compounds **5**–**8** the tetrahedral aluminum atom is found in an equatorial position. In the indium compound **9** the metal atom has a tbp geometry. For dithiazinanium rings **10**–**14** dipolar intra- and intermolecular interactions between halogen atoms and C–H and N–H are reported. Two different conformations for the N–CH_3 were found in compound **14**.

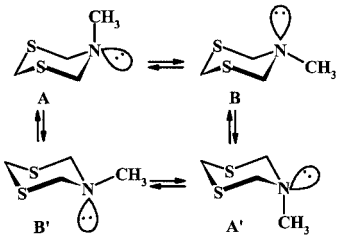
Introduction

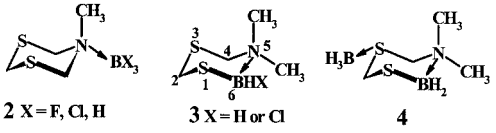
We are currently investigating the coordinating and conformational behavior of 5-methyl-1,3,5-dithiazinane (**1**).[1,2] This compound is in conformational equilibrium with the methyl group in an unexpected axial position and has five lone pairs available for coordination (Scheme 1). The geminal position of the heteroelements makes the CH protons relatively acidic,[2b] meaning that they could coordinate molecules bearing lone pairs through hydrogen bonding.



Scheme 1. A and A′ are the preferred conformers in the conformational equilibrium of 5-methyldithiazinane **1**; the processes from A to B and A′ to B′ involve nitrogen inversion and from A to B′ and A′ to B ring inversion

Dithiazinane rings are fragile in the presence of metals and moisture and, as a consequence, their coordination chemistry is practically unknown except for the results from our group.[1,2,3a]

Boron Lewis acids have been used as a probe for the basic sites of compound **1**, giving the N→BX_3 adducts **2**.[2] An excess of borane (BH_3 or $BHCl_2$) produces 6-borata-5-aza-1,3-dithiocyclohexanes **3**[1b,2d,2f] (Scheme 2). Nitrogen is always the preferred coordination site, and the S→B coordinative bond in **4** has been only observed when the borata heterocycle bearing a BH_2 group is treated with an excess of BH_3·THF; its weak S→BH_3 bond is readily broken upon removal of the solvent.[1c][2f]



Scheme 2

An important discovery has been the fact that the conformational equilibrium of **1** is abruptly stopped by N-coordination to BH_3 or boron halides. This unexpected result was explained by significant proton-hydride and proton-halide intramolecular stabilizing interactions.[2a,3]

These findings stimulated us to continue the exploration of the coordinating properties of compound **1** with other group 13 compounds. Here, the synthesis of N adducts of dithiazinane **1** with $Al(CH_3)_3$, $Al(CH_3)_2Cl$, $AlCl_3$, $AlBr_3$

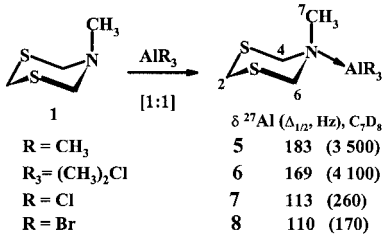
and $InCl_3$ is reported, as well as variable-temperature NMR experiments in order to obtain the $\Delta G^{\neq}$ of the ring inversion and to understand the coordination effect in the conformational equilibrium. The study of the molecules **5**−**8** in solution is complemented by X-ray diffraction analysis of **6**−**9**. The corresponding dithiazinanium salts **10**−**14** bearing the anions $AlBr_4^-$, $AlCl_4^-$ $GaCl_4^-$ and BCl_4^- and Cl^-, respectively, are formed in the presence of traces of moisture. Their X-ray diffraction data disclosed interesting intermolecular interactions in the solid state.

Results and Discussion

5-Methyl-1,3,5-dithiazinane Complexes

The reaction of compound **1** with equimolar amounts of $Al(CH_3)_3$, $Al(CH_3)_2Cl$, $AlCl_3$ or $AlBr_3$ in toluene (or $CHCl_3$) at 4 °C gave exclusively the N→Al mono adducts **5**−**8**, as established by NMR spectroscopy, especially by ^{27}Al NMR studies, which showed the characteristic resonances (δ = 110−183 ppm) for tetracoordinate aluminum atoms at room temperature (reported range between 100 and 200 ppm)[4] (Scheme 3). In the ^{13}C NMR spectra, the coordination effect is readily noted at room or at low temperature for C-2, C-4 and C-6, which are shifted to lower frequencies by up to 3 ppm, while N−CH_3 presents only a modest effect (Δδ = 1 ppm), indicating that it remains in an axial position. At room temperature, the ^1H NMR spectra of compounds **5**−**7** (at −10 °C for **8**) in C_7D_8 present separated and coupled signals for all the ring protons, showing that the rings are present in a fixed conformation due to the N-coordination. By comparison with the ^1H NMR spectra of N-boron adducts of dithiazinane,[1b,1c,2e] it was also deduced that the aluminum is placed in an equatorial position (Table 1). Opening of the dithiazinane ring in the presence of an excess of $AlMe_3$ proceeds by the breaking of two C−S bonds and the formation of an $MeEt_2N$-$AlMe_3$ adduct (^{27}Al δ = 139 ppm, $\Delta_{1/2}$ = 866 Hz). The ^{13}C NMR spectrum for this adduct shows signals for N−Et at δ = 49.66 and 9.27 ppm and for N−Me at δ = 40.79 ppm.



Scheme 3. Preferred conformation of compounds **5**−**8** and their ^{27}Al NMR data (in C_7D_8)

Variable temperature ^1H NMR experiments in C_7D_8 were performed in order to estimate the energies for ring inversion. The solutions were heated up to 75 °C without either a breaking of the Al−N bond or an opening of the ring, contrary to the situation observed for borane adducts.[1b,1c,2d] The ring-inversion energy is related to the size of the substituents at the nitrogen atom. A group with a big steric effect will be in an equatorial position, with a high ring-inversion energy.[5] On the other hand, a second effect — that the ring inversion energy is augmented by hydride-proton and halide-proton stabilizing interactions[2a,3a] — could be added to the anchorage of the ring conformation, as we have established for other boron adducts. The $\Delta G^{\neq}$ values for the ring inversion of compounds **5**−**8** are summarized in Table 1. All the aluminum groups

Table 1. ^1H NMR (400 MHz) data [δ (^nJ)] of anchored compounds **5**−**8** and their $\Delta G^{\neq}$ values (kJ/mol)

	Solvent	H-2eq	H-2ax	H-4eq and H-6eq	H-4ax and H-6ax	H-7	$\Delta G^{\neq}$

[a] Same value was found in $CDCl_3$/$CFCl_3$.[7] δ (ppm) of $AlCH_3$: for **5**, −0.69 (s) in [D_8]toluene and −0.89 (s) in $CDCl_3$; for **6**, −0.47(s) in [D_8]toluene and −0.63(s) in $CDCl_3$.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

fix the dithiazinane conformation as is seen from their $\Delta G^{\neq}$ values when compared with data of the free dithiazinane ($\Delta G^{\neq}$ = 46.0 kJ/mol in [D_8]THF and in $CDCl_3/CFCl_3$ [6]). In compounds **5**−**8** the size of the coordinating group determines the inversion of the ring, as in the case of $AlMe_3$ and $AlClMe_2$ adducts. A second effect stabilizing the inversion could be the interactions between the halogen atoms and the acidic C−H protons. Therefore, it is expected that $AlClMe_2$, $AlCl_3$ and $AlBr_3$ need a higher energy for the ring inversion due to possible cooperative, weak H···X interactions. Analyses of the results shows that the highest ring-inversion energy was found for the $AlCl_3$ adduct **7**. The lowest energy corresponds to the $AlBr_3$ adduct **8** but there is no clear explanation for this behavior, because the low energy is observed despite the fact that $AlBr_3$ is a big group and the Al−N bond length in **8** (1.982 Å) is the shortest in the series (**5**−**8**) indicating a strong bond {the same trend was found in the dissociation energy of pyridine·$AlCl_3$ (77.3 kJ/mol) and pyridine·$AlBr_3$ (73.6 kJ/mol)[7]}. Therefore, we have carefully analyzed the halide-proton contacts in the solid state in order to find the reason for the conformational behavior of this adduct. An explanation could be that bromine atoms present a weaker interaction than chlorine with the hydrogen atoms as a consequence of their lower electronegativity and their larger size.[8]

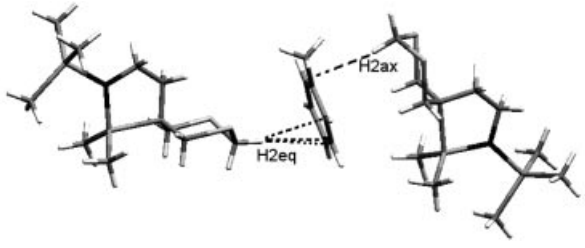

Figure 1. View of *O*-dimethylaluminum-*O*-trimethylaluminum-2(1,3,5)-dithiazinan-5-yl-ethanolate showing a polymeric array produced by π-interactions of toluene with SCH_2S protons (distances are: $H2_{eq}$−C_{ortho} 2.79 Å, $H2_{eq}$−C_{meta} 2.74 Å and $H2_{eq}$−C_{para} 2.80 Å, and $H2_{ax}$−C_{ipso} 2.75 Å)[9]

An interesting fact concerning the ^{1}H NMR chemical shifts of the C-2 protons in compounds **4**−**8** in toluene is that they are well shielded. This can be explained by an arrangement of the toluene aromatic ring density in front of the C-2 protons, as was observed in the solid state in the X-ray molecular structure of another derivative of dithiazinane[9] (Figure 1).

We were unable to obtain single crystals of compound **5,** in contrast to compounds **6** (obtained from $C_6H_5CH_3$ at −20 °C), **7** (from CH_2Cl_2 at 25 °C) and **8** (from $C_6H_5CH_3$ at 25 °C). In all cases the aluminum atoms are tetracoordinate and are found in equatorial positions. The angles at the nitrogen atoms deviate little from the ideal tetrahedral angles. The N−Al bond [**6**: 2.044(2) Å; **7**: 1.993(5) Å; **8**: 1.982(5) Å] is, in all cases, slightly shorter than the ideal covalent bond length (2.05 Å)[10] indicating a strong coordinative bond. The dithiazinane ring has a chair conformation. In all compounds one of the hydrogen atoms of the N-methyl group is pointing towards the space in the middle of the sulfur atoms where the sulfur orbitals (50% p character)[11] are also pointing. The C−H···S distances range from 2.76 to 2.85 Å. This is significantly shorter than the sum of the van der Waals radii (3.0 Å). The bond lengths and angles are given in Tables 2 and 3 and the crystallographic data and selected data collection in Table 4.

In compound **6** the chlorine atom is arranged in a staggered position between the methyl and a methylene group of the ligand (Figure 2a). Two short, weak contacts were found between Cl···H4eq (2.860 Å) and Cl···H7 (3.080 Å) (Σr_{VDW} = 3.1 Å). The Cl···H4eq interaction can be also

deduced from the sharp Cl−Al−N angle (101.25°), which means that Cl approaches H4eq. Intermolecular interactions are confined to a Cl1′···H2eq distance of 2.774 Å (Figure 2b).

In the N→$AlCl_3$ adduct **7**, the N→Al bond length is 1.993(5) Å. There are six weak cooperative intramolecular van der Waals contacts of the Cl atoms with the hydrogen atoms of neighboring CH units (range 2.92−3.00 Å) leading to a rather symmetrical orientation of the $AlCl_3$ molecule to the $H_3CN(CH_2)_2$ group. The Cl−Al−N angles are slightly sharper [105.9(2), 106.3(2) and 106.5(2)°] than those of a regular tetrahedron and cause the CH and Cl atoms to approach each other (Figure 3). A weak intermolecular S···Cl interaction of 3.467 Å is also observed[8a,8b,12] (Σr_{VDW} = 3.70 Å).

In the solid state, compound **8** has an N→Al bond length of 1.982(5) Å, with Br−Al−N bond angles of 107.1(2)°, 106.5(2)° and 106.4(2)°. Six short, weak intramolecular contacts between bromine and the neighboring hydrogen atoms are found, with H···Br distances ranging from 2.97 to 3.12 Å [Σr_{VDW} H···Br = 3.2 Å] (Figure 4b).

In the crystal, each molecule has three intermolecular interactions with three neighboring molecules, through H···Br van der Waals contacts [2.89, 2.90 and 3.04 Å]. The interaction of two sulfur atoms of one molecule with two bromine atoms,[13] each from a different molecule, is shown in Figure 5, including a short Br···H contact (2.887 Å).

The equimolecular reaction of compound **1** with $InCl_3$ in toluene at room temperature gives a white solid that crystallized from $CHCl_3$. It proved to be the 2:1 adduct **9** (Scheme 4).

The structure of **9** in the solid state reveals a pentacoordinate indium atom bound to two molecules of dithiazinane **1** through its N atoms, which are placed at the apical positions of a trigonal bipyramidal arrangement about the indium center. The molecule has C_2 symmetry, the two-fold axis running through the In−Cl2 bond (Figure 6). The N−In bond lengths are 2.413(3) Å. The N atoms of both

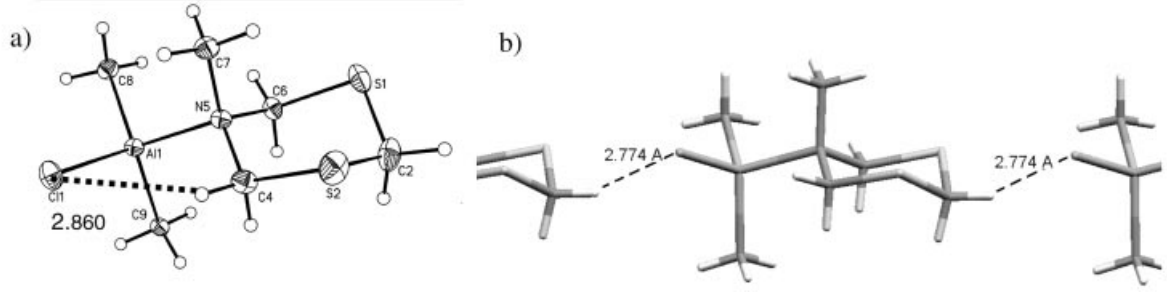

Figure 2. a) ORTEP representation of compound **6**; b) intermolecular Cl···H distances (Å)

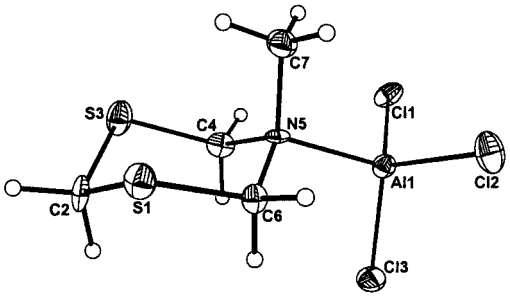

Figure 3. ORTEP representation of compound **7**

dithiazinane rings stand almost in orthogonal planes. The equatorial In−Cl bond lengths are 2.376(1) Å [Cl1 and Cl1A] and 2.383(3) Å [Cl2], the angles Cl−In−Cl are close to 120° and the N5−In1−N5A angle is 175.8(1)°. To the best of our knowledge, only two other similar structures corresponding to bis-adducts are reported in the Cambridge Crystallographic Database — bis(dibenzylamine)indium trichloride[14a] and bis(trimethylamine)indium trichloride.[14b] Similar structures have been found for ether adducts $[InCl_3(OR_2)_2]$.[14c] In the database, only one monoamine adduct $(Me_3Sn)_3N{\rightarrow}InCl_3$ is reported.[14d]

In compound **9**, the dithiazinane rings retain the chair conformation, with the methyl group in an axial position (Figure 6). Twelve H···Cl distances [three each of 2.630, 2.744, 2.800 and 2.885 Å] are shorter than the van der Waals contacts (Figure 7).

The orientation of the molecule **9** in the lattice is characterised by intermolecular interactions between sulfur atoms in a tail-to-tail arrangement (Figure 8). The S···S distances [3.429 and 3.433 Å; Σr_{VDW} = 3.60 Å] are similar to those found in elemental sulfur (3.502, 3.376 for monoclinic S_8).[15] Cl2 has two intermolecular hydrogen bonds (H···Cl = 2.684 Å)[16] with two axial C-2 hydrogen atoms of two different molecules.

5-Methyl-1,3,5-dithiazinan-5-ium Cations with $AlCl_4^-$, $AlBr_4^-$, $GaCl_4^-$ BCl_4^- and Cl^- Anions (10−14)

The 5-methyl-1,3,5-dithiazinanium salts with MX_4^- anions [$AlCl_4^-$ **10**, BF_4^- **11**, $GaCl_4^-$ **12**, $AlBr_4^-$ **13**, BCl_4^- and Cl^- **14**] are formed by hydrolysis of the corresponding N→MX_3 adducts. They are crystalline solids that are insoluble in organic solvents (CH_2Cl_2, $CHCl_3$, C_7H_8); their structures were established by X-ray diffraction analysis. The molecular structure of the free dithiazinane ligand in the solid state shows that the methyl group adopts an axial position.[1d] Here it is very interesting to note that the dithiazinane rings present two conformations in the solid state, one with the methyl group in an equatorial position (**10**−**12**) and the other of a dithiazinanium salt with the methyl in an equatorial position and connected to one molecule of free dithiazinane with the N−Me group in an axial position (**13**); the actual structure is $L(LH^+)AlBr_4^-$. In another extraordinary case, conformations with methyl groups in equatorial or in axial positions were found in the same crystal (**14**). To the best of our knowledge this is the first solid-state structure of a dithiazinanium ring with the methyl group in an axial position.

In compounds **10**−**12** the dithiazinane is protonated, the methyl group is present in the equatorial position and the anion is placed on top of the heterocycle. The distances

between N−H5 and the halogen atoms of the anion are: for compound **10** 2.470 and 3.100 Å, for **11** 2.280 and 2.502 Å and for **12** 2.216 and 2.958 Å. Hydrogen bonding closes the X−M−X angle of the atoms near N−H5 [in **10**, 106.98(5)° in **11**, 105.6(5)° and in **12**, 106.81(7)°]. The angle C7−N5−H5 is sharp [101.03(1)° in **12**, 104.4(4)° in **11** and 108(3)° in **10**]. The tetrahedral geometry of the nitrogen atoms is distorted in **10** and **12** due to the hydrogen bonds between the N−H and the halogen atoms; the angles for **10** are C4−N5−H5 99(3)° and C6−N5−H5 116(3)° and for **12** 105.09(1)° and 118.36(1)° (Figures 9 and 10).

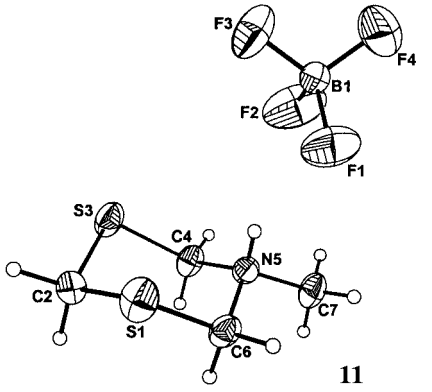

Figure 10. ORTEP representation of the crystal structure of **11**

In compounds **10**−**12** up to five dithiazinane hydrogen atoms participate in intermolecular interactions by

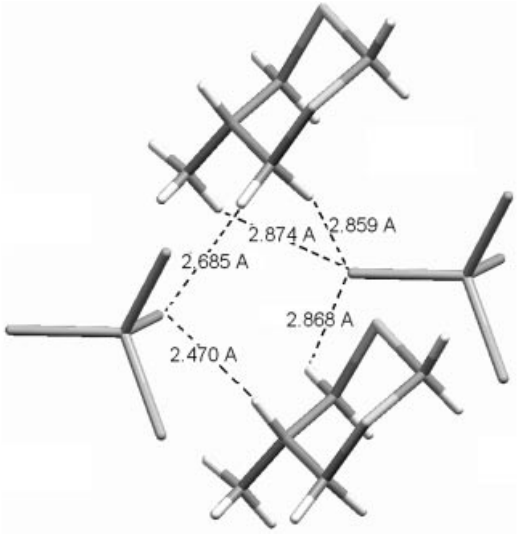

Figure 11. Arrangement (distances in Å) of anion and heterocyclic cations in compound **10**

hydrogen−halogen contacts. In Figure 11, the intermolecular interactions of anions and the heterocyclic cation in the lattice of **10** are shown. Around each anion five cycles are organized with five different interactions.

Compound **11** presents six intermolecular hydrogen bonds with six short distances (Figure 12). Compound **12** also has many intermolecular contacts in the unit cell, with seven intermolecular hydrogen halogen bonds for each molecular unit (Figure 13).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

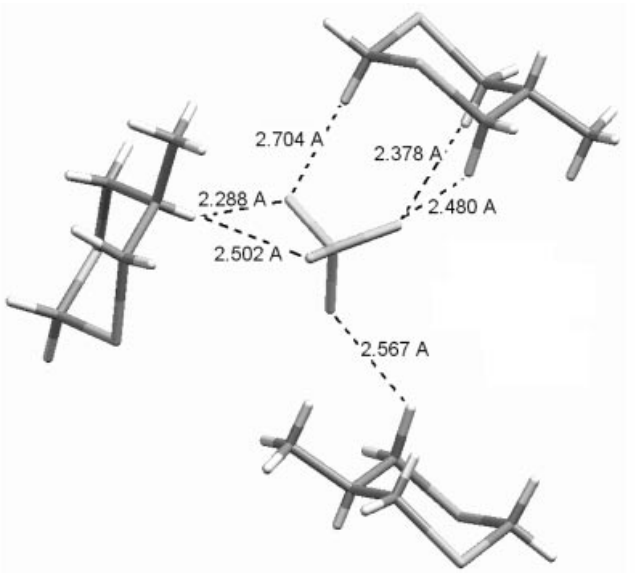

Figure 12. Arrangement of anions and heterocyclic cations in the cell of compound **11**

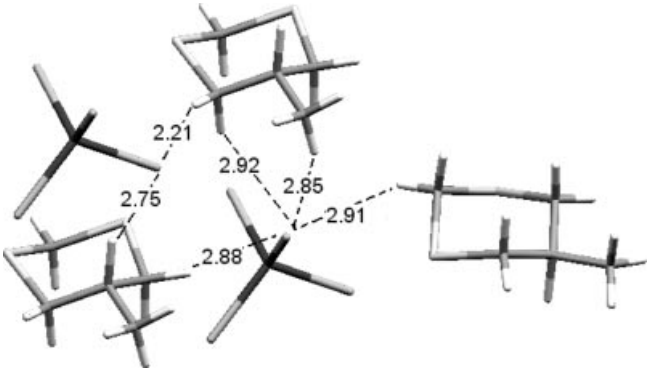

Figure 13. Arrangement of anions and heterocyclic cations in the unit cell of compound **12** (Å)

Compound **13** presents a very interesting molecular arrangement in the solid state because it co-crystallizes with a free dithiazinane molecule. In the asymmetric unit the free ligand has the methyl group in an axial position and the protonated ligand has the methyl group in an equatorial position (Figure 14). The heterocycles interact through a strong nitrogen-hydrogen bond N5H5A···N12 [2.068 Å] and one C−H···S hydrogen bond [2.974 Å].[6,17]

The unit cell of compound **14** is quite interesting because it shows a mixture of two different conformers of the protonated dithiazinane, one with the methyl group in an equatorial position and the other in an axial position. The cell also contains two different anions: BCl_4^- and Cl^-. The chloride ion is strongly bound to two N−H units (one axial and other equatorial) each one belonging to different conformers of the protonated dithiazinane. The corresponding H···Cl distances are H5···Cl1 (2.180 Å) and H5A···Cl1 (2.257 Å; Figure 15b). The interaction between the N−H and the chloride contributes to a significant distortion around the nitrogen atom. For the dithiazinanium with the axial methyl group, the C4−N5−H5 angle is 104(1)° and the C6−N5−H5 angle is 94(1)°. In the dithiazinanium with the equatorial methyl group the corresponding angles are 104(1)° and 103(2)°.

The position of the BCl_4^- group merits some comments: there are two face-to-face BCl_4^- anions, and the distance between the two Cl atoms of two BCl_4^- units (2.480 Å) is much shorter than the sum of the van der Waals radii (3.4−3.6 Å). This short distance, which, in principle, should produce a strong repulsive interaction between the chlorides, has no simple explanation, however, there are eight CH···Cl contacts altogether, and these may be responsible for stabilizing this molecular arrangement (Figure 16). Reports of Cl···Cl interactions in the solid state can be found in the literature.[18]

Conclusion

Dithiazinane is an interesting ligand which forms coordination compounds with dimethylaluminum chloride, aluminum trihalides and indium trichloride. The coordination occurs only through the nitrogen atom. It was found by NMR spectroscopy in solution that coordination leads to preferred conformations for the dithiazinane cycle. The ring-inversion energies were calculated from NMR experiments in solution. Opening of the cycle by $AlMe_3$ was found to occur by C−S bond breaking. In the solid state these compounds show many intramolecular and intermolecular interactions, most of them of van der Waals type, but others appear to be weak intermolecular polar interactions, which determine the preferred conformations. CH···Hal and NH···Hal intermolecular interactions were observed in many cases. The sulfur atoms are also involved in short intermolecular S···S contacts in compound **9** and S···Br contacts in **8**. In solution and in the solid state, C2H···π interactions were detected.

The dithiazinanium ion interacts with anions rich in lone pairs, such as MX_4^- or X^-, through its acidic NH hydrogen atoms, in very versatile ways, and through different conformers.

Experimental Section

All anhydrous solvents were freshly distilled prior to use. ^1H, ^{13}C and ^{27}Al NMR spectra were recorded with 270 or 400 MHz ^1H Jeol instruments and are referenced to TMS (^1H and ^{13}C) and $Al(OH)_6^{3+}$ for ^{27}Al. Melting points were measured on a Gallenkamp apparatus and are uncorrected.

Crystal data and data collection are reported in Table 4. Enraf−Nonius Kappa and Siemens−P4 diffractometers with CCD detectors were used. Absorption correction was performed using the program SADABS. Computations for all compounds were done by using SHELXS-97 (Sheldrick 1990) and SHELXL-97 (Sheldrick 1997).[19] Atomic scattering factors for neutral C, N, O and H atoms were taken from ref.[20] Hydrogen atoms were found in difference electron density maps. The NH hydrogen atoms were freely refined isotopically.

CCDC-217486 to -217494 (for **6**−**14**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

General Procedure for the Preparation of N→AlR$_{3-n}$X$_n$ (n = 3, 2, 0) Adducts: Two solutions in dry toluene and under an N_2 atmosphere containing equivalent stoichiometric amounts of the aluminum reagent $AlR_{3-n}X_n$ (n = 3,2,0) and compound **1** were slowly mixed at 4 °C and stirred for 20 min. A precipitate formed which was removed by filtration and recrystallized from toluene.

5-Methyl-1,3,5-dithiazinane(N-Al)trimethylalane (5): Compound **1** (225 mg, 1.66 mmol) in toluene (20 mL) and a solution of $AlMe_3$ in hexane (2 M, 1.66 mmol, 0.83 mL) were mixed. The white solid

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

formed was isolated and crystallized from toluene (yield: 310 mg, 90%). The crystals were not adequate for X-ray diffraction studies, m.p. 76−78 °C. ^{13}C NMR ($CDCl_3$, −10 °C): δ = 56.9 (C4 and C6), 36.6 (*C*7), 31.7 (C2), −9.8 (Al*C*H$_3$) ppm. ^{13}C NMR ($C_6D_5CD_3$ at −10 °C): δ = 56.5 (C4 and C6), 35.6 (C*7*), 30.6 (C2), −6.9 (Al*C*H$_3$) ppm. $C_7H_{18}AlNS_2$ (215.29): calcd. C 40.55, H 8.75, N 6.76; found C 40.43, H 8.73, N 6.57.

5-Methyl-1,3,5-dithiazinane(N-Al)dimethylaluminum Chloride (6): A 1 M solution of $AlMe_2Cl$ in hexane (1.33 mmol, 1.33 mL) was slowly added at room temp. to a solution of compound **1** (180 mg, 1.33 mmol) in toluene (20 mL). A yellow solid separated which was isolated and crystallized from toluene at −20 °C (yield: 270 mg, 90%), m.p. 91−93 °C. ^{13}C NMR ($CDCl_3$, 27 °C): δ = 56.9 (C4 and C6), 36.2 (C7), 31.5 (C2), −10.0 (Al*C*H$_3$) ppm. ^{13}C NMR ($C_6D_5CD_3$ at −15 °C): δ = 56.2 (C4 and C6), 35.1 (C7), 30.4 (C2), −7.7 (Al*C*H$_3$) ppm. $C_6H_{15}AlClNS_2$ (235.72): calcd. C 31.64, H 6.64, N 6.15; found C 30.88, H 6.21, N 5.60.

5-Methyl-1,3,5-dithiazinane(N-Al)aluminum Trichloride (7): A solution of $AlCl_3$ (165 mg, 1.23 mmol) in CH_2Cl_2 (20 mL) and a solution of compound **1** (167 mg, 1.23 mmol) in CH_2Cl_2 (20 mL) were mixed. Compound **7** precipitated as a white solid which was isolated and crystallized from toluene at room temp. (260 mg, 80%), m.p. 104−106 °C. ^{13}C NMR ($CDCl_3$, −10 °C): δ = 57.0 (C4 and C6), 36.1 (C7), 31.1 (C2) ppm. ^{13}C NMR ($C_6D_5CD_3$, 10 °C): δ = 56.8 (C4 and C6), 35.3 (C7), 30.1 (C2) ppm. $C_4H_9AlCl_3NS_2{\cdot}C_7H_8$ (286.98): calcd. C 25.42, H 3.93, N 4.68; found C 25.64, H 4.60, N 4.80.

5-Methyl-1,3,5-dithiazinane(N-Al)aluminium Tribromide (8): $AlBr_3$ (210 mg, 0.78 mmol) in toluene (20 mL) and compound **1** (106 mg, 0.78 mmol) dissolved in toluene (20 mL) were mixed. Adduct **8** was obtained as a yellow solid which was crystallized from toluene at room temp. (yield: 230 mg, 75%) and m.p. 110−112 °C. ^{13}C NMR ($CDCl_3$, −55 °C): δ = 57.1 (C4 and C6), 36.3 (C7), 31.5 (C2) ppm. ^{13}C NMR ($CDCl_3$, −55 °C): δ = 56.5 (C4 and C6), 35.2 (C7), 29.7 (C2) ppm. $C_4H_9AlBr_3NS_2$ (401.94): calcd. C 11.95, H 2.26, N 3.48; found C 11.75, H 2.56, N 3.41.

Bis[5-Methyl-1,3,5-dithiazinane(N-Al)]indium Trichloride (9): A solution of **1** (100 mg, 0.74 mmol) in $CHCl_3$ (20 mL) was added to a suspension of $InCl_3$ (164 mg, 0.74 mmol) in $CHCl_3$ at room temp. The mixture was stirred for 30 min and the solid was isolated by filtration. Crystallization of the white solid from $CHCl_3$ at room temp. gave 160 mg (90%) of **9**. $C_8H_{18}Cl_3InN_2S_4{\cdot}2CHCl_3$ (657.14): calcd. C 15.84, H 2.91, N 4.26; found C 16.19, H 2.94, N 3.89.

General Procedure for the Preparation of 5-Methyl-1,3,5-dithiazinan-5-ium Salts 10−14: Two solutions under a N_2 atmosphere, one of the aluminum or borane reagent ($AlR_{3-n}X_n$, BX_3) and the other of compound **1** in the same solvent, were slowly mixed (in a 1:1 ratio) at 4 °C, and stirred for 20 min. The precipitate was removed by filtration and the filtrate was stirred for 20 min in an open system. The salts were obtained as crystalline solids.

5-Methyl-1,3,5-dithiazinan-5-ium Tetrachloroaluminate (10): Compound **10** was obtained as crystals (m.p. 84−86 °C) in 90% yield. $C_8H_{20}AlCl_5N_2S_4$ (476.47): calcd. C 15.43, H 2.54, N 3.33; found C 15.65, H 2.66, N 3.41.

5-Methyl-1,3,5-dithiazinan-5-ium Tetrafluoroborate (11): A solution of $BF_3{\cdot}OEt_2$ (11.6 M, 0.032 mL, 0.37 mmol) was added at −78 °C to compound **1** (50 mg, 0.37 mmol) in $CDCl_3$ (1 mL) under an N_2 atmosphere. After two weeks of storing at room temp., some white crystals were obtained (m.p. 79−80 °C). $C_4H_{10}AlBF_4NS_2$ (223.06): calcd. C 21.54, H 4.52, N 6.28; found C 21.15, H 4.66, N 6.13.

5-Methyl-1,3,5-dithiazinan-5-ium Tetrachlorogallate (12): $GaCl_3$ (240 mg, 1.36 mmol) in toluene and compound **1** (184 mg, 1.36 mmol) dissolved in toluene (20 mL) were mixed at 4 °C. Compound **12** was obtained as a white solid. It was crystallized from toluene at room temp. and proved to have the composition (**1**·H$^+$)$GaCl_4{\cdot}C_7H_8$ (420 mg, 90%); m.p. 54−56 °C. ^{1}H NMR ($CDCl_3$): δ = 4.5 (s, 4 H), 4.0 (s, 2 H), 3.0 (s, 3 H) ppm. ^{13}C NMR: δ = 58.4 (C4 and C6), 36.9 (C7), 32.4 (C2) ppm. $C_4H_{10}Cl_4GaNS_2{\cdot}C_7H_8$ (439.84): calcd. C 15.43, H 2.54, N 3.33; found C 15.65, H 2.66, N 3.41.

5-Methyl-1,3,5-dithiazinan-5-ium Tetrabromoaluminate (13): The white solid was recrystallized from toluene at room temp. (m.p. 83−85 °C). $C_8H_{19}AlBr_4N_2S_4$ (618.11): calcd. C 15.43, H 2.54, N 3.33; found C 15.65, H 2.66, N 3.41.

Bis(5-Methyl-1,3,5-dithiazinan-5-ium) Tetrachloroborate Chloride (14): A solution of $BCl_3{\cdot}$DMS (4 M, 0.09 mL, (0.37 mmol) was added to a solution of compound **1** (50 mg, 0.37 mmol) in $CDCl_3$. The mixture was stored for one week at room temp., after which time some white crystals had separated; m.p. 109−111 °C. $C_8H_{19}BCl_4N_2S_4$ (424.13): calcd. C 22.66, H 4.52, N 6.60; found C 22.43, H 4.50, N 6.00.

Synthesis, Structure, and Redox Properties of a New Aqua Ruthenium Complex Containing the Tridentate [9]aneS$_3$ and the Didentate 1,10-Phenanthroline Ligands

Xavier Sala,[a] Albert Poater,[a] Isabel Romero,[a] Montserrat Rodríguez,[a] Antoni Llobet,*[a] Xavier Solans,[b] Teodor Parella,[c] and Teresa M. Santos[d]

Keywords: Thioether compounds / Catalysis / Oxidations / Redox chemistry / Ruthenium

The synthesis of a new Ru–H_2O complex [Ru(phen)(H_2O)([9]aneS$_3$)](ClO_4)$_2$, **2**, (phen = 1,10-phenanthroline, [9]aneS$_3$ = 1,4,7-trithiacyclononane) is described. The complex is characterized by UV/Vis and 1-D and 2-D NMR spectroscopy in solution. The complex has been further characterized in the solid-state by X-ray diffraction analysis which displays a distorted octahedral coordination geometry around the Ru metal center. The cyclic voltammetric experiments of the complex show a pH-dependent chemically irreversible wave at $E_{p,a}$ = 0.82 V, at pH = 7.0, indicating the low stability of the higher oxidation states. Nevertheless, before the complex decomposes, it is capable of electrocatalytically oxidizing benzyl alcohol (BzOH) to benzaldehyde with a second-order rate constant of 19.8 $M^{-1}s^{-1}$.

Introduction

Over the last two decades a large number of ruthenium polypyridyl complexes containing a water molecule directly bonded to the metal has emerged.[1] The [Ru(trpy)(bpy)(H_2O)]$^{2+}$ (trpy = 2,2′:6′,2′′-terpyridine and bpy = 2,2′-bipyridine) complex described by Meyer et al.[1a] constitutes a paradigm of this type of complexes, both from a structural and a reactivity point of view.

The Ru^{II}–H_2O complexes are of interest since the corresponding higher oxidation states can be reached within a relatively narrow potential range by sequential electron and proton loss, as shown in Equations (1) and (2) for [Ru(trpy)(bpy)(H_2O)]$^{2+}$.

$$[Ru^{II}(trpy)(bpy)(H_2O)]^{2+} \underset{+1H^+,+1e^-}{\overset{-1H^+,-1e^-}{\rightleftharpoons}} [Ru^{III}(trpy)(bpy)(OH)]^{2+} \quad (1)$$

$$E_{1/2}(Ru^{III/II} \text{ at pH} = 7) = 0.49 \text{ V vs. SSCE}$$

$$[Ru^{III}(trpy)(bpy)(OH)]^{2+} \underset{+1H^+,+1e^-}{\overset{-1H^+,-1e^-}{\rightleftharpoons}} [Ru^{IV}(trpy)(bpy)(O)]^{2+} \quad (2)$$

$$E_{1/2}(Ru^{IV/III} \text{ at pH} = 7) = 0.62 \text{ V vs. SSCE}$$

These higher oxidation states, especially Ru^{IV}=O, are active catalysts for a variety of oxidative reactions such as the oxidation of alkenes to epoxides,[2] sulfides to sulfoxides,[3] phosphane to phosphane oxides,[4] alcohols to aldehydes,[5] and even saturated alkanes to alcohols.[6] Furthermore, from a bioinorganic perspective, they have also been shown to be able to selectively bind and cleave DNA molecules.[7]

A challenging aspect associated with the chemistry of Ru–H_2O type of complexes is the understanding of how electronic factors transmitted by the ligands can influence the stability of the different oxidation states, and as a consequence its reactivity.[8] With this purpose several Ru–H_2O complexes have been described containing electron-donating and electron-withdrawing substituents in the polypyridylic ligands,[9] as well those that have a variety of ancillary ligands containing oxygen donors such as picolinate or acetylacetonate and phosphorus donors such as phosphanes.[10]

In this paper we report on the synthesis, structural and spectroscopic characterization of the first example of a Ru–H_2O polypyridylic complex containing a thioether type ligand, [Ru(phen)(H_2O)([9]aneS$_3$)]$^{2+}$ (phen = 1,10-phen-

anthroline. [9]aneS$_3$ = 1,4,7-trithiacyclononane). The electronic properties exerted by the thioether ligand to the metal center are discussed, together with its influence on the redox and catalytic properties.

Results and Discussion

Synthesis and Solid-State Structure

The synthesis of the complex [Ru(phen)(H$_2$O)([9]aneS$_3$)](ClO$_4$)$_2$ (**2**) is straight forward and consists of the addition of Ag^{I} to the corresponding Ru^{II}−Cl complex according to Equation (3).

$$[Ru(Cl)(phen)([9]aneS_3)]^+ + Ag^+ + H_2O \longrightarrow [Ru(phen)(H_2O)([9]aneS_3)]^{2+} + AgCl \quad (3)$$

The crystal structure of complex **2·2H$_2$O** was solved by means of single-crystal X-ray diffraction analysis and its crystallographic data, as well as selected bond lengths and angles are presented in Table 1 and Table 2, respectively. Figure 1 presents the ORTEP diagram for the cationic moiety of the molecule, including the corresponding labeling scheme.

The molecular structure of **2** shows that the Ru metal center has a distorted octahedral coordination environment. The [9]aneS$_3$ ligand coordinates facially through its sulfur atoms in an endodentate manner, while the phen ligand is chelated through its N atoms. The sixth coordination site is occupied by the oxygen atom of the aqua ligand. Bond lengths and angles are within the expected values for this type of complexes.[11,12] It is interesting to note here that the Ru−S bond lengths *trans* to the N atoms of the phen ligand are about 4 pm larger than the Ru−S distance *trans* to the aqua ligand, denoting the stronger *trans* effect of the former ligand with respect to the latter. The S−Ru−S *cis* angles are close to 90° indicating the good facial fit of the ligand for an octahedral type of geometry

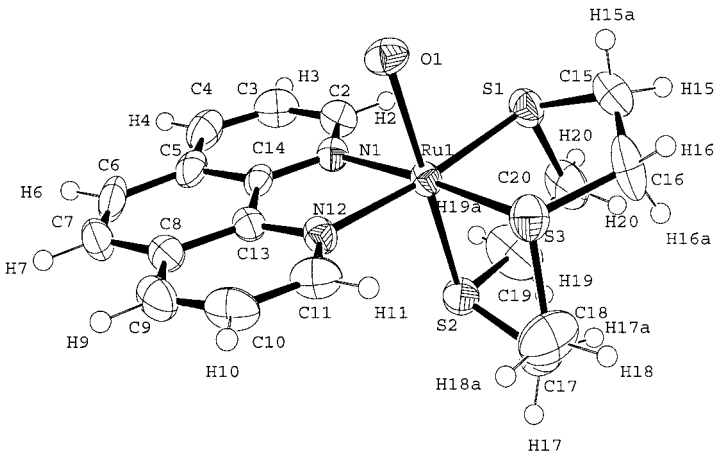

Figure 1. An ORTEP view (50% probability) of the molecular structure of cation **2**, including the atom labeling scheme

with no steric distortions from the other ligands.[13] In sharp contrast, the [9]aneS$_3$ ligand exerts a strong steric interaction over both the phen and the aqua ligands, which is clearly manifested, for instance, in the *trans* bonding angles that are all significantly smaller than 180°, ranging from 173.59(12)° to 177.54(10)°, thus producing a sort of umbrella folding [all *cis* X−Ru−S, X = N or O, angles are significantly larger than 90°, ranging from 91.03(10)° to 97.84(12)°, with a mean value for the six angles of 94.21(10)°]. Two disordered perchlorate anions balance the cationic charge. Finally, there are two waters of crystallization per complex that form an intricate network of hydrogen-bonds. O1w forms a strong hydrogen-bond with the aqua ligand bound to the Ru metal center and with the other crystallization water molecule (O2w). It also interacts weakly with one of the perchlorate counteranions. The other perchlorate ion interacts weakly with both the hydrogen atoms of the phen and the [9]aneS$_3$ ligands, whereas O2w interacts only with O1w and one of the perchlorate ions.

Spectroscopic Properties

The 1-D and 2-D NMR spectra for the aqua complex **2** were recorded in D_2O. The ^1H NMR spectrum of **2** is shown in Figure 2 (assignments are shown in the Exp. Sect.). The other NMR spectra are presented as supplementary information. All the resonances in the NMR spectra were unambiguously identified and are consistent with the same structure found in the solid-state. It is worth mentioning here that the cationic part of complex **2** is asymmetric. Nevertheless, from a magnetic point of view, at room temperature, it can be considered as having a plane of symmetry that bisects the [9]aneS$_3$ and the phen ligands in two halves, and which contains the Ru1, O1, and S2 atoms. The spectrum consists of a series of resonances in the δ = 2.4−3.6 ppm region that can be assigned to the thioether ligand, and a series of resonances in the δ = 5.8−9.6 ppm region arising from the phen ligand. There are three key NOESY effects together with the COSY map that allows for the unmistakable assignment of all the resonances observed in the ^1H NMR spectrum. The first two are interligand NOE effects observed between H11 (phen) and H17 (strong NOE effects, hydrogen atoms situated at a distance of 2.64 Å in the X-ray structure) and H18a (4.45 Å), which allows for the identification of the hydrogen atoms of the [9]aneS$_3$ ligand directed towards phen relative to those that are pointing away from the phen ligand. The third key NOE effect is also strong and is observed between H18 and H16a (2.47 Å), which allows for the clear differentiation of the H atoms of C17 from those of C18. Finally, the geminal protons can be assigned easily using the HETCOR ^1H-^{13}C map, and thus a complete assignment of the [9]aneS$_3$ ligand is achieved. With regard to the phen ligand, the resonances at δ = 7.95 and 8.15 ppm can be assigned to H10 and H7, respectively, based on their multiplicity. The doublet at 9.40 ppm is assigned to H11 based on the above-mentioned interligand NOE effects, and finally, the doublet at δ = 8.67 ppm is assigned to H9. The assignments for the phen ligand are consistent with the COSY map.

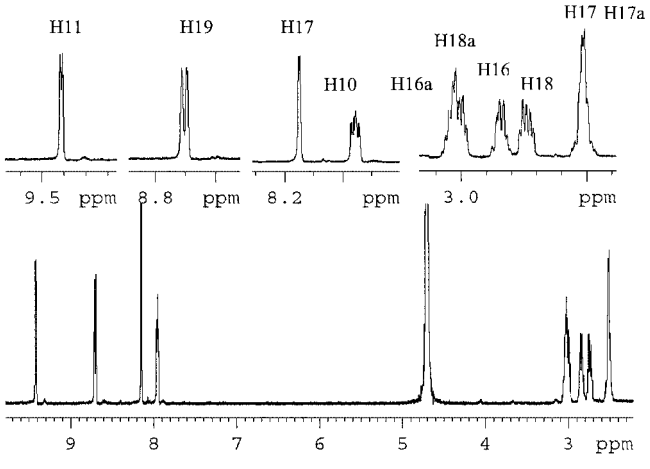

Figure 2. ^1H NMR spectrum of the complex **2** recorded in D_2O; amplifications of selected zones are displayed on top

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The electronic spectrum of the aqua complex **2** at pH 7.0 is shown in Figure 3. Below 300 nm two predominantly ligand based $\pi-\pi^*$ transitions appear at λ_{max} = 259 nm (ε = 39750 $cm^{-1}M^{-1}$) and 288 nm (15355 $cm^{-1}M^{-1}$); above 300 nm two bands appear at 353 nm (6766 $cm^{-1}M^{-1}$) and 410 nm (6578 $cm^{-1}M^{-1}$) that can be assigned to a series of MLCT $d\pi-\pi^*$(Ru−phen) transitions and their vibronic components, based on previous literature for related complexes.[1g,11,14] Under basic conditions complex **2** deprotonates generating the corresponding hydroxy derivative, $[Ru^{II}(OH)(phen)([9]aneS_3)]^+$ (**3**). For the hydroxo complex **3**, the two MLCT bands are shifted to higher wavelengths relative to those of the corresponding Ru−aqua complex **2** [410 nm (6816 $cm^{-1}M^{-1}$) and 432 nm (6811 $cm^{-1}M^{-1}$)] due to the relative destabilization of $d\pi$ (Ru) levels prompted by the hydroxo ligand.[1g,15] A pK_a of 10.1 is obtained from the acid-base spectrophotometric titration of **2** (shown as an inset in Figure 3), giving one isosbestic point at 379 nm, see Equation (4).

$$[Ru^{II}(phen)(H_2O)(9aneS_3)]^{2+} \longrightarrow [Ru^{II}(OH)(phen)(9aneS_3)]^{+} + H^{+} \quad (4)$$

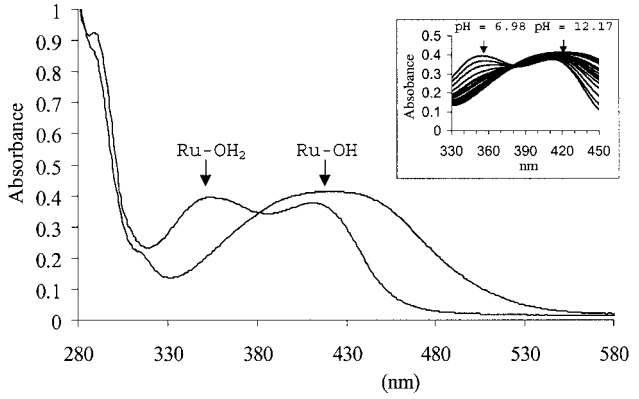

Figure 3. UV/Vis spectra of complex **2** at pH 7.0 phosphate buffer, and of complex **3** at pH 12.2. The inset shows the acid-base spectrophotometric titration of a $5\cdot10^{-5}$ M solution of **2** in the 330−450 nm region (the pH of the different spectra are 7.0, 9.2, 9.6, 9.9, 10.15, 10.3, 10.5, 10.7, 11.2, 11.3, 11.7, 10.05, 12.2)

Redox Chemistry and Catalytic Properties

The redox properties of the aqua complex **2** were investigated by means of cyclic voltammetric and coulometric techniques. Figure 4 shows the cyclic voltammograms of complex **2** at pH = 7.0, in the presence and absence of benzyl alcohol, BzOH, and their mathematical simulation has been performed using the software DIGISIM and is presented as Supporting Information.[16] As can be observed, a chemically irreversible wave is obtained at pH = 7.0 and at a scan rate of 100 mV/s, with $E_{p,a}$ = 0.82 V and a small returning wave at $E_{p,c}$ = 0.72 V ($E_{1/2}$ = 0.77 V; ΔE = 100 mV); these redox processes have been tentatively assigned to the Ru^{III}/Ru^{II} redox couple based on electronic arguments (vide infra) and whilst taking into consideration that the charge under the anodic wave is similar to that of the Ru^{III}/Ru^{II} couple of $[Ru^{II}(py)(phen)([9]aneS_3)]^{2+}$ [17] which behaves in a reversible manner. No further electrochemical processes are observed under these conditions for potentials up to 1.7 V. In sharp contrast, the homologous Ru−Cl complex **1**, displays a reversible wave due to the Ru^{III}/Ru^{II} couple with $E_{1/2}$ = 1.15 V ($E_{p,a}$ = 1.19 V, $E_{p,c}$ = 1.11 V, ΔE = 81 mV), in acetonitrile. For the Ru−OH_2 complex, **2**, the reduction potential observed varies with pH with a slope of 56.0 mV per pH unit, as expected for this type of compound. The corresponding Pourbaix diagram in the pH range from 6 to 10 is shown as supplementary information. Several attempts have been undertaken to further characterize the Ru^{III}/Ru^{II} couple by performing CV experiments at different temperatures and at different scan rates, but the results did not give further meaningful information. The instability of the Ru^{III}−OH species manifested in the CV is also displayed when it is oxidized using NaOCl as the oxidant at pH = 2.5, as expected. The process was followed spectrophotometrically and is shown as supplementary material. In the UV/Vis spectrum the initial bands of **2** at 353 and 410 nm progressively disappear on addition of NaOCl, generating a spectrum with new bands of low intensity at 320 and 370 nm, with two isosbestic points at 280 and 330 nm. Given this chemically irreversible behavior two possibilities arise: the formation of a μ-oxo species or disproportionation to Ru^{II} and Ru^{IV}, followed by the oxidation of the $[9]aneS_3$ ligand to the corresponding sulfoxide. The former is ruled out since Ru−O−Ru species have a very characteristic band in the 550−650 nm range[18] that is not observed in the present case, whereas strong evidence for the latter is obtained. The addition of NaOCl to **2** was also followed by NMR spectroscopy. A shift to lower field is observed for the signals of all the methylenic protons of $[9]aneS_3$, in agreement with the oxidation to their corresponding sulfoxide species. This statement is also supported by the fact that no electroactivity of the oxidized species is observed in the 0.0−1.2 V potential window at pH = 7.0, due to the strong electron-withdrawing capacity of the sulfoxide species which prevents further oxidations of the newly generated diamagnetic Ru^{II} complex.

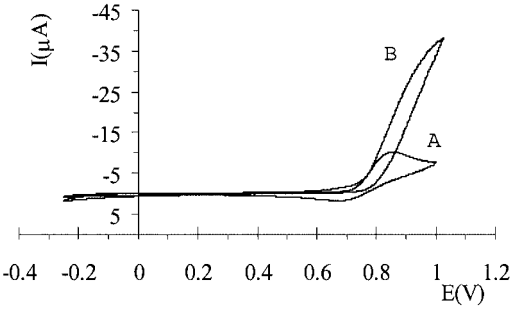

Figure 4. Cyclic voltammograms at a scan rate of 20 mV/s of complex **2** at pH = 7.0 in the absence (A) and presence of 0.2 M BzOH (B)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 3 presents the pK_a and electrochemical information of several polypyridylic Ru−Cl, Ru−OH_2, and Ru−py (py = pyridine). As can be seen, the redox properties of the Ru−H_2O type of complexes are highly sensitive to the nature of the ancillary ligands. Strong σ-electron donors stabilize the Ru^{III} oxidation state and thus a decrease in the Ru^{III}/Ru^{II} reduction potential is observed. The opposite effect is observed with good π-electron acceptor ligands which increase the Ru^{III}/Ru^{II} redox potential due to the stabilization of Ru^{II} by dπ−π* back-bonding.[10]

For **2**, comparison of the redox potentials can be made with $[Ru(tpm)(N\text{-}N)(L)]^{2+}$ (tpm, tris(1-pyrazolyl)methane; N-N is bpy or phen; L = H_2O, Cl, or py). The tpm complexes are a convenient choice since, like [9]aneS_3, tpm is a tridentate facial ligand, and therefore the influence of geometrical aspects on redox potentials is minimized. Thus, when comparing the Ru^{III}/Ru^{II} redox potential of the aqua complexes, $[Ru(T)(N\text{-}N)(H_2O)]^{2+}$ (T = tpm or [9]aneS_3), it is found that the thioether ligand produces an increase of 360 mV with regard to the corresponding tpm complex, due to both a much weaker σ-donor capacity and a stronger π-acceptor ability of the former ligand.[19] A similar phenomenon is also found for the Ru−Cl and Ru−py complexes where, as shown in Table 3, an increase of 480 and 420−470 mV in the Ru^{III}/Ru^{II} redox potential is observed, respectively.

The combination of σ- and π-electronic perturbations exerted by the [9]aneS_3 ligand over the ruthenium metal center results in an increase in the Ru^{III}/Ru^{II} redox potential for the Ru−aqua complex **2**, that in turn is responsible for the instability of the corresponding Ru^{III}−OH species, which undergoes a decomposition process. This increase in the redox potentials is also manifested by the fact that the corresponding Ru^{IV}/Ru^{III} redox wave is not found throughout the entire pH range, on scanning up to 1.7 V. The high reactivity of the Ru^{III}−OH species is also shown by its ability to oxidize BzOH. This is illustrated in Figure 4, where the cyclic voltammograms are recorded both in the presence and absence of BzOH. When the alcohol is present, there is a strong enhancement of the anodic peak current due to the electrocatalytic oxidation of the alcohol forming benzaldehyde.[20] Meyer and co-workers[20b] have previously proposed a Ru^{III}−OH species that is capable of oxidizing BzOH, even though it is usually the Ru^{IV} species that is capable of carrying out such an oxidation reaction. In our study, the strong electron-withdrawing nature of the [9]aneS_3 ligand results in a high increase in the Ru^{III}/Ru^{II} redox potential, and thus it is plausible that the +3 oxidation state is sufficiently reactive so as to oxidize BzOH.

Increasing amounts of BzOH (0.10, 0.18, 0.20 M) were added to the solution and a series of cyclic voltammograms were recorded with a scan rate of 20 mV/s (see Figure 4 and the Supplementary Information). At this scan rate, the system behaves in a steady-state condition, and thus the limiting current is predicted to be independent of scan rate.[21] A second-order rate constant, k_{cat} = 19.3 $M^{-1}s^{-1}$, is experimentally determined using the equation described by Shain et al.[21] A similar value is also obtained, k_{cat} = 19.8 $M^{-1}s^{-1}$, from the mathematical simulation (See supplementary material) of the process using DIGISIM. This value is of the same order of magnitude as for the polypyridylic Ru^{IV}=O complexes described previously in the literature,[22] which are capable of oxidizing the same substrate under similar conditions, with k_{cat} values ranging from 6.0 to 30.8 $M^{-1}s^{-1}$. The formation of benzaldehyde as the only product was corroborated in a bulk experiment using the following conditions: 1.46 mM **2**/0.145 M BzOH/$9.09\cdot10^{-3}$ M NaOCl/pH 6.9 phosphate. This system yields 8.55 mM benzaldehyde after 15 minutes at 22.0 °C.

In summary, a new Ru−aqua complex, **2**, containing the soft [9]aneS_3 ligand has been prepared and its structural, spectroscopic and redox properties are described. The bonding of the facial thioether ligand by the Ru metal center results in a high anodic shift of the Ru^{III}/Ru^{II} couple relative to the complex $[Ru(tpm)(phen)(H_2O)]^{2+}$, due to the weaker σ- and stronger π-bonding capacities exerted by [9]aneS_3 over the Ru metal center relative to the pyrazolylic ligand. These electronic interactions are also responsible for the instability of the corresponding Ru^{III}−OH species. However, the decomposition reaction coupled to the Ru^{III}−OH species is slower than the oxidation of BzOH that yields the initial Ru^{II}−OH_2 and benzaldehyde, thus generating a catalytic cycle.

Experimental Section

Materials: All reagents used in the present work were obtained from Aldrich Chemical Co and were used without further purification. Reagent grade organic solvents were obtained from SDS, and high purity deionized water was obtained by passing distilled water through a nanopure Mili-Q water purification system. The complex $[Ru^{II}(Cl)(phen)([9]aneS_3)]Cl$, **1**, was prepared according to literature procedures and recrystallized twice from methanol prior to its use.[11]

Preparations: All synthetic manipulations were routinely performed under a nitrogen atmosphere using Schlenk tubes and vacuum line techniques in the dark. Electrochemical experiments were performed in the dark under a N_2 or Ar atmosphere with degassed solvents.

Caution! The complex described in this section contains the perchlorate ion as a counteranion; perchlorate salts are potentially explosive.

$[Ru^{II}(phen)(OH_2)([9]aneS_3)](ClO_4)_2\cdot2H_2O$ (2·2H_2O): A sample of **1** (35 mg, 0.051 mmol) was added to a solution of $AgClO_4$ (27.0 mg, 0.130 mmol) dissolved in water/acetone (1:1) (15 mL). The resulting mixture was refluxed for 2 h. AgCl was filtered through a frit containing celite and the volume was reduced using a rotary evaporator under reduced pressure until the solution started to become turbid. A pale orange solid the precipitated. The solid was washed with hexane and diethyl ether and dried under vacuum. Yield: 23.5 mg (53%). $C_{18}H_{22}Cl_2N_2O_9RuS_3\cdot2H_2O$: found (calcd.) C 30.47 (30.25), H 3.72 (3.64), N 4.03 (3.92), S 13.30 (13.44). ^{1}H NMR (500 MHz, D_2O, 25 °C): δ, 2.50 (m, H17, H17a), 2.75 (m, H18), 2.85 (m, H16), 3.00 (m, H18a), 3.05 (m, H16a), 7.95 (dd, J_{9-10} = 7.7, J_{10-11} = 3.8 Hz, H10), 8.15 (d, J_{7-9} = 0.5 Hz, H7), 8.67 (d, J_{9-10} = 7.7 Hz, H9), 9.40 (d, J_{11-10} = 3.8 Hz, H11) ppm. ^{13}C NMR (500 MHz,

D_2O, 25 °C): δ, 32.5 (C18), 33.02 (C16), 35.07 (C17), 127.34 (C10), 129.07 (C7), 132.2 (C8), 139.8 (C9), 148 (C13), 155.1 (C11). For the NMR spectroscopic assignments we have used the same labeling scheme as those used in the X-ray structure shown in Figure 1. $E_{1/2}$ (pH, 7.0 phosphate buffer) = 0.77 V vs. SSCE. UV/Vis (pH, 7.0 phosphate buffer) $\lambda_{max,}$ nm (ε, $M^{-1}cm^{-1}$), assignment: 259 (39750) π−π*; 288 (15355) π−π*; 353 (6766) dπ−π*(phen); 410 (6578) dπ−π*(phen).

Instrumentation and Measurements: UV/Vis spectroscopy was performed on a Cary 50 Scan (Varian) UV/Vis spectrophotometer using 1 cm quartz cells. pH measurements were performed using a Micro-pH-2000 instrument from Crison. Cyclic voltammetric (CV) experiments were performed with a PAR 263A EG&G potentiostat or an IJ-Cambria IH-660 using a three electrode cell. A glassy carbon disc electrode (3 mm diameter) from BAS was used as the working electrode, platinum wire as auxiliary and SSCE as the reference electrode. All cyclic voltammograms presented in this work were recorded under a nitrogen atmosphere. The pH was adjusted from 0−2 with HCl, adding sodium chloride to keep a minimum ionic strength of 0.1 M. From pH 2−10, 0.1 M phosphate buffers were used, and from pH 10−12 diluted CO_2 free NaOH was used. All $E_{1/2}$ values reported in this work were estimated from cyclic voltammetry as the average of the oxidation and reduction peak potentials $(E_{p,a} + E_{p,c})/2$. Unless explicitly mentioned, the concentrations of the complexes were approximately 1 mM.

Catalytic studies at neutral pH have been performed in phosphate buffer solution. The conversion of benzyl alcohol to benzaldehyde was followed by GC using Shimadzu GC-17A gas chromatography apparatus in a TRA-5 Column (30 m × 0.25 mm diameter) incorporating a FID detector. GC conditions: initial temperature 80 °C for 1 min, ramp rate 10 °/min, final temperature 220 °C, injection temperature 220 °C, detector temperature 250 °C, carrier gas He at 25 mL/min. Under these conditions, the retention times for benzaldehyde and benzyl alcohol are 3.9 and 4.9 minutes, respectively.

NMR spectroscopy was performed on a Bruker 500 MHz or a Bruker DPX 200 MHz spectrometer. Samples were run in deuterium oxide. Elemental analyses were performed using a CHNS-O Elemental Analyser EA-1108 from Fisons.

X-ray Structure Determination: Suitable crystals of $[Ru(phen)(H_2O)([9]aneS_3)](ClO_4)_2{\cdot}2H_2O$ (**2·2H$_2$O**) were grown from water as yellow blocks. A prismatic crystal (0.1 × 0.1 × 0.2 mm) was selected and mounted on an Enraf−Nonius CAD4 four-circle diffractometer. Unit-cell parameters were determined from automatic centering of 25 reflections ($12 < \theta < 21°$) and refined by least-squares methods. Intensities were collected with graphite monochromatized Mo-*Kα* radiation, using the ω/2θ scan-technique. 7668 reflections were measured in the range $2.21 \leq \theta \leq 29.97°$, of which 7617 were independent ($R_{int} = 0.010$), and 3557 reflections were assumed as observed applying the condition $I > 2\sigma(I)$. Three reflections were measured every two hours as orientation and intensity controls, significant intensity decay was not observed. Lorentz-polarization but no absorption corrections were made.

The structure was solved by Patterson synthesis, using the SHELXS computer program[23a] and refined by full-matrix least-squares methods with the SHELXL-97 computer program[23a], using 7617 reflections. The function minimized was $\Sigma w\|F_o|^2 + |F_c|^2|^2$, where $w = [\sigma^2(I) + (0.0440P)^2]^{-1}$ and $P = (F_o^2 + 2F_c^2)/3$; f, f′, and f″ were taken from International Tables of X-ray Crystallography.[23b] All H atoms were computed and refined, using a riding model, with an isotropic temperature factor equal to 1.2 times the equivalent of the temperature factor of the atoms which are linked. The final R (on F) factor was 0.0386, wR (on F^2) = 0.0580 and the goodness of fit was 0.845 for all observed reflections. The number of refined parameters was 298. Max. shift/esd = 0.014, mean shift/esd = 0.002. Max. and min. peaks in the final difference synthesis was 0.538 and −0.677 $e{\cdot}Å^{-3}$, respectively.

Crystallographic data for the structure included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-204307. These data can be obtained free of charge at http://www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This research has been financed by MCYT of Spain through project BQU2000−0458. AL is grateful to CIRIT Generalitat de Catalunya (Spain) for the Distinction award and the aid SGR2001-UG-291. AL also thanks Johnson and Matthey for a $RuCl_3{\cdot}xH_2O$ loan. X.S and A.P are grateful for the award of a doctoral grant from the University of Girona and from CIRIT, respectively.

Electrochemical Behaviour of First Row Transition Metal Substituted Polyoxotungstates: A Comparative Study in Acetonitrile

Maria Salete Balula,[a,b] José A. Gamelas,[a,b] Helena M. Carapuça,[a] Ana M. V. Cavaleiro,*[a,b] and Walkiria Schlindwein[c]

Dedicated to Prof. Dr. João E. J. Simão on the occasion of his 75th birthday

Keywords: Polyoxometalates / Sandwich complexes / Transition metals / Electrochemistry

A comparative study of the electrochemical behaviour of several transition metal substituted polyoxotungstates in acetonitrile solution with tetra-*n*-butylammonium perchlorate as a supporting electrolyte is presented. Tetra-*n*-butylammonium salts of Keggin-type polyoxoanions, α-$[(C_4H_9)_4N]_4H_x[XW_{11}M(H_2O)O_{39}]\cdot nH_2O$, X = P, Si; M^{II} = Co, Ni, M^{III} = Fe, Mn, x = 0–2, n = 0–2, and sandwich-type polyoxoanions, α-B-$[(C_4H_9)_4N]_7H_3[M_4(H_2O)_2(PW_9O_{34})_2]$, M^{II} = Co, Mn, have been studied by cyclic voltammetry and spectroelectrochemistry. Under the conditions used, the tungsten-oxo framework of the metal substituted Keggin anions could accept up to three electrons in quasi-reversible one-electron consecutive processes. Comparison with the corresponding lacunary anions is presented. Redox processes at the metal centre have been detected for all metals M except Ni. For the anions α-$[XW_{11}M(H_2O)O_{39}]^{m-}$, the co-existence of species with a different degree of protonation was deduced from cyclic voltammetry results whenever protons were included in the molecular formula. The influence of the solids' composition on the electrochemical results is stressed. For the sandwich anions, cyclic voltammetry revealed redox processes occurring on the W atoms and also on the metallic belt. Two metal atoms in the belt of the α-B-$[Co^{II}_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ anion could be electrochemically oxidised to Co^{III} in two separate steps. A similar result was observed for the Mn^{II} analogue, but the corresponding first step was not as well defined. Re-oxidation was only detected for the Co anion. This work is the first comparative study of the electrochemical behaviour of such transition metal substituted polyoxotungstates in an organic medium.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Transition metal substituted polyoxotungstates have attracted special attention over the last two decades, due to their wide range of potential applications,[1–8] especially the Keggin-type polyoxoanions α-$[XW_{11}M(L)O_{39}]^{m-}$ (X = P, Si, etc., M = transition metal and L = monodentate ligand, abbreviated as $XW_{11}M$). These may be viewed as complexes where the lacunary anion α-$[XW_{11}O_{39}]^{n-}$ (XW_{11}) coordinates the transition metal ion M^{p+} in a pentadentate fashion.[9] A labile water molecule usually occupies the sixth coordination position, giving a pseudo-octahedral environment around the metal M (Figure 1, A). The inorganic tungsten-oxo framework is inert towards oxidation but can accept reversibly up to four electrons.[5,9] The metal M may also be involved in reversible redox processes. With this in mind, several metal substituted Keggin anions have been used as electrocatalysts to reduce pollutants such as NO_2^- or NO,[10,11] and also to reduce H_2O_2 and to oxidise alcohols or cleave aryl olefins.[12–16]

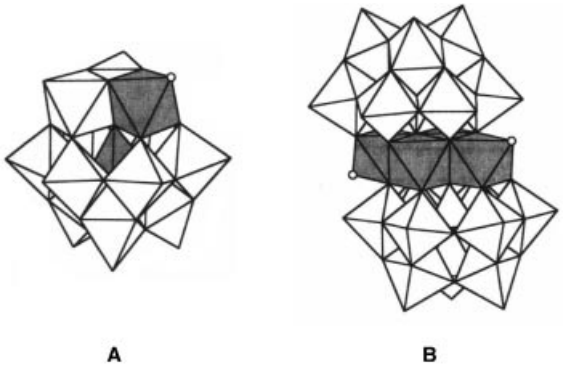

Figure 1. Structure of the complexes α-$[XW_{11}M(H_2O)O_{39}]^{m-}$ (A) and α-B-$[M_4(H_2O)_2(PW_9O_{34})_2]^{p-}$ (B). Each dashed octahedron represents a MO_6 group and the open circles represent the oxygen atom from a water molecule coordinated to M

Another interesting type of complex of general formula α-B-$[M_4(H_2O)_2(PW_9O_{34})_2]^{p-}$, abbreviated as $M_4(PW_9)_2$, has a sandwich structure in which two sub-units α-B-$[PW_9O_{34}]^{9-}$ are linked to a belt of four metal ions[9] (Figure 1, B). Because the several metal centres in these complexes could be activated separately in redox processes, studies on their potential as electrocatalysts are certainly needed.

In addition to electrocatalysis, the above metal substituted polyoxotungstates are, in general, active in liquid-phase oxidative catalysis, and several related reviews have appeared.[2−4] Their activity and selectivity depend on the type of substrate, experimental conditions (oxidant, solvent, temperature), and on the substituting metal.[2,3] Studies on the electrochemistry of such polyoxoanions in different solvents may help in understanding their behaviour as oxidative catalysts. Numerous electrochemical studies have been made, in aqueous media, of mono-substituted Keggin polyoxotungstates with X = P, Si, such as for Mn[16−19] and Fe,[10,12,20,21] among other metals.[5,22−24] Anions with X = Zn have also been examined.[25,26] Nevertheless, studies in organic solution are scarce. Cyclic voltammetry in acetonitrile has been reported for $[PW_{11}Cu^{II}O_{39}]^{5-}$,[27] $[H_xSiW_{11}(VO)O_{39}]^{(6-x)-}$,[28] $[XW_{11}M(H_2O)O_{39}]^{m-}$, X = P, Si, Ge, B, M = Ru^{III},[29] Ir^{IV},[11,30] $[PW_{11}TcO_{40}]^{4-}$,[31] and $[XW_{11}Re^{V,VI,VII}O_{40}]^{4-}$, X = P ($Re^{V}$), Si ($Re^{VI}$), B ($Re^{VII}$).[32] Also, co-solvent effects on the redox behaviour of the $[SiW_{11}Mn(H_2O)O_{39}]^{6-}$ anion have been analysed.[19] For the sandwich-type complexes $M_4(PW_9)_2$ in acetonitrile, studies on $[Cu_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ and $[Fe_4(H_2O)_2(PW_9O_{34})_2]^{6-}$ have been published.[27,33] Studies of $Mn_4(PW_9)_2$ in aqueous solution have also been performed.[18,34] There is an obvious lack of information on the electrochemistry of these two kinds of polyoxoanions in organic solvents, considering that many redox catalysis experiments are, in fact, performed in non-aqueous media, such as acetonitrile or 1,2-dichloroethane.[2,3]

In this context, we have studied the electrochemical behaviour, in acetonitrile, of the anions $[XW_{11}O_{39}]^{n-}$ and $[XW_{11}M(H_2O)O_{39}]^{m-}$, X = P, Si, M^{II} = Co, Ni, M^{III} = Fe, Mn, and $[M_4(H_2O)_2(PW_9O_{34})_2]^{10-}$, M^{II} = Co, Mn. Experiments were performed using TBA salts. Determination of the diffusion coefficient in acetonitrile was attempted for several polyoxoanions. The electrochemical behaviour of the above-mentioned polyoxoanions in acetonitrile is, to our knowledge, described for the first time in a systematic way. In terms of catalysis, special interest has been paid to reactions at the metal centres (Co, Fe, Mn).

Results and Discussion

Characterisation of the Tetrabutylammonium Compounds

TBA salts with $[PW_{11}O_{39}]^{7-}$ and $[PW_{11}M(H_2O)O_{39}]^{m-}$ anions have been synthesised and characterised previously.[35−39] The compounds with the anions $[SiW_{11}M(H_2O)O_{39}]^{m-}$, M^{II} = Co, Ni, M^{III} = Fe, Mn, have four TBA cations in the molecular formula, and are isostructural. Their powder X-ray diffraction patterns were similar to those of the P analogues with metals like Co^{II}, Ni^{II} or Fe^{III},[39] indicating that the Si compounds crystallise with the same body-centred cubic structure as the P-anions.[39,40] Conversely, the X-ray diffraction powder pattern of $TBA_4H_4[SiW_{11}O_{39}]$ was identical to that of the tetragonal phase of the corresponding $TBA_4H_3[PW_{11}O_{39}]$.[39]

The infrared spectra of the compounds with the sandwich polyoxoanions, $TBA_7H_3[M_4(H_2O)_2(PW_9O_{34})_2]$, M^{II} = Co, Mn, were similar. The spectra of the present TBA salts differ from those of the corresponding potassium salts in the ν_{as}(P−O) and ν_{as}(W−O−W) region. The band due to the P−O stretching vibration, at 1030−1040 cm^{-1} for the potassium salts of the polyoxoanions $M_4(PW_9)_2$, M = Co, Mn,[41] presented a shoulder at higher wave-number in the spectra of the TBA salts (Figure 2, a,b). Therefore, the TBA counter-cations probably induce a larger distortion of the central phosphate groups of the α-B-$[PW_9O_{34}]^{10-}$ sub-units.[42,43]

General Electrochemical Behaviour of the Keggin-Type Anions $XW_{11}M$ (X = P, Si) in Acetonitrile

Cyclic voltammograms (CV) of the $XW_{11}M$ anions in acetonitrile exhibited, in the negative potential region, one to three pairs of cathodic/anodic peaks corresponding to the redox processes of tungsten atoms (Figure 3). The substituting metal was reduced for Fe^{III} and Mn^{III} substituted anions. The voltammetric results, including those obtained for the lacunary XW_{11} anions, are summarised in Table 1. For comparison, results for $[XW_{12}O_{40}]^{3/4-}$, X = P, Si (XW_{12}), under the same experimental conditions, are included in Table 1. These are similar to previously published values.[11,29,44,45] Additionally, for M = Co^{II} (X = P, Si) and Mn^{III} (X = Si), anodic waves at positive potentials were observed, due to the oxidation of the metal M.

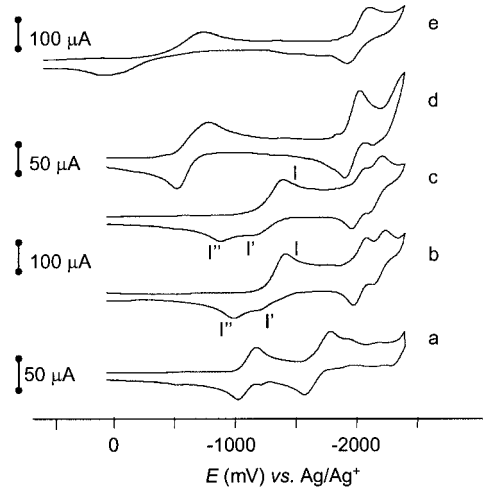

Figure 3. Cyclic voltammetry at a glassy carbon working electrode (scan rate = 100 mV/s) of acetonitrile solutions (10 mM) of (a) PW_{11}, (b) $PW_{11}Co^{II}$, (c) $PW_{11}Ni^{II}$, (d) $PW_{11}Fe^{III}$, (e) $PW_{11}Mn^{III}$

All the reduction processes of the W atoms in the metal substituted Keggin anions were quasi-reversible. The ΔE_p (anodic to cathodic peak separation) for the ferrocene/ferrocenium redox couple in acetonitrile was used as the reversibility reference (71 mV). There was an apparent decrease in the reversibility for the transition metal substituted heteropolyanions, relative to the parent structure XW_{12}. For the lacunary XW_{11} anions, the voltammetric behaviour is also consistent with W quasi-reversible reductions.

Controlled potential electrolysis revealed that each of the two first W reduction peaks corresponded to one-electron transfer processes. The number of electrons of the third W reduction (when observed) was estimated to be one, by comparison of the current of the corresponding voltammetric peak with those of the first and second reductions. Thus the tungsten-oxo framework of the heteropolyanions studied could accept one to three electrons, within the present experimental potential range.

The peak potentials of the two first W reductions were more negative for the substituted species than for the corresponding lacunary anions or for the parent Keggin anions. As found in aqueous solution,[5,21,22,46] there is no obvious correlation between the charge of lacunary or of the metal substituted anions and the reduction potentials of W (Figure 4), in contrast to the case of parent Keggin anions in aqueous[9] and non-aqueous systems[47] or for the anions $XW_{11}Ir^{IV}$, X = P, Si, Ge, B in acetonitrile.[11]

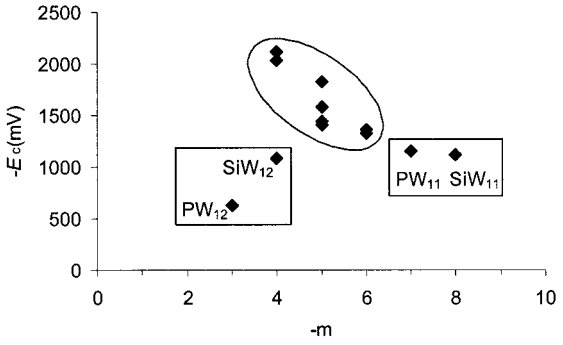

Figure 4. Potentials of the first tungsten reduction peaks of the cyclic voltammograms of XW_{12}, XW_{11}, and $XW_{11}M$ vs. the formal charge of the unprotonated anions

The redox potentials for the W atoms of the studied anions in acetonitrile were, in general, shifted towards more negative values than those reported in aqueous solution for the corresponding potassium salts.[10,18,21,22] This has been be explained by considering Lewis interactions between the polyoxoanions (bases) and the solvent molecules (acids). A correlation between the Guttmann acceptor number of the solvent[48] and the potential of the first one-electron re-

duction has been found for α-$[SiW_{12}O_{40}]^{4-}$.[49] For redox processes at the substituting metals, the fact that the solvent may act as a donor ligand, substituting the labile water molecules coordinated to the metal M, must be considered. Recent studies have shown that for the XW_{12} anions the number of transferred electrons and the corresponding potentials are affected by various solution conditions besides the solvent, namely the acidity and the presence of different cations.[5,44,45] The influence of charge distribution on the redox behaviour of some lacunary and metal-substituted Keggin and Dawson-type species was referred by Keita et al.[46] For the $XW_{11}M$ anions the interplay of all these factors is far from being understood, preventing straightforward comparison of results obtained in different media.

Keggin-Type Anions with M^{II} = Co, Ni

The cyclic voltammograms of $XW_{11}Co$ and $XW_{11}Ni$ (X = P, Si) in acetonitrile exhibited three tungsten one-electron redox couples at negative potentials. Two anodic counterparts (I′ and I′′) were observed for the first reduction peak (Figure 3), even when the potential scan was reversed at ca. −1800 mV, i.e. after the first 1-e⁻ reduction of tungsten.

On increasing the scan rate (from 20 to 200 mV/s, Figure 5) the first W electron transfer with the P-anions (Figure 5, A), i.e. the first reduction peak I (around −1400 mV), was shifted to more negative potentials (ca. 38 and 50 mV, respectively, for $PW_{11}Co$ and $PW_{11}Ni$); the anodic peak I′′ became less negative and increased in intensity compared with peak I′; the position of I′ was unchanged. The W peaks at potentials more negative than −1800 mV were unchanged.

The above-mentioned splitting of the anodic counterpart of peak **I** and the observed variations with scan rate are attributed to the co-existence of distinct polyoxoanion species with different degrees of protonation. Protons were introduced in solution due to the molecular formula of the salts $TBA_4H[PW_{11}M(H_2O)O_{39}]\cdot nH_2O$. The first anodic peak (I′) corresponds to the oxidation of the less protonated species (namely $[PW_{11}M(H_2O)O_{39}]^{6-}$) whereas peak I′′, at more positive potentials, must correspond to the oxidation of a more protonated species, possibly $H[PW_{11}M(H_2O)O_{39}]^{5-}$. As the first 1-e⁻ tungsten reduction produced a single peak it was assumed that protonation occurred after reduction. Similar behaviour has been observed previously for $SiW_{11}Mn^{II}$, in aqueous solutions,[18] i.e. depending on scan rate, reoxidation scans showed two peaks attributed to species with different degrees of protonation.

$SiW_{11}Co$ and $SiW_{11}Ni$ anions showed similar electrochemical behaviour to that of the P analogues (Figure 5, B), except that the first cathodic process was split into two peaks of approximately equal height (as found by semi derivative deconvolution) whose position did not change significantly with scan rate. Nevertheless, these first reduction processes for the Si-polyoxoanions corresponded to overall 1-e⁻ reductions (determined by coulometry). The observed splitting of the first cathodic W peak may indicate the existence of two stable species in the initial solutions, possibly differing in protonation degree. Protons were again introduced in solution due to the molecular formula $TBA_4H_2[SiW_{11}M(H_2O)O_{39}]\cdot nH_2O$.

Additionally, Co^{II} was oxidised at positive potentials. The voltammograms were better defined at a Pt working electrode, where the oxidation peaks occurred at E_{pa} = +954 mV for the $SiW_{11}Co$ anion and at E_{pa} = +1003 mV for $PW_{11}Co$ (100 mV/s). Bulk electrolysis with coulometric determination at a Pt working electrode, performed at +1100 mV for the $SiW_{11}Co$ and at +1200 mV for the $PW_{11}Co$ anions, gave 1.0 and 1.1 electrons transferred, respectively. The in situ visible spectra of the oxidised solutions revealed

a new band around 670 nm, indicating a $Co^{III}O_6$ chromophore.[50]

Different waves in the cyclic voltammograms corresponding to species with different degrees of protonation are uncommon with Keggin-type polyoxoanions, but have been reported for the anion $[H_xSiW_{11}(V^{IV}O)O_{39}]^{(6-x)-}$ in acetonitrile[28] and for $SiW_{11}Mn^{II}$ in aqueous solution.[18] Their appearance depends on the interplay of equilibrium and kinetic factors, namely acidity constants of the protonated anions, amount of protons present in solution and kinetics of proton exchange. The conditions here reported seem to favour their appearance.

Cyclic voltammograms of $PW_{11}Ni$ and $SiW_{11}Co$ in acid aqueous solutions (pH = 2.2) also show two anodic peaks as counterparts of the first cathodic wave (in this case, a 2-electron wave) that are attributed to the α-and β-isomers of the reduced anion.[22] In those voltammograms, the corresponding peak positions were not significantly altered by changing the scan rate and the intensity of the anodic peak at more positive potentials increased as the scan rate decreased. In the present study, the position of peak I′′ altered, and the variation in relative peak heights $I_{pa}(I')/I_{pa}(I'')$ with scan rate was the opposite of that in aqueous solution. These findings, together with the observation of peaks I′ and I′′ for the 1-electron reduced polyoxometalates, may indicate that the two observed anodic peaks do not correspond to different isomers. So far, for Keggin-type anions, except $[XW_{12}O_{40}]^{5-}$, X = Al, Ga,[51,52] the formation of β-isomers by spontaneous isomerization of the corresponding α-anions has been reported to occur after the uptake of, at least, two electrons.[21,22,52]

Himeno et al. have prepared β-$[PW_{12}O_{40}]^{3-}$ in water/acetonitrile solutions,[44] showing that CH_3CN, as an auxiliary solvent, stabilized markedly this isomer. Nevertheless, both α and β isomers of that anion were kinetically inert in the water/acetonitrile medium.[44] Accordingly, the results obtained here do not indicate that the organic solvent may favour α→β isomerization.

Keggin-Type Anions with M^{III} = Mn, Fe

The CV of the anions $XW_{11}M^{III}$ showed, at negative potentials, waves corresponding to the reduction of W and of the metal M^{III}. Those of $PW_{11}Fe^{III}$ and $PW_{11}Mn^{III}$ polyoxoanions exhibited two redox couples (Figure 3, d,e). Controlled potential bulk electrolysis at −1000 mV for the Fe and at −1200 mV for the Mn polyoxoanion indicated that, in both cases, the first reduction step was an one-electron reaction (0.85 and 0.90 electrons were transferred, respectively). The solution of $PW_{11}Fe^{III}$ in acetonitrile changed from yellow to purple and a band with the maximum at 536 nm appeared in the visible region spectrum (Figure 6), corresponding to the $PW_{11}Fe^{II}$ anion.[10] For the $PW_{11}Mn^{III}$ anion the characteristic bands of the $Mn^{III}O_6$ chromophore,[17,53] at 493 and 524 nm (sh), disappeared during electrolyses and the electronic spectrum of the electrolysed solution showed only a charge-transfer band extending to the UV region, indicating a $Mn^{II}O_6$ chromophore.[53,54] These results clearly show that the first reduction peak in the voltammograms of $PW_{11}Fe^{III}$ and $PW_{11}Mn^{III}$ was due to the one-electron transfer at the substituting metal centre ($Fe^{III}\rightarrow Fe^{II}$ and $Mn^{III}\rightarrow Mn^{II}$, respectively). For the Mn^{III}/Mn^{II} couple, $E_{pa} - E_{pc}$ was quite large and increased with scan rate (ΔE_p near 760 mV at 100mV/s). As the normalised current intensity of the peaks did not vary noticeably with scan rate, the large irreversibility of the Mn^{III}/Mn^{II} couple seems to be due to slow electron transfer. This differs from aqueous solutions, in which the Mn^{III}/Mn^{II} couple for the different manganese substituted Keggin anions originated quasi-reversible waves with a peak separation in the 70−170 mV range.[16,17,19] Nevertheless, the particular kinetic inertness of the Mn^{III}/Mn^{II} couple has been referred to for other Mn complexes.[55]

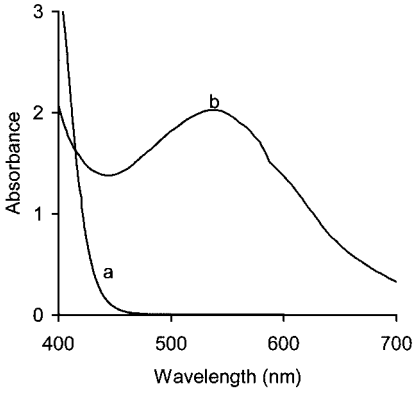

Figure 6. Visible electronic absorption spectra of the acetonitrile solution of $PW_{11}Fe^{III}$ before (a) and after bulk electrolyses at −1000 mV (b)

Except for the variation in ΔE_p corresponding to the M^{III}/M^{II} pairs (much larger for Mn than for Fe), the cyclic voltammograms of $PW_{11}Fe^{III}$ and $PW_{11}Mn^{III}$ did not change significantly with scan rate and the peaks were not split. As these polyoxoanions contain no protons in the molecular formula, no protonated species are expected. These results may further indicate that the behaviour described above for the $XW_{11}Co^{II}$ and $XW_{11}Ni^{II}$ anions is caused by protonated species.

The cyclic voltammetric data (Table 1) for the $XW_{11}Fe^{III}$ and $XW_{11}Mn^{III}$ compounds show more peaks for the Si-polyoxoanions than for the P-anions, as the tungsten atoms in the polyoxoanions containing Si are reduced at less negative potentials than the P analogues. This is another consequence of the presence of protons in solution. The voltammetric behaviour of the parent Keggin polyoxometalates in organic solvents is strongly sensitive to the presence of H^+.[45,56] In particular, the peak potentials of the W reduction waves shifted to less negative values as the amount of H^+ increased, to a point in which the one-electron reduction waves were changed into two-electron waves.[45,56] Of the compounds with metal substituted anions described in this work only $PW_{11}Fe$ and $PW_{11}Mn$ do not have protons in the molecular formula, and only for these anions is

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the first W reduction peak more negative than −2000 mV (Figure 3 and Table 1).

Another interesting feature in the CV of the Si anions is the unexpected splitting of the 1-e⁻ reduction process at the M atom. This is more clearly seen for the iron anion (Figure 7); the Mn^{III}/Mn^{II} couple gave less well-resolved waves. Thus, besides the main iron reduction peak at −693 mV (Table 1), another cathodic peak with low current intensity appeared near −1040 mV. Electrolysis at potentials near −1200 mV indicated that one 1-electron reduction took place, suggesting that both peaks correspond to one Fe atom. The observed splitting was interpreted in terms of an equilibrium between $SiW_{11}Fe(H_2O)$ and $SiW_{11}Fe(OH)$. Hydrolysis of Fe^{III} substituted Keggin anions has been reported,[20,57,58] with the formation of monomeric complexes and/or dimeric or other polynuclear species. The former seem to be obtained in the presence of non-aqueous solvents, whereas water leads to extensive dimerization. In particular, Kuznetsova et al. observed only the monomeric species $PW_{11}Fe(L)$, L = H_2O, OH^-, in acetonitrile solutions of TBA salts with $Fe:PW_{11}$ = 1:1.[57] The CV obtained in acetonitrile of the TBA salt of $PW_{11}Fe(OH)$, prepared as previously published,[39] also showed two reduction waves, cumulatively corresponding to the 1-electron reduction of Fe. In the CV of $SiW_{11}M^{III}$ anions, the anodic counterpart of the reduction peak at less negative potentials showed the same pattern as for $XW_{11}Co$ and $XW_{11}Ni$, i.e. two anodic peaks.

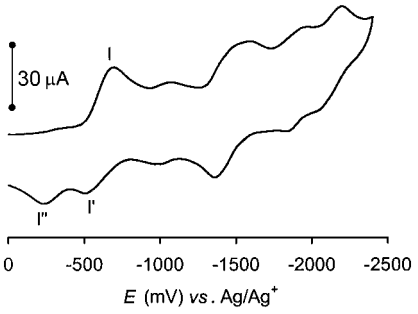

Figure 7. Cyclic voltammetry at a glassy carbon working electrode of $SiW_{11}Fe^{III}$ (10 mM acetonitrile solution, scan rate = 100 mV/s)

For the $SiW_{11}Mn^{III}$ anion, besides the $Mn^{III/II}$ redox couple, the oxidation of Mn^{III} to Mn^{IV} was observed at the Pt electrode at E_{pa} = +1046 mV (not observed for the analogue $PW_{11}Mn^{III}$). Electrolysis at +1200 mV gave 0.9 electrons transferred. Such Mn redox processes for $XW_{11}Mn^{III}$, X = P, Si, in acetonitrile are consistent with those reported for $XW_{11}Mn^{II}$ in aqueous solution.[16,17,19]

Lacunary Keggin-Type Anions

The lacunary polyoxotungstates XW_{11} (X = P, Si) gave well-defined cyclic voltammograms with two and three one-electron redox waves at negative potentials, respectively (Table 1). Under the conditions used the peak potentials of PW_{11} and SiW_{11} were similar, whereas, in the voltammogram of the parent Keggin anions, the W peak potentials in SiW_{12} were more negative than for PW_{12}, reflecting the higher charge of the anion. The different behaviour found for the parent and lacunary anions was again attributed to possible protonation of the latter, due to protons from the TBA salts (with formula $TBA_4H_3[PW_{11}O_{39}]$ and $TBA_4H_4[SiW_{11}O_{39}]$, respectively). These protons do not exist in the salts of XW_{12} anions.

Electrochemical Behaviour of the Sandwich-Type Polyoxoanions $M_4(PW_9)_2$

Cyclic voltammetry between 1300 and −2400 mV for the TBA salts of sandwich polyoxoanions in acetonitrile revealed no significant changes upon varying the scan rate from 20 to 200 $mV \cdot s^{-1}$. For potentials < −1000 mV three quasi-reversible waves, corresponding to tungsten reductions (Table 2), were observed. Figure 8 presents the voltammogram of the $Mn_4(PW_9)_2$ anion (the Co^{II} polyoxoanion showed similar electrochemical behaviour).

Oxidation processes at the metal M were clearly observed at a Pt working electrode. For the Co sandwich polyoxoanion, two oxidation peaks of identical intensity were detected at +811 and +1123 mV (Figure 9, a). In the corresponding reduction scan, the two cathodic peaks observed at less positive potentials are the counterparts of the first oxidation process (Figure 9, b). Electrolysis of the $Co_4(PW_9)_2$ solution at the Pt electrode with coulometric determination, performed at +950 mV, indicated the transfer of 0.8 electrons, meaning that each oxidation peak corresponds to a one-electron process (total loss of two electrons). Considering the structure of the polyoxoanion,[59,60] the oxidation processes might occur at the two more external Co atoms (atoms bound to a water molecule in Figure 1, B), more accessible for the electron transfer to the electrode surface. Previous studies of two salts of oxidized derivatives of the $Mn^{II}_4(PW_9)_2$ anion have suggested that oxidation occurred first at the more external Mn atoms.[34] From the above considerations the cobalt oxidation processes can be described as (L = H_2O and/or CH_3CN):

$$[Co^{II}_2(L)_2Co^{II}_2(PW_9)_2]^{10-} \rightarrow [Co^{III}(L)Co^{II}(L)Co^{II}_2(PW_9)_2]^{9-} + e^-$$

$$[Co^{III}(L)Co^{II}(L)Co^{II}_2(PW_9)_2]^{9-} \rightarrow [Co_2{}^{III}(L)_2Co^{II}_2(PW_9)_2]^{8-} + e^-$$

We could not explain unambiguously the two reduction peaks that are the cathodic counterparts of the first oxidation process. The shape of the cyclic voltammograms was not altered either by change of scan rate or by multiple successive scans.

The Mn sandwich polyoxoanion at the Pt working electrode showed two irreversible oxidation processes at the Mn centre (Figure 9, c), with the total electron transfer of two electrons (value obtained by electrolysis with coulometric determination at +860 mV using the Pt electrode). A similar irreversible behaviour had been observed in studies in aqueous solution, and attributed to slow electron transfer, possibly due to Jahn−Teller distortion of the $Mn^{III}O_6$ octahedra, rather than to chemical irreversibility.[34]

Diffusion Coefficients

Diffusion coefficients (D values) are not normally determined in mechanistic studies on electrochemical processes. However, the diffusion of species towards the electrode is important in the overall electrochemical reaction. The dependence of the cathodic and anodic peak currents on the square root of the scan rate indicates that the electrode processes are diffusion controlled. The diffusion coefficients may be estimated by applying the Randles-Sevcik equation, $|I_p| = 2.69\cdot A\cdot n^{3/2}\cdot C\cdot D^{1/2}\cdot v^{1/2}$; where A is the electrode area, C is the concentration, n is the number of electrons transferred and v is the scan rate. Here, we determined the electrode area to be $8.58\cdot10^{-2}$ cm^2, by chronoamperometry with a 4 mM $K_4Fe(CN)_6$ +2 M KCl solution at 25 °C, where $D = 6.29\cdot10^{-6}$ $cm^2\cdot s^{-1}$.[61] The diffusion coefficients were estimated only for the polyoxoanions where the reduction peak characteristics (ΔE_p and $E_p - E_{p/2}$)[61] were closer to what is expected for a reversible process. Within the scan rate range used for the Keggin-type anions (20 to 200 mV/s), all of the correlation coefficients determined were ca. 0.99. For the parent Keggin anions PW_{12} and SiW_{12} we obtained $6.0\cdot10^{-6}$ and $4.3\cdot10^{-6}$ cm^2/s, respectively. The reported $6.1\cdot10^{-6}$ for $[SiW_{12}O_{40}]^{4-}$ in aqueous solution (pH, 4.0),[62] is slightly higher than that obtained in acetonitrile. For the lacunary and metal substituted anions, the estimated values of $1.5\cdot10^{-7}$ to $1.3\cdot10^{-6}$ cm^2/s are lower than those reported in aqueous solution for identical anions of the same charge, e.g. $XW_{11}M$, X = P, Si, Ge, B; M = Cr, Fe, Ir,[11,14] (ca. $3-4\times10^{-6}$ cm^2/s) and others.[63] However, care must be taken in making direct comparisons with these literature values, since they were obtained not only with different solvent composition, but also with different countercations, which are important factors that affect D.[63]

Concluding Remarks

We have performed a comparative study by cyclic voltammetry and spectroelectrochemistry of the polyoxoanions $[XW_{11}M(H_2O)O_{39}]^{m-}$, and $[XW_{11}O_{39}]^{n-}$, X = P, Si, M^{II} = Co, Ni, M^{III} = Fe, Mn, in acetonitrile solutions obtained by solubilisation of the corresponding TBA salts. In general, cyclic voltammetry in acetonitrile revealed several differences between the electrochemical behaviour of the anions and previous results in aqueous solution.[10,18,21,22] Thus, tungsten one-electron reductions were detected in acetonitrile, with corresponding reduction potentials at more negative values than those in aqueous solution. These facts were not totally unexpected, as comparable results had been previously reported for other Keggin-type anions,[5] but had not been systematically observed for the transition-metal-substituted anions here reported, for which studies in organic solvents were unknown.

The preparative methods used here led to the TBA salts $TBA_4H_x[XW_{11}M(H_2O)O_{39}]$ and $TBA_4H_x[XW_{11}O_{39}]$. Because of this, protons were introduced in solution (except

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for $PW_{11}M^{III}$, with $x = 0$) with important consequences for redox behaviour observed by cyclic voltammetry in acetonitrile. The degree of protonation of the anions or of the corresponding reduced species in acetonitrile solution is not known, but the fact that the results reflected the composition of the solids used is worth noting. In summary, the different effects identified in the study of these compounds are:

(1) In the presence of protons, tungsten atoms were reduced at less negative potentials. Compounds for which, due to stoichiometry, protons were not added to the solution had a CV with fewer peaks in the potential range studied.

(2) For compounds with $x = 1$ or 2, equilibria established between species with different protonation degrees changed the general pattern of the voltammograms, splitting some waves (generally those at less negative potentials). However, for the lacunary anions, for which $x = 3$ or 4, no such splitting of the re-oxidation waves was observed.

Consequently, the CV of the $PW_{11}M^{III}$, presented only one tungsten redox pair, whereas, depending on the compound studied, two or three electrons were transferred to the tungsten-oxo framework of the other heteropolyanions upon reduction.

Redox processes were detected at the metal centre for all the studied metal substituted Keggin anions, except for $XW_{11}Ni$. Two of the chosen anions included reducible substituting metal ions (Mn^{III} and Fe^{III}), and the waves corresponding to the M^{III}/M^{II} redox pairs were identified. This contrasts with reported studies on Ru^{III} and Ir^{IV} complexes in acetonitrile, in which reduction of the metals was not detected by cyclic voltammetry.[11,29] Our results indicate that the oxidation $Mn^{II} \rightarrow Mn^{III}$ is more favourable in acetonitrile than in water.[17] This accords with the slow oxidation of Mn^{II} to Mn^{III} by atmospheric O_2 that is commonly found for these anions in acetonitrile solution. Further oxidation to Mn^{IV} was only observed for $SiW_{11}Mn$. Oxidation of cobalt(II), and the corresponding reduction, was observed for both $XW_{11}Co$ anions (X = P, Si). Nevertheless, oxidations at high potentials ($Mn^{III} \rightarrow Mn^{IV}$ and $Co^{II} \rightarrow Co^{III}$) were more conveniently studied at a Pt electrode.

We have performed the first electrochemical study of the Keggin-derived sandwich complexes $[M_4(H_2O)_2(PW_9O_{34})_2]^{10-}$, M^{II} = Co, Mn, in acetonitrile. Metal oxidation in two separate steps was observed for both anions, but only for cobalt could the corresponding reductions be detected by cyclic voltammetry. Thus, in acetonitrile, two atoms in the belt of the $[M^{II}_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ anions (possibly the more external metal atoms) could be electrochemically oxidised in two separate steps to M^{III}.

Experimental Section

Reagents and Methods: All reagents were used as received, including tetra-*n*-butylammonium perchlorate (Sigma) and acetonitrile (Panreac, for instrumental analyses, HPLC grade). Elemental and thermogravimetric analysis, spectroscopic studies (infrared and visible), and powder X-ray diffraction analysis were performed as described previously.[64]

Electrochemical Measurements: Cyclic voltammetry measurements were carried out on a BAS 100BW electrochemical analyser using a conventional three-electrode single compartment cell supplied by BAS Inc. The working electrode was a glassy carbon disc electrode (BAS) or a homemade platinum foil electrode. The surface of the glassy carbon electrode was polished with 0.3 μm alumina and washed with distilled water and acetonitrile before each experiment. The auxiliary electrode was a Pt wire. The reference electrode comprised an Ag wire immersed in a solution of $AgNO_3$ (0.01 M) and $TBAClO_4$ (0.1 M) in acetonitrile. The Ag/Ag^+ reference electrode was calibrated against ferrocene/ferrocenium redox couple (1 mM) in the same solvent/electrolyte system. At scan rates between 20 and 200 mV/s, ferrocene presented $E_{1/2} = +0.087$ V vs. Ag/Ag^+, with a peak separation, ΔE_p, (anodic to cathodic) of 71 mV. All potentials quoted are relative to the Ag/Ag^+ reference electrode. The measurements were made at room temperature (ca. 20 °C), within the potential window +1300 to −2400 mV. The solutions were degassed with pure nitrogen for 5 minutes before use and blanketed with nitrogen gas during the voltammetric scans. Acetonitrile solutions (0.1 M $TBAClO_4$) were prepared for TBA salts of $XW_{11}M$ ($1.00 \cdot 10^{-2}$ M) or for TBA salts of $M_4(PW_9)_2$ ($3.00 \cdot 10^{-3}$ M).

Controlled potential electrolysis experiments were performed using a BAS 100BW electrochemical analyser or an AUTOLAB PGSTAT 30 Potentiostat. The reference electrode was the same as above. A carbon cloth or a platinum mesh was used as the working electrode. The counter electrode was a platinum mesh of large surface area placed in a glass tube chamber filled with the supporting electrolyte (0.2 M $TBAClO_4$ in acetonitrile) and separated from the working electrode compartment (electrolysis solution) by a porous vycor frit. To remove oxygen, nitrogen was constantly bubbled through the electrolysis solution, which was continuously stirred with a magnetic bar. All experiments were performed at room temperature.

Spectroelectrochemical experiments were performed on a UNICAM UV1 spectrophotometer connected to an AUTOLAB PGSTAT 30 potentiostat, using a quartz cuvette (4 cm optical path). The three-electrode system was inserted in the cell and kept under continuous nitrogen bubbling and stirring during electrolysis. The working electrode was a platinum foil. Experiments were performed at room temperature.

Synthesis of the Tetrabutylammonium Compounds: Published procedures were used to prepare $[(C_4H_9)_4N]_3[PW_{12}O_{40}]$,[65] $[(C_4H_9)_4N]_4[SiW_{12}O_{40}]$,[65] $[(C_4H_9)_4N]_4H_3[PW_{11}O_{39}]$,[38] $[(C_4H_9)_4N]_4H_x[PW_{11}M(H_2O)O_{39}]\cdot nH_2O$, M^{II} = Co, Ni, $x = 1$, $n = 1-2$; M^{III} = Fe, $x = 0$, $n = 0$.[38] The general procedure described in ref.[38] was also used to prepare $[(C_4H_9)_4N]_4[PW_{11}Mn^{III}(H_2O)O_{39}]$.

$[(C_4H_9)_4N]_4H_4[SiW_{11}O_{39}]$, $[(C_4H_9)_4N]_4H_2[SiW_{11}M(H_2O)O_{39}]\cdot nH_2O$, $n = 1-2$; M^{II} = Co, Ni, $[(C_4H_9)_4N]_4H[SiW_{11}M(H_2O)O_{39}]$, M^{III} = Fe, Mn, were obtained from potassium salts using a procedure adapted from the literature.[66] The potassium compounds of $SiW_{11}M$ (or SiW_{11}) were prepared by reported methods.[20,50,53,67] An aqueous solution of the potassium salt (0.5 mmol in 30 mL) and a solution of TBABr in 1,2-dichloroethane (4 mmol in 45 mL) were mixed and vigorously stirred. The organic phase was then collected and the 1,2-dichloroethane removed by evaporation. The so-obtained oil was then dissolved in acetonitrile (ca.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

20 mL) and the resultant tetrabutylammonium compound was precipitated by the addition of the minimum amount of water.

$[(C_4H_9)_4N]_7H_3[M_4(H_2O)_2(PW_9O_{34})_2]$, M^{II} = Co, Mn. An aqueous solution of the potassium salt[41,68] of the $M_4(PW_9)_2$ anion (2.7 mmol in 270 mL) and a solution of TBABr (42 mmol) in an identical volume of 1,2-dichloroethane were prepared and the polyoxoanion was extracted into the organic phase. A second organic extract was collected by a further addition of TBABr organic solution. The organic extracts were then left to evaporate and the so-formed crystals were filtered off and washed with water.

The TBA salts of $SiW_{11}M$ (or SiW_{11}) and $M_4(PW_9)_2$ were re-crystallised in acetonitrile. Dissolution in the minimum amount of acetonitrile followed by the addition of water (with vigorous stirring) then afforded pure samples of TBA compounds.

*P**,*N*-Bidentate Amino Phosphoramidites: New Highly Effective Ligands for Pd-Catalysed Asymmetric Allylic Substitution

Konstantin N. Gavrilov,*[a] Vasily N. Tsarev,[b] Alexei A. Shiryaev,[a] Oleg G. Bondarev,[c] Sergey E. Lyubimov,[a] Eduard B. Benetsky,[a] Alexander A. Korlyukov,[b] Mikhail Yu. Antipin,[b] Vadim A. Davankov,[b] and Hans-Joachim Gais[c]

Keywords: Asymmetric catalysis / *P*,*N*-ligands / Allylation / Palladium / Rhodium

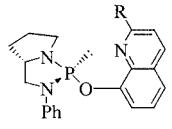
New chiral *P**,*N*-hybrid amino phosphoramidites have been obtained by one-step phosphorylation of amino alcohols. Complexation of the new ligands with $[Rh(CO)_2Cl]_2$ and $[Pd(allyl)Cl]_2$ gave the corresponding chelate complexes $[Rh(CO)Cl(\eta^2\text{-P,N})]$ and $[Pd(allyl)(\eta^2\text{-P,N})]^+BF_4^-$, which subsequently afforded up to 90% *ee* in the asymmetric Pd-catalysed sulfonylation of 1,3-diphenyl-2-propenyl acetate with sodium *p*-toluenesulfinate. In the enantioselective alkylation of 1,3-diphenyl-2-propenyl acetate with dimethyl malonate, up to 98% enantioselectivity was achieved with $[Pd(allyl)(\eta^2\text{-P,N})]^+BF_4^-$ complexes as chiral catalysts.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

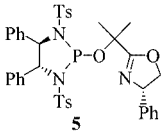
Chiral ligands with three P−O and/or P−N bonds have become increasingly important because of their synthetic availability, high π-acidity of the phosphorus atom, high resistance to oxidative destruction,[1−3] and their low cost. For example, BINOL-based monophosphites, which are highly efficient in asymmetric hydrogenation, are only 2% of the price of the well-known diphosphane BINAP.[4] Further modified heterobifunctional chiral phosphites, especially *P*,*N*-bidentate ones, have been applied to good effect in a wide range of catalytic processes, such as Cu-catalysed conjugate addition, Ir-catalysed hydrogenation and Rh-catalysed hydrosilylation.[1−3,5,6] In Pd-catalysed allylic substitution, work has concentrated mainly on nonsymmetric and sterically hindered substrates,[5−9] with only moderate results for the most common test substrate, 1,3-diphenyl-2-propenyl acetate (**1**, Scheme 1).[10]

Thus, pyridinophosphite ligands derived from (*S*)-BINOL provided product **2** with an enantioselectivity of up to 37%,[11,12] and phosphitooxazolines based on (*S*)- or (*R*)-BINOL afforded up to 43% *ee*.[13] Even more modest results − less than 31% *ee* − were delivered by the quinoline-derived phosphite ligands based on (*R*)-BINOL, (1*R*,2*R*)-*N*,*N*′-dimethyl-1,2-diphenylethylene-1,2-diamine, *N*-methylephedrine, (1*R*,2*R*)-1,2-bis(methylamino)cyclohexane, and (*S*)-prolinol.[14] The most effective *P*,*N*-bidentate ligands applied so far in the Pd-catalysed allylic substitution of **1** with dimethyl malonate are the compounds **4**−**6**.



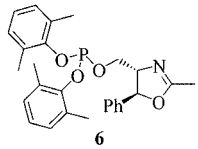
4 QUIPHOS (R=H)

85% *ee*[14-16]



5

88% *ee*[7]



6

85% *ee*[17]

Notably, variation of R did not increase the enantioselectivity of ligand **4**.[14] Thus, more effective phosphite ligands are still needed. Indeed, the only phosphite ligands used in asymmetric allylic sulfonylation (Scheme 1) appear to be the phosphitooxazolines **7** and **8** recently reported by us.[18,19] They delivered up to 92% *ee* in the synthesis of **3**, which is very close to the efficiency of Helmchen's phosphanyloxazolines.[20]

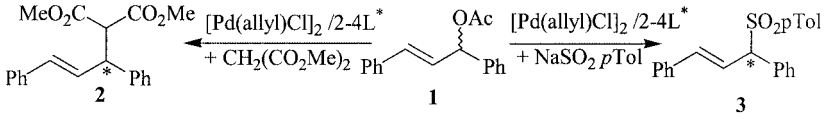
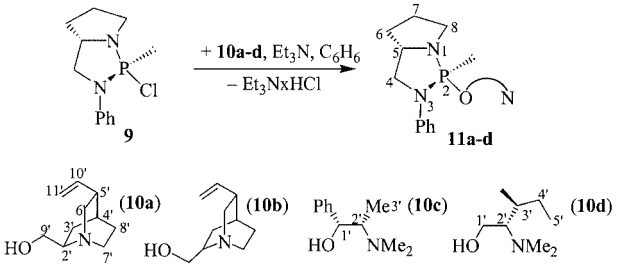


Scheme 1

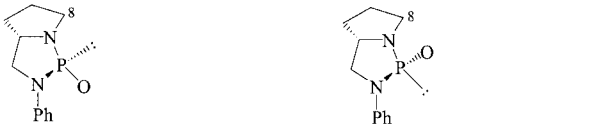
Results and Discussion

The novel *P*,*N*-ligands were synthesized through the one-step phosphorylation of appropriate amino alcohols **10a**−**d** with (2*R*,5*S*)-2-chloro-3-phenyl-1,3-diaza-2-phosphabicyclo-[3.3.0]octane (**9**) (Scheme 2).



Scheme 2

Compounds **11a**−**d** are both stable and very soluble in common organic solvents. The synthesis is highly stereoselective, yielding only epimers with exocyclic substituents at the phosphorus atom in a pseudo-equatorial location. Therefore, the *P**-stereocenter has an (*R*) absolute configuration, which is proved by the characteristic[16,19] $^2J_{C\text{-}8,P}$ coupling (34.3−38.5 Hz) in the ^{13}C NMR spectra of **11a**−**d** (see Table 2 and Exp. Sect.). The magnitude of $^2J_{C\text{-}8,P}$ seems to be strongly controlled by the dihedral angle associated with the lone-pair orbital of the phosphorus atom and C-8.[21]



cis-location of C(8) and phosphorus lone pair; $^2J_{C(8),P} \sim 40$ Hz

trans-location of C(8) and phosphorus lone pair; $^2J_{C(8),P} \sim 0$ Hz

The pseudo-equatorial location of exocyclic functions was previously found for ligands **4**,[16] **8**,[19] and for (*S*)-prolinol-based phosphacyclanes.[21,22] According to the ^{31}P NMR spectroscopic data (Table 1), from ligands **11a**−**d**, only **11d** contains some minor stereoisomer with an (*S*) configuration of the *P**-stereocenter.

Complexation of **11a**−**d** with $[Rh(CO)_2Cl]_2$ and [Pd(allyl)Cl]$_2$ (in the presence of $AgBF_4$) produced neutral and cationic metal *cis*-chelates, respectively (Scheme 3).

Thus, the $^1J_{P,Rh}$, $^1J_{C,Rh}$, $^2J_{C,P}$ and ν(CO) data for complexes **12a**,**c**,**d** (Tables 1 and 2) agree well with the suggested structures (see ref.[8] and refs. cited therein); ν(CO) and $^1J_{P,Rh}$ are sensitive indicators that allow us to estimate the π-acceptor ability of the phosphorus center and the degree of electronic nonsymmetry of *P*,*N*-ligands.[8,9,23] Accordingly, amino phosphoramidites **11a**−**d** are intermediate between amino phosphanes and amino phosphites.[6,24]

Besides chelate product **12d**, the reaction of **11d** with $[Rh(CO)_2Cl]_2$ afforded the *trans*-$[Rh(CO)Cl(\eta^1\text{-}L)_2]$ complex, where the ligands are coordinated in a *P*-monodentate manner. The complex clearly exhibits the characteristic doublet peak δ_P = 123.8 ppm, $^1J_{P,Rh}$ = 176.8 Hz (46%) in the ^{31}P NMR spectrum. Such side-products have been observed several times and arise from the sterically hindered nitrogen atom, which impedes chelation.[8,9,19]

In complex **12a**, the quinuclidine nitrogen atom is coordinated to the rhodium atom, as witnessed by the significant (up to 4 ppm) coordination shifts $\Delta\delta_C = \delta_C(\text{complex}) - \delta_C(\text{ligand})$ observed for C-2′, C-6′, and C-7′ (Table 2). Similar $\Delta\delta_C$ values have been observed for chelate Rh^I complexes with quincoridine-derived phosphites.[25] The large $^2J_{C\text{-}8,P}$ values in complex **12a** (19.7 Hz) clearly indicate that the quinuclidyl substituent is in a pseudo-equatorial position and, therefore, that the *P** atom had an (*R*) absolute configuration. This conclusion, and other findings on the structure of **12a**, agree well with the X-ray analysis data of its monocrystal. Thus, in the crystal of **12a** two independent molecules are characterized by (*S*) and (*R*) configurations of asymmetric N(1′) and P(2) atoms (without taking into account the formal priority of the metal atom). In one independent molecule, the phospholidine cycle has a twist conformation with deviations of C(4) and C(5) atoms of 0.27 and 0.20 Å, respectively, while in a second independent molecule this cycle is characterized by a slightly distorted envelope conformation with a deviation of N(3) of 0.29 Å. The pyrollidine cycles have envelope conformations [C(7) atoms deviate by 0.58 Å on average] with the phenyl substituent in a pseudo-equatorial position. The quincoridine substituent occupies a pseudo-equatorial position as related to the phospholidine cycle. In turn, the rhodium atom occupies an axial position.

Similarly to the compound described in ref.[16], the phosphorus atom in **12a** has a tetrahedral configuration (the sum basal N−P−O and N−P−N angles are 302 and 298°, respectively). The N(1)−P(2)−O(1) and N(3)−P(2)−O(1) angles are about 2−3° less than the analogous ones in ref.[16] The elongation of P−N bonds by up to 0.02 Å compared to those in ref.[16] may due to a *trans* effect of the chlorine substituent.

The rhodium atom has almost ideal square-planar coordination, with an average deviation from the mean plane of 0.02 Å. The bond lengths of coordination polyhedra of the rhodium atom are close to those in rhodium and palladium complexes with *P,N*-bidentate aryl phosphites[8] (Figure 1).

The principal structural difference between the two independent molecules is the geometry of the six-membered metallacycles, which are characterized by a distorted boat conformation. The C(2′) and P(2) atoms in the first molecule deviate from the basal plane by 0.62 and 0.50 Å, and C(2′A) and P(2A) in the second molecule deviate by 0.32 and 0.60 Å, respectively. Previously investigated rhodium and palladium complexes with the same type of coordination polyhedra have six-membered metallacycles with a chair conformation. However, the introduction of the bulky ferrocenyl moiety near the six-membered metallacycle[8] changed this conformation to a distorted boat. Thus, the distorted boat conformation of the metallacycles in **12a** can be attributed to steric overcrowding caused by the massive 1-azabicyclo[2.2.2]octane and 1,3-diaza-2-phosphabicyclo-[3.3.0]octane moieties.

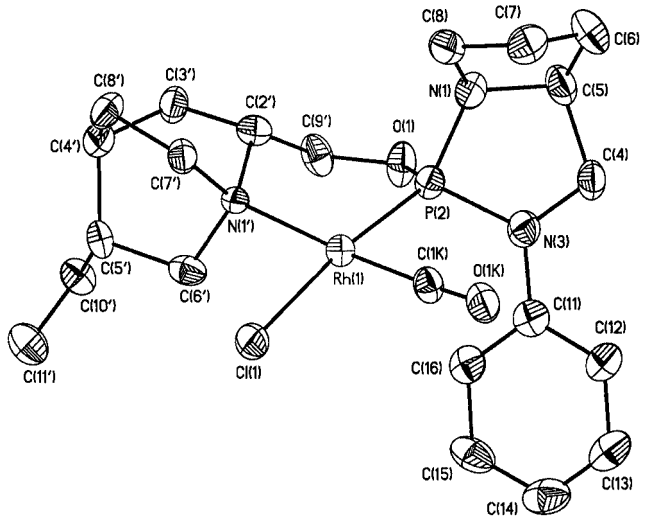

Figure 1. General view of one of the two independent molecules of **12a**; atoms are presented as thermal ellipsoids drawn at 50% probability level; selected averaged bond lengths [Å] and angles [°]: Rh(1)−P(2) 2.176(2), Rh(1)−Cl(1) 2.408(2), Rh(1)−N(1′) 2.174(6), Rh(1A)−C(1 K) 1.826(9), C(1 K)−O(1 K), O(1 K)−C(1 K) 1.11(1), P(2)−N(1) 1.656(8), P(2)−N(3) 1.706(7); P(2)−Rh(1)−C(1 K) 85.5(3), Cl(1)−Rh(1)−C(1 K) 89.4(3), Cl(1)−Rh(1)−N(1 K) 90.7(2), Cl(1)−Rh(1)−P(2) 172.29(8), N(1′)−Rh(1)−C(1 K) 176.0(3), N(1)−P(2)−N(3) 93.0(4)

Cationic palladium chelates **13a**−**d** are stable in air and very soluble in common organic media. There are two sets of peaks in the ^{31}P NMR spectra of **13a**, **13c**, and **13d** (Table 1), which indicate the existence of the *exo* and *endo* isomers of the compounds. Two peak sets are not seen for complex **13b**, because of either the fast interconversion of isomers or the absence of one of them (see refs.[8,9] and references cited therein).

Amino amidophosphites **12a**−**d** and the isolated complexes **13a**−**d** were tested in asymmetric Pd-catalysed allylic substitution processes (Scheme 1). For allylic sulfonylation (Table 3) moderate chemical (up to 66%) and good optical (up to 90% *ee*) yields of product **3** were achieved. For ligand **11a**, the enantioselectivity does not depend on the L*/[Pd] ratio (Entries 1−3). We suppose that the active catalytic particle here is represented by a cationic chelate $[Pd(allyl)(\eta^2\text{-}P,N)]^+X^-$ (X^- = Cl^-, BF_4^-). Indeed, its singlet peak δ_P = 125.0 ppm (28%) was found in the ^{31}P NMR spectrum of the $[Pd(allyl)Cl]_2$/4L* (L* = **11a**) solution in $CHCl_3$, together with signals of uncoordinated **11a** (δ_P = 122.9 ppm) and $[Pd(allyl)(\eta^1\text{-}P,N)(\eta^2\text{-}P,N)]^+Cl^-$ (AX system: δ_P = 100.3 ppm and δ_P = 61.4 ppm, $^2J_{P,P}$ = 87.7 Hz). With ligand **11d**, the L*/[Pd] ratio also did not influence the catalytic outcome (Entries 12,13,15). In contrast, when the ratio **11b**/[Pd] was increased from 1:1 to 2:1, the enantioselectivity improved sharply from 39 to 76% *ee* (Entries 4, 5). Most probably, here the palladium complex containing two molecules of the ligand possesses high catalytic activity

14	$[Pd_2(dba)_3] \times CHCl_3$	**11d**	1:1	15	20 (*S*)
15	**13d**		1:1	40	83 (*S*)

[a] Measured by HPLC [(*R*,*R*)-Whelk-01].

and is very stereoselective. In addition, a considerable counterion effect was observed for complexes with ligand **11b** (Entries 4, 7).[26]

As all the variations in the structures of both the N-containing fragment and the carbon bridge between the P and N atoms did not cause considerable changes in enantioselectivity, the catalytic performance of ligands **11a−d** is mostly determined by the bicyclic chiral phosphorus block.

With $[Pd_2(dba)_3] \times CHCl_3$ as a catalytic precursor, generally inferior results were obtained. For ligands **11c** and **11d** the enantioselectivity dropped very sharply (Entries 10, 14), and even a product with reversed absolute configuration was produced in one case (Entry 10).

Application of pre-formed palladium complexes **13a−d** in asymmetric allylic alkylation resulted in excellent chemical and optical yields (Table 4). The enantioselectivity of the reaction demonstrates a strong dependence on both the solvent (Entries 3 and 4) and the structure of the amino alcohol block (Entries 1 and 3). Comparison of the results (under identical reaction conditions) for sulfonylation (Table 3, Entries 3, 7, 11, 15) and for alkylation (Table 4, Entries 1, 3, 5, 7) reveals that the right choice of nucleophile is important in achieving high level of enantioselectivity in allylic substitution reactions.

Table 4. Enantioselective allylic alkylation of **1** with dimethyl malonate

Entry	Catalyst precursor	Solvent	Conv. [%][a]	*ee* [%][b]
1	**13a**	THF	> 99	95 (*S*)

8	**13d**	**CH_2Cl_2**	**92**	**98 (*S*)**

[a] Measured by HPLC. [b] Determined by HPLC analysis using a Daicel Chiralcel OD-H column.

The enantioselectivity obtained with ligands **11a−d** in the Pd-catalysed allylic alkylation of **1** with dimethyl malonate (98% *ee*) is the highest reported for chiral phosphite ligands and approaches the best overall results.[5,6,10]

Experimental Section

General Remarks: All reactions were performed under argon in dehydrated solvents. IR spectra were recorded with a Specord M80 or Nicolet 750 instrument. ^{31}P and ^{13}C NMR spectra were recorded with a Bruker AMX 400 instrument (162.0 MHz for ^{31}P, 100.6 MHz for ^{13}C). Complete assignment of all the resonances in ^{13}C NMR spectra was achieved with DEPT techniques. Chemical shifts (ppm) are given relative to Me_4Si (^{13}C NMR) and 85% H_3PO_4 (^{31}P NMR). Mass spectra were recorded with a Kratos MS890 spectrometer (EI), an MSVKh TOF spectrometer with ionization by Cf-252 fission fragments (plasma desorption technique, PD), and an AMD 402 spectrometer (FAB). Elemental analyses were performed at the Laboratory of Microanalysis (Institute of Organoelement Compounds, Moscow). $[Rh(CO)_2Cl]_2$,[27] $[Pd(allyl)Cl]_2$,[28] $[Pd_2(dba)_3] \times CHCl_3$,[29] amino alcohol **10d**,[30] and (2*R*,5*S*)-2-chloro-3-phenyl-1,3-diaza-2-phosphabicyclo[3.3.0]-octane (**9**)[19] were synthesized by published procedures. Complexes **12a** and **13a−d** were synthesized by techniques similar to that reported.[9] Rhodium complexes **12c**,**d** were synthesized for the ^{31}P NMR and IR experiments in $CHCl_3$ medium analogously to the known procedures.[8] Compound **10c** was purchased from Aldrich and dried in vacuo (2 Torr, 3 h) immediately before use. Amino alcohols **10a**,**b** (quincoridine and quincorine, Buchler GmbH) and **10d** were azeotropically dried with benzene and distilled before use.

Synthesis and Characterization

Preparation of Ligands. General Technique: A solution of (2*R*,5*S*)-2-chloro-3-phenyl-1,3-diaza-2-phosphabicyclo[3.3.0]octane (**9**) (1 g, 4.2×10^{-3} mol) in benzene (15 mL) was added dropwise to a stirred solution of the appropriate amino alcohol **10a−d** (4.2×10^{-3} mol) and Et_3N (0.6 mL, 4.2×10^{-3} mol) in the same solvent (15 mL) at 0 °C. The reaction mixture was then heated to boiling point, allowed to cool, stirred at 50 °C for 1 h, allowed to cool to room temperature and then filtered. The solvent was removed in vacuo (40 Torr), and the residue was dissolved in hexane (25 mL), filtered, concentrated and dried in vacuo (1 Torr, 2 h).

(2*R*,5*S*,2′*R*,4′*S*,5′*R*)-3-Phenyl-2-[(5′-vinyl-2′-quinuclidyl)methoxy]-1,3-diaza-2-phosphabicyclo[3.3.0]octane (11a): Colourless oil, 1.41 g (91% yield). MS (EI, 70 eV): *m*/*z* (%) = 371 (29) $[M]^+$, 289 (50), 221 (34), 205 (100), 197 (72), 136 (91). $C_{21}H_{30}N_3OP$ (371.2): calcd. C 67.90, H 8.14, N 11.31; found C 68.24, H 8.35, N 11.17.

(2*R*,5*S*,2′*S*,4′*S*,5′*R*)-3-Phenyl-2-[(5′-vinyl-2′-quinuclidyl)methoxy]-1,3-diaza-2-phosphabicyclo[3.3.0]octane (11b): Colourless oil, 1.391 g (90% yield). MS (EI, 70 eV): *m*/*z* (%) = 371 (30) $[M]^+$, 289 (48), 221 (34), 205 (100). $C_{21}H_{30}N_3OP$ (371.2): calcd. C 67.90, H 8.14, N 11.31; found C 68.17, H 8.28, N 11.20.

[Pd(allyl)(11d−P⌒N)]$^+BF_4^-$ (13d): Beige solid, 0.220 g (94% yield). MS (FAB): *m*/*z* (%): 496 (8) $[M - BF_4]^+$, 455 (5), 128 (100). $C_{22}H_{37}BF_4N_3OPPd$ (583.2): calcd. C 45.27, H 6.39, N 7.20; found C 45.51, H 6.23, N 7.33.

Crystallographic Data for 12a: Crystals of $C_{22}H_{30}ClN_3O_2PRh$ are monoclinic, space group $P2_1$, *a* = 8.410(3) Å, *b* = 11.557(4) Å, *c* = 23.267(8) Å, *V* = 2261.1(14) $Å^3$, *Z* = 4, *M* = 537.82, $d_{calcd.}$ = 1.580 $g·cm^{-3}$, μ(Mo-K_α) = 9.68 cm^{-1}, *F*(000) = 1104. Intensities of 13120 reflections were collected at 120 K with a SMART CCD 1000 diffractometer using Mo-K_α radiation (λ = 0.71072 Å, ω-scans with 0.3° step and 10 s exposure for each frame) and 8058 independent reflections (R_{int} = 0.0365) were used in further refinement. An absorption correction was applied semi-empirically from equivalents. The structure of **12a** was solved by direct methods and refined by a full-matrix techniques against F^2 in anisotropic approximation using the SHELXTL-97 5.1 program package[31]. The positions of hydrogen atoms were calculated geometrically and included in the refinement using the rigid body approximation. The refinement converged to wR_2 = 0.1238 and *GOF* = 1.020 for all independent reflections [R_1 = 0.0567 was calculated for 6829 observed reflections with $I > 2\sigma(I)$]. The absolute configuration was determined by use of the Flack parameter. CCDC-215598 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information: ^1H NMR spectroscopic data for compounds **11a−d** and the catalytic experimental procedures are provided (see also footnote on the first page of this article).

Acknowledgments

Flexidentate Behaviour of 2-Pyridylsulfonamides − Direct Electrochemical Synthesis and Spectroscopic and X-ray Characterisation of Neutral Copper(II) Complexes of *N*-(2-Pyridyl)sulfonamides

Inmaculada Beloso,[a] Joaquín Borrás,[b] Jesús Castro,*[a] José A. García-Vázquez,[c] Paulo Pérez-Lourido,[a] Jaime Romero,[c] and Antonio Sousa*[c]

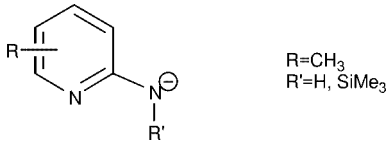
Dedicated to the memory of Professor D. G. Tuck

Keywords: Copper / S ligands / Electrochemical synthesis / N ligands

Copper complexes with potentially bidentate *N*-(2-*p*yridyl)-sulfonylamide ligands have been synthesised by the electrochemical oxidation of the metal in an acetonitrile solution of the neutral amide and additional bidentate N–N coligands. The compounds have been characterised by microanalysis and EPR, vibrational and electronic spectroscopy. In representative cases the structures were also determined by X-ray diffraction methods. Various coordination behaviour is found for the ligands, which act in a *N*,*N*′-bidentate or *N*,*O*-bidentate manner, the latter giving abnormally short Cu–O bonds. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

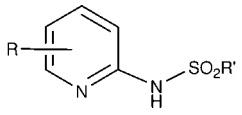
Introduction

Metal complexes containing amide ligands are of great recent interest[1−4] because they are easily made, and the substituents can be readily amended so as to tune their bite angle and steric hindrance. The chemistry of metal complexes containing pyridine-functionalised amido ligands of the type shown in Scheme 1 has received much attention.[5−9] The bulky substituents on these ligands stabilise the metal complexes.



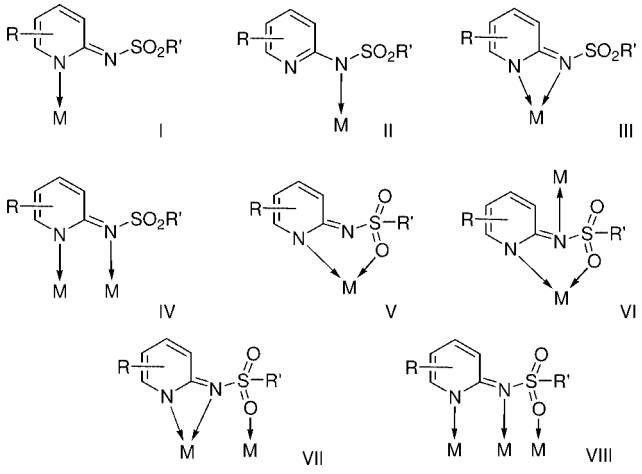
Scheme 1

Consequently, it was decided to study the chemistry of the metal complexes of sulfonyl-2-pyridine-amines. These ligands, Scheme 2, contain a bulky sulfonyl group as a substituent of the exocyclic nitrogen atom. In addition, its electron-withdrawing effect increases the acid character of the NH group and makes ligand deprotonation easier.[4]



Scheme 2

These ligands can coordinate to the metal in several different ways (Scheme 3).



Scheme 3

Coordination modes I and II have been found in zinc compounds. For complexes showing coordination mode I, a weak interaction between the metal and the exocyclic nitrogen atom is present,[10] while mode II exhibits a weak interaction between the zinc and the pyridine nitrogen atom.[11] Coordination mode III is the most common, and has been found in cobalt(II),[12] nickel(II),[13] and cadmium(II)[14,15] complexes. Coordination mode IV has only been found in copper(II)[9] and silver(I)[9,16] complexes, and coordination mode V has only been found in zinc(II)[11] and cadmium(II)[15] complexes. Coordination modes VI and VII have been found in a polymer compound of cadmium(II)[14] and the coordination mode VIII only occurs in silver(I) complexes.[16]

Coordination mode IV appears to have only been found with copper(II) and silver(I). When the ligand has no substituent on the pyridine ring (R = H) the compound is dinuclear.[9] To check if the nuclearity and the coordination mode could be modified, we introduced a methyl group at position 3 or 6 on the pyridine ring to determine the influence of the steric hindrance produced by such substitution on the coordination of the pyridine and the sulfonamide nitrogen atoms. Substitution at position 4 does not influence the coordination mode and a dinuclear compound is again obtained.[16] Therefore, and to continue similar studies on Zn^{II} [11] and Cd^{II},[15] we report here the electrochemical synthesis and characterisation of several heteroleptic copper(II) complexes with a number of benzenesulfonyl-2-pyridineamide ligands. The pyridine ring contains one methyl group and the benzene ring also contains one methyl group (*p*-toluene group) or, alternatively, three methyl groups (mesitylene group) (Scheme 4).

Results and Discussion

Anodic oxidation of copper metal in a non-aqueous solution containing a weakly acidic ligand alone or as a mixture with a coligand, such as 2,2′-bipyridine (bipy) or 1,10-phenanthroline (phen), yields the products $[CuL_2H_2O]$ or $[CuL_2L']$, respectively, were L is the deprotonated form of the parent ligand and L′ the coligand (i.e. bipy or phen) (see Exp. Sect.). The compounds are obtained by air concentration of the resulting solution as green air-stable crystalline products. They are insoluble in water and in most common organic solvents.

The electrochemical efficiency, defined as the amount of metal dissolved per number of Faradays, was close to 1.0 $mol \cdot F^{-1}$ in all cases. This fact, along with the evolution of hydrogen at the cathode, is compatible with a reaction mechanism involving the anodic oxidation to copper(I) and the deprotonation of the ligand at the cathode.

Anode: $Cu + L^- \rightarrow [CuL] + e^-$

Cathode: $HL + e^- \rightarrow L^- + 1/2\ H_2$

$[CuL] + HL + L' \rightarrow [CuL_2L'] + 1/2\ H_2$

The oxidation of copper(I) by another HL molecule has been observed in other electrochemical processes involving copper anodes.[17]

Description of the Structures

The crystal and molecular structures of several complexes and the ligand HMs3mepy have been determined by single crystal XRD. The crystal data are collected in Tables 12 and 13.

Structure of HMs3mepy

HMs3mepy crystallizes in the monoclinic *C*2/*c* space group, $Z = 4$, and consists of molecules of [(2,4,6-trimethylphenyl)sulfonyl]imino-1*H*-3-methyl-2-pyridine associated two-by-two by intermolecular hydrogen bonds established between the pyridine nitrogen atom of one molecule and two sulfonamide oxygen atoms, one of which forms an intramolecular contact while the other is involved in an intermolecular contact with a neighbouring molecule. The imine nitrogen is not implicated in these bonds. This arrangement contrasts with the hydrogen network found in HTspy[13] and HTs6mepy,[15] where the hydrogen bonds involve the N_{py} and the $N_{sulfonamide}$ atoms. The methyl group in position 3 of the pyridine ring precludes the use of the $N_{sulfonamide}$ atom with HTs3mepy for steric reasons. This explanation is supported by the observed ligational mode of HTs3mepy (vide infra).

The structure of HTs3mepy and the atomic numbering scheme (Figure 1), and selected bond lengths and angles and hydrogen bond parameters (Table 1 and Table 2), are given here.

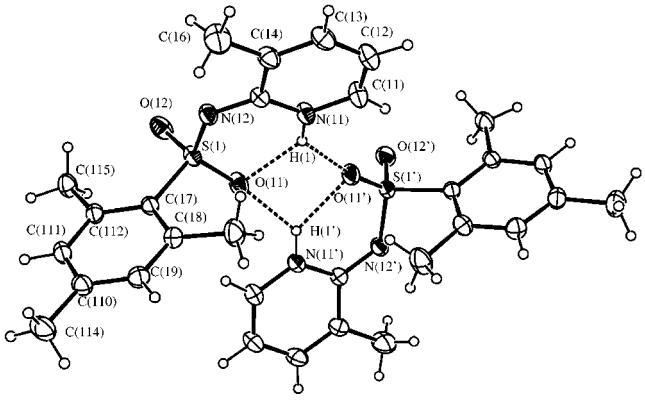

Figure 1. Structure of HMs3mepy

The bond lengths and bond angles are similar to those in other *N*-2-pyridinyl benzenesulfonamide derivatives.[11,13,15] The hydrogen atom on the *N*-pyridine ring shows that the free ligand is the imido tautomer (I) rather than the amido

Structure of [Cu(Ts3mepy)$_2$H$_2$O]

This compound crystallizes in the monoclinic $P2_1/c$ space group, $Z = 4$. Its structure is shown in Figure 2 together with the atomic numbering scheme.

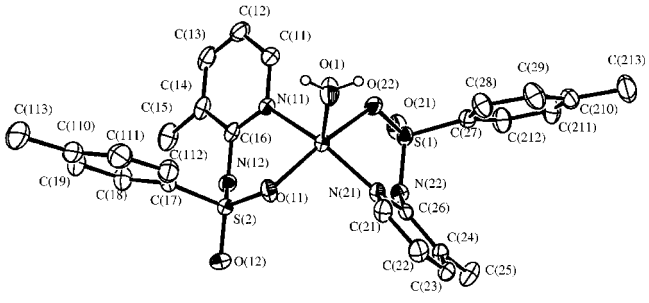

Figure 2. Molecular structure of [Cu(Ts3mepy)$_2$H$_2$O]

The crystal structure can be described as discrete molecules of [Cu(Ts3mepy)$_2$H$_2$O] associated by intermolecular interactions. The hydrogen atoms of the coordinated water molecule are involved in hydrogen bonds with the amide nitrogen atoms that are not coordinated to the metal in such a way that infinite chains are formed parallel to the *b* axis (Figure 3). Selected bond lengths and angles are given in Table 3 and Table 4.

The copper atom is coordinated by a molecule of water and two monoanionic (*N*,*O*)-bidentate ligands through the nitrogen of the pyridine ring and one oxygen atom of a sulfonic group. The sulfonamide nitrogen atoms are 3.039(2) and 3.093(2) Å, respectively, away from the copper atom, and so they are not bonded. Consequently, the coordination around the metal can be described as [CuN$_2$O$_3$]. This is quite surprising as sulfonyl oxygen atoms are not good donors, and copper(II) complexes containing ligands bonded through the sulfonamide oxygen donors are scarce.[18,19] The environment around the central atom is square pyramidal with a very small distortion towards a

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

trigonal bipyramidal geometry ($\tau = 0.07$).[20] The apical position of the pyramid is occupied by the oxygen atom of the water molecule and the base consists of an (N_2O_2) arrangement in a *trans* disposition. This base is almost planar (*rms* = 0.0353). The copper atom is 0.2273(11) Å above the plane.

The Cu−N bond lengths are in the normal range found for $Cu-N_{py}$ bonds.[4,21] However, the Cu−O bonds [$Cu-O_{water}$ = 2.160(2); Cu−O(11) = 2.0018(18) and Cu−O(22) = 2.0130(18) Å] are unusually short for such O-donor atoms.[21,22] Firstly, the apical $Cu-O_{water}$ in pentacoordinate copper complexes are normally much longer than the Cu−O bonds in the basal plane.[23,24] In addition, the $Cu-O_{sulfonamide}$ bond is the shortest found so far in sulfonamide copper complexes.

Structures of the Complexes [Cu(Ts3mepy)$_2$bipy], [Cu(Ts3mepy)$_2$phen], [Cu(Ms3mepy)$_2$bipy] and [Cu(Ts3mepy)$_2$phen]

Complexes [Cu(Ts3mepy)$_2$bipy] and [Cu(Ts3mepy)$_2$phen] crystallize in the triclinic $P\bar{1}$ space group, $Z = 2$. Complexes [Cu(Ms3mepy)$_2$bipy] and [Cu(Ms3mepy)$_2$phen] crystallize in the monoclinic $P2_1/c$ space group, $Z = 4$. The compounds consist of discrete molecules without relevant intermolecular interactions.

The molecular structures are shown in Figures 4−7, together with the atomic numbering schemes. Selected bond lengths and angles are given in Table 5.

In all the compounds, one of the sulfonamide ligands behaves in a (*N*,*O*)-bidentate manner and the other one is *N*-monodentate. The coligand (2,2-bipyridine or 1,10 phenanthroline) acts as an (*N*,*N*′)-bidentate ligand. The different

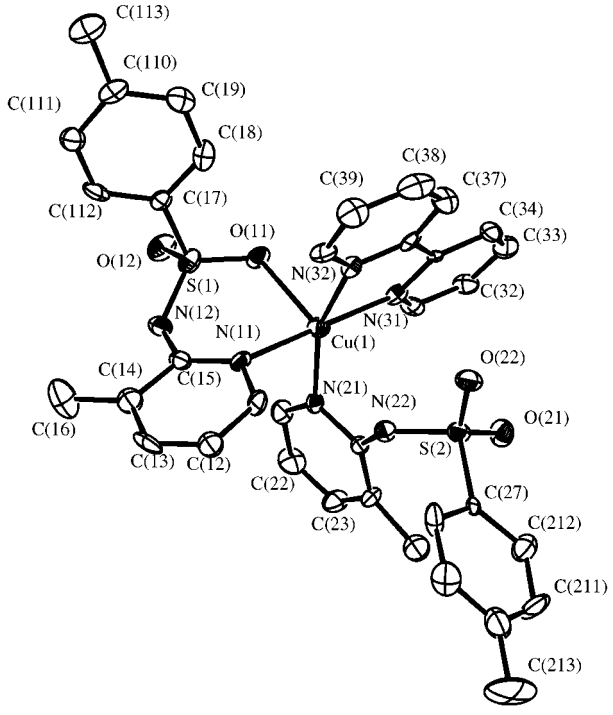

Figure 4. Molecular structure of [Cu(Ts3mepy)$_2$bipy]

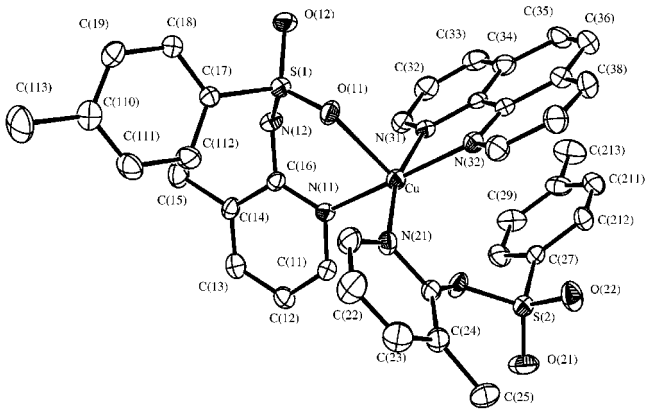

Figure 5. Molecular structure of [Cu(Ts3mepy)$_2$phen]

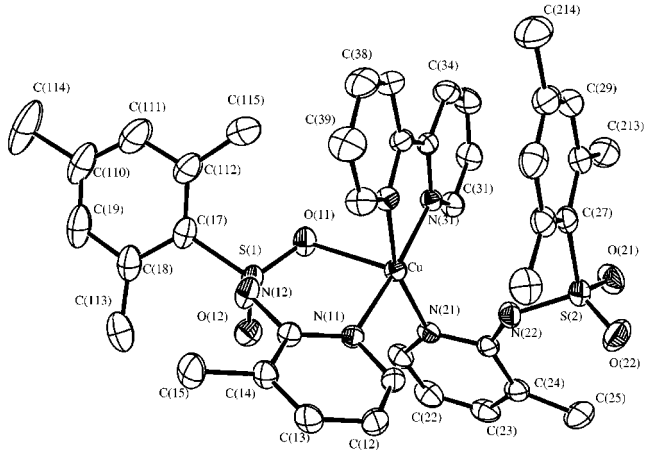

Figure 6. Molecular structure of [Cu(Ms3mepy)$_2$bipy]

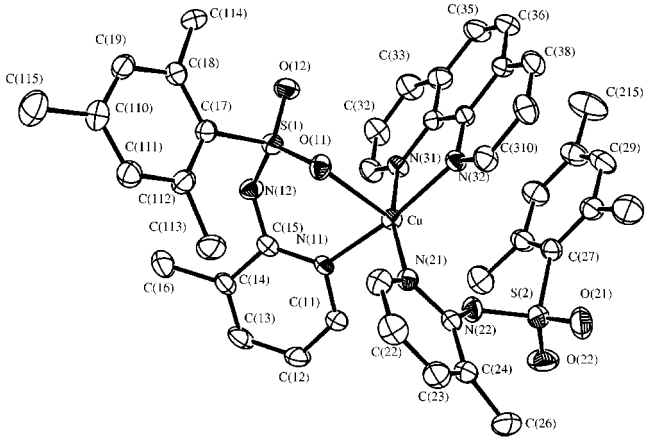

Figure 7. Molecular structure of [Cu(Ms3mepy)$_2$phen]

coordination behaviour of the two tosylamide ligands is the most significant feature of the structures.

The copper atom is in a pentacoordinate environment with four Cu−N bonds close to 2.0 Å, Cu−O bonds ranging from 2.209(6) to 2.291(2) Å and with another $Cu-N_{sulfonamide}$ interaction, not considered as a bond, ranging from 2.592(7) Å for [Cu(Ts3mepy)$_2$bipy] to 2.726(3) Å for [Cu(Ms3mepy)$_2$phen] (Table 5).

The coordination polyhedron is best described as square pyramidal with a distortion towards a trigonal bipyramidal

between 12 and 28% (τ = 0.12−0.28, see Table 6).[20] The oxygen atom occupies the apical position of the pyramid and the four nitrogen atoms of the three ligands form the basal plane. The copper atoms lies 0.203(2), 0.122(2), 0.114(1), and 0.069(2) Å out of this basal plane, respectively.

The Cu−N bond lengths are as expected for such complexes and do not warrant further comment. However, the Cu−O bonds [2.209(6) to 2.291(2) Å], although slightly longer than in [Cu(Ts3mepy)$_2$H$_2$O], are shorter than the Cu−O(apical) distances normally found in copper(II) square-pyramid complexes.[18,23] This distance is remarkable since the sulfonamide groups are not good O-donors.

Complexes [Cu(Ts3mepy)$_2$bipy] and [Cu(Ts3mepy)$_2$phen] crystallize in the same space group, but their molecular arrangements are different due to a twist around the S(2)−N(22) bond (Figure 4 and Figure 5). Thus, in [Cu(Ts-3mepy)$_2$phen], the planes of the 1,10-phenanthroline and the benzene ring of the monoanionic monodentate sulfonamide ligand are almost parallel, with a dihedral angle of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

5.3(2)° and distances between rings of 3.471(7) Å. This disposition produces an intramolecular π,π-stacking interaction that stabilises the structure.[24] This interaction does not seem to be present at an intermolecular level. Some short distances between rings are indicated in Table 7.

Conversely, complexes [Cu(Ms3mepy)$_2$bipy] and [Cu(Ms3mepy)$_2$phen] crystallize in the same space group, $P2_1/c$, and a intramolecular π,π-stacking interaction is found in both cases; the dihedral angles between rings are 3.2(1) and 1.41(8)°, respectively. However, the complexes are not identical, showing differences related to the spatial position of the mesitylene group, which is directed towards the π,π-stacking axis, or is twisted outward (Figure 8). Other parameters are also indicated in Table 7.

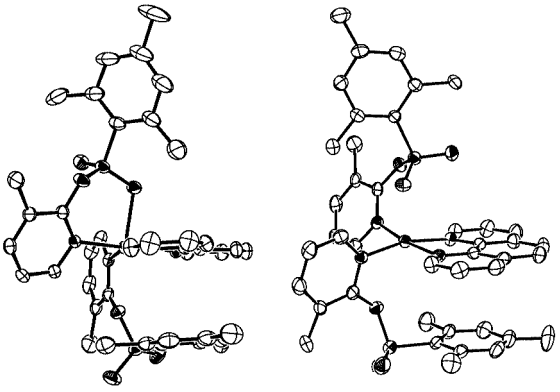

Figure 8. Spatial differences between [Cu(Ms3mepy)$_2$bipy] (left) and [Cu(Ms3mepy)$_2$phen] (right)

Structure of [Cu(Ms6mepy)$_2$phen]

This compound crystallizes in the triclinic $P\bar{1}$ space group with two chemically equivalent molecules in the asymmetric unit. Only one of the molecules is represented in Figure 9 (together with the atomic numbering pattern). Selected bond lengths and angles are given in Table 8.

The coordination behaviour of the anionic ligands in this complex is quite different from the other systems described here as the sulfonamide anionic ligands behave as (*N*,*N*)-bidentate ligands. A neutral 1,10-phenanthroline molecule acting as an (*N*,*N*)-donor completes the coordination sphere of the metal. Consequently, the coordination polyhedron around the copper(II) is best described as a highly distorted octahedron, CuN_6. There are several sources of distortion: Two Cu−N bond lengths are longer than the others, with a maximum of 2.506(5) Å. In addition, the anionic ligands form a four-membered chelate ring with angles of only 58.1(2) to 61.5(2)°. The theoretical equatorial plane is also highly distorted in that the dihedral angle between the planes formed by the central atom and the donors $N_{phen}-Cu-N_{phen}$ and $N_{py}-Cu-N_{py}$ is 32.66° [average values for the two molecules: 33.85(26) and 31.48(38)°].

Once again, significant intramolecular π,π stacking stabilisation is produced between the 1,10-phenanthroline unit and the benzene rings of the two sulfonamide ligands. This interaction does not seem to continue on an intermolecular level. The dihedral angles between the rings involved in this interaction are ∠6.2(4)° (average 3.6°). The centres of the three rings are ca. 3.704 and 3.651 Å apart. Some short distances between rings are indicated in Table 9.

Spectroscopic and Magnetic Studies

The IR spectra of the complexes do not show the band attributable to ν(N−H), which in the free ligand appears at 3248−3222 cm^{-1}. This change confirms that the hydrogen atom of the amide group is lost during electrolysis. The bands in the spectra of the ligands in the range 1594−1612 cm^{-1}, due to the ν(C=N) absorption, appear in similar po-

sitions in the complexes except when the ligands Ts6mepy$^-$ and Ms6mepy$^-$ are present, in which case the bands are shifted to lower frequencies due to coordination through the sulfonamide nitrogen atom. The bands of the ligands at 1338−1369 cm^{-1}, attributable to ν_{as}(S =O), are also seen for the complexes with Ts3mepy$^-$ and Ms3mepy$^-$ but in these cases they are shifted to slightly lower frequencies due to the coordination.

In addition, the IR spectra of the mixed complexes show absorptions that are typical of coordinated 2,2′-bipyridine (764 and 736 cm^{-1}) and 1,10-phenanthroline (1520, 850, and 720 cm^{-1}).

The electronic reflectance spectrum of the pentacoordinate complex [Cu(Ts3mepy)$_2$H$_2$O] shows a very broad band, probably a multicomponent band, at 15800 with a shoulder at ca. 11800 cm^{-1}, a situation in accord with a pseudo-square planar pyramidal environment forming a [CuN$_2$O$_3$] chromophore.[25]

The electronic reflectance spectra of [Cu(Ts3mepy)$_2$phen], [Cu(Ts3mepy)$_2$bipy], [Cu(Ms3mepy)$_2$phen], and [Cu(Ms3mepy)$_2$bipy] show two broad bands in the range 16300−15900 cm^{-1} and 12300−10600 cm^{-1}. This is similar to the spectra of copper(II) complexes involving a [CuN$_4$O] chromophore.[26]

The electronic reflectance spectrum of [Cu(Ms6mepy)$_2$phen] shows two bands at 14430 and 10955 cm^{-1}, which are similar to those found for [Cu(Ms6mepy)$_2$bipy], [Cu(Ts6mepy)$_2$bipy], and [Cu(Ts6mepy)$_2$phen], suggesting an octahedral [CuN$_6$] chromophore for all these compounds.[27]

The magnetic moments at room temperature are close to 1.8 B.M. in all cases, as expected for d^9 systems.

The X-band spectra of polycrystalline samples of the complexes were recorded at room temperature. Table 10 show the EPR parameters of the ternary complexes obtained by simulation.[28] As an example, Figure 10 shows both the obtained and simulated EPR spectrum of [Cu(Ms6mepy)$_2$phen].

All the spectra are axial with similar EPR parameters so that it can be predicted due to the similarity of the sulfonamide ligands and the bipy and phen. Bertini[29] has suggested that $A_{\|}$ may be a measure of the coordination polyhedron around copper(II). Accordingly $A_{\|}$ from 120 to 150 G indicates a square-pyramidal geometry while values of 160−200 G correspond to a square planar or six-coordinate stereochemistry. The $A_{\|}$s of[Cu(Ts3mepy)$_2$(H$_2$O)], [Cu(Ts3mepy)$_2$bipy] and [Cu(Ms3mepy)$_2$bipy] suggest a square-pyramidal arrangement, in agreement with their crystal structures. The $A_{\|}$s of [Cu(Ms6mepy)$_2$phen] indicate a six-coordinate geometry, which agrees with the crystal structure. The complexes [Cu(Ts3mepy)$_2$phen] and [Cu(Ms3mepy)$_2$phen] are in the limit between the pentacoordinate and the six-coordinate environment; their crystal structures both show a distorted square-pyramidal geometry. From the $A_{\|}$s of [Cu(Ms6mepy)$_2$bipy] we propose a six-coordinate around copper(II). Similar conclusions were obtained from the spectroscopic data.

Conclusion

The most important feature of these complexes is the coordinative behaviour of the anionic ligand and the presence or absence of π,π-stacking (Table 11).

The ligands behave in a (*N*,*O*) bidentate way with a substituent at position 3. However, for a substituent in position

6, they behave in a (*N*,*N*) bidentate way. Probably, the difference can be traced to a steric effect. A substituent in position 3 pushes the sulfonyl group towards the metal, and induces (*N*,*O*) bidentate behaviour.

In addition, when the coligand is 1,10-phenanthroline the third ring allows a π,π-stacking, either with the toluene ring or the mesytilene ring. When the coligand is 2,2′-bipyridine, π,π-stacking is only produced when the benzene ring is substituted by three methyl groups. This could be due to the electron-releasing effect of the three methyl groups in the ring, together with the increasing size of the group.

Experimental Section

Acetonitrile, dichloromethane, 2-amino-3-picoline, 2-amino-6-picoline, *p*-toluenesulfonyl chloride, 2-mesitylenesulfonyl chloride, 2,2′-bipyridine, 1,10-phenanthroline monohydrate, sodium carbonate, magnesium sulfate, and all other reagents were commercial products and were used as supplied. Copper (Aldrich) was used as 2 × 2 cm plates.

Preparation of the Ligands

Ligands were prepared by reaction of the corresponding amine and the sulfonyl chloride in a 1:1 ratio. Details are given for a representative example.

HMs3mepy: An aqueous solution of sodium carbonate (1.95 g, 18.4 mmol in 20 mL) was added dropwise to a solution of 2-amino-3-picoline (2.0 g, 18.4 mmol) and 2-mesitylenesulfonyl chloride (4.05 g, 18.4 mmol) dissolved in dichloromethane. The reaction mixture was then stirred overnight and water (100 mL) was added. The organic layer was then separated and dried over anhydrous magnesium sulfate. The solvent was evaporated and the crude product, an oil, was treated with ethanol. The resulting white solid was isolated by filtration and identified as HMs3mepy; yield 16.7%. $C_{15}H_{18}N_2O_2S$ (%): calcd. Preparation of Complexes. General Procedure: The complexes were obtained by an electrochemical procedure.[30] The cell consisted of a tall-form beaker (100 mL) fitted with a rubber bung through which the electrochemical leads entered. An acetonitrile solution of either the ligand or the ligand/coligand (1,10-phenanthroline·monohydrate or 2,2′-bipyridine) mixture containing tetraethylammonium perchlorate (ca. 20 mg) as electrolyte was electrolysed using a platinum wire as the cathode and a copper plate as the sacrificial anode. Direct current was supplied by a purpose-built d.c. power supply. The applied voltages (5−15 V) allowed sufficient current flow for smooth dissolution of the copper metal. The current was maintained at 10 mA for one hour. In all cases, hydrogen was evolved at the cathode. These cells can be summarised as $Cu_{(+)}/CH_3CN + HL + L'/Pt_{(-)}$ where L′ is 2,2′-bipyridine or 1,10-phenanthroline.

After one hour of electrolysis, the resultant clear green solutions were filtered to remove any particles of metal and then left to concentrate. This procedure afforded crystalline products in good yield. The solids were then washed with acetonitrile and diethyl ether and dried at room temperature.

[Cu(Ts3mepy)$_2$H$_2$O]: Electrochemical oxidation of a copper anode in a solution of the ligand *N*-(3-methyl-2-pyridyl)-*p*-toluenesulfonamide, (0.19 g, 0.75 mmol) in acetonitrile (50 cm^3), at 12 V and

8.0; found C 59.7, N 10.4, H 5.2, S 7.8. IR (KBr, cm^{-1}): 3443 (m), 2931 (w), 1598 (s), 1457 (s), 1343 (s), 1251 (m), 1125 (s), 1083 (m), 843 (m), 768 (w), 732 (w), 671 (w), 587 (w), 535 (w).

[Cu(Ms6mepy)$_2$phen]: By a similar procedure (15 V, 10 mA, 1 h), HMs6mepy, (0.22 g, 0.75 mmol) and 1,10-phenanthroline (0.07 g, 0.37 mmol) in acetonitrile (50 cm^3) led to the dissolution of metal (25 mg), E_f = 1.05 mol·F^{-1}. $C_{42}H_{42}CuN_4O_4S_2$ (%): calcd. C 61.1, N 10.2, H 5.2, S 7.8; found C 60.8, N 10.1, H 5.2, S 7.6. IR (KBr, cm^{-1}): 3445 (m), 2931 (w), 1594 (m), 1519 (w), 1457 (m), 1344 (m), 1250 (w), 1124 (s), 1082 (m), 845 (m), 722 (w), 689 (w), 588 (w), 533 (w).

Physical Measurements: The C, N, H, and S contents of the compounds were determined on a Carlo−Erba EA 1108 microanalyser. IR spectra in the solid state were recorded as KBr mulls on a Bruker Vector-22 spectrophotometer. The ^{1}H NMR spectra of the ligands were recorded on a Bruker ARX-400 MHz spectrometer using $CDCl_3$ as solvent. Solid-state electronic spectra were recorded on a Shimadzu UV 3101 PC. Magnetic measurements were made using a DMS VSM 1160. EI (70 eV, 250 °C), and LSI mass spectra were recorded on a VG Autospec-M Micromass, using 2-nitrobenzyl alcohol (2-NBA) as matrix material. EPR measurements on solid samples were recorded on a Bruker EMX spectrometer, using frequencies between 9400 and 9800 MHz (X-band).

X-ray Crystallographic Study: Data collections were taken on a SIEMENS Smart CCD area-detector diffractometer with graphite-monochromated Mo-K_α radiation. Absorption corrections were carried out using SADABS.[31]

All the structures were solved by direct methods and refined by full-matrix least-squares based on F^2.[32] All non-hydrogen atoms were refined with anisotropic displacement parameters. For HMs3mepy the hydrogen atoms (except those of the methyl groups) were located on a difference electron density map and refined with isotropic displacement parameters. For the complexes, hydrogen atoms were included in idealised positions and refined with isotropic displacement parameters, except for those of the water molecule of [Cu(Ts3mepy)$_2$H$_2$O], which were located and refined with isotropic displacement parameters. Atomic scattering factors and anomalous dispersion corrections for all atoms were taken from International Tables for X-ray Crystallography.[33] Details of crystal data and structural refinements are given in Tables 12 and 13.

CCDC 187516 and 209128−209133 contain the supplementary crystallographic data for this paper. Glycosyl-Curcuminoids as Potential New Chelating Agents in Iron Overload Chelation Therapy

Beatrice Arezzini,[a] Marco Ferrali,[a] Erika Ferrari,[b] Romano Grandi,[b] Stefano Monti,[b] and Monica Saladini*[b]

Keywords: Chelates / Iron / Gallium / Redox chemistry / Bioinorganic chemistry

The iron(III) chelating ability of some glycosyl derivatives of curcuminoids is tested by means of UV, potentiometric and NMR studies. The pK_a of the ligands and the stability constants of their Fe^{3+} and Ga^{3+} complexes are evaluated by UV spectroscopy. The only metal binding site of the ligand is the β-dioxo moiety; the glycosyl moiety does not interact with the metal ion at acidic pH values but it helps to stabilise metal/ligand (1:2) complexes by means of hydrophilic interactions. By comparing the pFe^{3+} of our ligands with those reported for other chelating agents we suggest using these molecules as pro-drugs in iron overload treatment. Some of the more water-soluble derivatives are also tested for their antioxidant properties "in vitro" in biological systems and proved to act as free-radical scavengers inhibiting the iron redox cycle.

Introduction

Iron regulation in the human body follows complex mechanisms that tend to limit external exchange and make the re-utilisation from internal sources more efficient. However, although essential for the proper functioning of living cells, iron is toxic when present in excess. In the presence of oxygen, "loosely bound iron" is able to switch between its two more stable oxidation states (Fe^{3+}/Fe^{2+}), thereby generating hydroxyl radicals and favouring the so-called "Fenton Chemistry".[1,2] In healthy individuals, iron levels are under tight control and there is little or no opportunity for iron-catalysed free radical generating reactions. However, there are situations where the iron status can change, either locally, as in ischaemic tissue, or systematically, as with genetic haemochromatosis or transfusion-induced iron overload, as for patients suffering from β-thalassemia. So it is intuitively derived that metal — in this particular case iron — intoxication should be treated with chelating agents.

The main feature of the design of a chelating agent for iron should be its affinity and selectivity towards this metal. The most widely used iron chelator is Desferrioxamine B (Desferal®, DFO), a hexadentate ligand from the family of siderophores that shows great affinity for iron(III), giving rise to a 1:1 complex. The main drawback of DFO, apart from side effects with prolonged treatment, is that it has to be administered by intravenous injection. Consequently, there is an urgent need for an orally active chelating agent able to improve the way of life of patients.

The main target in designing an orally active sequestering agent is its bio-availability, which is related to an efficient gastrointestinal tract (GIT) absorption. The ligand needs to be quite lipo-soluble in order to be absorbed by the gastrointestinal tract, although this property also enables it to penetrate critical barriers such as the blood-brain barrier (BBB) and the blood-placental barrier (BPB). A possible way to overcome the negative aspects of lipophilicity is to use a lipophilic pro-drug that is easily absorbed by the GIT and reach the bloodstream, where it can be cleared by the liver and finally converted into an iron-selective chelator in the hepatocytes. The complex formed by iron scavenging inside the hepatocytes can be excreted by bile and/or urine.

Curcumin is spice and pigment from *Curcuma longa* L. (Zingiberaceae) and it is best known for its antioxidant,[3–6] anti-inflammatory[4,7] and anticancer[3,4,8,9] activities. We have recently investigated the iron-chelating ability of curcumin and its diacetyl derivative (Scheme 1), observing a lowering of the pK_a value of the β-dioxo moiety in the presence of iron(III), and the formation of mixed hydroxo species ($[Fe(CURH_2)(OH)_2]$ and $[Fe(DCUR)(OH)_2]$) in a methanol/water (1:1) solution, whose stability is close to that of the Desferrioxamine complex. The main drawback in the clinical use of curcumin is its low water solubility. To overcome this handicap, we have synthesised new glycosyl

derivatives (Scheme 1). Apparently hexadentate ligands are the best iron chelators, and a recent study on a hydroxypyridinone derivative CP502 has shown good oral absorption and iron excretion, even though it is bidentate.[17] Glycosyl-curcuminoids have the great advantage of being administrated by oral formulation in their acetylated form, and even though their high molecular weight hinders the diffusion processes through the GIT, high dosages are completely safe. Acetyl-glycosyl-curcuminoids can probably be absorbed by the GIT thanks to their high lipophilicity. They then reach the liver where, through hydrolytic processes, the glycosyl-curcuminoids are set free to complex iron and then excreted in urine and/or bile.

Here we investigate by means of spectroscopic (UV/Vis and potentiometric) techniques the iron(III) and gallium(III) chelating ability of these ligands; NMR spectroscopic data are also useful in studying the metal complexation, therefore we substituted the paramagnetic iron(III) with diamagnetic gallium(III) as suggested in some recent works.[10−12] Some of the water-soluble derivatives were also tested for their antioxidant properties "in vitro" in a biological system.

Results and Discussion

Potentiometry

The low water solubility of compounds **1**−**6** ($\leq 5 \times 10^{-5}$ M) prevented the potentiometric analysis of these systems. The greater solubility of **7** (approx. 5×10^{-3} M) allowed us to perform a potentiometric study and the evaluated data are reported in Tables 1 and 2, together with the spectrophotometric data. Potentiometric analysis gives more accurate results than the other techniques but the stability constants' values are very similar to those calculated from the UV data, therefore we may consider spectrophotometric analysis a reliable probe in testing the chelating ability of slightly water soluble systems.

UV/Vis Spectroscopy

Glycosyl-curcuminoids, similarly to curcuminoids, maintain their dye properties — they are all characterised by an absorbance at ca. 400 nm.

Upon plotting absorbance vs. pH, only one equivalent point is observed for each ligand; the pK_a values calculated from the spectrophotometric data are reported in Table 1. The presence of the sugar moiety does not affect the pK_{a1} value, while some electronic effect is due to the substituents on the aromatic ring: the electron-withdrawing effect of OH groups stabilizes the conjugate base, lowering the pK_{a1} value, and as a consequence ligand **5** is the most acidic one in aqueous solution.

The addition of an iron(III) solution to the free ligands causes an LMCT[13] band to appear at ca. 500 nm, typical of (β-diketonate)Fe^{3+} complexes, and by monitoring the changes in the spectra upon progressive addition of Fe^{3+} solution, the stoichiometry of the complexes can be proposed.

Figure 1 shows the absorbance increase with the M/L molar ratio, which reaches a maximum at an M/L value of 0.5, corresponding to an M/L (1:2) complex. Once the 1:2 complex has formed no more significant changes in ab-

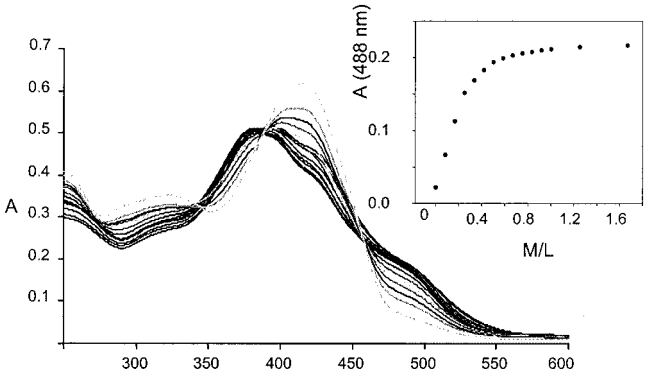

Figure 1. Spectrophotometric titration of **5** with Fe^{3+} solution and plot of absorbance vs. M/L at λ = 488 nm

sorbance are seen for the LMCT band, probably due to the small difference in the spectrophotometric curves of the 1:1 and 1:2 complexes. The addition of metal solution, causing a reduction in the pH value from 5 to 3, induces the formation of complex species even at a pH of about 3. The same experiments were carried out under buffered conditions (pH = 7), where the only difference is the increased intensity of the LMCT band. No differences were found in logβ values when taking into account the formation of a phosphate complex as its stability ($\log K[FeHL]^+ = 7.5$[14]) is significantly lower than those of our complexes.

Titration of the ligands with Ga^{3+} solution generates the same behaviour as observed in the presence of Fe^{3+}.

The pH-metric titration of the metal complexes was performed in aqueous solution for the glycosyl derivatives, while for the **3**/Fe^{3+} system a methanol/water (1:1) solution was used due to the poor solubility of the ligand in aqueous media. No hint of metal complex or metal hydroxide precipitation was observed.

The pH-metric titration of all L/Fe^{3+} (1:1) systems gives a typical UV spectral pattern and a plot of λ_{max} vs. pH, or *A* vs. pH at fixed λ gives a titration curve with two equivalent points (EP; Figure 2). The first EP (pH ≈ 4) is due to the deprotonation of the β-dioxo moiety, although it is several pH units lower than normal thanks to the great affinity for Fe^{3+}. The second one is probably due to the cleavage of

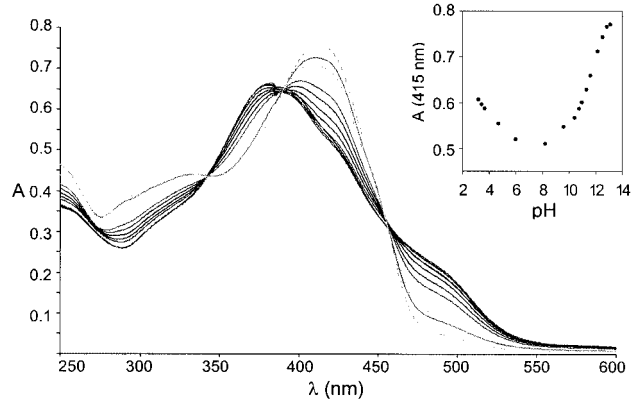

Figure 2. Spectrophotometric titration of a **7**/Fe^{3+} (1:1) system with NaOH and plot of absorbance vs. pH at λ = 415 nm

the metal complex under extremely basic conditions (pH > 10) and to the competition of hydroxide anions in metal complexation, although in **3**- and **5**-containing systems the involvement of dissociated catechol groups in metal coordination cannot be excluded.

The pH-metric titration of Ga^{3+}-glycosyl-curcuminoids parallels well the performance in the presence of Fe^{3+}.

The stability constants for Fe^{3+} and Ga^{3+} complexes are reported in Table 2. Comparison of the behaviour of glycosyl-curcuminoids with those of the parent curcuminoids shows that the former prefer M/L (1:2) complexes despite the steric hindrance of the saccharide units. This is because of the polar/non-polar character of the molecule. In aqueous solution the apolar core is tightly bound to the metal ion while the polar units form hydrophilic interactions (especially hydrogen bonds), giving a more stable structure and hindering the metal ion from coordinating additional ligands such as oxygen, therefore probably inhibiting oxidative processes.

In order to compare stability constants relative to the same kind of equilibrium, they need to be corrected by considering the ligand's protonation constants. It is more useful to consider the species distribution to understand which is the prevailing species under physiological conditions. In Figures 3−5 the species distribution curves for **7**/Fe^{3+}-, **5**/Fe^{3+}- and **3**/Fe^{3+}-containing systems are reported.

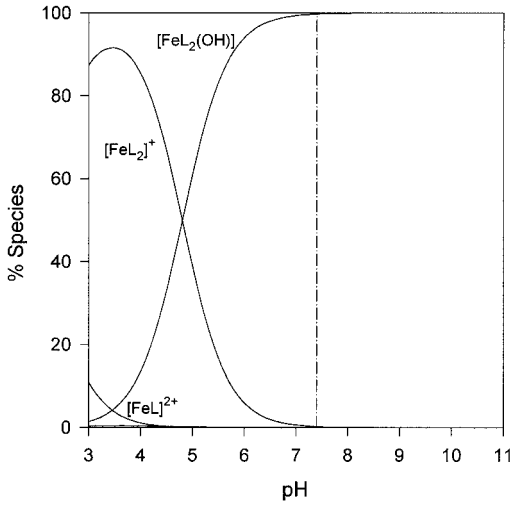

Figure 3. Species distribution curves for Fe/L systems in a 1:4 molar ratio; $[Fe^{3+}] = 5 \times 10^{-5}$ M, L = **7**

The prevailing species at physiological pH (7.4) have different stoichiometries for the three classes of ligands reported. Therefore a more proper comparison of the effective Fe^{3+}-chelating ability is represented by pFe^{3+}, defined as $-\log[Fe^{3+}]$.[15] This value is usually calculated with [L] = 10^{-5} M and $[Fe^{3+}] = 10^{-6}$ M, and, unlike stability constants, takes into account the effects of ligand protonation and denticity as well as differences in metal/ligand stoichiometry. A plot of pFe^{3+} versus pH provides a useful method for comparing the ability of chelators to bind iron(III) at different pH values as a high value of log*K* is not necessarily characterised by a high value of pFe^{3+}. Figure 6

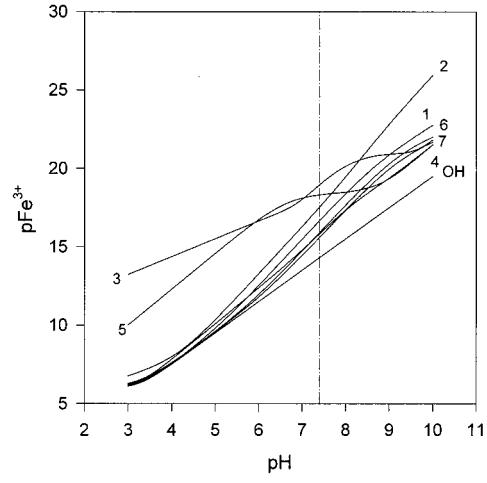

Figure 6. pFe^{3+} vs. pH for curcuminoids and glycosyl-curcuminoids; $[Fe^{3+}] = 10^{-6}$ M, [L] = 10^{-5} M; OH stands for Fe^{3+} aqueous solution

shows the plot of pFe^{3+} vs. pH for the curcuminoids and glycosyl-curcuminoids investigated in this work. Compounds **3** and **5** show the highest pFe^{3+} values at physiological and acidic conditions, despite their low $\log K_{a1}$ values; this behaviour may be due to the presence of phenolic functions that play an important role in the hydrogen bond network involving water molecules, and furthermore they are possibly involved in metal interactions. Table 3 shows the pFe^{3+} for different chelating agents. Notice how hexadentate ligands usually have higher pFe^{3+} values than bidentate one.

NMR Study

All spectra of glycosylated ligands are characterised by a sharp distinction between the pyranoside moiety and the aliphatic and aromatic ones; of particular interest are the protons on the double bond and the enolic proton, although the latter is quite mobile and tends to exchange in MeOD solution with D_2O. Gallium(III) can properly substitute iron(III) for the NMR study.[11−13] The study of its interactions in solution is useful in order to understand both the real chelating site and the stoichiometry of the complexes.

Titration of a solution of **5** with Ga^{III} (Figure 7) indicates the formation of new signals, in slow exchange on the NMR timescale, upon increasing the M/L molar ratio. The titration was performed without any buffer, since little changes are observed in the pH values (ca. 0.5 pH units). The formation of the new sets of signals is not a consequence of the pH decreasing induced by hydrolysis of Ga^{III}, but it is more reasonably attributed to the formation of complex species.

On increasing the Ga^{III} concentration the first kind of complex is formed; all of the ligand is complexed when the ratio mol of metal/mol of ligand is 0.5, therefore a 1:2 stoichiometry can be proposed for this species. The greatest downfield shift is for the 4-H signal; 4-H probably "feels" the positive charge in the resonance structure of the bis-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

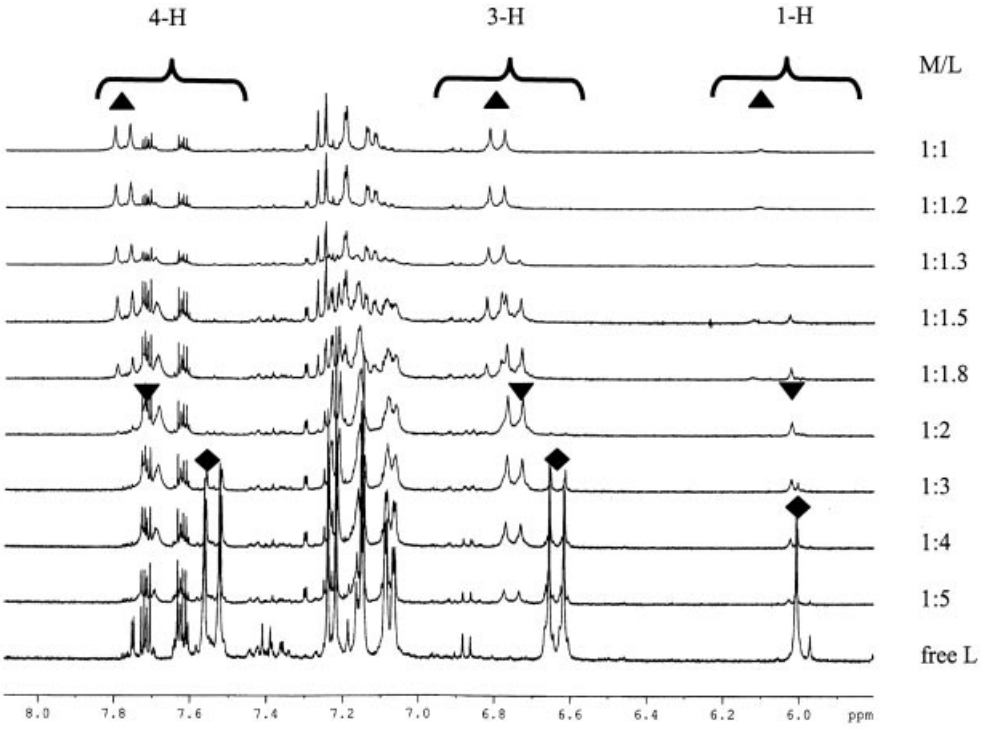

Figure 7. ^{1}H NMR titration of **5** with $Ga(NO_3)_3$ in MeOD solution; diamonds: free ligand signals; downward pointing triangles: M/L (1:2) complex signals; upward pointing triangles: M/L (1:1) complex signal

(chelate) complex, while a smaller shift is seen for the 3-H signal. Because of exchange processes with residual D_2O, the signal for 1-H is quite broad, making it difficult to follow its shift. Another important aspect of this titration is that the pH* value on the methanol scale is very low (ca. 2.5), and no addition of base is necessary to form the complexes, thus all these complex species are also present under very acidic conditions, and the affinity for metal ion is so high that it anticipates enolic deprotonation until pH* $\approx$ 3.

Upon increasing the quantity of metal further, the M/L (1:1) complex is formed. Its signals are more downfield shifted than those of the 1:2 complex, and this behaviour is in line with a more localised positive charge at the metal centre in the 1:1 complex than in the 1:2 complex. In line with the behaviour of curcumin, the phenolic groups in **5** do not interact with the metal ion, at least under the very acidic conditions that prevent catechol dissociation. Small changes are found for the aromatic protons due to the delocalisation of the metal charge along the aliphatic chain and aromatic rings. Finally, no evidence of an interaction between the sugar moiety and metal ion is observed by NMR spectroscopy in acid media, although we cannot exclude a possible glycoside interaction with the metal ion under physiological conditions, as reported in the literature in the solid state.[16−18]

The carbon atoms parallel the protons' behaviour. 2D inverse detection methods show a greater shift of the C-4 signal (δ = 4 ppm) followed by the C-3 signal (δ = 2 ppm) in the 1:1 complex, while in the 1:2 complex smaller shifts are observed.

Attempts to titrate the 1:1 complex solution with NaOH resulted in precipitation of the metal complex.

All glycosyl-curcuminoids share the same behaviour, confirming that the substituents on the aromatic rings and the nature of the sugar do not affect the metal coordination.

Effect of the Chelators on Lipid Peroxidation

Figure 8 shows the time-dependent formation of TBARS as a hint of iron-dependent lipid peroxidation in rat liver microsomes. Notice that the presence of the chelators **3** and **5** interferes — although to different extents — with the lipid peroxidation evolution. In particular, compound **3** almost completely inhibits TBARS formation even if it is present in the incubation mixture at one half or the same concentration as that of the metal. On the other hand, compound **5** completely prevents microsomal lipid peroxidation only when present at a concentration twice that of iron. As a consequence, compound **5** seems to prevent TBARS formation only when the M/L (1:2) complex is formed, while compound **3** is active independently of the complexation stoichiometry. This is due to the catecholic structure of compound **3**, which possibly also acts as a free-radical scavenger when iron is present in excess compared to the chelator. It therefore seems to have a double action: it blocks oxygen-active species generated by the iron redox cycle and inhibits its initiation in the iron-chelated form. Since compound **5** is a galactosyl ester of compound **3** it is possible that under in vivo conditions, after galactosidase action, it acquires the same properties as **3**. In conclusion, both compound **3** and its derivative esters appear to be useful anti-

oxidants preventing lipid peroxidation both in vitro and, presumably, in vivo.

Experimental Section

General: Compounds **4**−**7** were synthesised as reported in ref.[19], while compound **3** was synthesised according to the Pabon reaction.[20] $FeCl_3$ was used to avoid hydrolysis processes; standardisation of the stock methanolic solution was performed with a Spectroflame D ICP plasma spectrometer.

Potentiometry: Potentiometric measurements were performed in aqueous solution at 25 ± 0.1 °C according to the general procedures previously reported.[21] A constant ionic strength of 0.1 M (solid $NaNO_3$) and nitrogen gas were maintained in all experiments. The stability constants were refined with the Hyperquad program[22] taking into account the presence of $[Fe(OH)]^{2+}$ and $[Fe(OH)_2]^{+}$ species.[16] The protonation constant of the ligand was determined by the titration of 5×10^4 M solutions. The ligand/Fe system was investigated in 1:1, 1:2 and 1:4 molar ratios. Aqueous NaOH (5×10^{-3} M) was used as titrant in the pH range 3−10.

Spectroscopy: Spectrophotometric titrations were performed using a Perkin−Elmer Lambda 20 spectrophotometer at 25 ± 0.1 °C in the 200−600-nm spectral range, employing a 1-cm quartz cell. 2.5×10^{-5} M solutions of ligands **4**−**7** were investigated in aqueous solution while **3** was used in methanolic/aqueous (1:1, v/v) media; pH values were adjusted by adding small amounts of concentrated NaOH. In the titrations of **3** the glass electrode was calibrated using two appropriate buffers (pH = 5.57 and 8.02).[23] Constant additions (10 μL each time) of Fe^{III} solution (10^{-2} M) were performed using a micropipette in order to reach different M/L molar ratios. All the titrations were done also in a buffer solution (pH = 7.4, NaH_2PO_4/Na_2HPO_4). The pH-metric titration of the M/L (1:1) solutions was obtained varying the pH value by adding a small amount of concentrated NaOH. The protonation constants of the ligands and formation constants of metal complexes were evaluated from spectrophotometric titrations using the pHab2000 software.[24] ^1H NMR spectra were obtained with a Bruker Avance AMX-400 spectrometer at 400.13 MHz with a 5-mm broadband probe (inverse detection). Acquisition parameters were as follows: spectral bandwidth 17 ppm, pulse width 7.6 μs (90° pulse), pulse delay 1 s, number of scans 216−512. H,H COSY,[25] HMQC[26,27] and HMBC[28] were performed with typical averaged parameters: $^1J_{H,C} = 145$ Hz and $^3J_{H,C} = 7$ Hz, typical delay for inversion recovery optimised to give null for protons bound to ^{12}C, in BIRD sequence, is around 400 ms. The spectra of the ligands were recorded for mM solutions in CD_3OD, since their signals in D_2O solution were so broad that they could not be assigned, probably due to the formation of aggregate species. The combined electrode was standardised with CH_3OH buffers (pH = 5.79 and 7.53), pD values were then corrected by 0.4 units according to the relationship: pD = pH + 0.4.[25] All spectra were collected at 25 ± 0.1 °C and referenced to TMS. A solution of Ga^{III} was prepared by dissolving 2.5 mg of $Ga(NO_3)_3 \cdot 9H_2O$ in 0.1 mL of CD_3OD. Equimolar solutions of **3**−**7** in the same solvent were prepared. Constant additions (10 μL each time) of Ga^{III} solution were performed using a micropipette, the mixture was stirred and spectra were registered after a few minutes from the addition.

Biological Studies: Rat liver microsomes (MC) were prepared from fasted animals.[29] MC equivalent to 4 g of liver were resuspended in 36 mL of 50 mM trimaleate buffer (TM, pH = 7.4). The suspension was adjusted to 3 mg of microsomal protein per mL and 300 μM NADPH added just before the experimental procedure. A solution of 5 mM ADP plus 200 μM $FeCl_3$ was prepared in the same buffer. Solutions of ligands **3** and **5** (20 mM) in water/ethanol were prepared. To 3 mL of the microsomal suspension 0.6, 1.2, 2.4 μmol of the two chelators were added in separate flasks; then 3 mL of the ADP/iron solution was added and the incubation started at 37 °C in a shaking bath. After the indicated times, aliquots were withdrawn to measure the amount of TBARS formed.[30]

Kinetics and Mechanism of Axial Ligand Substitution of Alkyl Cobaloximes by Substituted Pyridines in Different Solvents

Basam M. Alzoubi,[a] Mohamed S. A. Hamza,[a,b] Alessandro Felluga,[c] Lucio Randaccio,[c] Giovanni Tauzher,[c] and Rudi van Eldik*[a]

Keywords: Cobaloximes / Solvent effects / *trans* effect / Ligand-substitution reactions / Nitrogen heterocycles

Ligand-substitution reactions of *trans*-RCo(Hdmg)$_2$S (where R = $PhCH_2$ or CF_3CH_2, Hdmg = dimethylglyoximate, and S = H_2O or MeOH) were studied for the nucleophiles 4-aminopyridine (4-NH_2Py), pyridine (Py) and 4-cyanopyridine (4-CNPy). From the pressure and temperature dependence of the substitution of methanol by 4-NH_2Py, Py, and 4-CNPy, the activation parameters $\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta V^{\neq}$ were estimated for the cases where R = $PhCH_2$ and CF_3CH_2. The activation parameters for the substitution of H_2O by Py and 4-CNPy in the case where R = CF_3CH_2 were also found. The kinetic data and activation parameters show that the dissociative character of the reaction decreases on changing the R group from $PhCH_2$ to CF_3CH_2 and the solvent from MeOH to H_2O.

Introduction

The study of the chemical and physical properties of organocobalt compounds, which serve as models for vitamin B_{12}, is of interest both to inorganic and bioinorganic chemists. Various pseudo-octahedral organometallic complexes of Co^{III}, containing equatorial ligands such as dioximes,[1−9] imino groups/oximes[10] and Schiff bases derived from diamines and salicylaldehyde[11] or acetylacetonate[12] have been proposed as models for the vitamin B_{12} coenzyme. Some of us recently studied the reaction of cyanide with various alkylcobalamins (RCbl, where R = CN, $CNCH_2$, CF_3, CF_3CH_2, CF_2H, CH_3, $BrCH_2$) and found that the nature of the alkyl group has an important influence on the thermodynamic equilibrium constants, and the kinetics and mechanism of the substitution reactions of the axial ligand *trans* to the alkyl group.[13,14]

The nature of the axial alkyl group in cobaloximes[2] and in related $[RCo\{(DO)(DOH)pn\}H_2O]^+$ complexes[15] has an effect on the substitution of the ligand in the *trans* position. This substitution is very rapid and involves a dissociative activation mode, similar to the substitution of labile cobalamin complexes. Ligand-substitution reactions of vitamin B_{12} and its models in general follow a dissociative (I_d or D) type of mechanism.[16−28] In the case of the coenzyme, evidence was initially reported for an associative substitution mode, which was, however, recently reinterpreted and instead assigned to a subsequent Co−C heterolysis reaction.[29] An interchange mechanism may involve either associative or dissociative activation (I_a or I_d mechanism), according to the relative importance of bond making and bond breaking in the transition state. Evidence that usually leads to the assignment of a dissociative mechanism includes the absence of any relationship between the nature of the entering nucleophile and the rate constant, an increase in lability with an increase in the electron donating ability of the alkyl group R in the *trans* position, and positive values for both $\Delta V^{\neq}$ and $\Delta S^{\neq}$.

In general, kinetic studies are performed under pseudo first order conditions using a large excess of ligand over the complex. A linear dependence of the observed pseudo first-order rate constant on the concentration of the entering nucleophile has been observed in almost in all cases, both for aquacobalamin and synthetic models in aqueous solution. The first deviation from linearity was reported for the reaction of $[RCo\{(DO)(DOH)pn\}H_2O]^+$ complexes (R = Me and Et).[15] Curvature in the plot of k_{obs} versus ligand concentration generally characterizes multistep processes, such as a limiting dissociative mechanism (D), which involves a pentacoordinate intermediate, or a mechanism in which intermediate species are formed in a rapid pre-equilibrium which precedes the slow substitution step. In the above-mentioned complexes, linear relationships between

k_{obs} and ligand concentration were found for the substitution of water by a number of nucleophiles. However, curvature was observed for L = imidazole, benzylamine, pyridine and 4-methylpyridine. Since the later four ligands all contain aromatic group, it was tentatively suggested that these are involved in forming the intermediate, perhaps through a π-π interaction with the conjugated system of the (DO)(DOH)pn equatorial ligand.

More recently, a non-linear dependence of k_{obs} on the concentration of the entering ligand has been reported for the reaction of aquacobalamin with substituted pyridines.[16] This was first incorrectly interpreted as evidence for the operation of a limiting dissociative mechanism, but later work clearly demonstrated that the observed deviation was due to the rapid formation of adducts involving the nucleophiles and cobalamin, preceding the slow substitution reaction according to a dissociative interchange mechanism.[17] This finding greatly enhanced our interest in mechanisms associated with the reactions of nucleophiles that contain an aromatic group because of the connection with the biochemistry of vitamin B_{12}. Therefore, in order to obtain a deeper understanding of this phenomenon, we extended the present study to cobaloximes, which are the most widely recognised model systems for the study of vitamin B_{12}. We report kinetic data for ligand-substitution reactions of $RCo(Hdmg)_2S$ with various pyridines, where R = $PhCH_2$ and CF_3CH_2, S = H_2O and MeOH and L = 4-NH_2Py, Py, and 4-CNPy, in order to study the kinetic *trans* effect in alkyl cobalt complexes as a function of nucleophile concentration, temperature and pressure.

Results and Discussion

The ligand-substitution reactions of *trans*-$RCo(Hdmg)_2S$ (where R = CF_3CH_2 and $PhCH_2$) with various nucleophiles L = 4-NH_2Py, Py, and 4-CNPy to form $RCo(Hdmg)_2L$, according to Equation (1), were studied with MeOH and H_2O as solvents.

$$RCo(Hdmg)_2S + L \rightarrow RCo(Hdmg)_2L + S \quad (1)$$

The results fall into two categories: (i) when the incoming ligand is Py or 4-NH_2Py, a non-linear concentration dependence is obtained for both $PhCH_2$ (S = MeOH) and CF_3CH_2 (S = MeOH or H_2O) derivatives, (ii) when the incoming ligand is 4-CNPy, a linear relationship is observed for both the $PhCH_2$ (S = MeOH) and CF_3CH_2 (S = MeOH or H_2O) derivatives. The reaction of $(4-10) \times 10^{-4}$ M *trans*-$RCo(Hdmg)_2(H_2O)$ with an excess of nucleophile (4-NH_2Py and Py) was studied at various temperatures in MeOH and H_2O. The results are shown in Figure 1 (R = CF_3CH_2, L = 4-NH_2Py in MeOH) and Figure 2 (R = CF_3CH_2, L = Py in H_2O); see also Figure S1 (R = $PhCH_2$, L = 4-NH_2Py in MeOH) and Figure S2 (R = CF_3CH_2, L = Py in MeOH) in the Supporting Information (see footnote on the first page of this article). The plots show significant curvature at high nucleophile concentration and negligible intercepts, which can be interpreted (see below) in terms of the interchange mechanism presented in Equations (2) and (3). The corresponding rate law is given in Equation (4), where K represents the equilibrium constant for precursor formation, and k the interchange rate constant. In these cases, k and K can be separated kinetically so that their values can be discussed individually.

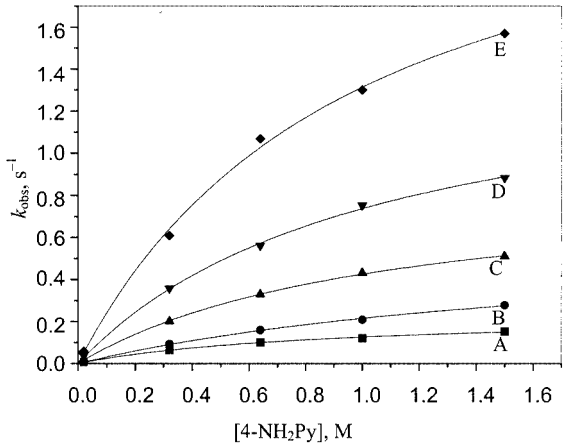

Figure 1. Plots of k_{obs} versus [4-NH_2Py] for the reaction with *trans*-$(CF_3CH_2)Co(Hdmg)_2(MeOH)$ as a function of temperature. Experimental conditions: $[Co^{III}] = 1 \times 10^{-3}$ M and temperature 20.0 (A), 25.0 (B), 30.0 (C), 35.0 (D), and 40.0 °C (E)

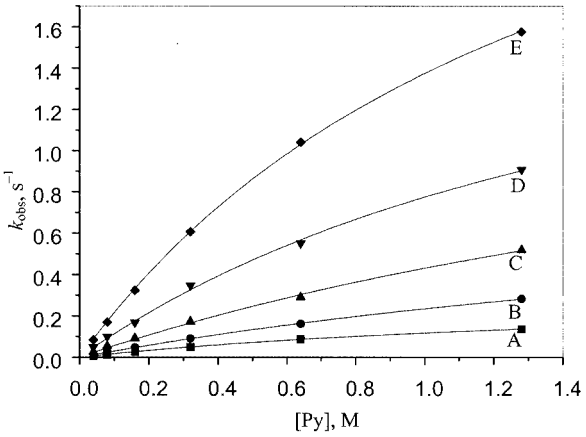

Figure 2. Plots of k_{obs} versus [Py] for the reaction with *trans*-$(CF_3CH_2)Co(Hdmg)_2(H_2O)$ as a function of temperature. Experimental conditions: $[Co^{III}] = 1 \times 10^{-3}$ M, pH = 8.0, I = 0.1 M $NaClO_4$ and temperature 20.0 (A), 25.0 (B), 30.0 (C), 35.0 (D), and 40.0 °C (E)

$$RCo(Hdmg)_2S + L \underset{}{\overset{K}{\rightleftharpoons}} [RCo(Hdmg)_2S.L] \quad (2)$$

$$[RCo(Hdmg)_2S.L] \xrightarrow{k} RCo(Hdmg)_2L + S \quad (3)$$

$$k_{obs} = kK[L]/(1 + K[L]) \quad (4)$$

Figures 3 and S3 (for the latter see the Supporting Information) show plots for k_{obs} versus [L] for the reaction of R = CF_3CH_2 with L = 4-CNPy in MeOH and H_2O, and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

R = $PhCH_2$ with L = Py and 4-CNPy in MeOH, respectively. The linear plots have negligible intercepts, which indicate that the back reactions do not contribute significantly and that no parallel reaction takes place. This behaviour can be expressed by the rate law given in Equation (5), from which it follows that the overall second-order rate constant (k_a) is a composite of k and K, and cannot be separated easily.

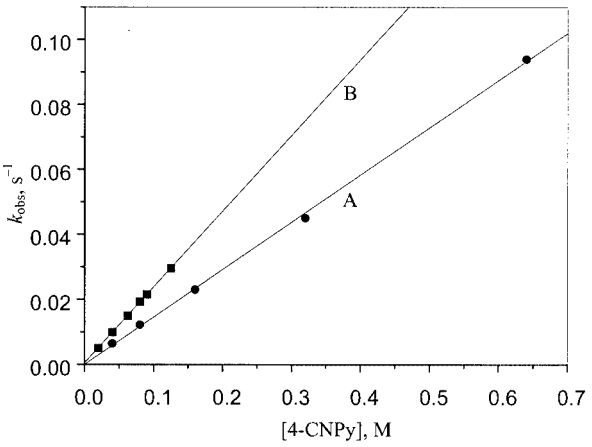

Figure 3. Plots of k_{obs} versus [4-CNPy] for the reaction with *trans*-$(CF_3CH_2)Co(Hdmg)_2S$ where S = MeOH (A) and H_2O (B) as a function of temperature. Experimental conditions: $[Co^{III}] = 1 \times 10^{-3}$ M, (pH = 8.0, I = 0.1 M $NaClO_4$ for S = H_2O) and temperature 25.0 °C

$$k_{obs} = k_a[L] = kK[L] \quad (5)$$

Tables 1, 2, 3, and 4 summarize the kinetic data obtained at different temperatures and pressures for the series of reactions investigated in this study. Plots of $\ln(k_a)$ versus pressure give good linear relationships as shown in Figure 4 for the reactions of *trans*-$(CF_3CH_2)Co(Hdmg)_2(MeOH)$

[a] $[PhCH_2Co(Hdmg)_2MeOH] = 4 \times 10^{-4}$ M, [4-NH_2Py] = 0.01−0.64 M in MeOH. [b] $[CF_3CH_2Co(Hdmg)_2MeOH] = 1 \times 10^{-3}$ M, [4-NH_2Py] = 0.02−1.5 M in MeOH.

with 4-NH_2Py, Py and 4-CNPy. Similar plots are presented in Figures S4 and S5 (see the Supporting Information) for the reactions between $RCo(Hdmg)_2H_2O$ and the nucleophiles L = 4-NH_2Py, 4-CNPy, and Py, where R = $PhCH_2$ and S = MeOH, and the nucleophiles L = 4-CNPy and Py, where R = CF_3CH_2 and S = H_2O, respectively. The activation parameters for the substitution of methanol by 4-NH_2Py, Py, and 4-CNPy in the case where R = $PhCH_2$ were found to be $\Delta H^{\neq}$ = 67 ± 2, 77 ± 1 and 80 ± 2 kJ·mol^{-1}, $\Delta S^{\neq}$ = +28 ± 7, +57 ± 5 and +71 ± 6 J·mol^{-1} K^{-1}, and $\Delta V^{\neq}$ = +9.8 ± 0.1, +10.3 ± 0.3 and +13.0 ± 0.3 cm^3 mol^{-1}, respectively. The activation parameters in the case where R = CF_3CH_2 were found to be $\Delta H^{\neq}$ = 90 ± 9, 91 ± 5 and 89 ± 3 kJ·mol^{-1}, $\Delta S^{\neq}$ = +49 ± 29, +42 ± 17 and +36 ± 8 J·mol^{-1} K^{-1}, and $\Delta V^{\neq}$ = +7.5 ± 0.3, +8.6 ± 0.1 and +9.4 ± 0.1 cm^3 mol^{-1}, respectively. The activation parameters for substitution of H_2O by Py and 4-CNPy, where R = CF_3CH_2, were found to be $\Delta H^{\neq}$ = 94 ± 4 and 93 ± 1 kJ·mol^{-1}, $\Delta S^{\neq}$ = +62 ± 14 and +55 ± 4 J·mol^{-1} K^{-1}, and $\Delta V^{\neq}$ = +5.7 ± 0.4 and +7.4 ± 0.1 cm^3 mol^{-1}, respectively. These activation parameters, in particular the values of $\Delta V^{\neq}$, support the operation of a dissociative mechanism.

The discussion of the kinetic data will focus on the observed second-order rate constants for the overall reaction given in Equation (1), which is a composite of K and k, as given in Equations (2) and (3). Although for some systems k and K could be separated kinetically, the activation parameters were always determined for the combined value of kK, i.e. k_a. Little is presently known about the temperature and pressure dependence of the precursor formation step, and for that reason the thermodynamic contributions of K form part of the overall reported parameters. This complication should be kept in mind when interpreting the overall rate and activation parameters.

The reactivity of the cobaloxime complexes shows a strong dependence on the nature of the alkyl substituent R. The lability of these complexes was affected by the electronic and steric properties of the alkyl group. The second-order rate constants for the reaction of *trans*-$(PhCH_2)Co(Hdmg)_2(MeOH)$ with 4-NH_2Py, Py, and 4-CNPy were found to be 356, 182, and 296 $M^{-1}\,s^{-1}$ at 25.0 °C, respectively. However, those obtained for the reaction with *trans*-$(CF_3CH_2)Co(Hdmg)_2(MeOH)$ were 0.330, 0.147 and 0.153 $M^{-1}\,s^{-1}$ at 25.0 °C, respectively. The second-order rate constants for the reaction of *trans*-$(CF_3CH_2)Co(Hdmg)_2(H_2O)$ with Py and 4-CNPy in H_2O were found to be 0.317 and 0.214 $M^{-1}\,s^{-1}$ at 25.0 °C, respectively. This trend shows that the kinetic *trans* effect is greater for R = $PhCH_2$ than for R = CF_3CH_2, in accordance with the donor properties of the alkyl group. For the complexes *trans*-$[RCo(LNHpy)(HLNHpy)]^+$, where HLNHpy is the tridentate 2-(2-pyridylethyl)amino-3-butanone oxime ligand and $LNHpy^-$ its conjugate base, the second-order rate constants for substitution of 2-(pyridylethyl) were found to be 19.1, 0.25, 2.2 × 10^{-2}, and 1.7 × 10^{-2} $M^{-1}\,s^{-1}$ for R = Et, Me, CF_3CH_2, and $-CH_2-$, respectively.[30] The reaction between alkylcobalamins

[a] [$CF_3CH_2Co(Hdmg)_2MeOH$] = 1 × 10^{-3} M and [Py] = 0.04−4.0 M. [b] [$CF_3CH_2Co(Hdmg)_2(H_2O)$] = 1 × 10^{-3} M, [Py] = 0.04−1.28 M, pH = 8 and I = 0.1 M $NaClO_4$.

(RCb1) and cyanide showed that the kinetic *trans* effect decreases in the order (R =) Pr > Me (ca. 10^4 $M^{-1}s^{-1}$) > CF_3CH_2 > CF_2H (10^3 M^{-1} s^{-1}) > CF_3 > $NCCH_2$ > CN (0.1 M^{-1} s^{-1}).[14] The substitution of H_2O by CN^- for various cobinamides (RCbi) increases in the order (R =) H_2O = DMBz < OH^- < CN^- < CH_2=CH, Me, and Et, with the corresponding rate constants ranging from about 10^3 to about 10^8 M^{-1} s^{-1}.[31]

The pK_{BH+} values for 4-NH_2Py, Py, and 4-CNPy are 9.17,[32] 5.23,[32] and 1.7[33] (estimated), respectively. Both in water and methanol, the second-order rate constants for the ligation of the pyridines are only slightly affected by their basicity. Such a weak sensitivity of the *kK* values is consistent with an I_d mechanism, which is controlled by the breaking of the Co−S bond. Analogously, the substitution rate constants of aquacobalamin by a variety of substituted pyridine ligands were found to be independent of their pK_{BH+} values.[25]

The second-order rate constants for substitution of H_2O in *trans*-(CF_3CH_2)Co(Hdmg)$_2$(H_2O) by Py and 4-CNPy are higher than that found for the corresponding reaction with cysteine,[34] and this was ascribed to metal-to-ligand π bonding. The range of rate constants for axial ligand binding to methylaquacobaloxime are 4.3−7.5 (RNH_2), 12.8−27.3 (RS^-), 49.6−55.2 (RSH), and 92−200 (X-py) M^{-1} s^{-1}.[35] That is, the π-acceptor ligands (X-Py, RS^- and RSH) react more rapidly than pure σ donors (RNH_2). In the ligand-substitution reactions of *trans*-MeCo(Hdmg)$_2$(H_2O), the higher reactivity of the substituted pyridines (as compared to neutral or anionic thiolates) stand in contrast to the opposite reactivity order for these same nucleophiles with various unsaturated carbon electrophiles.[35] The ratio of the second-order rate constants for the reaction of pyridine and 4-CNpy with alkylcobaloxime (R = CF_3CH_2) is 1.48, and that for R = Me is 1.24. The second-order rate constant in the case of R = Me is higher than for R = CF_3CH_2, which is due to the stronger labilization by R = Me.

The second-order rate constants for the substitution of H_2O in *trans*-RCo(Hdmg)$_2$(H_2O) by pyridine were found to

[a] [$PhCH_2Co(Hdmg)_2MeOH$] = (4−7) × 10^{-4} M, {[4-NH_2Py], [Py] = 0.04 M and at 5.0 °C}, {[4-CNPy] = 0.0225 M and at 10.0 °C}. [b] [$CF_3CH_2Co(Hdmg)_2MeOH$] = 2 × 10^{-3}, [NH_2Py] = 0.08 M, {[Py], [4-CNPy] = 0.16 M}, and at 40.0 °C. [c] [$CF_3CH_2Co(Hdmg)_2H_2O$] = 2 × 10^{-3}, [Py] and [4-CNPy] = 0.08 M, pH = 8, at 40.0 °C and I = 0.1 M $NaClO_4$.

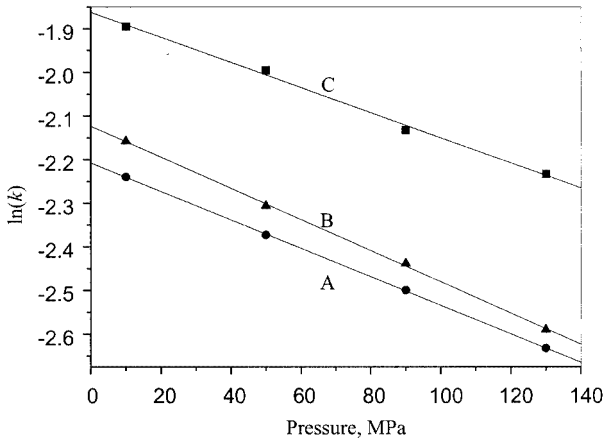

Figure 4. Plots of ln(k) versus pressure for the reaction between *trans*-$(CF_3CH_2)Co(Hdmg)_2(MeOH)$ and L, where L = Py (A), 4-CNPy (B) and 4-NH_2Py (C). Experimental conditions: [Co^{III}] = 2 × 10^{-3} M, [NH_2Py] = 0.08 M, [Py] and [4-CNPy] = 0.16 M, at 40.0 °C

be 1.49 × 10^4 (isopropyl), 1.17 × 10^3 (ethyl), 1.16 × 10^2 (methyl), 1.22 × 10^3 (phenylethyl), 1.64 × 10^2 (3-cyanopropyl), 1.65 × 10^2 (2-methoxyethyl), 2.34 × 10^1 (1-propenyl), 4.2 (iodomethyl), 3.17 × 10^{-1} (2,2,2-trifluoroethyl), 1.06 × 10^{-1} (chloromethyl), and 5.59 × 10^{-2} (cyanomethyl) $M^{-1}\ s^{-1}$ at 25 °C, respectively.[36] The second-order rate constants for substitution of methanol by pyridine in the complex *trans*-$(RSO_2)Co(Hdmg)_2(MeOH)$ were found to be 4.79 ± 0.01 and 3.56 ± 0.11 $M^{-1}\ s^{-1}$ for R = *p*-tolyl and methyl, respectively. Substitution of the solvent by pyridine in the complex $(CH_3C_6H_4SO_2)Co(Hdmg)_2S$ does have an effect on the second-order rate constants, which were found to be 1.12 × 10^{-1}, 4.79 × 10^{-2}, and 4.16 × 10^{-3} $M^{-1}\ s^{-1}$ for S = EtOH, MeOH, and H_2O, respectively.[37]

Ligand-substitution reactions of *trans*-$RCo(Hdmg)_2H_2O$, for R = $PhCH_2$ by Py and 4-CNPy in methanol, and also for R = CF_3CH_2 by 4-CNPy in H_2O and MeOH, are characterised by a linear dependence of the observed pseudo first-order rate constant on the concentration of the entering nucleophile as shown in Figures 3 and S3. In terms of the suggested dissociative interchange mechanism, this means that precursor formation is weak and does not show up in the kinetic data even at high concentrations of the entering ligand. The curvature observed in the nucleophile concentration dependence of k_{obs} for the substitution reactions of *trans*-$RCo(Hdmg)_2(H_2O)$ (R = $PhCH_2$ and CF_3CH_2) by 4-NH_2Py and Py suggests that an interchange mechanism involving a rapid pre-association of the complex with the incoming ligand is operating. The precursor-formation constant decreases when the electron donor ability of the alkyl group in the *trans* position is increased. It was found that the precursor-formation constants for the substitution of MeOH by 4-NH_2Py are 0.35 and 0.54 M^{-1} at 25.0 °C for R = $PhCH_2$ and CF_3CH_2, respectively. It is also apparent that the precursor-formation constant depends on the nature of the nucleophile. The π-electron density on the Py ring increases in the order 4-CNPy < Py < 4-NH_2Py,[38] which is also the order of increasing tendency for precursor formation.

It is generally known from the literature that a system must be sufficiently electron-rich in order that bonding through the π-electrons of pyridine can occur.[39] This π-interaction results in the effective binding of the nucleophile close to the metal centre during precursor formation, which is followed by an interchange of ligands controlled by

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

breakage of the Co−OH_2 bond by an I_d mechanism.[25] The pre-equilibrium constants for the reaction of $[MeCo\{(DO)(DOH)pn\}H_2O]^+$ with L = imidazole, benzylamine, Py and 4-MePy at 25 °C were found to be 0.26, 0.12, 1.00, and 1.81 M^{-1}, respectively.[15] The pre-equilibrium constants for the reaction of aquacobalamin with Py, 4-MePy, and 2,4-DMePy were found to be 1.1, 2.5, and 4.9 M^{-1}, respectively.[25]

By way of comparison, the lability of *trans*-$RRh(Hdmg)_2(H_2O)$ is affected by the steric and electronic effects of the alkyl group R, and in all cases the reaction rate is almost independent of the nucleophilicity of the incoming ligand.[40,41] There is a definite trend in the $\Delta V^{\neq}$ data: the values are significantly positive for the faster substitution reactions (R = CH_3) but significantly negative for the slower substitution reactions (R = CF_3CH_2).[42] This trend correlates well with the *trans*-influence of the R groups in the ground state, as observed for a series of pyridine (py) complexes: the Rh−Py bond length decreases in the order CH_3 [2.220(3) Å] > $ClCH_2$ [2.178(3) Å] > CF_3CH_2 [2.145(3) Å].[40,41] A similar trend is expected for the Rh−O bond in the corresponding aqua complexes: faster reactions are thus associated with the stronger *trans* influence of the methyl group, and slower reactions with the weaker *trans* influence of $ClCH_2$ and CF_3CH_2. Furthermore, the nature of the R group directly determines the substitution mechanism. The strong donor properties of CH_3 result in a dissociative substitution process (I_d), characterised by the significantly positive $\Delta V^{\neq}$ value, whereas the weaker donor properties of CF_3CH_2 favour a more associative substitution mechanism (I_a), as indicated by the significantly negative value of $\Delta V^{\neq}$.[42] Thus, in the transition state the degree of bond breakage (Rh−OH_2) and bond formation (Rh−L) is controlled by the donor properties of R.

The $\Delta H^{\neq}$ values for substitution reactions of *trans*-$RCo(Hdmg)_2(H_2O)$ (for R = $PhCH_2$ and CF_3CH_2) by pyridine derivatives in H_2O and methanol are relatively independent of the nature of the incoming ligand. It is expected that the reactions involve a dissociative activation process, since the ligands are loosely bound in the transition state. The activation enthalpy for the substitution reaction with R = CF_3CH_2 is higher than for R = $PhCH_2$ due to the strong Co−OH_2 bond in the ground state. Hence, $\Delta H^{\neq}$ values appear to be affected by both the electron-withdrawing and steric effects of the R group. The influence of these factors on $\Delta S^{\neq}$, however, cannot be rationalised. The entropy values should be slightly more positive since the transition state should be less ordered than the initial state, owing to the relief of steric strain. The organocobaloximes are about 10^5 times more labile than the corresponding nitro and iodo-aqua complexes. This very high rate enhancement is due to both the decrease in the activation enthalpy and the increase in the activation entropy.[43]

The values of $\Delta V^{\neq}$ obtained for R = CF_3CH_2 in methanol were found to be +7.5, +8.6, and +9.4 $cm^3\ mol^{-1}$, respectively. The values of $\Delta V^{\neq}$ for substitution of the solvent by pyridine derivatives (4-NH_2Py, Py, and 4-CNPy) in the complex *trans*-$(PhCH_2)Co(Hdmg)_2(H_2O)$ were found to be +9.8, +10.3 and +13 $cm^3\ mol^{-1}$, respectively. This is consistent with an enhanced dissociative (limiting D) character in the mechanism on going from the CF_3CH_2 derivative to the $PhCH_2$ derivative. Interestingly, $\Delta V^{\neq}$ for substitution of H_2O by Py and 4-CNPy (R = CH_2CF_3 in H_2O) were found to be +5.7 and +7.4 $cm^3\ mol^{-1}$, respectively. In these cases the small positive values of $\Delta V^{\neq}$ suggest that the mechanism is of an I_d nature. Thus the substitution mechanism changes from limiting D to I_d along the series from R = $PhCH_2$ to R = CF_3CH_2, on decreasing the basicity of the nucleophiles, and on changing the solvent from MeOH to H_2O. This mechanistic changeover is clearly seen in the size of $\Delta V^{\neq}$, and can be directly correlated with the donor properties of R, which in turn control the magnitude of the rate constants. The greater donating properties of $PhCH_2$ result in a limiting dissociative process as characterized by the significantly positive $\Delta V^{\neq}$. Similarly, the weaker donor properties of CF_3CH_2 favour more a dissociative interchange mechanism, as shown by the $\Delta V^{\neq}$ data. The activation parameters for substitution of aquacobalamin by thiourea, substituted thiourea and pyridine for the forward and reverse reactions conclusively confirm that the mechanism of the substitution is a dissociative interchange. For instance, the volumes of activation for both the forward and reversible reactions have values between +6 and +10 $cm^3\ mol^{-1}$.[16,17]

We conclude that all the available data underline the operation of a limiting dissociative (D) mechanism for substitution of methanol by 4-CNPy when R = $PhCH_2$. However, when R = CF_3CH_2, the mechanism is I_d for substitution of the solvent by 4-CNPy in methanol or H_2O. The non-linear concentration dependence must therefore be due to the operation of an I_d mechanism, and involve the formation of a precursor complex. The strong precursor formation is ascribed to an interaction of the π system of the pyridine ligand with the coordination sphere of the complex. This π interaction results in the effective binding of the entering nucleophile close to the metal centre during precursor formation, which is followed by an interchange of ligands controlled by the breakage of the Co−solvent bond by an I_d mechanism.

Experimental Section

Materials: All chemicals were of p. a. grade and used as received. 4-Aminopyridine and 4-cyanopyridine were purchased from Acros, tricine buffer from Sigma and pyridine from Baker. Ultra pure water was used in the kinetic measurements. *trans*-$RCo(Hdmg)_2H_2O$ (R = CF_3CH_2, $PhCH_2$) were prepared as previously reported.[44] Because alkyl cobaloximes are light sensitive, their solutions were prepared and handled away from light.

Instrumentation: The pH of the solution was measured using a Mettler Delta 350 pH meter. The pH meter was calibrated with standard buffer solutions at pH 4 and 7. UV/Vis spectra were recorded on Shimadzu UV-2101 and Hewlett Packard 8452A spectrophotometers.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Kinetic measurements were carried out on an Applied Photophysics SX 18MV stopped-flow instrument coupled to an online data acquisition system. At least eight kinetic runs were recorded under all conditions, and the reported rate constants represent the mean values. All kinetic measurements were carried out under pseudo-first order conditions, i.e. the entering nucleophile concentration was in at least a tenfold excess. Measurements at high pressure were carried out using a home-made high pressure stopped-flow unit.[45] Kinetic data were analyzed with the OLIS KINFIT program. All instruments used were thermostatted to the desired temperature (± 0.1 °C).

COVER PICTURE

The cover picture shows planar heterodinuclear phthalocyanine (Pc) dimers consisting of Pc and pyrazinoporphyrazine and of Pc and naphthalocyanine. In the picture, red spheres indicate nitrogen atoms. These dimers commonly show broad absorption bands between ca. 500 and 1000 nm, while the differential pulse voltammetry and molecular orbital calculations suggest that the dimers are unstable to oxidation, and that the two relatively independent chromophore units interact. Details are discussed in the article by N. Kobayashi and H. Ogata on p. 906 ff.

The Dynamic Status Quo of Polyhedral Silsesquioxane Coordination Chemistry

Rob W. J. M. Hanssen,[a] Rutger A. van Santen,[a] and Hendrikus C. L. Abbenhuis*[a]

Keywords: Catalysis / Organometallic chemistry / Si ligands / Silsesquioxanes / Silanol

The chemistry of polyhedral oligomeric silsesquioxanes (POSS) has taken a tremendous leap over the past decade. New synthetic approaches have been developed, and new complexes based on elements throughout the periodic table have been synthesized and applied in catalytic processes such as alkene epoxidation, Oppenauer oxidation, alkene polymerization, Diels–Alders reactions and alkene metathesis. The use of silsesquioxane ligands as models for silica surface has provided an intimate knowledge of the reactions on the surface of this much-used support. New methods have been developed to incorporate silsesquioxanes into new materials. Encapsulation in siloxane polymers has provided precision supports for catalysts and controlled calcination has produced materials with well-defined metal oxide particles. This paper reviews the history and the latest developments of silsesquioxane chemistry.

Silsesquioxanes: Introduction and History

Polyhedral oligomeric silsesquioxanes (POSS), or simply silasesquioxanes or silsesquioxanes is the general IUPAC name for a family of polycyclic compounds consisting of silicon and oxygen (See Figure 1). The name sil(a)sesquioxane is derived from *sil-oxane* (compounds of silicon and oxygen) and *sesqui* (Latin, meaning one and a half), and the general name reflects the ratio of silicon and oxygen in the completely condensed silsesquioxanes $[RSiO_{3/2}]_{2n}$ (vide infra).

Silsesquioxanes are part of a larger family of silicon-oxygen compounds, called spherosilicates. The main feature of

Rob Hanssen studied Chemical Engineering at Eindhoven University of Technology and graduated on the heterogenisation of titanium-based silsesquioxane epoxidation catalysts in MCM-41 type materials. After his graduation, he continued his stay at the Laboratory of Inorganic Chemistry and Catalysis to do a Ph.D. on the formation and reactivity of multinuclear silsesquioxane metal complexes, which he successfully defended in May 2003.

Rutger van Santen is a Full Professor in Catalysis. He received his Ph.D. from Leiden University in 1971 with Prof. L. J. Oosterhoff as supervisor. In 1971/72 he was a postdoctoral fellow at SRI, Menlo, California in the Molecular Physics Department. Next he joined the Koninklijke/Shell Laboratorium Amsterdam where he had several functions in catalysis research. In 1982/84 he was assigned to Shell Development Company in Houston, Texas. In 1986 he was appointed part-time Professor in Surface Chemistry at Eindhoven University of Technology followed by the appointment as Full Professor in Catalysis in 1988. His research interests are in the field of the molecular aspects of heterogeneous catalysis following three main themes: computational studies of surface-chemical reactivity, mechanism in heterogeneous catalysis and physical chemistry of catalyst synthesis. He is recipient of the gold medal of the Royal Dutch Chemical Society (1981), the Ciapetta Lectureship of the North American Catalysis Association (1991) and the Bourke lectureship of the Royal Society of Chemistry (1996), Spinoza award (1997, NWO) and the Alwin-Mittasch Medal (Dechema, 2001). In 2001 he became chairman of the Royal Dutch Chemical Society and Rector Magnificus of the TUE.

In 1992, Erik Abbenhuis obtained his PhD thesis at Utrecht University having worked in the group of Prof. Dr. G. van Koten on "Intramolecular Coordination in Tantalum Alkylidene Chemistry". He continued with academic research as a postdoc, first in Strasbourg, then at the ETH Zürich, following his appointment as a fellow of the Royal Dutch Academy of Arts and Sciences in 1994. He now has his own research group at Eindhoven University of Technology, coached by Prof. Dr. D. Vogt, in which emphasis is put on molecular aspects of heterogeneous catalysis.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

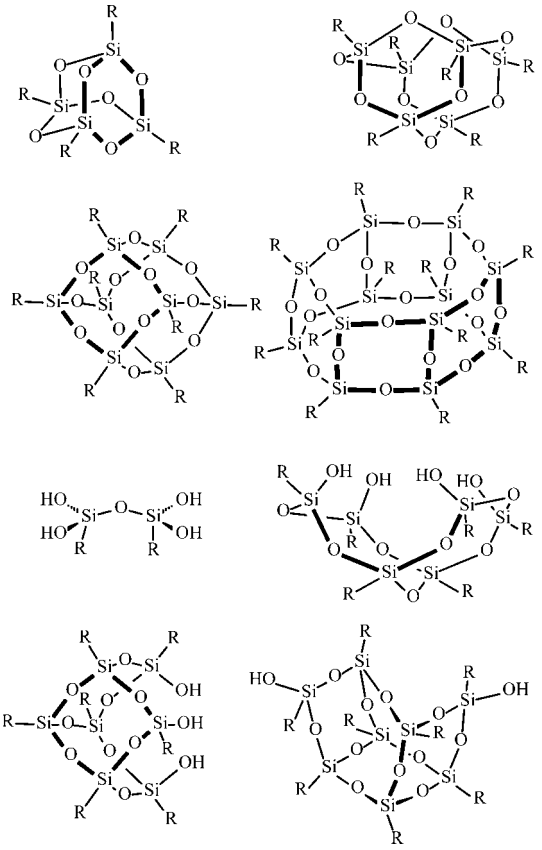

Figure 1. Overview of incompletely and completely condensed silsesquioxanes in the literature (typical R groups include: Me, Et, *i*Pr, *i*Bu, *i*Oc (isooctyl), Ph, *c*-C_5H_9, *c*-C_6H_{11}, *c*-C_7H_{13}, norbornyl)

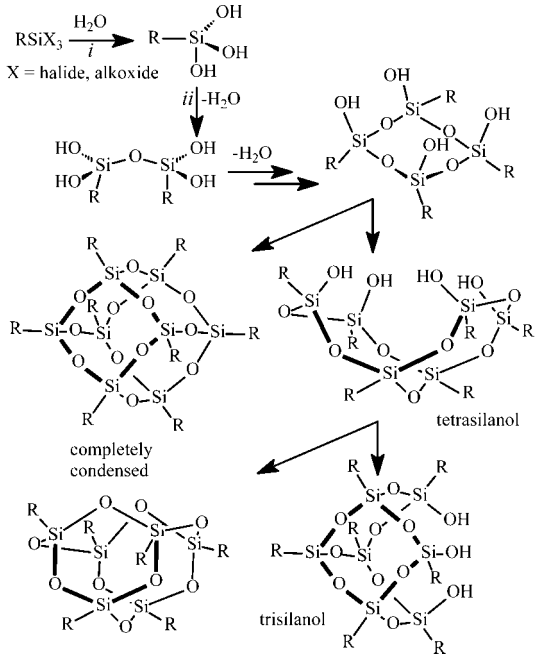
silsesquioxanes is the presence of one non-silicate, organic group on the silicon atoms. The initial discovery of silsesquioxanes dates back to 1946, when Scott[1] described completely condensed methyl-substituted silsesquioxanes. Although he was not able to assign their exact structure, he was able to determine that the general formula was $[(CH_3)SiO_{3/2}]_{2n}$, in which n was an integer. Nine years later, the molecular structure of a series of organosilsesquioxanes was determined by single-crystal X-ray diffraction by Barry et al.[2] They first showed the cubic or hexagonal prismatic shape of the completely condensed molecules.

A major contribution to the synthesis of silsesquioxanes (completely and incompletely condensed) was published by Brown and Vogt in 1965.[3] They described the polycondensation of cyclohexyltrichlorosilane in an acetone/water mixture. The main products that were formed at the beginning of the reaction were incompletely condensed dimers [$RSi(OH)_2ORSi(OH)_2$, R = cyclohexyl] and higher oligomers, that still contained silanol groups. After some time (days to months), the cubic, incompletely condensed silsesquioxane trisilanol $(R_7Si_7O_9)(OH)_3$ was formed to a greater extent together with the completely condensed $R_6Si_6O_9$ with no residual silanol groups. In the 1990s, Feher described the same procedure for cyclopentyl- and cycloheptyltrichlorosilane. In this case no completely condensed products were isolated. The hydrolytic polycondensation of cyclopentyltrichlorosilane led exclusively to the formation of the trisilanol $(c\text{-}C_5H_9)_7Si_7O_9(OH)_3$, while polycondensation of cycloheptyltrichlorosilane led to a mixture of the trisilanol $(c\text{-}C_7H_{13})_7Si_7O_9(OH)_3$ and the tetrasilanol $(c\text{-}C_7H_{13})_6Si_6O_7(OH)_4$. The application of norbornyl as the organic side-group was explored by Hambley et al. A mixture of trisilanol and tetrasilanol was formed.[4]

The process of formation of the silsesquioxane compounds is thought to be a multi-step hydrolysis-condensation reaction (see Scheme 1). The first step is the hydrolysis of an alkylsilane precursor with water, forming organopolysilanol compounds (step *i*). In the right environment, depending on the concentration of water and solvent, and the pH, these precursors can condense with each other, leading to the formation of oligosiloxanes (step *ii*). The thermodynamics,[5–7] kinetics and solubility of the products will determine the resulting product mixture, ranging from lower oligosiloxane dimers or tetramers, to polyhedral oligomeric silsesquioxanes like the tetra- and trisilanol silsesquioxanes.



Scheme 1. Generalized formation scheme for siloxanes and silsesquioxane-type compounds

For a long time the major hurdle in the use of silsesquioxanes was the long preparation time (ranging from a few weeks to 36 months) and the limitation of the organic side-groups on the silicon atoms. New developments and ideas have shortened the preparation times considerably. The use of high-throughput experimentation and synthesis robots may accelerate the optimization of synthesis conditions.[8] Recently, base-catalyzed polycondensation reactions have proven to be an excellent way to prepare large quantities of silsesquioxanes. Lichtenhan and Abbenhuis have applied for patents on the preparation of completely condensed and incompletely condensed silsesquioxanes with isobutyl and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

isooctyl side-groups that can be prepared on large scales in a short time.

Until recently, functionalization of silsesquioxane silanols has been limited to either corner-capping of trisilanols with a trihaloorganosilane moiety, leaving no further reactive silanol group (*a*), or reaction of the trisilanol with mono- or dihaloorganosilane reactants, leaving two or one silanol groups, respectively (*b*). In the first case, a large number of possible side groups can be introduced, ranging from simple alkyl groups to reactive alcohols, amines and alkenyl groups. These groups allow the silsesquioxane cores to be included in polymeric materials. Furthermore, there is a substantial interest in octafunctional silsesquioxanes where all the side groups on the silicon atoms are identical and reactive. In these cases the functionality ranges from alkyls, alcohols, amides and carboxylates to halides, nitrates and phosphanes.[9−24] These can even be used as building blocks for dendrimers, as shown by Cole-Hamilton et al. for use in catalytic hydroformylation reactions (vide infra).[25−28] In the second case, the introduction of reactive functional groups besides the silsesquioxane's silanols has proved to be more complex. To date, the groups in the added functionality are limited to trialkyl- and triarylsilicon and -tin groups, and these groups are more often used for protection of one or more of the silanol groups than for functionalization. Selectivity in these reactions either arises from the different acidities of the silanols of the starting material or from steric hindrance of the silylating agent.

Metal Silsesquioxanes

Feher et al. initiated the research towards the use of silsesquioxane molecules as ligands for main group and transition metals at the end of the 1980s,[29] considering silsesquioxanes as models for industrially used silica supports. The resemblance of silsesquioxanes to silica supports is not only apparent from the molecular structure, but the electronic properties of silsesquioxane silanol groups mimic the behavior of silica as well.

In Figure 2, a few important structural similarities between silsesquioxanes and schematized silica surfaces are depicted. First of all, the defined orientation of the silanol groups, which is also present in silsesquioxanes, may ensure a strong multi-dentate bonding to metals. Furthermore, silsesquioxanes have enough residual siloxane bridges to resemble the silica surface and these residual siloxane bridges can interact with the metal.

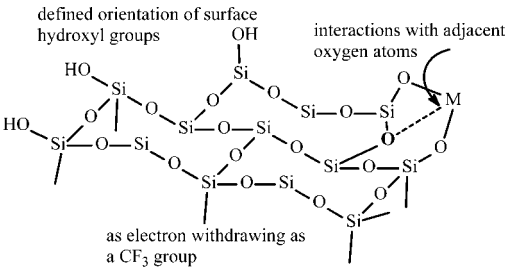


Figure 2. Schematic overview of a silica-based catalyst support, indicating important surface properties

Silsesquioxane silanols can be modified by silylation to resemble the different silanol sites that can be present on a silica surface. Dijkstra et al. performed an in-depth study on the synthesis and characterization of silsesquioxane models for silica silanol sites (see Figure 3).[30] By comparison of the relative ion-pair acidities in THF for the different silanol sites, they found that the geminal silanols are among the least acidic, and hence least reactive, silanol groups, closely followed by isolated silanol groups. Due to their ability for extensive hydrogen bonding, the Brønsted acidity of vicinal disilanol and trisilanol groups is orders of magnitude larger. These findings provide insight into the relative reactivity of species on a silica surface.

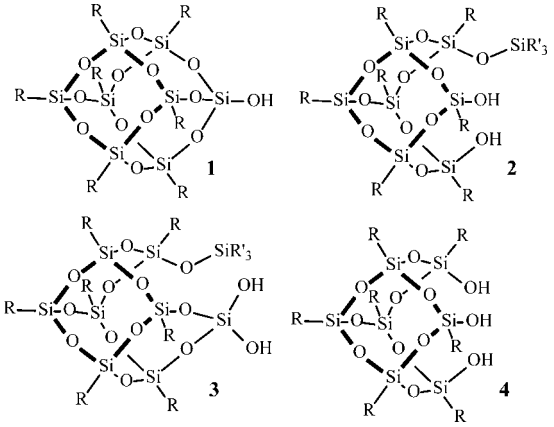

Figure 3. Silsesquioxane representations of silanol sites on silica surfaces: **1** isolated silanol; **2** vicinal disilanol; **3** geminal disilanol; **4** vicinal trisilanol

Since the discovery of silsesquioxanes, a rich coordination chemistry has been developed with elements throughout the periodic table; at present, these involve: Li, Na, K, Be, Mg, Sc, Y, La, U, Ti, Zr, Hf, V, Ta, Cr, Mo, W, Fe, Ru, Os, Co, Rh, Pt, Cu, Au, Zn, B, Al, Ga, Tl, Ge, Sn, Pb, N, P, As, Sb, Bi, S, F, Cl.

Group I (Li, Na, K)

Feher et al. have reported sodium complexes as intermediates in the synthesis of transition metal complexes.[31] These intermediates were either not isolated or found to be unstable out of solution. The groups of Aspinall, Edelmann and Abbenhuis have used lithium silsesquioxanes extensively as a transmetallation agent to prepare transition metal complexes.[32−34] In some cases the lithium ions remain present in the transition or main group metal complex.[32,34−36] Duchateau et al. reported a mixed boron-lithium silsesquioxane.[37] The group of Edelmann also reported a potassium silsesquioxane complex and gave a crystal structure, although no experimental details were provided.[34]

Group 2 (Be, Mg)

The chemistry of Group 2 elements has not been explored much in the past. Edelmann et al. published a crystal structure of a mixed beryllium-lithium silsesquioxane.[35]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Smet et al. reported the use of a magnesium-substituted silsesquioxane as an intermediate in the reaction with epoxides.[38] Lichtenhan reported a polymeric material based on a silsesquioxane disilanol and dialkylmagnesium.[39] Liu and Feher reported the application of magnesium-substituted silsesquioxanes as model supports for titanium-based alkene polymerization catalysts.[40,41] Hanssen described the synthesis and reactivity studies of a tetranuclear magnesium complex, and Maxim subsequently used this complex to prepare microporous magnesium-containing silica materials.[42,43]

Group 3 (Sc, Y, La, Lanthanides and Actinides)

Hermann et al. first mentioned the synthesis and crystal structures of Nd and Y silsesquioxanes complexes.[44] Due to the high solubility of Group 3 silsesquioxanes they were not able to isolate a "naked' Y silsesquioxane, but addition of coordinating triphenylphosphane oxide yielded crystals suitable for X-ray crystal-structure analysis. The large ion-size and high electrophilicity of the ion induced a high degree of coordination of siloxide and siloxane groups from the ligand to the metal showing, for the first time, an interaction of a siloxane bridge with a metal ion. Aspinall et al. isolated a PMDTA adduct of an yttrium silsesquioxane.[45] By applying the method of lithium transmetallation they also synthesized a mixed lithium-ytterbium complex.[32] Edelmann et al. displayed a great interest in the synthesis of Group 3 and lanthanide complexes. They reported samarium and scandium complexes of the isolated silanol silsesquioxane **1** (Figure 3),[36] a seven-coordinate cerium(IV) silsesquioxane (starting from a Ce^{III} precursor),[46] and various mixed-metal lithium-lanthanide complexes.[34] They also reported the synthesis of the first known actinide silsesquioxane complex: a six-coordinate uranium(VI) complex that was formed regardless of the uranium precursor.[34] Although most of the papers deal with models for catalysts on silica surfaces, no catalytic experiments were performed.

Group 4 (Ti, Zr, Hf)

Much work has been done on Group 4 silsesquioxane complexes and the application of these complexes in catalytic processes such as ethylene polymerization,[40,41,47–54] alkene epoxidation[8,38,55–68] and Oppenhauer oxidations.[69] Most of the work in this area has been the topic of several excellent review articles.[34,52][65] A specific interest in the group of Abbenhuis is the heterogenization of active and selective epoxidation catalysts (Figure 4). Krijnen et al. reported the heterogenization of titanium silsesquioxane complexes in mesoporous MCM-41 type materials.[60][62][64][70] No leaching was observed for all-silica MCM-41 materials, while aluminum-containing MCM-41 had to be silylated after impregnation of the titanium silsesquioxane complex.

Skowronska-Ptasinski et al. described the copolymerization and cross-linking of vinyl-substituted silsesquioxane titanium complexes with siloxane oligomers.[58] The resulting materials proved to be active and selective catalysts

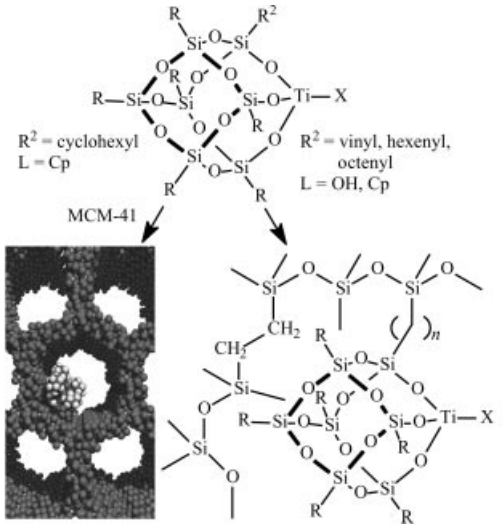

Figure 4. Immobilization of a titanium silsesquioxane complex by physisorption in a mesoporous MCM-41 host (left) or tethering to a 3D-netted siloxane polymer (right)

for the epoxidation of alkenes with the cheap oxidant hydrogen peroxide. A material obtained by physical encapsulation of a non-vinyl-functionalized titanium silsesquioxane complex was also active as a catalyst, while the titanium complex in solution could not activate hydrogen peroxide. This emphasies the importance of the physical surrounding of the catalytic center in epoxidation reactions, where one should avoid high concentrations of water and peroxide near the active metal center. More about Group 4 silsesquioxane complexes can be found in the literature.[29,31,39][71–76]

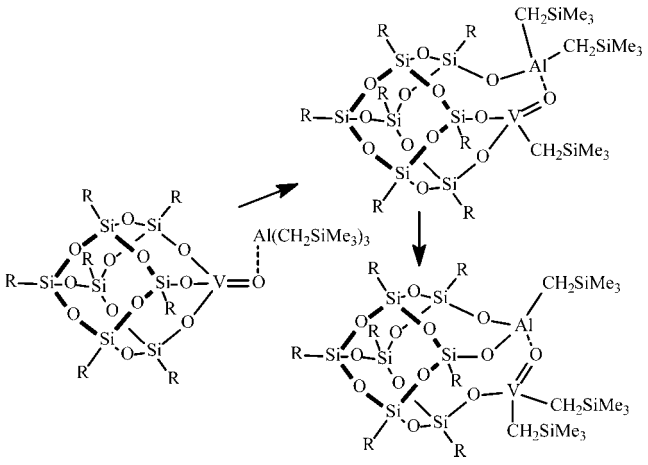
Group 5 (V, Ta)

Feher et al. explored the use of Group 5 metals ligated by silsesquioxanes by reacting vanadium(III) and vanadium(V) precursors with silsesquioxane trisilanol compounds.[76–79] The magnetic properties of the paramagnetic vanadium(III) silsesquioxanes were studied. The application of the diamagnetic vanadium(V) silsesquioxane complexes as precursors for ethylene polymerization was studied in-depth. Based on in situ NMR studies they were able to propose a catalytic model for the interaction of the vanadium systems with aluminium activators. One of the most important steps for the activation of the system was the breaking of metal-siloxy bonds in order for the metal to gain its catalytic activity, as shown in Scheme 2.

Wada et al. used the vanadium(V) complexes to prepare microporous vanadium silicates by controlled calcination of the complex in air at 723 K. The materials proved to be efficient catalysts for the photocatalytic oxidation of methane,[81] benzene and cyclohexane.[82]

The other metal in Group 5 that was investigated was tantalum. Basset et al. used a tantalum silsesquioxane complex as a model compound to explain the formation of tantalum alkylidene species on a silica surface.[83]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 2. Activation of a vanadium(V) silsesquioxane complex with an alkylaluminum compound

Group 6 (Cr, Mo, W)

Reaction of chromium oxide with a mono-protected trisilanol led to the formation of a bis-oxo chromium silsesquioxide ester (see Figure 5). Feher et al. tested this compound in the polymerization of ethylene as a surface model for the chromium-based Phillips catalyst.[80,84] It produced medium molecular weight polyethylene with a high polydispersity, indicating multiple active sites. Vorstenbosch et al. employed this type of chromium silsesquioxane ester for the catalytic epoxidation of alkenes with *tert*-butyl hydroperoxide. Although the respective epoxide was formed in high yield, it was found that the active species in the reaction was a non-silsesquioxane chromium species, an indication of metal leaching.[59] Maxim et al. used the chromium silsesquioxane for the synthesis of microporous-silica-supported chromium that was found to be active in the low-temperature catalytic oxidation of ammonia.[85,86]

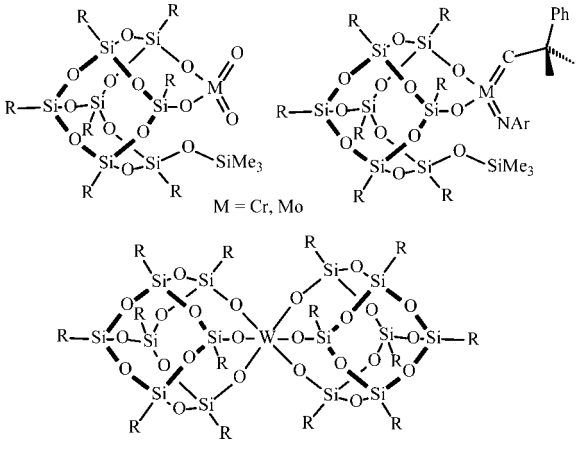


Figure 5. Examples of silsesquioxane group 6 metal complexes

Feher et al. also synthesized the corresponding molybdenum bis-oxo silsesquioxide ester by a thallium transmetallation route (vide infra).[87] A variant of the well-known molybdenum-based Schrock carbene complex showed high activity in olefin metathesis reactions (see Figure 5).[31] The high activity was attributed to the highly electron-withdrawing character of the silsesquioxane framework. Cross-metathesis of vinyl-substituted silsesquioxanes with the Schrock carbene complex $[Mo(CHCMe_2Ph)(NAr)\{OCMe(CF_3)_2\}_2]$ yielded a silsesquioxane with an alkylidene-metal fragment attached to the former vinyl side-group.[88] In an attempt to synthesize a model for silica-supported tungsten catalysts, Smet et al. synthesized a bis(silsesquioxane)-tungsten complex (Figure 5), for which the synthesis is atypical as no base is required to trap the HCl formed.[89] More reports of Group 6 metal silsesquioxanes can be found in the literature.[9,29,87,90–92]

Group 7

To date, no one has reported the synthesis of Group 7 metal silsesquioxanes where the metal is directly linked to the silanol groups. Attempts to synthesize rhenium silsesquioxane complexes resulted in either dehydration reactions of the silsesquioxane, or yielded complicated product mixtures.[93] Lücke et al. reported the synthesis of a octafunctionalized phosphorous silsesquioxane that was used a ligand for $[MnCp(CO)_2]$.[9]

Group 8 (Fe, Ru, Os)

Although the introduction of iron, in the form of ferrocene, as a side-group on the silicon was reported in 1993,[94–96] Ott et al.[97] and Edelmann et al.[98] have only recently reported the synthesis and application of iron silsesquioxanes where the iron atom is attached to the silanolate groups (Figure 6).

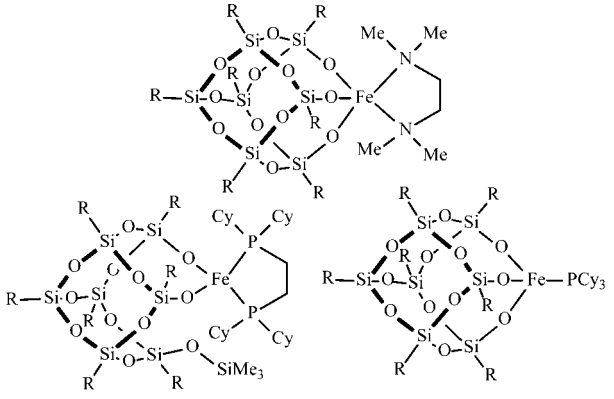

Figure 6. Iron silsesquioxanes reported by Ott et al. and Edelmann et al.

Ott et al. used monophosphanes and diphosphanes as stabilizing agents for the unfilled coordination space on the metal. Addition of small amounts of water to these compounds led to the loss of the phosphane ligand and the formation of anionic oxygen-bridged bis(iron-silsesquioxane) species. Because of structural similarities to the active center of iron found in zeolites, they applied the iron silses-

quioxane complexes in the catalytic oxidation of benzene with N_2O to phenol. No conversion into phenol was observed, possibly due to the low temperature. Edelmann et al. used TMEDA instead of diphosphanes. The complex of Edelmann was used by Maxim et al. to prepare iron on microporous silica by controlled calcination of the complex.[33] The iron was well dispersed in the material and was present as nanosized metal oxide particles of about 2−8 nm. The addition of extra silsesquioxane trisilanol to the mixture before calcination enabled them to vary the iron content in the material, while keeping the material properties unchanged. Mixing a third component into the pre-calcination mixture — the chromium silsesquioxide ester (vide supra) — allowed Maxim et al. to synthesize silica-supported mixed-metal materials.[99] These materials were tested in catalytic decomposition of N_2O to N_2 and O_2, and were found to be more active than the iron-only systems, and more selective than the chromium-only systems. A mixed metal-oxide phase (Fe−Cr−Si−O) was identified by Raman spectroscopy.

Four examples of ruthenium attached to a silsesquioxane core have been reported. Feher et al. synthesized one complex by a cross-metathesis route as described for molybdenum.[88] Wada et al. used a phosphorus-functionalized silsesquioxane as a ligand for ruthenium.[100] Marsmann et al. used thiol-functionalized silsesquioxanes to bind to ruthenium and osmium carbonyl clusters.[101] Hong et al. published $Ru(terpy)_3$ complexes covalently linked to a silsesquioxane dendrimer.[102]

Liu et al. reported the crystal structure of a silsesquioxane-substituted osmium cluster in 1990 (Figure 7).[103]

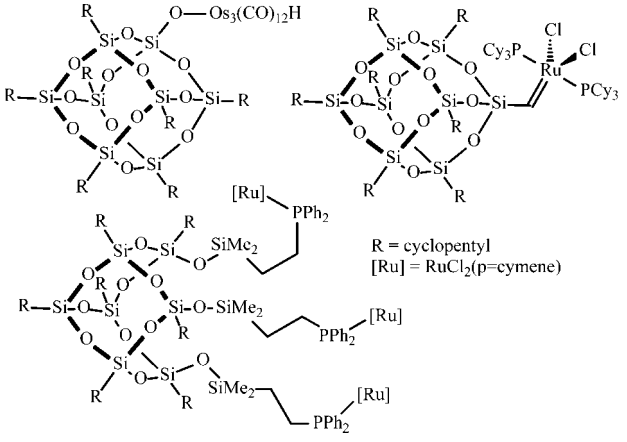

Figure 7. Examples of silsesquioxane complexes of osmium and ruthenium

Group 9−10 (Co, Rh, Pt)

The direct coupling of metals in this group to the silanol functionality of silsesquioxanes has been limited to platinum (see Figure 8). Abbenhuis et al. described the reaction of $Pt(CO_3)$(dppe) with trisilanol and mono-silylated disilanol silsesquioxane ligands.[104] Johnson et al.,[105] and Feher et al.[31] used mono-silylated thallium silsesquioxide complexes as a transmetallating agent to make silsesquioxane platinum compounds, although in some cases the use of thallium silsesquioxide complexes frustrated the synthesis of the complex due to residual thallium ions in the isolated materials.[105]

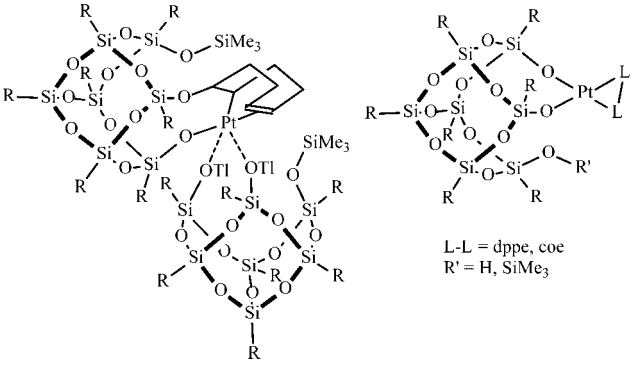

Figure 8. Pt silsesquioxane complexes by Abbenhuis, Feher and Johnson

Other reported ways of attaching Group 9−10 metals to silsesquioxanes are coordination of a donor group to the metal (S,[101][106] P[9,25,28,100,106−108]) and oxidative addition of a metal to Si−H (Co,[95,109] Rh[110]). Cole-Hamilton et al. used phosphorous-functionalized silsesquioxane-based dendrimers as ligands for rhodium to perform hydroformylation reactions.[25,28] They found a positive dendritic effect towards the linear product. Nowotny et al. used a phosphorous-functionalized silsesquioxane to chelate a Rh cluster to function as a model for a P-functionalized silica surface.[107] No catalytic tests were reported for the silsesquioxane compound.

Group 11−12 (Cu, Au, Zn)

Silsesquioxane complex chemistry has not been developed to a large extent for metals in these groups. Edelmann et al. treated $(CuO\mathit{t}Bu)_4$ with monosilylated disilanol and obtained a product with a crystal structure in which the tetrameric core of the copper alkoxide was maintained (see Figure 9). Pugin et al. used sulfur-functionalized silsesquioxanes as ligands for Au_{55} clusters and were able to correlate the increased Coulomb gap to the increased size of the cluster going from PPh_3 to the silsesquioxane-based ligand.[111] Abis et al. prepared di- and trisubstituted gold silsesquioxanes as a model for the interaction of gold carbamate precursors with silica surfaces (see Figure 9).[112]

Group 13 (B, Al, Ga, Tl)

Due to the high reactivity of the precursors from this group, particularly the alkyl complexes, with silanol groups, the silanolate coordination chemistry is well developed. Duchateau et al.,[113−115] Edelmann et al.,[116] and Feher et al.[117−119] prepared aluminum silsesquioxane complexes as models for aluminum sites in zeolites and on silica, and as models for methyl alumoxane compounds. Abbenhuis et al. applied aluminum-containing silsesquioxane polymers as heterogeneous catalysts for the acceleration of Diels−Alder reactions of enones.[120] Maxim et al. used aluminum silses-

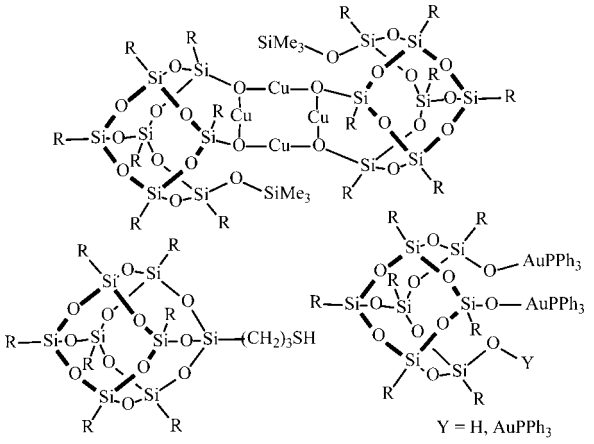

Figure 9. Examples of complexes of copper and gold and a thiol-functionalized ligand for gold clusters

quioxanes as precursors for microporous aluminosilicates by controlled calcination.[43]

Feher et al.[121] and Duchateau et al.[37] investigated the interaction of gallium precursors ($GaMe_3$ and $GaCl_3$).[122] Wada et al. used gallium silsesquioxane precursors to synthesize microporous gallium silicate materials with acidic sites by controlled calcination of the complexes in air.[123]

The interaction of boron with silsesquioxanes was the topic of research of Feher, Collins and Duchateau. Feher et al.[124] and Duchateau et al.[37] investigated the possible geometries that can be adopted by boron in a strained silsesquioxane environment. They found that boron can assume both trigonal-square and tetrahedral geometries. Collins[125] and Duchateau[50] synthesized silsesquioxane organoboranes and organoborates that could be used as models for silica-supported borane activators for Group 4 olefin polymerization catalysts (Figure 10). Reaction with bisalkylzirconocene complexes showed that both boranes and borates were susceptible to borane-zirconium exchange reactions, rendering the catalyst inactive. They concluded that the grafting of boranes on silica is not a useful method for subsequent immobilization of polymerization catalysts.

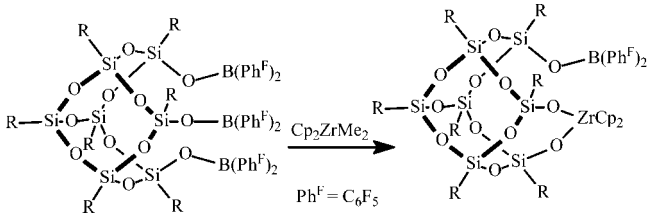

Figure 10. Interaction of dimethylzirconocene with a tris(organobora)silsesquioxane leading to borane-zirconocene exchange (Collins et al.)

Thallium silsesquioxane complexes have been mainly applied for transmetallation reactions where the thallium is replaced by high-valent transition metals.[31][87] Their ability to withstand dehydration reactions of the silsesquioxane framework, a common occurrence when using high-valent transition metals in combination with amine bases, make these complexes suitable for the synthesis of middle and late transition metal complexes, although the high toxicity is a serious disadvantage.

Outlook of Silsesquioxane Complex Chemistry

Besides extending the range of metals that can form complexes with silsesquioxane ligands, there are many challenges for the future of silsesquioxane chemistry. The introduction of functional groups besides the silanol groups could give new insights in the coordination chemistry of silsesquioxanes, and the introduction of coordinating groups like amines, thiols and phosphanes could have interesting effects on the catalytic performance of metal complexes. The introduction of silsesquioxane ligands and complexes in an approach as proposed by Skowronska-Ptasinski can revolutionize the way supported catalysts are made, due to the precise environment in which the metal center is incorporated. Controlled calcination of mixtures of silsesquioxane ligands and metal complexes yields highly dispersed, small metal oxide particles or even molecularly dispersed metal ions on a silica surface, with controllable multi-metallic content. Finally, the knowledge gained from the silsesquioxane model work should be transferred more to actual silica-supported systems or the ideas should be used to synthesize active and selective homogeneous catalysts, appropriate for industrial use.

Dimeric Metallo-Organic Supramolecular Quinoxaline Stacking Synthons

Fenton Heirtzler,*[a][‡] Sandra Dias,[a] and Markus Neuburger[b]

Keywords: Supramolecular chemistry / Helical structures / Heterocycles / Stacking interactions / Self-assembly / Sandwich complexes

Condensation of *ortho*-phenylene diamines with an unsymmetrical 2,6′-bipyridyl-2′′-pyridyl α-diketone (**2**) affords helical ligands **3a** and **3b** that self-assemble in the presence of copper(I) to produce the helical, dimeric metallo-organic complexes $[\mathbf{3a}_2Cu_2][PF_6]_2$ and $[\mathbf{3b}_2Cu_2][PF_6]_2$. These complexes have a flat, double-decker-like structure that results from atopomeric twisting in the ligand scaffolding, as confirmed by X-ray crystal structural analysis on $[\mathbf{3a}_2Cu_2][PF_6]_2$. This study also indicates a close parallel between the distances involved in inter- and intramolecular stacking phenomena. Detailed NMR spectroscopic analysis of both complexes indicates that their dications possess very closely related solution-state structures. Achieving this self-assembly program is an important step towards realizing dimerically self-assembled metallo-organic materials that have a discotic alignment.

Introduction

Oligopyridines and related compounds self-assemble in the presence of appropriate metal ions into tubular metallo-organic complexes with either a helical chirality[1] or a *meso*-configuration.[2] Ligands of less regular structure may form dimeric complexes with a flattened topology.[3] Our work concerns the synthesis[4] and metallo-organic supramolecular chemistry of hybrid pyrazine−pyridine ligands. These are 2,3-disubstituted with 2,6′-substituted oligopyridyl chains. In the presence of appropriate metal cations, they self-assemble to dimeric, intramolecularly stacked metallo-organic complexes.[5] Pyrazine derivatives of 2,5-disubstituted ligands with oligopyridyl chains undergo other metallo-organic self-assembly patterns.[6] Nevertheless, knowledge of the precise manner in which the structures of the 2,3-disubstituted ligands control their self-assembly behavior is limited. Solution- and solid-state studies have indicated that torsional congestion leads to helical twisting of the oligopyridyl strands about each other, and inter- and intramolecular π-stacking interactions occur in both the ligands and their complexes.[4b]

In the presence of copper(I), unsymmetrical ligand **1** forms a dimeric cation $[\mathbf{1}_2Cu_2]^{2+}$, which in principle may exist in either C_2-symmetric or *meso* configurations. In the C_2-form, pairs of pyrazine and pyridine rings overlap, whereas in the *meso* form two pyrazine−pyridine overlaps occur. However, only the chiral form of $[\mathbf{1}_2Cu_2]^{2+}$ has been detected. These double-decker dimers can also be arranged in stacked fashion in the crystal lattice.[5b] Thus, we were attracted to the use of related compounds to construct parallel metallo-organic π-stacking arrays, in particular those possessing discotic and lamellar ordering. Discotic macroscopic ordering is conductive to the formation of mesophase-forming, liquid-crystalline materials and facilitates their use in liquid-crystalline displays and electrically and photoelectrically conductive films.[7] The tetrahedral geometry of copper(I) hitherto has resulted in nematic (tubular) mesotropic ordering in oligopyridine-type metallo-organic complexes.[8]

Initial steps towards these goals include: (a) the preparation of ligands resembling **1** but containing long hydrophobic chains and (b) confirmation of the ligands' self-assembly pattern and stereochemistry {c.f. $[\mathbf{1}_2Cu_2]^{2+}$, C_2 or *meso*}. Ligand **1** is synthesized from α-diketone **2**, and we have presented a synthesis of **2** that is amenable to multigram amounts.[4b] Thus, simple condensation of **2** with aromatic 1,2-diamines already containing attachment points for hydrocarbon tails will afford quinoxaline-type ligands analogous to **1**. We chose attachment of alkyl groups through ether bonding because of this linkage's chemical robustness. An additional benefit of the overall strategy is the extension of the π-electronic stacking system to enhance graphite-like stacking interactions in the corresponding dimeric complexes.

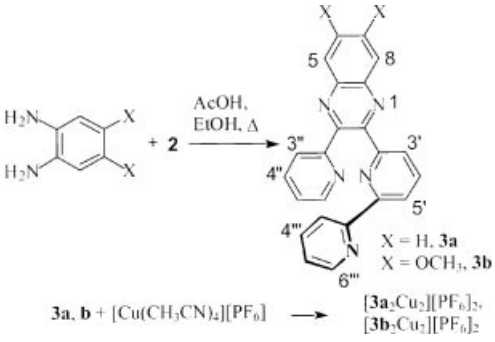
Results and Discussion

The α-diketone **2** was condensed under acidic conditions with *ortho*-phenylene diamine or 4,5-diaminoveratrole,[9] affording the unsymmetrical quinoxaline-pyridine **3a** and the dimethoxyquinoxaline homologue **3b** in 47 % and 48 % yields, respectively (Scheme 1).[10] The ^{1}H NMR spectra (Figure 1) of these two materials were completely assigned through combination of 2D techniques and comparison of the quinoxaline AA′BB′ systems. Just as for **1**, compounds **3a** and **3b** experience an upfield shifting of H-3′′′ attached to the terminal pyridine ring of the bipyridyl ring system (δ = 7.30 ppm), which is attributed to through-space interaction with the opposing solitary pyridine ring and a helical molecular conformation.



Scheme 1. Synthesis of quinoxaline-type ligands and their dimeric copper(I) complexes

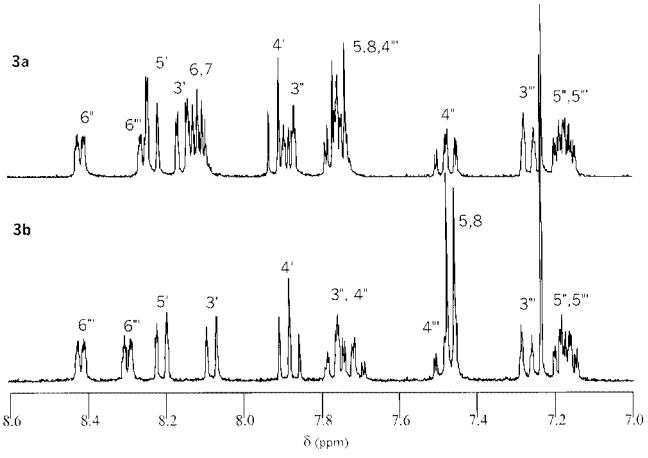


Figure 1. ^{1}H NMR spectra of ligands **3a** and **3b** ($CDCl_3$, 270 MHz)

Treatment of ligands **3a** and **3b** with one equivalent of copper(I)tetrakis(acetonitrilo) hexafluorophosphate in degassed methanol at room temperature gave purple-colored solutions, from which solids were deposited. Crystalline material resulted after slow diffusion of diethyl ether into concentrated acetonitrile solutions. Results of combustion analyses and electrospray mass spectrometry together indicated the presence of dimeric complexes $[\mathbf{3a}_2Cu_2][PF_6]_2$, and $[\mathbf{3b}_2Cu_2][PF_6]_2$.[11] The differential scanning calorimetric profiles of these two materials contain sharp endotherms at 329 and 250 °C, respectively, consistent with unitary compositions. Relative to the parent ligands, their UV-Vis spectra exhibit intensely absorbing, red- and blue-shifted maxima, as well as weak MLCT bands occurring at λ_{max} = 510 nm {$[\mathbf{3a}_2Cu_2][PF_6]_2$, ε = 4.000} and 479/580 nm {$[\mathbf{3b}_2Cu_2][PF_6]_2$, ε = 6.100/4.000}. The latter complex also displays strong adsorption bands at 353/368 nm, attributable to the dimethoxyquinoxaline chromophore (c.f. ligand **3b**: 362/387 nm). The presence of the MLCT bands in both complexes bespeaks of the existence of copper(I) centers surrounded by tetrahedral ligand fields. Yet, the lack of exceptional concentration dependence in the position of the λ_{max} values bespeaks of the absence of a pronounced solution-state aggregation.[12] The complexes were also investigated with cyclic voltammography (Figure 2). In particular, $[\mathbf{3a}_2Cu_2][PF_6]_2$ and $[\mathbf{3b}_2Cu_2][PF_6]_2$ display quasi-reversible Cu(I/II) processes centered at 0.44 V and 0.38 V, relative to the ferrocene/ferrocenium couple. Both metal centers within the same complex are active at identical potentials. Repeated redox cycling of the quinoxaline derivative complex resulted in the decomposition of this material, as evidenced by the appearance of additional redox processes at 1.04 V (reduction) and 0.48 V (oxidation). Gratifyingly, these processes were significantly less prominent in $[\mathbf{3b}_2Cu_2][PF_6]_2$. Since the introduction of electron-rich methyl ether groups into the ligand scaffolding should increase the ligand sensitivity to oxidative degradation, it is possible that greater ligand−metal interaction may account for the stability of $[\mathbf{3b}_2Cu_2][PF_6]_2$.

The ^{1}H NMR spectra of both complexes were completely assigned through use of 2D NMR spectroscopy and by comparison to related compounds[13] (Figure 3). The chemical shifts of the flanking 2,6′-bipyridyl groups for both complexes are generally coincident. The proton shifts attributed to the pyridine ring participating in the metallophane "decks" appear upfield as expected from their local anisotropy. In $[\mathbf{3b}_2Cu_2][PF_6]_2$, the aromatic positions adjacent to the methoxy groups appear at δ = 6.6/6.8 ppm, which we tentatively interpret as evidence of a mutual shielding effect between the two equivalents of disubstituted quinoxaline-like complexes. Of special note in both complexes is the shielding effect on H-3′′, which is attributable to an orthogonal π-stacking interaction with the bipyridyl ring system (c.f. H-3′′′ in **3a** and **3b**). Variable temperature NMR spectra, recorded in $[D_3]$MeCN and non-coordinating $[D_3]MeNO_2$ [14] down to −40 °C, exhibited negligible decoalescence phenomena. It is thus reasonable to assume that $[\mathbf{3a}_2Cu_2][PF_6]_2$ and $[\mathbf{3b}_2Cu_2][PF_6]_2$ possess similar structures in solution.

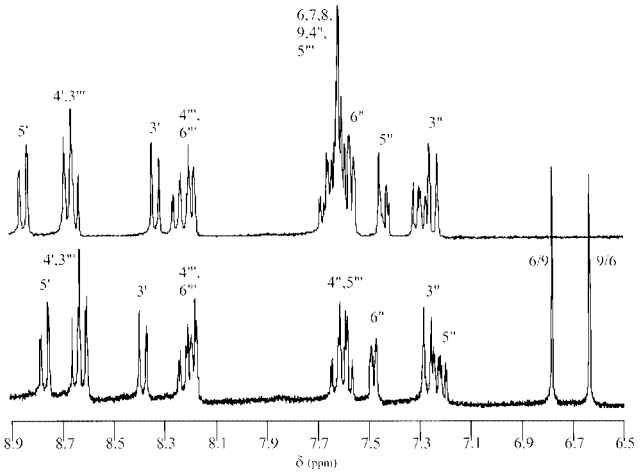

Figure 3. ^{1}H NMR Spectra of dicopper(I) metallophanes $[\mathbf{3a}_2Cu_2][PF_6]_2$ and $[\mathbf{3b}_2Cu_2][PF_6]_2$ (CD_3CN, 270 MHz)

A crystal structure analysis was undertaken on the complex $[\mathbf{3a}_2Cu_2][PF_6]_2$ to investigate its stereochemistry and lattice packing.[15] A double-decker geometry results from the combination of two bidentate sites (2,6′-bipyridyl and 2′,3"-pyridylquinoxalinyl) surrounding each tetrahedral metal center. Quinoxaline N adjacent to bipyridyl remains uncoordinated. While this arrangement is shared by both the C_2- and *meso*-diastereomers, the dication crystallizes in the C_2-symmetric form, that is, pyridyl quinoxaline moieties within the same dication are arranged in a parallel fashion. The overall crystal symmetry (space group *Pbca*) corresponds to a racemic crystal; one of the two equally likely enantiomers is displayed in Figure 4.

Intramolecularly, the quinoxaline ring fragments overlap in an offset fashion (Figure 5). This also results in classical parallel π-stacking overlap[16] between areas of low and high electron density. The geometrical center of the benzenoid subring on quinoxaline is separated from quaternary C(8a) by 3.45 Å, while the center of the pyrazinoid

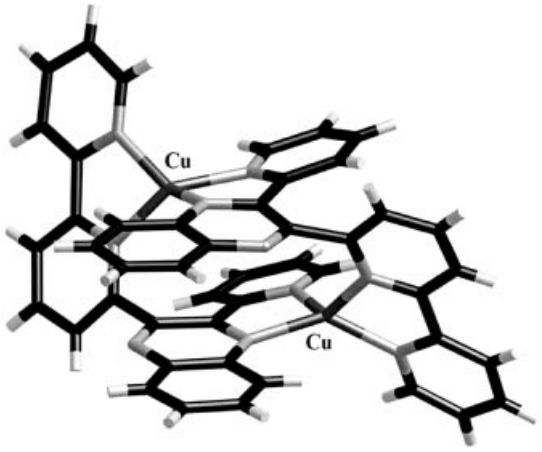

Figure 4. X-ray crystal structure of one of the two enantiomeric dicopper(I) cations from $[\mathbf{3a}_2Cu_2][PF_6]_2$

ring is closest to C(4a) at 3.40 Å. The stacked quinoxalinyl ring system is twisted by 18.67° relative to pyridyl. A consequence of this is that while the quinoxaline ring atoms are separated from the mean plane of the opposing quinoxaline ring by 3.36 ± 0.04 Å, the average atomic separation from the pyridylquinoxaline system to its opposing mean plane is 3.43 ± 0.16 Å. The two quinoxalinyl fragments deviate by 1.3° from coplanarity, while the two stacked pyridyl residues the deviation is 5.9°.

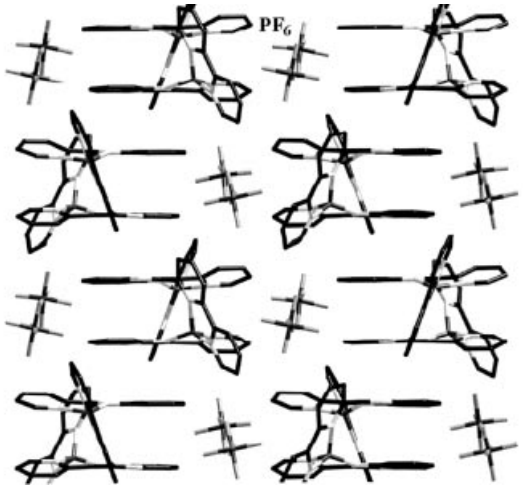

Figure 5. Crystal lattice of $[\mathbf{3a}_2Cu_2][PF_6]_2$

Homochiral dicationic complexes interact through offset stacking interactions involving the quinoxaline ring systems (average distance of quinoxaline atoms from the mean plane, 3.35 ± 0.09 Å; dihedral angle between planes: 3.90°); in particular those involving benzo and pyrazinyl domains overlap (distance between ring centers, 3.63 Å). Strata composed of Δ,Δ- and Λ,Λ−configured metallophane dimers are separated by weaker parallel edge-on contacts between 2,2′-bipyridyl flanks (ca. 4.8 Å) and the hexafluorophosphate counterions.

Conclusion

The applicability of quinoxaline-pyridine hybrids for engineering highly stacked, self-assembling metallo-organic networks has been confirmed. It employs a combination of heterocyclic synthesis, a new metallo-organic supramolecular synthon and intramolecular π-stacking effects over extended arene surfaces. At least for smaller alkoxy chains, a consequence of the complexes' C_2-symmetry is the location of all four ether functionalities on the same side of the complex dication. The extension of this strategy to the preparation of mesotropic, liquid-crystalline materials is currently under investigation.

Stannaborate Chemistry: Nucleophilic Substitution at the Cluster Sphere

Benno Ronig,[b] Torsten Bick,[b] Ingo Pantenburg,[b] and Lars Wesemann*[a]

Keywords: Boranes / Boron / Tin / Nucleophilic substitution

Nucleophilic substitution at (γ-chloropropyl)stanna-*closo*-dodecaborate $[Cl(CH_2)_3SnB_{11}H_{11}]^-$ with RLi [R = Ph, $Me_2NC_6H_4$, ferrocenyl (Fc)] and RMgBr (R = vinyl, benzyl) affords the substitution products containing the anion $[RSnB_{11}H_{11}]^-$. The reaction products have been characterized by elemental analysis, NMR spectroscopy and in the cases where R = Ph, $Me_2NC_6H_4$, Fc and vinyl by X-ray structure analysis.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The nucleophilic substitution at tin(IV) halides with organic derivatives of electropositive elements is a very important method for the formation of new tin−carbon bonds.[1] In another possible route, triorganylstannyl metal compounds find extensive use for the preparation of Sn−C units.[1] In this context, the nucleophilic substitution at tetraorganotin compounds with basic nucleophilic reagents such as alkyl- or phenyllithium is a less frequently used method and is more well-known in the case of the transmetallation reactions and the preparation of organolithium, organoboron or organocopper compounds. Thus, a straightforward procedure is the formation of vinyllithium by reaction between tetravinyltin and four equivalents of phenyllithium.[2] The equilibrium of this kind of reaction is driven completely to the right side when the stability of the formed organolithium compound is larger than that of the starting lithium reagent.

Currently we are exploring the chemistry of a heteroborate, the stanna-*closo*-dodecaborate $[SnB_{11}H_{11}]^{2-}$ dianion, which is accessible in amounts of about five grams following a two step procedure.[3] The investigation of the ligand abilities of this cluster with respect to its cocatalytic properties and use in metal cluster formation are of interest to us.[4,5] Furthermore, we are studying organic transformation reactions at the cluster sphere. So far it is well established that the dianion $[SnB_{11}H_{11}]^{2-}$ acts as a nucleophile with alkyl iodides or reactive alkyl bromides like propargyl bromide.[6] The reaction with alkyl iodides is equivalent to an oxidation of the tin nucleus deduced from ^{119}Sn NMR and Mössbauer spectroscopy studies.[7] In this publication, we present the nucleophilic substitution at the tin center in alkylated stanna-*closo*-dodecaborate derivatives.

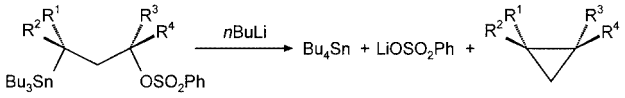
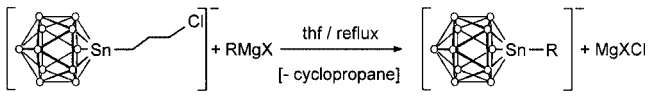
Results and Discussion

(γ-Benzenesulfonyloxy)alkyltributyltin derivatives (Scheme 1) have been used successfully for the synthesis of cyclopropane derivatives.[8] In the stereoselective reaction with *n*-butyllithium, the products are cyclopropane, tetrabutyltin and lithium phenylsulfonate (Scheme 1).[9]



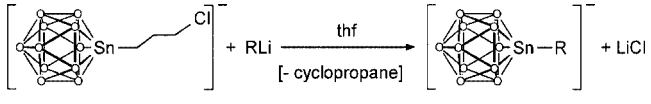
Scheme 1. Stereoselective formation of alkylated cyclopropane derivatives by nucleophilic attack at the tin atom in (γ-benzenesulfonyloxy)alkyltributyltin compounds (R^1−R^4 = alkyl substituent)

In analogy to this cyclopropane formation reaction, we have treated (γ-chloropropyl)stanna-*closo*-dodecaborate (**1**) with a variety of nucleophiles (Scheme 2 and 3). It turned out that the very reactive lithium reagents attack the tin center at room temperature and the desired products **2**, **3** and **4** can be isolated in high yield. Grignard reagents, however, have to be refluxed in THF in order to react successfully at the tin vertex.



$[Bu_3MeN][Cl(CH_2)_3(SnB_{11}H_{11})]$ (1) $[Bu_3MeN][R(SnB_{11}H_{11})]$

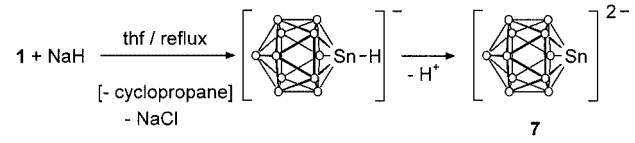
Scheme 2. Nucleophilic substitution at the tin vertex in (γ-chloropropyl)stanna-*closo*-dodecaborate with lithium organic reagents: R = Ph **2**, $[p\text{-}Me_2NC_6H_4]$ **3**, Fc **4**



$[Bu_3MeN][Cl(CH_2)_3(SnB_{11}H_{11})]$ (1) $[Bu_3MeN][R(SnB_{11}H_{11})]$

Scheme 3. Nucleophilic substitution in refluxing THF: R = $CH_2C_6H_5$ **5**, H_2CCH **6**

Reaction of an alkyl-substituted stanna-*closo*-dodecaborate derivative $\{[RSnB_{11}H_{11}]^-\}$ with a nucleophile $[R']^-$ would lead to an equilibrium mixture between $\{[RSnB_{11}H_{11}]^- + [R']^-\}$ and $\{[R'SnB_{11}H_{11}]^- + [R]^-\}$ with the ratios dependent on the stability of the respective anions $[R']^-$ and $[R]^-$. On use of the γ-chloropropyl substituent, this reaction is driven completely to the right side, since the leaving group cyclopropane and the chloride anion are formed. In order to use the γ-chloropropyl substituent as a protecting group, we treated the alkylated cluster **1** with hydride as the nucleophile. From this reaction the unsubstituted cluster **7** was isolated in high yield (Scheme 4).



7

Scheme 4. Substitution reaction with a hydride nucleophile followed by deprotonation

However, so far we were not able to isolate the postulated, protonated cluster anion $[HSnB_{11}H_{11}]^-$ from this reaction or by treatment of **7** with a mineral acid. The air-stable substitution products **2**−**6** have been characterized by elemental analysis, NMR spectroscopy and in the cases of **2**−**4** and **6** by X-ray crystal structure analysis. In the ^1H NMR spectrum of the substitution products, the absence of the characteristic signals of the $Sn-(CH_2)_3-Cl$ group is a very good indicator for a successful reaction. The ^{11}B NMR spectrum of the starting materials and the products exhibit almost no change; two signals around δ = −11 and −16 ppm (B12, B2−B11) are characteristic for the substituted cluster. In order to confirm the geometry of the product salts, X-ray crystal structure determinations have been

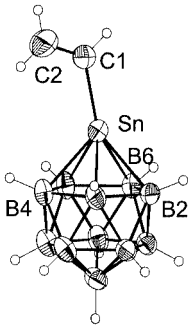

Figure 4. Molecular structure of the anion of $[Bu_3MeN][(H_2CCH)SnB_{11}H_{11}]$ (**6**) in the solid state; thermal ellipsoids are shown at the 50 % probability level; interatomic distances in [pm] (with estimated standard deviations in parentheses): Sn−C1 207.7(5), C1−C2 129.6(8), Sn−B2 229.1(5), Sn−B3 229.3(5), Sn−B4 229.5(6), Sn−B5 230.4(5), Sn−B6 230.3(5)

carried out. In Table 1, details of the X-ray structure solutions are listed and in Figures 1−4, the structures of the respective anions in the solid state are depicted.

The results of the crystal structure determinations are consistent with the findings of elemental analysis and NMR spectroscopy. The geometries of the substituted clusters exhibit no peculiarities and the Sn−B and B−B interatomic distances are in the range known from other derivatives. The deviation from linearity of the angle C−Sn−(antipodal)B (**2** 171.7°, **3** 175.8°, **4** 178.1°, **6** 167.2°) is a common effect in these substituted stannaborate derivatives and can be explained by packing forces in the solid state.

Conclusion

With this straightforward substitution at the tin center in γ-chloropropyl-substituted stanna-*closo*-dodecaborate, a method for the linkage of an aromatic cluster anion with π-systems like the phenyl, ferrocenyl or vinyl moiety has been found.

Experimental Section

General: All manipulations were carried out under dry N_2 in Schlenk glassware; solvents were dried and purified by standard methods and stored under N_2. NMR spectroscopy was performed on a Bruker AC 200 (^{1}H: 200 MHz, int. TMS; ^{11}B{^{1}H}: 64 MHz, ext. $BF_3{\cdot}Et_2O$). Elemental analysis was carried out by the Institut für Anorganische Chemie der Universität zu Köln, on a Heraeus C,H,N,O rapid elemental analyser.

$[Bu_3MeN][PhSnB_{11}H_{11}]$ (2): $[Bu_3MeN][H_{11}B_{11}SnC_3H_6Cl]$ (368 mg, M_r = 526.64 g/mol, 0.699 mmol) was dissolved in 20 mL THF and treated with an excess of phenyllithium (in Et_2O) at −78 °C. After stirring the solution overnight at room temperature, volatiles were removed in vacuo and the residue was washed with H_2O (20 mL). The product was dissolved in CH_2Cl_2, filtered and crystallized by slow diffusion of *n*-hexane to give **2** (234 mg, M_r = 526.21 g/mol, 0.445 mmol, 64 %). ^{1}H NMR (CD_2Cl_2): δ = 0.98 (t, 9 H, ^3J = 7.3 Hz, CH_2CH_3), 1.41 (m, 6 H, CH_2CH_3), 1.64 (m, 6 H, $CH_2CH_2CH_3$), 3.00 (s, 3 H, NCH_3), 3.16 (m, 6 H, NCH_2), 7.55 (m, 5 H, C_6H_5) ppm. ^{11}B{^{1}H} NMR (CD_2Cl): δ = −11.1 (s, B12), −16.4 (s, B2−B6 and B7−B11). $C_{19}H_{46}B_{11}NSn$ (526.21): calcd. C 43.37, H 8.81, N 2.66; found C 43.51, H 8.82, N 2.79.

$[Bu_3MeN][Me_2NC_6H_4SnB_{11}H_{11}]$ (3): $[Bu_3MeN][H_{11}B_{11}SnC_3H_6Cl]$ (477 mg, M_r = 526.64 g/mol, 0.906 mmol) was dissolved in 20 mL THF and treated with an excess of [*p*-$Me_2NC_6H_4Li$] in Et_2O at −78 °C. After stirring the solution overnight at room temperature, volatiles were removed in vacuo and the residue was washed with H_2O (20 mL). The product was dissolved in CH_2Cl_2, filtered and crystallized by slow diffusion of *n*-hexane to give **3** (186 mg, M_r = 569.28 g/mol, 0.327 mmol, 36 %). ^{1}H NMR (CD_2Cl_2): δ = 1.00 (t, 9 H, ^3J = 7.3 Hz, CH_2CH_3), 1.41 (m, 6 H, CH_2CH_3), 1.66 (m, 6 H, $CH_2CH_2CH_3$), 2.92 [s, 6 H, $C_6H_4N(CH_3)_2$], 3.01 (s, 3 H, NCH_3), 3.19 (m, 6 H, NCH_2), 7.20 (m, 4 H, C_6H_4) ppm. ^{11}B{^{1}H} NMR (CD_2Cl_2): δ = −12.1 (s, B12), −16.9 (s, B2−B6 and B7−B11). $C_{21}H_{51}B_{11}N_2Sn$ (569.28): calcd. C 44.31, H 9.03, N 4.92; found C 42.99, H 8.95, N 4.71.

$[Bu_3MeN][FcSnB_{11}H_{11}]$ (4): $[Bu_3MeN][H_{11}B_{11}SnC_3H_6Cl]$ (500 mg, M_r = 526.64 g/mol, 0.949 mmol) was dissolved in THF at −78 °C and treated with a solution of $Li[C_5H_4FeC_5H_5]$ (546 mg, M_r = 562.67 g/mol, 0.889 mmol) in THF (20 mL). After stirring the solution overnight at room temperature, volatiles were removed in vacuo and the residue was washed with H_2O (20 mL). The product was dissolved in CH_2Cl_2, filtered and crystallized by slow diffusion of *n*-hexane to give **4** (423 mg, M_r = 634.13 g/mol, 0.667 mmol, 75 %). ^{1}H NMR (CD_2Cl_2): δ = 1.02 (t, 9 H, ^3J = 7.8 Hz, CH_2CH_3), 1.48 (m, 6 H, CH_2CH_3), 1.66 (m, 6 H, $CH_2CH_2CH_3$), 3.01 (s, 3 H, NCH_3), 3.20 (m, 6 H, NCH_2), 4.37 (s, 5 H, FeC_5H_5), 4.52 [s, 2 H, SnC-$(CH)_2$-$(CH)_2$], 4.60 [s, 2 H, SnC-$(CH)_2$-$(CH)_2$] ppm. ^{13}C{^{1}H} NMR (CD_2Cl): δ = 13.8 (CH_2CH_3), 20.1 (CH_2CH_3), 24.7 ($CH_2CH_2CH_3$), 49.5 (NCH_3), 62.5 (NCH_2), 70.4 (FeC_5H_5), 72.1 [SnC-$(CH)_2$-$(CH)_2$], 75.1 [SnC-$(CH)_2$-$(CH)_2$] ppm. ^{11}B{^{1}H} NMR (CD_2Cl_2): δ = −12.6 (s, B12), −17.3 (s, B2−B6 and B7−B11). $C_{23}H_{50}B_{11}FeNSn$ (634.13): calcd. C 43.56, H 7.95, N 2.21; found C 43.35, H 8.05, N 2.25.

$[Bu_3MeN][PhCH_2SnB_{11}H_{11}]$ (5): $[Bu_3MeN][H_{11}B_{11}SnC_3H_6Cl]$ (670 mg, M_r = 526.64 g/mol, 1.27 mmol) was dissolved in THF (30 mL) and treated with $PhCH_2MgBr$ (0.95 mL, 2 M solution in THF, 1.90 mmol). After stirring overnight at reflux temperatures, the solution turned yellow and volatiles were removed in vacuo. The residue was washed with H_2O (20 mL). The remaining residue was dissolved in EtOH, filtered and crystallized to give **5** (0.61 g, M_r = 540.24 g/mol, 1.13 mmol, 89 %). ^{1}H NMR (CD_2Cl_2): δ = 1.01 (t, 9 H, ^3J = 7.3 Hz, CH_2CH_3), 1.41 (m, 6 H, CH_2CH_3), 1.62 (m, 6 H, $CH_2CH_2CH_3$), 3.01 (s, 3 H, NCH_3), 3.17 (m, 6 H, NCH_2), 3.98 (s, 2 H, -$SnCH_2Ph$), 7.32 (m, 4 H, C_6H_4) ppm. ^{11}B{^{1}H} NMR (CD_2Cl_2): δ = −12.5 (s, B12), −17.1 (s, B2−B6 and B7−B11). $C_{20}H_{48}B_{11}NSn$ (540.24): calcd. C 44.47, H 8.96, N 2.59; found C 43.93, H 9.16, N 2.67.

$[Bu_3MeN][(H_2CCH)SnB_{11}H_{11}]$ (6): $[Bu_3MeN][H_{11}B_{11}SnC_3H_6Cl]$ (850 mg, M_r = 526.64 g/mol, 1.61 mmol) was dissolved in THF (30 mL) and treated with vinylmagnesium bromide (1.93 mL, 1 M solution in THF). After stirring the reaction mixture under reflux overnight, all volatiles were removed in vacuo. The residue was washed with H_2O (20 mL). Crystallization from CH_2Cl_2 by diffusion of *n*-hexane affords **6** (0.71 g, M_r = 476.11 g/mol, 1.49 mmol, 87 %). ^{1}H NMR (CD_2Cl_2): δ = 1.01 (t, 9 H, ^3J = 7.1 Hz, CH_2CH_3), 1.46 (m, 6 H, CH_2CH_3), 1.68 (m, 6 H,

New Bulky Bis(amino)cyclodiphosph(III)azanes and Their Titanium(IV) Complexes: Synthesis, Structures and Ethene Polymerization Studies

Kirill V. Axenov,[a] Vasily V. Kotov,[b] Martti Klinga,[a] Markku Leskelä,[a] and Timo Repo*[a]

Keywords: Phosphazenes / Titanium / Homogeneous catalysis / Polymerization

Bis(amino)cyclodiphosph(III)azanes *cis*-[(RNH)(PN-*t*Bu)]$_2$, R = 2,6-*i*Pr$_2$C$_6$H$_3$ (**2**), 2-*t*BuC$_6$H$_4$ (**3**), 2-CF$_3$C$_6$H$_4$ (**4**), 2,5-*t*Bu$_2$C$_6$H$_3$ (**5**), Ph$_2$CH (**6**), 2,4-Me$_2$C$_6$H$_3$ (**7**), 2,6-Et$_2$C$_6$H$_3$ (**8**), have been synthesized in the presence of Et$_3$N by a nucleophilic substitution reaction of *cis*-(ClPN-*t*Bu)$_2$ (**1**) with the corresponding bulky aryl and alkylamines. The bis(amino)-cyclodiphosph(III)azanes **2**–**8** adopt the thermodynamically stable *cis*-configuration – a prerequisite for efficient metal complex formation. Deprotonation of bis(amino)cyclodiphosph(III)azanes with *n*BuLi slowly afforded the corresponding salts, *cis*-[(2,4-Me$_2$C$_6$H$_3$N)(PN-*t*Bu)]$_2$Li$_2$(THF)$_2$. The crystal structure of *cis*-[(2,4-Me$_2$C$_6$H$_3$N)(PN-*t*Bu)]$_2$Li$_2$(THF)$_2$ (**9**) consists of a heterocube of two lithium atoms, two nitrogen atoms and a cyclodiphosph(III)azane ring. Transmetallation of Li compounds by TiCl$_4$ was unselective and led to a complex mixture of products. The direct reaction of *cis*-bis(amino)cyclodiphosph(III)azanes with Ti(NMe$_2$)$_4$ is the most efficient method to prepare the corresponding titanium(IV) bis-amido complexes *cis*-[(RN)(PN*t*Bu)]$_2$Ti(NMe$_2$)$_2$ (**11a**, **12a**, **14a**, **15a**). In the solid state, *cis*-[(PhN)(PN-*t*Bu)]$_2$Ti(NMe$_2$)$_2$ (**11a**) adopts a highly distorted trigonal-bipyramidal configuration at the metal center. These bis-amido titanium(IV) complexes have been subsequently transformed into the dichlorides *cis*-[(RN)(PN-*t*Bu)]$_2$TiCl$_2$ (**12**–**15**) with Me$_3$SiCl. After MAO activation the complexes possess moderate catalytic activity in ethene polymerization and produce linear polyethylene with molar masses of up to 2.6×10^6 g/mol and with narrow polydispersities. The catalytic activity and polymer properties depend strongly on the bulkiness of the ligand substituents; *cis*-[(2,6-*i*Pr$_2$C$_6$H$_3$N)(PN-*t*Bu)]$_2$TiCl$_2$ (**14**) gave the highest activity (231 kg PE/mol$_{cat}$ × bar × h).

Introduction

The highly efficient homogeneous α-olefin polymerization catalysts based on methylalumoxane (MAO) activated Group 4 metallocene dichlorides have stimulated intensive polymerization catalysis research over the past three decades.[1] The major focus has been on the preparation of various *ansa*-metallocenes, especially ones intended for the stereoselective polymerization of propene.[2] Numerous studies have also been made on late transition metal complexes,[3] constrained geometry catalysts[4] and complexes of Group 4 metals with non-cyclopentadienyl ligands. The substantial progress on non-metallocene polymerization catalysis has been achieved by both the "right" choice of a transition metal and the rational design of the ligand systems. Recent highly successful catalysts have been based on titanium and zirconium phenoxyimino-type complexes having novel polymerization properties,[5] as well as on highly efficient C_1-symmetric Group 4 pyridyl-amine catalysts aimed for isospecific propene polymerization.[6]

Ligands containing heteroatoms (e.g. phosphorus, nitrogen) are candidates for catalyst components because they bind strongly to the early transition metals and their mode of coordination as well as ligand hapticity can be varied.[7a] This allows the electronic character, geometric properties and steric protection of the catalytic center to be modified.[7] Bis(amido) complexes of titanium(IV) have attracted considerable attention because of their high activity in ethene polymerization after activation with MAO.[7,8] Thus, we found bis-amino type *cis*-2,4-bis(amino)cyclodiphosph(III)-azanes of the general formula *cis*-[(RNH)(PN-*t*Bu)]$_2$ to be interesting ligand precursors for olefin polymerization catalysts. The coordination chemistry of simple *cis*-2,4-bis(amino)cyclodiphosph(III)azanes, namely *cis*-[(*t*BuNH)(PN-*t*Bu)]$_2$ and *cis*-[(PhNH)(PN-*t*Bu)]$_2$ (structure A), has been described in the synthesis of both main group compounds[9] and titanium(IV), zirconium(IV) and hafnium(IV) complexes (structure B).[10,11,12] Their polymerization properties have not, to our knowledge, been published.

The relatively straightforward synthesis of various *cis*-2,4-bis(amino)cyclodiphosph(III)azanes make them attractive candidates to study the ligand's influence on the polymerization properties. In the present work, a synthetic approach to new *cis*-2,4-bis(amino)cyclodiphosph(III)azane ligands, *cis*-[(RNH)(PN-*t*Bu)]$_2$ (**2**–**8**), bearing bulky amino substituents and their titanium(IV) complexes has been developed and ethene polymerization studies carried out.

Results and Discussion

Ligand Synthesis

Phosphazanes, both cyclic and acyclic,[13] are stable P–N compounds that are easily synthesized. Cyclodiphosph(III)-azanes (containing a P_2N_2 moiety) were first reported by Michaelis and Schroeter in 1894[14] but were fully characterized only in the 1970s.[15,16] They have attracted most attention as precursors for hybrid (organic-inorganic) P–N polymeric materials,[16c] and as ligand precursors for the synthesis of main group element compounds[9] and some, still rare, early transition metal complexes.[10,11,12] They preparation, in good yield, is commonly based on the reaction of *cis*-(ClPN-*t*Bu)$_2$ (**1**) with either lithium amide or an excess of a free amine.[9] We investigated both of these methods to access the new, bulky bis(amino)cyclodiphosph(III)azanes.

However, some modifications of these general procedures became necessary as, for instance, 2,4-dimethylphenyllithiumamide in THF reacted with **1** nonselectively, and according to ^{31}P NMR data the cyclodiphosph(III)azane P_2N_2 ring was destroyed. Direct aminolysis of the P–Cl bond with free amines was then explored but, even under severe conditions, direct substitution was negligible. For example, **1** and 2,6-diisopropylphenylamine, failed to react under various conditions, even after refluxing in THF for one week; ^{31}P NMR data revealed only the starting compound **1** and the free amine. Apparently, the nucleophilic substitution did not take place because of the steric demand of the amine.

Another synthetic possibility is the application of Et_3N as a base in the reaction of **1** with bulky arylamines.[9] Thus, the reaction of **1** with 2,6-diisopropylphenylamine and an excess of Et_3N (4 equiv.), after refluxing for four days, gave, finally, the desired disubstituted compound *cis*-[(2,6-*i*Pr$_2$C$_6$H$_3$NH)(PN-*t*Bu)]$_2$ (**2**) in good yield. Further experiments with different ratios of reactants and reaction times showed the limitations of this reaction; the selectivity depends strongly on the ratio of arylamine to Et_3N, and on the refluxing time (Scheme 1). This optimized synthetic procedure was then applied to give various bis(amino)cyclodiphosph(III)azanes (**3**–**8** in Scheme 2).

Scheme 2

Et_3N acts as more than a simple Brönsted base that scavenges the generated HCl – at least four equivalents of it are required to obtain good yields. Some of the Et_3N can assist the nucleophilic substitution by coordination and polarization of the P–Cl bonds of (ClPN-*t*Bu)$_2$ (**1**), while the rest acts as a traditional Brönsted base.

Structure of the Bis(amino)cyclodiphosph(III)azanes

The obtained bis(amino)cyclodiphosph(III)azanes are colorless, air-sensitive oils or solids that are very soluble even in aliphatic hydrocarbon solvents. Despite the long refluxing times, the reactions proceed selectively and, according to ^{31}P NMR, yield only one product from each reaction. Bis(amino)cyclodiphosph(III)azanes can exist as *cis* and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

trans isomers; the differences in chemical shifts in the ^{31}P NMR spectra indicate which is present.[17] According to NMR spectroscopic data, the synthesized bis(amino)cyclodiphosph(III)azanes (**2**–**8**) adopt the synthetically more desirable, and thermodynamically more stable, *cis*-conformation (Exp. Sect.).

The single-crystal X-ray measurements of **3**–**5** also support the exclusive presence of the *cis*-isomer. The solid-state structures (Figures 1–3) and selected structural parameters (Table 1) are presented here. The solid-state structures reveal that the P_2N_2 cyclodiphosph(III)azane rings are bent from the mean plane. Such disturbance of the P_2N_2 rings accords with the results of earlier molecular orbital calculations for *cis*-cyclodiphosph(III)azanes with small amino substituents,[18] and may be caused by repulsive lone pair–bond pair electronic interactions.[9] Despite the sterically bulky aryl or alkyl substituents on these bis(amino)cyclodiphosph(III)azanes the basic structural features (bond lengths and angles) of the ligand backbone are rather similar to ones reported earlier (Table 1).

The solid-state structure of *cis*-[(2-*t*BuC_6H_4NH)(PN-*t*Bu)]$_2$ (**3**) (Figure 1), which has only monosubstituted aniline groups, resembles that established for *cis*-[(PhNH)(PN-*t*Bu)]$_2$.[9,12] In both structures, the *tert*-butyl groups on the P–N ring are bent towards the P_2N_2 mean plane [for **3**: C(1)–P_2N_2 plane 161.05(3)° and C(5)–P_2N_2 plane 170.94(3)°] and the orientation of the anilines gives an overall C_{2v} symmetry. The slight asymmetry of the P_2N_2 ring in **3** is reflected by the P–N endocyclic bond lengths, which vary from 1.707(3) to 1.728(3) Å.

The structural features of *cis*-[(2-$CF_3C_6H_4$NH)(PN-*t*Bu)]$_2$ (**4**) resemble those of **3** (Figure 2). The electron-with-

drawing CF_3 substituents on the aniline groups have a significant influence only on the P(2)−N(2) and P(1)−N(1) bond lengths, while the puckering of the P_2N_2 ring is fairly similar to that for **3**. Owing to the second *tert*-butyl group on the aniline moiety *cis*-[(2,5-di-*t*BuC_6H_3NH)(PN-*t*Bu)]$_2$ (**5**) (Figure 3) has lost its superfacial C_{2v} symmetry. The bond lengths and angles in the P_2N_2 ring are nevertheless similar to those of **3**.

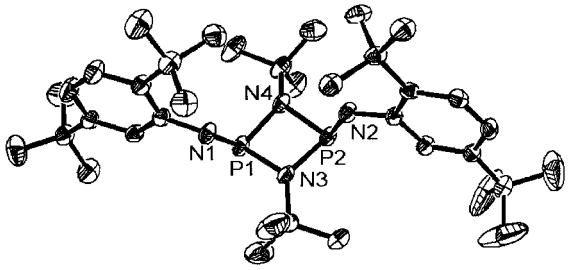

Figure 3. ORTEP diagram of *cis*-[(2,5-tBu$_2C_6H_3$NH)(PN-*t*Bu)]$_2$ (**5**)

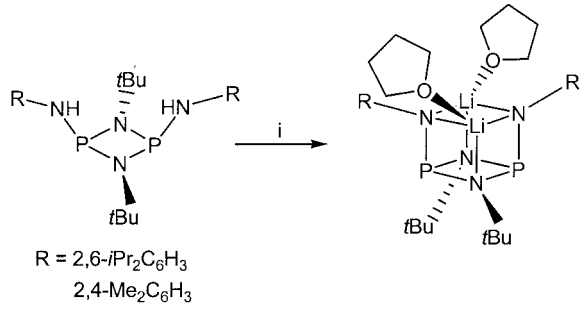
Synthesis of Titanium(IV) Complexes

Of the various literature methods for the preparation of early transition metal complexes the general route is the transmetallation reaction between transition metal halides and alkali or alkaline earth metal salts of the ligand.[19] Applying a procedure described earlier,[20] the desired dilithium salts of *cis*-[(2,6-di-*i*PrC_6H_3NH)(PN-*t*Bu)]$_2$ (**2**) (see supporting information) and *cis*-[(2,4-di-MeC_6H_3NH)(PN-*t*Bu)]$_2$ (**7**) were prepared in THF (Scheme 3). According to the ^{1}H and ^{13}C NMR spectra, the lithium salts contains two coordinated THF molecules. The phosphorus signal at 163.01 ppm in the ^{31}P NMR spectrum confirms the formation of the lithium salt *cis*-[(2,4-di-MeC_6H_3N)(PN-*t*Bu)]$_2$-Li$_2$(THF)$_2$ (**9**).[21]



i - *n*BuLi, THF, reflux, 5h

Scheme 3

Recrystallization of the dilithium salt **9** from THF/hexane solution provided crystals suitable for X-ray study (Figure 4). Selected bond lengths and angles are collected in Table 2. The P_2N_2 ring is almost planar, which is also related to the symmetry of the molecule and to the equal bond lengths in the ring. The P_2N_2 ring, exocyclic N, and both Li atoms form an inorganic heterocube that is surrounded by the aniline groups of the ligand and two coordinated THF molecules. The exocyclic P−N bonds are shorter than the endocyclic ones [1.674(3) vs. 1.768(3) Å]. The bond lengths between Li and the exocyclic nitrogen atoms are almost equal [from 2.071(6)Å to 2.095(6)Å] and similar to those in related lithium amides [Li−N in {Li[N(SiMe$_3$)$_2$]OEt$_2$}$_2$ are 2.06(1) Å].[22] Thus, the solid-state structure of compound **9** has similar features to those described for *cis*-[(*t*BuN)(PN-*t*Bu)]$_2$Li$_2$(THF)$_2$,[21] but in **9** the lithium atom and endocyclic nitrogen atoms are further apart [2.133(6) Å] and can be considered typical for bonds between a coordinated lithium cation and a donor nitrogen atom.

[a] Label "a" means a symmetry equivalent atom at $-x$, y, $-z + 1/2$.

To synthesize titanium(IV) dichloride complexes from the *cis*-2,4-bis(amino)cyclodiphosph(III)azanes the above-described lithium salts were treated with $TiCl_4$. Surprisingly, the transmetallation reaction failed and led to a complex mixture of unidentified products. Only one complex, [(*t*BuN)$_2$(PN-*t*Bu)$_2$]$TiCl_2$ (**10**), previously synthesized by Stahl et al.[23] was obtained. This might be due either to the

steric demand of the obtained lithium {see the solid-state structure of [(2,4-di-MeC_6H_3N)(*t*BuNP)]$_2Li_2(THF)_2$ (**9**)} salts, which slow down the reaction, or to titanium tetrachloride, a strong Lewis acid, which may attack the P−N bond of the P_2N_2 cycle or the phosphorus lone pair more readily than a N−Li or N−Mg bond.

An alternative approach, the direct metallation of the ligand precursors through amine elimination,[24] turned out to be efficient. The reaction of the less Lewis-acidic $Ti(NMe_2)_4$ with [(RNH)(*t*BuNP)]$_2$ (**2**, **5**, **6**, **8**) occurred selectively, according to ^1H and ^{31}P NMR data, and the bis-amido complexes [(RNH)(*t*BuNP)]$_2Ti(NMe_2)_2$ (**11a**−**15a**) were formed (Scheme 4). Such bis-amido complexes are usually oils, and are highly soluble in aliphatic solvents, making their separation and purification difficult. Therefore, they were characterized on the basis of ^1H, ^{13}C and ^{31}P NMR spectroscopic data (see Supporting Information). Their ^1H NMR spectra revealed the C_{2v} symmetry expected for such titanium(IV) complexes and indicate the equivalence of all alkyl and aromatic substituents. Only the ligand precursor **4**, with electron-withdrawing CF_3 substituents, behaved differently, and complex formation under similar reaction conditions was incomplete.

With *cis*-[$(PhN)_2$(PN-*t*Bu)$_2$]$Ti(NMe_2)_2$ (**11a**), crystals suitable for X-ray analysis were obtained from a saturated hexane solution at −20 °C. The ORTEP diagram of **11a** (Figure 5) and selected bond lengths and angles (Table 3) are given here. In the solid state, four metal−amide bonds and an additional donor bond from one of the cyclophosph(III)azane ring nitrogen atoms define a highly distorted trigonal-bipyramidal coordination at the central titanium atom, reducing the symmetry of this molecule from C_2 to C_s in the solid state. In general, the coordination sphere of **11a** resembles previously described structures for Ti, Zr and Hf complexes based on the *cis*-[(*t*BuNH)(PN-*t*Bu)]$_2$ ligand.[10,11,12] The cyclophosph(III)azane ring is almost planar and the phenyl rings are almost perpendicular to the P_2N_2 plane and, hence, leave the metal center relatively open to nucleophilic attack.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

compound $[(t\text{BuN})_2(\text{PN-}t\text{Bu})_2]\text{TiCl}_2$).[11] This may be due to NMe_2 substituents donating additional electron density from the sp^2-hybridized amido nitrogen atoms to the metal center, thereby decreasing the Lewis acidity of the titanium. Four amido nitrogen atoms are in a pseudo-tetrahedral environment around the metal center [N(1)−Ti−N(2) and N(5)−Ti−N(6) are 111.80 (1)° and 98.66 (2)° respectively] and the amido N−Ti bond lengths vary from 1.884 (4) to 2.020 (3) Å (Table 3).

Dichlorotitanium(IV) complexes are preferred as catalyst precursors in olefin polymerization due to their higher activity than the corresponding bis(amido) derivatives.[1a] The standard transformation of early transition metal bis(amido) complexes into their dichloride derivatives involves the reaction with an excess of Me_3SiCl.[25] Thus, we treated $[(RN)_2(\text{PN-}t\text{Bu})_2]\text{Ti}(NMe_2)_2$ (**11a**, **12a**, **14a**, **15a**) with an excess of Me_3SiCl (Scheme 4). The one-pot synthesis of $[(RN)_2(\text{PN-}t\text{Bu})_2]\text{TiCl}_2$ complexes is also possible, starting from a ligand precursor, tetrakis(dimethylamido)-titanium(IV) and Me_3SiCl (see Exp. Sect., **13**).

Evaporation of all solvents, followed by extraction with a mixture of CH_2Cl_2/hexane, gave the dichloro titanium(IV) complexes $[(RN)_2(\text{PN-}t\text{Bu})_2]\text{TiCl}_2$ (**12−15**) in good yield. All ^{1}H NMR spectra display a clear singlet at δ = 1.0−1.4 ppm for the imido *t*Bu groups, peaks at δ = 1.0-4.0 ppm for the alkyl substituents, and signals at δ = 7.0−7.8 ppm for the aromatic protons (see supporting information). Phosphorus signals in the ^{31}P NMR spectra appear in the same region as the peaks of the corresponding ligand. This indicates the covalent character of the Ti−amido bond, whereas in the lithium salts the Li−N bonds are strongly polarized.

With *cis*-$[(\text{PhN})_2(\text{PN-}t\text{Bu})_2]\text{Ti}(NMe_2)_2$ (**11a**), amine elimination by Me_3SiCl was unselective and led to the destruction of the parent bis-amido complex. This can be taken as a limitation of the synthetic route, since, without sufficient steric hindrance from the ligand side, breakage of the Ti−N phosphazane amido bond may occur instead of breakage of the Ti−N dimethylamido bond. Apparently, the phenyl group alone is not bulky enough to sufficiently protect the bonding between the metal center and ligand moiety and may be a reason for the lack of selectivity.

Ethene Polymerization

In addition to the preparative chemistry described above the ligand's influence on the titanium(IV) complexes in ethene polymerization was also investigated. After methylalumoxane (MAO) activation all dichloro titanium(IV) complexes $[(RN)_2(\text{PN-}t\text{Bu})_2]\text{TiCl}_2$ (**12−15**), regardless of polymerization temperature, produced high molar mass linear polyethylene. The polymerization results and the properties of the obtained polymers are summarized in Table 4.

Catalyst **10**/MAO bearing *tert*-butyl groups showed a remarkably high initial catalytic activity that severely declined after a few minutes (Figure 6, curve a). The polyethene produced had a high molar mass and a bimodal molar mass distribution, indicating at least two different active centers (run 1 in Table 4; M_w1 = 1 927 000 g/mol, M_w2 = 42 000 g/mol, for GPC curve see supporting information). After activation with MAO, complexes **12** with diphenylmethylamino substituents gave lower initial activities than **10**/MAO, but the steady state consumption of ethene was higher (run 2 in Table 4, curve b in Figure 6). Catalyst precursors **13** and **15** are slowly activated by MAO (Figure 6, curves c and e, respectively) but the high steady state of **15**/MAO is noteworthy. The polymers obtained with **12**/MAO and **13**/MAO exhibit a low molar mass shoulder in the GPC curve, which also explains the relatively large polydispersity (PD) values. **15**/MAO produces ultrahigh molar mass polyethene (M_w = 2.56 × 10^6 g/mol, M_w/M_n = 2.8).

Complex **14**/MAO displayed a combination of high initial activity and slow decline in productivity (Figure 6, d). After one hour of polymerization with the catalysts under similar conditions, the highest polymerization activity was recorded for **14**/MAO (121 kg of PE/(mol_{cat} × bar × h) (run 5 in Table 4). The polymer also exhibited a high molar mass (2.6 × 10^6 g/mol) and a narrow PD (2.17). In a further study, we examined the influence of catalyst concentration and polymerization temperature. Lower amounts of catalyst resulted in higher activities with no significant change in the molar mass of the polymers. For example, when the amount of catalyst **14**/MAO was halved (from 20 μmol to 10 μmol) and then to 5 μmol, the polymerization activity increased from 121 to 143 and 231 kg of PE/(mol_{cat} × bar

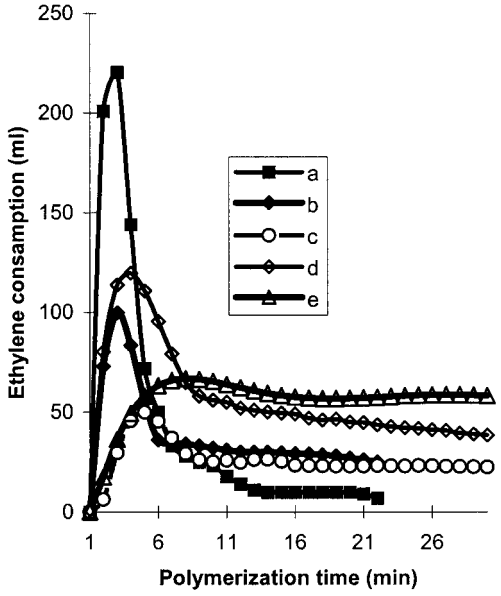

Figure 6. Ethylene consumption curves from polymerization experiments with (a) $[(t\text{BuN})(t\text{BuNP})]_2TiCl_2$ (**10**), (b) $[(Ph_2CHN)(t\text{BuNP})]_2TiCl_2$ (**12**), (c) $[(2,6\text{-}Et_2PhN)(t\text{BuNP})]_2TiCl_2$ (**13**), (d) $[(2,6\text{-}i\text{Pr}_2PhN)(t\text{BuNP})]_2TiCl_2$ (**14**), and (e) $[(2,5\text{-}t\text{Bu}_2PhN)(t\text{BuNP})]_2TiCl_2$ (**15**) as catalyst precursors

$\times$ h) (runs 5, 4 and 7, respectively, in Table 4). This indicates that mass transfer effects play an important role. On increasing the temperature from 50 to 70 °C (runs 5 and 6), the molar mass of the polymers clearly decreases, from 2.5 to 1.4 $\times$ 10^6 g/mol, while the PD is the same. This reveals that catalyst **14**/MAO is stable at higher temperatures.

From the results above, it appears that the catalytic performance of the bis(amido)cyclodiphosph(III)azane titanium(IV)dichlorides depends strongly on the ligand substituents. Activation with MAO was faster for the amido complexes $[(t\text{BuN})(t\text{BuNP})]_2TiCl_2$ (**10**) and $[(Ph_2CHN)(t\text{BuNP})]_2TiCl_2$ (**12**) than for the complexes **13**−**15** with aniline substituents. Moreover, the rate of decline of the polymerization and the steady state values depend on the catalyst precursors used. This indicates that the steric bulkiness of the ligand substituents can influence a sensitive equilibrium between active and dormant metal centers. The bulkiest aniline complex, **15**/MAO, exhibited the highest steady state activities followed by *cis*-$[(2,6\text{-}i\text{Pr}_2C_6H_3N)_2(PN\text{-}t\text{Bu})_2]TiCl_2$ (**14**) and *cis*-$[(2,6\text{-}Et_2C_6H_3N)_2(PN\text{-}t\text{Bu})_2]TiCl_2$ (**13**), i.e. in the order of steric bulkiness.

The polymerization behavior of **10**/MAO ($[(t\text{BuN})(t\text{BuNP})]_2TiCl_2$) is unique due to the bimodal molar mass distribution of the polymer. The relatively small *tert*-butyl groups not only leave the titanium center open for activation and polymerization but, at the same time, the catalyst is susceptible to side reactions. Coordination of the Lewis acidic cocatalyst (MAO) to the lone-pair electrons of phosphorus atoms can initiate destruction of the ligand,[11] which could explain the presence of different active centers and could also be one reason for the fast catalyst deactivation. Therefore, bulky aromatic groups attached directly to the amido nitrogen (**13**−**15**) have two roles: they protect the catalytic active center from side reactions and they prevent the phosphorus atoms of the ligand from destructive coordination to MAO.

Conclusion

New bis(amino)cyclodiphosph(III)azanes *cis*-$[(RNH)(PN\text{-}t\text{Bu})]_2$ **2**−**8** [R = 2,6-$i\text{Pr}_2C_6H_3$ (**2**), 2-$t\text{BuC}_6H_4$ (**3**), 2-$CF_3C_6H_4$ (**4**), 2,5-$t\text{Bu}_2C_6H_3$ (**5**), Ph_2CH (**6**), 2,4-$Me_2C_6H_3$ (**7**), 2,6-$Et_2C_6H_3$ (**8**)] bearing bulky substituents have been synthesized. According to NMR spectroscopic data and single-crystal X-ray analysis, all compounds adopt the thermodynamically more stable *cis*-configuration. Bis(amino)cyclodiphosph(III)azanes can be deprotonated with *n*BuLi, but an extended reaction time is required for complete formation of the lithium salts. The straightforward method of $TiCl_4$ transmetallation of these Li salts proceeded unselectively and gave a complex mixture of products. Direct reaction of $[(RNH)(t\text{BuNP})]_2$ (**2**, **5**, **6**, **8**) with the less Lewis acidic $Ti(NMe_2)_4$ and application of the amine elimination approach led to the desired bis(amido)cyclodiphosph(III)azane titanium(IV) dichloro complexes $[(RN)(t\text{BuNP})]_2TiCl_2$ (**12**−**15**) in high yield. According to the ^{31}P NMR spectra, the titanium(IV)-amido bonds in these complexes have covalent character.

MAO activated titanium(IV)dichloride complexes $[(RN)(t\text{BuNP})]_2TiCl_2$ (**12**−**15**) display moderate ethene polymerization activity. The polymerization behavior depends on the bulkiness of the ligand substituents. Large alkyl and aryl groups both protect the catalytically-active site from side reactions and prevent the phosphorus atoms of the ligand from destructive MAO coordination. Complex $[(t\text{BuN})(t\text{BuNP})]_2TiCl_2$ (**10**), bearing *t*Bu groups, exhibits an initially high polymerization activity, but ethene consumption falls off sharply after just a few minutes. $[(RN)(t\text{BuNP})]_2TiCl_2$ **12**−**15** produce very high molar mass polyethylene with a relatively narrow molar mass distribution. The bulky aromatic groups in **12**−**15** protect the metal center, which is seen in the slow decline of the catalytic activity during prolonged polymerization. The series of catalysts described here offers an efficient route toward very high or even ultrahigh molar mass linear polyethene. The focus of our future research is to introduce other early transition metals into the coordination chemistry of bis(amino)cyclodiphosph(III)azanes so as to enhance their catalytic performance.

Experimental Section

General Remarks: All manipulations were performed under an argon atmosphere using standard Schlenk techniques. The hydrocarbon and ethereal solvents were boiled under reflux over sodium and benzophenone, distilled, and stored under an inert atmosphere with pieces of sodium. Dichloromethane was boiled under reflux with CaH_2 powder and distilled before use. Mass spectra were measured on a JEOL SX102 spectrometer and the ^1H and ^{13}C

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

NMR spectra were recorded on a Varian Gemini 200 MHz spectrometer. The ^1H and ^{13}C NMR spectra are referenced relative to $CHCl_3$ (δ = 7.24 and 77.0 ppm, respectively) or C_6D_5H (δ = 7.15 and 128.0 ppm, respectively). ^{31}P NMR spectra were collected with a Bruker AMX 400 spectrometer, with phosphorus signals referenced to an external 85 % H_3PO_4 solution. Elemental analyses were performed Analytische Laboratorien Prof. Dr. H. Malissa and G. Reuter GmbH, Lindlar, Germany. High-temperature gel permeation chromatography of polyethylene samples (GPC) was performed in 1,2,4-trichlorobenzene at 145 °C by using a Waters HPLC 150 C.

tert-Butylamine and phosphorus trichloride were purchased from Merck and purified by distillation under argon (*t*BuNH$_2$ over sodium hydroxide). Arylamines and diphenylmethylamine were obtained from Aldrich and distilled in vacuo over sodium hydroxide before use. Chlorotrimethylsilane was purchased from Fluka and used as received. Ti(NMe$_2$)$_4$ was purchased from Aldrich and used as solution in toluene. Methylalumoxane (MAO, 30 wt.% solution in toluene) was received from Borealis Polymers Oy. *cis*-[Cl(*t*BuNP)]$_2$ (**1**),[16] *cis*-[(*t*BuNH)(*t*BuNP)]$_2$,[21] *cis*-[(C$_6$H$_5$NH)(*t*BuNP)]$_2$ [12] and *cis*-[(*t*BuN)$_2$(*t*BuNP)$_2$]Li$_2$(THF)$_2$ [21] were prepared according to modified literature procedures.

***cis*-[(2,6-*i*Pr$_2$C$_6$H$_3$NH)(PN-*t*Bu)]$_2$ (2):** 2,6-Diisopropylaniline (5.5 mL, 5.15 g, 29 mmol) and Et$_3$N (8.1 mL, 5.87 g, 58 mmol) were added to a stirred solution of *cis*-(ClPN-*t*Bu)$_2$ (**1**) (4 g, 14.5 mmol) in THF (100 mL) and the reaction mixture was boiled under reflux for four days. After filtration, all volatile compounds were removed under vacuum and pentane (20 mL) was added to the residue. The mixture was then kept in a freezer (−20 °C) overnight. After additional filtration and removal of pentane the required product was obtained as a colorless oil (6.42 g, 80 %). $C_{32}H_{54}N_4P_2$ (556.8): calcd. C 69.03, H 9.78, N 10.06; found C 69.65, H 9.88, N 9.31. ^1H NMR (200 MHz, [D$_6$]benzene, 29 °C): δ_H = 1.17 (s, 18 H, *t*Bu), 1.27 (d, 24 H, C*H*$_3$, *i*Pr), 2.90 (m, 4 H, C*H*, *i*Pr), 4.63 (s, 2 H, N*H*), 7.05−7.18 (m, 6 H, Ar*H*) ppm. $^{13}C\{^1H\}$ NMR (50.3 MHz, [D$_6$]benzene, 29 °C): δ_C = 24.2 (*C*H$_3$, *i*Pr), 29.2 (m, *C*H, *i*Pr), 31.4 (t, *C*H$_3$C), 51.7 (t, CH$_3$*C*), 118.8 (Ar), 124.0 (Ar), 136.3 (Ar), 141.0 (d, Ar) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, [D$_6$]benzene, 21 °C): δ_P = 114.8 (s) ppm. MS(EI): *m*/*z* (%) = 556 (48) [M$^+$], 380 (84), 204 (35), 176 (76), 57 (87).

***cis*-[(2-*t*BuC$_6$H$_4$NH)(PN-*t*Bu)]$_2$ (3):** Reaction of *cis*-(ClPN-*t*Bu)$_2$ (**1**) (0.65 g, 2.4 mmol), Et$_3$N (1.4 mL, 1.93 g, 9.6 mmol) and 2-*tert*-butylaniline (0.75 mL, 0.71 g, 4.7 mmol) and separation of the resulting crude product were carried out as for **2**. The obtained white solid was dissolved in pentane (10 mL) and the solution was concentrated to 3 mL and kept at −20 °C until colorless crystals appeared (0.90 g, 76 %). Crystals suitable for X-ray crystallography were obtained in this manner. $C_{28}H_{46}N_4P_2$ (500.6): calcd. product was then dissolved in pentane (20 mL) to give a solution that was kept in a freezer (−20 °C) overnight. After filtration and removal of solvent a colorless oil was obtained (7.46 g, 90 %) and used without further purification. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ_H = 1.32 (s, 18 H, *t*Bu), 2.15 (s, 6 H, CH_3Ar), 2.27 (s, 6 H, CH_3Ar), 4.91 (br.d, 2 H, N*H*, *J* = 5.5 Hz), 6.96 (d, 4 H, Ar*H*), 7.50 (d, 2 H, Ar*H*) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, $CDCl_3$, 29 °C): δ_C = 17.8 (*C*H_3Ar), 20.5 (*C*H_3Ar), 31.0 (t, *C*H_3C, $J_{P,C}$ = 6.5 Hz), 51.7 (t, CH_3*C*, $J_{P,C}$ = 13.7 Hz), 115.0 (Ar), 117.7 (Ar), 125.0 (Ar), 127.0 (Ar), 131.2 (Ar), 139.0 (d, Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, $CDCl_3$, 21 °C): δ_P = 99.0 (s) ppm.

***cis*-[(2,6-Et$_2$C$_6$H$_3$NH)(PN-*t*Bu)]$_2$ (8):** This was prepared in the same manner as **7**, starting from *cis*-(ClPN-*t*Bu)$_2$ (**1**) (2.6 g, 9.5 mmol), Et_3N (5.3 mL, 3.83 g, 37.8 mmol), and 2,6-diethylaniline (3.1 mL, 2.82 g, 18.9 mmol). A colorless oil (4.47 g; 94 %) was obtained and used without further purification. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ_H = 1.38 (s, 18 H, *t*Bu), 1.50 (t, 12 H, CH_3, Et), 3.13 (q, *J* = 7.7 Hz, 8 H, CH_2, Et), 4.86 (s, 2 H, N*H*), 6.80−7.50 (m, 6 H, Ar*H*) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, $CDCl_3$, 29 °C): δ_C = 15.3 (*C*H_3, Et), 26.7 (*C*H_2, Et), 31.8 (t, *C*H_3C, $J_{P,C}$ = 6.5 Hz), 52.1 (t, CH_3*C*, $J_{P,C}$ = 13.4 Hz), 123.2 (Ar), 130.0 (Ar), 136.1 (Ar), 141.2 (d, Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, $CDCl_3$, 21 °C): δ_P = 114.2 (s) ppm. MS (EI): *m*/*z* (%) = 500 (64) [M$^+$], 352 (83), 204 (20), 177(99), 57 (99).

[(2,4-Di-MeC$_6$H$_3$N)(*t*BuNP)]$_2$Li$_2$(THF)$_2$ (9): A solution of *n*BuLi in hexane (23 mL, 1.6 M, 35.5 mmol) was added dropwise to a stirred solution of **7** (7.46 g, 16.8 mmol) in THF (60 mL) at −30 °C. The reaction mixture was then stirred 20 min at −20 °C, allowed to warm to room temperature, and boiled under reflux for 5 h. The resulting yellow solution was then concentrated to 15 mL and pentane (40 mL) was added. This suspension was then stored overnight at −20 °C to give a white-yellow precipitate that was then separated and washed with several portions of pentane at −20 °C. The mother liquid was then concentrated to 8 mL and pentane (20 mL) was added. After two days at −20 °C a second lot of the white-yellow product was obtained (8.5 g in total; 84 %). Crystals suitable for X-ray analysis were obtained by crystallization from a THF/hexane mixture at −20 °C. ^{1}H NMR (200 MHz, [D$_6$]benzene, 29 °C): δ_H = 1.16 (m, 8 H, THF), 1.54 (s, 18 H, *t*Bu), 2.41 (d, 12 H, CH_3, Ar), 3.28 (m, 8 H, THF), 7.20 (m, 4 H, Ar*H*), 7.80 (d, *J* = 7.9 Hz, 2 H, Ar*H*) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, [D$_6$]benzene, 29 °C): δ_C = 20.5 (*C*H_3, Ar), 23.1 (*C*H_3, Ar), 25.3 (THF), 30.7 (t, *C*H_3C, $J_{P,C}$ = 7.60 Hz), 53.3 (t, CH_3*C*, $J_{P,C}$ = 16.0 Hz), 68.3 (THF), 116.72 (Ar), 118.5 (Ar), 124.3 (Ar), 127.2 (Ar), 133.8 (Ar), 142.1 (d, Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, [D$_6$]benzene, 21 °C): δ_P = 163.01 (s) ppm.

[(*t*BuN)(*t*BuNP)]$_2$TiCl$_2$ (10): $TiCl_4$ (1.3 g, 0.75 mL, 6.84 mmol) was added dropwise to a solution of *cis*-[(*t*BuN)(*t*BuNP)]$_2$Li$_2$(THF)$_2$ (3.45 g, 6.84 mmol) in toluene at 0 °C. The reaction mixture was then stirred at 0 °C for 20 min and boiled under reflux overnight. The resulting brown suspension was filtered off and toluene was removed in vacuo. The obtained brown solid residue was then dissolved in CH_2Cl_2 (30 mL), and hexane was added until precipitation commenced. The solution then was cooled to −20 °C and left overnight. The resulting suspension was filtered through Celite and the solvents were removed. After a second recrystallization, an orange-brown powder (1.61 g; 50.6 %) was isolated. $C_{16}H_{36}Cl_2N_4P_2Ti$ (465.2): calcd. C 41.31, H 7.80; found C 41.58, H 8.01. ^{1}H NMR (200 MHz, [D$_6$]benzene, 29 °C): δ_H = 1.23 (s, 18 H, *t*Bu, P_2N_2 cycle), 1.66 (s, 18 H, *t*Bu) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, [D$_6$]benzene, 29 °C): δ_C = 28.3 (t, $J_{P,C}$ = 7.25 Hz, *C*H_3, *t*Bu, P_2N_2 cycle), 33.7 (d, $J_{P,C}$ = 12.2 Hz, *C*H_3, *t*Bu), 54.6 (t, $J_{P,C}$ = 9.9 Hz, *C*, *t*Bu, P_2N_2 cycle), 60.2 (d, $J_{P,C}$ = 19.2 Hz, *C*, *t*Bu) ppm. ^{31}P{^{1}H} NMR (162 MHz, $CDCl_3$, 21 °C): δ_P = 117.4 (s) ppm. The complex was prepared earlier by a different procedure and the data given here are in good agreement with those reported.[21] MS(EI): *m*/*z* (%) = 465 (80) [M$^+$], 429 (40) [M$^+$ − Cl], 352 (98, ligand).

[(PhN)(*t*BuNP)]$_2$Ti(NMe$_2$)$_2$ (11a): A solution of Ti(NMe$_2$)$_4$ (1.3 g, 5.8 mmol) in toluene (10 mL) was added dropwise to a stirred solution of *cis*-[(PhNH)(*t*BuNP)]$_2$ (2.15 g, 5.5 mmol) in toluene (30 mL). The reaction mixture was then boiled under reflux overnight. All volatile components were removed in vacuo. The resultant red−brown residue was extracted with several portions of hexane. The extracts were then filtered, concentrated to 10 mL, and cooled to −20 °C to yield the product (1.34 g; 46.4 %) as a red-brown, crystalline solid. Crystals suitable for X-ray analysis were obtained by crystallization from hexane at −20 °C. $C_{24}H_{40}N_6P_2Ti$ (522.5): calcd. C 55.18, H 7.72, N 16.09; found C 55.53, H 8.00, N 15.53. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ_H = 1.50 (s, 18 H, *t*Bu), 3.43 (s, 12 H, NMe$_2$), 7.03 (t, *J* = 7.33 Hz, 2 H, *p*-H-Ph) 7.20−7.50 (m, Ph) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, $CDCl_3$, 29 °C): δ_C = 29.3 (t, $J_{P,C}$ = 7.2 Hz, *C*H_3, *t*Bu), 44.0 (NMe$_2$), 53.1 (t, $J_{P,C}$ = 11.1 Hz, *C*, *t*Bu), 117.7 (d, Ar), 119.5 (Ar), 128.6 (Ar), 151.0 (d, Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, $CDCl_3$, 21 °C): δ_P = 142.2 (s) ppm. MS(EI): *m*/*z* (%) = 522 (50) [M$^+$], 478 (64, M$^+$ − NMe$_2$), 434 (70, M$^+$ − 2NMe$_2$), 388 (90, ligand).

[(Ph$_2$CHN)(*t*BuNP)]$_2$TiCl$_2$ (12): *cis*-[(Ph$_2$CHNH)(*t*BuNP)]$_2$ (**6**) (2.23 g, 3.93 mmol) was dissolved in toluene and added via a syringe to a solution of Ti(NMe$_2$)$_4$ (0.87 g, 3.9 mmol) at 0 °C. The resultant mixture was boiled under reflux for 22 h to give the bis-dimethylamido titanium(IV) complex [(Ph$_2$CHN)(*t*BuNP)]$_2$-Ti(NMe$_2$)$_2$ (**12a**), which was analyzed by ^{1}H, ^{13}C and ^{31}P NMR. ^{1}H NMR (200 MHz, [D$_6$]benzene, 29 °C): δ_H = 1.22 (s, 18 H, *t*Bu), 1.82−2.40 (12 H, N*Me*$_2$), 3.54 (dd, 2 H, *J* = 14.0 Hz, C*H*, Ph$_2$CH), 7.11 (m, 16 H, *o*- and *m*-Ph), 7.25 (d, *J* = 7.1 Hz, 4 H, *p*-H-Ph) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, [D$_6$]benzene, 29 °C): δ_C = 30.9 (t, $J_{P,C}$ = 7.2 Hz, *C*H_3C), 43.0 (NMe$_2$) 52.0 (t, $J_{P,C}$ = 15.0 Hz, CH_3*C*), 59.3 (d, *J* = 13.0 Hz, Ph$_2$*C*H), 126.8 (Ar), 127.7 (Ar), 128.6 (Ar), 146.1 (d, Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, $CDCl_3$, 21 °C): δ_P = 103.8 (s) ppm.

Subsequently, to form the dichloride, an excess of Me_3SiCl (5.2 mL, 4.48 g, 41.2 mmol) was added and the reaction mixture was stirred overnight at room temperature. The solvent was then removed and the product purified similarly to **10**, washed with pentane and dried in vacuo. The product was isolated as a brown powder (2.13 g, 72 %). $C_{34}H_{40}Cl_2N_4P_2Ti{\cdot}C_5H_{12}$ (757.6): calcd. C 61.83, H 6.92, N 7.40; found C 62.47, H 6.60, N 8.04. ^{1}H NMR (200 MHz, [D$_6$]benzene, 29 °C): δ_H = 1.20 (s, 18 H, *t*Bu), 3.50 (dd, 2 H, *J* = 14.1 Hz, C*H*, Ph$_2$CH), 7.00 (t, *J* = 7.3 Hz, 8 H, *o*-H-Ph), 7.10 (t, *J* = 7.4 Hz, 8 H, *m*-H-Ph), 7.27 (d, *J* = 7.7 Hz, 4 H, *p*-H-Ph) ppm ^{13}C{^{1}H} NMR (50.3 MHz, [D$_6$]benzene, 29 °C): δ_C = 30.8 (t, $J_{P,C}$ = 7.0 Hz, *C*H_3, *t*Bu), 52.0 (t, $J_{P,C}$ = 14.3 Hz, *C*, *t*Bu), 59.0 (Ph$_2$*C*H), 109.0 (Ar), 126.8 (Ar), 128.6 (Ar), 146.1 (Ar) ppm ^{31}P{^{1}H} NMR (162 MHz, $CDCl_3$, 21 °C): δ_P = 100.0 (s) ppm. MS (EI): *m*/*z* (%) = 684 (10) [M$^+$], 649 (15) [M$^+$ − Cl], 568 (95, ligand).

[(2,6-Et$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$TiCl$_2$ (13): *cis*-[(2,6-Et$_2$C$_6$H$_3$NH)(*t*-BuNP)]$_2$ (**8**) (1.79 g, 3.58 mmol) in toluene and a toluene solution of Ti(NMe$_2$)$_4$ (0.8 g, 3.57 mmol) were treated as described above. To this solution Me_3SiCl (4.8 mL, 4.15 g, 38.2 mmol) was added and the reaction mixture was stirred overnight at room temperature. The solvent was removed then under vacuum to give a red-brown residue that was extracted first with hexane (30 mL) and then twice with a mixture of hexane (20 mL) and CH_2Cl_2 (7 mL).

After filtration and evaporation of solvent, the product was dried in vacuo to give a red-brown oil (1.9 g, 86.4 %). $C_{28}H_{44}Cl_2N_4P_2Ti$ (617.4): calcd. C 54.47, H 7.18, N 9.07; found C 54.08, H 7.41, N 9.51. ^{1}H NMR (200 MHz, [D$_6$]benzene, 29 °C): δ_H = 1.41 (s, 18 H, *t*Bu), 1.45 (t, 12 H, C*H*$_3$, Et), 3.16 (q, *J* = 7.3 Hz, 8 H, C*H*$_2$, Et), 7.10−7.40 (6 H, H−Ar) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, [D$_6$]benzene, 29 °C): δ_C = 14.9 (*C*H$_3$, Et), 26.3 (d, *J* = 9.9 Hz, *C*H$_2$, Et), 31.2 (t, $J_{P,C}$ = 6.5 Hz, *C*H$_3$, *t*Bu), 51.5 (t, $J_{P,C}$ = 14.5 Hz, *C,* *t*Bu), 123.3 (Ar), 127.1 (Ar), 135.7 (Ar), 138.1 (t, *J* = 1.9 Hz, Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, CDCl$_3$, 21 °C): δ_P = 114.6 (s) ppm. MS(EI): *m*/*z* (%) = 617 (55) [M$^+$], 583 (8) [M$^+$ − Cl], 500 (76, ligand).

[(2,6-*i*Pr$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$TiCl$_2$ (14): A toluene solution of *cis*-[(2,6-*i*Pr$_2$C$_6$H$_3$NH)(*t*BuNP)]$_2$ (**2**) (3.65 g, 6.56 mmol) and Ti(NMe$_2$)$_4$ (1.47 g, 6.55 mmol) were treated as described above. The titanium(IV) bis-amido complex, generated in situ, [(2,6-*i*Pr$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$Ti(NMe$_2$)$_2$ (**14a**) was then characterized by ^{1}H, ^{13}C, and ^{31}P NMR. ^{1}H NMR (200 MHz, [D$_6$]benzene, 29 °C): δ_H = 1.32 (s, 18 H, *t*Bu), 1.39 (d, 24 H, C*H*$_3$, *i*Pr), 3.00−3.23 (12 H, N*Me*$_2$), 3.91 (m, 4 H, C*H,* *i*Pr), 6.90−7.30 (6 H, H-Ar) ppm ^{13}C{^{1}H} NMR (50.3 MHz, [D$_6$]benzene, 29 °C): δ_C = 24.2 (*C*H$_3$, *i*Pr), 31.4 (t, $J_{P,C}$ = 6.5 Hz, *C*H$_3$, *t*Bu), 33.6 (d, *J* = 1 Hz, *C*H, *i*Pr), 45.7 (N*Me*$_2$), 51.6 (t, $J_{P,C}$ = 14.7 Hz, *C,* *t*Bu), 123.0 (Ar), 123.9 (Ar), 136.3 (t, *J* = 1.9 Hz, Ar), 140.9 (Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, CDCl$_3$, 21 °C): δ_P = 115.6 (s) ppm.

To obtain the dichloride complex, Me$_3$SiCl (9 mL, 7.47 g, 69 mmol) was added to the red-brown solution of [(2,6-*i*Pr$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$Ti(NMe$_2$)$_2$ (**14a**) via syringe, and the reaction mixture was stirred overnight at room temperature. The so-obtained product was then purified similarly to **13** to afford a red-brown oil that was treated with Et$_2$O to give a red-brown solid after drying in vacuo (3.60 g, 81 %). $C_{32}H_{52}Cl_2N_4P_2Ti$ (673.5): calcd. C 57.07, H 7.78, N 8.32; found C 56.83, H 7.98, N 8.44. ^{1}H NMR (200 MHz, [D$_6$]benzene, 29 °C): δ_H = 1.32 (s, 18 H, *t*Bu), 1.39 (d, 24 H, C*H*$_3$, *i*Pr), 3.88 (m, 4 H, C*H,* *i*Pr), 7.10−7.60 (6 H, H−Ar) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, [D$_6$]benzene, 29 °C): δ_C = 24.2 (*C*H$_3$, *i*Pr), 31.4 (t, $J_{P,C}$ = 6.7 Hz, *C*H$_3$, *t*Bu), 32.1 (d, *J* = 1 Hz, *C*H, *i*Pr), 51.3 (t, $J_{P,C}$ = 14.5 Hz, *C,* *t*Bu), 122.5 (Ar), 124.0 (Ar), 130.7 (Ar), 140.9 (Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, CDCl$_3$, 21 °C): δ_P = 115.6 (s) ppm. MS (EI): *m*/*z* (%) = 672 (10) [M$^+$], 639 (8) [M$^+$ − Cl], 556 (90, ligand).

[(2,5-*t*Bu$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$TiCl$_2$ (15): A toluene solution of *cis*-[(2,5-*t*Bu$_2$C$_6$H$_3$NH)(*t*BuNP)]$_2$ (**5**) (2.73 g, 4.46 mmol) and Ti(NMe$_2$)$_4$ (1.0 g, 4.46 mmol) was treated in the same way as **13**. The resultant titanium(IV) bis-amido complex, generated in situ, [(2,5-*t*Bu$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$Ti(NMe$_2$)$_2$ (**15a**) was characterized by ^{1}H, ^{13}C, and ^{31}P NMR. ^{1}H NMR (200 MHz, [D$_6$]benzene, 29 °C): δ_H = 1.44 (s, 36 H, *t*BuAr), 1.57 (s, 18 H, *t*Bu), 3.19 (12 H, N*Me*$_2$), 6.98 (dd, J_1 = 6.2, J_2 = 2.1 Hz, 2 H, 4-H−Ph), 7.36 (2 H, 3-H−Ph), 8.23 (dd, J_1 = 3.1, J_2 = 2.1 Hz, 2 H, 2-H−Ph) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, [D$_6$]benzene, 29 °C): δ_C = 31.0 (*C*H$_3$, 5-*t*BuAr), 31.3 (t, $J_{P,C}$ = 6.5 Hz, *C*H$_3$, *t*Bu), 31.5 (*C*H$_3$, 2-*t*BuAr), 33.1 (*C,* 5-*t*BuAr), 34.0 (*C,* 2-*t*BuAr), 45.2 (N*Me*$_2$), 51.7 (t, $J_{P,C}$ = 13.7 Hz, *C,* *t*Bu), 113.8 (Ar), 114.5 (Ar), 117.1 (Ar), 131.2 (Ar), 141.9 (Ar), 150.0 (t, *J* = 1.2 Hz, Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, CDCl$_3$, 21 °C): δ_P = 98.86 (s) ppm.

To obtain the dichloride complex, Me$_3$SiCl (5.9 mL, 5.09 g, 46.8 mmol) was added to the red-brown solution of [(2,5-*t*Bu$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$Ti(NMe$_2$)$_2$ (**15a**) and the reaction mixture stirred overnight at room temperature. All volatiles were then removed in vacuo and the residue was extracted three times with a mixture of hexane (30 mL) and CH$_2$Cl$_2$ (10 mL). After removal of the solvent, the product was washed with several portions (each 10 mL) of cold pentane and dried. A red−brown powder (2.40 g, 73.8%) was isolated. $C_{36}H_{60}Cl_2N_4P_2Ti$ (729.7): calcd. C 59.26, H 8.29, N 7.68; found C 58.94, H 8.41, N 7.86. ^{1}H NMR (200 MHz, [D$_6$]benzene, 29 °C): δ_H = 1.39 (s, 36 H, *t*BuAr), 1.52 (s, 18 H, *t*Bu), 6.93 (dd, ^1J = 6.2, ^2J = 2.1 Hz, 2 H2 Hz, 4-H−Ar), 7.32 (2 H, 3-H−Ar), 8.17 (dd, ^1J = 3.1, ^2J = 2.1 Hz, 2 H, 2-H−Ar) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, [D$_6$]benzene, 29 °C): δ_C = 31.0 (*C*H$_3$, 5-*t*BuAr), 31.4 (t, $J_{P,C}$ = 6.0 Hz, *C*H$_3$, *t*Bu), 31.5 (*C*H$_3$, 2-*t*BuAr), 33.1 (*C,* 5-*t*BuAr), 34.5 (*C,* 2-*t*BuAr), 51.7 (t, $J_{P,C}$ = 13.7 Hz, *C,* *t*Bu), 113.8 (Ar), 114.5 (Ar), 117.1 (Ar), 131.1 (Ar), 137.8 (Ar), 150.0 (Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, CDCl$_3$, 21 °C): δ_P = 99.72 (s) ppm. MS (EI): *m*/*z* (%) = 728 (20) [M$^+$], 693 (10) [M$^+$ − Cl], 612 (40, ligand).

Polymerization Experiments: A 1-L glass autoclave (manufacturer Büchi) was charged with toluene (200 mL) and cocatalyst (MAO) (Al/Ti ratio was 1000), thermostatted (50 or 70 °C), saturated with ethene (3.8 bar), and the desired amount of complex solution was then added. The monomer pressure (±50 mbar) and temperature (±0.5 °C) were kept constant during each polymerization run. Monomer consumption, polymerization temperature and pressure were controlled by real-time monitoring. The polymerizations were quenched with 10 % HCl solution in methanol, and the polymer precipitated quantitatively by pouring the solution into methanol (400 mL) acidified with aqueous hydrochloric acid. The samples were washed several times with methanol and water, and dried at 60 °C.

X-ray Crystallographic Study: Crystal data of compounds **3**−**5** were collected with an Enraf−Nonius CAD-4 single-crystal diffractometer at 193(2) K using Cu-K_α radiation (graphite monochromator), 1.54179 Å (scan-type omega/2-theta). Intensities were corrected for Lorentz and polarization effects with XCAD4.[26,27]

The crystal data of compound **9** were collected with a Rigaku AFC-7S single-crystal diffractometer at 193(2) K using Mo-K_α radiation (graphite monochromator), 0.71073 Å (omega/2-theta scans). Intensities were corrected for Lorentz and polarization effects with TEXSAN.[28] A psi-scan absorption correction was made for each compound.[29]

The crystal data of compound **11a** were collected with a Nonius KappaCCD area-detector diffractometer at 173(2) K using Mo-K_α radiation (graphite monochromator), 0.71073 Å. Data reduction: COLLECT;[30] absorption correction: SADABS.[31]

Solution and refinement: SHELX-97,[32,33] direct methods. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined on calculated positions. The displacement factors of the H-atoms were 1.2× (1.5×) that of the host atom. Data relating to the structure determinations are collected in Table 5. CCDC-213508 to -213512 (for compounds **3**−**5**, **9**, **11a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Manganese Oxydiacetate Complexes: Synthesis, Structure and Magnetic Properties

Abdessamad Grirrane,[a] Antonio Pastor,[a] Eleuterio Álvarez,[b] Carlo Mealli,[c] Andrea Ienco,[c] Patrick Rosa,[d] Francisco Montilla,[a] and Agustín Galindo*[a]

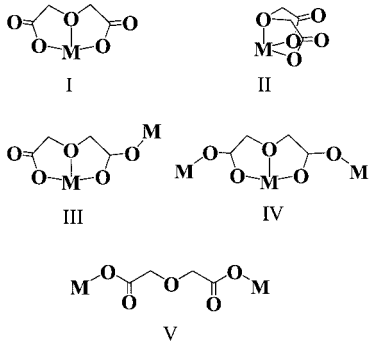
Keywords: Manganese / Tridentate ligands / Coordination modes / Magnetic properties

The aerobic aqueous solution syntheses and structures of monomeric and polymeric Mn^{II} complexes containing the oxydiacetate ligand [$O(CH_2COO)_2^{2-}$ = oda] are reported. The magnetic properties of the polymeric products have also been investigated. The initially obtained species $[\{Mn(oda)(H_2O)\}\cdot H_2O]_n$ (**1**) has been reacted with bidentate or tridentate N-donor ligands such as *o*-phenanthroline (phen), 2,2′-bipyridine (bipy) and 2,2′:6,2′′-terpyridine (terpy) to give the complexes $[\{Mn(oda)(phen)\}\cdot 4H_2O]_n$ (**2**), $[Mn(oda)(bipy)(H_2O)]\cdot 2H_2O$ (**3**) and $[Mn(oda)(terpy)]\cdot 2H_2O$ (**4**), respectively. Species **1**–**4** are the first Mn-oda structures determined by X-ray methods. In all cases, the oda acts as a tridentate ligand toward one metal and adopts the typical planar arrangement. However, while the **3** and **4** are monomers, **2** and **1** are polymers as oda exploits both atoms of its carboxylate groups to coordinate other metals; **1** consists of a three-dimensional diamond-type network, while **2** is one-dimensional, consisting of an extended chain of {Mn(oda)(phen)} subunits. For both compounds, magnetic susceptibility measurements down to 2 K showed only weak antiferromagnetic interactions between high-spin Mn^{II} ions. Despite the expectedly similar coordinating capabilities of N-donor ligands, the bipy complex **3** is a monomer with the six-coordination completed by one water ligand. The tridentate nature of simultaneously present oda and terpy ligands excludes the coordination of water in complex **4**, the geometry of which is distorted from the octahedron, most likely due to a peculiar packing effect. Finally, the known five-coordinate complex $[MnCl_2(terpy)]$ (**5**), a side product of our synthetic experiments, has also been structurally characterized.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

As the active sites of several mononuclear enzymes are five- or six-coordinate manganese species containing coordinated carboxylate groups, water and nitrogen-donor molecules (for instance, imidazole groups),[1−5] research on the coordination compounds of manganese with such co-ligands has grown. In particular, model compounds may provide better insight into the manganese-based biological systems and, thus, most of this chemistry has been attempted in aqueous solution.

The oxydiacetate anion [oda = $O(CH_2COO)_2^{2-}$] features two carboxylate functions joined by a three-membered chain that is centred on an ethereal oxygen atom. The bonding capabilities of the ligand have been tested with most first-row transition metals, and mono-, bi- and polynucleating behaviours have been ascertained through several X ray structure determinations. Scheme 1 shows these coordination modes, without considering *syn* and *anti* isomers for the carboxylate bridge.



Scheme 1

The ligand usually behaves as tridentate monometallic. Two possible isomers, I or II, are known, for which the ligand oda is overall planar[6−12] or puckered, respectively.[10,13,14] In six-coordinate complexes, these isomers are referred to as *mer* or *fac*, respectively. Our previous DFT

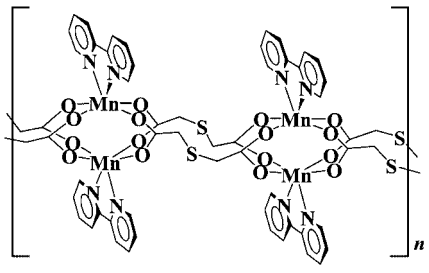
calculations for some nickel[12] and vanadium complexes,[15] as well as for the free oxydiacetic acid and the oxydiacetate anion,[12] all showed an energy difference between these isomers of a few kcal mol^{-1}. The highest ΔE of 8.5 kcal·mol^{-1} was found for the complex $[VO(oda)(H_2O)_2]$.[15] Our search in the Cambridge Database[16] on first row transition metals indicates that the most common binding mode for oda is planar (I in Scheme 1), with the external carboxylate oxygen atoms not involved in metal coordination. The residual nucleophilicity of the latter atoms is exerted usually through hydrogen bonding with crystallization water molecules.[6–12] There are other cases where the ligand oda still acts as tridentate toward one metal (in the overall planar arrangement), while the remaining carboxylate donors are also bound to one or two different metals (coordination modes III and IV, respectively, in Scheme 1). Two examples of these coordination modes are the complexes $[\{Co(oda)(H_2O)_2\}\cdot H_2O]_n$ [17] and $[\{Zn(oda)\}\cdot 0.3H_2O]_n$,[9] respectively. Finally, in some cases the ethereal oxygen atom of oda is uncoordinated and the whole ligand acts a μ-bridge between two equal metal centres, such as Ti^{IV} [7] and Zn^{II}, [18] (structure V, Scheme 1). Despite the widespread use of oda as a ligand with first row transition metals, there is still a paucity of data relative to chromium and manganese metals and, in particular, neither structural nor conformational data are available. For instance, only a potentiometric study of a Mn^{II}-oda system has been reported, without any stereochemical implication for the nature of the adduct investigated.[19]

We have recently found an interesting behaviour of the thio- analogue of oda [tda = $S(CH_2COO)_2^{2-}$] toward the Mn^{II} ion, with 2,2′-bipyridine as co-ligand. We have synthesized and documented the first example of a Mn^{II} dimer with the copper-acetate structure (sketch in Scheme 2).[20] $[Mn(tda)(bipy)]_n$, where the central sulfur atom of tda is not involved in coordination, is remarkable for at least three reasons: (i) the almost unobserved assembly of two local trigonal prisms through rectangular faces, (ii) the ascertained antiferromagnetism within the dimeric unit, (iii) the extended supramolecular arrangement formed in the solid state due to the interpenetration of the parallel bipyridine ligands in a gear-like arrangement. Encouraged by the above results, we have tested whether an aqueous solution of the ligand oda has an analogous reactivity pattern toward the Mn^{II} ion when associated with co-ligands such as 2,2′-bipyridine or other polydentate nitrogen bases. This chemistry is essentially unexplored and this paper presents the spectroscopic, magnetic and structural characterization of the synthesized products. The results are particularly interesting from the structural point of view as different stereochemical arrangements are observed for systems with components of similar nature.



Scheme 2

Results and Discussion

A summary is given in Scheme 3 of the reactions and products studied. Beside routine spectroscopic analyses, the structures of compounds **1**–**5** have been determined by X-ray diffraction analysis. While species **1**–**4** represent the first examples of structurally characterized manganese oxydiacetate complexes, the oda-free compound **5** has been previously obtained,[21–23] and characterized by powder X-ray techniques[24] but its precise molecular structure was still unknown. All of the current work is illustrated in detail below.

Synthesis and Characterization

Treatment of aerobic aqueous solutions of manganese dichloride with a 1:1 mixture of Na_2CO_3 and oxydiacetic acid, $O(CH_2COOH)_2$, affords, after work up, colourless crystals of complex $[Mn(oda)(H_2O)_2]$ (**1**), in good yields. Related oxydiacetate complexes of nickel and cobalt were prepared by a similar procedure.[12] Only X-ray analysis (see below) could clearly show that **1** is a polymeric solid and that only one of the two water molecules is coordinated to the metal centre, so that the correct formulation is $[\{Mn(oda)(H_2O)\}\cdot H_2O]_n$. Subsequently, complex **1** was found react readily with each of three different N-donor ligands, *o*-phenanthroline (phen), 2,2′-bipyridine (bipy) and 2,2′:6,2′′-terpyridine (terpy) (Scheme 3), to give, almost invariably, good yields of yellow crystalline solids. Elemental analyses and the IR spectra indicated that additional water molecules were present in the so-obtained compounds but it was not possible to asses any difference between their coordination or simple crystallization roles. Again, only the subsequent X-ray determinations allowed us to assign formulae to the various products: $[\{Mn(oda)(phen)\}\cdot 4H_2O]_n$ (**2**), $[Mn(oda)(bipy)(H_2O)]\cdot 2H_2O$ (**3**), and $[Mn(oda)(terpy)]\cdot 2H_2O$ (**4**), respectively. Accordingly, while **3** and **4** are monomers, **2** is polymeric.

An alternative attempt to prepare complex **4** in a single step (i.e. by mixing in one pot $MnCl_2$ with a 1:1 mixture of Na_2CO_3 and $O(CH_2COOH)_2$ and by adding subsequently terpy) provided, after some work up, **4** and small amounts of a new yellow crystalline material that was analytically and structurally characterized as $[MnCl_2(terpy)]$ (**5**). Most probably, the obtainment of **5** was due to a small stoichiometric defect of $O(CH_2COOH)_2$ in the experimental procedure. In fact, as reported, complex **5** is easily obtainable by direct reaction between the water solutions of manganese dichloride with terpy.[21–23] Complex **4** is also formed from the reaction of the isolated complex **5** with one equivalent of sodium oxydiacetate (see Exp. Sect.). Evidently,

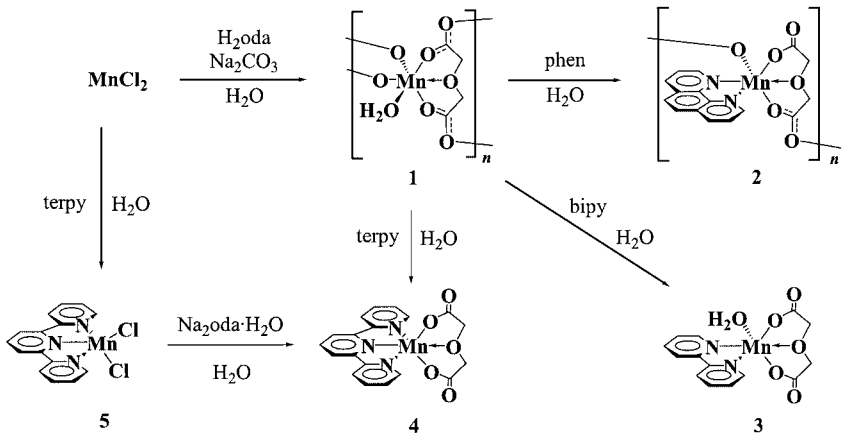

Scheme 3

species **5** is a sufficiently stable intermediate, which may or may not be isolated, in the reaction leading to **4**.

All of the synthesised compounds are air stable, both in solution and in the solid state. They may be dissolved in water but are not soluble in solvents of low polarity. The effective magnetic moments for **3** and **4** (solid state, room temperature) are in the range 5.7−5.9 μ_B, which are invariably consistent with five unpaired electrons in the ground-state configuration, and typical of high-spin mononuclear manganese(II) units. Similar manganese complexes that contain closely related ligands exhibit comparable μ_B values {e.g. 5.95 μ_B for [Mn(dipic)(bipy)]·2H_2O, dipic = pyridine-2,6-dicarboxylate}.[25] The magnetic behaviour of **1** and **2** is discussed below. Compounds **1**−**4** display the characteristic IR absorptions of oxydiacetate ligand. In particular, they feature a very strong, broad band at ca. 1600 cm^{-1}, which corresponds to the antisymmetric vibrations of the carboxylate groups, and a strong band at ca. 1430 cm^{-1}, which is assigned to the symmetric vibrations of the same groups. In many complexes of the first- and second-row[26,27] transition metals, and in all lanthanide and actinide complexes,[16] the ligand oda adopts a tridentate planar coordination mode. The non-planar arrangement of the ligand (II in Scheme 1) is uniquely found in some six-coordinate oxydiacetate compounds of nickel(II) and copper(II).[10,13,14] We have previously suggested and theoretically supported[12,15] the idea that the precise position of the C−O−C antisymmetric stretching band is diagnostic of the oda disposition in the various complexes. Thus, a planar oxydiacetate ligand is characterized by a sharp, strong band in the region 1150−1120 cm^{-1}, while the active IR band falls in the region around 1100 cm^{-1} when the arrangement is *fac*. Complexes **1**−**4** all display an absorption at ca. 1135 cm^{-1} that is attributable to C−O−C antisymmetric stretching; hence the planar disposition of oda is invariably assumed, and, indeed, is confirmed by the X-ray structural determinations.

Structural and Magnetic Studies

Compounds **1**−**5** have been structurally characterized by single-crystal X-ray diffraction analysis. In all cases, the Mn^{II} ion is high spin and, for **1**−**4**, the local coordination is pseudo-octahedral. Under these circumstances, the distribution of the five unpaired electrons in the 3d orbital shell is isotropic. Thus, the coordination bonds should be mainly due to the interaction of the ligands with the metal s and p orbitals, with a minor role for the d levels, as for d^0 (main group metals) and d^{10} configurations, i.e. the crystal field stabilization energy has little influence in these complexes, which have a good degree of hypervalency. This view is supported by the easy deformation of complex **4** from the octahedron (vide infra), and the stabilization of the five-coordinate compound **5** further confirms the minor role of the d orbitals in fixing the coordination sphere.

As discussed in textbooks,[28] the ease of substitution of one water ligand in Mn^{II} and Zn^{II} octahedral complexes, with respect to the Fe^{II}, Co^{II}, Ni^{II} and Cu^{II} analogues (Irving−Williams series), can be related to the ratio between the charge and the effective ionic radius (Shannon type[29]). In particular, the high-spin Mn^{II} ion has the largest radius in the series. Direct comparison between some of the present manganese structures and their equivalents with other metals allows a further check of the trends indicated. For instance, the complex [Mn(oda)(bipy)-(H_2O)]·2H_2O (**3**) has Co^{II}, Ni^{II} and Zn^{II} analogues. Similarly, [Mn(oda)(terpy)]·2H_2O (**4**) can be usefully compared with the Ni^{II} and Cu^{II} species. Detailed information is provided below when discussing the single structures.

None of the Mn^{II} complexes with the ligand oda and other N-donor chelates exhibit the unique features of the thiodiacetate complex $[Mn(tda)(bipy)]_n$ (Scheme 2), i.e. the two carboxylate functions of oda cannot be exploited to form a copper-acetate structural motif. This is probably because the affinity of the ethereal oxygen function for the manganese(II) ion is larger than with the thio-ethereal counterpart. The apparently difficult formation of $Mn^{II}-S_{ethereal}$ bonds (there are only a few structurally documented examples[30−34] favours the stretching of the tda chain and provides the best packing conditions to form the extended arrangement of the tetracarboxylate dimanganese units. Apparently, the $Mn^{II}-O_{ethereal}$ bond is readily

formed for Mn^{II}-oda, and the reactivity follows alternative routes.

3D-Polymeric Complex $[\{Mn(oda)(H_2O)\}\cdot H_2O]_n$ (1)

Each manganese(II) ion of the parent compound $[\{Mn(oda)(H_2O)\}\cdot H_2O]_n$ (**1**) is six-coordinate by the tridentate oxydiacetate ligand in the *mer* configuration (planar arrangement), one coordinated water ligand and two additional oxygen atoms of carboxylic groups coming from symmetry repeated $\{Mn(oda)(H_2O)\}$ units (Figure 1). In this manner all of the five oda oxygen atoms are engaged in donations to the metal (coordination mode IV in Scheme 1). The overall structure of **1** is evidently a polymer that extends in three dimensions due to the four connections (two incoming and two outgoing dative bonds) that each $\{Mn(oda)(H_2O)\}$ fragment establishes with its neighbouring equivalents. Selected interatomic distances and angles for the local coordination of **1** are collected in Table 1. As usual, the Mn−O3 bond involving the ethereal oxygen atom [2.230(3) Å] is slightly longer than any other Mn−O(carboxylate) bond, either formed within one $\{Mn(oda)(H_2O)\}$ unit [2.208(3) and 2.194(3) Å for Mn−O1 and Mn−O2, respectively] or in the combination of different units [2.114(3) and 2.182(3) Å, for Mn−O4′ and Mn−O5′′, respectively].

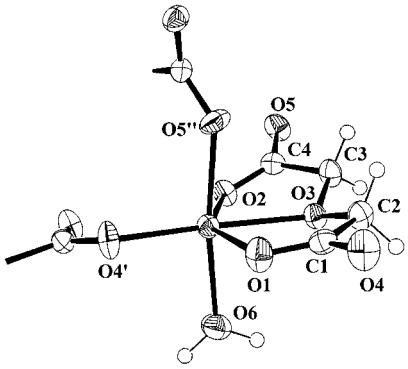

Figure 1. Local coordination environment about one Mn^{II} ion in $[\{Mn(oda)(H_2O)\}\cdot H_2O]_n$ (**1**). The atoms labelled with ′ and ′′ belong to two distinct $\{Mn(oda)(H_2O)\}$ units repeated by the symmetry operations $-x+2, y-1/2, -z+3/2$ and $x+1/2, -y+3/2, -z+2$, respectively

The overall topology of the polymeric system is a diamond-like network that is not interpenetrated, according to the useful schemes of O′Keeffe and co-workers.[35] Figure 2 (a) shows a scheme of such an arrangement limited to the manganese atoms. The arbitrary connections between them show apparent cavities occupied by the oxygen atoms of the solvate water molecules. The hydrogen bonding network is a key feature for this and the other manganese oda complexes described here and deserves a detailed analysis. As stated by Perec and co-workers,[9] the hydrogen bonding network due to the coordinated and solvent water molecules fixes the crystal packing of most oxydiacetate metal complexes. Complex **1** has channels that are parallel to the *a* axis (Figure 2, b). Inside these channels, the solvent water molecules

form a complicated structural pattern. For instance, the water molecule defined by O7 bridges two-coordinated water ligands (O6) of different $\{Mn(oda)(H_2O)\}$ units. The O7···O6 separations are as long as 2.760(4) and 2.843(5) Å, respectively. Additionally, O7 is involved in hydrogen bonding with O2 and O4 of oda carboxylate groups [O7···O2 and O7···O4 of 2.896(4) and 2.853(4) Å, respectively].

The molar magnetic susceptibility of complex **1** was measured in the range 1.9−300 K. Both the susceptibility, χ_{mol}, and its product with the temperature, $\chi_{mol}T$, (Figure 3) show typical paramagnetic behaviour. With 4.59 emu $K\cdot mol^{-1}$ at 300 K, $\chi_{mol}T$ is typical of uncorrelated high-spin Mn^{II} ions (theoretical value of 4.38 μ_B for five unpaired electrons and a Landé factor $g = 2$). On lowering the temperature, $\chi_{mol}T$ starts to decrease below 150 K, while χ_{mol} rises monotonically to a maximum at 5 K, revealing weak antiferromagnetic interactions between the Mn^{II} centers. A plot of the inverse susceptibility $1/\chi_{mol}$ versus temperature shows Curie−Weiss behaviour ($1/\chi_{mol} = (T - \theta)/C$) with a Curie constant $C = 4.705$ emu $K\cdot mol^{-1}$ and $\theta = -6.3$ K. The former magnitude corresponds to high-spin Mn^{II} with a *g*-factor of 2.074, which is far from the free-electron value expected for isotropic Mn^{II} and reflects experimental errors such as weighting. The θ value can be accounted for by the mean-field model. As described by Kahn,[36] $\theta = zJS(S+1)/3k$, where *J* is the interaction par-

ameter in the mean-field perturbation Hamiltonian $\hat{H} = -zJ\langle\hat{S}_z\rangle\cdot\hat{S}_z$, S is the spin of the interacting ion, and z is the number of nearest neighbours. For $z = 4$ (Figure 2, a) and $S = 5/2$, we find $J = -0.19$ cm^{-1} for this polymeric system. This weak interaction is thus in the -0.193 to -0.30 cm^{-1} range previously found for Mn^{II} complexes that are similarly bridged by a unique carboxylate moiety.[37]

1D-Polymeric Complex $[\{Mn(oda)(phen)\}\cdot 4H_2O]_n$ (2)

Compound **2** is also a polymer, in contrast with the related monomeric compounds $[M(oda)(phen)(H_2O)]$ (M = Ni,[10] Zn[9]). Each metal ion in **2** is six-coordinated by the three oxygen atoms of one oda ligand in the planar disposition, by the phen chelate and by an oxygen atom of a oda carboxylate group belonging to a symmetry repeated {Mn(oda)(phen)} unit (Figure 4, a). Here, the polymer extends as a one-dimensional chain (Figure 4, b) since each {Mn(oda)(phen)} unit acts both as an acceptor and as a donor with respect to its adjacent equivalents. The chains extend along the direction of the *a* axis. Selected bond lengths and angles for the local coordination of **2** are listed

in Table 2. Again, the coordination bond to the ethereal oxygen atom [Mn−O3 = 2.1876(17) Å] is slightly longer than any other Mn−O bond lengths. Amongst the latter, the distances within one {Mn(oda)(phen)} unit are longer than the corresponding inter-fragmental one [2.1680(17) and 2.1798(17) Å vs. 2.1168(18) Å, respectively]. There is no appreciable difference between the C−O bonds of the bidentate-dimetallic carboxylate group, but there is a minor asymmetry between the two C−O distances of the other carboxylate [compare the 1.241(3) and 1.262(3) Å for the C4−O5 and C4−O2 bonds, respectively]. At variance with **1**, one carboxylate oxygen atom (O5) of oda remains unused for metal coordination (coordination mode III in Scheme 1).

As with complex **1**, the hydrogen bonding network deserves a careful description. Solvent water molecules are interspersed between the parallel chains and participate to form a complicated hydrogen bonding network. In particular, the hydration molecules occupy the channels formed by the parallel disposition of the phenanthroline ligands (Figure 4, c). The carboxylate oxygen O5 forms two hydrogen bonds with two different water molecules centred at O7 and O9 [O5···O7 and O5···O9 are 2.812(3) and 2.851(3) Å, respectively]. A third water molecule (defined by O8) bridges the two previous ones [O8···O7 and O8···O9 of 2.940(4) and 2.775(4) Å, respectively]. A fourth hydration molecule, centred at O6, makes a hydrogen bonding with that at O7 [H71···O6 and H61···O7 of 2.00(5) and 1.86(5) Å, respectively]. Finally, the network features two similarly weak interactions between one water molecule and one-coordinated oxygen atom of ligand oda. In fact, O6 is 2.920(3) Å from O1, and O9 is 2.952(3) Å from O2.

The temperature dependence of the molar magnetic susceptibility of complex **2** was also measured. Both the susceptibility, χ_{mol}, and its product with the temperature, $\chi_{mol}T$, (Figure 5) again show typical paramagnetic behaviour. With 4.36 emu K·mol^{-1} at 300 K, the $\chi_{mol}T$ product corresponds to uncorrelated high-spin Mn^{II} ions. On lowering the temperature, $\chi_{mol}T$ starts to decrease below 50 K, while χ_{mol} rises monotonically without reaching a maximum. Though there are clearly antiferromagnetic interactions between the Mn^{II} centers, these are much weaker than those of complex **1**. The plot of the inverse susceptibility $1/\chi_{mol}$ versus temperature indicates Curie−Weiss behaviour with $\theta = -1.9$ K, and the expected theoretical value $C = 4.385$ emu K·mol^{-1}. For $z = 2$, for this polymeric chained system (Figure 4, b), and $S = 5/2$, we obtain $J = -0.11$ cm^{-1} through the mean-field model. Although weaker, this value is still close to the range previously cited for similarly bonded complexes.

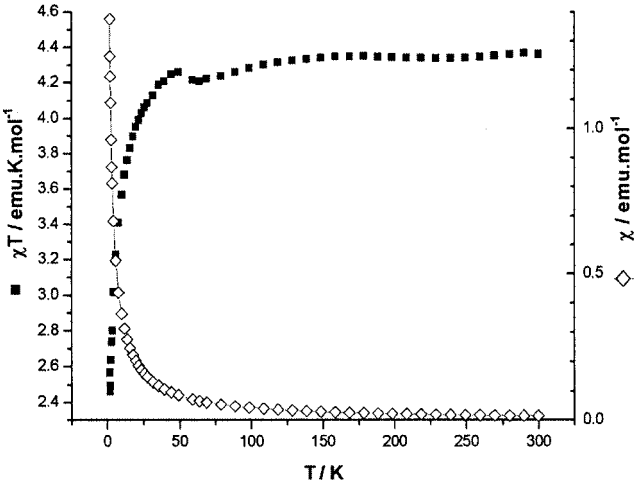

Figure 5. Molar magnetic susceptibility χ_{mol} (◇, cgs units) and its product with the temperature, $\chi_{mol}T$ (■, cgs units), of complex **2** between 1.9 and 300 K

Structure of [Mn(oda)(bipy)(H_2O)]·2H_2O (3)

Despite the expectedly similar coordinating capabilities of the phen and bipy ligands, the reaction of **1** with bipy affords the complex [Mn(oda)(bipy)(H_2O)]·2H_2O (**3**), which is monomer, in contrast to the polymeric character of **2**. There are other examples of similar metal-carboxylate complexes whose different structural motifs are imposed by the nature of the N-donor co-ligand. For example, a manganese succinato derivative that is a dimer when coordinated with 1,10-phenantroline[38,39] becomes polymeric (catena type) when 2,2′-bipyridine is used.[38−40] The manganese ion in **3**

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

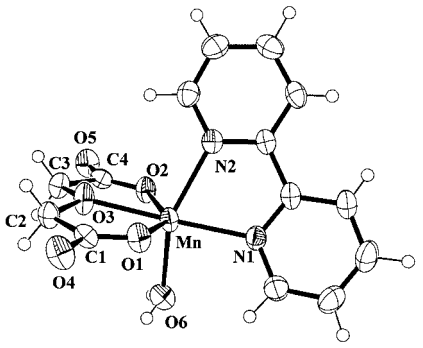

Figure 6. Molecular structure of the $[Mn(oda)(bipy)(H_2O)]\cdot 2H_2O$ complex (**3**); water molecules of crystallization not shown

is coordinated by the planar oxydiacetate anion, the bipy chelate and by one water molecule (Figure 6). The overall coordination mode is the most classic (I in Scheme 1) with only one oxygen atom per carboxylate group engaged as a donor towards the metal. Selected bond lengths and angles of complex **3** show no major differences in Mn-oda geometry compared with those of **2** (Table 2). However, even though only one oxygen atom per carboxylate is involved in metal coordination (O1 and O2), a delocalisation of the π bonding is observed, with all of the C−O distances being close to ca. 1.25 Å.

Although a monomer, compound **3** also has a peculiar hydrogen bonding network that certainly affects its crystal packing. The latter, described below, is certainly different from the one common to three isomorphous compounds that have the equivalent basic formula $[M(oda)(bipy)(H_2O)]$ (M = Ni,[12] Co[12] and Zn[9]). In fact, they, with 2.5 crystallization water molecules, belong to the space group *Fdd*2, while **3**, with only two hydration molecules, crystallizes in $P2_1/n$. In **3**, the O7 of one solvent water molecule forms two hydrogen bonds with the uncoordinated O4 and O5 of two carboxylate groups [O5···O7 and O4···O7 contacts are 2.83(4) and 2.85(4) Å, respectively]. The second H_2O molecule, centred at O8, acts as an hydrogen bonding acceptor from the metal-coordinated H_2O molecule (O6), while it is a donor with respect to both the carboxylate O5 atom and the O7 water atom. The three contacts projecting from O8 are 2.68(4), 2.76(4) and 2.83(5) Å, respectively. The Mn−O and Mn−N distances in **3** are the longest in the $[M(oda)(bipy)(H_2O)]$ series, the order being $Mn^{II} > Zn^{II} > Co^{II} > Ni^{II}$ (Table 3). As mentioned, the trend agrees with that of the Shannon radii and indirectly with the *q*/*r* ratios for these elements. The expanded coordination sphere of Mn^{II} also combines with larger distortions from the regular octahedral geometry. In particular, the O6−Mn−N2 angle deviates from linearity [151.17(10)°], a feature that, for instance, is much less evident for the other derivatives [cf. 170.4(1)° for nickel, 167.1(1)° for cobalt and 169.0(2)° for zinc].

Table 3. Comparison of selected bond lengths (Å) around the metal centre in $[M(oda)(bipy)(H_2O)]$ complexes

M	Mn	Ni[12]	Co[12]	Zn[9]
M–O1	2.156(2)	2.055(3)	2.050(3)	2.054(6)
M–O2	2.185(2)	2.054(3)	2.096(3)	2.084(5)
M–O3	2.195(2)	2.042(2)	2.115(3)	2.160(5)
M–N1	2.245(3)	2.046(3)	2.096(3)	2.102(5)
M–N2	2.242(3)	2.067(3)	2.115(3)	2.145(6)

Finally, the overall geometry of **3** resembles that of the closely relatable mononuclear complex [Mn(chedam)(bipy)-(H_2O)] (chedam = 4-hydroxypyridine-2,6-dicarboxylate).[25] The greater *trans* influence of the nitrogen donor of chedam with respect to that of the ethereal O3 atom of oda is evident. In fact, the Mn−N1 of 2.245(3) Å in **3** is significantly shorter than the corresponding Mn−N of 2.278(1) Å in the complex with the ligand chedam.

Structure of $[Mn(oda)(terpy)]\cdot 2H_2O$ (4)

The crystal structure of six-coordinate complex **4** is composed of discrete [Mn(oda)(terpy)] units (Figure 7, a), plus two water molecules of crystallization. Selected bond lengths and angles are given in Table 2. The connectivity requirements of both the oda and terpy ligands, both tridentate and planar arranged, prevents bite angles of 90° for any of the adjacent N−Mn−N or O−Mn−O. Accordingly, the geometry of the compounds is far from a regular octahedron. Moreover, the structure is distorted also from it highest possible symmetrical arrangement where the two oda and terpy planes could act as reciprocal mirror planes. These planes are still roughly almost perpendicular [the angle between the mean square planes is ca. 84.21(4)°] but the terpy molecule is significantly bent toward one of the lateral oxygen donors of oda (O2). Consider, for instance, the large difference between O2−Mn−N2 [96.59(6)°] and O1−Mn−N2 [120.34(5)°] (where N2 is the central donor of terpy). Interestingly, such a distortion does not seem to have an electronic origin but it is more likely due to the particular packing of [Mn(oda)(terpy)] molecules in the crystal. Figure 7 (b) shows that two terpy ligands of different molecules are clearly parallel (the planes are ca. 3.7 Å apart), but their π stacking involves only two of the three six-membered rings. Namely, only one central and one lateral ring of one terpy ligand eclipse precisely the equivalent rings of the other complex molecule. Furthermore, intermolecular hydrogen bonding also occurs (Figure 7, b). Generally, C−H groups of aromatic rings are not excellent hydrogen-bonding donors, but here one metal-coordinated carboxylate oxygen atom seems to be able to form such a bond [O2−H13′′ = 2.46(1) Å], and so causes the asymmetric orientation of oda, which should have a low energetic cost. This distortion is not so evident in the similar Ni and Cu complexes [M(oda)(terpy)]. In addition, these structures crystallize in different space groups ($P2_1/n$ and $P2_1/c$, respectively) and, as pointed out for **3**, the crystal packing and hydrogen bonding networks are, consequently, different. In particular, in **4** one lattice water molecule (O7) forms hydrogen bonds with the uncoordinated carboxylate oxygens O4 and O5 of two symmetry related [Mn(oda)(terpy)] molecules [O7···O4 and O7···O5 of 2.76(3) and 2.84(3) Å, respectively]. The second water molecule defined by O6 bridges, through two hydrogen bonds, the carboxylate oxy-

gens O1 and O5 of two [Mn(oda)(terpy)] units [O6···O1 and O6···O5 of 2.86(3) and 2.88(2) Å, respectively].

The bond to the ethereal oxygen atom [Mn−O3, 2.1727(15) Å] is again longer than the other two Mn−O1 and Mn−O2 lengths [2.1149(14) and 2.1501(14) Å, respectively]. This fact, although general for the manganese complexes discussed here, is in contrast with the equivalent structures of Ni^{II} [10] and Cu^{II} [6] ions (Table 4). In fact, the latter exhibit shorter $M-O_{ether}$ bonds than the other two M−O distances. Also, the Mn−N lengths in **4** are longer than the similar M−N in the Ni and Cu complexes, in agreement with the larger effective ionic radii,[29] as previously discussed.

Table 4. Comparison of selected bond lengths (Å) around the metal centre in [M(oda)(terpy)] complexes

M	Mn	Ni[10]	Cu[6]
M–O1	2.1149(14)	2.067(2)	2.202(5)

M–N3	2.2845(16)	2.105(3)	2.039(3)

Structure of [$MnCl_2$(terpy)] (5)

As mentioned, the complex [$MnCl_2$(terpy)] (**5**) has been previously reported,[21−23] and characterized by powder X-ray techniques,[24] but its molecular structure was unknown. Here, we observed that the manganese atom is five-coordinate and that the overall geometry is a distorted square pyramid (Figure 8). The only other example of a pentacoordinate manganese complex containing the terpy ligand is the compound [Mn(2,6-dimethoxybenzoato-*O*)$_2$(terpy)].[41]

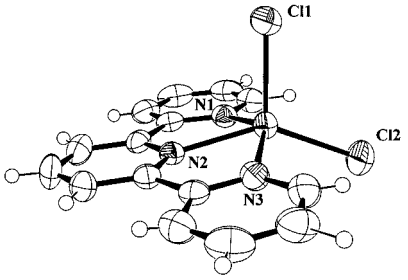

Figure 8. Molecular structure of [$MnCl_2$(terpy)] (**5**)

Selected bond lengths and angles of **5** are collected in Table 5. The Mn−Cl are similar [2.3611(15) and 2.3452(14) Å], whereas the three Mn−N compares well with those in complex **4**. The other structural parameters do not require further comments because they are unexceptional.

Table 5. Selected bond lengths and angles for **5**

		Cl2–Mn1–Cl1	111.07(5)

Conclusion

We have reported Mn^{II}-oda chemistry not previously explored. Four different types of compounds have been obtained and characterized that indicate the great propensity of this ligand to stabilize both monomeric and polymeric solid state compounds. Obviously, their characterization has required systematic X-ray diffraction studies that have allowed us to confirm the precise structural arrangements and also the easily deformable coordination sphere about the high-spin manganese(II) ion. The structural studies have highlighted the hydrogen bonding interactions in all the oda complexes studied, involving both the coordinated and the lattice water molecules and carboxylate oxygen atoms of oxydiacetate. These interactions may be fundamental in determining the crystal packing of various oda compounds. In particular, some of the manganese complexes have the same coordination sphere as other previously reported first-row transition metal compounds, but the overall crystal properties are different. Finally, the determined antiferromagnetic coupling constants for the present Mn^{II}-oda poly-

meric systems are very small and fall in the lowest range reported for related carboxylate-bridged Mn^{II} complexes.[37]

Experimental Section

General Remarks: All preparations and other operations were carried out under aerobic conditions. Microanalyses (C, H, N) were carried out by the Microanalytical Service of the Instituto de Investigaciones Químicas (CSIC). Infrared spectra were recorded with a Perkin-Elmer Model 883 spectrophotometer (Nujol emulsion in NaCl plates). Magnetic moments were measured in the solid state, at room temperature, with a Sherwood Scientific (Cambridge Research Laboratory) magnetic balance, and between 1.9 and 300 K with a Cryogenic S600 SQUID magnetometer. Molar susceptibilities were then corrected using Pascal's constants.[42] Oxydiacetic acid and other chemicals were obtained from commercial sources and were used without further purification. The experimental procedure for the synthesis of **5** has also been included, although its preparation has been reported previously.[21−23]

[{Mn(oda)(H$_2$O)}·H$_2$O]$_n$ (1): Na_2CO_3 (1.28 g, 12 mmol) was added to a solution of $O(CH_2COOH)_2$ (1.61 g, 12 mmol) in water (20 mL). The mixture was then stirred until the evolution of CO_2 ceased and then added to a solution of $MnCl_2·4H_2O$ (2.37 g, 12 mmol) in water (25 mL). The resulting solution was stirred for 15 minutes and then concentrated. Acetone was added and the solution was then kept at room temperature overnight. Colourless crystals of complex **1** were formed, filtered off, washed with acetone and Et_2O and air dried (1.80 g, 65 %). IR (cm^{-1}): $\tilde{\nu}$ = 3350 br. ν(OH), 1587 s br. ν($COO_{asymm.}$), 1431 s ν($COO_{symm.}$), 1137 s ν($COC_{asymm.}$). μ = 5.8 μ_B at 24 °C. $C_4H_8MnO_7$ (223.04): calcd. C 21.52, H 3.59; found C 21.43, H 3.62.

[{Mn(oda)(phen)}·4H$_2$O]$_n$ (2): A solution containing *o*-phenanthroline·H_2O (0.10 g, 0.5 mmol) in hot water (20 mL) was added to a solution of **1** (0.12 g, 0.5 mmol) in water (15 mL). The resulting solution was then stirred for a few minutes. Subsequently, compound **2** crystallized upon evaporation of the solvent at room temperature after a few days; yellow crystals were filtered off, washed with water and acetone and dried in air (0.15 g, 70 %). IR (cm^{-1}): $\tilde{\nu}$ = 3478, 3368 br. ν(OH), 1601 s br. ν($COO_{asymm.}$), 1431 s ν($COO_{symm.}$), 1137 s ν($COC_{asymm.}$). μ = 5.7 μ_B at 24 °C. $C_{16}H_{20}MnN_2O_9$ (439.28): calcd. C 43.73, H 4.55, N 6.38; found C 43.81, H 4.60, N 6.74.

[Mn(oda)(bipy)(H$_2$O)]·2H$_2$O (3): Following a similar synthetic procedure as described for compound **2**, but using **1** (0.48 g, 2 mmol) and bipy (0.31 g, 2 mmol), **3** was obtained as yellow crystals in 70 % yield. IR (cm^{-1}): 3359 br. ν(OH), 1601 s br. ν($COO_{asymm.}$), 1449 s ν($COO_{symm.}$), 1137 s ν($COC_{asymm.}$). μ = 5.7 μ_B at 22 °C. $C_{14}H_{18}MnN_2O_8$ (397.24): calcd. C 42.32, H 4.53, N 7.05; found C 41.87, H 4.61, N 7.17.

[Mn(oda)(terpy)]·2H$_2$O (4): A solution of **1** (0.12 g, 0.5 mmol) in water (20 mL) was added to a suspension of terpy (0.12 g, 0.5 mmol) in water (30 mL). The mixture was then stirred until all the solid was dissolved and then it was concentrated. Slow evaporation of water afforded yellow crystals of **4**, which were collected by filtration, washed with water, acetone and diethyl ether and dried (0.18 g, 80 %). Re-crystallization of the product in water yielded yellow crystals suitable for an X-ray study. IR (cm^{-1}): $\tilde{\nu}$ = 3533, 3432, 3350 br. ν(OH), 1614 s br. ν($COO_{asymm.}$), 1426 s ν($COO_{symm.}$), 1133 s ν($COC_{asymm.}$). μ = 5.9 μ_B at 24 °C. $C_{19}H_{19}MnN_3O_7$ (456.31): calcd. C 49.97, H 4.16, N 9.2; found C 49.96, H 4.27, N 9.30. As an alternative route to this complex a solution of $O(CH_2COONa)_2·H_2O$ (0.03 g, 0.15 mmol) in water (5 mL) was added to a solution of [$MnCl_2$(terpy)] (**5**) (0.05 g, 0.15 mmol) in water (10 mL) . The resultant mixture was then stirred for 3 h. Slow evaporation of the solvent then gave yellow crystals of **4**, which were collected by filtration and air dried (0.03 g; 45 %).

[MnCl$_2$(terpy)] (5): A suspension of terpy (0.24 g, 1 mmol) in water (10 mL) was added to a solution of $MnCl_2·4H_2O$ (0.20 g, 1 mmol) in water (10 mL). The mixture was then stirred until a yellow solution formed, which was then concentrated. Yellow crystals of compound **5** were obtained after slow evaporation of the solvent (0.27 g, 75 %). $C_{15}H_{11}Cl_2MnN_3$ (359.12): calcd. C 50.12, H 3.06, N 11.69; found C 48.35, H 3.03, N 11.38.

X-ray Crystallographic Study: The crystal data and structural refinement of compounds **1**−**5** are summarized in Table 6. While the X-ray data of compound **1** were collected on a Bruker SMART diffractometer equipped with a 6000 CCD detector, all other data sets were collected on an Enraf−Nonius CAD4 diffractometer. Therefore, two distinct descriptions of the technical details are given.

In addition to the 6000 CCD detector, the Bruker SMART apparatus is equipped with a rotating anode generator, Goebel optics monochromated Cu-K_α radiation (λ = 1.54178 Å), and a Kryoflex low-temperature device.[43] Six sets of frames covering a hemisphere of the reciprocal space were recorded for a well-formed crystal of **1** (3 × 600 frames to ϕ = 0°, 120° and 240° respectively with the CCD detector placed to 2θ = −40°, and others 3 × 600 frames to ϕ = 60°, 180° and 300° respectively with the CCD detector placed to 2θ = −100°, ω-scans, Δω = 0.3°, time per frame 5 s). Data reduction up to θ = 81° was performed with the program SAINT+, and corrections for absorption with SADABS; of 4361 reflections measured 1417 were independent, R_{int} = 0.063.[43] The structure was solved by direct methods and refined by full-matrix least-squares on F^2 using the program SHELXL-97.[44] All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were located on a difference Fourier map and refined with isotropic displacement parameters. The highest residual peaks (three) 0.70−0.69 e·Å^{-3} were located close to the heavier atoms Mn and have no chemical sense.

Well-formed yellow crystals of the compounds **2**−**5** were mounted on a Enraf−Nonius CAD4 diffractometer equipped with a graphite monochromator and Mo-K_α radiation (λ = 0.71073 Å). In all cases, the cell dimensions were refined by least-squares refinement of 25 reflections in the 2θ range 10−20°. The intensity data were corrected for Lorentz and polarization effects and semiempirical absorption corrections (ψ scan). Three standard reflections were monitored every two hours during data collection. Atomic scattering factors are those reported by Cromer and Waber.[45] The structures were solved by direct methods using the SIR97[46] package of programs. Refinements were made by full-matrix least-squares on all F^2 data using SHELXL-97.[44] In general, ΔF Fourier maps, calculated at a later stage of refinement, allowed the localization of the hydrogen atoms. These atoms were assigned isotropic temperature factors and were refined in the final least-squares cycles. Anisotropic thermal parameters were allotted to all of the non-hydrogen atoms. No unusual trend in ΔF vs. F_o or ($sin\theta$)/λ was observed. In no case was a significant electron density residue detected from the final ΔF maps.

The molecular drawings were made using the program ORTEP-III for Windows[47,48] and SCHAKAL (Figure 3, c).[49] All crystallographic computational work was performed by using the user-friendly graphic interface of WINGX.[50]

Acknowledgments

Financial support from both the Ministerio de Ciencia y Tecnología (BQU2001−3715) and Junta de Andalucía is gratefully acknowledged. Thanks are expressed to Mr. Dante Masi for technical assistance with the X-ray work carried out at ICCOM and to Professor Davide Proserpio for providing the SCHAKAL picture. We are also grateful to Mr. César J. Pastor Montero (Laboratorio de Difracción de Rayos X, Facultad de Ciencias, Universidad Autónoma de Madrid) for the acquisition of the X-ray diffraction data of complex **1**.

Note Added in Proof (November 18, 2003): The X-ray structure of an Mn(oda) complex has been reported (C. Jiang, X. Zhu, Z.-P. Yu, Z.-Y. Wang, *Inorg. Chem. Commun.* **2003**, *6*, 706) while our work was in progress.

Preparation of 17 Sulfur-Rich Chain-Like Thiaalkanes $R-S_x-R'-S_y-R$ and $R-S_x-R'-S_y-R'-S_z-R$ (x, y, $z > 2$) from Titanocene Thiolate Complexes[‡]

Vera Münchow[a] and Ralf Steudel*[b]

Keywords: Alkanes / Ligand effects / Sandwich compounds / Sulfur / Titanium

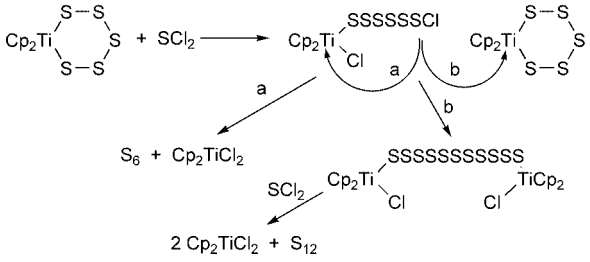
Two novel $Cp_2Ti(Cl)S_3R'S_3Tr$ complexes have been prepared by reaction of the six-membered metallacycles Cp_2TiS_4R' ($Cp = \eta^5$-C_5H_5, $R' = CMe_2$, 1,1-C_6H_{10}) with the sulfenyl chloride TrSCl ($Tr = CPh_3$) at 20 °C. These complexes were treated with: (a) sulfenyl chlorides (RSCl or RSSCl) to obtain 11 new thiaalkanes of the type $R–S_x–R'–S_y–R$ (R = Tr, 4-ClC_6H_4, 2-$C_{10}H_7$; $x = 3$, $y > 2$), or (b) with SO_2Cl_2, SCl_2 or S_2Cl_2 to prepare six sulfur-rich species of the type $Tr–S_x–R'–S_y–R'–S_z–Tr$ (x, z = 3, $y > 3$), as well as Cp_2TiCl_2. The thiaalkanes decompose upon heating to give mixtures of various linear and cyclic polysulfanes R_2S_n and $R'S_m$.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Thiaalkanes are derivatives of alkanes (including cycloalkanes) in which some of the CH_2 groups have been replaced by sulfur atoms. Numerous compounds of this type are known, both chain-like and cyclic and mainly with a single sulfane unit $-S_x-$ ($x = 1, 2,...$) between two organic residues R.[1] In a narrower sense, thiaalkanes are compounds with two or more sulfane units separated by organic groups, for example $R-S_x-R'-S_y-R''$. In the following we restrict our discussion to chain-like species of this type. While thiaalkanes with single sulfur atoms or disulfane groups have been prepared in large numbers by the classical methods of organosulfur chemistry,[2] and are widely used as chemically resistant polymers,[3] almost no such species with either tri-, tetra-, penta- or hexasulfane units are known.[4] This is most surprising and unsatisfactory in the light of the biological activity of many thiaalkanes, in particular cyclic species, which makes them interesting to the pharmaceutical industry as well as for applications in agroscience.[1,5] In this work we report on the synthesis of chain-like sulfur-rich thiaalkanes with two and three polysulfane units from suitable titanocene thiolate complexes by ligand-transfer reactions.

In recent years a number of mono- and dinuclear titanocene thiolate complexes have been used to synthesize sulfur-rich homocycles, heterocycles and linear organic polysulfanes R_2S_n ($n > 2$) by reaction with organic or inorganic S−Cl compounds.[1,6] These reactions take place at 25 °C or below and often proceed quantitatively. A good example is the synthesis of the homocycles S_6 and S_{12} from titanocene pentasulfide Cp_2TiS_5 (**1**; $Cp = \eta^5$-C_5H_5) and sulfur dichloride[7] shown in Scheme 1.



Scheme 1

The nucleophilic attack of the chlorine atoms of SCl_2 on the titanium atom opens the metallacycle producing an intermediate that either reacts intramolecularly by route (a) to give S_6 and Cp_2TiCl_2, or intermolecularly with another molecule of **1** to give a second linear intermediate which then reacts with SCl_2 to form S_{12} [route (b)]. While the reactive intermediates shown in Scheme 1 are hypothetical, the related dinuclear complex $(Cp_2TiCl)_2S_3$ has been isolated and characterized by X-ray crystallography.[8] Mononuclear complexes of the type $Cp_2TiX(S_xR)$ with sulfanido ligands containing more than one sulfur atom have also been isolated (e.g., X = Cl or SR with aryl or alkyl groups R; $x = 2, 3$[9]).

In this work we show how titanocene complexes with thiaalkane ligands can be used to prepare the title compounds containing up to 12 sulfur atoms. Most useful in

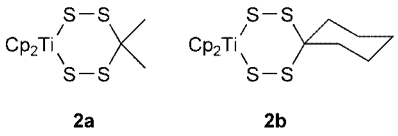
this context were the two metallacycles $Cp_2TiS_4CMe_2$ (**2a**) and $Cp_2TiS_4C_6H_{10}$ (**2b**) first prepared by Giolando and Rauchfuss[10] from Cp_2TiS_5 and acetone or cyclohexanone, respectively (Scheme 2).



2a **2b**

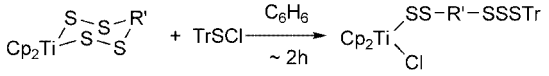
Scheme 2

These air-stable compounds are soluble in organic solvents. Both complexes have been used before to synthesize heterocyclic sulfur compounds by reaction with dichlorosulfanes S_nCl_2.[11,12]

Results and Discussion

Ring-Opening Reaction with Ph_3CSCl

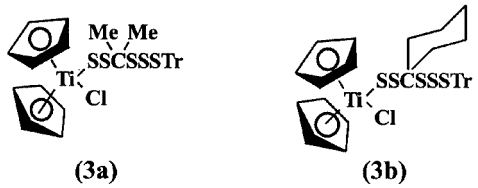
One aim of this work was to isolate the chain-like intermediates of the type shown in Scheme 1. To stabilize these reactive species we have chosen a particularly bulky substituent R on the sulfenyl chloride. Reaction of complexes **2a** or **2b** with triphenylmethylsulfenyl chloride Ph_3CSCl (tritylsulfenyl chloride, TrSCl) in a molar ratio of 1:1 at 20 °C in benzene produced the violet complexes **3a** and **3b** as shown in Scheme 3.



R': CMe_2 (**3a**), C_6H_{10} (**3b**)

Scheme 3

These reactions could easily be followed by HPLC analysis of the reaction mixtures since the retention times of **3a** and **3b** are higher than those of all other components in the mixture. Therefore, the corresponding peaks were well separated. Single crystals of **3a** and **3b** could not be obtained due to their instability in solution but the spectroscopic results (^1H and ^{13}C NMR, IR, Raman, UV/Vis) as well as their reactivity towards SCl compounds support the connectivities shown in Scheme 4 (see Exp. Sect.). In the ^1H NMR spectrum of **3a** there appears one singlet each for the



(3a) **(3b)**

Scheme 4

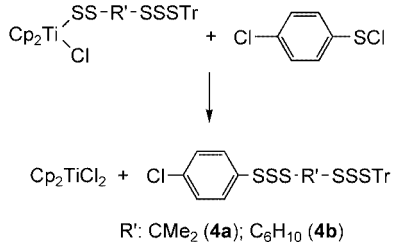
cyclopentadienyl (δ = 6.36 ppm) and methyl protons (δ = 1.69 ppm) besides the multiplet of the phenyl hydrogens near δ = 7.32 ppm. The violet color of the novel complexes in solution is caused by an absorption peaking at 560 ± 4 nm (in MeOH).

In the solid state complexes **3a** and **3b** are stable at 4 °C for several weeks but they decompose in solution at 20 °C, especially in the presence of air, with formation of Cp_2TiCl_2 and an ochre precipitate. Chlorinated solvents also initiate a slow decomposition. Therefore, the samples always contained a few percent of Cp_2TiCl_2 (probably with formation of mixed crystals) which also originates from the side reaction of TrSCl with **3a** or **3b**, respectively. However, for preparative purposes the purity was sufficient (see below). The content of Cp_2TiCl_2 can be determined by ^1H NMR spectroscopy (singlet at δ = 6.57 ppm). Complexes **3a** and **3b** are well soluble in benzene and carbon disulfide, but less so in *n*-hexane and methanol.

Attempts to isolate the corresponding complexes using other sulfenyl chlorides such as TrSSCl, 4-ClC_6H_4SCl and 2-$C_{10}H_7SCl$ failed due to rapid decomposition of the ring-opened complexes and their consecutive reactions with the sulfenyl chlorides.

Synthesis of Thiaalkanes

Treatment of complexes **3a** or **3b** with one equivalent of ClC_6H_4SCl in CS_2 at 20 °C expectedly yields the asymmetrical hexathiaalkanes **4a** and **4b** shown in Scheme 5. These reactions are rapid, as indicated by the immediate color change from violet to orange-red on addition of the sulfenyl chloride to the complexes **3a** and **3b**, respectively. The reactions are also very clean: only one peak was observed in the HPLC analysis of the isolated products **4a** and **4b** (besides the solvent peak).



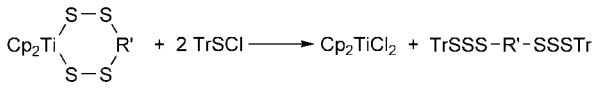
R': CMe_2 (**4a**); C_6H_{10} (**4b**)

Scheme 5

Both bis-trisulfanes **4a** and **4b** could be isolated in high purity as grayish-white powders in yields of 42% and 41%, respectively.

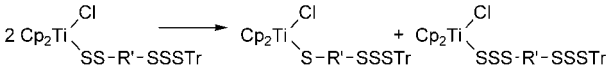
When we tried to synthesize the symmetrical bis-trisulfanes $Tr-S_3-R'-S_3-Tr$ by reaction of complexes **2a** and **2b** with *two* equivalents of TrSCl, according to Scheme 6, rather complex reaction mixtures were obtained regardless of whether the reaction was carried out in CS_2, CH_2Cl_2 or benzene at 20 °C.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 6

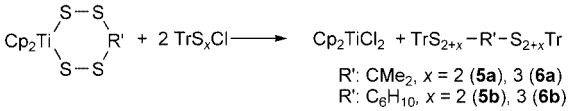
The reaction times of more than 15 hours for complete, or nearly complete, disappearance of the starting materials evidently favor side reactions, for example a sulfur transfer between the intermediate sulfanido complexes as shown in Scheme 7.



Scheme 7

As a consequence, three major thiaalkane products were detected by HPLC analysis, namely the expected $(TrS_3)_2R'$, the asymmetrical $TrS_3R'S_4Tr$ and the sulfur-rich $(TrS_3R')_2S_4$. The latter product most probably arises from the autoxidation of the intermediate $Cp_2TiCl(S_2R'S_3Tr)$ (see below). In addition, several minor products of similar retention time were detected but not identified. The identification of members of a homologous series is sometimes possible by inter- and extrapolation of the retention indices as they are linear functions of the sulfur content.[1,13] In other cases the independent preparation of the suspected species is necessary, and will be described below. Because of the complex composition of the reaction mixture no workup has been attempted since, even under an inert atmosphere, too many side-products were formed. Treatment of complexes **2a** and **2b** with TrCl also did not give the desired product $(TrS_2)_2R'$ since the reaction rate at 20 °C was very low, allowing parallel decomposition reactions.

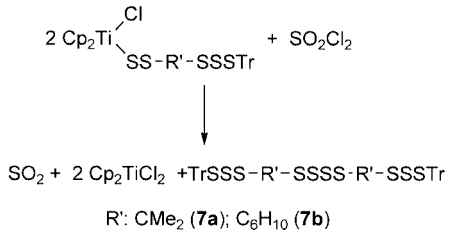
More successful were the reactions of complexes **2a** and **2b** with the sulfur-rich derivatives TrS_xCl with $x = 2$ and 3 resulting in the bis-tetra- and -pentasulfanes **5a,b** and **6a,b** (Scheme 8).



Scheme 8

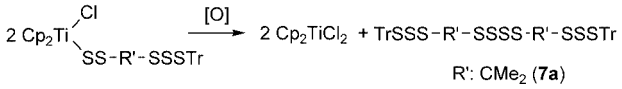
The starting materials TrS_xCl were prepared according to published procedures[14] and the reaction took place in benzene at 20 °C. The reactivity of TrS_xCl ($x = 0-3$) towards titanocene polysulfido complexes evidently increases with increasing x. $Tr-S_4-CMe_2-S_4-Tr$ (**5a**) was isolated in 7% yield as a champagne-colored powder of m.p. 55 °C while the cyclohexylidene derivative $Tr-S_4-C_6H_{10}-S_4-Tr$ (**5b**) melts at 60 °C (yield 34%). The corresponding bis-pentasulfanes $Tr-S_5-R'-S_5-Tr$ (**6a,b**) were obtained analogously in 67% and 26% yields, respectively.

The two particularly sulfur-rich thiaalkanes $Tr-S_3-R'-S_4-R'-S_3-Tr$ (**7a,b**), mentioned above, were obtained as pure materials by oxidation of complexes **3a** and **3b**, respectively, with sulfuryl chloride in CS_2 solution at 20 °C (see Scheme 9; yields: 41% **7a**, 45% **7b**).



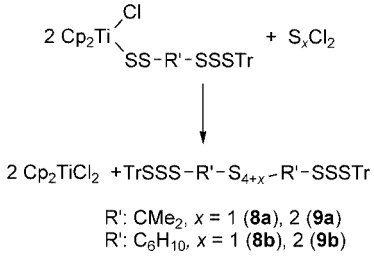
Scheme 9

Alternatively, **7a** could be obtained from **3a** by autoxidation with air in organic solvents at 20 °C (Scheme 10; yield 15%). Insoluble titanium-containing side products were observed as an ochre precipitate.



Scheme 10

Even more sulfur-rich derivatives were obtained by cleavage of complexes **3a** and **3b** with SCl_2 or S_2Cl_2 (Scheme 11), resulting in the corresponding penta- and hexasulfanes **8a,b** and **9a,b** (undecathia- and dodecathiaalkanes; yields: 19–36%).



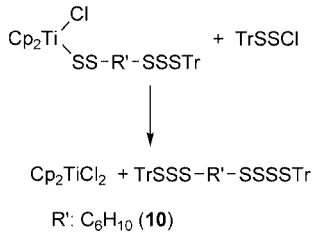
Scheme 11

These grayish-white or yellowish powder-like substances are soluble in methyl *tert*-butyl (MTB) ether.

Finally, we observed that various sulfenyl chlorides (RSCl) and disulfane chlorides (RSSCl) react with the complexes **3a** and **3b** to give the corresponding thiaalkanes. For

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

example, TrSSCl and **3b** produced the heptathiaalkane Tr−S_3−C_6H_{10}−S_4−Tr **10** (Scheme 12).



Scheme 12

The easily accessible aromatic sulfenyl chlorides ClC_6H_4SCl and $C_{10}H_7SCl$ produced the symmetrical bistrisulfanes **11a,b** and **12a,b** in 6−28% yield on reaction with complexes **2a** and **2b** (Scheme 13).

Scheme 13

General Properties of the Novel Thiaalkanes

The thiaalkanes prepared in this work can be stored for several weeks at 4 °C without decomposition. They are readily soluble in carbon disulfide, benzene and MTB ether, but less so in *n*-hexane, *n*-pentane and methanol. As with other polysulfanes,[1] heating initiates decomposition reactions. This can best be seen from the mass spectra of compounds **11a,b** and **12a,b**, which are of the type R−S_3−R′−S_3−R. The temperatures required to evaporate these large molecules in a high vacuum (150−200 °C) result in complete decomposition, and no molecular ions were observed. However, all major peaks in the EI mass spectra could be assigned to cations of the following degradation and interconversion products: R_2S_n (n = 0−4), R′S_m (m = 1−5), RS_3R', RS_2, RS, and related smaller fragments. Some of these polysulfanes are known as pure compounds.[1] Evidently, the S−S bonds break homolytically on heating and the fragments recombine to form chain-like species R_2S_n and cyclic polysulfanes R′S_m. The observation of R_2, however, indicates that C−S bonds are also broken on electron impact.

During the HPLC analyses of the reaction mixtures it was once more observed that the retention time of the members of a homologous series, differing only in the number of sulfur atoms, systematically depends on the number of sulfur atoms. This can best be shown if the retention index (RS) is used which is independent of the chromatographic system and is therefore a characteristic property of these compounds (similar to the NMR chemical shift).[15] To determine RS values the sulfur homocycles S_x (x = 6, 8, 9, 10) are used as reference substances and their retention times t_R are measured under the same conditions. Then, their capacity factors $k' = (t_R - t_0)/t_0$ are calculated (t_0: dead time), the logarithms of which depend linearly on the number of sulfur atoms (n_S) as follows: $\ln k' = a + b \times n_S$. The latter relationship can be used to calculate a formal n_S value for any other substance by substituting its k' value into this equation. The formal n_S value obtained in this way defines the retention index of the novel substance as follows: RS = $100 \times n_S$. From the RS values of three members of the series Tr−S_x−CMe_2−S_x−Tr (x = 3, 4, 5) the following linear regression has been derived: RS = $568 + 128 \times x$ (r = 0.998). For the analogous cyclohexylidene species Tr-S_x-C_6H_{10}-S_x-Tr we obtained: RS = $662 + 134 \times x$ (r = 0.997). These relationships can be used to estimate the retention times of other members of these series by inter- and extrapolation. Pure methanol was used as the eluent in both cases.

Considerably longer homologous series have been observed for the species $(TrS_3CMe_2)_2S_x$ (x = 4−11) and $(TrS_3C_6H_{10})_2S_x$ (x = 4−12). In these cases the linear regressions are: RS = $965 + 60 \times x$ (r = 0.9997) and RS = $1147 + 61 \times x$ (r = 0.99986). The slopes of these functions are practically identical. The higher members of these series were prepared by reaction of complexes **3a** and **3b** with solutions of chlorosulfanes S_nCl_2 ($n > 2$) obtained by chlorination of elemental sulfur.[16]

The NMR and vibrational spectra of the novel thiaalkanes mainly show the presence of the corresponding organic groups R and R′ with little, if any, dependence on the number of sulfur atoms. Even the Raman spectra contain little information about the SS bonds, the stretching vibrations of which usually show up as strong lines in the 400−520 cm^{-1} region. However, compared to the strongest lines of the organic substituents (e.g. Tr: 1002 cm^{-1}, $C_{10}H_7$: 1380 cm^{-1}), the SS stretching vibrations often gave rise to only relatively weak signals in the indicated region. Therefore, the Raman spectra have not been listed in the Exp. Sect.[17]

Summary

We have synthesized two new titanocene polysulfido complexes $Cp_2TiCl(S_2R'S_3Tr)$ and 17 novel chain-like thiaalkanes by reaction of Ti−S bonds with S−Cl compounds (sulfenyl chlorides, sulfuryl chloride and sulfurchlorides). The thiaalkanes are of types R−S_x−R′−S_y−R (x, $y > 2$) and R-S_x−R′−S_y−R′−S_z−R (x, z = 3, $y > 3$) and have been isolated in moderate to low yields as colorless, grayish-white or grayish-yellow powder-like substances (R = CPh_3, 4-ClC_6H_4; R′ = CMe_2, 1,1-C_6H_{10}). To the best of our knowledge, these are the most sulfur-rich acyclic thiaalkanes of these types ever prepared. It has previously been shown that polysulfido ligands coordinated to a titanium atom can be utilized for ligand-transfer reactions with S−Cl compounds and other metals can also function as coordination centers (e.g. Zn[18]). Since a large number

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of thiolate complexes of main group and transition metals are known[19] the ligand-transfer method bears a tremendous potential for further research in synthetic sulfur chemistry.

Experimental Section

General:[17] The reactions were carried out with exclusion of moisture using carefully dried solvents. The chromatographic system has been described previously (HPLC with UV absorbance detector).[12] Octadecylsilane (C18) was used as the stationary phase throughout and pure methanol as the eluent. The following spectrometers were used: mass spectrometer AMD Intectra (based on Varian MAT 311A equipment) with 70 eV electron energy; NMR spectrometer WH 270 and ARX 200 by Bruker. FT-IR spectrometer Magna System 750 by Nicolet; Raman spectrometer Ramanor U 1000 by Jobin Yvon, equipped with krypton ion laser (647 nm), and FT-Raman spectrometer RFS 100 by Bruker with Nd-YAG laser (1064 nm). UV/Vis diode array spectrometer 990 by Waters (190−800 nm; on-line connected to the chromatographic system). With one exception (**12b**) NMR spectra were recorded at 200 MHz. ^{13}C NMR spectra are ^{1}H broad-band decoupled. Elemental analyses were performed using a Hewlett−Packard CHN analyzer 185 as well as a Perkin−Elmer Series II CHNS analyzer 2400.

Synthesis of Chloro(3,3-dimethyl-7,7,7-triphenyl-1,2,4,5,6-pentathiaheptyl)titanocene (3a): TrSCl (1.75 g, 5.63 mmol) and **2a** (1.57 g, 4.51 mmol) were stirred in benzene at 30−40 °C for 150 min. After removal of the solvent in vacuo the residue was dissolved in CS_2 (30 mL), *n*-pentane (70 mL) was added and the solution was cooled to −26 °C whereupon a mixture of **3a** and Cp_2TiCl_2 (ca. 10%) crystallized out, which was isolated, washed with *n*-pentane (30 mL) and dried in air (red-blue powder). Yield: 2.4 g (2.16 g of pure **3a**, 73%). The Cp_2TiCl_2 can be removed by stirring the solution with silica gel but the yield is then dramatically lower. M.p. (dec.): 133 °C. $C_{32}H_{31}ClS_5Ti$ (659.3): calcd. C 57.29, H 4.72, S 21.89 (Cp_2TiCl_2 content taken into account); found C 55.33, H 4.72, S 22.21. The low carbon value is explained by titanium carbide formation on combustion in the CHN analyzer. UV/Vis (methanol): λ_{max} (%) = 223 nm (100), 241 (87), 295 (23), 382 (7), 556 (9). ^{1}H NMR (CD_2Cl_2): δ = 7.32 (m, 15 H), 6.36 (s, 10 H), 1.69 (s, 6 H) ppm. Retention index (RS): 570.

Synthesis of Chloro(3-cyclohexylidene-7,7,7-triphenyl-1,2,4,5,6-pentathiaheptyl)titanocene (3b): TrSCl (1.00 g, 3.22 mmol) and **2b** (1.00 g, 2.57 mmol) were stirred in benzene at 30−40 °C for 180 min. After removal of the solvent in vacuo the residue was dissolved in CS_2 (20 mL), *n*-pentane (60 mL) was added and the solution was cooled to −26 °C for 15 h, whereupon a mixture of **3a** and Cp_2TiCl_2 (ca. 10%) crystallized out, which was isolated, washed with *n*-pentane (40 mL) and dried in air (red-blue powder). Yield: 0.77 g (0.69 g of pure **3b**, 39%). The Cp_2TiCl_2 can be removed by stirring the solution with silica gel but the yield is then dramatically lower. M.p. (dec.): 95−100 °C. $C_{35}H_{35}ClS_5Ti$ (699.3): calcd. C 58.92, H 4.94, S 20.64 (Cp_2TiCl_2 content taken into account); found C 58.42, H 4.64, S 18.72. UV/Vis (methanol): λ_{max} (%) = 209 nm (100), 240 (49), 288 (15), 383 (4), 564 (7). ^{1}H NMR (CD_2Cl_2): δ = 7.32 (m, 15 H), 6.37 (s, 10 H), 1.2−2.2 (multiplets, 10 H) ppm. ^{13}C NMR (CD_2Cl_2): δ = 23.0, 24.9, 35.4, 71.5, 73.3, 115.9, 127.2, 128.0, 130.4, 143.5 ppm. RS: 686.

Synthesis of 1-(4-Chlorophenyl)-3-{1-methyl-1-[(triphenylmethyl)-trisulfanyl]ethyl}trisulfane (4a): A mixture of 4-ClC_6H_4SCl (1 mL) and CS_2 (49 mL) was used to titrate a solution of **3a** (0.45 g, 0.68 mmol) in 50 mL of CS_2 dropwise until the violet color had changed to orange-red. After filtration the solution was shaken with ca. 0.5 g of silica gel for a few minutes to remove residual Cp_2TiCl_2 (color change to yellow).The gel was filtered off and washed with CS_2 (50 mL). Removal of the solvent produced an oil which was dissolved in a mixture of MTB ether (5 mL) and *n*-pentane (10 mL). The solvent was partly evaporated until a turbidity appeared, whereupon the solution was cooled to −78 °C. After decantation from the precipitated oil the solution was evaporated in vacuo and the residue dissolved in MTB ether (5 mL) and *n*-pentane (5 mL). Stepwise cooling of this solution to −50 °C produced a champagne-colored powder which was isolated and washed with *n*-pentane (35 mL). Yield: 0.17 g (42%). M.p. 90−95 °C. $C_{28}H_{25}ClS_6$ (589.4): calcd. C 57.06, H 4.28, S 32.65; found C 57.09, H 4.37, S 31.93. UV/Vis (methanol): λ_{max} (%) = 207 nm (100), 238 (44), 277 (12), 316 (6). ^{1}H NMR (CD_2Cl_2): δ = 7.55 (dm, 2 H), 7.33 (m, 17 H), 1.69 (s, 6 H) ppm. ^{13}C NMR (CD_2Cl_2): δ = 28.3, 64.9, 73.4, 127.3, 128.0, 129.3, 130.3, 131.9, 134.5, 135.6, 143.3 ppm. RS: 908.

Synthesis of 1-(4-Chlorophenyl)-3-{1-[(triphenylmethyltri)sulfanyl]cyclohexyl}trisulfane (4b): In analogy to the preparation of **4a**, complex **3b** (0.27 g, 0.39 mmol) was titrated. After removal of the silica gel the solvent was evaporated in vacuo producing an oil which was dissolved in a small amount of MTB ether followed by partial evaporation of the solvent until a sticky foam had formed. Upon addition of MTB ether (5 mL) this turned into a beige powder. After addition of *n*-pentane (25 mL) and cooling to −50 °C for 2 h a crystalline product was obtained which was filtered off and washed with *n*-pentane. Yield: 0.10 g (41%). M.p. 162 °C. $C_{31}H_{29}ClS_6$ (629.4): calcd. C 59.16, H 4.64, S 30.57; found C 59.32, H 4.86, S 29.25. UV/Vis (methanol): λ_{max} (%) = 207 nm (100), 238 (39), 278 (13), 315 (6). ^{1}H NMR (CD_2Cl_2): δ = 7.52 (dm, 2 H), 7.33 (m, 17 H), 1.2−2.2 (multiplets, 10 H) ppm. ^{13}C NMR (CD_2Cl_2): δ = 23.0, 25.0, 35.4, 70.8, 75.3, 127.3, 128.1, 129.3, 130.4, 131.9, 134.4, 135.9, 143.3 ppm. RS: 1080.

Synthesis of 1-{1-Methyl-1-[(triphenylmethyl)tetrasulfanyl]ethyl}-3-(triphenylmethyl)tetrasulfane (5a): Solid TrSSCl (1.50 g, 4.37 mmol) was added in portions and with stirring to a solution of **2a** (0.76 g, 2.18 mmol) in benzene (100 mL). Stirring for 30 min resulted in a color change to red. After evaporation of the solvent the residue was dissolved in CH_2Cl_2 (50 mL) and shaken with some silica gel (5 min). After filtration and evaporation of the solvent the residue was recrystallized from a CS_2/*n*-pentane mixture (5:25). Yield: 0.12 g (7%). M.p.: 55 °C. $C_{41}H_{36}S_8$ (785.3): calcd. C 62.71, H 4.62, S 32.67; found C 62.95, H 4.85, S 33.03. UV/Vis (methanol): λ_{max} (%) = 231 nm (100), 301 (22). ^{1}H NMR ($CDCl_3$): δ = 7.30 (m), 1.58 (s) ppm. ^{13}C NMR ($CDCl_3$): δ = 29.0, 64.3, 73.7, 127.3, 128.0, 130.3, 143.0 ppm. RS: 1071.

Synthesis of 1-(Triphenylmethyl)-3-{1-[(triphenylmethyl)tetrasulfanyl]cyclohexyl}tetrasulfane (5b): Preparation in analogy to the synthesis of **5a** from complex **2b** (0.25 g, 0.64 mmol), TrSSCl (0.44 g, 1.29 mmol) in benzene (30 mL) and using less CH_2Cl_2 (20 mL). Yield: 0.18 g (34%). M.p.: 60 °C. $C_{44}H_{40}S_8$ (825.3): calcd. C 64.03, H 4.89, S 31.08; found C 64.03, H 4.95, S 30.25. UV/Vis (methanol): λ_{max} (%) = 217 nm (100), 261 (22), 305 (13). ^{1}H NMR ($CDCl_3$): δ = 7.34 (m), 1.2−2.3 (multiplets) ppm. ^{13}C NMR ($CDCl_3$): δ = 22.7, 24.8, 26.9, 35.6, 70.4, 73.6, 127.2, 128.0, 130.2, 143.0 ppm. RS: 1186.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Synthesis of 1-{1-Methyl-1-[(triphenylmethyl)pentasulfanyl]ethyl}-3-(triphenylmethyl)pentasulfane (6a): Solid **2a** (0.18 g, 0.52 mmol) was added in small portions with stirring to TrSSSCl (0.40 g, 1.07 mmol) in benzene (25 mL). After 10 min the solvent was evaporated, the residue was dissolved in CH_2Cl_2 (20 mL) and shaken with ca. 0.1 g of silica gel for a few minutes to remove Cp_2TiCl_2. After filtration and partial evaporation of the solvent excess *n*-pentane was added followed by complete evaporation of the solvent. The grayish-white residue was recrystallized from *n*-pentane. Yield: 0.30 g (67%). M.p.: 50 °C. $C_{41}H_{36}S_{10}$ (849.4): calcd. C 57.98, H 4.27; found C 58.51, H 3.75. UV/Vis (methanol): λ_{max} (%) = 240 nm (100), 294 (41). ^{1}H NMR (CD_2Cl_2): δ = 7.33 (m, 30 H), 1.71 (s, 6 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 28.9, 64.8, 73.9, 127.3, 128.0, 130.3, 142.9 ppm. RS: 1212.

Synthesis of 1-(Triphenylmethyl)-3-{1-[(triphenylmethyl)pentasulfanyl]cyclohexyl}pentasulfane (6b): TrSSSCl (0.48 g, 1.28 mmol) was added in small portions with stirring to complex **2b** (0.25 g, 0.64 mmol) in benzene (30 mL). After 10 min the solvent was removed in vacuo, the residue dissolved in CH_2Cl_2 (20 mL) and shaken with some silica gel until the color had changed to yellow. After filtration and evaporation of the solvent the crude product was recrystallized twice from a CS_2/*n*-pentane mixture (5:25 mL) by cooling to −78 °C. Yield: 0.15 g (26%). M.p.: 60 °C. $C_{44}H_{40}S_{10}$ (889.5): calcd. C 59.42, H 4.53, S 36.05; found C 60.14, H 4.60, S 34.26. UV/Vis (methanol): λ_{max} (%) = 209 nm (100), 263 (19), 298 (11). ^{1}H NMR ($CDCl_3$): δ = 7.28 (m), 1.2−2.1 (multiplets) ppm. ^{13}C NMR ($CDCl_3$): δ = 22.8, 24.8, 35.4, 70.9, 73.8, 127.3, 128.0, 130.3, 143.0 ppm. RS: 1338.

Synthesis of Bis{1-methyl-1-[(triphenylmethyl)trisulfanyl]ethyl}-tetrasulfane (7a). Method A: A solution of 0.61 mL of SO_2Cl_2 in 9.4 mL of benzene was added rapidly but dropwise to complex **3a** (0.90 g, 1.37 mmol) in CS_2 (80 mL) until the color had changed from purple to orange-red. After filtration the solution was shaken with some silica gel to remove residual Cp_2TiCl_2. Filtration and evaporation of the solvent yielded a yellow oil which was dissolved in MTB ether (30 mL). Cooling to −78 °C gave an oily residue which was dissolved again in MTB ether and the solvent evaporated again. Yield: 0.25 g (41%).

Method B: Complex **3a** (0.41 g, 0.59 mmol) was dissolved in a mixture of benzene (150 mL), CS_2 (75 mL) and CH_2Cl_2 (25 mL) and stirred for 3 days resulting in a red-brown solution and an ochre precipitate. The filtered solution was stirred with little silica gel for 5 min. and this was then filtered off and washed with CS_2 (25 mL). Evaporation of the solvent gave an oily residue which was dissolved in a mixture of CH_2Cl_2 (3 mL), *n*-pentane (6 mL) and ethanol (15 mL). On cooling to −78 °C the product precipitated as a beige powder. Yield: 0.04 g (15%).%). M.p.: 54 °C. $C_{44}H_{42}S_{10}$ (891.5): calcd. C 59.28, H 4.75, S 35.97; found C 58.91, H 4.97, S 36.41. UV/Vis (methanol): λ_{max} (%) = 213 nm (100), 297 (9). ^{1}H NMR (CD_2Cl_2): δ = 7.31 (m, 30 H), 1.71 (s, 12 H) ppm. ^{13}C NMR (CD_2Cl_2): δ = 28.6, 64.8, 73.1, 127.3, 128.0, 130.3, 143.3 ppm. RS: 1217.

Synthesis of Bis{1-methyl-1-[(triphenylmethyl)trisulfanyl]cyclohexyl}tetrasulfane (7b): Preparation in analogy to **7a** (method A) from **3b** (0.77 g, 1.10 mmol) in 80 mL of benzene. After the color change from purple to orange-red the solvent was evaporated, the residue dissolved in 50 mL CS_2 and stirred with some silica gel. The solution was filtered and the residue washed with 20 mL of CH_2Cl_2. Evaporation of the solvent resulted in an oil which was dissolved in a mixture of 10 mL of CH_2Cl_2 and 50 mL of MTB ether. At −78 °C an oil precipitated which was isolated by decantation and dissolved in 50 mL of MTB ether. After complete evaporation of the solvent a champagne-colored powder was obtained. Yield: 0.24 g (45%). M.p.: 60 °C. $C_{50}H_{50}S_{10}$ (971.6): calcd. C 61.81, H 5.19; found C 59.93, H 5.47. UV/Vis (methanol): λ_{max} (%) = 208 nm (100), 297 (7). ^{1}H NMR (CD_2Cl_2): δ = 7.31 (m, 30 H), 1.2−2.2 (multiplets, 20 H) ppm. ^{13}C NMR (CD_2Cl_2): δ = 23.0, 25.0, 35.7, 70.8, 73.3, 127.3, 128.1, 130.4, 143.3 ppm. RS: 1397.

Synthesis of Bis{1-methyl-1-[(triphenylmethyl)trisulfanyl]ethyl}-pentasulfane (8a): A solution of SCl_2 (1 mL) in CS_2 (50 mL) was added dropwise and with stirring to a solution of **3a** (0.90 g, 1.37 mmol) in CS_2 (80 mL) until the color had changed from blue to red-orange. After filtration some silica gel was added with stirring. The solid was filtered off and washed with CS_2 (20 mL). The solvent of the combined solutions was evaporated and the oily residue dissolved in MTB ether (25 mL). Cooling yielded a precipitate which was isolated and dissolved again in MTB ether. Removal of the solvent produced a beige powder. Yield: 0.20 g (32%). M.p.: 52 °C. $C_{44}H_{42}S_{11}$ (923.5): calcd. C 57.22, H 4.58, S 38.19; found C 57.42, H 4.88, S 37.31. UV/Vis (methanol): λ_{max} (%) = 212 nm (100), 297 (9). ^{1}H NMR (CD_2Cl_2): δ = 7.34 (m, 30 H), 1.74 s, 12 H) ppm. ^{13}C NMR (CD_2Cl_2): δ = 28.6, 65.0, 73.6, 127.3, 128.1, 130.0, 143.3 ppm. RS: 1252.

Synthesis of Bis{1-[(triphenylmethyl)trisulfanyl]cyclohexyl}pentasulfane (8b): Preparation in analogy to **8a** from complex **3b** (0.83 g, 1.19 mmol). Yield: 0.14 g (23%). M.p.: 58 °C. $C_{50}H_{50}S_{11}$ (1003.67): calcd. C 59.84, H 5.02, S 35.14; found C 59.30, H 4.75, S 33.94. UV/Vis (methanol): λ_{max} (%) = 208 nm (100), 297 (8). ^{1}H NMR (CD_2Cl_2): δ = 7.32 (m, 30 H), 1.2−2.3 (multiplets, 20 H) ppm. ^{13}C NMR (CD_2Cl_2): δ = 23.0, 25.0, 35.6, 70.9, 75.3, 127.3, 128.1, 130.3, 143.3 ppm. RS: 1451.

Synthesis of Bis{1-methyl-1-[(triphenylmethyl)trisulfanyl]ethyl}-hexasulfane (9a): A solution of S_2Cl_2 (1 mL) in CS_2 (50 mL) was added dropwise and with stirring to a solution of **3a** (0.81 g, 1.23 mmol) in CS_2 (80 mL) until the color had changed from violet to orange-red. After stirring for 5 min the precipitated Cp_2TiCl_2 was filtered off and the filtrate was shaken with a small amount of silica gel for 5 min. The solids were filtered off and washed with CS_2 (50 mL); the combined filtrates were evaporated and the resulting oil was dissolved in a mixture of MTB ether and CS_2 (40:5 mL). Evaporation of the solvent gave a foam-like product which was pulverized, dissolved in CS_2/ethanol/MTB ether (10:10:5 mL) and cooled to −78 °C. Most of the solvents (CS_2 and ether) were removed on a rotary evaporator and the ethanolic solution was decanted off from the oily product. The latter was mixed with CH_2Cl_2/*n*-hexane/ethanol (7:20:20) and cooled to −78 °C whereupon a sticky precipitate was obtained. This was isolated, dissolved in a CH_2Cl_2/*n*-hexane/ethanol (7:20:10) mixture and this was cooled to −78 °C, resulting in a solid precipitate. Yield: 0.11 g (19%). M.p.: 55 °C. $C_{44}H_{42}S_{12}$ (955.6): calcd. C 55.30, H 4.43, S 40.27; found C 54.78, H 4.71, S 41.29. UV/Vis (methanol): λ_{max} (%) = 216 nm (100), 297 (12). ^{1}H NMR (CD_2Cl_2): δ = 7.32 (m, 30 H), 1.73 (s, 12 H) ppm. ^{13}C NMR (CD_2Cl_2): δ = 28.6, 65.0, 73.4, 127.3, 128.0, 130.3, 143.3 ppm. RS: 1334.

Synthesis of Bis{1-[(triphenylmethyl)trisulfanyl]cyclohexyl}-hexasulfane (9b): Preparation in analogy to **9a** from complex **3b** (0.72 g, 1.03 mmol) in 100 mL of CS_2 by titration with sulfur dichloride. Cp_2TiCl_2 was filtered off and the solution stirred with some silica gel which was then filtered off and the residue washed with 20 mL of CS_2. The solvent was evaporated and the remaining oil dissolved in a mixture of 5 mL of CS_2 and 20 mL of MTB ether. The solvents were evaporated until a turbidity appeared. Cooling to −78 °C resulted in a precipitate which was dissolved in 20 mL

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of MTB ether. Complete evaporation of the ether yielded a white powder. Yield: 0.19 g (36%). M.p.: 55 °C. $C_{50}H_{50}S_{12}$ (1035.7): calcd. C 57.98, H 4.87, S 37.15; found C 57.30, H 5.23, S 37.65. UV/Vis (methanol): λ_{max} (%) = 208 nm (100), 297 (10). ^{1}H NMR (CD_2Cl_2): δ = 7.33 (m, 30 H), 1.3−2.3 (multiplets, 20 H) ppm. ^{13}C NMR (CD_2Cl_2): δ = 23.0, 25.0, 35.5, 71.0, 73.3, 127.3, 128.1, 130.3, 143.3 ppm. RS: 1540.

Synthesis of 1-(Triphenylmethyl)-3-{1-[(triphenylmethyl)trisulfanyl]-cyclohexyl}tetrasulfane (10): TrSSCl (0.22 g, 0.64 mmol) was added in portions to a solution of **3b** (0.45 g, 0.64 mmol) in benzene (60 mL) until the color had changed from violet to orange-red. After evaporation of the solvent the residue was dissolved in CS_2 (50 mL) and stirred with some silica gel for 5 min. After filtration and washing the solid with CS_2 (10 mL) the combined solutions were partly evaporated. Some MTB ether and ethanol were added until a turbidity appeared, whereupon the mixture was cooled to −50 °C. The precipitated oil was isolated by decantation and dissolved in a small amount of CS_2 and excess MTB ether. The solvents were evaporated on a rotary evaporator until a foam appeared which was dried in vacuo (beige powder). Yield: 0.04 g (8%). M.p.: 60 °C. $C_{44}H_{40}S_7$ (793.3): calcd. C 66.62, H 5.08, S 28.30; found C 66.43, H 5.33, S 27.62. UV/Vis (methanol): λ_{max} (%) = 207 nm (100), 267 (10), 298 (5). ^{1}H NMR ($CDCl_3$): δ = 7.30 (m, 30 H), 1.2−2.1 (multiplets, 10 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 22.78, 24.87, 35.28, 70.33, 73.15, 73.63, 127.16, 127.24, 127.97, 128.02, 130.33, 130.37, 143.12, 143.30 ppm. RS: 1125.

Synthesis of 3-(4-Chlorophenyl)-1-{1-methyl-1-[(4-chlorophenyl)trisulfanyl]ethyl}trisulfane (11a): Under nitrogen, a solution of ClC_6H_4SCl (0.50 g, 2.79 mmol) in CS_2 (10 mL) was added dropwise to complex **3a** (0.49 g, 1.41 mmol) in CS_2 (40 mL). Cp_2TiCl_2 was removed by filtration and stirring with a small amount of silica gel. The resulting clear solution was reduced to 5 mL, mixed with a little *n*-pentane and cooled to −78 °C. The precipitated beige powder was isolated and washed with *n*-pentane. Yield: 0.18 g (28%). M.p.: 49−54 °C. $C_{15}H_{14}Cl_2S_6$ (457.6): calcd. C 39.37, H 3.08, S 42.05; found C 39.15, H 2.89, S 41.87. UV/Vis (methanol): λ_{max} (%) = 214 nm (86), 241 (100), 275 (36), 306 (23). MS (150 °C): *m/z* (%) = 350 (1), 318 (17), 286 (73), 249 (21), 222 (9), 175 (45), 143 (100). ^{1}H NMR ($CDCl_3$): δ = 7.53 (dm, 4 H), 7.34 (dm, 4 H), 1.78 (s, 6 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 28.5, 65.1, 129.3, 131.8, 134.7, 135.3 ppm. RS: 805.

Synthesis of 1-(4-Chlorophenyl)-3-{1-[(4-chlorophenyl)trisulfanyl]-cyclohexyl}trisulfane (11b): Under an atmosphere of nitrogen, a solution of ClC_6H_4SCl (0.37 g, 2.06 mmol) in CS_2 (20 mL) was added dropwise to **3b** (0.40 g, 1.03 mmol) in CS_2 (60 mL) resulting in a color change from violet to orange-red. After filtration, addition of a little silica gel and shaking for 5 min the yellow solution was filtered again and the solvent evaporated in vacuo. The residue was dissolved in MTB ether in an ultrasound bath. Reduction of the volume to 5 mL and cooling to −50 °C yielded a solid precipitate which was isolated and dried in vacuo. Yield: 0.03 g (6%). M.p.: 95 °C. $C_{18}H_{18}Cl_2S_6$ (497.6): calcd. C 43.44, H 3.65, S 38.66; found C 43.02, H 3.78, S 38.17. UV/Vis (methanol): λ_{max} (%) = 206 nm (100), 241 (82), 277 (27), 304 (19). MS (180 °C): *m/z* (%) = 350 (2), 318 (20), 289 (43), 286 (34), 254 (4), 222 (6), 210 (19), 178 (13), 175 (64), 145 (82), 143 (78), 114 (63), 108 (47), 81 (100). ^{1}H NMR ($CDCl_3$): δ = 7.53 (dm, 4 H), 7.33 (dm, 4 H), 1.3−2.2 (multiplets, 10 H) ppm. RS: 956.

Synthesis of 1-{1-Methyl-1-[(2-naphthyl)trisulfanyl]ethyl}-3-(2-naphthyl)trisulfane (12a): Solid $C_{10}H_7SCl$ (0.22 g, 1.15 mmol) was added to **3a** (0.20 g, 0.57 mmol) in CS_2 (50 mL) with stirring. After filtration some silica gel was added to remove dissolved Cp_2TiCl_2 and this was then filtered off and washed with CS_2 (10 mL). The combined solutions were evaporated and the oily residue was dissolved in MTB ether in an ultrasound bath. Cooling of the solution to −50 °C gave a white powder which was isolated and dried in air. Yield: 0.04 g (13%). M.p.: 55−57 °C. $C_{23}H_{20}S_6$ (488.8): calcd. C 56.52, H 4.12, S 39.36; found C 55.98, H 4.61, S 38.20. UV/Vis (methanol): λ_{max} (%) = 216 nm (85), 237 (100), 278 (28), 311 (15). MS (200 °C): *m/z* (%) = 382 (4), 350 (67), 318 (38), 286 (35), 265 (6), 254 (23), 234 (26), 202 (45), 191 (88), 170 (66), 159 (68), 138 (37), 128 (19), 115 (100), 106 (46). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.05 (d, J_{meta} = 1.9 Hz, 2 H), 7.84 (m, 6 H), 7.67 (dd, J_{ortho} = 8.6 Hz, J_{meta} = 1.9 Hz, 2 H), 7.52 (m, 4 H), 1.78 (s, 6 H) ppm. RS: 952.

Synthesis of 1-(2-Naphthyl)-3-{1-[(2-naphthyl)trisulfanyl]-cyclohexyl}trisulfane (12b): Preparation in analogy to **12a** from **3b** (0.35 g, 0.90 mmol) and $C_{10}H_7SCl$ (0.35 g, 1.80 mmol). After dissolution in MTB ether a little ethanol and *n*-pentane were added and the volume was reduced in vacuo until a turbidity appeared. Stepwise cooling to −50 °C for precipitation and recrystallization from an MTB ether/*n*-hexane mixture with addition of a little ethanol to initiate the precipitation. Grayish-white powder. Yield: 0.09 g (19%). M.p.: 55−60 °C. $C_{26}H_{24}S_6$ (528.9): calcd. C 59.05, H 4.57, S 36.38; found C 58.26, H 4.18, S 35.66. UV/Vis (methanol): λ_{max} (%) = 216 nm (83), 238 (199), 277 (28), 309 (16). MS (160 °C): *m/z* (%) = 382 (3), 368 (10), 350 (58), 336 (48), 318 (21), 286 (26), 272 (21), 254 (9), 242 (15), 210 (34), 191 (100), 178 (19). ^{1}H NMR (CD_2Cl_2): δ = 8.06 (d, J_{meta} = 1.9 Hz, 2 H), 7.84 (m, 6 H), 7.69 (dd, J_{ortho} = 8.6 Hz, J_{meta} = 1.9 Hz, 2 H), 7.53 (m, 4 H), multiplets: 2.08−2.13 (4 H), 1.54−1.65 (4 H), 1.31−1.40 (2 H) ppm. ^{13}C NMR (CD_2Cl_2): δ = 22.93, 24.78, 35.47, 71.04, 126.80, 126.90, 127.68, 127.72, 127.78, 129.08, 129.54, 132.92, 133.36, 134.21 ppm. RS: 1070.

A Bis(diazadiene) Adduct of $MoCl_2$: Mononuclear, Octahedral, Undistorted and Diamagnetic

François Stoffelbach,[a] Bertrand Rebière,[a] and Rinaldo Poli*[a,b]

Keywords: Density functional calculations / Magnetic properties / Molybdenum / N ligands / X-ray diffraction

The complex $[MoCl_2(i Pr_2dad)_2]$ ($i Pr_2dad$ = *i*PrN=CH–CH=N–*i*Pr) is obtained in one step by reduction of $[MoCl_3(THF)_3]$ in the presence of $i Pr_2dad$. The X-ray structure reveals a relatively undistorted octahedral coordination geometry with a relative *cis* configuration and points to a more appropriate description of the ligands as enediamides. The NMR investigation is in agreement with the same *cis* structure in solution and underlines the diamagnetism of the compound, at odds with previously reported very similar complexes. A bulk magnetic susceptibility measurement further confirms the compound's diamagnetism. No equilibrium with a dinuclear, metal-metal bonded species is apparent from the solution studies. A DFT calculation on the real molecule and on two R_2dad model systems with R = Ph and 4-HOC_6H_4 reveals how the ligand periphery delicately controls the magnetic and structural properties of this system.

Introduction

The coordination chemistry of diazadiene ligands (RN=CH−CH=NR; R_2dad) has attracted attention for quite some time,[1,2] because their high electronic and coordination mode flexibility (i.e. see **A**, **B** and **C**) imparts unusual electron-donor and -acceptor properties to these ligands, combining the useful features of N-based donors such as bipy and unsaturated acceptors such as dienes. Consequently, these ligands are generally compatible with metal centers in both high and low oxidation states. For some time, we have been investigating the coordination chemistry and the organometallic chemistry of molybdenum in intermediate oxidation states, mostly II, III and IV. Ligands with mild π-acidic properties, such as phosphanes, are quite compatible with these systems, but a wide range of ligands with extreme σ- and π-donor/acceptor properties also afford isolable and stable compounds. It was therefore of interest to probe the coordination of diazadiene ligands to these ions. We have recently shown[3] that a variety of R_2dad ligands easily add to $[CpMoCl_2]$ to yield $[CpMoCl_2(R_2dad)]$ complexes and a crystallographic study indicates that the dad ligand adopts a coordination mode closest to **B**. The metal center, therefore, is most appropriately described as formally Mo^V. In this contribution, we report the synthesis, the structural and physical characterization, and a DFT study of a compound resulting from the formal addition of two $i Pr_2dad$ ligands to $MoCl_2$. The product presents several unusual features when compared with other compounds that are very closely related to it.

Results and Discussion

The complex $[MoCl_2(i Pr_2dad)_2]$ ($i Pr_2dad$ = *i*PrN=CH−CH=N*i*Pr) was prepared in one step from $[MoCl_3(THF)_3]$ by reduction with Zn in the presence of the diazadiene ligand. A similar strategy was previously used for the preparation of the related R_2dad complex with R = C_6H_4OMe-4,[4] and for the preparation of related $[MoCl_2(R_2dad)(CNMe)_2]$ complexes when conducted in the presence of methyl isocyanide, the main difference being the use of sodium as the reducing agent.[5] These other derivatives of $MoCl_2$, however, were not structurally characterized and no details of their stereochemistry (e.g. *cis* vs. *trans*) were evident from the spectroscopic studies.

The NMR properties unambiguously establish the diamagnetic nature of the compound and establish the cis stereochemistry of the molecule in solution. In fact, the four isopropyl methyl groups of an individual dad ligand are all inequivalent, as expected for the C_2 molecular symmetry, whereas they would all be equivalent for the C_{2v}-symmetric

trans isomer. Since the two dad ligands are symmetry related, four methyl peaks are observed overall in the ^1H NMR spectrum, each being split to a doublet by coupling with the corresponding methyne proton. The methyne protons correspondingly give rise to two different septets and the inner CH=N protons to two mutually coupled signals with a very small coupling constant (2.0 Hz).

Crystals of the [$MoCl_2$(*i*Pr$_2$dad)$_2$] derivative suitable for an X-ray structural study could be grown from diethyl ether at low temperature. The structural analysis confirms the identity of the molecule and establishes the cis stereochemistry (see Figure1). The geometry is essentially regular octahedral, the only slight deviations being attributable to the small bite of the chelating dad ligands [N(1)−Mo−N(2) = 75.55(8)° and N(3)−Mo−N(4) = 75.52(8)°]. The N(1) and N(3) ligands are essentially perfectly opposite to each other [N(1)−Mo−N(3) = 177.93(8)°] and at nearly right angles to both Cl atoms.

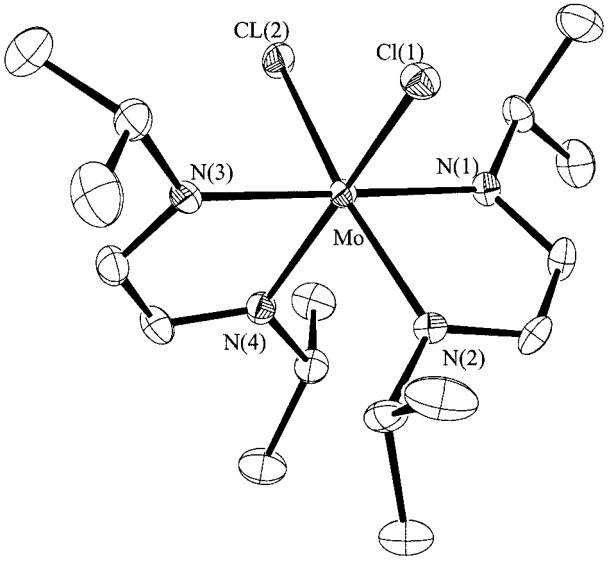

Figure 1. An ORTEP view of the geometry of [$MoCl_2$(*i*Pr$_2$dad)$_2$]

The Mo-dad five-membered rings are essentially planar [RMS deviation of fitted atoms = 0.0433 and 0.0256 for the MoN(1)C(1)C(2)N(2) and MoN(3)C(9)C(10)N(4) cycles, respectively; highest deviations from the plane: 0.0553(14) Å for atom N(2) and 0.0329(14) Å for atom N(3)]. The N−C distances average 1.338(8) Å and the C−C distances average 1.372(4) Å. These are considerably lengthened and shortened, respectively, when compared with those of free dad molecules such as *s-trans*-Cy$_2$dad [N−C: 1.258(2) Å; C−C: 1.457(2) Å] and also with those of complexes to which the bonding mode **A** can be clearly assigned (N−C: 1.26−1.30 Å; C−C: 1.40−1.46 Å).[1] The observed structural parameters are more consistent with a bonding description where the arrangement **B** plays a significant role and are very similar to those of our recently reported dad adduct of [$CpMoCl_2$].[3] Compounds such as the formally d^6 [$Mo(CO)_4$(R$_2$dad)] (R = *i*Pr or C$_6$H$_3$-*i*Pr$_2$-2,6),[6] d^4 [Mo(allyl)Br$(CO)_2$(R$_2$dad)] (R = *t*Bu, Ph),[7,8] and d^0 [MoO_2Cl_2(*t*Bu$_2$dad)],[9] on the other hand, show N−C and C−C parameters much closer to those of the free dad ligands, in better agreement with coordination mode **A**. Other Mo complexes with dad or dad-related ligands are also known.[10−13] We can advance the hypothesis that the dad ligand cannot operate as an effective π-acid in the above mentioned d^6 and d^4 complexes because of the competition with the stronger carbonyl ligands.

The Mo−N distances are slightly longer for the N(1) and N(3) atoms that are trans to each other, than for the N(2) and N(4) atoms located trans to the Cl atoms, reflecting the greater trans influence of the imino donors. The Mo−N distances are considerably shorter than in the structurally related complex [MoO_2Cl_2(*t*Bu$_2$dad)] [2.399(2) and 2.388(2) Å], where the two oxo ligands satisfy the maximum valence of the molybdenum center and therefore the dad ligand can only bind via the coordination mode **A**.[9] This is further supporting evidence for the description of the coordination geometry as **B** in the title compound. The Mo−Cl distances average 2.404(1) Å, these also being shorter than those found in other *cis*-dichloro complexes of Mo^{II} with strong *trans* ligands, for example 2.52(1) Å in [$MoCl_2$(dppe)$_2$],[14] and closer to typical Mo^{VI}−Cl distances, such as 2.356(1) Å in [MoO_2Cl_2(*t*Bu$_2$dad)][9] and 2.3251(7) Å in [(C$_5$H*i*Pr$_4$)MoO_2Cl],[15] in further agreement with the assignment of a higher formal oxidation state to the metal in compound **3**.

The compound's diamagnetism is the most surprising result concerning this compound, especially when compared with the paramagnetism (two unpaired electrons) measured for the very similar [$MoCl_2$(R$_2$dad)$_2$] and [$MoCl_2$(R$_2$dad)(CNMe)$_2$] (R = C$_6$H$_4$-OMe-4) complexes[4,5] and which is reasonably expected for low-spin octahedral d^4 Mo^{II} complexes, an example of which is [$MoCl_2$(PMe$_3$)$_4$].[16] Related W^{II} complexes with the same dad ligand are also paramagnetic.[4] The bulk diamagnetism of the title compound was confirmed by a magnetic susceptibility study. The striking difference between the two [$MoCl_2$(R$_2$dad)$_2$] compounds (diamagnetic for R = *i*Pr, paramagnetic for R = C$_6$H$_4$-OMe-4), under the assumption that the aryl derivative has a similar structure, leads to the hypothesis that the *i*Pr-substituted ligand is a better π-acceptor, delocalizing the metal electrons onto the ligand more effectively by adopting a binding mode closer to type **B** (as verified by the X-ray structural analysis), whereas the *p*-MeO-phenyl-substituted ligand leads to a molecule where the ligand adopts a binding mode closer to type **A** and which can be described more appropriately as a coordination compound of Mo^{II}. It seems rather surprising, however, that the 4-MeOC$_6$H$_4$ substitution would render the dad ligand a poorer π-acceptor than substitution by *i*Pr. This question has been addressed in more detail by a DFT investigation (see below).

Another peculiar feature of the title compound, given its diamagnetism, is the fact that no *major* distortion is revealed by the X-ray structural analysis. In fact, the large family of diamagnetic octahedral complexes of Mo^{II} (d^4) typically show rather severe distortions from the ideal octa-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hedral geometry, with angles between bonds in relative cis positions as low as 72° and as high as 120°.[17] In the title compound, on the other hand, the only evident structural deformation is a straightforward consequence of the small bite of the two dad ligands. This phenomenon can again be rationalized on the basis of the extensive back-bonding to the dad ligands which is revealed by the solid-state structural data, so that the compound can no longer be assimilated as an octahedral d^4 dichlorobis(dad) complex of Mo^{II}. An electrochemical investigation of the title compound in THF shows two reversible one-electron processes, a reduction at $E_{1/2} = -1.27$ V and an oxidation at $E_{1/2} = -0.24$ V (Figure 2). Evidently, the orbitals involved in the electron addition and removal processes are more or less delocalized between the metal center and the ligands.

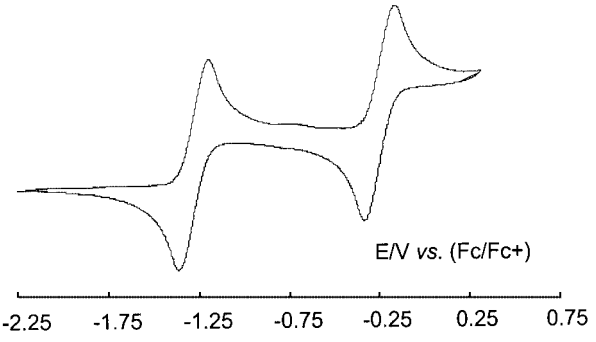

Figure 2. Cyclic voltammogram of a THF solution of [$MoCl_2(i\mathrm{Pr}_2\mathrm{dad})_2$]

In order to explore the details of the electronic structure for this compound and to understand the effect of the peripheral groups on the dad coordination mode, we have carried out DFT calculations on three different [$MoCl_2(R_2\mathrm{dad})_2$] systems with R = *i*Pr (the "real" system), Ph and 4-HOC_6H_4. The pairwise comparison between these three systems allows us to assess the electronic effect of aryl vs. alkyl groups on the dad ligand, as well as the effect of a para substituent with a mesomeric donating effect on the aryl groups. The computationally simpler OH substituent was used instead of the OMe substituent which is present in the literature compound,[4] since we only wish to probe the electronic effect of the OR conjugation with the aryl group. No major steric effect is expected to differentiate the electronic action of the *p*-OH and OMe groups.

All three systems have been fully optimized in both singlet and triplet states. The relative energies of the two spin states are reported in Table 1 together with relevant optimized geometrical parameters. First, it can be noted that the DFT-optimized structure for the real molecule in the spin singlet compares very closely with the experimentally determined structure (cf. first column of Table 1 with the data in Table 2). In particular, the C−N and C−C distances for the dad ligand are in close agreement with the experimental structure and with a description where the enediamido form **B** plays a significant role, whereas the triplet molecule shows longer C−N and shorter C−C distances, in agreement with reduced Mo-dad back-bonding. The angular parameters are not dramatically different in the two spin states. The opposite Cl−Mo−Cl and N−Mo−N(*cis*) angles become closer to the ideal octahedral values in the triplet state, whereas the N−Mo−N(*trans*) angle is less distorted in the singlet state. The optimized molecules with R = Ph and 4-HOC_6H_4 have geometrical features in close proximity to the R = *i*Pr system for both spin states.

The most interesting feature is the effect of R on the relative energy. For R = *i*Pr and Ph, the singlet state is more stable than the triplet by approximately the same amount (2−3 kcal mol^{-1}). Therefore, a change from an alkyl to an aryl group does not affect very much the electronic structure at the metal center. On the other hand, the addition of an OH substituent in the para position of the aryl group inverts the stability order in favor of the triplet state, in

perfect agreement with the experimental results reported by Pombeiro et al.[4] We have attempted to pinpoint the reason for this unexpected result by inspecting the orbital interactions that are responsible for the Mo-dad bonding. As it turns out, the observed trend results from the combination of minor energy changes caused by the *p*-OH group on several bonding molecular orbitals in the deep energy region. From a qualitative point of view, we can argue that the *p*-OMe group, through its π-donating effect, makes the aryl group less capable of accepting electron density from the dad system and consequently renders the dad ligand a poorer π-acceptor, the ultimate effect being a relative destabilization of the singlet state. Some support for this statement comes from an analysis of the Mulliken charges (see Table 3). In the singlet state, the metal atom has a lower positive charge in the order 4-HOC_6H_4 < Ph < *i*Pr and, significantly, the HOC_6H_4 group has a greater positive charge relative to Ph.

Table 3. Mulliken charges for compounds $[MoCl_2(R_2dad)_2]$

	R = *i*Pr		R = Ph		R = 4-HOC_6H_4	
	Singlet	Triplet	Singlet	Triplet	Singlet	Triplet

R (total)	0.719	0.783	1.026	1.042	1.058	1.077

The energies of the relevant frontier orbitals for the three calculated systems in both spin states are shown in Figure 3. The shape of the five orbitals for the singlet *i*Pr system, i.e. the title compound, are also shown. It can be seen that the overall trend of the MO energies is identical in all three cases, in particular on going from the Ph to the 4-HOC_6H_4 substituent. The Mo-dad back-bonding interaction is present with an approximately identical intensity in the HOMO and in the second highest occupied MO (SHOMO), as revealed by the contribution from the N atomic orbitals. For the SHOMO, this is quite evident from the contour plot included in Figure 3, whereas the HOMO maximizes its interaction with the dad ligand on the opposite side of the molecule (not visible). The LUMO is essentially a pure metal orbital, whereas the two higher energy empty orbitals are slightly Mo-dad antibonding (π*). The three lowest orbitals (SHOMO, HOMO and LUMO) also exhibit a small contribution from the Cl atoms which is Mo−Cl π* in nature.

The two Mo-dad π-interactions are responsible for the large splitting of the pseudo-octahedral "t_{2g}" set of orbitals and for the consequent adoption by the molecule of the singlet spin-state. It is to be noted that one of these two Mo-dad π bonding orbitals remains doubly occupied also in the triplet configuration, whereas one electron from the other orbital becomes Mo-dad nonbonding in the triplet state. Therefore, the overall Mo-dad π back-bonding interaction is only slightly reduced upon going from the singlet to the triplet. The MO analysis also shows that, in spite of the Mo-dad π-interaction, the major contribution to the

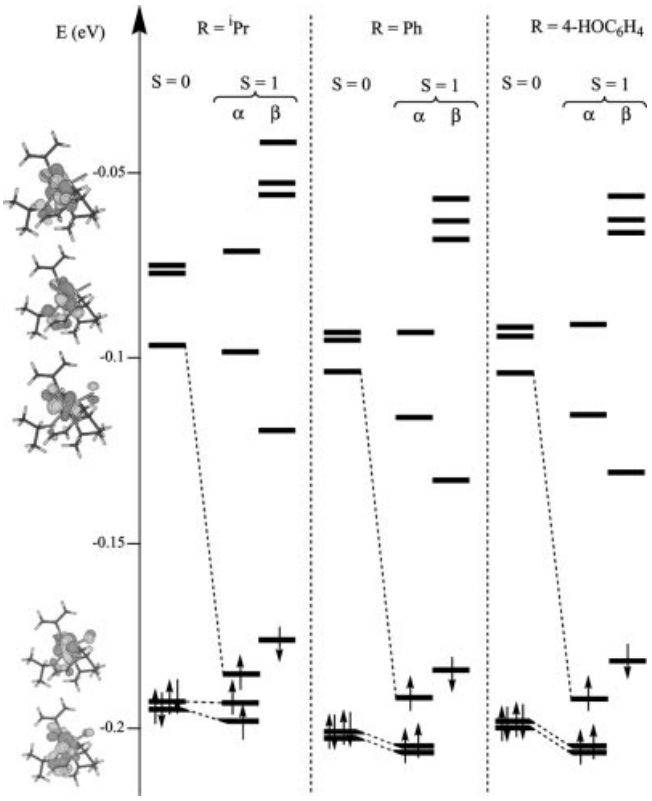

Figure 3. Energy diagram of the five 4d-derived frontier orbitals for singlet and triplet $[MoCl_2(R_2dad)_2]$ (R = *i*Pr, Ph, and 4-HOC_6H_4); on the left, MOLDEN views of the five orbitals for the singlet R = *i*Pr compound are also shown

HOMO remains that of the Mo atomic orbitals, while the Mulliken analysis shows that the majority of the spin density is localized on the Mo atom. Therefore, the one-electron oxidation process that is observed in the cyclic voltammetric study may be considered to be essentially a metal-based process. This observation serves to illustrate, once again, that the attribution of formal oxidation states has only a limited bookkeeping value when the ligands are able to adapt to their electronic environment via tunable π-interactions. This problem is commonplace in organometallic chemistry, for instance for M-olefin, M-diene, M-carbene complexes, and so forth.[18] The title compound may be described by the two limiting forms as a bis(diazadiene) Mo^{II} complex (bonding of type **A**), or as a bis(enediamido) Mo^{VI} complex (bonding of type **B**), or as anything in between. The real situation can only be revealed by the experimental observations (structural parameters, redox potentials, and so forth) and interpreted on the basis of the MO calculations.

A final interesting observation concerns the absence of any dinuclear product of formula $[Mo_2Cl_4(dad)_2]$, containing a quadruple Mo−Mo bond. There are numerous examples of $[Mo_2Cl_4L_4]$ compounds where the neutral ligands are N-based donors, mostly saturated amines,[19−24] but also nitriles,[25] pyridines,[26,27] bipyridines and other aromatic amines.[28] This observation may once again be rationalized by considering the strong π-accepting properties

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the dad ligand. It is known, in fact, that strongly π-acidic ligands disfavor metal-metal bonds[29,30] and favor the establishment of mononuclear structures.

Conclusions

Compound $[MoCl_2(i\mathrm{Pr}_2\mathrm{dad})_2]$ is a remarkable coordination compound because of its diamagnetism, at odds with very similar complexes. The X-ray structure shows a relatively undistorted mononuclear octahedral coordination geometry for the complex, with bond lengths that are in better agreement with a bis(enediamido) Mo^{VI} model than with a bis(diazadiene) Mo^{II} model. The greater propensity of the di-*i*Pr-substituted dad ligand to adopt an enediamido coordination relative to the bis(C_6H_4OMe-4)-substituted dad ligands was not anticipated. The theoretical investigation shows the propensity of the dad ligands to accept electron density from the metal center in the HOMO and SHOMO and to reorganize to a coordination mode closer to that of enediamido ligands. These orbitals, however, retain a substantial metal contribution.

Experimental Section

General procedures: All manipulations were carried out under an atmosphere of dry and oxygen-free argon with standard Schlenk techniques. Toluene and diethyl ether were purified by reflux over sodium benzophenone ketyl and distilled under argon prior to use. The cyclic voltammogram was obtained with an EG&G 362 potentiostat connected to a Macintosh computer through MacLab hardware/software. The electrochemical cell was fitted with a Ag-AgCl reference electrode, a platinum disk working electrode and a platinum wire counter electrode. $[Bu_4N]PF_6$ (ca. 0.1 M) was used as supporting electrolyte in THF. All potentials are reported relative to ferrocene standard, which was added to the solution at the end of the experiment and measured at 100 mV/s. $[MoCl_3(THF)_3]$[31] and the $i\mathrm{Pr}_2$dad ligand[32] were prepared as described in the literature. The elemental analyses were carried out by the analytical service of the laboratory with a Fisons EA 1108 apparatus. NMR spectra were recorded in C_6D_6 at 25 °C on a Bruker DRX 500 spectrometer. The peaks positions are reported with positive shifts in ppm downfield of TMS, as calculated from residual solvent peaks.

Synthesis of $[MoCl_2(i\mathrm{Pr}_2\mathrm{dad})_2]$: $[MoCl_3(THF)_3]$ (1.25 g, 2.99 mmol), Zn (0.2 g, 3.05 mmol) and $i\mathrm{Pr}_2$dad (0.903 g, 6.44 mmol) were suspended in 15 mL of toluene at room temperature. The mixture was then stirred for three days at room temperature. The solution was filtered through Celite to remove an insoluble residue, evaporated to dryness, and warmed to 70 °C under vacuum in order to sublime the residual $i\mathrm{Pr}_2$dad. A crude product was obtained as a red dark microcrystalline solid. Yield: 0.92 g (69.2%). Recrystallization by cooling from Et_2O at −80 °C afforded X-ray quality crystals, one of which was used for the X-ray structural study. $C_{16}H_{32}Cl_2MoN_4$ (447.3): calcd. C 42.96, H 7.21, N 12.53; found C 43.19, H 7.30, N 12.21. Cyclic voltammetry (THF): reversible oxidation at $E_{1/2} = -0.24$ V ($\Delta E_p = 185$ mV) and reversible reduction at $E_{1/2} = -1.27$ V ($\Delta E_p = 177$ mV) (the ferrocene peak shows $\Delta E_p = 248$ mV). IR data (Golden gate): $\tilde{\nu}$ = 2968m cm^{-1}, 2926m, 2867m, 1490s, 1457m, 1363m, 1229s, 1219s, 1172s, 1121m, 1097m, 1024m, 795s. ^{1}H NMR (C_6D_6, 25 °C): δ = 0.32 (d, J = 6.6 Hz, CH_3), 0.47 (d, J = 6.7 Hz, CH_3), 1.12 (d, J = 6.7 Hz, CH_3), 1.54 (d, J = 6.6 Hz, CH_3), 4.18 (sept, J = 6.6 Hz, CH), 5.15 (sept, J = 6.7 Hz, CH), 6.02 (d, J = 2.0 Hz, CH=N), 6.52 (d, J = 2.0 Hz, CH=N) ppm. $\chi_M = -143.2 \times 10^{-6}$ cgs units (calculated correction for the ligand diamagnetism: $\chi_M = -259.6 \times 10^{-6}$ cgs units).

X-ray Analysis of $[MoCl_2(i\mathrm{Pr}_2\mathrm{dad})_2]$: Intensity data were collected on a Nonius−Kappa CCD at 110 K. The structure was solved via a Patterson search program[33] and refined with full-matrix least-squares methods based on F^2 (SHELX-97)[33] with the aid of the WINGX program.[34] All non-hydrogen atoms were refined with anisotropic thermal parameters. H atoms were found in a difference Fourier map and refined freely with their isotropic displacement parameters fixed at 1.2 or 1.5 (for CH_3) times the U_{eq} of their parent atoms. Refinement of the Flack parameter[35] showed that the crystal is an inversion twin[36] with a twin fraction of 0.54(3). The crystal data and refinement parameters are collected in Table 4, whereas selected bond lengths and angles are listed in Table 2.

Computational Details: All calculations were performed using the Gaussian 98 program package.[37] The three-parameter form of the Becke, Lee, Yang and Parr functional (B3LYP),[38] was employed, in combination with the LanL2DZ library of basis functions, which includes both Dunning and Hay's D95 sets for H, C, O and N[39] and the relativistic Electron Core Potential (ECP) sets of Hay and Wadt for the 10 inner electrons of Cl and the 28 inner electrons of Mo.[40−42] All geometries were fully optimized without symmetry restrictions. For the open-shell species, the calculations used unrestricted open-shell methods. The mean value of the spin over the electronic density in an unrestricted calculations does not reproduce exactly the assigned spin multiplicity. In all our cases, though, it was considered to be suitable to identify unambiguously the spin state. Mean values of $<S^2>$ were in the narrow 2.097−2.174 range for triplets. In all cases, relative energies are given in kcal mol^{-1} and do not include a correction for zero-point energy.

Kinetic Studies of the Oxidative Addition and Transmetallation Steps Involved in the Cross-Coupling of Alkynyl Stannanes with Aryl Iodides Catalysed by η^2-(Dimethyl fumarate)(iminophosphane)palladium(0) Complexes

Bruno Crociani,*[a] Simonetta Antonaroli,[a] Luciano Canovese,[b] Paolo Uguagliati,[b] and Fabiano Visentin[b]

Keywords: Palladium / N,P ligands / Kinetics / Cross-coupling

The complexes [Pd(η^2-dmfu)(P–N)] {dmfu = dimethyl fumarate; P–N = 2-(PPh_2)C_6H_4–1-CH=NR, R = C_6H_4OMe-4 (**1a**), $CHMe_2$ (**2a**), $C_6H_3Me_2$-2,6 (**3a**), $C_6H_3(CHMe_2)_2$-2,6 (**4a**)} undergo dynamic processes in solution which consist of a P–N ligand site exchange through initial rupture of the Pd–N bond at lower energy and an olefin dissociation-association at higher energy. According to equilibrium constant values for olefin replacement, the complex [Pd(η^2-fn)(P–N)] (fn = fumaronitrile, **1b**) has a greater thermodynamic stability than its dmfu analogue **1a**. The kinetics of the oxidative addition of ArI (Ar = $C_6H_4CF_3$-4) to **1a** and **2a** lead to the products [PdI(Ar)(P–N)] (**1c**, **2c**) and obey the rate law, $k_{obs} = k_{1A} + k_{2A}$[ArI]. The k_{1A} step involves oxidative addition to a reactive species [Pd(solvent)(P–N)] formed from dmfu dissociation. The k_{2A} step is better interpreted in terms of oxidative addition to a species [Pd(η^2-dmfu)(solvent)(κ^1-P–N)] formed in a pre-equilibrium step from Pd–N bond breaking. The complexes **1c** and **2c** react with PhC≡$CSnBu_3$ in the presence of an activated olefin (ol = dmfu, fn) to yield the palladium(0) derivatives [Pd(η^2-ol)(P–N)] along with $ISnBu_3$ and PhC≡CAr. The kinetics of the transmetallation step, which is rate-determining for the overall reaction, obey the rate law: $k_{obs} = k_{2T}$[PhC≡$CSnBu_3$]. The k_{2T} values are markedly enhanced in more polar solvents such as CH_3CN and DMF. The solvent effect and the activation parameters suggest an associative S_E2 mechanism with substantial charge separation in the transition state. The kinetic data of the above reactions in various solvents indicate that, for the cross-coupling of PhC≡$CSnBu_3$ with ArI catalysed by **1a** or **2a**, the rate-determining step is represented by the oxidative addition and that CH_3CN is the solvent in which the highest rates are observed.

Introduction

The cross-coupling of organo-stannanes with carbon electrophiles catalysed by palladium complexes (Stille reaction) is a powerful synthetic method in organic chemistry.[1] The generally accepted catalytic cycle involves an initial oxidative addition of the organic electrophile to a palladium(0) species followed by transmetallation, *trans*-to-*cis* isomerisation if *trans*-diorganopalladium(II) intermediates are formed, and eventually reductive elimination of the coupled product.[1,2] As shown in previous studies,[3] for the complexity of the reactions involved the mechanism of the process can be variously affected by the nature of the ligand, the solvent, the reacting stannane and organic electrophile, and by the presence of additives such as LiCl or the free ligand. In fact, the rate-determining step of the cycle can either be the oxidative addition or the transmetallation or even the reductive elimination.[1c,2,4]

The mechanism described in Scheme 1 for the coupling of ArX (Ar = pentahalophenyl; X = halide, triflate) with $RSnBu_3$ (R = vinyl) has been recently proposed.[5]

In this mechanism, two transmetallation pathways may be present without any prior dissociation (or solvent displacement) of the ligand L in the intermediates *trans*-[$PdXArL_2$]. The associative S_E2 cyclic step (a) is favoured in weakly coordinating solvents of low polarity when X is a good bridging ligand such as a halide. It leads to a highly reactive *cis* species which undergoes an immediate reductive elimination and is strongly retarded by the presence of the free ligand L. The associative S_E2 open step (b) is favoured when L′ is a ligand or a polar coordinating solvent both of which lack bridging capability and when X is a good-leaving and poorly coordinating anionic ligand without bridging ability.

In contrast, the transmetallation of [{η^5-(1-Ph_2P)(2,4-Ph_2)C_5H_2}$(CO)_3$MoPdI(PPh_3)] by PhC≡$CSnBu_3$, leading to [{η^5-(1-Ph_2P)(2,4-Ph_2)C_5H_2}$(CO)_3$MoPd(C≡CPh)-

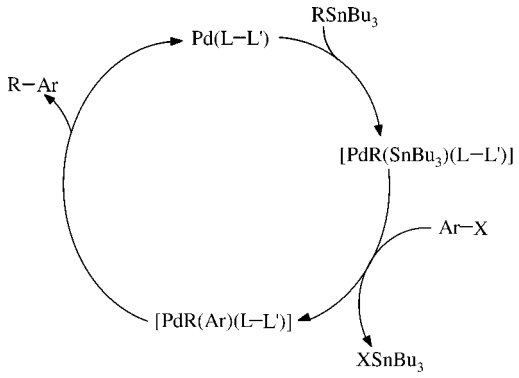
(L = PPh_3, $AsPh_3$; L' = ligand or solvent)

Scheme 1. Catalytic cycle for the cross-coupling reaction with palladium complexes containing monodentate ligands L



[L—L' = 2-(PPh_2)C_6H_4-1-CH=NC_2H_4Ph]

Scheme 2. Alternative catalytic cycle for the cross-coupling reaction with the system [PdCl(η^3-C_3H_5)]$_2$/L—L′ (1:2 molar ratio)

(PPh_3)] in dimethylformamide (DMF), was reported to proceed through a reactive species [{η^5-(1-Ph_2P)(2,4-Ph_2)C_5H_2}(CO)$_3$MoPdI(DMF)],formed in a displacement equilibrium of the ligand PPh_3 by the solvent when a low initial concentration of the starting complex was used.[6]

On the other hand, the complex *trans*-[PdIPh($AsPh_3$)$_2$] was also found to be in equilibrium with the species [PdIPh(solvent)($AsPh_3$)] (solvent = DMF) upon release of $AsPh_3$ in dimethylformamide,[7] in agreement with previous kinetic studies.[1b][3e] In a recent report, however, the concentration of [PdXR(solvent)($AsPh_3$)] (X = Cl, I; R = Ph, $C_6Cl_2F_3$) was found to be negligible in the presence of free arsane, indicating that under catalytic conditions the predominant transmetallation step involves the associative reaction of the stannane with the complex [PdXR($AsPh_3$)$_2$].[8]

In the coupling of pentahaloaryl triflates (ArX) with CH_2=CHSnBu$_3$ catalysed by [PdXAr(dppe)] [dppe = 1,2-bis(diphenylphosphanyl)ethane] the main intermediates, [PdAr(CH=CH_2)(dppe)] and [Pd(η^2-CH_2=CHAr)(dppe)], have been spectroscopically detected and characterised.[9]

The system [PdCl(η^3-C_3H_5)]$_2$/L—L′ (1:2 molar ratio) {L—L′ = 2-(PPh_2)C_6H_4—1-CH=NC_2H_4Ph}, was found to have a high catalytic efficiency in the coupling of 4-(trifluoromethyl)iodobenzene with PhC≡CSnBu$_3$.[10] From the detection of the labile complexes [PdI(SnBu$_3$)(L—L′)] and [Pd(C≡CPh)(SnBu$_3$)(L—L′)] in the ^{31}P NMR spectra of the reaction mixture, an alternative catalytic cycle was proposed involving the initial oxidative addition of PhC≡CSnBu$_3$ to an in situ generated palladium(0) species, Pd(L—L′) (Scheme 2).

The zero-valent complexes [Pd(η^2-dmfu)(P—N)] {dmfu = dimethyl fumarate; P—N = 2-(PPh_2)C_6H_4—1-CH=NR, R = alkyl and aryl group},[11] are quite active catalysts (or catalyst precursors) in the coupling of organostannanes with aryl halides.[12] The catalytic efficiency is retained for a prolonged period of time and increases considerably on going from alkyl to aryl *N*-substituents, and also in the presence of the free iminophosphane for a P—N/[Pd(η^2-dmfu)(P—N)] molar ratio ≥ 1. In a mechanistic investigation based mainly on IR and NMR spectroscopic data,[13] we have reported that the cross-coupling of PhC≡CSnBu$_3$ with $IC_6H_4CF_3$-4 proceeds through the classical cycle involving initial oxidative addition of the aryl iodide to [Pd(η^2-dmfu)(P—N)] {P—N = 2-(PPh_2)C_6H_4—1-CH=NR, R = C_6H_4OMe-4, $CHMe_2$}, or [Pd(η^2-dmfu)(P—N)$_2$] formed from the reaction of [Pd(η^2-dmfu)(P—N)] with one equivalent of the iminophosphane P—N, followed by trans-metallation of the product [PdI($C_6H_4CF_3$-4)(P—N)] and by fast reductive elimination of the alkyne PhC≡C$C_6H_4CF_3$-4 to regenerate the starting palladium(0) compound. With [Pd(η^2-dmfu)(P—N)] as the catalyst, the oxidative addition is the rate-determining step, while for [Pd(η^2-dmfu)(P—N)$_2$] the oxidative addition and transmetallation steps proceed at comparable rates.

We report herein the results of a kinetic investigation of the oxidative addition of $IC_6H_4CF_3$-4 to [Pd(η^2-dmfu)(P—N)] and the transmetallation of [PdI($C_6H_4CF_3$-4)(P—N)] by PhC≡CSnBu$_3$. The studies have been carried out using UV/Vis spectroscopic techniques in order to get a better understanding of the mechanism and of the factors which affect these fundamental steps of the catalytic cycle.

Results and Discussion

The structures of the palladium complexes used in the kinetic study are shown in Scheme 3.

According to the X-ray structural analyses of the iminophosphane derivatives [Pd(η^2-fn)(P—N)] (fn = fumaronitrile, **1b**)[14] and [PdI(Ph)(P—N)] {P—N = 2-(PPh_2)C_6H_4—1-CH=NR; R = Me, Et},[15] the olefin carbons are almost coplanar with the N—Pd—P coordination plane for the palladium(0) complexes, while in the palladium(II) complexes the iodide ligand is *trans* to the phosphorus atom.

In order to clarify the intimate mechanism governing the cross-coupling reaction between $IC_6H_4CF_3$-4 and PhC≡CSnBu$_3$ catalysed by the complexes **1a** and **2a**,[12,13]

Scheme 3. Structures of the (iminophosphane)palladium complexes [bornyl = *endo*-(1*R*)-1,7,7-trimethylbicyclo[2.2.1]hept-2-yl]

we have chosen to break the problem down into separate studies, i.e. the oxidative addition and the transmetallation/reductive elimination reactions. Preliminary studies on the relative stability of the palladium(0) olefin complexes **1a** and **1b**, and on the solution behaviour of the palladium(0) and the palladium(II) complexes of Scheme 3 have been also carried out.

Relative Stability of Palladium(0) Olefin Complexes from Olefin Exchange Equilibria

Previous results on the oxidative addition of $IC_6H_4CF_3$-4 to [Pd(η^2-ol)(P−N)] (ol = dmfu, fn) involved in the catalytic cycle of the cross-coupling reaction[12,13] have shown that only the dmfu complexes display appreciable reactivity. Thus, we have tried to attribute this feature to a lower thermodynamic stability of such species with respect to their fn analogues by studying the equilibrium 1 of olefin exchange in THF and $CHCl_3$ by UV/Vis spectrophotometry [Equation (1)].

$$\underset{\mathbf{1a}}{[Pd(\eta^2\text{-dmfu})(P\text{—}N)]} + fn \underset{}{\overset{K_E}{\rightleftharpoons}} \underset{\mathbf{1b}}{[Pd(\eta^2\text{-fn})(P\text{—}N)]} + dmfu \quad (1)$$

The resultant K_E values of 8520±300 in $CHCl_3$ and 640±20 in THF indicate that the position of equilibrium is strongly shifted to the right. The much greater stability of complex **1b** is largely due to the greater π-accepting properties of fumaronitrile which increase the strength of the palladium-olefin bond as already observed for the olefin exchange equilibria in similar zero-valent complexes [Pd(η^2-ol)(L−L′)] {L−L′ = 2-(iminomethyl)pyridine[16] or 2-(methylthio)pyridine[17]}. A reduced electron density on the metal in **1b** will render the complex less susceptible to oxidative addition by the organic halide, thereby explaining its lack of reactivity.

The equilibrium constant in $CHCl_3$ is one-order of magnitude higher than in THF. We have confirmed the observed solvent effect by comparing the corresponding K_E values for the 2-(iminomethyl)pyridine complex [Pd(η^2-dmfu)(C_5H_4N-2-CH=NC_6H_4OMe-4)]. In THF, a value of 731±32 was obtained whereas in $CHCl_3$ a value of 4000±400 was previously determined.[16] We surmise that such an effect predominantly stems from a different stabilisation, by solvation, of the olefins in the two solvents examined even though they have comparable dielectric constants.

Solution Behaviour of the Palladium(0) and Palladium(II) Complexes

It is known that palladium(0) olefin complexes with *P,N*-chelating ligands undergo various dynamic processes in solution such as olefin rotation around its bond axis to the central metal, olefin dissociation, Pd−N bond rupture and exchange between the free and coordinated olefin.[11,18] The dissociative processes lead to unsaturated (or solvent-coordinated) species which may be of importance in the mechanism of the oxidative addition.[19] For instance, olefin dissociation leads to a species of the type Pd(P−N), which can be generated in situ also from the reaction of a mixture of [PdCl(η^3-C_3H_5)]$_2$/L−L′ (1:2 molar ratio) {L−L′ = 2-(PPh_2)C_6H_4−1-CH=NC_2H_4Ph} with $NaCH(CO_2Me)_2$.[10] Such a species undergoes oxidative addition with PhC≡C$SnBu_3$ or $IC_6H_4CF_3$-4 to give the products [Pd(C≡CPh)($SnBu_3$)(P−N)] or [PdI($SnBu_3$)(P−N)]. We have therefore examined the ^{1}H NMR spectra of the complexes **1a** and **2a** at 25 °C in $CDCl_3$ and [D_8]toluene and at variable-temperatures in [D_8]toluene (Table 1).

As can be seen, the signals of the imino proton appear at lower frequencies (δ = 0.6−0.7 ppm) in the aromatic solvent whereas those of the olefin protons appear at higher frequencies (δ = 0.4−0.7 ppm) relative to the corresponding signals in $CDCl_3$. The proton resonances of **1a** are fairly sharp in CD_3Cl but broader in [D_8]toluene indicating the occurrence of dynamic processes at increasing rates in the latter solvent. At higher temperatures in [D_8]toluene, the olefin H_{cis} and H_{trans} resonances (Δν = 260 Hz) coalesce at 56 °C, from which a $\Delta G^{\neq}$ value of 63.4 kJ·mol^{-1} can be evaluated.[20] The olefin methyl signals also coalesce at ca. 35 °C but in this case, however, a more precise measurement of the coalescence temperature was prevented by overlapping with the iminophosphane OCH_3 singlet (at δ = 3.31 ppm in the spectrum at 25 °C). The ^{1}H NMR spectra of **2a** at 25 °C are characterised by sharp olefin signals in the solvents examined. Upon heating the [D_8]toluene solution, the H_{cis} and H_{trans} signals (Δν = 129 Hz) coalesce at 75 °C ($\Delta G^{\neq}$ = 69.3 kJ·mol^{-1}). At approximately the same temperature the olefin methyl resonances are also in coalescence but overlap largely with the $CHMe_2$ septet (at δ = 3.22 ppm in the spectrum at 25 °C) of the iminophosphane. It is interesting to point out that the isopropyl Me groups remain diastereotopic at the various temperatures exam-

ined. Even at 75 °C, they are detected as two sharp doublets at δ = 1.27 and 1.24 ppm, respectively.

The fluxional behaviour of complexes **1a** and **2a** may be explained either by olefin rotation, by olefin dissociation-association or by P−N ligand site exchange through initial rupture of the Pd−N bond. In order to ascertain which is the actual process operating in solution, we have examined the variable-temperature ^{1}H NMR spectra of the complexes **3a** and **4a** which contain *N*-aryl substituents with increasing steric requirements, as well as those of complex **5b** which contains a chiral iminophosphane ligand. We have also compared the olefin ^{13}C NMR signals of **1a** and **2a** with those of **3a** and **4a** (Table 2).

The ^{1}H NMR spectrum of **5b** at 25 °C shows the presence of two diastereoisomers in a molar ratio of 6.0:1. The olefin H_{cis} and H_{trans} signals of the major diastereoisomer (Δν = 138 Hz) coalesce at 73 °C ($\Delta G^{\neq}$ = 68.7 kJ·mol^{-1}). At this temperature, the other resonances of the two diastereoisomers are distinct and sharp, although the molar ratio between the major and minor isomer decreases to 3.6:1. These findings indicate that the observed dynamic process does not involve olefin dissociation-association (which would cause interconversion of the diastereoisomers and eventually coalescence of their signals). However, the olefin dissociation-association process does occur at a lower rate (on the NMR time-scale) as indicated by the change in the isomer molar ratio when the temperature is increased.

The ^{1}H NMR spectra of **3a** and **4a** at 25 °C are characterised by the non-equivalence of the 2,6 groups on the *N*-aryl moieties: for **3a**, two singlets can be detected for the protons of the 2,6-Me groups (the singlet at δ = 2.14 ppm partially overlapping with the solvent signals) whereas for **4a**, four doublets can be detected for the Me protons and two septets (at δ = 3.38 and 2.83 ppm, respectively) for the CH protons of the 2,6-$CHMe_2$ groups. This is clearly a consequence of the asymmetric nature of the complexes and

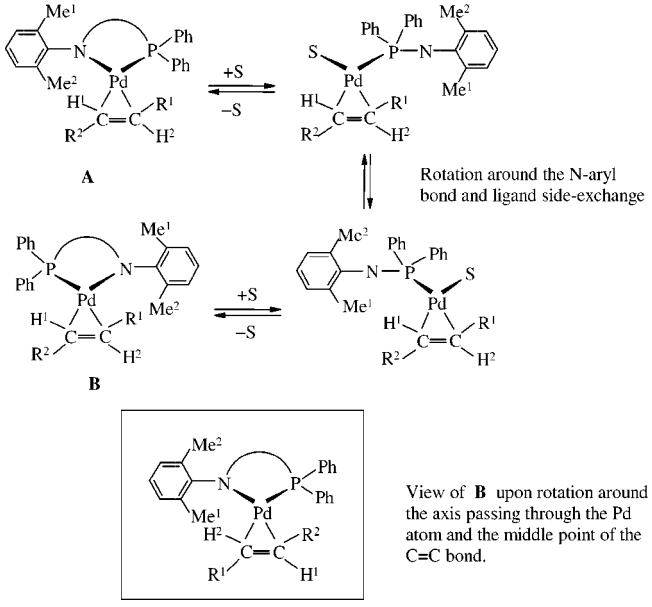
of the restricted rotation around the N−aryl bond. When the [D_8]toluene solution of **4a** is warmed up, all the olefin and the $CHMe_2$ signals progressively broaden but at 95 °C (the highest temperature explored) only the coalescence of the olefin methyl signals ($\Delta\nu$ = 70 Hz) can be observed ($\Delta G^{\neq}$ = 75.3 kJ·mol^{-1}). In contrast, for the solution of **3a**, the olefin methyl signals ($\Delta\nu$ = 23 Hz) coalesce at 53 °C ($\Delta G^{\neq}$ = 69.4 kJ·mol^{-1}), the methyl signals of the *N*-$C_6H_3Me_2$-2,6 substituent ($\Delta\nu$ = 91 Hz) coalesce at 72 °C ($\Delta G^{\neq}$ = 69.7 kJ·mol^{-1}) and eventually the olefin H_{cis} and H_{trans} signals ($\Delta\nu$ = 351 Hz) coalesce at 93 °C ($\Delta G^{\neq}$ = 70.0 kJ·mol^{-1}). The close values of the activation free energies indicate that the same dynamic process is operating which interconverts simultaneously the two olefin methyl groups, the two methyl groups of the *N*-$C_6H_3Me_2$-2,6 substituent and the olefin H_{cis} and H_{trans} protons. Such a process cannot be the olefin rotation because it would lead to interconversion of only the olefin protons. The dynamic behaviour of **3a**, as well as that of the other complexes examined, is better rationalised by a process involving an initial solvent-assisted rupture of the Pd−N bond, followed by rotation around the N−aryl bond in the *P*-monodentate iminophosphane and ligand site exchange, as depicted in Scheme 4.

As can be seen by comparing structure **A** and the (rotated) structure **B**, this process brings about the simultaneous interconversions $R^1 \rightleftarrows R^2$, $Me^1 \rightleftarrows Me^2$, and $H^1 \rightleftarrows H^2$.

It is worth noting that the same mechanism applied to complex **2a** leads to the observed interconversions $R^1 \rightleftarrows R^2$ and $H^1 \rightleftarrows H^2$, but not to $Me^1 \rightleftarrows Me^2$ because the Me groups of the *N*-$CHMe_2$ substituent cannot interconvert by a simple rotation around the N−C bond in the *P*-monodentate iminophosphane. For such an interconversion, an inversion of configuration at the $N-C_{isopropyl}$ carbon atom would also be required.

According to this mechanism, the decreasing rate of the dynamic process in the complexes with *N*-aryl groups (**1a** > **3a** > **4a**) can be explained by the increasing steric hindrance exerted by the 2,6-substituents on the *N*-aryl group towards the incoming solvent molecule. Inspection of the ^{13}C NMR spectroscopic data in Table 2 shows that the olefin C=C carbons have comparable electron density in the complexes



Scheme 4. Proposed mechanism for the dynamic behaviour of complex **3a** (R^1 = R^2 = CO_2Me; S = solvent)

1a, **3a**, and **4a** since they resonate in the narrow range of 50.4−49.6 ppm. In other words, this means that the extent of π back-donation in the Pd−η^2-dmfu bond and the electron donor properties of the P−N ligands (in essence, their bond strengths to the central metal) are comparable in this closely related series of complexes.

The different rate of the dynamic process observed for the complexes **1a** and **2a** (**1a** > **2a**) is essentially due to electronic factors since the *N*-C_6H_4OMe-4 and *N*-$CHMe_2$ groupings of the P−N ligands have similar steric requirements. From the data in Table 2 it appears that the olefin C=C carbons of **2a** are shielded by ca. 2 ppm relative to the corresponding carbons of **1a**, indicating a certain increase of π back-donation in the Pd−η^2-dmfu bond. This is clearly related to the electron-releasing isopropyl group which increases the σ donor properties of the imino nitrogen and, therefore, the strength of the Pd−N bond in **2a**. The imino ligands have been found to act more as σ-donors than as π-acceptors to palladium.[21] Conversely, the for-

mally zero-valent complexes [Pd(η^2-ol)(N−N′)] (ol = activated olefin, N−N′ = α-diimine) and [Pd(η^2-ol)(P−N)] are better described as Pd^{II}-cyclopropane complexes on the basis of spectroscopic and crystallographic data.[11,14,21]

The ^1H spectra of **1c** (in CD_3CN) and **2c** (in [D_8]toluene) at 25 °C show that these palladium(II) complexes exist as single geometrical isomers in solution. No isomerisation or other dynamic process was observed in the variable-temperature ^1H NMR spectra of **2c** in [D_8]toluene in the range 25−90 °C.

As suggested by electrical conductivity measurements in acetonitrile, the complexes **1c** and **2c** undergo the solvolytic equilibrium 2 [Equation (2)].

$$[PdI(Ar)(P{-}N)] + CH_3CN \underset{}{\overset{K_S}{\rightleftharpoons}} [Pd(CH_3CN)(Ar)(P{-}N)]^+ + I^- \quad (2)$$

(Ar = $C_6H_4CF_3$-4)

The cationic complexes $[Pd(CH_3CN)(Ar)(P-N)]^+$ have been isolated as BF_4^- or $CF_3SO_3^-$ salts upon addition of $AgBF_4$ or $AgCF_3SO_3$ to the solution (see Exp. Sect.). The equilibrium constants K_S were determined by conductivity and checked by UV/Vis experiments at 25 °C (see Exp. Sect.). From the measured values [$K_S = (6.9\pm0.9)\times10^{-6}$ for **1c**; $K_S = (2.1\pm0.5)\times10^{-5}$ for **2c**] it appears that more than 20% and 35% of the cationic species $[Pd(CH_3CN)(Ar)\{2\text{-}(PPh_2)C_6H_4\text{-}1\text{-}CH{=}NC_6H_4OMe\text{-}4\}]^+$ and $[Pd(CH_3CN)(Ar)\{2\text{-}(PPh_2)C_6H_4\text{-}1\text{-}CH{=}NCHMe_2\}]^+$, respectively, are present in acetonitrile solution at 25 °C under kinetic conditions ([**1c**]$_0$ and [**2c**]$_0 = 1\cdot10^{-4}$ M). Conductivity measurements in other solvents ($CHCl_3$, THF, toluene, DMF) suggest that only in CH_3CN does the solvolytic equilibrium (2) take place.

Oxidative Addition Reactions

The oxidative addition of $IC_6H_4CF_3$-4 (ArI) to the complexes **1a** or **2a** proceeds according to Equation (3).

$$\underset{\textbf{1a, 2a}}{[Pd(\eta^2\text{-dmfu})(P{-}N)]} + ArI \rightarrow \underset{\textbf{1c, 2c}}{[PdI(Ar)(P{-}N)]} + dmfu \quad (3)$$

The progress of the reaction was monitored by ^1H and ^{31}P NMR spectroscopy at 25 °C in various solvents ($CDCl_3$, [D_8]THF, [D_7]DMF, and CD_3CN) using **1a** or **2a**/ArI molar ratios in the range of 1:5−1:10. The spectra at different times showed the presence of the reactants and products of Equation (3). No signal attributable to intermediates or side-products was detected. Under the same experimental conditions, no reaction was observed to occur between the fumaronitrile derivative **1b** and ArI.

For kinetic measurements, the oxidative addition to **1a** was monitored in different solvents and at different temperatures (in the range 15−45 °C) in the presence of an excess of ArI ([ArI] ≥ 10 × [**1a**]$_0$). The rate of any single reaction obeys the mono-exponential law:

$$D_t = D_\infty + (D_0 - D_\infty)\exp(-k_{obs}\,t)$$

where D_t, D_0, and D_∞ represent the absorbance of the system at time t, at time $t = 0$ and at the end of the reaction respectively, and k_{obs} is the pseudo-first-order rate constant.

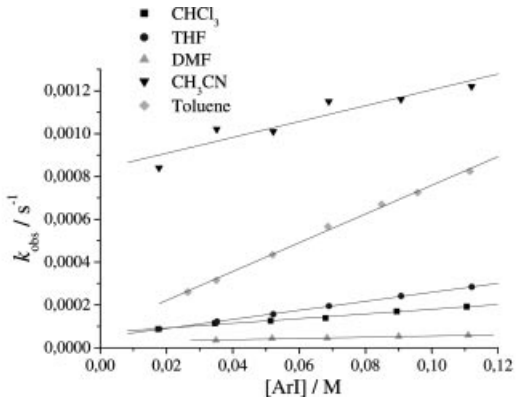

Figure 1. Plots of k_{obs} versus the aryl iodide concentration for the oxidative addition of ArI to complex **1a** in different solvents at 25 °C in the presence of dmfu ([**1a**]$_0 = 1\cdot10^{-4}$ M; [dmfu]$= 3\cdot10^{-3}$ M)

The ensuing k_{obs} values display a linear dependence on [ArI] in any solvent. As can be seen in Figure 1, a concentration independent (k_{1A}) and a concentration dependent (k_{2A}) path can always be detected so that the observed rate constants are represented by the following relationship:

$k_{obs} = k_{1A} + k_{2A}$[ArI]

The values of k_{1A} and k_{2A} in the solvents examined are reported in Table 3.

Table 3. Kinetic constants for the oxidative addition of ArI to **1a** in different solvents at 25 °C in the presence of dmfu ([**1a**]$_0 = 1\cdot10^{-4}$ M; [dmfu]$= 3\cdot10^{-3}$ M)

Solvent	k_{1A}/ s^{-1}	k_{2A}/ $M^{-1}s^{-1}$
DMF	$(2.6 \pm 0.2)\times10^{-5}$	$(2.9 \pm 0.3)\times10^{-4}$
THF	$(4.81 \pm 0.12)\times10^{-5}$	$(2.11 \pm 0.02)\times10^{-3}$
$CHCl_3$	$(7.1 \pm 0.4)\times10^{-5}$	$(1.09 \pm 0.06)\times10^{-3}$
Toluene	$(8.7 \pm 1.1)\times10^{-5}$	$(6.7 \pm 0.2)\times10^{-3}$
CH_3CN	$(8.3 \pm 0.5)\times10^{-4}$	$(3.8 \pm 0.7)\times10^{-3}$

The lowest k_{1A} and k_{2A} values were observed in DMF, while the highest k_{1A} value was observed in CH_3CN and the highest k_{2A} value in toluene. Such a reactivity clearly does not depend on the difference in dielectric constants, indicating that the transition states for both steps do not involve a substantial separation of electric charge. Furthermore, a radical mechanism can be ruled out since no diiodo derivative, which represents a typical by-product in the radical reactions, could be detected.

The kinetic constants were not appreciably influenced by different concentrations of free dmfu, as reported in Table 4.

From the kinetic data at different temperatures (Table 5), the activation parameters were determined using a re-parameterised Eyring equation.[22]

The negative activation entropies for the k_{1A} step suggest an essentially associative process. Negative $\Delta S^{\#}$ values were also obtained for the k_{2A} step, but these data should be regarded with caution (see further discussion).

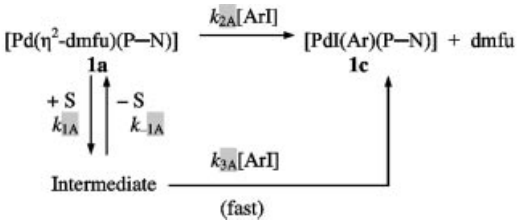
	25	$(1.57\pm0.04)\times10^{-4}$	$(5.97\pm0.05)\times10^{-3}$
	35	$(8.3\pm0.8)\times10^{-4}$	$(1.06\pm0.09)\times10^{-2}$
	45	$(1.39\pm0.03)\times10^{-3}$	$(3.87\pm0.17)\times10^{-2}$
		$\Delta H^{\neq} = 83\pm11$	$\Delta H^{\neq} = 67\pm2$
		$\Delta S^{\neq} = -38\pm4$	$\Delta S^{\neq} = -61\pm5$

On the basis of the above experimental data, the following mechanism can be proposed in which the reaction proceeds through two parallel pathways to yield the final product **1c**.



In the step k_{1A}, the interaction with the solvent produces a highly reactive intermediate which rapidly reacts with ArI to give **1c**. To a first approximation, step k_{2A} may be conceived as a bimolecular attack by the electrophile ArI on the starting complex **1a**. According to the solution behaviour of the complexes [Pd(η^2-dmfu)(P−N)] and to literature data on the mechanism of oxidative addition of iodobenzene to [Pd(η^2-dba)(L−L′)] (dba = dibenzylideneacetone; L−L′ = N, P ligand of the type aminophosphane or oxazolinophosphane),[19] the reactive intermediate may be formulated as a [Pd(solvent)(P−N)] species, resulting from the dissociation of the η^2-bound dmfu, or as a [Pd(η^2-dmfu)(solvent)(κ^1-P−N)] species, containing a P-monodentate iminophosphane and resulting from the Pd−N bond rupture (see Scheme 4). Under the steady state approach and with reasonable approximations,[23] the rate law:

$d[\mathbf{1a}]/dt = -[\mathbf{1a}](k_{1A} + k_{2A}[ArI])$

can be obtained which is identical to the experimental results irrespective of the nature of the reactive intermediate. However, a comparison of the $\Delta G^{\neq}$ value of 63.4 kJ·mol^{-1} {calculated at the coalescence temperature of 56 °C for the dynamic process of **1a** in [D_8]toluene, in which the intermediate [Pd(η^2-dmfu)(solvent)(κ^1-P−N)] is formed} and the $\Delta G^{\neq}$ value of 95.5 kJ·mol^{-1} (calculated at the same temperature from the activation parameters in Table 5 for step k_{1A} in toluene) rules out any intermediacy of [Pd(η^2-dmfu)(solvent)(κ^1-P−N)]. In the solvolytic pathway k_{1A}, a higher energy process is involved which is well represented by the solvent-assisted dissociation of the η^2-bound dmfu to form the intermediate [Pd(solvent)(P−N)] whose enhanced reactivity toward oxidative additions[10,13] is essentially due to the increased electron density on the central metal.

In order to get a better understanding of the second-order step k_{2A}, a kinetic study of the oxidative addition of ArI to the *N*-$CHMe_2$ complex **2a** was carried out in CH_3CN at 45 °C in the presence of dmfu ($[\mathbf{2a}]_0 = 1\cdot10^{-4}$ M; [dmfu] = $3\cdot10^{-3}$ M). The observed rate law is identical to that found for **1a**, with $k_{1A} = (2.71\pm0.03)\times10^{-4}$ s^{-1} and $k_{2A} = (6.3\pm0.4)\times10^{-4}$ $M^{-1}s^{-1}$. If compared with the corresponding rate constants for the reaction of **1a** under the same experimental conditions [$k_{1A} = (5.2\pm0.2)\times10^{-3}$ s^{-1} and $k_{2A} = (1.6\pm0.4)\times10^{-2}$ $M^{-1}s^{-1}$] one can see that for **2a** the k_{1A} value has decreased by one order of magnitude, while the k_{2A} value has decreased by two orders of magnitude. These changes are mainly related to electronic factors since the steric requirements of the *N*-substituents in these complexes are comparable. Thus, the decrease in k_{1A} can be explained by the presence of a stronger Pd−η^2-dmfu bond in **2a** due to the greater extent of π back-donation (see the ^{13}C NMR spectroscopic data in Table 2) which makes the olefin dissociation step more difficult. However, the marked decrease in k_{2A} is in contrast with the k_{2A} step, being a direct electrophilic attack on the palladium center of the complexes [Pd(η^2-dmfu)(P−N)]. The presence of a more electron-donating iminophosphane in **2a** increases the electron density on the central metal and, therefore, would favour such attack as reported for other palladium(0) complexes when the donor properties of the ancillary ligands are increased.[3f,24] The changes in the k_{2A} values can be rationalised if the oxidative addition of ArI in the path k_{2A} does not occur on the complexes [Pd(η^2-dmfu)(P−N)] but on the intermediates [Pd(η^2-dmfu)(solvent)(κ^1-P−N)] formed in a pre-equilibrium step (*K*).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In this case, the observed rate law becomes:

$k_{obs} = k_{1A} + k_{2A}'\cdot K[ArI]$

The measured k_{2A} term can now be represented by the product $k_{2A}'\cdot K$. Although the K constant cannot be experimentally determined due to the low, undetectable concentration of [Pd(η^2-dmfu)(solvent)(κ^1-P−N)] in the NMR solutions, its value is expected to decrease on going from **1a** to **2a** due to the presence of a stronger Pd−N bond in the latter complex. In contrast, it is reasonable to assume that the kinetic constants k_{2A}' are not particularly affected by the different electronic properties of the *N*-substituents in the intermediates with a *P*-monodentate iminophosphane.

Transmetallation and Reductive Elimination Reactions

The complexes **1c** and **2c** react with the stannane PhC≡CSnBu$_3$ in the presence of an activated olefin according to Equation (4).

$$\underset{\textbf{1c, 2c}}{[PdI(Ar)(P\!-\!N)]} + PhC{\equiv}CSnBu_3 + ol \rightarrow \underset{\substack{ol = dmfu : \textbf{1a, 2a}\\ ol = fn : \textbf{1b, 2b}}}{[Pd(\eta^2\text{-}ol)(P\!-\!N)]} + PhC{\equiv}CAr + ISnBu_3 \quad (4)$$

(Ar = $C_6H_4CF_3$-4)

As reported for palladium complexes with chelating bidentate ligands,[3d,9,10] the transmetallation of [PdI(Ar)(P−N)] by PhC≡CSnBu$_3$ leads to a labile intermediate [Pd(C≡CPh)(Ar)(P−N)] which undergoes reductive elimination of PhC≡CAr and η^2-coordination of the olefin to give the product [Pd(η^2-ol)(P−N)]. In the IR spectra (in THF) and in the ^{1}H, ^{119}Sn and ^{31}P spectra (in [D$_8$]THF) of the reaction mixtures at different times, only the starting materials and the final products were observed.[13] No side-product or intermediate of the type [Pd(C≡CPh)(Ar)(P−N)] was detected during the course of the reaction, indicating that the reductive elimination and η^2-coordination of the olefin are faster than the initial transmetallation step.

A kinetic study of reaction (4) was carried out under pseudo-first-order conditions using UV/Vis spectroscopy in different solvents and at different temperatures with an initial concentration [**1c**]$_0$ or [**2c**]$_0$ = $1\cdot10^{-4}$ M. Preliminary investigations in which the nature and the concentration of the activated olefin were changed (ol = dmfu, fn; [ol] in the range $2\cdot10^{-4}$ to $6\cdot10^{-4}$ M) led to the conclusion that the reaction rates are influenced neither by the different π-accepting properties nor by the concentration of the olefin. These findings along with the previous spectroscopic results[13] imply that i) transmetallation is the rate-determining step of the overall reaction (4) and ii) it is possible to choose the more π-accepting olefin fn that will impart a higher stability to the zero-valent products [Pd(η^2-fn)(P−N)] in order to asses unequivocally the mechanistic path without interference from side-reactions involving decomposition.

Irrespective of solvent and temperature, each reaction obeys the mono-exponential law:

$D_t = D_\infty + (D_0 - D_\infty)\cdot\exp(-k_{obs}\cdot t)$

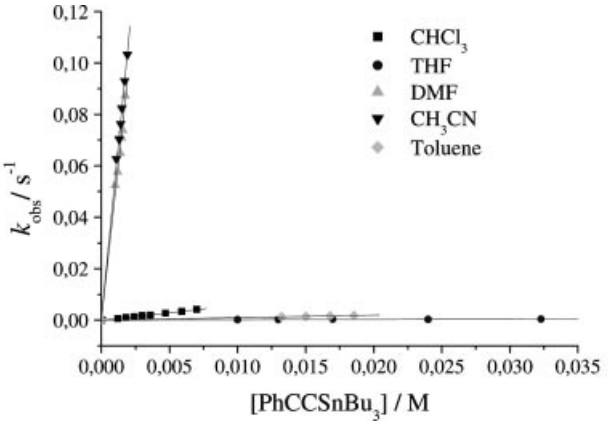


Figure 2. Plots of k_{obs} versus the stannane concentration for the transmetallation of **1c** with PhC≡CSnBu$_3$ in different solvents at 25 °C in the presence of fn ([**1c**]$_0$ = $1\cdot10^{-4}$ M; [fn]= $2\cdot10^{-4}$ M)

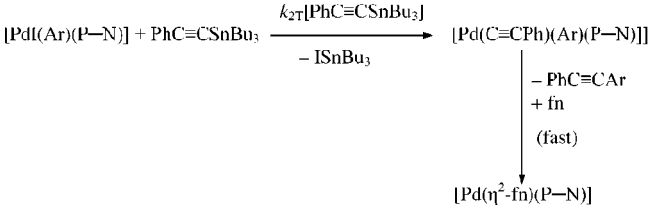
As reported in Figure 2 for the reactions of **1c**, the k_{obs} values at 25 °C depend on the stannane concentration in a linear manner so that the observed rate law can be represented by the relationship:

$k_{obs} = k_{2T}[PhC{\equiv}CSnBu_3]$

and the corresponding mechanism may be formulated as follows:



In all the solvents examined, the rate law does not display a solvolytic path, no intercept being detected in the plots in Figure 2. The measured k_{2T} values are listed in Table 6.

Table 6. Kinetic constants k_{2T} for the transmetallation of **1c** with PhC≡CSnBu$_3$ in different solvents at 25 °C in the presence of fn ([**1c**]$_0$ = $1\cdot10^{-4}$ M; [fn]= $2\cdot10^{-4}$ M)

Solvent	k_{2T}/ M^{-1}s^{-1}
THF	0.0107±0.0006
Toluene	0.10±0.01
$CHCl_3$	0.59±0.01
CH_3CN[a]	31±1
DMF	48±2

[a] In the presence of an excess of NEt_4I ([NEt_4I] = $1\cdot10^{-3}$ M).

As can be seen, a marked solvent effect is present with the highest k_{2T} values being observed in the more polar solvents CH_3CN and DMF. The kinetic measurements in CH_3CN were carried out in the presence of a large excess of NEt_4I in order to shift the position of equilibrium (2) completely to the left. In the absence of NEt_4I and with all other things being equal, the reaction in CH_3CN proceeds at a higher rate indicating that the cationic complex [Pd(Ar)(CH_3CN){2-(PPh_2)C_6H_4−1-CH=NC_6H_4OMe-4}]$^+$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is a more reactive species than the neutral complex **1c**. Unfortunately, the reactivity of $[Pd(Ar)(CH_3CN)\{2\text{-}(PPh_2)C_6H_4\text{-}1\text{-}CH{=}NC_6H_4OMe\text{-}4\}]^+$ (as $CF_3SO_3^-$ salt) could not be determined because extensive decomposition occurred in the reaction mixture in the absence of the I^- ions.

From kinetic measurements at variable temperature, the activation parameters shown in Table 7 were evaluated.

Table 7. Kinetic constants k_{2T} and activation parameters for the transmetallation of **1c** with $PhC{\equiv}CSnBu_3$ in different solvents

Solvent	T / °C	k_{2T}/ $M^{-1}s^{-1}$	$\Delta H^{\neq}$/ $kJ{\cdot}mol^{-1}$	$\Delta S^{\neq}$/ $J{\cdot}mol^{-1}K^{-1}$
$CHCl_3$[a]	15	0.334±0.006	31±3	−146±12
	25	0.59±0.01		
	35	0.80±0.02		
	45	1.00±0.03		
CH_3CN[a][b]	15	27±1	23±1	−139±9
	25	55±1		
	35	68±4		
	45	108±4		

[a] In each kinetic run: $[\mathbf{1c}]_0 = 1{\cdot}10^{-4}$ M; [fn] = $2{\cdot}10^{-4}$ M. [b] In each kinetic run: $[NEt_4I] = 1{\cdot}10^{-3}$ M.

The markedly negative $\Delta S^{\neq}$ values clearly point to an associative S_E2 mechanism for the transmetallation step in both solvents. Because complex **1c** has an iodide ligand of good bridging ability, a cyclic four-center transition state may be operative in solvents of low polarity (toluene, THF, $CHCl_3$).[5] However, the strong acceleration observed in highly polar solvents (CH_3CN, DMF) is very much in favour of an open transition state with substantial charge separation.[5]

In the case of complex **2c**, the kinetic study of reaction (4) was carried out at 25 °C in $CHCl_3$ and CH_3CN under the same experimental conditions as for **1c**. In CH_3CN, an excess of NEt_4I was added ($[NEt_4I] = 1{\cdot}10^{-3}$ M). The observed kinetic law is identical to that found for **1c**, with $k_{2T} = 0.32{\pm}0.01$ $M^{-1}s^{-1}$ in $CHCl_3$ and $k_{2T} = 27{\pm}4$ $M^{-1}s^{-1}$ in CH_3CN. When compared with the corresponding values of **1c** in Table 6, one can see that the transmetallation step proceeds at comparable rates for both complexes. Presumably, the lower electrophilic character of the palladium center in **2c**, due to the greater electron-donating properties of the *N*-$CHMe_2$ substituent, is compensated for by the increased lability of the iodide ligand as can be inferred from the difference in the K_S constants of the equilibrium 2 for these complexes.

Conclusion

From the solution behaviour of the complexes $[Pd(\eta^2\text{-dmfu})(P{-}N)]$ and kinetic data for the oxidative addition of ArI (Ar = $C_6H_4CF_3$-4), a mechanism can be proposed consisting of (i) a solvolytic path the rate of which is zero-order with respect to ArI and involves the reactive species [Pd(solvent)(P−N)] formed in the olefin dissociation and (ii) a parallel path the rate of which is first-order with respect to ArI and involves the species $[Pd(\eta^2\text{-dmfu})(solvent)(\kappa_1\text{-}P{-}N)]$ formed in a pre-equilibrium dissociation of the Pd−N bond.

The reaction of [PdI(Ar)(P−N)] with $PhC{\equiv}CSnBu_3$ in the presence of activated olefins yields the complexes $[Pd(\eta^2\text{-ol})(P{-}N)]$. For this reaction, the rate-determining transmetallation step obeys a rate law which is first-order with respect to the stannane. The kinetic data suggest an associative S_E2 mechanism via an open transition state with substantial charge separation in highly polar solvents such as CH_3CN and DMF (path b of Scheme 1).

From the present study it clearly emerges that the oxidative addition represents the rate-determining step in the cross-coupling of $PhC{\equiv}CSnBu_3$ with ArI catalysed by $[Pd(\eta^2\text{-dmfu})(P{-}N)]$. The nature of the solvent is of great importance for increasing the overall rate of the catalysed reaction. In this respect, CH_3CN (a solvent with good coordinating properties and a high dielectric constant) proves to be the best suited medium since it enhances the rates of both the oxidative addition and transmetallation steps involved in the Stille process. Moreover, in the case of transmetallation in CH_3CN, the absence of added iodide allows the formation of a significant amount of the cationic species $[Pd(CH_3CN)(Ar)(P{-}N)]^+$ which increases the apparent rate of the reaction without leading to secondary decomposition products.

Experimental Section

^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra were recorded on a Bruker AM400 spectrometer operating at 400.13, 100.61, and 161.98 MHz, respectively, using solutions of the palladium complexes with concentrations in the range of $1{\cdot}10^{-2}$ to $2{\cdot}10^{-2}$ M. Chemical shifts are reported in ppm relative to TMS (^1H, ^{13}C) or external 85% H_3PO_4 (^{31}P). For the ^1H NMR spectra at variable temperature, the probe temperature was controlled by a standard unit calibrated with a methanol reference. Coalescence temperatures were determined to within an accuracy of 3 K. The estimated error in the calculated $\Delta G^{\neq}$ values is 0.6−0.8 $kJ{\cdot}mol^{-1}$. IR spectra were carried out using a Perkin−Elmer 983 spectrophotometer. UV/Vis spectra at variable temperature were recorded on a Peltier equipped Perkin−Elmer lambda 40 spectrophotometer. Conductivities were measured with CDM83 and Metrohm 660 conductimeters at 25 °C. All solvents were purified and dried before use according to standard methods.[25] The reactions were carried out under N_2 unless otherwise stated. The compounds $PhC{\equiv}CSnBu_3$, dimethyl fumarate, fumaronitrile, $AgBF_4$, and $AgCF_3SO_3$ were commercial samples and were used without further purification. The aryl iodide $IC_6H_4CF_3$-4 was distilled at reduced pressure before use. The iminophosphane $2\text{-}(PPh_2)C_6H_4\text{-}1\text{-}CH{=}NR$ [R = $CHMe_2$, C_6H_4OMe-4, $C_6H_3Me_2$-2,6, $C_6H_3(CHMe_2)_2$-2,6, bornyl] and the complexes $[Pd(\eta^2\text{-dmfu})(P{-}N)]$ (**1a**, **2a**), $[Pd(\eta^2\text{-fn})(P{-}N)]$ (**1b**, **2b**, **5b**), $[PdI(C_6H_4CF_3\text{-}4)(P{-}N)]$ (**1c**, **2c**) were prepared by published methods.[11,13,26] The complex $Pd_2(dba)_3{\cdot}CHCl_3$ was synthesised as described in the literature.[27]

Preparations

$[Pd(\eta^2\text{-dmfu})(P{-}N)]$ (3a, 4a): The required iminophosphane (1.0 mmol) and dmfu (173 mg, 1.2 mmol) were added to a stirred

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

suspension of $Pd_2(dba)_3{\cdot}CHCl_3$ (1.035 g, 1 mmol) in dry acetone (30 mL). Stirring was continued for 2 h and the solution was then evaporated to dryness at reduced pressure. The solid residue was extracted with CH_2Cl_2 (20 mL) in the presence of activated charcoal. After filtration through celite, the clear red-brown solution was concentrated to a small volume (ca. 3 mL) and diluted with Et_2O to precipitate the products as yellow-orange solids. The complexes were purified by further precipitation from a toluene/*n*-hexane mixture.

3a: Yield 83% (535 mg). $C_{33}H_{32}NO_4PPd$ (644.0): calcd. C 61.54, H 5.01, N 2.17; found C 61.56, H 5.10, N 2.12%. IR (Nujol): $\tilde{\nu}$ = 1670 vs (C=O), 1615 ms (C=N) cm^{-1}. ^1H NMR ($CDCl_3$, 25 °C): δ = 8.06 (d, $J_{P,H}$ = 3.2 Hz, 1 H, N=CH), 7.6−6.9 (m, 17 H, C_6H_3 + C_6H_4 + C_6H_5), 4.24 (dd, $J_{H,H}$ = 10.0, $J_{P,H}$ = 2.4 Hz, 1 H, =CH *cis* to P), 3.77 (dd, $J_{H,H}$ = $J_{P,H}$ = 10.2 Hz, 1 H, =CH *trans* to P), 3.18 (s, 6 H, OCH_3), 2.16 (s, 3 H, CH_3), 1.90 (s, 3 H, CH_3) ppm. ^{31}P NMR ($CDCl_3$, 25 °C): δ = 19.69 (s) ppm.

4a: Yield 80% (560 mg). $C_{37}H_{40}NO_4PPd$ (700.1): calcd. C 63.47, H 5.76, N 2.00; found C 63.20, H 5.85, N 1.95%. IR (Nujol): $\tilde{\nu}$ = 1685 vs (C=O), 1622 ms (C=N) cm^{-1}. ^1H NMR ($CDCl_3$, 25 °C): δ = 8.06 (d, $J_{P,H}$ = 2.1 Hz, 1 H, N=CH), 7.6−6.9 (m, 17 H, C_6H_3 + C_6H_4 + C_6H_5), 4.25 (dd, $J_{H,H}$ = 10.4, $J_{P,H}$ = 2.5 Hz, 1 H, =CH *cis* to P), 3.49 (dd, $J_{H,H}$ = $J_{P,H}$ = 10.4 Hz, 1 H, =CH *trans* to P), 3.37 (spt, $J_{H,H}$ = 6.8 Hz, 1 H, $CHMe_2$), 3.24 (s, 3 H, OCH_3), 2.93 (s, 3 H, OCH_3), 2.64 (spt, $J_{H,H}$ = 6.8 Hz, 1 H, $CHMe_2$), 1.45 (d, $J_{H,H}$ = 6.8 Hz, 3 H, CH_3), 1.09 (d, $J_{H,H}$ = 6.8 Hz, 3 H, CH_3), 0.98 (d, $J_{H,H}$ = 6.8 Hz, 3 H, CH_3), 0.56 (d, $J_{H,H}$ = 6.8 Hz, 3 H, CH_3) ppm. ^{31}P NMR ($CDCl_3$, 25 °C): δ = 22.36 (s) ppm.

[Pd(CH_3CN)($C_6H_4CF_3$-4)[2-(PPh_2)C_6H_4−1-CH=NC_6H_4OMe-4)]CF_3SO_3: $AgCF_3SO_3$ (31 mg, 0.12 mmol) dissolved in CH_3CN (1 mL) was added to a solution of **1c** (93 mg, 0.12 mmol) in a CH_2Cl_2/CH_3CN mixture (7:1 v/v, 8 mL). After standing for 2 h in the dark, the insoluble AgI was removed by filtration and the resultant solution was evaporated to dryness at reduced pressure. The solid residue was redissolved in CH_2Cl_2 (10 mL). Addition of activated charcoal and filtration gave a clear solution which was concentrated to small volume (ca. 2 mL), then diluted with Et_2O to precipitate the product as a yellow microcrystalline solid. Yield 69% (69 mg). Λ_M ($1{\cdot}10^{-3}$ M, CH_3CN) = 134.4 $ohm^{-1}cm^2mol^{-1}$. $C_{36}H_{29}F_6N_2O_4PPdS$ (837.0): calcd. C 51.65, H 3.49, N 3.35; found C 51.81, H 3.55, N 3.45%. IR ($CHCl_3$): $\tilde{\nu}$ = 2289 ms (C≡N), 1636 m (C=N) cm^{-1}. ^1H NMR ($CDCl_3$, 25 °C): δ = 8.33 (s, 1 H, N=CH), 7.9−7.7 (m, 2 H, *o*-disubstituted C_6H_4), 7.59 (m, 1 H, *o*-disubstituted C_6H_4), 7.5−7.2 (m, 15 H, *o*-disubstituted C_6H_4 + *p*-disubstituted C_6H_4 + C_6H_5), 7.0−6.9 (m, 4 H, *meta* protons of *p*-disubstituted C_6H_4), 3.84 (s, 3 H, OCH_3), 2.30 (s, 3 H, CH_3CN) ppm. ^{31}P NMR ($CDCl_3$, 25 °C): δ = 34.74 (s) ppm.

[Pd(CH_3CN)($C_6H_4CF_3$-4)[2-(PPh_2)C_6H_4−1-CH=NCHMe_2)]BF_4: $AgBF_4$ (49 mg, 0.25 mmol) was added to a solution of **2c** (177 mg, 0.25 mmol) in CH_3CN (10 mL). The mixture was worked up as described above for the preparation of the analogous cationic complex to give the product as a yellow microcrystalline solid. Yield 73% (130 mg). Λ_M ($1{\cdot}10^{-3}$ M, CH_3CN) = 147.0 $ohm^{-1}cm^2mol^{-1}$. $C_{31}H_{29}BF_7N_2PPd$ (710.7): calcd. C 52.38, H 4.11, N 3.94; found C 52.15, H 4.02, N 3.86%. IR ($CHCl_3$): $\tilde{\nu}$ = 2316 mw, 2289 mw (C≡N), 1634 ms (C=N) cm^{-1}. ^1H NMR ($CDCl_3$, 25 °C): δ = 8.36 (s, 1 H, N=CH), 7.90 (m, 1 H, *o*-disubstituted C_6H_4), 7.78 (m, 1 H, *o*-disubstituted C_6H_4), 7.56 (m, 1 H, *o*-disubstituted C_6H_4), 7.5−7.2 (m, 13 H, *o*-disubstituted C_6H_4 + *p*-disubstituted C_6H_4 + C_6H_5), 6.95 (m, 2 H, *meta* protons of $C_6H_4CF_3$-4), 4.52 (spt, $J_{H,H}$ = 6.4 Hz, 1 H, $CHMe_2$), 2.30 (s, 3 H, CH_3CN), 1.37 (d, $J_{H,H}$ = 6.4 Hz, 6 H, CH_3) ppm. ^{31}P NMR ($CDCl_3$, 25 °C): δ = 32.70 (s) ppm.

Determination of the Equilibrium Constant K_E: To a thermostatically controlled (25 °C) solution of the complex under study (50 mL, ca. $1{\cdot}10^{-4}$ M) in the appropriate solvent were added successive micro-aliquots of the designated olefin and the absorbance changes were recorded in the range of 500−280 nm at 25 °C. The resultant array of absorbance data vs. the total concentration of added olefin was treated according to a published mathematical/statistical model.[16,17]

Determination of the Equilibrium Constant K_S: Several solutions of the complexes **1c** and **2c** at different concentrations (concentration intervals: $2.3{\cdot}10^{-5}$ to $2.4{\cdot}10^{-3}$ M, **1c**; $2.5{\cdot}10^{-5}$ to $2.6{\cdot}10^{-3}$ M, **2c**) in freshly distilled CH_3CN were prepared and thermostatically controlled at 25 °C. The specific conductivities were determined for each solution and the related molar conductivities were treated according to the method of Fuoss and Shedlovsky.[28]

A UV/Vis spectroscopic check was carried out as follows: the molar extinction coefficients (ε_k) of the starting complex (**1c** or **2c**) were determined from their solutions in the presence of a strong excess of NEt_4I, and those (ε_s) of the cationic species $[Pd(CH_3CN)(Ar)(P-N)]^+$ were determined from the solutions of their $CF_3SO_3^-$ or BF_4^- salts synthesised independently. The consistency of the conductivity determined K_S values and the reliability of the results was thus checked by a single spectrophotometric experiment by measuring the absorbance of a $1{\cdot}10^{-4}$ M solution of **1c** (or, **2c**) in CH_3CN. The ensuing absorbance values confirm, in both cases, the independently determined K_S constants.

Kinetic Measurements: The kinetics of the oxidative addition and transmetallation reactions were followed by UV/Vis spectroscopy upon addition of known micro-aliquots of a pre-thermostatically controlled solution of the appropriate reagent (ArI, or PhC≡CSnBu_3 and olefin) to a thermostatically controlled solution in the appropriate solvent of the complex under study {[Pd(η^2-dmfu)(P−N)] or [PdI(Ar)(P−N)} at the suitable temperature. The concentration of the reactant ensured in any case pseudo-first-order conditions and the reactions were followed by recording spectral changes in the suitable wavelength range or at a fixed wavelength. Mathematical and statistical data analysis was carried out on a PC equipped with a locally adapted non-linear regression procedure.

[20] The activation free energies have been estimated from the coalescence temperature (T_c) using the equation $\Delta G^{\neq} = -RT_c\ln[\pi h\Delta\nu/(2^{1/2}kT_c)]$. The palladium(0) species are fairly stable towards decomposition when the temperature is increased. A slight decomposition with formation of free dmfu is observed at the higher temperatures. The coalescence temperatures are, however, scarcely affected because the exchange between free and coordinated olefin is slow. Addition of free dmfu to the solution of **1a** at 56 °C actually caused only a slight broadening of the methyl signals of the free and coordinated olefin.

[23] The steady-state approach leads to the equation: $k_{obs} = k_{1A} + k_{2A}[ArI] - k_{1A}k_{-1A}/(k_{-1A} + k_{3A}[ArI])$ for [Pd(η^2-dmfu)(solvent)(κ^1-P−N)] as intermediate, or to the equation: $k_{obs} = k_{1A} + k_{2A}[ArI] - k_{1A}k_{-1A}[dmfu]/(k_{-1A}[dmfu] + k_{3A}[ArI])$ for [Pd(solvent)(P−N)] as intermediate. These equations become the observed rate law: $k_{obs} = k_{1A} + k_{2A}[ArI]$ when the reasonable approximations $(k_{-1A} + k_{3A}[ArI]) >> k_{1A}k_{-1A}$ or $(k_{-1A}[dmfu] + k_{3A}[ArI]) >> k_{1A}k_{-1A}[dmfu]$ are operative. On the other hand, the pre-equilibrium (K_1) condition:

$$[\text{Pd}(\eta^2\text{-dmfu})(\text{P—N})] \underset{-\text{S}}{\overset{+\text{S}}{\rightleftharpoons}} \text{Intermediate}$$
1a

was never taken into account since for both intermediates it leads to rate laws which do not correspond to the experimental one. As an example, for [Pd(η^2-dmfu)(solvent)(κ^1-P−N)] as the intermediate the rate law should become: $k_{obs} = (k_{2A}+k_{3A}K_1)[ArI]/(1+K_1)$.

Synthesis, Structures and Reactions of Novel 9,10-Dihydro-9,10-distannaanthracenes

Masaichi Saito,*[a] Natsumi Henzan,[a] Minehiko Nitta,[a] and Michikazu Yoshioka[a]

Keywords: Halogenation / Synthesis design / Tin

A method for the synthesis of 9,10-dihydro-9,10-distannaanthracenes has been improved and applied to the synthesis of novel unsymmetrical 9,10-dihydro-9,10-distannaanthracenes. The first 9,9,10,10-tetrahalo-9,10-dihydro-9,10-distannaanthracenes were successfully synthesized by halogenation of 9,9,10,10-tetrakis(*p*-methoxyphenyl)-9,10-dihydro-9,10-distannaanthracene. The structures of the newly obtained 9,10-dihydro-9,10-distannaanthracenes were determined by X-ray analysis.

Introduction

Since the first synthesis of 9,9,10,10-tetraphenyl-9,10-dihydro-9,10-disilaanthracene,[1] studies of the synthesis, structures, and reactions of 9,10-dihydro-9,10-disilaanthracene have been developed.[2] The corresponding germanium analogs, 9,10-dihydro-9,10-digermaanthracenes, have also been synthesized and characterized.[3] One of the interesting features of 9,10-dihydro-9,10-dimetallaanthracenes is the conformations of their central six-membered rings which are dependent on substituents on the metal.[4−7] Although a few 9,10-dihydroanthracenes having a tin atom at the 10-position have been reported,[4,8] only one report on the 9,10-dihydro-9,10-distannaanthracene has appeared, but without synthetic or structural details.[9] During the course of our studies on tin-containing compounds with unique structures, we have already reported the first syntheses and structures of 9,9,10,10-tetramethyl- and 9,9,10,10-tetra-*tert*-butyl-9,10-dihydro-9,10-distannaanthracenes.[7,10] The tetramethyl derivative has a butterfly conformation, while the tetra-*tert*-butyl derivative has a planar structure. The dependence of conformation on substituents prompted us to investigate some other 9,10-dihydro-9,10-distannaanthracenes having aryl groups and those with unsymmetrical structures. The utility of 9,10-dihydro-9,10-dimetallaanthracene derivatives as potential precursors for metal-containing reactive species is also of interest. Recently, fascinating silicon-containing reactive species such as a bis(silyl anion)[11] and a relatively stable silyl radical[6] have been reported to be derived from 9,10-dihydro-9,10-disilaanthracenes. 9,9,10,10-Tetrahalogenated 9,10-dihydro-9,10-distannaanthracenes are expected to be good precursors for reactive tin-containing species having a 9,10-distannaanthracene skeleton. However, no report on such halogenated derivatives has appeared.

We report herein an improved method for the synthesis of aryl-substituted and unsymmetrical substituted 9,10-dihydro-9,10-distannaanthracenes. Halogenation of 9,9,10,10-tetrakis(*p*-methoxyphenyl)-9,10-dihydro-9,10-distannaanthracene to give the first 9,9,10,10-tetrahalo-9,10-dihydro-9,10-distannaanthracenes is also reported. The structures of the newly obtained 9,10-dihydro-9,10-distannaanthracenes are discussed.

Results and Discussion

Improved Method for the Synthesis of 9,10-Dihydro-9,10-distannaanthracenes

A previous publication reported the synthesis of 9,9,10,10-tetramethyl-9,10-dihydro-9,10-distannaanthracene (**1**) from the reaction of bis(*o*-bromophenyl)dimethylstannane (**2**) and dichlorodimethylstannane with magnesium in the presence of a catalytic amount of copper(I) cyanide in 25% yield.[7] By using *tert*-butyllithium for the lithiation of **2** in THF at −78 °C, the yield of **1** was increased to 51% (Scheme 1).

Introduction of *p*-methoxyphenyl groups on the tin was examined using *tert*-butyllithium. Bis(*o*-bromophenyl)bis(*p*-methoxylphenyl)stannane (**3**) was synthesized by the reaction of (2-bromophenyl)lithium with bis(*p*-methoxyphenyl)-dichlorostannane[12] in 48% yield. Lithiation of **3** using *tert*-butyllithium and subsequent reaction with bis(*p*-methoxyphenyl)dichlorostannane gave the 9,9,10,10-tetrakis(*p*-methoxyphenyl)-substituted compound **4** in 46% yield (Scheme 1).

Synthesis of Unsymmetrically-Substituted 9,10-Dihydro-9,10-distannaanthracenes

This improved method can be applied to the synthesis of unsymmetrically-substituted 9,10-dihydro-9,10-distannaanthracenes. Thus, lithiation of **2** and **3** with *tert*-butyllithium in THF at −78 °C and subsequent treatment with di-*tert*-butyldichlorostannane and dichlorodimethylstannane gave the 9,9-di-*tert*-butyl-10,10-dimethyl-substituted and 9,9-bis(*p*-methoxyphenyl)-10,10-dimethyl-substituted compounds **5** and **6** in yields of 19 and 14%, respectively (Scheme 1). The structures of **5** and **6** were determined using ^{1}H and ^{13}C NMR spectroscopy and elemental analysis.

Halogenation of 9,10-Dihydro-9,10-distannaanthracenes

In order to prepare further functionalized 9,10-dihydro-9,10-distannaanthracenes, the halogenations of the tetra-*tert*-butyl-substituted 9,10-dihydro-9,10-distannaanthracene **7**[7] and the 9,9,10,10-tetrakis(*p*-methoxyphenyl)-substituted 9,10-dihydro-9,10-distannaanthracene **4** were investigated. Reaction of **7** with bromine (1 equiv.) gave the dibromide **8** (77%) through the cleavage of a tin−phenyl bond because the ease of cleavage of the Sn−C bond is in the order of Sn−aromatic > −vinyl > −alkyl (Scheme 2).[13] Conversely, chlorination of **4** using acetyl chloride and aluminum chloride[14] gave 9,9,10,10-tetrachloro-9,10-dihydro-9,10-distannaanthracene (**9**), reflecting the ease of cleavage of an Sn−*p*-methoxyphenyl bond (Scheme 3). The *p*-methoxyphenyl group on tin is easily substituted by a halogen.[14] Reaction of **4** with iodine gave the tetraiodide **10** (Scheme 3). These haloganated 9,10-dihydro-9,10-distannaanthracenes, the first examples of a 9,9,10,10-tetrahalo-9,10-dihydro-9,10-distannaanthracene, are expected to be good precursors for reactive tin-containing species such as 9,10-distannaanthracene.

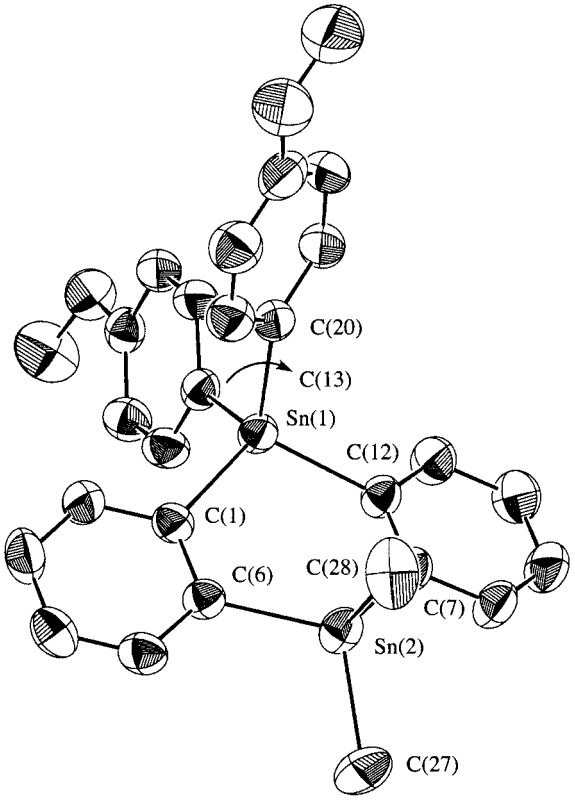

Figure 2. ORTEP drawing of **6** with thermal ellipsoids plots (40% probability for non-hydrogen atoms); selected bond lengths [Å] and angles (deg): Sn(1)−C(13) 2.137(3), Sn(1)−C(20) 2.146(4), Sn(2)−C(27) 2.145(5), Sn(2)−C(28) 2.128(5); C(1)−Sn(1)−C(12) 110.18(13), C(6)−Sn(2)−C(7) 108.63(13), C(13)−Sn(1)−C(20) 108.19(13), C(7)−Sn(2)−C(27) 112.3(2)

6 adopts a boat conformation and hence the tricyclic framework has a butterfly conformation with a dihedral angle of 156° as observed in the 9,9,10,10-tetramethyl derivative (143°).[7] Although 9,9,10,10-tetraphenyl-9,10-dihydro-9,10-disilaanthracene has a planar structure,[15] the central six-membered ring of **4** has a boat conformation with a dihedral angle of 149° due to the Sn−C_6H_4OMe-*p* bonds being longer than the Si−Ph bonds in the tetraphenyl compound so that the *p*-methoxyphenyl group can be orientated in a pseudoaxial position. The tetra-iodo derivative **10** has a planar structure, as observed in the 9,9,10,10-tetra-*tert*-butyl derivative,[7] probably due to the steric bulk of the iodine atom.

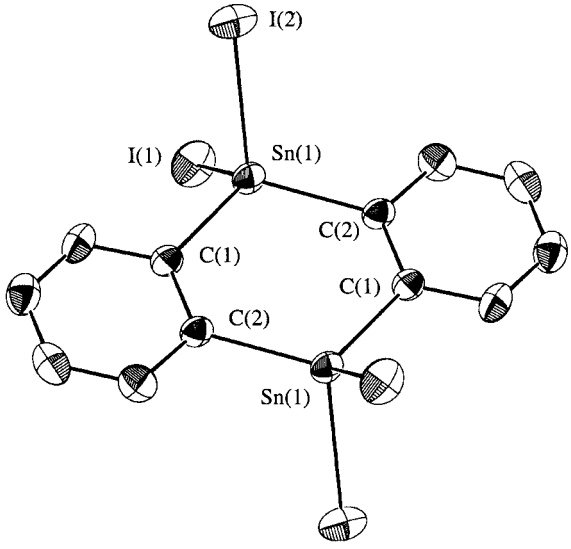

Figure 3. ORTEP drawing of **10** with thermal ellipsoids plots (40% probability for non-hydrogen atoms); selected bond lengths [Å] and angles (deg): Sn(1)−I(1) 2.6812(8), Sn(1)−I(2) 2.6795(8), Sn(1)−C(1) 2.129(7), Sn(1)−C(2) 2.124(8); C(1)−Sn(1)−C(2) 114.8(3), I(1)−Sn(1)−I(2) 104.76(3)

Conclusion

A novel method for the synthesis of 9,10-dihydro-9,10-distannanthracenes has been developed and novel 9,10-dihydro-9,10-distannanthracenes having unsymmetrical structures have been synthesized. Halogenation of 9,9,10,10-tetrakis(*p*-methoxyphenyl)-9,10-dihydro-9,10-distannaanthracene gave the first 9,9,10,10-tetrahalo-9,10-dihydro-9,10-distannaanthracenes. Although the 9,10-dihydro-9,10-distannanthracenes having *p*-methoxyphenyl groups on the tin have a butterfly conformation, the 9,9,10,10-tetraiodo derivative has a planar structure for steric reasons. Further investigations on the synthesis of reactive tin-containing species having a 9,10-distannaanthracene skeleton from 9,9,10,10-tetrahalo derivatives are currently in progress.

Experimental Section

General Procedure: All reactions were carried out under argon. THF and diethyl ether used in the syntheses were distilled from

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sodium benzophenone ketyl under an argon atmosphere before use. Magnesium (turnings) was purchased from Wako Pure Chemical Industries, Ltd. ^{1}H (400 MHz), ^{13}C NMR (101 MHz) and ^{119}Sn NMR (149 MHz) spectra were recorded on a Bruker AM-400 or an ARX-400 spectrometer in $CDCl_3$ with tetramethylsilane as an internal standard. Although ^nJ(Sn−^{13}C) couplings were observed in the ^{13}C NMR spectra as satellite signals, most of the ^nJ(^{119}Sn−^{13}C) and ^nJ(^{117}Sn−^{13}C) values could not be separately estimated because of broadening. The multiplicities of signals in the ^{13}C NMR spectra given in parentheses were deduced from DEPT spectra. Wet column chromatography (WCC) was carried out by using Merck Kieselgel 60 (SiO_2). All melting points were determined on a Mitamura Riken Kogyo MEL-TEMP apparatus and are uncorrected. Elemental analyses were carried out at the Microanalytical Laboratory of the Chemical Analysis Center, Saitama University. Data for the X-ray crystallographic analyses were collected on Mac Science Xdip or MXC18 K diffractometers with Mo-K_α radiation (λ = 0.71073 Å) and the structures were solved by direct methods.

Improved Synthesis of 9,9,10,10-Tetramethyl-9,10-dihydro-9,10-distannaanthracene (1): To a THF (10 mL) solution of bis(*o*-bromophenyl)dimethylstannnane[7] (**2**) (232 mg, 0.50 mmol) was added *t*BuLi (1.60 M in pentane; 1.25 mL, 2.00 mmol) at −78 °C and the resultant solution was stirred at this temperature for 1 h. After addition of a THF (5 mL) solution of dichlorodimethylstannane (110 mg, 0.50 mmol) at the same temperature, the reaction mixture was allowed to warm to room temperature. The resultant mixture was extracted with diethyl ether and the organic layer was washed with aqueous NH_4Cl. After removal of volatile components, the residue was subjected to WCC (SiO_2, hexane/ethyl acetate, 20:1) to afford 9,9,10,10-tetramethyl-9,10-dihydro-9,10-distannaanthracene[7] (**1**) (116 mg, 51%).

Preparation of Bis(*o*-bromophenyl)bis(*p*-methoxylphenyl)stannane (3): To a solution of butyllithium (1.56 M in hexane; 6.24 mL, 4.00 mmol) in a mixture of THF (10 mL) and diethyl ether (10 mL) was added 1,2-dibromobenzene (0.72 mL, 5.97 mmol) at −110 °C and the resultant solution was stirred at this temperature for 1.5 h. Subsequently, bis(*p*-methoxyphenyl)dichlorostannane[12] (1.304 g, 3.23 mmol) in THF (5 mL) and diethyl ether (5 mL) was added at −110 °C. The reaction mixture was allowed to warm to room temperature. The resultant mixture was extracted with diethyl ether and the organic layer was washed with aqueous NH_4Cl. After removal of volatile components, the residue was subjected to WCC (SiO_2, hexane/dichloromethane, 1:3) followed by recrystallization from dichloromethane and methanol to give bis(*o*-bromophenyl)bis(*p*-methoxylphenyl)stannane (**3**) (0.926 g, 48%). **3**: M.p. 142−145 °C (recrystallization from dichloromethane/methanol). ^{1}H NMR: δ = 3.82 (s, 6 H), 6.94−6.99 (m, 4 H), 7.25−7.27 (m, 4 H), 7.38−7.40 (m, 2 H), 7.52−7.68 (m, 6 H). ^{13}C NMR: δ = 55.0 (q), 114.4 [d, J(Sn−C) = 61 Hz), 126.9 [d, J(Sn−C) = 47 Hz), 128.4 (s), 130.9 (d), 132.1 [d, J(Sn−C) = 31 Hz), 132.5 [s, J(Sn−C) = 14 Hz], 138.6 [d, J(Sn−C) = 46 Hz], 139.3 [d, J(Sn−C) = 36 Hz), 144.5 (s), 160.4 (s). ^{119}Sn NMR: δ = −116.5 ppm. $C_{26}H_{22}Br_2O_2Sn$ (644.98): calcd. C 48.42, H 3.44; found C 48.54, H 3.35.

Preparation of 9,9,10,10-Tetrakis(*p*-methoxyphenyl)-9,10-dihydro-9,10-distannaanthracene (4): To a THF (10 mL) solution of **3** (1.006 g, 1.56 mmol) was added *t*BuLi (1.6 M in pentane; 3.0 mL, 4.8 mmol) at −78 °C and the resultant solution was stirred at this temperature for 20 min. After addition of a THF (5 mL) solution of bis(*p*-methoxyphenyl)dichlorostannane[12] (0.684 g, 1.69 mmol) at the same temperature, the reaction mixture was allowed to warm to room temperature. The resultant mixture was extracted with diethyl ether and the organic layer was washed with aqueous NH_4Cl. After removal of volatile components, the residue was subjected to WCC (SiO_2, hexane/dichloromethane, 1:4) followed by recrystallization from hexane and dichloromethane to give 9,9,10,10-tetrakis(*p*-methoxyphenyl)-9,10-dihydro-9,10-distannaanthracene (**4**) (0.584 g, 46%). **4**: M.p. 221−222 °C (recrystallization from hexane/dichloromethane). ^{1}H NMR: δ = 3.77 (s, 12 H), 6.79−6.83 (m, 8 H), 7.28−7.29 (m, 4 H), 7.34−7.36 (m, 8 H), 7.57−7.60 (m, 4 H). ^{13}C NMR: δ = 54.9 (q), 114.3 (d), 128.6 [s, ^1J(Sn−C) = 522, 546 Hz], 128.8 [d, J(Sn−C) = 49 Hz], 137.3 [d, J(Sn−C) = 45, 55 Hz], 138.4 [d, J(Sn−C) = 44 Hz], 150.8 [s, ^1J(Sn−C) = 520, 544, ^2J(Sn−C) = 52 Hz], 160.3 (s). ^{119}Sn NMR: δ = −173.6 [^3J(Sn−Sn) = 761 Hz] ppm. $C_{40}H_{36}O_4Sn_2$ (818.16): calcd. C 58.72, H 4.44; found C 58.63, H 4.29.

Preparation of 9,9-Di-*tert*-butyl-10,10-dimethyl-9,10-dihydro-9,10-distannaanthracene (5): To a THF (10 mL) solution of **2** (240 mg, 0.52 mmol) was added *t*BuLi (1.60 M in pentane; 1.30 mL, 2.08 mmol) at −78 °C and the resultant solution was stirred at this temperature for 30 min. To the reaction mixture was added a THF (5 mL) solution of di-*tert*-butyldichlorostannane (160 mg, 0.50 mmol) at the same temperature. After stirring for 2 h at −78 °C, the reaction mixture was gradually allowed to warm to room temperature. The resultant mixture was extracted with diethyl ether and the organic layer was washed with aqueous NH_4Cl. After removal of volatile components, the residue was subjected to WCC (SiO_2, hexane/ethyl acetate, 100:1) to afford 9,9-di-*tert*-butyl-10,10-dimethyl-9,10-dihydro-9,10-distannaanthracene (**5**) (52 mg, 19%). **5**: M.p. 77−79 °C (recrystallization from hexane/methanol). ^{1}H NMR: δ = 0.36 [s, 6 H, ^2J(Sn−H) = 52, 55 Hz], 1.30 [s, 18 H, ^3J(Sn−H) = 63, 65 Hz], 7.27−7.30 (m, 4 H), 7.54−7.56 (m, 4 H). ^{13}C NMR: δ = −7.7 [q, ^1J(Sn−C) = 329, 345 Hz], 29.9 [s, ^1J(Sn−C) = 365, 382 Hz], 31.5 (q), 127.6 (d), 128.1 (d), 136.3 [d, J(Sn−C) = 42, 48 Hz], 137.4 [d, J(Sn−C) = 42, 54 Hz], 152.0 [s, ^1J(Sn−C) = 362, 379, ^2J(Sn−C) = 53 Hz], 153.4 [s, ^1J(Sn−C) = 500, 523, ^2J(Sn−C) = 35 Hz]. ^{119}Sn NMR: δ = −156.3 [^3J(Sn−Sn) = 497, 546 Hz], −121.1 [^3J(Sn−Sn) = 497, 546 Hz] ppm. $C_{22}H_{32}Sn_2$ (533.94): calcd. C 49.49, H 6.04; found C 49.96, H 6.06.

Preparation of 9,9-Bis(*p*-methoxyphenyl)-10,10-dimethyl-9,10-dihydro-9,10-distannaanthracene (6): To a THF (5 mL) solution of **3** (196 mg, 0.30 mmol) was added *t*BuLi (1.60 M in pentane; 0.75 mL, 1.20 mmol) at −78 °C and the resultant solution was stirred at this temperature for 1 h. To the reaction mixture was added a THF (5 mL) solution of dichlorodimethylstannane (74 mg, 0.30 mmol) at the same temperature. After stirring for 1 h at −78 °C, the reaction mixture was gradually allowed to warm to room temperature. The resultant mixture was extracted with diethyl ether and the organic layer was washed with aqueous NH_4Cl. After removal of volatile components, the residue was subjected to WCC (SiO_2, hexane/ethyl acetate, 6:1) to afford 9,9-bis(*p*-methoxyphenyl)-10,10-dimethyl-9,10-dihydro-9,10-distannaanthracene (**6**) (27 mg, 14%). **6**: M.p. 115−118 °C (recrystallization from hexane/dichloromethane). ^{1}H NMR: δ = 0.32 [s, 6 H, ^2J(Sn−H) = 54, 56 Hz], 3.80 (s, 6 H), 6.93 (d, J = 9 Hz, 4 H), 7.24−7.28 (m, 2 H), 7.30−7.34 (m, 2 H), 7.38−7.50 (m, 4 H), 7.53−7.65 (m, 4 H). ^{13}C NMR: δ = −8.5 [q, ^1J(Sn−C) = 344 Hz], 55.0 (q), 114.5 [d, J(Sn−C) = 55 Hz], 128.3 (d), 128.6 (d), 128.9 (s), 136.1 [d, J(Sn−C) = 46, 56 Hz], 136.9 [d, J(Sn−C) = 55 Hz], 138.4 [d, J(Sn−C) = 44 Hz], 150.0 (s), 152.7 (s), 160.5 (s). ^{119}Sn NMR: δ = −171.6 [^3J(Sn−Sn) = 727, 796 Hz], −116.5 [^3J(Sn−Sn) = 727, 796 Hz] ppm. $C_{28}H_{28}O_2Sn_2$ (633.96): calcd. C 53.05, H 4.45; found C 53.32, H 4.38.

Reaction of 9,9,10,10-Tetra-*tert*-butyl-9,10-dihydro-9,10-distannaanthracene (7) with Bromine: To a carbon tetrachloride (15 mL) solution of **7** (162 mg, 0.26 mmol) was added a carbon tetrachloride (5 mL) solution of bromine (42 mg, 0.26 mmol) at room temperature. After removal of the solvent, the residue was recrystallized from dichloromethane and methanol to give [2- (bromodi-*tert*-butylstannyl)](2-bromophenyl)di-*tert*-butylstannane (**8**) (133 mg, 77%). **8**: M.p. 182−184 °C (recrystallization from dichloromethane/methanol). ^{1}H NMR: δ = 1.26 [s, 18 H, ^3J(Sn−H) = 81, 84 Hz], 1.36 [br. s, 18 H, ^3J(Sn−H) = 68 Hz], 7.04−7.17 (m, 3 H), 7.20−7.24 (m, 1 H), 7.31−7.35 (m, 1 H), 7.50−7.55 (m, 1 H), 7.73−7.75 (m, 1 H). ^{13}C NMR: δ = 30.8 (q), 31.6 (br. q), 35.9 [s, ^1J(Sn−C) = 360, 377 Hz], 125.8 [d, J(Sn−C) = 34 Hz], 126.4 [d, J(Sn−C) = 11, 62 Hz], 127.5 [d, J(Sn−C) = 15, 40 Hz], 129.0 (d), 131.7 (s), 131.8 (d), 136.8 [d, J(Sn−C) = 48, 83 Hz], 139.2 [d, J(Sn−C) = 23 Hz], 141.0 [d, J(Sn−C) = 38, 61 Hz], 151.4 [s, J(Sn−C) = 43 Hz], 151.9 (s), 153.3 [s, J(Sn−C) = 50 Hz]. ^{119}Sn NMR: δ = −78.5 (br.), 3.9 ppm. $C_{28}H_{44}Br_2Sn_2$ (777.92): calcd. C 43.23, H 5.70; found C 43.45, H 5.72.

Preparation of 9,9,10,10-Tetrachloro-9,10-dihydro-9,10-distannaanthracene (9): To a toluene (5 mL) solution of **4** (183 mg, 0.22 mmol) was added acetyl chloride (0.063 mL, 0.84 mmol) in the presence of a catalytic amount of aluminum trichloride at 0 °C. After separation of insoluble materials in dichloromethane by filtration, the residue was crystallized from chloroform and dichloromethane to afford 9,9,10,10-tetrachloro-9,10-dihydro-9,10-distannaanthracene (**9**) (24 mg, 18%). **6**: M.p. 285−288 °C (decomp.) (recrystallization from dichloromethane/chloroform). ^{1}H NMR: δ = 7.63−7.69 (m, 4 H), 7.74−7.94 (m, 4 H). ^{13}C NMR: δ = 133.1 [d, J(Sn−C) = 92 Hz, C_β], 137.1 [d, J(Sn−C) = 84, 103 Hz, C_α], 152.4 (s, C_{ipso}) ppm. $C_{12}H_8Cl_4Sn_2$ (531.4): calcd. C 27.12, H 1.52; found C 27.28, H 1.42.

Preparation of 9,9,10,10-Tetraiodo-9,10-dihydro-9,10-distannaanthracene (10): A dichloromethane (50 mL) solution of iodine (700 mg, 2.76 mmol) was added to a dichloromethane (10 mL) solution of **4** (566 mg, 0.69 mmol). The mixture was heated to reflux for 1 day. After separation of insoluble materials in diethyl ether by filtration, the residue was crystallized from dichloromethane to afford 9,9,10,10-tetraiodo-9,10-dihydro-9,10-distannaanthracene (**10**) (316 mg, 51%). **10**: M.p. 278−280 °C (recrystallization from dichloromethane). ^{1}H NMR: δ = 7.52−7.55 (m, 4 H), 7.63−7.83 (m, 4 H). ^{13}C NMR: δ = 132.2 [d, J(Sn−C) = 14, 66 Hz, C_β], 136.9 [d, J(Sn−C) = 46, 76 Hz, C_α], 148.3 (s, C_{ipso}). ^{119}Sn NMR: δ = 189.1 ppm. $C_{12}H_8I_4Sn_2$ (897.2): calcd. C 16.06, H 0.90; found C 16.16, H 0.77.

Crystal and Experimental Data at 298 K for 4: $C_{40}H_{36}O_4Sn_2$, M = 818.104, crystal size 0.30 × 0.30 × 0.20 mm, monoclinic, a = 18.191(5), b = 11.400(2), c = 19.522(10) Å, β = 118.23(6) °, V = 3572(2) Å^3, D = 1.521 Mg·m^{-3}, μ(Mo-K_α) = 1.437 mm^{-1}, Z = 4, space group $P2_1/c$. Data were collected on a Mac Science MXC18 K diffractometer by using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods using SIR[16] and refined by full-matrix least-squares procedures (SHELXL-97)[17] on F^2 for all reflections (7777 reflections) for 416 variable parameters. $R_1(wR_2)$ = 0.037 (0.091) for all data, GOF = 1.158.

Crystal and Experimental Data at 298 K for 6: $C_{28}H_{28}O_2Sn_2$, M = 633.91, crystal size 0.30 × 0.30 × 0.10 mm, monoclinic, a = 17.2610(5), b = 9.4070(3), c = 28.0101(6) Å, β = 144.904(1)°, V = 2615.0(1) Å^3, D = 1.610 Mg·m^{-3}, μ(Mo-K_α) = 1.931 mm^{-1}, Z = 4, space group $P2_1/c$. Data were collected on a Mac Science DIP3000 diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods using SIR[16] and refined by full-matrix least-squares procedures (SHELXL-97)[17] on F^2 for all reflections (5432 reflections) for 290 variable parameters. $R_1(wR_2)$ = 0.039 (0.090) for all data, GOF = 1.060.

Crystal and Experimental Data at 298 K for 10: $C_6H_4I_2Sn$, M = 448.596, crystal size 0.40 × 0.40 × 0.20 mm, triclinic, a = 7.407(5), b = 8.042(4), c = 9.203(7) Å, α = 102.42(5), β = 108.29(5), γ = 104.52(6)°, V = 477.4(5) Å^3, D = 3.121 Mg·m^{-3}, μ(Mo-K_α) = 9.066 mm^{-1}, Z = 2, space group $P\bar{1}$. Data were collected on a Mac Science MXC18 K diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods using SIR[16] and refined by full-matrix least-squares procedures (SHELXL-97)[17] on F^2 for all reflections (2175 reflections) for 83 variable parameters. $R_1(wR_2)$ = 0.052 (0.145) for all data, GOF = 1.041.

Synthetic and Structural Studies of Pd^{II} and Pt^{II} Complexes with Quincorine and Quincoridine Derivatives

Manfred Fild,[a] Carsten Thöne,*[a] and Stefania Tötös[a]

Keywords: N,P ligands / Heterocycles / Palladium / Platinum / Bioinorganic chemistry

A series of Pd^{II}-quincorine and -quincoridine complexes in which the ligands are coordinated through *N*,*O*-donor atoms have been synthesised, and their structural features determined by X-ray crystallography. Additionally, new chiral tetradentate *N*,*P*-ligands containing two quinuclidine cores bridged through a *cis*-enediyne fragment have been obtained. The different coordinating properties of the new ligands, which contain two soft phosphorus and two hard nitrogen donors, to Pd^{II} and Pt^{II} are emphasised. Several typical complexes were structurally characterised by X-ray crystallography.

Introduction

The development of asymmetric catalysis using chiral organic compounds or chiral metal complexes has induced an increased interest in the synthesis of new optically active ligands.[1,2] In this context *cinchona* alkaloids, such as quinine and quinidine and their derivatives, readily available in both pseudo-enantiomeric forms, play an important role and are extensively used. Among asymmetric synthetic procedures in organic chemistry, one of the best known is the asymmetric dihydroxylation of olefins using various *cinchona* alkaloid derivatives as chiral monodentate amine ligands for OsO_4 as developed by Sharpless.[3] The mechanism of this reaction was also extensively analysed by Corey, and the most efficient ligands for promoting face-selective dihydroxylation of olefins were found to be bis-*cinchona* alkaloids such as the $(DHQD)_2PHAL$ system (Figure 1).[3−5]

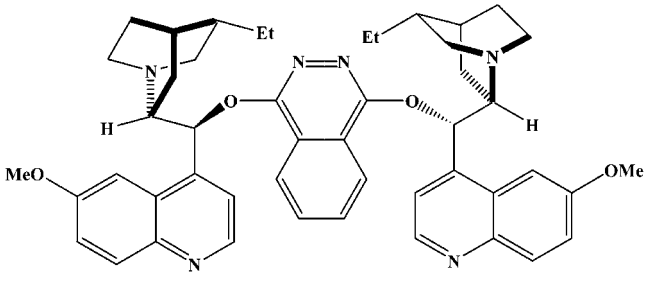

Figure 1. $(DHQD)_2PHAL$, a bis-*cinchona* alkaloid

Additionally, bidentate *N*,*P*-ligands have acquired a growing importance in the development of coordination chemistry and asymmetric catalysis.[6] A remarkable number of aminophosphane, -phosphite, -phosphonite and -phosphinite ligands have been developed and their complexes used for asymmetric catalytic reactions, such as cross-coupling, hydroformylation and hydrogenation.[7−9]

Beck et al. reported the first *N*,*O*-chelate complexes of cinchonidine and cinchonine, but only a few metal complexes of *cinchona* alkaloids have been described.[10] Quincoridine-based aminophosphite ligands and their Rh^{I} and Pd^{II} complexes have also been reported by Gavrilov and coworkers.[11] Recently, Lemaire et al. have developed a new family of *N*,*P*-ligands derived from quincorine (QCI) and quincoridine (QCD) with applications in hydroformylation, asymmetric hydrosilylation and asymmetric Grignard cross-coupling reactions.[12]

The chirality, in combination with the donor properties of QCI and QCD, should provide a useful ligand system for catalytic processes. QCI and QCD contain four stereogenic centres each, including the *N*-chiral 1*S*-configured bridgehead and also possess three potential donor sites: the OH group, a tertiary N-atom and an olefinic C=C bond (Figure 2).

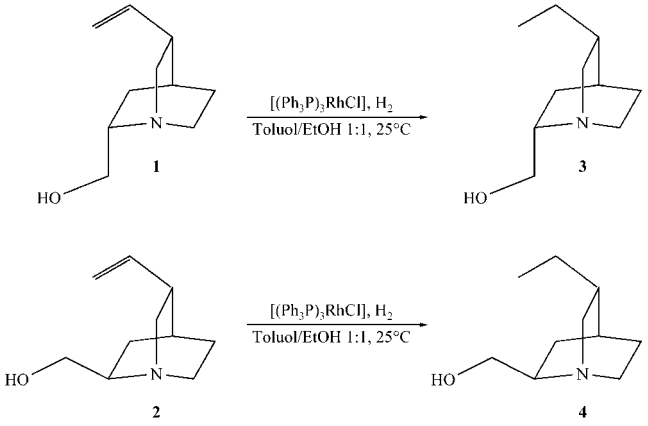
In the present work we report on new *N*,*O*-chelate and bis-*N*,*O*-chelate complexes of Pd^{II} with QCI and QCD and their corresponding saturated derivatives. New chiral aminophosphinites, containing two quinuclidine cores bridged through a *cis* enediyne fragment, are developed and their different coordination modes are described.

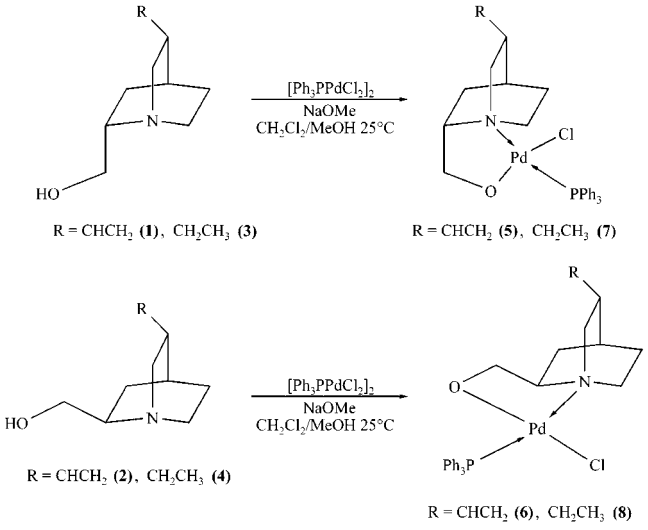
Results and Discussion

N,*O*-Chelate Complexes

In the course of this research program directed toward the synthesis and characterisation of new metal complexes, we have used QCI [(2*S*,4*S*,5*R*)-2-hydroxymethyl-5-vinyl-2-quinuclidine] (**1**) and QCD [(2*R*,4*S*,5*R*)-2-hydroxymethyl-5-vinyl-2-quinuclidine] (**2**) as ligands. The corresponding saturated derivatives [(2*S*,4*S*,5*R*)-5-ethyl-2-hydroxymethyl-2-quinuclidine] (**3**) and [(2*R*,4*S*,5*R*)-5-ethyl-2-hydroxymethyl-2-quinuclidine] (**4**) were prepared efficiently by hydrogenation, according to a known literature procedure (Scheme 1).[13]



Scheme 1. The synthesis of dihydro-QCI (**3**) and dihydro-QCD (**4**)



Scheme 2. The synthesis of phosphane Pd^{II}-QCI and -QCD complexes

Reactions of two equivalents of the ligands **1**−**4** with one equivalent of the chloro-bridged complex [$(Ph_3P)(Cl)Pd(\mu\text{-}Cl)_2Pd(Cl)(PPh_3)$] in the presence of NaOMe in CH_3OH/CH_2Cl_2 gave the corresponding five-membered ring chelate complexes **5**−**8** (Scheme 2).

All of the complexes **5**−**8** gave the expected fragmentation patterns in their positive FAB mass spectra. In the $^{31}P\{^1H\}$ NMR spectra of **5**−**8** all compounds display two singlets around δ = 26 (high intensity) and 23 ppm (low

intensity ≈ 5%). The signal with the high intensity was assigned to the *trans*-P−M−N isomer whereas the low intensity signal corresponds to the *cis*-P−M−N isomer. The formation of the five-membered chelate rings in **5**−**8** was also confirmed in the ^{1}H NMR spectra by the diastereotopicity of the 9-H atoms: an upfield shift of ca. 0.5 ppm was observed for one of them. The H-6 and H-7 atoms suffer a small downfield shift probably because of interaction with the d_z^2 orbital of the metal atom and the coordination of the tertiary N-atom.

Deep yellow crystals of the QCI-Pd^{II} complex **7** and the QCD-Pd^{II} complex **8**, suitable for X-ray analysis, were obtained from diethyl ether solutions by layering with hexanes. Single-crystal X-ray structure determinations (Figure 3 and 4) proved that the *trans*-P−M−N isomers were formed as the main products because of the steric demands of the bulky ligands. The chirality at C-2 is retained in the complexes. The coordination geometry around Pd is virtually square planar in both cases (mean dev. in **7**: 1.86 pm; **8**: 2.86 pm). The Pd atoms are incorporated into five-membered chelate rings. In the case of **7**, the ring adopts a twist conformation, and in **8** an envelope conformation, with C-8 as the flap. The similarity in the bonding situation around

Pd is also reflected in nearly identical bond lengths at Pd in both cases. They match the typically observed range for Pd−P, Pd−Cl and Pd−N bond lengths.

When one equivalent of *trans*-[$PdCl_2(PhCN)_2$] was reacted with two equivalents of **1**−**4** in the presence of NaOMe in methanol/dichloromethane, the bis-*N*,*O*-chelate complexes **9**−**12** were obtained in excellent yields (90%; Scheme 3).

All of the compounds **9**−**12** show the expected fragmentation patterns and the molecular ions in their EI mass spectra. Again, the ^{1}H NMR spectra confirmed the formation of the spiro complexes **9**−**12** because of the diastereotopicity of the 9-H atoms. These exhibit a downfield shift and an upfield shift associated with the different environment obtained through the closure of the five-membered chelate rings. The H-6 and H-7 atoms suffer a small downfield shift, perhaps because of the coordination of the tertiary N-atom to Pd and the interaction with the d_z^2 orbital of the metal.

Yellow crystals of **9** and **11** suitable for X-ray analysis were obtained from Et_2O by layering with hexanes. As shown in Figure 5 and 6, the coordination geometry around Pd is square planar (mean dev. **9**: 2.29 pm; **11**: 4.73 pm), with N(1) and N(2) occupying the *trans* positions. Because of the chelating ligands, Pd is in both cases the spiro atom and therefore part of two five-membered ring systems that display approximately envelope conformations, with the quinuclidine-bound carbon atoms in the flap positions.

Both compounds crystallised with water molecules (**9**: one; **11**: two). In complex **9** intra- and intermolecular hydrogen-bonding [O−H···O: H···O 207(2)[i], 201(3) pm; [i] x, $y + 1$, z] forms chains, which are also connected by non-classical C−H···O hydrogen-bonding [H···O 266[ii], 248 pm[iii]; [ii] $-x + 2$, $y - 0.5$, $-z + 1$, [iii] $-x + 1$, $y + 0.5$, $-z + 1$]. The hydrogen-bonding scheme in **11** is similar, but with stronger classical O−H···O bonds [H···O 179(5), 192(3), 203(3)[i], 201(5) pm[ii]; [i] $-x$, $y - 0.5$, $-z + 1.5$, [ii] x, $y + 1$, z] and comparable non-classical C−H···O bonds [H···O: 263[i], 233[i], 254[iii], 251 pm[iv]; [iii] $-x + 1$, $y + 0.5$, $-z + 1.5$, [iv] $-x$, $y + 0.5$, $-z + 1.5$]. Again, the bond lengths in the molecules are unexceptional and match the usual observed ranges.

N,P-Ligand Synthesis

For the synthesis of *N,P*-ligands we used 10,11-didehydroquincorine (**13**) and 10,11-didehydroquincoridine (**14**) as precursors. The terminal alkynes **13** and **14** were prepared efficiently from **1** and **2** according to a known literature procedure (Scheme 4).[13]

The symmetrical (*Z*)-enediynes **17** and **18** were obtained in good yields in a two-step procedure[14,15] involving two sequential $[Pd(PPh_3)_4]$- and $[PdCl_2(PhCN)_2]$-catalysed coupling reactions from (*Z*)-1,2-dichloroethene and **13** and **14**. Colourless single crystals of **18** were obtained by layering a CH_2Cl_2 solution with hexanes. A structure determination revealed a *cis*-arrangement in the molecule (Figure 7).

Classical hydrogen-bonding of the type O−H···N [H···N: 196(3)[i], 203(3) pm[ii]; [i] $-x + 1$, $y - 0.5$, $-z + 0.5$; [ii] $-x + 1$, $y + 0.5$, $-z + 0.5$] together with non-classical C−H···O hydrogen-bonding [H···O: 257[iii], 245 pm[iv]; [iii] $x + 1$, y, z; [iv] $-x + 2$, $y + 0.5$, $-z + 0.5$] leads to the formation of zigzag chains parallel to the crystallographic *b*-axis in the crystal packing (Figure 8).5

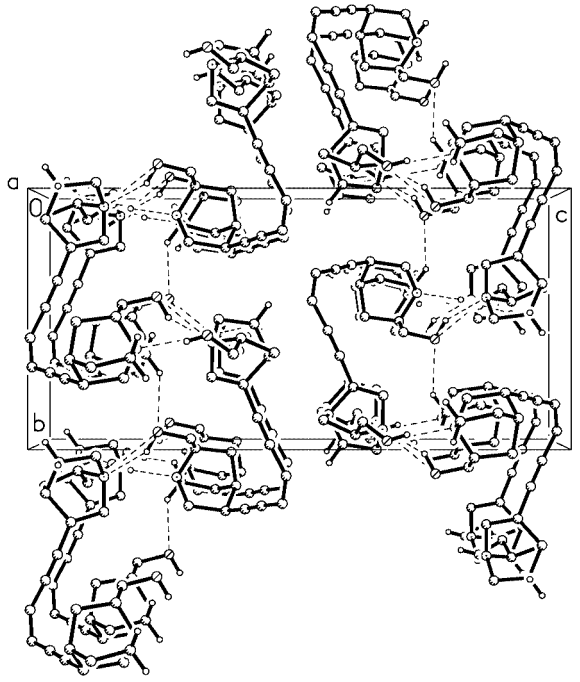

Figure 8. The packing of **18** in the crystal showing the hydrogen bonding; view along the *a* axis; molecules contain the OH group; other hydrogens omitted

Treatment of **17** and **18** with chlorodiphenylphosphane in dichloromethane, in the presence of triethylamine, gave the bis-aminophosphinites **19** and **20** in very good yields (Scheme 5).

These are pale yellow oils, which are stable under nitrogen atmosphere for a long time. In the $^{31}P\{^1H\}$ NMR spectra the resonances of the P atoms are found at $\delta = 115.29$ (**19**) and $\delta = 114.60$ ppm (**20**), respectively.

Platinum(II) and Palladium(II) Complexes

The bis-*N,P*-aminophosphinites **19** and **20**, having two soft electron-donating atoms and two hard electron-donating atoms, show different coordinating properties towards Pt^{II} and Pd^{II}. It is known that the formation of square-planar Pt^{II} complexes is strongly dependent on a number of factors, such as solvent polarity, the *trans* effect of the resident ligands, and the order of adding the reactants. When phosphorus is coordinated to ^{195}Pt, the geometry of the products can often be assigned from the magnitude of the coupling constants. These are strongly dependent on the

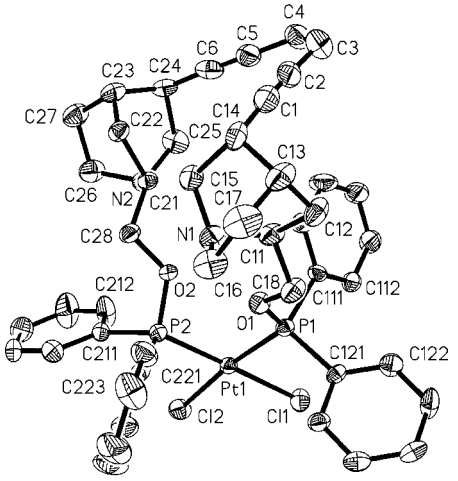

Figure 9. The molecular structure of **21**; hydrogen atoms and the disordered THF molecule are omitted for clarity; ellipsoids at 50% probability level; selected bond lengths [Å] and angles [°] (corresponding values of the second independent molecule in the asymmetric unit are given in brackets): Pt1−P1 2.2231(19) [2.2291(18)], Pt−1P2 2.229(2) [2.2349(18)], Pt1−Cl1 2.3642(19) [2.3564(18)], Pt1−Cl2 2.3532(19) [2.3536(18)], P1−O1 1.587(5) [1.597(5)], P2−O2 1.600(4) [1.601(4)], O1−C18 1.466(7) [1.459(6)], O2−C28 1.438(6) [1.442(6)], C1−C2 1.176(9) [1.204(9)], C2−C3 1.470(10) [1.473(11)], C3−C4 1.328(10) [1.299(14)], C4−C5 1.429(9) [1.363(15)], C5−C6 1.191(9) [1.227(15)], C1−C14 1.482(9) [1.459(8)], C6−C24 1.481(8) [1.415(15)], N1−C11 1.483(7) [1.456(6)], N1−C15 1.453(7) [1.461(7)], N1−C16 1.486(7) [1.490(8)], N2−C21 1.488(6) [1.515(8)], N2−C25 1.457(7) [1.478(10)], N2−C26 1.471(7) [1.501(12)], C(aliph.)−C(aliph.) 1.509(9)−1.580(7) [1.496(7)−1.583(11)]; P1−Pt1−P2 94.17(7) [93.23(7)], P1−Pt1−Cl1 85.41(7) [93.51(7)], P2−Pt1−Cl2 92.07(7) [85.85(7)], Cl1−Pt1−Cl2 88.29(7) [87.29(7)], C18−O1−P1 122.1(4) [116.2(3)], C28−O2−P2 127.5(4) [128.8(4)], O1−C18−C11 109.9(4) [111.0(4)], O2−C28−C21 107.9(4) [107.8(4)], C14−C1−C2 174.9(7) [177.3(7)], C1−C2−C3 176.0(7) [175.9(9)], C2−C3−C4 122.8(7) [126.3(10)], C3−C4−C5 128.6(7) [127.3(9)], C4−C5−C6 176.4(7) [176.9(10)], C5−C6−C24 175.9(6) [176.6(10)]

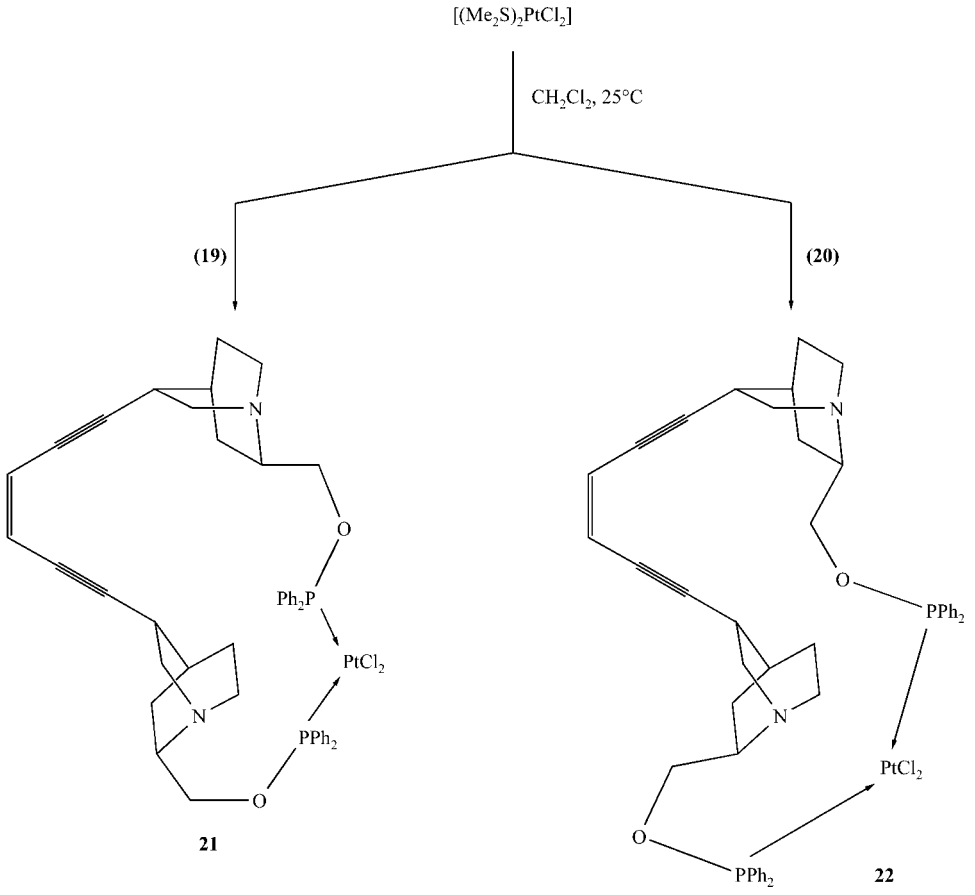

Scheme 6. Platinum(II) chelate complexes of the bis-*N*,*P*-aminophosphinites **19** and **20**

ligand *trans* to the phosphorus atom, because of the inductive effect of that ligand on the platinum-phosphorus bond. Ligands with a very strong σ-inductive character reduce the positive charge on the platinum atom and thus weaken the overlap of the phosphorus and the metal orbitals relative to the *trans*-ligands, which have weaker σ-inductive effects.[16]

When a solution of $[PtCl_2(SMe_2)_2]$ in dichloromethane was added to a solution of **19** or **20** in the same solvent, in a 1:1 molar ratio, the *cis* complexes **21** and **22** were obtained (Scheme 6).

In the $^{31}P\{^1H\}$ NMR spectra singlets, with ^{195}Pt satellites, at δ = 83.89 ppm ($^1J_{Pt,P}$ = 2099.28 Hz) (**21**) and δ = 85.10 ppm ($^1J_{Pt,P}$ = 2076.01 Hz) (**22**) are observed. The FAB mass spectra indicated that the complexes are monomeric. Slow diffusion of diethyl ether into a concentrated THF/dioxane solution of the complex **21** produced colourless crystals that crystallised in the non-centrosymmetric space group *P*1 with two independent molecules of **21** and one disordered and badly resolved THF molecule per formula unit (Figure 9).

The complex can be regarded as a 21-membered ring system with a $PtCl_2$ group that connects the phosphorus(III) ends of the ligand to form a macrocyclic complex with an essentially planar coordination geometry at platinum (mean dev. Pt1: 1.2; Pt2: 4.2 pm). Because of the steric demand of the aminophosphinite ligand, the bite angle at platinum is somewhat wider than 90° [94.17(7), 93.23(7)°]. The ligand is bound symmetrically with similar Pt−P bond lengths [222.31(19), 222.9(2); 222.91(18), 223.49(18) pm, respectively].

Attempts to synthesise the corresponding *trans* complex from **20** through the inverse addition of the reactants led, after 30 minutes at room temperature, to a complex mixture of products. The $^{31}P\{^1H\}$ NMR spectrum of this mixture displays many signals with different intensities and corresponding ^{195}Pt satellites, including the signal of the reactant. After 24 h at room temperature the *cis* complex **22** became the main product observed by ^{31}P NMR spectroscopy. Treatment of two equivalents of $[PtCl_2(SMe_2)_2]$ with one equivalent of **20**, in dichloromethane, again produced the *cis* complex **22**.

Armstrong and co-workers have reported recently that the bis-phosphane ligands 2,7-bis(3-diphenylphosphanylpropoxy)naphthalene (DPPN) and 2,7-bis(3-diphenylphosphanylethoxy)naphthalene (DPEN) form dimeric *cis*, *cis*/*trans* and *trans* complexes of platinum(II) depending on the conditions employed.[17] They have also demonstrated that an excess of the ligand catalyzes *trans*/*cis* isomerisation, either by adding an excess of the phosphane, or by having the excess present during the addition of the platinum precursor. Based on these and our results we conclude that the *cis* complexes **21** and **22** are the thermodynamic products.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The complex mixture formed by the inverse addition of the reactants should be a mixture of kinetic and thermodynamic products and thus the free unchanged ligand has catalysed a *trans*/*cis* isomerisation. The ligands **19** and **20** show a marked preference to form *cis*-P−M−P-monomeric metallamacrocycles with Pt^{II} centres, even though a 1:2 molar ratio was employed.

In view of the interesting complexes **21** and **22** we tried to obtain the corresponding complexes with Pd^{II}. The results were completely different. The reaction of one equivalent of **20** with one equivalent of $[(\eta^4\text{-}C_7H_8)PdCl_2]$ in dichloromethane produced a yellow solid. The $^{31}P\{^1H\}$ NMR spectrum of the crude product shows many singlets up to $\delta = 103$ ppm. Attempts to isolate a pure complex from the mixture were unsuccessful.

When one equivalent of **19** or **20** was allowed to react with two equivalents of $[(\eta^4\text{-}C_7H_8)PdCl_2]$ in dichloromethane yellow solids were again obtained (Scheme 7).

The $^{31}P\{^1H\}$ NMR spectra of these products show only one signal around $\delta = 103$ ppm. The ESI mass spectra indicated that the compounds are the bis-*N*,*P*-chelate complexes **23** and **24** (Scheme 5). The formation of the six-membered chelate rings in **23** and **24** is also confirmed by ^1H NMR spectra. The 6b-H and 7a-H atoms undergo downfield shifts of more than 1.5 ppm in comparison with the free ligands because of the anisotropy of the phenyl groups. Secondly, in the $^1H,^1H$-COSY spectra of **23** and **24** the cross-peaks corresponding to the vicinal correlations of the 2-H atom with the 9-H atoms disappear due to the changing of the dihedral angles through the closure of the six-membered rings.

In contrast to platinum(II), palladium(II) shows a marked preference to form bis-*N*,*P*-chelate complexes with ligands **19** and **20**.

Conclusion

We have shown that the *N*,*O*-chelate complexes and bis-*N*,*O*-chelate complexes of Pd^{II} with QCI and QCD and their saturated derivatives are easy to prepare. The syntheses of two new bis-*N*,*P*-aminophosphinite ligands, derived from QCI and QCD, have been developed. Both ligands have two soft and hard donor-atoms that can be exploited to form mononuclear and binuclear chelate complexes. Platinum(II) forms P−M−P metallamacrocycle complexes, but palladium(II) prefers to form bis-*N*,*P*-chelate complexes with these ligands.

Experimental Section

General Remarks: All reactions were performed under a dry nitrogen atmosphere using standard Schlenk techniques. CH_2Cl_2 was freshly distilled under nitrogen from P_4O_{10}, THF was dried over sodium/benzophenone and distilled prior to use. Et_3N was heated to reflux over sodium and distilled under nitrogen. Piperidine and nBuNH$_2$ were dried over NaOH and then distilled under nitrogen. Ph_2PCl and (*Z*)-1,2-dichloroethene were purchased from Aldrich. $Pd(PPh_3)_4$,[18] $[PdCl_2(PhCN)_2]$,[19] $[(\eta^4\text{-}C_7H_8)PdCl_2]$,[20] $[PdCl_2(PPh_3)]_2$ [21] and $[PtCl_2(SMe_2)_2]$[16] were prepared according to literature procedures. QCI (**1**) and QCD (**2**) were donated by Buchler GmbH. Dihydro-QCI (**3**), dihydro-QCD (**4**), didehydro-QCI (**13**), and didehydro-QCD (**14**) were prepared according to a literature procedure.[13] Preparative column chromatography was performed on Fluka silica gel (particle size 30−60 μm). Analytical TLC was carried out on Polygram Sil G/UV_{254} plates (0.2 mm silica gel). *tert*-Butyl methyl ether (MTBE) was purchased from Fluka.

NMR spectra were obtained from CD_2Cl_2, $CDCl_3$ and C_6D_6 solutions. ^{1}H, ^{13}C and ^{31}P NMR spectra were recorded using a Bruker DRX-400 spectrometer operating at 400, 100 and 162 MHz, respectively. Chemical shifts (δ) are given in ppm relative to residual $CHCl_3$ (δ = 7.27 ppm), CH_2Cl_2 (δ = 5.31 ppm) or C_6H_6 (δ = 7.16 ppm) for ^{1}H, $CDCl_3$ (δ = 77.0 ppm), CD_2Cl_2 (δ = 53.7 ppm) or C_6D_6 (δ = 128.7 ppm) for ^{13}C, and 85% H_3PO_4 (δ = 0.0 ppm, external) for ^{31}P. Coupling constants (*J*) are given in Hz. Mass spectra were obtained using a Finnigan MAT 90 spectrometer operating in FAB and ESI mode for coordination complexes (the isotope patterns matched calculated patterns in all cases), and in EI mode for the organic precursors. In all cases precision mass analyses confirmed the purity of the products. Melting points were determined on a Büchi 510 Melting Point apparatus and are uncorrected.

General Procedure for the Preparation of the Pd^{II}-Phosphane Complexes 5−8: A solution of ligand **1**−**4** and NaOMe in CH_2Cl_2/MeOH (1:1) was added dropwise to a suspension of $[PdCl_2(PPh_3)]_2$ in CH_2Cl_2 and the mixture was stirred for 3 h at room temperature. The solvent was then removed under vacuum and the residue was dissolved again in CH_2Cl_2 and stirred for 15 minutes. The suspension was filtered to removed NaCl and the resulting clear solution was concentrated to dryness. The crude product was recrystallised from diethyl ether and *n*-hexane.

5: From **1** (100 mg, 0.6 mmol), NaOMe (0.6 mmol) and $[PdCl_2(PPh_3)]_2$ (263 mg, 0.3 mmol). $C_{28}H_{31}ClNOPPd$ (570.41). M.p. 158−165 °C. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.96−1.02 (m, 1 H, H-3), 1.55−1.67 (m, 2 H, H-8), 1.76−1.79 (m, 1 H, H-4), 1.80−1.87 (m, 1 H, H-3), 2.32−2.43 (m, 1 H, H-5), 3.06−3.12 (m, 2 H, H-6, H-9), 3.16−3.24 (m, 1 H, H-2), 3.36−3.43 (m, 1 H, H-7), 3.61−3.69 (m, 1 H, H-7), 3.74 (t, *J* = 11.44 Hz, 1 H, H-9), 3.81 (dd, *J* = 13.7, *J* = 10.62 Hz, 1 H, H-6), 5.00−5.07 (m, 2 H, 11), 5.77−5.86 (m, 1 H, 10), 7.26−7.38 (m, 9 H, Ph), 7.56−7.61 (m, 6 H, Ph) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 22.26 (C-3), 27.13 (C-4), 27.72 (C-8), 39.62 (C-5), 43.50 (C-7), 58.09 (C-6), 67.96 (C-2), 73.57 (C-9), 115.22 (C-11), 128.03 (d, *J* = 10.85 Hz, Ph *o*-C), 129.51 (d, *J* = 51.52 Hz, Ph *i*-C), 130.56 (d, *J* = 2.63 Hz, Ph *p*-C), 134.67 (d, *J* = 10.98 Hz, Ph *m*-C), 140.57 (C-10) ppm. ^{31}P NMR (162 MHz, $CDCl_3$): δ = 26.84 (*trans* to N), 23.95 (*cis* to N) ppm. FAB: *m*/*z* = 570 $[M + H]^+$, 534 $[M - Cl]^+$.

FAB: *m*/*z* = 572 $[M + H]^+$, 536 $[M - Cl]^+$.

General Procedure for the Preparation of the Homoleptic Pd^{II} Complexes 9−12: A solution of ligand **1**−**4** and NaOMe in CH_2Cl_2/MeOH (1:1) was added dropwise to a solution of $[PdCl_2(PhCN)_2]$ in CH_2Cl_2 and the reaction mixture was stirred for 1 h at room temperature. The solvent was removed from the light yellow suspension under vacuum and the residue was dissolved again in CH_2Cl_2 and stirred for 15 minutes. The suspension was filtered to remove NaCl and the resulting yellow solution was concentrated to dryness. The crude product was recrystallised from diethyl ether and *n*-hexane.

9: From **1** (400 mg, 2.4 mmol), 2.4 mmol of NaOMe and $[PdCl_2(PhCN)_2]$ (460 mg, 1.2 mmol). $C_{20}H_{32}N_2O_2Pd$ (438.91). General Procedure for the Preparation of the Chloroenynes 15 and 16: A mixture of $[Pd(PPh_3)_4]$ (0.05 equiv.), (*Z*)-1,2-dichloroethene (3 equiv.), alkyne (1 equiv.), and piperidine or $nBuNH_2$ (2 equiv.) in absolute THF was stirred for 15 minutes at room temperature under a nitrogen atmosphere, and CuI (0.1 equiv.) was then added. The stirring was continued until TLC analysis indicated complete consumption of the alkyne (3−5 h). The reaction mixture was treated with a saturated aqueous solution of $NaHCO_3$ and extracted with CH_2Cl_2. The organic layer was dried over Na_2SO_4 and the solvent was removed in vacuo. The crude product was purified by column chromatography [MTBE/MeOH/NH_3(25%)] to yield the desired chloroenyne.

15: From **13** (2 g, 12 mmol), $[Pd(PPh_3)_4]$ (0.69 g, 0.59 mmol), CuI (0.23 g, 1.2 mmol), $nBuNH_2$ (1.75 g, 23.9 mmol) and (*Z*)-1,2-dichloroethene (3.49 g, 36 mmol). $C_{12}H_{16}ClNO$ (225.5). ^1H NMR (400 MHz, $CDCl_3$): δ = 0.74−0.80 (m, 1 H, H-3), 1.34−1.49 (m, 2 H, H-8), 1.89−1.93 (m, 1 H, H-4), 2.04−2.11 (m, 1 H, H-3), 2.49−2.57 (m, 1 H, H-7), 2.65−2.68 (m, 1 H, H-5), 2.85−2.93 (m, 2 H, H-7, H-6), 3.06−3.11 (m, 2 H, H-2, OH), 3.23 (dd, *J* = 13.17, *J* = 9.95 Hz, 1 H, H-6), 3.38−3.45 (m, 2 H, H-9), 5.79 (dd, *J* = 7.33, *J* = 2.23 Hz, 1 H, H-12), 6.26 (d, *J* = 7.33 Hz, 1 H, H-13) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 24.91 (C-3), 26.18 (C-8), 26.56 (C-4), 28.95 (C-5), 39.55 (C-7), 56.82 (C-2), 56.88 (C-6), 62.61 (C-9), 75.09 (C-11), 102.02 (C-10), 112.20 (C-12), 127.39 (C-13) ppm. General Procedure for the Preparation of the Bis-*N*,*P*-aminophosphinites 19 and 20: A solution of Ph_2PCl (2.05 equiv.) in dry CH_2Cl_2 was cooled to 0 °C and then a solution of (*Z*)-enediyne (1 equiv.) and NEt_3 (4 equiv.) in the same solvent was added dropwise. After the addition, the reaction mixture was allowed to warm up to room temperature and stirred until TLC analysis indicated complete consumption of the reactant **17** and **18**. The solution was concentrated in vacuo and the residue was dissolved in CH_2Cl_2/*n*-hexane (1:2) and stirred for 15 minutes. The suspension was filtered to remove $Et_3N{\cdot}HCl$ and the resulting clear solution was concentrated to dryness. The crude product was purified by column chromatography under a nitrogen atmosphere (MTBE/acetonitrile/NEt_3) to afford the desired bis-aminophosphinite in very good yield.

19: From **17** (1.22 g, 3.44 mmol), Ph_2PCl (1.52 g, 6.8 mmol) and NEt_3 (13.7 mmol). $C_{46}H_{48}N_2O_2P_2$ (722.85). ^1H NMR (400 MHz, C_6D_6): δ = 0.75−0.80 (m, 2 H, H-3), 0.88−0.96 (m, 2 H, H-8), 1.00−1.08 (m, 2 H, H-8), 1.74−1.75 (m, 2 H, H-4), 2.13−2.18 (m, 2 H, H-3), 2.24−2.31 (m, 2 H, H-7), 2.43−2.45 (m, 2 H, H-5), 2.74−2.82 (m, 2 H, H-7), 2.92−3.04 (m, 4 H, H-6), 3.29−3.36 (m, 2 H, H-2), 3.64−3.70 (m, 2 H, H-9), 3.77−3.84 (m, 2 H, H-9), 5.59 (s, 2 H, H-12), 7.01−7.05 (m, 4 H, Ph), 7.09−7.13 (m, 8 H, Ph), 7.61−7.64 (m, 8 H, Ph) ppm. ^{13}C NMR (100 MHz, C_6D_6): δ = 25.75 (C-3), 26.46 (C-8), 27.65 (C-4), 29.32 (C-5), 41.04 (C-7), 56.68 (d, *J* = 7.23 Hz, C-2), 71.71 (d, *J* = 18.3 Hz, C-9), 57.81 (C-6), 79.41 (C-11), 101.79 (C-10), 119.47 (C-12), 128.43 (d, *J* = 6.97 Hz, Ph *m*-C), 128.50 (d, *J* = 6.97 Hz, Ph *m*-C), 129.21 (d, *J* = 3.35 Hz, Ph *p*-C), 130.62 (d, *J* = 8.32 Hz, Ph *o*-C), 130.83 (d, *J* = 8.14 Hz, Ph *o*-C), 143.31 (d, *J* = 8.40 Hz, Ph *i*-C), 143.49 (d, *J* = 7.83 Hz, Ph *i*-C) ppm. ^{31}P NMR (162 MHz, C_6D_6): δ = 115.29 ppm. EI: *m*/*z* = 722 $[M]^+$, 645 $[M - C_6H_5]^+$, 521 $[M - Ph_2PO]^+$, 201 $[Ph_2PO]^+$.

General Procedure for the Preparation of the Platinacycles 21 and 22: A solution of $[PtCl_2(SMe_2)_2]$ in CH_2Cl_2 (4 mL) was added dropwise to a stirred solution of **19** and **20** in CH_2Cl_2 (5 mL). After 15 minutes, the solvent was removed to give a pale-yellow solid. Recrystallisation from THF and toluene gave a white solid.

21: From **19** (370 mg, 0.51 mmol) and $[PtCl_2(SMe_2)_2]$ (200 mg, 0.51 mmol). M.p. 195−197 °C. $C_{46}H_{48}Cl_2N_2O_2P_2Pt$ (988.83). ^1H NMR (400 MHz, $CDCl_3$): δ = 0.86−0.91 (m, 2 H, H-3), 1.37−1.44 (m, 4 H, H-8), 1.97 (br. s, 2 H, H-4), 2.04−2.10 (m, 2 H, H-3), 2.24−2.32 (m, 2 H, H-7), 2.48−2.50 (m, 2 H, H-7), 2.71−2.74 (m, 2 H, H-5), 2.86−2.89 (m, 2 H, H-6), 3.07−3.11 (m, 2 H, H-2), 3.21 (dd, *J* = 13.22, *J* = 10.07 Hz, 2 H, H-6), 3.28 (br. s, 2 H, H-9), 3.47−3.49 (m, 2 H, H-9), 5.88 (s, 2 H, H-12), 7.37−7.53 (m, 12 H, Ph), 7.70−7.74 (m, 4 H, Ph), 8.04−8.09 (m, 4 H, Ph), ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 25.57 (C-8), 25.61 (C-3), 26.27 (C-4), 28.57 (C-5), 40.44 (C-7), 54.89 (d, *J* = 8.02 Hz, C-2), 56.86 (C-6), 68.42 (C-9), 78.42 (C-11), 100.81 (C-10), 118.77 (C-12), 127.85 (d, *J* = 11.73 Hz, Ph *m*-C), 128.25 (d, *J* = 12.05 Hz, Ph *m*-C), 131.40 (d, *J* = 69.43, Ph *i*-C), 131.56 (Ph *p*-C), 131.75 (Ph *p*-C), 132.41 (d, *J* = 12.34 Hz, Ph *o*-C), 132.45 (d, *J* = 77.80 Hz, Ph *i*-C), 132.70 (d, *J* = 11.58 Hz, Ph *o*-C) ppm. ^{31}P NMR (162 MHz, $CDCl_3$): δ = 83.89 ($^1J_{Pt,P}$ = 2099.28 Hz) ppm. FAB: *m*/*z* = 988 $[M]^+$, 953 $[M - Cl]^+$.

22: From **20** (250 mg, 0.346 mmol) and $[PtCl_2(SMe_2)_2]$ (135 mg, 0.346 mmol). M.p. 215 °C. $C_{46}H_{48}Cl_2N_2O_2P_2Pt$ (988.83). ^1H NMR (400 MHz, $CDCl_3$): δ = 1.46−1.56 (m, 8 H, H-8, H-3), 1.92 (br. s, 2 H, H-4), 2.28−2.32 (m, 2 H, H-2), 2.62−2.75 (m, 8 H, H-7, H-5, H-6), 2.94−3.01 (m, 2 H, H-6), 3.73−3.82 (m, 2 H, H-9), 4.07−4.09 (m, 2 H, H-9), 5.79 (s, 2 H, H-12), 7.25−7.36 (m, 12 H, Ph), 7.66−7.71 (m, 4 H, Ph), 7.81−7.86 (m, 4 H, Ph) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 24.70 (C-8), 25.34 (C-3), 27.13 (C-4), 29.09 (C-5), 48.39 (C-7), 49.06 (C-6), 54.53 (d, *J* = 6.93 Hz, C-2), 70.27 (C-9), 79.12 (C-11), 100.10 (C-10), 119.03 (C-12), 127.84 (d, *J* = 12.06 Hz, Ph *m*-C), 128.10 (d, *J* = 11.89 Hz, Ph *m*-C), 131.40 (d, *J* = 7.15 Hz, Ph *p*-C), 131.90 (d, *J* = 11.86 Hz, Ph *o*-C), 132.47 (d, *J* = 11.56 Hz, Ph *o*-C), 132.56 (d, *J* = 74.00 Hz, Ph *i*-C), 133.47 (d, *J* = 75.00 Hz, Ph *i*-C) ppm. ^{31}P NMR (162 MHz, $CDCl_3$): δ = 85.10 ($^1J_{Pt,P}$ = 2076.01 Hz) ppm. FAB: *m*/*z* = 988 $[M]^+$, 953 $[M - Cl]^+$.

General Procedure for the Preparation of the Binuclear Pd^{II}-*N*,*P*-aminophosphinite Complexes 23 and 24: $[(\eta^4\text{-}C_7H_8)PdCl_2]$ was added to a solution of **19** or **20** in CH_2Cl_2 (20 mL) and the reaction mixture was stirred overnight at room temperature. The solvent of the clear yellow solution was removed under vacuum and the remaining yellow solid was washed twice with *n*-hexane and dried in vacuo for two days.

23: From **19** (160 mg, 0.22 mmol) and $[(\eta^4\text{-}C_7H_8)PdCl_2]$ (120 mg, 0.44 mmol). M.p. 210−214 °C. ^1H NMR (400 MHz, CD_2Cl_2): δ = 1.06−1.12 (m, 2 H, H-3), 1.49−1.67 (m, 4 H, H-8), 2.03 (br. s, 2 H, H-4), 2.25−2.31 (m, 2 H, H-3), 2.94−3.01 (m, 4 H, H-7, H-5), 3.19−3.24 (m, 4 H, H-6, H-2), 3.62−3.69 (m, 2 H, H-9), 3.84−3.95 (m, 2 H, H-9), 4.25−4.31 (m, 2 H, H-7), 5.09 (dd, *J* = 13.56, *J* = 10.4 Hz, 2 H, H-6), 5.80 (s, 2 H, H-12), 7.31−7.35 (m, 4 H, Ph), 7.42−7.47 (m, 6 H, Ph), 7.53−7.56 (m, 2 H, Ph), 7.59−7.65 (m, 4 H, Ph), 7.95−8.00 (m, 4 H, Ph) ppm. ^{13}C NMR (100 MHz, CD_2Cl_2): δ = 26.09 (C-4), 26.64 (C-8), 27.18 (C-3), 30.16 (C-5), 46.74 (C-7), 60.90 (d, *J* = 4.18 Hz, C-2), 62.07 (C-6), 67.85 (C-9), 79.83 (C-11), 98.95 (C-10), 119.87 (C-12), 128.39 (d, *J* = 12.46 Hz, Ph *m*-C), 128.96 (d, *J* = 12.07 Hz, Ph *m*-C), 130.85 (d, *J* = 62.07 Hz, Ph *i*-C), 131.86 (d, *J* = 49.16 Hz, Ph *i*-C), 132.42 (Ph *m*-C), 132.90 (d, *J* = 11.39 Hz, Ph *o*-C), 133.13 (Ph *p*-C), 134.61 (d, *J* = 13.04 Hz, Ph *o*-C) ppm. ^{31}P NMR (162 MHz, CD_2Cl_2): δ = 102.90 ppm. Crystal Structure Analyses: The crystal-structure data for **7**, **8**, **9**, **11**, **18 and 21** were collected on a Bruker SMART 1000CCD area detector (graphite-monochromated Mo-K_α radiation, λ = 71.073 pm) at −140 °C in the ω- and φ-scan mode. Empirical absorption corrections were applied using the program SADABS. The structures were solved by direct methods using SHELXS-86/97,[22] and subjected to full-matrix least-squares refinement on F^2 using SHELXL-93/97,[23] with anisotropic displacement parameters for non-H atoms. The crystal structure of **21** contains one disordered THF molecule per formula unit, which could not be resolved satisfactorily. This led to a residual electron density of 2.25 e·Å^{-3}. The crystal structure was therefore refined using the restraints SIMU and DELU for the carbon, nitrogen and oxygen atoms. Additionally, the restraint FLAT was added to describe the local symmetry of the phenyl rings. Methyls were treated as rigid groups and O-bonded hydrogens were refined freely. All other hydrogen atoms were included using a riding model.

Inorganic−Organic Hybrid Compounds: Synthesis and Structures of New Metal Organic Polymers Synthesized in the Presence of Mixed Dicarboxylates

A. Thirumurugan[a] and Srinivasan Natarajan*[a]

Keywords: Carboxylate ligands / Coordination modes / Thermochemistry / Lanthanides

A hydrothermal reaction of a mixture of 1,2-dicyanobenzene (1,2-DCB), 1,4-benzene-dicarboxylic acid (1,4-BDC) along with the corresponding lanthanide salts at a pH of ≈ 5, gives rise to a new series of carboxylate coordination polymers, $[M_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$, (M = La, Pr, Gd, Dy, and Y), which are three-dimensional in structure. The 1,2-DCB oxidized to the corresponding dicarboxylic acid, phthalic acid (1,2-BDC), during the reaction. The structures are of two types with the larger La and Pr lanthanides forming type-1 and the smaller ones, Gd, Dy, and Y, forming type-2. While La and Pr have an idealized D_{3h} triply capped trigonal prism coordination environment, Gd, Dy, and Y have a distorted dodecahedral arrangement with respect to the oxygen atoms. The three-dimensional structure consists of a column of M atoms connected through the 1,2-BDC, and is cross-linked through 1,4-BDC giving rise to rhombic one-dimensional channels. The water molecules, bound to the M atoms, project into the channels. The compounds also illustrate the lanthanide contraction principle. The compounds have been characterized using powder X-ray diffraction, TGA, IR, and photoluminescence measurements. Our continuing investigations clearly reveal that related compounds can be formed with all the rare earth metal ions.

Introduction

Design and synthesis of three-dimensional (3D) coordination polymers with well-defined pores is of current topical interest.[1−5] Large numbers of three-dimensional coordination polymers with porous structures and interesting adsorption properties have been prepared and characterized using a variety of benzene carboxylates.[6−25] Of these, benzene-1,4-dicarboxylic acid (H_2BDC) with a 180° separation between the two carboxylic groups and benzene-1,3,5-tricarboyxlic acid (H_3BTC) with a 120° separation have been proven to yield interesting structures. Recent studies have shown that it is profitable to explore mixed metal benzene dicarboxylates.[26–31] Hetero-bimetallic coordination polymers have traditionally been investigated for their many interesting properties, such as dimensionality and magnetism.[32] In addition, the variations in the coordination environment between the two different metals might also give rise to different structures. Though a large number of mixed metal carboxylates have been prepared, work on the use of mixed dicarboxylates is slow to emerge. Recently, H_2BDC and H_3BTC were used for the preparation of the first example of a Zn coordination polymer built-up from two different carboxylic acids.[21]

Most of the metal-organic frameworks reported in the literature have been prepared employing hydrothermal methods. The hydrothermal method, in some cases, gives rise to unexpected products due to side reactions.[33] We have been interested in the use of hydrothermal methods for the preparation of mixed carboxylate polymers, which invariably lead to uncharacterized dense precipitates. It is known that cyano groups on the phenyl ring are easily converted into carboxylic acid groups by hydrolysis.[34−36] Recently the use of 1,4-dicyanobenzene has been shown to give rise to a series of terephthalate coordination polymers under hydrothermal conditions.[36] In the present study, we have used 1,2-dicyanobenzene and 1,4-terephthalic acid in a hydrothermal system along with a series of lanthanide salts to produce new metal-organic polymers of the general formula, $[M_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$, (M = La, Pr, Gd, Dy, and Y) with three-dimensional structures. In addition, the present system with the rare earth elements of different ionic radii provide us with an opportunity to examine the established lanthanide contraction, and its role on the coordination of the lanthanide ion and the structure. The 1,2-benzene dicarboxylate (isophthalate), found in the products, has been obtained by the hydrolysis of 1,2-dicyanobenzene, under hydrothermal conditions. This is only the second example of the preparation of a metal-organic framework containing two different multi-carboxylates as

organic linkers. The first report was a Zn coordination polymer, $[Zn_3BDC{\cdot}2BTC{\cdot}2NH(CH_3)_2{\cdot}2NH_2(CH_3)_2]$, with three-dimensional connectivity.[21] In this paper, we report the synthesis, structure and characterization of the compounds.

Results

The title compounds, $[M_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$, (M = La, Pr, Gd, Dy, and Y) can be grouped into two distinct classes based on the coordination environment around the central metal ion and the connectivity with the carboyxlate units. Thus, $[M_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$, M = La and Pr, form type-1, and M = Gd, Dy, and Y, form type-2.

Structure of $[M_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$ M = La and Pr (Type-1)

The asymmetric unit of type-1 compounds contains 44 non-hydrogen atoms, of which two M atoms are crystallographically independent (Figure 1, a). The structure is built up by the connectivity involving M (M = La and Pr) and the carboxylate units. Each M atom is coordinated by two carboxylate ligands [C(1) and C(31)] and [CC(11) and C(21)] in an *O,O′* manner and also coordinated in a monodendate way by three other carboxylate ligands. The M atoms also possess two terminal oxygen atoms, which are found to be water molecules. In addition, two oxygen atoms, [O(1) and O(9)], connect the M atoms through a three-coordinate bond, a μ_3 connection, leading to an effective nine-coordination for the central metal. The coordination environment around M atoms is an idealized D_{3h} triply capped trigonal prism (Figure 1, b). The M atoms have distances in the range 2.397(6)−2.923(5) Å (average 2.568 Å for La and 2.531 Å for Pr). The longer M−O distances are associated with the oxygen atoms, [O(1) and O(9)], having the μ_3 connection, which link the two M centers and a carbon atom. The other bond lengths, C−O, C−C, have the expected values observed in many similar compounds.[6−25] The O−M−O bond angles for M = La and Pr are in the range 46.81(15)−151.25(18)°. The various structural parameters observed in type-1 compounds are in the range expected for this type of bonding. Both the M atoms in the asymmetric unit have two terminal M−O linkages with an average distances of 2.521 Å, which are water molecules. Selected bond lengths are listed in Table 1.

The structure of the type-1 compounds, $[M_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$ M = La and Pr, has two types of 1,2-BDC and 1,4-BDC acids. Thus, C2−C7 forms the benzene ring with C1 and C51 as the carboxylate units, and C22−C27 forms the benzene ring with C21 and C61 forming the carboxylate units completing the two 1,2-BDC. The 1,4-acid has an inversion center in the plane of the benzene ring (C12−C14 and C32−C34) with C11 and C31 being the carboxylate units. Of the carboxylate units, C1, C11, and C31 are bidentate and C51, C21, and C61 are monodentate, respectively, with respect to individual M ions. The framework structure of the type-1 compounds can

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

be understood in terms of simpler building units. Thus, two three-coordinate oxygen atoms, [O(1) and O(9)], connect two M atoms to give rise to an edge-shared M_2O_{16} dimer. The 1,2-BDC connects the dimers giving rise to a sheet of

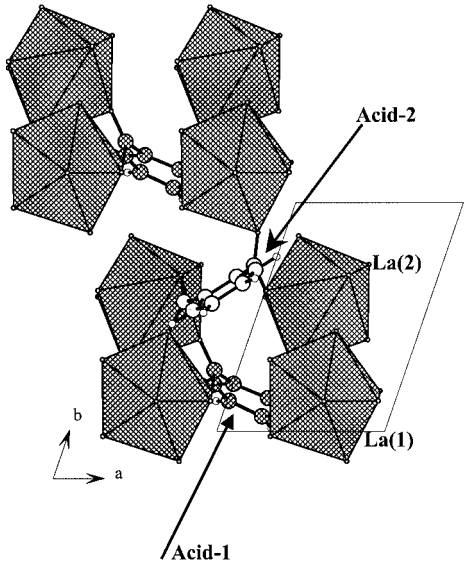

Figure 2. Figure showing the connectivity between La and the two 1,2BDC acids in the *ab* plane. Note that one of the 1,2BDC (acid 1) connects two La atoms forming an edge-shared La-dimer and the other (acid 2) connects the two such dimers together to form a column

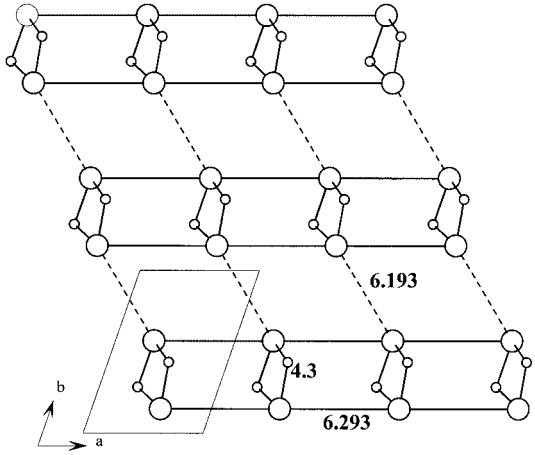

Figure 3. Figure shows the M-dimers, formed by the three-coordinate oxygen atoms, and its connectivity in the *ab* plane in Type-1 compounds. The connecting 1,2-BDC acids are not shown

M-carboxylate networks in the *ab* plane (Figures 2 and 3). While one 1,2-BDC connects a pair of M_2O_{16} dimers the second 1,2-BDC connects two different pairs forming a ladder-like arrangement. The arrangement of ladders and their connectivity gives rise to a corrugated sheet with steps in the *ab* plane. If we connect the M atom, the corrugated sheet is seen very clearly (Figure 3). The M−M atoms are separated by 4.3 Å within the dimer and 6.293 Å between the dimers in the same ladder. The distance between the two M dimers of different ladders is 6.193 Å (Figure 3). The corrugated sheets are cross-linked by the 1,4-BDC completing the three-dimensional structure as shown in Figure 4. The connectivity between the M, 1,2-BDC and 1,4-BDC gives rise to rhombic one-dimensional channels as shown in Figure 5. The two water molecules bound to the M ions (M = La and Pr) projects into the channels.

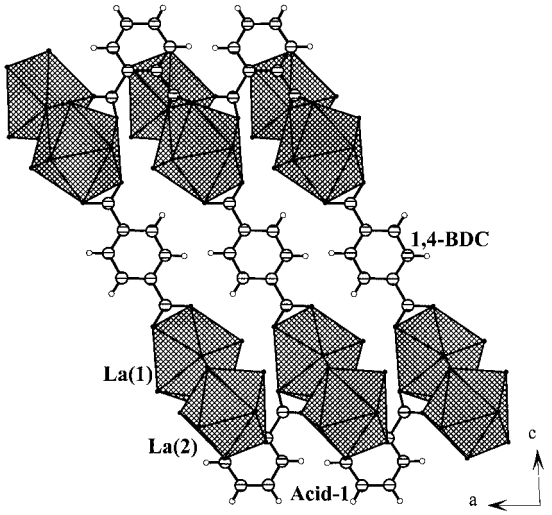

Figure 4. The view of the structure of the type-1 compound in the *ac* plane. The figure also shows the connectivity between two columns of dimers through 1,4-BDC. Only one of the 1,2-BDC acids is shown for clarity

Structure of $[M_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$ M = Gd, Dy, and Y (Type-2)

The asymmetric unit of the type-2 compounds $[M_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$ M = Gd, Dy, and Y, have 21 non-hydrogen atoms, of which one M atom is independent (Figure 6, a). The M atoms are eight-coordinated with oxygen atoms that have M−O distances in the range 2.262(4)−2.509(4) Å (av. 2.381 for Gd, 2.411 Å for Dy, and 2.370 Å for Y). The coordination environment around the central M atom is a distorted dodecahedron. The C−O, C−C bond lengths show typical values.[6−25] The O−M−O bond angles for M = Gd, Dy, and Y are in the range

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

52.50(12)−154.89(13)°. The various structural parameters observed in type-2 compounds are in the range expected for this type of bonding. The M atom has two terminal M−O linkages with an average distance of 2.405 Å, which are water molecules. Selected bond lengths are listed in Table 2.

Unlike type-1, type-2 compounds have only one type of 1,2-BDC and 1,4-BDC acids. Thus, C2−C7 forms the benzene ring with C1 and C21 forming the carboxylate units for the 1,2-BDC, while the 1,4-BDC has an inversion center in the plane of the benzene ring (C12−C14) with C11 being part of the carboxylate unit. While 1,2-BDC only has monodendate connectivity through all the oxygen atoms, that of 1,4-BDC has bidentate bonding with respect to the M atoms. In Figure 6, b the monodendate connectivity between the M atoms and 1,2-BDC is shown. The connectivity between the M atoms and the 1,2-BDC acid, similar to type-1 compounds, gives rise to a corrugated step-like ladder arrangement. If the M atoms are connected, it gives

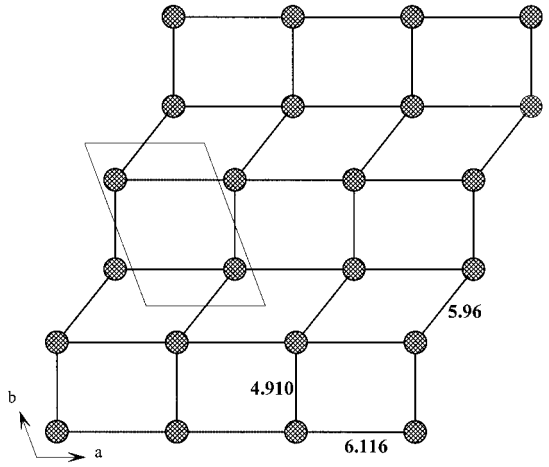

Figure 7. Figure shows the M atoms and its connectivity in Type-2 compounds. The connecting 1,2-BDC acids are not shown. Note that the M atom connectivity forms a corrugated four-connected net

rise to a four-connected network as shown in Figure 7. Similar to the type-1 compounds, the distance between the M atoms in the four-connected net varies between 4.910−6.116 Å (Figure 7). The connectivity between the 1,2-BDC, 1,4-BDC and the M atoms gives rise to rhombic one-dimensional channels (Figure 8). The two water mol-

ecules bound to the M atoms project into these channels.

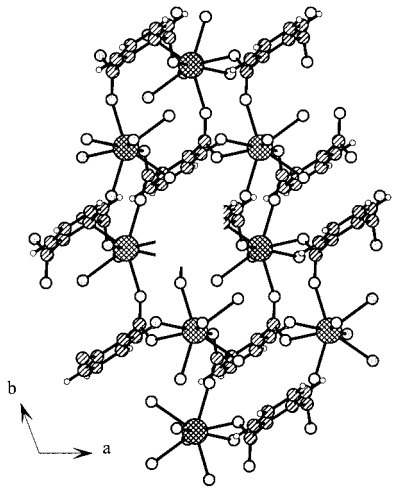

Figure 9. Structure of $[Gd_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$ in the *ab* plane showing the arrangement of the benzene rings of the acid

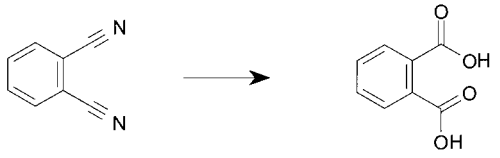
The packing diagram in the *ab* plane is shown in Figure 9. The arrangement of the benzene carboxylates in the *ab* plane clearly indicates that direct π···π interactions have been avoided.

Discussion

Five new compounds have been synthesized with the general formula, $[M_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$, M = La, Pr, Gd, Dy, and Y, employing mild condition hydrothermal reactions. The compounds have been prepared using 1,2-dicyanobenzene (1,2-DCB), but the final product contained benzene-1,2-dicarboxylic acid (phthalic acid). The 1,2-DCB compound has been hydrolyzed under the hydrothermal synthesis conditions to give rise to phthalic acid.



Since the product contained pthalic acid, we have made attempts to prepare the title compounds using pthalic acid in the starting synthesis mixture in place of 1,2-DCB. The experiments resulted in the desired product, but it was in the powder form with no single crystals being obtained. It is likely that the slow hydrolysis of 1,2-DCB to 1,2-BDC is needed to give rise to good quality single crystals of the coordination polymers described in this work.

All the compounds have been obtained as good quality single crystals and their structures were determined using single-crystal X-ray diffraction. Though the overall structure of the compounds appears to have close resemblance amongst them, there are minor differences between those formed with La and Pr and those formed with Gd, Dy, and Y. One of the differences is the absence of three-coordinate oxygen atoms (μ_3 connection) in the latter. The presence of three-coordinate oxygen atoms leads to the formation of M−O−M linkages and a dimer (M = La, Pr). Such a μ_3 connection of the oxygen atom in the M−O−M bridge is an electrostatic valence requirement of the bridging oxygen atoms. The μ_3 connections of the oxygen atoms are, probably, needed to accommodate the higher coordination of the large M ions.

The present study consists of a family of rare earth compounds with similar formulae and different structures. It appears that the size of the lanthanide ion possibly has a role in the final structure. In Figure 10, we have plotted the unit cell volume as a function of the covalent radii. We have considered the unit cell volume for the type-2 compounds to be double in order to be consistent with the formula. It is clear that there are two distinct slopes. The larger La and Pr appear to form a group while the smaller Gd, Dy, and Y belong to the other. This shows that there is a lanthanide contraction effect on the structure. Similar behavior has been noted in many compounds involving lanthanide ions, especially in intermetallic compounds.[37] The differences in the size of the lanthanide ions also results in different coordination for the M ions, which probably also leads to the observed differences in the structure.

From the TGA studies, it is clear that the bound water molecules leave at around 170−210 °C. In order to understand the thermal stability of these compounds, especially after the release of bound water molecules, we have performed careful experiments by heating the sample at different temperatures. For this purpose, we have selected the Y compound and heated the sample at each temperature in air for 120 min and the XRD patterns were recorded in the 2θ range of 5−30°. The results are shown in Figure 11. The samples appear to retain their structure only up to 150 °C, after which new peaks corresponding to yttrium oxide start appearing. From this, it is clear that the structure collapses after the loss of bound water of crystallization, unlike in

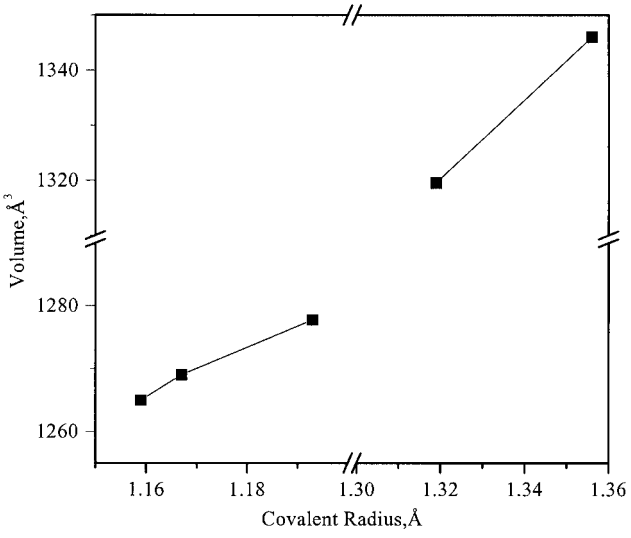


Figure 10. The variation of the crystal volume as a function of covalent radii of the lanthanide ions

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

some of the lanthanide coordination polymers reported recently.[38]

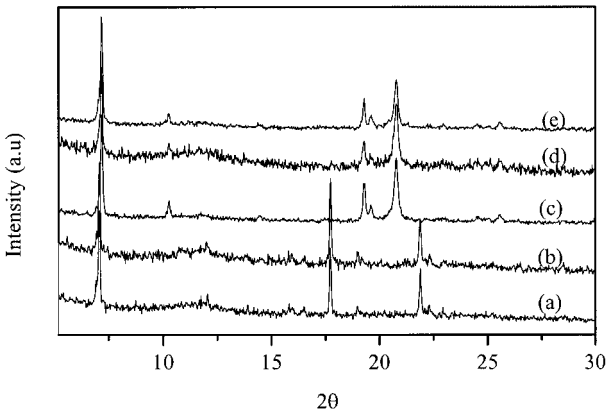

Figure 11. The XRD pattern of the $[Y_2(H_2O)_4\{(1,2BDC)_2$-$(1,4BDC)\}]$ as a function of temperature (a) 100, (b) 150, (c) 200, (d) 250, (e) 300 °C

The optical properties of the benzene carboxylates have been investigated since they involve the 4f orbitals, which are generally well shielded from their chemical environments by $5s^2$ and $5p^6$ electrons. The f-f transitions are parity forbidden, which leads to unfavorable excitation of the lanthanide ions. The photoluminescence studies indicate that both the acids, 1,2-BDC and 1,4-BDC, show photoluminescence (Figure 12). The main emission peak for the acids is located at the same position, at 240 nm. The emission bands for the acids, which also act as ligands in these compounds, may be attributable to the $\pi^* \rightarrow n$ transitions. Interestingly, the emission spectrum for the lanthanide coordination polymer shows a main peak at ≈ 400 nm. This peak corresponds to the intra-ligand fluorescent emission. In addition, the samples also exhibit additional emission bands when excited at 235 nm. These bands correspond to some of the expected $^5D_4 \rightarrow {}^7F_n$ transitions. The observed transitions are: $^5D_4 \rightarrow {}^7F_6$ = 508 (Gd), 494 (Dy), 483(Y); $^5D_4 \rightarrow {}^7F_5$ = 544 (Gd), 539 (weak, Dy), 542 (weak, Y); $^5D_4 \rightarrow {}^7F_4$ = 573, 592 (Gd), 584 (Dy), 574 (Y); $^5D_4 \rightarrow {}^7F_3$ = 616 (Gd). Similar behavior has been observed in many lanthanide coordination polymers.[8,39] As representative examples, the photoluminescence behavior for the acids along with Gd, Dy, and Y are given in Figure 12.

The pH of the initial reaction mixture also appears to play an important role in the formation of the compounds. A reaction mixture with a pH of ≈ 3 recrystallizes the 1,4-BDC acid and no other product was obtained. A reaction of a mixture of the 1,2-BDC and 1,4-BDC acids with a pH of ≈3 also recrystallizes only the acids. A starting reaction mixture containing both the acids at a pH of ≈ 5−6, however, gives rise to the desired product, but only in the powder form (very poor yield ≈ 5−10%) with no single crystals being obtained. In order to establish the pH conditions, we have also carried out reactions with piperidine and piperazine as the secondary base in place of NaOH, which resulted in the formation of the title compounds. From this, it appears that a pH of ≈ 5 is, probably, necessary to deprotonate the acid as the final product is devoid of any of the amine used in the synthesis, i.e., NaOH, piperidine, or piperazine.

Conclusions

A new series of coordination polymers of the general formula, $[M_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$, M = La, Pr, Gd, Dy, and Y, have been prepared and characterized employing hydrothermal methods. The large lanthanides show a higher coordination compared with the smaller ones. The structure consists of a column of M−O formed by the connectivity between 1,2-BDC and M atoms and are interconnected by 1,4-BDC to give rise to the three-dimensional structure. The secondary coordinated water molecule does not appear to be reversibly adsorbed. The photoluminescence studies show some of the expected $^5D_4 \rightarrow {}^7F_n$ transitions. It is likely that related compounds encompassing other lanthanide ions with similar structures can be prepared. We are currently pursuing research in this direction.

Experimental Section

Synthesis and Initial Characterization: All the compounds have been prepared by employing hydrothermal methods. In a typical synthesis for the lanthanum coordination polymer, $LaCl_3$ (0.245 g)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was dissolved in 5 mL of MilliQ water. 1,2-Dicyanobenzene (0.128 g) and terephthalic acid, [HOOC(C_6H_4)COOH; 1,4-BDC] (0.169 g) were then added to this under continuous stirring. Finally the pH was adjusted to ≈ 5 by the addition of 0.4 mL of 5 M NaOH and the mixture was homogenized for 30 min at room temperature. The final mixture with the composition, $LaCl_3$:1,2$(NC)_2C_6H_4$:1,4-BDC:2NaOH:278H_2O, was sealed in a 23 mL PTFE-lined acid digestion bomb and heated at 180 °C for 72 h under autogenous pressure. The pH after the reaction did not show an appreciable change. The resulting product contained rod-like crystals admixed with very small quantities of white powder were filtered under vacuum and dried at ambient temperature. The crystals were easily separated under an optical microscope and later by ultrasonification for further characterization. The yield of the single crystals was about ≈ 80% based on the La compound. The white powder was found to be amorphous by powder X-ray diffraction. The same compound can also be synthesized starting from other salts of La, [for ex. $La(NO_3)_3$], as well as by carrying our reactions in smaller capacity acid-digestion bombs (7 mL). Identical composition and synthesis conditions have been employed for the preparation of other compounds. In the case of the Gd and Dy compounds only good quality single crystals resulted from the reaction. The yield of the product in all the cases was 75−80%. The initial characterizations were carried out using elemental analysis, powder X-ray diffraction (XRD), thermogravimetric analysis (TGA) and Infra Red (IR) spectroscopy for all the compounds. Elemental analysis: for La, C 35.92% (34.20%), H 2.58% (2.37%); for Pr, C 34.38% (34.03%), H 2.47% (2.36%); for Gd, C 32.34% (32.76%), H 2.35% (2.27%); for Dy, C 32.61%(32.38%), H 2.11% (2.25%); and for Y, C 39.55% (38.80%), H 2.69% (2.94%). The powder XRD patterns were recorded on crushed single crystals in the 2θ range 5−50° using Cu *K*α radiation (Rich-Seifert, 3000TT). The XRD patterns indicated that the products were new materials; the patterns were entirely consistent with the structures determined using the single crystal X-ray diffraction.

Thermogravimetric analysis (TGA) has been carried out (Metler-Toledo) under an oxygen atmosphere (flow rate = 50 mL/min) in the temperature range 25 to 700 °C (heating rate = 10 °C/min). The studies show identical results for all the compounds with two sharp weight losses. The initial weight loss of 10% in the range 170−210 °C corresponds to the loss of four water molecules bound to La (calcd. 8.2%) and the second weight loss of 52.9% in the range 450−475 °C corresponds to the loss of the benzene carboxylates (calcd. 56%). The calcined sample was crystalline and the powder XRD lines match well with the corresponding pure oxides in all the cases.

Infra Red (IR) spectroscopic studies have been carried out in the mid-IR region as a KBr pellet (Bruker IFS-66v). The results indicate characteristic sharp lines with almost similar bands. Minor variations between the bands have been noticed between the compounds. The observed bands are: 3485−3620 (s) cm^{-1} − ν_{as}OH, 3292−3405 (s) cm^{-1} − ν_sOH, 3061 (w) cm^{-1} − ν_s(C−H)$_{aromatic}$, 1646−1669 (m) cm^{-1} − ν_s(C=O), 1605 (w) cm^{-1} − $\delta_s H_2O$, 1543(s) − (C−C)$_{skeletal}$, 1425 (s) cm^{-1} − δ_s(COO), 1405 (s) cm^{-1} − δ(OH), 1289−1294 (s) cm^{-1} − δ(CO), 1150 (s) cm^{-1} − δ(CH$_{aromatic}$)$_{in\text{-}plane}$, 750 (s) and 843 (s) cm^{-1} − δ(CH$_{aromatic}$)$_{out\text{-}of\text{-}plane}$.

Single Crystal Structure Determination: A suitable single crystal of each was carefully selected under a polarizing microscope and glued to a thin glass fiber. Crystal structure determination by X-ray diffraction was performed on a Siemen's Smart-CCD diffractometer equipped with a normal focus, 2.4 kW sealed tube X-ray source (Mo-*K*α radiation, λ = 0.71073 Å) operating at 40 kV and 40 mA. An empirical absorption correction based on symmetry equivalent reflections was applied using the SADABS program.[40] The structure was solved and refined using the

SHELXTL-PLUS suite of programs.[41] All the hydrogen atoms of the carboxylic acids were initially located in the difference Fourier maps and for the final refinement the hydrogen atoms were placed geometrically and held in the riding mode. The hydrogen atoms of the water molecules were not located in the difference Fourier maps. Final refinement included atomic positions for all the atoms, anisotropic thermal parameters for all the non-hydrogen atoms and isotropic thermal parameters for all the hydrogen atoms. Full-matrix least-squares refinement against $|F^2|$ was carried out using the SHELXTL-PLUS[41] suite of programs. Details of the structure solution and final refinements for the compounds $[M_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$, (M = La and Pr) are given in Table 3 and for M = Gd, Dy, and Y are given in Table 4. The Selected bond lengths for $[M_2(H_2O)_4\{(1,2BDC)_2(1,4BDC)\}]$, M = La and Pr, are listed in Table 1 and for M = Gd, Dy, and Y in Table 2.

Direct Hydride/Silyl Exchange — Synthesis and X-ray Study of the Bis(silyl) Complex $[Cp_2NbH(SiCl_3)_2]$

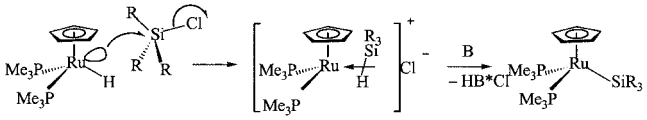
Konstantin Yu. Dorogov,[a] Andrei V. Churakov,[b] Lyudmila G. Kuzmina,[b] Judith A. K. Howard,[c] and Georgii I. Nikonov*[a]

Keywords: Hydride ligands / Niobium / Si ligands / X-ray diffraction

Niobocene trihydride reacts directly with the chlorosilanes $SiCl_2R'R''$ (R′, R″ = Me, Ph) and $SiCl_3Me$ to give the dihydridomonosilyl derivatives $[Cp_2Nb(H)_2(SiCl_nR_{3-n})]$ (n = 1, 2), whereas the analogous reaction with $SiCl_4$ affords $[Cp_2Nb(H)_2(SiCl_3)]$ and the bis(silyl) complex $[Cp_2NbH(SiCl_3)_2]$, whose X-ray structure was determined.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Silyl transition metal complexes are of great current interest as intermediates in silane dehydrogenative coupling reactions[1−3] and various hydrosilylation reactions.[4−6] It is therefore not surprising that a large number of silyl complexes have been prepared by oxidative addition of the H−Si bond.[7,8] We have been developing an alternative approach to main-group element substituted transition metal complexes L_nM-ER_m based on *direct interaction* of a basic transition metal hydride with the main-group element halides.[9−18] The niobocene trihydride Cp_2NbH_3 was a substrate of choice to test such reactivity because it possesses basic metal−hydride bonds but lacks any lone pair or a vacant coordination site, thus eliminating competing reaction pathways.[17] This approach works very well for the bond construction between metal atoms and group-5 (P, As, Sb, Bi)[9−15] and heavy group-4 (Ge, Sn, Pb)[16−18] atoms, but no such study has been done for silicon so far. In the literature there are only two reports dealing with the reactions of metal hydrides with halosilanes; both consider the reactivity of electron-rich metal centers bearing metal-centered lone pairs. Lemke et al. have recently reported that the reaction between the basic d^6 ruthenium complex $[CpRuH(PMe_3)_2]$ and chlorosilanes gives silyl derivatives by an anticipated *chloride/metal exchange* (Scheme 1).[19,20] Jutzi et al. have reported a similar reaction with the d^2 molybdenum complex $[Cp_2MoH_2]$, resulting in the silyl hydride derivatives $[Cp_2MoH(SiR_3)]$, although no mechanism was proposed.[21] There is also a practical aspect that motivated us to study the reactivity of metal−hydride bonds towards chlorosilanes: Chlorosilanes are precursors for industrially important silicones, but only a few are available by direct synthesis.[22] Metal-catalyzed hydrosilylation of unsaturated hydrocarbons,[4] which circumvents this problem, is believed to proceed by H−Si bond oxidative addition to metal atoms to generate metal hydride intermediates.[23,24] Therefore one can expect that any interaction of the resultant M−H bond with an excess of chlorosilane should have a significant impact on the overall process of hydrosilylation, for example by giving rise to side-products or deactivation of the catalyst.



Scheme 1

Here we report our investigation of the reactions of niobocene trihydride $[Cp_2NbH_3]$ (**1**) with a series of chlorosilanes and present evidence for both a single and double silyl/hydride exchange. This synthetic approach has a potential for the preparation of silyl complexes not accessible by the silane oxidative addition route.

Results and Discussion

Synthesis of Mono- and Bis(silyl) Derivatives

The addition of dichlorosilanes $SiCl_2R'R''$ (R′, R″ = Me, Ph) to **1** in the presence of NEt_3 as an HCl sponge

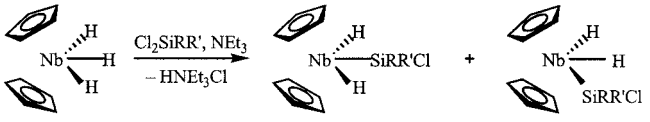
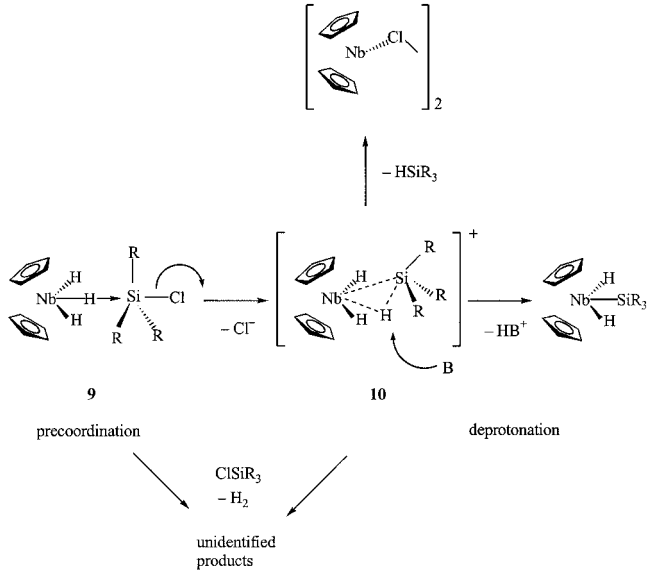
gives the mono(silyl) complexes **2**−**4** in moderate to high yields. Compounds **2**−**4** are produced as an almost equimolar mixture of the central (**a**) and lateral (**b**) isomers, the latter being stabilized by nonclassical interligand hypervalent interactions (IHI) between the hydrido and silyl ligands.[25] The analogous reaction of **1** with the trichlorosilane $SiCl_3Me$ affords a mixture, the main component of which is the lateral isomer $[Cp_2Nb(H)_2(SiMeCl_2)]$ (**5b**) together with a small amount of **5a** and the monochloride $[Cp_2NbCl]_2$.[26] In contrast, the reaction of $HSiCl_2Me$ with **1** does not give the expected complex $[Cp_2Nb(H)_2(HSiClMe)]$. Instead, **5b** is formed in high yield as an Si−H addition product (this reaction apparently proceeds by conventional H_2 elimination to give the transient Cp_2NbH, amenable to oxidative addition[27,28]). Treatment of pure **5b** with $SiCl_3Me$ results in a partial isomerization to **5a**, but **5b** remains the main component of the mixture (65%). Complexes **2**−**4** were prepared independently by oxidative addition of silanes to **1** according to established procedures.[25] Reaction of **1** with bulkier ($SiCl_2Et_2$, $SiCl_2iPr_2$) or less acidic [$SiCl(OMe)Me_2$, $SiClMe_3$] silanes does not give any significant amount of $[Cp_2Nb(H)_2(SiR_3)]$. In this case, the reaction is accompanied by dihydrogen evolution and formation of a mixture of unidentified products, the main component of which is insoluble in non-polar solvents. One of the target complexes, $[Cp_2Nb(H)_2(SiCliPr_2)]$ (**6a**), was obtained by the reaction of Cp_2NbBH_4 with $HSiCliPr_2$ in the presence of NEt_3. Only the central isomer was obtained, the structure of which was determined by an X-ray diffraction study (vide infra).



R = R' = Me **2**
R = R' = Ph **3**
R = Me, R = Ph **4**

Reaction of **1** with an excess of $SiCl_4$ is remarkable in that, in addition to the central and lateral mono(silyl) compounds $[Cp_2Nb(H)_2(SiCl_3)]$ (**7a**,**b**), the major product (60%) is the bis(silyl) complex $[Cp_2NbH(SiCl_3)_2]$ (**8**), which is formed by an unprecedented double hydride/silyl exchange. This compound was isolated from the more soluble **7a** and **7b** by washing the mixture with diethyl ether. The ^1H NMR spectrum of **8** shows the hydride resonance at $\delta = -3.29$ ppm, about 2 ppm downfield from the bis(silyl)-niobocene complexes with interligand hypervalent interactions (IHI),[25] suggesting a significantly reduced IHI. An X-ray diffraction study further confirmed this conclusion (vide infra). Compounds **7a** and **7b** were obtained independently by heating **1** with $HSiCl_3$ at 60 °C.

An important conclusion of this work is that the reactions of halosilanes with basic transition metal hydrides do not necessarily involve halogen/metal substitution/deprotonation steps because niobocene trihydride does not possess any metal-based lone-pair. Moreover, this molecule does not possess a vacant coordination site either, and the reaction occurs readily at temperatures below 25 °C, where dihydrogen elimination from pure $[Cp_2NbH_3]$ does not occur at any significant rate in the absence of silanes. Another thinkable pathway to **2**−**4** and **7** based on deprotonation of $[Cp_2NbH_3]$ by an amine, followed by nucleophilic substitution of the chloride of the silane can also be reliably ruled out, since it has previously been shown that amines cannot deprotonate $[Cp_2NbH_3]$.[17] The only reasonable option we are left with is that the reaction occurs by precoordination of the σ*-Lewis acid $Cl-SiR_3$ to the basic hydride center, forming a hypervalent $M-H\rightarrow SiR_3-Cl$ structure **9** (Scheme 2). Bridge formation is known to acidify the M−H−M′ bond drastically,[29] so that the hydride ion can now be abstracted from the complex **10** by a base as weak as an amine, affording eventually the silylated product. Several observations support this view. First, the hydrido ligands in **1** are Lewis bases of moderate strength (basicity factor $E_j = 0.93$).[30] Second, it is now recognized that even in the presence of metal-centered lone-pairs, the hydrido ligands are the kinetic sites for protonation,[31,32] and thus they are expected to be amenable for the interaction with other Lewis acids, too. It should be noted that Lewis acidity of silanes has precedents, for example, in the formation of hypervalent structures like $[H_2SiPh_3]^-$.[33] Third, the coordination of transition metal centers to M−H bonds is well established.[34] It is therefore reasonable to assume that this direct silyl/hydride exchange mechanism is general even for d^n ($n > 0$) systems, like the Ru and Mo complexes cited above. Complications can arise from the substitution of the silane in **10** by the chloride anion, leading (possibly) to the transient $[Cp_2Nb(H)_2Cl]$ and eventually to $[Cp_2NbCl]_2$ (as in the reaction with $SiCl_3Me$), and, in the case of bulkier or less acidic silanes [such as $SiCl_2Et_2$, $SiCl_2iPr_2$, $SiCl(OMe)Me_2$ and $SiClMe_3$], when Lewis acid induced dihydrogen elimination[35] occurs faster than deprotonation.



Scheme 2

X-ray Studies

The molecular structure of **8** is shown in Figure 1, and selected bond lengths and angles are given in Table 1. The Nb−Si bonds for the two chemically equivalent silyl groups are very short [2.5597(5) and 2.5776(5) Å] due to the presence of three electron-withdrawing chlorine substituents at the silicon atom. The Si−Cl bond lengths fall within a narrow range [2.0835−2.0989(7) Å] without any significant difference between the chlorine atoms in and out of the niobocene bisectral plane. This fact, and the large Si−Nb−Si bond angle of 109.61(2)°, close to the values in classical bis(silyl) systems[25,27,28,36] and about 5° larger than in complexes with IHI, suggests the absence of any significant interligand Si−H interactions. This open Si−Nb−Si bond angle results in long Si−H contacts of 2.14(3) and 2.11(3) Å, about 0.1 Å longer than in complexes with IHI. This unexpected lack of Si−H interactions is either due to the low basicity of the Nb−H bond stemming from the presence of a large number of electron-withdrawing chlorine substituents on both the silyl centers, or due to hyperconjugation between the in-plane (Si−Cl)* antibonding orbital with the out-of-plane chlorine lone pairs of electrons. It should be emphasised that high basicity of the hydride ligand is a prerequisite for this type of interligand interaction tooccur because IHI stems from the interaction of an M−H bonding orbital with the (Si−X)* antibonding orbital.[25]

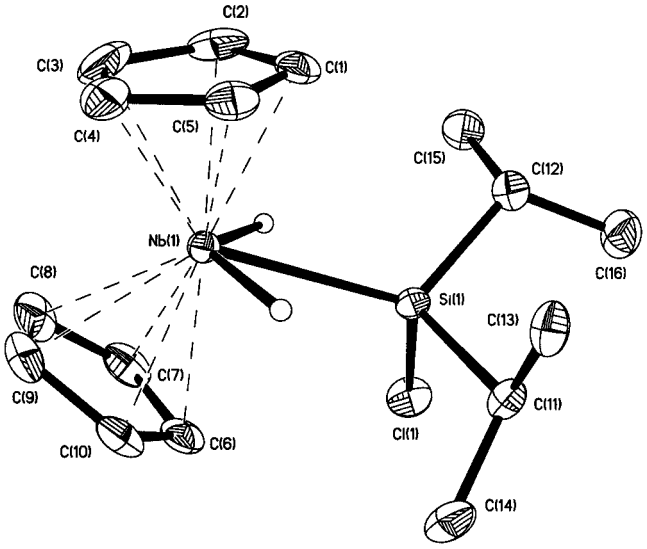

Figure 2. Molecular structure of $[Cp_2Nb(H)_2(SiCl\mathit{i}Pr_2)]$ (**6**); displacement ellipsoids are shown at the 50% probability level; all hydrogens apart from hydrides are omitted for clarity

The molecular structure of **6** is shown in Figure 2, and selected bond lengths and angles are given in Table 2. The silyl group is located in the central position in the niobocene bisectral plane, and two hydrides were found in the lateral positions with Nb−H distances of 1.65(3) Å. In spite of the presence of a chlorine substituent at silicon, the Nb−Si distance of 2.6496(7) Å is similar to the Nb−Si bond length in related alkyl- and aryl-substituted silyls.[25,27,28,36] Electron-withdrawing substituents X are known to diminish the M−Si bond lengths[37] due to the operation of Bent's rule.[38] Another exceptional feature in **6** is the long Si−Cl bond length of 2.1694(9) Å, which can be compared with the range 2.094−2.149 Å found in classical L_nMSiR_2Cl complexes (R = alkyl, aryl).[39−43] Apparently, these struc-

tural abnormalities are caused by the steric bulkiness of the two isopropyl groups at the silicon atom. Indeed, in the bulky silyl complex *fac*-[Ir(H)$_2$(Si*t*Bu$_2$Cl)(PMe$_3$)$_3$] both the Si−Cl bond of 2.187(4) Å and the Ir−Si bond of 2.392(3) Å are unusually long.[44] In the related complex [Ir(H)$_2${Si(H)Cl(C$_6$H$_3$-Mes$_2$-2,6)}(PEt$_3$)$_3$], with one very bulky substituent at the silicon atom, the Si−Cl bond length is 2.148(3) Å.[45]

Conclusion

This work has shown that halosilanes can interact with basic metal hydrides in the absence of metal-centered lone pairs, leading (depending on the silane) either to silyl derivatives or decomposition products. This reaction suggests new opportunities for the synthesis of silyl transition metal complexes and must be taken into account as a feasible (undesired) route during transition metal catalyzed hydrosilylation reactions of halosilanes.

Experimental Section

General Remarks: All manipulations were carried out using conventional Schlenk high vacuum and argon techniques. Solvents were dried with sodium or sodium benzophenone ketyl and distilled into the reaction vessel by high-vacuum gas-phase transfer. NMR spectra were recorded with a Varian VXR-400 spectrometer (^{1}H, 400 MHz; ^{13}C, 100.4 MHz). IR spectra were obtained in Nujol with an FTIR Perkin−Elmer 1600 series spectrometer. Silanes were purchased from Aldrich.

General Procedure for the Preparation of [Cp$_2$Nb(H)$_2$(SiClR$_2$)]: NEt$_3$ (2 mL, 6−7 equiv.) and 0.5 mL (ca. 2 equiv.) of the dichlorosilane were added to a solution of **1** (2−3 mmol) in diethyl ether (20 mL). A white voluminous precipitate formed immediately. The mixture was stirred for 3 h during which time a light-brown color developed. The solution was filtered and the residue washed with diethyl ether (10 mL). Volatiles were removed from the combined fractions in vacuo to give a brown solid. The material was recrystallized from a saturated diethyl ether solution at −26 °C to give the product as a mixture of two isomers. Yields: 29% (**2a**,**b**), 83% (**3a**,**b**), 35% (**4a**,**b**). **2a,b:** Characterization data as reported previously.[25] **3a:** ^{1}H NMR ([D$_6$]benzene): δ = −4.06 (s, 2 H, Nb−H), 4.53 (s, 10 H, Cp), 7.21−7.01 (Ph of **3a** and **3b**), 8.14 (d, $J_{H,H}$ = 7.1 Hz, 4 H, Ph) ppm. ^{13}C NMR ([D$_6$]benzene): δ = 148.39, 134.72 (Ph), 89.62 (s, Cp) ppm. **3b:** ^{1}H NMR ([D$_6$]benzene): δ = −3.93 (s, 1 H, Nb−H), −3.48 (s, 1 H, Nb−H), 4.62 (s, 10 H, Cp), 7.21−7.01 (Ph of **3a** and **3b**), 8.26 (d, $J_{H,H}$ = 7.4 Hz, 4 H, Ph) ppm. ^{13}C NMR ([D$_6$]benzene): δ = 145.78, 134.60 (Ph), 90.28 (s, Cp) ppm. C$_{22}$H$_{22}$ClNbSi (442.9): calcd. C 59.67, H 5.01; found C 59.34; H 5.14. **4a,b:** IR: ν(Nb−H) = 1725, 1694 cm^{-1}. **4a:** ^{1}H NMR ([D$_6$]benzene): δ = −4.15 (s, 2 H, Nb−H), 0.57 (s, 3 H, Me), 4.53 (s, 10 H, Cp), 7.20−7.02 (Ph of **4a** and **4b**), 8.26 (d, $J_{H,H}$ = 7.7 Hz, 4 H, Ph) ppm. ^{13}C NMR ([D$_6$]benzene): δ = 89.15 (s, Cp) ppm. **4b:** ^{1}H NMR ([D$_6$]benzene): δ = −4.50 (s, 1 H, Nb−H), −4.24 (s, 1 H, Nb−H), 0.91 (s, 3 H, Me), 4.50 (s, 5 H, Cp), 4.73 (s, 5 H, Cp), 7.20−7.02 (Ph of **4a** and **4b**), 8.15 (d, $J_{H,H}$ = 7.2 Hz, 4 H, Ph) ppm. ^{13}C NMR ([D$_6$]benzene): δ = 90.17 (s, Cp), 89.23 (s, Cp) ppm. C$_{17}$H$_{20}$ClNbSi (380.8): calcd. C 53.68, H 5.29; found C 53.47; H 4.90.

Preparation of [Cp$_2$Nb(H)$_2$(Si*i*Pr$_2$Cl)] (6): NEt$_3$ (2 mL) followed by HSi*i*Pr$_2$Cl (0.32 mL, 1.89 mmol) was added to a solution of Cp$_2$NbBH$_4$ (0.45 g, 1.89 mmol) in 40 mL of toluene. The mixture was stirred overnight. All volatiles were removed in vacuo and the residue was extracted with diethyl ether, filtered and concentrated under reduced vacuum until a yellow compound started to form. Keeping the mixture at −20 °C afforded **6** in the form of yellow crystals. The cold solution was further concentrated and decanted. Yield: 0.511 g (1.36 mmol, 72%). IR: ν(Nb−H) = 1736 cm^{-1}. ^{1}H NMR ([D$_6$]benzene): δ = −4.64 (s, 2 H, Nb−H), 1.35 (d, $J_{H,H}$ = 4.5 Hz, 6 H, Me), 1.32 (m, 2, CH), 1.19 (d, $J_{H,H}$ = 6.0 Hz, 6 H, Me), 4.66 (s, 10 H, Cp) ppm. ^{13}C NMR ([D$_6$]benzene): δ = 88.5 (s, Cp), 23.2 (CH), 18.9 (Me), 18.8 (Me) ppm. C$_{16}$H$_{26}$ClNbSi (374.8): calcd. C 51.27, H 6.99; found C 51.03; H 7.08.

Reactions of 1 with SiCl$_4$. Reaction a: NEt$_3$ (1.2 mL, 8.6 mmol, 2.5 equiv.) and SiCl$_4$ (0.42 mL, 3.66 mmol) were added to a solution of **1** (0.773 g, 3.42 mmol) in toluene (20 mL). A white precipitate formed immediately and the solution became amber, accompanied by gas evolution. The mixture was stirred overnight. The mixture was filtered and the residue washed with toluene (2 × 20 mL). Volatiles were removed from the combined fractions in vacuo to give a red crystalline substance. This was washed with diethyl ether (3 × 15 mL) and the volatiles were removed from the combined fractions affording a light amber crystalline solid, which according to the ^{1}H NMR spectrum was a mixture of **8**, **7a** and **7b**, along with some minor by-products. Yield: 0.361 g. The pink residue (0.100 g, 0.203 mmol, 6%) from the toluene-soluble fraction left after washing with diethyl ether was pure **8**. **Reaction b:** Compound **1** (0.77 g, 3.41 mmol) was added to a solution of NEt$_3$ (1.1 mL, 7.9 mmol, 1.1 equiv.) and SiCl$_4$ (0.8 mL, 7.0 mmol) in toluene (20 mL). Within 5 min, the solution became red-brown, accompanied by evolution of a gas that was not condensable by liquid nitrogen (apparently dihydrogen). After 0.5 h of stirring, a precipitate had formed. The mixture was then stirred overnight. The mixture was filtered and the residue washed with toluene (20 mL). The volatiles were removed from the combined fractions in vacuo to give an amber crystalline substance which, according to its ^{1}H NMR spectrum, was **8** along with a small amount of **7a** and **7b**. This material was recrystallized from diethyl ether. Yield: 0.21 g (0.43 mmol, 12%). **8:** IR: ν(Nb−H) = 1694 cm^{-1}. ^{1}H NMR ([D$_6$]benzene): δ = −3.29 (br. s, 1 H, Nb−H). 4.77 (s, 10 H, Cp) ppm. ^{13}C NMR ([D$_6$]benzene): δ = 96.6 (s, Cp) ppm. C$_{10}$H$_{11}$Cl$_6$NbSi$_2$ (492.98): calcd. C 24.36, H 2.25; found C 24.20, H 2.60. **7a:** IR: ν(Nb−H) = 1716 cm^{-1}. ^{1}H NMR ([D$_6$]benzene): δ = −3.86 (s, 2 H, Nb−H), 4.65 (s, 10 H, Cp) ppm. ^{13}C NMR ([D$_6$]benzene): δ = 90.4 ppm. **7b:** IR: ν(Nb−H) = 1766 cm^{-1}. ^{1}H NMR ([D$_6$]benzene): δ = −3.81 (s, 1 H, Nb−H), −3.69 (s, 1 H, Nb−H), 4.68 (s, 10 H, Cp) ppm. ^{13}C NMR ([D$_6$]benzene): δ = 92.2 ppm. C$_{10}$H$_{12}$Cl$_3$NbSi (359.58): calcd. C 33.41, H 3.36; found C 32.95, H 3.21.

X-ray Crystallographic Study. Crystal Data for 6: C$_{16}$H$_{26}$ClSiNb, M_r = 374.82, a = 9.32040(10), b = 11.8553(2), c = 15.60840(10) Å, β = 99.54°, V = 1700.82(4) Å^3, Z = 4, d = 1.464 g cm^{-3}, monoclinic, $P2_1/n$. Data collection: Bruker Smart three-circle diffractometer with CCD area detector with Mo-K_α radiation and graphite monochromator, μ(Mo-K_α) = 0.921 mm^{-1}, T = 120(2) °C, data-collection mode, 2.17° < Θ < 26.99°, 3706 reflections measured, 3041 symmetry-independent reflections with $I > 2\sigma(I)$. The structure was solved by direct methods and refined by full-matrix least-squares procedures with anisotropic approximation for all non-hydrogen atoms, using the SHELXTL software.[46] The hydrogen atoms were found from difference maps and refined isotropically, reflection/parameter ratio in the final refinement was

A Comparison of the Reactivity of Chloroalkanes and Chlorosilanes towards Activated Pt^{II} Complexes by DFT Calculations

Dietmar Sturmayr[a] and Ulrich Schubert*[a]

Keywords: Hemilabile ligands / Oxidative addition / Reductive elimination / Density functional calculations / Silanes

The pathways of the C–Cl bond activation of CCl_4 and CH_3Cl by the 14-electron Pt^{II} complexes $[PtMe_2(PH_3)]$ or the corresponding reactions of $SiCl_4$ and SiH_3Cl with $[PtMe(SiH_3)(PH_3)]$ were investigated by DFT calculations. The complexes $[Pt(EH_3)Me(PH_3)]$ (E = C, Si) are models for $[Pt(EH_3)Me\{(\kappa^2\text{-}P,N)\text{-}Ph_2PCH_2CH_2NMe_2\}]$, with hemilabile P,N chelating ligands, used in practical experiments. While the reaction of $[Pt(EH_3)Me(PH_3)]$ with ECl_4 results in an EH_3/ECl_3 exchange, reaction of $[Pt(EH_3)Me(PH_3)]$ with EH_3Cl results in the elimination of E_2H_6. Both reactions proceed via a five-coordinate Pt^{IV} intermediate. The elimination of Si_2H_6 is endothermic.

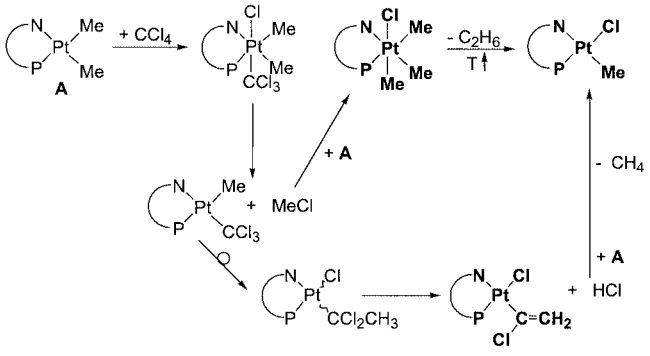
Introduction

Hemilabile chelating ligands (A∩B) are used in coordination chemistry to enhance the reactivity of metal complexes.[1] The activating effect of such ligands results from the different metal−ligand bond strengths: while one atom (A) remains coordinated to the metal, a more weakly bonded second center (B) decoordinates more easily and reversibly.

Coordinatively and electronically unsaturated complexes play a key role in many stoichiometric and catalytic reactions of Pt^{II} complexes based on oxidative addition/reductive elimination reactions. Three-coordinate Pt^{II} complexes are often required for the initial oxidative addition reactions.[2] They are generally transient species generated in situ by ligand elimination from the square-planar precursor complexes. After oxidative addition has occurred, five-coordinate Pt^{IV} complexes are key intermediates in the product-forming reductive elimination reactions.[3] The use of hemilabile chelating ligands should therefore promote both oxidative addition reactions starting from the Pt^{II} complexes and reductive elimination reactions from the corresponding Pt^{IV} intermediates.

In the chemistry of metal-silicon compounds hemilabile ligands have hardly been used. In a series of papers, we have recently shown that the reactivity of Pt^{II} complexes towards silanes is greatly enhanced by using hemilabile chelating ligands of the type $\kappa^2\text{-}Ph_2P-X-NR_2$ (denoted as P∩N).[4] Furthermore, these complexes were also found to activate C−Cl bonds.[5,6] The outcome of the reactions of $[PtMe_2\{(\kappa^2\text{-}P,N)\text{-}Ph_2PCH_2CH_2NMe_2\}]$ (**A**) with $CH_{4-n}Cl_n$ (n = 1−4) on one hand and with $PhMe_2SiCl$ on the other showed remarkable differences. In the reaction with CCl_4, the complexes $[Pt(Cl)Me(P\cap N)]$, $[Pt(Cl)Me_3(P\cap N)]$ and $[Pt(Cl)C(Cl)=CH_2(P\cap N)]$ were formed at room temperature. A suggested reaction mechanism is shown in Scheme 1 (the final products are drawn in bold). In this reaction, the complex $[Pt(Cl)Me(P\cap N)]$ can be formed by two different routes. At room temperature, this complex was only obtained by reaction of **A** with the HCl cleaved in the reaction forming the vinylidene complex. Ethane elimination from $[Pt(Cl)Me_3(P\cap N)]$ with concomitant formation of $[Pt(Cl)Me(P\cap N)]$ occurred only in boiling benzene.



Scheme 1

The analogous reactions of $CHCl_3$ and CH_2Cl_2 with $[Pt(Cl)Me(P\cap N)]$ were much slower, but resulted in analogous products; CH_3Cl only reacts slowly with $[PtMe_2(P\cap N)]$ in a hot benzene solution to form $[Pt(Cl)Me_3(P\cap N)]$ and $[Pt(Cl)Me(P\cap N)]$, and thus does not fit into the sequence.

In contrast, when $[PtMe_2\{(\kappa^2\text{-}P,N)\text{-}Ph_2PCH_2CH_2NMe_2\}]$ was reacted with $PhMe_2SiCl$, the disilane $Ph_2Me_4Si_2$ was

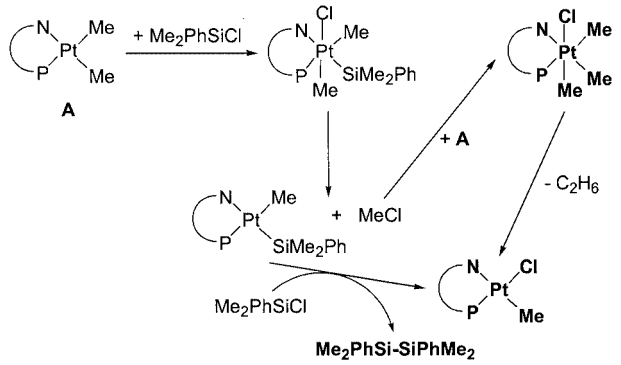

Scheme 2

formed quantitatively, together with the Pt^{IV} complex [Pt(Cl)Me_3(P∩N)] and the Pt^{II} complex [Pt(Cl)Me(P∩N)]. A possible reaction mechanism is shown in Scheme 2 (the final products are again drawn in bold).

The practical results suggested that the initial steps are the same in both the reaction of CCl_4 and $PhMe_2SiCl$. However, the [PtMe(SiMe$_2$Ph)(P∩N)] intermediate in the latter reaction reacted with another equivalent of $PhMe_2Si$-Cl to give the disilane, while the corresponding intermediate [Pt(CCl_3)Me(P∩N)] did not undergo C−C coupling.

These observations prompted us to investigate the pathways of the C−Cl and Si−Cl activation by the complexes [PtMe$_2$(P∩N)] using DFT calculations. While several theoretical calculations on the oxidative addition of silicon-element bonds to unsaturated PtL_2 (d^{10}) complexes have been performed,[7] little theoretical work has been carried out on such reactions with unsaturated d^8 $PtLX_2$ complexes.

Results and Discussion

As was already discussed in our earlier work,[8,9] at the key stage of the reaction the amino group of the chelating P∩N ligand was considered to be decoordinated, and therefore the chelate ligand was replaced by a PH_3 group in the calculations. In the four- and six-coordinate complexes, the chelating P∩N ligand was replaced by a PH_3 and NH_3 group. Further simplification was used in the reactions where the molecules $Me_2PhSiCl$ or Me_2PhSiH were involved. These were replaced by H_3SiCl and H_3SiH respectively.

Reaction of CCl_4 with [$PtMe_2(PH_3)$] (1)

As a first step in the reaction of [PtMe$_2$(P∩N)] with CCl_4, the oxidative addition of a C−Cl bond was suggested, followed by elimination of methyl chloride. The three-coordinate complex **1** and CCl_4 initially form the precursor complex $\mathbf{PC}_{1-2}$. This reaction requires 6.1 kcal/mol. In the distorted square-planar complex thus formed, the platinum atom interacts with CCl_4 through a weak Pt−Cl interaction (Pt−Cl 2.690 Å; Figure 1). The associated C−Cl bond is only slightly stretched from 1.793 Å in CCl_4 to 1.832 Å in $\mathbf{PC}_{1-2}$.

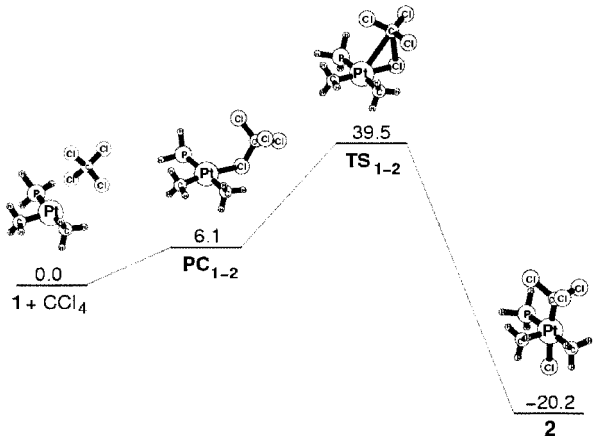

Figure 1. Reaction profile for the oxidative addition of CCl_4 to **1**; energies in kcal/mol

The transition state structure $\mathbf{TS}_{1-2}$ is formed by closing of the Pt−Cl−C angle from 118.7° in $\mathbf{PC}_{1-2}$ to 74.5° in $\mathbf{TS}_{1-2}$, corresponding to the formation of a new Pt−C bond. The C−Cl bond is now stretched to 2.788 Å, and the Pt−Cl bond is reduced to 2.481 Å. Additionally the C−Pt−Cl angle is increased from 170.9° in $\mathbf{PC}_{1-2}$ to 178.8° in $\mathbf{TS}_{1-2}$. The energy required for this change is 33.4 kcal/mol, which is quite high. On the other hand, the relaxation to [Pt(CCl_3)(Cl)$Me_2(PH_3)$] (**2**) liberates 59.7 kcal/mol. This high value is a result of the rearrangements during the relaxation to intermediate **2**, where the chlorine atom moves into the *trans* position to the CCl_3 group. The rearrangement of the chlorine is an effect of the stronger *trans* effect of the methyl group compared to the CCl_3 group.[8] The overall reaction of **1** with CCl_4 is best described as an oxidative addition via a three-center transition state. As expected from the different electronegativities, the Pt−Cl interaction develops faster than the Pt−C interaction.

The geometry optimization on the reactant side of $\mathbf{TS}_{3-4}$ leads to the square-pyramidal complex [Pt(CCl_3)(Cl)$Me_2(PH_3)$] (**3**) which is nearly equivalent to **2**. This shows that the two reaction profiles in Figure 1 and Figure 2 are connected. Hence the next stage of the reaction mechanism, which eventually leads to a reductive elimination of methyl chloride, begins with **3** (Figure 2). The energy required to form $\mathbf{TS}_{3-4}$ from intermediate **3** is 35.8 kcal/mol. The geometric changes on the way from **3** to **4** + $ClCH_3$ mirror those during the oxidative addition of CCl_4, i.e. the Cl−Pt−C angle closes from 96.1° in **3** to 53.9° in $\mathbf{TS}_{3-4}$, and the Pt−C bond is stretched from 2.072 Å to 2.603 Å. The change in the Pt−Cl bond length from 2.414 Å to 2.461 Å is much smaller. Through the changes in the geometry, a weak C−Cl interaction with 2.298 Å is formed.

The Pt−C bond is broken during the relaxation to $\mathbf{PC}_{3-4}$, and the C−Cl bond is fully formed. The bond length of 1.821 Å is close to the final C−Cl bond length of 1.806 Å in MeCl. The Pt−Cl bond length is increased to

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

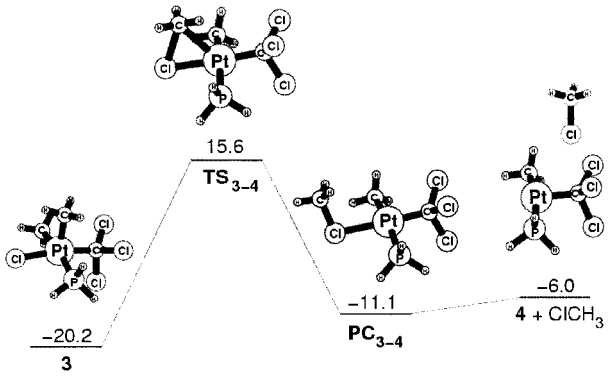

Figure 2. Continuing reaction profile for the reaction of **1** with CCl_4 (elimination of MeCl); energies in kcal/mol

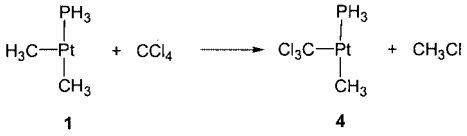
2.617 Å and the energy released by the relaxation is 26.7 kcal/mol. MeCl is eventually fully dissociated. The last step is endothermic by +5.1 kcal/mol, but the whole reaction [Equation (1)] is exothermic by −6.0 kcal/mol.

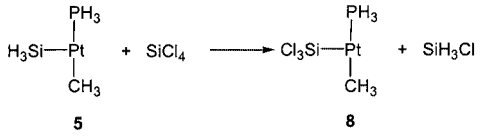


(1)

The formation of **4** is the key step for the reaction of CCl_4 with the dimethylplatinum complex **1**. This, in turn, allows further reactions to happen (Scheme 1), all of which are exothermic. Although there is a high activation energy barrier for the oxidative CCl_4 addition to **1**, these following exothermic reactions produce enough energy for this barrier to be overcome.[9]

Reaction of $SiCl_4$ with [Pt(SiH$_3$)Me(PH$_3$)] (5)

Though not yet practically investigated, the reaction between the three-coordinate complex **5** and $SiCl_4$ was also investigated for comparison. This is the silicon analogue to the previously discussed reaction, i.e. the SiH_3 group in the starting complex **5** is replaced by a $SiCl_3$ ligand [Equation (2)]. We have previously shown that the energetically preferred structure of the T-shaped complex **5** is the one where PH_3 and CH_3 are *trans* to each other.[8]



(2)

Complex **5** reacts with $SiCl_4$ to form the precursor complex $\mathbf{PC_{5-6}}$. The reaction requires 8.5 kcal/mol, and a weak Pt−Cl bond is formed. The Pt−Cl distance in $\mathbf{PC_{5-6}}$ (3.127 Å) is considerably longer than the corresponding distance in the reaction with CCl_4 (precursor complex $\mathbf{PC_{1-2}}$). This is due to the SiH_3 group in $\mathbf{PC_{5-6}}$ having a stronger *trans* effect than the methyl group in the *trans* position in $\mathbf{PC_{1-2}}$. The associated Si−Cl bond length (2.059 Å) is nearly unchanged relative to the free $SiCl_4$ molecule (2.047 Å).

As in the CCl_4 reaction, the Pt−Si bond forms by closing of the Pt−Cl−Si angle from 116.5° in $\mathbf{PC_{5-6}}$ to 65.2° in $\mathbf{TS_{5-6}}$, stretching of the Si−Cl bond to 2.205 Å and reducing the Pt−Cl bond length to 2.654 Å.

Compared to the reaction with CCl_4, the incoming $SiCl_4$ molecule is not as distorted in the transition-state structure as the CCl_4 molecule was. As a result, the energy required for this change is, at 11.8 kcal/mol, much lower than the 33.4 kcal/mol required for the reaction with CCl_4. On the other hand the relaxation to [Pt(Cl)Me(SiH$_3$)(SiCl$_3$)(PH$_3$)] (**6**) liberates only 18.9 kcal/mol. A rearrangement occurs during the relaxation to the intermediate **6**, where the chlorine atom moves *trans* to the $SiCl_3$ group, analogous to the CCl_4 reaction. This is again an effect of the stronger *trans* effect of the SiH_3 group compared to the $SiCl_3$ group. It is interesting to note that the formation of the intermediate **6** is slightly endothermic, in comparison to the analogous reaction with CCl_4, where the formation of the intermediate **2/3** was exothermic.

The geometry optimization on the reactant side of $\mathbf{TS_{7-8}}$ leads to the five-coordinate complex [Pt(Cl)Me(SiH$_3$)(SiCl$_3$)(PH$_3$)] (**7**) which is equivalent to **6**. Although the energy difference is 0.7 kcal/mol, the assumption that the two reaction profiles in Figure 3 and Figure 4 are connected is still valid. The energy required to form $\mathbf{TS_{7-8}}$ from **7** is

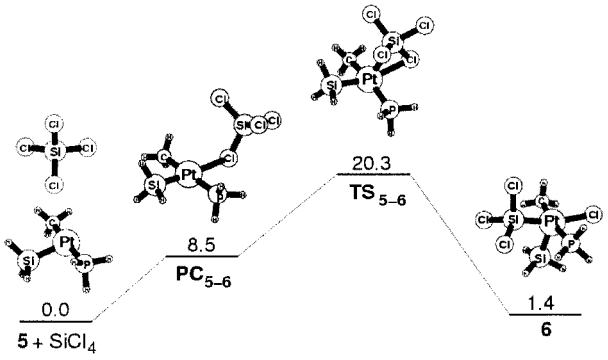


Figure 3. Reaction profile for the reaction of **5** with $SiCl_4$; energies in kcal/mol

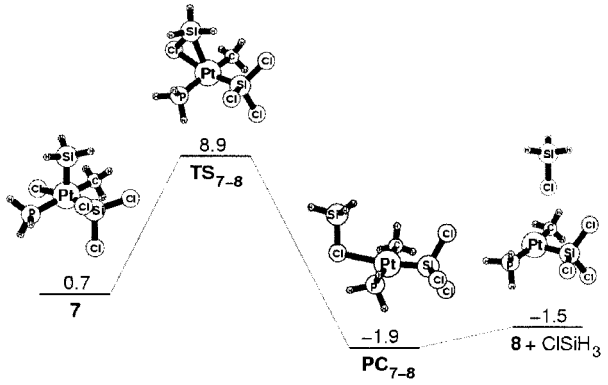

Figure 4. Continuing reaction profile for the reaction of **5** with $SiCl_4$ (elimination of H_3SiCl); energies in kcal/mol

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

8.2 kcal/mol. This is again much less than in the CCl_4 reaction. The Cl−Pt−Si angle is changed from 101.5° in **7** to 52.8° in $\mathbf{TS}_{7-8}$, the Pt−Si bond is stretched from 2.360 Å to 2.644 Å, and a weak Si−Cl bond (2.318 Å) is formed. The change in the Pt−Cl bond length (from 2.439 Å to 2.567 Å) is much larger than for the case of CCl_4.

During the relaxation of $\mathbf{TS}_{7-8}$ to $\mathbf{PC}_{7-8}$, the Pt−C bond is broken and the Si−Cl bond is fully formed. The bond length of 2.114 Å is close to that of 2.081 Å in the H_3SiCl molecule. The Pt−Cl bond is lengthened to 2.849 Å and the energy released by the relaxation is 10.8 kcal/mol. Finally the H_3SiCl molecule is fully dissociated. The whole reaction [Equation (2)] is slightly exothermic by −1.5 kcal/mol.

Reaction of CH_3Cl with $[PtMe_2(NH_3)(PH_3)]$ (9)

Practical experiments have shown that a six-coordinate Pt^{IV} complex is formed in the reaction of $[PtMe_2(P\cap N)]$ with MeCl [Equation (3)] in contrast to the reaction with CCl_4.[5] For the calculation of the reaction profile (Figure 5), the four-coordinate complex **9** was taken as a starting point. The first step in the reaction with MeCl is the formation of the four-coordinate precursor $\mathbf{PC}_{9-10}$, which requires 14.5 kcal/mol. For the formation of this precursor complex the nitrogen must decoordinate, and a weak Pt−Cl bond (2.709 Å) must form.

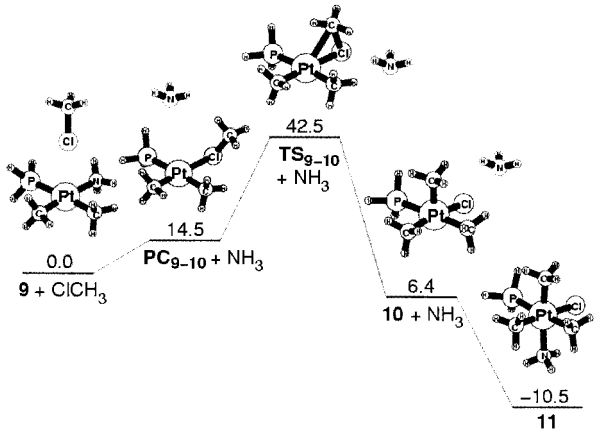

Figure 5. Reaction profile for the reaction of **9** with CH_3Cl; energies in kcal/mol

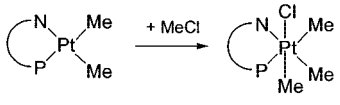

(3)

The energy required to form $\mathbf{TS}_{9-10}$ from $\mathbf{PC_{9-10}}$ is 28.0 kcal/mol, which is lower than the 33.4 kcal/mol for the case of CCl_4. In $\mathbf{TS}_{9-10}$ the carbon atom approaches the platinum atom (Pt−C 2.580 Å), while the corresponding C−Cl bond is stretched to 2.270 Å. The Pt−Cl bond is now 2.526 Å, and the Cl−Pt−C angle is 52.8°. During the relaxation to $[Pt(Cl)Me_3(PH_3)]$ (**10**) the Pt−C bond length is decreased to 2.063 Å while the C−Cl bond is broken. The Pt−Cl bond is now 2.466 Å and the Cl−Pt−C angle is 105.2°. Noticeably, the chlorine is not re-orientated as in the case of **2** (Figure 1). This is due to the fact that the incoming alkyl ligand is the same as the existing alkyl ligands (i.e. the chlorine is already *trans* to a methyl group).

The six-coordinate complex $[Pt(Cl)Me_3(NH_3)(PH_3)]$ (**11**) is formed through the re-coordination of the nitrogen. Here the platinum has an octahedral geometry as seen in the corresponding crystal structure of $[Pt(Cl)Me_3\{(\kappa^2\text{-}P,N)\text{-}Ph_2PCH_2CH_2NMe_2\}]$.[5] The reaction to form **11** is exothermic by −10.5 kcal/mol. The six-coordinate complex **11** is the only reaction product, because formation of a vinylidene complex is not possible. Elimination of MeCl would just reverse the reaction, but would not lead to the formation of a new complex.

Although the reaction to form **11** is exothermic, the practical results showed that ethane elimination can occur at elevated temperatures. The profile of this reaction is shown in Figure 6. Starting from the six-coordinate complex **11**, the five-coordinate intermediate $[Pt(Cl)Me_3(PH_3)]$ (**12**) is formed through the de-coordination of the nitrogen. This has a trigonal-bipyramidal geometry instead of a square-pyramidal geometry as in **10**. However, the trigonal-bipyramidal structure is only 0.4 kcal/mol higher in energy than the square-pyramidal structure. The formation of **12** needs 17.3 kcal/mol, and the C−C distance in **12** is 2.662 Å indicating that the two carbons approach each other.

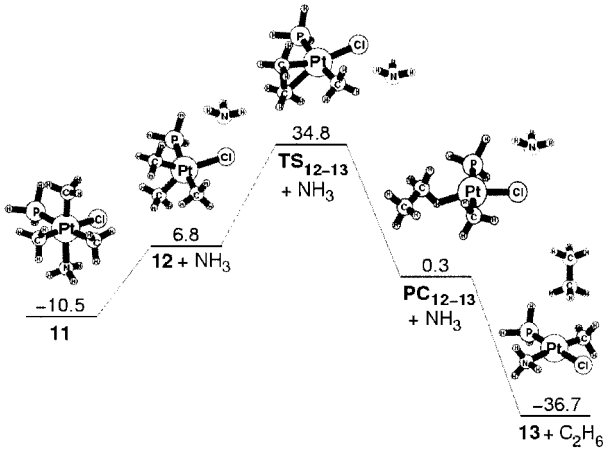

Figure 6. Elimination of ethane from **11**; energies in kcal/mol

An energy of 28.0 kcal/mol is required to form the transition state $\mathbf{TS}_{12-13}$. During this process both Pt−C bonds are lengthened, while a C−C bond (1.908 Å) is formed. On the other hand, the Pt−Cl bond is decreased from 2.443 Å in **12** to 2.367 Å in $\mathbf{TS}_{12-13}$. As shown in Figure 6, the vector of the outgoing C_2H_6 molecule is perpendicular to the plane of the remaining three-coordinate platinum complex. The C−C bond length of 1.530 Å and the Pt−C bond of 2.614 Å suggests that in the complex $\mathbf{PC}_{12-13}$ the ethane is fully formed. In the final step the nitrogen is re-coordinated, an energy of 37.0 kcal/mol is released and the complex $[Pt(Cl)Me(NH_3)(PH_3)]$ (**13**) is formed, where the chlorine is in the energetically favored *trans*-position to the phosphorus. Reductive elimination of ethane from the six-coor-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dinate complex **11** releases an overall energy of 26.2 kcal/mol.

Reaction of SiH_3Cl with [PtMe(SiH_3)(PH_3)] (5)

For a further comparison with the carbon complexes, and due to interesting practical results (the formation of disilane), the corresponding reaction with SiH_3Cl and the platinum complex **5** [Equation (4)] was investigated. Starting from reactants **5** and SiH_3Cl the precursor $\mathbf{PC_{5-14}}$ is formed. This requires 1.3 kcal/mol (Figure 7).

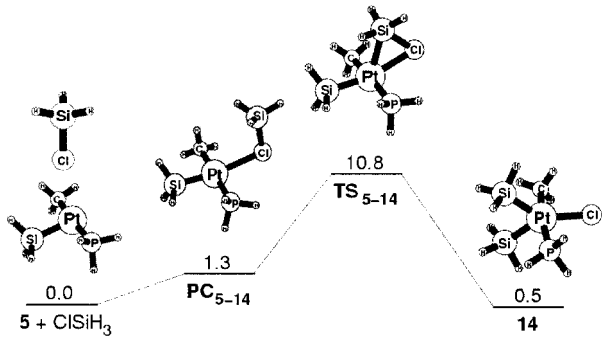

Figure 7. Reaction profile for the reaction **5** with SiH_3Cl; energies in kcal/mol

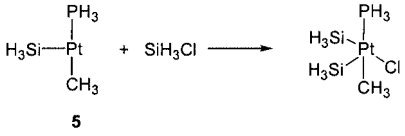

(4)

In the complex $\mathbf{PC_{5-14}}$, the chlorine of SiH_3Cl interacts weakly with the platinum (Pt−Cl 2.964 Å). Owing to the Pt−Cl interaction, the Si−Cl bond is weakened and stretched from 2.082 Å to 2.103 Å. The SiH_3Cl molecule approaches the platinum complex not quite perpendicularly to the Pt−Si bond but instead it tips slightly towards the carbon atom, giving a Si−Pt−Cl−Si dihedral angle of 27.7°.

In the transition state $\mathbf{TS_{5-14}}$ the Pt−Cl bond is further decreased to 2.608 Å, and the formation of a 2.599 Å long Pt−Si interaction can be observed. On the other hand, the Si−Cl bond is increased from 2.103 Å in $\mathbf{PC_{5-14}}$ to 2.316 Å in $\mathbf{TS_{5-14}}$. The energy required to form the transition state $\mathbf{TS_{5-14}}$ from the precursor $\mathbf{PC_{5-14}}$ is 9.5 kcal/mol.

The distorted trigonal-bipyramidal complex [Pt(Cl)Me(SiH_3)$_2$(PH_3)] (**14**) is formed from $\mathbf{TS_{5-14}}$, and 10.3 kcal/mol is released. During this process the Si−Cl bond is broken and the Pt−Si bond is fully formed. The final complex **14** consists of two equivalent SiH_3 groups. The geometry optimization on the reactant side of $\mathbf{TS_{15-16}}$ leads to the five-coordinate complex [Pt(Cl)Me(SiH_3)$_2$(PH_3)] (**15**), which is equivalent to **14**, with the SiH_3 and the Cl ligand in the trigonal plane.

The Si−Si distance of 3.026 Å in **15** is reduced to 2.492 Å in $\mathbf{TS_{15-16}}$ (Figure 8). In $\mathbf{TS_{15-16}}$ a 1.988 Å long Pt−H bond is formed, concurrently the corresponding Si−H bond increases from 1.488 Å to 1.564 Å and the Pt−Si bond is lengthened to 2.452 Å. The other Pt−Si bond (2.652 Å) is even longer. The energy required to form $\mathbf{TS_{15-16}}$, which can mainly be assigned to the formation of the Si−Si bond, is 30.1 kcal/mol. The five-coordinate complex [Pt(Cl)(H)Me(Si_2H_5)(PH_3)] (**16**) is formed freeing 19.9 kcal/mol. During the relaxation the Si−Si bond is reduced to 2.359 Å, and the Pt−H bond is fully formed with a bond length of 1.577 Å. The Si−Pt−H angle is 70.2° and the H−Pt−Cl angle 165.4°.

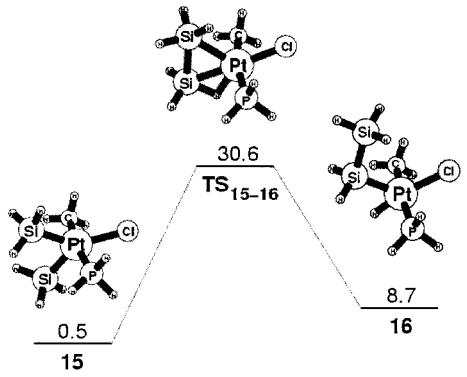

Figure 8. Continuing reaction profile for the reaction of **5** with $ClSiH_3$; energies in kcal/mol

The obvious final step would be the elimination of the disilane Si_2H_6. This step has not been calculated, but instead the comparable elimination of SiH_4 starting from [Pt(Cl)(H)Me(SiH_3)(PH_3)] (**17**) (Figure 9) was calculated.

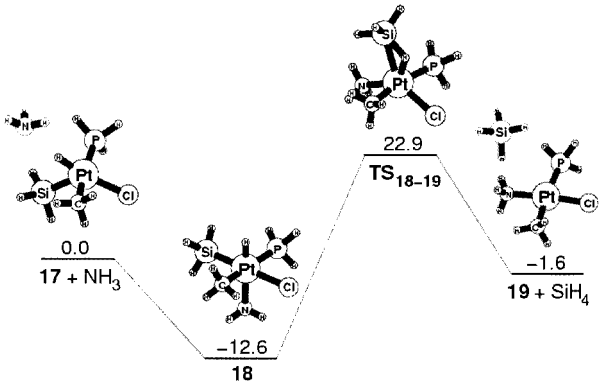

Figure 9. Reaction profile for the reaction of **17** with SiH_4; energies in kcal/mol

In the first step the nitrogen is re-coordinated to form the six-coordinate complex **18**, freeing 12.6 kcal/mol; 35.5 kcal/mol is required to form the transition state structure $\mathbf{TS_{18-19}}$. In $\mathbf{TS_{18-19}}$ the nitrogen is still coordinated, therefore the formation of the six-coordinate intermediate **18** is necessary to allow the reductive elimination of SiH_4. The elimination of SiH_4 and formation of [Pt(Cl)Me(NH_3)(PH_3)] (**19**) frees 24.5 kcal/mol. Although **19** is the energetically less favorable isomer (compared to **13**) the reaction energy is slightly exothermic at −1.6 kcal/

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mol. Rearrangement to the energetically favored isomer **13** would liberate an additional 9.0 kcal/mol. It is assumed that **16** can react in the same way as **17**, forming the disilane Si_2H_6.

In the practical experiment, the dimethylplatinum complex [$PtMe_2$(P∩N)] was reacted with $ClSiMe_2Ph$. In the first step of this reaction the methylsilylplatinum complex [PtMe($SiMe_2Ph$)(P∩N)] was formed, and the freed MeCl reacted with still available [$PtMe_2$(P∩N)] as described previously. The latter reaction is exothermic, which enables the total reaction to occur. It should be noted that in the reaction of [$PtMe_2$(P∩N)] with $ClSiMe_2Ph$ no hydrido silyl complex (corresponding to **16**) can be formed, because no hydrogen substituents are present. However, the energetics of the overall reaction for the elimination of the disilane directly from **15** (without the intermediacy of **16**) should be very similar to that calculated above.

Conclusions

A comparison of the chlorosilane and chloroalkane reactions with the three-coordinate Pt^{II} complexes shows that the reactions proceed in a geometrically very similar manner. A weak Pt−Cl interaction develops first, which then proceeds to a three-center transition state. The transition-state structures of incoming silanes are less disturbed than those of the corresponding carbon compounds. As a result the activation energies for CCl_4 and CH_3Cl (39.5 and 42.5 kcal/mol, respectively) are much higher than that for $SiCl_4$ and SiH_3Cl (20.3 and 10.8 kcal/mol). On the other hand, the product side relaxation of the transition state structures of the carbon compounds frees 59.7 kcal/mol for CCl_4 and 36.1 kcal/mol for CH_3Cl, which is much more than the 18.9 kcal/mol for $SiCl_4$, and 10.3 kcal/mol for SiH_3Cl.

For the distorted square-pyramidal intermediates **2**, **6**, **10** and **14** (Figures 1, 3, 5 and 7) the following points can be made: (i) When the substituents on the incoming alkyl or silyl group are different from that of the group in the T-shaped precursor complex (CCl_3 and $SiCl_3$ vs. CH_3 and SiH_3) then a rearrangement occurs, which puts the incoming groups (Cl and CCl_3 or $SiCl_3$) *trans* to each other in the square plane, i.e. the *axial* position of the square pyramid is occupied by a CH_3 or SiH_3 ligand, respectively; (ii) When the incoming alkyl or silyl group is the same as the ligand already present (CH_3 or SiH_3), then the incoming groups (Cl and CH_3 or SiH_3) are *cis* (axial/equatorial) in the square-pyramidal intermediate.

Starting from these intermediates (**2**, **6**, **10** and **14**), the reductive elimination of a C−Cl or Si−Cl bond is apparently preferred over the elimination of a C−C or Si−Si bond. When the incoming alkyl or silyl group is the same as the ligand already bonded to the T-shaped precursor complex, reductive C−Cl or Si−Cl elimination would only reverse the reaction.

The differences in the reactivity of CCl_4 and $Me_2PhSiCl$ found in the practical experiments (Scheme 1 and 2) can thus be traced back to the exothermic nature of the reaction leading from [Pt(CCl_3)Me(P∩N)] (corresponding to **4**) to the vinylidene complex [Pt(Cl)($CCl{=}CH_2$)(P∩N)] and HCl {which further reacts with [$PtMe_2$(P∩N)] in an exothermic reaction}. For the corresponding silyl complex (corresponding to **8**) this reaction is not possible, because it would lead to a highly energetic Si=C bond. This reaction is also not possible for [$PtMe_2$(P∩N)] (no chlorine present that can rearrange), therefore formation of **11** and elimination of ethane (at higher temperatures) is the only reaction possibility.

Computational Details

The geometry optimizations of the equilibrium geometries and transition structures were performed using the B3LYP version of DFT, which is comprised of Becke's hybrid three-parameter exchange functional and the correlation functional of Lee, Yang and Parr.[10,11] The 6-31G++(d) basis set was used an all atoms for the calculations. The relativistic effective core potential and basis set of Preuss and co-workers (which is available in the Gaussian 98 software package as SDD basis set) was used for platinum.[12] Vibrational mode analyses were carried out to confirm that on potential energy surfaces optimized geometries correspond to a local minimum without an imaginary frequency mode or a saddle point with only one imaginary mode. Corrections of zero-point vibrational energies were taken into account in stationary structures obtained. All of the calculations were carried out with the Gaussian 98 package of electronic structure programs.[13]

Structural Snapshots of a Dynamic Coordination Sphere in Model Complexes for Catechol 1,2-Dioxygenases

Michael Merkel,[a] David Schnieders,[a] Sascha M. Baldeau,[a] and Bernt Krebs*[a]

Keywords: Iron / Tripodal ligands / Coordination modes / Enzymes

A series of mononuclear iron(III) complexes as models for intradiol cleaving catechol dioxygenases has been synthesized. In all six compounds, the iron(III) core is coordinated by the ligand [(6-bromo-2-pyridyl)methyl]bis[(2-pyridyl)methyl]amine (brtpa) which mimics the endogenous ligands of this enzyme class and their dynamic behavior. Its steric hindrance pushes the α-substituted pyridine arm of the ligand away from the coordination site in the presence of nucleophiles. This effect turns the iron-brtpa system into an excellent model system for the first step in the reaction mechanism of intradiol cleaving chatechol dioxygenases. The proton acceptor abilities of the bromopyridyl arm are underlined by a hydrogen bond to a coordinated methanol molecule in one of the new compounds and by base dependent kinetic investigations. The presented model system is an effective catalyst that requires between 0.5 and 1.0 fewer equivalents of external base than most other complexes due to the integration of an internal base.

Introduction

The metabolism of aromatic compounds by aerobic bacteria plays an important role in the global carbon cycle.[1,2] Catechol dioxygenases are mononuclear non-heme iron enzymes that can be isolated from bacteria. They catalyze the insertion of dioxygen into catechols with simultaneous ring cleavage. With regards to their regioselectivity they are divided into two major subgroups namely the intradiol and the extradiol cleaving enzymes.[3,4] Protocatechuate 3,4-dioxygenase (3,4-PCD) belongs to the class of intradiol cleaving catechol dioxygenases which catalyze the incorporation of dioxygen into catechols yielding derivatives of *cis,cis*-muconic acid. The X-ray crystal structure of this metalloenzyme reveals a trigonal bipyramidal geometry around the iron(III) core.[5,6] The first ligand sphere consists of two histidines and two tyrosines as endogenous protein ligands (His460, His462, Tyr408, Tyr447) and one solvent derived hydroxide ligand. Spectroscopic and electronic structure studies confirm that the axial Tyr447-Fe^{III} bond is weaker than the equatorial tyrosinate-iron(III) bond.[7]

The interaction of a substrate with Fe^{3+} causes the dissociation of the axial tyrosine and the hydroxide ligand leading to a substrate-iron(III) complex that is best described as octahedral with a vacant site (see Figure 1).[8,9] The departing ligands are believed to act as proton acceptors resulting in a dianionic coordination of the substrate. This enhances its ketonization, yielding a transient carbanion or Fe^{II}-semiquinone radical. The subsequent reaction with O_2 yields a peroxy intermediate which is coordinated to the iron through the remaining open coordination site. Decomposition of this peroxy adduct by a Criegee-type rearrangement affords muconic anhydride.

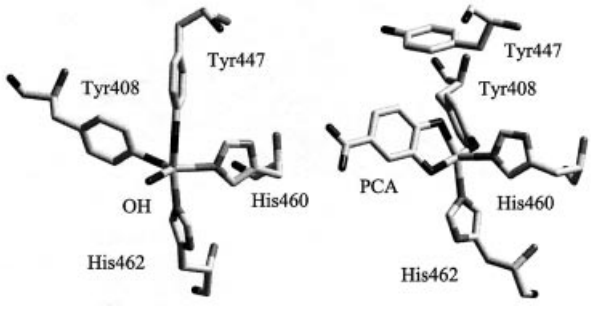

Figure 1. Active site of 3,4-PCD with hydroxide (left) and substrate (right)

In previous studies several functional models have been synthesized in order to gain insight in to the mechanism of catechol cleavage.[10] Whereas in models containing macrocyclic ligands no ligand exchange was observed,[11,12] partial substitutions were reported for coordinated tripodal ligands.[13] Herein we describe 6 crystal structures as well as functional investigations that demonstrate a weak bonding of the substituted arm of [(6-bromo-2-pyridyl)methyl]bis[(2-pyridyl)methyl]amine (brtpa) in iron complexes. The ability to act as an internal base and the replacement of the

bromo-substituted pyridine arm by other ligands makes it an excellent functional model for Tyr447 in the enzyme.

Results and Discussion

We were able to characterize six new iron(III) coordination compounds containing the ligand brtpa. In five of these complexes tetrachlorocatecholate (tcc) or tetrabromocatecholate (tbc) was used as a substrate analog, respectively. These catecholates yield compounds that are good structural models for the substrate bound active site of the enzyme and that are not sensitive to air.[14−17]

$[Fe^{III}(brtpa)Br_3]$ (1)

The unit cell of compound **1** consists of four complex molecules, the structure of one such molecule is shown in Figure 2. The structure of **1** is closely related to that of $[Fe^{III}(brtpa)Cl_3]$ reported by Mandon et al.[18] The distorted octahedral coordination sphere of the iron(III) core is composed of three bromide ions and the brtpa ligand. The substituted pyridine does not coordinate, resulting in a tridentate facial coordination mode of the ligand. The three Fe−Br bonds are almost identical [2.447(1), 2.446(1), and 2.441(1) Å] and, as expected, significantly longer than the Fe−Cl bonds in the complex reported by Mandon et al. With respect to the nature of the N donor moieties, the largest Fe−N bond length with a value of 2.298(4) Å occurs between Fe(1) and the tertiary amine nitrogen N(1). Due to their ability to act as π-donors the distances between the nitrogens of the coordinated pyridines and the iron core are significantly shorter [2.197(4) Å and 2.183(4) Å].

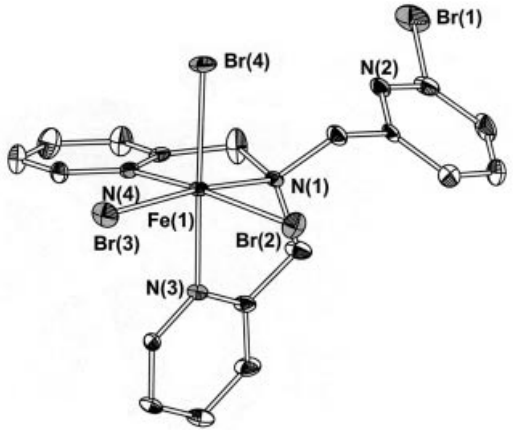

Figure 2. Ellipsoid plot of $[Fe^{III}(brtpa)Br_3]$ (50 % probability); hydrogen atoms omitted for clarity

The existence of five-membered chelate rings causes a distortion of the octahedron towards the tertiary amino group. This is reflected in the low values of the N−Fe−N angles [76.4(2) to 79.8(2)°]. Consequently the angles between the three bromide ligands are expanded [96.1(1) to 99.8(1)°].

$[Fe^{III}(brtpa)(tbc)]ClO_4·H_2O$ (2)

The monoclinic unit cell of compound **2** contains four complex cations, four disordered perchlorates and four water molecules. In contrast to Mandon's $[Fe(brtpa)Cl_3]$ complex[18] and the other iron complexes in this work, compound **2** is the first example of an iron(III) complex in which the brtpa ligand exhibits a tetradentate coordination mode. The remaining coordination sites are occupied by a tetrabromocatecholate dianion (tbc) resulting in a disordered octahedral coordination sphere (Figure 3).

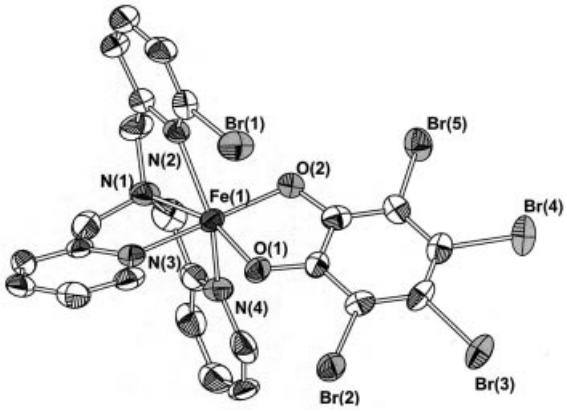

Figure 3. Ellipsoid plot of $[Fe^{III}(brtpa)(tbc)]^+$ (50 % probability); hydrogen atoms omitted for clarity

The similarity of the Fe−O bond lengths [Fe−O(1) = 1.941(5) Å and Fe−O(2) = 1.945(5) Å] demonstrates that the inhibitor substrate coordinates as a dianion rather than a semiquinone. The length of the Fe−N(2) bond [2.220(6) Å] which is the largest Fe−N distance in this complex indicates the weakness of this interaction. The character of this bond originates from the steric demand of the bromo substituent. As a result of this, the O(1)−Fe−N(2) angle is widened to 119.0(2)° which is the largest deviation from the ideal 90° angle and has two effects on the coordination of the catecholate. The first is a twist of 17.8° between the two planes through Fe, N(1), N(3) and Fe, O(1), O(2). Secondly the catecholate is bent down by 12.0° around the O(1)−O(2) axis (see Figure 4). Once again the preorganized five-membered chelate rings of the ligand lead to a significant contraction of the corresponding bond angles.

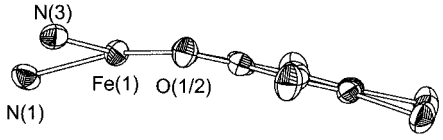

Figure 4. Ellipsoid plot of the catecholate binding in $[Fe^{III}(brtpa)(tbc)]^+$ (50 % probability)

$[Fe^{III}(brtpa)(tcc)(CH_3OH)]ClO_4·CH_3OH$ (3)

Four complex cations, four disordered perchlorate anions and four solvent molecules (methanol) form the unit cell of compound **3**. The iron(III) core is surrounded by the inhibitor substrate tetrachlorocatecholate (tcc), one methanol

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

molecule and brtpa which coordinates as a tridentate meridional ligand. The bromo-substituted ligand arm has been displaced by the methanol molecule but participates in an intramolecular hydrogen bond with the proton of the coordinated alcohol function. Thus N(2) is tied at a distance of 2.675(6) Å from O(3) and 3.650(4) Å from the iron core. Although methanol is not a particularly good ligand, hydrogen bonds seem to stabilize its coordination to metal centers.[19] Similar intramolecular hydrogen bonds between metal bound solvent molecules and pyridyl moieties have been reported for copper(II) complexes[20,21] and recently for an iron(III) complex.[22] The Fe−O(3) distance of 2.050(4) Å indicates a weaker Fe−O bond compared with the anionic Fe−O_{tcc} interaction [1.924(3) Å and 1.975(4) Å]. The difference in the Fe−O_{tcc} bonds is a consequence of the *trans* effect of the opposing amine nitrogen and oxygen [O(3)] donors.

Due to the limited bite of five-membered chelate rings, the complex cation in **3** reflects the typical distortion of the octahedral coordination sphere. N(1)−Fe−N(3) [77.2(2)°], N(1)−Fe−N(4) [76.6(2)°], and O(1)−Fe−O(2) [83.3(2)°] are reduced, whereas O(1)−Fe−N(3) [97.8(2)°] and O(1)−Fe−N(4) [108.8(2)°] are widened (Figure 5).

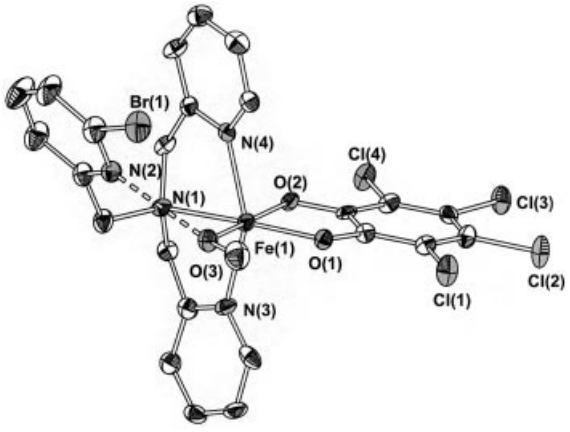

Figure 5. Ellipsoid plot of $[Fe^{III}(brtpa)(tcc)(CH_3OH)]^+$ (50 % probability); hydrogen atoms omitted for clarity

$[Fe^{III}(brtpa)(tcc)Cl]$ (4)

The monoclinic unit cell of compound **4** contains four complex molecules. As in compound **1** the brtpa ligand coordinates in a tridentate facial fashion. The equatorial plane of the octahedron is occupied by the two unsubstituted pyridine arms and the tcc dianion, whereas the axial positions are occupied by the tertiary amine nitrogen and a chloride ligand. As expected, the Fe−N(1) bond is the longest Fe−N bond in this complex [2.337(3) Å]. The slight difference in the Fe−O_{tcc} distance is caused by the asymmetry of the ligand's coordination. The N(1)−C(1) bond is almost in an eclipsed position towards the Fe(1)−O(2) bond, while the Fe(1)−O(1) bond is staggered between N(1)−C(1) and N(1)−C(7). This asymmetry also results in different O(1)−Fe−N(1) and O(2)−Fe−N(1) angles with values of 86.0(2) and 96.7(2)°, respectively. The non coordinating nitrogen atom N(2) of the bromo-substituted ligand arm lies at a distance of 5.278(4) Å from the iron core in this complex (Figure 6).

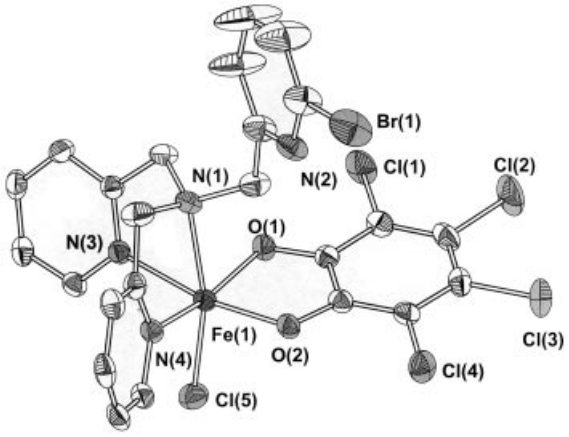

Figure 6. Ellipsoid plot of $[Fe^{III}(brtpa)(tcc)Cl]$ (50 % probability); hydrogen atoms omitted for clarity

$[Fe^{III}(brtpa)(tcc)NO_3]$ (5), $[Fe^{III}(brtpa)(tbc)NO_3]$ (6)

The crystal structures of compounds **5** and **6** show large resemblances to each other. In each of them the unit cell is composed of four iron(III) complexes. The brtpa ligand coordinates in a tridentate facial fashion with its two unsubstituted pyridine units. A nitrate anion and a dianionic catecholate (tcc in **5**; tbc in **6**) complete the octahedral coordination sphere.

The slight difference of 0.02 Å (**5**) and 0.03 Å (**6**) in the iron-catecholate bond lengths is a consequence of the orientation of the non-coordinating bromopyridine arm. This part of the ligand is orientated towards O(2) and thus the O(2)−Fe−N(1) angle is about 12° larger than O(1)−Fe−N(1) in both compounds. Characteristic for tripodal ligands are the long Fe−N(1) distances of 2.260(3) Å (**5**) and 2.252(4) Å (**6**), respectively, and the small angles along the five-membered chelate rings with values of less than 80°.

The large resemblances of **5** and **6** demonstrate that it is legitimate to compare compounds **2**, **3**, and **4** even though different inhibitor substrates are involved. As a representative of the two isostructural compounds the crystal structure of **5** is shown in Figure 7.

Selected bond lengths and angles for the iron(III) complexes are reported in Table 1.

Oxygenation of Bonded dbc in the Presence of Dioxygen

Stoichiometric Kinetic Studies

In order to gain information on the catechol cleavage activity, the decrease in the lower energy LMCT band was

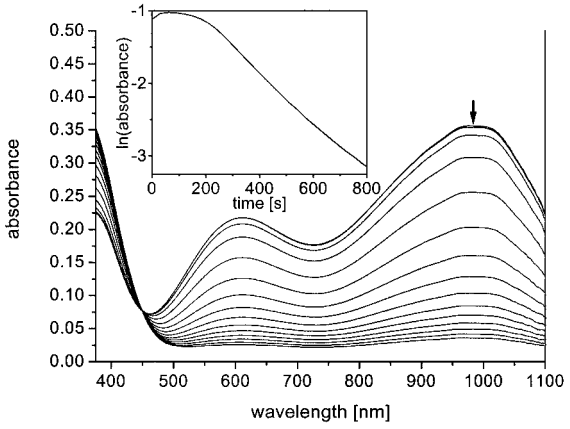

Figure 8. Progress of the reaction of $[Fe^{III}(brtpa)(dbc)]^+$ with dioxygen; inset: plot of ln(absorption)vs. time for this reaction (ambient temperature; 1.5 equiv. of base)

monitored by UV/Vis-spectroscopy. Figure 8 shows the decrease of this band during the reaction of in situ prepared $[Fe(brtpa)(dbc)]^+$ (where dbc = 3,5-di-*tert*-butylcatecholate) with dioxygen which is present in methanol saturated with air. A greater than tenfold excess of dioxygen ensures pseudo-first-order kinetics for the complete reaction and therefore a linear dependency of the plot of ln(absorbance) vs. time (inset in Figure 8) can be observed. By considering the concentration of dioxygen in air saturated methanol at ambient temperature, the reaction rate constant k can be obtained from the slope of this linear graph.

Different amounts of piperidine were added to the reaction mixture to ensure a dianionic binding of the substrate and thus a high reactivity. As can be seen from Figure 9, the highest reactivity was reached when 1.5 equivalents of base were added to the reaction mixture. Although complexes derived from similar tripodal ligands show catechol dioxygenase activity under the same conditions the highest activity can be observed upon addition of 2.0−2.5 equivalents of base in these systems.[14,16] The lower demand of base in the reaction of the new model compound can be explained by the peculiarity of the ligand and its weakly coordinated bromopyridine unit. As indicated by the intramolecular hydrogen bond in **3**, this unit can act as a proton acceptor and therefore as an internal base. Furthermore this behavior was confirmed by spectrophotometric titrations of a complex-catechol mixture with piperidine in which only 1.8 equivalents of the base were needed for an optimal dianionic binding of the catechol. The closely related me_1tpa system, where the bromine in brtpa is substituted by a methyl group, needs significantly more (2.4 equiv.) base to bind the catechol.[16]

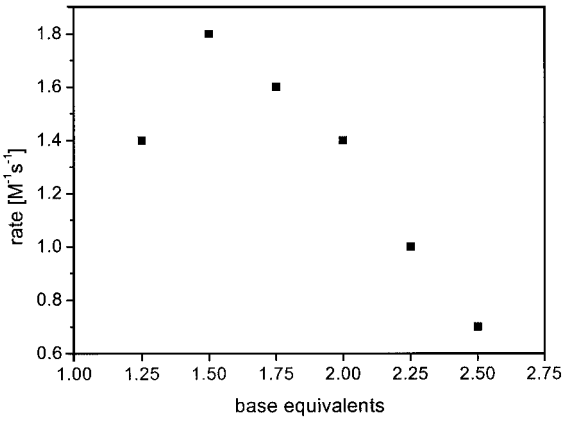

Figure 9. Correlation of reaction rates *k* and added equivalents of piperidine

As shown in Figure 9, a maximum reaction rate of 1.8 $M^{-1}s^{-1}$ was found for the iron brtpa system. This is of the same order of magnitude as those reported for other model compounds containing tripodal ligands. (For review articles see ref.[10])

Taking into consideration that Ogo et al. reported a model system in which coordinated acetylacetonate is used as an internal base,[23] it should be possible to generate the iron(III) complex $[Fe(brtpa)(acac)]^{2+}$ which allows cleavage of catechols without any further addition of base.

Identification of the Cleavage Products

The oxygenated products were characterized by GC/MS as well as ^1H NMR spectroscopy. Neither of these methods showed evidence for the undesired products of simple oxidation (quinones) or extradiol cleavage. The amount of external base in the reaction mixture (1.5 or 2.0 equiv.) had no effect on the product composition. In acetonitrile and dichloromethane, muconic anhydride was found as the exclusive reaction product whereas in methanol a mixture of muconic anhydride and its methanolysis product was detected by GC/MS. All results demonstrate that the present model system exclusively catalyzes the intradiol cleavage reaction.

Catalytic Reactions

The identification of the cleavage products was also performed for catalytic reactions. The substrate-catechol ratio in these experiments was 10:1 and 100:1, respectively. Even for the 100 fold excess of substrate, we observed complete conversion of the catechol. The GC/MS analysis revealed that only the desired intradiol cleavage products were formed in the reaction.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Conclusion

With the crystal structures and functional investigations reported in this work we have established an excellent model system for the first steps in the reaction mechanism of catechol dioxygenases. The substituted pyridine moiety is a good mimic for the departing tyrosine ligand in the enzyme. This was demonstrated by the different positions of the ligand arm resulting in an increase of the corresponding Fe−N distance from 2.22 to 5.28 Å. Furthermore, the base dependent kinetic investigations revealed that the bromopyridine arm acts as an internal base. This behavior is confirmed by the presence of a hydrogen bond in **3**.

Experimental Section

Materials: All chemicals were purchased from commercial sources and used without any further purification.

Physical Measurements: ^{1}H and ^{13}C NMR spectra were measured on a Bruker WH 300 spectrometer. UV/Vis spectroscopy was performed on a Hewlett−Packard 8453 diode array spectrometer.

Syntheses

[(6-Bromo-2-pyridyl)methyl][(2-pyridyl)methyl]amine (brbpa): 6-Bromo-2-pyridine carboxaldehyde (20.0 g, 107.5 mmol) was stirred in methanol (100 mL). After slow addition of 2-(aminomethyl)pyridine (11.6 g, 107.5 mmol, 11.2 mL) the solution was stirred for a further 2 h. At 0 °C sodium borohydride (3.0 g, 79.3 mmol) was carefully added. The reaction mixture was stirred overnight and allowed to warm to room temperature. The mixture was acidified with hydrochloric acid to pH 1 and extracted with chloroform (5 × 40 mL) to separate impurities and side products. In order to neutralize the hydrochloride, the pH was adjusted to 8 with an aqueous solution of sodium hydroxide and the free amine was extracted with chloroform (5 × 40 mL). The combined organic layers were dried over $MgSO_4$ and the solvent was removed in vacuo yielding 24.62 g (88.5 mmol; 82 %) of a yellow oil which was used without further purification. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.95 (s, 2 H, CH_2), 3.96 (s, 2 H, CH_2), 7.16 (m, 1 H, CH), 7.33 (m, 3 H, CH), 7.45 (t, 1 H, CH), 7.60 (m, 1 H, CH), 8.54 (d, 1 H, CH) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 54.3, 54.7, 121.0, 122.0, 122.3, 126.2, 136.4, 138.8, 141.7, 149.4 159.6, 161.8.

[(6-Bromo-2-pyridyl)methyl]bis[(2-pyridyl)methyl]amine (brtpa): To a stirred mixture of brbpa (14.33 g, 51.5 mmol) and 2-picolyl chloride hydrochloride (8.45 g, 51.5 mmol) in THF (100 mL) was added triethylamine (14.4 mL, 10.5 g, 103 mmol). After heating to reflux for 48 h the mixture was cooled to room temperature and the resultant precipitate removed by filtration. The red solution was concentrated in vacuo. The residual red oil was extracted with boiling diethyl ether and upon cooling to −18 °C the off-white product precipitated. Yield 13.69 g (37.1 mmol; 72 %). NMR spectroscopic data have already been published.[24]

[Fe^{III}(brtpa)Br$_3$] (1): Iron(III) bromide (30 mg; 0.1 mmol) and brtpa (37 mg; 0.1 mmol) were stirred in acetone/methanol (6 mL, 1:1 mixture) for a few minutes. The mixture was then heated to reflux for a few seconds and filtered. Red crystals of complex **1** formed

upon slow cooling. $C_{18}H_{17}Br_4FeN_4$ (664.82 g/mol). Crystal data are given in Table 2.

[Fe^{III}(brtpa)(tbc)]ClO_4·H_2O (2): To a stirred solution of iron(III) perchlorate hydrate (37 mg; 0.1 mmol) and brtpa (37 mg; 0.1 mmol) in of acetone (7 mL) was added tetrabromocatechol (42 mg; 0.1 mmol). After addition of triethylamine (20 mg, 28 μL, 0.2 mmol) the mixture was stirred for a few minutes and filtered. Upon slow diffusion of diethyl ether into the solution dark blue crystals of **2** preciptiated. $C_{24}H_{19}Br_5ClFeN_4O_7$ (966.26 g/mol). Crystal data are given in Table 2.

[Fe^{III}(brtpa)(tcc)(CH_3OH)]ClO_4·CH_3OH (3): $Fe(ClO_4)_3$·H_2O (37 mg; 0.1 mmol) and brtpa (37 mg; 0.1 mmol) were dissolved in methanol/acetone (9 mL, 3:1 mixture). After addition of tetrachlorochatechol monohydrate (26 mg; 0.1 mmol) and triethylamine (28 μL, 20 mg; 0.2 mmol) the mixture was stirred for a few minutes and filtered. Upon slow diffusion of diethyl ether into the solution dark blue crystals of compound **3** precipitated. $C_{26}H_{25}BrCl_5FeN_4O_8$ (834.52 g/mol). Crystal data are given in Table 2.

[Fe^{III}(brtpa)(tcc)Cl] (4): To a stirred solution of $FeCl_3$ (16 mg; 0.1 mmol), brtpa (37 mg; 0.1 mmol) and tetrachlorocatechol monohydrate (26 mg; 0.1 mmol) in methanol/acetone (7 mL, 1:3 mixture) was added triethylamine (20 mg, 28 μL, 0.2 mmol). After heating to reflux for a few seconds the mixture was filtered and slow diffusion of diethyl ether into the solution yielded red plates of complex **4**. $C_{24}H_{17}BrCl_5FeN_4O_2$ (706.44 g/mol). Crystal data are given in Table 2.

[Fe^{III}(brtpa)(tcc)NO_3] (5): To a stirred solution of $Fe(NO_3)_3$·$9H_2O$ (40 mg; 0.1 mmol), brtpa (37 mg; 0.1 mmol) and tetrachlorocatechol monohydrate (26 mg; 0.1 mmol) in methanol/acetone (7 mL, 3:1 mixture) was added triethylamine (20 mg, 28 μL, 0.2 mmol). After heating to reflux for a few seconds the mixture was filtered and slow diffusion of diethyl ether into the solution yielded red crystals of complex **5**. $C_{24}H_{17}Br_5FeN_5O_5$ (910.80 g/mol). Crystal data are given in Table 2.

[Fe^{III}(brtpa)(tbc)NO_3] (6) To a stirred solution of $Fe(NO_3)_3$·$9H_2O$ (40 mg; 0.1 mmol), brtpa (37 mg; 0.1 mmol) and tetrabromocatechol (42 mg; 0.1 mmol) in methanol/acetone (9 mL, 1:1 mixture) was added triethylamine (20 mg, 28 μL, 0.2 mmol). After heating to reflux for a few seconds the mixture was filtered and slow diffusion of diethyl ether into the solution yielded red plates of complex **6**. $C_{24}H_{17}BrCl_4FeN_5O_5$ (732.99 g/mol). Crystal data are given in Table 2.

Stoichiometric Kinetic Studies: The catechol cleavage activity of an in situ prepared complex solution was tested under addition of between 1.0 and 2.5 equivalents of piperidine as an external base. To a $2{\cdot}10^{-4}$ mol·L^{-1} methanolic solution (2 mL) consisting of $Fe(ClO_4)_3$·H_2O and the ligand was added a $2{\cdot}10^{-2}$ mol·L^{-1} (1 equivalent) solution of 3,5-H_2dbc (0.02 mL). The amount of base added to the reaction mixture was varied from 0.02 mL to 0.05 mL (1.0−2.5 equiv.; increment 0.005 mL; 0.25 equiv.) of a $2{\cdot}10^{-2}$ mol·L^{-1} solution. The decomposition of the complexes was followed at least three times by UV/Vis spectroscopy. Spectrophotometric titrations were carried out with the same solutions in a flow cell under an argon atmosphere.

Identification of the Cleavage Products

Stoichiometric Reactions: Identification of the reaction products was also carried out in presence of different amounts of base and in different organic solvents (dichloromethane, acetonitrile and methanol). To a stirred solution of $Fe(ClO_4)$·H_2O, the ligand brtpa and catechol (0.2 mmol) was added 1.5 or 2.0 equivalents of piperidine, respectively. After all catechol had reacted the solvent was evaporated under reduced pressure at ambient temperature. The iron complex was removed by silica gel filtration (CH_2Cl_2/$CHCl_3$, 1:2). After evaporation of the solvent (ambient temperature) the products were dried in vacuo and identified by GC/MS-coupling and ^{1}H NMR spectroscopy.

Catalytic Reactions: The reactions were carried out in acetonitrile solutions. To a stirred complex solution (0.1 and 0.01 mmol dissolved in 50 mL, respectively) were added 3,5-H_2dbc (222.3 mg, 1 mmol) and 1.5 equiv. of piperidine (relative to the iron complex). To ensure fast reactions, dioxygen was bubbled through the reaction mixture. Workup of the oxygenated products was done according to the procedure described for the stoichiometric reactions.

X-ray Crystal Structures

Intensity data of all complexes were collected on a Bruker AXS SMART 6000 CCD diffractometer (Cu-K_α, λ = 1.54178 Å, Göbel mirror) using the ω-scan technique. The collected reflections were corrected for absorption effects.[25] All structures were solved by direct methods and refined by full-matrix least-squares methods on F^2.[26] Further data collection parameters are summarized in Table 2.

CCDC-213838 to -213843 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Tandem Palladium-Catalyzed Cyclocarbonylation of Isolimonene: A Mechanistic Investigation and Theoretical Calculations on the Fully Diastereoselective Step

Géraldine Lenoble,[a] Corinne Lacaze-Dufaure,[b] Martine Urrutigoïty,[a] Claude Mijoule,[b] and Philippe Kalck*[a]

Keywords: Asymmetric induction / Cyclocarbonylation / Density functional calculations / Homogeneous catalysis / NMR spectroscopy / Palladium

Cyclocarbonylation of isolimonene catalyzed by complexes of the type $[HPd(SnCl_3)L_2]$ provides two cyclopentanone isomers (**2a** and **2b**) containing two new stereogenic centers with a good diastereomeric excess (up to 69 % with L_2 = dppf). These results show that chiral phosphane ligands are not necessary to ensure asymmetric induction. The diastereomeric excess is due, in fact, to the substrate itself, assisted by the steric hindrance of the diphosphanes. A full characterization of the two isomers by ^1H, ^{13}C and DPFGSE NOE NMR spectroscopy gives all the signal assignations and all the positions of the substituents of interest on the chiral carbon atoms. In order to have a better understanding of the catalytic process, we also present a density functional study of the crucial intermediate species **4** involved in the proposed catalytic cycle. Our calculations show that there is no coordination of the C=C bond in an *exo* mode. Conversely, we have found a pentacoordinate species with a trigonal bipyramidal geometry in which the C=C bond is coordinated in an *endo* mode. Selected bond lengths and bond orders are reported. The calculated net charge distribution supports the cyclization process, which proceeds through a C–C(O) and a C–Pd coupling. A β-hydride elimination reaction of **4** provides the two **2a** and **2b** isomers.

Introduction

Carbon monoxide is a very powerful building block in organic synthesis, provided it can be inserted into a framework with high selectivity. For several years we have used this strategy to functionalize monoterpenes.[1] Particularly interesting are the tandem reactions in which functionality already present on the terpene reacts with an active intermediate resulting from the insertion of carbon monoxide.[2] Recently, we have specially focused our attention on the cyclocarbonylation of isolimonene, where the endocyclic carbon-carbon double bond is involved in the process; preliminary results have been reported.[3] Rhodium and palladium play a central role in such carbonylation reactions and many papers have reported the catalytic activity of complexes such as $[HRh(CO)L_3]$ or $[PdCl_2L_2]$.[4] Palladium complexes, often with $SnCl_2$ as co-catalyst, are active in the alkoxycarbonylation of alkenes.[5] During the nineties, great effort went into developing enantio- or diastereoselective catalysts by introduction of chiral ligands into the coordination sphere of a metal.[6] Our studies on the carbonylation of (1*R*,2*S*,5*R*)-isopulegol, to provide the corresponding lactone, and our preliminary results on the carbonylation of (1*R*,4*R*)-isolimonene [(3*R*,6*R*)-3-isopropenyl-6-methylcyclohexene] have shown that the introduction of a chiral diphosphane ligand does not influence the diastereoselectivity of the two cyclocarbonylation reactions of interest.[2,3] Thus, the enantiofacial selectivity should be induced by the chiral substrate itself. The situation of isolimonene appeared to us particularly interesting because, of the three chiral centers present in the resulting product, two of them (C1 and C5 in Scheme 1) are obtained with exclusively one configuration (1*R* and 5*S*). Thus, the diastereomeric excess results in fact from an enantiomeric excess at C4 to provide **2a** and **2b** of Scheme 1.

In order to understand why the cyclization reaction catalyzed by palladium occurs exclusively at the C2 atom of isolimonene (which becomes C1 in the resulting product, see Scheme 1) and provides only the *R* configuration, we have performed quantum chemical calculations using the density functional theory (DFT) on the main intermediate which would give the enantioselective cyclization step.

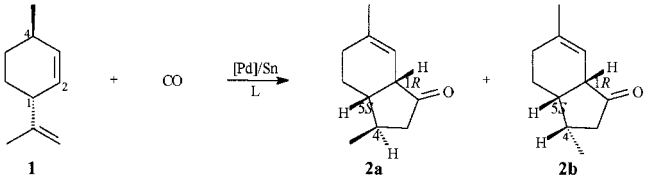
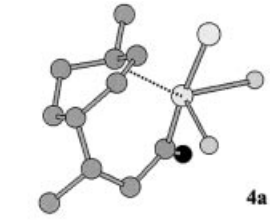
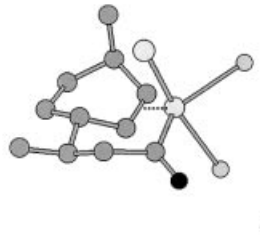


Scheme 1. Cyclocarbonylation of (1*R*,4*R*)-isolimonene (**1**) catalyzed by palladium

This paper deals with the complete identification of the two diastereomers **2a** and **2b** resulting from the carbonylation of (1*R*,4*R*)-isolimonene (**1**) based on DPFGSE NOE experiments[7] as well as the configuration at all the chiral carbon atoms. The analysis of the structure of these two isomers leads us to confirm that the active species contains a palladium-hydride bond. Calculations have been carried out on the two isomers **4a** and **4b**, and the two other possible diastereomers. DFT computations have been done on the crucial intermediate species, which contains an acyl group, and the fate of the endocyclic carbon-carbon double bond and the palladium center either in an *endo* or in an *exo* mode (Scheme 2); such calculations show that an enantioselective C1−C2 coupling in the *endo* mode is the only one possible. Finally, the full mechanism of the tandem carbonylation reaction is considered.





Scheme 2. Representation of two conceivable intermediates, **2a** resulting from an *endo* coordination mode and **2b** from an *exo* mode

Method of Calculation

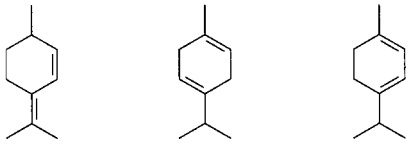
As the complex $[PdCl_2(PPh_3)_2]$ reacts to give the same products in catalysis as $[PdCl(SnCl_3)(PPh_3)_2]$, although somewhat more slowly, we chose to model the species $[PdCl_2(PH_3)_2]$ in which PPh_3 has been replaced by the PH_3 ligand, as is normal in these types of calculations. The system contains a palladium atom, which is a transition metal and thus has strongly correlated *d* electrons. Consequently, we chose to carry out our study by using the density functional approach, which is well adapted to this type of problem.[8,9]

All structures presented here were fully optimized using conjugate gradient methods without constraints at the density functional theory (DFT) level with the Gaussian 98 software package release A.3.[10] The method has been described extensively elsewhere.[11−13] We used the B3LYP hybrid functional.[14,15] For all optimizations a valence basis-set of double-ξ quality was employed and relativistic effects were addressed implicitly by the use of relativistic effective core potentials for Pd, P and Cl.[16−18] For H, C and O the standard Dunning−Hay D95V basis was used.[19] A Mulliken population analysis, together with significant Mayer bond orders between palladium and its neighbors were thus determined. Finally, the charge-transfer effects arising between the metal atom and the ligands were examined.

Results and Discussion

Catalytic Experiments

Carbonylation of (1*R*,4*R*)-isolimonene (**1**; Scheme 1) at 40 bar (4 MPa) catalyzed by $[PdCl_2(PPh_3)_2]$ in the presence of $SnCl_2{\cdot}2H_2O$ and a slight excess of PPh_3, leads to a mixture of the two cyclopentanones **2a** and **2b** with good selectivity. These two products have been shown by mass spectrometry to contain a C11 framework and a ketone function; further strong evidence for the presence of a CO group results from the ν_{CO} band at 1740 cm^{-1} in the IR spectrum of both products. The mixture was enriched in one product to reach a **2a**/**2b** ratio of 90:10 by column chromatography on silica. ^1H and ^{13}C NMR characterizations confirmed that **2a** and **2b** are two diastereomers, and a complete assignment of the various configurations at the carbon atoms was obtained by NOE experiments, as discussed later.



Scheme 3. Isomers of **1**

From Table 1 it can be seen that a 95 % conversion of the starting material can be obtained in 18 hours, giving a selectivity in **2a**+**2b** of 84 %, operating with a substrate-to-catalyst ratio of 50. The other products, which account for 16 %, were identified by GC-MS as isomers of **1**, the most abundant of which are shown in Scheme 3.

Addition of more substrate, as in runs 2 and 3, decreases the conversion but does not affect significantly the selectivity in **2**. The **2a**/**2b** ratio gives rise to a diastereomeric excess of 12 % in the three experiments.

We then introduced the classical chiral ligand (+)-DIOP into the coordination sphere of palladium and prepared the catalyst precursor $[PdCl_2\{(+)\text{-DIOP}\}]$ to carry out run 4.

Table 1. Cyclocarbonylation reactions of (1*R*,4*R*)-isolimonene (**1**)[a]

	Catalytic precursor	Substrate/catalyst	Conversion (%)	Selectivity (%)	**2a/2b**[b]	*de*[b] (%)
1	$[PdCl_2(PPh_3)_2]$	50	95	84	56:44	12
2	$[PdCl_2(PPh_3)_2]$	80	78	80	55:45	10
3	$[PdCl_2(PPh_3)_2]$	100	62	82	56:44	12
4	$[PdCl_2\{(+)\text{-DIOP}\}]$	100	75	52	85:15	70
5	$[PdCl_2\{(-)\text{-DIOP}\}]$	100	75	52	85:15	70
6	$[PdCl_2(dppb)]$[c]	100	75	65	82:18	64
7	$[PdCl_2(dppf)]$[c]	100	71	68	84.5:15.5	69

[a] General conditions: Catalytic precursor = 1 mmol, $SnCl_2{\cdot}2H_2O$ = 2.5 mmol, P/Pd = 4, toluene = 25 mL, temp. = 70 °C, p_{CO} = 40 bar, t = 18 h. [b] Determined by GC. [c] Temp. = 97 °C.

Under the same catalytic conditions as in run 3, a 75 % conversion of **1** and a 52 % selectivity in **2** were observed. However, a diastereomeric excess of 70 % was calculated from the relative amounts of **2a** and **2b**. A similar experiment carried out with $[PdCl_2\{(-)\text{-DIOP}\}]$ led to the same results, especially the **2a**/**2b** ratio, which is still 85:15 and not the reverse. Therefore, whatever the configurations of the two chiral carbons of the diphosphane ligand, they have no influence on the diastereoselectivity and we suspected that the reaction could be governed by the chirality of the substrate itself.

Various experiments, not reported here, showed that a change in the temperature, pressure, or L*/Pd ratio did not affect significantly these performances, except maybe a higher pressure, which improved the conversion somewhat; for instance, at 80 bar, the yield is 82 %.

For this reason we have prepared two catalyst precursors containing the classical diphosphane ligands bis(diphenylphosphanyl)butane (dppb) and bis(diphenylphosphanyl)ferrocene (dppf). Runs 6 and 7 show that the performances of these two non-chiral catalysts are essentially the same as those of the DIOP-containing catalysts: the two diastereomeric excess values are 64 % and 69 % respectively. In experiments not described here, we also checked that shorter carbon chains in the ligands, like bis(diphenylphosphanyl)ethane and -propane, did not lead to any catalytic activity.[20] It can therefore be concluded that simple diphosphane ligands can play an important role, and thus assist the asymmetric catalysis, presumably through their electronic effects during the various steps of the catalytic cycle, but also thanks to their bulkiness during the asymmetric induction.

Stereochemistry Determination of 2a and 2b by NMR Spectroscopy

In previous studies, due to the isolation in the solid state of one isomer of the lactone obtained by cyclocarbonylation of (1*R*,2*S*,5*R*)-isopulegol and solved by an X-ray crystal structure, we have been able to determine all the configurations of the chiral centers present in the molecule and its diastereoisomers by NMR spectroscopy.[2d,3] With this knowledge, we have used NOE experiments to assign the positions of the various substituents of interest in **2a** and **2b**. NMR spectroscopic data for the two diastereomers **2a** and **2b** are displayed in Table 2, with the numbering system shown in Scheme 4, which differs from normal terpene nomenclature. These data were obtained from 1D ^1H and ^{13}C NMR spectra and COSY (^1H,^1H), HMQC (^1H,^{13}C) ^1J (see Figure 1) as well as long-range experiments. Due to the presence of a five-membered cycle and an endocyclic carbon-carbon double bond, most of the substituents are labeled as pseudo-equatorial in Schemes 5 and 6.

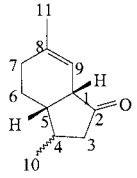

Scheme 4. Compound **2** (with IUPAC nomenclature)

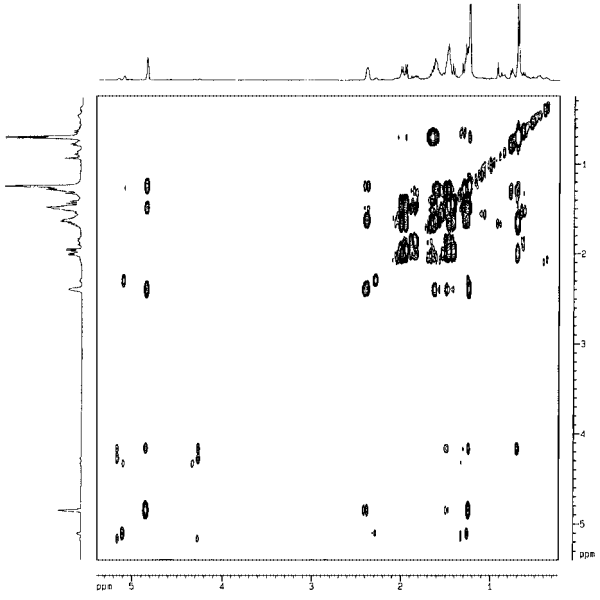

Figure 1. 2D COSY.DQF.GE ($^1H,^1H$) spectrum (400 MHz) of mixture of diastereomers **2a** and **2b** at 298 K in $CDCl_3$

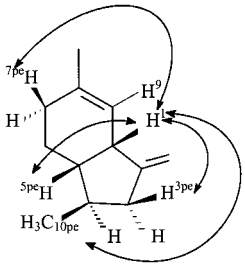
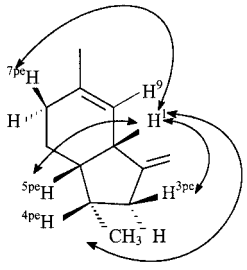


Scheme 5. Interactions observed for H1 in **2a**



Scheme 6. Interactions observed for H1 in **2b**

The measurement of NOE effects by a 1D DPFGSE method appears to be much more selective for resonances that are not well resolved, especially when this is due to the overlap of several signals. As the spatial arrangement at C5 does not change during the reaction [C1 (*R*) in isolimonene becomes C5 (*S*) in cyclopentanone], irradiation of H1 on C1 in **2a** (Figure 2) allowed us to detect interactions with H9, H7 in a pseudo-equatorial position (pe), H5pe, H10pe, H11pe and H3pe (Scheme 5) indicating that all these atoms or groups are in the up position. Thus, C1 presents an *R* configuration, and C4 an *R* one.

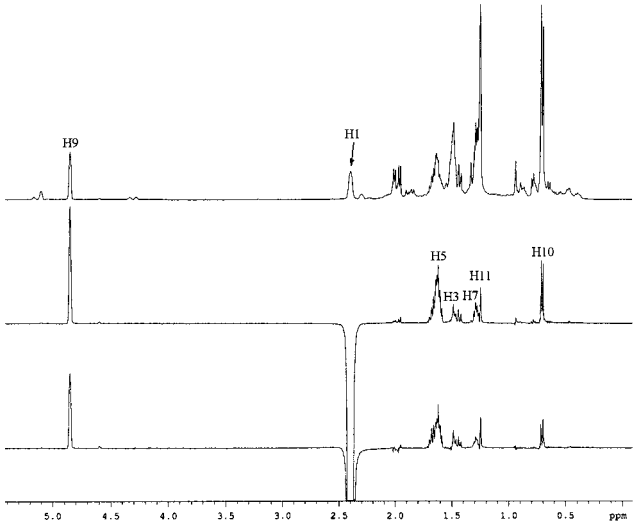


Figure 2. 1D NOESY-DPFGSE spectrum (400 MHz; irradiation of H1 on C1 in **2a**) of mixture of diastereomers **2a** and **2b** at 298 K in $CDCl_3$; top: full spectrum; middle: mixing time 800 ms; bottom: mixing time 400 ms

In the same 90:10 mixture of **2a**/**2b**, irradiation of H1 in **2b** (Figure 3) led us to assign the configurations C1 (*R*) and C4 (*S*; Scheme 6).

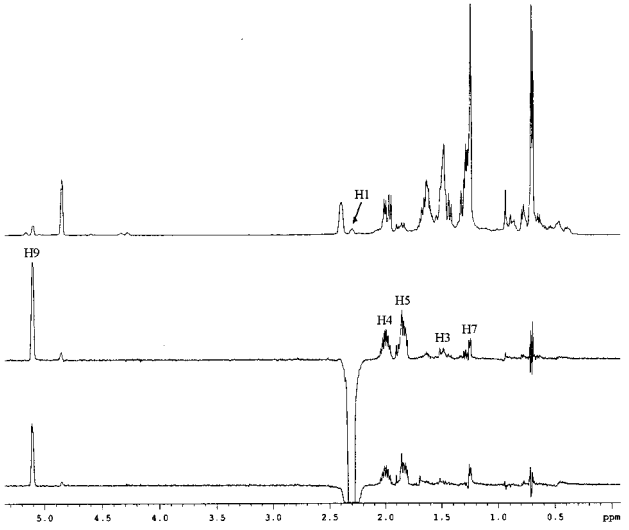

Figure 3. 1D NOESY-DPFGSE spectrum (400 MHz; irradiation of H1 on C1 in **2b**) of mixture of diastereomers **2a** and **2b** at 298 K in $CDCl_3$; top: full spectrum; middle: mixing time 800 ms; bottom: mixing time 400 ms

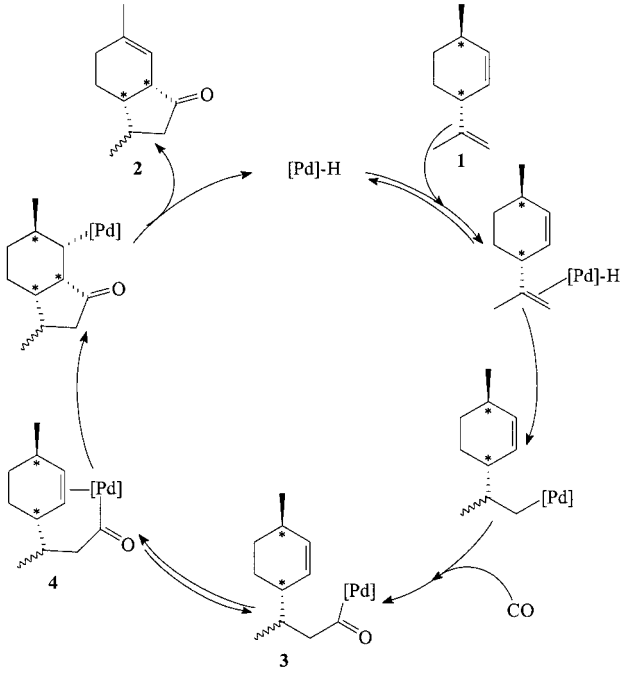
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

This NMR study shows that in the two products obtained in the cyclocarbonylation reaction, the stereochemistry of C1 is unchanged in both isomers. The diastereomeric excess of 70 % results in fact from the two (*S* and *R*) configurations at the C4 atom (*R*/*S* = 85:15).

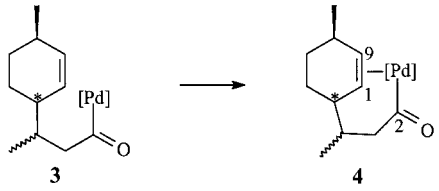
DFT Calculations

The shift of the endocyclic C=C bond from the substrate **1** to the resulting cyclopentanone **2** (Scheme 7) is indicative of a β-hydride elimination in an intermediate which affords a palladium hydride species. Thus, we have supposed the following sequence for the early steps of the catalytic cycle: formation of an alkylpalladium species by hydride transfer to the exocyclic C=C bond, and CO migratory insertion to afford the acyl intermediate **3**. During the cyclization process, which involves the carbon−carbon coupling of the two C1 and C2 atoms, we have considered that the stereoselectivity results from one privileged approach of the palladium center toward the endocyclic C=C bond in species **4** (Scheme 8). As the full system involves 39 atoms the potential hypersurface is rather complex, therefore we calculated only certain regions of this hypersurface, taking into account the classical geometries for d^8 complexes.



Scheme 7. Catalytic cycle of cyclocarbonylation of **1**

Our calculations show that there is no coordination of the C=C bond in an *exo* mode and we found two species with the C=C bond not coordinated to the metal center, which adopts a square-planar environment, at all (d_{Pd-C} = 4.75 and 5.63 Å for the more stable and 3.69 and 4.66 Å for the second one, which is 3 kcal·mol^{-1} higher in energy, as shown in Table 3). Moreover, we found a pentacoordinate species with a trigonal bipyramidal (TBP) geometry in which the C=C bond is coordinated in an *endo* mode (Scheme 9). Indeed, the two palladium−carbon bond lengths are 2.31 and 2.35 Å, corresponding to Mayer bond-orders of 0.36 and 0.31, respectively; in addition, the C−C bond length is 1.40 Å and its bond order is 1.53 (see Table 3). Among the various axial and/or equatorial positions for the ligands, the calculations seem to slightly favor (1.3 kcal·mol^{-1}) the Cl and CO-acyl ligands in the two axial positions.



Scheme 8. Coordination of the endocyclic C=C bond of **1** to the palladium center

Concerning the Mulliken population analysis, our results show clearly that there are no significant differences between the net charges on each atom in both species.

Proposed Catalytic Cycle

Our calculations give strong evidence that the TBP intermediate in which the (*endo*)C=C double bond and the CO-acyl are in close vicinity allows the next step in the catalytic cycle. Indeed, the C2−C1 distance is 2.97 Å, whereas it is 3.58 and 4.41 Å in the less- and more-stable square-planar palladium species. The resulting C1 configuration is thus 100 % *R*.

A further analysis of the mechanism shows that the new intermediate **5**, in which the cyclopentanone has been formed and the palladium atom is still bonded to C9, presents the two palladium and H8 hydrogen atoms in mutual *cis* positions. Thus, a β-hydride elimination reaction, which re-forms the active palladium hydride species, is possible. In addition, the H1 atom is *trans* to Pd and cannot provide the β-H elimination required for the further step. Moreover, it is worth mentioning that a possible intermediate resulting from the coordination of the C=C bond in the *exo* mode would provide the two H1 and H8 hydrogen atoms in *trans* positions to the palladium atom; such a situation, in which no β-H elimination can occur, precludes any catalytic reaction. We did not detect these two isomers. Scheme 7 shows the catalytic cycle that we propose.

Conclusion

The main point of this study is related to an asymmetric induction that is caused by the substrate itself so that chiral ancillary phosphane ligands are not necessary in the catalytic reaction. Moreover, the steric hindrance of the diphosphane ligands plays an essential role in obtaining a large diastereomeric excess.

Experimental Section

Materials: Solvents with high purity, as well as (1*R*,4*R*)-isolimonene, were used as received from Dérivés Résiniques et Terpéniques (DRT SA). $SnCl_2{\cdot}2H_2O$ (Prolabo 98 %), triphenylphosphane (Aldrich 99 %), 1,4-bis(diphenylphosphanyl)butane (dppb) (Acros 98 %), 1,1′-bis(diphenylphosphanyl)ferrocene (dppf) (Aldrich 97 %), (−)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphosphanyl)butane [(−)-DIOP] and (+)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphosphanyl)butane [(+)-DIOP] (Janssen 98 %). Column chromatography was performed with SiO_2 (Merck).

Instrumentation: The ^1H, ^{13}C and ^{31}P NMR spectra were recorded with $CDCl_3$ solutions containing TMS as internal standard on a Bruker AMX 400 spectrometer operating at 400.13 MHz (^1H) and 100.62 MHz (^{13}C), and a Bruker AM 250 spectrometer operating at 250.13 MHz, 62.90 MHz and 101.26 MHz, respectively. Data are reported as follows: chemical shift in ppm (δ), multiplicity (s = singlet, d = doublet, t = triplet, q = quadruplet and m = multiplet), coupling constant (*J*) in Hz (n.d. = no determined), integration, and assignment (pa = pseudo-axial and pe = pseudo-equatorial). IR spectra were obtained on a Perkin−Elmer 1710 spectrometer; absorptions are reported in cm^{-1}. Analytical GC was carried out on a Carlo Erba MFC 500 apparatus equipped with a Econo-Cap FFAP (30 m; 0.53 mm; 1.2 μm) capillary column and a flame ionization detector. Products were identified by GC/MS on a Perkin−Elmer QMass 910 Mass Spectrometer with ionization voltage of 70 eV, with a Crompack CP WAX 52 CB (50 m; 0.32 mm; 0.2 μm) polar column.

General Procedure: A mixture of dichlorobis(triphenylphosphane)-palladium(II) (0.702 g, 1 mmol), hydrated tin(II) chloride (0.474 g, 2.5 mmol) and triphenylphosphane (0.524 g, 2 mmol) was introduced into a 250 mL stainless steel autoclave with mechanical stirring. A nitrogen-saturated mixture of isolimonene (13.624 g, 100 mmol) in toluene (25 mL) was introduced into the evacuated autoclave by aspiration. It was heated to 70 °C under 40 bar pressure of carbon monoxide at constant pressure. After 18 h, the autoclave was cooled and then slowly depressurized. The yellow-orange reaction mixture was analyzed by gas chromatography. The same procedure was followed for other ligands maintaining the P/Pd ratio at 4.

After the catalytic reaction, the organometallic compounds and the excess phosphane were separated from the crude solution by washing with CCl_4. The deeply colored oily layer was decanted. After concentration by rotary evaporation, the oily residue was purified by column chromatography on silica gel (petroleum ether/dichloromethane/ethyl acetate, 70:24:6).

Complexes: $[PdCl_2(PPh_3)_2]$ was prepared according to the literature procedure.[21] Yield 95 %. $^{31}P\{^1H\}$ NMR (250 MHz, $CDCl_3$, 25 °C): δ = 23.47 (s) ppm. IR (KBr): $\tilde{\nu}$ = 1481, 1436, 1099, 746, 693 cm^{-1}. Complexes containing diphosphanes were prepared by addition of the diphosphane to $[PdCl_2(PhCN)_2]$[22] in hot acetone.
[$PdCl_2$(dppb)]: Yield 90 %. $^{31}P\{^1H\}$ NMR (250 MHz, $CDCl_3$, 25 °C): δ = 63.75 (s) ppm.
[$PdCl_2$(dppf)]: Yield 88 %. $^{31}P\{^1H\}$ NMR (250 MHz, $CDCl_3$, 25 °C): δ = 36.14 (s) ppm.
[$PdCl_2$[(+)-DIOP)] and [$PdCl_2$[(−)-DIOP)]: Yield 85 %. $^{31}P\{^1H\}$ NMR (250 MHz, $CDCl_3$, 25 °C): δ = 16.47 (s) ppm.

Anomalous Difference in Magnetic Behavior between Highly Saddled Iron(III) Porphyrin Complexes in the Solid State

Yoshiki Ohgo,*[a] Takahisa Ikeue,[a] Masashi Takahashi,[b] Masuo Takeda,[b] and Mikio Nakamura*[a,c]

Dedicated to the late Professor Oyo Mitsunobu of Aoyama Gakuin University

Keywords: Iron / Porphyrinoids / Spin crossover / Magnetic properties

The spin states of microcrystalline samples of $[Fe(OMTPP)L_2]^+$ (L = DMAP or Py) have been examined and interpreted using Mössbauer spectroscopy, SQUID magnetometry and X-ray crystallography. The Mössbauer spectra of $[Fe(OMTPP)(DMAP)_2]^+$ and $[Fe(OMTPP)Py_2]^+$ showed that both of these complexes maintain the low-spin (S = 1/2) state over the 77–300 K temperature range. The spin states of these complexes were further confirmed by SQUID magnetometry. Thus, the magnetic behavior of $[Fe(OMTPP)Py_2]^+$ is quite different from that of the structurally related species $[Fe(OETPP)Py_2]^+$. The latter complex exhibits a novel spin crossover between the S = 3/2 and S = 1/2 states as revealed by the spectroscopic and magnetic measurements. In order to understand the reasons for the absence of the spin crossover process in $[Fe(OMTPP)Py_2]^+$, we have compared the crystal and molecular structures of $[Fe(OMTPP)Py_2]^+$ with those of the recently reported species $[Fe(OETPP)Py_2]^+$. In the case of $[Fe(OMTPP)Py_2]^+$, the Fe–N_{axial} bond lengths hardly change with temperature and are 2.058(6) and 2.024(4) Å at 298 and 80 K, respectively. These results are in sharp contrast to those of the spin crossover complex $[Fe(OETPP)Py_2]^+$, in which the Fe–N_{axial} bonds contract from 2.201(3) Å at 298 K to 1.993(3) Å at 80 K. We have ascribed the difference in magnetic behavior between $[Fe(OMTPP)Py_2]^+$ and $[Fe(OETPP)Py_2]^+$ to the difference in molecular packing; the former adopts a densely packed cubic crystal system while the latter shows a less condensed monoclinic system. A cavity calculation has further confirmed the above mentioned assumption. While the cavity sizes around the pyridine ligands in $[Fe(OETPP)Py_2]^+$ are 32.08 and 28.88 $Å^3$ at 298 K, that in $[Fe(OMTPP)Py_2]^+$ is only 19.81 $Å^3$. Furthermore, the cavities contract by 17.7% in $[Fe(OETPP)Py_2]^+$ when the temperature is lowered from 298 to 80 K whereas the contraction is only 5.3% in the case of $[Fe(OMTPP)Py_2]^+$. On the basis of these results, we have concluded that the loosely packed crystal system and the wide cavities around the axial ligands are the important requirements for the occurrence of the spin crossover process in the solid state.

Introduction

The spin states of iron(III) porphyrin complexes are controlled by several factors[1–3] the most important being the number and nature of the axial ligands. For example, axially bound strong field ligands such as cyanide, imidazole, and pyridine form low-spin (S = 1/2) six-coordinate complexes. In contrast, anionic ligands such as Cl^- and F^- lead to the formation of five-coordinate high-spin (S = 5/2) complexes. Maltempo discussed a quantum mechanically spin admixed S = 3/2, 5/2 state and suggested that the S = 3/2 state is an important contributor to the spin states of cytochromes c′, which are recognized as histidine ligated five-coordinate iron(III) complexes.[4–6] In fact, the mono(imidazole) complexes of iron(III) porphyrin exhibit the S = 3/2, 5/2 admixed intermediate-spin in a series of $[Fe(TMP)(R-Im)]^+$ complexes, where R–Im indicates alkyl-substituted imidazoles and benzimidazoles.[7–9] In general, the degree of the S = 3/2 contribution in five-coordinate complexes correlates with the ligand field of the anionic axial ligands - it increases as the ligand field of the axial ligands weakens. Reed and co-workers thus ranked the relative field strengths of weak anionic ligands (X) in [Fe(TPP)X] on the basis of spectroscopic and magnetic properties and called the resultant hierarchy a magnetochemical series.[10,11] We and others have recently reported that the deformation of the porphyrin ring is also an important factor which affects the spin states[12,13] and the electron configurations of iron(III) ions.[14–21] Thus, highly nonplanar six-coordinate com-

plexes with weak field axial ligands such as the saddled $[Fe(OETPP)(THF)_2]^+$ and the ruffled $[Fe(T\textit{i}PrP)(THF)_2]^+$ exhibit an essentially pure intermediate spin state.[12] These results have been ascribed to the short $Fe-N_p$ (N_p: nitrogen atoms of porphyrin) bond lengths caused by the nonplanarity of the porphyrin rings[12,13,22–25] together with the weak coordinating ability of the axial ligands.[10,11] The strongly S_4 saddled OETPP ring stabilizes the intermediate spin state even in the presence of nitrogen bases. Thus the complexes $[Fe(OETPP)L_2]^+$ (L = Py and 4-CNPy) show the $S = 3/2$ state at room temperature and exhibit a novel spin transition from the $S = 3/2$ to the $S = 1/2$ state as the temperature is lowered.[26] In this paper, we report on the spin states of other saddle shaped complexes, namely $[Fe(OMTPP)L_2]^+$ (L = DMAP and Py) in the solid state on the basis of a combined analysis by Mössbauer spectroscopy, SQUID magnetometry, and X-ray crystallography. We also report on the anomalous difference in magnetic behavior between the structurally similar $[Fe(OMTPP)Py_2]^+$ and $[Fe(OETPP)Py_2]^+$ in the solid state and on the requirements for the occurrence of the spin crossover process (Scheme 1).

Results and Discussion

Structural Characteristics

Figure 1 shows the molecular structure of $[Fe(OMTPP)(DMAP)_2]ClO_4 \cdot 4CHCl_3$ determined at 298 K. Two of the four solvent molecules and a counter anion (not shown) exhibit two disordered structures, A and B, in each site. The site-occupancy factors of the two solvent molecules and the counter anion for A:B are 0.85:0.15, 0.72:0.28, and 0.54:0.46, respectively. Figure 2 shows the molecular structure of $[Fe(OMTPP)Py_2]ClO_4 \cdot 1/3HClO_4 \cdot 4/3CHCl_3$ determined at 298 K. Because the Fe1, N2, and C16 atoms lie on the four-fold inverted axis, only a quarter of the molecule is crystallographically independent. Similarly, because Cl1, O2, C17, and H17 are on the three-fold axis, one-third of the counter anion and solvent molecules are in an asymmetric unit. The counter anion is disordered and the site-occupancy factors for the disordered O1A and O1B are 0.59 and 0.41, respectively, at 298 K. The structure of the counter anion at 80 K is, however, ordered as a consequence of the increase in the packing force and the decrease in the thermal movement of the molecule. Figure 3 shows the molecular structure of $[Fe(OETPP)(DMAP)_2]ClO_4$ determined at 298 K. This crystal turns out to be a polymorph of the crystal reported previously by Walker et al.[27] The present crystal, the polymorph A, with the space group $P3_121$ (#152) contains no solvent molecules, while the crystal reported by Walker et al., the polymorph B, with space group $Pna2_1$ (#33) contains four chloroform molecules in crystallographically independent space. Figure 4 shows the deviation of each atom in $[Fe(OMTPP)L_2]^+$ (L =

DMAP, Py) and $[Fe(OETPP)L_2]^+$ (L = DMAP, Py[28]) from the average plane defined by the 24-atom porphyrin cores. Table 1 lists the crystal data for $[Fe(OMTPP)L_2]ClO_4$ (L = DMAP and Py) and $[Fe(OETPP)L_2]ClO_4$ (L = DMAP and Py[28]). Table 2 lists some structural parameters of the complexes[27,28] which are defined as follows: φ is the orientation angle of the axial ligand to the nearest N_P-Fe-N_P axis, θ is the dihedral angle between two axial ligands, τ is the dihedral angle between the average N4 plane and each pyrrole ring, ψ is the dihedral angle between two diagonal pyrrole rings, η is the twist angle between two diagonal pyrrole rings, ω is the dihedral angle between the phenyl group and the $C_\alpha-C_{meso}-C_{\alpha'}$ plane, and $|\Delta C_{meso}|$ and $|\Delta C_\beta|$ are the deviations of the *meso* and β-pyrrole carbon atoms from the mean porphyrin plane, respectively. They are also given in Scheme 2.

Figure 1 and Figure 4(a) clearly show that the porphyrin core of $[Fe(OMTPP)(DMAP)_2]^+$ is highly saddled. The average $Fe-N_p$ bond length of 1.979(3)Å is slightly shorter than that of 1.989 Å in the typical low-spin complex, $[Fe(TPP)(1\text{-}MeIm)_2]^+$.[29] The average $Fe-N_{axial}$ bond length of 2.009 Å is also quite close to the corresponding bond lengths of low-spin $[Fe(TPP)Py_2]^+$ and $[Fe(OEP)(DMAP)_2]^+$ which are 2.003 and 1.995 Å, respectively.[30,31] The β-pyrrole carbon atoms of each pyrrole ring are alternately displaced, on average, by ±0.94 Å from the 24-atom mean porphyrin plane. Because of the highly saddled structure, the complex has two mutually perpendicular clefts along the diagonal N_p-Fe-N_p axes. The DMAP ligands are situated almost exactly along these clefts. Thus, the φ values are only 1.3(3)° and 2.4(4)°. The

dihedral angle θ between the two DMAP ligands is 84.2°. The porphyrin core is ideally saddle shaped as indicated by the fairly small $|\Delta C_{meso}|$ and η values which are 0.01 Å and 1.3(4)°, respectively.

Replacement of the axially coordinated DMAP ligand by Py in $[Fe(OMTPP)L_2]^+$ causes some structural changes as shown in Figure 2 and Figure 4(a). The largest change is the elongation of the Fe−N_{axial} bonds from 2.009(3) to

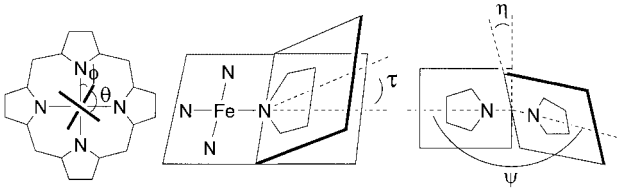

Scheme 2

2.058(6) Å. In contrast, the Fe−N_p bonds exhibit a small contraction of 0.016 Å. These results can be explained in terms of the difference in ligand field strength between DMAP and Py since DMAP is a much stronger field ligand than Py. Thus, the replacement of DMAP by Py weakens the axial coordination and lengthens the Fe−N_{axial} bonds, which in turn strengthens the equatorial coordination and causes concomitant contraction of the Fe−N_p bonds. The saddled motif in $[Fe(OMTPP)Py_2]^+$ is much deeper than that in $[Fe(OMTPP)(DMAP)_2]^+$ as indicated by the increase in the $|\Delta C_\beta|$ and τ values and the decrease in the ψ value; $|\Delta C_\beta|$ increases from 0.94 to 1.04 Å while ψ decreases from 143.0 to 128.2°. The $|\Delta C_{meso}|$ and η values are also different for two complexes - they are 0.01 Å and 1.3(4) ° for the DMAP, and 0.19 Å and 10.0(3)° for the Py complex. Such results indicate that, in contrast to the case of $[Fe(OMTPP)(DMAP)_2]^+$, the saddled structure of $[Fe(OMTPP)Py_2]^+$ contains some ruffling. Due to the mixing of the ruffled deformation, the mutually perpendicular clefts which are located along the diagonal N_p−Fe−N_p axes in the DMAP complex rotate to some extent about the Fe−N_{axial} axis. As a result, the axial ligands are aligned along the new clefts. This must be the reason why the φ value increased to 24.8(3)°.

As mentioned, $[Fe(OETPP)(DMAP)_2]^+$ has two polymorphs, A and B. Structural parameters of the polymorph A such as τ, ψ, and η are listed in Table 2. The same parameters of the polymorph B have been calculated on the basis of the molecular structure reported by Walker and co-workers[27] and these are also listed in Table 2. The average Fe−N_p and Fe−N_{axial} bond lengths are 1.977(2) and 2.030(3)Å in polymorph A, while those in polymorph B are 1.951Å and 2.000Å, respectively. The $|\Delta C_{meso}|$ and η values in A and B are also different from each other - they are 0.08 Å and 4.0° in A, and 0.28 Å and 17° in B. These data indicate that the saddled porphyrin ring in polymorph B contains some ruffling. The dihedral angles θ in A and B are 53.2° and 70°, respectively, which are much smaller than those of the other complexes.

The structural parameters of $[Fe(OMTPP)(DMAP)_2]^+$ can now be compared with those of polymorph A of $[Fe(OETPP)(DMAP)_2]^+$. As shown in Figure 3 and Figure 4(b), the saddled structure has increased on going from the OMTPP to the OETPP complex. The $|\Delta C_\beta|$ and ψ values are 0.94 Å and 143.0(2)° in $[Fe(OMTPP)(DMAP)_2]^+$ while they are 1.22 Å and 118.4(1)° in $[Fe(OETPP)(DMAP)_2]^+$. Although the average Fe−N_{axial} bond length has increased by 0.021 Å on going from OMTPP to OETPP, the average Fe−N_p bond lengths remain almost constant. In contrast to the ideally saddle shaped $[Fe(OMTPP)(DMAP)_2]^+$, the porphyrin core of $[Fe(OETPP)(DMAP)_2]^+$ exhibits a slight ruffling as revealed by the larger $|\Delta C_{meso}|$ and η values of 0.08 Å and 4.0(2)°. As a result, the φ values of the axial ligands have increased from 1.3(3)° and 2.4(4)° in $[Fe(OMTPP)(DMAP)_2]^+$ to 10.6(2) and 25.0(2)° in $[Fe(OETPP)(DMAP)_2]^+$.

Similarly, the structural parameters of $[Fe(OMTPP)Py_2]^+$ can be compared with those of $[Fe(OETPP)Py_2]^+$ reported in our previous communication.[28] The largest difference can be seen in the long Fe−N_{axial} bond lengths of 2.201Å in $[Fe(OETPP)Py_2]^+$. Even the Fe−N_p bonds show a small increase of 0.022 Å. As in the case of the DMAP complexes, the saddled structure has increased on going from the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

OMTPP to the OETPP complex. The $|\Delta C_\beta|$ and ψ values in $[Fe(OMTPP)Py_2]^+$ are 1.04 Å and 128.2(1)° compared with 1.24 Å and 115.2(2)° in $[Fe(OETPP)Py_2]^+$. While the porphyrin core of $[Fe(OMTPP)Py_2]^+$ exhibits some ruffling, that of $[Fe(OETPP)Py_2]^+$ shows quite a pure saddled structure. The $|\Delta C_{meso}|$ and η values are 0.03 Å and 1.2(3)°, respectively.[28] These results indicate that $[Fe(OETPP)Py_2]^+$ has two deep clefts along the diagonal N_p-Fe-N_p axes above and below the porphyrin ring. As a result, the pyridine ligands are situated almost exactly along the diagonal N_p-Fe-N_p axes and the φ values are only 1.1(4)° and 3.6(3)°. Thus, the orientation of planar axial ligands in highly saddled porphyrin complexes can be summarized as follows: the axial ligands are orientated along the diagonal N_p-Fe-N_p axes but they rotate toward the diagonal $C_{meso}-Fe-C_{meso}$ axes as the ruffling character increases.[32–34]

Spin States of $[Fe(OMTPP)L_2]^+$

(i) Mössbauer Spectra

Figure 5 shows the temperature dependence of the Mössbauer parameters such as isomer shift (IS) and quadrupole splitting (QS) for $[Fe(OMTPP)L_2]^+$ and $[Fe(OETPP)L_2]^+$ (L = DMAP, Py) determined for microcrystalline samples.[26] Table 3 lists the IS, QS and effective line widths (Γ_1 and Γ_2). The IS value increases from 0.16 to 0.23 mm·s^{-1} in the case of $[Fe(OMTPP)(DMAP)_2]^+$ as the temperature is lowered from 290 to 77 K. A similar increase has been observed for the IS values of $[Fe(OMTPP)Py_2]^+$ and $[Fe(OETPP)(DMAP)_2]^+$ which increase from 0.19 to 0.25 mm·s^{-1} and from 0.19 to 0.26 mm·s^{-1}, respectively. Only the IS value of $[Fe(OETPP)Py_2]^+$ shows a large decrease from 0.32 to 0.25 mm·s^{-1} as shown in Figure 5(a). The QS values of $[Fe(OMTPP)(DMAP)_2]^+$, $[Fe(OMTPP)Py_2]^+$, and $[Fe(OETPP)(DMAP)_2]^+$ are almost constant in the temperature range 290–77 K and are 1.86–1.90 mm·s^{-1} for $[Fe(OMTPP)(DMAP)_2]^+$, 2.13–2.18 mm·s^{-1} for $[Fe(OMTPP)Py_2]^+$, and 2.21–2.31 mm·s^{-1} for $[Fe(OETPP)(DMAP)_2]^+$. These three complexes thus maintain their low-spin states in the temperature ranges examined. The QS values of the low-spin complexes are in the range of 1.3–2.4 mm·s^{-1}.[26,35–37] In contrast, the QS value of 2.76 mm·s^{-1} for $[Fe(OETPP)Py_2]^+$ at 290 K is rather large and decreases to 2.29 mm·s^{-1} at 77 K. Since the S = 3/2 complexes are characterized by the large QS values,[10,12,13,24,26,38,39] this Mössbauer result suggests that $[Fe(OETPP)Py_2]^+$ exhibits a spin crossover from the predominantly S = 3/2 state at 290 K to the predominantly S = 1/2 state at 77 K.

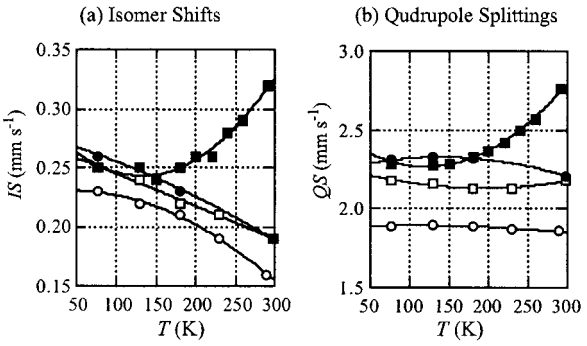

Figure 5. Temperature dependence of the Mössbauer parameters of $[Fe(OMTPP)L_2]ClO_4$ and $[Fe(OETPP)L_2]ClO_4$ measured on microcrystalline samples; open circles: $[Fe(OMTPP)(DMAP)_2]ClO_4$; open squares: $[Fe(OMTPP)Py_2]ClO_4$; filled circles: $[Fe(OETPP)(DMAP)_2]ClO_4$; filled squares: $[Fe(OETPP)Py_2]ClO_4$

(ii) SQUID Magnetometry

Figure 6 shows the temperature dependence of the effective magnetic moments of $[Fe(OMTPP)L_2]ClO_4$ (L = DMAP, Py) taken on microcrystalline samples using SQUID magnetometry. For comparison, the corresponding data for $[Fe(OETPP)L_2]ClO_4$ (L = DMAP, Py) reported in our previous communication are also given.[26] While the effective magnetic moments of $[Fe(OMTPP)(DMAP)_2]^+$, $[Fe(OMTPP)Py_2]^+$, and $[Fe(OETPP)(DMAP)_2]^+$ are 2.1–2.8 μ_B in the temperature range of 50–300 K, those of $[Fe(OETPP)Py_2]^+$ are 2.4–3.4 μ_B in the same temperature range. These results suggest that the former three complexes adopt mainly the S = 1/2 spin state while $[Fe(OETPP)Py_2]^+$ exhibits the spin transition from the predominantly S = 3/2 state to the predominantly S = 1/2 state as the temperature is lowered. The SQUID results are therefore consistent with the Mössbauer results.

Reasons for the Absence of the Spin Crossover Process in $[Fe(OMTPP)Py_2]^+$

In our previous communication, we reported the basis of the spectroscopic and magnetic results that are observed when a novel spin transition takes place from the S = 3/2 to the S = 1/2 spin state in $[Fe(OETPP)Py_2]^+$ both in solution and in the solid state as the temperature is lowered.[26] The X-ray crystallographic analysis of the same complex at three different temperatures revealed that the contraction of

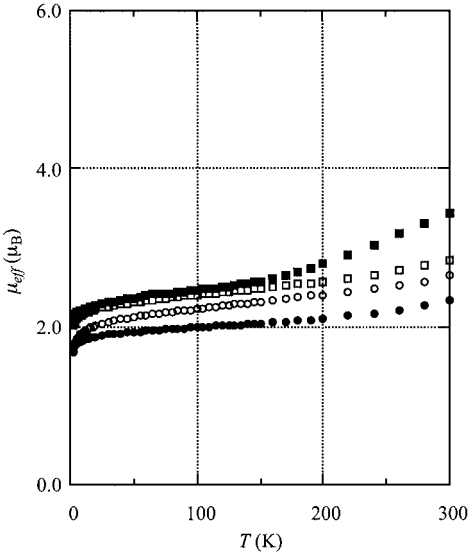

Figure 6. Temperature dependence of the effective magnetic moments of $[Fe(OMTPP)L_2]^+$ and $[Fe(OETPP)L_2]^+$ measured on microcrystalline samples using SQUID magnetometry; open circles: $[Fe(OMTPP)(DMAP)_2]ClO_4$; open squares: $[Fe(OMTPP)Py_2]ClO_4$; filled circles: $[Fe(OETPP)(DMAP)_2]ClO_4$; filled squares: $[Fe(OETPP)Py_2]ClO_4$

the Fe−N_{axial} bond is an important requirement for the spin crossover process to occur. The average Fe−N_{axial} bond length decreases from 2.201(3) to 1.993(3) Å as the temperature is lowered from 298 to 80 K.[28] Similar bond contractions have been reported by Scheidt and co-workers in $[Fe(OEP)(3\text{-}ClPy)_2]^+$, which could be ascribed to the spin transition from the $S = 5/2$ to the $S = 1/2$ state.[40,41] Thus, we expected such a spin transition should also occur in $[Fe(OMTPP)Py_2]^+$. Both the Mössbauer and SQUID measurements for the microcrystalline samples indicated, however, that such a phenomenon never occurs in the solid state. $[Fe(OMTPP)Py_2]^+$ maintains the $S = 1/2$ spin state over a wide range of temperatures. To understand the reasons for the absence of the spin crossover process in $[Fe(OMTPP)Py_2]^+$, we determined the crystal and molecular structures of this complex at 80 K. The crystal data and structural parameters are listed in Table 1 and Table 2, respectively. The data in Table 2 indicate that the Fe−N_{axial} bond in $[Fe(OMTPP)Py_2]^+$ shows only a slight decrease of 0.034 Å, as the temperature is lowered from 298 to 80 K whereas the corresponding decrease reaches as much as 0.208 Å in the case of the spin crossover complex, $[Fe(OETPP)Py_2]^+$. The data in Table 2 also indicate that the structural changes are fairly small in all respects including the values of φ, θ, τ, ω, ψ, and η. For example, while the axial ligands rotate by 5.2° and 8.0° as the temperature is lowered from 298 to 80 K in $[Fe(OETPP)Py_2]^+$, they rotate by only 1.4° in $[Fe(OMTPP)Py_2]^+$. These data are consistent with the Mössbauer and SQUID results, which indicate that $[Fe(OMTPP)Py_2]^+$ maintains the $S = 1/2$ spin state over a wide range of temperatures in the solid state.

The difference in the magnetic behavior can be ascribed to the difference in molecular packing between $[Fe(OMTPP)Py_2]^+$ and $[Fe(OETPP)Py_2]^+$ in the crystal lattices. The crystal data listed in Table 1 as well as those of $[Fe(OETPP)Py_2]^+$ reported in our previous communication indicate that the crystal systems for $[Fe(OMTPP)Py_2]^+$ and $[Fe(OETPP)Py_2]^+$ are different. The former adopts a cubic while the latter exhibits a monoclinic crystal system.[28] The monoclinic system is a less condensed packing form than the cubic system since the latter is the closest packing form as shown in Figure 7 (a and b). In fact, the density (D_x) of $[Fe(OMTPP)Py_2]^+$ with the cubic crystal system is 1.406 g cm^{-3}, while that of monoclinic $[Fe(OMTPP)(DMAP)_2]^+$ is 1.374 g cm^{-3} in spite of its larger molecular weight. It should be noted that the D_x value of the spin crossover complex, $[Fe(OETPP)Py_2]^+$, is only 1.296 g cm^{-3} at 298 K. Thus, $[Fe(OMTPP)Py_2]^+$ is the most densely packed among the three complexes. In other words, the Fe−N_{axial} bond contraction in $[Fe(OMTPP)Py_2]^+$ at lower temperature must be more difficult than that in $[Fe(OETPP)Py_2]^+$ since each molecule of $[Fe(OMTPP)Py_2]^+$ is placed in a densely packed crystal lattice even at ambient temperature. Consequently the spin crossover process, which requires a decrease in the Fe−N_{axial} bond length caused by the contrac-

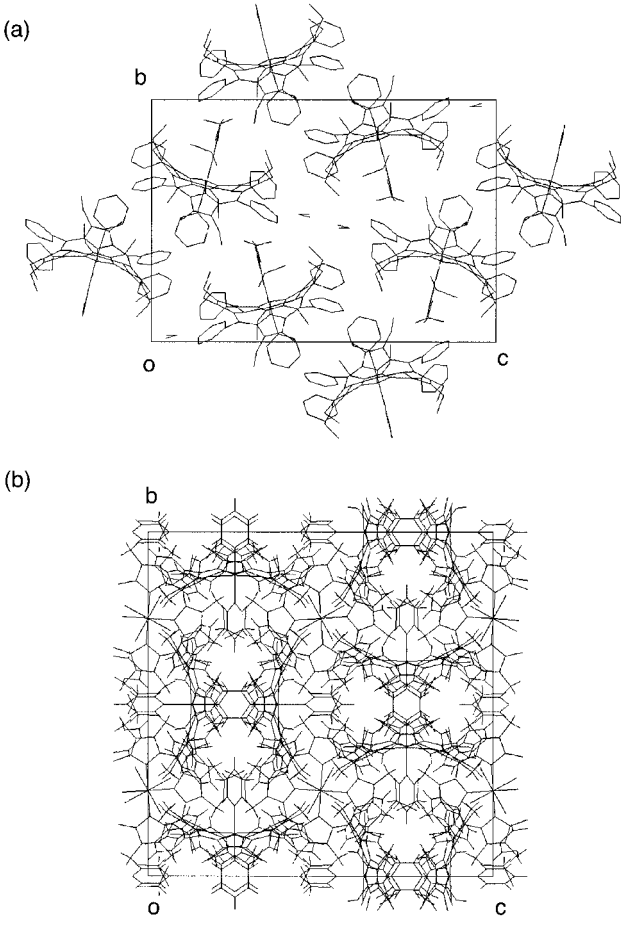

Figure 7. Crystal packing diagrams of (a) monoclinic $[Fe(OETPP)Py_2]^+$ and (b) cubic $[Fe(OMTPP)Py_2]^+$ viewed along the *a* axis

tion of the unit cell, takes place only in $[Fe(OETPP)Py_2]^+$. It should also be noted that the decrease in the crystal lattice occurs differently between $[Fe(OMTPP)Py_2]^+$ and $[Fe(OETPP)Py_2]^+$ because of the difference in crystal systems. Since the structure of $[Fe(OMTPP)Py_2]^+$ adopts a cubic system, the contraction of the crystal lattice should occur isotropically as the temperature is lowered. In the case of $[Fe(OETPP)Py_2]^+$, however, an anisotropic contraction is expected at lower temperature because of its monoclinic system. In fact, we have observed quite a direction-dependent contraction as reported in our previous communication. The major contraction takes place along the *b*-axis, which is tilted by only 15° from the $Fe-N_{axial}$ axis.[28] Thus, the contraction of the unit cell along the b-axis specifically decreases the $Fe-N_{axial}$ bonds and, consequently, induces the spin crossover process.

As mentioned, the displacement and rotation of the axial ligands are the major driving forces for the spin-crossover process in $[Fe(OETPP)Py_2]^+$.[28] The degree of displacement and rotation should correlate closely with the shape and size of the cavity around the axial ligand. The axial ligands situated in a wide cavity could easily alter their positions when the external conditions such as temperature and pressure are changed. In this respect, quantitative elucidation of the cavities around the axial ligands is quite important for clarifying the mechanism of the spin-crossover process. To reveal the spatial environment around the axial ligands of $[Fe(OETPP)Py_2]^+$ and $[Fe(OMTPP)Py_2]^+$, we have carried out a CAVITY calculation developed by Ohashi and co-workers.[42,43] In this calculation, the cavity for the axial ligand is defined as the concave space limited by the surface of the spheres,[42,43] where each atom in the vicinity of the pyridine ligand is located in the center of the sphere with the radius of each sphere being greater than the van der Waals radius by 1.2 Å.[44] Figure 8 (a and b) exhibit the change in orientation of the pyridine ligand of $[Fe(OMTPP)Py_2]^+$ as the temperature is lowered from 298 to 80 K. In this complex, a quarter of the molecule is crystallographically independent. Thus, the cavity size and shape of each ligand is exactly the same in a single molecule. Figure 8 (c and d) illustrate the change in orientation of one of the pyridine ligands of $[Fe(OETPP)Py_2]^+$. Since the complex has two independent pyridine ligands in a single molecule, the cavities of the ligands are different from each other. The cavity sizes of these complexes are also listed in Table 2. The data in Table 2 clearly indicate that the cavity sizes are quite different between the two complexes. The OETPP complex showing the spin-crossover phenomenon has cavities of 32.08 and 28.88 $Å^3$ at 298 K, while the OMTPP complex has a much smaller cavity size of 19.81$Å^3$. Thus, the cavity size of the Py ligand in $[Fe(OMTPP)Py_2]^+$ is only 65% of that in $[Fe(OETPP)Py_2]^+$. Close inspection of the cavities in Figure 8 (c and d) reveals that the pyridine ligand in the OETPP complex, signified as a bold line, is aligned along the diagonal N1−N3 axis and makes contact with a convex surface created by the neighboring atoms at 298 K. When the temperature is lowered to 80 K, the $Fe-N_{axial}$ bond contracts. Concomitantly, the pyridine ligand rotates toward the diagonal $C_{meso}-C_{meso}$ axis to minimize the repulsion with the porphyrin core until it makes contact with another convex surface. In other words, each pyridine ligand of $[Fe(OETPP)Py_2]^+$ has room for rotation, which in turn enables the contraction of the $Fe-N_{axial}$ bond and makes the spin crossover possible. In contrast, the pyridine ligand in $[Fe(OMTPP)Py_2]^+$ is confined to a limited space of only 65% of that available in $[Fe(OETPP)Py_2]^+$. Furthermore, the cavity shape around the pyridine ligand does not allow any rotation of the ligand as shown in Figure 8 (a and b). Both sides of the pyridine ligand make contact with the convex surfaces. Another notable difference is the compression ratio of the cavity as the temperature is lowered from 298 to 80 K. Although the cavity of the OETPP complex decreases on average by 17.7%, that of the OMTPP complex shows a much smaller decrease of 5.25%. Thus, the absence of the spin crossover process in $[Fe(OMTPP)Py_2]^+$ can be attributed to the fact that the molecules are placed in a densely packed crystal lattice even at room temperature and that the axial ligands are confined to narrow cavities. In other words, a loosely packed crystal system and wide cavities around the axial ligands which allow their displacement and rotation are the important requirements for the spin transition to occur in the solid state.

Conclusions

Combined analysis using Mössbauer spectroscopy and SQUID magnetometry has revealed that the spin state of the saddle shaped complex $[Fe(OMTPP)Py_2]^+$ is quite different from that of the corresponding $[Fe(OETPP)Py_2]^+$. While $[Fe(OETPP)Py_2]^+$ exhibited a novel spin crossover process over 80−300 K, $[Fe(OMTPP)Py_2]^+$ maintained the $S = 1/2$ spin state in the same temperature range. The molecular structures of $[Fe(OMTPP)Py_2]^+$ determined at 298 and 80 K by X-ray crystallography further support the Mössbauer and SQUID results. The $Fe-N_{axial}$ bond contraction, which is one of the most important requirements for the spin crossover process to occur, is only 0.034 Å even if the temperature is lowered from 298 to 80 K whereas the bond contraction reaches as much as 0.208 Å in the case of $[Fe(OETPP)Py_2]^+$. To further understand the spin crossover process in the solid state, we have determined the cavity size of each ligand in $[Fe(OMTPP)Py_2]^+$ and $[Fe(OETPP)Py_2]^+$ by Ohashi's method.[42−44] While the OETPP complex has cavities of 32.08 and 28.88 $Å^3$, the OMTPP complex exhibits a much smaller cavity with a volume of 19.81 $Å^3$. Furthermore, the cavities of the OETPP complex decreased by 15.6 and 19.7% as the temperature was lowered from 300 to 80 K. In contrast, the contraction of the cavity in the OMTPP complex was only 5.3%. On the basis of these results, we conclude that the absence of the spin crossover process in $[Fe(OMTPP)Py_2]^+$ can be attributed to the densely packed crystal lattice together with the narrow cavities around the axial ligands. In other words, the molecules have to be placed in a loosely packed crystal

lattice and the cavities around the axial ligands have to be wide for the occurrence of the spin crossover in the solid state.

Experimental Section

General Procedures: Iron-57 Mössbauer spectra were measured on a Wissel Mössbauer spectrometer system consisting of an MDU-1200 function generator, a DFG-1200 driving unit and an MVT-100 velocity transducer, incorporating a model 7800 multi-channel analyzer form Seiko EG&G Co. Ltd. The samples were kept in a Heli-Tran LT-3 gas-flow cryostat from Advanced Research System Inc. equipped with a 9620 digital temperature controller from Scientific Instruments Inc. and the ^{57}Co(Rh) source was kept at room temperature. The data were analyzed using the standard least-squares method. The isomer shifts (δ) are given relative to α-iron foil at room temperature. The solid state magnetic susceptibilities were measured over the temperature range 2−300 K in a magnetic field of 0.5 T with a SQUID magnetometer (Quantum Design MPMS-7). The measured data were corrected for diamagnetic contributions.

Synthesis: H_2(OMTPP) and the iron(III) chloride complex [Fe(OMTPP)Cl] were prepared according to the literature.[45−49] [Fe(OMTPP)(THF)$_2$]ClO_4 was prepared by the addition of a THF solution of $AgClO_4$ to a THF solution of [Fe(OMTPP)Cl].[49,50] The bis-ligated complexes, [Fe(OMTPP)L_2]ClO_4, were prepared by the addition of 10−15 equiv. of the ligand (DMAP or Py) to a $CHCl_3$ solution of [Fe(OMTPP)(THF)$_2$]ClO_4.[49]

Crystal Structure of [Fe(OMTPP)(Py)$_2$]ClO_4·1/3$HClO_4$·4/3$CHCl_3$ at 298 K

i) Preparation of Crystals: The purple solid [Fe(OMTPP)(THF)$_2$]ClO_4 was dissolved in $CHCl_3$ containing 10−15 equiv. of pyridine and allowed to stand at room temperature. One of the cubic crystals thus obtained was sealed within a glass capillary to prevent evaporation of solvent in the crystal lattice.

ii) X-ray Crystal Structure Analysis: All data were collected on a Rigaku AFC-7R diffractometer with filtered Mo-K_α radiation (λ = 0.71069Å) and a rotating anode generator. Cell constants and an orientation matrix for data collection were obtained from a least-squares refinement using the setting angles of 21 carefully centered reflections in the range $30.08 < 2\theta < 33.66°$ corresponded to an *I*-centered cubic cell. The data were collected at room temperature using the ω scan technique to a maximum 2θ value of 54.9°. Of the 1948 reflections which were collected, 1681 were unique (R_{int} = 0.0362). An empirical absorption correction based on azimuthal scans of several reflections was applied which resulted in transmission factors ranging from 0.80 to 0.98.[51] The structures were solved by direct methods with the program SIR97,[52] TEXSAN[53] and expanded using the program DIRDIF94.[54] The structure refinement was carried out by the full-matrix least-squares method with SHELXL-97.[55] All non-hydrogen atoms were refined anisotropically. All the hydrogen atoms were located in calculated positions. The positional parameters of the H atoms were constrained to have C−H distances of 0.96Å for primary, 0.97Å for secondary, and 0.93 Å for aromatic H atoms. The H-atom *U* values were constrained to have 1.2 times the equivalent isotropic *U* value of the atoms to which they are attached (1.5 for methyl groups). The atomic scattering factors were taken from the International Tables for Crystallography.

CCDC-208539 to -208542 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Crystal Structure of [Fe(OMTPP)(DMAP)$_2$]ClO_4·4$CHCl_3$

i) Preparation of Crystals: The purple solid [Fe(OMTPP)(THF)$_2$]ClO_4 was dissolved in $CHCl_3$ containing 10−15 equiv. of DMAP and allowed to stand at room temperature. One of the prismatic crystals thus obtained was sealed within a glass capillary to prevent evaporation of solvent in the crystal lattice.

ii) X-ray Crystal Structure Analysis: All measurements were carried out on a Rigaku RAXIS-RAPID Imaging Plate diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71069Å) and a rotating anode generator. Indexing was performed from 3 oscillations which were exposed for 7.5 minutes. The camera radius was 127.40 mm. Readout was performed in the 0.100 mm pixel mode. The data were collected at 80 K to a maximum 2θ value of 55.0°. A total of 110 images, corresponding to 222.0° oscillation angles were collected with 3 different goniometer settings. Exposure time was 2.70 minutes per degree. Data were processed with the PROCESS-AUTO program package. Of the 106877 reflections which were collected, 17126 were unique (R_{int} = 0.039). The linear absorption coefficient, μ, for Mo-K_α radiation is 6.9 cm^{-1}. A symmetry related absorption correction using the ABSCOR program was applied which resulted in transmission factors ranging from 0.869−0.933. The data were corrected for Lorentz and polarization effects.[55] The structure was solved by a procedure similar to that described above.

iii) Crystal Data, Experimental and Refinement Details for Crystal Structure Determination: Crystal data: $C_{70}H_{67}N_8O_4ClFe$. 4$CHCl_3$; M_r = 1602.02 g mol^{-1}; crystal color: purple; crystal dimensions: 0.2 × 0.1 × 0.1 mm; monoclinic, $P2_1/c$ (#14); a= 16.4556(5)Å, b = 23.7289(6)Å, c = 19.8424(6)Å; β = 91.924(1)°; V = 7743.6(4) Å^3; Z = 4; ρ = 1.374 gcm^{-3}; R_{int} = 0.0546, R_σ = 0.0278; $-19 < h < 21$, $-30 < k < 30$, $-25 < l < 25$; Refinement: Refinement on F^2; $R[F^2 > 2\sigma(F^2)]$ = 0.0899, *R*(all data) = 0.1205, wR^2 = 0.2543; *S* = 1.024; 17126 reflections; 0 restraints; 935 parameters; $w = 1/[\sigma^2(F_o^2) + (0.01785P)^2 + 2.5869P]$ where $P = (F_o^2 + 2F_c^2)/3$; $(\Delta/\sigma)_{max} < 0.001$; $\Delta\rho_{max}$ = 0.906 eÅ^3; $\Delta\rho_{min}$ = −0.725 eÅ^3

Crystal Structure of [Fe(OETPP)(DMAP)$_2$]ClO_4

i) Preparation of Crystals: The purple solid [Fe(OETPP)(THF)$_2$]ClO_4 was dissolved in $CHCl_3$ containing 10−15 equiv. of DMAP and allowed to stand at room temperature. One of the prismatic crystals thus obtained was sealed within a glass capillary to prevent evaporation of solvent in the crystal lattice.

Hydration of Propargylic Alcohols by Ruthenium Catalysts, with Dominant Anti-Markovnikov Regioselectivity, Formation of α,β-Unsaturated Products and Catalytic Decarbonylation to 1-Alkenes

Nicola d'Alessandro,[a] Milena Di Deo,[a] Monica Bonetti,[a] Lucia Tonucci,[a] Antonino Morvillo,[b] and Mario Bressan*[a]

Keywords: Ruthenium / Alkynes / Phthalocyanines / Hydration / Decarbonylation

Ruthenium catalysts — water-soluble ruthenium sulfophthalocyanine and heterogeneous ruthenium hydroxyapatite complexes — proved to be effective for the hydration of propargylic alcohols in entirely aqueous media. 1-Phenyl-2-propyn-1-ol underwent an unprecedented catalytic hydration-decarbonylation-dehydration reaction, giving rise to styrene and carbon monoxide; 2-propyn-1-ol and 3-butyn-2-ol gave predominantly the products of anti-Markovnikov addition, together with products of hydration-dehydration (α,β-rearrangement) and, to a minor extent, the decarbonylation products, ethene or propene, respectively. Hydrations were also conducted in D_2O, giving indications of the mechanism of the reactions and apparently ruling out the allenylidene route for the α,β-rearrangement.

Introduction

Alkynes are useful intermediates for the synthesis of carbonyl compounds through the well-known metal-catalyzed hydration reaction. Typically, the addition reactions of water to 1-alkynes are catalyzed by a variety of transition metal salts and complexes,[1−7] including $RuCl_3$,[8,9] all of which follow Markovnikov's rule to give ketones. Only very recently[10] has it been reported that the reaction can be regioselectively oriented to the formation of aldehydes (anti-Markovnikov addition) in the presence of catalytic amounts of some ruthenium(II) organometallic derivatives, containing either cyclopentadienyl[11,12] or indenyl[13] moieties, although temperatures of around 100 °C were still required. The accepted mechanism involves the rearrangement of the π-adduct deriving from the conventional interaction with the terminal alkynes at the metal center into a metal-vinylidene intermediate[13] or, alternatively, a hydrido-alkynyl complex,[12] the latter of which has recently been isolated as an intermediate in the activation of propargylic alcohols by [Cp*RuCl(dppe)];[14] both the proposed intermediates are prone to nucleophilic attack by water at the α-carbon atom. Previous results[15] showed the critical role played by the π-alkyne/vinylidene equilibrium in the regioselectivity of the hydration reactions, suggesting that addition of water to the π-adduct might follow Markovnikov's rule, eventually yielding methylketones, whereas addition to the vinylidene intermediate would lead to an acyl complex and, finally, aldehydes. However, only a few examples have reported good selectivity in the aldehyde formation,[11,13] as several alternative reaction pathways, not strictly dealing with conventional hydration, could become dominant. Among them, the catalytic cleavage of the carbon-carbon triple bond is particularly attractive, since it could represent an interesting topic from the synthetic point of view, if high selectivities can be attained in mild experimental conditions. So far, however, alkyne cleavage has also been demonstrated to work effectively in only a few cases.[16,17]

The potential for the use of both ruthenium catalysts and water as reagent prompted our interest in the subject. In the present work we tested the water-soluble ruthenium(II) complex ruthenium sulfophthalocyanine (RuPcS), previously studied by us as an effective catalyst for a variety of organic substrates in aqueous media,[18−22] and the heterogeneous ruthenium hydroxyapatite (RuHAP) catalyst, successfully tested for the aerobic oxidation of alcohols to aldehydes, reportedly via a metal-hydrido species,[23] which proved to work satisfactorily also in aqueous media.[24] This paper deals with the catalytic hydration of a number of propargylic (2-propyn-1-ol, 3-butyn-2-ol, 1-phenyl-2-propyn-1-ol and 1,1-diphenyl-2-propyn-1-ol) and non-propargylic alcohols (3-butyn-1-ol and 4-pentyn-1-ol). A variety of reaction pathways were observed, depending upon the nature of the substrate and the catalyst; among them, cleavage of

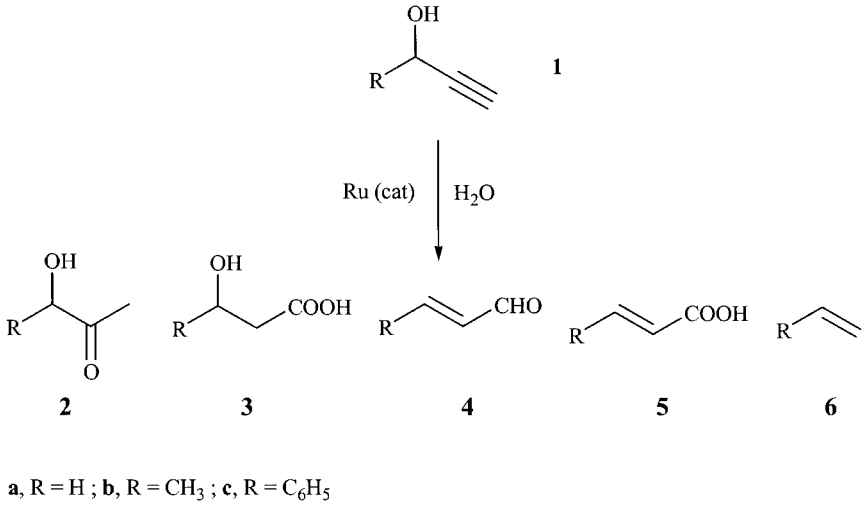

Scheme 1. Product distribution for the hydration of propargylic alcohols catalyzed by Ru^{II} derivatives

the triple bond, with formation of alkenes, was of particular interest (Scheme 1).

Results and Discussion

The RuHAP and RuPcS catalysts proved to be effective, at various selectivities, in the reaction of the terminal acetylenes 1-phenyl-2-propyn-1-ol, 2-propyn-1-ol, 3-butyn-2-ol and 4-pentyn-1-ol with water; no reaction took place in the absence of added catalyst or in the presence of calcium hydroxyapatite, whereas other simple ruthenium complexes, such as $[RuCl_2(DMSO)_4]$ (RuDMS) and $K_5[Ru(H_2O)PW_{11}O_{39}]$ (RuPW), behaved poorly. Very different and complex reaction patterns were found for each substrate examined, as reported in Table 1. The reactions were very slow below 80 °C.

In the presence of RuHAP and RuPcS, the non-propargylic alcohol 4-pentyn-1-ol was selectively transformed into 5-hydroxy-2-pentanone, the expected product of the conventional Markovnikov addition to the triple bond. The related substrate 3-butyn-1-ol (not shown) was poorly converted (about 10 %) during the 24 h reaction time and gave only minor amounts of products from both the Markovnikov and anti-Markovnikov addition, i.e. 4-hydroxy-2-butanone and 4-hydroxybutanoic acid, respectively, together with other unidentified compounds.

The propargylic alcohols behaved differently. Large amounts of 2-propyn-1-ol (**1a**) were converted, in the presence of both RuHAP and RuPcS, into hydroxyacetone (**2a**, the expected product of Markovnikov addition; Scheme 2), 3-hydroxy-propanoic acid (**3a**), acrylic acid (**5a**) and ethene (**6a**), together with minor amounts of glycolic and formic acid (Table 1), the latter likely arising from the oxidative cleavage of the substrate. No evidence was obtained for the presence of 3-hydroxypropanal, which should be the prod-

Table 1. Product analysis of the hydration reaction of propargylic alcohols by ruthenium catalysts[a]

Substrate	Catalyst	Conversion (mol %)	Yields (mol %) 2	3	4	5	6	By-products
1a	RuPcS	73	10	10	–	22	7[b]	8[c]

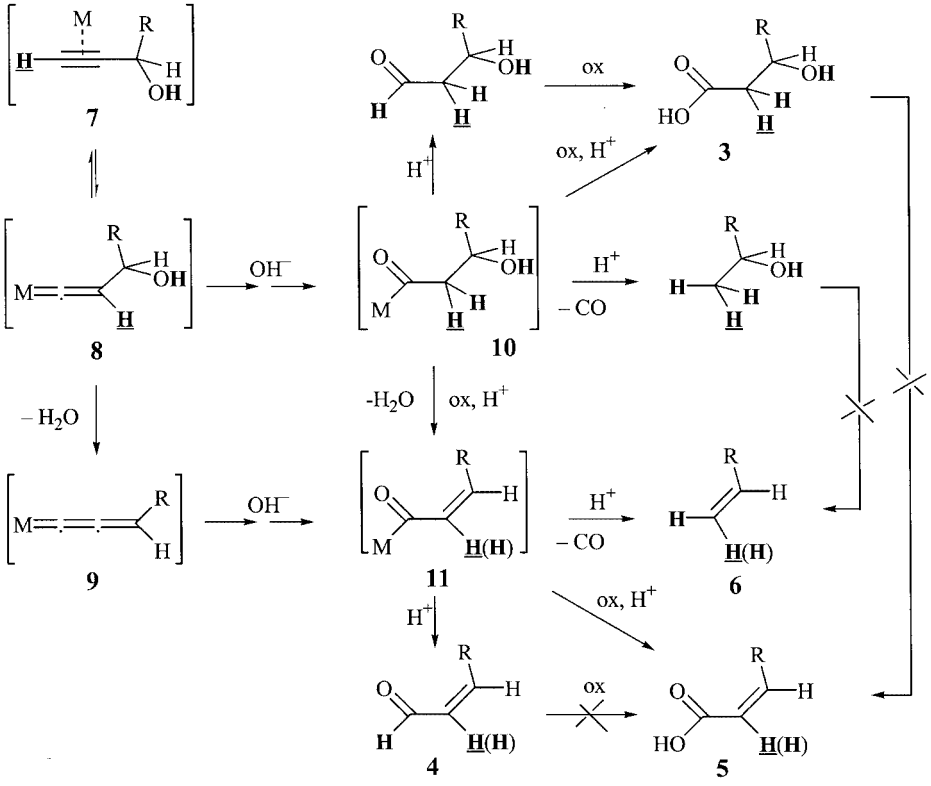
uct of anti-Markovnikov addition to the triple bond; instead, its oxidized product 3-hydroxy-propanoic acid, was detected in reasonable amounts. To avoid this undesired oxidation, we tried to conduct the reaction under an inert atmosphere (nitrogen), but the long times required for the formation of the products did not allow for a rigorous exclusion of oxygen and, indeed, only minor differences were observed with respect to the aerobic experiments, i.e. with no evidence for the aldehydic product. It should be noted here that aliphatic aldehydes, such as propionaldehyde and valeraldehyde, are easily oxidized to the corresponding carboxylic acids in the same reaction conditions and in the absence of added ruthenium catalysts. The third major reaction product, acrylic acid, could be conceivably attributed to a dehydration of 3-hydroxypropanoic acid. However, experiments conducted directly with β-propiolactone (a commercially available compound that rapidly hydrolyzes to 3-hydroxypropanoic acid in aqueous media) showed only minimal conversion into acrylic acid (less than 5 %) under these standard reaction conditions. The formation of the unsaturated product probably involves the well-known rearrangement of propargylic alcohols to α,β-unsaturated aldehydes, which is effectively catalyzed also by several ruthenium complexes.[25] More recently,[26] Wakatsuki has reported convincing evidence that the mechanism of the ruthenium-catalyzed rearrangement of propargylic alcohols to unsaturated aldehydes involves a series of organometallic intermediates, arising either by an initial anti-Markovnikov hydration of the vinylidene intermediate **8** (Scheme 3), followed by dehydration of the original OH group to **11** via **10**, or, alternatively, by an early dehydration of **8** to an allenylidene intermediate **9**, followed by the hydration step. Thus, the rearrangement of 2-propyn-1-ol was expected to produce acrolein; the observed formation of acrylic acid could again be due to the rapid oxidation of the aldehydic group, as in the case discussed previously. However, acrolein, as other α,β-unsaturated aldehydes, such as benzaldehyde and cinnamaldehyde, and contrary to the saturated aldehydes discussed above, is very difficult to oxidize under these reaction conditions. It is therefore reasonable to assume that acrylic acid is formed directly from the organometallic intermediate **11a** via a complex rearrangement-oxidation step. Finally, we also detected carbon monoxide and an appreciable amount of ethene (**6a**; see Exp. Sect.), which allowed a reasonable mass balance to be set for the overall transformation of **1a**.

The reaction of 3-butyn-2-ol (**1b**) with water closely resembles that of 2-propyn-1-ol and leads to all the expected products from the addition of water according to Markovnikov (hydroxybutanone, **2b**) and anti-Markovnikov rules (hydroxybutanoic acid, **3b**); we also detected the decarbonylated and dehydration/oxidation products, i.e. propene (**6b**) and 2-butenoic acid (**5b**), respectively, and carbon monoxide.

Hydration of 1-phenyl-2-propyn-1-ol (**1c**) reached 70 % and 95 % conversion (with RuPcS or RuHAP, respectively) of the starting material within 24 h (Table 1), but the reaction led to minimal amounts of the product of Markovni-



Scheme 3. Proposed pathway for ruthenium-catalyzed anti-Markovnikov hydration of propargylic alcohols (**H** coming from water; **H** coming from the acetylenic proton)

kov addition [1-hydroxy-1-phenylpropanone (**2c**)] and no conventional products from the anti-Markovnikov addition, i.e. 3-hydroxy-3-phenylpropanal or the corresponding carboxylic acid. In addition, the α,β-unsaturated aldehyde [cinnamaldehyde (**4c**)], arising from the ruthenium-catalyzed rearrangement of the propargylic alcohol, was detected as a minor product. It should be recalled that in the reaction conditions cinnamaldehyde, as with other α,β-unsaturated aldehydes, does not undergo oxidation to the corresponding carboxylic acid and therefore the reported yields must be considered highly significant. Quite unexpectedly, the major product formed during the reaction was styrene (**6c**), which was detected after extraction of the reaction mixtures with diethyl ether (16−20 %; Table 1), together with carbon monoxide and large (but not quantified) amounts of styrene-based polymeric materials, likely accounting for the final mass balance. It should be noted that in the cases of ethene and propene discussed previously, no water-insoluble polymeric materials were detected. However, ethene and propene, unlike styrene, accumulate in the gas phase and therefore are expected to escape from the reaction mixture before they can be polymerised. Therefore the low mass-balance values for both **1a** and **1b** (Table 1) were attributed to some further unidentified products.

No reaction was observed for the other propargylic alcohol, 1,1-diphenyl-2-propyn-1-ol, when suspended in water as it is only slightly soluble. However, when the hydration was carried out in an organic solvent (toluene) with small amounts of added water and in the presence of the lipophilic ruthenium phthalocyanine derivative RuPc, instead of the water-soluble RuPcS, small amounts of 1,1-diphenylethene and of β-phenylcinnamaldehyde were formed, thus indicating a reactivity closely related to that of 1-phenyl-2-propyn-1-ol in the water/RuPcS system.

A simple explanation for the formation of $C_{(n-1)}$ alkenes (styrene, propene and ethene) from the corresponding propargylic alcohols (1-phenyl-2-propyn-1-ol, 3-butyn-2-ol and 2-propyn-1-ol, respectively) might involve decarbonylation of the anti-Markovnikov acyl-metal intermediate **10** to 1-substituted ethanol derivatives followed by a dehydration step (Scheme 3). 2-Propanol and 1-phenylethanol were detected in trace amounts in the case of 1-phenyl-2-propyn-1-ol and 3-butyn-2-ol, respectively. However, the fact that direct experiments conducted in the presence of ethanol, 2-propanol and 1-phenylethanol under the same reaction conditions showed minimal (or no) dehydration to ethene, propene and styrene (less than 2 % in the most favorable case, namely 1-phenylethanol), indicates that the alkenes are formed directly from an organometallic intermediate (likely **11**), in competition with the 1-substituted ethanol derivatives. The formation of alkenes also implies formation of carbon monoxide, which was always detected among the products of the hydration reactions. Decarbonylation of terminal acetylenes by hydration is indeed a known process, first reported by Bruce[27] and thoroughly investigated by Bianchini[28] in the case of phenylacetylene, which, in the presence of water and of the Ru^{II} complex $[RuCl_2(PNP)(PPh_3)]$, was quantitatively transformed into toluene and the stable mono-carbonyl adduct $[RuCl_2(CO)(PNP)]$. Wakatsuki[10] has also reported decarbonylation (likely stoichiometric) during the hydration of benzylacetylene in the presence of 10 % $[RuCl_2(C_6H_6)\{PPh_2(C_6F_5)\}]$. In the present case, decarbonylation turned out to be catalytic, thus indicating lability of the putative carbonylruthenium adducts with either RuHAP or RuPcS. Indeed, RuPcS was previously reported by us[21] to be able to add carbon monoxide, giving a carbonyl product possessing a strong band at 1960 cm^{-1}, but only under very severe conditions (100 atm) and after 24 h reaction.

Hydration Reactions in D_2O

Deuterium distribution in the products was evaluated by ^1H NMR spectroscopy and GC-MS measurements on the reaction mixtures from 2-propyn-1-ol (**1a**) and 1-phenyl-2-propyn-1-ol (**1c**). It has to be noted that acetylenic-proton exchange of the pure substrates in 99.9 % D_2O turned out to be slow even at 80 °C, with 100 % deuteration being reached only after 4 h (Figure 1). The rate of deuterium exchange in the presence of the RuPcS catalyst was similar for 1-phenyl-2-propyn-1-ol, at least at early reaction times, whereas in the case of 2-propyn-1-ol deuteration was much slower and never exceeded 40 % substitution, even after long reaction times (Figure 1). The observed different deuteration rates of the acetylenic proton must be compared with the hydration rates of the corresponding substrates (Figure 1), clearly indicating that 2-propyn-1-ol (**1a**) underwent hydration in D_2O mainly as the protonated RC≡CH

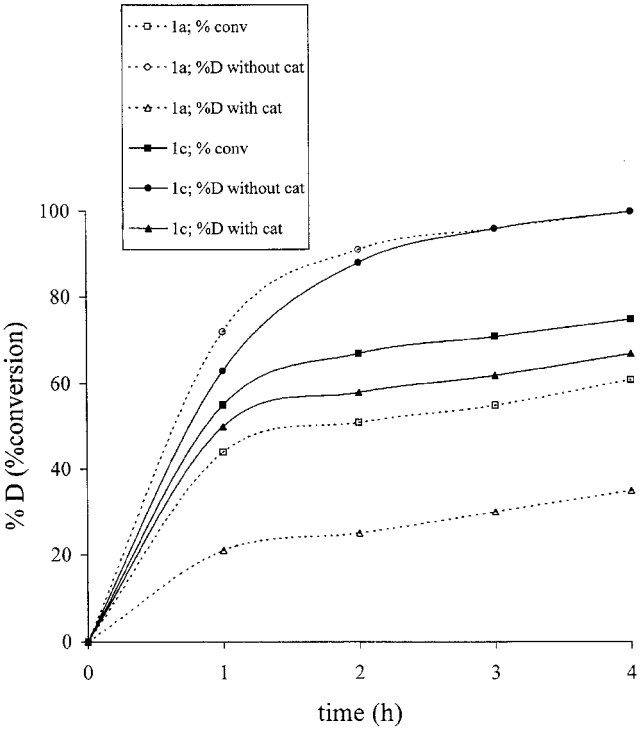

Figure 1. Incorporation of deuterium into 2-propyn-1-ol (**1a**; open squares and triangles, dotted lines) and 1-phenyl-2-propyn-1-ol (**1c**; filled squares and triangles, solid lines); % conversions of **1a** (open circles, dotted line) and **1c** (filled circles, solid line) are also reported

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

species, while 1-phenyl-2-propyn-1-ol (**1c**) reacts as the deuterated RC≡CD species.

The rapid and almost complete deuteration of the acetylene proton of 1-phenyl-2-propyn-1-ol unfortunately precluded any significant conclusion about the possible mechanism of the hydration of this substrate (Scheme 2 and 3). The ^{1}H NMR spectrum of the product of Markovnikov addition — 1-hydroxy-1-phenylacetone (**2c**) — shows complete disappearance of the singlet arising from the methyl protons, in agreement with the dominant presence of the $CO-CD_3^+$ fragment (46 amu) in the mass spectrum; the molecular ion $CH_3COCH(Ph)OH^+$ is almost undetectable. The ^{1}H NMR spectrum of cinnamaldehyde (**4c**) lacks the signals of the aldehydic proton (doublet) and that of the proton bonded to the α-carbon, whereas the signals of the Ph*C*H=CH−CHO proton are covered by those of the phenyl protons. MS measurements clearly indicated that PhCH=CD−CDO was the dominant species. The ^{1}H NMR spectrum of styrene (**6c**) lacks the multiplets arising from the terminal methylene group, whereas the multiplet of the PhCH= proton collapses into a very broad signal, strongly indicative of an effective coupling with the two deuterium atoms in the α-position; the formula Ph−CH=CD_2 was fully confirmed by the GC-MS data.

Because of the slow deuterium exchange of the acetylenic proton, a selective deuterium distribution in the products was expected for 2-propyn-1-ol. Hydroxyacetone (**2a**, the product of Markovnikov addition) exhibits the $COC\underline{H}H_2$ (see Scheme 2) singlet in the ^{1}H NMR spectra considerably broadened and reduced in intensity, when compared with that of the singlet of the CH_2OH protons, but indicative of ca. 70 % deuteration (Figure 2). The mass spectrum shows the peak of the molecular ion shifted by +3 amu and that of the $COCH_3^+$ fragment by +2 amu (45 instead of 43 amu), in agreement with the dominant presence of the $CD_2H-CO-CH_2OD$ species. The dideuteration of the methyl group in the formed methylketone confirms the slow exchange of the terminal CH, since fast exchange would have yielded trideuteration, as found in 1-hydroxy-1-phenylacetone. The anti-Markovnikov addition of D_2O to RC≡CH probably involves the interconversion of an η^2-alkyne species to a vinylidene, therefore bringing the acetylenic hydrogen onto the carbon substituted with the R group and eventually giving RCHD−CDO (or RCHD−COOD;

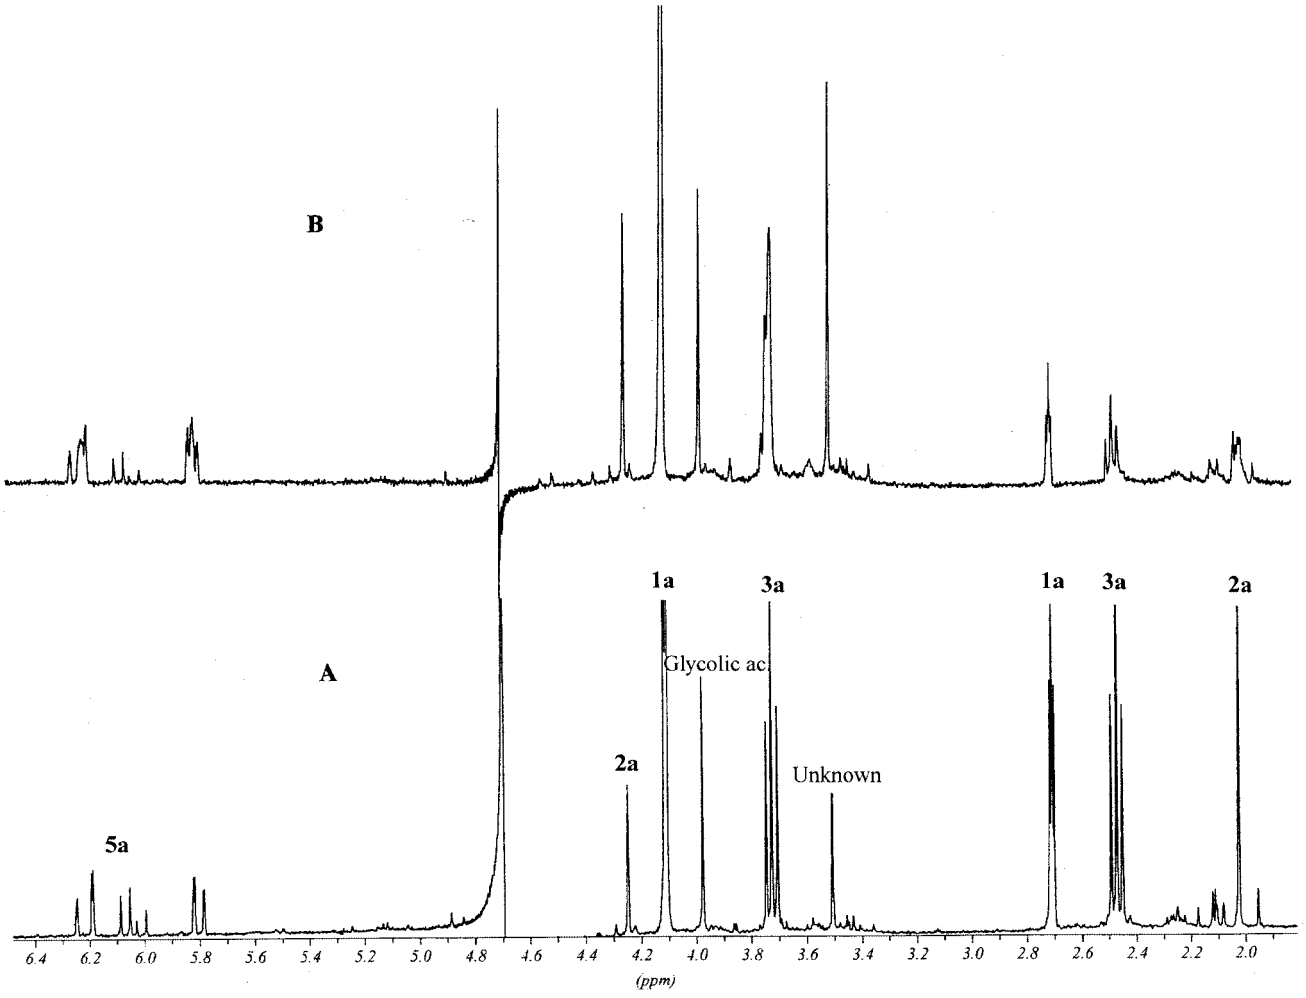

Figure 2. ^{1}H NMR spectra of the crude mixture of the hydration reaction of 2-propyn-1-ol (24 h, 80 °C) in H_2O (**A**) or in D_2O (**B**); the product numbers are the same as in Scheme 1

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 3), unless a rapid proton exchange is taking place on the vinylidene intermediate. We found that 3-hydroxypropanoic acid (**3a**) exhibits a distinctive deuteration at the methylene group next to the carbonyl carbon, with the ^{1}H NMR spectra showing a collapse of the two diagnostic triplets of the CH_2 signals at $\delta = 3.75$ and 2.50 ppm ($J = 6$ Hz) into a broad singlet and a triplet, respectively, in a roughly 2.5:1 intensity ratio (Figure 2) and therefore best fitting with an $HOCH_2-CHD-COOH$ species. No MS measurements were possible, since 3-hydroxypropanoic acid was not detectable in the GC. Acrylic acid (**5a**), arising from the hydration-dehydration reaction, shows the presence of both the $CH_2=CD-COOD$ ($m/z = 73$) and the $CH_2=CH-COOD$ species ($m/z = 72$), roughly in a 1:1 molar ratio. Accordingly, the ^{1}H NMR signals of the hydrogen atom bonded to the carbon atom next to the carboxylic function appear clearly weakened with respect to the signals of the methylene protons (ca. 50 % in intensity; Figure 2). Also ethene (**6a**), the decarbonylation product, exhibits only partial deuteration. The MS spectra of its dibromo adduct CH_2Br-CH_2Br shows an intense fragment arising from the loss of one Br atom as a series of peaks at 108 and 110 amu (^{79}Br) and at 109 and 111 amu (^{81}Br), in an intensity ratio of ca. 1:4, therefore suggesting the presence of both the dideuterated $C_2H_2D_2Br^+$ and monodeuterated $C_2H_3DBr^+$ ions. The latter two findings have some significance, since they apparently rule out the putative allenylidene route (i.e. **8a** → **9a** → **11a**, Scheme 3), for which complete deuteration of the carbon atom next to the metal-acyl function in **11a** was expected, thus eventually yielding exclusively the $CH_2=CD-COOH$ and $CD_2=CH_2$ species; the vinylidene route (i.e. **8a** → **10a** → **11a**, Scheme 3) is not contradictory with the observed formation of partially deuterated products.

Interaction of the Substrates with the Metal Complexes

The nature of the catalyst apparently influences the rate of the hydration more than it does the regioselectivity, which is strongly dependent upon the nature of the substrate. Since an attractive explanation of the observed behavior might be the different degree of stabilization of the π-adduct **7** in Scheme 2 vs. the metal-vinylidene intermediate **8** in Scheme 3, induced by the various substrates, we carefully analyzed an aqueous solution of RuPcS (10 mM) in the presence of increasing amounts of the substrates under investigation, and also, for comparison purposes, of other saturated and unsaturated alcohols (1-butanol, 2-propen-1-ol, ethanol). By increasing the substrate-to-metal ratios up to 20-fold, an enhancement of the measured acidity of the mixtures was generally observed, in some cases very sharp, but always irrespective of the nature of the substrates, and therefore hardly attributable to any significant metal/substrate interaction. Accordingly, ^{1}H NMR measurements of the propargylic alcohols/RuPcS systems in buffered solutions (with pHs varying between 0.5 and 9) exhibited only tiny and erratic shifts of the proton signals

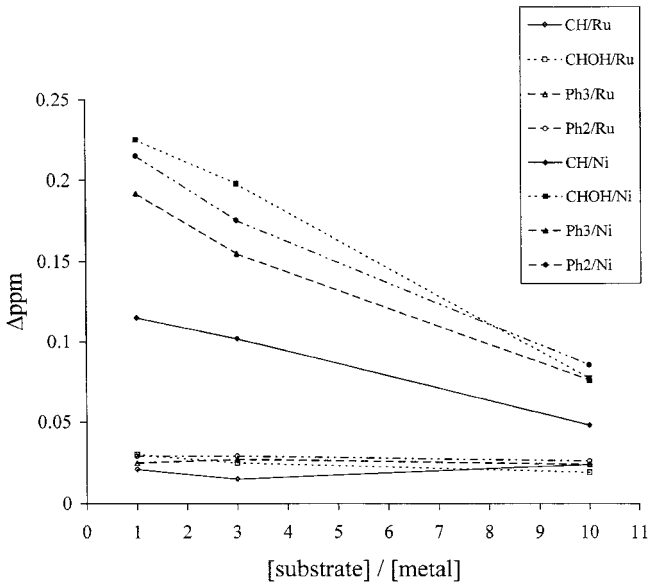

Figure 3. Differences in the ^{1}H NMR chemical shift for 1-phenyl-2-propyn-1-ol in the presence of MPcS's (10 mM), relative to the pure substrate: CH = acetylenic proton; CHOH = aliphatic proton; Ph_2 = *ortho* aromatic protons; Ph_3 = *meta* and *para* aromatic protons.

(±0.01 ppm), including the acetylenic one (Figure 3). For comparison purposes, we investigated other MPcS complexes (M = Fe, Co and Ni), all of them catalytically inactive for the reaction under investigation; for the 1-phenyl-2-propyn-1-ol/NiPcS system significant changes in the ^{1}H NMR spectra were detected by decreasing the substrate-to-metal ratios down to 1 to 1, with pronounced upfield shifts (up to 0.25 ppm) of the aromatic (Ph_2 and Ph_3) and aliphatic (CHOH) protons and less pronounced, but still significant, shifts of the acetylene proton (up to 0.15 ppm; Figure 3). This finding thus strongly suggests a substrate-metal interaction also involving the triple bond.

Conclusion

The first noteworthy finding in this paper is the different reactivity exhibited by the Ru^{II} derivatives in aqueous solution. Simple ruthenium complexes, like RuDMS and RuPW, gave almost exclusively products according to the Markovnikov rule and in very low yields (at least with 2-propyn-1-ol), whereas, when the metal is strongly complexed, i.e. with a phthalocyanine ring or a hydroxyapatite support, the reactivity was definitely enhanced. The regioselectivity was found to be strongly dependent upon the nature of the alkynol; in particular, only when the OH group is relatively close to the triple bond (propargylic alcohols) does the attack of water at the triple bond follow dominantly, if not exclusively, an *anti* Markovnikov pathway (in a broad sense), thus leading to aldehydic (or carboxylic acid) products, α,β-rearrangement of the substrate and/or decarbonylation. The selectivities in each of the above "anti-Markovnikov" products were however moderate and far lower

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

than those reported with other ruthenium catalysts.[10,13] We have no data to support a real participation of the OH group in the π-adduct/vinylidene species equilibrium, but the fact that definite evidence of a metal−ligand interaction was obtained only for the catalytically inactive NiPcS species, suggests that the driving force of the RuPcS hydrations is essentially kinetic. The other important findings deal with the observed smooth decarbonylation of the propargylic alcohols to corresponding $C_{(n-1)}$ alkenes, which represents, to the best of our knowledge, the first catalytic decarbonylation process of terminal alkynes.

Experimental Section

Materials: Ruthenium tetrasulfophthalocyanine (RuPcS),[21] cobalt tetrasulfophthalocyanine (CoPcS),[29] *cis*-[$RuCl_2(DMSO)_4$] (RuDMS),[30] $K_5[Ru(H_2O)PW_{11}O_{39}]$ (RuPW)[31] and ruthenium hydroxyapatite (RuHAP; Ru 17 %, corresponding to 1.6 mmol/g)[23] were prepared by published procedures. Ruthenium phthalocyanine (RuPc) was prepared by the procedure of Weber and Bush,[29] starting from ruthenium trichloride, phthalic acid and urea. Other metal complexes, organic substrates, chromatographic and spectroscopic standards were purchased from Aldrich. D_2O (D ≥ 99 %) was obtained from Isotec Inc.

Apparatus: Organic analyses by GC were performed on aliquots withdrawn with a microsyringe from the aqueous reaction mixtures and diluted 1:20 with diethyl ether, on a HP 6890 GLC instrument equipped with FID, using a 30-m HP-5 (0.32 mm i.d.; 0.25 μm film thickness) or a 30 m HP-Innowax (0.25 mm i.d.; 0.25 μm film thickness) capillary column with the injection port kept at 250 °C (carrier gas: He). The identity of each product was confirmed by comparison of the fragmentation pattern in the mass spectrum obtained with an MD 800 Fisons mass spectrometer operating in the electron ionization mode at 70 eV. ^{1}H NMR measurements were performed on a Bruker Avance 300 MHz spectrometer equipped with a BBO 5 mm probe, by adding small amount of D_2O to the reaction mixtures (1:3); water suppression was carried out by a presaturation sequence using a composite pulse (zgcppr Bruker sequence). A co-axial capillary tube containing a 30 mM solution of 3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid sodium salt (TSP) in water (D_2O) was used as reference. The identity of each product and their quantitation were confirmed by comparison of the position and intensity of suitable signals, by addition of measured amounts of pure compounds to the reaction mixtures.

Typical Procedure for the Hydration Reactions: The progress of the reactions was monitored by GC-MS and/or ^{1}H NMR spectroscopy; conversions, yields and rates were reproducible to within 10−15 %. We describe three different experimental procedures for the hydration reaction: (i) 2-propyn-1-ol, 3-butyn-2-ol, 1-phenyl-2-propyn-1-ol, 4-pentyn-1-ol, or 3-butyn-1-ol (equivalent to 400 mM of final solution) was added to an aqueous solution of RuPcS (10 mM) in a 5 mL vial in air or under a nitrogen atmosphere. The mixture was stirred for 24 h at 80 °C and analyzed by GC-MS and/or NMR spectroscopy. In the case of 1-phenyl-2-propyn-1-ol the reaction mixture was also treated with $CDCl_3$ (5 mL) and the extract analyzed by GC-MS and NMR spectroscopy; after the evaporation of the solvent, a polymeric film was obtained, which on the basis of IR analysis was shown to contain also polystyrene and/or styrene-based polymeric materials; (ii) the above substrates (400 mM) and RuHAP (78 mg/mL) in water were stirred at 80 °C for 24 h; the reaction mixtures were analyzed as above; (iii) 1,1-diphenyl-2-propyn-1-ol (400 mM) and RuPc (10 mM) in a water-saturated toluene solution were stirred at 80 °C for 24 h and directly analyzed by NMR spectroscopy and GC.

Hydration Reactions with D_2O: 2-Propyn-1-ol or 1-phenyl-2-propyn-1-ol (400 mM) and RuPcS (10 mM) or RuHAP (13.9 mg, 0.010 mmol) in D_2O (D ≥ 99.9 %) were reacted for 24 h at 80 °C. Hydroxyacetone, acrylic acid, 1-hydroxy-1-phenylacetone, cinnamaldehyde and styrene were detected by GC, GC-MS and NMR spectroscopy, either directly or, when necessary, after extraction with $CDCl_3$ from the reaction mixture; 3-hydroxypropanoic was directly analyzed only by NMR spectroscopy.

Detection of CO, Ethene and Propene: CO was captured by bubbling the evolved reaction gas through a CH_2Cl_2 solution of $[RuCl(dppp)_2]PF_6$; the amount of formed mono-carbonyl adduct $[RuCl(CO)(dppp)_2]PF_6$ was measured both by UV/Vis and IR analysis, by following the disappearance of the 460 nm band of the original complex or the appearance of the distinctive ν_{CO} absorption at 1930 cm^{-1} of the carbonyl adduct.[32] Although both UV and IR measurements might allow, in principle, the quantitation of the carbonyl adduct, and hence of the carbon monoxide produced, the quantitative results were erratic, probably due to the long reaction times required for the formation of the product. Ethene and propene were captured in a CH_2Cl_2 solution containing an excess of Br_2; the resulting 1,2-bromoalkane solutions were analyzed by GC, GC-MS and NMR spectroscopy, by comparing the results with those of the two commercial compounds (1,2-dibromoethane and 1,2-dibromopropane). Further qualitative data on the production of propene were obtained by headspace GC-MS analysis of the final reaction mixtures.

Dihydrobis(pyrazolyl)borate Alkylidyne Complexes of Tungsten[‡]

Anthony F. Hill,*[a,b] John M. Malget,[a] Andrew J. P. White,[a] and David J. Williams[a]

Keywords: Borates / Carbyne ligands / Multiple bonds / N Ligands / Tungsten

$[W(\equiv CR)Br(CO)_2(NC_5H_4Me\text{-}4)_2]$ (R = $C_6H_3Me_2$-2,6 **1a**, $C_6H_2Me_3$-2,4,6 **1b**) react with $K[H_2B(pz)_2]$ (pz = pyrazol-1-yl) to provide two interconverting isomers of $[W(\equiv CR)(CO)_2(NC_5H_4Me\text{-}4)\{H_2B(pz)_2\}]$ (**2**), one isomer having been structurally characterised for R = $C_6H_3Me_2$-2,6 (**2a**). The reactions of $[W(\equiv CR)Br(CO)_2(CNR')_2]$ (**5**: R′ = $C_6H_3Me_2$-2,6, $CNMe_3$) with $K[H_2B(pz)_2]$ or of $[W(\equiv CR)Br(CO)_2(NC_5H_4Me\text{-}4)\{H_2B(pz)_2\}]$ (**2**) with isocyanides are more complex due to the facile formation of unstable ketenyl derivatives. In the absence of light, the reaction of $[W(\equiv CR)Br(CO)_2(CNR')_2]$ (**5**) with $K[H_2B(pz)_2]$ provides $[W(\equiv CR)(CO)_2(CNR')\{H_2B(pz)_2\}]$ (**3**) in moderate yield, similar yields were obtained from $[W(\equiv CR)(CO)_2(NC_5H_4Me\text{-}4)\{H_2B(pz)_2\}]$ (**2**) and CNR′. Under mild photolytic conditions both combinations provide primarily the thermally unstable ketenyl complex $[W(\eta^2\text{-}OCCR)(CO)(CNR')_2\{H_2B(pz)_2\}]$ (**4**). The picoline ligand in $[W(\equiv CR)Br(CO)_2(NC_5H_4Me\text{-}4)\{H_2B(pz)_2\}]$ (**2**) is readily replaced by PMe_2Ph to provide $[W(\equiv CR)(CO)_2(PMe_2Ph)\{H_2B(pz)_2\}]$ (structurally characterised for R = $C_6H_3Me_2$-2,6 **6a**). The reaction of either $[W(\equiv CR)(CO)_2(PMe_2Ph)\{H_2B(pz)_2\}]$ (**6**) or $[W(\equiv CR)(CO)_2(NC_5H_4Me\text{-}4)\{H_2B(pz)_2\}]$ (R = $C_6H_2Me_3$-2,4,6 **2b**) with excess PMe_2Ph provides $[W(\equiv CR)(CO)(PMe_2Ph)_2\{H_2B(pz)_2\}]$ (**7**). This complex is also obtained from $K[H_2B(pz)_2]$ and $[W(\equiv CR)Br(CO)(PMe_2Ph)_3]$ (**8**), the latter arising from the reaction of $[W(\equiv CR)Br(CO)_2(NC_5H_4Me\text{-}4)_2]$ (**1b**) with PMe_2Ph.

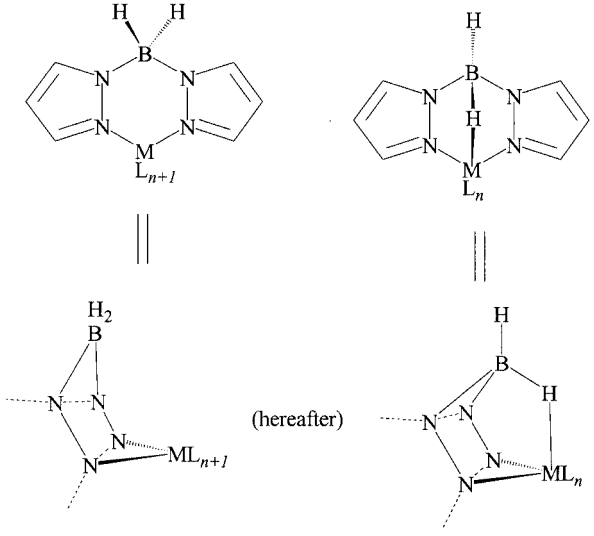
Introduction

The chemistry of alkylidyne complexes of tungsten[2] has been greatly enriched by use of hydrotris(pyrazolyl)borate ligands and their derivatives,[3] primarily from the works of Stone,[4] Angelici,[5] and Templeton.[6] The dihydrobis(pyrazolyl)borate chelate $[H_2B(pz)_2$; pz = pyrazol-1-yl; Scheme 1][3] is an intriguing ligand in its own right displaying a propensity for η^3-coordination through agostic and potentially hemilabile B−H−M interactions.

In the design of alkylidyne complexes for use in both stoichiometric and catalytic bond-forming processes, the incorporation of a vacant coordination site *cis* to the alkylidyne ligand remains a valuable goal, although this can present a challenge for low-valent metal centres which are typically more constrained by adherence to the 18-electron rule. Stone has described a range of tungsten alkylidyne complexes coligated by the $H_2B(pz)_2$ ligand and shown that they readily enter into bridge-assisted cluster-assembly reactions (Scheme 2).[7] The further observation that $[Mo(\equiv CC_6H_4OMe\text{-}2)(CO)\{P(OMe)_3\}_2\{H_2B(pz)_2\}]$ reacts stoichiometrically with $P\equiv CCMe_3$ under mild conditions



Scheme 1. Dihydrobis(pyrazolyl)borate coordination

to provide $[Mo(\equiv CCMe_3)(CO)\{P(OMe)_3\}_2\{H_2B(pz)_2\}]$[8] points toward the intermediacy of coordinatively unsaturated species, if an analogy with alkyne metathesis is entertained. However, no direct observation of the operation of the η^3-coordination mode was ever made in these processes. We considered that the $H_2B(pz)_2$ ligand might nevertheless, under suitably contrived circumstances, enter into η^3-coordination and thereby satisfy the above requirements by virtue of the hemilability of the agostic B−H−M interaction.

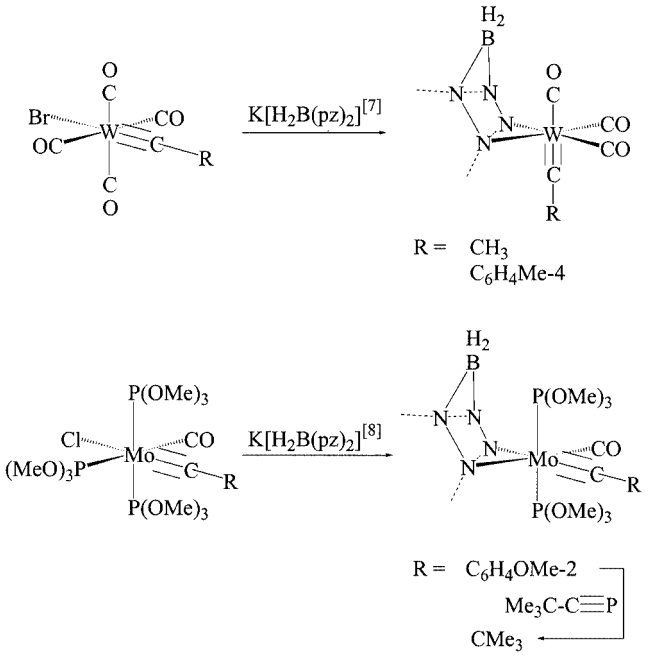


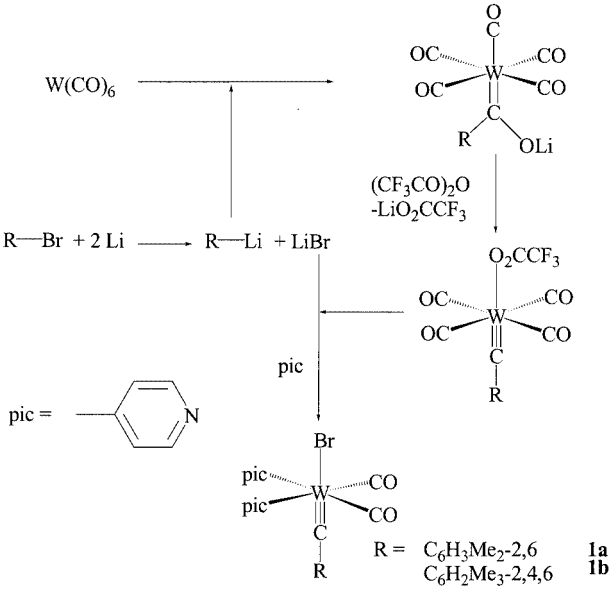
Scheme 2. Dihydrobis(pyrazolyl)borate alkylidynes[7,8]

The results described herein arise from an attempt to broaden the class of alkylidyne-$H_2B(pz)_2$ complexes in pursuit of such a situation. Although coordination of the $H_2B(pz)_2$ ligand has been structurally confirmed in the chemistry of chromium,[9] the Cambridge Crystallographic Data Centre contains no data for mononuclear $H_2B(pz)_2$ complexes of either molybdenum[10] or tungsten and accordingly, two crystallographic studies of complexes with the $H_2B(pz)_2W$ motif were undertaken.

Results and Discussion

Stone's original approach to alkylidyne complexes coligated by the $H_2B(pz)_2$ ligand, namely $[W(\equiv CR)(CO)_3\{\kappa^2\text{-}H_2B(pz)_2\}]$ (R = Me, C_6H_4Me-4; hereafter κ^2 implied unless otherwise indicated),[7] proceeded from Fischer's thermolabile precursors *trans*-$[W(\equiv CR)Br(CO)_4]$. Whilst the instability of the tetracarbonyl precursors did not preclude a detailed study of $[W(\equiv CR)(CO)_3\{H_2B(pz)_2\}]$, we sought a more convenient entry point. To this end, thermally stable bis(γ-picoline) precursor complexes were employed. We have previously employed the sterically congested xylylmethylidyne ligand to confer kinetic stability on alkylidyne complexes.[13] More recently, Berke employed the mesitylmethylidyne variant and this allowed the observation of rare examples of hydrido-alkylidyne complexes.[14]

The complexes *trans,cis,cis*-$[W(\equiv CR)Br(CO)_2(NC_5H_4Me\text{-}4)_2]$ (R = $C_6H_3Me_2$-2,6 **1a**, $C_6H_2Me_3$-2,4,6 **1b**) were readily obtained directly from $[W(CO)_6]$ in "one-pot" reactions by successive treatment with LiBr/LiR (from Li and RBr), $(CF_3CO)_2O$ and γ-picoline (Scheme 3), following a modification/combination of Mayr's syntheses of $[W(\equiv CPh)Cl(CO)_2(NC_5H_4)_2]$ and $[W(\equiv CPh)(O_2CCF_3)(CO)_2(tmeda)]$.[15,16] The 2-xylyl derivative **1a** has been previously employed for the preparation of various "half-sandwich" alkylidyne complexes, although its synthesis was not described.[13] The chloro(pyridine)mesitylmethylidyne complex $[W(\equiv CC_6H_2Me_3\text{-}2,4,6)Cl(CO)_2(NC_5H_5)_2]$ has recently been reported[14] by the Mayr synthesis from the reaction of Fischer's pre-isolated aroylate salt $[W\{C(=O)C_6H_2Me_3\text{-}2,4,6\}(CO)_5][NMe_4]$[17] with oxalyl chloride and pyridine. Whilst this salt would presumably also serve as a precursor for the subsequent introduction of the $H_2B(pz)_2$ ligand, the present high yielding "one-pot" synthesis of $[W(\equiv CC_6H_2Me_3\text{-}2,4,6)Br(CO)_2(NC_5H_4Me\text{-}4)_2]$ (**1a**) is both more convenient and atom efficient in a "green" sense. Specifically, by omitting the Li/NMe_4 metathesis step in the original Mayr synthesis, the bromide anion carried through from the original synthesis of the aryllithium replaces the trifluoroactetate ligand in the intermediate $[W(\equiv CR)(O_2CCF_3)(CO)_4]$. γ-Picoline was chosen to simplify the NMR data. Spectroscopic data for the complexes are unremarkable and conform to precedent.[2]

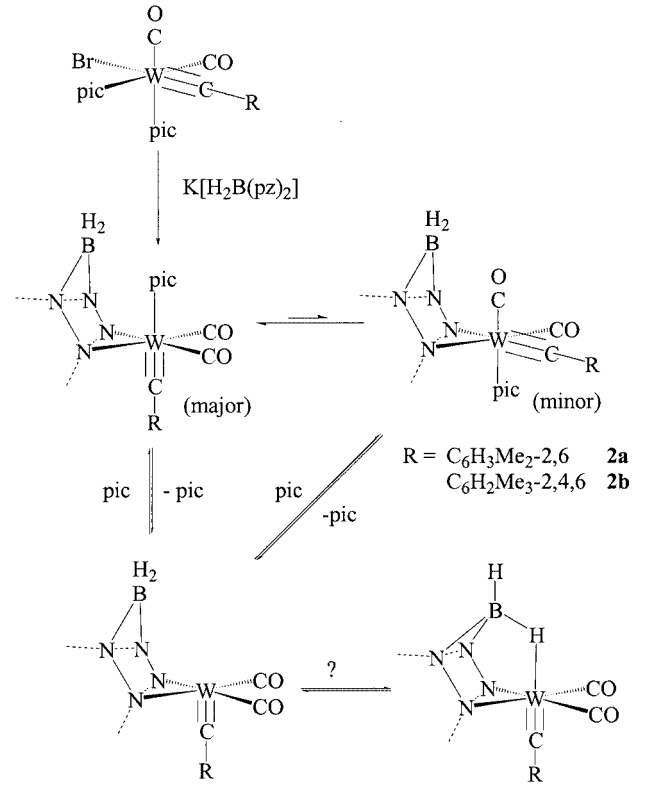


Scheme 3. One Pot Synthesis of alkylidyne tungsten precursors

The reactions of **1a** or **1b** with $K[H_2B(pz)_2]$ in propanone or dichloromethane provide high yields of the complexes formulated as $[W(\equiv CR)(CO)_2(NC_5H_4Me\text{-}4)\{H_2B(pz)_2\}]$ (R = $C_6H_3Me_2$-2,6 **2a**, $C_6H_2Me_3$-2,4,6 **2b**) on the basis of spectroscopic data and a crystallographic study (vide infra) of **2a**. Infrared (solution and solid-state) and ^1H NMR spectroscopic data for both **2a** and **2b** would appear to suggest the formation of one isomer, however, in this instance $^{13}C\{^1H\}$ NMR spectroscopic data appear more sensitive to the coordination environment around tungsten, revealing the coexistence of two isomers in solution (Scheme 4). Thus for **2b**, two carbyne associated resonances are observed at low field [δ = 294.5 (major), 284.5 (minor) ppm]. Similarly, the carbonyl resonances are observed in similar ratios; however, these latter data also allow the assignment of the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

stereochemistry at tungsten. Thus, the major isomer has only one carbonyl environment (δ = 225.3 ppm) whilst the minor isomer features two carbonyl resonances (δ = 227.5 and 221.5 ppm). Accordingly, the major isomer corresponds to the more symmetric geometry (i.e. with the picoline ligand *trans* to the alkylidyne substituent) which is also found in the solid state (Scheme 4, Figure 1). Similar behaviour was observed for **2b**.



Scheme 4

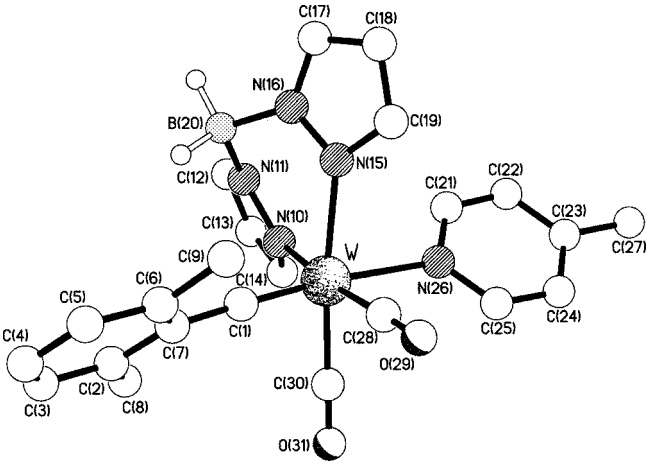


Figure 1. Molecular geometry of **2a**; hydrocarbon hydrogen atoms omitted

For both isomers to coexist and interconvert in solution, it may be surmised that the donor properties of the pyrazole and picoline groups are comparable. Since this equilibrium operates under mild conditions, it seems most likely that it occurs through dissociation of the picoline ligand, rearrangement of the five-coordinate complex and picoline recoordination, rather than unimolecular rearrangement of the octahedral complexes. The lability of the picoline ligand in **2** is also implicit in the ligand-substitution reactions discussed below. It might also be inferred that if tridentate coordination of the $H_2B(pz)_2$ ligand occurs to stabilize the five-coordinate intermediate, then this is easily replaced by picoline coordination since no spectroscopic evidence was obtained for such an intermediate.

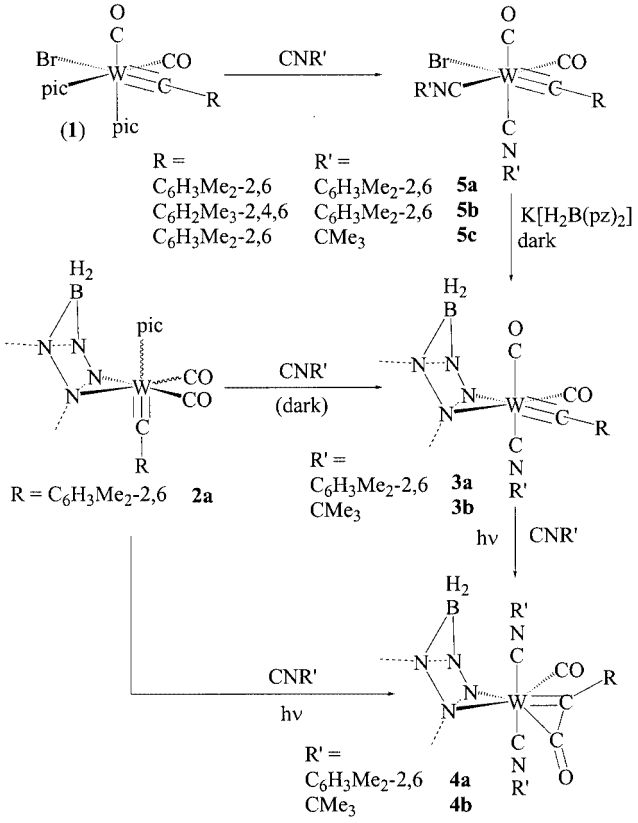
The reactions of **2** with a range of ligands were investigated. Under ambient conditions neither **2a** nor **2b** appear to react with carbon monoxide within spectroscopically (IR) determinable limits. This is in contrast to the complex $[Mo(\equiv CC_6H_4OMe\text{-}2)(CO)\{P(OMe)_3\}_2\{H_2B(pz)_2\}]$[8] which equilibrates to a mixture with the complex $[Mo(\equiv CC_6H_4OMe\text{-}2)(CO)_2\{P(OMe)_3\}\{H_2B(pz)_2\}]$ under one atmosphere of CO in dichloromethane.[18] However, it is not surprising given that introduction of a further carbonyl ligand would be disfavored by the competitive π-acidity of the two carbonyl and alkylidyne ligands already present. The complex $[W(\equiv CC_6H_4Me\text{-}4)(CO)_3\{H_2B(pz)_2\}]$[7] has already been discussed (see above) and the synthesis proceeds in the absence of other potential donor ligands.

Isonitriles (CNR′: R′ = CMe_3, $C_6H_3Me_2$-2,6) which are more nucleophilic and less π-acidic ligands than CO do react with **2** by displacement of the picoline ligand. However, these reactions are complicated by the competitive formation of the ketenyl species. Thus, treating **2a** with either $CNCMe_3$ or $CNC_6H_3Me_2$-2,6 leads to complex mixtures. This was eventually traced to the competition of thermal and photochemical processes, each leading to thermally sensitive products. The major identifiable products of the thermal reaction were the alkylidyne complexes $[W(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(CNR')\{H_2B(pz)_2\}]$ (**3**), whilst the major photo-products were the ketenyl complexes $[W(\eta^2\text{-}OCC_6H_3Me_2\text{-}2,6)(CO)(CNR')_2\{H_2B(pz)_2\}]$ (R′ = $C_6H_3Me_2$-2,6 **4a**, CMe_3 **4b**).

Kreiβl[19] studied the coupling of alkylidyne and carbonyl ligands to generate mononuclear ketenyl complexes in thermal reactions of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ with PMe_3, whilst Stone showed similar couplings in dinuclear systems.[20] Subsequently, Geoffroy demonstrated that such processes could be photochemically induced.[21] Ketenyl formation through alkylidyne/carbonyl coupling has since been reviewed,[22] whilst the synthetic utility of ketenyl complexes has been amply demonstrated by Kreiβl.[23] The clarification of the processes involved in the reactions of **2** with isocyanides called for selective synthesis of the products since the reactions themselves were not synthetically useful in that the mixtures obtained required cryostatic chromatography (−40 °C) and the purified products were unstable at room temperature. The purple ketenyl complex $[W(\eta^2\text{-}OCC_6H_3Me_2\text{-}2,6)(CO)(CNCMe_3)_2\{H_2B(pz)_2\}]$ (**4b**) could most easily be obtained in modest yield (40 %) by the addition of $CNCMe_3$ to **2a** under irradiation (domestic sun

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

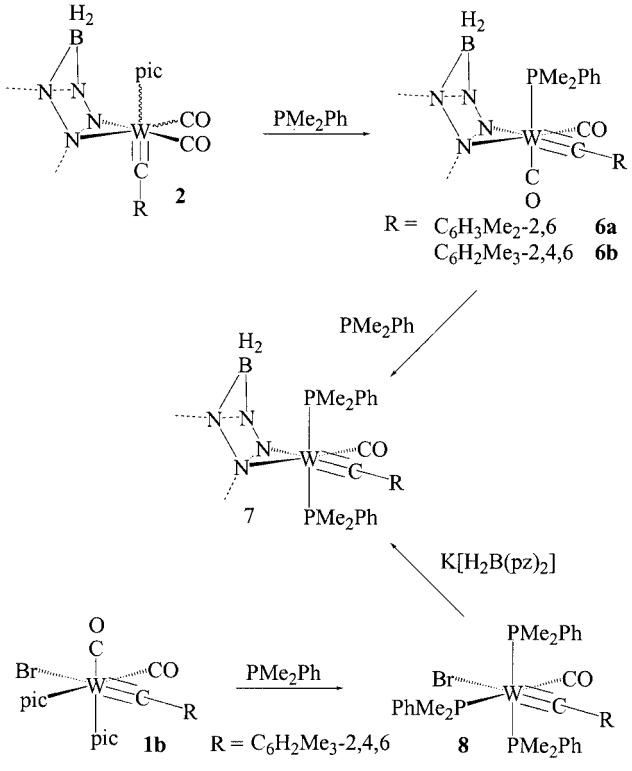
lamp) followed by cryostatic chromatography. Although they could be retrospectively identified amongst the products of the reactions of **2** with CNR′, the alkylidyne complexes $[W(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(CNR')\{H_2B(pz)_2\}]$ (R′ = $C_6H_3Me_2$-2,6 **3a**, CMe_3 **3b**) could most easily be obtained through the reactions of preformed $[W(\equiv CC_6H_3Me_2\text{-}2,6)Br(CO)_2(CNR')_2]$ (R′ = CMe_3 **5a**, $C_6H_3Me_2$-2,6 **5b**; Scheme 5)[24] with $K[H_2B(pz)_2]$, although exclusion of light was essential throughout their synthesis and isolation.



Scheme 5

The formulation of both the alkylidyne and ketenyl complexes rests upon spectroscopic and FAB-MS data, since their instability at ambient temperatures prevented us from obtaining either satisfactory elemental microanalysis or crystallographic grade crystals. Nevertheless, the spectroscopic data strongly support the formulations as do the unequivocal synthesis from bis(isocyanide) precursors. For the alkylidyne complex $[W(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(CNCMe_3)\{H_2B(pz)_2\}]$ (**3b**), both ^1H and $^{13}C\{^1H\}$ NMR spectroscopic data confirm two distinct pyrazolyl environments, the latter also indicating chemically inequivalent carbonyl ligands. Taken together, these data are only consistent with the geometry shown in Scheme 5. Such arguments also support a similar geometry for **3a**. For the ketenyl complex $[W(\eta^2\text{-}OCCC_6H_3Me_2\text{-}2,6)(CO)(CNCMe_3)_2\{H_2B(pz)_2\}]$ (**4b**) the stereochemistry at tungsten also follows from a combination of IR and NMR spectroscopic data, the gross formulation being confirmed by FAB-MS data. Thus one isocyanide-associated absorption is observed in the infrared spectrum and one albeit broad resonance in the $^{13}C\{^1H\}$ NMR spectrum indicating a *trans*-$W(CNCMe_3)_2$ arrangement. The observation of a single isocyanide environment would suggest that either inversion of the $B(NN)_2W$ boat arrangement is rapid on the NMR timescale or that the BH_2 group does not sufficiently closely approach the *tert*-butyl groups to render these inequivalent. Molecular models and the related structural studies (vide infra) would argue for the former interpretation.

In contrast to the reactions with isocyanides, the reactions of **2** with dimethylphenylphosphane are straightforward and proceed through picoline substitution to provide a single isomer with no indication of ketenyl formation. Thus, treating **2** with one equivalent of PMe_2Ph in dichloromethane provided the complexes $[W(\equiv CR)(CO)_2(PMe_2Ph)\{H_2B(pz)_2\}]$ (R = $C_6H_3Me_2$-2,6 **6a**, $C_6H_2Me_3$-2,4,6 **6b**) each in only one isomeric form. The complex $[W(\equiv CC_6H_4Me\text{-}4)(CO)_3\{H_2B(pz)_2\}]$ has been reported to react with PPh_3 or PMe_3 to provide the complexes $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(PR_3)\{H_2B(pz)_2\}]$ by carbonyl substitution with no evidence for ketenyl formation.[7] The stereochemistry of **6a** in solution (Scheme 6, Figure 2) follows unequivocally from spectroscopic data and was confirmed by X-ray crystallography (vide infra). The diastereotopicity of the phosphane methyl groups confirms the absence of a molecular element of symmetry excluding the isomer with phosphane *trans* to the alkylidyne group. This possibility may also be discounted by the low value of $^2J_{P\text{-}C}$ (8.9 Hz) for the alkylidyne ^{13}C resonance. IR data



Scheme 6

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

indicates a *cis*-$W(CO)_2$ arrangement whilst ^{13}C NMR spectroscopic data indicate that both the CO ligands and also the two pyrazolyl groups are chemically inequivalent. Similar arguments apply to the stereochemistry of **6b**.

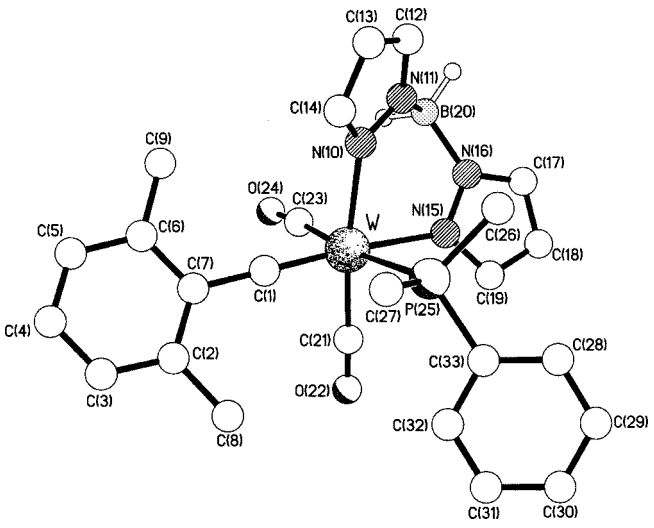


Figure 2. Molecular geometry of **6a**; hydrocarbon hydrogen atoms omitted

Treating the complex **6b** with excess PMe_2Ph leads to carbonyl substitution and formation of the *trans*-bis(phosphane) complex $[W(\equiv CC_6H_2Me_3\text{-}2,4,6)(CO)(PMe_2Ph)_2\{H_2B(pz)_2\}]$ (**7**). The stereochemistry at tungsten follows from ^1H, ^{31}P and ^{13}C NMR spectroscopic data. The chemical equivalence of the two phosphorus nuclei is manifest as a singlet resonance in the $^{31}P\{^1H\}$ NMR spectrum, whilst the *trans* arrangement is suggested by the virtual triplet nature of the ^{13}C resonance for the phosphane methyl groups. Notably this stereochemistry is equivalent to that proposed for $[Mo(\equiv CR)(CO)\{P(OMe)_3\}_2\{H_2B(pz)_2\}]$ (R = CMe_3, C_6H_4OMe-2).[8] The IR data [ν(CO) = 1992, 1903 cm^{-1}] for **6b** would suggest that the carbonyl ligands are not thermally labile. Accordingly, the facile formation of **7** from **6b** under mild conditions presumably proceeds through ketenyl formation followed by CO extrusion, as has been demonstrated in the synthesis of $[W(C\equiv CC_6H_4Me\text{-}4)(CO)(PMe_3)(\eta\text{-}C_5H_5)]$ from $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$.[19] Notably, the reactions of $[W(\equiv CR)(CO)_2\{HB(pz)_3\}]$ (R = C_6H_4Me-4, SMe) with PMe_3 or PEt_3 stop at the ketenyl stage providing $[W(\eta^2\text{-}OCCC_6H_4Me\text{-}4)(CO)(PMe_3)\{HB(pz)_3\}]$[7] and $[W(\eta^2\text{-}OCCSMe)(CO)(PEt_3)\{HB(pz)_3\}]$,[5a] respectively.

An alternative synthesis of **7** was developed by the reaction of $[W(\equiv CC_6H_2Me_3\text{-}2,4,6)Br(CO)(PMe_2Ph)_3]$ (**8**) with $K[H_2B(pz)_2]$. The new precursor **8** was obtained from the reaction of **1b** with PMe_2Ph. The closely related complex $[W(\equiv CPh)Cl(CO)(PMe_3)_3]$ has been reported previously by Mayr, arising from the reaction of $[W(\equiv CPh)Cl(CO)_2(PMe_3)_2]$ with PMe_3 over a period of 7 days.[27] In the present case however the stoichiometric amount of phosphane suffices and the reaction is complete in 15 h. The *mer* geometry follows from ^1H, ^{13}C and $^{31}P\{^1H\}$ NMR spectroscopic data for the phosphane groups and the doublet-triplet fine structure of the carbonyl and alkylidyne group resonances in the $^{13}C\{^1H\}$ NMR spectrum. The complex **8** reacts cleanly with $K[H_2B(pz)_2]$ in tetrahydrofuran to provide **7**. In this case it is not necessary to invoke ketenyl intermediates.

Crystal Structure of $[W(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(NC_5H_4Me\text{-}4)\{H_2B(pz)_2\}]\cdot 0.5CH_2Cl_2$ (2a·0.5CH_2Cl_2)

The complex crystallizes from a mixture of dichloromethane and petroleum ether as a dichloromethane hemisolvate, however, the solvent of crystallization which is disordered shows no directional interactions with the complex and neither are there any notable intermolecular interactions within the crystal lattice. The molecular geometry of the complex is depicted in Figure 1 and selected bond lengths and angles are presented in Table 1. The geometry at tungsten is distorted octahedral with angles between adjacent ligands lying in the range 82.9(2)−101.2(2)° such that the pyrazolyl groups bend away from the alkylidyne groups [C(1)−W−N(15) 100.5(2), C(1)−W−N(10) 101.2(2)°] whilst the carbonyl ligands bend less markedly towards it [C(1)−W−C(28) 85.6(3), C(1)−W−C(30) 87.9(3)°]. The bending of *cis* ligands away from metal−element multiple bonds is not uncommon and it has been suggested that this strengthens the multiple bonding.[28] The alkylidyne ligand is essentially linear at the carbyne carbon [W−C(1)−C(7) 178.0(5)°] and the W≡C separation of 1.810(6) Å falls within the range typical of alkylidyne tungsten complexes[2] and is similar to that found in, for example, $[W(\equiv CPh)(CO)_2(Ppy_3)]^+$ [1.811(7) Å].[29] The xylyl ring orientation is presumably dictated by steric effects as it places the *ortho* substituents between adjacent coligands, rather than allowing the aromatic π-system to conjugate with occupied metal t_{2g} orbitals. In a similar manner, the plane of the picoline ligand is approximately orthogonal (ca. 79°) to that of the alkylidyne, lying between the pyrazolyl rings of the $H_2B(pz)_2$ chelate and approximately bisecting the $W(CO)_2$ group. The octahedral γ-picoline complexes *trans*-$[W^{III}Cl_4(NC_5H_4Me\text{-}4)_2]^-$,[30] *cis,cis,trans*-$[W^{II}Br_2(bipy)(NC_5H_4Me\text{-}4)_2]$[31] and $[W^0(CO)_5(NC_5H_4Me\text{-}4)]$[32] have (mean) W−N bond lengths of 2.166, 2.176, and 2.257 Å, respectively, with a lengthening of the W−N bond on reduction of the metal centre (W^{III}, W^{II}, and W^0). For-

mal oxidation states have little meaning in compounds with metal−carbon multiple bonding. However, the sensitivity of the W−N bond lengths to the π-acidity of *trans*-disposed ligands has been demonstrated for the bis(pyridine) complex [W(≡CPh)Cl(CO)(ma)(py)$_2$][33] where the W−N bond *trans* to the strongly π-acidic maleic anhydride (ma) is longer (2.253 Å) than that *trans* to CO (2.233 Å). The W−N(26) bond length of 2.378(5) Å seen here for **2a** far exceeds those discussed above and is consistent with the lability demonstrated in reactions with CNR′ and PMe_2Ph and also its facile isomerism. This lengthening is also consistent with its location *trans* to an alkylidyne ligand which is generally considered to be strongest of all carbon π-acid ligands.

The W(pz)$_2$BH$_2$ metallacycle adopts a typical boat formation with both the tungsten and boron atoms lying ca. 0.65 Å out of the plane of the four nitrogen atoms which are coplanar to within 0.007 Å. This geometry is comparatively shallow and positions the BH_2 group well beyond any interaction with either the metal [BH···W 3.46 Å] or co-ligands. Thus, although the adopted conformation places the BH_2 adjacent to the alkylidyne, the BH···C(1) distance of 3.10 Å is probably too long to invoke any incipient nucleophilic interaction of the B−H bond with the carbyne carbon atom. The bite of the chelate at 83.6(2)° is somewhat contracted from 90° with the remaining angles within the chelate close to those expected for trigonal nitrogen [121.7(6)−125.0(4)°] and tetrahedral boron [107.9(6)°].

Crystal Structure of [W(≡CC$_6$H$_3$Me$_2$-2,6)(CO)$_2$(PMe$_2$Ph){H$_2$B(pz)$_2$}] (6a)

Yellow solvate-free needles were obtained by cooling a solution of the complex in a mixture of propanone and petroleum ether (40:60). The molecular geometry of the complex is depicted in Figure 2. As for complex **2a**, the tungsten center approximates octahedral geometry with angles between *cis*-ligands falling in the range 81.70(8)−100.00(11)° (Table 2). However, in contrast to **2a**, the $H_2B(pz)_2$ and alkylidyne groups assume a meridional disposition with the phosphane ligand *cis* to the alkylidyne group. The alkylidyne ligand displays a characteristically short W≡C separation [1.825(4) Å] (not significantly different from that in **2a**) and is slightly bent at the carbyne carbon atom [W−C(1)−C(7) 173.5(3)°], which lies within the range previously observed and generally attributed to crystal-packing effects.[2] The orientation of the xylyl group is such as to minimise steric interactions with *cis* coligands, which places the *ortho* substituents either side of the $W(CO)_2$ unit. The phosphane ligand has a W−P bond length of 2.564(1) Å which appears somewhat long. Limiting comparison to 6-coordinate tungsten complexes of PMe_2Ph with sterically modest co-ligands[34,35] there appears to be no obvious correlation between the oxidation state (d configuration) and the W−P bond length [d^6: 2.480−2.524; d^4: 2.484−2.512; d^3: 2.513−2.561; d^2: 2.481−2.538Å]. The dichotomy that clouds the assignment of oxidation states for alkylidyne complexes is shared by nitrosyl ligands and accordingly the most suitable structure for comparison is the complex *trans,cis,cis*-[W(NO)I(CO)$_2$(PMe$_2$Ph)$_2$] reported by Basolo[35] which also features particularly long W−P bond lengths [2.582(2), 2.554(2) Å].

The [H$_2$B(NN)$_2$W] chelate once again adopts a shallow boat conformation with here the tungsten and boron atoms that lie (0.54 and 0.65 Å, respectively) out of the N_4 plane which is coplanar to within 0.026 Å. The closest B−H hydrogen atom approach to the metal centre is 3.49 Å, too distant for any interaction. However, this hydrogen atom is positioned directly above one of the carbonyl ligands, the BH···C(23) distance being 2.87 Å, indicating a possible weak B−H···π* interaction. In contrast to **2a**, the low symmetry of **6a** allows the chelate to reveal the comparative *trans* influences of carbonyl and alkylidyne ligands. Thus the pyrazolyl group *trans* to the alkylidyne has a significantly (20σ) longer W−N bond length [2.292(3) Å] than that *trans* to the carbonyl [2.233(3) Å]. The difference in *trans* influence for the pyrazolyl and phosphane ligands is less obvious in the bonding of the carbonyl ligands with that *trans* to phosphorus [W−C(23) 2.014(5) Å], showing a smaller (7σ) lengthening relative to W−C(21) [1.980(4) Å]. The only intermolecular packing interaction of note is a parallel π−π stacking of the xylyl rings of centrosymmetrically related molecules with mean interplanar and centroid···centroid separations of 3.46 and 3.74 Å, respectively.

Experimental Section

General Procedures: All manipulations were carried out under an atmosphere of prepurified dinitrogen with conventional Schlenk-tube techniques. Solvents were purified by distillation from an appropriate drying agent [ethers and paraffins from sodium/potassium alloy with benzophenone as indicator; halocarbons from CaH_2]. Light petroleum ether refers to that fraction of boiling point 40−60 °C. Chromatographic separations were routinely performed using a cryostatically cooled column at −40 °C. ^{1}H, ^{13}C{^{1}H} and ^{31}P{^{1}H} NMR spectra were recorded with a Jeol JNM EX270 NMR spectrometer and referenced against internal Me_4Si (^{1}H), internal $CDCl_3$ (^{13}C) or external H_3PO_4 (^{31}P). Infrared spectra were recorded with a Perkin−Elmer 1720-X FT-IR spectrometer. FAB-Mass spectra were measured with an Autospec Q mass spectrometer using 3-nitrobenzyl alcohol as matrix ('pic' = γ-picoline). Photolyses were conducted with a domestic sun-lamp in cryo-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

statically cooled Schlenk-tubes. Commercial reagents were used as received and the salt $K[H_2B(pz)_2]$[3] prepared according to the following procedure. The original procedure involves heating $K[BH_4]$ and Hpz in a melt, with the progress of the reaction being monitored by the measurement of evolved hydrogen gas. In our laboratory, this usually provided samples of $K[H_2B(pz)_2]$ contaminated with both pyrazole and $K[HB(pz)_3]$. The following approach employs a solvent to moderate the reaction temperature and provide a homogeneous reaction mixture.

Synthesis of Potassium Dihydrobis(pyrazolyl)borate: Potassium tetrahydroborate (13.50 g, 0.25 mmol) and pyrazole (68.00 g, 1.00 mol), both finely ground, were suspended in toluene (250 mL) and gradually brought to reflux. After 12−16 h hydrogen gas evolution had effectively ceased. The clear solution was filtered whilst hot to remove any residual traces of unchanged $K[BH_4]$. The filtrate was allowed to cool with rapid stirring to about 40 °C whereupon a white precipitate formed that was filtered off. The finely divided white solid was washed with dichloromethane (3 × 50 mL), to remove any traces of unchanged pyrazole followed by diethyl ether (2 × 30 mL) and then dried in vacuo. Yield 32.60 g (70 % vs. $K[BH_4]$). The salt was characterised by comparison of spectroscopic data with those previously reported[3] and was found to be free of Hpz or $K[HB(pz)_3]$ within spectroscopically determinable limits (^{1}H NMR, IR).

Synthesis of $[W(\equiv CC_6H_3Me_2\text{-}2,6)Br(CO)_2(NC_5H_4Me\text{-}4)_2]$ (1a): This complex has been used previously for the preparation of various 2-xylyl methylidyne complexes, however, neither preparative details nor spectroscopic data were provided.[13a] Tungsten hexacarbonyl (4.25 g, 12 mmol) was suspended in diethyl ether (30 mL) to which 1.1 equivalents of $LiC_6H_3Me_2$-2,6·LiBr in 1 mL aliquots over 30 min were subsequently added. The pale yellow solution was cooled (dry ice/propanone) and trifluoroacetic anhydride (1.70 mL, 12.0 mmol) slowly added over a 5 min period. The mixture was stirred for 15 min after which γ-picoline (3.0 mL, 0.957 gcm^{-3}, 30 mmol) was added and allowed to warm to room temperature which resulted in evolution of carbon monoxide (CAUTION). After 12 h, a bright yellow precipitate was isolated from solution. This solid was redissolved in dichloromethane (20 mL) and the solution filtered under nitrogen through a plug of alumina (2 × 4 cm). The filtrate was diluted with diethyl ether (60 mL) and then cooled to −10 °C whereupon the bright orange solid which formed was isolated by filtration and dried in vacuo. Yield 6.38 g (85 %). IR (CH_2Cl_2): ν(CO) = 1984, 1895 cm^{-1}. Nujol: ν(CO) = 1980, 1888 cm^{-1}. ^{1}H NMR ($CDCl_3$, 25 °C): δ = 2.40, 2.45 [s × 2, 6 H × 2, $C_6H_3CH_3$ and $NC_5H_4CH_3$], 6.90 [d, 2 H, H3,5 (C_6H_3)], 7.03 [m, 1 H, H4 (C_6H_3)], 7.11, 8.97 [$(AB)_4$, 8 H, NC_5H_4, ^3J(AB) = 5.5 Hz] ppm. ^{13}C{^{1}H} NMR: δ = 266.4 [W≡C, ^1J (WC) = 207 Hz], 221.9 [WCO, ^1J (WC) = 171 Hz], 150.5−127.2 [C_6H_3 and NC_5H_4], 125.8 [C-3,5 (NC_5H_4)], 21.0, 20.5 ($C_6H_4CH_3$ and $NC_5H_4CH_3$) ppm. FAB-MS: *m*/*z* = 624 [M]$^+$, 596 [M − CO]$^+$, 568 [M − 2CO]$^+$, 543 [M − Br]$^+$, 529 [M − pic]$^+$, 503 [M − pic − CO]$^+$, 473 [M − pic − 2CO]$^+$, 450 [M − pic − Br]$^+$. $C_{23}H_{23}BrN_2O_2W$: calcd. CMe_3], 2.52 [s, 6 H, $C_6H_3(CH_3)_2$], 6.90 [d, 2 H, H-3,5(C_6H_3)], 7.10 [t, 1 H, H-4(C_6H_3)] ppm. $^{13}C\{^1H\}$ NMR: δ = 267.1 [W≡C, ^1J (WC) = 189 Hz], 206.8 [WCO, ^1J (WC) = 135 Hz], 147.0 (br., WC≡N), 146.1 [C-1(C_6H_3)], 140.3 [C-4(C_6H_3)], 127.4 [C-2,6(C_6H_3)], 127.2 [C-3,5(C_6H_3)], 57.4 [CMe_3], 30.5 [$C(CH_3)_3$], 20.8 [$C_6H_3(CH_3)_2$] ppm. FAB-MS: *m/z* = 606 $[M]^+$, 576 $[M - CO]^+$, 548 $[M - 2CO]^+$, 523 $[M - CNR]^+$, 492 $[M - CO - CNR]^+$. $C_{21}H_{27}BrN_2O_2W$: calcd. C 41.81, H 4.51, N 4.64; found C 41.7, H 4.4, N 4.5.

Synthesis of *fac*-[W(≡$CC_6H_3Me_2$-2,6)(CO)$_2$(PMe_2Ph){$H_2B(pz)_2$}] (6a): Dimethylphenylphosphane (0.12 mL, 0.97 gmL^{-1}, 0.12 g, 0.87 mmol) was added to *mer/fac*-[W(≡$CC_6H_3Me_2$-2,6)-(CO)$_2$(NC_5H_4Me-4){$H_2B(pz)_2$}] (**2a**, 0.50 g, 0.84 mmol) in dichloromethane (30 mL) and the mixture stirred for 12 h. The resulting orange solution was concentrated to about 10 mL and chromatographed on a silica-gel loaded column (2 × 30 cm, −30 °C) eluting with a mixture of dichloromethane and light petroleum ether (1:1). The major orange fraction was collected and concentrated under reduced pressure to about 10 mL and then diluted with diethyl ether (50 mL). This solution was cooled to −10 °C whereupon an orange microcrystalline solid was obtained. Yield 0.52 g (95 %). Crystals suitable for X-ray analysis were obtained upon recrystallization from hexane/propanone (4:1) at −10 °C. NB: The reaction is sufficiently clean that for most practical purposes the chromatography step may be omitted in which case, the solvent is simply removed and the resulting orange powder washed with light petroleum (10 mL) and dried thoroughly under high vacuum to remove liberated γ-picoline and unchanged phosphane. IR (CH_2Cl_2): 1992, 1903 [ν(CO)] cm^{-1}. Synthesis of *cis,trans,cis*-[W(≡$CC_6H_2Me_3$-2,4,6)(CO)(PMe_2Ph)$_2$-{$H_2B(pz)_2$}] (7): (a) Dimethylphenylphosphane (0.24 g, 1.60 mmol) was added to *mer/fac*-[W(≡$CC_6H_2Me_3$-2,4,6)(CO)$_2$(NC_5H_4Me-4){$H_2B(pz)_2$}] (**2b**, 0.50 g, 0.82 mmol) in dichloromethane (30 mL). The mixture was stirred for 12 h and the resulting red solution was then concentrated to about 10 mL under reduced pressure and purified on silica-gel (2 × 30 cm, −30 °C) eluting with a dichloromethane/light petroleum (1:1) mixture. The red eluate was concentrated in vacuo to about 10 mL and diluted with diethyl ether (50 mL). This solution was cooled to −10 °C whereupon a red crystalline solid was obtained, isolated by decantation and dried in vacuo. Yield 0.60 g (95 %). (b) A mixture of *mer*-[W(≡$CC_6H_2Me_3$-2,4,6)Br(CO)(PMe_2Ph)$_3$] (**8**, 0.50 g, 0.60 mmol) and K[$H_2B(pz)_2$] (0.12 g, 0.65 mmol) in dichloromethane (30 mL) was stirred for 1 h. The mixture was then purified as described in (a) (see above) to provide **7**. Yield 0.46 g (93 %). IR (CH_2Cl_2): 1860 [ν(CO)] cm^{-1}. IR (nujol): 2424, 2390, 2353, 2284 [ν(BH_2)]; 1857 [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$, 25 °C): δ = 1.40, 1.47 [vt × 2, 12 H, *trans*-$(PMe_2)_2$, $^{2,4}J_{P,H}$ ca. 3 Hz], 2.19 [s, 3 H, $C_6H_2CH_3$-4], 2.49 [s, 6 H, $C_6H_2(CH_3)_2$-2,6], 5.98, 6.11 [dd × 2, 2 H, H-4($C_3H_3N_2$), $^3J_{H,H}$ = 2, 2 Hz], 6.69 (s, 2 H, C_6H_2), 7.08−7.26 (m, 10 H, C_6H_5), 7.36, 7.44, 7.58, 7.85 [d × 4, 4 H, H-3,5($C_3H_3N_2$), $^3J_{H,H}$ = 2 Hz] ppm. $^{13}C\{^1H\}$ NMR: δ = 278.2 (t, W≡C, $^2J_{P,C}$ = 11 Hz), 249.9 (t, WCO, $^2J_{P,C}$ = 5.3 Hz), 144.9, 143.6 [C-3($C_3H_3N_2$)], 136.5, 136.1 [C-5($C_3H_3N_2$)], 135.7 [C-1(C_6H_5), $^1J_{P,C}$ = 36.0 Hz], 130.6 [C-3,5(C_6H_2)], 130.5−127.5 [C-3,5(C_6H_5)], 104.9, 104.6 [C-4($C_3H_3N_2$)], 21.6 [$C_6H_2CH_3$-4)], 20.6 [$C_6H_2(CH_3)_2$-2,6], 17.9 [vt, $P(CH_3)_2$, $^{1,3}J_{P,C}$ = 13.4 Hz] ppm. $^{31}P\{^1H\}$ NMR: δ = 0.28 [$^1J_{W,P}$ = 281.4 Hz] ppm. FAB-MS: *m/z* (%) [assignment] = 766 (12) $[M]^+$, 738 (4) $[M - CO]^+$, 628 (100) $[M - PMe_2Ph]^+$, 598 (35) $[M - PMe_2Ph - CO]^+$, 459 (10) $[M - 2PMe_2Ph - CO]^+$. $C_{33}H_{41}BN_4OP_2W$: calcd. Template Synthesis, Crystal Structure and Luminescent Properties of Neutral N_4O_3 Tripodal $Ln^{III}L$ Complexes (Ln^{III} = La^{3+}, Eu^{3+}, Gd^{3+}, Tb^{3+}, Dy^{3+}, Ho^{3+}, Er^{3+}, Tm^{3+} or Lu^{3+}; H_3L = Tris{[3′-(2′′-pyridyl)-5′-*tert*-butyl-2′-hydroxybenzylidene-2-imino]ethyl}amine)

Wai-Kwok Wong,*[a] Hongze Liang,[a] Jianping Guo,[a] Wai-Yeung Wong,[a] Wing-Kit Lo,[a] King-Fai Li,[b] Kok-Wai Cheah,[b] Zhongyuan Zhou,[c] and Wing-Tak Wong[d]

Keywords: Lanthanides / Luminescence / Schiff bases / Tripodal ligands

In the presence of Ln^{3+} (Ln = La, Eu, Gd, Tb, Dy, Ho, Er, Tm or Lu), tris(2-aminoethyl)amine condensed with three equivalents of 3-(2′-pyridyl)-5-*tert*-butyl-2-hydroxybenzaldehyde in methanol to give the neutral Schiff-base complex $Ln^{III}L$ (Ln = La **1**, Eu **2**, Gd **3**, Tb **4**, Dy **5**, Ho **6**, Er **7**, Tm **8** and Lu **9**; H_3L = tris{[3′-(2′′-pyridyl)-5′-*tert*-butyl-2′-hydroxybenzylidene-2-imino]ethyl}amine). The structures of compounds **4**–**7** were determined by X-ray crystallography. The crystal structure analyses revealed that the Schiff base behaves as a tri-deprotonated heptadentate ligand encapsulating the lanthanide metal ion within the N_4O_3 cavity, with all the pyridyl groups being pendant. Solution spectroscopic data suggest that the $Ln^{III}L$ complexes remain intact in methanol and exist as nine-coordinate non-electrolytes with the lanthanide metal ions coordinated to the N_4O_3 cavity of the tripodal Schiff base and two solvent molecules. The solution photoluminescent properties of these lanthanide Schiff-base complexes were also examined.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The potential application of lanthanide complexes as magnetic resonance contrasting agents has led to the synthesis of a number of lanthanide(III) complexes with heptadentate tripodal Schiff-base ligands and amine phenol ligands.[1−4] Numerous lanthanide complexes with macrocyclic polydentate Schiff-base ligands[5−8] and acyclic tripodal heptadentate Schiff-base ligands have been reported in the literature.[1,2,9−12] Recently, the coordination chemistry of the decadentate Schiff base tris[4-(2-hydroxy-3-methoxyphenyl)-3-aza-3-butenyl]amine toward p- and f-block elements[13−17] has been examined. Dinuclear homo-[13] and heterometallic[14−17] complexes were obtained. Some lanthanide ions possess strongly emissive and long-lived excited states, such as Eu^{3+} and Tb^{3+}, but do not exhibit intense absorption bands. Therefore, considerable effort has been devoted to the design of lanthanide complexes where light is absorbed by the ligands and the corresponding electronic energy is then transferred onto the emitting metal ion. The use of a Zn^{2+} Schiff-base complex as a sensitizer for Nd^{3+}, Yb^{3+} and Er^{3+} near-infrared luminescence has been reported recently.[18] We are interested in the coordination chemistry of the decadentate Schiff base tris{[5′-*tert*-butyl-2′-hydroxy-3′-(2′′-pyridyl)benzylidene-2-imino]-ethyl}amine (H_3L) toward f-block metal ions, and particularly its sensitizing effect on lanthanide(III) metal ions. The design of the ligand strands of H_3L prevents the introduction of metal ions into the terminal nine-coordinate cavity, as this would result in the formation of fused chelating six-membered rings. Thus, H_3L is expected to behave as a heptadentate podate with the inner N_4O_3 cavity coordinating to the lanthanide ions and the terminal 2-pyridyl groups pendant, and will be an ideal ligand used for the preparation of heterometallic complexes. In this report, we describe a one-pot synthesis and the photoluminescent properties of stable, neutral, polydentate Schiff-base complexes of lanthanide(III) metal ions.

Results and Discussion

Synthesis and Characterization

In the presence of one equivalent of $Ln(NO_3)_3{\cdot}5H_2O$ (Ln = La, Eu, Gd, Tb, Dy, Ho, Er, Tm or Lu), tris(2-

aminoethyl)amine (tren) undergoes condensation with three equivalents of 5-*tert*-butyl-2-hydroxy-3-(2′-pyridyl)benzaldehyde (Py-CHO) in methanol to give the neutral tripodal Schiff-base complexes $Ln^{III}L$ (Ln = La **1**, Eu **2**, Gd **3**, Tb **4**, Dy **5**, Ho **6**, Er **7**, Tm **8** and Lu **9**; H_3L = tris{[5′-*tert*-butyl-2′-hydroxy-3′-(2′′-pyridyl)benzylidene-2-imino]-ethyl}amine) in moderate to good yields (Scheme 1). Compounds **1**−**9** are remarkably stable towards air and moisture, are soluble in many organic solvents, and are even stable in protic solvents for weeks. They also show high thermal stability: when heated to as high as 200 °C, no discernible collapse of the crystals was observed. All these compounds gave satisfactory elemental analyses and exhibit a $\nu_{C=N}$ band at 1621−1623 cm^{-1} in their IR spectra and an $[M + H]^+$ peak in their positive FAB mass spectra. The structures of compounds **4**−**7** were determined by X-ray crystallography.

Compounds **4**−**7** are isomorphous and they all crystallized in the triclinic space group $P\bar{1}$ with two independent, but structurally similar, molecules per asymmetric unit. The crystal structure analyses reveal that the potentially decadentate tripodal ligand acts as a heptadentate ligand with the Ln^{3+} ion encapsulated within the N_4O_3 cavity of the Schiff base; all the pyridyl groups remain uncoordinated. A perspective drawing of **4** is shown in Figure 1.

For **4**, the Tb^{3+} ion is seven coordinate and its geometry can be considered as a mono-capped octahedron with the tertiary amine nitrogen N(4) capped on the triangular face formed by the three imino nitrogen atoms. The Tb−N distance of the capped tertiary nitrogen [Tb(1)−N(4) 2.686(4) Å] is longer than those of the imino nitrogens [Tb(1)−N(1) 2.456(4), Tb(1)−N(2) 2.475(4) and Tb(1)−N(3) 2.486(4) Å]. The Tb−O distances are 2.187(3) [Tb(1)−O(1)], 2.216(3) [Tb(1)−O(2)] and 2.205(3) Å [Tb(1)−O(3)]. The Tb−N(amino) distance and average Tb−N(imino) distance (2.472 Å) are slightly shorter than, whereas the average Tb−O (2.203 Å) distance is similar to, those of Pr(trensal)[9] [Pr−N(amino) 2.805(5), Pr−N(imino) 2.620 and Pr−O 2.282 Å] and Nd(trensal)[9] [Nd−N(amino) 2.799(4), Nd−N(imino) 2.601 and Nd−O 2.275 Å], after considering the influence of the lanthanide contraction. The carbon−nitrogen distances for the imino nitrogens [N(1)−C(1) 1.279(6), N(2)−C(32) 1.264(7) and N(3)−C(39) 1.258(8) Å] are in agreement with the C=N distance. All the pyridyl groups are pointing away from the metal and are not coplanar with the phenyl rings of the Schiff-base ligand. The torsion angles between the phenyl rings and the pyridyl groups are −33.4° [C(16)−C(10)−C(11)−C(15)], 37.7° [C(17)−C(18)−C(19)−C(23)] and 27.7° [C(54)−C(48)−C(49)−C(53)]. The

structures of compounds **5**−**7** are very similar to that of **4** and will not be discussed in detail here. Selected bond lengths and bond angles for compounds **4**−**7** are collectively listed in Table 1. Important structural properties of compounds **4**−**7** are given in Table 2. The M−N(imino), M−N(amino) and M−O(phenoxy) bond lengths decrease from **4** to **7**, reflecting the general rule of lanthanide contraction from the early to late f-elements.

Table 2. Structural properties of compounds **4**−**7**

	4	**5**	**6**	**7**
M−N(amino) (Å)	2.686	2.685	2.678	2.662
Average M−N(imino) (Å)	2.472	2.462	2.456	2.444
Average M−O (Å)	2.203	2.202	2.189	2.180
Torsion angle (°) [a]	**I** −33.4	**I** −33.0	**I** −34.8	**I** −35
	II 27.7	**II** 27.2	**II** 26.3	**II** 28
	III 37.7	**III** 36.0	**III** 36.8	**III** 35

[a] Torsion angles: **4** [**I** C(16)−C(10)−C(11)−C(15), **II** C(54)−C(48)−C(49)−C(53), **III** C(17)−C(18)−C(19)−C(23)]; **5** [**I** C(4)−C(5)−C(6)−C(7), **II** C(22)−C(23)−C(24)−C(25), **III** C(40)−C(41)−C(42)−C(43)]; **6** [**I** C(1)−C(2)−C(3)−C(4), **II** C(31)−C(30)−C(32)−C(33), **III** C(49)−C(48)−C(50)−C(51)]; **7** [**I** C(27)−C(26)−C(32)−C(33), **II** C(45)−C(44)−C(50)−C(51), **III** C(9)−C(8)−C(14)−C(15)].

Conductivity measurements show that compounds **1**−**9** behave as non-electrolytes in methanol solution. The electrospray ionization high-resolution mass spectrum (positive mode) of each complex in methanol shows a mass peak at *m*/*z* corresponding to $[M + H]^+$. For instance, the Eu^{3+} complex exhibits the mass peak at *m*/*z* = 1008.4032, which deviates less than 5 ppm from the theoretical peak value of 1008.4048 for the elemental composition $C_{54}H_{61}EuN_7O_3$. The observed isotopic distribution patterns of the $[M + H]^+$ peaks match well with the expected theoretical signals. The ^1H NMR spectrum of the Lu complex **9** in CD_3OD displays a single set of resonances attributed to the *tert*-butyl protons at δ = 1.35 (s, 27 H), the NCH_2CH_2N protons at δ = 2.82 (t, $J_{H,H}$ = 6.5 Hz, 6 H) and 3.10 ppm (t, $J_{H,H}$ = 6.5 Hz, 6 H), the 2-pyridyl protons at δ = 7.02 (t, $J_{H,H}$ = 6.5 Hz, 3 H), 7.15 (m, 3 H), 7.53 (m, 3 H) and 8.11 ppm (d, $J_{H,H}$ = 8.1 Hz, 3 H), the phenyl protons at δ = 7.63 (s, 3 H) and 8.00 ppm (s, 3 H) and the -N=C*H*- protons at δ = 8.47 ppm (s, 3 H). This indicates that there is only one species present in solution and the solution structure of the complex is similar to its solid-state structure, with the lanthanide ion coordinated in the N_4O_3 cavity of the ligand with pendant 2-pyridyl groups rotating freely in solution. Furthermore, luminescent studies (vide infra) on Eu^{3+} and Tb^{3+} complexes indicate that there are two methanol molecules coordinated to the lanthanide ions. The above data suggest that compounds **1**−**9** exist as nine-coordinate non-electrolytes in methanol solution, with the lanthanide metal ions coordinated in the N_4O_3 cavity of the tripodal ligand and also to two solvent molecules.

Photophysical Properties

At room temperature, compounds **1**−**9** exhibit similar solution absorption and emission spectra in the UV/Vis region. Their photophysical properties are summarized in Table 3. The absorptions between 255 and 383 nm can be assigned to $\pi \rightarrow \pi^*$ transitions of the tripodal Schiff-base ligand. The visible emission of compounds **1**−**9**, with lifetimes (τ) ranging from 3.8 to 9.4 ns and quantum yields (Φ_{em}) of 0.33−5.57 × 10^{-2}, can be assigned to the intra-

9	378 (3.97), 256 (4.35)	380	460 (4.5, 3.62)[d]

[a] Photophysical measurements were made in $2 \cdot 10^{-5}$ M CH_3OH solution at room temperature. [b] Quantum yields were determined relative to quinine sulfate in 0.1 N H_2SO_4 ($\Phi = 0.55$). [c] Phosphorescence band was also observed at 508 nm ($\tau = 776$ μs). [d] Phosphorescence band was also observed at 500 nm ($\tau = 26.3$ ms).

ligand emission. The absorption, emission and excitation (monitored at 465 nm) spectra of **7** are shown in Figure 2. The photoluminescence excitation (PLE) spectrum reflects where the maximum contribution of the photoluminescence (PL) comes from. Under steady-state conditions, excited electrons relax from the highest excited states to the lowest excited states before they recombine radiatively or non-radiatively. In this case, the PLE spectrum shows exactly this situation; the maximum PL contribution comes from the lowest excited bands, with a decreasing contribution from the higher-energy band. Thus, although the absorption bands coincide with the excitation bands, as they should, the relative intensities of the energy bands by the two techniques can reveal the origin of the physical process measured. The emission spectra and decay time measurements for Gd^{3+} complexes allowed the identification of the lowest ligand triplet state in the complexes.[19−22] This is possible because the metal-centered (MC) electronic levels of Gd^{3+} are known to be located at 31000 cm^{-1}, typically well above the ligand-centered electronic levels of aromatic ligands.[23] Therefore, ligand-to-metal energy transfer and the consequent MC luminescence cannot be observed.

Figure 3 shows the variable temperature emission spectra of **3** in methanol. The time-resolved spectra of **3** show that at room temperature the lifetimes at 455 and 508 nm are

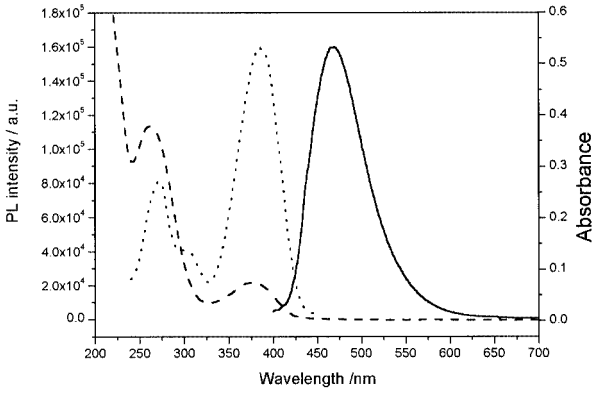

Figure 2. Room temperature absorption (− − − −), emission (———; excited at 380 nm) and excitation (·····; monitored at 465 nm) spectra of **7** in CH_3OH

both 3.8 ns, indicating that the emissions come from the same state and correspond to a ligand-centered (LC) short-lived fluorescence. At 77 K, on top of the weak LC fluorescence ($\tau = 4.1$ ns at 455 nm and 6.8 ns at 508 nm), an intense LC long-lived phosphorescence is also observed at 508 nm ($\tau = 776$ μs). This indicates that both LC singlet and triplet states exist at 77 K. The ligand-centered excited singlet state (^{1}LC) is estimated to be about 22000 cm^{-1} and the triplet state (^{3}LC) to be 19690 cm^{-1}.

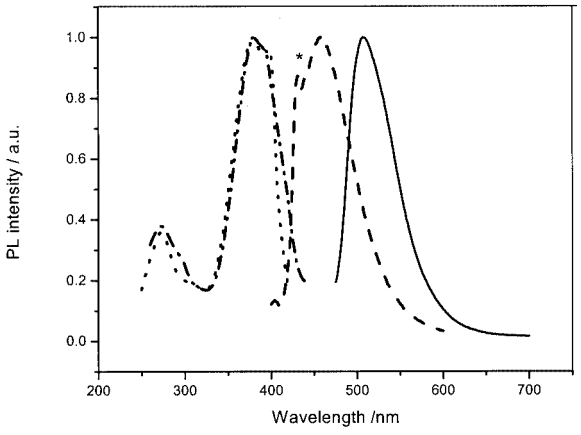

Figure 3. Variable-temperature emission and excitation spectra of **3** in CH_3OH; room temperature emission (− − −; excited at 380 nm) and excitation (·····; monitored at 455 nm) spectra, 77 K emission (———; excited at 380 nm) and excitation (−·−·−; monitored at 508 nm) spectra; the peak marked with an asterisk is due to scattering

The variable-temperature photoluminescent properties of compounds **2**, **4** and **7** in methanol have also been examined. Emission corresponding to the characteristic 4f−4f transitions of trivalent lanthanide metal ions was observed at 77 K but not at room temperature for **2** and **4**. Figure 4 and 5 show the room temperature and 77 K emission and excitation spectra of **2** and **4**, respectively. At room temperature, the time-resolved spectra of **2** and **4** taken at their emission peak ($\lambda_{max} = 470$ nm for **2**, $\tau = 4.5$ ns; $\lambda_{max} = 466$ nm for **4**, $\tau = 4.7$ ns) and 508 nm ($\tau = 4.5$ ns for **2** and 4.7 ns for **4**) show that the emission corresponds to a li-

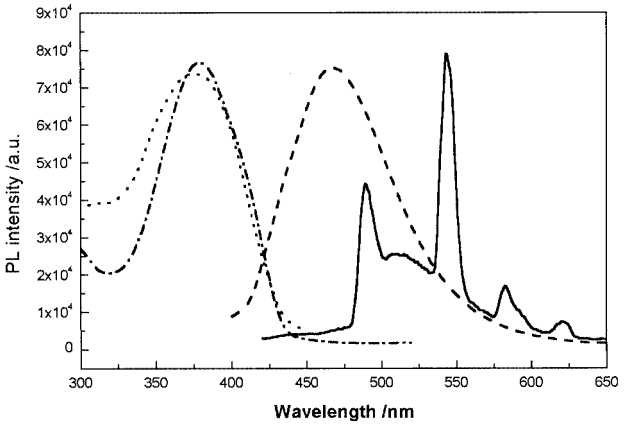

Figure 5. Variable-temperature emission and excitation spectra of **4** in CH_3OH; room temperature emission (– – –; excited at 380 nm) and excitation (·····; monitored at 465 nm) spectra, 77 K emission (———; excited at 380 nm) and excitation (–·–·–; monitored at 544 nm) spectra

gand-centered (^{1}LC) short-lived fluorescence. At 77 K, the lanthanide ion emission for compound **2**, which has a lifetime of 476 μs in CH_3OH and 787 μs in CD_3OD, corresponds to the $^5D_0 \rightarrow {}^7F_J$ transitions of Eu^{3+}, with the emission at 611 nm being assigned to the $^5D_0 \rightarrow {}^7F_2$ transition.[24] Other than the Eu^{3+} emission, a very broad and weak emission peak at around 470 nm was also observed at 77 K (Figure 4). Lifetime measurements confirmed that the emission was purely ^{1}LC fluorescence with no ^{3}LC phosphorescence (τ being 4.9 ns at 470 nm and 5.4 ns at 508 nm). The observation of ^{3}LC phosphorescence for the Gd^{3+} complex (**3**) but not for the Eu^{3+} complex (**2**) indicates that energy transfer from the ligand triplet ^{3}LC to Eu^{3+} excited states is quite efficient. The emission for compound **4** at 77 K, which has a lifetime of 572 μs in CH_3OH and 678 μs in CD_3OD, corresponds to the $^5D_4 \rightarrow {}^7F_J$ transitions of Tb^{3+}, with the emission centered at 551 nm arising from the $^5D_4 \rightarrow {}^7F_5$ transition.[24] Other than the Tb^{3+} emission, a very broad and weak emission centered around 466 nm and a medium-strong emission centered around 508 nm were also observed at 77 K (Figure 5). The time-resolved spectra show that there is only one lifetime at 466 nm (τ being 5.6 ns) and two different lifetimes at 508 nm (τ being 6.0 ns and 113 μs). This shows that the emission centered at 466 nm is due to ^{1}LC fluorescence and that at 508 nm to ^{3}LC phosphorescence. Unlike **2**, which does not show any ^{3}LC phosphorescence, **4** exhibits ^{3}LC phosphorescence, which is probably due to back energy-transfer from the metal excited state to the ^{3}LC. It has been shown that efficient back energy-transfer takes place in Tb^{3+} complexes when ΔE (^{3}LC – $^5D_4$) is less than 1850 cm^{-1}.[25] The energy of the ligand triplet state is about 2400 cm^{-1} higher than the energy of the $^5D_0$ Eu^{3+} luminescent level (17300 cm^{-1}) and lies at almost the same energy as the $^5D_4$ Tb^{3+} luminescent level (20450 cm^{-1}).[23] Thus, efficient ligand-to-metal energy transfer is observed for the Eu^{3+} complex and significant back energy-transfer for the Tb^{3+} complex. The excitation band of **2** (monitored at 613 nm for Eu^{3+}) and **4** (monitored at 545 nm for Tb^{3+}) is located around 380 nm in each case, and closely resembles their low-energy absorption band, indicative of their similar ori-

Table 4. Photophysical data of compounds **2** and **4** at 77 K[a]

Compound	Excitation (nm)	Emission (nm)	Transition	τ in CH_3OH[b] (μs)	τ in CD_3OD[b] (μs)
2	382	579	$^5D_0 \rightarrow {}^7F_0$		
		593	$^5D_0 \rightarrow {}^7F_1$		
		613	$^5D_0 \rightarrow {}^7F_2$		
		651	$^5D_0 \rightarrow {}^7F_3$	476	787
		681	$^5D_0 \rightarrow {}^7F_4$

gin. This clearly shows that the excitation of both Eu^{3+} and Tb^{3+} complexes originates from the $\pi \rightarrow \pi^*$ transitions of the Schiff-base antenna. Their low-temperature photophysical properties and assignments of the transitions are summarized in Table 4. Based on the different lifetimes of the lanthanide-ion emissions in CH_3OH and CD_3OD, the number of coordinated methanol molecules (*n*), which can be calculated from Horrocks equation,[26] is estimated to be 1.74 and 2.30 for Eu^{3+} and Tb^{3+}, respectively. This indicates that in methanol solution, there are two solvent molecules coordinated to the trivalent lanthanide metal ions.

However, even at 77 K, **7** exhibits no ^{3}LC emission in the visible region nor an emission corresponding to the $^4I_{13/2} \rightarrow {}^4I_{15/2}$ transition of Er^{3+} in the near-infrared region. This suggests that the Er^{3+} ion probably relaxes its energy, which it receives from the antenna, via vibrational modes to the environment.

Conclusion

In this paper, we have demonstrated that lanthanide Schiff-base complexes, $Ln^{III}L$, can be conveniently prepared by the condensation of tris(2-aminoethyl)amine with three equivalents of 5-*tert*-butyl-2-hydroxy-3-(2′-pyridyl)benzaldehyde in the presence of trivalent lanthanide metal ions. A photophysical study shows that the Schiff-base ligand can act as an antenna and transfer the absorbed light energy via its triplet state to the Eu^{3+} and Tb^{3+} metal ions.

Experimental Section

General Procedures: All reactions were carried out under an atmosphere of dry nitrogen. Solvents were dried by standard procedures, and distilled and deaerated prior to use. Hydrated lanthanide salts and tris(2-aminoethyl)amine (tren) were obtained from the Aldrich Chemical Company and used without further purification. 5-*tert*-Butyl-2-hydroxy3-(2′-pyridyl)benzaldehyde (Py-CHO) was prepared according to a literature method.[27] Microanalyses were performed by the Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, China. Electronic absorption spectra in the UV/Vis region were recorded on a Hewlett−Packard 8453 UV/Visible spectrophotometer, steady-state visible fluorescence and PL excitation spectra on a Photon Technology International (PTI) Alphascan spectrofluorimeter and visible decay spectra on a pico-N_2 laser system (PTI Time Master) with λ_{exc} = 337 nm. Quantum yields were computed according to a literature method[28] using quinine sulfate in 0.1 N H_2SO_4 as the reference standard (Φ = 0.55 in air-equilibrated water).[29] The number of coordinated solvent molecules (*n*) for the Eu^{3+} and Tb^{3+} complexes was calculated from the Horrocks equation $n = r(\tau_H^{-1} - \tau_D^{-1})$, where τ_H and τ_D are the excited-state lifetimes (in ms) in CH_3OH and CD_3OD, respectively, and the value of *r* is 2.1 and 8.4 for Eu^{3+} and Tb^{3+}, respectively.[26] Infrared spectra (KBr pellets) were recorded on a Nicolet Nagna-IR 550 spectrometer and NMR spectra on a JEOL EX270 spectrometer. Chemical shifts of ^{1}H NMR spectra were referenced to internal deuterated solvents and then recalculated to $SiMe_4$ (δ = 0.00 ppm). Low-resolution mass spectra (LRMS) were obtained on a Finnigan MAT SSQ-710 spectrometer in the positive FAB mode. Electrospray ionization high-resolution mass spectra (ESI-HRMS) were recorded on a QSTAR mass spectrometer. Conductivity measurements were carried out with a DDS-11 conductivity bridge for 10^{-4} mol dm^{-1} solutions in methanol.

Preparation of Lanthanide Schiff-Base Complexes: Compounds **1**−**9** were prepared using a similar method. A typical procedure for the preparation of the complexes is given for **1**.

Compound 1: A solution of $La(NO_3)_3{\cdot}6H_2O$ (0.044 g, 0.102 mmol) and Py-CHO (0.077 g, 0.304 mmol) in methanol (15 mL) was heated to 55 °C. Then, a solution of tren (0.015 g, 0.103 mmol) in methanol (10 mL) was added and the mixture was refluxed for an additional 2 h. The solution was then cooled to room temperature, filtered and the solvents evaporated to dryness in vacuo. The residue was re-dissolved in dichloromethane, filtered and slowly evaporated in air to give yellow crystals, which were filtered and dried in vacuo. Yield: 0.078 g, 74%; m.p. > 260 °C (decomp). ^{1}H NMR (in CD_3OD): δ = 1.36 (s, 27 H, *tert*-butyl), 2.82 and 3.10 (2 × t, $J_{H,H}$ = 6.5 Hz, 2 × 6 H, 3 × NCH_2CH_2N), 7.24 (t, $J_{H,H}$ = 6.2 Hz, 3 H, py-H), 7.55 (s, 3 H, Ar-H), 7.60 (m, 3 H, py-H), 7.86 (s, 3 H, Ar-H), 8.19 (m, 3 H, py-H), 8.28 (d, $J_{H,H}$ = 9.4 Hz, 3 H, py-H), 8.34 (s, 3 H, N=C*H*) ppm. IR (KBr): $\nu_{C=N}$ = 1623 cm^{-1}. ESI-HRMS (+ve mode, CH_3OH): *m*/*z* = 994.3854 [M + H]$^+$ ($C_{54}H_{61}LaN_7O_3$ requires 994.3899). $C_{54}H_{60}LaN_7O_3{\cdot}3.5H_2O$ (1057.06): calcd. C 61.35, H 6.40, N 9.28; found C 61.45, H 6.34, N 9.32.

Compound 2: $Eu(NO_3)_3{\cdot}6H_2O$ (0.045 g, 0.101 mmol), Py-CHO (0.077 g, 0.304 mmol) and tren (0.015 g, 0.103 mmol) were used. Yield: 0.064 g, 60%; light-yellow solid, m.p. > 210 °C (decomp). IR (KBr): $\nu_{C=N}$ = 1621 cm^{-1}. MS (FAB, +ve): *m*/*z* = 1008 [M + H]$^+$ for ^{153}Eu. ESI-HRMS (+ve mode, CH_3OH): *m*/*z* = 1008.4032 [M + H]$^+$ ($C_{54}H_{61}EuN_7O_3$ requires 1008.4048). $C_{54}H_{60}EuN_7O_3{\cdot}3.5H_2O$ (1070.12): calcd. C 60.60, H 6.26, N 9.16; found C 60.40, H 6.26, N 9.39.

Compound 3: $Gd(NO_3)_3{\cdot}6H_2O$ (0.045 g, 0.100 mmol), Py-CHO (0.077 g, 0.304 mmol) and tren (0.015 g, 0.103 mmol) were used. Yield: 0.072 g, 68%; light-yellow solid, m.p. > 250 °C (decomp). IR (KBr): $\nu_{C=N}$ = 1628 cm^{-1}. ESI-HRMS (+ve mode, CH_3OH): *m*/*z* = 1013.4004 [M + H]$^+$ ($C_{54}H_{61}GdN_7O_3$ requires 1013.4077). $C_{54}H_{60}GdN_7O_3{\cdot}2.5H_2O$ (1057.39): calcd. C 61.32, H 6.21, N 9.27; found C 61.36, H 6.10, N 9.29.

Compound 4: $Tb(NO_3)_3{\cdot}6H_2O$ (0.045 g, 0.099 mmol), Py-CHO (0.077 g, 0.304 mmol) and tren (0.015 g, 0.103 mmol) were used. Yield: 0.073 g, 69%, greenish-yellow solid, m.p. > 200 °C (decomp). IR (KBr): $\nu_{C=N}$ = 1623 cm^{-1}. MS (FAB, +ve): *m*/*z* = 1014 [M + H]$^+$ for ^{159}Tb. ESI-HRMS (+ve mode, CH_3OH): *m*/*z* = 1014.4061 [M + H]$^+$ ($C_{54}H_{61}N_7O_3Tb$ requires 1014.4089). $C_{54}H_{60}N_7O_3Tb{\cdot}2.5H_2O$ (1059.06): calcd. C 61.23, H 6.20, N 9.26; found C 61.24, H 6.06, N 9.28.

Compound 5: $DyCl_3$ (0.027 g, 0.100 mmol), Py-CHO (0.077 g, 0.304 mmol) and tren (0.015 g, 0.103 mmol) were used. Yield: 0.074 g, 71%, greenish-yellow solid, m.p. > 250 °C (decomp). IR (KBr): $\nu_{C=N}$ = 1622 cm^{-1}. MS (FAB, +ve): *m*/*z* = 1019 [M + H]$^+$ for ^{164}Dy. ESI-HRMS (+ve mode, CH_3OH): *m*/*z* = 1019.4180 [M + H]$^+$ ($C_{54}H_{61}DyN_7O_3$ requires 1019.4127). $C_{54}H_{60}DyN_7O_3{\cdot}H_2O$ (1035.61): calcd. C 62.62, H 6.05, N 9.47; found C 62.43, H 6.04, N 9.37.

Compound 6: $Ho(NO_3)_3{\cdot}5H_2O$ (0.044 g, 0.100 mmol), Py-CHO (0.077 g, 0.304 mmol) and tren (0.015 g, 0.103 mmol) were used. Yield: 0.071 g, 63%, yellow solid, m.p. > 170 °C (decomp). IR

Compound 7: $Er(NO_3)_3·5H_2O$ (0.045 g, 0.101 mmol), Py-CHO (0.077 g, 0.304 mmol) and tren (0.015 g, 0.103 mmol) were used. Yield: 0.088 g, 85%, yellow solid, m.p. > 340 °C (decomp). IR (KBr): $\nu_{C=N}$ = 1620 cm^{-1}. MS (FAB, +ve): m/z = 1021 [M + H]$^+$ for ^{166}Er. ESI-HRMS (+ve mode, CH_3OH): m/z = 1023.4086 [M + H]$^+$ ($C_{54}H_{61}ErN_7O_3$ requires 1023.4174). $C_{54}H_{60}ErN_7O_3·0.75H_2O$ (1035.87): calcd. C 62.60, H 6.00, N 9.47; found C 62.64, H 5.82, N 9.88.

Compound 8: $Tm(NO_3)_3·6H_2O$ (0.047 g, 0.102 mmol), Py-CHO (0.077 g, 0.304 mmol) and tren (0.015 g, 0.103 mmol) were used. Yield: 0.052 g, 50%, greenish-yellow solid, m.p. > 250 °C (decomp). IR (KBr): $\nu_{C=N}$ = 1623 cm^{-1}. MS (FAB, +ve): m/z = 1024 [M + H]$^+$ for ^{169}Tm. ESI-HRMS (+ve mode, CH_3OH): m/z = 1024.4192 [M + H]$^+$ ($C_{54}H_{61}N_7O_3Tm$ requires 1024.4178). $C_{54}H_{60}N_7O_3Tm·1.25H_2O$ (1046.55): calcd. C 61.96, H 6.03, N 9.37; found C 61.97, H 6.00, N 9.37.

Compound 9: $Lu(NO_3)_3·H_2O$ (0.036 g, 0.100 mmol), Py-CHO (0.077 g, 0.304 mmol) and tren (0.015 g, 0.103 mmol) were used. Yield: 0.066 g, 63%, yellow solid, m.p. > 220 °C (decomp). ^{1}H NMR (CD_3OD): δ = 1.35 (s, 27 H, *t*Bu), 2.81 and 3.10 (2 × t, $J_{H,H}$ = 6.5 Hz, 2 × 6 H, 3 × NCH_2CH_2N), 7.02 (t, $J_{H,H}$ = 6.5 Hz, 3 H, py-H), 7.15 (m, 3 H, py-H), 7.53 (m, 3 H, py-H), 7.63 (s, 3 H, Ar-H), 8.00 (s, 3 H, Ar-H), 8.11 (d, $J_{H,H}$ = 8.1 Hz, 3 H, py-H), 8.47 (s, 3 H, N=C*H*) ppm. IR (KBr): $\nu_{C=N}$ = 1623 cm^{-1}. ESI-HRMS (+ve mode, CH_3OH): m/z = 1030.4186 [M + H]$^+$ ($C_{54}H_{61}LuN_7O_3$ requires 1030.4243). $C_{54}H_{60}LuN_7O_3·H_2O$ (1048.08): calcd. C 61.87, H 5.97, N 9.36; found C 61.83, H 6.01, N 9.34.

X-ray Crystallography: Pertinent crystallographic data and other experimental details are summarized in Table 5. Crystals of **4**·H_2O, **5**·CH_3OH·0.75H_2O, **6**·1.5H_2O and **7**·2CH_3OH suitable for X-ray diffraction studies were grown by slow evaporation of a solution of the respective compound in methanol. The selected crystal of each complex was mounted on the top of a glass fiber for data collection. Intensity data were collected at 293 K on a Bruker Axs SMART 1000 CCD area-detector diffractometer (for **4**, **5** and **6**) and a Mar Research image plate scanner (for **7**) using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). For **4** and **5**, the collected frames were processed with the software SAINT[30] and an absorption correction was applied (SADABS)[31] to the collected reflections. A self-consistent semi-empirical absorption correction based on Fourier coefficient fitting of symmetry-equivalent reflections was applied using the ABSCOR program for **6**. For **7**, interframe scaling was employed for the absorption correction. The space groups of each crystal were determined from the systematic absences and Laue symmetry checks and confirmed by successful refinement of the structures. The structures of all compounds were solved by direct method (SHELXTL^{TM})[32] and refined by full-matrix least-squares analysis. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were generated in their idealized positions and allowed to ride on their respective parent carbon atoms. CCDC-157465 (**4**), -190555 (**5**), -190556 (**6**) and -212141 (**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Characterization and Near-Infrared Photoluminescence of Monoporphyrinate Lanthanide Complexes Containing an Anionic Tripodal Ligand

Hongshan He,[a,c] Jianping Guo,[a] Zhixin Zhao,[a] Wai-Kwok Wong,*[a] Wai-Yeung Wong,[a] Wing-Kit Lo,[a] King-Fai Li,[b] Li Luo,[b] and Kok-Wai Cheah[b]

Keywords: Lanthanides / Photoluminescence / Porphyrins / Tripodal ligands

Twelve neutral stable complexes of ytterbium(III) and erbium(III) coordinated by anionic hydridotris(pyrazol-1-yl)borate and *meso*-tetraphenylporphyrinate, and its derivatives with different substituents in the *para* position of the phenyl groups, were prepared and characterized. Crystal structure analyses revealed that seven nitrogen atoms, four from the porphyrinate dianion and three from the anionic tripodal ligand, are symmetrically coordinated to the lanthanide ions. Photophysical investigations of the complexes showed an enhancement of near-infrared photoluminescence as compared to aqua-coordinated monoporphyrinate lanthanide complexes. The solvent effect and substituent effects on the photoluminescent properties of the complexes were also investigated
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004).

Introduction

Recently, near-infrared (NIR) photoluminescence of three lanthanide ions, Nd^{3+}, Er^{3+} and Yb^{3+}, has attracted considerable attention for their potential application in optical amplification and fluoroimmunoassay.[1−8] Direct excitation of lanthanide ions is difficult because of the forbidden nature of their electronic transitions.[9] However, indirect excitation of an organic chromophore (antenna) that interacts closely with lanthanide the ions can make the energy of the triplet state of the ligand transfer efficiently to the excited state of the lanthanide ion and enable the ion to emit light;[10] the design of molecular systems with binding ability and photosensitizing properties for the construction of efficient photoluminescent lanthanide complexes is the key issue of this active area of research. Porphyrins are good candidates for this purpose because they can form stable complexes with lanthanide ions and have high absorbance.[11−15]

Several reports on NIR photoluminescent studies of porphyrinate lanthanide complexes have appeared in the literature during the past decades.[7,16−19] The results with Yb^{3+} and Er^{3+} complexes revealed that the porphyrin could indeed absorb the light and transfer the energy to lanthanide ions. However, the limited structural variation of the complexes tends to prohibit intensive investigation of the photophysical properties of lanthanide complexes, because most of them were prepared by the direct interaction of lanthanide β-diketonates with free porphyrin bases in 1,3,5-trichlorobenzene.[11−17] The lanthanide ion was therefore always coordinated by one porphyrinate dianion and one β-diketonate anionic ligand, which was very difficult to remove. Recently, we established a new method for the preparation of cationic lanthanide porphyrinate complexes of the general formula $[Ln(Por)(H_2O)_3]Cl$ (Ln = Yb^{3+}, Er^{3+} and Y^{3+}), in which one porphyrinate dianion and three aqua molecules are coordinated to the lanthanide ion.[18−21] The three aqua ligands in $[Ln(Por)(H_2O)_3]Cl$ can be substituted easily by other ligands, for example the (cyclopentadienyl)tris(diethylphosphito)cobaltate(I) anion, to form stable complexes.[18] This provides an opportunity for us to modify the monoporphyrinate lanthanide complexes for photoluminescent studies.

In this paper, we report the synthesis and characterization of a series of new stable ytterbium(III) and erbium(III) porphyrinate complexes coordinated by another anionic tripodal ligand, namely hydridotris(pyrazol-1-yl)borate (Scheme 1). The crystallographic analyses showed that seven N atoms, four from the porphyrinate dianion and three from the anionic tripodal ligand, are coordinated to the metal ions. The photoluminescence of lanthanide com-

Results and Discussion

Synthesis and Characterization

The free porphyrin bases 5,10,15,20-tetraphenylporphyrin (H_2TPP), 5,10,15,20-tetrakis(*p*-tolyl)porphyrin (H_2TTP), 5,10,15,20-tetrakis(*p*-methoxyphenyl)porphyrin (H_2TMPP), 5,10,15,20-tetrakis(*p*-chlorophenyl)porphyrin (H_2TCPP), 5,10,15,20-tetrakis(*p*-bromophenyl)porphyrin (H_2TBPP), and 5,10,15,20-tetrakis(*p*-fluorophenyl)porphyrin (H_2TFPP), were prepared by direct condensation of the respective benzaldehyde with pyrrole in propionic acid according to the literature method[21] and purified by column chromatography using silica gel. The yields are 7−10%. Under a nitrogen atmosphere, refluxing of the free porphyrin base with a fivefold excess of $Ln[N(SiMe_3)_2]_3{\cdot}x[LiCl(THF)_3]$, generated in situ from the reaction of anhydrous $LnCl_3$ with three equivalents of $Li[N(SiMe_3)_2]$ in THF, in bis(2-methoxyethyl)ether for 48 h,[19−21] followed by stirring of the resulting mixture with a slight excess of potassium hydridotris(pyrazol-1-yl)borate (KT_p^H) in air at room temperature, gave the purple complexes $[Ln(Por)(T_p^H)]$ (Ln = Yb^{3+}, Por = TPP^{2-}, **1**; $TMPP^{2-}$, **2**; TTP^{2-}, **3**; $TBPP^{2-}$, **4**; $TCPP^{2-}$, **5** and $TFPP^{2-}$, **6**; Ln = Er^{3+}, Por = TPP^{2-}, **7**; $TMPP^{2-}$, **8**; TTP^{2-}, **9**; $TBPP^{2-}$, **10**; $TCPP^{2-}$, **11** and $TFPP^{2-}$, **12**) in high yields (Scheme 1). The complexes are quite stable in air and very soluble in chloroform, dichloromethane and *N*,*N*′-dimethylforamide. The electronic absorption spectra of complexes **1**−**12** are characteristic of normal metalloporphyrins.[23] The Soret band is observed at about 422 nm, while the Q bands are observed at 551 and 588 nm. After complexation, the number of Q bands of the porphyrin ring (four for free porphyrin base) is reduced to two. This is in agreement with Gouterman's four-orbital model,[24] which predicts that, due to an increase in symmetry, the four Q bands of the free porphyrin base will be reduced to two upon the formation of a metalloporphyrin. In the absorption spectra of regular metalloporphyrins there are two Q bands between 500 and 600 nm. The lower-energy band (α band) is the electronic origin Q(0,0) of the lowest singlet excited state S_1. The second band (β band) is its vibrational overtone and is labeled as Q(1,0). The relative intensities of these bands can be a qualitative yardstick of just how stable is the metal ion complexed to the four porphyrin nitrogen atoms. Thus, when the intensity of α is greater than that of β, the metal forms a stable complex with the porphyrin, whereas when α is less than β, the metal is easily displaced by protons.[25] The α/β relative intensity ratio for Yb^{3+} complexes **1**−**6** ranges from 0.12−0.44 and for Er^{3+} complexes **7**−**12** from 0.18−0.34. The typical N−H vibration for free porphyrin bases disappears from the IR spectra upon formation of the complexes. Complexes **1**−**12** exhibit similar fragmentation patterns in their mass spectra. Low-resolution (FAB-MS) and high-resolution mass spectra (ESI-HSMS) of the complexes confirmed that they are 1:1 adducts of monoporphyrinate and the anionic tripodal ligand. The electrospray ionization high-resolution mass spectra (positive mode) of the complexes in methanol show a mass peak corresponding to $[M + H]^+$. For instance, the Er^{3+} and Yb^{3+} complexes of $[Ln(TPP)(T_P^H)]$ exhibit mass peaks at m/z = 992.2815 and 1000.2788, respectively, which deviate by less than 5 ppm from the theoretical values of 992.2755 and 1000.2840 for the elemental composition of $C_{53}H_{39}BErN_{10}$ and $C_{53}H_{39}BN_{10}Yb$, respectively. The observed isotopic distribution patterns of the $[Ln(Por)(T_P^H) + H]^+$ peaks also match the expected theoretical signals.

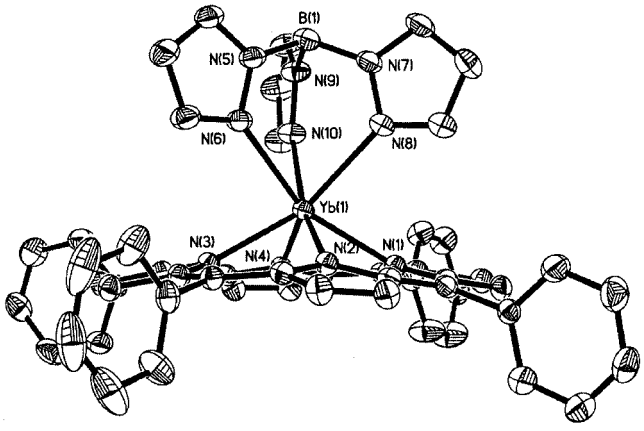
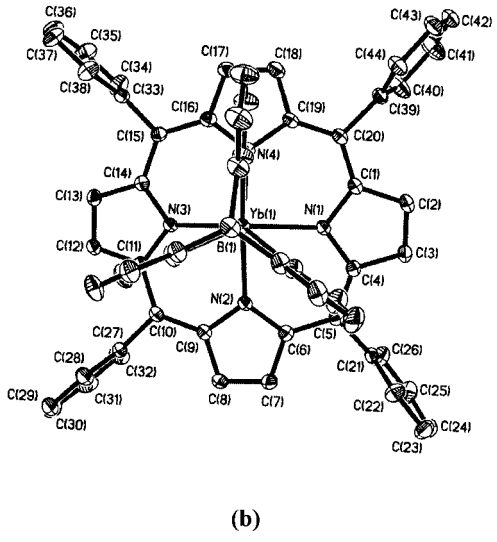
Crystals of **1**·2$CHCl_3$, **5**·$CHCl_3$·CH_3OH and **7**·2$CHCl_3$ suitable for X-ray diffraction studies were grown by slow evaporation of the solvents from solutions of the respective compounds in a chloroform/methanol (v/v, 1:1) solution. Compounds **1**, **5** and **7** are isomorphous and crystallized in the monoclinic space group $P2_1/n$ for **1** and **7**, and $P2_1/c$ for **5**. The selected bond lengths and bond angles of the complexes are given in the Supporting Information (Table S1). Perspective drawings of compounds **1** and **7** are shown in Figure 1 and 2, respectively. The structural analyses revealed that the lanthanide(III) ions are seven coordinate, surrounded by seven nitrogen atoms, four from the porphyrin dianion and three from the anionic tripodal ligand. The average bond length of Ln−N(porphyrin) is shorter than that of Ln−N(tripodal ligand), with Ln−N(porphyrin) and Ln−N(tripodal ligand) being 2.356 and 2.495 Å for **1**, 2.357 and 2.508 Å for **5**, and 2.373 and 2.518 Å for **7**, respectively.

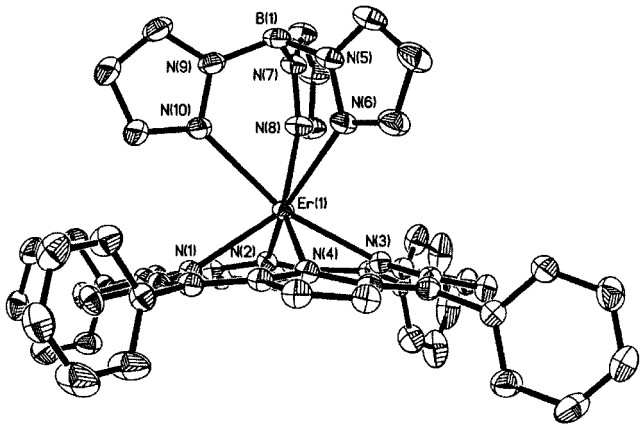


(a)

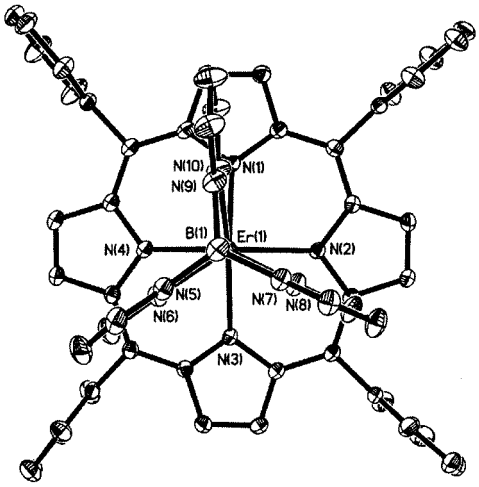


(b)

Figure 1. Perspective views of complex **1**: (a) side view; (b) top view



(a)



(b)

Figure 2. Perspective views of complex **7**: (a) side view; (b) top view

The mean nitrogen plane ($N_1N_2N_3N_4$) of the porphyrin dianion is almost parallel to the mean nitrogen plane ($N_6N_8N_{10}$) of the anionic tripodal ligand, forming a dihedral angle of 0.4°, 2.0° and 0.3° for **1**, **5** and **7**, respectively. The distance of the metal ion to the $N_1N_2N_3N_4$ mean plane is 1.172 Å for **1**, 1.167 Å for **5** and 1.195 Å for **7**, which is longer than that for [Ln(Por)$(H_2O)_3$]Cl[20] and shorter than that for [Ln(Por)(L_{OEt})] [L_{OEt} = cyclopentadienyltris(diethylphosphito)cobaltate(I)].[18] The distance of the metal ion to the $N_6N_8N_{10}$ mean plane is about 0.6 Å longer than that to the $N_1N_2N_3N_4$ mean plane, so the metal ion is much closer to the $N_1N_2N_3N_4$ mean plane. The substituents have little effect on the structural parameters except that the electron-withdrawing group (Cl) on the phenyl group gives a larger dihedral angle between the two planes (Table 1). The relative conformation of the tripodal ligand and the porphyrin dianion is slightly different between the Yb^{3+} and Er^{3+} complexes. A top view of their

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structures reveals that, for the Yb^{3+} complexes, one of the pyrazole planes of the tripodal ligand is just above one of the phenyl groups of the porphyrin dianion, while the other two pyrazole groups are above the pyrrole groups; for the Er^{3+} complex, all the three pyrazole groups are located above the pyrrole groups.

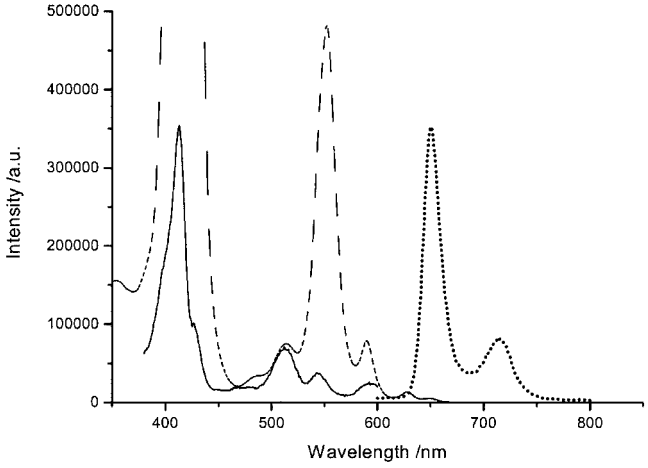

Figure 3. Room temperature absorption (– – –), emission (·····) (excited at 414 nm) and excitation (——) (monitored at 648 nm) spectra of **1** in $CHCl_3$

Photoluminescence Studies

The photophysical properties of compounds **1**−**12** were examined and the data are summarized in Table 2. The room temperature solution electronic absorption, excitation and emission spectra of compounds **1**−**12** in the UV/Vis region are almost identical and are characteristic of intra-ligand transitions of normal porphyrinate complexes.[13] Figure 3 shows the absorption, emission (excited at 414 nm) and excitation (monitored at 648 nm) spectra of **1**. The absorption bands at 421, 550 and 588 nm and emission peaks at 648 nm (τ = 12.9 ns and $\Phi_{em} = 0.11 \times 10^{-3}$) can be assigned to the intra-ligand $\pi \rightarrow \pi^*$ transitions of the porphyrinate ligand. The quantum efficiency of the metalloporphyrin is much lower than that of the corresponding free porphyrin base. For example, the quantum yield of **1** is less than 1% of the corresponding free porphyrin base H_2TMPP ($\Phi_{em} = 2.84 \times 10^{-2}$). Other than the visible emission, compounds **1**−**12** also exhibit typical emission corresponding to the lanthanide(III) ion in the near-infrared (NIR) region. Figure 4 shows the NIR emission and the excitation spectrum of **1**. The excitation bands of **1** in chloroform solution at 298 K (monitored at 980 nm) are observed at 560 and 596 nm, which almost coincide with its visible absorption bands at 550 and 588 nm. This clearly shows that the excitation of the Yb^{3+} ion is due to the $\pi \rightarrow \pi^*$ transitions of the porphyrinate antenna and excitation of the porphyrin is the photophysical pathway leading to the observable NIR luminescence. This is in agreement with our previous photoluminescent studies on related lanthanide porphyrinate complexes,[18,23] which show that the porphyrinate antenna transfers its absorbed visible energy of the Q band to the excited state of the metal ion, which then relaxes through emission in the NIR region. The NIR luminescence lifetime of **1**−**6** is about 20 μs and is much longer than the lifetime of the porphyrinate emission. Due to the limitation of our

equipment, we were unable to measure the excitation (monitored at 1540 nm) spectrum and the NIR luminescence lifetime of **7**–**12**.

The NIR emission spectra of the porphyrinate complexes are depicted in Figure 5. For the Yb^{3+} complexes, a strong emission due to the $^2F_{5/2} \rightarrow {}^2F_{7/2}$ transition is observed at 997 nm. This transition is split into six bands, one of these is sharp (980 nm) and the other five are weak (934, 953, 1002, 1020 and 1038 nm).For the Er^{3+} counterparts, two major peaks centered at 1018 and 1570 nm are observed. These can be attributed to the $^4I_{11/2} \rightarrow {}^4I_{15/2}$ and $^4I_{13/2} \rightarrow {}^4I_{15/2}$ transitions respectively. The first peak (1018 nm) splits into two others at 984 and 1020 nm, and the second peak (1570 nm) splits into five others at 1502, 1540, 1570, 1608 and 1634 nm.[2,4,8] The intensity of the emission of the complexes is enhanced relative to the aqua-coordinated monoporphyrinate complexes $[Ln(Por)(H_2O)_3]Cl$, as shown in Figure 6. Previously, we have investigated the photoluminescent properties of Yb^{3+} porphyrinate coordinated by L^-_{OEt}.[7] Well-split NIR emission peaks are also observed due to the strong bonding of the ligand to the Yb^{3+} ion. The present work further demonstrates that, upon coordination, the anionic tripodal ligand removes the degeneracy of the energy levels of the lanthanide ions by lowering the symmetry of these ions.

Figure 7 shows a simple, widely accepted photophysical model for the description of the sensitization process.[4,8] In this process, the porphyrin absorbs the light and is excited to its singlet state (S_1). The energy is then transferred to its triplet state (T_1), which is, in part, being transferred to the excited state of the lanthanide ion $(Ln^{3+})^*$ to produce the final luminescence. The overall NIR luminescence quantum yield (Φ) of the metal ion is the product of triplet yield (Φ_{ISC}), energy-transfer yield (Φ_{ET}) and the intrinsic luminescence quantum yield of the lanthanide ion (Φ_{Ln}). The structural and electronic variation of the porphyrin can disturb the excited energy level of the complexes and thus change the emission properties.[26,27] Therefore, we measured the NIR photoluminescence intensity of the complexes with different substituents in the *para* position of the phenyl groups of the porphyrin and found that both electron-do-

nating groups and halogen atoms are unfavorable for the NIR emission of Yb^{3+} complexes. For example, the unsubstituted complex **1** gave the strongest emission, with an intensity about six times higher than that of complex **2** and twice that of **6**. The reason for this is that electron donating groups (-OCH_3, -CH_3, etc.) allow the electrons on the phenyl groups to show greater π-conjugation with the porphyrin ring in the S_1 state, which results in an increase of the fluorescence quantum yield of the ligand and a decrease of the quantum yield of intersystem crossing Φ_{ISC}. Furthermore, the halogens can decrease the rate of intersystem crossing and thus make the Φ_{ISC} quite low.[26,28,29] The lower Φ_{ISC} leads to a weaker metal ion emission. As the emission of Er^{3+} complexes is much lower than that of Yb^{3+} complexes, the substituent effect was not apparent here.

We have also investigated the NIR photoluminescence of complex **7** in different solvents (Figure 8). The results showed that the NIR emission intensity of **7** is strongest in non-polar solvents such as benzene, gradually decreases as the polarity of the solvent increases and is completely quenched in methanol. According to the theory of non-radiative transitions in lanthanide complexes, the non-radiative relaxation between various J states may occur by interaction of the electronic levels of the lanthanide ion with suitable vibrational modes of the environment.[30] The presence of OH groups in methanol enhances the non-radiative deactivation of the lanthanide ion by vibronic coupling with the vibrational states of the O−H oscillators and thus quenches the emission.[31]

Concluding Remarks

In this paper, we have reported the synthesis of a series of lanthanide porphyrinate complexes of the general formula [Ln(Por)(T_P^H)] by the interaction of cationic porphyrinate complexes [Ln(Por)$(H_2O)_3$]Cl, generated in situ, with anhydrous KT_P^H and demonstrated that these complexes are good precursors for the preparation of other lanthanide porphyrinate complexes. We have also shown that porphyrinate ligands can behave as antennae by absorbing visible light and thus sensitize the NIR emission of lanthanide ions. Electron-donating groups and halogen atoms on the phenyl groups of the porphyrin ring are unfavorable for the emission of lanthanide ions.

Experimental Section

General: All reactions were carried out under an atmosphere of dry nitrogen. Solvents were dried by standard procedures, distilled and deaerated prior to use. All chemicals used were obtained from Aldrich Chemical Company. 5,10,15,20-Tetraphenylporphyrin (H_2TPP), 5,10,15,20-tetrakis(*p*-tolyl)porphyrin (H_2TTP), 5,10,15,20-tetrakis(*p*-methoxyphenyl)porphyrin (H_2TMPP), 5,10,15,20-tetrakis(*p*-chlorophenyl)porphyrin (H_2TCPP), 5,10,15,20-tetrakis(*p*-bromophenyl)porphyrin (H_2TBPP), 5,10,15,20-tetrakis(*p*-fluorophenyl)porphyrin (H_2TFPP) were prepared according to the literature methods by condensation of pyrrole and the corresponding aldehyde,[22] and characterized by TLC, ^{1}H NMR spectroscopy and FAB mass spectrometry. The IR spectra (KBr pellets) were recorded on a Nicolet Nagba-IR 550 spectrometer. NMR spectra were recorded on a Varian INOVA 400 spectrometer. Low-resolution mass spectra were obtained on a Finnigan MAT SSQ-710 in FAB (positive) mode. Electrospray ionization high-resolution mass spectra (ESI-HRMS) were recorded on a QSTAR mass spectrometer. Electronic absorption spectra in the UV/Vis region were recorded on a Hewlett−Packard 8453 UV/Visible Spectrophotometer, steady-state visible fluorescence and PL excitation spectra on a Photon Technology International (PTI) Alphascan spectro-fluorimeter and visible decay spectra on a pico-N_2 laser system (PTI Time Master) with λ_{exc} = 337 nm. NIR emission was detected by a liquid-nitrogen-cooled InSb IR detector (EG & G) with a preamplifier and recorded by a lock-in amplifier system as the third harmonic; the 355 nm line of an Nd:YAG laser (Quantel Brilliant B) was used as excitation light and also to pump the OPO (Opotek MagicPrism VIR) to provide a continuously tunable laser source from 410−670 nm with a pulse-width of 4 ns. NIR decay spectra were detected by an Oriel 77343 photomultiplier and monitored by a HP54522A 500 MHz oscilloscope. Quantum yields were computed according to the literature method[32] using [Ru(bipy)$_3$]Cl_2 as the reference standard (Φ = 0.028 in air-equilibrated

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

water).[33] To avoid any second-order light reaching the detector, 710 and 830 nm cutoff filters were used where applicable. The complexes in different solution were analyzed in quartz cells at a concentration of 2×10^{-5} M. The power on the cell was 1 W and all spectra were corrected for the detector response.

Preparations of Precursor Complexes: Stock solutions of the precursor complexes, $Ln[N(SiMe_3)_2]_3{\cdot}x[LiCl(THF)_3]$ (Ln = Yb^{3+} and Er^{3+}), were prepared in a similar manner. A detailed description is given for the Yb^{3+} complex.

$Yb[N(SiMe_3)_2]_3{\cdot}x[LiCl(THF)_3]$ Solution (Solution A): *n*BuLi (31.0 mL, 1.6 M in hexane, 49.6 mmol) was added slowly over a period of 30 min to a solution of $(Me_3Si)_2NH$ (10.8 mL, 8.26 g, 51.2 mmol) in THF (20 mL) cooled in an ice bath. The reaction mixture was stirred, warmed up slowly to room temperature and stirred for another 12 h until a clear pale yellow solution was obtained. Then, the resultant solution was transferred slowly to a suspension of $YbCl_3$ (4.45 g, 15.9 mmol) in THF (20 mL). The reaction mixture was stirred for 24 h at room temperature until all of the $YbCl_3$ had been consumed. The resulting solution was centrifuged, filtered and the filtrate was made up to 100 mL with THF to give an approximately 0.16 M solution of $Yb[N(SiMe_3)_2]_3{\cdot}x[LiCl(THF)_3]$ (solution **A**).

$Er[N(SiMe_3)_2]_3{\cdot}x[LiCl(THF)_3]$ Solution (Solution B): The procedure for the preparation of solution **B** was the same as for solution **A**. *n*BuLi (15.5 mL, 1.6 M in hexane, 24.8 mmol), $(Me_3Si)_2NH$ (5.4 mL, 4.13 g, 25.6 mmol) and $ErCl_3$ (2.18 g, 8.0 mmol) were used. The resulting solution was then made up to 50 mL with THF to give an approximately 0.16 M solution of $Er[N(SiMe_3)_2]_3{\cdot}x[LiCl(THF)_3]$ (solution **B**).

Preparations of Compounds 1−12: Compounds **1**−**12** were prepared by the same procedure. A typical procedure is given for **1**.

[Yb(TPP)(Tp^H)] (1): Solution **A** (5.0 mL) was added to a solution of H_2TPP (0.10 g, 0.16 mmol) in bis(2-methoxyethyl)ether (6 mL) under a nitrogen atmosphere. The resulting solution was refluxed and the progress of the reaction was monitored by UV/Vis absorption spectroscopy until most of the free base had coordinated to the metal ion. Then, anhydrous KT^H_P (0.10 g, 0.40 mmol) was added and the resulting mixture was stirred in air for another 12 h. After the reaction was complete, the solvent was removed in vacuo and the residue redissolved in chloroform, filtered and chromatographed on silica gel using chloroform to elute the unchanged free porphyrin base first, and then chloroform/methanol (v/v, 10:1) to elute the product. The solvent was removed on a rotary evaporator. The product was dissolved in chloroform (5 mL) and the solution was filtered. Diffusion of methanol into the chloroform solution gave purple crystals of the desired complex. Yield: 0.14 g (87%). M.p. > 300 °C. X-ray Crystallography. Pertinent crystallographic data and other experimental details are summarized in Table 3. Crystals suitable for X-ray diffraction studies were grown by slow evaporation of solutions of the respective compounds in chloroform/methanol. No decay in intensity was encountered during the data collection. Intensity data for **1**, **5** and **7** were collected at 293 K on a Bruker Axs SMART 1000 CCD area-detector diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The collected frames were processed with the software SAINT,[34] and an absorption correction was applied (SADABS)[35] to the collected reflections. The space groups of each crystal were determined from the systematic absences and Laue symmetry checks and confirmed by successful refinement of the structures. The structures of all compounds were solved by direct methods (SHELXTL)[36] and refined against F^2 by full-matrix least-squares analyses. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were generated in their idealized positions and allowed to ride on their respective parent carbon atoms.

CCDC-213538 (**1**), -213539 (**5**) and -213540 (**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EW, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Non-Heme Iron Complexes for Stereoselective Oxidation: Tuning of the Selectivity in Dihydroxylation Using Different Solvents

Marten Klopstra,[a] Gerard Roelfes,[a] Ronald Hage,[a] Richard M. Kellogg,[a] and Ben L. Feringa*[a]

Keywords: Dihydroxylation / Enzyme models / Epoxidation / Iron / N ligands / Oxidation

A new class of functional models for non-heme iron-based dioxygenases, including $[(N3Py\text{-}Me)Fe(CH_3CN)_2](ClO_4)_2$ and $[(N3Py\text{-}Bn)Fe(CH_3CN)_2](ClO_4)_2$ {N3Py-Me = [di(2-pyridyl)methyl]methyl(2-pyridyl)methylamine; N3Py-Bn = [di(2-pyridyl)methyl]benzyl(2-pyridyl)methylamine}, is presented here. NMR, UV and X-ray analyses revealed that six-coordinate low-spin Fe^{II} complexes with the pyridine N-atoms and the tertiary amine functionality of the ligand bound to Fe are formed. The two remaining coordination sites located *cis* to each other are occupied by labile CH_3CN groups that are easily exchanged by other ligands. We demonstrate that the reactivity and stereoselectivity of the complexes investigated depend on the choice of the solvent. The complexes have been examined as catalysts for the oxidation of both alkanes and olefins in CH_3CN. In this solvent alkanes are oxidized to alcohols and ketones and olefins to the corresponding *cis*-epoxides and *cis*-diols. In acetone as solvent a different reactivity pattern was found, with, as the most striking example, the *trans*-dihydroxylation of cis-olefins. ^{18}O-labeling studies in CH_3CN establish incorporation of ^{18}O from $H_2{}^{18}O_2$ and $H_2{}^{18}O$ in both the epoxide and the diol implicating an HO-Fe^{V}=^{18}O active intermediate originating from an $H_2{}^{18}O$-Fe^{III}OOH species. These results are in full agreement with mechanistic schemes derived for other dioxygenase model systems. Based on labeling studies in acetone an additional oxidation mechanism is proposed for this solvent, in which the solvent acetone is involved. This is the first example of a catalyst that can give *cis*- or *trans*-dihydroxylation products, just by changing the solvent.

Introduction

The catalytic oxidation of hydrocarbons using green oxidants like hydrogen peroxide or dioxygen is a topic of considerable interest.[1] Even though significant progress has been made, in particular with regard to epoxidation of alkenes using H_2O_2,[2−5] many challenges still remain. Among others, the hydroxylation of alkanes and the dihydroxylation of alkenes are highly interesting reactions from a synthetic point of view.

In nature an impressive variety of enzymes capable of performing these reactions with high selectivity under mild conditions exists. An important subset of this class of enzymes are the non-heme iron oxygenases, like, for example, methane monooxygenase,[6] which selectively oxidizes methane to methanol, the Rieske dioxygenases,[7,8] which are capable of stereospecifically dihydroxylating arenes, and iron-bleomycin, a metallo-glycopeptide that is capable of oxidative DNA cleavage,[9] but which can also oxidize a wide variety of organic substrates.[10]

The study of synthetic complexes that model the active site of these enzymes has been an important tool in the study of their functions. Some of these model complexes have proven to be very promising catalysts for the selective oxidation of organic substrates using H_2O_2 as the terminal oxidant. Stereoselective hydroxylation[11−14] epoxidation[4,14−16] and *cis*-dihydroxylation,[17−20] a reaction previously only available using osmium-,[21] ruthenium-[22] and manganese-based[23] catalysts, have been reported. Recently, even the first examples of enantioselective dihydroxylation have appeared in the literature.[24]

Recent studies have shed some light on the mechanism of these oxidation reactions. In the case of $[Fe(TPA)(CH_3CN)_2](ClO_4)_2$, a representative member of this class of catalysts, a strong and compelling case has been built in favor of the involvement of a formally HO-Fe^{V}O species that is formed by heterolysis of the O−O bond of a low spin Fe^{III}OOH intermediate.[13,20,25] This HO-Fe^{V}O species is postulated to be the active species responsible for the formation of both the epoxide and the *cis*-diol. The latter product is thought to be formed via a cyclic intermediate similar to reactions with $KMnO_4$.[15]

We have previously reported on the $[Fe(N4Py)(CH_3CN)](ClO_4)_2$ complex, which contains a pentadentate N ligand and reacts with H_2O_2 to form a well-defined and well-

characterized $Fe^{III}OOH$ intermediate.[26−28] This intermediate was demonstrated to have an unusually weak O−O bond,[29,30] which is thought to be the reason for its high activity as an oxidation catalyst. Reactivity studies using a broad spectrum of mechanistic probes revealed that radical-type oxidizing species are involved and, consequently, a mechanism involving homolysis of the $Fe^{III}OOH$ species to give $Fe^{IV}O$ and ·OH was proposed.[31] This notion was later supported by calculations, which indeed showed homolysis to be the favored reaction pathway.[32] A strong effect of the solvent was observed. In acetone higher kinetic isotope effect (KIE) values of cyclohexane oxidation and higher C3/C2 ratios in adamantane oxidation were found compared to acetonitrile. This was attributed to the ability of acetone to act as an ·OH trap.

Following the TPA precedent we decided to redesign the N4Py ligand into a tetradentate ligand in order to obtain iron complexes capable of stereoselective oxidation. In this paper we present a new class of iron complexes with tetradentate ligands based on N4Py, in which one of the picolyl groups is replaced with a non-coordinating moiety like a methyl or a benzyl group (Figure 1). The properties of the corresponding iron complexes and their application as catalysts in oxidation reactions with H_2O_2 will be discussed, with particular emphasis on the effect of the solvent used, i.e. acetonitrile or acetone.

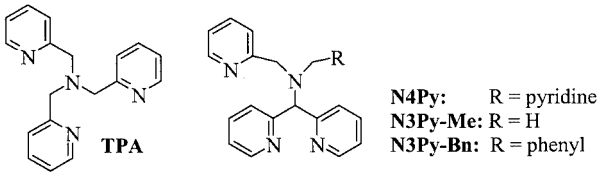

Figure 1. Ligands used for stereoselective epoxidation and *cis*-dihydroxylation of alkenes

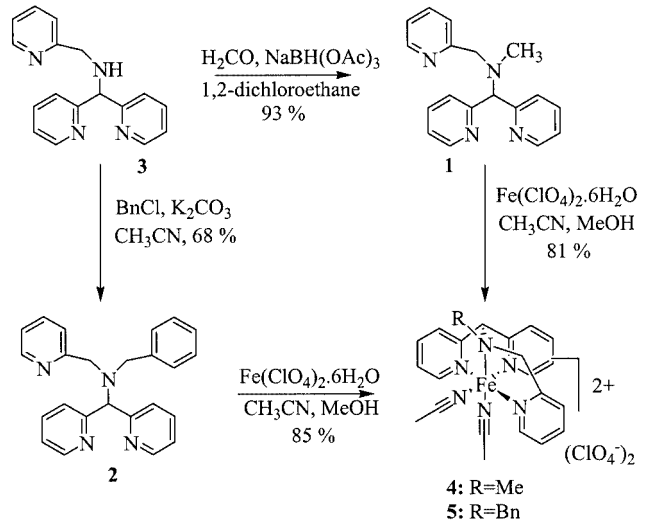
Results and Discussion

Synthesis and Properties of Iron Complexes

Ligands **1** and **2** were prepared from a common precursor, N3Py (**3**).[33] N3Py-Me was obtained in high yield by reductive amination with formaldehyde and $NaBH(OAc)_3$ (Scheme 1).[34] N3Py-Bn was prepared by alkylation of N3Py with benzyl chloride in the presence of K_2CO_3.

Complexation of the ligands **1** and **2** with $Fe(ClO_4)_2·6H_2O$ in methanol/acetonitrile resulted in the formation of red crystals, characterized as $[(N3Py\text{-}R)Fe(CH_3CN)_2](ClO_4)_2$, based on ^1H NMR and ES/MS analysis and confirmed by X-ray analysis for this complex with an *N*-methyl substituent (Figure 2).

The six-coordinate Fe^{II} center has a distorted octahedral geometry, with the iron bound to the three pyridine N atoms, the tertiary amine functionality of the ligand and two acetonitrile molecules, originating from the solvent used for crystallization. The open coordination sites, where acetonitrile molecules are bound, are located *cis* with respect to each other, as was expected. The $Fe-N_{ligand}$ distances vary from 1.909(8) Å for Fe1−N5 to 1.965(9) Å for Fe1−N3. These distances are similar to those found for other low-spin iron(II) complexes like $[(N4Py)Fe(CH_3CN)](ClO_4)_2$,[19] and $[(TPA)Fe(CH_3CN)_2](ClO_4)_2$.[35]



Scheme 1. Synthesis of ligands **1** and **2** and the corresponding iron(II) complexes **4** and **5**

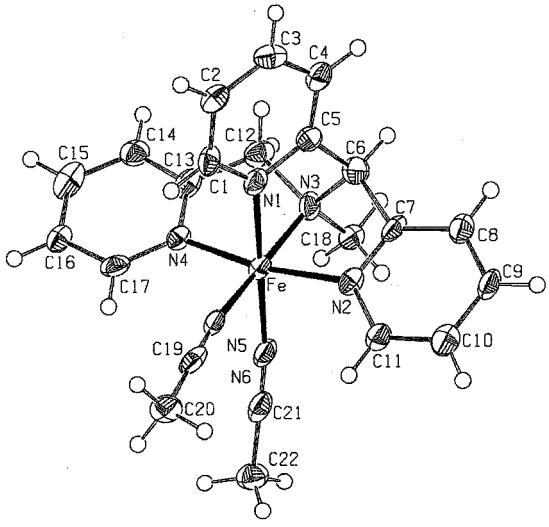


Figure 2. ORTEP plot of the cation of **4**

The ^1H NMR spectra in CD_3CN exhibit signals between $\delta = 0$ and 15 ppm, typical of a low-spin iron(II) complex. However, in contrast to the spectra of other low-spin iron(II) complexes like $[(TPA)Fe(CH_3CN)_2](ClO_4)_2$ and $[(N4Py)Fe(CH_3CN)_2](ClO_4)_2$,[28,35] which show very sharp signals, significant line broadening was observed for some of the signals of **4** and **5**. An example is the spectrum of **4** shown in Figure 3A. The line broadening is probably due to an equilibrium between the low-spin Fe^{II} bis-acetonitrile complex $[(N3Py\text{-}R)Fe(CH_3CN)_2]^{2+}$ and the paramagnetic high-spin Fe^{II} mono-acetonitrile complex $[(N3Py\text{-}R)Fe(CH_3CN)]^{2+}$, i.e. a reversible dissociation of one of the labile CH_3CN ligands. This was confirmed by the ^1H NMR

spectrum in [D_6]acetone, in which dissociation of acetonitrile is irreversible and results in signals in the δ = 0−180 ppm range, characteristic for a high-spin Fe^{II} complex (Figure 3B).[28] A similar solvent effect was found in the UV/Vis spectra of **4** in CH_3CN and acetone. In CH_3CN **4** exhibits a UV/Vis spectrum with absorption peaks at 352 ($\varepsilon = 5.3 \times 10^3$ $M^{-1}cm^{-1}$) and 428 nm ($\varepsilon = 4.3 \times 10^3$ $M^{-1}cm^{-1}$), whereas in acetone the complex exhibits an absorption peak at 331 nm ($\varepsilon = 4.2 \times 10^3$ $M^{-1}cm^{-1}$) with shoulders at 459 ($\varepsilon = 3.2 \times 10^2$ $M^{-1}cm^{-1}$) and 506 nm ($\varepsilon = 2.2 \times 10^2$ $M^{-1}cm^{-1}$), suggesting the formation of a different species in acetone.

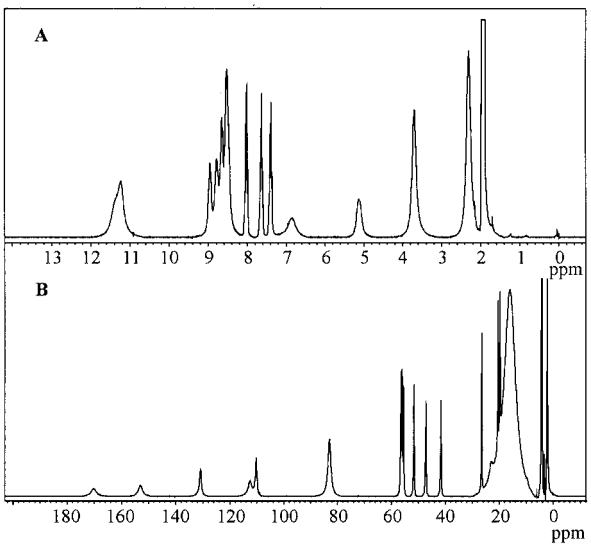

Figure 3. ^1H NMR spectrum of **4** (a) in CD_3CN and (b) in [D_6]-acetone

Cyclic voltammetry of **4** and **5** in CH_3CN showed one single quasi-reversible redox wave for the Fe^{II}/Fe^{III} couple at $E_{1/2}$ = 1180 mV (ΔE = 100 mV; i_a/i_p = 0.95) and 1200 mV vs. SCE (ΔE = 160 mV; i_a/i_p = 0.98), respectively. These values are significantly higher than those found for [(N4Py)Fe(CH_3CN)](ClO_4)$_2$ ($E_{1/2}$ = 1010 mV vs. SCE).[27] Apparently, in acetonitrile the low-spin iron(II) state is even more favored in the case of bis-acetonitrile complexes like **4** than mono-acetonitrile complexes like [(N4Py)-Fe(CH_3CN)](ClO_4)$_2$.

In acetone as solvent a different redox behaviour was observed for **4** (Figure 4). At a scan rate of 50 mV/s an oxidation wave was found at 1150 mV vs. SCE accompanied by a small reduction wave at 940 mV (i_a/i_p = 0.35) and a strong reduction wave at 350 mV vs. SCE. Increase of the scan rate leads to an increase of the reduction wave at 940 mV (i_a/i_p = 0.44 at 100 mV/s; i_a/i_p = 0.58 at 500 mV/s). When 600 mV vs. SCE was used as the vertex potential, i.e. without going through the oxidation at 1150 mV, no reduction wave was observed at 350 mV (Figure 4d). These results indicate that oxidation of the complex in acetone leads to an unstable species that decomposes to give a new species with a reduction potential at 350 mV.

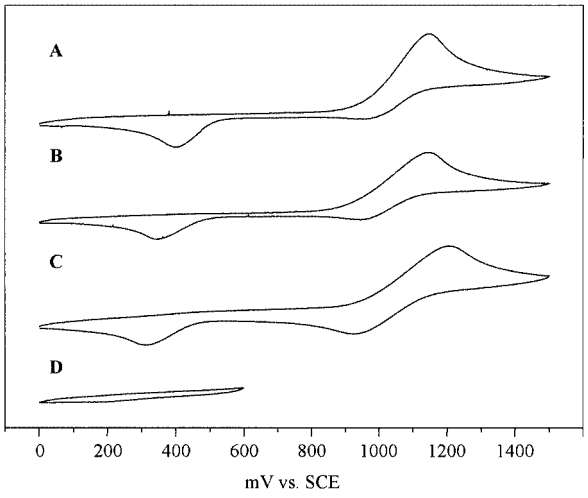

Figure 4. Cyclic voltammogram of 4 in acetone: (a) scan rate 50 mV/s; (b) Scan rate 100 mV/s; (c) scan rate 500 mV/s; (d) 600 mV used as vertex potential

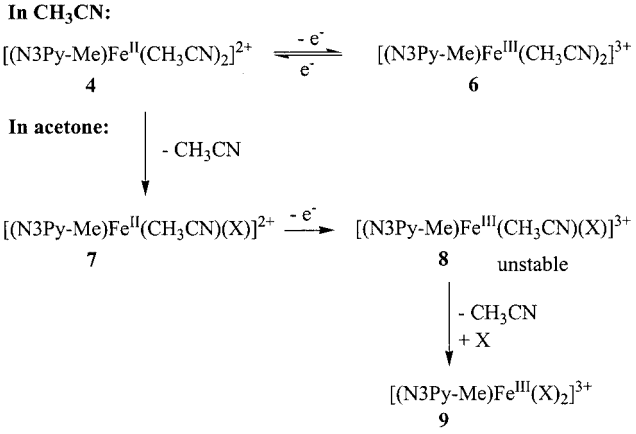
Combined with the NMR spectroscopic data the results can be rationalized in the following manner (Scheme 2). In acetone loss of a labile acetonitrile ligand can occur affording **7**, which is assumed to have a redox potential of 940 mV. Oxidation of this complex will lead to the formation of the unstable mono-acetonitrile iron(III) complex **8**. Loss of the final acetonitrile ligand will result in the formation of an $[(N3Py\text{-}Me)Fe(X)]^{3+}$ species **9**, in which X can be acetone or water. This species will exhibit a different electrochemical behavior, presumably giving rise to the reduction wave at 350 mV.



Scheme 2. Redox behavior of **4** in CH_3CN and acetone

Catalytic Oxidation with N3Py Iron Complexes

Complexes **4** and **5** were tested in catalytic oxidations of both alkanes and alkenes. The results are summarized in Table 1 and 2. In view of the different properties of the complexes in acetone and acetonitrile (vide supra), combined with the fact that it is known from catalytic oxidation with [(N4Py)Fe(CH_3CN)](ClO_4)$_2$ that the solvent can have a pronounced effect on the observed reactivity and selectivity,[31] both solvents were employed in catalytic oxidation.

[a] Turnover number = mol product/mol catalyst. [b] Reaction time 60 min. [c] Reaction time 30 min. [d] Reactions carried out under argon. [e] In acetone many other products were found, which were not identified. [f] 28 turnovers towards cyclohexenol and 7 turnovers towards cyclohexenone were observed. [g] 11 turnovers towards benzaldehyde were observed. [h] 13 turnovers towards benzaldehyde were observed.

Reactions were carried out under air, except in the case of substrates that are prone to undergo autoxidation in the presence of O_2, and an excess of substrate (1000 equiv.) was used to maximize turnover numbers. Hydrogen peroxide (50 equiv.) was introduced into the reaction mixture at 25 °C by syringe pump to reduce the loss of hydrogen peroxide due to catalase activity. Typical addition times are 60 and 30 min for acetonitrile and acetone, respectively. After the addition of H_2O_2 was complete the reaction mixture was stirred for another 5 min before a sample was taken and analyzed by GC.

Oxidation of Alkanes

Complexes **4** and **5** show a fair activity in the oxidation of cyclohexane in CH_3CN, with yields up to 19% based on hydrogen peroxide for complex **4** (Table 1, entry 1). These yields are slightly lower than those observed for $[(N4Py)Fe(CH_3CN)](ClO_4)_2$,[28] and $[(TPA)Fe(CH_3CN)_2](ClO_4)_2$,[36] and significantly lower than those found for $[(bpmen)Fe(CH_3CN)_2](ClO_4)_2$,[12,13] the most active non-heme iron cyclohexane oxidation catalyst known to date. The major product was cyclohexanol, with an alcohol/ketone (A/K) ratio of 3.8–5.8, significantly higher than those reported for radical chain autoxidation reactions (A/K ≈ 1).[37–39]

In acetone a similar reactivity and A/K ratio was obtained as in acetonitrile (Table 1, entry 1). However, one clear difference is seen with the KIE values for cyclohexanol formation, determined in a competition experiment between cyclohexane and $[D_{12}]$cyclohexane. In CH_3CN a k_H/k_D value of 3.5 was found for complex **4**, similar to the value observed for $[(TPA)Fe(CH_3CN)_2](ClO_4)_2$,[36] which was proposed to react via a formally Fe^VO species. Complex **5** gives a lower k_H/k_D value of 2.4. In acetone the k_H/k_D ratio increased significantly to 4.4 for **4** and 3.9 for **5**. The latter values are in the range of those typically observed in oxidations catalyzed by non-heme iron complexes using

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tert-butyl hydroperoxide as oxidant,[40] which were demonstrated to proceed via alkoxy radicals.[36−38]

The oxidation of *cis*- and *trans*-1,2-dimethylcyclohexane to the corresponding tertiary alcohols was studied to assess the stereoselectivity of the oxidation reaction. Although several isomeric secondary alcohols were also formed, these were not quantified. In CH_3CN the oxidation of *cis*-1,2-dimethylcyclohexane afforded rather low yields of tertiary alcohols with 85% and 82% retention of configuration at the tertiary carbon (i.e. formation of *trans*-1,2-dimethylcyclohexanol) for complexes **4** and **5**, respectively (Table 1, entry 2). Using *trans*-1,2-dimethylcyclohexane low yields of the tertiary alcohols, with 73% and 50% retention of configuration (i.e. *cis*-dimethylcyclohexanol) were also found for **4** and **5** (Table 1, entry 3). For comparison, more than 99% retention of stereochemistry was observed with $[(TPA)Fe(CH_3CN)_2](ClO_4)_2$,[41] $[(bpmen)Fe(CH_3CN)_2](ClO_4)_2$ [12] and cytochrome P-450 models,[42] whereas a complete lack of stereoselectivity was observed for $[(N4Py)Fe(CH_3CN)](ClO_4)_2$ [31] and in free-radical autoxidation.[43]

In acetone higher yields of tertiary alcohols were obtained, but generally with a lower degree of stereoselectivity. In the case of *cis*-1,2-dimethylcyclohexane 73% and 68% retention of configuration (Table 1, entry 2), and in the case of *trans*-1,2-dimethylcyclohexane 48% and 50% retention of configuration were obtained (Table 1, entry 3) with **4** and **5**, respectively.

Adamantane as substrate was oxidized both at the secondary and tertiary carbons. Using **4** a tertiary/secondary ratio (normalized on a per hydrogen basis) of 10.3 was obtained in acetonitrile (Table 1, entry 4). In acetone this ratio increased to 24.9 (Table 1, entry 4). For TPA and related tetradentate nitrogen-donor ligands values between 15 and 33 have been reported in CH_3CN as solvent.[13] For comparison, tertiary/secondary ratios of about 2 have been found for oxidation of alkanes by ·OH,[11] values of 3.1−3.3 for $[(N4Py)Fe(CH_3CN)](ClO_4)_2$,[31] 9.5−10 for oxidations by *t*BuOOH utilizing catalysts like $[Fe_2O(bipy)_4(H_2O)_2](ClO_4)_4$ and $[FeCl_2(TPA)](ClO_4)$,[44,45] and 11−48 for oxidations with PhIO catalyzed by P-450 mimics.[46]

Oxidation of Alkenes

The oxidation of symmetrical alkenes in CH_3CN with H_2O_2, catalyzed by **4** and **5**, gave both epoxidation and *cis*-dihydroxylation products (Table 2). Based on the results with Fe-TPA complexes this would be expected for iron complexes with two open coordination sites *cis* to each other.[15] All reactions could be carried out under air, except with cyclohexene as substrate, since this led to a strongly increased formation of the allylic alcohol and ketone. This indicates involvement of autoxidation pathways under air.[47]

Cyclooctene as a substrate afforded a very clean reaction giving only the epoxide and the *cis*-dihydroxylation product, i.e. the *meso*-diol (Table 2, entries 1 and 2). A small preference for *cis*-diol formation was observed with **4** whereas **5** displayed a small preference for epoxide formation.

Cyclohexene as substrate also gave the epoxide and the *meso*-diol as main products (Table 2, entry 3). However, with this substrate allylic oxidation products — cyclohexenol (28 turnovers) and cyclohexenone (seven turnovers) — were also formed.

With *cis*-stilbene and *cis*-4-octene the *cis*-oxide and *meso*-diol were also formed as major products, with a stereoselectivity of 93−95% (Table 2, entries 4 and 6). With *trans*-stilbene the *trans*-oxide, was the only detectable epoxidation product (Table 2, entry 5). The *cis*-dihydroxylation product, i.e. *rac*-1,2-diphenylethanediol, was obtained with a stereoselectivity of 94%. Besides the oxides and diols substantial amounts of benzaldehyde were also formed with the stilbenes — 11 and 13 turnovers for *cis*- and *trans*-stilbene, respectively. With *trans*-4-octene and norbornene a preference for epoxidation was found. For both substrates the corresponding diols were only formed in small amounts.

In acetone as solvent a very different reactivity pattern was observed. Generally, more side-products were found compared to oxidations in CH_3CN as solvent. Using cyclooctene as substrate, the epoxide and the 1,2-diols were obtained as major products (Table 2, entries 1 and 2). However, in contrast to the results in CH_3CN now the *trans*-dihydroxylation product, i.e. *rac*-1,2-cyclooctanediol, was obtained as major product, with a selectivity of 95% in the case of complex **4.** Complex **5** showed a little bit lower selectivity towards *rac*-diol (76%), but a significantly increased yield.

Cyclooctene oxide is known to be very robust so it is unlikely that the *rac*-diol is formed by epoxide ring-opening.[48] Furthermore, when cyclooctene oxide was subjected to the standard reaction conditions no diol formation was observed, which demonstrates that the *rac*-diol is formed independently and is not a decomposition product from the epoxide. Thus, by changing the solvent from acetonitrile to acetone the stereochemical outcome of the dihydroxylation reaction is changed from *cis* to *trans.*

With *cis*- and *trans*-4-octene and *cis*- and *trans*-stilbene the epoxides were formed in similar amounts as for the reaction in CH_3CN, with the *cis*-epoxidation product as major product (Table 2, entries 4−7). Hence, the stereochemistry of epoxidation is not dependent on the solvent.

With both *cis*- and *trans*-stilbene only small amounts of diol were found. However, substantial amounts of the corresponding acetonides were obtained, which are the products of the reaction of the diols with the solvent to form an acetal. Similar amounts of acetal were found by independent reaction of the corresponding diol under the same reaction conditions, indicating strongly that the acetonide is derived from the diol. When the acetonides are taken into account *cis*-stilbene gives the *trans*-dihydroxylation products — the *meso*-diol — as the main product and *trans*-stilbene affords mainly the corresponding *cis*-dihydroxylation products, i.e. the *rac*-diol.

With norbornene as substrate the main product was found to be *rac*-norbornanediol (Table 2, entry 8). When

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the epoxide was tested under these reaction conditions no diol formation was observed, again suggesting that the diol is not formed as a decomposition product of the epoxide. With cyclohexene as substrate many products were formed, including low yields of cyclohexene oxide and *rac*-1,2-cyclohexanediol (Table 2, entry 3). No evidence for *cis*-dihydroxylation products was found. However, many of the side-products that were formed have not been identified up to now, except the allylic oxidation products cyclohexenol (11 turnovers) and cyclohexenone (one turnover), which makes it difficult to compare the results for this substrate.

The most remarkable feature of the reactions in acetone is the fact that, in all cases, the *rac*-diol is the preferred product. For *cis*-alkenes like norbornene, cyclooctene, cyclohexene, and *cis*-stilbene, this amounts to a *trans*-dihydroxylation reaction. This is the first example of a catalyst that can give both *cis*- and *trans*-dihydroxylation just by changing the solvent. Catalytic *cis*-dihydroxylation is mostly achieved by OsO_4 complexes in the presence of a stoichiometric oxidant like $K_3Fe(CN)_6$ or *N*-methylmorpholine *N*-oxide.[21] *trans*-Diols are usually prepared from alkenes in two steps: first epoxidation followed by epoxide ring-opening.[49]

Labeling Studies

To obtain more information on the mechanism of the epoxidation and dihydroxylation reaction ^{18}O labeling experiments were performed. The oxidation of cyclooctene in acetonitrile was monitored by using 10 equivalents of a 2% solution of $H_2{}^{18}O_2$ in $H_2{}^{16}O$ under a N_2 atmosphere Table 3). Analysis was performed by GC/CI-MS. Only 50% of the epoxide contained ^{18}O. For the *meso*-diol predominantly the singly labeled product was found. In a complementary experiment using a 2% solution of $H_2{}^{16}O_2$ in $H_2{}^{18}O$ 28% of the epoxide contained an ^{18}O atom. For the *cis*-diol the main product was again singly labeled *cis*-cyclooctanediol. When a solution of 1% $H_2{}^{18}O_2$ in a 1:1 mixture of $H_2{}^{16}O$ and $H_2{}^{18}O$ was used, both singly and doubly labeled *cis*-cyclooctanediols were formed. These observations lend support to a proposed catalytically active species in which both oxygen atoms from hydrogen peroxide and water are present. Further evidence for such a mechanism was obtained by examining the incorporation of labeled oxygen as a function of concentration of water in the reaction mixture. The results are shown in Figure 5.

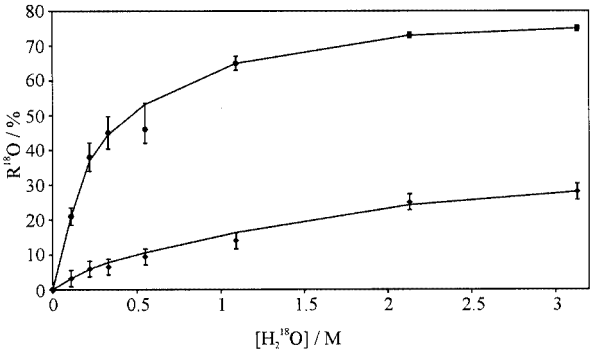

Figure 5. Incorporation of ^{18}O from $H_2{}^{18}O$: • diol; ◆ epoxide

At low concentration there is a more or less linear relationship between the concentration of water and the degree of incorporation of ^{18}O into the diol. At higher concentrations the extent of oxygen incorporation relative to the enhanced concentration decreases. This result is indicative of a pre-equilibrium between water and the active species of the catalyst. Similar results were found for the model systems $[(bpmen)Fe(CH_3CN)_2](ClO_4)_2$, $[(TPA)Fe(CH_3CN)_2](ClO_4)_2$, and several Fe-TPA derivatives for the oxidation of alkanes and alkenes.[50] Based on the cumulative data, which are in accordance with $[(TPA)Fe(CH_3CN)_2](ClO_4)_2$, the same mechanism for the oxidation in CH_3CN is proposed as was postulated for the oxidation with $[(TPA)Fe(CH_3CN)_2](ClO_4)_2$ (Scheme 3). In this mechanism the active $(HO)Fe^{V}{=}O$ species **13** is formed by heterolysis of the peroxide bond in intermediate **12**.

These labeling experiments were repeated in acetone, using *cis*-stilbene as substrate since it gives higher yields of *trans*-dihydroxylation products than cyclooctene. Here, incorporation of ^{18}O-oxygen into both epoxides and diols was investigated. The results are summarized in Table 4.

Even though a different substrate was used for the labeling studies and the level of ^{18}O incorporation is generally lower than in CH_3CN, the same pattern as in CH_3CN is discernible for the epoxidation and *cis*-dihydroxylation.

About one third of the label is built into the epoxide when $H_2{}^{18}O_2$ is used and about 40% incorporation is found when $H_2{}^{18}O$ is used. Also, in the case of the *cis*-diol the main fraction is singly labeled by $H_2{}^{18}O_2$. With $H_2{}^{18}O$ about one third of the product contains a single labeled oxygen, whereas with a combination of $H_2{}^{18}O_2$ and $H_2{}^{18}O$

[a] Margins of error in parentheses.

about 40% of the product is singly labeled and 43% doubly labeled. Taken together the data suggest that the epoxide and the *cis*-diol are formed by the same mechanism as with CH_3CN as solvent, involving a catalytically active species in which oxygen atoms from both hydrogen peroxide and water are present.

The labeling data for the *rac*-diol are somewhat harder to interpret. One complication is the fact that the *rac*-diol was obtained in two forms, the "free" diol and the acetonide. Since the acetonide is a secondary product, derived from the diol, only the free diol was considered in the experiments. In the experiment with $H_2{}^{18}O_2$ 63% of the product contains a single label whereas roughly equal amounts of non-labeled and doubly labeled diol were found. This appears to suggest that at least one oxygen of the diol comes from H_2O_2. The use of $H_2{}^{18}O$ resulted mainly in a product without a label whereas the experiment with $H_2{}^{18}O_2$ and $H_2{}^{18}O$ gave only a marginally higher amount of doubly labeled product. Thus, the second oxygen in the *trans*-diol does not have a clear origin and can stem from multiple sources like H_2O_2, H_2O or, most probably, the solvent acetone.

Since the experiments were performed under an inert atmosphere, incorporation of oxygen from O_2 can be excluded.

Mechanistic Interpretation

N3Py-R Fe complexes (**4** and **5**) are clearly very promising catalysts for stereoselective catalytic oxidation with H_2O_2. The reactivity profile in acetonitrile, not unexpectedly, is very characteristic of an iron complex with two *cis* open coordination sites: stereoselective hydroxylation of alkanes and stereoselective epoxidation and dihydroxylation of alkenes. The reactivity pattern of alkane oxidation, including the observed KIE values in cyclohexane oxidation, the 3:2 ratio in adamantane oxidation and the high degree of stereoselectivity in the oxidation of *cis*- and *trans*-1,2-dimethylcyclohexane observed with **4** and **5** is strongly reminiscent of those reported for other iron complexes of tetradentate N ligands like [(TPA)Fe$(CH_3CN)_2$]$(ClO_4)_2$ [36] and [(bpmen)Fe$(CH_3CN)_2$]$(ClO_4)_2$.[12] Furthermore, the oxidation of alkenes gives rise to the corresponding epoxides and *cis*-dihydroxylation products with high stereoselectivity. These results are also similar to what was reported for [(TPA)Fe$(CH_3CN)_2$]$(ClO_4)_2$ in CH_3CN.[15,36] These findings suggest that a common mechanistic pathway for these complexes exists. A mechanism involving heterolysis of the O−O bond of a low-spin $Fe^{III}OOH$ intermediate **12** to give a formally $Fe^{V}O$ species **13** is proposed, similar to that for [(TPA)Fe$(CH_3CN)_2$]$(ClO_4)_2$-catalyzed hydroxylation[12][50a]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

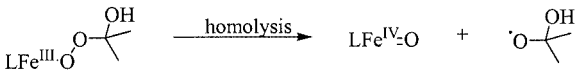
and *cis*-dihydroxylation (Scheme 3).[15,17] Addition to a double bond presumably produces a radical species **14** that is too short lived to isomerize and thus rapidly reacts with the coordinated OH to form the *cis*-diol. The same mechanism is expected to apply to the N3Py-R complexes discussed here. This is clearly supported by the labeling experiments.

The oxidation results obtained in acetone as solvent are quite different from those in CH_3CN, and it is hard to rationalize them in a single mechanistic proposal. Based on the results it is more likely that several competing pathways exist.

Based on the labeling studies it appears that an active species similar to that proposed in the mechanism in CH_3CN, resulting from heterolysis of a $Fe^{III}OOH$ intermediate, is responsible for the formation of epoxide and *cis*-diol. The fact that the second O atom in the product is clearly not only derived from water molecules is presumably caused by scrambling with the solvent.

However, from the data it is clear that this cannot be the sole pathway. In particular, the fact that *rac*-diols are an important product of the oxidation of alkenes suggests that another mechanistic pathway exists as well. Furthermore, the higher KIE in the oxidation of cyclohexane and the stronger preference for oxidation at tertiary carbons in adamantane suggest the presence of a more selective oxidizing species but could also indicate the presence of alkoxy-type radicals (vide supra). The lower stereoselectivity in the hydroxylation of *cis*- and *trans*-1,2-dimethylcyclohexane, alkene epoxidation and alkene dihydroxylation, combined with the fact that generally more side products are formed in acetone than in CH_3CN as solvent, are certainly more indicative of the involvement of radical species.

One possibility for radical species to be formed is through the formation of an iron-acetonylperoxy intermediate (**15**), by reaction of the iron center with the hydrogen peroxide adduct of acetone, followed by homolysis of the O−O bond to generate an $Fe^{IV}O$ complex (**1**) and an acetonyloxy radical species **17** (Scheme 4). Iron-alkylperoxo complexes have been demonstrated to be particularly predisposed to undergo O−O bond homolysis.[51]



15 **16** **17**

Scheme 4. Proposed formation of radical species by homolysis of the O−O bond of a iron-acetonyl peroxy species

Such radical species could also explain the formation of *rac*-diols: analogous to the proposal for TMP-Fe complexes (TMP = tetramesitylporphyrin),[52] the $Fe^{IV}O$ species could add to the double bond, leaving a carbon radical intermediate that is sufficiently long-lived to undergo isomerization to the thermodynamically more stable *trans* form before formation of either the epoxide, which explains the reduced stereoselectivity in acetone, or the *rac*-diol by reaction with another oxygen radical species.

Conclusions

In this paper we have presented a new class of tetradentate N-ligands for application in iron-catalyzed oxidations using H_2O_2: N3Py-R, with R being Me or Bn. Compared to the parent ligand of this class of catalysts, TPA, the N3Py-R ligands presented here have the added advantage that the R group can be readily modified, for example by the introduction of chiral groups for use in catalytic asymmetric oxidations.

The electrochemistry, NMR features and UV/Vis spectra of the N3Py-Fe complexes are solvent dependent. In acetone the labile acetonitrile ligands are rapidly displaced, presumably by the solvent, leading to the formation of a high-spin complex with different spectroscopic and electrochemical behaviour.

In both solvents good oxidation activity with H_2O_2 as sacrificial oxidant was found, but the reactivity, and in particular the selectivity, are strongly solvent dependent.

Not surprisingly the reactivity pattern in acetonitrile is quite similar to that of $[(TPA)Fe(CH_3CN)_2](ClO_4)_2$. The N3Py-Fe complexes are capable of stereoselective hydroxylation, epoxidation and *cis*-dihydroxylation. Mechanistic studies support a mechanism similar to that described for TPA-Fe, involving formally $Fe^{V}O$ species.

A major finding reported in this paper is the very different reactivity pattern observed in acetone, a solvent never reported for $[(TPA)Fe(CH_3CN)_2](ClO_4)_2$. The most striking example is the oxidation of alkenes to give the corresponding epoxides and the *rac*-diol as the main products. Mechanistic studies revealed that most likely more than one competing mechanistic pathway is available in acetone. Besides the heterolysis of a tentative $Fe^{III}OOH$ intermediate to give formally $Fe^{V}O$ species — the dominant mechanism in CH_3CN — a pathway involving $Fe^{IV}O$ species and acetonyloxo radicals, formed by homolysis of an intermediate iron-acetonylperoxy species, is proposed. The $Fe^{IV}O$ species may be responsible for the formation of *trans*-diols, following the TMP-Fe precedent.

The work described here constitute the first examples of a new generation of iron-based oxidation catalysts that can give either *cis*-dihydroxylation or *trans*-dihydroxylation of alkenes, simply by switching from CH_3CN to acetone as solvent.

Experimental Section

General Information: Commercially available chemicals were used without further purification unless noted otherwise. $H_2{}^{18}O_2$ (90% ^{18}O-enriched, 2% solution in $H_2{}^{16}O$) and $H_2{}^{18}O$ (95% ^{18}O-enriched) was obtained from ICON Services Inc. N3Py[33] and *cis*-4-octene[53] were prepared according to literature procedures.

^1H NMR and ^{13}C NMR spectra were recorded on a Varian Gemini 300 spectrometer at ambient temperature (^1H at 300 MHz and ^{13}C

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

at 75 MHz). Chemical shifts (in ppm) are referenced to the residual protic solvent peaks. X-band EPR spectra were obtained at liquid nitrogen temperature on a Bruker ECS106 instrument or at liquid helium temperatures on a Bruker E500 equipped with an Oxford Instruments ESR-10 cryostat. UV/Vis spectra were recorded on a Hewlett Packard 8453 diode array spectrophotometer, using a cell equipped with a home-built temperature-control device. Electrochemical studies were carried out with a PAR 273A potentiostat in acetonitrile with 0.1 M tetrabutylammonium perchlorate as the supporting electrolyte. Cyclic voltammograms (CV) were obtained by using a three-component system consisting of a glassy carbon working electrode, a platinum wire auxiliary electrode and a saturated calomel reference electrode. Mass spectra were recorded on a NERMAG R 3010 triple quadrupole mass spectrometer (Nermag, Argenteuil, France) equipped with a home-built atmospheric-pressure ionization source. GC analyses were performed on a Hewlett Packard 6890 Gas Chromatograph using a HP-1 dimethyl polysiloxane column or a HP-5 5%-phenyl methyl siloxane column, or a Hewlett Packard 5890 II Gas Chromatograph using a CP-wax 52 CB column or a CP-wax 57 CB column.

Caution: Perchlorate salts are potentially explosive and should be handled with care.

Crystallographic Studies. Crystal Structure Determination of 4: $(C_{22}H_{24}FeN_6)^{2+}\cdot(ClO_4^-)_2$, M_r = 627.22, triclinic, $P\bar{1}$, a = 10.504(8), b = 11.685(9), c = 12.449(9) Å, α = 77.20(1)°, β = 65.71(1)°, γ = 66.34(1)°, V = 1272.7(17) Å^3, Z = 2, D_x = 1.637 gcm^{-3}, λ(Mo-K_α) = 0.71073 Å, μ = 8.63 cm^{-1}, F(000) = 644, T = 90 K, $GooF$ = 0.970, $wR(F^2)$ = 0.2377 for 4307 reflections and 355 parameters and $R(F)$ = 0.0856 for 2378 reflections obeying $F_o \geq 4.0\ \sigma(F_o)$ criterion of observability.

The asymmetric unit consists of three moieties, a cationic Fe complex and two ClO_4^- anions. Crystals were obtained by recrystallization from a mixture of acetonitrile and pentane. The crystals were very fragile: contact with a glass fiber caused damage as crystal cracks. The recorded frames showed (broad) anisotropic mosaicity and duplicated reflections. A red parallelepiped-shaped crystal with the dimensions of 0.220 × 0.150 × 0.120 mm mounted on a glass fiber was aligned on a Bruker[54] SMART APEX CD diffractometer (Platform with full three-circle goniometer). The diffractometer was equipped with a 4 K CCD detector set 6.0 cm from the crystal. The crystal was cooled to 90 K using the Bruker KRYOFLEX low-temperature device. Intensity measurements were performed using graphite-monochromated Mo-K_α radiation from a sealed ceramic diffraction tube (SIEMENS). Generator settings were 50 kV/40 mA.

The structure was solved by Patterson methods (DIRDIF) and refined with SHELXL against F^2 of all reflections. Non-hydrogen atoms were refined freely with anisotropic displacement parameters. Hydrogen atoms were refined in rigid mode. Checking for higher symmetry and structure calculations were performed with the PLATON package.
CCDC-213726 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

***N*-[Di(2-pyridinyl)methyl]-*N*-methyl-*N*-(2-pyridinylmethyl)amine (N3Py-Me, 1):** Formaldehyde (37% solution in water, 0.45 mL, 6.0 mmol) was added to a solution of **3** (1.262 g, 4.59 mmol) in 1,2-dichloroethane (35 mL). $NaBH(OAc)_3$ (3.92 g, 18.5 mmol) was added in small portions. After stirring for 7 h at room temperature saturated $NaHCO_{3(aq)}$ (35 mL) was added and the 1,2-dichloroethane layer was separated. The aqueous layer was extracted with CH_2Cl_2 (3 × 20 mL). The combined organic layers were washed with 1 N NaOH (20 mL) and brine (20 mL), dried (Na_2SO_4) and the solvent removed in vacuo to give **1** (1.235 g, 4.27 mmol, 93%) as a slightly yellow oil. ^{1}H NMR ($CDCl_3$): δ = 2.19 (s, 3 H), 3.72 (s, 2 H), 4.96 (s, 1 H), 7.14 (m, 3 H), 7.71 (m, 6 H), 8.56 (m, 3 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 40.32 (q), 61.04 (t), 77.87 (d), 121.76 (d), 122.10 (d), 122.92 (d), 123.21 (d), 136.29 (d), 136.43 (d), 148.86 (d), 149.22 (d), 159.37 (s), 160.59 (s) ppm. MS (CI): m/z = 291 [M + 1].

***N*-Benzyl-*N*-[di(2-pyridinyl)methyl]-*N*-(2-pyridinylmethyl)amine (N3Py-Bn, 2):** A mixture of benzyl chloride (0.46 mL, 3.8 mmol), **3** (740 mg, 2.7 mmol) and K_2CO_3 (370 mg, 2.7 mmol) in CH_3CN (20 mL) was stirred under an argon atmosphere. The mixture was heated under reflux overnight and benzyl chloride (0.23 mL, 1.9 mmol) was again added. After heating under reflux for 24 h the solvent was evaporated and water (20 mL) was added to the residue. The product was extracted with ethyl acetate (3 × 30 mL) and the combined ethyl acetate layers were washed with brine (15 mL) and dried (Na_2SO_4). Evaporation of the solvent followed by column chromatography (Alox. neutral, akt. I, ethyl acetate/hexane/triethylamine, 10:6:1) afforded **2** (670 mg, 1.83 mmol, 68%) as a yellow oil. ^{1}H NMR ($CDCl_3$): δ = 3.79 (s, 2 H), 3.90 (s, 2 H), 5.30 (s, 1 H), 7.14 (m, 4 H), 7.29 (m, 2 H), 7.40 (m, 2 H), 7.66 (m, 6 H), 8.48 (m, 1 H), 8.56 (m, 2 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 54.93 (t), 56.47 (t), 71.24 (d), 121.62 (d), 121.90 (d), 122.60 (d), 123.75 (d), 126.77 (d), 128.14 (d), 128.70 (d), 136.11 (d), 136.23 (d), 138.94 (s), 148.81 (d), 149.15 (d), 160.04 (s) ppm. MS (CI): m/z = 367 [M + 1].

[(N3Py-Me)Fe(CH$_3$CN)$_2$](ClO$_4$)$_2$ (4): A solution of $Fe(ClO_4)_2\cdot 6H_2O$ (250 mg, 0.69 mmol) in CH_3CN (3 mL) was added to a solution of **1** (198 mg, 0.68 mmol) in MeOH (3 mL). The dark-red solution was placed in an ethyl acetate bath and after 3 days **4** (344 mg, 0.55 mmol, 81%) was isolated as dark-red crystals. ^{1}H NMR (CD_3CN): δ = 3.68, 5.12, 6.83, 7.40 (m, 1 H), 7.63 (m, 1 H), 8.02 (m, 1 H), 8.52, 8.65, 8.77, 8.95, 11.21 ppm. $C_{22}H_{24}Cl_2FeN_6O_8$: calcd. C 42.13, H 3.86, N 13.40; found C 41.98, H 3.78, N 13.27. UV/Vis (in CH_3CN): λ_{max} (ε) = 352 nm (5288 M^{-1}cm^{-1}), 428 (3261).

[(N3Py-Bn)Fe(CH$_3$CN)$_2$](ClO$_4$)$_2$ (5): Following the procedure as for **4**, starting from **2** (95 mg, 0.26 mmol) and $Fe(ClO_4)_2\cdot 6H_2O$ (105 mg, 0.29 mmol), **5** (152 mg, 0.22 mmol, 85%) was obtained as dark red crystals. ^{1}H NMR (CD_3CN): δ = 2.82, 4.44, 5.84, 6.98 (m, 3 H), 7.35 (m, 1 H), 7.49 (m, 3 H), 8.02 (m, 1 H), 9.40, 9.50, 9.64, 9.72, 9.79, 9.96, 10.78, 13.17 ppm. ES/MS: m/z = 521 [M − $(ClO_4)^-$ − 2(CH_3CN)]$^+$, 231.5 [M − 2(ClO_4)$^-$ − (CH_3CN)]$^{2+}$.

Catalytic Oxidations: All experiments were carried out under air, unless noted otherwise, in a water bath thermostatted at 25 °C. In a typical procedure cyclohexane (0.19 mL, 1000 equiv.) was added to a solution of **9** (8.75 × 10^{-4} M, 2 mL) and a known amount of bromobenzene (internal standard) in acetone. The reaction was started by syringe pump addition of 1 M H_2O_2 (88 μL, 50 equiv.) over 30 min. After the addition was complete the reaction mixture was stirred for an additional 5 min. An aliquot (1 mL) was taken from the reaction and filtered through a small silica column. The silica was thoroughly washed with diethyl ether or diethyl ether/10% methanol. The sample was concentrated to a volume of 2 mL by passing an Ar stream over the solution and then analyzed by GC.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Kinetic Isotope Effect Determination: Essentially the same procedure was used as described above, but now a mixture of cyclohexane and [D_{12}]cyclohexane was used (ratio cyclohexane/[D_{12}]cyclohexane varied from 1:1 to 1:4). The KIE was determined by comparing the turnover numbers for cyclohexanol and [D_{11}]cyclohexanol (determined by GC using the CP-wax 52 CB column) and corrected for relative concentration of cyclohexane and [D_{12}]cyclohexane.

Labeling Experiments: In a typical procedure cyclooctene (0.23 mL, 1000 equiv.) was added to a solution of **4** ($8.75 \cdot 10^{-4}$ M, 2 mL) in acetonitrile under a N_2 atmosphere. The reaction was started by syringe pump addition of $H_2{}^{18}O_2$ (10 equiv., 30 μL of 2% $H_2{}^{18}O_2$ in $H_2{}^{16}O$, diluted with 220 μL acetonitrile) over 60 min. After the addition was complete the reaction mixture was stirred for an additional 5 min. The reaction mixture was filtered through a small silica column. The silica was thoroughly washed with diethyl ether or diethyl ether/10% methanol. The sample was concentrated to a volume of 2 mL by passing an Ar stream over the solution and then analyzed by GC/CI-MS.

In the $H_2{}^{18}O$ experiment, $H_2{}^{16}O_2$ (50% in $H_2{}^{16}O$, 2 μL) and $H_2{}^{18}O$ (90%, 48 μL) were dissolved in acetonitrile (50 μL) and used for the oxidation as mentioned above.

In the $H_2{}^{18}O_2/H_2{}^{18}O$ experiment, $H_2{}^{18}O_2$ (2% in $H_2{}^{16}O$, 25 μL) and $H_2{}^{18}O$ (90%, 25 μL) were dissolved in acetonitrile (50 μL) and used for the oxidation as mentioned above.

Acknowledgments

Financial support for this research from NWO-CW (project supramolecular catalysis) (M. K., B. L. F.) is gratefully acknowledged. We wish to thank Prof. L. Que Jr. (University of Minnesota) for helpful discussions and A. Meetsma for performing the X-ray analysis.

Synthesis, Structure and Hydrolytic Properties of a Family of New Zn Complexes Containing Hexaazamacrocyclic Ligands

Miquel Costas,[a] Carmen Anda,[a] Antoni Llobet,*[a] Teodor Parella,[b] Helen Stoeckli Evans,[c] and Elena Pinilla[d]

Keywords: Zinc / Cooperative effects / Coordination chemistry / Fluxionality / Homogeneous catalysis / Macrocyclic ligands

The synthesis, structure and spectroscopic properties of a family of Zn complexes containing a dinucleating hexaazamacrocyclic ligand (L) and anionic ligands (X) of general formula $[Zn_2(X)_{4-n}(L)]^{n+}$ (**1**–**8**; L = H2p, H3p, Me2p, Me2m, Me3p, Me3m; X = Cl, n = 0; X = NO_3, n = 2) have been investigated. The solid-state structural characterisation has been performed by means of X-ray diffraction analysis for complexes **3**, **5**, **7·1/3CH$_2$Cl$_2$** and **8**. The Zn complexes **5**, **7·1/3CH$_2$Cl$_2$** and **8** containing chloride ligands present a distorted N_2Cl_2 tetrahedral coordination with two non-coordinated N atoms of the macrocyclic ligand. On the other hand, complex **3**, which contains nitrate ligands, displays an N_3O_2 pentacoordination with all the N atoms of the macrocyclic ligand bonded to the metal centres. The different factors governing the relative Zn–Zn disposition are discussed. NMR spectroscopy in solution reveals the presence of fluxional behaviour and a completely different structural arrangement than in the solid state. In particular, evidence for the formation and breaking of Zn–N bonds involving all the macrocyclic ligand aminic N atoms is obtained for the chloride complexes **2** and **4**–**8**. Finally, complexes **1**, **3**, **5** and **7** hydrolyse *p*-nitrophenyl acetate (NA) with second-order rate constants ranging from 0.045 to 0.193 $M^{-1}s^{-1}$, thus manifesting the influence of the ligands over the hydrolytic activity.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Macrocyclic polyamines are well-known to participate in molecular recognition phenomena with different kinds of substrates, such as organic and inorganic cations, anions and neutral molecules.[1] Such interactions have attracted interest from environmental, catalytic and health-related domains.[2] Macrocyclic molecules containing two polyamine units linked by a spacer are also capable of ligating two metal atoms in close proximity. In some cases this leads to interactions between the two metallic centres that results in interesting magnetic,[3] electronic[4,5] and/or catalytic properties.[6–8] The ability of macrocyclic ligands to preorganise two metal centres at a particular distance has also been used in the design of Zn complexes that efficiently catalyse the hydrolysis of phosphate and carboxy esters[9–11] thus mimicking the activity of zinc enzymes that mediate hydrolytic reactions.[12–16] However, exhaustive characterisation of Zn complexes with macrocyclic polyamines is scarce. In this work we have synthesised and characterised a series of Zn complexes with hexaazamacrocyclic ligands where the metal coordination and the metal-metal relative disposition are modulated by the characteristics of the macrocyclic ligand. We have also studied the ability of these complexes to perform the hydrolysis of *p*-nitrophenyl acetate (NA). Our results demonstrate that small changes in the macrocyclic backbone lead to important changes in the Zn−Zn distance and in the hydrolytic ability manifested by the complexes.

Results and Discussion

Synthesis and Solid-State Structure

The six macrocyclic ligands used in this work are shown in Scheme 1 and were prepared according to literature procedures.[17–20] This family of ligands comprises secondary amines and their hexamethylated analogues and is

		= $(CH_2)_n$	
		$n = 2$	$n = 3$
R = H	*p*	**H2p**	**H3p**
R = Me	*p*	**Me2p**	**Me3p**
	m	**Me2m**	**Me3m**

Scheme 1. Macrocyclic ligands used in this work

characterised by the number of methylenic units linking the amines, which can be two or three, and by the aromatic substitution that takes place in the *meta* or *para* positions.

Reaction of those ligands at room temperature with two times the stoichiometric amount of the appropriate Zn^{II} salt in methanol affords the corresponding dinuclear Zn^{II} complexes **1**−**8** as white microcrystalline solids in modest to good yields (ranging from 34 to 77%), as shown in Equation (1) for the particular case of **5**.

$$\text{Me2p} + 2\ ZnCl_2 \xrightarrow{\text{MeOH}} [Zn_2Cl_4(\text{Me2p})] \quad (1)$$

The crystal structures of $[Zn_2(NO_3)_2(H3p)](NO_3)_2$ (**3**), $[Zn_2Cl_4(Me2p)]$ (**5**), $[Zn_2Cl_4(Me3p)]\cdot 1/3CH_2Cl_2$ (**7·1/3CH$_2$Cl$_2$**) and $[Zn_2Cl_4(Me3m)]$ (**8**) have been determined by means of single-crystal X-ray diffraction analysis. Table 1 contains their crystallographic data whereas Table 2 contains their selected bond lengths and angles. Figure 1 shows the ORTEP diagrams obtained for the cationic molecular structure of complex **3** (top left) and the neutral molecular structures of complexes **5** (top right), **7** (bottom left) and **8** (bottom right), together with the atom labelling system used.

The cationic part of **3** consists of the macrocyclic ligand, which binds to two zinc atoms, and an NO_3^- anion bonded to each metal adopting an (η^2-*O*,*O*-NO_3) chelating mode (Δr_{Zn-O} = 0.075 Å). The whole molecule has an inversion centre that relates the metal atoms and half of the macrocyclic ligand with the other half. The Zn metal centres are five-coordinate, binding to three N atoms from the macrocyclic ligand and two oxygens from the nitrate ligand. The Zn−N distances range from 1.992(6) to 2.054(7) Å and the two Zn−O bonds are significantly different [Zn−O1: 2.206(8) Å; Zn−O2: 2.281(9) Å], although all of them compare well with the observed values of complexes containing an N_3ZnO_2NO coordination environment.[21] The N−Zn−N bond angles range from 92.5(3)° to 128.1(3)° whereas the N−Zn−O angles range from 89.3(3)° to 141.0(3)°, reflecting the distortions imposed by the rigidity of the macrocyclic ligand and the asymmetry of the coordinated nitrate anion.

Table 1. Crystallographic data of **3**, **5**, **7** and **8**

Complex	**3**	**5**	**7·1/3CH$_2$Cl$_2$**	**8**
Empirical formula	$C_{28}H_{46}N_{10}O_{12}Zn_2$	$C_{30}H_{52}Cl_4N_6Zn_2$	$C_{34.33}H_{58.67}Cl_{4.67}N_6Zn_2$	$C_{34}H_{60}Cl_4N_6OZn_2$
