Figure 4. ORTEP view of the molecular structure of $[PtI_2(Me_2\text{-phen})(DMSO)]$ (**2e**), thermal ellipsoids are drawn at 30% probability level

2f, respectively]. The expected values are 180° for a regular square-planar species and 143° for a trigonal bipyramidal species in which the bite angle of the bidentate Me_2-phen lying in the trigonal plane is 74°. The Pt−N(1) bond lengths are similar within experimental errors [2.108(6) and 2.094(5) Å for **2e** and **2f**, respectively] and are in agreement with a comparable *trans* influence of the two ligands. In contrast, the Pt−S distances are significantly different [2.200(2) and 2.264(2) Å for **2e** and **2f**, respectively] reflecting the different oxidation state of the sulfur atom in DMSO and DMS.

The molecular structures of **2g** (L = py) and **2h** (L = NH_2nPr) are depicted in Figure 6 and 7, respectively. The square-planar coordination of the Pt atoms is less distorted than that observed in the previous two cases. The steric bulk of the pyridine and propylamine ligands with respect to the *cis* iodo ligand, is small, and therefore both I−Pt−L angles are close to 90°; this was not the case for the DMSO and DMS complexes previously considered. In **2g** there is an apparent interaction between the pyridine and the phenanthroline ligands so that the planes of the two ligands are

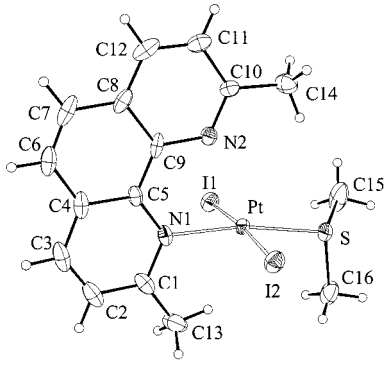

Figure 5. ORTEP view of the molecular structure of $[PtI_2(Me_2\text{-phen})(DMS)]$ (**2f**), thermal ellipsoids are drawn at 30% probability level

canted on the coordination plane in opposite directions and make a dihedral angle of 30.1(2)°. This steric interaction results in a greater twisting of the phenanthroline in **2g** than in **2e** and **2f** [displacement of the C(14) and C(13) carbon atoms from the mean plane of the phenanthroline of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

−0.35(1) Å and 0.19(1) Å, respectively]. In **2h** the propyl group of the $H_2(C_3H_7)N$ ligand extends into the half space of the coordination plane opposite to that of the N(2) atom and is *quasi* orthogonal to the coordination plane [I(1)−Pt−N(3)−C(15) torsion angle of −88.0(8)°]. The phenanthroline is perfectly planar and makes a dihedral angle of 88.4(1)° with the coordination plane. The degree of transition from four- to five-coordination is smaller in **2g** and **2h** than it was in **2e** and **2f**; moreover there is a small difference between **2g** and **2h** [N(1)−Pt−N(3) angles of 176.5(2)° and 178.6(3)° for **2g** and **2h**, respectively]. Despite the different hybridization of the L donor atom (sp^2 and sp^3 for **2g** and **2h**, respectively) the Pt−N(3) bond length is similar for the two compounds (Table 2). Also the *trans* influence appears to be rather similar for the two compounds as indicated by the values of the Pt−N(1) bond lengths, which are equal within experimental errors. Moreover the Pt−N(1) bond lengths are about 0.06 Å shorter in **2g** and **2h** than they were in **2e** and **2f**, consistent with a greater *trans* influence of S-donor ligands with respect to N-donor ligands.

2c. Ab initio Calculations

Ab initio calculations were carried out with the aim of confirming that the observed solid-state molecular structures correspond to the computed ground-state structures and correlating the switch from a four-coordinate (monodentate Me_2-phen) to a five-coordinate structure (bidentate Me_2-phen) with the electronic properties of the L ligand. The calculations were performed at the Hartree−Fock level in order to take advantage of an energy partitioning described below and implemented at this level of theory in a computer code available to us. The use of the HF approach implies the neglect of correlation effects. While this certainly affects some of the computed properties, the physics of the interaction is properly described.

A direct comparison between the results of the geometry optimization and those of the X-ray structures is given in Table 3. In general, the agreement between the ab initio HF and the experimental results is good, in particular as far as the Pt−N(2) distance and the N(1)−Pt−L angle — the main parameters used to characterise the extent of the π-back bonding to L — are concerned. Only in the case of the CO complex does the computed structure not agree perfectly with the experimental structure: the Pt−N(2) distance and the N(1)−Pt−L angle are greater in the calculated than in the experimental geometries (by 0.10 Å and 10°, respectively). However, it should be mentioned that a change in the N(1)−Pt−C angle of 10° causes only a small change in the total energy (a few kJ/mol). For the Pt−L distances greater differences between calculated and experimental values (Table 3) have been observed for the sulfur- and phosphorus-donor ligands, but this is mainly due to the neglecting of correlation effects in the calculations. The fact that the calculations reproduce the experimental geometries correctly indicates that the electronic structure of each complex has been described in a satisfactory way even at the HF level.

An energy decomposition technique, the CSOV method,[16,17] has been employed to analyze the HF wave function and to identify the relative values of the charge transfer from L to the PtI_2(phenanthroline) residue (hereafter referred to as σ-donation) and of the reverse process, charge transfer from PtI_2(phenanthroline) to L (π back-donation). The interaction energy of the complex is divided into the sum of intra-unit polarization and charge-transfer contributions. Details of the procedure are not given here and can be found elsewhere.[16,18] The extent of charge transfer can be deduced from two independent parameters: the first one is the contribution of each charge-transfer process to the interaction energy (E_{int} in kJ·mol^{-1}), and the second parameter is related to a wavefunction property, the dipole moment. With the assumed orientation of the I−Pt−I atoms along the *x* axis and the N−Pt−L groups along the *y* axis, the change in the *y* component of the dipole moment μ at each CSOV step ($\Delta\mu$) provides a direct measure of the charge flow from L to Pt and vice versa: a positive $\Delta\mu$ value indicates donation, a negative $\Delta\mu$ indicates back-donation. This is a much more reliable measure of the charge transfer than, for instance, the Mulliken charge.[18] Still, one has to keep in mind the qualitative nature of this partitioning.

The CSOV analysis allows the evaluation of the donating/back-donating properties of the ligands considered here (Table 4). As far as the donor properties are concerned, all ligands are good electron donors, as would be expected given the +2 formal oxidation state of the Pt atom. In more detail, the E_{int} values can be grouped into two domains: 180−230 and 130−160 kJ·mol^{-1}. Similarly, two ranges of $\Delta\mu$ values are clearly distinguishable: 0.59−0.65 (with a peak of 0.91 for PH_3) and 0.46−0.47 au. Therefore PH_3, CO, C_2H_2, and C_2H_4 are the strongest donors both from the E_{int} and $\Delta\mu$ values. In contrast C_5H_5N and NH_3 are the poorest donors in the series both from E_{int} and $\Delta\mu$. $(CH_3)_2SO$ and $(CH_3)_2S$ lie between the two groups since they fall in the group of poor donors according to E_{int} but in the group of strong donors according to $\Delta\mu$.

Table 4. Donation and back-donation contributions in [PtI_2(phen)(L)] complexes as derived from a CSOV analysis; E_{int} is the contribution to the total interaction energy and $\Delta\mu$ the change in dipole moment associated with the donation or back-donation mechanisms

	Donation		Back-donation	
L	E_{int} (kJ/mol)	$\Delta\mu$ (au)	E_{int} (kJ/mol)	Δμ (au)
C_2H_4	219	+0.61	175	−0.93
C_2H_2	181	+0.59	154	−0.80
CO	230	+0.61	93	−0.46
PH_3	207	+0.91	48	−0.23
$(CH_3)_2SO$	143	+0.65	39	−0.23
$(CH_3)_2S$	132	+0.63	32	−0.13
C_5H_5N	160	+0.46	51	−0.43
NH_3	146	+0.47	23	−0.11

The π-acceptor properties, on the other hand, are quite different for the various ligands; moreover in this case both E_{int} and $\Delta\mu$ give very similar descriptions (E_{int} was chosen in drawing Figure 8). Acetylene and ethylene exhibit the strongest back-donating contributions. CO is halfway in between the alkene and the alkyne on one side and the amine ligand on the other. All other ligands fall in between the CO and the amine. The direct correlation between the π-acidity of the L ligand, as determined by the CSOV analysis, and the coordination mode of the phenanthroline ligand is surprising: bidentate when L is a good π-acceptor able to decrease the electron density in the trigonal plane, monodentate in most of the other cases with the CO positioned halfway in between the two extremes (Figure 8).

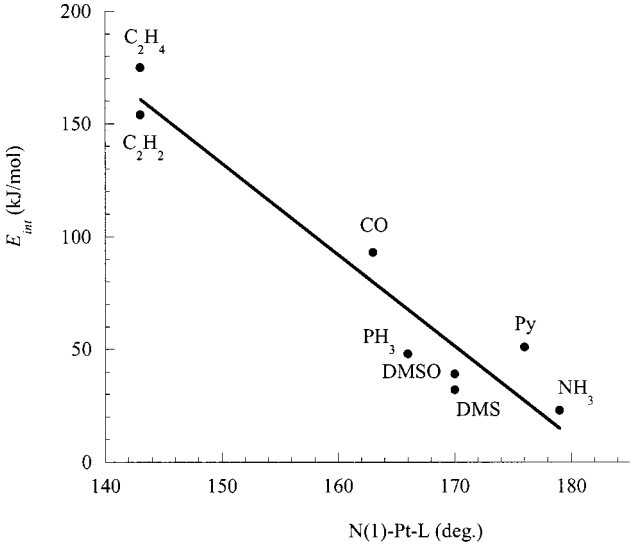

Figure 8. Plot of the computed π-acceptor ability of the L ligands (interaction energy E_{int}, Table 4) versus the experimental values of the N(1)−Pt−L angle (Table 3)

3. Discussion and Conclusion

The [PtI_2(Me_2-phen-*N*,*N*′)] system is characterized by an extremly high steric interaction between the *ortho* substituents of the phenanthroline and the *cis* halogen ligands.[3−7] The steric constrictions within the square-planar geometry can be released by displacement of one end of the phenanthroline and addition of an extra ligand, forming a *trans*-[PtI_2(Me_2-phen-*N*)(L)] species. The coordinated Me_2-phen can then assume an orthogonal orientation with respect to the coordination plane so as to minimize the steric interactions with the *cis* ligands.

The coordination of the free end of the phenanthroline from the top side (the *z* direction assuming the square plane to be *xy*) is prevented by filled d orbitals of the metal lying in the same plane as the phenanthroline (d_{yz} and d_{z^2} electrons assuming as *x* direction that of the I−Pt−I vector).[19] However if the L ligand is a π-acid able to remove electron charge from the *yz* plane, the second end of the phenanthroline can also interact with the metal center and the complex switch from a square-planar four-coordinate to a

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

trigonal-bipyramidal five-coordinate geometry comprising all possible intermediate situations. The X-ray technique is ideally suited for the observation of ground-state structures, particularly when intermolecular interactions are weak. This is the case here since the two large iodo ligands in *trans* positions (*x* axis) shield the *yz* plane, leaving the Me_2-phen ligand free to ride on the metal center and to assume the position which corresponds to the minimum of energy.

Therefore a direct correlation appears to exist between the N(1)−Pt−L angle (180° in four-coordinate and 143° in five-coordinate environments) and the ability of the ligand to remove electron charge from the *yz* plane. Alkenes and alkynes are found to be among the best π-acids and lead to a regular five-coordinate species. On the other hand the CO ligand is found to have a π-acidity much weaker than that of alkenes and alkynes. In our opinion the main difference between CO and alkenes or alkynes is that in CO the π*-orbitals of the ligand are disposed end-on with respect to the metal center, while in the case of alkenes and alkynes the π*-orbitals are disposed side-on with respect to the metal. Therefore the overlap of the platinum d-orbitals with the π*-orbitals of the carbonyl ligand is smaller than that with the π*-orbitals of alkenes and alkynes.

As expected, the phosphane ligand is found to be a better π-acid than ligands with sulfur and nitrogen donor atoms.

There is no significant difference between sulfoxide and sulfide from a crystallographic point of view, although theoretical calculations indicate a slightly better π-electron acceptor capacity for the sulfoxide.

The difference between pyridine and *n*-propylamine is also rather small [N−Pt−L angles of 176.5(2)° and 178.6(3)° for C_5H_5N and $H_2(C_3H_7)N$, respectively]. This small difference contrasts with the theoretical calculations reporting a π-acidity for pyridine similar to that of the phosphane. A very likely explanation for this apparent contradiction is that the N−Pt−L angle measures the ability of the L ligand to remove electron charge only from the *yz* plane and, for steric constrictions, such an ability is very small for pyridine. In fact, in order to reduce the steric interaction with the *cis* ligands, the plane of the pyridine will tend to be orthogonal to the coordination plane (*xy* plane) and, as a consequence, the empty π*-orbitals of the pyridine will be set roughly orthogonal to the *yz* plane and therefore will be unable to remove electron density from the platinum d-orbitals lying in this plane. In contrast, theoretical calculations measure the overall back-donation from platinum to L and this can be significant for pyridine due to the circumstances that the empty π*-orbitals of the pyridine are coplanar with the filled d_{xy} orbital of the metal. Therefore, for a pyridine oriented *quasi* orthogonal to the coordination plane, only the X-ray structural analysis gives an accurate description of the electron-acceptor ability of this ligand with respect to metal d-electrons localized in the *yz* plane. The same molecular device also allows a direct measure of the free-energy difference between ground state (four-coordinate species with singly bonded Me_2-phen) and transition state (five-coordinate species with doubly bonded Me_2-phen) when the former configuration is sufficiently low in energy to allow detection, by NMR spectroscopy, of different signals for the two inequivalent halves of the Me_2-phen ligand. By measuring the rate constants at different temperatures for the exchange between the two ends of singly bonded Me_2-phen, it is possible to evaluate $\Delta G^{\ddagger}_{T}$ ($\Delta G^{\ddagger}_{T} = \Delta G^{\ddagger}$ at the temperature T). In the case of the two amine ligands considered here the calculated values of $\Delta G^{\ddagger}_{295}$ (51 ± 2 and 52 ± 2 kJ·mol^{-1} for pyridine and *n*-propylamine, respectively) are very similar and in good agreement with the similar π-acceptor capacities deduced from X-ray data.

It cannot be excluded, however, that the possibility that, by using bidentate ligands with a lower tendency to act as a chelate than 2,9-dimethyl-1,10-phenanthroline, it is possible to destabilize the five-coordinate geometry to such an extent that the rate of exchange between free and coordinated ends of the bidentate ligand becomes observable by NMR spectroscopy also for compounds having L ligands with higher π-acidity than amines.

4. Experimental Section

Starting Materials: Commercial reagent-grade chemicals, 2,9-dimethyl-1,10-phenanthroline (Me_2-phen), ethylene (C_2H_4) (**a**), dimethyl sulfoxide (DMSO) (**e**), dimethyl sulfide (DMS) (**f**), pyridine (py) (**g**), and *n*-propylamine (NH_2Pr^n) (**h**), were purchased from Aldrich and used without further purification. [PtI_2(Me_2-phen)] (**1**) was prepared by a previously reported procedure.[3]

Preparation of *trans*-[PtI_2(Me_2-phen)(L)] Complexes (2): For L = C_2H_4 (**2a**) a rubber bladder filled with ethylene gas was connected to a flask containing a solution of [PtI_2(Me_2-phen)] (**1**) (0.3 mmol) in CH_2Cl_2 (20 mL).[5] After 30 minutes stirring, addition of diethyl ether to the mixture caused the precipitation of a red solid which was collected, washed with diethyl ether, and dried in air, yield 90%. $C_{16}H_{16}I_2N_2Pt$ (**2a**; 685.2): calcd. C 28.1, H 2.4, N 4.1; found C 28.4, H 2.1, N 4.0.

The complexes with L = DMSO (**2e**) and DMS (**2f**) were synthesized according to a procedure reported previously.[8] Yield 90%. $C_{16}H_{18}I_2N_2OPtS$ (**2e**; 735.3): calcd. C 26.1, H 2.5, N 3.8; found C 26.2, H 2.6, N 3.7. $C_{16}H_{18}I_2N_2PtS$ (**2f**; 719.3): calcd. C 26.7, H 2.5, N 3.9; found C 26.7, H 2.6, N 3.8.

The complexes with L = py (**2g**) and NH_2nPr (**2h**) were synthesized by addition of a dichloromethane solution of the L ligand (0.3 mmol in 5 mL of solvent) to a solution containing the stoichiometric amount of [PtI_2(Me_2-phen)] (0.3 mmol) in the same solvent (15 mL). After 2 minutes stirring, addition of diethyl ether to the mixture caused the precipitation of a dark-red solid which was collected, washed with diethyl ether, and dried in air, yield 90%. $C_{19}H_{17}I_2N_3Pt$ (**2g**; 736.2): calcd. C 31.0, H 2.3, N 5.7; found C 30.8, H 2.4, N 5.5. $C_{17}H_{21}I_2N_3Pt$ (**2h**; 716.3): calcd. C 28.5, H 3.0, N 5.9; found C 28.3, H 3.1, N 5.7.

Crystals of the compounds suitable for X-ray structure determinations were obtained from solutions of the platinum complexes in chloroform. Diethyl ether was gently stratified upon the above solutions in order to induce crystallization.

Physical Measurements: ^{1}H NMR spectra were recorded on a Bruker AM 300 instrument equipped with a temperature control unit; the data are reported in Table 1. The spectral simulation was performed using D NMR6.[20] The methyl protons of the 2,9-substituted phenanthroline were used to analyse the exchange between

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the free and coordinated ends of singly bonded Me_2-phen (flipping of the Me_2-phen ligand) in compounds **2g** and **2h**. Values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ were calculated from plots of $\ln(k/T)$ against $1/T$. IR spectra were recorded as KBr pellets on Perkin−Elmer 283 and FT 1600 spectrophotometers.

X-ray Data Collection, Structure Determination, and Refinement for Complexes 2a, 2e, 2f, 2g, and 2h: The crystallographic data are summarized in Table 5. Accurate unit-cell parameters were determined by least-squares refinement of the setting angles of 30 randomly distributed and carefully centerd reflections with θ in the range 10−20°. The data collections were performed at 293 K on a Siemens AED diffractometer by using the $\theta/2\theta$ scan mode. One standard reflection was monitored every 100 measurements, no significant decay was noticed over the time of data collection for all the compounds. The structures were solved by direct methods (SIR92)[21] and refined by full-matrix least-squares based on F_o^2 (**2a**, **2f**, and **2h**) or F_o (**2e** and **2h**) using the SHELXL-97 program,[22] first with isotropic then with anisotropic thermal parameters for all the non-hydrogen atoms. A semi-empirical method of absorption correction was applied for all the compounds (maximum and minimum values for the transmission coefficient were 1.000 and 0.904 for **2a**, 1.000 and 0.903 for **2e**, 1.000 and 0.725 for **2f**, 1.000 and 0.908 for **2g** and 1.000 and 0.937 for **2h**).[23,24] All the hydrogen atoms were placed at their geometrically calculated positions and refined as "riding" on their parent carbon or nitrogen atoms, except those of the ethylene (**2a**), which were found and refined isotropically. For compound **2h** the methyl group of the propylamine ligand was found to be disordered over two positions with occupancy factors of 0.66 and 0.34, respectively.

CCDC-216146 to -216150 (**2a**, **2e**, **2f**, **2g**, and **2h**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; or E-mail: deposit@ccdc.cam.ac.uk).

Computational Details: Ab initio calculations were performed to obtain an internally consistent measure of the π-acceptor ability of the L ligands. This was done according to an energy decomposition technique, the Constrained Space Orbital Variation (CSOV), implemented in the computer code HONDO 8.5[25] at the Hartree−Fock (HF) level. For this reason the electronic structures of the *trans*-[PtI_2(phen)(L)] complexes were determined at the ab initio HF level. Recently, the CSOV method has been implemented also at the Density Functional Theory (DFT) level, and test calculations have shown that the qualitative trends obtained as to the extent of donation/back-donation processes are very similar at the HF and DFT levels.[26] Therefore we expect the conclusions of this analysis not to be affected by the use of an HF wavefunction and to be valid in general. Except for the heavy atoms Pt and I, where an Effective Core Potential (ECP) was used, all other atoms were treated at the all-electron level. 68- and 46-Electron relativistic ECP's were used for Pt and I, respectively.[27] The 2,9-dimethyl-1,10-phenanthroline ligand (Me_2-phen) was represented by a 1,10-phenanthroline (phen). The L ligands considered were: C_2H_4, C_2H_2, CO, H_3P, $(CH_3)_2SO$, $(CH_3)_2S$, C_5H_5N, and H_3N. The ligands actually present in the real compounds were: C_2H_4, $C_2(C_6H_5)_2$, CO, $(C_6H_5)_3P$, $(CH_3)_2SO$, $(CH_3)_2S$, C_5H_5N, and $H_2(C_3H_7)N$. Therefore in the calculation procedure alkyl and phenyl substituents were represented by H atoms to reduce the computational burden. In the analysis of the results one has to take into account that some small differences between theory and experiment can be due to the use of simplified ligands in the calculations. The basis sets were of double-zeta quality for the ECPs of the Pt and I atoms,[27] for the C and N atoms directly bound to Pt, and for the P and S atoms.[28] Polarization functions (*d*),[29] particularly important for second-row

atoms like S and P,[18] were added to these atoms. All the remaining C and H atoms were treated by a MINI basis set.[30]

The geometry of the complexes was fully optimized by means of analytical gradients. Only one plane of symmetry was imposed: this is the plane containing the phenanthroline ligand and perpendicular to the straight line connecting the two iodo ligands (C_s symmetry). The L ligand was completely free to rotate and change position with respect to the phenanthroline. This is essential in order to guarantee that the calculations reproduce the correct geometry.

The Ligating Ability of Functionalised Diaminodimethylsilanes towards Zirconium(IV)

Vincenzo Passarelli,*[a] Franco Benetollo,[a] and Pierino Zanella[a]

Keywords: Chelates / NMR spectroscopy / N,O ligands / Silanes / Zirconium

The functionalised diaminodimethylsilanes $SiMe_2[NH(CH_2)_nX]_2$ (X = NMe_2, n = 2, H_2L^1; n = 3, H_2L^2; X = OMe, n = 2, H_2L^3; n = 3, H_2L^4) have been synthesised by aminolysis of $SiMe_2Cl_2$ with $NH_2(CH_2)_nX$, and their ligating ability towards zirconium(IV) has been investigated. The syntheses of $[ZrY_2(L)]$ (Y = Cl, NMe_2, Me; L = L^1, L^2, L^3, L^4) are reported and the solid-state structures of some selected compounds determined by X-ray crystallography. In addition, the solution molecular structures of all the metal derivatives have been elucidated by variable-temperature multinuclear 1D/2D NMR spectroscopy, and the dynamics have been investigated in some selected cases.

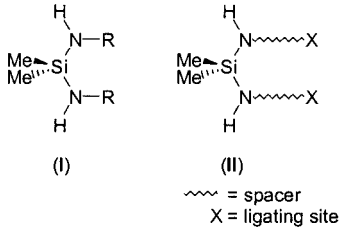
Introduction

Due to the observed peculiar catalytic and structural properties of metal amide derivatives,[1] increasing attention has been devoted to the synthesis of novel compounds of this class. Silylamides of the type $NRSiR'_3$ are widely reported in the literature,[1a–1c] while only a limited number of papers are available[2] dealing with the ligating ability of diaminosilanes (**I**). Nevertheless, in the case of the zirconium derivatives, it appears that the substituents of the $SiMe_2N_2$ core, i.e. the hydrocarbyl groups on the nitrogen atoms, play a fundamental role in determining the nature of the product(s). For instance, the *tert*-butyl derivative $[Zr\{(NtBu)_2SiMe_2\}_2]$[2a] is mononuclear, while the isopropyl analogue is dinuclear,[2r] containing both bridging and terminal $SiMe_2(NiPr)_2$ amido ligands. In addition to the molecular structure of $[Zr\{(NiPr)_2SiMe_2\}_2]_2$,[2r] relevant to this paper are the crystallographically established pentacoordinate or hexacoordinate zirconium derivatives, namely $[Zr(NMe_2)_2(NHMe_2)\{(NAr)_2SiMe_2\}]$,[1d] $[ZrCl_2\{(NAr')_2SiMe_2\}(THF)_2]$[2p] and $[AlMe_2(THF)_2][Zr_2Cl_5\{(NAr')_2SiMe_2\}_2]$[2p] (Ar = 2,6-$Me_2C_6H_3$; Ar′ = 2,6-$iPr_2C_6H_3$). These results suggest that when the starting diaminosilane contains the $Si(NHR)_2$ moiety, the zirconium centre of the formally resulting $[ZrX_2\{(NR)_2SiMe_2\}]$ moiety is coordinatively unsaturated and therefore able to bond additional ligands, thus yielding mononuclear solvento species or ligand-bridged structures.

In light of this, it appeared of interest to synthesise novel functionalised diaminodimethylsilanes (**II**), containing potential ligating sites besides the SiN_2 moiety, investigate their ligating ability towards zirconium, and elucidate the molecular structure of the complexes both in solution and in the solid state.



Results and Discussion

Synthesis of $SiMe_2[NH(CH_2)_nX]_2$ (H_2L; n = 2, 3; X = NMe_2, OMe) and Li_2L

The aminolysis of $SiMe_2Cl_2$ by $NH_2(CH_2)_nX$ (n = 2, 3; X = NMe_2, OMe) yields the diaminodimethylsilanes $SiMe_2[NH(CH_2)_nX]_2$ (**1**, H_2L^1, n = 2, X = NMe_2; **2**, H_2L^2, n = 3, X = NMe_2; **3**, H_2L^3, n = 2, X = OMe; **4**, H_2L^4, n = 3, X = OMe), the chlorides being removed as the ammonium salt $NH_2(CH_2)_nX{\cdot}HCl$ (see Scheme 1). The resulting silanes H_2L are readily deprotonated by MeLi (1:2 molar ratio) yielding the lithium salts Li_2L (Scheme 1).

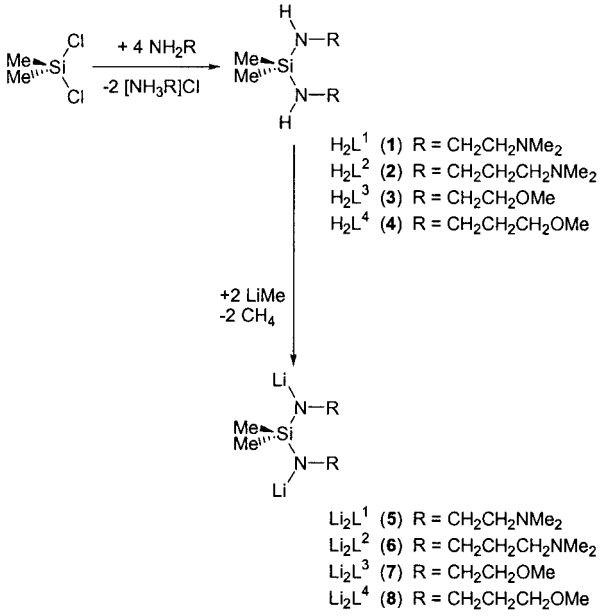
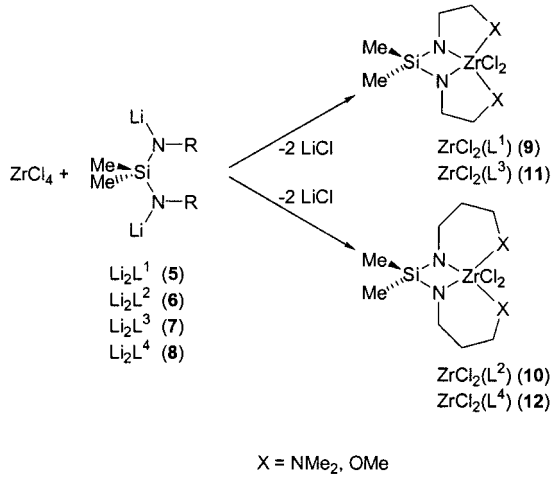


Scheme 1

The ^1H and ^{13}C NMR spectra of H_2L and Li_2L (L = L^1, L^2, L^3, L^4) show high-field resonances for the $SiMe_2$ group, while the peaks of the $NH(CH_2)_nX$ moiety are observed in the range δ = 1−4 ppm (^1H) and δ = 30−80 ppm (^{13}C). The ^{29}Si NMR resonances of the lithium salts Li_2L are high-field shifted with respect to H_2L due to the formal doubly negative charge on L in Li_2L.

Synthesis of $[ZrY_2(L)]$ (Y = Cl, Me, NMe_2; L = L^1, L^2, L^3, L^4)

The reaction of $ZrCl_4$ with Li_2L yields the dichloro derivatives $[ZrCl_2(L)]$ (**9**, L = L^1; **10**, L = L^2; **11**, L = L^3; **12**, L = L^4) as pure materials after recrystallisation from pentane at 249 K (Scheme 2).



Scheme 2

The solid-state molecular structures of compounds **10** and **12** were determined by single-crystal X-ray diffraction analysis, showing the $ZrCl_2$ moiety to be coordinated to the tetradentate ligand L (Figure 1A and 1B). The arrangement of the donor atoms in **10** is intermediate between the *cis*- and *trans*-octahedral isomers[3a] [Cl(1)−Zr−Cl(2): 109.0(1)°; N(3)−Zr−N(4): 160.1(1)°; the dihedral angle between the ZrCl(1)Cl(2) and ZrN(1)N(2) planes is 28.3(1)°]. Compound **12** shows a more symmetric coordination sphere in which the tetradentate ligand defines the equatorial plane (containing the metal centre) and the chlorine ligands occupy opposite sites with respect to it [Cl(1)−Zr−Cl(2): 140.7(1)°; O−Zr−O′: 122.4(2)°; the dihedral angle between the ZrCl(1)Cl(2) and ZrNN′ planes is 90.0°].

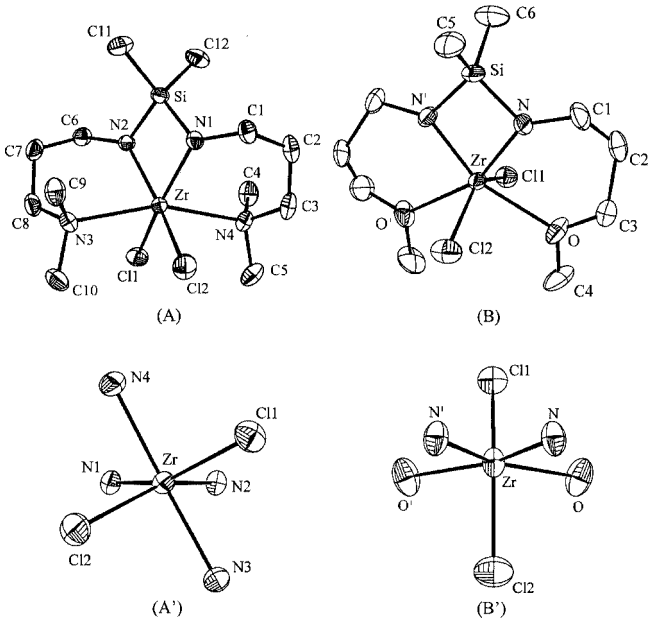


Figure 1. Molecular structures of (A) $[ZrCl_2(L^2)]$ (**10**) and (B) $[ZrCl_2(L^4)]$ (**12**)] with the numbering schemes adopted and the coordination polyhedra {$[ZrCl_2(L^2)]$ (A′); $[ZrCl_2(L^4)]$ (B′)}

As far as the SiN_2Zr moiety in **10** and **12** is concerned, similar bond lengths and angles (Table 1 and 2) have been observed in related compounds {e.g. Zr−N: 2.052 Å (av.); Si−N: 1.753 Å (av.) in $[Zr\{(NtBu)_2SiMe_2\}_2]$[2a]} and it is important to note that the shorter the Zr−N [**10**, Zr−N(1); Zr−N(2); **12**, Zr−N] and Si−N [**10**, Si−N(1); Si−N(2); **12**, Si−N] bond lengths, the wider the N−Zr−N [**10**, N(1)−Zr−N(2); **12**, N−Zr−N′] and N−Si−N angles [**10**, N(1)−Si−N(2); **12**, N−Si−N′; cf. Table 1, 2].

Concerning the neutral ligating sites NMe_2 and OMe, it should be noted that in agreement with the trends in zirconium(IV) compounds, the Zr−N distance is longer than the Zr−O one [**10**, Zr−N(3), 2.427(2) Å, 2.438(2) Å; **12**, Zr−O, 2.330(4) Å].[4]

Coordination polyhedra similar to **10** and **12** have already been observed for zirconium complexes[2p,5] but, to the best of our knowledge, **10** is the first structurally charac-

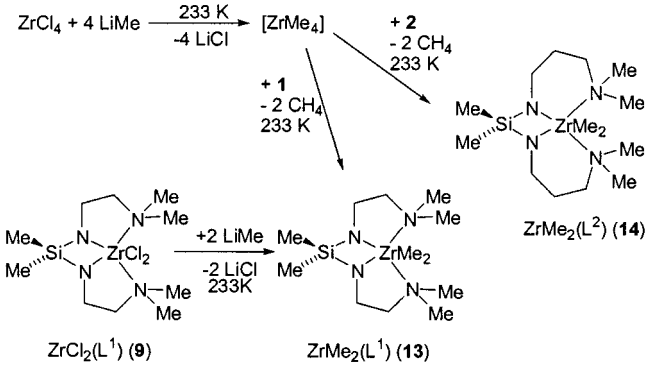
[a] Equivalent atom generated by $-x, y, z$.

terised hexacoordinate derivative containing a linear open-chain N_4 ligand bonded to the $ZrCl_2$ moiety. With regards to **12**, the molecular structure of the solvento zirconium derivative $[ZrCl_2\{(NAr)_2SiMe_2\}(THF)_2]$[2p] (Ar = 2,6-*i*$Pr_2C_6H_3$) is to be considered because of the strictly similar arrangement of the donor atoms, i.e. the zirconium, the oxygen and the nitrogen atoms define the equatorial plane, while the chlorides occupy the apical sites.

The solution molecular structures of **9**−**12** were investigated by NMR spectroscopy. The ^1H and ^{13}C NMR spectra show the expected patterns (see Exp. Sect.) and, relevant to the structure elucidation, the ^1H NMR resonances of the CH_2NMe_2 (**9**, **10**) and the CH_2OMe (**11**, **12**) moieties are shifted with respect to the uncomplexed ligands, thus indicating their coordination to the metal centre, and the two halves of the silane ligands, namely $SiN(CH_2)_nNMe_2$ and $SiN(CH_2)_nOMe$ are equivalent[3b] even at 188 K (^1H and ^{13}C NMR), suggesting the symmetric coordination[3a] of the ligand to the metal centre. The solution molecular structures of **9**−**12** should therefore be essentially similar to the solid-state structures of **10** and **12**.

In order to extend the class of the zirconium derivatives containing L^1 and L^2 the synthesis of complexes containing ancillary ligands other than Cl, namely Me and NMe_2, was investigated. The dimethyl derivatives $[ZrMe_2(L)]$ (**13**, L = L^1; **14**, L = L^2) were prepared by reacting $ZrMe_4$ (generated in situ by treating $ZrCl_4$ with MeLi, 1:4 molar ratio, 233 K) with H_2L (L = L^1, L^2, Scheme 3). Alternatively, **13** could be obtained from the reaction of **9** with MeLi (1:2 molar ratio, 233 K; Scheme 3). The products are extremely air and moisture sensitive and thermally unstable (samples of both **13** and **14** were found to decompose within one week, even if stored under dinitrogen at 249 K).



Scheme 3

Similar to $[ZrCl_2(L)]$, the ^1H and/or ^{13}C NMR resonances of the $CH_2N(CH_3)_2$ group of $[ZrMe_2(L)]$ (L = L^1, L^2) are shifted with respect to the uncomplexed ligands, thus proving the coordination of the neutral NMe_2 units to the zirconium centre. In addition, the equivalence of the two arms of the diaminosilane ligands (^1H, ^{13}C) indicates a symmetric coordination of the ligand.[3b]

The reaction of $[Zr(NMe_2)_4]$ with **1** yields the mixed amido derivative $[Zr(NMe_2)_2(L^1)]$ (**15**) as a microcrystalline solid, after removing all the volatiles from the reaction mixture (Scheme 4). Unfortunately, H_2L^2 reacts with $[Zr(NMe_2)_4]$ to give a mixture of products that we were unable to separate and characterise. However, $[Zr(NMe_2)_2(L^2)]$ (**16**) could be obtained as a pure material from the reaction of **10** with $LiNMe_2$ (1:2 molar ratio, Scheme 4); formation of the chloroamido derivative $[ZrCl(NMe_2)(L^2)]$ (**17**) was also observed in the course of the reaction. As a matter of fact, when **10** was treated with $LiNMe_2$ (1:1 molar ratio), **17** was isolated as a pure material in high yield, and the treatment of **17** with $LiNMe_2$ (1:1 molar ratio) yielded **16**.

The solid-state molecular structure of **15** was determined by X-ray diffraction analysis, showing the zirconium centre to be coordinated to the tetradentate dianionic ligand L^1 and to the dimethylamido ligands (Figure 2). To the best of our knowledge, $[Zr(NMe_2)_2(L^1)]$ (**15**) is the first structurally characterised hexacoordinate zirconium complex containing a linear open-chain N_4 ligand coordinated to the $Zr(NMe_2)_2$ moiety. The coordination polyhedron can be described as a distorted octahedron or a bicapped tetrahedron (amino NMe_2 groups capping two faces). In any case, the four donor atoms from the silane ligand define the equa-

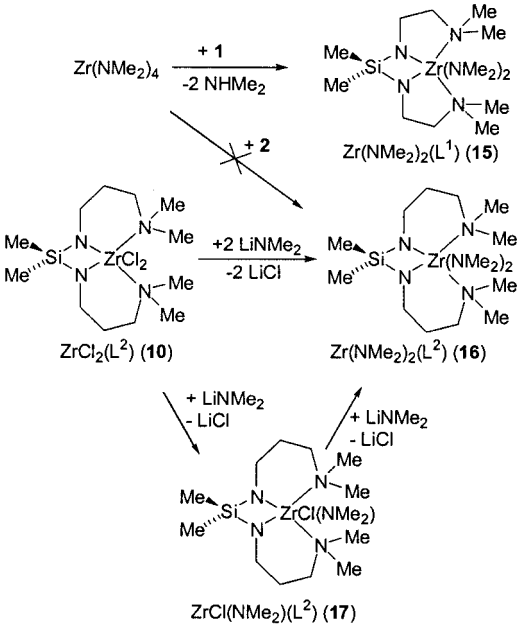

Scheme 4

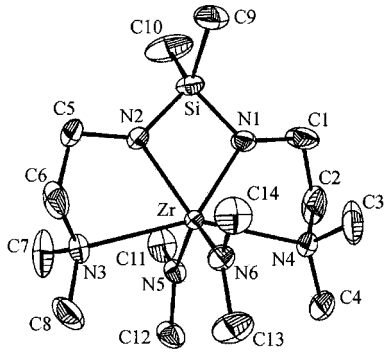

Figure 2. Molecular structure of $[Zr(NMe_2)_2(L^1)]$ (**15**) with the numbering scheme adopted

torial plane of the molecule and the dimethylamido groups occupy opposite coordination sites with respect to it. Concerning bond lengths and angles (Table 3), the Si−N(1), Si−N(2), Zr−N(1) and Zr−N(2) distances and the N(1)−Si−N(2) and N(1)−Zr−N(2) angles of the SiN_2Zr core are similar to those observed in **10**, **12** and related compounds (vide supra). The Zr−N(3) and Zr−N(4) distances [2.566(6), 2.580(7) Å, respectively] in **15** are longer than those in **10** [2.427(2), 2.438(2) Å, respectively], and we propose that the different hydrocarbon chains (the shorter ethylene one in **15** vs. the longer propylene one in **10**), the different arrangement of the tetradentate ligand (Figure 1 and 2), and the presence of the more sterically demanding dimethylamido ligand (with respect to Cl) might be responsible for this.

Table 3. Selected bond lengths (Å) and angles (°) for $[Zr(NMe_2)_2(L^1)]$ (**15**)

Zr−N(1)	2.103(6)	Zr−N(2)	2.117(6)
Zr−N(3)	2.566(6)	Zr−N(4)	2.580(7)
Zr−N(5)	2.075(6)	Zr−N(6)	2.084(6)
Si−N(1)	1.683(7)	Si−N(2)	1.684(7)
Si−C(9)	1.87(1)	Si−C(10)	1.85(1)
N(4)−Zr−N(1)	67.9(3)	N(4)−Zr−N(2)	136.7(2)
N(4)−Zr−N(3)	154.4(2)	N(4)−Zr−N(5)	84.2(2)
N(4)−Zr−N(6)	83.5(3)	N(1)−Zr−N(2)	69.1(3)
N(1)−Zr−N(5)	110.6(3)	N(1)−Zr−N(3)	137.7(3)
N(1)−Zr−N(6)	113.7(3)	N(2)−Zr−N(3)	68.8(3)
N(2)−Zr−N(5)	115.4(3)	N(2)−Zr−N(6)	110.1(3)
N(3)−Zr−N(5)	84.4(3)	N(3)−Zr−N(6)	84.5(3)
N(5)−Zr−N(6)	124.8(3)	N(1)−Si−N(2)	90.6(3)
N(1)−Si−C(9)	115.9(5)	N(1)−Si−C(10)	114.7(6)
N(2)−Si−C(9)	114.6(5)	N(2)−Si−C(10)	116.0(7)
C(9)−Si−C(10)	105.2(6)		

The ^1H and ^{13}C NMR spectra of $[Zr(NMe_2)_2(L)]$ (**15**, **16**) show only two (**15**) and three (**16**) methylene resonances, suggesting a symmetrical coordination[3b] of L to the $Zr(NMe_2)_2$ moiety, and, consequently, that the solid-state molecular structure of **15** is preserved in solution. A similar arrangement of the donor atoms can be proposed for **16** (vide infra).

As far as the chloroamido derivative $[ZrCl(NMe_2)(L^2)]$ (**17**) is concerned, only one ^{29}Si NMR signal (δ = −22.1 ppm) is observed, while the ^{13}C NMR spectrum shows three resonances for the methylene carbons atoms (even at 188 K), thus indicating that the ligand should be symmetrically coordinated to the metal centre.[3b] In addition: i) the $SiMe_2$ moiety yields two ^1H and two ^{13}C resonances, ii) non-equivalent methylene protons of both the CH_2NMe_2 and the $CH_2CH_2CH_2$ units are observed, and iii) the $SiNCH_2$ signal is broad and unresolved (Scheme 5), suggesting that the coordinated L^2 should approximately define a plane and the Cl and dimethylamido groups should occupy opposite coordination sites with respect to it (Scheme 5). This would make the two faces of the molecular plane nonequivalent. This is confirmed by the *negative* cross-peaks observed in the ^1H NOESY spectrum of **17** (298 K) between the resonances of the dimethylamido ligand (δ = 2.99 ppm) and the H*b* (δ = 1.56 ppm), H*c* (δ = 2.05 ppm) and Me′ (δ = 0.28 ppm) resonances, thus leading to the assignment given in Scheme 5.[6]

	δ_H (298 K)	δ_C (298 K)
	3.57 [Ha, Ha']	48.1 [C*a*]
	1.56 [H*b*], 1.40 [H*b*']	30.3 [C*b*]
	2.05 [Hc], 2.82 [Hc']	64.0 [Cc]
	0.28 [Me']	1.1 [Me']
	0.31 [Me"]	1.4 [Me"]

Scheme 5

Dynamics

Variable-temperature 1D/2D NMR spectra of selected compounds, namely LiL^2 (**6**), $[ZrCl_2(L^2)]$ (**10**), $[Zr(NMe_2)_2(L^1)]$ (**15**) and $[ZrCl(NMe_2)(L^2)]$ (**17**) showed that dynamic processes occur in solution, i.e. the inversion

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the six-membered [MN_2C_3] ring (**6**, **10**) and rotation of the amido ligand NMe_2 around the Zr−N bond (**15**, **17**).

Six-Membered [MN_2C_3] Ring Inversion

Despite the different nature of Li_2L^2 (**6**) and [$ZrCl_2(L^2)$] (**10**), the L^2 ligand exhibits similar dynamics in both compounds, i.e. the inversion of the six-membered [MN_2C_3] ring. As far as **10** is concerned, its ^{1}H NMR spectrum is strongly affected by the temperature: at 188 K each methylene resonance in the ^{1}H NMR spectrum splits into two signals (Scheme 6, cf. ESI) and the two NMe_2 methyls are nonequivalent. As both the solid-state and the proposed solution structure of **10** indicate the presence of a six-membered ZrN_2C_3 ring, we are dealing here with the slowing down of its inversion — on lowering the temperature the exchange between the equatorial and axial positions of the ring slows down, thus making both the geminal methylene protons and the NMe_2 groups nonequivalent (Scheme 6). The correlation peaks in the COSY spectrum at 188 K are indicative of both the geminal and the vicinal couplings of the methylene protons, and the observed pattern of the resonances in the 1D ^{1}H NMR spectrum (188 K) indicates that both the geminal and vicinal (axial-axial) couplings are responsible for the structure of the signals (as estimated from the spectrum, the geminal and the vicinal coupling constants are similar, i.e. about 12 Hz, cf. ESI). Likewise, the ^{13}C NMR spectrum at 188 K shows six signals (δ = 68.6, 56.9, 55.2, 49.0, 35.0, 5.6 ppm) and the ^{1}H-^{13}C HMQC spectrum indicates that the methylene carbons (δ = 68.6, 55.2 and 35.0 ppm) bear two nonequivalent protons (δ = 3.27, 1.52; 4.06, 3.18; 1.20, 1.10 ppm, respectively; cf. Scheme 6).

	δ_H (188 K)	
	M = Zr	M = Li
Ha, Ha'	4.06, 3.18	3.28 (broad)
Hb, Hb'	1.20, 1.10	1.36, 1.61
Hc, Hc'	3.27, 1.52	2.01, 2.30
Me', Me"	2.04, 2.68	1.99 (broad)

Scheme 6

A line-shape analysis[7] of the NMe_2 resonances has been carried out at different temperatures in order to obtain the kinetic constants of the ring inversion (cf. ESI) and the activation parameters [ΔH_{act} = (32.5 ± 0.7) kJ·mol^{-1}; ΔS_{act} = (−44 ± 3) J·mol^{-1}·K^{-1}]. The observed negative ΔS_{act} suggests that the ring inversion does not occur through a dissociative pathway, and that we are dealing with a cyclohexane-like ring inversion.

Despite the observation of one ^{7}Li peak and one ^{29}Si signal even at 188 K for **6**, the ^{1}H resonances of the $SiNCH_2$ and NCH_3 groups broaden and appear unresolved at 188 K; moreover, the ^{1}H resonances of both the CH_2NMe_2 and $CH_2CH_2CH_2$ groups split into two signals (Scheme 6), thus indicating that, independent of the coordination sphere around lithium, **6** should contain a six-membered LiN_2C_3 ring (Scheme 6), and that, as a consequence, the slowing down of ring inversion is responsible for the nonequivalence of the CH_2NMe_2 and $CH_2CH_2CH_2$ geminal protons and for the broadening of the $SiNCH_2$ and NCH_3 resonances (cf. Scheme 6 for assignment).

Zr−NMe_2 Rotation

The ^{1}H and ^{13}C NMR spectra of [$Zr(NMe_2)_2(L^1)$] (**15**) and [$ZrCl(NMe_2)(L^2)$] (**17**) at about 200 K show two resonances for the amido NMe_2 groups (Scheme 7), indicating that the two methyl groups experience different chemical environments at that temperature. As a matter of fact, the ^{1}H NOESY spectra of the compounds (**15**, 203 K; **17**, 193 K) show negative cross-peaks between the resonances of the $SiMe_2$ group and one of the amido NMe_2 methyl groups (**15**, δ = 3.03 ppm; **17**, δ = 2.94 ppm), and between the other amido NMe_2 methyl group (**15**, δ = 2.68 ppm; **17**, δ = 3.00 ppm) and the amino NMe_2 moiety, thus indicating that: i) one methyl group of the amido NMe_2 moiety points towards the $SiMe_2$ group, ii) the other one faces the coordinated NMe_2 unit (Scheme 7), similar to the solid-state structure of **15** (Figure 2), and iii) at these temperatures the rotation of the amido NMe_2 group is slow enough to prevent the exchange of the two methyl groups.

	δ_H (203 K)	δ_C (203 K)
Me' (α)	2.68	43.8

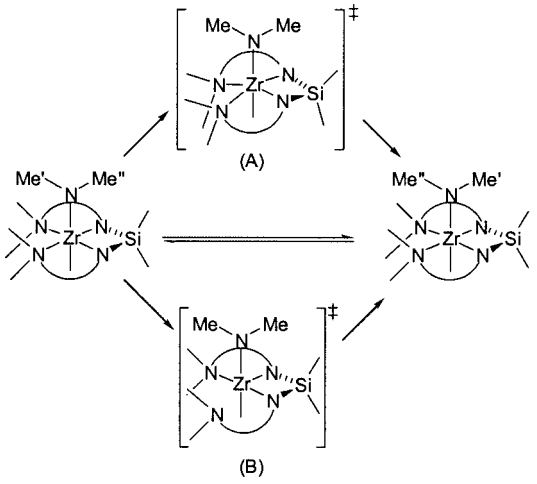
Scheme 7

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In order to further elucidate the dynamics, a line-shape analysis of the methyl resonances was undertaken, and the kinetic constants and the activation parameters were calculated [**15**, ΔH_{act} = (61.5 ± 0.8) kJ·mol^{-1}; ΔS_{act} = (55 ± 3) J·mol^{-1}·K^{-1}; **17**, ΔH_{act} = (27 ± 1) kJ·mol^{-1}; ΔS_{act} = (−73 ± 7) J·mol^{-1}·K^{-1}].

As far as the exchange between the two methyls of the amido NMe_2 group in **15** and **17** is concerned, two mechanisms could be proposed: i) a distortion of the [ZrL] framework, allowing free rotation of the amido NMe_2 group (A in Scheme 8), or ii) dissociation of one amino NMe_2 moiety, yielding a pentacoordinate derivative in which the rotation of the amido NMe_2 group should be no longer restricted (B in Scheme 8).

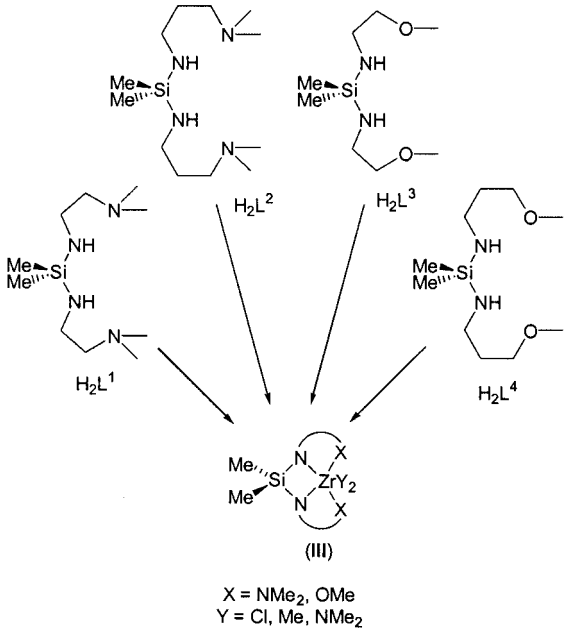


Scheme 8

Provided the activation entropy is negative for **17** and positive for **15** (vide supra), we propose that the exchange mechanisms are different for the two compounds and that the dissociative pathway (B in Scheme 8) is operative in **15**, while in **17** a distortion of the coordinated ligand should allow the exchange to occur (A in Scheme 8). In light of this, it is relevant that the activation enthalpy of **15** is about twice that of **17**, in agreement with the proposed dissociation of the Zr−N (amino) bond in **15** and the distortion in **17**. Moreover, L^2 is expected to be more flexible than L^1, due to the longer hydrocarbon chain between NMe_2 and SiN, and Cl is less sterically demanding than NMe_2, thus making the distortion of L in **17**, rather than in **15**, possible.[8]

Conclusions

The aminolysis of $SiMe_2Cl_2$ with the appropriate amine yields the functionalised diaminodimethylsilanes $SiMe_2[NH(CH_2)_nX]_2$ (H_2L, n = 2, 3; X = NMe_2, OMe, Scheme 9), which are able to coordinate to a ZrY_2 moiety, the zirconium derivatives of general formula $ZrY_2(L)$ (Scheme 9, **III**; Y = Cl, Me, NMe_2; L = L^1, L^2, L^3, L^4) being readily prepared according to the appropriate procedures.



Scheme 9

The solid-state structures of selected compounds, namely $[ZrCl_2(L)]$ (L = L^2, L^4) and $[Zr(NMe_2)_2(L^1)]$, show that L is tetradentate, coordinating to the metal centre through both the $Si(NR)_2$ and the neutral X moieties (X = OMe, NMe_2; Scheme 9). The coordination polyhedra are strongly affected by the nature of the diaminosilane ligand and by the zirconium ancillary ligands. To the best of our knowledge, $[ZrCl_2(L^2)]$ and $[Zr(NMe_2)_2(L^1)]$ are the first examples of hexacoordinate zirconium complexes containing a linear open-chain N_4 tetradentate ligand coordinated to the ZrY_2 moiety (Y = Cl, NMe_2).

1D/2D multinuclear NMR spectroscopic investigations on the compounds $[ZrY_2(L)]$ have shown that L is tetradentate and symmetrically coordinated to the metal centre, similar to the solid-state structures. In addition, variable-temperature 1D/2D multinuclear NMR measurements have allowed the dynamics of some selected compounds to be investigated, the kinetics of the six-membered $[MN_2C_3]$ ring inversion in $[Li_2L^2]$ and $[ZrCl_2(L^2)]$, and the rotation of the dimethylamido ligand around the Zr−N bond in $[Zr(NMe_2)(L^1)]$ and $[ZrCl(NMe_2)(L^2)]$ being elucidated.

Experimental Section

General: All operations were carried out in a glove-box under an atmosphere of dinitrogen. Elemental analyses (C, H, N) were performed using a Fisons Instruments analyser (Mod. EA 1108); the chlorine content in the samples was determined by potentiometric titration using a standard solution of silver nitrate (Aldrich). NMR spectra were recorded with a Bruker AMX 300 spectrometer

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(300 MHz for ^{1}H). ^{1}H, ^{13}C and ^{29}Si NMR spectra are referenced to TMS; LiCl (1 M, D_2O) was used as reference for the ^{7}Li NMR spectra. Multiplicity is indicated as s (singlet), t (triplet), q (quadruplet), quint (quintuplet), m (multiplet). Variable-temperature NMR measurements were carried out on [D_8]toluene solutions.

Zirconium tetrachloride ($ZrCl_4$, Fluka) was washed with boiling toluene, then with pentane, dried in vacuo and stored under an atmosphere of dinitrogen. *N*,*N*-dimethylethylenediamine ($C_4H_{12}N_2$, Aldrich) was refluxed over BaO for one day, then distilled and stored under dinitrogen. *N*,*N*-dimethylpropanediamine ($C_5H_{14}N_2$, Aldrich), 3-methoxypropylamine ($C_4H_{11}NO$, Aldrich), 2-methoxyethylamine (C_3H_9NO, Aldrich), MeLi (Et_2O solution, 1.6 M, Aldrich) and dichlorodimethylsilane ($SiCl_2Me_2$, Aldrich) were used as received. $Zr(NMe_2)_4$ was prepared according to the published procedure.[9] $LiNMe_2$ was obtained as a colourless solid by bubbling $NHMe_2$ (Fluka) into an Et_2O solution of MeLi.

Synthesis of $SiMe_2[NH(CH_2)_nX_2]_2$ (H_2L; X = NMe_2, OMe; *n* = 2, 3): Only the synthesis of $SiMe_2(NHCH_2CH_2NMe_2)_2$ is reported in detail, the other reactions being carried out similarly. A pentane solution (50 mL) of $SiMe_2Cl_2$ (2.00 g, 15.5 mmol) was added dropwise to a pentane solution (50 mL) of $NH_2CH_2CH_2NMe_2$ (5.46 g, 61.9 mmol) and the prompt precipitation of a colourless solid was observed. After 12 h stirring, the suspension was filtered and the solid identified (vide infra) as $NH_2CH_2CH_2NMe_2$·HCl (3.77 g, 98% yield). The filtrate was evaporated to dryness and the residual liquid identified as $SiMe_2(NHCH_2CH_2NMe_2)_2$ (**1**, H_2L^1, colourless, 3.46 g, 96% yield). $C_{10}H_{28}N_4Si$ (232.44): calcd. C 51.7, H 12.1, N 24.1; found 52.0, H 12.0, N 24.0. ^{1}H NMR (C_6D_6, 298 K): δ = 0.17 (s, 3 H, $SiCH_3$), 1.22 (br., 1 H, NH), 2.18 (s, 6 H, NCH_3), 2.31 (t, $^3J_{H,H}$ = 6.1 Hz, 2 H, CH_2NMe$_2$), 2.94 (t, $^3J_{H,H}$ = 6.1 Hz, 2 H, $SiNCH_2$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = −1.20 ($SiCH_3$), 39.2 ($SiNCH_2$), 45.5 (NCH_3), 63.5 (*C*H_2NMe$_2$) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −8.7 ppm.

$NH_2CH_2CH_2NMe_2$·HCl: $C_4H_{13}ClN_2$ (124.61): calcd. C 38.6, H 10.5, Cl 28.5, N 22.5; found C 38.5, H 10.3, Cl 28.7, N 22.5. ^{1}H NMR ($CDCl_3$, 298 K): δ = 2.20 (s, 6 H, NCH_3), 2.52 (t, $^3J_{H,H}$ = 6 Hz, 2 H, CH_2), 2.96 (t, $^3J_{H,H}$ = 6 Hz, 2 H, CH_2), 7.2 (br., 3 H, NH) ppm. ^{13}C NMR ($CDCl_3$, 298 K): δ = 37.7 (CH_2), 45.4 (CH_3), 57.1 (CH_2) ppm.

$SiMe_2(NHCH_2CH_2CH_2NMe_2)_2$ (2, H_2L^2): Colourless liquid (4.2 g, 92% yield). $C_{12}H_{32}N_4Si$ (260.50): calcd. C 55.3, H 12.4, N 21.5; found 55.0, H 12.5, N 21.3. ^{1}H NMR (C_6D_6, 298 K): δ = 0.10 (s, 3 H, $SiCH_3$), 0.63 (br., 1 H, NH), 1.52 (quint, $^3J_{H,H}$ = 6.2 Hz, 2 H, $CH_2CH_2CH_2$), 2.11 (s, 6 H, NCH_3), 2.23 (t, $^3J_{H,H}$ = 6.2 Hz, 2 H, CH_2NMe$_2$), 2.84 (t, $^3J_{H,H}$ = 6.2 Hz, 2 H, $SiNCH_2$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = −1.02 ($SiCH_3$), 33.0 ($CH_2CH_2CH_2$), 39.8 ($SiNCH_2$), 45.7 (NCH_3), 57.9 (*C*H_2NMe$_2$) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −9.3 ppm.

$NH_2CH_2CH_2CH_2NMe_2$·HCl: $C_5H_{15}ClN_2$ (138.64): calcd. C 43.3, H 10.9, Cl 25.6, N 20.2; found C 42.9, H 11.0, Cl 21.0, N 20.5. ^{1}H NMR ($CDCl_3$, 298 K): δ = 1.81 (quint, $^3J_{H,H}$ = 6.0 Hz, 2 H, CH_2), 2.27 (s, 6 H, NCH_3), 2.52 (t, $^3J_{H,H}$ = 6.0 Hz, 2 H, NCH_2), 3.09 (t, 2 H, NCH_2, $^3J_{H,H}$ = 6.0 Hz), 6.1 (br., 3 H, NH) ppm.

$SiMe_2(NHCH_2CH_2OMe)_2$ (3, H_2L^3): Colourless liquid (2.5 g 90% yield). $C_8H_{22}N_2O_2Si$ (206.36): calcd. C 46.6, H 10.7, N 13.6; found 46.5, H 10.5, N 13.8. ^{1}H NMR (C_6D_6, 298 K): δ = 1.10 (br., 1 H, NH), 1.28 (s, 3 H, $SiCH_3$), 2.88 (q, $^3J_{H,H}$ = 5.40 Hz, 2 H, NCH_2), 3.14 (s, 3 H, OCH_3), 3.18 (t, $^3J_{H,H}$ = 5.4 Hz, 2 H, OCH_2) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = −1.24 ($SiCH_3$), 41.1 (NCH_2), 58.4 (OCH_3), 76.1 (OCH_2) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −8.0 ppm.

$NH_2CH_2CH_2OMe$·HCl: $C_3H_{10}ClNO$ (111.57): calcd. C 32.3, H 9.0, Cl 31.8, N 12.6; found C 32.2, H 9.2, Cl 31.7, N 12.4. ^{1}H NMR ($CDCl_3$, 298 K): δ = 3.16 (t, 2 H, OCH_2, $^3J_{H,H}$ = 5.1 Hz), 3.29 (s, 3 H, OCH_3), 3.62 (t, $^3J_{H,H}$ = 5.1 Hz, 2 H, NCH_2), 8.02 (br., 3 H, NH) ppm. ^{13}C NMR ($CDCl_3$, 298 K): δ = 39.3 (OCH_2), 58.8 (OCH_3). 68.0 (NCH_2) ppm.

$SiMe_2(NHCH_2CH_2CH_2OMe)_2$ (4, H_2L^4): Colourless liquid (3.7 g, 94% yield). $C_{10}H_{26}N_2O_2Si$ (234.41): calcd. C 51.2, H 11.2, N 12.0; found 51.5, H 11.0, N 11.9. ^{1}H NMR (C_6D_6, 298 K): δ = −0.04 (s, 3 H, $SiCH_3$), 0.56 (br., 1 H, NH), 1.54 (m, 2 H, CH_2), 2.76 (t, $^3J_{H,H}$ = 6.6 Hz, 2 H, NCH_2), 3.11 (s, 3 H, OCH_3), 3.24 (t, $^3J_{H,H}$ = 6.2 Hz, 2 H, OCH_2) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = −1.23 ($SiCH_3$), 34.1 (CH_2), 38.6 (NCH_2), 58.3 (OCH_3), 70.7 (OCH_2) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −8.9 ppm.

$NH_2CH_2CH_2CH_2OMe$·HCl: $C_4H_{12}ClNO$ (125.60): calcd. C 38.3, H 9.6, Cl 28.2, N 11.2; found C 38.4, H 10.0, Cl 28.0, N 11.0. ^{1}H NMR ($CDCl_3$, 298 K): δ = 2.02 (m, 2 H, CH_2), 3.15 (t, 2 H, NCH_2, $^3J_{H,H}$ = 6.5 Hz), 3.30 (s, 3 H, OCH_3), 3.52 (t, 2 H, OCH_2, 5.7 Hz), 8.2 (br., 3 H, NH) ppm. ^{13}C NMR ($CDCl_3$, 298 K): δ = 38.4 (CH_2), 58.8 (NCH_2), 61.6 (OCH_3), 70.3 (OCH_2) ppm.

Synthesis of $Li_2\{SiMe_2[N(CH_2)_nX]_2\}$ (Li_2L, X = NMe_2, OMe; *n* = 2, 3): Only the synthesis of $Li_2[SiMe_2(NCH_2CH_2NMe_2)_2]$ is reported in detail, the other reactions being similar. A solution of $SiMe_2(NHCH_2CH_2NMe_2)_2$ (1.50 g, 6.45 mmol) in Et_2O (25 mL) was treated with MeLi (1.6 M, in Et_2O, 8.1 mL, 13.0 mmol) at room temperature. Prompt gas evolution was observed and after 2 h stirring the solution was evaporated to dryness yielding a colourless solid identified as $Li_2[SiMe_2(NCH_2CH_2NMe_2)_2]$ (**5**, Li_2L^1, 1.45 g, 92% yield). $C_{10}H_{26}Li_2N_4Si$ (244.31): calcd. C 49.2, H 10.7, N 22.9; found C 49.0, H 11.0, N 23.0. ^{1}H NMR (C_6D_6, 298 K): δ = 0.33 (s, 3 H, $SiCH_3$), 2.06 (s, 6 H, NCH_3), 2.29 (t, $^3J_{H,H}$ = 5.4 Hz, 2 H, CH_2NMe$_2$), 3.32 (t, $^3J_{H,H}$ = 5.4, 2 H, $SiNCH_2$) ppm. ^{7}Li NMR (C_6D_6, 298 K): δ = 9.9 ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 0.57 ($SiCH_3$), 44.4 ($SiNCH_2$), 44.8 (NCH_3), 68.3 (*C*H_2NMe$_2$) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −9.5 ppm.

$Li_2[SiMe_2(NCH_2CH_2CH_2NMe_2)_2]$ (6, Li_2L^2): Colourless solid (1.2 g, 95% yield). $C_{12}H_{30}Li_2N_4Si$ (272.36): calcd. C 52.9, H 11.1, N 20.6; found C 53.0, H 11.0, N 20.8. ^{1}H NMR (C_6D_6, 298 K): δ = 0.27 (s, 3 H, $SiCH_3$), 1.51 (m, 2 H, $CH_2CH_2CH_2$), 2.06 (s, 6 H, NCH_3), 2.24 (m, 2 H, CH_2NMe$_2$), 3.37 (m, 2 H, $SiNCH_2$) ppm. ^{7}Li NMR (C_6D_6, 298 K): δ = 10.5 ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 1.76 ($SiCH_3$), 34.7 ($CH_2CH_2CH_2$), 45.7 (NCH_3), 50.7 ($SiNCH_2$), 63.7 (*C*H_2NMe$_2$) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −11.6 ppm.

$Li_2[SiMe_2(NCH_2CH_2OMe)_2]$ (7, Li_2L^3): Colourless solid (1.7 g, 90% yield). $C_8H_{20}Li_2N_2O_2Si$ (218.22): calcd. C 44.0, H 9.2, N 12.8; found C 44.2, H 9.1, N 12.7. ^{1}H NMR (C_6D_6, 298 K): δ = 0.28 (s, 3 H, $SiCH_3$), 3.15 (s, 3 H, OCH_3), 3.37 (t, $^3J_{H,H}$ = 4.5 Hz, 2 H, NCH_2), 3.44 (t, $^3J_{H,H}$ = 4.5 Hz, 2 H, OCH_2) ppm. ^{7}Li NMR (C_6D_6, 298 K): δ = 9.6 ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 2.19 ($SiCH_3$), 47.6 (NCH_2), 58.5 (OCH_3), 80.5 (OCH_2) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −11.1 ppm.

$Li_2[SiMe_2(NCH_2CH_2CH_2OMe)_2]$ (8, Li_2L^4): Colourless solid (1.0 g, 93% yield). $C_{10}H_{24}Li_2N_2O_2Si$ (246.28): calcd. C 48.8, H 9.8, N 11.4; found C 48.9, H 9.7, N 11.3. ^{1}H NMR (C_6D_6, 298 K): δ = 0.29 (s, 3 H, $SiCH_3$), 1.68 (m, 2 H, CH_2), 3.12 (s, 3 H, OCH_3), 3.27 (t, $^3J_{H,H}$ = 4.8 Hz, 2 H, NCH_2), 3.46 (m, 2 H, OCH_2) ppm. ^{7}Li NMR (C_6D_6, 298 K): δ = 10.2 ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 1.01 ($SiCH_3$), 39.0 (CH_2), 48.9 (NCH_2), 59.6 (OCH_3), 77.4 (OCH_2) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −11.0 ppm.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Synthesis of [$ZrCl_2${SiMe[$N(CH_2)_nX$]}] [$ZrCl_2(L)$; X = NMe_2, OMe; *n* = 2, 3]: Only the synthesis of [$ZrCl_2(L^1)$] is reported in detail, the other ones being similar. A solution of Li_2L^1 (800 mg, 3.27 mmol) in Et_2O (30 mL) was cooled to 243 K and then $ZrCl_4$ (762 mg, 3.27 mmol) was added. After 3 h stirring at 243 K, the suspension was allowed to warm up to room temperature and then filtered (260 mg of colourless solid). The filtrate was evaporated to dryness and [$ZrCl_2${$SiMe_2(NCH_2CH_2NMe_2)_2$}] (**9**, 770 mg g, 60% yield) was obtained as a colourless solid after recrystallisation from pentane at 249 K. $C_{10}H_{26}Cl_2N_4SiZr$ (392.56): calcd. C 30.6, H 6.7, Cl 18.1, N 14.3; found C 31.0, H 6.5, Cl 18.0, N 14.0. ^{1}H NMR (C_6D_6, 298 K): δ = 0.23 (s, 3 H, $SiCH_3$), 2.35 (s, 6 H, NCH_3), 2.81 (t, $^3J_{H,H}$ = 5.4 Hz, 2 H, CH_2NMe_2), 3.37 (t, $^3J_{H,H}$ = 5.4 Hz, 2 H, $SiNCH_2$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 0.11 ($SiCH_3$), 46.3 (NCH_3), 46.8 ($SiNCH_2$), 63.9 (CH_2NMe_2) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −23.3 ppm.

[$ZrCl_2${$SiMe_2(NCH_2CH_2CH_2NMe_2)_2$}] [10, $ZrCl_2(L^2)$]: Colourless solid, recrystallised from pentane at 249 K (560 mg, 70% yield). $C_{12}H_{30}Cl_2N_4SiZr$ (420.61): calcd. C 34.3, H 7.2, Cl 16.9, N 13.3; found C 34.0, H 7.0, Cl 17.0, N 13.5. ^{1}H NMR (C_6D_6, 298 K): δ = 0.17 (s, 3 H, $SiCH_3$), 1.34 (m, 2 H, $CH_2CH_2CH_2$), 2.41 (s, 6 H, NCH_3), 2.59 (m, 2 H, CH_2NMe_2), 3.62 (m, 2 H, $SiNCH_2$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 0.33 ($SiCH_3$), 29.9 ($CH_2CH_2CH_2$), 48.2 (NCH_3), 49.6 ($SiNCH_2$), 63.8 (CH_2NMe_2) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −28.8 ppm.

[$ZrCl_2${$SiMe_2(NCH_2CH_2OMe)_2$}] [11, $ZrCl_2(L^3)$]: Colourless solid, recrystallised from pentane at 249 K (612 mg, 70% yield). $C_8H_{20}Cl_2N_2O_2SiZr$ (366.47): calcd. C 26.2, H 5.5, Cl 19.3, N 7.6; found C 26.0, H 5.5, Cl 19.5, N 7.6. ^{1}H NMR (C_6D_6, 298 K): δ = 0.41 (s, 3 H, $SiCH_3$), 3.48 (t, $^3J_{H,H}$ = 5.7 Hz, 2 H, NCH_2), 3.56 (s, 3 H, OCH_3), 3.58 (t, $^3J_{H,H}$ = 5.7 Hz, 2 H, OCH_2) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 1.24 ($SiCH_3$), 47.2 (OCH_3), 61.1 (NCH_2), 78.4 (OCH_2) ppm.

[$ZrCl_2${$SiMe_2(NCH_2CH_2CH_2OMe)_2$}] [12, $ZrCl_2(L^4)$]: Colourless solid, recrystallised from pentane at 249 K, 850 mg, 70% yield]. $C_{10}H_{24}Cl_2N_2O_2SiZr$ (394.52): calcd. C 30.4, H 6.1, Cl 18.0, N 7.1; found C 30.3, H 6.2, Cl 17.9, N 7.0. ^{1}H NMR (C_6D_6, 298 K): δ = 0.44 ($SiCH_3$), 1.77 (m, 2 H, CH_2), 3.23 (s, 3 H, OCH_3), 3.24 (t, $^3J_{H,H}$ = 5.6 Hz, 2 H, NCH_2), 3.55 (m, 2 H, OCH_2) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = −1.02 ($SiCH_3$), 32.7 (CH_2), 48.1 (NCH_2), 60.5 (OCH_3), 76.9 (OCH_2) ppm.

Synthesis of $ZrMe_2${$SiMe_2[N(CH_2)_nNMe_2]_2$} [$ZrMe_2(L^1)$, *n* = 2; $ZrMe_2(L^2)$, *n* = 3] From $ZrMe_4$ and H_2L (L = L^1, L^2): Only the procedure yielding [$ZrMe_2(L^1)$] is reported in detail, the other reaction being similar. A solution of MeLi in Et_2O (1.6 M, 12.9 mL, 20.6 mmol) was added to 20 mL of Et_2O, cooled to 243 K and treated with $ZrCl_4$ (1.20 g, 5.15 mmol). After 1 h stirring at 243 K, H_2L^1 (1.20 g, 5.16 mmol) was added dropwise. After a further 2 h stirring at 243 K, the suspension was allowed to warm to room temperature and then filtered (820 mg of a colourless solid). The solution was evaporated to dryness yielding a pale-orange sticky material identified as [$ZrMe_2${$SiMe_2(NCH_2CH_2NMe_2)_2$}] (**13**, 1.72 g, 95% yield). $C_{12}H_{32}N_4SiZr$ (351.72): calcd. C 41.0, H 9.2, N 15.9; found C 41.2, H 9.0, N 16.0. ^{1}H NMR (C_6D_6, 298 K): δ = −0.12 (s, 3 H, $ZrCH_3$), 0.40 (s, 3 H, $SiCH_3$), 2.23 (s, 6 H, NCH_3), 2.61 (t, $^3J_{H,H}$ = 5.5 Hz, 2 H, CH_2NMe_2), 3.54 (t, $^3J_{H,H}$ = 5.5 Hz, 2 H, $SiNCH_2$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 1.55 ($SiCH_3$), 33.2 ($ZrCH_3$), 46.3 (NCH_3), 46.4 ($SiNCH_2$), 65.3 (CH_2NMe_2) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −22.4 ppm.

[$ZrMe_2${$SiMe_2(NCH_2CH_2CH_2NMe_2)_2$}] [14, $ZrMe_2(L^2)$]: Pale-yellow solid (950 mg, 90% yield). $C_{14}H_{36}N_4SiZr$ (379.77): calcd. C 44.3, H 9.6, N 14.8; found C 44.2, H 9.8, N 14.8. ^{1}H NMR (C_6D_6, 298 K): δ = −0.07 (s, 3 H, $ZrCH_3$), 0.41 (s, 3 H, $SiCH_3$), 1.62 (q, $^3J_{H,H}$ = 6.4 Hz, 2 H, $CH_2CH_2CH_2$), 2.01 (s, 6 H, NCH_3), 2.27 (t, $^3J_{H,H}$ = 6.4 Hz, 2 H, CH_2NMe_2), 3.58 (t, $^3J_{H,H}$ = 6.4 Hz, 2 H, $SiNCH_2$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 59.3 (CH_2NMe_2), 47.3 ($SiNCH_2$), 45.7 (NCH_3), 34.0 ($CH_2CH_2CH_2$), 15.4 ($ZrCH_3$), 2.87 ($SiCH_3$) ppm.

From [$ZrCl_2(L^1)$] and MeLi: A solution of [$ZrCl_2(L^1)$] (212 mg, 0.54 mmol) in Et_2O was cooled to 243 K and treated with a solution of MeLi in Et_2O (1.6 M, 0.68 mL, 1.09 mmol), yielding a pale-yellow solution, which was allowed to slowly warm up to room temperature (about 30 min). The precipitation of a colourless solid was observed and the suspension was stirred at room temperature for 1 h. The solid was filtered off (42 mg) and the solvents were evaporated from the pale-yellow filtrate, yielding a pale-orange sticky material analytically and spectroscopically identified as [$ZrMe_2(L^1)$] (175 mg, 350 mg, 92% yield).

Synthesis of [$Zr(NMe_2)_2${$SiMe_2(NCH_2CH_2NMe_2)_2$}]: A toluene solution (25 mL) of $Zr(NMe_2)_4$ (452 mg, 1.69 mmol) was treated with H_2L^1 (395 mg, 1.70 mmol). After 2 h stirring, the solution was evaporated to dryness and the colourless residue identified as $Zr(NMe_2)_2$[$SiMe_2(NCH_2CH_2NMe_2)_2$] [**15**, $Zr(NMe_2)_2(L^1)$, 630 mg, 91% yield]. $C_{14}H_{38}N_6SiZr$ (409.80): calcd. C 41.0, H 9.3, N 20.5; found C 41.2, H 9.5, N 20.3. ^{1}H NMR (C_6D_6, 298 K): δ = 0.35 (s, 3 H, $SiCH_3$), 2.04 (s, 6 H, CH_2NCH_3), 2.39 (t, $^3J_{H,H}$ = 5.7 Hz, 2 H, CH_2NMe_2), 2.81 (s, 6 H, $ZrNCH_3$), 3.51 (t, $^3J_{H,H}$ = 5.7 Hz, 2 H, $SiNCH_2$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 1.09 ($SiCH_3$), 44.2 ($ZrNCH_3$), 46.0 ($SiNCH_2$), 46.1 (CH_2NCH_3), 64.3 (CH_2NMe_2) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −20.3.

Synthesis of [$ZrCl_{2-x}(NMe_2)_x${$SiMe_2(NCH_2CH_2CH_2NMe_2)_2$}] (*x* = 1, 2). Only the procedure yielding [$Zr(NMe_2)_2(L^2)$] is described, the other one being similar. A solution of [$ZrCl_2(L^2)$] (324 mg, 0.77 mmol) in Et_2O (25 mL) was treated with $LiNMe_2$ (79 mg, 1.55 mmol) and the prompt precipitation of a colourless solid was observed. After 30 min stirring, the suspension was filtered and the filtrate evaporated in vacuo to dryness yielding a colourless solid identified as [$Zr(NMe_2)_2${$SiMe_2(NCH_2CH_2CH_2NMe_2)_2$}] (**16**, 296 mg, 88% yield). $C_{16}H_{42}N_6SiZr$ (437.86): calcd. C 43.9, H 9.7, N 19.2; found C 44.0, H 10.0, N 19.0. ^{1}H NMR (C_6D_6, 298 K): δ = 0.46 (s, 3 H, $SiCH_3$), 1.69 (quint, $^3J_{H,H}$ = 6.4 Hz, 2 H, $CH_2CH_2CH_2$), 2.05 (s, 6 H, CH_2NCH_3), 2.32 (t, $^3J_{H,H}$ = 6.4 Hz, 2 H, CH_2NMe_2), 2.95 (s, 6 H, $ZrNCH_3$), 3.51 (t, $^3J_{H,H}$ = 6.4 Hz, 2 H, $SiNCH_2$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 1.06 ($SiCH_3$), 32.7 (CH_2), 42.4 ($ZrNCH_3$), 46.8 (CH_2NCH_3), 47.8 ($SiNCH_2$), 61.0 (CH_2NMe_2) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −24.7 ppm.

[$ZrCl(NMe_2)${$SiMe_2(NCH_2CH_2CH_2NMe_2)_2$}] [17, $ZrCl(NMe_2)(L^2)$]: Colourless solid (512 mg, 85% yield). $C_{14}H_{36}ClN_5SiZr$ (429.23): calcd. C 39.2, H 8.5, Cl 8.3, N 16.3; found C 39.0, H 8.4, Cl 8.0, N, 16.2. ^{1}H NMR (C_6D_6, 298 K): δ = 0.28 (s, 3 H, $SiCH_3$), 0.31 (s, 3 H, $SiCH_3$), 1.40 (br., 2 H, $CH_2CH_2CH_2$), 1.56 (br., 2 H, $CH_2CH_2CH_2$), 2.05 (m, 2 H, CH_2NMe_2), 2.28 (s, 12 H, CH_2NCH_3), 2.82 (m, 2 H, CH_2NMe_2), 2.99 (s, 6 H, $ZrNCH_3$), 3.57 (br., 4 H, $SiNCH_2$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 1.1 ($SiCH_3$), 1.4 ($SiCH_3$), 30.3 (CH_2), 45.1 ($ZrNCH_3$), 48.1 ($SiNCH_2$), 48.2 (CH_2NCH_3), 64.0 (CH_2NMe_2) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −22.1 ppm.

Crystal Structure determination of [$ZrCl_2(L^2)$] (10), [$ZrCl_2(L^4)$] (12) and [$Zr(NMe_2)_2(L^1)$] (15): Crystals of **10**, **12** and **15** were grown by slowly evaporating pentane (**10**, **15**) or Et_2O (**12**) from solutions of the compounds. The crystals were placed in Lindemann glass

[a] $R1 = \|\|F_o| - |F_c\|/|F_o|$; $wR2 = \{[w(F_o^2 - F_c^2)^2]/[w(F_o^2)^2]\}^{1/2}$.

capillaries and centred on a four-circle Philips PW1100 diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), at room temperature, following standard procedures. The diffraction data were corrected for Lorentz polarisation effects and for absorption, as described by North et al.[10]

The structures were solved by standard direct methods[11] and subsequently completed by Fourier syntheses. Non-hydrogen atoms were refined anisotropically in all the structures. The hydrogen atoms were introduced at the calculated positions with fixed isotropic thermal parameters (1.2 U_{equiv} of the parent carbon atom), except for the hydrogens of the CH_2 moiety of $ZrCl_2(L^2)$ (**10**), which were located from Fourier maps and refined isotropically. The C(2) carbon of **12** is disordered in two positions with an occupation factor of 0.5. Figure 1B shows only one of the two positions of C(2).

Structure refinement and final geometrical calculations were carried out with the SHELXL-97[12] program, implemented with the WinGX package.[13] Drawings were produced by using the ORTEP II program.[14] Crystallographic data are listed in Table 4. CCDC-207384 (**10**), -220157 (**12**) and -207385 (**15**) contain the supplementary crystallographic data for this paper. The data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The authors thank Mrs Annarosa Moresco (ICIS-CNR, Padova) for the elemental analyses. VP is indebted to Prof. Fausto Calderazzo (Università di Pisa), Dr. Lorella Marchetti (Università di Pisa) and Dr. Sergio Tamburini (ICIS-CNR) for helpful discussions and insightful comments.

[3] [3a] Assuming an octahedral coordination polyhedron for the metal centre in $ZrY_2(L)$, two coordination modes can be proposed, namely symmetric and asymmetric, and two isomers are postulable for the symmetric mode, namely *cis* and *trans* (vide infra). [3b] As far as the NMR-based solution molecular structure elucidation of $ZrY_2(L)$ is concerned, when symmetrically coordinated to the ZrY_2 moiety, L should show equivalent methylene (^{1}H, ^{13}C) resonances for the two $SiN(CH_2)_nX$ moieties. On the other hand, the two halves of the asymmetrically coordinated L should be nonequivalent.

[6] At room temperature the amino NMe_2 methyl groups are equivalent (^1H, ^{13}C), but at 193 K they yield two signals in agreement with the proposed molecular structure, suggesting exchange of the two methyl groups at room temperature.

[7] Harald Günther, "NMR spectroscopy", 2nd edition, John Wiley & Sons, Chichester, **1994**, p. 335.

[8] In principle, also electronic factors should be taken into account, specifically the Zr−NMe_2 π-bonding. Nevertheless, due to the similar nature of **15** and **17**, this contribution is expected to be similar in the two complexes, thus making the above-mentioned steric factors decisive in influencing the exchange mechanism.

Electronic Structures and Reactivities of Corrole−Copper Complexes

Inna Luobeznova,[a] Liliya Simkhovich,[a] Israel Goldberg,*[b] and Zeev Gross*[a]

Keywords: Copper / Cyclic voltammetry / Electronic structure / Porphyrinoids / Structure elucidation

The spectroscopic and electrochemical examination of the mononuclear copper complexes of 5,10,15-tris(pentafluorophenyl)corrole and 5,10,15-tris(2,6-dichlorophenyl)corrole (**1a** and **2a**, respectively) and of the corresponding dinuclear corrole dimers **1b** and **2b** reveal the existence of two almost degenerate electronic states. The lower state consists of copper(III) ions coordinated by closed-shell corrolato trianions and the higher state is composed of copper(II) ions chelated by open-shell corrolato dianions. The contributions from both states are evident in the molecular structure of monomeric and mononuclear **2a**, which displays a distorted square-planar coordination geometry around the metal ion and short Cu–N bond lengths typical of copper(III), together with some non-equivalence of the C_{α}–C_{meso} bond lengths that might reflect the open-shell character of the macrocycle. The latter state is most likely to be responsible for the dimerization process.

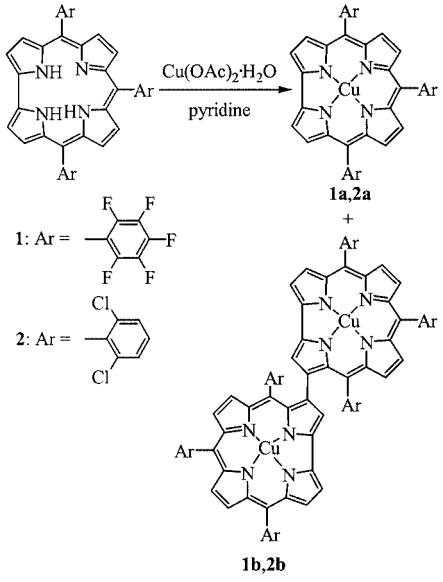
Introduction

Recent years have evidenced a real renaissance in the chemistry of corroles,[1,2] due to the introduction of three facile synthetic methodologies for preparation of triarylcorroles: the solvent-free condensation of pyrrole and aldehydes,[3] the modified Rothemund procedure,[4] and the condensation of dipyrromethane with aldehydes.[5,6] Among all the new corroles, the *meso*-pentafluorophenyl-substituted derivative H_3(tpfc) (**1** in Scheme 1) is by far the most intensively studied. This single corrole and its variants have been shown to support a large variety of metal ions (Cr,[7] Mn,[8] Fe,[9] Ru,[10] Co,[9,11] Rh,[9,12] Ni,[13] Pd,[12] Cu,[12] Zn,[14] Al,[15] Ga,[16] Ge,[9b] Sn,[9b] P[9b]) and many of these complexes have been fully characterized in several oxidation and coordination states. The novel features that were found for **1** and its metal complexes include very high fluorescence quantum yields,[13,14] easily achieved chirality,[10,12] potent catalytic activity,[17] facile methodologies for further functionalization,[18] and selective interactions with tumor cells.[19] Another important development is the introduction of corroles with *meso*-aryl groups that contain large *ortho*-phenyl substituents (Cl, CH_3), whose impact in affecting catalysis was demonstrated recently.[20]



Scheme 1

One of the first metal ions inserted into the N_4 coordination core of corroles was copper,[21] but both the structural and electronic features of the complexes remained ill-defined for a very long time until, in 1997, Vogel and coworkers provided new insights into these issues by the isolation and full characterization of Cu(tetmc).[22a] This complex displays a square-planar coordination geometry, consistent with a d^8 copper(III) ion chelated by a closed-shell corrolato trianion. This appeared to be the ground state in solution as well, although the large shifts and broad signals of the resonances in the ^{1}H NMR spectra obtained at room

temperature clearly demonstrate that the electronic state with a copper(II) ion coordinated by an open-shell corrole (formally a dianion radical, but usually referred to as a corrole cation radical) is only slightly higher in energy. This coexistence of copper(III) and copper(II) radicals was also predicted by the DFT calculations of Ghosh et al.[22b] An additional complication exists in the electrochemistry of corrole−copper complexes, as demonstrated by Kadish and co-workers.[23] Reduction of Cu(oec) provided a simple copper(II) complex, but a dimeric product was formed upon oxidation. The latter was assigned as a non-covalent dimer held together by strong interactions between the π-systems of the corroles. This is reminiscent of the features of metalloporphyrin π-cation radicals,[24] although definite structural proof is still not available for corroles.

As part of our interest in the preparation and utilization of the metal complexes of **1**, isolation of its copper complex was one of the earliest goals that we wanted to achieve.[12] Insertion of copper proceeded well, but the corresponding complex, Cu(tpfc) (**1a**), was not stable in solution. Even carefully purified **1a** was converted within a few hours into a mixture of new complexes, which, according to mass spectrometry, are dimeric. This is reminiscent of our recent observation with the cobalt complexes of **1**: pentacoordinate [Co(tpfc)(PPh_3)] and hexacoordinate [Co(tpfc)(pyridine)$_2$] are very stable complexes, but the tetracoordinate Co(tpfc) is converted in high yield into a single isomer of a C−C-bound corrole dimer with two cobalt(III) ions.[11] This suggests that the complexes obtained from **1a** are analogous dimers, with a lower selectivity in the C−C bond formation being responsible for the observation of several isomers. In any case, the instability of **1a** in solution significantly hampered further research as it complicates the spectroscopic investigations and interferes with attempts to grow X-ray quality crystals. Because of these shortcomings, we have prepared the copper complex of 5,10,15-tris(2,6-dichlorophenyl)corrole [H_3(tdcc),[3a,3g] **2** in Scheme 1], anticipating that dimerization of this sterically protected corrole will be a less severe problem. Indeed, the much higher stability of monomeric **2a** allowed for its characterization by X-ray crystallography and the electronic states of the complexes were elucidated by a combination of spectroscopic methods and electrochemistry.

Results and Discussion

Synthesis

All the copper complexes were obtained from the reactions of the corresponding corrole with $Cu(OAc)_2{\cdot}H_2O$ in pyridine (Scheme 1). The insertion of copper was found to be a facile process for both **1** and **2**, proceeding to completion at room temperature within 30 min, and the red complexes **1a** and **2a** were obtained in 73 and 85% yield, respectively. The lower yield for the formation of **1a** was found to reflect its instability in solution: it is transformed into a mixture of green compounds within a few hours at room temp. All the green complexes display identical mass spectra, consistent with two copper ions coordinated by a dimeric corrole. This was confirmed by isolation of the major green complex (**1b**), whose spectroscopic features are consistent with the structure shown in Scheme 1. The other green complexes are most likely isomers of **1b** that differ in the identity of the carbon atoms that form the bond between the corroles. Three isomers are possible, even when only the more reactive carbon atoms of rings A and D are taken into account. The red complex **2a** is much more stable: only a minute amount of green dinuclear material is obtained when its solutions in CH_2Cl_2 are left for two weeks at room temp. This allowed us to grow X-ray quality crystals of **2a** and for its characterization by various spectroscopic methods. It was also possible to obtain appreciable amounts of the dinuclear complex **2b** (as a single isomer) by performing the copper insertion reaction at higher temperatures.

Electrochemistry

The cyclic voltammograms (CVs) of **1a** (freshly prepared) and **2a** displayed in Figure 1 show that the half-wave potentials of the former complex are more positive (easier to reduce and harder to oxidize) than for the latter, as expected for a corrole with more electron-withdrawing *meso* substituents. Based on a comparison with non-transition-metal complexes of **1**, wherein corrole-centered reductions occur below −1.0 V, the reduction waves [Cu(tpfc): $E_{1/2}$ = 0.22 V; Cu(tdcc): $E_{1/2}$ = 0.06 V] may be confidently assigned as reflecting metal-centered processes. The processes occurring with $E_{1/2}$ of 1.01 and 0.92 V for **1a** and **2a**, respectively, were assigned as reflecting corrole-centered oxidations based on the similarity of the oxidation potentials to that of gallium(III) complexes of **1** and **2**. The quite different spacing of the redox couples in **1a** (0.79 V) and **2a** (0.86 V) is also consistent with different centers involved in the reduction and oxidation processes. Taken together, the CVs of **1a** and **2a** indicate that while their reduction is metal-centered, the oxidation is corrole-centered. This was further confirmed

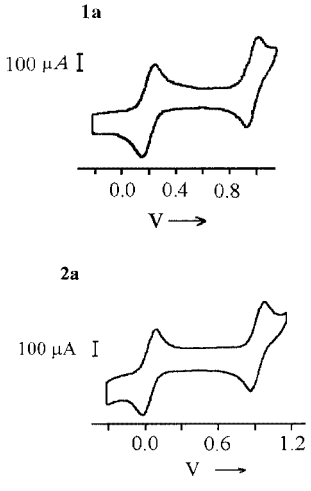

Figure 1. Cyclic voltammograms of Cu(tpfc) (**1a**: $E_{1/2}$ = 0.22 V and 1.01 V) and Cu(tdcc) (**2a**: $E_{1/2}$ = 0.06 and 0.92 V), in benzonitrile/5 × 10^{-4} M TBAP

for **2a** by its chemical reduction ($Na_2S_2O_4$, EtOH/H_2O/Ar) and oxidation {[(4-Br-C_6H_5)N]$^+SbCl_6^-$, CH_2Cl_2}: the EPR spectra (see below for more details) are characteristic of corrole−copper(II) and −copper(III) radicals, respectively.

The CV of **2b** (Figure 2) shows that the subunits of the dinuclear dimeric corrole are not strongly interacting. Both the reduction and the oxidation waves are partially resolved, with $E_{1/2}$ = −0.17, 0.05 V and 0.82, 0.95 V, respectively. The similarities of the redox potentials of **2b** to those of **2a** suggest that the former complex undergoes stepwise reduction of the copper(III) ions at low potentials and stepwise oxidation of the corrole subunits at more positive potentials.

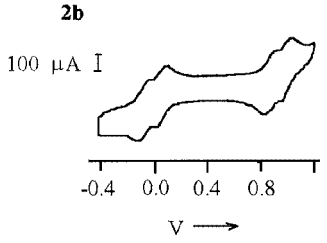

Figure 2. Cyclic voltammogram of the dinuclear corrole dimer **2b** ($E_{1/2}$ = −0.17, 0.05 V and 0.82, 0.95 V) in benzonitrile/5 × 10^{-4} M TBAP

Spectroscopy

Complexes **1a** and **2a** are EPR-silent and their NMR spectra at low temperature (Figure 3a, c) display resonances that are sharp enough to determine the characteristic vicinal coupling constants of the β-pyrrole hydrogen and the *meso*-C_6F_5 fluorine atoms ($J_{H,H} \approx 4$, $J_{F,F} \approx 23$ Hz). This data is consistent with expectations for diamagnetic square-planar d^8 complexes, suggesting that **1a** and **2a** contain low-spin copper(III) ions coordinated by closed-shell corroles. The first clue that this description might be oversimplified is that the ^{1}H NMR chemical shifts are at higher field (δ = 6.9−7.7 ppm) than in the corresponding free-base corroles and their complexes with other diamagnetic metal ions (δ = 8.2−9.2 ppm).[3−5,11,15,16] What is more, both the ^{1}H and the ^{19}F NMR resonances are much broader in the spectra recorded at higher temperatures (Figure 3b, d). These changes are fully reversible, suggesting a coexistence of dia- and paramagnetic electronic states, with the former being dominant at lower temperatures. There are three conceivable possibilities that might explain the indications for diamagnetism at low temperatures and paramagnetism at high temperatures: a low-spin vs. high-spin corrole−copper(III) complex, a dimeric (cofacial) vs. monomeric corrole−copper(II) radical, and a corrole−copper(III) complex vs. a corrole−copper(II) radical. The first suggestion is the least likely: the large ligand field stabilization energy (LFSE) of copper(III) enforces a d^8 low-spin configuration in square-planar geometry, while higher coordination numbers should actually be less populated at high temperatures. The second proposal is more probable, especially since similar temperature effects have been observed for porphyrin−copper(II) radicals. However, non-covalent dimerization of π-cation radical complexes (of porphyrins and corroles) is only effective in the absence of prohibitive steric effects.[24] This is not the case for **1a** and **2a**, as proven by the crystal structure of the latter (vide infra). Accordingly, the only reasonable explanation that remains is that the ground state of the corrole−copper(III) complex is only slightly lower in energy than that of the corrole−copper(II) radical (Scheme 2). The contribution of the latter state increases with temperature, exactly as proposed by Vogel and co-workers for the copper complex of β-alkyl-substituted

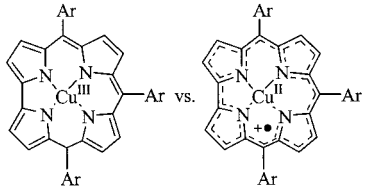
corroles.[22] The small difference between the electronic states could also account for the apparent sensitivity of the electronic absorption spectra of triarylcorrole−copper complexes to substitution on the aryl groups.[25]



Scheme 2

The mass spectra of **1b** and **2b** correspond to $[(\mathbf{1a})_2-2H]$ and $[(\mathbf{2a})_2-2H]$, respectively, and are consistent with two copper ions coordinated by covalently bound corrole dimers (Scheme 1). The seven rather than eight β-pyrrole hydrogen atoms that are evident in the NMR spectra of **2b** (Figure 4) confirm the loss of two protons upon dimerization. What is more, since there is only a total number of seven different β-pyrrole hydrogen atoms in each of the complexes, substitution must have occurred at the same carbon atom in each of the subunits, otherwise 14 different β-pyrrole hydrogen atoms should be apparent. The same conclusion holds for **1b**, whose ^{19}F NMR spectrum (Figure 4) reveals three rather than six types of C_6F_5 rings. Unfortunately, we were not able to grow X-ray quality crystals of **1b** or **2b**. However, the independently demonstrated high reactivity of C3 in other metal complexes of corrole **1** and the full characterization of the cobalt(III) analog of **1b**,[11,18] suggest that the single bond in **1b** and **2b** is also between the C3 atoms of the subunits.

Since all isolated complexes are EPR-silent, we turned our attention to the spectra of the reduced and oxidized complexes. Chemical reduction of **2a** leads to a spectrum that is typical of copper(II) (Figure 5a). The spectrum is centered at $g = 2.033$, with a four-line hyperfine splitting due to the $I = {}^3/_2$ ^{63}Cu ion, with $a_{Cu} = 207.12$ G. The expected nine-line superhyperfine splitting from the ^{14}N atoms of the corrole is best seen in the high-field part of the spectrum, with $a_N = 17.64$ G. These values are similar to those obtained by Kadish and co-workers for $[(oec)Cu]^-$, where $a_{Cu} = 227$ G.[23,26] The spectrum of one-electron-oxidized **2a** ($[\mathbf{2a}]^+$) is very different (Figure 5b). It contains a single and quite sharp line, resembling that of the corrole−gallium(III) radical $[Ga(tpfc^{+\cdot})]^+$.[16] In addition, a comparison between the electronic spectra of $[\mathbf{2a}]^+$ and **2a** reveals that the Soret-like band of the former is less intense and blue-shifted and that it contains a new band at long

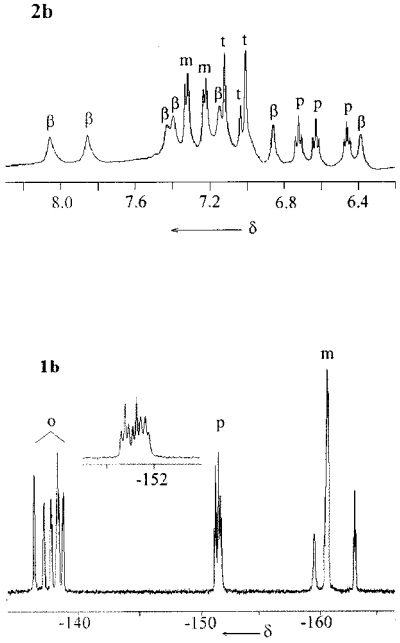


Figure 4. ^1H NMR spectrum of **2b** at 320 K (β = β-pyrrole CH, p = *para*-H, m = *meta*-H, t = $[D_7]$toluene), and ^{19}F NMR spectrum of **1b** at 275 K, in $[D_8]$toluene; inset: extension of the *para*-F resonances

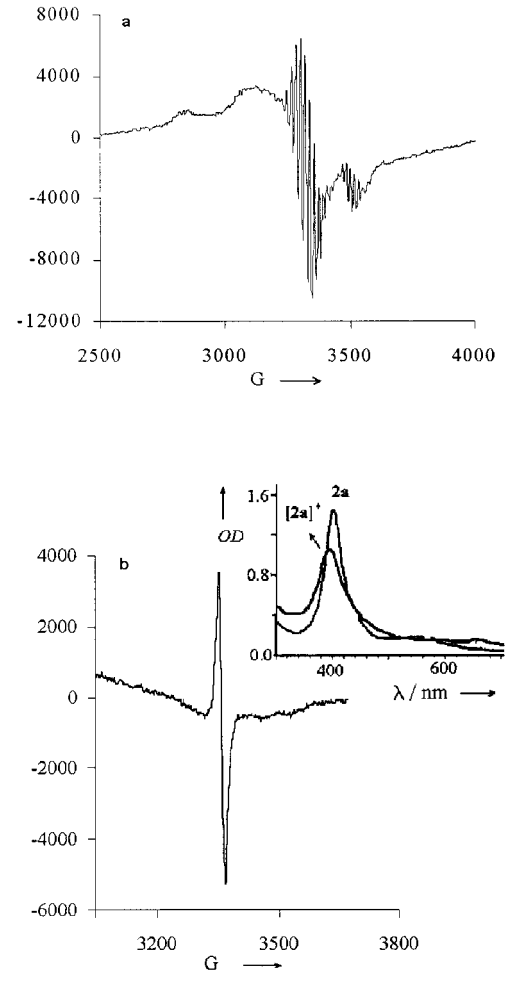

Figure 5. EPR spectra of (a) reduced **2a** (by $Na_2S_2O_4$ in EtOH/H_2O/Ar; instrument settings: power 20.070 mW, modulation frequency 100 kHz, modulation amplitude 10 G, $T = 150$ K) and (b) oxidized **2a** {by $[(BrC_6H_4)_3N]^+SbCl_6^-$, recorded in CH_2Cl_2; instrument settings: power 0.635 mW, modulation frequency 100 kHz, modulation amplitude 10 G, $T = 150$ K}; inset: UV/Vis spectra of **2a** and its oxidation product in CH_2Cl_2

wavelengths (λ_{max} = 654 nm; Figure 5b, inset). This data allows for quite a confident identification of $[\mathbf{2a}]^+$ as a corrole−copper(III) cation radical. This is remarkably different from the situation for β-pyrrole-alkylated corroles, which dimerize to as yet unidentified products.[23]

Structural Aspects

The X-ray structure of **2a** determined at ca. 110 K is presented in Figure 6. There are two structurally similar but crystallographically independent molecules of the corrole in the asymmetric unit (labeled as unprimed and primed atoms). The 23-atom corrole macrocycle is significantly ruffled, the individual atoms deviating from the mean plane by between −0.28 and +0.21 Å in one species and between −0.22 and +0.23 Å in the other unit (the r.m.s. of these deviations is 0.13 Å). The copper ion resides at the center of the corrole ring and, as is commonly observed for porphyrinoid−copper systems (see below), is four-coordinate. The Cu−N(pyrrole) bond-length range is 1.874(3)−1.891(3) Å in one unit and 1.880(3)−1.890(3) Å in the other unit. In the crystal, the monomeric units of **2a** are arranged in columns along the *b* axis, alternating in their relative orientation (Figure 6b). The dihedral angle between the mean planes of neighboring corrole rings is 44°. This allows the copper center of any given moiety to form van der Waals contacts from above and below with one of the chlorine substituents of the adjacent corroles in the column. The corresponding contact distances are Cu···Cl′ 3.366 and 3.521 Å and Cu′···Cl 3.663 and 3.730 Å. There is no interaction between the antiparallel inversion-related columns in the triclinic crystal, and the *n*-heptane crystallization solvent is included between them. The Cu−N coordination distances in **2a** are similar to those observed in Cu(tetmc), the only other corrole−copper complex for which crystallographic data are available.[22] In the latter, the d^8 Cu^{III} ion is four-coordinate as well, and the observed Cu−N bonds are within 1.866−1.896 Å. However, due to the apparent π-π dimerization of the Cu(tetmc) molecules, at 3.43 Å between the parallel and overlapping units within the dimer, their central corrole framework is somewhat less corrugated (with deviations of individual atoms from the corrole plane confined within −0.21 to +0.17 Å, and r.m.s. deviation of 0.08 Å) than **2a**.

It is of further interest to compare the current findings with those observed for the copper complex of tetra(2,6-dichlorophenyl)porphyrin.[24b] In this compound the porphyrin ring is only slightly saddled (r.m.s. deviation of the porphyrin atoms from their mean plane is 0.11 Å), with the four-coordinate copper ion residing at the center of the ring. However, the Cu−N bonds within the porphyrin macrocycle (1.957−2.019 Å) are significantly longer than in the corrole. Adjacent porphyrin units in this structure are also markedly inclined with respect to each other, but no specific interaction is evident between them. Moreover, in many tetracoordinate Cu^{II} complexes of tetraarylporphyrins the Cu−N bond lengths are within a similar general range of 1.97−2.00 Å, irrespective of the intermolecular organization.[27] Based on the above, and related evidence from other square-planar $Cu^{III}-N_4$ complexes with noncyclic ligands,[28] we may thus safely conclude that the much shorter Cu−N bonds in **2a** are supportive of the corrole−copper(III) electronic state.

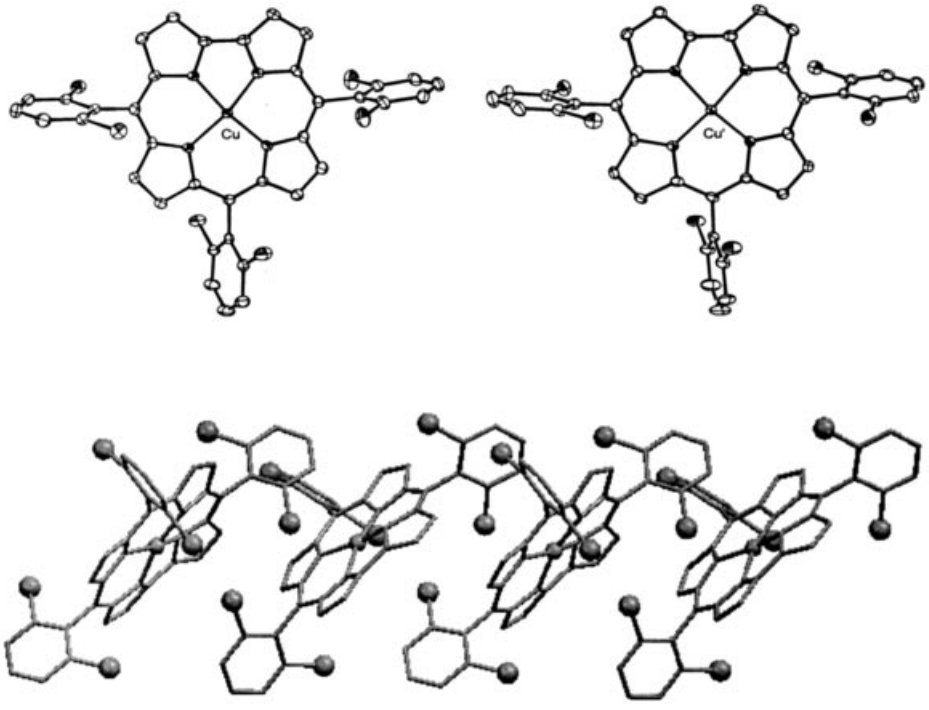

Figure 6. (top) ORTEP illustration of the two crystallographically independent corrole species of **2a** (the atomic displacement parameters are represented by 50% probability ellipsoids); (bottom) the columnar intermolecular organization of the corroles along the *b* axis of the crystal, showing that the corrole ring is approached from both sides by the chlorine substituents

Another interesting comparison can be made with the copper complexes of octaethyltetraphenylporphyrin, where both the Cu^{II} and formally Cu^{III} complexes are available.[24c] In this case, due to the steric crowding around the molecular periphery caused by the substitution of eight alkyl and four aryl residues, the porphyrin core is severely distorted from planarity, adopting a highly puckered S4-saddle conformation. This seems to have little effect on the coordination distances of the copper ions positioned at the center, which are within 1.966−1.980 Å in the porphyrin−Cu^{II} complex and within 1.968−1.979 Å in the oxidized porphyrin−Cu perchlorate moiety, mostly due to the fact that the oxidation of this system is porphyin-centered rather than metal-centered.

In porphyrins, an alternation of shorter and longer bonds within the inner 16-membered ring π-network (comprised of the N, α-C and *meso*-C) atoms is one of the criteria for oxidation of the macrocycle.[29] Although not always present, it provides a strong indication that oxidation of the copper(II) complex of octaethyltetraphenylporphyrin affects the porphyrin rather than the metal ion, resulting in a porphyrin−Cu^{II} cation radical species. In the same context, we have examined the distribution of bond lengths within the two crystallographically independent corrole rings of **2a**, as displayed in Figure 7. The observed structure clearly

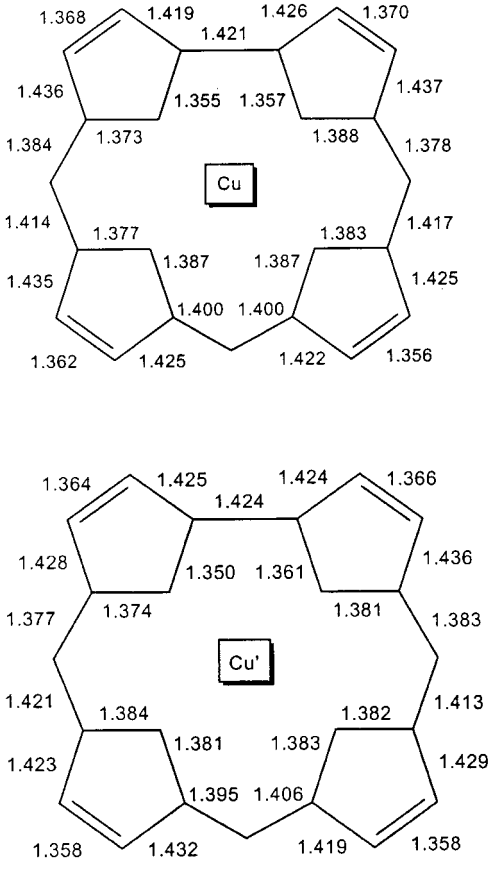

Figure 7. Observed distribution of bond lengths within the central corrole ring of **2a**; the estimated standard deviations for the shown values are 0.005 Å; two crystallographically independent species of the asymmetric unit are shown

shows a portion of an alternating bond length pattern in the "upper" section of the ring close to the C1−C19 bond. This pattern consists of systematically short C_α−N (av. 1.356 Å), long N−C_α (av. 1.379 Å), short C_α−C_{meso} (av. 1.380 Å) and long C_{meso}−C_α (av. 1.416 Å) bonds, while for a closed-shell fully delocalized corrolato trianion one might expect all bond lengths within the N−C_α and the C_{meso}−C_α sets to be equivalent. The observed structural data are thus consistent with the related spectroscopic evidence described above, that the paramagnetic corrole−copper(II) radical state contributes to the structure of **2a** even at the low applied temperature. A different aspect that is emphasized in Figure 7 is that the β-pyrrole bonds are much shorter than all other C−C bonds — they have the characteristics of non-aromatic double bonds. This is a common feature in all crystallographically characterized corroles,[9−11,20] apparently responsible for the facile electrophilic substitution at those positions.

In a broader sense, and of particular relevance to ongoing debates about the assignment of oxidation states in corrole complexes with transition metal ions,[9c,13,30] it is of interest to examine this aspect with the increasing number of crystallographically characterized complexes of **1** and **2**.[31] Accordingly, we have summarized the available data in Table 1.

Inspection of these data reveals that the differences in C_α−C_{meso} bond lengths are smallest in [Ga(tpfc)(py)] (average 0.004 Å), the prototype of closed-shell corrolato−metal complexes, and largest in **2a** (average 0.028 Å), for which the evidence for contribution of open-shell electronic states is the strongest. Within the limit of experimental errors (average ESD of the relevant bond lengths being 0.005 Å), the complexes may be classified by the average difference between C_α−C_{meso} bond lengths: less than 0.01 Å in [Co(tpfc)$(py)_2$], [Ga(tpfc)(py)], [Fe(tpfc)$(py)_2$], and [Ru(tpfc)NO], 0.01−0.014 Å in [Rh(tpfc)(PPh_3)(py)], [Rh(tpfc)(PPh_3)], and [Rh(tdcc)(PPh_3)(py)], and 0.019−0.028 Å in [Fe(tdcc)(NO)], [Fe(tpfc)(NO)], [Fe(tpfc)(Cl)], and [Cu(tdcc)]. Based on this criterion only, this could be indicative for ranking the complexes in terms of the contribution of open-shell electronic states therein. However, one must keep in mind that in all the corrole complexes the $C_{\beta\text{-pyrrole}}$−$C_{\beta\text{-pyrrole}}$ bonds are particularly short, the average differences in C_α−N bond lengths are quite similar, and that even the largest average difference between C_α−C_{meso} bond lengths (0.028 Å) is significantly smaller than in porphyrin radical complexes (> 0.04 Å).

Summary and Conclusions

The reactions of 5,10,15-tris(pentafluorophenyl)corrole and 5,10,15-tris(2,6-dichlorophenyl)corrole with $Cu(OAc)_2{\cdot}H_2O$ lead to the tetracoordinate mononuclear copper complexes **1a** and **2a**, respectively, which can be further transformed into the corresponding dinuclear corrole dimers **1b** and **2b**. All complexes are EPR-silent, and electrochemical measurements coupled with EPR spectroscopy revealed that their reduction and oxidation pro-

cesses are metal- and corrole-centered, leading to corrole−copper(II) and −copper(III) radicals, respectively. The temperature-dependent NMR spectra of **1a** and **2a** revealed the existence of two almost degenerate electronic states. The diamagnetic ground states, favored at lower temperatures, were analyzed as consisting of copper(III) coordinated by closed-shell corrolato trianions and the paramagnetic state as being composed of copper(II) chelated by open-shell corrolato dianions. The contributions from both states are evident in the molecular structure of **2a**, which displays a distorted square-planar coordination geometry around the metal ion and short Cu−N bond lengths typical of copper(III), together with some non-equivalence of the $C_\alpha-C_{meso}$ bond lengths that might reflect the open-shell character of the macrocycle. The radical character is also likely to be responsible for the facile C−C coupling process that leads to the dimerization products. Nevertheless, the contribution of the copper(II) radical state is much lower than in analogous complexes of porphyrins and octaethylbilindione (a noncyclic tetrapyrrole with three protonated N atoms as in corroles),[32] where the Cu−N bonds are much longer. The latter case may be considered at the opposite extreme, based on its magnetic moment and the very large paramagnetic isotopic shifts in its NMR spectrum.

Experimental Section

Physical Methods: The ^1H and ^{19}F NMR spectra were recorded with a Bruker AM 200, operating at 200 MHz for ^1H and 188 MHz for ^{19}F, a Bruker AM 300, operating at 300 MHz for ^1H and 282 MHz for ^{19}F, or a Bruker AM 500, operating at 500 MHz for ^1H. Chemical shifts are reported in ppm relative to residual hydrogen atoms in the deuterated solvents: δ = 7.24, 7.15, 7.00 ppm for chloroform, benzene and toluene, respectively, for the ^1H NMR spectra and relative to $CFCl_3$ (δ = 0.00 ppm) in the ^{19}F NMR spectra. The electronic spectra were recorded with an HP 8452A diode array spectrophotometer and gas chromatographic analysis was performed with an HP-5890 GC equipped with an HP-5 capillary column and FID detector. Mass spectrometry was performed with a Finnigan mat TSQ 70 instrument with isobutane as carrier gas and IR measurements with an FT-IR Bruker Vector 22. The redox potentials were determined by cyclic voltammetry (CV) at ambient temperatures with a home-made voltammograph, using C_6H_5CN solutions, 0.05 M in tetra-*n*-butylammonium perchlorate (TBAP, Fluka, recrystallized three times from absolute ethanol) and about 0.5 mM in substrate. Ag/AgCl was used as the reference electrode. The other experimental conditions are reported in the captions of the corresponding spectra.

Materials: C_6H_5CN (BioLab Ltd.), dichloromethane (Bio-Lab Ltd.), pyridine (Merck), ethanol (Bio-Lab Ltd.), *n*-heptane (Carlo-Erba), *n*-hexane (Bio-Lab Ltd.), $Cu(OAc)_2{\cdot}H_2O$ (Riedel−de Haën), $Na_2S_2O_4$ (Merck), $(BrC_6H_4)_3NSbCl_6$ (Aldrich) and deuterated solvents (Aldrich and Cambridge Isotopes products) were used as received.

Synthetic Methods: The synthetic details for the preparation of H_3(tpfc) and H_3(tdcc) are provided in previous publications.[3a,3b,3e−3g]

Cu(tpfc) (1a) and the Dinuclear Complex 1b: An approximate threefold excess of $Cu(OAc)_2{\cdot}H_2O$ (66 mg, 0.34 mmol) was added to a solution of **1** (100 mg, 0.126 mmol) in pyridine (5 mL) in one portion. TLC examinations (silica gel; *n*-hexane/CH_2Cl_2, 2:1) revealed that the starting material was fully consumed at room temp. within 30 min. The solvents were evaporated from the red-green mixture and **1a** was obtained as a red powder (75 mg, 73% yield) after column chromatography (silica gel; *n*-hexane/CH_2Cl_2, 4:1), together with trace amounts of **1b**. When an identical reaction mixture was heated to reflux for 10 min, both **1a** (32 mg, 30% yield) and **1b** (42.8 mg, 40% yield) could be isolated by column chromatography (silica gel; *n*-hexane/CH_2Cl_2, 10:3). Complexes **1a** and **1b** could not be further purified by recrystallization because of their transformation (within hours) into a mixture of green compounds, all of which were analyzed by mass spectrometry as dinuclear complexes of dimeric corrole (isomers of **1b**).

1a: UV/Vis (benzene): λ_{max} ($\varepsilon \times 10^{-4}$) = 410 (6.17), 550 (0.81) nm. MS (DCI$^-$): *m*/*z* (%) = 856 (100) [M$^-$]. ^1H NMR (toluene, 500 MHz, room temp.): δ = 7.76 (br. s, 2 H), 7.23 (br. s, 2 H), 7.14 (br. s, 2 H), 6.93 (br. s, 2 H) ppm. ^1H NMR (toluene, 200 MHz, 233 K): δ = 7.67 (d, *J* = 3.99 Hz, 2 H), 7.32 (d, *J* = 3.98 Hz, 2 H), 7.23 (unresolved d, 2 H), 7.18 (unresolved d, 2 H) ppm. ^{19}F NMR ($CDCl_3$, 300 MHz, room temp.): δ = −137.11 (d, m, 4 F, *o*-F), −137.97 (m, 2 F, *o*-F), −152.12 (t, *J* = 21.2 Hz, 1 F, *p*-F), −152.35 (t, *J* = 21.2 Hz, 2 F, *p*-F), −160.89 (m, 6 F, *m*-F) ppm.

1b: UV/Vis (benzene): λ_{max} ($\varepsilon \times 10^{-4}$) = 412 (10.95), 566 (1.44) nm. MS (DCI$^-$): *m*/*z* (%) = 1710 (100) [M$^-$]. ^1H NMR ($CDCl_3$, 200 MHz, room temp.): δ = 7.84 (br. s, 2 H), 7.58 (br. s, 2 H), 7.33 (br. s, 2 H), 7.21 (br. s, 2 H), 7.14 (br. s, 2 H), 6.94 (m, 4 H) ppm.

^{19}F NMR ([D$_8$]toluene, 300 MHz, room temp.): δ = −136.04 (s, 2 F, *o*-F), −136.98 (d, *J* = 21.17 Hz, 2 F, *o*-F), −137.56 (d, *J* = 21.17 Hz, 2 F, *o*-F), −138.12 (m, 4 F, *o*-F), −138.62 (d, *J* = 21.17 Hz, 2 F, *o*-F), −151.62 (t, *J* = 21.17 Hz, 2 F, *p*-F), −152.01 (dt, 4 F, *p*-F), −159.79 (s, 2 F, *m*-F), −160.81 (m, 8 F, *m*-F), −163.06 (t, *J* = 21.17 Hz, 2 F, *m*-F) ppm.

Cu(tdcc) (2a) and the Dinuclear Complex 2b: A threefold excess of $Cu(OAc)_2 \cdot H_2O$ (25 mg, 0.12 mmol) was added to a solution of **2** (30 mg, 0.04 mmol) in pyridine (5 mL) in one portion and mixed for 30 min at room temp. After solvent evaporation and column chromatography (silica gel; *n*-hexane/CH_2Cl_2, 4:1), **2a** was isolated as a red powder (26 mg, 85% yield). X-ray quality crystals were obtained by recrystallization from CH_2Cl_2/*n*-heptane. When an identical reaction mixture was heated to reflux for 30 min, **2a** (15 mg, 45% yield) and **2b** (14 mg, 42%% yield) were separated by column chromatography (silica gel; *n*-hexane/CH_2Cl_2, 10:3).

2a: UV/Vis (benzene): λ_{max} (ε × 10^{-4}) = 406 (4.71), 548 (0.56) nm. MS (DCI$^-$): *m*/*z* (%) = 794 (100) [M$^-$]. ^{1}H NMR (toluene, 500 MHz, room temp.): δ = 7.69 (br. s, 2 H), 7.26 (br. s, 2 H), 7.17 (br. s, 2 H), 6.86 (unresolved d, 2 H), 7.10 (d, *J* = 8 Hz, 4 H, *m*-H), 7.04 (d, *J* = 8 Hz, 2 H, *m*-H), 6.68 (t, *J* = 8.25 Hz, 2 H, *p*-H), 6.63 (t, *J* = 8.25 Hz, 1 H, *p*-H) ppm. ^{1}H NMR (toluene, 500 MHz, 240 K): δ = 7.43 (d, *J* = 4.37 Hz, 2 H), 7.19 (d, *J* = 4.37 Hz, 2 H), 7.01 (d, *J* = 4.77 Hz, 2 H), 6.97 (d, *J* = 4.77 Hz, 2 H), 6.92 (d, *J* = 8.34 Hz, 4 H, *m*-H), 6.83 (d, *J* = 8.34 Hz, 2 H, *m*-H), 6.56 (t, *J* = 8.25 Hz, 2 H, *p*-H), 6.50 (t, *J* = 8.25 Hz, 1 H, *p*-H) ppm.

2b: UV/Vis (benzene): λ_{max} (ε × 10^{-4}) = 410 (12.8), 560 (2.14) nm. MS (DCI$^-$): *m*/*z* (%) = 1584 (100) [M$^-$]. ^{1}H NMR (toluene, 500 MHz, room temp.): δ = 7.77 (br. s, 4 H), 7.64 (br. s, 4 H), 6.86 (d, *J* = 4 Hz, 4 H), 6.53 (unresolved d, 4 H), 7.19 (unresolved d, 6 H, *m*-H), 7.06 (unresolved d, 4 H, *m*-H), 6.67 (d, *J* = 8 Hz, 2 H, *m*-H), 6.68 (t, *J* = 8 Hz, 2 H, *p*-H), 6.58 (t, *J* = 8.25 Hz, 2 H, *p*-H), 6.40 (t, *J* = 8 Hz, 2 H, *p*-H) ppm. ^{1}H NMR (toluene, 500 MHz, 235 K): δ = 7.38 (br. s, 2 H), 7.33 (d, *J* = 3.97 Hz, 2 H), 7.26 (d, *J* = 3.97 Hz, 2 H), 6.85 (d, *J* = 4.37 Hz, 2 H), 6.73 (d, *J* = 4.77 Hz, 2 H), 6.44 (unresolved d, 2 H), 7.01 (unresolved d, 2 H), 6.98 (m, 6 H, *m*-H), 6.79 (m, 6 H, *m*-H), 6.54 (t, *J* = 8 Hz, 2 H, *p*-H), 6.54 (t, *J* = 8.25 Hz, 2 H, *p*-H), 6.25 (t, *J* = 8 Hz, 2 H, *p*-H) ppm. ^{1}H NMR (toluene, 500 MHz, 320 K): δ = 8.06 (br. s, 2 H), 7.86 (br. s, 2 H), 7.42 (br. s, 2 H), 7.38 (br. s, 2 H), 7.15 (br. s, 2 H), 6.86 (br. s, 2 H), 6.39 (br. s, 2 H), 7.32 (d, *J* = 7.9 Hz, 6 H, *m*-H), 7.23 (d, *J* = 7.8 Hz, 6 H, *m*-H), 6.72 (t, *J* = 8.07 Hz, 2 H, *p*-H), 6.63 (t, *J* = 8.07 Hz, 2 H, *p*-H), 6.45 (t, *J* = 8.07 Hz, 2 H, *p*-H) ppm.

Chemical Oxidation of [Cu(tdcc)] (2a): Solid $(BrC_6H_4)_3NSbCl_6$ (13 mg, 18 μmol) was added in one portion to a well-stirred solution of **2a** (5 mg, 6 μmol) in CH_2Cl_2. The color changed to yellow-green within a few minutes, after which the solution was filtered and used for the spectroscopic examinations.

Chemical Reduction of [Cu(tdcc)] (2a): A saturated solution of $Na_2S_2O_4$ (2 mg, 0.011 mmol) in H_2O (2 mL) was added in one portion to a 50-mL three-necked, round-bottomed flask containing a solution of **2a** (5 mg, 6 μmol) in ethanol (2 mL). The mixture was stirred under Ar for 5 min, during which time the color changed from red to green. This solution was used for the EPR measurements, still under Ar.

Electrochemistry: The cyclovoltammograms of the complexes were measured for approximately 0.5 mM substrate in 0.05 M TBAP/C_6H_5CN solutions at scan rates of 100 V/s with Ag/AgCl reference electrode. The redox potentials are reported vs. the ferrocene/ferrocenium redox couple observed at 0.4 V vs. Ag/AgCl.

X-ray Crystallography of [Cu(tdcc)] (2a): The crystalline sample of **2a** was covered with a thin layer of light oil and cooled to 110 K in order to minimize the escape of the volatile crystallization solvent and minimize thermal motion/structural disorder effects. The intensity data were corrected for absorption. The structure was solved and refined by standard crystallographic techniques. All non-hydrogen atoms of the corroles were refined anisotropically. The hydrogen atoms were located in calculated positions, and were refined using a riding model with fixed thermal parameters [U_{ij} = 1.2 U_{ij}(eq.) for the atom to which they are bonded]. Complex **2a** crystallized as an *n*-heptane solvate. $2C_{37}H_{17}Cl_6N_4Cu \cdot 1/2C_7H_{16}$, *M* = 1637.68, triclinic, space group $P\bar{1}$, *a* = 12.3630(2), *b* = 16.5760(3), *c* = 17.8710(4) Å, α = 93.615(1), β = 92.401(1), γ = 97.352(1)°, *V* = 3401.9(1) Å^3, *Z* = 2, *T* = 110(2) K, D_c = 1.599 g·cm^{-3}, μ(Mo-K_α) = 1.15 mm^{-1}, 15035 unique reflections to $2\theta_{max}$ = 56.6°, 902 refined parameters, R_1 = 0.055 for 120571 observations with $I > 2\sigma(I)$, R_1 = 0.096 (wR_2 = 0.108) for all unique data, $\Delta\rho \leq 0.64$ e/Å^3. The asymmetric unit consists of two corrole species and half of the *n*-heptane solvate molecule which is located on, and disordered about, a center of inversion. CCDC-206173 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The First Amine-Templated Layered Metal Selenates

D. Udayakumar,[a] Meenakshi Dan,[a] and C. N. R. Rao*[a]

Keywords: Open-framework / Selenium / Hydrothermal chemistry / Amines / Template synthesis

Although a few open-framework metal sulfates and selenites have been synthesized and characterized recently, it has not been possible to prepare the corresponding selenates, probably because of the instability of the +6 oxidation state of Se in alkaline media. We have been able to synthesize, for the first time, organically templated open-framework rare earth selenates with the general formula $0.5[C_2N_2H_{10}][Ln(H_2O)_2(SeO_4)_2]$ (**I**) (Ln = La, Nd or Pr) and $0.5[C_4N_2H_{14}][La(SeO_4)_2]\cdot 0.5H_2O$ (**II**), under hydrothermal conditions in an acidic medium. Crystal data: **I** (Ln = La): triclinic, space group = $P\bar{1}$, *M*r = 491.91, *a* = 7.0105(8) Å, *b* = 7.3772(9) Å, *c* = 9.526(1) Å, α = 82.014(2), β = 84.514(2), γ = 84.247(2)°, *V* = 483.76(1) Å^3, *Z* = 2; **II**: triclinic, space group = $P\bar{1}$, *M*r = 478.91, *a* = 5.94(2), *b* = 7.408(3), *c* = 11.048(2) Å, α = 86.899(2), β = 75.971(1), γ = 79.456(2)°, *V* = 463.7(2) Å^3, *Z* = 4. Being the first report of complex layered selenates, it is likely to stimulate efforts to synthesize other novel open-framework structures making use of the selenate ion as the building unit.

Introduction

A wide variety of organically templated inorganic open-framework materials are known today. Although metal silicates,[1] phosphates[2] and carboxylates[3−5] dominate this area, several organically templated open-framework metal sulfates[6−8] and selenites[9−11] have also been prepared more recently. The first organically templated layered selenite was synthesized by Harrison et.al,[9] followed by the reports of three-dimensional as well as other layered metal selenites.[10−11] To the best of our knowledge, no organically templated layered metal selenates are known hitherto. While the most stable oxidation state of S is +6 as in SO_4^{2-}, that of Se is +4 (SeO_3^{2-} or $Se_2O_5^{2-}$). The reduction potential of the SO_4^{2-}/SO_3^{2-} couple is 0.119V while that of the SeO_4^{2-}/SeO_3^{2-} couple is only 0.03V in alkaline media. This has direct implications on the stability of the compounds of oxy anions of selenium. Selenites are thus commonly obtained as products even though one may start with H_2SeO_4 as source of Se. This has been encountered by us in few instances[10] and it is probably because of this difficulty that it has not been possible to prepare open-framework metal selenates in the presence of amines. In this article, we report the first successful synthesis and characterization of organically templated open-framework lanthanum selenates, $0.5[C_2N_2H_{10}][Ln(H_2O)_2(SeO_4)_2]$ (**I**) (Ln = La, Nd or Pr) and $0.5[C_4N_2H_{14}][La(SeO_4)_2]\cdot 0.5H_2O$ (**II**), prepared hydrothermally under acidic conditions.

Results and Discussion

$0.5[C_2N_2H_{10}][Ln(H_2O)_2(SeO_4)_2]$ (I) (Ln = La, Nd or Pr)

We shall discuss the structure of the La compound as a representative of this isomorphous group of compounds. The asymmetric unit of **I** contains 14 non-hydrogen atoms of which twelve belong to the inorganic framework and two to the amine (ethylenediamine) as shown in Figure 1 (a). There are two crystallographically distinct Se atoms and a unique La atom, with half of the amine appearing in the asymmetric unit. The lanthanum atoms are nine-coordinate with seven oxygen atoms from two selenate anions [Se(1)X2, Se(2)X5] and two oxygen atoms from water ligands. Each La is connected to two neighboring La atoms by La−μ-O−La linkages, through three-coordinate oxygen atoms (O2 and O6). The Se(1)O_4 tetrahedron shares corners (O1 and O3) with two adjacent LaO_9 polyhedra. The remaining two oxygen atoms O7 and O8 are part of terminal Se=O groups. The Se2 atom forms five Se−O−La linkages via a two-coordinate O10 atom, and the three-coordinate O2 and O6 atoms. We thus observed three types of Se−O bonds: Se−O, Se=O and Se−μ_3-O, with average bonds lengths of 1.637 Å, 1.62 Å and 1.645 Å respectively. Bond Valence Sum (BVS) calculations for the La and Se atoms [La(1) = 3.13, Se(1) = 6.14 and Se(2) = 5.98] clearly show the oxidation states of the La and Se to be +3 and +6 respectively. The framework stoichiometry of $La(H_2O)_2(SeO_4)_2$ creates a net framework charge of −1, which is balanced by the presence of half of the diprotonated ethylenediamine.

The structure of **I** involves a two-dimensional covalently bonded framework built up of LaO_9 polyhedra and SeO_4 tetrahedra, the former being connected through La−μ_3-

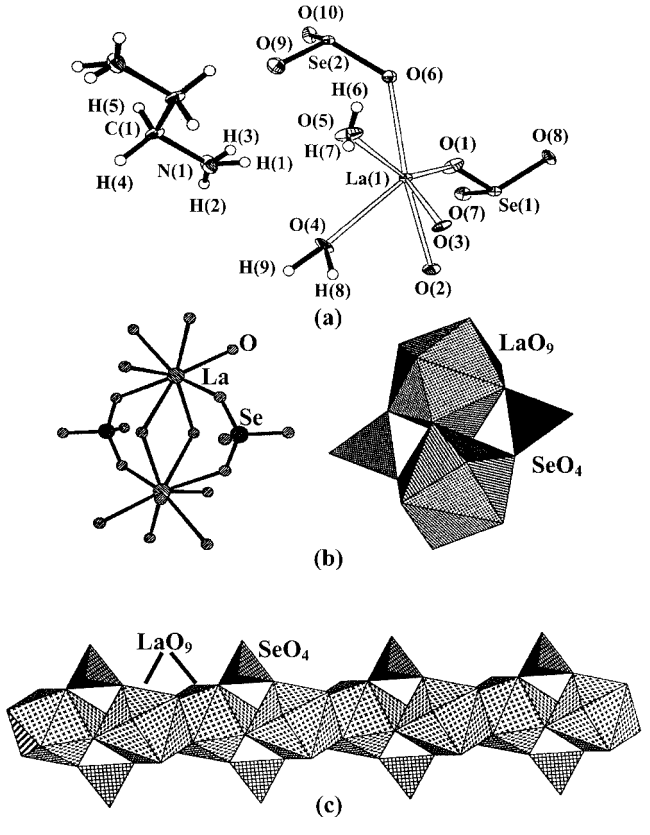

Figure 1. (a) ORTEP plot of $0.5[C_2N_2H_{10}][La(H_2O)_2(SeO_4)_2]$ (**I**); the asymmetric unit is labeled; thermal ellipsoids are given at the 50% probability level; (b) ball and stick, and polyhedral representation of the secondary building unit, SBU-4 in **I**; note the presence of two three-membered rings (La_2Se); c) connectivity between the SBU-4 units creating an infinite chain of edge-shared LaO_9 polyhedra

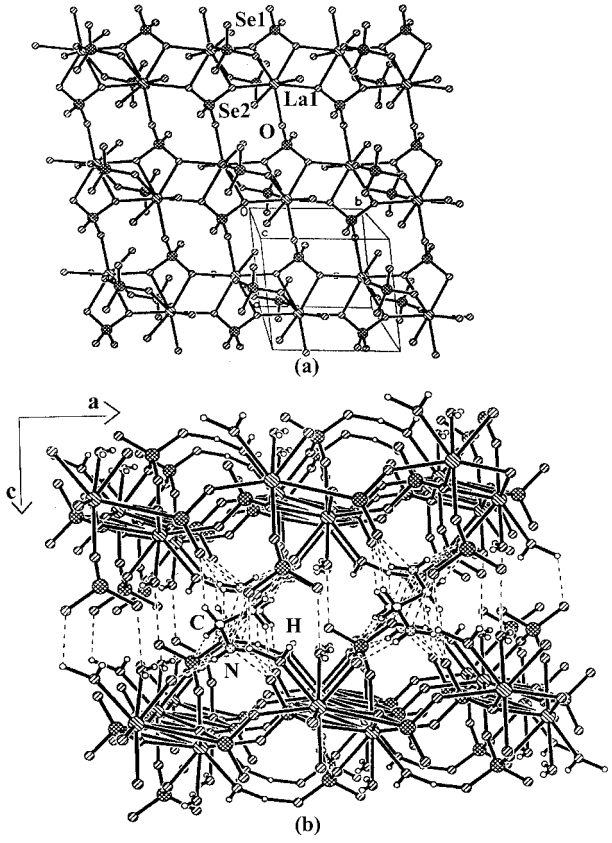

Figure 2. (a) Ball and stick representation of the inorganic layer of **I**, in the *ab* plane; note the presence of two different types of chains; (b) view down the crystallographic *b* axis showing the packing of layers in **I**; hydrogen-bonding interactions between the amine and the framework oxygen atoms are shown by dotted lines

O−La linkages. The topology of the layer in **I** can be described in terms of a secondary building unit (SBU), constructed by capping the two edge-shared LaO_9 polyhedra by two $Se(1)O_4$ groups as shown in Figure 1 (b). Such SBUs, described as SBU-4 by Ferey,[15] have been observed in several metal phosphate systems.[16] The SBU-4 units are linked by three-coordinate oxygen atoms (O2 and O6) forming an infinite chain-like structure consisting of edge-shared LaO_9 polyhedra propagating in a zig-zag fashion as shown in Figure 1 (c). Such a chain can be considered as a tetrahedrally decorated rutile type chain as in a recently reported FePO system.[17] The chains run parallel to the *b* axis and are covalently connected by the $Se(2)O_4$ groups via La−O−Se linkages creating edge-shared four-membered rings (ladder). The $Se(2)O_4$ units also share an edge with neighboring LaO_9 polyhedra along the chain, where as the $Se(1)O_4$ units are involved only in capping the LaO_9 polyhedra along the chain. The structure of **I** is thus made of two types of chains arranged in an ABAB fashion in the *ab* plane (Figure 2, a). The ethylenediamine cations occupy the interlayer sites, forming hydrogen bonds with the framework oxygen atoms (Figure 2, b).

$0.5[C_4N_2H_{14}][La(SeO_4)_2]\ 0.5H_2O$ (II)

The asymmetric unit of **II** (Figure 3, a) contains fifteen non-hydrogen atoms of which eleven belong to the inorganic framework and three to the amine (piperazine). There are two crystallographically distinct Se atoms and a unique La atom, with half of the amine appearing in the asymmetric unit. Two bidentate and five monodentate selenate anions give rise to the nine-coordination of the La atoms. In the framework structure, each lanthanum atom is connected to three neighboring lanthanum centers by La−μ-O−La linkages through three-coordinate oxygen atoms (O3, O4 and O8). The average La−O bond length is 2.61(8) Å. The Se1 atom makes four Se−O−La linkages with the three neighboring La atoms through a three-coordinate oxygen atom O3 ($Se-\mu_3-O-La_2$ bridge), and two two-coordinate oxygen atoms O1 and O5 (Se−O−La bridge). The Se2 atom is connected to four neighboring La atoms through Se−O−La linkages via two three-coordinate oxygen atoms, O4 and O8 ($Se-\mu_3-O-La_2$), and a two-coordinate oxygen atom, O2 (Se−O−La bridge). The O6 and O7 atoms form terminal Se=O groups. The average Se−O

bond lengths, which are in the range 1.609(9)−1.665(8) Å, are in agreement with the literature value.[18,19] The coordination environments of La and Se are shown in Figure 3 (b). Bond Valence Sum (BVS) calculations show the La and Se atoms to be in +3 and +6 oxidation states, respectively. The framework stoichiometry of La $(SeO_4)_2$ creates a net framework charge of −1, which is compensated by the +1 charge of half of the diprotonated piperazine.

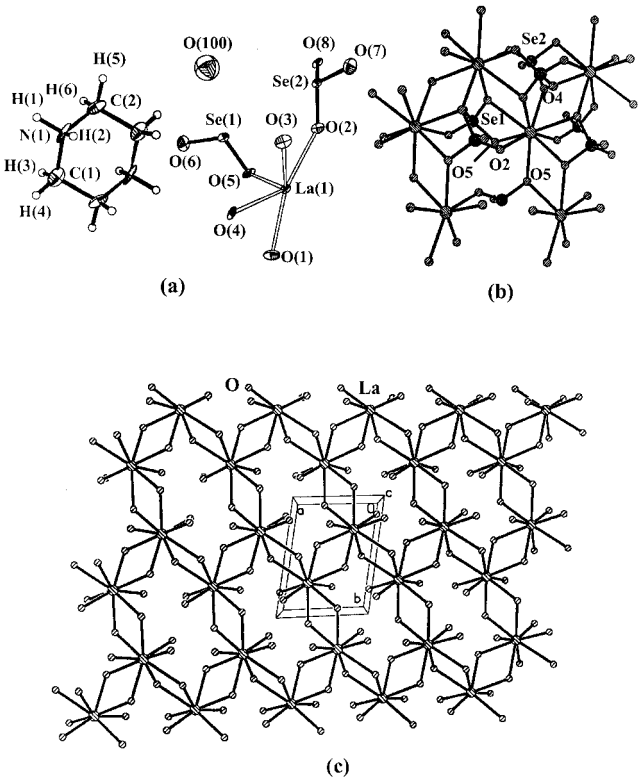

Figure 3. (a) ORTEP plot of $0.5[C_2N_2H_{14}][La(SeO_4)_2]\cdot 0.5H_2O$ (**II**); the asymmetric unit is labeled; thermal ellipsoids are given at the 50% probability level; (b) ball and stick representation showing the coordination environment of La and Se atoms in **II**; (c) the LaO layer in **II**; note the presence of six-membered rings made up of edge-shared LaO_9 polyhedra

The structure of **II** is constructed from macro-anionic framework layers of $[La(SeO_4)_2]^{-1}$, held together by hydrogen-bonding interactions with the amine molecules located in the interlamellar space. The structure involves LaO sheets formed by the edge-sharing LaO_9 polyhedra in the *ab* plane (Figure 3, c). The LaO_9 polyhedra are connected by La−μ-O−La linkages forming chains running parallel to the *b* axis with the alternate La atoms of the chains being bridged by La−μ-O−La linkages along the perpendicular direction. Such connectivity between the chains creates hexanuclear lanthanide rings as shown in Figure 3 (c). Along the chain two LaO_9 polyhedra are capped on either side by the $Se(2)O_4$ units alternatively, which are also connected to the two La atoms in the neighboring chains through a three-coordinate oxygen (O8). In the perpendicular direction, the bridging La atoms are capped by two $Se(1)O_4$ units which share an edge with a LaO_9 polyhedron of the neighboring chains. Accordingly, the SeO_4 units are involved in both capping and bridging the La atoms in the LaO sheets. Such a dual connectivity of the SeO_4 units produces corner-shared four-membered rings (La_2Se_2) propagating along the *a* direction as shown in Figure 4 (a).

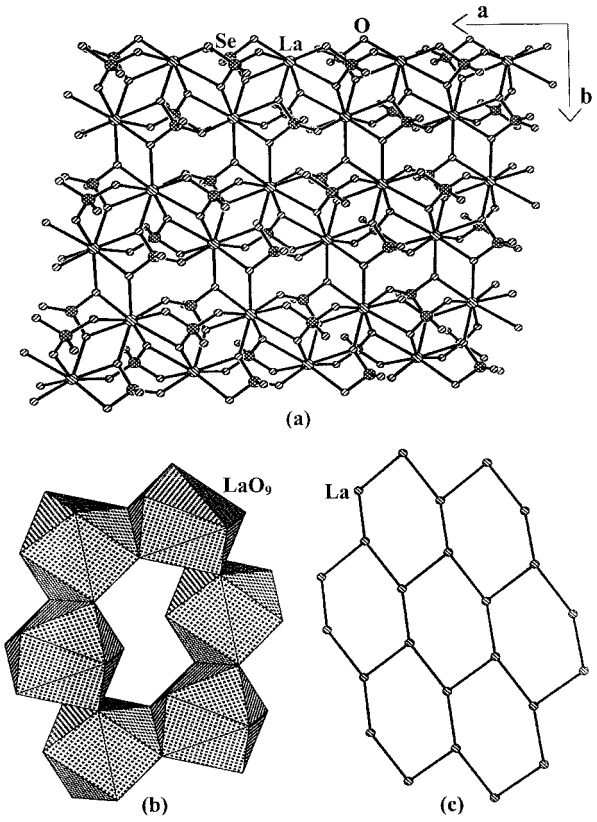

Figure 4. (a) The inorganic layer in **II**; note the capping and bridging of the LaO_9 dimers by two selenate units, resulting in corner-shared four-membered rings along the *a* axis; (b) polyhedral view of a hexanuclear lanthanide ring in **II**; (c) the (6,3) net in **II**

The thermogravimetric analyses (TGA) of **I** and **II** were carried out under N_2 from 30−900 °C at a heating rate of 5 °C/min. Compound **I** decomposes to the selenite in the temperature range 100−330 °C, with the removal of the amine, water and SeO_2 (wt.loss: calcd. 33.02%, obsd. 33.89%) which on further heating, decomposes to a mixture of La_2Se_3 and La_2O_3 (JC, PDS file, card nos: 22-0369, 19-0659), as indicated by the PXRD of the residue at 950 °C. Such thermal decomposition of selenate to selenite has been observed in the case of simple lanthanum selenate hydrates,[20] but the reduction to selenide is unusual. A similar decomposition scheme was observed for **II**, except that in the final stage, all the selenium was lost as SeO_2 to give La_2O_3 as the residue. The overall weight losses for **I** and **II** are 55.94% (calcd. 55.55%) and 57.25% (57.12%), respectively.

Besides being the first examples of two-dimensional organically templated metal selenates, **I** and **II** exhibit several

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

interesting structural features. The La atoms are nine-coordinate in both **I** and **II**, but there are definitive differences between their structures. The layer structure of **I** is constructed from two types of chains: type A consisting of chains formed by the SBU-4 units and type B chains consisting of ladders, arranged in an ABAB fashion. **I** appears to be a unique case whereby the layer structure is formed by alternating chains of SBU-4 units and ladders. An important feature of **II** is the two-dimensional network of edge-sharing LaO_9 polyhedra to form a hexanuclear lanthanide ring (Figure 4, b). The hexanuclear lanthanide rings are surrounded by six similar rings resulting in the (6,3) net shown in Figure 4 (c). This is probably the first such layer architecture in the open-framework compounds containing XO_4^{2-} units. Similar rings containing twelve and 14 edge-shared MO_6 octahedra (M = Mn, Co) occur in metal-organic hybrid compounds containing dicarboxylate units.[21] These organic moieties covalently connect the neighboring metal atoms of the ring through C−O−M bonds. A similar connectivity occurs in **II** whereby the two selenate units connect the La atoms in a ring through Se−μ_3-O−La_2 linkages. The zig-zag chains made from edge-sharing LaO_9 polyhedra run parallel in **I** (Figure 2, b), but the chains in **II**, shifted along the *a* direction, are linked to form the LaO sheet in the *ab* plane (Figure 4, c).

Conclusion

In conclusion, the successful synthesis of amine-templated open-framework metal selenates with layered structures has been demonstrated. The results suggest that it may indeed be possible to prepare other complex metal selenates with 2-D and 3-D networks.

Experimental Section

Synthesis and Initial Characterization: Compounds **I** and **II** were synthesized by employing the hydrothermal method in the presence of organic amines. In a typical synthesis of **I** with Ln = La, $LaCl_3$ (0.25 g) was dissolved in water (2 mL) in a Teflon beaker. To this solution selenic acid (0.26 mL, 40 wt%) was added with stirring followed by ethylenediamine (0.08 mL) and the stirring continued for a further 20 min until a homogeneous gel was obtained. The resultant gel with the molar ratio $LaCl_3/H_2SeO_4/1.2en/111H_2O$ was transferred to a 7 mL capacity PTFE-lined stainless steel autoclave and heated at 150 °C for 48 h. The pH of the starting reaction mixture was 4, and there was no change in pH after the completion of the reaction. Colorless plate-like crystals of **I** were collected, washed with de-ionized water, and dried under ambient conditions. For the synthesis of the Nd and Pr analogues of compound **I**, Nd_2O_3 and $Pr_2(CO_3)_3$ were used as metal sources, respectively. The Nd analogue of **I** was obtained by heating a mixture of molar composition $Nd_2O_3/6H_2SeO_4/4en/600H_2O$ at 100 °C for 120 h whereas the Pr analogue of **I** was synthesized starting with the following mixture: $Pr_2(CO_3)_3$ (0.23 g), H_2SeO_4 (0.78 mL), en (0.1 mL), and H_2O (1.8 mL) at 150 °C for 48 h. For the synthesis of **II**, hydrothermal reactions were carried out at 150 °C for 70 h starting with the following composition, $LaCl_3$ (0.25 g, 1 mmol)/H_2SeO_4 (0.4 mL, 1.5 mmol)/PIP (0.17 g, 2 mmol)/H_2O (1.8 mL, 100 mmol) (PIP = piperazine). Initial characterization of both **I** and **II** was carried out by powder X-ray diffraction (PXRD), energy dispersive analysis of X-rays (EDAX), elemental CHN analysis and thermogravimetric analysis (TGA).

The compounds gave satisfactory elemental analysis. The experimental and calculated (in wt%) values for C, H, and N are as follows: **I** (Ln = La): calcd. C 2.43, N 2.80, H 1.84; found C 2.4, N 2.69, H 1.86; **II**: calcd. C 5.02, N 2.94, H 1.67; found: C 5.12, N 2.92, H 1.61. EDAX indicated that the ratios of Ln (Ln = La, Nd or Pr) and Se are 1: 2 for **I** and **II**, which is in agreement with

and 40 mA. The structures were solved by direct methods using SHELXS-86,[12] which readily revealed all the heavy atom positions (La, Se) and enabled us to locate the other non-hydrogen (C, N and O) positions from the difference Fourier maps. Empirical absorption corrections based on symmetry-equivalent reflections were applied using SADABS.[13] All the hydrogen positions were found in the difference Fourier maps. For the final refinements, hydrogen atoms for both the framework as well as the amine were placed geometrically and held in the riding mode. The last cycles of refinement included atomic positions, anisotropic thermal parameters for all the non-hydrogen atoms and isotropic thermal parameters for all the hydrogen atoms. However hydrogen positions for the extra-framework water (O100) for **II** were not included in the final refinement because of disorder at that site. Full-matrix least-squares structure refinement against $|F^2|$ was carried out using the SHELXTL-PLUS[14] package of programs. Details of the structure determinations and final refinements for **I** (M = La) and **II** are listed in Table 1. Selected bond lengths and bond angles in **I** and **II** are given in Tables 2 and 3, respectively. Various hydrogen-bonding interactions in **I** and **II** are listed in Table 4. The powder X-ray diffraction patterns of **I** and **II** were in good agreement with the simulated patterns based on single-crystal data, indicative of their phase purity. CCDC-212329 (**I**) and -212330 (**II**) contain the supplementary crystallographic data for this paper. These data can be

Iminohydroxamato Early and Late Transition Metal Halide Complexes − New Precatalysts for Aluminoxane-Cocatalyzed Olefin Insertion Polymerization

Alexander Krajete,[a] Georg Steiner,[a] Holger Kopacka,[a] Karl-Hans Ongania,[b] Klaus Wurst,[a] Marc O. Kristen,[c] Peter Preishuber-Pflügl,[d] and Benno Bildstein*[a]

Keywords: N,O ligands / N ligands / Chelates / Transition metals / Polymerization

We report on new families of non-metallocene metal precatalysts for olefin polymerization with titanium, zirconium, vanadium and nickel as the active metal sites. The novel ligand design concept is based on iminohydroxamic acids and their derivatives as the principal chelating units. Various anionic and neutral [*N*,*O*] and [*N*,*N*] ligand systems are easily accessible by a modular synthetic sequence of imidoyl chlorides with substituted hydroxylamines or hydrazines, respectively. Steric protection of the metal coordination site, a necessary requirement for suppression of chain termination pathways of non-metallocene catalysts, is brought about by bulky aryl substituents on the imino nitrogen atoms. Crystal structures of some of the hydroxamato ligands reveal interesting intermolecular hydrogen-bridged structures, whereas in the solid-state structure of one titanium precatalyst a five-membered chelate was observed, in line with the design principle of these systems. Preliminary ethylene polymerization studies with methylaluminoxane-activated metal complexes (M = Ti, Zr, V, Ni) show that the most active systems are [*N*,*O*]$NiBr_2$ catalysts containing neutral *O*-alkyl iminohydroxamate ligands.

Introduction

Olefin polymerization catalysis based on transition metal complexes containing non-cyclopentadienyl ligand frameworks is an extremely active research area[1] since the recent key discoveries of very active (i) (diimine)nickel[2] catalysts, (ii) [bis(imino)pyridine]iron[3] catalysts, and (iii) (salicylaldiminato)nickel[4] and -titanium[5] catalysts. These new systems show some significant advantages in comparison with the more familiar traditional Ziegler−Natta titanium/zirconium or Phillips chromium systems, including (i) simplified ligand design, (ii) metal centers ranging from early to late transition metals, (iii) decreased oxophilicity of the late transition metal complexes, allowing polymerizations and/or copolymerizations of polar monomers or even polymerizations in water,[6] (iv) access to new branched microstructures of the polymers due to "chain-walking" of the catalytically active species,[7] and (v) living polymerization of olefins,[8] giving precise control of polymer molecular weights and giving access to block copolymers and other new materials. Due to the economic importance of polyolefinic materials in general, academic and industrial research activity in this area is very high and an ever increasing number of catalyst improvements and developments are being published and/or patented.[1]

Here we introduce a new family of ligands based on the iminohydroxamate backbone and we report on their transition metal halide complexes as new precatalysts for methylaluminoxane (MAO) activated olefin polymerizations.[9] Our design principle is based on chelating [*N*,*O*] and [*N*,*N*] ligands in accordance with (salicylaldiminato)nickel and -titanium systems reported by the groups of Grubbs[4] and Fujita[5] (Scheme 1). Such salicylaldimine ligands form six-membered metal chelates and for steric protection they usually contain bulky aromatic imine moieties (in most cases 2,6-diisopropylphenyl) and sterically shielding groups in the *ortho* position of the oxygen donor site. In contrast, in our newly designed iminohydroxamate ligands, the metal chelate is an energetically favored five-membered ring and steric protection is provided by bulky arylimino substituents. This is similar to most non-cyclopentadienyl transition metal polymerization catalysts.[1] Scheme 1 outlines the chemical relationships between the parent iminohydroxamic acids (**A**), their *O*-alkyl esters (**B**), their *N*-mono- (**C**) and *N*,*N*-disubstituted amides (**D**), showing the large structural

varieties possible and indicating the obvious ligand design opportunities in these [*N*,*O*] and [*N*,*N*] ligand families.

In a historical perspective, in situ generated hydroxamic acids are well known in qualitative organic analysis for their formation of magenta- or burgundy-colored Fe^{III} complexes,[10] a more or less specific color test for carboxylic acid derivatives in the presence of hydroxylamine. Simple (iminohydroxamato)metal complexes have been investigated for over 100 years,[11] mainly in spectrophotometric and pharmaceutical studies. However, no applications as olefin polymerization precatalysts have been reported up to now.

Results and Discussion

Synthesis and Characterization of Ligands

In general, ligand design is an essential part of the search for new and improved metal catalysts because steric bulk and stereoelectronic effects of the ligand architecture control the selectivity and activity of the metal complexes in their function as catalysts. From a preparative viewpoint the synthetic route should be straightforward, avoid tedious workup and separations, and should be of wide scope, thereby allowing parallel synthetic optimization.

The preparation of our new families of hydroxamate-based ligands fulfill these requirements (Scheme 2). *N*-Substituted benzamides **1a**−**1d** containing *N*-aryl groups with different substitution pattern are easily available in large quantities from the corresponding anilines and benzoyl chloride. Conversion into the corresponding imidoyl chlorides **2a**−**2d** can be brought about quantitatively by treatment with an excess of thionyl chloride employing standard published chemistry.[12] Usually these synthons were prepared in situ only, and used in the following reactions without being isolated. In one case, however, single crystals were obtained by chance (Table 2).

Figure 1 shows the molecular structure of **2a** in the solid state, clearly visible is the steric shielding of the imine functionality by the bulky *N*-(2,6-diisopropyl) group. As a result of the two *ortho*-alkyl substituents the aryl group is tilted by 80.56(10)° in relation to the imidoyl chloride plane, as anticipated and in line with our design principle of axial steric shielding brought about by bulky *N*-imino substituents (vide infra).

Iminohydroxamic acids **3a**−**3f** can be quite easily synthesized by iminoacylation of *N*-monosubstituted hydroxylamines. Similar chemistry has been reported earlier in the literature employing *N*-phenylhydroxylamine.[11b] As antici-

pated, the more nucleophilic nitrogen atom is acylated first in these ambident substrates affording the desired ligands in isolated yields of 18−63%, followed by *O*-acylation which always occurs to a certain degree, dependent on the substitution pattern of the building blocks. Due to the much higher polarity of the mono(iminoacylated) hydroxamic acids **3a**−**3f** in comparison with the undesired *N*,*O*-bis(iminoacylated) side products, separation and purification of the hydroxamic acids can be conveniently accomplished by a simple filtration through a short silica column (see Exp. Sect.). In two cases, **4a** and **4b**, the undesired *N*,*O*-bis(iminoacylated) products were isolated and characterized spectroscopically.

In principle any hydroxylamine can be derivatized in this manner, including the parent unsubstituted hydroxylamine. However, the starting hydroxylamines containing one *N*-organo substituent were chosen because the *N*−H acidic site in these iminohydroxamic acids is blocked. This enables activation of the corresponding metal complexes with methylaluminoxane (vide infra) without undesired *N*-deprotonation or *N*-alumination, respectively.

Iminohydroxamic acids **3a**−**3f** are stable organic compounds and white to yellow in color. Relevant spectroscopic properties include characteristic IR stretching vibrations due to the imino groups ($\nu_{C=N}$ = 1598−1630 cm^{-1}), and diagnostic low-field ^{13}C NMR chemical shifts of the imino functionalities ($\delta_{C=N}$ = 147.7−150.5 ppm). The ν_{O-H} bands of the hydroxy groups (3600 to 3100 cm^{-1}) are very weak and broad in the IR spectra, due to line broadening and association. Also in the ^1H NMR spectra the signals of the hydroxy hydrogen atoms are usually not observed, due to exchange and overlapping with other signals (compare Exp. Sect.). For three of these iminohydroxamic acids, suitable single crystals for X-ray structural analyses were obtained (Figures 2−4).

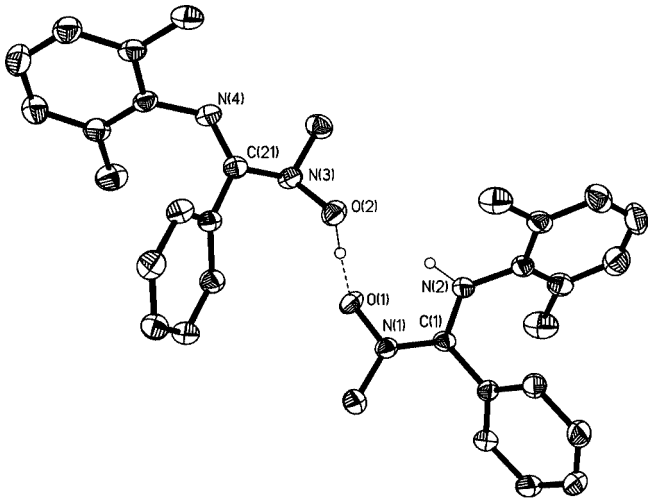

Figure 3. Molecular structure of **3b**; except for N−H and O−H hydrogen atoms, all other hydrogen atoms are omitted for clarity; selected bond lengths [pm]: C(1)−N(1) 130.6(3), N(1)−O(1) 135.1(2), C(1)−N(2) 135.7(3), C(21)−N(3) 139.0(3), N(3)−O(2) 142.2(2), C(21)−N(4) 128.1(3), N(2)−H(2N) 94(2), O(2)−H(2O) 106(3); tilt angles [°]: plane of phenyl ring of C(1) versus plane N(1)−C(1)−N(2): 62.26(13); plane of 2,6-dimethylphenyl ring of N(2) versus plane N(1)−C(1)−N(2): 70.93(16); plane of phenyl ring of C(21) versus plane N(3)−C(21)−N(4): 43.52(10); plane of 2,6-dimethylphenyl ring of N(4) versus plane N(3)−C(21)−N(4): 76.18(18)

A common feature in all three structures is the tilting of both aryl rings relative to the plane of the principal N=C−N−O unit. These tilt angles range from 43.5 to 83.5° for the *C*-phenyl ring, and from 34.0 to 88.6° for the substituted *N*-aryl moiety, respectively. Clearly the tilting in both cases is caused by steric crowding, especially in the latter case, due to the two *ortho*-alkyl groups on the *N*-aryl sub-

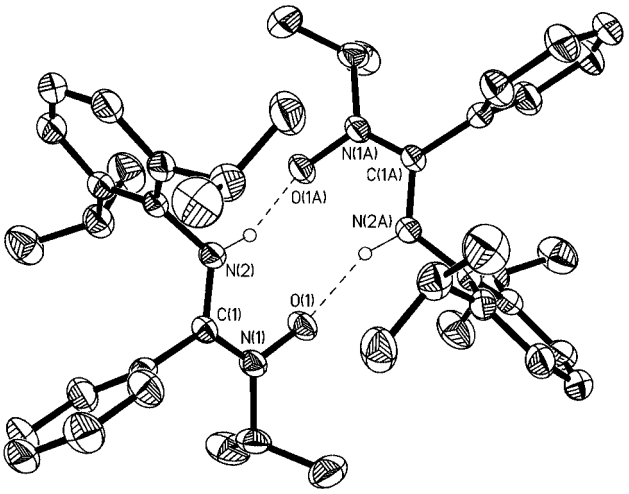

Figure 4. Molecular structure of **3e**; except for N−H−O hydrogen bonds, hydrogen atoms are omitted for clarity; selected bond lengths [pm]: C(1)−N(1) 130.5(4), N(1)−O(1) 134.0(3), C(1)−N(2) 135.9(4), N(2)−H(2N) 98(4); tilt angles [°]: plane of phenyl ring of C(1) versus plane N(1)−C(1)−N(2): 78.74(15); plane of 2,6-diisopropylphenyl ring of N(2) versus plane N(1)−C(1)−N(2): 34.02(23)

stituent. As anticipated, in all three structures, hydrogen-bridging plays a decisive role in the solid-state packing of the molecules. In all three structures two molecules are paired by one or two O−H−N hydrogen bonds. Interestingly, both possible tautomers of the iminohydoxamic acid functionality were observed, depending on the substitution pattern of the principal N=C−N−OH unit. Compounds **3a** and **3e** exist in the solid state solely in their zwitterionic iminium hydroxamate $^{+}$NH=C−N−O^{-} forms connected by two hydrogen bonds (see Figures 2 and 4), whereas in the case of compound **3b** both tautomers with only one hydrogen bond are present, the expected and "usual" neutral N=C−N−OH form and the unexpected and "exotic" zwitterionic $^{+}$NH=C−N−O^{-} form (Figure 3). It is quite clear, however, that this tautomerism is dominated by solid-state forces and in solution the position of equilibrium will be almost totally on the side of the uncharged normal iminohydroxamic acid species.

The synthesis of iminohydoxamic esters **5a**−**5d** can be very easily accomplished by iminoacylation of *N*,*O*-bis(alkylated) hydroxylamines (Scheme 2). The isolated yields of 78−94% are much higher than those of the iminohydroxamic acids discussed above, simply because there is only one nucleophilic site in the substrates. Ligands **5a**−**5d** are stable compounds which are white to yellow in color. Spectroscopically, the imine functionalities may be corroborated by their typical IR absorptions ($\nu_{C=N}$ = 1628−1636 cm^{-1}), shifted to higher wave numbers compared with the hydroxamic acids **3a**−**3f**, and by their ^{13}C NMR chemical shifts (δ = 160.8−162.8 ppm) which are also shifted to lower field in comparison with compounds **3a**−**3f**. The signals of the methyl groups of the ester functionalities were detected at δ = 3.38−3.54 ppm in the ^{1}H NMR spectra and at δ = 60.2−60.6 ppm in the ^{13}C NMR spectra; both sets of chemical shifts are in accordance with expectations at lower field in comparison with those of the *N*-alkyl substituents of **3a**−**3f** and **5a**−**5d**, respectively.

Amino derivatives of iminohydroxamic acids are accessible similarly by iminoacylation of hydrazines. In our hands, however, this chemistry was only possible for alkylated hydrazines affording ligands **6a** and **6b**, but on attempted mono(iminoacylation) of *N*,*N*′-diphenylhydrazine only the bis(derivative) **7** was obtained. This is a rather unfortunate result because diarylhydrazines can be easily synthesized from azobenzenes by reduction, and various substituted diarylhydrazines would allow a convenient stereoelectronic fine-tuning on the amino *N*-donor site of ligands of type **6**. The spectroscopic data of **6a**, **6b** and **7** are consistent with their structures with values similar to those of the other ligand families discussed above. As a minor issue, we note that the imidoyl hydrazide **6b** is the only ligand of all these compounds with an *N*−H substituent on the benzamidine moiety, in this case no protection of the *N*−H acidic moiety is present (vide infra).

Metal Complexes

[N,O] Iminohydroxamato Complexes

In principle, with tetravalent early transition metals, [*N*,*O*]MX_3 mono- and [*N*,*O*]$_2$MX_2 bis(complexes) should be accessible. Hence six differently substituted iminohydroxamic acids (**3a**−**3f**) and three different metal halides ($ZrCl_4$, $TiCl_4$, VCl_4) would afford a series of 36 different metal complexes. In this work, however, only selected examples from this rather large number of compounds were synthesized on a preparative scale (Scheme 3), based on the following criteria and objectives: (i) in order to compare the stereoelectronic influence of all six ligands **3a**−**3f**, all six zirconium mono(complexes) [*N*,*O*]$ZrCl_3$ **8a**−**8f** were synthesized, (ii) for comparing the difference between mono- and bis(complexes), one [*N*,*O*]$_2$$ZrCl_2$ complex (**9a**) was prepared, (iii) to study the effect of different metals, two additional complexes **10b** [M = Ti] and **11b** [M = V] with ligand **3b** were synthesized, and (iv) to facilitate characterization of the complexes by NMR spectroscopy we focused on the diamagnetic Zr and Ti complexes. Furthermore we note that [*N*,*O*]NiRL complexes (L = phosphane, R = alkyl or aryl) in analogy to Grubbs' (salicylaldiminato)Ni complexes[4] are also accessible, but unfortunately such compounds are very labile and, according to our preliminary results, decompose very quickly.

As anticipated, the synthesis of metal complexes of [*N*,*O*]H ligands **3a**−**3f** was rather simple. Deprotonation with *n*-butyllithium in THF followed by treatment with the appropriate transition metal halide afforded complexes **8a**−**11b** (Scheme 3) in isolated yields ranging from 64 to 95% (see Exp. Sect.). All the compounds are stable under dry and inert conditions. On exposure to air, however, they are quickly hydrolyzed as expected. The zirconium and titanium complexes **8a**−**10b** are diamagnetic and are yellow to orange in color, in contrast to the dark green vanadium complex **11b** which is strongly paramagnetic.

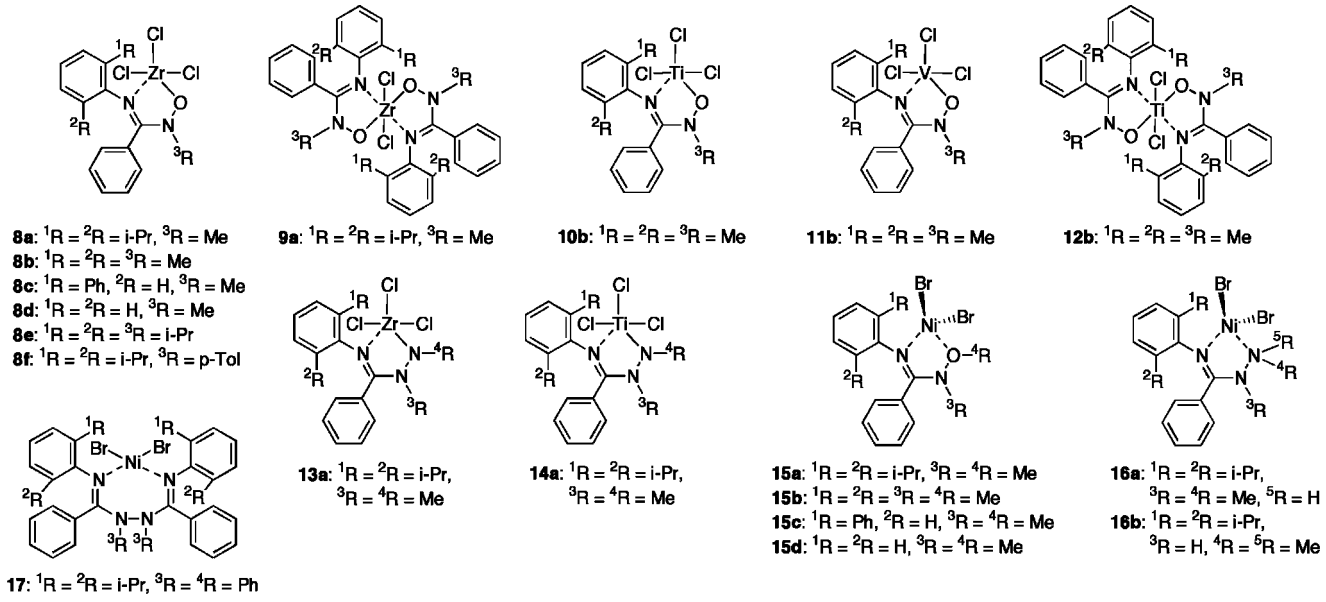
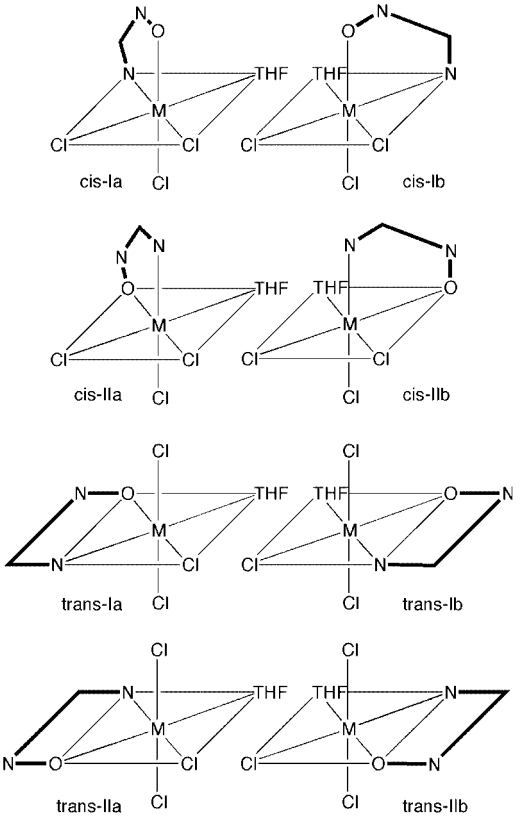


Scheme 3. Metal complexes of [*N*,*O*] and [*N*,*N*] iminohydroxamato ligands

The characterization of the diamagnetic compounds relies mainly on NMR spectroscopy. In the ^{13}C NMR spectra the coordinated imino functionalities ($\delta_{C=N}$ = 159−162 ppm) are shifted to lower field by approximately 10 ppm compared with the chemical shifts of the imine carbon signals of the free ligands ($\delta_{C=N}$ = 146−151 ppm). Other resonances were shifted as well, but to a much lesser degree. Most significantly, the ^1H and ^{13}C NMR spectra clearly show that the [*N*,*O*]$ZrCl_3$ mono(complexes) **8a**−**8f** exist predominantly as mixtures of isomers containing THF as an additional neutral ligand in an octahedral coordination environment. In principle, 4 pairs of chiral diastereoisomers are possible with these heterotopic [*N*,*O*] chelate ligands in combination with three chloride ions and one THF ligand (Scheme 4). Mono-Zr complexes containing the *N*-(2,6-diisopropylphenyl) substituent exist as one isomer (**8a**, **8e**, **8f**), whereas those with sterically less demanding *N*-aryl groups give rise to the observation of two diastereoisomers (**8b**, **8c**, **8d**) according to their NMR spectra (compare Exp. Sect.).

In contrast to the [*N*,*O*]$ZrCl_3$ complexes **8a**−**8f**, no coordinated THF was present in the titanium complex **10b**, most likely due to the smaller size of the lighter transition metal atom. Also, complex **9a** with two chelating [*N*,*O*] ligands had no coordinated THF, but four structural isomers of the theoretically possible 5 isomers (Scheme 5) were observed in this heterotopic and non-homoleptic complex.

In most of the zirconium compounds **8a**−**9a** (with the exception of **8a**, **8e**, **8f**) the occurrence of a mixture of isomers was clearly evident from NMR spectroscopy. On the one hand this is an expected and interesting stereochemical observation, on the other hand, however, it hampers further characterization of these complexes by X-ray crystallography. Unfortunately, under no circumstances we were able to obtain single crystals. In the case of the titanium complex



Scheme 4. Structural isomers of [*N*,*O*]$ZrCl_3$(THF) complexes

10b, however, suitable red single crystals grew after one year, together with some amorphous colorless material. Figure 5 shows the molecular structure of this crystalline material. Unexpectedly, the structure corresponds to the [*N*,*O*]$_2$-$TiCl_2$ bis complex **12b** which must have been formed from

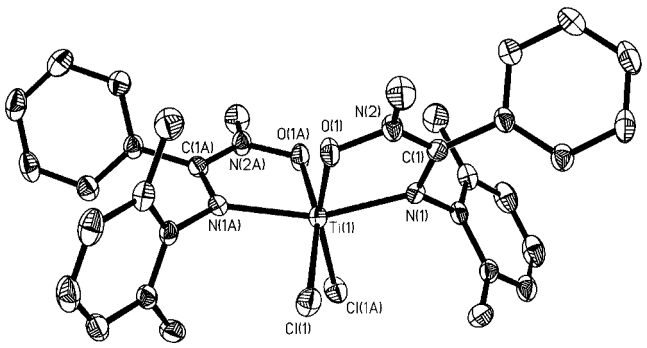

Figure 5. Molecular structure of **12b**; hydrogen atoms are omitted for clarity; selected bond lengths [pm]: Ti(1)−Cl(1) 231.97(7), Ti(1)−N(1) 210.83(18), Ti(1)−O(1) 192.44(17), C(1)−N(1) 132.9(3), C(1)−N(2) 132.4(3), N(2)−O(1) 136.1(3); selected angles [°]: Cl(1)−Ti(1)−Cl(1A) 90.22(4), O(1)−Ti(1)−O(1A) 95.10(12), N(1)−Ti(1)−O(1) 74.54(7), N(1)−Ti(1)−Cl(1) 105.26(5), O(1)−Ti(1)−Cl(1) 89.74(6), N(1)−Ti(1)−N(1A) 159.57(10), Ti(1)−N(1)−C(1) 115.12(15), N(1)−C(1)−N(2) 114.9(2), Ti(1)−O(1)−N(2) 120.79(13); tilt angle plane of phenyl group of C(1) versus plane N(1)−C(1)−N(2): 66.71(26); tilt angle of 2,6-dimethylphenyl group of N(1) versus plane N(1)−C(1)−N(2): 82.46(19)

the $[N,O]TiCl_3$ mono(complex) **10b** by ligand scrambling. Despite the obvious serendipity of this result, the molecular structure clearly demonstrates the chelating nature of the hydroxamato ligand **3b**, indicating that in all other cases such five-membered metal chelates are also present. Overall, the stereochemistry of **12b** corresponds to isomer *cis*-**II** of Scheme 5 with *cis*-oriented chloro ligands and *trans*-oriented imino donor sites of the heterotopic iminohydroxamato ligands. The coordination geometry at the central titanium atom is principally octahedral with only minor deviations from the ideal 90° (0.3−15.5°) and 180° (16.8−20.4°) angles. The bond lengths of the titanium atom to the nitrogen, oxygen, and chlorine atoms of the ligands are given in the caption of Figure 5. They are unexceptional and in the commonly observed range. In contrast to the more or less undistorted coordination geometry, the peripheral phenyl groups of the iminohydroxamato ligands are strongly tilted (66.7 and 82.5°) with respect to the hydroxamate plane, showing that steric shielding by the *N*-arylimino substituent is effective, in accordance with the general design principle of these olefin polymerization precatalysts (vide supra).

The syntheses of the imidoyl hydrazido complexes **13a** and **14a** are analogous to the preparation of the iminohydroxamato complexes discussed above (Scheme 3). Deprotonation of ligand **6a** in THF by *n*-butyllithium followed by treatment with $ZrCl_4$ or $TiCl_4$ in a 1:1 stoichiometric ratio afforded complexes **13a** and **14a**, respectively. Besides the additional *N*-methyl resonances, both compounds show NMR spectroscopic properties very similar to those of the iminohydroxamato complexes **8a**−**8f** and **10b**. Stereochemically, Zr complex **13a** exists as a mixture of two octahedral isomers containing one additional THF ligand (in analogy to the isomers in Scheme 4), whereas **14a** seems to be either five-coordinate or more likely a chloro-bridged dimer with no coordinated THF.

The synthesis of nickel(II) complexes starting from the neutral (non-acidic) iminohydroxamic esters **5a**−**5d**, imidoyl hydrazides **6a**−**6b** and **7** was very straightforward. Treatment with $NiBr_2$ in dichloromethane at room temperature overnight afforded the corresponding $[N,O]NiBr_2$ complexes **15a**−**15d** and $[N,N]NiBr_2$ complexes **16a**, **16b**, **17** in good yields (Scheme 3).

With the exception of **17**, which is a seven-membered chelate in contrast to all other complexes, all the Ni complexes are dark green or brown, air-sensitive and paramagnetic, thereby thwarting their characterization by NMR spectroscopy. In general, broad and shifted signals were observed in the ^1H NMR spectra and signal intensities in the ^{13}C NMR spectra were very low allowing, only in one case, the detection of the carbon resonances (see Exp. Sect.). The paramagnetism of these complexes clearly indicates a non-quadratic, non-planar coordination geometry and these compounds exist either as four-coordinate tetrahedrally distorted monomers or as bromo-bridged five-coordinate dimers. Clearly, crystal structures would provide the best information on the structures of these compounds, but despite many attempts with different solvents employing various crystallization procedures no suitable crystals could be obtained. On the other hand, the observed paramagnetism shows that steric shielding of the ligands is sufficient to distort the orientation of the bromo ligands from their preferred square-planar geometry, as in Grubbs'[4] and Brookhart's[2] $[N,O]$- and $[N,N]$Ni catalysts.

Polymerization Studies

The main question to be answered by this work is: "How active and selective are these newly designed catalyst families for the polymerization of olefins?" To evaluate the catalytic performance of complexes **8a**−**17** a standard polymerization procedure was applied. A steel autoclave containing a toluene solution of the precatalyst was activated with an excess of methylaluminoxane and at a temperature of 70 °C

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 1. Polymerization of ethylene (MAO as activator, 70 °C, 40 bar)

Complex (metal)	Amount precatalyst [mg]	Polymerization time [min]	Yield polymer [g]	Viscosity of polymer [dL/g]	Activity [g mmol^{-1} h^{-1} bar^{-1}]
8a (Zr)	4.8	30	9.5	9.51	50.2
8b (Zr)	6.0	30	12.0	14.01	45.1
8c (Zr)	1.5	35	4.8	11.41	68.4
8d (Zr)	0.9	60	6.7	24.95	78.7
8e (Zr)	1.2	90	11.9	4.43	88.4
8f (Zr)	2.0	75	8.8	8.76	51.3
9a (Zr)	4.0	90	9.4	41.38	30.6
10b (Ti)	4.0	60	7.4	54.33	18.8
11b (V)	8.0	90	6.2	19.18	5.3
13a (Zr)	1.4	45	6.2	15.6	76.8
14a (Ti)	1.7	15	1.0	–	28.0
15a (Ni)	3.9	5	7.25	3.62	302.8
16a (Ni)	2.7	90	1.0	2.15	3.3
16b (Ni)	1.4	90	1.3	2.57	8.4
17 (Ni)	1.8	90	1.7	2.50	14.6

ethylene was added up to a pressure of 40 bar, the reaction was allowed to proceed for 5−90 min while maintaining a 40 bar pressure by adjusting the feed of ethylene (Table 1, for further details see Exp. Sect.).

In terms of activity, all [*N*,*O*]- and [*N*,*N*]zirconium complexes showed a moderate activity of 30.6−88.4 g polyethylene × mmol^{-1} × catalyst × h^{-1} × bar^{-1}. The bis(complex) [*N*,*O*]$_2$ZrCl$_2$ (**9a**) had the lowest activity of all Zr complexes, clearly indicating that one ligand per metal center ([*N*,*O*]ZrCl$_3$) is superior to a 2:1 ratio. Changing the metal to either titanium or vanadium resulted in a significantly reduced activity with either the [*N*,*O*] or [*N*,*N*] ligand architecture. In the case of the nickel complexes, compound **15a** truly stands out as a precatalyst with a (very) high activity of 302.8, suggesting that neutral *O*-alkyl iminohydroxamate is the best ligand framework developed in this work. However, the long-term stability of the [*N*,*O*]NiBr$_2$ complexes **15a**−**15d** in their MAO-activated form has not yet been optimized and only with **15a** under short polymerization times was a polymer obtained, indicating fast deactivation pathways. Future work towards improvements of these systems will focus on altering the *O*-alkyl substituent to create better shielding of the active metal center and to increase the stability of the activated complex.

In terms of polymer properties, the polyethylene samples obtained by the zirconium catalyst family were very high molecular weight (Mv = 1.5 to 10 × 10^6 g/mol, derived from viscosity measurements) polymers with viscosities ranging from 4.43 to 54.33 dl/g, dependent on the substitution pattern of the ligands. In contrast, PE samples obtained from nickel complexes **15a**−**17** were of the HDPE type with no detectable branches and molar masses (Mv) of 1.0 to 2.5 × 10^5 g/mol.

In addition, polymerization of propylene and copolymerization of ethylene with *n*-hexene was briefly investigated. In both cases, only low activities below 150 g polymer × mmol^{-1} × catalyst × h^{-1} were achieved.

Summary and Conclusions

New bidentate chelate ligands based on an iminohydroxamate backbone architecture have been developed. These new ligands contain an imino nitrogen donor site with a substituted aryl group to effect steric shielding and an anionic or neutral oxygen or nitrogen donor site, respectively. The free ligands show interesting solid-state structures in which hydrogen bonding is responsible for unusual zwitterionic tautomeric structures. New metal complexes of zirconium, titanium, vanadium, and nickel have been synthesized and evaluated for their performance as olefin polymerization catalysts. Structurally, the five-membered metal chelates exist in most cases as a number of different octahedral stereoisomers in the case of early transition metals, and as tetragonally distorted paramagnetic four- or five-coordinated compounds in the case of nickel. Polymerization studies were performed in homogeneous solution using methylaluminoxane as the cocatalyst. These showed that [*N*,*O*]NiBr$_2$ complexes containing neutral iminohydroxamate with *O*-alkyl substituents are the most active systems of these various catalyst families. Further optimization of the ligand substitution pattern is expected to improve long term stability of the catalysts and the catalytic performance for applications on a technical scale.

Experimental Section

General: Commercially available starting materials were used as obtained. Solvents were dried, deoxygenated and saturated with argon according to standard procedures in organometallic chemistry. Reactions of air-sensitive materials were performed in Schlenk glassware under argon by techniques common in inorganic/organometallic chemistry. New compounds were characterized by IR, NMR, MS, etc. using current state-of-the-art procedures, details of instrumentation have been published previously.[13]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Synthesis of Ligands

Representative Procedure for Iminohydroxamic Acids 3a−3f: A Schlenk tube was charged with *N*-(2,6-diisopropylphenyl)benzamide (**1a**, 1.9 g, 6.7 mmol) and an excess of thionyl chloride (10 mL). The mixture was heated to reflux for 1 h and the excess thionyl chloride was removed in a vacuum line, yielding a yellow oil of the corresponding imidoyl chloride **2a**. This material was dissolved in dry dichloromethane (20 mL). A second Schlenk vessel was charged with *N*-methylhydroxylamine hydrochloride (0.56 g, 6.7 mmol), dry ethanol (50 mL), and triethylamine (10 mL, 72 mmol). After the stirred mixture was cooled to −40 °C, a dropping funnel was attached to the Schlenk vessel, and a dichloromethane solution of imidoyl chloride **2a** (from above) was added dropwise over a period of 30 min. The mixture was warmed to room temperature and stirred at ambient temperature for further 60 min, resulting in a yellow suspension. Workup: the reaction mixture was hydrolyzed by addition of water (100 mL), the organic materials were extracted three times with diethyl ether, the combined organic layers were dried with Na_2SO_4 and the volatile materials were removed in a rotary evaporator yielding a semi-solid crude product consisting of *N*-(2,6-diisopropylphenyl)-*N*′-hydroxy-*N*′-methylbenzamidine (**3a**) and the apolar side product *N*-(2,6-diisopropylphenyl)-*N*′-{[2,6-diisopropylphenyl)imino]phenylmethoxy}-*N*′-methylbenzamidine (**4a**). To separate this mixture, the crude product mixture was dissolved in a small volume of dichloromethane and filtered through a short column of silica. In this manner, apolar **4a** (0.76 g, 1.3 mmol, 19.8% yield) could be removed by filtration, whereas the polar product **3a** remained immobilized on the column. Elution with ethanol and subsequent removal of ethanol in a rotary evaporator afforded 0.83 g of pure **3a** as an off-white solid in 40% yield.

All other iminohydroxamic acids **3** were prepared according to this procedure except that different benzamides and hydroxylamines were employed as starting materials. The bis(imino)-substituted hydroxylamines **4** (the apolar side product) were usually only separated and not isolated. Isolated yields of ligands **3** ranged from 18 to 63%, depending on the substitution pattern of the building blocks.

***N*-(2,6-Diisopropylphenyl)-*N*′-hydroxy-*N*′-methylbenzamidine (3a):** Starting materials: *N*-(2,6-diisopropylphenyl)benzamide (**1a**, 1.9 g, 6.7 mmol) and *N*-methylhydroxylamine hydrochloride (0.56 g, 6.7 mmol). Yield: 0.83 g (40%). IR (KBr): $\tilde{\nu}$ = 3065 (w), 2962 (m), 2869 (m), 1630 (s), 1586 (m), 1505 (m), 1470 (s), 1445 (m), 1432 (m), 1383 (m), 1324 (m), 1225 (m), 1187 (s), 1162 (m), 1105 (s), 1077 (w), 1044 (m), 971 (m), 917 (w), 807 (s), 780 (s), 758 (s), 700 (s) cm^{-1}. MS (FAB): *m*/*z* = 311 $[M + H]^+$. Representative Procedure for Iminohydroxamic Esters 5a−5d and Iminohydroxamic Amides 6a, 6b: A dichloromethane solution of imidoyl chloride **2a** (*c* = 0.108 g/ml or 0.36 mmol/ml, respectively) was prepared as described above. A second Schlenk vessel was charged with *N*-methyl-*O*-methylhydroxylamine hydrochloride (0.78 g, 8.0 mmol), dry ethanol (50 mL), and triethylamine (2.2 mL, 16 mmol). After the stirred mixture was cooled to −40 °C, a dropping funnel was attached to the Schlenk vessel, and a stoichiometric amount of a dichloromethane solution of imidoyl chloride **2a** was added dropwise over a period of 30 min. The mixture was warmed to room temperature and stirred at ambient temperature for further 60 min, resulting in a yellow suspension. Workup: the reaction mixture was hydrolyzed by addition of of water (100 mL), the organic material was extracted three times with diethyl ether, the combined organic layers were dried with Na_2SO_4, the volatile materials were removed in a rotary evaporator, yielding **5a** in 93% yield as a yellow viscous oil which solidified on drying in vacuo.

All other iminohydroxamic esters **5** and amides **6** were prepared according to this procedure, only different benzamides and hydroxylamines or hydrazines were employed as starting materials, respectively. Isolated yields of ligands **5** and **6** ranged from 78 to 99%, depending on the substitution pattern of the building blocks.

Synthesis of Metal Complexes

Representative Procedure for Iminohydroxamato and Imidoyl Hydrazido Complexes 8a−14a: A Schlenk tube was charged with **3a** (0.28 g, 0.90 mmol) and dry, deoxygenated THF (20 mL). After the mixture was cooled to −80 °C, a 2.0 M *n*-pentane solution of *n*-butyllithium (0.90 mmol, 0.45 mL) was added through a syringe. The stirred mixture changed gradually in color from orange to dark red, indicating deprotonation of **3a**. After 1 h of stirring at −80 °C, $ZrCl_4$ (0.21 g, 0.90 mmol, 1 mol-equiv. in relation to **3a**) was added under protection from air and the external cooling bath was removed. Stirring was continued overnight, resulting in a brown solution. Workup: THF and other volatile materials were removed in a vacuum line, the brown residue was dissolved in dry, deoxygenated dichloromethane giving a brown solution and a precipitate of lithium chloride. The inorganic salt was removed by filtration through a Schlenk frit, the dichloromethane was removed in a vacuum line, and the residue was triturated with dry, deoxygenated *n*-hexane (10 mL) to remove apolar impurities from the solid product. The precipitate was allowed to settle, *n*-hexane was removed by pipette followed by drying in vacuo, affording the product as an orange air-sensitive powder in 90% yield.

Trichloro[*N*-(2,6-diisopropylphenyl)-*N'*-methyl-*N'*-oxybenzamidinato]zirconium(IV) (8a): Starting materials: **3a** (0.28 g, 0.90 mmol), *n*-butyllithium (0.90 mmol, 0.21 g), $ZrCl_4$ (0.90 mmol, 1 mol-equiv. in relation to **3a**). Yield: 0.41 g (90%) as an orange, air-sensitive powder. ^1H NMR (300 MHz, CD_2Cl_2): δ = 1.04 [d, 6 H, 2 × $CH(CH_3)_2$], 1.81 (br. s, 4 H, CH_2 of coordinating THF), 3.33 [m, 5 H, NCH_3, 2 × $CH(CH_3)_2$], 3.83 (br. s, 4 H, CH_2 of coordinating THF), 6.94−7.02 (m, 3 H, C_6H_3), 7.10−7.35 (m, 5 H, C_6H_5) ppm. ^{13}C NMR (75.432 MHz, CD_2Cl_2): δ = 24.2, 25.9, 28.1 [$CH(CH_3)_2$], 41.6 (NCH_3), 123.6, 124.2, 126.1, 128.5, 128.7, 129.1, 129.3, 129.4, 130.6, 143.9, 144.2 (C_6H_3, C_6H_5), 161.7 (C=N) ppm. $C_{20}H_{25}Cl_3N_2OZr{\cdot}THF$ = $C_{24}H_{33}Cl_3N_2O_2Zr$ (579.11): calcd. C 46.80, H 4.17, N 6.82; found C 45.72, H 4.25, N 6.70.

Trichloro[*N*-(2,6-diisopropylphenyl)-*N*′-methylamino-*N*′-methylbenzamidinato]zirconium(IV) (13a): Starting materials: **6a** (0.52 g, 1.61 mmol), *n*-butyllithium (1.6 mmol, 0.49 g), $ZrCl_4$ (2.1 mmol, 1.3 mol-equiv. in relation to **6a**). Yield: 0.71 g (85%) as a yellow, air-sensitive powder. ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 0.93−1.24 [4 × d, 12 H, 2 × $CH(CH_3)_2$], 1.82 (br. s, 4 H, CH_2 of coordinating THF), 2.94, 3.07, 3.18, 3.29 [4 × s, sept, 5 H, NCH_3, 2 × $CH(CH_3)_2$], 3.39, 3.48, 3.57, 3.89 (4 × s, 3 H, NCH_3), 3.84, 4.56 (2 × br. s, 4 H, CH_2 of coordinating THF), 6.90−7.60 (m, 8 H, C_6H_3, C_6H_5) ppm. ^{13}C NMR (75.432 MHz, CD_2Cl_2): δ = 21.8, 22.6, 24.2, 25.3, 25.9, 27.0, 28.2, 29.2 [$CH(CH_3)_2$], 34.9, 38.8, 40.4 (NCH_3), 123.0, 124.0, 124.3, 128.3, 128.6, 128.9, 129.5, 129.7, 129.8, 133.0, 143.8, 144.0, 146.1 (C_6H_3, C_6H_5), not observed: (C=N) ppm. $C_{21}H_{28}Cl_3N_3Zr\cdot THF$ = $C_{25}H_{36}Cl_3N_3Zr$ (576.16): calcd. C 52.12, H 6.30, N 7.29; found C 52.06, H 6.26, N 7.21.

Trichloro[*N*-(2,6-diisopropylphenyl)-*N*′-methylamino-*N*′-methylbenzamidinato]titanium(IV) (14a): Starting materials: **6a** (0.40 g, 1.24 mmol), *n*-butyllithium (1.24 mmol, 0.49 g), $TiCl_4$ (1.5 mmol, 1.2 mol-equiv. in relation to **6a**). Yield: 0.56 g (95%) as a green, air-sensitive powder. ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 1.05 [d, $^3J_{H,H}$ = 6.9 Hz, 6 H, $CH(CH_3)_2$], 2.93 [sept, $^3J_{H,H}$ = 6.9 Hz, 2 H, $CH(CH_3)_2$], 3.38 (s, 3 H, NCH_3), 4.38 (s, 3 H, NCH_3), 6.99−7.36 (m, 8 H, C_6H_3, C_6H_5) ppm. ^{13}C NMR (75.432 MHz, CD_2Cl_2): δ = 23.9, 25.3, 28.6 [$CH(CH_3)_2$], 38.0, 45.2 (NCH_3), 123.8, 128.0, 128.7, 128.9, 129.0, 131.4, 141.2, 150.9 (C_6H_3, C_6H_5), 160.0 (C=N) ppm. $C_{21}H_{28}Cl_3N_3Ti$ (476.71): calcd. C 52.91, H 5.92, N 8.81; found C 53.03, H 5.88, N 8.75.

Representative Procedure for Iminohydroxylamino and Hydrazido Complexes 15a−17: A Schlenk tube was charged with **5a** (0.97 g, 3.0 mmol), dibromo(dimethoxethane)nickel(II) (1.25 g, 3.1 mmol) and dry, deoxygenated dichloromethane (20 mL). The mixture was stirred overnight, resulting in a dark green solution/suspension. Workup: dry dichloromethane (60 mL) was added, the solution was filtered through a Schlenk frit, the green solution was concentrated in a vacuum line, and the residue was dried in vacuo affording a green air-sensitive powder in 94% yield.

Dibromo[*N*-(2,6-diisopropylphenyl)-*N*′-methoxy-*N*′-methylbenzamidinato]nickel(II) (15a): Starting materials: **5a** (0.97 g, 3.0 mmol), $NiBr_2\cdot$DME (1.25 g, 3.1 mmol). Yield: 1.53 g (94%) as a green, paramagnetic, air-sensitive powder. ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 1.10−1.49 [br. m, 12 H, $CH(CH_3)_2$], 2.97−3.56 [br. m, 8 H, $CH(CH_3)_2$, NCH_3, OCH_3], 6.80−8.30 (br. m, 8 H, C_6H_3, C_6H_5) ppm. ^{13}C NMR (75.432 MHz, CD_2Cl_2): due to paramagnetism, only very weak signals were observed. $C_{21}H_{28}Br_2N_2NiO$ (542.96): calcd. C 46.45, H 5.20, N 5.16; found C 46.52, H 5.25, N 5.07.

Dibromo[*N*-(2,6-dimethylphenyl)-*N*′-methoxy-*N*′-methylbenzamidinato]nickel(II) (15b): Starting materials: **5b** (0.79 g, 2.94 mmol), $NiBr_2\cdot$DME (1.17 g, 2.94 mmol). Yield: 1.08 g (66%) as a green, paramagnetic, air-sensitive powder. ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 2.75 [br. s, 12 H, $CH(CH_3)_2$], 3.99 [br. m, 8 H, $CH(CH_3)_2$, NCH_3, OCH_3], 6.80−7.70 (br. m, 8 H, C_6H_3, C_6H_5) ppm. ^{13}C NMR (75.432 MHz, CD_2Cl_2): due to paramagnetism, no informative signals were observed. $C_{17}H_{20}Br_2N_2NiO$ (486.86): calcd. C 41.94, H 4.14, N 5.75; found C 42.02, H 4.16, N 5.70.

Dibromo[*N*-(biphenyl-2-yl)-*N*′-methoxy-*N*′-methylbenzamidinato]-nickel(II) (15c): Starting materials: **5c** (0.87 g, 2.75 mmol), $NiBr_2\cdot$DME (1.10 g, 2.75 mmol). Yield: 1.43 g (97%) as a green,

paramagnetic, air-sensitive powder. ^{1}H NMR (300 MHz, CD_2Cl_2): only one very broad signal from δ = −4 to +24 ppm centered at δ = 12.0 ppm was observed. ^{13}C NMR (75.432 MHz, CD_2Cl_2): due to paramagnetism, no informative signals were observed. $C_{21}H_{20}Br_2N_2NiO$ (534.90): calcd. C 47.15, H 3.77, N 5.24; found C 47.04, H 3.81, N 5.18.

Dibromo[*N*′-methoxy-*N*′-methyl-*N*-phenylbenzamidinato]nickel(II) (15d): Starting materials: **5d** (0.62 g, 2.58 mmol), $NiBr_2$·DME (1.03 g, 2.58 mmol). Yield: 0.70 g (59%) as a green, paramagnetic, air-sensitive powder. ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 0.07, 0.87, 1.27, 4.33 (4 × br. s, 6 H, NCH_3, OCH_3), 6.84−9.96 (br. m, 10 H, C_6H_5) ppm. ^{13}C NMR (75.432 MHz, CD_2Cl_2): due to paramagnetism, no informative signals were observed. $C_{15}H_{16}Br_2N_2NiO$ (458.80): calcd. C 39.27, H 3.52, N 6.11; found C 39.19, H 3.56, N 6.06.

Dibromo[*N*-(2,6-diisopropylphenyl)-*N*′-methylamino-*N*′-methylbenzamidinato]nickel(II) (16a): Starting materials: **6a** (0.44 g, 1.36 mmol), $NiBr_2$·DME (0.56 g, 1.4 mmol). Yield: 0.70 g (95%) as a brown, paramagnetic, air-sensitive powder. ^{1}H NMR (300 MHz, CD_2Cl_2): δ = −0.16, 1.76, 5.16, 5.41 [4 × br. s, 20 H, $CH(CH_3)_2$, NCH_3, OCH_3], 15.38, 19.63, 22.57 (3 × br. s, 8 H, C_6H_3,C_6H_5) ppm. ^{13}C NMR (75.432 MHz, CD_2Cl_2): due to paramagnetism, no informative signals were observed. $C_{21}H_{29}Br_2N_3Ni$ (541.98): calcd. C 46.54, H 5.39, N 7.75; found C 46.40, H 5.44, N 7.67.

Dibromo[*N*-(2,6-diisopropylphenyl)-*N*′-(dimethylamino)benzamidinato]nickel(II) (16b): Starting materials: **6b** (0.52 g, 1.6 mmol), $NiBr_2$·DME (0.70 g, 1.8 mmol). Yield: 0.66 g (76%) as a brown, slightly paramagnetic, air-sensitive powder. ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 0.89, 0.95, 1.08, 2.04, 2.40, 3.47, 5.99 [6 × br. s, 21 H, $CH(CH_3)_2$, NCH_3, NH], 7.11, 7.14, 7.39, 7.82, 8.19, 8.48, 8.57, 8.96 (8 × br. s, 8 H, C_6H_3, C_6H_5) ppm. ^{13}C NMR (75.432 MHz, CD_2Cl_2): δ = 13.1, 21.8, 22.2, 24.7, 29.8, 30.7 [$CH(CH_3)_2$], 50.8 (NCH_3), 124.0, 126.0, 127.7, 129.7, 131.2, 131.7, 135.5, 140.0, 143.8 (C_6H_3, C_6H_5), not observed: (C=N) ppm. $C_{21}H_{29}Br_2N_3Ni$ (541.98): calcd. C 46.54, H 5.39, N 7.75; found C 46.58, H 5.32, N 7.70.

Dibromo[*N*-2,6-diisopropylphenyl-*N*′-({[(2,6-diisopropylphenyl)-imino]benzyl}phenylamino)benzamidino]nickel(II) (17): Starting materials: **7** (0.26 g, 0.37 mmol), $NiBr_2$·DME (0.17 g, 0.40 mmol). Yield: 0.30 g (88%) as a pale green, air-stable powder. ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 1.07 [d, $^3J_{H,H}$ = 6.9 Hz, 12 H, $CH(CH_3)_2$], 1.31 [d, $^3J_{H,H}$ = 6.6 Hz, 12 H, $CH(CH_3)_2$], 3.14 [sept, 4 H, $CH(CH_3)_2$], 6.97 (d, 4 H, C_6H_3), 7.09 (d, 8 H, C_6H_5), 7.18−7.39 (m, 14 H, C_6H_3, C_6H_5) ppm. ^{13}C NMR (75.432 MHz, CD_2Cl_2): δ = 21.8, 26.7, 29.5 [$CH(CH_3)_2$], 124.2, 125.1, 125.3, 125.4, 127.5, 127.9, 128.1, 129.1, 129.2, 129.7, 129.8, 130.2, 133.1, 135.5, 138.4, 145.9 (C_6H_3, C_6H_5), 165.5 (C=N) ppm.

$C_{50}H_{54}Br_2N_4Ni$ (929.50): calcd. C 64.61, H 5.86, N 6.03; found C 64.72, H 5.90, N 5.98.

Crystallography: Single-crystal X-ray measurements and structure determinations of **2a**−**3a**, **3b**, **3e**, **12b** (Table 2). The data collection was performed with a Nonius−Kappa CCD instrument equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) and a nominal crystal to area detector distance of 36 mm. Intensities were integrated using DENZO and scaled with SCALEPACK.[15] Several scans in φ and ω directions were made to increase the number of redundant reflections, which were averaged in the refinement cycles. This procedure replaces an empirical absorption correction. The structures were solved with direct methods (SHELXS 86) and refined against F^2 (SHELX 97).[16] Hydrogen atoms at carbon atoms were added geometrically and refined using a riding model. Hydrogen atoms at nitrogen and oxygen atoms of compounds **3a**, **3b**, **3e** were located and refined isotropically. All non-hydrogen atoms were refined with anisotropic displacement parameters. CCDC-213598 (for **2a**), -213599 (**3a**), -213600 (**3b**), -213601 (**3e**) and -213602 (**2b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Polymerizations: All polymerization studies and polymer characterizations were performed at Basell/BASF AG in Ludwigshafen, Germany. Ethylene polymerization: a dry 1000-mL steel autoclave was charged under strict exclusion of air with toluene (400 mL) and a small amount (1−6 mg, compare Table 1) of precatalyst **8a**−**17**. A 30% toluene solution of methylaluminoxane (MAO) was added (2 mL) and the temperature of the autoclave was kept constant at 70 °C. Ethylene gas was added up to a pressure of 40 bar and the reaction was allowed to proceed for 5−75 minutes, depending on the activity of the catalyst. After the polymerization time given in Table 1, the reaction was terminated by releasing the pressure in the autoclave. The solid polymer was isolated by filtration, washed with methanol, and dried in vacuo. Propylene polymerization: conditions were similar as those in ethylene polymerizations, but propylene was used as monomer. Ethylene/*n*-hexene copolymerizations: conditions were similar as in ethylene homopolymerizations, but in addition to the other reagents *n*-hexene (12.5 mL) was employed.

Synthesis and Monitoring of α-$Bi_2Mo_3O_{12}$ Catalyst Formation using Thermo-Raman Spectroscopy

Anil Ghule,[a] Shin-Hwa Tzing,[a] Jia-Yaw Chang,[a] Kalyani Ghule,[a] Hua Chang,[a] and Yong Chien Ling*[a]

Keywords: Thermo-Raman spectroscopy / Thermochemistry / Dehydration / Phase transformations / Bismuth / α-$Bi_2Mo_3O_{12}$ catalyst

Thermo-Raman spectroscopy was used to monitor the dehydration and phase transformations of $Bi_2Mo_3O_{12}\cdot 5H_2O$. The hydrated forms $Bi_2Mo_3O_{12}\cdot 5H_2O$, $Bi_2Mo_3O_{12}\cdot 4.75H_2O$, $Bi_2Mo_3O_{12}\cdot 3H_2O$, $Bi_2Mo_3O_{12}\cdot 2H_2O$, and anhydrous $Bi_2Mo_3O_{12}$ were observed during dehydration in the wavelength range from 200 to 1400 cm^{-1}. Representative Raman spectra of these compounds are reported for the first time. The thermo-Raman intensity thermogram showed a systematic dehydration in four steps, and the differential thermo-Raman intensity thermogram confirmed this. Thermogravimetry, differential thermogravimetry, and differential scanning calorimetry results were in harmony with the results of the thermo-Raman spectroscopy. Additionally, the dehydration resulting in formation of anhydrous $Bi_2Mo_3O_{12}$ (amorphous $Bi_2Mo_3O_{12}$ phase) and the final transformation into the α-$Bi_2Mo_3O_{12}$ phase was observed to be a dynamic thermal process. The slow, controlled heating rate produced α-$Bi_2Mo_3O_{12}$ catalyst with a particle size averaging 200 nm. The catalyst formed was further characterized by Fourier transform infrared spectroscopy, X-ray diffraction, time of flight SIMS, transmission electron microscopy, and energy-dispersive X-ray analysis.

Introduction

Bismuth molybdates (α-$Bi_2Mo_3O_{12}$, β-$Bi_2Mo_2O_9$, and γ-Bi_2MoO_6 phases) are very popular and widely studied catalysts because of their commercial importance.[1] Extensive investigation of their ability to catalyze the selective oxidation and ammoxidation of alkenes[1−4] and hydrogen sulfide[5] has been carried out. The importance of bismuth molybdates is not limited to catalysis since they also show interesting physical properties with potential technological applications. Vannier et al.[6] reported $Bi_{26}Mo_{10}O_{69}$ as being the first unidimensional bismuth-based oxide ion conductor. Bismuth molybdates also show good optical quality with a wide transmission window between 0.415 and 5.2 μm.[7] Additionally, single crystals with large photon-phonon scattering cross-sections have attracted increasing interest as acousto-optical materials. They possess low optic and acoustic absorptions, good mechanical properties, and chemical stability (e.g. insolubility in water).[8,9] The tetragonal phases of thin-film bismuth-derived compounds are efficient photoconductors[10] and thin films of bismuth molybdates are effective gas sensors showing potential applications in breathalyzer devices.[11]

Bismuth molybdate catalyst systems have been structurally characterized,[12] and studied extensively by different techniques such as X-ray absorption,[13] X-ray diffraction,[14] neutron diffraction,[15] time-of-flight SIMS,[16] electron diffraction techniques,[17] high-resolution electron microscopy and vibrational spectroscopy.[18−20] Raman spectroscopy has proved to be an effective tool for the characterization of the structures of transition metal oxides in the bulk and two-dimensional surface phases.[21] Thus, a systematic study has been made of Raman stretching frequency, bond length, and bond strength empirical correlations. However, all these studies concentrated on the α-$Bi_2Mo_3O_{12}$ phase and little attention has been paid to $Bi_2Mo_3O_{12}\cdot 5H_2O$ and the other hydrated species, which could be important in optics and acoustic applications. The catalytic α-$Bi_2Mo_3O_{12}$ phase used in earlier studies was usually prepared by co-precipitation,[22] sol-gel methods,[23] solid-state reactions,[20] spray drying,[24] high-temperature calcination of solid mixtures or several other methods.[25] However, co-precipitation techniques result in co-precipitation of pure hydroxides and also precipitate bismuth with polymerized Mo ions. Solid-state reactions yield byproducts (phases) formed as a result of non-stoichiometric compositions,[26] and thus require several high-temperature calcination steps and regrinding to give a single, selective phase of the catalyst. Attempts to use mechanical mixtures have been made because of co-operative catalytic effects in multiphase systems where individual catalytic phases were prepared separately before mixing. Occasionally, pure forms, often contaminated with small amounts (ca. 2%) of other phases, have been reported.[27] Thus, monitoring of the

preparation process is important to obtain selectively a single phase. This should enable a clarification of the roles and stabilities of individual bismuth molybdate phases during selective oxidations.

Thermogravimetry (TG), differential thermal analysis (DTA), and differential scanning calorimetry (DSC) are techniques generally used to study the thermal properties of solid samples in dynamic and static thermal processes.[28] However, these techniques fail to provide direct information about the phases and their compositions during a dynamic process. Thermo-Raman spectroscopy (TRS) is a useful technique in which successive collection of Raman spectra yields many details about a dynamic thermal process. The compositional changes of all the intermediates and phase transformations can be easily monitored and identified on a time scale of seconds and in temperature increments of one degree. The Raman intensity and the derivative of the Raman intensity of the characteristic band are plotted as a function of temperature and are the thermo-Raman intensity (TRI) and differential thermo-Raman intensity (DTRI) thermograms, respectively. These provide detailed quantitative information about the compositional changes and phase transformations[29] and can be compared with thermograms from TG, DTA, and DSC. Thus, thermo-Raman spectroscopy should be an ideal technique for monitoring and study of the morphological and compositional changes occurring during heating and calcinations.

In this work, the compositional variations of $Bi_2Mo_3O_{12}\cdot 5H_2O$ were observed by thermo-Raman spectroscopy in the temperature range from 25 to 600 °C. Spectral variation monitored in the H_2O and MoO_4^{2-} regions revealed four dehydrations resulting in formation of $Bi_2Mo_3O_{12}\cdot 4.75H_2O$, $Bi_2Mo_3O_{12}\cdot 3H_2O$, $Bi_2Mo_3O_{12}\cdot 2H_2O$, and $Bi_2Mo_3O_{12}$, respectively. Characteristic Raman spectra representing all the intermediates were obtained. The TRI thermogram and DTRI thermogram for the H_2O bands were plotted revealing four steps of dehydration with a proportionate loss of water in each step. The TG thermogram showed loss of 9% weight for the entire dehydration process suggesting loss of five H_2O molecules, with differential thermogravimetry (DTG) thermograms showing dips at 95, 148, 190, and 221 °C. Formation of anhydrous $Bi_2Mo_3O_{12}$ (amorphous $Bi_2Mo_3O_{12}$) in the temperature range from 290 to 320 °C was followed by transformation to the α-$Bi_2Mo_3O_{12}$ phase, which was identified by its Raman spectrum in the temperature range from 320 to 345 °C. This resulting α-$Bi_2Mo_3O_{12}$ phase was subjected to morphological and phase purity characterization.

Results and Discussion

Thermograms

The TG thermogram of $Bi_2Mo_3O_{12}\cdot 5H_2O$ in the temperature range from 25 to 600 °C is shown in Figure 1(a). It indicates a weight loss of 9% for the entire dehydration process suggesting the loss of five water molecules (calculated weight loss for five water molecules = 9.1%). The TG thermogram shows weight losses of 0.5% or 0.25 water molecules (T = 90−100 °C to form $Bi_2Mo_3O_{12}\cdot 4.75H_2O$), 3.5% or 1.9 water molecules (T = 100−165 °C to form $Bi_2Mo_3O_{12}\cdot 3H_2O$), 5.4% or 2.93 molecules (T = 165−200 °C to form $Bi_2Mo_3O_{12}\cdot 2H_2O$), and 9% or 4.94 water molecules (T = 200−290 °C to form anhydrous $Bi_2Mo_3O_{12}$) in the first, second, third, and fourth steps of dehydration, respectively. The entire dehydration process extended up to 290 °C. The observed weight losses were in close agreement with the theoretical weight losses of 0.5, 3.6, 5.4, and 9.1%, in the respective dehydration steps. Further heating gave a slight loss in weight upon transformation into the α-$Bi_2Mo_3O_{12}$ phase. This might be due to the diffusion of lattice oxygen atoms to the surface and its subsequent loss, as the bulk is known to act as an oxygen carrier.[1]

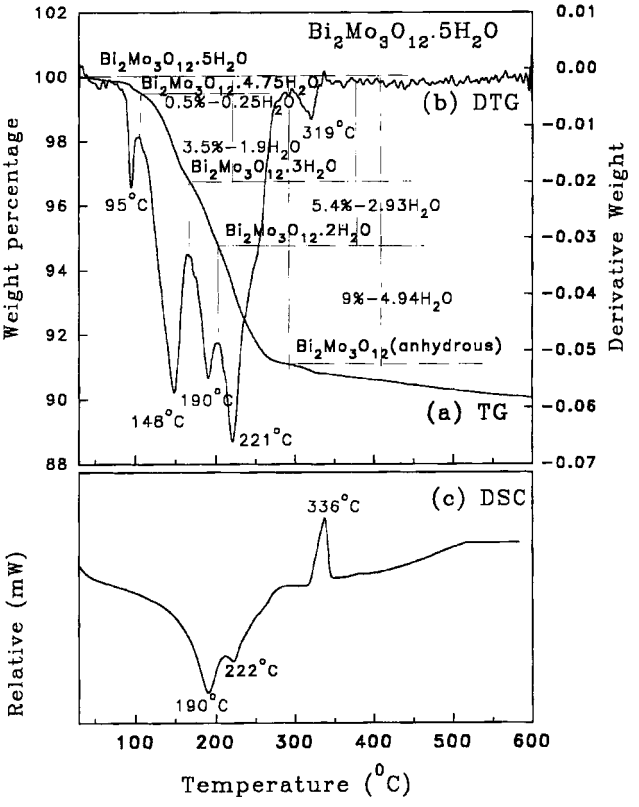

Figure 1. (a) TG, (b) DTG, and (c) DSC thermograms from 25 to 600 °C starting from $Bi_2Mo_3O_{12}\cdot 5H_2O$

The DTG thermogram, which is the derivative of the TG thermogram, is shown in Figure 1(b). It shows dips at 95, 148, 190, and 221 °C indicating maximum weight losses during the first, second, third, and fourth dehydration steps, respectively. A slight shoulder at 250 °C to the dip at 221 °C is due to the prolonged fourth step of dehydration. The dip at 319 °C is assigned to the transformation from the anhydrous form to the α-$Bi_2Mo_3O_{12}$ phase. No further information could be extracted at higher temperatures.

There are several reports about the presence of the hydrated species. Murakami and Imai[30] reported the presence of $Bi_2Mo_3O_{12}\cdot 4.75H_2O$ and anhydrous $Bi_2Mo_3O_{12}$ (amorphous) based on thermogravimetric (TG) analysis.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The amorphous phase formation occurred at 150 °C based on the X-ray diffraction pattern, contradicting their TGA data, which indicated a transition at 250 °C. Yinjie and Aimin[31] estimated the presence of $Bi_2Mo_3O_{12}\cdot 3.86H_2O$ based on their TGA data. Thus, it was of interest to determine the different hydrated species of $Bi_2Mo_3O_{12}\cdot 5H_2O$.

The DSC thermogram of $Bi_2Mo_3O_{12}\cdot 5H_2O$ in the temperature range from 25 to 600 °C is shown in Figure 1(c). It has a broad endotherm at 190 °C accounting for the first three dehydration steps and an endotherm at 222 °C for the fourth dehydration step . The sharp exotherm at 336 °C (enthalpy = −22.6 J/g) is as a result of the phase transformation from the amorphous phase to the α-$Bi_2Mo_3O_{12}$ phase. The DSC thermogram also shows that the entire dehydration process extends up to 290 °C, in contrast to the earlier report by Murakami and Imai.[30]

Thermo-Raman Studies

Extensive theoretical considerations and experimental studies have shown that vibrational spectroscopy of powdered samples provides information not only about the phases, but also about the size, shape, and state of aggregation of the particles that constitute the powder.[32] Assuming the internal and external modes of the sample to be independent of one another, the internal modes of metal oxide molecules within the unit cell of a crystal occur in the medium- and high-frequency regions (> 400 cm^{-1} for the MoO_4^{2-} species). External modes, including translational and librational modes, occur at lower frequencies (< 400 cm^{-1}). This helps in identification and assignment of species based on their characteristic Raman spectra. The internal modes in the range from 400 to 1200 cm^{-1} provide information about the environment around the MoO_4^{2-} ions. The free molybdate ion, MoO_4^{2-}, is tetrahedral with point group T_d symmetry. It has four vibrational modes $\nu_1(A_1)$, $\nu_2(E)$, $\nu_3(T_2)$, and $\nu_4(T_2)$. The stretching modes connect $\nu_1(A_1)$ and $\nu_3(T_2)$, while the bending modes connect $\nu_2(E)$ and $\nu_4(T_2)$. In addition, the α-$Bi_2Mo_3O_{12}$ phase contains three different tetrahedra which might result in different band positions. Matsuura et al.[18] reported six bands around 900 and 800 cm^{-1} attributed to the stretching modes of each tetrahedral species. Theobald et al.,[15] in their XANES experiments, observed that the Mo^{6+} ions in

α-$Bi_2Mo_3O_{12}$ are surrounded by five oxygen atoms in an asymmetric Mo−O_5 coordination environment, with an average Mo−O interatomic distance of 1.91 Å. However, the Fourier transform EXAFS data revealed a substantial structural complexity. The irregular oxygen coordination about the Mo^{6+} ions results in three peaks at 1.26, 1.53, and 1.97Å. The more distant Bi and Mo cations around this molybdenum give rise to three peaks at 2.86, 3.30, and 3.65 Å, which are due to Mo···Mo, Mo···Bi, and Mo···Mo/Bi back scatterings, respectively.[13] Generally, in dynamic thermal process within crystals, structural distortions may occur, which lower the symmetry causing shifting and splitting of the bands. Raman bands for $Bi_2Mo_3O_{12}$ fall between 200 and 1200 cm^{-1} and are assigned as in Table 1. The broad band in the range from 3200 to 3600 cm^{-1} is due to lattice H_2O (antisymmetric and symmetric OH stretching).[21]

Dehydration

First Dehydration

Figure 2(A)(a) shows the characteristic Raman spectrum of $Bi_2Mo_3O_{12}·5H_2O$ at 25 °C in the H_2O region from 3000 to 3700 cm^{-1}. The two broad bands at 3453 and 3265 cm^{-1} at 25 °C represent the lattice H_2O. As the temperature rises above 60 °C, these bands shift to 3451 and 3285 cm^{-1}, respectively, as $Bi_2Mo_3O_{12}·4.75H_2O$ forms during the first dehydration step. The characteristic Raman spectrum of $Bi_2Mo_3O_{12}·4.75H_2O$ in the water region is shown in Figure 2(A)(b) (100 °C). The actual transformation occurs in the temperature range from 60 to 75 °C, where the weakly bound water molecule (water of crystallization) is easily lost.

The corresponding characteristic Raman spectrum of $Bi_2Mo_3O_{12}·5H_2O$ at 25 °C in the MoO_4^{2-} region (from 200 to 1200 cm^{-1}) is shown in Figure 2(B)(a). A slight decrease in intensity of the two bands at 920 and 866 cm^{-1} is observed with the rise in temperature to 100 °C. The bands at 684, 649, 525, 499, 467, 418, 374, 352, 342, 292, and 267 cm^{-1} show a slight broadening. No distinct changes in spectrum and symmetry of MoO_4^{2-} were observed since only a small amount of water is lost in this step. Among the noticeable changes, the weak band at 499 cm^{-1} appears as a shoulder to the band at 525 cm^{-1} and the doublet at 352 and 342 cm^{-1} disappears as the temperature rises above 60 °C. These spectral changes were especially evident in the temperature range from 60 to 75 °C and are represented in the characteristic spectrum of $Bi_2Mo_3O_{12}·4.75H_2O$ shown in Figure 2(B)(b). The first dehydration is the transformation from $Bi_2Mo_3O_{12}·5H_2O$ to $Bi_2Mo_3O_{12}·4.75H_2O$. To the best of our knowledge, no crystal data are available for $Bi_2Mo_3O_{12}·5H_2O$. However, the structure of $Bi_2Mo_3O_{12}·5H_2O$ could be similar to that of $Bi_2Mo_3O_{12}·4.75H_2O$ (reported by Murakami and Imai,[30]) based on the similarity of their Raman spectra. The crystal structure of $Bi_2Mo_3O_{12}·4.75H_2O$ has a monoclinic unit cell, with lattice parameters calculated to be a = 6.334, b = 11.593, c = 5.777 Å and β = 113.166° as indexed from the X-ray diffraction pattern.

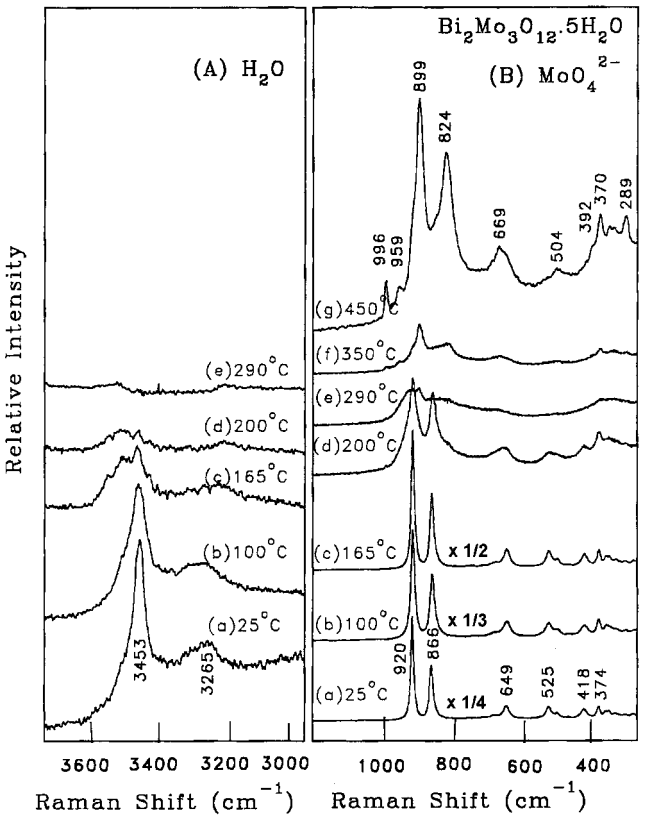

Figure 2. Characteristic thermo-Raman spectra of $Bi_2Mo_3O_{12}·5H_2O$ during the dehydration and of the intermediate hydrated species observed: (a) $Bi_2Mo_3O_{12}·5H_2O$ (25 °C; intensity reduced 4 times); (b) $Bi_2Mo_3O_{12}·4.75H_2O$ (100 °C; intensity reduced 3 times); (c) $Bi_2Mo_3O_{12}·3H_2O$ (165 °C; intensity reduced 2 times); (d) $Bi_2Mo_3O_{12}·2H_2O$ (200 °C); (e) $Bi_2Mo_3O_{12}$ (290 °C); (f) $Bi_2Mo_3O_{12}$ amorphous phase (350 °C); (g) α-$Bi_2Mo_3O_{12}$ (450 °C) in (A) the H_2O region from 3000 to 3700 cm^{-1} and (B) the MoO_4^{2-} region from 200 to 1200 cm^{-1}

Second Dehydration

The spectral variations in the H_2O region for the second dehydration in the temperature range from 100 to 165 °C were observed and the characteristic Raman spectrum of $Bi_2Mo_3O_{12}·3H_2O$ is shown in Figure 2(A)(c). The broad band at 3451 cm^{-1} further broadens and shifts to 3462 cm^{-1} as the temperature rises above 128 °C. Two broad bands at 3549 and 3502 cm^{-1} emerge and become distinct with the rise in temperature to 165 °C. The broad band at 3285 cm^{-1}splits into bands at 3305, 3273, and 3233 cm^{-1}. Overall, a decrease in intensity of the H_2O bands was observed with major spectral changes in the temperature range from 128 to 132 °C.

Similar changes were observed in the MoO_4^{2-} region for the second dehydration in the temperature range from 100 to 165 °C, and the characteristic Raman spectrum of $Bi_2Mo_3O_{12}·3H_2O$ is shown in Figure 2(B)(c). The bands observed at 920 and 866 cm^{-1} show a notable decrease in intensity as the temperature rises to 165 °C. The singlet at 351 cm^{-1}, observed at 100 °C, splits into two bands at 352 and 342 cm^{-1} as the temperature rises above 128 °C. The

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

band at 322 cm^{-1} becomes distinct and the bands at 289 and 263 cm^{-1} shift to 291 and 267 cm^{-1}, respectively. The spectral changes in the temperature range from 128 to 132 °C correspond to a second dehydration to form $Bi_2Mo_3O_{12}·3H_2O$ from $Bi_2Mo_3O_{12}·4.75H_2O$. The two water molecules lost below 165 °C are attributed to the water of crystallization. To the best of our knowledge, the Raman spectrum of $Bi_2Mo_3O_{12}·3H_2O$ is reported here for the first time and crystal structure data for $Bi_2Mo_3O_{12}·3H_2O$ are yet to be reported. However, based on the similarity of their Raman spectra, its structure is expected to be similar to $Bi_2Mo_3O_{12}·4.75H_2O$ with a slight variation in lattice parameters. Yinjie and Aimin,[31] reported the crystal structure of $Bi_2Mo_3O_{12}·3.86H_2O$ as monoclinic, with lattice parameters calculated to be a = 6.338, b = 11.658, c = 5.787 Å and β = 113.168° as indexed from the X-ray diffraction pattern.

Third Dehydration

Spectral variations were observed in the H_2O region for the third dehydration in the temperature range from 165 to 200 °C with a transformation temperature at 192 °C. The characteristic Raman spectrum of $Bi_2Mo_3O_{12}·2H_2O$ obtained after the third dehydration is shown in Figure 2(A)(d). The spectrum at 165 °C shows broad bands at 3549 and 3462 cm^{-1}. These bands gradually shift to 3542 and 3458 cm^{-1}, respectively, with the rise in temperature above 190 °C. The band at 3502 cm^{-1} further broadens and the weak bands at 3305 and 3273 cm^{-1} disappear as the temperature approaches 200 °C. The weak band at 3233 cm^{-1} shifts to 3220 cm^{-1}.

Spectral variations were also observed in the MoO_4^{2-} region for the third dehydration step in the temperature range from 165 to 200 °C and the characteristic spectrum of $Bi_2Mo_3O_{12}·2H_2O$ is shown in Figure 2(B)(d). The band at 920 cm^{-1} broadens and drastically decreases in intensity. A shoulder at 820 cm^{-1} to the band at 864 cm^{-1} starts appearing at 193 °C and gradually resolves as the temperature rises to 200 °C. The band at 649 cm^{-1} broadens and shifts to 657 cm^{-1} and the shoulder at 684 cm^{-1} gradually disappears as the temperature rises to 200 °C. Similarly, the band at 525 cm^{-1} becomes weak and the shoulder at 501 cm^{-1} and the weak band at 467 cm^{-1} disappear. The doublet at 352 and 342 cm^{-1} merges to form a broad singlet at 342 cm^{-1}. The lower modes at 322, 291, and 267 cm^{-1} also disappear as the temperature rises to 200 °C. The major changes observed in the spectra indicate the drastic change in symmetry of MoO_4^{2-}, even though only one water molecule is lost in this step, resulting in the transformation from $Bi_2Mo_3O_{12}·3H_2O$ to $Bi_2Mo_3O_{12}·2H_2O$. This shows that the water molecule evolved in this third dehydration must be different from the two water molecules evolved in the previous dehydrations and that it is associated directly with the structural composition. It is assigned as a water of constitution. The crystal structure of $Bi_2Mo_3O_{12}·2H_2O$ is yet to be reported.

Fourth Dehydration

The spectral variations in the H_2O region for the fourth dehydration in the temperature range from 200 to 290 °C were monitored and the characteristic Raman spectrum for anhydrous $Bi_2Mo_3O_{12}$ is shown in Figure 2(A)(e). The weak, broad bands observed at 3542, 3502, 3458, and 3220 cm^{-1} gradually disappear when the temperature reaches 290 °C. This indicates a complete loss of water to form anhydrous $Bi_2Mo_3O_{12}$. The Raman spectral profile appears almost flat.

Similarly, spectral changes were clearly observed in the MoO_4^{2-} region for the fourth dehydration in the temperature range from 200 to 290 °C with a transformation temperature observed at 220 °C. The characteristic Raman spectra of the anhydrous $Bi_2Mo_3O_{12}$ is shown in Figure 2(B)(e). The broad band at 920 cm^{-1} gradually shifts to 928 cm^{-1} and a new band at 905 cm^{-1} starts to appear as the temperature rises above 220 °C. The band at 864 cm^{-1} and its shoulder at 820 cm^{-1} disappear and a broad band at 844 cm^{-1} appears as the temperature approaches 290 °C. The band at 657 cm^{-1} decreases in intensity and shifts to 681 cm^{-1}. The weak bands at 525 and 420 cm^{-1} disappear and the weak bands at 374 and 342 cm^{-1} broaden and decrease in intensity as the temperature rises to 290 °C. Major spectral changes observed in the temperature range from 220 to 240 °C are the result of the fourth dehydration where $Bi_2Mo_3O_{12}·2H_2O$ transforms to anhydrous $Bi_2Mo_3O_{12}$. The crystal structure of anhydrous $Bi_2Mo_3O_{12}$ has not been reported. However, an X-ray diffraction pattern recorded contained no measurable peaks suggesting that the powder is amorphous (data not shown).

Phase Transformations

Figure 2(B)(f) shows the representative spectral variations in the MoO_4^{2-} region from 200 to 1200 cm^{-1} for the onset of crystallization of the α-$Bi_2Mo_3O_{12}$ phase from the $Bi_2Mo_3O_{12}$ amorphous phase. The crystallization process began at 312 °C. The spectrum at 350 °C shows traces of the amorphous phase as well as the α-$Bi_2Mo_3O_{12}$ phase. The weak bands at 996, 959, 504, 374, and 289 cm^{-1} are due to the α-$Bi_2Mo_3O_{12}$ phase whereas the sharp bands at 905, 672, and 328 cm^{-1} represent the amorphous phase. The band at 928 cm^{-1} (290 °C) shifts to 905 cm^{-1} as the temperature approaches 350 °C. A further increase in temperature to 450 °C, as in Figure 2(B)(g), shows sharp bands at 996, 959, 899, 824, 669, 504 370, 340, 324, and 289 cm^{-1} characteristic of the α-$Bi_2Mo_3O_{12}$ phase. A major shift in the band at 905 cm^{-1} to 899 cm^{-1} was observed. There were no further spectral changes up to 600 °C indicating a complete transformation into the pure α-$Bi_2Mo_3O_{12}$ phase. The crystal structure of the α-$Bi_2Mo_3O_{12}$ phase (scheelite structure) has been extensively studied and reported to be monoclinic (trigonal-bipyramidal or distorted tetrahedral) with space group $P2_1/c$ and unit cell parameters a = 7.685, b = 11.491, c = 11.929 Å with characteristic edge β = 115.40°.[33] The crystal structure, reported by Cesari et

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

al.,[34] shows that the α-$Bi_2Mo_3O_{12}$ phase consists of two kinds of twin tetrahedra $\alpha_1\alpha_1$ and $\alpha_2\alpha_3$, one of which ($\alpha_1\alpha_1$) contains a center of symmetry; α_1 and α_2 have Bi ions adjacent to the tetrahedra, while there is a Bi ion vacancy in the α_3 tetrahedron. In all cases, there are three different and distorted tetrahedra, resulting in complicated absorption bands.

Intensity Variation

The thermo-Raman intensity (TRI) and the derivative of the thermo-Raman intensity (DTRI) of the water bands in the range from 3100 to 3700 cm^{-1} from 25 to 300 °C were plotted as shown in Figure 3(a) and (b), respectively. Based on the TGA information, the loss in intensity is equated with loss of five molecules of water. Slopes in the TRI thermogram indicate loss of water and plateaus imply intermediate formation. The TRI thermogram shows four slopes and four plateaus corresponding to four steps of dehydration. The temperature range, percentage reduction in intensity (between two intermediates), equivalent number of molecules of water lost and dip observed in the DTRI during each step of dehydration are tabulated in Table 2. The entire dehydration process extended up to 290 °C and no further decrease in intensity was observed, indicating completion of the dehydration. The slight temperature variations in the starting and end point of each of the dehydration steps in the TRS and TGA can be attributed to the different physical properties monitored by these techniques. TRS monitors the surface of the sample whilst TGA monitors the bulk. However, the end point of the completion of the dehydration process was the same for both techniques.

Band Shift

Figure 4 shows the shifts of the bands at 920 and 866 cm^{-1} plotted as a function of temperature (from 25 to 600 °C). No noticeable shift in the band at 866 cm^{-1} was observed until it gradually disappeared during the fourth step of dehydration. A similar trend was observed for the characteristic band at 920 cm^{-1}, although it showed a gradual shift to 928 cm^{-1} during the fourth step of dehydration. This clearly indicates that a major structural transformation occurs during the fourth dehydration, where two water molecules (water of constitution) are lost, distorting the structure and the environment around the MoO_4^{2-} ions. Furthermore, a drastic shift of the band from 928 to 905 cm^{-1} was observed around 310 °C during the onset of crystallization towards the formation of α-$Bi_2Mo_3O_{12}$ phase. As the temperature rose above 310 °C the band shifted gradually to 899 cm^{-1} after which no further shift was noted marking completion of transformation into the α-$Bi_2Mo_3O_{12}$ phase.

Characterization of the α-$Bi_2Mo_3O_{12}$ Phase

Morphological characteristics depend on the rate of heating and calcination time. The particle size is important and

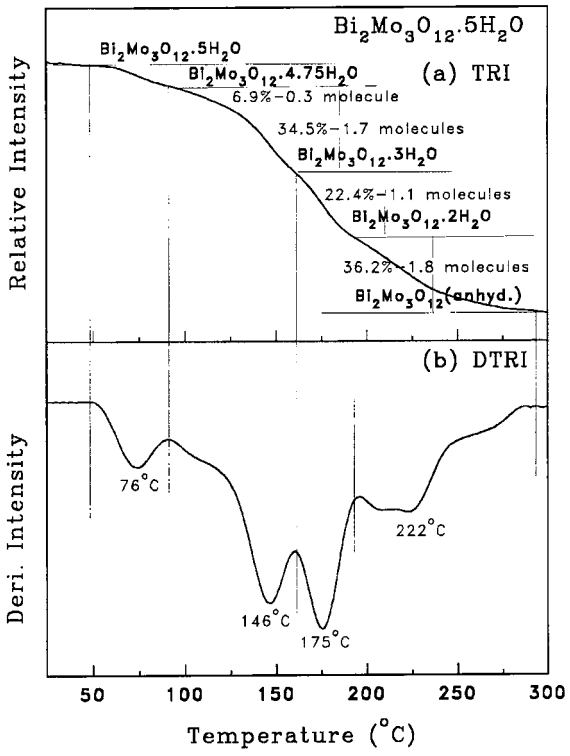

Figure 3. (a) Thermo-Raman intensity (TRI) thermogram and (b) differential thermo-Raman intensity (DTRI) thermogram for the stretching bands of H_2O during dehydration of $Bi_2Mo_3O_{12}\cdot 5H_2O$ in the temperature range from 25 to 300 °C

governs the activity and selectivity of bismuth molybdates, which must provide sufficient lattice oxide ions during catalytic redox cycles.[35]

Fourier Transform Infrared Spectroscopy

Figure 5 shows the FT-IR spectra of as-synthesized $Bi_2Mo_3O_{12}\cdot 5H_2O$ and the α-$Bi_2Mo_3O_{12}$ phase (sample collected at 450 °C). The IR spectra and the bands of the α-$Bi_2Mo_3O_{12}$ phase are in agreement with those observed by Matsuura et al.[18] The major difference observed was the disappearance of water bands and the bands at 1189 and 1879 cm^{-1}. In addition, a drastic decrease in intensity was noted in the spectra of the α-$Bi_2Mo_3O_{12}$ phase with a major splitting around 900 cm^{-1}.

X-ray Diffraction (XRD)

The XRD patterns of $Bi_2Mo_3O_{12}\cdot 5H_2O$ and the α-$Bi_2Mo_3O_{12}$ phase are shown in Figure 6. The XRD pattern of the amorphous phase contains no diffraction peaks (data not shown). The crystalline nature of $Bi_2Mo_3O_{12}\cdot 5H_2O$ and the α-$Bi_2Mo_3O_{12}$ phase is demonstrated by the presence of distinct diffraction peaks. However, notable changes in the diffraction patterns between the two crystalline forms was observed which agrees with the considerable spectral changes observed in our thermo-Raman study. The diffraction pattern of pure α-$Bi_2Mo_3O_{12}$ is in close agreement with that reported by Li and Cheng.[5] Measurement of the XRD

Table 2. TRI and DTRI data obtained during dehydration of $Bi_2Mo_3O_{12}·5H_2O$

Dehydration	Temperature. range [°C]	Intensity drop (% of H_2O)	H_2O molecules [equiv.]	DTRI endotherm [°C]
First step ($Bi_2Mo_3O_{12}·5H_2O$ to $Bi_2Mo_3O_{12}·4.75H_2O$)	50−95	6.9	0.3	76
Second step ($Bi_2Mo_3O_{12}·4.75H_2O$ to $Bi_2Mo_3O_{12}·3H_2O$)	100−160	34.5	1.7	146
Third step ($Bi_2Mo_3O_{12}·3H_2O$ to $Bi_2Mo_3O_{12}·2H_2O$)	165−190	22.4	1.1	175
Fourth step ($Bi_2Mo_3O_{12}·2H_2O$ to anhyd. $Bi_2Mo_3O_{12}$)	190−290	36.2	1.8	222

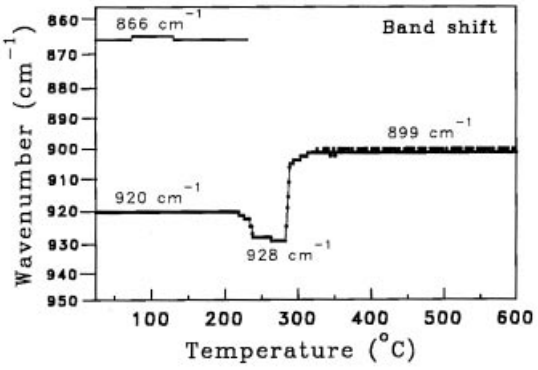

Figure 4. Band-shift measurements for the bands at 920 and 866 cm^{-1} of $Bi_2Mo_3O_{12}·5H_2O$ observed in the temperature range from 25 to 600 °C

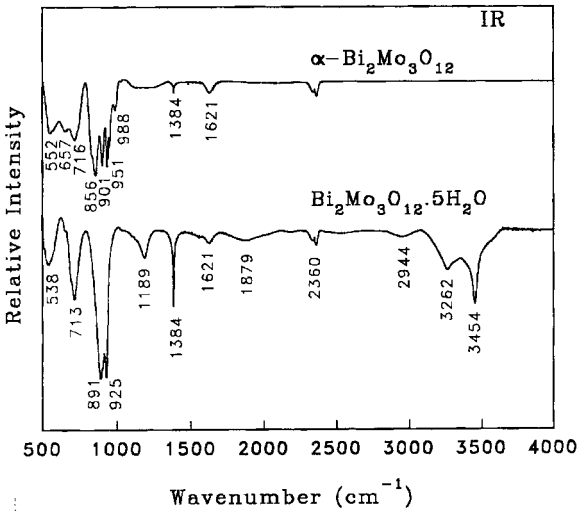

Figure 5. Fourier transform infrared spectra of as-synthesized $Bi_2Mo_3O_{12}·5H_2O$ and α-$Bi_2Mo_3O_{12}$ in the range from 500 to 4000 cm^{-1}

patterns of the intermediate hydrated species should be of interest for a better comparison with the data obtained from thermo-Raman spectroscopy. Ideally, an in situ measurement of the temperature dependence of the XRD spectrum over the temperature range of interest is required to obtain accurate data.

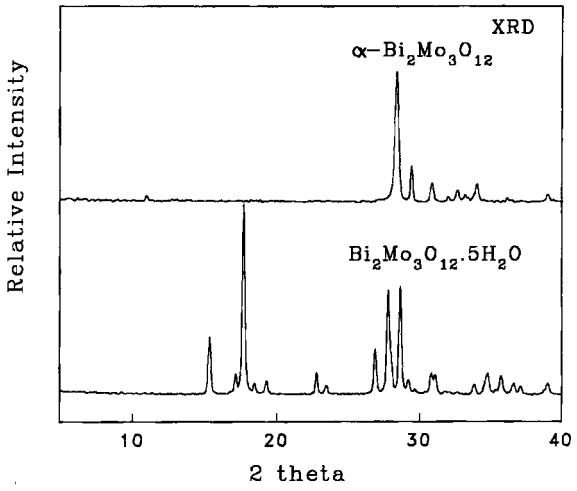

Figure 6. XRD pattern of as-synthesized $Bi_2Mo_3O_{12}·5H_2O$ and α-$Bi_2Mo_3O_{12}$ (heated to 450 °C)

Time of Flight Secondary Ionization Mass Spectrometry (TOF SIMS)

The positive ion static TOF-SIMS spectrum of the α-$Bi_2Mo_3O_{12}$ phase was also recorded and is presented in Figure 7. The observed spectral pattern and the $Bi_3O_4^+/Bi^+$ ratio of 0.0004 are in close agreement with that previously reported for the α-$Bi_2Mo_3O_{12}$ phase.[16] Considering the sensitivity of TOF-SIMS, the phase purity of α-$Bi_2Mo_3O_{12}$ can be confirmed. However, the peaks at m/z = 487 and 565 reported by Weng et al.[16] were not observed.

Electron Microscopic Study and EDS Analysis

Electron microscopy is extensively used for structural, chemical (composition), and morphological studies (grain size, crystallinity, and phase identification). Figure 8(a) shows a TEM image of the α-$Bi_2Mo_3O_{12}$ phase obtained after controlled heating to 450 °C at a rate of 5 °C·min^{-1}. The distribution of the particle size was in the range of several hundreds of nanometers (avg. 200 nm) as observed from the particle size distribution profile deduced from TEM images [Figure 8,(b)]. However, in most of the earlier reports where the calcination step probably involved fast heating rates, the particle size was reported to be in the

micrometer range (100−400 μm).[36] EDS is useful for quantitative analysis. EDS measurements were carried out on $Bi_2Mo_3O_{12}·5H_2O$, α-$Bi_2Mo_3O_{12}$ (heated at 450 °C), and α-$Bi_2Mo_3O_{12}$ (heated at 550 °C). The presence of bismuth, molybdenum, and oxygen was examined and a representative EDS spectrum of α-$Bi_2Mo_3O_{12}$ (heated at 550 °C) is shown in Figure 8(c). The bismuth and molybdenum contents, and the Bi/Mo ratios in all the samples were identical. The atomic ratio of Bi/Mo was observed to be 43:57 which is in close agreement with the molar ratios of Bi_2O_3/$Na_2MoO_4·2H_2O$ in the starting solution.

According to AFM, XRD, and XPS experiments carried out by Yanina and Smith,[37] a loss of Mo was observed on heating to temperatures higher than 500 °C in dry air or air with 2.3% H_2O due to volatilization. This resulted in precipitation of traces of γ-Bi_2MoO_6 and β-$Bi_2Mo_2O_9$ on the surface of the α-$Bi_2Mo_3O_{12}$ catalyst. However, no such changes were observed in our experiments even though the heating was performed in the presence of air. This might be due to the slow and controlled heating rate used in our experiment. Additionally, TOF-SIMS data also support the presence of the α-$Bi_2Mo_3O_{12}$ phase. This provides evidence for the formation of the pure form of the α-$Bi_2Mo_3O_{12}$ catalyst under a controlled heating rate in the presence of air. In addition, the particle size observed from TEM images lies in the hundreds of nanometers range, suggesting that the controlled heating rate is also important in governing the particle size of the catalyst.

Conclusion

A systematic study of the dehydration and phase-transformation processes of $Bi_2Mo_3O_{12}·5H_2O$ was carried out using thermo-Raman spectroscopy in the temperature range from 25 to 600 °C. Three different hydrated species, $Bi_2Mo_3O_{12}·4.75H_2O$, $Bi_2Mo_3O_{12}·3H_2O$, $Bi_2Mo_3O_{12}·2H_2O$, and anhydrous $Bi_2Mo_3O_{12}$ were observed as intermediates, based on the spectral variations observed in the H_2O and MoO_4^{2-} absorption regions during temperature increments of 1 °C. Characteristic Raman spectra of these hydrated species have been reported for the first time. The TRI thermogram for the H_2O bands supported the results revealing four dehydration steps with a proportionate loss of water in each step. The DTRI thermogram was also in harmony with the TRI and TGA data. The phase transformation of anhydrous $Bi_2Mo_3O_{12}$ to the α-$Bi_2Mo_3O_{12}$ phase was also observed and characterized by other techniques. Slow and controlled heating resulted in the α-$Bi_2Mo_3O_{12}$ phase without precipitating γ-Bi_2MoO_6 and β-$Bi_2Mo_2O_9$ phases and the particle size thus obtained was in the range of a few hundreds of nanometers as observed from the morphological characterization. The characterization of the α-$Bi_2Mo_3O_{12}$ phase by XRD, EDS, and FTIR for phase purity was further supported by TOF-SIMS analysis. The fact that the thermo-Raman spectroscopy setup could detect all the dehydration steps involved and also the transformation to the α-$Bi_2Mo_3O_{12}$ phase indicates its sensitivity and potential future applications in monitoring catalyst formation if a commercial instrument can be developed.

Experimental Section

Sample Preparation: Bi_2O_3 (Aldrich Chem., WI, USA) and $Na_2MoO_4·2H_2O$ (Riedel−de Haën, Seelze, Germany) were used as received without further purification. Bi_2O_3 and $Na_2MoO_4·2H_2O$ (1:3 molar ratio) were dissolved in 1 M nitric acid and stirred vigorously at 60 °C until a slurry was obtained. This slurry was cooled, filtered, and the residue washed thoroughly with distilled water until the washings reached pH = 6. The sample was dried at room temperature to ensure the retention of water of hydration. This sample was lightly ground prior to analysis.

Thermo-Raman Study: The Raman spectra were obtained using laser excitation at a wavelength of 514.5 nm (50 mW) from an argon ion laser (Coherent, Innova 100-15). A filter was used to remove the plasma lines. The scattered light was collected at right angles, dispersed by a single spectrometer (Spex, 0.5 m) with a resolution of 2 cm^{-1} and detected by a CCD camera (Princeton Instruments, 1024 × 1024 pixels). A notch filter was set in front of the spectrometer to remove the Rayleigh scattered light. The sample was placed in a sample holder and mounted on the thermocouple in a homemade oven in stationary air. The temperature of the oven was programmed to increase from 25 to 600 °C at a rate of 5 °C min^{-1}. Thermo-Raman spectra were collected continuously during heating without disturbing the sample. The exposure time of the CCD was set such that the temperature range covered by each spectrum was 1 °C. Overall, 575 spectra were collected and their reproducibility checked in the spectral range from 200 to 1400 cm^{-1} for MoO_4^{2-} whilst 275 spectra in the range from 2900 to 3900 cm^{-1} were collected for H_2O. A BASIC computer program was written to systematically determine the intensity variation for TRI thermogram and the band-shift measurements.

Characterization: A thermogravimetric analyzer (Perkin−Elmer TGA6) was used to record the thermogram in the temperature range from 25 to 600 °C with a heating rate of 5 °C·min^{-1} in a flow of air at 20 mL·min^{-1}. The DSC thermogram of the same sample was recorded with a Setaram DSC131 in a crimped aluminum crucible in the temperature range from 25 to 550 °C with a heating rate of 5 °C·min^{-1} in a flow of air at 30 mL·min^{-1}. Fourier transform infrared spectroscopy was carried out with a Bomem Hartmann & Braun (MB-series) spectrometer. The X-ray diffraction patterns of the product were measured with a Material Analysis and Characterization (MAC) advanced powder X-ray diffractometer using Cu-$K_{\alpha 1}$ radiation (1.54056 Å). Positive TOF SIMS (ION-TOF) measurements were performed using pulsed Ga^+ ions (15 keV) and a post-acceleration of 10 kV. The analysis area of 100 μm × 100 μm with data acquisition time of 200 s was used for static TOF-SIMS conditions. The best resolution obtained was $M/\Delta M \approx 8000$. The powders were pressed on to the carbon tape supported on a clean Si wafer. Excess particles were removed by blowing with compressed air such that the layer thickness was minimal. The particle morphology was studied by transmission electron microscopy (TEM) (Philips, Tecnai 20) working at a 200 kV accelerating voltage. A drop of sample suspension, which had been previously dispersed in methanol by ultrasonication, was placed on the microgrid and dried before microscopy study. The elemental composition of the material was analyzed by energy-dispersive X-ray analysis (EDS) (Philips, Tecnai 20).

Linear Multinuclear Ru^{II} Photosensitizers

Simona Vaduvescu[a] and Pierre G. Potvin*[a]

Keywords: Ruthenium / Tridentate ligands / Bridging ligands / Electron transfer / Photochemistry

Four ditopic bridging ligands, containing 2,2′:6′,2′′-terpyridine and 2,6-dipyrazinylpyridine (dpp) metal-binding units attached through *p*- or *m*-phenylene linkages, have been incorporated into eight mono-, di- and trinuclear linear Ru^{II} complexes. These were characterized by UV/Vis spectroscopy and cyclic voltammetry, and by their ability to undergo light-induced electron transfers to methylviologen. The dpp-bearing complexes were more difficult to prepare but were superior sensitizers, a fact attributable to longer excited state lifetimes and an electrostatically favored reductive quenching pathway.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Ruthenium(II)−polypyridine complexes act as light absorption sensitizers,[1] a characteristic that can be put to use in solar energy conversion and storage applications. A critical limitation on the photo-responsiveness is the concentration of the sensitizer's excited state that can be achieved, and this notably depends on the excited state lifetime (τ) and on the extinction coefficient (ε) for the metal-to-ligand charge transfer (MLCT) absorption that leads to the excited state. One approach to improving the photoactivity is to increase the number of metal atoms in the sensitizer and the probability of light absorption. Dendritic assemblies epitomize this idea,[2] but electrostatic considerations make them unattractive because their globular structures and high charges would impede electron transfers to positively charged acceptors, such as methylviologen (MV^{2+}), and/or, in the case of neutral or anionic acceptors, would facilitate the energy-wasting reverse electron transfer that regenerates the initial states. The effect of charge repulsion can be minimized with linear multinuclear arrays, where an end-on approach by an electron acceptor is minimally affected by repulsions from the more distal metal centers. Hence, the electrostatics can be relatively insensitive to the sensitizer chain length while the light absorption would increase with chain length.

We have recently communicated the preparation and characterization of a linear trinuclear Ru^{II} complex in which the "back-to-back" bis(terpy) ligand **A** bridges the metal centers. This material was assessed as a photosensitizer relative to the mono- and dinuclear analogues.[3] In the above-mentioned report, the assessment used measurements of the rates of formation of the methylviologen radical cation ($MV^{\cdot+}$) from methylviologen (MV^{2+}) in CH_3CN in the presence of a sacrificial reductant (triethanolamine) according to a set protocol.[4] Comparisons were also made with $[Ru(\mathbf{ttpy})_2]^{2+}$ (**ttpy** = 4′-*p*-tolyl-2,2′:6′,2′′-terpyridine), a related complex of known τ (0.95 ns in CH_3CN).[5] This paper provides full details of that work and extends it by exploring the photoactivity of several new complexes of related bridging ligands, namely the *meta* isomer of **A** (ligand **B**) and the dipyrazinylpyridine (dpp) analogues of **A** and **B** (ligands **C** and **D**). It was anticipated that the *meta* linkages

of **B** and **D** would enable electrostatically easier access, by MV^{2+}, to the areas between metal atoms in di- and trinuclear complexes and to the central metal atoms in trinuclear cases, while the dpp ligands would be expected to promote longer τ values.[6]

Results and Discussion

Synthesis

Bis(terpyridine) **A** is known, and has been prepared by two routes.[7,8] We prepared it by the one-pot method developed for the synthesis of dpp ligands,[6] and recently applied this to other terpy-based materials.[9] In this remarkable reaction, a total of seven reactant molecules condense and expel six molecules of H_2O, then undergo two cycles of aerial dehydrogenation. The isolated yield (39%) was entirely similar to those of the previous preparations but with less effort and in less time. The linkage isomer **B** was produced under the same conditions from isophthalaldehyde and in a similar yield (37%).[10] Its X-ray crystal structure showed a lack of co-planarity consistent with the absence of a resonance pathway of communication between terpy units. Its NMR spectra showed a single set of pyridine signals, which implies free rotation about the terpy-to-linker bonds. A useful spectroscopic marker for the complexes of **A** and **B** was the most downfield ^{1}H NMR signal, i.e. the singlet from the central pyridine 3′/5′-H (at δ = 8.83 ppm in free **A**; δ = 8.84 ppm in free **B**).

By similar reactions with acetylpyrazine, the bis(dpp) ligands **C** and **D** were obtained in isolated yields of 42% and 37%, respectively. Those materials are soluble only in trifluoroacetic acid (TFA) and could not be properly recrystallized. Their NMR spectra in [D]TFA were inconclusive, but their identities were confirmed by EI-MS and, for **C**, by conversions to Ru^{II} complexes (see below).

The monotopic **ttpy** was used as a terminal ligand. It could also be prepared by the one-pot method from acetylpyridine and *p*-tolualdehyde in 46% yield after recrystallization, while a 70% yield was obtained by our earlier, two-step method.[11]

[Ru(**ttpy**)Cl_3][12] was activated with $AgBF_4$,[13] then treated with 1 equiv. of **A** to form [(**ttpy**)Ru(**A**)]$(PF_6)_2$ in 70% yield, after chromatography and anion exchange. In contrast, [Ru(**A**)$_2$]$(PF_6)_2$ was obtained in only 40% yield, by treatment of $RuCl_3$ with 2 equiv. of **A**; 2 equiv. of [(**ttpy**)Ru(**A**)]$(PF_6)_2$ and 1 equiv. of $RuCl_3$ were heated in 1,2-ethanediol to form the trinuclear complex [(**ttpy**)Ru(**A**)Ru(**A**)-Ru(**ttpy**)]$(PF_6)_6$ in 87% yield, after anion exchange and recrystallization. The dinuclear analogue [(**ttpy**)Ru(**A**)-Ru(**ttpy**)]$(PF_6)_4$ was needed for comparative purposes. It is a known species[14] which we prepared from 2 equiv. of $AgBF_4$-activated [(**ttpy**)$RuCl_3$] and **A** in a yield of 19% (not optimized), after anion exchange, chromatography and a second cycle of anion exchange.

^{1}H and COSY NMR spectroscopy were used to confirm the structures. Complexation was indicated by a strong upfield migration of the doublets from 6-H, which juts out above the plane of the perpendicular ligand and experiences the effect of its ring current. Two sets of terpy signals were obtained with [Ru(**A**)$_2$]$(PF_6)_2$, including singlets for 3′/5′-H at δ = 9.14 ppm and 8.98 ppm for the complexed and free terpy units, respectively, and the phenylene singlet of **A** was replaced by a pair of doublets in this less symmetrical species. Though [(**ttpy**)Ru(**A**)]$(PF_6)_2$ has been previously reported,[15] it was characterized only by NMR spectroscopy. Here, three sets of partially overlapping terpy signals were evident, including three distinct 3′/5′-H singlets at δ = 9.12, 9.02 and 8.97 ppm for bound **A**, **ttpy** and free **A** terpyridine units, respectively, as well as phenylene doublets. With the trinuclear complex [(**ttpy**)Ru(**A**)Ru(**A**)Ru(**ttpy**)]$(PF_6)_6$, three sets of terpy ^{1}H NMR signals were expected but the majority overlapped considerably, reflecting the similarities in the three ligand environments, including those from the phenylene spacer, which appeared together as one large singlet. However, the three distinct central pyridine 3′/5′-H singlets at lowfield positions (δ = 9.23, 9.21 and 9.06 ppm) confirmed the lack of symmetry and metal coordination. [(**ttpy**)Ru(**A**)Ru(**ttpy**)]$(PF_6)_4$ showed only two sets of terpy signals reflecting the higher symmetry, including a phenylene singlet and 3′/5′-H singlets at δ = 9.19 and 9.05 ppm for metal-bound terpy units of **A** and **ttpy**, respectively.

An entirely analogous sequence from the *m*-linked ligand **B** led to PF_6^- salts of [(**ttpy**)Ru(**B**)]$^{2+}$, [(**ttpy**)Ru(**B**)Ru(**B**)-Ru(**ttpy**)]$^{6+}$ and [(**ttpy**)Ru(**B**)Ru(**ttpy**)]$^{4+}$. The yields were slightly lower than in the *p*-linked cases (65%, 70% and 17%, respectively). In the latter preparation, we found that [Ru(**ttpy**)$_2$]$^{2+}$ was a contaminant, presumably arising from a ligand exchange process. This contaminant and the reduced yields imply some resistance to coordinate to **B**, in comparison with **A**, perhaps due to steric encumbrance or increased repulsions between metal centers. The dinuclear [(**ttpy**)Ru(**B**)Ru(**ttpy**)]$^{4+}$ also appeared as a side-product in the preparation of [(**ttpy**)Ru(**B**)]$^{2+}$ and necessitated chromatographic purification. The ^{1}H NMR spectra of the **B** complexes were very similar to those of the **A** series, except for the singlet-doublet-triplet pattern from the *m*-phenylene linkage, and showed only one set of pyridine signals per distinct terpy unit, again consistent with free rotation of the terpy units about the linkage.

The reactions with the pyrazine-containing ligands were less straightforward. Attempted preparation of [(**ttpy**)Ru(**C**)]$^{2+}$ from (**ttpy**)$RuCl_3$ and **C** in ethane-1,2-diol produced only the ligand-exchange product [Ru(**ttpy**)$_2$]$^{2+}$, owing to the poor solubility of **C**. Using TFA as a co-solvent was helpful, and the best solvent found was a TFA/ethane-1,2-diol (5:1) mixture that led to a 70% yield of [(**ttpy**)Ru(**C**)]$(PF_6)_2$ after anion exchange and chromatography. The ^{1}H NMR spectra differ from those of the all-terpy series in that the lowest field signals are now due to the pyrazinyl 3/3′′-H instead of the pyridine 3′/5′-H. The pyrazinyl 5-H and 6-H are weakly coupled but COSY spectroscopy revealed a long-range W-coupling between 3-H and 5-H. The dinuclear species [(**ttpy**)Ru(**C**)Ru(**ttpy**)]$(PF_6)_4$ was obtained in 20% yield from Ag^+-activated [(**ttpy**)$RuCl_3$]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and **C** in a mixture of TFA and ethane-1,2-diol. Chromatography was required to separate the desired material from the now abundant $[Ru(\mathbf{ttpy})_2]^{2+}$ impurity. The ^1H NMR spectrum was similar to that of the mononuclear analogue, simplified by symmetry, and COSY spectroscopy was used to identify one pyrazinyl 3-H singlet, two pyridine 3′/5′-H singlets and one phenylene singlet, all consistent with the structure. Unfortunately, all attempts at preparing the trinuclear analogue failed, producing only a brown-black, paramagnetic material. Similarly, all complexation reactions with ligand **D** failed as well. Treatment of $[(\mathbf{ttpy})RuCl_3]$ with 1 equiv. of **D** also produced a paramagnetic product. With 0.5 equiv., $[Ru(\mathbf{ttpy})_2]^{2+}$ was the major product and the desired dinuclear species was only a minor constituent detectable by NMR spectroscopy and ESI-MS. It became obvious that the *m*-phenylene linkage and the lower basicity of dpp units, relative to terpy, decreased the reactivity of the ligand. An alternate route was attempted to circumvent the latter problem. Treatment of $RuCl_3$ with 0.5 equiv. of **D** in EtOH provided a brown-black precipitate, putatively $[Cl_3Ru(\mathbf{D})RuCl_3]$, but treatment of this with **ttpy** in ethane-1,2-diol to produce the dinuclear compound led to $[Ru(\mathbf{ttpy})_2]^{2+}$ as the only detectable product.

As is common with aromatic materials and Ru complexes, elemental analyses often return correct H compositions but low C and/or N compositions, even in the presence of extra oxidation catalyst, presumably due to incomplete combustion and/or the formation of stable carbides and nitrides. Mass and isotopic distribution analyses (ESI, MALDI or high resolution MALDI) were used to confirm the structural assignments. Fortunately, the precipitation of PF_6^- salts enabled purification, which was made evident by chromatographic homogeneity and the absence of extraneous NMR peaks.

UV/Vis Spectroscopy

The electronic spectra of all complexes in CH_3CN showed intense π-π* bands below 350 nm and MLCT bands ($\lambda_{max.}$) at 490−500 nm, reported in Table 1, in complete analogy with $[Ru(\mathbf{ttpy})_2]^{2+}$.[16] In addition, the complexes of **C** showed shoulders near 450 nm. With the *p*-linked ligands **A** and **C**, the position of $\lambda_{max.}$ drifted slightly toward the red with an increasing number of metal centers, while $\lambda_{max.}$ remained constant with the *m*-linked ligand **B**. Relative to $[Ru(\mathbf{ttpy})_2]^{2+}$, each added dpp or terpy unit and each added metal center constitutes an electron-withdrawing group. The drift with a *p*-linkage is likely a result of electron withdrawal on the ligands' π systems and stabilization of the ligand π* orbitals, relative to the metal-centered orbitals. The lack of such a drift with the *m*-linkage is probably owing to the absence of a resonance path for electronic transmission, and the 2 nm shift in $\lambda_{max.}$ with $[(\mathbf{ttpy})Ru(\mathbf{B})]^{2+}$ then represents the inductive contribution of an added terpy unit. At the same time, the ε values grew upon increasing the number of metal atoms, as expected. It is interesting to note that the ε values of all the mononuclear complexes $[(\mathbf{ttpy})RuL]^{2+}$ (L = **A**−C) are larger than for the homoleptic case, where L = **ttpy**. This is even more pronounced with the homoleptic $[Ru(\mathbf{A})_2]^{2+}$ ($\lambda_{max.}$ = 496 nm, ε = 42700 $M^{-1}\cdot cm^{-1}$). Because the MLCT $\lambda_{max.}$ values are all of lower energies than with $[Ru(\mathbf{ttpy})_2]^{2+}$, it is reasonable to conclude that the bridging ligands have lower π* orbital energies than does the terminal ligand **ttpy**, and are therefore the repositories of the excited electron density.

Electrochemistry

The results of cyclic voltammetry are also reported in Table 1. As is typical for complexes of this nature,[14,17] the new complexes show single reversible oxidation waves at potentials that are practically insensitive to chain length and at least two reduction waves that are somewhat less constant. Owing to their additional nitrogen atoms, the two complexes of **C** show particularly positive $E(Ru^{III/II})$ potentials, lying between the value for the homoleptic dpp complex $[Ru(\mathbf{E})_2]^{2+}$ (+1.62 V)[6] and that for the bis(terpy) complex $[Ru(\mathbf{ttpy})_2]^{2+}$ (+1.25 V).[18] The first reduction potentials of the new complexes are all positive compared with that of $[Ru(\mathbf{ttpy})_2]^{2+}$. Along with the spectroscopic evidence, this suggests that reduction adds an electron to the bridging ligands, rather than to the terminal **ttpy** whose π* orbital is evidently at a higher energy.

In accordance with the more negative reductions of the terpy-based ligands, we can assign the first and second reduction waves shown by the complexes of **C** to reductions

of the relatively electron-poor bridging and electron-rich terminal ligands, respectively. Since $E(Ru^{III/II}) - E(L^{0/-})$ is known to correlate with the MLCT energy,[19] the higher-energy MLCT bands of the **C** complexes can then be assigned to Ru→**ttpy** transitions, and the lower-energy bands to Ru → **C** transitions. With these pairings, the correlation is fairly good ($r^2 > 0.92$).

Photochemistry

Under visible light irradiation and in the presence of triethanolamine (TEOA) as a sacrificial reductant, Ru^{II} complexes are able to generate the methylviologen radical cation ($MV^{\cdot+}$) from methylviologen (MV^{2+}) to different degrees. In real-life photoredox applications, there would be no sacrificial donor present, but the excited state could be reductively quenched at an electrode surface or by a reversibly reduced electron relay molecule such as MV^{2+} at an illuminated organic-aqueous interface. Comparisons between sensitizers in terms of the kinetic parameters governing this process have previously enabled us to probe steric, electrostatic and solvent effects on activity,[16,20,21] and we wished, in the present work, to probe the effect of increasing the Ru chain length *N*. Using our standard protocol,[4] we measured the time courses of $MV^{\cdot+}$ development at room temperature in CH_3CN at 600 nm with a sensitizer concentration of 4×10^{-5} M. The key results presented in Table 1 are the first-order rate constants k_f and k_q for $MV^{\cdot+}$ formation and anaerobic quenching, respectively, and the anaerobic yields χ, given by $k_f[MV^{2+}]_0/(k_f + k_q)$. The usual mechanism is oxidative quenching of the excited state of the sensitizer ($Ru^{II*} + MV^{2+} \rightarrow Ru^{III} + MV^{\cdot+}$) followed by reverse electron transfer to (quenching of) $MV^{\cdot+}$ ($Ru^{III} + MV^{\cdot+} \rightarrow Ru^{II} + MV^{2+}$), or competitive trapping ($Ru^{III} + TEOA \rightarrow Ru^{II} + TEOA^{\cdot+}$) which allows $MV^{\cdot+}$ to accumulate. Additionally, Table 1 reports estimates of $\Delta G^{\ddagger}_{FET}$ and $\Delta G^{\ddagger}_{RET}$, the Marcus activation energies for the forward and reverse electron transfers, respectively, for end-on approaches by $MV^{2+/\cdot+}$ to the terminal metals. Their computations and the values for electrostatically less favorable approaches are detailed in the Supporting Information (see also the footnote on the first page of this article).

All of the new complexes are better sensitizers than $[Ru(\mathbf{ttpy})_2]^{2+}$,[4] with higher k_f and χ values. This may reflect generally longer τ values owing to a greater π-delocalization and π^* stabilization in the bridging ligands which, as discussed earlier, are the preferred sites for the excited electrons. Clearly, there is variation between the **A** and **B** series, in spite of similarities in structures, properties (E_{ox}, E_{red}, λ, ε/N) and even $\Delta G^{\ddagger}$ values. Part of the success of $[\{(\mathbf{ttpy})Ru\}_2\mathbf{B}]^{4+}$ relative to the **A** analogue may be due to easier access to the areas between the metal atoms, but this advantage does not appear to carry forward to the trinuclear case.

Because of similar properties *within* a ligand series and virtually identical structures at the metal termini, we can make the a priori assumption that the differences in sensitizer activities within a series should be largely electrostatic and not photophysical in origin, an assumption which our results should confirm or deny. The constant k_f incorporates the concentration of excited state species (Ru^{II*}) and will depend on $\Delta G^{\ddagger}_{FET}$, which contains the electrostatic barrier to the forward electron transfer which increases with increasing *N*, while k_q incorporates the concentration of the Ru^{III} photoproduct and depends on $\Delta G^{\ddagger}_{RET}$, which contains the corresponding electrostatic barrier. The constants k_q and k_f, however, are linked because a higher k_f leads to a higher concentration of Ru^{III} and therefore a higher k_q. Both, then, also depend on the photophysical properties that govern the production of Ru^{II*}, including ε and τ. However, the ratio k_q/k_f ($= [MV^{2+}]_0/\chi - 1$) was previously shown to equal $k_r[MV^{2+}]_0/k_t[TEOA]_0$,[4] where k_r and k_t are the second-order rate constants for the reactions of the Ru^{III} photoproduct with the $MV^{\cdot+}$ co-product (reverse electron transfer) and with TEOA (trapping), respectively. This ratio is therefore a measure of the competition between the non-productive and productive fates of the Ru^{III} form of the sensitizer. The first constant, k_r, will vary within a series according to $\exp(-\Delta G^{\ddagger}_{RET})$, while k_t involves encounters with the neutral TEOA and should remain constant within a series. Hence, if the sensitizers within a series only differed in electrostatic terms, k_q/k_f should steadily decrease as $\Delta G^{\ddagger}_{RET}$ steadily increases with *N*. The values in Table 1 reveal that this is not so, with $[\{(\mathbf{ttpy})Ru\}_2\mathbf{A}]^{4+}$ and $[\{(\mathbf{ttpy})Ru(\mathbf{B})\}_2Ru]^{6+}$ being particularly outstanding. Moreover, k_f should vary with $\varepsilon \exp(-\Delta G^{\ddagger}_{FET})$, but $\ln(k_f/\varepsilon)$ does not uniformly decrease as $\Delta G^{\ddagger}_{FET}$ increases. These findings imply that the sensitizers within a series also differ in their photophysical characteristics, such as τ, orbital overlap, approach geometry or approach distance, which this study cannot probe. Nevertheless, Table 1 identifies the most effective sensitizers $[\{(\mathbf{ttpy})Ru(\mathbf{A})\}_2Ru]^{6+}$, $[\{(\mathbf{ttpy})Ru\}_2\mathbf{B}]^{4+}$, and especially the two complexes of **C**, as meriting further study.

The two **C**-containing complexes show higher activities in spite of having the highest barriers $\Delta G^{\ddagger}_{FET}$. They probably benefit from longer τ values than the all-terpy complexes of **A** and **B** because the first dpp complex, $[Ru(\mathbf{E})_2]^{2+}$, showed a longer τ (18 ns at 667 nm)[6] than its terpy analogue $[Ru(\mathbf{ttpy})_2]^{2+}$ (0.95 ns at 640 nm).[22] In addition, the redox potentials for the **C**-containing complexes lie about 0.2 V more positive of those of the other complexes and this is probably sufficient to enable reductive quenching (formally $Ru^{II*} + TEOA \rightarrow Ru^{I} + TEOA^{\cdot+}$), as was the case in other complexes with high E_{ox} values.[23–25] Reductive quenching has an electrostatic advantage over oxidative quenching because it involves initial encounters with neutral TEOA instead of cationic MV^{2+}, and because the wasteful reverse electron transfer (formally $Ru^{I} + TEOA^{\cdot+} \rightarrow Ru^{II} + TEOA$) is electrostatically disfavored relative to the forward reaction, whereas the opposite is true in oxidative quenching ($Ru^{III} + MV^{\cdot+} \rightarrow Ru^{II} + MV^{2+}$). Moreover, the $TEOA^{\cdot+}$ by-product can be deprotonated in an alkaline medium ($TEOA^{\cdot+} \rightarrow H^+ + H_{-1}TEOA^{\cdot}$) to generate a reducing species[26] that is depleted by O_2.[4] This consumption of $TEOA^{\cdot+}$ further reduces the probability of reverse electron transfer, thereby leaving more of the re-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

duced form of the sensitizer able to produce $MV^{\cdot+}$ (Ru^{I} + $MV^{2+} \rightarrow Ru^{II}$ + $MV^{\cdot+}$) in electrostatically more favorable encounters than is the case in oxidative quenching. These combined electrostatic advantages would contribute to a faster net accumulation of the ultimate photoproduct, $MV^{\cdot+}$, as witnessed with ligand **C**.

Conclusion

Ditopic bridging ligands can be assembled in a one-pot reaction and incorporated into short, linear multinuclear assemblies that act as photosensitizers in spite of electrostatic repulsions. The photochemical experiments have identified $[\{(\mathbf{ttpy})Ru(\mathbf{A})\}_2Ru]^{6+}$, $[\{(\mathbf{ttpy})Ru\}_2\mathbf{B}]^{4+}$ and both complexes of **C** as candidates for photophysical studies, in order to elucidate the origins of the difference in behavior between the **A** series and the **B** series and the origin of the better activity for the **C** series. However, the dpp-containing ligands **C** and **D** were fraught with solubility and reactivity problems that need to be addressed. An obvious improvement to the general design is to add negatively charged groups to the peripheries which can constitute binding sites for positively charged electron acceptors such as MV^{2+} since this has proven to be of great benefit in mononuclear species.[21] However, the ideal linear multinuclear sensitizer will absorb light anywhere along the chain and relay the excited electron to the ends (the so-called antenna effect), where electrostatic repulsions with acceptors can be minimized. Another improvement would therefore be to use the most electron-poor ligands at the termini.

Experimental Section

General Remarks: NMR spectroscopic data were obtained with a Bruker AMX 400 MHz spectrometer in CD_3CN (unless indicated otherwise) at 25 °C and are reported relative to $SiMe_4$. The signal assignments were made on the basis of COSY spectra and use the position letters appearing in the structural diagrams. A Kratos Profile mass spectrometer was used for EI-MS acquisitions. MALDI-MS data were acquired with a Voyager-DE STR MALDI/TOF instrument and ESI-MS data with a Sciex Targa 6000E MS/MS system. High resolution MALDI-MS (HR-MALDI-MS) was performed by the McMaster Regional Center for Mass Spectrometry, Hamilton, ON, Canada with a Micromass TofSpec 2E instrument. UV/Vis spectra were obtained at room temperature with a Hewlett−Packard 8452A diode array spectrophotometer, with 10^{-5} M solutions in spectroscopic-grade solvents. Cyclic voltammetry was performed with a Cypress System three-electrode configuration consisting of a reference Ag/AgCl wire electrode and platinum wire working and auxiliary electrodes, using CH_3CN distilled from P_2O_5 and stored over 4-Å molecular sieves, in solutions containing 0.1 M n-Bu_4NPF_6. Half-wave potentials were calculated as the average of the cathodic and anodic peak potentials.[27] The current-scan rate dependence was evaluated for each sample to check the reversibility, and ferrocene was added at the end of each run as an internal reference (+0.425 V vs. SCE in CH_3CN).[28] Photochemical data were obtained using the apparatus and data treatment described earlier,[4] with stirred CH_3CN solutions containing the sensitizer (4×10^{-5} M), $MV(PF_6)_2$ (0.01 M) and triethanolamine (0.05 M). Reagents and spectroscopic-grade solvents (Sigma−Aldrich) were used directly. Anhydrous solvents were purchased in Sigma−Aldrich Sure-seal bottles. All other solvents were reagent-grade quality (Caledon Chemical Ltd.) and used directly. $[Ru(\mathbf{ttpy})Cl_3]$ was prepared in 71% yield by a literature method[12], with its identity verified by ESI-MS [m/z (%) = 531 (100)]. Thin-layer chromatography was used to monitor reactions and chromatography and was carried out on Macherey−Nagel Polygram Sil G/UV silica gel plates and Alox N/UV alumina plates. Column chromatography was performed employing silica gel (ca. 200−400 mesh, 60 Å) or neutral alumina (ca. 150 mesh, 58 Å), both from Sigma−Aldrich. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, ON, Canada.

4′-*p*-Tolyl-2,2′:6′,2"-terpyridine (ttpy): 2-Acetylpyridine (1.00 g, 8.3 mmol) was added to a solution of *p*-tolualdehyde (0.50 g, 4.2 mmol) in CH_3OH (32 mL). 15% aq. KOH (2.9 mL) and conc. NH_4OH (29 mL) were then added to the solution and vigorous stirring was maintained for 3 d. The yellow precipitate that formed was removed by vacuum filtration, washed with water to neutral pH and dissolved in $CHCl_3$ (40 mL). The solution obtained was washed with H_2O (3 × 30 mL). The organic fraction was dried with $MgSO_4$ and freed of solvent in vacuo. The residue was recrystallized from $CHCl_3/Et_2O$ to yield 0.61 g (46%) of **ttpy**, m.p. 168 °C. ^1H NMR ($CDCl_3$): δ = 8.77 (2 s, 4 H, *a* + *e*), 8.71 (d, $^3J_{H,H}$ = 8 Hz, 2 H, *d*), 7.92 (dd, 2 H, *c*), 7.87 (d, $^3J_{H,H}$ = 7.9 Hz, 2 H, *f*), 7.39 (dd, $^3J_{H,H}$ = 5 Hz, 2 H, *b*), 7.35 (d, $^3J_{H,H}$ = 7.9 Hz, 2 H, *g*), 2.46 (s, 3 H, CH_3) ppm. EI-MS: m/z (%) = 324 (100) [$M^{\cdot+}$], in agreement with the literature data.[11,29,30]

1,4-Bis(2,2′:6′,2"-terpyridin-4′-yl)benzene (A): The same procedure as for **ttpy** was applied, using 2-acetylpyridine (1.00 g, 8.3 mmol) and terephthalaldehyde (0.2764 g, 2.1 mmol) at reflux for 48 h. Recrystallization from $CHCl_3$ and CH_3OH yielded 0.4427 g of **A** (39%), m.p. > 300 °C. ^1H NMR ($CDCl_3$): δ = 8.83 (s, 4 H, *e*), 8.79 (d, $^3J_{H,H}$ = 4.2 Hz, 4 H, *a*), 8.74 (d, $^3J_{H,H}$ = 7.0 Hz, 4 H, *d*), 8.09 (s, 4 H, *f*), 7.92 (dd, $^3J_{H,H}$ = 7.0 Hz, 4 H, *c*), 7.39 (dd, $^3J_{H,H}$ = 4.2 Hz, 4 H, *b*) ppm. MALDI-MS: m/z (%) = 541 (100) [M^+]. $C_{36}H_{24}N_6$ (540.6): calcd. C 79.98, H 4.47, N 15.54; found C 79.57, H 4.73, N 12.31.

1,4-Bis(2,6-dipyrazinylpyridin-4-yl)benzene (C): A mixture of acetylpyrazine (500 mg, 4.1 mmol) and terephthalaldehyde (135 mg, 1.0 mmol) in CH_3OH (50 mL) containing 15% aq. KOH (1.2 mL) and conc. NH_4OH (11.5 mL) was vigorously stirred while heating to reflux for 48 h. The precipitate formed was removed by vacuum filtration and washed with water to neutral pH. The compound proved to be soluble only in TFA and insoluble in all common organic solvents. It was dried under vacuum and a yield of 42% (0.2285 g) was obtained, m.p. > 300 °C. EI-MS: m/z (%) = 545 (100) [M^+]. $C_{32}H_{20}N_{10}$ (544.6): calcd. C 70.58, H 3.70, N 25.72; found C 69.90, H 3.80, N 25.10.

1,3-Bis(2,6-dipyrazinylpyridin-4-yl)benzene (D): The same procedure as for **C** with isophthalaldehyde produced 0.2013 g (37% yield) of **D**, which was similarly insoluble, m.p. > 300°C. EI-MS: m/z (%) = 545 (100) [M^+]. $C_{32}H_{20}N_{10}$ (544.6): calcd. C 70.58, H 3.70, N 25.72; found C 69.93, H 3.81, N 25.13.

$[Ru(A)_2](PF_6)_2$: A solution of **A** (80.0 mg, 0.15 mmol) in DMF (10 mL) was added to a solution of $RuCl_3 \cdot 3H_2O$ (19.4 g, 0.07 mmol) in DMF (10 mL) and the mixture was heated to reflux under Ar for 24 h. Addition of the cooled red solution to a saturated aqueous solution of NH_4PF_6 precipitated the product as a red solid. Purification by column chromatography (alumina; CH_3CN/satd. KNO_3/H_2O, 7:1:0.5, containing 1% $N(C_2H_5)_3$] pro-

duced 41.2 mg (40%). ^{1}H NMR: δ = 9.14 (s, 4 H, *e*), 8.98 (s, 4 H, *e′*), 8.82 (m, 8 H, *a′*, *d′*), 8.74 (d, $^3J_{H,H}$ = 8 Hz, 4 H, *d*), 8.45 (d, $^3J_{H,H}$ = 7.8 Hz, 4 H, *f*), 8.36 (d, $^3J_{H,H}$ = 7.8 Hz, 4 H, *f′*), 8.10 (t, $^3J_{H,H}$ = 7 Hz, 4 H, *c′*), 8.01 (t, $^3J_{H,H}$ = 7 Hz, 4 H, *c*), 7.57 (m, 8 H, *b′*, *a*), 7.24 (t, $^3J_{H,H}$ = 7 Hz, 4 H, *b*) ppm. MALDI-MS: *m*/*z* (%) = 593 (100) [M^{2+}]. $C_{72}H_{48}F_{12}N_{12}P_2Ru$ (1472.3): calcd. C 58.74, H 3.29, N 11.42; found C 59.15, H 3.49, N 10.89.

[(ttpy)Ru(A)](PF$_6$)$_2$: A mixture of [Ru(**ttpy**)Cl$_3$] (55.0 mg, 0.1 mmol) and $AgBF_4$ (62.5 mg, 0.3 mmol) was heated to reflux in acetone (25 mL) for 3 h. The AgCl precipitate was filtered off and the volume of the resultant violet solution was halved under reduced pressure. DMF (15 mL) was added and the remaining acetone removed. The resultant solution was added to a pre-heated (80 °C) solution of **A** (84.0 mg, 0.15 mmol) in DMF (25 mL) and the mixture was heated to reflux under Ar for 2 h. The cooled red solution was added to a saturated aqueous solution of NH_4PF_6. The red precipitate was collected by vacuum filtration, washed with water (3 × 30 mL) and Et_2O (3 × 30 mL), and freed of solvent under vacuum. Column chromatography (alumina; CH_3CN/satd. KNO_3/H_2O, 31:2:1, containing 0.66% $N(C_2H_5)_3$] and re-precipitation (NH_4PF_6) afforded 87.8 mg (70% yield) of [(**ttpy**)Ru(**A**)](PF$_6$)$_2$. The ^{1}H NMR spectroscopic data are in agreement with literature data.[15] ESI-MS: *m*/*z* (%) = 483 (100) [M^{2+}]. $C_{58}H_{41}F_{12}N_9P_2Ru$ (1255.0): calcd. C 55.51, H 3.29, N 10.04; found C 55.86, H 3.50, N 9.77.

[(ttpy)Ru(B)](PF$_6$)$_2$: This complex was prepared by the same procedure as with **A**, using [Ru(**ttpy**)Cl$_3$] (55.0 mg, 0.1 mmol), $AgBF_4$ (62.5 mg, 0.3 mmol), DMF (10 mL), ligand **B**[10] (84.0 mg, 0.15 mmol) in DMF (15 mL), previously heated to 80 °C, and heating at reflux under Ar for 2 h. Workup, chromatography and re-precipitation (NH_4PF_6) as before afforded a yield of 65% (0.0816 g) of [(**ttpy**)Ru(**B**)](PF$_6$)$_2$. ^{1}H NMR: δ = 9.13 (s, 2 H, **B**-*e*), 9.00 (s, 4 H, **B**-*e′*, **ttpy**-*e*), 8.78 (m, 4 H, **B**-*a′*, **B**-*d′*), 8.70 (d, $^3J_{H,H}$ = 4.5 Hz, 2 H, **B**-*d*), 8.65 (d, $^3J_{H,H}$ = 8 Hz, 2 H, **ttpy**-*d*), 8.33 (m, 2 H, **B**-*f*/*f′*), 8.21 (m, 2 H, **B**-*g*, **B**-*h*), 8.12 (m, 4 H, **ttpy**-*f*, **B**-*c′*), 7.97 (m, 4 H, **B**-*c*, **ttpy**-*c*), 7.60 (m, 4 H, **ttpy**-*g*, **B**-*b′*), 7.45 (m, 4 H, **B**-*a*, **ttpy**-*a*), 7.21 (2 t, 4 H, **B**-*b*, **ttpy**-*b*), 2.54 (s, 3 H, CH_3) ppm. ESI-MS: *m*/*z* (%) = 482 (75) [M^{2+}]. $C_{58}H_{41}F_{12}N_9P_2Ru$ (1255.0): calcd. C 55.51, H 3.29, N 10.04; found C 55.86, H 3.49, N 9.68.

[(ttpy)Ru(C)](PF$_6$)$_2$: This complex was prepared by the same procedure as for **A**, using [Ru(**ttpy**)Cl$_3$] (112.0 mg, 0.2 mmol) and $AgBF_4$ (125.0 mg, 0.6 mmol) in acetone (40 mL), complete removal of the acetone, 1,2-ethanediol (15 mL) instead of DMF, **C** (170.0 mg, 0.3 mmol) in TFA (25 mL) and heating to reflux under Ar for 3 h. Workup, chromatography (CH_3CN/satd. KNO_3/H_2O, 50:2:1) and re-precipitation (NH_4PF_6) as before afforded a yield of 70% (0.1763 g) of [(**ttpy**)Ru(**C**)](PF$_6$)$_2$. ^{1}H NMR: δ = 9.99 (s, 2 H, **C**-*d′*), 9.91 (s, 2 H, **C**-*d*), 9.31 (s, 2 H, **C**-*e*), 9.03 (s, 2 H, **C**-*e′*), 8.97 (s, 2 H, **ttpy**-*e*), 8.79 (m, 4 H, **C**-*b′*, **C**-*a′*), 8.69 (d, $^3J_{H,H}$ = 7.7 Hz, 2 H, **ttpy**-*d*), 8.49 (d, $^3J_{H,H}$ = 8.5 Hz, 2 H, **C**-*f*), 8.39 (m, 4 H, **C**-*a*, **C**-*f′*), 8.16 (d, $^3J_{H,H}$ = 7 Hz, 2 H, **ttpy**-*f*), 8.02 (t, 2 H, **ttpy**-*c*), 7.62 (m, 4 H, **ttpy**-*g*, **C**-*b*), 7.41 (d, $^3J_{H,H}$ = 5 Hz, 2 H, **ttpy**-*a*), 7.23 (t, 2 H, **ttpy**-*b*), 2.58 (s, 3 H, CH_3) ppm. HR-MALDI-MS: *m*/*z* (%) = 969.237 (100); $[RuC_{54}H_{37}N_{13}]^{2+}$ requires 969.044. $C_{54}H_{37}F_{12}N_{13}P_2Ru$ (1259.0): calcd. C 51.52, H 2.96, N 14.46; found C 52.20, H 3.56, N 13.94.

[(ttpy)Ru(A)Ru(ttpy)](PF$_6$)$_4$: This complex was prepared by the same procedure as for [(**ttpy**)Ru(**A**)](PF$_6$)$_2$, using [Ru(**ttpy**)Cl$_3$] (53.0 mg, 0.1 mmol), $AgBF_4$ (77.5 mg, 0.3 mmol) in acetone (25 mL), DMF (10 mL), **A** (27.0 mg, 0.05 mmol) in DMF (10 mL), and heating at reflux under Ar for 3 h. Workup as before afforded a yield of 19% (18.7 mg) of [(**ttpy**)Ru**A**Ru(**ttpy**)](PF$_6$)$_4$. ^{1}H NMR: δ = 9.19 (s, 4 H, **A**-*e*), 9.05 (s, 4 H, **ttpy**-*e*), 8.78 (d, $^3J_{H,H}$ = 8 Hz, 4 H, **A**-*d*), 8.71 (d, $^3J_{H,H}$ = 8 Hz, 4 H, **ttpy**-*d*), 8.62 (s, 4 H, **A**-*f*), 8.17 (d, $^3J_{H,H}$ = 7.6 Hz, 4 H, **ttpy**-*f*), 8.03 (m, 8 H, **A**-*c*, **ttpy**-*c*), 7.64 (d, $^3J_{H,H}$ = 7.5 Hz, 4 H, **ttpy**-*g*), 7.51 (m, 8 H, **A**-*a*, **ttpy**-*a*), 7.26 (m, 8 H, **A**-*b*, **ttpy**-*b*), 2.58 (s, 6 H, CH_3) ppm. ESI-MS: *m*/*z* (%) = 348 (75) [M^{4+}].

[(ttpy)Ru(B)Ru(ttpy)](PF$_6$)$_4$: This complex was prepared by exactly the same procedure as for [(**ttpy**)Ru(**A**)Ru(**ttpy**)](PF$_6$)$_4$, using [Ru(**ttpy**)Cl$_3$] (52.6 mg, 0.1 mmol), $AgBF_4$ (79.3 mg, 0.3 mmol) and **B**[10] (28.0 mg, 0.05 mmol), affording a yield of 17% (16.7 mg) of [(**ttpy**)Ru(**B**)Ru(**ttpy**)](PF$_6$)$_4$. ^{1}H NMR: δ = 9.27 (s, 4 H, **B**-*e*), 9.02 (s, 4 H, **ttpy**-*e*), 8.80 (d, $^3J_{H,H}$ = 7.3 Hz, 4 H, **B**-*d*), 8.68 (d, $^3J_{H,H}$ = 8.3 Hz, 4 H, **ttpy**-*d*), 8.47 (m, 4 H, **B**-*f*, **B**-*g*, **B**-*h*), 8.13 (d, $^3J_{H,H}$ = 7.6 Hz, 4 H, **ttpy**-*f*), 7.99 (m, 8 H, **B**-*c*, **ttpy**-*c*), 7.60 (d, $^3J_{H,H}$ = 7.6 Hz, 4 H, **ttpy**-*g*), 7.48 (m, 8 H, **B**-*a*, **ttpy**-*a*), 7.23 (m, 8 H, **B**-*b*, **ttpy**-*d*), 2.55 (s, 6 H, CH_3) ppm. ESI-MS: *m*/*z* (%) = 347 (100) [M^{4+}]. $C_{80}H_{58}F_{24}N_{12}P_4Ru_2$ (1969.4): calcd. C 48.79, H 2.97, N 8.53; found C 48.24, H 3.45, N 8.45.

[(ttpy)Ru(C)Ru(ttpy)](PF$_6$)$_4$: This was prepared by the same procedure as for [(**ttpy**)Ru(**C**)](PF$_6$)$_2$, using [Ru(**ttpy**)Cl$_3$] (96.0 mg, 0.2 mmol) and $AgBF_4$ (130.0 mg, 0.6 mmol) in acetone (25 mL), ethane-1,2-diol (10 mL), and a solution of **C** (50.0 mg, 0.1 mmol) in TFA (5 mL) and ethane-1,2-diol (10 mL), with heating to reflux under Ar for 24 h in the presence of *N*-methylmorpholine (2 drops). Workup, chromatography (CH_3CN/satd. KNO_3/H_2O, 7:1:0.5), to remove the minor impurity of [Ru(**ttpy**)$_2$](PF$_6$)$_2$, and re-precipitation (NH_4PF_6) as before afforded a yield of 20% (39.5 mg) of [(**ttpy**)Ru(**C**)Ru(**ttpy**)](PF$_6$)$_4$. ^{1}H NMR: δ = 9.84 (s, 4 H, **C**-*d*), 9.34 (s, 4 H, **C**-*e*), 9.04 (s, 4 H, **ttpy**-*e*), 8.70 (d, $^3J_{H,H}$ = 8 Hz, 4 H, **ttpy**-*d*), 8.64 (s, 4 H, **C**-*f*), 8.41 (d, 4 H, **C**-*a*), 8.16 (d, $^3J_{H,H}$ = 7.9 Hz, 4 H, **ttpy**-*f*), 8.03 (t, $^3J_{H,H}$ = 7.5 Hz, 4 H, **ttpy**-*c*), 7.64 (m, 8 H, **C**-*b*, **ttpy**-*g*), 7.42 (d, $^3J_{H,H}$ = 5 Hz, 4 H, **ttpy**-*a*), 7.23 (t, $^3J_{H,H}$ = 6 Hz, 4 H, **ttpy**-*b*), 2.57 (s, 6 H, CH_3) ppm. HR-MALDI-MS: *m*/*z* (%) = 1393.297 (60), $[Ru_2C_{76}H_{54}N_{16}]^{4+}$ requires 1393.509. $C_{76}H_{54}F_{24}N_{16}P_4Ru_2$ (1973.4): calcd. C 46.26, H 2.76, N 11.36; found C 46.75, H 3.07, N 11.55.

[(ttpy)Ru(A)Ru(A)Ru(ttpy)](PF$_6$)$_6$: To a solution of $RuCl_3 \cdot 3H_2O$ (9.0 mg, 0.03 mmol) in ethane-1,2-diol (30 mL) was added [(**ttpy**)-Ru(**A**)](PF$_6$)$_2$ (90.0 mg, 0.07 mmol) and *N*-methylmorpholine (9 drops). Ths solution was heated to reflux under Ar for 24 h. The addition of the cooled red solution to a saturated aqueous solution of NH_4PF_6 precipitated the product as a red solid. Recrystallization using CH_3CN/Et_2O of the red solid yielded the desired pure product in 87% yield (75.8 mg). ^{1}H NMR: δ = 9.23 (s, 4 H, **A**-*e*), 9.21 (s, 4 H, **A**-*e′*), 9.06 (s, 4 H, **ttpy**-*e*), 8.79 (2 t, 8 H, **A**-*d*, **A**-*d′*), 8.71 (d, $^3J_{H,H}$ = 7.9 Hz, 4 H, **ttpy**-*d*), 8.64 (s, 8 H, **A**-*f*, **A**-*f′*), 8.17 (d, $^3J_{H,H}$ = 7.4 Hz, 4 H, **ttpy**-*f*), 8.03 (m, 12 H, **A**-*c*, **A**-*c′*, **ttpy**-*c*), 7.64 (d, $^3J_{H,H}$ = 7.4 Hz, 4 H, **ttpy**-*g*), 7.58 (d, $^3J_{H,H}$ = 5.3 Hz, 4 H, **A**-*a*), 7.52 (m, 8 H, **A**-*a′*, **ttpy**-*a*), 7.28 (m, 12 H, **A**-*b*, **A**-*b′*, **ttpy**-*b*), 2.58 (s, 6 H, CH_3) ppm. ESI-MS: *m*/*z* (%) = 339.2 (70) [M^{6+}]. $C_{116}H_{82}F_{36}N_{18}P_6Ru_3$ (2901.0): calcd. C 48.03, H 2.85, N 8.69; found C 47.52, H 2.89, N 7.89.

[(ttpy)Ru(B)Ru(B)Ru(ttpy)](PF$_6$)$_6$: The same procedure used for [(**ttpy**)Ru(**A**)Ru(**A**)Ru(**ttpy**)](PF$_6$)$_6$ was applied using [(**ttpy**)-Ru(**B**)](PF$_6$)$_2$ (100 mg, 0.07 mmol) and $RuCl_3 \cdot 3H_2O$ (11 mg, 0.03 mmol), to produce the desired pure product in 70% yield (61 mg). ^{1}H NMR: δ = 9.29 (s, 4 H, **B**-*e*), 9.27 (s, 4 H, **B**-*e′*), 9.05 (s, 4 H, **ttpy**-*e*), 8.81 (2 t, $^3J_{H,H}$ = 9.3 Hz, 8 H, **B**-*d*, **B**-*d′*), 8.71 (d, $^3J_{H,H}$ = 8 Hz, 4 H, **ttpy**-*d*), 8.54 (m, 4 H, **B**-*f*, **B**-*f′*), 8.16 (d, $^3J_{H,H}$ = 8 Hz, 4 H, **ttpy**-*f*), 8.02 (m, 16 H, **B**-*c*, **B**-*c′*, **ttpy**-*c*, **B**-*g*, **B**-*h*), 7.63

COVER PICTURE

The cover picture shows the calix[6]arene-based tris(imidazole) ligand coordinated to divalent metal ions. These supramolecular edifices mimic enzyme environments. These funnel complexes present an exchangeable coordination site located in the heart of the hydrophobic cavity of the calixarene. The interplay between the strength of the host–guest noncovalent interactions and the flexibility of the system allows a variety of geometries for the metal complexes, either tetrahedral, trigonal-bipyramidal or square-pyramidal. Details are discussed in the article by O. Reinaud et al. on p. 1817ff.

A Rational Self-Sacrificing Template Route to β-Bi_2O_3 Nanotube Arrays

Baojun Yang,[a,b] Maosong Mo,[a] Hanmei Hu,[a] Cun Li,[a] Xiaogang Yang,[a] Qiaowei Li,[a] and Yitai Qian*[a]

Keywords: Bismuth oxide / Nanostructures / Nanotubes / Synthesis design

Arrayed β-Bi_2O_3 nanotubes (NTs) were synthesized for the first time through a rational "self-sacrificing template" route, simply by oxidizing the precursor metallic bismuth NT arrays in air at 200–220 °C for 14–18 h. XRD, TEM, and HRTEM characterizations show that the prepared β-Bi_2O_3 samples are all phase pure and the β-Bi_2O_3 NTs have uniform diameters of approximately 3–6 nm and lengths up to several micrometers. The optical absorption and photoluminescence (PL) characteristics of the prepared samples were investigated.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The discovery of carbon nanotubes (NTs) in 1991 has lead to a fruitful and growing interest in NTs for both basic and application-oriented industrial research.[1] Over the past years, various template-directing synthetic methods have been used to generate tubular forms of different oxides. For example, template-assisted soft chemistry routes have lead to the synthesis of VO_x,[2] TiO_2,[3] and SiO_2[4] NTs; pre-structured materials (including carbon NTs and polymer fibers) have been employed as structure-directing templates for tubular forms of SiO_2, Al_2O_3, V_2O_5,[5] TiO_2,[6] MoO_3, RuO_2,[7] ZrO_2,[8] and SnO_2;[9] porous aluminum oxide and polymer membrane templates for NTs or ordering arrays of oxide NTs[10] have also been used.

Bismuth trioxide (Bi_2O_3) and various bismuth-containing materials are very important in modern solid-state technology, owing to their peculiar physical properties (electrical, optical, and excellent ionic conductivity, etc.). They are widely used in gas sensors,[11] optoelectronic devices, optical coatings, transparent ceramic glass manufacturing,[12] cathode ray tubes,[13] as catalysts for the soft oxidation of hydrocarbons,[14] and so on. This special interest explains the great effort devoted to the investigation of Bi_2O_3 polymorphs over the last years.

Bi_2O_3 shows four main structures that are denoted by α-, β-, γ-, and δ-Bi_2O_3.[15] Among them, the tetragonal β-Bi_2O_3, which has a distorted defect-fluorite structure, is a metastable phase at ambient conditions, and usually transforms into the stable monoclinic α-Bi_2O_3 at about 870 K. The formation of the tetragonal β-Bi_2O_3 is observed at about 920 K on cooling the high-temperature cubic-phase δ-Bi_2O_3, although several synthetic procedures for obtaining these materials at relatively low temperatures have been reported.[14–16]

Recently, we have developed an aqueous chemical route to synthesize bamboo raft-like bismuth NT arrays at room temperature.[17] Herein, we also report on a novel "self-sacrificing template" approach for the synthesis of crystalline tetragonal β-Bi_2O_3 NT arrays, by oxidizing the precursor bismuth NT arrays directly in air at 200–220 °C. To the best of our knowledge, this is the first time that a method for the synthesis of β-Bi_2O_3 NTs has been reported.

Results and Discussion

Figure 1 shows a typical XRD pattern of a prepared sample. All the intensive and sharp reflection peaks can be indexed to a pure tetragonal phase (space group: $C\bar{4}b2$)

of crystalline β-Bi_2O_3. The calculated cell constants are a = 10.94 Å and c = 5.64 Å [the root mean square value (RMS) is 1.5×10^{-4}] and are in good agreement with the literature values of a = 10.93 Å and c = 5.62 Å (JC,PDS 74−1374). This XRD pattern indicates that the oxidization of metallic bismuth is complete and phase-pure crystalline β-Bi_2O_3 products can be obtained under the present synthetic conditions.

The morphologies and the size of the prepared samples were characterized by TEM. As shown in Figure 2 (see a, b, and c), a significant amount of the sample dispersed on the TEM copper grids exhibited nanotubular morphology, although other block-like morphologies also appeared. All of the β-Bi_2O_3 NTs are straight with uniform diameters of approximately 3−6 nm and lengths up to several micrometers. Most of them are also surprisingly aligned together, side by side, along the axial direction, in a similar way to that of the precursor metallic Bi NT arrays, to form bamboo raft-like NT arrays. This phenomenon suggests that the precursor bismuth NT arrays may serve as self-sacrificing templates and maintain their original tubular morphology in the oxidizing process. The SAED pattern, of a "bamboo raft", indicates the crystalline nature of the NT array (see a, the inset of Figure 2). The concentric diffraction rings could be indexed outwards as [110], [311], and [400] diffractions of tetragonal β-Bi_2O_3. Figure 2 (d) shows a representative HRTEM image of a section of a "bamboo raft". The lattice fringes are perpendicular to the axial direction of the NTs; the fringe spacing is about 7.8 Å, close to the interplanar spacing of the [110] lattice planes of the tetragonal β-Bi_2O_3. This means that the axial direction of the NTs is along the normal direction of the [110] lattice planes of the tetragonal β-Bi_2O_3.

Figure 2 (see e) shows the typical optical absorption spectrum of a prepared β-Bi_2O_3 sample, along with the PL of the same sample (λ_{exe} = 291 nm). The band edge is found to be around 3.90 eV (318 nm) and it shifts to much higher energy than that of the bulk bandgap at 2.58 eV.[15] The material also exhibits photoluminescence. A Stokes shift is observed; such effects have been attributed to either band-edge emission or shallow-trap emission in recent publications.[18]

Here, the use of precursor metallic bismuth NT arrays is crucial to the formation of β-Bi_2O_3 NT arrays. The reaction between the precursor metallic bismuth and oxygen in air can be simply formulated as:Bi (NT arrays) + O_2 (in air) → β-Bi_2O_3 (NT arrays)

In this reaction, the precursor metallic Bi NT arrays may serve as "self-sacrificing templates" which maintain their original tubular morphology in the oxidizing process, thus resulting in the formation of the β-Bi_2O_3 NT arrays.

The materials and experimental conditions have significant effects on the formation of the β-Bi_2O_3 NT arrays. Under similar experimental conditions, almost no Bi_2O_3 is formed after oxidization (24 h) by using commercial Bi powder (about 200 mesh) instead of the precursor metallic Bi NT arrays. On the other hand, the relatively low melting point of metallic Bi (273.1 °C) greatly limited the selection

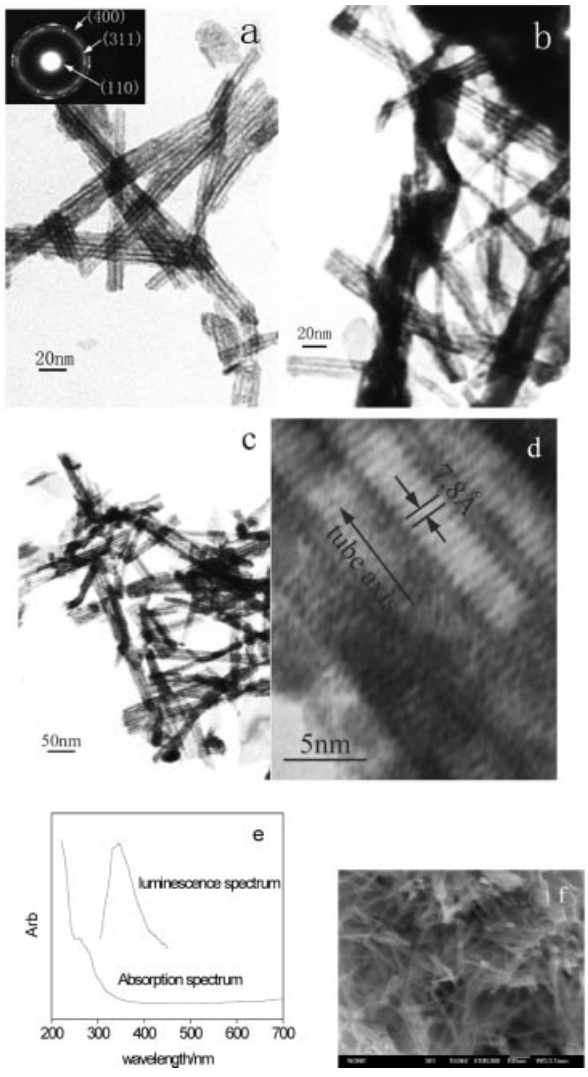

Figure 2. Typical TEM images (a, b, c), HRTEM image (d), UV/Vis absorption, PL spectra (e) of theprepared β-Bi_2O_3 samples and FESEM image (f) of the Bi precursor

of reaction temperature for our experiments. When the reaction temperature is below 160 °C, a mixture of β-Bi_2O_3 and unreacted metallic Bi was detected by XRD . When the reaction temperature was above 240 °C, a great deal of block-like and a small amount of tube-like β-Bi_2O_3 was observed by TEM. This phenomenon can be simply explained as follows: the precursor metallic Bi NTs may have a lower melting point than the bulk Bi due to the well-known small-size effects. When the experimental temperature (above 240 °C) is close to the melting point of the Bi precursor, local melting and aggregation of the precursor may occur before oxidization, which may further result in the formation of block-like β-Bi_2O_3. Based on the results mentioned above, we believe that the ratio of the NTs in the final β-Bi_2O_3 products can be greatly affected by varying the temperature of thermal oxidization of the Bi precursor. Thus, the optimal experimental temperature we selected is 200−220 °C. Under these conditions, the precursor metallic Bi NT arrays

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

may keep their origin tubular morphology during oxidization, and once the β-Bi_2O_3 NTs are formed, the tubular morphology of β-Bi_2O_3 could be kept due to its thermal stability, which is higher than that of the Bi NTs.

Conclusion

In summary, we have presented a simple self-sacrificing template route for the synthesis of β-Bi_2O_3 NT arrays, by oxidizing the precursor Bi NT arrays. The prepared β-Bi_2O_3 samples are all phase-pure and stable at room temperature. This method requires no complex apparatus or technique and the conditions are much more mild, which makes it possible to produce β-Bi_2O_3 NTs on a large scale. The present study supplies a novel route to synthesize phase-pure β-Bi_2O_3, enlarges the family of oxide NTs, and may provide a facile method for the synthesis of other one-dimensional oxide nanomaterials.

Experimental Section

Reactions and Conditions: All reagents used in our experiments were analytically pure, purchased from Shanghai Chemicals Co. (China), and used without further purification. The precursor metallic bismuth NT arrays were prepared following a prodecure found in the literature,[17] as shown in Figure 2 (see f). A high proportion of the precursor sample exhibits 1D morphology with lengths from several hundred nanometers to several micrometers. TEM observations show that the 1D morphology is in fact present as nanotubular arrays (special TEM images and descriptions have been shown in our previously published paper).[17] Then, an appropriate amount of the prepared precursor bismuth powder was transferred into a ceramic boat. The boat was placed into the center of a temperature-controlled electrothermal oven (DHG-9076A) in which the temperature was previously kept at 200−220 °C (dry air), and maintained for 14−18 h. After the reaction was complete, the boat was taken out and the yellow powder obtained was immediately sealed in a small glass bottle filled with anhydrous alcohol to prevent direct contact with carbon dioxide in air (see Figure 3). The samples were characterized by X-ray powder diffraction (XRD), which was recorded on a Japan Rigaku Dmax-γA X-ray powder diffractometer with graphite-monochromatized Cu-K_α radiation (λ = 1.54178 Å). Transmission electron microscopy (TEM) images and high-resolution transmission electron microscopy (HRTEM) images were obtained with a JEOL-2010 transmission electron microscope, employing an accelerating voltage of 200 kV. Field-emission scanning electron microscope (FESEM) images were taken on a field-emission microscope (JEOL JSM-6700F, 15 kV). UV/Vis absorption spectra were recorded on a Shimadzu UV-2401PC UV/Vis spectrophotometer. Photoluminescence spectroscopy was carried out on a Shimadzu RF-5301PC spectrofluorophotometer with an Xe lamp at room temperature.

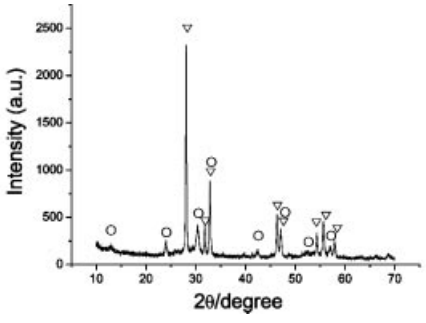

Figure 3. Typical XRD pattern of a prepared β-Bi_2O_3 sample exposed directly to air for about two hours (the triangle represent β-Bi_2O_3, the circle represent $Bi_2O_2CO_3$)

Ruthenium-Catalyzed Hydrogenation of Carbon Dioxide to Formic Acid in Alcohols

Siu Man Ng,[a] Chuanqi Yin,[a] Chi Hung Yeung,[a] Tak Chung Chan,[a] and Chak Po Lau*[a]

Keywords: Ruthenium / Hydrogenation / Alcohols / Carbon dioxide / Formic acid

Catalytic hydrogenation of CO_2 to formic acid with the (solvento)metal hydride complex, $TpRu(PPh_3)(CH_3CN)H$ [Tp = hydrotris(pyrazolyl)borate], in various alcohols was studied. High-pressure NMR monitoring of the catalytic reaction in non-acidic methanol shows that the observable intermediate is a formate complex resulting from CO_2 insertion into the Ru–H bond and is stabilized by the hydrogen-bonding interaction between the formato ligand and a methanol molecule. However, in the case of the acidic alcohol, CF_3CH_2OH, the observable intermediates are $[TpRu(PPh_3)(CH_3CN)_2]^+$-$CF_3CH_2O^-$ and the alkyl carbonate complex, $TpRu(PPh_3)(\eta^2$-$O_2COCH_2CF_3)$, which are formed by the reaction of CO_2 with the alkoxide species, $TpRu(PPh_3)(CH_3CN)(OCH_2CF_3)$, generated by a very facile reaction between $TpRu(PPh_3)(CH_3CN)H$ and CF_3CH_2OH. We propose that the productive catalytic cycles of the reactions conducted in a variety of alcohols are similar to the one we formulated for the catalytic hydrogenation of CO_2 in hydrous THF. The formic acid is produced by the transfer of a hydride and a proton from the transient alcohol hydride intermediate, $TpRu(PPh_3)(ROH)H$, to an approaching CO_2 molecule. The activity of $TpRu(PPh_3)(CH_3CN)H$ is higher in CF_3CH_2OH than in methanol and other non-acidic alcohols and it is probably due to the enhanced electrophilicity of the carbon atom of CO_2, which results from the strong interaction between the proton of the highly acidic alcohol in $TpRu(PPh_3)(CF_3$-$CH_2OH)H$ and an oxygen atom of CO_2. The electrophilic carbon atom of CO_2 could in turn abstract the hydride from Ru–H in a more facile manner.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Transition-metal-catalyzed CO_2 hydrogenation to formic acid remains an area of interest, as it provides a promising approach for utilizing carbon dioxide as a raw material for large-scale chemical synthesis.[1] Although it has been known for some time that addition of water to active Pd,[2] Rh,[3] and Ru[4] systems is effective in enhancing the catalytic hydrogenation of CO_2 to formic acid, no compelling experimental and theoretical data had been provided to explain the positive "water effect" until the publication of our recent work on the promoting effect of water in the catalytic hydrogenation CO_2 with the ruthenium complex $TpRu(PPh_3)(CH_3CN)H$ (**1**) [Tp = hydrotris(pyrazolyl)borate]. With the support of high-pressure NMR spectroscopy and theoretical calculations, we proposed a reaction mechanism to account for the "water effect". The key intermediate in the catalytic cycle is an (aquo)ruthenium hydride species, $TpRu(PPh_3)(H_2O)H$, which is generated through ligand displacement by H_2O. It transfers a hydride and a proton of the coordinated H_2O to the approaching CO_2 molecule to give formic acid and is converted into a transient hydroxo species, which then associates an H_2 molecule to regenerate $TpRu(PPh_3)(H_2O)H$ by σ-metathesis between the hydroxo and the η^2-H_2 ligands.[5]

Continuing our investigation on the catalytic hydrogenation of CO_2 to formic acid with **1**, we studied the **1**-catalyzed reactions in alcohols. The accelerating effects of certain alcohols on the hydrogenation of carbon dioxide, catalyzed by (trimethylphosphane)ruthenium complexes, have recently been reported.[6]

Results and Discussion

Hydrogenation of Carbon Dioxide to Formic Acid with 1

We have previously learned that **1** catalyzes the hydrogenation of carbon dioxide to yield formic acid with a low turnover number in anhydrous THF (see Entry 1, Table 1), but the catalytic activity of **1** was greatly enhanced when 5% (by volume) of water was added to the system (Entry 2, Table 1).[5] Perusal of Table 1 reveals significant increase in the catalytic activity of **1** in alcohols too (relative to that of **1** in anhydrous THF), although the enhancement effects are not as large as in THF/H_2O, except for the acidic alcohol, CF_3CH_2OH. In the catalytic reactions using alcohols as solvents, the yields of the ester side products are very low. Also noteworthy is the trend of decreasing turnover numbers of

[a] Typical reaction conditions: catalyst 0.013 mmol; NEt_3 2 mL; solvents 20 mL; total pressure 50 atm (CO_2/H_2 = 1:1); temperature 100 °C; reaction time 16 h. [b] Turnover no: mol of product/mol of complex. [c] THF/H_2O (19 mL/1 mL). [d] Reaction time 4 h.

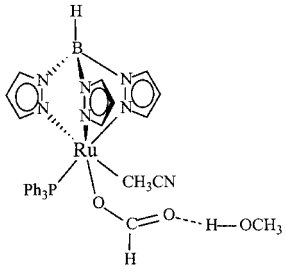
formic acid with increasing bulkiness of the alcohols (Entries 4−9, Table 1).

In Situ High-Pressure NMR Studies

To gain more insight into the mechanisms of the catalytic CO_2-hydrogenation reactions by **1** in alcohols, we carried out a series of in situ high-pressure NMR studies.

(a) Reaction of 1 with CO_2 in Methanol/THF

A $CH_3OH/[D_8]THF$ (1:1 by volume) solution of **1** in a 5-mm Wilmad pressure-valved NMR tube was pressurized with 6 atm of $^{13}CO_2$ at room temperature. The $^{31}P\{^1H\}$ NMR spectrum of the resulting solution recorded after 10 min shows the disappearance of **1** and the presence of a new complex **2** which gives a singlet at δ = 52.9 ppm. The $^1H\{^{13}C\}$ NMR spectrum of the same solution clearly shows the set of nine peaks pertaining to the Tp ligand. A singlet at δ = 2.30 ppm, integrated for 3 H, is assignable to the coordinated CH_3CN, a singlet (1 H) at δ = 7.63 ppm can be attributed to the hydrogen atom of a formate ligand. This signal is split into a doublet in the ^{13}C-coupled ^1H NMR spectrum by the formato carbon atom, half of it is unfortunately masked by the peaks of the Tp and PPh_3 ligands. The $^{13}C\{^1H\}$ NMR spectrum of the solution exhibits a singlet at δ = 174.7 ppm, pertaining to the formato carbon atom, which is split into a doublet in the ^1H-coupled ^{13}C NMR spectrum with an H-C coupling constant of 194.9 Hz. If the ^{31}P, ^1H, and ^{13}C NMR spectroscopic data of **2** are taken together, it is obvious that the ligand set of the complex consists of a Tp, a PPh_3, a formate, and an acetonitrile ligand. With reference to our recently reported formate complex, $TpRu(PPh_3)(CH_3CN)(\eta^1\text{-}OCHO)$, generated by CO_2 insertion into the Ru−H bond of **1** in anhydrous THF, and $TpRu(PPh_3)(CH_3CN)(\eta^1\text{-}OCHO)\cdot H_2O$, which is formed by the reaction of **1** with CO_2 in hydrous THF and stabilized by hydrogen-bonding interactions between the formato ligand and a water molecule,[5] we propose that the molecular formula of **2** is $TpRu(PPh_3)(CH_3CN)(\eta^1\text{-}OCHO)\cdot HOCH_3$. The formato ligand in **2** is hydrogen-bonded to a methanol molecule. Unfortunately, we have not been able to observe any downfield-shifted OH proton signals due to the hydrogen-bonded CH_3OH, probably because of its undergoing rapid exchange with the molecules in the bulk, or because the signal is masked by the large number of peaks due to the Tp and phosphane ligands in the region.



2

Attempts to synthesize **2** on a preparative scale by treating **1** with pressurized CO_2 were frustrated by its decomposition to the hydride species and some intractable materials during workup, in which the CO_2 pressure has to be removed. Similar problems were encountered in our previous efforts to isolate the formate complexes, $TpRu(PPh_3)(CH_3CN)(\eta^1\text{-}OCHO)$ and $TpRu(PPh_3)(CH_3CN)(\eta^1\text{-}OCHO)\cdot H_2O$.[5] Treatment of the chloro complex $TpRu(PPh_3)(CH_3CN)Cl$ with sodium formate also resulted in the formation of the hydride complex **1** as the major product. It seems that all these (Tp)ruthenium formate species are only stable under CO_2 pressure.

(b) Reaction of 1 with CO_2 and H_2 in Methanol/THF

A $CH_3OH/[D_8]THF$ (1:1 by volume) solution of **1** containing 20 equiv. of Et_3N was pressurized with 6 atm of $^{13}CO_2$ and H_2 in a 5-mm Wilmad pressure-valved NMR tube; the $^{31}P\{^1H\}$ and ^1H NMR spectra of the solution taken within 10 min at room temperature shows the disappearance of **1** and the formation of **2**. A minute amount of formic acid, indicated by a very small doublet at δ = 8.60 ppm ($J_{C,H}$ = 189 Hz) in the ^1H NMR spectrum, was formed. After heating the tube at 100 °C for 3 h, ^1H NMR spectroscopy showed a very significant increase of the formic acid signal. In the downfield region, in addition to the set of peaks pertaining to the Tp ligand of **2**, some minute peaks were also visible. The $^{31}P\{^1H\}$ spectrum, however, shows only one singlet due to **2**. The CO_2-hydrogenation reaction was basically complete within 3 h because the ^1H NMR spectrum taken 3 h later did not show any visible increase in the formic acid signal. It is, however, worth noting that, after heating the solution at 100 °C for 2 d, the ^1H NMR spectrum showed that the amount of formic acid decreased, while the downfield region of the spectrum became relatively complex, indicating the presence of a few sets of Tp signals. A doublet of doublets ($J_{H,P}$ = 26.4, $J_{C,H}$ = 9.3 Hz) is observed in the upfield region at δ = −11.81 ppm, which can be assigned to the carbonyl hydride

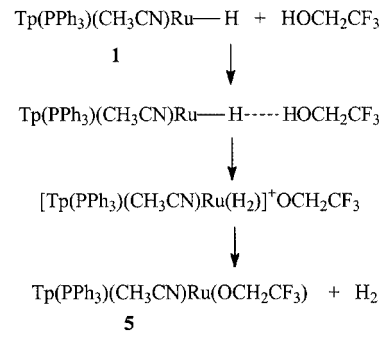
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complex $TpRu(PPh_3)(CO)H$ (**3**), which we have previously reported.[7] The $^{31}P\{^1H\}$ spectrum exhibits a major singlet at $\delta = 52.9$ ppm, which is due to **2**. A singlet at $\delta = 66.1$ ppm is assignable to **3**, while the singlet at $\delta = 30.9$ ppm is identified as the signal of triphenylphosphane oxide, which was probably formed by CO_2 oxidation of PPh_3. A number of small, unidentified signals can be observed in the region between the signals of **2** and **3**. After heating at 100 °C for 3 d, a further decrease in the amount of formic acid was evidenced by ^1H NMR spectroscopy and a set of Tp signals of $TpRu(PPh_3)(CO)H$ (**3**) was observed in the downfield region. The hydride signal of **3** also shows enhanced intensity. The $^{31}P\{^1H\}$ NMR spectrum was also simplified, showing a major peak at $\delta = 66.1$ ppm, which is due to **3**. The phosphane oxide peak at $\delta = 30.9$ ppm and an unidentified peak at $\delta = 63.3$ ppm are the only two minor signals in the spectrum. In our previous work, high-pressure NMR spectroscopy monitoring of the catalytic CO_2 hydrogenation with **1** in hydrous THF revealed that the carbonyl hydride complex **3** was the major ruthenium-containing species after prolonged heating at 100 °C. Moreover, in the course of the reaction, a very small amount of $TpRu(PPh_3)(H_2)H$ (**4**)[7] was also detected by ^1H NMR spectroscopy. Independent NMR experiments showed that **4** reacted slowly with formic acid in $[D_8]$THF to yield $TpRu(PPh_3)(CO)H$. We believe that in the course of the **1**-catalyzed CO_2 hydrogenation in $CH_3OH/[D_8]$THF, the carbonyl hydride complex **3** was formed by the reaction of $TpRu(PPh_3)(H_2)H$ (**4**) with formic acid and the dihydrogen hydride species was present in such low concentration that it eluded detection by NMR spectroscopy. Examples relevant to the formation of **3** can be found in the literature.[8−10] An authentic sample of **3** was found to be inactive in catalyzing CO_2 hydrogenation in methanol.

Reaction of CF_3CH_2OH with 1

In view of the superiority of CF_3CH_2OH in promoting the CO_2-hydrogenation reaction, studies to gain insight into its role in the catalytic reaction were carried out. The ^1H NMR spectrum taken a few minutes after the dissolution of **1** in $CF_3CH_2OH/[D_8]$THF (1:1 by volume) in a 5-mm Wilmad pressure-valved NMR tube showed that the alkoxide complex $TpRu(PPh_3)(CH_3CN)(OCH_2CF_3)$ (**5**) was formed and **1** was no longer detectable. The spectrum shows a new set of nine peaks pertaining to the Tp ligand. A singlet at $\delta = 2.27$ ppm integrated for 3 H is assignable to the coordinated acetonitrile. Two multiplets, each integrated for 1 H, are observed at $\delta = 3.04$ and 3.45 ppm; these peaks can be attributed to the methylene hydrogen atoms of the coordinated $-OCH_2CF_3$ group. A singlet at $\delta = 4.65$ ppm signals the presence of free hydrogen. The trifluoroalkoxo ligand was verified by ^{19}F NMR spectroscopy, which shows the signal of $-OCH_2CF_3$ as a triplet at $\delta = -75.05$ ppm ($J_{H,F} = 10$ Hz). The $^{31}P\{^1H\}$ NMR spectrum shows a singlet at $\delta = 52.8$ ppm.

Formation of **5** probably resulted from protonation of the hydrido ligand of **1** by CF_3CH_2OH via a dihydrogen-bonded intermediate $Tp(PPh_3)(CH_3CN)$ $Ru-H\cdots H-OCH_2CF_3$ and the η^2-dihydrogen complex (see Scheme 1). The relevancy of dihydrogen bonding to the protonation reaction is suggested by independent NMR studies involving reactions of **1** with limited amounts of CF_3CH_2OH. Upon addition of 1.5 and 7.5 equiv. of CF_3CH_2OH to $[D_8]$toluene solutions of **1**, the ^1H NMR spectra of the solutions show that the hydride signal of **1** becomes broadened and shifted upfield by 0.16 and 0.63 ppm, respectively. Variable-temperature T_1 measurements for the hydrido ligand of **1** yielded a T_1(min) of 252 ms (at 400 MHz and 235 K) and 65 ms (at 400 MHz and 233 K) for the **1**/1.5 equiv. CF_3CH_2OH and the **1**/7.5 equiv. CF_3CH_2OH solutions, respectively. The two T_1(min) values are much lower than that of the hydrido ligand of **1** in $[D_8]$toluene in the absence of CF_3CH_2OH (540 ms at 400 MHz and 257 K). These T_1(min) measurements thus suggest the presence of $Ru-H\cdots H-OCH_2CF_3$ dihydrogen-bonding interaction. Reactions of acidic alcohols with transition-metal hydride complexes to generate $M-H\cdots H-OR$ dihydrogen-bonded species are well documented.[11] For example, a dynamic equilibrium between the dihydrogen-bonded ruthenium hydride species and the η^2-dihydrogen complex $(dppm)_2HRu-H\cdots H-OR$ $[(dppm)_2HRu(H_2)]^+OR^-$ is established in the presence of phenol. The more acidic alcohol, hexafluoro-2-propanol, shifts the equilibrium to the side of the η^2-dihydrogen complex and eventually yields the alkoxide complex $(dppm)_2Ru[OCH(CF_3)_2]_2$.[11c]



Scheme 1

Attempts to synthesize **5** on a preparative scale, unfortunately, were not successful, due to its decomposition into some intractable materials during the workup processes. It seems that **5** is only stable in CF_3CH_2OH solutions.

Reaction of $TpRu(PPh_3)(CH_3CN)(OCH_2CF_3)$ (5) with CO_2

Et_3N (20 equiv.) was added to a $CF_3CH_2OH/[D_8]$THF solution of **5**; $^{31}P\{^1H\}$ NMR spectroscopy indicated that **5** was unaffected by the base. The solution was then subjected to 8 atm of CO_2 at room temperature; NMR spectroscopy showed that **5** was converted into a 1:1 mixture of $[TpRu(PPh_3)(CH_3CN)_2]^+$ (**6**) and another complex **7** after 2 h. Complex **6**, which we have previously reported,[12] can

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

be easily identified by ^1H and $^{31}P\{^1H\}$ NMR spectroscopy. The ^1H NMR spectrum of the mixture clearly shows two sets of signals (six peaks each) in the downfield region, one of which pertaining to the Tp ligand of complex **6**, while the other set belongs to the Tp ligand of **7**. A six-peak pattern for the Tp ligand implies that two of the three legs *trans* to the Tp ligand in an octahedral configuration are equivalent. The assumption that the two legs in **7** are due to the bidentate alkyl carbonato ligand $CF_3CH_2OCO_2^-$ is supported by the ^{13}C NMR study of an identical reaction using $^{13}CO_2$ in place of the unlabeled carbon dioxide. The ^{13}C NMR spectrum of the resulting solution shows a characteristic carbonate singlet resonance at δ = 172.3 ppm. Since only one carbonate signal was detected in the ^{13}C NMR spectrum, the counterion of **6** is not a free alkyl carbonato anion but it is the alkoxide anion $CF_3CH_2O^-$, which is confirmed by ^{19}F NMR spectroscopy showing a triplet signal at $\delta = -76.02$ ($J_{H,F}$ = 10 Hz). The methylene hydrogen signals of the $CF_3CH_2OCO_2$ ligand are unfortunately masked by a huge peak in the ^1H NMR spectrum due to the free alcohol. The $^{31}P\{^1H\}$ spectrum of the solution shows two singlets: one at δ = 50.8 ppm pertaining to **6** and another one at δ = 63.9 ppm, ascribable to the phosphane ligand of **7**. When all the NMR spectroscopic data are taken together, **7** can be identified as the alkyl carbonato complex $TpRu(PPh_3)(\eta^2\text{-}O_2COCH_2CF_3)$. Apparently, **7** was formed by CO_2 insertion into the $Ru-OCH_2CF_3$ bond of **5** [see Equation (1)]. Insertion of CO_2 into metal−oxygen bonds of metal alkoxides and phenoxides to form metal carbonate species is well documented.[13]

$$\underset{\mathbf{5}}{2\ TpRu(PPh_3)(CH_3CN)(OCH_2CF_3)} + CO_2 \longrightarrow [TpRu(PPh_3)(CH_3CN)_2]^+\ CF_3CH_2O^- + TpRu(PPh_3)(\eta^2\text{-}O_2COCH_2CF_3) \quad (1)$$

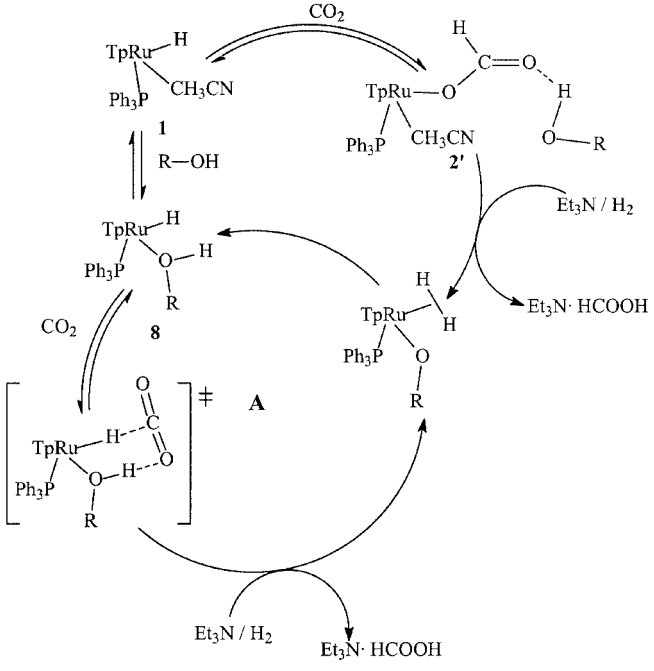
$$\mathbf{6.CF_3CH_2O^-} \qquad\qquad \mathbf{7}$$

Reaction of 1 with CO_2/H_2 in $CF_3CH_2OH/[D_8]THF$

A $CF_3CH_2OH/[D_8]THF$ (1:1 by volume) solution of **1** containing 20 equiv. of Et_3N was pressurized with 6 atm of CO_2 and H_2 at room temperature in a 5-mm Wilmad pressure-valved NMR tube. The $^{31}P\{^1H\}$ NMR spectrum taken 1 h later at room temperature indicates the formation of a 1:1 mixture of **6** and **7**. ^1H NMR spectroscopy shows, in addition to **6** and **7**, a small amount of formic acid, evidenced by a small singlet at δ = 8.42 ppm. A few hours later, ^1H NMR measurements showed that the amount of formic acid increased, and it also suggested the presence of a minute amount of $TpRu(PPh_3)(CO)H$ (**3**), as evidenced by a very small doublet at $\delta = -11.83$ ppm ($J_{H,P}$ = 26.8 Hz). After heating the NMR tube at 100 °C for 1 d, it was found by ^1H and $^{31}P\{^1H\}$ studies that **6** and **7** disappeared and **3** was the only ruthenium complex present in the solution.

Mechanism of CO_2 Hydrogenation in Non-Acidic Alcohols

Our high-pressure NMR studies show that reactivity of **1** in the CO_2-hydrogenation reaction in methanol is very similar to that in hydrous THF and it is therefore reasonable to propose that the mechanism of **1**-catalyzed CO_2-hydrogenation reactions in non-acidic alcohols (Entries 4−9, Table 1) is analogous to that of the catalysis in hydrous THF. Therefore, in analogy to the active aquo hydride species $TpRu(PPh_3)(H_2O)H$ in hydrous THF, the key intermediate in the catalytic cycle **A** (see Scheme 2) is the transient alcohol hydride species **8**, which is mainly formed by displacement of the acetonitrile ligand of **1** by ROH. The interaction of the OH proton of the alcohol in **8** with one of the oxygen atoms of the approaching CO_2 increases the electrophilicity of the carbon atom, which is then able to abstract the hydride from Ru−H. The turnover numbers of the catalytic reactions decrease with increasing bulkiness of the alcohols (Entries 3−7, Table 1) and this observation supports the fact that the availability of **8** might have a large effect on the overall efficiency of the catalytic system. It is more difficult for a hindered alcohol to displace the acetonitrile ligand of **1**. In view of the detection of a small amount of $TpRu(PPh_3)(H_2)H$ (**4**) by NMR spectroscopy in our previous study of **1**-catalyzed CO_2 hydrogenation in hydrous THF, we propose that **4** is present in a minute amount in the alcohols, although it has not been successfully detected by NMR spectroscopy. Reaction of $TpRu(PPh_3)(H_2)H$ with formic acid to yield $TpRu(PPh_3)(CO)H$ was verified by an independent experiment.



Scheme 2

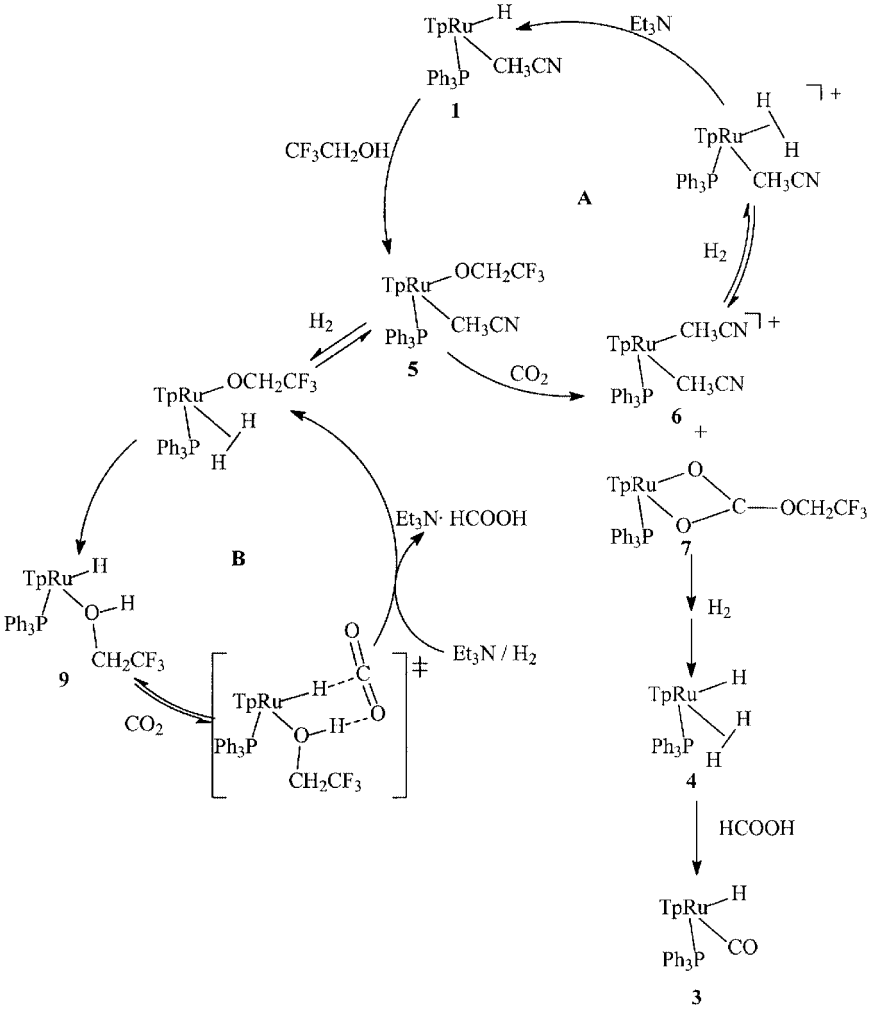
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Mechanism of CO_2 Hydrogenation in Acidic Alcohol CF_3CH_2OH

Unlike the CO_2-hydrogenation reaction in methanol, no metalloformate intermediate is observable in the course of the catalysis in CF_3CH_2OH because complex **1** reacts rapidly with the acidic alcohol to form the metal alkoxide **5**, which then reacts with CO_2 to give the observable intermediate species $[TpRu(PPh_3)(CH_3CN)_2]^+$ (**6**) and $TpRu(PPh_3)(\eta^2\text{-}O_2COCH_2CF_3)$ (**7**). Although the observable intermediates in the catalyses in methanol and CF_3CH_2OH are different, we propose that the sequence in cycle **B** (see Scheme 3), which is basically identical to the catalytic cycle **A** of Scheme 2, is the productive route for the catalytic process in trifluoroethanol. Under H_2 pressure, a minute quantity of the active alcohol hydride species $TpRu(PPh_3)(CF_3CH_2OH)H$ (**9**) might be generated through the alkoxo dihydrogen intermediate $TpRu(PPh_3)(OCH_2CF_3)(H_2)$. The much higher catalytic activity of **1** in CF_3CH_2OH than in the non-acidic alcohols is probably related to the much stronger interaction of the proton of the coordinated CF_3CH_2OH in **9** with an oxygen atom of CO_2, which enhances significantly the positive charge at the carbon atom of the molecule, making the hydride abstraction from Ru−H facile. Again, the final ruthenium complex $TpRu(PPh_3)(CO)H$ results from the reaction of formic acid with $TpRu(PPh_3)(H_2)H$ (**4**) after prolonged heating. The action of H_2 on the alkyl carbonato intermediate **7** is believed to be one of the routes to generate **4**, although the sequence of the reaction is unknown.

Conclusion

Continuing our study on the promoting effect of water in the **1**-catalyzed hydrogenation of CO_2 to formic acid, we have studied the effect of alcohols on the catalysis. Our study suggests that, although the NMR-detectable intermediates in the catalysis in methanol (and probably in other non-acidic alcohols) and in acidic CF_3CH_2OH are different, the catalytic cycles of CO_2 hydrogenation in both cases are probably identical. The key species of the catalytic process, $TpRu(PPh_3)(ROH)H$, is the alcohol analogue of the aquo hydride complex that we have proposed for our previously studied hydrous THF system. The exceptionally



Scheme 3

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

high promoting effect of CF_3CH_2OH among the alcohols studied is due to the stronger interaction of the highly acidic hydrogen of the trifluoroethanol in $TpRu(PPh_3)(CF_3CH_2OH)H$ with an oxygen atom of the approaching CO_2, greatly enhancing the electrophilicity of the carbon atom of the molecule, and enabling its abstraction of the hydride from Ru−H.

Experimental Section

General Remarks: Ruthenium trichloride, $RuCl_3·3H_2O$, pyrazole, and sodium borohydride were obtained from Aldrich. Triphenylphosphane was purchased from Merck and was recrystallized from ethanol before use. The complex $TpRu(PPh_3)(CH_3CN)H$ was synthesized according to published procedures.[13] Solvents were distilled under dry nitrogen with appropriate drying agents.[14] High-purity hydrogen gas and carbon dioxide were supplied by Hong Kong Oxygen. ^1H NMR spectra were obtained with a Bruker DPX 400 spectrometer. Chemical shifts are reported relative to residual protons of the deuterated solvents. ^{31}P, ^{19}F, and ^{13}C NMR spectra were recorded with a Bruker DPX 400 spectrometer at 161.70, 376.31 and 100.60 MHz, respectively. ^{31}P NMR chemical shifts were externally referenced to 85 % H_3PO_4 in D_2O. ^{19}F NMR chemical shifts were externally referenced to $CFCl_3$ in $CDCl_3$. ^{13}C NMR chemical shifts were internally referenced to the residual peak of the deuterated solvents. High-pressure NMR studies were carried out in commercial 5-mm Wilmad pressure-valved NMR tubes.

Safety Warning: It is advisable not to add more than 12 atm of gas(es) to the 5-mm Wilmad pressure-valved NMR tubes at room temperature.

Catalytic Hydrogenation of CO_2 with $TpRu(PPh_3)(CH_3CN)H$ (1): The reactions were performed in a 100-mL stainless steel autoclave. In a typical run, about 0.013 mmol of **1** in 20 mL of alcohol and 2 mL of NEt_3 was added to the autoclave. After being flushed with H_2 three times, the system was heated whilst stirring at 100 °C under 50 atm of CO_2/H_2 (1:1). At the end of the required length of time, the autoclave was cooled rapidly and vented carefully. The formic acid in the resulting solution was analyzed by ^1H NMR spectroscopy. The relative intensities of the formato hydrogen signal of the product and the formato hydrogen signal of the internal standard (DMF) were measured, and with the help of a calibration curve, the turnover number of the catalysis was derived.

Multicomponent Ionic Complexes of Cobalt(II) Tetraphenylporphyrin with C_{60} Fullerides − Transition from the σ-Bonded [($Co^{II}TPP$)·(C_{60}^{-})] Anion to Nonbonded $Co^{II}TPP$ and $C_{60}^{\cdot-}$ Components

Keywords: Fullerenes / Porphyrinoids / Crystal engineering / Solid-state structures / IR and EPR spectroscopy

New multicomponent ionic complexes containing [(Cation$^+$)·(C_{60}^-)] fullerides and neutral $Co^{II}TPP$ molecules were obtained [the cations are Cs^+ (**1**), tetramethylammonium $(CH_3)_4N^+$ (**2**) and *N*-methylpyridinium *N*-$MePy^+$ (**3**)]. The crystal structure of **1** determined from single-crystal X-ray diffraction analysis contains chains of alternating $Co^{II}TPP$ and $C_{60}^{\cdot-}$ units with voids accommodating solvated [(Cs^+)·($C_6H_5CN)_{1.64}$]·CH_3CN counter cations. Relatively long Co···C distances between $Co^{II}TPP$ and $C_{60}^{\cdot-}$ in **1** (2.55–3.05 Å) indicate the absence of noticeable bonding of $Co^{II}TPP$ and $C_{60}^{\cdot-}$. This is consistent with the EPR spectrum of **1**, which manifests two EPR signals with g = 2.0009 and 2.4982 attributable to $C_{60}^{\cdot-}$ and $Co^{II}TPP$, respectively. In contrast to **1**, complexes **2** and **3** contain EPR-silent, σ-bonded [($Co^{II}TPP$)·(C_{60}^-)] anions. The influence of the size of counter cations on the stability of σ-bonded [($Co^{II}TPP$)·(C_{60}^-)] anions in ionic [(Cation$^+$)·($Co^{II}TPP$)·(C_{60}^-)] complexes is analyzed.

Introduction

Fullerene C_{60}-based compounds possess unique magnetic, conductive, and photoactive properties.[1,2] From this variety of compounds, fullerene assemblies with metal-containing porphyrins are of special interest due to possible applications in energy transducers and the modeling of artificial photosynthesis.[2,3] About several tens of fullerene donor−acceptor complexes ranging from molecular to ionic ones,[4−9] as well as covalently and noncovalently linked dyads and triads[3] were obtained with metal octaethyl- and tetraphenylporphyrins. In this context it is very important to understand the metal−fullerene interaction that occurs in such assemblies. Neutral fullerenes are considered to be relatively weak ligands when they coordinate with metal-containing porphyrins.[8,9] Among different metalloporphyrins only iron(II), iron(III), and cobalt(II) tetraphenylporphyrins form short M···C(C_{60}) contacts of 2.58−2.63, 2.57, and 2.58−2.69 Å, respectively, with C_{60}.[10−13] These contacts are shorter than the sum of the van der Waals radii of the M and C atoms, but essentially longer than typical M···C distances when a strong M···C bond is formed, for example, in alkylcobalamins (1.99−2.03 Å).[14]

The preparation of the multicomponent ionic complexes [{$Cr^I(C_6H_6)_2^{\cdot+}$}·($Co^{II}TPP$·fullerene$^-$)·($C_6H_4Cl_2$)] allows us to study the interaction of cobalt(II) tetraphenylporphyrin with fullerene radical anions of C_{60}, C_{70}, and $C_{60}CN_2$. It turned out that the fullerene radical anions are bound more strongly to $Co^{II}TPP$ than neutral fullerenes and form unusual diamagnetic σ-bonded ($Co^{II}TPP$·fullerene$^-$) anions with shortened Co···C(fullerene$^-$) distances of 2.28−2.32 Å.[13,15] However, these interatomic distances are longer than those for the strong M···C bond in alkylcobalamins and indicate a relatively weak σ-bond in ($Co^{II}TPP$·fullerene$^-$) anions. Therefore, the dissociation of these anions could be expected. Indeed, the study of another multicomponent ionic complex with bulkier tetrakis(dimethylamino)ethylene — [(TDAE$^{\cdot+}$)·($Co^{II}TPP$·C_{60}^-)] — indicates the presence of diamagnetic σ-bonded [$Co^{II}TPP$·C_{60}^-] anions in the 2−190 K range, which dis-

sociate to paramagnetic and EPR-active, nonbonded Co^{II}-TPP and $C_{60}^{\cdot-}$ components at temperatures higher than 190 K.[16]

Here we report on new multicomponent ionic complexes containing [Cation$^+$·C_{60}^{-}] fullerides and neutral Co^{II}TPP, where the cations are Cs^+ (in **1**), tetramethylammonium $(CH_3)_4N^+$ (in **2**), and *N*-methylpyridinium *N*-MePy$^+$ (in **3**). The crystal structure of [(Cs^+)·$(Co^{II}TPP)$·$(C_{60}^{\cdot-})$·$(C_6H_5CN)_{1.64}$·$(C_6H_4Cl_2)_{0.36}$·CH_3CN] (**1**), the IR and EPR spectra of **1**, [{$(CH_3)_4N^+$}·$(Co^{II}TPP·C_{60}^{-})$·(C_6H_5CN)·$(C_6H_4Cl_2)$] (**2**), and [(*N*-MePy$^+$)·$(Co^{II}TPP·C_{60}^{-})$·$(C_6H_4Cl_2)_{1.2}$] (**3**) are presented. For the first time, the complex containing nonbonded Co^{II}TPP and $C_{60}^{\cdot-}$ components in the 4−290 K range is described and its properties are compared with those of the complexes containing diamagnetic σ-bonded [$Co^{II}TPP·C_{60}^{-}$] anions.

Results and Discussion

The resulting complexes are presented in Table 1. Crystals of **1**−**3** were obtained by diffusion of *n*-hexane into a solution containing the corresponding [Cation$^+$·$C_{60}^{\cdot-}$] salts and Co^{II}TPP in anaerobic conditions. The crystal structure of **1** was studied at 110 K.[17] Two crystallographically independent Co^{II}TPP molecules are located in inversion centers, whereas $C_{60}^{\cdot-}$, Cs^+, and the solvent C_6H_5CN, $C_6H_4Cl_2$, and CH_3CN molecules are in general positions. The $C_{60}^{\cdot-}$ units are disordered between two orientations (40:60 occupancy) related to each other by their rotation about the noncrystallographic fourfold axis passing through the molecular centroid and the midpoints of two 6−6 bonds.

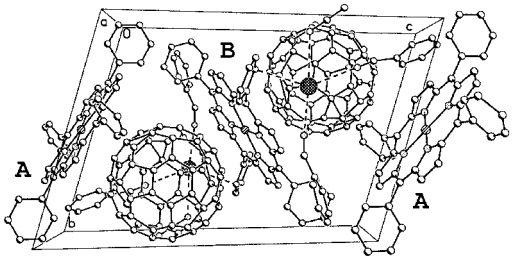

Figure 1. The crystal structure of **1**; the disordered $C_6H_4Cl_2$ molecules are omitted; only the major orientation of $C_{60}^{\cdot-}$ is shown

The main structural motif of the complex is a zigzag chain of alternating Co^{II}TPP and $C_{60}^{\cdot-}$ molecules (Figure 1). Similar motifs were found in the neutral complexes of fullerenes with both metal-containing and metal-free tetraphenylporphyrins.[5−7,13] Each C_{60} unit forms shortened contacts with two Co^{II}TPP molecules (Figure 1). The shortest Co···C(C_{60}) contacts are in the 2.55−3.07 Å range for both orientations of C_{60}. These contacts are of the σ-type (Figure 2); however, they are longer than those in the σ-bonded diamagnetic [$Co^{II}TPP·fullerene^{-}$] anions (fullerene: C_{60} and $C_{60}CN_2$; 2.28−2.32 Å)[13,15] and close to those in the neutral complexes of Fe^{II}, Fe^{III}, and Co^{II}TPP with C_{60} (2.57−2.69 Å)[10−13]. Thus, in contrast to the previously studied ionic complexes [{$Cr^{I}(C_6H_6)_2^{\cdot+}$}$_{1.7}$·{$(Co^{II}TPP·C_{60})_2$}$^{1.7-}$·$(C_6H_4Cl_2)_{3.3}$] and [$(TDAE^{\cdot+})$·$(Co^{II}TPP·C_{60}^{-})$], **1** contains nonbonded Co^{II}TPP and $C_{60}^{\cdot-}$ components at 110 K. The weakness of the Co···$C_{60}^{\cdot-}$ bonding in **1** is also justified by the rotation disorder of the $C_{60}^{\cdot-}$ radical anions, whereas they are ordered in the complex [{$Cr^{I}(C_6H_6)_2^{\cdot+}$}$_{1.7}$·{$(Co^{II}TPP·C_{60})_2$}$^{1.7-}$·$(C_6H_4Cl_2)_{3.3}$].[13] A dihedral angle of 63.8° between the planes of the porphyrin macrocycles of **A** and **B** (Figure 1) is larger in **1** than those in the neutral complexes of tetraphenylporphyrins with fullerenes: 39.0° in [$Cu^{II}TPP·C_{70}$·$(C_6H_5Me)_{1.5}$·$(Cl_2C=CHCl)_{0.5}$];[6] 44.1° in [$Co^{II}TPP·C_{60}$·$(C_6H_4Cl_2)_{2.5}$],[13] and 45.3° in [$H_2TPP·C_{60}$·$(C_6H_5Me)_3$].[5]

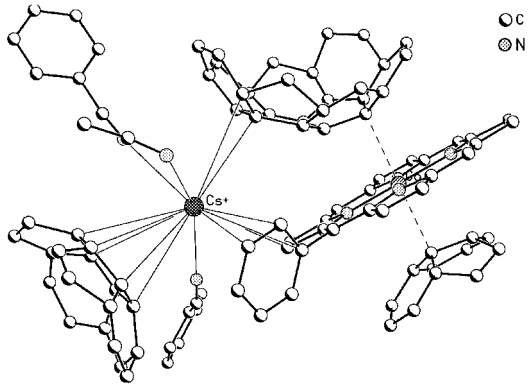

Figure 2. Coordination surrounding of the Cs^+ cation and the cobalt atom of Co^{II}TPP in the crystal structure of **1**; the disordered $C_6H_4Cl_2$ molecules are omitted; only the major orientation of $C_{60}^{\cdot-}$ is shown

Cesium cations occupy the voids in the $Co^{II}TPP$ and $C_{60}^{\cdot-}$ packing and have an irregular environment. The coordination sphere of Cs^+ (Figure 2) involves nitrogen atoms of one CH_3CN and two disordered C_6H_5CN molecules, six carbon atoms from a hexagonal facet of one $C_{60}^{\cdot-}$ in one orientation or five carbon atoms from a pentagonal facet in the other orientation, two carbon atoms of a 6−6 bond of another closest $C_{60}^{\cdot-}$ (in both orientations), and four carbon atoms from phenyl substituents of $Co^{II}TPP$. The total number of carbon and nitrogen atoms coordinated to Cs^+ is 15; the Cs···N distances are in the 3.05−3.21 Å range and the Cs···C distances in the 3.43−3.86 Å range. However, the (Cs^+)···$(C_{60}^{\cdot-})$ interaction is unable to lower the rotational disorder of $C_{60}^{\cdot-}$. In other Cs^+-containing compounds (according to the Cambridge Structural Database) the coordination number of Cs varies between 14−19, the Cs···N distances are in the range 3.07−3.30 Å, and the Cs···C distances are in the range 3.44−3.69 Å. Cesium fulleride Cs_6C_{60}[18] provides an example of a carbon-only coordination sphere of Cs that contains 22 atoms with Cs···C(C_{60}) distances of 3.37−3.69 Å.

Fullerene radical anions are located in pairs isolated from one another by the $Co^{II}TPP$ molecules and the $[(Cs^+)\cdot(C_6H_5CN)_{1.64}\cdot(C_6H_4Cl_2)_{0.36}\cdot CH_3CN]$ aggregates. A center-to-center distance between two $C_{60}^{\cdot-}$ radical anions in the pair is 9.88 Å and the interfullerene C···C distances are in the range 3.07−3.48 Å. The intercenter and the interfullerene C···C contacts in the pair of $C_{60}^{\cdot-}$ are slightly shorter than those in van der Waals neutral complexes of C_{60}.[19] It is quite unusual that in spite of the rather short C···C contacts between $C_{60}^{\cdot-}$, they are not dimerized at temperatures as low as 110 K, whereas in various ionic complexes of C_{60} with metallocenes, such dimerization is observed even at 160−250 K.[20]

The porphyrin macrocycle of $Co^{II}TPP$ retains its planar shape (the root-mean-square deviation of atoms from the mean plane in the porphyrin macrocycle is only 0.017 and 0.015 Å for molecules **A** and **B** in Figure 1, respectively). Such conformation is characteristic of most of the metal-containing tetraphenylporphyrins in the complexes with C_{60}.[5−7,13] The cobalt atom of $Co^{II}TPP$ does not deviate from the mean plane of the porphyrin macrocycle towards the fullerene indicating the absence of noticeable Co···C($C_{60}^{\cdot-}$) bonding in **1**. On the contrary, these deviations are essentially larger (0.091−0.113 Å) in $[\{Cr^I(C_6H_6)_2^{\cdot+}\}\cdot(Co^{II}TPP\cdot fullerene^-)\cdot C_6H_4Cl_2]$ (fullerene: C_{60} and $C_{60}CN_2$).[13,15]

Thus, complex **1** differs from the previously studied multicomponent ionic complexes of $Co^{II}TPP$ with C_{60}^- by the presence of nonbonded $Co^{II}TPP$ and $C_{60}^{\cdot-}$ components. The IR and EPR spectra of **1** support this assertion.

The IR spectrum of **1** is a superposition of the spectra of neutral $Co^{II}TPP$, $C_{60}^{\cdot-}$, and solvent molecules.[21] The position of the $F_{1u}(4)$ C_{60} mode at 1397 cm^{-1} coincides with those for other radical anion salts of C_{60} with a −1 charge on the C_{60} molecule.[22,23] The integral intensity of the $F_{1u}(2)$ mode at 576 cm^{-1} is also essentially higher than that of the $F_{1u}(1)$ mode at 526 cm^{-1}. The bands attributable to "silent" modes of C_{60} are not observed in the spectrum of **1**[21] indicating the retention of $C_{60}^{\cdot-}$ symmetry and the absence of noticeable σ-bonding between $Co^{II}TPP$ and $C_{60}^{\cdot-}$ at room temperature (RT = 290 K). On the contrary, the formation of σ-bonded ($Co^{II}TPP\cdot C_{60}^-$) anions in $[\{Cr^I(C_6H_6)_2^{\cdot+}\}_{1.7}\cdot\{(Co^{II}TPP\cdot C_{60})_2\}^{1.7-}\cdot(C_6H_4Cl_2)_{3.3}]$ results in the appearance of weak additional bands due to C_{60} symmetry breaking.[13]

The EPR spectrum of **1** contains two intense EPR signals with g = 2.0009 [Figure 3 (a)] and 2.4982 [(Figure 3 (b)] and the line halfwidth (ΔH) of 4.78 and 51.2 mT, respectively. The total integrated intensity of these signals corresponds to approximately two spins per one formula unit. On the contrary, the σ-bonded ($Co^{II}TPP\cdot C_{60}^-$) anions are diamagnetic and EPR silent.[13,15,16] The first signal in **1** is unambiguously attributed to the nonbonded $C_{60}^{\cdot-}$ radical anions. The line halfwidth of this signal monotonically decreases down to 0.3 mT at 4 K. Such behavior is also characteristic of the EPR signal from $C_{60}^{\cdot-}$. The second signal can be attributed to $Co^{II}TPP$ with S = 1/2 ground state. This signal is essentially different from that of the parent porphyrin $Co^{II}TPP$ (the asymmetric signal with $g_\perp$ = 3.322 and g_{II} = 1.798)[24] and similar to the EPR signals from $Co^{II}TPP$ in the neutral complexes with fullerenes C_{60}, C_{70}, and $C_{60}CN_2$ (the asymmetric signals with $g_\perp$ = 2.51−2.64 and ΔH = 15−30 mT, g_{II} = 2.28−2.42 and ΔH = 31−45 mT).[13] The difference implies that the EPR signal in **1** is a symmetric Lorentzian line down to 4 K, whereas the EPR signals in the neutral complexes with fullerenes are asymmetric and contain two components down to 4 K. The g-factor of the EPR signal of $Co^{II}TPP$ in **1** shifts to smaller values as the temperature decreases

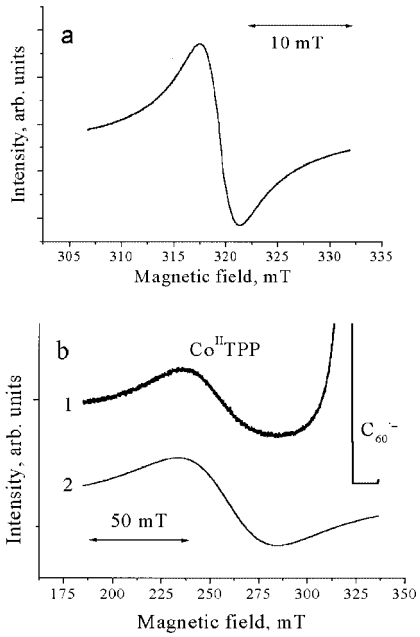

Figure 3. EPR spectrum of polycrystalline **1** at T = 290 K; (a) the signal attributable to $C_{60}^{\cdot-}$; (b) the signals attributable to $Co^{II}TPP$ and $C_{60}^{\cdot-}$ (1); the simulation of the signal from $Co^{II}TPP$ by one Lorentzian line is shown below (2)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and the line halfwidth becomes narrower (g = 2.3785 and ΔH = 41.5 mT at 4 K).

When Rb was used instead of Cs, in the absence of CH_3CN, the complex [(Rb^+)·$Co^{II}TPP$·$(C_{60}^{\cdot-})$] did not crystallize. We used the reaction of cationic metathesis to substitute the Rb^+ counter cations for other small cations such as Me_4N^+ (in **2**) and *N*-$MePy^+$ (in **3**). The crystallization of these complexes by the diffusion of *n*-hexane affords [(Me_4N^+)·$(Co^{II}TPP$·$C_{60}^-)$·(C_6H_5CN)·$(C_6H_4Cl_2)$] (**2**), and [$(N$-$MePy^+)$·$(Co^{II}TPP$·$C_{60}^-)$·$(C_6H_4Cl_2)_{1.2}$] (**3**). The IR spectra of **2** and **3** justify their ionic ground state (the spectra manifest the absorption bands attributable to $C_{60}^{\cdot-}$) and show additional silent modes of C_{60} due to its symmetry breaking.[21] The EPR spectra of **2** and **3**, in contrast to **1**, show no signals from 290 down to 4 K indicating the formation of diamagnetic and EPR-silent σ-bonded ($Co^{II}TPP$·C_{60}^-) anions, which are stable in the 4−290 K range.

Thus, two extreme cases can be found in **1**−**3**. Complex **1** contains nonbonded $Co^{II}TPP$ and $C_{60}^{\cdot-}$ components in the 4−290 K range, whereas complexes **2** and **3** contain σ-bonded ($Co^{II}TPP$·C_{60}^-) anions stable in the 4−290 K range. Previously studied ionic [$\{Cr^I(C_6H_6)_2^{\cdot+}\}_{1.7}$·$\{(Co^{II}TPP$·$C_{60})_2\}^{1.7-}$·$(C_6H_4Cl_2)_{3.3}$][13] and [$(TDAE^{\cdot+})$·$(Co^{II}TPP$·$C_{60}^-)$][16] are intermediates between **1**, and complexes **2** and **3**. At low temperatures they contain σ-bonded [$Co^{II}TPP$·C_{60}^-] anions. The broadening of the EPR signal above 200 K in [$\{Cr^I(C_6H_6)_2^{\cdot+}\}_{1.7}$·$\{(Co^{II}TPP$·$C_{60})_2\}^{1.7-}$·$(C_6H_4Cl_2)_{3.3}$] can be associated with the appearance of a small contribution from nonbonded $Co^{II}TPP$ and $C_{60}^{\cdot-}$.[16] Evident dissociation of σ-bonded ($Co^{II}TPP$·C_{60}^-) anions to nonbonded $Co^{II}TPP$ and $C_{60}^{\cdot-}$ components is observed in [$(TDAE^{\cdot+})$·$(Co^{II}TPP$·$C_{60}^-)$] above 190 K, and it is accompanied by an increase of the magnetic moment, the essential broadening of the EPR line, and the shift of its *g*-factor to larger values. At 290 K approximately 20 % of total $Co^{II}TPP$ and $C_{60}^{\cdot-}$ exists in a nonbonded state.[16]

The temperature ranges of the existence of σ-bonded ($Co^{II}TPP$·C_{60}^-) anions in the ionic multi-component complexes of $Co^{II}TPP$ with C_{60}^- and the counter cations used are listed in Table 2. The complexes are given in Table 2 in order of increasing size of the counter cations. The increase in the size of counter cations is seen to destabilize the σ-bonded [$Co^{II}TPP$·C_{60}^-] anions. The use of large cations like Cs^+ solvated by one CH_3CN and nearly two C_6H_5CN molecules forces the units $Co^{II}TPP$ and $C_{60}^{\cdot-}$ apart, and does not allow them to approach each other so closely to form a Co···C($C_{60}^{\cdot-}$) σ-bond. Thus, in spite of the obvious ability of $Co^{II}TPP$ and $C_{60}^{\cdot-}$ to form σ-bonds, steric factors (namely, the size of the counter cations) also determine the possibility of the formation of σ-bonded [$Co^{II}TPP$·C_{60}^-] anions. Similarly, in ionic charge transfer complexes of C_{60} with metallocenes, the stability of single-bonded $[C_{60}^-]_2$ dimers varies in a wide range (the beginning of dissociation is in the 160−250 K range) and is determined by the size of the donor and even the solvent molecules involved in the complex.[20]

Experimental Section

General Remarks: $Co^{II}TPP$ and Me_4NI were purchased from Aldrich. *N*-MePyI was obtained by the reaction of Py with MeI and then recrystallized from *N*,*N*-dimethylformamide. C_{60} of 99.98 % purity was purchased from MTR Ltd. All solvents were distilled under argon: *o*-dichlorobenzene ($C_6H_4Cl_2$) over CaH_2, benzonitrile (C_6H_5CN) over Na/benzophenone under reduced pressure, acetonitrile over CaH_2, P_2O_5, and K_2CO_3. The solvents were degassed prior to use and were stored in a glove box. All manipulations during the synthesis and isolation of the crystals of **1**−**3** were carried out in a MBraun 150B-G glove box; the content of H_2O and O_2 was less than 1 ppm. The crystals were stored in the glove box and sealed in 2 mm quartz tubes for EPR measurements under 10^{-5} Torr. KBr pellets for IR measurements were also prepared in the glove box. UV-Vis-NIR spectra were measured on a Shimadzu-3100 spectrometer in the 240−2600 nm range. FT-IR spectra were measured with KBr pellets on a Perkin−Elmer 1000 Series spectrometer (400−7800 cm^{-1}). EPR spectra were recorded down to 4 K with a JEOL JES-TE 200 X-band ESR spectrometer equipped with a JEOL ES-CT470 cryostat.

Synthesis: The crystals of **1**−**3** were obtained by the diffusion of *n*-hexane into a solution containing the corresponding [$C_{60}^{\cdot-}$·Cation$^+$] salt and $Co^{II}TPP$ porphyrin complex. The diffusion was carried out in a glass tube of 1.5 cm in diameter and 40 mL volume with a ground glass plug. The crystals of **1**−**3** were formed as large black prisms of up to 1 × 1 × 0.5 mm^3. The composition of the compounds was determined from X-ray diffraction on a single crystal for **1** and by elemental analysis for **2** and **3** (Table 1). In **2** and **3**, the difference [(100 %)-(C, H, N, Cl, %)] exceeds the calculated content of metals (Co and Cr) indicating the addition of oxygen to the complexes during the elemental analysis. Indeed, the complexes are sensitive to oxygen. The addition of ap-

proximately one O_2 molecule per one formula unit of the complex is observed. Thus, the calculated C, H, N, and Cl (%) content was corrected for the composition (Formula unit:O_2). We assumed that oxygenation occurring during elemental analysis was extrinsic and omitted oxygen throughout the manuscript.

Complex 1: The cesium salt of fullerene $(Cs^+)\cdot(C_{60}^{\cdot-})$ was obtained by the dissolution of C_{60} (25 mg, 0.035 mmol) with Cs (5.2 mg, 0.038 mmol) in benzonitrile which was stirred for 2 hours at 60 °C. The purity of the salt was justified by the presence of characteristic $(C_{60}^{\cdot-})$ absorption bands in the solution NIR spectrum. The solution was cooled down to room temp. filtered, and $C_6H_4Cl_2$ and CH_3CN were added (the $C_6H_4Cl_2/C_6H_5CN/CH_3CN$ volume ratio is 50:45:5, the total volume is 20 mL). $Co^{II}TPP$ (23.5 mg, 0.035 mmol) was dissolved in this solution at 60 °C; the resulting solution was cooled down to room temp., filtered into a glass tube and layered with *n*-hexane (20 mL). Crystals of **1** that precipitated after 1 month were washed with *n*-hexane and dried (yield 31 mg, 50 %).

Complexes 2 and 3: Complexes **2** and **3** were obtained similarly. The $(Rb^+)\cdot(C_{60}^{\cdot-})$ complex was obtained by the dissolution of C_{60} (100 mg, 0.14 mmol) with Rb (13.2 mg, 0.152 mmol) in benzonitrile (40 mL) at 60 °C by stirring for 2 hours. The solution was cooled down to room temp. and filtered. The purity of the $(Rb^+)\cdot(C_{60}^{\cdot-})$ salt was justified by the solution NIR spectrum. The solution 10 mL) containing of $(Rb^+)\cdot(C_{60}^{\cdot-})$ was treated with an excess of tetramethylammonium iodide (**2**) or *N*-methylpyridinium iodide (**3**) at 60 °C. After 4 hours the solution was cooled down, filtered, and mixed with $C_6H_4Cl_2$ at a 50:50 volume ratio (the total volume was 20 mL). $Co^{II}TPP$ (23.5 mg, 0.035 mmol) was dissolved in the obtained solution at 60 °C, allowed to cool to room temp., filtered into a glass tube and layered with *n*-hexane (20 mL). Crystals of **2** and **3** that precipitated after 1 month were washed with *n*-hexane and dried (yield 30 mg, 50% for **2**; 34.6 mg, 60% for **3**).

X-ray Crystallographic Study: X-ray diffraction data were collected at 110 K on a Bruker SMART CCD diffractometer with an area detector (sealed tube, Mo-K_α radiation, $\lambda = 0.71073$ Å). A series of three ω scans with a 0.3° frame width were collected. Reflection intensities were integrated using the SAINT program.[25] The structure was solved with direct methods using SHELXTL program package[26] and refined by full-matrix least-squares on F^2. The ordered non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions and refined within the "riding atom" model. Both C_6H_5CN molecules are statistically substituted by $C_6H_4Cl_2$ ones per 20 % and 16 %. One of the $Co^{II}TPP$ phenyl rings is also disordered between two positions in a 40:60 ratio.

Introduction

The growing interest on uniform nanometric particles is related to the novel properties associated with systems that are intermediate in size between isolated atoms or molecules and bulk materials.[1] These properties extend the interest in nanostructured materials not only to evident areas, such as microelectronics or catalysis, but also to more original applications, such as the separation of magnetically-labelled biomolecules. In fact, magnetic nanomaterials are currently considered the most promising candidates for data-storage devices, due to the possibility of exploiting the quantum-tunnelling of magnetization effect, which is typical of nanomagnets.[2] Notwithstanding, the special properties of nanoparticulate materials strongly depend on morphological aspects. Control of the size and shape of the particles and the attainment of good dispersity levels are essential requirements.[2] In addition, the use of nanoparticles is limited because of their tendency to form large aggregates, which means that the properties associated with the nanometer range are lost. A well-known solution to overcome this problem consists in the dispersion and/or encapsulation of the nanoparticles in an inert matrix. Indeed, nanosized magnetic materials have been produced by using polymers as a support.[3,4] In this context, silica-based micro- and mesoporous solids, such as zeolites and MCM-41-like materials, are attracting increasing attention as a way to stabilize highly dispersed metal or metal oxide particles.[5] In practice, the functionality of the M41 mesoporous solids has been greatly expanded in recent years by incorporating organic groups or inorganic elements in the pore voids and/or inside the silica walls. Thus, in the search for magnetic materials, a diversity of guest species (semiconductors, metals, metal oxides, clusters, organic molecules, and even single-molecule magnets) have been hosted in the M41 matrices.[6−14] There are relatively few studies concerning Co-containing related materials. These studies are basically focussed on catalytic applications and involve materials in which the cobalt load was carried out after the matrix synthesis.[15−19] As far as we know, there are only two previous publications dealing with the magnetic properties of nanometric cobalt oxides hosted in MCM-41 solids, and, in both cases, the nanocomposites were prepared by post-synthesis impregnation treatments.[20,21] Although soaking really is a common procedure for functionalizing mesoporous silicas, this approach is multistep and, more importantly, frequently leads to necking or even blocking of the pore system.

We report here on a one-pot, reproducible surfactant-assisted procedure yielding superparamagnetic CoO-MCM-

41 mesoporous nanocomposites, in which the high dispersion of the CoO-like nanoclusters inside the silica walls is maintained for a high compositional range (up to Si/Co = 23 molar ratio) without blocking of the mesopore system.

Results and Discussion

Mesoporous materials of the MCM-41 type that are rich in CoO-like nanoclusters were synthesized through a one-pot approach using CTABr as a surfactant in a $TEAH_3$–water medium (CTABr = cetyltrimethylammonium bromide; $TEAH_3$ = triethanolamine). The molar ratio of the reagents in the starting solution was 2 Si: *x* Co: 7 $TEAH_3$: 0.50 NaOH/ 0.50 CTABr: 180 H_2O (see Table 1). Our synthesis strategy is based on the use of complexes containing $TEAH_3$ ligands as hydrolytic inorganic precursors. Under basic conditions, and working in an excess of $TEAH_3$, this method unifies the precursor nature (by forming metal-atranes) and it favours the preparation (through co-hydrolysis) of mixed oxides displaying a high chemical homogeneity.[22] Moreover, this approach overcomes, as far as possible, problems related to restrictions on the final stoichiometry. In any case, we should not forget that the replacement of silicon atoms by divalent transition metal cations in a silica matrix is a thermodynamically unfavourable process, and phase segregation must be expected a priori. Thus, the preparative technique is designed to optimize the dispersion of the Co-guest species in the mesoporous host matrix.

EPMA data show that all the samples are chemically homogeneous at micrometric level (spot area about 1μm). Furthermore, only one type of particle morphology, with a hexagonal microstructure that becomes progressively distorted as the Co content increases, is observed in the TEM images of each sample (see Figure 1). Also, the absence of XRD peaks (characteristic of cobalt oxides) at high 2θ values confirms that no extra wall-phase segregation occurs. Hence, at the present scale, which is limited by these techniques, the samples can be considered CoO-MCM-41 monophasic systems. Consequently, the maximum expected dimensions of the possible CoO-like aggregates should be close to the pore-wall size.

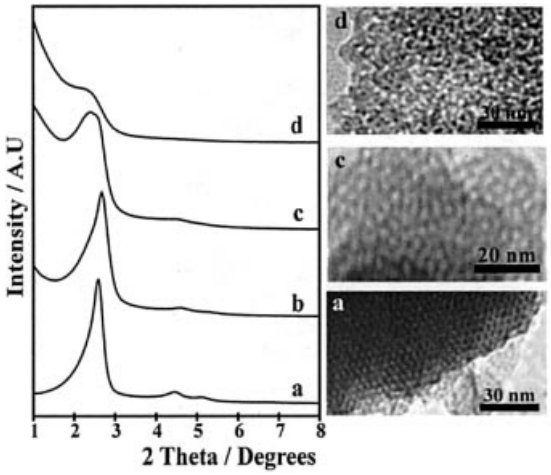

Figure 1. XRD patterns and selected TEM images of CoO-MCM-41 samples; (a) Si/Co = 155; (b) Si/Co = 98; (c) Si/Co = 49; (d) Si/Co = 23

All the samples show XRD patterns that are characteristic for mesoporous hexagonal MCM-41 materials, with at least one strong peak in the low-angle zone and two additional small reflections (exception made of the sample with Si/Co = 23) at higher 2θ values. Nevertheless, the quality and definition of the XRD patterns diminishes as the Co content increases. This evolution indicates progressive lowering of order in the pore array as the cobalt content increases, from ordered hexagonal through disordered hexagonal to wormhole-like systems. The trend is clearly confirmed by the TEM micrographs (see Figure1). Additionally the cell parameter increases with the Co content (see Table 1), an effect typically induced by an effective incorporation of heteroelements in the pore wall of the mesoporous silicas.[23] This behaviour probably results form the interaction of the heteroelement in the growing of the silica network in one-pot (co-hydrolysis) synthesis methods. In our case it could be attributed to a poor charge matching between the CTABr and silica moieties due to the cobalt species, which, in turn, would constitute an indirect probe of the incorporation of cobalt in the pore walls. On the contrary, in mesoporous silicas with metal oxide nanoparticles filling the pores or coating the pore surfaces, prepared through post synthesis treatments, the a_0 value does not significantly depend on the nanoparticle amount.[13,14,17]

Table 1. Co content and selected physical data for CoO-MCM-41

Si/Co (solid)[a]	a_0 [nm][b]	Pore size [nm]	S_{BET} [$m^2\ g^{-1}$]	Pore-wall thickness [nm]
155	3.80	2.50	908.5	1.30
98	3.80	2.48	662.0	1.32
49	4.09	2.47	526.3	1.63
23	4.14	2.50	478.6	1.64

[a] Values averaged from the EPMA of about 40 different particles. [b] Calculated cell parameters assuming an MCM-41 type hexagonal cell.

The loss of X-ray intensity observed in the XRD, corresponding to the solid with the highest Co content, must be attributed to a significant loss of order more than to phase-cancellation phenomena, which are associated with the introduction of scattering material into the pores or to a partial collapse of the mesostructure. In fact, as indicated above, the observation by TEM of a single type of particle of homogeneous morphology containing mesopores allows us to discard the presence of collapsed bulk materials.

Mesoporosity is evaluated by N_2 adsorption−desorption isotherms (see Figure 2). All the curves display one well-defined step at intermediate P/P_0 values typical of type IV isotherms. Although incorporation of Co results in a gradual decrease of the surface area, the high surface area and porosity, characteristic of the MCM-41 silica, are retained in all cases. Moreover, the fact that the pore size remains practically constant as the cobalt content increases, together with the absence of significant hysteresis loops in the isotherms, indicates that no necking or blocking of the pore system occurs. The thickness of the pore walls (estimated from XRD and porosity data) increases with the Co content, which explains the decrease of the S_{BET}. Thus, it is reasonable to propose that CoO nanoclusters are incorporated into the silica walls.

The UV/Vis spectra of some selected CoO-MCM-41 samples dehydrated at 400 °C are shown in Figure 3. All the spectra display a strong absorption in the visible region

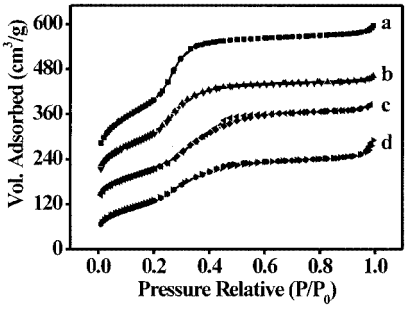

Figure 2. N_2 adsorption−desorption isotherms (curves are shifted for clarity) of CoO-MCM-41 samples; (a) Si/Co = 155; (b) Si/Co = 98; (c) Si/Co = 49; (d) Si/Co = 23

(15000−20000 cm^{-1}) with three maxima at around 15000, 17000 and 19000 cm^{-1}. This triplet can be unambiguously assigned to the $^4A_2(F) \rightarrow {}^4T_1(P)$ transition of cobalt(II) ions in tetrahedral oxygen environments, which allows us to discard the presence of Co^{III} atoms. In all cases, the characteristic blue colour of the materials is typical of tetrahedral $Co^{II}O_4$ sites. The intensity of this band significantly decreases with hydration, and it recovers reversibly by posterior drying. This behaviour clearly indicates that a certain proportion of the tetrahedral cobalt atoms becomes octahedrally coordinated by water uptaking and lies on the surface of the pore wall. Taking into account the large difference between the absorption molar coefficients of the bands due to electronic transitions associated to octahedral vs. tetrahedral Co^{II} sites, it can be reasonably assumed that the area under the vis curve is proportional to the number of non-hydrated tetrahedral cobalt centres. With this simplification, we can estimate the ratio of "surface" (water accessible)-to-"bulk" (inaccessible) Co ions by the intensity variation of the band after hydration. Remarkably, this ratio is practically constant and close to 2:7, irrespective of the cobalt content in the sample. This result strongly suggests that the nature of the CoO clusters does not depend on the Co concentration in the sample and supports the existence of a regular interaction of the clusters with the pore walls that become progressively distorted by increasing the cluster concentration.

The results of the magnetic measurements offer definitive evidence for the fact that the particle size remains constant, independent of the Si/Co molar ratio. Thus, all the samples show identical behaviour: (i) a sharp increase of the DC magnetic susceptibility below 12−17 K; (ii) a frequency-dependent AC signal with maxima at 4−7 K in the in-phase signal (χ') and at 3−5 K in the out-of-phase signal (χ''; see Figure 4); (iii) deviations in the zero-field-cooled and field-cooled susceptibilities below 10−15 K, with a remnant magnetization that vanishes at around 15 K for all the samples; and (iv) hysteresis cycles in the isothermal magnetization at low temperatures. All these features suggest a superparamagnetic behaviour with a blocking temperature

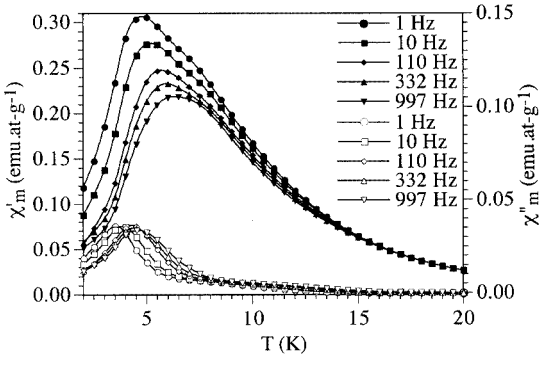

Figure 4. Thermal variation of χ' (filled symbols, scale on the left) and χ'' (empty symbols, scale on the right) at different frequencies for the sample with Si/Co = 49

Table 2. CoO particle size determined from magnetic measurements

Si/Co (solid)	T_B [K][a]	E_a [K]	D [nm][b]
155	13	123.1	2.0
49	14	107.2	1.9
23	16	105.8	1.9

[a] Defined as the temperature at which $\chi'' \neq 0$. [b] Diameter determined from the E_a data ($E_a = K \cdot V$).

of around 15 K (see Table 2). It should be noted that possible spin-glass behaviour is excluded since the conditions for a spin-glass system are not fulfilled and the activation energies obtained from the frequency dependence of the maxima in χ'' (see below) are much lower than those expected for spin-glass systems.[19]

A way of estimating the particle size is to use the relationship between the activation energy of the blocking process of the resultant moments on the particles (E_a) and the particle volume (V), that is, $E_a = K \cdot V$, where K is the energy density of the magnetic anisotropy.[17] With the activation energies (E_a ca. 90−120 K, see Table 2) obtained from the Arrhenius law for the temperatures of the maxima in χ'' (T_m) as a function of the frequency (ν), $\nu = \nu_0 \cdot \exp(-E_a/kBT_m)$, and taking $K = 3.8 \cdot 10^6$ erg·cm^{-3},[20] we can estimate that the particle sizes are between 1.8 and 2.0 nm (see Table 2).

In any case, the relevant conclusion from the magnetic and spectroscopic studies is that, regardless of the Si/Co ratio, the CoO particles are similar and homo-disperse with sizes close to 2 nm. Assuming that the structure is sphalerite, these nanoclusters should contain around 200 CoO units. Taking the "nonaccessible"-to-"accessible" Co ratio found by spectroscopy into account, we postulate a model for these CoO-MCM-41 nanocomposites in which the CoO nanodomains are partially embedded (about 25 %) in the silica matrix.

Conclusion

In summary, we present a simple one-pot surfactant-assisted approach for obtaining superparamagnetic mesoporous materials with high cobalt content and well-dispersed uniform CoO nanoparticles within the inorganic walls, without blocking of the pore system. The homogeneity in size, nature and dispersion of the CoO nanoparticles can be explained by the fact that the growing process of the nucleated CoO species, generated by the hydrolysis of the Co precursor, is blocked by the relatively slower condensation of the mesostructured silica network. In short (in the experimental Si/Co concentrations) the time consumption for the nucleation and growing of the CoO particles is constant and limited by the silica polymerisation process. These materials may be described as nanocomposites of CoO clusters on mesoporous silicas. The nanometric organization of highly dispersed and accessible CoO nanodomains could be of catalytic interest in Fischer−Tropsch and ODH processes.

Experimental Section

CoO-MCM-41 Mesoporous Nanocomposites: The molar ratio of the reagents in the starting solution was 2 Si: x Co: 7 $TEAH_3$: 0.50 NaOH/ 0.50 CTABr: 180 H_2O (Table 1). In a typical synthesis leading to the Si/Co = 49 mesoporous material, 0.49 g of NaOH were dissolved at 60 °C in 20 mL of $TEAH_3$. After a few minutes, 10.5 mL of TEOS and 0.20 g of $CoCl_2$ were added whilst stirring, and the mixture was heated at 150 °C for 5 min. The resulting solution was cooled down to 100 °C, and 4.68 g of CTABr were added while stirring. Then, 80 mL of water were added with vigorous stirring at 60 °C. After a few minutes, a pale-blue suspension resulted, and it was aged at room temperature for 24 hours. The resulting powder was filtered off, washed with water and ethanol, and air dried. Finally, to open the mesopore system, the surfactant was removed by calcination at 550 °C in the course of 5 hours under air atmosphere.

All samples were analyzed and characterized by electron probe microanalysis (EPMA, Philips SEM-515), XRD techniques (Seifert 3000TT diffractometer; Cu-K_α radiation), TEM (Philips CM10 microscope), N_2 adsorption−desorption isotherms (Micromeritics ASAP2010), UV/Vis spectroscopy (UV-250 1PC Shimadzu), magnetic susceptibility measurements (DC and AC magnetic fields) and isothermal magnetization (PPMS-9 and SQUID susceptometer MPMS-XL-5, Quantum Design).

The First Pure Mesoporous Aluminium Phosphonates and Diphosphonates – New Hybrid Porous Materials

Jamal El Haskouri,[a] Carmen Guillem,[a] Julio Latorre,[a] Aurelio Beltrán,[a] Daniel Beltrán,[a] and Pedro Amorós*[a]

Keywords: Hybrid materials / Mesoporous / Template synthesis / Aluminium / Phosphonates

Organophosphorus moieties have been incorporated into mesoporous ALPOs through a one-pot surfactant-assisted procedure leading, for the first time, to periodic mesoporous aluminium phosphonates and diphosphonates. The number of organic groups on the surface or in the network can be modulated continuously up to the maximum incorporation level of the respective organophosphorus entities (100 %).
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Since the discovery of three-dimensional aluminium phosphates (ALPOs),[1] the chemistry of open metal phosphates and phosphonates was extensively explored in the search for expanding microporous availability.[2] Organophosphorus reagents have been used as both anionic species able to construct layered or open structures[2] (one-pot) and coupling agents[3] for the preparation of hybrid materials based on metal oxides (grafting). Interest in these materials is currently related to the broad range of their potential applications in fields such as catalysis, molecular sieves and biomedical sciences.[4] The current trend of expanding pore sizes by using supramolecular templates has been successfully adapted for obtaining MCM-41-like aluminium phosphates.[5] Notwithstanding, reports on organically modified mesoporous phosphates are very scarce when compared to those dealing with hybrid organosilicas.[6] In fact, once the preparation of mesoporous silicas began to be controlled, a key objective was the functionalisation of the walls with organic groups (housed in the pore space or embedded in the walls).[6] In contrast, as far as we know, there are only three publications in which mixed mesoporous phosphate-phosphonate (containing Ti[7] and Zr[8]) or mesoporous phosphate-diphosphonate (based on Al[9]) materials are described. In the case of the Ti[7] and Zr[8] derivatives, by using terminal RPO_3 substituting groups, the phosphonate incorporation to the final materials is limited (< 50 %) and restricted to the pore surface. Dealing with the Al-containing solid, although diphosphonate moieties with bridged methylene groups have been used to connect the Al centres (in the mesostructured solid), the thermal evolution of the surfactant to prepare the corresponding mesoporous material leads to a significant degradation of diphosphonate moieties that decompose into terminal RPO_3 and phosphate groups. Hence, this solid must be understood as a mixed phosphate–phosphonate–diphosphonate mesoporous material constructed, as stated by the author, from aluminophosphate-like domains interconnected through bridged organic groups instead of a pure mesoporous aluminium-diphosphonate.[9]

Results and Discussion

We report here a generalised one-pot method that has allowed us to prepare for the first time pure mesoporous aluminium phosphonates and diphosphonates (henceforth denoted as UVM-9 for University of Valencia Materials) showing that a good selection of reagents, conditions and procedures allow the full extension of the ALPO derivatives to as broad a family as mesoporous organosilicas. In fact, a great variety of terminal organic groups [$(RO)_{4-n}Si-R'_n$, $1 \leq n \leq 3$] have been incorporated into the silica matrix through cohydrolysis or post-treatments. In any case, these terminal groups are usually housed in the pore space.[6] As an alternative, a novel strategy based on the use of bridge-bonded silsesquioxanes [$(RO)_3-Si-R'-Si(OR)_3$] leads to the incorporation of the organic functional groups embedded in the silica walls (PMO materials).[11] Thus, surface and framework organic modifications have been carried out by using RPO_3^{2-} terminal phosphonates [instead of $R'Si(OR)_3$][6] or $^{2-}O_3P-R-PO_3^{2-}$-bridged diphosphonates [instead of $(RO)_3-Si-R'-Si(OR)_3$],[10] respectively. Our method al-

lows the progressive incorporation of organic groups, which originates from organic-free ALPOs to pure mesoporous aluminium phosphonates or diphosphonates (100 % of organophosphorus groups) through ALPOs with organically modified surfaces (terminal phosphonates) and/or frameworks (bridged diphosphonates).

The procedure is based on the use of a simple and commercial structural-directing agent (CTABr = cetyltrimethylammonium bromide) and a complexing polyalcohol (2,2′,2′′-nitrilotriethanol = TEAH3), which has proved its capability to harmonise the rates of the hydrolytic reactions of the aluminium species in water−phosphoric acid media and the subsequent processes of self-assembling with the surfactant aggregates.[11] The same general procedure has been used for obtaining solids with diphosphonates (using ethylenephosphonic acid), phosphonates (using methylphosphonic acid) or mixed phosphate−phosphonate/diphosphonate derivatives (starting from mixtures of phosphoric and organophosphorus acids; see Exp. Sect.). In all cases, the molar ratio of the reagents was adjusted to 2 Al/3 P (H_3PO_4 + phosphonic acid)/8 TEAH3/0.52 CTABr/270 H_2O. Table 1 summarises the main synthesis variables and physical data.

EPMA shows that all UVM-9 samples are chemically homogeneous (spot area ca. 1 μm) and have a constant and well defined composition. In all cases, UVM-9 solids containing diphosphonate groups show Al/P proportions close to the idealised Al/P molar ratio (1:1), typical of stoichiometric ALPOs, in contrast to the aluminium phosphate−phosphonate materials previously described (Al/P = 1.37[9]), while deviations from the Al/P ratio have been observed when monophosphonate groups were present. This fact indicates that the UVM-9 solids may basically be regarded as aluminophosphonates rather than a compound consisting, to a significant degree, of alumina domains connected through organophosphorus moieties. Moreover, the high-angle XRD patterns do not show peaks associated to segregated bulk phases. Based on these facts and taking into account the difficulty to condense phosphate, phosphonate and/or diphosphonate groups among them (leading to P−O−P bonds) under aqueous conditions, we can propose that the UVM-9 materials display a regular distribution of Al and P atoms along the pore walls. The high chemical homogeneity and dispersion achieved for Al and P atoms indicates that the good reactivity control previously reached with Al-TEAH3 complexes as an aluminium source in water/phosphoric media is maintained when phosphoric acid is partially or totally replaced by phosphonic or diphosphonic acids.

Elemental CNH analysis of all mesoporous UVM-9 samples reveals that they are nitrogen-free materials. This fact confirms the efficiency of the soft surfactant extraction procedure we have used. Moreover, the absence of signals associated to surfactant molecules in the ^{13}C NMR spectra supports the total CTA^+ evolution. Thus, CNH analysis allows an estimation of the content of organic groups in the final mesoporous materials to be calculated (see Table 1). The phosphonate/phosphate molar ratio in the materials containing diphosphonate species is close to that present in the mother liquor (samples 5 and 7), but it significantly drops when monophosphonates are involved (samples 2 and 3). Very likely, this difference is related to the capability of the phosphate and diphosphonate groups to act as network building blocks (bridging Al atoms); a role that monophosphate groups do not play (RPO_3^{2-} groups are necessarily terminal). As in the case of the PMO organosilicas, the bridging nature of the diphosphonates and their ability to interact through six O atoms allows their easy incorporation as network-forming groups. For this reason, the isolation of practically stoichiometric (Al/P = 1) diphosphonate materials is possible. Without prejudice to the observed preferential incorporation of the phosphate groups vs. monophosphonate groups, the existence of pure Al-monophosphonates (sample 4) and Al-diphosphonates (sample 7) is proof of the cooperative ability of the organophosphorus and aluminium moieties to construct stable networks around the surfactant aggregates. This last result accords well with previous results on organosilicas (with terminal organic groups), suggesting an upper functionalisation limit of about 40 %;[12] probably because at least 50 % of SiO_4^{3-} units is required to stabilise the pore wall network. Effectively, the intrinsic compositional nature of the UVM-9 materials (Al/P ≈ 1:1) warrants the presence of a similar amount of network-forming groups. Indeed, the slightly higher aluminium content in the Al-monophosphonates (Al/P = 1.15−1.25:1), should be viewed as a requirement for the pore wall stabilisation.

^{31}P MAS NMR spectra (Figure 1) confirm the incorporation of phosphate and phosphonate groups and provide useful information on their evolution as the functionalis-

ation level increases. The spectrum of sample 1 (ALPO) shows a broad signal centred at −25 ppm, which can be attributed to tetrahedral phosphates connected to aluminium centres.[5] As expected, according to the CNH analysis, the spectra clearly show the evolution of the P environments as the phosphonic/phosphoric acid ratio increases (samples 2−4 and 5−7); the intensity of the signals associated with the phosphate groups decreases while that of the signals characteristic of the phosphonate increases (10−22 ppm range).[13] Finally, the spectra of samples 4 and 7 (Al-methylphosphonate and Al-ethylenediphosphonate, respectively) only display the ^{31}P signal typical of phosphonate groups. Hence, while samples 2, 3, 5 and 6 present two different phosphorus environments, the UVM-9 materials with a functionalisation level of 100 % (samples 4 and 7) show only one environment for the P atoms both before and after (mesoporous) surfactant evolution. The small ^{31}P signal shifts observed in the NMR spectra can be associated to different parameters such as the proportion of octahedral aluminium sites and OH groups bonded to the P atoms and also to the presence of variable water amounts inside the mesopores.[14] In our case, the soft chemical treatment used to extract the surfactant allows us to maintain the chemical integrity of methylphosphonate and ethylenediphosphonate groups in the final mesoporous solids. This strategy avoids the degradation of the bridged diphosphonate.[9] All UVM-9 materials have ^{27}Al MAS NMR spectra that include two resonance signals at approximately $\delta = 0$ and 50 ppm (see Supporting Information; see also the footnote on the first page of this article). These signals are indicative of six- and four-coordinate Al centres, respectively. In the case of ALPO (sample 1), the majority of the Al centres are in tetrahedral sites. The proportion of octahedral Al sites increases as more of the phosphonate or diphosphonate groups are incorporated, and finally they become dominant in samples 4 and 7 where a significant amount of hydroxyl groups, probably bonded to aluminium atoms, would be required to balance the charge. Moreover, the coordination of the aluminium atoms at the pore surface should be increased by water molecules.

Selected XRD patterns of UVM-9 samples are shown in Figure 2. All materials display XRD patterns with at least one strong peak at low 2θ values (associated with the [100] reflection if a hexagonal cell is assumed), which is typical of periodic mesoporous materials. The shift of the d_{100} peak at low 2θ values as the content of organophosphorus groups increases suggests that both phosphonates and diphosphonates should be effectively incorporated into the inorganic walls. The resolution from the background of this intense peak decreases with increasing functionalisation level. Such an evolution indicates that incorporation of phosphonate or diphosphonate groups implies a progressive lowering of order in the pore system from hexagonal partially ordered (sample 1) to clearly disordered materials (samples 4 and 7). TEM micrographs (Figure 3) fully correlate to

XRD observations. Whereas small domains with partially ordered hexagonal (H_d) mesopore arrays are observed in the ALPO (sample 1) and materials with low amounts of organophosphorus moieties, the solids having medium and high proportions of phosphonate or diphosphonate groups show disordered topologies. On the other hand, all UVM-9 samples show one well-defined step in their N_2 adsorption−desorption curves, characteristic of type IV isotherms (see Supporting Information). Although XRD and TEM data suggest that a progressive loss of order occurs as the amount of organophosphorus moieties increases, the relatively sharpness of these steps (unusual in nonsilica based materials) indicates a reasonable uniformity of the mesopores. A high surface area and pore volume are retained in all UVM-9 solids.

Conclusion

In short, periodic mesoporous aluminium phosphonates and diphosphonates (100 % of organophosphorus groups) have been synthesised for the first time through a generalised surfactant-assisted procedure. This method is applicable to the preparation of materials including other cations (different from Al) and/or phosphonic acids, which implies in turn new opportunities for applications of mesoporous phosphates. The control of the pore size and the wall properties such as hydrophobicity and the easy incorporation of organic functional groups attached to the P atoms confers on this new family of hybrid porous materials potential interest in areas such as chemical sensors, separations, catalysis and environmental sciences.

Experimental Section

UVM-9 Mesoporous Hybrid Materials: A typical synthesis leading to sample 7 (a pure Al-diphosphonate) is as follows: 1) $Al(OBus)_3$ (12.7 mL) was slowly added to liquid TEAH3 (26.2 mL) and heated at 150 °C to give aluminium atrane complexes (compounds containing TEAH3 ligands); 2) after cooling this solution to 110 °C, CTABr (4.68 g) were added; 3) the resulting solution was cooled to 60 °C and mixed with a solution of 1,2-ethylenediphosphonic acid (7.03 g in 120 ml water). After a few minutes a white powder precipitated out and was filtered off, washed with water and ethanol and air dried. Finally, the surfactant was extracted from the obtained powder with an acetic acid/ethanol solution (ca. 1 g of powder, 16 mL of acetic acid and 130 mL of ethanol; t = 24 h, at room temperature). The final porous material was separated by filtration, washed with ethanol and air dried.

All samples were characterised by CNH elemental analysis and electron probe microanalysis EPMA (Philips SEM-515), ^{13}C, ^{27}Al and ^{31}P MAS NMR (Varian Unity-300), XRD (Seifert 3000TT diffractometer using Cu-K_α radiation), TEM (JEOL JEM-1010 operating at 100 kV) and N_2 adsorption-desorption isotherms (ASAP2010).

Synthesis and Structure of 1-D Heterometallic Thiocyanato-Bridged $Cu^{II}Gd^{III}$ Polymers with Ferromagnetic Properties

Ghenadie Novitchi,[a] Jean-Pierre Costes,*[a] and Bruno Donnadieu[a]

Keywords: Heterometallic complexes / Copper / Lanthanides / Magnetic properties

Reaction of the tetracoordinate CuL_A and CuL_B complexes with $Gd(NCS)_3$ leads to two unique one-dimensional $\{Cu–Gd\}_n$ thiocyanato-bridged (I) and hydrogen-bonded (II) polymers, depending on the periphery of the L_A and L_B ligands, with ferromagnetic properties.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

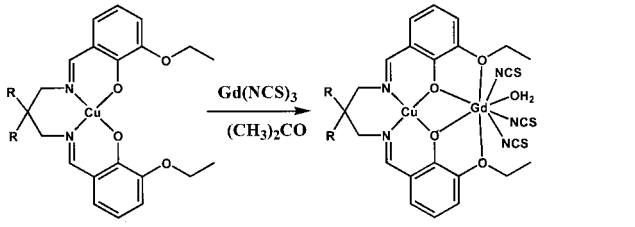
Introduction

The synthesis and the design of solid-state architectures with ferromagnetic ordering is one of the major challenges in magnetochemistry.[1–4] The controlled assembly of these structural units in the solid state is determined by a number of factors: (i) coordination bonding,[5] (ii) versatile hydrogen-bonding interaction[6] (iii) π-π-stacking[7] and (iv) electrostatic interactions.[8] Thiocyanates with orbitals oriented in various directions have been used to build up coordination networks for two different reasons. On the one hand, they can furnish directional conformation to structures, owing to linear coordination modes as well as π-π overlapping interactions;[9] on the other hand, they can provide different super-exchange pathways, transmitting magnetic interactions between paramagnetic metal centres, owing to the diversity of their bonding modes.[10]

We have previously shown that ferromagnetic interactions are predominant in Cu–Gd complexes.[11] The linking of these units through intermolecular ferromagnetic interactions could yield high-spin species. So far, only tetranuclear entities have been obtained.[12,13] In the present study, we report on the synthesis, crystal structure and magnetic properties of one heterometallic coordination polymer and one hydrogen-bonded polymer, which are based on the Cu^{II}-Gd^{III} core, on thiocyanate ligands and on water molecules.

Results and Discussion

The reaction of 3-ethoxysalicylaldehyde and propylenediamine or 2,2-dimethylpropylenediamine in methanol (2:1 molar ratio), followed by addition of $CuOAc_2{\cdot}H_2O$, yielded the "compartmental complex ligands" $CuL_A{\cdot}H_2O$ and $CuL_B{\cdot}H_2O$.[14] These complexes possess a convenient O_2-O_2 metal-binding site, made of two phenoxide and two ethoxy oxygen atoms, which are able to accommodate 4f ions. Heterometallic Cu^{II}-Gd^{III} complexes were synthesized by reaction of the "compartmental complex ligands" CuL_A and CuL_B with $Gd(NCS)_3$ in acetone. $Gd(NCS)_3$ was prepared by metathesis with equimolar, warm solutions of $Gd(NO_3)_3$ /$6H_2O$ and KNCS in acetone (see Scheme 1).



CuL_A R=H; CuL_B R=CH_3

$[L_ACuGd(NCS)_3H_2O]{\cdot}2(CH_3)_2CO$ (I)

$[L_BCuGd(NCS)_3H_2O(CH_3)_2CO]$ (II)

Scheme 1

The IR spectra of the two complexes are nearly identical. The C=N stretching vibrations are observed at 1603 and 1610 cm^{-1}. Very strong bands (2076, 2054 cm^{-1}) corresponding to coordinated thiocyanate anions are observed for **I** and **II**. The splitting indicates the different structural functions of the thiocyanate ligands.[15]

The structures of **I** and **II** were studied by X-ray diffraction methods at 180 K.[16] The structure of complex **I** is shown in Figure 1 (top). Cu^{II} is bound to two imino nitrogen and to two phenoxide oxygen atoms of the deprotonated L_A ligand. The Cu^{II} and Gd^{III} centres are bridged by two phenoxide oxygens, with a Cu–Gd distance of 3.460(1) Å. The copper-atom deviation from the least-squares N_2O_2 plane, formed by the four coordinating

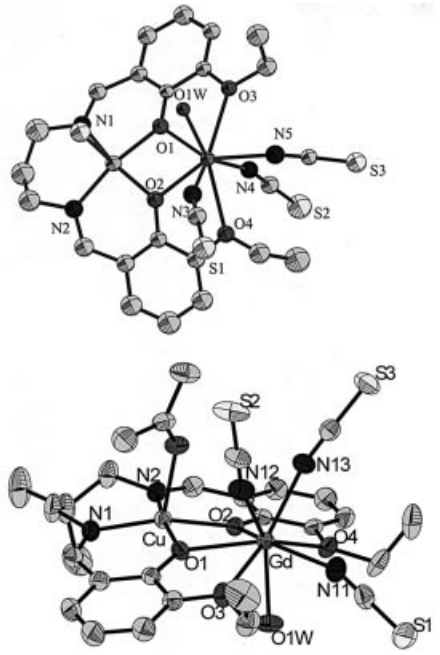

Figure 1. Views of the $\{LCuGd(NCS)_3H_2O\}$ units, **I** (top) and **II** (bottom); hydrogen atoms and solvent molecules are omitted for clarity

atoms, is −0.135(2) Å. The axial site is occupied by the sulfur atom of an NCS group, belonging to a neighbouring molecule (Cu−S = 2.744(2) Å]. The Gd^{III} centre is eight-coordinate, with three nitrogen atoms from the thiocyanate ligands, four oxygen atoms from the "compartmental complex ligand'' CuL_A, and one from a water molecule. The CuO_2Gd segment is not planar: the dihedral angle between the CuO1O2 and GdO1O2 planes is equal to 17.1(2)°. The molecules form zigzag chains through Cu(SCN)Gd′ bridges (see Figure 2). It is worth mentioning the π-π stacking interactions at 3.65(8), between two neighbouring chains.

The structure of **II** consists of $L_BCu^{II}Gd^{III}$ binuclear units (see Figure 1, bottom), in which the metal ions are doubly bridged by the phenoxide oxygen atoms. Acetone occupies the apical position in the copper-coordination sphere, with a Cu−O bond length of 2.293(2) Å. As in **I**, the copper(II) ion is situated in the inner N_2O_2 site of the Schiff-base ligand, L_B^{2-}. The Cu atom is displaced from this equatorial plane towards the apical position by 0.14(1) Å. The Cu−Gd distance is 3.454(1) Å and the dihedral angle between the GdO1O2 and CuO1O2 planes is 19.18(4)°. The Gd atom in **II** is again eight-coordinate ($N_3O_4O_w$). The supramolecular arrangement of the heteronuclear unit $\{L_BCuGd(NCS)_3H_2O\}$ is realised with hydrogen bonds that connect the coordinated water molecule to two sulfur atoms of thiocyanate ligands belonging to neighbouring molecules [$O1_W\cdots S2$ = 3.197(3); $O1_W\cdots S3$ = 3.292(3) Å (see Figure 3)].

The magnetic behaviour of **I** is shown in Figure 4 (top), as the thermal variation of the $\chi_M T$ product; χ_M is the molar susceptibility corrected for diamagnetism. At 300 K, $\chi_M T$ for I is equal to 8.4 $cm^3\ mol^{-1}\ K$, which corresponds to the value expected for two uncoupled metal ions. Lowering the temperature causes $\chi_M T$ to increase to 9.8 $cm^3\ mol^{-1}\ K$ at 7 K. This value compares well with that of 9.85 $cm^3\ mol^{-1}\ K$, expected for an $S = 4$ spin state, resulting from ferromagnetic coupling between Cu^{II} ($S = 1/2$) and Gd^{III} ($S = 7/2$) and assuming that $g_{Cu} = g_{Gd} = 2$.

A quantitative analysis for **I** was performed employing an expression derived from the spin-only Hamiltonian $H = -J_1 S_{Cu} S_{Gd}$. Taking into consideration the g values associated with the low-lying levels E(4) = 0 [$g_4 = (7g_{Gd} + g_{Cu})$/

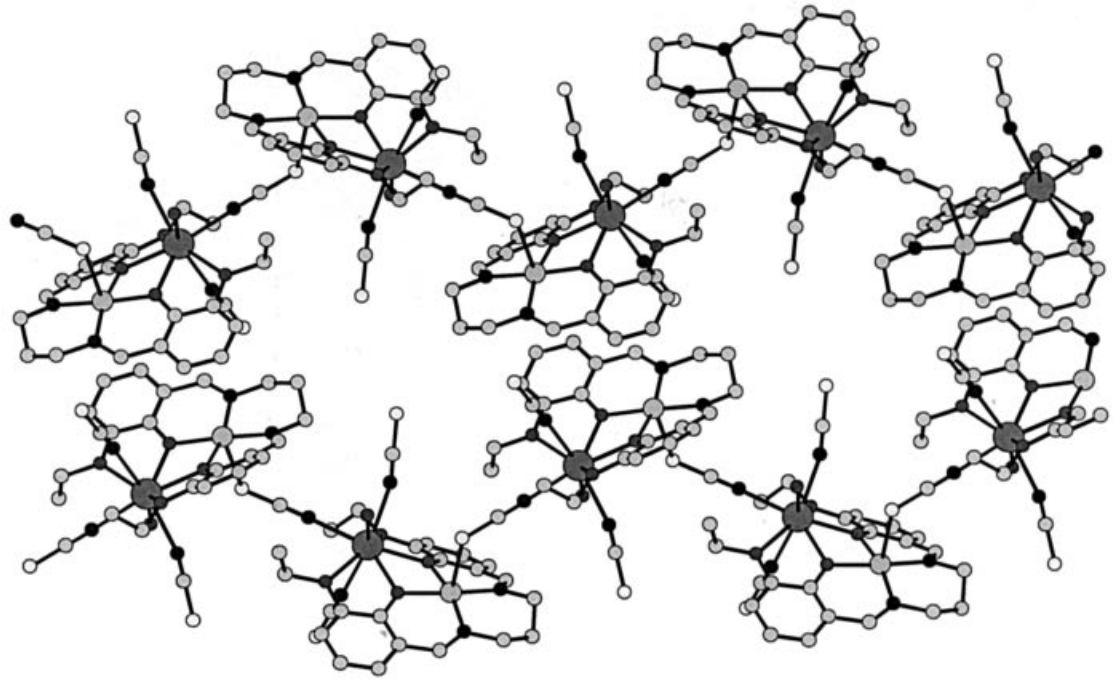

Figure 2. Stack of the polymeric **I** molecules; hydrogen atoms and solvent molecules are omitted for clarity

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

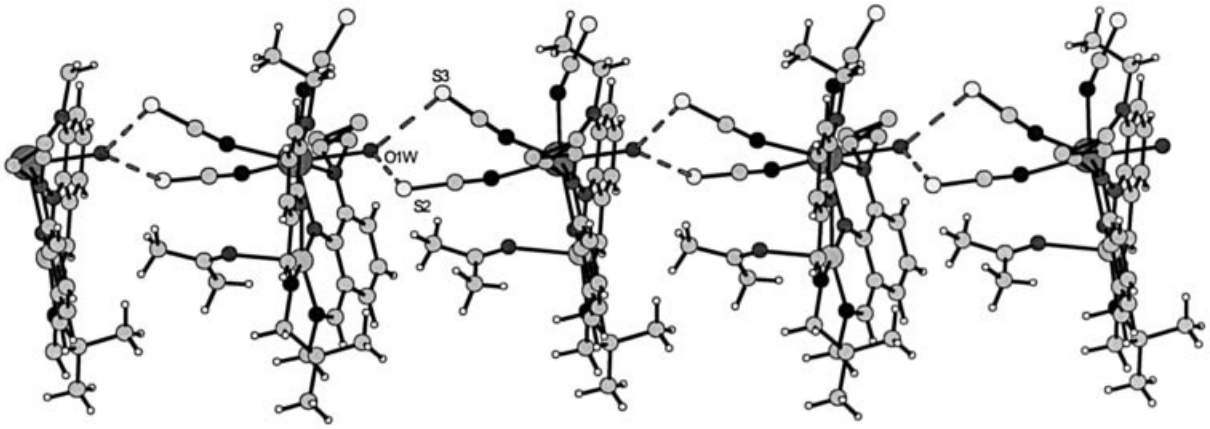

Figure 3. A portion of the hydrogen-bonded chain in **II**

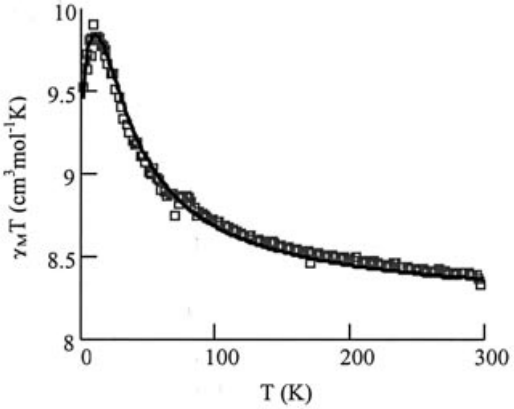

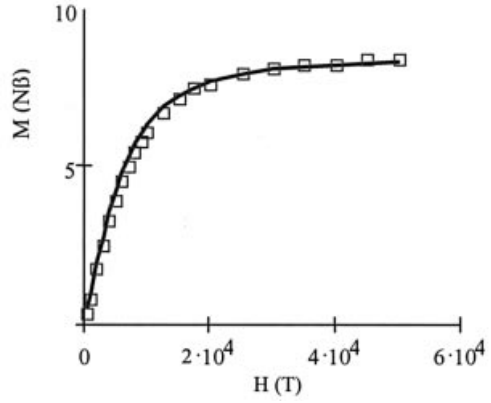

Figure 4. Magnetic behaviour of complex **I** between 2 and 300 K ($\chi_M T$ vs. T plot) and at 0.1 T (top), the solid line corresponds to the best fit; field dependence of the magnetization for compound **II** at 2 K (bottom), the solid line corresponds to the $S = 4$ ground state

8] and E(3) = $4J_1$ [$g_3 = (9g_{Gd} - g_{Cu})/8$],[17] the following expression [Equation (1)] is obtained:

$$\chi_d T = \frac{4N\beta^2 T}{\kappa(T-\theta)} \cdot \frac{15g_4^2 + 7g_3^2 \cdot \exp(-\frac{4J_1}{kT})}{9 + 7 \cdot \exp(-\frac{4J_1}{kT})} \quad (1)$$

Least-squares fitting of the experimental data led to the following set of parameters: $g_{Gd} = 1.99$, $g_{Cu} = 2.04$, $J_1 = 9.20\ cm^{-1}$, $\theta = -0.11$ for **I** and $g_{Gd} = 1.99$, $g_{Cu} = 2.02$, $J_1 = 5.5\ cm^{-1}$, $\theta = -0.14$ for **II**. The agreement factors R [$R = \Sigma(\chi T_{calc} - \chi T_{obs})^2/\Sigma(\chi T_{obs})^2$ are equal to 2×10^{-5} and 3×10^{-5}, respectively. From these values, it is clear that, from a magnetic point of view, these chain complexes behave as single dinuclear units.

For a better estimation of the magnetic interaction in the heterometallic Cu−Gd 1D chain, **I**, we adopted the model previously developed in the literature, in which the dimeric unit is assumed to act as an effective S_d classical-spin system.[18]

$$S_d = \frac{-1 + \sqrt{1 + 4\left(\chi_d T / 0{,}1251\bar{g}^2\right)}}{2} \quad (2)$$

The ladder chain can then be treated as a linkage of dimers and its contribution, χ_{chain}, to the total magnetic susceptibility, χ, according to Fisher's model[19] using the Drillon function,[20] is determined by Equation (3).

$$\chi_{chain} = \frac{Ng^2\beta^2 S_d(S_d+1)}{3k_B T} \cdot \frac{1+u}{1-u}$$
$$u = \coth\left[\frac{2J_2 S_d(S_d+1)}{k_B T}\right] - \frac{kT}{2J_2 S_d(S_d+1)} \quad (3)$$

where J_2 is the inter-dimer coupling constant. Least-squares fitting of the experimental data for **I** leads to a J_2 value of $-0.003\ cm^{-1}$. A similar result can be obtained for **II**. This very weak J_2 value confirms, as expected, that the dinuclear model can be retained to study the magnetic behaviour of these chain complexes. Indeed, the copper magnetic orbital is of the $d_{x^2-y^2}$ type while the interaction with

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the gadolinium ion occurs via the axially coordinated SCN ligand, in a region of very low spin density. The experimental values of magnetization for **I** and **II**, measured at 2.0 K, are correctly fitted by the Brillouin function for an $S = 4$ spin state, which confirms the ferromagnetic nature of the Cu−Gd interaction and the dinuclear character of these polymers (see Figure 4, bottom).

In conclusion, we have shown that heterobimetallic chains are obtained by using thiocyanate ligands. Depending on the ligand coordinating the Cu and Gd ions, the arrangement of the dinuclear units furnishes chains involving either Gd−Gd bridges through hydrogen bonding (**II**) or Cu−Gd bridges through NCS binding (**I**). These types of binding could be responsible for weak antiferromagnetic interactions in the present complexes, **I** and **II**. Nevertheless, from a supramolecular point of view, we have demonstrated that a change at the periphery of the ligand complex can drastically change the assembling mode of the heterodinuclear complexes.

Experimental Section

All starting materials and solvents were purchased from Aldrich and were used without further purification. Elemental analyses (C, H, N) were carried out by the Service de Microanalyse du Laboratoire de Chimie de Coordination, Toulouse. Magnetic susceptibility data were collected on powdered samples of a SQUID-based sample magnetometer on a Quantum Design model MPMS instrument. All data were corrected for diamagnetism of the ligands, estimated from Pascal's constants.[21]

$[L_ACuGd(NCS)_3H_2O]\cdot 2(CH_3)_2CO$ (I): $CuL_A\cdot H_2O$ (0.5 mmol), dissolved in acetone (50 mL), was added slowly to an acetone solution (20 mL) of $Gd(NCS)_3$ (0.5 mmol) under vigorous stirring. After partial evaporation of the solvent, blue-green crystals were formed. They were separated by filtration, washed with cold acetone and air dried. $C_{30}H_{38}CuGdN_5O_5S_3$ (897.62):calcd. C 40.14, H 4.27, N 7.80; found C 40.42, H 4.41, N 7.85.

$[L_BCuGd(NCS)_3H_2O(CH_3)_2CO]$ (II): prepared following a similar procedure. $C_{29}H_{36}CuGdN_5O_6S_3$ (867.60): calcd. C 40.15, H 4.18, N 8.07; found C 40.95, H 4.23, N 8.11.

$[Cu^{I}(im)]_{\infty}$: Is this Air-Stable Copper(I) Imidazolate ($8^2$10)-Net Polymer the Species Responsible for the Corrosion-Inhibiting Properties of Imidazole with Copper Metal?

Yun-Qi Tian,[a,b,c] Hai-Jun Xu,[a] Lin-Hong Weng,[b] Zhen-Xia Chen,[b] Dong-Yuan Zhao,*[b] and Xiao-Zeng You*[a]

Keywords: Coordination polymers / Copper / Heterocycles / N ligands / Solvothermal synthesis

An air-stable two-dimensional (2D) copper(I) imidazolate polymer, $[Cu^{I}(im)]_{\infty}$ (**1**), with a d^{10}-d^{10} interaction, was synthesized solvothermally and structurally characterized by X-ray crystallography: a = 8.069(2), b = 8.068(2), c = 13.425(3) Å, β = 99.414(3)°, monoclinic, $C2/c$. This is the first example of an air-stable copper(I) imidazolate polymer that may play a significant role in the corrosion-inhibition mechanism of imidazole (or its derivatives) with copper metal.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Imidazolate is an important ligand since it participates in the construction of the active sites of various bioenzymes, such as superoxide dismutase (SOD)[1] and cytochrome c.[2] As an exobidentate ligand, imidazolate can form metal coordination polymers,[3,4] a good example being the cobalt(II) imidazolate polymer,[4] which is a potential metal-organic porous material since its extended polymorphic framework demonstrates not only the necessary relatively high thermal stability but also a zeolitic porous structure. Moreover, according to recent publications,[5] imidazole and its derivatives are of interest as corrosion inhibitors for copper metal and its alloys. Despite extensive studies on the issue, until now it is still questionable which mechanism is adequate to explain the inhibition of copper corrosion by imidazole, in particular what is the substance formed on the surface of the copper metal. It is generally thought that a Cu^{II}-based imidazolate polymer may form a strong anti-corrosion layer[6] since copper(II) imidazolate polymers are known to afford five different polymorphs that show different spectroscopic and structural properties.[3a] However, there are also researchers who regard a Cu^{I}-based imidazolate polymer (or monomer) as the anti-corrosion substance[7] even though an air-stable copper(I) imidazolate polymer was, until now, unknown [Masciocchi et al. have reported a copper(I) imidazolate polymer whose structure, and even its cell parameters, are still not known due to the poor X-ray powder diffraction pattern of the easily oxidizable sample[3b]]. Here we describe an air-stable 2D copper(I) imidazolate polymer, $[Cu(im)]_{\infty}$ (**1**), whose structure should be different from Masciocchi's species since its simulated XRPD pattern from a single crystal (Figure S3) is very different from the XRPD pattern measured by Masciocchi et al.[8]

Results and Discussion

The reaction of $Cu(CH_3COO)_2{\cdot}4H_2O$ (1.0 g, 5 mmol) with imidazole (0.68 g, 10 mmol) in 3-methyl-1-butanol (MB; 30 mL) under solvothermal conditions at 140 °C gave golden transparent single crystals that were suitable for X-ray diffraction. The elemental analysis reveals a copper(I) compound formulated as $C_3H_3N_2Cu$ {$[Cu(im)]_{\infty}$, **1**}. Although the yield of the substance is very low, its synthesis is reproducible. An EPR measurement on a sample of the compound exposed to air for almost half a year demonstrates that the substance remains unchanged. The formation of a copper(I) compound from a copper(II) precursor may be due to a redox reaction between the precursor and the reductive organic solvent under the solvothermal conditions employed. In order to compare Masciocchi's species with our air-stable compound spectroscopically, it was also prepared in our laboratory. However, we could not charac-

terize it spectroscopically since the white polymer rapidly turned blue after being formed in acetonitrile, especially upon removal of the solvent.

X-ray crystallography showed that the copper(I) ions in the crystal of **1** are bridged by imidazolates in a *trans* manner[3b] (Cu−N: 1.867 Å) forming infinite 1D chains. The parallel chains run along the [110] direction and intersect with those running along the [1−10] direction in a Cu−Cu (d^{10}-d^{10}) interaction, forming the 2D sheet of a typical ($8^2$10) net (Figures 1 and 2).[9] Within the imidazolate-bridged chains, the distance between adjacent Cu···Cu centers is 5.75 Å, while between the intersected chains the nearest Cu−Cu distance is 2.783 Å, slightly shorter than two times 1.40 Å, which is the van der Waals radius of copper, and 0.23 Å longer than the Cu−Cu distance in Cu metal (2.56 Å). Within the sheet, if the imidazolato ring planes in the chains running along [110] vary in +22.3° and 157.7° dihedral angles alternately with the *ab* plane, those imidazolato rings in the chains along [1−10] should vary in −22.3° and −157.7° dihedral angles alternately with the *ab* plane. In other words, the dihedral angles between adjacent imidazolato ring planes in all the chains are ±44.6°, and imidazolato rings with the same orientation are parallel to each other between the parallel chains.

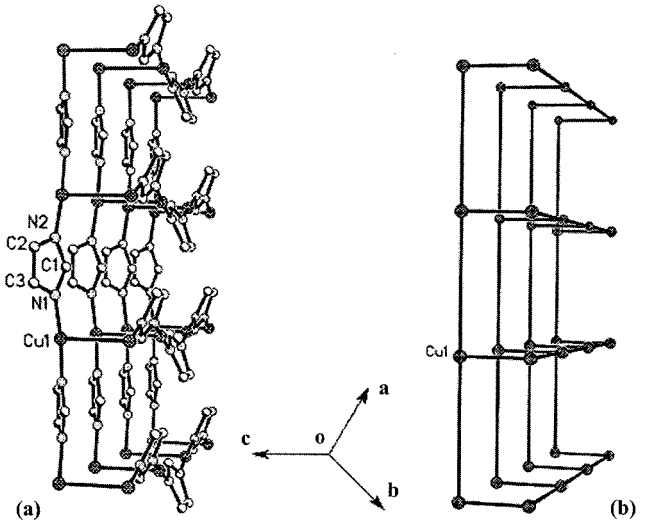

Figure 1. Cu−Cu (d^{10}-d^{10}) interaction forming a 2D sheet: (a) ball-and-stick diagram of $[Cu(im)]_\infty$ (**1**) (hydrogen atoms are omitted for clarity); (b) ($8^2$10) net of **1**, the spheres represent Cu atoms and the sticks represent imidazolates

In the crystal, these ($8^2$10) sheets are parallel to the *ab* plane and separated by 1/2*c* along the *c* axis. However, the imidazolato ring planes are not always parallel to each other between the parallel intersheet chains. Therefore, the imidazolato rings in the asymmetric unit of the crystal are statistically disordered, with dihedral angles of +22.3° and +157.7° (or −22.3° and −157.7°) relative to the *ab* plane (Figure 3).This phenomenon is not due to molecular thermal vibration. The layer structure depicted in Figures 1 and 2 is to be expected bearing in mind that copper(I) usually has a linear coordination geometry when it is coordinated

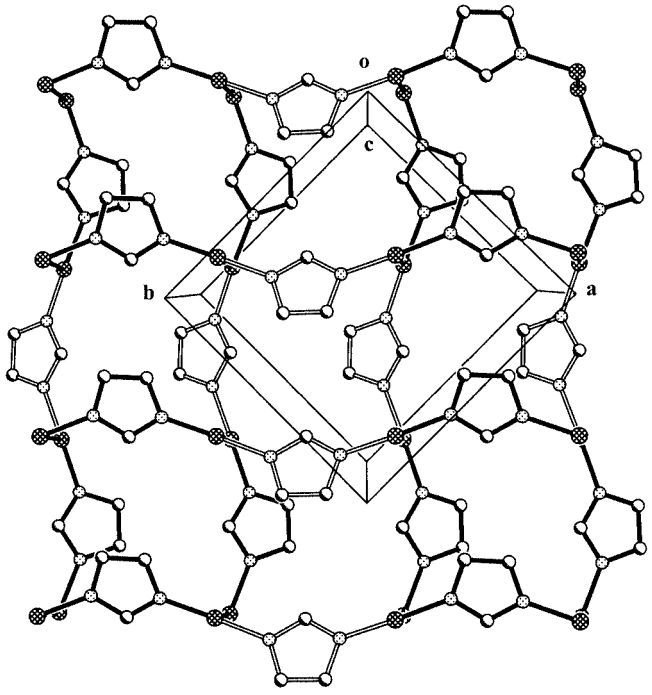

Figure 2. View of $[Cu(im)]_\infty$ (**1**) along the [001] direction; the imidazolate rings with solid or open bonds are those in the asymmetric unit

to deprotonated imidazole molecules, as is also observed in $[CoCu_2(im)_4]_\infty$,[10] and that molecules in parallel will suffer from the smallest degree of steric interaction (Figure 3).

It has been reported that the geometrical constraints of some ligands can produce Cu^I clusters and oligomers with a d^{10}-d^{10} interaction[11] that have an even shorter Cu−Cu distance than the Cu−Cu separation in Cu metal. Nevertheless, extended Hückel MO calculations have shown that the Cu−Cu interactions in these compounds are only weakly attractive.[12] Since imidazolate possesses none of the above-mentioned geometrical constraints, the short Cu−Cu distance in **1** is due only to the weakly attractive Cu−Cu interaction. Therefore, the Cu−Cu d^{10}−d^{10} interaction should be the same as those in the Cu^I clusters or oligomers.

Coordination polymers resulting from d^{10}-d^{10} interactions in Au^I [13] and Ag^I [3b,14] complexes with geometrically unconstrained ligands have already been reported. Of them, polymeric silver(I) imidazolate has a 3D structure constructed from one-dimensional $[Ag(im)]_\infty$ chains in a *cis-trans-cis-trans* sequence through these d^{10}-d^{10} interactions.[3b] However, the copper(I) imidazolate polymer reported here is only a 2D structure due to the relatively large dihedral angles between adjacent imidazolato rings in the chains {±44.6° in $[Cu(im)]_\infty$ and ±8° in $[Ag(im)]_\infty$} that prevent the copper(I) ions between the sheets from bonding to each other to form a 3D structure. Nevertheless, this is the first reported copper(I) coordination polymer resulting from a d^{10}-d^{10} interaction, and it may give a clue as to why imidazole and its N-substituted derivatives are good corrosion inhibitors for copper metal.[6c] We propose that the

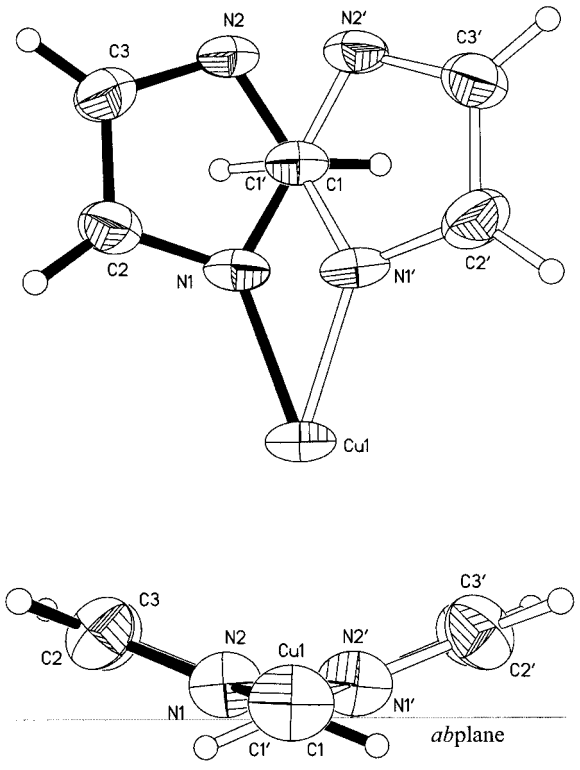

Figure 3. ORTEP drawing of the asymmetric unit of **1** showing the position disorder of the imidazolate rings; thermal ellipsoids are at the 30% probability level; top: view of the molecule along [001]; bottom: view of the molecule along [1−10]; the disordered imidazolate rings each have 30% occupancy

copper(I) imidazolate polymer (or monomer) may form an anti-corrosion layer on the copper metal surface and that the stability of this layer is enhanced by a Cu−Cu (d^{10}-d^{10}) interaction between the copper(I) polymer (or monomer) and the copper surface. Paradies et al. have reported a Cu−Cu distance of 2.85 Å in their EXAFS studies[15] on colloidal copper with adsorbed imidazole. However, although they were surprised by the result they did not give any reasonable explanation. Therefore, the air-stable copper(I) polymer with Cu−Cu bonds, in combination with the EXAFS results of Paradies et al., is good evidence that a copper(I) imidazolate polymer (or monomer) produces the anti-corrosive effect with copper metal[15] (Scheme 1), since Cu−Cu (d^{10}-d^{10}) interactions cannot be formed in a Cu^{II}-based imidazolate polymer. We suppose that if the inhibition were actually based on a Cu^{II}-related polymer layer, the hydrophobic interactions between the polymer (or monomer) and the copper surface should play a key role. However, such a copper(II) imidazolate polymer should not be formed under acidic conditions. Copper(II) *N*-substituted imidazolate monomers also cannot form the anti-corrosion layer since such monomers are water-soluble under acidic conditions. In fact, imidazole inhibits copper corrosion even in 1 M HNO_3 [5] and *N*-substituted imidazoles are even better inhibitors than imidazole itself in acidic solution.[6c] Therefore, it is reasonable for us to propose the copper(I) imidazolate as the anti-corrosion substance. However, the role of the Cu−Cu interactions must be stressed as they not only prevent the Cu^{I} complex from being oxidized to Cu^{II}, but they also bind the Cu^{I} complex polymer (or monomer) tightly to the copper metal surface. Without these Cu−Cu interactions a copper(I) imidazolate polymer may even be air-sensitive and therefore not able to provide the anti-corrosion effect. We propose that Masciocchi's white species may be a copper(I) imidazolate polymer without Cu−Cu interactions.

Conclusion

An air-stable copper(I) imidazolate polymer containing ($8^2$10) nets due to Cu−Cu (d^{10}-d^{10}) interactions can be synthesized under solvothermal conditions. This is the first structurally characterized copper(I) imidazolate polymer and is the only structural example supporting the proposal that a copper(I) imidazolate polymer (or monomer) produces the anti-corrosive effect of imidazole with copper metal.

Experimental Section

General Remarks: Imidazole, copper(II) acetate monohydrate and 3-methyl-1-butanol were purchased from commercial sources and used without further purification. Elemental analyses for C, H and N were performed with a Perkin−Elmer 240 analyzer. FT-IR spectra were measured from KBr pellets.

$[Cu^{I}(Im)]_{\infty}$ (1): $Cu(OAc)_2 \cdot H_2O$ (0.50 g, 5 mmol) and imidazole (0.68 g, 10 mmol) were added to 30 mL of 3-methyl-1-butanol. After stirring at room temperature for 12 h, this heterogeneous mixture was transferred into a Teflon-lined autoclave (34 mL). The autoclave was then sealed and heated at 140 °C for 24 h. After cooling to room temperature, golden crystals of **1** mixed with a large amount of amorphous substance (the XRPD pattern is shown in Figure S3) were collected, washed three times with 15 mL of ethanol and dried in vacuo. About 0.05 g of **1** was separated by

Funnel Complexes with Co^{II} and Ni^{II}: New Probes into the Biomimetic Coordination Ability of the Calix[6]arene-Based Tris(imidazole) System

Olivier Sénèque,[a] Morgane Campion,[b] Michel Giorgi,[c] Yves Le Mest,[b] and Olivia Reinaud*[a]

Keywords: Bioinorganic chemistry / Calixarenes / Cobalt / N ligands / Nickel

The coordination properties of the calix[6]arene-based tris(imidazole) ligand $X_6Me_3Imme_3$ were further explored with Co^{II} and Ni^{II}. This imidazole system stabilizes tetrahedral mononuclear Co^{II} complexes with an exchangeable fourth exogenous ligand (water, alcohol, amide) located at the heart of the hydrophobic calixarene cavity. With a weak donor ligand such as a nitrile, both four-coordinate tetrahedral and five-coordinate trigonal bipyramidal complexes were obtained. The latter contains a second nitrile molecule *trans* to the included guest nitrile. These complexes were characterized in solution as well as in the solid state. The Ni^{II} complexes are square-based pyramidal five-coordinate edifices with a guest nitrile inside the cavity and a water molecule outside. A comparison with previously described Zn^{II} and Cu^{II} complexes emphasizes the flexibility of this ligand. A comparison with carbonic anhydrase, a mononuclear zinc enzyme with a tris(histidine) coordination core, shows that $X_6Me_3Imme_3$ displays many structural features of this enzyme except for the *cis* coordination of the exogenous ligands.

Introduction

Coordination of metal ions by nitrogen donors is ubiquitous in metalloenzyme active sites. This has been a tremendously rich source of inspiration for coordination chemists, and over the last 25 years or so the syntheses of countless poly-aza ligands have been developed and their coordination chemistry explored. The tris(histidine) motif, frequently encountered in the case of zinc and copper enzymes,[1,2] has guided the architecture of the tri-aza ligands. Among the most famous artificial tripodal systems are the tris(pyrazolyl)borates,[3] also called scorpionate ligands, and triazacyclononanes.[4,5] However, the use of tris(imidazole) ligands, although closer to the tris(histidine) core, is somewhat rare in the modeling of active sites.[6−8]

In recent years we have described a novel supramolecular system based on a calix[6]arene bearing three nitrogen arms. Upon coordination to Cu^{I},[9,10] Cu^{II} [11,12] or Zn^{II} [13,14] the calixarene structure becomes constrained in a cone conformation accessible to a guest molecule. The most biomimetic ligand of the series, a tris(imidazole)-based system, provided the first structurally characterized model for the aqua dicationic tetrahedral Zn^{II} center found in hydrolytic enzymes.[15] The Cu^{I} complexes were able to bind CO reversibly, just as Cu^{I} enzymes do.[10]

A usual probe for the coordinating ability and flexibility of enzymatic active sites is the substitution of the native metal by other metals displaying different coordination requirements. As we were interested in further exploring the new perspectives offered by our supramolecular system and evaluating its flexibility as well as the geometrical constraints that it is able to provide on the metal ion coordination core, we decided to study its ability to bind to other first-row elements. In this paper, we describe the synthesis, characterization and host-guest behavior of Co^{II} and Ni^{II} complexes obtained with the tris(imidazole)-based system $X_6Me_3Imme_3$. A comparison with Zn^{II} and Cu^{II} complexes as well as with carbonic anhydrase, a zinc enzyme prototype,[16,17] highlights this ligand's biomimetic behavior.

Results

Synthesis and Characterization of a Tetrahedral Co^{II}-Aqua Complex

The calix[6]arene-based tris(imidazole) ligand $X_6Me_3Imme_3$ [13] was reacted with $[Co^{II}(H_2O)_6(ClO_4)_2]$ in THF.

Upon addition of 1.1 equivalents of $X_6Me_3Imme_3$ to the pale pink cobalt solution, the color immediately changed to an intense purple. Precipitation with Et_2O led to a purple solid. Its IR spectrum attested to the presence of the perchlorate counterions, and its elemental analysis was in good agreement with a 1:1 ligand/Co ratio. The magnetic moment at 300 K was assessed by the Evans method in $CDCl_3$.[18,19] The measured value of 4.6(2) μ_B,[20] although exceeding the spin-only value of 3.87 μ_B for $S = 3/2$, falls in the typical range for high-spin cobalt(II) complexes.[21] The UV/Vis spectrum in CH_2Cl_2 exhibits three bands between 450 and 650 nm with extinction coefficients above 300 $M^{-1}\cdot cm^{-1}$ characteristic of the $^4A_2 \rightarrow {}^4T_1(P)$ d-d transitions of a tetrahedral (Td) high-spin cobalt(II) ion.[21,22]

In $CDCl_3$, the ^1H NMR spectrum of the complex (Figure 1A) displays well-defined isotropically shifted resonances in the $\delta = 0-90$ ppm spectral window, with the expected number of signals for a C_{3v} symmetrical species, thereby suggesting the coordination of all three imidazoles to Co^{II}. The assignment of the resonances was performed by integration of the peaks and comparison with similar complexes obtained with ligands bearing ethyl substituents instead of methyl on the phenyoxyl or imidazolyl rings.[10] Two sets of signals could be distinguished: the imidazole protons (OCH_2, NCH_3 and both ImH) are shifted downfield in the $\delta = 15-80$ ppm region, whereas the protons of the calixarene skeleton (ArH, *t*Bu, $ArCH_2Ar$, OMe) appear in the diamagnetic region with chemical shifts quite similar to those of the parent diamagnetic zinc(II) complex (Figure 1B).

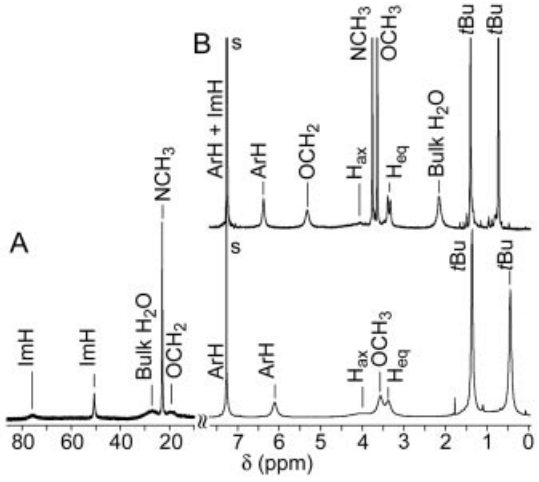

Figure 1. ^1H NMR spectra (250 MHz, 300 K, $CDCl_3$) of (A) $[Co(X_6Me_3Imme_3)(H_2O)](ClO_4)_2$ and (B) $[Zn(X_6Me_3Imme_3)(H_2O)\cdot(H_2O)](ClO_4)_2$; the residual solvent peak is labeled "s"

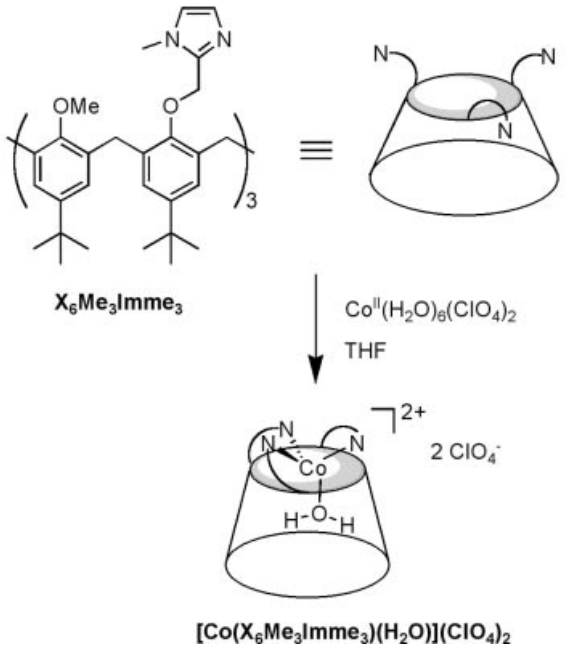
The very small shifts observed for the calixarene protons are highly suggestive of a tetrahedral geometry, for which the magnetic susceptibility is isotropic and the Fermi-contact interaction, which propagates along covalent bonds, is the only contribution to the hyperfine shift (no dipolar contribution).[19] Indeed, in this system, the calixarene protons are separated from the cobalt ion by at least eight bonds.

Since no other ligand beside water is available in a non-coordinating solvent such as THF, diethyl ether or chloroform, in agreement with all the above described spectroscopic data, we conclude that the isolated species is a tetrahedral cobalt(II) complex in which a water molecule is the fourth ligand, as was found in the parent zinc complex (Scheme 1).[23]



Scheme 1. Formation of the tetrahedral Co^{II}-aqua complex

Host/Guest Chemistry: A Solid-State Study

X-ray quality crystals of the complex $[Co(X_6Me_3Imme_3)(CH_3COCH_3)](ClO_4)_2$ were obtained by slow diffusion of Et_2O into a solution of the aqua complex in acetone. Three other complexes $[Co(X_6Me_3Imme_3)(L)](ClO_4)_2$ (L = DMF, EtOH and EtCN) were crystallized using the same procedure, but with the addition of about 10 equivalents of L to the acetone solution.

All four complexes display a nearly tetrahedral cobalt(II) ion coordinated by the three imidazole rings of the calixarene ligand, which stands in a flattened-cone conformation (Figure 2, Table 1). The fourth ligand, L, sits inside the calixarene cavity. Two perchlorate ions attest to the dicationic nature of the complexes. The average $Co-N_{Im}$ distances are short and very similar in all complexes (2.003, 2.003, 2.004 and 2.000 Å for L = Me_2CO, DMF, EtOH and EtCN, respectively). The bond between the metal ion and the coordinating atom of the guest ligand is also quite short, thereby reflecting the high Lewis acidity of the metal center in such a tetrahedral dicationic environment. Supramolecular interactions are observed between the calixarene host cavity and the guest ligand L. The structure of the acetone complex displays several CH···π interactions: each methyl group of the guest selectively faces an anisole ring at a short perpen-

	Co1−N7	1.956(4)				

dicular distance, C···Ar, of 3.23 and 3.30 Å. With L = DMF, the guest methyl groups also appear selectively oriented towards an aromatic ring [d(C···Ar) = 3.37 and 3.45 Å] and an additional CH···π contact is observed between the O=C−H group and an anisole ring (3.90 Å). For L = EtOH and EtCN, CH···π interactions with both CH_2 and CH_3 groups are observed. In the case of the EtOH adduct, a hydrogen bond between the coordinated hydroxy group and one oxygen linked to an imidazole arm [*d*(O,O) = 2.78 Å] further stabilizes the edifice. Finally, it is noteworthy that the average distances between two *t*Bu groups in the "out" position (those of the aromatic rings bearing imidazole) are almost identical in all four complexes (12.89 Å, 12.67 Å, 12.70 Å and 12.81 Å for L = CH_3COCH_3, DMF, EtOH and EtCN, respectively) whereas those between two *t*Bu groups in the "in" position differ significantly (6.39 Å, 7.07 Å, 6.30 Å and 6.83 Å, respectively). This shows that coordination to Co^{II} ion freezes the positions of the *p*-*t*Bu-ArO-CH_2Im moieties, the equality of the *t*Bu−*t*Bu distances reflecting the equality of the $Co-N_{Im}$ bond lengths and geometry in the four complexes. In contrast, the positions of *p*-*t*Bu-ArOMe are adjusted by the supramolecular system

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in order to optimize the size of the cavity and the stabilizing interactions with the guests.

In addition to these four tetrahedral complexes, another complex was crystallized from pure MeCN by Et_2O vapor diffusion. The structure (Figure 3, Table 2) shows a cobalt ion surrounded by five ligands in a distorted trigonal bipyramidal geometry (TBP, $\tau = 0.69$).[24] The three imidazole moieties of $X_6Me_3Imme_3$ sit in the equatorial positions and the two axial positions are occupied by MeCN molecules, one of them being buried inside the calixarene cavity and the other lying outside. The average $Co-N_{Im}$ and Co−N7 (inner nitrile) bond lengths are longer (2.053 and 2.078 Å, respectively) in this complex than in the tetrahedral EtCN adduct. The Co−N8 distance (2.171 Å) reveals that the outer nitrile is bound more weakly to Co than the inner one.

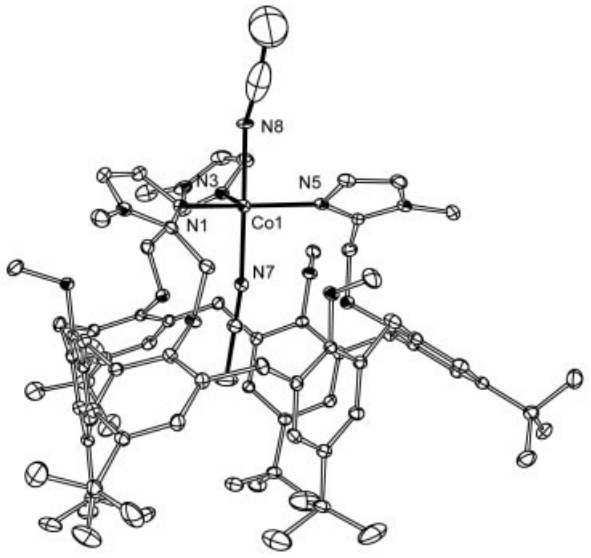

Figure 3. X-ray structure of $[Co(X_6Me_3Imme_3)(MeCN)_2](ClO_4)_2$ showing ellipsoids at 20% probability; hydrogen atoms, perchlorate counterions and solvent of crystallization are omitted for clarity

Table 2. Selected bond lengths (Å) and angles (°) for $[Co(X_6Me_3Imme_3)(MeCN)_2](ClO_4)_2$

Bond length (Å)			
Co1−N1	2.046(4)	Co1−N7	2.078(4)
Co1−N3	2.053(4)	Co1−N8	2.171(4)
Co1−N5	2.061(4)		
Angles (°)			
N1−Co1−N3	110.00(15)	N5−Co1−N7	93.76(14)
N1−Co1−N5	133.15(15)	N1−Co1−N8	84.95(15)
N3−Co1−N5	115.88(15)	N3−Co1−N8	89.93(16)
N1−Co1−N7	91.10(15)	N5−Co1−N8	86.13(15)
N3−Co1−N7	95.12(15)	N7−Co1−N8	174.43(17)

Thus, these structures confirm that the $X_6Me_3Imme_3$ system can stabilize dicationic tetrahedral cobalt(II) complexes with a guest in the cavity. The inner aqua ligand that is present in the complex isolated during the synthesis in a non-coordinating solvent is easily displaced by a coordinating molecule. In the specific case of MeCN, coordination of a second nitrile ligand was evidenced, yielding a five-coordinate species. This was further studied in solution.

Host/Guest Chemistry: UV/Vis and ^{1}H NMR Spectroscopic Studies in Solution

In solution the host/guest behavior of the calix[6]arene-Co^{II} system towards alcohols, nitriles and amides was monitored by UV/Vis and ^{1}H NMR spectroscopy by adding aliquots of these coordinating co-solvents, L, to a CH_2Cl_2 or $CDCl_3$ solution of $[Co(X_6Me_3Imme_3)(H_2O)](ClO_4)_2$. With L = EtOH, the extinction coefficients of the three $^4A_2 \rightarrow {}^4T_1(P)$ d-d transitions increased until a plateau was reached with ε values of 280, 400 and 450 $M^{-1}\cdot cm^{-1}$ at 524, 566 and 593 nm, respectively. An isosbestic point was observed at 615 nm, demonstrating the presence of only two species in solution. When increasing amounts of EtOH were introduced into an NMR tube containing a solution of $[Co(X_6Me_3Imme_3)(H_2O)](ClO_4)_2$ in $CDCl_3$ (approx. 10^{-2} M), resonances characteristic of a new complex progressively appeared while those of the aqua complex diminished. The profile of the new species resembled that of the tetrahedral aqua complex and remained unchanged whatever the EtOH concentration, with constant shifts for all signals. Here again, the signals of the calixarene structure were weakly hyperfine-shifted compared to the zinc analogue. Although the bound EtOH resonances were not located, these UV/Vis and NMR titrations are in agreement with the progressive exchange of the aqua ligand by EtOH until complete formation of the tetrahedral $[Co(X_6Me_3Imme_3)(EtOH)]^{2+}$ complex. A similar behavior was observed with other alcohols (*n*PrOH and *i*PrOH).

With MeCN as a co-solvent, no isosbestic point was observed during the UV/Vis titration, suggesting that more than two species are present. Two steps were observed in the evolution of the electronic spectra. Upon addition of MeCN, the apparent extinction coefficients of three $^4A_2 \rightarrow {}^4T_1(P)$ bands first increased to over 500 $M^{-1}\cdot cm^{-1}$, then subsequently decreased, down to a plateau with lower ε values (170, 260 and 230 $M^{-1}\cdot cm^{-1}$ at 530, 566 and 595 nm, respectively). This can be interpreted as the successive formation of a four-coordinate complex, namely $[Co(X_6Me_3Imme_3)(MeCN)]^{2+}$, as shown by the increase of ε values, and then a five-coordinate one, $[Co(X_6Me_3Imme_3)(MeCN)_2]^{2+}$ becoming predominant at a high $MeCN/CH_2Cl_2$ ratio, in agreement with the decrease of ε, with final values lower than 300 $M^{-1}\cdot cm^{-1}$. ^{1}H NMR spectroscopy confirmed this observation (Figure 4). When aliquots of MeCN were added to a $CDCl_3$ solution of the aqua complex (approx. 10^{-2} M), additional sharp resonances developed, attesting to the coordination of MeCN to Co^{II}. At substoichiometric MeCN concentration, the CH_3 resonance of a bound MeCN was detected at $\delta \approx 40$ ppm; the new OCH_2, NCH_3 and ImH signals were close to those of the aqua complex. Upon further addition of MeCN, the

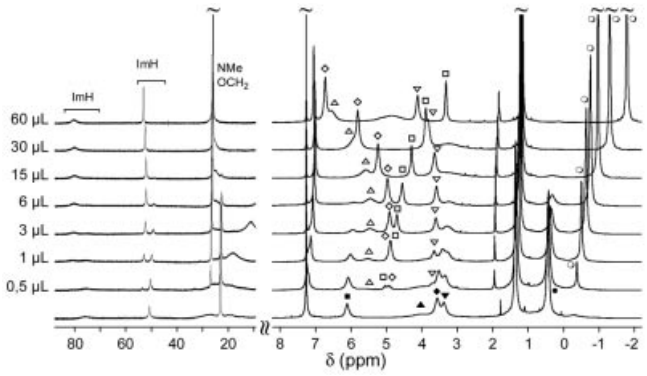

Figure 4. Evolution of ^{1}H NMR spectrum (250 MHz, 300 K) after successive additions of aliquots of acetonitrile (CH_3CN for the first spectrum, CD_3CN for the others) to a $CDCl_3$ solution of complex $[Co(X_6Me_3Imme_3)(H_2O)](ClO_4)_2$ (initial concentration: 12 mM); protons of the cobalt-aqua complex are indicated by filled symbols (ArH^1: ν, $ArCH_{ax}H_{eq}Ar$: ▲, $ArCH_{ax}H_{eq}Ar$: ▼, OCH_3: ◆, tBu^1: •) and those of the new species with open symbols (ArH^1: □, $ArCH_{ax}H_{eq}Ar$: Δ, $ArCH_{ax}H_{eq}Ar$: ▽, OCH_3: ★, tBu^1: ○); ArH^1 and tBu^1 belong to the anisole rings; the small shift of the aqua complex resonances during the titration is ascribed to a small change in the magnetic susceptibility of the solvent (spectra were calibrated with respect to residual $CHCl_3$) as they all shift the same way

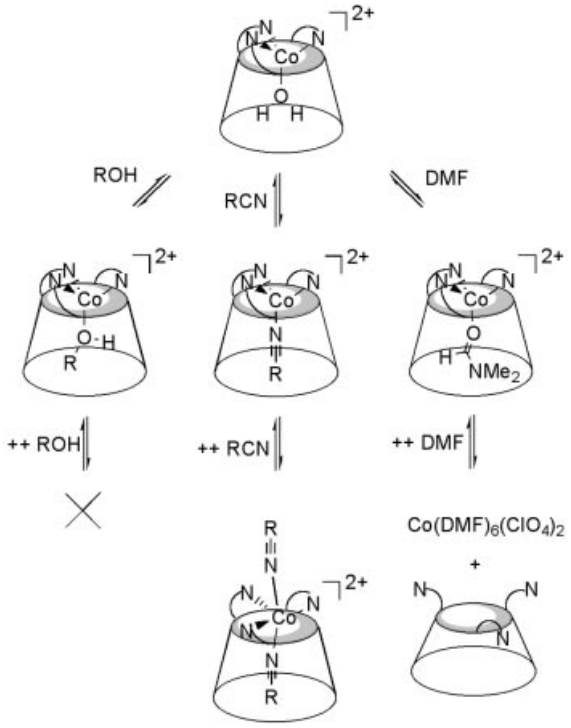

Scheme 2. Reaction of complex $[Co(X_6Me_3Imme_3)(H_2O)]^{2+}$ with small coordinating organic molecules

guest resonance moved upfield, whereas some protons belonging to the calixarene structure shifted upfield (one *t*Bu and one ArH) and others shifted downfield (OMe and $ArCH_{ax}H_{eq}Ar$). In addition, the larger the MeCN concentration, the larger the shifts, which stands in strong contrast to the experiment with EtOH described above. In accordance with the UV/Vis titration, this attests to the formation of two different species that are in fast equilibrium on the NMR timescale. The up- and downfield shifts observed for the calix structure are indicative of a dipolar contribution to their hyperfine shifts, and, thus, of an anisotropy in the magnetic susceptibility consistent with a five-coordinate complex. All these observations account for an equilibrium between a four-coordinate tetrahedral nitrile complex, predominant at low MeCN concentration, and a five-coordinate bis(nitrile) complex, predominant at high MeCN concentration (Scheme 2).

In order to evaluate the geometry of the five-coordinate species, the experimental hyperfine chemical shifts measured in CD_3CN, δ^{HF}_{exp} (see Table 3), were compared to the theoretical value δ^{HF}_{calc} calculated from the X-ray structure of $[Co(X_6Me_3Imme_3)(MeCN)_2]^{2+}$. A TBP complex is known to display an axial anisotropy in the magnetic susceptibility ($\chi_z \neq \chi_{xy}$, z being the nitrile−Co−nitrile axis) with a dipolar shift given by $\delta^{dip} = A \times [3 \times \cos^2(\theta) - 1]/r^3_{Co-H}$ (r_{Co-H} is the distance between the cobalt ion and a proton and θ the angle between Co−H and the anisotropy

Table 3. Hyperfine chemical shifts δ^{HF}_{calc} calculated from the X-ray structure of complex $[Co(X_6Me_3Imme_3)(MeCN)_2](ClO_4)_2$ and experimental values δ^{HF}_{exp}

Protons	r_{Co-H} (Å)	θ (°)[a]	δ^{HF}_{calc} (ppm)[b]	δ_{Zn} (ppm)[c]	δ_{Co} (ppm)[d]	δ^{HF}_{exp} (ppm)[e]

axis). For *t*Bu, $ArCH_{ax}H_{eq}Ar$, OCH_3 and ArH, the Fermi-contact contribution is zero and thus $\delta^{HF}_{calc} = \delta^{dip}$. The plot of $(3 \times \cos^2(\theta) - 1]/r^3_{Co-H}$ versus δ^{HF}_{exp} displayed in Figure 5 shows a nice linear relationship; the δ^{HF}_{calc} and δ^{HF}_{exp} values are reported in Table 3.

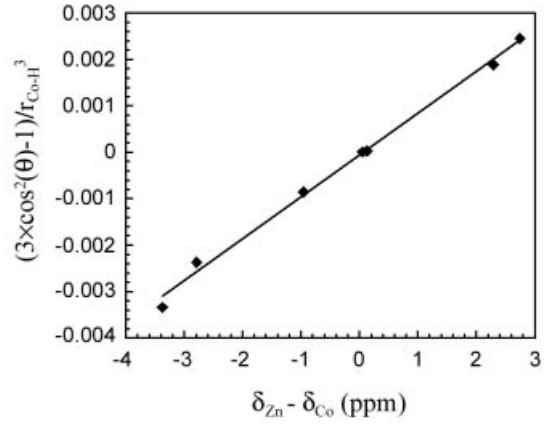

Figure 5. Plot of $(3 \times \cos^2(\theta) - 1]/r^3_{Co-H}$ vs. δ^{HF}_{exp}; $y = x \times 9.05 \times 10^{-4}$; $R = 0.997$

The excellent agreement between the values calculated from the X-ray structure and those measured by NMR spectroscopy confirms the existence of a bipyramidal $[Co(X_6Me_3Imme_3)(MeCN)_2]^{2+}$ species in solution. A similar behavior was observed with EtCN, but no evidence for an interaction between PhCN and the aqua complex could be found.

Interaction with DMF was monitored by UV/Vis spectroscopy as for ROH and RCN. First, upon addition of DMF to the CH_2Cl_2 solution of the Co-aqua complex, the extinction coefficients of three $^4A_2 \rightarrow {}^4T_1(P)$ bands increased (up to a maximum over 500 $M^{-1}\cdot cm^{-1}$) attesting to the formation of tetrahedral $[Co(X_6Me_3Imme_3)(DMF)]^{2+}$. This was confirmed by ^1H NMR spectroscopy at low DMF concentration (coordinated DMF was identified at δ_{COH} = 135 ppm, δ_{CH_3} = 23.2 and 22.8 ppm). In the second part of the titration, the bands near 500 nm broadened and their intensities decreased. The final spectrum, in nearly pure DMF, displays a broad transition between 450 and 700 nm with ε_{max} = 25 $M^{-1}\cdot cm^{-1}$, characteristic of $[Co(DMF)_6(ClO_4)_2]$. All this accounts for the formation of a tetrahedral Co-DMF complex followed by demetallation at high DMF concentration (Scheme 2).

Electrochemistry

The electrochemical behavior of the tris(imidazole)-Co^{II} complex was examined under a nitrogen atmosphere in acetonitrile. Cyclic voltammetry showed a totally irreversible Co^{II}/Co^{I} reduction peak at $E_p(red) = -1.8$ V,[25] together with metal deposition at the electrode, as evidenced by an anodic redissolution peak on the reverse scan. A very broad irreversible oxidation wave was observed at $E_p(ox) \approx 1.3$ V, ascribed to ligand oxidation. The same behavior was observed in dichloromethane. No interaction with O_2 could be evidenced. This indicates that the calix[6]arene-based tris(imidazole) system cannot stabilize any other oxidation state than Co^{II}. This was confirmed by the fact that all attempts to reduce the Co^{II} with a chemical reagent ($NaBH_4$ or $CoCp_2$) were unsuccessful, leading to decomplexation.

Synthesis and Characterization of a Five-Coordinate Ni^{II} Complex

Reaction of the tris(imidazole) ligand $X_6Me_3Imme_3$ with one equivalent of $[Ni(H_2O)_6(ClO_4)_2]$ in a THF/MeCN mixture,[26] followed by precipitation with Et_2O, yielded a green solid. IR spectroscopy and elemental analysis were consistent with the formula $[Ni(X_6Me_3Imme_3)(MeCN)(H_2O)](ClO_4)_2$. X-ray quality crystals were obtained by slow diffusion of Et_2O into an acetone/acetonitrile solution of the complex. The molecular structure (Figure 6) displays a five-coordinate nickel(II) ion in a distorted square-based pyramid geometry (SBP, $\tau = 0.45$).[24] The base of the pyramid is formed by two imidazole arms of the calixarene ligand, one acetonitrile molecule, buried in the conic cavity of the calixarene, and a water molecule, *trans* to the acetonitrile guest. The axial ligand is the third imidazole arm. The Ni−O7 bond is slightly longer than the four Ni−N bonds (see Table 4). The coordinated water is part of a hydrogen bonding network implying a second water molecule and an Et_2O molecule [*d*(O7,O16) = 2.688 Å and *d*(O16,O17) = 2.833 Å].

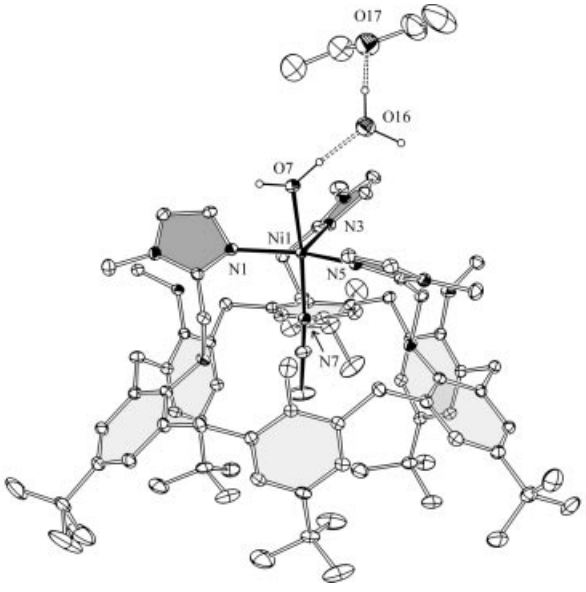

Figure 6. X-ray structure of $[Ni(X_6Me_3Imme_3)(MeCN)(H_2O)](ClO_4)_2\cdot H_2O\cdot Et_2O$ showing ellipsoids at 20% probability; some hydrogen atoms, perchlorate counterions and solvent of crystallization are omitted for clarity; all hydrogen atoms were located experimentally except those of the acetonitrile molecule

The magnetic moment of this Ni^{II} complex assessed by the Evans method in CD_3CN is 3.1(1) μ_B, which corresponds to a high-spin Ni^{2+} ion in a tetragonal environment.[27,28] Its UV/Vis spectrum in MeCN with five broad bands and weak extinction coefficients ε is suggestive of an SBP geometry. The ^1H NMR spectrum in CD_3CN presents

few resonances in the $\delta = -200$ to 200 ppm range. However, the diamagnetic region contains peaks attributable to $ArCH_2Ar$, ArH and *t*Bu, close to those of the tris(imidazole)Zn^{II} complex.[14] This shows that the dipolar contribution to the chemical shift is negligible and agrees with the non-degenerate $^3B_1$ ground state.[29] A putative attribution[30] of the UV/Vis data in MeCN is given in Table 5.

Table 5. UV/Vis data in MeCN of $[Ni(X_6Me_3Imme_3)(MeCN)(H_2O)](ClO_4)_2$

545	4	$^3B_1 \rightarrow {}^3B_2$
965	5	$^3B_1 \rightarrow {}^3E$

The electrochemical behavior of the Ni^{II} complex was studied in acetonitrile under nitrogen. Cyclic voltammetry showed no oxidation wave up to 1.8 V. An irreversible reduction peak, corresponding to Ni^{II}/Ni^{I} was observed at $E_p(red) = -1.35V$ with Ni^0 deposition at the electrode, as shown by the redissolution peak on the reverse scan. In benzonitrile, the reduction wave was broader and shifted to −1.45 V indicating a slower reduction process. However, the Ni^{I} state was not stable enough to yield a reversible reduction, even at high scan-rates. Similar to cobalt, the calix[6]arene-based tris(imidazole) system does not appear to be capable of stabilizing nickel ions in any other oxidation state than +2.

Discussion and Conclusion

The calix[6]arene-based tris(imidazole) ligand $X_6Me_3Imme_3$ thus appears particularly well suited for the stabilization of Co^{II} and Ni^{II} complexes, but not for higher or lower oxidation states. All complexes display a host/guest behavior, with a preferential binding of the exogenous organic ligand inside the hydrophobic cavity of the calixarene.

As previously described with Cu^{II}, reaction of the N_3 ligand with Ni^{II} yields five-coordinate complexes with an SBP environment. Also, in both cases, the organic ligand (RCN) is selectively bound in the heart of the hydrophobic calixarene cavity whereas a water molecule, standing outside, caps the structure.

With Co^{II}, four-coordinate species that strongly resemble the parent Zn^{II} complexes were characterized. Indeed, the aqua complex resulting from the synthesis in a non-coordinating solvent was easily exchanged for various small molecules L (alcohol, nitrile or amide), yielding novel tetrahedral complexes with included L. In the specific case of L = RCN, the four-coordinate Co complex was found to be in equilibrium with a trigonal bipyramidal species containing a second nitrile ligand bound outside the cavity and *trans* to the first one. Interestingly, such a five-coordinate species could not be evidenced with L = H_2O or ROH. This can be explained by the lower σ-donor ability of RCN compared to water or alcohol and by its π-acceptor character. Indeed, its first binding weakens the Co^{II} electronic density, thereby enhancing its affinity for a fifth ligand.[31]

A comparison of the X-ray structural parameters of the five-coordinate acetonitrile complexes of each of these metal ions is given in Table 6. Zinc and cobalt are in a TBP geometry whereas copper and nickel are in an SBP geometry. This follows the tendency generally observed for these metal ions in a five-coordinate environment.[27,28] As expected because of its lack of a crystal field, zinc is closer to pure TBP. On the other hand, there is a strong axial

Table 6. Comparison between complexes $[M^{II}(X_6R_3ImR_3)(MeCN)(L)]^{2+}$ (R = Me or Et) with M = Zn, Cu, Ni (L = H_2O) and Co (L = MeCN)

Compound	Geometry[a]	τ[b]	$d(M,L_{ax})$[c] (Å)	$d(M,L_{eq})$[c] (Å)
$[Zn^{II}(X_6Et_3Imet_3)(MeCN)(H_2O)]^{2+}$ [d]	TBP	0.86	2.13 $(MeCN)_i$ [e] 2.37 $(H_2O)_o$	2.03
$[Co^{II}(X_6Me_3Imme_3)(MeCN)(MeCN)]^{2+}$	TBP	0.69	2.08 $(MeCN)_i$ 2.17 $(MeCN)_o$	2.05
$[Cu^{II}(X_6Me_3Imme_3)(MeCN)(H_2O)]^{2+}$ [f]	SBP	0.49	2.19 (Imme)	2.01
$[Ni^{II}(X_6Me_3Imme_3)(MeCN)(H_2O)]^{2+}$	SBP	0.45	2.05 (Imme)	2.04

[a] TBP: trigonal bipyramid, SBP: square-based pyramid. [b] τ quantifies the distortion between ideal TBP (τ = 1) and SBP (τ = 0) geometries.[24] [c] $d(M,L_{ax})$ is the distance between metal and axial ligand and $d(M,L_{eq})$ is the mean distance between metal and equatorial ligands. [d] $X_6Et_3Imet_3$ is the OEt and NEt analogue of $X_6Me_3Imme_3$. See supporting information for the X-ray structure of the complex. [e] "*i*" refers to the ligand included in the calixarene cavity and "*o*" to the external one. [f] See ref.[11]

distortion in the case of copper due to the Jahn−Teller effect, which does not exist for nickel.

It thus appears that the calix[6]arene-based tris(imidazole) ligand is flexible enough to allow the metal ion to adopt the most favorable geometry, although it precludes a six-coordinate environment. The position of the acetonitrile guest in the cavity does not seem to be influenced by the nature of the metal ion, as variations of the CH_3···Ar, C···O and N···O distances remain minor (± 0.015 Å). This shows that the calixarene/guest interaction is relatively strong and that the nitrogen arms are flexible enough to accommodate the metal ion with a fixed calixarene conformation. This flexibility is reminiscent of what has been observed in carbonic anhydrase.[16,17] In its native form, this enzyme presents a mono-zinc active site, with a tetrahedral environment provided by three histidine residues and a water molecule. For the Co^{II}-substituted protein, both four- and five-coordinate metal centers have been characterized, whereas Cu^{II} is in a TBP environment and Ni^{II} octahedral. Hence, like the calixarene-based system, carbonic anhydrase favors a tetrahedral environment for Zn and can stabilize both four- and five-coordinate Co^{II} species. For copper, the two systems differ in the geometry of the metal ion. This shows that the calixarene system is more flexible than the enzyme active site as it does not constrain Cu^{II} in a TBP geometry. On the other hand, the enzyme active site can provide an octahedral environment for Ni, which seems to be precluded by the calixarene system. In conclusion, comparison with carbonic anhydrase confirms that the calixarene-based supramolecular system is a good model for Michaelis adducts, reproducing many structural aspects encountered in natural active sites but not the *cis* coordination of the exogenous ligands. We are currently working on controlling the fifth (outer) coordination site.

Experimental Section

Material and Methods: All solvents and reagents were obtained commercially. THF was distilled from over sodium/benzophenone under argon. CH_2Cl_2 and MeCN were distilled from over CaH_2 under argon. ^1H NMR spectra were recorded on a Bruker ARX 250 spectrometer. Electrochemical experiments were carried out under a dry dioxygen-free atmosphere (N_2) in a dry-box manufactured by Jacomex. The electrochemical cell was specifically designed to fit the rotating disk electrode (EDI Tacussel) for a minimum volume of solution in the main compartment. The auxiliary and reference (ferrocenium/ferrocene = Fc^+/Fc) electrodes were in separate compartments connected to the main compartment through ground joints terminated by frits (Vycor tips from PAR). For voltammetric measurements, a platinum disk (diameter = 2 mm) was employed, and the electrolyses were performed with the same electrode, but rotated, equipped with a 4 mm diameter disk. A model PAR 173 potentiostat equipped with a PAR 179 digital coulometric unit, was monitored by a PAR 175 programmer. The chart recorder was a T-2Y SEFRAM ENERTEC. IR spectra were recorded on a Perkin−Elmer 783 spectrometer. UV/Vis spectra were recorded on a SAFAS UVmc^2 spectrophotometer. Elemental analyses were performed at the Institut de Chimie des Substances Naturelles, France.

Safety Note. Caution! *Although we have not encountered any problems, please note that perchlorate salts of metal complexes with organic ligands are potentially explosive and should be handled only in small quantities with appropriate precautions.*

[31] It was not possible to study the host/guest property of the $X_6Me_3Imme_3$-Ni^{II} system because of its poor solubility in non-coordinating solvents. We have already noticed with other $X_6Me_3N_3$-M^{II} systems that the addition of a small excess of coordinating molecule enhances solubility: in these systems, the complexes seem to be maintained in solution by the included guest exchange. The low solubility might be related to the great inertia of Ni^{II} for the exchange of its ligands.

Palladium Chemistry in Anhydrous HF/AsF_5 Superacid Medium

Zoran Mazej,*[a] Primož Benkič,[a] Alain Tressaud,[b] and Boris Žemva[a]

Keywords: Palladium / Fluorine / Superacids / Structure elucidation / Magnetic properties

Pd metal dissolves in anhydrous HF (aHF) acidified with AsF_5 in the presence of F_2 at ≈298 K to give a blue-green solution from which green $Pd(AsF_6)_2$ can be isolated. The latter was also prepared by the interaction of PdF_2 and AsF_5 in aHF or by the reaction between PdO and F_2 in aHF acidified with AsF_5. Powdered $Pd(AsF_6)_2$ slowly loses AsF_5 in a dynamic vacuum. It can therefore be isolated from solution at $T < 253$ K. Single-crystals of $Pd(AsF_6)_2$ were prepared by solvothermal synthesis from a $Pd/AsF_5/F_2$/aHF mixture at 393 K. $Pd(AsF_6)_2$ is triclinic with a = 500.9(5), b = 538.3(5), c = 864.9(9) pm, α = 74.46(3), β = 89.97(4), γ = 62.47(2)°, V = 0.1972(3) nm^3, and Z = 1, space group $P\bar{1}$ (No. 2). The six-coordinate Pd atoms (coordinated with fluorine) are well separated by isolated AsF_6 units. In the 2–175 K temperature range $Pd(AsF_6)_2$ follows the Curie–Weiss law with μ_{eff} = 3.53 B.M., T_n = 8 K and θ_p= −13 K. Because of cation-anion interactions, the AsF_6^- anions deviate from ideal O_h symmetry. The reduced symmetry can be seen in vibrational spectra, where splitting of the anion vibrational modes can be observed. The oxidation of Pd metal or PdO with F_2 in neutral aHF yielded Pd_2F_6. No reaction was observed between Pd, PdO or Pd_2F_6 and AsF_5 in aHF. All attempts to prepare $PdFAsF_6$ were unsuccessful.

Introduction

Ususally, self-ionization of pure anhydrous hydrogen fluoride (aHF) yields solvated protons $H^+_{(solv)}$ (the acid) and solvated fluoride anions $F^-_{(solv)}$ (the base).[1] On addition of Lewis bases (fluoro bases) or acids (fluoro acids) to aHF, a massive displacement in aHF self-ionization occurs. In this way it is possible to adjust the acidity (or basicity) of aHF. Addition of Lewis bases (donors of F^-, e.g. CsF) causes an enhancement of the F^- concentration, that is, an increase in basicity (a decrease in acidity) and, conversely, addition of Lewis acids (acceptors of F^-, e.g. AsF_5) causes a lowering of the F^- concentration and consequently an increase in acidity (decrease in basicity) of aHF. In absolutely pure aHF, the concentration of $F^-_{(solv)}$ equals that of $H^+_{(solv)}$ and aHF is neutral. We can talk about acidic, neutral and basic aHF, expressions which are generally accepted in fluorine chemistry and are also generally valid for any other solvent (including water) which can be acidic, neutral or basic.[1] The acidity (or basicity) of the solvent is important for the generation of desired oxidation states of transition metals.[1–6] The oxidation of noble metals by elemental fluorine conveniently shows the influence of acidity of aHF on the final oxidation state of the noble metal in the products. Basic aHF, with a high concentration of $F^-_{(solv)}$, favours anion formation with the metal in a high oxidation state, whereas acidic aHF, with a low concentration of $F^-_{(solv)}$, favours compounds with the metal in a cationic form and a low oxidation state.[7,8] In neutral aHF, binary fluorides are formed.

In previous investigations it was found that oxidation of palladium metal by elemental fluorine in basic aHF yielded the Pd(IV) high oxidation state in the PdF_6^{2-} anion (Li_2PdF_6 [8], K_2PdF_6,[8] $(NH_4)_2PdF_6$ [7]), whereas in acidic aHF (acidified with SbF_5) the final product of oxidation, i.e. $Pd(SbF_6)_2$,[8] contained a low-oxidation state Pd^{II} cation. Our preliminary results showed that clear blue-green solutions of the Pd^{II} salt [$Pd(AsF_6)_2$], when treated with alkali fluoride in aHF, gave a light-brown precipitate of a new variety of PdF_2 (low-temperature form),[9] while the same procedure on $Pd(SbF_6)_2$ gave the previously known lilac rutile-type form of PdF_2.[8] For that reason we decided to study palladium chemistry in AsF_5/aHF superacid media in more detail. The aim of this work was to find out what happens when palladium metal and different palladium compounds (i.e. PdO, PdF_2 and Pd_2F_6) are treated with aHF acidified with AsF_5 (a Lewis acid weaker than SbF_5) in the presence or absence of elemental fluorine. The results of investigations of palladium chemistry in neutral aHF are also reported.

Results and Discussion

Syntheses

AsF_5 is able to oxidize 3*d*-metals at room temperature using AsF_3 or anhydrous hydrogen fluoride (aHF) as the solvent, giving $M(AsF_6)_2$, $MFAsF_6$ or $M(AsF_6)_2{\cdot}2AsF_3$ types of compounds.[10] In contrast, the use of elemental fluorine is necessary for the oxidation of 4*d*− and 5*d*−metals,[7,8] including palladium, in aHF acidified with AsF_5. In the superacidic system AsF_5/aHF, palladium was slowly oxidized and finally completely dissolved yielding a green-blue solution of solvated Pd^{2+} cations, from which green $Pd(AsF_6)_2$ was isolated [Equation (1)]

$$\underset{m = 2.5\text{-}8,\ n = 1\text{-}2}{Pd + mAsF_5 + nF_2} \xrightarrow{aHF} Pd(AsF_6)_2 + (m\text{-}2)AsF_5 + (n\text{-}1)F_2 \quad (1)$$

There was no noticeable difference in the course of the reactions when different forms of Pd metal were used (Pd black, gray or sponge). In some experiments with Pd and AsF_5 in aHF we observed a green-blue solution, indicating a possible reaction. Later we discovered, however, that the reason lay in impure AsF_5 contaminated by traces of fluorine. When superacid AsF_5/aHF was first treated with hydrogen and then allowed to react with palladium, no such coloring of the liquid phase was observed.

PdO does not dissolve in an AsF_5/aHF superacidic system, contrary to some other oxides of 3*d*- and 5*f*-transition metals which can yield oxonium salts.[11,12] On addition of elemental fluorine to a suspension of PdO in AsF_5/aHF, the reaction proceeds with formation of a green-blue solution from which $Pd(AsF_6)_2$ can be isolated [Equation (2)].

$$\underset{m = 8,\ n = 1.3}{PdO + mAsF_5 + nF_2} \xrightarrow{aHF} Pd(AsF_6)_2 + (m\text{-}2)AsF_5 + (n\text{-}1)F_2 + 0.5O_2 \quad (2)$$

$Pd(AsF_6)_2$ can be prepared directly by the reaction between PdF_2 and AsF_5 in aHF [Equation (3)].

$$\underset{m = 3}{PdF_2 + mAsF_5} \xrightarrow{aHF} Pd(AsF_6)_2 + (m\text{-}2)AsF_5 \quad (3)$$

For the first two reactions [Equations (1) and (2)] the amount of fluorine is very important. In the literature it has been reported that addition of fluorine to a solution of AgF_2 in AsF_5/aHF causes the partial oxidation of Ag^{II} to Ag^{III} and formation of $(Ag^{II}F)_2(Ag^{III}F_4)AsF_6$.[13] On prolonged exposure to F_2 of the highly aHF−soluble $Au(SbF_6)_2$, part of the Au^{II} is oxidized to Au^{III}, yielding mixed−valence, poorly soluble $Au^{II}(SbF_6)_2Au^{II}(Au^{III}F_4)_2$.[5] If the excess of fluorine in reactions (1) and (2) is too great, black aHF−insoluble mixed-oxidation state Pd_2F_6, i.e. $Pd^{II}(Pd^{IV}F_6)$,[14] is formed besides aHF−soluble $Pd(AsF_6)_2$ [Equation (4)].

$$\underset{m = 2.5\text{-}8,\ n = 4}{Pd + mAsF_5 + nF_2} \xrightarrow{aHF} \begin{matrix} x\,Pd(AsF_6)_2 \\ (1\text{-}x)Pd_2F_6 \end{matrix} \quad (4)$$

The precipitation of black Pd_2F_6 also occurred when fluorine was added to a clear green−blue solution of solvated Pd^{2+} in AsF_5/aHF. Reactions between Pd or PdO and F_2 in neutral aHF also yielded Pd_2F_6 [Equation (5)].

$$\begin{matrix} 2Pd \\ 2PdO \end{matrix} \xrightarrow{+\,nF_2 \ \text{in aHF}} \begin{matrix} Pd_2F_6 + (n\text{-}3)F_2 \\ Pd_2F_6 + (n\text{-}3)F_2 + O_2 \end{matrix} \quad (5)$$

$n = 12\text{-}18$

Even when PdO and F_2 in aHF were left to react for a longer time (48 days) than Pd and F_2 in aHF (4 days), unchanged PdO was still present in the solid and only ≈60 mol % of starting PdO was converted into Pd_2F_6. It is also worth noting that there was no sign of any reaction between PdF_2 and F_2 in aHF, even after several days, probably due to kinetic reasons.

The formation of Pd_2F_6 shows that the oxidation of Pd metal by fluorine can also partly proceed to Pd(IV) in acidic aHF [Equation (4)] as well as in basic[7,8] and neutral aHF media [Equation (5)].

This is in agreement with previous results showing that, by using a stronger oxidizer (KrF_2) than fluorine in neutral or acid aHF (acidified with AsF_5), all Pd is oxidized to $Pd^{IV}F_4$.[15] The main driving forces for the formation of $Pd(AsF_6)_2$ or $PdPdF_6$ are the fluoride ion affinities of AsF_5 (PdF_4) and the lattice energy differences between PdF_2 and the complex fluoroanion salts $Pd(AsF_6)_2$ ($PdPdF_6$). Since even PdF_4 prepared in situ does not react with AsF_5 [15] and precipitates on addition of AsF_5 to aHF solutions of PdF_6^{2-} alkali metal salts,[16] it can be concluded that the Lewis acidity (fluoroacidity or fluoride ion affinity) of PdF_4 is weaker than that of AsF_5. The driving force for the formation of Pd_2F_6 (PdF_2+PdF_4), despite the presence of the stronger fluoro acid AsF_5, is its high lattice energy. This explains why AsF_5 is not able to precipitate PdF_4 from Pd_2F_6 although it has a higher fluoride ion affinity than PdF_4.

Solvated Pd^{II} in green-blue solutions of $Pd(AsF_6)_2$ can, on the other hand, be easily oxidized or reduced, yielding finely powdered Pd_2F_6 or Pd metal, respectively [Equation (6)].

$$Pd^{2+}{}_{(solv.)}\ \text{in}\ AsF_5/aHF \begin{matrix} \xrightarrow{+\,nF_2} 0.5Pd_2F_6 + 2AsF_5 + (n\text{-}1.5)F_2 \\ \xrightarrow{+\,nH_2} Pd + 2HF + 2AsF_5 + (n\text{-}1)H_2 \end{matrix} \quad (6)$$

Additionally it was found that Pd_2F_6 can also be reduced by hydrogen in aHF yielding powdered Pd metal [Equation (7)].

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$Pd_2F_6 + nH_2 \xrightarrow{aHF} 2Pd + 6HF + (n\text{-}3)H_2 \quad (7)$$

To prepare pure $Pd(AsF_6)_2$ according to reactions (1), (2) and (3), the temperature of recovery from solution is important. It was found that $Pd(AsF_6)_2$ releases AsF_5 in a dynamic vacuum. Pure $Pd(AsF_6)_2$ can be isolated from solution in aHF by pumping away volatiles at temperatures lower than 253 K. At room temperature, the isolated products had varied compositions "$PdF_x(AsF_6)_{2-x}$" with $0 < x \leq 1$ depending on temperature, time of isolation and vacuum conditions. For all compositions, the X−ray powder diffraction patterns showed only lines which could be attributed to $Pd(AsF_6)_2$. Even the X−ray powder pattern of the phase close to a "$PdFAsF_6$" composition was the same as that of $Pd(AsF_6)_2$. We also tried to prepare $PdFAsF_6$ by displacing a weak acid from its alkali metal salt, similar to that reported for $AgFBiF_6$ from $Ag(BiF_6)_2$ [17] but, instead of $PdFAsF_6$, a mixture of $Pd(AsF_6)_2$ and a low-temperature modification of PdF_2 [9] was always obtained [Equation (8)].

$$Pd(AsF_6)_2 + KPF_6 \xrightarrow{aHF} 0.5Pd(AsF_6)_2 + 0.5PdF_2 + KAsF_6 + PF_5 \quad (8)$$

On the basis of these results we conclude that phases with compositions $PdF_x(AsF_6)_{2-x}$ ($0 < x \leq 1$) are mixtures of $Pd(AsF_6)_2$ and PdF_2 and not mixtures of $Pd(AsF_6)_2$ and $PdFAsF_6$. The possible preparation and existence of $PdFAsF_6$ is thus still in question. The instability of $Pd(AsF_6)_2$ in a dynamic vacuum could be a consequence of the inadequate fluoroacidity of AsF_5. When a stronger fluoroacid SbF_5 (FIA[SbF_5,g] ≈ −506 (± 63) kJ/mol)[18] was used instead of AsF_5 (FIA[AsF_5,g] ≈ −421 (± 22) kJ/mol)[18] the resultant $Pd(SbF_6)_2$ was stable at room temperature.[8] However care must be exercised in this type of comparison, in that the relative volatilities of AsF_5 and SbF_5 are also important factors in the stabilities of the resultant $Pd(AsF_6)_2$ and $Pd(SbF_6)_2$.

Crystal Structure of $Pd(AsF_6)_2$

$Pd(AsF_6)_2$ crystallizes in the same structural category as many other compounds obtained in the systems MF_2/XF_5 (M = transition metal, XF_5 = Lewis acid), e.g. $Mn(SbF_6)_2$,[19] $Ag(XF_6)_2$, X = Sb,[20] Nb,[21] Ta,[21] Bi,[17] $Au(SbF_6)_2$.[5] Pertinent crystallographic data are given in Exp. Sect.

A view of the crystal structure of $Pd(AsF_6)_2$ perpendicular to the slab that contains all palladium atoms in the same plane is shown in Figure 1. Pd atoms are in octahedral environments of fluorine, and PdF_6 octahedra are connected through their vertices to six AsF_6 units on either side of the plane formed by the Pd atoms. There are only van der Waals contacts of fluorine atoms between neighboring slabs and the network is a derivative of the $CdCl_2$ structural type. The structure can be alternatively described as being derived from the $LiSbF_6$ type (ordered ReO_3) with ordered vacancies (□) for half of the cationic sites, i.e. $Pd_{0.5}\square_{0.5}AsF_6$.

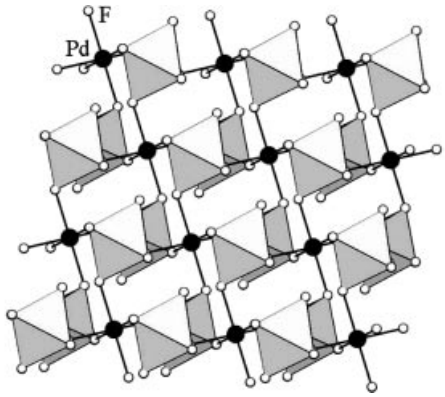

Figure 1. Part of the crystal structure of $Pd(AsF_6)_2$ perpendicular to the slab containing the palladium atoms.

The six-fold coordination of Pd^{II} in $Pd(AsF_6)_2$ is different from similar Ag and Au compounds in which, due to the Jahn−Teller effect, the metal octahedral environments are so distorted that coordination around Ag^{II} and Au^{II} is better described as square-planar rather than octahedral. The Pd−F bond lengths [218.3(5)−219.0(5) pm] of hexacoordinated Pd^{II} are slightly longer than the Pd−F bond lengths in PdF_2 [9,22,23] (Figure 2, Table 1).

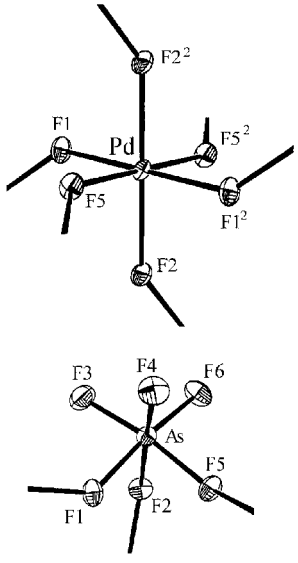

Figure 2. Coordination of the Pd^{II} atom and AsF_6 unit (thermal ellipsoids are shown at the 50% probability level)

The AsF_6^- anions are highly distorted by their interaction with the cation (Figure 2, Table 1). Consequently three As−F bonds with bridging fluorine atoms are considerably longer [179.8(5), 178.6(5), 176.8(5) pm] than the other three As−F bonds with non−bridging fluorine atoms [166.3(5), 167.9(3), 168.8(5) pm]. From the gross distortion of the AsF_6^- unit, it is evident that Pd^{II} strongly attracts the fluorine ligands of the surrounding AsF_6 species. The reason

Pd−F5	218.3(5)			Pd−F2−As	143.5(3)
				Pd−F5−As	138.0(3)

must be due to the high effective nuclear charge (i.e, the charge density; Z^+/r ratio) of the Pd^{II} cation.

Magnetic Properties of $Pd(AsF_6)_2$

Because of the peculiar d^8 electronic configuration of divalent palladium, the Pd^{II} based fluoro-compounds may exhibit either paramagnetic or diamagnetic behavior depending on whether the configuration of the transition element is high-spin or low-spin, respectively. The corresponding coordination numbers are so various that this element has been called an "inorganic chameleon".[24] $MPdF_4$ (M = Ca, Sr, Ba, Pb) and $M'MPdF_5$ compounds (M′ = K, Rb, Cs) are examples of the latter, low-spin case, in which the Pd^{II} has a square planar environment.[24] In the former case, Pd^{II} exhibits a regular octahedral coordination, as in rutile-type PdF_2 and $PdM^{IV}F_6$ phases (M^{IV} = Pd, Pt) derived from ReO_3 structures by cationic ordering.[25] Due to the ordering of Pd electronic orbitals, ferromagnetism occurs in these Pd_2F_6-derived materials. An intermediate case is that of $CsPd_2F_5$, in which half of the Pd^{II} centers are in a high-spin configuration and the other half in a low−spin state.[26]

$Pd(AsF_6)_2$ is paramagnetic and the reciprocal susceptibility follows the Curie−Weiss law with a Weiss constant of −13 K and possible three dimensional ordering below 8 K (C = 1.56 and μ_{eff} = 3.53 B.M.) (Figure 3). The absence of 3D interactions over a large temperature range is in agreement with the structural features. Pd atoms are isolated from each other and there is thus no possible Pd−F−Pd superexchange coupling. The average μ_{eff} is considerably higher than the calculated μ_{eff} considering only spin (2.83 B.M). Such high values of μ_{eff} were also previously reported for palladium fluorosulfates [$Pd(SO_3F)_2$: 3.39 B.M.,[27,28] $Pd(M^{IV}(SO_3F)_6]$: 3.45 B.M. for M = Pd,[27−29] 3.37 B.M. for M = Pt[29] and 3.60 B.M. for M = Sn[29]].

It should be noted that a second Pd^{II} compound with a similar formula, i.e. $Pd(SbF_6)_2$, is structurally related to $Pd(AsF_6)_2$. A preliminary crystal structure was reported,[30] but was incomplete possibly because of twinning of the crystals. The only difference is that in $Pd(SbF_6)_2$, a disordered distribution of Pd^{II} occurs in all octahedral sites. Magnetic data have been determined[8,31] over the range 2−82 K (at 82 K $Pd(SbF_6)_2$ has a μ_{eff} = 3.09 B.M.).

Vibrational Spectra of $Pd(AsF_6)_2$

More bands were observed in the vibrational spectra than would be expected for a regular AsF_6^- anion with O_h symmetry (Figure 4), consistent with a highly distorted AsF_6 octahedral structure in solid $Pd(AsF_6)_2$. The bands in the region 640−790 cm^{-1} can be assigned to $As-F_{terminal}$ stretching modes. Bands in the region 490−530 cm^{-1}, which are weaker than the stretching ones for terminal fluorine atoms, are typical for species where one fluorine bridges two different atoms,[1] and can be readily assigned to As−F−Pd stretching modes. Bands below 400 cm^{-1} were assigned to deformation and lattice modes (Table 2).

Table 2. Vibrational spectra of $Pd(AsF_6)_2$

IR[a]	Raman	Partial assignments[b]
782(sh)	784(40)	As−F_t stretching modes
759(vs)	751(25)	As−F_t stretching modes
745(vs)		As−F_t stretching modes
	737(20)	As−F_t stretching modes
701(w)	699(5)	As−F_t stretching modes
	662(100)	As−F_t stretching modes
641(s, br)		As−F_t stretching modes
528(s)		As−F−Pd stretching modes
509(s)	509(30)	As−F−Pd stretching modes
	495(sh)	As−F−Pd stretching modes
399(w)	393(20)	deformation modes
377(w)	374(50)	deformation modes
362(w)	366(35)	deformation modes
	264(5)	lattice modes
	246(10)	lattice modes

[a] Intensities are given in parentheses; w = weak, m = medium, s = strong, vs. = very strong, sh = shoulder. [b] F_t = terminal (non-bridging) fluorine atom.

Conclusion

In this study we have investigated the reactions of Pd metal and different Pd compounds (PdF_2, PdO, Pd_2F_6) with AsF_5, with or without elemental fluorine, in liquid aHF. The observed reactions follow the general scheme for the dependence of the generation of low- or high-oxidation states of transition metals on the acid-base properties of the solvent. In neutral aHF, the binary fluoride Pd_2F_6 is formed, whereas acidic aHF favors the metal in a cationic form in the low oxidation state, with formation of $Pd(AsF_6)_2$. Additionally it was found that the oxidation of Pd metal by fluorine can also partly proceed to Pd(IV) in acidic aHF. It can be concluded that Pd_2F_6 is thermodynamically favorable but kinetically unfavorable relative to $Pd(AsF_6)_2$.

The partial oxidation of Pd with elemental fluorine to Pd(IV) in acidic or neutral aHF and formation of Pd_2F_6 ($Pd^{II}Pd^{IV}F_6$) with no further oxidation to PdF_4 is more likely a consequence of unfavorable thermodynamics than kinetics. For the latter, the main reason lies in aHF insoluble Pd_2F_6 which has to be oxidized by fluorine in aHF to insoluble PdF_4. However, if KrF_2 [15] or ultraviolet photolyzed F_2 [32] are used instead of elemental F_2 in liquid aHF then Pd_2F_6 is quantitatively converted into PdF_4. Treatment of Pd with KrF_2 in aHF is energetically favorable because of the lower heat of atomization of KrF_2 (97.8 kJ·mol^{-1}) in comparison with elemental fluorine (157.7±0.4 kJ·mol^{-1}), making it a better low-temperature source of fluorine atoms.[33] In the case of the reaction of ultraviolet photolyzed F_2 and Pd in aHF, UV-irradiation provides the energy for the cleavage of the chemical bonds in F_2 and access to atomic fluorine.

The solubility of the reactants and products is not always the governing factor for the generation of the desired oxidation states of transition metals in liquid aHF. For example, elemental fluorine oxidizes MnF_2 in aHF yielding only pure MnF_3. In the presence of a UV source, MnF_2 is completely oxidized by photodissociated F_2 in aHF to MnF_4.[34] The same thing happens if KrF_2 is used as the oxidizing agent.[35] However, the suppression of kinetic barriers (insolubility of reactants and products) has a great influence on the preparation of LnF_4 (Ln = Pr, Tb) in liquid aHF. Reactions between LnF_3 and elemental F_2 in aHF at room temperature were incomplete even in the presence of ultraviolet light and gave mixtures of LnF_3 and LnF_4. However when the corresponding Ln oxides were used as starting materials LnF_4 were obtained in a quantitative yields, because the coatings of the reaction products on the surface of the solid reagents were destroyed by gas evolution, thereby accelerating the process.[36]

When oxidation of Pd by elemental fluorine is carried out in basic aHF (*A*F/aHF systems; *A* = alkali metal) with a high concentration of $F^-_{(solv)}$, the forming Pd(IV) instantaneously dissolves as PdF_6^{2-}. Although Pd^{II} is formed as an intermediate it has to compete with a stronger Lewis base, i.e. A^+ for the formation of PdF_6^{2-} salts.

The crystal structure of $Pd(AsF_6)_2$ confirms the presence of highly distorted AsF_6^- anions as predicted by vibrational spectroscopy. It is composed of 2D slabs containing Pd atoms in the center and AsF_6 groups on either side. Only van der Waals bonding exists between neighboring slabs. The network can be described as being based on the $CdCl_2$ structural type or the $LiSbF_6$ type (ordered ReO_3), with ordered vacancies (□) for half the cationic sites, i.e. $Pd_{0.5}□_{0.5}AsF_6$. As found by single-crystal X-ray analyses and X-ray powder diffraction, this structure is adopted by most of the known compounds with formula $M^{II}(X^{V}F_6)_2$ (*M* = transition metal; *X* = As, Sb, Bi, Nb, Ta). Two exceptions are $Mn(AsF_6)_2$ [37] and $Pd(NbF_6)_2$.[38]

The paramagnetic behavior of $Pd(AsF_6)_2$ is in good agreement with the structural data because no Pd−F−Pd superexchange interaction is possible.

Experimental Section

Apparatus and Reagents: Volatile materials (AsF_5, PF_5, aHF) were manipulated in an all-PTFE vacuum line equipped with PTFE valves. Non-volatile materials were manipulated in a dry-box (M.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Braun). The residual water in the atmosphere within the dry-box never exceeded 1 ppm. The reactions were carried out in translucent fluorocarbon polymer (FEP) reaction vessels (height 250−300 mm with inner diameter 15.5 mm and outer diameter 18.75 mm) equipped with PTFE body valves and PTFE coated stirring bars. Reaction vessels combined from two FEP tubes in a T-shape manner and equipped with PTFE body valves were used in some experiments. Each reaction vessel was pre-treated with F_2 (to about 1 bar) for several hours before use.

Pd black (Alfa Products, 99.9%), Pd black (Aldrich, 99.9%), Pd gray (Johnson Matthey & Co-limited, 99.9%), Pd gray (Merck, 99.9%), Pd sponge (Aldrich, 99.9), PdO (Cerac Incorporated, 99.99%), and KF (Ventron, 99.9%) were used as supplied. AsF_5 was synthesized by pressure fluorination of arsenic trioxide with elemental fluorine in a nickel reactor at 573 K as described for the synthesis of PF_5.[39] KPF_6 was prepared from KF and PF_5 in aHF. The lilac rutile form of PdF_2 was prepared as described.[40] Fluorine was used as supplied (Solvay, 99.98%). Anhydrous HF (Praxair, 99.9%) was treated with K_2NiF_6 for several hours prior to use.

CAUTION: aHF, AsF_5, and PF_5 should only be handled in a well-ventilated hood, and protective clothing should be worn at all times!

Instrumentation: Infrared spectra were recorded on a Perkin−Elmer FTIR 1710 spectrometer on powdered samples between AgCl plates in a leak-tight brass cell. Raman spectra were recorded on a Renishaw Raman Imaging Microscope System 1000, with a He−Ne laser of wavelength 632.8 nm. X-ray powder diffraction patterns were obtained using the Debye−Scherrer technique with Ni-filtered Cu-K_α radiation. Samples were loaded into quartz capillaries (0.3 mm) in a dry-box.

Chemical Analyses: Palladium was determined by complexometric titration;[41−43] total fluoride ion content was determined with a fluoride ion selective electrode;[44,45] AsF_6^- species were determined gravimetrically as insoluble tetraphenylarsonium salts;[46,47] arsenic was determined by the ICP method.[48] The results of chemical analyses are given in mass percentages.

Syntheses

General Procedure: Starting materials were loaded into an FEP reaction vessel in a glove box. aHF and, when necessary, AsF_5 were condensed onto solid reactants at 77 K, which were then brought to room temperature. Fluorine was added when needed. The reaction mixtures were vigorously agitated and after some time volatiles were pumped away. Isolated products were characterized by mass balance, chemical analysis, vibrational spectroscopy, X-ray powder diffraction patterns (XRPD-pattern) and/or magnetic measurements.

Reaction between Pd and F_2 in aHF: Reaction mixture: Pd (0.242 g, 2.27 mmol) and F_2 (13.99 mmol) in aHF (6 mL). After 4 days no visible change was observed (colorless liquid was present above a black solid). Final mass: 0.401 g (calcd. for Pd_2F_6: 0.371 g). XRPD-pattern and Raman spectrum (563 cm^{-1}, 281 cm^{-1} and 213 cm^{-1}) corresponded to Pd_2F_6. Pd_2F_6 (326.8): calcd. F 34.88, Pd 65.12; found F 34.6, Pd 63.9.

Reaction between PdO and F_2 in aHF: Reaction mixture: PdO (0.191 g, 1.56 mmol) and F_2 (12.92 mmol) in aHF (4 mL). After 48 days no visible change was observed (colorless liquid was present above a black solid). Pd_2F_6 (326.8): calcd. F 34.88; found F 23.4. XRPD-pattern showed a mixture of PdO and Pd_2F_6.

Reaction between PdF_2 and F_2 in aHF: Reaction mixture: rutile form of PdF_2 (0.275 g, 1.90 mmol) and F_2 (12.92 mmol) in aHF (4 mL). After 13 days, the liquid was colorless and starting PdF_2 remained as an insoluble brown solid, characterized by XRPD-pattern. PdF_2 (144.4): calcd. F 26.32, Pd 73.68; found F 26.9, Pd 72.1.

Reactions between Pd and AsF_5 in aHF: Two experiments were carried out. In the first experiment, a reaction mixture of Pd (0.110 g) and AsF_5 (2.000 g) in aHF (4 mL) was prepared. After 3 days a green-blue solution was observed above unchanged Pd metal. The Raman spectrum of the solution showed a strong band at 703 cm^{-1}, which could be attributed to $As_2F_{11}^-$. After 42 days the volatile components were pumped away. The XRPD-pattern of the isolated solid showed only Pd metal. Chemical analysis showed 4.78% As in the isolated solid.

In the second experiment a solution of AsF_5 (2.000 g) in aHF (3 mL) was treated with 4 bar of hydrogen. After one day of intensive stirring the solution was cooled to 77 K, and volatile components were pumped away. The mixture of AsF_5/aHF was then brought to room temperature and condensed onto Pd metal (0.118 g, 1.11 mmol). The Raman spectrum of the liquid phase showed a strong band at 703 cm^{-1}. After 42 days the liquid phase was still colorless. The XRPD−pattern of the isolated solid showed it to consist of metallic Pd. Pd (106.4): calcd. Pd 100; found Pd 98.2.

Reaction between PdO and AsF_5 with and without F_2 in aHF: Reaction mixture: PdO (0.182 g, 1.49 mmol) and AsF_5 (11.77 mmol) in aHF (4 mL). The Raman spectrum of the solution showed a strong band at 703 cm^{-1}. After 8 days the liquid phase was still colorless. Because there was no sign of reaction, F_2 (1.96 mmol) was added to the reaction vessel. The liquid phase became green-blue over few hours. Within 13 days a clear green-blue solution was obtained. Volatiles were pumped away at 253 K. Final mass of isolated green solid: 0.799 g [calcd. for $Pd(AsF_6)_2$: 0.726 g]. $Pd(AsF_6)_2$ (484.2): calcd. Pd 21.97; F 47.09; As 30.94; AsF_6 78.03; found Pd 21.4; F 46.3; As 33.3; AsF_6 76.0 [corresponding to molar ratio: n(Pd):n(As):n(AsF_6):n(F) = 1.0:2.2:2.0:12.1].

Reaction between PdF_2 and AsF_5 in aHF: Immediately after warming to room temperature, a reaction mixture of PdF_2 (0.270 g,1.87 mmol) and AsF_5 (5.90 mmol) in aHF (4 mL) became green-blue in color. After three days, some of the volatiles were pumped away at room temperature until 1 mL of solution was left. Finally, all volatiles were pumped away over 6 days at 243 K. Final mass of the green solid: 0.913 g, calcd. for $Pd(AsF_6)_2$: 0.906 g. $Pd(AsF_6)_2$ (484.2): calcd. Pd 21.97, F 47.09, AsF_6 78.03; found Pd 21.7, F 46.3, AsF_6 76.6.

Reaction between Pd_2F_6 and AsF_5 in aHF: Reaction mixture: Pd_2F_6 (0.138 g, 0.84 mmol) and AsF_5 (3.53 mmol) in aHF (6 mL). After 6 days the liquid phase was still colorless, and the insoluble solid was black. The XRPD-pattern and Raman spectrum (563, 283 and 215 cm^{-1}) of the isolated solid showed only starting Pd_2F_6. Pd_2F_6 (326.8): calcd. F 34.88; found F 34.9.

Reactions between Pd and AsF_5 in aHF in the Presence of Fluorine: Many experiments were performed with different forms of Pd. Only two typical ones will be described. Reaction mixture: Pd (0.292 g, 2.74 mmol), AsF_5 (7.06 mmol) and F_2 (4.95 mmol) in aHF (10 mL). After one hour the color of the solution became green−blue. After 5 days a clear green-blue solution was obtained. Volatiles were pumped away at room temperature. The final mass of isolated grayish−green solid was 1.246 g, corresponding to a

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

molar ratio $n(PdF_2):n(AsF_5)$ = 1:1.87. $Pd(AsF_6)_2$ (484.2): calcd. Pd 21.97, F 47.09, As 30.94, AsF_6 78.03; found Pd 23.2, F 45.3, As 30.6, AsF_6 76.1 [corresponding to molar ratio $n(PdF_2):n(AsF_5)$ = 1:1.87]. In other experiments different final molar ratios $n(PdF_2):n(AsF_5)$ were obtained giving "$PdF_x(AsF_6)_{2-x}$" where $0 < x \leq 1$ depending on the temperature and time of isolation and vacuum conditions. Reaction mixture: Pd (0.281 g, 2.64 mmol), AsF_5 (20.56 mmol) and F_2 (3.53 mmol) in aHF (8 mL). After 5 days a clear green−blue solution was obtained. Volatiles were pumped away for 10 days at 253 K. The isolated solid product was green. $Pd(AsF_6)_2$ (484.2): calcd. Pd 21.97, F 47.09, As 30.94, AsF_6 78.03; found Pd 21.4, F 46.1, As 33.8, AsF_6 77.3 [corresponding to molar ratio n(Pd):n(As):$n(AsF_6):n$(F) = 1.0:2.2:2.0:12.1].

Reaction between Pd and AsF_5 in aHF in the Presence of a Large Excess of Fluorine: Reaction mixture: Pd (0.326 g, 3.06 mmol), AsF_5 (25.15 mmol) and F_2 (11.95 mmol) in aHF (8 mL). After bringing the reaction mixture to room temperature, the color of the liquid phase changed to green-blue. After 10 days a clear green−blue solution was visible above an insoluble black solid. The solution was decanted. The mass of black solid was 0.359 g. Its Raman spectrum (565, 291 and 219 cm^{-1}) showed only Pd_2F_6. The XRPD-pattern of green solid isolated from decanted solution showed only $Pd(AsF_6)_2$.

Reaction between Pd_2F_6 and H_2 in aHF: Pd_2F_6 (0.239 g, 1.46 mmol) was suspended in HF (7 mL) and agitated intensively at room temperature. Immediately after addition of hydrogen the sample deposited on the bottom of the reaction vessel despite intensive stirring. The final pressure of hydrogen was 3.7 bar. After one day volatiles were pumped away at room temperature. Final mass: 0.169 g (calcd. for Pd: 0.155 g). Pd (106.4): calcd. Pd 100; found Pd 97.8. The XRPD-pattern showed Pd metal.

Reduction and Oxidation of Solvated Pd^{2+} Dissolved in AsF_5/aHF: A clear green blue solution was prepared from Pd (0.133 g, 1.26 mmol), AsF_5 (3.700 g, 21.78 mmol) and F_2 (1.50 mmol) in aHF (8 mL). The excess fluorine was pumped away at 77 K. After addition of 2 bar of hydrogen at room temperature, the liquid phase became colorless over 10 minutes. A metallic, shiny solid precipitated on the walls of reaction vessel. Volatiles were pumped away at room temperature. Final mass: 0.167 g. Chemical analysis: % Pd, 92.5,% As, 4.2. The XRPD-pattern showed only Pd metal.

A green blue solution of Pd metal was prepared as above. After addition of elemental fluorine, a black solid started to precipitate. The amount of insoluble solid increased with time and the intensity of the green-blue color of the liquid phase decreased. The XRPD-pattern of the isolated solid showed only Pd_2F_6.

Attempted Synthesis of $PdFAsF_6$: A T-shaped FEP reactor with two PTFE valves as described before[49] was loaded with Pd (0.155 g, 1.46 mmol) in one arm and KPF_6 (0.266 g, 1.46 mmol) in the other. aHF (about 4 mL), AsF_5 (2 g) and F_2 (1.60 mmol) were condensed onto the Pd and in the other arm aHF (3 mL) was condensed onto KPF_6, yielding a colorless solution. After one day the Pd metal completely dissolved, yielding a blue-green solution. Volatiles were pumped away at 253 K and fresh aHF was added. The solution of KPF_6 in aHF was slowly poured onto the clear solution of $Pd(AsF_6)_2$ in aHF. A light-brown solid immediately precipitated. After two days a green-blue solution was visible above the light-brown solid. The solution was decanted. The XRPD-pattern of the insoluble brown solid corresponded to the low-temperature form of PdF_2.[9] The XRPD-pattern and Raman spectrum of the solid precipitated from the decanted solution showed a mixture of $KAsF_6$ and $Pd(AsF_6)_2$.

Preparation of Single-Crystals of $Pd(AsF_6)_2$ and Structure Determination: The crystal structure of $Pd(AsF_6)_2$ was first determined on our single-crystals with the help of Dr. H. Borrmann, Max Planck Institut für Chemische Physik fester Stoffe, Dresden, Germany. Later the determination of the crystal structure of $Pd(AsF_6)_2$ was repeated on new crystals. All crystallographic data presented in this paper are from repeated crystal structure determinations.

Single-crystals of $Pd(AsF_6)_2$ were prepared by solvothermal syntheses. The reaction between Pd (0.110 g, 1.03 mmol), AsF_5 (1.5 g, 8.83 mmol), aHF (0.050 g) and F_2 (1.5 mmol) was carried out in a special stainless steel autoclave with a PTFE liner (V = 6 mL). After entering all reactants into the autoclave it was heated to 393 K for 43 days. After cooling to ambient temperature all volatiles were quickly pumped away. A large piece of brown solid was found inside. When it was broken up, blue-green crystals of $Pd(AsF_6)_2$ were found inside. Single-crystals were selected in a dry-box and mounted in 0.3 mm quartz capillaries.

Single-crystal data from $Pd(AsF_6)_2$ were collected on a Mercury CCD area detector coupled with a Rigaku AFC7S diffractometer using monochromated MoK_α radiation. Data were corrected for Lorentz, polarization, and absorption effects and processed using the Rigaku Crystalclear software suite program package.[50] The structure was solved by direct methods[51] and expanded using Fourier techniques. Some details of the single-crystal data collection, data processing, and refinement are given in Table 3. Further details of the crystal-structure investigation may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-

Table 3. Crystal data and structure refinement for $Pd(AsF_6)_2$

Formula	$Pd(AsF_6)_2$
Crystal system	triclinic

Magnetic Measurements: Cylindrical screw-capped sample containers ($V \approx 0.5$ mL, $m \approx 0.250$ mg) for magnetic measurements of $Pd(AsF_6)_2$ were made of Kel-F (polytrifluorochloroethylene) and were additionally tightened with PTFE gaskets. Prior to their use, both the container and Kel-F packing tool were made passive with elemental fluorine. The field dependence of the magnetization was measured for various temperatures in the 4.2−300 K range using a SQUID magnetometer (MPMS-5S, Quantum Design).

Methacrylate-Substituted Titanium-Yttrium Mixed-Metal Oxo Clusters

Myhedin Jupa,[a] Guido Kickelbick,[a] and Ulrich Schubert*[a]

Keywords: Cluster compounds / Yttrium / Titanium / Organic-inorganic hybrids / Hydrogen bonding / Alkoxides

Upon reaction of titanium propoxide and yttrium 2-methoxyethoxide with a sevenfold excess of methacrylic acid, three different mixed-metal clusters were obtained, depending on the titanium to yttrium alkoxide ratio. Clusters of the type $Ti_4Y_2(\mu_3\text{-}O)_4(\mu_2\text{-methacrylate})_{12}(\mu_1\text{-methacrylate})_2L_2$ (L = $MeOCH_2CH_2OH$ or methacrylic acid), with two $[TiO_6]$ octahedra condensed to a zigzag chain of two $[YO_8]$ dodecahedra and two $[TiO_6]$ octahedra, were formed when the Ti/Y ratio in the precursor mixture was ≥ 3.5. The structure of $Ti_4Y_2O_4(OMc)_{12}(OCH_2CH_2OMe)_2(McOH)_2$ obtained with a Ti/Y ratio of 2 in the precursor mixture, consists of a ring of four corner-sharing $[TiO_6]$ octahedra to which two $[YO_8]$ dodecahedra are condensed.

Introduction

The traditional sol-gel route to inorganic-organic hybrid polymers, in which the organic and inorganic entities are connected by covalent bonds, is based on molecular precursors of the general composition $(RO)_nM-X-A$ with a hydrolyzable group $(RO)_nM$, and a polymerizable organic group A connected by an inert spacer X. In a typical preparative protocol the precursors are first reacted with water. After formation of the inorganic network, the organic groups A are polymerized or crosslinked to form oligomeric or polymeric organic structures. Modification of the type, structure and proportions of the organic and inorganic constituents allows, in principle, tailoring of the properties of the resulting hybrid polymer. A special challenge of increasing importance is to tailor also structural features of the hybrid materials, especially the dimension (especially on a nanometer scale), geometry and mutual arrangement of the organic and inorganic building blocks.

Such a structural control is hardly possible with the traditional procedure. It is more easily reached when the formation of the inorganic and organic structures is done at different times in clearly separated reaction steps. Hydrolysis and condensation of metal or semi-metal alkoxides may lead to structurally defined molecular cage compounds (clusters), instead of oligomers or polymers with broad size distributions, if the reaction with water is performed in a very controlled manner. Such clusters can be used for the preparation of inorganic-organic hybrid polymers as structurally well-defined oligomeric building blocks. In order to connect the clusters with polymeric organic structures, the cluster surface must be covered with reactive organic groups (polymerizable groups, for example).

We previously synthesized a variety of methacrylate-substituted mono- (Ti, Zr, Hf, Nb, Ta), di- (Ti/Zr, Ti/Hf) and trimetallic (Ti/Zr/Hf) oxo/alkoxo clusters of different size and shape for this purpose.[1] It was shown that the cluster type has a distinct influence on the properties of the resulting hybrid materials;[2] the origin of this effect is not yet known. The methacrylate-substituted metal oxo clusters can be obtained in high yields by reaction of metal alkoxides with methacrylic acid (McOH). The formation of the clusters can be rationalized by the sequence of three reactions. One or more alkoxide ligands of the starting alkoxide $M(OR)_x$ are first substituted by methacrylate groups to give $M(OR)_{x-n}(OMc)_n$. Water is generated in situ by esterification of excess methacrylic acid with alcohol (either liberated by the substitution reaction or present as solvent)[3] and hydrolyzes all or part of the remaining alkoxide groups. The very slow in situ production of water allows a very controlled growth of clusters $M_nO_x(OR/OH)_y(OMc)_z$, the size and shape of which can be influenced to a certain degree by the reaction conditions. The most important parameter is the metal alkoxide/carboxylic acid ratio,[4] and a second parameter is the type of alkoxide group in the parent alkoxide.[5]

In this article we report the preparation of three methacrylate-substituted titanium-yttrium mixed-metal oxo clusters obtained by this route, viz. $Ti_4Y_2O_4(OMc)_{14}(MeOCH_2CH_2OH)_2$ (**1**), $Ti_4Y_2O_4(OMc)_{14}(McOH)_2$ (**2**) and $Ti_4Y_2O_4(OMc)_{12}(OCH_2CH_2OMe)_2(McOH)_2$ (**3**), and their structural characterization.

Results and Discussion

We have previously prepared a series of mixed Ti/Zr oxide clusters, viz. $Ti_2Zr_4O_4(OBu)_2(OMc)_{14}$ (Ti_2Zr_4),

[a] Institute of Materials Chemistry, Vienna University of Technology,
Getreidemarkt 9/165, 1060 Wien, Austria

$Ti_4Zr_2O_4(OBu)_6(OMc)_{10}$ (Ti_4Zr_2), $Ti_4Zr_4O_6(OBu)_4(OMc)_{16}$ and $Ti_2Zr_6O_6(OMc)_{20}$, and related Ti/Hf and Ti/Zr/Hf clusters, by reacting titanium and zirconium (hafnium) butoxide mixtures with methacrylic acid in different molar ratios.[6,7] The same procedure was used in the present work to prepare Ti/Y clusters from $Ti(O\textit{n}Pr)_4$ and $Y(OCH_2CH_2OMe)_3$. The latter alkoxide, with a decameric ring structure,[8] was employed as a ca. 11% solution in 2-methoxyethanol. The metal alkoxide [$Ti(OR)_4$ + $Y(OME)_3$]/methacrylic acid molar ratio (OME = OCH_2CH_2OMe)was kept at about 1:7 in each experiment, but the $Ti(OR)_4/Y(OME)_3$ ratio was varied from 2:1 to 3.5:1 and 18:1. Each precursor composition resulted in a different mixed-metal cluster **1**−**3** which was isolated in high yields in each case and structurally characterized by single crystal diffraction. The NMR spectra, both in benzene solution and in the solid state, are of little diagnostic value, because only one group of signals is observed for each type of ligand.

Interestingly, each of the clusters **1**−**3** has the general composition $Ti_4Y_2O_4X_{14}(HY)_2$ (X,Y = OMc and/or OME) despite the different Ti/Y ratio in the precursor mixture. The clusters differ by the distribution of X and Y, and by the arrangement of the titanium and yttrium polyhedra as discussed in the following.

Cluster **1** was obtained from a $Ti(OR)_4/Y(OME)_3$ ratio of 3.5. An X-ray structure analysis revealed that the composition of **1** is $Ti_4Y_2(\mu_3\text{-}O)_4(\mu_2\text{-}OMc)_{12}(\mu_1\text{-}OMc)_2(MeOCH_2CH_2OH)_2$. The structure of **1** (Figure 1, Table 1) is very similar to that of Ti_4Zr_2 [= $Ti_4Zr_2(\mu_3\text{-}O)_4(\mu_2\text{-}OMc)_{10}(\mu_2\text{-}OBu)_2(\mu_1\text{-}OBu)_2$] (Figure 2).

The common structural motive of the hexanuclear clusters Ti_2Zr_4 and Ti_4Zr_2 is a zigzag chain of two central [ZrO_8] dodecahedra and two terminal [TiO_6] tetrahedra. Two additional [ZrO_8] dodecahedra (in Ti_2Zr_4) or [TiO_6] octahedra (in Ti_4Zr_2) are condensed to the zirconium atoms of the main chain by a shared edge. The central structural motif of **1** is the same zigzag chain as in Ti_4Zr_2 with [YO_8] instead of [ZrO_8] dodecahedra. The main structural difference is that the additional [TiO_6] octahedra are condensed to the main chain via corners.

		Ti(1)−O(20)−Y(1)	94.29(7)

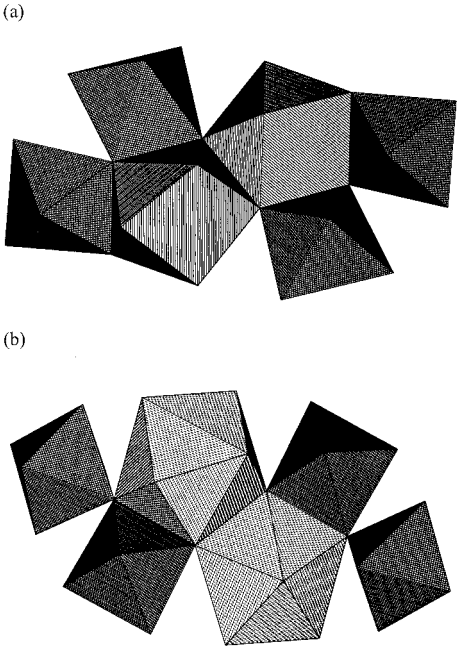

Figure 2. Cluster cores of connected polyhedra in $Ti_4Zr_2O_4(OBu)_6(OMc)_{10}$ (Ti_4Zr_2) (a) and **1/2** (b). The central polyhedra are eight-coordinate Zr or Y, and the terminal polyhedra six-coordinate Ti

While the sum of the metal coordination numbers in Ti_4Zr_2 and **1** is the same, the total metal charge in **1** is smaller by two units [Y^{III} instead of Zr^{IV}). That means that two of the 16 ligands in **1** must be neutral, i.e. must be coordinated in their protonated form. The protonated ligands are clearly identified by comparing the Ti−O and Y−O distances. The Ti−O distance associated with the OME group in **1** [Ti(2)−O(45) 218.0(2) pm] is much longer

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

than comparable Ti−OR distances *trans* to a μ_3-oxo ligand [for example, Ti−OPr 180.3(2) in $Ti_3O(OPr)_9(OOCPh)_2$,[9] 179.3(3) in $Ti_6O_4(OEt)_8(OAc)_8$,[10] or 178.7(2) in $Ti_4O_2(OiPr)_6(OMc)_6$ [5]]. Thus, O(45) *trans* to the μ_3-oxo group at Ti(2) is the oxygen atom of a coordinated alcohol rather than an alkoxide ligand. The alcoholic hydrogen atom at O(45) undergoes an intramolecular hydrogen bond with the non-coordinated oxygen atom O(41) of the neighboring μ_1-OMc ligand [O(41)−O(45) 259.4 pm]. The presence of a weakly coordinating ROH ligand also manifests itself in the very short Ti(2)−O(20) distance [173.4(2) pm] [for comparison, Ti-μ_3-O distances *trans* to Ti−OR are 185.6(2) in $Ti_3O(OPr)_9(OOCPh)_2$, 209.9(1) in $Ti_6O_4(OEt)_8(OMc)_8$ and 208.9(2) in $Ti_4O_2(OiPr)_6(OMc)_6$].

A very similar cluster was obtained when the $Ti(OR)_4/Y(OME)_3$ ratio in the starting mixture was 18. The structure of **2** (Figure 2 and 3, Table 2) is basically the same as that of **1** with coordinated methacrylic acid molecules instead of the coordinated alcohols [i.e., $Ti_4Y_2(\mu_3\text{-}O)_4(\mu_2\text{-}OMc)_{12}(\mu_1\text{-}OMc)_2(McOH)_2$]. This can be rationalized by the smaller concentration of methoxyethanol in the starting mixture due to the low portion of $Y(OME)_3$ (which is employed as a solution in methoxyethanol).

Table 2. Bond lengths [pm] and angles [deg] for **2** (*: $-x+1, -y, -z+1$)

O(21)−Y(1)−O(48)*	149.29(8)		

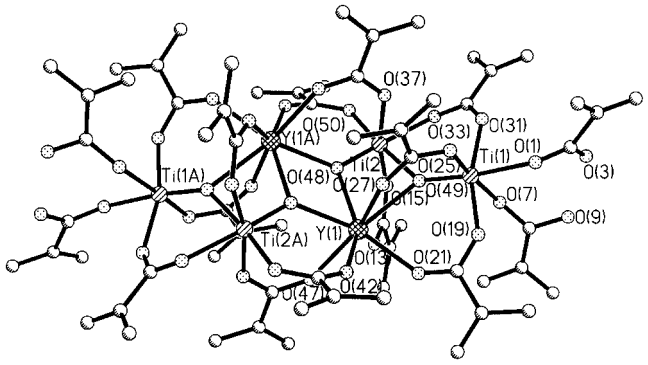

Figure 3. Molecular structure of $Ti_4Y_2O_4(OMc)_{14}(McOH)_2$ (**2**)

The coordinated methacrylic acid molecules are coordinated via the oxygen atom of their C=O double bond, while the OH hydrogen atom once again forms a hydrogen bond to the non-coordinated oxygen atom of the neighboring μ_1-OMc ligand [O(3)−O(9) 222.1(11) pm]. The Ti(1)−O(1) distance of the (neutral) methacrylic acid ligand [212.6(2) pm] is clearly longer than that of the (anionic) μ_1-methacrylate ligand [Ti(1)−O(7) 198.0(3) pm].

When the $Ti(OR)_4/Y(OME)_3$ ratio in the precursor mixture was lowered to 2, cluster **3** was obtained. The blueprint of **3** is completely different from that of **1** and **2**, although cluster **3** has the same overall composition as **1** (i.e. clusters **1** and **3** are geometric isomers). The neutral (protonated) ligand in **3** is McOH rather than $HOCH_2CH_2OMe$, as in **1**. This shift in protons results in dramatic structural changes. The structure (Figure 4, Table 3) consists of a ring of four corner-sharing [TiO_6] octahedra to which two [YO_8] dodecahedra are condensed (Figure 5). This arrangement of the polyhedra implies that only two of the oxo ligands are μ_3 [O(26)], while the other two oxo ligands are μ_2 [O(39)].

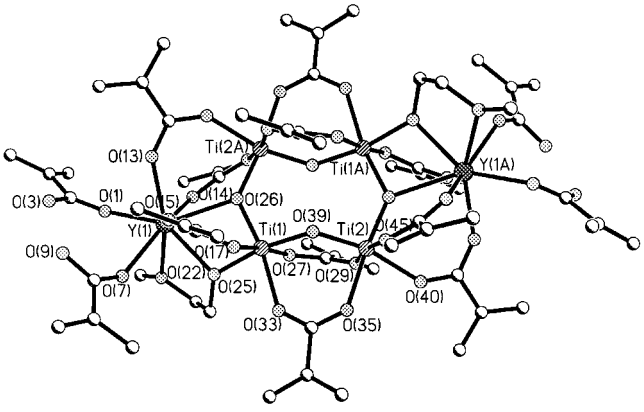

Figure 4. Molecular structure of $Ti_4Y_2O_4(OMc)_{12}(OCH_2CH_2OMe)_2(McOH)_2$ (**3**)

As in **2**, the neutral ligands are methacrylic acid molecules. However, in **3** both the monodentate OMc and HOMc ligands are bonded to the yttrium atoms. The methacrylic acid ligands are again coordinated via the oxygen atom of their C=O double bonds, and there is again a hydrogen bond between the OH hydrogen atom of the methacrylic acid and the non-coordinated oxygen atom of the neighboring μ_1-OMc ligand [O(3)−O(9) 240.8 pm].

Due to two oxo ligands now being μ_2 (rather than μ_3 as in **1** and **2**), each OCH_2CH_2OMe ligand in **3** must now occupy three coordination sites. In fact, the alkoxy oxygen atom [O(25)] bridges Ti(1) and Y(1), and the ether oxygen [O(22)] additionally coordinates to Y(1), thus **3** is $Ti_4Y_2(\mu_3\text{-}O)_2(\mu_2\text{-}O)_2(\mu_2\text{-}OMc)_{10}(\mu_1\text{-}OMc)_2(\mu,\eta^2\text{-}OCH_2CH_2OMe)_2(McOH)_2$.

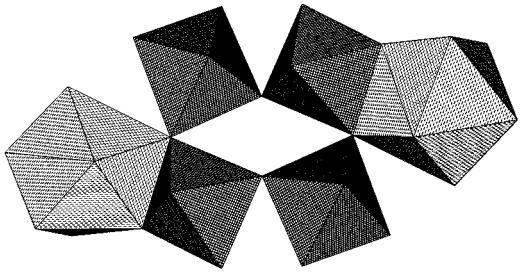

Figure 5. Cluster core of connected polyhedra in $Ti_4Y_2O_4(OMc)_{12}(OCH_2CH_2OMe)_2(McOH)_2$ (**3**). The central polyhedra are six-coordinate Ti and the terminal eight-coordinate Y.

Conclusions

Titanium-yttrium mixed-metal oxo clusters capped by polymerizable methacrylate ligands were prepared by reaction of mixtures of $Ti(OnPr)_4$ and $Y(OCH_2CH_2OMe)_3$ with methacrylic acid. Only the ratio between the two alkoxides was varied while the metal alkoxide/methacrylic acid ratio was kept constant. This procedure resulted in two different cluster types. At a Ti/Y ratio of 2 in the precursor mixture, the cluster $Ti_4Y_2O_4(OMc)_{12}(OCH_2CH_2OMe)_2(McOH)_2$ (**3**) was formed with a ring of four corner-sharing [TiO_6] octahedra as the central structural motive to which two [YO_8] dodecahedra are condensed. At a Ti/Y ratio $\geq$ 3.5, clusters of the type $Ti_4Y_2O_4(OMc)_{14}L_2$ (**1**: L = $MeOCH_2CH_2OH$, **2**: L = McOH) were formed. The basic structural motive is a zigzag chain of two central [YO_8] dodecahedra and two terminal [TiO_6] octahedra to which two additional [TiO_6] octahedra are condensed. The second cluster type is very similar to the previously obtained titanium-zirconium mixed-metal clusters $Ti_2Zr_4O_4(OBu)_2(OMc)_{14}$ and $Ti_4Zr_2O_4(OBu)_6(OMc)_{10}$. The formation of the two different Ti/Y oxo clusters is difficult to rationalize in terms of reactivity of the two alkoxide precursors. It must be kept in mind, however, that the $Ti(OPr)_4/Y(OME)_3$ precursor combination is more complicated than in previous syntheses of methacrylate-substituted oxo clusters: (i) An alcoholic solvent was involved, since $Y(OME)_3$ was employed as a methoxyethanol solution. Thus, when the $Y(OME)_3$ proportion was varied, the amount of methoxyethanol was also varied. It is well-known that the use of 2-methoxyethoxy groups changes sol-gel reactions of metal alkoxides significantly due to the coordination ability of the ether oxygen. (ii) The alkoxide ligands of the two metal precursors were different, and alkoxide exchange reactions may occur prior to reaction with the acid and/or water.

Another noteworthy feature of the clusters **1**−**3** is the presence of monodentate carboxylate ligands and coordinated alcohol or acid molecules. Both types of ligands are always in a *cis* position at the same metal. This allows the formation of a hydrogen bond between the alcoholic or carboxylic OH group and the C=O group of the monodentate methacrylate ligand, which probably stabilizes this unusual ligand combination. A similar situation was previously observed in the clusters $Zr_6(OH)_4O_4(OOCR)_{12}(n$PrOH) (R = Ph, CMe=$CH_2$).[11] The question whether conversion of a bidentate carboxylate ligand to a monodentate ligand, with concomitant coordination of a neutral ligand to the opened coordination site, is connected with the reactivity of the clusters is currently under investigation.

Experimental Section

All operations were carried out in Schlenk tubes under argon. $Ti(OPr)_4$ (98% in propanol) and $Y(OCH_2CH_2OMe)_3$ (11% in methoxyethanol) were used as received.

$Ti_4Y_2O_4(OMc)_{14}(MeOCH_2CH_2OH)_2$ (1): An amount of methacrylic acid (1.02 g, 11.8 mmol) was added dropwise at room temperature to a stirred mixture of $Ti(OPr)_4$ (0.38 g, 1.32 mmol) (98% in propanol) and 0.39 mmol of $Y(OCH_2CH_2OMe)_3$ (1.11 g of a ca. 11% methoxyethanol solution). After 7 days at room temperature, 0.31 g of colorless crystals were formed (87% yield relative to Y). The crystals were separated and dried at in vacuo. $C_{62}H_{86}O_{36}Ti_4Y_2$ (1776.7): calcd. C 41.9, H 4.9, TiO_2/Y_2O_3 30.6; found C 42.1, H 4.6, TiO_2/Y_2O_3 32.8 (TGA). IR-ATR: $\tilde{\nu}$ = 2927 (w, CH), 1668 (w, C=C), 1566 (s, sh, COO), 1464 (s), 1424 (s), 1270 (s), 1129 (m), 1031 (m), 978 (m,$CH_{C=CH_2}$), 849 (m), 797 (m) cm^{-1}.

$Ti_4Y_2O_4(OMc)_{14}(McOH)_2$ (2): An amount of methacrylic acid (2.57 g, 29.9 mmol) was added dropwise at room temperature to a stirred mixture of $Ti(OPr)_4$ (1.11 g, 3.8 mmol) (98% in propanol) and 0.21 mmol of $Y(OCH_2CH_2OMe)_3$ (0.60 g of a ca. 11% methoxyethanol solution). After 8 days at room temperature, 0.23 g of colorless crystals were formed (quantitative yield relative to Y). The crystals were separated and dried at in vacuo. $C_{64}H_{82}O_{36}Ti_4Y_2$ (1796.7): calcd. C 42.8, H 4.6, TiO_2/Y_2O_3, 30.2; found C 41.6, H 4.7, TiO_2/Y_2O_3, 32.4 (TGA). IR-ATR: $\tilde{\nu}$ = 2927 (w, CH), 1642 (w, C=C), 1546 (s, sh, COO), 1454 (s), 1405 (s, sh), 1241 (s), 1112 (m), 1007 (m), 940 (m, $CH_{C=CH_2}$), 827 (m), 764 (m) cm^{-1}.

$Ti_4Y_2O_4(OMc)_{12}(OCH_2CH_2OMe)_2(McOH)_2$ (3): Methacrylic acid (0.74 g, 8.6 mmol) was added dropwise at room temperature to a

X-ray Structure Analyses of 1−3: See also Tables 1−4. Selected crystals were mounted on a Bruker AXS SMART diffractometer with an APEX CCD area detector. Graphite-monochromated Mo-K_α radiation (71.073 pm) was used for all measurements. The crystal-to-detector distance was 5.00 cm. A hemisphere of data was collected by a combination of three sets of exposures at 173 K. Each set had a different φ angle for the crystal, and each exposure took 20 s and covered 0.3° in ω. The data were corrected for polarization and Lorentz effects, and an empirical absorption correction (SADABS) was applied. The cell dimensions were refined with all unique reflections. The structure was solved by direct methods (SHELXS-86). Refinement was carried out with the full-matrix least-squares method based on F^2 (SHELXL-93) with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were inserted in calculated positions and refined riding with the corresponding atom. In **2**, O(48) is disordered and was refined with a 0.5:0.5 occupation of O(48) and O48(A). Crystallographic data (excluding structure factors) for the structures of **1**−**3** have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-220753 (**1**), -220751 (**2**), -220752 (**3**). Nucleobase Oxidation of DNA by (Terpyridyl)chromium(III) Derivatives

Vaidyanathan Ganesan Vaidyanathan[a] and Balachandran Unni Nair*[a]

Keywords: Chromium / DNA cleavage / Photo cleavage / Terpyridyl ligands

The chromium(III) complexes $[Cr(ttpy)_2](ClO_4)_3$ (**1**) and $[Cr(Brphtpy)_2](ClO_4)_3$ (**2**), containing the terpyridyl derivatives ttpy and Brphtpy [ttpy = *p*-tolylterpyridine; Brphtpy = (*p*-bromophenyl)terpyridine] have been synthesized and characterized by ESI-MS, electronic spectroscopy, and cyclic voltammetry. Absorption titration and thermal denaturation studies reveal that both complexes are moderate binders of calf thymus DNA (CT DNA), while viscosity measurements show that they bind with partial intercalation. Binding of the two chromium complexes to DNA and mononucleotides dGMP, dAMP, dCMP, and dTMP decreases the emission intensity of complex **2**. However, the emission intensity of complex **1** is quenched only by DNA and the nucleotides dGMP and dAMP. Excited state potentials of both **1** and **2** have been estimated to be 1.65 and 1.85 V vs. NHE. These results demonstrate that **2** is a stronger photooxidant than **1**, and other (diimine)chromium complexes, and that it can oxidize nucleobases. The photonuclease activity of **1** and **2** has been confirmed by gel electrophoresis.

Introduction

The interaction of various metal ions with DNA has been investigated in great detail to understand the mode of binding of metal ions to DNA. Changes in ligand structure can alter the DNA binding properties of metalloporphyrins, Schiff-base−Mn^{III} complexes, phenanthroline−Cu^{II} complexes, and macrocyclic Ni^{II} complexes.[1−13] We have reported previously the influence of ligand structure on the DNA binding properties of Cr^{III} complexes.[14−18] A main offshoot of these studies has been the development of metal complexes that cleave DNA. Synthetic reagents that cleave DNA are of considerable interest as tools for molecular biologists − such cleavage has led to the development of both sequence-specific nucleases and footprinting agents. The redox properties of various transition metal complexes have been exploited for DNA cleaving. The anticancer drug bleomycin relies on a metal redox center for its DNA-cleaving reaction.[19−20] Polypyridyl complexes of oxoruthenium(IV) are efficient oxidative DNA-cleaving agents.[21] Another class of DNA-cleaving agents are those activated by light. Indeed, light-activated metal complexes have some distinct experimental advantages as they can be added to a protein−DNA complex and remain inert until photoactivation. One, therefore, has control over the timing of these reactions and hence the potential to examine protein−DNA interactions directly with some time resolution. (Polypyridyl)metal complexes of d^6 systems, such as Ru^{II}, Rh^{III}, and Co^{III}, are used extensively as photophysical probe and as photochemical agents because of their room-temperature luminescence.[22−26] Because these complexes are coordinatively saturated, there is no opportunity for reactions other than electron and energy transfer. Thus cleavage of DNA by complicated hydrogen atom or oxo transfer pathways is unlikely, and the binding modes of the complexes can be studied exclusively. Coordinatively saturated phenanthrenequinone diimine (phi) complexes of Rh^{III}, $[Rh(phi)(bpy)_2]^{3+}$, are conformationally selective photocleaving agents.[24−26] Surprisingly, despite its extensive photochemistry, Cr^{III} complexes have found little use as photoprobes for nucleic acids. Even though certain Cr^{III} complexes exhibit nuclease activity, the photochemistry of only some diimine complexes, such as $[Cr(bpy)_3]^{3+}$, $[Cr(phen)_3]^{3+}$, $[Cr(phen)_2(dppz)]^{3+}$, and $[Cr(TMP)_3]^{3+}$, has been investigated in the presence of DNA because of their strong room-temperature luminescence ($^2E_g \rightarrow {}^4A_{2g}$ phosphorescence).[27−29] We report here the synthesis and characterization of the terpyridyl−Cr^{III} complexes **1** and **2** and the photocleavage of DNA in the presence of these complexes.

Results and Discussion

Synthesis and Characterization

The chromium(III) complexes **1** and **2** were synthesized by the reaction of $[Cr(H_2O)_6]^{2+}$ and the corresponding ligand under nitrogen followed by air oxidation. Both complexes showed satisfactory elemental analyses and IR spectra. Their authenticity was confirmed by their ESI mass spectra.

Like other polypyridyl and terpyridyl complexes of Cr^{III}, complexes **1** and **2** exhibit multiple absorbances between 200 and 800 nm (Table 1), as well as ligand-centered absorbances at 285 and 287 nm, respectively. The visible absorption bands can be attributed to ligand field transitions. The lowest energy ligand field transition for complex **1** appears at 576 nm and the same transition for **2** appears at 564 nm. Other ligand field transitions occur at 481 and 450 nm for complex **1** and at 472 and 442 nm for **2**. Both complexes are electrochemically active and exhibit multiple reduction processes. Their cyclic voltammograms show well-separated reduction waves at −0.19, −0.5, −0.96, −1.913, and −2.196 V (for **1**) and −0.14, −0.45, −0.94, −1.767, and −2.20 V (for **2**) (Figure 1). The first three electrochemical waves are reversible one-electron processes with ΔE_p = 58−65 mV at all scan rates (Table 2). The first two reduction potentials at −0.18 and −0.5 V (**1**) and −0.14 and −0.45 V (**2**) could be due to two reversible one-electron reduction processes arising from Cr^{III}/Cr^{II} and Cr^{II}/Cr^{I} couples, respectively. For $Cr(tpy)_2{}^{3+}$, the Cr^{III}/Cr^{II} and Cr^{II}/Cr^{I} couples are reported to be at −0.28 and −0.69 V vs. SCE, respectively.[30] The less negative reduction potential observed here for these complexes, compared with the parent terpyridyl ligand, could be due to the substituent effect on the terpyridyl ligand. In the present case, on substituting tolyl and bromophenyl group to the terpyridyl ligand, the metal-centered redox potentials shift toward more positive values than for the parent terpyridyl complex of chromium.

DNA Binding Experiments

Absorption Titration of Chromium Complex with Calf Thymus DNA

Interaction of the complexes with DNA was investigated by monitoring the absorption spectra of the complexes in the presence and absence of DNA (Figure 2). The absorption maxima of both chromium(III) complexes are shifted by 3−5 nm in the presence of DNA. A noticeable hypochromicity arises due to interaction of the two chromium complexes with DNA. The intraligand transitions show a decrease in intensity to the maximum of 22% for complex **1** and 19% for complex **2** on addition of an incremental amount of DNA. These spectroscopic changes suggest that there are interactions between the metal complexes and DNA. Such hypochromicity has been attributed to intercalative binding.[31] Notably, the hypochromicities of the peaks are lower than those of classical intercalators such as ethidium bromide and $[Ru(phen)_2(dppz)]^{2+}$ whose percentage hypochromicities are > 25%.[32] The binding constants of the complexes with DNA have been measured from absorption titration as reported earlier.[15] Intrinsic binding constants for complexes **1** and **2** with DNA calculated to be $3.1\pm0.2\times10^3$ and $1.252\pm0.2\times10^4$ M^{-1}, respectively, which are lower than the 10^6-10^7 M^{-1} of classical intercalators,[32] but similar to some of the chromium and ruthenium complexes, which prefer surface binding to DNA.[14−18] These results indicate that the preferred binding mode of complexes **1** and **2** to DNA is surface binding or electrostatic interaction.

Viscosity Measurements

A critical test for a binding model in solution in the absence of crystallographic structural data is hydrodynamic measurement, which is more sensitive to the length change of nucleic acid. Of the hydrodynamic measurements, viscosity measurements provide a tool for the study of metal−DNA interaction since optical studies provide necessary but not sufficient clues to support the binding model. Generally, classical intercalators increase the viscosity of DNA due to the accommodation of the ligand between the base pairs of the helix. In contrast, non-classical intercalators could bend or kink the DNA helix, reduce its effective length and concomitantly its viscosity. Here, the viscosity of CT DNA increased with increasing concentration of **1** and **2** (Figure 3). Such a trend is typical of intercalators. However, since complexes **1** and **2** have octahedral geometry and the ligands are not strictly coplanar one can expect only partial intercalation of these molecules between the DNA bases.

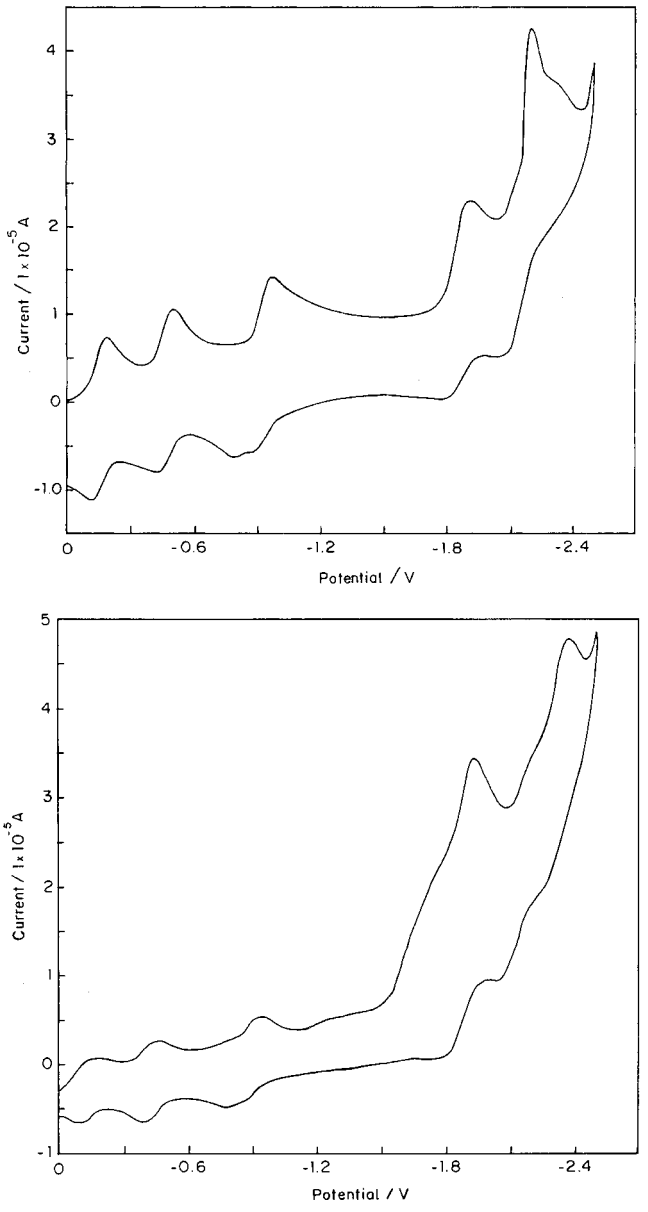

Figure 1. Cyclic voltammogram of the complexes **1** (top) and **2** (bottom) in CH_3CN (0.1 M TBAP as supporting electrolyte, scan rate = 100 mV/s)

Thermal Denaturation Study

The melting of DNA can be used to distinguish between those molecules that bind by intercalation and those that bind externally, i.e. electrostatically. Two parameters can be derived from the thermal denaturation curves of DNA, namely the melting temperature (T_m) at which 50% of the DNA has become single-stranded, and the curve width (σ_T), the temperature range within which 10−90% of the denaturation occurs.[33] DNA melting revealed ΔT_m values of calf thymus DNA in the presence of complexes **1** and **2** of 3±0.5 and 5±0.5 °C, respectively; $\Delta\sigma_T$ values for the duplex in the presence of **1** and **2** were 3±0.5 and 5±0.5 °C, respectively. Generally, one would expect a much larger increase in T_m and σ_T for classical intercalators, e.g. ethidium bromide, which shows an increase in the T_m of DNA of 14 °C and a curve width of 22 °C.[34] The magnitude of the increase in T_m and σ_T for DNA in the presence of **1** and **2** indicates that their interaction with DNA is non-intercalative binding. This is also reflected in the binding constant.

[a] This complex also shows two ligand-centered redox waves with $E_{1/2}$ of −1.99 and −2.37 V.

Luminescence Study

Aqueous solutions of the complexes **1** and **2** emit strongly at room temperature. In aqueous solution, complexes **1** and **2** show strong emission bands ($^2E_g \rightarrow {}^4A_{2g}$) at 773 nm and 707 nm, respectively, on excitation at 340 nm. The emission spectral bands, which represent the 0−0 transition of $^2E_g \rightarrow {}^4A_{2g}$, are only slightly sensitive to the nature of ligand substituents with diimine systems. For example, on substitution of a phenyl group on the bipyridyl ligand, there is a red-shift of 14 nm in the emission spectra of the corresponding chromium complex. $[Cr(tpy)_2]^{3+}$ shows a red-shift of 42 nm in the emission bands compared with $[Cr(bpy)_3]^{3+}$.[35] The $^2E_g \rightarrow {}^4A_{2g}$ band is seen at 728 nm for $[Cr(bpy)_3]^{3+}$ but occurs at 770 nm for $[Cr(tpy)_2]^{3+}$. Interestingly, substituting the bromophenyl group on the terpyridyl ligand results in a drastic blue-shift in the emission band of $[Cr(Brphtpy)_2]^{3+}$, by 63 nm compared with the parent (terpyridyl)chromium complex. However, a *p*-tolylterpyridyl substituent yields a red-shift of 3 nm in the emission maxima compared with the emission maxima of $[Cr(tpy)_2]^{3+}$. Generally, the binding of a luminescent compound to DNA or polynucleotides leads to an increase in the emission and excited state lifetime due to the rigidity of DNA microenvironment and protection from solvent quenching. The influence of DNA on the emission of **1** and **2** has been examined. Interestingly, the emission intensity of the complexes is quenched by the addition of incremental amounts of DNA, in contrast to $[Cr(bzimpy)_2]^+$.[36] Effects of nucleotides dGMP, dAMP, dCMP, and dTMP on the emission intensity of **1** and **2** have also been examined. The emission intensity of complex **1** at 773 nm was quenched by

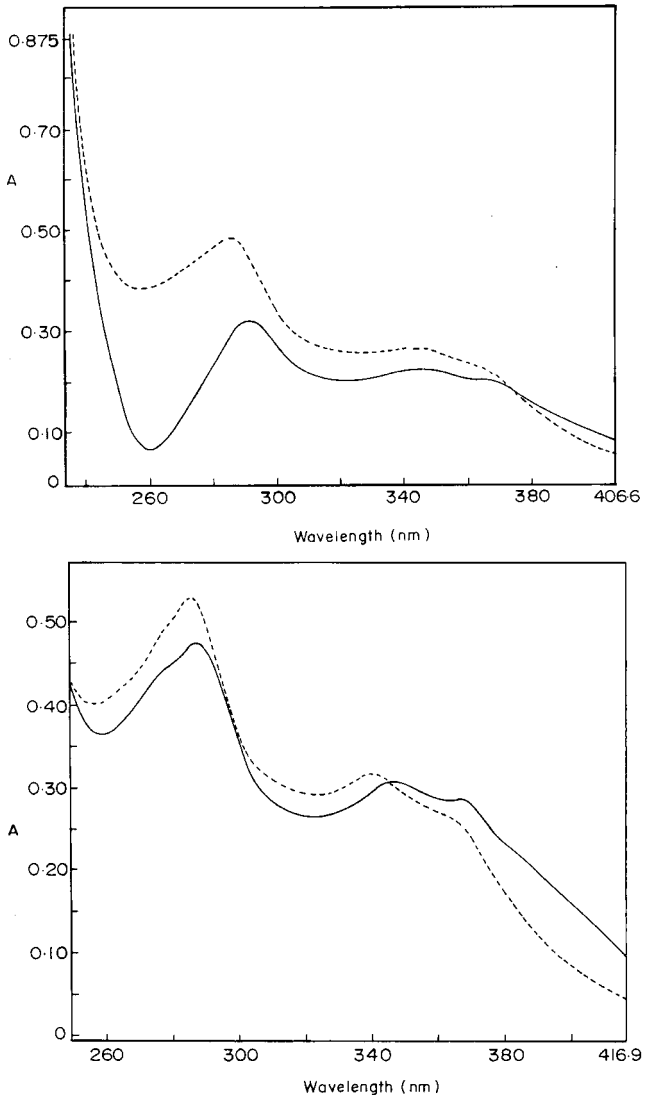

Figure 2. Absorption spectra of **1** (top) and **2** (bottom) in the absence (---) and presence (—) of increasing amounts of CT DNA; [Cr] = 10 μM; [DNA] = 0−220 μM

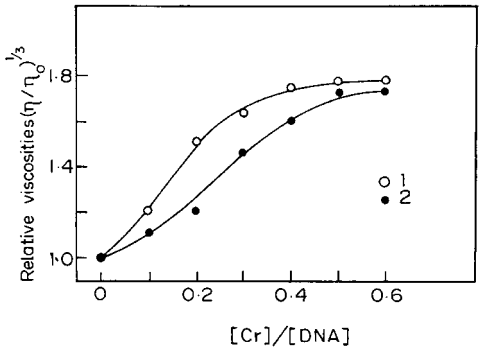

Figure 3. Effect of increasing $[Cr(ttpy)_2]^{3+}$ (**1**) and $[Cr(Brphtpy)_2]^{3+}$ (**2**) on the relative viscosity of DNA

dGMP and dAMP, but not affected by dCMP and dTMP (Figure 4, top). Conversely, the emission intensity complex **2** was quenched by all four mononucleotides (Figure 4, bottom). Stern−Volmer plots for steady-state emission intensity quenching are expected to be a straight line for dynamic quenching. Figure 4 (top and bottom), show plots with upward curvature at higher nucleotide concentrations. Such behavior indicates an additional deactivation pathway involving static quenching, attributed in this case to nucleotide-bound chromium(III) complex. To probe the mechanism for the quenching of the complexes **1** and **2** by DNA and mononucleotides, the excited state potentials were calculated using Equation (1), where $E°(Cr^{3+}/Cr^{2+})$ is the ground-state reduction potential and $E_{0-0}(Cr^{3+}/Cr^{2+})$ is the potential calculated from the emission energy. The excited state potentials for complexes **1** and **2** were calculated as +1.65 V and +1.85 V vs. NHE, respectively. The excited state potential of complex **1** is higher than that of dGMP (1.29 V) and dAMP (1.4 V) but similar to those of dCMP (1.53 V) and dTMP (1.63 V).[37] However, for complex **2**, $E°(*Cr^{3+}/Cr^{2+})$ is much higher than that of all the four nucleotides. Hence, the quenching process clearly could be due to electron transfer from a nucleobase to an excited state complex. Such luminescent quenching has been reported for various ruthenium compounds as well as chromium complexes containing diimine systems. However, in the present investigation, chromium(III) complexes having a triimine system, such as the (*p*-bromophenyl)terpyridyl derivative, exhibited a much higher excited-state oxidizing power than complex **1** and also diimine−Cr^{III} systems such as $[Cr(bpy)_3]^{3+}$, $[Cr(phen)_3]^{3+}$, and $[Cr(TMP)_3]^{3+}$. Notably, coordination of triimine ligands like ttpy and Brphtpy gives chromium complexes with a much higher excited state potential than that observed for the diimine−Cr^{III} complexes such as $[Cr(bpy)_3]^{3+}$, $[Cr(phen)_3]^{3+}$, and $[Cr(TMP)_3]^{3+}$, whose excited state potentials are in the range of 1.2−1.5 V.

$$E°(*Cr^{3+}/Cr^{2+}) = E°(Cr^{3+}/Cr^{2+}) - E_{0-0}(Cr^{3+}/Cr^{2+}) \quad (1)$$

Photonuclease Activity

One possible consequence of electron transfer from a nucleobase to a molecule in the ground state or excited state is a single strand break of DNA. This process is generally demonstrated by gel electrophoresis of plasmid DNA, because the conversion of the supercoiled, closed circular form of plasmid DNA into an open circular form, induced by a single strand nick, is easily monitored. To support the electron transfer from the nucleobase to the excited state of a chromium(III) complex, we have carried out gel electrophoresis of plasmid DNA after irradiating it in the presence of the complexes **1** and **2**. On excitation of complexes **1** and **2** at 340 nm in the presence of supercoiled plasmid DNA, a single strand break was observed (lanes 4 and 5 of Figure 5). DNA cleavage was not observed for the complex with DNA without irradiation (lanes 2 and 3). A possible role of singlet oxygen has also been ruled out in the present case because the strand break was not inhibited by the addition of a singlet oxygen scavenger such as sodium azide (lanes 6 and 7); furthermore, reactions carried out in D_2O

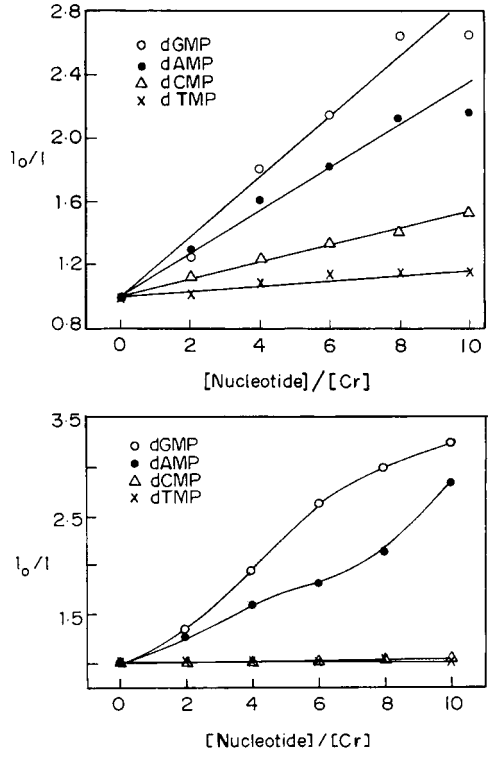

Figure 4. Relative emission intensity of the complexes **1** (bottom) and **2** (top) in the presence of mononucleotides; [Cr]= 10 μM; [nucleotides] = 20−100 μM

showed no enhancement in cleavage reaction (not shown). From the above observations, it is assumed that formation of a radical cation of guanine by electron transfer to the excited state of the complex plays a key role in this damage event since the guanine base is the most oxidizable base of all the four bases. Similar photonuclease activity has also been reported for photooxidizing agents such as $[Ru(TAP)_3]^{2+}$, $[Ru(bzimpy)_2]^{2+}$, $[Ru(bpz)_3]^{2+}$, and $[Ru(bpz)_2(DPPZ)]^{2+}$.[38−41]

Conclusions

The cations $[Cr(ttpy)_2]^{3+}$ and $[Cr(Brphtpy)_2]^{3+}$ exhibit very high excited-state oxidizing power and bring about electron transfer from DNA bases to the excited state of the complex. These complexes also bring about cleavage of plasmid DNA upon photoirradiation. Such photonuclease activity by metal complexes can be exploited to develop footprinting agents in molecular biology.

Experimental Section

Chemicals: 2-Acetylpyridine and *p*-tolualdehyde were obtained from Sigma Aldrich chemicals and used as received. *p*-Bromobenzaldehyde was purchased from Lancaster chemicals, and used as received. Calf thymus DNA, Hepes, Tris, and mononucleotides were obtained from SRL chemicals, Mumbai. The stock solution of DNA was prepared by stirring the sample, dissolving in Hepes buffer (10 mM, pH = 7.0), at 4 °C. The solution was then dialyzed exhaustively against buffer for 48 h and filtered using a membrane filter obtained from Sartorius (0.45 μm). Filtered DNA solution in the buffer gave a UV absorbance ratio A_{260}/A_{280} of about 1.9, indicating that the DNA was sufficiently free from protein.[42] The concentration of DNA was determined by using the molar absorption coefficient of 6600 $M^{-1}\cdot cm^{-1}$ at 260 nm.[43] The stock solution of the Cr^{III} complex was prepared in water and its concentration estimated according to a reported procedure.[44] All solvents used were of analytical grade, received from Ranbaxy, Mumbai, and were used without further purification. All experiments were carried out in Hepes buffer at pH = 7.0 in Milli Q water.

Methods: UV/Vis spectra of the chromium(III) complexes and DNA binding studies were recorded with a Perkin−Elmer Lambda 35 double beam spectrophotometer at 25 °C. Elemental analyses were performed using a Heraeus-CHN-Rapid Analyzer at RSIC, IIT, Madras. Emission spectra were recorded with a Hitachi 650-40 spectrofluorimeter. Electrospray ionisation (ESI) mass spectra of the complexes were recorded with a Hewlett Packard 1100 mass spectrometer equipped with an electron spray source. Infrared spectra of the complex were recorded with a Perkin−Elmer FT-IR spectrometer. Cyclic voltammetry experiments were performed with an EG and G PAR 173 potentiostat/Galvanostat analyzer. Tetrabutylammonium perchlorate (TBAP) was used as supporting electrolyte. A standard three-electrode system was used, consisting of a glassy carbon as working electrode, platinum electrode as auxiliary electrode and a saturated calomel solution as reference electrode (SCE).

Synthesis of $[Cr(ttpy)_2](ClO_4)_3$ (1): The ligand ttpy was prepared according to a literature procedure.[45] Subsequently, ttpy (0.646 g, 2 mmol), dissolved in methanol (10 mL), was taken and purged with nitrogen for 20 min. To this a deaerated solution of the ligand, a $[Cr(H_2O)_6]^{2+}$ solution (1 mmol), was added under nitrogen. The resulting brown solution was then bubbled with air for 3 h. The resultant orange-yellow compound was filtered off and recrystallized from a mixture of acetone/water (2:1). The recrystallized product was then filtered off, washed with diethyl ether, and dried under vacuum. ESI-MS: m/z = 696 $[M - 2H^+ - 3ClO_4]^+$. $C_{44}H_{34}Cl_3CrN_6O_{12}$ (997.12): calcd. C 53.00, H 3.44, N 8.43, Cr 5.21; found C 52.85, H 3.32, N 8.38, Cr 5.11.

Synthesis of $[Cr(Brphtpy)_2](ClO_4)_3$ (2): The ligand Brphtpy was prepared according to a literature procedure.[46] The chromium(III) complex was synthesized according to the above procedure, using Brphtpy in place of ttpy. ESI-MS: m/z = 826 $[M - 2H^+ - 3ClO_4]^+$. $C_{42}H_{28}Br_2Cl_3CrN_6O_{12}$ (1126.86): calcd. C 44.70, H 2.50, N 7.46; Cr, 4.61; found C 44.75, H 2.41, N 7.38; Cr, 4.43.

Caution! Although we had no difficulty during working, perchlorate salts are potentially explosive! Utmost care should be exercised in handling perchlorate salts.

DNA Binding Studies: Electronic spectra of Cr^{III} complexes were monitored in the presence and absence of DNA. The binding constants for the interaction of Cr^{III} complexes with DNA were obtained from absorption titration data. A fixed amount of the complex (10 μM) was titrated with increasing amounts of DNA, over the range 20−220 μM. The binding constant was then determined using Equation (2), where ε_A, ε_F, and ε_B correspond to A_{obsd}/[Cr], the molar absorption coefficient for the free chromium complex and the molar absorption coefficient for the chromium complex in the fully bound form, respectively. A plot of [DNA]/($\varepsilon_A - \varepsilon_F$) vs. [DNA], gives K_b as the ratio of the slope to intercept.

$$[DNA]/(\varepsilon_A - \varepsilon_F) = [DNA]/(\varepsilon_B - \varepsilon_F) + 1/K_b(\varepsilon_B - \varepsilon_F) \quad (2)$$

Thermal denaturation studies were conducted in a Perkin−Elmer Lambda 35 spectrophotometer equipped with thermostatted cell holder. The temperature was controlled by a Peltier system (±0.1 °C). The absorbance at 260 nm was monitored for DNA in the absence and the presence of the complexes. Viscometric experiments were carried out using an Ostwald-type viscometer (2 mL capacity), thermostated in a water bath maintained at 25±1 °C. Flow rates of buffer (10 mM), DNA (150 μM), and DNA in the presence of Cr^{III} complex at various concentrations (15−90 μM) were measured with a manually operated timer at least three times to agree within 1 s. The viscosity was calculated according to $\eta = (t - t_0)/t_0$, where t_0 is the flow time for the buffer and t is the observed flow time for DNA in the presence and absence of the complex. Plots of $(\eta/\eta_0)^{1/3}$ vs. R (R = [complex]/[DNA]) were constructed from the viscosity measurements.[47] Steady-state emission spectra of complexes **1** and **2** in the presence of DNA were recorded. The concentration of complexes was fixed (10 μM) while that of DNA was varied from 20 to 100 μM. The Cr^{III} complexes were excited at 340 nm and the emission intensity of the complexes **1** and **2** monitored at 773 and 707 nm, respectively. Time-resolved fluorescence for the complexes was determined using a picosecond-laser-excited TCSPC spectrometer. The excitation source was a tunable Ti-Sapphire laser (Tsunami, Spectrophysics, USA) with a pulse width of < 2 ps and repetition rate of 82 MHz. Samples were excited at 340 nm and the emission monitored using an MCP-PMT (Hamamatsu-C 4878) detector. The decay traces were deconvoluted using a non-linear least-squares analysis with IBH software.

Gel electrophoresis of plasmid DNA (pBR322 DNA) was carried out with a reaction mixture (25 μL) containing plasmid DNA (4 μL of 200 μg·mL^{-1}), a solution of complex **1** and **2** (5 μL of 0.1 mM) and remaining buffer. NaN_3 solution (5 μL) was then added to one of the samples. Metal/DNA solutions were preincubated for 1 h in the dark and the samples were kept in a spectrofluorimeter sample chamber. The sample was then irradiated at 340±5 nm for 20 min and subsequently analyzed by 0.8% agarose gel electrophoresis (Tris/boric acid/EDTA buffer, pH = 8.0) at 50 V for 4 h. The gel was stained with 0.5 μg·mL^{-1} ethidium bromide and then illuminated under a UV lamp and photographed with Polaroid film using a Kodak DC-40 digital camera.

Activation of H_2 and CO by Sulfur-Rich Nickel Model Complexes for [NiFe] Hydrogenases and CO Dehydrogenases[‡]

Dieter Sellmann,[a][†] Raju Prakash,*[a] and Frank W. Heinemann[a]

Keywords: Hydrogenases / H_2 activation / Nickel / N ligands / S ligands

Reactions of the trinuclear complexes [Ni($^{R}S_3$)]$_3$ [$^{H}S_3^{2-}$ = bis(2-mercaptophenyl)sulfide(2–) (**1a**) or $^{si}S_3^{2-}$ = bis(2-mercapto-3-trimethylsilylphenyl)sulfide(2–) (**1b**)] with nucleophiles L (L = NHP*n*Pr$_3$, NHPCy$_3$, NHSPh$_2$, P*n*Pr$_3$) afforded the corresponding mononuclear complexes [Ni(L)($^{R}S_3$)] [R = si = SiMe$_3$; L = NHP*n*Pr$_3$ (**2b**); L = NHPCy$_3$ (**3a**,**b**); L = NHSPh$_2$ (**4a**,**b**); L = P*n*Pr$_3$ (**5a**)]. X-ray structural determinations showed that **2b**, **3a**, **3b**, **4a**, and **5a** exhibit tetrahedrally distorted planar [Ni(L)($^{R}S_3$)] fragments. Complex **2b** dimerizes through intermolecular N–H···N hydrogen bonding. In contrast to **2b**, complexes **3a** and **4a** exhibit intramolecular hydrogen bonds between thiol groups and NH protons. Complexes **2**–**4** possess weakly acidic NH protons and undergo D$^+$/NH exchange reactions with D_2O or CD_3OD. Complexes **2**–**4** and [Ni(S*t*Bu)($^{R}S_3$)]$^-$ (**9a**,**b**) also catalyze D_2/H$^+$ exchange in [D_8]THF/H_2O under an elevated pressure of D_2 (18 bar), as confirmed by ^{1}H NMR spectroscopy. It is proposed that D_2 heterolysis is achieved through attack of the Lewis-acidic nickel centers and the Brönsted-basic sulfur atoms at an η^2-D_2 ligand. Complexes **9a** and **9b** are the first sulfur-only nickel complexes that enable the modeling of the [NiFe] hydrogenase catalyzed D_2/H$^+$ exchange reaction. Evidence for labile five-coordinate [Ni(CO)(L)($^{R}S_3$)] has been found in the reaction between [Ni(L)($^{R}S_3$)] complexes and CO. The CO adducts of complexes with nitrogenous ligands L such as N_3^-, NHPR$_3$ (R = *n*Pr$_3$, Cy$_3$), or NHSPh$_2$ showed rapid consecutive reactions. The reaction between Et$_4$N[Ni(N_3)($^{si}S_3$)] (**8b**) and CO gave Et$_4$N[Ni(NCO)($^{si}S_3$)] (**10b**), whereas reactions between **2**–**4** and CO afforded only **1a** or **1b**. Mechanisms are suggested which have the formation of reactive five-coordinated [Ni(CO)(L)($^{R}S_3$)] intermediates in common.

Introduction

Modeling active sites in metalloenzymes is the motivation for the synthesis of low-molecular-weight complexes that exhibit the structural and reactivity features of the enzyme centers.[1] A key feature of the active sites of hydrogenases and CO dehydrogenases are nickel atoms in sulfur-dominated coordination spheres.[1–5] X-ray structural determinations of several [NiFe] hydrogenases[2,3] and two CO dehydrogenases[4,5] have established that the active sites contain four-coordinate nickel atoms in tetrahedrally distorted planar coordination spheres of sulfur atoms[2–5] (Figure 1). These centers are generally accepted to be the location of the reactions catalyzed by hydrogenases [Equation (1a), (1b)] and CO dehydrogenases [Equation (2)].

$$2\,H^+ + 2\,e^- \rightleftharpoons H_2 \quad (1a)$$

$$H_2 \rightleftharpoons H^+ + H^- \quad (1b) \qquad (1)$$

$$CO + H_2O \rightleftharpoons CO_2 + 2\,H^+ + 2\,e^- \qquad (2)$$

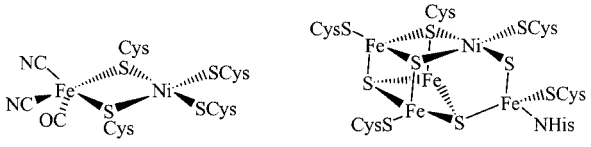

Figure 1. Schematic structures of the active centers in fully reduced [NiFe] hydrogenase from *D. vulgaris* Miyazaki[2] (left) and the CO dehydrogenase from *C. hydrogenoformans*[4,5] (right)

Catalysis of the reactions in Equations (1) and (2) makes hydrogenases and CO dehydrogenases essential for energy metabolism in nature. Low-molecular-weight nickel complexes with sulfur-dominated coordination spheres and reactivity towards H_2, CO, or CO_2 thus have considerable significance for gaining closer insights into the mechanisms of the reactions according to Equations (1) and (2), and for the development of competitive catalysts. Such complexes,

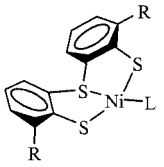
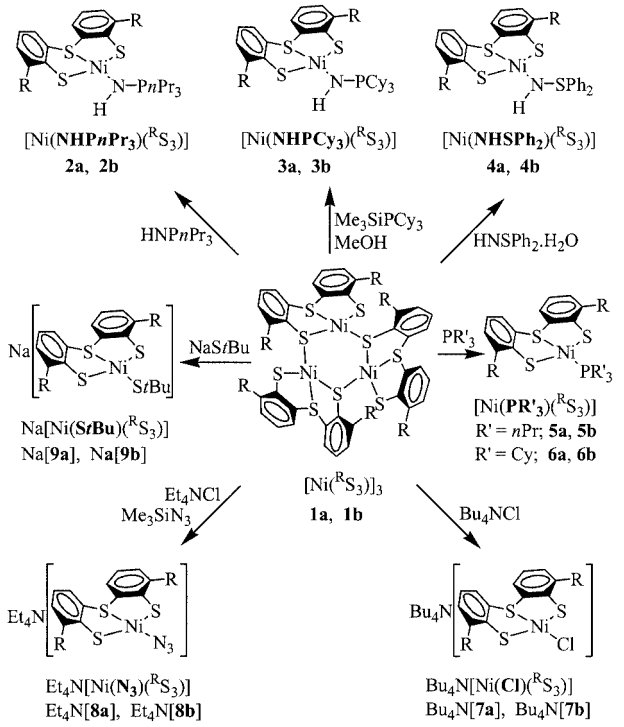
[†] Deceased.

however, are extremely rare. [Ni(L)($^{R}S_3$)] is one of the very few examples of complexes of type **A**, in which $^{R}S_3$ denotes the tridentate sulfur ligands $^{H}S_3^{2-}$ [bis(2-mercaptophenyl)sulfide(2−)] or $^{si}S_3^{2-}$ [bis(2-mercapto-3-trimethylsilylphenyl)sulfide (2−)] and L neutral or anionic ligands, such as PR_3, HNP*n*Pr$_3$, Cl^-, N_3^-, or S*t*Bu$^-$.[6−9]



A [Ni(L)($^{R}S_3$)]

Recent findings that the neutral phosphorane imine complex [Ni(NHP*n*Pr$_3$)($^{H}S_3$)] catalyzes the heterolytic activation of H_2 [Equation (1b)][6] and the anionic complex [Ni(N_3)($^{H}S_3$)]$^-$ reacts with CO to give [Ni(NCO)($^{H}S_3$)]$^-$ [7] prompted us to explore this type of complex in greater detail. This paper focuses on the synthesis and characterization of [Ni(L)($^{H}S_3$)] and its analogous [Ni(L)($^{si}S_3$)] complexes, and their reactivity towards H_2. In addition, we extend our investigation towards the reactivity of [Ni(L)($^{R}S_3$)] complexes with CO in an effort to identify the possible five-coordinate intermediate species by means of spectroscopic techniques.



Scheme 1. Synthesis of [Ni(L)($^{R}S_3$)] complexes (R = H → **a**; R = $SiMe_3$ → **b**)

Results and Discussion

Synthesis and Characterization of [Ni(L)($^{H}S_3$)] and [Ni(L)($^{si}S_3$)] Complexes

[Ni(L)($^{R}S_3$)] complexes containing different ligands L are a prerequisite for probing the influence of L upon the potential activation of H_2 and CO. Scheme 1 summarizes the synthesis of such [Ni(L)($^{R}S_3$)] complexes. The letters **a** and **b** always designate the unsubstituted (R = H) and substituted (R = $SiMe_3$ = si) complexes, respectively. For the sake of completeness, Scheme 1 also includes complexes **2a**, **5b**, **6a**/**6b**, Bu$_4$N[**7a**/**7b**], and Et$_4$N[**8b**], which have been reported previously.[8,9] In most cases, the new complexes were obtained by cleavage of the trinuclear starting complexes [Ni($^{R}S_3$)]$_3$ (**1a**,**b**) with nucleophiles L.

Treatment of **1b** with NHP*n*Pr$_3$ in THF gave purple [Ni(NHP*n*Pr$_3$)($^{si}S_3$)] (**2b**) in analogy to the known synthesis of **2a**. The bulkier phosphorane imine $HNPCy_3$ had to be generated in situ through methanolysis of $Me_3SiNPCy_3$ and treated with **1a** and **1b** to afford [Ni(NHPCy$_3$)($^{R}S_3$)] (**3a**,**b**). These reactions could be monitored visually by the color change of the THF suspension (**1a**) or THF solution (**1b**) from red-brown to purple-red. Complex **1b** reacted much faster than complex **1a**.

Diphenylsulfimine, $HNSPh_2$, can potentially coordinate through either its nitrogen or sulfur atom. Reactions of **1a** and **1b** in THF with equimolar amounts of diphenylsulfimine hydrate, $NHSPh_2{\cdot}H_2O$, afforded the first examples of sulfimine sulfur-only nickel complexes as red-brown [Ni(NHSPh$_2$)($^{H}S_3$)] (**4a**) and dark-red [Ni(NHSPh$_2$)($^{si}S_3$)] (**4b**). The X-ray structure determination of **4a** proved that $HNSPh_2$ coordinates to the nickel atom through its N atom like the phosphorane imines.[8c]

Red-yellow crystals of [Ni(P*n*Pr$_3$)($^{H}S_3$)] (**5a**) formed instantaneously when a black-brown THF suspension of **1a** was treated with an equivalent amount of P*n*Pr$_3$. The analogous synthesis of **5b** could be carried out in homogeneous phase in THF. The chloro complexes Bu$_4$N[Ni(Cl)($^{H}S_3$)] (Bu$_4$N[**7a**]) and Bu$_4$N[Ni(Cl)($^{si}S_3$)] (Bu$_4$N[**7b**]) were obtained from **1a** and **1b** with Bu$_4$NCl. The anions **7a** and **7b** were required as precursors for the synthesis of the azido complexes Et$_4$N[Ni(N_3)($^{H}S_3$)] (Et$_4$N[**8a**]) and Et$_4$N[Ni(N_3)($^{si}S_3$)] (Et$_4$N[**8b**]), which formed from the reaction of **1a** and **1b**, respectively, with Et$_4$NCl and subsequent reaction with Me_3SiN_3. The sodium derivatives Na[Ni(S*t*Bu)($^{H}S_3$)] (Na[**9a**]) and Na[Ni(S*t*Bu)($^{si}S_3$)] (Na[**9b**]) were obtained from **1a** and **1b** with NaS*t*Bu, similar to the formation of similar Bu$_4$N derivatives reported in the literature.[8,9]

All new complexes were isolated in analytically pure form, are soluble in THF, CH_2Cl_2, acetone, DMF, or DMSO, and were characterized by IR and NMR spectroscopy, and mass spectrometry. The molecular structures of **2b**, **3a**, **3b**, **4a**, and **5a** were determined by X-ray crystallography.

The IR (KBr) spectra of the complexes exhibit absorption patterns typical for complexes with [Ni($^{H}S_3$)] or [Ni($^{si}S_3$)] fragments. The HNPR$_3$ and $HNSPh_2$ ligands of **2**−**4** give rise to sharp ν(NH) bands in the region

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3365−3200 cm^{-1} and ν(NP) or ν(NS) bands in the region 995−915 cm^{-1}. The ν(NH), ν(NP), and ν(NS) bands correspond to those of $HNPR_3$ [10] and $HNSPh_2$ [11] complexes reported previously. In comparison to the ν(NH) band of free $HNPnPr_3$ (3368 cm^{-1}), the ν(NH) band in **2b** (3298 cm^{-1}) is significantly red-shifted. Similarly, the ν(NH) band of **4a** (3202 cm^{-1}) and **4b** (3210 cm^{-1}) appears at lower wavenumbers than that of free $HNSPh_2$ (3306 cm^{-1}).[11b] The solid-state IR spectra of **3a** and **4a** also contain weak bands at 2560 cm^{-1} (**3a**) and 2559 cm^{-1} (**4a**), indicating the existence of N−H···S(thiolate) bridges. Such hydrogen-bond bridges were confirmed by the X-ray structure determinations.

As judged by their well-resolved NMR spectra, the complexes are diamagnetic. The ^1H NMR spectra of all complexes show a characteristic splitting pattern for the aromatic protons, consisting of either four or three multiplets depending on the fragment [Ni($^HS_3$)] or [Ni($^{si}S_3$)]. In **4a** and **4b**, some of these aromatic multiplets are superimposed by SPh_2 signals. The $SiMe_3$ protons in the [Ni(L)($^{si}S_3$)] complexes give rise to a sharp singlet in the region between δ = 0.5 and 0.3 ppm. The ^1H and ^{13}C NMR spectra are consistent with the C_s symmetry of all complexes in solution. The NH singlet signals of **2a/b**, **3a/b**, and **4a/b** appear in the high-field region between δ = 0.9 and −1.9 ppm, and their chemical shifts are solvent-dependent. They are always shifted to higher fields when compared with the NH singlets of free $HNPnPr_3$ (δ = 0.51 ppm) or $HNSPh_2$ (δ = 1.12 ppm), possibly indicating a decrease of NH acidity of the $HNPR_3$ and $HNSPh_2$ ligands. It should be noted that the NH protons exhibit slightly lower shifts in the [Ni(L)($^{si}S_3$)] complexes **2b**, **3b**, and **4b** than in the corresponding [Ni(L)($^HS_3$)] complexes **2a**, **3a**, and **4a**. This might indicate a slightly higher NH acidity of the [Ni(L)($^{si}S_3$)] complexes, caused by the electron-withdrawing effect of the $SiMe_3$ groups.

The NH shifts of the $HNPR_3$ and $HNSPh_2$ complexes allowed us to determine whether the N−P and N−S bonds in $HNPR_3$ and $HNSPh_2$ exhibit single- or double-bond character. Protons at sp^2-hybridized N atoms in HN=X compounds (X = NH, NO, CH_2, CR_2) such as diazene, nitroxyl, methyleneimines, or ketimines usually exhibit strong low-field shifts (δ = 10−20 ppm), both in the free and coordinated state.[12] The high-field NH shifts of the $HNPR_3$ and $HNSPh_2$ complexes **2**−**4** (δ = 0.9 to −1.9 ppm) thus rather resemble the NH shifts in hydrazine and ammonia complexes and indicate N−P and N−S single bonds with sp^3-hybridized N atoms. These considerations suggest the ylidic structures **I** and **II** for the $HNPR_3$ and $HNSPh_2$ ligands.

I

II

In agreement with these structures, the ^1H and ^{13}C NMR spectra of the $HNPR_3$ and $HNSPh_2$ complexes **2**−**4** do not show any splitting of the signals when the temperature was lowered to −80 °C, indicating a free rotation of the PR_3 and SPh_2 fragments around the N−P or N−S bonds, as well as of the NH groups around the Ni−N bonds.

X-ray Crystal Structure Determinations

The molecular structures of [Ni($NHPnPr_3$)($^{si}S_3$)] (**2b**), [Ni($NHPCy_3$)($^HS_3$)] (**3a**), [Ni($NHPCy_3$)($^{si}S_3$)] (**3b**), [Ni($NHSPh_2$)($^HS_3$)] (**4a**), and [Ni($PnPr_3$)($^HS_3$)] (**5a**) were determined by X-ray structure analysis. Figure 2 depicts the molecular structures and Table 1 lists selected distances and angles.

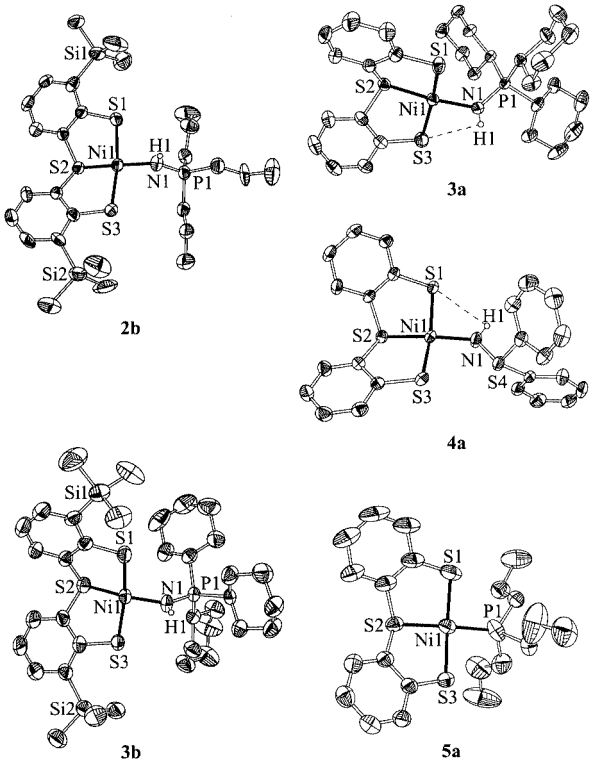


Figure 2. Thermal ellipsoid plots of [Ni($NHPnPr_3$)($^{si}S_3$)] (**2b**), [Ni($NHPCy_3$)($^HS_3$)] (**3a**), [Ni($NHPCy_3$)($^{si}S_3$)] (**3b**), [Ni($NHSPh_2$)($^HS_3$)] (**4a**), [Ni($PnPr_3$)($^HS_3$)] (**5a**) (50% probability ellipsoids; H atoms, except for *N*-bound ones, omitted)

The unit cells of all complexes contain discrete molecules whose four-coordinate nickel atoms exhibit a tetrahedrally distorted planar coordination, as evidenced by the non-linear S1−Ni1−S3 and S2−Ni1−L angles. This tetrahedral distortion can be traced back to the sp^3 hybridization of the central thioether sulfur atom in the $^RS_3$ ligands. It leads to a butterfly shape of the nickel−sulfur fragments, the characteristic topology of which also causes a very short Ni−S(thioether) distance of 208−213 pm, which is distinctly shorter than the Ni−S(thiolate) distances (216−220 pm).[7−9]

The Ni−N distances of **2b** [190.6(7) pm], **3a** [193.1(3) pm)], **3b** [192.3(4) pm], and **4a** [189.5(2) pm] are similar to that of [Ni($NHPnPr_3$)($^HS_3$)] (**2a**) reported previously,[8c] and indicate the presence of Ni−N single bonds. They are all considerably shorter than the Ni−N distances observed in

[a] N1=P1. [b] P1=S4.

other diamagnetic four-coordinate Ni^{II} complexes (201−203 pm).[10a,13] The Ni−P distances of $[Ni(PnPr_3)(^{H}S_3)]$ (**5a**) [219.0(2) pm] and previously reported $[Ni(PR_3)(^{R}S_3)]$ complexes (R = Me, Ph or Cy) lie in the same range of 219−221 pm.[8,9] The N−P distances (160 pm) of **2b**, **3a**, and **3b** are identical within the limit of the 3σ criterion. Hydrogen bonds are observed for **2b**, **3a**, and **4a**. Figure 3 illustrates that N−H···N bridges lead to the formation of dimers of $[Ni(NHPnPr_3)(^{si}S_3)]$ (**2b**) which possesses crystallographically imposed inversion symmetry. The hydrogen bonds are concluded from the distances H1···N1a (246 pm) and N1···N1a [322(2) pm], which are shorter than the sum of the corresponding van der Waals radii (N = 155 pm; H = 120 pm).[14] With respect to the hydrogen bonds, complex **2b** contrasts with the analogous complex $[Ni(NHPnPr_3)(^{H}S_3)]$ (**2a**) which contains the parent ligand $^{H}S_3^{2-}$. Complex **2a** also dimerizes in the solid state, however through N−H···S(thiolate) bridges rather than N−H···N bridges.[8c]

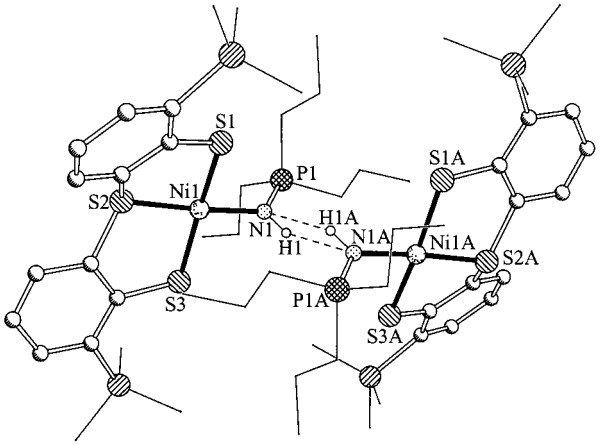

Figure 3. View of the N−H···N hydrogen bond dimers of $[Ni(NHPnPr_3)(^{si}S_3)]$ (**2b**) (H atoms, except for *N*-bound ones, omitted)

Intramolecular N−H···S(thiolate) bridges are found in $[Ni(NHPCy_3)(^{H}S_3)]$ (**3a**) and $[Ni(NHSPh_2)(^{H}S_3)]$ (**4a**). This can be deduced from the distances H1···S3 in **3a** [269(5) pm] and H1···S1 in **4a** [283(3) pm] as well as the distances N1···S3 in **3a** [289.1(3) pm] and N1···S1 in **4a** [295.5(2) pm], which are shorter than the sum of van der Waals radii (N = 155 pm; H = 120 pm; S = 180 pm).[14] No hydrogen bonds are found in $[Ni(NHPCy_3)(^{si}S_3)]$ (**3b**).

Reactions with Molecular Hydrogen

The heterolytic cleavage of H_2 into H^+ and H^- according to Equation (1b) and formation of HD from H_2 and D_2O, respectively, is one of the key reactions catalyzed by hydrogenases. Such a heterolytic H_2 cleavage and H_2/D^+ or D_2/H^+ exchange reaction could be proved to be catalyzed by the phosphorane imine and sulfimine complexes. The NH−R′ ligands (R′ = P*n*Pr$_3$, PCy$_3$, SPh$_2$) in these complexes are excellent probes for unambiguously establishing the H_2 or D_2 heterolysis because they have weakly acidic NH protons that exchange for D^+. Such an NH/D^+ exchange was similarly observed for the complexes **2a/b**, **3a/b**, and **4a/b** according to Equation (3).

$$[Ni(NH\text{-}R)(^{R}S_3)] + D^+ \longrightarrow [Ni(ND\text{-}R)(^{R}S_3)] + H^+ \quad (3)$$

A concentrated CD_2Cl_2/CH_2Cl_2 solution of the respective complex was treated with D_2O or CD_3OD, and the NH/D^+ exchange was monitored by $^1H/^2D$ NMR spectroscopy. In the course of 5−20 min, the NH signals of the starting complexes (between δ = 0.80 and −1.96 ppm) disappeared, while the ND signals of the resulting deuterated product complexes could be observed at the same region in the ^2D NMR spectrum. After completion of the reactions, the solvents were removed in vacuo; ν(ND) bands in the region of 2480−2420 cm^{-1} of the IR (KBr) spectra of the residues further corroborated the formation of the deuterated complexes.

The D_2/NH exchange was probed with complexes **2b**, **3a/3b**, and **4a/4b** and the formation of HD was monitored by ^1H NMR spectroscopy. In high-pressure NMR tubes, concentrated CD_2Cl_2 or [D$_8$]THF solutions of **2b**, **3a/3b**, and **4a/4b** were pressurized with D_2 (18 bar). ^1H NMR spectra recorded at regular time intervals showed the appearance of the 1:1:1 triplets of HD ($J_{H,D}$ = 42.5 Hz) formed according to Equation (4). The HD triplets in the region of δ = 4.2−4.8 ppm reached maximum intensity after 80 h in the case of **2b** and 120 h in the case of **4a**.

$$[Ni(NH\text{-}R)(^{R}S_3)] + D_2 \longrightarrow [Ni(ND\text{-}R)(^{R}S_3)] + HD \quad (4)$$

The reactions in Equations (3) and (4) thus prove that the $[Ni(NHR')(^{R}S_3)]$complexes **2b**, **3a**, **3b**, **4a**, and **4b** catalyze the heterolytic cleavage of D_2 and the exchange of molecular hydrogen with protons that ultimately result from protic solvents such as H_2O or CH_3OH. In a further experiment

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

we therefore tried to combine these reactions. Initially, we chose the complex **3b** because it proved to have the highest stability towards methanolysis leading to $[Ni(^{si}S_3)]_3$ and free $NHPCy_3$. In a high-pressure NMR tube, a concentrated CD_2Cl_2 solution of **3b** and MeOH (50 μL) was pressurized with D_2 (18 bar) and the reaction was monitored by ^1H NMR spectroscopy. Unfortunately, due to the large signals of the MeOH protons the HD signal could not be identified. However, repeating this experiment by changing the solvent to $[D_8]THF$ and the proton source to H_2O yielded a favorable result. A ^1H NMR spectrum of **3b** recorded after 4 d showed the appearance of the 1:1:1 triplets ($J_{H,D}$ = 42.5 Hz) of HD in the region of δ = 4.2−4.8 ppm. Interestingly, the intensity of the triplet increases with an increase in reaction time and nearly triples in size after 15 d. The complexes **2a**, **2b**, **3a**, **4a**, and **4b** also exhibit the same behavior.

These positive results prompted us to extend our investigations to complexes Bu_4N[**9a**] and Bu_4N[**9b**] as, like in the active sites of [NiFe] hydrogenases, they exhibit all-sulfur nickel coordination. These complexes were investigated first in the form of their sodium salts Na[**9a**] and Na[**9b**]. In a high-pressure NMR tube, a concentrated solution of Na[**9a**] or Na[**9b**] in a $[D_8]THF/H_2O$ (50 μL) mixture was pressurized with D_2 (18 bar) and the reaction was monitored by ^1H NMR spectroscopy at various time intervals. Figure 4 depicts the ^1H NMR spectra of the HD region of Na[**9a**] in $[D_8]THF/H_2O$ with D_2 pressure at various time intervals. The ^1H NMR spectrum of Na[**9a**] recorded after 1 d does not show any new peaks (Figure 4a), while after 5 d it shows a small 1:1:1 triplet of HD ($J_{H,D}$ = 42.5 Hz) in the region between δ = 4.8 and 4.2 ppm (Figure 4b). The concomitant formation of HDO could not be identified due to the large H_2O signal. However, the intensity of the HD triplet increases with increasing reaction time (Figure 4b−d). The reaction was prolonged for 15 d and the intensity of the HD triplet was enhanced to three times that of the initial one, suggesting that the reaction is catalytic. Compound Na[**9b**] undergoes an identical reaction but is more active, giving rise to HD formation in a shorter reaction time (initial HD triplet showed up after 4 d). It is worth mentioning that the complexes remain intact even after 15 d of reaction time. Identical experiments performed without either the complexes Na[**9b**] and Na[**9b**] or H_2O did not show any HD signals. These results unambiguously prove that the reaction is catalytic and the heterolytic cleavage of D_2 must take place at the nickel center via a five-coordinated D_2 intermediate species.

These results suggest that the D_2 heterolysis is achieved through the concerted action of the Lewis-acidic nickel center and the Brönsted-basic thiol atoms upon η^2-D_2 ligands. The resulting acidic thiol deuteron exchanges with the H_2O proton to give HDO. The thiol proton and nickel deuteride ion combine to give HD. Release of HD in the consecutive step leaves $[Ni(L)(^RS_3)]$ intact, which can then add another molecule of D_2 to complete the reaction cycle (Scheme 2). It is worthwhile to note that Na[**9a**] and Na[**9b**] are the first completely characterized sulfur-only nickel

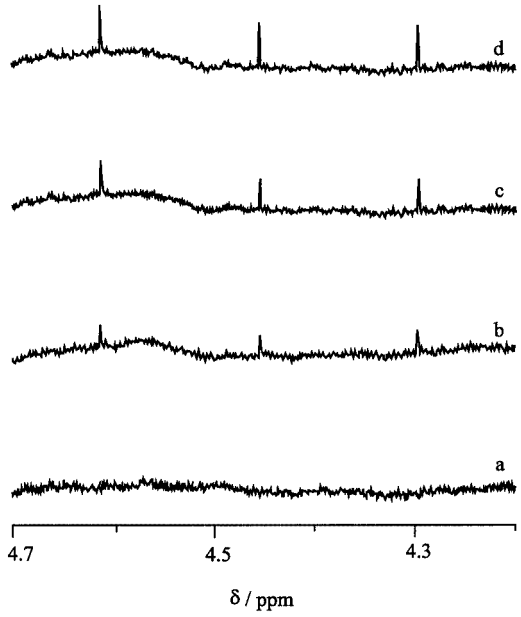

Figure 4. ^1H NMR spectra of the HD region of Na[Ni(S*t*Bu)($^HS_3$)] Na[**9a**] in $[D_8]THF/H_2O$ under D_2 (18 bar), recorded after: (a) 1, (b) 5, (c) 10, and (d) 15 d

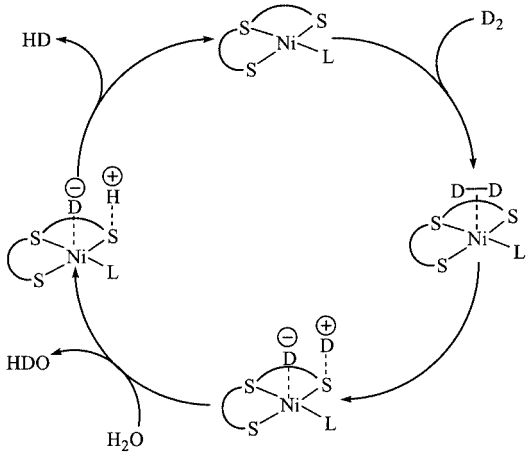
complexes that model the [NiFe] hydrogenase catalyzed D_2/H^+ exchange reaction.



Scheme 2. Mechanism of $[Ni(L)(^RS_3)]$-catalyzed D_2/H_2O exchange reaction

Reactions with CO

Coordination of CO to tetrahedrally distorted planar $[NiS_4]$ sites is postulated as the primary key step in CO dehydrogenase reactions[15] and is possibly responsible for the inhibition of [NiFe] hydrogenases by CO.[16] Complexes exhibiting $[Ni(CO)(S_4)]$ cores, however, have never been identified or isolated. Recently, the five-coordinate carbonyl−Ni^I−chalcogenate complexes $[Ni(DAPA)(EPh)_2(CO)]^-$ {DAPA = 2,6-bis[1-(phenylimino)ethyl]pyridine; E = S or Se} and the first five-coordinate carbonyl−Ni^{II}−thiolate complex $[Ni(PS3^*)(CO)]^-$ [PS3* =

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tris(3-phenyl-2-thiophenyl)phosphane] were reported.[17] For this reason, the reaction of the nickel complexes [Ni(L)($^{R}S_3$)] (**2**−**9**) with CO was investigated. They all possess at least [NiS_3] cores, and it has been pointed out previously[8,9] that the characteristic tetrahedral distortion of [Ni(L)($^{R}S_3$)] complexes could be crucial for their capability to add a fifth ligand.

The distances and angles in the [Ni($^{R}S_3$)] cores of all the complexes investigated are almost identical, although the reactivity of the individual [Ni(L)($^{R}S_3$)] complexes towards CO proved to be extremely different, clearly showing the decisive influence of the coligands L. The influence of the R substituents of the $^{R}S_3$ ligands is evidenced by the fact that the [Ni(L)($^{si}S_3$)] complexes always reacted faster than their [Ni(L)($^{H}S_3$)] counterparts.

Because the S*t*Bu$^-$ complex [Ni(S*t*Bu)($^{H}S_3$)]$^-$ (**9a**) has an all-sulfur coordination sphere, it was investigated first in form of its sodium salt Na[**9a**]. Bubbling CO gas through a THF solution of Na[**9a**] for 3−5 min gave rise to a ν(CO) band in the IR spectrum at 2131 cm^{-1}. When this solution was stored under CO for 24 h, a second ν(CO) band appeared at 2040 cm^{-1}. These bands were assigned to [Ni(CO)(S*t*Bu)($^{H}S_3$)]$^-$ (2131 cm^{-1}) and [$Ni(CO)_4$] (2040 cm^{-1}) which form according to Equation (5).

$$[Ni(S\mathit{t}Bu)(^{H}S_3)]^- + CO \xrightarrow{5\ min} [Ni(CO)(S\mathit{t}Bu)(^{H}S_3)]^- \xrightarrow[24\ h]{+\ exc.\ CO} \mathit{t}BuS\text{–}S\mathit{t}Bu + [^{H}S_3]_x + [Ni(CO)_4] \quad (5)$$

The reduction of Ni^{II} to Ni^0 is possibly initiated by the reductive elimination of the (labile) S*t*Bu$^-$ ligand. This is suggested by the observation that the substitutionally inert phosphane complex [Ni(PCy_3)($^{si}S_3$)] does not yield [$Ni(CO)_4$] when treated with CO (vide infra).

The ν(CO) assignment was corroborated by the following experiments. Purging the solutions with N_2 for 10 min led to complete disappearance of the ν(CO) bands. This indicated that the first step yielding [Ni(CO)(S*t*Bu)($^{H}S_3$)]$^-$ is reversible. Carrying out the experiment [according to Equation (5)] with ^{13}CO gave rise to ν(CO) bands at 2085 cm^{-1} ([Ni(^{13}CO)(S*t*Bu)($^{H}S_3$)]$^-$) and 1995 cm^{-1} ([Ni($^{13}CO)_4$]). The isotopic shifts of 45 cm^{-1} agree with theoretical expectations. Formation of the five-coordinate intermediate [Ni(CO)(S*t*Bu)($^{H}S_3$)]$^-$ was further corroborated by monitoring the reaction by ^{13}C NMR spectroscopy. The ^{13}C NMR spectrum shows that treatment of a [D_8]THF solution of Na[**9a**] with ^{13}CO (5 bar) in a medium-pressure NMR tube gave rise to ^{13}C NMR signals at δ = 198.5, 192.1, and 184.7 ppm, which could be assigned to [Ni(^{13}CO)(S*t*Bu)($^{H}S_3$)]$^-$, [Ni($^{13}CO)_4$], and free ^{13}CO, respectively. This assignment was checked by recording the ^{13}C NMR spectra of ^{13}CO and [$Ni(CO)_4$] in [D_8]THF. In summary, these results suggest that nickel thiolate complexes with a tetrahedrally distorted planar [NiS_4] core can reversibly coordinate CO, but afford [$Ni(CO)_4$] when treated with an excess of CO for longer periods of time.

In the next step, the influence of the phosphane coligands upon CO coordination was probed with [Ni(PCy_3)($^{si}S_3$)](**6b**). When CO was bubbled through a THF solution of **6b** according to Equation (6), a ν(CO) band appeared at 2135 cm^{-1} in the IR spectrum. Purging the solution with a stream of N_2 led to disappearance of the ν(CO) band and **6b** was regained. This result suggests that [Ni(PR_3)($^{R}S_3$)] complexes can also reversibly add CO. In addition, the ν(CO) frequency of [Ni(CO)(PCy_3)($^{si}S_3$)] at 2135 cm^{-1} is similar to that of [Ni(CO)(S*t*Bu)($^{H}S_3$)]$^-$ (2131 cm^{-1}), indicating that the electron density at the nickel atom is a little lower in the neutral phosphane than in the anionic S*t*Bu$^-$ complex. However, the relatively high wavenumbers indicate a weak binding of the CO ligands, rationalizing their reversible coordination.

$$[Ni(PCy_3)(^{si}S_3)] \underset{+\ N_2,\ -\ CO}{\overset{+\ CO}{\rightleftharpoons}} [Ni(CO)(PCy_3)(^{si}S_3)] \quad (6)$$

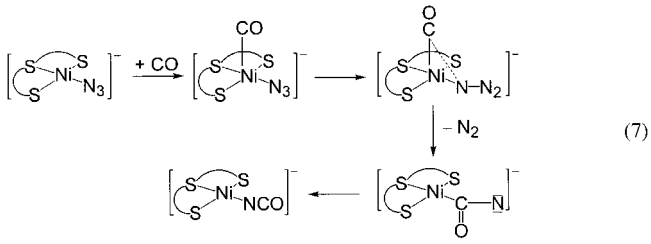
The coligands S*t*Bu$^-$ or PCy_3 in the [Ni(L)($^{R}S_3$)] complexes [Ni(S*t*Bu)($^{H}S_3$)]$^-$ (**9a**) and [Ni(PCy_3)($^{Si}S_3$)] (**6b**) do not react with CO, either in the free or complexed state, whereas the nitrogen-containing ligands $NHPR_3$, $NHSPh_2$, and N_3^- show a distinctly different behavior. In the free state they, too, do not react with CO, however, when functioning as ligands in the [Ni(L)($^{R}S_3$)] complexes **2**−**4** and **8b**, they undergo rapid reactions with equimolar amounts of CO. This demonstrates that the reactions are mediated by the [Ni($^{R}S_3$)] fragments, and indicates that both CO and nitrogenous ligands can be activated.

From the mechanistic point of view, the reaction between Et_4N[Ni(N_3)($^{si}S_3$)] (**8b**) and CO can be rationalized best. In THF solution, complex **8b** is thermally stable and resistant to UV photolysis (150 W Hg lamp) over extended periods of time (3 d). When treated with equimolar amounts of CO gas in the dark, however, it rapidly transforms into the NCO complex Et_4N[Ni(NCO)($^{si}S_3$)] (**10b**) and N_2, and complex **10b** could be isolated in nearly quantitative yield (92%). Monitoring the reaction by IR spectroscopy demonstrated that the ν(N_3) band of **8b** at 2037 cm^{-1} continuously decreases in intensity while the ν(NCO) band of **10b** at 2227 cm^{-1} increases.

The analogous reaction of the $^{H}S_3$ complex Bu_4N-[Ni(N_3)($^{H}S_3$)] (Bu_4N[**8a**]) with CO afforded Bu_4N-[Ni(NCO)($^{H}S_3$)][7] and enabled us to detect a short-lived [Ni(CO)(N_3)($^{H}S_3$)]$^-$ intermediate, with a ν(CO) band at 2129 cm^{-1} by IR spectroscopy. Such an intermediate could not be found in the reaction between Et_4N[**8b**] and CO, probably owing to the greater reactivity of **8b** and its intermediates. However, the close analogy between Bu_4N[**8a**] and Et_4N[**8b**] suggests identical mechanisms for their reaction with CO [Equation (7)].

Coordination of CO to the [Ni(N_3)($^{R}S_3$)]$^-$ anion leads to activation of CO and N_3^-, release of N_2 and formation of the NCO complex. Related mechanisms have previously

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



(7)

been suggested for four-coordinate azido(phosphane) complexes of Pd^{II}, Pt^{II}, Rh^{I} and Ir^{I}.[18] The phosphorane imine complexes **2a/2b**, **3a/3b**, and the sulfimine complexes **4a/4b** also react quickly with CO under standard conditions (1 bar, 20 °C). However, the mechanisms of the reactions are less obvious. When a stream of CO was bubbled through CH_2Cl_2 solutions of **2a/2b**, **3a/3b**, or **4a/4b**, the parent complexes $[Ni(^{R}S_3)]_3$ (**1a** or **1b**) formed and could be isolated in high yields. When the CH_2Cl_2 solutions were each treated with 1 equiv. of CO gas, the reactions proceeded more slowly, and monitoring of the reactions by IR and NMR spectroscopy, and mass spectrometry, yielded hints as to the nature of the intermediates. Experiments with the respective $[Ni(L)(^{H}S_3)]$ and $[Ni(L)(^{si}S_3)]$ complexes complemented each other. For example, after addition of 1 equiv. of CO, the IR spectrum of the CH_2Cl_2 solution of the phosphorane imine complex $[Ni(NHP\textit{n}Pr_3)(^{H}S_3)]$ (**2a**) shows a weak band at 2146 cm^{-1}. This band disappeared in the course of 25 h, and a new band at 2227 cm^{-1} developed simultaneously; its intensity increased over 45 h and then decreased again, while $[Ni(^{H}S_3)]_3$ (**1a**) started precipitating from the solution (Figure 5). The weak band at 2040 cm^{-1} corresponds to the side product $[Ni(CO)_4]$ that forms and disappears during the reaction. The same IR spectroscopic behavior was found for CH_2Cl_2 solutions of $[Ni(NHP\textit{n}Pr_3)(^{si}S_3)]$ (**2b**).

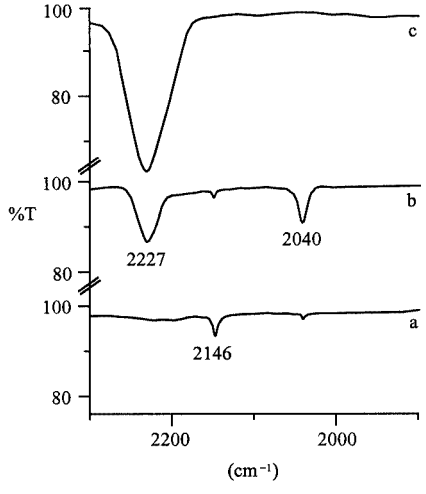


Figure 5. IR spectroscopic monitoring of the reaction between equimolar amounts of $[Ni(NHP\textit{n}Pr_3)(^{H}S_3)]$ (**2a**) and CO in CH_2Cl_2 solution; the spectra were recorded after (a) 3, (b) 20, and (c) 48 h

The ^1H NMR spectrum of **2a** in CD_2Cl_2 shows the NH signal at $\delta = -1.82$ ppm. After injecting an equimolar amount of CO, this NH signal gradually broadens and disappears and a new doublet appears at $\delta = 4.85$ ppm ($J_{P,H}$ = 550 Hz). Similarly, in the ^{31}P NMR spectrum of **2a**, the signal at $\delta = 50.8$ ppm disappears gradually in the presence of CO and a new peak appears at $\delta = 55.1$ ppm. This new peak, in turn, vanishes over the course of 30 h to give a new low-intensity doublet at $\delta = 34.2$ ppm ($J_{P,H}$ = 527 Hz). All ^1H and ^{31}P NMR signals disappear when $[Ni(^{H}S_3)]_3$ (**1a**) precipitates from the solution. These findings can be interpreted as follows: the initial step is the coordination of CO to give a five-coordinate $[Ni(CO)(NHP\textit{n}Pr_3)(^{H}S_3)]$ intermediate showing a ν(CO) band at 2146 cm^{-1} (^{31}P NMR: $\delta = 55.1$ ppm). As above, the high frequency of this band indicates that the CO is only weakly bound. Subsequently, the intramolecular nucleophilic addition of the N atom of $NHP\textit{n}Pr_3$ to CO is followed by the removal of $P\textit{n}Pr_3$ to give an unstable acylimide species. Then, the deprotonation of the N–H bond by the free $P\textit{n}Pr_3$ gives $[HP\textit{n}Pr_3]^+$ (doublet in the ^1H and ^{31}P NMR spectra) and the acyl azide complexes. A similar reactivity has already been reported in coordinated phosphanylamine complexes of Ni^{II} and free PMe_3 to give $[HPMe_3]^+$.[10a] These acyl azides can rearrange to give $[HP\textit{n}Pr_3][Ni(NCO)(^{H}S_3)]$ [ν(NCO) = 2227 cm^{-1}] according to Equation (8). Unlike $Et_4N[Ni(NCO)(^{si}S_3)]$ (**10b**), $[HP\textit{n}Pr_3][Ni(NCO)(^{H}S_3)]$ is unstable and undergoes further reactions to give **1a** as the final product. Monitoring the reactions of the $^{si}S_3$ complex **2b** by ^1H and ^{31}P NMR spectroscopy only showed the replacement of the signals of **2b** by those of **1b**, but did not allow us to draw further conclusions. All attempts to isolate the intermediate species were unsuccessful, even at −78 °C.

After addition of 1 equiv. of CO, the IR spectrum of the CH_2Cl_2 solution of the sulfimine complex $[Ni(NHSPh_2)(^{H}S_3)]$ (**4a**) shows a weak band at 2148 cm^{-1}. This band disappeared over the course of 1 h, and simultaneously a new band appeared at 2185 cm^{-1}, whose intensity increased over 5 h and then decreased again, while $[Ni(^{H}S_3)]_3$ (**1a**) started precipitating from the solution. The same IR spectroscopic behavior was found for CH_2Cl_2 solutions of $[Ni(NHSPh_2)(^{si}S_3)]$ (**4b**). The $SiMe_3$ substituents of **4b** were also used as a spectroscopic probe. The ^1H NMR spectra of the reactions in CD_2Cl_2 show that the $SiMe_3$ singlet of **4b** at $\delta = 0.36$ ppm broadens slightly and is replaced by the two singlets of $[Ni(^{si}S_3)]_3$ (**1b**) at $\delta = 0.55$ and 0.08 ppm.

These findings are interpreted in the following way. The primary step is again the coordination of CO to give a five-coordinate $[Ni(CO)(NHSPh_2)(^{R}S_3)]$ intermediate showing a ν(CO) band at 2148 cm^{-1}. Subsequent reaction between CO and the $HNSPh_2$ ligands leads to deoxygenation of CO resulting in $OSPh_2$ and coordinated HC=N or HN=C ligands, which give rise to the band at 2185 cm^{-1}. Transition metal complexes with HCN or HNC ligands show ν(CN) bands in the region of 2200–2100 cm^{-1}.[19] Subsequent decoordination of the HCN ligands results in the formation of $[Ni(^{R}S_3)]_3$ [Equation (9)].

(9)

The mass spectra of the reaction solutions recorded when the band at 2185 cm^{-1} had attained maximum intensity support this interpretation. These spectra exhibit peaks at $m/z = 202$ assignable to $OSPh_2$ and at 335 (**4a**) or 479 (**4b**), which are compatible with the formation of $[Ni(HCN)(^{R}S_3)]$ complexes.

Table 2 summarizes the ν(CO) frequencies of the CO adducts initially formed and demonstrates that complexes with $^{H}S_3$ and $^{Si}S_3$ ligands show identical ν(CO) frequencies. Therefore, the sometimes remarkably different reaction rates of $^{H}S_3$ and $^{si}S_3$ complexes might be caused by differences in solubility rather than by changes in the electronic properties. Anionic complexes give rise to lower ν(CO) frequencies than neutral complexes. This trend of ν(CO) frequencies is well known from classical carbonylmetal complexes, and it strongly suggests that structurally similar five-coordinate $[Ni(CO)(L)(^{R}S_3)]$ species form in all cases. These five-coordinate species can reversibly dissociate CO or undergo rapid consecutive reactions if L is a nitrogenous species having lone-pairs at the N donor such as azide or the ylidic $HNPR_3$ and $HNSPh_2$ ligands. The subsequent reactions lead to conversion of CO and the nitrogenous ligand. The final products, which could be isolated, depend on the nitrogenous ligands. If they release inert species such as N_2 in the case of azide, the resulting NCO^- complexes $[Ni(NCO)(^{R}S_3)]^-$ can be isolated in good yields. In the case of the phosphorane imine or sulfimine complexes, an analogous cleavage of N−P or N−S bonds yields species that are still highly reactive and go on reacting until the stable trinuclear $[Ni(^{R}S_3)]_3$ complexes form.

It should be noted that the ν(CO) frequencies of all five-coordinate intermediates (Table 2) are relatively high and, in some cases, even slightly higher than that of free CO in the gas phase (2143 cm^{-1}). Additional measurements corroborated that these bands do not result from dissolved CO.

The CO adducts of the phosphorane imine and sulfimine complexes thus belong to the class of "non-classical" carbonylmetal complexes which can exhibit ν(CO) frequencies of up to 2280 cm^{-1}.[20] The high ν(CO) frequencies of these complexes are rationalized by a subtle interplay of σ-donor, π-acceptor and semipolar contributions in the M−CO bonds.[21] In accordance with this rationalization, the results obtained here show that binding CO to $[Ni(L)(^{R}S_3)]$ complexes not only enhances the polarity of the CO bond but also increases the susceptibility of CO towards attack by nucleophiles. This may be a reason why coordination of CO to the $[NiS_4]$ core of CO dehydrogenase centers can enable the CO/CO_2 conversion according to Equation (2) (vide infra).

Table 2. ν(CO) frequencies of the primary five-coordinate species $[Ni(CO)(L)(^{R}S_3)]$ resulting from $[Ni(L)(^{R}S_3)]$ and CO (1 bar) at 20 °C

Conclusion

In the quest for sulfur−nickel complexes that enable us to model the reactivity features and key intermediates of [NiFe] hydrogenases and CO dehydrogenases, $[Ni(L)(^{R}S_3)]$ complexes were synthesized, completely characterized, and investigated with regard to their reactivity towards H_2 and CO. All $[Ni(L)(^{R}S_3)]$ complexes exhibit sulfur-dominated and tetrahedrally distorted square-planar coordination

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

spheres. Complexes **4a** and **4b** are rare examples of sulfimine complexes and are the first sulfimine complexes with only sulfur as ancillary coligands. Introduction of the $^{si}S_3$ ligand enabled us to overcome the solubility problems frequently encountered with nickel complexes of the $^{H}S_3$ parent ligand.

It has been demonstrated that the phosphorane imine and sulfimine complexes **2**−**4** possess weakly acidic NH protons and catalyze D_2/NH exchange reactions through heterolysis of D_2. The D_2/H^+ exchange reaction between D_2 and protons from H_2O is also catalyzed by complexes **2**−**4** and **9**. These reactions unambiguously prove that the D_2/H^+ exchange is catalytic in nature. The D_2 heterolysis most likely proceeds through attack of the Lewis-acidic nickel and Brönsted-basic sulfur atoms at η^2-D_2 ligands. It is worthwhile to note that **9a** and **9b** are the first completely characterized sulfur-only nickel complexes that enable us to model the [NiFe] hydrogenase catalyzed D_2 heterolysis and D_2/H^+ exchange reactions.

Coordination of CO to four-coordinate nickel centers in sulfur coordination spheres is assumed to be the decisive step in the activation of CO catalyzed by CO dehydrogenases. Evidence for labile five-coordinate [Ni(CO)(L)($^{R}S_3$)] has been found in the reactions of CO with [Ni(L)($^{R}S_3$)] complexes containing neutral and anionic ligands L. The CO adducts of complexes with nitrogenous ligands L such as N_3^-, $NHPR_3$, or $NHSPh_2$ showed rapid consecutive reactions demonstrating the activation of CO and ligands L. In extrapolation of these findings it can be hypothesized that simultaneous coordination of CO and H_2O to [Ni($^{R}S_3$)] fragments possibly enables the biological CO dehydrogenase reaction.

Experimental Section

General Methods: Unless noted otherwise, all reactions and manipulations were carried out under nitrogen at room temperature using standard Schlenk techniques. Reaction solutions were stirred continuously. Solvents were freshly dried and distilled before use. As far as possible, reactions were monitored by IR or NMR spectroscopy. Physical measurements were carried out with the following instruments: IR (KBr discs or CaF_2 cuvettes, solvent bands were compensated for): Perkin−Elmer 983, 1620 FT-IR and 16PC FT-IR. NMR: Jeol JMM-GX 270, Jeol JMM-EX 270, and Lambda LA 400 with the residual protio-solvent signal used as an internal reference. Chemical shifts are quoted in the δ scale (downfield shifts are positive) relative to tetramethylsilane (^{1}H, ^{13}C{^{1}H} NMR) or 85% H_3PO_4 (^{31}P{^{1}H} NMR). MS: Jeol MSTATION 700 spectrometer. Elemental analysis: Carlo Erba EA 1106 or 1108 analyzer. Me_3SiCl, $HNSPh_2{\cdot}H_2O$, Et_4NCl, and Bu_4NCl were purchased from either Aldrich or Fluka. HNP*n*Pr_3, $Me_3SiNPCy_3$,[22] [Ni($^{H}S_3$)]$_3$ (**1a**), [Ni(NHP*n*Pr_3)($^{H}S_3$)] (**2a**), [Ni(PCy_3)($^{H}S_3$)] (**6a**), Bu_4N[Ni(Cl)($^{H}S_3$)] (Bu_4N[**7a**]), and Bu_4N[Ni(N_3)($^{H}S_3$)] (Bu_4N[**8b**]) were prepared as described in the literature.[8] The syntheses of [Ni($^{si}S_3$)]$_3$ (**1b**), Et_4N[Ni(N_3)($^{si}S_3$)] (Et_4N[**8b**]), [Ni(P*n*Pr_3)($^{si}S_3$)] (**5b**), [Ni(PCy_3)($^{si}S_3$)] (**6b**), and Bu_4N[Ni(Cl)($^{si}S_3$)] (Bu_4N[**7b**]) were described in our previous paper.[9]

[Ni(NHP*n*Pr_3)($^{si}S_3$)] (2b): HNP*n*Pr_3 (0.52 mL, 2.35 mmol) was added to a solution of [Ni($^{si}S_3$)]$_3$ (**1b**; 800 mg, 0.59 mmol) in THF (10 mL), and the color changed from black-brown to purple-red in the course of about 6 h. The solution was filtered after 15 h, the purple-red filtrate was reduced in volume to 3 mL and layered with CH_3CN (20 mL). Pink crystals precipitated at −25 °C which were separated after 10 d, washed with cold CH_3CN and dried in vacuo. Yield: 765 mg (69%). $C_{27}H_{46}NNiPS_3Si_2$ (626.71): calcd. C 51.75, H 7.40, N 2.23, S 15.35; found C 51.88, H 7.53, N 2.10, S 15.21. IR (KBr): $\tilde{\nu}$ = 3298 [ν(NH)], 995 [ν(NP)] cm^{-1}. ^{1}H NMR (269.7 MHz, [D$_8$]THF): δ = 7.57 (d, $J_{H,H}$ = 7.9 Hz, 2 H, C_6H_3), 7.19 (d, $J_{H,H}$ = 6.8 Hz, 2 H, C_6H_3), 6.84 (t, $J_{H,H}$ = 7.6 Hz, 2 H, C_6H_3), 2.04 (m, 6 H, PCH_2), 1.73 (m, 6 H, PCH_2CH_2), 1.08 (t, $J_{H,H}$ = 6.9 Hz, 9 H, $PCH_2CH_2CH_3$), 0.38 (s, 18 H, $SiMe_3$), −1.06 (s, 1 H, NH) ppm. ^{13}C NMR (67.8 MHz, [D$_8$]THF): δ = 159.9, 139.6, 134.8, 134.3, 129.0, 121.3 (C_6H_3), 29.7 (d, $^1J_{P,C}$ = 62.9 Hz), 15.7 (d, $J_{P,C}$ = 3.3 Hz), 15.5 (d, $J_{P,C}$ = 16.1 Hz, P*n*Pr_3), −0.7 ($SiMe_3$) ppm. ^{31}P NMR (161.8 MHz, [D$_8$]THF): δ = 50.3 (P*n*Pr_3) ppm. MS (FD, THF): *m*/*z* = 626 [Ni(NHP*n*Pr_3)($^{si}S_3$)]$^+$.

[Ni(NHPCy_3)($^{H}S_3$)] (3a): A solution of $Me_3SiNPCy_3$ (825 mg, 2.24 mmol) in THF (5 mL) and MeOH (1 mL) was added to a black-brown suspension of [Ni($^{H}S_3$)]$_3$ (**1a**; 525 mg, 0.57 mmol) in THF (15 mL). A purple-red solution formed which was concentrated to dryness after 15 h. The purple-red residue was redissolved in THF (10 mL), and traces of undissolved materials were removed by filtration. The filtrate was reduced in volume to 3 mL, layered with CH_3CN (30 mL) and stored at −25 °C. Pink microcrystals precipitated which were separated after 3 days, washed with cold CH_3CN and Et_2O, and dried in vacuo. Yield: 815 mg (79%). $C_{30}H_{42}NNiPS_3$ (602.54): calcd. C 59.80, H 7.03, N 2.32, S 15.96; found C 59.82, H 7.19, N 2.35, S 15.58. IR (KBr): $\tilde{\nu}$ = 3364 [ν(NH)], 978 [ν(NP)] cm^{-1}. ^{1}H NMR (269.7 MHz, [D$_8$]THF): δ = 7.58 (d, $J_{H,H}$ = 7.6 Hz, 2 H, C_6H_4), 7.20 (d, $J_{H,H}$ = 7.9 Hz, 2 H, C_6H_4), 6.97 (t, $J_{H,H}$ = 7.1 Hz, 2 H, C_6H_4), 6.83 (t, $J_{H,H}$ = 7.1 Hz, 2 H, C_6H_4), 2.23−1.32 (m, 33 H, PCy_3), −1.88 (s, 1 H, NH) ppm. ^{13}C NMR (67.8 MHz, [D$_8$]THF): δ = 154.2, 134.2, 129.6, 128.5, 128.0, 121.9 (C_6H_4), 35.3 (d, $^1J_{P,C}$ = 55.3 Hz), 27.8, 27.5 (d, $^3J_{P,C}$ = 15 Hz), 26.9 (PCy_3) ppm. ^{31}P NMR (161.8 MHz, [D$_8$]THF): δ = 59.2 (PCy_3) ppm. MS (FD, THF): *m*/*z* = 602 [Ni(NHPCy_3)($^{H}S_3$)]$^+$.

[Ni(NHPCy_3)($^{si}S_3$)] (3b): A solution of $Me_3SiNPCy_3$ (272 mg, 0.74 mmol) in THF (5 mL) and MeOH (1 mL) was added to a solution of [Ni($^{si}S_3$)]$_3$ (**1b**; 300 mg, 0.22 mmol) in THF (15 mL), and the color changed from black-brown to purple-red in the course of about 3 h. After 15 h, the solution was concentrated to dryness to give a purple-red residue, which was redissolved in THF (10 mL). Undissolved material was removed by filtration. The filtrate was reduced in volume to 3 mL, layered with CH_3CN (30 mL) and stored at −25 °C. Pink microcrystals precipitated which were separated after 4 d, washed with cold CH_3CN and Et_2O, and dried in vacuo. Yield: 412 mg (83%). $C_{36}H_{58}NNiPS_3Si_2$ (746.90): calcd. C 57.89, H 7.83, N 1.87, S 12.88; found C 57.47, H 7.44, N 1.80, S 12.63. IR (KBr): $\tilde{\nu}$ = 3364 [ν(NH)], 985 [ν(NP)] cm^{-1}. ^{1}H NMR (269.7 MHz, [D$_8$]THF): δ = 7.56 (d, $J_{H,H}$ = 7.9 Hz, 2 H, C_6H_3), 7.18 (d, $J_{H,H}$ = 7.1 Hz, 2 H, C_6H_3), 6.82 (t, $J_{H,H}$ = 7.5 Hz, 2 H, C_6H_3), 2.35−1.30 (m, 33 H, PCy_3), 0.38 (s, 18 H, $SiMe_3$), −1.62 (s, 1 H, NH) ppm. ^{13}C NMR (67.8 MHz, $CDCl_3$): δ = 158.0, 139.5, 134.2, 133.2, 127.9, 126.8 (C_6H_3), 34.3 (d, $^1J_{P,C}$ = 49.5 Hz), 27.0 (d, $^2J_{P,C}$ = 6.8 Hz), 26.7 (d, $^3J_{P,C}$ = 2.7 Hz), 25.9 (PCy_3), −0.5 ($SiMe_3$) ppm. ^{31}P NMR (161.8 MHz, [D$_8$]THF): δ = 54.5 (PCy_3) ppm. MS (FD, THF): *m*/*z* = 746 [Ni(NHPCy_3)($^{si}S_3$)]$^+$.

[Ni(NHSPh_2)($^{H}S_3$)] (4a): $HNSPh_2{\cdot}H_2O$ (425 mg, 1.93 mmol) was added to a black-brown suspension of **1a** (500 mg, 0.54 mmol) in THF (10 mL). The resulting suspension was stirred for 12 h, in the course of which it became red-brown. The solution was filtered,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the filtrate reduced in volume to about 3 mL and layered with Et_2O (20 mL). Dark red crystals precipitated at −25 °C, which were separated after 7 d, washed with Et_2O and dried in vacuo. Yield: 680 mg (82%). $C_{24}H_{19}NNiS_4$ (508.38): calcd. C 56.70, H 3.77, N 2.75, S 25.23; found C 56.82, H 3.91, N 2.71, S 25.07. IR (KBr): $\tilde{\nu}$ = 3202 [ν(NH)], 924 [ν(NS)] cm^{-1}. ^1H NMR (269.7 MHz, [D$_8$]THF): δ = 7.75−7.40 (m, 12 H, C_6H_4, SPh_2), 7.21 (d, $J_{H,H}$ = 7.5 Hz, 2 H, C_6H_4), 7.00 (t, $J_{H,H}$ = 6.5 Hz, 2 H, C_6H_4), 6.85 (t, $J_{H,H}$ = 6.4 Hz, 2 H, C_6H_4), 0.89 (s, 1 H, NH) ppm. ^{13}C NMR (67.8 MHz, [D$_8$]THF): δ = 153.0, 134.6, 132.4, 131.8, 130.4, 130.0, 128.9, 128.4, 127.8, 122.4 (C_6H_4, SPh_2) ppm. MS (FD, THF): *m*/*z* = 508 [Ni(NHSPh$_2$)(^{H}S$_3$)]$^+$.

[Ni(NHSPh$_2$)(^{si}S$_3$)] (4b): A solution of $HNSPh_2 \cdot H_2O$ (128 mg, 0.58 mmol) in THF (5 mL) was added to a solution of **1b** (250 mg, 0.18 mmol) in THF (10 mL) and the color changed from black-brown to brown-red in the course of about 6 h. The solution was filtered after 12 h, reduced in volume to 3 mL and layered with pentane (20 mL). Dark-red microcrystals precipitated at −25 °C which were separated after 7 d, washed with pentane and dried in vacuo. Yield: 282 mg (78%). $C_{30}H_{35}NNiS_4Si_2$ (652.75): calcd. C 55.20, H 5.40, N 2.15, S 19.65; found C 55.91, H 5.90, N 2.28, S 19.02. IR (KBr): $\tilde{\nu}$ = 3210 [ν(NH)], 916 [ν(NS)] cm^{-1}. ^1H NMR (269.7 MHz, [D$_8$]THF): δ = 7.75−7.40 (m, 12 H, C_6H_3, SPh_2), 7.19 (d, $J_{H,H}$ = 6.1 Hz, 2 H, C_6H_3), 6.84 (t, $J_{H,H}$ = 6.8 Hz, 2 H, C_6H_3), 0.83 (s, 1 H, NH), 0.36 (s, 18 H, $SiMe_3$) ppm. ^{13}C NMR (67.8 MHz, [D$_8$]THF): δ = 159.2, 139.8, 134.9, 134.8, 132.3, 131.8, 130.4, 129.3, 128.4, 121.6 (C_6H_3, SPh_2), −0.4 ($SiMe_3$) ppm. MS(FD, THF): *m*/*z* = 653 [Ni(NHSPh$_2$)(^{si}S$_3$)]$^+$.

[Ni(P*n*Pr$_3$)(^{H}S$_3$)] (5a): P*n*Pr$_3$ (0.3 mL, 1.49 mmol) was added to a black-brown suspension of **1a** (445 mg, 0.48 mmol) in THF (10 mL). In the course of about 10 min, a red-yellow solution formed which was filtered after 1 h. The filtrate was reduced in volume to 2 mL, layered with hexane (20 mL) and stored at −25 °C. Dark red crystals precipitated which were separated after 2 d, washed with hexane and dried in vacuo. Yield: 645 mg (95%). $C_{21}H_{29}NiPS_3$ (467.33): calcd. C 53.97, H 6.26, S 20.58; found C 54.06, H 6.38, S 20.37. ^1H NMR (269.7 MHz, $CDCl_3$): δ = 7.66 (dd, $J_{H,H}$ = 1.2, 8.1 Hz, 2 H, C_6H_4), 7.39 (d, $J_{H,H}$ = 1.3, 7.9 Hz, 2 H, C_6H_4), 7.09 (dt, $J_{H,H}$ = 1.3, 7.9 Hz, 2 H, C_6H_4), 6.98 (dt, $J_{H,H}$ = 1.4, 7.3 Hz, 2 H, C_6H_4), 1.72 (m, 6 H, PCH_2), 1.65 (m, 6 H, PCH_2CH_2), 1.04 (t, $J_{H,H}$ = 6.6 Hz, 9 H, $PCH_2CH_2CH_3$) ppm. ^{13}C NMR (100.4 MHz, $CDCl_3$): δ = 152.1(d, $^3J_{P,C}$ = 12.5 Hz), 132.4, 129.8, 128.5, 127.4, 122.5 (C_6H_4), 25.4 (d, $^1J_{P,C}$ = 26.4 Hz), 17.8 (d, $J_{P,C}$ = 1.7 Hz), 16.0 (d, $J_{P,C}$ = 14.0 Hz) (P*n*Pr$_3$) ppm. ^{31}P NMR (161.8 MHz, $CDCl_3$): δ = 13.5 (P*n*Pr$_3$) ppm. MS (FD, THF): *m*/*z* = 467 [Ni(P*n*Pr$_3$)(^{H}S$_3$)]$^+$.

D$^+$/NH Exchange Reactions of 2a/2b, 3a/3b, and 4a/4b with D_2O or CD_3OD: In an NMR tube, D_2O or CD_3OD (50 μL) was added to a saturated solution of the respective complex (ca. 50 mg) in CD_2Cl_2 or CH_2Cl_2. The reactions were monitored by recording the $^1H/^2D$ NMR spectra and measuring the intensity of the NH or ND signals. After completion of the reactions (5−20 min), the solvents were removed in vacuo and the resulting residue was identified by IR (KBr) spectroscopy. The deuterated complexes each exhibited a ν(ND) band in the region 2480−2420 cm^{-1}.

D$_2$/NH Exchange Reactions of 2b, 3a/3b, and 4a/4b with D_2 and Identification of HD: In a high-pressure NMR tube (524-PV-1, Wilmad, USA), a concentrated solution of the respective complex (ca. 50 mg) in CD_2Cl_2 or [D$_8$]THF was pressurized with D_2 (18 bar). The reactions were monitored by recording ^1H NMR spectra. The formation of HD gave rise to a 1:1:1 triplet ($J_{H,D}$ = 42.5 Hz) in the region of δ = 4−5 ppm after 80−120 h.

D$_2$/H$_2$O Exchange Reaction of 2a/2b, 3a/3b, 4a/4b, and Na[9a]/Na[9b]: In a high-pressure NMR tube, a concentrated solution of the respective complex (ca. 50 mg) in [D$_8$]THF, after addition of H_2O (50 μL), was pressurized with D_2 (18 bar). The reactions were monitored by recording ^1H NMR spectra at regular time intervals for 15 d. The formation of HD gave rise to a 1:1:1 triplet ($J_{H,D}$ = 42.5 Hz) in the region of δ = 4−5 ppm.

Et$_4$N[Ni(NCO)(^{si}S$_3$)] (10b) from Et$_4$N[Ni(N$_3$)(^{si}S$_3$)] (8b) and CO: CO gas (16.5 mL, 0.74 mmol) was injected into a Schlenk tube in the dark containing a solution of **8b** (450 mg, 0.72 mmol) in THF (10 mL) and fitted with a septum. The color of the solution changed from purple to dark-red in the course of ca 15 h. The solution was filtered after 24 h, reduced in volume to ca. 2 mL and layered with pentane (20 mL). Dark-red microcrystals precipitated at −25 °C which were separated after 4 d, washed with pentane and dried in vacuo. Yield: 412 mg (92%). $C_{27}H_{44}N_2NiOS_3Si_2$ (623.73): calcd. C 51.99, H 7.11, N 4.49, S 15.42; found C 52.41, H 7.43, N 4.27, S 15.38. IR (KBr): $\tilde{\nu}$ = 2227 [ν(NCO)] cm^{-1}. ^1H NMR (269.7 MHz, [D$_8$]acetone): δ = 7.63 (d, $J_{H,H}$ = 7.9 Hz, 2 H, C_6H_3), 7.20 (d, $J_{H,H}$ = 7.1 Hz, 2 H, C_6H_3), 6.89 (t, $J_{H,H}$ = 7.9 Hz, 2 H, C_6H_3), 3.42 (m, 8 H, NCH_2), 1.29 (t, $J_{H,H}$ = 7.3 Hz, 12 H, NCH_2CH_3), 0.35 (s, 18 H, $SiMe_3$) ppm. ^{13}C NMR (67.8 MHz, [D$_8$]acetone): δ = 160.4, 139.7, 135.0, 133.9 (C_6H_3), 132.0 (NCO), 129.1, 121.4 (C_6H_3), 53.1, 7.7 (Et_4N), −0.5 ($SiMe_3$) ppm.

[Ni(^{H}S$_3$)]$_3$ (1a) from [Ni(NHR)(^{H}S$_3$)] [R = P*n*Pr$_3$ (2a), PCy$_3$ (3a), SPh$_2$ (4a)] and CO. General Procedure: An equimolar amount of CO was injected into a Schlenk tube containing a CH_2Cl_2 solution (ca. 10 mL) of the respective complex and fitted with a septum. In the course of several hours, depending on the complex, the color of the CH_2Cl_2 solution changed from purple or yellow-red to dark-red. Subsequently, dark-brown microcrystals of **1a** precipitated, which were separated, washed with MeOH and/or pentane and dried in vacuo.

[Ni(^{H}S$_3$)]$_3$ (1a) from 2a and CO: From 215 mg (0.445 mmol) of **2a** and 10.0 mL (0.446 mmol) of CO. The reaction was complete after 50 h. Yield: 93 mg (67%). $C_{36}H_{24}Ni_3S_9$ (921.25): calcd. C 46.94, H 2.63, S 31.33; found C 46.81, H 2.56, S 30.83. MS (FD, DMF): *m*/*z* = 921 [Ni(^{H}S$_3$)]$_3^+$, 614 [Ni(^{H}S$_3$)]$_2^+$.

[Ni(^{H}S$_3$)]$_3$ (1a) from 3a and CO: From 210 mg (0.348 mmol) of **3a** and 7.85 mL (0.350 mmol) of CO gas. Reaction time 78 h. Yield: 79 mg (74%).

[Ni(^{H}S$_3$)]$_3$ (1a) from 4a and CO: From 200 mg (0.393 mmol) of **4a** and 8.9 mL (0.397 mmol) of CO gas. Reaction time 5 h. Yield: 94 mg (78%).

[Ni(^{si}S$_3$)]$_3$ (1b) from [Ni(NHR)(^{si}S$_3$)] [R = P*n*Pr$_3$ (2b), PCy$_3$ (2b), SPh$_2$ (4b)] and CO. General Procedure: An equimolar amount of CO was injected into a Schlenk tube containing a CH_2Cl_2 solution (ca. 10 mL) of the respective complex and fitted with a septum. In the course of several hours, depending on the complex, the color of the CH_2Cl_2 solution changed from purple or yellow-red to red-brown. The solution was filtered, reduced in volume to ca. 2 mL and layered with MeOH (20 mL). Dark-red crystals of **1b** precipitated at −25 °C, which were separated after 3−7 d, washed with MeOH and dried in vacuo.

[Ni(^{si}S$_3$)]$_3$ (1b) from 2b and CO: From 185 mg (0.295 mmol) of **2b** and 6.7 mL (0.299 mmol) of CO gas. Reaction time 40 h. Yield: 81 mg (61%).

[Ni(^{si}S$_3$)]$_3$ (1b) from 3b and CO: From 224 mg (0.300 mmol) of **3b** and 6.8 mL (0.304 mmol) of CO gas. Reaction time 65 h. Yield: 87 mg (64%).

[Ni(^{si}S$_3$)]$_3$ (1b) from 4b and CO: From 112 mg (0.172 mmol) of **4b** and 3.9 mL (0.174 mmol) of CO gas. Reaction time 3 h. Yield: 62 mg (80%).

Monitoring the Reactions of 2a/2b, 3a/3b, and 4a/4b with CO by ^{1}H and ^{31}P NMR Spectroscopy: An equimolar amount of CO was injected into an NMR tube containing the solution of the respective complex (ca. 50 mg) in CD_2Cl_2 (ca. 0.6 mL) and fitted with a septum. ^{1}H and ^{31}P NMR spectra were recorded at regular time intervals.

X-ray Structure Determination of [Ni(NHP*n*Pr$_3$)(^{si}S$_3$)] (2b), [Ni(NHPCy$_3$)(^{H}S$_3$)] (3a), [Ni(NHPCy$_3$)(^{si}S$_3$)] (3b), [Ni(NHSPh$_2$)(^{H}S$_3$)] (4a), and [Ni(P*n*Pr$_3$)(^{H}S$_3$)] (5a): In the course of 10 d, red-brown blocks of **2b** crystallized at −25 °C from a saturated THF solution of **2b** layered with CH_3CN. In an NMR tube at −25 °C, in the course of 3 d dark-red blocks of **3a** crystallized from a $CDCl_3$ solution of **3a** layered with Et_2O. Red-violet plates of **3b** crystallized from a hot CH_3CN solution (65 °C) of **3b**, which was slowly cooled to −30 °C. Red-brown crystals of **4a** were grown in the course of 7 d from a saturated CH_2Cl_2 solution of **4a** that was layered with hexane at −30 °C. Red-brown blocks of **5a** crystallized from a concentrated THF solution of **5a**, which was layered with hexane at −30 °C. Suitable single crystals were either embedded in protective perfluoro polyether oil or sealed in glass capillaries under N_2. Data were collected at 210 K (**2b** and **5a**), 220 K (**3a** and **4a**), or 295 K (**3b**) with a Siemens P4 diffractometer using Mo-K_α radiation (λ = 71.073 pm), a graphite monochromator, and the ω-scan technique. With the exception of **2b**, semiempirical absorption corrections using ψ-scans were performed. All structures were solved by direct methods, and full-matrix least-squares refinement was carried out on F^2 using SHELXTL NT 5.1.[23] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of **3a** and **4a** were located in a difference Fourier map and were either refined with a fixed common isotropic displacement parameter (**3a**) or were refined isotropically (**4a**). In all other compounds, the H atoms were geometrically positioned with isotropic displacement parameters being 1.5-times U(eq) of the corresponding C or N atom. One of the *n*-propyl groups of **5a** is disordered. Two alternative sites were refined giving site-occupancy factors of 0.711(8) (site A) and 0.289(8) (site B). The unit cell of **2b** contains two symmetrically independent molecules. Selected crystallographic data are summarized in Table 3.[24]

Acknowledgments

Support of these investigations by the Deutsche Forschungsgemeinschaft (SFB 583: "Redoxaktive Metallkomplexe") and the Fonds der Chemischen Industrie is gratefully acknowledged. We thank Prof. Dr. Horst Kisch for his fruitful discussions.

Preparation and Characterization of Cu_2SnSe_4 Nanoparticles Using a Microwave-Assisted Polyol Method

Haviv Grisaru,[a] V. G. Pol,[a] Aharon Gedanken,*[a] and Israel Nowik[b]

Keywords: Nanoparticles / Microwave heating / Polyol method / Copper / Tin / Selenium

The microwave-assisted polyol method has been applied to the preparation of nanosized Cu_2SnSe_4. Cheap materials such as CuCl (or $CuCl_2{\cdot}2H_2O$), Sn and Se were used as starting materials. Polyethylene glycol (PEG) is the only solvent in which the reaction takes place and the materials did not react in ethylene glycol, tri-, or tetraethylene glycol. Mössbauer spectroscopic measurements revealed a single doublet whose isomer shift of 1.81 mm/s is typical of that seen in tetravalent covalent tin semiconductors. The final product was characterized by X-ray powder diffraction, transmission electron microscopy (TEM), high resolution TEM (HR-TEM), scanning electron microscopy (SEM), X-ray photoelectron spectroscopy (XPS) and electron paramagnetic resonance (EPR) spectroscopy.

Introduction

In recent years, there has been special interest in new multinary metal chalcogenido materials.[1−3] These compounds have the specific properties that are required for technological devices and have been used in optoelectronic devices, lasers and solar cells.[4,5] The compound Cu_2SnSe_4, or more precisely $Cu_2Sn\square Se_4$, where □ denotes the cation vacancy that is included to maintain the same number of cations and anion sites, belongs to one of the families of fourfold defect derivatives of the $A^{II}B^{VI}$ binary semiconductors.[6] It is expected, that in order to maintain an average of four valence electrons per lattice site, the copper atoms should be divalent (Cu^{+2}) in Cu_2SnSe_4.

The multinary metal chalcogenides can be divided into two main groups. In the first group the metal is an alkali metal, and these materials can be prepared either by reactive-flux methods at temperatures between 300−600 °C or by the solvothermal method at relatively low temperatures.[2,7] The second group of multinary metal chalcogenides consists mostly of transition metals instead of alkali metals. These compounds can be synthesized by a simple combination of the elements followed by heating to high temperatures for a prolonged period of time.[8] Marcano and co-workers[9] have prepared ingots of Cu_2SnSe_4 by the vertical Bridgman−Stockbarger technique. The mixture of Cu, Sn and Se, in the ratio of 2:1:4 was sealed in an evacuated quartz ampoule, and heated to 1150 °C for 24 h. Later, it was annealed at 500 °C for 120 h and then cooled to room temperature. Bulk compounds with large sized particles have been prepared using this method, but it is unsuitable for the synthesis of nanomaterials.

Recently, two solvothermal reactions were described by Qian's group.[10,11] B. Li et al.[10] prepared Cu_2SnSe_4 nanocrystals at 140 °C for 15 h using $CuCl_2{\cdot}2H_2O$, $SnCl_2{\cdot}2H_2O$ and Se as the reagents and Q. Li et al.[11] also synthesized nanocrystals in a similar solvothermal process using $CuCl_2{\cdot}2H_2O$, Sn, and Se as the reactants in ethylenediamine (en) at 180 °C for 12 h. They also investigated the effect of different solvents on the formation of the product. Ethylenediamine, diethylamine, benzene, and ethanol were examined as solvents in a sealed autoclave maintained at 140 °C for 15 h. The disadvantage of this method is the need for relatively high pressures and prolonged heating.

In our continuing effort to prepare semiconducting nanoparticles we have developed a general method, the so-called microwave-assisted polyol method, which is general and very efficient. We have applied this method to the preparation of binary and ternary nanosized chalcogenides (selenides and tellurides).[12−14] In most experiments the microwave reaction is complete within a few minutes, the maximum duration being one hour.

The polyol method has been developed over the past two decades and has been applied to the preparation of submicrometer nanoparticles of the easily reducible transition metals.[15] This method is based on alcohols (such as ethylene glycol as well as other glycols) reducing metallic cations to form the corresponding metals. In almost all the reactions, the polyol also plays the role of the solvent.

The application of microwaves to inorganic chemistry began only in the late 1980s.[16] Ethylene glycol (and other glycols) has been proposed as a solvent for microwave di-

[a] Department of Chemistry, Bar-Ilan University, Ramat-Gan 52900, Israel

[b] The Racah Institute of Physics, The Hebrew University, Jerusalem 91904, Israel

electric heating because it is highly susceptible to microwave radiation due to its high permanent dipole and high dissipation factor.[17] An added advantage is that ethylene glycol is a good reducing agent only at high temperatures. The metallic particles that are produced as intermediates in the polyol reaction are also susceptible to microwave radiation, and therefore undergo rapid heating. While the solvent temperature is expected to be that of boiling ethylene glycol, it is likely that the temperature in the reaction cell will be much higher than that of the surrounding liquid. Mingos and Whittaker[18] recently reported that high boiling point alcohols are superior solvents in microwave-assisted reactions because they help prevent arcing, which is known to lead to the decomposition of solvents resulting in carbon and carbonaceous residues. Arcing is considered the main source of the high levels of impurities that are found in the end-products.

In this study, the microwave-assisted polyol method has been shown to be an excellent method for the preparation of Cu_2SnSe_4 nanoparticles. Their crystal structure, morphology, and properties have been investigated using various analytical techniques, and the results are reported below.

Results and Discussion

Powder XRD Studies

The XRD patterns of the prepared and annealed products are shown in Figure 1 (a and b), respectively. The prepared product was not obtained as clean Cu_2SnSe_4 but as a mixture of about 90% Cu_2SnSe_4 (face-centered cubic, PDF: 78−0600), and 10% $SnSe_2$ (PDF: 23−0602), the latter being obtained as a secondary phase. To purify the material, the mixture was heated at 450 °C for 12 h. The X-ray diffraction patterns of the annealed product are presented in Figure 1 (b). No evidence for any impurity was detected and only diffractions characteristic of polycrystalline Cu_2SnSe_4 (PDF: 78−0600) were indexed. To check for other impurities in the annealed compound, we carried out an elemental analysis for carbon and hydrogen. It was found that the levels of carbon and hydrogen impurities after the annealing of Cu_2SnSe_4 were less than 0.2%. The Scherrer equation was used to calculate the particle dimensions.[19] The sizes of the Cu_2SnSe_4 particles are ≈ 40 nm. The calculated lattice parameter found for the compound is a = 5.71 Å. These results are in agreement with previously published data.[9−11] Additional analyses were conducted in order to verify the stoichiometry of the heated sample. Elemental analysis is especially important for Cu_2SnSe_4, because of the secondary phase that was observed for the prepared material. The stoichiometric ratio of Cu:Sn:Se in the annealed sample, measured using EDS, is 2.01:1:3.3. The EDS results show a deficiency of Se. It cannot be claimed that the product is Cu_2SnSe_3 because the positions of the diffraction peaks of this compound are very different from those of Cu_2SnSe_4.[20] For example, Cu_2SnSe_3 has a remarkably intense diffraction peak at 2θ = 36.50°, which was not observed in our measurements. By analyzing the XRD and the EDS measurements we confirmed Cu_2SnSe_4 to be the sole product of the heated sample.

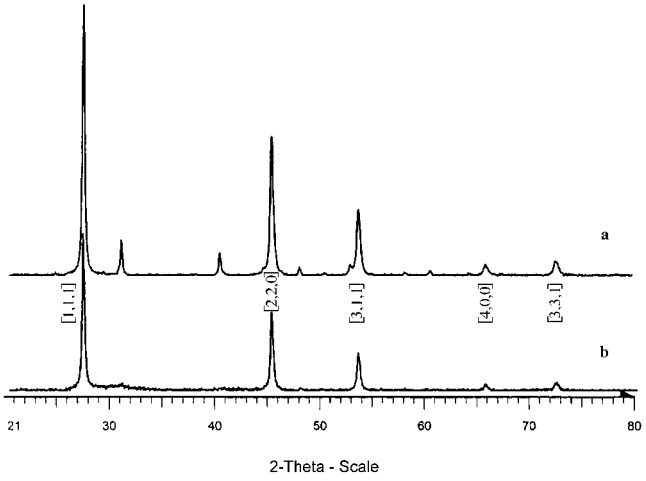

Figure 1. Powder XRD patterns of: (a) Cu_2SnSe_4 compound prepared in PEG and (b) annealed face-centered cubic product after heating at 450 °C for 12 h

TGA Measurements

The thermogravimetric measurements of the prepared product in the temperature range of 30 to 600 °C revealed two main mass losses. The first loss was ca. 1.6% and occurred in the temperature range of 240−450 °C. This loss can be attributed to the removal of PEG from the surface of the product. A second mass decrease of 4.3% was seen over the range 480−600 °C. This loss may perhaps be due to the removal of $SnSe_2$.

Electron Microscopy Studies (TEM, SEM and HR-TEM)

The morphology of the heated sample was studied by TEM and SEM measurements. The TEM image of Cu_2SnSe_4 is shown in Figure 2. The diameters of most of the particles are in the 30−50 nm range. We also observed agglomerated particles with an average diameter of about 150 nm. The prepared nanoparticles were also found to be

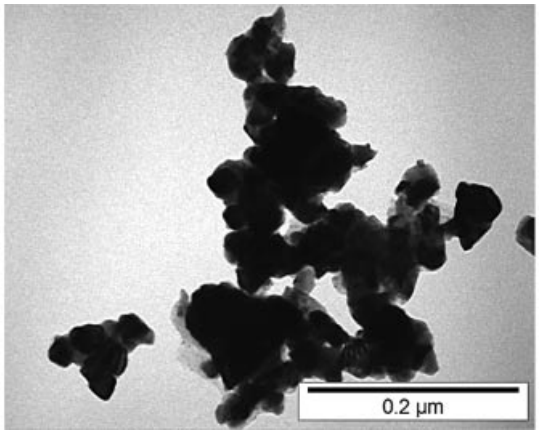

Figure 2. TEM image of the heated Cu_2SnSe_4 sample

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

aggregated and the aggregation mode changed only slightly upon annealing. The size of the individual particles, of 30−50 nm, is in agreement with the results calculated from the XRD data. The polycrystalline nature of Cu_2SnSe_4 was established from electron diffraction measurements. The SEM micrograph of the product (Figure 3) is consistent with the overall view of the TEM image. It also showed aggregated nanoparticles resulting in large clusters.

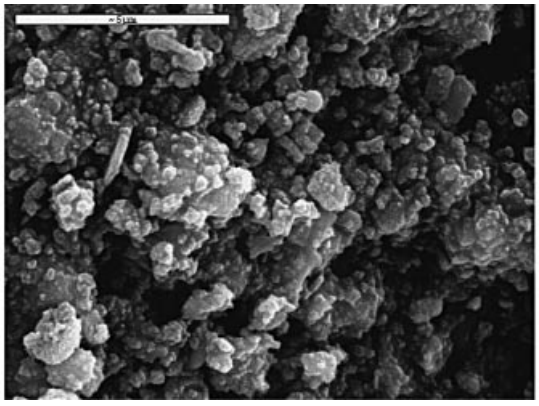

Figure 3. SEM image of the heated Cu_2SnSe_4 sample (scale bar equal to 5 μm)

The HR-TEM is depicted in Figure 4 and provides further evidence for the identification of the product as Cu_2SnSe_4. The micrograph shown in Figure 4 is a picture of the edge of the Cu_2SnSe_4 particle. The image was recorded along the [111] zone. It illustrates the perfect arrangements of the atomic layers and the lack of defects. The measured distance between these [111] lattice planes is 0.315 nm, which is very close to the distance between the planes reported in the literature (0.328 nm) for the face-centered cubic lattice of Cu_2SnSe_4 (PDF: 78−0600). An outer amorphous shell was also observed at the edge of the nanocrystalline Cu_2SnSe_4 particles and is marked by an arrow. The thickness of this shell measured for many particles is approximately 1 nm. The Fast Fourier Transform filtered (FFT) image of this lattice is shown in the insert.

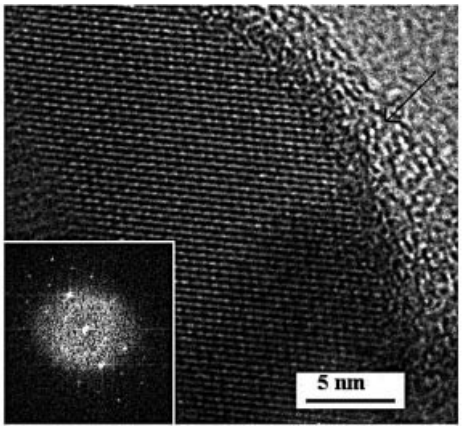

Figure 4. HR-TEM image of the heated Cu_2SnSe_4 sample. The FFT image of this lattice and the computer generated diffraction pattern is shown in the insert

The aggregated nature of the product was also evident from BET measurements. The surface area measured was 5.7 m^2g^{-1}.The surface area for a 40 nm sphere of Cu_2SnSe_4, assuming a density of 5.1 gcm^{-3}, was calculated as 29.4 m^2g^{-1}. This indicates the aggregated nature of the product. However, the aggregated initially prepared material or the aggregated annealed material both form colloidal solutions upon dissolving in 2-mercaptoethanol.

XPS Measurements

X-ray photoelectron spectroscopy (XPS) is known to probe only the surface of the particles. In XPS, excitation by X-rays enables core atomic levels to be probed, and the resultant chemical shift provides an indication of the oxidation state of the surface materials. In Figure 5 (a) we present the wide XPS spectrum of the heated sample. The overall XPS spectrum of the Cu_2SnSe_4 nanoparticles is in agreement with previously published data.[11] The binding energies obtained in the XPS analysis were corrected for specimen charging by referencing the C 1s to 285.2 eV, and are presented in Table 1. Peaks for carbon and oxygen were also observed, and we have assigned them to organic impurities adsorbed on the surface of the powders due to solvent decomposition. The XPS picture of the peaks of the doublet of Sn in Cu_2SnSe_4 nanoparticles is shown in Figure 5 (b). The energy of the Sn $3d_{5/2}$ band is 486.6 eV, and is probably an average value between that of Sn^{+4} in SnO_2 (486.9 eV) and that of Sn^{+2} in SnO (486.3 eV).[21,22] According to the recent literature, Sn undergoes a chemical shift of at least 0.4 eV when reduced from Sn^{+4} to Sn^{+2}.[23] We have attributed the presence Sn^{+2} ions to the reduction that the Sn^{+4} undergoes upon X-ray irradiation. Similar examples are well documented in the literature.[24,25] It can therefore be concluded that the XPS measurements cannot confirm unequivocally that the oxidation state of Sn in the prepared or annealed materials is Sn^{+4}. We therefore required another spectroscopic tool in order to determine the oxidation state of the Sn in the heated sample.

Mössbauer Spectroscopic Measurements

In order to verify our conjecture that the oxidation state of Sn in the heated sample of Cu_2SnSe_4 nanoparticles is +4, Mössbauer spectroscopic measurements were performed. The Mössbauer spectrum of Cu_2SnSe_4 at room temperature is shown in Figure 6. A similar spectrum was obtained at 90 K. The spectrum was analyzed in terms of two quadrupole doublets, one corresponding to Cu_2SnSe_4 (isomer shift: 1.81 mm/s relative to $BaSnO_3$, and quadrupole splitting: 0.90 mm/s), while the second (less than 5%) is perhaps due to an Sn^{+2} impurity, which was also observed in the XPS spectrum. The value obtained for the isomer shift of ^{119}Sn in Cu_2SnSe_4 is typical of Sn^{+4} in essentially covalent semiconductors,[26] and quite similar to the $SnSe_2$ system.[27] This conclusion leads to the determination of the oxidation state of the copper as +2 in Cu_2SnSe_4. The oxidation states of the Sn and Cu as determined by Mössbauer spectroscopy are bulk properties, which are different from the surface values.

EPR Measurements

The electron paramagnetic resonance (EPR) spectrum of the heated sample of Cu_2SnSe_4 nanoparticles was measured at room temperature (not shown here). The Cu_2SnSe_4

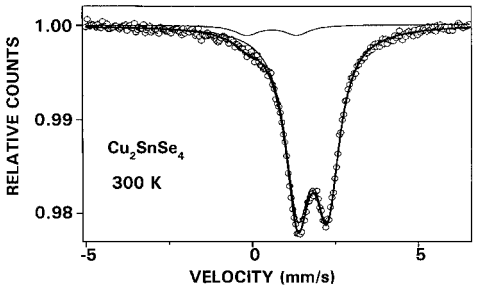

Figure 6. The ^{119}Sn Mössbauer spectrum of Cu_2SnSe_4 nanoparticles at room temperature

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sample showed a peak-to-peak separation (ΔHpp) of 320 G and a *g* value 2.178. The *g* factor is equal to 2.00232 for the unbound electron.[28] The paramagnetic resonance signal in Cu_2SnSe_4 is associated with the paramagnetic nature of Cu^{+2}. This is consistent with the fact that copper atoms should be divalent in Cu_2SnSe_4 in accordance with the Sn oxidation state of +4 obtained from the Mössbauer measurements. The experimental *g* value of 2.178 for this sample is within the experimental error of the *g* values reported for Cu^{+2}.[29]

Reaction Mechanism

The main question regarding the preparation of Cu_2SnSe_4 is the mechanism of its formation. In previous work, we proposed a mechanism for the formation of $CuInSe_2$ (CIS) and $CuInTe_2$ (CIT) nanoparticles.[14] The proposed mechanism was based on the fact that the reduced metallic particles react with a second metallic element and with the chalcogenide under microwave irradiation in order to form a ternary chalcogenide compound. For the above-mentioned compounds, CIS and CIT, the additional metallic element was indium. We refer to these reactions as "wet solid-state reactions". A control experiment in which metallic copper powder, an In^{+3} salt, and Se (or Te) reacted together (Cu/In^{3+}/Se or Te), did not result in ternary chalcogenides (a binary copper selenide was obtained instead).

Copper(I) or copper(II) are known from previous experiments to be reduced by the ethylene glycol to the corresponding metallic nanoparticles. This was demonstrated when CuCl or $CuCl_2$ were treated with EG in the absence of Se and Sn, yielding copper nanoparticles as the sole products. In the current reaction, both copper(I) and copper(II) yielded the same product, Cu_2SnSe_4, when treated with Sn and Se. The mixture reacted in the microwave field forming Cu_2SnSe_4 nanoparticles. As in previous cases, we have attributed the ability of the two metals (Cu and Sn) to reduce Se to their strong interaction with microwave radiation. The experiments to reduce tin salts under the same reaction conditions were unsuccessful. In another control experiment, metallic copper powder, a Sn^{+2} salt, and Se reacted together but did not yield the ternary compound (instead a binary copper selenide was obtained). We also tried to synthesize Cu_2SnTe_4 using the same starting materials but replacing Se with Te but only copper telluride was obtained. We could not find any report in the literature of the synthesis of bulk or nanoparticles of Cu_2SnTe_4.

Finally, we discuss the role of the PEG in this reaction. We could not synthesize Cu_2SnSe_4 when Cu^{II} or Cu^{I} was treated with Sn and Se in ethylene glycol, triethylene, or tetraethylene glycol. The only solvent *in* which these materials react and *with* which these materials react is PEG. We have attributed these observations to the higher boiling temperature of PEG (around 400 °C) compared with those of ethylene glycol (198 °C) and the other glycols.

Conclusions

Cu_2SnSe_4 nanoparticles have been prepared by using the microwave-assisted polyol method. Two routes have been suggested for the synthesis. The starting materials did not react when ethylene glycol, tri-, or tetraethylene glycol were used as solvents. They did react, however, when PEG was used as a solvent, and the reaction took 2 h. The sizes of the nanoparticles measured from transmission electron microscopy are in the range of 30−50 nm, which is in agreement with the results calculated from the XRD data.

Experimental Section

Materials: All reagents were of the highest purity. Elemental Se, Sn, copper(I) chloride, $CuCl_2{\cdot}2H_2O$, polyethylene glycol (PEG) (MW = 400 g/mol), and 2-mercapto ethanol were all purchased from Aldrich and used without further purification.

Instrumentation: The X-ray diffraction patterns of the products were recorded using a Bruker AXS D8 Advance Powder X-ray Diffractometer (using Cu-K_α radiation, λ = 0.15418 nm at 40 kV/40 mA) with a secondary graphite crystal monochromator. The transmission electron micrographs (TEM) were obtained with a JEOL-JEM 100SX microscope, working at an 80 kV accelerating voltage, and a JEOL-2010 HR-TEM instrument using an accelerating voltage of 200 kV. EDS measurements were conducted using an X-ray microanalyzer (Oxford Scientific) built on a JSM-840 Scanning Electron Microscope (JEOL). Elemental analyses (Carbon) were carried out with an EA 1110 CHNS-O instrument. Thermogravimetric analyses (TGA) were performed with a Mettler−Toledo TGA/SDTA851 instrument using nitrogen or argon as the purging gas with a scanning rate of 5 °C/min. X-ray photoelectron spectra (XPS) were measured with an AXIS, HIS 165, Kratos Analytical, ULTRA instrument. Mössbauer spectroscopic studies of a Cu_2SnSe_4 sample were performed using a $Ba^{119m}SnO_3$ source (10 mCi) and a conventional constant acceleration Mössbauer drive. Electron paramagnetic resonance (EPR) spectra were recorded with a Bruker EPR spectrometer (ER083 CS) operating at X-band (υ = 9.77 GHz), with a 100-kHz magnetic field modulation. The Brunauer−Emmett−Teller (BET) surface area measurements were performed using a Micromeritics (Gemini 2375) surface area analyzer. The nitrogen adsorption and desorption isotherms were measured at a temperature of 77 K after heating the sample at 100 °C for 1 h.

Microwave-assisted reactions were conducted in a domestic microwave oven, Kenwood-900 W, 2.45 × 10^9 Hz working frequency, modified with a refluxing system. In all the experiments the microwave oven worked in the following cycling mode: on for 21 s, off for 9 s, and the total power was always 900 W. This cycling mode was chosen in order to prevent the violent "bump" boiling of the solvent. All reactions were conducted under a flow of nitrogen.

Preparation of Cu_2SnSe_4: CuCl (0.197 g, 2 mmol) was dissolved in PEG (50 mL) by gentle heating in the microwave oven for approximately 1 minute. The stoichiometric quantities of Sn (0.118 g, 1 mmol), and Se (0.315 g, 4 mmol) powder were then added. The system was purged for 10 minutes with nitrogen and then the microwave reactor was turned on. The process was carried out for 2 h.

In the post reaction treatment, the product was centrifuged once at 9500 rpm with the mother liquor to separate the powder from the liquid, and was then washed a few times with ethanol at 20 °C at 9500 rpm. The product was then dried overnight under vacuum. The sample was annealed under argon for 12 h at 450 °C.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Another attempt to fabricate Cu_2SnSe_4 nanoparticles was carried out using $CuCl_2 \cdot 2H_2O$ (0.341 g, 2 mmol) instead of CuCl under the same conditions as in the first route. The results discussed can be applied to samples prepared by either of these methods.

Acknowledgments

Prof. A. Gedanken thanks the German Ministry of Science through the Deutsche-Israel Program (DIP) for supporting this research. The assistance of Dr. Y. Gofer with the XPS measurements is gratefully acknowledged. The authors are also grateful to Prof. Z. Malik of the Faculty of Life Sciences for extending the use of his facilities to us, and to Dr. Y. Grinblat and Dr. T. Tamary of the Chemistry Department for their assistance with TEM and HR-TEM measurements.

Structural and Theoretical Studies of New Ruthenium-Amidato Complexes with Phenanthroline Ligands Containing H-Bonding Groups

Daniela Rais,[a] Ian R. Gould,[a] Ramón Vilar,*[a] Andrew J. P. White,[a] and David J. Williams[a]

Keywords: Chelates / Tridentate ligands / Ligand design / Ruthenium / pi interactions

The syntheses, characterization and coordination chemistry of two new 1,10-phenanthroline-based ligands are presented here. Crystallographic studies have shown that both molecules display hydrogen-bonding and π–π stacking interactions, generating interesting supramolecular assemblies in the solid state. The reactions of these ligands with $[RuCl_2(PPh_3)_3]$ have been performed and two new ruthenium-amidato complexes have been prepared. In both cases, the presence of a pyridyl group in the ligand backbone favours the deprotonation of one of the carboxyamido moieties leading to a tridentate coordination mode of the ligands. The structural characterization of one of the ruthenium complexes is also reported.

Introduction

Transition metal complexes featuring *N*-amidato [−NRC(=O)R′] ligands are relatively less common than those containing other *N*-based species such as amines (−NR_3) or amides (−NR_2). Nevertheless, increasing interest has recently been paid to *N*-amidato-containing systems due to their role as models for the interactions between metal centres and proteins.[1] To date, studies have largely focused on iron- and copper-amidato species[2,3] because of their biological relevance, and on cobalt systems due to their interesting catalytic properties.[4] Although some reports exist on the chemistry of *N*-amidato-ruthenium complexes, these have mainly dealt with pentaaminoruthenium amido species. Examples of compounds where the carboxyamido moiety is part of a more complex coordination environment are somewhat rare. However, the ability of ruthenium to participate in a wide range of catalytic and photochemical processes[5] coupled with the stability, ease of preparation and strong σ-donating properties of the amidato ligands have contributed to the renewed interest in these systems.[6,7] Synthetic and structural information on Ru^{II} and Ru^{III} complexes of deprotonated *N*-aryl-2-pyridinecarboxamide ligands has been reported by Bhattacharya[6] while Wright has investigated a series of Ru^{II} complexes of doubly deprotonated *N*,*N*′-bis(6-methyl-2-pyridinyl)-2,6-pyridinedicarboxamide.[7] In this context, the pendant pyridine moieties were found to interact with appropriately positioned ruthenium-bound molecules, thereby mimicking many metalloenzymes that influence the reactivity of bound substrates through interactions with the metal centre and functional groups present on the nearby protein backbone. The general ability of *N*-amidato ligands to stabilize metals in high coordination states was further confirmed by the generation and characterization of the Ru^{IV} species $[RuL_2]\cdot H_2O$ [H_2L = *N*,*N*′-bis(2-phenyl)-2,6-pyridinedicarboxamide].

As part of our interest in the chemistry of transition metal complexes that possess hydrogen bonding capabilities,[8] we have recently focused our efforts on the synthesis of 2,9-carboxyamido-substituted phenanthroline molecules. Metal complexes with hydrogen-bonding properties are of great interest due to their applications in the design of molecular receptors[9] as well as in the fields of crystal engineering[10] and supramolecular catalysis.[11] Herein we report the synthesis and characterization of two phenanthroline-carboxamide ligands (H_2L1 and L2 in Scheme 1) and the products resulting from their reactions with $[RuCl_2(PPh_3)_3]$.

Results and Discussion

Synthesis of Phenanthroline-Based Ligands H_2L1 and L2

The two molecules *N*,*N*′-bis(2-amino-6-pyridyl)-1,10-phenanthroline-2,9-carboxamide (in its protonated form, H_2L1) and *N*,*N*′-bis(2-pyridyl)-1,10-phenanthroline-2,9-carboxyamide (L2) (Scheme 1) were obtained in good yields (60 and 91 %, respectively) by reaction of 1,10-phenanthroline-2,9-dicarbonyl chloride (prepared from neocuproine by previously reported methods[12]) with the corresponding amine.

The new compounds were characterized by analytical and spectroscopic means. The IR spectra of the two species showed broad bands centred at $\tilde{\nu}$ = 3326 and 3333 cm^{-1} for H_2L1 and L2, respectively, which were assigned to the ν(NH) band of the carboxyamido groups. In the ^1H NMR spectra, the CO−N*H* proton was found to resonate as a singlet at δ = 10.33 and 11.17 ppm for H_2L1 and L2, respectively. A single set of resonances was observed for the two halves of the molecules indicating their equivalence on the NMR time scale.

The structural features of the newly synthesized molecules were elucidated by performing single-crystal X-ray analyses. It should be noted that attempts to crystallise the protonated H_2L1 species were not successful; instead, a very small number of single crystals of the deprotonated form of this compound (i.e. L1) were obtained and structurally characterised. This suggests that, although the bulk of the material is isolated as the diprotonated form (see below) a small amount of the neutral form is also present (which forms single crystals).

In the solid state L1 has a nonplanar hemi-helical conformation, there being a significant twist of the phenanthroline unit with rings **B** and **D** inclined by approximately 9° (see Figure 1). One of the amide groups [associated with N(16)] is held in an almost co-planar arrangement with its adjacent phenanthroline pyridyl ring **B** by an intramolecular N−H···N hydrogen-bond (**f** in Figure 1); rings **A** and **B** are inclined by approximately 3°. By contrast, the other amide group is rotated substantially out of plane, the torsional twists about C(11)−C(24) and N(25)−C(26) being approximately 24 and 33°, respectively [cf. ca. 4 and 3° about C(2)−C(15) and N(16)−C(17)]. However, these rotations are in opposite senses such that rings **D** and **E** which are inclined by approximately 8°, are in a stepped relationship to each other. This second amide group is not intramolecularly hydrogen-bonded to its adjacent phenanthroline pyridyl ring **D** (N···H 2.40 Å), entering instead into intermolecular hydrogen-bonding with the carbonyl oxygen atom of the "first" amide of a centrosymmetrically related counterpart (**b** in Figure 2). There is also an intermolecular N−H···N hydrogen bond between the N(23) terminal amino group of one molecule and the pyridyl nitrogen atom N(18) of another across an independent inversion centre (**a** in Figure 2). These interactions, combined with π−π stacking interactions **c** and **d**, create a continuous "staircase-like" chain of alternating hemi-helices that progresses along the crystallographic *a* direction. Adjacent chains are cross-linked by N−H···O hydrogen bonds between the other terminal amide group N(32) in one chain and the carbonyl oxygen O(24) of the next [N···O, H···O 3.00, 2.10 Å; N−H···O 175°].

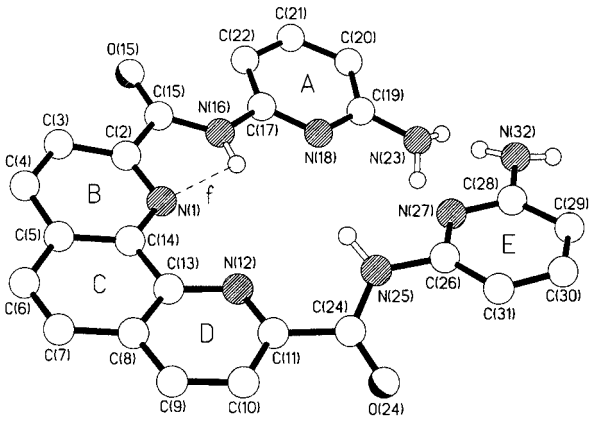

Figure 1. Molecular structure of L1; the intramolecular N−H···N hydrogen bond **f** has N···N, H···N 2.69, 2.24 Å and N−H···N 111°; the nonbonded N(23)···N(32) separation is 3.47 Å

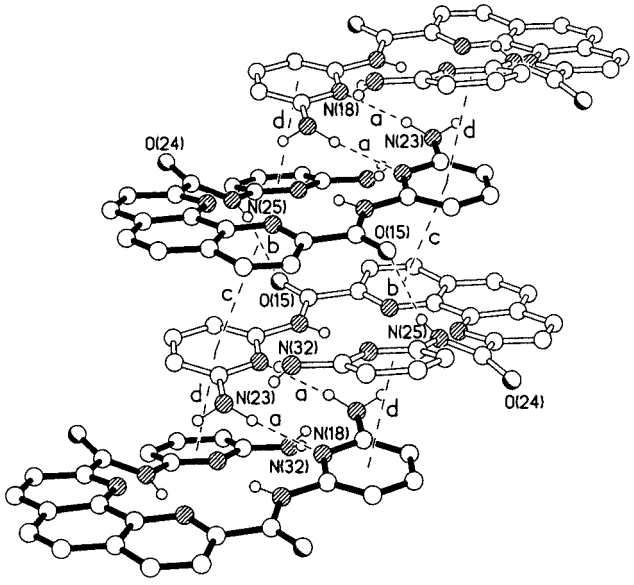

Figure 2. Part of one of the continuous "staircases" in the solid-state structure of L1; the hydrogen bonding geometries [N···X, H···X (Å), N−H···X (°)] are **a** 3.08, 2.18, 174; **b** 2.97, 2.16, 149; the centroid···centroid separations are **c** 3.58 Å and **d** 3.67 Å, the interacting rings being inclined by 3 and 19°, respectively

The related molecule L2 has a similar conformation but with a smaller distortion of the central phenanthroline ring system-rings **B** and **D** being inclined by approximately 4° (see Figure 3). Rings **A** and **B** are inclined by approximately 9°, and **D** and **E** by approximately 35°. The two amide groups, however, are both essentially co-planar with, and intramolecularly N−H···N hydrogen bonded to (**f** and **g** in Figure 3), their adjacent phenanthroline pyridyl rings; the torsional twists about C(11)−C(23) and C(2)−C(15) are

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

approximately 2 and 11°, respectively. The molecules pack to form continuous stacks along the crystallographic *a* direction (Figure 4), there being a parallel π−π stacking interaction between ring **B** of one molecule and its centrosymmetrically related counterpart in another (centroid···centroid and mean interplanar separations of 3.87 and 3.57 Å, respectively). The other stacking interaction is more unusual, and involves an orthogonal approach of the amide N($p\pi$) orbital of N(24) in one molecule to ring **C** of another and *vice versa* across an independent inversion centre; the N···centroid distance **b** is 3.42 Å and the N···centroid vector is inclined by approximately 86° to the {C(23)−N(24)−C(25)} plane.

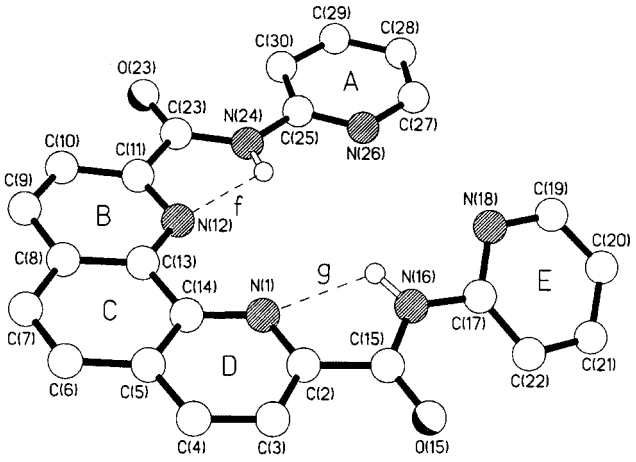

Figure 3. Molecular structure of L2; the intramolecular N−H···N hydrogen bonding geometries [N···N, H···N (Å), N−H···N (°)] are **f** 2.65, 2.16, 114; **g** 2.67, 2.21, 111

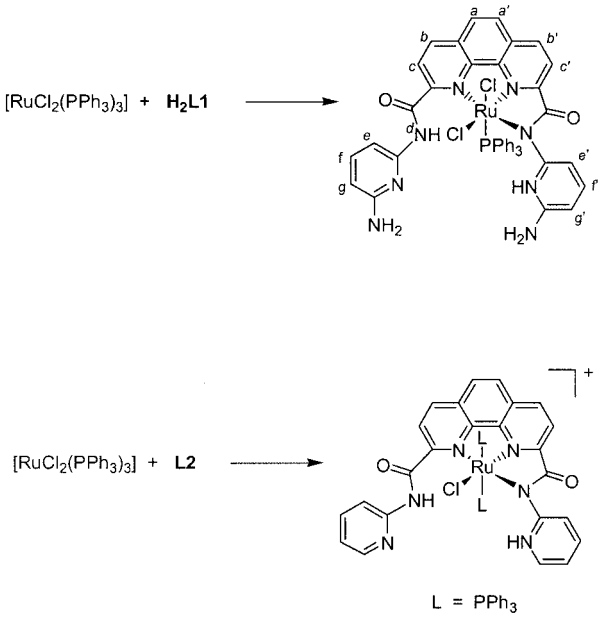
Synthesis of $[RuCl_2(L1)(PPh_3)]$ (1)

Reaction of $[RuCl_2(PPh_3)_3]$ with H_2L1 in a DMF/toluene solvent mixture led to isolation of complex $[RuCl_2(L1)(PPh_3)]$ (**1**) in 84% yield (Scheme 2). The initially dark brown suspension was refluxed for 4 hours under a N_2 atmosphere, turning dark purple after approximately 30 min. Filtration of the suspension yielded **1** as a dark purple powder.



Scheme 2

The new compound was found to be air stable and could be characterized by means of IR, $^{31}P\{^1H\}$ and ^1H NMR spectroscopy, FAB^+ mass spectrometry and elemental analyses. The formulation based on the analytical and spectroscopic data was further confirmed by a single-crystal X-ray structural determination. Suitable crystals were obtained by layering diethyl ether onto a solution of **1** in DMF.

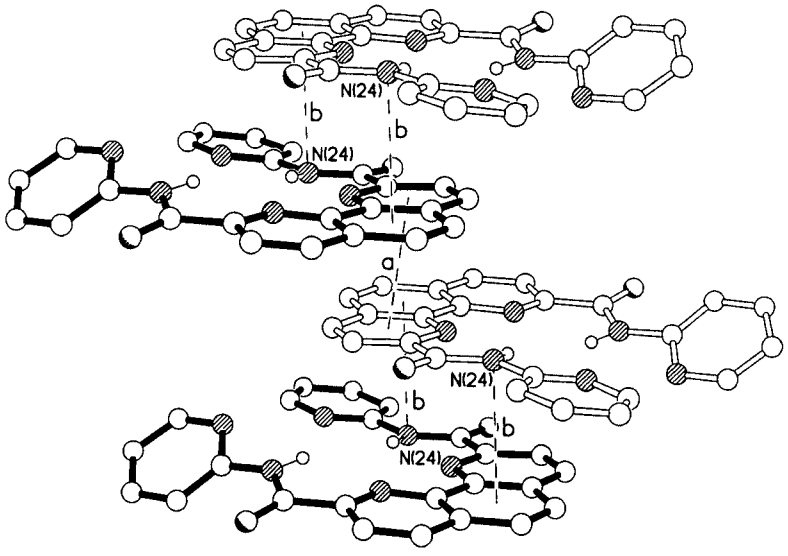


Figure 4. Part of one of the continuous stacks of molecules in the structure of L2; the centroid···centroid separation **a** is 3.87 Å and the N···centroid distance **b** is 3.42 A

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The X-ray analysis showed L1 to be coordinated to the ruthenium centre in an asymmetric tridentate fashion, forming two coordinative Ru−N bonds with the phenanthroline nitrogen atoms and a Ru−N amidato bond with a deprotonated carboxyamido unit, the amido proton having been transferred to N(18) of the adjacent aminopyridine ring (Figure 5).

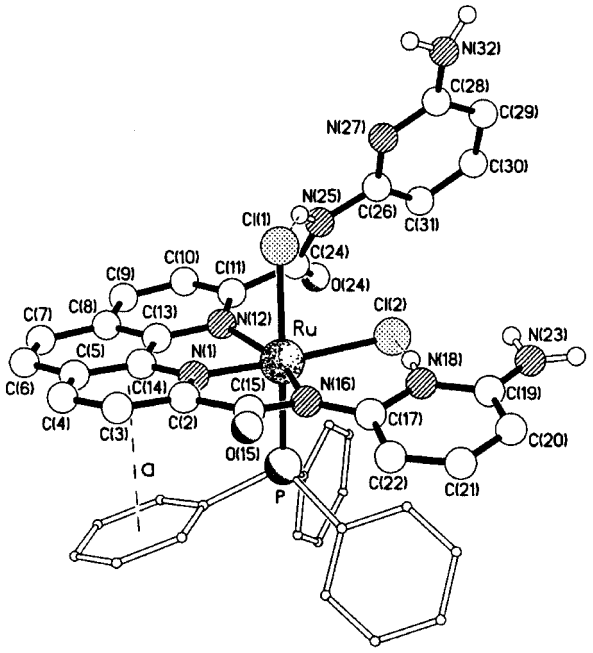

Figure 5. Molecular structure of $[RuCl_2(L1)(PPh_3)]$ (**1**); the centroid···centroid separation **a** is 3.47 Å and the rings are inclined by approximately 16°

The coordinated amido arm of the ligand lies within the equatorial coordination plane, the torsional twists about C(2)−C(15) and N(16)−C(17) being approximately 5 and 17°, respectively, a geometry that facilitates an intramolecular N−H···Cl hydrogen bond from the pyridinium nitrogen N(18) to the equatorially coordinated chloride Cl(2) [N···Cl, H···Cl 2.99, 2.12 Å; N−H···Cl 163°]. By contrast the other arm is rotated substantially out of plane−the torsional twists about C(11)−C(24) and N(25)−C(26) are approximately 54 and 12°, respectively, thereby directing the amide N−H group towards the axially coordinated chloride Cl(1); here the N−H···Cl hydrogen bond is noticeably weaker [N···Cl, H···Cl 3.36, 2.55 Å; N−H···Cl 150°]. The phenanthroline unit has a warped geometry very similar to that seen in the free ligand, the two pyridyl rings being inclined by approximately 10°. The geometry at ruthenium is distorted octahedral with *cis* angles in the range 77.4(2) to 93.0(1)°, the most acute angles being associated with the five-membered chelate rings (see Table 1 and Table 2) which are coplanar to within 0.06 Å. There is a substantial distortion of the *trans* N(12)−Ru−N(16) angle [156.8(2)°] which is a consequence of the geometrical constraints of the chelating ligand. The Ru−N(1) bond [1.951(5) Å] is, as expected, significantly shorter than those to N(12) [2.163(5) Å] and N(16) [2.156(5) Å]. The Ru−Cl(1) bond [2.469(2) Å], *trans* to P, is noticeably shorter than that to Cl(2) [2.493(1) Å] *trans* to N(1). It is interesting to note that the asymmetric chelating mode of the ligand is also reflected in an asymmetric pattern of bonding within the phenanthroline ring system−for example, though the N(1)−C(2) [1.332(8) Å] and N(1)−C(14) [1.340(8) Å] bond lengths are the same, those between N(12)−C(13) [1.392(7) Å] and N(12)−C(11) [1.329(8) Å] differ significantly. A similar (but expected) asymmetry is seen between the two amide groups, with the C−N bond in the deprotonated amide [C(15)−N(16) 1.380(8) Å] being significantly elongated compared with its counterpart [C(24)−N(25) 1.327(9) Å]. This asymmetry is also observed in the solution ^{1}H NMR spectra and in the solid-state infrared spectra (vide infra). The orientation of the triphenylphosphane is to some extent influenced by an intramolecular π−π stacking interaction (**a** in Figure 5) between one of the phosphane phenyl rings and the N(1) pyridyl ring of the phenanthroline. The only inter complex interaction of note is a π−π stacking interaction between the N(12) containing pyridyl ring of the phenanthroline unit in one molecule and the N(18) aminopyridinium ring of another, the centroid···centroid separation is 3.65 Å and the rings are inclined by approximately 14°. The only other noteworthy intermolecular interactions are N−H···O hydrogen bonds between the terminal amine groups and included dimethylformamide (DMF) solvent molecules. The N(32) amino group is involved in two N−H···O hydrogen bonds to the oxygen atoms of two centrosymmetrically related DMF molecules, linking pairs of complexes [N···O, H···O (Å), N−H···O (°); 2.95, 2.07, 167; 3.02, 2.13, 170]. The other terminal amino group [N(23)] forms a single hydrogen bond to an independent DMF solvent molecule [N···O, H···O 2.69, 1.81 Å, N−H···O 165°].

The ligand's asymmetric coordination was reflected in the IR spectrum of complex **1** which showed two different carbonyl absorptions: the one at $\tilde{\nu}$ = 1683 cm^{-1} was assigned to the CO stretching of the noncoordinated carboxamide while the one at $\tilde{\nu}$ = 1638 cm^{-1} was attributed to the CO stretching of the *N*-coordinated amidato group, in agreement with values reported in the literature for analogous *N*-bound amidato ligands (see the calculations section for a discussion of these values). Several bands were observed in the N−H bond stretching region but their assignment was found to be problematic given the numerous N−H groups present in the molecule; only after quantum mechanical calculations were performed it was possible to assign these values (see calculations section). The $^{31}P\{^{1}H\}$ NMR spectrum showed a singlet at δ = 45.0 ppm, shifted downfield with respect to the starting material ($[RuCl_2(PPh_3)_3]$, 42.0 ppm). The ^{1}H NMR spectrum of **1** in $[D_6]$DMF displayed an extremely complicated pattern in the aromatic region, consistent with the asymmetric coordination of the ligand to the ruthenium centre (as shown in the solid-state structure). The N−H group of the noncoordinated carboxamide was observed as a singlet at δ = 10.58 ppm while a signal at δ = 13.74 ppm was assigned to the pyridinium proton.

Synthesis of *trans*-[RuCl(L2)(PPh_3)$_2$]Cl (*trans*-2)

By analogy with the synthesis of **1**, the reaction of $[RuCl_2(PPh_3)_3]$ with one equivalent of L2 was investigated. However, instead of the expected $[RuCl_2(L2)(PPh_3)]$ a complex with formula $[RuCl(L2)(PPh_3)_2]Cl$ was obtained (Scheme 2). Upon mixing the reactants in DMF/toluene, a deep purple solution was immediately formed. The mixture was stirred at room temperature for 2 hours yielding a dark purple precipitate. The $^{31}P\{^{1}H\}$ NMR spectrum of the solid in $[D_2]$-dichloromethane showed two doublets at δ = 49.7 and 39.6 ppm ($J_{P,P}$ = 36.0 Hz), indicating the presence of two nonequivalent phosphane ligands in this species. However, during the course of the NMR studies it was observed that the compound was not stable since a dark purple solid precipitated few minutes after the $[D_2]$-dichloromethane solution (originally highly coloured and perfectly clear) had been prepared. After 1 hour the entire soluble compound had been transformed into the dichloromethane-insoluble product and no $^{31}P\{^{1}H\}$ NMR signal could be detected in the supernatant solution. The resulting purple solid was isolated by filtration and analyzed by $^{31}P\{^{1}H\}$ NMR and IR spectroscopy, FAB^+ mass spectrometry and elemental analyses. On the basis of the spectroscopic and analytical data, the compound was formulated as *trans*-$[RuCl(L2)(PPh_3)_2]Cl$ (*trans*-**2**).

The $^{31}P\{^{1}H\}$ NMR spectrum of *trans*-**2** in $[D_6]$DMF showed the presence of a singlet resonance at δ = 25.5 ppm, in contrast to the value of 43.0 ppm observed for **1**. The chemical shift of 25.5 ppm is consistent with previously reported data for ruthenium complexes where two triphenylphosphane ligands are *trans* to each other (and *cis* to chlorides and chelating *N*-ligands).[13] The formulation of *trans*-**2** was further supported by FAB^+ mass spectrometry which showed a molecular ion peak a.m.u. at 1081 corresponding to $[RuCl(L2)(PPh_3)_2]^+$. The IR spectrum of *trans*-**2** was also consistent with the proposed formulation showing two bands at $\tilde{\nu}$ = 1690 and 1648 cm^{-1} that were assigned to the carbonyl stretching modes of a nondeprotonated amide (i.e. the noncoordinated one) and a coordinated amidato group, respectively, on the basis of quantum-mechanical calculations (see below). The asymmetric coordination of ligand L2 in complex *trans*-**2** found support in the ^{1}H NMR spectrum of the compound, which showed a very complicated pattern for the protons on the phenanthroline and the pyridine moieties and the presence of two different CO-N*H* resonances (whose values were consistent with that of a noncoordinated carboxamide and a protonated pyridine group). Elemental analyses agreed with the proposed formulation.

The identity of the solid obtained during the first stage of the reaction between L2 and $[RuCl_2(PPh_3)_3]$ is uncertain. However, the available spectroscopic and analytical data [$^{31}P\{^{1}H\}$ NMR spectrum, elemental analyses and FAB^+ mass spectrum] are compatible with a formulation of the purple powder as *cis*-$[RuCl(L2)(PPh_3)_2]Cl$ (*cis*-**2**). It is reasonable to propose that compound *cis*-**2** is formed as the kinetic product of the reaction and isolated as a solid due to its insolubility in the reaction medium. However, once in either dichloromethane or DMF solution, it rapidly converts to its thermodynamically more stable isomer *trans*-**2**.

Quantum-Mechanical Calculations

To gain a better understanding of the nature of the ruthenium-amidato complexes and be able to rationalize some of their spectroscopic and structural parameters, a quantum mechanical study of complexes **1** and **2** was carried out. It was also of interest to compare the relative energy of the *cis* and *trans* isomers of complex **2**.

Selected structural parameters for compounds **1** and *trans*-**2** are reported in Table 3 and Table 4. It can be seen that the calculated structure of **1** is in reasonably good agreement with that determined crystallographically (see Tables 1 and 2). The calculated molecular structure of *trans*-**2** is shown in Figure 6, the bond lengths and angles around the ruthenium centres being in good agreement with the crystallographic data of **1**. As would be expected, the largest difference between the calculated structures of **1** and *trans*-**2** is observed in the bond length between the Ru and the P atoms due to the different *trans* influence of the chloride (in **1**) and the phosphane (in *trans*-**2**).

Minima have been obtained for both *cis*-**2** and *trans*-**2** and, as expected on steric grounds, the *trans* isomer is calculated to be more stable than the *cis* isomer by ca. 30 kcal mol^{-1}. These findings sustain our hypothesis that *cis*-**2** may indeed be the kinetic product of the reaction of L2 and $[RuCl_2(PPh_3)_3]$ which, however, easily coverts to its thermodynamically more stable isomer *trans*-**2**.

Inspection of the vibrational modes of **1** shows good correlation with the experimental data. There are two distinct carbonyl absorptions: one at $\tilde{\nu}$ = 1661 cm^{-1}, corresponding to the CO stretch of the noncoordinated carboxamide (cf. experimental $\tilde{\nu}$ = 1683 cm^{-1}), while the CO of the

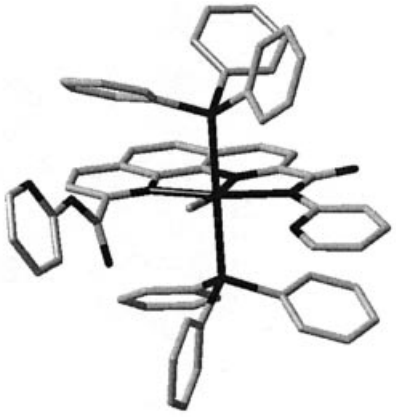

Figure 6. Calculated molecular structure of $[RuCl(L2)(PPh_3)_2]Cl$ (**2**)

N−coordinated amidato group is identified by two bands at $\tilde{\nu}$ = 1651 and 1648 cm^{-1} (cf experimental $\tilde{\nu}$ = 1638 cm^{-1}). We have also identified a very distinct N−H stretch at $\tilde{\nu}$ = 3062 cm^{-1} (cf. experimental $\tilde{\nu}$ = 3050 cm^{-1}), associated with the protonated pyridine group which forms a hydrogen bond with Cl(2). A second strong stretching frequency at $\tilde{\nu}$ = 3244 cm^{-1} (cf. experimental $\tilde{\nu}$ = 3234 cm^{-1}), is associated with the N−H bond of the noncoordinated amide [i.e. N(25)−H] which forms a hydrogen bond to the apical Cl(1) chloride.

We observe the same vibrational progression in *trans*-**2** with the carboxamide CO stretch at $\tilde{\nu}$ = 1669 cm^{-1}, the amidato CO at $\tilde{\nu}$ = 1657 cm^{-1}, the N−H···Cl (from the protonated pyridine group) at $\tilde{\nu}$ = 3048 cm^{-1} and the N−H (from the noncoordinated amide) at $\tilde{\nu}$ = 3442 cm^{-1} (cf. experimental $\tilde{\nu}$ = 1683, 1648, 3048 and 3342 cm^{-1}, respectively). It is worth noting that the frequency associated with the N−H of the noncoordinated amide in *trans*-**2** (calculated value of $\tilde{\nu}$ = 3442 cm^{-1}) is larger than the frequency associated with the same moiety in compound **1** (calculated value of $\tilde{\nu}$ = 3244 cm^{-1}). This is not surprising since in **1** the N−H group of the noncoordinated amide is hydrogen-bonding to the apical chloride of the complex weakening the bond and hence lowering the stretching frequency.

Conclusions

Two new phenanthroline-carboxamide ligands have been prepared and fully characterised. Crystallographic studies have shown that both ligands display various supramolecular interactions in the solid state. Particularly interesting are those observed for L1 where a combination of H-bonding and π−π stacking interactions create a continuous "staircase-like" chain of alternating hemi-helices. The reactions of H_2L1 and L2 with $[RuCl_2(PPh_3)_3]$ result in the formation of two different type of complexes. While the reaction with H_2L1 yields $[RuCl_2(L1)(PPh_3)]$ (**1**), the reaction with L2 leads to formation of *trans*-$[RuCl(L2)(PPh_3)_2]Cl$ (*trans*-**2**). The difference in reactivity could be due to the fact that, while **2** is formed from the neutral ligand L2, **1** is prepared using the hydrochloride salt of L1 (i.e. H_2L1) and hence there is a different concentration of chloride anions in the reaction mixtures. It is also possible that the difference could result from the sterically more demanding nature of L1 (due to the presence of the amino group in position 6 of the pyridine ring) in comparison to L2. However, in both cases the deprotonation of one of the carboxyamido moieties leads to the formation of a ruthenium-amidato bond and consequent tridentate coordination mode of the ligands. Structural characterisation of complex **1** has confirmed this coordination mode. On the basis of our results, we propose that the generation of complex *trans*-**2** takes place through a process in which the corresponding *cis* isomer (presumably kinetically favoured) is likely to be initially formed. However, this isomer rapidly rearranges to the thermodynamically more stable *trans*-**2** once it is dissolved in an appropriate solvent. Quantum mechanical calculations indicate that *trans*-**2** is indeed thermodynamically more stable than *cis*-**2** supporting the experimental observations. Furthermore, these calculations have allowed us to make a detailed assignment of some of the stretching frequencies observed in the IR spectrum of the new complexes. The experimental and calculated structural parameters for compound **1** are in good agreement.

Experimental Section

General: All manipulations were carried out in an atmosphere of purified and dry N_2 using standard Schlenk line techniques unless otherwise stated. Solvents were dried from the appropriate drying agent, degassed and stored under N_2. All commercially available solid starting materials were not further purified. ^1H and $^{31}P\{^1H\}$

NMR spectra were recorded on a JEOL-EX270 spectrometer (δ = 270.17 and 109.38 MHz, respectively) with TMS and H_3PO_4, respectively, as internal references. IR spectra were recorded on Research Series FT-IR using KBr disks in the range 4000−500 cm^{-1}.

Protonated Form of *N,N′*-Bis(2-amino-6-pyridyl)-1,10-phenanthroline-2,9-carboxamide (H_2L1): A solution of 2,6-diaminopyridine (2.5 g, 22.8 mmol) in CH_2Cl_2 (50 cm^3) was added dropwise to a suspension of 1,10-phenanthroline-2,9-dicarbonyl chloride (1.21 g, 3.8 mmol) in CH_2Cl_2 (50 cm^3) over 1 hour. A pale yellow precipitate formed immediately. The suspension was stirred overnight at room temperature. The mixture was filtered and the resulting precipitate washed with ethanol to extract excess amine, yielding H_2L1 as a pale yellow solid. Yield 1.2 g (60%). $C_{24}H_{18}N_8O_2$·2HCl (523): calcd. C 55.07, H 3.82, N 21.42; found C 55.02, H 3.86, N 21.51. IR (KBr): $\tilde{\nu}$ = 3443 (s), 3399 (m) (NH_2), 3326 (s) (CO−*NH*), 1680 (vs) (CO), 1644 (m), 1605 (m), 1580 (m) (C=N). ^{1}H NMR ([D_6]DMSO): δ = 10.33 (s, CO−N*H*, 1 H), 8.83 (d, H_b, $^3J_{H,H}$ = 8.4 Hz, 1 H), 8.57 (d, H_c, $^3J_{H,H}$ = 8.4 Hz, 1 H), 8.25 (s, H_a, 1 H), 7.53−7.40 (m, H_e, H_f, 2 H), 6.35 (d, H_g, $^3J_{H,H}$ = 5.7 Hz, 1 H), 5.82 (s, NH_2, 2 H) (see Scheme 1 for assignments). FAB$^+$−MS: *m*/*z* = 451 [M − 2HCl]$^+$

***N,N′*-Bis(2-pyridyl)-1,10-phenanthroline-2,9-carboxamide (L2):** A solution of 2-aminopyridine (1.75 g, 18.64 mmol) in CH_2Cl_2 (20 cm^3) was added dropwise to a suspension of 1,10-phenanthroline-2,9-dicarbonyl chloride (1.43 g, 4.7 mmol) in CH_2Cl_2 (20 cm^3). A dark brown solution formed immediately and was stirred at room temperature overnight yielding a white precipitate. The suspension was filtered and the precipitate washed with EtOH (3×10 cm^3) to extract the excess amine, yielding L2 as an off-white powder. Yield: 1.06 g, (91%). $C_{24}H_{16}N_6O_2$ (420): calcd. C 68.57, H 3.81, N 20.0; found C 68.48, H 3.95, N 19.73. IR (nujol): $\tilde{\nu}$ = 3353 (w), 3333 (w) (CO−*NH*), 1690 (vs) (C=O), 1587 (w), 1574 (w) (C=N). ^{1}H NMR ($CDCl_3$): δ = 11.17 (s, CO−*NH*, 1 H), 8.64 (d, H_b, $^3J_{H,H}$ = 8.4 Hz, 1 H), 8.49−8.43 (m, H_c, H_e, H_h, 3 H), 7.95 (s, H_a, 1 H), 7.81 (t, H_f, $^3J_{H,H}$ = 8.6 Hz, 1 H), 7.16−7.13 (m, broad, H_g, 1 H) (see Scheme 1 for assignments). FAB$^+$−MS: *m*/*z* = 421 MH^+.

[$RuCl_2$(L1)(PPh_3)] (1): Solid [$RuCl_2(PPh_3)_3$] (0.72 g, 0.75 mmol) was added to a solution of H_2L1 (0.34 g, 0.66 mmol) in a mixture of DMF/toluene (in a 1:5 ratio). The brown mixture was refluxed for 4 hours turning purple after ca 30 minutes then stirred overnight at room temperature. The suspension was then filtered and the precipitate washed several times with toluene and diethyl ether yielding **1** as a dark purple solid. Yield: 0.493 g, (84%). $C_{42}H_{33}Cl_2N_8O_2PRu$ (884.1): calcd. C 57.01, H 3.73, N 12.67; found calcd. C 57.07, H 3.68, N 12.67. IR (KBr): $\tilde{\nu}$ = 3234 (m) (CO−*NH*, noncoordinated carboxamide), 3050 (m) (py*H*), 1683 (s) (CO, noncoordinated carboxamide), 1638 (vs) (CO, *N*−bound amidato group). ^{1}H NMR ([D_6]DMF): 13.74 (s, py*H*, 1 H), 10.58 (s, CO−*NH*, 1 H), 8.41 (d, $H_{b'}$, $^3J_{H,H}$ = 8.3 Hz, 1 H), 7.97 (d, $H_{c'}$, $^3J_{H,H}$ = 8.3 Hz, 1 H), 7.94−7.81 (m, H_e, $H_{e'}$, H_g, $H_{g'}$ 4 H), 7.79 (s, H_a and $H_{a'}$, 2 H), 7.63 (d, H_b, $^3J_{H,H}$ = 8.3 Hz, 1 H), 7.46 (d, H_c, $^3J_{H,H}$ = 8.3 Hz, 1 H), 7.37 (t, H_f, $^3J_{H,H}$ = 8.3 Hz, 1 H), 7.25 (t, H_f, $^3J_{H,H}$ = 8.0 Hz, 1 H), 6.93−6.71 (m, PPh_3, 20 H) (see Scheme 2 for assignment); ^{31}P{^{1}H} NMR ([D_6]DMF): δ = 45.0; FAB$^+$−MS: *m*/*z* = 885 [M]$^+$, 849 [Ru(L1)(PPh_3)Cl]$^+$, 813 [Ru(L1)(PPh_3)]$^+$, 550 [Ru(L1)]$^+$.

***trans*-[RuCl(L2)(PPh_3)$_2$]Cl (*trans*-2):** Solid [$RuCl_2(PPh_3)_3$] (0.51 g, 0.53 mmol) was added to a solution of **L2** (0.22 g, 0.53 mmol) in a mixture of DMF/toluene (in a 1:5 ratio). A dark violet solution formed immediately and after few minutes a dark purple precipitate started forming. The suspension was stirred for 2 hours and the solid formed filtered off. The precipitate was washed several times with toluene and diethyl ether. The solid was re-dissolved in CH_2Cl_2 yielding a purple solution. After a few minutes the solution

Crystallography: Table 5 provides a summary of the crystallographic data for compounds L1, L2 and **1**. Data were collected on Siemens P4 diffractometers using ω-scans. The structures were solved by direct methods and refined based on F^2 using the SHELXTL program system.[14] CCDC-191577 (for L1), -191578 (for **1**) and -191579 (for L2) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Details

Ab initio molecular orbital calculations on compound **1** and the *cis* and *trans* isomers of compound **2** were performed All three molecules have been subjected to geometry optimisation using density functional theory (DFT) at the B3LYP level of theory[15−17] using the 3−21G* basis set.[18] The structures were model built with no reference to the crystal structure of compound **1**. All stationary points have been characterised as minima by calculation and inspection of the vibrational modes. We have not scaled the vibrational frequencies reported in this paper. All calculations were performed with Gaussian 98.[17]

The reaction of the tridentate salicylaldimine of 2-picolylamine, $C_6H_4(OH)CHNCH_2C_5H_4N$ (HL), with bis(acetylacetonato)oxovanadium(IV) at room temperature under oxygen (or with $VOSO_4 \cdot 5H_2O$ plus H_2O_2) furnished crystalline greenish-yellow α-VO_2(L) and green β-VO_2(L) from methanol (or ethanol) and acetonitrile (or dichloromethane), respectively. The dimorphs give rise to the same solution species as revealed by spectroscopic data (UV/Vis, ^{1}H and ^{51}V NMR). Both forms react with 3,5-bis(*tert*-butyl)catechol (H_2dbcat) furnishing the known pseudooctahedral complex VO(L)(dbcat). In the α form the V(L) fragment is planar and the VO_3N_2 coordination sphere is distorted trigonal bipyramidal (τ = 0.55) with the two oxo oxygen atoms and the azomethine nitrogen atom defining the trigonal plane. In β-VO_2(L) the V(L) moiety, like that in VO(L)(dbcat), is not planar but consists of two planar parts rotated away from each other along the C–N single bond. In this case the coordination sphere is distorted square pyramidal (τ = 0.20) with the three donor sites of the L ligand and an oxo oxygen atom defining the tetragonal plane. Both the α and β crystal lattices consist of dimers which associate further to form supramolecules. The noncovalent intradimer and interdimer bonding interactions are predominantly of aromatic π-π stacking (aryl···pyridyl and pyridyl···pyridyl) and C–H···O hydrogen bonding (azomethine···oxo and aryl···phenolato) types in the α and β dimorphs, respectively. It is proposed that the low polarizability of methanol promotes π-π stacking of planar V(L) fragments, resulting in crystallization of the α form. When the polarizability is relatively high, as in acetonitrile, the β form crystallizes. The geometrically isomeric coordination spheres of the α and β forms are sustained by the respective supramolecular architectures. The Schiff base HL′ of 2-hydroxynapthaldehyde and 2-picolylamine has also afforded two forms of VO_2(L′) in the same manner as for VO_2(L).

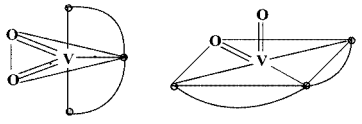
Introduction

The long-standing interest in the structure and properties of mononuclear VO_2^+ complexes[1] has multiplied with the emergence of bioinorganic linkages to the RNase transition state,[2] vanadium dependent haloperoxidase[3,4] and insulin mimicry.[5] The coordination number of the metal in VO_2^+ complexes can be six,[1,6] but the focus of the present work is on pentacoordinate species of type VO_2(tridentate), which have attracted special attention in recent years. The geometry of structurally characterized compounds of the latter type is (relatively rarely) distorted trigonal bipyramidal (dtbp, α form, as shown in **1**),[7] the common geometry being distorted square pyramidal (dsp, β form, as in **2**).[8−10] The latter geometry is particularly relevant in the context of the RNase transition state[2] and haloperoxidase activity.[3]



dtbp (α form) dsp (β form)

1 **2**

In the present work we report the synthesis and characterization of a remarkable pentacoordinate VO_2^+ system which has been isolated in two distinct crystalline forms by merely varying the solvent employed in the synthesis. The solid-state structural features of the dimorphs (which otherwise display identical chemical composition and solution properties) differ dramatically in coordination geometry, ligand conformation and supramolecular architecture. To the best of our knowledge, structural dimorphism of the present type is unprecedented in VO_2^+ solid-state chemistry.

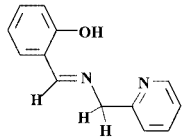
Results and Discussion

Synthesis of Dimorphs

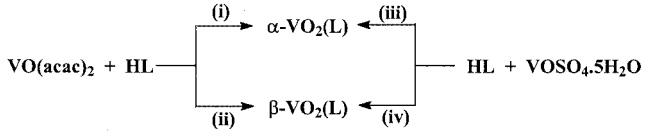
The tridentate ligand concerning us in this work is the salicylaldimine of 2-picolylamine (HL, **3**). It reacted smoothly with $VO(acac)_2$ in methanol solution at room temperature in the presence of oxygen, furnishing in excellent yield a greenish-yellow crystalline complex of composition $VO_2(L)$, designated as the α dimorph.



HL

3

A similar reaction occurred in acetonitrile solution to give the β dimorph; this complex had the same composition, but was green. The same dimorphs were also synthesized by reacting $VOSO_4{\cdot}5H_2O$ with HL using hydrogen peroxide as the oxidant (Scheme 1). The possible role of the solvent in crystallization of specific dimorphs will be considered later.



Scheme 1. Synthesis of dimorphic $VO_2(L)$ at room temperature; (i) MeOH, O_2; (ii) MeCN, O_2; (iii) MeOH, H_2O_2; (iv) MeCN, H_2O_2

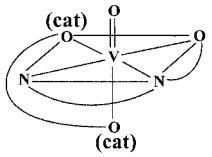
Spectra and Solution Behaviour

Spectral data are given in the Exp. Sect. Both forms display two V=O stretches near 920 and 940 cm^{-1} (KBr disk), consistent with *cis* geometry of the VO_2 moiety. Both dimorphs are insoluble except in solvents like *N*,*N*-dimethylformamide and dimethyl sulfoxide. The pale yellow solutions display identical UV/Vis spectra (within experimental error), and display a band at 395 nm. In dimethyl sulfoxide solutions the two forms give rise to identical ^{51}V NMR spectra, with a signal at $\delta = -535$ ppm. The well-resolved ^1H NMR spectra of both the α and β forms in $[D_6]$dimethyl sulfoxide are also superimposable. Thus, α-$VO_2(L)$ and β-$VO_2(L)$ must give rise to the same species in mobile solution.

Reaction with a Catechol

In dichloromethane suspension, both α and β-$VO_2(L)$ react [as shown in Equation (1)] with aromatic diols such as 3,5-di-*tert*-butylcatechol (H_2dbcat) furnishing the violet complex VO(L)(dbcat) (**4**), which is already known from the reaction of $VO(acac)_2$ with HL and H_2dbcat in air.[11] The conformation of the L ligand in VO(L)(dbcat) has close similarities to that in β-$VO_2(L)$; the significance of this is considered later.

$$VO_2(L) + H_2dbcat \rightarrow VO(L)(dbcat) + H_2O \quad (1)$$



4

Structure

The α and β dimorphs have distinctive crystal, molecular and supramolecular structures. They belong respectively to the monoclinic and triclinic crystal systems. Molecular views are given in Figure 1 and 2; selected bond parameters are listed in Table 1. In both forms, the VO_2 fragment has a *cis* geometry and the tridentate ligand is meridionally disposed. The coordination sphere is of type VO_3N_2. The metal−ligand bond lengths in the two forms are equal to within 0.02 Å. However, there are major differences in the coordination geometry, V(L) conformation and noncovalent intermolecular interactions.

O(3)−V−N(2)	83.8(1)	83.4(1)
N(1)−V−N(2)	75.2(1)	74.2(1)

Coordination Geometry

In the α form, the V(L) fragment constitutes a plane (mean deviation, 0.03 Å), which makes a dihedral angle of 90.5 with the VO_2 plane. The double bonds in the latter fragment constrain the O1−V−O2 angle to about 109°, as is generally observed among pentacoordinated VO_2 complexes.[7−10]

An important feature of the α structure is that the metal atom is shifted only by about 0.1 Å from the O1−O2−N2 plane towards the O3 atom, and the N2 atom is approximately symmetrically positioned with respect to the Ol and O2 atoms, the O1−V−N2 and O2−V−N2 angles being 123.0(1) and 125.8(1)°, respectively [N2···O1, 3.301(7) Å and N2···O2, 3.341(7) Å]. The rigidity of the L ligand constrains the O3−V−N1 angle to 159.0(1)°.

The coordination geometry of α-VO_2(L) is thus best described as dtbp (trigonal plane O1−O2−N2). The τ parameter[12] (equal to Δ/60°, where Δ is the difference between the largest and the next-to-largest ligand−metal−ligand angles) is a useful geometrical discriminator; Δ = 60, τ = 1 for idealized tbp and Δ = 0, τ = 0 for idealized sp).[12] The τ value of α-VO_2(L) is 0.55. In representative structures of VO_2(tridentate) species the τ values generally lie well below 0.50 and in most cases below 0.40.[7−10] Thus α-VO_2(L) approaches the tbp geometry more closely than any other known member of the VO_2(tridentate) family.

The V(L) moiety in the β form is not planar and it actually consists of two highly planar fragments: C1−C6, N1, V (plane A, mean deviation, 0.01 Å) and C7−C13, N2, O3 (plane B, mean deviation, 0.02 Å). Plane A is rotated away from plane B by 11.2° along the C6−N2 bond. The metal atom is shifted from plane B by 0.53 Å, and thus the six-membered chelate ring is folded by 20.4° along the N2···O3 line.

Whereas the rigid O1−V−O2 angle remains virtually unchanged near 109°, V(L) nonplanarity results in major changes in the other angles at the metal compared to those in the α form. Thus, the O1−V−N2 angle decreases by about 14° to 109.4(1)° and the O2−V−N2 angle increases by a similar amount to 139.7(1)°. The O3−V−N1 angle is also contracted by about 7° to 151.7(1)°. The net result of these angular changes is that the O2, O3, N1 and N2 atoms in the β form constitute an approximate tetragonal plane, from which the metal atom is displaced by 0.51 Å towards the O1 atom. Therefore, the coordination geometry in the β form can be aptly described as dsp, which is also consistent with its low τ value of 0.20.

The structure of β-VO_2(L) bears certain qualitative similarities to that[11] of pseudooctahedral V(L)(dbcat) **4**. A significant feature is that the nonplanar V(L) fragment in **4** also consists of two planar fragments of types A and B (dihedral angle 19.7°). The approximate tetragonal plane is again of N_2O_2 type from which the metal atom is displaced towards the oxo atom (by 0.28 Å). The nonplanarity of the V(L) fragment appears to be crucial for achieving a tetragonal equator, be it in β-VO_2(L) or in VO(L)(dbcat).

Aromatic Stacking and Hydrogen Bonding: Dimers and Supramolecules

All the hydrogen atoms in both α-VO_2(L) and β-VO_2(L) were directly located by difference Fourier maps. Both the lattices consist of dimers, which associate further to form supramolecules. The noncovalent intradimer and interdimer bonding interactions are primarily of the π-π stacking and C−H···O hydrogen-bonding type. These interactions can be seen in the partial packing diagrams shown in Figure 3 and 4; the relevant distances are listed in Table 2.

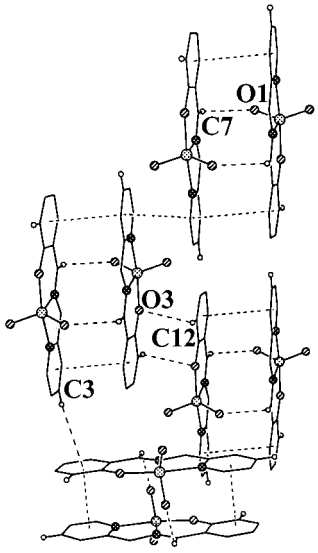

Figure 3. Supramolecular structure of the α-VO_2(L) lattice; hydrogen atoms other than H3, H7 and H12 have been omitted for clarity and noncovalent interactions are indicated by dotted lines

In the α dimers the (virtually parallel) V(L) planes are held together by a pair of aryl···pyridyl π-π interactions and a pair of azomethine···oxo (C7−H7···O1) hydrogen bonding interactions(Figure 3). The distance between the centroids of the overlapping aryl and pyridyl rings (ar···py in Table 2), 3.716(7) Å, is consistent[13,14] with the presence of an attractive π-π interaction. The ar···py line subtends an

H(12)···O(3)	2.95(8)	2.56(9)
C(7)−H(7)···O(1)	120(1)	123(1)
C(12)−H(12)···O(3)	123(1)	176(1)

[a] ar = aryl ring centroid; py = pyridyl ring centroid.

angle of 10.4° with the aryl ring normal, and 10.8° with the pyridyl ring normal. The offset of the parallel rings is thus small, signifying strong stacking. In metal complexes of pyridyl ligands π-π stacking is usually associated with a larger offset (about 20°).[13] The bond parameters of the C7−H7···O1 fragment (Table 2) are consistent with the presence of significant hydrogen bonding. The accepted ranges are 3.0−3.5 Å (C···O), 2.3−3.0 Å (H···O) and 100−180° (C−H···O).[15−18]

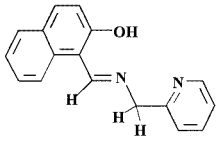
Interdimer bonding in the α form consists of a relatively strong pyridyl···pyridyl π−π overlap [py···py, 3.520(6) Å] with a very small offset (5.6°), and aryl···phenol (C12−H12···O3) hydrogen bonding which is significantly weaker than the intradimer C7−H7···O1 bonding. There is also a weak interdimer edge-to-face interaction[13,17,19] between the pyridyl C3−H3 and aryl fragments, the centroid of the latter being 3.31(9) Å and 3.889(8) Å away from the H3 and C3 atoms, respectively. The C3−H3···ar angle is 124°. The C10 carbon atom of the aryl ring lies closest to H3 [distance 2.91(8) Å].

The nonplanarity of the V(L) fragment in the β form results in increased intradimer aryl···pyridyl separation, marginalizing the π-π interaction [ar···py, 4.086(8) Å]. On the other hand, the azomethine function now lies closer to the O1 atom, thus resulting in stronger intradimer C7−H7···O1 hydrogen bonds than in the α dimer (Table 2). The interdimer association is also dominated by the relatively strong hydrogen bonding which occurs between the aryl and phenolato functions, the site of action being the nearly linear C12−H12···O3 moiety. Interdimer aryl···pyridyl stacking (offset 19.9°) also contributes to supramolecule formation in the β form.

Solvent Specific Crystallization

In summary, π-π stacking and C−H···O hydrogen bonding are the respective dominant features in the supramolecular architectures of the α and β forms of VO_2(L). This provides some insight into the possible nature of the role of solvent in dimorph crystallization. It is known that solvents like water and small alcohols with low polarizability and high cohesive interaction lead to aggregation of lipophilic molecular π surfaces in solutes.[13,20] It is therefore logical to propose that such effects lead to π-π stacking in the case of VO_2(L), with consequent crystallization of the α form from methanol (we have found ethanol to be just as effective). The planar V(L) configuration and the associated dtbp geometry may very well be the consequence of maximization of the π-π stacking interactions in the lattice. The tendency towards lipophilic aggregation is considerably diminished in solvents of significantly higher polarizability such as acetonitrile (dichloromethane is found to behave similarly);[20c] in these cases the β form crystallizes, with a structure dominated by polar interactions (viz. strong C−H···O hydrogen bonding) rather than π-π stacking. This is best achieved when the V(L) configuration is nonplanar and consequently the coordination geometry is dsp. The synthesis of α and β forms of VO_2(L) is an instance of solvent-directed crystal engineering. The two geometrical isomeric coordination spheres are sustained by their characteristic supramolecular architectures.

On the basis of the above logic we expected that 2-hydroxynapthaldimine(HL′, **5**) of 2-picolylamine should also yield dimorphs. Indeed, two forms of VO_2(L′) have been isolated by the same procedures employed for the VO_2(L) dimorphs.



HL′

5

Selected characterization data is given in the Exp. Sect. Unfortunately, neither α-VO_2(L′) nor β-VO_2(L′) afforded single crystals suitable for structure determination. A search for other examples of the VO_2(tridentate) family showing similar dimorphism is continuing.

Conclusions

A remarkable case of solvent-directed crystal engineering has been revealed in the synthesis of VO_2(L) in dimorphic α and β forms, isolated from methanol and acetonitrile, respectively.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The two forms differ strongly in both their coordination geometries (dtbp versus dsp) and supramolecular architecture (aromatic π-π stacking versus C−H···O hydrogen bonding), the former being a consequence of the latter.

This solvent-specific dimorph crystallization is qualitatively consistent with relative polarizability; the $VO_2(L')$ dimorphs appear to be similar to those of $VO_2(L)$.

Experimental Section

General: Bis(acetylacetonato)oxovanadium(IV) was prepared by literature methods.[21] 2-Picolylamine, salicylaldehyde, 2-hydroxynapthaldehyde and acetylacetone were obtained from Aldrich. Vanadyl sulfate pentahydrate was purchased from Loba Chemie (India) and 30% hydrogen peroxide was obtained from S. D. Fine Chem. (India). All other chemicals and solvents were of analytical grade and were used as received. Spectra were recorded using the following equipment: IR (KBr disk), Nicolet Magna 750 Series II spectrometer. UV/Vis, Shimadzu UVPC 1601 spectrometer. ^{1}H NMR, Bruker FT 300 MHz spectrometer (assignments were based on chemical shifts and spin-spin structures) and ^{51}V NMR, Varian 78.8 MHz spectrometer ($VOCl_3$ external reference). A Perkin−Elmer 240C elemental analyzer was used for microanalysis (C, H, N).

HL: 2-Picolylamine (0.885 g, 8.2 mmol) was added to a solution of salicylaldehyde (1 g, 8.2 mmol) in ethanol (15 mL). After refluxing the mixture for half an hour, the solvent was removed in a rotary evaporator and the yellow oil thus obtained used without further purification.

HL′: Prepared similarly, using 2-hydroxynapthaldehyde in place of salicylaldehyde.

α-VO_2(L): A solution of HL (0.159 g, 0.75 mmol) in methanol (5 mL) was added to a solution of $VO(acac)_2$ (0.2 g, 0.75 mmol) in methanol (50 mL). Pure oxygen was bubbled through the deep red solution for 5 h with stirring. The greenish-yellow precipitate that appeared was filtered off, washed with dichloromethane, and dried in vacuo over fused $CaCl_2$. Yield: 0.171 g (77%). $C_{13}H_{11}N_2O_3V$ (294.18): calcd. C 53.08, H 3.77, N 9.52; found C 53.14, H 3.85, N 9.58. IR (KBr): $\tilde{\nu}$ = 921, 939 (s, V=O), 1621 (s, C=N) cm^{-1}. UV/Vis (DMF): $\lambda_{max.}$ (ε, M^{-1}·cm^{-1}) = 395 nm (1810). ^{1}H NMR ([D$_6$]DMSO): δ = 5.60 (s, 2 H, −CH_2−), 9.06 (s, 1 H, −CH=N), 8.95 (br., 1 H, −C_6H_4), 8.15 (t, J = 6.0 Hz, 1 H, −C_6H_4), 7.80 (d, J = 6.0 Hz, 1 H, −C_6H_4), 7.52 (t, J = 7.5 Hz, 1 H, −C_6H_4), 7.64 (t, J = 6.0 Hz, 2 H, −C_5H_4N), 6.87 ppm (d, J = 6.0 Hz, 2 H, −C_5H_4N) ppm. ^{51}V NMR ([D$_6$]DMSO): δ = −535 ppm.

Synthesis from $VOSO_4$·5H_2O: 30% Hydrogen peroxide (1 mL) was added to a suspension of $VOSO_4$·5H_2O (0.2 g, 0.79 mmol) in methanol (50 mL). 15 min of stirring resulted in the formation of an orange-red solution, to which a solution of HL (0.168 g, 0.79 mmol) in methanol (5 mL) was added. The dark-brown solution was kept undisturbed in air at room temperature. After 24 h, the crystalline product deposited was filtered off, washed with methanol and dried in vacuo under fused $CaCl_2$. This afforded 0.168 g (72%) of α-VO_2(L).

β-VO_2(L): Prepared as for α-VO_2(L), but using acetonitrile instead of methanol. Yield: 0.164 (74%). $C_{13}H_{11}N_2O_3V$ (294.18): calcd. C 53.08, H 3.77, N 9.52; found C 53.19, H 3.82, N 9.57. IR (KBr): $\tilde{\nu}$ = 918, 939 (s, V= O), 1626 (s, C=N) cm^{-1}. UV/Vis (DMF): $\lambda_{max.}$ (ε, M^{-1}·cm^{-1}) = 395 nm (1789). ^{1}H NMR ([D$_6$]DMSO): δ = 5.60 (s, 2 H, −CH_2−), 9.06 (s, 1 H, −CH=N), 8.95 (br., 1 H, −C_6H_4), 8.15 (t, J = 6.0 Hz, 1 H, −C_6H_4), 7.80 (d, J = 6.0 Hz, 1 H, −C_6H_4), 7.52 (t, J = 7.5 Hz, 1 H, −C_6H_4), 7.64 (t, J = 6.0 Hz, 2 H, −C_5H_4N), 6.87 ppm (d, J = 6.0 Hz, 2 H, −C_5H_4N) ppm. ^{51}V NMR ([D$_6$]DMSO): δ = −535 ppm.

Synthesis from $VOSO_4$·5H_2O: Prepared as for α-VO_2(L), but using acetonitrile instead of methanol. Yield: 0.174 g (75%).

α-VO_2(L′): Prepared as for α-VO_2(L), but using HL′ instead of HL. Yield: 0.197 g (76%). $C_{17}H_{13}N_2O_3V$ (344.24): calcd. C 59.32, H 3.81, N 8.14; found C 59.38, H 3.89, N. 8.17. IR (KBr): $\tilde{\nu}$ = 925, 941 (s, V=O), 1626 (s, C=N) cm^{-1}. UV/Vis (DMF): $\lambda_{max.}$ (ε, M^{-1}·cm^{-1}) = 412 nm (2068). ^{1}H NMR ([D$_6$]DMSO): δ = 5.76 (s, 2 H, −CH_2−), 9.89 (s, 1 H, −CH=N), 8.94 (d, J = 6.0 Hz, 1 H, −$C_{10}H_6$), 8.42 (d, J = 6.0 Hz, 1 H, −$C_{10}H_6$), 8.21 (t, J = 6.0 Hz, 1 H, −$C_{10}H_6$), 8.09 (d, J = 9.0 Hz, 1 H, −$C_{10}H_6$), 7.42 (t, J = 7.5 Hz, 1 H, −$C_{10}H_6$), 7.14 (d, J = 9.0 Hz, 1 H, −$C_{10}H_6$), 7.88 (t, J = 7.5 Hz, 2 H, −C_5H_4N), 7.65 (d, J = 9.0 Hz, 2 H, −C_5H_4N) ppm.

Synthesis of α-VO_2(L′) from $VOSO_4$·5H_2O: Prepared as for α-VO_2(L), but using HL′ instead of HL. Yield 0.193 g (71%).

β-VO_2(L′): Prepared as for α-VO_2(L′), but using acetonitrile instead of methanol. Yield: 0.183 g (71%). $C_{17}H_{13}N_2O_3V$ (344.24): calcd. C 59.32, H 3.81, N 8.14; found C 59.34, H 3.85, N. 8.15. IR (KBr): $\tilde{\nu}$ = 923, 942 (s, V=O), 1623 (s, C=N) cm^{-1}. UV/Vis (DMF): $\lambda_{max.}$ (ε, M^{-1}·cm^{-1}) = 412 nm (2026). ^{1}H NMR ([D$_6$]DMSO): δ = 5.76 (s, 2 H, −CH_2−), 9.89 (s, 1 H, −CH=N), 8.94 (d, J = 6.0 Hz, 1 H, −$C_{10}H_6$), 8.42 (d, J = 6.0 Hz, 1 H, −$C_{10}H_6$), 8.21 (t, J = 6.0 Hz, 1 H, −$C_{10}H_6$), 8.09 (d, J = 9.0 Hz, 1 H, −$C_{10}H_6$), 7.42 (t, J = 7.5 Hz, 1 H, −$C_{10}H_6$), 7.14(d, J = 9.0 Hz, 1 H, −$C_{10}H_6$), 7.88 (t, J = 7.5 Hz, 2 H, −C_5H_4N), 7.65 (d, J = 9.0 Hz, 2 H, −C_5H_4N) ppm.

Synthesis of β-VO_2(L′) from $VOSO_4$·5H_2O: Prepared as for α-VO_2(L′), but using acetonitrile instead of methanol. Yield: 0.201 g (74%).

Conversion of VO_2(L) to VO(L)(dbcat): 3,5-Bis(*tert*-butyl)catechol (H_2dbcat) (0.076 g, 0.34 mmol) was added to a suspension of either form of VO_2(L) (0.10 g, 0.34 mmol) in dichloromethane (20 mL). The mixture was stirred for 8 h and the violet-coloured solution concentrated and left to evaporate in the air. The crystalline product thus obtained was washed with cold methanol and dried in vacuo over fused $CaCl_2$. Yield: 0.134 g (76%). This complex was found to be identical in all respects with that reported earlier.[11]

Crystal Structure Determination: Single crystals of α-VO_2(L) and β-VO_2(L) were obtained directly during synthesis but without stirring of the oxygen-saturated reaction mixture (vide supra). The undisturbed solution deposited suitable single crystals within a few days. Data were collected with a Nicolet R3m/V four-circle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) using the ω-scan technique ($3 \le 2\theta \le 48°$ for both the α and β forms). All data were corrected for Lorentz polarization, and an empirical absorption correction[22] was performed on each set of data on the basis of the azimuthal scans of six reflections. All calculations of data reduction, structure solution and refinement were done with the programs of SHELXTL, version 5.03.[23] The two structures were solved by direct methods and refined by full-matrix least-squares on F^2. All non-hydrogen atoms were refined anisotropically. All the hydrogen atoms in two structures were located in the difference Fourier maps. Significant crystal data are listed in Table 3. Supplementary crystallographic data have been deposited.

Ruthenium Tetraammines as a Model of Nitric Oxide Donor Compounds

José Carlos Toledo,[a] Hildo A. S. Silva,[a] Marciela Scarpellini,[a] Vânia Mori,[b] Ademir J. Camargo,[a] Mauro Bertotti,[b] and Douglas W. Franco*[a]

Dedicated to our friend and colleague Luiz Manoel Aleixo in memoriam

Keywords: Nitric oxide / Ruthenium / NO donor / N-heterocyclic ligands

The nitric oxide liberation from *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$ (where L = py, 4-pic, isn, nic, L-His, 4-Clpy, imN) after one-electron-chemical or electrochemical reduction was investigated through spectroscopic and electrochemical techniques, reaction-product analysis and quantum-mechanic calculations. These complexes can be formally viewed as a $Ru^{II}(NO^+)$ species and the reduction site is located on the NO ligand. The $E°$ for the *trans*-$[Ru^{II}(NH_3)_4(L)(NO^+)]^{3+}$/*trans*-$[Ru^{II}(NH_3)_4(L)(NO)]^{2+}$ redox process ranges from 0.072 V vs. NHE (nic) to –0.118 V vs. NHE (imN). The specific rate constants for NO dissociation from *trans*-$[Ru^{II}(NH_3)_4(L)(NO)]^{2+}$, evaluated through double-step chronoamperometry, range from 0.025 s^{-1} (nic) to 0.160 s^{-1} (ImN) at 25 °C. The $[Ru^{II}NO^+/Ru^{II}NO^0]$ redox potential and the specific rate constant (k_{-NO}), key steps for designing nitrosyl complexes as NO-donor drug prototypes, proved to be controlled by a judicious choice of the ligand (L) trans to NO.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Since the physiological roles of nitric oxide (NO) were discovered,[1,2] a great deal of effort has been put into the development of NO-carrier drugs.[3,4] The great affinity of d^6 and d^5 low-spin-metal complexes for NO and the versatility of NO on its own right as a ligand[5–7] make the nitrosyl complexes a good alternative for such a proposal.[8,9] Indeed, many metal complexes have been suggested as both promising NO scavengers and NO donors.[10–17] In general, the bonding between a d^6 low-spin-metal center and NO, which preferably assumes the MNO^+ form, is remarkably strong.[5,6] Therefore, for tailoring NO-donor compounds, procedures to generate MNO^0 species, in which NO is labile, are essential. Strategies involving photochemistry[18,19] and reduction activation[20] of nitrosyl complexes have been proposed as alternatives.

In this context, the photochemical[9,21,22] and reductive pathways[9,15,16] to induce NO liberation in *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$ complex ions have been explored. This is a promising system, since these complexes are generally resistant to air oxidation and are water-soluble and robust under physiological conditions.[21,22] Furthermore, it is well-known that ammine ligands localized in the equatorial positions are inert towards substitution reactions,[23] allowing the control of the NO reactivity in relation to the properties of the ligand trans to NO. This paper reports on the activation of the *trans*-$[Ru(NH_3)_4L(NO)]^{3+}$ species, (where L = N-heterocyclic ligands) to induce NO release through reduction. Two main requirements for these complexes to work as NO donors in biological media are: i) the reduction potential of coordinated NO must be accessible to biological reducing agents; ii) it is necessary to control the dissociation of NO^0 from the intermediate *trans*-$[Ru(NH_3)_4L(NO)]^{2+}$. As described here, both requirements can be fulfilled by means of a judicious choice of L.

Results and Discussion

The systems dealt with in this study, the *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$ complex ions, are EPR silent. In addition, their ν_{NO} is always higher than 1900 cm^{-1} and the Ru–N–O angle obtained by X-ray crystallography is close to 180°: *trans*-$[Ru(NH_3)_4(nic)(NO)](SiF_6)_3$ (177.0°),[21] *trans*-$[Ru(NH_3)_4(H_2O)(NO)]Cl_3$ (178.1°),[24] *trans*-$[Ru(NH_3)_4(4\text{-pic})(NO)](SiF_6)(BF_4)\cdot H_2O$ (178.6°) and *trans*-$[Ru(NH_3)_4P(OEt)_3(NO)](CF_3COO)_3$ (174.9°).[25] Based on these properties, it is reasonable to assign the $[Ru^{II}NO^+]$ formula to all these *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$ complexes. The result of the reaction with hydroxide ions, always yielding the corresponding nitro compound,[9,21,22,26] *trans*-$[Ru(NH_3)_4(L)(NO_2)]^+$, confirms the nitrosonium character of the NO ligand in such species.

It is well-known that nitrosyl complexes in aqueous solution react with hydroxide ions yielding the respective nitro compounds (see Equation 1), depending on both the pH of the solution and the nature of L.[5,6,21,22,26] Since nitro compounds are not expected to exhibit the hypotensive effect observed in nitrosyl complexes, the equilibrium established between the two species, *trans*-$[Ru(NH_3)_4L(NO)]^{3+}$ and *trans*-$[Ru(NH_3)_4L(NO_2)]^{+}$, in physiological pH, is a fundamental factor to be considered when utilizing nitrosyl complexes as nitric oxide donors. According to the K_{eq} data[9,21,22,26] for Equation 1, the *trans*-$[Ru(NH_3)_4L(NO)]^{3+}$ form accounts for more than 98 % of the nitrosyl complexes at pH 7.

$$trans\text{-}[Ru(NH_3)_4L(NO)]^{3+} + 2\,OH^- \overset{K_{eq}}{\rightleftharpoons} trans\text{-}[Ru(NH_3)_4L(NO_2)]^{+} + H_2O \quad (1)$$

Cyclic voltammograms of *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$ aqueous solutions show only one monoelectronic redox process between −0.6 V and 1.0 V versus SCE,[21,22] which was attributed to the couple $Ru^{II}NO^+/Ru^{II}NO^0$, in Equation (2):

$$trans\text{-}[Ru^{II}(NH_3)_4(L)(NO^+)]^{3+} + e^- \longrightarrow trans\text{-}[Ru^{II}(NH_3)_4(L)(NO^0)]^{2+} \quad (2)$$

DFT computation[27] for *trans*-$[Ru^{II}(NH_3)_4(L)(NO^+)]^{3+/2+}$ (where L = NH_3, Cl^-, OH^-, py and pz), indicates that the LUMO is always predominantly on the π* of NO (68−70%), although the HOMO is dependent on the nature of L: 90−95 % Ru (dxy) for L = NH_3, Cl^-, OH^- and 100 % L (πL) for L = pyridine and pyrazine. Thus, the one-electron reduction of these complexes is expected to generate $[Ru^{II}NO^0]$ species. Indeed, the coordinated NO radical have been detected through electron paramagnetic-resonance spectroscopy[28] for the reduced form of the *trans*-$[Ru(NH_3)_4(H_2O)(NO)]^{3+}$ ion. Considering the structural and chemical similarities among all title complexes, such behavior is expected to be general for the whole series. A similar EPR spectrum[28] was also observed for the one-electron reduced species of *trans*-$[RuPP(Cl)(NO)]^{2+}$ PP = $(C_2H_5)_2P(CH_2)_2P(C_2H_5)_2$ or $(C_6H_5)_2P(CH_2)_2P(C_6H_5)_2$, *trans*-$[Ru(cyclam)(Cl)(NO)]^{2+}$ and $[Ru(bipy)_2(Cl)(NO)]^{2+}$.[29]

The reduced species, *trans*-$[Ru(NH_3)_4(L)(NO)]^{2+}$, releases NO^0 according to Equation (3).

$$trans\text{-}[Ru(NH_3)_4(L)(NO)]^{2+} + H_2O \longrightarrow trans\text{-}[Ru(NH_3)_4(L)(H_2O)]^{2+} + NO^0 \quad (3)$$

The presence of free NO in solution, after reduction of the nitrosyl complexes, was detected by cyclic voltammetric and differential-pulse polarographic experiments ($E°$ NO^+/NO^0 = +0.80 V vs. SCE).[30−32] The presence of the resulting aqua species, *trans*-$[Ru(NH_3)_4(L)(H_2O)]^{2+}$, was also evident from the electronic spectra and voltammetric behavior. Furthermore, the resulting solutions are EPR silent at liquid nitrogen temperature.

The *trans*-$[Ru(NH_3)_4L(NO)]^{2+}$ ions were generated through chemical [Cd(Hg) and Eu^{II}] or electrochemical reduction. Figure 1 shows typical UV/Vis spectra for *trans*-$[Ru(NH_3)_4(py)(NO)]^{3+}$, when the solution is electrolyzed in a spectroelectrochemical experiment as a function of time. The observed bathochromic shift (from λ_{226} and λ_{267} to λ_{256} and λ_{330})[33] is consistent with the lower π-acceptor ability of the NO^0 ligand relative to the NO^+ ligand. The appearance of a band at 406 nm during the experiment is in agreement with the formation of *trans*-$[Ru(NH_3)_4(py)(H_2O)]^{2+}$, since this species absorbs strongly in this region (ε_{406} = 3.4 × 10^3 M^{-1} cm^{-1}).[32]

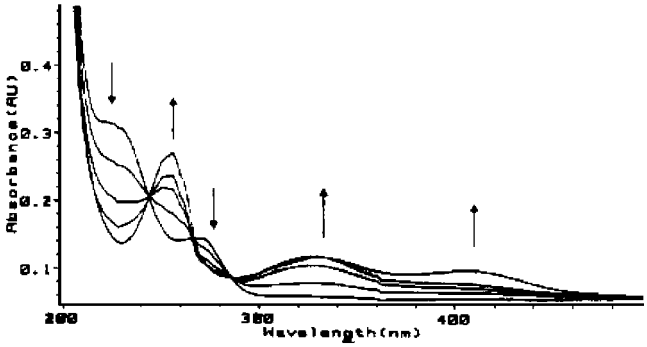

Figure 1. UV/Vis spectra for solutions containing *trans*-$[Ru(NH_3)_4(py)(NO)]^{2+}$ ions subjected to electrolysis as a function of time (applied potential: −0.40 V vs. SCE; μ = 0.1 $NaCF_3COO$; T = 15 °C, [Ru] = 5.0 × 10^{-4} M)

As expected, the chemical reduction of the *trans*-$[Ru(NH_3)_4L(NO)]^{3+}$ ions using Eu^{II} ions or Cd(Hg) also produces the respective aqua species. Differential-pulse polarographic experiments of *trans*-$[Ru(NH_3)_4(py)(NO)]^{3+}$ solutions show that after the addition of Eu^{II} ions ($E°$ = −0.60 V vs. SCE), the reduction wave corresponding to the $Ru^{II}NO^+/Ru^{II}NO^0$ redox process completely disappears with the simultaneous formation of a redox wave, which corresponds to the Ru^{III}/Ru^{II} couple in *trans*-$[Ru(NH_3)_4(py)(H_2O)]^{2+}$. In addition, the IR spectrum of the resulting solution does not show the easily identifiable NO-stretching frequency at 1931 cm^{-1}, indicating that the NO ligand is no longer present in the ruthenium-coordination sphere.

The rate-constant values for NO dissociation were determined by double-potential-step chronoamperometry (see Table 1) and are consistent with the rate law:

d/dt [*trans*-$[Ru(NH_3)_4(L)(H_2O)]^{2+}$] = k_{-NO} [*trans*-$[Ru(NH_3)_4(L)(NO)]^{2+}$]

According to the data shown in Table 1, the rate constants for NO dissociation in *trans*-$[Ru(NH_3)_4(L)(NO)]^{2+}$ ions vary from 0.025 s^{-1} (isn) to 4.00 s^{-1} (imC) at 25 °C. The sequence of k_{-NO} as a function of L increases as follows: pic ≈ nic ≈ H_2O ≈ py < L-His ≈ imN < pz < imC, which is the same sequence observed for water[34] or

[a] ($\mu = 0.1$, $NaCF_3COO$; $T = 25$ °C; [Ru] = 1.0×10^{-3} M, pH = 5). [b] Estimated by chronoamperometric method; most of the reported values are the average of at least three determinations; uncertainty of ± 15%. [c] Estimated by cyclic voltammetric method (Nicholson and Shain).

sulfate[32] lability in *trans*-$[Ru(NH_3)_4L(Y)]^{2+}$ complexes (where L = N-heterocyclic ligand, Y = H_2O or SO_4^{2-}).

According to the dissociative pathway for octahedral complexes, NO labilization should reflect the affinity of the *trans*-$[Ru(NH_3)_4(L)(H_2O)]^{2+}$ complex ions for the NO ligand and should be directly connected to the effective ruthenium charge in these complexes. Due to the similarities of the ion complexes studied, the ruthenium effective charge could be discussed on the basis of the electronic properties of the trans N-heterocyclic ligands. It is well-accepted that the higher the π-withdrawing ability of L, the more positive the redox potential of the $Ru^{III/II}$ couple and, therefore, the lower the specific rate constant for the dissociation of the ligand leaving. Since the $M^{n+/(n-1)+}$ redox potential is an indication of the metal-center-effective charge, it is expected that the higher the *trans*-$[Ru(NH_3)_4(L)(H_2O)]^{3+/2+}$ redox potential,[35] the lower the k_{-NO} value. Indeed, as observed for other leaving ligands, a linear tendency ($k_{-NO}/s^{-1} = -0.7 \times E^\circ$ *trans*-$[Ru(NH_3)_4(L)(H_2O)]^{3+/2+} + 0.07$; $R = 0.97$; pyrazine value not considered) is observed when the *trans*-$[Ru(NH_3)_4(L)(H_2O)]^{3+/2+}$ redox potential is plotted against the k_{-NO} values (see Figure 2). The ligand electrochemical parameter (E_L), introduced by Lever,[36] is known to be helpful in predicting the metal redox potential and we expected to find a correlation between the k_{-NO} values and the sum of E_L (ΣE_L) (see Table 1). This correlation exists and as can be observed in Figure 3 ($k_{-NO}/s^{-1} = -0.81 \times \Sigma E_L + 0.48$; $R = 0.997$, pyrazine value not considered). Since E_L values for a large number of N-heterocyclic ligands are available in the literature,[36] this correlation could become a very convenient tool for estimating the rate constants for NO dissociation from *trans*-$[Ru(NH_3)_4(L)(NO)]^{2+}$ species.

As observed in Table 1, the values for NO dissociation when L = pz, imC and $P(OEt)_3$ do not follow the trend observed for the other N-heterocyclic ligands (see Figure 3). The imC and $P(OEt)_3$ properties differ substantially from the N-based ligands as they are coordinated through carbon and phosphorus atoms, respectively. The trans labilizing effect of these two ligands is notable and therefore their

complexes do not fit the correlation implied by Figure 3 [imC and $P(OEt)_3$ values were omitted for clarity]. The behavior of the pyrazine ligand has not yet been understood

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and is currently under investigation in our laboratory. However, the same behavior has been observed for pyrazine derivatives in studies on sulfate dissociation from *trans*-$[Ru(NH_3)_4(L)(SO_4)]$ (L = N-heterocyclic ligands).[32]

From the discussion above, it is clear that the $[Ru^{II}NO^+/Ru^{II}NO^0]$ reduction potential is one of the key steps in activating nitrosyl complexes to release NO. If the target is to tailor a compound that can be activated in vivo through reduction, the $[Ru^{II}NO^+/Ru^{II}NO^0]$ redox potential must be in a range suitable to reducing agents present in the biological medium. The $[Ru^{II}NO^+/Ru^{II}NO^0]$ redox potential for the nitrosyl complexes dealt with here (Table 1) ranges from −0.118 for L = imN to 0.072 V vs. NHE for L = nic, suggesting that all these complexes could be reduced by biological reducing agents[37] such as NADH, the flavin coenzymes $FADH_2$ and $FMNH_2$ and iron sulfur proteins. Recent studies have suggested that the *trans*-$[Ru(NH_3)_4P(OC_2H_5)_3(NO)]^{3+}$ nitrosyl complex can be reduced by mitochondrial reducing power[38] and that this compound exhibits an effective hypotensive effect in mice.[15,16] This biological activity is attributed to its NO-donor ability. The $[Ru^{II}NO^+/Ru^{II}NO^0]$ redox potential for *trans*-$[Ru(NH_3)_4L(NO)]^{3+}$ complexes was shown to be sensitive to the nature of the ligand L, trans to NO. This was expected, since the most accessible site for reduction in these complexes is localized on the nitrosyl ligand. Thus, the NO electronic density and therefore the $[Ru^{II}NO^+/Ru^{II}NO^0]$ redox potential are a function of the competition between the axial ligands, NO and L, on the ruthenium 4dπ electron density. Indeed, a correlation between the *trans*-$[Ru(NH_3)_4L(NO)]^{3+/2+}$ and the respective aqua species *trans*-$[Ru(NH_3)_4L(H_2O)]^{3+/2+}$ redox potential was observed. In addition, a linear correlation was also observed plotting the *trans*-$[Ru(NH_3)_4L(NO)]^{3+/2+}$ redox potential and the ligand electrochemical parameters ΣE_L (Table 1) for L = N-heterocyclic ligands.[39] This correlation is valuable since E_L is available in the literature and was proved to be useful in previously estimating the *trans*-$[Ru(NH_3)_4L(NO)]^{3+/2+}$ redox potential.

It is important to stress that, depending on the electronic characteristics of L, the latter could be displaced instead of NO. In complexes where Cl^- is localized trans to NO,[24,25] as in *trans*-$[Ru(NH_3)_4(Cl)(NO)]^+$, *trans*-[Ru(cyclam)-$(Cl)(NO)]^+$ and *trans*-[Ru(dppe)$(Cl)(NO)]^+$, chloride is preferentially released before NO.

In contrast to the inertia of the $Ru^{II}NO^+$ species, the lability of NO in $Ru^{II}NO^0$ species seems to be common in species where L is a π-acid and should reflect the strength of the Ru−NO bond in both species. To investigate the origin of this different behavior, DFT computations for *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$ and *trans*-$[Ru(NH_3)_4(L)(NO)]^{2+}$ (L = py) were performed. The results obtained in terms of bond lengths and bond angles are similar to those reported for the two systems:[40] $[Ru(CN)_5(NO)]^{2-}$ and $[Ru(CN)_5(NO)]^{3-}$,[41] $[Ru(NH_3)_5(NO)]^{3+}$ and $[Ru(NH_3)_5$-$(NO)]^{2+}$ (Table 2).

The MO composition (see Table 3) for *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$ shows that the π interaction between Ru^{II} and NO^+ consists of a combination of the filled d_{xy} and d_{xz} orbitals (Ru) and the double degenerate, empty π* orbitals of nitric oxide besides the p_y* orbitals of pyridine: HOMO-5 (Ru d_{xy} 33 %, NO p_y 11 %, py p_y 54 %) and HOMO-6 (Ru d_{xz} 69 %, NO p_z 22 %, py p_z 6 %). Figure 4 (left) shows the HOMO-6 graphical representation of *trans*-$[Ru(NH_3)_4(py)(NO)]^{3+}$. The percentage [11−22 % (π* NO)] in the HOMO-5 and HOMO-6 orbitals is consistent with the well-known back bonding from Ru^{II} to NO^+, while 54 % for py (p_y) in the HOMO-5 orbital, which could be considered responsible for the influence of the *trans* ligand on the NO electronic density, is reflected on the $[Ru^{II}NO^+/Ru^{II}NO^0]$ redox potential and ν_{NO}, as observed.

As expected, the LUMO and LUMO+1 for the *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$ complexes [an example of these molecular orbitals is shown in Figure 4 (right)] are antibonding with relation to the Ru−NO π-bond. These π-antibonding orbitals are predominantly on NO π* (66−69 %) (Table 3), which is in agreement with the formation of *trans*-$[Ru(NH_3)_4(L)(NO)]^{2+}$ as a result of *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$ one-electron reduction and with the additional electron occupying one of these π* MOs. Indeed, a similar DFT MO calculation performed on *trans*-$[Ru(NH_3)_4(L)(NO)]^{2+}$ agrees with this prediction and the singly occupied MO (HOMO) and the LUMO, which correspond to the LUMO and LUMO+1 of *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$, respectively, are composed of HOMO Ru (d_{xz}) 35 %, NO (p_z) 50 % and py (p_z) 13 % and LUMO Ru (d_{xy}) 28 %, NO (p_y) 70 % and py (p_y) 2 %. As expected from previous DFT calculations for the $[Ru(CN)_5(NO)]^{3-}$ and $[Ru(NH_3)_5(NO)]^{2+}$ systems,[40,41] a pronounced bend of 139° in the Ru−N−O angle is observed (Table 2). Although, a π-bonding interaction between Ru and NO still exists, that is, HOMO-3 and HOMO-4 [see Table 4 and an orbital representation in Figure 5 (left)], this Ru−*N*−O bending induces a considerable

HOMO-1	−18.3	nonbonding	0	0	4	96 (p_z)
HOMO-2	−18.8	nonbonding	4 (d_{xz})	5 (p_z)	4	87 (p_z)
HOMO-3	−19.7	nonbonding	68 (d_{z^2},$d_{x^2-y^2}$)	1	4	25 (s)
HOMO-4	−20.2	π*L	23 ($d_{x^2-y^2}$)	5 (s)	1	71 (p_x)
HOMO-5	−20.5	π	33 (d_{xy})	11 (p_y)	3	54 (s,p_x,p_y)
HOMO-6	−20.6	π	69 (d_{xz})	22 (p_z)	4	6 (p_z)

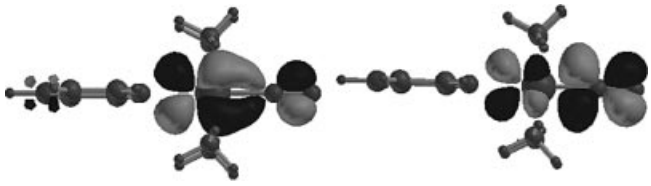

Figure 4. Molecular orbital description of a (nitrosyl)metal complex; (left) HOMO-6: ligand π interaction between Ru (either d_{xy} and d_{xz}) and NO π* orbitals (p_y* and p_z*); (right) LUMO: antiligand π interaction between Ru (either d_{xy} and d_{xz}) and the NO π* orbitals (p_y* and p_z*)

reduction of Ru and NO π-bonding [compare Figure 4 (left) and 5 (left)].

As a consequence, Ru−NO bond weakening is expected and it is comprehensible that the nitric oxide ligand is much more susceptible to dissociation in the *trans*-$[Ru(NH_3)_4(L)(NO)]^{2+}$ species than in the the oxidized analogues. Although, the HOMO and the LUMO for *trans*-$[Ru(NH_3)_4(L)(NO)]^{2+}$ ions, which were totally antibonding

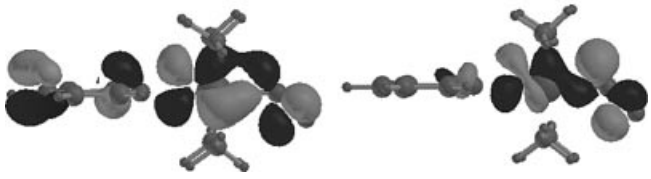

Figure 5. Molecular orbital interaction in a bent (nitrosyl)metal complex; (left) HOMO-3: bending the NO ligand minimizes the overlap between the metal orbitals (either d_{xy} and d_{xz}) and the NO π* orbitals (either p_y* and p_z*); (right) HOMO: the antibonding character presents a compensatory bonding interaction between the NO (p_z*) and the metal (d_{xz}) orbitals as Ru−*N*−O bend

MOs for *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$ (LUMO and LUMO+1, respectively), assume a partial bonding character, they do not seem to be strong enough to keep the metal-coordination sphere intact, as observed. The calculated Ru−NO bond lengths for *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$ (1.82 Å) and *trans*-$[Ru(NH_3)_4(L)(NO)]^{2+}$ (1.91 Å) are in agreement with the Ru−NO bond weakening (Table 2) and they are accompanied by a measurable lengthening of the N−O bond, from 1.130 Å to 1.174 Å (Table 2), which is consistent since the HOMO for the *trans*-$[Ru(NH_3)_4(py)(NO)]^{2+}$ ion has a considerable population and its composition is predominant on NO π* orbitals. As shown in Table 2, Ru−NO and N−O bond lengthening is usual as the same is also observed for $[Ru(CN)_5(NO)]^{3-}$ and $[Ru(NH_3)_5(NO)]^{2+}$ systems.[40,41]

Conclusion

The *trans*-$[Ru(NH_3)_4L(NO)]^{3+}$ complex ions are better described as formally $Ru^{II}NO^+$ and they are stable towards substitution reactions. Following activation by one-electron reduction, species having a labile NO^0 ligand are produced, which makes these compounds good NO-donor drug prototypes.

The rate of NO dissociation from the *trans*-$[Ru(NH_3)_4(L)(NO)]^{2+}$ and the *trans*-$[Ru(NH_3)_4L(NO)]^{3+/2+}$ redox potential, could be modulated by a judicious choice of the ligand, L. These two critical steps for NO-donor-drug designing can be predicted by plots of k_{-NO} versus ΣE_L and from the *trans*-$[Ru(NH_3)_4L(NO)]^{3+/2+}$ redox potential versus ΣE_L, respectively.

Experimental Section

Chemicals and Reagents: High purity chemicals (Aldrich) were used as supplied. $RuCl_3$ was obtained from Johnson Matthey. All solvents were purified following the known procedures.[43] Doubly distilled water was used throughout the experiments. All preparations and measurements were performed under argon. $[Ru(NH_3)_5Cl]Cl_2$,[44] *trans*-$[Ru(NH_3)_4(SO_2)(Cl)]Cl$,[45,46] *trans*-$[Ru(NH_3)_4(SO_4)(L)]Cl$[47] and *trans*-$[Ru(NH_3)_4(L)(NO)](BF_4)_3$[21,22] were prepared as described previously. ESR spectra were recorded in a Bruker ESP 300 E spectrophotometer at the temperature of liquid nitrogen. Electrochemical measurements were performed in both an EG&G Princeton Applied Research model 264A Par and an Autolab potentiostat/galvanostat PGSTAT30. Experiments were conducted using a glassy carbon or gold disks as working electrodes, a saturated calomel electrode (SCE) as a reference electrode and a platinum wire as an auxiliary electrode. The supporting electrolyte consisted of an aqueous buffer solution (pH = 5.0 at μ = 0.1 maintained with $NaCH_3COO/CH_3COOH$) kept under argon atmosphere during measurements. Electrolysis experiments were performed on an EG&G PARC model 173/interface model 276 potentiostat/galvanostat using an optically transparent gold minigrid as a working electrode, Ag/AgCl as a reference electrode and a platinum wire as auxiliary electrode, in a 0.1 cm quartz cell. Spectral changes during the electrolysis were recorded in an HP 8453 diode-array spectrophotometer.

Infrared spectra in aqueous solution (pH = 4) were performed in a calcium fluoride cell in an FTIR Bomen MB-102 spectrometer.

Kinetic experiments were conducted by double-potential-step chronoamperometry. The potential was briefly stepped from a value in which the compound is not reduced at the electrode surface to one in which the reduction proceeds at diffusion-controlled rate. After a period of time, the potential was stepped back to a potential in which the reduced form is oxidized. The kinetic information is obtained from the ratio between the currents measured on both potential steps as a function of time and by comparing these data with those obtained from working curves described in the literature.[48]

All the calculations were performed using the Gaussian 98 suite of programs.[49] The starting molecular geometries were obtained at the UHF/3−21G level of theory.[50−52] The final molecular geometry optimizations were performed using the Kohn−Shan density functional theory (DFT)[53−56] with the 6−31(d) basis set for the H, C, N, O, and P atoms, and an effective core potential LanL2DZ[57−59] for the Ru atom and the Becke three-parameters hybrid exchange-correlation functional known as B3LYP.[60−62] The analytical evaluation of the derivative matrix cartesian coordinates of the second energy (Hessian matrix) at the same level of approximation confirmed the nature of the minimum of the potential surface points associated to the optimized structures.

Unusual Two-Dimensional Nickel(II) Complexes Based on $[Ni(dien)]^{2+}$ and $[M(CN)_4]^{2-}$ Building Blocks (M = Ni, Pd and Pt) − Synthesis, Structural Diversity and Magnetic Properties

Iñaki Muga,[a] Juan M. Gutiérrez-Zorrilla,*[a] Pablo Vitoria,[a] Pascual Román,[a] Luis Lezama,[a] and Javier I. Beitia[a]

Keywords: Nickel / Palladium / Platinum / Cyanides / Bridging ligands

Three novel polymeric compounds $[Ni(dien)Ni(CN)_4]_n(H_2O)_n$ (**1**), $[Ni(dien)Pd(CN)_4]_n$ (**2**), and $[Ni(dien)Pt(CN)_4]_n$ (**3**) were synthesised by reaction of $[\{Ni(dien)(H_2O)\}_2(\mu\text{-ox})](PF_6)_2$ with $[M(CN)_4]^{2-}$ (M = Ni, Pd, Pt) in aqueous solution. The structure of these compounds contains two $[Ni(dien)]^{2+}$ cationic units bridged by two $[M(CN)_4]^{2-}$ anions in a *cis* fashion, generating a square-shaped $[Ni_2–M_2]$ metal core. The different linking modes between the cores afford a 2D bilayer with encapsulated water in compound **1** and corrugated layers in compounds **2** and **3**. These coordination modes are compared to the different bridging modes of tetracyanometalate-containing compounds retrieved from the CSD database. The three compounds present a very weak antiferromagnetic coupling between the octahedrally coordinated Ni^{II} ions.

Introduction

The design and synthesis of molecular magnetic materials have been the focus of increasing attention over the past three decades.[1] So, the study of magnetic interactions in di- and polynuclear complexes, as a function of structural and electronic factors, is still a main challenge in inorganic chemistry. Significant research has been devoted to analyzing the role of the cyanide group as a bridging ligand, both from an experimental[2] and a theoretical[3] point of view. Because it is a good exchange pathway between paramagnetic centres, it is widely employed in the preparation of molecular magnetic materials.[4]

Cyanometalate anions have been extensively used as design elements in supramolecular systems, where they can act as bridging ligands to form high dimensionality coordination polymers with transition metal cations.[5] An approach to the synthesis of these materials is the use of $[M(CN)_4]^{2-}$ groups in conjunction with a transition-metal-ion complex, due to the ability of the cyanide group to connect various central atoms, for building molecular assemblies with various degrees of dimensionality. As can be seen in Table 1, a wide structural diversity can be found in compounds containing bridging tetracyanometalate anions.[6] In this context, it is worth underlining the works of Shore et al.[7] on polymeric systems based on lanthanides, with a variety of Lewis bases and tetracyanometalate anions, and those of Long et al.[8] on cubic-cluster systems. Furthermore, some Hofmann clathrates present cooperative spin-crossover behaviour.[9]

The work described here is part of our research program on the chemistry of first-row transition metal oxalate and cyanide complexes.[10] We employed the nickel dinuclear precursor, $[\{Ni(dien)(H_2O)\}_2(\mu\text{-ox})](PF_6)_2$, due to the lability of its water molecules, which may be replaced by a plethora of ligands. In this paper we report the synthesis, vibrational study, crystal structure and magnetic properties of the following polymeric compounds: $[Ni(dien)Ni(CN)_4]_n(H_2O)_n$ (**1**), $[Ni(dien)Pd(CN)_4]_n$ (**2**), and $[Ni(dien)Pt(CN)4]_n$ (**3**), obtained from the above-mentioned precursor and the cyano complexes $[Ni(CN)_4]^{2-}$, $[Pd(CN)_4]^{2-}$ and $[Pt(CN)_4]^{2-}$, respectively.

Results and Discussion

Synthesis and Spectroscopic Studies

In the synthesis of Ni^{II} complexes based on bridging oxalate and tetracyanometalates, the dinuclear cationic complex $[\{Ni(dien)(H_2O)\}_2(\mu\text{-ox})]^{2+}$ was used as a precursor, owing to the lability of its water molecules, which may be substituted by a plethora of ligands, such as pseudohalide ligands and cyanometalates. As can be seen in Scheme 1, the reaction of the precursor with $[M(CN)_4]^{2-}$ (M = Ni, Pd, Pt) gives at first an insoluble precipitate, which correspond to the polymeric compounds $[\{Ni(dien)M(CN)_4\}]_n$, and then the trinuclear molecular compounds $[\{Ni(dien)\}_2(\mu\text{-ox})\{M(CN)_4\}]$.[6d,10b] The formation of com-

pound **1**, by using KCN as starting material, is probably a consequence of the high stability of the $[Ni(CN)_4]^{2-}$ complex, which leads to the initial formation of the tetracyanonickelate(II) anion when cyanide salt is added to a solution of the precursor.

The IR and Raman spectra of the compounds displaying the stretching vibrations associated to the CN group are shown in Figure 1. The similitude between the spectra of compounds **2** and **3** suggests that the coordination modes of the tetracyanometalate anions are very similar and quite different from that observed in compound **1**. Besides, as the number of independent $[M(CN)_4]^{2-}$ groups increases (one for **1** and two for **2** and **3**), the number of CN stretching-vibration bands also becomes greater.

Crystal Structures

The crystal structures of the compounds present two-dimensional arrangements, based on $[Ni(dien)]^{2+}$ cationic fragments, bridged by $[M(CN)_4]^{2-}$ groups.

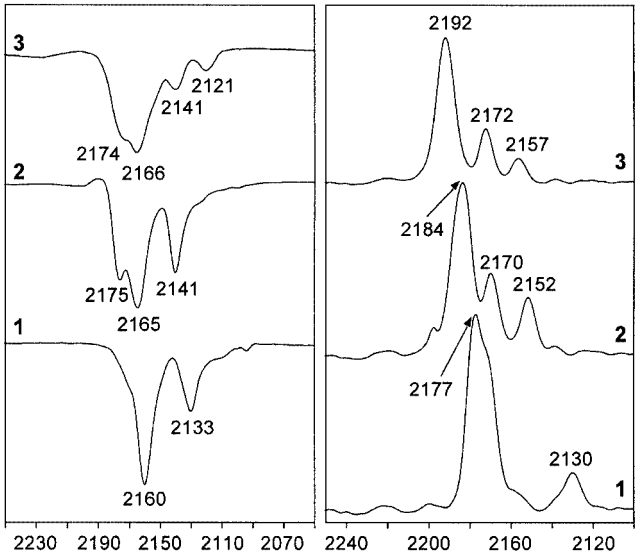

Figure 1. IR (left) and Raman (right) spectra of the compounds

[Ni(dien){Ni(CN)$_4$}]$_n$(H$_2$O)$_n$ (1)

The asymmetric unit of compound **1** consists of one $[Ni(dien)]^{2+}$ unit, one $[Ni(CN)_4]^{2-}$ anion and a water molecule, as illustrated in Figure 2. Selected bond lengths and angles are listed in Table 2. The structure of this compound contains two $[Ni(dien)]^{2+}$ cationic groups, bridged by two $[Ni(CN)_4]^{2-}$ anions in a *cis* fashion, generating a square-shaped $[Ni_2-Ni_2]$ metal core. Each core is linked to another four cores through cyano groups, creating a two-dimensional bilayer parallel to the (011) plane (see Figure 3). In this arrangement, the distorted octahedral environment of Ni1 is set up by three nitrogen atoms from a diethylenetriamine ligand in *fac* and three nitrogen atoms from the corresponding cyanide ligands; thereby, each tetracyanonickelate anion connects three $[Ni(dien)]^{2+}$ moieties and the remaining uncoordinated cyano groups are parallel or antiparallel to the [100] direction giving rise to CN-rich hydrophilic regions (see Figure 4). The water molecule remains encapsulated inside the bilayer and is weakly hydrogen-bonded to the N atoms of the dien ligands. The bilayers are held together by hydrogen bonds, which involve the N1 and

[Ni(dien){Pd(CN)$_4$}]$_n$ (2) and [Ni(dien){Pt(CN)$_4$}]$_n$ (3)

Compounds **2** and **3** are isostructural and the asymmetric unit of both consists of one *fac*-$[Ni(dien)]^{2+}$ cationic group and two centrosymmetric $[M(CN)_4]^{2-}$ anions, as illustrated in Figure 5 [M = Pd (**2**), Pt (**3**)]. Selected bond lengths and angles are listed in Table 2. The repeating molecular unit of **2** and **3** is similar to that of compound **1**: two $[Ni(dien)]^{2+}$ moieties bridged by two $[M(CN)_4]^{2-}$ anions in a *cis* mode, generating a $[Ni_2-M_2]$ metal core. Nevertheless, some differences between the two metallic cores, concerning the dien orientation around the nickel atoms, can be appreciated. Thus, in compound **1**, the N4 dien atom occupies an equatorial position with respect to the metallic core, whereas in compounds **2** and **3** its position is axial. Moreover, these metallic cores form ribbons running along the [010] direction, where each tetracyanometalate(II) group connects four $[Ni(dien)]^{2+}$ cations, as in compound $\{[\{Cu(medpt)\}_2Ni(CN)_4]\}(ClO_4)_2\}_n$.[6n] These ribbons are linked by $[M(CN)_4]^{2-}$ anions that are bound to the Ni^{2+} centres through the cyanide bridges in a *trans* fashion to generate a puckered sheet along the (011) plane (see Figure 6). The 2D planes are connected by hydrogen bonds in a weakly held 3D array (see Figure 7), which involves all dien N atoms and the uncoordinated N11 atoms of the M2 centres together with the N10 atom (see Table 3).

Bridging Modes of [M(CN)$_4$]$^{2-}$ Anions

A total of 60 compounds, containing tetracyanometalates as bridging units, were retrieved from the Cambridge Structural Database. Table 1 summarizes their bridging modes and main features (coordination modes, dimensionality, abbreviated formula and CSD refcode of a representative example). More than half present coordination 2, a bridging mode that usually gives 1D arrangements, in which the metal is usually a lanthanide. Coordination 3 is only present in four cases with variable dimensionality. Although compound **1** shows coordination 3, its structure stands for a new packing mode. Coordination 4 is mainly present in cubic clusters and square-planar arrangements. On the other hand, in compounds **2** and **3**, the tetracyanometalate anions present two coordination modes, 4 to form ribbons along one direction and 2 in order to connect the ribbons in a corrugated layer.

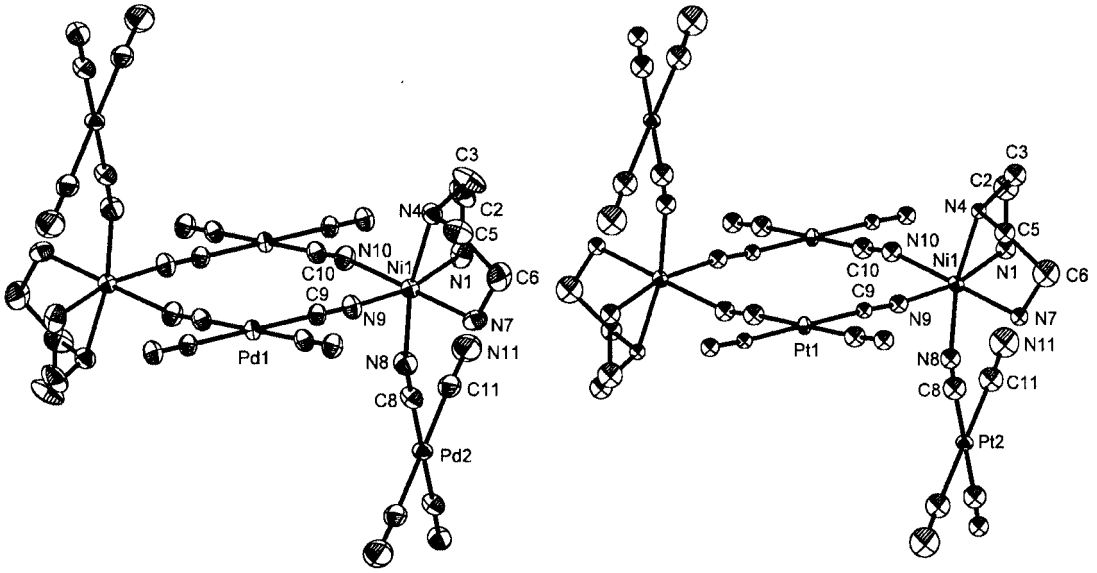

Figure 5. ORTEP views of the metallic core in compounds **2** (left) and **3** (right)

Magnetic Measurements

The temperature dependence of the magnetic susceptibilities of compounds **1**−**3** was measured in the temperature range 5−300 K. Plots of $\chi_m T$ and $\chi_m{}^{-1} T$ vs. T were deposited (see Supporting Information). The thermal evolution of χ_m satisfies the Curie−Weiss law at high temperatures. The values of C and θ are equal to 1.14 $cm^3 \cdot K \cdot mol^{-1}$ and −0.8 K, respectively, for compound **1**, 1.13 and −0.9 for **2** and 1.16 and −0.6 for **3**. These results, together with the continuous decrease in the $\chi_m T$ values, is indicative of antiferromagnetic exchange coupling in the compounds. On the basis of the crystal structures, the compounds were treated as 2D square-planar Heisenberg systems with S = 1 and only magnetic interactions between the nickel(II) ions inside the layers were considered. It was possible to fit the χ_m experimental values using the analytical expression reported by Lines[11] for a 2D square-planar Heisenberg system, from a high-temperature expansion series studied by Rushbrooke and Wood [Equation (1)], where $x = J/kT$, A = 5.333333, B = 9.777778, C = 9.481482, D = 19.06173, E = 45.08971, F = 25.46392.[12]

$$\chi = \frac{2Ng^2\beta^2}{3kT}\left[1 + Ax + Bx^2 + Cx^3 + Dx^4 + Ex^5 + Fx^6\right]^{-1} \quad (1)$$

The least-squares fittings to the experimental data (J = −0.10 cm^{-1} and g = 2.134 for compound **1**, −0.11 and 2.127 for **2** and −0.08 and 2.150 for **3**) show the presence of very weak antiferromagnetic interactions between the paramagnetic nickel ions within each layer through the diamagnetic $[M(CN)_4]^{2-}$ groups.

On the other hand, octahedrally coordinated Ni^{II} compounds frequently exhibit large zero-field splittings of the $^3A_2$ ground state that, qualitatively, produce similar effects to those of antiferromagnetic interactions. In this sense, we have tried to fit the experimental data to the analytical equation for magnetic susceptibility, calculated by application of van Vleck's equation. However, no satisfactory fit could be obtained using that expression and the calculated curves show that the experimental decrease of the magnetic effective moment starts at higher temperatures that those predicted by this simple model (deposited as Supporting Information). Therefore, we can conclude that magnetic exchange is the dominant term in the magnetic properties of compounds **1**−**3**, even if the obtained J values could be somewhat overestimated, due to the possible influence of the Ni^{II} single-ion zero-field splitting.

Conclusions

The reaction between group 10 tetracyanometalates and the cationic complex $[\{Ni(dien)(H_2O)\}_2(\mu\text{-ox})]^{2+}$ leads to the formation of the title polymeric compounds, followed by the trinuclear molecular compounds $[\{Ni(dien)\}_2(\mu\text{-ox})\{M(CN)_4\}]$. Compound **1** contains an encapsulated water molecule, while compounds **2** and **3** are anhydrous and isostructural.

The repeating molecular unit for the three compounds consists of two $[Ni(dien)]^{2+}$ cationic building blocks bridged by two $[M(CN)_4]^{2-}$ anions in a *cis* mode, generating a $[Ni_2-M_2]$ metal core. Nevertheless, some structural differences between both metallic cores could be appreciated, concerning the dien orientation around the nickel atoms and the dihedral angle between the metallic core and the $[M(CN)_4]^{2-}$ groups. This fact could be explained by the different types of hydrogen-bonding present in the compounds, which are strongly influenced by the presence of the water molecule of compound **1**.

These compounds present two novel bridging modes for tetracyanometalate groups. Compound **1** could be used as

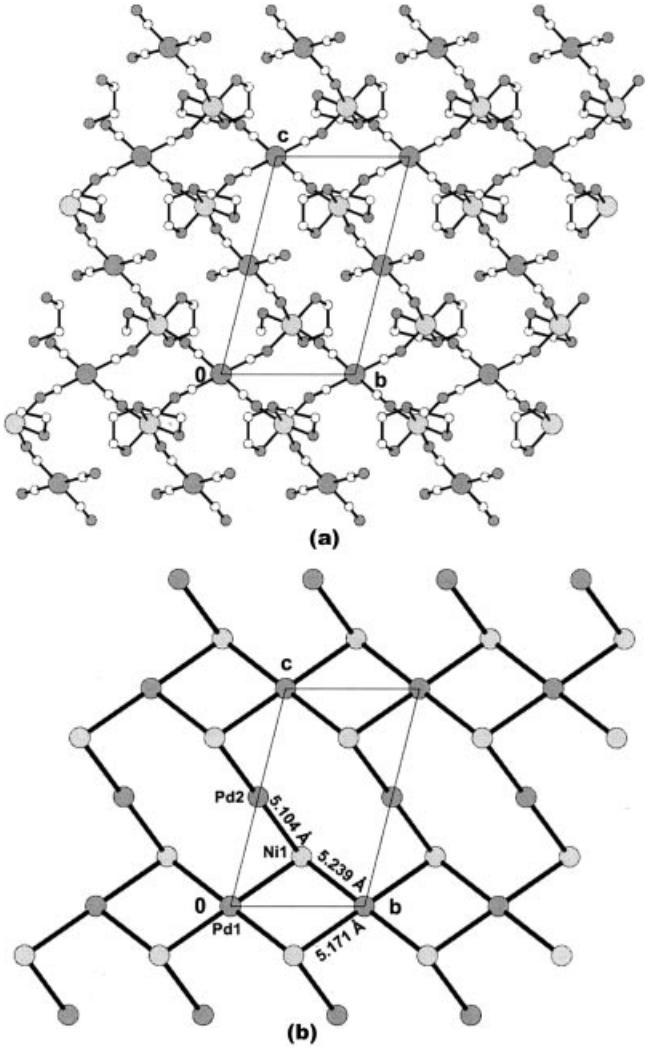

Figure 6. Compound **2**: (a) projection along the *a* axis of a corrugated layer; (b) metallic skeleton formed by cyanide-bridged Ni and Pd atoms with indication of the Ni···Pd distances shorter than 6 Å

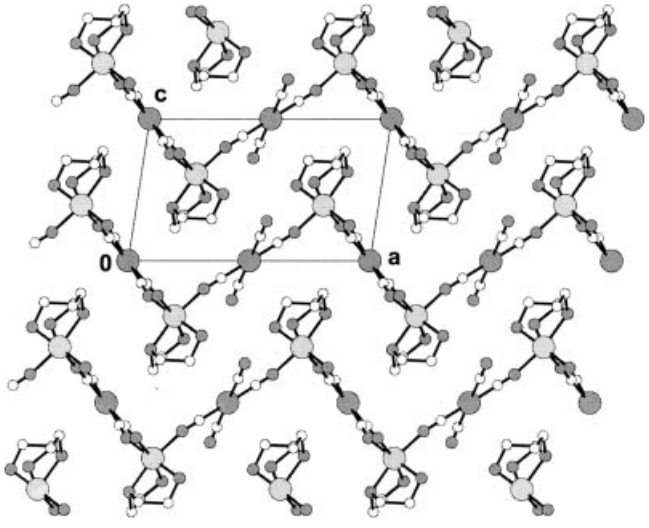

Figure 7. Arrangement of corrugated layers in compound **2**

an intercalation precursor, due to the special arrangement of the uncoordinated cyanide groups of the $[Ni(CN)_4]^{2-}$ anions. On the other hand, compounds **2** and **3** present two types of bridging modes for the tetracyanometalate groups (coordination numbers 2 and 4), giving rise to a structure containing corrugated layers.

The very low values in the coupling constants confirm the poor exchanging capabilities of the tetracyanometalate groups.

Experimental Section

General: Potassium cyanide (KCN; Fluka), potassium tetracyanonickelate $\{K_2[Ni(CN)_4]$; Aldrich$\}$, potassium tetracyanopalladate $\{K_2[Pd(CN)_4]$; Aldrich$\}$, and potassium tetracyanoplatinate $\{K_2[Pt(CN)_4]$; Aldrich$\}$ were used as purchased without further purification. The complex $[\{Ni(dien)(H_2O)\}_2(\mu\text{-ox})](PF_6)_2$ was prepared using a previously described method.[13] Infrared spectra for solid samples were obtained as KBr pellets with a Mattson 1000 FT-IR spectrometer. Raman spectra were measured as pressed pellets using a dispersive micro-probe Renishaw spectrometer, equipped with a high-power 785 nm excitation laser of 500 mW nominal output power. Filters were used to reduce the laser power at the sample to 10 or 1 %. For each spectrum 5−10 scans were collected and the acquisition times ranging from 100 to 300 s. Magnetic susceptibility measurements on polycrystalline samples were performed in the temperature range 5−300 K with a Quantum Design MPMS-7 SQUID magnetometer. The magnetic field used in the experiments was of 0.1 T, a value at which the magnetization versus magnetic-field curve was still linear at 5.0 K. Experimental susceptibility values were corrected for the diamagnetic contributions of the constituent atoms, evaluated from Pascal's constants ($-185\cdot10^{-6}$, $-187\cdot10^{-6}$ and $-201\cdot10^{-6}$ cm^3/mol for compounds **1**−**3**, respectively), and for the temperature-independent paramagnetism (estimated to be $200\cdot10^{-6}$ cm^3/mol).

Synthesis of $[Ni(dien)\{Ni(CN)_4\}]_n(H_2O)_n$ (1): This compound precipitated as a highly insoluble pink residue when KCN (0.25 g, 3.84 mmol) was added, whilst stirring, to an aqueous solution (50 mL) of the precursor complex, $[\{Ni(dien)(H_2O)\}_2(\mu\text{-ox})](PF_6)_2$ (1.42 g, 1.84 mmol). An alternative method involved mixing aqueous solutions of $K_2[Ni(CN)_4]$ (0.058 g, 0.24 mmol) and the precursor (0.36 g, 0.475 mmol). After removing the pink precipitate by filtration, the solvent was refluxed for 20 min and single crystals of compound **1** appeared after one week, yield 0.062 g (75%). $C_8H_{13}N_7Ni_2\cdot H_2O$ (342.69): calcd. C 28.04; H 4.41; N 28.61; found C 27.54; H 4.26; N 28.44.

Synthesis of $[Ni(dien)\{Pd(CN)_4\}]_n$ (2): This compound was obtained as a insoluble pink residue when the precursor (0.25 g, 0.324 mmol) was added to an aqueous solution (20 mL) of $K_2[Pd(CN)_4]$ (0.115 g, 0.40 mmol), yield 0.10 g (65%). Single crystals of this compound were obtained by slow diffusion in a test tube of a methanolic solution of $K_2[Pd(CN)_4]$, into an aqueous solution of the precursor. $C_8H_{13}N_7NiPd$ (372.36): calcd. C 25.81; H 3.52; N 26.33; found C 25.56; H 3.58; N 26.08.

Synthesis of $[Ni(dien)\{Pt(CN)_4\}]_n$ (3): Following the same procedure, compound **3** was prepared as a violet precipitate by using $K_2[Pt(CN)_4]$ (0.051 g, 0.136 mmol) and the precursor (0.25 g, 0.324 mmol), yield 0.035 g (55%). Single crystals of compound **3** were obtained by slow diffusion in a test tube of a methanolic solution of $K_2[Pt(CN)_4]$ into an aqueous solution of the precursor.

$C_8H_{13}N_7NiPt$ (461.05): calcd. C 20.84; H 2.84; N 21.27; found. C 20.55; H 3.00; N 20.94.

X-ray Crystallographic Studies: Single crystals suitable for X-ray analysis were obtained for the three compounds. Data collections for **1** and **3** were performed with a STOE IPDS diffractometer, equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) and an image-plate detector. A total of 200 frames (oscillation range of 1°/frame and exposure time 5 min/frame) were collected, which were processed and corrected for Lorentz and polarization effects with the Stoe IPDS X-RED software package.[14] Indexes and unit-cell refinement were based on all observed reflections from ten frames collected with an oscillation range of 1°/frame and exposure time of 3 min/frame. Data for compound **2** were taken at room temperature with an Xcalibur single-crystal diffractometer (graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å) fitted with a Sapphire CCD detector. A total of 764 frames of data were collected with an exposure time of 10 s/frame, using the ω-scan technique with a frame width of $\Delta\omega = 0.6°$. Data frames were processed (unit cell determination, intensity data integration and correction for Lorentz and polarization effects) using the CrysAlis software package.[15] Visual inspection of the frames collected clearly indicated that compounds **2** and **3** crystallize as non-merohedral twins in the triclinic space group $P\bar{1}$. For compound **2**, an initial orientation matrix and initial cell parameters were obtained by indexing and post-refinement with the CrysAlis software package. This orientation matrix only indexed ca.75 % of the total data. The reflections not indexed by this orientation matrix were then extracted from the measured CCD images and indexed. Both orientation matrices are related by a twofold rotation around the [100] direction in reciprocal space. All frames were then evaluated twice using the CrysAlis software. An HKLF4 reflection file was first output using the data from the major component to aid in the solution of the structure. After the structure was solved, both data sets were given different batch numbers for SHELXL-97 refinement with HKLF5. Overlapping reflections occur twice in the reflection list with the indices of both domains. The twin refinement was performed with SHELXL-97 using the data in HKLF5 format and refinement of batch scale factors. Symmetry-equivalent reflections were not merged (SHELXL-97 procedure); all measured intensities were treated as independent data in the refinement. The refinement resulted in a ratio of 77.0(2):23.0(2) for the two twin domains. Following the same procedure, but using the Stoe IPDS software, the twin law for compound **3** was determined and found to be the same as for **2**. Due to the lower quality of the data collected for compound **3**, only the intensities from the major component of the twin were used for solution and refinement of the structure. All structures were solved using a combination of Patterson and direct methods.[16] Either all non-hydrogen atoms (compounds **1** and **2**) or metal atoms only (compound **3**) were refined anisotropically by the full-matrix least-squares method. Hydrogen atoms of the dien ligands were placed in calculated positions and refined with a riding model. SHELXL-97[17] was used for all structure refinements. Neutral atom scattering factors and anomalous dispersion factors were taken from the literature.[18] Experimental details and crystal data for compounds **1**−**3** are given in Table 4. The April 2003 release of the Cambridge Structural Database[19] was used in this work to obtain the different bridging modes of the group 10

Carboxy Ester Hydrolysis Promoted by a Dicopper(II) Macrocyclic Polyamine Complex with Hydroxypropyl Pendant Groups

Jin Huang,[a] Shu-An Li,[a] Dong-Feng Li,[a] De-Xi Yang,[a] Wei-Yin Sun,*[a] and Wen-Xia Tang[a][†]

Keywords: Copper / Hydrolysis / Macrocyclic ligands / Mass spectrometry / Potentiometric titrations

A dinuclear Cu^{II} complex containing a hexaaza macrocyclic ligand bearing two 2-hydroxypropyl pendants, 3,6,9,16,19,22-hexaaza-6,19-bis(2-hydroxypropyl)tricyclo-[22.2.2.2^{11,14}]triaconta-1,11,13,24,27,29-hexaene (L), was synthesized. The title complex $[Cu_2(H_{-2}L)Cl_2]\cdot 6.5H_2O$ was isolated as a blue crystal, orthorhombic, space group *Fddd*, with a = 16.4581(12), b = 32.248(2), c = 35.830(2) Å, V = 19017(2) Å^3, Z = 16, $R1$ = 0.0690, and $wR2$ = 0.1546 [$I > 2\sigma(I)$]. The protonation constants of Cu_2L were determined by potentiometric titration, and it was found that the alcoholic hydroxypropyl group of the complex Cu_2L exhibits low pK_a values of pK_{a1} = 7.31, pK_{a2} = 7.83 at 25 °C. The hydrolysis kinetics of 4-nitrophenyl acetate (NA) promoted by the title complex have also been studied. The pH-rate profile for Cu_2L gave a sigmoidal curve and showed a second-order rate constant of 0.39 ± 0.02 M^{-1} s^{-1} in 10% CH_3CN/H_2O(v/v), which is greater than that of the dinuclear Cu^{II} complex formed by a hexaaza macrocycle without pendants. The reason for the higher catalytic activity of the title complex is discussed. We found that the volume of nucleophile RO^- can effect the hydrolysis of the carboxy ester, the nucleophilicity of RO^- and the Lewis acidity of the metal macrocycle also affect the carboxy ester hydrolysis.

Introduction

Metal hydroxides and metal alkoxides play important roles in hydrolytic metalloenzymes. Metal hydroxides have been implicated in the carbonic anhydrase catalyzed hydration of carbon dioxide[1] as well as in the carboxypeptidase-catalyzed hydrolysis of amides.[2] The role of the metal ions in the activation of proximate alcoholic OH groups is well documented in natural metalloenzymes. The key role of the metal atom in promoting hydrolysis appears to be the intramolecular delivery of the nucleophile. By virtue of its Lewis acidity, the metal ion reduces the pK_a of a coordinated water molecule, thereby producing a good nucleophile at neutral pH. In addition, the hydration sphere normally associated with water molecules in bulk solution does not interfere with nucleophilic attack in an inner-sphere reaction.[3]

Kimura's group discovered that the pendant alcohol can be deprotonated to form a Zn^{II}-bound alkoxide anion, which acts as a strong nucleophile at physiological pH.[4,5] Chin's group has investigated the reactivities and mechanisms of copper(II) hydroxide and copper(II) alkoxide for the cleavage of phosphate diesters, and discovered that the copper(II) alkoxide-promoted transesterification path is two orders of magnitude faster than the hydrolysis path, i.e., the copper(II) hydroxide path.[6] A mechanistic study of Cu^{II}-catalyzed ester hydrolysis has yielded a variety of kinetic behaviors and proposed active species. We use a macrocycle dinucleating ligand with two hydroxypropyl pendants (L in Scheme 1) to further explore the influence of the alcohol pendant on the behavior of the corresponding Cu^{II} complexes. Here, we report the crystal structure of the dinuclear Cu^{II} complex of L. The stability constants of Cu^{II} complexes of L and carboxy ester hydrolysis were also investigated. Indeed, we found that the catalytic activity of Cu_2L is higher than that of the dicopper complex with a macrocyclic ligand without hydroxy pendants. Our results indicate that the volume of nucleophile RO^-, the nucleophilicity and the Lewis acidity of the metal macrocycle may effect the carboxy ester hydrolysis.

Results and Discussion

Structure Description of $[Cu_2(H_{-2}L)Cl_2]\cdot 6.5H_2O$

The compound crystallizes in the orthorhombic system with space group *Fddd* and consists of a neutral unit of $[Cu_2(H_{-2}L)Cl_2]$ and six and a half water molecules of crystallization. Selected bond lengths and bond angles relevant to the Cu^{II} coordination sphere are given in Table 1.

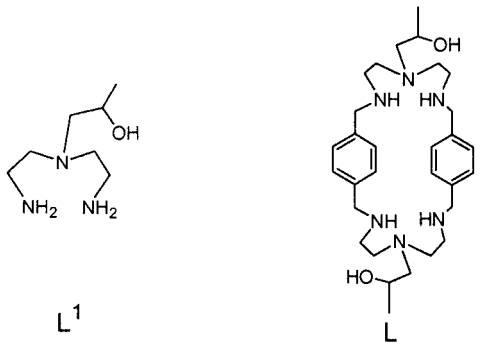

Scheme 1

Table 1. Select bond lengths [Å] and angles [°] for $[Cu_2(H_{-2}L)Cl_2]\cdot 6.5H_2O$

Cu1−Cl1	2.2486(15)	Cu1−N3	2.056(4)
Cu1−N1	2.018(5)	Cu1−O1	2.177(4)
Cu1−N2	2.087(4)		
N1−Cu1−Cl1	173.93(16)	N2−Cu1−O1	105.28(17)
N1−Cu1−N2	84.28(19)	N3−Cu1−Cl1	98.39(15)
N1−Cu1−N3	85.4(2)	N3−Cu1−N2	128.81(18)
N1−Cu1−O1	81.63(18)	N3−Cu1−O1	122.46(16)
N2−Cu1−Cl1	96.93(14)	O1−Cu1−Cl1	92.32(12)

As illustrated in Figure 1, each macrocycle binds two Cu^{II} ions by its diethylenetriamine moieties, which provide three nitrogen atoms to each Cu^{II} ion; the rest of the coordinated atoms are a chloride anion and an oxygen atom from the hydroxypropyl pendant. The Cu1 atom deviates 0.216 Å from the trigonal equatorial plane formed by O1, N2 and N3 towards the Cl ion with N3−Cu1−N2 = 128.81°, N3−Cu1−O1 = 122.46° and N2−Cu1−O1 = 105.28°, while the axial positions are occupied by N1 of the macrocycle and Cl1 with an N1−Cu1−Cl1 angle of 173.93°, and Cu1−N1 and Cu1−Cl1 bond lengths of 2.018 and 2.249 Å, respectively. The distortion (Δ) of the coordination polyhedron from an ideal trigonal bipyramid (Δ = 0) to a square pyramid (Δ = 1) has been calculated according to the method reported by Muetterties[7] and Galy.[8] The Δ value of 0.086 indicates that each Cu ion has a coordination geometry much closer to a trigonal bipyramid in the pentacoordinate environment. The distance between two Cu^{II} ions is 8.128 Å, which is similar to those observed in other dicopper(II) macrocyclic complexes.[9] With the center-to-center distance of 5.662 Å, the two phenyl rings form a dihedral angle of 83.3° to each other. Additionally, the two hydroxypropyl arms are located on the same sides of the plane defined by the nitrogen atoms and the phenyl groups of the macrocyclic ligand, thus ligand L in the title complex has a boat-like (*syn*) conformation.

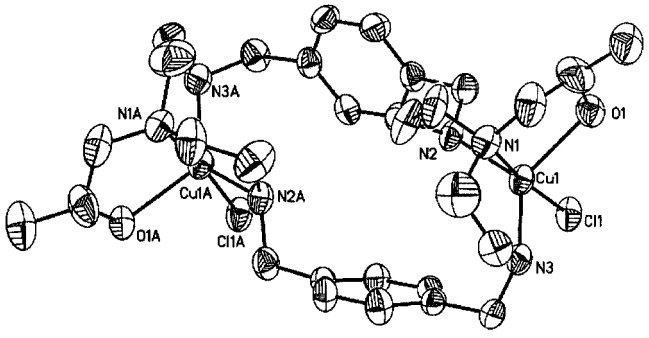

Figure 1. ORTEP drawing (30% probability ellipsoids) of $[Cu_2(H_{-2}L)Cl_2]\cdot 6.5H_2O$; hydrogen atoms and water molecules are omitted for clarity

We noticed that the Cu^{II}−O(ROH) bond length (2.177 Å) in the title complex is shorter than the Cu^{II}−O distance of 2.186 Å in the dicopper complex of a 26-membered macrocycle ligand with two hydroxyethyl groups.[9] Since shorter water oxygen−copper bonds always lead to greater acidity, and hence to lower pK_a values,[6] the discrepancy in the structure between these two Cu^{II}−macrocycle complexes may be responsible for the different deprotonation behavior.

Complexation Constants of L with Cu^{II}

The complexation constants of the species formed by L and Cu^{II} in a 1:2 [L/Cu^{II}] system with I = 0.10 M ($NaNO_3$) in aqueous solution at 298 K have been determined by potentiometric titration (6 equiv. of HCl added to acidify the pure ligand before titration). As shown in Figure S1 (see Supporting Information), when 2 equiv. of Cu^{II} are added to the solution, the titration reveals two inflexions at a = 6 and a = 8 (a is the number of mol of NaOH added per mol of ligand), respectively. The inflexion at a = 6 corresponds to the completion of the neutralization of the six ammonium ions in the diethylenetramine moieties, which are easily deprotonated to form dinuclear complexes. The inflection at a = 8 indicates the further deprotonation of two titratable protons from two hydroxypropyl pendants bound to the Cu^{II}.

To rationalize the model selection and data process, several different analysis processes were conducted and evaluated. In the first case, the deprotonated species were set to be the dinuclear complexes of $[Cu_2H_{-1}L]^{3+}$ and $[Cu_2H_{-2}L]^{2+}$. In the second case, the deprotonated species were set for both dinuclear and mononuclear complexes; i.e., the species CuL, CuHL, CuH_2L, Cu_2L, $[Cu_2H_{-1}L]^{3+}$, $[Cu_2H_{-2}L]^{2+}$ and $[CuH_{-1}L]^{+}$ were included. In the third case, all possible deprotonated species and hydroxide species were included. In the third case, reasonable results were given by BEST, with a σ-fit value optimized to be 0.028. However, in other cases, the σ-fit values are all larger than 0.2. Thus, we chose the third case as the most rational one.

Figure 2 displays the species distribution as a function of pH at a total Cu^{II} concentration of 2 mM and a total L concentration of 1 mM at 25 °C. As shown in Figure 2, $[CuH_2L]^{4+}$, $[Cu_2L]^{4+}$, $[Cu_2H_{-1}L]^{3+}$, $[Cu_2H_{-2}L]^{2+}$, $[Cu_2H_{-2}L(OH)]^{+}$ and $[Cu_2H_{-2}L(OH)_2]$ exist as the major Cu^{II} complex species under the employed experiment conditions, and the other species were less than 1 ppm in concentration. The dinuclear complex $[Cu_2L]^{4+}$ is the predominant species over the pH range of 5−6.5. The monodepro-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tonated $[Cu_2H_{-1}L]^{3+}$ has a favourable pH of 7.4, above which it is gradually converted into $[Cu_2H_{-2}L]^{2+}$, $[Cu_2H_{-2}L(OH)]^{+}$, $[Cu_2H_{-2}L(OH)_2]$; $[Cu_2H_{-2}L]^{2+}$ predominates at pH values of about 8.5, and this is in accordance with the X-ray crystal structure analysis. To illustrate the process clearly, the stepwise complexation of L with Cu^{II} via these species is shown in Scheme 2. ES-MS data (shown in Figure 3a) for the complex in 10% CH_3CN/H_2O (v/v) at a pH of about 6.0 in aqueous solution evidence the stable existence of $[Cu_2LCl_2]^{2+}$ (m/z = 362.1) and $[Cu_2LCl_3]^{+}$ (m/z = 759.0). The stable existence of these species indicates that the dinuclear complex $[Cu_2L]^{4+}$ is the predominant species at a pH of about 6.0.

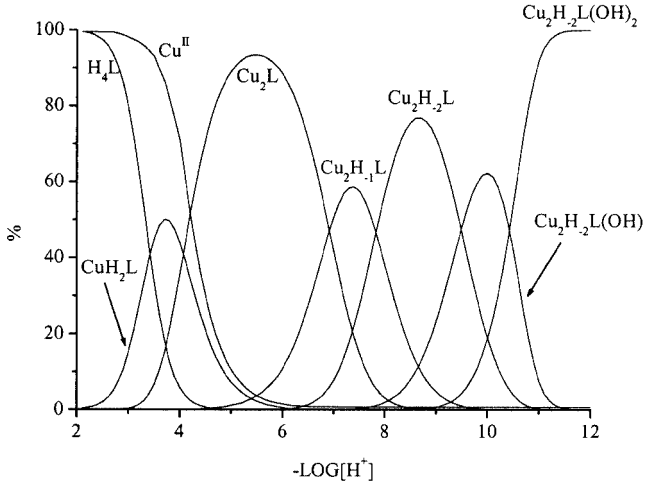

Figure 2. Species distribution graph as a function of pH for the 1 mM L + 2 mM Cu^{II} system at 25 °C and I = 0.10 M ($NaNO_3$)

The program BEST was used to analyze the titration data, and the obtained log K and the deprotonation constant pK_a for the Cu^{II} complexes with L at 25 °C are listed in Table 2. The most significant finding from Table 2 is the rather facile deprotonation of the alcoholic function with pK_a = 7.31 at 25 °C, which is lower than that found by Kimura et al.[4] for the Zn^{II} complex of 1-(2-hydroxyethyl)-1,5,9-triazacyclodecane (pK_a = 7.40 at 25 °C) and a dicopper complex of a 26-membered macrocyclic ligand with two hydroxyethyl pendants (pK_a = 7.60).[9] This lower pK_a value implies that the title complex is a strong enough nucleophile hydroxyethyl pendants (pK_a = 7.60).[9] This lower pK_a value implies that the title complex is a strong enough nucleophile to attack an ester bond in catalytic hydrolysis.

Hydrolysis of 4-Nitrophenyl Acetate

The reactivity of the dinuclear complex toward the hydrolysis of phosphate ester or carboxy ester has also been checked. Since phospho monoesters undergo slow hydrolysis with the complex, we only describe the hydrolytic cleav-

age of 4-nitrophenyl acetate (NA). The activity of the dinuclear species has been investigated by monitoring the hydrolysis of NA (0.4−1.0 mM) promoted by Cu_2L at different concentrations (0.5−2.0 mM) at pH = 7.3−9.3, as described in the Exp. Sect. The spontaneous hydrolysis of NA by buffered solution was subtracted from the Cu complex promoted hydrolysis. A second-order kinetics of Cu_2L promotion NA hydrolysis was observed at different pH values. The initial rate constant, k_{in}, observed rate constant, k_{obs}, the spontaneous hydrolysis constant, v_{buffer}, and second-order constant, k_{cat}, are defined as follows:

$v_{total} = v_{Cu} + v_{buffer} = k_{in}[NA]$
$v_{buffer} = (k_{OH^-}[OH^-] + ...)\cdot[NA]$
$v_{Cu} = k_{NA}\cdot[Cu^{II}complex]_{total}\cdot[NA] = k_{cat}\cdot[Cu_2H_{-2}L][NA]$

The first-order constant k_{obs} [s^{-1}] is calculated from the slope of the straight line v_{Cu} vs. [NA]. The plot of k_{obs} vs. $[Cu^{II}\ complexes]_{total}$ gives a straight line with the slope denoted as k_{cat} ($M^{-1}s^{-1}$).[6] The second-order rate constant k_{cat} for Cu_2L is 0.39 $M^{-1}s^{-1}$ at pH = 9.5 (shown in Figure 4), where $[Cu_2H_{-2}L]^{2+}$ is the main species in aqueous solution.

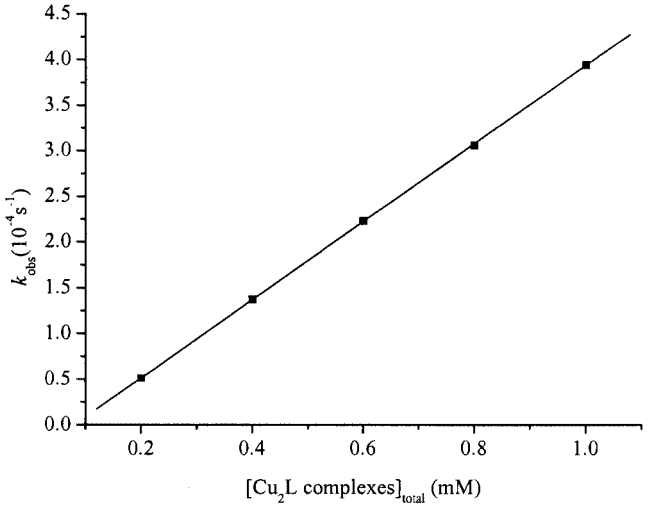

Figure 4. Dependence of k_{obs} on [total Cu^{II} complexes] at pH = 0 9.5, ionic strength 0.1 M ($NaNO_3$), and at 25 °C in the presence of 10% CH_3CN/H_2O (v/v); correlation coefficient > 0.99

To examine whether the whole process is a catalytic hydrolysis or transesterification, we followed the release of NP up to more than one cycle with the NA concentration set at 6.0 mM and the Cu^{II} complex concentration at only 0.2 mM in buffer solution (pH = 9.0) by monitoring the absorbance at 400 nm at 25 °C. The resulting v_{total} vs. time curve reveals that the rate constant for Cu_2L is identical to the initial rate constant determined above. Thus, the mechanism is catalytic hydrolysis. The second-order constants k_{cat} are plotted as a function of pH, and the resulting sigmoidal curve is shown in Figure 5. This curve is characteristic of a kinetic process controlled by an acid/base equilibrium with an inflexion at pH ≈ 8.75, and, as shown in Figure 2, $[CuH_{-2}L]^{2+}$ is the major species in aqueous solution at pH ≈ 8.7. Therefore, the main promoter species is proposed to be the deprotonated species $[CuH_{-2}L]^{2+}$. Different from the reported dicopper complex of a 26-membered macrocyclic ligand with two hydroxyethyl pendants,[9] the maximum value of k_{cat} for Cu_2L appears at pH ≈ 9.0 because the concentration of $[CuH_{-2}L]^{2+}$ species decreases significantly when the solution's pH is higher than 9.0. As with the reported dicopper complex,[9] the value of k_{cat} increases further when the solution's pH is higher than 9.5 because the doubly deprotonated species is still the major component.

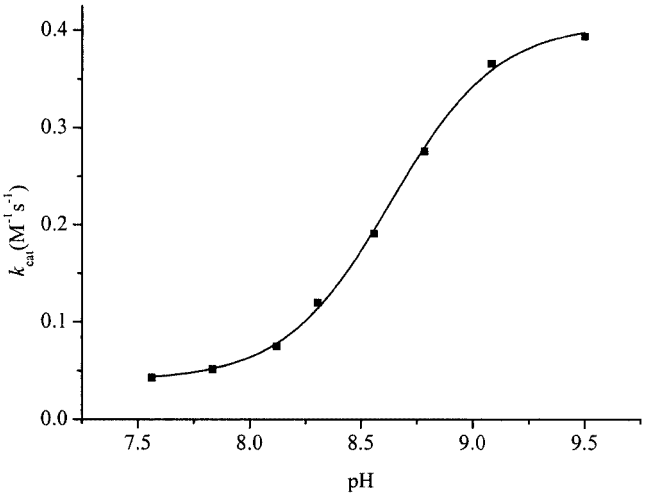

Figure 5. pH/rate profile for the second-order rate constant of NA hydrolysis with the Cu_2L complex at 25 °C and I = 0.1 M ($NaNO_3$) in 10% CH_3CN/H_2O (v/v)

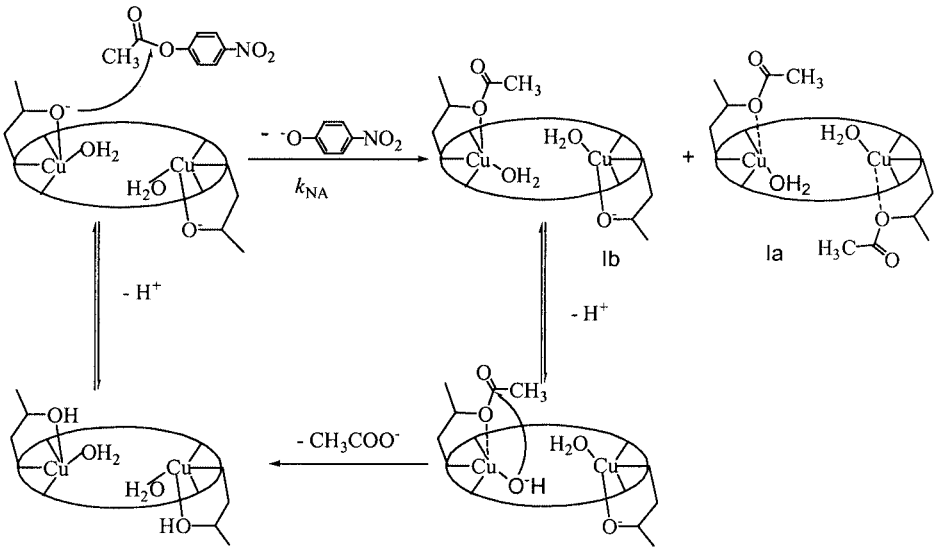
In the course of catalytic NA hydrolysis, we suspected that a transient "acetyl intermediate" is formed, which then disappears very rapidly to give the final product acetate anion and Cu_2L. At pH values of 6 or lower, the intermediate can exist in aqueous solution for long time and it will disappear quickly when the pH of the solution is adjusted to 8.8.[10] A non-buffered solution (pH ≈ 6) of Cu_2L/NA = 1:1 in 10% CH_3CN/H_2O (v/v) was analyzed by ES-MS (shown in Figure 3b). When compared to Figure 3a, a new peak at m/z = 839.0 appears after the addition of NA and this peak is assigned to the intermediate $[\mathbf{Ia}H_{-2}Cl(CH_3OH)]^+$ (Scheme 3). On this basis, we propose

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3

the overall possible catalytic reaction depicted in Scheme 3, with the initial formation of an "acyl intermediate" being the slowest step. The formation of a similar intermediate was also observed by the groups of Kimura, Bencini and ourselves in NA hydrolysis catalyzed by Zn^{II} complexes.[4,10–12]

Comparing the kinetic data for Cu_2L and other dicopper(II) macrocyclic complexes, we found that the rate constant for Cu_2L is similar to that of a dicopper complex of a 26-membered macrocyclic ligand with two hydroxyethyl pendants (0.41 $M^{-1}s^{-1}$), and approximately 14 times higher than the Cu^{II} complex of the macrocyclic ligand without hydroxy pendants (0.027 $M^{-1}s^{-1}$).[9] These results suggest that a Cu^{II}-bound alkoxide is a better nucleophile than a Cu^{II}-bound hydroxide. The similar hydrolysis rate constants of Cu_2L and the reported dicopper hydroxyethyl macrocycle complex[9] may be related to this. The substitution of 2-hydroxypropyl for hydroxyethyl increases the nucleophilicity of the metal macrocycle and thus increases the hydrolysis rate constant, while the addition of a methyl group can increase the nucleophilic reaction's steric constraint and does not benefit the nucleophilic attack. The other reason may be the Lewis acidity of the metal complex. This trend of increasing Lewis acidity with increasing macrocycle size can be observed through the comparison of the pK_a of Cu_2L (pK_{a1} = 7.31, pK_{a2} = 7.83) and a reported dicopper complex of a hydroxyethyl macrocycle (pK_{a1} = 7.60, pK_{a2} = 8.07).[9] Since Cu_2L is a stronger Lewis acid than the Cu^{II} hydroxyethyl macrocycle complex, Cu_2L is expected to activate the coordinated carboxy ester toward nucleophilic attack to a greater degree than the other complex, although as the metal complex becomes a stronger Lewis acid, the nucleophilicity of the coordinated hydroxide decreases.

Conclusions

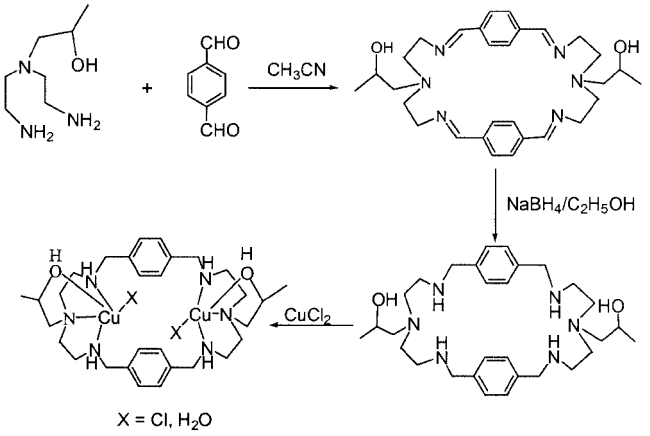
A new dinuclear Cu^{II} complex of a macrocyclic ligand with two 2-hydroxypropyl pendants has been synthesized. X-ray crystal analysis reveals that the two pendant alcohol groups are deprotonated to bind two Cu^{II} ions, which both adopt a trigonal-bipyramid geometry with a Cu···Cu distance of 8.129 Å. The solution complexation studied by potentiometric titration on the Cu^{II} complexes of L has revealed that $[Cu_2H_{-2}L]^{2+}$ is the major species when the pH of an aqueous solution is around 8.7, which is in accordance with the X-ray crystal analysis result. The 4-nitrophenyl acetate hydrolysis promoted by Cu_2L shows a second-order rate constant of 0.39 $M^{-1}s^{-1}$, which is approximately 14 times higher than that of the dicopper macrocycle complex without hydroxy pendants, while it is similar to that of a similar Cu^{II} complex of a macrocycle with hydroxyethyl pendants, which suggests that a Cu^{II}-bound alkoxide is a better nucleophile than a Cu^{II}-bound hydroxide. In spite of the volume of RO^-, the nucleophilicity and the Lewis acidity of the metal macrocycle can also effect the carboxy ester hydrolysis.

Experimental Section

Instrumentation and Materials: C, H and N analyses were performed with a Perkin–Elmer 240C elemental analyzer. ES mass spectra were obtained with a Finnigan MAT LCQ ES mass spectrometer with an *m*/*z* range of 2000. A CH_3OH/water (1:1) mixture was used as the solvent, and the concentration used in the experiment was 1.0 μmol/L. 1-[Bis(2-aminoethyl)amino]-2-propanol (L^1, Scheme 1) was prepared as described previously.[13] The other reagents were of analytical grade from commercial sources and were used without further purification. The synthesis of L and its Cu^{II}

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complex is shown in Scheme 4. L was synthesized as a mixture of diastereomers by $NaBH_4$ reduction of the corresponding Schiff base obtained from the [2 + 2] condensation between 1-[bis(2-aminoethyl)amino]-2-propanol (L^1) and terephthaldehyde similar to the reported procedures,[9] and then the Cu_2L complex was synthesized by reaction of L with $CuCl_2$.



Scheme 4

Preparation of the Dinuclear Copper Complex $[Cu_2(H_{-2}L)Cl_2]\cdot 6.5H_2O$: A solution of L (0.0512 g, 0.10 mmol) in H_2O (2 mL) was added dropwise with stirring to an aqueous solution (2 mL) containing $CuCl_2\cdot 2H_2O$ (0.0341 g, 0.20 mmol), at 25 °C, to give a blue solution (pH ≈ 8.5). After being stirred for 2 h, the reaction mixture was filtered. Blue polyhedral crystals were obtained by slow evaporation of the solvents from the filtered solution for several days at ambient temperature. $[Cu(H_{-2}L)Cl_2]\cdot 6.5H_2O$ (839.83): calcd. C 43.09, H 6.94, N 10.13; found C 43.07, H 6.82, N 10.05.

X-ray Crystallographic Study of $[Cu_2(H_{-2}L)Cl_2]\cdot 6.5H_2O$: Diffraction data for the crystal were collected with a Siemens SMART CCD system equipped with monochromated Mo-K_α radiation (λ = 0.71073 Å) at room temperature in the range of $2.20° \le \theta \le 25.00°$. Data integration and empirical absorption corrections were carried out with the SAINT[14] and SADABS[15] programs. The structure was solved by direct methods (SHELXS 97) and refined on F^2 by full-matrix least-squares techniques (SHELXL 97).[16] All the non-H atoms were refined anisotropically. Hydrogen atoms were introduced in calculated positions and treated as riding atoms using the SHELXL-97 default parameters. All of the crystalline water molecules were found to be disordered and the site occupancy factors (s.o.f.s) for these oxygen atoms (O1W, O2W, O3W, O1W′, O2W′, O3W′, O4W, O5W, O6W) are 0.5, 0.25, 0.25, 0.5, 0.5, 0.25, 0.5, 0.5 and 0.25, respectively. The O5W atom is located on the twofold axis. The crystallographic data and details of the data collection are summarized in Table 3. CCDC-210142 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Potentiometric Measurements: Potentiometric experiments were conducted with an Orion 91−04 glass combination pH electrode and an Orion microprocessor analyzer/901 at 25 °C. All solutions were carefully protected from air by a stream of humidified nitrogen. Standard NaOH (0.1 M, CO_2 free) was added by a spiral micro-injector. The $CuCl_2$ solution was calibrated by standard EDTA, and doubly distilled water with a pH of about 6 was used. The temperature of the cell was controlled by a thermostat. K_w was chosen as 13.69 for 25 °C, 0.1 M $NaNO_3$ was contained to adjust the ionic strength to 0.1 M. Solutions containing 1 mM L with or without 2 mM $CuCl_2\cdot 2H_2O$ were titrated to pH > 11. The complexation and protonation constants were calculated using the program BEST.[17] All data represent the average of at least two independent experiments and all the sigma fit values have been reduced to less than 0.03 after optimization.

Table 3. Summary of crystal data, data collection and refinement for $[Cu_2(H_{-2}L)Cl_2]\cdot 6.5H_2O$

Empirical formula	$C_{30}H_{61}Cl_2Cu_2N_6O_{8.5}$

Unique reflections	4034 (R_{int} = 0.0613)
Observed reflections [$I > 2\sigma(I)$]	2288
μ [mm^{-1}]	1.051
Goodness-of-fit on F^2	1.026
$R1$,[a] $wR2$[b] [$I > 2\sigma(I)$]	0.0694, 0.1566
Largest difference peak/hole [e Å^{-3}]	0.578/−0.339

[a] $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. [b] $w = 1/[(F_o^2)^2 + (0.0354P)^2 + 0.0000P]$, where $P = (F_o^2 + 2F_c^2)/3$.

Kinetic Studies: The hydrolysis rate of 4-nitrophenyl acetate (NA) was measured by an initial slope method by monitoring the increase in the 400-nm absorption of the released 4-nitrophenolate in 10% CH_3CN/H_2O (v/v) aqueous solution at 25.0 ± 0.5 °C with a UV-3100 spectrophotometer by using the procedures reported previously.[9,10] Buffered solutions containing Tris buffer (pH = 7.3−9.0) or CHES buffer (pH = 9.3−9.6) were used, and the ionic strength was adjusted to 0.10 M with 1.0 M $NaNO_3$. The initial rate determination was carried out according to the typical procedure previously reported by Kimura and ourselves.[4,5,9,10,18] NA and Cu^{II} complex were mixed in the buffered solution, the UV absorption increase at 400 nm was recorded immediately and monitored generally until 2% formation of 4-nitrophenolate. The observed first-order rate constant k_{obs} [s^{-1}] was calculated from the decay slope of 4-nitrophenolate release rate vs. [NA] and the slope of k_{obs} vs. $[Cu^{II}\ complex]_{total}$ was denoted as the second-order rate constant k_{NA} [M^{-1}s^{-1}]. All the experiments were conducted at least twice, and the tabulated data represent the average of these experiments.

Synthesis, Solution-State and Solid-State Structural Characterization of Monocationic Nitrido Heterocomplexes $[M(N)(DTC)(PNP)]^+$ (M = ^{99}Tc, Re; DTC = Dithiocarbamate; PNP = Heterodiphosphane)

Cristina Bolzati,[a] Fiorenzo Refosco,[a] Aldo Cagnolini,[a] Francesco Tisato,*[a] Alessandra Boschi,[b] Adriano Duatti,[b] Licia Uccelli,[b] Alessandro Dolmella,[c] Ester Marotta,[d] and Michela Tubaro[d]

Keywords: Technetium / Rhenium / Radiopharmaceuticals / NMR spectroscopy / P ligands

Mono-cationic nitrido heterocomplexes of general formula $[M(N)(DTC)(PNP)]^+$ (where M is ^{99}Tc or Re, DTC is the monoanionic form of a dithiocarbamate ligand, and PNP is a diphosphane ligand with a tertiary amine-containing five-membered spacer) were prepared by ligand-exchange reactions with the labile precursors $[M(N)Cl_2(PPh_3)_2]$ in dichloromethane/alcohol mixtures. The molecular structure of the representative rhenium complex $[Re(N)(dedc)(pnp2)][PF_6]$ (**1**) displays a distorted, square-pyramidal geometry with the dithiocarbamate sulfur and the diphosphane phosphorus atoms spanning the four coordination positions on the equatorial plane. If the additional interactions between the nitrido nitrogen and the weakly bonded *trans N*-diphosphane heteroatom, the molecular geometry can be viewed as pseudo-octahedral. The structure in solution, as established by multinuclear NMR spectroscopy and ESI spectrometry, is monomeric, and identical to that shown in the solid state. Replacement of the phenyl groups on the phosphorous atoms in complexes **1**, **2**, **5**, and **6** with alkyl groups modified neither the course of the reaction nor the composition of the resulting complexes. These results, together with the observation that no symmetrical complexes containing two identical bidentate ligands were produced in these reactions, strongly supports the conclusion that a mixed coordination sphere, composed by a combination of π-donor and π-acceptor atoms around the $[M{\equiv}N]^{2+}$ group, constitutes a highly stable system. Compounds containing dangling alkyl-substituted groups in the outer sphere (**3**, **4**, **7**, and **8**) were fully characterized by multinuclear NMR spectroscopy and ESI mass spectrometry.

Introduction

Radioactive isotopes of the two elements technetium and rhenium play an important role in nuclear medicine for diagnostic and therapeutic applications. In particular, the γ-emitting radionuclide ^{99m}Tc has almost ideal properties (E_γ = 142 keV, $t_{1/2}$ = 6.06 h) for the imaging of internal organs. Similarly, the β-emitting radionuclide ^{188}Re is currently considered to be an important candidate for the development of therapeutic agents for the treatment of degenerative diseases. Selective uptake into the target organ is one of the key issues that should be always considered in the development of effective diagnostic or therapeutic agents. Ultimately, this requires the design of radiopharmaceuticals possessing specific molecular features. Metal complexes of technetium and rhenium characterized by a selective reactivity toward a selected set of coordinating atoms are currently attracting much interest as suitable precursors for the design and preparation of new radiopharmaceuticals.[1−3] These complexes can be viewed as being composed of a robust metal-containing fragment with a few substitution-labile coordination positions, spanned by some weakly bound ancillary ligands. It turns out that these ancillary substituents can be easily replaced by ligands which only carry a specific set of coordinating atoms. The metal unit, therefore, manifests a selective reactivity towards a specific class of ligands, and is almost completely inert towards other types of reagents. Examples of this specific class include the low-valent aqua-carbonyl $[Tc^I(CO)_3(OH_2)_3]^+$ complex[4,5] and high-valent, nitrido-diphosphane $[Tc(N)(PNP)Cl_2]$ complexes.[6,7] In these complexes, the $[Tc(CO)_3]^+$ and $[Tc(N)(PNP)]^{2+}$ fragments are the stable molecular units. In contrast, the water and halide

ligands can be efficiently substituted by a series of bi-functional tridentate σ-donor ligands (L) and bidentate π-donor ligands (L′), respectively, to yield mixed heterocomplexes of the type $[Tc(CO)_3(L)]^+$ [8,9] and [Tc(N)(PNP)(L′)].[10,11]

In the last few years, we have investigated the design of nitrido-containing species by exploiting the strong electrophilic character exhibited by the $[M(N)(PNP)]^{2+}$ metal fragment, which selectively reacts with nucleophilic bidentate ligands having a π-donor set of coordinating atoms. In particular, emphasis was placed on bidentate ligands containing both heteroatomic chelating sites (such as cysteine, thiocarboxylic acids, and aminothiols) and homoatomic sites (such as dithiols and dithiocarbamates). For example, small peptides having a terminal cysteine residue have been efficiently labeled with the $[^{99m}Tc(N)(PNP)]^{2+}$ complex at a high-specific-activity level.[10] A cysteine-conjugated 2-methoxyphenylpiperazine ligand was linked to the same metal fragment to investigate the binding affinity of the resulting heterocomplex for 5-HT_{1A} receptors in the central nervous system.[12]

Within the class of homoatomic bidentate ligands, monoanionic dithiocarbamates (DTC) were found to possess a strong affinity for the $[^{99m}Tc(N)(PNP)]^{2+}$ complex. Reactions with these ligands, carried out at tracer level (μM concentrations), yielded mono-cationic nitrido heterocomplexes, thought to be of general formula $[^{99m}Tc(N)(DTC)(PNP)]^+$. Biological evaluation of these new products demonstrated that they selectively accumulate in the myocardium of rats. For some derivatives, retention in this region was accompanied by a very fast blood, lung and liver clearance, suggesting that these tracers could be potentially utilized for obtaining SPECT myocardial images of superior quality compared to those obtained using currently available commercial agents.[13,14] The elucidation of the molecular structure of these compounds, therefore, appears to be of utmost importance for the comprehension of their peculiar biological properties. For this reason, we synthesized and structurally characterized a series of nitrido heterocomplexes of technetium and rhenium, obtained by treating the nitrido precursors $[M(N)Cl_2(PNP)]$ (M = Re, Tc) with the appropriate dithiocarbamate ligand.

The present study describes the synthesis, and solid-state and solution-state determination of the molecular structure of ^{99}Tc and Re mono-cationic compounds $[M(N)(DTC)(PNP)]^+$, where DTC indicates the derivatives diethyldithiocarbamate (dedc) and *N*,*N*′-bis(ethoxyethyl)dithiocarbamate (dbodc), and PNP represents the diphosphane ligands bis[(diphenylphosphanyl)ethyl]methoxyethyl-

Results and Discussion

Synthesis of Technetium and Rhenium Complexes

Technetium and rhenium nitrido heterocomplexes containing one diphosphane and one dithiocarbamate ligand bound to the same Tc≡N group were prepared by a one-pot procedure, as shown in Scheme 1. Reaction of equimolar amounts of $[M(N)Cl_2(PPh_3)_2]$ and the relevant diphosphane ligand in dichloromethane/ethanol yielded the intermediate precursor $[M(N)Cl_2(PNP)]$, which in turn provided the mixed-ligand complex on treatment with a slight excess of dithiocarbamate. Formation of the corresponding bis-substituted complexes with two identical polydentate ligands was not observed, even when 3:1 or 1:3 PNP/DTC ratios were used.

The reaction was faster for the technetium species, and afforded nearly quantitative yields. The preparation of the rhenium analogues required more drastic conditions (i.e. prolonged reflux), and yields dropped sharply, owing to the concomitant production of unstable side-products.

Characterization of the Complexes

The complexes were characterized by elemental analysis, spectroscopic methods and, in the case of complex **1**, X-ray diffraction. The IR spectra of both **1** and **2** exhibit bands of medium intensity at ca. 1060 cm^{-1}, attributable to the $\nu_{Re\equiv N}$ stretching vibration. Complex **1** displays an additional strong vibration at 840 cm^{-1}, characteristic of the hexafluorophosphate counter-anion.

Re−S(1)	2.425(3)	Re−S(2)	2.413(3)
Re−P(1)	2.408(3)	Re−P(2)	2.396(3)
Re−N(1)	1.660(9)	Re···N(2)	2.73(1)
S(1)−C(8)	1.75(1)	S(2)−C(8)	1.72(1)
S(1)−Re−S(2)	72.5(1)	N(1)−Re−P(1)	93.3(4)
P(1)−Re−P(2)	101.2(1)	N(1)−Re−P(2)	96.8(3)
N(1)−Re−S(1)	105.4(3)	N(1)−Re···N(2)	164.4(5)
N(1)−Re−S(2)	106.4(4)	S(1)−C(8)−S(2)	110.9(7)

Crystalline **1** is made up of well-separated mono-cationic units and PF_6^- anions, which do not show any interaction below the sum of the van der Waals radii. The environment around the Re atom is square pyramidal, or pseudo-octahedral if we consider the additional weak interaction of N(2) with the metal, with the base plane defined by the P(1), S(1), S(2) and P(2) atoms (Figure 4).

None of these atoms deviate more than 0.02 Å from the mean plane, whereas Re is located 0.41 Å above the plane, towards N(1). The Re≡N(1) distance of 1.660(9) Å is close to the average of 1.675 Å found for terminal nitride-Re^V compounds (29 entries in the Cambridge Structural Database[15]). A similar search for the diphenylphosphinorhenium(v) synthon gave an average value of 2.484 Å for the Re^V-PPh_2R bond (25 entries), a distance markedly longer than those found for **1** [for which Re−P(1) and Re−P(2) are 2.408(3) and 2.396(3) Å, respectively). This shortening can be ascribed to the cationic nature of the complex, as previously observed for similar [Re(N)(pnp2)(L)][BF_4] and [Re(N)(pnp2)(POP)][BF_4] compounds (L = *S*-methyl 2-methyldithiocarbazate monoanion, POP = bis[(diphenylphosphanyl)ethyl]ether).[7] The S(1)−Re−S(2) bite angle of 72.5(1)° and the Re−S(1) and Re−S(2) bond lengths of 2.425(3) and 2.413(3) Å are in agreement with the reported data (average Re−S distance and S−Re−S angle of 2.433 Å and 71.3°, respectively).

The position assumed by the phenyl rings bound to the phosphorous atoms deserves comment. The two facing phenyl groups (labeled as A and D in Figure 3) adopt the so-called "parallel displaced" arrangement, characterized by the X(A) and X(D) centroid distance of 4.11 Å, and the C(1A)−X(A)−X(D)−C(1D) "twist angle" of 24.1°. These values corroborate the hypothesis of a possible role for π-bonds in stabilizing the *cis*-P coordination. On the other hand, the two rings bound to each phosphorous atom are roughly orthogonal to each other, with dihedral angles of 83.9° and 103.9° between the mean planes of A and B, and C and D, respectively. The A, B, C, and D phenyl rings have dihedral angles with the S_2P_2 equatorial plane of 93.3, 117.0, 114.7, and 69.3,°respectively. This plane has a dihedral angle of 13.6° to the dithiocarbamate plane [sp^2 geometry at N(3)], defined by the six S(1), S(2), C(8), N(3), C(9), and C(11) atoms. The methylene carbons of the diphosphane chain, C(1), C(4), C(2), and C(3), are located, respectively, at 1.69, 1.81, 2.64 and 2.64 Å below the mean S_2P_2 basal plane, whereas N(2) faces this plane at the intermediate distance of 2.29 Å. This additional metal−N(2) interaction provides further thermodynamic stability to the system and contributes to the kinetic inertness shown by this class of mixed nitrido heterocomplexes.

ESI Mass Spectrometry

The ESI mass spectra of the rhenium complexes **1**−**4** each show a peak corresponding to the molecular ion with

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

no additional detectable fragments, indicating the high stability of the cation in the oxidative/reductive conditions typical of ESI experiments. To gain further information on the ligand-rhenium bond strengths, a series of collision experiments was undertaken. Such collisions (performed with an ion trap) inidicate the presence of decomposition channels with a low critical energy; the eventual products represent the more energetically favored pathways. For complex **4**, under these conditions, many fragment ions become detectable (as summarized in Scheme 2). The related collision-induced decomposition pathway is illustrated in Scheme 3. Collision of the molecular cation (m/z = 933) produces abundant fragments at m/z = 755 and 727, both corresponding to the unexpected loss of phosphorous-containing residues originating from the pnp5 ligand. As shown in Scheme 3, the resulting species at m/z = 727 most likely adopt a five-coordinate structure (the common arrangement for nitrido-containing rhenium compounds), in which a native bidentate *P*,*N*-phosphinoamine ligand shares the coordination positions around the Re=N group with the dithiocarbamate unit. It should be noted that this first fragmentation is identical to that exhibited by the isostructural technetium complex **8**, which was separately investigated in a previous study.[16]

No variation in the first collision-induced fragmentation profile is observed for any of the complexes investigated,

either by decreasing the bulkiness at the dithiocarbamate ligand (bdodc → dedc, **4** → **3**), replacing dangling methoxyethyl substituents at the diphosphane phosphorous with rigid phenyl groups (pnp3 → pnp2, **3** → **1**), or by diminishing the steric hindrance at the *N*-diphosphinoamine function (pnp2 → pnp24, **1** → **2**).

Further MS^n experiments implied the loss of ethanol followed by release of other groups originating from the di-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

thiocarbamate and/or the phosphinoamine ligands. In the latter case, the substituents begin to play a significant role in the decomposition pathways. For example, dedc complexes 1−3 always retain the dithiocarbamate ligand intact, in contrast to the dbodc complex **4**, which undergoes cleavage of the C−N bond C−N, with retention of carbon disulfide. Moreover, the bidentate P,N-phosphinoamine ligand in complexes **1** and **2** releases the diarylalkylphosphane arm and retains the amine group, whereas the reverse is observed for complexes **3** and **4**, which carry the more strongly donating trialkylphosphanes.

Multinuclear NMR Spectroscopy

The remarkable downfield shift of the ^{31}P signal from negative values typical of uncoordinated diphosphanes to positive values for these complexes is diagnostic of metal-phosphorus coordination. Consistent with the expected magnetic equivalence of the two diphosphane phosphorus atoms, complexes 1−8 exhibit a singlet in the ^{31}P NMR spectrum, the peak profile being narrow ($\nu_{1/2} \approx 25$ Hz) in the case of rhenium and broad ($\nu_{1/2} \approx 350$ Hz) in the case of technetium.

One-dimensional proton and carbon spectra are quite complicated owing to the presence of overlapping methyl and methylene signals. However, the use of several two-dimensional experiments including homonuclear ^{1}H-^{1}H COSY and heteronuclear ^{1}H-^{13}C HETCOR makes the assignment of each signal possible. By way of example, COSY and HETCOR maps and the corresponding proton and carbon spectra for the technetium complex **8** are shown in Figure 5.

The assignment was determined as follows. Methyl carbons may be distinguished from methylene carbons with the ^{13}C DEPT-135 experiment (as shown in the bottom right

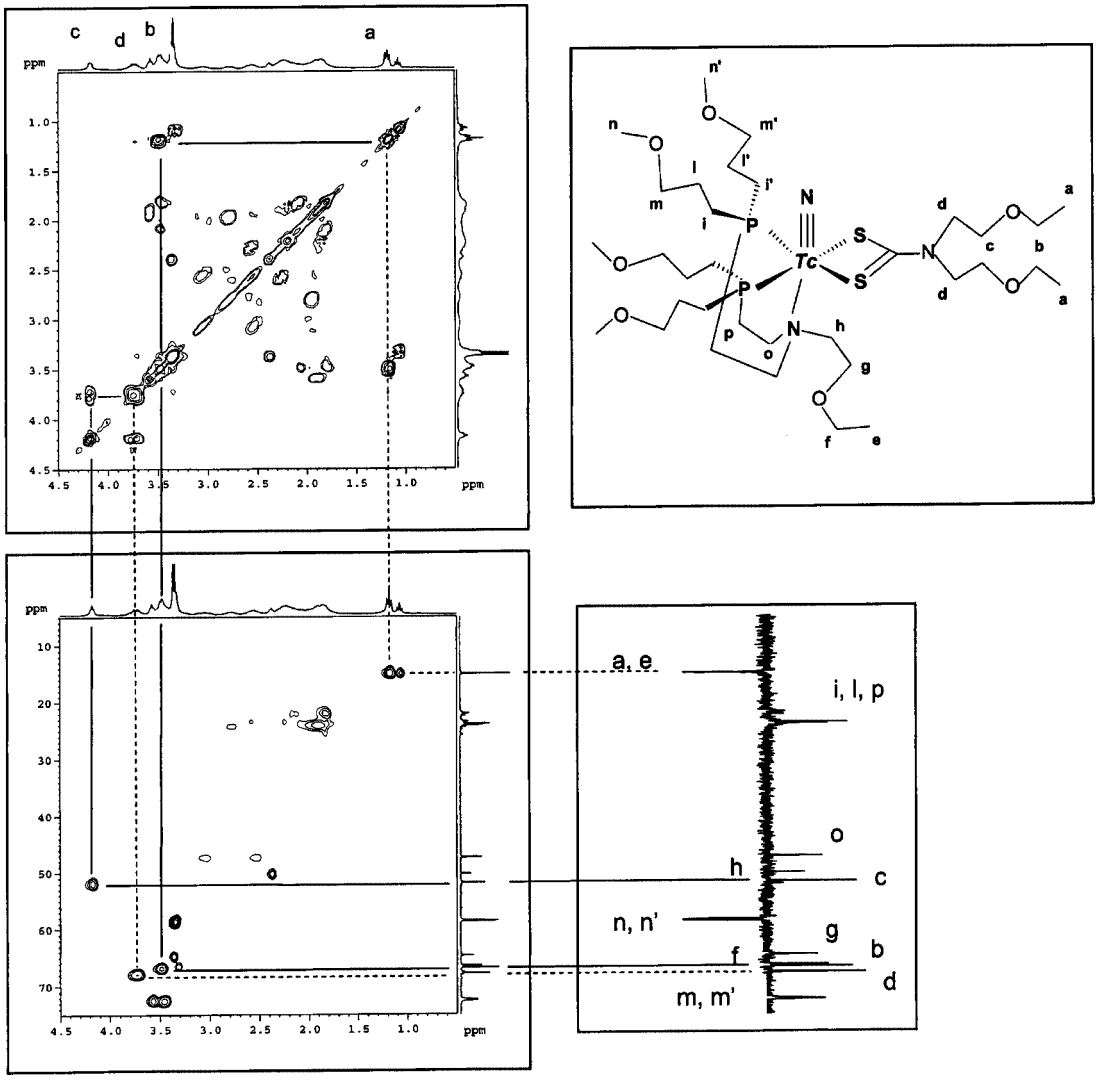

Figure 5. NMR spectra and maps of complex **8**; ^{1}H-^{1}H COSY spectrum (top left); ^{1}H-^{13}C HETCOR spectrum (bottom left); ^{13}C-DEPT 135 spectrum (bottom right); atom numbering scheme (top right); example of interpretation: carbon **b** is connected (solid line) with methylene protons **b** (multiplet at ca. 3.5 ppm) through a unique spot in the HETCOR map; protons **b** are coupled with methyl protons **a** (triplet at ca 1.20 ppm) in the COSY map; protons **a** are in turn connected with carbon **a** (dotted line) through another spot in the HETCOR map; the same interpretation strategy is applied for carbon and protons **c** and **d**, and for the other networks

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

diagram in Figure 5), the former being phased "down" (on the left of the spectrum, as shown) and the latter being phased "up" (on the right of the spectrum). The downfield-shifted methyl carbons correspond to the terminal methoxy groups of the phosphane substituents (C-n and C-n′); the splitting is determined by the relative *syn* and *anti* orientation of each substituent with respect to the Tc≡N core. The upfield-shifted methyl signal in the carbon spectrum consists of two overlapping signals (split correctly into two components in the proton spectrum), due to the presence of two chemically inequivalent ethoxy groups (Me-a and Me-e). The related methylene protons of the terminal ethoxy groups CH_2-b and CH_2-f, as well as the methylene network of the dithiocarbamate (CH_2-c and CH_2-d) are distinguished in the COSY spectrum. Analogously, the methylene chain of the pendant *N*-diphosphane ethoxyethyl fragment (CH_2-h and CH_2-g) shows cross peaks in the COSY spectrum, as well as two distinct peaks in the HETCOR spectrum. Regarding the terminal methoxy groups Me-n and Me-n′ outlined above, the diphosphane methoxypropyl chains are oriented *syn* and *anti* with respect to the Tc≡N core, giving two distinct proton networks (i, l and m, and i′, l′ and m′). The peaks due to the bridging diphosphane methylene protons (o and p) are widely separated and show a cross-peak in the COSY spectrum. The diastereotopic nature of the bridging methylene protons is clear from the HETCOR map, which shows two distinct spots for each bridging carbon.

Comments

The efficient synthesis of mono-cationic heterocomplexes $[M(N)(DTC)(PNP)]^+$ (M = Tc, Re) described here provides a clear example of reactions able to form complexes containing two different polydentate ligands coordinated to the same Tc≡N group. As previously noted for the similar compound $[M(N)(L)(POP)]^+$ [L = *S*-methyl 2-methyldithiocarbazate mono-anion, POP = bis[(diphenylphosphanyl)ethyl]ether],[7] the remarkable stability of this class of complexes results from a balance of π-acceptor and π-donor properties provided by the combination of the diphosphane and dithiocarbamate ligands bound to the same $[M{\equiv}N]^{2+}$ group. The exclusive formation of the mixed complexes $[M(N)(DTC)(PNP)]^+$, without the concomitant production of the symmetrical species $[M(N)(DTC)_2]$, is attributed to the strong electrophilic character of the metal fragment $[M(N)(PNP)]^{2+}$. This electrophilic character results from removal of electronic density from the two residual positions of the five-coordinate arrangement determined by the two π-acceptor atoms. As a consequence, these two bonding sites are activated only towards soft, π-donor atoms, and the whole metal fragment $[M(N)(PNP)]^{2+}$ becomes strongly stabilized upon substitution with an appropriate bidentate π-donor ligand. The additional contact between the metal center and the PNP diphosphane nitrogen helps to explain the remarkable kinetic inertness demonstrated by these class of heterocomplexes toward transchelation by other chelating agents.[14] In this regard, it should be mentioned that diphosphanes incorporating merely methylene groups in the spacer or diphosphanes carrying a quaternary ammonium group in the middle of the spacer yielded only mixtures from which the isolation of stable compounds was unsuccessful, thus supporting the view that contact of the lone pair of the amine nitrogen with the metal is important.

The high chemical stability of mono-cationic $[M(N)(DTC)(PNP)]^+$ heterocomplexes is also partially responsible for their interesting biological properties. These complexes showed selective localization into the myocardium of rats and retention in this region for a prolonged time.[13,14] Modification of the outer sphere pendant groups was found to influence both the kinetics of uptake by the heart and clearance from the background organs, giving unprecedentedly high heart/liver and heart/lung uptake ratios.[14] Hence, the prototype agent $[^{99m}Tc(N)(dbodc)(pnp5)]^+$ was proposed as a potential candidate for the development of a new myocardial perfusion tracer.[17] These findings prompted us to prepare and characterize macroscopic amounts of the corresponding ^{99}Tc and Re complexes with the aim to elucidate their molecular structure. As outlined in Figure 4, the solid-state geometry exhibited by the representative rhenium complex **1** is distorted square pyramidal [or pseudo-octahedral if we consider the additional Re−N(2) contact]. However, the flexiblity of the methoxypropyl groups made it impossible to grow crystals suitable for X-ray diffraction studies. Therefore, we were forced to characterize alkyldiphosphane-containing compounds in the solution state by means of combined mass spectrometry and multinuclear NMR investigations. These experiments confirmed that the molecular structure of these complexes (shown in Figures 2 and 5) is monomeric and, most importantly, identical to that shown by the aryldiphosphane-containing species (Figure 4). In particular, the diphosphane phosphorous atoms, as well as the pendant arms of the dithiocarbamate unit, were found to be magnetically equivalent, whereas the

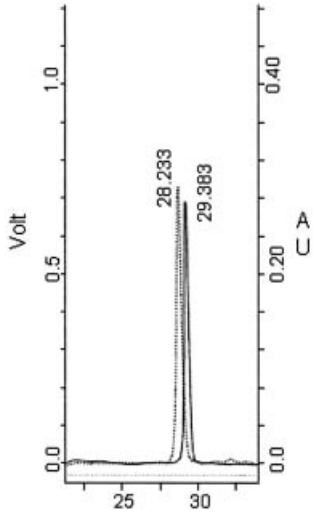

Figure 6. HPLC co-injection profiles for the complexes $[^{99m}Tc(N)(dbodc)(pnp5)]^+$ and $[^{99}Tc(N)(dbodc)(pnp5)]^+$ **8** (solid line, radiometric trace; dashed line, UV/Vis trace)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

methoxypropyl substituents on the phosphorous atoms were magnetically inequivalent, and oriented *syn* and *anti* with respect to the terminal nitrido group.

Strong support for the conclusion that the chemical nature of the complex $[^{99m}Tc(N)(dbodc)(pnp5)]^+$ (prepared at tracer level) is similar to that of the corresponding ^{99m}Tc analogue (isolated in macroscopic amounts) was obtained by comparison of their chromatographic profiles after HPLC co-injection. As shown in Figure 6, the two species co-eluted at 29.38 min (radiometric trace) and at 28.23 min (UV/Vis trace).

Conclusion

A new family of cationic mixed nitrido heterocomplexes of general formula $[M(N)(DTC)(PNP)]^+$, where M is ^{99}Tc or Re, DTC is the mono-anionic form of a dithiocarbamate ligand and PNP is a heterodiphosphane incorporating a tertiary amine group in a five-membered spacer, has been synthesized and completely characterized both in the solid and in the solution state. The molecular structure of this class of mixed complexes is best described as pseudo-octahedral, with the diphosphane ligand facing the dithiocarbamate unit on the equatorial plane. The terminal nitrido and the weakly bound heterodiphosphane nitrogen complete the octahedron in a reciprocal *trans*-axial arrangement. The peculiar combination of π-acceptor phosphorous and π-donor sulfur around the M≡N group ensures remarkable thermodynamic stability and associated high kinetic inertness towards transchelation reactions. One of these complexes prepared at tracer level, $[^{99m}Tc(N)(dbodc)(pnp5)]^+$, has shown interesting biological properties in animal models.

Experimental Section

General Remarks: ***Caution!*** ^{99}Tc is a weak β-emitter (E_β = 0.292 MeV, $t_{1/2} = 2.12 \times 10^5$ years). All manipulations were carried out in laboratories approved for low-level radioactivity using monitored hoods and glove-boxes. When handled in milligram amounts, ^{99}Tc does not present a serious health hazard since common laboratory glassware provides adequate shielding. Bremsstrahlung radiation is not a significant problem due to the low-energy of the β-particles. However, normal radiation safety procedures must be used at all times, especially with solid samples, to prevent contamination and inhalation. Methanolic solutions (concentration ca. 2×10^{-6} M) were used for mass spectrometric measurements (ESI). For a 50-minute analysis at a flow-rate of 5 μL/min, the amount of ^{99}Tc injected into the mass spectrometer led to a radioactivity level lower than the environmental background.

Technetium (as $[NH_4][^{99}TcO_4]$) was obtained from Oak Ridge National Laboratory. Samples were dissolved in water and treated with excess aqueous ammonia and 30% H_2O_2 at 80 °C prior to use to eliminate residual TcO_2. Solid samples of purified ammonium pertechnetate were obtained by slow evaporation of the solvent at 40 °C. Literature methods were applied to prepare the starting compounds $[M(N)Cl_2(PPh_3)_2]$[18,19] and the intermediate species $[M(N)Cl_2(PNP)]$.[7] Finely powdered rhenium was obtained as a gift from H. C. Starck GmbH, Germany. Samples were first oxidized to perrhenate and then reduced to suitable Re^V compounds prior to use. Diethyldithiocarbamate sodium salt (dedcNa) was purchased from Aldrich Chimica and *N,N′*-bis(ethoxyethyl)dithiocarbamate sodium salt (dbodcNa) was prepared according to literature methods or obtained from Alchemy, Italy.[20] Aryl diphosphanes (pnp2 and pnp24) and alkyl diphosphanes (pnp3 and pnp5) were synthesized as reported previously[21,22] or purchased from Argus Chemicals, Italy. Aryl diphosphanes are stable both as solids and in solution, but alkyl diphosphanes are air and moisture sensitive, and should be handled carefully under a nitrogen atmosphere and stored under nitrogen at −20 °C to avoid oxidation of the tertiary diphosphane to the corresponding diphosphaneoxide. Common laboratory solvents and other chemicals were used as received.

Elemental analyses (C, H, N, S) were performed on a Carlo−Erba 1106 elemental analyzer. FT IR spectra were recorded on a Nicolet 510P Fourier-transform spectrometer in the range 4000−400 cm^{-1} in KBr mixtures using a Spectra-Tech diffuse-reflectance collector accessory for technetium compounds and on a Mattson 3030 Fourier-transform spectrometer in the range 4000−400 cm^{-1} in KBr pellets for rhenium compounds. Proton and ^{31}P NMR spectra were collected on a Bruker AC-300 instrument, using $SiMe_4$ as an internal reference (for ^1H) and 85% aqueous H_3PO_4 as an external reference (for ^{31}P). Mass spectrometric measurements were performed with a LCQ DECA instrument (ThermoFinnigan, Palo Alto, CA, USA) using ca. 5×10^{-6} M methanol solutions of rhenium complexes **1−4**, which were injected by a syringe pump at a flow rate of 5 μL/min. MS^n experiments were performed by selection of the ionic species of interest followed by collision with He inside the ion trap (He pressure 10^{-4} Torr) accomplished by resonant excitation. The supplementary rf voltage was in the range 0.25−4.00 V. Thin-layer chromatography (TLC) was performed using plates from Merck (Silica gel 60 F 254).

Ligands

Diphosphanes and Dithiocarbamates: The diphosphane ligands utilized in this work were prepared according to published methods.[21,22] The full NMR characterizations of these diphosphanes and of the branched dithiocarbamate Nadbodc are detailed below.

Bis[(diphenylphosphanyl)ethyl]methoxyethylamine (pnp2): ^1H NMR (300 MHz, Me_4Si, $CDCl_3$): δ = 2.07 [m, 4 H, N−(CH_2−CH_2−PPh_2)$_2$], 2.59 [m, 4 H + 2 H, N−(CH_2−CH_2−PPh_2)$_2$ and N−CH_2−CH_2−O−CH_3], 3.20 (s, 3 H, N−CH_2−CH_2−O−CH_3), 3.26 (t, ^3J = 9 Hz, 2 H; N−CH_2−CH_2−O−CH_3), 7.30−7.40 (−PPh_2, 20 H) ppm. ^{13}C NMR (300 MHz, Me_4Si, $CDCl_3$): δ = 25.0 (d, $^1J_{C,P}$ = 13 Hz; N−CH_2−CH_2−PPh_2), 50.1 (d, $^2J_{C,P}$ = 35 Hz; N−CH_2−CH_2−PPh_2), 52.8 (s, N−CH_2−CH_2−O−CH_3), 58.7 (s, N−CH_2−CH_2−OCH_3), 70.7 (s, N−CH_2−CH_2−OCH_3), 128.4 (d, $^3J_{C,P}$ = 8 Hz), 128.5 (s), 132.7 (d, $^2J_{C,P}$ = 22 Hz), 138.4 (d, $^1J_{C,P}$ = 8 Hz) (aromatic *C*) ppm. ^{31}P NMR (300 MHz, 85% H_3PO_4, $CDCl_3$): δ = −21.5 (s).

Bis[(diphenylphosphanyl)ethyl]methylamine (pnp24): ^1H NMR (300 MHz, Me_4Si, $CDCl_3$): δ = 2.14 [m, 4 H, N−(CH_2−CH_2−PPh_2)$_2$], 2.24 (s, 3 H, N−CH_3), 2.48 [m, 4 H, N−(CH_2−CH_2−PPh_2)$_2$], 7.30−7.41 (−PPh_2, 20 H) ppm. ^{13}C NMR (300 MHz, Me_4Si, $CDCl_3$): δ = 22.1 (d, $^1J_{C,P}$ = 18 Hz; N−CH_2−CH_2−PPh_2), 39.6 (s, N−CH_3), 52.7 (d, $^2J_{C,P}$ = 29 Hz, N−CH_2−CH_2−PPh_2), 128.9 (d, $^3J_{C,P}$ = 7 Hz), 129.5 (s), 132.7 (d, $^1J_{C,P}$ = 20 Hz), 135.6 (d, $^2J_{C,P}$ = 9 Hz) (aromatic *C*) ppm. ^{31}P NMR (300 MHz, 85% H_3PO_4, $CDCl_3$): δ = −21.5 (d) ppm.

Bis[(dimethoxypropylphosphanyl)ethyl]methoxyethylamine (pnp3): ^1H NMR (300 MHz, Me_4Si, $CDCl_3$): δ = 1.36−1.75 (4 H +16 H,

N−(CH2−CH2)2−[P−(CH2−CH2−CH2−O−CH3)2]2), 2.62 [m, 2 H +4 H, CH3−O−CH2−CH2−N−(CH2−CH2)2−P], 3.30 (s, 3 H +12 H, O−CH3), 3.38 (t, 3J = 9 Hz, 8 H, P−CH2−CH2−CH2−O−CH3), 3.42 (t, 3J = 9 Hz, 2 H, N−CH2−CH2−O−CH3) ppm. 13C NMR (300 MHz, Me4Si, CDCl3): δ = 23.4 (d, 1JC,P = 12 Hz, P−CH2−CH2−CH2−O−CH3), 24.2 [d, 1JC,P = 13 Hz; P−(CH2−CH2)2−N], 26.0 (d, 2JC,P = 13 Hz; P−CH2−CH2−CH2−O−CH3), 50.9 [d, 2JC,P = 21 Hz; P−(CH2−CH2)2−N], 52.5 (s, N−CH2−CH2−O−CH3), 58.5 (s, P−CH2−CH2−CH2−OCH3), 58.9 (s, N−CH2−CH2−OCH3), 71.1 (s, N−CH2−CH2−OCH3), 73.4−73.6 (P−CH2−CH2−CH2−OCH3) ppm. 31P NMR (300 MHz, 85% H3PO4, CDCl3): δ = − 34.4 (s).

Bis[(dimethoxypropylphosphanyl)ethyl]ethoxyethylamine (pnp5): 1H NMR (300 MHz, Me4Si, CDCl3): δ = 1.19 (t, 3J = 7 Hz, 3 H, P2N−CH2−CH2−O−CH2−CH3), 1.45 (m, 8 H, P−CH2−CH2−CH2−O−CH3), 1.54 [m, 4 H, (P−CH2−CH2)2N−), 1.68 [m, 8 H, P(CH2−CH2−CH2−O−CH3)2], 2.65 [m, 4 H + 2 H, P−(CH2−CH2)2−N−CH2−CH2−O−CH2−CH3], 3.33 [s, 12 H, P(CH2−CH2−CH2−O−CH3)2], 3.40 [t, 3J = 6 Hz, 8 H, P−(CH2−CH2−CH2−O−CH3)2], 3.49 (m, 2 H + 2 H, >N−CH2−CH2−O−CH2−CH3) ppm. 13C NMR (CDCl3, ppm): δ = 15.1 (s, >N−CH2−CH2−O−CH2−CH3), 23.4 (d, 1JC,P = 12 Hz; P−CH2−CH2−CH2−O−CH3), 24.3 [d, 1JC,P = 12 Hz; P−(CH2−CH2)2−N], 26.0 (d, 2JC,P = 14 Hz; P−CH2−CH2−CH2−O−CH3), 51.0 [d, 1JC,P = 21 Hz; P−(CH2−CH2)2−N], 52.5 (s, >N−CH2−CH2−O−CH2−CH3), 58.5 (s, P−CH2−CH2−CH2−O−CH3), 66.5 (s, >N−CH2−CH2−O−CH2−CH3), 69.0 (s, >N−CH2−CH2−O−CH2−CH3), 73.4 and 73.6 (P−CH2−CH2−CH2−O−CH3) ppm. 31P NMR (300 MHz, 85% H3PO4, CDCl3): δ = − 31.7 (s).

***N,N′*-Bis(ethoxyethyl)dithiocarbamate Sodium Salt (Nadbodc):** 1H NMR (300 MHz, D2O): δ = 1.20 [t, 6 H, S2CN(CH2−CH2−O−CH2−CH3)2], 3.62 [q, 4 H, S2CN(CH2−CH2−O−CH2−CH3)2], 3.85 [t, 4 H, S2CN(CH2−CH2−O−CH2−CH3)2], 4.29 [t, 4 H, S2CN(CH2−CH2−O−CH2−CH3)2] ppm. 13C NMR (300 MHz, D2O ppm): δ = 17.1 [s, S2CN(CH2−CH2−O−CH2−CH3)2], 57.2 [s, S2CN(CH2−CH2−O−CH2−CH3)2], 69.6 and 69.9 [s, S2CN(CH2−CH2−O−CH2−CH3)2], 213.9 [s, S2CN(CH2−CH2−O−CH2−CH3)2].

Synthesis of Technetium and Rhenium Complexes: A general one-pot procedure was adopted for the preparation of both technetium and rhenium complexes.

[M(N)(DTC)(PNP)][Cl] (M = 99Tc, Re) (1−8): A solution of the appropriate diphosphane (0.05 mmol) in ethanol (10 mL) was added under a nitrogen atmosphere to a three-neck round-bottomed flask containing a suspension of [M(N)Cl2(PPh3)2] (0.05 mmol) in dichloromethane (10 mL). The mixture was stirred for 60 min at room temperature (or at reflux for rhenium complexes) to give a clear bright yellow solution. A solution of DTC sodium salt (0.055 mmol) in ethanol (5 mL) was added, and, after reflux for an additional 60 min (overnight reflux is necessary for rhenium complexes), the yellow solution was cooled and the solvent removed by a gentle stream of nitrogen. The residue was treated with dichloromethane (5 mL) and a white precipitate was separated by filtration. The filtrate was again evaporated to dryness to give a pale yellow solid residue (for compounds containing aryl diphosphanes), or a yellow oil (for compounds containing alkyl diphosphanes). Technetium complexes **5** and **6** were purified by treating the residue with ethanol (3 mL). A yellow precipitate was collected by filtration, washed with diethyl ether (4 × 5 mL) and dried under vacuum. The oily products **7** and **8** were placed under vacuum overnight to afford pure compounds as a yellow-orange oils (yield >90%). For all rhenium complexes, column chromatography (described below) was necessary to separate the pure species. The filtrate was evaporated to dryness and then re-dissolved in the minimum amount of chloroform. The resulting solution was loaded onto a silica column (diameter 2 cm, length 30 cm) previously conditioned with chloroform. Elution was conducted with chloroform (100 mL) followed by a mixture of ethanol/chloroform/toluene/0.5 M ammonium acetate (5:3:3:0.5) to provide the pure compounds in low-to-moderate yields (25−40%). The light yellow residue obtained after chromatography of complex **1** was dissolved in methanol (2 mL) and added to an excess of NH_4PF_6 in methanol (3 mL). Trituration with diethyl ether (20 mL) yielded a yellow-orange powder, which was filtered off, washed with diethyl ether (2 × 5 mL) and dried under vacuum.

X-ray Crystallographic Study: Single crystals of complex **1** were grown by slow evaporation from DMSO solutions as light yellow blocks. Pertinent crystallographic data and structure refinement data are summarized in Table 2. The data set was collected at room temperature on a Nicolet Siemens R3m /V diffractometer with graphite-monochromatized Mo-K_α radiation. Cell parameters were obtained by fitting a set of 50 high-angle reflections. After Lorentz, polarization and absorption corrections (Ψ-scans method), the structure was solved using the SHELXTL NT computer program[23] and refined with SHELXL-97[24] by the full-matrix least-

Deprotonation of μ_3-Methylidyne Groups on a Ti_3O_3 Support: A Way to Build Oxotitanocubanes Containing Alkali and Alkaline-Earth Metals

Avelino Martín,[a] Miguel Mena,*[a] María del Carmen Morales-Varela,[a] and Cristina Santamaría[a]

Keywords: Alkali metals / Alkaline earth metals / Alkylidyne complexes / Oxo ligands / Titanium

The μ_3-methylidyne group of the complex [{TiCp*(μ-O)}$_3$(μ_3-CH)] (**1**) (Cp* = η^5-C_5Me_5) was deprotonated by amides of the group 1 elements, [MN(SiMe$_3$)$_2$] (M = Li, Na, K, Rb, Cs) to form the oxoheterometallocubane complexes [M(μ_3-O)$_3${Ti$_3$Cp*$_3$(μ_3-C)}] [M = Li (**3**), Na (**4**), K (**5**), Rb (**6**), Cs (**7**)]. Similar treatments of **1** with the alkaline-earth amides [M{N(SiMe$_3$)$_2$}$_2$(thf)$_2$] (M = Mg, Ca, Sr) afforded the heterometallocubane derivatives [{(thf)$_x$(Me$_3$Si)$_2$NM}(μ_3-O)$_3${Ti$_3$Cp*$_3$(μ_3-C)}] [M = Mg, *x* = 0, (**8**); Ca, *x* = 1, (**9**); Sr, *x* = 1, (**10**)] in high yields. The addition of ligands such as cyclopentadiene (C_5H_6) or pentamethylcyclopentadiene (C_5Me_5H) to the compounds **3**–**7** allowed recovery of the μ_3-methylidyne oxocomplex **1**. The analogous reaction of **8**–**10** with C_5H_6 caused the displacement of the amide fragment to give the heterometallocubanes [(CpM)(μ_3-O)$_3${Ti$_3$Cp*$_3$(μ_3-C)}] [M = Mg (**11**), Ca (**12**), Sr (**13**)], while C_5Me_5H reacts only with **9** and **10** to give the compounds [(Cp*M)(μ_3-O)$_3${Ti$_3$Cp*$_3$(μ_3-C)}] [M = Ca (**14**), Sr (**15**)]. Furthermore, heating of the species **8**–**10** in the presence of the starting complex **1** produced amine elimination and afforded the corner-shared heterometallodicubanes [M{(μ_3-O)$_3$Ti$_3$Cp*$_3$(μ_3-C)}$_2$] [M = Mg (**16**), Ca (**17**), Sr (**18**)]. Treatment of **1** with the amide [Ba{N(SiMe$_3$)$_2$}$_2$(thf)$_2$] or dialkyl derivatives of magnesium [MgR$_2$(thf)$_2$] (R = CH_2Ph, *t*Bu) and barium [Ba(CH_2Ph)$_2$] provided the corner-shared metallodicubanes [M{(μ_3-O)$_3$Ti$_3$Cp*$_3$-(μ_3-C)}$_2$] [M = Mg(**16**), Ba(**19**)]. The molecular structures of complexes **9**, **16**, **17** and **18** have been established by single-crystal X-ray analyses.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Our efforts to explore the behavior of alkylidyne groups on a trinuclear support in the complexes [{TiCp*(μ-O)}$_3$(μ_3-CR)] [R = H (**1**), Me (**2**)],[1] as a molecular approach to hydrocarbon-metal(oxo) surface interactions, have revealed surprising and unprecedented chemical reactivity. Thus, we have shown that metal carbonyl hydrides,[2] carbon monoxide,[3] isocyanides,[3] ketones,[4] *N*-benzylidene(phenyl)amine,[5] amines, diamines and the imine Ph_2C=NH[6] are incorporated into the Ti_3O_3 core by transformation of the alkylidyne units. In these systems, the role of the oxygen atoms is considerable, bridging the titanium atoms firmly and enhancing the cooperative effect between them but we do not have evidence for its direct participation in those processes. Furthermore, in the course of our studies we have discovered other kinds of reactivity for the complexes [{TiCp*(μ-O)}$_3$(μ_3-CR)] [R = H (**1**), Me (**2**)] as preorganized neutral tridentate six electron donor ligands without implication of the alkylidyne groups.[7] In fact, they provide an effective route to heterometallocubanes upon treatment with appropriate metal carbonyl complexes, where the metal carbonyl fragment shares electron density with the titanium atoms. Therefore the [(μ_3-CR)Ti$_3$Cp*$_3$(μ_3-O)$_3$M(CO)$_n$] cores of these oxoheterometallocubanes are discrete models for studying the oxide-to-metal catalyst-support interaction.

Recently, we have communicated the intercalation of alkali metal ions into layered organometallic titanium oxides by treatment of the complex [{TiCp*(μ-O)}$_3$(μ_3-CH)] (**1**) with alkali metal (Li, Na, K) alkyls and amides.[8] This process takes place with the incorporation of the alkali metal at the free vertex of the incomplete cube-type core Ti_3O_3C and the deprotonation of the μ_3-methylidyne ligand. Consequently, the active cooperation between the oxo and alkylidyne groups is possible in the singular chemistry of the complexes [{TiCp*(μ-O)}$_3$(μ_3-CR)].

We have expanded this preliminary study and herein we describe the behavior of the complex [{TiCp*(μ-O)}$_3$(μ_3-CH)] (**1**) towards alkali and alkaline-earth dialkylamides and alkyls.

Results and Discussion

When the complex [{TiCp*(μ-O)}$_3$(μ-CH)] (**1**) was treated with the alkyl derivatives [MR] (M = Li, R = CH_2SiMe_3, CH_2CMe_3, *n*Bu; M = Na, K, R = *t*Bu) at room temperature or with the amides [MN(SiMe$_3$)$_2$] (M = Li,

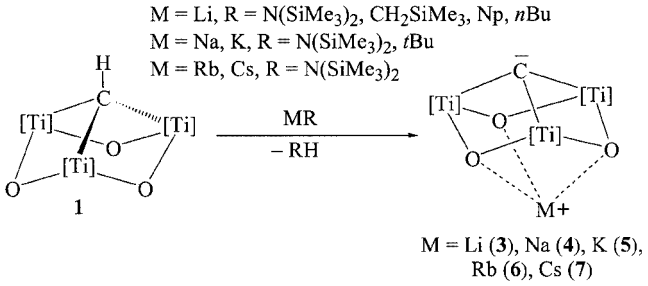
Na, K), at 60 °C overnight in a 1:1 ratio in toluene or hexane, the compounds **3**−**5** were obtained (70−90%) (see Scheme 1). On the other hand, the amides $[MN(SiMe_3)_2]$ (M = Rb, Cs), react with complex **1** in a 1:1 ratio at 60 °C in tetrahydrofuran to give the derivatives **6** and **7** in high yields (70−80%). The isolated solids were found to be stable under argon at room temperature and practically insoluble in common solvents such as toluene, hexane and dichloromethane, with the exception of tetrahydrofuran, which allowed their NMR spectroscopic characterization.



Scheme 1. Reaction of **1** with alkaline amide and alkyl reagents. [Ti] = $Ti(\eta^5\text{-}C_5Me_5)$

The ^1H and ^{13}C NMR spectra in $[D_8]$tetrahydrofuran, of these species, show signals assignable to equivalent η^5-C_5Me_5 groups and singlets for the apical μ_3-carbon atoms in the range 577−587 ppm, consistent with symmetrical structures in solution and the removal of the protons of the μ_3-methylidyne fragments.

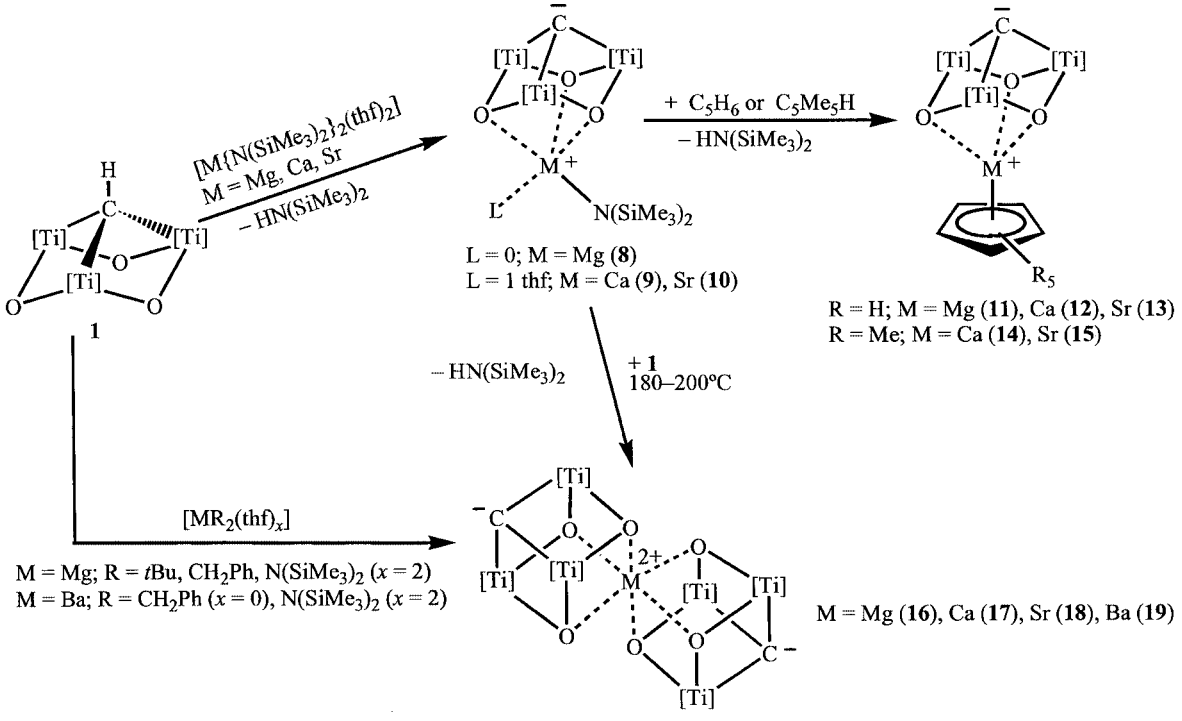
To unequivocally probe the existence of the μ_3-carbido group, the reactions of **3**−**7** with MeI in $[D_6]$benzene were performed, which slowly yielded the μ_3-ethylidyne complex $[Ti_3Cp^*_3(\mu_3\text{-}O)_3(\mu_3\text{-}CMe)]$ (**2**). In a similar way, addition of ligands with acidic protons such as C_5H_6 or C_5Me_5H to the compounds **3**−**7** in $[D_6]$benzene caused the protonation of the carbide species and recovery of the μ_3-methylidyne complex **1**.

The X-ray diffraction study of **3** was reported in a previous communication and showed a dimeric structure in the solid state.[8] The lithium atoms are incorporated at the free vertex of the deprotonated oxoalkylidyne **1** derivative and two cube-type cores LiO_3Ti_3C are directly linked through two Li−O bonds.

In an attempt to extend our studies on the incorporation of s-block metals into the preorganized structure of **1**, we have also designed reactions with alkaline-earth derivatives. With this aim, we chose as starting reagents the dialkylamides $[M\{N(SiMe_3)_2\}_2(thf)_2]$ (M = Mg, Ca, Sr, Ba) and the dialkyls $[MgR_2(thf)_2]$ (R = CH_2Ph, *t*Bu) and $[Ba(CH_2Ph)_2]$.

The reactions of **1** with equimolecular amounts of $[M\{N(SiMe_3)_2\}_2(thf)_2]$ (M = Mg, Ca, Sr) also appeared to take place through the deprotonation of the μ_3-methylidyne group and amine elimination, to give soluble green microcrystalline solids of the complexes **8**−**10** in high yields (82−95%). The X-ray diffraction study of **9** and the analytical and spectroscopic data of all compounds support the structures shown in Scheme 2.

The structure of **9** was determined by a single-crystal X-ray diffraction study (Figure 1). Geometrical parameters



Scheme 2. Reactivity of **1** with alkaline-earth metal reagents. [Ti] = $Ti(\eta^5\text{-}C_5Me_5)$

are summarized in Table 1. At first sight, the core of the molecular structure can be described as a cube in which the metallic centers alternate their positions with the oxygen and carbon atoms. The titanium atoms exhibit three-legged stool environments, while the calcium atom is five-coordinate with three sites occupied by the tridentate ligand, [{TiCp*(μ-O)}$_3$(μ-C)], and the remainder of the coordination sphere being filled by one amide group and one tetrahydrofuran molecule.

Distances from the calcium to the oxygen atoms of the preorganized ligand are in the range of 2.425(3)−2.483(3) Å, the latter corresponding to a *trans* position of the calcium to the amido group. These distances are similar to those seen in other calcium complexes found in the literature with higher coordination numbers.[9] In the same way, the calcium−nitrogen bond length of 2.291(4) Å is close to that found for complexes containing the Ca−N(SiMe$_3$)$_2$ moiety.[10] The Ti−C(1) bond length, 1.963 Å (av.), is shorter than those shown in [{TiCp*(μ-O)}$_3$(μ-CH)] (**1**) [Ti−C(1) = 2.10 Å av.],[1b,1c] **2** [Ti−C(1) = 2.12 Å av.][1a,1c] and the oxoheterometallodicubane [{Li(μ$_3$-O)$_3$[Ti$_3$(η^5-C$_5$Me$_5$)$_3$(μ$_3$-C)]}$_2$] (Ti−C$^-$ 2.055 Å av.),[8] and close to that in the zwitterionic derivative [{Ti(η^5-C$_5$Me$_5$)(μ-O)}$_3${μ$_3$-η^2-C$^-$C(Me)N$^+$(2,6-Me$_2$C$_6$H$_3$)}] (Ti−C$^-$ 2.017(5) Å].[3]

The ^{1}H NMR spectra for complexes **8**−**10** in [D$_6$]benzene each show only one signal assignable to the η^5-C$_5$Me$_5$ groups due to the rotation of the organometallic ligand around the metallic center, analogous to the situation found in other similar compounds.[11] In the ^{13}C NMR spectra of these complexes the singlets for the apical carbides at very low field (δ = 588−598 ppm) are particularly noteworthy.

Again, the chemical evidence for the existence of the μ$_3$-carbido groups in **8**−**10** was obtained by their treatment with MeI in [D$_6$]benzene, which quantitatively afforded the μ$_3$-ethylidyne complex [Ti$_3$Cp*$_3$(μ-O)$_3$(μ$_3$-CMe)] (**2**).

Unlike the alkali metal complexes **3**−**7**, the reactions of compounds **8**−**10** with cyclopentadiene (C$_5$H$_6$) did not involve carbide protonation, but led to the metathesis reaction of the amide group to give the new heterometallocubane derivatives [(CpM)(μ$_3$-O)$_3${Ti$_3$Cp*$_3$(μ$_3$-C)}] [M = Mg (**11**), Ca (**12**), Sr (**13**)]. The analogous reaction with pentamethylcyclopentadiene (C$_5$Me$_5$H) afforded the compounds [(Cp*M)(μ$_3$-O)$_3${Ti$_3$Cp*$_3$(μ$_3$-C)}] [M = Ca (**14**), Sr (**15**)]. Pentamethylcyclopentadiene did not react, however, with the magnesium compound **8**, probably due to the steric hindrance and lower acidity of the C$_5$Me$_5$H ligand. The compounds **11**−**15** were isolated as green solids in good yields and the analytical and spectroscopic data are in agreement with the formulations given in Scheme 2.[12]

Compounds **11**, **12**, **13** and **14** are soluble in hydrocarbon and aromatic solvents, which allowed their NMR spectroscopic characterization. The strontium compound **15**, however, is scarcely soluble in benzene, toluene or tetrahydrofuran. The presence of the apical μ$_3$-carbido in all the cases was confirmed by ^{13}C NMR spectroscopy in [D$_6$]benzene, a singlet in the range δ = 580−594 ppm being observed in each case.

On the other hand, the elimination of the amido group could also be achieved by thermal treatment (over 150 °C) of **8**−**10** in toluene with one equivalent of the starting complex [{TiCp*(μ-O)}$_3$(μ$_3$-CH)] (**1**), producing green solids identified as the corner-shared double heterometallocubanes species [M{(μ-O)$_3$Ti$_3$Cp*$_3$(μ$_3$-C)}$_2$] M = Mg (**16**), Ca (**17**), Sr (**18**).[13] These complexes are insoluble in all the usual solvents such as toluene, hexane and even tetrahydrofuran. Fortunately, after numerous trials their solid-state structures were determined by X-ray diffraction (vide infra).

The complex [Mg{(μ-O)$_3$Ti$_3$Cp*$_3$(μ$_3$-C)}$_2$] (**16**) could also be obtained in 80−87% yield by irradiation or heating of a toluene solution of **1** and [Mg(CH$_2$Ph)$_2$(thf)$_2$] or [Mg*t*Bu$_2$(thf)$_2$]. In both cases, the reaction occurred with alkane elimination. Similar thermal treatment of **1** with [Ba{N(SiMe$_3$)$_2$}$_2$(thf)$_2$] in toluene at 100 °C for two days or with [Ba(CH$_2$Ph)$_2$] at 90 °C overnight afforded the oxoheterometallodicubane barium analogue, in good yield

(66−78%), [Ba{(μ-O)$_3$Ti$_3$Cp*$_3$(μ$_3$-C)}$_2$] (**19**), as a microcrystalline green solid, which was insoluble in practically all solvents.

X-ray Crystal Structures of 16, 17 and 18

The solid-state structures of **16**, **17** and **18** determined from X-ray diffraction data are comprised of two trinuclear [Ti$_3$Cp*$_3$O$_3$C] units that are joined to each other by an alkaline-earth metal atom, which lies on the center of symmetry. In this arrangement, the tridentate organometallic ligands are situated in alternate positions relative to the pentamethylcyclopentadienyl groups in each case .

As shown in Figure 2, the geometry around the central metal atom can be described as distorted octahedral in each case. An examination of the values of the bond lengths and angles for these complexes (see Table 2) reveals an increasing distortion from magnesium to strontium, with the latter being best described as a trigonal antiprism with wider O−M−O intercube and closer intracube angles. The distance M−O increases in the same way, in agreement with the increasing size of the atomic radii of the central atom upon descending the group. In the case of calcium [Ca−O = 2.435(4) Å av., **17**], this value is close to that mentioned above for the metallocubane compound **9** [Ca−O = 2.445(3) Å av.]. The M−O bond lengths in the magnesium and strontium derivatives are in the expected ranges for oxocomplexes with high numbers of oxygen atoms.[14]

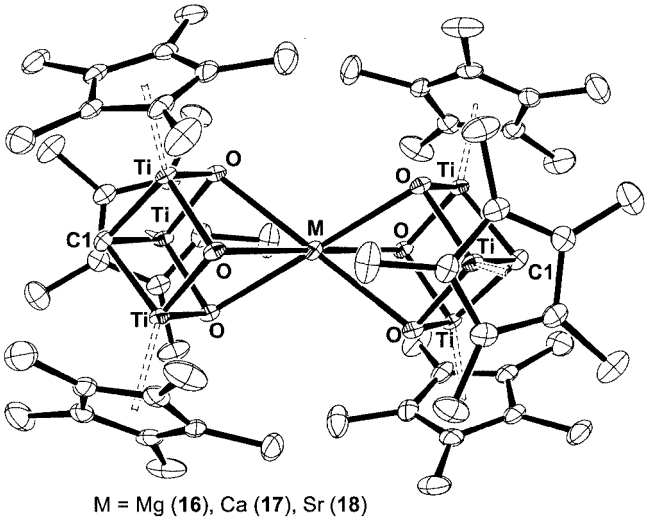

Figure 2. Simplified view of the molecular structures of **16**, **17** and **18**

The Ti−C(1) bond lengths decrease from magnesium to strontium [Mg = 2.020(10) Å av., Ca = 1.990(7) Å av., Sr = 1.970(2) Å av.], consistent with the higher steric requirement of the metal center. In all cases, these bond lengths are slightly shorter than those shown in **1** [Ti−C(1) = 2.10 Å av.][1b,1c] and **2** [Ti−C(1) = 2.12 Å av.],[1a,1c] and in the same range as those found in the zwitterionic derivative [{Ti(η^5-C$_5$Me$_5$)(μ-O)}$_3${μ$_3$-η^2-C$^-$C(Me)N$^+$(2,6-Me$_2$C$_6$H$_3$)}] [Ti−C$^-$ 2.017(5) Å].[3]

Table 2. Selected averaged distances (Å) and angles (°) for **16**, **17** and **18**

	M = Mg, **16**	M = Ca, **17**	M = Sr, **18**
Ti−O	1.905(6)	1.907(4)	1.896(2)

[a] The narrower values correspond to the O−M−O angles of the same cube.

Conclusion

As outlined in the introduction, the active cooperation between the oxo and methylidyne groups is possible in the singular trinuclear chemistry of titanium. The results presented here demonstrate the peculiar behavior of the μ_3-methylidyne complex [{TiCp*(μ-O)}$_3$(μ$_3$-CH)] (**1**) with alkali and alkaline-earth metal amides and alkyls. In all cases, the processes go via the alkylidyne deprotonation and the anchorage of the group 1 or 2 cation metal on the [Ti$_3$O$_3$] system to form heterometallocubane or corner-shared heterometallodicubane species.

Experimental Section

General Remarks: All syntheses and subsequent manipulations of the described compounds were carried out with the exclusion of air and moisture using Schlenk or glovebox techniques. Solvents were carefully dried from the appropriate drying agents and distilled prior to use.

[{TiCp*(μ-O)}$_3$(μ$_3$-CH)] (**1**) was synthesized according to the published procedures.[1a,1c] *n*BuLi was purchased from Aldrich as a 1.6 M solution in hexane. [LiCH$_2$SiMe$_3$] and [LiNp] were prepared as described in the literature,[15] as were [Na*t*Bu] and [K*t*Bu].[16] [MN(SiMe$_3$)$_2$] (M = Li, Na, K) were purchased from Aldrich and used as supplied. [MN(SiMe$_3$)$_2$] (M = Rb, Cs),[17] [MgR$_2$(thf)$_2$] (R = CH$_2$Ph,[18] *t*Bu[19]), [Ba(CH$_2$Ph)$_2$],[20] and [M{N(SiMe$_3$)$_2$}$_2$(thf)$_2$], (M = Mg,[21] Ca,[22] Sr,[22] Ba[22]) were prepared following the literature methods. Pentamethylcyclopentadiene and dicyclopentadiene were purchased from Aldrich.

Elemental analyses (C,H,N) were performed with a Heraeus CHN-O-RAPID and/or Perkin−Elmer 2400-Serie II C, H, N, S/O instrument. IR spectra were obtained in KBr pellets by using an FT-IR Perkin−Elmer SPECTRUM 2000 spectrophotometer. NMR spectra were recorded with a Varian 300 spectrometer. Chemical shifts are given in ppm (δ) downfield from TMS (δ = 0.0) using the residual protons or carbon atoms of the solvent as an internal reference. Thermal reactions were carried out in a Roth autoclave model III (300 mL), with heater model 30S (20−300 °C) and temperature regulator model DR 500.

Preparation of [Li(μ$_3$-O)$_3${Ti$_3$Cp$_3$*(μ$_3$-C)}] (3): *n*BuLi (0.35 mL, 0.56 mmol) was added to a solution of **1** (0.35 g, 0.57 mmol) in hexane (40 mL) in a 100-mL Carius tube. The reaction mixture was stirred at room temperature overnight. The green solid was then filtered, washed with hexane and vacuum dried to afford 0.33 g of **3** (Yield: 93%). ^{1}H NMR (300 MHz, [D$_8$]tetrahydrofuran, 20 °C, TMS): δ = 1.99 (s, C$_5$*Me*$_5$) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_8$]tetrahydrofuran, 20 °C, TMS): δ = 12.0 (C$_5$*Me*$_5$), 115.3 (*C*$_5$Me$_5$), 581.4 (μ$_3$-*C*) ppm. IR (KBr, cm^{-1}): ṽ = 2907 (s), 2856 (vs), 1491 (w), 1437 (s), 1373 (s), 1023 (m), 801 (w), 681 (vs), 616 (vs), 464 (w), 416 (s). $C_{31}H_{45}LiO_3Ti_3$ (616.27): calcd. C 60.42, H 7.36; found C 60.81, H 7.59.

Preparation of [Na(μ$_3$-O)$_3${Ti$_3$Cp$_3$*(μ$_3$-C)}] (4): A 100-mL Carius tube was charged with **1** (0.30 g, 0.49 mmol), [NaN(SiMe$_3$)$_2$] (0.09 g, 0.49 mmol), and hexane (40 mL). The reaction mixture was heated at 60 °C overnight and the red solid formed was filtered, washed with hexane and dried under vacuum to give 0.26 g of **4** (Yield: 83%). ^{1}H NMR (300 MHz, [D$_8$]tetrahydrofuran, 20 °C, TMS): δ = 1.95 (s, C$_5$*Me*$_5$) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_8$]tetrahydrofuran, 20 °C, TMS): δ = 11.7 (C$_5$*Me*$_5$), 115.4 (*C*$_5$Me$_5$), 586.7 (μ$_3$-*C*) ppm. IR (KBr, cm^{-1}): ṽ = 2907 (vs), 2850 (vs), 1493 (w), 1437 (s), 1372 (s), 1023 (m), 795 (w), 681 (vs), 621 (vs), 467 (w), 411 (s). $C_{31}H_{45}NaO_3Ti_3$ (632.32): calcd. C 58.88, H 7.17; found C 58.65, H 7.45.

Preparation of [K(μ$_3$-O)$_3${Ti$_3$Cp$_3$*(μ$_3$-C)}] (5): In a similar fashion to **4**, a solution of **1** (0.30 g, 0.49 mmol) and [KN(SiMe$_3$)$_2$] (0.10 g, 0.49 mmol) in hexane (40 mL) was heated at 60 °C overnight. The red solid formed was filtered and dried under vacuum to give 0.23 g of **5** (Yield: 72%). ^{1}H NMR (300 MHz, [D$_8$]tetrahydrofuran, 20 °C, TMS): δ = 1.94 (s, C$_5$*Me*$_5$) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_8$]tetrahydrofuran, 20 °C, TMS): δ = 11.5 (C$_5$*Me*$_5$), 115.1 (*C*$_5$Me$_5$), 582.0 (μ$_3$-*C*) ppm. IR (KBr, cm^{-1}): ṽ = 2910 (vs), 2857 (vs), 1597 (w), 1495 (w), 1439 (s), 1375 (s), 1247 (w), 1067 (w), 916 (m), 899 (m), 852 (s), 784 (vs), 680 (s), 624 (m), 573 (m), 411 (s). $C_{31}H_{45}KO_3Ti_3$ (648.43): calcd. C 57.42, H 6.99; found C 56.99, H 7.10.

Preparation of [Rb(μ$_3$-O)$_3${Ti$_3$Cp$_3$*(μ$_3$-C)}] (6): In a 100-mL Carius tube with a valve were placed [{TiCp*(μ-O)}$_3$(μ$_3$-CH)] (**1**) (0.50 g, 0.82 mmol), [RbN(SiMe$_3$)$_2$] (0.20 g, 0.82 mmol) and tetrahydrofuran (40 mL). The reaction mixture was heated at 60 °C and stirred overnight. The red solution was then filtered, and the solvent removed under vacuum to afford 0.46 g of **6** (Yield: 81%). ^{1}H NMR (300 MHz, [D$_8$]tetrahydrofuran, 20 °C, TMS): δ = 1.94 (s, C$_5$*Me*$_5$) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_8$]tetrahydrofuran, 20 °C, TMS): δ = 11.7 (C$_5$*Me*$_5$), 115.1 (*C*$_5$Me$_5$), 579.5 (μ$_3$-*C*) ppm. IR (KBr, cm^{-1}): ṽ = 2905 (vs), 2854 (s), 1493 (w), 1431 (m), 1375 (s), 1260 (w), 1023 (w), 800 (w), 776 (w), 657 (vs), 630 (vs), 583 (m), 436 (m), 382 (m). $C_{31}H_{45}O_3RbTi_3$ (694.80): calcd. C 53.59, H 6.53; found C 53.02, H 6.85.

Preparation of [Cs(μ$_3$-O)$_3${Ti$_3$Cp$_3$*(μ$_3$-C)}] (7): The preparation was similar to that for **6** from [{TiCp*(μ-O)}$_3$(μ$_3$-CH)] (**1**) (0.50 g, 0.82 mmol), [CsN(SiMe$_3$)$_2$] (0.24 g, 0.82 mmol) and tetrahydrofuran (40 mL). The light red solid of **7** was obtained in a 73% yield (0.44 g). ^{1}H NMR (300 MHz, [D$_8$]tetrahydrofuran, 20 °C, TMS): δ = 1.94 (s, C$_5$Me$_5$) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_8$]tetrahydrofuran, 20 °C, TMS): δ = 11.6 (C$_5$*Me*$_5$), 114.7 (*C*$_5$Me$_5$), 577.3 (μ$_3$-*C*) ppm. IR (KBr, cm^{-1}): ṽ = 2908 (s), 2856 (s), 1494 (w), 1438 (w), 1373 (w), 1261 (w), 1021 (w), 800 (w), 681 (vs), 628 (s), 476 (w), 418 (s). $C_{31}H_{45}CsO_3Ti_3$ (742.24): calcd. C 50.16, H 6.11; found C 49.08, H 6.45.

Preparation of [{(Me$_3$Si)$_2$NMg}(μ$_3$-O)$_3${Ti$_3$Cp$_3$*(μ$_3$-C)}] (8): A solution of compound **1** (0.20 g, 0.33 mmol) and [Mg{N(SiMe$_3$)$_2$}$_2$(thf)$_2$] (0.16 g, 0.33 mmol) in toluene (30 mL) was placed in a 100-mL Carius-tube. The ampoule was sealed under vacuum by flame and the reaction mixture was heated at 180 °C for two days. The solution was then filtered, and the solvent removed to afford **8** as a green microcrystalline solid. Yield: 0.21 g, 82%. ^{1}H NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 0.40 [s, 18 H, N(Si*Me*$_3$)$_2$], 2.04 (s, 45 H, C$_5$*Me*$_5$); ^{13}C{^{1}H} NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 6.3 [N(Si*Me*$_3$)], 11.8 (C$_5$*Me*$_5$), 120.6 (*C*$_5$Me$_5$), 598.3 (μ$_3$-*C*) ppm. IR (KBr, cm^{-1}): ṽ = 2940 (s), 2909 (vs), 2858 (s), 1491 (w), 1435 (m), 1377 (s), 1242 (s), 1001 (vs), 931 (w), 888 (s), 829 (vs), 789 (s), 752 (m), 670 (vs), 610 (vs), 467 (m), 430 (s). $C_{37}H_{63}MgNO_3Si_2Ti_3$ (794.03): calcd. C 55.97, H 8.00, N 1.76; found C 55.99, H 8.39, N 1.73.

Preparation of [{(thf)(Me$_3$Si)$_2$NCa}(μ$_3$-O)$_3${Ti$_3$Cp$_3$*(μ$_3$-C)}] (9): A solution of **1** (0.50 g, 0.82 mmol) and [Ca{N(SiMe$_3$)$_2$}$_2$(thf)$_2$] (0.41 g, 0.82 mmol) in hexane (50 mL) was placed in a 100-mL Carius-tube with Young's valve. The reaction mixture was heated at 90 °C for 36 h. The green solution was then filtered, and the solvent was removed under vacuum to give **9** as a green powder (0.68 g, 94%). The slow evaporation of the solvent from a concentrated solution in hexane led to single-crystals of **9** suitable for an X-ray analysis. ^{1}H NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 0.34 [s, 18 H, N(Si*Me*$_3$)$_2$], 1.36 (m, 4 H, thf), 2.12 (s, 45 H, C$_5$*Me*$_5$), 3.87 (m, 4 H, thf) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 5.8 [N(Si*Me*$_3$)$_2$], 12.1 (C$_5$*Me*$_5$), 24.9 and 70.4 (thf), 118.9 (*C*$_5$Me$_5$), 592.7 (μ$_3$-*C*) ppm. IR (KBr): ṽ = 2944 (m), 2909 (s), 2856 (m), 1493 (w), 1437 (m), 1376 (m), 1256 (m), 1057 (s), 1027 (s), 931 (w), 879 (m), 793 (s), 675 (vs), 615 (s), 467 (m), 423 (m). $C_{41}H_{71}CaNO_4Si_2Ti_3$ (881.91): calcd. C 55.84, H 8.12, N 1.59; found C 56.27, H 8.12, N 1.30.

Preparation of [{(thf)(Me$_3$Si)$_2$NSr}(μ$_3$-O)$_3${Ti$_3$Cp$_3$*(μ$_3$-C)}] (10): Compound **10** was prepared similarly to **9** from **1** (0.40 g, 0.66 mmol), [Sr{N(SiMe$_3$)$_2$}$_2$(thf)$_2$] (0.36 g, 0.66 mmol) and hexane (50 mL). The solution was heated at 90 °C for 36 h. The green solution was filtered, and the solvent was removed to yield 0.58 g (95%) of **10** as a crystalline green solid. ^{1}H NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 0.32 [s, 18 H, N(Si*Me*$_3$)$_2$], 1.32 (m, 4 H, thf), 2.13 (s, 45 H, C$_5$*Me*$_5$), 3.77 (m, 4 H, thf) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 5.6 [N(Si*Me*$_3$)$_2$], 12.0 (C$_5$*Me*$_5$), 25.0 and 69.8 (thf), 118.5 (*C*$_5$Me$_5$), 588.0 (μ$_3$-*C*) ppm. IR (KBr): ṽ = 2910 (s), 2860 (s), 1493 (w), 1441 (m), 1377 (m), 1254 (m), 1178 (w), 1037 (m), 932 (w), 818 (s), 678 (vs), 615 (s), 467 (w), 421 (m). $C_{41}H_{71}NO_4Si_2SrTi_3$ (929.45): calcd. C 52.98, H 7.70, N 1.51; found C 53.24, H 8.10, N 1.32.

Preparation of [(CpMg)(μ$_3$-O)$_3${Ti$_3$Cp$_3$*(μ$_3$-C)}] (11): Addition of cyclopentadiene (25 μL, 0.38 mmol) to a solution of **8** (0.30 g, 0.38 mmol) and heating in toluene (30 mL) at 70 °C overnight led to the product **11** as a green solid in 73% yield (0.19 g). ^{1}H NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 2.03 (s, 45 H, C$_5$*Me*$_5$), 6.49 (s, 5 H, C$_5$*H*$_5$) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 11.7 (C$_5$*Me*$_5$), 106.3 (*C*$_5$H$_5$), 120.5 (*C*$_5$Me$_5$), 594.3 (μ$_3$-*C*) ppm. IR (KBr): ṽ = 2909 (s), 2857 (m), 1494 (w), 1435 (m), 1375 (m), 1246 (m), 1025 (w), 789 (vs), 672 (vs), 618 (m), 419 (m). $C_{36}H_{50}MgO_3Ti_3$ (698.74): calcd. C 61.88, H 7.21; found C 61.10, H 7.75.

Preparation of [(CpCa)(μ$_3$-O)$_3${Ti$_3$Cp$_3$*(μ$_3$-C)}] (12): Compound **12** was prepared in a similar way to **11** from **9** (0.50 g, 0.57 mmol) and cyclopentadiene (40 μL, 0.60 mmol) in toluene (40 mL) at room temperature. After 2 h, 0.34 g of dark green solid **12** (84% yield) was obtained. ^{1}H NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 2.06 (s, 45 H, C$_5$*Me*$_5$), 6.44 (s, 5 H, C$_5$*H*$_5$) ppm. ^{13}C{^{1}H} NMR

(300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 11.8 (C_5Me_5), 110.3 (C_5H_5), 119.1 (C_5Me_5), 588.3 (μ_3-*C*) ppm. IR (KBr): $\tilde{\nu}$ = 3078 (w), 2908 (s), 2857 (m), 1493 (w), 1436 (m), 1375 (m), 1259 (w), 1068 (w), 1024 (m), 788 (vs), 735 (s), 676 (vs), 619 (s), 466 (w), 419 (m), 396 (m). $C_{36}H_{50}CaO_3Ti_3$ (714.51): calcd. C 60.52, H 7.05; found C 60.96, H 7.44.

Preparation of [(CpSr)(μ_3-O)$_3${Ti$_3$Cp$_3$*(μ_3-C)}] (13): Cyclopentadiene (40 μL, 0.60 mmol) was added to a solution of **10** (0.50 g, 0.54 mmol) in toluene (40 mL) and kept at room temperature. After 2 h, **13** was isolated as a green solid in 76% yield (0.31 g) by removing the solvent. ^{1}H NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 2.14 (s, 45 H, C_5Me_5), 6.36 (s, 5 H, C_5H_5) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 12.0 (C_5Me_5), 108.9 (C_5H_5), 117.6 (C_5Me_5), 591.6 (μ_3-*C*) ppm. IR (KBr): $\tilde{\nu}$ = 2909 (s), 2858 (s), 1493 (w), 1437 (m), 1377 (m), 1259 (w), 1068 (w), 1025 (w), 788 (vs), 735 (s), 675 (vs), 608 (s), 466 (w), 421 (m). $C_{36}H_{50}O_3SrTi_3$ (762.05): calcd. C 56.74, H 6.61; found C 56.76, H 6.88.

Preparation of [(Cp*Ca)(μ_3-O)$_3${Ti$_3$Cp$_3$*(μ_3-C)}] (14): Pentamethylcyclopentadiene (55 μL, 0.35 mmol) was added to a solution of **9** (0.30 g, 0.34 mmol) in hexane (40 mL). The reaction mixture was heated at 90 °C for 6 h to afford a green solution. The solvent was removed under vacuum and the product was isolated in 75% yield (0.20 g). ^{1}H NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 2.04 (s, 45 H, C_5Me_5), 2.21 (s, 15 H, C_5Me_5) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 11.2 and 11.8 (C_5Me_5), 114.3 and 119.4 (C_5Me_5), 588.6 (μ_3-*C*) ppm. IR (KBr): $\tilde{\nu}$ = 2962 (m), 2910 (s), 2855 (m), 1495 (w), 1438 (m), 1375 (m), 1259 (w), 1084 (m), 1020 (m), 790 (vs), 733 (m), 676 (vs), 615 (m), 467 (m), 420 (m). $C_{41}H_{60}CaO_3Ti_3$ (784.64): calcd. C 62.76, H 7.71; found C 63.07, H 7.96.

Preparation of [(Cp*Sr)(μ_3-O)$_3${Ti$_3$Cp$_3$*(μ_3-C)}] (15): Compound **15** was prepared similarly to **14** from **10** (0.30 g, 0.32 mmol) and C_5Me_5H (50 μL, 0.32 mmol) in hexane (40 mL). The solution was heated at 90 °C for 6 h to yield 0.22 g of **15** as a green microcrystalline solid (82% yield). ^{1}H NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 2.03 (s, 45 H, C_5Me_5), 2.17 (s, 15 H, C_5Me_5) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): δ = 11.5 and 12.4 (C_5Me_5), 114.0 and 118.8 (C_5Me_5), 580.0 (μ_3-*C*) ppm. IR (KBr): $\tilde{\nu}$ = 2964 (m), 2910 (s), 2586 (m), 1495 (w), 1439 (m), 1375 (m), 1258 (w), 1081 (m), 1022 (m), 790 (vs), 731 (m), 678 (vs), 616 (s), 468 (m), 420 (m). $C_{41}H_{60}O_3SrTi_3$ (832.19): calcd. C 59.18, H 7.27; found C 59.72, H 7.49.

Preparation of [Mg{(μ-O)$_3$Ti$_3$Cp*$_3$(μ_3-C)}$_2$]·C$_7$H$_8$ (16). Method A: [{TiCp*(μ-O)}$_3$(μ_3-CH)] (**1**) (0.50 g, 0.82 mmol), [Mg(CH$_2$Ph)$_2$(thf)$_2$] (0.14 g, 0.41 mmol) or [Mg*t*Bu$_2$(thf)$_2$] (0.12 g, 0.41 mmol) and toluene (50 mL) were placed in a Carius tube with Young's valve. The argon atmosphere pressure was reduced and the reaction mixture was irradiated with an ultraviolet lamp for 2 days. The green solution was then filtered and cooled to 4 °C to afford **16** as green crystals suitable for an X-ray diffraction analysis. After several crystallizations the isolated product was dried under vacuum giving a total yield of 80% (0.44 g) in the reaction with [Mg(CH$_2$Ph)$_2$(thf)$_2$] and 87% (0.48 g) with [Mg*t*Bu$_2$(thf)$_2$]. **Method B:** In a 100-mL Carius tube **1** (0.12 g, 0.19 mmol) and **8** (0.15 g, 0.19 mmol) were dissolved in toluene (20 mL) and then the ampoule was sealed under vacuum by flame. The solution was heated at 200 °C for 2 days. Slow crystallization led to green needles of **16** (0.20 g, 79%) which were vacuum dried. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 2906 (vs), 2848 (vs), 1494 (m), 1437 (s), 1374 (s), 1261 (w), 1023 (m), 858 (s), 786 (s), 729 (s), 676 (m), 607 (vs), 464 (w), 424 (s). $C_{69}H_{98}MgO_6Ti_6$ (1335.12): calcd. C 62.07, H 7.40; found C 62.28, H 7.57.

Preparation of [{M{(μ_3-O)$_3$Ti$_3$Cp*$_3$(μ_3-C)}$_2$] [M = Ca (17), Sr (18)]: The preparations of **17** and **18** were similar to that of **16**. **1** (0.10 g, 0.17 mmol) and **9** (0.15 g, 0.17 mmol) or **10** (0.15 g, 0.16 mmol) in toluene (20 mL) react at 180 °C over 36 h to afford **17** or **18**, respectively, as green needles (Yields: 0.18 g, 84% **17**; 0.15 g, 71% **18**).

17: IR (KBr): $\tilde{\nu}$ = 2908 (s), 2858 (s), 1489 (w), 1437 (m), 1384 (m), 1376 (m), 1257 (w), 1025 (w), 790 (m), 675 (vs), 606 (s), 464 (m), 425 (m). $C_{62}H_{90}CaO_6Ti_6$ (1258.75): calcd. C 59.16, H 7.21; found C 59.58, H 7.20.

18: IR (KBr): $\tilde{\nu}$ = 2908 (s), 2857 (m), 1492 (w), 1439 (m), 1376 (m), 1025 (w), 790 (w), 675 (vs), 608 (vs), 467 (m), 426 (s). $C_{62}H_{90}O_6SrTi_6$ (1306.29): calcd. C 57.01, H 6.94; found C 57.07, H 6.95.

Preparation of [Ba{(μ_3-O)$_3$Ti$_3$Cp*$_3$(μ_3-C)}$_2$] (19): This complex can be synthesized either by thermal treatment at 100 °C for two days of a solution of [{TiCp*(μ-O)}$_3$(μ_3-CH)] (**1**) (0.40 g, 0.65 mmol) and [Ba{N(SiMe$_3$)$_2$}$_2$(thf)$_2$] (0.20 g, 0.33 mmol) in toluene (50 mL) or by heating at 90 °C overnight a solution of **1** (0.30 g, 0.49 mmol) and [Ba(CH$_2$Ph)$_2$] (0.08 g, 0.24 mmol). Following this, the reaction mixture was repeatedly concentrated, cooled and filtered to afford a green microcrystalline solid identified as **19** (Yield: 0.22−0.35 g, 66−78%). IR (KBr): $\tilde{\nu}$ = 2911 (vs), 2858 (s), 1493 (w), 1436 (m), 1377 (s), 1262 (w), 1103 (m), 1023 (m), 795 (vs), 668 (m), 616 (s), 394 (m). $C_{62}H_{90}BaO_6Ti_6$ (1356.00): calcd. C 54.92, H 6.69; found C 54.40, H 6.96.

X-ray Crystallographic Studies of Complexes 9, 16, 17 and 18

X-ray quality crystals of **16** were grown as described in the Exp. Sect. Crystals were mounted in glass capillaries in a random orientation and transferred to an Enraf−Nonius CAD4 diffractometer for characterization and data collection at room temperature. Crystals of complexes **9**, **17** and **18** were grown as described in the Exp. Sect., removed from the Schlenk vessels and covered with a layer of a viscous perfluoropolyether (Fomblin®Y). A suitable crystal was selected with the aid of a microscope, attached to a glass fiber, and immediately placed in the low temperature nitrogen stream of the diffractometer. The intensity data sets were collected at 100 K on a Bruker−Nonius KappaCCD diffractometer equipped with an Oxford Cryostream 700 unit. Crystallographic data for all the complexes are presented in Table 3.

The structures were solved using the WINGX package[23] by direct methods (SHELXS-97) and refined by least-squares against F^2 (SHELXL-97).[24]

Complex **9** exhibited severe disorder both in the pentamethylcyclopentadienyl rings and in the coordinated THF molecule, two sites with 50% occupancy were found for all the disordered atoms. Only the carbon atoms of the C31−C40 pentamethylcyclopentadienyl ring were isotropically refined, the rest of the non-hydrogen atoms were refined anisotropically. The hydrogen atoms were not added.

All non-hydrogen atoms of **16**, except the methyl carbon atoms C14, C15 and C16 of one pentamethylcyclopentadienyl ring and those of the disordered solvent, were anisotropically refined. Only the hydrogen atoms of the pentamethylcyclopentadienyl rings were included, positioned geometrically and refined by using a riding model.

Complex **17** also exhibited disorder in both molecules of the solvent and C16, all these atoms were refined with 50% of occupan-

New Nitrosylrhenium Hydrides as Precursors of "Diazo" Complexes: Preparation of Hydrazine and Diazene Derivatives

Gabriele Albertin,*[a] Stefano Antoniutti,[a] Alessia Bacchi,[b] Barbara Fregolent,[a] and Giancarlo Pelizzi[b]

Keywords: Diazene / Hydrazine / P ligands / N ligands / Rhenium

The reaction of $[ReCl_2(OCH_3)(NO)(PPh_3)_2]$ with phosphane in the presence of $NaBH_4$ gives different dihydride $[ReH_2(NO)\{PPh_2(OEt)\}_3]$ (**1**) and alkoxy-hydride $[ReH(OR^1)(NO)P_3]$ (**2**, **3**) [$R^1 = CH_3$, C_2H_5; P = $PPh(OEt)_2$, $P(OEt)_3$] derivatives depending on the nature of the phosphane and the solvent used. The protonation reactions of the new hydrides with Brønsted acid were performed and led to thermally unstable $[Re(OR^1)(\eta^2\text{-}H_2)(NO)P_3]^+$ (**2***, **3***) dihydrogen cations. Hydrazine complexes $[ReH(RNHNH_2)(NO)\{PPh_2(OEt)\}_3]BPh_4$ (**4**) (R = H, CH_3,C_6H_5) and $[Re(OR^1)(RNHNH_2)(NO)P_3]BPh_4$ (**5**, **6**) [$R^1 = CH_3$, C_2H_5; R = H, CH_3,C_6H_5; P = $PPh(OEt)_2$] were prepared by allowing the hydrides $[ReH_2(NO)P_3]$ and $[ReH(OR^1)(NO)P_3]$ to react first with triflic acid and then with hydrazine. The complexes were characterized spectroscopically and by the X-ray crystal structure determination of $[Re(OC_2H_5)(NH_2NH_2)(NO)\{PPh(OEt)_2\}_3]BPh_4$ (**5a**). Oxidation of the hydrazine complexes **4**–**6** was studied with $Pb(OAc)_4$ at –30 °C and, depending on the nature of the hydrazine and the stoichiometry of the complexes, led to aryldiazene $[ReH(C_6H_5N{=}NH)(NO)\{PPh_2(OEt)\}_3]BPh_4$ (**7c**), $[Re(OC_2H_5)(C_6H_5N{=}NH)(NO)\{PPh(OEt)_2\}_3]BPh_4$ (**8c**), methyldiazene $[ReH(CH_3N{=}NH)(NO)\{PPh_2(OEt)\}_3]BPh_4$ (**7b**) and a mixture of methyldiazene $[Re(OCH_3)(CH_3N{=}NH)(NO)\{PPh_2(OEt)\}_3]BPh_4$ (**9b**) and methyleneimine $[Re(OCH_3)(\eta^1\text{-}NH{=}CH_2)(NO)\{PPh_2(OEt)\}_3]BPh_4$ (**9*b**) derivatives. Mono- and binuclear aryldiazene complexes $[ReH(ArN{=}NH)(NO)\{PPh_2(OEt)\}_3]BPh_4$ (**10**), $[\{ReH(NO)[PPh_2(OEt)]_3\}_2(\mu\text{-}HN{=}NAr{-}ArN{=}NH)](BPh_4)_2$ (**11**), $[Re(OR^1)(ArN{=}NH)(NO)P_3]BPh_4$ (**12**, **14**, **16**) and $[\{Re(OR^1)(NO)P_3\}_2(\mu\text{-}HN{=}NAr{-}ArN{=}NH)](BPh_4)_2$ (**13**, **15**) [$R^1 = CH_3$, C_2H_5; P = $PPh(OEt)_2$, $P(OEt)_3$; Ar = C_6H_5, 4-$CH_3C_6H_4$; Ar-Ar = 4,4′-C_6H_4-C_6H_4] were also prepared by allowing hydrides $[ReH_2(NO)[PPh_2(OEt)]_3]$ and $[ReH(OR^1)(NO)P_3]$ to react with mono- and bis-aryldiazonium cations.

Introduction

The chemistry of transition metal complexes containing partially reduced dinitrogen ligands such as aryldiazenido, ArN_2, diazene, RN=NH, or hydrazine, $RNHNH_2$, has developed considerably in the past 25 years,[1−3] not only because of the similarity of these derivatives with the intermediates in nitrogen fixation, but also for the interesting reactivity modes and structural properties that this class of compounds may exhibit.[1−4]

Among the metal centers used to bind diazo molecules, rhenium plays a prominent role and a number of studies on aryldiazenido [Re]−N_2Ar complexes have been reported.[5] Less attention, however, has been devoted to hydrazine and diazene chemistry. A glance through the literature shows, in fact, that hydrazine or substituted hydrazine complexes are rather rare and include, apart from the pioneering work on $[Re(NCO)(CO)_2(NH_2NH_2)P_2]$ (P = tertiary phosphane) complexes,[6] only two papers[7] on $[ReCp^*Me_3(NH_2NH_2)]CF_3SO_3$ (Cp* = pentamethylcyclopentadienyl) and $[Re(NH_2NH_2)(CO)_3(PPh_3)_2]CF_3SO_3$ hydrazine derivatives, and another on the substituted hydrazine complex $[ReCl_2(PPh_3)_2\{NNC(O)Ph\}\{H_2NNHC(S)Ph\}]$.[8]

Only a few studies on aryldiazene complexes have been reported and include, apart from chelate organodiazene complexes[9] such as $[ReCl(HN{=}Npy)(NNpy)(PPhMe_2)_2]^+$, $[ReCl_2(NNC_4H_2N_2CF_3)(HN{=}NC_4H_2N_2CF_3)(PPh_3)]$, and $[ReCl_3(NNC_5H_4NH)(HN{=}NC_5H_4N)]$, only two types[10] of stable aryldiazene complexes — $[Re(\eta^5\text{-}C_5H_5)(CO)_2(HN{=}NR)]$ (R = 4-$CH_3C_6H_4$, 4-$CH_3OC_6H_4$) and $[Re(NH{=}NPh)(CO)_3(PPh_3)]BF_4$.

We are active in this field[3] and have recently reported[11,12] on the synthesis and reactivity of aryldiazene and hydrazine complexes of rhenium stabilized by mixed phosphane-carbonyl ligands of the type $[Re(ArN{=}NH)(CO)_nP_{5-n}]BPh_4$ and $[Re(RNHNH_2)(CO)_nP_{5-n}]BPh_4$ [P = $P(OEt)_3$, $PPh(OEt)_2$ and PPh_2OEt; $n = 1-4$] obtained from the hydride $[ReH(CO)_nP_{5-n}]$[13] as precursor. We now extend these studies to include nitrosyl and phosphane as supporting ligands with the aim both to increase the knowledge of the "diazo" chemistry of rhenium and to determine

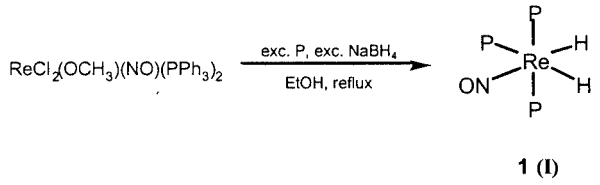
the influence of these ligands on the stability and on the properties of both diazene and hydrazine derivatives. The precursors for these syntheses needed to be mixed-ligand hydride complexes with the phosphanes $P(OEt)_3$, $PPh(OEt)_2$, PPh_2OEt and nitrosyl, whose synthesis has not previously been reported.[14,15] We therefore began to study how to prepare rhenium hydrides containing both phosphane and nitrosyl ligands to use as precursors in diazo chemistry. The results of these studies, which include the preparation of new rhenium hydrides and their use as precursor for the synthesis of new diazene and hydrazine complexes, are reported here.

Results and Discussion

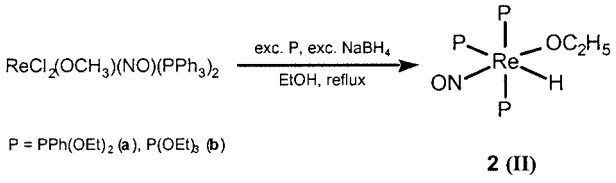
Preparation of Hydride Complexes

The outcome of the reaction of the dichloro complex $[ReCl_2(OCH_3)(NO)(PPh_3)_2]$ with phosphanes and $NaBH_4$ depends on the nature of the phosphorus ligands and the solvent used, as shown in Schemes 1 and 2.



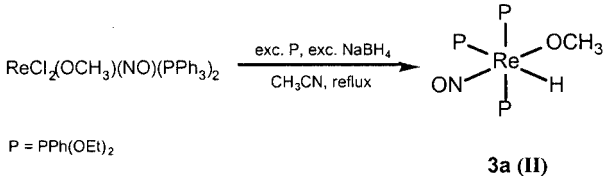
1 (I)

Scheme 1. P = PPh_2OEt



P = $PPh(OEt)_2$ (**a**), $P(OEt)_3$ (**b**)

2 (II)



P = $PPh(OEt)_2$

3a (II)

Scheme 2

In the presence of ethoxydiphenylphosphane PPh_2OEt, the reaction of $[ReCl_2(OCH_3)(NO)(PPh_3)_2]$ with $NaBH_4$ in ethanol proceeds to give the dihydride $[ReH_2(NO)P_3]$ (**1**; P = PPh_2OEt) which was isolated as white microcrystals in about 83% yield (Scheme 1). In the presence of $PPh(OEt)_2$ and $P(OEt)_3$ the reaction proceeds to give exclusively the monohydride $[ReH(OC_2H_5)(NO)P_3]$ (**2**) [P = $PPh(OEt)_2$ (**a**), $P(OEt)_3$ (**b**)] containing the ethoxide group OC_2H_5 as a supporting ligand (Scheme 2). The presence of this OC_2H_5 ligand in the final complex **2** as well as the absence of traces of the dihydride $[ReH_2(NO)P_3]$ in the raw reaction product prompted us to use a different solvent for the reaction. The reaction of $[ReCl_2(OCH_3)(NO)(PPh_3)_2]$ with $NaBH_4$ in acetonitrile, in the presence of $PPh(OEt)_2$ and $P(OEt)_3$, however, also only gives the monohydride $[ReH(OCH_3)(NO)P_3]$ (**3**) [P = $PPh(OEt)_2$ (**a**)] which, in this case, contains the OCH_3 group as a ligand. The hydride was isolated as a stable solid with $PPh(OEt)_2$ (**3a**), while with $P(OEt)_3$ only an oily product was obtained (Scheme 2). The reaction of $[ReCl_2(OCH_3)(NO)(PPh_3)_2]$ with $NaBH_4$, in the presence of ethoxydiphenylphosphane PPh_2OEt, in acetonitrile solvent was also performed and gave the dihydride $[ReH_2(NO)P_3]$ (**1**), as in the reaction in ethanol but with a lower yield.

These results seem to indicate that the nature of the phosphane ligand determines the stoichiometry of the hydride obtained from the reaction of $[ReCl_2(OCH_3)(NO)(PPh_3)_2]$ with $NaBH_4$. The dihydride **1** can be obtained under all conditions with PPh_2OEt, which is a bulkier ligand[16] than $PPh(OEt)_2$ and $P(OEt)_3$, but less π-acid, while only the alkoxy-monohydrides $[ReH(OR^1)(NO)P_3]$ (**2**, **3**) were obtained with the ligands $PPh(OEt)_2$ and $P(OEt)_3$. The good π-acceptor ability[16] of these latter phosphanes probably requires the presence of an alkoxy ligand bonded to an $\{ReNO\}^6$-metal fragment[17] for the stabilization of the complexes. The nature of the solvent is important in determining the type of OR^1 group in the monohydride species.

Although a number of mono- and polyhydride complexes of rhenium have been reported,[14,15] few of them contain phosphanes as an ancillary ligand and none, to the best of our knowledge, an alkoxy group. The use of $[ReCl_2(OCH_3)(NO)(PPh_3)_2]$ as a precursor in the reaction with phosphanes and $NaBH_4$ allows the synthesis of new types of nitrosyl-hydride complexes to be achieved.

The hydride complexes **1**−**3** are white diamagnetic solids that are stable in air and in solution in the more common organic solvents, where they behave as non-electrolytes. Analytical and spectroscopic data (Table 1) support the proposed formulation and a geometry in solution was also established. The IR spectrum of $[ReH_2(NO)(PPh_2OEt)_3]$ (**1**) show two ν_{ReH} bands at 1914 and 1841 cm^{-1} suggesting a mutually *cis* position of the two hydride ligands. A strong band at 1637 cm^{-1} attributed to the ν_{NO} of the nitrosyl ligand is also present. In the temperature range between +20 and −80 °C the $^{31}P\{^1H\}$ NMR spectra of the complex appear as an AB_2 multiplet, in agreement with the presence of two magnetically equivalent phosphanes that are different to the third. The ^1H NMR spectrum confirms the presence of the hydride ligand showing, besides the signals of the PPh_2OEt groups, a multiplet between δ = −2 and −4 ppm. Taking into account the AB_2 pattern of the ^{31}P NMR spectra, the hydride multiplet can be simulated using an AB_2XY model (X, Y = H) with the parameters reported in Table 1. This model involves two inequivalent hydride ligands, one hydride with two very similar $J_{P,H}$ values, while the other has different $J_{P,H}$ values (29.5 and 39.8 Hz). On the basis of these data a geometry of type **I** (Scheme 1) can reasonably be proposed for the dihydride complex.

[a] In KBr pellets. [b] In CD_2Cl_2 at 25 °C unless otherwise noted. [c] Positive shift downfield from 85% H_3PO_4. [d] At −30 °C. [e] At −70 °C. [f] $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 165−121 (m, Ph), 64.0 (br, s, $CH_2{=}NH$), 63.0 (m, CH_2), 62.5 (s, $CH_3N{=}NH$), 16.6 (m, CH_3) ppm.

The infrared spectra of the alkoxide complexes [Re-H(OR^1)(NO)P$_3$] (**2**, **3**) show only one medium-intensity band at 1864−1832 cm^{-1} attributed to ν_{ReH} of the hydride ligand and one strong absorption at 1657−1635 cm^{-1} due to the ν_{NO} of the nitrosyl group. In the temperature range between +20 and −80 °C the $^{31}P\{^1H\}$ NMR spectra appear, for each of the hydrides, as an A_2B multiplet in agreement with the presence of two magnetically equivalent phosphanes that are different from the third. The ^1H NMR spectra confirm the presence of both the hydride and the alkoxide ligand showing, besides the signals of the phosphane protons, a multiplet at δ = 0.86−0.26 ppm attributed to the hydride ligand and the characteristic signals of either an OC_2H_5 or an OCH_3 group. The multiplet of the hydride can be easily simulated using an A_2BX model (X = H) with the parameters reported in Table 1. The values of the two $J_{P,H}$ coupling constants deduced from this simulation are rather different between each other and suggest that the hy-

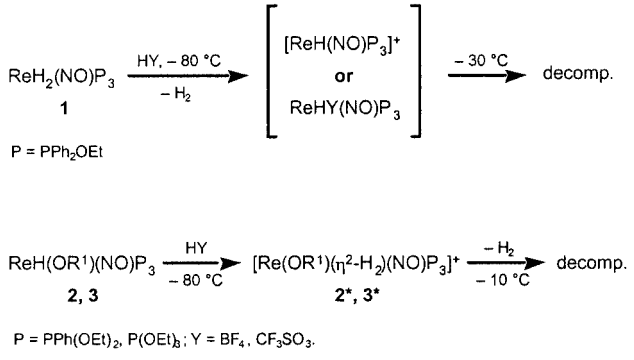
dride occupies a *trans* position with respect to one phosphane and a *cis* position with respect to the other two. On this basis a geometry of type **II** (Scheme 2) can be reasonably proposed in solution for all the monohydride $[ReH(OR^1)(NO)P_3]$ (**2**, **3**) derivatives.

Protonation Reactions

The protonation reaction of the new hydrides **1**−**3** with Brønsted acids was studied in an NMR tube at temperatures between +20 and −80 °C. The results are summarized in Scheme 3.



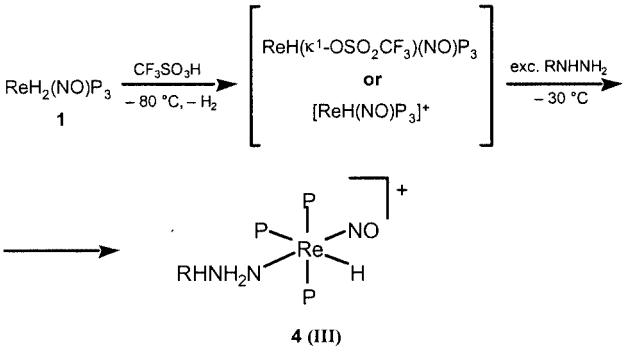
Scheme 3

Addition of an equimolar amount of CF_3SO_3H or $HBF_4{\cdot}Et_2O$ to a solution of the dihydride $[ReH_2(NO)P_3]$ (**1**) in CD_2Cl_2 at −80 °C causes a change in the ^1H and ^{31}P NMR spectra of the solution with evolution of H_2 at this temperature. The formation of H_2 suggests that the protonation forms a dihydrogen $[ReH(\eta^2\text{-}H_2)(NO)P_3]^+$ intermediate[18] which is unstable to the loss of H_2 even at −80 °C, yielding either a coordinatively unsaturated $[ReH(NO)P_3]^+$ cation or a neutral $[ReHY(NO)P_3]$ species (Y = BF_4 or CF_3SO_3). The formation of a dichloromethane complex[19] of the type $[ReH(CH_2Cl_2)(NO)P_3]^+$, however, cannot be excluded. These complexes are thermally unstable and decompose above −30 °C, preventing their isolation in the solid state. The loss of H_2 at low temperatures (−70 °C) was also observed in the protonation with CF_3COOH of similar[15c] $[ReH_2(CO)(NO)L_2]$ [L = P(*i*Pr)$_3$, P(O*i*Pr)$_3$] hydride complexes which yield, in this case, the trifluoroacetate $[ReH(OOCCF_3)(CO)(NO)L_2]$ derivatives.

The protonation of the alkoxy-hydride $[ReH(OR^1)(NO)P_3]$ (**2**, **3**) with CF_3SO_3H or $HBF_4{\cdot}Et_2O$ at −80 °C proceeds with the disappearance of the hydride multiplet in the ^1H NMR spectra at δ = 0.86−0.26 ppm and a simultaneous change in chemical shift of all the other signals of both the phosphanes and the alkoxide groups. The $^{31}P\{^1H\}$ NMR spectra also show the disappearance of the A_2B multiplet of the hydride precursor and the appearance of a new A_2B pattern (Table 1). These data may be interpreted on the basis of the formation of a dihydrogen[18] complex of the type $[Re(OR^1)(\eta^2\text{-}H_2)(NO)P_3]^+$ obtained by the attack of the acid on the hydride ligand. In the ^1H NMR spectra, however, no signal attributable to the η^2-H_2 resonance was clearly observed, and this may make the presence of the dihydrogen complex uncertain. In order to obtain further information, we increased the temperature of the sample and observed no change in the profile of the spectra until −10 °C. At this temperature a signal at δ = 4.58 ppm due[20] to free H_2 appears in the ^1H NMR spectra, which increases in intensity with time with the simultaneous lowering of all the other signals. The ^{31}P NMR spectra also show a decrease in the intensity of the A_2B multiplet and the formation of decomposition products near −10 °C. The appearance of free H_2 as the temperature is increased seems to confirm the formation of the $[Re(OR^1)(\eta^2\text{-}H_2)(NO)P_3]^+$ (**2***, **3***) dihydrogen cation whose η^2-H_2 signal is probably masked by the intense methyl multiplet of the phosphane ligands. The chemical shift of the η^2-H_2 ligand,[18] in fact, generally falls at lower values than those of the related hydride precursor, making the signal, in our case, probably superimposed by the methyl multiplet of the phosphane. The formation of the dihydrogen complexes **2*** and **3*** also indicates that among the three potential sites for protonation in $[ReH(OR^1)(NO)P_3]$ complexes — the alkoxy, the hydride or the NO — the hydride is probably the most accessible and affords the corresponding η^2-H_2 complex. Unfortunately, this species is thermally unstable and the loss of H_2 already at −10 °C prevents its isolation in the solid state.

Preparation of Hydrazine Complexes

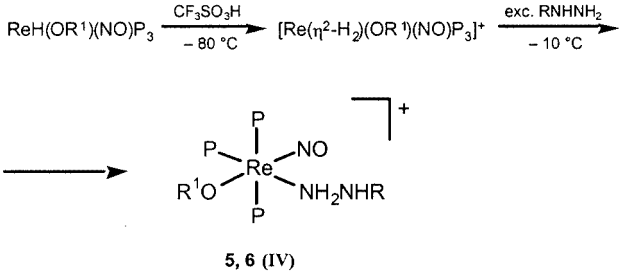
The unstable complexes formed by the protonation of the hydrides **1**−**3** are either coordinatively unsaturated or contain one labile ligand (Y or η^2-H_2) and should therefore react easily with the appropriate ligands, allowing the synthesis of new complexes. This reaction does occur with hydrazine and a series of new complexes was prepared and characterized (Schemes 4 and 5).



Scheme 4. P = PPh_2OEt; R = H (**a**), CH_3 (**b**), C_6H_5 (**c**)

The new hydrazine complexes **4a**−**c**, **5a**−**c**, **6a**−**c** were isolated in good yields as BPh_4^- salts and are white or pale-yellow solids that are stable in air and in solution in polar organic solvents, where they behave as 1:1 electrolytes.[21] Their characterization is supported by analytical and spectroscopic data (IR, NMR, Table 1) and by the X-ray crystal structure determination (Table 2) of the derivative $[Re(OC_2H_5)(NH_2NH_2)(NO)\{PPh(OEt)_2\}_3]BPh_4$ (**5a**).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 5. P = $PPh(OEt)_2$; R = C_2H_5 (**5**), CH_3 (**6**); R^1 = H (**a**), CH_3 (**b**), C_6H_5 (**c**)

The molecular structure adopted by the cation in the solid state is shown in Figure 1, along with the labelling scheme. The metal coordination is octahedral, with the nitrosyl ligand placed *trans* to the ethoxy group, while the hydrazine molecule is coordinated *trans* to a phosphane. The ligands NO^+, NH_2NH_2 and $CH_3CH_2O^-$ are in a *mer* arrangement, and two more phosphanes complete the coordination. The relevant bond lengths and angles for the cationic complex are in Table 3.

The hydrazine ligand is in a Z configuration relative to the nitrosyl molecule and is almost perfectly coplanar with it [N1−Re−N2−N3 = 2.5(6)°]. The Re−N2 and N2−N3 bonds (Table 3) are typical of coordination by a single σ-bond via the terminal -NH_2 group, with a bonding geometry similar to that observed previously for the coordination of methylhydrazine to rhenium [Re−N = 2.235(3), N−N = 1.445(4) Å].[3d] The nitrosyl bonding mode [Re−N1 = 1.763(7), N1−O8 = 1.215(9) Å] agrees with the average geometry found in the literature {e.g. Re−N = 1.765, N−O = 1.200 Å in $[ReCl_3(NO)(PPh_3)_2]$}.[22] The ethoxy group is also roughly coplanar with the hydrazine, and the α-carbon is oriented towards N2 [C31−O7−Re−N2 = −12.8(8)°].

The Re−P bond *trans* to the hydrazine ligand is significantly shorter [Re−P2 = 2.352(2) Å] than the Re−P bond of the phosphanes *trans* to each other [Re−P3 = 2.443(2) and Re−P1 = 2.418(2) Å, respectively], which are similar to those observed for *trans* $PPh(OEt)_2$ groups bonded to rhenium, ranging between 2.41 and 2.46 Å.[3d] This trend has already been observed in $[ReCl(CH_3N_2)(CH_3NHNH_2)\{PPh(OEt)_2\}_3]BPh_4$,[3d] where the Re−P distance *trans* to the methylhydrazine [2.362(1) Å] is remarkably

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

shorter than those observed for the phosphanes situated *trans* to each other [2.406(1) and 2.412(1) Å]. As also pointed out in the above paper, the Re−P elongation is supported by a system of intramolecular hydrogen bonds between the hydrazine NH groups and the ethoxy substituents carried by the adjacent phosphanes [N2···O5 = 2.871(9) Å, N2−H···O5 = 131.6(4)°, N2···O2 = 2.941(9) Å, N2−H···O2 = 139.2(4)°], and is accompanied by a bending of the phosphanes P1 and P3 towards the hydrazine [P3−Re−N2 = 86.9(2)° and P1−Re−N2 = 88.5(2)°].

The IR spectra of all the hydrazine complexes **4**−**6** show, besides the bands of the phosphane and the BPh_4 anion, a strong absorption at 1697−1670 cm^{-1} due to the ν_{NO} of the nitrosyl ligand and three or four medium-intensity bands between 3609 and 3215 cm^{-1} attributed to the ν_{NH} of the hydrazine ligand. In some compounds the δ_{NH_2} band is also observed at 1630−1620 cm^{-1}.

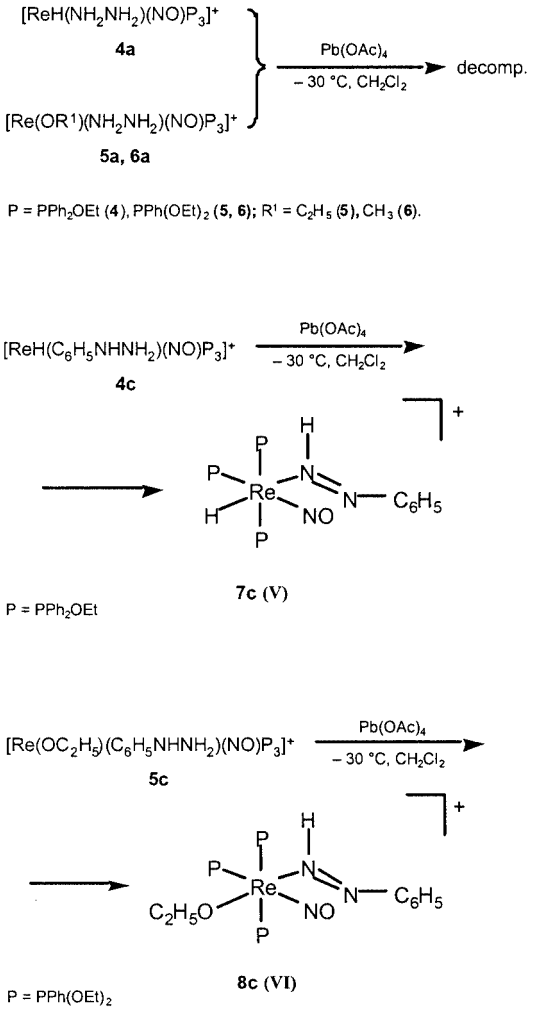
The presence of the hydrazine ligand is confirmed by the ^1H NMR spectrum, which show the characteristic broad multiplets between δ = 6 and 3 ppm (Table 1) of the NH_2 and NH protons of the $RNHNH_2$ ligand. Integration measurements and ^1H COSY experiments confirm the proposed attributions.

In the ^1H NMR spectra of complexes $[ReH(RNHNH_2)(NO)P_3]BPh_4$ (**4**) one multiplet at δ = −3.40 and at −3.48 ppm is also present, attributed to the hydride ligand, and can be simulated by using an AB_2X (X = H) model with the parameters reported in Table 1. The two $J_{P,H}$ coupling constants have different values (20 and 30 Hz) which suggests that the hydride should be *trans* to one phosphane and *cis* to the other two. In the temperature range between +20 and −80 °C the $^{31}P\{^1H\}$ NMR spectra appear as an AB_2 multiplet, in agreement with the presence of two magnetically equivalent phosphanes that are different from the third. On this basis a geometry of type **III** can be reasonably proposed for the hydride-hydrazine complexes **4**.

The ^1H NMR spectra of the alkoxy derivative **5** and **6** show, besides the signals of the phosphanes and of the hydrazine, the resonance of the OR^1 ligands, which appear as a triplet and a quadruplet for OC_2H_5 and as a singlet for OCH_3. The $^{31}P\{^1H\}$ NMR spectra also indicate that for these complexes an AB_2 multiplet is present. These data, however, do not allow us to unambiguously assign a geometry for the alkoxy complexes although, by analogy with the solid state, a complex of type **IV** can reasonably be proposed. The preparation of complexes **4**−**6** highlights the fact that both hydride $[ReH(NO)P_3]$ and alkoxy $[Re(OR^1)(NO)P_3]$ nitrosyl fragments can bind the hydrazine molecule to give stable derivatives that can be isolated.

Oxidation of Hydrazine Complexes

The oxidation reaction of the hydrazine complexes **4**−**6** with $Pb(OAc)_4$ was studied extensively and the results are summarized in Schemes 6 and 7.



Scheme 6

The outcome of the oxidation reactions depends on the nature of both the metal fragment and the hydrazine used. The NH_2NH_2 complexes **4a**, **5a** and **6a** do not give any diazene complexes in the reaction with $Pb(OAc)_4$ and only decomposition products were obtained. The reaction proceeds with a color change of the reaction mixture but probably leads to unstable species. Instead, the phenylhydrazine is selectively oxidized in both the hydride (**4c**) and the ethoxy (**5c**) derivatives to the corresponding phenyldiazene compounds (**7c** and **8c**, respectively), which were isolated in the solid state and characterized. Surprisingly, the reaction of methylhydrazine gives the methyldiazene complex **7b** in the oxidation of the hydride $[ReH(CH_3NHNH_2)(NO)P_3]^+$ (**4b**), while a mixture of the methyldiazene complex $[Re(OCH_3)(CH_3N{=}NH)(NO)P_3]^+$ (**9b**) and the methyleneimine[11] complex $[Re(OCH_3)(\eta^1\text{-}NH{=}CH_2)(NO)P_3]^+$ (**9*b**) was obtained in the reaction with the methoxy-methylhydrazine derivative $[Re(OCH_3)(CH_3NHNH_2)(NO)P_3]^+$ (**6b**). The hydride-methyldiazene complex **7b** was isolated in the solid state and in a pure form, whereas the two compounds **9b** and **9*b** were obtained as a mixture and were not sepa-

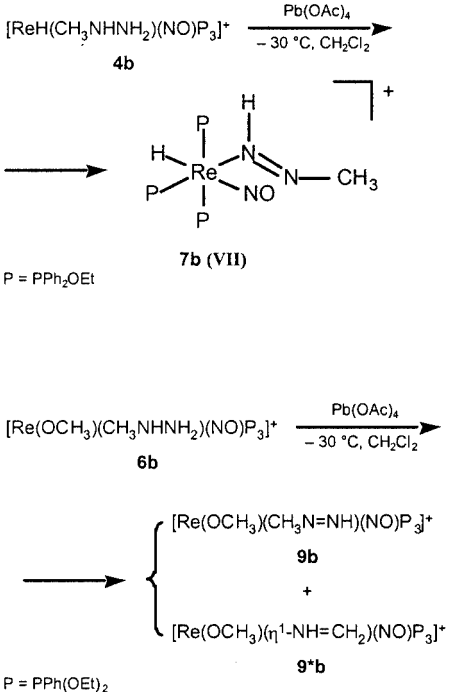


Scheme 7

rated. The spectroscopic data, however, strongly support their formulation (see below).

The different behavior of the hydrazine complexes towards oxidation may be explained by taking into account that, whereas coordinated aryldiazenes[1−3] are generally stable and can be easily isolated, 1,2-diazene complexes [M]−NH=NH are rare and few metal fragments are able to stabilize the unstable NH=NH species.[23] Our $[ReH(NO)P_3]$ and $[Re(OR^1)(NO)P_3]$ fragments are not among these, although they are able to stabilize the methyldiazene $CH_3N{=}NH$ giving **7b** and **9b**. Furthermore, the oxidation of methylhydrazine bonded to the $[Re(OCH_3)(NO)P_3]$ fragment with $Pb(OAc)_4$ shows a second example of a new reaction[11] of coordinated methylhydrazine, which can give both methyldiazene and methyleneimine η^1-NH=CH_2 species. This reaction depends on the nature of the metal fragment, and only in the case of the alkoxy precursor $[Re(OCH_3)(CH_3N{=}NH)(NO)P_3]^+$ were both **9b** and **9*b** obtained; with the hydride derivative $[ReH(CH_3N{=}NH)(NO)P_3]^+$ only the formation of methyldiazene **7b** was observed. These results show that the substitution of only one ligand — H^- with OCH_3^- — in the rhenium nitrosyls changes the nature of the reaction course in the oxidation of the methylhydrazine ligand with $Pb(OAc)_4$. Furthermore, a comparison with related carbonyl complexes[11] highlights the fact that both the nitrosyl $[Re(OCH_3)(CH_3NHNH_2)(NO)P_3]^+$ and the carbonyl $[Re(CH_3NHNH_2)(CO)_2P_3]^+$ methylhydrazine derivatives react with $Pb(OAc)_4$ to give a mixture of η^1-NH=CH_2 and $CH_3N{=}NH$ complexes. A different behavior is shown by the hydride-nitrosyl $[ReH(CH_3NHNH_2)(NO)P_3]^+$ cation, which only gives the methyldiazene **7b**. Studies were also carried out to identify the product of the reaction with $Pb(OAc)_4$ in order to obtain information on a possible reaction path giving **9*b**. Unfortunately, apart from acetic acid and traces of NH_3, no other nitrogen-containing products were unambiguously identified in the reaction mixture and therefore no proposal can be made about the mechanism of the reaction, which involves the cleavage of the N−N bond of methylhydrazine to give an η^1-NH=CH_2 species.

Good analytical data were obtained for all the diazene complexes **7**−**9** which are pale-yellow solids stable in air and in solutions of polar organic solvents, where they behave as 1:1 electrolytes.[21] The IR and NMR spectra (Table 1) support the proposed formulation and a geometry in solution was also established. The presence of the diazene ligand is confirmed by the ^1H NMR spectra, which show the characteristic, slightly broad NH signal at δ = 16−18 ppm.

In the ^1H NMR spectra of the complexes $[ReH(RN{=}NH)(NO)P_3]BPh_4$ (**7b**, **7c**) a quadruplet at δ = 3.68−3.67 ppm also appears, which can be attributed to the hydride ligand coupled to the phosphorus nuclei of the phosphanes. This attribution was confirmed by ^1H, ^{31}P NMR spectra and HMQC experiments. The two $J_{P,H}$ coupling constants have the same value of 6 Hz, suggesting that the hydride should be in the same position relative to all the phosphane ligands. It should also be noted that the chemical shifts of the hydride fall at very high frequencies as compared to known rhenium hydrides,[14,15] and this feature may be due to the combined influences of both the diazene and the NO ligands. In the temperature range between +20 and −80 °C the $^{31}P\{^1H\}$ NMR spectra of **7b** and **7c** appear as AB_2 multiplets, in agreement with the presence of two magnetically equivalent phosphanes that are different from the third. These data do not allow us to unambiguously assign a geometry to the complexes. However, further information comes from a comparison of the IR spectra of the diazene compounds **7b** and **7c** with those of the precursors **4b** and **4c**, which shows that the ν_{NO} values are similar for **4b** and **7b** (1683 and 1696 cm^{-1}, respectively) whereas a higher value is found in the phenyldiazene complex $[ReH(C_6H_5N{=}NH)(NO)P_3]BPh_4$ (**7c**) (ν_{NO} = 1736 cm^{-1}) than in the precursor **4c** (1690 cm^{-1}). This high ν_{NO} value for **7c** seems to indicate that the NO ligand is *trans* to a good π-acceptor ligand such as the phosphane and therefore, taking into account the ^1H and the ^{31}P NMR spectra, a geometry such as **V** can be proposed. In the methyldiazene complex **7b** the NO group should be *trans* to a σ-donor ligand as in a type-**VII** geometry.

The IR spectrum of the alkoxy complex $[Re(OC_2H_5)(C_6H_5N{=}NH)(NO)P_3]BPh_4$ (**8c**) shows the ν_{NO} at higher value (1729 cm^{-1}) than its hydrazine precursor **5c** (1685 cm^{-1}) suggesting, also in this case, the mutually *trans* position of NO and one phosphane ligand. Taking into account that the ^{31}P NMR spectra is an A_2B multiplet, a type-**VI** geometry may be proposed.

The IR spectrum of the oxidation product of $[Re(OCH_3)(CH_3NHNH_2)(NO)P_3]BPh_4$ (**6b**) shows two ν_{NO} bands at 1723 and 1650 cm^{-1} and two AB_2 multiplets in the $^{31}P\{^1H\}$ NMR spectra, suggesting the presence of two

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

compounds formulated as a mixture of $[Re(OCH_3)(CH_3N{=}NH)(NO)P_3]^+$ (**9b**) and $[Re(OCH_3)(\eta^1\text{-}NH{=}CH_2)(NO)P_3]^+$ (**9*b**). The ^1H NMR spectra show, besides the phosphane and BPh_4 signals, two slightly broad signals at $\delta = 18.69$ and 15.73 ppm attributed to two NH groups. A singlet at $\delta = 3.73$ ppm and a slightly broad signal at $\delta = 4.05$ ppm are also present. The singlet at $\delta = 3.73$ ppm is correlated to the broad signal at $\delta = 18.69$ ppm (^1H COSY experiment) and can be attributed to the $CH_3N{=}NH$ group. An APT experiment confirmed this attribution. The slightly broad signal at $\delta = 4.05$ ppm is correlated to the proton resonance at $\delta = 15.73$ ppm (^1H COSY) and an APT experiment indicated a CH_2 group attributable to the $CH_2{=}NH$ ligand. The $^{13}C\{^1H\}$ spectra show, besides the signals of the phosphane and BPh_4 anion, two singlets at $\delta = 62.5$ and 64.0 ppm, and HMBC and HMQC experiments allow the attribution of these carbon resonances to the $CH_3N{=}NH$ and $CH_2{=}NH$ groups, respectively, and are thus in agreement with the proposed formulation for the mixture of the two compounds **9b** and **9*b**. These attributions, indeed, are strongly supported by a comparison with the data we previously reported on methyleneimine $[Re(\eta^1\text{-}NH{=}CH_2)(CO)P_4]BPh_4$ and methyldiazene $[Re(CH_3N{=}NH)(CO)P_4]BPh_4$ complexes.[11] In conclusion, although the two compounds **9b** and **9*b** cannot be separated, the strong similarity of their spectroscopic data with those of known complexes[11] supports their proposed formulation.

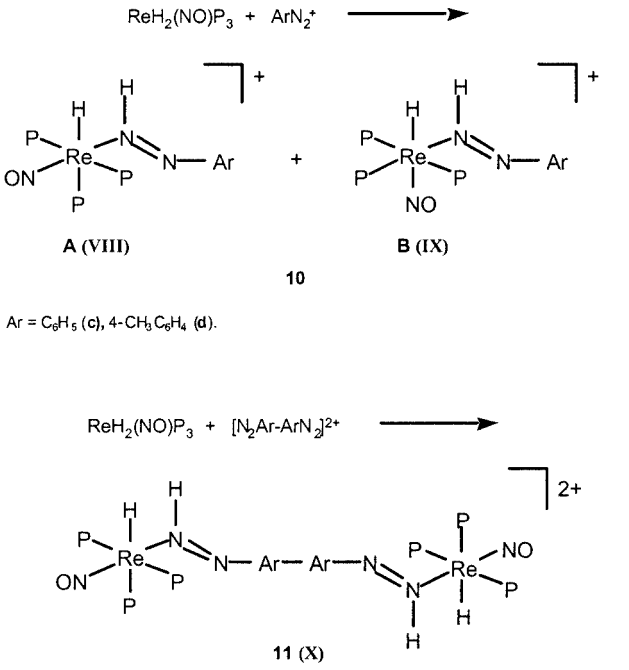
Reactions with Aryldiazonium Cations

The synthesis of the aryldiazene complexes **7c** and **8c** prompted us to test whether analogous compounds can be prepared by the insertion reaction of aryldiazonium cations into the Re−H bond of our hydrides **1**−**3**. The reaction was studied extensively and the results can be summarized in Schemes 8 and 9.

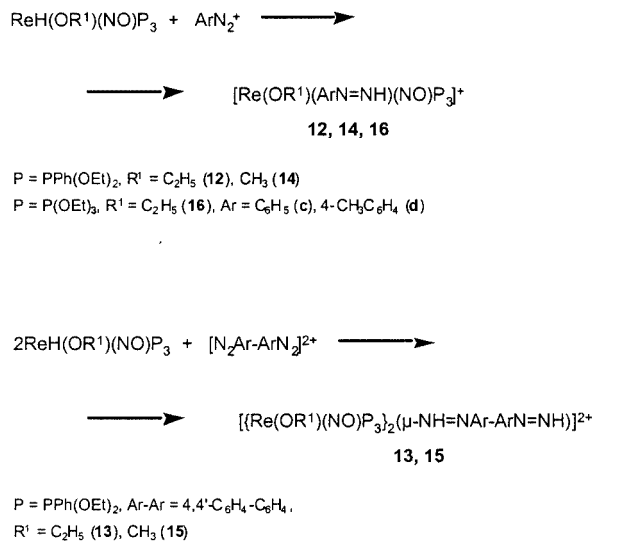
Aryldiazonium cations react quickly with an equimolar amount of dihydride $[ReH_2(NO)P_3]$ to give the aryldiazene complexes **10**, which were isolated and characterized as BPh_4 salts. The reaction was also studied in the presence of an excess of ArN_2^+ to test whether the insertion of two diazonium salts can take place giving bis(aryldiazene) complexes. Although the reaction proceeds, the solid obtained contains several products which decomposed during crystallization and were not separated. The NMR spectra reveal the presence of new diazene complexes besides **10**, but also of large amounts of decomposition products which prevent any further investigation.

Bis(aryldiazonium) cations $[N_2Ar{-}ArN_2]^{2+}$ also react with the hydride $[ReH_2(NO)P_3]$ yielding the binuclear complexes **11** containing the bis(diazene) $NH{=}NAr{-}ArN{=}NH$ as a bridging unit (Scheme 8).

Parallel to the behavior of the dihydride, the hydride-alkoxy complexes $[ReH(OR^1)(NO)P_3]$ also react with both mono- $[ArN_2]^+$ and bis(aryldiazonium) $[N_2Ar{-}ArN_2]^{2+}$ cations to give the corresponding aryldiazene derivatives **12**−**16**, which were isolated and characterized (Scheme 9).



Scheme 8. P = PPh_2OEt



Scheme 9

These results highlight that the same aryldiazene complexes of rhenium (**7c** and **10c**) and (**8c** and **12c**) can be prepared both by the oxidation of the arylhydrazine derivative with $Pb(OAc)_4$ and by the insertion of an aryldiazonium cation into the Re−H bond of the appropriate hydride. The two methods, however, give isomers with a different geometry, as will be discussed below. Furthermore, a comparison of the results obtained in the reaction of our nitrosyl hydrides **1**−**3** with ArN_2^+ with those we[12] previously reported on the carbonyls $[ReH(CO)_nP_{5-n}]$ shows that, in both cases, aryldiazene rhenium complexes can be obtained by "apparent" insertion of aryldiazonium cations into the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Re−H bond of all the hydride species. The reaction seems to be general for both the carbonyl and nitrosyl hydrides yielding stable aryldiazene complexes. Some differences, however, were observed in the reaction with bis(aryldiazonium) salts, which allow, in the case of carbonyls $[ReH(CO)_nP_{5-n}]$ containing the bulky PPh_2OEt ligand, the preparation of "diazo-diazene" $[Re(CO)_nP_{5-n}(HN{=}NAr{-}ArN{\equiv}N)]^{2+}$ (n = 1, 2) derivatives[12] through the insertion of only one end of the $^+N_2Ar{-}ArN_2^+$ ligand with the hydride. The same mononuclear compounds were not obtained with the nitrosyl-hydride $[ReH_2(NO)(PPh_2OEt)_3]$ which gives exclusively binuclear bis(aryldiazene) derivatives, under all conditions.

The aryldiazene complexes **10**, **11**, **14** and **15** were isolated with the BPh_4 anion whereas the ethoxy derivatives **12**, **13** and **16** were obtained as BF_4 salts. All are yellow or pale-yellow solids, stable in air and in solution in polar organic solvents where they behave as 1:1 or 2:1 electrolytes, respectively. Some decomposition was observed for the alkoxy derivatives **12**, **13** and **16** in solutions of ethanol. Analytical and spectroscopic data (Table 1) support the proposed formulation for the complexes and for the hydride-diazene derivatives **10** and **12** a geometry in solution can also be established.

The ^1H NMR spectra of the cations $[ReH(ArN{=}NH)(NO)P_3]^+$ (**10**) show two slightly broad signals in the high-frequency region (δ = 13.84−13.45 ppm) attributed to two diazene protons. This attribution is confirmed by the spectra of the labeled complex **10c$_1$** which show two high-frequency doublets centered at the same chemical shift of the two slightly broad signals of unlabeled **10c** and with a $^1J^{15}_{N,H}$ coupling constant of 65 Hz, in agreement with the presence of two diazene ligands. This is also confirmed by the $^{15}N\{^1H\}$ NMR spectrum of **10c$_1$** which shows two AB_2Y (Y = ^{15}N) multiplets at δ = −2.57 and at δ = −8.70 ppm (Table 4) due to the coupling with the phosphorus nuclei. Because the compounds contain only one aryldiazene ligand, the presence of two NH signal may suggest the existence of two isomers. This was confirmed by the ^{31}P NMR spectra, which show two AB_2 multiplets which can be simulated using the parameters reported in Table 1. The formation of two isomers for **10** is not unexpected due to the chemical non-equivalence of the two hydrides in the $[ReH_2(NO)P_3]$ precursors which give two isomers through the insertion of only one ArN_2^+ into each of the two Re−H bonds. Whether or not an isomerization may be excluded, the insertion should only give the two isomers **A** and **B** (Scheme 8) which were isolated in a 30:70 ratio. This ratio is probably related to the different insertion rate of ArN_2^+ into the two different hydrides.

In the ^1H NMR spectra of **10c** one AB_2X (X = H) multiplet at δ = 2.83 ppm is also present which can be attributed to one of the hydride ligands. The H^- signal of the other isomer probably overlaps the multiplet of the methylene protons, as well as those of **10d**. Furthermore, the ν_{NO} band observed in the IR spectrum appears slightly broad in **10c** and also contains a shoulder in **10d** in agreement with the presence of more nitrosyl compounds. These data confirm the formulation proposed for the hydride-aryldiazene complexes, but do not allow us to unambiguously propose a geometry in solution. However, a comparison of the spectroscopic data of **10c** with those of the related complex **7c** obtained by the oxidation of phenylhydrazine shows different chemical shift values for both the NH proton signals and the ^{31}P nucleus suggesting that the complex **7c** has a geometry that is different from those of the two isomers. Since a geometry of type **V** (Scheme 6) for **7c** had been proposed and the structure of the $[ReH(ArN{=}NH)(NO)P_3]^+$ complex can be discussed in terms of only three geometries, it follows that **VIII** and **XI** should be proposed for the two isomers **A** and **B** of complexes **10**.

The ^1H and ^{31}P NMR spectra of the dinuclear complexes **11** indicate the presence of only one isomer. In fact, only one diazene signal at δ = 13.45 ppm is present in the ^1H NMR spectrum of **11a**, which is split into a doublet with a $^1J^{15}_{N,H}$ coupling constant of 64 Hz in the labeled compound **11a$_1$**. In the ^1H NMR spectrum one AB_2X (X = H) multiplet, simulated with the parameters reported in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 1, is also present which was attributed to the hydride ligand. The two $J_{P,H}$ coupling constants deduced from the spectra have different values of 20.4, 29.4 Hz, respectively, suggesting that the hydride should be in *trans* to one phosphane and *cis* to the other two. In the temperature range between +20 and −80 °C the ^{31}P NMR spectra show only one AB_2 multiplet in agreement with the presence of only one isomer with two magnetically equivalent phosphanes that are different from the third. On the basis of these data a geometry of type **IX** can reasonably be proposed for the binuclear complex **11a**.

The formation of only one isomer with the bis(aryldiazonium) cation may be explained on the basis of the faster insertion rate of the aryldiazonium cation into one of the two Re−H bonds which affords, in the case of the dinuclear complexes, only traces of the other isomers that were discarded by crystallization.

The ^1H NMR spectra of the alkoxy complexes **12**−**16** confirm the presence of the diazene ligand showing the characteristic high-frequency NH signal which splits into a doublet in the ^{15}N-labeled complexes (Table 1). In the spectra the characteristic resonance of the alkoxy OR^1 ligand is also present, along with the signals of the phosphane and BPh_4 anion. The $^{31}P\{^1H\}$ NMR spectra show, for some complexes, the presence of only one AB_2 multiplet, while two AB_2 multiplets are present in the spectra of **13**, **14** and **15**, suggesting the probable presence of two isomers. These data support the proposed formulation for the complexes but, in the absence of an X-ray determination, do not allow us to unambiguously propose a geometry in solution for these aryldiazene derivatives.

Conclusion

In this contribution we have reported the synthesis of new rhenium nitrosyl hydrides of the $[ReH_2(NO)P_3]$ and $[ReH(OR^1)(NO)P_3]$ type containing both phosphane and alkoxy groups as supporting ligands. Their protonation with Brønsted acids allows thermally unstable η^2-H_2 complexes to be obtained. Both classical and non-classical rhenium hydrides behave with an easy entry into "diazo" chemistry and allow the synthesis of the first hydrazine and diazene complexes stabilized by nitrosyl ligands. The structural parameters for one hydrazine complex, $[Re(OC_2H_5)(NH_2NH_2)(NO)\{PPh(OEt)_2\}_3]BPh_4$, are also reported. Reactivity studies also show that aryldiazene $[ReH(ArN{=}NH)(NO)P_3]BPh_4$ and $[Re(OR^1)(ArN{=}NH)(NO)P_3]BPh_4$ complexes can be prepared both by insertion of an aryldiazonium cation into the Re−H bond of an appropriate hydride and by the oxidation of the related arylhydrazine derivatives with $Pb(OAc)_4$. Furthermore, the oxidation of the methylhydrazine complex $[Re(OCH_3)(CH_3NHNH_2)(NO)\{PPh(OEt)_2\}_3]BPh_4$ with $Pb(OAc)_4$ shows a new example of formation of a methyleneimine $[Re(OCH_3)(\eta^1\text{-}NH{=}CH_2)(NO)\{PPh(OEt)_2\}_3]BPh_4$ derivative.

Experimental Section

General: All synthetic work was carried out under an inert atmosphere using standard Schlenk techniques or in a Vacuum Atmospheres dry box. Once isolated, the complexes were found to be relatively stable in air, but were stored under an inert atmosphere at −25 °C. All solvents were dried over appropriate drying agents, degassed on a vacuum line and distilled into vacuum-tight storage flasks. The phosphanes $PPh(OEt)_2$ and PPh_2OEt were prepared by the method of Rabinowitz and Pellon,[24] whereas $P(OEt)_3$ was an Aldrich product, purified by distillation under nitrogen. Diazonium salts were obtained in the usual way.[25] The related di-diazonium salts $[N_2Ar{-}ArN_2](BF_4)_2$ (Ar−Ar = 4,4′-C_6H_4-C_6H_4) were prepared by treating the amine precursors H_2NAr-$ArNH_2$ with $NaNO_2$ as described in the literature for the common monodiazonium salts.[25] The labeled diazonium tetrafluoroborate $[C_6H_5N{\equiv}^{15}N]BF_4$ and $[4,4'\text{-}^{15}N{\equiv}NC_6H_4{-}C_6H_4N{\equiv}^{15}N](BF_4)_2$ were prepared from $Na^{15}NO_2$ (99% enriched, CIL) and the appropriate amine. The hydrazines $C_6H_5NHNH_2$, $C_6H_5CONHNH_2$ and CH_3NHNH_2 were Aldrich products and used as received. Hydrazine (NH_2NH_2) was prepared by decomposition of hydrazine cyanurate (Fluka) following the reported method.[26] High-grade (99.99%) lead(IV) acetate was purchased from Aldrich. Other reagents were purchased from commercial sources in the highest available purity and used as received. Infrared spectra were recorded on a Nicolet Magna 750 FT-IR spectrophotometer. NMR spectra (^1H, ^{13}C, ^{31}P, ^{15}N) were obtained on Bruker AC200 or Avance 300 spectrometers at temperatures varying between −90 and +30 °C, unless otherwise noted. ^1H and ^{13}C chemical shifts are referenced to internal tetramethylsilane, while $^{31}P\{^1H\}$ chemical shifts are reported with respect to 85% H_3PO_4, with downfield shifts considered positive. ^{15}N NMR spectra are referenced to external $CH_3{}^{15}NO_2$, with downfield shifts considered positive. The SwaN-MR software package[27] was used to treat NMR spectroscopic data. The conductivities of 10^{-3} M solutions of the complexes in CH_3NO_2 at 25 °C were measured with a Radiometer CDM 83 instrument.

Synthesis of Complexes: $[ReCl_2(OCH_3)(NO)(PPh_3)_2]$ was prepared following a reported method.[15a]

$[ReH_2(NO)(PPh_2OEt)_3]$ (1): An excess of PPh_2OEt (2.05 mL, 8.9 mmol) and then an excess of $NaBH_4$ (0.404 g, 10.68 mmol) in 15 mL of ethanol were added to a suspension of $[ReCl_2(OCH_3)(NO)(PPh_3)_2]$ (1.5 g, 1.78 mmol) in 30 mL of ethanol. Upon refluxing the reaction mixture both a color change of the solution from red-brown to yellow and the separation of a yellow solid were observed. After about 90 min of reflux the mixture was cooled and the solid obtained was filtered and crystallized from CH_2Cl_2 and ethanol; yield 1.34 g (83%). $C_{42}H_{47}NO_4P_3Re$ (908.96): calcd. C 55.5, H 5.2, N 1.5; found C 55.7, H, 5.3, N 1.4.

$[ReH(OC_2H_5)(NO)P_3]$ (2) [P = $PPh(OEt)_2$ (a), $P(OEt)_3$ (b)]: An excess of the appropriate phosphane (12 mmol) and then an excess of $NaBH_4$ (0.45 g, 12 mmol) in 15 mL of ethanol were added to a suspension of $[ReCl_2(OCH_3)(NO)(PPh_3)_2]$ (2 g, 2.37 mmol) in 45 mL of ethanol. The reaction mixture was refluxed for 1 h, cooled to room temperature, filtered and concentrated to about 20 mL by evaporation of the solvent under reduced pressure. At this point, the method to obtain solid samples of the complexes depends on the nature of the phosphane ligand. In the case of $PPh(OEt)_2$ yellow crystals of **2a** were obtained by cooling the resulting solution to −25 °C. These were filtered and dried under vacuum. In the case of $P(OEt)_3$, the solid obtained by cooling the solution to −25 °C gave PPh_3. Finally, by further concentrating

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and cooling of the solution, yellow crystals of **2b** separated out, which were filtered and dried under vacuum; yield 1.58 g for **2a** (78%); 0.36 g for **2b** (20%).
2a: $C_{32}H_{51}NO_8P_3Re$ (856.88): calcd. C 44.9, H 6.0, N 1.6; found C 44.7, H 6.0, N 1.5.
2b: $C_{20}H_{51}NO_{11}P_3Re$ (760.74): calcd. C 31.6, H 6.8, N 1.8; found C 31.4, H 6.9, N 1.8.

[ReH(OCH$_3$)(NO){PPh(OEt)$_2$}$_3$] (3): An excess of $PPh(OEt)_2$ (2.76 g, 12 mmol) and then an excess of $NaBH_4$ (0.45 g, 12 mmol) in 20 mL of CH_3CN were added to a solution of $[ReCl_2(OCH_3)(NO)(PPh_3)_2]$ (2 g, 2.37 mmol) in 30 mL of CH_3CN. The reaction mixture was refluxed for about 2 h and then the solvent was removed by evaporation under reduced pressure. The oil obtained was treated with 8 mL of ethanol and the resulting solution, after filtration, was allowed to stand at −25 °C. A yellow-green solid slowly separated out which was filtered and crystallized from CH_2Cl_2 and ethanol; yield 1.04 g (52%). $C_{31}H_{49}NO_8P_3Re$ (842.85): calcd. C 44.2, H 5.9, N 1.7; found C 44.3, H 5.7, N 1.6.

[ReH(RNHNH$_2$)(NO)(PPh$_2$OEt)$_3$]BPh$_4$ (4) [R = H (a), CH$_3$ (b), C$_6$H$_5$ (c)]: An equimolar amount of CF_3SO_3H (9.7 μL, 0.11 mmol) was added to a solution of $[ReH_2(NO)(PPh_2OEt)_3]$ (100 mg, 0.11 mmol) in 8 mL of CH_2Cl_2 cooled to −196 °C. The reaction mixture was warmed to about −10 °C, stirred for 1 h and then an excess of the appropriate hydrazine (0.22 mmol) was added. After two hours of stirring at −10 °C, the solvent was removed under reduced pressure to give an oil which was treated with ethanol (2 mL) containing an excess of $NaBPh_4$ (75 mg, 0.22 mmol). A yellow solid slowly separated out from the resulting solution which was filtered and crystallized from CH_2Cl_2 and ethanol; yield 93 mg for **4a** (67%), 91 mg for **4b** (65%), 100 mg for **4c** (98%).
4a: $C_{66}H_{70}BN_3O_4P_3Re$ (1259.2): calcd. C 63.0, H 5.6, N 3.3; found C 63.2, H 5.7, N 3.2. Λ_M = 48.7 Ω^{-1} mol^{-1} cm^2.
4b: $C_{67}H_{72}BN_3O_4P_3Re$ (1273.3): calcd. C 63.2, H 5.7, N 3.3; found C 63.0, H 5.6, N 3.2. Λ_M = 51.8 Ω^{-1} mol^{-1} cm^2.
4c: $C_{72}H_{74}BN_3O_4P_3Re$ (1335.3): calcd. C 64.8, H 5.6, N 3.2; found C 64.6, H 5.7, N 3.1. Λ_M = 50.3 Ω^{-1} mol^{-1} cm^2.

[Re(OC$_2$H$_5$)(RNHNH$_2$)(NO){PPh(OEt)$_2$}$_3$]BPh$_4$ (5) [R = H (a), C$_6$H$_5$ (c)]: An equimolar amount of CF_3SO_3H (10.3 μL, 0.117 mmol) was added to a solution of $[ReH(OC_2H_5)(NO)\{PPh(OEt)_2\}_3]$ (100 mg, 0.117 mmol) in 8 mL of CH_2Cl_2 cooled to −196 °C and the reaction mixture brought to 0 °C and stirred for 1 h. The solution was cooled to −196 °C again and an excess of the appropriate hydrazine (0.24 mmol) added. The reaction mixture was brought to 0 °C, stirred for about 2 h and then the solvent removed under reduced pressure. The solid obtained was treated with ethanol (3 mL) containing an excess of $NaBPh_4$ (85 mg, 0.25 mmol). A pale-yellow solid slowly separated out from the resulting solution, which was filtered and crystallized from CH_2Cl_2 and ethanol; yield 80 mg for **5a** (55%), 86 mg for **5c** (58%).
5a: $C_{56}H_{74}BN_3O_8P_3Re$ (1207.2): calcd. C 55.7, H 6.2, N 3.5; found C 55.5, H 6.3, N 3.5. Λ_M = 49.5 Ω^{-1} mol^{-1} cm^2.
5c: $C_{62}H_{78}BN_3O_8P_3Re$ (1283.2): calcd. C 58.0, H 6.1, N 3.3; found C 57.8, H 6.0, N 3.3. Λ_M = 51.4 Ω^{-1} mol^{-1} cm^2.

[Re(OC$_2$H$_5$)(CH$_3$NHNH$_2$)(NO){PPh(OEt)$_2$}$_3$]CF$_3$SO$_3$ (5b$_2$): This complex was prepared following the method used for the related BPh_4 complex **5a** by reacting $[ReH(OC_2H_5)(NO)\{PPh(OEt)_2\}_3]$ first with CF_3SO_3H and then with an excess of CH_3NHNH_2 in CH_2Cl_2 as a solvent. After the reaction was finished, the solvent was removed under reduced pressure to give a pale-yellow solid which was triturated with ethanol (1.5 mL). A yellow solid slowly separated out from the resulting solution, which was cooled to −25 °C to complete the precipitation. The solid was filtered, washed with cold ethanol and dried under vacuum; yield 52 mg (42%). $C_{34}H_{56}F_3N_3O_{11}P_3ReS$ (1051.01): calcd. C 38.9, H 5.4, N 4.0; found C 39.0, H 5.5, N 3.9. Λ_M = 78.5 Ω^{-1} mol^{-1} cm^2.

[Re(OCH$_3$)(RNHNH$_2$)(NO){PPh(OEt)$_2$}$_3$]BPh$_4$ (6) [R = H (a), CH$_3$ (b), C$_6$H$_5$ (c)]: These complexes were prepared exactly like the related ethoxy complexes **5a** and **5c** by reacting $[ReH(OCH_3)(NO)\{PPh(OEt)_2\}_3]$ first with CF_3SO_3H and then with an excess of the appropriate hydrazine. After precipitation with $NaBPh_4$ in ethanol, the yields were 95 mg for **6a** (65%), 89 mg for **6b** (63%) and 101 mg for **6c** (68%).
6a: $C_{55}H_{72}BN_3O_8P_3Re$ (1193.1): calcd. C 55.4, H 6.1, N 3.5; found C 55.2, H 6.0, N 3.5. Λ_M = 54.8 Ω^{-1} mol^{-1} cm^2.
6b: $C_{56}H_{74}BN_3O_8P_3Re$ (1207.2): calcd. C 55.7, H 6.2, N 3.5; found C 55.6, H 6.3, N 3.4. Λ_M = 53.3 Ω^{-1} mol^{-1} cm^2.
6c: $C_{61}H_{76}BN_3O_8P_3Re$ (1269.2): calcd. C 57.7, H 6.0, N 3.3; found C 57.9, H 6.2, N 3.3. Λ_M = 49.6 Ω^{-1} mol^{-1} cm^2.

[ReH(CH$_3$N=NH)(NO)(PPh$_2$OEt)$_3$]BPh$_4$ (7b) and [ReH(C$_6$H$_5$N=NH)(NO)(PPh$_2$OEt)$_3$]BPh$_4$ (7c): A sample of the appropriate hydrazine complex $[ReH(RNHNH_2)(NO)(PPh_2OEt)_3]BPh_4$ (**4**) (R = CH_3 or C_6H_5; 0.07 mmol) was placed in a three-necked 25-mL round-bottomed flask fitted with a solid-addition sidearm containing an equimolar amount of $Pb(OAc)_4$ (31 mg, 0.07 mmol). The system was evacuated, CH_2Cl_2 (10 mL) was added, the solution cooled to −30 °C and the $Pb(OAc)_4$ was added portionwise over 10−20 min. The reaction mixture was then allowed to warm to 0 °C, stirred for 10 min and the solvent removed under reduced pressure. The oil obtained was treated at 0 °C with ethanol (2 mL) containing $NaBPh_4$ (34 mg, 0.10 mmol). A white solid slowly separated out upon stirring the resulting solution at 0 °C, which was filtered and crystallized at 0 °C from CH_2Cl_2 and ethanol; yield 64 mg for **7b** (72%) and 65 mg for **7c** (70%).
7b: $C_{67}H_{70}BN_3O_4P_3Re$ (1271.2): calcd. C 63.3, H 5.6, N 3.3; found C 63.1, H 5.4, N 3.2. Λ_M = 49.9 Ω^{-1} mol^{-1} cm^2.
7c: $C_{72}H_{72}BN_3O_4P_3Re$ (1333.3): calcd. C 64.9, H 5.4, N 3.2; found C 64.6, H 5.3, N 3.0. Λ_M = 52.1 Ω^{-1} mol^{-1} cm^2.

[Re(OC$_2$H$_5$)(C$_6$H$_5$N=NH)(NO){PPh(OEt)$_2$}$_3$]BPh$_4$ (8c): This complex was prepared exactly like the related complexes **7** by oxidation of the phenylhydrazine derivative $[Re(OC_2H_5)(C_6H_5NHNH_2)(NO)\{PPh(OEt)_2\}_3]BPh_4$ (**5c**) with $Pb(OAc)_4$ at −30 °C; yield 56 mg (62%). $C_{62}H_{76}BN_3O_8P_3Re$ (1281.2): calcd. C 58.1, H 6.0, N 3.3; found C 57.9, H 6.1, N 3.2. Λ_M = 52.0 Ω^{-1} mol^{-1} cm^2.

[Re(OCH$_3$)(CH$_3$N=NH)(NO){PPh(OEt)$_2$}$_3$]BPh$_4$ (9b) and [Re(OCH$_3$)(η^1-NH=CH$_2$)(NO){PPh(OEt)$_2$}$_3$]BPh$_4$ (9*b): These complexes were obtained as a mixture by oxidation of the methylhydrazine compound $[Re(OCH_3)(CH_3NHNH_2)(NO)\{PPh(OEt)_2\}_3]BPh_4$ (**6b**) with $Pb(OAc)_4$ at −30 °C following the method used for the related **7** and **8** complexes.

[ReH(ArN=NH)(NO)(PPh$_2$OEt)$_3$]BPh$_4$ (10) [Ar = C$_6$H$_5$ (c), 4-CH$_3$C$_6$H$_4$ (d)]: Solid samples of $[ReH_2(NO)(PPh_2OEt)_3]$ (0.1 g, 0.11 mmol) and the appropriate aryldiazonium salt $[ArN_2]BF_4$ (0.11 mmol) were placed into a 25-mL three-necked round-bottomed flask. The mixture was cooled to −196 °C and CH_2Cl_2 (8 mL) slowly added. The reaction mixture was allowed to warm to room temperature, stirred for about 8 h and then the solvent removed under reduced pressure. The oil obtained was treated with ethanol (2 mL) containing an excess of $NaBPh_4$ (75 mg, 0.22 mmol). A yellow solid slowly separated out from the resulting solution which was filtered and crystallized from CH_2Cl_2 and ethanol; yield 107 mg for **10c** (73%) and 105 mg for **10d** (71%).

Protonation Reactions: The protonation of the hydrides [ReH_2(NO)(PPh_2OEt)$_3$] (**1**) and [ReH(OR^1)(NO)P_3] (**2**, **3**) was carried out in a 5-mm NMR tube at temperatures of between −80 and +20 °C. A typical experiment involved the preparation, in an argon-filled dry-box, of a solution of the appropriate hydride (0.04 mmol) in CD_2Cl_2 (0.5 mL). The solution was placed in a screw-cap NMR tube, cooled to −80 °C, and then an equivalent amount (0.04 mmol, 3.5 μL) of CF_3SO_3H was added. The tube was transferred into the NMR probe (pre-cooled to −80 °C) and the ^{1}H and ^{31}P NMR spectra of the solution were recorded.

X-ray Crystal Structure Determination of [Re(OC_2H_5)-(NH_2NH_2)(NO){PPh(OEt)$_2$}$_3$]BPh_4 (5a): A pale-yellow single crystal was mounted on a glass fiber and X-ray diffraction data were collected on a Bruker-Siemens SMART AXS 1000 equipped with CCD detector, using graphite monochromated Mo-K_α radiation (λ = 0.71069 Å). Data collection details are: crystal to detector distance = 5.0 cm, 2424 frames collected (complete sphere mode), time per frame = 30 s, oscillation Δω = 0.300°. Crystal decay resulted negligible. Data reduction was performed up to d = 0.90 Å with the SAINT package[28] and data were corrected for absorption effects by the SADABS[29] procedure (T_{max} = 1.000, T_{min} = 0.746). The phase problem was solved by direct methods[30] and refined by full-matrix least-squares on all F^2,[31] implemented in the WinGX package.[32] Anisotropic displacement parameters were refined for all non hydrogen atoms, while hydrogen atoms were introduced in calculated positions, except for hydrazine hydrogens, which were located from Fourier maps and refined isotropically. Use of the Cambridge Crystallographic Database[33] facilities was made for

Keywords: Cations / Density functional calculations / Ligand Effects / Phosphorus / Zirconium

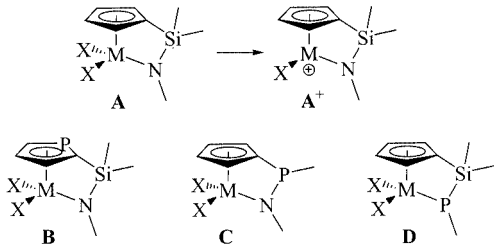
Density functional calculations are reported for the neutral and cationic forms of the "CpPN" zirconium complexes **E** and **F** featuring a phosphazene and phosphinimido pendant arm, respectively.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The past 15 years have witnessed tremendous developments in the design and application of non-metallocene complexes as olefin polymerization catalysts.[1] Spectacular achievements have been reported for the *ansa*-monocyclopentadienylsilylamido group IV catalysts, initially developed by Bercaw[2a] and Okuda,[2b] the so-called constrained-geometry catalysts (CGC) **A** (Scheme 1). Abstraction of one of the X ligands surrounding the metal centre provides the corresponding unsaturated d^0 cationic complexes $\mathbf{A}^+$ that are generally agreed to be the catalytically active species in olefin polymerization.[3] The applications of CGC catalysts are based not only on their electronic unsaturation, but also on their sterically unhindered reactive sites, combined with rigidity of the molecular framework and thermal stability. Of special interest is that the coordination of linear α-olefins is facilitated, allowing for their incorporation into polyethylene.

Numerous structural analogues of the initial "CpSiN" catalyst **A** have already been investigated by varying the nature of the cyclopentadienyl ligand,[4] the bridging unit,[5] the metal substituents[6] and/or by replacing the amido group with another type of donor.[7–9] Although phosphorus-containing complexes such as **B**–**D** have attracted considerable attention,[10] the incorporation of a phosphazene or phosphinimido unit in constrained-geometry



Scheme 1. Structure of "CpSiN" complexes **A** and $\mathbf{A}^+$ and representative examples of related phosphorus-containing systems **B**–**D**

complexes has not yet been investigated. These phosphorus-containing nitrogen-based moieties are, however, common ligands for transition metals, whose properties can be readily be tuned by varying their substituents. Due to the highly polarized $N^{\delta-}P^{\delta+}$ bond, phosphazenes ($R_3P{=}NR$)[11] are rather "hard" sp^2-nitrogen donors that have recently been successfully involved in ethylene oligomerisation[12a] as well as asymmetric cyclopropanation[12b,12c] and allylic substitution.[12d] Phosphinimido ligands ($R_3P{=}N^-$)[13] possess a particularly versatile coordination chemistry. Their coordination to a single transition metal can involve from two to six electrons and result in linear as well as bent geometries. Their analogy with cyclopentadienyl ligands has been pointed out by Dehnicke[14] and has been investigated by Stephan and co-workers for group IV complexes.[15]

Here we report the theoretical investigation of two new "CpPN" models **E** and **F** (Scheme 2), featuring a pendant phosphazene and phosphinimido unit, respectively. DFT calculations were performed in order to determine if these constrained-geometry complexes deserve to be studied experimentally. For both models, the geometries of the neutral complexes as well as of their cationic analogues (derived by

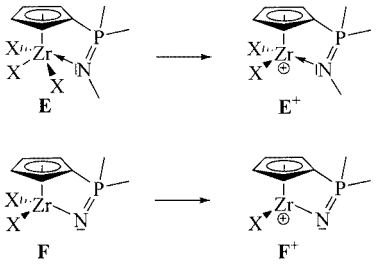
halide abstraction) were optimized. The resulting structural data and charges are discussed and compared with those of a model silicon-based complex of type **A**. During this study, particular emphasis has been placed upon the coordination of the phosphazene arm as well as substituent effects in complexes **E**.



Scheme 2. Structure of the phosphazene- and phosphinimido-based constrained geometry complexes **E** and **F**

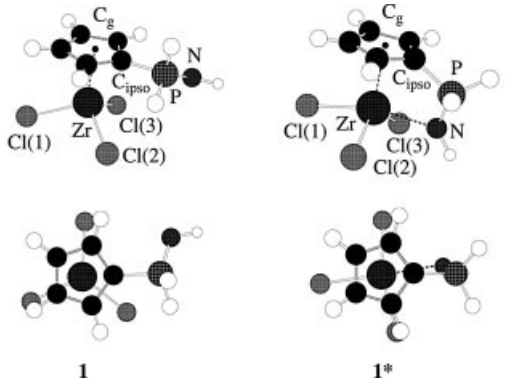
Results and Discussion

Complexes featuring a pendant phosphazene unit were first investigated both in the parent form and for various substitution patterns. Replacement of the phosphazene unit by a phosphinimido moiety was then studied for the parent form. For both model complexes, halide dissociation was evaluated geometrically and energetically.

Complexes Featuring a Pendant Phosphazene Unit $[R_2P(\eta^5\text{-}C_5H_4)(R'N)ZrX_3]$ and $[R_2P(\eta^5\text{-}C_5H_4)(R'N)ZrX_2]^+$

Parent Complex $[H_2P(\eta^5\text{-}C_5H_4)(HN)ZrCl_3]$ (1)

Two energy minima were located on the potential energy hypersurface. The corresponding complexes **1** and **1*** are represented in Scheme 3, and selected geometric parameters are collected in Table 1.

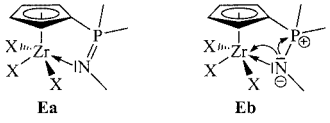


Scheme 3. Schematic representation (side and top views) of the B3LYP-optimized geometry of complexes **1** and **1***

In complex **1**, the phosphazene arm is in a position *cis* to the metal centre relative to the cyclopentadienyl ring (Cp) (torsion angle $Zr-C_{ipso}-P-N$: 64.0° where C_{ipso} is the substituted carbon of the Cp ring), but not coordinated to the zirconium centre, as indicated by the Zr−N distance (4.085 Å). The environment around the zirconium centre is very similar to that of the model complex $[CpZrCl_3]$ (**2**), which is a more or less distorted tetrahedral geometry ("three-legged piano-stool"). As expected, the distance between the centroid (C_g) of the Cp ring and the metallic centre (2.265 Å) is almost identical (2.242 Å) to that observed for **2**.

The geometric parameters predicted for complex **1*** clearly indicate the rotation of the phosphazene arm (torsion angle $Zr-C_{ipso}-P-N$: 10.9°) and the presence of a Zr−N interaction. Considering the centroid (C_g), the three chlorides and the nitrogen atom, the environment around the metal can be depicted by a pseudo-square-pyramidal ("four-legged piano-stool"[16]) or trigonal bipyramidal structure. The constrained-geometry structure is indicated by the pyramidalization of C_{ipso} (sum of the bond angles Σ = 352.9° and $C_g-C_{ipso}-P$ angle = 158.1°). As a consequence, the C_g-Zr distance for **1*** (2.341 Å) is significantly longer than that predicted for **1** (2.265 Å). The Zr−Cl distances are also elongated (**1***: 2.425 Å on average; **1**: 2.373 Å), but there is no preferential elongation of the Zr−Cl bond in a position *trans* to the phosphazene unit in **1*** (2.432 Å). The N−Zr bond (2.357 Å) is notably longer than that predicted for the unconstrained complex $[CpZrCl_3(HN{=}PH_3)]$ (**3**) (2.252 Å) and the N−P bond length in **1*** (1.613 Å) is half-way between those of **1** (1.587 Å) and **3** (1.633 Å). All these data suggest only a weak coordination of the pendant arm.

The bonding interaction between the phosphazene and transition metal can be represented by two schematic forms **Ea** and **Eb** (Scheme 4). The phosphazene behaves only as a σ-donor in **Ea**, but both as a σ- and π-donor in **Eb**.[17] The contribution of both σ- and π-type interactions in **1*** is clearly apparent from the appropriate orbitals localized according to the Boys method[18] (Scheme 5).



Scheme 4. Schematic representations of complex **E**

Scheme 5. Isosurfaces for the localized molecular orbitals associated with σ and π N−Zr overlaps

The coordination strength of the phosphazene arm may be estimated by the energy difference between **1** and **1***. The

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

phosphazene coordination was found to be favoured by ca. 8.4 kcal/mol[19] (free enthalpy difference at 298 K, taking into account the vibrational and entropic corrections). This rather small value might result from the geometric constraint associated with the phosphazene coordination, or alternatively can be inherent to the coordination of the phosphazene to the $CpZrCl_3$ fragment. The latter hypothesis is supported by the only slightly larger value predicted for the coordination of the parent phosphazene $HN{=}PH_3$ to $CpZrCl_3$ leading to the unconstrained complex $[CpZrCl_3(HN{=}PH_3)]$ (**3**; free enthalpy difference of 10.2 kcal/mol).

Substituent Effects: Complexes [$R_2P(\eta^5\text{-}C_5H_4)(R'N)\text{-}ZrX_3$] (4−7)

Variation of the halide, phosphorus and nitrogen substituents was first investigated separately by geometry optimizations of complexes **4**-R, **5**-R′ and **6**. For each complex, two energy minima were located on the potential energy hypersurface. The following discussion will be focussed on structures **4***−**6*** featuring a phosphazene-zirconium interaction (Table 2). The C_{ipso} pyramidalization and $C_g{-}C_{ipso}{-}P$ bond angles are very similar in all complexes, suggesting that the geometric constraint is imposed by the framework and is essentially unaffected by the substituents. More significant modifications are observed for the Zr−N and N−P bond lengths. As far as the phosphorus substituents are concerned (complexes **4***-R), the Zr−N bond length decreases and the P−N bond length increases in the series $Cl/H/NH_2/CH_3/C_6H_5$. The pronounced P−N bond shortening and Zr−N distance elongation on going from H to Cl can readily be related to the strong electron-withdrawing inductive effect (-I) of the chlorine atoms, which significantly decreases the electron density at the nitrogen[20] and thus weakens the phosphazene-zirconium interaction. In contrast, the NH_2 (+M), CH_3 (+I) and C_6H_5 (+M) donor substituents (+M and +I for electron-donating mesomeric and inductive effects, respectively) increase the $N^{\delta-}P^{\delta+}$ polarity of the P=N bond[20] and thereby reinforce the phosphazene coordination. With regard to the nitrogen substituents, almost no structural modifications were observed with a methyl group, whereas introduction of an amino group induces a shortening of the Zr−N distance and an elongation of the P−N bond length. By analogy with that discussed for the phosphorus substituents, these modifications can be related to the +M effect of the amino group. Lastly, replacement of the chlorine by iodine atoms at zirconium (complex **6***) results in only negligible geometric modifications.

Susbtituent effects on the coordination strength of the phosphazene arm were then evaluated quantitatively. For all complexes **4**−**6**, except **4**-NH_2 (see below), the second minimum located on the energy surface is strongly related to **1**, with no interaction between the phosphazene and zirconium centre. As discussed previously, the coordination energy was thus obtained from the free enthalpy energy difference between the two energy minima (Table 3).

No energy minimum without interaction could be located for R = NH_2. Indeed, a stabilizing interaction between the

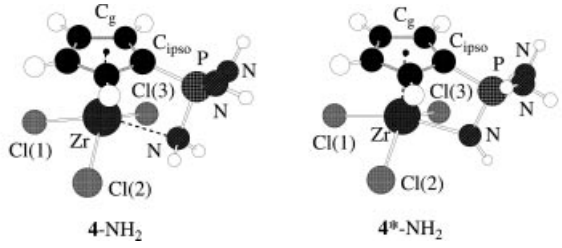
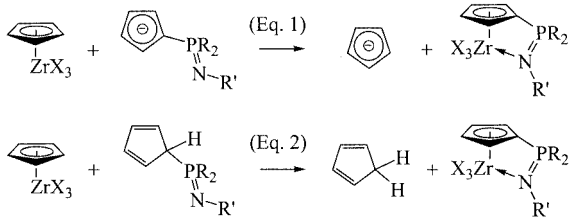
[a] Method 1 refers to the energy difference between the two energy minima, with and without an N−Zr interaction. [b] Methods 2 and 3 refer to the isodesmic reactions 1 and 2, respectively.

zirconium centre and one of the amino substituents at the phosphorus was observed for **4**-NH_2 (Scheme 6). As a consequence, the coordination strength cannot be accurately estimated in this case by the energy difference between **4**-NH_2 and **4***-NH_2.



Scheme 6. Schematic representation of the B3LYP-optimized geometry of complexes **4**-NH_2 and **4***-NH_2

To circumvent this difficulty, we chose to evaluate the coordination energies through an isodesmic reaction.[21,22] The coordination exchange between the anionic ligands $(Cp)^-$ and $(Cp-PR_2=NR')^-$ was investigated first [Equation (1)]. The coordination was found to be endothermic $\{\Delta_rG°_{N-Zr\ interaction}$ [Equation (1)] $> 0\}$ and the predicted values differ significantly from those obtained previously (Table 3). This divergence has tentatively been attributed to an electronic delocalization phenomenon, $C_{ipso} \rightarrow P$, within $(Cp-PR_2=NR')^-$. To confirm this hypothesis, coordination exchange between the corresponding neutral (protonated) ligands was then investigated [Equation (2)]. The resulting $\Delta_rG°_{N-Zr\ interaction}$ [Equation (2)] values are now in very good agreement with those obtained previously (Method 1). Methods 1 and 3 differ significantly only in the case of **4***-Cl, the value of $\Delta_rG°_{N-Zr\ interaction}$ [Equation (2)] having probably been overestimated in this case due to the strong −I effect of the chlorine atoms. For all other complexes, these two methods are almost perfectly correlated (slope: 0.97, correlation factor: 0.984), so that the coordination energy for R = NH_2 estimated using Equation (2) (14.4 kcal/mol) is likely to be reliable.



The value of $\Delta_rG°_{N-Zr\ interaction}$ was found to be negative for all complexes **4***−**6*** (from −16.9 to −2.5 kcal/mol). However, the phosphazene-zirconium interaction weakens significantly when chlorine atoms are introduced at phosphorus (**4***-Cl: −2.5 kcal/mol compared to −8.4 kcal/mol for **1***), in agreement with previously discussed structural modifications. To a first approximation, the values of $\Delta_rG°_{N-Zr\ interaction}$ are inversely proportional to the Zr−N bond lengths. Indeed, the substituents that induce the shorter Zr−N distances (NH_2, CH_3 and C_6H_5 at phosphorus, NH_2 at nitrogen) are associated with the larger coordination strengths (**4***-NH_2: 14.4, **4***-CH_3: 14.7, **4***-C_6H_5: 16.9, **5***-NH_2: 15.8 kcal/mol).

A more sophisticated complex was then studied in order to determine whether the various substituents have additive effects or not. A combination of iodine at zirconium, phenyl at phosphorus and methyl at nitrogen (complex **7***) results in the shortest N−Zr bond length (2.245 Å) and longest N−P bond length (1.639 Å) among all the complexes investigated (Table 2). The corresponding value of $\Delta_rG°_{N-Zr\ interaction}$ (given by the energy difference between **7** and **7*** i.e. 19.5 kcal/mol) is more than twice as large as that for the parent complex (Table 3). This result suggests that the various substituents indeed have additive effects. This is further corroborated by the validity of Equation (3), in which the overall substituent effect in **7*** is expressed by the combination of related single-site terms (20.1 kcal/mol).

$$\Delta_r G^\circ_{\text{N-Zr interaction}}(\mathbf{7^*}) \approx \Delta_r G^\circ_{\text{N-Zr interaction}}(\mathbf{1^*}) + \Delta_r G^\circ_{\text{effect}}(C_6H_5) + \Delta_r G^\circ_{\text{effect}}(CH_3) + \Delta_r G^\circ_{\text{effect}}(I) \quad \text{(Eq. 3)}$$

with $\Delta_r G^\circ_{\text{effect}}(C_6H_5) = \Delta_r G^\circ_{\text{N-Zr interaction}}(\mathbf{4^*}\text{-}C_6H_5) - \Delta_r G^\circ_{\text{N-Zr interaction}}(\mathbf{1^*})$,

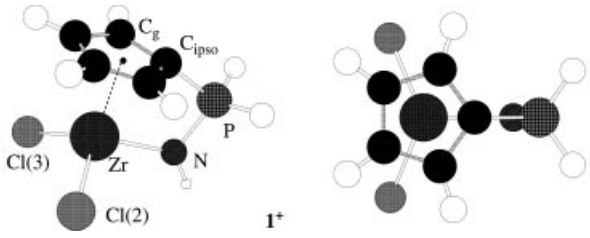
$\Delta_r G^\circ_{\text{effect}}(CH_3) = \Delta_r G^\circ_{\text{N-Zr interaction}}(\mathbf{5^*}\text{-}CH_3) - \Delta_r G^\circ_{\text{N-Zr interaction}}(\mathbf{1^*})$,

$\Delta_r G^\circ_{\text{effect}}(I) = \Delta_r G^\circ_{\text{N-Zr interaction}}(\mathbf{6^*}) - \Delta_r G^\circ_{\text{N-Zr interaction}}(\mathbf{1^*})$.

Cationic Complexes $[R_2P(\eta^5\text{-}C_5H_4)(R'N)ZrX_2]^+$ (1^+ and 4^+-7^+)

Calculations were then performed on the cationic complexes obtained by dissociation of one of the halides. The coordination of the phosphazene arm is strongly favoured here by the high electrophilicity of the metallic centre. Accordingly, a single minimum was located on the energy hypersurface for the parent system $\mathbf{1^+}$ (Scheme 7, Table 4). The zirconium centre adopts a pseudo-tetrahedral geometry with C_s symmetry (planar environment around the nitrogen atom and eclipsed conformation of the phosphazene arm: Zr−C_{ipso}−P−N dihedral angle of 0.2°). As expected, the halide dissociation induces a significant shortening of the Zr−N bond ($\mathbf{1^+}$: 2.166 Å compared to **1***: 2.357 Å) associated with a slight elongation of the N−P bond ($\mathbf{1^+}$: 1.647 Å compared to **1***: 1.613 Å). These modifications appear to have limited impact upon the coordination geometry, as suggested by the value of the C_g−C_{ipso}−P bond angle ($\mathbf{1^+}$: 154.9° compared to **1***: 158.1°).

The bridging $(R_2P)^+$ and (R_2Si) fragments are isolobal, and the cationic phosphorus-bridged complex $\mathbf{1^+}$ was thus also compared to the neutral silicon-bridged complex $[H_2Si(\eta^5\text{-}C_5H_4)(HN)ZrCl_2]$ (**8**) (Table 5). Since the phosphorus and silicon atoms are almost identical in size, the geometric constraint is very similar (C_g−C_{ipso}−P bond angle for **8**: 154.5°). But, as expected, the Zr−N bond is shorter in the neutral complex **8** (2.054 Å), which formally features a strongly donating silylamido arm.



Scheme 7. Schematic representation (side and top views) of the B3LYP-optimized geometry of complex $\mathbf{1^+}$

According to NBO calculations (Table 6), the natural charges for the (NH) and (PH_2) fragments remain almost identical upon halide dissociation. In fact, the positive charge of $\mathbf{1^+}$ mainly develops on the metal centre (0.92 for the $ZrCl_2$ fragment in $\mathbf{1^+}$ compared to 0.16 for the $ZrCl_3$ fragment in **1***). Interestingly, the charge distribution in $\mathbf{1^+}$ is half-way between those of the neutral and cationic silicon-bridged complexes $[H_2Si(\eta^5\text{-}C_5H_4)(HN)ZrCl_2]$ (**8**) and $[H_2Si(\eta^5\text{-}C_5H_4)(HN)ZrCl]^+$ ($\mathbf{8^+}$) (0.74 for the $ZrCl_2$ fragment in **8** and 1.52 for the ZrCl fragment in $\mathbf{8^+}$). Complex $\mathbf{1^+}$, represented by schematic forms $\mathbf{E^+a-c}$ (Scheme 8), can

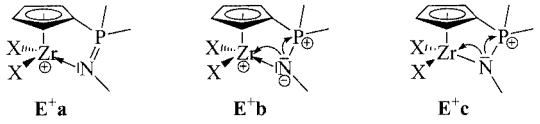
thus be considered as the cationic version of the "CpSiN" complex **A**.

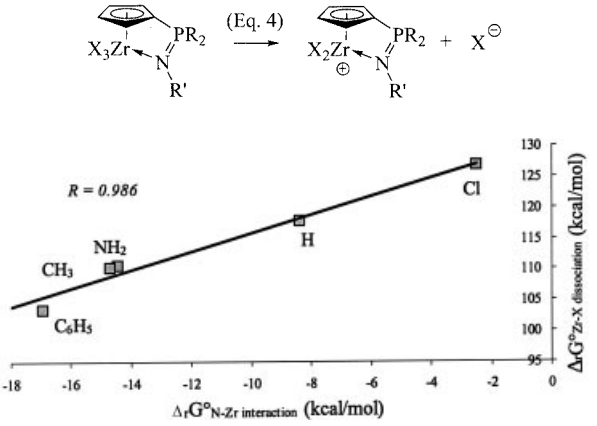


Scheme 8. Schematic representations of complex **E**$^+$

The cationic complexes **4**$^+$−**6**$^+$ featuring the various substitution patterns were then studied (Table 4). The resulting structural modifications are very similar to those observed for the neutral precursors **4***−**6***. Comparison of the free enthalpies for the halide dissociation at 298 K in the gas phase [Equation (4)] yields a quantitative determination of the substituent effects (Table 7). As expected, the ionic dissociation of the neutral complexes **1*** and **4***−**6*** is highly endothermic. The absolute values for $\Delta_rG^\circ_{Zr-X\ dissociation}$ cannot be discussed properly, since solvation and counteranion effects were not taken into account, although comparisons give more insight into the substituent effects. With regard to changes in the nature of the substituent at phosphorus (complexes **4**$^+$-R), $\Delta_rG^\circ_{Zr-X\ dissociation}$ decreases along the series Cl > H > NH_2 > CH_3 > C_6H_5 with a maximum variation of 23.3 kcal/mol. The least and most favourable patterns for the halide dissociation are encountered by introduction of chlorine atoms and phenyl groups, respectively. These results parallel those observed for the phosphazene coordination (see above), and indeed, the influence of the phosphorus substituents on the Zr−X dissociation is nicely correlated with that on the N−Zr interaction (Scheme 9). In marked contrast, introduction of an amino group at the nitrogen atom (**5***-NH_2) induces a strong reinforcement of the Zr−N interaction, but only a small variation of $\Delta_rG^\circ_{Zr-X\ dissociation}$. In other words, the substituents at nitrogen have a much less pronounced effect on $\Delta_rG^\circ_{Zr-X\ dissociation}$ than those at phosphorus. Lastly, the halide dissociation is obviously more favourable for **6**$^+$ (X = iodine) than for **1**$^+$ (X = chlorine). Here again substituent effects are basically cumulative. Association of the most favourable substituents results in a decrease in $\Delta_rG^\circ_{Zr-X\ dissociation}$ by 37.4 kcal/mol for **7**$^+$ compared to **1**$^+$.

Table 7. Estimated free enthalpy change for the halide dissociation from neutral complexes $[R_2P(\eta^5\text{-}C_5H_4)(R'N)ZrX_3]$ (**1***, **4***-R, **5***-R′, **6*** and **7***) to the related cationic complexes $[R_2P(\eta^5\text{-}C_5H_4)(R'N)ZrX_2]^+$ (**1**$^+$, **4**$^+$-R, **5**$^+$-R′, **6**$^+$ and **7**$^+$)

Complex	$\Delta_rG^\circ_{Zr-X\ dissociation}$
1$^+$ (R = R′ = H, X = Cl)	117.9
4$^+$-R (R′ = H, X = Cl)	
Cl	126.7
NH_2	110.7
CH_3	110.2
C_6H_5	103.4
5$^+$-R′ (R = H, X = Cl)	
CH_3	115.7
NH_2	119.7
6$^+$ (R = R′ = H, X = I)	95.3
7$^+$ (R = C_6H_5, R′ = CH_3, X = I)	80.5



Scheme 9. Correlation of the influence of the phosphorus substituents on the N−Zr interaction and Zr−X dissociation; $\Delta_rG^\circ_{N-Zr\ interaction}$ determined with Method 1, except for R = NH_2 (Method 3)

Complexes Featuring a Pendant Phosphinimido Unit $[H_2P(\eta^5\text{-}C_5H_4)(N)ZrCl_3]^-$ (**9**$^-$), $[H_2P(\eta^5\text{-}C_5H_4)(N)ZrCl_2]$ (**9**) and $[H_2P(\eta^5\text{-}C_5H_4)(N)ZrCl]^+$ (**9**$^+$)

Calculations were then carried out on the related complexes **9**$^-$, **9** and **9**$^+$ featuring the dianionic ligand $(Cp-PR_2=N)^{2-}$ and the $ZrCl_3^+$, $ZrCl_2^{2+}$ and $ZrCl^{3+}$ fragments, respectively (Scheme 10). The presence of the strongly donating phosphinimido unit clearly favours the N−Zr interaction, which was observed for all these complexes.

Coordination of $(Cp-PR_2=N)^{2-}$ to the $ZrCl_3^+$ fragment does not induce the spontaneous dissociation of one chloride from the zirconium coordination sphere, and the anionic complex **9**$^-$ remains an energy minimum. The zirconium in **9**$^-$ adopts a pseudo-square-pyramidal environment, and the imido is inherently bent (Zr−*N*−P: 102.2°). The major difference concerns the N−Zr bond length, which is, as expected, considerably shorter in **9**$^-$ (2.075 Å) than in **1*** (2.357 Å). The reinforcement of this N−Zr interaction induces some increase in the geometry constraint, as illustrated by the bending of the $C_g-C_{ipso}-P$ bond angle (**8**$^-$: 149.6° compared to **1***: 158.1°). According to the NBO analysis, the excess negative charge is distributed over the $ZrCl_3$ fragment (−0.18) and the nitrogen atom (−1.31), in agreement with schematic structures **9**$^-$**a** and **9**$^-$**c** (Scheme 10).

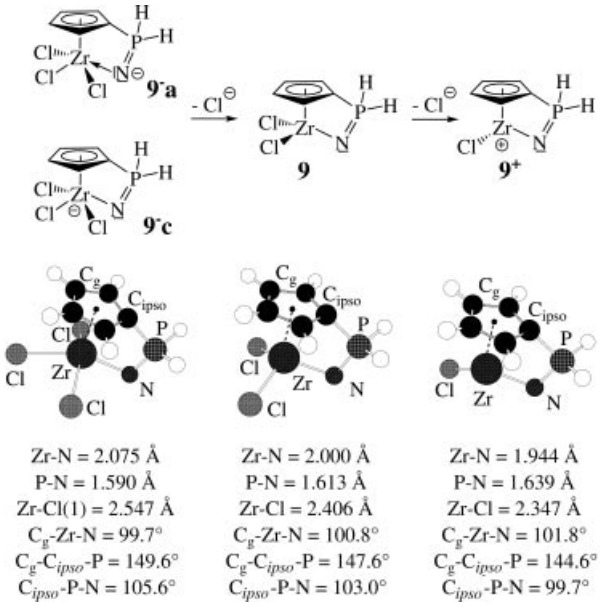
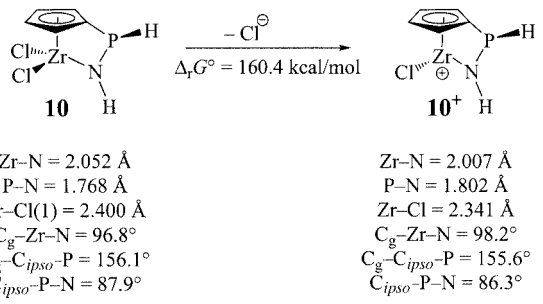


Scheme 10. Structure, schematic representation and selected geometric data of the B3LYP-optimized complexes **9**$^-$, **9** and **9**$^+$

Not surprisingly, dissociation of one chlorine leads to the neutral complex **9**, featuring a pseudo-tetrahedral geometry. Chlorine dissociation is much more favourable for **9** ($\Delta_rG°_{Zr-X\ dissociation}$ = 18.9 kcal/mol) than for **1*** (117.9 kcal/mol). The N−Zr bond length (2.000 Å) is shorter than that of **9**$^-$, but the difference is significantly smaller than that predicted for the phosphazene-containing complexes **1**. Dissociation of a second chlorine affords the cationic complex **9**$^+$ featuring a pyramidal zirconium centre[23] and a yet shorter N−Zr bond length (1.944 Å).

Complexes **9** and **9**$^+$ are strongly related to the silicon-bridged systems **8** and **8**$^+$. The N−Zr bond lengths are only slightly shorter and the geometry constraint marginally higher in the phosphorus-bridged complexes. This analogy is corroborated by the similarity of both the NBO charges for the $ZrCl_2$ (**9**: 0.68/**8**: 0.74) and ZrCl (**9**$^+$: 1.45/ **8**$^+$: 1.52) fragments (Table 6) and the free enthalpies calculated for **9** → **9**$^+$ (155.2 kcal/mol) and **8** → **8**$^+$ (159.7 kcal/mol).

Lastly, phosphinimido-based complexes **F** were compared with their phosphinamido-based isomers **C**.[10b] Isomerization between (NH)-aminophosphanes [R_2P-(NH)R′] and (PH)-phosphazenes [R_2(PH)=NR′] is indeed a well-known process, including in metal complexes.[24] Calculations were thus carried out on model complexes of type **C** and, accordingly, the phosphinamido complexes **10** and **10**$^+$ are predicted to be 25.7 and 20.6 kcal/mol more stable than the related phosphinimido complexes **9** and **9**$^+$ (Scheme 11). These values are in the same range as that reported by Schoeller for the free ligands $(H_2P\text{-}NH)^-$ and $(H_3P{=}N)^-$ (31 kcal/mol in favour of the NH tautomer).[24d] The stabilization of the PH tautomer usually observed upon metal coordination is thus strongly balanced in this case by the ensuing increase in the geometric constraints (from **9** to **10** and **9**$^+$ to **10**$^+$, the N−Zr and N−P bonds are noticeably elongated and the bending of C_{ipso} is significantly released).



Scheme 11. Structure and selected geometric data of the B3LYP-optimized complexes **10** and **10**$^+$

Concluding Remarks

Theoretical investigations of phosphazene- and phosphinimido-based complexes **E** and **F** reveal numerous similarities but also noticeable differences with the "CpSiN" catalysts **A**. In particular, NBO natural charges suggest a significantly higher metal electrophilicity for **E** than for **A** (the positive charge is mainly localized on the $ZrCl_2$ fragment). Substituent effects are predicted to be additive and they influence strongly the structure and properties of both neutral and cationic complexes **E** and **E**$^+$. Their influences on the N−Zr coordination strength and Zr−X dissociation appear to be strongly correlated, at least with respect to the nature of the phosphorus substituents. Phosphinimido-based complexes **F** are geometrically and electronically strongly related to the "CpSiN" catalysts **A**, but significantly more constrained than the related phosphinamido complexes **C**. Accordingly tautomerization of the parent complexes **9** → **10** and **9**$^+$ → **10**$^+$ is predicted to be energetically favoured.

These results as a whole suggest that constrained-geometry complexes featuring phosphazene and phosphinimido arms might indeed be interesting alternatives for the "CpSiN" catalysts. Accordingly, the interaction of complexes **E** and **F** with alkenes clearly deserves to be studied, and detailed investigations in this field are planned.

Computational Details

All calculations were carried out with the Gaussian 98[25] suite of programs at the DFT level of theory using the hybrid functional B3LYP as implemented in that program.[26,27] Halide, phosphorus, silicon and zirconium atoms were treated with the Averaged Relativistic Effective Core Potentials (AREPs) optimized by the Dresden-Stuttgart-Bonn group (Cl, I, P, Si[28] and Zr[29]). Basis sets adapted to the AREPs augmented with a d polarization function were used for the atoms of the *p*-block (exp_P = 0.387, exp_{Si} = 0.284,[30] exp_{Cl} = 0.643, exp_I = 0.730[31]) and an f polarization function was used for the zirconium atom (exp_{Zr} = 0.975[32]). Carbon, nitrogen and hydrogen were treated with an all-electron double-ζ 6-31G(d,p) basis set.[33] Geometry optimiza-

tions were performed without spatial symmetry constraints and the nature of the extrema was verified by analytical calculations of vibrational frequencies. The atomic charges were obtained by NBO analyses.[34]

Switch of the Lowest Excited-States of Terpyridylplatinum(II) Acetylide Complexes Bearing Amino or Azacrown Moieties by Proton and Cations

Qing-Zheng Yang,[a] Qing-Xiao Tong,[a] Li-Zhu Wu,*[a] Zi-Xin Wu,[a] Li-Ping Zhang,[a] and Chen-Ho Tung*[a]

Keywords: Crown compounds / N ligands / Platinum / Sensors

The investigation of the synthesis and unique photophysical properties of two terpyridylplatinum(II) acetylide complexes [Pt(terpy)(C≡CC_6H_4-4-R)] where terpy is 2,2′:6′,2′′-terpyridyl and R = $N(CH_3)_2$ (**1**) or *N*-15-monoazacrown-5 (**2**) has been carried out. These complexes exhibit an absorption band in the region of 460–650 nm in neutral or basic solution that corresponds to a ligand-to-ligand charge transfer (LLCT) transition from the amino-substituted acetylide to the terpyridyl acceptor. In acidic solutions the complexes show the lowest-energy absorption band at 380–500 nm, which is assignable to a dπ(Pt)→π*(terpy) metal-to-ligand charge transfer (MLCT) transition. In acidic media the complexes are emissive with quantum yields of 1×10^{-3} to 2×10^{-3}, and lifetimes of 20–50 ns. Compound **2** may complex metal cations through its azacrown ether moiety. For Na^+, Ba^{2+}, Ca^{2+} and Mg^{2+}, a 1:1 binding mode with log *K*s of 2.52 to 4.18 was observed. As in the case of acidic solution, the cation-bound complex also features the lowest-lying MLCT excited state.

Introduction

The creation of host molecules that can selectively recognize specific guest molecules at their receptor site and produce a measurable physical change has been the subject of intense study.[1,2] Of particular interest is the design of molecules that show dramatic and reversible changes in color and/or luminescence in the visible spectral region upon exposure to specific substrates.[3−6] In this context square-planar platinum(II) complexes show considerable promise due to their rich and medium-sensitive spectroscopic and photophysical behavior.[7−10] In particular, alkynyl complexes of platinum(II) have received much attention because these complexes generally display bright luminescence with high quantum yields and long lifetimes, and a number of excellent studies have been performed.[11−23] Che and co-workers[11] reported a luminescent platinum(II) acetylide complex with aromatic diimine ligands in 1994. The [Pt(C≡CPh)$_2$(phen)] (phen = 1,10-phenanthroline) complex exhibits intense emission in fluid solution at room temperature, which was attributed to a triplet metal-to-ligand charge transfer [^{3}MLCT: dπ(Pt) → π*(phen)] excited state. Later on, Eisenberg and co-workers,[12−14] and Schanze and co-workers[15] investigated the excited-state properties of a series of complexes of the type [Pt(C≡C−Ar)$_2$(diimine)], where diimine is a series of 2,2′-bipyridine or 1,10-phenanthroline ligands and C≡C−Ar is a series of substituted arylacetylide ligands. They systematically examined the influence of the electronic demand of the diimine and arylacetylide ligands on the properties of the MLCT excited state, and revealed that in most cases the photophysics of the complexes is dominated by the energetically low-lying dπ(Pt) → π*(diimine) ^{3}MLCT state. Some of the complexes also feature a low-lying triplet intraligand (^{3}IL) ππ* excited state that is derived from transitions between π-type orbitals localized largely on the arylacetylide ligands.[16] Recently, Che and co-workers have used diiminepalatinum(II) bis(arylacetylide) complexes as emitters in organic light-emitting devices.[17,18]

The photoluminescence of [*trans*-Pt(C≡CR)$_2$](PEt_3)$_2$, where R = H or phenyl, in the solid state and frozen glass solution at 77 K was investigated by Demas and co-workers.[19] The emission was assigned as arising from a charge transfer excited state involving Pt d_{z^2} and acetylide π* orbitals. Yam and co-workers reported the luminescence of branched alkynylplatinum(II) complexes containing the [PtCl(C≡CC_6H_4C≡C)(PEt_3)$_2$] moiety, and suggested that the emission originates from a mixed π → π* (C≡CR) intraligand (IL)/$d_{z(Pt)}$ → π* (C≡CR) MLCT triplet state with predominantly IL character.[20] The photophysics of terpyridylplatinum(II) acetylide complexes and tridentate cyclometalated platinum(II) complexes bearing σ-alkynyl ligands was also reported.[21−23] Yam and co-workers investigated the photophysics and electrochemistry of a series of terpyridylplatinum(II) acetylide complexes with the general for-

mula $[Pt(C{\equiv}CC_6H_4R)(terpy)]PF_6$, and found that the emission energies depend on the nature of the acetylide ligands with different substituents on the phenyl ring:[21] an electron-withdrawing group on the phenyl ring increases the emission energy. Our laboratory has reported the photoluminescence of a series of 4′-*p*-tolyl-terpyridylplatinum(II) acetylide complexes.[22] These complexes exhibit long-lived emission from the ^{3}MLCT states with high emission quantum yields. The complexes bearing (C≡CR) ligands with R = alkyl in dichloromethane solution at room temperature show lifetimes greater than 10 μs and emission quantum yields greater than 0.25. We found that the cyclometalated platinum(II) complexes [Pt(C^N^N)(C≡CC_6H_4R)] where HC^N^N = 6-phenyl-4-*p*-tolyl-2,2′-bipyridine, also show photoluminescence with long lifetimes.[23]

Although the spectroscopic properties of alkynylplatinum(II) complexes have been extensively studied,[11−23] the utilization of such complexes for applications in molecular recognition and chemosensing work is rare.[21] In this paper we describe the syntheses and unique photophysical properties of two terpyridylplatinum(II) acetylide complexes [Pt(C≡ CC_6H_4-4-R)(terpy)] where R = $N(CH_3)_2$ (**1**) or *N*-15-monoazacrown-5 (**2**; Scheme 1). The amino groups in these complexes serve as proton receptors. In neutral or basic solutions, **1** and **2** are non-emissive and their low-energy absorption arises from a ligand-to-ligand charge transfer (LLCT) transition from the amino-substituted acetylide to the terpyridyl acceptor with a deep purple color. Upon protonation, these complexes display luminescence and their MLCT dπ→ π*(terpy) transition becomes the lowest energy absorption and the solutions are yellow in color. Thus, these complexes can be utilized as a chemosensor for proton detection by monitoring the changes both in luminescence and color. Significantly, the azacrown moiety in complexes **2** can also serve as metal-ion receptor. Upon complexing a metal cation, its ^{1}LLCT excited state shifts energetically to be above the ^{1}MLCT excited state, hence producing color changes from deep purple to yellow. Thus, **2** can also be employed as a chemosensor for the detection of metal ions. To the best of our knowledge, this is the first example to use the switch of the lowest excited state from the ^{3}LLCT to the ^{3}MLCT state of metal complexes for chemosensors.

Results and Discussion

Synthesis

The synthetic strategy for making the terpyridylplatinum(II) acetylide complexes is based on a CuI-catalyzed chloride-to-acetylide metathesis. Complexes **1** and **2** were prepared by reaction of [PtCl(terpy)]Cl with two equivalents of 4-(dimethylamino)phenylacetylene and 4-ethynylphenyl-*N*-15-monoazacrown-5 ether, respectively, in DMF in the presence of CuI and triethylamine at room temperature. After the metathesis reaction with KBF_4 for **1** or $LiClO_4$ for **2**, and recrystallization of the crude products by vapor diffusion of diethyl ether into an acetonitrile solution, **1** and **2** were obtained as dark-blue crystals in 70−76% yield. The identity of complexes **1** and **2** was confirmed by ^{1}H NMR spectroscopy, MS spectrometry and satisfactory elemental analyses. For comparison, the complex [Pt(C≡CC_6H_5)(terpy)]ClO_4 (**3**; Scheme 1) was also synthesized by a similar procedure.

Crystal Structure of Complex 1

A dark-blue single-crystal of dimensions 0.05 × 0.2 × 0.5 mm^3 in a glass capillary was used for data collection at 296 K on a Bruker Smart1000 X-ray diffractometer. The molecular structure and perspective drawing of the complex are depicted in Figure 1. The crystal belongs to the triclinic crystal system of centrosymmetric space group $P\bar{1}$ with unit cell parameters of a = 9.4033(8) Å, b = 11.0229(10) Å, c = 12.4015(11) Å; α = 101.619(2)°, β = 106.128(2)°, γ = 103.441(2)°, Important bond lengths and angles are given in Table 1. The coordination geometry about the platinum is essentially square planar with the bond from platinum to the central nitrogen atom of the terpyridine ligand slightly shorter than that to the other two outer nitrogen atoms, as is required by the steric demands of the terpyridine ligand. All the Pt−N distances are in the range found for typical platinum(II) terpyridine complexes.[21,28,29] The N−Pt−N angles [N(1)−Pt(1)−N(2): 80.59(17); N(2)−Pt(1)−N(3): 80.63(18); N(1)−Pt(1)−N(3): 161.18(19)] deviate from the idealized values of 90° and 180° as a consequence of the geometric constraints imposed by the terpyridyl ligands. The Pt−C bond length is 1.977 Å, which compares well with a value of 1.98 Å for other terpyridylplatinum(II) ace-

tylide complexes.[21] The C≡C bond length of 1.193 Å is similar to those of the other related platinum(II) acetylide complexes.[12,21,30] The phenyl ring of the acetylide ligand is almost coplanar to the platinum-terpyridine plane, with a dihedral angle of 4.5°. The crystal packing of **1** reveals a head-to-tail stacking between pairs of complex cations. The intermolecular Pt···Pt distance of 8.146 Å and the intermolecular separation of 6.718 Å between the terpy ligand and the phenyl group of the acetylide moiety are suggestive of a lack of intermolecular interactions between the metal centers and the aromatic groups.

Absorption Spectra

Figure 2 presents the UV/Vis spectra of complexes **1** and **2** in acetonitrile solution. For comparison, the absorption spectrum of **3** is also shown in Figure 2. All the complexes exhibit intense vibronic-structured absorption bands at wavelengths below 350 nm, with extinction coefficients (ε) of the order of 10^4 $dm^3 \cdot mol^{-1} \cdot cm^{-1}$, and a less-intense band at 380−500 nm (centered at ca. 410, 411 and 432 nm with ε = 2860, 2950 and 4410 $dm^3 \cdot mol^{-1} \cdot cm^{-1}$ for **1**, **2** and **3** respectively). Significantly, complexes **1** and **2** show a moderately intense low-energy absorption band in the region of 460−650 nm (absorption maximum λ_{max} = 535 and 548 nm, ε = 4920 and 5370 $dm^3 \cdot mol^{-1} \cdot cm^{-1}$ for **1** and **2**, respectively). Complex **3** does not show such a band. The absorption spectral properties are found to follow Beer's Law at concentrations below 1×10^{-3} $mol \cdot dm^{-3}$, suggesting that no significant complex aggregation occurs. With reference to previous spectroscopic work on terpyridylplatinum(II) complexes,[21,22,31−34] the absorption bands at wavelengths below 350 nm are assigned to the intraligand (IL) transition of terpyridyl and acetylide ligands, while the absorption band at 380−500 nm is ascribed to the $d\pi(Pt) \rightarrow \pi^*$ (terpy) MLCT transition. The low-energy absorption band in the region of 460−650 nm for **1** and **2** is tentatively assigned to the LLCT transition from the amino-substituted acetylide ligand to the terpyridyl acceptor. This assignment is based on the following observations. First, the energy of the band increases with solvent polarity. For example, λ_{max} of the band for **1** is blue-shifted from 595 nm in dichloromethane to 535 nm in acetonitrile. This suggests that the ground state of the complex is more polar than its excited state, and is consistent with the notion that in the ground state the acetylide ligand is carbanionic in nature, and in the LLCT excited state the terpyridyl-acetylide ligands are like a diradical. Second, we have performed cyclic voltammetry studies on complexes **1** and **3** in acetonitrile. Both complexes exhibit two quasi-reversible cathodic waves in the potential region −0.8 to −1.5 V vs. SCE. By analogy to previous studies on other terpyridylplatinum(II) complexes,[21,22] these waves are ascribed to the reduction of the terpyridyl ligand with some mixing of the Pt^{II} character. Complex **3** displays an irreversible anodic wave with E_p at +1.22 V vs. SCE which has been assigned to a metal-centered oxidation from Pt^{II} to Pt^{III} by Yam and co-workers.[21] On the other hand, for complex **1** we observed an irreversible anodic wave near +0.63 V vs. SCE. Upon addition of an acid to the solution, this wave disappeared. Cyclic voltammetry of the uncomplexed ligand, *p*-(dimethylamino)-phenylacetylene exhibits a similar anodic wave at a slightly more positive potential (ca. +0.85 V vs. SCE). Thus, we

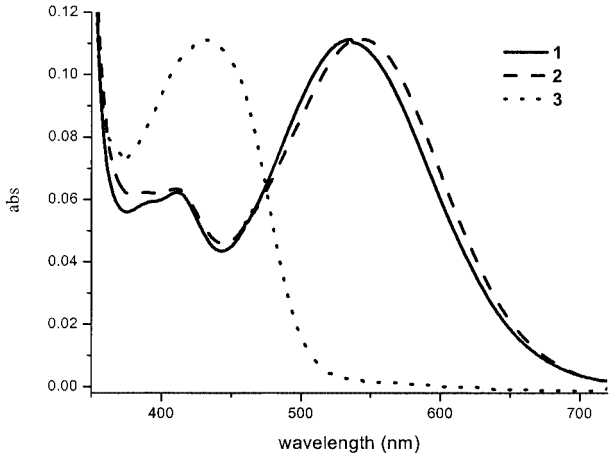

Figure 2. The normalized absorption spectra of complexes **1**−**3** in acetonitrile solutions at room temperature

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

assign the wave near +0.63 V to the oxidation of the amino-substituted acetylide ligand. Obviously, the LLCT transition in **1** should be at lower energy than the MLCT transition. Third, the lowest energy absorption band (λ_{max} = 535 and 548 nm) for **1** and **2** is red-shifted by more than 100 nm compared with that of **3** (λ_{max} = 432 nm). This observation is not consistent with the assignment of the 535 and 548 nm bands to a MLCT transition, because it has been established[12,21] that variation of the acetylide in platinum(II) acetylide complexes does not lead to very large changes in the Pt-based HOMO and the terpyridyl-based LUMO, hence it is not expected to affect the energy of the MLCT transition very much.

An Acid/Base-Controlled Molecular Switch based on Complexes 1 and 2

An initial observation when working with an acetonitrile solution of complex **1** was the change of the deep-purple color in neutral solution to yellow when exposed to a micromolar concentration of HBF_4. Such a dramatic color change, especially the large blue-shift of the absorption band in a dilute acidic medium, prompted an investigation of the nature of the acid-dependent absorption. Figure 3 shows the absorption spectra of complex **1** (3.87×10^{-5} mol·dm^{-3}) in acetonitrile as a function of added HBF_4. Upon addition of HBF_4 to the solution, the decrease in the absorption band at 535 nm is accompanied by a growth in the band with a maximum at 418 nm. Isosbestic points are observed at 457, 358, 344, 337 and 279 nm, indicative of the presence of only two absorbing species in the solution. The insert in Figure 3 shows a plot of the absorbance at 535 nm vs. the concentration of added HBF_4. Similar changes in the absorption spectrum were observed for complex **2** upon addition of HBF_4. In contrast, addition of HBF_4 to a solution of complex **3** in acetonitrile causes no marked changes in the absorption. These observations are evidently attributed to the protonation of the amino group in the acetylide ligands for complexes **1** and **2**. As the amino receptor is protonated in the presence of HBF_4, its electron-donating ability is decreased. This would dramatically lower the HOMO of the acetylide ligand. The Pt-based HOMO would also be lowered, but the extent of this lowering is expected to be much less than that of the acetylide ligand (Scheme 2). As a result, the LLCT transition from the amino-substituted acetylide ligand to the terpyridyl acceptor shifts to higher energy, and the dπ(Pt) → π*(terpy) MLCT transition becomes the lowest-energy transition.

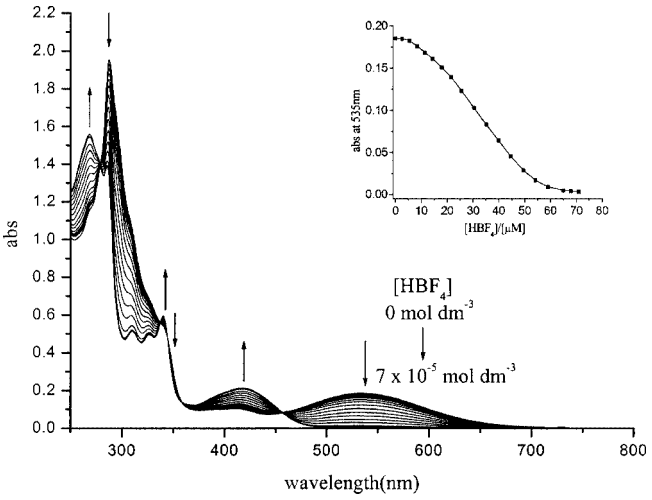

Figure 3. Absorption spectrum changes of complex **1** (3.87×10^{-5} mol·dm^{-3}) upon addition of various concentrations ($0-7 \times 10^{-5}$ mol·dm^{-3}) of HBF_4 in acetonitrile; the insert gives the titration curve for the plot of the absorbance at 535 nm vs. the concentration of HBF_4

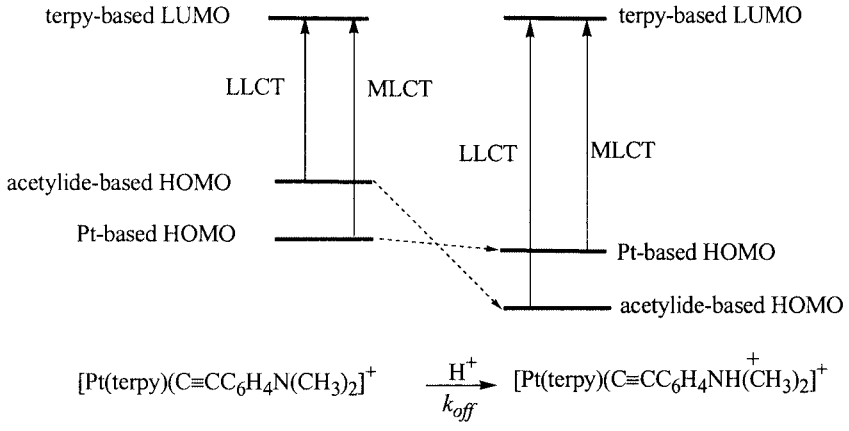
The change in the luminescence response of complexes **1** and **2** towards protons was found to be even more pronounced. In neutral or basic solution **1** and **2** are non-emissive. The lack of emission upon excitation of the MLCT band is attributed to the transfer of the electron pair on the amino groups to the Pt^{III} metal center, resulting in an LLCT excited state. Because of the low energy, the ^{3}LLCT excited state decays via a non-radiative pathway. However, in acidic medium **1** and **2** exhibit a structureless emission band centered at about 560 nm. Figure 4 shows the change in the emission spectrum of **1** as a function of HBF_4 concentration. Throughout the titration, the excitation wavelength corresponds to the isosbestic point found at 457 nm in Figure 3. The emission intensity is noticeably



Scheme 2

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

enhanced upon increasing HBF_4 concentration, with saturation observed toward the end of the titration, while the shape and energy of the emission band remain unchanged. With reference to previous work on the emission of terpyridylplatinum(II) complexes,[21,22,29,31] this emission is assigned as being derived from the $d\pi(Pt)\rightarrow\pi^*$(terpy) ^{3}MLCT excited state. The insert in Figure 4 shows a plot of the emission intensity at 560 nm against the concentration of HBF_4. The emission quantum yields of **1** and **2** in their protonated form were measured to be 0.001 and 0.002, respectively, and their lifetimes 0.02 and 0.05 μs, respectively. Similar to the absorption studies, control experiments with complex **3** under the same conditions showed no change in the emission character upon addition of HBF_4. Evidently, the emission of complexes **1** and **2** upon addition of HBF_4 originates from protonation of the amino group. As mentioned above, upon protonation the ^{3}MLCT excited state becomes the lowest state and displays luminescence.

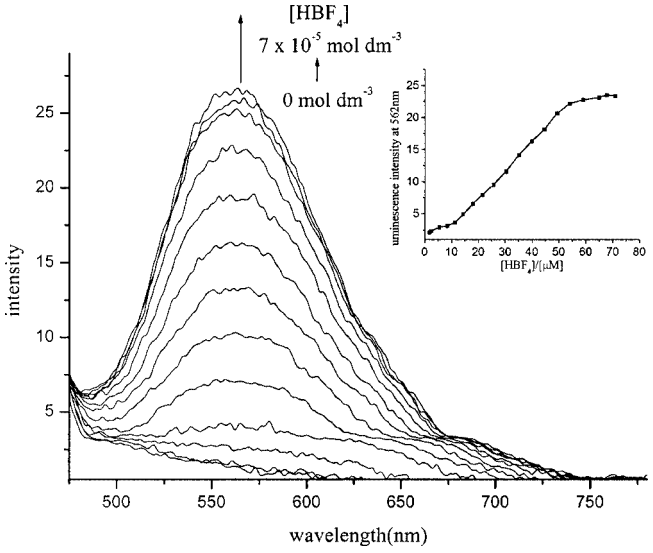


Figure 4. Luminescence spectrum changes of **1** (3.87×10^{-5} mol·dm^{-3}) upon addition of various concentrations ($0-7 \times 10^{-5}$ mol·dm^{-3}) of HBF_4 in acetonitrile; the insert shows the luminescence intensity at 560 nm as a function of HBF_4 concentration

The changes in absorption and emission behavior for complexes **1** and **2** are fully reversible. For example, subsequent addition of a base (e.g. triethylamine) to the acidic solution of **1** in acetonitrile led to the observation of a reverse trend: the luminescence was gradually quenched, and the absorbance at 418 nm dropped, with a concomitant rise in the absorption at 535 nm. Eventually the LLCT band in the absorption spectrum was totally recovered, and the solution became deep purple again. This result is indicative of the reversible nature of the protonation and deprotonation processes for the amino group in complexes **1** and **2**.

Cation-Binding Properties of Complex 2

Alkali and alkaline earth metal cations have profound effects on the absorption spectrum of **2**. Addition of Na^+, Ba^{2+}, Ca^{2+} or Mg^{2+}, as their perchlorate salts, to a solution of **2** in acetonitrile leads to dramatic changes in the absorption spectrum. Figure 5 presents the changes in the UV/Vis spectrum of **2** upon addition of Ca^{2+}. The lowest energy band at 548 nm decreases monotonically throughout the addition, while the band at 390−470 nm concomitantly grows-in with increasing Ca^{2+} concentration. Well-defined isosbestic points at 465, 375, 347, 342 and 283 nm were clearly observed. The solution becomes yellow at the end of the titration. Similar results were observed upon addition of other cations to the solution of **2**. This phenomenon evidently arises from the complexation of the cation with the azacrown ether receptor in the acetylide ligand, which decreases the electron-donating ability of the acetylide ligand, hence lowering the acetylide-based HOMO. Thus, the LLCT transition from the azacrown-containing acetylide ligand to the terpyridyl acceptor shifts to higher energy, and the $d\pi(Pt)\rightarrow\pi^*$(terpy) MLCT transition becomes the lowest energy absorption. Indeed, control experiments with the crown-free analogues **1** and **3** showed no such absorption spectrum changes upon addition of the cations under identical conditions. The insert in Figure 5 shows the plot of $A_0/(A_0 - A)$ vs. $[Ca^{2+}]^{-1}$, where A and A_0 refer to the absorbance at 548 nm for complex **2** in the presence and absence of Ca^{2+}, respectively. The straight line suggests that the complexation of the cation to the azacrown ether is in a 1:1 ratio. The bonding constants (log *K*s) determined from such plots for the cations are Na^+ (2.52), Ba^{2+} (3.01), Ca^{2+} (4.18) and Mg^{2+} (3.76), and their absolute values are very similar to those of other aza-15-crown-5 ionophores reported in the literature.[35]

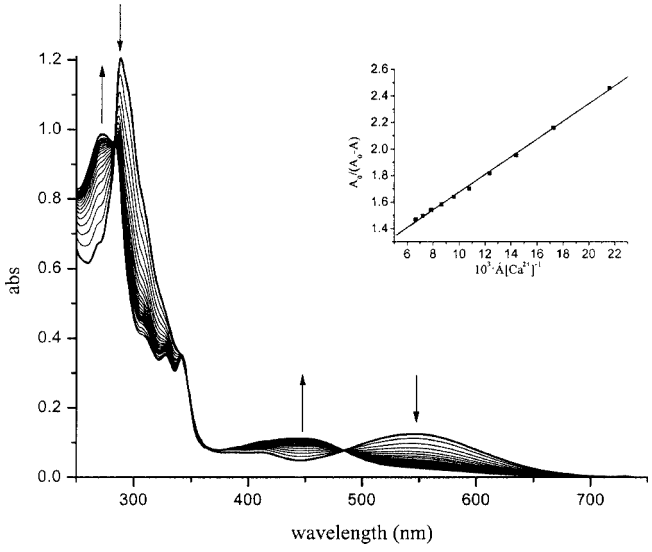

Figure 5. Absorption spectrum changes of **2** upon addition of various concentrations of Ca^{2+} in acetonitrile solution; the insert shows the plot of $A_0/(A_0 - A)$ vs. $[Ca^{2+}]^{-1}$

Complexation of cations with the azacrown ether receptor in **2** also affects the MLCT transition. We noted that the λ_{max} of the MLCT band of **2** complexed with the cations shifts to the blue side along the series Na^+ (481 nm),

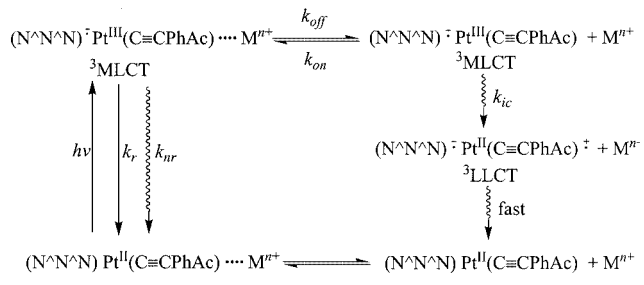
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Ba^{2+} (470 nm), Ca^{2+} (446 nm) and Mg^{2+} (430 nm). This reflects the difference in the strength of the ion-dipole interaction between the cations and the crown nitrogen. A strong interaction will further reduce the electron-donating ability of the acetylide and would make the metal center in **2** less electron-rich, and hence decrease the dπ(Pt)-orbital energy and cause the MLCT transition to occur at higher energy. It is well-known that the charge densities[36] of the metal ions increase in the following order: Na^+ (0.10) < Ba^{2+} (0.13) < Ca^{2+} (0.24) < Mg^{2+} (0.75). Mg^{2+} has the highest charge density in the series of metal ions studied in this work, and its value is considerably larger than the other cations. As a result, the interaction between Mg^{2+} and the crown nitrogen would be strongest, and complexation with this cation leads to the highest energy of the MLCT transition among the **2**·M^{n+} complexes.

In contrast to protonated **1** and **2**, complexation with metal cations does not cause luminescence from complex **2**, although the ^{3}MLCT state becomes the lowest energy excited state after complexation, as reflected in the absorption spectrum changes. This lack of emission may be interpreted by a kinetic model (Scheme 3) proposed by Schanze[37] for explanation of ion effect on the photophysics of a Re^I complex. In this scheme (N^N^N) and (C≡CPhAc) represent, respectively, the terpyridyl ligand and the acetylide with monoazacrown in complex **2**. Excitation of the **2**·M^{n+} complex produces the ^{1}MLCT state, which undergoes an intersystem crossing to the ^{3}MLCT state. Since the metal center in MLCT excited states (Pt^{III}) is much more electrophilic than that in the ground state (Pt^{II}), the charge density on the amino group will be reduced. This in turn decreases the binding ability of the azacrown, leading to the dissociation of the crown-complexed cation from the azacrown within the lifetime of the MLCT state. Thus, in addition to the normal radiative and non-radiative pathways, the ^{3}MLCT state of **2**·M^{n+} can also decay by a non-radiative pathway involving the dissociation of the crowned cation (k_{off}) followed by rapid internal conversion into the ^{3}LLCT state (k_{ic}). As a result, no emission could be detected from the acetonitrile solution of **2**·M^{n+}. The K_{off} values can be estimated by reference to the lifetime of the ^{3}MLCT state of protonated **2**. Assuming the deprotonation of **2**·H^+ in its ^{3}MLCT state is not competitive with the normal ^{3}MLCT decay rate, the lifetime (τ_1) of the ^{3}MLCT state of protonated **2** can be used to estimate the "normal" decay rate [$1/(k_r + k_{nr})$] of the ^{3}MLCT state of **2**·M^{n+}; k_{off} can then be obtained approximately from the lifetime (τ_2) of the ^{3}MLCT state of the **2**·M^{n+} complexes.

$$k_{off} = 1/\tau_2 - 1/\tau_1$$

The limiting value for the lifetime measurements in our instruments is > 0.2 ns, thus τ_2 for the complexes of **2** with cations is smaller than 0.2 ns. The emission lifetime (τ_1) of protonated **2** was measured to be 50 ns, as mentioned above. The k_{off} values obtained should therefore be greater than 5×10^9 s^{-1} for the cation-crowned complexes.



Scheme 3

Conclusion

Two terpyridylplatinum(II) acetylide complexes, one having an amino group and the other containing a monoazacrown moiety in their acetylide ligand, were prepared and their medium-sensitive photophysical properties were investigated. Incorporation of the amino or azacrown group into the acetylide destabilizes the HOMO of this ligand, hence in neutral or basic solutions the low-energy absorption of these complexes arises from the LLCT transition from the acetylide ligand to the terpyridyl acceptor. These complexes are non-emissive due to the fast non-radiative decay of the ^{3}LLCT excited state. Upon protonation of the amino group the HOMO of the acetylide ligand is lowered, thus the LLCT transition shifts to high energy, and the dπ(Pt)→π* (terpy) MLCT transition becomes the lowest energy absorption. In this case, the ^{3}MLCT state displays luminescence with a reasonably high quantum yield and long lifetime. Complexing a metal cation with the azacrown in complex **2** also results in a switch between the LLCT and MLCT transitions and dramatic absorption spectrum changes. The lack of emission for the cation-bound **2** is due to the dissociation of the crowned cation from the azacrown within the lifetime of the ^{3}MLCT state, and the rapid internal conversion from the ^{3}MLCT to the ^{3}LLCT states for the cation-free complex. These complexes can be utilized for molecular recognition and chemosensors specific for detection of proton and metal cations.

Experimental Section

Materials: 4-(Dimethylamino)phenylacetylene and [PtCl(terpy)]Cl·$2H_2O$ were prepared by literature methods.[24,25] 4-Ethynylphenyl-*N*-15-azacrown-5 ether was synthesized by a modified literature method.[24,26] Acetonitrile was distilled after refluxing for 3 h in the presence of P_2O_5. Other reagents were of analytical grade and used as received.

[Pt{C≡CC_6H_4-4-N$(CH_3)_2$}(terpy)]BF_4 (1): A mixture of [Pt(terpy)Cl]Cl·$2H_2O$ (100 mg, 0.19 mmol), CuI (10 mg), 4-(dimethylamino)phenylacetylene (55 mg, 0.38 mmol), 3 mL of DMF, and 4 mL of trimethylamine was sonicated under nitrogen for 8 h. An excess of an aqueous solution of KBF_4 was then added to the mixture. Dark-blue crystals were obtained after stirring for 1 h. The product was isolated, washed with water and diethyl ether. Subsequent recrystallization by diffusion of diethyl ether vapor into an acetonitrile solution of the product gave **1** as dark-blue crystals. Yield: 96 mg (76%). FAB-MS: *m/z* = 572 [M^+]. ^{1}H NMR ([D_6]DMSO): δ = 2.93 (s, 6 H), 6.68 (d, *J* = 8.4 Hz, 2 H), 7.34 (d,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

J = 8.2 Hz, 2 H), 7.95 (t, J = 6.3 Hz, 2 H), 8.58 (m, 7 H), 9.21(d, J = 5.1 Hz, 2 H). $C_{25}H_{21}BF_4N_4Pt\cdot0.5H_2O$ (668.36): calcd. C 44.92, H 3.29, N 8.39; found C 44.87, H 3.59, N 8.58.

[Pt(C≡CC$_6$H$_4$-4-*N*-15-monoazacrown-5)(terpy)]ClO$_4$ (2): The synthesis of **2** was similar to that for complex **1**, except 4-ethynylphenyl-*N*-15-azacrown-5 ether was used in place of 4-(dimethylamino)phenylacetylene, and $LiClO_4$ was used in place of KBF_4. Yield: 110 mg (70%). FAB-MS: m/z = 746 [M^+]. ^{1}H NMR ([D$_6$]DMSO): δ = 3.64−3.82 (m, 20 H), 6.76 (d, J = 8.8 Hz, 2 H), 7.40 (d, J = 8.8 Hz, 2 H), 8.00 (t, J = 6.1 Hz, 2 H), 8.56−8.73 (m, 7 H), 9.16 (d, J = 5.1 Hz, 2 H). $C_{33}H_{35}ClN_4O_8Pt\cdot0.5H_2O$ (855.21): calcd. C 46.35, H 4.24, N 6.55; found C 46.32, H 4.18, N 6.15.

Physical Measurements and Instrumentation: UV/Vis spectra were obtained on a Shimadzu UV-1601PC spectrophotometer. Steady-state emission spectra were recorded on a Perkin Elmer LS50B spectrofluorometer. Elemental analysis was performed on a Carlo Erba 1106 elemental analyzer. ^{1}H NMR spectra were recorded on a Bruker-400 FT NMR spectrometer with chemical shifts (in ppm) relative to tetramethylsilane. FAB-MS spectra were run on a KYKY-ZHP mass spectrometer. X-ray analysis was performed on a Bruker Smart1000 X-ray diffractometer. Excited-state lifetimes were measured using a conventional laser system. The excitation source was the 355 nm line from the output of a Nd:YAG laser (third harmonic, 10 ns). All solutions were purged with argon for 15 min for emission spectra and lifetime measurements. The quantum yields of the emission were obtained by the optical dilute method using a degassed acetonitrile solution of $[Ru(bpy)_3](PF_6)_2$ as a reference (Φ = 0.062).[22] The ion-binding constants for **2** were calculated from the Hildebrand−Benesi equation: [27]

$$A_0/(A_0 - A) = A_0/\alpha[\text{complex } \mathbf{2}] + (A_0/\alpha[\text{complex } \mathbf{2}]\ Ks)\cdot(1/[M^{n+}])$$

where A and A_0 are the absorbance for complex **2** in the presence and absence of a metal ion, respectively, α is the ratio of complexation between complex **2** and the cation and Ks is the binding constant.

Easy Synthesis of New Chiral Tridentate Schiff Bases and Their Use as [N,N,O] Ligands for Ni and Pd Complexes − Catalytic Behaviour versus Hydrogenation Reactions[‡]

Camino González-Arellano,[a,b] Enrique Gutiérrez-Puebla,[a] Marta Iglesias,*[a] and Félix Sánchez*[b]

Keywords: Palladium / Nickel / Chiral Schiff bases / Hydrogenation / Tridentate ligands

The chiral [N,N,O] tridentate unsymmetrical Schiff bases **3**–**5** (aryl = phenyl, 1-naphthyl, 2-naphthyl) were synthesised easily in high purity and good yields. All the organic compounds were characterised by elemental analysis, mass spectrometry, IR, ^{1}H and ^{13}C NMR spectroscopy. Palladium(II) and nickel(II) Schiff-base complexes were prepared as air-stable solids. Because the [N,N,O] ligand is tridentate after deprotonation of the –OH group, the coordination of the metal ion is completely stereospecific and gives rise to only one diastereoisomer. The X-ray crystal structures of the complexes [Ni(**3**)(OAc)] and [Pd(**4**)(OAc)] were determined. These complexes were shown to be very active catalysts (TOF up to 10^6 h^{-1}) for the hydrogenation of olefins and imines under mild conditions.

Introduction

The development of efficient catalytic asymmetric reactions is one of the most challenging tasks in current synthetic chemistry, much effort having been devoted to the creation of new chiral N-ligands and their metal complexes for evaluation in advanced asymmetric catalysis.[1] The condensation of an amine and an aldehyde, to form Schiff bases, was one of the earliest reported reactions in chemistry;[2] these compounds are now an important class of ligands in coordination chemistry, and have been studied extensively[3] because of their selectivity for various metal ions. Jacobsen and Katsuki have developed tetradentate salen ligands, now one of the most intensely studied classes of bis-chiral Schiff bases, able to coordinate easily to a wide variety of metals. The interest in such bases has increased since the discovery of manganese(III) salen complexes, which are excellent catalysts for the enantiomeric epoxidation of unfunctionalized alkenes;[4] the development of chiral salen metal complexes and catalysts in the last decade has therefore shown a very rapid growth.[5] Chiral salen-containing complexes are now used as catalysts for a variety of enantioselective reactions such as oxidation, aziridination, cyclopropanation, Diels−Alder cyclisation, and hydrogenation.[6]

In this report, we focus on new simpler chiral Schiff-base ligands containing pyrrolidinylamino functionalities (in place of one of the phenolic groups on salen ligands), the synthesis of the complexes [Pd(**L**)(OAc)] (**LPd**), [Ni(**L**)(OAc)] (**LNi**), as well as the X-ray crystal structures of **3Ni** and **4Pd**. The method we have developed should allow the easy synthesis of a wide variety of chiral Schiff-base ligands. The iminophenoxy ligands were designed to coordinate to Pd^{II} and Ni^{II}; the amino substituent could be varied in order to improve the stability of the complexes in the catalytic hydrogenation of alkenes and imines.

Results and Discussion

Synthesis of Ligands

The synthesis of chiral ligands **3**−**5** is based on the condensation of enantiomerically pure (*S*)-(1-benzylpyrrolidin-2-yl)methylamine (**2a**), (*S*)-[1-(1-naphthylmethyl)pyrrolidin-2-yl]methylamine (**2b**) and (*S*)-[1-(2-naphthylmethyl)pyrrolidin-2-yl]methylamine (**2c**) with 3-*tert*-butyl-2-hydroxy-5-methylbenzaldehyde (**1**) in the presence of 3 Å molecular sieves (Scheme 1). The chiral amines **2b** and **2c** were synthesized from (*S*)-proline in a simple sequence of reactions (Scheme 2), with the chiral centre remaining unmodified. The preparation of the benzyl analogue **2a** was efficiently

[‡] Preliminary results were presented in the 6th International Symposium on Catalysis Applied to Fine Chemicals (Delft, 2003).

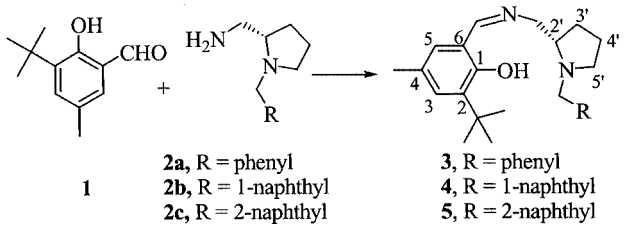
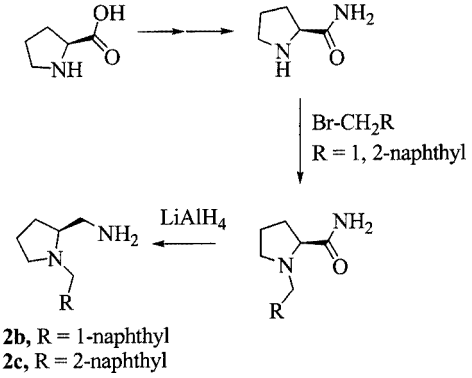
carried out by the procedure published by us previously.[7] Compounds **3−5** were characterised by elemental analysis (C, H, N), ^{1}H and ^{13}C NMR and mass spectrometry. In the ^{1}H NMR spectra, the OH protons appear at δ = 9.80 ppm (for **4**) and the imine protons appear as singlets at δ = 8.18 (for **3**), 8.00 (for **4**) and 8.30 (for **5**) ppm. NOE experiments indicate unequivocally that the ligands prefer the *anti* configuration.



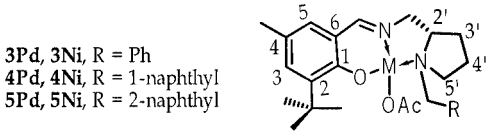
Scheme 1. General synthesis of chiral Schiff bases **3−5**



Scheme 2. Synthesis of chiral amine precursors

Synthesis of the Complexes

The interest in making new salen-type ligands lies in their ability to form stable complexes with transition metals, thus serving as potential precursors for homogeneous catalysis of a variety of reactions.[5,8] We decided to use a chiral catalyst employing a chiral ligand in which the stereogenic centres are in close proximity to the metal (Scheme 3); chiral predetermination was observed for all of the palladium and nickel complexes.[9] When the chiral ligands are coordinated to the metal, two chiral centres are introduced, at the coordinated nitrogen atom and at the metal. From the ORTEP diagrams and the NMR spectroscopic data, we can deduce that the coordination of the metal ion is completely stereospecific, and gives rise to only one of the two possible diastereoisomers.



Scheme 3. General structural formulae of complexes **3Pd, 3Ni**, **4Pd**, **4Ni**, **5Pd** and **5Ni**

All the complexes were prepared by addition of the divalent metal salts [$Pd(OAc)_2$, $Ni(OAc)_2$] to an ethanolic solution of ligand; one of the acetate groups is displaced by the phenolic anion whereas the amine and imine nitrogen atoms coordinate to the metal in a square planar arrangement (Scheme 3). The complexes, which were precipitated from EtOH, were obtained with high purity and in high yields as microcrystalline stable solids, which are soluble in organic solvents. The structures of all the complexes were confirmed by elemental analysis (C, H, N and M), IR spectroscopy, and ^{1}H and ^{13}C NMR spectroscopy. They were also characterised by electro-spray mass spectrometry. The ES-MS spectra of complexes show the molecular ion peaks, [M^+], and peaks from the fragments due to elimination of the acetate ion [$M^+ - OAc$]. All assignments were confirmed by good agreement between the observed and calculated isotopic distributions.

Infrared and Electronic Spectra

IR stretching frequencies were used to characterize the binding of the imine nitrogen. Bands at 1600 cm^{-1} were assigned to the $\nu_{C=C}$ and $\nu_{C=N}$ vibrations, shifted to lower wavenumbers (relative to the free ligands) due to N-coordination of the imine.[10] The absence of the ν_{O-H} band (present in the spectra of the free ligands at ca. 3430 cm^{-1}) is in accordance with loss of the hydroxyl proton. The IR spectra also show strong bands at 1290 and ca. 1500 cm^{-1}; these were assigned to the symmetric and asymmetric ν_{COO} bands, respectively, in agreement with the values expected for monocoordinate acetate ligands.[11] New bands in the 500−600 cm^{-1} region were ascribed to ν_{M-O}.

The electronic absorption spectra for all complexes in the 200−800 nm range were obtained using 10^{-3} to 10^{-5} M solutions in ethanol. The complexes show several band maxima in the UV region, assigned to the intraligand π→π* and n→π* transitions in the aromatic ring and the azomethine group and the charge-transfer transitions.[12] The higher molar extinction coefficient of the bands in the 260−350 nm range may be due to the coincidence of the charge transfer, d→π* and intraligand π→π* and n→π* transitions. The bands in the 400−450 nm region correspond to the d→d transitions expected for planar complexes[13] and MLCT bands.

NMR Spectra

The diamagnetic palladium and nickel complexes were characterised by ^{1}H and ^{13}C NMR spectroscopy. All assignments were based on several correlations in the 2D spectra, and are fully consistent with the structures depicted in Scheme 3. In all cases, the spectra show the simultaneous occurrence of two sets of signals, which are attributable to the substituted benzaldimine entity and the aliphatic part of the ligand. In the ^{1}H NMR spectra all the resonances were high-field shifted compared to the uncoordinated ligand, and they were in agreement with metallation of the ligand and coordination of the metal atom to the imine nitrogen atom. The most noticeable shifts observed were

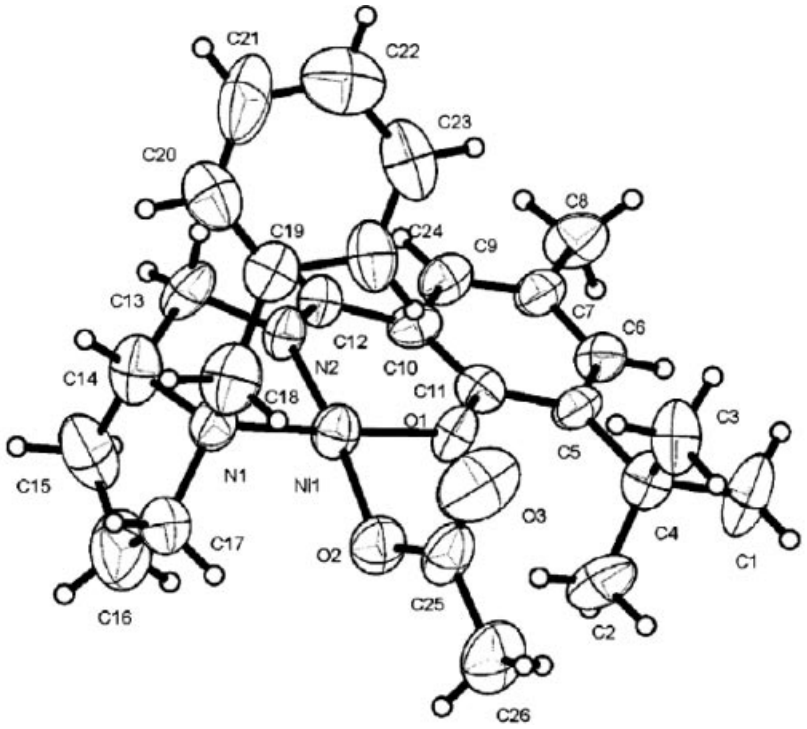

Figure 1. Molecular structure of **3Ni**, with labelling scheme; only one molecule has been shown for clarity

those for C*H*=N, CH=NCH_2, H-2′ and H-5′. Deprotonation of the hydroxyl group was confirmed by the absence of OH resonances in the ^{1}H NMR spectrum. The resonance corresponding to the C*H*=N proton appears as a singlet (δ = 7.9−7.2 ppm), shifted to high field due to the coordination of the imine group to the metal atom through the lone pair of the nitrogen atom.[14] The ^{1}H NMR spectrum shows the *Me*COO protons as a singlet at δ = 2.10 ppm. The ^{13}C NMR spectra show that the signals assigned to the *C*=N carbons are shifted to high-field and those due to C-1 shifted downfield (to δ ≈ 162 ppm), confirming that metallation had occurred.

Crystal Structure Studies of 3Ni and 4Pd

Suitable crystals were grown by slowly evaporating an ethanolic solution of the complex. The molecular structures are shown in Figure 1 and Figure 2. Crystal data are given in Table 4, and selected bond lengths and angles with estimated standard deviations are shown in Table 1.

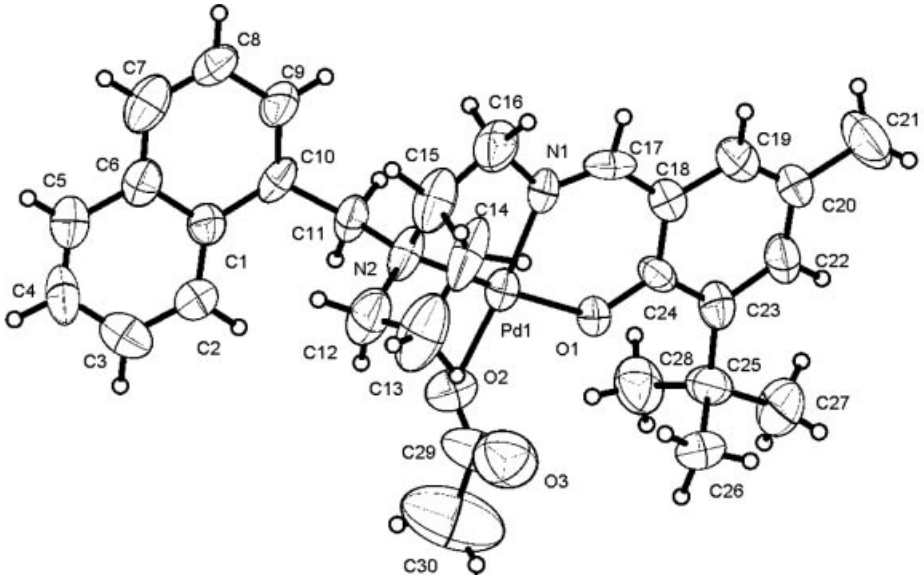

Figure 2. Molecular structure of **4Pd**, with labelling scheme

N(3)−Ni(2)−O(4)	169.3(3)		
O(3)−Ni(2)−N(4)	176.0(3)		
N(3)−Ni(2)−N(4)	88.0(3)		
O(4)−Ni(2)−N(4)	91.5(3)		

The structure consists of ML(OAc) molecules; each asymmetric unit of **3Ni** contains two crystallographically independent molecules (only one molecule is shown). The absolute configuration is assigned on the basis of known chirality of the amine used. The ligands are tridentate, and bond to the M^{II} atom by the deprotonated phenolic oxygen atom (O_{phe}) and the imine (N_{im}) and tertiary amine nitrogens (N_{am}); each metal also coordinates to one acetate group. The geometry of metal coordination sphere is distorted square planar, and the sum of the angles around the metal atom is 360.7(4)° for the Ni complex and 359.8(4)° for the Pd complex. The angles between adjacent atoms in the coordination sphere are close to the expected value of 90°, with the most noticeable distortions found for the N−M−N angle, due to chelation [N(2)−Ni(1)−N(1): 87.7(3)°, N(3)−Ni(2)−N(4): 88.0(3)°, N(1)−Pd−N(2): 83.0(3)°]. The $M-O_{phe}$, $M-N_{im}$ and $M-N_{am}$ distances were found to be 1.825, 1.863; 1.834, 1.841 and 1.947, 1.941 [Ni(1), Ni(2)] for **3Ni** and 1.975, 1.925 and 2.072 for **4Pd** in good agreement with the literature values.[15] Furthermore, the pyrrolidine metal distances [$M-N_{am}$: 1.947(6) for the free ligand, 1.941(6) for **3Ni** and 2.072(6) Å for **4Pd**] are longer than the $M-N_{im}$ distances, despite the fact that amine nitrogen atoms usually show stronger coordination than imine nitrogen atoms. This effect, however, is probably caused by greater steric hindrance of the tertiary amine nitrogen compared to the mono-substituted imine nitrogen. The coordinated atoms lie exactly in plane (the maximum deviation from least-squares plane is 0.002 Å) and are arranged at the corners of an irregular quadrilateral, reflecting the difficulty that the ligand has in spanning the square-planar coordination positions. The structures contain one six-membered and one five-membered chelate ring. The six-membered metallacycle containing the imino moiety is practically coplanar with the O(1)−O(2) coordination plane [dihedral angles 8.21(0.27)° for Ni(1), 10.07(0.27)° for Ni(2) in **3Ni**, 7.13(0.46)° for **4Pd**]. The five-membered metallacycle is in an envelope conformation, on C(15) for **4Pd**, and on C(14) [Ni(1)] and C(40′) [Ni(2)] for **3Ni**. The pyrrolidine rings are also in an envelope conformation. In **3Ni**, the 1-benzylpyrrolidine group of the ligand **3** is in close proximity to the nickel ion.

Catalytic Hydrogenation

These structurally well-defined Ni^{II} and Pd^{II} complexes enable us to explore their application to catalytic hydrogenation. The hydrogenation of the simple alkenes **I** and **II**, the functionalized alkenes **III**−**V** and the imines **VI** and **VII** (Figure 3) with Pd and Ni complexes were carried out under standard conditions (EtOH, 4 atm. H_2, 40 °C). The results are summarised in Table 2 and Table 3.

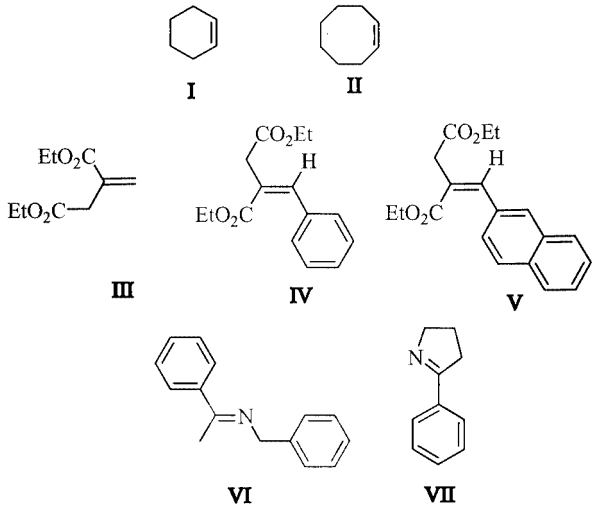

Figure 3. Substrates used in the hydrogenation reactions

Table 2. Turnover rates for catalytic hydrogenation with ligand **3** (TOF: h^{-1}; Conditions: 4 atm, 40 °C, S/C ratio 1000:1)

Substrate	Pd	Ni
I	5460	4020
II[a]	25500	22800
III	3360	2400
IV	640	220
V	153	117
VI	3240	4800
VII	167	93

[a] S/C ratio 10000:1.

The nature of the metal center has an influence on the catalytic activity. In general, the palladium catalysts were more active than their nickel analogues when **3** was used as ligand under our conditions; the nickel complexes were the most active when **4** or **5** were used. The complexes **4Pd**, **4Ni**, **5Pd** and **5Ni** contain naphthyl groups as substituents in the pyrrolidinyl group, and display TOFs of 8×10^5 to 10^6 h^{-1} for the hydrogenation of cyclooctene (**II**) and 3−5

Table 3. Turnover rates for catalytic hydrogenation with ligands **4** and **5** (TOF: h^{-1}; Conditions: 4 atm, 40 °C S/C ratio 100000:1).

Catalyst	II	VI
4Pd	842760	337500
4Ni	964320	410940
5Pd	684000	309240
5Ni	961920	461520

$\times 10^5$ h^{-1} for imine **VI**. This may be due to the closeness of the phenyl group to the metal (Figures 1 and 2). Use of these Pd and Ni complexes led to quantitative conversion of the olefins under the hydrogenation conditions employed. No palladium black or nickel was formed in any of the hydrogenation reactions. Low enantiomeric excesses (< 10% *ee*) resulted in all cases, as shown by ^{1}H NMR spectroscopy and chiral GCMS of the reaction mixtures.

The accumulated evidence concerning the mechanisms of homogeneously catalysed hydrogenations indicates that there are three principal modes of hydrogen activation: oxidative addition, and homolytic or heterolytic hydrogen cleavage. In the case of the Pd and Ni complexes, heterolytic cleavage is preferred to a hydride intermediate, which would have to involve charge separation without any oxidation of the metal.[16]

Conclusion

A series of chiral [N,N,O] tridentate Schiff bases were synthesised with high purity and in good yield. Treatment of these ligands with palladium(II) and nickel(II) acetate in EtOH gave only one diastereoisomer of the respective air-stable complexes. These complexes were shown to be active catalysts for hydrogenation, with high reactivity under mild conditions (TOF up to 10^6 h^{-1}). These simple catalysts, especially the cheaper Ni complexes, are a real alternative to conventional Pd catalysts for hydrogenation in industrial processes.

Experimental Section

General Remarks: All preparations of metal complexes were carried out under nitrogen by conventional Schlenk techniques. Solvents were carefully degassed before use. C, H, N analyses were carried out by the analytical department of the Institute of Materials Science (C.S.I.C.) with a perkin-Elmer 240C apparatus. Metal contents were analysed by atomic absorption using Perkin−Elmer Analyst 300 atomic absorption and Plasma ICP Perkin−Elmer 40 spectrometers. IR spectra were recorded with a Nicolet XR60 spectrophotometer (range 4000−200 cm^{-1}) in KBr pellets. ^{1}H NMR and ^{13}C NMR spectra were taken on Varian XR300 and Bruker 200 spectrometers. Chemical shifts are referred to tetramethylsilane (internal standard). Optical rotation values were measured using the sodium-D line (589 nm) with a Perkin−Elmer 241 MC polarimeter. Gas chromatography analysis was performed using a Hewlett−Packard 5890 II apparatus with a flame ionisation detector in a cross-linked methylsilicone column.

2-*tert*-Butyl-4-methyl-6-[(*E*)-({[(2*S*)-1-benzylpyrrolidin-2-yl]methyl}-imino)methyl]phenol (3): A solution of (*S*)-(1-benzylpyrrolidin-2-yl)methylamine (**2a**) (380 mg, 2 mmol) in ethanol (20 mL) was added to a solution of 3-*tert*-butyl-5-methylsalicylaldehyde (384 mg, 2 mmol) in ethanol (20 mL) at room temperature over a period of 30 min with stirring. The solvent was removed under vacuum, and the residue purified by flash chromatography (hexane:EtOAc, 5:1) to give a yellow oil (640 mg). Yield 88%. $[\alpha]_D^{25} = -14.3$ (c = 0.5, EtOH). $C_{24}H_{32}N_2O$ (364): calcd. C 79.1, H 8.8, N 7.7; found C 78.9, H 8.6, N 7.4. IR (film, cm^{-1}): $\tilde{\nu}$ = 1628, 1592 (C=C + C=N). Preparation of Metal Complexes. General Method: An solution of $Pd(OAc)_2$ or $Ni(OAc)_2$ in ethanol (0.5 mmol/15 mL) was added to a solution of the ligand in EtOH (15 mL) at room temperature. The resulting mixture was stirred under reflux for 4 hours, cooled to room temperature and then concentrated under vacuum. The residue was washed several times with diethyl ether, dried and filtered to afford the complex in almost quantitative yield.

ppm. ^{13}C NMR ($CDCl_3$): δ = 163.50 (C−O−Ni), 163.25 (*C*H=N), 142.63, 134.77, 134.52, 133.67, 132.71, 131.70, 130.75, 130.10, 130.00, 129.52, 129.22, 128.21, 128.01, 124.17, 121.14 (C_{arom}), 64.10 ($C^{2'}$), 63.07 (CHN=*C*H_2), 61.23 ($CH_2^{naphthyl}$), 58.56 ($C^{5'}$), 32.32 [*C*$(CH_3)_3$], 30.63 [C(*C*$H_3)_3$], 29.39 ($C^{3'}$), 25.97 (CH_3), 24.45 ($C^{4'}$), 21.79 (OCO*C*H_3). MS^+ (EI) (*m*/*z*, %): 472 (M^+ − Ac, for ^{59}Ni); 473 (M^+ − Ac, for ^{60}Ni).

Catalytic Experiments: The catalytic properties of the Pd and Ni complexes with respect to hydrogenation were examined under conventional conditions for batch reactions in a 100 mL reactor (Autoclave Engineers) at 40 °C, using 4 atm. hydrogen pressure and a metal/substrate molar ratio of 1/1000. The progress of the reaction and the optical purity (*ee*) of the hydrogenated product were monitored by gas chromatography with a chiral glass capillary column {stationary phase: a mixture of methyl silicone (OV-1701) and methylsilicone heptakis[2,3-dipentyl-6-(*tert*-butyldimethylsilyl)]-β-cyclodextrin}.[19]

X-ray Crystallography: Three-dimensional, room temperature X-ray data were collected on a Bruker−Siemens Smart CCD diffractometer equipped with a normal focus, 2.4 kW sealed tube X-ray source (molybdenum, λ = 0.71073 Å) operating at 50 kV and 20 mA. Data were collected over a quadrant of the reciprocal space by a combination of two frame sets. The cell parameters were determined and refined by least-squares fit of all the reflections collected. Each frame exposure time was 10 s covering 0.3° in ω. The crystal-to-detector distance was 6.05 cm. Coverage of the unique set was over 81.1% (**3Ni**), 97.7% (**4Pd**), complete to at least 31.10° (Ni), 26.40° (Pd) in θ. The first 50 frames were re-collected at the end of the data collection to monitor crystal decay; this showed a drop in the intensities to about 60% of their initial values. The Flack *x* parameters were 0.02(6) and 0.08(6), indicative of a correct absolute structure. The structure was solved by Multan and Fourier methods using SHELXTL.[20] Full matrix least-square refinement was carried out by using SHELXTL[20] minimising $w(F^2_o - F^2_c)^2$. The crystal of **3Ni** showed a very poor spectrum at high angles; thus, about 18% of the reflections gave negative intensities after the integration process. Because of this, only positive reflections (81.1%) were taken into account. Weighted *R* factors (*Rw*) and all goodness of fit parameters *S* are based on F^2, conventional *R* factors (*R*) are based on *F*. Crystal data are given in Table 4.

CCDC-218738 (for **4Pd**) and -218739 (for **3Ni**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Structural Studies of Two New Base Adducts of Bis(2,4-pentanedionato)cobalt(II)

Stefania Tanase,[a] Elisabeth Bouwman,*[a] Jan Reedijk,[a] Willem L. Driessen,[a] Marilena Ferbinteanu,[b] Martina Huber,[c] Allison M. Mills,[d] and Anthony L. Spek[d]

Keywords: Cobalt / 2,4-Pentanedione / 3,5-Dimethylpyrazole / Dimethylethanolamine / Coordination modes

The syntheses, spectroscopic properties and crystal structures of two new base adducts of bis(2,4-pentanedionato)cobalt(II) with 3,5-dimethylpyrazole (Hdmpz) (**1**) and dimethylethanolamine (Hdmea) (**2**) are described. The crystal structures of both compounds contain monomeric Co^{II} complexes with *cis*-distorted octahedral environments, even for the monodentate Hdmpz ligand which is quite unique. These mononuclear complexes are linked by hydrogen bonds between the anionic 2,4-pentanedionato groups and the neutral Hdmpz or Hdmea ligands. The low-temperature polycrystalline-powder EPR spectra display unresolved metal hyperfine coupling. The *g* values are anisotropic in both cases; the anisotropy is larger for the Hdmea adduct. Interesting insights into the coordination effects were gained with the help of electron-density descriptors (Laplacian of density and Natural Bond Orbitals). This revealed a slight deviation of the coordinating lone pairs of the pentanedionato ligands from the Co–O axis, as well as a nonstandard hybrid composition. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The β-diketonato complexes of cobalt(II) are of interest in the field of coordination chemistry as structural prototypes and because of their tendency to form unanticipated oligomeric structures where the metal centre achieves a coordination number greater than four. Bis(acetylacetonato)cobalt(II) is a very common and easily accessible coordination complex, which exists as a tetranuclear complex in nonpolar solvents.[1] If a small amount of some neutral donor ligand (L) is introduced into a solution of the tetrameric $Co(acac)_2$ in a noncoordinating solvent, complex equilibria involving the following types of compounds are established: $[Co(acac)_2]_4$, $[Co(acac)_2L]$, $[Co(acac)_2L]_2$ and $[Co(acac)_2L_2]$.[2] Thus, upon treatment of $[Co(acac)_2]_4$ with pyridine (py), the compound *trans*-$[Co(acac)_2py_2]$ was isolated and its structure determined.[3] Similarly, *trans*-$[Co(acac)_2L_2]$ compounds (where L represents water, 6-methylquinoline, imidazole and 2-aminopyridine) were also prepared and their crystal structures reported.[4−7] With water as the donor molecule, two intermediate products were isolated: $[Co(acac)_2(H_2O)]_2$ and $[Co(acac)_2]_3(H_2O)$.[8,9] The crystal structures of both are derived from that of the tetrameric complex $[Co(acac)_2]_4$.

Our current interest in the autoxidation drying mechanism occurring in alkyd paints,[10,11] which involves cobalt complexes that are present as additives, led us to investigate the coordination chemistry and the catalytic activity of bis(2,4-pentanedionato)cobalt(II) in the presence of some organic ligands as possible co-catalysts.[12] In this context, it is of interest to probe the stability and reactivity of such adducts and additional information can be gained by contrasting the properties of chelating ligands, constrained to adopt *cis* geometry, with those of monodentate ligands, which typically yield *trans* complexes.[13]

In this paper, the syntheses, crystal structures and spectroscopic properties of *cis*-$[Co(acac)_2(Hdmpz)_2]$ (**1**) and $[Co(acac)_2(Hdmea)]$ (**2**) are described. Both complexes are new base adducts of bis(2,4-pentanedionato)cobalt(II) with Hdmpz (3,5-dimethylpyrazole) or Hdmea (dimethylethanolamine). Furthermore, compound **1** offers an interesting chromophore, distinguished as having the anisotropy of π effects in the N−Co−N moiety qualitatively different (in-plane) as compared to those encountered in chelating diamines (perpendicular to the N−Co−N plane).

Results and Discussion

Synthetic and Spectroscopic Studies

The compounds *cis*-[Co(acac)$_2$(Hdmpz)$_2$] (**1**) and [Co(acac)$_2$(Hdmea)] (**2**) were obtained in good yields by adding a stoichiometric amount of either Hdmpz or Hdmea to a solution of anhydrous cobalt acetylacetonate in toluene. Suitable crystals were obtained by slow evaporation of the solvent. Although compound **1** appeared to be unstable in solution (see below), the reaction that forms the oxidized product is sufficiently slow to allow the crystallisation of the pure cobalt(II) complex. The IR spectra of both compounds show the bands expected for the organic ligands coordinated to the cobalt centre. In particular, the peak at $\tilde{\nu}$ = 3348 cm^{-1} observed in the IR spectrum of **2**, indicates the presence of the protonated ligand Hdmea.

The solid-state electronic spectra of both compounds show two principal regions of absorption, as expected for octahedral Co^{II} complexes. The absorption spectrum of compound **1** is dominated by a broad band with a maximum at 1170 nm and a multicomponent band at 510 nm which together suggest the presence of pseudo-octahedral high spin Co^{II} centres. Compound **2** has a similar absorption spectrum with two main bands, one at 1125 nm and the other at 502 nm. These two bands correspond to the $^4T_{1g}(F)\rightarrow{}^4T_{2g}(F)$ and $^4T_{1g}(F)\rightarrow{}^4T_{1g}(P)$ transitions. The multiple structure of the band near 500 nm arises from a number of effects, but primarily from the admixture of spin-forbidden transitions to doublet states mainly derived from ^2G and ^2H.[14]

Study of the complexation reaction that occurs upon adding Hdmpz or Hdmea to [Co(acac)$_2$(H$_2$O)$_2$] in various solvents (methanol, ethanol, acetone, benzene and toluene) reveals that compounds with the composition [Co(acac)$_2$(Hdmpz)$_2$] or [Co(acac)$_2$(Hdmea)] are formed, irrespective of the nature of the solvent used. The electronic spectrum of the violet solution of **1** is typical for a distorted octahedral Co^{II} compound and it shows similar features as observed for other base adducts of bis(2,4-pentanedionato)-cobalt(II).[2,14] When a toluene solution of **1** is stored in a closed atmosphere it gradually transforms into a red colour over a number of days. The electronic spectrum of the red solution shows a broad absorption band with the maximum at 560 nm that is characteristic for an octahedral cobalt(III) species (Figure 1);[14] however, traces of cobalt(II) might still be present. This transformation suggests the oxidation of Co^{II} to Co^{III} and indicates that the complex *cis*-[Co(acac)$_2$(Hdmpz)$_2$] is unstable in solution. Red crystals have been isolated, but these thin plates are prone to stacking faults. Although X-ray diffraction data were collected for one of the plates, the stacking disorder could not be resolved. However, a preliminary crystal structure solution revealed the presence of the cobalt ion surrounded by two 2,4-pentanedionato groups and two neutral Hdmpz ligands in the *trans* positions, showing that the assumed oxidation of Co^{II} to Co^{III} in **1** is accompanied by a *cis*/*trans* isomerisation process. Complex **2** does not display such solution redox behaviour.

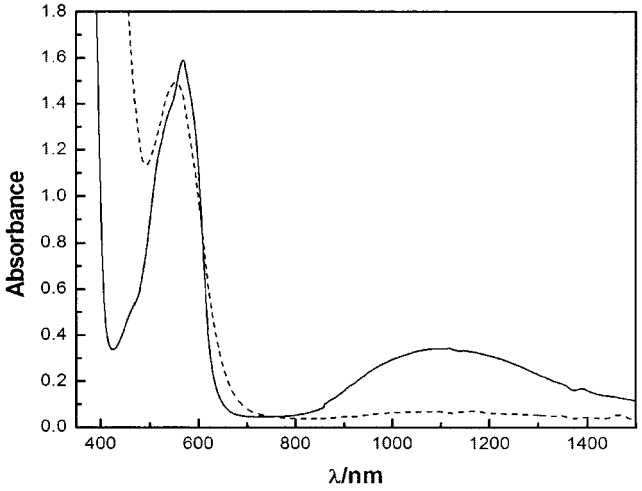

Figure 1. Spectral changes observed for a toluene solution of compound **1**; (a) just after preparation (—); (b) after 12 d (---)

Crystal Structures

The structures of **1** and **2** were determined by X-ray crystallography. Selected bond lengths and angles are listed in Table 1.

As shown in Figure 2, the crystal structure of **1** consists of isolated *cis*-[Co(acac)$_2$(Hdmpz)$_2$] molecules. To the best of our knowledge, this is the first base adduct of bis(2,4-pentanedionato)cobalt(II) to contain the two monodentate ligands in *cis* positions. The cobalt ion is in a distorted octahedral environment; it is coordinated by four oxygen atoms from two chelating acetylacetonato groups and two nitrogen atoms from two monodentate Hdmpz ligands. The Co−O bond lengths, in the range 2.0571(17)−2.0978(18) Å, are similar to those reported for *trans*-[Co(acac)$_2$L$_2$] complexes. The Co−N bonds of 2.159(2) and 2.166(2) Å are shorter than the corresponding Co−N bonds in *trans*-[Co(acac)$_2$L$_2$] complexes with L = pyridine,[5] 6-methylquinoline[4] and 2-aminopyridine,[6] but are longer than those observed for other Co^{II} complexes with 3,5-dimethylpyrazole.[15,16] The most interesting feature of the crystal structure of **1** is the presence of hydrogen bonds that may play an important role in the stabilisation of the *cis* configuration of the monodentate ligands. The details of these interactions are presented in Table 2. The NH groups of both Hdmpz ligands each participate in one intramolecular and one intermolecular hydrogen bond. Thus, molecules of **1** are linked into one-dimensional chains along the *c*-direction by the propagation of two bifurcated hydrogen bonds of the N−H···(O)$_2$ type (Figure 3). The closest separation between the metal ions of neighbouring molecules is 6.1035(5) Å.

The molecular structure of [Co(acac)$_2$(Hdmea)] (**2**) is similar to that of **1** concerning the topology of the Co(acac)$_2$ moiety and the position of the donor atoms (Figure 4). The base adduct **2** is constrained to adopt the *cis* configuration due to the chelating nature of Hdmea. The Co^{II} ion has a distorted octahedral coordination sphere consisting of four oxygen atoms from two acetylacetonato

OH groups of the Hdmea molecules and 2,4-pentanedionato O atoms link each pair of molecules (Table 2). The separation between the metal ions of neighbouring molecules is 5.47(9) Å.

EPR Spectroscopy and Magnetic Properties

The EPR spectra of polycrystalline *cis*-[Co(acac)$_2$(Hdmpz)$_2$] and [Co(acac)$_2$(Hdmea)] recorded at 4.2 K are shown in Figure 5. As previously observed for *trans* adducts of bis(2,4-pentanedionato)cobalt(II),[17] the large anisotropy of cobalt(II) complexes is such that the intermolecular exchange interactions do not cause exchange narrowing and the signals of individual molecules are resolved. However, the high- and low-field features are very broad, due to unresolved metal hyperfine coupling. Assuming an effective $S = 1/2$ ground state and neglecting interactions between the two Co^{II} ions, the following *g*-values are obtained;[18] for **1** they are: $g_1 = 2.1$, $g_2 = 2.5$ and $g_3 = 6.5$; for **2** they are: $g_1 = 1.9$, $g_2 = 4.3$ and $g_3 = 10.7$. The large variation of the *g*-values is expected in view of the high sensitivity of the *g*-values of Co^{II} with respect to any weak distortion of the ligand field. The average *g*-value ($<g>$) of complex **1** ($<g> = 3.7$) is similar to those observed for distorted octahedral cobalt(II) complexes. For such complexes, $<g> = 4.3$ and *g*-tensor components in the range from 1.5 to 7 have been reported.[19] For compound **2**, $<g> = 5.6$ and g_3 are larger than usual.

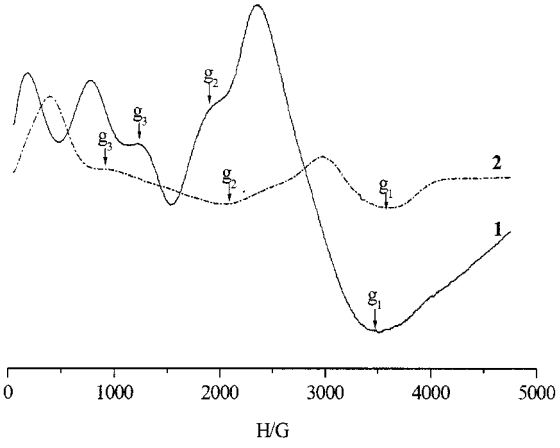

Figure 5. EPR spectra of polycrystalline powders of **1** and **2** recorded at 4.2 K and 9 GHz

The magnetic properties of **1** and **2** were investigated in the range 5−300 K. The $\chi_m T$ product at room temperature is 1.92 emu·K·mol^{-1} for **1** and 2.19 emu·K·mol^{-1} for **2**. Both values are slightly larger than the spin-only value for an isolated high-spin Co^{II} centre (1.875 emu·K·mol^{-1} for $S = 3/2$ assuming $g_{Co} = 2$) because of the orbital contribution. The $\chi_m T$ curves of both compounds exhibit a continuous decrease as the temperature is lowered from 300 to 5 K. Such behaviour, characteristic for Co^{II} complexes, is essentially due to single-ion anisotropy which may be combined with minor contributions from antiferromagnetic exchange between the Co^{II} centres by hydrogen bonds.

Electron Structure Analysis of the Ligand Binding in Complexes 1 and 2

A synoptic perception of the coordination bonding is obtained using the Laplacian of electron density and the density difference maps drawn in the ligand planes. The following results are based on the unrestricted DFT-B3LYP calculation with the 6-31G basis set.[20,21] The Laplacian pattern of each coordinated ligand [Figure 6 (a−c)] is in its gross part similar to those of the free ligands. The metal ion is mapped in complexes by areas with $\nabla^2\rho > 0$, corresponding to the electron-density depletion due to its ionic positive status.[22,23] The Laplacian can in principle detect the location of the lone pairs among the areas with $\nabla^2\rho > 0$. Figure 6 (a−c) shows, however, that the lone pairs are not very prominent at the oxygen donors, but are more pronounced at the nitrogen donor atoms. A similar aspect is observed comparing the different donor atoms of the amino alcohol ligand Hdmea. This may be due to the high chemical hardness of the oxygen atoms as compared to nitrogen atoms (the resistance of the electron cloud to deformations).

The formation of lone pairs in the valence shell is revealed in a rather spectacular way by taking the difference of the electron density of the ligand in the complex and that of the free ligand (taken in the same location and with the same geometry). In these representations [Figure 6 (d−f)] the lone pairs are detected as density depletion areas (dashed, grey contours). This is practically a direct visualisation of the density flow corresponding to the donation of the lone pair towards the metal ion.

Another method suitable for the detection and the analysis of lone pairs is the Natural Bond Orbital theory.[24,25] The orbital pictures in Figure 7 were drawn with the "molekel" PC program.[26] Surprisingly, for the 2,4-pentanedionato ligand it was found that the coordinating lone pairs have a content of about *s*(10 %)*p*(90 %) [see λ_1(O) and λ_1(O′) in Figure 7], rather than the *s*(33 %)*p*(67 %) character of the expected sp^2 hybrids. Besides, the λ_1 hybrids are not perfectly aligned along the Co−O axis, which has a deviation of about 10° inward of the chelating ring. The noncoordinating lone pairs at the oxygen atoms (denoted λ_2 in Figure 7) have approximately an *s*(50 %)*p*(50 %) composition and are inclined toward the metal ion with an angle of about 100° (instead of the expected 120°). The higher content in *p* character at the coordinating lone pairs λ_1(O) may be interpreted as favourable to the coordination process, because the lower ionisation potential of the *p* shell as compared to *s* ensures a better σ-donor action. This effect occurs at the expense of a lower *p* content at λ_2. The hybrid of the oxygen atom devoted to the σ(C−O) bond has approximately *s*(40 %)*p*(60 %) composition, which is closer to the expected sp^2 scheme. The composition of the hybrids around the oxygen atom in the M−O−C plane practically sums up to the total sp^2 content. Surprisingly, the abovementioned nonstandard compositions of lone pairs represent a real electronic structure effect that remains quali-

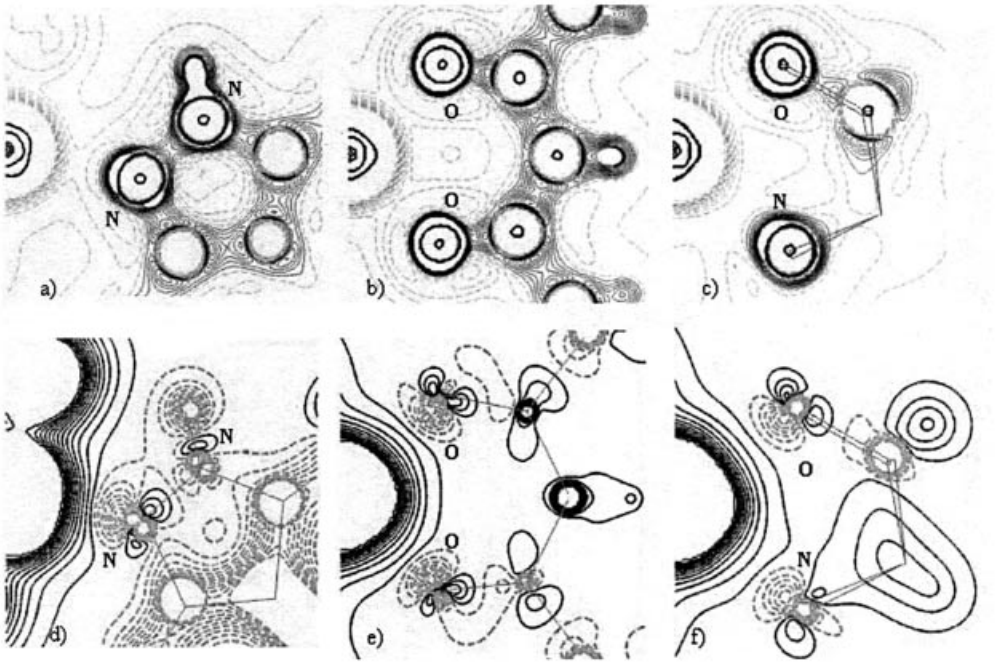

Figure 6. The electron-density descriptors applied to the ligands in complexes **1** and **2**: (a), (b) and (c) the Laplacian density maps in the CoNN, CoOO and CoON coordination planes of pyrazole, acac and amino alcohol Hdmea, respectively; in (d), (e) and (f) the electron density difference maps (complex minus free ligand) are presented for the same series of ligands; the acac ligand shown is taken from complex **1**, the situation for complex **2** being quite similar; in all the figures the dark, continuous lines correspond to density accumulation, dashed lines to depletion areas

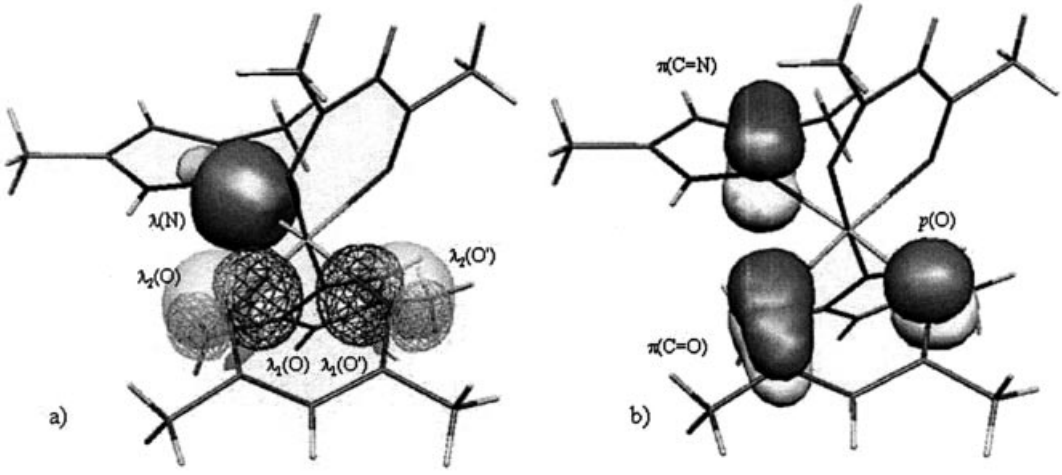

Figure 7. a) The σ-type lone pairs and b) *p*-π coordinating bond orbitals of the 2,4-pentanedionato and pyrazole ligands resulting from the application of NBO analysis on **1**

tatively stable at different levels of calculation. The calculated situation does not offend the concept of sp^2 hybridisation.

Keeping in mind that the sp^2 concept is only a qualitative or average rule, a careful look at the data offered by NBO analysis provides interesting new information for chemical intuition. It should be noted that the regular sp^2 hybridisation at a symmetric AX_3 triangular substitution of a main group central atom means that the three necessary orbitals are decided by symmetry to be one *s* plus two *p* (in plane) orbitals. The sp^2 notation is a convention concerning, in fact, the sum of hybrid compositions. Each of the equivalent hybrids can be more precisely noted $s^{1/3}p^{2/3}$, namely with *s*(33.33 %)*p*(66.67 %) composition. When the substituents at the central atom are of a different chemical nature, the electronegativity difference is a supplementary factor that determines the *s*/*p* content of each hybrid (keeping the total sp^2 composition). In the same respect, when the angles between substituents differ from the ideal 120°, the detailed composition should vary due to trigonometric reasons in order to accomplish the orientation of the hybrids along the bond. In certain circumstances the electronegativity versus

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

geometric factors may result in slight deviations of the hybrid orbitals from the bond axis, as is the case in the coordinating lone pair.

Conclusion

The synthesis and characterisation of two new base adducts of bis(2,4-pentanedionato)cobalt(II) with 3,5-dimethylpyrazole (Hdmpz) and dimethylethanolamine (Hdmea) are reported. The crystal structures of **1** and **2** show mononuclear Co^{II} complexes with *cis*-distorted octahedral geometries; these complexes are linked by hydrogen bonds between the coordinated 2,4-pentanedionato anions and the neutral Hdmpz or Hdmea ligands. In solution, compound **1** is kinetically unstable. Its slow oxidation into a Co^{III} complex is accompanied by a *cis*/*trans* isomerization. In contrast, complex **2** does not display this behaviour. In subsequent studies the results presented here will be applied to the investigation of the antioxidant properties of these complexes as antiskinning agents in alkyd paints. The properties of chelating ligands, constrained to adopt *cis* geometry, may be compared with those of monodentate ligands, which typically yield *trans* complexes except in the case of the Hdmpz complex reported here. Interesting particularities of the lone pair topology at the pentanedionato ligands were revealed with the help of various analyses based on DFT calculations.

Experimental Section

General Remarks: All chemicals were of reagent grade, and were used as received. The anhydrous cobalt acetylacetonate was synthesised as previously reported.[27] All experiments were carried out in air. Elemental analyses for C, H and N were performed with a Perkin−Elmer 2400 Series II analyzer. Infrared spectra (4000−300 cm^{-1}) were recorded with a Perkin−Elmer Paragon 1000 FTIR spectrometer equipped with a Golden Gate ATR device, using the reflectance technique. UV/Vis spectra were obtained with a Perkin−Elmer Lambda 900 spectrophotometer using the diffuse reflectance technique, with MgO as the reference. X-band EPR spectra were recorded with a Bruker Elexsys 680 spectrometer using a rectangular cavity with an Oxford flow cryostat. Magnetic susceptibility measurements (5−300 K) were carried out at 1000 G using a Quantum Design MPMS-5 5T SQUID magnetometer. Data were corrected for magnetisation of the sample holder and for diamagnetic contributions, which were estimated from the Pascal constants.

[Bis(acetylacetonato)bis(3,5-dimethylpyrazole)Co^{II}] (1): Compound **1** was synthesised by adding 3,5-dimethylpyrazole (0.384 g, 4 mmol) to a hot solution of anhydrous cobalt acetylacetonate (0.513 g, 2 mmol) in toluene (20 mL) and stirring for 1 h. The resulting solution was allowed to stand at room temperature; violet crystals of **1** formed overnight. These were collected by filtration, washed with methanol and dried in air. Yield 0.75 g (83%). $C_{20}H_{30}CoN_4O_4$ (449.81): calcd. C 53.40, H 6.66, N 12.44; found C 53.63, H 6.32, N 12.66. IR: $\tilde{\nu}$ = 3284 (N−H), 2923 (C−H), 1595 (C=N), 1571 (C−O), 1516 (C−C), 1357 (C−H), 1014 (C−H), 765 (C−H) cm^{-1}. UV/Vis/NIR: $\tilde{\nu}_{max}$ = 8547, 19607 cm^{-1}.

[Bis(acetylacetonato)(dimethylethanolamine)Co^{II}] (2): Compound **2** was synthesised by adding *N*,*N*-dimethylethanolamine (0.178 g, 2 mmol) to a hot solution of anhydrous cobalt acetylacetonate (0.513 g, 2 mmol) in toluene (20 mL) and stirring for 1 h. The resulting solution was allowed to stand at room temperature for 5 d during which time red crystals formed. These were collected by filtration, washed with diethyl ether and dried in air. Yield 0.92 g (67 %). $C_{14}H_{25}CoNO_5$ (346.02): calcd. C 48.59, H 7.22, N 4.04; found C 48.03, H 6.90, N 4.23. IR: $\tilde{\nu}$ = 3348 (O−H), 2918 (C−H),

2820 (C−H), 1654 (C−N), 1575 (C−O), 1557 (C−C), 1386 (C−H), 1015 (C−H), 751 (C−H) cm^{-1}. UV/Vis/NIR: $\tilde{\nu}_{max}$ = 8889, 19920 cm^{-1}.

X-ray Crystal Structure Analysis: Intensity data for a single crystal were collected using Mo-K_α radiation (λ = 0.71073 Å) with either a Nonius Kappa CCD diffractometer with a rotating anode as for **1**, or with an Enraf−Nonius CAD4 diffractometer with a sealed tube for **2**. A correction for absorption was considered unnecessary in both cases. The structures were solved by automated Patterson methods using DIRDIF99,[28] and were refined on F^2 by least-squares procedures using SHELXL-97.[29] All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydroxy hydrogen atom in **2** was refined freely with an isotropic displacement parameter. All other hydrogen atoms were constrained to idealised geometries and allowed to ride on their carrier atoms with an isotropic displacement parameter related to the equivalent displacement parameter of their carrier atoms. In **2**, the Hdmea ligand is disordered over two conformations, with refined relative occupancies of 0.845(5):0.155. Structure validation and molecular graphics preparation were performed with the PLATON package.[30] Crystallographic data are presented in Table 3. CCDC-219606 (for **1**) and -219607 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

[20] The discussed calculation results are based on the experimental geometries. However, optimisisation of the molecular geometry was performed, finding a satisfactorily agreement with the experimental one. For **1** the mean deviation in computed vs. experimental bond lengths and angles is 0.011 Å and 0.274°, respectively. For **2**, these values are 0.009 Å and 0.221°. The good ab initio retrieval of experimental structures proves the reliability of the applied computation technique, in spite of the average level of sophistication.

COVER PICTURE

The cover picture shows the characteristic crystal form of elemental bismuth in the background and a perspective view of the crystal structure $Bi(Bi_9)[NbCl_6]_3$ containing three-capped trigonal prismatic Bi_9^{5+} clusters. The Bi^+ cations in the channels made up of the octahedral halometalate anions are disordered and can be treated in different ways in the crystallographic description. A remarkable feature of the compound is the paramagnetic behaviour, which shows the presence of Nb in the less common oxidation state +IV. Details are discussed in the article by J. Beck and T. Hilbert on p. 2019ff.

The Structural Role of the Triflate Anion in the Non-Covalent Silver Polymer $[Ag(LOH)_2(CF_3SO_3)(CH_3CN)]$ {LOH = α-(4-Pyridyl)benzhydrol}

Alessia Bacchi,*[a] Elsa Bosetti,[a] Mauro Carcelli,[a] Paolo Pelagatti,[a] and Dominga Rogolino[a]

Keywords: Crystal engineering / Non-covalent interactions / Hydrogen bonds / Molecular tectonics / Silver compounds

$Ag(CF_3SO_3)$ was reacted with the ligand α-(4-pyridyl)benzhydrol (LOH) in order to build a mixed organic/inorganic analogue of wheel-and-axle diols. In the resulting $[Ag(LOH)_2(CF_3SO_3)(CH_3CN)]$ complex, the metal is four-coordinate, with two pyridines *trans* each other and a triflate and an acetonitrile group completing a sawhorse geometry. The main structural motif is based on the strongest and most directional tectons, the coordination bond Ag–O and the hydrogen bonds –OH···O–S–O···HO–. Secondly, the sixfold phenyl embrace, $CH_3\cdots\pi$, $CH_3\cdots CF_3$ and Ag···F tectons also direct the crystal assembly. A new synthon originating from the combination of the S–O···HO–, the $\pi\cdots CH_3$ and the $CH_3\cdots CF_3$ individual tectons is identified. The structural roles of the anion and of the solvent are discussed.

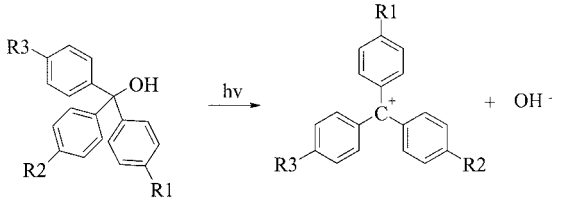
Introduction

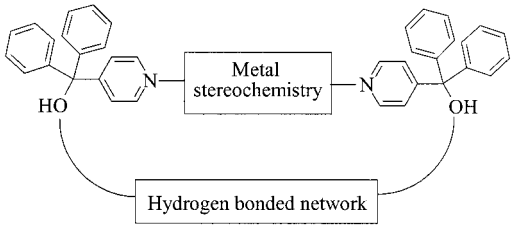
We are currently pursuing the engineering of crystalline systems built by combining photoactivatable triphenylmethanol derivatives with metal centers structured in porous networks.



Scheme 1

Triphenylmethanol derivatives (TPMs) (Scheme 1) are actively studied because they show C−OH photocleavage, accompanied by an intense chromatic change on irradiation by UV/Visible light both in polar solvents and in the solid state.[1] Furthermore, compounds with the general formula Ar_3X−OH (X = C, Si, Ge) have a propensity to crystallize giving trimeric or tetrameric molecular aggregates based on hydrogen-bonded −OH clusters, and they also frequently form clathrate compounds with hydrogen-bond acceptor solvent molecules.[2] Remarkable clathrating properties are shown also by the diol derivatives of the general formula $HOC(Ar)_2$-L-$(Ar)_2COH$, where L is a suitable rigid organic spacer,[3a] the so-called "wheel-and-axle" systems.

Our purpose is to incorporate a metal center into the L spacer of the $HOC(Ar)_2$-L-$(Ar)_2COH$ host framework, in order to combine the clathrating nature of the diol organic matrix with the potential host-guest reactivity triggered by the inorganic functionality (Scheme 2). The coordination of a metal center at the peripheral rim of the TPM molecule could tune the electronic properties of the chromophore and concomitantly drive the organization of the crystal architecture.



Scheme 2

Our approach to the rational design of these architectures is based on the molecular tectonics method,[4] in which the crystal structure is deconvoluted in the contributions of the single inorganic and organic building blocks, which are separately analyzed and optimized.

The first step in modeling these organic-inorganic "wheel-and-axle" complexes consists in the introduction of a transition metal as a bridge between two aromatic rings; this aim is pursued by synthesizing the transition metal complexes of the ligand α-(4-pyridyl)benzhydrol (LOH, Scheme 2).[5] Here, we report and analyze the solid-state arrangement of the new silver complex $[Ag(LOH)_2$-

(OTf)(CH_3CN)], with the aim of establishing a hierarchy in the importance and robustness of the supramolecular motifs observed in the compound and of elucidating the structural role of the counteranion. Currently, we also report our first results on the supramolecular organization of two $Ag(LOH)_2^+$ complexes with weakly coordinating anions, BF_4^- and PF_6^-.[6]

The analysis of the relevant interactions in the crystal packing of [$Ag(LOH)_2$(OTf)(CH_3CN)] will follow the scheme: (i) search for hydrogen bonds involving the −OH donor; (ii) search for short contacts (less than the sum of the van der Waals radii); among the above short contacts, detect weak hydrogen bonds, π interactions, aromatic···aromatic association; (iii) heuristic search for other supramolecular long range arrangements, such as multiple phenyl embrace and long F···Ag contacts, to complete the metal environment; (iv) analysis of the combination of the patterns to determine recurrent motifs for the structure, in comparison also to other $Ag(LOH)_2^+$ complexes.[6]

Results and Discussion

[$Ag(LOH)_2$(OTf)(CH_3CN)] is obtained by reacting LOH with an excess of $Ag(CF_3SO_3)$. The complex is stable in the solid state in the dark, while its solution slowly releases silver. The spectroscopic characterization does not show any remarkable feature: in the ^1H NMR spectrum, the protons H4 and H5 of the pyridyl ring are deshielded with respect to the free ligand, and the singlet assigned to the acetonitrile molecule is present (δ = 2.00 ppm); in the IR spectrum, there are the typical bands assigned to the triflate anion. Crystals suitable for X ray diffraction analysis were obtained from the mother liquor within a couple of days.

The metal is coordinated to two pyridine N_{py} atoms, one oxygen atom of the anion and to one acetonitrile molecule (Figure 1), in a sawhorse geometry already observed for similar Ag complexes[7] [N2−Ag−O2 = 127.7(4)°]. The acetonitrile molecule is loosely bound, in fact the Ag−N2 distance [2.650(9) Å] is one of the longest ever observed in the solid state for $Ag-N{\equiv}C-CH_3$ coordination. The Ag atom, the CH_3CN and CF_3SO_3 ligands are placed on a symmetry plane that cuts the complex perpendicularly to the $N_{py}-Ag-N_{py}$ vector.

In a related work,[6] we found that in [$Ag(LOH)_2$]BF_4 and [$Ag(LOH)_2$]PF_6 the silver ion coordinates linearly two ligand molecules. In [$Ag(LOH)_2(CF_3SO_3)(CH_3CN)$], a new element is introduced into the organization of the crystal structure around the $[Ag(LOH)_2]^+$ unit; namely, the metal atom also employs covalent bonds to expand its supramolecular environment by directly coordinating the anion and the acetonitrile molecule. Scheme 3 shows the geometric descriptors chosen to represent the conformation of the complex. Selected parameters are: the dihedral angle between pyridines (ψ: C4−N1−N1′−C4′), the orientation of the C−OH vectors with respect to the adjacent pyridine (φ: O1−C1−C2−C3 and O1′−C1′−C2′−C3′), and the reciprocal orientation of the two C−OH vectors (χ: O1−C1−C1′−O1′). The classification of the triaryl groups has been made following Dance's analysis of triphenylphosphanes,[8] by calculating the torsion angles $C_{(ortho)}-C_{(ipso)}-C_{(sp3)}-O$ for each ring (labeled so that |torsion| < 90°), and then considering the cases: *rotor* (20° < |T1| ≈ |T2| ≈ |T3| < 70°, same sign), *anti-rotor* (20° < |T1| ≈ |T2| ≈ |T3| < 70°, opposite sign), *parallel flipper* (|T1| < 20°, T2 ≈ −T3), *orthogonal flipper* (70° < |T1| < 90°,

T2 ≈ −T3). Table 1 lists the results of the conformational analysis and contains the key features of the supramolecular arrangement; symmetry operations cited in the text are also reported in Table 1. The pyridine rings are coplanar (Ψ = 0°), while the −OH groups deviate by Φ = −24.3(5)° from the pyridine plane. The complex exhibits the *syn* configuration for the two −OH groups (χ = 0°), in contrast with the *anti* configuration usually found in similar cases;[6,13] this will be related to the crystal packing in the course of the discussion. The triaryl group has a regular rotor conformation, with *T*1, *T*2 and *T*3 values falling in the range indicated by Dance.[8]

The coordination of the anion and acetonitrile group can be considered as the first stage of the supramolecular organization of the $[Ag(LOH)_2]^+$ unit; the analysis of the assembly of the $[Ag(LOH)_2(OTf)(CH_3CN)]$ molecules follows the steps outlined in the introduction.

(i) The −OH donors are strongly linked to the triflate acceptors of adjacent molecules by OH···O hydrogen bonds [O1···O3(ii) = 2.849(5) Å, O1−H···O3(ii) = 171(5)°]: the $[Ag(LOH)_2(OTf)(CH_3CN)]$ molecule uses its two −OH groups to hydrogen bond with the two triflate groups of a pair of adjacent molecules related by a twofold screw axis; concomitantly each triflate anion accepts two hydrogen bonds from the −OH groups of two adjacent molecules, generating the −OH···O−S−O···HO− tecton, with a OH···OH(vi) distance of 7.544(6) Å. The overall arrangement consists of a double strand along the *b* axis (Figure 2).

(ii) The short contacts (Table 1) involve the methyl group of the acetonitrile ligand, which is sandwiched between two aromatic rings giving two symmetric CH_3···π[9] interactions [C20···C9(v,vii) = 3.552(7) Å, H20···C9(v,vii) = 2.87 Å, H···π = 2.76 Å]. The two aromatic rings belong to a pair of triaryl groups in an adjacent double strand. The same methyl group also interacts with the triflate bridging the two aryl groups by means of a CH_3···CF_3 interaction [C20···F3(iv) = 3.00(1) Å]. Both interactions connect the double strands in a sheet (Figure 3). A short non-bonded H···H(vi) distance (2.36 Å, vi = *x*, 5/2 − *y*, *z*) between two almost coplanar aromatic rings which belong to the pair of molecules held together by the triflate bridge is also present in the structure. The local mirror symmetry would impose a much shorter contact between the two H atoms facing each other (1.66 Å), but this distance is relaxed by tilting the rings out of the common plane and introducing local disorder.

(iii) A sixfold phenyl embrace[10] [6PE, C1···C1(v) = 6.535(7) Å, O1−C1···C1(v) = 175.9(2)°] is formed between triaryl groups that are also involved in the CH_3···π interactions (Figure 4). The rotor conformation of the triaryl groups fits well in the 6PE and dictates the reciprocal orientation of the rings also involved in the H···H contact. Recently it has been shown by Bader and co-workers[11] that short H−H contacts between hydrogen atoms with similar charges can contribute up to 10 kcal/mol to the stabilization of the system where they occur. The assignment of stabiliz-

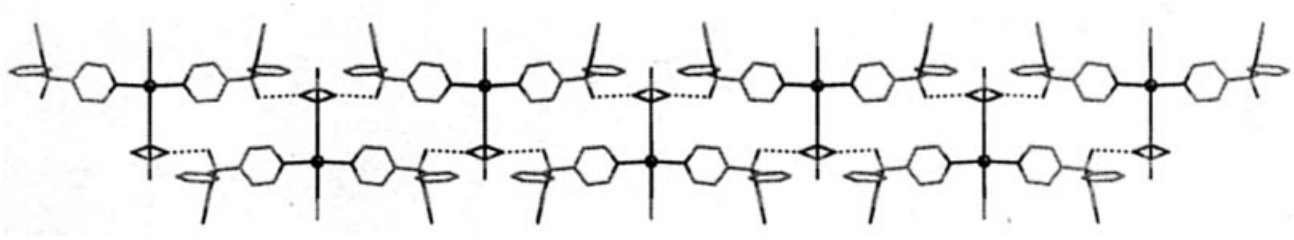

Figure 2. Association of the −OH···O−S−O···HO− tectons in double strands

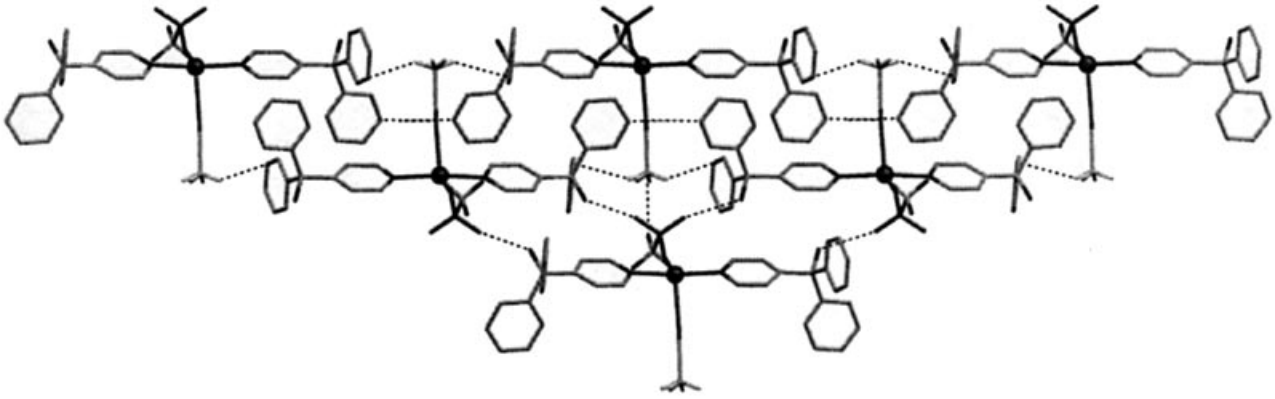

Figure 3. Association of the hydrogen-bonded double strands in sheets, via $CH_3\cdots\pi$ and $CH_3\cdots CF_3$ interactions (dashed); the short H···H contacts are also dashed (2.36 Å)

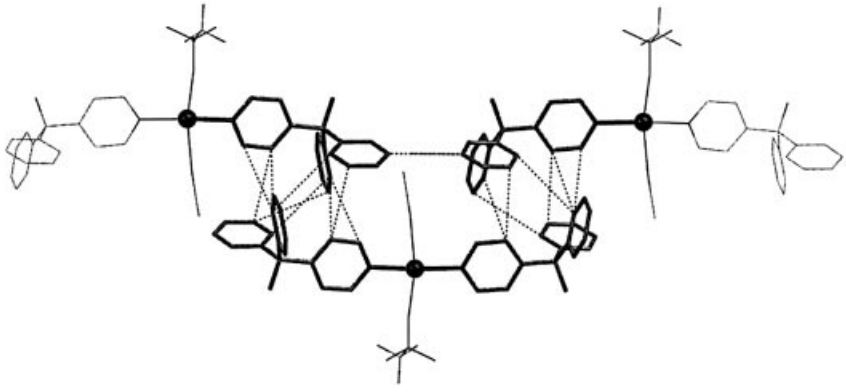

Figure 4. Sixfold phenyl embrace (6PE) involving molecules in the sheets shown in Figure 3; C···C contacts are dashed; the H···H short interaction is also shown

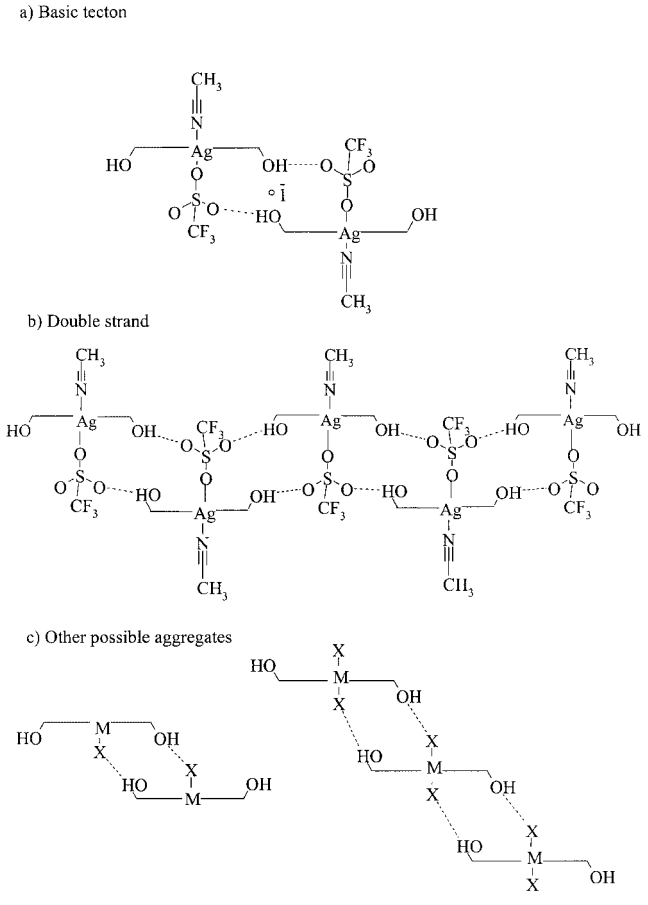
ing character to a short H−H interaction relies on the analysis of the experimental electron-density topology; in the absence of such evidence, it can be noted that the observed contact results from the balance of a local compression required to optimize the 6PE geometry in the presence of mirror symmetry, and a consequent rearrangement due to local overcrowding. The stabilization arising from the 6PE geometry can equal up to 20 kcal mol^{-1},[12] and this could counterbalance the possible repulsion between symmetry-related aromatic rings, whilst the H−H stabilization could justify a slight distortion from the best 6PE geometry.

Finally, an examination of the metal environment shows that a long Ag···F3(iii) [3.542(6) Å] contact completes the silver environment giving a distorted trigonal bipyramidal geometry [O2−Ag···F3(iii) = 117.3(2)°, N2−Ag···F3(iii) = 115.0(3)°].

(iv) The main structural motif, the double strand, is based on the strongest and most directional tectons, the coordination bond Ag−O and the hydrogen bonds −OH···O−S−O···HO− involving the cation and the anion. The first useful observation to interpret and rationalize the supramolecular arrangement of $[Ag(LOH)_2(OTf)(CH_3CN)]$ is that the coordination of the anion to the $[Ag(LOH)_2]^+$ structural unit sets the concomitant presence of a pair of hydrogen-bond donors (LOH) and a pair of hydrogen-bond acceptors ($-SO_3^-$) on the complex neutral molecule. The molecule is divided into two halves, each one bearing a −OH and a $-S-O^-$ function and behaving as a self-complementary moiety. Each half of the $[Ag(LOH)_2(OTf)]$ unit

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

[−Ag(OSO)(LOH)] thus presents the requirements for self-association, which may be triggered by an inversion center or by some twofold rotation relating two adjacent molecules (see a in Scheme 4). Also the basic $[Ag(LOH)_2]^+$ cation, found in $[Ag(LOH)_2]BF_4$ and $[Ag(LOH)_2]PF_6$, bears two −OH groups, both potential hydrogen bond donors and acceptors, but in that case the self-association could be disfavored for two reasons: cation···cation repulsion, and the relatively poor accepting nature of alcoholic −OHs. We can consider the dimeric system defined by the association of two centrosymmetric [−Ag(OSO)(LOH)] moieties as the basic tecton for building the structural motif based on hydrogen bonds. The association of the tectons in the double strands of collinear complexes (see b in Scheme 4) is governed by the nature of the anion: since the triflate fuses two $-S-O^-$ acceptors together, in the *cis* position relative to the metal, the complex must present a *syn* configuration of the C−OH vectors ($\chi = 0°$, Table 1) in order to pair all the donors and all the acceptors in the self-complementary structure. Different motifs could be engineered by choosing a single hydrogen-bond acceptor X (formation of dimers, with unsaturated terminal −OH groups) or a pair of single hydrogen-bond acceptors as *trans* ligands (formation of chains with *anti* configuration of the complex, $\chi = 180°$) (see c in Scheme 4). Both cases have been studied for Pd complexes.[13]



Scheme 4

The association of the double strands described above, built by the coordination bond Ag−O and the hydrogen bonds −OH···O−S−O···HO−, is governed by the formation of a 6PE tecton, which holds the strands together in sheets. The sheets are also held together by the solvent, which adopts a structuring role, through the coordination bond Ag−N and the short $CH_3\cdots\pi$ and $CH_3\cdots CF_3$ interactions .

Finally, the sheets interact using the Ag···F tecton, involving the anion. To investigate the role of the anion and of the solvent in the crystal organization of $[Ag(LOH)_2(OTf)(CH_3CN)]$, the local environment of the triflate anion was examined, see Figure 5. It appears that the combination of the S−O···HO−, the $\pi\cdots CH_3$, and the $CH_3\cdots CF_3$ individual tectons gives rise to a tetrafunctional cyclic pattern that is very similar to the one already observed in the related complexes $[Ag(LOH)_2]BF_4$ and $[Ag(LOH)_2]PF_6$ (Scheme 5).[6] In these complexes there are two basic independent supramolecular tectons (the OH···F−X−F···HO pattern and the cyclic pattern involving Ag···F, Ag···π and −OH···F interactions around the metal), which concur in creating two packing motifs: a chain motif, generated by hydrogen bonds around the anions $[\cdots F-X-F\cdots HO\cap Ag\cap OH\cdots F-X-F\cdots]_n$, and a layer motif, generated by the repetition of the Ag···F···HO−C-π cycle around the metal centers.

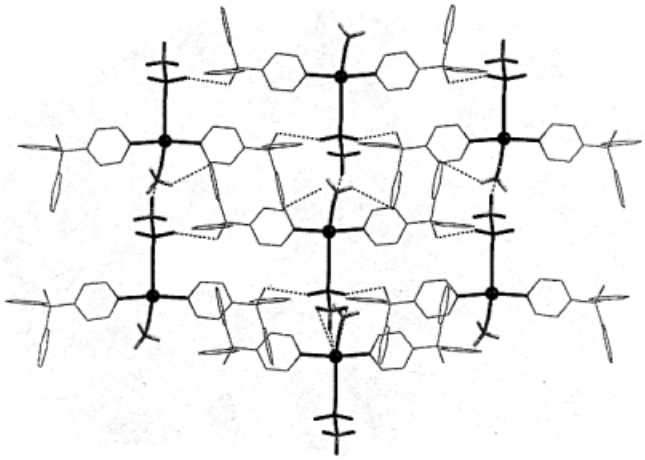


Figure 5. Structural role of the coordinated triflate anion; two mirror-related tetrafunctional cyclic patterns are organized by combining the S−O···HO−, the $\pi\cdots CH_3$ and the $CH_3\cdots CF_3$ individual tectons

In the present case, the methyl group of the acetonitrile plays the structural function of the Ag atoms in the above complexes, by bridging a triarylcarbinol group and the related hydrogen-bonded anion (Scheme 6). A pair of tetrafunctional cyclic patterns surround the anion in a mirror symmetry linking five molecules together: one covalently coordinated to the anion, two coordinated through hydrogen bonds, one through $CF_3\cdots CH_3$ interactions, and one through a $CF_3\cdots Ag$ long contact. The long axes of the five $Ag(pyridine)_2$ systems are approximately parallel.

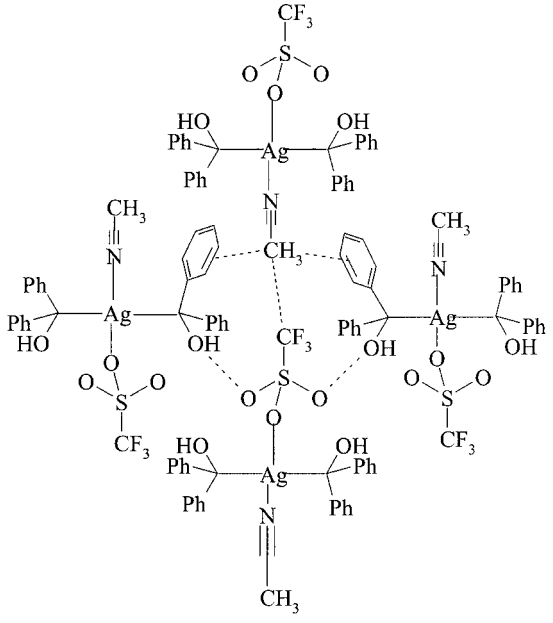

Scheme 6

Conclusions

In $[Ag(LOH)_2(OTf)(CH_3CN)]$, the structural role of the anion is expressed through the coordination to the metal, with the concomitant presence of the acetonitrile molecule. We have uncoupled the function of the two LOH ligands by observing that the anion triggers the formation of the double strands of collinear complexes in the *syn* configuration: this results in a non-covalent supramolecular polymer.[14] The solvent assists in the stabilization of the association of the strands in sheets. The most striking feature of the solid-state arrangement of $[Ag(LOH)_2(OTf)(CH_3CN)]$ is the plasticity of the molecule in response to the structural function of the anion, which allows for the tuning of both the coordination geometry and the configuration of the terminal −OH groups in order to achieve the best self-complementary shape, thus giving the multitude of diverse interactions highlighted in the course of the analysis.

Experimental Section

Synthesis: A solution of LOH (62 mg, 0.237 mmol) in THF (40 mL) was added to a solution of $Ag(CF_3SO_3)$ (61 mg, 0.237 mmol) in CH_3CN (10 mL). The solution was stirred for 3 hours; diethyl ether was added until a white precipitate formed. The mixture was filtered and the precipitate was washed with diethyl ether. Yield 72%, m.p. > 123 °C (dec.). Colorless crystals suitable for X-ray analysis were obtained by cooling mother liquors. $C_{39}H_{33}AgF_3N_3O_5S$ (820.372): calcd. C 57.09, H 4.02, N 5.12, S 3.90; found C 56.61, H 4.11, N 5.55, S 3.94. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ= 8.57 (d, $^3J_{H,H}$ = 6 Hz, 4 H, C(4)−H + C(5)−H), 7.57 (d, $^3J_{H,H}$ = 6 (Hz), 4 H, C(3)−H + C(6)−H), 7.33−7.23 (m, 20 H, Ar), 3.09 (br., 2 H, −OH), 2.00 (s, 3 H, CH_3CN). IR [KBr (cm^{-1})]: ν(OH): 3458 (m), ν(CN): 2255 (m), ν(SO): 1267 (m).

Crystallographic Analysis: Mo-K_α radiation (λ = 0.71073 Å), T = 293 K (SMART AXS 1000 CCD diffractometer). Lorentz and polarization corrections were applied.[15] Structure solved by direct methods using SIR97 [16] and refined by full-matrix least-squares on all F^2 using SHELXL-97,[17] implemented in the WingX package.[18] Hydrogen atoms located on Fourier difference maps and refined isotropically except for the disordered parts, where they have been introduced in idealized positions. Anisotropic displacement parameters refined for all non-hydrogen atoms. The phenyl group C13−C18 is disordered over two equally populated orientations, in order to release steric overcrowding due to a crystallographic mirror plane passing close to C17. The removal of the mirror plane and the modeling of the structure in the corresponding $P2_1$ space group did not result in a unique conformation of the ring. Hydrogen bonds have been analyzed with SHELXL-97[17] and PARST97.[19] Crystal data: $C_{39}H_{33}AgF_3N_3O_5S$, 0.10 × 0.08 × 0.03 mm, monoclinic, space group $P2_1/m$, a = 8.4826(7), b = 21.475(2), c = 10.5455(9) Å, β = 101.144(2)°, V = 1884.8(3) Å^3, ρ = 1.446 Mg·m^{-3}, 2369 unique reflections, 1958 observed [$I > 2\sigma(I)$], 318 parameters, $R1$ = 0.0355, $wR2$ = 0.0933 [on $I > 2\sigma(I)$] and $R1$ = 0.0453, $wR2$ = 0.0978 (on all data). For the analysis of the organization of supramolecular tectons in the observed structures and for comparison with literature data, extended use has been made of the software of the Cambridge Structural Database (CSD).[20] The van der Waals radii used for assigning threshold values to intermolecular contacts are (Å): Ag 1.72, C 1.70, F 1.47, H 1.20, N 1.55, O 1.52, S 1.80 (taken from CSD reference values). CCDC-226532 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Lanthanide(II) and -(III) Porphyrinogens − Rational Synthesis and Derivatisation of Mononuclear, Alkali-Metal-Free Lanthanide(II) and -(III) *meso*-Octaalkylporphyrinogen Complexes

Jun Wang,[a] Andrew K. J. Dick,[a] Michael G. Gardiner,*[a] Brian F. Yates,[a] Evan J. Peacock,[b] Brian W. Skelton,[c] and Allan H. White[c]

Keywords: Lanthanides / Macrocyclic ligands / Metallocenes / Porphyrinoids / Samarium

Modifying the porphyrinogen framework in lanthanide porphyrinogen complexes by *trans*-*N*,*N*′-dimethylation results in Sm^{II} and Sm^{III} derivatives that are remarkably simple in structure and formulation, and are amenable to highly controllable further reaction chemistry. The Sm^{II} bis(tetrahydrofuran) adduct, Sm^{III} chloride and bis(trimethylsilyl)amide complexes have been synthesised and characterised by elemental analysis, ^1H and ^{13}C NMR spectroscopy and X-ray crystal structure determinations.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The metallo-*meso*-octaalkylporphyrinogen complexes of the lanthanides reported to date are structurally diverse, and their unique reactivities have highlighted a range of important potential applications in the area of small-molecule activation and catalysis.[1] The reactivities of Sm^{II} and Sm^{III} complexes have been noted in some cases to exceed those of decamethylsamarocenes, which to date have been the mainstay of organolanthanide-based synthetic transformations and catalysis. Invariably, these complexes have featured (i) the retention of alkali metals arising from metathetical exchange synthetic pathways, and/or (ii) two lanthanides binding within the macrocyclic cavity. These features are clearly the result of the four acidic N−H moieties of the pyrrole units and/or the divergent nature of the macrocyclic cavity in the 1,3-alternate conformation typically adopted when binding large metals by an $\eta^5{:}\eta^1{:}\eta^5{:}\eta^1$- binding mode. The inclusion of alkali metals in these complexes can, in some cases, be seen to have added to the stabilising framework that led to the trapping of reactive species such as $(N_2)^{2-}$, $(N_2)^{4-}$, $(C_2)^{2-}$ and $(C_2H_4)^{2-}$ in stoichiometric reactions.[1b−1h] However, the incorporation of alkali metals (and halides) is generally regarded as limiting the catalytic utility of organolanthanides, as it can lead to the occupation of vital metal coordination sites or, at least, to poorly defined catalytically active species. Significantly, lanthanoid complexes based on tetraanionic porphyrinogens have also proven difficult to derivatise. Indeed, the reaction of the Y^{III} complex $[(THF)_2LiY(L)\cdot LiOEt]$ (where H_4L = *meso*-octaethylporphyrinogen **1**) with lithium reagents led to loss of yttrium from the porphyrinogen.[1a] A single Sm^{III} alkyl complex in which the alkyl group is not involved in bridging with an alkali metal is known, $[(THF)_4(Cl)Li_3(\mathbf{1}-4H)SmMe]$, but its subsequent chemistry is influenced by the incorporation of the alkali metal.[1i] Thus, access to "simple" lanthanocene analogues of the archetypical motif $(L)_nLn^{II/III}R$(solvent) [where $(L)_n$ = a dianionic porphyrinogen-containing unit and R = solvent, alkyl, amide, hydride etc.], often implied in catalysis, has not been realised in the porphyrinogen chemistry of the lanthanide metals. Perhaps then, the full potential of metalloporphyrinogen complexes has not been established in the absence of such desired complexes?

We recently reported that improved structural control is possible through *N*-alkylation of the porphyrinogens by the synthesis of the dipotassium complex **3** derived from *trans*-*N*,*N*′-dimethyl-*meso*-octaethylporphyrinogen **2**.[2] The schematic representation of **3** highlights the steric restraints that the *N*-methyl substituents impose on the macrocyclic cavity in the 1,3-alternate macrocyclic conformation that allows only one potassium cation to bind within the cavity. We report herein the rational synthesis of the first mononuclear, alkali-metal-free metalloporphyrinogens of a lanthanide(II) and -(III) metal, derived from the modified porphyrinogen **2** by metathetical exchange reactions and subsequent derivatisation involving oxidation and halide/amide exchange.

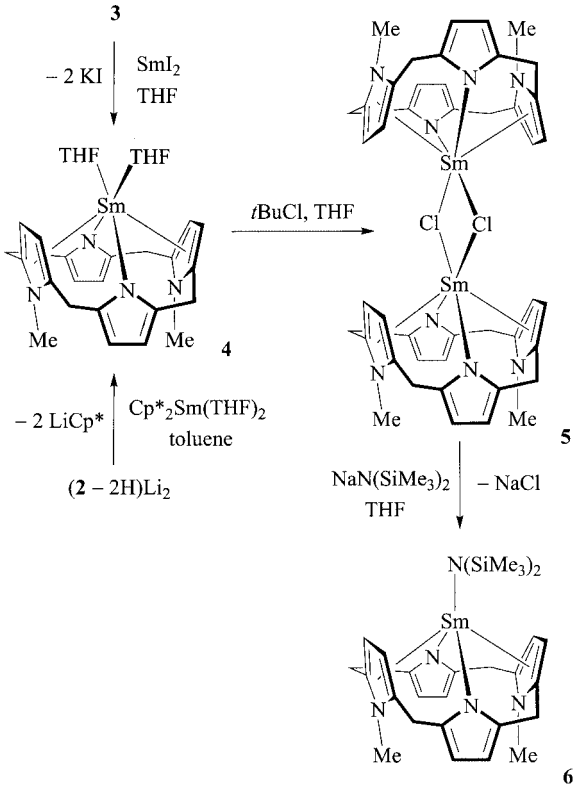
3

Results and Discussion

Complexes **4**−**6** were synthesised according to the route shown in Scheme 1. The reaction of **3** with SmI_2 in THF afforded a brown solution of the Sm^{II} complex **4**, which was isolated in high yield as dark purple/brown crystals. Complex **4** was also prepared in low yield by the reaction of the dilithium complex derived from **2**, $(\mathbf{2}-2H)Li_2$, with $[(\eta^5\text{-}C_5Me_5)_2Sm(THF)_2]$ in toluene, where the driving force is presumably the precipitation of the insoluble $[\{(\eta^5\text{-}C_5Me_5)Li\}_n]$. The Sm^{II} complex **4** was oxidised to the Sm^{III} chloride **5** by reaction with *t*BuCl in THF/toluene, which precipitates nearly quantitatively as a brown/red solid, that could be recrystallised from toluene. The Sm^{III} amide **6** was prepared by the reaction of **5** with sodium bis(trimethylsilyl)-amide in THF and isolated as orange crystals in high yield from a solution of the same color. Complexes **4**−**6** were characterised by ^1H and ^{13}C NMR spectroscopy,[3] microanalysis and X-ray crystal structure determinations.[4]



Scheme 1. Synthesis of Sm^{II} and Sm^{III} complexes (*meso*-octaethyl groups omitted for clarity)

The ^1H NMR chemical shifts of **4** and **6** were highly influenced by the paramagnetic shift influence of the $Sm^{II/III}$ centers, covering a wide chemical shift range of 42.19 to −21.07 ppm for the Sm^{II} complex **4** at 25 °C, and a narrower range of 6.10 to −0.17 ppm for the Sm^{III} complex **6** at 25 °C. Variable-temperature ^1H NMR experiments established rigid macrocycle conformations for **4** and **6** in toluene, on the basis of the Curie−Weiss Law being obeyed in the temperature range −50 to 50 °C. The ^{13}C NMR chemical shifts of **4** and **6** revealed only slight paramagnetic shift influences. The poor solubility of **5** prevented NMR spectroscopic studies.

The crystal structures of **4**−**6** (Figures 1, 2, and 3), show the Sm centers bound within the macrocyclic cavities by η^5:η^1:η^5:η^1- binding modes. Of particular note are the eclipsed η^5-interactions to the neutral *N*-methylpyrrole units, with σ-contacts being through the anionic pyrrolide units. η^5-Bound neutral pyrrole units are uncommon,[5] and unknown in lanthanide chemistry. They are a forced constraint, resulting from either the macrocyclic ring strain or steric interference of the *N*-methyl substituents, which is likely to feature in other bonding situations in which large-radii metals are hosted within the macrocycle. The macrocycle is formally a 16-electron donor, 4 greater than the bis-(cyclopentadienyl) ligand set. The Sm−centroid distance in **4** [2.75_6 Å] is longer than in **5** and **6** [2.63_4 and 2.65_3 Å, respectively], reflecting the relative sizes of Sm^{II} and Sm^{III}. The ensuing conformational changes to the macrocycle are mainly restricted to the "metallocene bend angle", being $154.4_3°$ in **4** and in the range $160.0_8-162.3_1°$ in **5** and **6** (N−Sm−N angles are within 120.5 ± 1° for **4**−**6**). The Sm^{III} centers in **5** and **6** reside deeper in the macrocyclic cavities as a result. The Sm−N distances in **4**−**6** also correlate with the Sm oxidation states and are greatly influenced (± 0.13 Å) by the details of the chloride and amide coordination in **5** and **6** (vide infra). The metallocene bend angle in **4** is much larger than in $[(\eta^5\text{-}C_5Me_5)_2Sm(THF)_2]$ ($136.7_0°$),[6] but the small β-pyrrole H substituents in **4** effectively result in a wider coordination arc available for ligand binding in the region of the η^5- bound pyrrole rings, relative to the samarocene. Conversely, the O−Sm−O angle in **4**, 70.13(6)°, is smaller than in $[(\eta^5\text{-}C_5Me_5)_2Sm(THF)_2]$, 82.7(4)°, indicating reduced space for additional ligand binding in the region of the σ-bound pyrrolide units, compared with the samarocene.

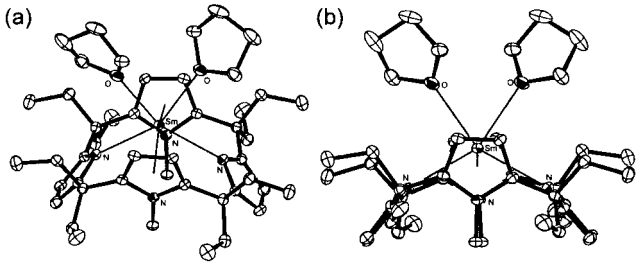


Figure 1. Structure of **4**: (a) general view of **4**, (b) "side" view of **4**

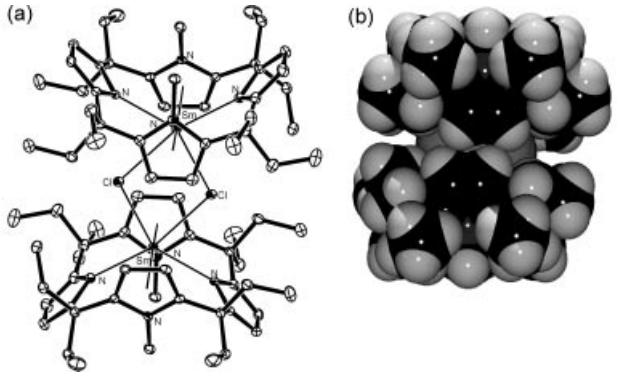

Figure 2. Structure of **5**: (a) general view of **5**, (b) space-filling "side" view of **5**

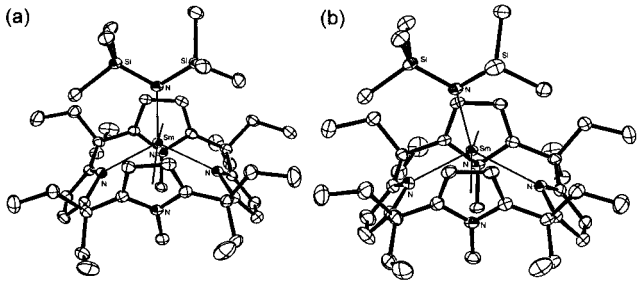

Figure 3. Structure of **6**: (a) general view of a molecule of **6** with a symmetrically bound amide, (b) general view of a molecule of **6** with a "tilted" amide

Both single- and two-fold additional coordination is known for Sm^{II} and Sm^{III} complexes of tetraanionic porphyrinogens, and is seemingly influenced by conformational changes in the macrocycle caused by additional binding of alkali metals and counter-anions in the macrocyclic cavity.[1] Complexes **4** and **5** feature two-fold coordination through THF molecules and two μ_2-Cl ligands, respectively, and **6** displays single-fold coordination through the amide ligand (see Figures 1, 2, and 3).

The Sm−O distances in **4** [2.655(1) Å] are crystallographically equivalent. The Sm−Cl distances in **5** are markedly different [2.7511(5) and 2.9290(5) Å], which is a consequence of the steric interactions between the macrocycles [see Figure 2(b)]. A long terminal Sm−Cl bond [3.15(2) Å] has been reported for a porphyrinogen complex.[1b] The disparate Sm−N(pyrrolide) distances in **5** [2.488(2) and 2.538(2) Å], are also a consequence of the asymmetrically bound chlorides, the former "*trans*" to the short Sm−Cl bond. Decamethylsamarocene(III) chloride forms both a monomeric THF adduct, $[(\eta^5\text{-}C_5Me_5)_2Sm(Cl)(THF)]$, and a more "open" Cl-bridged trimer, $[\{(\eta^5\text{-}C_5Me_5)_2Sm(\mu\text{-}Cl)\}_3]$,[7] whereas non-peralkylated samarocenes, e.g. $[\{[\eta^5\text{-}1,3\text{-}(Me_3Si)_2C_5H_3]_2Sm(\mu\text{-}Cl)\}_2]$, dimerise by symmetrical $(\mu_2\text{-}Cl)_2$-bridging (Sm−Cl = 2.758(2) and 2.771(2) Å].[8]

In addition to the coordination of the Sm center through the nitrogen center of the amide in **6**, one of the three crystallographically independent molecules exhibits a highly "tilted" amide ligand, diagnostic of a putative weak agostic interaction involving a NSiMe unit, [see Figure 3(b)]. The relevant parameters are: Sm···N 2.314(2), Sm···Si 3.3856(7), Sm···C 3.338(3) Å, Sm−N−Si 113.3(1), N−Si−C 109.5(1)°, and, for the opposite NSiMe unit: Sm···Si 3.6762(9), Sm···C 4.059(3) Å, Sm−N−Si 129.94(9), N−Si−C 114.8(1)°. The Sm···γ-methyl distance is substantially longer than in bona fide agostic interactions of lanthanocene amides featuring a single agostic interaction from a tilted amide, e.g. 2.901(8) Å for $[\{\eta^5,\eta^5\text{-}C_5H_4Si(Me)_2C_{13}H_8\}DyN(SiMe_3)_2]$, but this should be placed in the context of the shorter Dy−N distance of 2.207(5) Å relative to **6**.[9] γ-Agostic interactions in "symmetrically bound" lanthanocene amides where two NSiMe units are inclined towards the metal center, e.g. $[(\eta^5\text{-}C_5Me_5)_2SmN(SiMe_3)_2]$,[10] feature NSiMe···Sm geometries (Sm···N 2.301(3), Sm···Si 3.40_2, Sm···C 3.24_9 Å, Sm−N−Si 115.7_5, N−Si−C 106.3_5°) similar to those for the silyl group nearest the Sm center in the tilted amide of **6**. Steric interactions between the amide and the macrocycle (absent in lanthanocene amides — recall the discussion of the small O−Sm−O angle in **4**) may be limiting further development of agostic interactions in **6**, or indeed the higher coordination number from the modified porphyrinogen may negate the tendency for the agostic interaction. The putative weak agostic interaction in **6** is "*trans*" to a closely bound σ-bound pyrrolide [Sm−N 2.470(2) Å] [cf. opposite counterpart, 2.604(2) Å]. In comparison, asymmetry is absent in molecules of **6** having non-tilted amides [2.514−2.543(2) Å]. We have yet to delineate the steric and electronic effects on the structure of **6**, and the tendency for the agostic interaction remains an important matter of discussion, of relevance to the reactivity of lanthanide(II) and -(III) complexes of the modified porphyrinogen **2**.

The preparation of the Sm^{II} and Sm^{III} complexes in this report has demonstrated that improved composition, structure and reactivity control is achievable by efforts to match the charge (in its deprotonated form) and steric restraints of a modified porphyrinogen to the metal ions under study. The "simplicity" of the prepared complexes makes this clear. Despite substantial electronic differences that could be expected to exist between the modified porphyrinogen complexes **4**−**6** and both lanthanocenes and unmodified porphyrinogen complexes (viz. η^5-interactions to neutral pyrrole units) we have demonstrated that imperative structure and reactivity patterns relevant to catalytic applications are common to both systems. A rigid macrocycle conformation in solution for **6** is evident from NMR experiments, thus the macrocycle promises to be an extremely well-defined non-participative ligand for subsequent reactivity studies and applications for which "$(\eta^5\text{-}C_5Me_5)_2Ln^{II/III}R$" systems are utilised. We are continuing synthetic, reactivity and computational studies of this new class of "metallocenes" and related modified porphyrinogen complexes.

Experimental Section

Compound 4: Potassium metal (0.16 g, 4.1 mmol) was added to a solution of **2**[11] (1.14 g, 2.00 mmol) in THF (80 mL) and refluxed

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for 6 h. SmI_2 (0.10 M solution in THF, 20 mL, 2.0 mmol) was added dropwise to the crude stirred slurry of **3** over 20 min and allowed to stir for 12 h. The reaction mixture was filtered and the purple solution concentrated in vacuo to ca. 20 mL, giving dark purple/brown crystals (1.38 g, 80 %). ^{1}H NMR (399.694 MHz, [D$_6$]benzene, 25 °C): δ = −21.07 (m, 4 H, CH_2), −8.15 (t, 12 H, CH_3), −4.89 (m, 4 H, CH_2), 0.93 (t, 12 H, CH_3), 1.12 (s, 4 H, =CH, pyrA), 1.26 (m, 4 H, CH_2), 4.51 (br. s, 8 H, CH_2, THF), 5.17 (m, 4 H, CH_2), 10.83 (br. s, 8 H, OCH_2, THF), 19.22 (s, 4 H, =CH, pyrB), 42.91 ppm (s, 6 H, NCH_3) ppm. ^{13}C NMR (100.512 MHz, [D$_6$]benzene, 25 °C): δ = 10.8 (2 × CH_3), 21.3 (CH_2), 32.0 (CH_2), 44.3 (=CH, pyrA), 50.0 (CEt_2), 68.2 (=CH, pyrB), 108.7 (=CR, pyrB), 188.0 ppm (=CR, pyrA) ppm. $C_{46}H_{70}N_4O_2Sm$ (861.43): calcd. C 64.14, H 8.19, N 6.50; found C 63.98, H 8.27, N 6.43.

Alternative preparation of compound 4: *n*BuLi (6.0 mL, 9.6 mmol) was added to a stirred solution of **2** (2.0 g, 3.5 mmol) in toluene (60 mL) at 0 °C. A colorless solid immediately formed and the mixture was left to stir for 6 h at 50 °C. After being allowed to settle at 20 °C, the solvent was removed by cannula, the colorless solid washed with hexane (20 mL) and dried in vacuo. Toluene (25 mL) was added to a stirred mixture of $[(\eta^5\text{-}C_5Me_5)_2Sm(THF)_2]$[6] (400 mg, 0.718 mmol) and the above-described crude lithium reagent (416 mg, 0.714 mmol) at 20 °C. The mixture was then heated at 50 °C for 4 h to give a dark purple/brown solution. The solution was filtered to remove a colorless solid and the toluene removed in vacuo to give a purple/brown solid. Recrystallisation from THF gave dark purple/brown crystals (163 mg, 27 %) that, by ^{1}H NMR spectroscopy, were identical to the product prepared by the alternative route.

Compound 5: A solution of *t*BuCl (0.093 g, 1.0 mmol) in THF (10 mL) was added to a stirred solution of **4** (0.86 g, 1.0 mmol) in toluene (50 mL) dropwise over 5 minutes and left to stir for 1 h. The resulting pale brown solid was filtered, washed with toluene and dried in vacuo (0.68 g, 91 %). MS (EI): *m*/*z* (%) = 755 (14) [M^+], 726 (64) [M^+ − Et], 568 (33) [$\mathbf{2}^+$], 539 (100) [$\mathbf{2}^+$ − Et]. $C_{38}H_{54}ClN_4Sm$ (752.68): calcd. C 60.64, H 7.23, N 7.44; found C 60.68, H 7.18, N 7.39.

Compound 6: A solution of *t*BuCl (0.093 g, 1.0 mmol) in THF (10 mL) was added to a stirred solution of **4** (0.86 g, 1.0 mmol) in toluene (50 mL) dropwise over 5 minutes and left to stir for 1 h. $NaN(SiMe_3)_2$ (1.0 M solution in THF, 1.0 mL, 1.0 mmol) was added to the mixture and stirring was continued for 12 h. The solution was filtered and concentrated to ca. 15 mL to give orange crystals (0.64 g, 73 %). ^{1}H NMR (399.694 MHz, [D$_6$]benzene, 25 °C): δ = −0.17 (m, 12 H, CH_3), 0.75 (m, 12 H, CH_3), 0.87 (m, 4 H, CH_2), 1.08 (s, 18 H, CH_3), 1.37 (m, 4 H, CH_2), 1.95 (m, 8 H, CH_2), 3.74 (s, 4 H, =CH, pyrMe), 4.87 (s, 6 H, NMe), 6.10 (s, 4 H, = CH, pyr) ppm. ^{13}C NMR (100.512 MHz, [D$_6$]benzene, 25 °C): δ = 7.9 ($SiCH_3$), 8.1 (CH_3), 8.3 (CH_3), 23.1 (CH_2), 28.7 (CH_2), 36.6 (NCH_3), 41.7 (CEt_2), 100.2 (=CH, pyrMe), 103.5 (=CH, pyr) 139.8 (=CR, pyrMe), 149.9 (=CR, pyr) ppm. $C_{44}H_{72}N_5Si_2Sm$ (877.61): calcd. C 60.22, H 8.27, N 7.98; found C 60.10, H 8.36, N 7.94.

Acknowledgments

We thank the Australian Research Council for financial support of this research and Dr. Gary Fallon, Monash University, for measurement of the 123 K X-ray diffraction data.

[3] Full ^{1}H and ^{13}C assignments for **6** were made by gCOSY, gHMBC and gNOESY and VT ^{1}H NMR spectroscopy. The *Me*N ^{13}C resonance of **4** could not be located. A low signal-to-noise ratio caused by paramagnetic line broadening in the gCOSY, gHMQC and gHMBC spectra of **4** did not allow full assignment of ^{1}H and ^{13}C resonances (unique assignment of the pyrrolide and *N*-methylpyrrole units and no conformational information was obtained). Full details of the NMR analyses will be published separately.

[4] Crystallographic data for **4**−**6**: recorded at 123 K (for **4** and **5**) and 150 K (for **6**), with Mo-K_α (0.71073 Å) radiation: **4**: orthorhombic, space group *Pbcn*, *a* = 21.3197(2), *b* = 10.5498(1), *c* = 18.5892(2) Å, *V* = 4181.06(7) Å^3, *Z* = 4, *R* = 0.024 for 4197 [$I > 2\sigma(I)$] data and *wR* = 0.069 for 5187 all data; **5**: monoclinic, space group *C*2/*c*, *a* = 19.4523(2), *b* = 13.8795(1), *c* = 26.9726(3) Å, β = 106.1366(4)°, *V* = 6995.37(12) Å^3, *Z* = 4, *R* = 0.026 for 6738 [$I > 2\sigma(I)$] data and *wR* = 0.050 for 8572 all data; **6**: triclinic, space group $P\bar{1}$, *a* = 12.1952(7), *b* = 23.2630(10), *c* = 24.728(2) Å, α = 88.925(2), β = 78.125(2), γ = 75.229(2)°, *V* = 6634.0(7) Å^3, *Z* = 6, *R* = 0.042 for 41973 [$I > 2\sigma(I)$] data and *wR* = 0.049 for 65461 all data. CCDC 219394−219396 (**4**−**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223-336033; or deposit@ccdc.cam.ac.uk).

Clear-Cut Lanthanide(III)/Actinide(III) Differentiation in Coordination of Pyrazine to Tris(cyclopentadienyl) Complexes of Cerium and Uranium, Involving Reversible $U^{III} \rightarrow U^{IV}$ Oxidation

Thouraya Mehdoui,[a] Jean-Claude Berthet,*[a] Pierre Thuéry,[a] and Michel Ephritikhine*[a]

Keywords: Actinides / Lanthanides / Nitrogen ligands / Selective complexation

In contrast to the $[Ce(C_5H_4R)_3]$ complexes (where R = *t*Bu, $SiMe_3$), which react with pyrazine to give the Lewis base adducts $[Ce(C_5H_4R)_3(pyz)]$ (where R = *t*Bu **1**, $SiMe_3$ **2**), the uranium analogues are oxidized by the azine molecule to the dinuclear U^{IV} complexes $[\{U(C_5H_4R)_3\}_2(\mu\text{-pyz})]$ (R = *t*Bu **3**, $SiMe_3$ **4**). The U–N distances of approximately 2.32 Å in the crystal structures of **3** and **4** are characteristic of U^{IV}–N bond lengths of terminally-coordinated amide groups. The formation constants of **1** and **3** in THF at 23 °C are 0.28(6) and $8(1) \times 10^3$, respectively, permitting the clear differentiation between the two metallocenes by means of the nitrogen ligand.

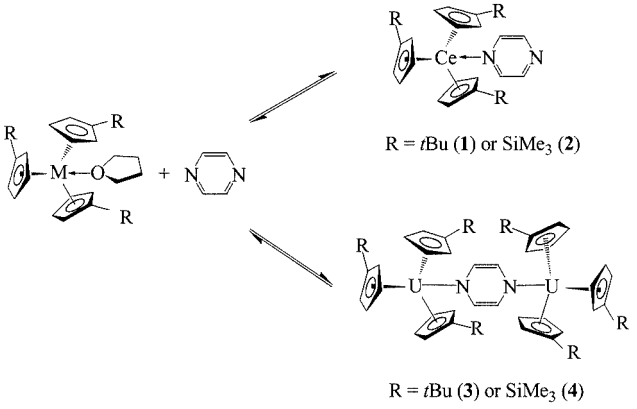
Introduction

The separation of trivalent minor actinides (An) from trivalent lanthanides (Ln) is a challenging goal in the management of nuclear waste; this key step in the advanced reprocessing of spent nuclear fuels would permit the subsequent transmutation of the long-lived americium and curium radionuclides into short-lived isotopes, by neutron bombardment.[1] A number of extractant molecules have been designed and tested for the selective complexation of An^{III} ions in solution; polydentate aromatic amines proved to be the most promising.[2] The better affinity of these molecules for An^{III} rather than Ln^{III} ions is generally explained by the stronger interaction between the softer (or less hard) 5f ion and the nitrogen atom. The greater stability of the An−N bond, in relation to its more covalent character, would result from π back donation of the f orbitals into the π* orbitals of the aromatic ligand, which is less likely in the lanthanide counterpart.[3] This assumption was consolidated after our recent studies on the complexation of the organometallic compounds $[M(C_5H_4R)_3]$ (where M = Ce, U; R = *t*Bu, $SiMe_3$) with various azines, which revealed that the selectivity of the nitrogen ligand in favour of U^{III} is proportional to its π-accepting ability, measured by its reduction potential.[4] Since extensive π back donation would eventually lead to metal oxidation and formation of an An^{IV}−N bond, a conceptual question arising from these results then concerned the possibility of clearly differentiating the trivalent actinide form the lanthanide ions by a reversible oxido-reduction reaction between the An^{III} compound and the extractant molecule. This scenario, which would open new routes to the selective complexation of An^{III} over Ln^{III} ions and the discrimination of minor actinides (americium and curium), should turn out to be successful as the formation of the An^{IV} complex is thermodynamically favoured over that of the simple An^{III} and Ln^{III} Lewis base adducts. Here we demonstrate the feasibility of such a process by presenting the distinct behaviour of the uranium and cerium compounds $[M(C_5H_4R)_3]$ (M = Ce, U; R = *t*Bu, $SiMe_3$) in the presence of pyrazine.

Results and Discussion

Addition of pyrazine (pyz) to a solution of $[Ce(C_5H_4R)_3]$ in THF led to an equilibrium between $[Ce(C_5H_4R)_3(THF)]$



Scheme 1. The distinct reactions of $[M(C_5H_4R)_3]$ (M = Ce, U) with pyrazine

and $[Ce(C_5H_4R)_3(pyz)]$ (see Scheme 1). The formation constants K_{CeL} of the pyrazine adducts were calculated by using Equation (1), where C_0 is the initial concentration of $[Ce(C_5H_4R)_3(THF)]$, n the number of molar equivalents of pyrazine added to the solution, and x_{CeL} the molar fraction of $[Ce(C_5H_4R)_3(pyz)]$, which was determined from the ^1H NMR spectra of the mixtures.

$$K_{CeL} = [Ce(C_5H_4R)_3(pyz)]/[Ce(C_5H_4R)_3(THF)][pyz] = x_{CeL}/C_0(1 - x_{CeL})(n - x_{CeL}) \quad (1)$$

The formation constants at 23 °C of $[Ce(C_5H_4tBu)_3(pyz)]$ (**1**) and $[Ce(C_5H_4SiMe_3)_3(pyz)]$ (**2**) in THF are equal to 0.28(6) and 0.23(2), respectively. These constants are smaller than those measured for the equilibrating formation of **1** and **2** from $[Ce(C_5H_4R)_3]$ and pyrazine in toluene [0.44(3) and $1.4(1) \times 10^2$],[4] because of the competing coordination of THF to the Lewis acidic metal centre. The formation constants of **1** and **2** in toluene are quite similar to those of $[Ce(C_5H_4R)_3(3,5\text{-}Me_2pyz)]$ [0.33(3) and $1.6(1) \times 10^2$ for R = *t*Bu and $SiMe_3$, respectively] which are themselves lower than those of the uranium analogues [1.5(1) and $1.5(2) \times 10^3$]. The slightly greater stability of the U^{III} compounds was explained by the presence of a π backbonding interaction between the uranium atom and the 3,5-dimethylpyrazine ligand.[4]

In striking contrast with dimethylpyrazine, pyrazine reacted with two molar equivalents of $[U(C_5H_4R)_3]$ in toluene to give the dinuclear compounds $[\{U(C_5H_4R)_3\}_2(\mu\text{-pyz})]$ (R = *t*Bu **3**; R = $SiMe_3$ **4**) in quantitative yields. The mononuclear species $[U(C_5H_4R)_3(pyz)]$ could not be detected, even after further addition of free pyrazine. The ^1H NMR spectra of **3** and **4** exhibit three signals, of relative intensities 54:12:12, corresponding to the six equivalent C_5H_4R groups and a single resonance attributed to the four equivalent protons of the nitrogen ligand. These uranium complexes were stable in the toluene or pentane solutions from which they were isolated as black powders after evaporation. It is noteworthy that the complexes $[\{U(C_5H_4R)_3\}_2(\mu\text{-pyz})]$ (R = H or Me) were synthesized in a similar way from $[U(C_5H_4R)_3(THF)]$ and pyrazine and, in the absence of structural information, were considered as π-bridged dimers of U^{III}.[5]

Black crystals of $[\{U(C_5H_4tBu)_3\}_2(\mu\text{-pyz})]\cdot 0.5pyz$ (**3**·0.5pyz) and $[\{U(C_5H_4SiMe_3)_3\}_2(\mu\text{-pyz})]\cdot 2pyz$ (**4**·2pyz) were obtained by cooling concentrated solutions of $[U(C_5H_4R)_3]$ and excess pyrazine in pentane. The crystal structures of **3** and **4** are very similar; **3** is shown in Figure 1 with selected bond lengths and angles. The two $U(C_5H_4R)_3$ fragments are bridged by a pyrazine ring, coordinated through its nitrogen atoms; the middle of the U−U′ segment in **4** is an inversion centre. The pyrazine rings are planar within ±0.019(6) and ±0.001(3) Å in **3** and **4**, respectively. The U(1) and U(2) atoms in **3** are located out of the plane, on the same side, at a distance of 0.075(13) and 0.257(12) Å, respectively; because of the imposed symmetry, U and U′ in **4** are on either side of the plane, at a distance of 0.071(9) Å. The U−N distances of 2.323(6) and 2.325(6) Å in **3**, and 2.318(4) Å in **4**, are much shorter than those measured in the series of trivalent $[U(C_5H_4R)_3(azine)]$ complexes, which vary from 2.646(4) Å in $[U(C_5H_4SiMe_3)_3(lutidine)]$ to 2.688(7) Å in $[U(C_5H_4SiMe_3)_3(pyrimidine)]$;[4] they are also 0.34 Å shorter than the average U−N(pyrazine) distance in $[UI_3(tpza)(MeCN)]$ {tpza = tris[(2-pyrazinyl)methyl]amine}.[3a] In fact, the U−N distances in **3** and **4** are in the range of U^{IV}−N bond lengths of terminally-coordinated amide groups[6] and are, in particular, similar to that of 2.29(2) Å in $[U(C_5H_5)_3(NPh_2)]$.[7] Concomitantly with the oxidation of the metal centre, the pyrazine ligand in **3** and **4** appears to be reduced to its dianionic form, since the average C−N and C−C distances of 1.405(5) and 1.340(5) Å are, respectively, longer and shorter than those in the free or coordinated neutral molecule, which are typically equal to 1.34 and 1.38 Å. These distances are equal to 1.33(2) and 1.37(2) Å in the Yb^{III} complex $[\{Yb(C_5H_5)_3\}_2(\mu\text{-pyz})]$,[8] and to 1.339(1) and 1.378(6) Å in $[Ce(C_5H_4tBu)_3(pyz)]$.[4]

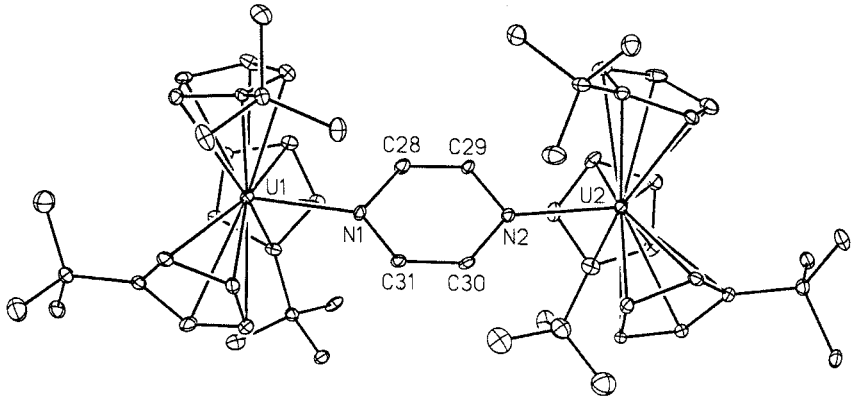

Figure 1. View of $[\{U(C_5H_4tBu)_3\}_2(\mu\text{-pyz})]$; hydrogen atoms are omitted for clarity; only one position of the disordered C_5H_4tBu group is represented; the displacement ellipsoids are drawn at the 10 % probability level; selected bond lengths (Å) and angles (°), the corresponding values for $[\{U(C_5H_4SiMe_3)_3\}_2(\mu\text{-pyz})]$ are given in brackets: U(1)−N(1) 2.323(6) [2.318(4)], U(2)−N(2) 2.325(6), N(1)−C(28) 1.406(11) [1.410(6)], N(1)−C(31) 1.399(9) [1.411(6)], N(2)−C(29) 1.399(10), N(2)−C(30) 1.404(10), C(28)−C(29) 1.335(12) [1.342(7)], C(30)−C(31) 1.344(11); Cp−U(1)−Cp 110.6−124.3 [114.9−118.0], Cp−U(2)−Cp 115.7−117.1, Cp−U(1)−N(1) 94.4−107.7 [98.6−102.3], Cp−U(2)−N(2) 99.2−103.8; Cp is the centroid of the C_5H_4R rings

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The crystal structures of **3** and **4** clearly revealed that the remarkable difference between the reactions of $[U(C_5H_4R)_3]$ and $[Ce(C_5H_4R)_3]$ with pyrazine is related to the actual $U^{III} \rightarrow U^{IV}$ oxidation; this process is clearly favoured by the electron richness of the trivalent metallocenes. Reduction of pyrazine with the divalent lanthanide compounds $[Yb(C_5Me_5)_2(OEt_2)]$[9] and $[Sm\{HB(3,5\text{-}Me_2\text{-}pyrazolyl)_3\}_2]$[10] has also been reported, but the products have not been identified. The distinct reactions of pyrazine and dimethylpyrazine with $[U(C_5H_4R)_3]$ should be related to their reduction potentials $E_{1/2}$ which are equal to −2.17 and −2.28 V vs. Ag/AgCl, respectively.[11] Thus, azine molecules with $E_{1/2}$ values higher than about −2.2 V vs. Ag/AgCl should be reduced by the trivalent metallocenes, while the less reducible ones should give the simple U^{III} Lewis base adducts.

Most notably, compounds **3** and **4** were found to undergo reversible reductive elimination of pyrazine in coordinating solvents, like THF and pyridine. The equilibrium between $[U(C_5H_4R)_3(THF)]$, free pyrazine and $[\{U(C_5H_4R)_3\}_2(\mu\text{-pyz})]$ in THF (Scheme 1) was studied by ^1H NMR spectroscopy, and the formation constants K_{U2L} of the dinuclear compounds were determined from Equation (2), where C_0 is the initial concentration of $[U(C_5H_4R)_3(THF)]$, n the number of molar equivalents of pyrazine and x_{U2L} the molar fraction of **3** or **4**. This expression is simplified to Equation (3) for $n = 0.5$ (stoichiometric ratio).

$$K_{U2L} = [\{U(C_5H_4R)_3\}_2(\mu\text{-pyz})]/[U(C_5H_4R)_3(THF)]^2[pyz]$$
$$K_{U2L} = x_{U2L}(1 + x_{U2L})^2/C_0^2(1 - x_{U2L})^2[n(1 + x_{U2L}) - x_{U2L}] \quad (2)$$

$$K_{U2L} = 2x_{U2L}(1 + x_{U2L})^2/C_0^2(1 - x_{U2L})^3 \ (n = 0.5) \quad (3)$$

The values of K_{U2L} at 23 °C are $8(1) \times 10^3$ and $1.5(1) \times 10^2$ for **3** and **4**, respectively. The difference between these constants reflects the more important electron richness of the $[U(C_5H_4tBu)_3]$ fragment, with respect to $[U(C_5H_4SiMe_3)_3]$,[4] which has a double beneficial effect on the reaction: it impedes the competitive coordination of THF and favours the oxidation of the U^{III} centre. The K_{U2L}/K_{CeL} ratios of 2.8×10^4 and 6.5×10^2, for R = *t*Bu and $SiMe_3$, respectively, are considerably higher than those found in the case of the complexation of $[M(C_5H_4R)_3]$ (M = Ce or U) with various azines in toluene, which do not exceed the value of nine for the reactions of $[M(C_5H_4SiMe_3)_3]$ with 3,5-dimethylpyrazine.[4] The distinct nature of the reactions of $[Ce(C_5H_4R)_3]$ and $[U(C_5H_4R)_3]$ with pyrazine is also reflected in the thermodynamic parameters ΔH and ΔS corresponding to the formation of $[Ce(C_5H_4R)_3(pyz)]$ and $[\{U(C_5H_4R)_3\}_2(\mu\text{-pyz})]$ in THF, which were determined from the van't Hoff diagrams (see Table 1). The difference between the enthalpies of formation of **1** and **3** is as high as 54 kJ·mol^{-1}, whereas the corresponding $\Delta(\Delta H)$ values for the $[M(C_5H_4R)_3(azine)]$ adducts (M = Ce, U) range from 3 to 17 kJ·mol^{-1}.[4]

Table 1. Values of K, $-\Delta H$ (kJ·mol^{-1}) and $-\Delta S$ (J·mol^{-1} K^{-1}) for the formation of the complexes in THF

Compound	K	$-\Delta H$	$-\Delta S$
$[Ce(C_5H_4tBu)_3(pyz)]$ (**1**)	0.28(6)	0(3)	12(7)
$[Ce(C_5H_4SiMe_3)_3(pyz)]$ (**2**)	0.23(2)	19(2)	79(5)
$[\{U(C_5H_4tBu)_3\}_2(\mu\text{-pyz})]$ (**3**)	$8(1) \times 10^3$	54(5)	109(20)
$[\{U(C_5H_4SiMe_3)_3\}_2(\mu\text{-pyz})]$ (**4**)	$1.5(1) \times 10^2$	35(3)	76(15)

As expected from the thermodynamic parameters, the competition reactions of $[Ce(C_5H_4R)_3]$ and $[U(C_5H_4R)_3]$ with pyrazine in THF favoured the formation of the dinuclear uranium compounds **3** and **4**. Thus, the ^1H NMR spectrum of an equimolar mixture of the two trivalent metallocenes $[M(C_5H_4tBu)_3]$ (C_0 = 0.049 M) in the presence of 0.5 molar equivalent of pyrazine {which is identical to that of a 2:1 mixture of $[Ce(C_5H_4tBu)_3]$ and **3**} showed that 45 % of the U^{III} complex was transformed into **3**, while the quantity of **1** was too small to be measured; the molar fraction of **1** should be less than 5×10^{-3}, from Equation (1). In the presence of 9 molar equivalents of pyrazine, 90 % of $[U(C_5H_4tBu)_3]$ and 17 % of $[Ce(C_5H_4tBu)_3]$ were converted into **3** and **1**, respectively. Similar experiments with $[U(C_5H_4SiMe_3)_3]$ and $[Ce(C_5H_4SiMe_3)_3]$ showed that pyrazine is less efficient in the differentiation of these metallocenes, since 18 molar equivalents of the nitrogen ligand were necessary for a 45 % conversion of the U^{III} complex into **4**, and 12 % of **2** were also formed.

Conclusion

The reactions of $[Ce(C_5H_4R)_3]$ and $[U(C_5H_4R)_3]$ with pyrazine are very different because the former is a Lewis acid−Lewis base reaction whereas the latter is a redox reaction. These two reactions led to the equilibrium between $[M(C_5H_4R)_3(THF)]$ (M = Ce and U), $[Ce(C_5H_4R)_3(pyz)]$ (R = *t*Bu **1**; R = $SiMe_3$ **2**) and $[\{U(C_5H_4R)_3\}_2(\mu\text{-pyz})]$ (R = *t*Bu **3**; R = $SiMe_3$ **4**) in THF solution. The greater stability of the dinuclear U^{IV} compounds **3** and **4** with respect to the Ce^{III} complexes **1** and **2** permits a clear differentiation of the two metallocenes by means of the nitrogen ligand. As expected from an oxidation process, the selectivity in favour of uranium(III) is backed by an increased electron density on the metal centre. Oxidation of U^{III} can be seen as the ultimate result of extensive π back donation of the metal orbitals into the π* orbitals of the aromatic ring, which is thought to play a major role in the selective complexation of An^{III} over Ln^{III} ions by nitrogen ligands. It is, however, important to note that Am^{III} and Cm^{III} are less easily oxidized than U^{III}; their extraction based on a redox process would be rendered possible if their oxidation potentials were lowered by using anionic and/or neutral donor ligands, or by operating in specific media, like ionic liquids.

Experimental Section

General: All reactions were carried out under argon (< 5 ppm oxygen or water) using standard Schlenk-vessel and vacuum line tech-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

niques or in a glove box. Solvents were dried by standard methods and distilled immediately before use; deuterated toluene and THF (Eurisotop) were distilled from over Na/K alloy and stored over 3 Å molecular sieves. Pyrazine (Aldrich) was used as received; the metallocenes $[M(C_5H_4tBu)_3]$ (M = Ce,[12] U[13]) and $[M(C_5H_4SiMe_3)_3]$ (M = Ce,[12] U[14]) and the pyrazine adducts **1** and **2**[4] were prepared by published methods. The ^{1}H NMR spectra were recorded on a Bruker DPX 200 instrument and referenced internally using the residual protio-solvent resonances relative to tetramethylsilane (δ = 0 ppm). Elemental analyses were performed by Analytische Laboratorien at Lindlar (Germany).

Synthesis of 3 and 4: A flask was charged with $[U(C_5H_4tBu)_3]$ (200 mg, 0.33 mmol) and pyrazine (26.6 mg, 0.33 mmol) in pentane (15 mL). After 3 h at 20 °C, the dark blue solution deposited a black powder of **3**; a greater quantity of precipitate was obtained after cooling at −78 °C for 3 h. The product was then filtered off and dried under vacuum. Yield: 134 mg (63 %). ^{1}H NMR (200 MHz, [D$_8$]toluene): δ = −70.26 (4 H, pyz), −13.67 (12 H, C_5H_4R), −12.91 (12 H, C_5H_4R), 0.85 (54 H, C_5H_4R) ppm. $C_{58}H_{82}N_2U_2$ (1283): calcd. C 54.29, H 6.40, N 2.18; found C 54.44, H 6.25, N 2.31. The same reaction with $[U(C_5H_4SiMe_3)_3]$ gave **4** in 65 % yield. ^{1}H NMR (200 MHz, [D$_8$]toluene): δ = −69.79 (4 H, pyz), −15.24 (12 H, C_5H_4R), −10.68 (12 H, C_5H_4R), 0.24 (54 H, C_5H_4R).

Determination of the Formation Constants K_{CeL}: An NMR tube was charged with a 0.1 M solution of $[Ce(C_5H_4R)_3]$ in [D$_8$]THF. Under fast exchange conditions, successive addition of pyrazine lead to the displacement of the three resonances of the metallocene towards the limit positions corresponding to the complete formation of $[Ce(C_5H_4R)_3(pyz)]$. The observed chemical shifts for the C_5H_4R ligands, δ_{obs}, are a weighted average of the chemical shifts of these cyclopentadienyl groups in $[Ce(C_5H_4R)_3(THF)]$ and $[Ce(C_5H_4R)_3(pyz)]$, δ_{Ce} and δ_{CeL}, proportional to their relative concentrations, according to $\delta_{obs} = (1 - x_{CeL})\delta_{Ce} + x_{CeL}\delta_{CeL}$, in which x_{CeL} is the molar fraction of $[Ce(C_5H_4R)_3(pyz)]$; the values of x_{CeL} were thus obtained by $x_{CeL} = (\delta_{obs} - \delta_{Ce})/(\delta_{CeL} - \delta_{Ce})$.[4] After each addition of pyrazine, the complexation reactions were monitored by recording the ^{1}H NMR spectra from +23 to −30 °C with intervals of 5 °C. For a 0.146 M solution of $[Ce(C_5H_4tBu)_3(THF)]$ at 23 °C, ^{1}H NMR (200 MHz, [D$_8$]THF): δ_{Ce} = −3.29 (27 H), 11.22 (6 H), 11.72 (6 H) ppm; δ_{CeL} = −3.17 (27 H), 10.17 (6 H), 12.39 (6 H) ppm; δ_{obs} (n = 11.5) = −3.23 (27 H), 10.83 (6 H), 11.91 (6 H) ppm. For a 0.100 M solution of $[Ce(C_5H_4SiMe_3)_3(THF)]$ at 23 °C, ^{1}H NMR (200 MHz, [D$_8$]THF): δ_{Ce} = −0.97 (27 H), 6.75 (6 H), 10.03 (6 H) ppm; δ_{CeL} = −1.52 (27 H), 6.88 (6 H), 10.95 (6 H) ppm; δ_{obs} (n = 14.5) = −1.10 (27 H), 6.76 (6 H), 10.25 (6 H) ppm. The K_{CeL} constants and the corresponding ΔH and ΔS values are given in Table 1.

Determination of the Formation Constants K_{U2L}: In a typical experiment, an NMR tube was charged with a 0.037 M solution of $[U(C_5H_4tBu)_3]$ in [D$_8$]THF. ^{1}H NMR (200 MHz, [D$_8$]THF): δ = −23.16 (6 H), −7.76 (27 H), −2.85 (6 H) ppm. After addition of pyrazine, new signals corresponding to **3** appeared. ^{1}H NMR (200 MHz, [D$_8$]THF): δ = −72.95 (4 H, pyz), −14.93 (12 H, C_5H_4R), −12.97 (12 H, C_5H_4R), 0.76 (54 H, C_5H_4R) ppm. In the presence of 0.5 molar equivalent of pyrazine, the spectrum was identical to that obtained by dissolving **3** in [D$_8$]THF, showing the presence of $[U(C_5H_4tBu)_3(THF)]$ and **3** in relative proportions of 55:45. Similarly, an NMR tube was charged with a 0.025 M solution of $[U(C_5H_4SiMe_3)_3]$ in [D$_8$]THF. ^{1}H NMR (200 MHz, [D$_8$]THF): δ = −17.61 (6 H), −5.97 (6 H), −4.03 (27 H) ppm. Addition of 0.5 molar equivalent of pyrazine had practically no influence on these signals, in agreement with the fact that **4** is almost totally dissociated into $[U(C_5H_4SiMe_3)_3(THF)]$ and pyrazine in THF. After addition of 8.8 molar equivalents of pyrazine, new signals corresponding to **4** appeared. ^{1}H NMR (200 MHz, [D$_8$]THF): δ = −73.73 (4 H, pyz), −16.25 (12 H, C_5H_4R), −10.84 (12 H, C_5H_4R), −0.16 (54 H, C_5H_4R) ppm. The two complexes $[U(C_5H_4SiMe_3)_3(THF)]$ and **4** were in relative proportions of 70:30. The K_{U2L} constants and the corresponding ΔH and ΔS values are given in Table 1.

X-ray Crystallography: The data were collected at 100(2) K on a Nonius Kappa-CCD area detector diffractometer[15] using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The crystals were introduced in glass capillaries with a protecting "Paratone-N" oil (Hampton Research) coating. The unit cell parameters were determined from ten frames, then refined on all data. A 180° φ-range was scanned with 2° steps during data collection, with a crystal-to-detector distance fixed to 28 mm. The data were processed with DENZO-SMN.[16] The structures were solved by direct methods (**3**) or Patterson map interpretation (**4**) with SHELXS-97 and subsequent Fourier-difference synthesis and refined by full-matrix least-squares on F^2 with SHELXL-97.[17] Absorption effects were corrected empirically with the program DELABS from PLATON.[18] One C_5H_4tBu group in compound **3** was found to be disordered over two positions sharing two aromatic and one terminal methyl carbon atom, which were refined with occupancy parameters constrained to sum to unity and with some restraints on bond lengths and displacement parameters. Some short intramolecular C···C contacts result from the imperfect location of the disordered parts. The solvent pyrazine molecule in **3** is disordered around a symmetry centre and the position of the nitrogen atom was not determined. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were introduced at calculated positions (except in the disordered parts when present) and were treated as riding atoms with a displacement parameter equal to 1.2 (CH) or 1.5 (CH_3) times that of the parent atom. The molecular plot was drawn with SHELXTL.[19] CCDC-231705 (**3**·0.5pyz) and -231706 (**4**·2pyz) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Crystal Data for 3·0.5pyz: $C_{60}H_{84}N_3U_2$, M = 1323.36 g mol^{-1}, monoclinic, $P2_1/c$, a = 15.9661(6), b = 10.6364(4), c = 31.6769(11) Å, β = 94.115(2)°, U = 5365.6(3) Å^3, Z = 4, μ(Mo-K_α) = 6.068 mm^{-1}, 35622 reflections measured, 10137 unique (R_{int} = 0.086) which were used in all calculations. Final R values: R_1 = 0.047, wR_2 = 0.105 (all data).

Crystal Data for 4·2pyz: $C_{60}H_{90}N_6Si_6U_2$, M = 1539.98 g mol^{-1}, triclinic, $P\bar{1}$, a = 11.0619(7), b = 11.1804(6), c = 15.1358(10) Å, α = 105.831(3), β = 105.869(3), γ = 103.017(4)°, U = 1638.86(19) Å^3, Z = 1, μ(Mo-K_α) = 5.084 mm^{-1}, 11306 reflections measured, 5732 unique (R_{int} = 0.038) which were used in all calculations. Final R values: R_1 = 0.030, wR_2 = 0.073 (all data).

Regioselective Functionalization of Tetrabromophenanthroline−Ruthenium Complexes

Sven Rau,*[a] Reinald Fischer,[a] Michael Jäger,[a] Bernhard Schäfer,[a] Susann Meyer,[b] Günter Kreisel,[b] Helmar Görls,[a] Manfred Rudolf,[a] William Henry,[c] and Johannes G. Vos[c]

Keywords: Ruthenium / Nucleophilic substitution / Phenanthroline

Structural, photophysical and photochemical characterization and reactivity of a novel polypyridyl ruthenium complex based on 3,5,6,8-tetrabromophenanthroline are discussed.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Signal storage at a molecular level is a great challenge for chemistry.[1] The possibility of connecting different functionalities selectively to one ligand of a metal complex may open the route towards higher integrated molecular units capable of processing various external stimuli in a predesignated order. The implementation of this concept demands ligands with a multitude of potential connecting groups which can selectively be transformed.[2] 3-bromo- and 3,8-dibromophenanthrolines have proved useful for the preparation of mononuclear[3] and multiheteronuclear complexes.[4] These systems have found applications ranging from DNA photoprobes,[5] to metalloligands in catalysis.[6] A very useful and well-established feature of these bromophenanthroline−ruthenium complexes is their susceptibility towards nucleophilic aromatic substitution.[7]

We have improved the bromination reaction of phenanthroline first published by Dénes and Chira,[8] which allows for the selective formation of 3,5,6,8,-tetrabromophenanthroline (Br_4phen) in a one-step multigram reaction, Figure 1.[8]

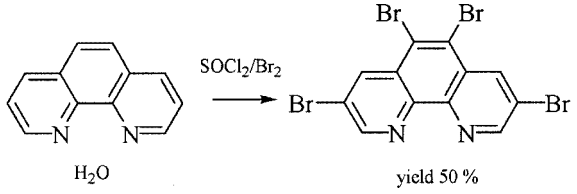

Figure 1. Improved preparation of 3,5,6,8-tetrabromophenanthroline (Br_4phen)

Br_4phen readily forms a complex with $[tbbpy]_2RuCl_2$ resulting in $[(tbbpy)_2Ru(Br_4phen)]^{2+}$, **1**. The structural characterization using two-dimensional NMR spectroscopy suggests that a symmetrical complex is formed as indicated by the presence of only two signals for the four phenanthroline-based protons. ^{13}C, HSQC, and HMBC spectroscopy allows the complete assignment of all signals in the ^1H- and ^{13}C NMR spectra, which together with mass spectroscopy suggests that Br_4phen coordinates in a similar fashion as the unsubstituted phenanthroline. The X-ray crystallographic characterization confirms this assumption, and as seen from Table 1 shows no significant differences compared with the parent complex $[(tbbpy)_2Ru(phen)]^{2+}$, **2** (see Supporting Information). The molecular structure is depicted in Figure 2.

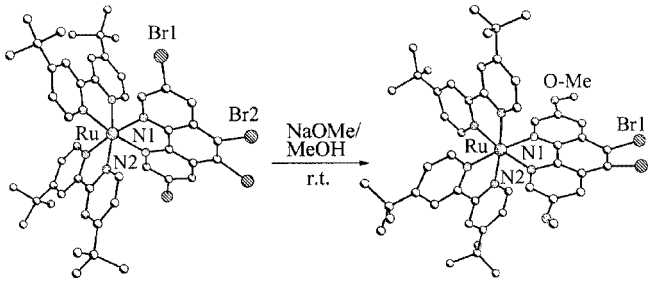

Figure 2. Regioselective nucleophilic substitution of **1** with NaOMe leading to **3**; molecular structure of **1**; anions and hydrogen atoms omitted, and the structural motif of **3** confirming the regioselective substitution

Reaction of **1** with NaOMe at room temperature in methanol leads to the selective formation of one product that contains two bromine and two new methoxy functions, as confirmed by ESI-MS. The fact that the positions of all the bipyridine-based signals in the ^{1}H NMR spectra did not change, together with the presence of only one new signal at $\delta = 4.15$ ppm for the methoxy function, suggests the formation of a symmetrical species where substitution at the phenanthroline moiety has taken place. The regioselective formation of the 5,6-dibromo-3,8-dimethoxyphenanthroline ruthenium complex **3** could be confirmed by a structural motive depicted in Figure 2.

Photophysical investigation of compounds **1** to **3** suggests that tetrabromo substitution lowers the electron density of the phenanthroline ligand considerably. The absorption and emission wavelength of **1** are red-shifted relative to **2**, see Table 2. This finding correlates well with the data obtained for the oxidation potential of $Ru^{II/III}$, which clearly shows that the four bromine substituents significantly decrease the electron density at the metal center (difference of 137 mV). Introduction of the methoxy groups increases the electron density, as expected.[9] The introduction of two methoxy groups has a pronounced influence on the photophysical properties, and this is in agreement with an electron-donating substituent.

Table 2. Photophysical and electrochemical properties of complexes **1**−**3** in acetonitrile

Compound	$E_{1/2}$ ox in V (vs. Fc/Fc$^+$)	λ_{max} in nm	λ_{em} in nm
1	0.92	470	680
2	0.783	444	610
3	0.845	450	615

In conclusion, rutheniumpolypyridyl complexes based on the ligand Br_4phen are readily obtainable. Most importantly a regioselective nucleophilic substitution with NaOMe at the 3,8-position is possible. It is evident from the conventional reactivity of bromine-substituted aromatics that **1** and **3** are potentially very interesting synthons in itself, opening the possibility to derivatise the previously not easily accessible 5,6-position. Initial investigations on the photochemical reactivity of **3** using ion exchange HPLC suggest that Br_2OMe_2phen is very photolabile.

Experimental Section

All solvents used for spectroscopic measurements were of Uvasol (Merck) grade. All other reagents were of HPLC grade. *cis*-[Ru(tbbpy)$_2$Cl$_2$]·2H$_2$O,[10] was prepared by standard procedures. All reagents for synthesis, $RuCl_3 \cdot 3H_2O$ (Chempur), 1,10-phenanthroline (Aldrich) and all other materials were commercially available and of reagent grade.

3,5,6,8-tetrabromophenanthroline (Br_4phen): 1,10-phenanthroline monohydrate (4.0 g, 20 mmol) was dissolved in $SOCl_2$ (200 mL). Freshly distilled Br_2 (9.3 g, 120 mmol) was carefully added. This mixture was refluxed for 31 h and cooled to room temperature, and the bright yellow precipitate was filtered off (3,5,6,8,-tetrabromophenanthroline). The precipitate was washed with aqueous NH_3 until a colorless solution was obtained. The white solid was recrystallized from toluene. ^{1}H NMR ($CDCl_3$): $\delta = 9.16$ (2 H, d), 8.91 (2 H, d) ppm. ^{13}C NMR ($CDCl_3$): $\delta = 122.0$, 125.1, 129.6, 139.0, 143.6, 152.4 ppm. MS (DCI with H_2O): 497 [M + H$^+$] 417 (M − Br + H$^+$), 338 (M − Br_2 + H$^+$), 257 (M$^+$ − Br_3). Yield 5.22 g (52% based on phen).

Synthesis of [(tbbpy)$_2$Ru(Br_4phen)](PF$_6$)$_2$ (1): 3,5,6,8-Tetrabromo-1,10-phenanthroline (1.15 g, 2.32 mmol) and [(tbbpy)$_2$RuCl$_2$] (1.5 g, 2.11 mmol) were refluxed in a mixture of ethanol (80 mL) and H_2O (20 mL) for 8 hours. The crude reaction mixture was filtered, washed twice with ethanol/H_2O (80:20), and the combined filtrate was concentrated to the half volume. On addition of NH_4PF_6 and stirring at room temperature for 1 hour, the crude product precipitated. Recrystallization from acetone/water gave the desired product. Crystals suitable for X-ray analysis were obtained from acetone/water. ^{1}H NMR ([D$_6$]DMSO): $\delta = 8.997$ [4,7, 2 H, s (lc)], 8.792 [3′′, 2 H, s (lc)], 8.788 [3′, 2 H, s (lc)], 8.055 [2,9, 2 H, s (lc)], 7.599 [5′′, 2 H, d (lc)], 7.527 (6′,6′′, 4 H, m), 7.310 [5′, 2 H, d (lc)], 1.391 [CH$_3$(*tert*-butyl), 18 H, s], 1.362 [CH$_3$(*tert*-butyl), 18 H, s] ppm. MS (Micro-ESI in $CHCl_3$ + methanol); *m*/*z* (relative intensity) with matching isotope pattern: 1279 (100) (**1** + PF_6), 1201 (34) (**1** − Br + PF_6), 567 (51) (**1**$^{2+}$). Crystal data for **1**: $[C_{48}H_{52}Br_4N_6Ru]^{2+} \cdot 2\,[PF_6]^-$, $M = 1423.61$ g mol^{-1}, bordeaux-red prism, size 0.02 × 0.02 × 0.01 mm, tetragonal, space group $I4_1/a$, $a = b = 32.5281(3)$, $c = 20.5151(4)$ Å, $V = 21706.6(5)$ Å^3, $T = -90$ °C, $Z = 16$, $\rho_{calcd.} = 1.742$ g cm^{-3}, μ (Mo-K_α) = 33.74 cm^{-1}, psi-scan, trans(min): 0.5565, trans(max): 0.7367, $F(000) = 11264$, 20023 reflections in $h(-42/42)$, $k(-29/29)$, $l(-19/26)$, measured in the range $2.66° \le \Theta \le 27.49°$, completeness $\Theta_{max} = 99.8\%$, 12423 independent reflections.

Synthesis of [(tbbpy)$_2$Ru(phen)](PF$_6$)$_2$ (2): 1,10-phenanthroline (0.018 g, 0.09 mmol) and [(tbbpy)$_2$RuCl$_2$] (0.06 g, 0.085 mmol) were reacted and purified according to **1**. Yield 96 mg (95%). Crystals suitable for X-ray analysis were obtained from acetone/water. ^{1}H NMR ([D$_3$]acetonitrile): $\delta = 8.613$ [4,7, 2 H, s (lc)], 8.504 [3′, 2 H, s (lc)], 8.456 [3′′, 2 H, s (lc)], 8.299 (5,6, 2 H, s), 8.058 [2,9, 2 H, s (lc)] 7.753 (3,8, 2 H, m), 7.705 (6′, 2 H, d), 7.463 [5′, 2 H, d (lc)], 7.405 (6′′, 2 H, d), 7.200 [5′′, 2 H, d (lc)], 1.437 [CH$_3$(*tert*-butyl), 18 H, s], 1.322 [CH$_3$(*tert*-butyl), 18 H, s] ppm. MS FAB in nba *m*/*z* (relative intensity) with matching isotope pattern: 980 (22) (**2** + PF_6); 834 (15) (**2**). Crystal data for **2**: $[C_{48}H_{56}N_6Ru]^{2+} \cdot 2\,[PF_6]^- \cdot 2\,C_3H_6O$, $M = 1224.15$ g mol^{-1}, red-brown prism, size 0.12 × 0.10 × 0.09 mm, triclinic, space group $P\bar{1}$, $a = 12.1999(7)$, $b =$

13.3243(7), c = 18.989(1) Å, α = 76.854(2), β = 74.819(3), γ = 78.206(3)°, V = 2866.3(3) Å^3, T = −90 °C, Z = 2, $\rho_{calcd.}$ = 1.418 g cm^{-3}, μ (Mo-K_α) = 4.13 cm^{-1}, psi-scan, trans(min): 0.9521, trans(max): 0.9637, F(000) = 1264, 19624 reflections in h(−15/15), k(−17/14), l(−24/24), measured in the range 2.11° ≤ Θ ≤ 27.44°, completeness Θ_{max} = 97.4%, 12753 independent reflections.

Synthesis of [(tbbpy)$_2$Ru(OMe$_2$Br$_2$phen)](PF$_6$)$_2$ (3): 1 (200 mg, 0.14 mmol), was dissolved in a solution of freshly prepared NaOMe (1 M) in MeOH (100 mL). The solution was stirred for 6 h and H_2O (200 mL) was added. The pH of the solution was slowly adjusted to 7 by adding dilute HCl. The resulting opaque orange solution was extracted with CH_2Cl_2 until colorless, and the solvent was removed from the combined organic phases. The precipitate was dissolved in a minimal amount of EtOH and concentrated aqueous NH_4PF_6 added. The precipitate was recrystallized from acetone/water. Yield 170 mg (90%). ^{1}H NMR ([D$_6$]acetone): δ = 8.879 [3′, 2 H, s (lc)], 8.844 [3′′, 2 H, s (lc)], 8.174 [4,7, 2 H, s (lc)], 7.939 (6′, 2 H, d), 7.845 [2,9, 2 H, s (lc)], 7.828 (6′′, 2 H, d), 7.618 [5′, 2 H, d (lc)], 7.397 [5′′, 2 H, d (lc)], 4.156 [CH$_3$(OMe), 6 H, s], 1.428 [CH$_3$(*tert*-butyl), 18 H, s], 1.367 [CH$_3$(*tert*-butyl), 18 H, s] ppm . MS FAB in nba *m*/*z* (relative intensity) with matching isotope pattern: 1181 (5) (**3** + PF$_6$); 1035 (5) (**3**). Crystal data for **3**: $C_{52}H_{61}Br_2F_{12}N_6O_2P_2Ru$, M = 1304.72 g mol^{-1}, red prism, size 0.02 × 0.02 × 0.01 mm, monoclinic, space group $P2_1/n$, a = 13.983(3), b = 39.063(5), c = 10.4711(15) Å, β = 100.945(13)°, V = 5615.4(17) Å^3, T = −153 °C, Z = 4, $\rho_{calcd.}$ = 1.543 g cm^{-3}, μ(Mo-K_α) = 6.22 cm^{-1}, F(000) = 2654, 21731 reflections in h(−15/13), k(−45/45), l(−12/12), measured in the range 1.52° ≤ Θ ≤ 14.56°, completeness Θ_{max} = 72.1%, 6903 independent reflections.

CCDC-216455 and -216456 contain the supplementary crystallographic data for this paper. $[\{Zn(enMe)_2\}_2(enMe)_2\{Zn_2As_8V_{12}O_{40}(H_2O)\}]\cdot 4H_2O$: A Hybrid Molecular Material Based on Covalently Linked Inorganic Zn−As−V Clusters and Transition Metal Complexes via enMe Ligands

Shou-Tian Zheng,[a] Jie Zhang,[a] and Guo-Yu Yang*[a,b]

Keywords: Polyoxometalate / Vanadium / Arsenic / Zinc / Inorganic−organic hybrids

A novel zinc-substituted polyoxovanadate, $[\{Zn(enMe)_2\}_2(enMe)_2\{Zn_2As_8V_{12}O_{40}(H_2O)\}]\cdot 4H_2O$ **1** (enMe = 1,2-diaminopropane), which is built up from $Zn_2As_8V_{12}O_{40}(H_2O)$ clusters and $Zn(enMe)_2$ complexes, and further connected together by *trans*-enMe ligands, has been hydrothermally prepared and characterized by X-ray crystallography. The study of the magnetic susceptibility of **1** demonstrates the presence of antiferromagnetic interaction between V^{IV} cations in **1**.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The design and synthesis of inorganic−organic hybrid materials have been of great interest for their unusual topological properties and potential applications in the fields of catalysis, biochemistry, magnetism and material science.[1−4] In recent years, the design of inorganic−organic hybrid polyoxometalates (POMs) made possible architectures that contribute to the increasing understanding of the methods that control the synergistic interaction between organic and inorganic chemical compositions.[1] A number of transition metal (TM) coordination complex-linked POMs with one-, two- and three-dimensional inorganic−organic hybrid frameworks, as well as some POMs-supported TM complexes have been reported.[5−15] In general, the early transition metals (TMs), especially V, Mo, and W, are flexible and are able to form POMs by using various coordination geometries (from regular and distorted octahedra and square pyramids to tetrahedra) in their highest or mixed oxidation states;[16] however, in contrast, the post TMs, such as Cu^{2+}, Zn^{2+}, and Cd^{2+}, tend to form various TM coordination complexes in which they act as the countercations, the decorated fragments or bridging units in inorganic−organic hybrid POMs. Since the post TMs exhibit extensive coordination chemistry involving a variety of organic ligands, the post TM-substituted POMs may, in principle, incorporate appropriate organic ligands. This offers opportunity for making new inorganic−organic hybrid complexes containing an inorganic cluster backbone decorated with organic functionalities. Such compounds are much less developed. We are currently exploring the potential of this approach in order to obtain some POMs with unusual structures and properties. This report describes the hydrothermal synthesis and characterization by IR and EPR spectroscopy, TGA, elemental analysis, magnetic properties and single-crystal X-ray structure analysis of the first zinc-substituted polyoxovanadate: $[\{Zn(enMe)_2\}_2(enMe)_2\{Zn_2As_8V_{12}O_{40}(H_2O)\}]\cdot 4H_2O$ **1**, in which *trans*-enMe molecules serve as bridges between the inorganic Zn−As−V clusters and $Zn(enMe)_2$ complexes.

Results and Discussion

Single-crystal X-ray analysis reveals that compound **1** is a neutral zinc-substituted polyoxovanadate: $[\{Zn(enMe)_2\}_2(enMe)_2\{Zn_2As_8V_{12}O_{40}(H_2O)\}]\cdot 4H_2O$. As shown in Figure 1, an unusual feature of **1** is that two Zn^{2+} take the place of two VO^{2+} groups located between the As_2O_5 units of the well-known $[As_8V_{14}O_{42}(X^{n-})]^{(8-n)-}$ (X = SO_4^{2-}, SO_3^{2-}, 0.5 H_2O) anion[17,18] and form a new metal cluster anion $[Zn_2As_8V_{12}(H_2O)]^{4-}$. Each $[Zn_2As_8V_{12}O_{40}(H_2O)]^{4-}$ anion is then decorated by two novel TM complexes $[(enMe)Zn(enMe)_2]^{2+}$ to generate an unprecedented inorganic−organic cluster **1**. In the structure of **1**, four crystallographically distinct zinc sites display two different coordination environments: $NZn(1,2)O_4$ square pyramids and distorted $N_2Zn(3,4)N_3$ trigonal bipyramids. The equatorial positions of the $NZnO_4$ square pyramids are occupied by four μ_3-O atoms linked to neighboring OVO_4 square pyramids and four As atoms [Zn−O = 2.007(8)−2.076(7) Å],

and the axial position is occupied by one N atom from a enMe ligand [Zn−N = 2.030(10) Å]. Two distorted N_2ZnN_3 trigonal bipyramids are defined by five N donors of three enMe ligands, respectively, with the Zn−N bond lengths of 2.071(10)−2.203(10) Å. All V centers have a distorted OVO_4 square pyramidal environment with V−O bond lengths in the usual range, 1.596(8)−1.622(7) Å for the terminal oxygen atoms and 1.919(7)−2.007(7) Å for μ_3-O atoms. In the As_2O_5 fragments, the As−O distances vary from 1.741(8) to 1.805(8) Å.

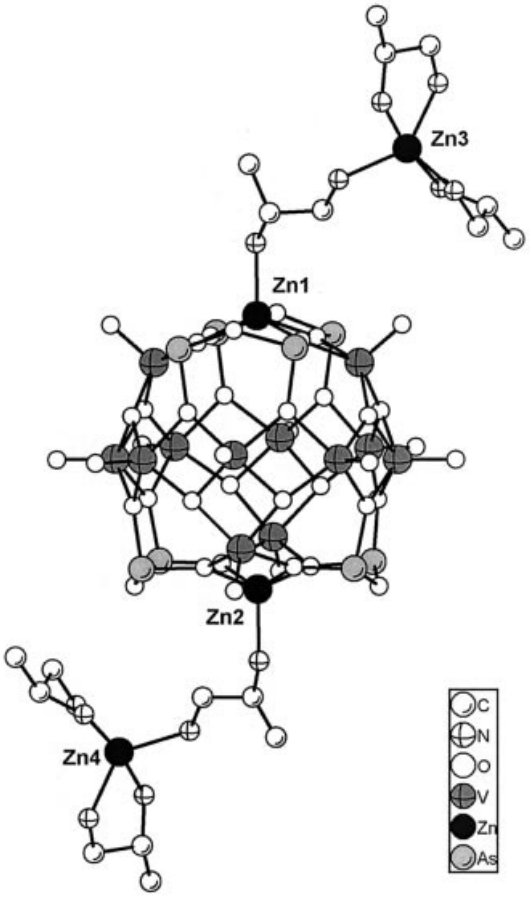

Figure 1. Molecular drawing of **1** (all H atoms are omitted for clarity)

Another unusual feature of **1** is the coordination modes of enMe. There are two types of configuration modes for *cis*- and *trans*-enMe. The *cis*-enMe molecules act as a bidentate chelating ligand and coordinate to the Zn(3) and Zn(4) atoms to form $Zn(enMe)_2$ fragments, while the *trans*-enMe molecules bridge the Zn center of the Zn−As−V cluster and $Zn(enMe)_2$ fragment in an end-to-end fashion, acting as a pillar between the polyoxoanion and the TM coordination fragment. To the best of our knowledge, this linking mode between polyoxoanion and TM coordination fragment in **1** has not been described in other polyoxometalates to date, although the topology of the $\{Zn(enMe)_2\}(enMe)$ group has already been described by Khan et al. in the free complex $[Zn_2(en)_5]^{2+}$.[15]

In compound **1**, each zinc-substituted polyoxovanadium cluster joins eight other adjacent clusters through strong hydrogen bonds between the amine nitrogen atoms and the oxygen atoms, thus resulting in an interesting three-dimensional supramolecular array (Figure 2).

On the basis of valence sum (Σ_s) calculations[19] in **1**, the oxidation states of all V atoms are +4 (Σ_s = 3.972-4.146), the eight As atoms are +3 (Σ_s = 3.043-3.176), and the four Zn atoms are +2 (Σ_s = 1.944−2.096). The EPR spectrum of **1** at liquid nitrogen temperatures shows that the *g* value is 1.9476, corresponding to the signal of V^{4+}. This is consistent with the results from the valence sum calculations.

The thermogravimetric study of compound **1**, which was carried out under a flow of nitrogen and at a heating rate of 10 °C min^{-1}, indicates that the weight loss of **1** cannot be completely divided into distinct stages. The whole stage, which occurs from 45 to 795 °C, is attributed to the loss of H_2O, enMe and the sublimation of As_2O_3. Assuming that the residue corresponds to VO_2 and ZnO, the observed weight loss (50.41%) is in good agreement with the calculated value (50.13%).[20,21]

The variable temperature magnetic susceptibility of **1** was measured between 5 and 300 K. The magnetism may be attributed solely to the presence of V^{4+} ions ($3d^1$, S = 1/2). Figure 3 shows the magnetic behavior of **1** in the form of a reciprocal molar susceptibility (χ_M^{-1}) and $\chi_M T$ vs. temperature. The $\chi_M T$ at room temperature, 1.23 emu K mol^{-1} (3.10 μ_B), is much lower than that expected for 12 uncoupled S = 1/2 spins with g = 2 (4.5 emu K mol^{-1}, 6.0 μ_B). This lower value is similar to that reported for $[V^{IV}{}_8V^{V}{}_4As_8O_{40}(HCOO-)]^{2-}$ or $[H_3KV^{V}{}_8V^{IV}{}_4As_3O_{39}(AsO_4)]^{6-}$ polyoxovanadate (1.2−1.26 emu K mol^{-1}),[22,23] corresponding to four uncoupled electrons (1.5 emu K mol^{-1} for g = 2, 3.46 μ_B). The fact that compound **1** has a much lower χT value at high temperature suggests that there is a possibility that at least eight electrons are already completely paired at room temperature, while the remaining four are unpaired, an observation which is similar to those seen in polyoxovanadates containing V^{IV} centers.[24,25] In compound **1**, all the equatorial vanadium atoms are bridged by one μ-oxo and a μ-arsenato group with a mean distance of 3.014 Å. The capped V atoms are connected to equatorial vanadium atoms through two different exchange pathways. One pathway is formed by a single μ-oxo bridge with a large V−V distance with a mean of 3.733 Å, while the other is formed by two μ-oxo groups with short V−V distance (2.903 Å). It is well-known[26] that μ-oxo bridges are more effective in transmitting antiferromagnetic exchange interactions between several transition metal elements, generally the extent of the coupling in dioxo-bridges is expected to be stronger than for single bridges, and the short metal-metal distance associated to these bridges gives the possibility of direct V−V overlap. The short distances of neighboring V···V pairs with dioxo-bridges, V1···V6 [2.900 Å], V3···V7 [2.895 Å], V8···V11 [2.903 Å] and V9···V10 [2.917 Å], lie in the range expected

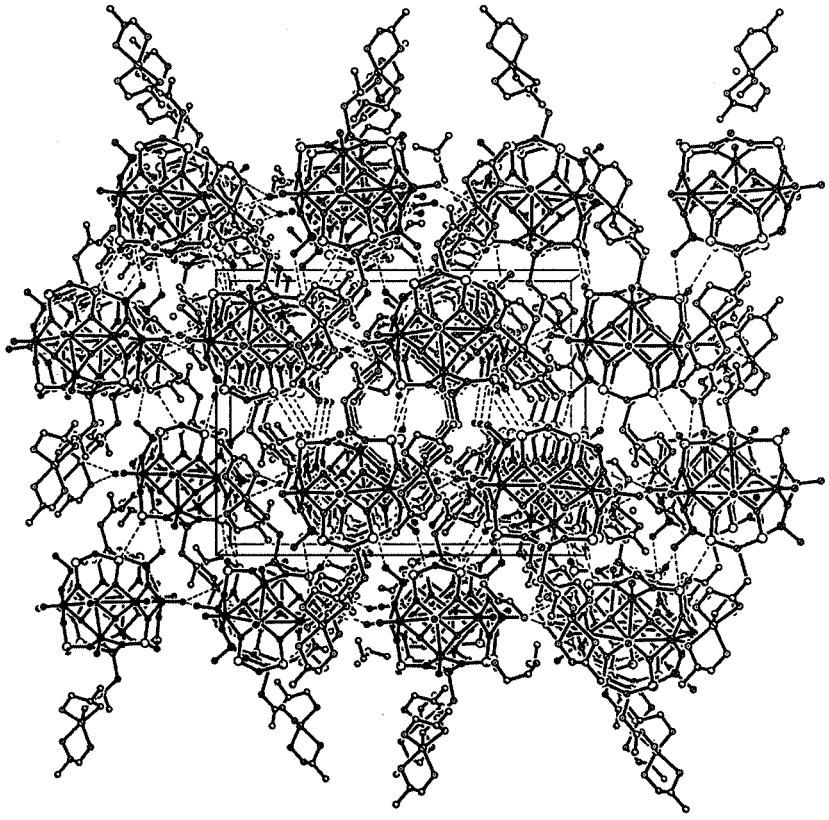

Figure 2. Packing of compound **1** down *a*-axis showing the intercluster hydrogen bonds (water molecules and all H atoms are omitted for clarity)

for strong antiferromagnetic coupling,[27] thus, it is reasonable to assume that these four pairs of vanadium centers between equatorial and capped sites are in the ground $S = 0$ state at relatively high temperature due to the very strong antiferromagnetic coupling provided by the di-μ-oxo bridge, leaving four uncoupled vanadium centers at the equator of the cluster in an approximate square arrangement. On cooling from room temperature, the $\chi_M T$ value decreases slowly until 50 K and then sharply falls to a minimum value of 0.4 cm^3 K mol^{-1} (1.79 μ_B) at 5 K, indicative of antiferromagnetic coupling between the remaining vanadium centers. This dominant antiferromagnetic character is in agreement with a negative Weiss constant ($\theta = -10$ K) obtained from a linear fitting of $\chi_M{}^{-1}$ vs. T using the Curie−Weiss equation. The susceptibility data at low temperature were analyzed using expressions[28,29] for an $S = 1/2$ tetramer based on the Heisenberg Hamiltonian $H = -J(\boldsymbol{S}_1 \cdot \boldsymbol{S}_2 + \boldsymbol{S}_2 \cdot \boldsymbol{S}_3 + \boldsymbol{S}_3 \cdot \boldsymbol{S}_4 + \boldsymbol{S}_4 \cdot \boldsymbol{S}_1)$, the intercluster interactions were included in the model in the molecular field approximation $\chi = \chi_{cluster}/[1 - (2zJ'/Ng^2\beta^2)\,\chi_{cluster}]$.[30] The best fit was obtained with $J = -3.59\ cm^{-1}$, $zJ' = -1.85\ cm^{-1}$, $g = 1.79$ and $R = 8.13 \times 10^{-4}$ for 36 observations at $T \leq 100$ K. R is the agreement factor defined as $\Sigma i[(\chi_M T)_{obs}(i) - (\chi_M T)_{cal}(i)]^2/\Sigma i\,[(\chi_M T)_{obs}(i)]^2$.

Conclusion

In this communication we show the first zinc-substituted inorganic−organic hybrid polyoxovanadium cluster. This is a rare complex in which the organonitrogen ligand serves

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

as a bridge between the metal oxide cluster and the TM coordination fragment. The results demonstrate the potential of post TM-substituted POMs as molecular building blocks for the construction of novel inorganic−organic materials. The substituted Zn centers can also be replaced with other TM ions.[31] Further investigation in this area is in progress.

Experimental Section

Synthesis and Initial Characterization: In a typical synthesis, a mixture of V_2O_5 (0.3 g, 1.66 mmol), As_2O_3 (0.36 g, 1.82 mmol), $ZnAc_2{\cdot}4H_2O$ (1.0 g, 3.98 mmol), enMe (1.1 mL, 14.86 mmol) and H_2O (10 mL, 555.56 mmol), in a molar ratio of 4:4.5:10:37:1389 was stirred under ambient conditions. The resulting gel was sealed in a Teflon-lined steel autoclave and heated at 180 °C for 7 days, and then cooled to room temperature. The resulting product, consisting of single crystals in the form of brown blocks, was recovered by filtration, washed with distilled water and dried in air. Yield 0.553 g (76.1% based on V). Elemental analysis showed that the sample contains 8.02, 2.58, and 6.42 wt% of C, H, and N, respectively, in good agreement with the expected values of 8.09, 2.67, and 6.38 wt%, respectively, on the basis of the empirical formula given by the single-crystal structure analysis. IR (KBr pellet ν/cm^{-1}): 3318 (s), 3262 (s), 2964 (m), 1587 (s), 1458 (w), 1390 (w), 1016 (s), 983 (vs), 718 (vs), 637(s), 460 (s).

X-ray Crystallography

$[\{Zn(enMe)_2\}_2(enMe)_2\{Zn_2As_8V_{12}O_{40}(H_2O)\}]{\cdot}4H_2O$ (1): Monoclinic, space group $P2_1/n$ (no.14), a = 14.9617(6), b = 19.1992(8), c = 24.9403(11) Å, β = 90.050(1)°, V = 7164.2(5) Å^3, Z = 4, D_c = 2.454 g cm^{-3}, $F(000)$ = 5128, M = 2646.98, S = 1.116, T = 293 K. λ(Mo-K_α) = 0.71073 E, θ range 1.34−25.03°. Bruker Smart CCD diffractometer. ω and scan. 12308 reflections are unique, 8482 reflections with $I > 2\sigma(I)$ were used in the refinement and the calculation of R_1 and wR_2. The last successful full-matrix least-squares refinement with anisotropic thermal parameters for all non-hydrogen atoms converged to R_1 = 0.0631, wR_2 = 0.1209. The positions of hydrogen atoms were calculated in ideal positions and not refined. The structure was solved by direct methods.

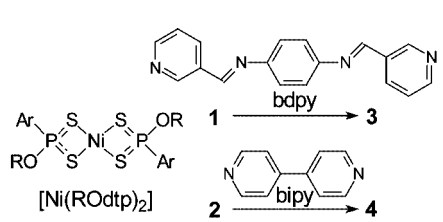
Introduction

Crystal engineering is an important form of supramolecular synthesis, which utilises the understanding of intermolecular interactions in the design of new solids with desired physical and chemical properties.[1] In this view, the involvement of transition metals in crystal engineering can introduce specific physical properties,[2] such as optical properties,[3] electrical conductivity and magnetism,[4] and allows us to exploit a well-established know-how, based on the principles of coordination chemistry.[5] The most employed approach to coordination polymers with predetermined molecular architecture is the rational self-assembly of cleverly selected, multifunctional ligands and metal ions.[6] However, the nature of the counterion, the choice of the solvent, and various phenomena, such as supramolecular isomerism and interpenetration, introduce some uncertainty into the outcome of a particular experiment.[7] In this regard, by reducing the degrees of freedom of the system, for instance by using *cis*-protected metal blocks in place of the "naked" metal ions,[8] or by using a neutral, coordinatively unsaturated metal complex, less uncertainty can be expected. Moreover, the use of neutral synthons leads to self-reliant supramolecular assemblies, which do not require the presence of a counterion. Therefore, the use of suitable coordination compounds as molecular building blocks[9] is a logical extension of the self-assembly approach and is becoming an important synthetic strategy, as attested by the extensive work done on the use of di- and tricarboxylic acids to link adjacent equatorial sites in dimetal units and, more recently, on the use of axial linking to connect simple oligomers to form one- and two-dimensional polymers.[10] However, apart from the massive work on metal carboxylates,[10] this strategy remains largely untapped. Our aim in this study is to exploit this building strategy by using neutral coordinatively unsaturated (phosphonodithioato)Ni^{II} complexes, [Ni(ROdtp)$_2$], [where ROdtp = (4-MeOPh)(RO)PS$_2$; R = Me (**1**), Et (**2**)] and bipyridyl-type ligands as neutral building blocks.[11]

Results and Discussion

Recently, following the one-step reaction between alcohols and diorgano-dithiadiphosphetane disulfides (ArPS$_2$)$_2$ (where Ar = 4-MeOPh, Ph), in the presence of nickel chloride, square planar phosphonodithioato complexes have been synthesised.[12]



R = Me (**1**), Et (**2**); Ar = 4-MeOPh

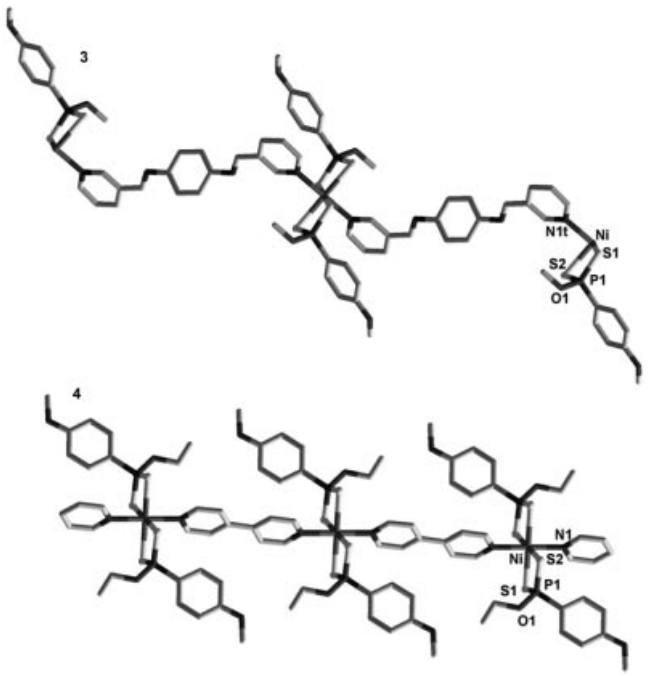

Figure 1. Linear and zigzag polymeric chains of compounds **3** and **4**; hydrogen atoms have been omitted for clarity

The reactivity of these complexes towards pyridine ligands to form octahedral adducts has been studied both in solution and in the solid state,[13] and given the high values of the formation constants of the corresponding adducts,[14] we decided to exploit the tendency of these square-planar (dtp)Ni complexes to be axially coordinated by N−R−N multidentate ligands, such as bidentate bipyridyl-based spacers, to form [Ni(ROdtp)$_2$]−(N−R−N)−[Ni(ROdtp)$_2$]−(N−R−N)− neutral polymers. We report here the synthesis and the structural characterisation of the 1:1 coordination polymers [Ni(MeOdtp)$_2$(bdpy)]$_\infty$ (**3**) and [Ni-(EtOdtp)$_2$(bipy)]$_\infty$ (**4**), obtained by treating [Ni(MeOdtp)$_2$] (**1**) with *N*,*N*′-bis-(3-pyridinylmethylene)-benzene-1,4-diamine (bdpy), and [Ni(EtOdtp)$_2$] (**2**) with 4,4′-bipyridine (bipy), respectively. The bipy and bdpy spacers differ not only in the directionality of the two nitrogen donor atoms, but also in the distance between the N donor atoms, which is of about 7.2 and 14.1 Å for bipy and bdpy, respectively. In both **3** and **4** the nickel ion displays a distorted octahedral environment and the two bidentate phosphonodithioato units occupy the equatorial positions. Each pyridine unit of both bipy and bdpy is axially coordinated to the Ni^{II} ion of two [Ni(ROdtp)$_2$] units [Ni−N, **3**: 2.129(3) Å; **4**: 2.136(2)], thus forming polymeric structures.

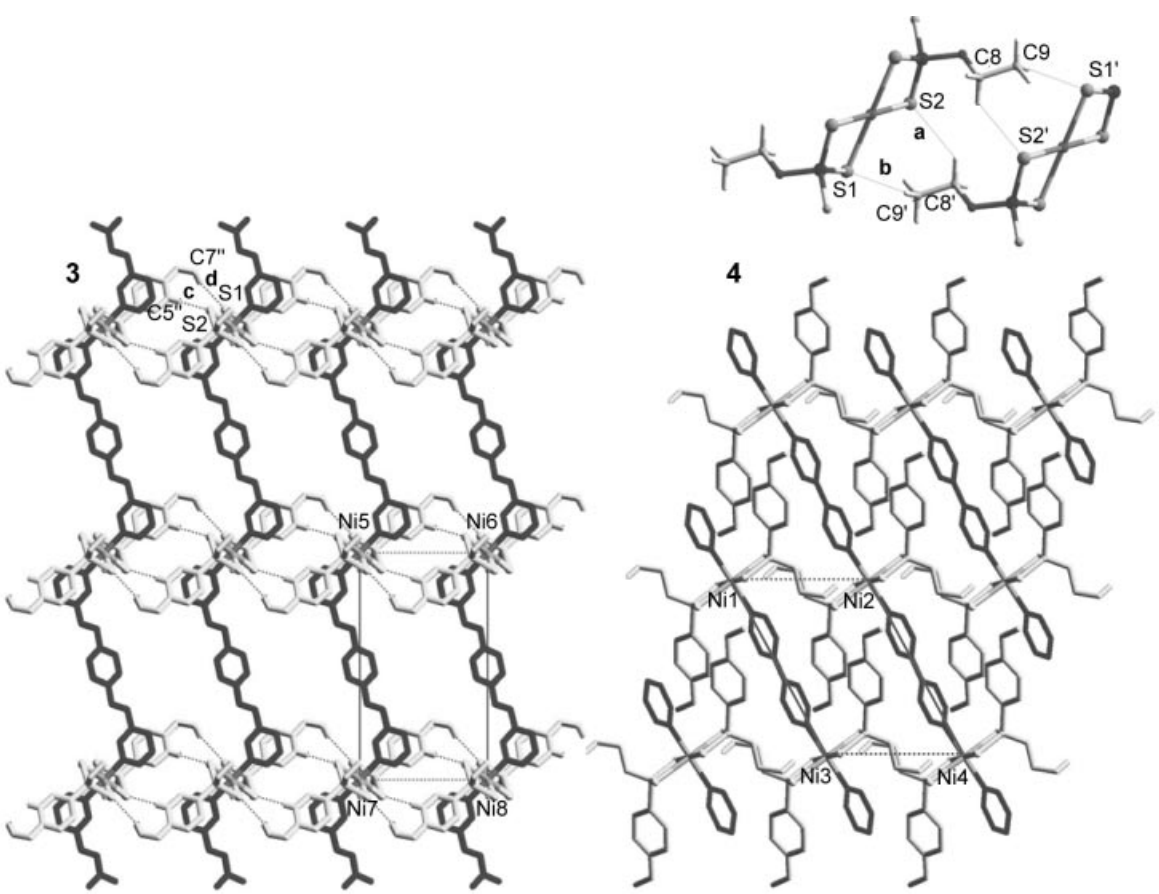

Figure 2. 2D grids viewed down the crystallographic axes *c* and *b* for **3** and **4**, respectively; bipy and bdpy are shaded to evidence the coordination polymers; interactions **a**···**b** (enlarged at the top for clarity reasons) and **c**···**d** connect adjacent chains: **a** S2···C8′ 3.76, H···S 2.96 Å; **b** S1···C9′ 3.90, H···S 3.01 Å; **c** S2···C5′′ 3.74, H···S 2.80 Å; **d** S1···C7′′ 4.00, H···S 3.05 Å; Ni1···Ni2 8.12; Ni1···Ni3 11.38; Ni5···Ni6 10.02, Ni5···Ni7 16.72 Å. Ni2−Ni1−Ni3 60°; Ni5−Ni6−Ni7 90°; ′: 1 + x, *y*, *z*; ′′: −x, −*y*, −*z*; hydrogen atoms except those involved in the described interactions have been omitted for clarity

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The coordination of the pyridyl bases causes an increase in the Ni−S bond lengths [**1**: 2.2330(6), 2.2340(6); **2**: 2.2197(8), 2.2225(8); **3**: 2.4729(9), 2.4997(9); **4**: 2.4646(10), 2.4763(8) Å] and variations in the bond angles in the PS_2Ni metallacycle [S1−Ni−S2, **1**: 88.24(2), **2**: 88.14(3), **3**: 82.19(3), **4**: 82.54(2)°; S1−P−S2, **1**: 102.15(3), **2**: 101.57(4), **3**: 110.16(5), **4**: 109.43(4)°]. These variations closely resemble those found in analogous molecular adducts between phosphonodithioato complexes and pyridine derivatives.[13]

The main, common, structural feature of **3** and **4** is the presence of $[Ni(ROdtp)_2]-N-R-N-[Ni(ROdtp)_2]-N-R-N-$ neutral parallel chains running in linear and zigzag lines with an Ni−Ni distance, through coordinate bonds, of 16.72 and 11.38 Å for **3** and **4**, respectively (see Figure 1). It is interesting to note that in **3** and **4** the 4-MeOPh rings bound to the phosphorus atom show different torsion angles with respect to the P−S bonds [**3**: S2−P−C1−C2 164.4(3)°; **4**: S1−P−C1−C2 99.1(2)°]. Moreover, the orientations of the 4-MeOPh groups with respect to the pyridyl rings in **3** and **4** are different: the mean planes of the two types of rings form an angle of 19.7° in the case of **3**, and 72.5° in the case of **4** (Figure 1). Weak hydrogen bonds, especially of the C−H···S type,[15] between the phosphonodithioato units connect the linear polymers in 2D rectangular and rhombic grids in the case of **3** and **4**, respectively, due to the different geometries of the spacers (see Figure 2). In the case of **3**, the grids feature openings of about 10 × 17 Å; however, in the crystal lattice two sets of symmetry-equivalent parallel and specular grids, shifted by *a*/2, *b*/2, *c*/2, pack in such a way that the bulky nodes of one net are complementary to the spaces within the other net (see Figure 3). Moreover, the sheets interact through weak hydrogen bonds between the bdpy and ROdtp units generating a three-dimensional network. In contrast, in the case of **4**, due to the short length of the bipy rods, the rhombic grids, arising from hydrogen bonding of the chains, do not have enough room to host anything else but the 4-MeOPh rings of two different ligand units (Figure 2).

In conclusion, the use of neutral (phosphonodithioato)Ni^{II} complexes, with predefined coordination sites, as molecular building blocks and suitable bipyridyl-based spacers allows us to assemble one-dimensional coordination polymers. The architecture of the polymers strongly depends on the geometrical features of the spacers and on the weak hydrogen bonds involving the substituents at the

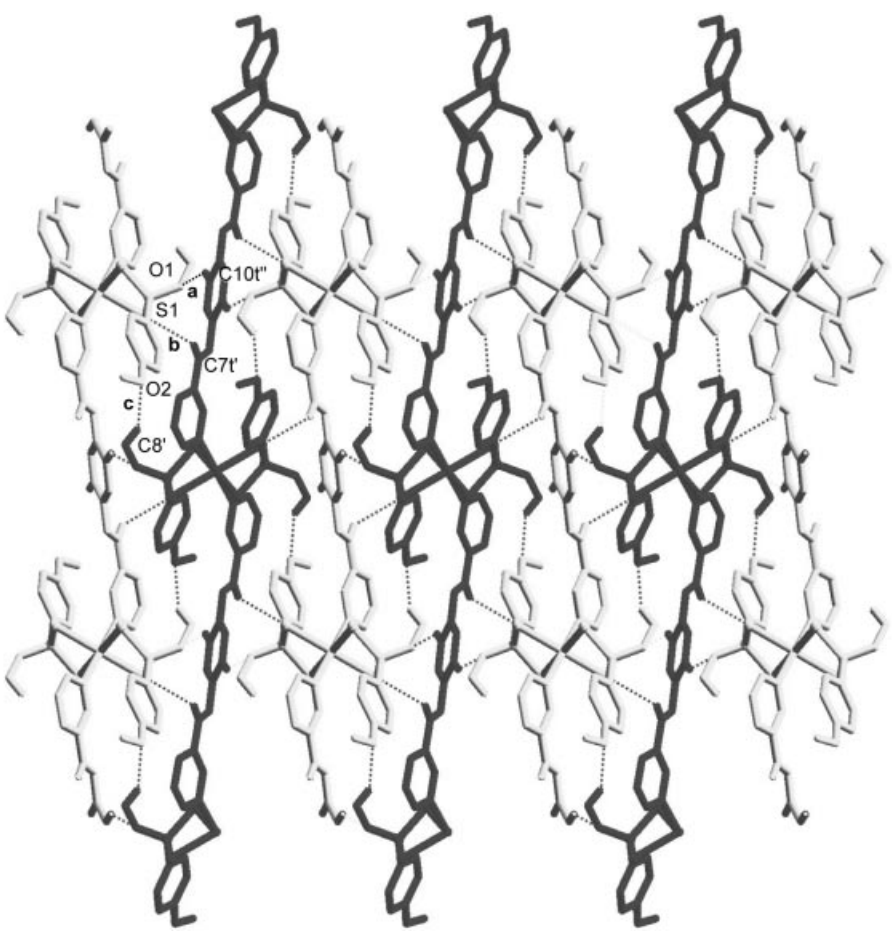

Figure 3. 2D view (*bc* plane) of **3** showing the complementary arrangement of the two sets of grids (dark and light) formed by H bonding of the chains. Hydrogen interactions: **a** O1···C10t′′ 3.42, H···O 2.61 Å; **b** S1···C7t′ 3.80, H···S 2.99 Å; **c** O2···C8′ 3.17, H···O 2.35 Å; ′: −x − 1/2, y − 1/2, −z − 1/2; ′′: x + 1/2, −y + 3/2, z + 1/2; hydrogen atoms except those involved in the described interactions have been omitted for clarity.

phosphorus atoms, which play an important role in the packing of the molecules. Further systematic work is now in progress in our laboratories with the aim of studying the effects of the structural features of building blocks on the resulting supramolecular structures.

Experimental Section

Materials and Methods: Solvents and reagents were Aldrich products and used as purchased. The degree of purity of each compound was checked by CHNS and TLC analyses. Elemental analyses were performed with an EA1108 CHNS-O Fisons instrument. Infrared spectra were recorded on a Bruker IFS55 spectrometer at room temperature using a flow of dried air. Far-IR (500−50 cm^{-1}) spectra (resolution 2 cm^{-1}) were recorded as polythene pellets with a Mylar beam splitter and polythene windows. Middle-IR spectra (resolution 2 cm^{-1}) were recorded as KBr pellets, with a KBr beam splitter and KBr windows. FT-Raman spectra were recorded on the solid sample, dispersed in a KBr matrix (resolution of 2 cm^{-1}) on a Bruker RFS100 FT-Raman spectrometer, fitted with an In-Ga-As detector (room temperature) operating with a Nd-YAG laser (excitation wavelength 1064 nm) with an 180° scattering geometry, at an excitation power of 350 mW.

Syntheses: *N*,*N*′-Bis-(3-pyridinylmethylene)benzene-1,4-diamine (bdpy) was synthesised by an adaptation of literature procedures.[16] Compounds **1** and **2** were prepared as previously reported.[12]

$[Ni(MeOdtp)_2(bdpy)]_\infty$ (3): 1 (26.4 mg, 0.05 mmol) and bdpy (14.6 mg, 0.05 mmol) were reacted at 100 °C in a high-pressure Aldrich tube in 40 mL of a MeOH/$CHCl_3$ (1:1 v/v) mixture. After the reagents had completely dissolved, the reaction mixture was slowly cooled to room temperature. **3** (20.6 mg, 0.025 mmol, 50 % yield) was obtained as bright green crystals; m.p. 190 °C (decomp.). $C_{34}H_{34}N_4O_4P_2S_4Ni$ (811.55): calcd. C 50.3, H 4.2, N 6.9, S 15.8; found C 50.3, H 4.2, N 7.0, S 15.6. FT-IR: 1700 w, 1653 mw, 1625 ms, 1593 vs, 1541 mw, 1498 s, 1456 ms, 1365 mw, 1319 mw, 1305 m, 1295 ms, 1255 vs, 1182 s, 1112 vs, 1006 vs, 893 ms, 835 s, 800 s, 777 vs, 694 s, 659 vs, 645 s, 623 s, 546 vs, 525 m, 438 m, 418 mw, 383 m, 353 w, 326 w, 302 w, 280 mw, 267 w, 247 w, 227 mw, 203 w, 172 mw, 151 m, 140 mw, 121 mw, 101 m, 91 w cm^{-1}. FT-Raman (solid state, relative intensities in parentheses related to the highest peak taken equal to 10.0): 3054 (0.4), 1630 (2.6), 1582 (10.0), 1429 (0.6), 1320 (0.2), 1193 (2.1), 1157 (3.4), 1111 (0.7), 1034 (1.0), 984 (0.5), 892 (0.2), 824 (0.2), 664 (0.2), 545 (0.9), 399 (0.3), 265 (0.7), 136 (2.1), 89 (2.8) cm^{-1}.

$[Ni(EtOdtp)_2(bipy)]_\infty$ (4): 2 (10.2 mg, 0.018 mmol) and bipy (4.8 mg, 0.03 mmol) were reacted at 100 °C in a high-pressure Aldrich tube in 35 mL of an EtOH/$CHCl_3$ (1:1 v/v) mixture. After the reagents had completely dissolved, the reaction mixture was slowly cooled to room temperature. The product was obtained quantitatively as tiny yellow-green needles. M.p.: 230 °C (decomp.). $C_{28}H_{32}N_2O_4P_2S_4Ni$ (709.45): calcd. C 47.4, H 4.5, N 3.9, S 18.1; found C 47.4, H 4.2, N 4.0, S 17.4. FT-IR : 1598 vs, 1568 m, 1531 mw, 1500 s, 1484 m, 1455 m, 1440 m, 1403 ms, 1389 mw, 1297 s, 1259 vs, 1216 m, 1178 ms, 1114 vs, 1064 m, 1029 vs, 949 vs, 830 m, 810 ms, 784 s, 728 mw, 660 ms, 646 s, 628 ms, 545 s, 521 mw, 500 w, 475 w, 438 m, 383 m, 353 w, 326 w, 302 w, 279 mw, 254 w, 247 w, 227 mw, 203 w, 176 w, 151 m, 140 mw, 121 mw, 101 m, 91 w cm^{-1}. FT-Raman (solid state, relative intensities in parentheses related to the highest peak taken equal to 10.0): 3066 (1.2), 3045 (1.5), 2941 (1.6), 2924 (1.6), 1604 (8.7), 1284 (10.0), 1113 (5.7), 1062 (3.1), 1018 (8.1), 659 (1.7), 633 (1.1), 545 (5.8), 379 (0.9), 359 (1.5), 101 (9.3), 68 (6.7) cm^{-1}.

X-ray Crystal Structure Determination: Data collection for **3** was performed on a Bruker SMART APEX CCD area detector diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), equipped with an Oxford Cryosystems open-flow cryostat.[17] Data collection for **4** was performed on a Siemens SMART CCD diffractometer with a monochromated synchrotron radiation (λ = 0.68710 Å, ω rotation with narrow frames) using a silicon 111 monochromator, at 120(2) K. SADABS corrections were applied for **3**, while no absorption corrections were applied for **4**. The structures were solved by direct methods using SHELXS-97[18] and all non-hydrogen atoms were located using subsequent difference Fourier methods.[19] Hydrogen atoms were placed in calculated positions and thereafter allowed to ride on their parent atoms, except for the methyl groups for **4**, which were located by difference Fourier methods and treated as rigid rotors. All crystal structure diagrams were prepared using the OLEX program.[20]

Compound 3: $C_{34}H_{34}N_4NiO_4P_2S_4$, monoclinic, space group $P2_1/n$, a = 10.016(2) Å, b = 16.724(3) Å, c = 11.412(2) Å, β = 103.902(4)°, V = 1855.6(11) $Å^3$, Z = 2, $D_{calcd.}$ = 1.452 Mg/m^3. R = 0.0465, wR = 0.0908 for 2670 observed independent data.

Compound 4: $C_{28}H_{32}N_2NiO_4P_2S_4$, triclinic, space group $P\bar{1}$, a = 8.13(3) Å, b = 9.910(3) Å, c = 10.126(3) Å, α = 89.479(7), β = 76.330(5), γ = 77.675(6)°, V = 773.0(4) $Å^3$, Z = 1, $D_{calcd.}$ = 1.524 Mg/m^3. R = 0.0397, wR = 0.0884 for 2981 observed independent data.

CCDC-227421 for **3** and CCDC-227422 for **4** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We would like to thank the EPSRC and RFBR 03−03−32401 for funding and for provision of X-ray diffractometers.

Direct Synthesis of Tricarbonyl(cyclopentadienyl)rhenium and Tricarbonyl(cyclopentadienyl)technetium Units from Ferrocenyl Moieties − Preparation of 17α-Ethynylestradiol Derivatives Bearing a Tricarbonyl(cyclopentadienyl)technetium Group

Stéphane Masi,[a] Siden Top,*[a] Leila Boubekeur,[a] Gérard Jaouen,*[a] Stefan Mundwiler,[b] Bernhard Spingler,[b] and Roger Alberto*[b]

Keywords: Technetium / Rhenium / Estradiol / Radiopharmaceuticals / Bioorganometallics

The preparation of new tricarbonyl(cyclopentadienyl)rhenium and tricarbonyl(cyclopentadienyl)technetium derivatives is described. The approach used was applied to a cold target model, 17α-ethynylestradiol substituted at the 17α position by a ketotricarbonyl(cyclopentadienyl)rhenium group. The novel organometallic reaction applied here, when extended to potential radiopharmaceuticals, consists of a cyclopentadienyl-ligand transfer between ketoferrocenes and *fac*-$[^{99m}Tc(H_2O)_3(CO)_3]^+$ in a water/DMSO 1:1 mixture. This reaction lead to the synthesis of a new estradiol derivative, labeled with ^{99m}Tc. The synthesis of another product was performed by using $[^{99}TcCl_3(CO)_3]^{2-}$ as the Tc precursor and its X-ray crystal structure was determined. In each case high yields were obtained.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The synthesis of new radiolabeled estrogen derivatives has generated much interest during the last decade.[1] The design of new molecules labeled with technetium, ^{99m}Tc, or rhenium, ^{188}Re, for imaging and therapy of breast tumors, respectively, is of current interest since most of the compounds prepared have not yet shown enough affinity or selectivity towards estrogen receptors (ER) and, in addition, their synthesis is rather circuitous. Many different systems have been envisaged for the labeling of ligands with technetium or rhenium. One general approach is the coordination of a Tc^V moiety through chelation with heteroatom systems, but the molecules obtained are not always stable in solution.[1,2] Therefore, we have elaborated an organometallic approach, in which a low-oxidation-state-rhenium core is tethered to a cyclopentadienyl (Cp) ligand.[3] The organometallic tether using this ligand seems to be particularly attractive. This group has the advantage of being lipophilic, fairly small in size and very robust. Furthermore, this approach can be easily extended to the preparation of tricarbonyl(cyclopentadienyl)technetium compounds because Re and Tc complexes exhibit very similar chemical behavior.

The search for an easy route to $CpM(CO)_3$ complexes (where M = Re, Tc) bearing a functional substituent on the Cp ring, with the purpose of being compatible with the handling of radioactive compounds, has attracted much interest.[4] Wenzel reported a unique double ligand-transfer reaction where the technetium source is $[^{99m}TcO_4]^-$.[5] More recently, Alberto et al. reported the preparation of different $[(R\text{-}Cp)^{99m}Tc(CO)_3]$ molecules (R = ketone), where the *fac*-$[^{99m}Tc(H_2O)_3(CO)_3]^+$ compound, generated in physiological media, is the ^{99m}Tc precursor.[6] With regard to rhenium, Top et al. reported various syntheses of $[(R'\text{-}Cp)Re(CO)_3]$ molecules (R′ = organic fragment) based on the use of $[Re(CO)_6][BF_4]$ with particular monosubstituted ferrocene compounds in DMSO. This method is compatible with aqueous media as we obtained promising results in a water/DMSO 1:1 mixture.[7]

The first step in the transformation of $[Re(CO)_6][BF_4]$ in DMSO seems to be the departure of three carbonyl ligands from the $[Re(CO)_6]^+$ cation. Thus, we postulated the formation of the *fac*-$[Re(DMSO)_3(CO)_3]^+$intermediate. It is believed that *fac*-$[Re(DMSO)_3(CO)_3]^+$ may react with the cyclopentadienyl ligands the same way that *fac*-$[^{99m}Tc(H_2O)_3(CO)_3]^+$ does.[6,7] Combining these aspects, we decided to extend our work with ferrocene derivatives and the $[Re(CO)_6]^+$ cation to the preparation of [(R-

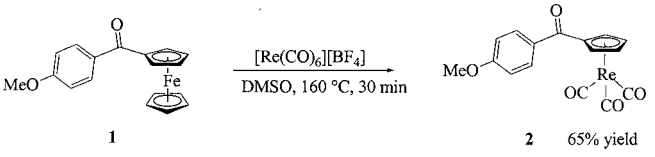
Cp)^{99m}Tc(CO)$_3$] from the same ferrocene derivatives and using *fac*-[^{99m}Tc(H$_2$O)$_3$(CO)$_3$]$^+$ as the reagent.

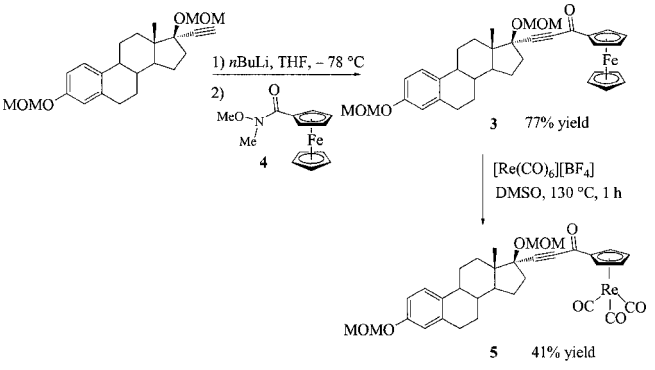
Results and Discussion

The ketoferrocene **1** was first used as a model for the reaction between [Re(CO)$_6$][BF$_4$] and *fac*-[^{99m}Tc(H$_2$O)$_3$(CO)$_3$]$^+$. It was prepared from ferrocene and *p*-anisoyl chloride following the procedure described in the literature.[8] The reaction with [Re(CO)$_6$]$^+$ was carried out by heating the DMSO solution of **1** and [Re(CO)$_6$]$^+$ at 160 °C for 30 min and **2** was obtained in 65 % yield (see Scheme 1).



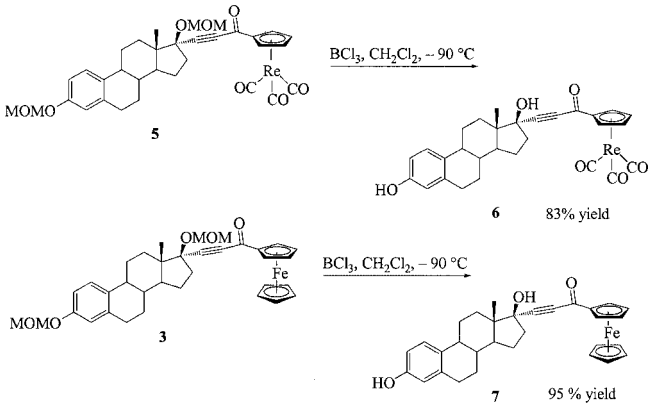
Scheme 1. Ligand-transfer reaction between ketoferrocene **1** and the hexacarbonylrhenium cation

In the hormone series, the ferrocenyl-β-estradiol derivative, **3**, was prepared. The amidoferrocene **4**, prepared according to the Weinreb method,[9] was reacted with the lithium compound generated from 17α-ethynylestradiol, diprotected with methylmethoxy (MOM) to produce **3** (see Scheme 2). Heating **3** with [Re(CO)$_6$][BF$_4$] in DMSO for one hour affords the rhenium compound **5** in 41 % yield.

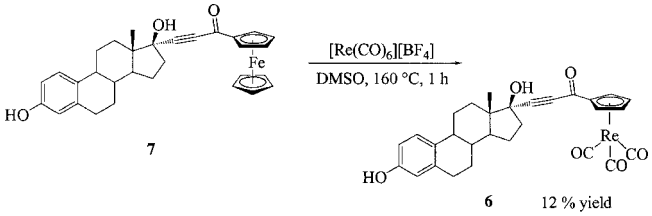


Scheme 2. Synthesis of tricarbonyl(cyclopentadienyl)rhenium derivative **5**

The removal of the methoxymethyl groups was achieved by using BCl$_3$ in dichloromethane (see Scheme 3). The rhenium compound **6** and the ferrocenyl derivative **7** were obtained in good yields. Compound **6** had already been prepared by another method.[10] Heating the unprotected ferrocenyl steroid **7** with [Re(CO)$_6$][BF$_4$] also gives the rhenium complex **6** but in low yield (12 %) (see Scheme 4).

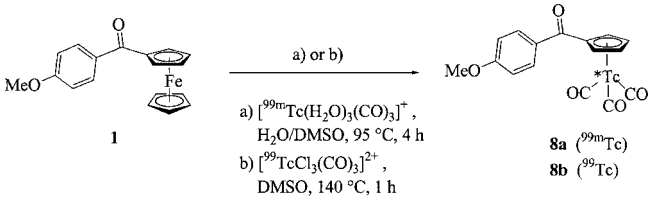


Scheme 3. Deprotection of the ethynyl estradiol derivatives



Scheme 4. Ligand-transfer reaction between **7** and the rhenium-hexacarbonyl cation

Since the chemistry of Re is similar to that of Tc, the above reaction between [Re(CO)$_6$]$^+$ and the ferrocenyl derivative may be adapted to Tc analogs. Recently, Alberto et al. have found a very convenient synthetic method for [^{99m}Tc(H$_2$O)$_3$(CO)$_3$]$^+$ starting from ^{99m}TcO$_4^-$.[11] Therefore, it would be interesting to use the reagent [^{99m}Tc(H$_2$O)$_3$(CO)$_3$]$^+$ in the exchange reaction. According to the procedure already described for the reaction of *fac*-[^{99m}Tc(H$_2$O)$_3$(CO)$_3$]$^+$ with NaCp derivatives,[6] an aliquot of 0.5 mL of an aqueous solution containing [^{99m}Tc(H$_2$O)$_3$(CO)$_3$]$^+$ (nM–μM range) was mixed with 0.5 mL of a DMSO solution, where an excess of **1** had been previously dissolved (1.5–2 μmol). The mixture was heated at 95 °C and the reaction was monitored by HPLC (high-pressure liquid chromatography) equipped with a γ radiodetector. The expected complex, **8a**, was formed in > 80 % radiochemical yield after heating for 4 h (see Scheme 5). The presence of **8a** (^{99m}Tc) was confirmed by comparing its HPLC chromatogram, measured by γ-detection, with the HPLC chromatogram of the analogous cold compound, **2** (Re). Due to the very low concentration of the ^{99m}Tc species, characterization is only possible by chromatographic comparison.



Scheme 5. Synthesis of a cyclopentadienyltechnetium derivative from the corresponding ferrocene precursor

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

After the successful formation of **8a** from *fac*-$[^{99m}Tc(H_2O)_3(CO)_3]^+$, we attempted to synthesize **8** on a larger scale, in order to identify it with more accuracy. Starting from $[^{99}TcCl_3(CO)_3]^{2-}$, larger quantities of complex **8** can be produced and handled because the long half-life of ^{99}Tc results in weak radiation of this isotope. Thus, **1** was treated in 0.5 mL of DMSO at 140 °C with $[^{99}TcCl_3(CO)_3][Et_4N]_2$. Within 1 h, **8b** had formed in about 74 % yield and was crystallized from a diethyl ether/hexane 2:1 solution. The reaction was monitored with HPLC equipped with a β radiodetector. The retention time of the isolated **8b** (^{99}Tc) is very close to that of **8a** (^{99m}Tc) (24.3 min for **8b** and 24.4 min for **8a**, respectively), thus proving the identity of **8a**. The structure of **8b** was elucidated by an X-ray study. An ORTEP representation of this complex is given in Figure 1.

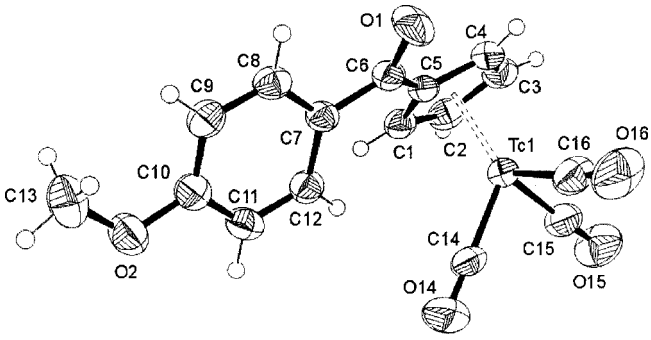


Figure 1. Ortep plot of **8b**, ellipsoids drawn with 50 % probability

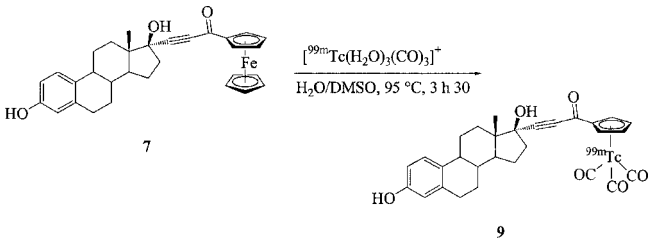
We next applied the reaction between ketoferrocene compounds and the reagent *fac*-$[^{99m}Tc(H_2O)_3(CO)_3]^+$ to steroid **7** and obtained molecule **9** with excellent yields. Thus, using the conditions described above with **1** and heating for 3 h 30 min, allowed us to form **9** in quantitative yield (> 90%) (see Scheme 6). It is remarkable that such a mild and efficient reaction has never been reported for the synthesis of molecules belonging to the class of ethynylestradiol. Additionally, it is noteworthy that our approach for the labeling of ^{99m}Tc on (bio)organic molecules constitutes a real improvement, with regard to the transformations of ferrocene derivatives into corresponding tricarbonyl(cyclopentadienyl)technetium derivatives, described in the literature.[5,12]



Scheme 6. Synthesis of a novel 17α-ethynyl estradiol derivative labeled with ^{99m}Tc, in a water/DMSO 1:1 mixture at atmospheric pressure

Conclusion

In summary, we have presented the synthesis of new complexes bearing tricarbonyl(cyclopentadienyl)rhenium or tricarbonyl(cyclopentadienyl)technetium functionalities, where the target molecules belong to the estradiol series. In addition, the first synthesis of tricarbonyl(cyclopentadienyl)-technetium derivatives from the organometallic aqua complex *fac*-$[^{99m}Tc(H_2O)_3(CO)_3]^+$ and ferrocene-containing compounds has been successfully investigated. Thanks to this convenient method, the efficient radiochemical synthesis of a novel 17α-ethynylestradiol derivative can be achieved in aqueous media under mild conditions, without protecting the estradiol substituents. On the basis of these encouraging results, the reaction should be useful in the development of a wide variety of radiolabeled compounds in aqueous media.

Experimental Section

DMSO was used without any purification. TLC chromatography was performed on silica gel 60-GF254. Infrared spectra were recorded on an IR-FT BOMEM Michelson-100 spectrometer. ^1H- and ^{13}C NMR spectra were recorded on 200 MHz and 400 MHz Bruker spectrometers. Mass spectrometry was performed with a Nermag R 10−10C spectrometer. Melting points were measured with a Kofler device. Elemental analyses were performed by the regional microanalysis department of Université Pierre et Marie Curie.

1: $AlCl_3$ (0.477 g, 3.49 mmol) was added to a 5 mL dichloromethane solution of ferrocene (0.5 g, 2.69 mmol). *p*-Anisoyl chloride (0.305 g, 1.79 mmol) was then added dropwise and the resulting solution was stirred for 4 h at room temperature. The mixture was hydrolyzed with water (40 mL) and the aqueous solution was extracted with diethyl ether (3 × 80 mL). All the organic fractions were combined, dried over magnesium sulfate, filtered and the solvents evaporated. The compound was purified by a silica-gel plate (dichloromethane) to give **1** (0.18 g, 31% yield); m.p. 74−76 °C. ^1H NMR (200 MHz, $CDCl_3$): δ = 3.82 (s, 3 H, -OCH_3), 4.13 (s, 5 H, Cp), 4.49 (s, 2 H, 2,5-H of C_5H_4), 4.83 (s, 2 H, 3,4-H of C_5H_4), 6.89 (d, *J* = 8.0 Hz, 2 H, Ar), 7.88 (d, *J* = 8.0 Hz, 2 H, Ar) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 55.4 (-OCH_3), 70.1 (C_{Cp}), 71.4 (C_{Cp}), 72.1 (C_{Cp}), 113.4 (C_{Ar}), 130.4 (C_{Ar}), 162.4 (C_{Ar}), 197.3 (CO) ppm. IR (CH_2Cl_2): $\tilde{\nu}$ = 1635 (ν_{CO}) cm^{-1}. MS (EI): *m*/*z* = 56 $[Fe]^+$, 77, 92, 121, 135 $[M - Fc]^+$, 171, 277, 320 $[M]^+$.

2: $[Re(CO)_6][BF_4]$ (0.073 g, 0.166 mmol) was dissolved in DMSO (1 mL) in a 5 mL round-bottomed flask equipped with a magnetic stirring bar. Compound **1** (0.166 g, 0.518 mmol) was added and the solution was heated for 30 min at 160 °C. The mixture was allowed to warm to room temperature and then water (10 mL) was added. The product was extracted with dichloromethane (2 × 50 mL). The organic phase was washed, dried ($MgSO_4$), filtered and concentrated. The mixture was purified by chromatography on a silica-gel plate (ethyl acetate/petroleum ether 1:7) to give **2** (0.051 g, 65 % yield); m.p. 186 °C. ^1H NMR (200 MHz, $CDCl_3$): δ = 3.88 (s, 3 H, -OCH_3), 5.45 (t, *J* = 2.2 Hz, 2 H, 3,4-H of C_5H_4), 6.05 (t, *J* = 2.2 Hz, 2 H, 2,5-H of C_5H_4), 6.95 (d, *J* = 8.0 Hz, 2 H, Ar), 7.83 (d, *J* = 8.0 Hz, 2 H, Ar) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 55.4 (-OCH_3), 85.1 (2 C_{Cp}), 89.4 (2 C_{Cp}), 113.8 (2 C_{Ar}), 130.8 (2

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

C_{Ar}) ppm. IR (CH_2Cl_2): $\tilde{\nu}$ = 2030 s, 1938 s, 1652 w (ν_{CO}) cm^{-1}. MS (EI): *m/z* = 386 [M − 3 CO]$^+$, 412, 442 [M − CO]$^+$, 469 [M]$^+$. $C_{16}H_{11}O_5Re$ (469.46): calcd. C 40.93, H 2.36; found C 40.97, H 2.29.

4: The synthesis of **4** was performed using the procedure for the preparation of *N*-methoxy-*N*-methylamides (see reference [9]). Oxalyl chloride (7.250 g, 57 mmol) was added to ferrocenecarboxylic acid (0.550 g, 2.39 mmol) placed in a Schlenk tube and cooled in an ice bath. The mixture was stirred for 3 h, then the excess oxalyl chloride was removed under vacuum. Chloroform (20 mL) was added, followed by addition of *N*,*O*-dimethylhydroxyamine hydrochloride (0.260 g, 2.63 mmol). Anhydrous pyridine (0.420 g, 5.26 mmol) was added dropwise to the mixture, cooled in an ice bath. The mixture was stirred for 2 h 30 min to allow the temperature to rise to room temperature. Then, dichloromethane (200 mL) was added and the solution obtained was washed with a saturated K_2CO_3 solution, dried over magnesium sulfate, filtered and the solvents were evaporated. The compound obtained was crystallized in pentane to give **4** (0.524 g, 83 % yield); m.p. 28 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 3.31 (s, 3 H, -NCH_3), 3.74 (s, 3 H, -$NOCH_3$), 4.22 (s, 5 H, Cp), 4.39 (t, *J* = 1.8 Hz, 2 H, 3,4-H of C_5H_4), 4.91 (t, *J* = 1.8 Hz, 2 H, 2,5-H of C_5H_4) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 33.4 (-NCH_3), 61.0 (-$NOCH_3$), 69.5 (C_{Cp}), 70.6 (C_{Cp}), 71.0 (C_{Cp}), 73.0 (C_{Cp}), 171.0 (CO) ppm. IR (CH_2Cl_2): $\tilde{\nu}$ = 1616 s (ν_{CO}) cm^{-1}. MS (EI): *m/z* = 56 [Fe]$^+$, 65 [Cp]$^+$, 121 [FeCp]$^+$, 129, 185 [Fc]$^+$, 213 [FcCO]$^+$, 273 [M]$^{+\cdot}$. $C_{13}H_{15}FeNO_2$ (273.05): calcd. C 57.17, H 5.54, N 5.13; found C 57.02, H 5.73, N 5.15.

3: In a Schlenk tube, 17α-ethynylestradiol diprotected with a methoxymethyl group (0.665 g, 1.73 mmol) was dissolved in THF (6 mL) and cooled to −78 °C. *n*BuLi (0.8 mL, 2.05 mmol, 2.5 M solution in hexane) was added dropwise and the mixture was stirred for 1 h. By that time the temperature had risen to −50 °C. Then, a solution of **4** (0.429 g, 1.57 mmol) in THF (4 mL) was added dropwise. After 15 min of stirring, the ice bath was removed and the stirring was maintained for two more hours . Then, dichloromethane (200 mL) was added and the solution obtained was washed with water, dried over magnesium sulfate, filtered and the solvents were evaporated. The crude product was purified by chromatography on a silica-gel plate (diethyl ether/petroleum ether 1:1) to give **3** (77 %); m.p. 102 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.99 (s, 3 H, CH_3-18), 2.88 (m, 2 H, H-6), 3.47 (s, 3 H, -OCH_3), 3.48 (s, 3 H, -OCH_3), 4.28 (s, 5 H, Cp), 4.61 (t, *J* = 2 Hz, 2 H, 3,4-H of C_5H_4), 4.90 (d, *J* = 6.6 Hz, 1 H, -OCH_2O-17), 4.94 (t, *J* = 2 Hz, 2 H, 3,4-H of C_5H_4), 5.13 (d, *J* = 6.6 Hz, 1 H, -OCH_2O-17), 5.16 (s, 2 H, -OCH_2O-3), 6.79 (d, *J* = 2.6 Hz, 1 H, H-4), 6.84 (dd, *J* = 8.4, 2.6 Hz, 1 H, 2-H), 7.24 (d, *J* = 8.4 Hz, 1 H, 1-H) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 13.0 (C-18), 29.6 (C-6), 23.1, 26.3, 27.3, 33.5 and 37.3 (C-7, C-11, C-12, C-15 and C-16), 39.1, 43.7, 49.3 (C-8, C-9 and C-14), 48.5 (C-13), 55.8 and 56.0 (2 MeO-3), 70.3 and 73.3 (C_{Cp}), 85.4 and 87.4 (C_{Cp} and C-17), 91.0, 93.9 and 94.4 (C-19, C-20, and -OCH_2O-), 113.7 (C-2), 116.2 (C-4), 126.3 (C-1), 133.5 (C-10), 137.9 (C-5), 155.1 (C-3) ppm. IR (CH_2Cl_2): $\tilde{\nu}$ = 2207 w ($\nu_{C\equiv C}$), 1623 s (ν_{CO}) cm^{-1}. MS (EI): *m/z* = 45 [CH_2OCH_3]$^+$, 596 [M]$^{+\cdot}$. MS (IC, DCI/NH_3): *m/z* = 597 [M + H]$^+$. $C_{35}H_{40}FeO_5$ (596.22): calcd. C 70.47, H 6.76; found C 70.17, H 7.17.

5: [$Re(CO)_6$][BF_4] (0.540 g, 1.22 mmol) was dissolved in DMSO (1 mL) in a 5 mL round-bottomed flask equipped with a magnetic stirring bar. Compound **3** (0.640 g, 1.07 mmol) was added and the solution was heated for 1 h at 130 °C. The mixture was allowed to warm to room temperature and then water (10 mL) was added. The product was extracted with dichloromethane (2 × 150 mL). The organic phase was washed, dried ($MgSO_4$), filtered and concentrated. The mixture was purified by chromatography on a silica-gel plate (ethyl acetate/petroleum ether 1:5) to give **5** (0.331 g, 41 % yield); m.p. 119 °C. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.94 (s, 3 H, CH_3-18), 2.85 (m, 2 H, H-6), 3.43 (s, 3 H, -OCH_3), 3.47 (s, 3 H, -OCH_3), 4.84 (d, *J* = 7.2 Hz, 1 H, -OCH_2O-17), 4.99 (d, *J* = 7.2 Hz, 1 H, -OCH_2O-17), 5.15 (s, 2 H, -OCH_2O-3), 5.41 (m, 2 H, 3,4-H of C_5H_4), 6.21 (m, 2 H, 2,5-H of C_5H_4), 6.78 (d, 1 H, 4-H), 6.83 (dd, *J* = 8.4 Hz, 1 H, 2-H), 7.20 (d, *J* = 8.4 Hz, 1 H, 1-H) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 13.2 (C-18), 29.8 (C-6), 23.1, 26.3, 27.2, 33.7 and 37.4 (C-7, C-11, C-12, C-15 and C-16), 39.1, 43.5 and 49.5 (C-8, 9 and C-14), 48.8 (C-13), 56.0 (2 CH_3O), 85.1 and 85.4 (C_{Cp} and C-17), 85.5, 89.2 and 89.3 (C_{Cp}), 94.0 (-OCH_2O-17), 94.5 (-OCH_2O-3), 94.3 and 96.5 (C-19 and C-20), 113.8, 116.3 and 126.5 (C-1, C-2, and C-4), 133.4 (C-10), 138.0 (C-5), 155.1 (C-3), 171.3 (CO, ketone), 191.4 (Re-CO) ppm. IR (CH_2Cl_2): $\tilde{\nu}$ = 2205 w ($\nu_{C\equiv C}$), 2032 s, 1940 vs, 1642 w (ν_{CO}) cm^{-1}. MS (EI): ^{187}Re *m/z* = 45 [CH_2OCH_3]$^+$, 746 [M]$^+$. MS (IC, DCI/NH_3): ^{187}Re *m/z* = 747 [M + H]$^+$, 764 [M + NH_4]$^+$. $C_{33}H_{35}O_8Re$ (746.19): calcd. C 53.14, H 4.73; found C 53.07, H 5.00.

6: The deprotection of **5** was carried out according to a procedure described in the literature.[13] Under an inert atmosphere, **5** (0.070 g, 0.094 mmol) was dissolved in 8 mL of dichloromethane. The solution was cooled to −90 °C and BCl_3 (1 mL, 1 M in CH_2Cl_2) was added dropwise. A rapid evolution of the color from beige to orange was observed. The solution was stirred for 30 min, the temperature of the cooling bath was thus −30 °C. The bath was removed and dichloromethane (150 mL) was poured into the mixture. This organic phase was washed with water (50 mL) and neutralized with 50 mL of K_2CO_3 (10 %). The organic phase was washed, dried ($MgSO_4$), filtered and concentrated. The mixture was purified by silica-gel chromatography (diethyl ether/petroleum ether 2:1) to give **6** (0.051 g, 83% yield); m.p. 156 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.95 (s, 3 H, CH_3-18), 2.75 (m, 2 H, 6-H), 5.78 (m, 2 H, 3,4-H of C_5H_4), 6.34 (m, 2 H, 2,5-H of C_5H_4), 6.53 (d, 1 H, 4-H), 6.59 (dd, 1 H, 2-H), 7.09 (d, 1 H, 1-H) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 12.8 (C-18), 23.1 (C-15), 26.3, 27.1 (C-7 and C-11), 29.6 (C-6), 33.3 (C-16), 39.0 and 39.4 (C-12 and C-8), 43.5 (C-9), 48.1 (C-13), 50.3 (C-14), 80.4 (C-17), 85.5 and 89.4 (4 C_{Cp}), 83.0, 96.3 and 96.6 (1 C_{Cp} and C≡C), 112.8 (C-2), 115.3 (C-4), 126.7 (C-1), 132.3 (C-10), 138.3 (C-5), 153.5 (C-3), 171.4 (CO), 191.5 (Re-CO) ppm. IR (CH_2Cl_2): $\tilde{\nu}$ = 2033 s, 1943 vs, 1653 w (ν_{CO}) cm^{-1}. MS (IC, DCI/NH_3): ^{187}Re *m/z* = 659 [M + H]$^+$, 676 [M + NH_4]$^+$. $C_{29}H_{27}O_6Re$ + 1 Et_2O (732.21): calcd. C 54.16, H 5.10; found C 54.35, H 5.01.

7: The deprotection of **3** was carried out according to the procedure described above for the deprotection of **5**. The crude material was purified by silica-gel chromatography (diethyl ether/petroleum ether 1:1) to give **7** (0.081 g, 95% yield); m.p. 143 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.97 (s, 3 H, CH_3-18), 2.84 (m, 2 H, 6-H), 4.28 (s, 5 H, Cp), 4.63 (t, 2 H, 3,4-H of C_5H_4), 4.93 (t, 2 H, 2,5-H of C_5H_4), 6.59 (d, 1 H, 4-H), 6.64 (dd, *J* = 8.4 Hz, 1 H, 2-H), 7.17 (d, *J* = 8.4 Hz, 1 H, 1-H) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 12.8 (C-18), 23.0 (C-15), 26.3, 27.3 (C-7 and C-11), 29.6 (C-6), 33.2 (C-16), 39.0 and 39.3 (C-12 and C-8), 43.5 (C-9), 47.9 (C-13), 50.2 (C-14), 70.6 (C_{cp} and 2 $C_{cp'}$), 73.7 (2 $C_{cp'}$), 80.1 (C-17), 84.9 and 94.8 (1 $C_{Cp'}$ and C≡C), 112.8 (C-2), 115.3 (C-4), 126.5 (C-1), 131.8 (C-10), 137.9 (C-5), 153.9 (C-3), 181.7 (CO) ppm. IR (CH_2Cl_2): $\tilde{\nu}$ = 1623 s (ν_{CO}) cm^{-1}. MS (EI): *m/z* = 43, 73, 147, 207, 221, 281, 508 [M]$^{+\cdot}$. $C_{31}H_{32}FeO_3$ + H_2O (526.43): calcd. C 70.72, H 6.52; found C 71.33, H 6.78.

6 from 7: The compound **6** was also prepared according to the procedure described above for the synthesis of **2** or **5** (see also Scheme 4). 12 % yield of **6** was obtained.

8a: 0.5 mL of an aqueous solution containing the starting material $[^{99m}Tc(H_2O)_3(CO)_3]^+$ was prepared as described in the literature.[11] Compound **1** (0.6 mg, 1.9 μmol) in 0.5 mL of DMSO was added to the aqueous solution. Subsequent heating at 95 °C for 4 h afforded **8a** in an overall yield of > 80%.

8b: Compound **1** (0.0170 g, 0.053 mmol) in 0.5 mL of DMSO was added to $[NEt_4]_2[TcCl_3(CO)_3]$ (0.0225 g, 0.041 mmol) in a Schlenk tube equipped with a magnetic stirring bar. The mixture was heated for 1 h at 140 °C, yielding a brownish precipitate containing the product, as shown by HPLC analysis. The crude product was purified by column chromatography on a silica-gel plate (ethyl acetate/petroleum ether 1:7). Yield: 74 %. The product was dissolved in a diethyl ether/hexane 2:1 solution, slow evaporation of the solvents gave crystals suitable for an X-ray study. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 3.89 (s, 3 H, -OCH_3), 5.37 (t, J = 2.4 Hz, 2 H, 3,4-H of C_5H_4), 6.01 (t, J = 2.4 Hz, 2 H, 2,5-H of C_5H_4), 6.96 (d, J = 9.0 Hz, 2 H, Ar), 7.84 (d, J = 9.0 Hz, 2 H, Ar) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 55.5 (-OCH_3), 87.0 (2 C_{Cp}), 91.85 (2 C_{Cp}), 113.8 (2 C_{Ar}), 130.7 (2C_{Ar}), 163.2 (CO, ketone) ppm. ^{99}Tc NMR (740 Hz, $CDCl_3$): δ = −2478 ppm. IR (KBr): $\tilde{\nu}$ = 2040 s, 1957 vs, 1930 vs, 1631 w (ν_{CO}) cm^{-1}. MS (FAB): m/z = 382 $[M]^+$.

X-ray Crystal-Structure Determination of 8b: ($C_{16}H_{11}O_4Tc$), orange needle, 0.3 × 0.1 × 0.1 mm^3, Stoe IPDS diffractometer, λ = 0.71073 Å, φ oscillation scan, monoclinic, space group $P21/c$, a = 18.2751(5), b = 13.1242(8), c = 6.1913(17) Å, β = 90.380(11)°, V = 1484.9(4) Å^3, Z = 4, $D_{calcd.}$ = 1.634 g cm^{-3}, $R_1(I \geq 2\sigma(I)]$ = 0.0437, $wR_2(F^2, I \geq 2\sigma(I)]$ = 0. 0995 for 2595 data (total 14235 reflections collected, 4435 independent (R_{int} = 0.0984), 2595 observed (I, ≥ 2σ(I)]), θ range: 3.10 to 30.55°, completeness 97.4 %, 200 parameters, refinement with SHELXL-97[14] against F^2, calculated positions of hydrogen atoms, no absorption correction, μ = 0.981 mm^{-1}. CCDC-209247 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

9: 0.5 mL of an aqueous solution containing the starting material $[^{99m}Tc(H_2O)_3(CO)_3]^+$ was prepared as described in the literature.[11] Compound **7** (0.8 mg, 1.6 μmol) in 0.5 mL of DMSO was added to the aqueous solution. Subsequent heating at 95 °C for 3 h 30 min afforded **9** in an overall yield of > 90%.

Crystal Structure and Magnetic Properties of $Bi(Bi_9)[NbCl_6]_3$, a New Member of the Structure Family $Bi(Bi_9)[MX_6]_3$, and the Crystal Structure of $Bi_8[Ta_2O_2Br_7]_2$

Johannes Beck*[a] and Tobias Hilbert[a]

Keywords: Bismuth / Niobium / Tantalum / Magnetic properties / X-ray diffraction

Bi and Bi^{III} halides comproportionate to form subvalent cationic Bi clusters of various size and shape that can be stabilized in the solid state in the presence of suitable complex ions. Transition metal chlorides and bromides of group 4 elements lead to compounds of the $Bi(Bi_9)[MX_6]_3$ family, of which all members with M = Zr, Hf; X = Cl, Br are known. At 550 K Bi, $BiCl_3$ and $NbCl_5$, surprisingly, yield the isotypic $Bi^+(Bi_9^{5+})([NbCl_6]^{2-})_3$ containing Nb^{IV} formed by reduction of Nb^V. The crystal structure [hexagonal; $P6_3/m$; a = 1377.1(2), c = 1065.5(2) pm; Z = 2] contains Bi_9^{5+} clusters, octahedral $[NbCl_6]^{2-}$ and disordered Bi^+ ions. The low, temperature-dependent paramagnetic moment (76 K: 0.99 B.M.; 295 K: 1.22 B.M.) confirms the reduction of Nb to the +IV state. $Bi_8[Ta_2O_2Br_7]_2$, formed by a trace of H_2O in a reaction of Bi, $BiBr_3$ and $TaBr_5$ at 570 K, adopts a new structure type [tetragonal; $P4/mnc$; a = 1448.0(1), c = 1830.6(2) pm; Z = 4] and consists of square-antiprismatic Bi_8^{2+} clusters and one-dimensional polymeric bromooxotantalate(V) anions.

Introduction

Bismuth was one of the first elements for which subvalent species with oxidation states between 0 and +III were studied systematically. The series of discrete, homonuclear cations Bi^+, Bi_2^{4+}, Bi_3^+, Bi_5^+, Bi_5^{3+}, Bi_6^{2+}, Bi_8^{2+}, and Bi_9^{5+} has made bismuth the classical example of naked clusters among the main group elements. Because of these exceptional properties bismuth has been called "The Wonder Metal".[1] The tricapped trigonal-prismatic Bi_9^{5+} is the largest known molecular cluster of bismuth. It was first characterized in the binary subchloride Bi_6Cl_7 together with polymeric chlorobismuthate(III) anions of composition $[Bi_3Cl_{14}]^{5-}$,[2,3] and later also in the ternary phase $Bi(Bi_9)[HfCl_6]_3$.[4] With tetrachloroaluminate counterions bismuth tends to form smaller clusters such as the square-antiprismatic Bi_8^{2+} in $Bi_8[AlCl_4]_2$ [3,5,6] and the trigonal-bipyramidal Bi_5^{3+} in $Bi_5[AlCl_4]_3$.[5,7] Subsequent studies focused on replacing $[AlCl_4]^-$ with other anions and led to the preparation of several compounds like Bi_6Br_7,[8] $Bi(Bi_9)[ZrBr_6]_3$,[9] $Bi(Bi_9)[ZrCl_6]_3$ [10] and $Bi_5[GaCl_4]_3$.[11] New clusters, Bi_2^{4+} in $Bi_2[M_4X_8]$ (M = Al, Ga; X = S, Se)[12] and Bi_5^+/Bi_6^{2+} in $Bi_{34}Ir_3Br_{37}$ [13] were found in the thus far unexplored ternary systems.

Numerous articles deal with theoretical approaches to explain the bonding situation in these predominantly deltahedral clusters. The structures of Bi_5^{3+} and Bi_8^{2+} can be understood as *closo* and *arachno* clusters that fulfill Wade's rules.[14] The nine-atomic Bi_9^{5+} shows substantial deviation from the predicted structure of a monocapped square antiprism, which is adopted by the isoelectronic Zintl ion Sn_9^{4-}.[15] The actual three-capped trigonal-prismatic structure is related to a *closo* structure. Elongation along the threefold axis is the result of the antibonding character of the HOMO. The molecular geometries and electron configuration of different main group element clusters have been compared in several reviews.[16,17] The high degree of electron delocalization in the polyhedral clusters was recently termed "three-dimensional" or "spherical" aromaticity.[18,19]

We intended to expand the structure family $Bi(Bi_9)[MX_6]_3$ and to obtain new structure types by a varied cation/anion ratio using anions with a lower charge. We chose $NbCl_5$ as Lewis acid, since hexachloroniobates(V) are suitable for stabilizing naked clusters such as chalcogen polycations.[20,21] Thus, a compound composed of polycationic Bi clusters and $[NbCl_6]^-$ ions was expected. Instead, $Bi^+(Bi_9^{5+})([NbCl_6]^{2-})_3$ was obtained under reduction to Nb^{IV}. A special feature of this structure type of the general formula $Bi(Bi_9)[MX_6]_3$ is the occurrence of Bi^+ ions as a one-dimensional chain in a wide channel made up of $[MX_6]^{2-}$ anions. Alternative split-position models for these one-dimensionally disordered Bi^+ ions will be discussed. Finally, a new structure type is presented: $Bi_8[Ta_2O_2Br_7]_2$, which contains the known square-antiprismatic Bi_8^{2+} ions and a new bromooxotantalate(V) ion.

Results and Discussion

Syntheses of $Bi(Bi_9)[NbCl_6]_3$ and $Bi_8[Ta_2O_2Br_7]_2$

A common method for synthesizing polycationic bismuth clusters is the crystallization as tetrachloroaluminates from NaCl/$AlCl_3$ melts. This involves the difficulty of separating the crystals from the solidified melt. Compounds containing polyatomic bismuth clusters are also available by chemical vapor deposition. We avoided a melt by applying relatively low reaction temperatures compared with those described in the literature.[9] The two compounds presented here can be seen as arising from comproportionation of elemental bismuth and the corresponding trihalide, since Bi_6Cl_7 or Bi_6Br_7 can be isolated as a subvalent intermediate, followed by a Lewis acid/base reaction of these intermediates with the respective metal halide.

$$9\ Bi + BiCl_3 + 3\ NbCl_5 \rightarrow Bi(Bi_9)[NbCl_6]_3$$

Even under optimized conditions the yields did not exceed 30%. Apparently, a multicomponent equilibrium involving Bi, $BiCl_3$, bismuth subhalides, transition metal halide and gas phase species is present, which prevents higher conversion rates. Removing the $Bi(Bi_9)[NbCl_6]_3$ crystals from the reaction mixture led to a second yield of about the same amount. Large pure samples are hard to obtain by this method. The bismuth subchloride Bi_6Cl_7 is formed as black crystals under the same conditions and must be separated mechanically. This is complicated by the various crystal forms of Bi_6Cl_7 which makes visual distinction from crystals of $Bi(Bi_9)[NbCl_6]_3$ difficult.

$Bi_8[Ta_2O_2Br_7]_2$ was obtained only in small yield by partial hydrolysis of $TaBr_5$. An overall reaction equation can be written, although the attempts to repeat the reaction with stoichiometric amounts of oxygen, introduced into the reaction system either via Ta_2O_5 or by short exposure of the reaction mixture to air were unsuccessful.

$$22\ Bi + 2\ BiBr_3 + 12\ TaBr_5 + 12\ H_2O \rightarrow 3\ Bi_8[Ta_2O_2Br_7]_2 + 24\ HBr$$

Crystal Structure of $Bi(Bi_9)[NbCl_6]_3$

$Bi(Bi_9)[NbCl_6]_3$ crystallizes isotypically to $Bi(Bi_9)[HfCl_6]_3$,[4] $Bi(Bi_9)[ZrBr_6]_3$,[9] and $Bi(Bi_9)[ZrCl_6]_3$.[10] All compounds that adopt this structure type are built of a close packing of two sorts of discrete molecular ions: triply μ_4-capped trigonal-prismatic Bi_9^{5+} cations and octahedral $[MX_6]^{2-}$ anions (Figure 1). The projection along the crystallographic *c*-axis (Figure 2) shows that each Bi_9 cluster is surrounded by six MX_6 octahedra in a coplanar arrangement. As in hexagonal closest sphere packing, six further anions are in a trigonal arrangement placed below and above. The hexahalometalate anions form wide channels that are centered around the cell edges and run perpendicular to the hexagonal plane. The channels are ca. 630 pm in diameter and are filled with columns of disordered Bi^+ ions (vide infra).

Figure 1. Figure 2. Unit cell of $Bi(Bi_9)[NbCl_6]_3$ in a perspective projection along the *c*-axis; the drawing combines shaded polyhedra and ball-and-stick models

The tri-capped trigonal-prismatic Bi_9^{5+} has crystallographic C_{3h} symmetry and is defined by two independent Bi atoms. Bi−Bi bonds, with the exception of the non-bonding prism edges (373.8 pm), have an average length of 314.7 pm. This agrees well with the literature values.[4] The difference between Bi−Bi bond lengths from a capping Bi(2) atom to the four corresponding Bi(1) atoms in the prism vertices is only 0.8%. This small irregular capping indicates only small distortions from the approximately fulfilled D_{3h} symmetry of the cluster ion.

Cl−Nb−Cl angles of the $[NbCl_6]^{2-}$ ion deviate by less than 3° from rectangularity; the Nb−Cl bonds, however, show considerable alternation in their lengths, between

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

234.8 and 248.7 pm. Both Cl(3) atoms of the $[NbCl_6]^{2-}$ ion, which have the longest Nb−Cl bonds, take a bridging position over edges of the cluster cation, with the shortest Bi−Cl distances of 333.5 pm. Distortions of the hexachloro metalate anions in this structure type from the ideal octahedral shape reflect the electrophilic properties of the Bi_9^{5+} clusters.

Disorder of the Bi^+ Ions in the Structure Type $Bi(Bi_9)[MX_6]_3$

Several crystal structures with a one-dimensional disorder of atoms or ions located in channels are known. $Bi_{5,6}Ni_5I$[22] contains double-walled channels of nickel and bismuth atoms. Their central axis is filled with a coaxial string of disordered Bi atoms that, statistically, occupy only every fifth possible site. Other examples include the compounds Th_7S_{12},[23] $K_2Sn_5Cl_{12}$ [24] and several apatite[25] and hollandite type structures.[26] With $Bi(Bi_9)[NbCl_6]_3$ the electron density along the *c*-axis is sufficient for only two additional Bi^+ ions per unit cell. X-ray experiments gave no direct evidence for disorder in the form of diffuse scattering. Precession photographs and imaging plate exposures did not show any continuous streaks in the reciprocal lattice along *c**.

The split-position model involves 14 closely neighbored atomic positions along one translation period on the sixfold axis in (0,0,*z*). Of the four independent split sites position C has the highest occupation factor (Figure 3). This marked preference might be due to the almost octahedral coordination with Cl atoms of the surrounding hexahalometalate(IV) ions (d_{Bi-Cl}: 3 × 320 pm, 3 × 337 pm). To measure the interaction between the various Bi(3) sites and the neighboring anions we calculated the electrostatic potential for a hypothetical atom in (0,0,*z*) using the program MAPLE (Madelung Part of Lattice Energy).[27] The results show only a very flat modulation of the potential in the center of the channel, while even small shifts of the dummy atom towards one of the $[NbCl_6]^{2-}$ octahedra increased its potential significantly (Figure 4). The tendency to localization on one particular split position is expected to be small. The closest distance between sixfold axes is 1377 pm, and no correlation can be expected for the parallel running chains.

The origin of the elongated displacement ellipsoids in the refinements with anisotropic displacement parameters was examined by low-temperature X-ray diffraction. One set of independent reflections was collected at 223 and 173 K. The temperature dependence of the mean-square displacement parameters of the disordered Bi(3) and of Bi(1), a fully occupied atom site making up the Bi_9 cluster, is represented in Figure 5. For a thermally vibrating atom one expects a linear decrease of the mean square displacements, to approximately zero when extrapolated to 0 K. Bi(1) shows such regular behavior, while Bi(3) behaves differently. While the unusual long axis of the displacement ellipsoid diminishes on decreasing temperature, the two symmetry-equivalent short axes perpendicular to the crystallographic *c*-axis, however, turned out to be temperature-independent. For both low-temperature data sets, difference Fourier maps

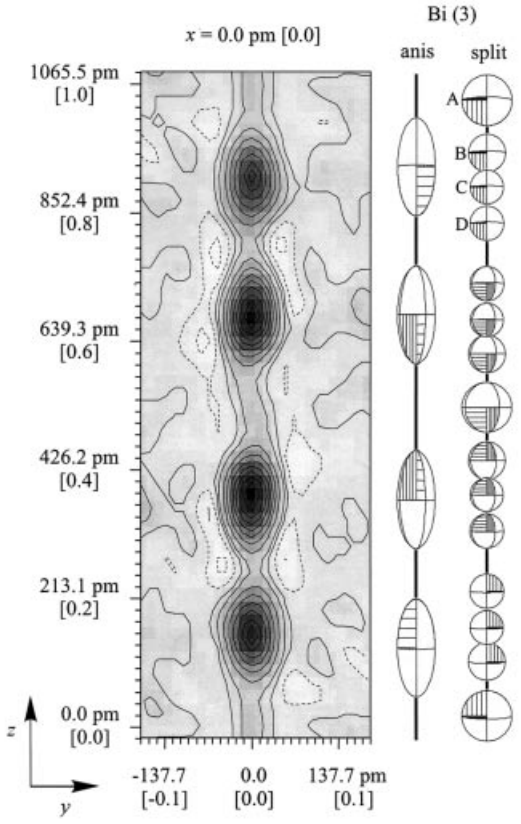

Figure 3. Difference Fourier electron density plot along the unit cell edge [001] in the structure of $Bi(Bi_9)[NbCl_6]_3$ − based on a structure model that was complete apart from the disordered Bi atoms in (0,0,*z*) and representations of the split positions and the disorder model for the Bi(3) site; displacement ellipsoids and spheres are scaled to enclose a 50% probability density

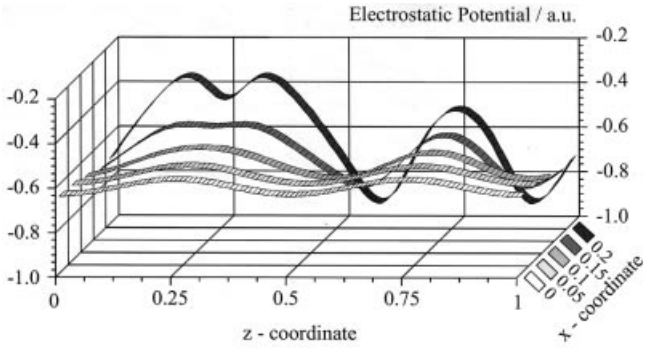

Figure 4. Electrostatic potential (arbitrary units) for a hypothetical atom on a site (0,0,*z*) under the influence of the anionic environment of $[NbCl_6]^{2-}$ ions in $Bi(Bi_9)[NbCl_6]_3$; since the dummy atom was assumed to be uncharged negative potentials indicate favorable positions for positively charged ions

show a contraction of the electron density maxima for the Bi(3) positions, but a diffuse density along the *c*-axis remains. Thus, elongation of the Bi(3) ellipsoids can not be attributed solely to a dynamical vibration phenomenon.

While previous structure determinations of compounds of this family[4,9] left it unclear whether the distribution of

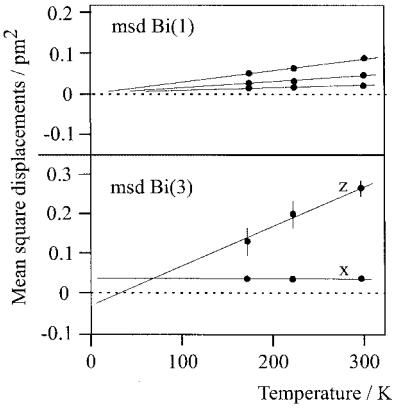

Figure 5. Temperature dependence of the mean square displacements of the atoms Bi(1) and Bi(3) in $Bi(Bi_9)[NbCl_6]_3$; errors of $\pm 3\sigma$ are indicated by vertical lines when bigger than the diameter of the dots

the disordered Bi ions should be interpreted as isolated Bi^+ ions or if two ions are associated in Bi_2^{2+} pairs with a bond length of ca. 300 pm, cationic Bi_2 dumbbells have been discovered in the phases $Bi_2M_4X_8$ (M = Al, Ga; X = S, Se).[12] The average Bi−Bi distances in the Bi_2^{4+} ions is 314 pm. Shorter Bi−Bi bonds are found in dibismuthanes with arene ligands, e.g. in Bi_2Ph_4 (d_{Bi-Bi} = 299 pm)[28] or in dibismuthenes ($d_{Bi=Bi}$ = 282 pm).[29] The presence of Bi_2^{2+} dumbbells may explain the distances (296 pm) between neighboring split atom positions in the ordered structure model of $Bi(Bi_9)[NbCl_6]_3$. The centers of gravity of these diatomic molecules are at (0,0,0) and (0,0,1/2). However, the intermolecular distance is only 237 pm, and only every second position can be statistically occupied by Bi_2^{2+}.

For $Bi_2[M_4X_8]$ (M = Al, Ga; X = S, Se) the Raman stretching vibration of the Bi_2^{4+} dumbbells is at 108 cm^{-1}.[12] Examination of $Bi(Bi_9)[ZrCl_6]_3$ and $Bi(Bi_9)[ZrBr_6]_3$ as easily obtainable model compounds for the structure type $Bi(Bi_9)[MX_6]_3$, and of Bi_6Cl_7, by IR and Raman spectroscopy show only a few lines in the region below 500 cm^{-1} {$Bi(Bi_9)[ZrCl_6]_3$: IR: $\tilde{\nu}$ = 289, 232, 162, 142, 112; Raman: $\tilde{\nu}$ = 224, 197, 158, 108, 93; $Bi(Bi_9)[ZrBr_6]_3$: IR: $\tilde{\nu}$ = 223, 189, 142, 108; Raman: $\tilde{\nu}$ = 170, 140, 106; Bi_6Cl_7: IR: $\tilde{\nu}$ = 422, 367, 212, 144, 107 cm^{-1}}. Comparison of $Bi(Bi_9)[ZrCl_6]_3$ and $Bi(Bi_9)[ZrBr_6]_3$ reveals a large drift for some of the IR absorption bands and some Raman lines. This indicates that the bands at 289, 232, 197, 162/158 cm^{-1} for $Bi(Bi_9)[ZrCl_6]_3$, and the bands at 223, 189, 170 cm^{-1} $Bi(Bi_9)[ZrBr_6]_3$ are attributable to vibration modes of the $[ZrX_6]^{2-}$ octahedra. The lines around 140 and 108 cm^{-1} appear for both compounds in the IR and Raman spectra but are also observed for Bi_6Cl_7. Since all three compounds contain Bi_9^{5+} clusters, these lines can, probably, be attributed to vibrations of the cluster ions. Distinct vibration bands attributable to Bi_2^{2+} groups are not present.

Neither of the two models, discrete Bi^+ ions or dinuclear Bi_2^{2+} ions, can be assigned on the basis of the present diffraction experiments and vibrational spectra.

Thermomagnetic Properties of $Bi(Bi_9)[NbCl_6]_3$

Analysis of the magnetic measurement unequivocally confirms the expected oxidation state of Nb^{IV}. The substance shows paramagnetic behavior, which is in contrast to the diamagnetic properties of $Bi(Bi_9)[HfCl_6]_3$ [4] and directly reflects the electronic state of the niobium atom. The effective magnetic moment at room temperature is well below the 1.72 B.M. for a spin-isolated single electron. Further, the simple Curie−Weiss law cannot be applied because the determined magnetic moment displays a distinct temperature dependency: its values increase from 0.99 at 76 K to 1.22 B.M. at 295 K per magnetic ion Nb^{IV} (Figure 6). Comparable behavior has been reported for other d^1-systems, e.g. in the compounds $M_2[NbCl_6]$ (M = Rb, Cs)[30] and $[N(C_2H_5)_4]_2[NbCl_6]$.[31]

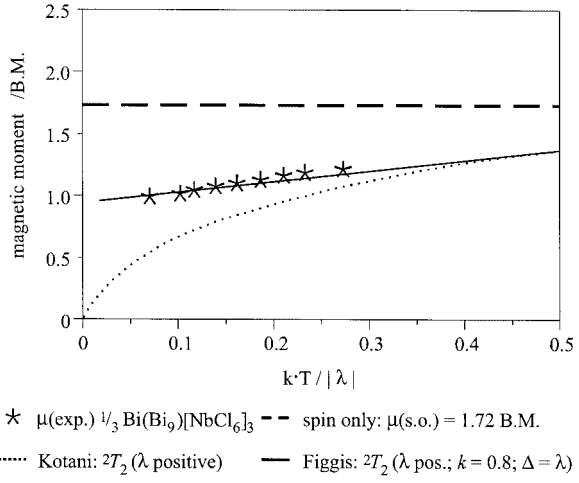

Figure 6. Temperature dependence of the effective magnetic moment of $Bi(Bi_9)[NbCl_6]_3$ scaled to a single magnetic Nb^{IV} ion; experimental data are set in relation to different theoretical approaches

The magnetic properties can be interpreted in terms of the models introduced by Kotani[32] and Figgis.[33] The effective magnetic moment arising from the $^2T_{2g}$ ground state of a transition metal complex ion in a centric symmetry ligand field depends upon several ligand field parameters: the spin-orbit coupling constant λ ($\lambda_{Nb^{IV}}$ = 750 cm^{-1} [34]), the orbital separation Δ between levels of the $^2T_{2g}$ term created by an axial ligand field, and the so-called orbital reduction factor k, which takes into consideration the delocalization of t_{2g} electrons into the orbitals of the ligand atoms.[35] The simplified Kotani model only takes into account the spin-orbit coupling, disregarding any distortion of the octahedral ions (k = 1 and Δ = 0 cm^{-1}). For the temperature dependence of the magnetic moments of $Bi(Bi_9)[NbCl_6]_3$ the best fit is reached in a model with Δ = 750 cm^{-1} and k = 0.8, reflecting the marked distortion of the $[NbCl_6]^{2-}$ polyhedra (Figure 6).

Crystal Structure of $Bi_8[Ta_2O_2Br_7]_2$

The structure contains square-antiprismatic Bi_8^{2+} clusters formerly known exclusively in $Bi_8[AlCl_4]_2$.[3] The coun-

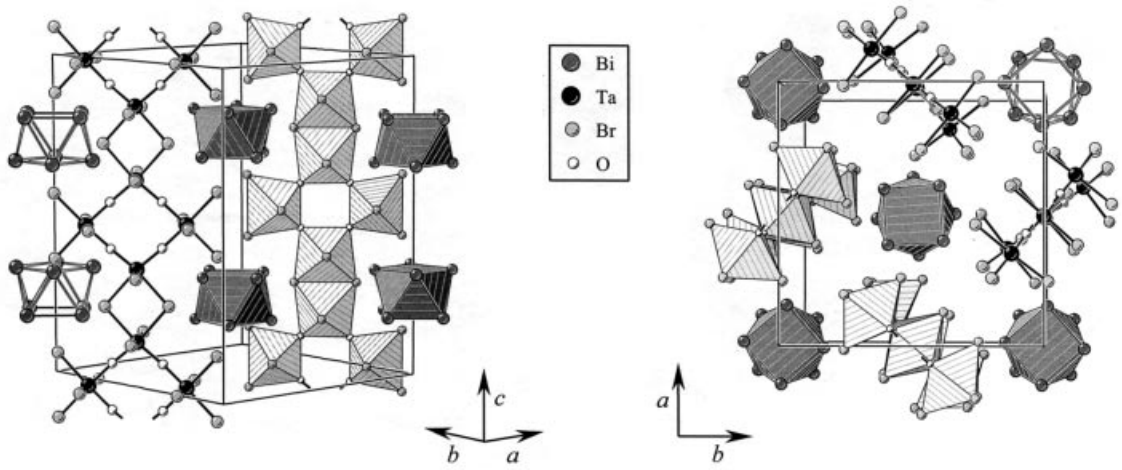

Figure 7. Unit cell of $Bi_8[Ta_2O_2Br_7]_2$ in two different views, along [110] and [001]; the drawing combines shaded polyhedra and ball-and-stick representations

terion is a novel, one-dimensional polymeric bromooxotantalate(v). Stacks of bismuth clusters and anionic chains are arranged in a tetragonal rod-packing along the crystallographic *c*-axis. Figure 7 shows two different views of the unit cell, along and perpendicular to the chains.

The Bi_8^{2+} cation has C_4 symmetry and is defined by two independent bismuth sites (Figure 8). The square faces are coplanar. Their twisting angle of 45.5° and the small difference in bond lengths [Bi(1) face: 312.6 pm; Bi(2) face: 311.7 pm] indicate only small distortions from the higher symmetrical point group D_{4d} (Table 1). Due to the lower charge per atom (*cpa*) the average Bi−Bi bond of 310.7 pm for Bi_8^{2+} (*cpa* = +0.25) is significantly shorter than the 314.7 pm observed for Bi_9^{5+} (*cpa* = +0.55). The cluster has to be considered as "naked" since the shortest anion−cation contacts are beyond 365 pm, and there are no intermolecular Bi−Bi distances shorter than 617 pm. The structure of the Bi_8^{2+} cluster ion in $Bi_8[Ta_2O_2Br_7]_2$ is very closely related to the cluster ion in $Bi_8[AlCl_4]_2$ [3,5,6] where Bi_8^{2+} has C_s symmetry and is generated by five crystallographically independent Bi atoms. There is a significant difference in the interionic intercations. In contrast to $Bi_8[Ta_2O_2Br_7]_2$ the shortest contacts between Bi atoms of neighboring Bi_8^{2+} ions in $Bi_8[AlCl_4]_2$ are only 390 and 410 pm, which indicate weak interactions between the clusters.

After $Te_4[Ta_2OBr_{10}]$[18] and $(NH_4)_2[Ta_3O_5Br_7]$,[36] $[Ta_2O_2Br_7]^-$ is only the third crystallographically characterized bromooxotantalate(v) reported. In contrast to $[Ta_2OBr_{10}]^{2-}$ ($Te_4[Nb_2OCl_{10}]$[37]) and $[Ta_3O_5Br_7]^{2-}$ {$(NH_4)_2[Nb_3O_5Cl_7]$[38]} no isostructural Nb/Cl analogue is known for $[Ta_2O_2Br_7]^-$. This anion consists of two symmetrically independent TaO_2Br_4 octahedra. Four vertex-sharing octahedra are connected by common oxygen atoms. The resulting tetrameric cyclic subunits are linked by common edges via four μ_2-Br atoms and form a one-dimensional polymeric anionic string (Figure 8). With Ta−O distances of 187 and 190 pm and Ta−O−Ta angles of 175.1° the oxygen bridges are nearly linear and symmetric. These

Figure 8. bridging character of Br(2) and the terminal character of all other Br atoms. In the dinuclear ion $[Ta_2OBr_{10}]^{2-}$ the static *trans* effect elongates the Ta−Br bonds *trans* to the allenic linear Ta=O=Ta group by 12 pm. This elongation, which is expected especially for the Br(4) atoms, is not present in $[Ta_2O_2Br_7]^-$.

Experimental Section

General: All compounds were handled in an argon-filled glove box. Reactions were carried out in evacuated and sealed glass ampoules (1.4 cm in diameter and 10−15 cm long), which were placed in horizontal tube furnaces. The ampoules were dried at 600 K before use. $BiCl_3$, $BiBr_3$, $NbCl_5$, and $TaBr_5$ were prepared from the elements as described[40] and sublimated under vacuum prior to use. Bismuth powder (Riedel−de Haën) was used without further treatment.

$Bi(Bi_9)[NbCl_6]_3$: A glass ampoule was filled under anhydrous conditions with Bi, $BiCl_3$ and $NbCl_5$ in the molar ratio 8:2:3 (310 mg in total). The ampoule was then evacuated, sealed and placed asymmetrically in a tube furnace that was heated to 550 K. The hot end of the ampoule contained the starting mixture; the empty end was at 535 K. Within several days black crystals formed on top of the mixed reagents and on the glass walls of the hot side of the ampoule. Even after several weeks, no conversion of more than about 30% was observed. When the product was mechanically removed and the remaining reaction mixture mortared, and again subjected to the same reaction conditions, a second crop of crystals of comparable yield was obtained. Larger crystals, suitable for X-ray investigations, formed at the glass walls of the warmer parts of the ampoule.

$Bi_8[Ta_2O_2Br_7]_2$: Traces of H_2O in the ampoule were responsible for the formation of $Bi_8[Ta_2O_2Br_7]_2$ in a reaction of Bi, $BiBr_3$ and $TaBr_5$ (molar ratio 8:2:3, 262 mg in total). A few black crystals of $Bi_8[Ta_2O_2Br_7]_2$ with the typical form of needles with a square cross section were obtained within 4 d in a temperature gradient from 570 to 550 K.

Bi_6Cl_7, $Bi(Bi_9)[ZrCl_6]_3$, and $Bi(Bi_9)[ZrBr_6]_3$: Used as reference samples for vibrational spectroscopy, were prepared from Bi and $BiCl_3$, $ZrCl_4$, and $ZrBr_4$, respectively, according to literature procedures.[3,9,10]

Crystal Structure Analyses: Since all compounds are moisture-sensitive the selected crystals were sealed under argon in glass capillaries. Crystallographic data and further details of the data collection and refinement (Table 2) and the positional parameters of the atoms (Table 1) are given here. Data collections were performed with a STOE IPDS image plate diffractometer equipped with a graphite monochromator and Mo-K_α radiation at room temperature and at low temperature using a cold nitrogen stream. All reflection intensities were corrected for Lorentz and polarization effects, and a numerical absorption correction was applied to each data set. The crystal shapes were optimized with the aid of the program HABITUS.[41] The program DIAMOND[26] was used for the graphical representations of the structures. Further details of the crystal structure analyses have been deposited at the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, and are available by quoting the authors, the literature citation and the deposit number CSD-410927 for $Bi(Bi_9)[NbCl_6]_3$, and CSD-410929 for $Bi_8[Ta_2O_2Br_7]_2$.

$Bi(Bi_9)[NbCl_6]_3$: In analogy to the isotypic compounds,[4,9] precession photographs showed the expected hexagonal crystal system with Laue class 6/*m*. The serial reflection condition 00*l*, only present for $l = 2n$, led to the space groups $P6_3/m$ or $P6_3$, of which the centrosymmetric space group was confirmed by structure analyses. A preliminary structure model, containing the atoms of the Bi_9 clusters and the $NbCl_6$ ions, was obtained by Patterson methods[42] and refined against F^2 by full-matrix least-squares calculations with anisotropic displacement parameters for all atoms.[43] A further difference Fourier calculation showed a high remaining electron density distributed along the edge of the unit cell at (0,0,*z*) with a diffuse maximum at $z/c \approx 0.1$ (Figure 3), which could be interpreted as two additional Bi^+ ions in each unit cell. Problems arise as the symmetry of the site 4*e* (0,0,*z*) generates four equivalent Bi atoms instead of two, and adjacent atoms come too close, with Bi−Bi distances just above 200 pm. Previously, a structure model implying disorder with four half-occupied Bi sites was used for $Bi(Bi_9)[HfCl_6]_3$ [4] and $Bi(Bi_9)[ZrBr_6]_3$.[9] As reported for these two crystal structures, refinement with anisotropic displacement parameters resulted in strongly elongated, "zeppelin-shaped" thermal ellipsoids for the Bi^+ ions. Further difference peaks between the positions of the disordered bismuth ions, especially on (0,0,0), allow refinement to a slightly modified structure model: four closely neighbored split positions in the interval (0,0,0) to (0,0,$^1/_4$) form a linear arrangement of partially occupied atom positions. Because of their proximity only isotropic displacement parameters could be refined for the split atoms. The site occupation factors have been refined without restraints and add up to 2.08(4) Bi atoms per unit

cell. Although this alternative structure model slightly reduced the residual electron density, it had no significant effect on the overall quality of the refinement. The positions of the other atoms remained unchanged within their standard deviations.

$Bi_8[Ta_2O_2Br_7]_2$: Precession photographs showed the tetragonal crystal system with Laue class 4/*mmm*. Reflection conditions led to the space groups *P*4/*mnc* or *P*4*nc*, of which the centrosymmetric one was confirmed through structure analysis. The structure was solved by direct methods[42] and refined against F^2 by full-matrix least-squares calculations with anisotropic displacement parameters for all atoms.[43] A relatively large residual electron density was located at the origin of the unit cell. However, all attempts to include an atom at this position in the calculations did not enhance the quality of the structure refinement.

Magnetic Measurements: The thermomagnetic properties of $Bi(Bi_9)[NbCl_6]_3$ were determined on a sample (176 mg) of selected single crystals over the temperature range 76−295 K using a Faraday susceptometer. Measurements at several field forces showed no significant dependence. A diamagnetic correction was applied on the data. The purity of the sample was checked by powder X-ray diffractometry. Only a small impurity of Bi_6Cl_7 (ca. 5%) could be detected in the diffractogram.

Vibrational Spectroscopy: Infrared and Raman spectra were recorded using a Bruker IFS113V and a Bruker RFS100 spectrometer, respectively. For infrared spectroscopy, samples were prepared in a glove box as KBr discs. For Raman measurements, samples were finely ground with KBr in a mass ratio of 1:1 and placed in glass capillaries (1 mm diameter). We could not record a Raman spectrum of Bi_6Cl_7 as, even on cooling the sample capillary to 123 K, the compound decomposed in the laser beam.

Acknowledgments

Support of this work by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

Anchoring of Copper(II) Acetylacetonate onto an Activated Carbon Functionalised with a Triamine

Ana Rosa Silva,[a] Magda Martins,[a] M. Madalena A. Freitas,[b,c] José Luís Figueiredo,[b] Cristina Freire,*[a] and Baltazar de Castro[a]

Keywords: Copper / Schiff bases / Activated carbon / Anchoring / EPR spectroscopy

Copper(II) acetylacetonate was anchored onto a triamine functionalised activated carbon by Schiff condensation using a four-step procedure: (i) oxidation of activated carbon with nitric acid; (ii) treatment with thionyl chloride to convert carbon surface carboxylic acids into acyl chlorides; (iii) condensation of acyl chloride functionalities with amine groups of bis(3-aminopropyl)amine (*trien*); and (iv) Schiff condensation between free amine groups of bound *trien* with the oxygen atoms of acetylacetonate coordinated to the copper(II) ion. The same complex was also anchored to the unmodified activated carbon and to the acyl chloride functionalised carbon prepared in (ii). The resulting carbon-based materials were characterised by elemental analysis, surface techniques (SEM and XPS), temperature programmed desorption, and nitrogen adsorption at 77 K and EPR spectroscopy for the materials with copper(II) complexes. Data from all techniques provided evidence for (i) the covalent binding of *trien* to acyl chloride functionalities; and (ii) the irreversible attachment of $[Cu(acac)_2]$ to all carbon-based materials. Data for the materials with copper(II) proved conclusively that only the immobilisation procedure based on Schiff condensation with *trien* led to copper(II) complexes in which the metal centre remains four-coordinate.

Introduction

Aziridines are very important intermediates in organic synthesis and copper(II) acetylacetonate has been described as a very efficient homogeneous catalyst for the aziridination of olefins.[1] Copper(II) Schiff-base complexes have also been used as homogeneous catalysts in the aziridination of olefins,[2] as well as in the cyclopropanation of olefins,[3] oxidation of sulfides to sulfoxides[4] and in the peroxidative oxidation of phenol to dihydroxy benzynes.[5] Currently, transition metal complexes with Schiff-base ligands (*salen*) are the subject of intense research as they present high activity, chemoselectivity and enantioselectivity in a large range of catalytic processes.[6]

The last decade has witnessed a growing interest in the heterogenisation of homogeneous metal complexes using several types of supports,[6−10] with the aim to overcome some limitations of homogeneous catalysts − separation from the reaction media and subsequent recycling. Initially the complexes were ion exchanged or adsorbed on the porous supports and, consequently, could be susceptible to leaching.[10−12] More recently, several grafting and tethering procedures have been developed to covalently attach transition metal complexes to organic polymers,[8] silica, zeolites and other micro and mesoporous inorganic materials.[7,9,10]

Activated carbons and other carbon materials are widely used as catalysts and as supports for metals in its reduced state,[13,14] and few reports have appeared in the last years on the heterogenisation of homogeneous metal complexes, mainly of noble metals with simple ligands, to be used in hydrogenation and hydroformylation reactions.[15−17] Nevertheless, activated carbons present several advantages when compared to inorganic supports;[13] they are thermally stable, resistant to chemical attack in acid and basic media and, generally, of low cost.[13] On the other hand, several thermal and chemical processes can be used to tailor the porous structure and the type and concentration of specific oxygen surface groups.[13,18] These groups can be used as building blocks to bridge the metal complex to the support, and their variety allows for the use of various immobilisation procedures. Iron−phthalocyanine complexes supported by impregnation on carbon[19] and activated carbon blacks[20] have been used as heterogeneous catalysts in the oxidation of alkanes, but no reference to leaching or

reuse was made, despite the method used being susceptible to leaching of the active phase. Anchorage of copper(II) and cobalt(II) acetylacetonates to surface groups of an activated carbon using a diamine as linking agent has also been reported, and resulting materials have not only proved to be efficient heterogeneous catalysts in the oxidation of pinane, but were also resistant to leaching of the complexes.[21]

We are pursuing the development of several strategies for the immobilisation of functionalised Schiff-base transition metal complexes onto activated carbons in order to gather information on whether the modifications of their surface groups can lead to a more efficient anchoring without loss of catalytic activity of the complex, with the overall aim of optimising procedures to prepare carbon-based heterogeneous catalysts. Recently, we have reported the anchoring of nickel(II) Schiff-base complexes onto activated carbon using two different routes;[22,23] in the first a linking agent, cyanuric chloride, was used to react with hydroxyl groups on both the activated surface and the metal complex;[22] and in the second, two metal complexes bearing uncoordinated amine groups were anchored onto an activated carbon functionalised with an acyl chloride that acted as the anchoring building block functionality.[23] The direct anchoring of a copper(II) Schiff-base complex functionalised with uncoordinated hydroxyl groups was achieved[24] and the process was applied to the heterogenisation of their manganese(III) counterparts, which were shown to act as efficient and reusable heterogeneous catalysts in the epoxidation of styrene,[25,26] with similar styrene epoxide chemoselectivities as the corresponding homogeneous phase reactions.[25,26,27]

Copper(II) complexes with pentadentate N_3O_2 Schiff bases have also been encapsulated in zeolites[28,29] and in aluminium pillared layered clays using the ship in a bottle procedure,[30,31] by reaction of copper(II) acetylacetonate with bis(3-aminopropyl)amine (*trien*), and using the simultaneous pillaring and copper(II) complex encapsulation in a montmorilonite.[32] In the present work, we report an extension of these procedures in which copper(II) acetylacetonate is irreversibly anchored onto a chemically oxidised activated carbon functionalised with *trien* by Schiff condensation between the free amine groups of *trien* covalently attached to the activated carbon surface (see Scheme 1) with the oxygen atoms of acetylacetonate coordinate to copper(II) (see Scheme 2). To assess the effectiveness of this method we have compared its anchoring efficiency with those obtained by direct adsorption onto unmodified oxidised activated carbon and onto a carbon functionalised with acyl chloride groups. In order to get information on the effect of the various treatments on the surface chemical and physical properties of the carbon materials, these were characterised by proximate and elemental analysis, surface techniques (scanning electron microscopy and X-ray photoelectron spectroscopy), nitrogen adsorption at 77 K, and thermal methods (temperature-programmed desorption). Copper(II) carbon-based materials were also characterised by electron paramagnetic resonance, which can provide information on the changes in the coordination sphere of the metal centre.

Results and Discussion

Immobilisation of copper(II) acetylacetonate onto the activated carbon was performed in four steps: (i) oxidation of the activated carbon with nitric acid, (ii) reaction with $SOCl_2$, (iii) functionalisation with *trien*, bis(3-aminopropyl)-amine, and then (iv) anchoring of the complex onto the modified carbon. The materials obtained after the first two steps of the anchoring procedure (carbon A2 and A3) have been extensively characterised by us in a previous report,[23] and thus the characterisation and discussion will be focused on the new materials obtained from the two last steps.

Functionalisation of Thionyl-Chloride-Modified Activated Carbon with Bis(3-aminopropyl)amine (*trien*)

Composition and Texture

The proximate and elemental analyses of carbon materials are collected in Table 1. The volatile matter and the nitrogen and hydrogen content increase when carbon A3 is modified with *trien* (Table 1), suggesting that *trien* reacted with the activated carbon surface groups and therefore was covalently attached to the activated carbon surface. This is also supported by a decrease, relative to carbon A3, of 16% in the micropore volume and of 19% in the larger pore area (Table 2), arising from the presence of a relatively voluminous compound at the surface of the activated carbon.

Table 1. Proximate and elemental analyses for carbon-based materials.

Carbon atom	Proximate analysis (wt.-%) volatiles	C_{fixed}	ash	Elemental analysis (wt.-%) C	H	N

X-ray Photoelectron Spectroscopy

There is a significant increase in the nitrogen content following the introduction of *trien* in carbon A3, which is accompanied by a decrease in the chlorine content as can be seen in Table 3. This indicates that reaction between the amine groups of the triamine and the acyl chloride functionalities has occurred, with formation of new amide groups and loss of hydrogen chloride (Scheme 1, a). A superficial loss of oxygen is also observed which may be explained by Schiff condensation between the amine groups and the surface carbonyl groups (Scheme 1, b, see TPD section, below), that increases the effectiveness of the *trien* anchoring process.

Table 3. Area under the XPS bands in the O 1s, N 1s, Cl 2p, C 1s, and Cu $2p_{3/2}$ regions of the carbon-based materials

Carbon atom	Atomic % O	N	Cl	C	Cu	O/C	N/C	Cl/C	N/Cu
A1	7.66	0.58	0.86	90.41	–	0.0847	0.0064	0.0095	–

A5	14.01	4.48	2.20	78.16	0.66	0.1792	0.0573	0.0281	6.8

The Cl 2p spectrum of carbon A4 exhibits bands at the same binding energy as those found in the parent material (Figure 1, a), thus providing evidence that not all surface acyl chloride functionalities have reacted with the amine groups of *trien*. A new band is also observed at about 199 eV, which corresponds to chloride ions produced in the reaction of acyl chloride with amine groups (Scheme 1, a).

The spectra of carbons A3 and A4 in the O 1s region are similar (Figure 1, b), but that of carbon A4 shows a very slight band broadening, which may suggest an increase in the amount of oxygen atoms in different chemical environments resulting from the new amide ligation (Scheme 1, a).

The XPS spectrum of carbon A4 in the N 1s region (Figure 1, c) presents an almost symmetrical large band, centred at about 400 eV, which corresponds to different types of nitrogen atoms present at the surface of the carbon material – primary amines, secondary amines, amides and imines (Scheme 1).[33]

Temperature Programmed Desorption (TPD)

The TPD profiles for the $m/z = 28$ and $m/z = 44$ fragments of carbon atoms A3−A5 are represented in Figure 2, and the areas under the peaks for all carbon-based materials are collected in Table 4. We have already described in a previous report[23] that oxidation of activated carbons with nitric acid increases the number of carboxylic acid groups which are observed at 560 K in the $m/z = 44$ TPD profile.

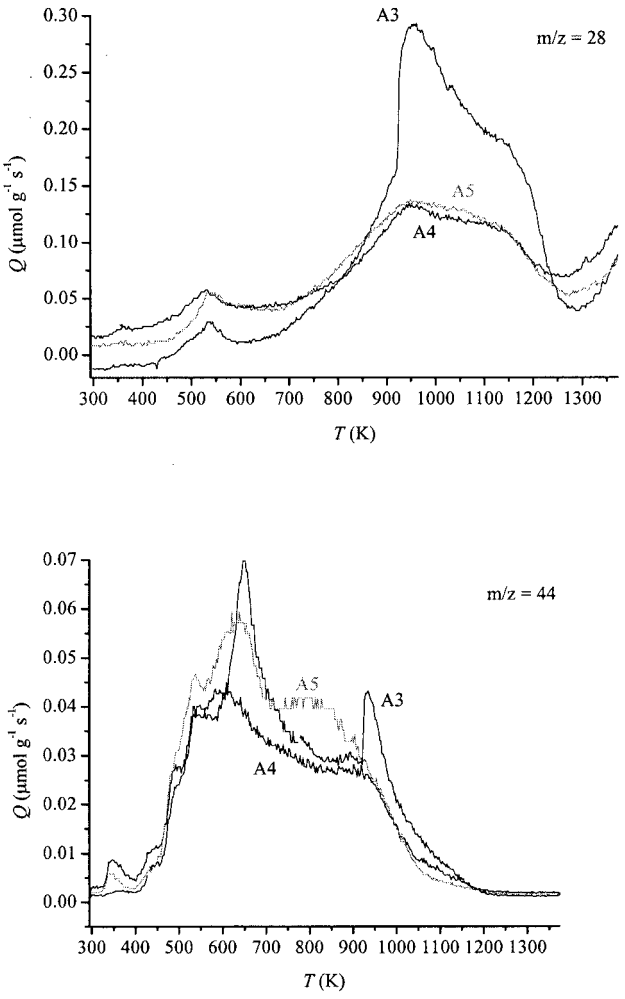

Figure 2. TPD profiles for the fragments $m/z = 28$ and 44 for A3−A5 carbon-based materials

Table 4. Amounts of fragments with $m/z = 28$ and $m/z = 44$ released during the TPD experiments, obtained by integration of the areas under the peaks, for the carbon-based materials

Carbon atom	$m/z = 28$ (μmol g^{-1})	$m/z = 44$ (μmol g^{-1})	$m/z = 28 + 44$ (μmol g^{-1})
A1	476	140	616
A2	1046	374	1420
A3	1270	245	1515
A4	712	201	913
A5	787	254	1041
A6	1041	314	1355
A7	1014	259	1273

These bands disappear after reaction with thionyl chloride, giving rise to a new intense band at 960 K in the $m/z = 28$ TPD profile, which has been attributed to the acyl chloride functionalities.[23] These functionalities decompose to carbon monoxide, but at lower temperature than the carbonyl/quinone functionalities (1100 K) due to the electron density withdrawing effect of chlorine atom. Introduction of the triamine at the surface of carbon A3 causes a significant decrease in intensity of the band at 960 K in the $m/z = 28$ TPD profile (Figure 2). This phenomenon was also observed upon the attachment of nickel(II) complexes functionalised with amines onto an activated carbon surface with acyl chloride functionalities and was attributed to the reaction between the amine groups and the acyl chloride groups, with the formation of amide ligations.[23] The same explanation is presupposed for the decrease in intensity of this band after the reaction of amine groups of *trien* with acyl chloride surface groups (Scheme 1, a).

There is also a significant intensity decrease in the high temperature region of the $m/z = 28$ TPD profile (Figure 2, b) assigned to carbonyl groups, which may be attributed to Schiff condensation reactions between these groups and the amines (Scheme 1, b), in accordance with the results of XPS analysis (vide supra).

Anchoring of the Copper(II) Acetylacetonate onto the Modified Activated Carbons

Evidence for the effective anchorage of the copper complexes onto the surface of carbon A4 is provided by noting that (a) the blue colour of complex solution disappears during the adsorption reaction, and (b) colourless solutions are obtained when the material is purified by Soxhlet extraction.

Adsorption of copper(II) acetylacetonate (toluene solutions) onto carbons A2 and A3 was also performed using similar experimental conditions and a decrease in the blue colour of solution was observed. During the purification steps of these materials no colour due to copper(II) complexes were observed in the washing solutions, suggesting that the adsorbed copper(II) acetylacetonate was not leached.

Copper content of carbons A5−A7 was determined by ICP-AES and from this it was possible to calculate the loading (mass of copper/mass of carbon × 100) and the efficiency of adsorption (amount of adsorbed complex/amount in original solution × 100) which are both summarised in Table 5. The data shows that metal loading in A6 and A7 are similar, but are about half of that in A5, with a similar pattern for the efficiency of adsorption. These results clearly indicate that functionalisation of the activated carbon surface with a triamine increases the efficiency of copper(II) acetylacetonate immobilisation.

Composition and Texture

Table 5. ICP-AES results for copper containing carbon-based materials

Carbon atom	n_i[a] (μmol g^{-1})	Cu (wt-%)	n_f[b] (μmol g^{-1})	η[c] (%)	N/Cu[d]
A5	145	0.779 (3.12)[e]	123	85	6.8
A6	168	0.396	62	37	–
A7	114	0.382	60	53	–

[a] n_i = initial $[Cu(acac)_2]$ mol (solution)/weight activated carbon. [b] n_f = adsorbed $[Cu(acac)_2]$ moles/weight activated carbon. [c] $\eta = n_f \times 100/n_i$. [d] N/Cu (atomic ratio) =[N(wt%) × relative atomic mass(Cu)]/[Cu(wt%) × relative atomic mass(N)]; N(wt%) from Table 1. [e] Copper weight% calculated from XPS in Table 3. Weight Cu% = atomic% Cu × Ar(Cu)/[atomic% O × Ar(O) + atomic% N × Ar(N) + atomic% Cl × Ar(Cl) + atomic% C × Ar(C) + atomic% Cu × Ar(Cu)].

A4) show an increase in ash content, and a decrease in hydrogen content. The first is due to the presence of copper(II) in the material, and the second further supports the immobilisation of $[Cu(acac)_2]$ by the processes represented in Scheme 2, due to loss of water during Schiff condensation.

The decrease of volatile matter after complex anchorage may be attributed to the inclusion of *trien* in the copper(II) coordination sphere (Scheme 2), which increases its stability relative to that of *trien* bound only to the activated carbon surface.

The immobilisation of copper(II) acetylacetonate onto carbon A4 causes pore blockage and thus a decrease in pore volume. The observation that the decrease (59%) in wide pore volume is much larger than that observed (13%) in micropore volume suggests that the metal complexes are anchored preferentially onto the mesopore and macropore surface.

X-ray Photoelectron Spectroscopy

High resolution XPS spectra of carbons A3−A5 in the O 1s region are depicted in Figure 1, and the areas under the high resolution XPS peaks in the regions O 1s, N 1s, Cl 2p, C 1s, and Cu $2p_{3/2}$ are summarised in Table 3.

When $[Cu(acac)_2]$ is immobilised onto the activated carbon functionalised with *trien* there is an increase in oxygen and copper surface content (Table 3), but no significant changes are observed in the XPS spectra, with the exception of the O 1s XPS profile, for which an increase in intensity of the lower energy band (531.6 eV) is observed (Figure 1). Since we reported that oxygen atoms coordinated to transition metal cations possess similar O 1s binding energies,[22−26] this increase may be assigned to oxygen atoms from $[Cu(acac)_2]$.

By using the Cu atomic% from XPS and converting to Cu wt% we get 3.12 (Table 5), a value that when compared with Cu wt% from bulk analysis (0.779), indicates that the complexes are located preferentially at the outer pores.

An atomic ratio N/Cu of 6.8 is obtained by both XPS (Table 3) and elemental analysis (Table 5), which provides an indication that the anchoring mechanism of $[Cu(acac)_2]$ is the same within the matrix. The atomic ratio N/Cu for anchored complexes must lie between 3 and 6 (Scheme 2), thus the observed value is consistent with the presence of uncomplexed *trien*, but does not provide any conclusive information on *trien* binding to copper.

Temperature Programmed Desorption

Carbons A4 and A5 exhibit TPD profiles that are practically identical for $m/z = 28$ and slightly different for $m/z = 44$ (Figure 2), which suggests that the main anchoring process takes place by reaction with the amine groups immobilised at the carbon A4 surface, and that direct complex anchoring to the oxygen groups on the carbon surface must be virtually absent. The small differences in the $m/z = 44$ profile between A5 and A4 carbons may be assigned to fragments arising from decomposition of acetylacetonate ligand.

This result must be contrasted with the changes in the TPD profiles of carbon atoms A6 and A7, which exhibit a decrease in band intensity when compared with those of their precursors (A2 and A3) (Figures 3 and 4, respectively). For A6, those corresponding to carbonyl/quinone groups

(higher temperatures in the m/z = 28 profile)[18] and to lactones and anhydrides (m/z = 44 profile).[18] A similar pattern is also observed for A7, but the most characteristic feature is the decrease in the band which was assigned to acyl chloride functionalities.[23] These changes suggest direct anchoring [Cu(acac)$_2$] to surface functional groups of the activated carbons and we propose that it takes place by axial coordination of the copper(II) complex to these surface groups.

Electronic Paramagnetic Resonance

Carbon A5 exhibits an EPR spectrum of axial type which shows hyperfine splitting in the lowest magnetic field region, due to the interaction of the unpaired electron with the copper nucleus (^{65}Cu/^{63}Cu I = 3/2) (Figure 5, a). The EPR spectrum is typical of magnetically diluted copper(II) species, despite the large band broadening, which indicates that [Cu(acac)$_2$] is regularly distributed within the carbon matrix, which acts as a diamagnetic host.

The similarity between the EPR spectrum of carbon A5 with those observed for free [Cu(acac)$_2$] (Figure 5, b) and [Cu(acac)$_2$*trien*] (Figure 5, c) complexes allows the same

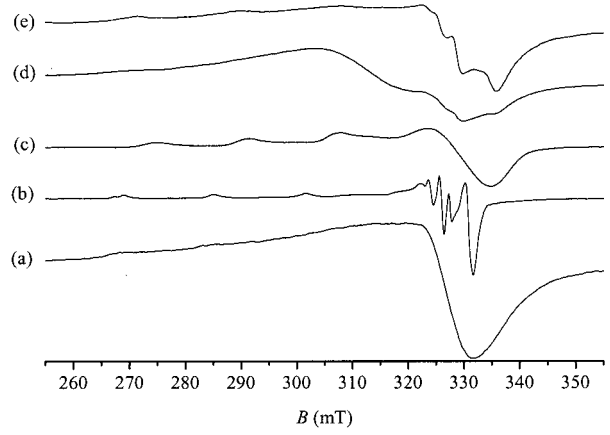

Figure 5. EPR spectra (ν = 9.41 GHz) at 120 K for: (a) carbon A5, 1% in KBr; (b) [Cu(acac)$_2$], frozen methanol solution; (c) [Cu(acac)$_2$-*trien*], frozen methanol solution; (d) A7, 5% in KBr, and (e) carbon A6, 5% in KBr

orientation scheme for the tensor axes: $g_1 = g_z$, $g_2 = g_x$, $g_3 = g_y$, where g_1 and g_3 refer to the lowest and highest magnetic fields g values (obviously, $A_1 = A_z$, $A_2 = A_x$, and $A_3 = A_y$);[34,35] in this context, as $g_z > g_x$, g_y, the ground

state proposed for $[Cu(acac)_2]$ anchored onto activated carbon functionalised with *trien* is d_{xy}.[35]

The values of tensors g and A obtained by simulation are compiled in Table 6, as well as the values for similar copper(II) free complexes. It must be pointed out that band broadening can be attributed not only to solid state effects, but also to the presence of distinct copper(II) species with very similar structures, a consequence of the different copper coordination spheres that arise from the anchorage (Scheme 2). The existence of several species for which the g and A values are very similar makes it impossible to resolve individual spectra and the EPR simulated values must be taken as average values. Nevertheless, a careful comparison with g an A values for free copper(II) complexes can provide insights into the possible structures of the anchored complexes.

The g value of carbon atom A5 is similar to those of $[Cu(acac)_2]$ in several solvents where axial coordination is incipient or nonexistent (Table 6), suggesting that the majority of *trien* based anchored complexes are four-coordinate (probably with some tetrahedral distortion) and with no axial coordination to the nitrogen of the secondary amine of *trien* (Scheme 2). However, direct anchoring of $[Cu(acac)_2]$ by axial coordination to carbon surface groups cannot be ruled out on the basis of the EPR data, as axial coordination and tetrahedral distortion of the equatorial plane may cause similar changes in the EPR spectra.[36,37]

The EPR spectrum of carbon atom A7 (Figure 5, d) is more complex, and as it can be interpreted assuming the existence of an octahedral species (strong axial coordination to carbon surface groups), either with pseudo isotropic EPR signals or low intensity magnetic interactions between vicinal copper(II) centres, its full interpretation was not further pursued.

In contrast, the EPR spectrum of carbon atom A6 (Figure 5, e) is similar to that of A5, thus also typical of magnetically diluted species, and for which the same orientation scheme for the g and A tensor can be used, and a d_{xy} ground state proposed. However, as the g value is similar to that of $[Cu(acac)_2$*trien*] (Table 6), axial coordination of the copper(II) atom to the carbon surface groups is proposed.

Conclusion

Direct anchoring of copper(II) acetylacetonate onto an oxidised activated carbon can be achieved using either the unmodified or an acyl chloride functionalised form (Scheme 1), but in either case direct coordination of the copper(II) centres to carbon surface groups takes place. The copper(II) complex can also be immobilised in activated carbons functionalised with acyl chlorides to which bis(3-aminopropyl)amine have been immobilised, thus making the available amine groups distant from the carbon surface, which are able to covalently attach $[Cu(acac)_2]$ by amide ligations, formed by Schiff condensation of the unbound amines with the oxygen atoms of the acetylacetonate ligands.

In all methods the complexes are bound to the carbon surface and thus leaching of complexes is prevented, but the anchoring method that uses *trien* has two significant advantages. On the one hand it allows for the loading of the copper(II) complex to be larger than the other methods by a factor of two, and more importantly the separation of the copper centres from the carbon surface which implies that the majority of the anchored complexes remain four-coordinate. This latter aspect is of crucial importance if these heterogeneous materials, with anchored copper(II) complexes, are to be used to catalyse reactions for which $[Cu(acac)_2]$ acts as a homogeneous catalyst. This means that the tethered complexes retain the same coordination sphere as that in solution, making these materials very promising heterogeneous catalysts for the aziridination of olefins.

Experimental Section

Materials: The starting carbon material was a NORIT ROX 0.8 activated carbon (rodlike pellets with 0.8 mm diameter and 5 mm length). This material has a pore volume of 0.695 $cm^3 \cdot g^{-1}$ determined by porosimetry (corresponding to meso and macropores), an ash content of 2.6% (w/w), an iodine number of 1000 and the mercury and helium densities are 0.666 and 2.11 $g \cdot cm^{-3}$, respectively. The activated carbon was purified by Soxhlet extraction with HCl 2 $mol \cdot dm^{-3}$ for 6 hours, washed with deionised water until pH 6−7 and then dried in an oven at 150 °C for 13 hours, under vacuum (carbon A1).

All reagents and solvents used in the modification of the activated carbon and in the anchoring of the copper(II) complex were purified by distillation, except for copper(II) acetylacetonate, which was used as received. Copper(II) acetylacetonate and bis(3-aminopropyl)-amine (*trien*) were from Aldrich, and thionyl chloride, toluene and all other chemicals were from Merck (pro analysi).

$[Cu(acac)_2]$, XPS spectrum (eV): C 1s, 285.0 and 287.2; O 1s, 532.0; Cu $2p_{3/2}$, 934.8.

Functionalisation of Activated Carbon

Oxidation of Activated Carbon: The purified NORIT ROX 0.8 activated carbon (carbon A1; 22.0 g) was refluxed with a 5 mol·dm^{-3} solution of nitric acid (600 cm^3) for 7 hours. The oxidised carbon was extensively washed with deionised water until pH 6−7 and then dried in an oven at 150 °C for 13 hours, under vacuum (carbon A2).[18,23]

Reaction with Thionyl Chloride ($SOCl_2$): The oxidised activated carbon (12.0 g) was refluxed with 40 cm^3 of a 5% (v/v) solution of thionyl chloride in toluene for 5 hours, extensively washed with toluene, and then purified by Soxhlet extraction with toluene for 2 hours, and finally dried in an oven at 150 °C for 13 hours, under vacuum (carbon A3).[23,38]

Functionalisation with Bis(3-aminopropyl)amine (Trien): Carbon A3 (3.0 g) was refluxed with a solution containing 390 μmol of bis(3-aminopropyl)amine (*trien*) in 40 cm^3 toluene for 4 hours, then filtered and extensively washed with toluene. The material was also Soxhlet extracted for 2 hours with toluene and dried in an oven at 150 °C for 13 hours, under vacuum (carbon A4).

Anchoring of [Cu(acac)$_2$] onto the A4 Carbon: The activated carbon functionalised with *trien* (A4, 2.0 g) was added to 100 cm^3 of a solution of [Cu(acac)$_2$] in toluene (290 μmol), and the mixture was refluxed for 5 hours; during the reflux a progressive disappearance of the solution colour was observed. The resulting material was extensively washed with toluene and then purified by Soxhlet extraction with toluene for 7 hours, and dried in an oven at 150 °C for 13 hours, under vacuum (carbon A5).

Anchoring of [Cu(acac)$_2$] onto the A2 Carbon: The oxidised activated carbon A2 (2.0 g) was added to 100 cm^3 of a solution of [Cu(acac)$_2$] in toluene (335 μmol), and the mixture was refluxed for 5 hours, and a progressive disappearance of the solution colour was also observed. The resulting material, carbon A6, was extensively washed with toluene and then purified by Soxhlet extraction with toluene for 7 hours, and dried in an oven at 150 °C for 13 hours, under vacuum (carbon A6).

Anchoring of [Cu(acac)$_2$] onto the A3 Carbon: The activated carbon functionalised with acyl chloride groups (A3, 2.0 g) was added to 100 cm^3 of a solution of [Cu(acac)$_2$] in toluene (229 μmol), the mixture was refluxed for 5 hours, and a progressive disappearance of the solution colour was observed. The resulting material was extensively washed with toluene and then purified by Soxhlet extraction with toluene for 7 hours, and dried in an oven at 150 °C for 13 hours, under vacuum (carbon A7).

Physico-Chemical Measurements

X-ray photoelectron spectroscopy was carried out at "Centro de Materiais da Universidade do Porto" (Portugal), in a VG Scientific ESCALAB 200A spectrometer using a non-monochromatized Mg-*Kα* radiation (1253.6 eV). The metal complex was compressed into a pellet prior to the XPS study. In order to correct for possible deviations caused by electric charge on the samples, the C 1s line at 284.6 eV was taken as internal standard.[39,40]

The textural characterisation of carbon-based materials was based on the N_2 adsorption isotherms, which were determined at 77 K with a Coulter Omnisorp 100 CX apparatus. The samples were degassed at 350 °C (A1) or at 120 °C (all other samples) until a final vacuum of 10^{-6} Torr was reached. The volume (V_{micro}) and mesopore surface area (S_{me}) were determined by the *t*-method, using the standard isotherm for carbon materials proposed by Reinoso et al.[41] The pore volume at $p/p_0 = 0.95$ ($V_{0.95}$) was estimated from the N_2 uptake (using the value of 0.8081 as the density of N_2 in its normal liquid state); the porosity volume, other than that due to the micropores (which accounts for most of mesopores − V_{me}), was calculated by subtracting the micropore volume, (V_{micro}), obtained by the *t*-method at $p/p_0 = 0.95$, ($V_{0.95}$), from the pore volume.[42]

Elemental analysis of C, H, and N were performed with a Carlo−Erba EA 1108 Elemental Analyzer. Metal analysis was performed by Kingston Analytical Services, U.K.

The thermograms were recorded with a Mettler TA 4000 thermal analyser, using a heating rate of 5 K·min^{-1} and a flow rate of the N_2 carrier gas of 200 cm^3·min^{-1}. The TPD profiles were obtained with a custom built set-up, consisting of a U-shaped tubular microreactor, placed inside an electrical furnace. The flow rate of the helium carrier gas (25 cm^3·min^{-1}) and the heating rate of the furnace (5 K·min^{-1}) were controlled with appropriate units. The masses at $m/z = 28$ and 44 were monitored with a Spectramass Dataquad quadrupole mass spectrometer.

EPR spectra of powdered samples diluted in KBr (5%) were obtained with an X band Bruker ESP 300 E spectrometer, at room temperature and at 120 K. The spectra were calibrated with diphenylpicrylhydrazyl (dpph) with $g = 2.0037$, and the magnetic field was calibrated using Mn^{II} in MgO. Typical experimental conditions were − modulation frequency: 100 kHz; modulation amplitude: 9 G; microwave power: 5 mW. The EPR parameters were obtained by simulation using the program Win EPR Simfonia (Bruker) assuming axial or rhombic Spin Hamiltonians. The reported values of $g_\perp$ (or g_x and g_y) and $A_\perp$ (or A_x and A_y) are less accurate because of their dependence on the used line widths (20−60 G).

Investigation of Multi-Nickel-Substituted Tungstophosphates and Their Stability and Electrocatalytic Properties in Aqueous Media

Darine Jabbour,[a] Bineta Keita,[a] Israel-Martyr Mbomekalle,[a] Louis Nadjo,*[a] and Ulrich Kortz[b]

Keywords: Electrochemistry / Nickel / Polyoxometallates / Sandwich complexes / UV/Vis spectroscopy

Several sandwich-type polyoxometallates based on the trivacant $[PW_9O_{34}]^{9-}$ fragment with different Ni nuclearities were selected. Their stability and redox behaviour in aqueous media were evaluated by UV/Vis spectroscopy and cyclic voltammetry as a function of pH with the aim of finding the conditions under which these compounds could be suitable candidates for electrocatalytic processes. Two polyoxoanions — $[Ni_3Na(H_2O)_2(PW_9O_{34})_2]^{11-}$ and (to a lesser extent) $[Ni_4Mn_2P_3W_{24}O_{94}]^{17-}$ — were found to be stable over a wide pH domain, while $[Ni_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ requires the pH to be greater than 4 for its stability. The other derivatives are only suitable for solid-state studies. The stable polyoxoanions were tested for their activity in the electrocatalytic reduction of nitrate. The results suggest unambiguously that an increase in the number of Ni centres within these sandwich-type polyanions has a beneficial effect on the electrocatalytic process.

Introduction

Polyoxometallate ions are gaining widespread attention owing to their possible applications in catalysis, electrocatalysis, medicine, materials science, photochemistry, analytical chemistry and magnetochemistry.[1−5] The impetus was partly triggered by the pioneering remark by Baker[6] that monosubstituted heteropolyanions can be considered as the analogues of metallated porphyrins, and used in catalytic processes with the advantage, over their organic counterparts, of thermal stability, robustness and inertness toward oxidizing environments. With regard to their electrochemistry and, correspondingly, their use in electrocatalysis, we are currently studying the parameters, which eventually in conjunction with pH effects, could improve the catalytic properties of heteropolyanions (HPAs). The incentive behind this search is to trigger those energetically favourable cathodic processes that require several electrons for their effectiveness by reduced HPAs.[7−11] Among several possibilities, substitution effects on the polyoxometallates are considered with attention: the location of the metal atom in the framework; the nature and number of substituents are expected to influence more or less the interactions between the electroactive centres within the HPA molecule.

The present paper is devoted to a study of the effects of the accumulation of nickel centres in HPAs on their stability and electrocatalytic behaviour. Several reasons have dictated this choice. Recently, we have demonstrated, for the first time to the best of our knowledge, that Cu^{2+}- or Ni^{2+}-containing HPAs are the only monosubstituted polyoxoanions to be effective in the electrocatalytic reduction of nitrate in mildly acidic aqueous media.[12] Also, we have shown that the accumulation of Cu^{2+} centres within HPAs is useful in enhancing the catalytic properties of the polyoxometallate.[13] Specifically, a comparison of the catalytic activity of $\alpha\beta\beta\alpha$-$(Cu^{II}OH_2)_2Cu^{II}_2(H_4AsW_{15}O_{56})_2^{18-}$ based on the novel Wells−Dawson complex $H_4AsW_{18}O_{62}^{7-}$ [14] with those of the analogous monosubstituted Cu-HPAs demonstrated a favourable effect of the accumulation of Cu centres in the electrocatalytic reduction of nitrate; hence the idea that multi-nickel derivatives might be interesting in this respect. A large family of Ni-substituted tungstophosphates with a sandwich-type structure is known[15] and some other structures exist as well.[16−19] Novel polyoxoanions are often difficult to obtain owing to the fact that the mechanism of formation is far from well understood. Numerous sandwich-type compounds have been synthesised and characterised since the pioneering work of Weakley et al.,[20] but the nickel-containing Keggin derivative $[Ni_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ has been isolated only recently under severely controlled experimental conditions to avoid or minimize other side products.[18] The synthesis con-

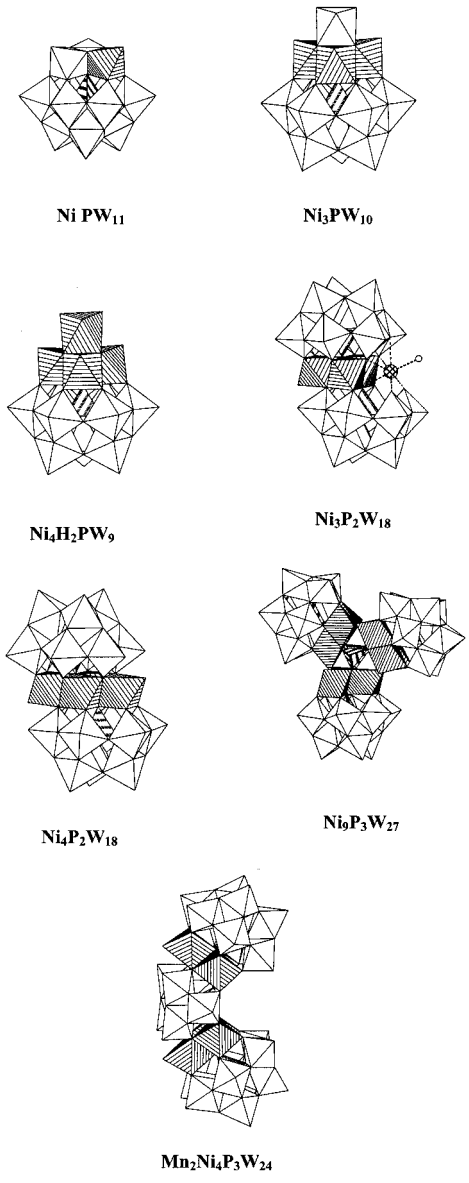
ditions suggest strongly that some species might be stable only in narrow pH domains in solution. Our choice of (PW_9O_{34})-based derivatives allows us to study several species with different nuclearities. However, there are also complications that have been reviewed recently, for example the existence of multiple isomers and their transformation pathways.[21] It has been demonstrated recently that the triferric sandwich-type complex $[Fe_2(FeOH_2)(NaOH_2)(P_2W_{15}O_{56})_2]^{14-}$ is significantly more stable than its diferric and tetraferric analogues.[22] The unique coordination environment of its single external iron site and the incorporated sodium ion most likely play an important, stabilizing role. This observation suggests that the nuclearity and the geometry of the incorporated transition metal centres might also influence the stability of other sandwich-type polyanions. Finally, the aforementioned catalytic activity of a monosubstituted Ni-HPA towards nitrate[12] and the diversity of multi-nickel HPAs available at present justify the search for a unified view of their behaviour in aqueous media.

Results and Discussion

Selection of Relevant Heteropolyanions

All polyanions studied here are derived from the Keggin fragment $[PW_9O_{34}]^{9-}$. The trilacunary $[A,\beta\text{-}PW_9O_{34}]^{9-}$ ($A,\beta\text{-}PW_9$) and the monolacunary $[\alpha\text{-}PW_{11}O_{39}]^{7-}$ (PW_{11}) were synthesised according to literature procedures.[23,24] Preparation of $[B,\alpha\text{-}PW_9O_{34}]^{9-}$ ($B,\alpha\text{-}PW_9$) was accomplished from $A,\beta\text{-}PW_9$ by heating according to the procedure first reported by Finke and co-workers[25] and then by Domaille.[24] The solution behaviour of the various isomers of the mono- and trilacunary Keggin species can be helpful for understanding possible transformation pathways of the Ni-containing compounds of interest. The following polyoxoanions were synthesised by literature methods and thoroughly characterised as pure samples. The mixed nickel/manganese-substituted $[Ni_4Mn_2P_3W_{24}O_{94}]^{17-}$ constitutes a novel polyanion:[27] $[H_2PW_9Ni_4O_{34}(OH)_3(H_2O)_6]^{2-}$ ($Ni_4H_2PW_9$);[19] $[Ni_3(H_2O)_3PW_{10}O_{39}H_2O]^{7-}$ (Ni_3PW_{10});[18] $[Ni_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ ($Ni_4P_2W_{18}$);[18] $[Ni_9(OH)_3(H_2O)_6(HPO_4)_2(PW_9O_{34})_3]^{16-}$ ($Ni_9P_3W_{27}$);[18] $[Ni_3Na(H_2O)_2(PW_9O_{34})_2]^{11-}$ ($Ni_3P_2W_{18}$);[15,26] $[Ni_4Mn_2P_3W_{24}O_{94}]^{17-}$ ($Mn_2Ni_4P_3W_{24}$).[27] Also $[Ni_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ ($Ni_4P_4W_{30}$)[28] will be considered for a brief comparison. The structures of $Ni_4H_2PW_9$, Ni_3PW_{10}, $Ni_4P_2W_{18}$, $Ni_9P_3W_{27}$, $Ni_3P_2W_{18}$, $Mn_2Ni_4P_3W_{24}$, and $Ni_4P_4W_{30}$ are shown in Scheme 1.



Scheme 1. Structures of polyanions $Ni_4H_2PW_9$, Ni_3PW_{10}, $Ni_4P_2W_{18}$, $Ni_9P_3W_{27}$, $Ni_3P_2W_{18}$, $Mn_2Ni_4P_3W_{24}$, and $Ni_4P_4W_{30}$

Cyclic Voltammetry (CV) Study of Selected Multi-Nickel HPAs in pH 3 Sulfate Medium

The cyclic voltammograms of the various electroactive species were monitored as a function of time. Therefore, their recording was started shortly after addition of the relevant HPA to the previously deaerated supporting electrolyte. The choice of CV in this issue stems from our primary interest to detect stable electroactive species that constitute the sole useful candidates for electrocatalysis. Three main classes will be discussed: two compounds — $Ni_3P_2W_{18}$ and $Mn_2Ni_4P_3W_{24}$ — are stable over a wide pH domain; $Ni_4P_2W_{18}$ requires pH values higher than 4 for its stability; no pH domain could be found for an appreciable stability of $Ni_4H_2PW_9$, Ni_3PW_{10} and $Ni_9P_3W_{27}$.

$[H_2PW_9Ni_4O_{34}(OH)_3(H_2O)_6]^{2-}$ ($Ni_4H_2PW_9$)

The very first voltanmmogram of $Ni_4H_2PW_9$ shows a composite reduction wave located between −0.600 V and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

−0.900 V vs. SCE. (Figure 1A). The proton reduction wave which followed this immediately is not shown. Roughly 10 min after the addition of $Ni_4H_2PW_9$ to the solution a modification of the voltammetric pattern was observed, characterised by two main features: (i) the whole voltammogram experiences a shift to positive potential; (ii) the two waves become better and better defined and separated. For the sake of clarity, only the "initial" cyclic voltammogram and those recorded after 30 min and 4 h are shown in Figure 1A. The two waves are attributed to the reduction of W^{VI} centres. This hypothesis was confirmed by controlled potential electrolysis. The cyclic voltammograms recorded after more than 4 h are nearly identical to that recorded after 4 h, except for a small increase of the second wave at the expense of the first one. It should be noted that the first wave remains slightly composite. The next issue concerns the nature of the new product(s). In particular, the possibility that one or several Ni^{2+} ions are lost from the new complexes should be considered. As a matter of fact, the present transformations resemble those of B,α-PW_9. In the supporting electrolyte used here, it was checked that B,α-PW_9 is rapidly converted into a species whose cyclic voltammogram is identical to that of PW_{11}, in agreement with the literature.[21] In contrast, Figure 1B indicates a difference of 58 mV between the potentials of the first reduction peaks of the transformation products of $Ni_4H_2PW_9$ and B,α-PW_9, the former complex being the more negative of the two. Finally, Figure 1C shows that the new complex from $Ni_4H_2PW_9$ has a cyclic voltammogram very close to that of $[PW_{11}O_{39}Ni(H_2O)]^{5-}$ ($PW_{11}Ni$).

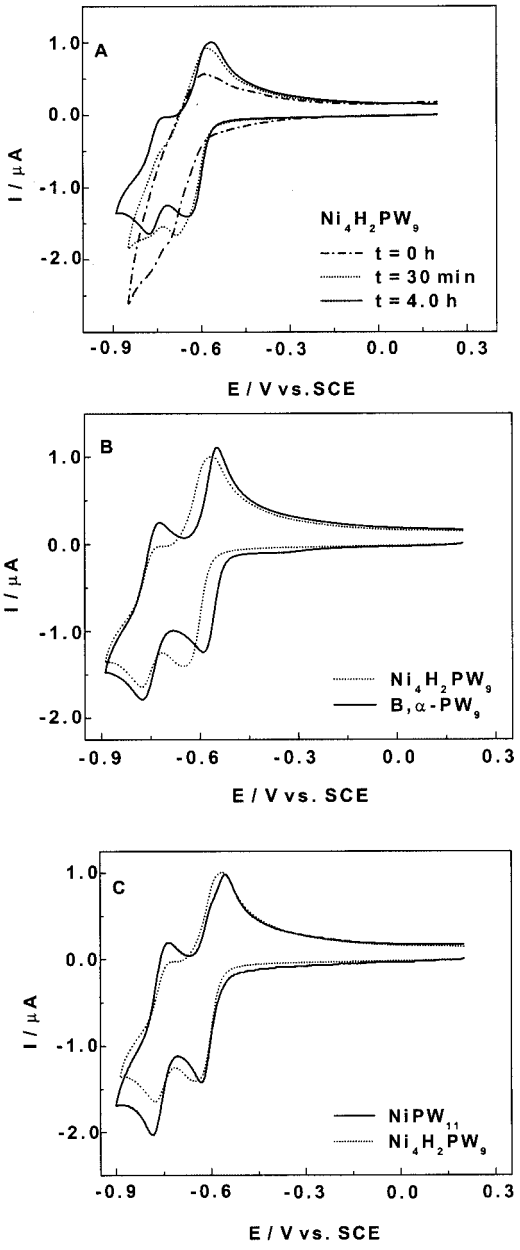


Figure 1. A: Cyclic voltammetry monitoring of the transformations of 2×10^{-4} M $Ni_4H_2PW_9$ as a function of time; medium 0.2 M Na_2SO_4 + H_2SO_4 (pH = 3); scan rate: 10 mV·s^{-1}; working electrode: polished glassy carbon; reference electrode: SCE; B: superimposition of the final cyclic voltammetry patterns for $Ni_4H_2PW_9$ and B,α-PW_9; the experimental conditions are the same as in A; C:) superimposition of the final cyclic voltammetry patterns for $Ni_4H_2PW_9$ and $NiPW_{11}$; the experimental conditions are the same as in A; for further details see text

Comparison with Other Multi-Nickel Derivatives

The "initial" cyclic voltammogram of Ni_3PW_{10} is different from that of $Ni_4H_2PW_9$; its conversion ends up in $NiPW_{11}$ in roughly 5 h (Figure 2A). The trimeric $Ni_9P_3W_{27}$ is also unstable in the pH 3 medium (0.2 M Na_2SO_4 + H_2SO_4) and its conversion is relatively fast. The first-wave current increases at the expense of the second one, which has a larger current intensity than the first wave and which is composite. Figure 2B shows, in superimposition, the "initial" cyclic voltammogram of $Ni_9P_3W_{27}$ and that recorded after 1.5 h. A longer duration does not bring about substantial changes in this cyclic voltammogram. The final pattern is different from that of $NiPW_{11}$, except for the first wave, which shows a peak located at the same potential in the two systems. However, no conclusion can be drawn at this stage (vide infra UV/Vis studies). For $Ni_4P_2W_{18}$, the "initial" cyclic voltammogram comprises a first composite wave, followed by a second wave close to the reduction of protons (Figure 2C). This pattern does not resemble any of the preceding ones. However, a very slow and gradual transformation of the cyclic voltammogram is observed as a function of time; in particular, the current intensity of the second wave decreases significantly, while the wave itself becomes better and better defined, with a gradual move of its reduction peak potential in the negative direction. In Figure 2C the "initial" cyclic voltammogram and those recorded after 3 h and 9 h are compared. Even after 9 h of transformation of $Ni_4P_2W_{18}$ the first wave remains slightly composite, which could indicate the presence of a mixture of products. No attempt was made to identify these other products but it is likely that the mixture contains $Ni_3P_2W_{18}$. This assumption is supported by Figure 2D, which compares the last cyclic voltammogram recorded with $Ni_4P_2W_{18}$ to that of $Ni_3P_2W_{18}$. Such a possibility is reminiscent of the aforementioned higher stability of the triferric

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

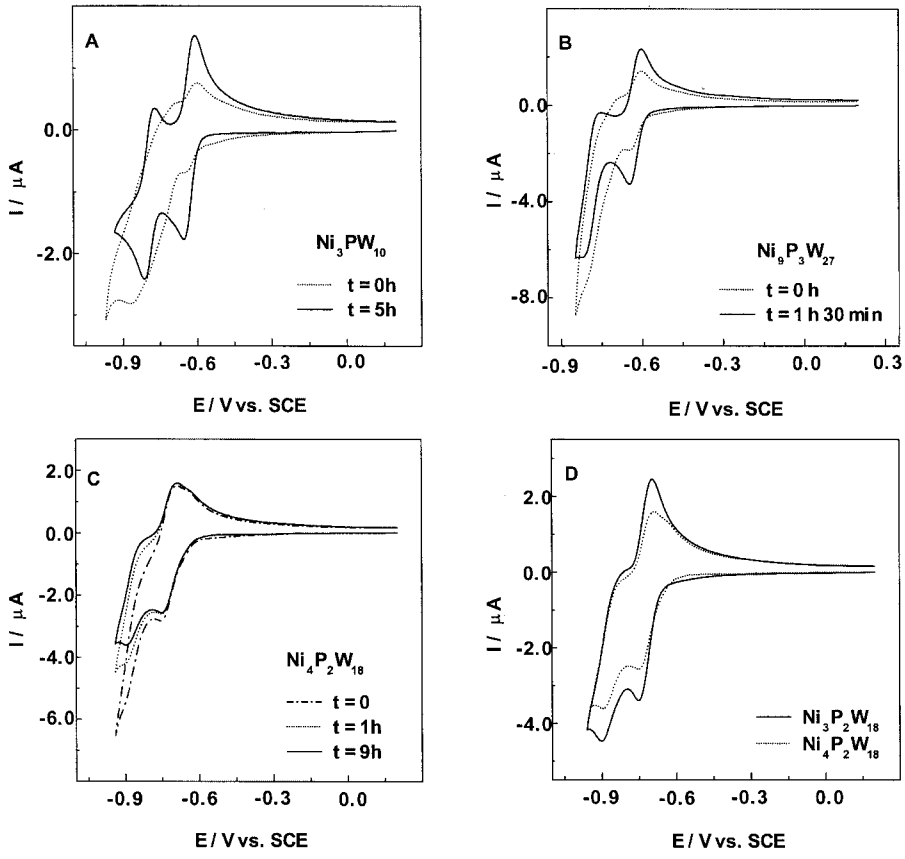

Figure 2. A: Comparison of the "initial" and "final" cyclic voltammograms of 2×10^{-4} M Ni_3PW_{10}; medium 0.2 M Na_2SO_4 + H_2SO_4 (pH = 3); scan rate: 10 $mV \cdot s^{-1}$; working electrode: polished glassy carbon; reference electrode: SCE; B: superimposition of the "initial" cyclic voltammogram of $Ni_9P_3W_{27}$ and that recorded after 1.5 h; the experimental conditions are the same as in A; C: cyclic voltammetry monitoring of the transformations of 2×10^{-4} M $Ni_4P_2W_{18}$ as a function of time; the experimental conditions are the same as in A; for further details see text; D: superimposition of the "final" cyclic voltammogram of $Ni_4P_2W_{18}$ with that of the stable $Ni_3P_2W_{18}$; the experimental conditions are the same as in A

sandwich complex $[Fe_2(FeOH_2)(NaOH_2)(P_2W_{15}O_{56})_2]^{14-}$ than its diferric and tetraferric analogues.[22] These complexes show remarkable differences in their junction connectivities. The tetrairon-substituted $[Fe_2(FeOH_2)_2(P_2W_{15}O_{56})_2]^{12-}$ has two β-junctions, the diiron-substituted $[Fe_2(NaOH_2)_2(P_2W_{15}O_{56})_2]^{16-}$ has two α-junctions and the triiron-substituted $[Fe_2(FeOH_2)(NaOH_2)(P_2W_{15}O_{56})_2]^{14-}$ has one β-junction and one α-junction.[22,29–31] The junction connectivity of the Keggin-based $Ni_3P_2W_{18}$ is ααβα[15] and therefore in complete agreement with the triiron Wells–Dawson derivative of Hill et al.[22] The unique coordination environment of the single external Ni site and the incorporated sodium ion seem to enhance the stability of the trinickel species, in analogy with the triiron derivative. Provisionally, it is worth recalling that $Ni_3P_2W_{18}$ is stable in the present medium, as reported previously.[15,26]

In summary, all of the above Ni-substituted tungstophosphates can be distinguished from each other, provided their very first cyclic voltammograms are recorded shortly after dissolution in the supporting electrolyte. With the exception of $Ni_3P_2W_{18}$ and $Mn_2Ni_4P_3W_{24}$ all polyoxoanions studied here are unstable upon standing in the pH 3 sulfate medium.[15,27] The slow transformation of $Ni_4P_2W_{18}$ in this pH 3 medium is also worth noting.

Influence of Counteranions

In the case of $Ni_4H_2PW_9$ it was checked that replacement of the countercation Na^+ by Li^+ in the supporting electrolyte has a negligible influence on the observed electrochemical processes. Therefore, in the following study of the influence of the counteranion and the pH of the electrolyte we selected the sodium counterion in all cases. This study was performed with $Ni_4H_2PW_9$ as a representative polyoxometallate. The choice of anions was restricted to those classically used in the electrochemistry of HPAs, namely ClO_4^-, $H_2PO_4^-$, CH_3COO^- and Cl^-; SO_4^{2-} has already been studied above. For easier comparisons, all the experiments were carried out at pH = 3 with 0.4 M Na^+.

The cyclic voltammogram of $Ni_4H_2PW_9$ also changes as a function of time for $H_2PO_4^-$ and CH_3COO^-, resulting in a mixture of electroactive products, and $NiPW_{11}$ appears to be the main product. To illustrate this conclusion, Figure 3A shows in superimposition the so-called "final state" cyclic voltammograms recorded in the presence of these two

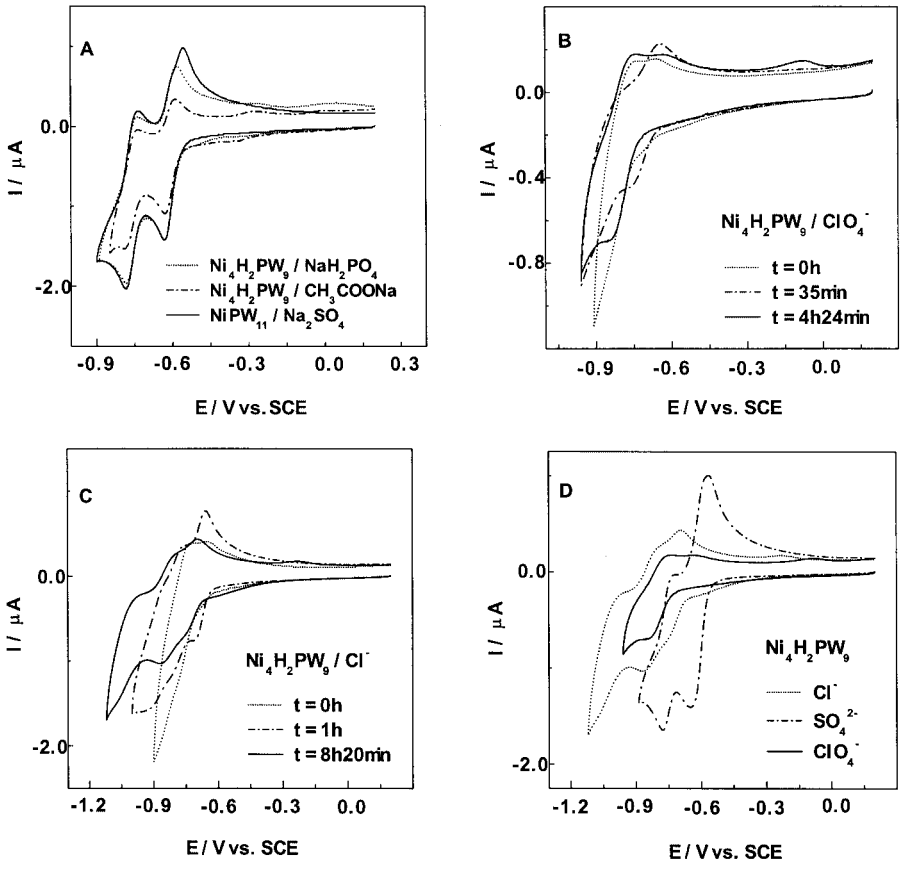

Figure 3. A: Superimposition of the so-called "final state" cyclic voltammograms recorded for 2×10^{-4} M $Ni_4H_2PW_9$ in pH 3 phosphate (0.4 M NaH_2PO_4 + H_3PO_4) and acetate (0.4 M CH_3COONa + CH_3COOH) media (pH = 3), respectively, and the cyclic voltammogram of $NiPW_{11}$ in sulfate medium (pH = 3); scan rate: 10 $mV \cdot s^{-1}$; working electrode: polished glassy carbon; reference electrode: SCE; B: cyclic voltammetry monitoring of the transformations of 2×10^{-4} M $Ni_4H_2PW_9$ as a function of time in the presence of 0.4 M $NaClO_4$ + $HClO_4$ (pH = 3); the experimental conditions are the same as in A; C: cyclic voltammetry monitoring of the transformations of 2×10^{-4} M $Ni_4H_2PW_9$ as a function of time in the presence of 0.4 M NaCl + HCl (pH = 3); the experimental conditions are the same as in A; D: superimposition of the "final" cyclic voltammograms of 2×10^{-4} M $Ni_4H_2PW_9$ observed in the presence of sulfate, chloride and perchlorate anions (pH = 3), respectively; the experimental conditions are the same as in A; for further details see text

anions and the cyclic voltammogram of $NiPW_{11}$ in sulfate medium. The transformation yield into $NiPW_{11}$ is smaller with CH_3COO^-. The presence of this anion induces an important formation of secondary species, as could be detected by their electroactivity between 0 and −0.4 V. It should also be noted that these "final states" were obtained after 2 h and 3 h for CH_3COO^- and $H_2PO_4^-$, respectively.

More intricate observations are made for $Ni_4H_2PW_9$ in the presence of ClO_4^- or Cl^- as illustrated in Figure 3B and C, respectively. These figures represent the "initial" cyclic voltammogram in superimposition with two other selected states; as a matter of fact, even after more than 6.5 h of standing, no "final state" could be reached. It is clear, however, that several electroactive species are formed irrespective of which of the two anions is present. Figure 3D compares the cyclic voltammograms recorded after 6.5 h in the presence of ClO_4^- and Cl^- with that recorded as a "final state" in sulfate medium. The remarkable influence of the two counteranions is obvious. The more marked effect is seen in the presence of ClO_4^- for which a small composite wave is observed, followed by the proton reduction wave (not shown).

In short, $Ni_4H_2PW_9$ is converted into respectable amounts of $NiPW_{11}$ in the presence of SO_4^{2-}, $H_2PO_4^-$ and CH_3COO^-. The transformation yield is similar for SO_4^{2-} and $H_2PO_4^-$, but is smaller for CH_3COO^-. No attempt was made to identify the secondary products. In contrast to this first group of anions, more complex observations are made in the presence of ClO_4^- and Cl^-; in their presence, $Ni_4H_2PW_9$ is gradually converted into various products with decreased overall electroactivity. This trend is representative of the main observations in the series of unstable multi-nickel compounds, except for $Ni_4P_2W_{18}$. The behaviour of the latter is illustrated in Figure 4, where the voltammograms obtained in the presence of SO_4^{2-}, ClO_4^- and Cl^- are compared. Unlike the other compounds of the series, no new electroactive species is detected in the explored potential domain. The two well-behaved waves recorded in the pH 3 sulfate medium undergo a general move in the negative potential direction, with a slight distortion of the second wave. Such behaviour has been observed previously for a large selection of stable Keggin and Wells−Dawson HPAs and has been ascribed to the buffer capacity of the electrolytes as a function of the coun-

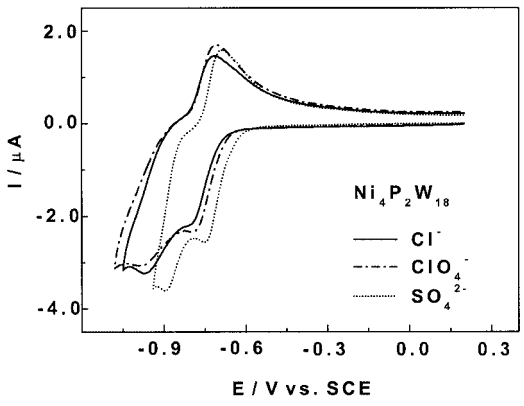

Figure 4. Superimposition of the "final" cyclic voltammograms of 2×10^{-4} M $Ni_4P_2W_{18}$ observed in the presence of sulfate, chloride and perchlorate anions (pH = 3), respectively; scan rate: 10 $mV \cdot s^{-1}$; working electrode: polished glassy carbon; reference electrode: SCE; for further details see text

teranion present in the medium.[32] Again, the clear observation of this phenomenon indicates a relatively large stability of $Ni_4P_2W_{18}$ in the pH 3 media.

UV/Vis Investigations

This study was performed as a function of pH. $Ni_4H_2PW_9$ was selected as a representative example showing the main UV/Vis features repeatedly encountered with all the other compounds. Only the observations at pH = 3 (0.2 M Na_2SO_4 + H_2SO_4) are shown. Typically, a 4.3×10^{-5} M solution of $Ni_4H_2PW_9$ in a 1.00-cm optical-path quartz cuvette was monitored as a function of time by UV/Vis spectroscopy between 380 and 200 nm. Figure 5A shows the evolution of the spectrum over 10 h. The general variation trends of the absorbance are sketched by arrows and indicate a transformation of the complex. The very first spectrum recorded does not go through the apparent isosbestic point in Figure 5A. It was checked that the variation of absorbance remains negligible from 10 h to 24 h, thus indicating that a complex stable in the pH 3 medium is already obtained. Figure 5B shows the initial spectrum of $Ni_4H_2PW_9$ and the final spectrum recorded after 24 h of standing. This last spectrum peaks at 252 nm. As it was checked previously that B,α-PW_9 is rapidly converted, in the supporting electrolyte used here, into a species whose cyclic voltammogram is identical to that of PW_{11}, we wondered whether the final complex from $Ni_4H_2PW_9$ could be the lacunary species PW_{11}, the UV/Vis spectrum of which peaks at 248 nm. However, this peak is preceded by a shoulder located between 280 and 260 nm, which rules out the presence of this lacunary complex. In contrast, the spectrum of an authentic sample of $NiPW_{11}$, which is stable in the pH 3 medium, peaks at 252 nm and has exactly the same shape as the spectrum recorded after 24 h shown in Figure 5B. These observations are in complete agreement with the conclusions from the CV investigations.

In short, the initial spectrum observed with each of the multi-nickel-substituted tungstophosphates of this work

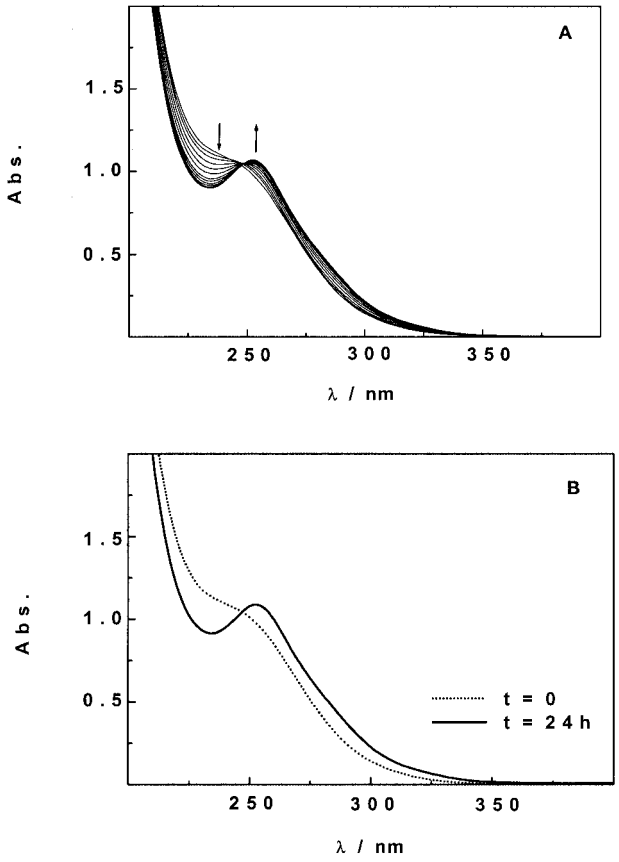

Figure 5. UV/Vis spectra of 4.3×10^{-5} M $Ni_4H_2PW_9$, recorded in a pH 3 medium (0.2 M Na_2SO_4 + H_2SO_4) with a 1.00-cm optical-path quartz cuvette; A: evolution of the spectrum with time; the arrows indicate the direction of variation of the absorbance with time; B: the initial spectrum and that recorded after 24 h of standing; for further details see text

was clearly different from those of $NiPW_{11}$ or $[PW_{11}O_{39}]^{7-}$. Long-term UV/Vis spectra and CV experiments on solutions aged for appropriate durations converge to indicate that the transformations of $Ni_4H_2PW_9$ and Ni_3PW_{10} end up, at least partly, in $NiPW_{11}$. Also, UV/Vis spectroscopy confirms the presence of $NiPW_{11}$ as a decomposition product of $Ni_9P_3W_{27}$, a conclusion already suggested by CV experiments.

Influence of pH

The pH influence was studied for all selected HPAs All solutions, except for the 0.5 M H_2SO_4 (pH = 0.33) solution, contained Na^+ at a concentration of 0.4 M as the major cation, in order to avoid any possibility of cation effect. The compositions of these media are indicated in the Exp. Sect.

Unstable HPAs

The polyanions $Ni_4H_2PW_9$, Ni_3PW_{10}, and $Ni_9P_3W_{27}$ are unstable at all pH values studied in this work. Occasionally, identification of a major transformation product by CV was achieved.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Media of pH ≤ 3

In 0.5 M H_2SO_4 (pH = 0.33) $Ni_4H_2PW_9$ is not stable and precipitates gradually. In pH 1 and 2 media (0.2 M Na_2SO_4 + H_2SO_4), its current intensity for the whole pattern decreases steadily, without any other significant modifications of the CV characteristics, nor any appearance of significant new waves. The decomposition products are probably not electroactive in these two media. The decomposition is noted to be faster the higher the proton concentration. Also, the decompositions of Ni_3PW_{10} and $Ni_9P_3W_{27}$ are so fast at pH = 2 that further studies at lower pH were not carried out. For instance, CV monitoring of the transformation of Ni_3PW_{10} shows its concentration to decrease by a factor of two in less than 2 h; no new wave was observed, which indicates that the decomposition products do not show any electrochemical activity in this medium. In contrast, the decomposition of $Ni_9P_3W_{27}$ is characterised by several new waves indicating the presence of various electroactive species.

Media of pH ≥ 3

In pH 4 or 5 buffer media $Ni_4H_2PW_9$, Ni_3PW_{10} and $Ni_9P_3W_{27}$ are converted into $PW_{11}Ni$ as the major product, with Ni_3PW_{10} being by far the most unstable. At pH = 6, only $Ni_4H_2PW_9$ is slowly converted (7 h) into $NiPW_{11}$ as the major product. Compounds resulting from decomposition of Ni_3PW_{10} and $Ni_9P_3W_{27}$ have cyclic voltammograms with characteristics close to those of $NiPW_{11}$; these cyclic voltammograms might feature isomers of $NiPW_{11}$. At pH = 7, the three complexes and $NiPW_{11}$ exhibit ill-defined cyclic voltammograms, with a steady decrease in current and no new waves appearing.

The preceding sections have revealed that $Ni_4P_2W_{18}$ must be considered as a special case among the series of unstable multi-nickel species. Figure 6 illustrates the evolution of the cyclic voltammograms of $Ni_4P_2W_{18}$ as a function of pH. As expected, this polyanion behaves differently from the other three unstable HPAs as a function of pH variation. The transformation at pH < 3 leads to the same (not fully identified) product as observed in the pH 3 medium. The only difference is the faster kinetics at lower pH. The steady decrease of the transformation kinetics with increasing pH values could explain why $Ni_4P_2W_{18}$ is stable at pH > 4. The tendency for separation of waves with decreasing pH is not unusual in polyoxometallate electrochemistry.[33] Anyhow, despite the limited pH stability domain for $Ni_4P_2W_{18}$, the behaviour of this polyanion is distinctly more favourable than that of the Wells−Dawson analogue $[Ni_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ ($Ni_4P_4W_{30}$) described by Ruhlmann and co-workers, for which slow degradation was observed during any titration between pH = 1 and 6.[28]

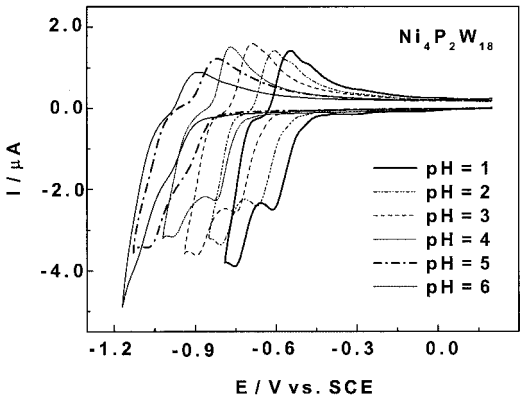

Figure 6. Superimposition of the "final" cyclic voltammograms of 2×10^{-4} M $Ni_4P_2W_{18}$ observed as a function of pH; scan rate: 10 mV·s^{-1}; working electrode: polished glassy carbon; reference electrode: SCE; for further details see text

Stable Multi-Nickel HPAs: Preliminary Evaluation of Electrocatalytic Processes

The representatives of this group are $Ni_3P_2W_{18}$ and $Mn_2Ni_4P_3W_{24}$, to which $Ni_4P_2W_{18}$ can be added at pH > 4. The electrochemistry of the two "fully" stable species at pH = 3 and 5 has been described in detail previously.[15,27] However, in order to envision electrocatalytic applications we decided to investigate the stability and redox behaviour of these polyanions from pH = 0 to 7 by UV/Vis spectroscopy and CV. The stability conclusions were deduced from the comparison of the UV/Vis spectra run on the freshly prepared solution and on the same solution after standing for 24 h. This duration is much longer than necessary for an electrochemical characterisation, but was considered useful to envision electrocatalytic applications. The results indicate that $Ni_3P_2W_{18}$ is very stable from pH = 1 to 6. The stability domain of $Mn_2Ni_4P_3W_{24}$ ranges from pH = 2 to 6. However, even at pH = 7 its decomposition is not very fast and reaches only 34% of the starting complex after 24 h. The characteristics of the W centres within the complexes were monitored by cyclic voltammetry as a function of time and pH. The results confirm the stability of the two HPAs. In agreement with previous observations at pH = 3 and 5,[15,27] the redox behaviour of the W centres is pH-dependent. Figure 7A shows the evolution of the cyclic voltammogram of $Ni_3P_2W_{18}$ for pH = 1−6. The curve for pH = 3 fits perfectly in the scheme, but it has been published previously[15] and is therefore omitted here for clarity. Coulometric determinations have also already been performed at pH = 3 and 5 and indicate that the first wave features an overall four-electron/four-proton process.[15] From a more qualitative point of view, the evolution of cyclic voltammograms with pH is illustrative of a behaviour frequently encountered in multi-electron/multi-proton processes. The distribution of the formal potentials and pK_a values of the various intermediate species will determine the broadness of the corresponding waves (and the current intensity of the wave). The same parameters will favour the merging of waves (or eventually their splitting) when their displacements as a function of pH are different. A remarkable example of such behaviour has been described recently in the electrochemistry of the tetrameric polyanion $[H_7P_8W_{48}O_{184}]^{33-}$.[33]

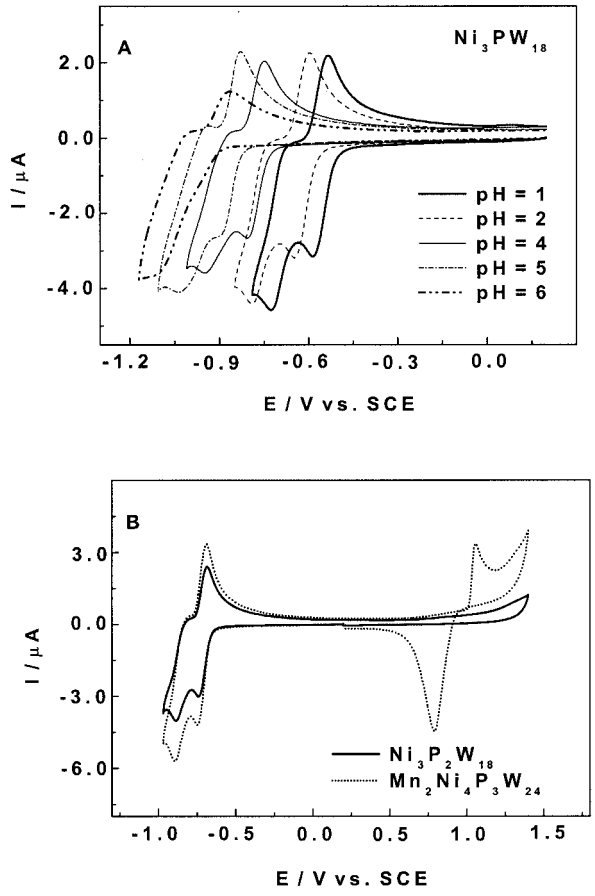

Figure 7. A: Superimposition of the cyclic voltammograms of 2×10^{-4} M $Ni_3P_2W_{18}$ observed as a function of pH; scan rate: 10 $mV \cdot s^{-1}$; working electrode: polished glassy carbon; reference electrode: SCE; B: comparison of the cyclic voltammograms of 2×10^{-4} M $Ni_3P_2W_{18}$ and $Mn_2Ni_4P_3W_{24}$ at pH = 3 (0.2 M Na_2SO_4 + H_2SO_4); for further details see text

Figure 7B compares the cyclic voltammograms of $Ni_3P_2W_{18}$ and $Mn_2Ni_4P_3W_{24}$ at pH = 3. The redox processes of the Mn centres in the latter complex do not require further comments. For both polyanions the W-centred redox processes are very similar in shape, with the current intensities being larger for $Mn_2Ni_4P_3W_{24}$ than for $Ni_3P_2W_{18}$. Coulometry in the pH 3 sulfate medium indicates a six-electron process for the first W wave of $Mn_2Ni_4P_3W_{24}$. These trends comply with expectations if it is assumed that all relevant parameters in the electrochemistry of the two complexes are close or even equal, except for their different diffusion coefficients.

Cyclic voltammetry was used to evaluate the activity of $Ni_3P_2W_{18}$ and $Mn_2Ni_4P_3W_{24}$ in the electrocatalytic reduction of nitrate. The choice of the substrate is tricky, as nitrate is difficult to reduce. To the best of our knowledge, the only examples where HPAs have proven to be useful in this system have been described recently by our group.[12,13,34] For this purpose, the excess parameter is an operational parameter defined as $\gamma = C^{\circ}_{NO_3^-}/C^{\circ}_{HPA}$ where C° designates the concentration of the relevant species. The electrocatalysis is characterised by the catalytic efficiency, CAT, defined as: $CAT = 100 \times [I_{(HPA+NO_3^-)} - I^d_{(HPA)}]/I^d_{(HPA)}$, where $I_{(HPA+NO_3^-)}$ is the peak current for reduction of the heteropolyanion (HPA) in the presence of NO_3^- and $I^d_{(HPA)}$ is the corresponding diffusion peak current for the HPA alone. CAT values are sufficient to compare the efficiencies for a given electrocatalytic process either for one compound as a function of pH or for two compounds under the same experimental conditions. However, it must be recognized that a more detailed comparison would necessitate determination of the nature and yields of the final products, which is beyond the scope of this work. As a first example, CAT values were measured in the presence of $Ni_3P_2W_{18}$ for the electrocatalytic reduction of nitrate in a pH 2 sulfate medium. CAT was measured at −0.840 V and varied from 2098 to 2733 for $\gamma = 500$ and 1000, respectively. These values indicate an efficient electrocatalysis of the reduction of nitrate by $Ni_3P_2W_{18}$ at pH = 2. Furthermore, several tests with NO_2^- and/or with NO under the aforementioned conditions confirm that these species are easily reduced electrocatalytically at substantially less negative potentials than nitrate.[35] Insofar as nitrite and NO are known to appear as intermediates in the reduction of nitrate by various metals, the present results suggest that highly reduced species should be obtained in the electrocatalytic reduction of nitrate in the presence of $Ni_3P_2W_{18}$. Also, the number of accumulated electrons in the polyoxoanion framework at the potential where the transformation of nitrate takes place is large enough for a complete reduction, which supports also the assumption of reduction of intermediates.

The media of pH = 3 and 5 were selected to compare the efficiencies of $Ni_3P_2W_{18}$ and $Mn_2Ni_4P_3W_{24}$, respectively, in the electrocatalytic reduction of nitrate because the latter complex is not very stable at pH = 2. Whatever the pH, $Mn_2Ni_4P_3W_{24}$ was found to be the more efficient of the two complexes: its CAT values were four and seven times larger at pH = 3 and 5, respectively, than those measured for $Ni_3P_2W_{18}$ under the same conditions.

The results for these two complexes were compared with the efficiencies obtained with $Ni_4P_2W_{18}$ and $NiPW_{11}$ in the pH 5 medium where all these complexes are stable. The efficiencies for $Ni_3P_2W_{18}$ and $Ni_4P_2W_{18}$ turned out to be comparable. In contrast, $NiPW_{11}$ shows a negligibly small activity toward the electrocatalytic reduction of nitrate in this medium.

Finally, comparisons of the efficiencies of several Ni-substituted tungstophosphates vis-à-vis the catalytic electroreduction of nitrate suggest that an increase of the number of Ni centres incorporated in stable sandwich-type polyoxoanions has a very beneficial effect.

Concluding Remarks

Several conclusions emerge from this work. The stability of a large variety of Ni-containing sandwich-type polyoxoanions has been investigated by electrochemistry in aqueous media. Such an evaluation is necessary in order to detect those species suitable for solid-state studies. Simul-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

taneously, such a study permits the selection of good candidates for electrocatalysis applications along with the appropriate pH conditions. At least two complexes turned out to be stable over a fairly wide pH domain. To the best of our knowledge such a broad, comparative overview has not been performed previously. The remarkable stability of the Keggin-based $Ni_3P_2W_{18}$ must be emphasised and is reminiscent of that demonstrated by Hill and co-workers for the Wells−Dawson-based triiron analogue.[22] Concerning electrocatalysis perspectives, it is worth noting that reduction of the W centres in the present complexes provides an appreciable electron reservoir under conditions where modification of electrode surfaces does not take place. The accumulated electrons in the HPA framework might therefore be useful for various electrocatalytic processes.

Experimental Section

General Methods and Materials: Pure water was used throughout. It was obtained by passing through a RiOs 8 unit followed by a Millipore-Q Academic purification set. H_2SO_4, Na_2SO_4, HCl, NaCl, $HClO_4$, $NaClO_4$, CH_3CO_2H, CH_2ClCO_2H, CH_3CO_2Na, H_3PO_4, NaH_2PO_4 were of high-purity grade and were used as purchased (Prolabo) without further purification. The UV/Vis spectra were recorded with a Perkin−Elmer Lambda 19 spectrophotometer from 600 to 200 nm using solutions that contained 2.5×10^{-5} M or 4.3×10^{-5} M of the relevant HPA. The measurements were performed in matched 1.000-cm optical-path quartz cuvettes. The preparation and characterisation of $Ni_4H_2PW_9$, Ni_3PW_{10}, $Ni_4P_2W_{18}$, $Ni_9P_3W_{27}$, $Ni_3P_2W_{18}$, and $Ni_4P_4W_{30}$ have already been described in detail.[15,18,19,26,28] The synthesis and characterisation of the novel polyanion $Mn_2Ni_4P_3W_{24}$ are described elsewhere.[27]

Electrochemical Experiments: The same media as for UV/Vis spectroscopy were used for electrochemistry, but the HPA concentration was at least 2×10^{-4} M. All cyclic voltammograms were recorded at a scan rate of 10 $mV \cdot s^{-1}$, unless otherwise stated. The solutions were deaerated thoroughly for at least 30 min with pure argon and kept under a positive pressure of this gas during the experiments. The source, mounting and polishing of the glassy carbon (GC, Tokai, Japan) electrodes has been described previously.[36] The glassy carbon samples had a diameter of 3 mm. The electrochemical setup was an EG & G 273 A driven by a PC with the M270 software. Potentials are quoted against a saturated calomel electrode (SCE). The counter electrode was a platinum gauze of large surface area. All experiments were performed at laboratory temperature.

Investigations on the Reactivity of Bis(bromomagnesio)trimethylsilylmethane – Molecular Structure of a Tebbe-Type Spiro-Organomagnesium Compound

Marijke Hogenbirk,[a,b] Gerrit Schat,[a] Franciscus J. J. de Kanter,[a] Otto S. Akkerman,[a] Friedrich Bickelhaupt,*[a] Huub Kooijman,[c] and Anthony L. Spek[c][‡]

Keywords: Magnesium / Zirconium / Metallocenes / Metallacycles / Structure elucidation

The reactivity of the 1,1-di-Grignard reagent $Me_3SiCH(MgBr)_2$ (**8**) towards transition metal dihalides has been investigated. While most transformations were sluggish and gave no well-defined products, the reaction of **8** with $[Cp_2ZrCl_2]$ in a 1:1 ratio gave, in low yield, the novel spiro-organomagnesium compound $[Cp_2ZrCHSiMe_3(\mu\text{-}Br)]_2Mg$ (**12**), which is stable at room temperature and does not disproportionate on addition of dioxane. An X-ray crystal structure determination has shown that, in the solid state, **12** is present as the C_2 symmetric stereoisomer **12a**; it is sterically very crowded due to the trimethylsilyl substituents. Partial metalla-alkene character is indicated by the short zirconium–carbon bonds, and agostic zirconium–hydrogen interactions by the short zirconium–hydrogen distances (Zr···H–C) and small $^1J_{C,H}$ coupling constants. In benzene solution, equilibrium between **12a** and its C_1 symmetric stereoisomer **12b** was detected by ^1H and ^{13}C NMR spectroscopy.

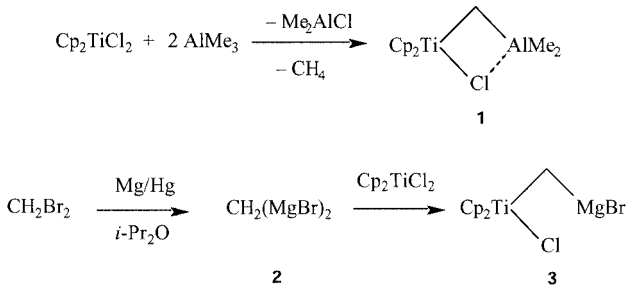
Introduction

Organometallic reagents carrying two metals at the same carbon atom are often not easily accessible, but they are of interest both because of their intriguing structures and their synthetic applications. A well-known example is Tebbe's reagent (**1**), which is conveniently obtained from titanocene dichloride and trimethylaluminium[1] (Scheme 1); it has found application, for example, in Wittig-type olefinations of ketones.[1,2] We have reported the synthesis of **3**,[3,4] the magnesium analogue of **1**, from bis(bromomagnesio)methane (**2**)[3,5–9] and titanocene dichloride. The chemistry of **2** and of other 1,1-di-Grignard reagents has been reviewed.[10–13]



Scheme 1

Like **1** or related 1,1-bismetal-substituted reagents, **3** reacts with alkenes or alkynes to give titanacyclobutanes (**4**) or titanacyclobutenes (**5**), respectively (Scheme 2).[3] Reaction with trimethylphosphane yields the carbene complex **6**.[14] Of special interest here is the elimination of magnesium halide from **3** by evaporation of an ethereal solution followed by dissolution in toluene, which gave, based on its analytical data, $MgBr_2(CH_2TiCp_2)_2$ which was tentatively formulated as the spiro-organomagnesium compound **7**.[4]

Few known derivatives of **2** carry additional substituents at the carbon atom. We previously prepared the mono- and bis(trimethylsilyl)-substituted derivatives **8**[15] and **9**,[16] respectively (Scheme 3). However, silyl substitution stabilizes these di-Grignard reagents considerably. In particular, **9** was extremely sluggish to react even with benzophenone, and attempted reactions with metal dihalides were unproductive. The low reactivity was ascribed both to steric protection and to electronic stabilization of the negatively charged central carbon atom by silicon.[15,16]

Not surprisingly, the reactivity of **8** was intermediate between those of **2** and **9**. Thus, **8** did react with chlorotrimethylstannane; with benzophenone, it gave the expected Wittig-type product 1,1-diphenyl-2-trimethylsilylethene.[15]

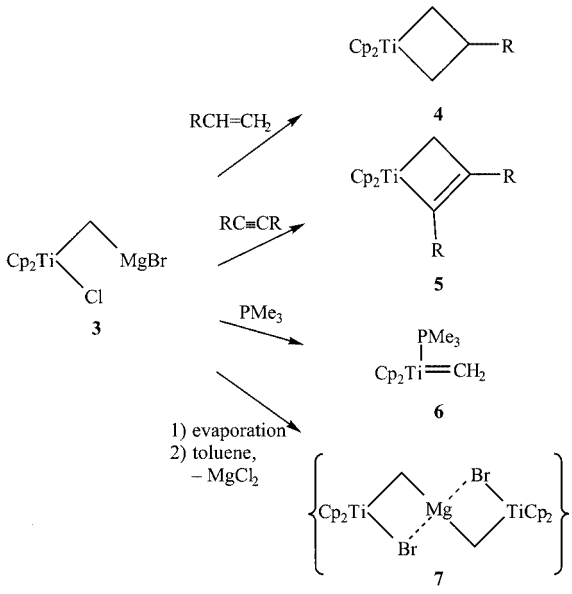
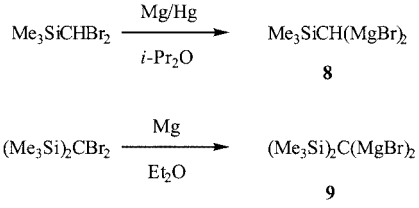


Scheme 2



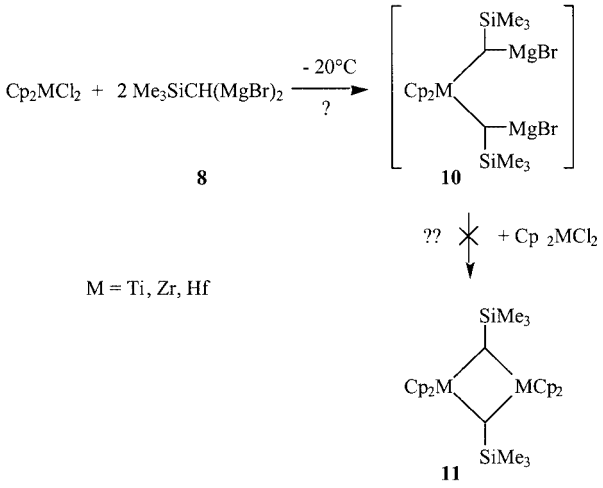
Scheme 3

Thus, we have investigated possible applications of **8**, analogous to those depicted in Schemes 1 and 2, to access the corresponding trimethylsilyl-substituted derivatives.

Results and Discussion

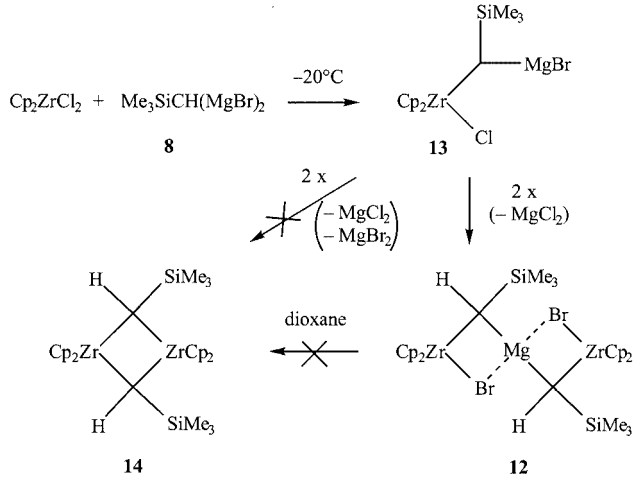
Reactions of $Me_3SiCH(MgBr)_2$ (8)

In analogy to the preparation of 1,3-dimetallacyclobutanes from **2**,[3,10–13] one of our main goals was the reaction of a group 4 metallocene dichloride [Cp_2MCl_2] (M = Ti, Zr, Hf) with **8** in a ratio of 1:2 to obtain the formal 1,3-di-Grignard reagent **10** which was then to be converted with the same (or a different) metal dichloride into the desired 1,3-dimetallacyclobutane **11** (Scheme 4). However, despite considerable efforts, including variation of solvents, reaction conditions etc., complicated reaction mixtures were obtained; even attempted interception of **10** with chlorotrimethylgermane did not furnish clear-cut results.



Scheme 4

In contrast, the reaction of [Cp_2ZrCl_2] with **8** in a 1:1 ratio gave an unforeseen product; after workup and purification, **12** was isolated by crystallization from a saturated toluene solution upon standing at room temperature for several weeks. The yield was low; the ^1H NMR spectrum of the crude product revealed several other compounds that could not be identified. A possible reaction pathway via the "Tebbe-type" reagent **13** is depicted in Scheme 5.



Scheme 5

Although there is no direct evidence for the occurrence of **13**, we assume it is formed by substitution of one of the chlorides of zirconocene dichloride by one of the two organomagnesium functions of **8**. Possibly, in the process of evaporating the reaction mixture and extracting the residue with toluene, **13** undergoes a partial "Schlenk equilibrium" by elimination of $MgCl_2$. Remarkably, the expected second Schlenk equilibrium step under elimination of $MgBr_2$ to furnish the 1,3-dizirconacyclobutane **14** does not proceed, neither from **13** nor from **12**. The latter reaction was tried separately by addition of dioxane to a solution of previously isolated **12**; however, **12** remained unchanged.

Molecular Structure of $[Cp_2ZrCHSiMe_3(\mu\text{-}Br)]_2Mg$ (12) in the Crystal

From a saturated solution of **12** in toluene, crystals were obtained after standing for two months at room temperature. The pale yellow-orange rectangular crystals were collected and transferred to Lindemann-glass capillaries under a nitrogen atmosphere; the capillaries were then sealed by melting off. The X-ray crystal structure was determined (Figure 1). Selected bond lengths, nonbonded contacts, bond angles, and torsion angles are presented in Table 1−4, respectively.

Table 1. Selected bond lengths of **12**

[a]	Bond length [Å]		Bond length [Å]
Zr(1)−Cp(1)[a]	2.227(4)	Mg−Br(1)	2.672(3)
Zr(1)−Cp(2)[a]	2.239(4)	Mg−Br(2)	2.626(3)
Zr(2)−Cp(3)[a]	2.236(5)	Mg−C(11)	2.188(8)
Zr(2)−Cp(4)[a]	2.222(5)	Mg−C(25)	2.188(8)

Cp(3)··Zr(1)··Cp(4)	128.76(19)		

Although the distances and angles in the two four-membered 1,3-metallacycles that constitute **12** are not equal, the compound has nearly C_2-symmetry. The "C_2"-axis passes through magnesium, perpendicular to the Zr(1)−Zr(2) vector, bisecting the Br−Mg−Br angle. As discussed below, in solution, **12** occurs as two equilibrating stereoisomers, **12a** and **12b**. Presumably, **12a** corresponds to the crystal structure, the only difference being that it *does* possess perfect C_2-symmetry, presumably due to time averaging.

Complex **12** is solvent-free, so the magnesium atom is not stabilized by coordinating diethyl ether molecules! This situation is unknown for monomeric organomagnesium compounds; rather, unsolvated organomagnesium compounds tend to crystallize in the form of polymeric ladder-type structures.[17,18] Nevertheless, the magnesium does show the usual tetracoordination with two carbon atoms and two bromine atoms forming the coordination sphere. The geometry around magnesium is distorted tetrahedral, the smallest angle being C−Mg−Br in the four-membered

rings [92.2(2) and 93.9(2)], the largest one C(11)−Mg−C(25) (132.6°).

Crowding due to the trimethylsilyl substituents at the methine carbon atoms in combination with the cyclopentadienyl ligands at the zirconium atoms appears to be a prominent feature in the structure of **12**. The *trans*-orientation of the trimethylsilyl substituents reduces the crowding. They stick in between the neighboring cyclopentadienyl rings such that they minimize close contacts with these ligands. In addition, the Zr−C−Si angles are very large (average 140°). As a result, the silicon−carbon bonds form relatively small angles with the average planes of their metallacycle, as evidenced by the torsion angles Si(1)−C(11)−Mg−Br(1), Si(1)−C(11)−Zr(1)−Br(1), Si(2)−C(25)−Mg−Br(2), and Si(2)−C(25)−Zr(2)−Br(2) of 173.5(3)°, −158.6(6)°, 163.2(3)°, and −148.8(6)°, respectively; consequently, the trimethylsilyl substituents are close to the (approximate!) plane of the four-membered rings to which they are attached. However, the close Zr−Si contacts of 3.76 Å (Table 2, mean value) indicate that a really favorable orientation is not achieved as the sum of their contact radii is 4.46 Å. Due to this steric repulsion, the cyclopentadienyl groups are not bonded symmetrically to the zirconium atoms; the Zr−C(Cp) distances range from 2.48 to 2.56 Å.

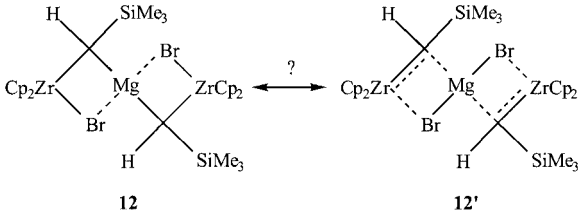
Apparently, the sterically demanding trimethylsilyl groups also influence the geometry of the two four-membered rings. Firstly, these rings are not planar, as evidenced by the torsion angles Zr(1)−Br(1)−Mg−C(11) of −15.3(2)° and Zr(2)−Br(2)−Mg−C(25) of −10.4(2)°; in contrast, the four-membered ring is planar in the neopentyl-substituted Tebbe reagent $Cp_2ZrCH(CH_2CMe_3)AlCl$[19] (i.e. the zirconium derivative of **1**, in which the methylene group is substituted by the sterically *even more demanding* neopentyl group). Secondly, the two rings are not oriented orthogonally with respect to each other, as indicated by the angle of 85.53(17°) between their average planes. Finally, the axes of these average planes are bent towards each other, the Zr−Mg−Zr angle being 157.09(9)°. Despite these strong steric interactions **12** is, remarkably, thermally quite stable.

In addition to its rather unique spiro-Tebbe character, a closer analysis of the data for **12** reveals an intriguing duality of structural features. At first sight, **12** might be described as a dialkylmagnesium compound. This is in line with the seemingly normal Mg−C bond lengths of 2.188(8)Å, the usual range being 2.17−2.19Å.[17,18] In addition, the wide C−Mg−C angle of 132.6(3)° falls within the normal range (120−140°). Bonds to more electronegative ligands such as oxygen are smaller than tetrahedral; here, the negative ligand is bromine, and the Br−Mg−Br angle of 103.80(9)° fits into the general trend.

However, the Zr−C bonds [2.147(7) and 2.160(7)Å] are ca. 0.15 Å shorter than those in related compounds with "normal" σ-bonds between zirconium(IV) and sp^3-hybridized carbon atoms {[$Cp_2ZrMeCl$]: 2.35 and 2.36 Å;[20] [Cp_2ZrMe_2]: 2.280(5) and 2.273(5) Å;[20] [$Cp_2Zr\{CH(SiMe_3)_2\}Ph$]: 2.329(6)[21]}. Even the Zr−C bond in [$Cp_2Zr(\mu\text{-}\eta^1,\eta^2\text{-}Me_3SiCCPh)(\mu\text{-}Cl)AlMe_2$], in which an sp^2-hybridized carbon is σ-bonded to zirconium, is slightly longer [2.186 (3) Å].[22] The repulsion between the trimethylsilyl groups and the cyclopentadienyl ligands would be expected to lengthen the Zr−C bond.[21] We explain these short Zr−C bonds by invoking a certain amount of metalla-alkene character. A partial double bond will shift the hybridization of carbon from sp^3 towards sp^2 with concomitant bond shortening; in addition, the bond may be shortened by hyperconjugative interactions with silicon.[16] In addition, the Zr−C−Si angle will increase and so create more space for the trimethylsilyl groups; indeed, the Zr−C−Si angle is large [141.8(4)° and 138.6(4)°]. Conversely, the Zr−Br bond lengths are long (Zr1−Br1: 2.7232(11)Å, Zr2−Br2: 2.7236(11)Å]; most Zr−Br bonds are about 2.60 Å. We found only one other example of a long Zr−Br bond involving tetracoordinate zirconium: [$Cp_2ZrBr\{C(SiMe_3)=CHPh)\}$][23] [2.721(1) Å]. All this structural information suggests a description in terms of a loose complex **12′** between [$Cp_2Zr=CHSiMe_3$] and $MgBr_2$ (Scheme 6).

However, the situation is not so clear cut. The metalla-alkene/Lewis-acid character in "Tebbe-type" reagents such as **1**, involving titanium and zirconium in combination with

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 6

aluminium, has been discussed on the basis of NMR spectroscopic data, reactivity patterns, and theoretical calculations.[19,25–27] The general conclusion is that the metal–carbene character is not very pronounced for titanium and even less so for zirconium.

As indicated above, the Mg–C bond lengths of 2.188(8) Å seems to fit better with **12** as a dialkylmagnesium.[17,18] For a loose interaction as in **12′**, the bond would be expected to be even longer, and this effect should be enhanced by steric congestion. However, these observations may be interpreted differently by looking at the structure of **9** $[(MeSi_3)_2C(MgBr{\cdot}2THF)_2]$[16] which has rather short Mg–C bonds (2.10–2.14 Å), even though two large trimethylsilyl groups and two large MgBr·2THF functions exert considerable steric pressure around the central carbon. Electrostatic effects which find their origin in the substitution of carbon by four electropositive elements (2 magnesiums, 2 silicons) have been invoked to explain the short Mg–C bonds in **9**.[16] With **12′**, similar factors might play a role, though to a lesser extent: the inherently loose interaction between magnesium and carbon is partly stabilized by polarizing effects due to zirconium and silicon. Conversely, the chemical shift of the bridging carbon in the four-membered ring, $\delta(^{13}C)$ = 153.7 ppm, is not indicative of strong metalla-alkene character, which is usually concomitant with a much more deshielded shift, as illustrated by the Ti=*C*H_2 carbon in **6** with $\delta(^{13}C)$ = 285.2 ppm.[14] The slightly elongated Mg–Br bonds (average 2.65 Å) are compatible with both **12** (μ-bridging between two metals)[17,18] and **12′** (loose interaction of $[Cp_2Zr{=}CHSiMe_3]$ with the Lewis acid $MgBr_2$).

A thorough theoretical analysis is clearly required, which was beyond the scope of the present investigation. From of the qualitative arguments discussed here, we propose that the structure of the compound is intermediate between the two extreme models, which is indicated by the resonance relation depicted in Scheme 6; apparently, **12** is preponderant, but contributions from **12′** are clearly indicated.

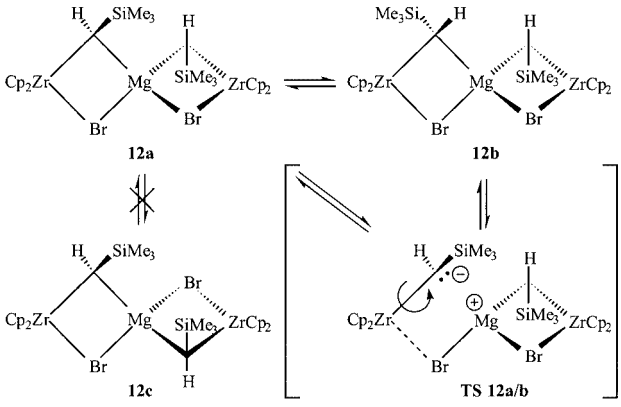
Another aspect to discuss briefly is a weak agostic interaction[24,25] between zirconium and the α-CH bond; **12** has short M···H distances and small $^1J_{C,H}$ coupling constants, both of which are characteristic of M···H–C agostic interactions. The Zr···H distances [2.496(7) and 2.546(7) Å] are more than 1 Å shorter than the sum of their contact radii, and $^1J_{C,H}$ = 91.4 Hz is small, though in the upper range for sp^3-hybridized agostic systems (60–90 Hz).

However, two caveats seem appropriate. First, the positions of the α-hydrogens – as light atoms next to the heavy zirconium – were restrained during refinement. Although the C–H moiety as a whole was allowed to reorient itself, the C–H bond was fixed at the ideal value of 0.98 Å. This makes the position of these hydrogens slightly less reliable. Typical β-agostic contacts are shorter, as exemplified by *d*(Zr···H) = 2.19 Å in $[Cp_2ZrBr(CSiMe_3{=}CHPh)]$.[23] Even so, the Zr···H contacts in **12** indicate a weak agostic interaction. Secondly, with regard to the small $^1J_{C,H}$ = 91.4 Hz, one has to consider that substitution of an sp^3-hybridized carbon by electropositive elements increases the s-character in the C–M bonds, and thus reduces s-contribution to the C–H bonds. For instance, we observed $^1J_{C,H}$ = 104.4 Hz for the joint effect of magnesium and silicon in Me_3Si-CH_2MgBr, while the additional silicon in $(Me_3Si)_2$-CHMgBr (**8**) further decreases $^1J_{C,H}$ to 93.1 Hz. However, against this background, it is unlikely that the small $^1J_{C,H}$ = 91.4 Hz of **12** can be fully accounted for by the effect of only three electropositive substituents on carbon (Mg, Zr, Si).

Finally, the X-ray crystal structure of **12** supports the previously suggested hypothetical assignment[4] of an analogous spiro-magnesium structure to **7** (Scheme 2).

Structure of 12 in Solution

Crystals of **12** dissolved in C_6D_6 for NMR analysis showed two species, **12a** and **12b**, in equilibrium; directly after dissolution, **12a** was the dominant species. Its simple ^{1}H NMR spectrum is indicative of C_2 symmetry: δ = 7.43 (s, 2 H, C*H*), 6.09 (s, 10 H, Cp), 5.94 (s, 10 H, Cp), 0.43 (s, 18 H, $SiMe_3$) ppm. Such a spectrum is also in line with the C_2 symmetric structure **12c** (Scheme 7). The immediate appearance of this spectrum after dissolving crystals of **12**, which have been proven to have the (approximate) C_2 structure (Figure 1), strongly suggests that the species in solution is **12a**; its ideal C_2 symmetry must be due to rapid time averaging. This structure assignment is further supported by inspection of models that reveal that the alternative conceivable C_2 isomer **12c** would experience severe steric hindrance because it has two trimethylsilyl groups at the two four-membered rings that point directly towards each other.



Scheme 7

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Compound **12b** is, apparently, an isomer of **12a**, but it has C_1 symmetry, as evidenced by two methine proton signals [δ = 7.80 and 7.17 ppm (2 s, 2 H)], four cyclopentadienyl signals at δ = 6.14, 6.04, 5.95 and 5.94 ppm (4 s, 20 H) and two trimethylsilyl signals at δ = 0.43 and 0.40 ppm (2 s, 18 H). The isomeric relation is in line with the chemical shifts of **12b** all being in the same range as the corresponding signals of **12a**; moreover, **12b** must contain a $MgBr_2$ unit because this species could not be removed from the solution on treatment with THF or dioxane, and free $MgBr_2$ would have precipitated in C_6D_6.

As mentioned above, crystals of **12**, when dissolved in C_6D_6, formed a mixture of **12a** and **12b** where the initial concentration of **12b** was very low. After standing for several days at room temperature, an equilibrium ratio of **12a/12b** = 1.14 was reached. At higher temperatures, the amount of **12a** increased (Table 5); this change was reversible. Below room temperature, the composition of the mixture showed no further changes; apparently, the rate of isomerization was too low.

Table 5. Equilibrium constants and equilibration times of **12a/b** in C_6D_6

T (K)[a]	K (**12a/12b**)	Equilibrium time[b]
293	1.14	several days
313	4.33	50 h
328	4.91	8.5 h
343	4.29	4 h

[a] Equilibrium constants K are based on the integrals of the cyclopentadienyl groups in the ^{1}H NMR spectra. [b] Time required to reach equilibrium when dissolving **12** at 293 K and warming to the temperature cited.

A pathway for the interconversion between **12a** and **12b** is tentatively proposed (Scheme 7). Formally, the transformation involves the interchange of the orientation of H and Me_3Si in one of the two four-membered rings (shown for the left ring in Scheme 7). The process must be intramolecular as the reactive metalla-alkene units could not be liberated by coordination of magnesium bromide upon addition of dioxane. Furthermore, the position of the equilibrium is concentration independent; at 313 K, in a separate experiment with a diluted solution of the **12a/b** mixture, the same reaction rate and equilibrium constant as in the undiluted experiment were found. We propose that, in **12a** or **12b**, one of the carbon−magnesium bonds is cleaved such that the formal $Cp_2Zr-CHSiMe_3^-$ substructure can rotate around the Zr−C bond, followed by reclosure of the C−Mg bond; simultaneous cleavage of the Zr−Br bond, with formation of the more or less free metalla-alkene [$Cp_2Zr{=}CHSiMe_3$], can be excluded as it should lead to decomposition with formation of free $MgBr_2$ and dimerization of [$Cp_2Zr{=}CHSiMe_3$] to give **14** (Scheme 5).

The temperature dependence of the equilibrium between **12a** and **12b** was studied by ^{1}H NMR spectroscopy with a sample in a sealed NMR tube (Table 5); at higher temperatures, the equilibrium shifted in favor of **12a**. Consequently, we expected the highest **12a/b** ratio at 343 K, but this was not observed. It is not clear what caused this deviation as the compounds did not decompose; for several measurements of the same NMR sample at higher temperatures the **12a/b** ratio returned to the initially determined K of 1.14 at 20°C. In view of this anomaly, the interpretation of these results must remain speculative and we refrain from a quantitative analysis; however, some qualitative conclusions may be justified. Thus, **12b** appears to be enthalpically more stable than **12a**. This seemed surprising as, intuitively, one would assume that **12a** with its two bulky trimethylsilyl groups *trans* at the two four-membered rings will experience less steric hindrance than **12b**, where they are somewhat closer; however, inspection of models suggests that in both isomers the trimethylsilyl groups do not interfere directly with each other. Conversely, the trimethylsilyl groups of **12b** can adopt a favorable position between the bulky cyclopentadienyl groups with less distortion of the two four-membered rings, and less concomitant strain, than those of **12a**. In contrast, the reaction entropy appears to favor **12a**; given the close similarity of the two isomers, we have at present no satisfactory explanation for this effect.

Conclusion

In line with earlier results on the reduced reactivity of organomagnesium reagents that carry electropositive substituents at the organometallic carbon atom,[15,16] the 1,1-di-Grignard reagent $Me_3SiCH(MgBr)_2$ (**8**) reacts sluggishly with transition metal dihalides and, mostly, gave no well-defined products. An exception is the reaction of **8** with [Cp_2ZrCl_2] (1:1) which, in low yield, furnished the novel spiro-organomagnesium compound [$Cp_2ZrCHSiMe_3(\mu\text{-}Br)]_2Mg$ (**12**). Compound **12** is stable at room temperature and does not disproportionate on addition of dioxane. An X-ray crystal structure determination showed that, in the solid state, **12** is present as the C_2 symmetric stereoisomer **12a**; it is sterically very crowded due to the trimethylsilyl substituents. Partial metalla-alkene character is indicated by the short zirconium−carbon bonds, and agostic zirconium−hydrogen interactions by the short zirconium−hydrogen distances (Zr···H−C) and small $^1J_{C,H}$ coupling constants. In benzene solution, an equilibrium between **12a** and its C_1 symmetric stereoisomer **12b** was detected by ^{1}H and ^{13}C NMR spectroscopy.

Experimental Section

General Remarks: Experiments with **8** and **12** were performed using high-vacuum sealed glass apparatus.[26] Solvents were dried before use by distillation from a liquid Na−K alloy. For spectroscopy, the solvent was first removed from a sample by distillation with liquid nitrogen, followed by evacuation; subsequently, the residue was redissolved in a deuterated solvent in a high-vacuum system and, finally, the NMR tube was sealed. NMR spectra were measured with a Bruker WM 250 spectrometer. GCMS analysis was per-

formed on a Hewlett Packard 5890 GC/5970 MS combination with a 50 m Chrompack CP Sil 5 column.

2,2,6,6-Tetracyclopentadienyl-3,7-bis(trimethylsilyl)-1,5-dibroma-4-magnesa-2,6-dizirconaspiro[3.3]heptane (12): In a sealed glass vessel, **8**[15] (0.202 mmol) was dissolved in 2-methyltetrahydrofuran (10 mL). [Cp_2ZrCl_2] (59 mg, 0.202 mmol) was then added to this solution at −20 °C, resulting in a colorless solution. After 50 min stirring at −20 °C, the mixture was still colorless and homogeneous. The vessel was then warmed to +5 °C and, after 25 min, the mixture turned light yellow. Subsequently, the vessel was warmed and kept at room temperature for 4 h. The reaction mixture was yellow, and no precipitation was observed. After a further 17 h at room temperature, the solution became yellow-brownish. The solvent was then removed by distillation and pumping. The resultant residue was partly crystalline, partly oily. It was extracted with toluene to give a brownish solution, which was decanted from the precipitate of salts. Attempts to prepare crystals on cooling this solution (at −10 °C or −80 °C) failed. Toluene was removed by distillation into a vessel cooled by liquid nitrogen; a yellow oil was left in which crystals formed after several weeks. These were then washed with hexane; the light yellow hexane solution was decanted. The residue was made solvent free by distillation with liquid nitrogen and then toluene was added. Some precipitate (probably magnesium salts) formed, and the solution was decanted. After several further weeks at room temperature, a few pale yellow-orange crystals precipitated from this solution; they were used for X-ray crystal structure determination and for NMR measurements. The mother liquor, which contained mainly **12** (NMR analysis), was treated with dioxane. A small amount of a white precipitate ($MgBr_2$) formed, but NMR analysis of an aliquot revealed that no apparent change had taken place. **12a:** ^{1}H NMR (250 MHz, C_6D_6, ref.C_6D_5H δ = 7.17 ppm): δ = 7.43 (s, 2 H, methine), 6.09 (s, 10 H, Cp), 5.94 (s, 10 H, Cp), 0.43 (s, 18 H, Me) ppm. ^{13}C NMR (62.9 MHz, C_6D_6, ref.C_6D_6 δ = 128.0 ppm): δ = 153.3 (d, $^1J_{C,H}$ = 91.4 Hz, methine), 111.4 (dquint., $^1J_{C,H}$ = 172.5, $J_{C,H}$ = 6.9 Hz, Cp), 110.1 (dquint., $^1J_{C,H}$ = 173.1, $J_{C,H}$ = 6.8 Hz, Cp), 6.4 (q, $^1J_{C,H}$ = 117.2 Hz, Me) ppm. **12b:** ^{1}H NMR (250 MHz, C_6D_6, ref.C_6D_5H δ = 7.17 ppm): δ = 7.80 (s, 1 H, methine), 7.17 (s, 1 H, methine), 6.14 (s, 5 H, Cp), 6.04 (s, 5 H, Cp), 5.95 (s, 5 H, Cp), 5.94 (s, 5 H, Cp), 0.43 (s, 9 H, Me), 0.40 (s, 9 H, Me) ppm. ^{13}C NMR (62.9 MHz, C_6D_6, ref.C_6D_6 δ = 128.0 ppm): δ = 152.5 (d, $^1J_{C,H}$ = 88.5 Hz, methine), 145.6 (d, $^1J_{C,H}$ = 90.3 Hz, methine), 111.8 (dquint., $^1J_{C,H}$ = 172.7, $^1J_{C,H}$ = 6.7 Hz, Cp), 111.5 (dquint., $^1J_{C,H}$ = 173, $J_{C,H}$ = 7 Hz, Cp), 110.7 (dquint., $^1J_{C,H}$ = 173.2, $J_{C,H}$ = 6.8 Hz, Cp), 109.9 (dquint., $^1J_{C,H}$ = 173.1, $J_{C,H}$ = 6.7 Hz, Cp), 6.9 (q, $^1J_{C,H}$ = 117.2 Hz, Me), 6.2 (q, $^1J_{C,H}$ = 117.2 Hz, Me) ppm.

X-ray Crystal Structure Determination of 12: $C_{28}H_{40}Br_2MgSi_2Zr_2$. M = 799.35, pale orange crystal, 0.21 × 0.23 × 0.40, monoclinic, space group $P21/c$ (no. 14) with a = 14.7539(5), b = 12.3679(4), c = 17.8513(7) Å; β = 93.83(3)°, V = 3250.1(2) Å^3, Z = 4, $\rho_{calcd.}$ = 1.633 g·cm^{-3}, $F(000)$ = 1592, μ(Mo-K_α) = 3.17 mm^{-1}. Of the 9029 reflections measured on an Enraf−Nonius CAD4-T diffractometer, on a rotating anode [λ(Mo-K_α) = 0.71073 Å, T = 295 K, $\theta_{max.}$ = 27.5°], 7430 were unique (R_{int} = 0.029); 4477 reflections with $I > 2.5\sigma(I)$ were used in the structure solution and refinement. Application of empirical and analytical absorption correction algorithms on the measured data had no significant effect. A final model without absorption correction was therefore preferred. The structure was solved with Patterson methods (SHELXS-86[27]); 317 parameters were refined with SHELX-76,[28] including anisotropic displacement parameters for all non-hydrogen atoms. Hydrogen atoms were placed at calculated positions, riding on their carrier atoms, with the exception of hydrogen atoms bonded to C11 and C25 (the carbon atoms bonded to Mg, Br, and Zr). The coordinates of these hydrogen atoms were allowed to refine, albeit that the C−H bond length was constrained to the ideal value of 0.98 Å. Final figures of merit are R = 0.054, R_w = 0.073, S = 2.94. Residual density was in the range −1.34, 1.13 e·Å^3. CCDC-222722 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Oxidative Addition of RX to Soluble and Polymer-Bound Molybdenum Carbonyl Complexes

Katja Heinze,*[a] Volker Jacob,[a] and Christian Feige[a]

Keywords: Allyl Ligands / Molybdenum / Polymer-bound complexes / Solid-phase synthesis

Oxidative addition of $PhSnCl_3$ or allyl halides to molybdenum tetracarbonyl complexes proceeds both in solution and on polymer matrices. The structures of the soluble Mo^{II} complexes have been determined by single-crystal X-ray diffraction in the solid state and by NMR and IR spectroscopy in solution. The identity and stability of the polymer-bound complexes have been elucidated by spectroscopic techniques directly on the solid support and by releasing the complexes from the support.

Introduction

Homogeneous organometallic catalysis has several advantages over heterogeneous catalysis as the activity and selectivity can be tuned by the choice of suitable ligands. On the other hand soluble catalysts are more difficult to separate and to handle than the technically well-established heterogeneous ones. A promising strategy to combine the advantages of both catalyst types is the immobilisation of active metal complexes on supports, which can be separated by filtration. However, many of the heterogeneous systems are very difficult to characterise and are not well understood. Improved characterisation should lead to better reproducibility, whereas understanding on a molecular level, if possible, can help to improve existing concepts and to develop new catalytic systems.[1] This is even more important as some stoichiometric and catalytic reactions performed on polymer matrices give different results from the reactions performed in a homogeneous phase.[2] A polymer matrix can confer higher stability to reactive intermediates,[3,4] can stabilise catalytically active species ("site isolation" effect [5−7]) and thus lead to higher activity, but can also reduce catalyst activity and influence catalyst selectivity,[8] even enantioselectivity.[9] Thus it is desirable to identify and control the species bound to the polymer support.

As part of our program to synthesise and characterise metal complexes bound to a solid support[10−12] we investigated the transformation of polymer-bound Mo^0 complexes to Mo^{II} complexes by oxidative addition of RX and elimination of carbon monoxide. The oxidative addition of RX to Mo^0 is one of the first steps in the synthesis of the precatalyst of the molybdenum(0)-catalysed allylic alkylation developed by Trost et al.[13−15] This catalytic reaction has become an important tool in asymmetric organic synthesis. Control of catalyst regioselectivity and enantioselectivity has been achieved by designing suitable ligands and using suitable metal catalyst precursors.[13−16] Microwave flash heating has been employed to improve catalyst activity and the immobilisation of the nucleophile on a solid support has been reported.[17] An allylpalladium phosphane complex has been anchored to a polystyrene/poly(ethylene glycol) graft copolymer and has been used for the palladium-catalysed allylic substitution.[18] An allylmolybdenum complex has been synthesised on a solid support and released from the solid phase for biolabelling purposes.[19]

The solid-phase reaction system employed here allows the synthesis of metal complexes on an insoluble polystyrene/divinyl benzene copolymer, the transformation of these complexes on the support and finally release of the product complexes from the support under mild conditions to prove their identity and integrity.[11,12]

Results and Discussion

The Solid-Phase Synthesis of 3a−6a via 3b−6b and Solution Synthesis of 3a−6a

For the solid-phase synthesis the bidentate Schiff-base ligand **1a** was attached to polystyrene/2% divinyl benzene by a silyl ether linker to yield the immobilised ligand **1b** (Scheme 1).[10−12] This silyl ether can be cleaved by fluoride ions under mild conditions compatible with metal complexes.[11,12]

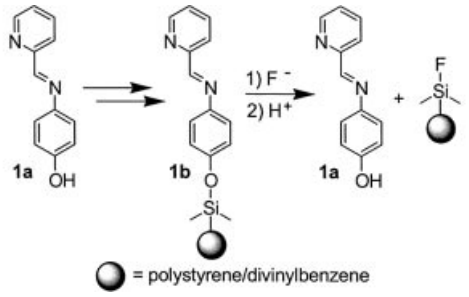
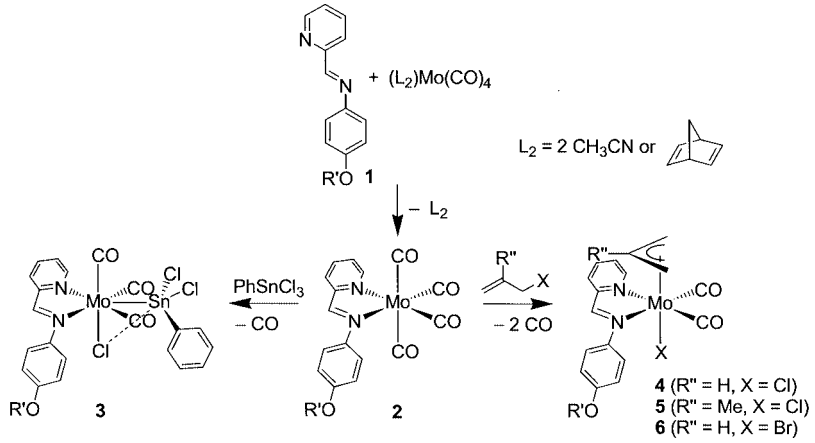


Scheme 1. Immobilisation of ligand **1a** and release of **1a** from the polymer

Solid-State Structures of 3a·Et_2O, 4a·THF, 5a·THF and 5a

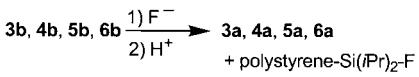
The heterobimetallic complex **3a** crystallises in the monoclinic space group $P2_1/c$ with inclusion of one diethyl ether molecule (Figure 1, Table 1). The solvent molecule is attached to the complex by an O−H···O hydrogen bond (O1···O100 2.74 Å). Hydrogen bonds from the hydroxy group of the Schiff-base ligand to solvent molecules have been previously observed.[20] The molybdenum atom is seven-coordinate and the tin atom is five-coordinate with one chlorine atom occupying a bridging position between the two metal atoms. The coordination geometry around



Scheme 2. Solid-phase and solution syntheses of **3**−**6** [a: R′ = H; b: R′ = polystyrene−Si(*i*Pr)$_2$]

The synthesis of Mo^{II} complexes from Mo^0 complexes on the solid phase and in solution is depicted in Scheme 2. The tetracarbonyl complexes **2a** and **2b** were prepared from the soluble ligand **1a** or the immobilised ligand **1b** and an $Mo(CO)_4$ source.[11] Oxidative addition of RX gives the seven-coordinate heterobimetallic complexes **3a** and **3b** with concomitant loss of one equivalent of carbon monoxide (RX = $PhSnCl_3$)[11] and the allyl complexes **4a**−**6a** and **4b**−**6b** [RX = CH_2CHCH_2Cl, $CH_2C(CH_3)CH_2Cl$, CH_2CHCH_2Br] with loss of two equivalents of carbon monoxide.

Release of the immobilised complexes from the solid support is accomplished by fluoridolysis of the silyl ether linker followed by protonation of the anionic complexes with acetic acid (Scheme 3).



Scheme 3. Cleavage of the complexes from the solid support

All soluble complexes **3a**−**6a** have been completely characterised by spectroscopic methods and the solid-state structures of **3a**−**5a** have been determined by X-ray crystallography. The immobilised complexes **3b**−**6b** have been analysed by IR spectroscopy, diffuse reflection UV/Vis spectroscopy and thermogravimetric analysis.

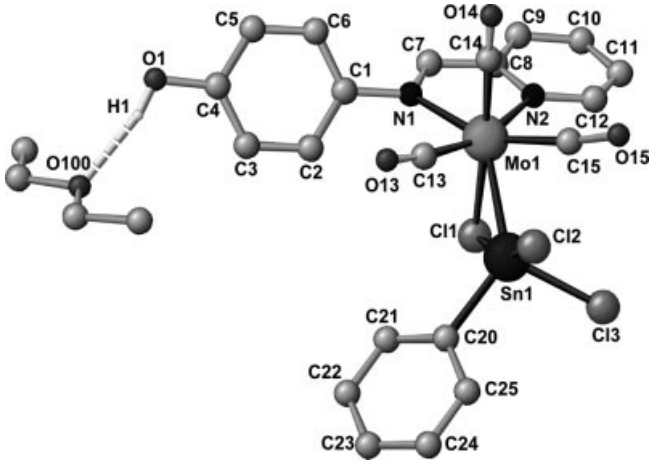


Figure 1. Structure of 3a·Et_2O in the solid state

molybdenum can be described as capped octahedral with the tin atom occupying the seventh position above an octahedral face defined by the bridging chloride Cl1 and two carbon atoms (C13 and C15). The angles between the atoms defining the capped face are larger (104−109°) than the angles between the atoms defining the opposite triangular face (73−96°). Thus, the octahedral symmetry is distorted to accommodate the seventh ligand — similar to the structure of [(bpy)Mo(CO)$_3$Cl(SnCl$_2$CH$_3$)].[21]

The allyl complex **4a** crystallises in the monoclinic space group $P2_1/c$ with inclusion of one THF molecule. Unlike the structure of **3a** the solvent molecule is isolated from the molybdenum complex. Instead, the hydroxy group of the ligand forms a hydrogen bond to the chloro ligand of a neighbouring molecule (Figure 2). The molecules are thus connected by O−H···Cl hydrogen bonds (O1···Cl1 3.12 Å) and form a chain consisting of alternating enantiomeric complexes along the *c*-axis (*c* glide plane).

The methallyl complex **5a** can be crystallised with and without inclusion of solvent molecules (**5a**·THF and **5a**). In the former pseudo-polymorph the THF molecule is isolated from the complex molecules which are connected by O−H···Cl hydrogen bonds (O1···Cl1 3.15 Å) to give the same motif as the allyl complex **4a** with the chain going along the crystallographic *n* axis. (Figure 3).

The solvent-free pseudo-polymorph of **5a** also displays an O−H···Cl hydrogen bonding motif (O1···Cl1 3.12 Å, Figure 4). Here the complexes form a helix along the crystallographic twofold axis and thus the helices consist of molecules with like stereochemistry (homochiral chain). A further difference is observed for the orientation of the OH group of the ligand in the pseudo-polymorphs **5a**·THF and **5a**: in the former structure the OH bond points away from the metal centre (torsion angle C3−C4−O1−H1 −178.7°, Figure 3) and in the latter it points towards the metal centre (torsion angle C3−C4−O1−H1 −1.2°, Figure 4) as a consequence of the arrangement of the molecules. Obviously the mere presence (**4a**·THF, **5a**·THF) or absence of solvent molecules (**5a**) controls the hetero- or homochirality of the chains without affecting the mode of connection. The O−H···Cl hydrogen bond indeed appears to be the most stable one in this system as no hydrogen bonds between the OH group and solvent molecules {as found for example for **3a** or [(**1a**)$Mo(CO)_3(PPh_3)$]·Et_2O[20]} or metal-bound carbonyl groups [as found for example in complexes {[(**1a**)$M(CO)_3(CNR)$];[20,22] M = Cr, Mo, W} are observed. DFT calculations for **4a** and **5a** with a water molecule (as a model hydrogen donor) hydrogen-bonded to chloride, to the carbonyl ligands, and to the hydroxo group show that the first hydrogen-bonded system is the most stable (although the calculated relative energies might not be be very accurate due to the basis set superposition error BSSE,[23] see Supporting Information).

Properties of 3a, 4a, 5a and 6a

The hydrogen bonding present in the solid-state structures of **3a**, **4a** and **5a** is also confirmed by the signals of the ν_{OH} vibrations at 3444, 3265 and 3256 cm^{-1} in the IR spectra. For the bromo derivative **6a** this band is found at 3173 cm^{-1} which also indicates a hydrogen-bonded structure in the solid state.

Complex **3a** shows three ν_{CO} absorption bands both in solution (Figure 5) and in the solid state, at similar energies, proving that only one isomer is present in solution which most likely has the same geometry as in the solid state (Figure 1).

The signals of the symmetric and asymmetric carbonyl stretching vibrations of the allyl complexes **4a**−**6a** are found at around 1950 and 1874 cm^{-1} (Table 2) at similar energies to the signals of complexes with phenanthroline ligands where the bidentate ligand occupies two equatorial positions, but at considerably higher energies than the sig-

nals of complexes where the bidentate ligand occupies one equatorial and one axial position.[24] Thus the IR data suggest that **1a** exclusively coordinates at two equatorial positions in **4a**−**6a** in solution.[24,25]

For the allyl complexes **4a**−**6a** the symmetric and asymmetric carbonyl stretching vibrations are shifted slightly to lower energy in the solid state than in solution (Table 2; $\Delta\tilde{\nu}_{sym/asym}$ = 3/6, 7/11 and 14/11 cm^{-1} for **4a**, **5a** and **6a**). The same shift is predicted by DFT calculations on **4a** and **5a** upon addition of a water molecule hydrogen bonded to the chloro ligand — $\Delta\tilde{\nu}_{sym/asym}$ = 5/9 and 5/10 cm^{-1} for **4a** and **5a**, respectively — explaining the shift by the hydrogen bond to the rather remote chloro ligand. For hydrogen bonds to metal-coordinated carbonyl groups larger shifts are observed experimentally and predicted theoretically[20,22] (for water attached to carbonyl groups of **4a** and **5a** $\Delta\tilde{\nu}_{sym/asym}$ = 9−10/30−36 cm^{-1} are calculated, see Supporting Information).

5a	1951, 1874[d]	1944, 1863[d]	3256
6a	1952, 1874[d]	1938, 1863[d]	3173

[a] In THF. [b] In CsI. [c] Totally symmetric vibration of all three CO ligands, symmetric vibration of the equatorial CO ligands, asymmetric vibration of the equatorial CO ligands, respectively. [d] Symmetric vibration of the equatorial CO ligands, asymmetric vibration of the equatorial CO ligands, respectively.

In the UV/Vis spectra all complexes display π-π* transitions of the Schiff-base ligand at around 356 nm (Figure 6, Table 3). The seven-coordinate complex **3a** has an MLCT absorption band at λ = 474 nm and is irreversibly reduced at E = −850 mV (Table 3). The allyl complexes **4a**−**6a** show MLCT absorption bands between 500 and 620 nm (Figure 6). The allyl and halide ligands influence the energy of the MLCT absorption according to their electron-donating and -withdrawing properties. The same consideration applies for the potentials of the metal-centred oxidations, as **5a** and **6a** are easier to oxidise than **4a**.

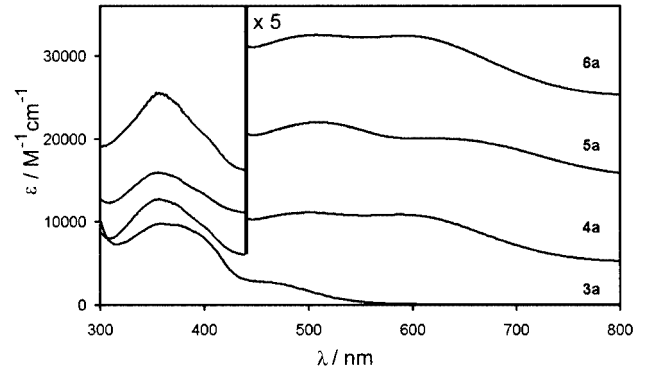

Figure 6. UV/Vis spectra of **3a**−**6a**

The solution structures of the complexes **4a**−**6a**, i.e. the orientations of the allyl ligands with respect to the Schiff-base ligands, have been determined by ^{1}H and ^{13}C NMR spectroscopy (Table 4 and 5). In the ^{1}H NMR spectra the allyl complexes **4a** and **6a** display an ABCDX pattern for the signals of the allyl ligand and **5a** shows an ABCD pattern, both of which suggest static structures in solution (e.g. absence of η^3-η^1-η^3 rearrangements of the allyl ligands). In the NOESY spectra, in addition to cross-peaks between intraligand protons (allyl and Schiff-base ligand), cross-peaks between allyl protons and Schiff-base ligand protons are observed (Figure 7). These observations show that the η^3-allyl ligands are oriented with the open face towards the carbonyls, which is the same orientation as found in the solid state for **4a** and **5a**. This is substantiated by the similar solution and solid state IR spectra of **4a**, **5a** and **6a** (Table 2).

Polymer-Bound Complexes 3b−6b

All polymer-bound complexes were characterised by IR and diffuse reflection UV/Vis spectroscopy and thermogravimetric analysis (Table 6).[11,12]

The IR spectra of the immobilised complexes **3b**−**6b** are shown in Figure 8. In addition to the intense signals of vibrations of the polymer backbone, signals in the characteristic ν_{CO} region are observed. These data compare well with those for the soluble complexes **3a**−**6a** (Table 2 and 6) confirming the presence of immobilised carbonyl complexes with the same stereochemistry as found in the solid state and in solution.

The UV/Vis absorption maxima of resins **3b**−**6b** (Figure 9) are shifted to lower energy than their solution counterparts (Table 3 and 6) but the trend of the MLCT transitions λ_{max}(**3**) << λ_{max}(**4**) < λ_{max}(**6**) < λ_{max}(**5**) is the same for the soluble and polymer-bound complexes. A similar behaviour has been observed for soluble and immobilised Mo^0 complexes.[11,12]

The thermal stability of **3b**−**6b** has been investigated by thermogravimetric analysis. For **3b** a larger weight loss of

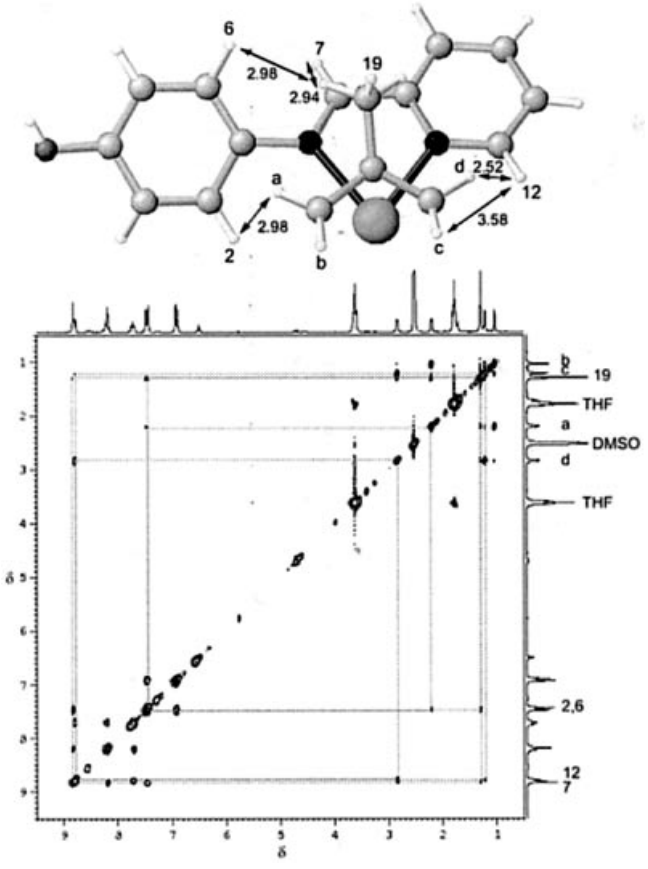

Figure 7. Relevant NOE contacts and distances [Å] (solid-state structure) between protons of the allyl ligand and the Schiff-base ligand in complex **5a** (top); NOESY spectrum of **5a**·THF in [D$_6$]DMSO (bottom)

6.1% is observed at 200 °C, which can be accounted for by a loss of three carbon monoxide ligands and one chloro ligand, while the immobilised allyl complexes **4b**−**6b** only lose coordinated carbonyl ligands up to 200 °C (Table 6). Carbon monoxide loss has also been detected for immobilised Mo^0 carbonyl complexes.[12] These data show that these complexes are formed quantitatively on the solid support and that allyl complexes are thermally more stable than the seven-coordinate molybdenum-tin complex.

Treating the resins **3b**−**6b** with tetra-*n*-butylammonium fluoride in dichloromethane (Scheme 3) results in deeply coloured solutions of the deprotonated complexes **3a**$^-$−**6a**$^-$ which were characterised by IR spectroscopy (Table 7). The signals of the ν_{CO} vibrations of **3a**$^-$−**6a**$^-$ are shifted to lower energy relative to the signals of the neutral parent complexes **3a**−**6a** (Table 2), as expected.

After washing the resins and concentrating the filtrates careful acidification with acetic acid yields solutions of the complexes **3a**−**6a**. In all cases no spectroscopic evidence was observed for the formation of side products, confirming the identity and stability of the polymer-bound complexes.

Conclusion

Oxidative addition of RX ($PhSnCl_3$ or allyl halides) to the molybdenum tetracarbonyl complexes **2a**/**2b** furnishes the molybdenum(II) complexes **3a**−**6a**/**3b**−**6b**.

The stereochemistry of the complexes has been elucidated by single-crystal X-ray diffraction in the solid state and by NMR and IR spectroscopy in solution. The bimetallic molybdenum-tin complex **3a** has a capped octahedral coordination geometry with the tin occupying the seventh position above an octahedral face. The allyl complexes **4a**−**6a** have an octahedral coordination geometry with the bidentate Schiff-base ligand occupying two equatorial positions and the η^3-allyl ligand oriented with the open face towards the carbonyl ligands.

The reactions with polymer-bound complexes proceed quantitatively, as shown by IR spectroscopy and thermogravimetric analysis. The stereochemistry of the polymer-bound complexes **3b**−**6b** is the same as for the soluble complexes **3a**−**6a** in solution and in the solid state. The stability and identity of polymer-bound complexes has been demonstrated by release of the complexes from the polymer. These results pave the way for the immobilisation of active and selective molybdenum catalysts for (enantioselective) allylic alkylation reactions on polymeric supports.

Experimental Section

Unless noted otherwise, all manipulations were carried out under argon by means of standard Schlenk techniques. All solvents were dried by standard methods and distilled under argon prior to use. Complexes **1a**−**3a** and **1b**−**3b** were prepared by a literature method.[11,12] All other reagents were used as received from commercial sources.

NMR: Bruker Avance DPX 200 at 200.15 MHz (^1H), 50.323 MHz (^{13}C) at 303 K; chemical shifts (δ) in ppm with respect to residual solvent peaks as internal standards: $[D_6]DMSO$ (^1H: δ = 2.49 ppm; ^{13}C: δ = 39.7 ppm), $[D_8]THF$ (^1H: δ = 1.73, 3.58 ppm; ^{13}C: δ = 25.5, 67.7 ppm). IR spectra were recorded on a BioRad Excalibur FTS 3000 spectrometer using CaF_2 cells or CsI disks. UV/Vis/NIR spectra were recorded on a Perkin−Elmer Lambda 19 instrument with 0.2 cm cells (Hellma, suprasil). DRS-UV/Vis spectra were measured with the same instrument using the Perkin−Elmer inte-

grating sphere and poly(tetrafluoroethylene) as reference. Cyclic voltammetry was performed using a glassy carbon electrode, a platinum electrode and an SCE electrode, 10^{-3} M in 0.1 M nBu$_4$NPF$_6$/CH$_2$Cl$_2$, potentials are given relative to that of SCE. Mass spectra were recorded on a Finnigan MAT 8400 spectrometer with a matrix of 4-nitrobenzyl alcohol (FAB). Elemental analyses were performed by the microanalytical laboratory of the Organic Chemistry Department, University of Heidelberg. Thermogravimetric measurements were carried out on a Mettler TC 15; heating rate: 10 K min^{-1} under argon from 30−800 °C.

Solution Syntheses of 4a−6a: The appropriate 3-halopropene (2 mmol) was added to a solution of **2a** (406 mg, 1 mmol) in THF (30 mL). The solution was heated under reflux until IR spectroscopy indicated disappearance of the bands of **2a** and complete formation of the product (3−4 h). The solvent was removed under reduced pressure and the crude product was washed with diethyl ether and recrystallised from THF/diethyl ether or CH$_2$Cl$_2$/diethyl ether.

4a: Yield: 311 mg, 0.73 mmol (73%). C$_{17}$H$_{15}$ClMoN$_2$O$_3$ (426.71): calcd. C 47.85, H 3.54, N 6.57; found C 48.04, H 3.79, N 6.40. MS (FAB): *m/z* (%) = 428 (100) [M$^+$ + H], 393 (41) [M$^+$ − Cl], 372 (97) [M$^+$ − 2CO].

5a: Yield: 366 mg, 0.83 mmol (83%). C$_{18}$H$_{17}$ClMoN$_2$O$_3$·THF (440.73·THF): calcd. C 51.52, H 4.91, N 5.46; found C 51.32, H 5.20, N 5.86. MS (FAB): *m/z* (%) = 442 (42) [M$^+$ + H], 407 (21) [M$^+$ − Cl], 386 (100) [M$^+$ − 2CO].

6a: Yield: 419 mg, 0.89 mmol (89%). C$_{17}$H$_{15}$BrMoN$_2$O$_3$·0.5THF (471.16·0.5THF): calcd. C 44.99, H 3.78, N 5.52; found C 45.18, H 4.02, N 5.27. MS (FAB): *m/z* (%) = 472 (12) [M$^+$ + H], 393 (100) [M$^+$ − Br], 416 (23) [M$^+$ − 2CO].

Solid-Phase Synthesis of 4b−6b: The appropriate 3-halopropene (1 mmol) was added to a suspension of **2b** (500 mg, 0.25 mmol) in THF (30 mL). The suspension was heated under reflux until IR spectroscopy of a polymer sample indicated formation of the product and complete conversion of the starting complex (8−10 h). The dark polymer was isolated by filtration, washed with THF and diethyl ether and dried in vacuo.

Cleavage procedure: A solution of tetra-*n*-butylammonium fluoride TBAF·3H$_2$O (2 equivalents) in THF was added to a suspension of the appropriate resin in THF (10 mL). The suspension was stirred for 6 h at room temperature. IR spectroscopy of the solution indicated release of the anionic complexes **4a**$^-$**−6a**$^-$. The mixture was filtered and the polymer was washed with THF until the solution was colourless. The combined filtrates were acidified with acetic acid giving **4a−6a** in 60%, 52% and 71% yield, respectively, based on the loading of **1b**. After cleavage, mass spectrometry of the remaining silyl fluoride polymer indicated complete removal of the complexes.[10]

Computational Methods: Density functional calculations were carried out with the Gaussian98/DFT[26] program series. The B3LYP formulation of density functional theory was used employing the LanL2DZ basis set.[26] Harmonic vibrational frequencies and infrared intensities were calculated by numerical second derivatives using analytically calculated first derivatives. Frequencies are not scaled.

Crystallographic Structure Determinations: The measurements were carried out on an Enraf−Nonius Kappa CCD diffractometer using graphite monochromated Mo-K_α radiation. The data were processed using the standard Nonius software.[27] All calculations were performed using the SHELXT PLUS software package. Structures were solved using direct or Patterson methods with the SHELXS-97 program and refined with the SHELXL-97 program.[28] Graphical handling of the structural data during refinement was performed using XMPA[29] and WinRay.[30] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-squares calculations. Data relating to the structure determinations are collected in Table 8.

Reactivity of a Phosphanylalane Complex towards Lewis Bases

Ulf Vogel,[a] Karl-Christian Schwan,[a] and Manfred Scheer*[a]

Dedicated to Prof. R. Schmutzler on the occasion of his 70th birthday

Keywords: Aluminum / Phosphorus / Hydrides / Reactivity / Lewis bases

The reactivity of the Lewis acid/base stabilized complex of phosphanylalane $[(CO)_5W(H_2PAlH_2{\cdot}NMe_3)]$ (**1**) towards the Lewis bases THF and NMe_3 has been investigated. The reaction with THF leads to decomposition of the complex. One of the decomposition products was identified as containing the anion $[\{(CO)_5W\}_2PH_2]^-$ (**2**). This anion could be synthesized independently by reaction of $[(CO)_5WPH_3]$ with KH in the presence of $[(CO)_5W(THF)]$ and was isolated as the tetraphenylphosphonium salt $[Ph_4P][\{(CO)_5W\}_2PH_2]$ (**2a**). The treatment of **1** with NMe_3 leads to the formation of $[(CO)_5W(H_2PAlH_2{\cdot}2\,NMe_3)]$ (**3**) containing a five-coordinate aluminum atom. Compound **3** exhibits a fast exchange of the NMe_3 ligands in solution containing an excess of NMe_3. The products were characterized by spectroscopic methods and X-ray crystallography.

Introduction

Compounds containing bonds between group 13 and group 15 elements are especially interesting due to their potential use as molecular precursors for the generation of thin films of group 13/15 semiconductors. Compounds of the type $(R_2EE'R'_2)_n$ (R, R′: organic substituents, E′: group 13 element, E: group 15 element) have been intensively investigated[1] and usually form oligomeric structural frameworks. These compounds are monomeric if they possess bulky R and R′ groups to block the intermolecular aggregation. To obtain monomers, the steric influence of the substituents can be neglected if both a Lewis base is coordinated at the group 13 element and the group 15 element still possesses bulky substituents or if, besides the Lewis base at the group 13 element, the lone pair of the group 15 element is occupied by a Lewis acid. Examples of the former mode are the compounds $[Mes_2EAlH_2{\cdot}NMe_3]$,[2] obtained by the treatment of $ClAlH_2{\cdot}NMe_3$ with $LiEMes_2$ (E = P, As), and $[(Me_3Si)_2EAlMe_2{\cdot}dmap]$[3] synthesized by treating oligomers of the type $[Me_2AlE(Me_3Si)_2]_n$ (E = P, As; n = 2, 3) with the Lewis base *N*,*N*′-dimethylaminopyridine (dmap). We developed the latter concept of monomeric group 13/15 compounds by the stabilization of the hydrogen substituted parent compounds $[(CO)_5W(PH_2E'H_2{\cdot}NMe_3)]$ (**1**: E′ = Al, **2**: E′ = Ga, **3**: E′ = B). These phosphanylalane and -gallane complexes were synthesized by a hydrogen elimination reaction,[4] whereas the boron compound was accessible by a salt elimination route.[5] Herein we report on the reactivity of **1** towards the Lewis bases THF and NMe_3, respectively.

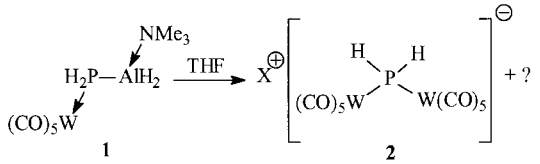
Results and Discussion

Decomposition of 1 in THF

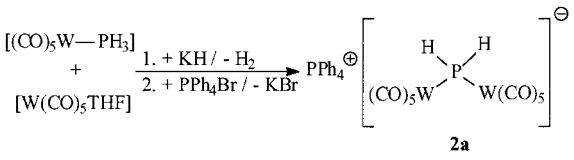
Upon dissolving in THF, **1** reacted with vigorous H_2 evolution [Equation (1)]. The ^{31}P NMR spectrum of the reaction mixture gave some hints of the possible formation of an anionic complex with the formula of **2**. The $^{31}P\{^1H\}$ NMR spectrum of the reaction mixture shows two main P containing products as single peaks having tungsten satellites which split into triplets when the proton coupled spectrum was recorded. Compound **2** shows a triplet at −267.7 ppm ($^1J_{P,H}$ = 268, $^1J_{W,P}$ = 146 Hz). The other product, whose structure could not be assigned yet, shows a triplet at −100.3 ppm ($^1J_{P,H}$ = 340, $^1J_{W,P}$ = 220 Hz). The ratio of the integrals of the tungsten satellites towards the central peak of **2** suggests that two tungsten atoms are bound to each phosphorus atom as in $[\{(CO)_5W\}_2PH_2]^-$. By adding Ph_4PBr to the mixture of reaction (1) some yellow crystals appeared which were identified crystallographically by their unit cell to be $[Ph_4P][\{(CO)_5W\}_2PH_2]$ (**2a**) (cf. discussion below).



1 **2** (1)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200300637

In order to develop a more efficient approach to **2a** it was synthesized by the reaction of $[(CO)_5WPH_3]$ with KH in the presence of $[(CO)_5W(THF)]$ [Equation (2)]. Cation exchange using PPh_4Br and crystallization from CH_2Cl_2/*n*-hexane afforded pure $[PPh_4][\{(CO)_5W\}_2PH_2]$ (**2a**) which showed identical NMR spectra to the decomposition product **2**. The IR spectrum of **2a** revealed a PH stretching absorption at 2306 cm^{-1} as well as three CO valence stretching modes at 2048, 1930 and 1872 cm^{-1} for the two $W(CO)_5$ moieties showing a local C_{4v} symmetry.



2a (2)

The X-ray Crystal Structure Analysis of 2a

The molecular structure of **2a** shows a $[PPh_4]^+$ cation and a $[\{(CO)_5W\}_2PH_2]^-$ anion. An ORTEP plot of the anion is depicted in Figure 1, while selected bond lengths and angles are listed in Table 1.

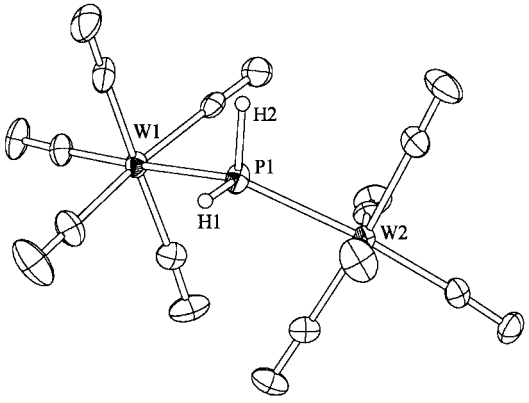


Figure 1. Molecular structure of the anion of **2a** in the crystal (ORTEP plot, 50% probability displacement ellipsoids)

Table 1. Selected bond lengths [Å] and angles [°] for **2a**

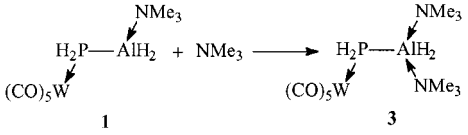
W1−P	2.579(2)	W2−P	2.580(2)
W−C_{trans} [a]	1.978(8)	W−C_{cis} [a]	2.029(9)
W1−P−W2	126.79(7)		

[a] Averaged bond lengths.

The anion of **2a** (Figure 1) shows a PH_2 group which is coordinated to two $W(CO)_5$ moieties. The W−P bond lengths are 2.579(2) and 2.580(2) Å, respectively, and the W1−P−W2 angle is 126.79(7)°. Comparison of these values with the compounds $[Cp(CO)_3W(\mu\text{-}PPh_2)W(CO)_5]$ [W−P−W 118.4(1)°; W−P 2.626(3) Å],[6] $[Cp(CO)_2Fe(\mu\text{-}PPh_2)W(CO)_5]$ (W−P−Fe 118.42(6)°; W−P 2.581(1) Å][7] and $[Et_4N][Cp'(CO)_2Mn(\mu\text{-}PPh_2)W(CO)_5]$ (Cp′ = η^5-C_5H_4Me) [W−P−Mn 119.8(1)°; W−P 2.622(3) Å][8] show that, in particular, the W−P−W angle is significantly larger in **2a**. This can be explained by the low steric shielding of the H substituents at the P atom. Complex **2a** represents the first parent compound (R = H) of the class $[(L_nM)_2PR_2]^-$, which exists amongst only a few organic substituted examples.[8]

Reaction of 1 with NMe_3

In contrast to the reaction with THF, **1** did not show decomposition when allowed to react with the nitrogen-centered Lewis base NMe_3. The product of this reaction is complex **3** which contains a pentacoordinated Al atom in a trigonal bipyramidal arrangement containing two NMe_3 molecules [Equation (3)]. A similar reaction is also known from $H_3Al{\cdot}NMe_3$ with NMe_3 which forms the adduct $H_3Al{\cdot}2\ NMe_3$,[9] exhibiting a trigonal bipyramidal coordinated aluminum atom.[10] The solid-state Raman spectrum of **3** showed bands in the region of the terminal CO stretching frequencies as well as for the PH valence at 2331 and 2315 cm^{-1} and one AlH stretch at 1744 cm^{-1}. The EI-mass spectrum did not show a molecular ion peak. However, $[(CO)_5WPH_2AlH_2{\cdot}NMe_3]^+$ was detected as the ion with the highest mass. Moreover, signals for its degradation, resulting from CO and NMe_3 loss were also found. The $^{31}P\{^1H\}$ NMR spectrum of **3** shows a singlet at $\delta = -251$ ppm which exhibits tungsten satellites ($^1J_{W,P}$ = 149 Hz). The ^1H NMR spectrum reveals a doublet for the PH_2 protons at $\delta = 1.58$ ppm ($^1J_{P,H}$ = 268 Hz), a singlet for the NMe_3 groups at $\delta = 1.71$ ppm and a broad signal for the AlH_2 protons at $\delta = 3.15$ ppm.



1 **3** (3)

In the presence of an excess of trimethylamine, **3** shows dynamic behavior in solution which can be attributed to fast exchange of the coordinated trimethylamine molecules. The variable temperature ^1H NMR spectra are shown in Figure 2. At low temperatures two signals can be detected for the NMe_3 groups: one can be assigned to coordinated (A) and one to free trimethylamine (B). With rising temperature, the two signals are shifted towards each other, and at the coalescence temperature of ca. −45 °C only one broad signal is observed. At higher temperatures only one signal is detected for coordinated and free trimethylamine (C). For this process the free activation enthalpy at the coalescence temperature was calculated to be 45.3 kJ·mol^{-1}.

The Solid-State Structure of 3

The solid-state structure of **3** was determined by a single-crystal X-ray diffraction study. Selected bond lengths and angles are reported in Table 2. An ORTEP plot of the molecular structure of **3** is depicted in Figure 3. The central motif of the crystal structure of **3** is a H_2AlPH_2 moiety which is connected to a $W(CO)_5$ fragment by the P atom. Two NMe_3 molecules are coordinated to the Al atom,

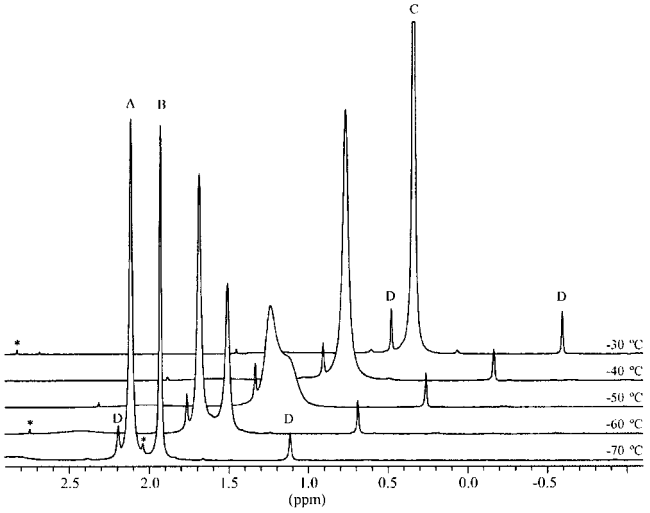

Figure 2. Variable temperature ^{1}H NMR spectra of a mixture of **3** and an excess of NMe_3 in CD_2Cl_2; at −70 °C the spectrum shows signals for coordinated NMe_3 (A), free NMe_3 (B) and the PH_2 protons (D); at −30 °C only the PH_2 protons and one signal for NMe_3 (C) are detected; impurities are marked with *

Table 2. Selected bond lengths [Å] and angles [°] for **3**

W−P	2.566(1)	P−Al	2.432(2)
Al−N1	2.160(4)	Al−N2	2.155(4)
W−C_{trans} [a]	1.988(5)	W−C_{cis} [a]	2.034(5)
Al−P−W	128.58(6)	N1−Al−P	94.7(1)
N2−Al−P	94.2(1)	N1−Al−N2	171.1(2)

[a] Averaged bond lengths.

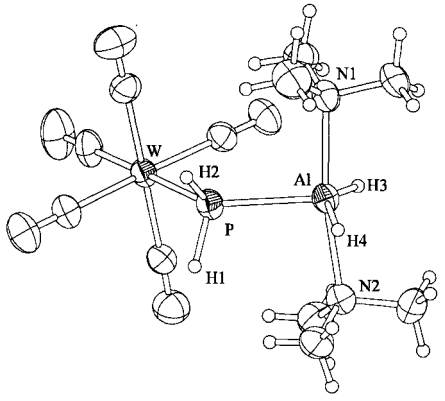

Figure 3. Molecular structure of **3** in the crystal (ORTEP drawing, 50% probability displacement ellipsoids)

which thus exhibits a coordination number of five in a distorted trigonal bipyramidal arrangement. Both trimethylamine ligands occupy the apical positions of the trigonal bipyramid with similar Al−N bond lengths of 2.160(4) and 2.155(4) Å, respectively. The N1−Al−N2 angle is 171.1(2)°. At 2.432(2) Å the Al−P bond length in **3** is significantly longer than in **1** [2.377(1) Å],[4] although in both compounds the aluminum atom is pentacoordinate (**1** reveals an intermolecular dimerization via H bridges). The longer Al−P bond in **3** can be attributed to the steric shielding at the aluminum atom by the second NMe_3 group. The slightly longer P−W bond (**3**: 2.566(1) Å, **1**: 2.549(1) Å] and the larger W−P−Al angle (**3**: 128.58(6)°, **1**: 118.44(4)°] in **3** further support this explanation.

Conclusion

The results have shown that the Lewis-acid/base stabilized phosphanylalane is very sensitive towards reactions with different Lewis bases. The ability of the Al atom to achieve pentacoordination enables firstly an addition of the Lewis base which leads, depending upon its nature, to stable adducts (as in the case of NMe_3) or to decomposition as in the case of THF via cleavage of the Al−P bond and removal of the Al moiety.

Experimental Section

General Remarks: All manipulations were carried out under an atmosphere of dinitrogen using standard Schlenk techniques. All solvents were dried via standard procedures and distilled freshly before use. NMe_3 was dried by condensing it over Na/benzophenone at −78 °C and stirring the mixture until the solution showed a dark blue color. PPh_4Br was heated to 100 °C in vacuo for one hour to remove traces of moisture. $[(CO)_5W(H_2PAlH_2{\cdot}NMe_3)]$ (**1**) was prepared according to our published method.[4] All NMR spectra were recorded on a Bruker AC 250 spectrometer with δ referenced to external $SiMe_4$ (^{1}H) or H_3PO_4 (^{31}P), respectively. IR spectra were measured on a Bruker IFS 28 instrument and Raman spectra on a Bruker FRA 106 spectrometer. All mass spectra were recorded on a Varian MAT 711 instrument at 70 eV.

$[Ph_4P][\{(CO)_5W\}_2PH_2]$ (2a): To a solution of $[(CO)_5W(THF)]$, which was produced by irradiating $[W(CO)_6]$ (352 mg, 1.00 mmol) in THF (50 mL), $[(CO)_5WPH_3]$ (358 mg, 1.00 mmol) and KH (40 mg, 1.00 mmol) were added subsequently. After the gas evolution had ceased the mixture was stirred for three hours to ensure complete reaction. To the clear yellow solution solid PPh_4Br (419 mg, 1.00 mmol) was added resulting in the formation of a white solid which was separated by filtration. The filtrate was reduced to dryness in vacuo and the remaining residue dissolved in CH_2Cl_2 (10 mL). After removal of the insoluble material by filtration the solution was layered with *n*-hexane (20 mL) affording yellow crystals of **2a** after two days. Yield 643 mg (63%). IR (CH_2Cl_2): $\tilde{\nu}$ = 3055 (m), 2987 (w), 2306 (w), 2048 (m), 1930 (vs), 1872 (s), 1440 (m), 1422 (m), 1271 (vs), 1259 (vs), 1109 (w), 896 (w) cm^{-1}. ^{1}H NMR (250 MHz, CD_2Cl_2): δ = 1.91 (d, $^1J_{P,H}$ = 268 Hz, 2 H, PH_2), 7.52−7.92 (m, 20 H, PPh_4) ppm. ^{31}P{^{1}H} NMR (101 MHz, CD_2Cl_2): δ = −267.7 (s, $^1J_{P,W}$ = 146 Hz, PH_2), 23.0 (s, PPh_4) ppm. ^{31}P NMR (101 MHz, CD_2Cl_2): δ = −267.7 (t, $^1J_{P,H}$ = 268, $^1J_{P,W}$ = 146 Hz, PH_2), 23.0 (s, PPh_4) ppm.

$[(CO)_5W(H_2PAlH_2{\cdot}2\,NMe_3)]$ (3): NMe_3 (0.36 mmol) was condensed into a solution of $[(CO)_5W(H_2PAlH_2{\cdot}NMe_3)]$ (53 mg, 0.12 mmol) in *n*-hexane (20 mL) at −196 °C. The reaction mixture was allowed to warm to ambient temperature over 20 minutes. Any insoluble material formed was removed by filtration, and the solution was kept at −20 °C. Light yellowish colored crystals of **3** were formed over two days. Yield 32 mg (53%). Raman (solid state): $\tilde{\nu}$ = 3004 (w), 2977 (m), 2929 (m), 2905 (m), 2855 (m), 2788 (w), 2331 (m), 2315 (m), 2063 (s), 1956 (vs), 1936 (w), 1904 (s), 1880 (w), 1744 (w, br), 821 (w), 435 (m), 434 (m), 116 (m) cm^{-1}. ^{1}H NMR

(250 MHz, [D$_8$]toluene, −50 °C): δ = 1.58 (d, $^1J_{P,H}$ = 268 Hz, 2 H, PH_2), 1.71 (s, 18 H, NMe_3), 3.15 (br. s, 2 H, AlH_2) ppm. $^{31}P\{^1H\}$ NMR (101 MHz, [D$_8$]toluene, −70 °C): δ = −251 (s, $^1J_{P,W}$ = 149 Hz, PH_2) ppm. ^{31}P NMR (101 MHz, [D$_8$]toluene, −70 °C): δ = −251 (t, $^1J_{P,W}$ = 268, $^1J_{P,W}$ = 149 Hz, PH_2) ppm. EI-MS (70 °C): *m*/*z* = 445 ($M^+ - NMe_3$, 1%), 417 ($M^+ - NMe_3 - CO$, 1%), 386 ($M^+ - 2\ NMe_3$, 2%), 358 ($M^+ - 2\ NMe_3 - CO$, 13%), 330 ($M^+ - 2\ NMe_3 - 2\ CO$, 5%), 302 ($M^+ - 2\ NMe_3 - 3\ CO$, 16%), 302 ($M^+ - 2\ NMe_3 - 3\ CO$, 16%), 272 ($M^+ - 2\ NMe_3 - 4\ CO - 2\ H$, 16%), 244 ($M^+ - 2\ NMe_3 - 5\ CO - 2\ H$, 11%).

Variable Temperature NMR of 3: In a typical experiment [$(CO)_5W(H_2PAlH_2{\cdot}2\ NMe_3)$] (30 mg, 0.06 mmol) was weighed into an NMR tube, and NMe_3 (0.18 mmol) was condensed into the tube at −196 °C. CD_2Cl_2 was then condensed into the tube, and it was sealed in vacuo. After variable temperature NMR measurements, starting from −70 °C, the samples decompose slowly at room temperature.

X-ray Crystallographic Studies: Crystal structure analyses of **2a** and **3** were performed on a STOE IPDS diffractometer with Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods with the program SHELXS-97,[11a] and full-matrix least-squares refinements on F^2 using SHELXL-97[11b] were performed with anisotropic displacements for non-H atoms. Hydrogen atoms at the carbon atoms were located in idealized positions and refined isotropically according to the riding model. The hydrogen atoms at the phosphorus and aluminum atoms were freely refined. Further details of the structural refinements are given in Table 3.

Synthesis, Structures and Luminescent Properties of σ-Alkynyl Complexes of Orthomercuriated Schiff Bases

Wai-Yeung Wong,*[a] Guo-Liang Lu,[a] Li Liu,[a] Jian-Xin Shi,[a,b] and Zhenyang Lin[c]

Keywords: Alkyne ligands / Luminescence / Mercury / Schiff bases

A novel series of σ-alkynyl complexes of orthomercuriated Schiff bases of substituted benzylideneanilines and anthracenylmethyleneanilines were synthesised in good yields by alkynylation of the mercuric chlorides of the appropriate Schiff bases with terminal alkynes RC≡CH (R = Ph, ferrocenyl, *p*-ferrocenylphenyl) at room temperature in a basic medium. All the new compounds generally displayed good solubility in polar organic solvents and their identities were completely elucidated by various spectroscopic methods. The X-ray crystal structures of these acetylide-functionalised compounds represent the first structurally characterised examples of such alkynylmercury(II) complexes and confirmed that the alkynylmercury(II) moiety is directed to the *ortho* position of the *N*-phenyl ring of the Schiff bases. In one instance, the crystal structure reveals that a loose 1D polymeric aggregate is formed for the first time through a combination of weak intermolecular Hg···Hg and Hg···η^2-C≡C interactions to afford an infinite zigzag chain of Hg atoms supported by acetylide linkages. All the complexes in this study were found to exhibit rich luminescence and solution redox behaviour and correlation of these data with the theoretical calculations by the density functional theory was made.

Introduction

The synthesis, structure and luminescence properties of transition metal complexes of alkynyl ligands have attracted enormous attention in the past two decades.[1] Metal alkynyls are common for many transition metals, particularly those of groups 8−11, and their chemistry has been developed extensively.[1,2] The interest in the study of mono-, di- and polynuclear gold(I) σ-acetylide complexes stems not only from their rich photochemistry but also from the observation of weak intermolecular d^{10}-d^{10} Au···Au interactions which can play important roles in materials science and crystal engineering.[3] In many cases, it is the combination of the complementary intermolecular forces of aurophilic interactions, hydrogen bonding, π−π stacking and other non-covalent interactions that determines the solid-state luminescent properties of these materials. In contrast to the large body of work on alkynylgold(I) compounds, the chemistry of group 12 metal alkynyls, especially d^{10} alkynylmercury(II) compounds, has not been so thoroughly investigated, and related research work on the isoelectronic mercury(II) system is still in its infancy.[4] Although mercury(II) acetylides were reported as early as the 1920s, they are limited to those of simple alkyl- and arylmercury derivatives.[5] Indeed, mono- and dialkynylmercury complexes have been shown to be useful in the analysis of toxic mercury(II) species[6] and to be valuable building blocks for the synthesis of luminescent metal-organic polymers and supramolecular aggregates.[4]

Very recently, a comprehensive program was launched in our laboratory to develop the chemistry of alkynylmercury complexes. We have reported a new class of bis(alkynyl)mercury(II) complexes incorporating a series of aromatic groups.[4d,4e] These molecules were shown to display a rich photophysical behaviour and interesting structural properties. The crystal structures of [MeHgC≡CRC≡CHgMe] (R = thiophene-2,5-diyl, [2,2′]-bithiophene-5,5′-diyl) reveal the formation of a loose polymeric structure in each case through weak intermolecular non-covalent Hg···Hg interactions.[4e] The solid-state aggregation of [Hg(C≡CR)$_2$] (R = Ph, SiMe$_3$) has been discussed by Nicholson et al. in which both mercuriophilic and Hg-η^2-C$_2$ interactions appear to contribute to the supramolecular aggregation process.[4b] π-Coordination of some transition metal ions to bis-alkynylmercury complexes has also been explored recently in which some compounds reveal weak anion···cation interactions and the structure of $\{[Hg(C{\equiv}CTol)_2Ag][BF_4]\}_n$ shows a polymeric skeleton comprised of helices cross-linked by C−H···π in-

teractions.[4a] In the pursuit of unsymmetrical diorganomercurials bearing an alkynyl ligand, we set out a strategy to synthesise some σ-acetylide complexes of orthomercuriated Schiff bases.[7] Perusal of the literature suggested that there were no examples of such kinds of alkynylmercury(II) compounds and their structures and luminescence behaviour have not been described before. We present here the synthesis and structural characterisation of the first σ-alkynyl complexes of orthomercuriated Schiff bases of substituted benzylideneanilines and anthracenylmethyleneanilines. The luminescence and electrochemical properties of these complexes have been examined.

Results and Discussion

Syntheses and Spectroscopic Properties

Condensation reactions of *p*-nitrobenzaldehyde and 9-anthraldehyde with the respective *para*-substituted anilines readily afforded the Schiff bases **1a**, **1b**, **2a** and **2b** in high yields.[7b] The mercuric chloride precursors of the corresponding Schiff bases (**3a**, **3b**, **4a** and **4b**) were prepared by in situ reaction of the Schiff bases with one molar equivalent of mercuric acetate in dry MeOH under reflux for 4 h, followed by the addition of lithium chloride (Scheme 1). The products were precipitated from the reaction mixture and isolated in very good overall yields.

The general alkynylation routes leading to new compounds **5**−**12** are shown in Scheme 1. Based on the classical dehydrohalogenation method,[3h,4d,4e] room temperature reactions of the orthomercuriated derivatives with a slight excess of the terminal alkynes RC≡CH (R = Ph, Fc, *p*-FcC_6H_4, where Fc = ferrocenyl) in THF in the presence of NaOMe in MeOH furnished compounds **5**−**12** in 82−87% yields. Pure samples of these products were obtained after extraction of the crude compounds with hot $CHCl_3$ followed by subsequent recrystallisation from CH_2Cl_2/hexane. Compounds **5**−**12** were isolated as air-stable yellow to yellow-brown solids. They exhibit fairly good solubility in chlorinated solvents such as CH_2Cl_2 and $CHCl_3$ and the solubility of the complex is enhanced by increasing the chain length of the alkoxy group from MeO to $C_{16}H_{33}O$. They were satisfactorily characterised by elemental analyses, IR, MS, ^1H and ^{13}C NMR spectroscopy.

All the spectroscopic data of new compounds are in agreement with their proposed structures. Each of the IR spectra of **5**−**12** displays a characteristic absorption band in the range 2137−2141 cm^{-1} corresponding to the ν(C≡C) stretching modes. The ^1H NMR spectra of **1**−**12** all show features pertaining to the protons of the aromatic and other organic groups. The position of the mercury atom in **5**−**12** was determined by ^1H NMR spectroscopy. The four *C*-phenyl protons for each of **5**−**8** consists of a group of left-right symmetrical multiplet peaks in the aromatic region typical of a four-spin AA′BB′ system at lower field due to the electron-withdrawing effect of the NO_2 group. At higher field, the two doublets and a doublet of doublets which belong to the three-spin AMX system correspond to the three *N*-phenyl protons. Such spectral assignments show that mercuriation takes place at the *ortho* position of the *N*-phenyl ring rather than at the *ortho* position of the *C*-phenyl ring. The ^{13}C NMR spectra of the σ-acetylide complexes show two resonances for the sp carbon atoms of the C≡C units in which the chemical-shift values are virtually unaffected upon varying the substituents; assignment of these ^{13}C signals was made by analogy with other similar acetylide compounds.[4a,5c] In each case, we can detect the respective molecular ion peak $[M]^+$ or $[MH]^+$ in the FAB mass spectra,

and for **5**−**12** we also observe the peaks corresponding to the detachment of the HgC≡CR groups.

Crystal-Structure Analysis

The molecular structures of complexes **5** (Figure 1), **6** (Figure 2), **7** (Figure 3), **9** (Figure 4), and **10** (Figure 5) are shown, and selected structural parameters are listed in Table 1. In each case, the crystal structure shows an unsymmetrical diorganomercurial species in which the Hg^{II} centre is σ bonded to an alkynyl ligand as well as an *ortho*-carbon atom of the *N*-phenyl ring of the corresponding Schiff base. The geometry about the Hg atom in each case is very similar, with the Hg^{II} centre being two-coordinate and essentially linear [$C(sp^2)-Hg-C(sp)$ 177.6(4)−179.3(4)°]. The Hg−C(sp) bonds are similar in length to those in other Hg^{II} acetylide compounds.[4,8] The near linearity of the Hg−C≡C fragment is confirmed from the Hg(1)−C(sp)−C(sp) angles [170.2(6)−178.5(13)°] and the slight deviations from 180° for **5** and **6** are consistent with the presence of short intermolecular interactions (vide infra). The C≡C bond lengths span the narrow range of 1.162(16)−1.196(9) Å, typical of other known Hg^{II} acetylides.[8] The Hg···N nonbonded contacts, which range from 2.860 to 3.126 Å, and the Hg(1)−$C(sp^2)$−$C(sp^2)$ bond angles [112.3(4)−118.2(9)°], which are less than 120°, suggest the opportunity for a secondary N→Hg intramolecular interaction with a four-membered ring. The presence of such weak Hg···N contacts can be justified based on the currently acceptable van der Waals radius of each element.[9] The present structural investigations corroborate the proposed reaction mechanism, in which the mercuriation at the *ortho* position of the *N*-phenyl ring was facilitated by the imino moiety upon formation of a coordination complex with $Hg(OAc)_2$ in the first step, followed by a subsequent electrophilic substitution at the *ortho* position of the *N*-phenyl ring.[7b]

Examination of the crystal packing diagram for each compound reveals the involvement of various intermolecular contacts in their structures. Interestingly, there is a strong tendency for the molecules in **5** to aggregate, and the lattice structure of **5** is highlighted by the presence of extensive non-covalent Hg···Hg and Hg···η^2-C≡C interactive vectors, which link up the molecular units to form a loose polymeric structure. Such a polymeric aggregate shows a zigzag 1D chain of Hg atoms with an Hg···Hg interaction distance of ca. 3.959 Å between adjacent molecules; the average Hg−Hg−Hg bond angle is 135.9° (Figure 6). To the best of our knowledge, this represents the first structurally characterised example of a mercury(II) acetylide compound exhibiting infinite polymeric chains of Hg atoms, although it is known that crystals such as $Hg_3(AlCl_4)_2$ and Hg_3AsF_6 also contain zigzag mercury chains in their lattices.[4c,10] A similar chain-like structure supported by alkynyl ligands is also found for silver(I) in $[(Me_3P)AgC{\equiv}CR]_\infty$ (R = Ph, $SiMe_3$).[11] While the Hg···Hg contacts in **5** indicate that each of the individual interac-

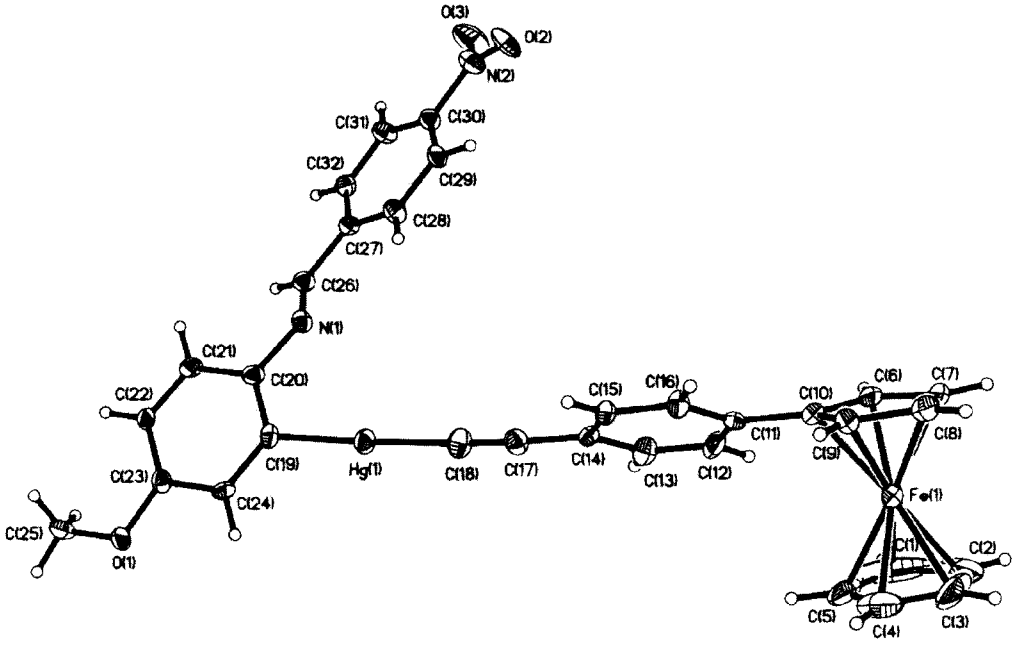

Figure 3. Molecular structure of **7**, with thermal ellipsoids shown at the 25% probability level

tions is relatively weak, it is the large number of them that play a supramolecular role and generate a significant driving force for solid-state aggregation. We believe that such mercuriophilic forces are more than just van der Waals interactions in these chemical systems. The intermolecular distances from the Hg atom to C_α [Hg(1)···C(15)] and C_β [Hg(1)···C(16)] are 3.398 and 3.783 Å, respectively, which compare well with the values quoted for [Hg(C≡CR)$_2$] (R = Ph, SiMe$_3$)[4b] but are significantly longer than the intramolecular distances found in some heterometallic

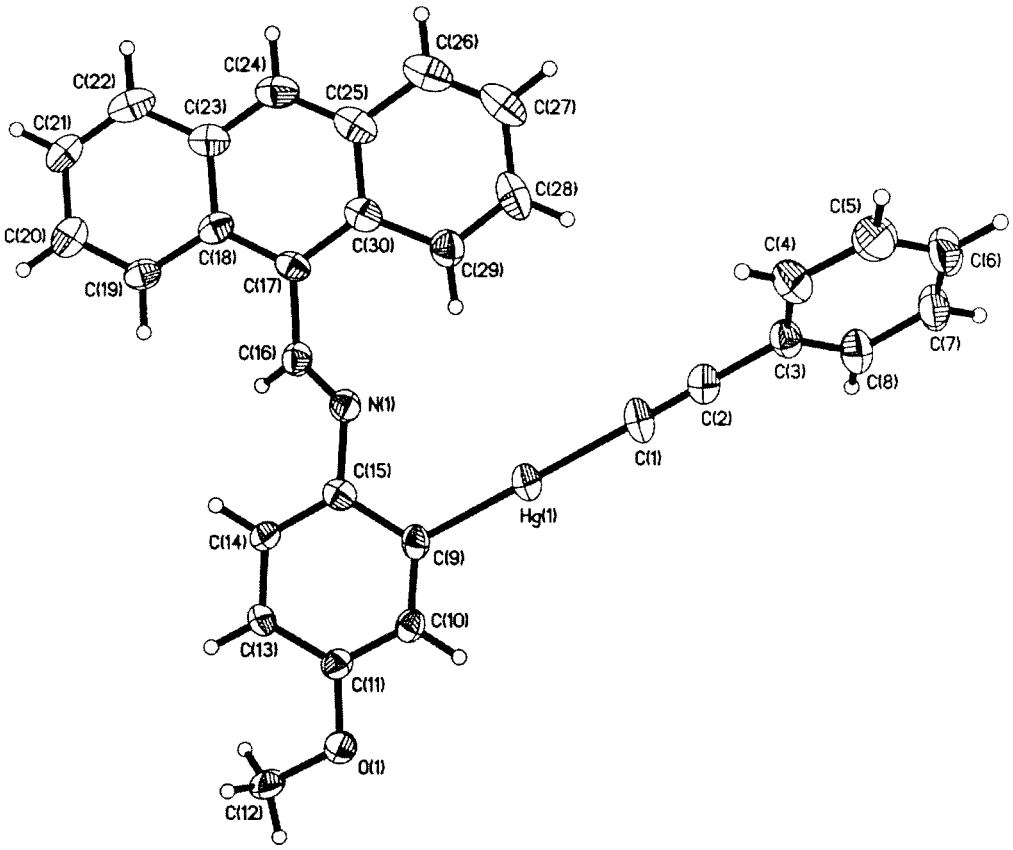

Figure 4. Molecular structure of **9**, with thermal ellipsoids shown at the 25% probability level

bis(η^2-alkyne)mercury complexes.[4g][4h] While the closest intermolecular contacts in **6** are attributed to the hydrogen-bonding interactions [O(1)···H(15) 2.44 Å; O(2)···H(15) 2.72 Å), the weak mercuriophilic (4.21 Å) and Hg···η^2-C≡C attractions [Hg(1)···C(1) 3.41 Å; Hg(1)···C(2) 3.57 Å) also contribute to the overall intermolecular packing. The van der Waals radius of mercury has been the subject of much debate and a value of up to 2.2 Å has been proposed recently,[4c,7a,9] which is conceived to be a better estimate than the value quoted by Bondi in 1964.[12] In light of this, the observed Hg···Hg separations which are similar to the values of 3.71−4.25 Å for [Hg(C≡CR)$_2$] (R = Ph, SiMe$_3$)[4b] are towards the upper limit of those accepted as representing metallophilic interactions and are consistent with other previous interpretations.[4e,4f] For **7**, **9** and **10**, the Hg···Hg and Hg···C≡C interactions become unimportant and the nearest intermolecular contacts involve the Hg centre, the methoxy oxygen atom and a hydrogen atom from the aromatic rings. These contacts arise from Hg(1)···H(25) (3.372 Å), Hg(1)···O(1) (3.698 Å) and O(2)···H(32) (2.376 Å) interactions for **7**, whereas each molecular unit of **9** is linked to two adjacent units through short Hg(1)···O(1) contacts (3.084 Å). Presumably because of the greater steric bulk of both anthryl and ferrocenyl rings, there are no other significant short contacts for **10** other than the Hg(1)···H(25) interactions (2.921 Å). None of these five structures show close π−π stacking of the arene rings in the solid state.

Absorption and Luminescence Properties

The electronic absorption and emission data of our compounds are given in Table 2. In general, these orthomercuriated complexes absorb strongly in the range 383−413 nm. The dependence of the solution absorption spectra on the nature of the original Schiff bases suggests that the transitions are mainly π−π* ligand-centred, and the apparent insensitivity of the low-energy absorption bands towards the ancillary groups R on the mercury centre (cf. **5**, **6** and **7**) precludes a metal-centred origin for these transitions.[4e] We also note that the lowest-energy absorption features show slight bathochromic shifts when the alkynylmercury(II) fragments are introduced at the *ortho* position of the Schiff bases (cf. **2a** and **9**), reflecting a certain degree of through-metal π-delocalisation due to metal-to-ligand back-donation to the π*(C≡CR) orbital. Hence, the electronic absorption spectra are probably dominated by intraligand π−π* transitions, but possibly mixed with a small contribution from the metal in the HOMO and the LUMO.[13] The π,π* character of the electronic states involved is consistent with the molecular orbital calculations. Figure 7 depicts the contour plots of the HOMOs and LUMOs for **2a**, **9** and **10**, showing the common bonding features in the frontier region. The HOMOs and LUMOs for the three complexes resemble each other and correspond to the π and π* orbitals of the conjugated organic unit. The substituents HgC≡CPh in **9** and HgC≡CFc in **10** only af-

[a] sp^2 carbon atoms of the *N*-phenyl ring.

fect the energies of those orbitals above the LUMO and below the HOMO. The second LUMO for both **9** and **10** has significant contribution from the Hg's empty p orbitals. The presence of the ferrocenyl group in **10** introduces the two Fe(d_δ) orbitals as the second and third HOMOs (we define the δ-type d orbital by viewing the orbitals along the Ct−Fe−Ct direction where Ct is the centre of each cyclopentadienyl ring). The order of calculated HOMO−LUMO gaps **2a** (3.40 eV) > **10** (3.33 eV) > **9** (3.17 eV) is in line with our experimental observations.

Complexes **5**−**12** were found to exhibit luminescence in the solid state at 290 and 11 K (Table 2). There is little change in the emission spectra upon variation of the excitation wavelength, indicating that a single emissive state or multiple states in equilibrium is (are) responsible for the observed emission. The emission energy is dependent on the nature of the structure of the Schiff bases (Figure 8), but does not vary much with respect to the identity of R′. The striking similarity of the emission peak shapes of these σ-alkynyl complexes and those of their parent Schiff bases

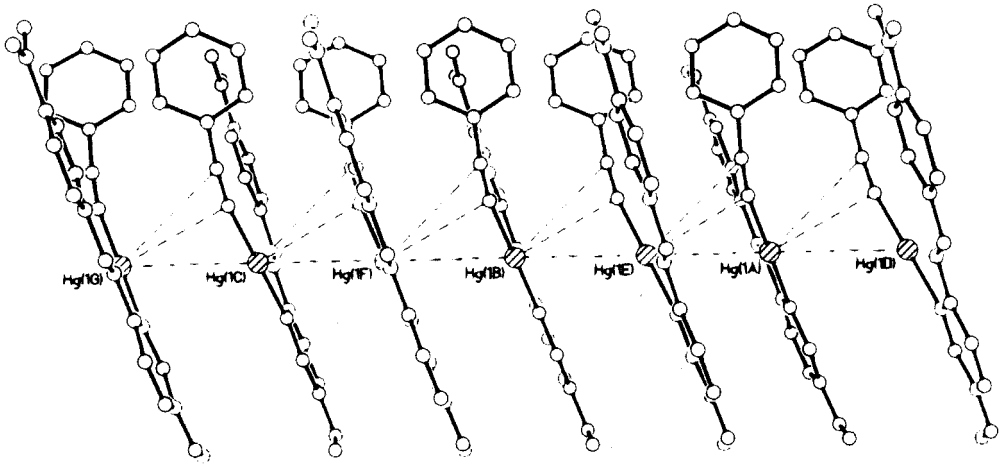

Figure 6. Crystal packing diagram for **5** showing the polymeric chain of Hg atoms aggregated through Hg···Hg and Hg···η^2-C≡C intermolecular contacts; all hydrogen atoms are omitted for clarity

and organomercuric chlorides are suggestive of a ligand-dominated emissive state, and the lowest emissive states in these complexes can tentatively be assigned as metal-perturbed intraligand $\pi-\pi^*$ transitions. The emission energies of the complexes in the solid state at 11 K roughly follow the order **9** > **5**, **10** > **6** and **12** > **8**, which is in agreement with the electron-withdrawing ability of the nitro group in the latter which tends to reduce the HOMO−LUMO gap. However, compounds **7** and **11** were found to be weakly emissive both in solution and as solids, and the appearance of the low-energy emission bands as broad shoulders or weak peaks makes it difficult for one to determine their exact maxima for comparative studies. In most cases, the marked red shift in the emission wavelengths for the solid-state spectra is a manifestation of the formation of aggregates in the ground state due to the presence of intermolecular interactions in the solid lattice, which is not present in solution (vide supra).[3b,13]

Electrochemistry

Table 3 collects the electrochemical data for our complexes in CH_2Cl_2. Each of the cyclic voltammograms of **5**−**12** essentially shows an irreversible oxidation wave (+0.77 to +1.11 V) which is suggested to arise from Schiff-base ligand-centred oxidation since the potentials within the same ligand class are found to have similar values. For the NO_2-substituted Schiff bases and their organomercury complexes, we observe one quasi-reversible reduction couple which can be attributed to reduction of the nitro moiety; these $E_{1/2}$ values (−1.41 to −1.45 V) are almost invariant of the structures. For each of **6**, **7**, **10** and **11**, the cyclic voltammogram is also characterised by one quasi-reversible oxidation wave due to the ferrocenyl electrophore that is present. The ferrocenyl oxidation potential is less anodic for **7** (+0.07 V) and **11** (+0.06 V) than for **6** (+0.13 V) and **10** (+0.10 V) because of the greater degree of electron delocalisation along the metal-capped ethynyl bridges with an additional C_6H_4 unit which would increase the ease of oxidation.

Concluding Remarks

This report has demonstrated that orthomercuriated Schiff bases are useful precursors to afford a range of luminescent diorganomercurial σ-alkynyl compounds. Structural characterisations of complexes **5**, **6**, **7**, **9** and **10** are particularly interesting and constitute the first examples of this type. The results also provide further evidence for the existence of N→Hg intramolecular coordination and the fact that the initial mercuriation step occurs at the *ortho* position of the *N*-phenyl ring instead of the *C*-phenyl ring. Depending on the geometric and steric properties of the end groups anchored on the alkynyl unit and the type of Schiff base employed, we were able to build up polymeric mercury(II) acetylide systems in the solid state aggregated through Hg···Hg and Hg···η^2-C≡C secondary interactions. Such a supramolecular aggregation process is best favoured for orthomercuriated molecules with the least steric bulk, such as **5**. The absorption and emission properties of **5**−**12** are dominated by mildly mercury-perturbed organic $\pi-\pi^*$ transitions, which are consistent with the results obtained from theoretical calculations. A comparison of the *p*-nitrophenyl and 9-anthryl substituents illustrates that the emission maximum is bathochromically shifted in the presence of the electron-accepting NO_2 group in the former case.

Experimental Section

General Procedures: All reactions were conducted under an atmosphere of dry nitrogen with the use of standard Schlenk techniques. Solvents for preparative work were dried and distilled before use. IR spectra were obtained using a Nicolet FTIR-550 spectrometer. NMR spectra were recorded on a JEOL JNM-EX 270 or a Varian Inova 400 MHz FT NMR spectrometer. Fast atom bombardment (FAB) mass spectra were recorded on a Finnigan-SSQ 710 spectrometer. Electronic absorption spectra were measured with a HP 8453 UV/Vis spectrometer. For emission spectral measurements, the 325 nm line of a He-Cd laser was used as an excitation source. The luminescence spectra were analysed by a 0.25 m focal length

[a] Excitation wavelength is 325 nm. sh = shoulder. vw = very weak. [b] All absorption spectra were recorded in CH_2Cl_2 at 290 K.

double monochromator with a Peltier cooled photomultiplier tube and processed with a lock-in amplifier. For the low temperature experiments, samples were mounted in a closed-cycle cryostat (Oxford CC1104) in which the temperature can be adjusted from 10 to 330 K. Cyclic voltammetry experiments were performed with a Princeton Applied Research (PAR) model 273A potentiostat. A conventional three-electrode configuration consisting of a glassy-carbon working electrode, a Pt-wire counter electrode and a Ag/$AgNO_3$ reference electrode was used at a scan rate of 100 mV s^{-1}. The solvent in all measurements was deoxygenated CH_2Cl_2 and the supporting electrolyte was 0.1 M $[Bu_4N]PF_6$. Ferrocene was added as an internal standard after each set of measurements and all potentials reported were quoted with reference to the ferrocene-ferrocenium couple. Unless otherwise stated, all reagents were from commercial sources and used as received. The compounds **1a**,[7b] **3a**,[7b] ethynylferrocene[14] and *p*-ethynylphenylferrocene[15] were prepared according to the reported procedures. The synthesis of **3b**, **4a** and **4b** was described in the supplementary materials. Density functional calculations at the B3LYP level[16] were performed on **2a**, **9** and **10** on the basis of their experimentally determined geometries obtained from crystallographic data. The basis set used for C, O, N and H atoms was 6−31G,[17] while effective core potentials with a LanL2DZ basis set[18] were employed for Fe and Hg atoms. The Gaussian 98 program was used for the calculations.[19]

Caution! *Organomercurials are extremely toxic, and appropriate handling conditions should be used for their generation and disposal.*

General Procedures for the Synthesis of σ-Alkynyl Complexes of Orthomercuriated Schiff Bases 5−12: Basic MeOH was added dropwise to a mixture of each of the mercuric chloride derivatives (**3a**, **3b**, **4a** or **4b**, 0.10 mmol) and two molar equivalents of RC≡CH (R = Ph, Fc or *p*-FcC_6H_4) in THF. In a typical run, a 0.5 M solution of NaOH in MeOH (5 mL, 1.00 mmol) was added to the mixture of **3a** (49.1 mg, 0.10 mmol) and PhC≡CH (0.022 mL, 0.20 mmol) in THF (5 mL). The resulting mixture was stirred for 3 h at room temperature before all the volatile components were removed under reduced pressure. The residue was extracted with hot $CHCl_3$ and the yellow extract was then filtered through a thick layer of Celite. After evaporation of solvent, the crude product was recrystallised from CH_2Cl_2/hexane to afford an essentially pure yellow solid in high yield.

Compound 5: Yellow solid. Yield 86% (47.9 mg). IR (KBr): ν(CH=N) = 1621 and ν(C≡C) = 2141 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 3.85 (s, 3 H, Me), 6.88 (dd, $J_{H,H}$ = 2.7, 8.9 Hz, 1 H, H_4), 7.08 (d, $J_{H,H}$ = 2.7 Hz, 1 H, H_5), 7.32−7.35 (m, 3 H, Ph), 7.47 (d, $J_{H,H}$ = 8.9 Hz, 1 H, H_3), 7.51−7.54 (m, 2 H, Ph), 8.05 (d, $J_{H,H}$ = 8.8 Hz, 2 H, H_2), 8.32 (d, $J_{H,H}$ = 8.8 Hz, 2 H, H_1), 8.70 (s, 1 H, CH=N) ppm. ^{13}C NMR ($CDCl_3$): δ = 55.58 (Me), 106.46, 115.03 (C≡C), 117.18, 122.16, 122.84, 124.00, 128.18, 128.24, 128.92, 131.94, 132.10, 141.68, 148.79, 148.84, 152.71, 159.24 (Ar), 162.54 (CH=N) ppm.

10	+0.79 (+0.10)	
11	+0.77 (+0.06)	
12	+1.07, +0.77	

[a] E_{pa} refers to the anodic peak potential of the irreversible oxidation wave. $E_{1/2} = (E_{pa} + E_{pc})/2$ where E_{pa} and E_{pc} are the anodic and cathodic peak potentials of the quasi-reversible oxidation couple due to the ferrocenyl group, respectively. [b] $E_{1/2}$ refers to the half-wave potential of the quasi-reversible reduction wave. [c] Limited solubility.

FAB MS: *m*/*z* = 557 [M$^+$]. $C_{22}H_{16}HgN_2O_3$ (557): calcd. C 47.44, H 2.90, N 5.03; found C 47.15, H 2.83, N 4.99.

Compound 6: Brownish-yellow solid. Yield 81% (53.9 mg). Final R indices [$I > n\sigma(I)$][a]	$R1$ = 0.0336	R = 0.047	$R1$ = 0.0489	$R1$ = 0.0510	$R1$ = 0.0284
	$wR2$ = 0.0740	R_w = 0.044	$wR2$ = 0.0908	$wR2$ = 0.1081	$wR2$ = 0.0716

[a] $R = R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w(F_o)^2]^{1/2}$. $wR2 = [\Sigma w(|F_o^2| - |F_c^2|)^2/\Sigma w|F_o^2|^2]^{1/2}$.

ation of the solvents from their respective solutions in a hexane/CH_2Cl_2 mixture. Geometric and intensity data were collected using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) on a Rigaku AFC7R diffractometer (**6**) and Bruker AXS SMART CCD area-detector (for the rest). Absorption corrections based on the ψ-scan method[20] (**6**) or SADABS program[21] (for the other four compounds) were applied. The structure was solved by the direct methods (SIR92[22] for **6**, SHELXTL[23] for the rest) in conjunction with standard difference Fourier techniques and subsequently refined by full-matrix least-squares analyses. All non-hydrogen atoms were assigned with anisotropic displacement parameters. Hydrogen atoms were generated in their idealised positions and allowed to ride on the respective carbon atoms. Crystallographic data for the alkynylmercury complexes are collected in Table 4. For **2a**, the crystal and other experimental details are given in the Supporting Information.

CCDC-217511 to -217516 (for **2a**, **5**, **6**, **7**, **9** and **10**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EW, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Five- and Six-Coordinate Ruthenium(II) Complexes Containing the Bidentate Phosphane (−)-*N*,*N*-Bis(diphenylphosphanyl)-(*S*)-1-phenylethylamine [(*S*)-peap]: X-ray Crystal Structure of the First 16-Electron Ruthenium Complex Bearing a Four-Membered Ring $[RuCl\{\kappa^2\text{-}P,P\text{-}(S)\text{-peap}\}_2][SbF_6]\cdot C_2H_4Cl_2$

Josefina Díez,[a] M. Pilar Gamasa,*[a] José Gimeno,[a] Yolanda Rodríguez,[a] and Santiago García-Granda[b]

Dedicated to Professor José Vicente Soler on the occasion of his 60th birthday

Keywords: Ruthenium / (*S*)-peap ligand / Five-coordinate complexes / Octahedral complexes

The complex *trans*-$[RuCl_2\{\kappa^2\text{-}P,P\text{-}(S)\text{-peap}\}_2]$ (**1**) has been stereoselectively prepared by the treatment of a stoichiometric mixture of complex $[RuCl_2(DMSO)_4]$ (DMSO = dimethyl sulfoxide) and (*S*)-peap [(*S*)-peap = (–)-*N*,*N*-bis(diphenylphosphanyl)-(*S*)-1-phenylethylamine] in refluxing toluene. Irradiation of a dichloromethane solution of **1** with a UV lamp (400 W) at –15 °C affords the complex *cis*-$[RuCl_2\{\kappa^2\text{-}P,P\text{-}(S)\text{-peap}\}_2]$ (**2**). The thermodynamically stable *trans* isomer **1** has also been obtained by heating complex **2** in toluene. The reaction of **1** with $AgSbF_6$ in dichloromethane yields the complex $[RuCl\{\kappa^2\text{-}P,P\text{-}(S)\text{-peap}\}_2][SbF_6]$ (**3**), the first 16-electron cationic ruthenium complex bearing a four-membered chelate diphosphane ligand which has been fully characterized including its X-ray crystal structure. The reaction of unsaturated derivative **3** with CO gives the six-coordinate complex *cis*-$[RuCl(CO)\{\kappa^2\text{-}P,P\text{-}(S)\text{-peap}\}_2][SbF_6]$ (**4**) in a stereoselective manner, which slowly transforms into *trans*-$[RuCl(CO)\{\kappa^2\text{-}P,P\text{-}(S)\text{-peap}\}_2][SbF_6]$ (**5**) in a dichloromethane solution. The reaction of $[RuCl\{\kappa^2\text{-}P,P\text{-}(S)\text{-peap}\}_2][BF_4]$ with 1-phenyl-2-propyn-1-ol in 1,2-dichloroethane (60 °C) affords the allenylidene derivative *trans*-$[RuCl(=C=C=CHPh)\{\kappa^2\text{-}P,P\text{-}(S)\text{-peap}\}_2][BF_4]$ (**6**). The *cis*-$[Ru(acac)\{\kappa^2\text{-}P,P\text{-}(S)\text{-peap}\}_2][SbF_6]$ (**7**) is prepared by reaction of **3** and Na[acac].

Introduction

Six-coordinate ruthenium(II)diphosphane complexes $[RuX_2(P-P)_2]$ (X = halide), and especially the unsaturated five-coordinate derivatives $[RuX(P-P)_2]^+$, have attracted increasing attention in recent years, due in part to their potential interest involving homogeneous catalysis.[1] The 18-e six-coordinate diphosphane complexes, containing five- and six-membered chelate rings, can dissociate one of the halide ligands to give the unsaturated systems $[RuX(P-P)_2]^+$. Only a few of them have been characterized by X-ray crystallography i.e., $[RuCl(dppe)_2]^+$ [dppe = 1,2-bis(diphenylphosphanyl)ethane],[2] $[RuCl(dcpe)_2]^+$ [dcpe = 1,2-bis(dicyclohexylphosphanyl)ethane],[3] $[RuCl(bnpe)_2]^+$ [bnpe = 1,2-bis(1-naphthylphenylphosphanyl)ethane],[1e] $[RuX(dppp)_2]^+$ [dppp = 1,3-bis(diphenylphosphanyl)propane] (X = Cl,[4] F[5]). Apparently, the tendency to dissociate increases as the ring size of the chelate increases in the order six- > five- >> four-membered. So, diphosphane ligands, Ph_2PYPPh_2 [Y = CH_2, C=CH_2, CMe_2, N(R)], which form four-membered chelate rings, exclusively give six-coordinate *cis*- or *trans*-mononuclear complexes[6,7] and no examples of 16-electron five-coordinate cationic complexes have been reported to date.[8]

Continuing our interest in the chemistry of ruthenium complexes containing enantiopure bis(diphenylphosphanyl-)amine ligands,[9] we report in this paper the synthesis of the first 16-electron cationic ruthenium complex bearing a four-membered chelate diphosphane ligand namely $[RuCl\{\kappa^2\text{-}P,P\text{-}(S)\text{-peap}\}_2][SbF_6]$ (**3**), which has been fully characterized including its X-ray crystal structure. The precursor six-coordinate complex *trans*-$[RuCl_2\{\kappa^2\text{-}P,P\text{-}(S)\text{-peap}\}_2]$ (**1**), its *cis* isomer (**2**) and analogous cationic derivatives, *cis*-$[RuCl(CO)\{\kappa^2\text{-}P,P\text{-}(S)\text{-peap}\}_2][SbF_6]$ (**4**), *trans*-

[RuCl(CO){κ²-*P*,*P*-(*S*)-peap}₂][SbF₆] (**5**), *trans*-[RuCl(=C=C=CHPh){κ²-*P*,*P*-(*S*)-peap}₂][BF₄] (**6**) and [Ru(acac){κ²-*P*,*P*-(*S*)-peap}₂][SbF₆] (**7**) have also been prepared.

Results and Discussion

Synthesis of *trans*-[RuCl₂{κ²-*P*,*P*-(*S*)-peap}₂] (1) and *cis*-[RuCl₂{κ²-*P*,*P*-(*S*)-peap}₂] (2)

The complex *trans*-[RuCl₂{κ²-*P*,*P*-(*S*)-peap}₂] (**1**) is stereoselectively prepared by the treatment of a stoichiometric mixture of complex [RuCl₂(DMSO)₄] (DMSO = dimethyl sulfoxide) and (*S*)-peap [(−)-*N*,*N*-bis(diphenylphosphanyl)-(*S*)-1-phenylethylamine] in refluxing toluene. The complex **1** has been isolated as an air stable yellow solid (78%) (Scheme 1).

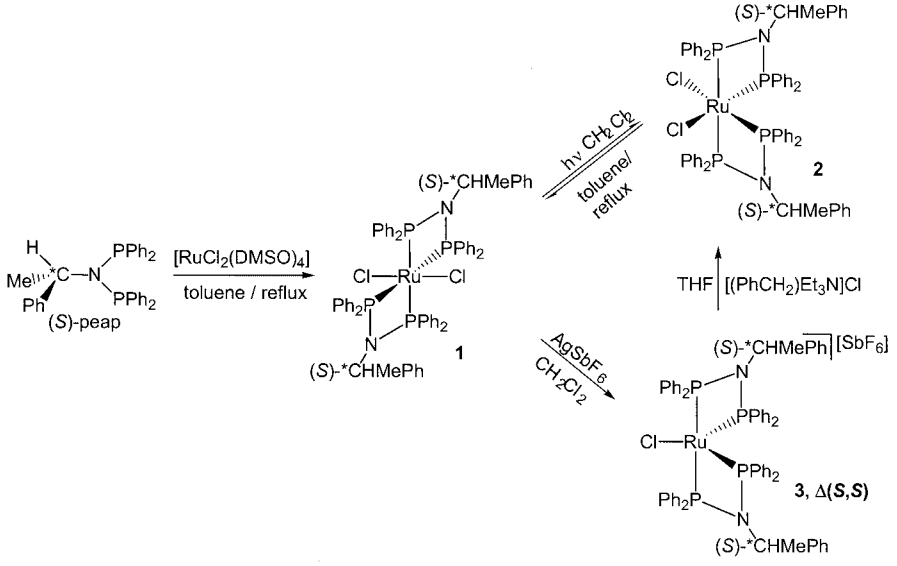
Irradiation with a UV lamp (400 W) of a dichloromethane solution of complex **1** at −15 °C for 1 h leads to an orange solution from which complex *cis*-[RuCl₂{k²-*P*,*P*-(*S*)-peap}₂] (**2**) can be isolated as an air stable orange solid (92%) (Scheme 1).

The complexes **1**−**2** are soluble in chlorinated solvents and insoluble in hexane and have been characterized by IR and NMR (^{1}H, ^{31}P{^{1}H} and ^{13}C{^{1}H}) spectroscopy (details are given in the Exp. Sect.). A sharp absorption band, assignable to the symmetrical vibration of the P-*N*−P group, is observed at ca. 850−870 cm^{-1} in the IR spectra.[10]

The ^{31}P{^{1}H} NMR spectrum of **1** shows a singlet signal at δ = 78.5, which is clearly downfield with respect to that of the free ligand (δ = 55.3 ppm, br), the deshielding ($\Delta\delta = \delta_{complex} - \delta_{ligand} = +23.2$) being intermediate to those found in the analogous *trans*-[RuCl₂{κ²-*P*,*P*−Ph₂PN(R)PPh₂}₂] [R = *i*Pr (Δδ = +27.1); H (Δδ = +18.0)].[7b] The ^{31}P{^{1}H} NMR spectrum of **2** shows two triplets (A_2X_2 spin system) at 72.57 and 87.73 ppm ($^2J_{P,P'}$ = 31.1 Hz) indicating that a single diastereoisomer, Δ(*S*,*S*) or Λ(*S*,*S*), is formed.[11] These signals can be assigned to the axial (P *trans* to P) and equatorial (P *trans* to Cl) phosphorus nuclei, respectively. Only one of the two diastereoisomers, Δ(*S*,*S*), is drawn in Scheme 1. Completion of the *trans*- to *cis*-isomerization is determined by the disappearance of the singlet resonance of complex **1** and the simultaneous appearance of two new signals assigned to complex **2**.

cis- to *trans*-Rearrangements

Complexes **1** and **2** undergo either *trans*/*cis* isomerization under thermal or photochemical conditions. The *cis* isomer **2** can be quantitatively converted into the thermodynamically stable *trans* isomer by heating in toluene (5 h) (Scheme 1).[12] The *cis*- to *trans*-isomerization does not take place at room temperature. It is interesting to note that the formation of the kinetically controlled *cis* isomer was not observed during the thermal synthesis of **1** starting from [RuCl₂(DMSO)₄] and (*S*)-peap. It can be suggested that if the *cis* isomer is actually formed in solution during the process, it immediately isomerizes to the thermodynamically more stable *trans* isomer **1**. On the other hand, the *trans*- to *cis*-rearrangement takes place by irradiation with a UV lamp as has been seen above. On the contrary, complexes [RuX₂{κ²-*P*,*P*−Ph₂PYPPh₂}₂] (X = halide; Y = CH₂,[13] C=CH₂ [14] or NH[8a]) undergo *trans*- to *cis*-isomerization by heating the *trans* isomers in refluxing chlorobenzene or 1,2-dichloroethane, and the reverse *cis*- to *trans* photochemical rearrangement has also been described for *cis*-[RuCl₂(dppm)₂].[13b] The factors responsible for determining the thermodynamically preferred forms of the *trans*/*cis* isomers are not entirely clear. Sullivan and Meyer argued, in the case of *cis*/*trans*-[RuCl₂(dppm)₂][13b] that the *cis* isomer is thermodynamically stable since it is stabilized by π-donation from the Cl atom through the Ru center to a *trans*-P atom, whereas this favorable interaction is not possible in the *trans* isomer. At present, we have no explanation



Scheme 1

for the different results obtained in our case, with the auxiliary ligand (*S*)-peap.

Electrochemical Behavior of Complexes 1 and 2

In order to compare the electrochemical properties of *trans*/*cis* isomers with those of the $[RuX_2(P-P)_2]$ analogues, the electrochemical behavior of *trans*- and *cis*-$[RuCl_2\{\kappa^2$-*P*,*P*-(*S*)-peap$\}_2]$ complexes has been studied by cyclic voltammetry in CH_2Cl_2 solutions. All potentials are referenced to a silver-wire electrode. It was found that the *trans* isomer **1** undergoes one-electron oxidation [a chemically and electrochemically reversible process under the experimental conditions ($E_{1/2} = 1/2(E_p^{ox} + E_p^{red}) = 0.61$ V)], while the $E_{1/2}$ values for the analogous *trans* derivatives with dppm and $Ph_2N(R)PPh_2$ (R = H, Me) are 0.42 [13b] and 0.175−0.240 V,[7b] respectively. This means that the (*S*)-peap ligand is a much better stabilizing ligand for +2 oxidation state than dppm and the other bis(diphenylphosphanyl)amines. A second, chemically irreversible wave, corresponding to the Ru^{IV}/Ru^{III} couple, appears for all of the *trans*-ruthenium(III) complexes [for Ru^{III} complex containing the (*S*)-peap ligand at 1.25 V]. On the other hand, the *cis* isomer **2** only exhibits an irreversible anodic wave ($E_p^{ox} = 1.19$ V), while two waves are observed for *cis*-$[RuCl_2(dppm)_2]$ and *cis*-$[RuCl_2(\{\kappa^2$-*P*,*P*−$Ph_2N(Me)PPh_2)]$, the first one being chemically reversible, ($E_{1/2} = 0.79$ and 0.35 V, respectively) and the second one chemically irreversible.

The oxidation wave from the *cis* isomer **2** is at a higher potential than the corresponding *trans* isomer **1**. This increasing potential in going from the *trans* to the *cis* isomer is well established in ruthenium(II) chemistry.[7b,13b]

Synthesis of Five-Coordinate Complex $[RuCl\{k^2$-*P*,*P*-(*S*)-peap$\}_2][SbF_6]$ (3)

Complex **1** reacts with $AgSbF_6$ in dichloromethane at room temperature to give, after filtration of AgCl, the cationic complex $[RuCl\{\kappa^2$-*P*,*P*-(*S*)-peap$\}_2][SbF_6]$ (**3**) isolated as an air stable red solid (93%) (Scheme 1). Analogous tetrafluoroborate (BF_4) and triflate (OSO_2CF_3) salts can be obtained similarly. Conversely, Higgins has recently reported that the treatment of *trans*-$[RuCl_2\{\kappa^2$-*P*,*P*-$Ph_2PYPPh_2\}_2]$ (Y = C=CH_2, NH) in 1,2-dichloroethane at room temperature with $AgBF_4$ or $AgOSO_2CF_3$ gives the *trans*-$[RuCl\{\kappa^2$-*P*,*P*-$Ph_2PYPPh_2\}_2(\mu$-Cl)Ag]X (X = BF_4, OSO_2CF_3) and no AgCl precipitate is formed.[14b]

Complex **3** has been fully characterized by elemental analyses, IR and NMR (^1H, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$) spectroscopy (details are given in the Exp. Sect.) as well as an X-ray diffraction study (see below). All the data suggest the formation of only one diastereoisomer. In particular, the $^{31}P\{^1H\}$ NMR spectrum shows two pseudotriplets (A_2X_2 spin system) at $\delta = 69.63$ (P_{ax}) and 101.67 (P_{eq}) (t, $^2J_{P,P'} = 42.3$ Hz)[15] which are consistent with the formation of a sole diastereoisomer with a stereochemically rigid trigonal-bipyramidal structure (TBP). This pattern remains unchanged over a wide temperature range (193 to 353 K) in dichloromethane or 1,2-dichloroethane solution, indicating that a dynamic process involving an equilibrium between the two diastereoisomers $\Delta(S,S)$ and $\Lambda(S,S)$ is unlikely.

The five-coordinate species seems to remain unchanged in more concentrated solutions since no change in the chemical shifts is observed. Therefore, an equilibrium between the monomer and the chloride-bridged dimer, as observed for the complex $[RuCl(\kappa^2$-*P*,*N*−$Ph_2PCH_2CH_2$-2-py$)_2]^+$ can be discarded.[16] In addition, the solutions maintain the typical red colour due to pentacoordinate species.[17]

To the best of our knowledge, **3** is the first example of a five-coordinate ruthenium(II) complex with four-membered chelate ligands that could be isolated and characterized by an X-ray diffraction analysis. Several attempts to prepare analogous complexes having diphosphane ligands Ph_2YPPh_2 (Y = CH_2, C=CH_2; NH) have been reported in the literature, but they did not lead to pure products.[8a] Steric and electronic effects apparently cooperate in stabilizing the Lewis-acidic 16-electron complex **3** containing the bulkier phosphane (*S*)-peap.

Structure of Complex $[RuCl\{\kappa^2$-*P*,*P*-(*S*)-peap$\}_2]$-$[SbF_6]\cdot C_2H_4Cl_2$ (3)

The structure of the pentacoordinate complex $[RuCl\{\kappa^2$-*P*,*P*-(*S*)-peap$\}_2][SbF_6]$ has been determined by a single X-ray analysis. Suitable crystals have been obtained by slow diffusion of pentane into a solution of complex **3** in 1,2-dichloroethane. ORTEP type views of the cation of complex **3** are shown in Figure 1 and selected bond lengths and angles are collected in Table 1.

The five coordinate cation $[RuCl\{\kappa^2$-*P*,*P*-(*S*)-peap$\}_2]^+$ displays a distorted trigonal-bipyramidal structure (Y-shaped)[18] with the bidentate (*S*)-peap ligands spanning axial and equatorial positions and the chloride atom occupying the remaining equatorial position as expected for π-stabilized 16-electron complexes.[1e,11] The P(4)−Ru−P(2) [167.87(3)°], Cl−Ru−P(4) [95.65(3)°] and Cl−Ru−P(2) [96.39(3)°] angles are indicative of a distorted TBP geometry. The Y-equatorial plane is further distorted, with an angle P(3)−Ru−P(1) of 99.76(3)°, and two different P−Ru−Cl angles [P(1)−Ru−Cl [136.61(4)°] and P(3)−Ru−Cl [123.53(4)°], as already observed in pentacoordinate ruthenium systems with other diphosphanes.[1e,2,3] The angle between the planes defined by [P(1), P(3), Ru] and [Cl, P(1), P(3)] is 1.55(2)°, indicating that the ruthenium atom is slightly displaced towards P(2) from the equatorial plane. The bite angles P(1)−Ru−P(2) [69.32(3)°] and P(3)−Ru−P(4) [69.61(3)°] of the chelate (*S*)-peap ligands show values similar to those found in the complex $[RuH(\eta^5$-$C_9H_7)\{\kappa^2$-*P*,*P*-(*S*)-peap$\}]$ [70.44(12)°].[9]

The distance Ru−Cl [2.3722(9) Å] lies in the range found for analogous five coordinate diphosphane complexes, like $[RuCl(dppe)_2]^+$,[2] and $[RuCl(dcpe)_2]^+$,[3] and is ca. 0.05 Å shorter than those observed in *trans*-$[RuCl_2\{\kappa^2$-*P*,*P*−$Ph_2PN(R)PPh_2\}_2]$ (R = Me, *i*Pr),[7b] a feature that supports the chloride ligand-to-metal π-donation. Other typical features are the shorter Ru−P_{eq} distances, [Ru−P(1) 2.2425(8) and Ru−P(3) 2.2265(9) Å], compared with the

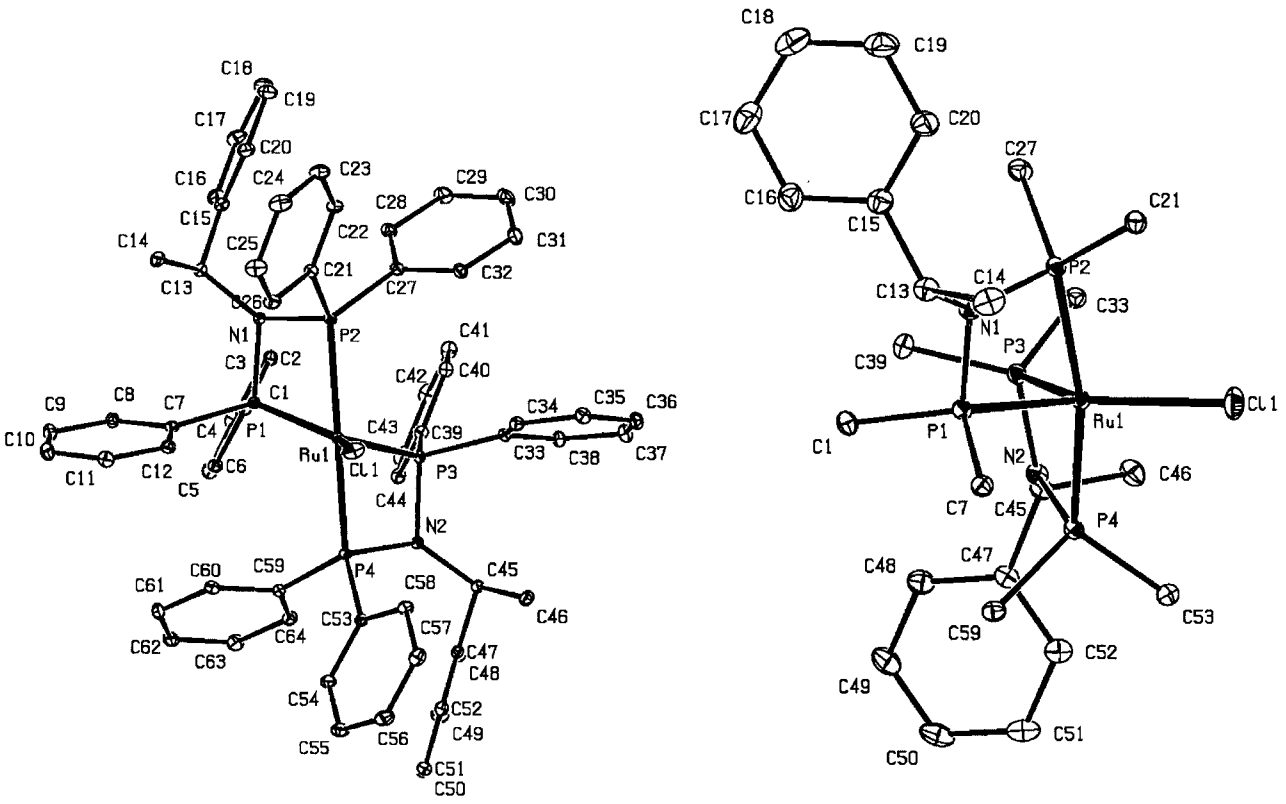

Figure 1. ORTEP type views of the molecular structure of the [RuCl{κ²-*P,P*-(*S*)-peap}₂][SbF_6]·$C_2H_4Cl_2$ (**3**); hexafluoroantimoniate anion and $C_2H_4Cl_2$ molecule have been omitted for clarity; (left) view of cation complex projected along the Ru−Cl vector, drawn at 10% probability level; (right) view of cation complex projected perpendicular to the Ru−Cl vector, drawn at 30% probability level; for clarity, only the C *ipso* of the aryl groups of PPh_2 are depicted

Ru−P_{ax} ones [Ru−P(2) 2.3768(8) and Ru−P(4) 2.3726(8) Å], thus suggesting that the former form strong phosphorous metal-dative bonds.[5,11] Usual Ru^{II}−P distances for phosphane ligands are in the range of 2.35−2.40 Å. Therefore it appears that these P_{eq} atoms as well as the chloride ligand make up for the electron deficiency of the ruthenium(II).

The configuration at the ruthenium atom is Δ [diastereoisomer Δ(*S,S*)]. Analogously, only one diastereoisomer, Λ(*S,S*), was found for complex [RuCl(bnpe)₂][PF_6] [bnpe = (*S,S*)-1,2-bis(1-naphthylphenylphosphanyl)ethane] whose structure was determined by an X-ray study.[1e] So, complex [RuCl{κ²-*P,P*-(*S*)-peap}₂][SbF_6] (**3**) is a five-coordinate system both, in the solid state and in solution (in ^{31}P NMR) and only one diastereoisomer has been found.

The catalytic activity of unsaturated complex **3** in the hydrogen transfer reaction of acetophenone has been investigated. The reaction has been performed in 2-propanol at 82 °C, in the presence of NaOH (acetophenone/cat/NaOH, 500:1:24) and monitored by gas chromatography. The ketone is rapidly reduced with 91% conversion in 1 h. Unfortunately, the enantioselective process fails because the (*S*)-peap ligand does not promote, in this case, any chiral induction. The remote location of the chiral centers from the reaction site might explain the lack of enantioselectivity.[19]

Synthesis of Cationic Complexes *cis*-[RuCl(CO){κ²-*P,P*-(*S*)-peap}₂][SbF_6] (4), *trans*-[RuCl(CO){κ²-*P,P*-(*S*)-peap}₂][SbF_6] (5), *trans*-[RuCl(=C=C=CHPh){κ²-*P,P*-(*S*)-peap}₂][BF_4] (6) and *cis*-[Ru(acac){κ²-*P,P*-(*S*)-peap}₂][SbF_6] (7)

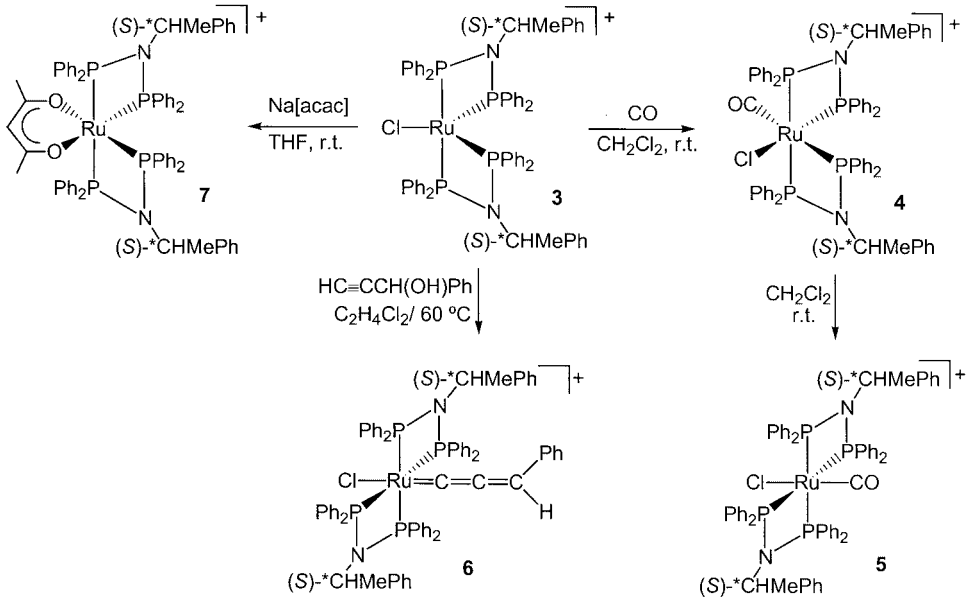
As expected, the unsaturated complex **3** reacts with carbon monoxide at 1 atm to stereoselectively form the corresponding six-coordinate complex *cis*-[RuCl(CO){κ²-*P,P*-(*S*)-peap}₂][SbF_6] (**4**) (93%). Complex **4** slowly isomerizes in CH_2Cl_2 solution to give, quantitatively, the isomer *trans*-[RuCl(CO){κ²-*P,P*-(*S*)-peap}₂][SbF_6] (**5**) (Scheme 2).

These complexes are air stable pale yellow solids. Spectroscopic data (IR, ^1H, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR) support the proposed formulation. In particular, the IR spectra of complexes **4** and **5** show a strong ν(CO) absorption at 1997 and 1982 cm^{-1}, respectively. The $^{31}P\{^1H\}$ NMR spectra exhibit the expected pattern ABMX system for **4** (see Exp. Sect.) and a multiplet centered at δ = 72.83 ppm, typical of a closely spaced A_2B_2 system, occurs for **5**.

Similar *cis*- to *trans*-isomerization has been observed in analogous diphosphane complexes, i.e. [RuCl(CO)-(dcpe)₂]⁺,[20] and [RuCl(CO)(dppm)₂]⁺.[8a]

Complex [RuCl{κ²-*P,P*-(*S*)-peap}₂][BF_4] has also proven to be an excellent precursor for stabilized unsaturated car-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 2

bene complexes. Thus, the treatment of 1-phenyl-2-propyn-1-ol with [RuCl{κ²-*P*,*P*-(*S*)-peap}$_2$][BF_4] in 1,2-dichloroethane (60 °C) affords the allenylidene derivative *trans*-[RuCl(=C=C=CHPh){κ²-*P*,*P*-(*S*)-peap}$_2$][BF_4] (**6**) (76%) (Scheme 2). The formation of the allenylidene complex **6** requires heating the reaction at 60 °C for four hours in a minimum amount of solvent (around 0.5 mL for a 0.1 mmol scale) and an excess of alkynol (complex **3**/alkynol, 1:5). The synthesis of **6**, under more dilute conditions, does not go to completion but formation of decomposition products is observed. Probably, the higher steric requirement of the allenylidene fragment leads directly to the thermodynamically stable *trans* complex **6** and the *cis* isomer is not observed.

Analytical and spectroscopic data (IR, ^{1}H, ^{31}P{^{1}H} and ^{13}C{^{1}H} NMR) support the proposed formulation. Significantly, the ^{13}C{^{1}H} NMR spectrum of **6** is in agreement with the presence of the cumulene moiety, showing the expected resonances for C_α (δ = 322.32 ppm, pseudo triplet, $^2J_{C,P}$ = 14.8 Hz), C_β (δ = 218.14 ppm, s) and C_γ (δ = 150.11 ppm, s).[21] In addition the IR spectrum shows a strong absorption at 1939 cm^{-1} assigned to the ν(C=C=C) vibration.

The reaction of complex **3** with Na[acac] gives the complex [Ru(acac){κ²-*P*,*P*-(*S*)-peap}$_2$][SbF_6] (**7**) wherein the [acac]$^-$ acts as an anionic bidentate chelate ligand (see Scheme 2). Complex **7** is isolated as an air stable yellow solid in 81% yield. Spectroscopic data (IR, ^{1}H, ^{31}P{^{1}H} and ^{13}C{^{1}H} NMR) are in accordance with the proposed formulation. The ^{31}P{^{1}H} NMR spectrum of **7** shows two triplets (A_2X_2 spin system) at 68.50 and 83.11 ppm ($^2J_{P,P}$ = 34.9 Hz) and suggest the formation of the *cis* product. Complex **3** also reacts with an excess of [$(PhCH_2)Et_3N$]Cl to yield the 18-electron *cis* isomer **2**, the preparation of which has been described above (Scheme 1).

Experimental Section

General Conditions: The reactions were carried out under dry nitrogen using standard Schlenk techniques. Solvents were dried by standard methods and distilled under nitrogen before use. The complex [$RuCl_2(DMSO)_4$][22] and $(Ph_2P)_2N$[(*S*)-*CHMePh] [(*S*)-peap][23] were prepared by literature methods. Infrared spectra were recorded with a Perkin−Elmer FT-1720-Y spectrometer using KBr disks. The conductivities were measured at room temperature, in *ca* 5 × 10^{-4} mol·L^{-1} acetone solutions, with a Jenway PCM3 conductimeter. C, H and N analyses were carried out with a Perkin−Elmer 240-B microanalyzer (inconsistent analyses are found for complexes **2**, **4**−**6** due to incomplete combustion). Mass spectra (FAB) were recorded using a VG-Autospec spectrometer, operating in the positive mode; 3-nitrobenzyl alcohol (NBA) was used as the matrix. NMR spectra were recorded with a Bruker AC300 (DPX-300 or AV-300) instrument at 300 MHz (^{1}H), 121.5 MHz (^{31}P) or 75.4 MHz (^{13}C) or a Bruker AC200 instrument at 200 MHz (^{1}H), 81.01 MHz (^{31}P) or 50.32 MHz (^{13}C), using $SiMe_4$ or 85% H_3PO_4 as standards.

Synthesis

Synthesis of *trans*-[$RuCl_2${κ²-*P*,*P*-(*S*)-peap)}$_2$] (1): A mixture of [$RuCl_2(DMSO)_4$] (0.98 g, 2 mmol) and (*S*)-peap (1.958 g, 4 mmol) in 60 mL of toluene was heated under reflux for 3 h. The solvent was removed under reduced pressure and the yellow precipitate was washed with toluene and diethyl ether. The crude solid was recrystallized from dichloromethane/pentane, yielding 1.80 g of the solid **1** (78%). MS (FAB): *m*/*z* = 1150 [M$^+$ − 1], 1115 [M$^+$ − Cl − 1], 1079 [M$^+$ − 2 Cl − 1] (correct isotope patterns observed for each fragment). IR (KBr): $\tilde{\nu}$ = 853 cm^{-1} (s, PNP). ^{31}P{^{1}H} NMR

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(CD_2Cl_2): δ = 78.5 (s) ppm. ^1H NMR ($CDCl_3$): δ = 1.45 (d, $J_{H,H}$ = 7.1 Hz, 6 H, *CCH_3), 5.14 (m, 2 H, *CH), 6.72−7.76 (m, 50 H, PPh_2, *CPh) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 23.44 (s, *C*CH_3), 62.45 (s, *C), 126.37−136.77 (PPh_2, *C*Ph*), 142.08 (s, *CC_{ipso}) ppm. $C_{64}H_{58}Cl_2N_2P_4Ru{\cdot}CH_2Cl_2$ (**1**·CH_2Cl_2) (1150.99·CH_2Cl_2): calcd. C 63.17, H 4.89, N 2.27; found C 63.76, H 4.88, N 2.05.

Synthesis of *cis*-[$RuCl_2${κ²-*P,P*-(*S*)-peap}$_2$] (2): A solution of complex **1** (0.345 g, 0.5 mmol) in 80 mL of dichloromethane was irradiated at −15 °C with a UV lamp (400 W) for 1 h. The solvent was removed to dryness and the product recrystallized from dichloromethane/diethyl ether yielding 0.317 g of **2** (92%). IR (KBr): $\tilde{\nu}$ = 849 cm^{-1} (s, PNP). $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 72.57 (t, $^2J_{P,P'}$ = 31.1 Hz, 2 P_{ax}), 87.73 (t, $^2J_{P,P'}$ = 31.1 Hz, 2 P_{eq}) ppm. ^1H NMR (CD_2Cl_2): δ = 1.33 (d, $J_{H,H}$ = 7.2 Hz, 6 H, *CCH_3), 4.75 (m, 2 H, *CH), 6.38−8.26 (m, 50 H, PPh_2, *CPh) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 23.26 (s, *C*CH_3), 61.87 (s, *C), 125.15−139.07 (PPh_2, *C*Ph*), 140.69 (s, *CC_{ipso}) ppm.

Synthesis of [RuCl{κ²-*P,P*-(*S*)-peap}$_2$][SbF_6] (3): A mixture of complex **1** (1.15 g, 1 mmol) and $AgSbF_6$ (0.344 *g*, 1.1 mmol) was stirred at room temperature in 50 mL of dichloromethane for 1 h in the absence of light. The solution, whose color changed from yellow to red, was filtered through celite and the solvent removed to dryness. The oil obtained was recrystallized from diethyl ether to yield 1.26 g of complex **3** as a red solid (93%). The corresponding tetrafluoroborate (BF_4) or triflate (OSO_2CF_3) salts could be similarly prepared. MS (FAB): *m*/*z* = 1116 [M $^+$], 1080 [M^+ − Cl] (correct isotope patterns observed for each fragment). IR (KBr): $\tilde{\nu}$ = 849 (s, PNP), 658 cm^{-1} (s, SbF_6^-). Conductivity (acetone, 20 °C): 148 Ω^{-1} cm^2 mol^{-1}. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 69.63 (t, $^2J_{P,P'}$ = 42.3 Hz, 2 P_{ax}), 101.67 (t, $^2J_{P,P'}$ = 42.3 Hz, 2 P_{eq}) ppm. ^1H NMR (CD_2Cl_2): δ = −0.06 ppm (d, $J_{H,H}$ = 7.2 Hz, 6 H, *CCH_3), 3.90 (m, 2 H, *CH), 6.49−7.70 (m, 50 H, PPh_2, *CPh) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 21.25 (s, *C*CH_3), 64.42 (s, *C), 124.88−136.55 (PPh_2, *C*Ph*), 140.36 (s, *CC_{ipso}) ppm. $C_{64}H_{58}ClF_6N_2P_4RuSb{\cdot}0.5CH_2Cl_2$ (**3**·0.5CH_2Cl_2) (1351.27·0.5CH_2Cl_2): calcd. C 55.58, H 4.27, N 2.01; found C 55.52, H 4.68, N 1.73.

Synthesis of *cis*-[RuCl(CO){κ²-*P,P*-(*S*)-peap}$_2$][SbF_6] (4): Complex **3** (0.676 g, 0.5 mmol) was dissolved in 20 mL of dichloromethane, and CO gas was bubbled though the solution for 5 minutes. The solution immediately changed from red to colorless. The solvent was removed to dryness and the crude product recrystallized from dichloromethane/diethyl ether to yield 0.641 g of the pale yellow solid **4** (93%). IR (KBr): $\tilde{\nu}$ = 1997 (s, CO), 876 (m, PNP), 658 cm^{-1} (s, SbF_6^-). Conductivity (acetone, 20 °C): 126 $\Omega^{-1}{\cdot}cm^2{\cdot}mol^{-1}$. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): ABMX system, δ = 55.79 [P_{eq} (P_M)], 63.63 [P_{ax} (P_A)], 68.26 [P_{ax} (P_B)], 76.79 [P_{eq} (P_X)] (J_{AB} = 270.2, J_{BM} = 54.4, J_{AX} = 51.3, J_{AM} = 28.0, J_{MX} = 21.7, J_{BX} = 18.6) ppm. ^1H NMR (CD_2Cl_2): δ = 0.73 (d, $J_{H,H}$ = 6.8 Hz, 3 H, *CCH_3), 0.83 (d, $J_{H,H}$ = 7.1 Hz, 3 H, *CCH_3), 4.44 (m, 2 H, *CH), 6.28−7.99 (m, 50 H, PPh_2, *CPh) ppm.

Synthesis of *trans*-[RuCl(CO){κ²-*P,P*-(*S*)-peap}$_2$][SbF_6] (5): Complex **4** (0.414 g, 0.3 mmol) was dissolved in 40 mL of dichloromethane and the solution was stirring at room temp. for 5 days until its complete conversion into the *trans* isomer. The solvent was removed to dryness and the crude product recrystallized from dichloromethane/diethyl ether yielding 0.393 g of **5** (95%). MS (FAB): *m*/*z* = 1144 [M $^+$], 1116 [M^+ − CO], 1080 [M^+ − CO − Cl] (correct isotope patterns observed for each fragment). IR (KBr): $\tilde{\nu}$ = 1982 (s, CO), 877 (m, PNP), 658 cm^{-1} (s, SbF_6^-). Conductivity (acetone, 20 °C): 126 $\Omega^{-1}{\cdot}cm^2{\cdot}mol^{-1}$. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 72.83 (m) ppm. ^1H NMR (CD_2Cl_2): δ = 1.18 (d, $J_{H,H}$ = 6.8 Hz, 6 H, *CCH_3), 4.84 (m, 2 H, *CH), 6.90−7.65 (m, 50 H, PPh_2, *CPh) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 23.52 (s, *C*CH_3), 65.24 (s, *C), 128.19−135.52 (PPh_2, *C*Ph*), 140.03 (s, *CC_{ipso}), 198.09 (t, $^2J_{C,P}$ = 11.8 Hz, CO) ppm.

Synthesis of *trans*-[RuCl(=C=C=CHPh){κ²-*P,P*-(*S*)-peap}$_2$][BF_4] (6): To a mixture of complex [RuCl{κ²-*P,P*-(*S*)-peap}$_2$][BF_4] (0.120 g, 0.1 mmol) in 0.5 mL of 1,2-dichloroethane, the alkynol HC≡CCH(OH)Ph (0.66 g, 0.5 mmol) was added. The reaction mixture was heated at 60 °C for 4 h and the solution color changed from red to scarlet. The addition of 30 mL of diethyl ether lead to the precipitation of a scarlet solid which was washed with diethyl ether (3 × 10 mL) and vacuum-dried to yield 0.1 g of complex **6** (76%). IR (KBr): $\tilde{\nu}$ = 1939 (s, C=C=C), 1059 (br. s, BF_4^-), 864 cm^{-1} (m, PNP). Conductivity (acetone, 20 °C): 125 $\Omega^{-1}{\cdot}cm^2{\cdot}mol^{-1}$. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 70.30 (m), 73.36 (m) ppm. ^1H NMR (CD_2Cl_2): δ = 1.36 (d, $J_{H,H}$ = 7.2 Hz, 6 H, *CCH_3), 5.10 (m, 2 H, *CH), 6.97−7.73 (m, 55 H, PPh_2, *CPh, C_γPh), 8.38 (s, 1 H, C_γH) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 23.75 (s, *C*CH_3), 64.53 (s, *C), 127.88−135.80 (PPh_2, *C*Ph*, C_γ*Ph*), 140.54 (s, *CC_{ipso}), 142.49 (s, $C_\gamma C_{ipso}$), 150.11 (s, C_γ), 218.14 (s, C_β), 322.32 (t, $^2J_{C,P}$ = 14.8 Hz, Ru=C_α) ppm. $C_{73}H_{64}BClF_4N_2P_4Ru$ (1316.44): calcd. C 66.60, H 4.90, N 2.13; found C 65.85, H 4.83, N 1.63.

Synthesis of [Ru(acac){κ²-*P,P*-(*S*)-peap}$_2$][SbF_6] (7): A mixture of complex **3** (0.676 g, 0.5 mmol) and Na[acac] (0.122 g, 1 mmol) in 10 mL of tetrahydrofuran was stirred at room temp. for 1 h. The solution was then evaporated to dryness and the residue obtained was extracted with CH_2Cl_2 and filtered through celite. The concentration of the resulting solution to ca. 2 mL followed by the addition of 20 mL of hexane precipitated a pale yellow solid, which was washed with hexane (2 × 20 mL) and dried in vacuo, yielding 0.573 g of **7** (81%). MS (FAB): *m*/*z* = 1179 [M $^+$], 1080 [M^+ − acac] (correct isotope patterns observed for each fragment). IR (KBr): $\tilde{\nu}$ = 1580, 1518 (s, acac), 872 cm^{-1} (m, PNP), 658 (s, SbF_6^-). Conductivity (acetone, 20 °C): 117 $\Omega^{-1}{\cdot}cm^2{\cdot}mol^{-1}$. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 68.50 (t, $^2J_{P,P'}$ = 34.9 Hz, 2 P_{ax}), 83.11 (t, $^2J_{P,P'}$ = 34.9 Hz, 2 P_{eq}) ppm. ^1H NMR (CD_2Cl_2): δ = 0.73 (d, $J_{H,H}$ = 6.7 Hz, 6 H, *CCH_3), 1.69 (s, 6 H, 2COCH_3), 4.32 (m, 2 H, *CH), 4.38 (s, 1 H, CH), 6.49−7.87 (m, 50 H, PPh_2, *CPh) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 23.64 (s, *C*CH_3), 27.98 (s, 2CO*C*H_3), 63.00 (s, *C), 99.34 (s, CH), 127.55−137.06 (PPh_2, *C*Ph*), 140.12 (s, *CC_{ipso}), 186.61 (s, 2CO) ppm.

Electrochemical Measurements: The electrochemical experiments were performed with an EG&G PAR potentiostat/galvanostat model 273. Cyclic voltammetry measurements were carried out in a two-compartment three-electrode cell. The working electrode was a platinum disc electrode probed by a Luggin capillary connected to a silver-wire pseudo-reference electrode, a platinum auxiliary electrode was employed. Electrochemical solutions contained 0.1 M [NBu_4][PF_6] and 10^{-3} M complex in dichloromethane. Solutions were purged and maintained under nitrogen. The scan rate was 100 $mV{\cdot}s^{-1}$. All values are referenced to an internal $[Fe(\eta^5\text{-}C_5H_5)_2]^{+/0}$ couple ($E°$ = 0.59 V).

General Procedure for Hydrogen Transfer Reaction: Acetophenone (5 mmol) and complex **3** (0.01 mmol) were placed in a three-bottomed Schlenk flask under dry nitrogen and 2-propanol (50 mL) was added. The solution was heated at 82 °C and the corresponding amount of base from a 0.080 M solution in 2-propanol was added after 15 min. The reaction was monitored by gas chromatography. 1-phenylethanol, acetophenone and acetone were the only products detected.

X-ray Structure Determination of 3·$C_2H_4Cl_2$: X-ray suitable single crystals were obtained by slow diffusion of pentane into a solution of complex **3** in 1,2-dichloroethane. Diffraction data were recorded with a Nonius Kappa CCD single-crystal diffractometer. The crystal distance was fixed at 29 mm, and 1100 frames were collected using the oscillation method, φ and ω−scans with 2° oscillation and 40 s exposure time per frame. Data collection strategy was calculated with the program Collect.[24] Data reduction and cell refinement were performed with the programs HKL Denzo and Scalepack.[25] Unit cell dimensions were determined from 11743 reflections. All data completeness was 99.4%. Data collection, crystal, and refinement parameters are collected in Table 1. The structure was solved by DIRDIF-96.[26] An empirical absorption correction was applied using XABS2.[27] Anisotropic least-squares refinement was carried out with SHELXL-97.[28] All non-hydrogen atoms, were anisotropically refined. H atoms were geometrically placed and their coordinates were refined riding on their parent atoms with isotropic displacement parameters set to 1.2 times the U_{eq} of the atoms to which they are attached (1.5 for methyl groups). The final cycle of full-matrix least-squares refinement based on 11860 reflections and 742 parameters converged to final values of R_1 [$F^2 > 2\sigma(F^2)$] = 0.0324. Atomic scattering factors were taken from International Tables for X-ray Crystallography.[29] The function minimized was $([\Sigma wF_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$ where $w = 1/[\sigma^2(F_o^2) + (00498P)^2 + 2.3959P]$ where P = (Max. $(F_o^2 + 2F_c^2)/3$ with $\sigma^2(F_o^2)$ from counting statistics. Geometrical calculations were made with PARST.[30] The crystallographic plots were made with PLATON.[31] CCDC-216434 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

3,11,19-Trithia[3.3.3]pyridinophane: Structural Diversity in Its Transition Metal Complexes

Muthalagu Vetrichelvan,[a] Yee-Hing Lai,*[a] and Kum Fun Mok[a]

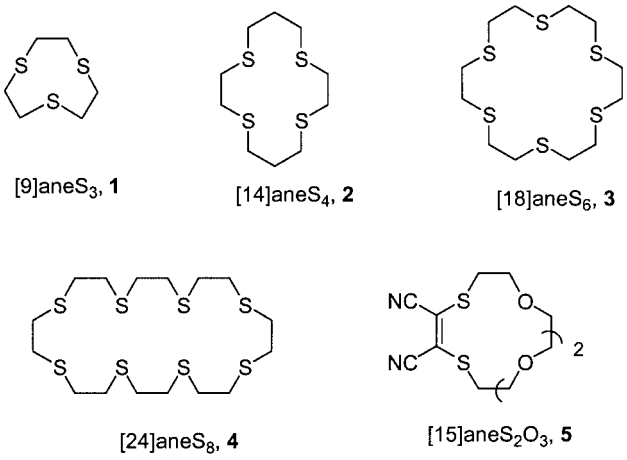
Keywords: Coordination polymers / Macrocycles / Structural diversity / Transition metals / Zwitterions

The pyridine-containing aza-thia macrocycle 3,11,19-trithia-[3.3.3]pyridinophane (**10**) and its complexes with Ni^{II}, Pd^{II}, Cu^{I}, Ag^{I} and Hg^{II} were synthesised and their crystal structures were determined. The Ni^{II} and Hg^{II} complexes (**11**, **12**) are mononuclear with **10** serving as an unusual quinquedentate ligand. The Cu^{I} complex **13** is also mononuclear with **10** being tetra-coordinated to a tetrahedral Cu^{I}. Palladium(II) forms a binuclear complex **14** which exists as an inorganic zwitterion and both Pd^{II} metal ions adopt the expected square-planar geometry with facial coordination. Silver(I) forms one-dimensional coordination polymers (**15** and **16**) with **10** and these exhibit two different coordination modes, namely tetrahedral and trigonal planar. It was found that the macrocycle **10** did not show any selectivity among a series of metal ions. The electronic and redox properties of several complexes were studied.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Crystal engineering remains one of the most fascinating areas of research in modern inorganic chemistry. It has given rise to many remarkable structures by using transition metals through the development of coordination polymers, the construction of molecular architectures and the self-assembly of complex molecular structures.[1−12] The coordination chemistry of pyridine-containing macrocycles is of particular interest due to the effective coordination ability of pyridine.[13] Parallel to this, binuclear macrocyclic complexes have also attracted much attention as catalysts and models for certain metalloenzymes.[14,15] There is also a need to understand the nature and extent of metal-metal interactions. Schröder et al.[16−18] and others[19−22] have reported a series of coordination polymers derived from Ag^{I} and thioether macrocycles **1**−**5** as well as other functionalised thioether macrocycles.[23,24] The search for appropriate organic building blocks for the construction of coordination polymers and the study of binuclear complexes led us to investigate the ligand **10**. The intramolecular layout of the three pyridine rings in **10** means that it is able to form a cone-like conformation similar to that of calixarenes and thus **10** was expected to exhibit interesting complexation properties.

We report herein a new synthetic route to the macrocycle **10** and the preparation of a series of its transition metal complexes **11**−**16**. The solid-state structures of the metal complexes, their electronic and redox properties and an extraction study of the macrocycle are discussed. To the best of our knowledge, complexes **15** and **16** are the first examples of one-dimensional Ag^{I} coordination polymers exhibiting two different coordination geometries with the same macrocyclic ligand. The palladium complex **14** is dinuclear and exists as an inorganic zwitterion while Cu^{I}, Ni^{II} and Hg^{II} form mononuclear complexes **11**−**13** having different degrees of coordination.



Results and Discussion

Syntheses

The macrocycle **10** was previously isolated as a side-product in a reaction between bis(bromomethyl)pyridine and

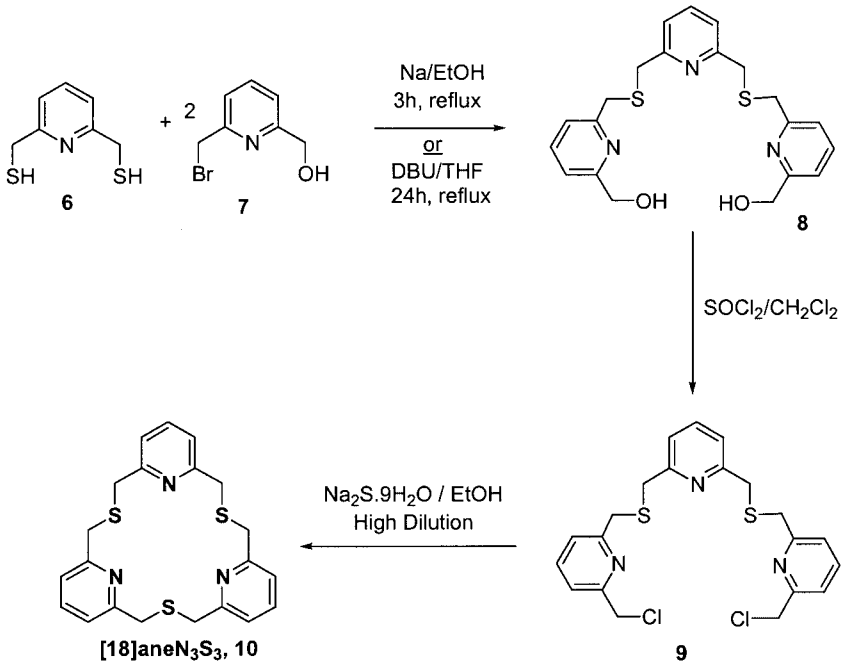

Scheme 1. Synthetic scheme for the preparation of the macrocycle **10**

thioacetamide.[25] An improved synthetic route to **10** was employed in this work starting from known precursors[26] **6** and **7** (Scheme 1) giving a 50% overall yield of **10**. The reaction between **6** and **7** to afford the diol **8** could be achieved in two ways: in the presence of DBU/THF or with Na/ethanol. The latter was found to need a shorter reaction time and gave a higher yield of **8**. Treatment of the diol **8** with thionyl chloride gave the dichloride **9** in a 90% yield. The macrocycle [18]aneN$_3$S$_3$ **10** was isolated in a 70% yield via an intramolecular coupling reaction of **9** with sodium sulfide under high-dilution conditions.[27,28]

The metal complexes **11**−**16** (Figure 1) of the macrocycle **10** were prepared by reactions of the ligand with the appropriate metal salts, respectively; details are given in the Exp. Sect.

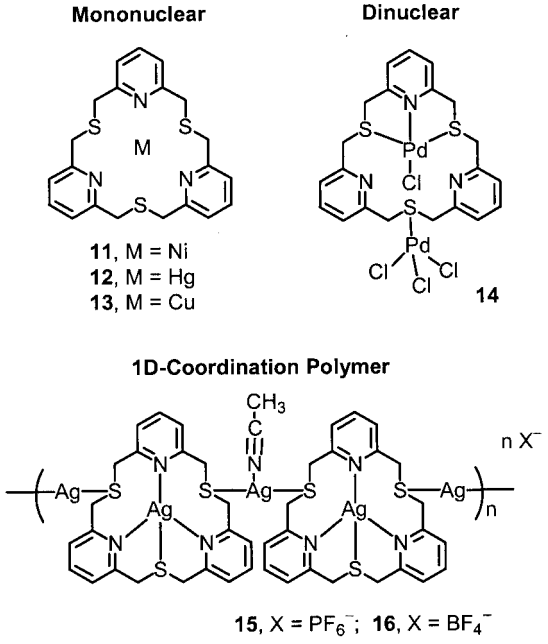

Figure 1. Structural diversity of complexes **11**−**16**

Structure Description of [Ni(10)(ClO$_4$)$_2$] (11)

In the crystal structure of the nickel complex **11** (Figure 2), the nickel centre is five-coordinate. Although the macrocycle **10** has six donor atoms, a rare pentacoordinate nickel is observed in this case, which is probably due to a relatively large macrocyclic cavity. The asymmetric unit contains two independent halves of the molecule. The ORTEP diagram of the complex is shown in Figure 2 (left) and selected bond lengths and bond angles are given in Table 1 and Table 2, respectively.

The geometric parameter τ, which is equal to zero for a perfect square pyramid and becomes unity for a perfect trigonal bipyramid,[29] was calculated to be about 0.65, thus indicating that the nickel in complex **11** adopts a distorted trigonal bipyramidal geometry. Three pyridine nitrogens form a trigonal plane and two of the benzylic sulfur atoms occupy the axial positions of the trigonal bipyramids. Pentacoordination is relatively rare for Ni^{II}, which more often forms either high-spin octahedral or low-spin square-planar complexes.[30] In addition, Ni^{II} complexes with pentadentate ligands are often hexacoordinate due to bonding

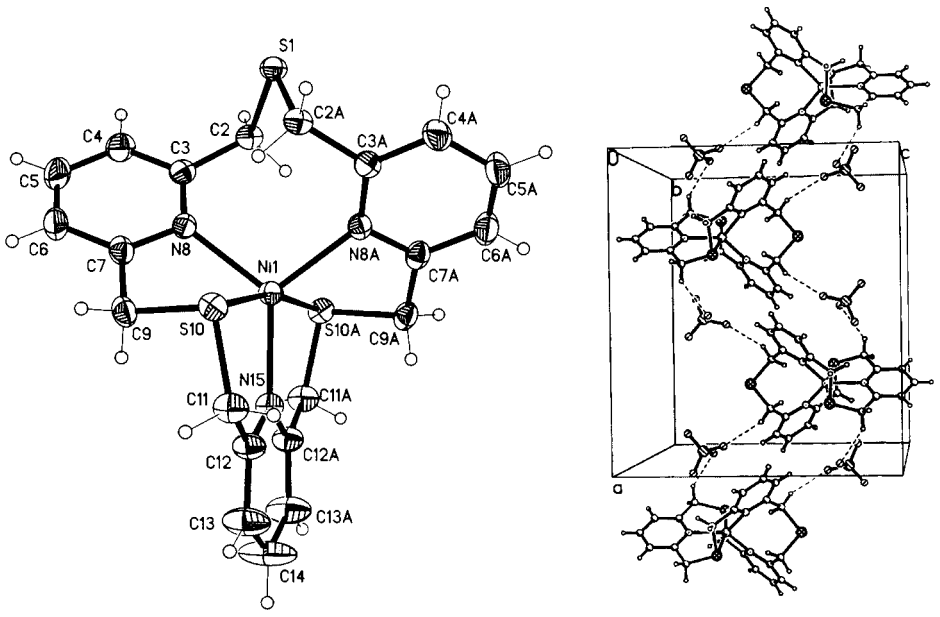

Figure 2. (left) ORTEP drawing of the Ni^{II} complex **11**; (right) packing diagram of complex **11** along the *b*-axis

to a solvent molecule or an anion.[31] A ligand with a 15- or 16-membered ring offers an ideal cavity for a six-coordinate nickel ion. The 18-membered ring in **10** is supposedly sufficiently large for this purpose. In the novel Ni^{II} complex **11**, a pentacoordinate nickel is unusually entrapped by a hexadentate macrocycle. This may be due to unfavourable steric interactions or geometrical strain developed in the ligand if all six donor groups in **11** are bonded to the Ni^{II} ion in an octahedral arrangement.[32] In addition hydrogen bonding may play a role in stabilizing the helical structure of the complex in the crystal packing [Figure 2 (right)] thus discouraging the utilisation of the sixth coordination position of the metal centre. This, we believe, is an unusual type of geometry rarely reported in the literature.

The Ni−N and Ni−S bond lengths in **11** are similar to those reported in the literature.[33] The Ni−N bond lengths are typical of high-spin Ni^{II} complexes with nitrogen donor atoms.[30] The perchlorate anions have the expected tetrahedral geometry although the variation in bond lengths and angles and the large thermal parameters suggest that some degree of disorder is present.

The packing diagram of **11** in the solid state along the *b*-axis is shown in Figure 2 (right). The adjacent molecules are linked through weak intermolecular hydrogen bonding of the type Cl−O···H−C via the benzylic C−H of the pyridine units and the oxygen atom of the perchlorate anions. The adjacent molecules are in an antiparallel array and thereby the overall crystal packing appears as a helix involving two types of hydrogen bonding, with typical bond lengths[34−36] of 2.500Å and 2.473 Å, respectively. Such hydrogen bonding has been found to be important in influencing the nature of the molecular packing in solid-state structures.[37] There is, however, no interaction between two adjacent helices in the crystal packing of **11**.

Structure Description of [Hg(10)(ClO_4)$_2$] (12)

A mononuclear mercury(II) complex of formula Hg(10)(ClO_4)$_2$ is formed when either a 1:2 or a 1:1 ratio of macrocycle **10** and metal salt were used. The X-ray structure of the complex shows that the mercury is coordinated to three pyridine nitrogens and two thioether sulfurs of the macrocycle. The geometric parameter τ for the mercury complex is 0.48, which indicates a distorted square-pyramidal geometry. The ORTEP diagram of the complex is shown in Figure 3 and Table 1 and 2 list the bond lengths and bond angles around the metal ion. One of the thioether sulfurs is not coordinated and it is in an exodentate position even after complexation. Three pyridine nitrogens form a perfect trigonal plane and two of the thioether sulfurs occupy approximately axial positions. The bond angles are very distorted due to two additional interactions of the metal ion with oxygens of the two perchlorate anions. The O···Hg distances are about 3.283 and 3.198 Å, which are too long to be considered as bonding interactions.[38] Due to these weak Hg···O interactions, the mercury ion is pseudo-seven coordinate. The N_{py}−Hg distances in the macrocycle are somewhat shorter than reported earlier.[39]

Similar to the nickel analogue, the mercury complex has four five-membered rings and one nine-membered ring which may explain the difference in bond angles and bond lengths. In the solid state, there are some weak interactions between mercury and oxygen atoms of the perchlorate anions. In addition to that, hydrogen bonding of the type -C···H-, with a bond length of 2.483 Å, is also present between the benzylic hydrogen and the oxygen of the perchlorate anions. Due to these interactions, a chain-like structure is formed.

Close inspection of the complex crystal structure along the *c*-axis shows that there are six complex cations and six perchlorate anions packed alternately, resulting in a six-membered cyclic ring. The structure forms a hexagonal-shaped space, which may be useful for specific guests.

Structure Description of [Cu(10)(PF_6)] (13)

Similar to the nickel complex, the copper complex **13** also has two independent formula units present in one asymmetric unit. The basic molecular geometries are essentially identical, although some insignificant differences in bond lengths and bond angles are observed. The ORTEP diagram of the complex is shown in Figure 4 (left) and Table 1 and 2 provides selected bond lengths and bond angles.

Two exodentate sulfurs are not coordinated to the copper(I) and all attempts to form a coordination polymer containing other metal ions as a bridge between the molecules by using these non-coordinated sulfurs failed. The molecule itself looks like a model of a person, with two exodentate sulfurs as two folded arms, one pyridine as its head and another two pyridines as two legs, as can be easily visualized from the space-filling diagram in Figure 4 (right).

The Cu^I ion is encapsulated by the ligand **10** bonding directly to three pyridine nitrogens (N9, N18 and N27 in Cu1 and N39, N48 and N57 in Cu2) and one thioether sulfur (S2 in Cu1 and S32 in Cu2). The remaining two sulfurs are not coordinated to the copper metal and are found at an average non-bonding distance of 4.0 Å. The Cu^I ion

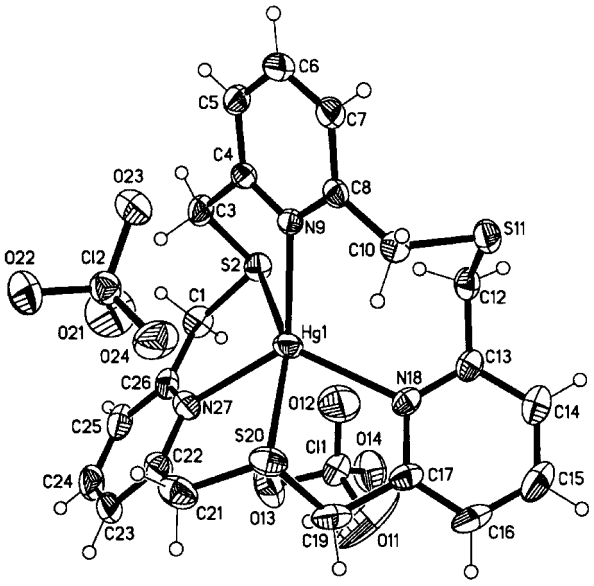

Figure 3. ORTEP drawing of the mercury complex **12**

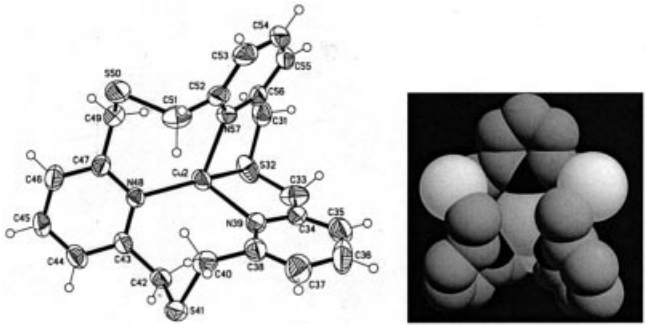

Figure 4. (left) ORTEP drawing of the copper(I) complex **13**; (right) space-filling model of **13** (hydrogen atoms omitted for clarity)

is in a tetrahedral environment with N−Cu−N angles ranging from 119.87(2) to 120.81(2)° for the eight-membered rings and S−Cu−N angles ranging from 85.64(1) to 87.09(1)° for the five-membered rings. The Cu−N and Cu−S distances are in the expected range.[40−43] In the solid-state, the molecules are not discrete but form a network structure through some hydrogen bonding and weak interactions.

Structure Description of [10(PdCl)($PdCl_3$)] (14)

The X-ray structure of the complex confirms the binuclear complex of formula [(**10**(PdCl)($PdCl_3$)]. Figure 5 shows an ORTEP diagram of the complex and Table 1 lists selected bond lengths for the metal coordination environment. The two palladium centres are not encapsulated by the ligand but are in a facial coordination. This may be because the cavity of the macrocycle is too small to accommodate two palladium metal ions or to avoid the steric interaction between the metal ions.

Each macrocyclic ligand coordinates to two palladium ions and the structure comprises two different distorted square-planar geometries. In Site A, Pd(1) is coordinated to only one sulfur [Pd−S(2) 2.306 Å] and three chlorine anions (Pd−Cl 2.297, 2.305 and 2.316 Å) and in Site B the metal ion is coordinated to one pyridine nitrogen (Pd−N 1.988 Å), two of the three sulfurs (Pd−S 2.240, 2.275 Å) and one chloride anion (Pd−Cl 2.291 Å). Thus the macrocycle acts simultaneously as a tridentate (NS_2) and a monodentate (S) ligand. The remaining two pyridine nitrogens are not coordinated to the palladium metal and are oriented away from it, with non-bonding distances of Pd(2)−N(27) 3.635 Å and Pd(2)−N(9) 3.752 Å. The Pd−N, Pd−S and Pd−Cl distances are within the expected range.[44,45]

The distance between palladium and the non-bonded nitrogens [N(9) and N(27)] is sufficiently large to permit the atoms to be non-interacting, but the nature of the macrocyclic ligand defines a limit for the furthest distance of the non-bonded nitrogens. A value of about 3.6 Å is intermediate between the normal distances for an inner-sphere or coordinated ligand (ca. 2.0 Å) and an outer-sphere or non-coordinated ligand (ca. 4.0 Å). This type of environment may cause unusual and interesting effects in the solution studies.[46] Pd(1) deviates from the mean square plane (S2, Cl1, Cl2, Cl3) by about 0.024 Å, and Pd(2) deviates by about 0.049 Å. It is of interest to note the differences in the Pd−Cl distances found for both coordination sites. Interestingly, the charges of the two palladium centres [Pd(1) and Pd(2)] in each neutral molecule are −1 and +1, respectively, resulting in an inorganic zwitterion.

The intramolecular distance between the two palladium atoms is about 6.9 Å and a short inter-ionic distance of 4.1 Å is observed between palladiums in adjacent dimeric units within the unit cell. These distances are much longer than the 2.751 Å in palladium metal[33] and preclude any metal-metal interaction. When viewed along the *a*-axis, successive layers of the complexes are arranged in an antiparallel fashion [see Figure 6 (left)]. This is due to some hydrogen bonding and other weak interactions[34−37] in the crystal lattice that are listed in Table 1 and 2. In this complex, the three pyridine rings are arranged in a cone-like conformation, as seen in Figure 6 (right). In the crystal packing and along the *c*-axis there are rectangular voids of about 13.3 Å due to these interactions and π-π stacking (3.347 Å to 4.168 Å) of the pyridine rings. Water molecules are also involved in the weak hydrogen-bonding networks.

Structure Description of [(10)$Ag_2(CH_3CN)(PF_6)_2]_\infty$ (15) and [(10)$Ag_2(CH_3CN)(BF_4)_2]_\infty$ (16)

X-ray analysis of complex **15** shows that it is a one-dimensional coordination polymer. The ORTEP diagram of the asymmetric unit of the coordination polymer is shown in Figure 7 (top). One Ag^I resides in the cavity of the macrocycle, coordinated by three N and one S donors; it adopts a distorted tetrahedral geometry with (N,S)−Ag−(S,N)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

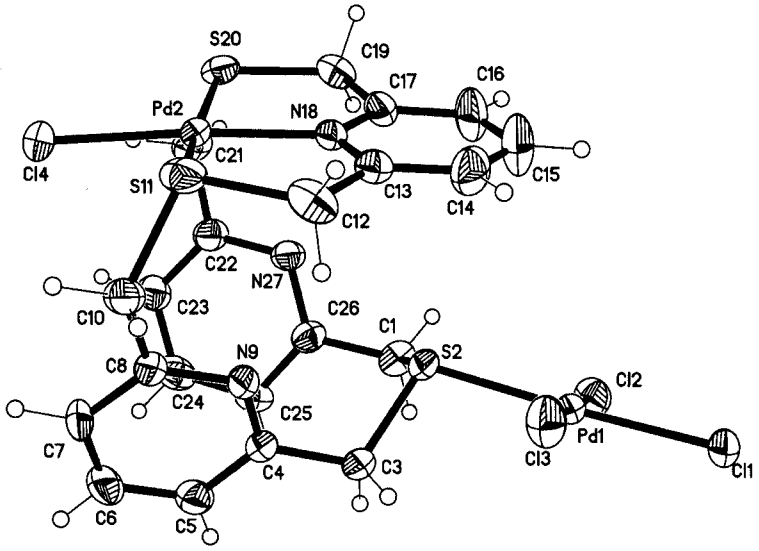

Figure 5. ORTEP diagram of the binuclear palladium complex **14**

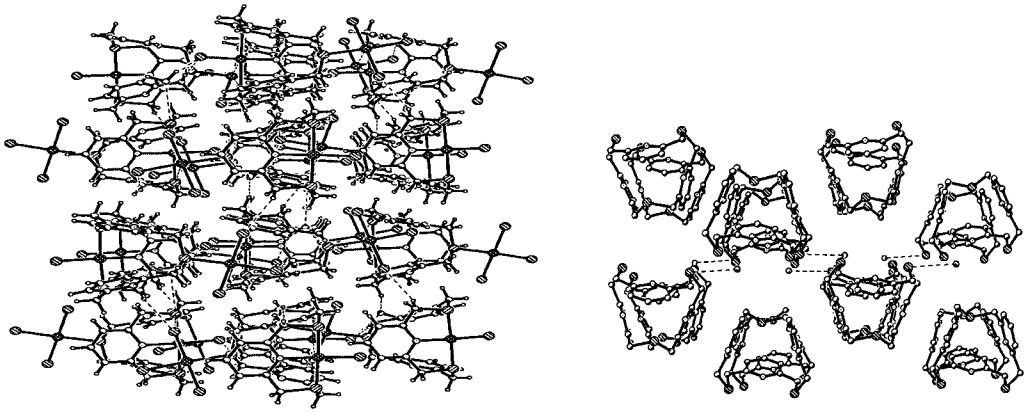

Figure 6. (left) Packing in complex **14** showing the molecules arranged into antiparallel sheets along the *a*-axis; (right) cone conformation in the packing of complex **14**

angles ranging from 78.02(9) to 149.58(8)°, Ag−N bond lengths between 2.213(3) and 2.436(4) Å and an Ag−S distance of 2.532(1) Å. The second Ag^{I} is coordinated to two S-donors from two different macrocyclic molecules with distances of 2.454(1) and 2.517(1) Å and an acetonitrile solvent molecule(Ag−N−C−CH_3 2.245 Å), with a trigonal planar geometry. The silver-acetonitrile nitrogen atom distance of 2.245 Å falls in the range of 2.18−2.33 Å reported previously.[47] Consequently all six donors of each macrocyclic molecule are engaged in coordination. The second Ag^{I} deviates by about 0.13 Å from the trigonal plane. Two different modes of coordination in a single silver complex are uncommon and the two modes of coordination are shown in Figure 7 (bottom).

Adjacent linear chains are arranged an antiparallel manner, most likely stabilized by the π-π stacking interaction of the pyridine rings. The distance between the π-π pyridine rings is about 3.6 Å, close enough for an interaction. The PF_6 counteranion is situated nicely in the voids between adjacent linear polymer layers and the linear polymers are arranged in a zig-zag fashion along the *c*-axis. Selected bond lengths and bond angles are summarised in Table 1 and 2.

The four-coordinate Ag1 has a long-range interaction with two fluorine atoms of the counterion (Ag1···F 3.379 and 3.562 Å) and hence a pseudo-octahedral geometry is observed. The trigonal planar geometry of the Ag(2) centre is stabilized by interaction of one of the fluorine atoms of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

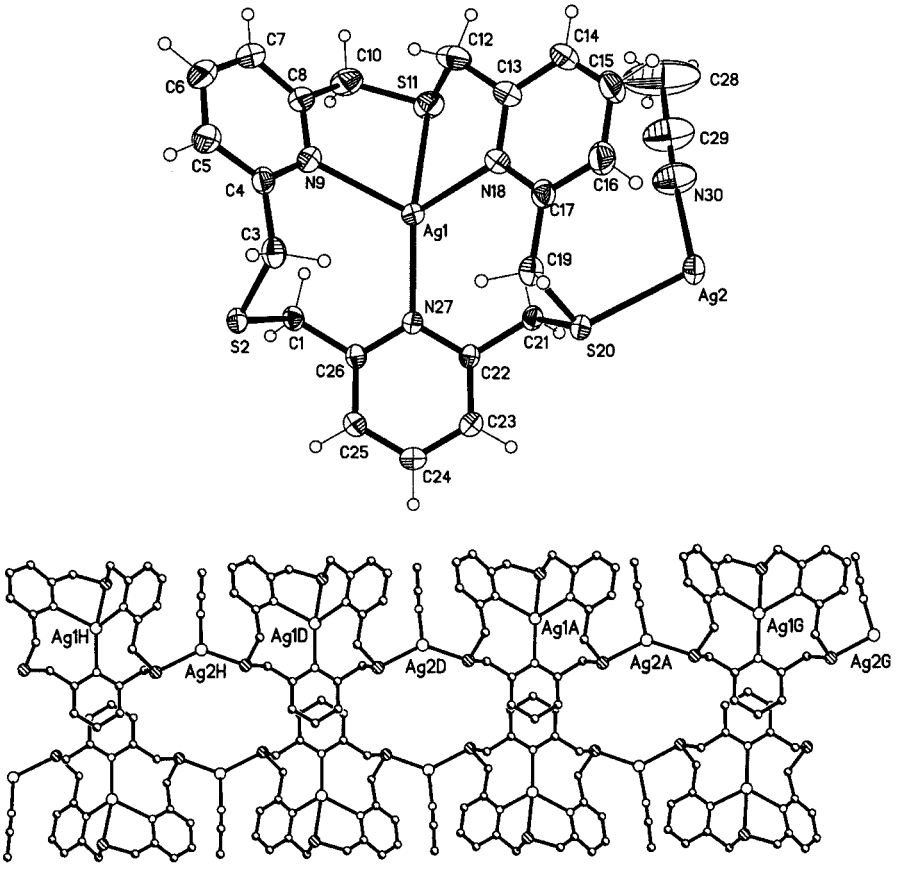

Figure 7. (top) ORTEP diagram of an asymmetric unit of the coordination polymer **15**; (bottom) the two coordination modes of silver in the coordination polymer **15**

the counterion PF_6, at a distance of 2.883 Å, resulting in a pseudo four-coordination. A polymeric disilver complex with two different geometries (tetrahedral and linear) was reported previously[48] with a small macrocycle. To the best of our knowledge, this is the first example of a polymeric complex with a pyridine-containing macrocycle with two different modes of four- and three-coordination. The distance between Ag1 and Ag2 is 5.742 Å and the intermolecular distance between Ag2 and Ag1 of the adjacent macrocycle is about 5.9 Å, which is significantly longer than the sum of their van der Waals radii.

There is no major difference in the X-ray structure when the metal salt is changed from $AgPF_6$ to $AgBF_4$. The complex formed with $AgBF_4$ is also a coordination polymer, with two different coordination modes of silver, with the formula $C_{23}H_{24}Ag_2B_2F_8N_4S_3$. One of the fluorine atoms in BF_4 in the complex **16** is disordered. The bond lengths and bond angles are similar to those of complex **16** listed in Table 1 and 2. The intra- and intermolecular Ag−Ag distances (5.865 Å and 5.657 Å respectively) are different from those in complex **15**. No good quality single crystals could be obtained when $AgNO_3$ was used.

UV/Vis and Redox Properties of the Complexes

The UV/Vis absorption spectrum data of the dinuclear palladium complex is given in the Exp. Sect. The palladium complex is orange and shows an absorption maximum at 374 nm with a further intense absorption band at 272 nm. A peak of this type is absent in most mononuclear complexes and seems to be characteristic of dinuclear palladium complexes, possibly arising from a metal-metal interaction. From previous work the absorption at 272 nm can be assigned to the spin-allowed $4d_{\sigma^*} \rightarrow 5p_\sigma$ transition.[49] The p_σ orbital is a hybrid of the $5p_z$(Pd) and π* (ligand) orbitals. Whether this kind of interaction would lead to some net metal-metal bonding still remains uncertain.

The redox properties of complexes **15** and **16** have been studied by cyclic voltammetry in acetonitrile solution with tetrabutylammonium perchlorate as the supporting electrolyte. Two irreversible reductions are observed at −1.1 and −0.25 V for complex **15** and −1.4 and −0.35 V for complex **16** together with an intense desorption spike at 0 V at a scan rate of 200 $mV \cdot s^{-1}$. Both reductions correspond to a one-electron transfer of Ag^I to Ag^0. No oxidation waves are observed in the cyclic voltammograms up to +2.0 V. However, for complex **15** there is an oxidation peak observed at −1.25 V. Similar potential ranges have been reported for related macrocyclic silver complexes.[50]

Extraction Studies

The complexing abilities of the macrocycle **10** with the selected metal cations Ag^I, Cd^{II}, Cu^{II}, Co^{II}, Hg^{II}, Ni^{II}, Pb^{II}

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and Zn^{II} were assessed by solvent extraction of the metal chlorides from aqueous solutions into chloroform. The procedure was based on the method used by Kumar et al. and Nishimura et al., in their investigation of mixed nitrogen and sulfur/oxygen-donor cyclophanes.[51,52] The extraction results, presented in Table 3, indicate that the macrocycle has poor selectivity and it extracts all the metals appreciably. Among these metals, macrocycle **10** exhibits a slightly higher preference for Ni^{II}. The observed extraction selectivity order is $Ni^{II} > Co^{II} > Zn^{II} > Pb^{II} > Cu^{II} > Cd^{II} > Hg^{II} > Ag^{I}$.

Table 3. Relative selectivity in extraction of metal ions by macrocycle **10**

Metal ion	Cd^{II}	Cu^{II}	Co^{II}	Pb^{II}	Hg^{II}	Ni^{II}	Ag^{I}	Zn^{II}
% Extraction	76	77	84	78	69	89	50	83

Conclusions

A hexadentate macrocyclic ligand containing mixed donor atoms, namely [18]aneN_3S_3 (**10**), has been synthesised by a new synthetic route and characterised by analytical and spectroscopic methods. The Ni^{II}, Pd^{II}, Pt^{II}, Cu^{I}, Ag^{I} and Hg^{II} complexes **11**−**16** of **10** have been prepared and their crystal structures investigated by X-ray crystallography. From the X-ray crystal structures of the complexes, **10** forms mononuclear complexes with nickel, copper and mercury metal ions, a binuclear complex with palladium and coordination polymers with silver. Both nickel and mercury adopt an unusual geometry due to the ligand conformation. The binuclear palladium complex exists as an unusual inorganic zwitterion and a cone conformation of the macrocycle was achieved upon metal ion complexation. The silver complex formed a one-dimensional coordination polymer with two different modes of coordination of silver. Changing the anion of the silver salt does not result in any structural changes in the silver complex. The electronic spectra of the complexes were also investigated. The extraction ability of the macrocycle shows a slightly higher preference for nickel(II). The solid-state packing diagrams in the X-ray structures of the complexes were explained by hydrogen bonding and other weak interactions.

Experimental Section

Materials and Physical Measurements: ^1H and ^{13}C NMR spectra were recorded on a Bruker ACF 300 Fourier-transform spectrometer. All chemical shifts are reported in ppm downfield from a tetramethylsilane internal standard. Mass spectra were recorded on a VG Micromass 7035 spectrometer at 70 eV in electron impact mode. Elemental analyses were performed by the Chemical and Molecular Analysis Centre, Department of Chemistry, National University of Singapore. The electronic spectra were recorded using a HP 8452A diode-array UV/Vis spectrophotometer. Cyclic voltammograms were recorded using a single compartment three-electrode cell. A platinum disc of 3 mm in diameter was used as a working electrode. The counter electrode consisted of a platinum wire. All the potentials were measured against the Ag/AgCl couple. An EG&G Princeton Applied Research 273 potentiostat, controlled by M270 software, was used to measure all the electrochemical data. Acetonitrile used for electrochemical studies was triply distilled under nitrogen from calcium hydride and stored over 4-Å molecular sieves. Tetrabutylammonium perchlorate employed as a supporting electrolyte was vacuum dried for 24 h prior to use. All solutions were purged with dry argon for 15 minutes prior to any electrochemical study. The following compounds were prepared according to the literature: 2,6-bis(mercaptomethyl)pyridine (**6**),[53] and 2-bromomethyl-6-hydroxymethylpyridine (**7**).[54]

CAUTION! *Perchlorate salts are potentially explosive and should be handled with care.*

2,6-Bis[(6-hydroxymethyl-2-pyridylmethyl)sulfanylmethyl]pyridine (8): Compound **6** (1.00 g, 5.85 mmol) was added to a solution of sodium ethoxide prepared by dissolving sodium metal (0.27 g, 11.70 mmol) in anhydrous EtOH (200 mL) and the mixture was stirred for 1 h. A solution of compound **7** (2.35 g, 11.70 mmol) in anhydrous EtOH (75 mL) was then added dropwise over 2 h while the reaction mixture was maintained at solvent refluxing temperature. The reaction mixture was allowed to stir for an additional 2 h and cooled to room temperature. The solvent was removed under reduced pressure yielding an orange oil. The crude product was extracted with CH_2Cl_2 and the organic phase was washed with water followed by saturated sodium chloride solution. The solvent was removed and the residue was chromatographed on silica gel (hexane/acetone, 1:1) to give the desired diol **8** as colourless crystals. Yield: 1.95 g (81%); m.p. 83−85 °C. MS: *m*/*z* = 413.2 [M^+]. ^1H NMR ($CDCl_3$): δ = 7.50−7.60 (m, 3 H), 7.20−7.30 (m, 4 H), 7.10 (d, *J* = 7.62 Hz, 2 H), 4.71 (s, 4 H), 4.30 (br., 2 H), 3.82 (s, 4 H), 3.80 (s, 4 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 158.9, 157.8, 157.3, 137.2, 121.6, 121.3, 118.6, 64.5, 37.2, 37.0 ppm.

2,6-Bis[(6-chloromethyl-2-pyridylmethyl)sulfanylmethyl]pyridine (9) Thionyl chloride (1.04 g, 8.71 mmol, 20% excess) was added slowly with a syringe to a solution of the diol **8** (1.50 g, 3.63 mmol) in CH_2Cl_2 (75 mL) and the mixture was stirred for 6 h at room temperature. A saturated solution of $NaHCO_3$ (50 mL) was added and the mixture was stirred for 1 h. The organic layer was separated and dried. The solvent was removed under reduced pressure yielding brown oil which solidified on standing at 0 °C. Yield: 1.50 g (91%). ^1H NMR ($CDCl_3$): δ = 7.62 (m, 2 H), 7.52 (t, *J* = 7.62 Hz, 1 H), 7.30 (m, 4 H), 7.20 (d, *J* = 7.62 Hz, 2 H), 4.60 (s, 4 H), 3.76 (s, 4 H), 3.72 (s, 4 H) ppm. ^{13}C NMR: δ = 158.3, 157.8, 156.0, 137.5, 122.5, 121.3, 120.8, 53.3, 37.3, 37.2 ppm. Dichloride **9** decomposes slowly upon standing and was therefore used for the following reaction without further purification.

3,11,19-Trithia[3.3.3]pyridinophane (10): A catalytic amount of NaOH was added to a solution of $Na_2S{\cdot}9H_2O$ (0.58 g, 2.40 mmol) in 95% ethanol (250 mL). This was maintained under N_2 at room temperature and a solution of **9** (1.10 g, 2.40 mmol) in EtOH (100 mL) was added dropwise over a period of 6 h. The resulting mixture was then heated to reflux for 6 h. The bulk of the EtOH was removed under reduced pressure and the residue was extracted with chloroform. The organic layer was washed with 0.1 M aqueous NaOH followed by water and dried. The solvent was removed and the residue was recrystallised from acetone to give compound **10**. Yield: 0.68 g (68%); m.p. 158−160 °C. $C_{21}H_{21}N_3S_3$ (411.60): calcd. C 61.28, H 5.15, N 10.21; found C 60.57, H 5.34, N 10.20. MS: *m*/*z* = 411.1 [M^+]. ^1H NMR ($CDCl_3$): δ = 7.59 (t, *J* = 7.62 Hz, 3 H), 7.27 (d, *J* = 7.62 Hz, 6 H), 3.81 (s, 12 H) ppm. ^{13}C NMR: δ = 157.7, 137.4, 120.7, 36.7 ppm.

Complex 11: A solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (72.0 mg, 0.18 mmol) in acetonitrile (5 mL) was added to a solution of **10** (40.0 mg, 0.09 mmol) in CH_2Cl_2 (5 mL). The mixture was stirred for 4 h. Slow concentration of the solution gave green crystals of complex **11**. Yield: 53.0 mg (82%). $C_{21}H_{21}N_3NiS_3(ClO_4)_2 \cdot 2H_2O \cdot (CH_2Cl_2)_2$ (960.04): calcd. C 30.03, H 3.25, N 4.38, S 10.02; found C 25.92, H 3.64, N 4.40, S 9.85. FAB-MS: *m*/*z* = 469 [Ni·**10**].

Complex 12: A solution of $Hg(ClO_4)_2 \cdot 6H_2O$ (39.0 mg, 0.10 mmol) in methanol (5 mL) was added to a solution of **10** (20.0 mg, 0.05 mmol) in CH_2Cl_2 (5 mL). A colourless solid precipitated immediately. Diffusion of diethyl ether into a solution of the complex **12** in acetonitrile resulted in isolation of colourless crystals of **12**. Yield: 23.0 mg (60%). $C_{21}H_{21}HgN_3S_3(ClO_4)_2 \cdot 2H_2O$ (847.14): calcd. C 29.77, H 2.95, N 4.96, S 11.36; found C 29.17, H 2.45, N 4.84, S 10.96. FAB-MS: *m*/*z* = 610.9 [Hg·**10**].

Complex 13: $Cu(CH_3CN)_4(PF_6)$ (37.0 mg, 0.10 mmol) was added to a solution of **10** in a mixture of CH_2Cl_2 (5 mL) and methanol (5 mL). The reaction mixture was stirred for 3 h and the solution was concentrated. Slow addition of diethyl ether precipitated light grey crystals of the copper(I) complex **13**. Yield: 29.0 mg (96%); m.p. 136−138 °C (dec.). $C_{21}H_{21}CuF_6N_3PS_3$ (620.13): calcd. C 40.67, H 3.41, N 6.78, S 15.51; found C 42.10, H 3.63, N 7.01, S 15.65. FAB-MS: *m*/*z* = 474.0 [Cu·**10**].

Complex 14: A mixture of **10** (40.0 mg, 0.09 mmol) in CH_2Cl_2 (10 mL) was added to $[PdCl_2(CH_3CN)_2]$ (52.0 mg, 0.18 mmol) in methanol (10 mL) and the mixture was stirred at room temperature for 6 h. On standing dark-orange crystals of complex **14** precipitated from the solution. Yield: 68.0 mg (91%); m.p. 212−215 °C (dec.). $C_{21}H_{21}Cl_4N_3Pd_2S_3 \cdot H_2O$ (784.28): calcd. C 32.16, H 2.95, N 5.35; found C 32.18, H 2.93, N 4.93. FAB-MS: *m*/*z* = 517.0 [Pd·**10**], 552.5 [Pd·**10**·Cl], 624.0 [Pd_2·**10**·H], 658.0 [Pd_2·**10**·Cl]. UV/Vis: λ_{max} (ε) = 272 (13658), 374 nm (23030 $M^{-1}\,cm^{-1}$).

Complex 15: A solution of $AgNO_3$ (25.0 mg, 0.14 mmol) in acetonitrile (5 mL) was added to a solution of **10** (30.0 mg, 0.07 mmol) in CH_2Cl_2 (5 mL) and the mixture was stirred for 4 h. Addition of a large excess of NH_4PF_6 followed by partial removal of the solvent afforded a white solid. Recrystallisation of this solid from methanol gave a light-sensitive colourless precipitate. Colourless crystals of complex **15** were obtained by diffusion of diethyl ether into a solution of **15** in acetonitrile. Yield: 60.0 mg (86%); m.p. 154−156 °C (dec.). ^1H NMR (CD_3CN): δ = 7.88 (t, *J* = 7.62 Hz, 3 H), 7.47 (d, *J* = 7.62 Hz, 6 H), 4.10 (s, 12 H) ppm. ^{13}C NMR: δ = 157.7, 140.5, 124.8, 38.3 ppm. FAB-MS: *m*/*z* = 518.0 [Ag·**10**], 625.9 [Ag_2·**10**·H].

Complex 16: A solution of $AgBF_4$ (15.0 mg, 0.16 mmol) in acetonitrile (5 mL) was added to a solution of **10** (30.0 mg, 0.08 mmol) in CH_2Cl_2 (5 mL) and the mixture was stirred for 4 h. Slow concentration of the solution gave colourless crystals of complex **16**. Yield: 55.0 mg (90%); m.p. 144−146 °C (dec.). ^1H NMR (CD_3CN): δ = 7.87 (t, *J* = 7.62 Hz, 3 H), 7.46 (d, *J* = 7.62 Hz, 6 H), 4.02 (s, 12 H) ppm. ^{13}C NMR: δ = 157.8, 140.4, 124.7, 38.2 ppm. FAB-MS: *m*/*z* = 518.0 [Ag·**10**], 605.0 [Ag·**10**·BF_4], 711.9 [Ag_2·**10**·BF_4·H].

Crystallographic Data Collection and Refinement: Details of the crystal data and refinement of the structures are given in Table 4. Data collection was performed at 293 K using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) on a Siemens CCD diffractometer. Structures were solved by Patterson or direct methods. All non-hydrogen atoms were refined anisotropically, except for those of solvent molecules where present. Refinement was done by full-matrix least- squares based on F^2 using SHELXL-93.[55] Hydrogen atoms were introduced at a fixed distance from carbon atoms and their isotropic thermal parameters were based on a riding mode of the parent atoms.

Keywords: Cadmium / Coordination polymers / Crystal engineering / Hydrothermal synthesis / Mixed ligands / Structural topology

Four novel compounds, $[Cd(tp)(bpp)]_n$ (**1**), $[Cd(tp)(bpy)]_n$ (**2**), $[\{Cd_4(bpa)_4(bpy)_6\}\cdot(bpy)_{0.5}\cdot 7H_2O]_n$ (**3**) and $[Cd_2\{(Htp)(tp)_{1.5}\}(bpe)]_n$ (**4**) [tp = terephthalate, bpp = 1,3-bis(4-pyridyl)propane, bpy = 4,4′- bipyridine, bpa = 4,4′-biphenyldicarboxylate, bpe = 1,2-bis(4-pyridyl)ethane], of cadmium(II) polycarboxylate coordination polymers based on mixed ligands were obtained by a hydrothermal method. Complex **1** ($C_{21}H_{18}CdN_2O_4$) crystallizes in the orthorhombic *Pbca* space group [a = 11.9401(0) Å, b = 16.8148(3) Å, c = 20.2743(3) Å, and Z = 8]. Complex **2** ($C_{18}H_{12}CdN_2O_4$) belongs to the monoclinic *C2/m* space group [a = 20.299(3) Å, b = 10.720(1) Å, c = 11.764(2) Å, β = 110.944(2)°, and Z = 6]. Complex **3** ($C_{121}H_{98}Cd_4N_{13}O_{23}$) belongs to the monoclinic $P2_1/c$ space group [a = 23.2208(0) Å, b = 11.8103(1) Å, c = 45.4670(6) Å, β = 104.516(1)°, and Z = 4]. Complex **4** ($C_{32}H_{23}Cd_2N_2O_{10}$) belongs to the monoclinic $P2_1/n$ space group [a = 6.9896(1) Å, b = 22.6294(1) Å, c = 19.7738(3)Å, β = 99.380(1)°, and Z = 4].The Cd^{II} centers in the four compounds are bridged by mixed polycarboxylate ligands with bpy and related species to form the twofold parallel interpenetration topology of an undulating 2D 4^4 net for **1**, a twofold interpenetration topology of a 3D α-Po net for **2**, a fourfold interpenetration topology of a 3D 5-connected borazone 4^66^4 net for **3** and an interesting 3D spiral pipe-like structure with a bolt for **4**. These four compounds exhibit strong fluorescent emissions at 549 and 582 nm (λ_{ex} = 532 nm) for **1**, 493 nm (λ_{ex} = 360 nm) for **2**, 413 and 424 nm (λ_{ex} = 315 nm) for **3** and 350 nm (λ_{ex} = 220 nm) for **4** in the solid state at room temperature. These are novel structural topologies and could be significant in the field of photoactive materials.

Introduction

There has been an enormous growth in the crystal engineering of coordination-polymeric solids in recent decades owing to their intriguing applications, including catalysis, nonlinear optics, sensors, magnetism and molecular recognition.[1−10] Although a number of new coordination-polymeric solids with beautiful architectures and interesting topologies based on the assembly of bridging ligands and metal centers using the principles of crystal engineering have been reported,[11−31] a rational synthesis strategy to manipulate the assembly of donor and acceptor building blocks to generate desired supramolecular architectures is still one of the great challenges in this areas. For the design of coordination-polymeric solids that mimic mineral architectures such as quartz, clays and zeolites, an effective strategy is the choice of rigid "tecton" ligands containing O- or N-donors to bind metal centers as building blocks of the extended framework used to construct novel supramolecular architectures.[32,33] Polycarboxylates are often employed as bridging ligands to construct porous coordination polymers due to their versatile coordination modes and high structural stability.[7,8,26,34−53] These polymeric solids can be essentially regarded as a class of metal polycarboxylate salts. Hence, the structures of the resulting compounds are influenced by the degree of deprotonation, the coordination modes and capabilities, the sizes and shape of the polycarboxylic acids, as well as by the coordination sphere of the metal centers. Thus, it is possible to synthesise polymeric frameworks with interesting topologies through the appropriate choice of ligand, and tailoring and manipulation of the reaction conditions, including pH, temperature, stoichiometry, and the addition of templates or structure-directing agents.[26,33−46] In order to resolve the poor solubility of

reactants and products, the hydrothermal reaction technique offers a powerful synthetic route to prepare polymeric solids with better crystallinity[7,54] than traditional solution techniques such as evaporation, diffusion and cooling etc. In most cases, water is not only a solvent but also acts as a competing ligand in these hydrothermal reactions. An interesting phenomenon can be observed whereby many coordination polymers constructed from polycarboxylate ligands usually contain water molecules as terminal or bridging ligands in the coordination sphere of the metal, thus increasing the variety of the assembled structural topology of the polymers. It is therefore possible to obtain metal polycarboxylates with novel coordination architectures of diverse sizes and shapes by use of other suitable compounds with different steric demands and ligating capabilities as the competing bridging ligand to substitute the water ligands mentioned above. Taking account of the potential of these approaches, we have embarked on a program aimed at using mixed ligands containing O- and N-donors to prepare coordination-polymeric solids that mimic mineral architectures. Herein, we report four interesting examples of coordination polymeric architectures based upon mixed bridging ligands: $[Cd(tp)(bpp)]_n$ (**1**), $[Cd(tp)(bpy)]_n$ (**2**), $[\{Cd_4(bpa)_4(bpy)_6\}\cdot(bpy)_{0.5}\cdot 7H_2O]_n$ (**3**), and $[Cd_2\{(Htp)(tp)_{1.5}\}(bpe)]_n$ (**4**) [tp = terephthalate, bpp = 1,3-bis(4-pyridyl)propane, bpy = 4,4′- bipyridine, bpa = 4,4′-biphenyldicarboxylate, bpe = 1,2-bis(4-pyridyl)ethane]. X-ray single-crystal analyses show that these four polymers possess novel structural topologies, namely the twofold parallel interpenetration topology of an undulating 2D 4^4 net for **1**, the twofold interpenetration topology of a 3D α-Po net for **2**, the fourfold interpenetration topology of a 3D 5-connected borazone 4^66^4 net for **3** and an interesting 3D spiral pipe-like structure with a bolt for **4**. The compounds display strong fluorescent emissions at 549 and 582 nm (λ_{ex} = 532 nm) for **1**, 493 nm (λ_{ex} = 360 nm) for **2**, 413 and 424 nm (λ_{ex} = 315 nm) for **3** and 350 nm (λ_{ex} = 220 nm) for **4** in the solid state at room temperature, implying that they may be excellent candidates for potential photoactive materials.

Results and Discussion

Synthesis and Characterization

The four coordination polymers were obtained in a similar way. The appropriate acidity or basicity of the reactants for deprotonation of polycarboxylates is very important for preparing these four compounds, as is the case for some other metal polycarboxylate coordination polymers reported in our earlier studies.[26] These four compounds were also prepared at different pHs: compound **1** at pH 5.5, compound **2** at pH 9.1, compound **3** at pH 8.0 and compound **4** at pH 5.6. We tried to prepare these four compounds at different pHs but without success. Besides the pH, a suitable steric geometry of the reactants is also very important for fabrication of the resulting coordination architectures. As described in the Exp. Sect., although the synthesis conditions are very similar, only a small difference in the steric demands of the reactants, for example between bpp and bpe, results in the different coordination architectures of compounds **1** and **4**. In addition, the synthesis of compounds **1** and **4** cannot be performed in the absence of $(Ph_3PCH_2Ph)Cl$, while another supramolecular isomer of compound **2**, reported by Chen,[21] was obtained when the synthesis of compound **2** was carried out in the absence of hexamethylenetetraamine, even though neither $(Ph_3PCH_2Ph)Cl$ nor hexamethylenetetraamine are found as ligands or guests in the resulting coordination polymers. This suggests that both $(Ph_3PCH_2Ph)Cl$ and hexamethylenetetraamine play a template or structure-directing role in the construction of the resulting coordination architectures.

The elemental analysis data for the four compounds are in good agreement with the formulas $[Cd(tp)(bpp)]_n$ (**1**), $[Cd(tp)(bpy)]_n$ (**2**), $[\{Cd_4(bpa)_4(bpy)_6\}\cdot(bpy)_{0.5}\cdot 7H_2O]_n$ (**3**) and $[Cd_2\{(Htp)(tp)_{1.5}\}(bpe)]_n$ (**4**). The IR spectra of these compounds show the characteristic bands of the dicarboxylate groups in the usual region[55] at 1400−1375 cm^{-1} for the symmetric vibration and at 1610−1539 cm^{-1} for the asymmetric vibration, as well as the bands of the bpp ligand at 2953, 2939, 2860, 1616, 1504 and 1429 cm^{-1} for **1**, the bands of the bpy ligand at 1491 cm^{-1} for **2**, the bands of the bpy or bpa ligand at 1585, 1489, 3082 and 3055 cm^{-1} for **3**, and the bands of the bpe ligand at 1504, 1551, 1574, 3051 and 2929 cm^{-1} for **4**. The splitting of $\nu_{asym}(CO_2)$ in both **2** and **4** confirms that the carboxylate groups have a variety of coordination fashions. Moreover, for **4**, the peak at 1705 cm^{-1} suggests the presence of a protonated carboxylate group. These proposals are consistent with the crystal structures. The TGA traces for **1**, **2** and **4** show that the decomposition of the three compounds occurs at ca. 297−524 °C, 373−587 °C and 210−600 °C, respectively. The TGA trace for **3** shows an obvious weight loss starting at about 50 °C up to 100 °C to give a total weight loss of ca. 5.4%, corresponding to the loss of seven water molecules per formula unit (calcd. 4.9%). Subsequent to this no obvious weight loss occurs for **3** up to 186.9 °C, followed by an obvious weight loss up to 271.9 °C to give a total weight loss of ca. 2.9% corresponding to the loss of 0.5 bpy molecules per formula unit (calcd. 3.1%). Complete decomposition of **3** occurs at 271.9 °C and finishes at ca. 511 °C. This is consistent with the structure of **3** and suggests that the framework of **3** possesses a similar thermal stability to the above three compounds.

Crystal Structures

X-ray single-crystal analysis revealed that the crystal structure of **1** is a twofold parallel interpenetration topology of a 2D 4^4 network polymer. As shown in Figure 1, the fundamental building unit of **1** is composed of a six-coordinate Cd^{II} center, a tp ligand and a bpp ligand, in which each Cd center is coordinated in a distorted tetrahedral geometry to two tp ligands and two bpp ligands through two chelating carboxylate groups (O1, O2 and O3a, O4a) [Cd−O: 2.254(3)−2.444(3) Å] and two nitrogen donors (N1, N2b) [Cd−N: 2.295(3) Å]. Each tp and bpp ligand is

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bridged to two different Cd centers, which provides the 4-linking nodes resulting in an interesting square-grid motif with a window of about 11.9 × 11.1 Å (Figure 1). No guest molecules are found in this square grid. The square-grid motifs are linked to each other to form a typical 2D 4^4 network.[8,14,32,56] Neither tp ligands nor bpp ligands bridging to the same Cd center are coplanar; the N−Cd−N bond angle is 98.57(12)°, while the angle between two adjacent tp ligands chelated to the same Cd center is 132.5°. This 2D 4^4 network is interesting as the 4-linking nodes come from a tetrahedral geometry rather than from a pseudo-octahedral geometry; 4-linking nodes of tetrahedral geometry usually result in adamantoid networks. Due to the N−Cd−N bond angle of 98.57(12)° and the flexibility of the bpp ligands, an interesting pipe-comb-like 2D layer structure with a channel of about 11.4 × 11.1 Å occurs in this single 4^4 network along the *ab* plane (Figure 2). Moreover, the 4-linking nodes allow the 2D 4^4 network to have the undulating nature of the square grid polycatenated by another independent, symmetry-related 4^4 network, thus showing a twofold parallel interpenetration topology (Figure 3). This interpenetration means that the effective voids in the crystal structure of **1** actually have a volume of only 58.1 $Å^3$, which is 1.4% of the unit-cell volume, even though the single 4^4 network contains a big window and channel as described above.

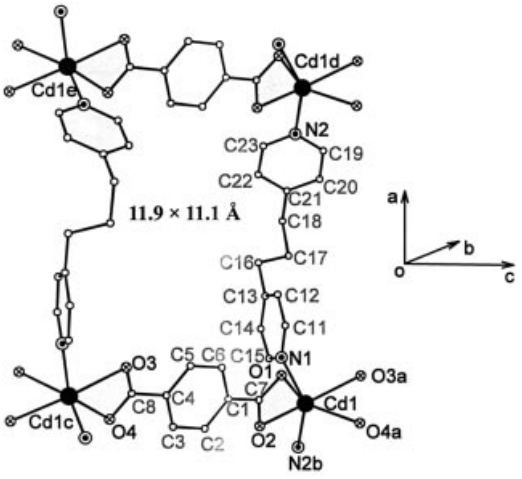

Figure 1. A drawing of **1** depicting the coordination environment around the Cd^{II} center to form a typical 4^4 net with a 11.9 × 11.1 Å window; the hydrogen atoms are omitted for clarity: (*a*) *x*, −*y* + 1/2, *z* + 1/2; (*b*) *x* − 1, *y*, *z*; (*c*) *x*, −*y* + 1/2, *z* − 1/2; (*d*) *x* + 1, *y*, *z*; (*e*) *x* + 1, −*y* + 1/2, *z* − 1/2

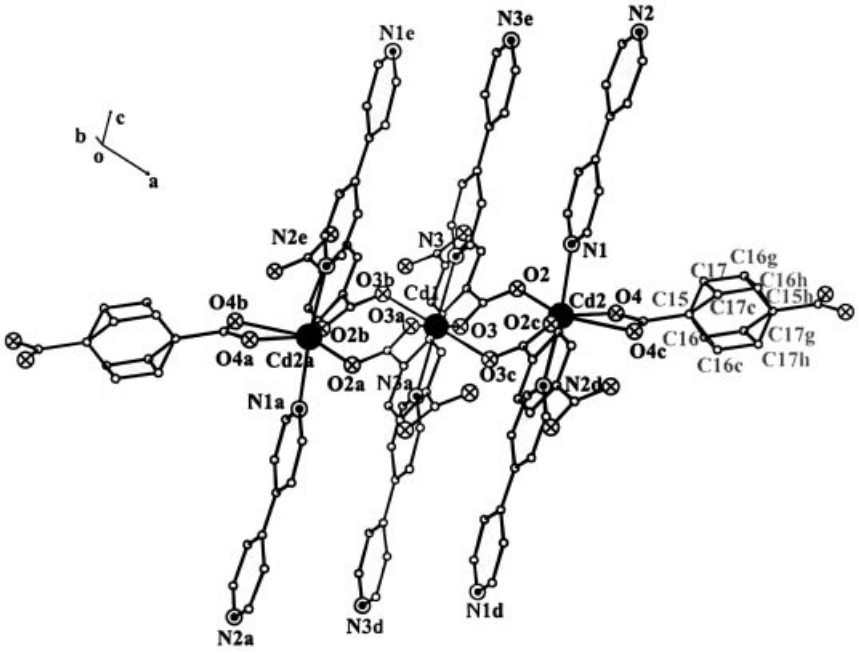

Figure 4. The coordination environment around the Cd^{II} centers in **2**; the hydrogen atoms are omitted for clarity: (*a*) $-x, -y, -z$; (*b*) $-x, y, -z$; (*c*) $x, -y, z$; (*d*) $x, y, z-1$; (*e*) $-x, -y, -z+1$; (*g*) $-x+1, y, -z+1$; (*h*) $-x+1, -y, -z+1$

two bis-bidentate tp ligands, the distance between the two metal centers (Cd1···Cd2) being 4.099 Å (Figure 4). The Cd1 center is in a distorted octahedral coordination sphere completed by two nitrogen atoms (N3, N3a) [Cd1−N: 2.342(12) Å] of two bpy ligands as the apices and four oxygen atoms (O3, O3a, O3b and O3c) [Cd1−O: 2.304(9) Å] in the equatorial positions; these oxygen atoms come from four bis-bidentate carboxylate groups of four different tp ligands. The Cd2 center also lies in a distorted octahedral coordination sphere, and is coordinated by two nitrogen atoms (N1, N2d) [Cd2−N: 2.338(14)−2.366(12) Å] of the other two bpy ligands as the apices and four oxygen atoms [Cd2−O: 2.231(8)−2.399(10) Å] in the equatorial positions, two (O2, O2c) of which are from two bridging bis-bidentate carboxylate groups of two different tp ligands, and the other two (O4, O4c) belong to a chelating carboxylate group of a tp ligand, whose aromatic ring shows positional disorder over two sites (C15, C16, C17g, C15h, C16h, C17c and C15, C16c, C17h, C15h, C16g, C17; see Figure 4). These two Cd^{II} centers (Cd1, Cd2) as well as Cd2a, an equivalent atom related to the Cd2 center, are bridged to construct a linear trinuclear $\{Cd_3O_{12}N_6\}$ cluster. In this way, the trinuclear $\{Cd_3O_{12}N_6\}$ clusters are interconnected through tp ligands to yield an interesting rectangular sheet

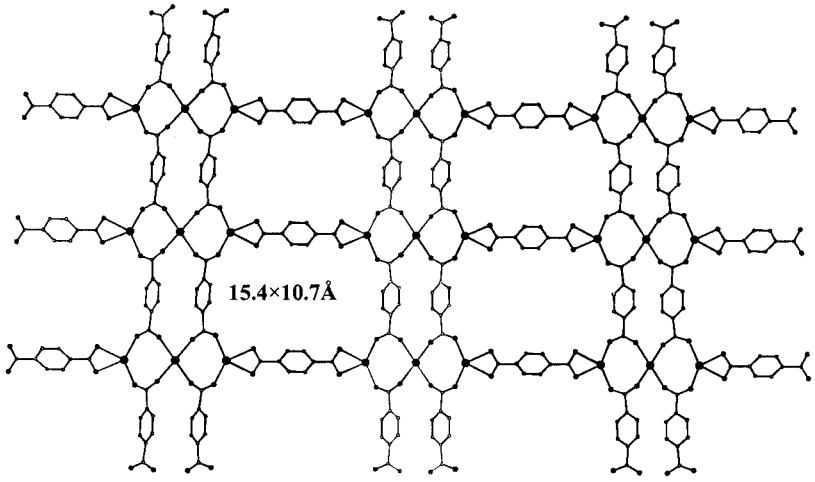

Figure 5. A view of the 2D rectangular {Cd(tp)} sheet subunit with a window of 15.4 × 10.7 Å in **2**; the hydrogen atoms are omitted for clarity

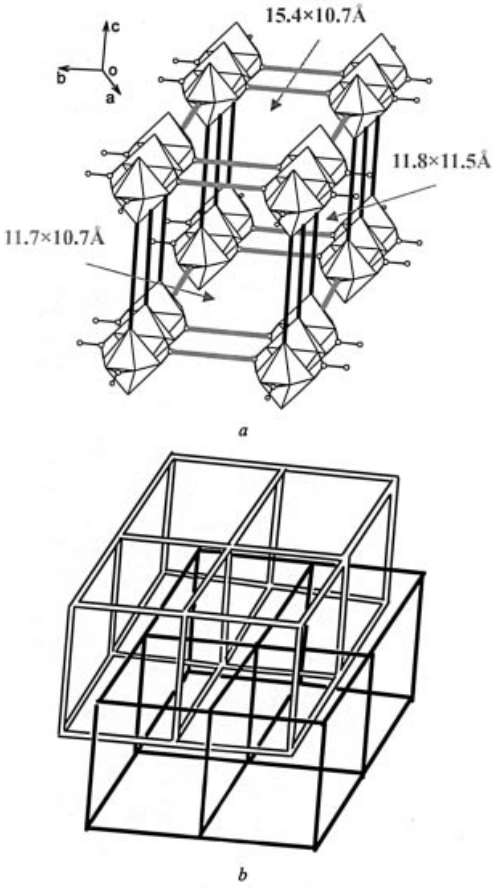

Figure 6. (a) A view depicting a 3D α-Po net topology in **2** assembled by the rectangular sheet subunits and bpy pillars (gray lines indicate the tp struts, black lines represent bpy struts); (b) the twofold interpenetration topology of **2**

with a window of 15.4 × 10.7 Å (Figure 5), which is different from similar reported structures.[21] The rectangular sheets are further pillared by bpy ligands to form a box-like 3D supramolecular architecture, a topology attributed to the α-Po net (Figure 6a), and the whole crystal structure of **2** exhibits twofold interpenetration (Figure 6b).

The crystal structure of **3** is a 3D porous framework composed of a well-separated host polymer, guest bpy molecules and lattice water molecules. There are four independent seven-coordinate Cd^{II} centers in the building unit of **3**, and the coordination sphere of each seven-coordinate Cd^{II} center is equivalent (Figure 7). In the host polymer, each seven-coordinate Cd^{II} center lies in a distorted pentagonal bipyramidal sphere, completed by two pairs of oxygen donors of two chelating carboxylate groups from two separate bpa ligands and three nitrogen donors from three different bpy ligands, in which two bpa and a bpy ligands are in the equatorial positions with the other two bpy ligands as the apices (Figure 7). Every bpa and bpy ligand links to two Cd^{II} centers through two chelating carboxylate groups and two nitrogen donors, respectively. Due to the angles between two adjacent bpa ligands and between bpa and bpy ligands coordinated to the same Cd^{II} center in the equatorial plane (130.5° and 112.6°, respectively), the Cd^{II} center and the bridging ligands actually form a slightly distorted trigonal-bipyramidal subunit, which has seldom been observed in metal-organic polymers.[32] In the crystal, these subunits are arranged to generate a honeycomb-like 3D supramolecular architecture, an unprecedented 5-connected borazone $4^6 6^4$ net topology,[57,58] with giant hexagonal channels about 30.5 × 24.8 Å across (Figure 8). To the best of our knowledge, this structural topology is still very rare

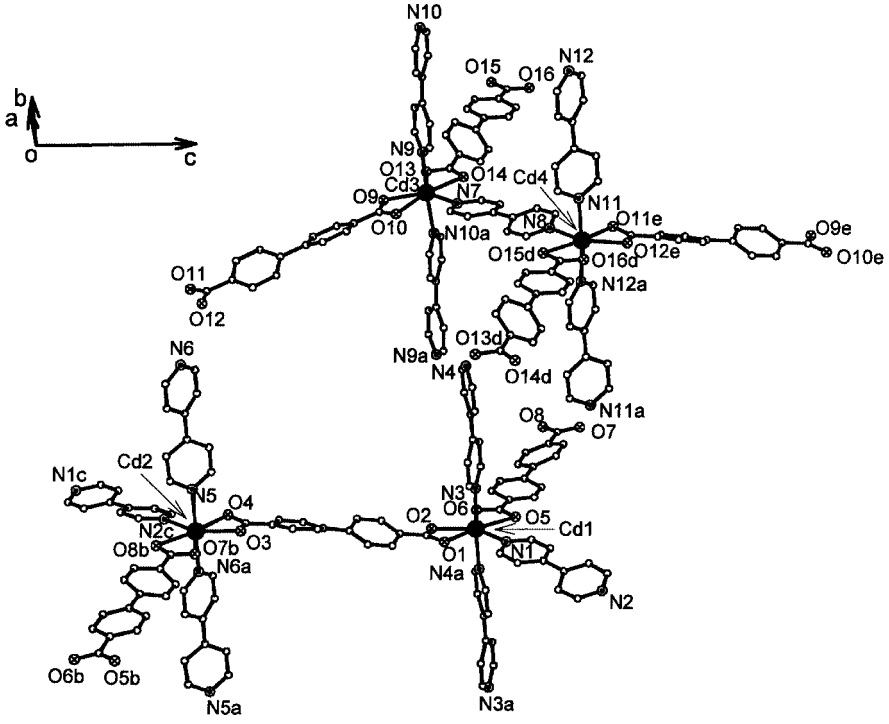

Figure 7. A view of **3** depicting the coordination environment around the Cd^{II} centers; hydrogen atoms, guest bpy and water molecules are omitted for clarity: (*a*) $x, y - 1, z$; (*b*) $x - 1, -y - 3/2, z - 1/2$; (*c*) $x, -y - 3/2, z - 1/2$; (*d*) $x - 1, y, z$; (*e*) $x, -y + 1/2, z + 1/2$

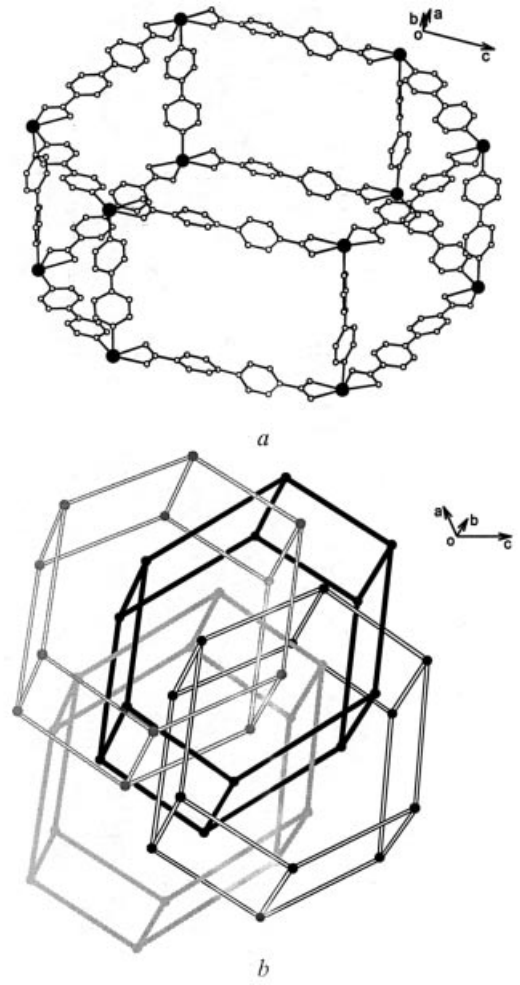

Figure 9. (*a*) A single hexagonal unit of the 3D honeycomb-like architecture in **3**;(*b*) the fourfold interpenetrating model of **3**

in coordination polymer chemistry.[32,58] Each hexagonal channel has a giant cavity of about 30.5 × 24.8 Å, while the actual crystal structure of compound **3** is a fourfold interpenetrating 3D supramolecular architecture (Figure 9). The resulting effective cavities, after removal of encapsulated guests − aqua and bpy molecules — in **3** has a volume of about 2609 $Å^3$, which is only 22% of the unit-cell volume.

The local coordination environment around the Cd^{II} centers in **4** is depicted in Figure 10. The two crystallographically distinct Cd^{II} centers (Cd1, Cd2) are each coordinated in a distorted octahedral sphere by five oxygen donors (O1, O21, O22, O24b and O12a for Cd1; O2, O11, O22, O23d and O24d for Cd2) and one nitrogen donor (N1 for Cd1; N2c for Cd2), in which the oxygen donors are from the carboxylate groups of four different tp ligands and the nitrogen donor is from a separate bpe ligand. Four different tp ligands bridge two Cd^{II} centers alternately in three different coordination fashions − chelating/bridging bis-bidentate, bis-bidentate and bidentate to form Cd-tp chains along the *a* axis (Figure 11a). Extension of these Cd-tp chains along the *ac* plane therefore gives a novel 2D abatis-like sheet (see b in Figure 11). These adjacent 2D abatis-like sheets are further crosslinked in a staggered fashion through bridging bpe ligands to generate an interesting 3D spiral pipe-like structure with a bolt (Figure 12). Although there is no interpenetration or incorporated guest molecule in **4**, the actual crystal structure has an effective void of an only 107 $Å^3$, which is 3.5% of the unit cell volume, due to the bolt described above.

Fluorescent Properties

To study the fluorescent properties of these four polymeric solids, the emission spectra of **1**−**4** were recorded for a polycrystalline sample of each of these materials in the solid state at ambient temperature. Intense fluorescent emissions at 549 and 582 nm (λ_{exc} = 532 nm) for **1**, 493 nm (λ_{exc} = 360 nm) for **2**, 413 and 424 nm (λ_{exc} = 315 nm) for **3** and 350 nm (λ_{exc} = 220 nm) for **4**, were observed, which can be assigned to ligand-to-metal charge transfer (LMCT) transitions. It is noticeable that compound **2** exhibits a quenching of the fluorescence with τ = 5.44 ns. This suggests that **2** may be an excellent candidate for potential photoactive material.

Experimental Section

General Remarks: All the syntheses were performed in Parr Teflon-lined stainless steel autoclaves under autogenous pressure. Chemicals were purchased commercially and used as received without further purification. Infrared spectra were recorded on a Magna 750 spectrometer as KBr pellets. The C, H, O and N elemental microanalyses were carried out with a Vario EL III elemental analyzer. Fluorescent data were collected on an Edinburgh FL-FS920 TCSPC system at the Spectroscopy Lab of Fuzhou University, and TGA (thermal gravimetric analysis) was performed under nitrogen with a heating rate of 10 °C·min^{-1} using a TA5200/MDSC2910 system at the Thermal Analysis Lab of Huaqiao University. The pore-volume analysis was perfomed with the PLATON software package.[59]

[Cd(tp)(bpp)]$_n$ (1): Compound **1** was synthesized hydrothermally from the reaction of cadmium acetate dihydrate (1.5 mmol), H_2tp (1 mmol), bpp (1.075 mmol), $(Ph_3PCH_2Ph)Cl$ (1 mmol) and water (5 mL) in a molar ratio of 3:2:2.15:1:556 at 200 °C for 4 days. The mixture was then cooled at a rate of about 3.5 °C·h^{-1} to give a 32% yield of **1** (228.8 mg), based on Cd, as colorless block crystals, which were collected by hand and washed with water and absolute alcohol. $C_{21}H_{18}CdN_2O_4$ (474.77): calcd. C 53.12, H 3.82, N 5.90, O 13.48; found C 53.39, H 3.32, N 5.43, O 13.67. IR (KBr pellet): $\tilde{\nu}$ = 3401 cm^{-1} (w, br), 3064 (vw), 2953 (w), 2939 (w), 2860 (w),

[a] See footnotes to Table 2 for symmetry operations for each compound.

of about 3.5 °C·h^{-1}. The resulting primrose needle crystals were separated by hand from the reaction mixture and washed with water and absolute alcohol to give about a 39% yield of **1** (373.0 mg) based on Cd. $C_{121}H_{98}Cd_4N_{13}O_{23}$ (2551.7): calcd. C 56.95, H 3.87, N 7.14, O 14.42; found C 56.92, H 2.97, N 7.17, O 14.18. FT-IR (KBr pellet): $\tilde{\nu}$ = 3390 cm^{-1} (s), 3082 (w), 3055 (w), 1942 (w), 1585 (s), 1539 (s), 1489 (m), 1385 (s), 1219 (s), 1176 (w), 1105 (w), 1074 (m), 1043 (w), 1005 (s), 833 (s), 806 (s), 775 (s), 764 (s), 729 (w), 702 (w), 677 (m), 629(s), 567 (w), 492 (m).

$[Cd_2\{(Htp)(tp)_{1.5}\}(bpe)]_n$ (4): Similar to the synthesis of **1**, the hydrothermal reaction of cadmium acetate dihydrate (1.5 mmol), H_2tp (1 mmol), bpe (1 mmol), $(Ph_3PCH_2Ph)Cl$ (0.5 mmol) and water (5 mL) in a molar ratio of 3:2:2:1:556 was performed at 200 °C for 4 days, then the reactant was cooled at a rate of about 3.5 °C·h^{-1}. The resulting colorless crystals were separated by hand from the reaction mixture and then washed with water and absolute alcohol to give about a 37% yield of **4** (227.2 mg) based on Cd. $C_{32}H_{23}Cd_2N_2O_{10}$ (820.32): calcd. C 46.85, H 2.83, N 3.41, O 19.50; found C 46.78, H 2.12, N 3.51, O 19.72. IR (KBr pellet): $\tilde{\nu}$ = 3051 cm^{-1} (vw), 2929 (vw), 2617 (vw), 2480 (vw), 1954 (vw), 1705 (s), 1610 (vs), 1574 (vs), 1551 (vs), 1504 (s), 1394 (vs), 1313 (m), 1242 (s), 1111 (m), 1072 (m), 1016 (m), 881 (w), 831 (m), 777 (m), 735 (s), 677 (w), 633(w), 544 (m), 513 (m), 445 (w).

Crystallographic Studies: Intensity data for the four compounds were collected at 293(2) K on a Siemens Smart CCD area-detector diffractometer with Mo-K_α radiation (λ = 0.71073Å) and a graphite monochromator using the ω-scan mode. Data reductions and absorption corrections were performed with the SMART and SADABS software packages, respectively. The structures were solved by direct methods using SHELXS-97[60] and were refined by full-matrix least-squares methods using SHELXL-97.[61] Anisotropic displacement parameters were refined for all non-hydrogen atoms except for the disordered benzene ring of tp molecules. No attempt was made to locate the hydrogen atoms of water and disordered atoms; the other hydrogen atoms were added in the riding model and not refined. Final $R = (F_o - F_c)/F_o$, $R_w = \{w[(F_o^2 - F_c^2)^2]/w[(F_o^2)^2]\}^{1/2}$, with $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ [where $P = (F_o^2 + 2F_c^2)/3$]. The structure reliability factors for **2** and **3** were not satisfactory (R = 0.0720 and 0.0725, respectively), probably as a result of the presence of disordered tp molecules and guest water and not refined. The crystallographic data are summarized in Table 1, and selected bond lengths and bond angles of the three compounds are listed in Tables 2 and 3, respectively.

CCDC-224384 to -224387 (for compounds **1**−**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallograghic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk).

The Reaction of Diazocyclopentadienyl Compounds with Cyclomanganated Arenes as a Route to Ligand-Appended Cymantrenes

Jean-Pierre Djukic,*[a] Christophe Michon,[a] Dirk Heiser,[b] Nathalie Kyritsakas-Gruber,[c] André de Cian,[c] Karl Heinz Dötz,[b] and Michel Pfeffer[a]

Keywords: Diazo compounds / Cyclopentadienyl ligands / Insertion / Manganese / Ligand design

The thermolysis of various cyclomanganated arenes in the presence of 5-diazocyclopentadiene, 7-diazoindene or 9-diazofluorene afforded the corresponding arenes tethered with cymantrenyl, benzocymantrenyl or dibenzocymantrenyl groups in fair to good yields. This reaction implies a multifacetted mechanism that consists of three steps: the insertion of an alkylidene moiety into a C–Mn bond, a C_{Ar}–C bond formation and several haptotropic ring-slippages. The coupling reaction has proven to be particularly efficient with $Mn(CO)_4$ chelates derived from acetylarenes and nitrogen-containing heterocycles. In one case of a 2-phenyl-2-oxazoline complex, the coupling with 9-diazofluorene yields a new η^1-dibenzocymantrene complex in which the $Mn(CO)_4$ moiety is chelated and is part of a six-membered metallacycle. The results of this study are mainly supported by the molecular structures of nine new complexes obtained by X-ray diffraction analyses.

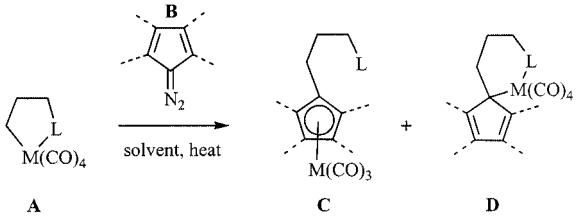
Introduction

We recently reported the thermolytic coupling of cyclomanganated compounds with non-cyclic diazoalkanes, which may efficiently yield new spiralenes.[1] We also showed that the same experiments carried out with 9-diazofluorene could lead to the corresponding tethered η^5-fluorenyl complex resulting from the insertion of a fluorenylidene into the $C_{Ar}-Mn$ bond of the substrate [Equation (1)].[1a] Such an insertion reaction of an alkylidene ligand into a $C_{Ar}-Mn$ bond of a cyclomanganated compound, which leads to an appended dibenzocymantrene derivative, was unprecedented, although similar insertions of alkylidenes were already known but never thoroughly applied to a wide range of substrates. The first reactions of that kind were between diazocyclopentadiene and $(CO)_5MnX$ (X = Cl, Br, I), and yielded halocymantrenes, as reported by Shaver and later by Herrmann.[2] More recently, a series of reactions involving carbonylrhenium complexes were disclosed by Katzenellenbogen and co-workers[3] who were focusing on the synthesis of cyrhetrenes (Re analogues of cymantrenes) for various applications as contrast agents in imaging.[4] Both cymantrenes and their Re analogues can be used as labels for biomolecules[5,6] and in radiopharmaceuticals.[7]



A C D (1)

Our previous results indicated that cymantrenes or -rhetrenes with either an η^5- or an η^1-bonding mode [**C** and **D**, Equation (1)] and appended with various internal ligands can be easily synthesised from readily available cyclomanganated complexes [**A**, Equation (1)] and 9-diazofluorene [**B**, Equation (1)]. One potential application of such complexes could be as chelating ligands for homogeneous catalysis.[8] Indeed, appended cyclopentadienyl-type ligands have received a great deal of attention and are widely investigated for the design of organometallic complexes of both early and late transition metals, which are expected to be active catalysts in various transformations such as the

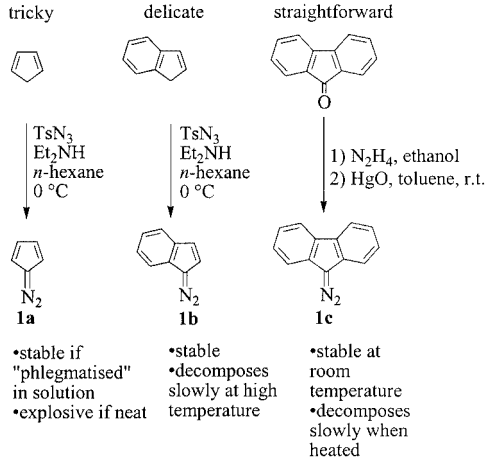
Ziegler−Natta polymerisation.[9] These valuable appended Cp-like ligands can be synthesized by several different methods. In this article we disclose our recent findings on the investigation of the reactivity of a series of cyclomanganated compounds towards 1-diazocyclopentadiene, 7-diazoindene and 9-diazofluorene. With the support of various examples, we show that arenes tethered by cymantrenes can be efficiently synthesised by a multi-facetted reaction consisting of three steps: the insertion of an alkylidene moiety into a C−Mn bond, C_{Ar}−C bond formation and a series of haptotropic ring-slippages. We further show that the supposedly temperature-sensitive diazocyclopentadiene and diazoindene react efficiently as alkylidene sources even at temperatures as high as 100 °C.

Results and Discussion

The Preparation of 5-Diazocyclopentadiene (1a), 7-Diazoindene (1b), and 9-Diazofluorene (1c)

The poor reputation of diazomethane has thrown a shadow of suspicion on all the members of this class of reagents, although recent research has contributed to give a better and friendlier image, at least, to diazocyclopentadienes. For instance, natural diazofluorenes, such as some kinamycins, are active antitumor and antibiotic agents as they display some capabilities to cleave DNA,[10,11] and diazocyclopentadiene (**1a**) has been found to regulate ethylene production in tomatoes.[12]

When we decided to synthesise **1a**−**c**, most of the problems we encountered were not related to the putative explosive and unstable nature of diazoalkanes, which is not marked for most aryl-substituted diazoalkanes, but rather to their purification. The chemical stability and the feasibility of the targeted reagents conditioned our choice of synthetic pathway among all the known methods (Scheme 1). There are several different ways to introduce the diazo function that were compiled and detailed in pertinent reviews or books several years ago; these procedures will therefore not be detailed here.[13]



Scheme 1

An efficient synthesis of 9-diazofluorene (**1c**) was achieved by oxidation of the commercially available fluorenone hydrazone by yellow mercury(II) oxide (or activated manganese dioxide).[14] This reaction afforded a stable, deep-purple crystalline compound that can be stored at −10 °C for months. The thermal decomposition of this reagent in solution in toluene mostly produces the corresponding azines and alkenes.[15]

The synthesis of diazoindene **1b** was performed by applying the method described by Weil and Cais,[16] and improved by Rewicki and Tuchscherer by the diazo-transfer reaction of tosyl azide with a large excess of freshly distilled indene in the presence of diethylamine at 0 °C.[17] This reagent can also be obtained from a Bamford−Stevens-type transformation[18] of the indenone tosylhydrazone[19] prepared in several steps[20] from indanone. This diazoalkane is quite unstable and decomposes slowly in a non-explosive manner above 0 °C. When synthesised it can be stored for weeks if cooled to a temperature lower than −20 °C. In our hands, **1b** was formed in high yields and had to be extracted from a crude mixture that mostly contained limited amounts of insoluble tosylamide and large amounts of unchanged indene. The extraction and isolation of a highly enriched sample of diazoindene implied two critical and crucial steps, as already discussed by Herrmann and coworkers: (1) the removal of the large amounts of unchanged indene by distillation under reduced pressure, which had to be carried out carefully with mild and slow heating of the crude mixture in an oil-bath, and (2) a low-temperature (−10 °C) chromatographic separation on silica gel of the red-orange diazoindene **1b** from the brownish tar formed during step (1).

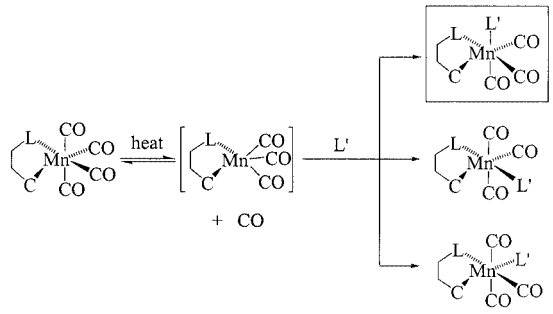
The synthesis of diazocyclopentadiene (**1a**) first reported by Doering and DePuy in 1953[21] and later improved by Weil and Cais and by Regitz and Liedhegener,[22] was even more tricky, although still possible. It was based on the above-mentioned diazo-transfer reaction between tosyl azide and freshly cracked cyclopentadiene in the presence of diethylamine in hexane at 0 °C. Because of its sensitive nature we did not attempt to isolate diazocyclopentadiene (**1a**) neat; it was handled instead in solution in an aliphatic solvent. It could be readily extracted from the crude reaction medium and purified by a low-temperature chromatographic separation on silica gel to remove tosylamide that was formed during the diazo-transfer reaction. The concentration of **1a** was readily assessed, as advocated by Weil and Cais, by a gravimetric titration of the phosphazine obtained from reaction of an aliquot of the mother solution with triphenylphosphane.

The Reaction of Monomanganated Complexes with 1a−c

It has long been known that cyclomanganated complexes of formula *cis*-[(LC)Mn(CO)$_4$] (LC: carbanionic chelating ligand) can undergo the replacement of one carbonyl ligand by a σ-donor ligand upon heating (Scheme 2).[23] In every reported case the incoming ligand occupies the axial position formerly occupied by the displaced carbonyl ligand, although this does not mean that the thermolysis of tetra-

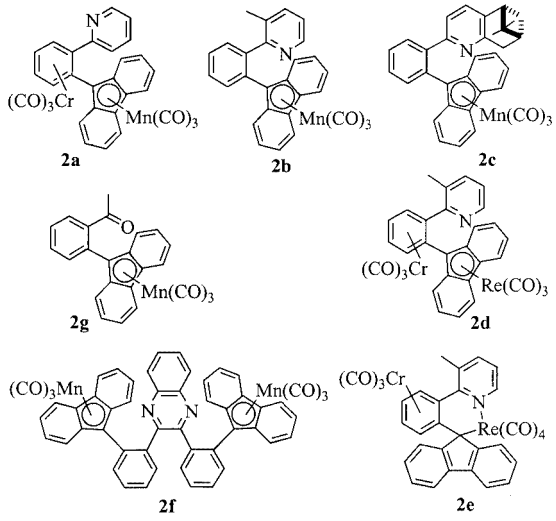
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

carbonylmanganese chelates proceeds by the selective expulsion of one of the axial ligands. Although the mechanism of this thermolytic decarbonylation is still not known, a thermodynamic control is probably responsible for the formation of a *fac*-tricarbonylmanganese chelate.

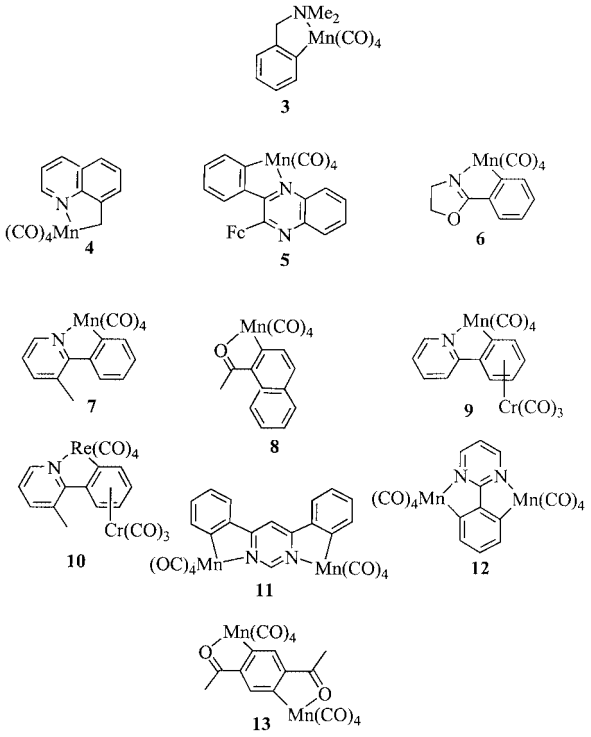


Scheme 2

Among all the possible adducts that may arise from the coordination of a donor ligand to the electron-deficient Mn^I centre, only the facial stereoisomer presents three *trans* influences that may significantly contribute to the stabilisation of the complex. When the exogenous ligand is a diazoalkane, we previously proposed that its coordination to Mn leads to a zwitterionic transient species — a manganese ylide — that evolves by elimination of N_2 to give a metallaalkylidene intermediate. A *cis* migration of the aromatic carbon atom bonded to the manganese atom creates a C−C bond between the exogenous alkylidene fragment and the chelate. At this point, we previously showed that the fluorenylidene species not only inserts into the carbon−metal bond, but the chelate itself is dismantled by the cleavage of the Mn−L bond, which is followed by a series of haptotropic shifts. In most cases, the final compounds are the corresponding [(η^5-fluorenyl)$Mn(CO)_3$] complexes **2a**−**d** and **2g**.



In the case of the rhenium(I) complex **2d**, we showed that it could undergo a haptotropic shift upon reaction with dissolved CO to give the [(η^1-fluorenyl)$Re(CO)_4$] complex **2e**. To check the validity of this coupling reaction with substrates containing various sorts of internal ligands, we decided to address the reactivity of diazocyclopentadienyl compounds such as **1a**−**c** with complexes **3**−**10**. Each thermolytic coupling reaction was carried out with an excess of the diazoalkane in order to compensate for the loss of reagent caused by a concomitant thermo-promoted conversion into azines and olefins. The course of the reaction could also be monitored by IR spectroscopy. The reaction was generally stopped when the characteristic four carbonyl-ligand stretching vibration bands generated by the $M(CO)_4$ group of the substrate completely faded out and were replaced by the characteristic two CO A_1 and E stretching vibration bands of the final product arising from the *fac*-$Mn(CO)_3$ fragment.



We first focussed our attention on the reactivity of **3** with **1c** [Equation (2) and Table 1, Entry 1]. Unfortunately, every attempted reaction between these two reagents led to the decomposition of **3** into dark-brown intractable compounds. More promising results were obtained with **4** [Equation (3)] and **5** [Equation (4)], which reacted readily and cleanly with **1c** to yield the corresponding substituted (η^5-fluorenylidene)$Mn(CO)_3$ complexes **4a** and **5a** (Table 1, Entries 2 and 3). The treatment of complex **6** with an excess of **1c** yielded a new brownish tetracarbonylmanganese chelate that was later identified by crystallographic means as complex **6a**, an analogue of **2e** [Equation (5) and Table 1, Entry 4]. The former plausibly arises from the carbonylation of the corresponding (η^5-fluorenyl)$Mn(CO)_3$ precursor, which was not isolated or detected in the crude mixture.

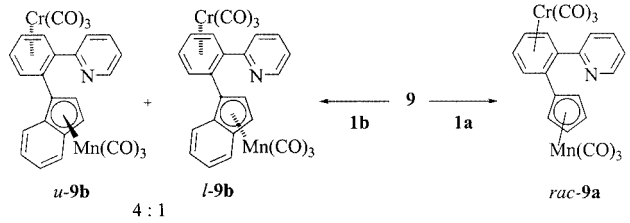
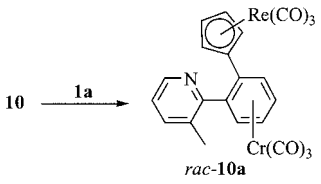


Scheme 4

treated with **1b**; complex **7** yielded **7b** (Scheme 3 and Table 1, Entry 6). The latter displayed a surprising dynamic behaviour when analysed by NMR spectroscopy in $CDCl_3$. A sample of **7b** dissolved in $CDCl_3$ was analysed at various sub-ambient temperatures until the resolution of the spectrum was sufficient to assume that a slow exchange had been reached. At 243 K we observed two sets of signals belonging to two isomers of this tris(aromatic) organometallic compound in a 1:3 ratio (Figure 1). Figure 1 displays the two signals of the olefinic protons of the indenyl fragment and their dependence on temperature. At first we thought that one of the two species might result from a combination of reversible coordination of the internal pyridyl group to the Mn^I centre and a haptotropic shift — or ring slippage[24] — from an η^5 to an η^3 mode, which indeed should cancel out the isochronicity of the three carbonyl ligands of the $Mn(CO)_3$ moiety.



(6)

Complexes **7** (Scheme 3), **9** (Scheme 4) and **10** [Equation (6)] reacted readily with **1a** to give the corresponding substituted (η^5-cyclopentadienyl)$Mn(CO)_3$ complexes **7a**, **9a** and **10a**, respectively (Table 1, Entries 5, 8 and 10). Similar results were obtained when the same substrates were

A ^{13}C NMR spectrum recorded at −30 °C displayed only one intense signal at δ = 225 ppm, which is rather consistent with a rapidly rotating $M(CO)_3$ group (Figure 2). We therefore deduced that the observed dynamic effect was probably the consequence of a conformational equilibrium

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

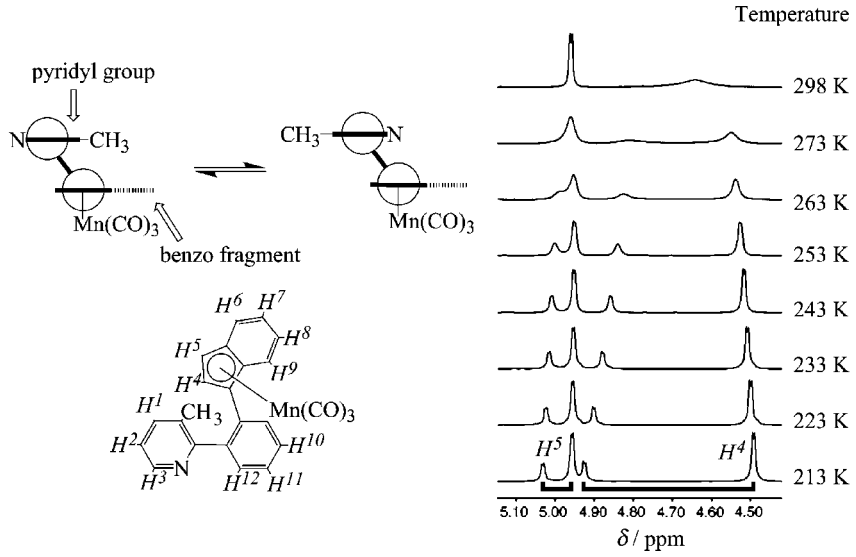


Figure 1. Temperature dependence of the ^{1}H NMR spectrum of **7b** in $CDCl_3$; enlargement of the olefinic indenyl protons region; the temperature dependency plausibly stems from a conformational equilibrium between two unequally populated conformers, whose Newman-type projections are depicted

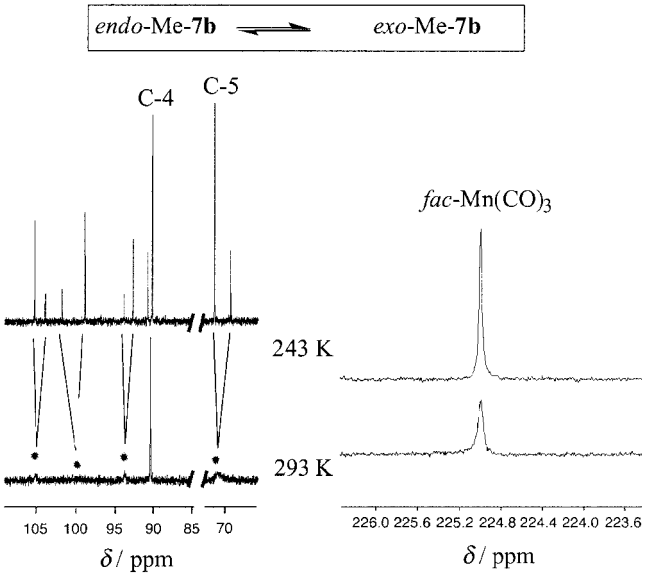

Figure 2. Temperature dependence of the ^{13}C NMR spectrum of **7b** in $CDCl_3$; enlargements of the areas of resonance of the η^5-bonded indenyl ^{13}C atoms (left) and of the $Mn(CO)_3$ fragment (right)

involving the rotation of the disubstituted pyridyl group. Such a conformational equilibrium should likely involve two conformers differing only in the orientation of the pyridyl group, which should place the methyl group either *endo* or *exo* with respect to the rest of the molecule (Figure 1). Strikingly, the ^{13}C NMR signals belonging to the indenyl group are distinguishable as sharp singlets only when the temperature drops down to 243 K. They appear as two sets of five signals between δ = 65 and 110 ppm (Figure 2). At room temperature, only the signal of the olefinic carbon atom C-4 (connected to 4-H) is well resolved since the difference in chemical shift between the two corresponding signals amounts to only 0.6 ppm at the slow exchange rate (Figure 2). From the analysis of the cross-peak correlation between the two sets of signals, a two-dimensional ^{1}H-^{1}H ROESY experiment carried out at 243 K allowed us to confirm that within the timescale of ^{1}H NMR a slow exchange exists between two unequally populated species (see Supporting Information). Unfortunately, we could not deduce any clue as to the structure of the major conformer because of the intricate mixing of the cross-peak correlations generated by pure nuclear Overhauser effects with those arising from the chemical exchange.

The reaction of complex **9** with **1b** yielded the two diastereomers *u*-**9b** and *l*-**9b** in a 4:1 ratio (Scheme 4 and Table 1, Entry 9). The predominance of *u*-**9b**, whose structure was firmly ascertained by X-ray diffraction analyses (vide infra), can be explained by the intervention of a late transition state in which the Mn-to-indenyl electronic interaction would define the activation barrier of the alkylidene insertion step. This is a proposal somewhat similar to that made for the mechanism of formation of "spiralenes".[1b] Indeed, prior to insertion, the indenylidene ligand may adopt several conformations, among which only two are rel-

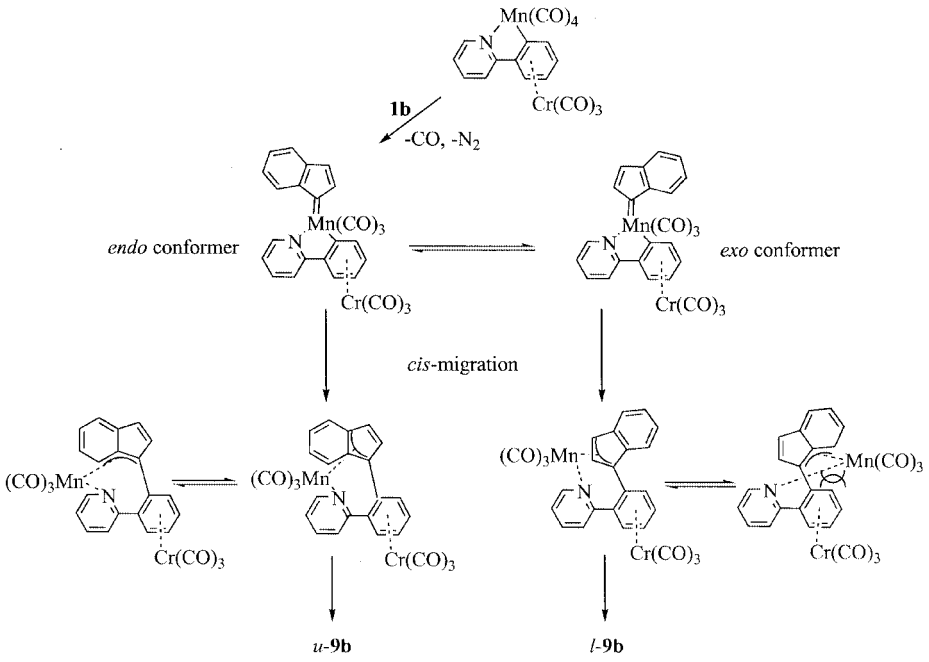

Scheme 5

evant for the *cis*-migration step: on the one hand, the benzo fragment of the indenylidene is placed at an *endo* position, and on the other the same fragment is found at an *exo* position with respect to the chelate (Scheme 5).

Upon insertion of the indenylidene, the formation of the carbon−carbon bond is accompanied by the creation of a vacant coordination site at the manganese centre that can be filled by an interaction with the π-system of the indenyl species. The ratio between the two products illustrates the intracyclic strains, which are putatively lower in the *endo* stereoisomer than in the *exo* isomer.

Complex **8** successfully reacted with an excess of **1b** to yield the aromatic ketone **8a** in good yield [Equation (7) and Table 1, Entry 7].

The Reaction of Dimanganated Complexes with 1c

Complexes **11** and **12**, derived from pyrimidine, were treated with an excess of **1c** and gave the corresponding dinuclear complexes **11a** and **12a** in good yields [Equations (8) and (9), Table 1, Entries 11 and 12]. Both complexes could be purified by column flash chromatography in spite of their polarity. The reaction of **13** with **1c** under the same conditions also afforded the corresponding dimetallic product **13a**, which precipitated immediately [Equation (10), Table 1, Entry 13].

This complex displays a pronounced insolubility even in polar solvents such as tetrahydrofuran, which prevented its purification by chromatography and its full characterisation by NMR spectroscopy. Its IR spectrum measured with a KBr pellet displays the expected stretching bands related to the $Mn(CO)_3$ group at $\tilde{\nu}$ = 2013 and 1926 cm^{-1} and that related to the ketone functions at $\tilde{\nu}$= 1694 cm^{-1}.

Structural and Spectroscopic Properties of Complexes 4−8a, 9b and 10−12a

Most of the new complexes reported here crystallised readily. In this article, we present the structures obtained by

X-ray diffraction analyses for **4a** (Figure 3), **5a** (Figure 4), **6a** (Figure 5), **7a** (Figure 6), **8a** (Figure 7), **9a** (Figure 8), *u*-**9b** (Figure 9), **11a** (Figure 10) and **12a** (Figure 11). Main acquisition and refinement data are collected at the end of the Exp. Sect.; ORTEP diagrams of the relevant structures are given in the relevant figure, along with the atom numbering scheme and selected geometrical information.

In most structures where the Mn centre is bonded to the cyclopentadienyl moiety, there are disparities among the Mn−C_{Ar} bond lengths that reveal a sensitivity of the $Mn(CO)_3$ moiety to steric hindrance (Table 2). In η^5-fluorenyl complexes (Figures 3, 4, 10 and 11) the C_{ipso}−Mn distance can vary from 2.126(2) to 2.157(3) Å while the other C_{Ar}−Mn bonds remain unaffected, with an interatomic distance of about 2.195 Å. In a similar way, with η^5-indenyl complexes, the largest variation of the carbon−manganese distances is noticed for the C_{ipso}−Mn and $<C_{olefinic}-Mn>$ distances from 2.139(2) to 2.155(4) Å and from 2.126(2) to 2.141(2) Å in **8a** (Figure 7) and **9b** (Figure 9), respectively.

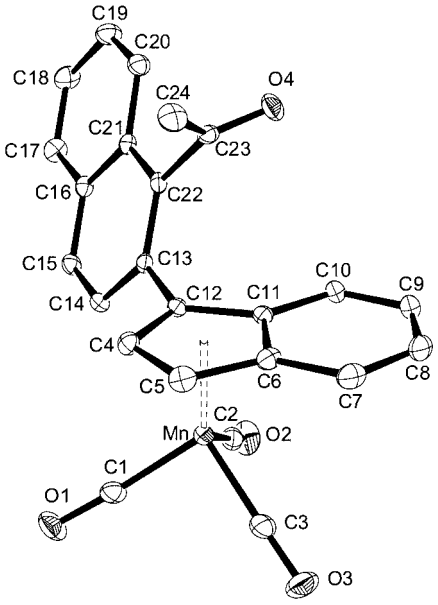

Figure 7. ORTEP diagram of compound **8a**, with the atom numbering scheme; atoms of hydrogen have been omitted for clarity; the ellipsoids are drawn at the 30% probability level; selected interatomic distances [Å] and angles [°]:Mn−C12 2.139(2), C12−C13 1.484(3), C22−C23 1.516(3), C23−O4 1.211(2); C4−C12−C11 106.4(2)

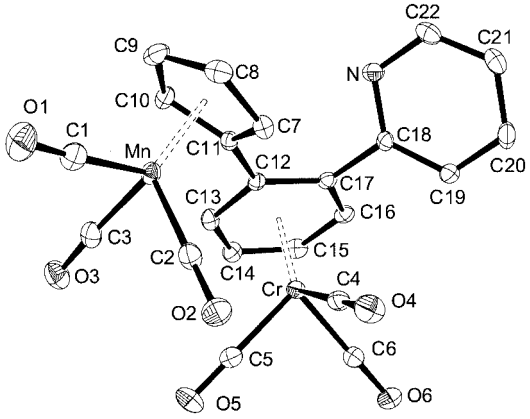

Figure 8. ORTEP diagram of compound *rac*-**9a**, with the atom numbering scheme; the molecule of solvent and hydrogen atoms have been omitted for clarity; the ellipsoids are drawn at the 30% probability level; selected interatomic distances [Å]: Cr−C12 2.240(4), Cr−C17 2.215(3), Cr−C15 2.217(4), Mn−C11 2.167(4), Mn−C9 2.137(4), Mn−C7 2.144(4), C17−C18 1.506(5), C11−C12 1.484(5)

Again the C_{Ar}−Mn bond lengths remain almost unaffected and remain at an average value of 2.202 Å.

Likewise, within the η^5-cyclopentadienyl complexes the disparity existing between C_{Cp}−Mn bond lengths is larger and directly related to the presence of bulky groups such as $Cr(CO)_3$ in the close vicinity of the $Mn(CO)_3$ group. For instance, in **7a** the C_{ipso}−Mn and the C4−Mn interatomic distances are the longest, with values of 2.154(2) and 2.145(2) Å, respectively, whereas the C(5−7)−Mn bond lengths are all equal to 2.137(2) Å (Figure 6). More dramatic distortions are observed in the dinuclear complex **9a**, in which C_{ipso}−Mn is the largest C_{Cp}−Mn distance with a value of 2.167(4) Å and C9−Mn is the smallest distance with a value of 2.137(4) Å (Figure 8). In the (η^6-aryl)tricarbonylchromium fragment the largest C−Cr distance is Cr−C12, with a value of 2.240(4) Å, whereas the remaining C(13−17)−Cr distances amount to about 2.216 Å.

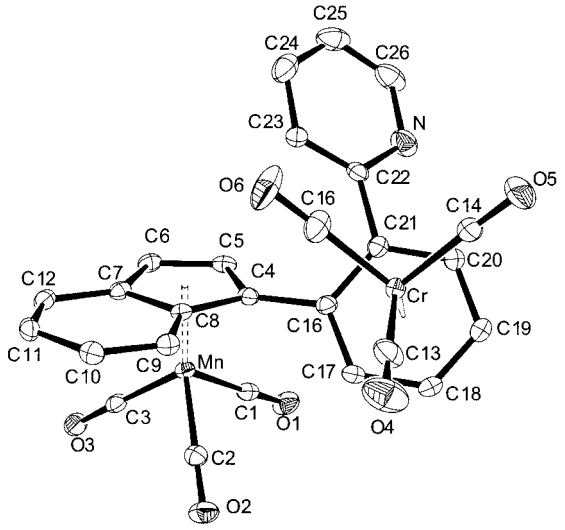

Figure 9. ORTEP diagram of compound *u*-**9b**, with the atom numbering scheme; atoms of hydrogen have been omitted for clarity; the ellipsoids are drawn at the 30% probability level; selected interatomic distances [Å]: Mn−C4 2.155(2), Mn−C5 2.138(2), Mn−C6 2.144(2), Cr−C16 2.259(2)

If we look closely at the reported structures of cymantrenes and benzo- and dibenzocymantrenes stored in the Cambridge Structural Database (CSD), we notice that the centroid−Mn distance clearly increases from cyclopentadienyl- to fluorenyl-type ligands. As already mentioned, and revealed previously by Calhorda and Veiros, this relative increase of the metal−cyclopentadienyl ligand distances stems from intrinsically different metal-to-π-system bonding modes, which is truly η^5 in Cp derivatives and seemingly more η^3-η^2 in indenyl derivatives.[24,25] The C_{ipso}−Mn distances seem much more sensitive to a factor such as steric hindrance than to changes in the electronic properties of neighbouring substituents. This can be readily assessed by the relative dispersion of the C_{ipso}−Mn distances collected from the CSD for monosubstituted cymantrenes.[26] Table 3 lists the statistical data related to centroid−Mn and C_{ipso}−Mn distances of 20 structures of monosubstituted cymantrenes deposited with the CSD.[27] For the benzo and dibenzo analogues, only two and three examples, respectively, have been selected based on their substitution pattern and their structural analogy with the complexes reported herein (Table 4).

In complex **6a**, the Mn atom sits in an octahedral environment (Figure 5). The manganese atom is chelated by the pentacyclic ligand and is included in a slightly twisted six-membered metallacycle consisting of atoms N, C7, C8, C13, C14 and Mn. The ^{13}C NMR analysis of a solution of this compound at room temperature reveals a dynamic

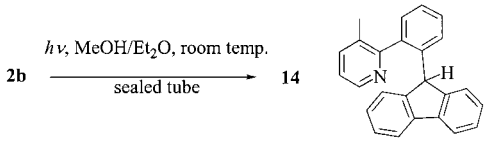
behaviour. The four carbonyl ligands give rise to three very broad and poorly resolved ^{13}C signals at δ = 213.6, 213.0 and 211.8 ppm. Decreasing the temperature to −50 °C allowed the detection of sharper signals at δ = 213.9, 212.7 and 211.51 ppm, but did not allow us to distinguish separate signals for the two non-isochronous axial carbonyl ligands. This dynamic behaviour possibly stems from the conformational changes of the six-membered metallacycle that imply a partial rotation of the organic ligand around the C14−Mn axis via a transition state wherein the Mn−N bond is eclipsed by the C14−C13 bond. A similar broadening was observed in the ^1H NMR spectra, although we could not assign this exactly. To the best of our knowledge **6a** is only the second example of a carbonyl(η^1-fluorenyl)-manganese complex that has been characterised by X-ray diffraction analyses.[28] The Mn−C distance of 2.254(2) Å is in the range reported for similar compounds.[29]

In the crystalline state the homodimetallic complex **11a** (Figure 10) consists of a pentaaromatic distorted helix of 1,2- and 1,3-disubstituted arenes. The distance between the two Mn atoms is ca. 1 nm (10.7 Å). In this compound the helical arrangement optimises the electrostatic repulsion and minimises the steric interactions. The C_2-symmetric compound **12a** (Figure 11) is a rare case of a 1,2,3-heterotrisubstituted arene with an encapsulated heterocyclic aromatic ligand. In this compound the pyrimidyl ring stands almost perpendicular to the trisubstituted benzene. The two metal centres are about 0.9 nm apart.

Conclusion

Cyclomanganated aromatic compounds are generally readily accessible by the thermolysis of (alkyl)pentacarbonylmanganese compounds in the presence of an aromatic ligand. Such complexes have been studied for their reactivity towards various inorganic and organic reagents. Most interesting are those reactions that yield new organomanganese compounds and allow further chemical or physical investigations. We have shown here a valuable synthetic method for appended cymantrenes that could be of interest in various domains such as the design of polytopic ligands for homogeneous catalysts or in the preparation of coordination polymers from bidentate ligands containing two dibenzocymantrenyl substituents.[1a] Most coupling reactions with diazocyclopentadienyl compounds gave excellent yields of cymantrenes when the manganated substrate contained a pyridyl ring, a parent heterocycle or a ketone as internal donor ligand. In all other cases, the course of the reaction was not clear and definitely deserves more attention. We have shown that dinuclear substrates could also react even when the steric congestion is important, as in the case of one di-*ortho*-manganated 2-phenylpyrimidine.

The release of the cyclopentadienyl ligand, or in other words the removal of the $Mn(CO)_3$ fragment, is seemingly readily achievable by applying the method recently suggested by Jaouen and co-workers.[30] In a preliminary experiment, the photolysis of complex **2b** in MeOH efficiently afforded compound **14** [Equation (11)] as a white solid in 71% yield.



(11)

In summary, two synthetic steps are necessary to convert an aromatic compound into a polycyclic tethered cymantrene. Both the cyclomanganation and the coupling steps involve neutral reagents and are overall relatively efficient.

Experimental Section

General Remarks: All experiments were carried out under dry argon with dry and degassed solvents. The (η^6-arene)tricarbonylchromium complexes were synthesised according to published procedures.[1b] Ligands such as 2-phenylpyrimidine,[31] 4,6-diphenylpyrimidine[32] and 2-ferrocenyl-3-phenylquinoxaline[33] as well as tetracarbonyl[8-(methyl-κ$C^{l'}$)quinoline-κN]manganese(I) (**4**)[34] were synthesised according to published procedures. Other ligands were purchased from commercial sources and used without further purification. NMR spectra were acquired with Bruker DRX 500 (^1H and ^{13}C nuclei) and AC 300 (^1H nucleus) spectrometers at room temperature unless otherwise stated. Chemical shifts are reported in ppm downfield of $SiMe_4$. IR spectra were measured with a Perkin−Elmer FT spectrometer. Mass spectra were recorded at

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the Service of Mass Spectrometry of University Louis Pasteur (FAB+PEG matrix) or at the Analytical Centre of the Chemical Institute of the University of Bonn (EI). Elemental analyses were performed at the Service d'Analyses of the "Institut de Chimie de Strasbourg" and at the analytical centre of the "Institut Charles Sadron" in Strasbourg.

***p*-Tosyl Azide:** *p*-Toluenesulfonyl chloride (85 g, 0.45 mol) was added to a stirred solution of sodium azide (35 g, 0.54 mol) in a mixture of 35 mL of water and 500 mL of absolute ethanol. The resulting mixture was stirred overnight. After this time, 500 mL of water was added and the resulting slurry was extracted with diethyl ether. The organic phases were combined and dried with magnesium sulfate and then stripped of solvent under reduced pressure to afford a pale yellow oil.

5-Diazocyclopentadiene (1a): Freshly cracked cyclopentadiene (6.6 g, 0.1 mol), *p*-tosyl azide (19.7 g, 0.1 mol) and diethylamine (7.3 g, 10.4 mL, 0.1 mol) were dissolved in 50 mL of distilled acetonitrile and stirred under argon at 3 °C for 96 h. The resulting brownish reaction mixture was extracted with 300 mL of *n*-hexane and the organic phase was washed with 200 mL of water. The organic phase was washed twice with an aqueous solution of KOH (6% mass) and with water. The combined organic phases were dried with $MgSO_4$ and concentrated by the removal of half of the solvents under reduced pressure. The resulting solution was then loaded on the top of a column of SiO_2 packed in *n*-hexane and cooled to −10 °C. A large orange band containing the product was eluted with *n*-hexane and the corresponding solution was concentrated to 30 mL and titrated with triphenylphosphane. Thus, a 2-mL aliquot of mother solution was added to a solution of triphenylphosphane (1.8 g, 6 mmol) in diethyl ether and stirred under argon for 15 min. To the resulting mixture, 30 mL of *n*-hexane was added and the mixture stirred for an additional 15 min. The resulting orange precipitate was filtered off, washed with 40 mL of hexane and 30 mL of pentane, and dried under vacuum. The amount of cyclopentadienonetriphenylphosphazine (0.37 g, 1.04 mmol) recovered from this gravimetric titration gave an approximate concentration of 0.52 M of 5-diazocyclopentadiene. Yield: 1.44 g, 16%.

Diazoindene (1b): Freshly distilled indene (27.4 g, 0.236 mol) and *p*-tosyl azide (44.3 g, 0.224 mol) were dissolved in diethylamine (50 mL) and stirred at 0 °C under argon for 72 h. The resulting mixture was extracted with *n*-hexane and the organic phases washed with water and brine. The organic phases were combined, dried with Na_2SO_4 and concentrated under a reduced pressure of ca. 20 Torr at 30 °C. The resulting solution was distilled under a reduced pressure of 9 Torr, using a Vigreux column to improve the separation of the components of the raw mixture. A large fraction of indene was distilled at a temperature of 58 ± 4 °C. To avoid any explosive behaviour, the boiler was heated with an oil bath that was warmed slowly and whose temperature was homogenised by gentle stirring. The distillation of indene was stopped as soon as the temperature at the head of the Vigreux column started to fall. The boiler was then swiftly cooled to room temperature and the remaining residue separated by chromatography on an SiO_2 column refrigerated at 4 °C and packed in *n*-hexane. A red band containing the product was eluted with dry and distilled *n*-hexane. Removal of the solvent under reduced pressure afforded a red oil consisting of 92% of diazoindene and 8% of unchanged indene. This oil could be kept over long periods of time provided it was kept at a temperature lower than −20 °C. Yield: 15%.

9-Diazofluorene (1c): 9-Fluorenone hydrazone (1.0 g, 5.3 mmol) was dissolved in 75 mL of toluene and yellow mercuric oxide (3.41 g, 15.8 mmol) was added. The resulting suspension was stirred for 1 d, filtered and the filtrate dried with $MgSO_4$. The removal of solvents under reduced pressure afforded **1c** as a purple-red stable solid. Yield: 0.948 g, 94%.

General Procedure for the Reaction of 1a−c with Cyclometalated Arenes: The cyclometalated substrate was dissolved in a mixture of *n*-heptane and toluene and the resulting solution was brought to reflux. A solution of diazoalkane in toluene was added dropwise from a syringe and the resulting solution was stirred for an additional period of time. The solvents were then evaporated to dryness. The residue was dissolved in dichloromethane and SiO_2 was added. The suspension was stripped of solvent under reduced pressure and the coated silica gel was loaded on the top of a refrigerated SiO_2 column packed in *n*-hexane.

8-[1′-(Dibenzocymantren-1-yl)methyl]quinoline (4a): From **4** (0.32 g, 1 mmol), a 1:1 mixture of *n*-heptane (7 mL) and toluene (7 mL), and a solution of **1c** (0.4 g, 2.1 mmol) in toluene (4 mL). Addition 25 min, stirring for an additional 35 min. An initial SiO_2 column chromatography (60 μm, 5 °C) gave a raw sample of **4a** contaminated with various organic pollutants upon elution with pure dichloromethane. A second chromatographic separation (0 °C) with a different grade of SiO_2 (15−25 μm) gave **4a** after elution with dichloromethane/*n*-hexane (1:1). Yield: 0.35 g (70%). $C_{26}H_{16}MnNO_3$ (445.3): calcd. C 70.12, H 3.62, N 3.15; found C 69.79; H 3.54, N 3.01. IR (CH_2Cl_2): ṽ: 2015 vs, 1931 s cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ = 9.09 (d, ^3J = 2.9 Hz, 1 H), 8.17 (d, ^3J = 7.8 Hz, 1 H), 8.11 (m, 2 H), 7.66 (d, ^3J = 8.1 Hz, 4 H), 7.49 (m, 1 H), 7.20 (m, 4 H), 7.12 (d, ^3J = 7.0 Hz, 1 H), 5.31 (s, 2 H) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 263 K): δ = 225.5 (3 CO), 149.7, 146.4, 138.3, 136.7, 128.3, 127.8, 127.7, 126.6, 126.4, 125.3, 124.6, 123.6, 121.5, 107.2, 93.6, 77.7, 26.4 ppm.

Tetracarbonyl[2-ferrocenyl-3-(phenyl-κ$C^{2'}$)-quinoxaline-(κN^1)]-manganese(I) (5): 2-Ferrocenyl-3-phenylquinoxaline (0.37 g, 0.95 mmol) and $(PhCH_2)Mn(CO)_5$ (0.3 g, 1.1 mmol) were dissolved in a mixture of cyclohexane (10 mL) and toluene (5 mL). The resulting mixture was brought to reflux for 9 h, the solvents removed under reduced pressure and the resulting residue redissolved in dichloromethane. Silica gel was added to this solution and the suspension was stripped of solvent to afford a coated silica gel residue that was loaded on the top of a refrigerated (6 °C) SiO_2 column packed in *n*-hexane. A red band containing the product was eluted with a 1:1 mixture of *n*-hexane and dichloromethane. Compound **5** could be recovered as a red powder upon removal of the solvents under reduced pressure. Yield: 0.34 g, 65%. $C_{28}H_{17}FeMnN_2O_4$ (556.2): calcd. C 60.47, H 3.08, N 5.03; found C 60.18, H 3.14, N 4.90. IR (CH_2Cl_2): ṽ: 2075 w, 1993 vs, 1978 s, 1936 m cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$): δ = 8.50 (d, ^3J = 7.9 Hz, 1 H), 8.11 (d, ^3J = 7.1 Hz, 1 H), 8.05 (d, ^3J = 7.3 Hz, 1 H), 7.72 (m, 2 H), 7.55 (d, ^3J = 8.2 Hz, 1 H), 7.20 (t, ^3J = 7.3 Hz, 1 H), 6.90 (t, ^3J = 7.6 Hz, 1 H), 4.98 (t, ^3J = 2.0 Hz, 2 H), 4.47 (t, ^3J = 1.9 Hz, 2 H), 4.05 (s, 5 H) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 221.1 (CO), 214.3 (CO), 213.9 (2 CO), 178.9, 162.2, 153.4, 148.6, 141.9, 141.2, 140.7, 131.3, 130.0, 129.9, 129.7, 129.4, 126.7, 122.7, 85.3, 71.6 (2 C), 70.4 (5 C), 69.9 (2 C) ppm.

3-[2′-(Dibenzocymantren-1-yl)phenyl]-2-ferrocenylquinoxaline (5a): From **5** (0.124 g, 0.22 mmol), 10 mL of cyclohexane, 1 mL of toluene and a solution of **1c** (0.09 g, 0.47 mmol) in 2 mL of toluene. Addition for 20 min, additional stirring for 40 min. Chromatography on an SiO_2 column (6 °C) gave **5a** after elution with a 70:30 mixture of *n*-hexane/acetone. Deep red powder. Yield: 0.11 g (74%). $C_{40}H_{25}FeMnN_2O_3 \cdot 1/2CH_2Cl_2$ (734.8): calcd. C 60.80, H 3.44, N

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3.42; found C 60.81, H 3.40, N 3.53. IR (CH_2Cl_2): ṽ: 2016 s, 1934 s cm^{-1}. ^1H NMR (500 MHz, $CDCl_3$, 263 K): δ = 8.18 (d, ^3J = 4.5 Hz, 1 H), 8.01 (d, ^3J = 8.4 Hz, 1 H), 7.96 (t, ^3J = 4.6 Hz, 1 H), 7.86 (d, ^3J = 8.6 Hz, 1 H), 7.78 (m, 3 H), 7.64 (t, ^3J = 8.4 Hz, 2 H), 7.58 (t, ^3J = 7.6 Hz, 1 H), 7.01 (m, 2 H), 6.95 (m, 1 H), 6.79 (t, ^3J = 7.6 Hz, 1 H), 6.66 (d, ^3J = 8.8 Hz, 1 H), 6.24 (t, ^3J = 7.6 Hz, 1 H), 4.24 (s, 1 H), 3.91 (s, 1 H), 3.83 (s, 1 H), 3.74 (s, 5 H), 3.44 (s,1 H) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 263 K): δ = 225.3 (3 CO), 154.1, 152.1, 141.3, 141.1, 139.7, 135.0, 131.9, 130.1, 129.8, 129.7, 129.1, 128.7, 128.6, 127.9, 127.1, 125.2, 125.1, 124.8, 124.6, 124.3, 124.1, 123.2, 107.4, 103.2, 95.5, 90.9, 82.1, 81.5, 71.2, 70.1, 69.7, 69.6 (5 C), 68.2 ppm.

Tetracarbonyl[2-(phenyl-κ*C*^{2})-2-oxazoline-κ*N*]manganese(I) (6): 2-Phenyl-2-oxazoline and $(PhCH_2)Mn(CO)_5$ were dissolved in *n*-heptane and the resulting mixture was boiled for 9 h. The resulting suspension was stripped of solvent and the residue loaded on the top of an SiO_2 column packed in *n*-hexane. A pale yellow band was eluted with a 1:1 mixture of *n*-hexane/CH_2Cl_2, and the resulting solution stripped of solvents to afford a yellow powder. Yield: 1.61 g, 71%. M.p.: 106 °C. $C_{13}H_8MnNO_5$ (313.1): calcd. C 49.86, H 2.58, N 4.47; found C 49.70, H 2.61, N 4.45. HRMS: calcd. for $C_{13}H_8MnNO_5$ 312.9782; found 312.9782. IR (*n*-hexane): ṽ = 2077 w, 1991 vs, 1982 m, 1943 s cm^{-1}. ^1H NMR (500 MHz, $CDCl_3$): δ = 7.96 (ddd, $^3J_{H,H}$ = 7.4, $^4J_{H,H}$ = 1.0, $^5J_{H,H}$ = 0.6 Hz, 1 H), 7.52 (ddd, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.5, $^5J_{H,H}$ = 0.6 Hz, 1 H), 7.35 (td, $^3J_{H,H}$ = 7.4, $^4J_{H,H}$ = 1.5 Hz, 1 H), 7.14 (ddd, $^3J_{H,H}$ = 7.6, $^3J_{H,H}$ = 7.4, $^4J_{H,H}$ = 1.0 Hz, 1 H), 4.75 (t, $^2J_{H,H}$ = 9.4 Hz, 2 H, N-CH_2), 3.82 (dd, $^2J_{H,H}$ = 9.6, $^2J_{H,H}$ = 9.3 Hz, 2 H, OCH_2) ppm. ^{13}C NMR (125 MHz, $CDCl_3$): δ = 219.6 (MnCO), 215.3 (MnCO), 213.3 (2 MnCO), 179.0, 175.3, 141.8, 133.6, 131.8, 126.7, 123.7, 71.3 (NCH_2), 54.1 (OCH_2) ppm. EI-MS: *m*/*z* = 313 [M^+], 285 [M^+ − CO], 257 [M^+ − 2 CO], 229 [M^+ − 3 CO], 157 [M^+ − 4 CO − C_3H_4NO − H], 147 [M^+ − $Mn(CO)_4$ + H].

Tetracarbonyl{9-[2′-(2′′-oxazolin-2′′-yl-κ*N*$^{3''}$)phenyl]-fluorenyl-κ*C*^{9}}manganese(I) (6a): From **6** (782 mg, 2.5 mmol), *n*-hexane (10 mL) and a solution of **1c** (5 mmol) in toluene (17.5 mL). Addition 60 min, stirring for an additional 60 min. Chromatography on SiO_2 (5 °C) gave a brownish mixture containing mainly **6a** after elution with *n*-hexane/dichloromethane (1:1). A second chromatographic separation gave a brown-yellow solution of **6a**. Yield: 0.76 mg (63%). The air sensitivity of **6a** prevented its complete characterisation by elemental analysis. HRMS: calcd. for $C_{25}H_{16}MnNO_4$ [M − CO] 449.0459; found 449.0453. IR (*n*-hexane): ṽ = 2071 w, 1993 vs, 1986 s, 1940 s cm^{-1}. ^1H NMR (300 MHz, CD_2Cl_2): δ = 7.96 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H, $H_{fluorene}$), 7.89 (dd, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.2 Hz, 1 H, H_{Ph}), 7.45 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H, $H_{fluorene}$), 7.25 (m, 7 H), 4.75 (dd, $^2J_{H,H}$ = 9.8, $^3J_{H,H}$ = 9.5 Hz, 2 H, NCH_2), 4.01 (dd, $^2J_{H,H}$ = 9.8, $^3J_{H,H}$ = 9.5 Hz, 2 H, O-CH_2) ppm. ^1H NMR (500 MHz, $CDCl_3$, −50 °C): δ = 8.04 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H), 7.86 (d, $^3J_{H,H}$ = 7.6 Hz, 1 H), 7.50 (br. s, 2 H), 7.36 (m, 3 H), 7.30 (m, 3 H), 7.21 (t, $^3J_{H,H}$ = 7.6 Hz, 1 H), 4.83 (t, $J_{H,H}$ = 9.6 Hz, 2 H, NCH_2), 4.01 (t, $J_{H,H}$ = 9.6 Hz, 2 H, OCH_2) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 293 K): δ = 213.7 (MnCO), 213.1 (MnCO), 211.7 (2 MnCO), 169.4 (OC=N), 157.6, 157.6 (2 C), 150.4, 133.5, 133.5 (2 C), 133.2, 130.2, 126.8, 126.1, 126.1, 125.0, 122.9, 122.8, 122.8, 120.8, 120.8, 120.1, 120.1, 67.5 (NCH_2), 61.1 (OCH_2), 52.2 ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 263 K): δ = 213.9 (MnCO), 212.7 (MnCO), 211.5 (2 MnCO), 168.8 (O-C=N), 157.3, 157.3 (2C), 149.4, 133.0, 133.0 (2 C), 132.9, 130.1, 126.5, 126.0, 126.0, 125.1, 122.4, 122.3, 122.3, 120.7, 120.7, 119.9, 119.9 (2 C), 67.4 (NCH_2), 61.0 (OCH_2), 51.5 (C-9) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 223 K): δ = 213.7 (MnCO), 212.9 (MnCO), 211.6 (2 MnCO), 169.1 (OC=N), 157.4, 157.4 (2 C), 150.0, 133.3, 133.3 (2 C), 133.2, 130.2, 126.6, 126.1, 126.1, 125.1, 122.7, 122.6, 122.6, 120.8, 120.8, 120.0, 120.0 (2 C), 67.4 (NCH_2), 61.0 (OCH_2), 51.9 (C-9) ppm. EI-MS: *m*/*z* = 449 [M^+ − CO], 421 [M^+ − 2 CO], 393 [M^+ − 3 CO], 369 [M^+ − 4 CO].

2-[2′-(Cymantren-1′′-yl)phenyl]-3-methylpyridine (7a): From **7** (0.205 g, 0.61 mmol), *n*-heptane (10 mL) and a solution of **1a** in *n*-hexane (2 mL, 1.04 mmol, 0.52 M). Addition 5 min and stirring for an additional 25 min. Chromatography on hydrated SiO_2 (5 °C) gave **7a** upon elution with a mixture of *n*-hexane and acetone (4:1). Canary-yellow powder. Yield: 0.149 g (66%). $C_{20}H_{14}MnNO_3$ (275.2): calcd. C 64.70, H 3.80, N 3.77; found C 64.51, H 3.68, N, 3.70. IR (CH_2Cl_2): ṽ = 2020 s, 1934 s cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ = 8.51 (d, ^3J = 4.8 Hz, 1 H), 7.54 (d, ^3J = 7.7 Hz, 1 H), 7.50 (d, ^3J = 7.5 Hz, 1 H), 7.41 (t, ^3J = 7.1 Hz, 1 H), 7.35 (t, ^3J = 7.0 Hz, 1 H), 7.23 (m, 2 H), 4.53 (m, 4 H), 2.02 (s, 3 H) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 263 K): δ = 224.9 (3 CO), 158.8, 146.9, 139.2, 138.1, 132.0, 131.2, 129.9, 129.5, 128.4, 128.0, 122.9, 103.1, 84.6, 84.3, 82.0, 80.7, 19.2 ppm.

[1-(Acetyl-κ*O*)naphthyl-κ*C*^{2}]tetracarbonylmanganese(I) (8): $(PhCH_2)Mn(CO)_5$ (1.43 g, 5 mmol) and 1-acetylnaphthalene (1.02 g, 6 mmol) were dissolved in *n*-heptane (20 mL) and refluxed for 15 h. The resulting mixture was stripped of solvents and the residue subjected to flash chromatography on SiO_2. Compound **8** was eluted with a 1:1 mixture of dichloromethane/*n*-hexane. Yellow solid. Yield: 0.93 g (56%). $C_{16}H_9MnO_5 \cdot 1/2CH_2Cl_2$ (378.7): calcd. C 54.62, H 2.66; found C 54.65, H 2.71. HR-MS: calcd. for $C_{16}H_9MnO_5$ 335.9830; found 335.9831. IR (*n*-hexane): ṽ = 2082 m, 1997 vs, 1946 s, 1562 w cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ = 8.31 (d, ^3J = 8.8 Hz, 1 H), 8.27 (d, ^3J = 8.3 Hz, 1 H), 7.93 (d, ^3J = 8.1 Hz, 1 H), 7.81 (d, ^3J = 8.0 Hz, 1 H), 7.60 (t, ^3J = 7.7 Hz, 1 H), 7.47 (t, ^3J = 7.5 Hz, 1 H), 3.03 (s, 3 H) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 220.6 (CO), 215.1 (CO), 213.2 (CO), 210.9 (CO), 210.2 (CO), 140.7, 138.3, 134.2, 133.4, 132.4, 130.5, 128.1, 124.7, 121.7, 32.2 ppm. EI-MS: *m*/*z* = 336 [M], 280 [M − 2 CO], 252 [M − 3 CO], 224 [M − 4 CO], 196 [M − 5 CO], 170 [M − Mn − 4 CO].

1-Acetyl-2-(benzocymantren-1′-yl)naphthalene (8a): From **8** (0.2 g, 0.6 mmol), *n*-heptane (5 mL), toluene (5 mL) and **1b** (0.2 g, 1.4 mmol) in toluene (3 mL). Addition 30 min and stirring for an additional 30 min. Chromatography on a hydrated SiO_2 column (5 °C), elution with pure dichloromethane. Canary-yellow powder. Yield: 0.19 g (76%). $C_{24}H_{15}MnO_4$ (422.3): calcd. C 68.26, H 3.58: found C 68.12, H 3.40. IR (KBr): ṽ = 2017 vs, 1942 s, 1925 s, 1694 m cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$): δ = 8.02 (d, ^3J = 8.5 Hz, 2 H), 7.96 (m, 1 H), 7.76 (m, 1 H), 7.57 (m, 3 H), 7.49 (d, ^3J = 8.7 Hz, 1 H), 7.23 (t, ^3J = 7.4 Hz, 1 H), 7.16 (t, ^3J = 7.4 Hz, 1 H), 5.36 (d, ^3J = 2.7 Hz, 1 H), 5.25 (d, ^3J = 2.8 Hz, 1 H), 2.08 (s, 3 H) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 224.6 (3 CO), 206.9 (CO), 141.0, 133.1, 130.4, 129.8, 128.7, 128.6, 128.0, 127.9, 127.0, 126.6, 126.2, 124.6, 122.9, 105.9, 100.4, 92.8, 90.7, 77.4, 72.1, 32.8 ppm.

2-[2′-(Benzocymantren-1′′-yl)phenyl]-3-methylpyridine (7b): From **7** (0.22 g, 0.79 mmol) cyclohexane (15 mL), **1b** (0.24 g, 1.7 mmol) and *n*-hexane (3 mL). Addition 10 min, stirring for an additional 50 min. Chromatography on SiO_2 (5 °C), elution with *n*-hexane/acetone (70:30). Red waxy solid. Yield: 0.24 g (87%). $C_{24}H_{16}MnNO_3 \cdot 1/2CH_2Cl_2$ (463.7): calcd. C 63.45, H 3.69, N 3.02; found C 63.92, H 3.86, N 3.05. Complexes *u*-9b and (*rel*)-*l*-9b: From **9** (0.2 g, 0.4 mmol), cyclohexane (10 mL), toluene (1 mL) and a solution of **1b** (0.12 g, 0.9 mmol) in toluene (3 mL). Addition 20 min, stirring for an additional 25 min. Chromatography on SiO_2 (−5 °C), *u*- and (*rel*)-*l*-**9b** were eluted with *n*-hexane/acetone (70:30). ^{1}H NMR spectroscopy indicated that the two diastereomers are in a 78:22 ratio. Conversion: 0.13 g (55%). $C_{26}H_{14}CrMnNO_6$ (543.3): calcd. C 57.48, H 2.60, N 2.58; found C 57.67, H 2.42, N 2.65. IR (CH_2Cl_2): ṽ = 2023 s, 1970 vs, 1937m, 1899 m cm^{-1}. *u*-**9b**: ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 8.42 (d, ^3J = 4.8 Hz, 1 H), 7.36 (d, ^3J = 8.7 Hz, 1 H), 7.25 (m,1 H), 7.19 (t, ^3J = 6.5 Hz, 1 H), 7.00 (m, 3 H), 6.85 (t, ^3J = 7.6 Hz, 1 H), 6.02 (d, ^3J = 6.4 Hz, 1 H), 5.90 (d, ^3J = 6.4 Hz, 1 H), 5.65 (t, ^3J = 6.3 Hz, 1 H), 5.59 (t, ^3J = 6.4 Hz, 1 H), 5.54 (d, ^3J = 3.0 Hz, 1 H), 5.14 (d, ^3J = 3.0 Hz, 1 H) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 263 K): δ = 232.5 [$Cr(CO)_3$], 224.0 [$Mn(CO)_3$], 154.2, 149.1, 135.7, 126.8, 126.7, 125.6, 125.1, 123.2, 122.7, 112.5, 105.0, 103.2, 101.9, 99.0, 93.6, 93.5, 92.8, 91.1, 90.5, 69.5 ppm. (*rel*)-*l*-**9**: ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ = 8.55 (d, ^3J = 5.4 Hz, 1 H), 7.97 (d, ^3J = 8.9 Hz, 1 H), 7.49 (m, 2 H), 7.30 (t, ^3J = 7.8 Hz, 1 H), 7.13 (m, 1 H), 6.91 (m, 2 H), 6.10 (d, ^3J = 6.4 Hz, 1 H), 5.96 (d, ^3J = 6.2 Hz, 1 H), 5.65 (t, ^3J = 6.3 Hz, 1 H), 5.59 (t, ^3J = 6.4 Hz, 1 H), 5.04 (d, ^3J = 3.4 Hz, 1 H), 4.49 (d, ^3J = 3.1 Hz, 1 H) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 263 K): δ = 232.6 [$Cr(CO)_3$], 224.1 [$Mn(CO)_3$], 154.5, 149.4, 136.0, 128.0 (2 C), 126.4, 126.3, 123.5, 123.4, 109.7, 105.5, 105.4, 99.0, 93.6, 93.5, 92.8, 91.1, 90.5, 69.5 ppm.

Complex 10a: From **10** (0.2 g, 0.44 mmol), heptane (10 mL) and a solution of **1a** (1.9 mL, 1.0 mmol, 0.52 M) in *n*-hexane, added in 3 fractions: 1 mL was added over 7 min, followed by an additional 0.45 mL after 1 h of reaction, and finally 0.45 mL after 2 h of reaction. The reaction mixture was then stirred for an additional hour. Chromatography on SiO_2 (5 °C), elution of **10a** with *n*-hexane/acetone (9:1). Yellow powder. Yield: 0.112 g, 71%. $C_{23}H_{14}CrNO_6Re$ (638.6): calcd. C 43.26, H 2.21, N 2.19; found C 43.05, H 2.45, N 2.02. IR (CH_2Cl_2): ṽ = 2026 s, 1972 vs, 1928 s, 1901 m cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 8.53 (d, ^3J = 4.2 Hz, 1 H), 7.55 (t, ^3J = 7.6 Hz, 1 H), 7.28 (m, 1 H), 5.65 (m, 1 H), 5.49 (t, ^3J = 5.6 Hz, 1 H), 5.41 (d, ^3J = 6.6 Hz, 1 H), 5.38 (d, ^3J = 6.2 Hz, 1 H), 5.32 (t, ^3J = 5.8 Hz, 1 H), 5.20 (m, 1 H), 4.98 (m, 1 H), 4.84 (m, 1 H), 2.19 (s, 3 H) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 263 K): δ = 232.4 [$Cr(CO)_3$], 193.5 [$Re(CO)_3$], 152.9, 147.3, 138.4, 132.6, 124.0, 102.0, 93.9, 92.1 (2 C), 91.9, 89.8 (2 C), 88.1, 87.8, 83.9, 82.6, 19.8 ppm.

[4,6-(Diphenyl-κ*C*$^{2'}$,κ*C*$^{2''}$)pyrimidine-(κ*N*^{1},κ*N*^{2})]bis(tetracarbonylmanganese(I)] (11): 4,6-Diphenylpyrimidine (0.4 g, 1.7 mmol) and $(PhCH_2)Mn(CO)_5$ (1.48 g, 5.2 mmol) were dissolved in a mixture of *n*-heptane (10 mL) and toluene (10 mL) and the resulting mixture heated to reflux for 11 h. The mixture was then stripped of its solvents, the residue was dissolved in dichloromethane and SiO_2 was added to this solution. After removal of the solvent under reduced pressure, the coated silica gel was loaded on the top of an SiO_2 column packed in *n*-hexane and refrigerated at 6 °C. A large band containing pure compound **11** was eluted with dichloromethane/*n*-hexane (3:2). Yellow powder. Yield: 0.71 g, 73%. $C_{24}H_{10}Mn_2N_2O_8$ (564.2): calcd. C 51.09, H 1.79, N 4.96; found C 50.97, H 1.46, N 5.03. IR (CH_2Cl_2): ṽ = 2082 w, 2000 vs, 1985 s, 1937 m cm^{-1}. ^{1}H NMR (300 MHz, [D$_6$]acetone): δ = 9.70 (s, 1 H), 8.79 (s, 1 H), 8.44 (d, ^3J = 7.3 Hz, 2 H), 8.01 (d, ^3J = 7.4 Hz, 2 H), 7.42 (t, ^3J = 7.3 Hz, 2 H), 7.29 (t, ^3J = 7.5 Hz, 2 H) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 221.1 (CO), 214.7 (CO), 214.0 (2 CO), 180.2, 173.0, 166.4, 145.4, 142.2, 133.2, 128.3, 125.4, 109.2 ppm.

4,6-Bis[2′-(dibenzocymantren-1′′-yl)phenyl]pyrimidine (11a): From **11** (0.2 g, 0.35 mmol), *n*-heptane (5 mL), toluene (5 mL) and a solution of **1c** (0.27 g, 1.42 mmol) in toluene (3 mL). Addition 25 min, stirring for an additional 35 min. Chromatography on SiO_2 (6 °C), **11a** was eluted with pure acetone. Yellow powder. Yield: 0.25 g, 84%. $C_{42}H_{22}N_2Mn_2O_6 \cdot 1/3CH_2Cl_2$ (788.8): calcd. C 64.48, H 2.90, N 3.55; found C 64.38, H 2.97, N 3.61. IR (CH_2Cl_2): ṽ = 2016 s, 1935 s cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 8.23 (d, ^3J = 7.7 Hz, 2 H), 8.08 (s, 1 H), 8.06 (d, ^3J = 8.2 Hz, 4 H), 7.67 (t, ^3J = 7.6 Hz, 2 H), 7.43 (t, ^3J = 7.6 Hz, 2 H), 7.17 (t, ^3J = 7.3 Hz, 4 H), 7.04 (m, 8 H), 6.71 (d, ^3J = 7.8 Hz, 2 H), 6.29 (s, 1 H) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 263 K): δ = 224.9 (3 CO), 165.2, 157.3, 139.4, 136.3, 130.6, 130.5, 129.5, 128.8, 128.2, 125.1, 124.8, 123.0, 120.6, 107.2, 92.9, 83.3 ppm.

[2-(Phenyl-κ*C*$^{2'}$,κ*C*$^{2''}$)pyrimidine-(κ*N*^{1},κ*N*^{2})]bis(tetracarbonylmanganese(I)] (12): 2-Phenylpyrimidine (0.79 g, 5.06 mmol) and $(PhCH_2)Mn(CO)_5$ (3.46 g, 1.21 mmol) were dissolved in a mixture of *n*-heptane (5 mL) and toluene (10 mL). The mixture was refluxed for 10 h and the solution was cooled to −20 °C overnight. Then the supernatant was removed and the solid residue was washed three times with 20 mL of diethyl ether and twice with 20 mL of pentane and dried under vacuum. Yield: 2.0 g (81%). $C_{18}H_6Mn_2N_2O_8$ (488.1): calcd. C 44.29, H 1.24, N 5.74; found C 44.49, H 1.15, N 5.60. IR (CH_2Cl_2): ṽ = 2072 w, 1997 vs, 1981 s, 1938 m cm^{-1}. ^{1}H NMR (400 MHz, [D$_6$]acetone): δ = 8.98 (d, ^3J =

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

5.4 Hz, 2 H), 7.53 (d, ^3J = 4.9 Hz, 2 H), 7.34 (t, ^3J = 5.5 Hz, 1 H), 7.21 (t, ^3J = 7.3 Hz, 1 H) ppm.

2-[2′,6′-Bis(dibenzocymantren-1′′-yl)phenyl]pyrimidine (12a): From **12** (0.3 g, 0.62 mmol), toluene (10 mL) and a solution of **1c** (0.47 g, 2.46 mmol) in toluene (3 mL). Addition 25 min, stirring for an additional 35 min. Chromatography on SiO_2 (5 °C), **12a** was eluted with dichloromethane/*n*-hexane (80:20). Yellow powder. Yield: 0.28 g (61%). $C_{42}H_{22}Mn_2N_2O_6{\cdot}1/3CH_2Cl_2$ (516.4): calcd. C 64.48, H 2.90, N 3.55; found C 64.38, H 2.97, N 3.61. IR (CH_2Cl_2): $\tilde{\nu}$ = 2018 s, 1934 s cm^{-1}. ^{1}H NMR (500 MHz, $CDCl_3$, 263 K): δ = 8.52 (d, ^3J = 7.8 Hz, 2 H), 8.03 (t, ^3J = 7.7 Hz, 1 H), 7.98 (d, ^3J = 8.6 Hz, 4 H), 7.56 (d, ^3J = 4.9 Hz, 2 H), 7.29 (d, ^3J = 8.7 Hz, 4 H), 7.10 (t, ^3J = 7.6 Hz, 4 H), 7.05 (t, ^3J = 7.6 Hz, 4 H), 6.15 (t, ^3J = 4.9 Hz, 1 H) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 263 K): δ = 225.3 (3 CO), 166.0, 155.3, 142.4, 136.2, 132.2, 130.1, 127.6, 124.6, 124.5, 123.9, 117.5, 107.3, 92.6, 84.6 ppm.

1,4-Diacetyl-2,5-bis(dibenzocymantren-1′-yl)benzene (13a): From **13** (0.22 mmol), *n*-hexane (7 mL) and a solution of **1c** (0.88 mmol) in toluene (5 mL). Addition 30 min, stirring for an additional 60 min. Compound **13a** precipitated as a yellow solid. Due to its insolubility in most polar solvents (THF, DMSO) it could not be further purified. This precipitate was washed several times with *n*-hexane and acetone and dried under reduced pressure. M.p. 233−240 °C. IR (KBr): $\tilde{\nu}$ = 2013 vs, 1926 s, 1694 w cm^{-1}. FAB-MS+: *m*/*z* = 767 [M + H]$^+$, 682 [M − 3 CO + H]$^+$, 613 [4 matrix + H]$^+$, 599 [M − $Mn(CO)_3$ − 3 CO + H]$^+$, 488 [M − 2 $Mn(CO)_3$]$^+$, 460 [3 matrix + H]$^+$.

2-{2′-(9-Fluorenyl)phenyl}-3-methylpyridine (14): Compound **2b** (0.2 g, 0.5 mmol) was dissolved in a mixture of diethyl ether (5 mL) and methanol (10 mL). The sealed Schlenk tube containing the solution was then irradiated with the aid of a medium-pressure Hg lamp. A slight precipitation of brownish air-sensitive solid was noticed shortly after the beginning of the UV irradiation. The organic product **14** was purified by chromatography on SiO_2 and recovered as an off-white solid. Yield: 0.1 g (71%). HRMS (FAB+): calcd. for $C_{25}H_{20}N$ [MH$^+$] 334.159565; found 334.159575. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 8.59 (m, 1 H), 7.85 (d, ^3J = 7.5 Hz, 2 H), 7.77 (d, ^3J = 7.5 Hz, 1 H), 7.45 (m, 1 H), 7.34 (m, 6 H), 7.24 (t, ^3J = 7.4 Hz, 2 H), 7.14 (t, ^3J = 7.4 Hz, 1 H), 6.42 (d, ^3J = 6.7 Hz, 1 H), 4.88 (s, 1 H), 2.41 (s, 3 H) ppm. ^{13}C NMR (75 MHz, [D_6]acetone): δ = 160.1, 149.7, 147.7, 142.4, 141.1, 138.9, 132.6, 129.9, 129.1, 128.7, 128.2, 128.1, 127.2, 126.5 (2 C), 123.5, 120.6, 51.2, 19.8 ppm.

Experimental Procedure for the X-ray Diffraction Analysis of Compounds 4a, 5a, 6a, 7a, 8a, 9a, 9b, 11a and 12a: Acquisition and processing parameters are displayed in Tables 5 and 6. Reflections were collected with a Nonius KappaCCD diffractometer using Mo-K_α graphite-monochromated radiation (λ = 0.71073 Å). The structures were solved by direct methods and were refined against |*F*| with the Nonius OpenMoleN package.[35] Hydrogen atoms were introduced as fixed contributors. Flack's *x* parameter for **9a** was determined to be *x* = 0.36(2). CCDC-220450 to -220458 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information: One- and two-dimensional (^{1}H-^{1}H COSY, ROESY and ^{1}H-^{13}C HETCORR) NMR spectra for compound **7b**

Reaction of $[In(NEt_2)_3]_2$ with $N(CH_2CH_2NSiMe_3H)_3$: Synthesis and Characterization of New Azaindatranes and Azaindocane

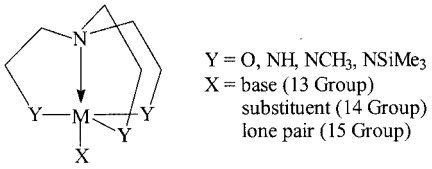
Pavel L. Shutov,[a] Sergey S. Karlov,*[b] Klaus Harms,[a] Andrei V. Churakov,[c] Jörg Lorberth,[a] and Galina S. Zaitseva[b]

Keywords: N ligands / Indium / Tripodal ligands / Amides

$[In(NEt_2)_3]_2$ and $N(CH_2CH_2NSiMe_3H)_3$ react to yield monomeric azaindatrane **1**, $N(CH_2CH_2NSiMe_3)_3In$, which is unstable without additional donor (e.g. pyridine), turning into dimeric azaindatrane **2**, $[N(CH_2CH_2NSiMe_3)_2(CH_2CH_2NH)In]_2$. An intermediate product of this transformation is oligomeric azaindocane **3**, $[N(CH_2CH_2NSiMe_3)_2In(CH_2CH_2NSiMe_3)]_3$. The composition and structures of new compounds have been established by ^1H and ^{13}C NMR spectroscopy. The crystal structures of **1**·Py, *trans*-**2**, and **3** have been determined by X-ray diffraction studies.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The chemistry of indium amido compounds continues to be of interest due to their importance in preparing nitride ceramic materials and semiconductors.[1−3] During our studies of groups 13−15 metallatranes (**A**, Scheme 1, Y = O) and azametallatranes (**A**, Scheme 1, Y = NR)[4−8] we have reported the synthesis and X-ray investigation of the first azaindatrane − $[N(CH_2CH_2NMe)_3In]_2$.[8] This compound is dimeric both in the solid phase and in solution due to the formation of an $(In-N)_2$ core with a very unusual set of In−N distances.[8]



A

Scheme 1

Monomeric tris-amides of group 13 elements are a promising class of precursors of technologically important group 13 nitride semiconductors.[1−3] Bulky substituents R in the parent tetramine $N[CH_2CH_2NRH]_3$ are expected to stabilize the monomeric structure of azaindatranes. We report here the reactions of $[In(NEt_2)_3]_2$ and $InCl_3$ with $N[CH_2CH_2N(SiMe_3)H]_3$ (Me_3Si-tren) and the lithium salt of Me_3Si-tren $\{N[CH_2CH_2N(SiMe_3)Li]_3\}$, respectively. We aimed to prepare Me_3Si-containing azaindatranes and to estimate the influence of bulky Me_3Si groups on structure and stability of monomeric species.

We therefore synthesized four new indium tris-amides containing $[N(CH_2CH_2NSiMe_3)_3]^{3-}$ or $[N(CH_2CH_2NSiMe_3)_2(CH_2CH_2NH)]^{3-}$ moieties: $N(CH_2CH_2NSiMe_3)_3In$ (**1**), $N(CH_2CH_2NSiMe_3)_3In{\cdot}C_5H_5N$ (**1**·Py), dimeric derivative **2**, and oligomeric compound **3** (Scheme 2). The structures of compounds **1**·Py, *trans*-**2**, and **3** have been confirmed by X-ray diffraction studies.

Results and Discussion

Verkade et al. have carried out syntheses, NMR spectroscopy investigations and X-ray diffraction studies of closely related tris(*N*,*N*′′,*N*′′-trimethylsilyl)azaatranes of boron (**4**), aluminium (**5**), and gallium (**6**) (Scheme 3).[9−11] The reaction of $B(NMe_2)_3$ with Me_3Si-tren afforded **4** in low yield (6%),[9] which was explained by the preferred formation of polymeric products. However, the structure of these polymeric products was not established. Compounds of the type $N(CH_2CH_2NSiMe_3)_3M$ [M = Al (**5**), yield 18%;[9] Ga (**6**), yield 88%[11]] were synthesized also, via transamination of $M(NMe_2)_3$ with Me_3Si-tren. Dimeric aluminium azaatrane **7**, the structure of which is analogous to azaindatrane **2**, was obtained during attempts to grow single crystals of **5** from pentane solution.[10]

Our synthetic results are summarized in Scheme 4. Treatment of $[In(NEt_2)_3]_2$ with Me_3Si-tren in the presence of an

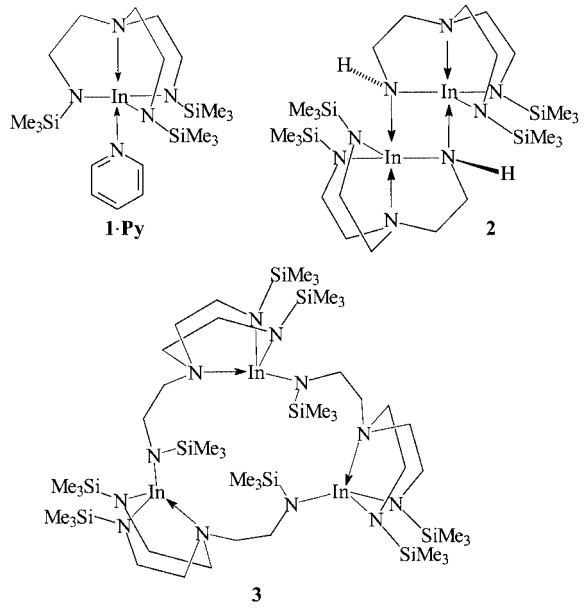
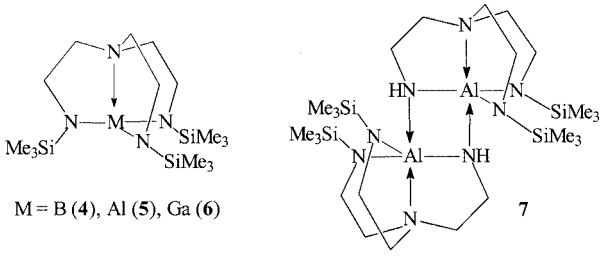
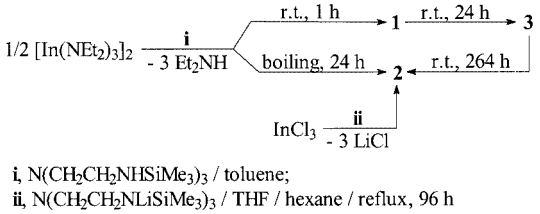


Scheme 2



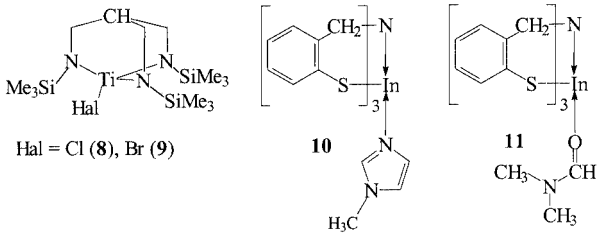
Scheme 3

excess of C_5H_5N led, after standard workup, to **1**·Py in good yield. Notably, carrying-out this reaction without pyridine led to complex **1** (NMR spectroscopic data). Unfortunately, **1** could not be obtained as a pure solid. According to NMR spectroscopic data this compound is an adduct of **1** with one molecule of $HNEt_2$ formed during transamination. However, no additional evidence of this structure was obtained by other methods. Compound **1** is unstable in toluene and in C_6D_6 and turns over 24 h into the oligomeric compound azaindocane **3**, which was obtained after recrystallization from pentane (−30 °C). This transformation might be explained by the lesser steric hindrances in **3** compared with monomeric complex **1**. To the best of our knowledge no similar reactions have been found in "atrane" chemistry.



Scheme 4

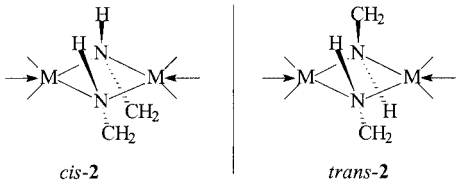
Further standing of solutions of **3** at room temperature afforded dimeric azaindatrane **2**. The conversion (≈ 70%, ^{1}H NMR data) of the oligomeric ocane **3** into the dimer **2** was observed after 11 days. Formally, the bulky Me_3Si group is substituted by hydrogen during this reaction. However, the true nature of this transformation is unclear. An analogous dimerization passing through desilylation processes has been found for $(Me_3Si)_3$-azaalumatrane **6**[10] and related titanium derivatives (compounds **8** and **9**, Scheme 5).[12] A hydrolytic pathway in the first case, and the reaction of titanium complexes with solvent protons (THF), have been proposed as possible explanations for the formation of desilylated dimers. However, all attempts to prepare **7** by controlled hydrolysis of monomeric **6** failed.[10] The authors did not report the formation of any oligomeric products during both dimerization reactions.[10,12]



Scheme 5

Complex **1**·Py also turns into **2** at room temperature (40 days, 100%). However, the formation of **3** was undoubtedly detected by NMR spectroscopy in this reaction. Azaatrane **2** was obtained in moderate yield from the reaction of $[In(NEt_2)_3]_2$ with Me_3Si-tren at 95 °C (24 h) − no traces of **1** and **3** being detected in reaction mixture after heating. Compound **2** was the only product that contains an atrane framework in the reaction between $InCl_3$ and the Li_3-salt of Me_3Si-tren. The lithium salt was prepared in situ by treatment of tetramine (Me_3Si-tren) with three equivalents of *n*BuLi.

Compound **2** has a *trans* structure for the central $(In-NH)_2$ core, as confirmed by X-ray data (vide infra). However, the ^{13}C NMR spectra of all the reaction mixtures that lead to **2** contain signals (trace amounts) that may be assigned to *cis*-**2** (Scheme 6), but the *cis*-isomer was not isolated as a pure solid. Conversely, only the *cis*-isomer of **7** was formed in the dimerization of $N(CH_2CH_2NSiMe_3)_3Al$ (**6**).[10] Analogously, we recently found that only the *cis*-isomer of $[N(CH_2CH_2NMe)_3In]_2$ was formed in the reaction of $[In(NEt_2)_3]_2$ with Me-tren $[N(CH_2CH_2NMeH)_3]$, with no traces of *trans*-isomer.[8]



Scheme 6

Thus, we conclude that the dimeric azaatrane **2** is the most thermodynamically stable product of the transamination reaction of $[In(NEt_2)_3]_2$ with Me_3Si-tren. Donor ligands (e.g. pyridine) partially stabilize the monomeric structure of azaindatrane (compound **1**·Py).

Both ^1H and ^{13}C NMR data agree with the suggested structures for **1**, **1**·Py, **2**, and **3**. In the ^1H NMR spectra of **1** and **1**·Py, signals of methylene protons of the azaindatrane skeleton appear as a set of two pseudo-triplets, forming an AA′MM′ spin system (J = 4.9−5.1 Hz). This pattern is a general feature of the "azaatrane" framework for various azametallatranes.[13] The δ_C signals of the azaatrane skeleton lie within the range typical of those in closely related monomeric derivatives of group 13 elements.[9−11] Thus, **1** and **1**·Py are monomeric in C_6D_6 solution.

In contrast, the ^1H and ^{13}C NMR spectra of **2** and **3** are more complicated. For **2** the data are consistent with a dimer. After purification, **2** was found in solution as one of two geometrical isomers (according to X-ray data − *trans*-**2**) of the In_2N_2 core (Scheme 6). This is documented by two singlets of the Me_3Si groups and twelve partially overlapping multiplets of six CH_2 groups in the ^1H NMR spectrum of **2**. Eight signals of the atrane skeleton carbon atoms appear in the ^{13}C NMR spectrum of **2**. The hydrogen atoms of six methylene groups and methylene carbon atoms as well as each Me_3Si group of one monomeric unit in **3** are also non-equivalent.

Notably, no molecular ions $[M^+]$ or heavy ions that contain at least one In atom were found in mass-spectra (EI, 70 eV) of studied compounds (**1**·Py, **2** and **3**).

Herein we report the crystal structures of azaindatranes **1**·Py and **2** and also of **3** [Figure 1 (one independent molecule), Figure 2 and Figure 3, respectively]. Important bond lengths and angles for **1**−**3** are summarized in Table 1.

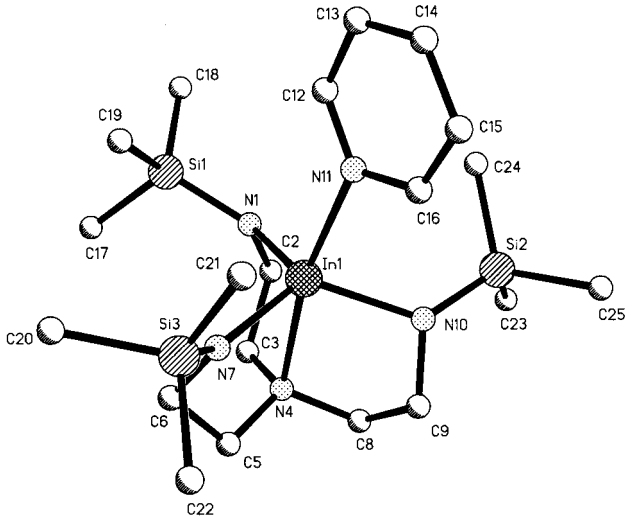

Figure 1. Molecular structure of **1**·Py (one independent molecule); hydrogen atoms omitted for clarity

'The coordination polyhedron of the In atom in complex **1**·Py represents a distorted trigonal bipyramid (TBP) with N(4) (N_{ax}) and N(11) (N^b_{ax}) (Scheme 7) occupying the axial

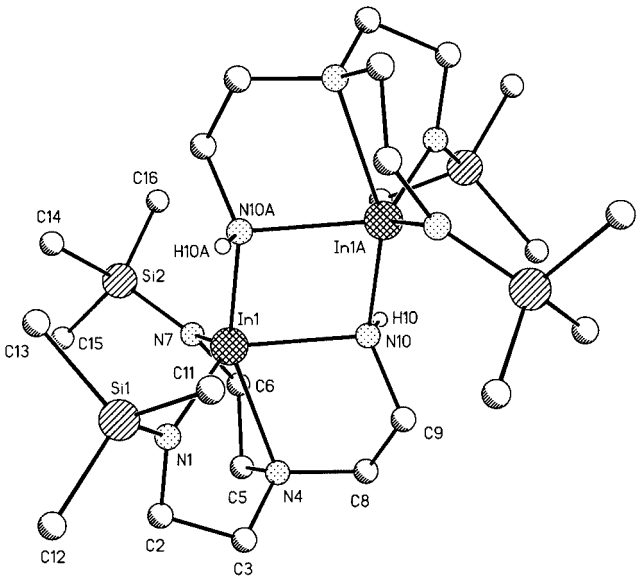

Figure 2. Molecular structure of **2**; hydrogen atoms (except H10 and H10A) omitted for clarity

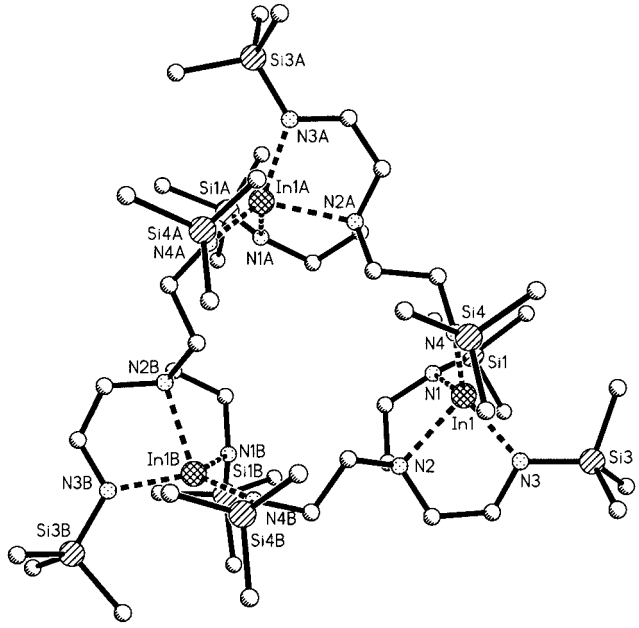

Figure 3. Molecular structure of **3**; hydrogen atoms and solvate cyclohexane molecule omitted for clarity

positions. Three other nitrogen atoms [N(1), N(7), and N(10)] lie in equatorial sites (N_{eq}); $N_{eq}-In-N_{eq}$ angles range between 112.3(1)° and 121.5(1)°, $N_{ax}-In-N_{eq}$ angles range between 78.4(1)° and 80.9(1)°, and $N^b_{ax}-In-N_{eq}$ angles range between 90.8(1)° and 107.3(1)° for **1**·Py. The N(4)−In−N(11) fragment is close to linear for both independent molecules of **1**·Py [169.3(1), 169.2(1)°]. These angles are smaller than those of closely related structures: 179.1(2)° for **10** and 178.4(4)° for **11** (Scheme 5).[14] However, they are greater than those in the dimer $[N(CH_2CH_2NMe)_3In]_2$: 150.3(1)−157.77(9)° for two independent molecules.[8] The latter proves that there is less

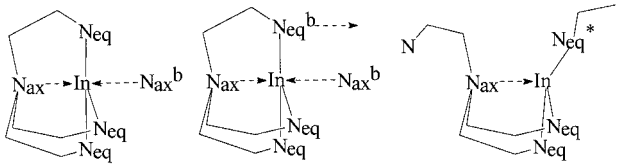
steric hindrance in **1**·Py than in dimeric $[N(CH_2CH_2NMe)_3In]_2$. Analogously to **1**·Py, the coordination environment at the In atom in **2** is formed by three covalently linked nitrogen atoms [N_{eq}: N(1), N(7); N^b_{eq}: N(10)] and two-coordinated nitrogen atoms – N_{ax}: N(4) and N^b_{ax}: N(10A) and may be regarded as TBP, which is more distorted than that in **1**·Py due to the steric influence of second azaatrane framework. For compound **2**, the central $(In-N)_2$ unit is planar, differing from that of closely related $[N(CH_2CH_2NMe)_3In]_2$ and **7** where central arrays form a puckered rectangle.[8,10]



Scheme 7

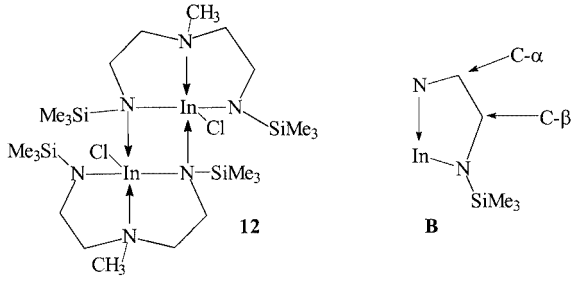
For both **1**·Py and **2**, the indium atoms are displaced by 0.38 Å (**1**·Py, both independent molecules) and 0.44 Å (**2**) from the plane defined by the three equatorial nitrogen atoms toward pyridine ring (**1**·Py) or N(10A) (**2**). These values characterize the extent of TBP distortion (this displacement should be zero in an ideal TBP).

The transannular bond lengths $N_{ax}\rightarrow In$ [2.412(3), 2.398(3) Å for **1**·Py; 2.427(1) for **2**] and $N^b_{ax}\rightarrow In$ [2.340(3), 2.326(3) Å for **1**·Py; 2.206(1) Å for **2**] in both compounds lie within the typical range for similar indium–nitrogen interactions [2.099(2)–2.62 Å]. Interestingly, the considerable contraction of $N^b_{ax}\rightarrow In$ in **2**, compared with that in **1**·Py, does not noticeably influence the $N_{ax}\rightarrow In$ contact. To the best of our knowledge, the structures of only two tris(amido) indium species containing pyridine as additional ligand $[(C_6H_5)_2N]_3In\cdot Py$, $(2,6\text{-}iPr_2C_6H_3NH)_3In\cdot 2Py$] have previously been studied by X-ray diffractometry.[2,3] Notably, $N^b_{ax}\rightarrow In$ (Py→In) in **1**·Py [2.340(3), 2.206(1) Å, two independent molecules] are shorter than those in (2,6-$iPr_2C_6H_3NH)_3In\cdot 2Py$ [2.460(4), 2.421(4) Å] with a pentacoordinate In atom,[3] but similar to that in the complex $[(C_6H_5)_2N]_3In\cdot Py$ [2.264(4) Å] with a tetracoordinate indium atom.[2]

Compound **3** appears to be only the second ''azaindocane'', the first being the structurally characterized dimeric **12** (Scheme 8)[15]. In contrast to the type of In atom coordination environment found in **1**·Py and **2**, the coordination polyhedron of In atoms in trimeric compound **3** represents a strongly distorted trigonal monopyramid. Each indium atom in **3** is displaced by 0.22 Å from the plane defined by the two N_{eq} and one N_{eq}* atoms towards the N_{ax} atom (Scheme 7). The angles formed by the three equatorial nitrogen atoms and indium atom deviate by less than 7° from the ideal value of 120°, and both $N_{ax}-In-N_{eq}$ angles are close to 90°. However, the $N_{ax}-In-N_{eq}$* angle is noticeably greater than 90°. The lower In coordination number in **3** ($CN = 4$) compared with **1**·Py and **2** ($CN = 5$) leads to considerable shortening of $N_{ax}-In$ in **2** [2.294(4) Å] as against those in **1**·Py [2.412(3), 2.427(1) Å] and **2** [2.398(3) Å].

All five-membered rings of the atrane skeleton in **1**·Py and **2** as well as the ocane framework of **3** adopt an ''envelope''-like conformation (Scheme 8, **B**). All carbon atoms in β-positions to the N_{ax} atom in **1**·Py and **2** occupy ''flap'' sites, while C-α atoms form the base of the envelope plane.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 8

This is contrary to conformations of ocane rings in **3** and those previously found for ''usual'' metallatranes (without C-β substituents).[16] However, as observed for azametallatranes, C-β as well as C-α atoms may occupy ''flap'' sites of the ''envelope''.[6,17]

Conclusion

Transamination of $[In(NEt_2)_3]_2$ and $N(CH_2CH_2NSiMe_3H)_3$ affords the monomeric azaindatrane **1**, which is converted into the dimeric azaindatrane **2** via the unexpected azaindocane **3**. The desilylated dimer **2** has also been obtained from the reaction of $InCl_3$ with $N(CH_2CH_2NSiMe_3Li)_3$. The structures of **2** and **3** as well as of the adduct **1**·Py have been confirmed by X-ray diffraction analyses.

Experimental Section

General Remarks: All manipulations were performed under dry, oxygen-free argon using standard Schlenk techniques. Solvents were dried by standard methods and distilled prior to use. $InCl_3$ (Aldrich) was used as supplied. The starting materials Me_3Si-tren[18] and $[In(NEt_2)_3]_2$ [19] were prepared according to the literature. C_6D_6 was obtained from Deutero GmbH and dried with sodium. ^1H and ^{13}C NMR spectra were recorded with Bruker AC200, AC300, AC500 spectrometers at 300 K. ^1H and ^{13}C chemical shifts are reported in ppm relative to Me_4Si as external standard. Elemental analyses were carried out by the Microanalytical Laboratory of the Fachbereich Chemie of the Philipps-University of Marburg (Heraeus Rapid Analyser). Mass spectra (EI-MS) were recorded with a Varian CH-7a device using electron impact ionization at 70 eV; mass spectra (FD-MS) were recorded with a HP-5989B device; all assignments were made with reference to the most abundant isotopes.

Azaindocane 3 (Reaction of $[In(NEt_2)_3]_2$ with Me_3Si-tren): A solution of Me_3Si-tren (0.85 g, 2.35 mmol) in toluene (15 mL) was added at room temperature to a solution of $[In(NEt_2)_3]_2$ (0.78 g, 1.18 mmol) in toluene (10 mL). The NMR spectrum of reaction mixture revealed the presence of **1**[20] after 1 h. The reaction mixture was then stirred for a further 24 h, and all volatiles were subsequently removed under reduced pressure. The resultant solid residue was recrystallized from *n*-pentane (10 mL) to give colorless crystals **3** (yield 0.95 g, 85%). All attempts to obtain an analytically pure sample failed, probably due to the presence of traces of dimeric **2** (analytical data below) as well as variable amounts of solvent, which could not completely be removed. Single crystals of **3** suitable for X-ray analysis were collected by recrystallizaton from cyclohexane.

Data for 1: ^1H NMR (C_6D_6, 300.130 MHz): δ = −0.26 (s, 27 H, $3SiMe_3$), 2.04 (t, $^3J_{H,H}$ = −5 Hz, 6 H, $N(CH_2)_3$], 3.02 (t, $^3J_{H,H}$ = −5 Hz, 6 H, $3SiNCH_2$) ppm. ^{13}C NMR (C_6D_6, 75.47 MHz): δ = −2.21 ($SiCH_3$), 45.61 ($SiNCH_2$), 58.06 [$N(CH_2)_3$] ppm.[21]

Data for 3: ^1H NMR (C_6D_6, 500.130 MHz): δ = −0.19 (s, 27 H, $3SiMe_3$), 0.32, 0.33 (2s, 54 H, $6SiMe_3$), 2.10−2.15 (m, 3 H), 2.30−2.32 (m, 6 H), 2.55−2.61 (m, 3 H), 2.83−2.89 (m, 3 H), 2.91−2.98 (m, 6 H), 3.15−3.17 (m, 3 H), 3.20 (br. s, 6 H), 3.27−3.33 (m, 3 H), 3.42−3.48 (m, 3 H) ($18CH_2$ groups) ppm. ^{13}C NMR (C_6D_6, 50.32 MHz): δ = −1.72 ($SiCH_3$), 1.77 ($SiCH_3$), 3.05 ($SiCH_3$), 40.79, 42.75, 44.82, 54.61, 57.28, 58.20 (CH_2 groups) ppm. EI-MS and FD-MS: [M^+] was not found. $C_{45}H_{117}In_3N_{12}Si_9$ (1423.73): calcd. C 37.96, H 8.28, N 11.81; found C 36.82, H 8.68, N 10.93.

Conversion of 3 into 2: After standing for 11 days at room temperature, a toluene solution of **3** was converted into dimeric **2** (70%), as detected by NMR spectroscopy.

***trans*-*N*,*N*′-Bis(trimethylsilyl)azaindatrane Dimer 2.**[22] **Method A (Reaction of $[In(NEt_2)_3]_2$ with Me_3Si-tren):** A solution of Me_3Si-tren (1.67 g, 4.62 mmol) in toluene (25 mL) at room temperature was added to a solution of $[In(NEt_2)_3]_2$ (1.53 g, 2.31 mmol) in toluene (15 mL). The reaction mixture was then boiled under reflux for 24 h, and then all volatiles were removed under reduced pressure. The so-obtained solid residue was recrystallized from *n*-pentane (10 mL) to give colorless crystals **2** (yield 1.45 g, 66%) after standing at −30 °C.

Method B (Reaction of $InCl_3$ with Li_3-Salt of Me_3Si-tren): A solution of trilithium salt, freshly prepared from Me_3Si-tren (3.8 g, 10.5 mmol) and *n*-butyllithium (1.6 M in *n*-hexane, 19.7 mL, 9.8 mmol), in THF (15 mL) at room temperature, with stirring, was added dropwise to a suspension of $InCl_3$ (2.32 g, 10.5 mmol) in THF (20 mL). The reaction mixture was then boiled under reflux for 96 h, and all volatiles were subsequently removed under reduced pressure. *n*-Pentane (40 mL) was then added to the residue, and insoluble substances were removed by filtration. The solution was then reduced in volume to 10 mL and stored at −30 °C for 3 days to obtain colorless crystals, which were separated by rapid decantation of the cold mother liquor to give **2** (yield 2.41 g, 57%). An analytically pure sample was obtained by recrystallization from pentane. ^1H NMR (C_6D_6, 500.130 MHz): δ = −0.28 (br. s, 36 H, $4SiMe_3$), 1.72−1.98 (m, 4 H), 2.08−2.29 (m, 8 H), 2.49−2.67 (m, 4 H), 2.80−3.11 (m, 8 H) ($12CH_2$ groups) ppm; the NH proton signals could not be located, probably due to overlap with CH_2 multiplets. ^{13}C NMR (C_6D_6, 75.47 MHz): δ = −2.24 ($SiCH_3$), 3.21 ($SiCH_3$), 42.62, 43.31, 43.82, 59.29, 60.55, 60.93 (CH_2 groups) ppm. EI-MS and FD-MS: [M^+] was not found. $C_{24}H_{62}In_2N_8Si_4$ (804.79): calcd. C 35.82, H 7.77, N 13.92; found C 35.05, H 8.04, N 13.09.

Adduct of *N*,*N*′*N*′′-Tris(trimethylsilyl)azaindatrane with Pyridine, 1·Py (Reaction of $[In(NEt_2)_3]_2$ with Me_3Si-tren in the Presence of Pyridine): Pyridine (5 mL) and then a solution of Me_3Si-tren (2.99 g, 8.25 mmol) in toluene (20 mL) were added at room temperature to a solution of $[In(NEt_2)_3]_2$ (2.73 g, 4.12 mmol) in toluene (10 mL). The reaction mixture was then stirred for 12 h, and all volatiles were subsequently removed under reduced pressure. The resultant solid residue was recrystallized from *n*-pentane (10 mL) to give colorless crystals **1**·Py (yield 3.59 g, 79%). Single crystals of **1**·Py suitable for X-ray analysis were collected by recrystallizaton from *n*-pentane (−30 °C, saturated solution). ^1H NMR (C_6D_6,

Conversion of 1·Py into 2: After standing at room temperature for 40 days, a toluene solution of **1**·Py was converted into dimer **2** (100%), as detected by NMR spectroscopy. According to ^1H NMR data the reaction mixture contained **1**·Py, **2**, and **3** (ratio 5:3:2) after 18 days.

X-ray Crystallographic Study: Crystal data, data collection, structure solution and refinement parameters for compounds **1**·Py, **2**, and **3** are presented in Table 2. Experimental intensities were measured with a Stoe IPDS diffractometer using graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å) at 193(2) K. The structures were solved by direct methods[23] and refined by full-matrix least-squares on F^2 [24] with anisotropic thermal parameters for all non-hydrogen atoms. All H atoms were placed in calculated positions and refined using a riding model.

CCDC-224379 (for **1**·Py), -224380 (for **2**), and -224381 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Characterisation of Two Supramolecular Polymers $[CuAg_4(CN)_6(tacn)]_n$ and $[CuAu_2(CN)_4(tacn)]_n$ Containing Metal−Metal Interactions

Wei Han,[a] Long Yi,[a] Zhan-Quan Liu,[a] Wen Gu,[a] Shi-Ping Yan,*[a,b] Peng Cheng,[a] Dai-Zheng Liao,[a] and Zong-Hui Jiang[a]

Keywords: Silver / Gold / Macrocyclic ligands / Metal−metal interactions

Two novel heterobimetallic supramolecular polymers, $[CuAg_4(CN)_6(tacn)]_n$ (**1**) and $[CuAu_2(CN)_4(tacn)]_n$ (**2**) (tacn = 1,4,7-triazacyclononane), have been synthesised from the building block $[Cu(tacn)]^{2+}$, together with $[Ag(CN)_2]^-$ (for **1**) and $[Au(CN)_2]^-$ (for **2**). The large difference in structural type between **1** and **2** is probably due to the fact that the Ag^I centre is three-coordinate and trigonal whereas the Au^I centre is linear. Metal–metal interactions play an important role in the formation of the supramolecular framework of **1** and the novel topology of **2**.

Introduction

The construction of supramolecular arrays by coordination has developed into a central theme of supramolecular chemistry.[1] Many novel supramolecular complexes have been produced with single metal centres linked by bi- or multifunctional ligands.[2] Cyanometalate anions, because of their ability to form strong bonds with transition metal cations, have been extensively used as building blocks in supramolecular coordination polymers.[3] Compared to the higher-coordination counterparts of various transition metals, there has been less investigation of two-coordinate, linear cyanometalate building blocks in the construction of coordination polymers.[3] Therefore, we chose the linear units $[Ag(CN)_2]^-$ and $[Au(CN)_2]^-$ in order to construct multi-dimensional structures and novel topologies. At the same time, investigations into the attractive interactions between closed-shell metal atoms and ions continue to generate much interest.[4] As well as being able to use their cyano groups as bridging ligands, $[Ag(CN)_2]^-$ and $[Au(CN)_2]^-$ can also produce polymeric structures through Ag···Ag and Au···Au interactions. It is now well-established that Ag^I and Au^I complexes aggregate with a metal−metal interaction that is shorter than the sum of their van der Waals radii (3.44 Å for Ag and 3.6 Å for Au).[4,5] Although crystal engineering of supramolecular structures by Ag···Ag and Au···Au interactions is well-documented,[6] most of the reported structures contain only gold or silver without other metals, and there are few reports on heterobimetallic M−Ag or M−Au supramolecular compounds.[7] Leznoff has reported some Cu−Ag and Cu−Au complexes with capping amine ligands,[7] however, to the best of our knowledge, the use of the tacn ligand in a such system has not been reported.

Our interest has focused especially on the field of the d^{10}-d^{10} interactions of Ag^I and Au^I complexes. The energy of these interactions is similar to that of hydrogen bonds,[7] and they have been employed in the construction of multi-dimensional structures and novel topologies. We would therefore like to report the structural properties of two novel supramolecular polymers **1** and **2**, containing the tacn ligand and the linear units $[Ag(CN)_2]^-$ (in **1**) and $[Au(CN)_2]^-$ (in **2**). The differences between the structural properties, novel topologies and metal−metal interactions of both complexes form the subject of this contribution.

Results and Discussion

The coordination environment of **1** is shown in Figure 1; selected bond lengths and angles are listed in Table 1. Each of the $[Cu(tacn)]^{2+}$ cations is connected to two cyano groups; each copper(II) ion is therefore five-coordinate. The copper centre adopts a distorted square-pyramidal coordination, such that one nitrogen atom of the tacn ligand is coordinated apically, and the four equatorial positions are occupied by the two nitrogen atoms of the tacn ligand and the two cyano groups. The apical Cu−N bond length [Cu1−N1 = 2.171(8) Å] is slightly shorter than those of the previously reported distorted copper complexes (apical

Symmetry transformations used to generate equivalent atoms: #1: $-x+3, -y+1, -z+1$; #2: $x, y, -z+1/2$; #3: $x, -y+3/2, -z+1$; #4: $x, y, -z+3/2$.

Cu−N bond length = 2.2−2.7 Å).[8] It should be noted that the coordination numbers of the Ag centres for Ag1 and Ag2 are 3 and 4, respectively.

The X-ray crystal analysis of **1** revealed a one-dimensional structure constructed from necklace-shaped rings. Each ring contains one copper, six silver and seven cyano groups, as shown in Figure 2. These necklaces-shaped rings are linked by shared edges up and down in the [011] direction. To the best of our knowledge, this structure is the first example of a necklace-shaped topology. The 1D structures in **1** are alternately linked via Ag···Ag interactions of 3.2940(13) Å [which is significantly less than the sum of the van der Waals radii of the two Ag(I) centres], and creates a 2D array in the *a* direction. Figure 3 shows the Ag···Ag metallic bonds that exist between the planes of the 2D array. As a result, the silver−silver interactions have increased the dimensionality of **1** from one to two, and can thus be viewed as a tool with which to increase structural dimensionality.[3]

The 2D arrays are connected into a weakly bonded supramolecule through further weak interactions between silver ladders (Figure 4). Within each silver ladder, there are

no significant silver−silver interactions. The sum of the van der Waals radii of the two Ag^I centres is 3.44 Å, and is thus at the upper limit of a distance for a viable aurophilic interaction.[5] The Ag1B···Ag1E distance of 3.486 Å is beyond this threshold, and the Ag1B···Ag2A distance of 3.748 Å is even larger. As shown in Figure 4, the frameworks of AgCN exhibit a hexagon-like supramolecular structure. The siting of copper ions within these hexagons is an example of a rather rare topology.

Complex **2** was obtained by repeating the same procedure as for the preparation of **1**, but by using $[Au(CN)_2]^-$ instead of $[Ag(CN)_2]^-$. The coordination environment of **2** is shown in Figure 5; selected bond lengths and angles are listed in Table 2. Each of the $[Cu(tacn)]^{2+}$ cations is five-coordinate and adopts a distorted square-pyramidal coordination, similar to the Cu^{II} ions of **1**. The apical Cu1−N10 and Cu2−N12 bond lengths are 2.176(13) Å and 2.159(15) Å, respectively.

The packing structure of **2** reveals that there are two kinds of gold chains (see Figure 6), and that the copper ions act as bridges to link these gold chains together to form a 3D polymer. The zigzag chain is formed from gold ions in four kinds of coordination environment, in an **ABCDABCD** pattern. The distances of Au3A···Au4A and Au3A···Au5A are 3.2295(12) and 3.2614(12) Å, respectively; much shorter than the van der Waals separation of Au···Au. Chain b shows two kinds of centrosymmetric trinuclear units and two kinds of free $[Au(CN)_2]^-$ units, which are connected alternately with Au1A···Au2A and Au1A···Au6A interactions of 3.1321(11) and 3.33(8) Å, respectively. The axis of these gold chains is in the *a* direction, and they alternate along the *b* direction. As in **1**, the copper centre is five-

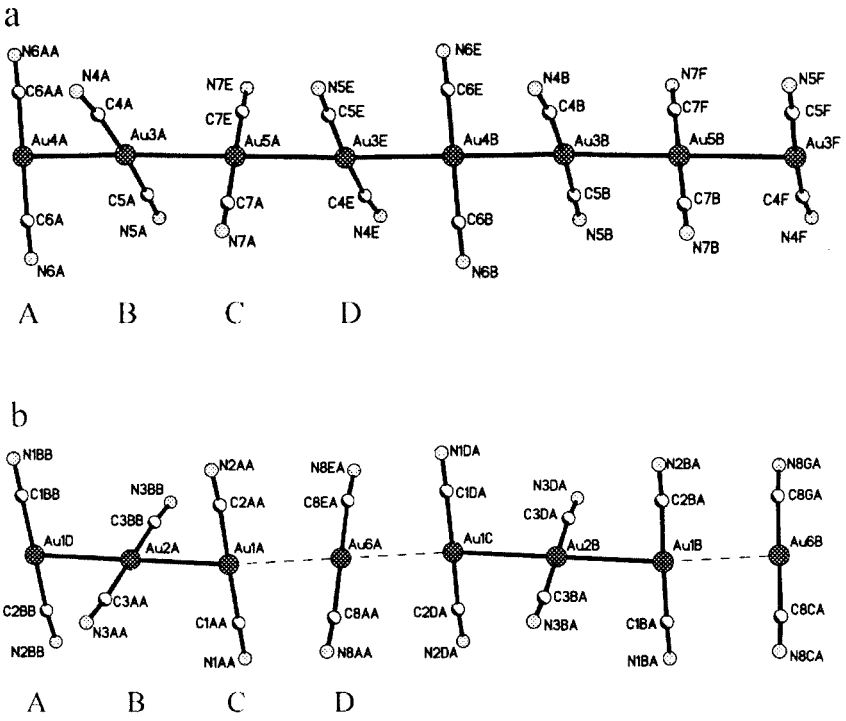

Figure 6. The two kinds of gold chains in complex **2**

coordinate with two sites occupied by nitrogen atoms of the cyano groups; thus the copper atoms function as bridges. In the *bc* plane, the copper ions linking two kinds of chains with single and double bridges form a 3D polymer of **2** (Figure 7). Leznoff has reported some Au−Cu complexes similar to **2**,[7] which also demonstrated the importance of Au···Au interactions in forming coordination polymers.

Complexes **1** and **2** exhibit different structures and topologies, which is probably mainly due to the different coordination numbers of Ag and Au (the Ag^I centre is three coordinate and trigonal, whereas the Au^I centre is linear). In addition, the different metallic radii of Ag and Au have led to the fact that silver−silver interactions have been reported and calculated to be weaker than gold−gold interactions,[3] which may also be the reason for the different structures of **1** and **2**. In the FT-IR spectra (KBr discs), there are three sharp ν_{CN} bands at 2174.4, 2136.2, and 2113.7 cm^{-1} for **1**, and at 2189.9, 2151.9, and 2138.5 cm^{-1} for **2**. The IR band at 2113.7 cm^{-1} is unusually low for an $[Ag(CN)_2]^-$-containing system (free $[Ag(CN)_2]^-$ is at 2139 cm^{-1}); this is somewhat hard to rationalise. It is noticeable that the vibration frequencies of the three bands in **1** are lower than those in **2**, which could be due to the slightly stronger coordination of the cyano group with Au than

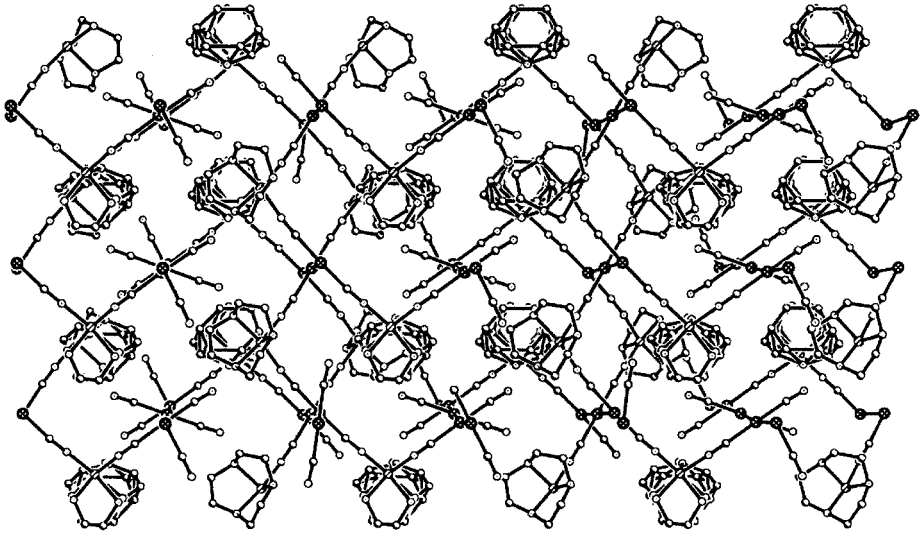

Figure 7. View of the three-dimensional polymeric structure of complex **2** along the *b* axis; hydrogen atoms are omitted for clarity

with Ag. The UV/Vis spectra of both **1** and **2** in DMF solution (concentration 0.10 mol/L) have similar strong absorption bands in the 200−270 nm range; **2** also displays two weak peaks at 279 and 289 nm, which may be assigned to the lower-energy MLCT absorption bands ($^1\Pi_u$-1 and $^3\Pi_u$-1).[9] Although Patterson has reported the UV/Vis spectra of $[Ag(CN)_2]^-$ and $[Au(CN)_2]^-$, we get different results in our work because of the different solvents and the nature of our complexes. In the visible range, the peaks at 566 nm (for **1**) and at 643 nm (for **2**) can be attributed to the *d-d* bands of Cu^{II}.[10]

Experimental Section

Materials and Methods: All of the starting materials were of reagent grade and were used without further purification. The macrocycle ligand tacn was prepared according to the procedures previously described.[11,12] C, H, N elemental analyses were carried out with a Perkin−Elmer analyzer, model 240. Electronic spectra were recorded with a Shimadzu UV-2101PC spectrophotometer in the 200−2000 nm range at room temperature. The FT-IR spectra were recorded with KBr pellets in the range 4000−400 cm^{-1} with a Bio-Rad FTS 135 spectrometer.

Synthesis of $C_{12}H_{15}Ag_4CuN_9$ (1): A solution of $CuCl_2{\cdot}2H_2O$ (0.17 g, 1 mmol) in water (2.5 mL) was slowly added to a solution of tacn (0.13 g, 1 mmol) in methanol (2.5 mL) with stirring. The deep blue solution was stirred for 30 min and then filtered. The above-mentioned deep blue filtrate was introduced to one arm of an H-shaped tube and a solution of $K[Ag(CN)_2]$ (0.20 g, 1 mmol) in water (5 mL) was added to the other arm. After a few weeks, deep blue blocks of complex **1** (0.302 g, 68%, based on Ag salts) were obtained. $C_{12}H_{15}Ag_4CuN_9$: calcd. C 18.55, H 1.79, N 16.48; found C 18.46, H 1.92, N 16.14.

Synthesis of $C_{10}H_{15}Au_2CuN_7$ (2): This was synthesised according to the procedure described above (using similar reaction conditions), but using $K[Au(CN)_2]$ instead of $K[Ag(CN)_2]$, to provide deep blue needles of **2** (0.317 g, 46%, based on gold salts). $C_{10}H_{15}Au_2CuN_7$: calcd. C 17.15, H 2.31, N 14.26; found C 17.37, H 2.17, N 14.19.

X-ray Crystallographic Study: Single crystal X-ray diffraction measurements of the two complexes were carried out with a Bruker Smart 1000 CCD area detector using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Intensity data were measured at 293(2) K by the $\omega/2\theta$ technique. Semi-empirical absorption analysis was performed using the SADABS program. The structures were solved by direct-method successive Fourier difference analysis (SHELXS-97)[13] and refined by the full-matrix least-squares method on F^2 with anisotropic thermal parameters for all non-hydrogen atoms (SHELXS-97).[13] Hydrogen atoms were added theoretically and refined with riding model position parameters and fixed isotropic thermal parameters. The crystallographic data and processing parameters for structural analyses of complexes **1** and **2** are summarised in Table 3.

CCDC-219629 (for **1**) and -219957 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

$[Rh(\eta^5\text{-}C_5H_5)(C_8H_4S_8)]$ and $[M(\eta^5\text{-}C_5Me_5)(C_8H_4S_8)]$ [M = Rh^{III} and Ir^{III}. $C_8H_4S_8^{2-}$ = 2-{(4,5-ethylenedithio)-1,3-dithiole-2-ylidene}-1,3-dithiole-4,5-dithiolate(2–)] were prepared by reactions of $[NMe_4]_2[C_8H_4S_8]$ with $[Rh(\eta^5\text{-}C_5H_5)Cl_2]_2$ or $[M(\eta^5\text{-}C_5Me_5)Cl_2]_2$ (M = Rh and Ir). They exhibit oxidation potentials of between +0.16 and +0.24 V (versus Ag/Ag^+) with oxidation of the dithiolate ligand. The geometries and electronic states of their one-electron-oxidized species $[M(L)(C_8H_4S_8)]^+$ and $[RhX(L)(C_8H_4S_8)]$ (M = Rh and Ir; X = Br and I; L = η^5-C_5H_5 and η^5-C_5Me_5), obtained by reactions of the above complexes with bromine, iodine, or the ferrocenium cation are discussed based on their ESR spectra. The oxidized η^5-C_5Me_5-metal complexes exhibit electrical conductivities of between 10^{-6} and 10^{-4} S cm^{-1}, while some oxidized η^5-C_5H_5-Rh complexes show conductivities of between 10^{-3} and 10^{-2} S cm^{-1} measured for compacted pellets at room temperature. The X-ray crystal structures of the two-electron-oxidized species $[MI(\eta^5\text{-}C_5Me_5)(C_8H_4S_8)](I_3)$ (M = Rh and Ir) were also clarified.

Introduction

Metal complexes with the sulfur-rich dithiolate ligands $C_3S_5^{2-}$ [4,5-disulfanyl-1,3-dithiole-2-thiolate(2−)] and $C_8H_4S_8^{2-}$ [2-{(4,5-ethylenedithio)-1,3-dithiole-2-ylidene}-1,3-dithiole-4,5-dithionate(2−)] have attracted much attention because the oxidized species exhibit unusual electrical and magnetic properties.[1−4] In particular, the oxidized $C_8H_4S_8$-metal complexes often form effective electron-conduction pathways through several sulfur-sulfur non-bonding contacts in the solid state, resulting in the formation of good electrical conductors. Although planar metal complexes are generally efficient for molecular packing in the solid state, non-planar $C_8H_4S_8$-metal complexes may also form a unique molecular packing with some sulfur-sulfur non-bonding contacts in the solid state and are expected to exhibit new physical properties.

From this standpoint, oxidized cyclopentadienyl- and pentamethylcyclopentadienyl-metal complexes with sulfur-rich dithiolate ligands as non-planar species are of much interest. In our previous studies we reported the related C_3S_5-Co^{III} [5] and -Rh^{III} complexes[6] and some non-planar cyclopentadienyl-metal complexes with the $C_8H_4S_8$ ligand exhibiting high electrical conductivities.[7−9]

This paper reports the preparation and properties of $[Rh(\eta^5\text{-}C_5H_5)(C_8H_4S_8)]$ and $[M(\eta^5\text{-}C_5Me_5)(C_8H_4S_8)]$ (M = Rh and Ir) and their oxidation. Furthermore, the geometries and electronic states of their one-electron-oxidized species $[M(L)(C_8H_4S_8)]^+$ and $[RhX(L)(C_8H_4S_8)]$ (M = Rh and Ir; X = Br and I; L = η^5-C_5H_5 and η^5-C_5Me_5), obtained by reaction of the above complexes with bromine, iodine, or the ferrocenium cation, are discussed based on their ESR spectra. The electrical conductivities of the one-electron- and further electron-oxidized species obtained, together with X-ray crystal structures of $[MI(\eta^5\text{-}C_5Me_5)(C_8H_4S_8)](I_3)$ [M = Rh^{III} and Ir^{III}], are also described.

Results and Discussion

Electrochemical Properties of $[Rh(\eta^5\text{-}C_5H_5)(C_8H_4S_8)]$ (1), $[Rh(\eta^5\text{-}C_5Me_5)(C_8H_4S_8)]$ (2) and $[Ir(\eta^5\text{-}C_5Me_5)(C_8H_4S_8)]$ (3)

Figure 1 shows the cyclic voltammogram of complex **2** measured in dichloromethane. The coupled oxidation/reduction peak potentials at +0.15/+0.05 V and at +0.55/+0.45 V (versus Ag/Ag^+) are ascribed to the almost reversible processes of the $[Rh(\eta^5\text{-}C_5Me_5)(C_8H_4S_8)]$/$[Rh(\eta^5\text{-}C_5Me_5)(C_8H_4S_8)]^+$ and $[Rh(\eta^5\text{-}C_5Me_5)(C_8H_4S_8)]^+$/$[Rh(\eta^5\text{-}C_5Me_5)(C_8H_4S_8)]^{2+}$ species, respectively. These oxidation peak potentials are lower than those (+0.55 and +0.66 V) of the corresponding complex $[Rh(\eta^5\text{-}C_5Me_5)(C_3S_5)]$,[6] since many $C_8H_4S_8$-metal complexes exhibit

[a] Department of Applied Chemistry and Frontier Research Center, Graduate School of Engineering, Osaka University

E-mail: matsu@ch.wani.osaka-u.ac.jp

somewhat lower oxidation potentials than the corresponding C_3S_5-metal complexes.[4,7−11] The oxidation occurs essentially on the sulfur-rich dithiolate ligand, as observed for other metal complexes with $C_8H_4S_8^{2-}$ [4,7−9] or $C_6S_8R_2^{2-}$ (R = long alkyl chains) dithiolate ligands.[12]

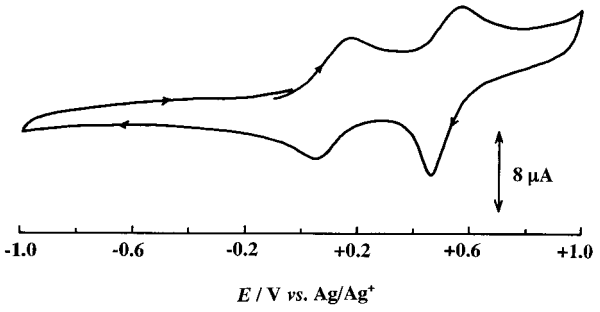

Figure 1. Cyclic voltammogram of complex **2** (1.0×10^{-3} mol·dm^{-3}) in dichloromethane; supporting electrolyte, 0.1 mol·dm^{-3} [N*n*Bu$_4$][ClO$_4$]; sweep rate 500 mV s^{-1}

Complex **1** exhibits somewhat higher oxidation potentials (+0.20 and +0.71 V versus Ag/Ag$^+$) than those of **2**. This finding is ascribed to the more electron-releasing property of the η^5-C_5Me_5 group, as observed for other η^5-C_5H_5- and η^5-C_5Me_5-metal complexes with the $C_8H_4S_8$ ligand [M = Co^{III},[7] Ti^{IV} and Zr^{IV} [8,9]].

The oxidation potentials (+0.44 and +0.65 V versus Ag/Ag$^+$) of the η^5-C_5Me_5-Ir^{III} complex **3** are somewhat higher than those of the corresponding η^5-C_5Me_5-Rh^{III} complex **2**, as has also been observed for the related C_3S_5-metal complexes: [Rh(η^5-C_5Me_5)(C_3S_5)], +0.45 and 0.73 V;[6] [Ir(η^5-C_5Me_5)(C_3S_5)], +0.54 and +0.78 V (versus Ag/Ag$^+$).[13]

Thus, complexes **1**−**3** can be oxidized by bromine, iodine and the ferrocenium ion.

Oxidation of Complexes 1−3

The electronic absorption spectra of complex **2** in dichloromethane in the presence of varying amounts of iodine as an oxidizing agent are shown in Figure 2. Addition of excess amounts of the oxidant gives the final spectrum of the two-electron-oxidized species [RhI(η^5-C_5Me_5)($C_8H_4S_8$)]$^+$, as described below. The band at 700 nm due to the intramolecular charge transfer (CT) transition from the η^5-C_5Me_5 group to the Rh^{III} ion/$C_8H_4S_8$ ligand moiety[7] is shifted to the region around 1100 nm. Upon addition of iodine a broad band ascribed to the one-electron-oxidized species appears initially at around 1200 nm and finally the strong band due to the two-electron-oxidized species appears at 1040 nm. Addition of bromine to **2** in dichloromethane also affords similar bands due to the oxidized species. For the oxidation of the Ir^{III} complex **3** similar bands due to the one- and two-electron-oxidized species occur at 1050−1200 nm.

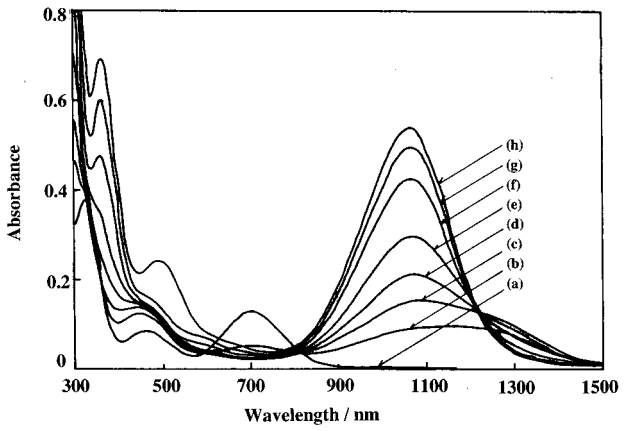

Figure 2. Electronic absorption spectra of complex **2** (2.0×10^{-5} mol·dm^{-3}) in dichloromethane in the presence of iodine; concentration of iodine (mol·dm^{-3}): (a) 0, (b) 0.6×10^{-5}, (c) 1.0×10^{-5}, (d) 1.4×10^{-5}, (e) 2.0×10^{-5}, (f) 3.0×10^{-5}. (g) 4.0×10^{-5}, (h) 2.0×10^{-4}

The reaction of **1** with bromine or iodine gives the one-electron-oxidized species [Rh(η^5-C_5H_5)($C_8H_4S_8$)](Br) (**4**), [Rh(η^5-C_5H_5)($C_8H_4S_8$)](I) (**6**) and [Rh(η^5-C_5H_5)($C_8H_4S_8$)]($I_{4.2}$) (**7**). The oxidized species **7** obtained by the reaction with an excess amount of iodine contains formally the $4.2I^-$ ion, actually made up from approximately equimolar amounts of both the I_3^- and I_5^- ions, as confirmed by the Raman spectrum, which exhibits bands at 114 and 166 cm^{-1} ascribed to the I_3^- and I_5^- ions, respectively.[14,15] Oxidation reactions of **2** with bromine, iodine or [Fe(η^5-C_5H_5)$_2$][PF$_6$] gave the one-electron-oxidized complexes [RhBr(η^5-C_5Me_5)($C_8H_4S_8$)] (**5**), [RhI(η^5-C_5Me_5)($C_8H_4S_8$)] (**9**), [Rh(η^5-C_5Me_5)($C_8H_4S_8$)][PF$_6$] (**13**), and the two-electron-oxidized species [RhI(η^5-C_5Me_5)($C_8H_4S_8$)](I_3) (**10**). Similarly, complex **3** was oxidized to afford the one-electron-oxidized species [IrBr(η^5-C_5Me_5)($C_8H_4S_8$)] (**6**), [IrI(η^5-C_5Me_5)($C_8H_4S_8$)] (**11**), [Ir(η^5-C_5Me_5)($C_8H_4S_8$)][PF$_6$] (**14**), and the two-electron-oxidized complex [IrI(η^5-C_5Me_5)($C_8H_4S_8$)](I_3) (**12**). The presence of M−X bonds (M = Rh and Ir; X = Br and I) in the oxidized complexes **5**, **6**, **9** and **11** was confirmed by the ESR spectra, as described below.

ESR Spectra of the Oxidized Species

Figure 3 shows the ESR spectra of the one-electron-oxidized species [RhBr(η^5-C_5Me_5)($C_8H_4S_8$)] (**5**) and [Rh(η^5-C_5Me_5)($C_8H_4S_8$)][PF$_6$] (**13**) dissolved in dichloromethane at room temperature. Complex **13** shows an intense, sharp isotropic signal at g = 2.009 (peak-to-peak line width, 0.51 mT). This is ascribed to the radical species of the oxidized $C_8H_4S_8$ ligand moiety, as observed for other oxidized $C_8H_4S_8$-metal [Co^{III},[7] Ti^{IV},[8] Pt^{II},[10] V^{IV} and Mo^{IV},[11] and Au^{III} [16]] complexes with a dithiolate ligand-centered oxidation. The one-electron-oxidized Ir^{III} analog **14** also exhibits a sharp ESR signal at g = 2.009 (peak-to-peak line width, 0.49 mT). Both these complexes in the solid state have shown a somewhat broad isotropic signal at g = 2.008 (peak-to-peak line width, 6.0−7.0 mT).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

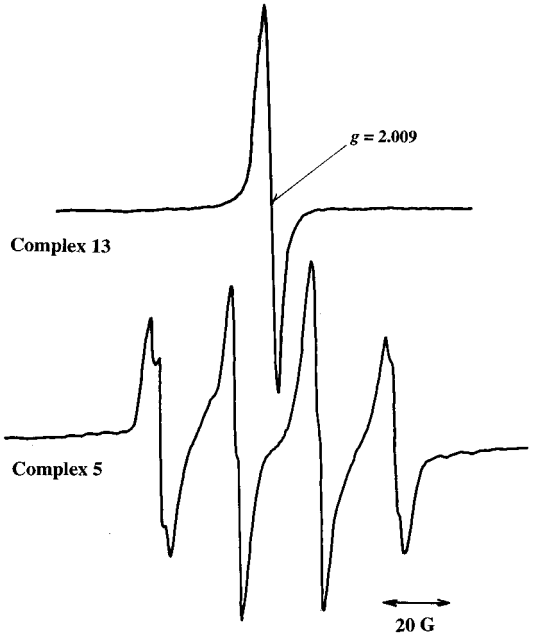

Figure 3. ESR spectra of one-electron-oxidized complexes **5** and **13** in dichloromethane at room temperature

Complex **5** shows an isotropic signal at $g = 2.007$ which consists of a doublet (^{103}Rh, $I = 1/2$) of quadruplets [^{79}Br (50.54%) and ^{81}Br (49.46%), $I = 3/2$]; the ^{103}Rh and $^{79/81}$Br hyperfine couplings are 0.27×10^{-3} and 2.1×10^{-3} cm^{-1}, respectively. This confirms the Rh−Br bond for the oxidized species in solution. These small hyperfine coupling values indicate much lower spin-densities on the metal and bromine atoms, which is very similar to the cases of [RhBr(η^5-C_5Me_5)(C_3S_5)][6] and [CoBr(η^5-C_5Me_5)(C_3S_5)].[5] For the present complex, a one-electron oxidation also occurs at the $C_8H_4S_8$ ligand moiety, as confirmed by the Mulliken spin densities calculated for [RhBr(η^5-C_5Me_5)(C_3S_5)][6] and [CoBr(η^5-C_5Me_5)(C_3S_5)].[5] The ^{103}Rh and $^{79/81}$Br hyperfine couplings for the present complex are appreciably smaller than those (0.47×10^{-3} and 3.0×10^{-3} cm^{-1}, respectively) of [RhBr(η^5-C_5Me_5)(C_3S_5)],[6] suggesting the delocalization of more spin density onto the $C_8H_4S_8$ ligand.

Figure 4 shows the ESR spectra of a dichloromethane solution of [Rh(η^5-C_5Me_5)($C_8H_4S_8$)] in the presence of varying amounts of iodine. [RhI(η^5-C_5Me_5)($C_8H_4S_8$)] is formed in solution (Figure 4a), as indicated by an isotropic signal coupled with the ^{127}I ($I = 5/2$) nucleus [hyperfine coupling, 3.3×10^{-3} cm^{-1}]. The spectrum of isolated [RhI(η^5-C_5Me_5)($C_8H_4S_8$)] (**9**) is the same as that shown in Figure 4a. Upon further addition of iodine to the solution (Figure 4b and 4c) the intensity of the signal is weakened, since the amount of the diamagnetic two-electron-oxidized species is increased. In the presence of an excess amount of iodine (Figure 4d), the signal essentially disappears, with the presence of a very small amount of the one-electron-oxidized species [Rh(η^5-C_5Me_5)($C_8H_4S_8$)]$^+$. The two-electron-oxidized species [RhI(η^5-C_5Me_5)($C_8H_4S_8$)](I_3) (**10**) was obtained by the reaction of **2** with excess amounts of iodine and its crystal structure determined, as discussed below.

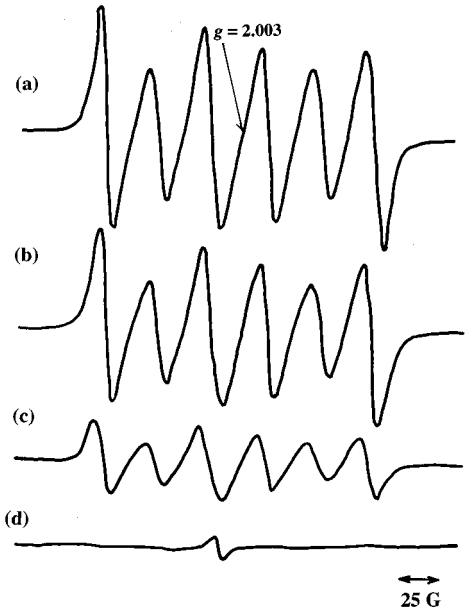

Figure 4. ESR spectra of complex **2** (5.0×10^{-4} mol·dm^{-3}) in dichloromethane in the presence of varying amounts of iodine; concentration of iodine (mol·dm^{-3}): (a) 2.5×10^{-4}, (b) 3.5×10^{-4}, (c) 5.0×10^{-4}, (d) 2.0×10^{-4}

Oxidation of the Ir^{III} analog **3** by the reaction with bromine or iodine yielded both [IrX(η^5-C_5Me_5)($C_8H_4S_8$)] (X = Br and I) and [Ir(η^5-C_5Me_5)($C_8H_4S_8$)]$^+$ as one-electron-oxidized species. Figure 5 shows the ESR spectra of the one-electron-oxidized complex [IrI(η^5-C_5Me_5)($C_8H_4S_8$)] (**11**) dissolved in dichloromethane and in the solid state. The spectrum in solution consists of a sharp signal of [Ir(η^5-C_5Me_5)($C_8H_4S_8$)]$^+$ and a sextet for [IrI(η^5-C_5Me_5)($C_8H_4S_8$)] due to coupling with the ^{127}I nucleus, indicating that the complex consists of both the oxidized species. The solid-state spectrum also shows signals due to both species.

Oxidation of [Rh(η^5-C_5H_5)($C_8H_4S_8$)] (**1**) with bromine or iodine affords essentially the oxidized species without Rh−Br and Rh−I bonds. The ESR spectra of these oxidized species **4**, **6** and **7** show a sharp isotropic signal at $g = 2.006-2.008$. They are one-electron-oxidized species with a $C_8H_4S_8$ ligand-centered oxidation.

X-ray Crystal Structures of [RhI(η^5-C_5Me_5)($C_8H_4S_8$)](I_3) (**10**) and [IrI(η^5-C_5Me_5)($C_8H_4S_8$)](I_3) (**12**)

The crystal structure of **10** consists of three independent molecules which have very similar geometries. This also occurs for **12**. The molecular structure of one of the three cation moieties of **10** is shown in Figure 6, together with the atom-labeling scheme. Selected bond lengths and angles relevant to the $C_8H_4S_8$-Rh moieties of **10**, as well as those of **12**, are listed in Table 1. The Rh(1) atom is bonded to one η^5-C_5Me_5 subunit with Rh−C distances of 2.180−2.218 Å [Rh(2)−C: 2.157−2.201; Rh(3)−C:

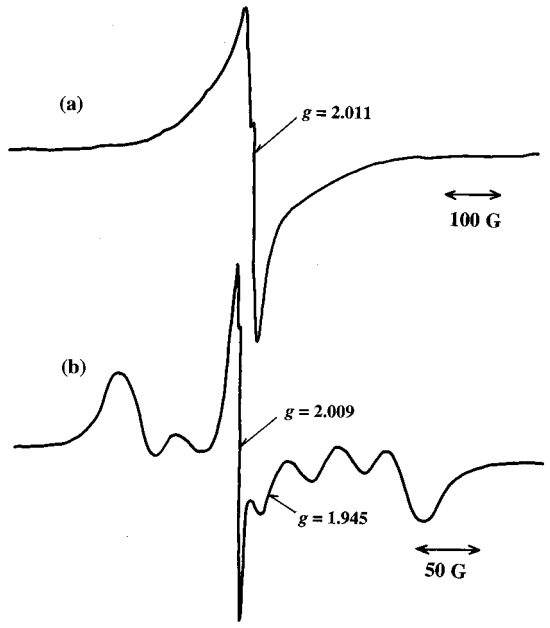

Figure 5. ESR spectra of complex **11** in the solid state (a) and in dichloromethane (b)

2.153−2.204 Å] and to the bidentate chelating dithiolate ligand with Rh(1)−S(1) and −S(8) bonds of 2.326(1) and 2.346(2) Å, respectively, [Rh(2)−S(9) and −S(16): 2.355(2) and 2.308(2) Å; Rh(3)−S(17) and −S(24): 2.328(2) and 2.300(2) Å], which, together with the Rh−I bond, give a formally hexacoordinate geometry. This is close to the geometry of [CoBr(η^5-C_5Me_5)(C_3S_5)].[5] The Rh−S distances are similar to those of related η^5-C_5Me_5-Rh^{III} dithiolate complexes, such as [Rh(η^5-C_5Me_5)(C_3S_5)]$_2$ (2.3571, 2.3774 Å),[6] [Rh(η^5-C_5Me_5){$S_2C_2(CN)_2$}] (2.345, 2.346 Å)[17] and [Rh(η^5-C_5Me_5){$S_2C_2(CN)_2$}]$_2$ (2.350, 2.351 A).[18] The Rh−I distances [2.6854(7), 2.6932(7), 2.7001(5) Å] are also close to that [2.709(1) Å] of [RhI(COEt)(PPh_3){$S_2C_2(CN)_2$}].[19] For the coordinating $C_8H_4S_8$ ligand, the dihedral angle between the Rh(1)−S(1)−S(8) plane and the S(1)−C(1)−C(8)−S(8) plane is 5.72°, and the $C_8H_4S_8$ moiety is almost planar (±0.07 Å). This is also the case for the Rh(2) and Rh(3) moieties. These findings are similar to those of other oxidized $C_8H_4S_8$-metal complexes with a $C_8H_4S_8$ ligand-centered oxidation — [Pt(bpy)($C_8H_4S_8$)][BF_4] (bpy = 2,2′-bipyridine)[20] and [Au(ppy)($C_8H_4S_8$)]$_2$[PF_6] [ppy^- = *C*-deprotonated-2-phenylpyridine(−)][21] — but are in great contrast to the characteristic folding of the TiS_2C_2 plane along the S(1)−S(8) axis, by 35.9°, observed for [Ti(η^5-C_5Me_5)$_2$($C_8H_4S_8$)].[8] The Ir−I, Ir−S and Ir−C bond lengths of **12** are also very close to those of the corresponding Rh−I, Rh−S and Rh−C bonds of **10**.

The crystal structure of **10** is illustrated in Figure 7. Between the three non-equivalent [RhI(η^5-C_5Me_5)($C_8H_4S_8$)]$^+$ cation moieties there are many S−S non-bonding contacts (< 3.7 Å; 3.518−3.662 Å) (19 S···S contacts in a unit cell), together with many other S···I contacts (< 4.0 Å;

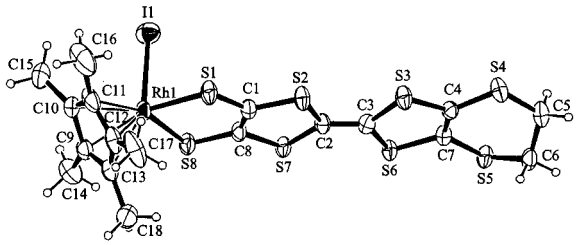

Figure 6. Molecular geometry of one of the cation moieties of complex **10** together with the atom-labeling scheme

Table 1. Relevant bond lengths (Å) and angles (°) for complexes **10** and **12**

	10 (M = Rh)	**12** (M = Ir)

3.648−3.989 Å) (27 S···I contacts in a unit cell) between the $C_8H_4S_8$ moieties and the I_3^- ions, which results in the formation of a two-dimensional molecular array along the *a* and *b* axes. These molecular arrays are separated by both the η^5-C_5Me_5 moieties and the I_3^- ions along the *c* axis. Complex **12** has essentially the same crystal structure as that of **10**.
