
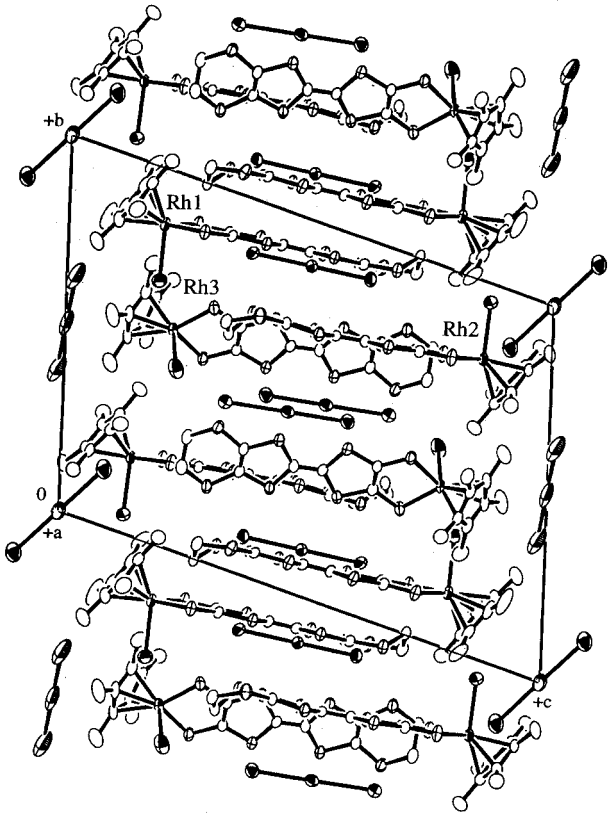

Figure 7. Packing diagram of complex **10**

Electrical Conductivities of the Oxidized Complexes

The electrical conductivities of the oxidized complexes measured for compacted pellets at room temperature are listed in Table 2.

Table 2. Electrical conductivities (σ) of the oxidized complexes[a]

Complex[a]	σ_{RT} (S cm^{-1})
[Rh(η^5-C_5H_5)($C_8H_4S_8$)](Br) (**4**)	6.5×10^{-3}
[Rh(η^5-C_5H_5)($C_8H_4S_8$)](I) (**7**)	2.5×10^{-2}
[Rh(η^5-C_5H_5)($C_8H_4S_8$)]($I_{4.2}$) (**8**)	7.6×10^{-5}
[RhBr(η^5-C_5Me_5)($C_8H_4S_8$)] (**5**)	6.1×10^{-6}
[RhI(η^5-C_5Me_5)($C_8H_4S_8$)] (**9**)	2.0×10^{-4}
[RhI(η^5-C_5Me_5)($C_8H_4S_8$)](I_3) (**10**)	1.2×10^{-5}
[RhI(η^5-C_5Me_5)($C_8H_4S_8$)][PF_6] (**13**)	2.4×10^{-6}
[IrBr(η^5-C_5Me_5)($C_8H_4S_8$)] (**6**)	3.0×10^{-6}
[IrI(η^5-C_5Me_5)($C_8H_4S_8$)] (**11**)	1.1×10^{-6}
[IrI(η^5-C_5Me_5)($C_8H_4S_8$)](I_3) (**12**)	5.0×10^{-6}
[IrI(η^5-C_5Me_5)($C_8H_4S_8$)][PF_6] (**14**)	$< 10^{-7}$

[a] Measured for compacted pellets at room temperature.

The conductivities of the one-electron-oxidized η^5-C_5Me_5-Rh^{III} and -Ir^{III} complexes are very low. This seems essentially to come from an inadequate molecular packing in the solid state, which results in ineffective S−S nonbonding interactions between the oxidized $C_8H_4S_8$ ligand moieties. On the other hand, the one-electron-oxidized η^5-C_5H_5-Rh^{III} species **4** and **7** exhibit considerably higher electrical conductivities. These species without Rh−X (X = Br and I) bonds seem to have a more effective molecular packing through S···S interactions. These packing modes may be similar to those of the [Co(η^5-C_5H_5)($C_8H_4S_8$)]$^+$ species, which also exhibits high electrical conductivity.[7] The present study also shows the effectiveness of the $C_8H_4S_8$ ligand for the construction of an electron conduction pathway even for non-planar metal complexes.

Experimental Section

Materials: [Rh(η^5-C_5H_5)Cl_2]$_2$,[22] [Rh(η^5-C_5Me_5)Cl_2]$_2$ [22,23] and $C_8H_4S_8(CH_2CH_2CN)_2$,[10,24,25] as a pro-ligand for the $C_8H_4S_8^{2-}$ dithiolate ligand, as well as [Fe(η^5-C_5Me_5)$_2$][PF_6],[26] were prepared according to the literature procedures.

Preparation of [Rh(η^5-C_5H_5)($C_8H_4S_8$)] (1), [Rh(η^5-C_5Me_5)($C_8H_4S_8$)] (2) and [Ir(η^5-C_5Me_5)($C_8H_4S_8$)] (3): All the following reactions were performed under an argon atmosphere. A methanol (0.48 mL) solution of NMe_4OH (120 mg, 1.3 mmol) was added with vigorous stirring to a tetrahydrofuran (50 mL) solution of $C_8H_4S_8(CH_2CH_2CN)_2$ (190 mg, 0.42 mmol) and the mixture was stirred for 15 min. The resulting red brown [NMe_4]$_2$[$C_8H_4S_8$] was filtered, and dissolved in ethanol (50 mL). A dichloromethane (20 mL) solution of [Rh(η^5-C_5H_5)Cl_2]$_2$ (100 mg, 0.21 mmol) was then added with stirring, and the mixture was stirred for 5 min at room temperature. The resulting black **1** was collected by filtration, washed with ethanol and hexane, and dried in vacuo (200 mg, 89%). $C_{13}H_9RhS_8$ (524.65): calcd. C 29.76, H 1.73; found C 29.60, H 1.89. ^{1}H NMR ([D_6]DMSO): δ = 3.41 (s, 5 H, CH_2), 5.97 (s, 5 H, C_5H_5) ppm.

Similarly, violet **2** was prepared by the reaction of an ethanol solution of [NMe_4]$_2$[$C_8H_4S_8$] with a dichloromethane solution of [Rh(η^5-C_5Me_5)Cl_2]$_2$ (94% yield). $C_{18}H_{19}RhS_8$ (594.79): calcd. C 36.34, H 3.51; found C 36.35, H, 3.22. ^{1}H NMR (CD_2Cl_2): δ = 2.01 (s, 15 H, C_5Me_5), 3.27 (s, 4 H, CH_2) ppm.

Complex **3** was also prepared by the reaction of [NMe_4]$_2$[$C_8H_4S_8$] with [Ir(η^5-C_5Me_5)Cl_2]$_2$ as a violet solid by the same procedure as described for **2** (94%). $C_{18}H_{19}IrS_8$ (684.10): calcd. C 31.60, H 2.80; found C 31.68, H 3.06. ^{1}H NMR (CD_2Cl_2): δ = 2.10 (s, 15 H, C_5Me_5), 3.28 (s, 4 H, CH_2) ppm.

Preparation of [Rh(η^5-C_5H_5)($C_8H_4S_8$)](Br) (4), [RhBr(η^5-C_5Me_5)($C_8H_4S_8$)] (5) and [IrBr(η^5-C_5Me_5)($C_8H_4S_8$)] (6): A dichloromethane (1.0 mL) solution of bromine [2.6 mm^3 (d = 3.1 g cm^{-3}), 0.050 mmol] was added with stirring to a dichloromethane (500 mL) solution of **1** (53 mg, 0.10 mmol), and the mixture was stirred for 15 h. The obtained black **4** was collected by filtration, washed with dichloromethane and hexane, and dried in vacuo (18 mg, 30%). $C_{13}H_9BrRhS_8$ (604.56): calcd. C 25.83, H 1.50; found C 25.26, H 1.76.

Similarly, the reaction of **2** (0.10 mmol) with bromine (0.05 mmol) in dichloromethane (100 mL) afforded black **5** (80%).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$C_{18}H_{19}BrRhS_8$ (674.69): calcd. C 32.04, H 2.84; found C 32.17, H 2.92. The presence of the Rh−Br bond in **5** was confirmed by ESR spectroscopy, as described above.

Complex **6** was also obtained by the reaction of **3** with bromine in dichloromethane as a black solid according to the procedure described for **4** (81%). $C_{18}H_{19}BrIrS_8$ (764.00): calcd. C 28.30, H 2.51; found C 27.71, H 2.70. The presence of the Ir−Br bond of **6** was confirmed by ESR spectroscopy, as described above.

Preparation of [Rh(η⁵-C_5H_5)($C_8H_4S_8$)](I) (7) and [Rh(η⁵-C_5H_5)($C_8H_4S_8$)]($I_{4.2}$) (8): A dichloromethane (10 mL) solution of iodine (6.3 mg, 0.025 mmol) was added with stirring to a dichloromethane (500 mL) solution of **1** (53 mg, 0.10 mmol) and the solution was stirred for 15 h. The obtained black **7** was collected by filtration, washed with dichloromethane and hexane, and dried in vacuo (12 mg, 19%). $C_{13}H_9IRhS_8$ (651.55): calcd. C 23.96, H 1.39; found C 24.28, H 1.50.

Similarly, black **8** was obtained from the reaction of **1** with 10 molar equivalents of iodine in dichloromethane (57%). $C_{13}H_9I_{4.2}RhS_8$ (1331.98): calcd. C 14.76, H 0.86; found C 14.56, H 0.96. The Raman spectrum of **8** showed that it contains both the I_3^- and I_5^- ions [114 cm^{-1} $\nu(I_3^-)$, 166 cm^{-1} $\nu(I_5^-)$].[14,15]

Preparation of [RhI(η⁵-C_5Me_5)($C_8H_4S_8$)] (9), [RhI(η⁵-C_5Me_5)($C_8H_4S_8$)](I_3) (10), [IrI(η⁵-C_5Me_5)($C_8H_4S_8$)] (11) and [IrI(η⁵-C_5Me_5)($C_8H_4S_8$)](I_3) (12): A dichloromethane (100 mL) solution of **2** (60 mg, 0.10 mmol) was added with stirring to a dichloromethane (10 mL) solution of iodine (13 mg, 0.050 mmol) and the solution was stirred for 5 min. The volume of the solution was reduced to 50 mL under reduced pressure and hexane was added to the solution (500 mL) to afford black **9**. This was collected by filtration, washed with hexane, and dried in vacuo (60 mg, 83%). $C_{18}H_{19}IRhS_8$ (787.01): calcd. C 29.96, H 2.65; found C 29.19, H 2.66. The presence of the Rh−I bond of **9** was confirmed by ESR spectroscopy, as described below.

In a similar procedure, a dichloromethane (200 mL) solution of **2** (120 mg, 0.20 mmol) was added to a dichloromethane (40 mL) solution of iodine (100 mg, 0.40 mmol) to afford black **10** (170 mg, 77%). $C_{18}H_{19}I_4RhS_8$ (1363.67): calcd. C 19.61, H 1.74; found C 19.88, H 1.68. The presence of the I_3^- ion was confirmed by the Raman spectrum [112 cm^{-1} $\nu(I_3^-)$]. Black plates of **10** suitable for X-ray crystallography were obtained by recrystallization from a dichloromethane (20 mL) solution of **2** (0.020 mmol) and iodine (0.030 mmol) upon addition of hexane (40 mL).

Complexes **11** and **12** were also obtained by reaction of **3** with iodine according to the procedures described for **9** and **10**, respectively, as black solids (65 and 70%, respectively). For **11**. $C_{18}H_{19}IIrS_8$ (811.00): calcd. C 26.30, H 2.51; found C 26.29, H, 2.51. For **12**. $C_{18}H_{19}I_4IrS_8$ (1191.70): calcd. C 18.14, H 1.61; found C 18.18, H 1.79. The Raman spectrum of **12** showed the presence of both the I_3^- and I_5^- ions [109 and 166 cm^{-1}, respectively]. Black plates of **12** suitable for X-ray crystallography were obtained by recrystallization from a dichloromethane (30 mL) solution of **12** (0.010 mmol) upon further addition of hexane (60 mL).

Preparation of [Rh(η⁵-C_5Me_5)($C_8H_4S_8$)][PF_6] (13) and [Ir(η⁵-C_5Me_5)($C_8H_4S_8$)][PF_6] (14): A dichloromethane (100 mL) solution of [Fe(η⁵-C_5H_5)$_2$][PF_6] (33 mg, 0.10 mmol) was added with stirring to a dichloromethane (100 mL) solution of **2** (60 mg, 0.10 mmol). The volume of the solution was reduced to 50 mL under reduced pressure and then hexane (500 mL) was added, to yield black **13**. This was collected by filtration, washed with hexane, and dried in vacuo (60 mg, 81%). $C_{18}H_{19}F_6PRhS_8$ (739.75): calcd. C 29.23, H 2.59; found C 30.23, H 2.70.

By a similar procedure, a dichloromethane (200 mL) solution of **3** (68 mg, 0.10 mmol) was added to a dichloromethane (100 mL) solution of [Fe(η⁵-C_5H_5)$_2$][PF_6] (33 mg, 0.10 mmol) to give black **14** (69 mg, 83%). $C_{18}H_{19}F_6IrPS_8$ (829.06): calcd. C 26.08, H 2.33; found C 26.78, H 2.55.

Physical Measurements: IR, electronic absorption, ESR[27] and powder reflectance spectra[12] were recorded as described previously. ^1H NMR spectra were also measured as reported previously.[28] Raman spectra were measured using a Nippon-bunko NR-1800 laser-Raman spectrophotometer at the Graduate School of Science, Osaka University. Cyclic voltammograms of the complexes in dichloromethane were measured using [NBu_4][ClO_4] as an electrolyte.[29] The electrical resistivities of the oxidized complexes were measured at room temperature for compacted pellets by the conventional two-probe method.[29]

Crystal-Structure Determinations of [RhI(η⁵-C_5Me_5)($C_8H_4S_8$)](I_3) (10) and [IrI(η⁵-C_5Me_5)($C_8H_4S_8$)](I_3) (12): Diffraction data were collected up to $2\theta = 60.0°$ for **10** and 55.0° for **12** on a Rigaku RAXIS-RAPID imaging plate diffractometer equipped with a Rigaku low-temperature device (liquid nitrogen as the coolant) and graphite-monochromated Mo-K_α ($\lambda = 0.71069$ Å) radiation at the Graduate School of Engineering, Osaka University. Indexing was performed for reflections obtained from three oscillations exposed for 200 s. The final values of the cell parameters were obtained from least-squares refinement of the positions of 32780 observed reflections for **10** and of 39553 reflections for **12**. Equivalent reflections were merged by use of the PROCESS-AUTO program package. For **10**, 25640 reflections were unique ($R_{int} = 0.047$) from 50511, and for **12** 19335 reflections were unique ($R_{int} = 0.047$) from 37695. The data were corrected for absorption using the program ABSCOR[30] (transmission factors: 0.475−0.900 for **10** and 0.322−0.634 for **12**) and for Lorentz and polarization effects. Crystallographic data are summarized in Table 3.

Table 3. Crystallographic data for [IrI(η⁵-C_5Me_5)($C_8H_4S_8$)](I_3) (**10**) and [RhI(η⁵-C_5Me_5)($C_8H_4S_8$)](I_3) (**12**)

The structure was solved by the Patterson method (PATTY),[31] expanded using Fourier techniques (DIRDIF94)[32] and refined on F^2 by the full-matrix least-squares method (SHELXL-97).[33] All the non-hydrogen atoms were refined anisotropically. The positions of all hydrogen atoms were calculated geometrically and refined with isotropic thermal parameters riding on those of the parent atoms. Atomic scattering factors were taken from the usual sources.[34] Figure 1 and 2 were drawn with ORTEP II.[35]
CCDC-219811 (for **10**) and -219812 (for **12**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.au.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to Professor S. Suzuki (Graduate School of Science) for measurement of ESR spectra. This research was supported in part by grants-in-Aid for scientific research (nos. 14044056 and 15550049) from the Ministry of Education, Science, Sports and Culture, Japan, and by a Strategic Research Base Upbringing Special Coordination Fund for Promoting Science and Technology.

Self-Assembly of Novel Silver Polymers Based on Flexible Sulfonate Ligands

Daofeng Sun,[a] Rong Cao,*[a] Wenhua Bi,[a] Xiaoju Li,[a] Yanqin Wang,[a] and Maochun Hong[a]

Keywords: Self-assembly / Silver / Sulfonate / Polymers

Self-assembly reactions of sulfonates with $AgNO_3$ in the presence of secondary N- or P-containing ligands result in the formation of four new silver-sulfonate polymers, $[Ag(PIP)]_n \cdot [Ag(pesp)]_n \cdot 2nH_2O$ (**1**), $[Ag_2(pesp)(dabco)]_n \cdot 5nH_2O$ (**2**), $[\{Ag(pesp)_{1/2}(hmt)_{1/4}\} \cdot 0.5H_2O]_n$ (**3**) and $[Ag(PPh_3)\text{-}(pesp)_{1/2}]_n \cdot n$MeOH (**4**), whose structures change from one-dimensional chains to three-dimensional open frameworks based on the secondary ligands.

Introduction

In the past decades, much attention has been focused on the design and synthesis of metal-organic coordination networks (MOCNs)[1−3] based on coordination bonds and non-covalent interactions (such as hydrogen bonding, π-π−stacking and/or weak interactions between molecules),[4] due to their interesting molecular topologies and crystal-packing motifs, along with potential applications as functional materials.[5] In the construction of MOCNs, the stereo and interactive information stored in the ligand, as well as the coordination geometry of the metal ions, should be taken into account.[6] Previous studies have proved that careful selection of a suitable, polyfunctional, organic ligand containing certain features, such as, flexibility, versatile binding modes, and the ability to undergo hydrogen bonding, is helpful for constructing and tailoring the architectures of MOCNs.[7]

Recently, much effort has been devoted to the investigation of new synthetic strategies for constructing MOCNs possessing special architectures, such as, 1D helical-chain and 3D channel-like structures, with the use of rigid or flexible ligands containing oxygen or hybrid oxygen/nitrogen atoms, namely, multi-carboxylate, 4,4′-bipy or their derivatives.[8−12] Surprisingly, fewer examples containing sulfonate ligands have been reported, probably due to their weak coordination ability compared to N- or O-containing ligands.[13] However, the recent development of supramolecular chemistry has made it possible to rationally design and synthesize MOCNs by using ligands that in the past have been regarded as poorly coordinating anions, such as sulfonate ligands. Almost no systematic study in the field of sulfonate ligands has been reported. Only recently, the diversity of complexes, particularly transition-metal complexes, constructed by sulfonates has attracted much interest, not only because of the value of these compounds as inorganic synthons,[14] but also because of their important role in proteins.[13b] However, most of the studies reported are focused on aromatic sulfonates, for example when $-SO_3$ is directly connected to the aromatic ring,[15,16] and the studies on non-aromatic flexible sulfonates are almost neglected[17] because the coordination ability of the latter is much weaker than that of the former.

We have begun to study the reactions of flexible sulfonate ligands with silver(I) salts[18] by self-assembly with twofold aims: one is to obtain coordination information on such ligands and the other is to construct novel coordination polymers. Our strategy, in order to overcome the weak coordination ability of flexible sulfonate ligands, is to employ additional coordination sites in the ligand other than the $-SO_3$ group. Thus, we selected the dipotassium salt of piperazine-1,4-bis(2-ethanesulfonic acid) (K_2pesp) (see Scheme 1) as assembly ligand in view of the following characteristics: a) it contains a piperazine ring and the additional coordi-

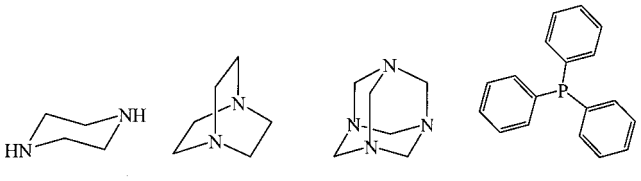
nation from the piperazine nitrogen may be useful for improving the coordination ability; b) it contains the flexible ethyl group that may allow the ligand to adapt to the geometric requirements of the metal ions;[19] c) it can act as a hydrogen-bond acceptor due to the sulfonate oxygen atoms and the nitrogen atoms of the piperazine ring, which may allow the formation of a high-dimensional supramolecular architecture.

A novel, one-dimensional silver polymer containing two different helical chains, $[Ag(PIP)]_n{\cdot}[Ag(pesp)]_n{\cdot}2n$H2O (**1**),[20] was obtained by the self-assembly reaction of the dipotassium salt of piperazine-1,4-bis(2-ethanesulfonic acid) (K_2pesp) with $AgNO_3$, in the presence of piperazine (PIP) in a mixed water/MeOH solution. To extend our work, we carried out systematic studies by introducing other secondary ligands, such as 1,4-diazabicyclo[2.2.2]octane (dabco), hexamethylenetetramine (hmt) and PPh_3, and three other interesting polymers were successfully synthesized. Herein, we describe the details of the preparation and characterization of the four novel silver(I) polymers: $[Ag(PIP)]_n{\cdot}[Ag(pesp)]_n{\cdot}2nH_2O$ (**1**), $[Ag_2(pesp)(dabco)]_n{\cdot}5nH_2O$ (**2**), $[\{Ag(pesp)_{1/2}(hmt)_{1/4}\}{\cdot}0.5H_2O]_n$ (**3**) and $[Ag(PPh_3)(pesp)_{1/2}]_n{\cdot}n$MeOH (**4**), based on mixed sulfonate and N- or P-containing ligands.

Results and Discussions

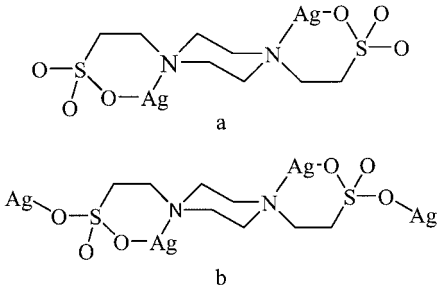
Syntheses

Previous studies have established the role of the secondary ligand in mixed ligand systems, for example, a bridging secondary ligand, such as 4,4′-bipy, generates extended frameworks,[21] whereas a terminal ligand, such as phen, often yields low-dimensional structures.[22] In order to obtain novel structural topologies based on secondary ligands, different N-containing secondary ligands, such as piperazine (PIP), 1,4-diazabicyclo[2.2.2]octane (dabco), hexamethylenetetramine (hmt) (see Scheme 2), were introduced in our study. It was found that increasing the coordination sites of the secondary ligand increased the dimensionality of the complex thus formed. When a terminal PPh_3 ligand was employed as a secondary ligand, complex **4**, which possesses a one-dimensional branch-like chain structure, was successfully isolated. The result is similar to previous observations.[21,22] Unfortunately, the effort to extend the study to diphosphane-bridging ligands, such as dppe [ethylenebis(diphenylphosphane)], failed and only a one-dimensional helical chain constructed by dppe was obtained,[23] indicating that the diphosphane-bridging ligands have higher coordination ability than $pesp^{2-}$.



Scheme 2. The secondary ligands introduced in our work

An interesting reaction was observed during the preparation of complexes **1** and **2**. When the pH value was adjusted to 7 or 8 by $HClO_4$, a previously reported complex, $[Ag_2(\mu_2\text{-}OH_2)(pesp)]_n$, was obtained.[18] This result may arise from partial protonation of piperazine or 1,4-diazabicyclo[2.2.2]octane and then loss of their coordination ability. In complexes **1**−**4**, all the piperazine rings in $pesp^{2-}$, as well as in the PIP ligands, adopt the most stable "chair" configuration (see Scheme 1), as found in other Ag-PIP complexes.[24] The strong peaks at 1250−1150 cm^{-1} in the IR spectra correspond to the sulfonate groups in **1**−**4**.[13c] Complexes **1**−**4** are insoluble in water and other organic solutions such as MeOH, EtOH, and DMF. The coordination modes of $pesp^{2-}$ in **1**−**4** are given in Scheme 3.



Scheme 3. The coordination modes of $pesp^{2-}$ in **2**−**4**

Structural Description

The structure of complex **1** has already been reported[20] and a detailed discussion will not be carried out here.

X-ray diffraction shows that complex **2** has a pseudo-two-dimensional layer structure, made up of a 1D zigzag chain containing a three-coordinate silver center. As shown in Figure 1(a), each silver ion is coordinated to one oxygen atom from the sulfonate group and to two nitrogen atoms from the $pesp^{2-}$ and dabco ligands, in a trigonal geometry. The coordination mode of $pesp^{2-}$ is similar to that seen in **1** as a μ_2-chelating ligand with the oxygen atom of the sulfonate group and the nitrogen atom of the piperazine ring (see a in Scheme 3). The average $Ag{-}N_{pesp}$ distance is 2.283(5) Å, which is shorter than that observed in **1** [2.334(9) Å],[20] presumably due to the coordination influence of the secondary ligand. Thus, each $pesp^{2-}$ ligand chelates two silver ions to form an $[Ag_2pesp]$ unit and such units are linked head-to-tail by dabco [the average $Ag{-}N_{dabco}$ distance is 2.237(6) Å] to form a 1D, infinite, zigzag chain structure (see Figure 1b). Although the coordination mode of $pesp^{2-}$ is the same in complexes **1** and **2**, the structures of the chains are quite different: in **1**, the helical chain is formed only by $pesp^{2-}$ and each $pesp^{2-}$ ligand links two silver ions and vice versa to form the 1D helical chain; whereas in **2**, the 1D polymer is formed by the mixed ligands, $pesp^{2-}$ and dabco, that alternate in the chain. Complex **2** can also be regarded as a variation of complex **1**, in which every second $pesp^{2-}$ ligand is replaced by dabco.

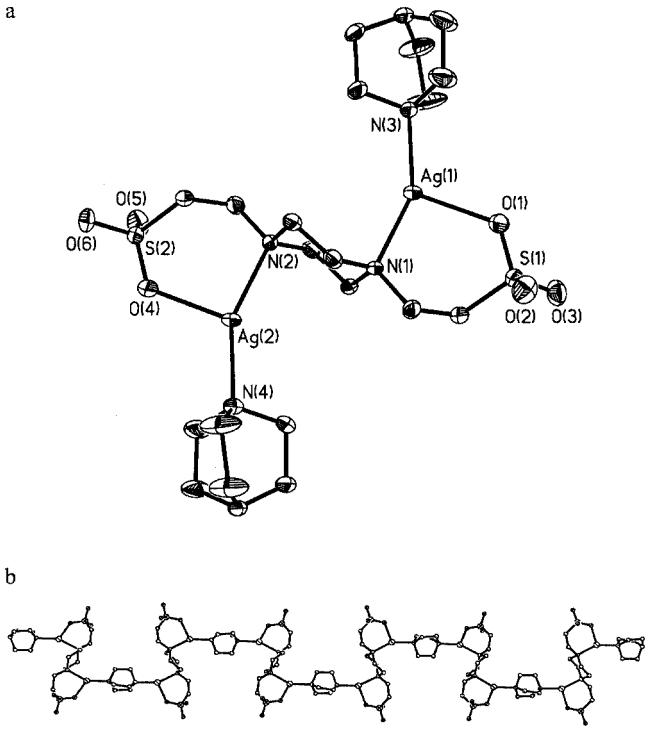

Figure 1. Coordination environment of the silver ion in **2** (a); the 1D chain structure of **2** (b)

There are weak interactions between the chains: the oxygen atom of the sulfonate group is weakly coordinated to the silver ion of the adjacent chain; the Ag−O distance is 2.665 Å (see Figure 2). These weak interactions make the complex a 2D brick-wall-like supramolecular structure [Figure 2 (top)], in which, if considering the weak Ag−O bond, the silver ion is four-coordinate, in a tetrahedral geometry, as in **1**. The free water molecules reside in the grids and form hydrogen bonds with the uncoordinated sulfonate oxygen atoms (O···O distances 2.790−2.987 Å). It should be noted that the 2D brick wall is one of the supramolecular isomers found in the self-assembly of T-shape modules.[25] Meanwhile, a 1D helical chain, $[Ag_2pesp]_n$, is generated by the weak Ag−O bonds [Figure 2 (bottom)]. Thus, the 2D layer can also be viewed as consisting of ladders sharing side pieces, which are formed by $[Ag_2pesp]_n$ helical chains and the rungs by dabco ligands, and **2** can be described as a pseudo-two-dimensional supramolecular architecture formed by weak coordinate bonds.

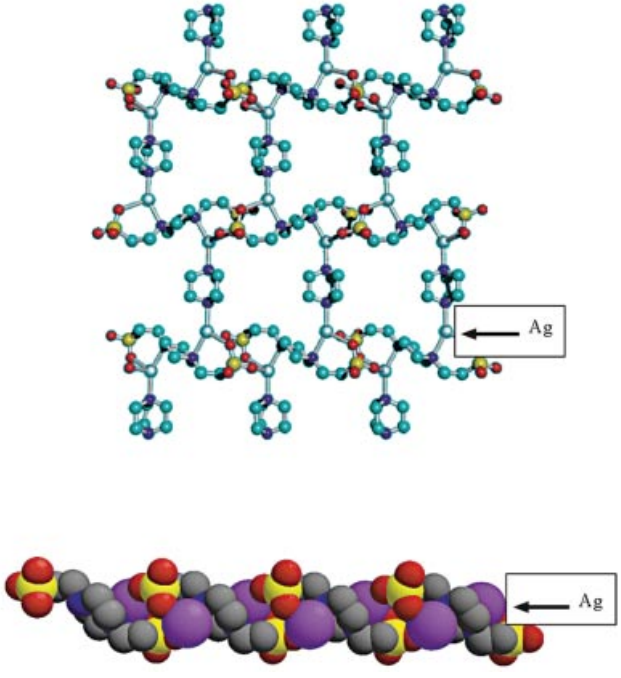

Figure 2. Two-dimensional layer structure (top) and one-dimensional helical chain (bottom) generated by the weak Ag−O bonds in **2**

In contrast with complexes **1** and **2**, X-ray diffraction shows that **3** is a three-dimensional polymer with open-square channels. The central silver ion is coordinated to two oxygen atoms from two different $pesp^{2-}$ ligands and to two nitrogen atoms from hmt and $pesp^{2-}$ in a tetrahedral geometry (see Figure 3); the average Ag−O and Ag−N distances are 2.395(9) and 2.346(7) Å, respectively. The Ag−N distance is longer than that observed in **1** and **2**, probably due to the influence of the secondary ligand. Each $pesp^{2-}$ adopts a chelating-bridging coordination mode to link four silver ions (see b in Scheme 3), which is not observed in **1** and **2**. The hmt ligand acts as a μ_4-bridge, which links four silver ions to four nitrogen atoms, as observed in $[Ag_2(\mu_4\text{-hmt})(SO_4)(H_2O)]\cdot 4H_2O$,[26] to form an $[Ag_4(hmt)]$ tetrahedral core, in which the four silver ions occupy the vertexes and hmt stands at the center (average Ag−Ag distance and Ag−Ag−Ag angle 6.262 Å and 60°, respectively). Each silver ion in the Ag_4 core is chelated by one oxygen of the $-SO_3$ group and the adjacent nitrogen of the piperazine ring of $pesp^{2-}$ (see b in Scheme 3) to form an $[Ag_4(hmt)(pesp)_4]$ unit that may be viewed as the basic building unit of the entire structure. The Ag_4 units are joined together by $pesp^{2-}$ ligands to form a 2D layer structure along the *ab*

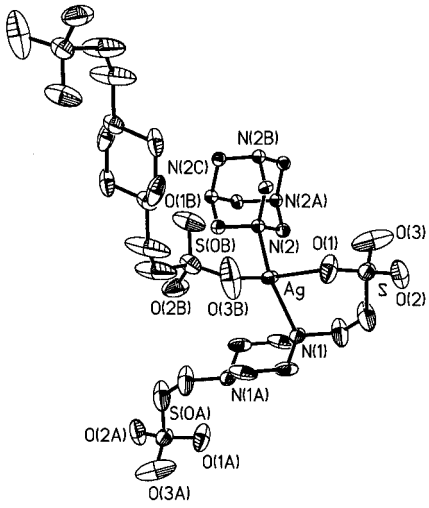

Figure 3. Coordination environment of the silver ion in **3**

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

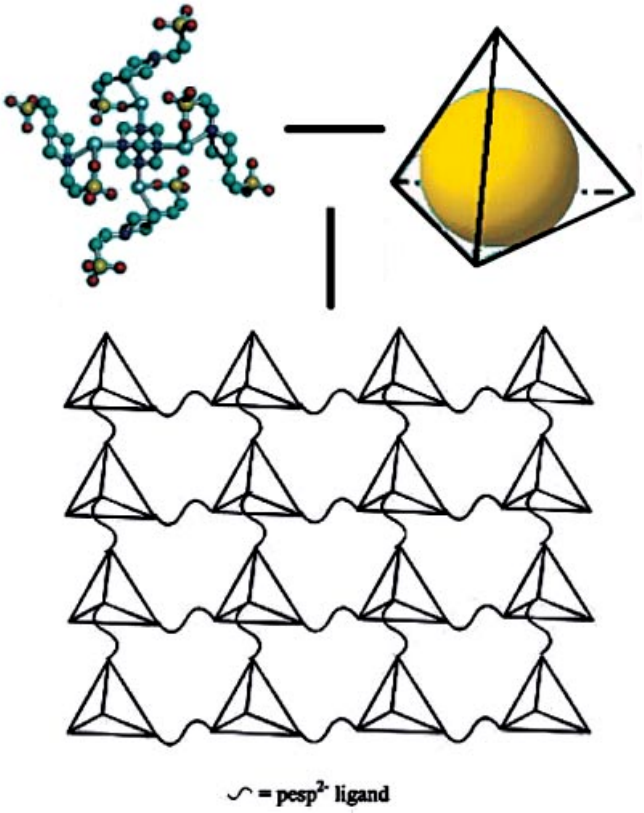

Figure 4. Two-dimensional diagram showing the connections between the Ag_4 cores that form the 2D layer in **3**

plane (see Figure 4). The adjacent layers are further connected by Ag−O bonds, provided by the remaining oxygen atoms of the sulfonate groups, to complete the tetrahedral coordination environments of the AgI ions, thereby generating a 3D open framework with square channels along the *a* axis, in which the free water molecules reside (see Figure 5). Hydrogen-bonding interactions between the uncoordinated sulfonate oxygen atoms and the free water molecules are present; the O···O distance is 2.965 Å.

X-ray diffraction analysis shows that **4** is a one-dimensional branch-like polymer containing a 1D helical backbone made up of an $[Ag_2(pesp)]$ unit and PPh_3 "leaves". As shown in Figure 6, the central silver ion is coordinated to two oxygen atoms and one nitrogen atom from two $pesp^{2-}$ ligands, and the remaining coordination site is occupied by the phosphorous atom of PPh_3 [the Ag−O, Ag−N and Ag−P distances are 2.431(8), 2.317(9) and 2.371(3) Å, respectively], in a tetrahedral geometry. The $pesp^{2-}$ ligand adopts the same coordination mode as in **3** (see b in Scheme 3), linking four silver ions. The dinuclear unit $[Ag_2(pesp)]$, formed by one chelating $pesp^{2-}$ ligand and two silver ions, may be viewed as the basic building block of the whole structure. Each Ag_2 unit is connected to another Ag_2 unit through Ag-O bonding to generate a one-dimensional branch-like chain structure (see Figure 7), in which every silver is coordinated to a PPh_3 "leaf" to prevent the framework from extending to a two- or three-dimensional architecture. It should be noted that the backbone of the polymer possesses a one-dimensional helical chain, namely $[Ag_2(pesp)]_n$, which is similar to that found in **2** except that the Ag-O interactions between the chains in **2** are weak. When considering the weak Ag−O bond in **2**, the coordination environments of the metal ion and $pesp^{2-}$ are the same in **2** and **4**. The solvent molecules are located at the two sides of the chain.

Thermogravimetric Analysis for 3

Thermogravimetric analysis (TGA) for complex **3** shows that there is a weight loss of 2.85 % from 42 °C to 140 °C, which is equivalent to the loss of 0.5 uncoordinated water molecules (calcd. 2.97 %). At temperatures above 150 °C, complex **3** starts to decompose and the decomposition ends above 800 °C. In order to determine whether the backbone can be retained after removal of the guest water molecules,

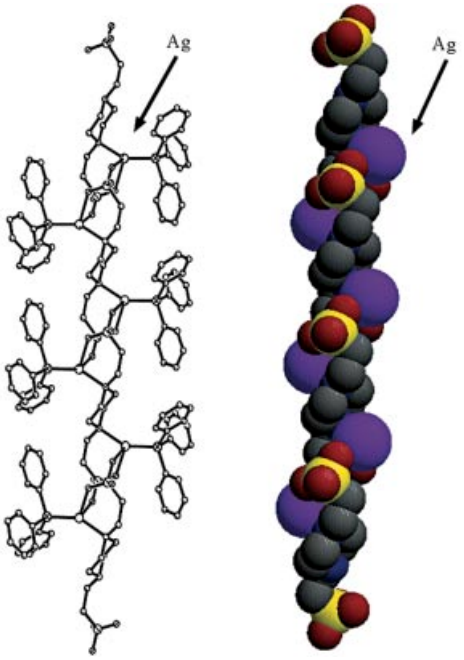

Figure 7. One-dimensional chain structure of **4**

heating-cooling and dehydrate-hydrate experiments were carried out according to the TGA results and monitored by X-ray powder diffraction (XRPD). When **3** was heated to 140 °C, part of the guest water molecules evolved from the sample and the samples were changed into powders; XRPD determination showed that most of the characteristic XRPD peaks had disappeared. After rehydrating the sample for 24 hours, the XRPD pattern showed that hardly any characteristic XRPD peaks were recovered. These results illustrate that the backbone collapses after removal of the water molecules, indicating that complex **3** possesses low thermal stability.

Conclusions

Four novel silver polymers possessing different architectures were synthesized by self-assembly reactions of flexible sulfonate ligands with silver salts, in the presence of secondary ligands, at room temperature, in mixed solvents (H_2O/DMF or H_2O/MeOH). Contrary to our previously reported complex, $[Ag_2(\mu_2\text{-}OH_2)(pesp)]_n$,[18] the flexible ligand $pesp^{2-}$ adopts bent configurations in the four complexes, acting as a μ_2-bridge in **1** and μ_4-bridges in **2**, **3** and **4** through bridging and/or chelating modes. The formation of the four complexes may be controlled by the secondary ligands,[27] and the dimensionality of the complexes increases when increasing the coordination sites of the secondary ligands (see Table 1). Our results indicate that the flexible ligand is more adjustable than the rigid one and can adopt various configurations and coordination modes to meet the different geometric requirements of the metal ions.[19] The architecture of the MOCNs can be tailored by changing the secondary ligands.

Experimental Section

Materials and Analyses: All chemicals were used are as purchased without further purification. IR spectra were recorded on a Magna 750 FT-IR spectrophotometer as KBr pellets. Elementary analyses were carried out in the elementary analysis group of this institute.

Synthesis of $[Ag_2(pesp)(dabco)]n\cdot 5nH_2O$ (2): K_2pesp (0.045 g, 0.125 mmol) and dabco (0.015 g, 0.125 mmol) were dissolved in water (5 mL) and placed on the bottom of a glass tube. A solution of $AgNO_3$ (0.043 g, 0.25 mmol) in MeOH (5 mL) was carefully layered on it through an H_2O/MeOH (5 mL) buffer. The tube was left standing in the dark for about two weeks and colorless prism-like crystals were obtained (0.054 g). Yield 30 %. $C_{14}H_{38}Ag_2N_4O_{11}S_2$ (718.33): calcd. C 23.41, H 5.33, N 7.80; found C 23.25, H 5.25, N 7.85. IR (KBr, cm^{-1}): 3450 (vs), 2966 (m), 2949 (m), 2825 (s), 1655 (m), 1462 (s), 1356 (s), 1315 (s), 1250 (s), 1213 (vs), 1196 (vs), 1167 (vs), 1055 (vs), 1039 (vs), 1009 (s), 781 (m), 652 (s), 586 (vs), 526 (s).

Synthesis of $[\{Ag(pesp)_{1/2}(hmt)_{1/4}\}\cdot 0.5H_2O]_n$ (3): K_2pesp (0.045 g, 0.125 mmol) and hmt (0.035 g, 0.25 mmol) were dissolved in water (5 mL) and placed on the bottom of a glass tube. A solution of $AgNO_3$ (0.043 g, 0.25 mmol) in DMF (5 mL) was carefully layered on it through an H_2O/DMF (5 mL) buffer. The tube was left standing in the dark for about two weeks and colorless, large prism-like crystals were obtained (0.042 g). Yield 55 %. $C_{5.5}H_{12}AgN_2O_{3.5}S$ (302.09): calcd. C 21.87, H 4.00, N 9.27; found C 21.88, H 4.10, N 9.25. IR (KBr, cm^{-1}): 3448 (vs), 2949 (s), 1655 (m), 1462 (m), 1356 (m), 1315 (s), 1248 (s), 1215 (vs), 1200 (vs), 1167 (vs), 1039 (vs), 1007 (vs), 816 (s), 688 (s), 588 (vs).

Synthesis of $[Ag(PPh_3)(pesp)_{1/2}]_n\cdot n$MeOH (4): K_2pesp (0.045 g, 0.125 mmol) was dissolved in a mixed H_2O/MeOH solution (v/v = 1:1; 4 mL) and placed on the bottom of a glass tube. A solution of $AgNO_3$ (0.043 g, 0.25 mmol) and PPh_3 (0.065 g, 0.25 mmol) in a mixed MeOH/EtOH solution (v/v = 1:1; 4 mL) was carefully layered on it through an H_2O/MeOH (5 mL) buffer. The tube was left standing in the dark for about three weeks and colorless well-formed prism-like crystals were obtained (0.055 g). Yield 40 %. $C_{23}H_{27}AgNO_4PS$ (552.37): calcd. C 50.01, H 4.93, N 2.54; found C 50.15, H 4.80, N 2.45. IR (KBr, cm^{-1}): 3450 (s), 3055 (s), 1585 (m), 1479 (s), 1437 (vs), 1398 (vs), 1385 (vs), 1296 (vs), 1095 (s), 1028 (m), 744 (vs), 694 (vs), 515 (vs).

Crystallographic Analyses: The intensity data of **1**−**4** were collected on a SIEMENTS SMART CCD diffractometer with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation at room tem-

Ruthenium(II) Complexes Bearing Carboxylato and 2-Oxocarboxylato Ligands

Rainer Müller,[a] Eike Hübner,[a] and Nicolai Burzlaff*[a]

Keywords: Scorpionate ligands / Ruthenium / Bioinorganic chemistry / Tripodal ligands

The syntheses of ruthenium(II) acetato and benzoato complexes [Ru(bdmpza)(O_2CCH_3)(PPh_3)] (**6**) and [Ru(bdmpza)(O_2CPh)(PPh_3)] (**7**) [bdmpza = bis(3,5-dimethylpyrazol-1-yl)-acetate] are reported. The complexes **6** and **7** are synthesized in high yield from [Ru(bdmpza)Cl(PPh_3)$_2$] (**1**) and thallium acetate (**2**) or thallium benzoate (**3**). In a similar substitution reaction a benzoylformate complex [Ru(bdmpza){$O_2CC(O)Ph$}(PPh_3)] (**8**) is obtained from **1** and thallium benzoylformate (**4**). Reaction of **6** or **7** with benzoylformic acid also yields **8**. In analogous reactions several 2-oxocarboxylato ruthenium(II) complexes [Ru(bdmpza){$O_2CC(O)R$}(PPh_3)] (**9**: R = $CH_2CH_2CO_2H$, **10**: R = Me, **11**: R = Et) can be obtained. The low-spin ruthenium(II) complexes **8** to **11** exhibit a purple or brownish-red colour caused by MLCT transitions and thus a HOMO–LUMO gap which is almost identical to that of high-spin 2-oxoglutarate dependent iron oxygenases. **6** crystallises as a water adduct, **6**·H_2O and **8** forms an acetonitrile adduct **12**. Crystal structures of the water adduct **6**·H_2O and **8** were obtained.

Introduction

In recent years the 2-His-1-carboxylate facial triad, an iron binding motif that is found in the active sites of mononuclear non-heme iron(II) and iron(III) dependent enzymes, has attracted increasing interest.[1] The class of 2-oxoglutarate (α-ketoglutarate) dependent iron(II) enzymes, especially, are representative examples of such enzymes. Two iron binding histidines and one aspartate are conserved throughout many of these enzymes.[2] Several protein structures of 2-oxoglutarate (2-OG) dependent iron(II) enzymes have been solved in the last decade, such as deacetoxycephalosporin C synthase (DAOCS),[3] clavaminic acid synthase (CAS),[4] proline hydroxylase,[5] taurine dioxygenase (TauD) (Figure 1)[6] or anthocyanidin synthase (ANS).[7]

Pseudo-kinetic X-ray diffraction experiments on the related enzyme isopenicillin N synthase (IPNS)[2] showed several changes in the electron density close to the substrate but no changes to the 2-His-1-carboxylate facial triad throughout the catalytic cycle.[8] This fixed geometry of the three iron binding amino acids renders them perfect targets for structural model complexes. Especially bulky hydridotris-(pyrazol-1-yl)borato (Tp) and tris(2-pyridylmethyl)amine (TPA) have been used to mimic the active sites of these enzymes.[9,10] Iron benzoylformate complexes with Tp, TPA or TPA-related ligands have been investigated as structural models for more than ten years.[11,12] Recently, we reported on the bis(3,5-dimethylpyrazol-1-yl)acetato ligand

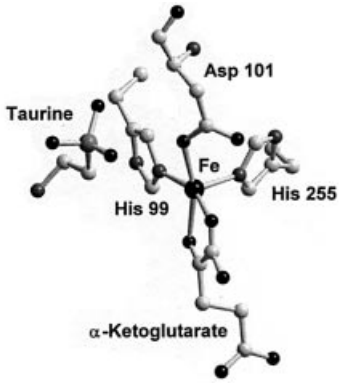

Figure 1. Active site of taurine dioxygenase TauD with 2-oxoglutarate bound to iron(II) and taurine substrate (PDB-Code: 1GY9)[6]

(bdmpza) and its application in ferrous and ferric iron complexes [Fe(bdmpza)$_2$] and [NEt_4][Fe(bdmpza)Cl_3].[13,14] The mono-anionic heteroscorpionate ligand proved, in these cases, to be a promising structural mimic for the facial 2-His-1-carboxylate triad. The O_2 adduct formation and oxygen-activation, key steps in the catalytic pathway of 2-oxoglutarate dependent enzymes, have also been studied upon oxygen-treatment of ruthenium(II) complexes with Tp or trispyridylalkoxymethane ligands.[15] Ruthenium(II) bis(pyrazol-1-yl)acetato complexes such as [Ru(bdmpza)Cl(PPh_3)$_2$] or enantiopure [Ru(bpa^{4cam})Cl(PPh_3)$_2$] and [Ru(bpa^{4menth})-Cl(PPh_3)$_2$] {bpa^{4cam}: bis[4,5,6,7-tetrahydro-7,8,8-trimethyl-(4*S*,7*R*)-methano-N^1,N^1-indazolyl]acetate; bpa^{4menth}: bis[4,5,6,7-tetrahydro-(4*R*)-methyl-(7*R*)-isopropyl-N^1,N^1-indazolyl]-acetate} have recently been described by us.[16,17] We now report on ruthenium(II) bis(3,5-dimethylpyrazol-1-yl)acet-

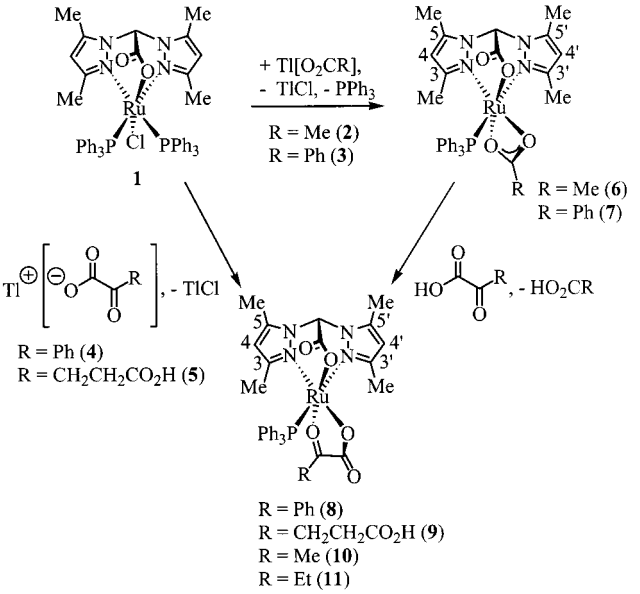
ato complexes bearing carboxylato or 2-oxocarboxylato ligands.

Results and Discussion

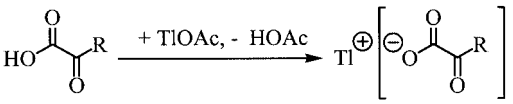
Ferrous iron complexes with N,N,O ligands are often difficult to investigate, due to their paramagnetic high-spin constitution, and they are very sensitive to oxidation and ligand exchange. In contrast, ruthenium(II) complexes are low spin and thus suitable for NMR characterisation and are also easier to handle. In our attempt to find suitable models for the active site of 2-oxoglutarate dependent iron enzymes, we therefore focused on bis(3,5-dimethylpyrazol-1-yl)acetato ruthenium(II) complexes.

The complex [Ru(bdmpza)Cl(PPh_3)$_2$] (**1**) reacts slowly with thallium carboxylates Tl[O_2CR] (**2**: R = Me, **3**: R = Ph) to produce the $\kappa^2O^1,O^{1\prime}$-carboxylato complexes [Ru(bdmpza)(O_2CR)(PPh_3)] **6** and **7** through loss of one PPh_3 and the chloro ligand (Scheme 1).



Scheme 1. Formation of carboxylato and 2-oxocarboxylato ruthenium(II) complexes

The thallium benzoate (**3**) and thallium 2-oxocarboxylates (see below) used in this work are easily available by the reaction of thallium acetate with benzoic acid or 2-oxocarboxylic acids [Equation (1)].



R = Ph (**4**)
R = $CH_2CH_2CO_2H$ (**5**) (1)

These syntheses take advantage of the lower pK_a values of these acids (benzoic acid: 4.22, benzoylformic acid: 1.2, 2-oxoglutaric acid: 2.31/5.14, pyruvic acid: 2.49) compared with acetic acid (4.76).[18] The free acetic acid is distilled off with water as an azeotrope and the thallium carboxylates are obtained in high purity.

Two sets of ^{1}H and ^{13}C signals are detected for the pyrazolyl groups of the bdmpza ligand. Therefore a chiral geometry with a PPh_3 *trans* to one of the pyrazolyl groups has to be assumed for **6** and **7**. A single ^{31}P NMR signal for each of the resulting ruthenium(II) complexes at δ = 62.0 ppm (**6**) and 60.2 ppm (**7**) proves the loss of one PPh_3. For **6** the ^{1}H NMR signal ($CDCl_3$) at δ = 1.00 ppm and the ^{13}C NMR signals (CD_2Cl_2) at δ = 23.6 ppm and 189.0 ppm are assigned to the acetato ligand. The benzoato ligand of **7** shows ^{13}C NMR signals ($CDCl_3$) at 127.1, 127.5, 131.1, 132.1 and 183.8 ppm. The ^{31}P NMR signals as well as the ^{13}C NMR signals correspond well with those of [Ru(Tp)(η^2-O_2CCHPh_2)(PPh_3)] [^{31}P: 63.7 ppm, ^{13}C(CO_2^-): 186.97 ppm].[19]

Admixing three equivalents of water to an NMR sample of **6** in CD_2Cl_2 causes an additional set of signals besides those of **6** which we assign to the formation of an adduct **6**·H_2O. In particular, a slight high-field shift of the acetate ^{13}C NMR signal (CO_2^-: 187.4 ppm) is indicative of this adduct, **6**·H_2O. The shift is in good agreement with the results recently reported by Alper et al. for the formation of [Ru(OAc)$_2$(H_2O)($Ph_2PProMe$)$_2$].[20] An NMR sample of sodium acetate and three equivalents of water in CD_2Cl_2 shows a ^{13}C NMR signal at δ = 181.6 ppm. Therefore, release of acetate and formation of [Ru(bdmpza)(H_2O)$_2$(PPh_3)][O_2CCH_3] can be excluded. After drying the sample in vacuo, only signals of **6** with no water can be detected. This proves that the formation of **6**·H_2O is fully reversible.

An X-ray structure determination of **6** revealed the water adduct of **6**·H_2O, with H_2O coordinated to ruthenium(II) and a monodentate κ*O*-acetato ligand (Figure 2, Table 1).

An intramolecular hydrogen bond between the water molecule and the non-coordinated oxygen atom of the acetate is indicated by the short distance *d*[O(4)···O(5)] = 2.720(6) Å. The presence of water can be explained by the fact that the crystals were grown under humid conditions and is proven by a CHN analysis of the crystals. Thus, $\kappa^2O^1,O^{1\prime}$-carboxylato ligands are hemilabile, chelating ligands. Once water is present, it can readily displace one of the oxygen atoms of the coordinating carboxylate. A very similar hydrogen bond was recently observed in a DAOCS protein structure presenting a DAOCS:Fe^{II}:CO_2:succinate:H_2O complex.[3b] The ring tension of the metalla-tetracycle is probably reduced by this water coordination.

The reaction of [Ru(bdmpza)Cl(PPh_3)$_2$] (**1**) with thallium 2-oxocarboxylates Tl[O_2CC(O)R] (**4**: R = Ph, **5**: R = $CH_2CH_2CO_2H$) produces κ^2O^1,O^2-2-oxocarboxylato complexes (Scheme 1). Single ^{31}P NMR signals at δ = 57.9 ppm (**8**) and 58.2 ppm (**9**) once again prove the loss of one PPh_3 ligand. Traces of a second structural isomer can be observed at δ = 57.1 ppm for **9**. The coordination of the 2-oxocarboxylates is backed by the [M^+] peaks in the FAB-

MS and the ^{13}C NMR signals of the 2-oxo groups (**8**: 202.8 ppm, **9**: 215.5 ppm). Both complexes exhibit one (**8**) and two (**9**) additional CO_2^- signals in the ^{13}C NMR spectra. As to be expected for a chelate binding of the 2-oxocarboxylate, the complexes exhibit a chiral environment and therefore two sets of signals in the ^1H and ^{13}C NMR spectra for the pyrazolyl groups. Due to this chirality in **9**, an ABXY system in the ^1H NMR spectrum can be assigned to CH_2CH_2 of the 2-oxoglutarate. The X-ray structure determination of **8** establishes the chelate binding of the benzoylformate (Figure 3, Table 2).

The most striking feature of this structure is the position of the 2-oxo group *trans* to the carboxylate donor of the bdmpza ligand. This configuration agrees well with the coordination of the 2-oxoglutarate in the active site of 2-oxoglutarate dependent enzymes where the 2-oxo group is found *trans* to the iron binding aspartate (Figure 1).

As shown in Figure 3, the phenyl group of the benzoylformate ligand is almost parallel to one of the phenyl groups of PPh_3. Despite this parallel orientation the torsion

angle O(5)−C(62)−C(63)−C(68) of 20.4° indicates that there is still conjugation to the CO_2^- group via the 2-oxo group. The distances and angles of the [Ru(bdmpza)(PPh_3)] fragments in **6** and **8** agree well with those reported earlier for [Ru(bdmpza)Cl(PPh_3)$_2$] (**1**).[16]

The complexes **8** and **9** can also be obtained in high yield and high purity by reaction of benzoylformic acid and 2-oxoglutaric acid with the acetato complex **6** or the benzoato complex **7**. It is noteworthy, that this exchange of a carboxylato ligand by a 2-oxocarboxylato ligand is similar to the regeneration step of the biocatalytic pathway postulated for the 2-oxoglutarate dependent enzymes. In these enzymes an iron(II) bound succinate is replaced by 2-oxoglutarate to "reload" the active site of the enzyme after the hydroxylation of the substrate.[6]

It is even possible to combine the two synthetic steps: Reaction of the chloro complex **1** with thallium acetate and 2-oxocarboxylic acid affords the 2-oxocarboxylato ruthenium(II) complexes [Ru(bdmpza){$O_2CC(O)R$}(PPh_3)] (**8**: R = Ph, **9**: R = $CH_2CH_2CO_2H$, **10**: R = Me, **11**: R = Et) within 2 h (**8**, **10** and **11**) or 24 h (**9**). The ^{31}P NMR spectra of the complexes **10** and **11** exhibit a single signal

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

each [δ = 58.1 ppm (**10**) and 58.5 ppm (**11**)]. The coordination of the 2-oxocarboxylates follows from the [M^+] peaks in the FAB MS, the ^{13}C NMR signals assigned to the 2-oxo carbonyl groups (**10**: δ = 215.8 ppm, **11**: δ = 217.9 ppm) and additional CO_2^- signals. Again the complexes are chiral and therefore two sets of signals appear in the ^1H and ^{13}CNMR spectra for the pyrazolyl groups. Complex **11** presents an ABX_3 system in the ^1H NMR spectrum that can be assigned to the CH_2CH_3 group. In some of the IR spectra of **8**−**11** two resonances occur around 1660 cm^{-1} which can be assigned to the two $\nu_{asym}(CO_2^-)$ of the bdmpza ligand and the 2-oxocarboxylate. It was not possible to assign unambiguously $\nu_{sym}(CO_2^-)$ of the complexes **6**−**11** to absorptions in the region of 1300 to 1500 cm^{-1}. This is due to the weakness of the signals and several overlapping absorptions of the PPh_3 ligand in that region.

In the case of **8**, **10** and **11** longer reaction times cause the occurrence of additional NMR signal sets, which are probably due to the formation of structural isomers. A mixture of the isomers was isolated for the 2-oxoglutarate complex **9**. We are currently investigating the character of these minor isomers, which most likely exhibit a geometry that involves the 2-oxo group being *trans* to a pyrazolyl group.

The formation of the 2-oxocarboxylato complexes is clearly indicated by a purple (**8**) or brownish-red (**9**−**11**) colour (Figure 4).

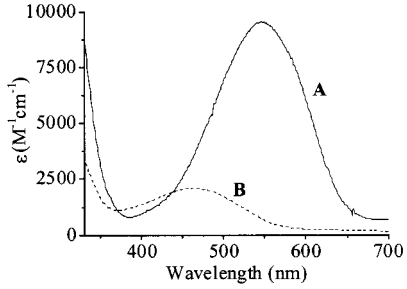

Figure 4. Electronic spectra of (A) [Ru(bdmpza){O_2CC(O)Ph}(PPh_3)] (**8**) (−) and (B) [Ru(bdmpza){O_2CC(O)CH_3}(PPh_3)] (**10**) (--) in CH_2Cl_2. Spectra of **9** and **11** are almost identical to **10**

Also, for the 2-oxoglutarate dependent enzymes, the addition of Fe^{II} and 2-oxoglutarate to the enzymes under anaerobic conditions results in a purple colour with a broad absorption band centred near 530 nm.[10c] The colour has been attributed to charge-transfer transitions from the metal centre to the coordinated 2-oxo group (MLCT absorption).[10c,11d,12c,21] Complexes **8**−**11** exhibit extinction coefficients at 546 nm (**8**) or 463 nm (**9**−**11**), which are almost 20-fold larger than those of the iron(II) models or enzymes {e.g. [Fe^{II}(Tp^{Ph2}){O_2CC(O)Ph}] ε (M^{-1}·cm^{-1}) = 540; [Fe^{II}TauD(2-OG)] ε (M^{-1}·cm^{-1}) = 140}.[10c] To verify this MLCT hypothesis for these ruthenium(II) complexes, extended Hückel[22] and DFT calculations were performed. The calculated HOMO−LUMO energy gaps of the DFT calculations are too small by a factor of about 2.5 compared with the measured, longest $\lambda_{max.}$. This is a well-known behaviour involving the gap between the HOMO−LUMO eigenvalues of DFT calculations, due to theoretical reasons.[23] According to the DFT calculations the band at the longest wavelength should shift to longer wavelengths by about 150 nm when the 2-oxocarboxylato complex **10** (R = Me) is replaced by **8** (R = Ph). Such a shift to longer wavelengths is indeed observed in the UV/Vis spectra, although to a smaller extent (Figure 4). The calculated results could be confirmed by the HOMO−LUMO energy gaps of the Hückel-calculation which also predicts this shift. Contour plots of the HOMO and LUMO for both complexes are shown in Figure 5.

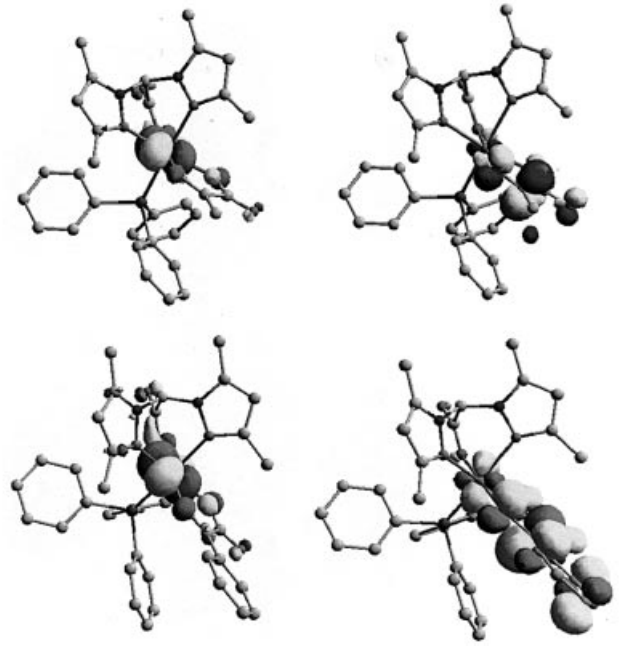

Figure 5. Contour plots of the delocalised HOMO (left) and LUMO (right) (DFT calculation) for **10** (top) and **8** (bottom)

The HOMO is clearly localised at the ruthenium(II) metal centre in **10** as well as in **8**. Two other MOs are only slightly lower in energy in both cases. Contour plots of these three orbitals exhibit geometries that are characteristic for d_{xy}, d_{xz} and d_{yz} orbitals. This is quite reasonable for a $4d^6$ low spin ruthenium(II) complex. Thus, all six d-electrons are available for a HOMO−LUMO transition. As a result of the good orientation of two of the HOMOs towards the LUMO, the HOMO−LUMO orbital overlap in the ruthenium(II) complexes should be better than in the iron complexes or iron enzymes. Moreover, this is true for ruthenium(II) 4d orbitals and not iron(II) 3d orbitals. These findings might explain why the extinction coefficients for the MLCT bands are almost 20-fold larger than those of the iron(II) models or enzymes.

The LUMOs in **8** and **10** are localised at the 2-oxocarboxylato ligands. They are composed of p_z density on the 2-oxo group with some conjugation to the carboxylate p_z. This is in good agreement with the π* LUMO of a coordinated pyruvate which was reported earlier by Solomon.[21] In **8** the LUMO is also delocalised into the aromatic substituent. The missing delocalisation into an aromatic system

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

can explain the hypsochromic shift of the longest wavelength absorption of **10**. The structure of the LUMO is supported by the results of the Hückel calculations, which deliver a nearly identical electron density distribution.

Therefore, the calculations verify the metal-to-ligand charge transfer (MLCT). Although the ruthenium(II) complexes **8** and **10** have a low-spin t_{2g}^6 configuration they exhibit a HOMO−LUMO gap which is almost identical in size to that of the $t_{2g}^4e_g^2$ iron centres of the enzymes.

A solution of the benzoylformate complex **8** in acetonitrile changes its colour from purple to yellow upon heating. This can be explained by the formation of an adduct [Ru(bdmpza){$O_2CC(O)Ph$}($NCCH_3$)(PPh_3)] (**12**) with the solvent acetonitrile. A similar behaviour was reported earlier for 2-oxocarboxylato iron complexes.[11b,12] Besides the colour change the adduct formation is documented by IR and ^1H NMR spectroscopic data as well as an 802 [MH^+] peak in the FAB-MS. Due to the rather labile coordination of CH_3CN in **12** we were unable to obtain a correct CHN elemental analysis and ^{13}C NMR spectroscopic data.

Therefore, the 2-oxocarboxylates as well as the carboxylates are hemilabile ligands and should render the additional coordination of reactive species possible. Although **8** seems to be rather stable under aerobic conditions, a solution of **8** in 1,2-dichloroethane, when exposed to air, decomposed within two weeks to form red crystals of the ruthenium(III) complex [Ru(bdmpza)Cl_2(PPh_3)] (**13**), which we reported recently.[16] Further work will focus on these oxidation reactions.

Experimental Section

General Remarks: All operations were carried out under either nitrogen or argon by using conventional Schlenk techniques. Solvents were distilled from appropriate drying agents and degassed before use. The yields refer to analytically pure compounds and were not optimised. IR: Biorad FTS 60, CaF_2 cuvettes (0.5 mm). ^1H NMR and ^{13}C NMR: Bruker AC 250, Varian Inova-400, δ values relative to TMS. ^{31}P NMR: JEOL GX 400, Bruker DRX 600 Avance, δ values relative to an external standard from Wilmad (H_3PO_4 100%). 2D NMR experiments: Bruker DRX 600 Avance, Varian Inova-400. Mass spectra were recorded on a modified Finnigan MAT 312 using the FAB technique and 3-nitrobenzyl alcohol as matrix. Elemental analyses: Heraeus CHN−O-Rapid. UV/Vis: Hewlett−Packard Diode-Array spectrophotometer 8452A (silica cuvette; d = 1 cm). A modified Siemens P4 diffractometer was used for X-ray structure determination.

Thallium acetate (**2**), benzoic acid, pyruvic acid, 2-oxobutyric acid, benzoylformic acid and 2-oxoglutaric acid were used as purchased. Ruthenium(III) trichloride hydrate was a generous gift of the Degussa AG. The synthesis of [Ru(bdmpza)Cl(PPh_3)$_2$] (**1**) was reported recently.[16]

Method A. General Procedure for the Synthesis of Thallium Carboxylates: Equimolar amounts of thallium acetate (**2**) and the carboxylic acid were dissolved in water. The water/HOAc mixture was removed by azeotropic distillation and the procedure was repeated once. The remaining residue was washed with acetone and re-crystallised from acetone/water to yield thallium carboxylate suitable for further reactions.

Method B. General Procedure for the Synthesis of Carboxylato Ruthenium(II) Complexes: A solution of [Ru(bdmpza)Cl(PPh_3)$_2$] (**1**) and a slight excess of thallium carboxylate in CH_2Cl_2 was stirred at ambient temperature. The mixture was filtered through celite and dried in vacuo. Precipitation from CH_2Cl_2 solution with pentane yielded the carboxylato ruthenium(II) complex.

Method C. General Procedure for the Synthesis of Ruthenium(II) 2-Oxocarboxylato Complexes: A solution of [Ru(bdmpza)Cl(PPh_3)$_2$] (**1**), a slight excess of thallium acetate and an excess of a 2-oxocarboxylic acid were stirred in CH_2Cl_2 at ambient temperature. The mixture was filtered through celite and dried in vacuo. Precipitation from CH_2Cl_2 solution with pentane yielded the 2-oxocarboxylato ruthenium(II) complex.

Tl[O_2CPh] (3): Reaction of thallium acetate (**2**) (2.01 g, 7.63 mmol) and benzoic acid (0.933 g, 7.64 mmol) in water (2 × 100 mL) according to procedure A yielded **3** as a white microcrystalline powder. Yield 1.99 g (80%); m.p. > 300 °C. ^1H NMR (D_2O + 1% v/v [D_6]acetone, 250 MHz): δ = 7.30−7.41 (m, 3 H, *p*-Ph and *m*-Ph), 7.73 (m, 2 H, *o*-Ph) ppm. ^{13}C NMR (D_2O + 1% v/v [D_6]acetone, 62.9 MHz): δ = 129.7, 130.2, 132.7, 137.6 (Ph), 176.8 (CO_2^-) ppm. $C_7H_5O_2Tl$ (325.50): calcd. C 25.83, H 1.55; found C 26.00, H 1.68.

Tl[$O_2CC(O)Ph$] (4): Reaction of thallium acetate (**2**) (2.01 g, 7.63 mmol) and benzoylformic acid (1.22 g, 8.13 mmol) in water (2 × 50 mL) according to procedure A yielded **4** as a white microcrystalline powder. Yield 2.50 g (93%); m.p. 140 °C (dec.). ^1H NMR (D_2O +1% v/v [D_6]acetone, 250 MHz): δ = 7.45 (vt, 2 H, *m*-Ph), 7.61 (t, 1 H, *p*-Ph), 7.81 (d, 2 H, *o*-Ph) ppm. ^{13}C NMR (D_2O +1% v/v [D_6]acetone, 62.9 MHz): δ = 129.5, 130.0, 132.3, 135.5 (Ph), 173.0 (CO_2^-), 197.0 (CO) ppm. $C_8H_5O_3Tl$ (353.51): calcd. C 27.18, H 1.43; found C 27.36, H 1.31.

Tl[$O_2CC(O)CH_2CH_2CO_2H$] (5): Reaction of thallium acetate (**2**) (1.00 g, 3.80 mmol) and 2-oxoglutaric acid (555 mg, 3.80 mmol) in water (50 mL) according to procedure A yielded crude **5** after removing HOAc and H_2O at 55 °C and reduced pressure. Re-crystallisation from H_2O/Acetone yielded white microcrystalline powder. Yield 1.20 g (90%); m.p. 130 °C (dec.). ^1H NMR (D_2O + 1% v/v [D_6]acetone, 250 MHz): δ = 2.49 (t, $^3J_{H,H}$ = 6.6 Hz, 2 H, $CH_2CO_2^-$), 2.85 (t, $^3J_{H,H}$ = 6.6 Hz, 2 H, CH_2CO) ppm. ^{13}C NMR (D_2O + 1% v/v [D_6]acetone, 62.9 MHz): δ = 28.6 (CH_2CO), 34.6 ($CH_2CO_2^-$), 170.3 (CO_2^-), 178.6 (CO_2H) ppm. $C_5H_5O_5Tl$ (349.47): calcd. C 17.18, H 1.44; found C 16.82, H 1.40.

[Ru(bdmpza)(O_2CCH_3)(PPh_3)] (6): Reaction of [Ru(bdmpza)-Cl(PPh_3)$_2$] (**1**) (663 mg, 0.730 mmol) and thallium acetate **2** (235 mg, 0.892 mmol) in CH_2Cl_2 (50 mL) according to method B yielded product **6** as a yellow solid after 60 h. Yield 0.367 g (75%); m.p. 200 °C (dec.). ^1H NMR ($CDCl_3$, 250 MHz): δ = 1.00 (s, 3 H, Ac−CH_3), 1.77 (s, 3 H, C^3−CH_3), 2.41 (s, 3 H, $C^{3'}$−CH_3), 2.44 (s, 3 H, C^5−CH_3), 2.51 (s, 3 H, $C^{5'}$−CH_3), 5.68 (s, 1 H, H_{pz}), 6.11 (s, 1 H, $H_{pz'}$), 6.36 (s, 1 H, CH), 7.15−7.75 (m, 15 H, PPh_3) ppm. ^1H NMR (CD_2Cl_2, 400 MHz): δ = 0.93 (s, 3 H, Ac−CH_3), 1.66 (s, 3 H, C^3−CH_3), 2.31 (s, 3 H, $C^{3'}$−CH_3), 2.35 (s, 3 H, C^5−CH_3), 2.42 (s, 3 H, $C^{5'}$−CH_3), 5.62 (s, 1 H, H_{pz}), 6.06 (s, 1 H, $H_{pz'}$), 6.23 (s, 1 H, CH), 7.05−7.40 (m, 15 H, PPh_3) ppm. ^{13}C NMR ($CDCl_3$, 62.9 MHz): δ = 11.2 (C^5−CH_3), 11.5 ($C^{5'}$−CH_3), 12.5 ($C^{3'}$−CH_3), 14.6 (C^3−CH_3), 23.5 (Ac−CH_3), 68.8 (CH), 108.0 (C^4), 109.2 ($C^{4'}$), 127.8 (d, $^3J_{C,P}$ = 9.1 Hz, *m*-PPh_3), 129.1 (*p*-PPh_3), 134.3 (br., *o*-PPh_3), 140.9 ($C^{5'}$), 142.2 (C^5), 155.0 (C^3), 158.2 ($C^{3'}$), 168.2 (CO_2^-), 188.7 (CO_2^-) ppm. ^{13}C NMR (CD_2Cl_2, 100.5 MHz): δ = 11.2 (C^5−CH_3), 11.5 ($C^{5'}$−CH_3), 12.5 ($C^{3'}$−CH_3), 14.5 (C^3−CH_3), 23.6 (Ac−CH_3), 69.0 (CH), 108.2 (C^4), 109.3 (d, $^4J_{C,P}$ = 2.8 Hz, $C^{4'}$), 128.0 (d, $^3J_{C,P}$ = 9.2 Hz, *m*-PPh_3), 129.4 (*p*-PPh_3), 134.3 (br., *o*-

C 59.99, H 4.78, N 8.75; CHN analysis not obtained due to loss of CH_3CN.

Calculations: DFT-calculations and full geometry optimisations were carried out by using Jaguar 5.0[24] running on Linux-2.4.18−3smp on three Athlon MP 2400+ dual-processor workstations (Beowulf-cluster) parallelised with MPICH 1.2.4. The crystal structure of the ruthenium(II) benzoylformate complex was used as starting geometry. Complete geometry optimisations were carried out on the implemented BP86/LACVP* basis set (using the 6−31G* basis set and Hay−Wadt effective core potentials on Ru). Extended Hückel MO calculations were performed with the program package Hyperchem[25] running on a single Athlon 1.3 GHz workstation with Windows NT 4.0. The HOMO−LUMO gap energies were calculated using standard parameters as given in the program from the optimised structures of the DFT-calculations. Orbital plots were obtained using Maestro 5.1, the graphical interface of Jaguar.[24]

X-ray Structure Determinations: Single crystals of **6** and **8** were mounted with Paratone-N on a glass fibre. A modified Siemens P4-Diffractometer was used for data collection (graphite monochromator, Mo-K_α radiation, λ = 0.71073 Å, scan rate 4−30°min^{-1} in ω). The structures were solved by using direct methods and refined with full-matrix least-squares against F^2 {Siemens SHELX-97}.[26] A weighting scheme was applied in the last steps of the refinement with $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ and $P = [2F_c^2 + \max(F_o^2,0)]/3$. Hydrogen atoms were included in their calculated positions and refined in a riding model.

In the asymmetric unit of **6**·H_2O one molecule of dichloromethane was found and refined. The hydrogen atom of the coordinated water molecule bridging to O(4) of the acetato ligand was found. Restraints had to be applied to refine the water hydrogen atoms. About 100 different crystallisation experiments were necessary to obtain crystals of **8**. Finally a mixture of 1,2-dichloroethane with traces of methanol and H_2O (400:2:1, v/v/v) was successful. Using this mixture ten out of ten crystallisation experiments yielded suitable crystals of **8** for X-ray structure determination. **8** crystallised with one molecule of water and methanol each, and half a molecule of 1,2-dichloroethane. Restraints were used in the refinement of the 1,2-dichloroethane. The water molecule forms hydrogen bonds to the methanol and the 2-oxo O(5) atom of other asymmetric units. There is also a hydrogen bond between the methanol and a bdmpza O(1) atom of another asymmetric unit. All details and parameters

of the measurements are summarised in Table 3. The structure pictures were prepared with the program Diamond 2.1e.[27] CCDC-222723 (for **6**·H_2O) and -222724 (for **8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Generous financial support by the Fonds der Chemischen Industrie (Liebig-Stipendium granted to N. B.) and the European Commission (Copernicus 2 Program, Contract no° ICA2-CT-2000-10002) is gratefully acknowledged. Special thanks to Prof. Dr. H. Fischer for support and discussion. We are indebted to Mr Galetskiy for recording mass spectra, Ms Friemel for 2D NMR experiments and Mr. Haunz for ^{31}P NMR experiments. We acknowledge a generous gift of ruthenium(III) trichloride hydrate by the Degussa AG.

Bis(phosphane oxide) Adducts of $Rh_2(MTPA)_4$ — Kinetics and Chirality Discrimination

Tamás Gáti,[a] András Simon,[a] Gábor Tóth,*[a] Anna Szmigielska,[b] Anna M. Maj,[b] K. Michał Pietrusiewicz,[b,c] Stefan Moeller,[d] Damian Magiera,[d] and Helmut Duddeck*[d]

Dedicated to the memory of Prof. Dr. Dr.h.c.(H) Günther Snatzke (1928−1992)[‡]

Keywords: Rhodium / Phosphane ligands / NMR spectroscopy / Complexation modes / Chiral discrimination

The symmetrical bis(phosphane oxide) **1** and its chiral derivatives **2** and **3** form a variety of adduct species with the dirhodium complex **[Rh–Rh]** which can be identified by low-temperature ^1H and ^{31}P NMR spectroscopy by using varying **[Rh–Rh]**:ligand ratios. The asymmetric bis(phosphane oxide) **3** shows a distinct preference for binding through the Ph_2P=O (P^a) as compared to the *t*Bu(Ph)P=O (P^b) functionality due to the bulky *tert*-butyl group. The chiral bis(phosphane oxides) **2** and **3** form complex mixtures of various adduct species. Nevertheless, it is possible to monitor enantiomeric compositions from various NMR signal duplications at 213 K and even at room temperature or slightly elevated temperatures.

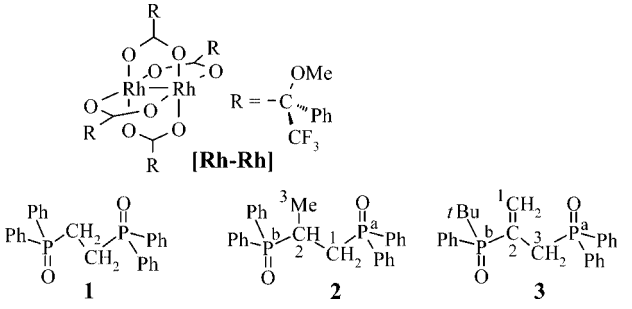
Introduction

Dirhodium complexes as well as their phosphane adducts have been the focus of interest for many years.[1] They were first introduced as homogeneous catalysts in various reactions[2] and have even found medicinal applications.[3] We have shown that the enantiomers of chiral phosphane chalcogenides can easily be discriminated by adding an equimolar amount of the dirhodium complex $[Rh^{II}_2\{(R)\text{-}(+)\text{-MTPA}\}_4]$ (**[Rh−Rh]**, MTPA-H = methoxytrifluoromethylphenylacetic acid ≡ Mosher's acid; see Scheme 1) to their $CDCl_3$ solution and monitoring the diastereomeric dispersion Δν of their ^1H or ^{31}P NMR signals at room temperature ("dirhodium method" of chirality recognition).[4] However, we noticed that coalescence effects may broaden the NMR signals even at room temperature and that phosphane oxides seemed to have a different ligand behaviour from their sulfide and selenide analogues.[4c] Moreover, when we attempted to study some chiral bis(phosphane oxides) (Scheme 1) by variable-temperature NMR spectroscopy we found signals of complicated mixtures of free and ligated species.



Scheme 1. Structures of the dirhodium complex and the phosphanyl chalcogenides studied

Recently, Deubel has communicated a theoretical study based on density-functional theory (DFT) calculations of donor-acceptor interactions contributing to the binding energy in the adducts of dirhodium(II) tetraformate and a representative choice of strong and weak ligands (e.g., methylene carbene vs. benzene).[5] As a result, attractive contri-

butions were shown to be a blend of electrostatic and HOMO−LUMO interactions, the former always dominating.[5] In a comparative study of the ligand properties of the triphenylphosphane chalcogenides $Ph_3P{=}X$ (X = Se, S, and O), and of methyldiphenylphosphane oxide, $Ph_2(CH_3)P{=}O$, we have recently found that, in contrast to phosphane selenides and sulfides, phosphane oxides bind primarily by an electrostatic attraction, and orbital interactions can be neglected.[6] Moreover, this binding energy is strongly sensitive to steric crowding around the P=O group.[6] For $Ph_3P{=}O$, the binding constant *K* is only about 1 (weak donor). In contrast, *K* is larger than 100 for $Ph_2(CH_3)P{=}O$ (strong donor); no free ligand molecules can be detected in the presence of an excess of rhodium sites in the latter case, for example in an equimolar mixture of **[Rh−Rh]** and $Ph_2(CH_3)P{=}O$.[6] Since bis(phosphane oxides) are considered to be useful ligands in homogeneous catalysis, we extended this work to the bis(phosphane oxides) **1**−**3** in order to explore how bifunctional phosphane oxide ligands behave under "dirhodium method" experimental conditions and whether or not chirality recognition is still possible. In addition, we wanted to see whether there is a binding competition between the two P=O groups in each of the asymmetric compounds **2** and **3**.

[a] For both P atoms of **2** and for P^a of **3** two entries exist for each aromatic ^1H and ^{13}C nucleus because the phenyl groups are diastereotopic. The first entry belongs to one phenyl group and the second entry to the other; a stereochemical differentiation is not possible. [b] n.d.: not detectable. [c] Compound **2**: $^3J(^{31}P^a,^{31}P^b)$ = 49.4 Hz; compound **3**: $^3J(^{31}P^a,^{31}P^b)$ = 18.2 Hz. [d] The protons of the methylene group (=CH_2) can be differentiated because of their $^3J(^{31}P,^1H)$-values to P^b: H^a is *trans* to P^b (^3J = 39.8 Hz), and H^b is *cis* (^3J = 17.2 Hz).

Results and Discussion

NMR Signal Assignment

The assignment of the NMR signals of the free ligands **1**−**3** (cf. Scheme 1) was straightforward in most cases when routine NMR methods such as DEPT, HMQC, HMBC and NOE techniques were applied. Thereby, all ^{1}H, ^{13}C and ^{31}P NMR signals could be identified; the unequivocal assignment of the ^{31}P signals of the two heterotopic phosphorus sites in **2** and **3** was achieved by $\{^{31}P\}$ ^{1}H-detected HMBC experiments correlating P^{b} with the methyl or the *tert*-butyl protons, respectively. In the case of **[Rh−Rh]** adducts the identification of the ligand signals was occasionally hampered by overlapping Mosher acid signals, particularly when aromatic signals were involved. All NMR signals of the free ligands **1**−**3**, as well their complexation shifts Δδ (in ppm), for 1:1 adducts at room temperature are collected in Table 1 and 2.

Table 2. Complexation shifts in **1**−**3** in 1:1 adducts (in ppm); recorded at room temperature[a]

[a] For both P atoms of **2** and for P^a of **3** two entries exist for each aromatic ^{1}H and ^{13}C nucleus because the phenyl groups are diastereotopic. The first entry belongs to one phenyl group and the second entry to the other; a stereochemical differentiation is not possible. [b] No ^{13}C NMR spectroscopic data were recorded for the **[Rh−Rh]-1** mixture because precipitation of solid material from the solution occurred after a few hours. [c] Signal duplication due to dispersion effects (see text).

Identification of the Various Adduct Species

1,2-Bis(diphenylphosphinoyl)ethane (**1**) contains two chemically equivalent P=O residues; each is connected to two phenyl rings and to the ethylene chain. Thus, one can expect that its complexing properties are similar to those of triphenylphosphane oxide and methyldiphenylphosphane oxide.[6]

The low-temperature (213 K) ^{31}P NMR spectra of **1** at various molar ratios (Figure 1) allow the identification of the adduct species involved (Scheme 2). Spectrum **a** (0.5:1) was recorded for a solution with an excess of rhodium sites, spectrum **b** (1:1) for a solution with equimolar amounts of both **[Rh−Rh]** and **1**, and spectra **c** and **d** with an excess of P=O sites. The ratios were chosen in such a way that the molar amount of **1** relative to that of **[Rh−Rh]** is doubled when going from one spectrum to the next (**a** to **b**, **b** to **c**, and **c** to **d**) so that the P=O content increases strongly from bottom to top.

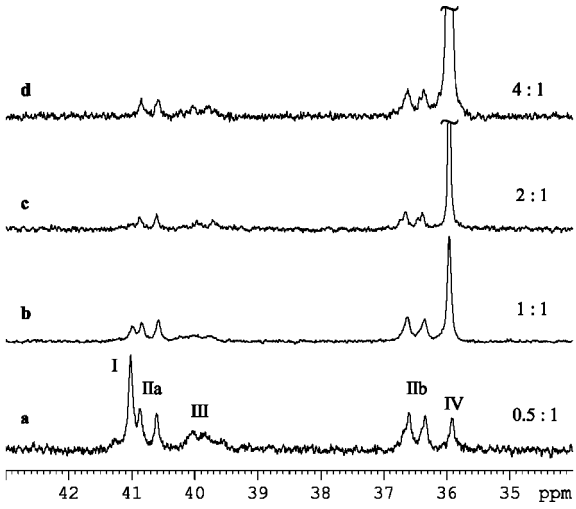

Figure 1. ^{31}P NMR spectra of **1** and **[Rh−Rh]**, recorded at 213 K; molar ratios are (a) 0.5:1, (b) 1:1, (c) 2:1 and (d) 4:1

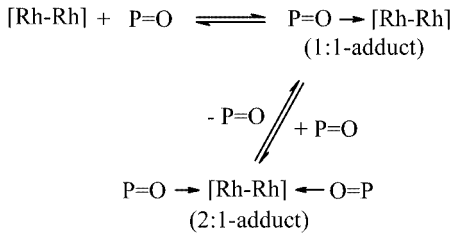

Scheme 2. Equilibria between free components and the adducts[a]
[a] "P=O" symbolizes phosphane oxide groups

By comparing the ^{31}P NMR signals and their relative intensities in Figure 1, the following assignments can be deduced. There are two different signal groupings: one at δ = 39.5−41.5 ppm for ligated P=O sites (Rh···O=P) and another at δ = 36−37 ppm for free P=O sites. The free ligand of **1** corresponds to the signal at δ = 36.1 ppm (**IV**; Scheme 3) as proven by its strong intensity increase upon further addition of **1** (spectra **b**, **c** and **d**). The signal at δ =

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

41.2 ppm (singlet) belongs to a doubly complexed ligand molecule which is in a symmetrical environment and therefore does not show the typical doublet splitting due to the $^{31}P,^{31}P$ coupling in unsymmetric bis(phosphane oxides) or analogous adducts. Thus, this species is of type **I** (Scheme 3). The intensity of this peak is rather large in spectrum **a** (Rh site excess), low in spectrum **b** (1:1), and the signal vanishes totally in spectra **c** and **d** with their increasing P=O site excess.

I: Rh—Rh ← O=P-CH_2-CH_2-P=O → Rh—Rh

II: Rh—Rh ← O=P^a-CH_2-CH_2-P^b=O

III: ···CH_2-P=O → Rh—Rh ← O=P-CH_2-CH_2-P=O → Rh—Rh ← O=P-CH_2···

IV: O=P-CH_2-CH_2-P=O (free ligand)

Scheme 3. Adduct species of **1** and **[Rh−Rh]** identified by low-temperature ^{31}P NMR spectroscopy (see text and Figure 1); the Mosher acid residues in **[Rh−Rh]** and the phenyls at the phosphoryl groups have been omitted for clarity

The two doublets at δ = 40.7 and 36.5 ppm correspond to an unsymmetrically ligated molecule of type **II** (Scheme 3). The former doublet (signal **IIa**) is from the complexed end of **1** (P^a=O) and the latter (signal **IIb**) from the free one (P^b=O). The signal splitting is the vicinal $^3J_{^{31}P,^{31}P}$ coupling constant (53.5 Hz). Finally, there is a broad hump at δ = 39.7−40.5 ppm corresponding to Rh···O=P situations of type **III**; apparently, these are the ^{31}P NMR resonances of doubly complexed ligand molecules incorporated in oligomeric structures (Scheme 3).

This interpretation is supported by the ^1H NMR signals of the methoxy group of the Mosher acid residues of **[Rh−Rh]** at low-temperature, as displayed in Figure 2, taken from the same samples as used for Figure 1. Signal **A** (δ = 3.14 ppm) representing the free **[Rh−Rh]** complexes without any ligating **1** has an intensity of about 40% in the solution at 0.5:1 molar ratio, falling to about 25% at P=O site excess. The majority of dirhodium moieties (ca. 50%), however, are in the 1:1 adduct situation represented by signal **B** (δ = 3.03 ppm). There is hardly any change in the proportion of this adduct with increasing amounts of **1**. Finally, signal **C** (δ = 2.93 ppm) can be attributed primarily to a Mosher methoxy signal in the 2:1 adduct situation; its proportion varies from about 10% at a 0.5:1 ratio to about 20% at a 4:1 ratio. This proportion of the 2:1 adducts is surprisingly low, especially with high P=O site excess, and is a consequence of the low donor properties of **1** and the severe steric congestion around the P=O group, similar to Ph_3P=O.[6] Additionally, this small amount of 2:1 adducts may be associated with the observation that some insoluble material precipitated from the $CDCl_3$ solution after several hours. We suspect that this material is a copolymer of type **III** (Scheme 3).

It should be noted that the temperature dependence of the ^1H NMR spectrum proves that a small part of signal **C** in spectrum **a** belongs to the CH_2 signal, which is averaged

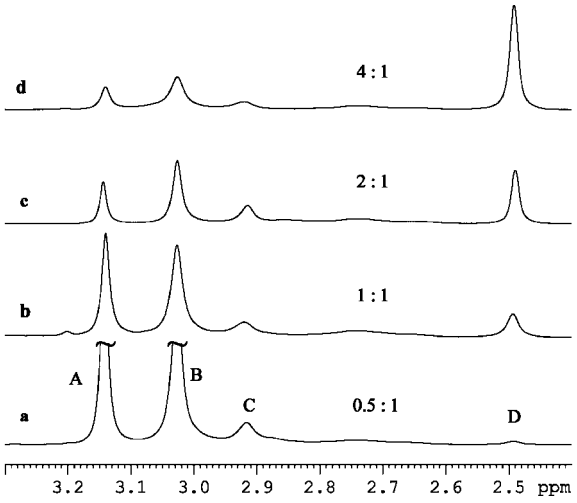

Figure 2. Sections of the ^1H NMR spectra of **1** and **[Rh−Rh]**, recorded at 213 K; molar ratios (a) 0.5:1, (b) 1:1, (c) 2:1 and (d) 4:1

at room temperature (δ = 2.77 ppm) but splits into two (δ = 2.93 and 2.52 ppm) at 213 K. The former part (δ = 2.93 ppm) belongs to Rh···O=P−CH_2 situations and the latter one (δ = 2.52 ppm) to free O=P−CH_2 groups (signal **D**); the relative proportion of signal **D** is strongly increased upon addition of larger amounts of **1** when going from spectrum **a** to spectrum **d** in Figure 2. The exchange barrier of the adduct formation can be estimated easily from the temperature dependence of the CH_2 and the methoxy protons ($\Delta G_c^{\ddagger}$ = 51.3 ± 1 kJ/mol). This value is somewhat higher than those of the monophosphane chalcogenides ($\Delta G_c^{\ddagger}$ = 46.4−48.0 ± 1 kJ/mol).[6]

All these spectra lead to the conclusion that the phosphane oxide group of **1** is only a weak donor; even under Rh site excess there is a substantial proportion of free P=O sites (P^b=O in **II** and **IV**; Scheme 3). Thus, the steric congestion in **1** must be higher than in $Me(Ph_2)P$=O and more similar to that of Ph_3P=O.[6] The majority of the molecules of **1** form adducts **II** and, eventually, oligomers **III** with their composition depending on the P=O site excess: oligomers become more and more dominant the higher the P=O content becomes.

In contrast to **1**, 1,2-bis(diphenylphosphinoyl)propane (**2**) is a *C*-chiral compound derived from **1** by formal methylation of one methylene carbon (cf. Scheme 1). Here, the two Ph_2P=O groups are heterotopic, and separate NMR signals are observable for each of them. In order to distinguish the two phosphoryl groups we use the superscript "a" for that Ph_2P=O group which is attached to CH_2 (C-1) and thereby structurally closest to **1**. The same procedure was applied to differentiate the two P=O groups in **3** (see below). The method of assigning the two phosphorus atoms to the two ^{31}P signals has already been described above.

The room-temperature ^{31}P NMR signals of **2** in the presence of **[Rh−Rh]** are broad humps showing averaged peaks. As can be seen in Figure 3, however, the low-temperature spectra (213 K) display a number of signals indicating the existence of several species, the concentrations of which de-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pend on the molar ratio of the components **2** and **[Rh−Rh]**. The ratio producing the lower spectrum was 2:1 — it was recorded under P=O site excess — whereas that in the top spectrum was 0.5:1 — Rh site excess. It should be noted that further spectra were taken from samples with 1:1 and 4:1 molar ratios. These are not displayed in Figure 3 but support the following conclusions.

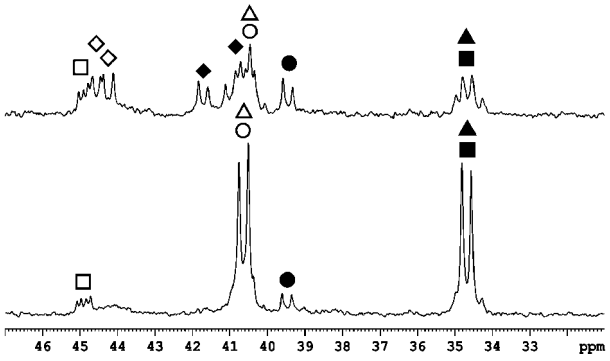

Figure 3. ^{31}P NMR spectra of **2** in the presence of various amounts of **[Rh−Rh]**, recorded at 213 K; top, molar ratio **2**:**[Rh−Rh]** 0.5:1, bottom 2:1; see Scheme 4 for the meaning of the symbols

The different ratio conditions enabled us to assign the peaks. Moreover, we recorded a ^{31}P,^{31}P COSY spectrum (not depicted) correlating the two heterotopic ^{31}P nuclei within each species. For sake of clarity we used the following icons for the ^{31}P signal assignment (Scheme 4): ▲/Δ for the free ligand OP^a∼P^{b}O, ●/○ for the adduct Rh···OP^a∼P^{b}O, ■/□ for the adduct OP^a∼P^{b}O···Rh and ◆/◇ for the adduct Rh···OP^a∼P^{b}O···Rh; filled icons refer to P^a and open ones to P^b (see also Scheme 4; "∼" depicts the carbon chain between the phosphorus atoms).

▲	OP^a ∼ P^{b}O	△
●	Rh → OP^a ∼ P^{b}O	○
■	OP^a ∼ P^{b}O ← Rh	□
◆	Rh → OP^a ∼ P^{b}O ← Rh	◇

Scheme 4. Assignment of the symbols to the phosphorus atoms in the Rh*-ligand species; filled icons refer to P^a and open ones to P^b, "∼" represents the carbon chain between the phosphorus atoms

It is obvious that the two doublet signals of the free ligand **2** (▲/Δ) are the largest ones in the bottom spectrum due to an excess of **2**. On the other hand, four small signals appear in the top spectrum that are not visible in the bottom spectrum; they were assigned to ″symmetrical″ adduct species (◆/◇). The fact that each of them appears twice can be attributed to the existence of two diastereomeric adducts (*R*)-**[Rh−Rh]**···[(*R*)-OP^a∼P^{b}O]···(*R*)-**[Rh−Rh]** and (*R*)-**[Rh−Rh]**···[(*S*)-OP^a∼P^{b}O]···(*R*)-**[Rh−Rh]**, an example of chirality recognition (**2** exists as a racemate). The signals of the "unsymmetrical" species (●/○ and ■/□) are visible in both spectra. Taking the relative intensities (●/○ vs. ■/□) into account and the fact that the signals of the free ligand **2** (▲/Δ) still exist under excess Rh site conditions, one can state that, like in **1**, both phosphoryl groups, P^a=O as well as P^b=O, of bis(phosphane oxide) **2** are weak donors, and that there is no significant selection between the two competing P=O groups.

This interpretation is supported by the low-temperature (213 K) ^{1}H NMR spectrum in the ligand methyl group region recorded under **2**:**[Rh−Rh]** = 0.5:1 molar ratio conditions (Rh site excess; Figure 4). It shows signals of the various species whereas at room temperature the averaged signal is a doublet of doublets due to the $^3J_{^1H,^1H}$ (7.0 Hz) and $^3J_{^{31}P,^1H}$ (16.8 Hz) couplings (not depicted). The assignment shown was proven unequivocally by a {^{31}P} ^{1}H-detected HMBC spectrum (not depicted) correlating the methyl protons with the P^b atoms in each species. The integration shows that only about 30% of all ligand molecules are complexed to rhodium on both sides (◇); the content of free ligand molecules (Δ) cannot be derived safely due to signal overlap but there is no doubt that a considerable amount of it exists. Moreover, the amount of the species with only one complexed phosphoryl (○ for Rh···OP^a∼P^{b}O and □ for OP^a∼P^{b}O···Rh) is roughly similar so that the complexation constants of both phosphoryl groups must be similar as well; the methyl group has, indeed, no significant directing effect for an adduct formation preference of P^a vs. P^b (or vice versa).

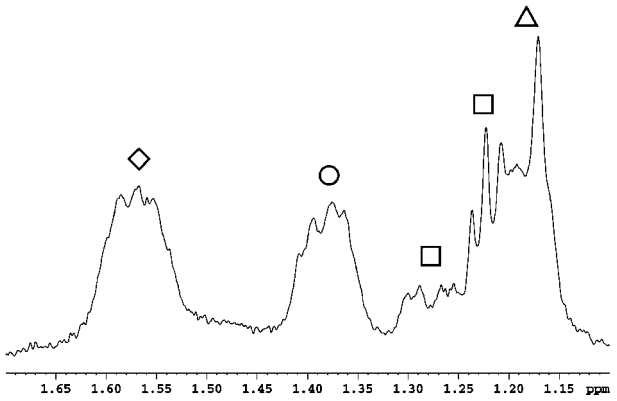

Figure 4. Methyl ^{1}H NMR signal of **2** in the presence of two molar equivalents of **[Rh−Rh]**, recorded at 213 K

Three factors make the ^{1}H NMR signals appear as broad multiplets instead of doublets of doublets: (a) the existence of different species regarding the 1:1 and 2:1 adduct situations of the Rh−Rh fragments, (b) high-order spin systems (ABX) because the methylene protons are diastereotopic, and (c) diastereomeric dispersion effects (compare the two signals marked by "□").

Whereas the bis(phosphane oxide) **2** has a chiral carbon center, 2-(*tert*-butylphenylphosphinoyl)-3-(diphenylphosphinoyl)propene (**3**) is *P*-chiral (P^b). In analogy to **2**, the two ^{31}P NMR signals of **3** were unambiguously assigned by a {^{31}P} ^{1}H-detected HMBC experiment at room temperature. Figure 5 shows the ^{31}P NMR spectra of **3** in the presence of three different molar equivalents of **[Rh−Rh]**, recorded at 213 K. The assignment of the various species was performed in analogy to those of **2** and is given in Figure 5 by icons similar to those used for **2** in Scheme 4. The signals

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of P^a appear at δ = 35−39 ppm (filled icons) and those of P^b at δ = 44−49.5 ppm (open icons).

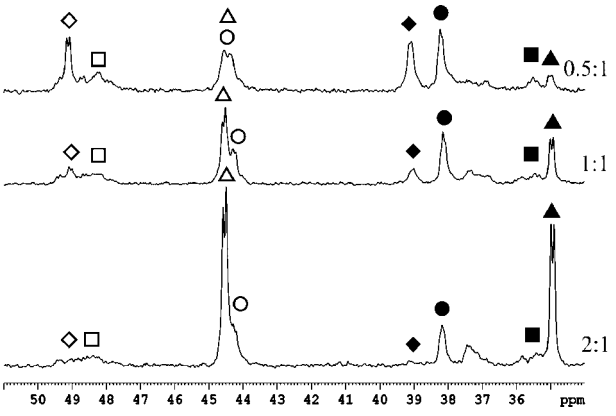

Figure 5. ^{31}P NMR spectrum of **3** in the presence of various amounts of **[Rh−Rh]**, recorded at 213 K; top: 0.5:1 molar ratio (**3**:**[Rh−Rh]**), middle: 1:1, bottom: 2:1; the icons used for the assignment of the various species of **3** have the same meaning as for **2** (see Scheme 4)

The basic difference in the complexing behaviour of the bis(phosphane oxides) **2** and **3** lies in the relative concentrations of the monoligated species Rh···OP^a∼P^bO (●/○) and OP^a∼P^bO···Rh (■/□). ^{31}P NMR signal integrations show that the ratio of the former relative to the latter is about 1.4 (**3**:**[Rh−Rh]** = 2:1, P=O site excess; Figure 5, bottom), about 1.7 (1:1; middle) and about 2.5 (0.5:1, Rh site excess; Figure 5, top). This clearly reflects the steric effects during complexation and reveals that the *tert*-butyl group at P^b creates a larger steric congestion during adduct formation and thereby repels approaching **[Rh−Rh]** molecules much more than the second phenyl group at P^a. Figure 6 shows the ^1H NMR signals of the *tert*-butyl group attached to P^b; some of these signals are multiplets for the same reasons as those described for the methyl protons of **2** (see above). The signal group at δ ≈ 1 ppm appears to be two overlapping doublets of the Rh···OP^a∼P^bO species, apparently another case of chirality recognition (see below).

The difference in adduct formation energies of the two P=O groups is also evident when comparing the intensities of the *tert*-butyl ^1H NMR signal (○ vs. □; Figure 6).

Chirality Recognition

Dispersion effects, Δν, due to the existence of diastereomeric adducts have been identified in some low-temperature ^1H NMR spectra (see previous section). They are difficult to detect at room temperature because most NMR signals are severely broadened by coalescence effects. However, some atoms in the aliphatic part of the two chiral bis(phosphane oxides) **2** and **3** offer the possibility of enantiomeric discrimination. In the case of the racemic **2**, the ^{13}C NMR signals are split: $\Delta\nu(CH_3)$ = 11.1 Hz, $\Delta\nu(CH_2)$ = 18.2 Hz and $\Delta\nu(CH)$ = 9.9 Hz. The time-averaged *tert*-butyl signal in the ^1H NMR spectrum of **3** (ratio **3**:**[Rh−Rh]** = 2:1) recorded at elevated temperature (330 K; Figure 7) displays a signal dispersion of 4.9 Hz (recorded at 11.74 T).

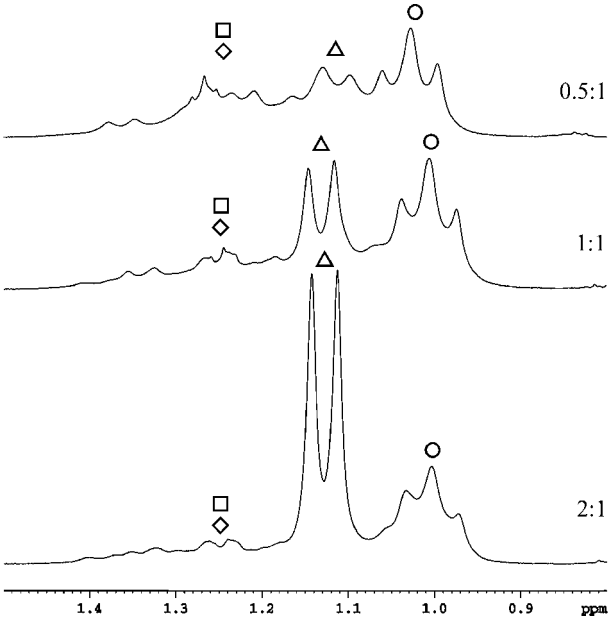

Figure 6. ^1H NMR signals of the *tert*-butyl group of **3**, recorded at 213 K; top: 1:2 molar ratio (**3**:**[Rh−Rh]**), middle: 1:1, bottom: 2:1; the icons used for the assignment of the various species of **3** have the same meaning as for **2** (see Scheme 4)

Moreover, the carbon signals of the *tert*-butyl group (recorded at 300 K) are duplicated as well: $\Delta\nu(CH_3)$ = 2.5 Hz and $\Delta\nu[C(t\text{Bu})]$ = 6.5 Hz. Interestingly, these diastereomeric dispersions occur preferably at the phosphane oxide group of **3** (P^b) that is clearly the weaker donor and, time-averaged, is further away from the Rh sites. Apparently, the branched structure of **3** guarantees that free P^b=O moieties cannot easily escape such interactions so that they come into closer spatial contact with the Mosher acid residues.

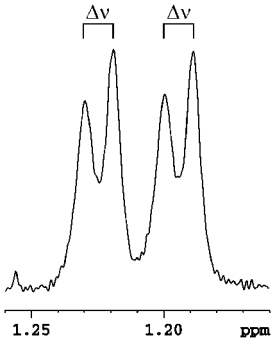

Figure 7. ^1H NMR signal of the *tert*-butyl group of **3** in the presence of an equimolar amount of **[Rh−Rh]**, recorded at 330 K, resolution enhanced; Δν = 4.9 Hz and $^3J_{^{31}P,^1H)}$ = 15.1 Hz

Conclusion

The bidentate 1,2-bis(diphenylphosphinoyl)ethane derivatives **1**−**3** are weak donors in adducts to the dirhodium complex **[Rh−Rh]**. Consequently, all conceivable species exist: free ligands, 1:1 adducts, 2:1 adducts and various iso-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mers and oligomers thereof. Their relative concentrations strongly depend on the molar ratio of **[Rh−Rh]** and the ligands so that an identification by low-temperature ^{31}P NMR spectroscopy is possible. Enantiomers can easily be resolved in the case of chiral bidentate ligands **2** and **3**.

Experimental Section

Substances: The synthesis of **[Rh−Rh]** has been communicated by us previously.[7] 1,2-Bis(diphenylphosphinoyl)ethane (**1**)[8] was prepared from the respective commercially available bisphosphane by oxidation with H_2O_2 in water.

1,2-Bis(diphenylphosphinoyl)propane (2): Diphenylphosphane oxide (1.19 g, 5.9 mmol) and diphenyl(propadienyl)phosphane oxide[9] (1.43 g, 5.9 mmol) were dissolved in toluene (25 mL), and the resulting solution was heated to reflux for 3 days. Evaporation of the solvent and recrystallization of the solid residue from toluene/diethyl ether (10:1) gave 1.84 g of 2,3-bis(diphenylphosphinoyl)propene as white crystals. Yield 70%; m.p. 132−133 °C. IR (KBr): $\tilde{\nu}$ = 1482, 1437, 1397, 1261, 1199 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 3.39 (br. d, J = 12.7 Hz, 1 H), 3.46 (br. d, J = 12.2 Hz, 1 H), 5.49 (dd, J = 20.5, 2.5 Hz, 1 H), 6.64 (dd, J = 41.6, 1.7 Hz), 7.21−7.89 (m, 20 H) ppm. ^{31}P NMR ($CDCl_3$): δ = 30.5 (d, J = 24 Hz), 32.6 (d, J = 24 Hz) ppm. $C_{27}H_{24}O_2P_2$ (442.4) calcd. C 72.96, H 5.84; found C 72.51, H 5.96.

Pd/C (20%; 0.096 g) was added to a solution of 2,3-bis(diphenylphosphinoyl)propene (0.2 g, 0.45 mmol) in 10 mL of methanol, and the resulting mixture was stirred at room temperature under a hydrogen atmosphere (balloon) for 2 days. The catalyst was then removed by filtering the reaction mixture through a thin bed of celite, and the methanol was evaporated to dryness. Recrystallization of the solid residue from toluene/hexane gave 0.175 g of **2**. Yield 87%; m.p. 128−131 °C. EI-HRMS: $C_{27}H_{26}O_2P_2$ [M^+] calcd. 444.1408; found 444.1399. See Table 2 for ^1H, ^{13}C and ^{31}P NMR spectroscopic data.

2-(*tert*-Butylphenylphosphinoyl)-3-(diphenylphosphinoyl)propene (3): *tert*-Butylphenylphosphane oxide (0.38 g, 2.1 mmol) was added to a solution of diphenyl(propadienyl)phosphane oxide[9] (0.51 g, 2.1 mmol) in 15 mL of toluene and the resulting solution was heated to 110 °C for 2 days. Evaporation of the solvent and recrystallization of the solid residue from diethyl ether/hexane (20:1) gave 0.51 g of **3**. Yield 57%; m.p. 84−86 °C. IR (KBr): $\tilde{\nu}$ = 1484, 1474, 1462, 1439, 1277, 1258, 1214, 1184 cm^{-1}. $C_{25}H_{28}O_2P_2$ (422.4) calcd. C 71.08, H 6.68; found C 70.71, H 6.80. See Table 2 for ^1H, ^{13}C and ^{31}P NMR spectroscopic data.

NMR Spectroscopy: Room-temperature ^1H (400.1 MHz), $^{13}C\{^1H\}$ (100.6 MHz), and $^{31}P\{^1H\}$ (161.9 MHz), NMR measurements were performed on a Bruker Avance DPX-400 spectrometer (9.4 T). Chemical shift standards were internal tetramethylsilane (δ = 0 ppm) for ^1H and ^{13}C, and external aqueous H_3PO_4 for ^{31}P (δ = 0 ppm). Signal assignments were assisted by NOE-difference, COSY, HMQC and HMBC (standard Bruker software) as well as by inspecting couplings to ^{31}P. Digital resolutions were 0.14 Hz/point in the ^1H, 0.24 Hz/point in the ^{13}C, and 0.22 Hz/point in the ^{31}P NMR spectra. One drop of [D_6]acetone was added to each NMR sample before measurement in order to increase the solubility of **[Rh−Rh]**.[10]

Variable-temperature ^1H (500.1 MHz) and $^{31}P\{^1H\}$ NMR (202.4 MHz) spectra were recorded in the presence of **[Rh−Rh]** on a Bruker Avance DRX-500 spectrometer (11.74 T). Temperatures varied from 213 to 330 K (333 K in the case of **1**) and were read from the instrument panel; no further measurements for more precise temperature determinations were taken.

$\{^{31}P\}$ ^1H-detected HMBC experiments were recorded at 213 K; relaxation delay 1.5 s, number of scans 32, delay optimized for long-range couplings (8 Hz); spectral width δ = 30−50 (^{31}P) and δ = 0−9 (^1H). Gradient-edited ^{31}P,^{31}P COSY spectra were recorded at 213 K; relaxation delay 4.0 s, number of scans 32, spectral width δ = 31−52 (^{31}P).

Synthesis and Characterization of Homoleptic Lanthanide Guanidinate Complexes and Their Catalytic Activity for the Ring-Opening Polymerization of Trimethylene Carbonate

Liying Zhou,[a] Yingming Yao,[a] Yong Zhang,[a] Mingqiang Xue,[a] Jinglei Chen,[a] and Qi Shen*[a,b]

Keywords: Insertion / Lanthanides / N ligands / Polymerization

Two methods to synthesize homoleptic guanidinate lanthanide complex are described. The samarium guanidinate complex $[Sm\{Ph_2NC(NCy)_2\}_3]\cdot 2C_7H_8$ (**1**) can be synthesized by the metathesis reaction of lithium guanidinate with anhydrous samarium trichloride in a 3:1 molar ratio. The analogous complexes $[Ln\{Ph_2NC(NCy)_2\}_3]\cdot 2C_7H_8$ [Ln = Yb (**2**), Nd (**3**)] can also be synthesized by the insertion reaction of *N*,*N*′-dicyclohexylcarbodiimide into the Ln–N bond of $[(THF)_4Li][Ln(NPh_2)_4]$ in a 3:1 molar ratio in good yield. Complexes **1**–**3** were characterized by elemental analysis, IR and ^1H NMR spectroscopy. The molecular structures of complexes **1** and **3** were further determined by X-ray diffraction techniques. These complexes showed high activity for the ring-opening polymerization of trimethylene carbonate (TMC), giving polymers with M_w/M_n ranging from 1.41–1.73.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

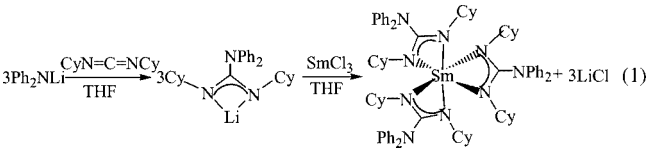
Lanthanocene complexes exhibit a variety of catalytic abilities for the polymerization of olefins, polar monomers and for organic transformations, such as hydrogenation, cyclic hydroamination of both alkynes and alkenes and so on.[1] Although guanidinate ligands have been well established as a versatile and flexible ligand system that is a potential alternative to cyclopentadienyl-based systems, and its application in organolanthanide complexes has led to the synthesis of a number of guanidinate derivatives of lanthanides,[2−7] the catalytic behavior of these complexes was not investigated until quite recently, when it was first reported that a monoguanidinate derivative of lanthanum $[La\{CyNC[N(SiMe_3)_2]NCy\}(OC_6H_3tBu_2\text{-}2,6)_2]$ can catalyze the ring-opening polymerization of D,L-lactide.[6] Very recently, methyllanthanide bis(guanidinate) complexes were found to be effective catalysts not only for the polymerization of ε-caprolactone and MMA,[5] but also for the polymerization of styrene,[8] which is normally quite difficult to polymerize with organolanthanide complexes. These fascinating results prompted us to study the chemistry of lanthanide guanidinate complexes further.

In this paper we report the synthesis of the homoleptic guanidinate lanthanides $[Ln\{Ph_2NC(NCy)_2\}_3]\cdot 2C_7H_8$ (Ln = Sm, Yb, and Nd) by a metathesis reaction (Sm) or by the insertion of *N*,*N*′-dicyclohexylcarbodiimide into the Ln−N bond of $[(THF)_4Li][Ln(NPh_2)_4]$ (Yb and Nd). All these complexes show good catalytic activity for the ring-opening polymerization of trimethylene carbonate (TMC).

Results and Discussion

Synthesis and Characterization of the Lanthanide Guanidinate Complexes

The metathesis reaction is one of the most versatile methods for the synthesis of organolanthanide derivatives. Thus, the new complex $[Sm\{Ph_2NC(NCy)_2\}_3]$ was prepared in good yields by the metathesis reaction of anhydrous $SmCl_3$ with $Li[Ph_2NC(NCy)_2]$, freshly prepared by the reaction of $LiNPh_2$ with CyN=C=NCy in THF [Equation (1)].



(1)

It has been reported that the insertion of one equivalent of the carbodiimide into the Ln−N bond of lanthanide amides leads to the formation of the corresponding lanthanide

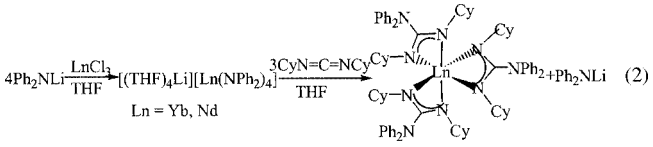
monoguanidinate derivatives,[6,7] so we wondered whether three molecules of the carbodiimide could insert into three Ln−N bonds of homoleptic lanthanide amides to give the corresponding homoleptic lanthanide guanidinate complexes. To answer this question, the reaction of *N*,*N*′-dicyclohexylcarbodiimide with $[(THF)_4Li][Ln(NPh_2)_4]$ in a 3:1 molar ratio was tried in THF. After workup, the homoleptic lanthanide guanidinate complexes $[Ln\{Ph_2NC(NCy)_2\}_3]\cdot 2C_7H_8$ [Ln = Yb (**2**), Ln = Nd (**3**)] were isolated in good yields. It is interesting that neither $LiLn[Ph_2NC(NCy)_2]_4$ nor $Li[Ph_2NC(NCy)_2]$ was obtained; the only Li product recovered was $LiNPh_2$ [Equation (2)]. This result indicates that the insertion of carbodiimide into the Ln−N bond is easier than into the Li−N bond.



All these lanthanide complexes are air and moisture sensitive, and are soluble in toluene, THF, and diethyl ether. They were characterized by elemental analysis and IR spectroscopy. The IR spectra of these complexes exhibit strong absorptions in the range of 1600−1640 cm^{-1}, which are consistent with a partial C=N double-bond character, indicating that the π-electrons are delocalized within the double bond of the N−C−N linkage.

Crystal Structure Analyses

The molecular structures of **1** and **3** were further determined by X-ray diffraction. Crystals of **1** and **3** suitable for X-ray diffraction were grown from toluene solutions. The molecular structures of **1** and **3** are shown in Figure 1 and 2, respectively. Selected bond lengths and angles are given in Table 1.

As shown in Figure 1 and 2, complexes **1** and **3** have analogous solid-state structures: they are both monomeric with a six-coordinate lanthanide center ligated by six nitrogen atoms of three chelating bidentate guanidinate ligands. The coordination geometry around the lanthanide ion for each complex is best described as a distorted trigonal prism. The C−N distances within the chelating guanidinate ligands (see Table 1) are approximately equivalent and significantly shorter than C−N single bond lengths, indicating that the π-electrons in these complexes are delocalized within the N−C−N fragment. The Sm−N bond lengths in complex **1** range from 2.425(6) to 2.460(6) Å, giving an average of 2.442(6) Å. This value is similar to that in $[Sm\{CH(SiMe_3)_2\}\{CyNC[N(SiMe_3)_2]NCy\}_2]$ [av. 2.417(4) Å].[3] As expected, the coordinated guanidinate group and the lanthanide atom form essentially a planar four-membered ring [N(1)−Sm(1)−N(2) = 54.6(2)°, C(1)−N(1)−Sm(1) = 94.4(5)°, C(1)−N(2)−Sm(1) = 94.9(4)°, N(1)−C(1)−N(2) = 115.9(7)°; sum of angles: 359.8°]. The N(1)−Sm(1)−N(2), N(4)−Sm(1)−N(5), and N(7)−Sm(1)−N(8) bond angles are 54.6(2)°, 55.2(2)°, and 54.8(2)°, respectively, and are similar to the corresponding angles in $[Sm\{CH(SiMe_3)_2\}\{CyNC[N(SiMe_3)_2]NCy\}_2]$ [55.06(13)°, and 55.59(13)°][3] and $[Yb\{CyNC(Ph)NCy\}_3]\cdot 2THF$ [58.1(2)° and 57.98(17)°].[9]

The Nd−N bond lengths vary from 2.464(4) to 2.494(4) Å, similar to those in $[\{(Me_3Si)_2NC(NiPr)_2\}_2Nd(\mu\text{-}Me)_2Li(TMEDA)]$ [2.476(7) to 2.523(6)Å].[5] The guanidinate groups bind to Nd through two nitrogen atoms to yield a

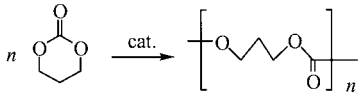
Ring-Opening Polymerization of Trimethylene Carbonate (TMC)

Polycarbonate is a biomaterial with good biodegradability, biocompatibility, and low toxicity, and therefore the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

study of its preparation has attracted much attention. The ring-opening polymerization of a cyclic carbonate is an easy way to get a polycarbonate, and several Lewis acids are effective catalysts for this polymerization reaction. However, there are only a few papers dealing with the polymerization of cyclic carbonates catalyzed by organolanthanide complexes.[10−15] Evans et al. have found that a Sm^{II} complex can catalyze the copolymerization of ε-caprolactone (ε-CL) and ethylene carbonate, but cannot catalyze the homopolymerization of ethylene carbonate,[10] and Yasuda et al. have reported that Sm^{II} complexes show catalytic activity for the homopolymerization of trimethylene carbonate and the copolymerization of trimethylene carbonate with ε-CL.[11] Recently, Shen et al. have found that homoleptic lanthanide(III) aryloxides are effective initiators for the ring-opening polymerization of 2,2-dimethyltrimethylene carbonate.[12b] We therefore decided to examine the catalytic activity of the homoleptic guanidinate lanthanide complexes in the ring-opening polymerization of TMC (Scheme 1).



Scheme 1

The preliminary results are listed in Table 2, where it can be seen that all the complexes tested show high activity for the ring-opening polymerization of TMC. The monomer conversion is over 85% for all the polymerizations under the conditions of [M]/[I] = 500 (mole ratio) at 40 °C in 30 min (entries 1, 5, and 10). An effect of the central metal on the catalytic activity can also be observed. For example, the conversion reaches 95% in the case of [M]/[I] = 700 at 40 °C in 30 min using **2** as the initiator, while it is only 56% and 12% for complexes **1** and **3**, respectively (entries 2, 7 and 11). The conversion was still 89.5% even when the [M]/[I] ratio was increased to 1000 with **2** as the initiator (entry 8). Therefore, the activity order under the present polymerization conditions is Yb > Sm > Nd, which is opposite to the order of the ionic radii.

An effect of the polymerization temperature on the conversion can also be observed. The conversion increases with an increase of temperature from 20 to 60 °C with **1** or **3** as the initiator (entries 2, 3, 9, 10).

The catalytic activity of these tris(guanidinate) lanthanide complexes is similar to that of $La(OAr)_3$ (OAr = 2,6-di-*tert*-butyl-4-methyl phenolate) for the ring-opening polymerization of TMC,[12c] but is higher than that of $LnCl_3$ [12e] and $BX_3{\cdot}Et_2O$.[16] In comparison with the above catalysts, our lanthanide tris(guanidinate) complexes give polymers with a relatively narrow molecular-weight distribution.

Conclusion

In summary, homoleptic guanidinate lanthanide complexes can be easily prepared in good yield by the metathesis reaction of lithium guanidinate with anhydrous lanthanide trichlorides or by the insertion reaction of carbodiimide into the Ln−N bonds of $[(THF)_4Li][Ln(NPh_2)_4]$ in a 3:1 molar ratio. Their structural features have been determined by X-ray diffraction. These complexes show good catalytic activity for the ring-opening polymerization of trimethylene carbonate and the polymerization gives polymers with a relatively narrow molecular-weight distribution (M_w/M_n = 1.41−1.73).

Experimental Section

General Procedures: All manipulations were performed under pure Ar with rigorous exclusion of air and moisture using standard Schlenk techniques. Solvents were distilled from Na/benzophenone ketyl prior to use. Anhydrous $LnCl_3$,[17] $[Li(THF)_4][Ln(NPh_2)_4]$[18] and trimethylene carbonate (TMC)[19] were prepared according to the literature procedures. *N*,*N*′-Dicyclohexylcarbodiimide was purchased from Aldrich and used as received without further purification. Melting points were determined in sealed Ar-filled capillary tubes. Metal analyses were carried out by complexometric titration. Carbon, hydrogen and nitrogen analyses were performed by direct combustion on a Carlo−Erba EA = 1110 instrument. The IR spectra were recorded on a Magna-IR 550 spectrometer. Molecular weight and molecular weight distributions were determined against

a polystyrene standard by gel-permeation chromatography (GPC) on a waters 1515 apparatus with three HR columns (HR-1, HR-2 and HR-4); THF was used as an eluent at 30 °C. ^{1}H NMR spectra were measured on a Unity Inova-400 spectrometer.

Synthesis of [Sm{Ph$_2$NC(NCy)$_2$}$_3$]·2C$_7$H$_8$ (1): A Schlenk flask was charged with Ph_2NH (2.1 mL,15.0 mmol), THF (30 mL), and a stir bar. The solution was cooled to 0 °C, and *n*BuLi (9.6 mL, 15.0 mmol, 1.56 M in hexane) was added. It was then slowly warmed to room temperature and stirred for 1 h. *N*,*N*′-Dicyclohexylcarbodiimide (3.15 g, 15.3 mmol in 10 mL of THF) was then added to this solution at 0 °C. The solution was slowly warmed to room temperature, stirred for 1 h and then added slowly to a pale-gray slurry of $SmCl_3$ (1.28 g 5.11 mmol) in 20 mL of THF. The resulting solution was stirred for 1 h at 273 K and then stirred for 48 h at room temperature. The solvent was removed in vacuo and the residue was extracted with toluene and LiCl removed by centrifugation. After the extracts were concentrated, colorless crystals (5.50 g, 74%)were obtained at room temperature after a few days. M.p. 212 °C (dec.). ^{1}H NMR (400 MHz, C_6D_6, 25 °C): δ = 6.88−7.39 (m, 42 H, Ph), 3.62 (m, 6 H, unique H-Cy), 0.34−2.15 (br., 60 H, C_6H_{10}) ppm. $C_{89}H_{112}N_9Sm$ (1458.3): calcd. C 73.30, H 7.75, N 8.64, Sm 10.31; found C 73.24, H 7.20, N 8.63, Sm 9.85. IR (KBr pellet): $\tilde{\nu}$ = 3426 cm^{-1} (s), 2928 (m), 2855 (w), 1636 (s), 1590 (m), 1559 (w), 1493 (m), 1454 (w), 1400 (w), 1366 (w), 1235 (s), 1158 (s), 891 (w), 756 (w), 694 (w), 625 (w), 505 (m).

Synthesis of [Yb{Ph$_2$NC(NCy)$_2$}$_3$]·2C$_7$H$_8$ (2): A Schlenk flask was charged with a solution of [Li(THF)$_4$][Yb(NPh$_2$)$_4$] (4.56 g, 4.0 mmol) in 30 mL of THF and a stir bar. Then, a solution of *N*,*N*′-dicyclohexylcarbodiimide (2.47 g, 12.0 mmol) in 20 mL of THF was added slowly. The color of the solution slowly became yellow. The solution was then stirred for another 48 h and the solvents evaporated to dryness in vacuo. The residue was extracted with toluene and LiCl was removed by centrifugation. The solution was concentrated and stored at room temperature for crystallization. Complex **2** was obtained as yellow crystals (4.62 g, 78%). M.p. 287−289 °C (dec.). ^{1}H NMR (400 MHz, C_6D_6, 25 °C): δ = 6.88−7.40 (m, 42 H, Ph), 3.16−3.98 (m, 6 H, unique H-Cy), 0.34−2.15 (br., 60 H, C_6H_{10}) ppm. $C_{89}H_{112}N_9Yb$ (1481.0): calcd. C 72.18, H 7.62, N 8.51, Yb 11.69; found C 71.96, H 8.05, N 8.79, Yb 10.73. IR (KBr pellet): $\tilde{\nu}$ = 3430 cm^{-1} (s), 2928 (s), 2855 (m), 1640 (s), 1590 (m), 1493 (m), 1451 (w), 1308 (w), 1235 (w), 1154 (w), 1076 (w), 1030 (w), 891 (w), 752 (m), 694 (m).

Synthesis of [Nd{Ph$_2$NC(NCy)$_2$}$_3$]·2C$_7$H$_8$ (3): Following the procedure for the synthesis of **2**, the reaction of *N*,*N*′- dicyclohexylcarbodiimide (1.36 g, 6.6 mmol) in 20 mL of THF with [Li(THF)$_4$][Nd(NPh$_2$)$_4$] (2.45 g, 2.2 mmol) in 30 mL of THF afforded **3** as light-blue crystals (2.88 g, 65%). M.p. 131 °C. ^{1}H NMR (400 MHz, C_6D_6, 25 °C): δ = 6.87−7.40 (m, 42 H, Ph), 3.56−3.62 (m, 6 H, unique H-Cy), 0.34−2.15 (br., 60 H, C_6H_{10}) ppm. $C_{89}H_{112}N_9Nd$ (1452.2): calcd. C 73.61, H 7.77, N 8.68, Nd 9.94; found C 73.25, H 7.96, N 8.92, Nd 9.55. IR (KBr pellet): $\tilde{\nu}$ = 3442 cm^{-1} (s), 3280 (m), 3257 (m), 2964 (m), 1628 (m), 1405 (w), 1266 (m), 1088 (s), 1027 (s), 918 (w), 888 (w), 803 (s), 695 (w), 533 (w), 440 (w).

Typical Procedure for the Polymerization Reactions: A 50-mL Schlenk flask equipped with a magnetic stir bar was charged with a solution of TMC (0.3583 g, 3.51 mmol) in 2.8 mL of toluene. To this solution was added 0.7 mL of a solution of complex **2** in toluene (1.0×10^{-2} M, 7.00×10^{-3} mmol) with a syringe. The contents of the flask were then vigorously stirred for 30 min at 20 °C. The polymerization was quenched by adding a 5% solution of HCl in methanol,. The polymer precipitated from methanol and was dried under vacuum.

X-ray Structural Determination of 1 and 3: Suitable single crystals of complexes **1** and **3** were each sealed in a thin-walled glass capillary, and intensity data were collected on a Rigaku Mercury CCD equipped with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation. Details of the intensity data collection and crystal data are given in Table 3. The crystal structures of these complexes were solved by direct methods and expanded by Fourier techniques. Atomic coordinates and thermal parameters were refined by full-matrix least-squares analysis on F^2. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were all generated geometrically with assigned appropriate isotropic thermal parameters. CCDC-224364 (for **1**) and -224365 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Cobalt(II), Nickel(II), Copper(II), and Zinc(II) Complexes with a *p-tert*-Butylcalix[4]arene Fitted with Phosphinoyl Pendant Arms

Vladimira Videva,[a] Anne-Sophie Chauvin,[b] Sabi Varbanov,[c] Christophe Baux,[b] Rosario Scopelliti,[b] Mariana Mitewa,[a] and Jean-Claude G. Bünzli*[b]

Keywords: Calix[4]arene / Transition metals / Stability constants / X-ray diffraction / Polynuclear compounds

A series of complexes of $M^{II}X_2$ transition metal salts (X = ClO_4, M = Co, Ni, Cu, Zn; X = Cl, M = Cu, Zn) with a calix[4]arene substituted at the lower rim {L = 5,11,17,23-tetra-*tert*-butyl-25,26,27,28-tetrakis[(dimethylphosphinoyl)-methoxy]calix[4]arene} are isolated and characterized. Two different stoichiometries are evidenced, 1:1 for the Co^{II}, Ni^{II}, and Cu^{II} complexes, independently of the anion (Cl^- or ClO_4^-), as well as for the $Zn(ClO_4)_2$ complex, while a 2:1 metal/ligand ratio is found for the complex with $ZnCl_2$. The coordination mode and structure of the complexes are investigated by several spectroscopic and magnetochemical methods, both in the solid state and in solution. Coordination through the phosphoryl groups of the ligand is ascertained by X-ray diffraction and IR and NMR spectroscopic data. The crystal structure of the 2:1 Zn compound (triclinic, $P\bar{1}$, $Z = 2$) shows the presence of the tetrametallic species Zn_4L_2 with three different tetrahedral Zn environments, $ZnCl_2O_2$, $ZnCl_3O$, and $ZnClO_3$, the latter bridging two ligand molecules. Magnetic susceptibility, EPR data, and electronic spectra are indicative of a tetrahedral arrangement of the ligands in the Co^{II} (high-spin d^7) 1:1 complex, which is also most probably the ligand geometry in the Ni^{II} and Cu^{II} 1:1 complexes. In solution, the extent of the interaction between L and the M^{II} ions has been determined by UV/Vis spectrophotometric titrations. The resulting stability constants for 1:1 complexes are in the range $\log K_1 = 4.8–5.4$.

Introduction

During the last decade, a great deal of interest has been devoted to the design of functionalized calixarenes in view of their excellent coordination and extraction properties.[1−4] Phosphorus-containing calixarenes have proven particularly useful in the separation of lanthanides and actinides.[5] Moreover, transition metal complexes with calixarenes are good models for mimicking biological processes.[6] For example, Co^{II} or $Cu^{I/II}$ complexes can be used to transport and activate small molecules of biological interest, such as dioxygen, and/or for studying the catalytic effect of copper enzymes in non-aqueous solvents.[7a] Other applications lie in analytical chemistry, as recently reported for calixarene-based luminescent sensors for Cu^{II} [7b] and Zn^{II},[7c] for instance. In the recent past, we have reported the synthesis of narrower-rim substituted *p-tert*-butylcalix[*n*]arenes fitted with either ether−amide (n = 4,[8a] 6[8b]) or phosphinoyl groups [n = 4 (L),[8c] 6[4]]. In particular, the thermodynamic and photophysical properties of the 1:1 and 1:2 (metal/ligand) complexes of L (see scheme) with trivalent lanthanide ions (La^{III}, Eu^{III}, Tb^{III}) were studied in detail.[8c] The ligand itself adopts a flattened cone conformation and a Δ-enantiomeric form which should also be quite convenient for the binding of 3d transition metal ions forming tetracoordinated species. In this paper we therefore investigate the coordination ability of L towards Co^{II}, Ni^{II}, Cu^{II} and Zn^{II} perchlorates, as well as the structural properties of the resulting isolated complexes. Influence of the anion on the stoichiometry of the complexes is tested for Cu^{II} and Zn^{II} by replacing perchlorate with chloride.

Results and Discussion

Isolation of the Complexes and Solid-State Properties

The complexes were isolated from ethanolic solutions and elemental analyses are consistent with the formation of compounds with a 1:1 metal/ligand stoichiometry: $M(ClO_4)_2L{\cdot}2H_2O$ [M = Co (**1**), Ni (**2**), Zn (**5**); $Cu(ClO_4)_2L{\cdot}4H_2O$ (**3**), and $CuCl_2L{\cdot}4H_2O$ (**4**)], while a compound with a 2:1 (M/L) stoichiometric ratio was isolated with zinc chloride: Zn_2Cl_4L (**6**). IR spectroscopic data (Table S1, Figure S1, Supporting Information) are consistent with an interaction taking place through the P=O groups of the ligand. In the free ligand, the P=O stretching vibration appears as an intense split band with components at 1160 and 1171 cm^{-1}, pointing to inequivalent phosphoryl groups. In the chloride complexes (1:1, Cu^{II} and 2:1, Zn^{II}) this band undergoes a further splitting leading to the observation of **3** (Zn^{II}, 2:1 complex) and **4** (Cu^{II}, 1:1 complex) components, all of them being red-shifted with respect to those of the free ligand. That is, the P=O groups become more inequivalent in the complexes; as a matter of fact, the crystal structure of the Zn^{II} 2:1 complex (vide infra) shows three types of P=O groups, coordinated to monodentate $ZnCl_3^-$, bidentate bridging $ZnCl_2$ and tridentate bridging $ZnCl^+$ units. The shift of the more intense component with respect to the ligand, $\Delta\tilde{\nu} \approx 50$ cm^{-1}, is considerably larger than the one reported for $ZnCl_2(Ph_3PO)_2$[9] or for zinc halide adducts with (aminomethyl)dimethylphosphane oxide[10] (ca. 35 cm^{-1}), pointing to a stronger interaction with the metal ion, despite the fact that chloride ions remain coordinated. Analysis of the P=O vibrations for the 1:1 perchlorate complexes is not easy in view of the overlap with the perchlorate modes. The spectra of all complexes are relatively similar, with three components in the ranges 1104−1109, 1121−1123 and 1143−1144 cm^{-1} (the middle component is not seen in the spectrum of the Co^{II} complex). The shifts are difficult to determine since the more intense band does not correspond to the same components in the various spectra, but they range between 27 and 60 cm^{-1}, again indicating a substantial interaction between the phosphoryl groups and the metal ions. Several vibrations are seen in the 627−636 cm^{-1} range, so that the presence of non-ionic (possibly coordinated) perchlorate ions cannot be ruled out. For instance, in $[Co(ClO_4)(topo)_4]ClO_4$ (topo = trioctylphoshane oxide) in which perchlorate anions are coordinated, $\Delta\tilde{\nu}(P{=}O) \approx 30$ cm^{-1}.[11]

In order to obtain additional information about the geometrical arrangement of the ligating atoms in the paramagnetic complexes, susceptibility measurement and EPR spectra have been recorded for Co^{II}, Ni^{II} and Cu^{II} (Figure 1), as well as electronic spectra. The effective magnetic moment μ_{eff} of the Co^{II} complex amounts to 5.0 B.M. at room temperature and is temperature-dependent, which is typical of a high-spin d^7 complex with either octahedral or tetrahedral ligand arrangements. The relatively large value of μ_{eff} could be more consistent with an octahedral arrangement (reported values are in the range 4.7−5.2 B.M., while four-coordinate high-spin compounds have μ_{eff} in the range 4.2−4.9 B.M. [4.76 B.M. for $(Ph_3PO)_2CoCl_2$, for instance].[12] On the other hand, the intense blue color of the complex points to the latter being more likely tetrahedral.[13] Reasoning in terms of idealized symmetries, a tetrahedral arrangement generates three spin-allowed transitions, $^4A_2 \rightarrow {}^4T_2$, $^4T_1(F)$, $^4T_1(P)$; the latter is situated between 600 and 650 nm and is usually the more intense, while the other two transitions are in the NIR range (1−2 μm). Octahedral d^7 complexes also display three d-d transitions $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$, $^4A_{2g}$, $^4T_{2g}$ the first being the more intense one and occurring between 500 and 600 nm; it often appears as being split because the $^4A_{2g}$ level is close to $^4T_{1g}(P)$; the transition to $^4T_{2g}$ occurs in the NIR region; generally speaking these transitions are about one order of magnitude less intense than the transitions of the tetrahedral complexes.[13] In our case, the reflectance spectrum displays two weak d-d transitions at 473 and 516 nm, a main component at 597 nm, and two additional broad and very weak bands at 916 and ca. 1450 nm. In CH_3CN solution (2.7×10^{-3} M, Figure 2), the corresponding bands appear at 454(86) (ε = 112 $M^{-1}{\cdot}cm^{-1}$), 515(11), 586(65), and 1407(55) nm. The relatively large values of the molar absorption coefficients are more in line with a tetrahedral arrangement of the ligands; the latter appears to be severely distorted, leading to a low symmetry, henceforth the observation of several transitions in the range 450−600 nm [splitting of the $^4T_1(P)$ level]. The effective magnetic moment of the Ni^{II} complex at room temperature is equal to 3.1 B.M. and is temperature-independent, down to about 30 K. For a hexacoordinate, octahedral complex, a value between 2.9 and 3.4 B.M. is expected, while tetrahedral complexes have μ_{eff} in the range

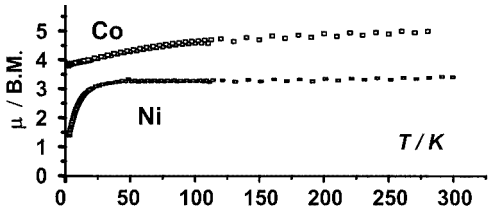

Figure 1. Temperature dependence of the effective magnetic moment of the Co^{II}, and Ni^{II} complexes

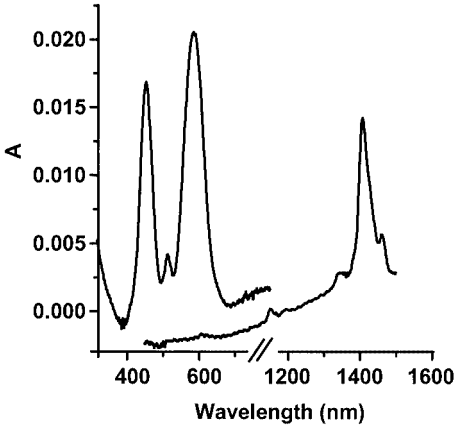

Figure 2. Parts of the electronic spectrum of $CoL(ClO_4)_2{\cdot}2H_2O$, 2.7×10^{-3} M in CH_3CN

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3.0−3.5, if they are severely distorted, or 3.5−4.0 B.M., if they are less distorted.[12,13] The value we find for the calixarene complex is therefore clearly compatible with either one of the first two situations. The reflectance spectrum displays a band at 446 nm, with two shoulders on the low energy side and a weak one at 905 nm and is therefore compatible with a tetrahedral coordination. While Co^{II} and Ni^{II} complexes are EPR-silent, the Cu^{II} chloride compound exhibits a single anisotropic line with $g = 2.13 \pm 0.01$, both at room and low (130 K) temperatures, again consistent with a distorted tetrahedral coordination geometry.

Crystals of complex **6** have been obtained by slow concentration of a methanolic solution of L and $ZnCl_2$ (each 10^{-3} M) and its solid-state structure has been elucidated by X-ray diffraction. The structure is comprised of discrete units encompassing two molecules of ligand linked to four Zn^{II} cations. The coordination of the metal ions is tetrahedral, even if the nature of the coordinating atoms differ (Figure 3): Zn1 is coordinated by one chloride anion and three oxygen atoms from phosphinoyl arms belonging to two calixarenes, thus creating a bridge between them; Zn2 and Zn4 are coordinated by two chloride anions and two oxygen atoms from neighboring phosphinoyl arms on the same ligand; Zn3 is coordinated by three chloride anions and only one oxygen atom from the last phosphinoyl arm. The mean P=O bond length, 1.51(1) Å, is in the range expected for P=O double bonds, although this distance is larger than the one observed in the free ligand (1.483 Å).[8c] The lengthening of the P=O bond upon coordination is consistent with the red-shift observed for the $\tilde{\nu}$(P=O) vibration. The Zn−Cl bond lengths are comparable for the four zinc atoms [2.237(6)Å], while the Zn−O distance ranges from 1.92(1) to 2.01(1) Å. The two different donor atoms around the Zn^{II} ions generate distorted tetrahedral coordination polyhedra, essentially with respect to the Ln−X distances; angles deviate less than 10° from the expected tetrahedral value (Table S2, Supporting Information). The two calixarenes adopt a typical flattened cone conformation (Table S3, Supporting Information) with two opposite phenolic units almost parallel to each other while the other two are approximately at right angles.

Solution Properties of the Complexes

The complexes have also been characterized in solution. Electrospray mass spectrometry (ES-MS) confirms that the metal:ligand ratios are maintained in solution (Table 1).

The corresponding spectra display peaks due to the free ligand as $[L]^+$, $[L + 2\ H]^{2+}$ species in addition to the expected cations $[L + Co]^{2+}$, $[L + Ni]^{2+}$, $[L + Cu]^{2+}$, $[L + Zn]^{2+}$. Hydrated ligand species are also seen in the case of **3**, **5** and **6**, but only the spectrum of **5** presents peaks attributable to a hydrated metal ion (Zn^{II}). For complexes **1**−**5**, dissociation of the complexes occurs according to Equations (1) and (2).

$$MLX_2 \rightarrow L + MX_2 \quad (1)$$

$$MLX_2 \rightarrow [ML]^{2+} + 2\,X^- \quad (2)$$

Spectra of the dimetallic Zn^{II} complex **6**, have been recorded in both positive and negative modes and the following species were unambiguously identified: $[ZnL]^{2+}$, $[ZnCl(L)]^+$, $[Zn_2Cl(L)]^{3+}$ and $[ZnCl_3]^-$. The presence of these species, particularly the negatively charged trichloride, leads to the hypothesis that the complex in solution may be formulated as $[ZnCl(L)][ZnCl_3]$. The dimetallic species is more difficult to account for. One may think that dissolution of the tetrametallic complex characterized by X-ray diffraction results in a reorganization of the Zn1 and Zn3 coordination sphere to give monomeric dimetallic complexes Zn_2Cl_4L with each metal ion coordinated to two chloride ions and two phosphoryl groups. However, spectrophotometric titrations (vide infra) point to the sole pres-

ence of 1:1 species in solution, so that the dimetallic species probably forms under the electrospray conditions, when the droplets evaporate.

The ^1H and $^{31}P\{^1H\}$ NMR spectroscopic data obtained for the free ligand and its Zn^{II} complex in $[D_6]$DMSO are reported in Table 2. Although the latter occurs within a fast exchange process, the coordination mode in solution through the phosphoryl groups is confirmed: both ^1H and $^{31}P\{^1H\}$ NMR shifts are affected by the complexation. The signal of the $CH_3P(O)$ protons is shifted by $\Delta\delta$ = 0.06−0.11 ppm. Large ^{31}P shifts are observed for the coordinated phosphoryl groups: $\Delta\delta$ = 4.27 ppm, from 36.81 for the free ligand to 41.08 ppm for $ZnL(ClO_4)_2{\cdot}2H_2O$, and $\Delta\delta$ = 7.98 ppm, to 44.79 ppm for the Zn_2LCl_4 complex **6**. Analogous ^{31}P chemical shifts are measured in CD_3OD: $\Delta\delta$ = 2.69 ppm for **5** and $\Delta\delta$ = 6.08 ppm for **6**.

On the other hand, the difference in chemical shifts between **5** and **6**, with $\Delta\delta(\mathbf{6}-\mathbf{5})$ = 3.71 ppm, strongly suggests that the species in solution are quite different. Addition of 1 equiv. of tetramethylammonium chloride or zinc chloride directly to the solution containing $ZnL(ClO_4)_2$, followed by heating of the NMR tube for 2 min, for solubility reasons, results in the observation of only one peak in the $^{31}P\{^1H\}$ spectrum, at δ = 44.30 ppm, meaning that complex **5** immediately evolves into **6** upon chloride addition. Despite that the ratio of Zn/L/Cl not being the same (1:1:1 upon addition of Me_4NCl and 2:1:2 upon addition of $ZnCl_2$), the same species forms.

Table 2. ^1H and $^{31}P\{^1H\}$ NMR spectroscopic data of $[ZnL](ClO_4)_2\ 2H_2O$ (**5**) and $[Zn_2L]Cl_4$ (**6**) in $[D_6]$DMSO

Interaction of L with Co^{II}, Ni^{II}, Cu^{II} and Zn^{II} in Acetonitrile

To assess the strength of the calixarene−metal interaction, we have determined stability constants in acetonitrile or acetonitrile containing a small amount of dichloromethane by spectrophotometric titrations of dilute solutions of L by the metal perchlorates $M(ClO_4)_2 \cdot 6H_2O$ (M = Cu, Zn) and chlorides $MCl_2 \cdot nH_2O$ (M = Co, Ni, n = 6; M = Cu, n = 2; M = Zn, n =0), at 25 °C. For solubility reasons, no supporting electrolyte could be added. Figure 4 shows a typical example of such a titration. Data were analyzed by Specfit[14] and factor analysis gave only two absorbing species for all the systems studied while absorbance versus metal/ligand ratios R displayed breaks at R = 1 (Figure S2, Supporting Information), so that under the experimental conditions used, only 1:1 complexes are formed, in line with the NMR spectroscopic data discussed above. The results reported in Table 3 show that the thermodynamic stability of the complexes is moderate, log K_1 being in the range 4.2−5.4 and increasing slightly with increasing charge density of the metal ions. For zinc and copper complexes, stability constants were determined both with perchlorate and chloride salts to assess the influence of the anion. Only slight differences were obtained, which lie within experimental errors. The fact that perchlorate salts were hexahydrated (M = Cu, Zn) also has to be taken into account: the presence of water molecules can interfere with the formation of the $M(ClO_4)_2L$ complexes while analogous titrations with chloride salts were performed with less hydrated salts (Cu, Zn). In contrast, much larger stability constants are reported for the 1:1 and 1:2 complexes formed with lanthanum perchlorate, e.g. 11.4 ± 1.5 (log K_1) and 19.6 ± 1.8 ($\log\beta_2$),[8c] this much larger stability can be traced back to the larger positive charge borne by the lanthanide cations.

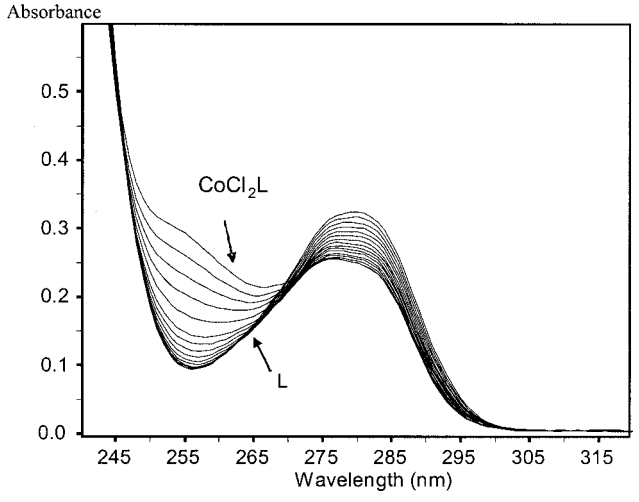

Figure 4. Variation of the absorption spectra observed during the spectrophotometric titration of [L] = 9.51 × 10^{-5} M with [$CoCl_2 \cdot 6H_2O$] = 1.01 × 10^{-3} M

Conclusion

The lower-rim phosphinoyl-substituted calix[4]arene L interacts with divalent 3d transition metal ions M^{II} (M = Co, Ni, Cu and Zn) to yield reasonably stable 1:1 complexes in ethanol. Isolated complexes also display 1:1 stoichiometry, except in the case of the Zn^{II} chloride system for which a tetrametallic species crystallizes, which could be characterized by X-ray crystallography. Both IR and ^{31}P NMR spectroscopic data show the coordination of phosphoryl groups through strong M^{II}−O=P bonds. Magnetochemical measurements and optical spectra cannot be interpreted unambiguously, but most of the reported features point to a tetrahedral arrangement of the ligands around Co^{II} (high-spin d^7), Ni^{II} and Cu^{II}. In view of the ligand conformation, tetrahedral coordination of the four phosphoryl groups can be ruled out, so that the coordination sphere of the metal ions probably contains either 1−2 water molecules and/or chloride or perchlorate ions. We note that magnetic susceptibility data are consistent with isolated and non-interacting magnetic centers, which means that if polymetallic species are also present in the isolated Co, or Ni complexes, such as those evidenced in $[Zn_2Cl_4L]_2$ (**6**), the metal−metal distances are large enough (cf. 7.8−11 Å in **6**) to prevent magnetic interaction.

Experimental Section

Solvent and Starting Materials: The ligand was obtained as described previously.[8c] The metal salts were analytically pure and purchased from Fluka AG and Aldrich. All reagents and solvents were research grade and were used without further purification.

Caution: Perchlorate salts combined with organic ligands are potentially explosive and should be handled in small quantities and with adequate precautions.[15]

Analytical and Physico-Chemical Measurements: Elemental analyses were performed by Dr H. Eder from the Microchemical Laboratory of the University of Geneva (for the determination of C and H) or by the Ilse Beetz Laboratory (96301 Kronach, Germany) for the determination of P and Cl. Atomic absorption (AAS) analyses were performed with a Perkin−Elmer 1100 B spectrometer. IR spectra were obtained from KBr pellets with a Perkin−Elmer Spectrum One FT-IR spectrometer. The ES-MS spectra were obtained with a Finnigan SSQ 710C spectrometer using a capillary tempera-

ture of 200 °C and acceleration potential of 4.5 kV. The $10^{-5}-10^{-4}$ M solutions of the free ligand or its complexes dissolved in methanol were infused in a mixture of $CH_3OH/H_2O/HCOOH$ (50:50:1, v/v) for the ligand, or pure CH_3CN for the complexes. ^1H and $^{31}P\{^1H\}$ NMR spectroscopic data ([D_6]DMSO or CD_3OD) were collected with a Bruker AVANCE 400-DRX spectrometer (400 MHz) while EPR spectra of powdered samples were measured with a Bruker B-ER 420 spectrometer. Magnetic susceptibility measurements were performed with a MPMS5 SQUID susceptometer (Quantum Design Inc.) operating at a magnetic field strength of 1 kOe. Corrections for diamagnetism were estimated from Pascal constants.[16] Effective magnetic moments were calculated as $\mu_{eff} = 2.828\ (\chi_{para}\cdot T)^{1/2}$ where χ_{para} is the molar paramagnetic susceptibility of the metal ion.

Spectrophotometric Titrations: For the titrations with chloride salts $MCl_2\cdot nH_2O$ (M = Co, Ni, n = 6; M = Cu, n = 2; M = Zn, n = 0), the electronic spectra in the UV/Vis range were recorded at 298 K with a Perkin−Elmer Lambda-7 connected to an external computer, using quartz cells of 0.100 cm path length. Solutions were prepared in a thermostatted vessel (Metrohm 6.1418.220) kept under Ar and the titrant solution was added with an automated burette from Metrohm (6.1569.150 or.210) fitted with an anti-diffusion device. In a typical experiment, 50 mL of L (10^{-4} M) was titrated with 10^{-3} M solutions of M^{II} salts. After each addition of 0.5 mL and a delay of 15 min to equilibrate the solution, the spectrum was measured and transferred to the computer. Alternatively, titrations with perchlorate salts $M(ClO_4)_2\cdot 6H_2O$ (M = Cu, Zn) were performed with a J&M diode array TIDAS II spectrometer using a thermostatted (20.0 ± 0.1 °C) glass-jacketed vessel filled with Ar. The starting volume was 25 mL and aliquots of the titrant (0.2 mL) were added using a Socorex® micropipette. The solvents used (CH_3CN, CH_2Cl_2) were of spectroscopic grade and purchased from Fluka AG (Buchs, Switzerland). Acetonitrile was dried with molecular sieves (3 Å) and the solutions were stored under argon. The metal-ion content was determined by AAS after decomposition of the samples in boiling 60% $HClO_4$, or, in the case of **5**, by complexometric titration with H_2edta^{2-} in the presence of xylenol orange and urotropine. The phosphorus content of some samples was determined spectrophotometrically using the phosphomolybdate method.[17]

Preparation of the Complexes

$CoL(ClO_4)_2\cdot 2H_2O$ (1): An ethanolic solution (1 mL) of $Co(ClO_4)_2\cdot 2H_2O$ (0.0292 g; 0.0798 mmol) was slowly added to 3 mL of a solution of L (0.1000 g; 0.0957 mmol) in EtOH (3 mL), at room temp. and under constant stirring. A light blue precipitate formed immediately. The reaction mixture was stirred for 8 h. and the precipitate was centrifuged, washed repeatedly with ethanol and dried under high vacuum over P_4O_{10} for 4 h. Yield 0.1029 g (99%). $C_{56}H_{84}Cl_2CoO_{16}P_4\cdot 2H_2O$ (1303.0): calcd. C 51.62, H 6.81, Cl 5.44, Co 4.52, P 9.51; found C 52.05, H 6.87, Cl 5.39, Co 4.59, P 9.74.

$NiL(ClO_4)_2\cdot 2\ H_2O$ (2): A solution of $Ni(ClO_4)_2\cdot 6H_2O$ (0.0292 g; 0.0797 mmol) in 1 mL of ethanol was added dropwise at constant stirring and ambient temperature to a solution of L (0.1000 g; 0.0957 mmol) in 2 mL ethanol. The reaction mixture was stirred for 10 h; the resulting, pale-yellow precipitate was centrifuged, washed repeatedly with ethanol and dried under high vacuum for 4 h. Yield 0.0888 g (85%). $C_{56}H_{84}Cl_2NiO_{16}P_4\cdot 2H_2O$ (1302.83): calcd. C 51.63, H 6.81, Cl 5.44, Ni 4.51, P 9.51; found C 51.60, H 6.80, Cl 5.59, Ni 4.18, P 9.48.

$CuL(ClO_4)_2\cdot 4H_2O$ (3): An ethanolic solution (1 mL) of $Cu(ClO_4)_2\cdot 7H_2O$ (0.0186 g; 0.0478 mmol) was slowly added to 1.5 mL of a solution of L (0.0500 g; 0.0478 mmol) in EtOH, at room temp. and under constant stirring. A lemon-yellow precipitate formed immediately. The reaction mixture was stirred for 8 h. The resulting precipitate was centrifuged, washed repeatedly with ethanol and dried under high vacuum over P_4O_{10} for 4 h. Yield 0.0513 g (82%). $C_{56}H_{84}Cl_2CuO_{16}P_4\cdot 4H_2O$ (1307.7): found C 50.06, H 6.90, Cl 5.33, P 9.25; calcd. C 49.88, H 6.55, Cl 5.28, P 9.22.

$CuLCl_2\cdot 4\ H_2O$ (4): An ethanolic solution of $CuCl_2\cdot 2H_2O$ (0.0272 g; 0.1595 mmol; 0.5 mL was added dropwise to 1 mL of an ethanolic solution of L (0.2000 g; 0.1914 mmol) at constant stirring and room temp. A few minutes after being mixed, an intensely yellow precipitate formed. The complex was centrifuged, washed repeatedly with ethanol and dried under high vacuum over P_4O_{10} for 4 h. Yield 0.1102 g (57%). $C_{56}H_{84}Cl_2CuO_8P_4\cdot 4H_2O$ (1215.7): found C 54.95, H 7.28, Cl 5.96, Cu 5.54, P 10.12; calcd. C 55.33, H 7.63, Cl 5.83, Cu 5.22, P 10.19.

$ZnL(ClO_4)_2\cdot 2H_2O$ (5): A solution of $Zn(ClO_4)_2\cdot 6H_2O$ (0.0323 g, 0.0869 mmol) in ethanol (1.2 mL) was added dropwise to a solution of L (0.1035 g, 0.0956 mmol) in ethanol (0.5 mL) at constant stirring and room temp. The prepared reaction mixture was stirred for 12 h. The white precipitate formed was separated by centrifugation and washed repeatedly with ethanol and dried under high vacuum at 60 °C for 15 h. Yield 0.1160 g (quantitative). $C_{56}H_{84}Cl_2O_{16}P_4Zn\cdot 2H_2O$ (1309.5): found C 51.67, H 6.78, Cl 5.44, P 9.46, Zn 5.05; calcd. C 51.36, H 6.77, Cl 5.44, P 9.46, Zn 4.99.

Zn_2LCl_4 (6): An ethanolic solution (1 mL) of $ZnCl_2$ (0.0237 g; 0.1739 mmol) was added dropwise to 2 mL of an ethanolic solution of L (0.2000 g; 0.1913 mmol), while stirring and the prepared mixture was stirred at room temp. for a further 10 h. The white precipitate obtained was centrifuged, washed repeatedly with ethanol and dried under high vacuum over P_4O_{10} for 30 h. Yield 0.1050 g (94%). $C_{56}H_{84}Cl_4O_8P_4Zn_2$ (1281.76): found C 52.53, H 6.77, Cl 11.16, P 9.95, Zn 10.24; calcd. C 52.48, H 6.60, Cl 11.06, P 9.66, Zn 10.20.

Crystal Structure of 6: Crystals have been obtained by slow concentration of a methanol solution of L and $ZnCl_2$ (each dissolved in 10^{-3} M). Data collection was performed at 140 K with a marresearch mar345 IPDS. Data reduction was carried out with CrysAlis RED, release 1.7.0.[18] An empirical absorption correction was applied to the data set.[19] Structure solution and refinement as well as molecular graphics and geometrical calculations were performed with the SHELXTL software package, release 5.1.[20] The structures were refined using the full-matrix least squares on F^2 with all non-H atoms anisotropically defined. H atoms were placed in calculated positions using the "riding model" (except those belonging to water molecules, which were not included in the final model) and fixing their U_{iso} to 0.08 Å^2. The crystals are triclinic, space group $P\bar{1}$, Z = 2, with a = 16.033(8) Å, b = 16.654(7) Å, c = 26.727(17) Å, α = 100.07(4)°, β = 93.18(5)°, γ = 95.07(4)°. CCDC-219688 contains the supplementary crystallographic data for this paper which can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The authors thank Assoc. Prof. Dr. Elena Russeva for her help in the determination of the phosphorus contents, Dr. Lucia Bonomo and Dr. Geoffroy Guillemot for magnetic susceptibility measurements, Dr Vittorio Esposito for a gift of *p-tert*-butylcalix[4]arene, and Dr. Natacha Guérin for collecting some of the NMR spectro-

scopic data. This work was supported through a grant from the Swiss National Science Foundation (Project SCOPES 7BUPJ062293.00/1).

Structure, Bonding, and Tyrosinase-Like Reactivity of Copper Complexes Coordinated by Mononucleating Tridentate N−O−N Type Ligands

Yen-Ting Cheng,[a] Hsiao-Lan Chen,[a] Shiou-Yuan Tsai,[a] Chan-Cheng Su,*[a] Huan-Sheng Tsang,[a] Ting-Shen Kuo,[a] Yi-Chou Tsai,[b] Fen-Ling Liao,[b] and Sue-Lein Wang[b]

Keywords: Enzyme models / N,O ligands / Copper / Oxidations

Copper complexes with mononucleating tridentate ligands of the N–O–N type, including 1,3-bis(benzimidazol-2-yl)-2-oxapropane (bbmo), 1,3-bis(*N*-methylbenzimidazol-2-yl)-2-oxapropane (bb^{Me}mo), 1,3-bis(*N*-*n*-propylbenzimidazol-2-yl)-2-oxapropane (bb^{Pr}mo), and 1,3-bis(pyrid-2-yl)-2-oxapropane (bpmo), were tested for the oxygenation of phenols. Mixed ligand copper complexes of [Cu(N–O–N)(N–N)](ClO$_4$)$_2$, where N–N denotes 2,2′-bipyridine (bipy), 1,10-phenanthroline (phen), ethylenediamine (en), and/or *N*,*N*,*N*′,*N*′-tetramethylethylenediammine (tmen), were prepared and characterized by elemental analyses, and electronic, vibrational, and epr spectroscopic measurements. The molecular structures of *fac*-[Cu(bb^{Me}mo)(bipy)(H$_2$O)](ClO$_4$)$_2$(H$_2$O) (**1a**), *fac*-[Cu(bb^{Me}mo)(phen)](ClO$_4$)$_2$(CH$_3$CN) (**4a**), *fac*-[Cu(bb^{Pr}mo)(phen)](ClO$_4$)$_2$ (**5a**), and *fac*-[Cu(bpmo)(bipy)(ClO$_4$)](ClO$_4$) (**7a**) were determined by X-ray diffraction methods. The structures of these complexes are square pyramids or elongated octahedra with the heterocycle nuclei forming the basal or equatorial planes. The terminal heterocycles of the facially coordinated tridentate ligands are nearly perpendicular to the basal or equatorial planes. Similar structures are proposed for the remaining complexes, based on spectroscopic data. Both stoichiometric and catalytic oxidation reactions of 2,4-di-*tert*-butylphenol and 2,4-di-*tert*-butylphenolate with dioxygen adducts of [Cu(bb^{Pr}mo)]$^+$ at room temperature afforded 3,3′,5,5′-tetra-*tert*-butyl-2,2′-biphenol and 3,5-di-*tert*-butyl-*o*-quinone. Similar reactions with the dioxygen adduct of [Cu(bpmo)]$^+$ yielded only 3,3′,5,5′-tetra-*tert*-butyl-2,2′-biphenol. In light of the tyrosinase-like reactivity, the possible intermediates, [(bb^{Pr}mo)$_2$Cu$_2$(μ-η^2:η^2-peroxo)]$^{2+}$, [(bb^{Pr}mo)$_2$Cu$_2$(μ-oxo)$_2$]$^{2+}$, and [(bpmo)$_2$Cu$_2$(μ-oxo)$_2$]$^{2+}$ are proposed.

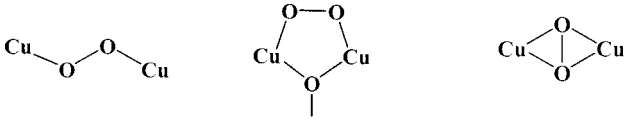
Introduction

Tyrosinase and hemocyanins represent type 3 copper proteins that have been extensively characterized.[1−3] Their dicopper active sites bind dioxygen via the redox process, 2 Cu^{I} + O$_2$ → Cu^{II}(O$_2^{2-}$)Cu^{II}, to form (μ-η^2:η^2-peroxo)dicopper(II) units.[4] The formation of (μ-η^2:η^2-peroxo)dicopper(II) cores is likely governed by enclosure by the bulky protein residues and by the bonding capability of the three-coordinated imidazoles of the histidine residues to each copper. These peroxo units may be further involved in O$_2$ activation, via the *o*-hydroxylation of the phenol of tyrosine by tyrosinase, or take the reverse process, functioning as O$_2$ carriers in hemocyanins. To date some well-characterized peroxodicopper(II) complexes have been reported involving ligands with heterocycles other than imidazole,[5−8] or even without heterocycles.[9−14] Although these complexes are generally not stable at room temperature in contrast to their biological counterparts, they can be used as models to mimic the structures and/or functions of the active centers of the native systems. Among the three classes of synthetic peroxodicopper(II) complexes shown in Scheme 1,[15] μ-η^2:η^2-peroxodicopper(II) behaves differently from the other two and has a nonbasic or electrophilic reactivity.[16−18] Depending on the specific ligand, steric bulk, counterion, and solvent effects, μ-η^2:η^2-peroxodicopper(II) complexes have been shown to be in equilibrium with the isoelectronic bis(μ-oxo)dicopper(III) species.[11,19−23] Their substrate reactivities are different. The μ-η^2:η^2-peroxodicopper(II) favors oxygen atom transfer reactions,[18] while the bis(μ-oxo)dicopper(III) prefers hydrogen atom abstraction.[24] The oxidation reactions of phenolates with μ-η^2:η^2-peroxodicop-



trans-μ-1,2-peroxo *cis*-1,2-peroxo μ-η^2 : η^2-peroxo

per(II) mainly afford catechols and *o*-quinones,[25] whereas similar reactions of phenols with bis(μ-oxo)dicopper(III) give rise to biphenols.[26]

In this report we describe the structures and substrate reactivity of a class of copper complexes coordinated by mononucleating tridentate ligands of N−O−N type, including 1,3-bis(benzimidazol-2-yl)-2-oxapropane (bbmo), 1,3-bis(*N*-methylbenzimidazol-2-yl)-2-oxapropane ($bb^{Me}mo$), 1,3-bis(*N*-*n*-propylbenzimidazol-2-yl)-2-oxapropane ($bb^{Pr}mo$), and 1,3-bis(pyrid-2-yl)-2-oxapropane (bpmo). The oxidation reactions of 2,4-di-*tert*-butylphenol and 2,4-di-*tert*-butylphenolate with dioxygen in the presence of stoichiometric or catalytic amounts of $[Cu(bb^{Pr}mo)]^+$ or $[Cu(bpmo)]^+$ at room temperature resulted in the generation of 3,3′,5,5′-tetra-*tert*-butyl-2,2′-biphenol and/or 3,5-di-*tert*-butyl-*o*-quinone, inferring the formation of bis(μ-oxo)dicopper(III) and/or (μ-η^2:η^2-peroxo)dicopper(II) intermediates during the reactions. The purpose of this report is to elucidate the conformation and coordination properties of the N−O−N tridentate ligands in order to reveal their roles in the peroxodicopper(II)/bis(μ-oxo)dicopper(III) equilibrium and substrate reactivity.

Results and Discussion

Synthesis of Complexes

The mixed-ligand complexes, $[Cu(bbmo)(LL)]^{2+}$, $[Cu(bb^{Me}mo)(LL)]^{2+}$, $[Cu(bb^{Pr}mo)(LL)]^{2+}$, and $[Cu(bpmo)(LL)]^{2+}$ (LL = phen and/or bipy), were prepared by the addition of one equivalent of the bidentate ligand, phen or bipy, to a 1:1 mixture of Cu^{II} perchlorate and the tridentate ligand, bbmo, $bb^{Me}mo$, $bb^{Pr}mo$, or bpmo. Attempts to prepare the 1:1 complexes, $[Cu(N-O-N)]^{2+}$, by mixing equivalent amounts of the ligands and copper perchlorate were unsuccessful. Instead, the 1:2 complexes, $[Cu(N-O-N)_2]^{2+}$, were isolated. In the case of the en and tmen complexes, only $[Cu(bb^{Pr}mo)(en)](ClO_4)_2$ (**6**) and $[Cu(bpmo)(tmen)](ClO_4)_2$ (**9**) complexes were isolated in pure form. As evidenced from X-ray structure results (vide infra) and spectroscopic studies, the tridentate ligands bond to the central Cu^{II} ion in a facial conformation for all of the mixed ligand complexes, in agreement with the usual findings that the strong benzimidazole and pyridine donors tend to bind at the equatorial positions and the weak ether oxygen at the axial site for the Cu^{II} complexes.

X-ray Structures

fac-$[Cu(bb^{Me}mo)(bipy)(H_2O)](ClO_4)_2(H_2O)$ (1a), *fac*-$[Cu(bb^{Me}mo)(phen)](ClO_4)_2(CH_3CN)$ (4a), and *fac*-$[Cu(bb^{Pr}mo)(phen)](ClO_4)_2$ (5a)

The molecular structures of mixed ligand complexes **1a**, **4a**, and **5a** are shown in Figures 1, 2, and 3, respectively. Selected bond lengths and angles are listed in Table 1. These complexes are composed of discrete copper complex cations, perchlorate anions, and/or solvent molecules. In the case of complex **1a**, the copper cation binds a H_2O molecule at the axial site to complete an elongated octahedron, with the copper slightly above the equatorial plane, inclined toward the H_2O. The deviations from the best equatorial plane of CuN_4 are Cu(1) +0.1709 Å, N(1) −0.1320 Å, N(2) +0.0499 Å, N(3) −0.1298 Å, and N(5) +0.0411 Å. The structures of the complex cations of **4a** and **5a** are square pyramidal [τ = 0.162 (**4a**); τ = 0.017 (**5a**)], because the perchlorate ions are too far away from the central copper ions. The deviations from the best basal plane of CuN_4 are Cu(1) +0.0467 Å, N(1) −0.0358 Å, N(2) +0.0136 Å, N(3) −0.0351 Å, and N(5) +0.0106 Å for **4a**, Cu(1) +0.0101 Å, N(1) −0.0087 Å, N(2) +0.0039 Å, N(3) −0.0084 Å, and N(5) +0.0032 Å for **5a**. The complex cations contain a facial $bb^{Me}mo$ or $bb^{Pr}mo$, with an elongated axial Cu−O of 2.570(4) Å for **1a**, 2.520(3) Å for **4a**, and 2.527(4) Å for **5a**. The fact that these axial Cu−O distances are significantly shorter than the corresponding axial Cu−N of 2.597(6) Å for the *trans*-*fac*-$[Cu(bbmn)_2](ClO_4)_2(H_2O)_2$ complex[27] (bbmn = 1,3-bis(benzimidazol-2-yl)-2-azapropane) is unexpected. The mean Cu−N distances and the intraligand ∠N−Cu−N angles of the tridentate ligands are 1.984±0.004 Å and 91.6(2)° for **1a**, 1.981±0.004 Å and 89.8(1)° for **4a**, and 1.995±0.006 Å and 88.1(2)° for **5a**. The mean bite angles of the five-member chelates of the tridentate ligands are 73.3±0.3° for **1a**, 75.6±0.2° for **4a**, and 75.6±0.2° for **5a**. The benzimidazole nuclei of these complexes lie nearly perpendicular to the CuN_4 basal or equatorial plane, with dihedral angles of 94.6° and 111.7° for **1a**, 89.4° and 105.9° for **4a**, and 86.5° and 93.5° for **5a**. All these geometric figures are analogous to those reported for *trans*-*fac*-$[Cu(bbmn)_2](ClO_4)_2(H_2O)_2$[27] (mean Cu−N of 2.010±0.008 Å; intraligand ∠N−Cu−N of 88.1°; mean bite angle of the five-member chelates ∠N−Cu−N of 74.9±0.4°), suggesting that the coordination capabilities of

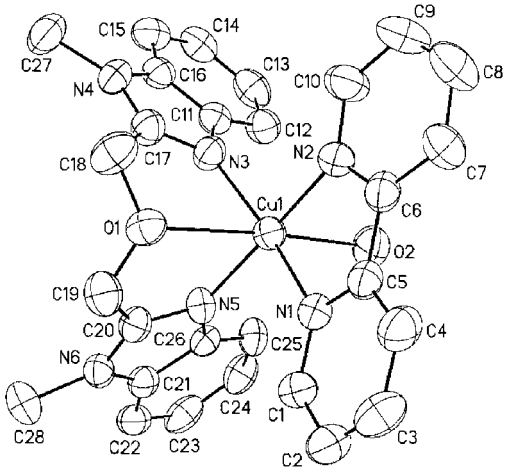

Figure 1. ORTEP diagram of *fac*-$[Cu(bb^{Me}mo)(bipy)(H_2O)](ClO_4)_2(H_2O)$ (**1a**); perchlorates, H_2O, and hydrogen atoms have been omitted for clarity

the tridentate ligands of these mixed ligand complexes are similar.

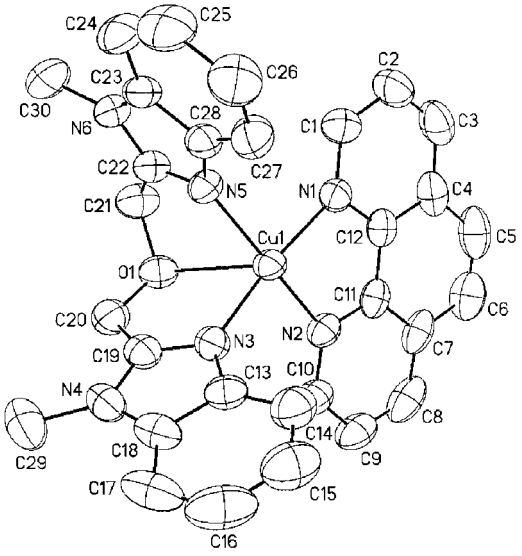

Figure 2. ORTEP diagram of *fac*-[Cu(bb^{Me}mo)(phen)]-$(ClO_4)_2(CH_3CN)$ (**4a**); perchlorates, CH_3CN, and hydrogen atoms have been omitted for clarity

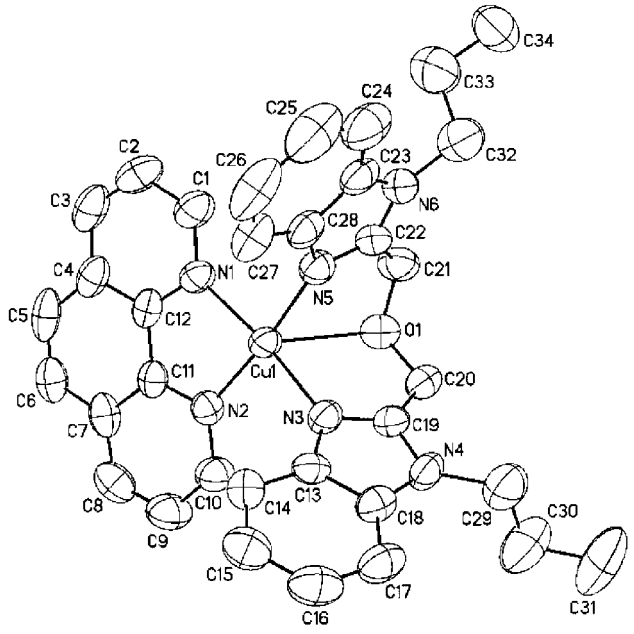

Figure 3. ORTEP diagram of *fac*-[Cu(bb^{Pr}mo)(phen)]$(ClO_4)_2$ (**5a**); perchlorates and hydrogen atoms have been omitted for clarity

It is interesting to note that the mean Cu−N bond lengths of 2.010±0.016 Å and the bite angles of 81.3±0.5° for the diimine ligands of these three complexes are also very similar, indicative of similar bonding abilities of the diimine ligands. Although the thermal vibrations are somewhat large for some oxygen atoms of the perchlorates, the bond lengths and angles of these complexes are in the normal ranges.[27−29] The largest difference peaks of 1.108 for **1a** and 1.281 for **5a** appear near the Cl(1) atom for **1a** and Cl(2) for **5a**, respectively.

fac-[Cu(bpmo)(bipy)(ClO_4)](ClO_4) (7a)

The molecular structure of **7a** is shown in Figure 4. Selected bond lengths and angles are listed in Table 1. The discrete elongated octahedral copper(II) complex cation comprises a facial bpmo, an equatorial bipy, and a perchlorate anion at the axial site. The deviations from the best equatorial plane of CuN_4 are Cu(1) +0.088 Å, N(1) −0.012 Å, N(2) −0.033 Å, N(3) −0.010 Å, and N(4) −0.033 Å. The facial bpmo has a mean Cu−N distance of 2.030±0.002 Å,

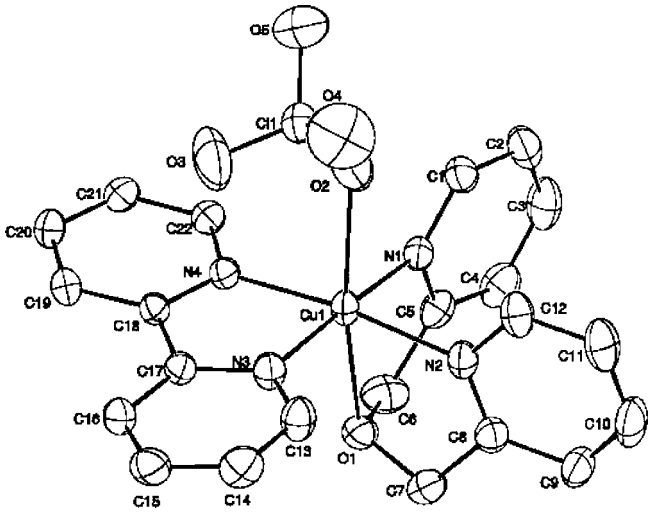

Figure 4. ORTEP diagram of *fac*-[Cu(bpmo)(bipy)(ClO_4)](ClO_4) (**7a**); one perchlorate and hydrogen atoms have been omitted for clarity

which is slightly longer than that of complex **1a** of 1.984±0.004 Å. However, the axial Cu−O of 2.323(4) Å of the bpmo is shorter than that of complex **1a** of 2.570(4) Å. It is likely that the bonding ability of the pyridine nucleus in bpmo is weaker than that of the benzimidazole nucleus.

[a] X-band EPR spectra measured at room temperature for powder samples, and at 77 K for glass. Hyperfine coupling constants in 10^{-4} cm^{-1}. [b] N′ denotes the second nitrogen. [c] Rhombic powder spestrum with g_y and g_x. [d] Not observed.

The pyridine nuclei of the bpmo lie nearly perpendicular to the CuN_4 equatorial plane, with dihedral angles of 89.6° and 92.9°. A comparison of the mean Cu−N bond lengths of bipy of 1.999±0.005 Å for **7a** with that of 2.010±0.016 Å for complex **1a** suggests that the bonding capability of the bipy is nearly equal in these two complexes. The bond lengths and angles of complex **7a** are in the normal ranges.

Spectroscopic Studies

Selected i.r. data are listed in the Experimental section. In the 3500 cm^{-1} region, broad O−H stretching absorption peaks appear for some of the complexes, suggesting the presence of H_2O. Two characteristic N−H stretching peaks at 3345 and 3283 cm^{-1} indicate the en ligand in (**6**). There are some characteristic vibration absorptions for the heterocycle nuclei including the C=N and C=C stretching at ca.1600 to 1480 cm^{-1}, aromatic C−H bending at ca. 740 cm^{-1}, and ring deformation at ca. 430 cm^{-1}. It is generally useful to account for the coordination of the perchlorate by counting the number of very strong ν(Cl−O) at ca. 1100 cm^{-1}. However, care must be exercised in elucidating the complexes with N−O−N tridentate ligands, because of the interference by the strong ν(C−O) peaks in the same region. For some complexes, the Cu−N stretching peaks in the ca. 300 cm^{-1} region are tentatively assigned.

Table 2 lists e.p.r. spectroscopic data of the compounds. The powder e.p.r. spectra of the axial or axial rhombic types of these complexes are consistent with square pyramidal and tetragonal structures and indicative of a $d_{x^2-y^2}$ or d_{xy} ground state.[30−31] For the glass spectra in dmf, CH_3OH/CH_3CN, or CH_3CN matrices, characteristic superhyperfine splittings were observed for all of the complexes. The g_z values are larger in dmf glass than in CH_3OH/CH_3CN or CH_3CN matrices, while the reverse is true for the A_z values. It is likely that the coordination of the axial ether oxygen of the tridentate ligand is replaced by the dmf molecule, consistent with the UV/Vis spectroscopic data (vide infra), and that the basal or equatorial plane is also slightly distorted toward a tetrahedron.[32]

Electronic spectroscopic data for the tridentate complexes are shown in Table 3. The reflectance LF spectra of the mixed-ligand complexes exhibit similar envelopes with a main peak at ca. 524 nm to ca. 710 nm and a pronounced shoulder or small peak on the low energy side of ca. 900 nm extending to ca. 1200 nm. In CH_3OH/CH_3CN or CH_3CN solution, these complexes show a peak at ca. 560 nm to ca. 610 nm with a shoulder at ca. 900 nm extending to 1200 nm, suggesting that the structures of the dissolved complexes are either square pyramidal or tetragonal, as are their solid counter species. The LF band maxima suggest that the bonding strengths of the N-donor ligands are consistent with their σ-donating capabilities, namely, amines are stronger than imines. However, it is noteworthy that the d-d bands (reflectance and acetonitrile solution) appear in general at higher energy region for bpmo complexes than the corresponding $bb^{R}mo$ (R = Pr, Me, and H) complexes. Because pyridine and benzimidazole have comparable basicities, the differences in the ligand field spectra are attribu-

table to the π-interactions between the copper d_π orbitals and the π orbitals of the heterocycles of the tridentate ligands.

The intraligand transitions for the N−O−N tridentate ligands are assigned in the ca. 245 nm to ca. 290 nm region. There are essentially no shifts of the π→π* transition peaks of the tridentate ligands for the en and tmen complexes as compared with those of the corresponding free ligand molecules. Despite some interference due to the diimine ligands, blue shifts of the π→π* transition peaks of the tridentate ligands were observed for the mixed-ligand bipy complexes, indicative of π interactions involved in the coordination bonds between the central copper and the heterocycles of the tridentate ligands.

While dissolving these complexes in dmf, the blue solution gradually turned green. The LF bands at ca. 600 nm were red-shifted by ca. 30 nm to ca. 40 nm, but not the low energy peak or shoulder. New CT bands were observed in the 300 nm region. These spectral changes indicate that the central ether oxygen atoms of the tridentate ligands are replaced by the dmf molecules, in agreement with the e.p.r. data (vide supra).

Oxidation of Phenols or Phenolates

The results of stoichiometric and catalytic oxidation reactions of DBP and phenolates, DBP−NEt_3, are summarized in Table 4. It is obvious that the N−O−N tridentate ligands are indispensable for the oxidation reactions, since no oxidized products were observed for the reactions of DBP with $[Cu(CH_3CN)_4]^+$ (entries 5 and 10).

In the stoichiometric reactions, both TBBP (3,3′,5,5′-tetra-*tert*-butyl-2,2′-biphenol) and DBQ (3,5-di-*tert*-butyl-*o*-quinone) were produced in nearly equal amounts for the reactions of DBP, and DBP−NEt_3 as well, with Cu(bb^{Pr}mo)−O_2 adduct in CH_2Cl_2 at 25 °C (entries 1 and 2). Although mechanistic studies[16−18] have indicated that the aromatic ligand hydroxylation involves an electrophilic attack on the arene ring by (μ-η^2:η^2-peroxo)dicopper(II) intermediate, most of the reported studies on the intermolecular oxidations of DBP with peroxo intermediate report TBBP as a major product.[15,23,33−35] Our results with high DBQ generation are in reasonably good agreement with the mechanistic studies, inferring the formation of (μ-η^2:η^2-peroxo)dicopper(II) and bis(μ-oxo)dicopper(III) intermediates supported by bb^{Pr}mo during the reactions. The reactions of DBP, and also DBP-NEt_3, with the Cu(bpmo)-O_2 adduct in CH_2Cl_2 at 25 °C (entries 3 and 4), however, generate only TBBP, implying the presence of a bis(μ-oxo)dicopper(III) intermediate. These reactions can also be carried out under catalytic conditions (entries 6−9). The catalytic reactions require a much longer reaction time (3 to 14 days), due to

[a] The dioxygen adducts for the stoichiometric reactions were prepared by the reaction of O_2 with a solution of equimolar Cu^I and N−O−N at room temperature for 24 h. [b] DBP = 2,4-di-*tert*-butylphenol. DBP−NEt_3 = DBP/NEt_3 (1:1). [c] Isolated yield. TBBP = 3,3′,5,5′-tetra-*tert*-butyl-2,2′-biphenol. [d] Isolated yield. DBQ = 3,5-di-*tert*-butyl-*o*-quinone. [e] Recovered DBP. [f] Molar ratio of Substrate/Cu(N−O−N) = 1:1. The reactions were carried out in CH_2Cl_2 at 25 °C for 24 h. [g] Molar ratio of Substrate/Cu(N−O−N) = 1:0.01. The reactions were carried out in CH_2Cl_2 at 25 °C. [h] 14 days. [i] 3 days. [j] Not measured.

the small amount (one hundredth) of the copper catalyst employed, and the turn over numbers are in the order of 10^3.

The oxygenation reactions of phenolates to catechols by $[(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)Cu_2(L\text{-}66)]$[36−39] {L-66 = α,α′-bis{bis[2-(1-methyl-2-benzimidazolyl)ethyl]amino}-*m*-xylene} and by $[(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)Cu_2(L^{Py2Bz})_2]$[40] {$L^{Py2Bz}$ = *N*,*N*-bis[2-(2-pyridyl)ethyl]-α,α-dideuteriobenzylamine} have been demonstrated. The oxidation of 4MP-Li (lithium 4-methylphenolate) with Cu($bb^{Pr}mo$)−O_2 adduct afforded 3,5-di-*tert*-butyl-1,2-catechol in 37% isolated yield further assuring that the adduct is mainly ($\mu\text{-}\eta^2\text{:}\eta^2$-peroxo)dicopper(II). It is noteworthy that the copper complex with the mononucleating ligand, L-6 {*N*,*N*-bis[2-(1-methyl-2-benzimidazolyl)-ethyl]amine},[37] is inactive in the monooxygenase reaction. The reactivity with respect to oxygenation can be attributed to the conformations of the coordinated tridentate ligands. The L-6 ligand tends to coordinate to copper(II) in a meridional fashion, while N−O−N ligands, bb^Rmo and bpmo, should assume a facial conformation. Accordingly, it would be proper for $[Cu(N-O-N)]^+$ to accommodate a side-on O_2, but not $[Cu(L\text{-}6)]^+$.

Conclusion

The oxygenation reactions of DBP (2,4-di-*tert*-butylphenol) and DBP−NEt_3 (2,4-di-*tert*-butylphenolate) with the Cu($bb^{Pr}mo$)−O_2 adduct give rise to the production of DBTQ (3,5-di-*tert*-butyl-*o*-quinone). The same reaction of 4MP-Li (lithium 4-methylphenolate) produces 4-methyl-1,2-catechol. These tyrosinase-like reactions infer strongly the presence of $\mu\text{-}\eta^2\text{:}\eta^2$-peroxodicopper(II) intermediate supported by $bb^{Pr}mo$. The intermediate coordinated by $bb^{Pr}mo$ having a facial conformation is likely stabilized by π-interactions of the two perpendicularly oriented terminal benzimidazole nuclei, and tends to become stable at room temperature. Further investigation on π-interactions is currently in progress.

Experimental Section

General Remarks: Electronic spectra were recorded on a Hitachi U-3501 spectrophotometer equipped with an integrating sphere for reflectance measurements. IR spectra were recorded as Nujol mulls on a BIO-RAD FTS-40 FTIR spectrometer and a JASCO FT/IR 700 spectrometer. Nuclear magnetic resonance (NMR) spectra were recorded with Varian Gemini 2000 (200 MHz) and Bruker AV-400 (400 MHz) spectrometers. EPR spectra were obtained by using a Bruker EMX 10 spectrometer. The EPR simulations were performed using WINEPR SimFonia program. Mass spectra were acquired on a Finnigan TSQ 700 spectrometer. Elemental analyses were carried out by the microanalysis laboratories of National Chung-Hsin University, Taichung, Taiwan.

Preparation of Ligands

bbmo (L1):[41] Diglycolic acid (6.05 g, 45 mmol) and *o*-phenylenediamine (9.75 g, 90 mmol) in 4 N HCl solution (250 mL) were refluxed for 14 h. After cooling to room temperature, the precipitates were filtered and then dissolved in hot H_2O. The aqueous solution was neutralized with conc. NH_4OH. The precipitates were filtered and dissolved in CH_3OH and treated with activated carbon to afford white products. Yield 72%. mp, 280 °C. MS (EI): *m*/*z* = 279 [M + 1] (100). ^1H NMR (200 MHz [D_6]DMSO): δ = 4.87 (s, 4 H, CH_2), 7.23−7.17 (m, 4 H, benzimidazolyl-5,6-*H*), 7.59−7.54 (m, 4 H, benzimidazolyl-4,7-*H*) ppm. {^1H NMR, ([D_6]DMSO): δ = 4.95 (s, 4 H), 7.3 (m, 4 H), 7.7 (m, 4 H) ppm[42]}; {^1H NMR (CD_3OD): δ = 4.95 (s, 4 H), 7.15 (m, 4 H), 7.7 (m, 4 H) ppm[41]}. IR (cm^{-1}): ν(C=C, C=N) 1623 mw, 1587 mw, 1533 mw, 1465 s, ν(C−O) 1102 s, 1039 m, δ(CH, bim) 768 m, 748 s, δ(bim) 434 mw.

$bb^{Me}mo$ (L2): This compound was prepared similarly as bbmo but using *N*-methyl-*o*-phenylenediamine. Yield 65%. mp, 174 °C. MS (FAB^+): *m*/*z* = 307 [M + 1] (40). ^1H NMR (400 MHz, $CDCl_3$): δ = 3.81 (s, 6 H, CH_3), 4.93 (s, 4 H, CH_2), 7.34−7.28 (m, 4 H, benzimidazolyl-5,6-*H*), 7.77−7.75 (m, 4 H, benzimidazolyl-4,7-*H*) ppm. IR (cm^{-1}): ν(C=C, C=N) 1615 mw, 1506 w, 1475 s, ν(C−O) 1081 s, 1021 m, δ(CH, bim) 771 ms, 756 s, 747 s, δ(bim) 411 w.

$bb^{Pr}mo$ (L3):[43] Powdered KOH (1.40 g, 25 mmol) was added to a stirred suspension of 1,3-bis(benzimidazol-2-yl)-2-oxapropane (1.39 g, 5 mmol) in acetone (10 mL). After 20 min, iodopropane (1.70 g, 10 mmol) of was added to the white cloudy reaction mixture. After stirring at room temperature for 2 h, the orange reaction mixture was transferred to a separating funnel containing benzene (100 mL). The organic layer was washed with water (1 × 20 mL) and saturated sodium chloride solution (20 mL) and was dried with $MgSO_4$ (5 g). The filtered organic solution was rotary evaporated and then added with diethyl ether to give white precipitates. Yield 70%. Mp, 79 °C. MS (FAB^+): *m*/*z* = 363 [M + 1] (100). ^1H NMR (400 MHz, [D_6]DMSO): δ = 0.79 (t, *J* = 7 Hz, 3 H, CH_3), 1.69 (h, *J* = 7 Hz, 2 H, CH_2), 4.20 (t, *J* = 7 Hz, 2 H, CH_2), 4.87 (s, 4 H, CH_2), 7.22−7.17 (m, 4 H, benzimidazolyl-5,6-*H*), 7.59−7.54 (m, 4 H, benzimidazolyl-4,7-*H*) ppm. IR (cm^{-1}): ν(C=C, C=N) 1667 s, 1614 s, 1515 ms, ν(C−O) 1089 s, 1007 s, δ(CH, bim) 743 s, δ(bim) 434 mw.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bpmo (L4):[44] 2-(Hydroxymethyl)pyridine (2.89 g, 25.9 mmol) was added to a solution of NaH (60%, 2.10 g, 52.5 mmol) in DMF (75 mL). The solution was stirred at 40 °C for 2 h and then cooled to room temperature. 2-(Bromomethyl)pyridine hydrobromide (6.48 g, 25.6 mmol) was added to a DMF solution (50 mL) of NaH (60%, 1.35 g, 33.7 mmol), and stirred at room temperature for 2 h. The solutions were mixed, heated at 70 °C for 2 h, and then quenched by adding H_2O (10 mL). Both H_2O and DMF were removed by vacuum distillation. The residue was dissolved in H_2O (100 mL) and extracted with diethyl ether (2 × 100 mL). The organic extract was rotary evaporated to give yellow products. Yield 22%. MS (FAB^+): *m/z* = 201.06 [M + 1] (100). ^1H NMR (400 MHz, $CDCl_3$): δ = 4.81 (s, 4 H, C*H*$_2$), 7.22 (t, *J* = 7 Hz, 2 H, pyridyl-4-*H*), 7.55 (d, *J* = 8 Hz, 2 H, pyridyl-3-*H*), 7.74 (t, *J* = 7 Hz, 2 H, pyridyl-5-*H*), 8.58 (d, *J* = 4 Hz, 2 H, pyridyl-6-*H*) ppm. IR (cm^{-1}): ν(C=C, C=N) 1634 m, 1591 s, ν(C−O) 1117 s, δ(CH, py) 755 s, δ(py) 425 mw.

Preparation of Complexes

[Cu(bb^{Me}mo)(bipy)](ClO$_4$)$_2$ (1): To a stirred CH_3OH solution (5 mL) of $Cu(ClO_4)_2·6H_2O$ (741 mg, 2 mmol), a solution of bb^{Me}mo (612 mg, 2 mmol) in CH_3OH (10 mL) was added. After reaction at room temperature for 2 h, a solution of bipy (313 mg, 2 mmol) in CH_3OH (10 mL) was added dropwise to the cloudy green solution and the reaction solution was stirred for another 2 h. The blue products were filtered and dried under vacuum. Yield 90%. M.p. 246 °C (dec.); found C 46.71, H 3.37, N 11.20. $C_{28}H_{26}Cl_2CuN_6O_9$: calcd. C 46.39, H 3.61, N 11.59%. IR (cm^{-1}): ν(C=C, C=N) 1605 m, 1508 s, 1500 s, ν(ClO_4^-) 1094 vs br., 623 s, ν(C−O) 1048 s, 1033 s, δ(CH, bipy) 784 ms, δ(CH, bim) 772 ms, 763 ms, 753 ms, δ(bim) 432 w, ν(Cu−N) 345 w, 304 mw, 282 mw. The purple crystals, *fac*-[Cu(bb^{Me}mo)(bipy)(H_2O)](ClO$_4$)$_2$(H_2O) (**1a**), suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether to a dmf solution.

[Cu(bb^{Pr}mo)(bipy)](ClO$_4$)$_2$(H_2O) (2): This blue complex was prepared similarly as the previous complex but using bb^{Pr}mo and was recrystallized from CH_3CN and diethyl ether. Yield 42%. M.p. 240 °C (dec.); found C 48.05, H 4.22, N 10.80. $C_{32}H_{36}Cl_2CuN_6O_{10}$: calcd. C 48.10, H 4.54, N 10.52%. IR (cm^{-1}): ν(O−H) 3562 m br., ν(C=C, C=N) 1610 s, 1605 s, 1567 m, 1503 s, 1495 s, ν(ClO_4^-) 1081 vs br., 623 s, δ(CH, bipy) 767 s br., δ(CH, bim) 730 s, δ(bim) 438 w, δ(bipy) 415w.

[Cu(bbmo)(bipy)](ClO$_4$)$_2$(CH_3CN)$_{0.5}$ (3): This blue complex was prepared similarly as the previous complex but using bbmo and was recrystallized from CH_3CN/CH_3OH (1:1) and diethyl ether. Yield 81%. M.p. 234 °C (dec.); found C 45.08, H 3.15, N 12.60. $C_{27}H_{23.5}Cl_2CuN_{6.5}O_9$: calcd. C 45.19, H 3.28, N 12.69% IR (cm^{-1}): ν(N−H) 3274 m br., ν(C=C, C=N) 1612 m, 1603 m, 1540 w, 1498 m, ν(ClO_4^-) 1093 vs br., 622 s, δ(CH, bipy) 770 ms, δ(CH, bim) 752 s, 743 s, δ(bim) 431 w, ν(Cu−N) 330 w, 304 w, 292 mw, 282 mw.

[Cu(bb^{Me}mo)(phen)](ClO$_4$)$_2$(H_2O)$_3$ (4): This blue complex was prepared similarly as the previous complex but using bb^{Me}mo and phen. Yield 90%. M.p. 232 °C (dec.); found C 45.17, H 3.87, N 10.42. $C_{30}H_{32}Cl_2CuN_6O_{12}$: calcd. C 44.87, H 4.01, N 10.46%. IR (cm^{-1}): ν(OH) 3625w br, 3400w br, ν(C=C, C=N) 1610 mw, 1591 mw, 1542 mw, 1508 m, ν(ClO_4^-) 1091 vs br., 624 s, ν(C−O) 1044 m sh, 1012 mw, δ(CH, phen) 852 ms, δ(CH, bim) 757 s, 750 ms, 745 ms, δ(bim) 432 mw, ν(Cu−N) 341 mw, 312 mw, 282 mw. The blue crystals, *fac*-[Cu(bb^{Me}mo)(phen)](ClO$_4$)$_2$(CH_3CN) (4**a**), suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether to an acetonitrile solution.

[Cu(bb^{Pr}mo)(phen)](ClO$_4$)$_2$(H_2O)$_2$ (5): This green complex was prepared similarly as the previous complex but using bb^{Pr}mo. Yield 51%. M.p. 242 °C (dec.); found C 48.33, H 4.16, N 10.35. $C_{34}H_{38}Cl_2CuN_6O_{11}$: calcd. C 48.55, H 4.55, N 9.99%. The purple crystals, *fac*-[Cu(bb^{Pr}mo)(phen)](ClO$_4$)$_2$ (**5a**), suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether to a dmf solution.

[Cu(bb^{Pr}mo)(en)](ClO$_4$)$_2$ (6): This purple complex was prepared similarly as the previous complex but using bb^{Pr}mo and en. Yield 55%. M.p. 226 °C (dec.); found C 42.04, H 5.02, N 11.95. $C_{24}H_{34}Cl_2CuN_6O_9$: calcd. C 42.08, H 5.00, N 12.27%. IR (cm^{-1}): ν(NH) 3345 ms, 3283 ms, ν(C=C, C=N) 1611 m, 1594 s, 1503 s, 1496 s, ν(ClO_4^-) 1107 vs br., 626 s, ν(C−O) 1035 s sh, 1050 s, δ(CH, bim) 800 m, 765 s, 705 m, δ(bim) 435 mw.

[Cu(bpmo)(bipy)](ClO$_4$)$_2$(H_2O)$_{0.5}$ (7): This blue complex was prepared similarly as the previous complex but using bpmo and bipy. Yield 75%. M.p. 206 °C (dec.); found C 41.76, H 2.99, N 8.96. $C_{22}H_{21}Cl_2CuN_4O_{9.5}$ calcd. C 42.09, H 3.37, N 8.92%. IR (cm^{-1}): ν(OH) 3442 ms br., ν(C=C, C=N) 1606 s, 1573 m, ν(ClO_4^-) 1098 vs br., 623 s, ν(C−O) 1030 s, 985 m, δ(CH, bipy) 775 s, δ(CH, py) 765 s sh, 730 s, δ(py) 420 mw. The blue crystals, *fac*-[Cu(bpmo)(bipy)(ClO$_4$)](ClO$_4$) (**7a**), suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether to an acetonitrile solution.

[Cu(bpmo)(phen)](ClO$_4$)$_2$(H_2O)$_{0.5}$ (8): This blue complex was prepared similarly as the previous complex but using bpmo and phen. Yield 74%. M.p. 201 °C (dec.); found C 44.11, H 3.34, N 8.25. $C_{24}H_{21}Cl_2CuN_4O_{9.5}$ calcd. C 44.22, H 3.24, N 8.59%. IR (cm^{-1}): ν(OH) 3600 w br., 3445 w br., ν(C=C, C=N) 1633 m, 1608 ms, 1586 m, 1520 ms, ν(ClO_4^-) 1092 vs br., 623 s, ν(C−O) 1052 m, 1008 w, δ(CH, phen) 853 ms, δ(CH, py) 782 m, 762 ms, δ(py) 434 mw.

[Cu(bpmo)(tmen)](ClO$_4$)$_2$ (9): This purple complex was prepared similarly as the previous complex but using bpmo and tmen. Yield 38%. M.p. 78 °C; found C 37.70, H 5.03, N 10.13. $C_{18}H_{28}Cl_2CuN_4O_9Cl_2$: calcd. C 37.35, H 4.84, N 9.68%. IR (cm^{-1}): ν(C=C, C=N) 1609 m, 1573 w, ν(ClO_4^-) 1093 vs br., 623 s, ν(C−O) 1164 m, δ(CH, py) 770 s, δ(py) 424 w.

Oxidation of Phenol or Phenolate with Peroxodicopper(II) and/or Bis(μ-oxo)dicopper(III): The μ-η^2:η^2-peroxodicopper(II) and/or bis(μ-oxo)dicopper(III) intermediates were generated by the reaction of [Cu(CH_3CN)$_4$](ClO$_4$) (185 mg, 0.56 mmol) and tridentate ligand (0.56 mmol) in CH_2Cl_2/CH_3CN (8:2, 10 mL) with O_2 at room temperature overnight. After removal of excess O_2 by bubbling N_2 gas into the solution for 15 min, a solution of DBP (117 mg, 0.56 mmol) with or without NEt_3 (0.56 mmol) in CH_2Cl_2 (5 mL) was added into the solution by cannulation. The mixture was stirred under N_2 at room temperature for 24 h. After evaporation of the solvent, the residue formed was columned on silica gel (ethyl acetate/hexane, 1:8), affording 3,3′,5,5′-tetra-*tert*-butyl-2,2′-biphenol, 3,5-di-*tert*-butyl-*o*-quinone, and the starting 2,4-di-*tert*-butylphenol. The oxygenation of 4MP-Li (lithium 4-methylphenolate) was carried out similarly in acetone, yielding 4-methylcatechol.[40]

Catalytic Oxidation of 2,4-Di-*tert*-butylphenol (DBP) or 2,4-Di-*tert*-butylphenolate (DBP-NEt$_3$) in the Presence of Copper(I) Complexes of bb^{Pr}mo or bpmo: A CH_2Cl_2 solution (10 mL) of 2,4-di-*tert*-butylphenol (1.65 g, 7.98 mmol) with or without NEt_3 (7.98 mmol)

was added to a mixture of $[Cu(CH_3CN)_4](ClO_4)$ (26.1 mg, 0.0798 mmol) and tridentate ligand (0.0798 mmol) in CH_2Cl_2/CH_3CN (8:2, 10 mL) under N_2. The reaction solution was stirred under an O_2 atmosphere at room temperature and was monitored by checking the UV/Vis absorption in the region of 300 nm to 800 nm. After the absorption peaks stopped growing, the reaction mixture was worked up as described above, yielding 3,3′,5,5′-tetra-*tert*-butyl-2,2′-biphenol, and/or 3,5-di-*tert*-butyl-*o*-quinone.

X-ray Crystallographic Study: Details of crystal data and intensity collection are summarized in Table 5, using Siemens Smart-CCD or Bruker−Kappa CCD diffractometers. Intensity data [θ/2θ scan] were collected at ca. 298 K and corrected for Lorentz and polarization effects and absorption. The structures were solved by direct methods using the SIR92 for (**7a**) and SHELXS-97 for the rest. The hydrogen atoms included in the refinement were located in succeeding difference Fourier syntheses or with ideal positions after the non-hydrogen atoms were refined anisotropically. CCDC-217573 to -217576 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

COVER PICTURE

The cover picture shows the successful cooperation between biotechnology, main-group chemistry and organometallic chemistry to generate a highly enantioselective diphosphane ligand for homogeneous catalysis. The details are described in the article by W. Braun, A. Salzer et al. on p. 2235ff. The work was sponsored by the Deutsche Forschungsgemeinschaft (DFG) within the Collaborative Research Centre (SFB 380) "Asymmetric Syntheses with Chemical and Biological Methods". The authors are indebted to Mr. M. Stauten, Cologne, for his help concerning the artwork of the cover picture.

Engineering and Prosthetic-Group Modification of Myoglobin: Peroxidase Activity, Chemical Stability and Unfolding Properties

Raffaella Roncone,[a] Enrico Monzani,[a] Stefania Nicolis,[a] and Luigi Casella*[a]

Keywords: Bioinorganic chemistry / Heme proteins / Enzyme models / Protein engineering / Structure-activity relationships / Myoglobin

The role of myoglobin (Mb) is not yet completely understood and recent evidence indicates it is involved in a variety of pseudo-enzymatic functions. Mb is also extensively used as a tool to redesign novel active-site features and introduce new activities into a protein. This review summarizes our approach to enhance the peroxidase-like activity of Mb toward phenolic compounds by combining two different strategies of protein modification, i.e. active-site engineering and cofactor replacement. The main objective of active-site engineering is to increase the rate of hydrogen peroxide activation upon reaction at the iron(III) center, while cofactor replacement facilitates substrate interaction at the protein active site, thereby increasing the efficiency of the catalytic process and stereoselective recognition of the substrate. The thermodynamic stability of the modified Mb derivatives has been evaluated through guanidinium chloride induced and thermal unfolding experiments. As expected, both protein mutation and cofactor replacement decrease the stability of the protein, the latter effect being somewhat more pronounced for the Mb derivatives studied here. For evaluating the catalytic efficiency of the protein in non-natural reactions, the chemical stability of the protein during catalysis is also important and therefore a new protocol was developed to evaluate the competitive degradation undergone by the protein upon substrate oxidation. It was found that autodegradation can occur through two different pathways involving oxidation of protein residues by the Mb active species or by a substrate-derived phenoxy radical. The peroxidase-like nitrating activity and the sulfoxidation reactions promoted by Mb, both involving the nitrite ion as a cosubstrate, have also been briefly described.

Introduction

Myoglobin (Mb), "the hydrogen atom of biology",[1] is a monomeric protein which gives muscles their red color. It has a globular structure consisting of eight α helices wrapping around a central hydrophobic pocket containing iron protoporphyrin IX as the prosthetic group. Since the early 19th century, Mb was believed to function in the storage of dioxygen and in facilitating its transport from the periphery of the cell to the mitochondria,[2] although, the situation has now changed and it appears that Mb may play additional roles. Four conserved cavities surrounding the heme group, termed xenon cavities because they can host Xe atoms, are lined with highly conserved hydrophobic residues and appear to be actively involved in the binding of small molecules like O_2, CO and NO.[3] This suggests that Mb is built like a miniature chemical reactor with the iron atom as active centers and the cavities as chambers in which reactants are concentrated and oriented. Since different molecules react at different sites of the protein, Mb could be considered as an allosteric enzyme.[1,3] In the case of NO, for example, binding of the ligand to the oxygenated form of Mb (oxyMb) is followed by rapid conversion into the nitrate.[4−6] Since NO is an inhibitor of cytochrome *c* oxidase, it has been suggested that the scavenging effect of Mb protects the cell from inhibition of cellular respiration.[3,7] Other recent observations support a multiple role for Mb. Studies using a gene disruption strategy to produce mice that lack Mb show that the protein acts as an important modulator of cardiac function.[8] In addition, in vitro Mb is active in oxidative phosphorylation, shows some peroxidase and P450-like catalytic activities,[9] and protects cells against oxidative damage.[10,11] In vivo Mb may be present up to a concentration of 0.2 mM within the cytosol of myocardial cells and exists prevalently as oxyMb. However, high concentrations of oxidants, such as those present under in-

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

flammatory conditions, or acidic pH may induce autoxidation of the protein with formation of metMb. This is the state in which Mb can exhibit a peroxidase-like behavior.

The similarity that the Mb heme environment shares with other heme proteins, like cytochromes or peroxidases, makes Mb so widely employed for engineering novel metalloproteins by redesign of the existing metal-binding site.[12] Redesign of heme proteins gives insight into the factors governing structure and function within members of a closely related family and is invaluable for the developing area of de novo protein design. In this respect, Mb has several advantages because of its relatively small size, compact structure, and the extensively accumulated biochemical and biophysical characterization, including a large number of X-ray crystal structures available for both the native proteins from various sources and several mutants.[13] The current strategies for the modification of heme proteins follow four different approaches: i) rational design of heme enzymes; ii) directed evolution of heme enzymes; iii) exon shuffling of hemoglobin; and iv) replacement of the native heme prosthetic group (reconstitution).[14] For instance, the engineering of heme proteins is used as a strategy to develop new blood substitutes.[15,16] The availability of the expression system for recombinant Mb in *E. coli* and the relatively easy methods of site-directed mutagenesis make the engineering approach of extreme importance for investigating the role of critical residues and for introducing non-natural activities into the protein.[17,18] On the other hand, reconstitution of Mb with a modified prosthetic group (Figure 1) allows the introduction into the protein of a specific binding site for exogenous substrates or protein−protein interactions.[19,20] In this review, we summarize the results obtained in our group on the peroxidase-like activity of Mb upon modification of the protein by site-directed mutagenesis and by altering the prosthetic group. Combining the two approaches allowed us to develop a powerful method to enhance the reactivity and selectivity of Mb derivatives. Peroxidative processes mediated by Mb appear to be important in the oxidative degradation of lipid compounds in biological systems and foods.[21] Moreover, the transient protein radical, produced by the reaction between Mb and hydrogen peroxide, appears to be a key determinant of oxidative damage in ischemic heart.[10]

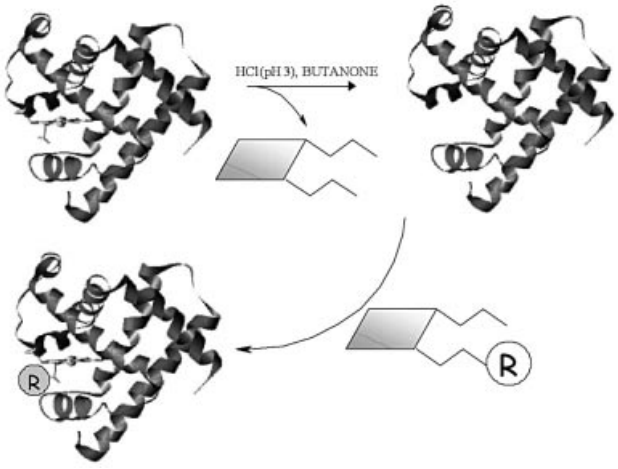

Figure 1. Two steps of the Mb reconstitution process: (i) extraction of the native heme with an organic solvent at acidic pH, and (ii) introduction of the chemically modified heme cofactor into apoMb

Characteristic Features of Peroxidases

Peroxidases are a class of ubiquitous heme enzymes that catalyze the oxidation of a wide range of substrates by hydrogen peroxide.[22,23] The stoichiometry of the reaction is normally as follows:

$$2\,SH + H_2O_2 \rightarrow 2\,S^{\cdot} + 2\,H_2O \quad (1)$$

Raffaella Roncone was born in Vigevano (Pv, Italy). She obtained her degree in Chemistry from the University of Pavia in 1999 and her Ph.D. degree in Chemistry in 2003 under the supervision of Prof. L. Casella. She was responsible for a Young Scientist Project with the title: "A Potential Nitric Oxide Dependent Toxicity: Reactive Nitrogen Species Generated by Metallo-Proteins" at the University of Pavia. Her current research interests focus on the chemistry of heme proteins and the study of protein modification induced by oxidative radical species.

Enrico Monzani was born in Locate Triulzi (Mi, Italy). He received his degree in Industrial Chemistry at the University of Milan in 1991 and his Ph.D. degree in Chemistry at the University of Pavia in 1994. He did his post-university training at the enzymology laboratory of the "Istituto di Ricerche Farmacologiche Mario Negri", Milan, Italy. From 1997 he obtained a permanent position as a Research Associate in Inorganic Chemistry at the University of Pavia. His research interest is in the field of Bioinorganic chemistry, in particular, on the structural and functional characterization of heme and copper proteins, covering both studies on the macromolecules and on the low molecular weight model systems.

Stefania Nicolis was born in Brescia in 1977. She obtained her degree in Chemistry from the University of Pavia in 2001. Since 2001 she is a Ph.D. student with Prof. L. Casella at the Faculty of Sciences at the University of Pavia.

Luigi Casella was born in Milano in 1947. He obtained his degree in Chemistry from the University of Milano in 1973. In the period between 1978-1979 he did his postdoc with J.A. Ibers at Northwestern University, Evanston (USA) with a CNR-NATO fellowship. Since 1990 he is a full professor of Inorganic Chemistry at the Faculty of Sciences at the University of Pavia. He is the Chairperson of the European COST Chemistry Action D21 "Metalloenzymes and chemical biomimetics". His scientific interest lies in the chemistry of metal enzymes containing heme or copper cofactors involved in oxidative processes. He is the author of more than 150 papers in international chemical and biochemical journals, and he has an international patent.

which emphasizes that the typical activity of these enzymes involves the one-electron oxidation of two substrate molecules by hydrogen peroxide or other peroxides. In their catalytic cycle, the resting state Fe^{III} center of peroxidases is oxidized by H_2O_2 to generate an intermediate containing an $Fe^{IV}=O$ group with a porphyrin or protein cation radical, which is known as Compound I. In the presence of a suitable substrate Compound I is reduced to a second ferryl intermediate, known as Compound II, and subsequently to the resting state by two sequential one-electron oxidations of substrate molecules.[23,24] The reaction with H_2O_2 is facilitated by a "push−pull" mechanism, to which suitably positioned residues located in both the heme proximal and distal sites contribute.[25,26] The distal arginine and histidine residues favor O−O bond polarization of the Fe-bound hydroperoxide and proton transfer from the Fe-bound oxygen atom to the other to form, after cleavage of the O−O bond, the $Fe^{IV}=O$ species and a water molecule (Figure 2). The proximal aspartate participates in the weakening of the peroxide O−O bond by increasing the electron-donating character of the proximal histidine through a hydrogen bond to the imidazole NH group, which enhances back-donation from Fe into the peroxide π* orbitals[27] (Figure 2).

Typical low molecular weight substrates processed by peroxidases according to reaction 1 are electron-rich organic compounds such as phenols or aromatic amines.[28] These bind to the enzyme near the heme edge but cannot enter into the heme distal pocket, the access to which is controlled by several aromatic residues.[29−31] The disposition of the substrate at the heme edge allows an efficient transfer of electrons to the enzyme active species through the extended porphyrin π system.[32] In the past decades we have extensively studied the kinetics and mechanisms of these reactions using a variety of phenolic compounds and enzymes from various sources.[33−36] In particular, by using paramagnetic NMR spectroscopic and relaxation rate measurements we could gain an understanding of the selectivity and stereoselectivity effects observed in the enzymatic reactions in terms of the interaction between the enzymes and the substrates.

In addition to the classical peroxidase reaction, phenolic substrates can be efficiently nitrated on the aromatic ring by peroxidases in the presence of nitrite and hydrogen peroxide.[37,38] This reaction is important in vivo because nitration of tyrosine, to give 3-nitrotyrosine, has been associated with a wide range of human and animal diseases.[39,40] In fact, nitrite is a major product of nitrogen monoxide metabolism[41] and accumulates upon activation of NO synthases under inflammatory and other disease conditions. Interestingly, we have recently found that both peroxidases[42,43] and myoglobin[44] perform nitration of tyrosine derivatives through two distinct pathways which involve nitrogen dioxide or peroxynitrite, respectively, as nitrating agents depending on the conditions.

Reconstitution of Myoglobin with Chemically Modified Hemins and Site-Directed Mutagenesis

Mb, with peroxidases, shares the same heme cofactor and the same heme distal and proximal His residues (His64 and His93, respectively, in Mb). However, its globular shape, the different functional oxidation state of the iron atom, and the differences in heme environment and overall polarity of the active site, make the catalytic activity of Mb in peroxidase-type reactions markedly lower than that of the enzymes. In particular, Mb lacks the amino acid residues that are essential for the activation of hydrogen peroxide, i.e. a distal arginine and a proximal aspartate (Figure 2), and a specific cleft for substrate binding near the heme. The scope of our modifications of Mb basically aimed at introducing these characteristic features into the protein. In our initial attempts an Arg−Ala residue was covalently linked to one of the propionate side chains of protohemin and the resulting complex, HM−RA (Scheme 1), was inserted into horse heart apoMb.[45] Insertion of a modified hemin into Mb affects the pre-existing network of hydrogen bonds be-

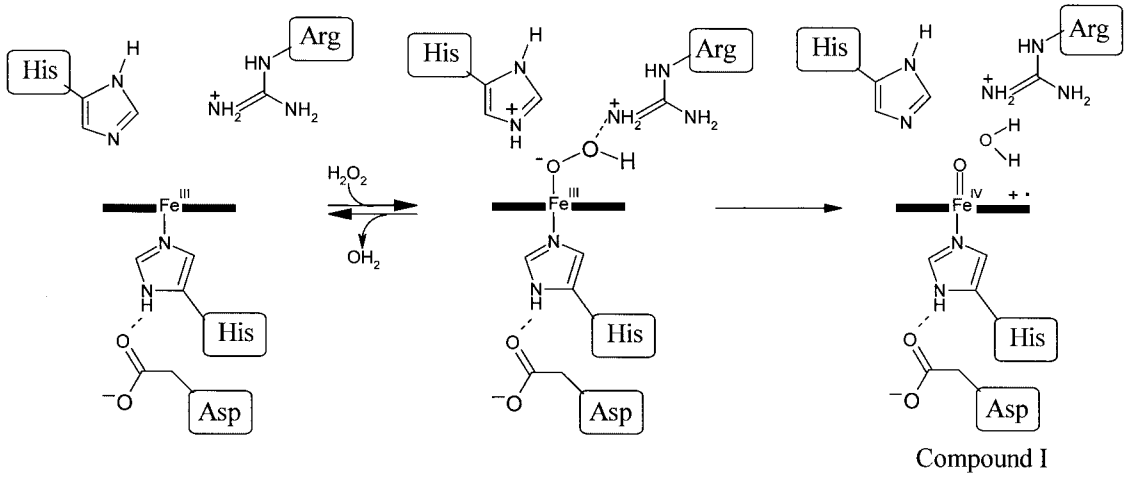

Figure 2. Mechanism of compound I formation in peroxidases promoted by general acid−base catalysis of polar residues in the active site

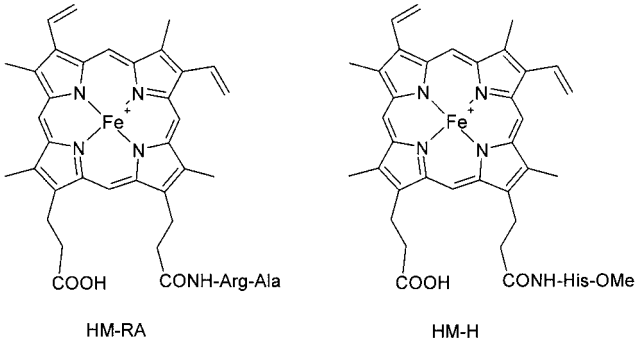
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tween the propionate groups of the cofactor and side chain residues of the protein. In the case of HM−RA, the polypeptide fragment Phe43−Lys47 of Mb acquired sufficient mobility to allow collapse of the distal helix and binding of distal His to the sixth coordination position of the iron.[45] The presence of distal His as the sixth ligand hindered the binding of hydrogen peroxide to the iron and reduced the activity of the reconstituted protein. On the contrary, when the heme cofactor was modified by attachment of a histidine residue, HM−H (Scheme 1), the reconstituted Mb contained a significant portion of high spin form, which reacted normally with hydrogen peroxide. Since the His imidazole group of the HM−H prosthetic group is partially protonated at physiological pH, it could play a role similar to that of distal arginine in peroxidases.

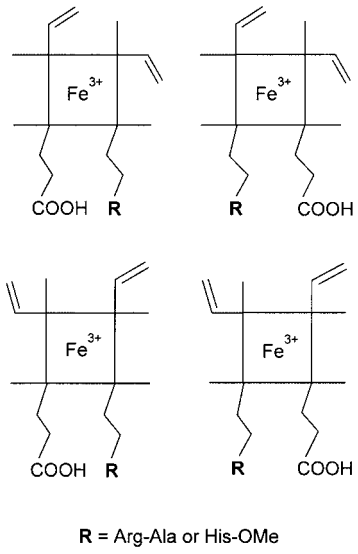


Scheme 1

Reconstitution of Mb with monosubstituted protohemins like HM−RA and HM−H unavoidably leads to a mixture of protein isomers. The hemin derivatives are in fact obtained as 1:1 mixtures of isomers containing the covalent modification at positions 6 or 7 of the porphyrin ring. Therefore, upon reconstitution of apoMb four protein isomers are obtained, depending on the type of substitution on the porphyrin and the mode of incorporation (“up” or “down”) of the prosthetic group into the protein (Scheme 2).[45] The ratio of these protein isomers is dictated by their relative stability and generally produces one major and one minor isomer for both 6- and 7-substituted HM−H derivatives, assessed by NMR spectroscopy.

The problem of Mb reconstitution isomers is reduced in the approach followed by Hayashi and Hisaeda, where Mb was reconstituted with synthetic protohemins bearing identical substituents at both the porphyrin propionates;[19,20] although, it is expected that the resulting protein derivatives will bear additional loss of stability because the interactions between the prosthetic group and the protein are further weakened.

In further developments we produced site-directed mutants of sperm whale Mb containing those amino acid residues critical for peroxide activation in peroxidases. In particular, we replaced the distal Thr67 with either Arg (T67R Mb)[46] or the more flexible Lys residue (T67 K Mb)[47] and obtained a double mutant where, in addition to the Thr67Arg mutation, the proximal Ser92 was substituted



Scheme 2

with an Asp residue (T67R/S92D Mb) (Figure 3).[48] The mutants T67 K Mb and T67R/S92D Mb were also reconstituted with HM−H, while with T67R Mb we could not obtain a stable derivative. The reconstituted sperm whale Mb derivatives will be indicated as WT Mb−H, T67 K Mb−H and T67R/S92D Mb−H.

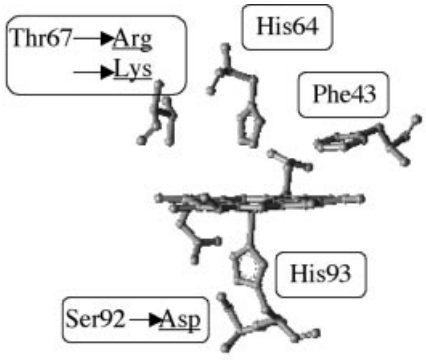


Figure 3. Engineering of the Mb active site: site-directed mutated residues are underlined

In general, point mutations do not appreciably affect the overall protein structure and only marginally perturb the heme environment.[46] The most significant change has been shown by the X-ray structure of T67R/S92D Mb to consist of an increase in the conformational mobility of the porphyrin propionate-7, which allows this group to span the heme proximal and distal sides through hydrogen-bonding interactions with water molecules.[46] The conformational mobility of propionate-7 is confirmed by marked shift of its signal in the ^{1}H NMR spectra of all Mb mutants with respect to the position of the signal in the spectrum of wild type Mb.[48] Reconstitution of Mb with synthetic hemins results in more substantial changes in the NMR spectra,

but the problem of the existence of several protein isomers makes a detailed analysis of the NMR spectra impossible.

Ligand Binding Data, Peroxide Activation and Catalytic Activity

Two representative ligands of different charge and size, azide and imidazole, were used as probes to investigate the effect of Mb modification on the affinity and accessibility of the iron site to external donor molecules. The affinity for azide is systematically increased upon introduction of a positively charged Arg, Lys or His residue into Mb by either engineering or reconstitution of the protein with HM−H, whereas with the bulky imidazole ligand a significant increase in the binding affinity is generally obtained only with the reconstituted proteins, due to the higher protein mobility at the entrance of the distal pocket (Table 1). The enhanced azide binding affinity exhibited by the modified Mb derivatives is expected to similarly stabilize the binding of H_2O_2 to the iron as a hydroperoxide ligand. As with peroxidases, this binding step is rapidly followed by cleavage of the O−O bond in the Fe^{III}−O−OH complex to produce a ferryl Mb species and a protein radical ($^{\cdot}MbFe^{IV}$=O). The positively charged residue introduced into the modified Mbs is expected to favor the heterolytic cleavage of the bound hydroperoxide, even though it cannot be suitably positioned to produce such a strong polarization effect of the O−O bond as that promoted by distal Arg in peroxidases. The rate constants for the formation of the Fe^{IV}=O Mb radical species (k_1) indeed show an appreciable increase for the modified Mbs, from a value of 760 ± 10 M^{-1} s^{-1} for WT Mb to 2100 ± 40 M^{-1} s^{-1} for the T67R/S92D Mb mutant.[46−48] Regarding the location of the protein radical, several studies indicate that it is distributed among several residues, including tyrosine, tryptophan and histidine residues,[49−53] with tyrosine being largely preferred, leading to the formation of Tyr−Tyr cross-links and Mb dimerization.[54]

To investigate the peroxidase activity of the Mb derivatives we followed a similar approach as in our previous studies with peroxidases.[33−35] We therefore selected a group of phenolic substrates which are related to tyrosine and contain substituents on the aromatic ring that can be useful for investigating selectivity effects in the enzymatic reaction. During activity, the phenolic substrates undergo one-electron oxidation to phenoxy radicals by the Mb active species, according to a reaction scheme analogous to that of peroxidases, which can be summarized as follows.

$$MbFe^{3+} + H_2O_2 \xrightarrow{k_1} {}^{\cdot}MbFe^{IV}{=}O + H_2O \quad (2)$$

$$^{\cdot}MbFe^{IV}{=}O + PhOH \xrightarrow{k_2} MbFe^{IV}{=}O + PhO^{\cdot} + H^+ \quad (3)$$

$$MbFe^{IV}{=}O + PhOH + H^+ \xrightarrow{k_3} MbFe^{3+} + PhO^{\cdot} + H_2O \quad (4)$$

$$2\ PhO^{\cdot} \longrightarrow \text{Dimers} \quad \text{(fast)} \quad (5)$$

The phenoxy radicals evolve independently of the protein catalyst in solution, giving a fast coupling reaction to dimeric products,[46] which subsequently yield complex mixtures of oligomers, as in the peroxidase-catalyzed reactions.[36,55] As discussed above, the rate constant k_1 can be determined by the reaction between Mb and hydrogen peroxide. The rate of reduction of the first protein intermediate ($^{\cdot}MbFe^{IV}$=O) by the substrate (k_2) is difficult to determine because this intermediate has optical features similar to the second intermediate ($MbFe^{IV}$=O), but the process is probably fast. Considering that $^{\cdot}MbFe^{IV}$=O does not accumulate in solution, the catalytic scheme can be reduced to a bimolecular ping-pong mechanism.[33] A further simplification in the in vitro kinetic scheme can be obtained by operating under saturating H_2O_2 conditions because in this case the rate equation reduces to conventional Michaelis−Menten kinetics, rate = k_{cat}[substrate]/(K_M + [substrate]).[46] Under these conditions, the third step, reduction of $MbFe^{IV}$=O by substrate, is rate limiting, and we can assume that the rate constant k_3 coincides with the turnover rate constant (k_{cat}).

The kinetic parameters for the catalytic oxidation of (*p*-hydroxyphenyl)propionic acid obtained with the various Mb derivatives exemplify how the catalytic performance of Mb is enhanced in an additive fashion by engineering and cofactor reconstitution (Table 2). The k_{cat} parameter, in particular, measures the electron transfer rate from the substrate to the $MbFe^{IV}$=O center. For a given substrate, this parameter depends on (i) the redox potential of the ferryl species, which is likely to increase by introduction of positively charged residues into Mb, and (ii) the mode of substrate interaction with the protein, which allows a closer approach to the heme, especially in the case of the reconstituted proteins. This interpretation is confirmed by the selectivity effects observed in the catalytic reactions, which could

be rationalized according to a structural model for the protein-substrate interaction deduced from paramagnetic ^1H NMR spectroscopic relaxation measurements. According to this technique it is possible to obtain an estimate of the distances between the protons of the bound substrate and the paramagnetic Fe center through the enhancement of the relaxation rate of the nuclei caused by the proximity of the paramagnetic, high-spin Fe center of the protein (Figure 4).[46,47]

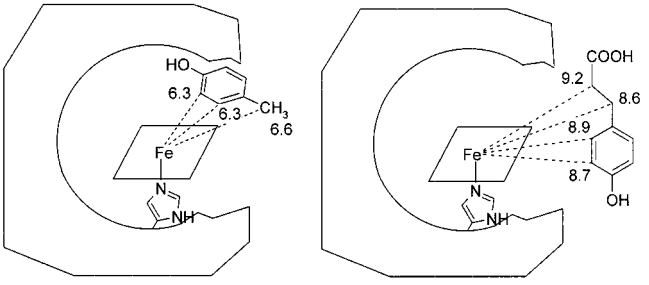

Figure 4. Distances (in Å), deduced by NMR spectroscopic relaxation measurements, between the paramagnetic Mb iron(III) center and the protons of protein-bound aromatic substrates: *p*-cresol (left) and (*p*-hydroxyphenyl)propionic acid (right)

(*p*-Hydroxyphenyl)propionic acid carries a side chain with a charge complementary to that of the residues introduced in the Mb heme environment and is therefore favored from the point of view of the protein-substrate interaction. Among the Mb derivatives, the highest catalytic activity (both in terms of k_{cat} and k_{cat}/K_M) is exhibited by T67 K Mb−H and T67R/S92D Mb−H (Table 2), because with these reconstituted proteins (*p*-hydroxyphenyl)propionic acid can reach closest to the Fe center and thus offer the most favorable arrangement for the electron transfer process.[47,48] The opposite trend holds for tyramine, which carries a positive charge in the side chain, while tyrosine is a very poor substrate for all Mb derivatives because it binds strongly to the protein but at a distance from the heme.[46−48]

The best performance by the Mb derivatives, in terms of k_{cat}/K_M, is obtained with *p*-cresol. The behavior of this substrate is unusual since its size is comparable with that of imidazole, and it can enter into the distal cavity of Mb, as shown by the short distance to the heme (Figure 4).[46] The reaction between *p*-cresol and the Mb active species is therefore unusually fast (almost similar to that of peroxidases),[46] and becomes limited by the reaction between the Fe^{3+} species and H_2O_2, making the comparison between the various Mb derivatives difficult.

Thermodynamic Stability and Stability of the Proteins during Catalysis

Many globular proteins can be reversibly unfolded in solution by addition of a denaturant, like urea or guanidinium chloride (Gdn−HCl), to the solution.[56,57] The stability of the protein, in terms of the unfolding free energy, can be determined by the analysis of a denaturant-induced unfolding curve as a function of the denaturant concentration. Unfolding of Mb has been studied intensively, and in the urea or Gdn−HCl denaturation experiments the behavior of the protein has been satisfactorily described by a two-state model (native/unfolded), without any defined intermediate state.[58−62] We obtained thermodynamic data on the stability of the various Mb derivatives through thermal and Gdn−HCl denaturation experiments, which were analyzed according to the two-state model.[62] The Gdn−HCl induced denaturation process was found to be completely reversible, indicating that the heme remains bound to the polypeptide chain even at high concentration of denaturant. On the contrary, the behavior of the proteins with temperature is different since they tend to precipitate at higher temperatures and the denaturation process becomes irreversible, possibly because, in this case, the heme is released by the protein. Nevertheless, the trend of thermal stabilities follows the same order as that found in the Gdn−HCl denaturation experiments.[47] As shown by the data reported in Table 3, both protein mutation and protein reconstitution decrease the stability of Mb, but in the latter case the effect is more pronounced. The observed trend can be accounted for in terms of the interactions involved in the binding of the heme to the protein, since heme binding gives the most prominent contribution to the stability of the holo protein. This contribution has been factored into that of the covalent bond between the iron atom and proximal His93 (25%), those of hydrophobic interactions between the heme and apolar residues in the pocket (50%), and those of specific interactions, which include hydrogen bonds and charge effects, between the protein and the propionate

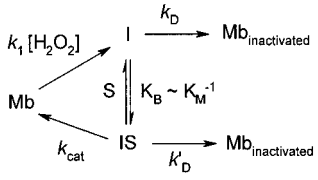
groups (25%).[63] The specific hydrogen-bonding and electrostatic interactions involving the propionates in sperm whale Mb are with Leu89, Ser92, His93 and His97 for propionate-7, and with His64 and Arg45 for propionate-6.[64][65] The decrease in stability of Mb upon mutation of the Thr67 residue can be attributed mainly to a change in conformation of the propionate-7 group, which is shown by the NMR spectra of the Mb mutants[46−48] and is confirmed by the X-ray structure of T67R/S92D Mb.[48] The loss of the hydrogen-bonding structure can be partially compensated by new interactions established by the mutated residue. This is suggested by the observation that the most stable Mb mutant, T67 K Mb, is the one that contains the engineered residue with most flexible side chain that can more easily establish interactions with other groups in the protein. The parameter $-m$ that is related to the protein−water interaction and the surface roughness of the protein is reported in Table 3. Surprisingly, this parameter is much smaller for T67R/S92D Mb−H than the other Mb derivatives. This may indicate a significant difference in the solvent-exposed surface area of the reconstituted Mb double mutant or, more likely, the existence of some intermediate state in the unfolding process. The decrease in stability observed for the reconstituted Mb derivatives is largely due to the loss of one of the hydrogen-bonding networks maintained by the two heme propionates in the native protein. This increases the protein mobility around the heme, facilitating the interaction with the denaturant. The lowest free energy of unfolding is observed for the engineered and reconstituted Mb−H derivatives; here, an additional repulsive interaction occurs between the positively charged Lys or Arg residues and the His residue present in the HM−H cofactor. Although the reconstitution isomers of each Mb−H derivative may have different stabilities, the fact that, in every case, the various protein isomers are formed in similar amounts indicates that such differences in stability are limited.

Of particular interest is the problem of protein stability during catalysis since this is an important aspect for the assessment of biological catalysts. The Mb active species formed during turnover are not only able to oxidize exogenous substrates but can competitively react with amino acid residues, which ultimately leads to loss of catalytic activity. When the Mb derivative reacts with hydrogen peroxide in the absence of a substrate, a fast inactivation process occurs, which is characterized by an autodegradation rate constant k_D. The inactivation depends on the formation of radical species, produced at various protein residues, as discussed above.[49−54] In the presence of substrate the catalytic reaction competes with protein degradation and the possible pathways are summarized in Scheme 3. In this scheme, I is the Mb active species, S the substrate, IS the complex substrate−Mb active species, and $Mb_{inactivated}$ the degradation product (e.g. the protein derivative resulting from autoxidation of amino acid residues or the porphyrin) which can be formed directly or through a process mediated by the bound substrate. The latter process is characterized by rate constant k'_D.



Scheme 3

The competition between the catalytic reaction and protein degradation depends on substrate concentration but, at least with the phenolic substrates, inactivation can never be completely neglected. In fact, the substrate-bound by Mb can also promote protein inactivation, and the relative importance of this process with respect to substrate oxidation is governed by the ratio between the rate constants k'_D/k_{cat}. Different situations can be envisaged according to whether $k_D \approx k'_D$, $k'_D > k_D$, or $k'_D < k_D$ (Table 4 and Figure 5). Protein autodegradation may not be affected by the presence of the substrate ($k'_D < k_D$), as in the case of T67R Mb and T67R/S92D Mb, or only marginally affected by the presence of the substrate ($k_D \approx k'_D$), as in the case of WT Mb, WT Mb−H and T67 K Mb. This situation occurs when the active site is relatively closed and the phenoxy radicals produced by the Mb active species rapidly diffuse in the solution, thus preventing the substrate-induced degradation of the protein. The protecting effect exerted by the protein accounts for the longer lifetime of these biocatalysts with respect to simple hemins or microperoxidases where the active site is quite open and allows for a close approach of the substrate to the heme, which strongly facilitates the substrate induced degradation process.[66−68] A

similar situation is observed with T67 K Mb−H only, for which the inactivation process in the presence of substrate is faster than in the absence of substrate ($k'_D > k_D$). This is consistent with the already mentioned increased accessibility of the heme site of T67 K Mb−H to the substrate. In this case, the phenoxy radical produced by the Mb active species can attack the porphyrin before diffusing into the solution, thus causing protein inactivation. However, it is worth emphasizing that the closer binding of the substrate to the heme has the advantage of increasing the catalytic turnover, and we can see from the data in Table 2 and Table 4 that the increase in k_{cat} exhibited by T67 K Mb−H with respect to WT Mb is significantly larger than the increase in k'_D. An increase in the ratio k_{cat}/k'_D always improves the performance of the biological catalyst. In general, at least with phenolic substrates, the numerical values of the protein degradation rate constants k_D and k'_D are about two orders of magnitude smaller than the turnover rate constants (k_{cat}), indicating that all Mb derivatives perform a large number of catalytic turnovers before undergoing significant degradation.

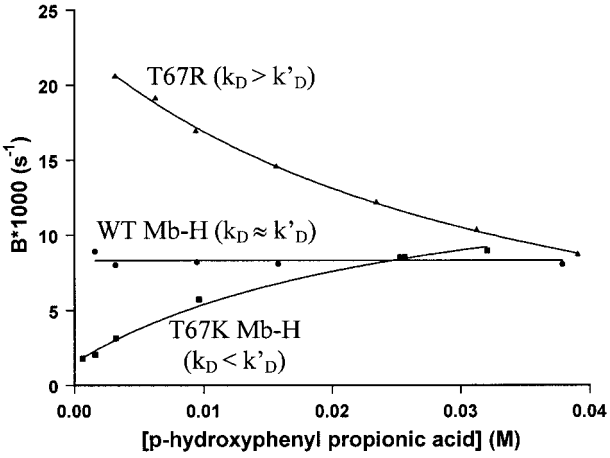

Figure 5. Types of behavior of Mb derivatives in the degradation processes undergone during catalysis; the dependence of parameter B [defined as $B = (k_D K_M + k'_D[S])/(K_M + [S])$][47] on (*p*-hydroxyphenyl)propionic acid concentration is shown under the various conditions that can affect the degradation process: $k_D \approx k'_D$, $k'_D < k_D$ or $k'_D > k_D$, depending on the way the substrate interacts with the protein; protein autodegradation may be only marginally affected ($k_D \approx k'_D$), unaffected ($k'_D < k_D$), or strongly affected ($k'_D > k_D$) by the presence of substrate

New Peroxidase-Like Reactions of Myoglobin Promoted by Nitrite Activation

Nitrite is a major product of nitrogen monoxide metabolism.[69,70] Although nitrite is considered a harmless metabolite, its accumulation is reported in some pathological conditions.[71] Actually, NO_2^- dramatically enhances hydrogen peroxide toxicity in the presence of heme proteins because these systems can generate powerful oxidizing and nitrating species.[39,40][72] We have recently demonstrated that enzymatic nitration of tyrosine derivatives[43] promoted by peroxidase/H_2O_2/NO_2^- proceeds through two distinct pathways which involve nitrogen dioxide or peroxynitrite, depending on the conditions, as nitrating agents. A similar behavior is exhibited by the metMb/NO_2^-/H_2O_2 system.[44] At low nitrite concentration Mb reacts through the classical peroxidase-like cycle, with two active intermediates which can either react with the phenolic substrate, according to reactions (2)−(4), or with nitrite to generate nitrogen dioxide in the competing reactions:

$$^{\cdot}MbFe^{IV}{=}O + NO_2^- \rightarrow MbFe^{IV}{=}O + NO_2^{\cdot} \quad (6)$$

$$MbFe^{IV}{=}O + NO_2^- \rightarrow MbFe^{3+} + NO_2^{\cdot} \quad (7)$$

The enzymatically produced phenoxy radical and $NO_2^{\cdot}$ can give then a fast recombination reaction producing the nitrophenol:

$$NO_2^{\cdot} + Ph{-}O^{\cdot} \rightarrow O_2N\text{-}Ph\text{-}OH \quad (8)$$

$$NO_2^{\cdot} + Ph{-}OH \rightarrow Ph{-}O^{\cdot} + NO_2^- \quad (9)$$

The phenoxy radical can also be produced by reaction of $NO_2^{\cdot}$ with phenol. At high nitrite levels this acts as a ligand for the iron center, and hydrogen peroxide reacts with the iron-bound nitrite producing an active species that we formulate as a protein-bound peroxynitrite, $MbFe^{3+}{-}N(O)OO^-$. This is capable of nitrating the phenol in a two-electron process:

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$MbFe^{3+} + NO_2^- \rightleftarrows MbFe^{3+}-NO_2^- \quad (10)$$

$$MbFe^{3+}-NO_2^- + H_2O_2 \rightarrow MbFe^{3+}-N(O)OO^- + H_2O \quad (11)$$

$$MbFe^{3+}-N(O)OO^- + PhOH \rightarrow MbFe^{3+} + O_2N\text{-}PhOH \quad (12)$$

In the absence of an exogenous substrate Mb catalyzes its own nitration. Mb contains several amino acid residues that can be nitrated. Upon treatment of Mb with peroxynitrite Bourassa et al.[73] found that nitration occurs at the exposed Tyr103, while Herold et al.[74] found that nitration occurs at Tyr146. By reacting Mb with nitrite and hydrogen peroxide, we found that the first and most important nitration site is the heme (30% to 50% yield depending on the conditions), while a secondary protein nitration site has been identified as Tyr146 (about 5% yield).[44] This is a surprising result considering that Tyr146 is an inner residue lined to the Xe1 cavity of Mb and it is farther from the heme iron center than Tyr103 (the closest C atom of the phenol ring is 9.7 Å from the iron atom for Tyr146 and 3.3 Å for Tyr103).[3][75] Therefore, the nitrating agent responsible for the self nitration of Mb does not come from the outside of the protein but diffuses from the heme to the Xe1 cavity and reacts through an intramolecular reaction.

Heme peroxidases catalyze the oxidation of organic sulfides to sulfoxides with a certain degree of stereoselectivity.[28,76] This type of reaction is catalyzed much more efficiently by chloroperoxidase.[77–79] Through the engineering of Mb, the group of Watanabe obtained mutants that exhibit catalytic turnovers and interesting stereoselectivity effects in the sulfoxidation of thioanisole.[80–82] We have studied the effect of nitrite in the oxidation of aromatic sulfides catalyzed by various Mb derivatives. As shown before, in the presence of hydrogen peroxide nitrite produces nitrogen dioxide or peroxynitrite, which are both powerful nitrating and oxidizing species. The idea was that these species could participate in the sulfoxidation catalytic cycle of Mb and increase the efficiency and/or selectivity of the reaction. Indeed, nitrite caused a general improvement in the enantioselectivity in the produced sulfoxide (with *ee* up to about 50% for sulfoxidation of thioanisole).[83] By analogy with peroxidases,[79] the catalytic scheme we propose for the sulfoxidation by Mb is the following:

$$MbFe^{3+} + H_2O_2 \rightarrow {}^{\cdot}MbFe^{IV}=O + H_2O \quad (12)$$

$${}^{\cdot}MbFe^{IV}=O + S \rightarrow MbFe^{3+} + SO \quad (13)$$

$${}^{\cdot}MbFe^{IV}=O + S \rightarrow MbFe^{IV}=O + S^{\cdot+} \quad (14)$$

$$MbFe^{IV}=O + S \rightarrow MbFe^{3+} + S^{\cdot+} \text{ (slow)} \quad (15)$$

$$S^{\cdot+} + S^{\cdot+} + H_2O \rightarrow S + SO + 2\,H^+ \quad (16)$$

where S indicates the sulfide and SO the sulfoxide. The first protein intermediate, ${}^{\cdot}MbFe^{IV}=O$, can convert sulfide to sulfoxide by a direct *O*-transfer reaction [formally a two-electron process, reaction (13)], or to a sulfur cation radical by a one-electron oxidation according to reaction (14). The second protein intermediate, $MbFe^{IV}=O$, can only produce a sulfur cation radical. The former reaction gives the sulfoxide with a certain degree of enantioselectivity, while dismutation of sulfur cation radicals by reaction (16) gives racemic sulfoxide.[79,84–86] Therefore, the observed enantioselectivity depends on the fraction of Mb that reacts by reaction (13). Nitrite efficiently reduces intermediate $MbFe^{IV}=O$ to the native state[44] according to:

$$MbFe^{IV}=O + NO_2^- \rightarrow MbFe^{3+} + NO_2^{\cdot} \quad (17)$$

and this process is faster than reaction (15). Therefore, the effect of nitrite is to reduce the contribution of the pathway that produces the sulfoxide through the stereochemically unproductive coupling of sulfur cation radicals.

Concluding Remarks

In this review we summarized our contribution to the search for new catalytic activities of Mb by combining site-directed mutagenesis with prosthetic-group modification. We focused on peroxidase-type reactions promoted by the activation of hydrogen peroxide because this reagent transforms the iron center into an active species that can, in principle, perform controlled reactions on exogenous substrates. Due to similarities between the active sites of Mb and peroxidases, the changes that are introduced in the protein are insignificant relative to those that are necessary for the simulation of the activities of other enzymes using Mb. In general, the results obtained so far clearly indicate that the strategies of active-site engineering and cofactor modification are cumulative in enhancing the pseudo-peroxidase activity of Mb, and can be further elaborated to introduce more sophisticated substrate recognition sites into the protein. We have also introduced a new experimental method to evaluate the relative stability of the Mb catalysts under operational conditions and identified the pathways by which the protein undergoes competitive degradation. Although the investigated reactivities are not natural for Mb, both peroxide and nitrite activation by this protein may bear particular importance under pathological conditions where bursts of nitric oxide and hydrogen peroxide are produced by the immune defense system.[87] Manipulating protein activities by chemical or genetic methods is an intellectual challenge that will strongly affect the way chemists devise new approaches to synthetic methods and applications.

Intermolecular Interactions between Chelate Rings and Phenyl Rings in Square-Planar Copper(II) Complexes

Zoran D. Tomić,*[a] Sladjana B. Novaković,[a] and Snežana D. Zarić*[b]

Keywords: Chelate rings / Delocalized π-bonds / Copper / Aromaticity / Stacking interactions

Analysis of the geometrical parameters in crystal structures of square-planar copper(II) complexes from the CSD shows that the short noncovalent copper(II)–phenyl carbon distances are a consequence of the interaction between the phenyl ring and the chelate ring with delocalized π-bonds. The data show a correlation between the distances between the centers of the chelate and phenyl rings and the copper(II)–carbon distances, as well as a mutual slipped-parallel orientation of the phenyl and chelate rings.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The investigation of noncovalent interactions is of continuing interest.[1−8] Noncovalent interactions involving metal atoms has gained particular attention with the recognition that metal atoms can bind to the phenyl ring; and this can be explained in terms of cation−π interactions.[9−14] Cationic metal complexes are involved in similar metal−ligand aromatic cation−π interactions[15−18] that can also be considered as a type of X−H···π hydrogen bond.[19−22] The importance of this interaction in protein structures has been shown previously.[15]

Recently, a few studies of noncovalent interactions of chelate rings with delocalized π-bonds have been published.[23−25] We have reported[24] the structure of the square-planar bis(acetone-1-naphthoylhydrazinato)copper(II) complex. In this structure the closest intermolecular distance between the copper(II) and aromatic carbon atom is 3.185(3) Å, which is below the sum of van der Waals radii (4.05 Å). Similar arrangements have been found previously,[26−28] and on the basis of geometrical characteristics it was proposed that phenyl carbon is part of the copper(II) coordination sphere. Besides providing linkages, these contacts may also serve as a path for exchange interactions. The EPR studies on the single-crystal samples of (L-tryptophanyl-glycinato)copper(II)[29] suggest that magnetic interactions are transmitted through cation−π contacts.

The observed mutual slipped-parallel (offset face to face) orientation of the chelate ring, with delocalized π-bonds, and the phenyl ring,[24] resemble the stacking orientation of two benzene molecules.[30] We assumed that chelate rings with delocalized π-bonds can be involved in noncovalent interactions in ways similar to aromatic organic molecules. A calculation of the partial atomic charges of the chelate and phenyl rings in the bis(acetone-1-naphthoylhydrazinato)copper(II) complex has been performed.[24] The distribution of charges in these two rings is very similar to that observed in complexes with the slipped-parallel interaction between two benzene rings, further supporting the stacking interaction between the phenyl and chelate rings.[24]

The role of the chelate ring in the position of the phenyl ring has also been discussed in the analysis of the crystal structure of aqua(2-benzylmalonato)(1,10-phenanthroline)-copper(II) trihydrate.[25]

The assumption that copper(II)−carbon contacts arise as a result of the interactions between the chelate and phenyl rings prompted us to investigate the chelate-ring to phenyl-ring interactions in the crystal structures of copper(II) complexes. We now report on a study based on analyzing the crystal structures in the Cambridge Structural Database (CSD), since by analysing crystal structures from databases it is possible to elucidate the facts about intermolecular and intramolecular interactions.[31−33] To the best of our knowledge this is the first systematic study of chelate-ring to phenyl-ring interactions.

Results and Discussion

For the investigated data set of 487 crystal structures we calculated the closest intermolecular distance between the copper(II) and phenyl carbon (D) atoms (Scheme 1). This distance has a range of 3.06−8.96 Å. In order to establish

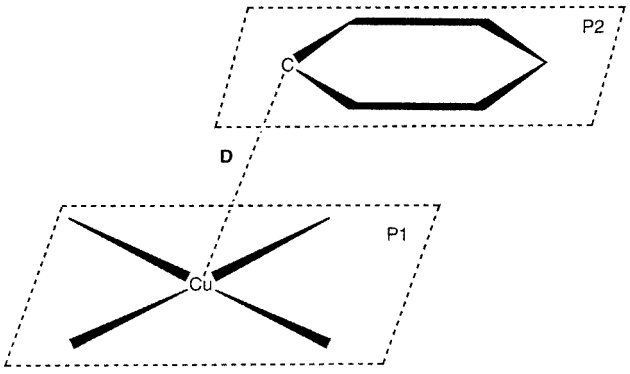
if the presence of the chelate ring has an influence on the copper(II)−carbon distance, the distribution for the copper(II)−carbon distances (D) were compared for complexes with and without a chelate ring (Figure 1).



Scheme 1

In the complexes without a chelate ring the peak of distribution is in the region above the sum of the van der Waals radii (4.05 Å), while in the complexes with a chelate ring the peak of distribution is in the region below the sum of the van der Waals radii. Hence, in the presence of a chelate ring with delocalized π-bonds there is a close contact between the copper(II) atom and the carbon atom of the phenyl ring.

Another important difference between complexes with and without a chelate ring is seen when looking at the distribution of the dihedral angles θ, the angle between the mean plane of the phenyl ring (P2) and the mean coordination plane (P1) (plane consisting of copper and coordinated atoms). The planes are shown in Scheme 1. In the histogram for the structures with chelate rings, the peak of distribution is in the region of the small angle θ, where the phenyl ring is oriented in an approximately parallel manner to the mean coordinating plane (Figure 2). In the histogram for the structures without the chelate rings the peak of distribution is in the region of the large angle θ, where the phenyl ring is almost normal to the coordinating plane; there are no structures with a dihedral angle of less than 10° (Figure 2).

The data in Figure 1 and Figure 2, the short copper(II)−carbon distances, and the tendency for a parallel orientation of the phenyl ring in complexes with chelate rings, indicate possible phenyl-ring to chelate-ring stacking interactions.

In order to verify that the interaction between the chelate ring and the phenyl ring is really responsible for the shorter copper(II)−carbon distances observed in the complexes with chelate rings, the values of the distances between the centers of the chelate and phenyl rings (Ct) are plotted versus the copper(II)−carbon distance (D) (Figure 3). The plot shows that there is a correlation between the distance Ct and the distance D; the copper(II)−carbon distances are shorter when there is a short distance between the centers of the chelate and phenyl rings. This correlation can only exist if the chelate and phenyl rings tend to overlap each other. Hence, the interaction between the phenyl and chelate rings is responsible for the short copper(II)−carbon distances.

The positions of the phenyl rings with respect to the chelate rings, indicates that, in all cases with small θ angles, the two rings are in mutual slipped-parallel orientations (offset face to face). This is in agreement with the previously observed slipped-parallel orientation in the bis(acetone-1-naphthoylhydrazinato)copper(II) complex.[24] Additional support for the idea that the interaction between the chelate ring and the phenyl ring is similar to the interaction between two benzene molecules has been provided by the distribution of the calculated partial atomic charges[24] which are similar to those observed in complexes with stacking interactions between two benzene molecules.[30]

Conclusion

Our analyses of the geometrical parameters in the crystal structures of copper(II) square-planar complexes from the CSD show that in cases where a chelate ring with delocalized π-bonds is present, the peak of the distribution of the copper(II)−phenyl carbon distances is in the region be-

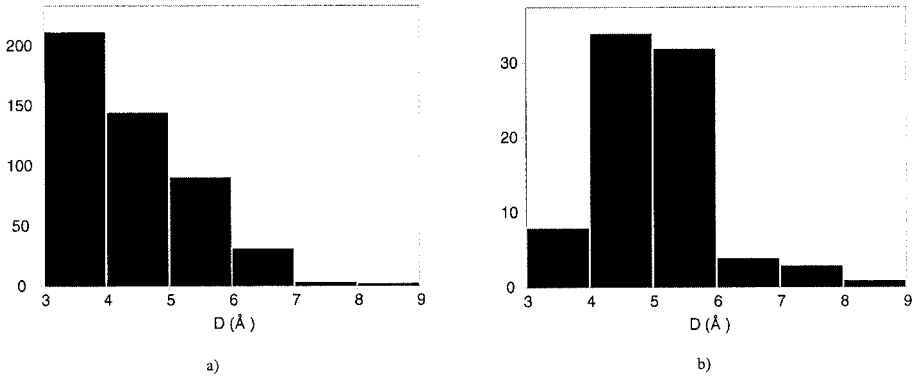


Figure 1. Histograms showing the distribution of the parameter *D*, copper(II)−carbon distance, in structures with (a) and without (b) chelate rings

low the sum of van der Waals radii. The correlation between the copper(II)−carbon distances and the distances between the centers of the chelate and phenyl rings, as well as the mutual slipped-parallel orientation of the two rings, show that stacking interactions between phenyl and chelate rings are similar to the stacking interactions between two benzene rings.

Experimental Section

A Cambridge Structural Database (CSD)[34] search was performed for mononuclear copper(II) complexes having exactly four single bonds to atoms belonging to groups 5A, 6A or 7A. The oxidation state of copper was taken as those given by the authors. To exclude the possible influence of the constraints in the molecule we only looked at the intermolecular contacts between the copper(II) atom and the carbon atom of the phenyl ring. As a convenient choice for this investigation, we concentrated on square-planar copper(II) complexes due to the relative planarity of such molecules, and the absence of steric hindrance for the approach of other molecule into the axial position. To minimize the possible steric influence towards the approach of two molecules, the *trans* angles around the copper atom were constrained to lie between the 150 and 180°. To avoid problems which could possibly arise as a result of "structural inhomogeneity", we used structures that contain the phenyl ring as part of the complex molecule, and only those with one complex species in the asymmetric unit. Polymeric, disordered, and structures with $R > 0.10$ were excluded. This gave 487 entries. Among them 405 structures had five-membered or six-membered chelate rings. The bond lengths in the chelate rings indicate that in all the structures the chelate rings have delocalized π-bonds. When considering the influence of the chelate ring on the position of the phenyl ring, we took the distance between the centroids of the phenyl and chelate rings as a criteria. In cases with more than one chelate ring in the complex, we accepted the closest chelate ring as the one that is involved in the interaction with the phenyl ring.

An Ni_4 Single-Molecule Magnet: Synthesis, Structure and Low-Temperature Magnetic Behavior

María Moragues-Cánovas,[a] Madeleine Helliwell,[b] Louis Ricard,[c] Éric Rivière,[a] Wolfgang Wernsdorfer,[d] Euan Brechin,*[b] and Talal Mallah*[a]

Keywords: Nickel / Ferromagnetism / Single-molecule studies / Cubane complexes / Tripodal ligands

The reaction of $Ni(NO_3)_2 \cdot 6H_2O$ with H_3thme (trihydroxymethylethane) in the presence of NaOMe leads to a tetranuclear Ni_4 complex with a cubane-like structure. Intramolecular ferromagnetic interactions [$J = 10$ cm^{-1} based on $H = -J(S_1 \cdot S_2 + S_1 \cdot S_3 + S_1 \cdot S_4 + S_2 \cdot S_3 + S_2 \cdot S_4 + S_3 \cdot S_4)$] lead to an $S = 4$ ground state stabilized by 40 cm^{-1} from the first $S = 3$ excited state. Magnetization vs. field studies at different temperatures above 2 K suggest the presence of an axial magnetic anisotropy. Single-crystal magnetization measurements show a single-molecule-magnetic behavior below $T = 0.5$ K with fast relaxation of the magnetization due to resonant quantum tunneling.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Cubane-like Ni_4 tetranuclear complexes have been extensively studied since the first report by Andrew and Blake in 1969 of a ferromagnetic interaction that lead to an $S = 4$ ground state.[1] The origin of the exchange interaction in such compounds is well-understood and is correlated to the Ni−O−Ni angle within the cubane;[1,2] ferromagnetic interaction is found when the Ni−O−Ni angle is lower than 98°.[1,3] The discovery of Single-Molecule Magnetism (SMM) in Ni(II) high spin molecular clusters[4] and particularly in cubane-like Ni_4 tetranuclear complexes[5] revived the interest in such compounds in order to study the correlation between the magnetic anisotropy of the high spin ground state and the relaxation of the magnetization at low temperature.

Here, we report on the preparation, crystal structure, and magnetic behavior of a new cubane-like Ni_4 tetranuclear complex with the general formula $[Ni_4(C_5H_{11}O_3)_4(CH_3CN)_4](NO_3)_4 \cdot 1.33\ NaNO_3$, obtained using 1,1,1-trihydroxymethylethane (H_3thme) as the bridging organic ligand.

Results and Discussion

The reaction between $Ni(NO_3)_2 \cdot 6H_2O$, H_3thme and $NaOCH_3$ in methanol affords, after evaporation of the solvent and extraction of the solid with acetonitrile, blue crystals suitable for structure determination (see Experimental Section). The organic ligand H_3thme has the ability to act as a terminal and/or bridging ligand depending on its degree of protonation. In the present case the single-crystal studies show that the ligand is a monoanion and the complex has a cubane-like structure. Each Ni atom of the cubane is surrounded by two protonated oxygen atoms of H_2thme$^-$ that act as terminal atoms and by the alkoxo-like oxygen atom that bridges three Ni atoms of the cubane core. The coordination sphere of Ni is completed with one acetonitrile molecule (Figure 1). The complex has four positive charges which are compensated by four NO_3^- ions. The crystal contains Na^+ and NO_3^- ions (see formula). The molecule has a principal C_2 axis parallel to the Ni−N bonds. The geometry around Ni is slightly distorted. The shortest Ni−O distances correspond to the oxygen atoms that belong to the cubane core (2.023 and 2.043 Å), and the remaining four Ni−X distances are slightly longer (around 2.056 Å). The main distortion is due to the O−Ni−O angle within the cubane which is equal to 82.01°, while the other X−Ni−X angles are around 92°. There are three different Ni−O−Ni angles; these are equal to 97.25° for the two opposite faces and to 97.04° and 97.95° for the remaining four faces.

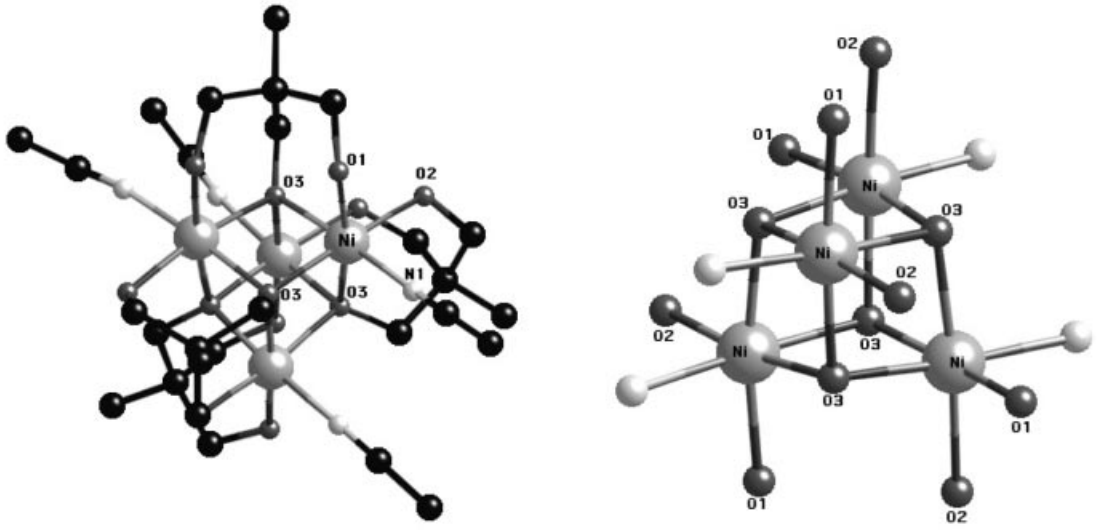

Figure 1. View of the molecular structure of Ni_4

The magnetic data which are presented in the form of $\chi_M T = f(T)$ show that the exchange interaction is ferromagnetic; the $\chi_M T$ product increases on cooling (Figure 2). The maximum $\chi_M T$ value at low temperature (11.85 $cm^3\ mol^{-1}\ K$ at $T = 9$ K) is in agreement with that expected for a $S = 4$ ground state with a g-value larger than 2. The decrease in $\chi_M T$ below 9 K is assumed to be due to zero-field splitting within the ground state, even though the presence of weak intermolecular interactions cannot be excluded. The data were fitted to the theoretical expression of the susceptibility derived from the above-mentioned spin Hamiltonian including the Zeeman term ($g\beta HS$ where S is the spin operator corresponding to the total spin and β the Bohr Magneton) and the zero-field splitting ($D[S_z^2 - S(S + 1)/3]$ where D is the axial zero-field splitting parameter within the $S = 4$ ground state) within the $S = 4$ ground state. Therefore, we first assumed only one exchange coupling parameter between the four Ni atoms. The fit gives the following parameters: $J = 10\ cm^{-1}$, $g = 2.18$, $|D| = 0.5\ cm^{-1}$, and an agreement factor $R = 1.5 \times 10^{-4}$. The magneto-structural correlations for Ni_4 cubane-like complexes lead to the conclusion that a change from ferromagnetic to antiferromagnetic exchange coupling corresponds to a Ni−O−Ni angle of about 98°.[3] For the present complex there are two different sets of Ni−O−Ni angles so that two exchange coupling parameters may be used corresponding to the spin Hamiltonian (Equation 1).

$$H = -J_1(S_1 \cdot S_2 + S_3 \cdot S_4) - J_2(S_1 \cdot S_3 + S_1 \cdot S_4 + S_2 \cdot S_3 + S_2 \cdot S_4) \quad (1)$$

The fit of the magnetic data assuming two exchange parameters leads to the following results: $J_1 = 15\ cm^{-1}$, $J_2 = 8\ cm^{-1}$, $g = 2.18$, $|D| = 0.5\ cm^{-1}$, and an agreement factor $R = 10^{-4}$. The larger ferromagnetic exchange coupling parameter (J_1) corresponds to the smaller Ni−O−Ni angles, as expected from magneto-structural correlations based on the idea that the overlap integral is weaker for angles closer to 90°. It must be stressed here that although two exchange parameters are used, the quality of the fit is not particularly improved. On the other hand, trying to fit the $\chi_M T = f(T)$ data by introducing intermolecular intercations does not lead to satisfactory results. The decrease in $\chi_M T$ at low temperature can thus be (at this level) ascribed mainly to zero-field splitting within the ground state even though the sign of D cannot usually be determined from susceptibility data on powder.

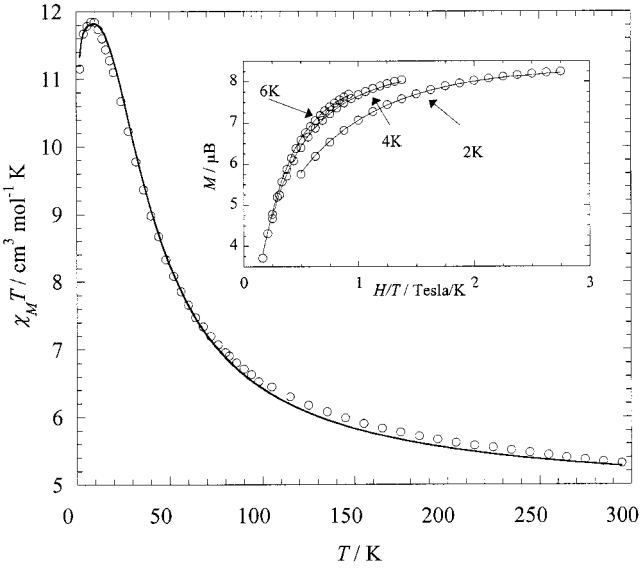

Figure 2 $\chi_M T = f(T)$ for Ni_4, the line corresponds to the best fit with $J = 10\ cm^{-1}$, $g = 2.18$ and $|D| = 0.5\ cm^{-1}$; inset: $M = f(H/T)$ for Ni_4 for $T = 2$, 4 and 6 K, the lines correspond to the best fit with $D = -0.43\ cm^{-1}$, $E/D = 0.04$ and $g = 2.22$

In order to have a better estimation of the zero-field splitting parameters, magnetization vs. field studies at $T = 2$, 4 and 6 K were carried out. The $M = f(H/T)$ plots for H between 1 and 5.5 Tesla (Figure 2 inset) are not superimposable and therefore indicate the presence of magnetic an-

isotropy within the ground state. Since the $S = 3$ first excited state is separated by about 40 cm^{-1} from the ground state, we assume that only the ground state is responsible for the magnetization response. The magnetization data were fitted by diagonalizing the energy matrix for different orientations of the magnetic field. Two reasonable sets of parameters may be obtained depending on the starting values: $D = -0.43$ cm^{-1}, $E/D = 0.04$, $g = 2.22$, $R = 2 \times 10^{-5}$ and $D = -0.48$ cm^{-1}, $E/D = 0.23$, $g = 2.25$, $R = 6.6 \times 10^{-5}$. It is not unusual to find more than one set of parameters with very different E/D values since the E parameter has little influence on the shape of the $M = f(H)$ plots. However, the D values as found are generally very close and can be considered as very good estimates of the magnetic anisotropy of the ground state. The negative sign of D indicates that there is an easy magnetization axis. In such a case one may expect a blocking of the magnetization as a result of a long relaxation time at low temperature.[6] On the other hand, it is well-understood that the magnitude of the E parameter which defines the deviation from purely axial anisotropy is crucial for relaxation by a quantum tunneling process. For large E/D values it is expected that fast relaxation occurs at $H = 0$ and at low temperatures because of the relatively large mixing between the low-lying $M_S = +4$ and -4 sublevels. This may completely preclude the observation of a hysteresis loop in the magnetization plots. However, for weak rhombicity (E/D close to zero) relaxation by quantum tunneling may occur, but not fast enough such that hysteresis may still be present.[7]

In order to get insight into the behavior at very low temperatures, magnetization studies were carried out on a single-crystal using an array of micro-SQUIDs.[8] The measurements were performed with the magnetic field parallel to the easy axis of the crystal. The applied magnetic field was swept at different rates between -1 and 1 Tesla and then back to -1 Tesla at different temperatures between 0.4 and 0.04 K. The data obtained at a sweep rate of 0.14 Tesla/s show a hysteresis loop which includes two steps: a broad one at about 0.3 Tesla and the other very close to zero (Figure 3). The presence of a hysteresis loop indicates that below $T = 0.4$ K, the magnetization is blocked. However, the presence of two steps is the result of rapid relaxation of the magnetization at a given magnetic field where level crossing is avoided. As the temperature decreases, the number of molecules that undergo relaxation by thermal activation diminishes and those that undergo relaxation by tunneling increases. The result is a narrowing of the hysteresis loop with steeper steps. This observation is seen in the present Ni_4 complex. In order to confirm the quantum tunneling of the magnetization, measurements were performed at $T = 0.04$ K for different sweep rates of the magnetic field. The magnetic field was set at $H = -1$ Tesla and then swept towards $H = 1$ Tesla (Figure 4). At $H = -1$ Tesla, all the molecules are in the $M_S = +4$ state. When the magnetic field reaches zero, there is resonance between the $+4$ and the -4 M_S levels and part of the molecules tunnel to $M_S = -4$, while the remaining stay in the former state. This explains the observation of a step at $H = 0$. The height of the step indicates that the tunneling process is relatively fast and thus there is sufficient mixing of the low-lying $M_S = +4$ and -4 levels. On increasing the field above zero, one expects another step corresponding to the molecules tunneling from the $M_S = +4$ to the $M_S = -3$ sublevel. This should occur when H is very close to $D/g\beta$ (about $H = 0.41$ Tesla).[9] A step is actually observed, but at a field closer to 0.32 Tesla. Furthermore, the step is not very steep and this may be due to the presence of different tunneling processes that are not resolved. One possible explanation for such a shift is the presence of very weak intermolecular interactions (exchange or dipolar).[10,11] The tunnel probability de-

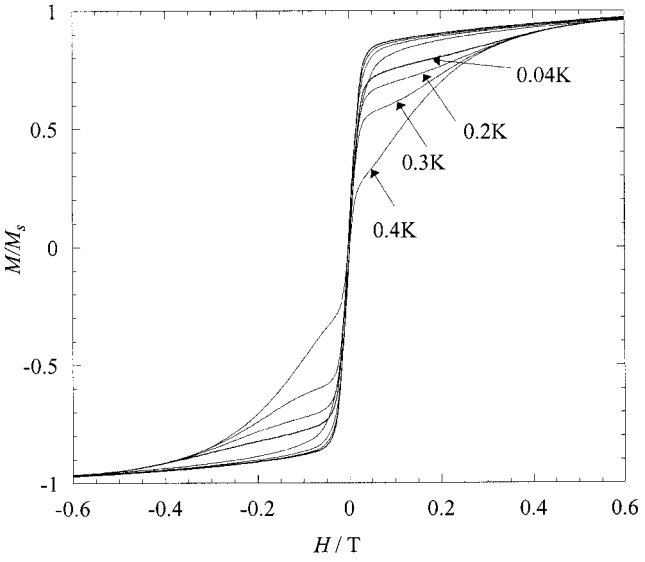

Figure 3. $M/M_S = f(H)$ for a single crystal of Ni_4 with H parallel to the easy axis at different temperatures

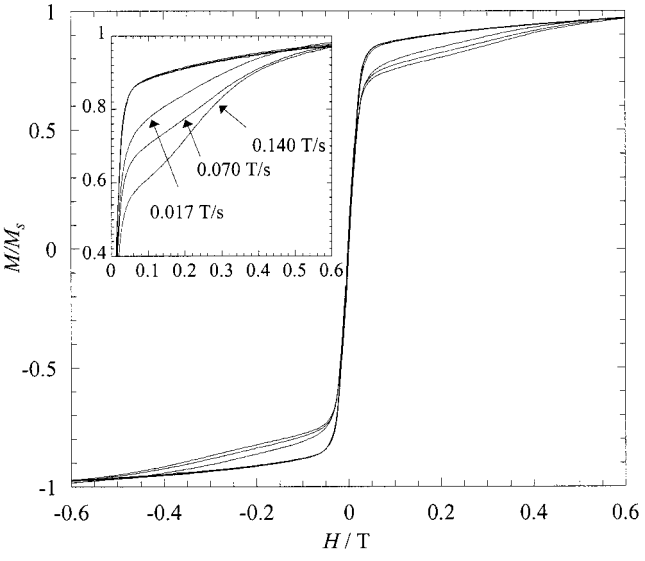

Figure 4. $M/M_S = f(H)$ for a single crystal of Ni_4 with H parallel to the easy axis at different sweep rates of H from -1 to 1 Tesla and back to -1 Tesla; inset: $M/M_S = f(H)$ for a single crystal of Ni_4 with H parallel to the easy axis at different sweep rates of H from 0 to 1 Tesla and back to 0 Tesla

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

creases when the sweep rate is increased,[12] therefore, when the same experiment is carried out at higher sweep rates, the number of molecules tunneling at zero field is less important and the hysteresis loop is larger as shown in Figure 4.

The width of the hysteresis loop depends on the magnetic "history" i.e. the starting magnetic state before varying the magnetic field. Thus, when the field is swept from zero rather than from −1 Tesla (T = 0.04 K), the hysteresis is larger (Figure 4 inset). This can be understood by the fact that there are an almost equal number of molecules in the $M_S = -4$ and $M_S = +4$ states when starting at zero field. When the field is increased from zero, the number of molecules that stay in the $M_S = +4$ state is larger than when the field is swept from $H = -1$ Tesla, resulting in a larger hysteresis. This is true especially for systems with relatively fast relaxation by tunneling processes, as is the case for the present complex.

From the above studies, one may conclude that the Ni_4 complex presents a rich magnetic behavior at low temperature. The magnitude of the rhombicity is clearly weak and a value of E/D of about 0.04 seems more reasonable than 0.23. High-field high-frequency EPR studies are underway in order to accurately determine the spin Hamiltonian parameters D and E and confirm the magnitude of the transverse anisotropy term E responsible for the resonant tunneling at very low temperatures.

Experimental Section

Synthesis: Solid H_3thme (137 mg, 1.14 mmol) and $NaOCH_3$ (185 mg, 3.4 mmol) were added to a solution of $Ni(NO_3)_2 \cdot 6\,H_2O$ (1 g, 3.4 mmol) in methanol (25 mL). The mixture was stirred at room temperature for 24 h, affording a dark green solution which was evaporated to dryness. Extraction of the green powder with 15 mL of MeCN afforded blue crystals suitable for X-ray diffraction. $C_{28}H_{56}N_{9.33}Na_{1.33}Ni_4O_{28}$; M = 1236.98 g mol^{-1}; anal. calcd Na 1.90, Ni 19.43; ; found Na 1.20, Ni, 19.4.

General Remarks: Crystal data: $C_{28}H_{56}N_{9.33}Na_{1.33}Ni_4O_{28}$, M = 1236.98, cubic, a = 24.190(3) Å, U = 14155(3) Å^3, T = 100 K, space group I-43d, Z = 12, Mo-$K(\alpha 1)$ = 0.71069 Å, 16171 reflections measured, of which 2091 were unique (R_{int} = 0.1176). The structure was solved by direct methods (SHELXS-97) and refined with SHELXL-97.[13,14] The final conventional R-factor (based on F and 1876 data with $F > 4(F)$) was 0.0841.

Scanning Tunneling Study of the Assembly of Octa- and Tetraruthenium Supermolecules on Graphite

Dong-Lin Shieh,[a] Kom-Bei Shiu,[a] and Jong-Liang Lin*[a]

Keywords: Supermolecular chemistry / Scanning tunneling microscopy / Graphite / Ruthenium

Surface layer structures of $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCO_2)]_4$ and $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCH_2CO_2)]_2$ with $[Ru_2(CO)_4(PMe_3)_2]$ building blocks *cis*-ligated by either O_2CCO_2 or $O_2CCH_2CO_2$ on highly oriented pyrolytic graphite (HOPG) have been investigated by scanning tunneling microscopy and spectroscopy. STM images of well-ordered assemblies of these two molecules with molecular or submolecular resolution were obtained. These two molecules can adopt an orientation with their Ru–Ru bonds parallel or perpendicular to the substrate surface forming ordered 2D-arrays with different layer structures and tunneling spectra.

Introduction

The design and applications of unique molecular structures containing special functional units, such as rigid *cis*-bridge transition-metal macrocycles, are major subjects of supermolecular chemistry. An ordered arrangement of supermolecules with rigid macrocyclic structures on surfaces or in their film states is of interest in producing nanoscale devices. Thin-film materials based on tetrametallic squares have been preliminarily proven to show the properties of nanoscale porosity, size-selective transport, and molecular or ionic sensing.[1−3] As an example, it has been reported that the bridge-ligated Re/Pd square cationic complexes, prepared by the reaction of $Re(CO)_3Cl(4,4'\text{-bpy})_2$ and $Pd(dppp)(triflate)_2$, show photoluminescent characteristics which can be used for ClO_4^- anion sensing.[1] However, to date we know of no reported surface structure investigations of either a monolayer or a thin film of rigid superstructures of bridged transition metals.

In the present work we investigate the two dimensional (2D) structures of $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCO_2)]_4$ (**1**) and $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCH_2CO_2)]_2$ (**2**) as the first model for supermolecules based on dimetal building units coordinated by *cis*-bridging ligands on HOPG using scanning tunneling microscopy. Figure 1 shows the molecular structures of **1** and **2**. Molecule **1** has an octametallic square shape with four nominally equivalent corner components containing dimetal $[Ru_2(CO)_4(PMe_3)_2]$ building units. Molecule **2** is a molecular loop with two nominally equivalent building blocks. Their crystal structures have been well-characterized by X-ray crystallography.[4] The unique shapes and known dimensions of these molecules allow for the submolecular analysis of the measured STM images. Supermolecules based on dimetal building units can contain various organic ligands that control properties such as solubility, pore size, and electrochemical activity.[5] Furthermore, the spectroscopic and magnetic properties of the dimetal units can be varied for diversified applications.

Results and Discussion

Our scanning tunneling results of $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCO_2)]_4$ are shown in Figures 2 and 3, and of $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCH_2CO_2)]_2$ in Figures 4 and 5. Figure 2 (a) shows a 1000×1000 nm^2 STM image with a step separating two terraces after deposition of **1** on the HOPG. The tunneling image and spectrum obtained around point A in the lower area (the dark terrace) is similar to those of a clean graphite surface. Therefore, the dark terrace is attributed to an uncovered area of the graphite surface. Figure 2 (b) shows the STM image recorded at point B on the bright terrace. In this image, the bright lobes form an ordered array and have the same size and tunneling characteristics, suggesting that they are caused by the same molecular or submolecular groups. In Figure 2 (b), the rows of bright lobes along directions C and D have an included angle of $93 \pm 2°$. The distance between two neighboring lobes in both directions is 6.8 ± 0.2 Å. The geometric characteristics of the STM image corresponds to the angle of Ru4−Ru1−Ru8 (92.5°) and the Ru···Ru distance of Ru1−Ru4 or Ru1−Ru8 (6.9 Å) of **1** as shown in Figure 1.

As molecules of **1** are adsorbed with their 2.7 Å Ru−Ru bonds of $[Ru_2(CO)_4(PMe_3)_2]$ building units perpendicular to the HOPG surface, that is, with the PMe_3 groups pointing either toward or away from the HOPG surface; the adsorbed molecular orientation explains the observed

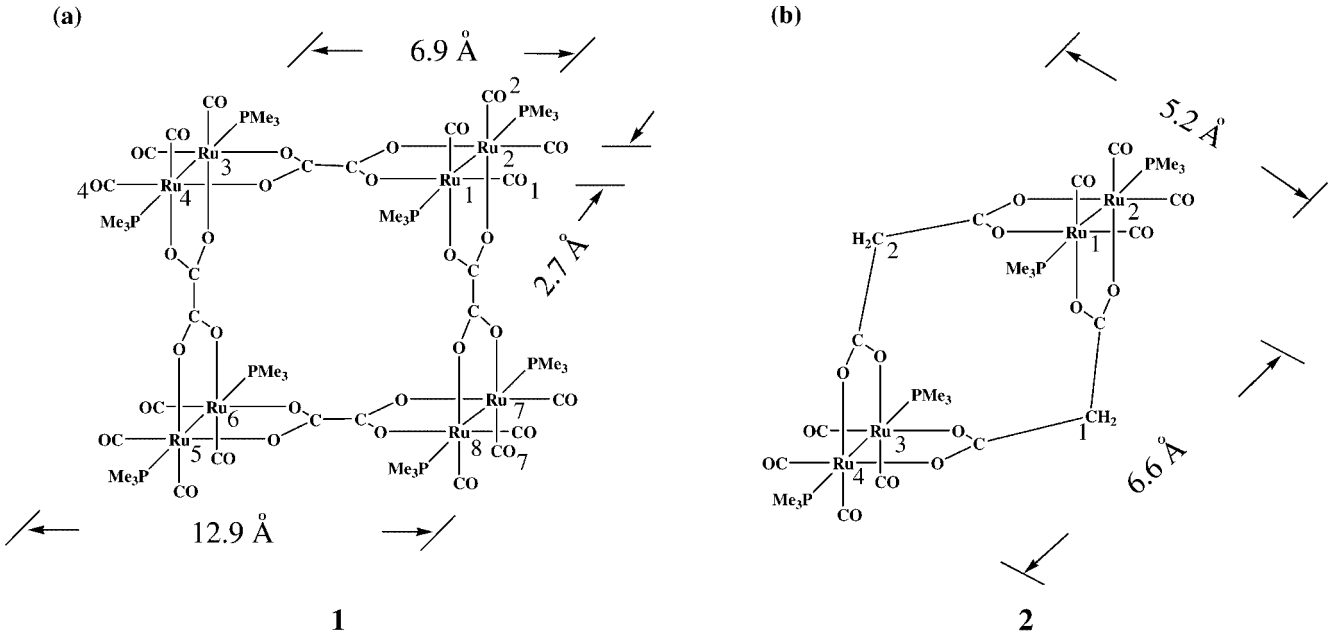

Figure 1. (a) Molecular structure of $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCO_2)]_4$; the shape of this molecule is close to a square, with four approximately equivalent $[Ru_2(CO)_4(PMe_3)_2]$ corner components; (b) molecular structure of $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCH_2CO_2)]_2$

distance and angle of the neighboring lobes exactly. The four lobes connected by the square shown in Figure 2 (b) corresponds to a molecule of **1**. Each lobe represents the submolecular image of one corner component, that is, one $[Ru_2(CO)_4(PMe_3)_2]$ unit of **1**. We were able to record a well-ordered 2D domain of approximately 35 × 35 nm^2 at submolecular resolution. Figure 2 (c) shows the proposed molecular adsorption orientation, as well as the 2D assembly of **1** that matches the observed STM image. This layer structure has a surface unit cell of 13.6 × 13.6 Å^2 with a 93° included angle. The size of the unit cell is slightly larger than that of a unit of **1** [O1−O4 = O2−O7 = 12.9 Å as shown in Figure 1 (a)]; that is, the surface molecules are closely packed together.

This packing characteristic has been observed in the previous STM investigation of the $(Co_4L_4)(AsF_6)_8$ layer on HOPG [L = 4,6-bis(2′,2′′-bipyridyl-6-yl)pyrimidine].[6,7] The monolayer has a periodicity of 25 × 24 Å^2, which corresponds to the size of the Co_4L_4 complex ion with a metal grid unit as well. Figure 2 (d) contains the line profiles taken along the directions of C and D shown in Figure 2 (b); the corrugation is approximately 2.2 Å in both cases. Figure 2 (e) compares the tunneling spectra recorded for the area covered by **1** (similar I-V curves are recorded when the tip is positioned on the peaks and valleys of the corrugation) and for a clean graphite surface. The close packing of the bright lobes [c.a. 6.8 Å between two neighboring lobes, Figure 2 (b)] for **1** excludes the possibility that the adsorbed molecules of **1** adopt an orientation where the Ru−Ru bonds (Ru1−Ru2, Ru3−Ru4, Ru5−Ru6, and Ru7−Ru8) are approximately parallel to the HOPG surface [see Figure 1 (a)], because the distance from the H atoms of a PMe_3 group to those of the opposite PMe_3 group in the same corner unit $[Ru_2(CO)_4(PMe_3)_2]$ is approximately 11.5 Å. Taking the van der Waals radius into account, if the adsorbed molecules of **1** on the HOPG have this orientation, the length between two neighboring bright lobes in either the C or D direction should be larger than 11.5 Å [Figure 2 (b)]. Interestingly, an adsorption orientation with the Ru−Ru bonds approximately parallel to the surface is also observed (Figure 3).

Figure 3 (a) shows another STM image (400 × 400 nm^2), with a step separating two terraces, after deposition of **1** on the HOPG. The dark terrace is attributed to the uncovered area of the graphite surface based on the tunneling images and spectra taken in this area. Figure 3 (b) shows the STM image recorded at point A on the bright terrace. In Figure 3 (b) the size of the bright lobes (c.a. 12.8 × 11.6 Å^2) is about four times that found in Figure 2 (b), and corresponds to the size of a molecule of **1** as shown in Figure 3 (c); implying that each bright lobe in Figure 3 (b) represents a molecule of **1**. In other words, this matched dimension implies that **1** adopts an orientation where the four Ru−Ru bonds are approximately parallel to the HOPG surface. Note that the molecular adsorption orientation in this case is perpendicular to that shown in Figure 2 (c). The ordered array of the bright lobes in Figure 3 (b) has a unit cell of 13.7 ± 0.2 × 14.7 ± 0.2 Å^2 with an included angle of 120 ± 2°. Figure 3 (d) shows the proposed molecular adsorption orientation and the 2D assembly of **1** that matches the observed STM image of Figure 3 (b) according to the size of the bright lobes and the unit cell. Although the included angle of 120 ± 2° [i.e. approximately hexagonal symmetry, Figure 3 (b)] may indicate the superperiodic pattern of a bare HOPG surface, other tunneling features are not consistent with this argument. First, in Figure 3 (b) the corru-

(a) STM image of 1000 × 1000 nm² with a step separating a bright terrace representing a $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCO_2)]_4$-covered area and a dark terrace representing uncovered area of HOPG; (b) high-resolution STM image of the $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCO_2)]_4$-covered area on HOPG; (c) proposed 2D array that matches the STM image; (d) line profiles in the directions of C and D; (e) comparison of tunneling spectra of the $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCO_2)]_4$-covered surface and a bare HOPG surface. V = 0.1 V and I = 0.25 nA were used to record the STM images

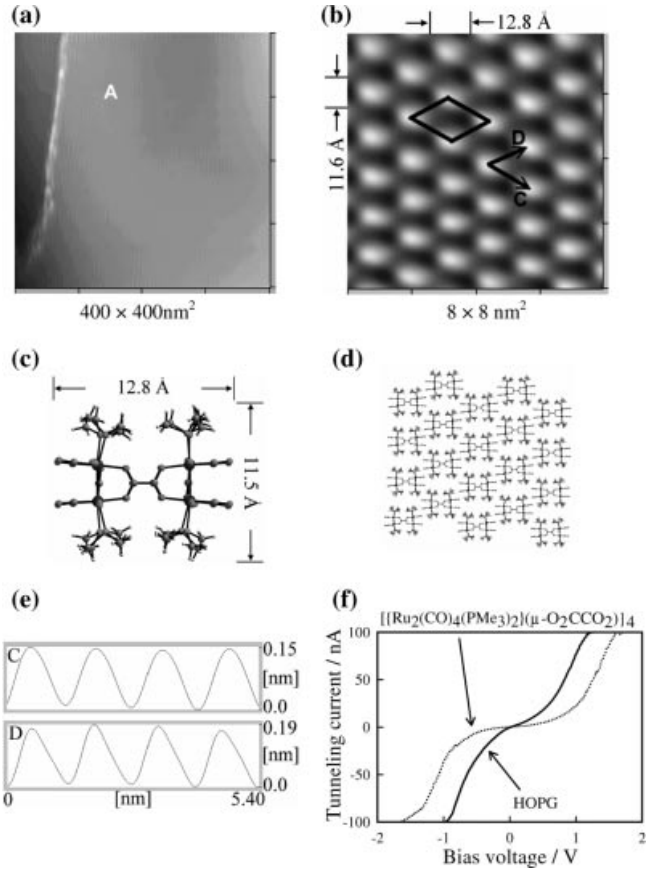

Figure 3. (a) STM image of 400 × 400 nm² with a step separating a bright terrace representing a $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCO_2)]_4$-covered area and a dark terrace representing uncovered area of HOPG; (b) high-resolution STM image of the $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCO_2)]_4$-covered area on HOPG; (c) $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCO_2)]_4$ structure with the indicated dimensions similar to those of the bright lobes in the STM image; (d) proposed 2D array that matches the STM image; (e) line profiles in the directions of C and D; (f) comparison of tunneling spectra of the $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCO_2)]_4$-covered surface and a bare HOPG surface; V = 0.1 V and I = 0.25 nA were used to record the STM images

gations in the C and D directions [these are approximately 0.17 nm, as shown in Figure 3 (e)] are much smaller than the approximate 1−1.5 nm reported for HOPG superlattices.[8,9] Second, no graphite atomic fringes were observed in Figure 3 (b), which were also observed in the STM images of HOPG superlattices.[8,9] Figure 3 (f) shows the tunneling spectrum of Figure 3 (b).

Figure 4 (a) shows the STM image of a covered area comprising molecules of **2** on the HOPG. The rows of bright lobes along directions C and D have an included angle of 110 ± 2°. The distance between two neighboring lobes in either direction is 6.8 ± 0.2 Å. This length corresponds to 6.6 Å between the equivalent parts of the $[Ru_2(CO)_4(PMe_3)_2]$ unit, as shown in Figure 1 (b), suggesting that the bright lobes in Figure 4 (a) are due to $[Ru_2(CO)_4(PMe_3)_2]$ units. Note that the distance between the two CH_2 groups of **2** is only 5.2 Å, which is approximately 1.6 Å less than the distance between two neighboring lobes in Figure 4 (a). Furthermore, the sizes of the bright lobes in Figure 2 (b) for **1** and in Figure 4 (a) for **2** are similar. Therefore, the bright lobes in Figure 4 (a) are not attributed to the CH_2 groups of **2**, but rather to the $[Ru_2(CO)_4(PMe_3)_2]$ units, and as a result, we propose that **2** is adsorbed in such a way that the PMe_3 groups of $[Ru_2(CO)_4(PMe_3)_2]$ point either toward or away from the HOPG surface. Because each bright lobe in Figure 4 (a) corresponds to a $[Ru_2(CO)_4(PMe_3)_2]$ unit, there are three possible 2D assemblies [as shown in Figure 4 (b)] that match the observed STM image. The three different 2D layer structures have surface unit cells of 12.1 × 15.8 Å² with an 87° included angle, 12.1 × 8.0 Å² with a 99° angle, and 13.5 × 8.0 Å² with an 124° angle. Note that the three different layer structures displayed next to each other in Figure 4 (b) do not mean that they co-exist in the STM sampling area of Figure 4 (a). Figure 4 (c) shows the line profiles in the directions of C and D of Figure 4 (a). Figure 4 (d) compares the tunneling spectra recorded for the layer of **2** and

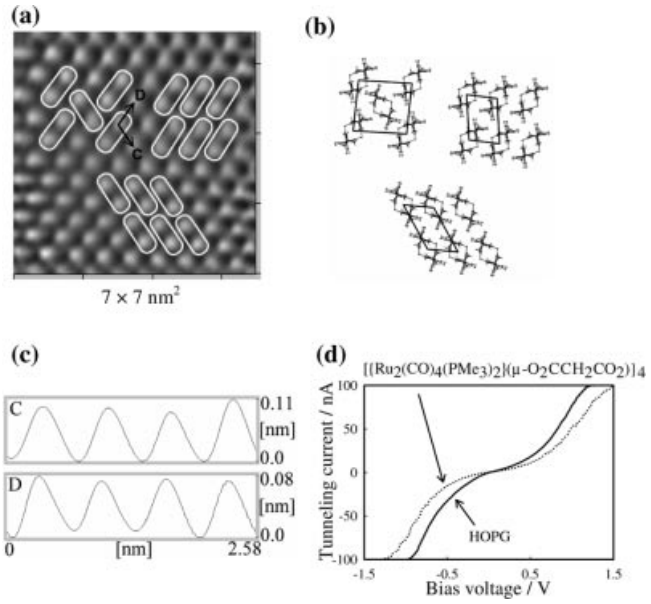

Figure 4. (a) STM image of a $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCH_2CO_2)]_2$-covered area on HOPG; (b) proposed three possible 2D arrays that match the STM image; (c) line profiles in the directions of C and D; (d) comparison of tunneling spectra of the $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCH_2CO_2)]_2$-covered surface and a bare HOPG surface; $V = 0.05$ V and $I = 0.34$ nA were used to record the STM image

a clean HOPG surface. Note that because the molecular adsorption orientations of **1** and **2** are similar [Figure 2 (c) and Figure 4 (b), respectively], that is, with the PMe_3 groups pointing either toward or away from the HOPG surface, the tunneling spectra of **1** and **2** are also similar [Figure 2 (e) and Figure 4 (d), respectively].

Figure 5 (a) shows another observed STM image of **2**, consisting of an ordered array of bright lobes with an approximate size of 11.5×10.2 Å^2. Similar dimensions of a molecule of **2** are shown in Figure 5 (b). This similarity suggests that each lobe in Figure 5 (a) corresponds to a molecule of **2** adsorbed with the two Ru−Ru bonds approximately parallel to the HOPG surface. Note that the orientation of the surface molecules in this case is perpendicular to that shown in Figure 4 (b). The ordered array of the bright lobes in Figure 5 (a) has a unit cell of $11.3 \pm 0.2 \times 13.8 \pm 0.2$ Å^2 with an included angle of $83 \pm 3°$. Figure 5 (c) shows the proposed molecular adsorption orientation and the 2D assembly of molecules of **2** that match the STM image of Figure 5 (a). Figure 5 (d) shows the line profiles in the directions of C and D of Figure 5 (a). Figure 5 (e) compares the tunneling spectra recorded for a layer of **2** with a clean HOPG surface.

Conclusion

In summary, we find that on the HOPG the studied octa- and tetraruthenium supermolecules can both adopt an orientation with their Ru−Ru bonds parallel or perpendicular to the substrate surface, forming ordered 2D arrays with different layer structures and tunneling spectra. We

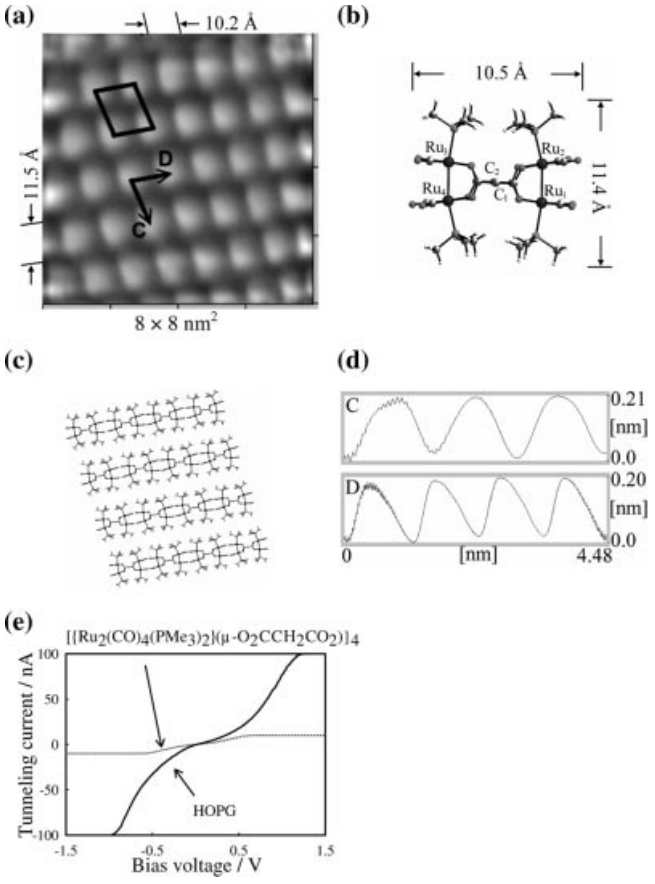

Figure 5. (a) STM image of a $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCH_2CO_2)]_2$-covered area on HOPG; (b) $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCH_2CO_2)]_2$ structure with the indicated dimensions similar to those of the bright lobes in the STM image; (c) proposed 2D array that matches the STM image; (d) line profiles in the directions of C and D; (e) comparison of tunneling spectra of the $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCH_2CO_2)]_2$-covered surface and a bare HOPG surface. $V = 0.05$ V and $I = 0.34$ nA were used to record the STM image

compare, with the aid of the software *Diamond*, the observed 2D structures of the molecules of **1** and **2** on the HOPG to the crystallographic planes of 3D structures of **1** and **2** and find no similar cases that simultaneously have both the same dimensions of the unit cells and the same molecular orientations as those in Figure 2 (c), 3 (d), 4 (b), or 5 (c). This result indicates the influence of the HOPG surface on the 2D assemblies of molecules of **1** and **2**.

Experimental Section

General: $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCO_2)]_4$ (**1**) and $[\{Ru_2(CO)_4(PMe_3)_2\}(\mu\text{-}O_2CCH_2CO_2)]_2$ (**2**) were synthesized through the reactions of freshly prepared $Ru_3(CO)_{12}$, oxalic acid, and PMe_3 in THF according to a procedure previously described.[5] In the preparation of adsorption films of **1** and **2** on HOPG, a droplet of **1** (0.01 M) or **2** (0.03 M) in CH_2Cl_2 was deposited onto a freshly cleaved surface of HOPG (ZYB quality). The CH_2Cl_2 was allowed to vaporize before STM images were recorded (Seiko Instruments, SPA 400) at constant current mode under ambient conditions. The film systems were stable, permitting repeated scans within several months of the

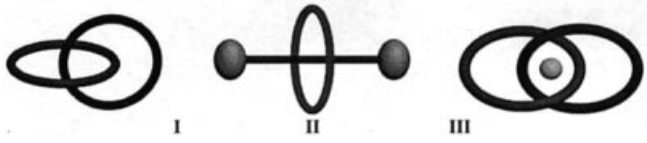
A Novel 3-D Self-Penetrating Topological Network Assembled by Mixed Bridging Ligands

Xing Li,[a] Rong Cao,*[a] Daofeng Sun,[a] Wenhua Bi,[a] and Daqiang Yuan[a]

Keywords: Mixed bridging ligands / Interlocking / Self-penetrating

The assembly of 5-sulfoisophthalic acid (H_3sipa) and 4,4′-bipyridine (bpy) with Cd^{2+} ions gave rise to a new polymeric complex $\{[Cd_3(sipa)_2(bpy)_4(H_2O)_2]\cdot 3H_2O\}_n$ (**1**). X-ray diffraction analysis reveals that complex **1** has a 3-D self-penetrating network formed by the interlocking and interweaving of two types of one-dimensional chains comprising two kinds of $Cd_4(sipa)_4$ and $Cd_4(bpy)_4$ units, respectively. The $sipa^{3-}$ ligand serves as the connector and the Cd^{2+} ion as the node. Thermogravimetric analysis (TGA) and the luminescence property of **1** are discussed.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

The analyses and studies of diverse topological networks have recently received much attention.[1] In these reports a variety of fascinating types of entanglements of individual motifs observed are of special interest due to their important role in natural organic entities.[2] In the past decades, a number of new types of entanglements that are often described as interpenetrating networks,[3] have been constructed from organic building units. Among these entangled polymeric systems, some representative species such as catenanes(**I**), rotaxanes (**II**) or pseudocatenate/rotaxanes (**III**), have been reported (Scheme 1).[4−8] Based on studies on catenane and rotaxane molecules, the introduction of metal ions into polymeric frameworks greatly intrigued many chemists. Aside from unique topological features, these entangled metal-containing species are attractive for use in new functional materials, as well as for the development of molecular devices and studies on bionics.[9−11] The formation of different entanglements or interpenetrations may result from the presence of large free voids in a single network.[3b,7a] It has been shown that long bridging ligands can produce large voids, which may generate interpenetrating structures or large open cavities. For example, 1,3,5-benzenetricarboxylate (btc) which serves as a three-part connector that affords the (6,3) graphite-like sheet and terephthalate and 4,4′-bipyridine that generate the (4,4) sheet, were widely used to design and synthesize directed compounds with interpenetrating or large open cavity structures.[12] Our synthetic approach starts by focusing on the construction of new topological frameworks using different kinds of bridging ligands. Two long bridging ligands, 4,4′-bipyridine (bpy) and 5-sulfoisophthalic acid (H_3sipa), were used, together with Cd^{2+} ions. We hoped each of them could form independent structural units with large voids, and the interlocking or interpenetrating of the two kinds of units with each other could generate an entangled structure. In this communication, we report on a 3-D self-penetrating coordination polymer, $\{[Cd_3(sipa)_2(bpy)_4(H_2O)_2]\cdot 3H_2O\}_n$ (**1**), constructed by the interlocking and interconnecting of two types of metal-ligand rings $Cd_4(sipa)_4$ and $Cd_4(bpy)_4$.



Scheme 1

The hydrothermal reaction of NaH_2sipa, $Cd(NO_3)_2\cdot 4H_2O$, 4,4′-bipyridine and water at 160 °C for 3 days resulted in the formation of light-yellow crystals of **1**. The element analysis and IR spectrum confirm the formula of **1**. Single-crystal X-ray diffraction reveals complex **1** has a 3-D self-penetrating framework constructed from Cd^{2+} ions, and the ligands $sipa^{3-}$ and bpy. There are two types of coordination environments around the Cd^{2+} ions in the crystal structure: Cd(1), which is at the center of a distorted octahedral geometry, is coordinated by two oxygen atoms from two $-SO_3$ groups of different $sipa^{3-}$ ligands and four nitrogen atoms from four bpy ligands; Cd(2) is coordinated by two nitrogen atoms from two bpy ligands, four oxygen atoms from a water molecule and two carboxylate groups, in a highly distorted octahedral geometry. Here, two coordination oxygen atoms from two $-SO_3$ groups on Cd(1) and two coordination nitrogen atoms from two bpy on Cd(2) are located in *cis*-positions with bond angles of 86.00 and

97.48° for O−Cd(1)−O and N−Cd(2)−N, respectively. Such *cis* positions that are sterically hindered have rarely been observed in reported studies,[13] and may induce the formation of the ring structures $Cd_4(sipa)_4$ and $Cd_4(bpy)_4$. The formation of open cavities or channels may be favored by the *trans* locations of the ligands.

In **1**, four cadmium ions and four bpy ligands form a $Cd_4(bpy)_4$ unit with a side length of 11.46 × 11.79 Å and diagonal measurement of 15.55 × 17.28 Å based on the metal−metal distances. Different metal−metal distances in the tetragonal sheet arise as a result of the different torsions and curves of the bpy ligands linking Cd(1) and Cd(2), respectively. The fully deprotonated $sipa^{3-}$ ligand acts as a tridentate ligand linking three cadmium ions by its monodentate sulfonic, monodentate carboxylate and chelating carboxylate groups. Four $sipa^{3-}$ ligands and four cadmium ions form a 32-membered ring unit, $Cd_4(sipa)_4$. The two kinds of units, $Cd_4(sipa)_4$ and $Cd_4(bpy)_4$, interlock and interconnect with each other to produce a self-penetrating structural unit (Figure 1),[2c,14] in which the $sipa^{3-}$ ligand penetrates through the $Cd_4(bpy)_4$ ring and strong face to face π-π stacking interactions involving the aromatic rings from the closest neighboring $sipa^{3-}$ and bpy ligands (with an average distance of about 3.50 Å) is observed. Each $Cd_4(bpy)_4$ unit interlocks two $Cd_4(sipa)_4$ units and each $Cd_4(sipa)_4$ unit interlocks two $Cd_4(bpy)_4$ units through cadmium ion nodes, yielding an interwoven structure that is extended in different directions forming a three-dimensional self-penetrating topological network.

In the $Cd_4(bpy)_4$ unit, four cadmium ions are coplanar, and two such adjacent planes have a dihedral angle of 57°. Therefore, through the sharing of the vertex cadmium ion knots, the $Cd_4(bpy)_4$ units are further extended into a one-dimensional twisted 8-like chain (see a in Figure 2). Through the sharing of the $sipa^{3-}$ sides, the $Cd_4(sipa)_4$ units propagate a one-dimensional ladder-like chain (see b in Figure 2), in which all the cadmium ions are coplanar and the $sipa^{3-}$ ligands are situated in the zygomorphic sites of the plane. The two types of one-dimensional chains interlock and interweave together to form a two-dimensional framework through the sharing of cadmium ions in the *ab* plane (see c in Figure 2). The 1-D ladder-like chains comprising $Cd_4(sipa)_4$ units possess an AB array (left, direction up; right, direction down) along the *a* axis and AA array along the *c* axis, while the 1-D twisted 8-like chains formed by the $Cd_4(bpy)_4$ units have an AA illustration down the *b* axis and ABC display along the *c* axis. The two-dimensional structure extend in different directions generating a 3-D packing network with micro channels that can accommodate free water molecules (Figure 3). It is worth noting that the structure of **1** reveals a new topological net: Cd1 acts as a "6-connected" center, Schäfli symbol (4^2; 6^4; 8^9); Cd2 as a "4-connected" center, Schäfli symbol (4; 6^4; 8); and $sipa^{3-}$ as a "3-connected" center, Schäfli symbol (6^2; 8). Considering the stoichiometry, the overall topology is $(Cd1)(Cd2)_2(sipa)_2$, Schäfli symbol (4^2; 6^4; 8^9)(4; 6^4; $8)_2$ (6^2; $8)_2$.

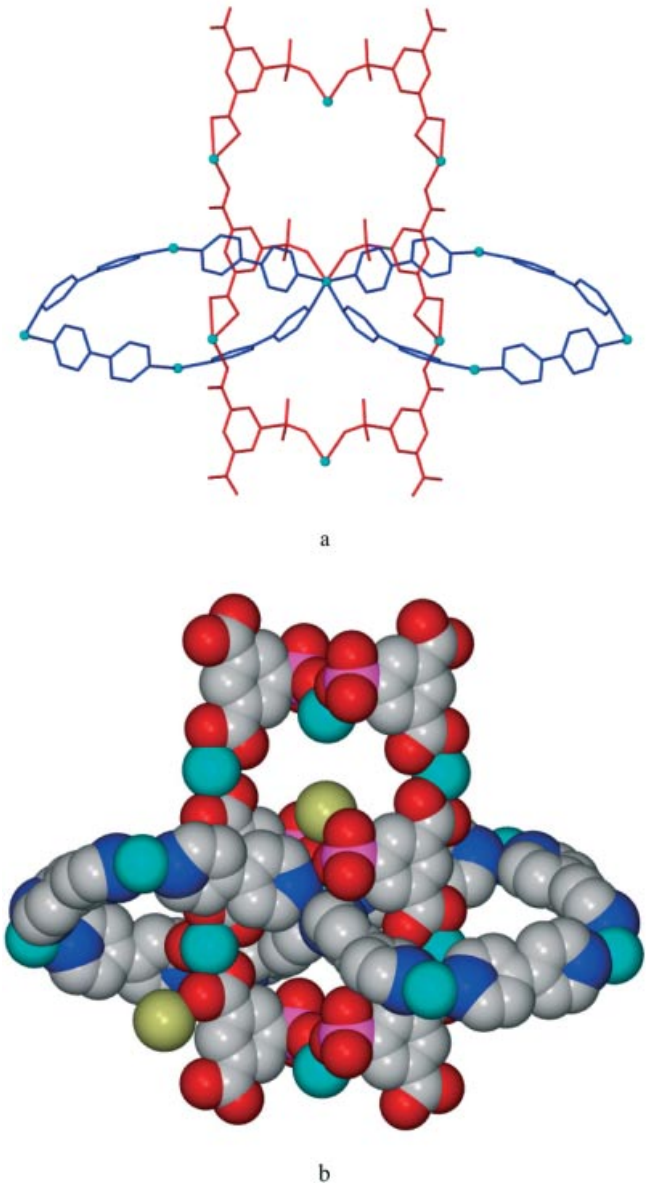

Figure 1. (a) The interlocking self-penetrating unit formed by $Cd_4(sipa)_4$ (red) and $Cd_4(bpy)_4$ (blue) units through sharing node Cd^{2+} ions; (b) space-filling diagram: turquoise sphere representing Cd^{2+} ion, brown-yellow: free water, scarlet red: oxygen, gray: carbon, blue: nitrogen, pink: sulfur

The thermogravimetric analysis (TGA) study shows that the first weight loss of 5.75% (calcd: 5.86%) observed from 63 to 144 °C corresponds to the loss of three free water and coordinated water molecules per formula unit ($5H_2O$/$\{[Cd_3(sipa)_2(bpy)_4(H_2O)_2]\cdot 3H_2O\}$), and the structural framework begins to collapse at 340 °C. Heating-cooling and dehydrate-hydrate experiments were carried out according to the TGA results, and monitored by X-ray powder diffraction. The crystalline sample of complex **1** is heated to 145 °C under autogenous pressure for 4 hours, the guest water molecules are lost from the sample and some characteristic XRPD peaks become weaker or disappear. However, when the resulting dehydrated products are immersed

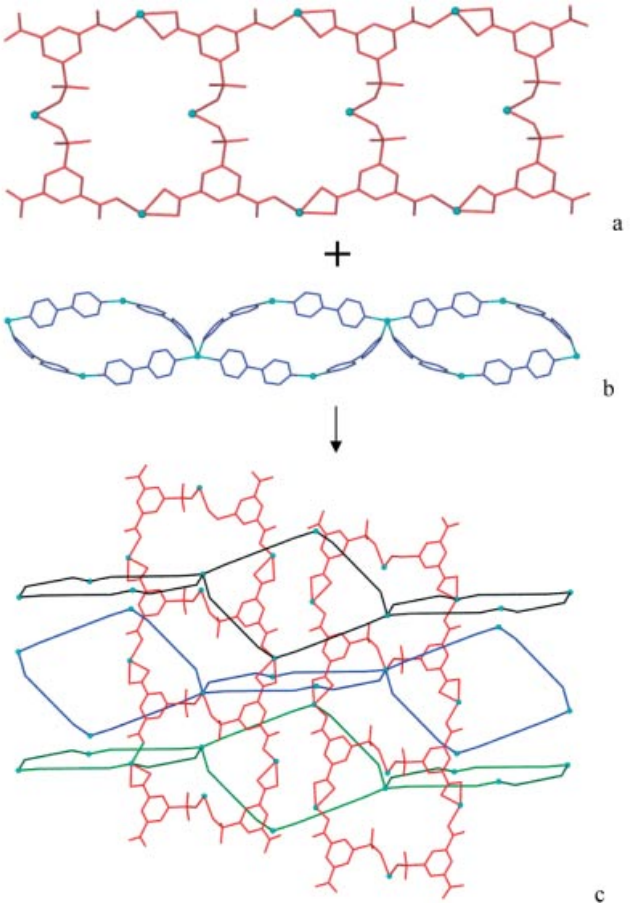

Figure 2. (a) 1-D ladder-like chains formed by $Cd_4(sipa)_4$ units(red); (b) 1-D twisted 8-like chains formed by $Cd_4(bpy)_4$ units (blue); (c) schematic presentation of 2-D framework in the *ab* plane

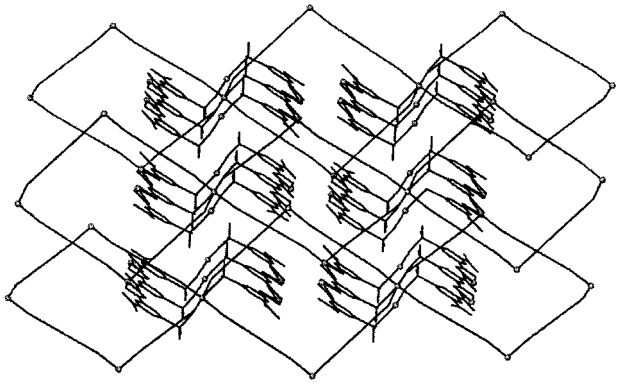

Figure 3. 3-D packing structure for **1** along the *b* axis, guest water molecules are omitted for clarity

in water for 12 hours, the XRPD pattern and infrared spectrum for the rehydrated sample are almost the same as those of the original sample, illustrating that the framework of **1** is retained on the removal of guest water molecules. The details of the XRPD analyses for **1** are provided as Supporting Information. The luminescence spectrum of **1** in the solid state at ambient temperature exhibits an intense broadband fluorescent emission at 453 nm on photo-excitation at 354 nm, suggesting that **1** may be suitable as a candidate for a stable and solvent-resistant blue fluorescent material due to its stability in air and insolubility in common solvents.[15]

In summary, a novel three-dimensional self-penetrating network constructed from two mixed bridging ligands has successfully been prepared; although many entangled structures have been reported, those constructed by mixed bridging ligands are rather few. The present work shows that a novel structure can be designed and assembled through the combination of the topology of organic ligand and the coordination geometry of metal ion. Further studies on this subject are still underway.

Experimental Section

Synthesis of 1: A mixture of NaH_2sipa (0.266 g, 1.0 mmol), $Cd(NO_3)_2{\cdot}4H_2O$ (0.231 g, 0.75 mmol), 4,4′-bipyridine dihydrate (0.192 g, 1.0 mmol) and water (10 mL) was placed in a 25 mL Teflon^R-lined stainless autoclave under autogenous pressure at 160 °C for 3 days after which it was cooled slowly to room temperature over a 24 hour period. The light yellow block-like crystals of **1** were separated from the reaction mixture in about a 23% yield (0.35 g). $C_{56}H_{48}Cd_3N_8O_{19}S_2$: calcd. Final GooF = 1.077, R_1 = 0.0469, wR_2 = 0.0833 with $I > 2\sigma(I)$.

Data collection for **1** was performed on a Siemens SMART-CCD diffractometer equipped with a graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 293 K. All absorption corrections were applied using the SADABS program. The structures were solved by direct methods, the metal atoms were located from the E-maps, and other non-hydrogen atoms were derived from the successive difference Fourier syntheses. The hydrogen atoms were located from the difference map and refined isotropically. The structure was refined on F^2 by full-matrix least-squares using the SHELXTL-97 program package.

CCDC-221212 (for **1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

D_{5h} Cu_5H_5X: Pentagonal Hydrocopper Cu_5H_5 Containing Pentacoordinate Planar Nonmetal Centers (X = B, C, N, O)

Si-Dian Li,*[a] Chang-Qing Miao,[b] and Guang-Ming Ren[b]

Keywords: Ab initio calculations / Density functional calculations / Hydrocopper / Pentacoordinate planar carbon / Electronic structures

Pentacoordinate planar nonmetals (PPNs) centered in perfect pentagonal hydrocopper complexes Cu_5H_5X (X = B, C, N, O), as determined by density functional theory methods, are presented in this communication. The results obtained in this work complete the hypercoordinate planar carbon series with high symmetries (D_{4h}, D_{5h}, and D_{6h}), and may shed new insight in catalyst chemistry.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Exploring the bonding nature of carbon beyond the tetrahedral concept in organic chemistry has attracted considerable attention since Hoffmann et al.[1] proposed the possibility of tetracoordinate planar carbon (TPC) thirty years ago. Recent experimental and theoretical investigations have confirmed the existence of TPCs in Al_4C^- with D_{4h} symmetry,[2] Al_3XC and Al_3XC^- with C_{2v} symmetry (X = Si, Ge),[3,4] and $[CAl_4]^{2-}$.[5] A similar observation was reported for tetracoordinate planar Si and Ge in MAl_4 and MAl_4^-.[6] Even more interesting, the possibility of pentacoordinate planar carbons (PPC) in $-C_3B_3-$, $-C_2B_4-$, and $-CB_5-$ subgroups and hexacoordinate planar carbons (HPCs) in B_6C^{2-} with D_{6h} symmetry was also explored by Schleyer et al.[7–9] recently at the density functional theory (DFT) level. In a very recent paper,[10] our group performed an ab initio investigation of tetracoordinate planar nonmetals (TPNs) centered in perfect square hydrometals M_4H_4 in D_{4h} M_4H_4X complexes (X = B, C, N and O; M = Cu and Ni), and extended the tetracoordinate planar centers from carbon to other first-row nonmetal elements and the ligands from *p*-block elements to transition metal atoms. However, unlike D_{4h} TPCs and D_{6h} HPCs observed in simple molecules, a PPC center with a high D_{5h} symmetry is still missing. Here, we present theoretical investigations of pentacoordinate planar nonmetals (PPNs) in Cu_5H_5X (X = B, C, N, O) complexes that contain D_{5h} X centers in a perfect pentagonal hydrocopper (Cu_5H_5) proposed by Tsipis et al.[11] To the best of our knowledge, there have been no investigations reported to date on D_{5h} PPCs or other TPNs centered in perfect pentagonal structures composed of transition metal ligands. The results obtained in this work complete the hypercoordinate planar carbon series with the high symmetries of D_{4h}, D_{5h}, and D_{6h}.

Initial structures obtained at DFT B3LYP/Lanl2d$_z$ were further optimized at DFT B3LYP/6-311+G(3df,p) and imaginary frequencies were checked at the same level of theory.

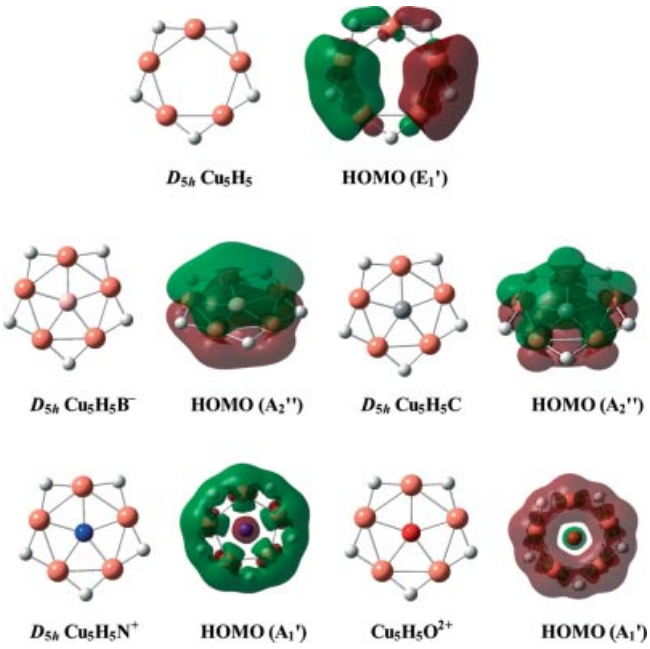

Figure 1. Optimized structures of D_{5h} Cu_5H_5X complexes (X = B, C, N, O) and their HOMO diagrams compared with that of hydrocopper D_{5h} Cu_5H_5 at the B3LYP/6-311+G(3df,p) level

H NMR tensors /ppm	32.5		34.5		36.1		35.3		39.5	

The calculated binding energy ΔE = 255.7 kJ/mol for the reaction $Cu_5H_5C = Cu_5H_5 + C$ clearly demonstrates the stability of the D_{5h} Cu_5H_5C with respect to dissociation to the hydrocopper Cu_5H_5 and the free C atom. When refined at the MP2/6-311+G(d,p) level of theory, the DFT bond lengths are systematically shortened by about 2 to 5%. The NMR shielding tensors were calculated using the gauge-independent atomic orbital (GIAO) procedure[12] at the B3LYP/6-311+G(3df,p) level. The optimized DFT structures and corresponding highest occupied molecular orbital (HOMO) diagrams of the D_{5h} Cu_5H_5X series are depicted and compared with that of the pentagonal hydrocopper Cu_5H_5 at the same level of theory in Figure 1. The optimized bond parameters, lowest vibrational frequencies and NMR shielding tensors at DFT, and the bond lengths at MP2 are summarized in Table 1. All the calculations were performed using the Gaussian 03 suite of programs.[13]

Different from the squared Cu_4H_4X series,[10] all the isoelectronic Cu_5H_5X neutral and charged ions possess perfect planar pentagonal structures with the highest symmetry, D_{5h} (see Figure 1). As can be seen from Figure 1 of ref. 10,[10] the Cu_4H_4 square is too small to accommodate the B and C centers. However, the Cu_5H_5 pentagon studied here is shown to have the correct size such that the first-row nonmetal centers (from B, C, N to O) can be accommodated to form D_{5h} Cu_5H_5X complexes without imaginary frequencies (see Table 1). In addition, structures with initial C_{5v} symmetry and off-plane X atoms along the fivefold axis are found to be automatically converted into perfect planar pentagons during structural optimization, further confirming that these D_{5h} complexes are true minima on their potential energy surfaces. Various initial structures with lower symmetries have also been tested; however, optimized structures with lower energies are not obtained. These high symmetry D_{5h} geometries with the lowest energies obtained in this work possess high stabilities as discussed above for D_{5h} Cu_5H_5C and have no imaginary frequencies that lead to structural distortions. The Cu−Cu separations in the Cu_5H_5X complexes are systematically shorter than those in the parent Cu_5H_5, but these distances increase from $Cu_5H_5N^+$ to $Cu_5H_5O^{2+}$. The bonding characteristics of the HOMOs of the complex series are clearly demonstrated in the molecular orbital diagrams shown in Figure 1. The molecular orbital analyses indicate that for $Cu_5H_5B^-$ and Cu_5H_5C, the doubly occupied highest occupied molecular orbitals (HOMOs) are delocalized π bonds (A_1') mainly composed of the $2p_z$ orbitals of the central atoms (with a slight contribution from the 3d orbitals of the Cu ligands), while the HOMOs of $Cu_5H_5N^+$ and $Cu_5H_5O^{2+}$ are delocalized σ bonds (A_2'') with the largest contribution from the 4s and 3d orbitals of the Cu ligands and partial contribution from the 2s orbitals of the central atoms. The delocalized σ HOMOs obtained here for $Cu_5H_5N^+$ and $Cu_5H_5O^{2+}$ are similar to the σ HOMOs observed in D_{4h} $Cu_4H_4N^+$ and $Cu_4H_4O^{2+}$.[10]

Natural bond orbital (NBO) analyses give new insights into the understanding of the atomic charge distribution and electron configurations of these complexes. The NBO results indicate that in the Cu_5H_5X complexes the X atoms serve as the negatively charged nonmetal centers, the Cu atoms at the periphery form a positively charged ring, and the bridging H atoms carry negative charges to maintain the overall charge balance. For example, Cu_5H_5C has the atomic charges of C −1.91 |e|, Cu +0.79 |e|, and H −0.41 |e|, and the corresponding values for $Cu_5H_5B^-$ are B −2.36|e|, Cu +0.72|e|, and H −0.44|e|. Even in the positively charged $Cu_5H_5N^+$ and $Cu_5H_5O^{2+}$ structures, the N and O centers carry the negative charges of −1.54|e| and −1.19|e|, the Cu atoms possess the positive charges of +0.87|e| and +0.96|e|, and the H atoms have negative charges of −0.37|e| and −0.33 |e|, respectively. This "sandwich" charge distribution reflects the consequence of electron transfer from the Cu ligands to the nonmetal centers X and the bridging H atoms, and results in the nearly pure lone pairs of electrons in the $2p_z$ orbitals of the central atoms. The high occupancies of the $2p_z$ orbitals are clearly demonstrated in the atomic electron configurations of $B[He]2s^{1.75}2p_x^{0.82}2p_y^{0.82}2p_z^{1.88}$, $C[He]2s^{1.86}2p_x^{1.05}2p_y^{1.05}2p_z^{1.92}$, $N[He]2s^{1.93}2p_x^{1.30}2p_y^{1.30}2p_z^{1.95}$, and $O[He]\ 2s^{1.97}2p_x^{1.60}2p_y^{1.60}2p_z^{1.97}$ in the corresponding complexes. It is interesting to note that in $Cu_5H_5B^-$ and Cu_5H_5C the nearly doubly occupied $2p_z$ orbitals of the central atoms dominate the formation of the π-typed HOMOs, while in the positively charged $Cu_5H_5N^+$ and $Cu_5H_5O^{2+}$ structures, the $2p_z$ orbitals mainly participate in the formation of the molecular orbitals next to the HOMOs (HOMO−1), which are also π-typed orbitals (not shown in Figure 1). For all the D_{5h} TPNs studied in this work, the 2s, $2p_x$, and $2p_y$ valence orbitals of the central atom form sp^2 hybrids to form five equivalent partial bonds with the periphery copper ligands.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The orbital hybridization pattern observed here for PPNs parallels those in the TPCs in planar D_{4h} CH_4 and Ni_4H_4C structures, where the C center with three sp^2 hybrids forms equivalent bonds with its four equivalent ligands.[1,10] These D_{4h} TPC and D_{5h} PPN structures are achieved by resonances between equivalent structures allowed by the hybridization patterns of the central atoms and the arrangements of the specific ligands around them, as discussed in the case of D_{4h} CH_4.[1]

In order to assess the aromaticity of Cu_5H_5X complexes we observe the variation of the NMR spectroscopic chemical shifts of the H atoms relative to the NMR shielding tensor of the H atoms in tetrahedral $Si(CH_3)_3$ (δ = 31.9 ppm), since the geometrical center of the Cu_5H_5 pentagon is occupied by a nonmetal center. For X = B, C, N and O the calculated δ_H = +2.6, +4.2, +3.4, and +7.6 ppm, respectively. These up-field chemical shifts calculated for the H atoms outside the Cu_5 ring clearly indicate that the ring current effects in Cu_5H_5[11] vanish because of the introduction of the X atoms at the ring centers, and therefore the Cu_5H_5X complexes studied here are nonaromatic in nature. This finding is in agreement with the results obtained for the M_4H_4X series.[10]

In this work we have presented ab initio evidence of PPCs and other PPNs centered in perfect pentagonal Cu_5H_5X complexes. Investigations on heteropentagonal systems $M_xM'_yH_5X$ ($x + y = 5$) containing PPNs are under progress. Dimerization or formation of even higher aggregates are also possible, similar to the systems containing double HPCs.[9] Hydrometal complexes centered with hypercoordinate planar nonmetals are important in fundamental research and could have important applications in catalyst chemistry.

In memoriam Othmar Stelzer

Keywords: Iron / Chromium / Sandwich complexes / P ligands / Asymmetric catalysis

An improved synthesis of (*R*,*R*)- and (*S*,*S*)-hexane-2,5-diol is presented. The (*S*,*S*)-derivative was converted into a cyclic sulfate, which on treatment with $NaPH_2$ in liquid ammonia ultimately gave the secondary (*R*,*R*)-2,5-dimethylphospholane. This phospholane can be introduced into the side chain of chiral tricarbonylchromium and ferrocene derivatives to give new bidentate ligands of the Josiphos and Daniphos type. Both the ferrocene- and tricarbonylchromium-based diphosphanes have been characterized by X-ray diffraction analysis. A discussion of their structural features is included. The new ligands were successfully applied to the enantioselective hydrogenation of itaconic acid esters.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Enantioselective homogeneous catalysis remains one of the most challenging topics in organic and organometallic chemistry. Continuous improvements are being made, largely due to the development of new families of ligands. The Nobel committee recognized this by awarding the 2001 Nobel Prizes in chemistry for achievements in this field.[1]

In the search for novel catalysts and ligands, chemists have used all types of organic backbones, natural as well as unnatural. Whereas earlier research focused on ligands derived from the "chiral pool", e.g. tartaric acid, terpenes, amino acids, and sugars, the emphasis has shifted somewhat towards other ligand systems not derived from natural sources. This is largely due to the enormous success of such ligand families as BINAP and its derivatives, the DUPHOS ligands,[2,3] as well as the "Josiphos" family of ligands.[4,5] It should be noted that these ligands contain unusual elements of chirality, such as planar and axial chirality. The Josiphos ligands are also special in that they incorporate a transition metal containing unit as the central core around which the ligand framework is constructed. This transition metal itself is not involved in the catalysis, but is part of the scaffold to which the ligand functions are attached. The function of the metal is to create a chiral environment, the spatial and dynamic properties of which could not be achieved by an organic framework alone.

We have recently described a similar class of metal complexes, known as "Daniphos" complexes, which are based on chiral arenetricarbonylchromium complexes.[6−10] In many aspects, these ligands are similar to the Josiphos ligands but differ both in steric as well as electronic properties. They also match the ferrocene ligands in enantioselectivity in a number of catalytic applications. The major advantage of the chromium systems is their easy availability in an optically active form without any need for resolution, because the organic ligand itself (phenylethylamine), is commercially available in both enantiomers and with a variety of functional derivatives. Furthermore, the simple and straightforward synthetic route to the Daniphos ligands allows the construction of these diphosphanes in a modular fashion, a concept that has attracted considerable attention in the last decade.[11]

We sought to combine the advantages of both the metal-containing chiral frameworks of ferrocene and chromium-arene derivatives with the chirality of the phospholane units used in DUPHOS ligands. A necessary prerequisite was the availability of the secondary chiral phospholane (*R*,*R*)-2,5-dimethylphospholane, which has been briefly mentioned in

the literature but was not isolated or fully characterized.[12] We therefore sought a route to prepare this phospholane directly from PH_3, and to incorporate it into both Josiphos and Daniphos ligands.

Results and Discussion

Optically active 2,5-hexanediol can be prepared by several routes, preferably by asymmetric homogeneous hydrogenation or enzymatic methods. Due to the commercial success of the DUPHOS ligands, larger quantities of this chemical in both the (*R*,*R*)- and (*S*,*S*)-forms are now in demand, and therefore we tried to scale the enzymatic route to allow the synthesis of kilogram amounts. The synthesis of both enantiomers could be achieved with quantitative conversion and with excellent diastereo- and enantioselectivities (> 96% *de*, > 99% *ee* for the (*R*,*R*)-isomer and 99% *de*, > 99% *ee* for the (*S*,*S*)-isomer) (Scheme 1).[13] Both enantiomers prepared by this route are now also commercially available.[13c]

The introduction of phospholane units into suitable organic frameworks remains a synthetic challenge even nowadays. The standard method employed today for the synthesis of the various DUPHOS ligands starts from a bis(primary)phosphane [e.g. the benzene derivative *o*-$C_6H_4(PH_2)_2$], which has to be synthesized by an elaborate route. This compound is then deprotonated and treated with the cyclic sulfate derived from hexanediol (Scheme 2).[3] A possible alternative is the reductive cleavage of a phenylphospholane with lithium metal, which then can be treated with organic halides.[14] Once again, however, this method is quite elaborate and (with larger substituents) can result in epimerization at C-2 and C-5. A third route has recently been described by Börner et al., in which *P*-(trimethylsilyl)phospholane, prepared from $P(TMS)_3$ in a two-step cyclization, undergoes nucleophilic addition to dichloromaleic anhydride.[15]

A fourth possible alternative is the use of a secondary phospholane, which proved to be difficult to isolate and characterize due to its volatility and extreme sensitivity. It was stabilized as a borane adduct, which however restricted its use to the synthesis of ligands with remote phospholane groups.[12]

Unfortunately, none of the above-mentioned reagents can be used for the introduction of phospholane units into the side-chain of Josiphos or Daniphos ligands. We therefore sought a route to prepare the secondary phospholane directly from PH_3. $NaPH_2$ was generated by deprotonation of PH_3 with sodium in liquid ammonia, and then treated with the cyclic sulfate of (*S*,*S*)-2,5-hexanediol. By following the reaction with ^{31}P and ^{1}H NMR spectroscopy, we were able to show that the ring-opening phosphination of the cyclic sulfate proceeded much faster than the second insertion step. The intermediate primary phosphane **1** (δ_P = −110.7 ppm) can be isolated and appears to be quite stable. By using two equivalents of $NaPH_2$, the reaction can be driven to completion, and after 48 h at −35 to −40 °C the secondary phospholane **2** (δ_P = −27.7 ppm) was isolated in the (*R*,*R*)-form with no evidence of epimerization, as the substitution proceeds cleanly by double inversion. The phospholane **2** can be purified by distillation, but due to its high volatility and pyrophoric nature, we were not able to obtain an elemental analysis. This compound can be stabilized as a BH_3 adduct **3**, as described earlier (Scheme 3).[12]

The standard method of introducing phosphanes onto the side chain of chiral (*R*,*R*)-1-[1-(dimethylamino)ethyl]-2-diphenylphosphanylferrocene is by refluxing this compound

with a secondary phosphane in glacial acetic acid.[16] With the phospholane **2**, this reaction gave the desired diphosphane **4** in 55% yield. A somewhat different reaction path is necessary for the chromium complexes — an acetone solution of (*R*,*R*)-[1-(1-chloroethyl)-2-diphenylphosphanyl-η^6-benzene]chromium tricarbonyl was treated with **2**. An acetone solution of $TlPF_6$ was then slowly added to this mixture over one hour by an automatic syringe. The same reaction was also performed with the (*S*,*S*)-chromium com plex and the two diastereomeric products **5** and **6** were isolated in 80% and 96%, respectively (Scheme 4).

We were able to grow single crystals of the ferrocene derivative **4** (Figure 1). Not surprisingly, **4** adopts a conformation in which the bulky phospholane is above the plane of the cyclopentadienyl ring. Some relevant dihedral angles are shown in Table 1.

For applications to catalysis, we also prepared the (norbornadiene)Rh complexes of both the iron and chromium compounds (**7**−**9**). Again, we were fortunate to obtain single crystals of the Fe−Rh complex **7** (Figure 2) and the Cr−Rh complex **9** (Figure 3). We also synthesized and structurally characterized the bis(ferrocene) rhodium complex **10** (Figure 4). Experimental crystallographic and crystal data are collected in Table 7.

As expected, the diphosphane **4**, on coordination to the square-planar environment of rhodium, has to undergo a considerable conformational change (Figures 1, 2 and 4). By comparing rhodium complexes of both Josiphos and Daniphos ligands, we were able to show that this conformational change is even more severe for the chromium complexes than for the iron complexes (Table 1), possibly due to the narrower bite angle of the benzene ring relative to the cyclopentadienyl ring.[9] Some selected bond lengths and angles for complexes **4**, **7**, **9** and **10** are summarized in Tables 2−5.

The respective conformations of each ligand are also manifested by the P,P coupling constants in the ^{31}P NMR spectra. This is normally governed by the orientation of the lone pairs on the phosphorus atoms with respect to each other and the accompanying dihedral angle.[18] As can be seen from Figure 1, the phospholane moiety in compound **4** adopts a position away from the bulky diphenylphosphane group, so that the two phosphorus atoms are almost anti-periplanar. As a consequence, no P,P coupling constant can

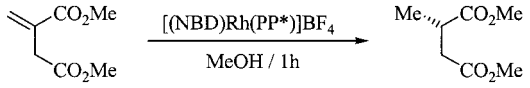
be observed in the ^{31}P NMR spectrum of **4**. In contrast, when the ligand is attached to rhodium, it has to undergo a severe conformational change (as mentioned above). The two phosphorus atoms are now synperiplanar, and consequently the NMR spectrum shows a clear set of two double doublets, revealing a P,P coupling constant of 45.8 Hz ($J_{P,Rh}$ = 150.2 Hz). The same can be said for the chromium ligands: whereas the (*R*,*R*)-diastereomer **5** as the free ligand shows only singlets, a set of two double doublets is observed for its rhodium complex **8**. In contrast, the (*S*,*S*)-diastereomer **6** shows "normal" behaviour in its uncomplexed form, with two doublets and a set of two double doublets in the rhodium complex **9**.

Hydrogenation of Dimethyl Itaconate

For an assessment of the catalytic performance of the ligands, some preliminary hydrogenations were carried out, using dimethyl itaconate as the substrate (Scheme 5). The results are summarized in Table 6.



Scheme 5

Table 6. Results of the hydrogenation of itaconate (reaction time = 1 h)

Ligand	Conversion [%]	chemical yield [%]	*ee* [%][a]	Configuration	TOF [1/h]
4	100	100	> 99	*S*	200
5	12	12	25	*S*	24
6	53	53	86	*S*	106

[a] Determined by GC on a Lipodex *E* column at 100 °C.

It should be noted that the experiments were stopped after one hour in order to get an insight into the reaction rate of each ligand, which explains the incomplete conversions in some cases. Taking into account that a relatively high substrate-to-catalyst ratio of 200 was chosen, it can be concluded that the ferrocene ligand **4** is working quite efficiently, whereas its chromium analogues are somewhat slower. It also shows excellent enantioselectivity, whereas the enantiomeric excess is considerably lower for the chromium ligands. It is noteworthy that diastereomer **6** results in a much higher *ee* than diastereomer **5**. This exemplifies vividly that the stereochemical outcome of a catalysis is very sensitive to the steric as well as the electronic features of the employed ligand, because the ferrocene derivative **4** possesses the same stereochemical features as chromium ligand **5**, but a different backbone, whereas the stereochemistry in the backbone of **6** is reversed. (It should be noted that, due to its carbonyl ligands, the chromium tripod is strongly electron-withdrawing, whereas the ferrocene unit is a potent electron donor). In this context it seems desirable to have an analogous ferrocene diastereomer in hand for comparison.

In conclusion, it seems likely that the *ee* value of the product is not governed by the phospholane unit alone, but that the configuration (and nature) of the planar chiral backbone plays an important role as well. More detailed investigations in that respect are currently being carried out.

Conclusion

A novel method for preparing the secondary (*R*,*R*)-dimethylphospholane has been elaborated, making it available in moderate-to-good yields from enantiopure (*S*,*S*)-hexanediol, itself synthesized on a large scale by an improved enzymatic route. The phospholane has been successfully introduced onto ligand scaffolds both of the Daniphos and the Josiphos type. These have been structurally studied in detail by X-ray analyses. Preliminary catalytic studies on the hydrogenation of itaconic acid esters showed encouraging results. Further studies on catalysis employing these ligands are currently under investigation and are due to be published soon.

Experimental Section

General Remarks: All manipulations were carried out under nitrogen using standard Schlenk techniques. Solvents were dried and deoxygenated by standard procedures. Chromatography was carried out with Merck alumina 90. NMR spectra were recorded with Varian Mercury 200 (^1H: 200 MHz, ^{13}C: 50 MHz, ^{31}P: 81 MHz), Varian Unity 500 (^1H: 500 MHz, ^{13}C: 125 MHz, ^{31}P: 202 MHz), Bruker AC 250 (^1H: 250 MHz, ^{13}C: 63 MHz, ^{31}P: 101 MHz) and Bruker AMX 400 (^1H: 400 MHz, ^{13}C: 100 MHz, ^{31}P: 162 MHz) spectrometers at ambient temperature. IR spectra were recorded with a Perkin−Elmer FT-IR model 1720 X spectrometer. Mass spectra were obtained with a Finnigan MAT 95 spectrometer, using CI (with isobutane as the reactant gas) and SIMS recording techniques for the chromium and rhodium complexes, respectively.

(2*S*,5*S*)-Hexanediol and (2*R*,5*R*)-Hexanediol: In a thermostatted vessel (30 °C) glucose (169.2 g, 0.858 mol glucose) was dissolved in distilled water (1.5 L). Baker's yeast (*Saccharomyces cerevisiae*) (271.5 g) was then added portionwise. The pH was adjusted to 6

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with 4 N NaOH, and 2,5-hexanedione (4.63 mL, 25 mmol) added. Quantitative conversion was achieved after 24 h (96% *de*, > 99% *ee*). The biomass was separated by centrifugation (20 min, 5000 *g*). The resulting supernatant liquid was extracted with ethyl acetate (3 L) and the organic phase evaporated. (2*S*,5*S*)-hexanediol crystallized overnight at 4 °C and was recrystallized from 1-octanol (75% yield). For a detailed description of the synthesis of (2*R*,5*R*)-hexanediol see ref.[13]

(2*R*,5*R*)-Dimethylphospholane (2): Ammonia (300 mL) was condensed into a three-necked flask at −78 °C. Sodium (5.4 g, 234 mmol) was added in small portions. Using a slight pressure excess (0.1 bar), PH_3 was added until the solution was saturated (yellow colour). The cyclic sulfate of (2*S*,5*S*)-hexanediol (21.1 g, 117 mmol) was added. After complete evaporation of the ammonia, the residue was dissolved in Et_2O (300 mL) and stirred for two days. The sodium sulfate was then filtered off and washed with Et_2O (100 mL). The solvent was removed by distillation and the remaining residue distilled at ambient pressure. Yield 7.4 g (63.8 mmol, 55%). ^{1}H NMR (C_6D_6): δ = 2.75 (ddd, $J_{P,H}$ = 181.8, $J_{H,H}$ = 11.2, $J_{H,H}$ = 8.9 Hz, 1 H, PH), 2.55−2.45 (m, 1 H, CH), 1.92−1.82 (m, 1 H, CH), 2.05 −1.82 (m, 2 H, CH_2), 1.22−1.02 (m, 2 H, CH_2), 1.10 (dd, $J_{P,H}$ = 17.6, $J_{H,H}$ = 7.6 Hz, 3 H), 1.11 (dd, $J_{P,H}$ 11.4, $J_{H,H}$ = 6.3 Hz, 3 H) ppm. ^{13}C NMR (C_6D_6): δ = 40.75 (d, $J_{P,C}$ = 6.1 Hz, CH_2), 38.70 (d, $J_{P,C}$ = 3.1 Hz, CH_2), 32.46 (d, $J_{P,C}$ = 8.6 Hz, CH), 29.31 (d, $J_{P,C}$ = 6.6 Hz, CH), 21.65 (d, $J_{P,C}$ = 31.0 Hz, CH_3*cis*P(l.p.)], 19.43 (s, CH3*trans*P(l.p.)] ppm. ^{31}P NMR (C_6D_6): δ = −27.7 (d, $^1J_{P,H}$ = 181.1 Hz) ppm.

(2*R*,5*R*)-Dimethylphospholane−BH_3 Adduct: Equimolar amounts of the phospholane **2** and borane−dimethylsulfide complex (10.0 M solution in dimethyl sulfide) were stirred at room temperature for 4 h. All volatile components were then removed in vacuo to provide the adduct (quantitative conversion). ^{1}H NMR (C_6D_6): δ = 4.34 (m, $J_{P,H}$ = 349.3 Hz, PH), 2.71−2.56 (m, 1 H, CH_2−CH_2), 2.29−2.11 (m, 3 H, CH_2−CH_2), 1.48−1.32 (m, 2 H, CH), 1.27 (dd, $J_{P,H}$ = 15.5, $J_{H,H}$ = 6.9 Hz), 1.16 (dd, $J_{P,H}$ = 17.0, $J_{H,H}$ = 7.4 Hz), 0.49 (m, $J_{B,H}$ = 98.0 Hz) ppm. ^{13}C NMR (C_6D_6): δ = 37.04 (d, $J_{P,C}$ = 3.1 Hz, CH_2), 36.79 (s, CH_2), 33.77 (d, $J_{P,C}$ = 36.6 Hz, CH), 28.15 (d, $J_{P,C}$ = 34.6 Hz, CH), 17.52 (d, $J_{P,C}$ = 3.1 Hz, CH_3), 16.04 (d, $J_{P,C}$ = 5.1 Hz, CH_3) ppm. ^{31}P{^{1}H} NMR: δ = 24.0 (d, $J_{P,B}$ = 44.3 Hz) ppm. ^{31}P NMR: δ = 24.0 (d, $J_{P,H}$ = 349.3 Hz) ppm. $C_6H_{16}BP$ (129.97): calcd. C 55.34, H 12.39; found C 53.47, H 12.16.

For convenience, in the following experimental descriptions, the abbreviation "DMP" is used for the structural unit "2,5-dimethylphospholane".

(*R*,*R*)-[(C_5H_5)Fe{C_5H_3(CHMe{(*R*,*R*)-DMP})(PPh_2)}] (4): (*R*,*R*)-2,5-Dimethylphospholane (0.14 g, 1.20 mmol) was added to a stirred solution of (*R*,*R*)-[(C_5H_5)Fe{C_5H_3(CHMeNMe_2)(PPh_2)}] (0.53 g, 1.20 mmol) in glacial acetic acid (7 mL), and heated to 75 °C for 1 h. The solvent was removed in vacuo and the resulting solid was washed with ethanol twice. The pure product was obtained as an orange solid by recrystallization from ethanol. Yield 0.34 g (0.66 mmol, 55%). ^{1}H NMR (500 MHz, C_6D_6): δ = 7.72 (m, 2 H, arom. H), 7.55 (m, 2 H, arom. H), 7.03 (m, 6 H, arom. H), 4.40 (m, 1 H, Cp), 4.19 (m, 2 H, Cp), 3.83 (s, 5 H, Cp), 3.29 (m, 1 H, Fc-C*H*CH_3), 1.90 (m br., 1 H, PC*H*CH_3), 1.76 (dd, $J_{H,H}$ = 6.7, J_{PH} = 16.2 Hz, 3 H, Fc-CHCH_3), 1.44 (m br., 1 H, PC*H*CH_3), 1.40−0.80 (m br., 4 H, CH_2), 1.21 (t, $J_{H,H}$ = 8.1 Hz, 3 H, PCHCH_3), 0.96 (dd, $J_{H,H}$ = 7.0, $J_{P,H}$ = 17.1 Hz, 3 H, PCHCH_3) ppm. ^{13}C NMR (125 MHz, C_6D_6): δ = 135.68, 135.50, 133.49, 133.34, 129.14 (PPh_2), 70.21 (*Cp*), 69.64 (*Cp*), 69.12 (CpC_{ipso}), 36.63 (*Me*-Phospholane), 36.49 (*Me*-Phospholane), 34.85 (CH_2), 31.68 (CH_2), 25.43 [d, $J_{C,P}$ = 31.3 Hz, PCH(Me)CH_2], 24.27 [d, $J_{C,P}$ = 14.2 Hz, PCH(Me)CH_2], 21.13 (d, $J_{C,P}$ = 13.7 Hz, CHMe), 14.33 (CH*Me*) ppm. ^{31}P NMR (80 MHz, C_6D_6): δ = 20.22 (α-P), −30.49 (*ortho*-P) ppm. $C_{30}H_{34}FeP_2$ (512.4): calcd. C 70.32, H 6.69; found C 69.95, H 6.67.

General Procedure for the Synthesis of the Chromium Tricarbonyl Ligands 5 and 6: (*R*,*R*)-2,5-Dimethylphospholane (1 equiv.) was added to a stirred solution of the appropriate chloride-substituted chromium complex[8,10] (1 equiv.) in dry acetone (20 mL/mmol). Subsequently, $TlPF_6$ (1 equiv.), dissolved in 20 mL/mmol of acetone, was added dropwise over a period of one hour with an automatic syringe. The reaction mixture was stirred overnight at ambient temperature, quenched by adding NEt_3, filtered, evaporated and subjected to column chromatography (Al_2O_3, pentane followed by Et_2O).

[η^6-(*R*,*R*)-{[(*R*,*R*)-DMP]CHMe}$C_6H_4PPh_2$]Cr(CO)$_3$ (5'): Compound **5** was made from (*R*,*R*)-2,5-dimethylphospholane (0.25 g, 2.15 mmol), [η^6-(*R*,*R*)-{(Cl)CHMe}$C_6H_4PPh_2$]Cr(CO)$_3$ (0.99 g, 2.15 mmol) and $TlPF_6$ (0.71 g, 2.04 mmol) according to the general procedure described above. Yield: 0.93 g (1.72 mmol, 80%). ^{1}H NMR (500 MHz, C_6D_6): δ = 7.63−7.53 [m, 2 H, $H_{ar.}$(PPh_2)], 7.43−7.34 [m, 2 H, $H_{ar.}$ (PPh_2)], 7.14−6.99 [m, 6 H, $H_{ar.}$(PPh_2)], 5.17 (ddt, $J_{H,H}$ = 6.5, $J_{H,P}$ = 3.2, $J_{H,H}$ = 1.1 Hz, 1 H, $H_{ar.}$), 4.69 (dt, *J* = 6.1, *J* = 1.3 Hz, $H_{ar.}$), 4.52 (t, *J* = 6.5 Hz, $H_{ar.}$), 4.29 (td, *J* = 6.3, *J* = 1.1 Hz, $H_{ar.}$), 3.64 (sext, *J* = 6.7, *J* = 1.1 Hz, 1 H, C*H*Me), 1.77 [m, 1 H, PC*H*(Me)CH_2], 1.63 (dd, $J_{H,P}$ = 15.6, $J_{H,H}$ = 6.8 Hz, 3 H, CH*Me*), 1.42−1.34 (m br., 2 H, CH_2), 1.20 [m, 1 H, PC*H*(Me)CH_2], 0.95 [dt, *J* = 8.1, *J* = 1.5 Hz, 3 H, PCH(*Me*)CH_2], 0.77 (d, *J* = 7.0 Hz, *J* = 17.0 Hz, 3 H, PCH(*Me*)CH_2], 0.58 (m, 1 H, CH_2), 0.48 (m, 1 H, CH_2) ppm. ^{13}C NMR (125 MHz, C_6D_6): δ = 233.18 (*C*O), 135.24−127.12 [12 C, $C_{ar.}$(PPh_2)], 127.54 (d, *J* = 21.1 Hz, $C_{ipso,ar.}$), 104.53 (d, *J* = 20.1 Hz, $C_{ipso,ar.}$), 96.32 (d, *J* = 2.0 Hz, $C_{ar.}$), 92.95 (dd, $^2J_{C,P}$ = 15.4, $^4J_{C,P}$ = 3.8 Hz, $C_{ar.}$), 92.55 ($C_{ar.}$), 91.55 ($C_{ar.}$), 37.49 (d, *J* = 2.9 Hz, CH_2), 36.44 (s, CH_2), 36.28 (d, *J* = 17.2 Hz, *Me*-phospholane), 34.26 (d, *J* = 12.4 Hz, *Me*-phospholane), 24.85 [d, *J* = 28.8 Hz, PC*H*(Me)CH_2], 20.82 [d, *J* = 36.1 Hz, PC*H*(Me)CH_2], 15.19 (*C*HMe), 5.67 (CH*Me*) ppm. ^{31}P NMR (80 MHz, C_6D_6): δ = 29.16 (s, α-P), −20.63 (s, *ortho*-P) ppm. IR (C_6D_6): ν_{CO} = 1967, 1893 cm^{-1}. $C_{29}H_{30}CrO_3P_2$ (540.5): calcd. C 64.44, H 5.59; found C 64.22, H 5.69.

[η^6-(*S*,*S*)-{[(*R*,*R*)-DMP]CHMe}$C_6H_4PPh_2$]Cr(CO)$_3$ (6): Compound **6** was made from (*R*,*R*)-2,5-dimethylphospholane (0.227 g, 1.953 mmol), [η^6-(*S*,*S*)-{(Cl)CHMe}$C_6H_4PPh_2$]Cr(CO)$_3$ (0.90 g, 1.953 mmol) and $TlPF_6$ (0.648 g, 1.855 mmol) according to the general procedure described above. Yield: 1.01 g (1.77 mmol, 96%). ^{1}H NMR (500 MHz, C_6D_6): δ = 7.64 [m, 2 H, $H_{ar.}$ (PPh_2)], 7.42 [m, 2 H, $H_{ar.}$ (PPh_2)], 7.15−7.05 [m, 6 H, $H_{ar.}$ (PPh_2)], 4.87 (dt, *J* = 6.1, *J* = 1.2 Hz, $H_{ar.}$), 4.63 (t, *J* = 6.4 Hz, $H_{ar.}$), 4.56 (m, 1 H, $H_{ar.}$), 4.26 (dt, *J* = 6.4, *J* = 0.9 Hz, $H_{ar.}$), 4.01 (q, *J* = 7.0 Hz, 1 H, C*H*Me), 1.91 [m, 1 H, PC*H*(Me)CH_2], 1.74 [m, 1 H, PC*H*(Me)CH_2], 1.62 (m, 1 H, CH_2), 1.50 (m, 1 H, CH_2), 1.41 (m, 1 H, CH_2), 1.33 (dd, *J* = 7.0, *J* = 4.0 Hz, 3 H, CH*Me*), 1.00 [PCH(*Me*)CH_2], 0.96 [PCH(*Me*)CH_2], 0.82 (m, 1 H, CH_2) ppm. ^{13}C NMR (125 MHz, C_6D_6): δ = 233.10 (*C*O), 136.58 [d, *J* = 6.5 Hz, $C_{ipso,ar.}$(PPh_2)], 136.36 [d, *J* = 13.7 Hz, $C_{ipso,ar.}$(PPh_2)], 135.26−125.30 (10 C, P*Ph*$_2$), 127.00 (d, *J* = 23.0 Hz, $C_{ipso,ar.}$), 103.62 (d, *J* = 17.5 Hz, $C_{ipso,ar.}$), 98.74 ($C_{ar.}$), 93.80 ($C_{ar.}$), 90.23 ($C_{ar.}$), 88.45 (dd, *J* = 6.9 Hz; *J* = 3.6 Hz, $C_{ar.}$), 37.80 (d, *J* = 3.8 Hz, CH_2), 36.95 (s, CH_2), 35.65 [d, *J* = 18.1 Hz, PC*H*(Me)CH_2], 30.65 [d, *J* = 18.7 Hz, PC*H*(Me)CH_2], 21.50 [PCH(*Me*)CH_2], 21.23 [PCH(*Me*)CH_2], 18.18 (*C*HMe), 14.78 (CH*Me*) ppm. ^{31}P NMR

(80 MHz, C_6D_6): δ = 19.96 (d, $J_{P,P}$ = 20.1 Hz, α-P), −18.99 (d, $J_{P,P}$ = 20.1 Hz, *ortho*-P) ppm. IR (C_6D_6): $\tilde{\nu}_{CO}$ = 1968, 1898 cm^{-1}. $C_{29}H_{30}CrO_3P_2$ (540.5): calcd. C 64.44, H 5.59; found C 64.25, H 5.71.

General Procedure for the Synthesis of the Rhodium Complexes: $[NBDRhCl]_2$ (1 equiv.) and $AgBF_4$ (2 equiv.) were dissolved in THF (10 mL) in a Schlenk flask and the solution was stirred vigorously for 30 minutes at ambient temperature. The clear solution was removed from the precipitated AgCl by a syringe equipped with a filter needle, and dripped into a solution of the diphosphane (2 equiv.) in THF (5 mL). After stirring for 10 minutes, the product [(diene)Rh(PP*)]BF_4 was precipitated by adding Et_2O. The ethereal solution was discarded and the solid dried in vacuo.

[(NBD)Rh{(*R*,*R*)-(C_5H_5)Fe[C_5H_3(CHMe{(*R*,*R*)-DMP})(PPh_2)]}]-BF_4 (7): Compound **7** was obtained by treating complex **4** (44 mg, 0.085 mmol) with $[NBDRhCl]_2$ (20 mg, 0.043 mmol) and $AgBF_4$ (17 mg, 0.085 mmol), according to the general procedure described above. Yield: 50 mg (0.063 mmol, 74%). ^{31}P NMR (200 MHz, $CDCl_3$): δ = 61.03 (dd, $J_{P,P}$ = 45.8, $J_{P,Rh}$ = 150.2 Hz, α-P), 20.08 (dd, $J_{P,P}$ = 45.8, $J_{P,Rh}$ = 150.2 Hz, *ortho*-P) ppm. MS (SIMS): *m*/*z* (rel. int.) = 86.8 (100) $[BF_4]^-$, 707.5 (3.2) [(NBD)-Rh{(*R*,*R*)-(C_5H_5)Fe[C_5H_3(CHMe{(*R*,*R*)-DMP})(PPh_2)]}]$^+$.

[(NBD)Rh{[η^6-(*R*,*R*)-{[(*R*,*R*)-DMP]CHMe}$C_6H_4PPh_2$]Cr($CO)_3$}]-BF_4 (8): Compound **8** was obtained by treating complex **5** (125 mg, 0.232 mmol) with $[NBDRhCl]_2$ (53 mg, 0.116 mmol) and $AgBF_4$ (45 mg, 0.232 mmol), according to the general procedure described above. Yield: 122 mg (0.150 mmol, 64%). ^{31}P NMR (200 MHz, $CDCl_3$): δ = 68.92 (dd, $J_{P,P}$ = 38.5, $J_{P,Rh}$ = 130.0 Hz, α-P), 30.87 (dd, $J_{P,P}$ = 38.5, $J_{P,Rh}$ = 130.0 Hz, *ortho*-P) ppm. MS (SIMS): *m*/*z* (rel. int.) = 86.9 (100) $[BF_4]^-$, 734.8 (8.0) [(NBD)Rh{[η^6-(*R*,*R*)-{[(*R*,*R*)-DMP]CHMe}$C_6H_4PPh_2$]Cr($CO)_3$}]$^+$.

[(NBD)Rh{[η^6-(*S*,*S*)-{[(*R*,*R*)-DMP]CHMe}$C_6H_4PPh_2$]Cr($CO)_3$}]-BF_4 (9): Compound **9** was obtained by treating complex **6** (140 mg, 0.260 mmol) with $[NBDRhCl]_2$ (60 mg, 0.130 mmol) and $AgBF_4$ (51 mg, 0.260 mmol), according to the general procedure described above. Yield: 130 mg (0.160 mmol, 61%). ^{31}P NMR (200 MHz, $CDCl_3$): δ = 61.07 (dd, $J_{P,P}$ = 43.0, $J_{P,Rh}$ = 156.6 Hz, α-P), 28.66 (dd, $J_{P,P}$ = 43.0, $J_{P,Rh}$ = 156.6 Hz, *ortho*-P) ppm. MS (SIMS): *m*/*z* (rel. int.) = 87.0 (100) $[BF_4]^-$, 734.8 (20) [(NBD)Rh{[η^6-(*S*,*S*)-{[(*R*,*R*)-DMP]CHMe}$C_6H_4PPh_2$]Cr($CO)_3$}]$^+$.

{(*R*,*R*)-[C_5H_5]Fe[C_5H_3(CHMe{(*R*,*R*)-DMP})(PPh_2)]}$_2BF_4$ (10): Compound **10** was obtained by treating complex **4** (30.0 mg, 0.0586 mmol) with $[(NBD)_2Rh]BF_4$ (11.0 mg, 0.0293), according to the general procedure described above. Recrystallization from MeOH afforded single crystals suitable for X-ray diffraction.

Hydrogenation of Dimethyl Itaconate: Hydrogenations were carried out by putting a weighed amount of the [(NBD)Rh(PP*)]BF_4 complex (approx. 3 mg) in a glass vial and adding (under argon) the appropriate amount of a stock solution of the substrate in methanol (0.25 mmol/mL), in order to give a substrate-to-catalyst ratio of 200. After purging with hydrogen three times, the reaction was left to run for one hour.

X-ray Crystallographic Study: Single crystals suitable for X-ray analyses were grown from dry methanol. Crystal data and details of the structure determination are listed in Table 7. Data set for **4** was collected with an Enraf Nonius CAD4 diffractometer (Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator). The unit cell parameters were obtained by the least-squares refinement of 25 re-

flections. The data collection for **7**, **9** and **10** was performed with a Bruker Smart CCD (Mo-K_α radiation, λ= 0.71073 Å, graphite monochromator) area detector. The unit cell parameters were obtained by the least-squares refinement of 8096 reflections. All structures were solved by direct methods (SHELXS-97)[19] and refined by full-matrix least-squares procedures based on F^2 with all measured reflections (SHELXL-97.[19] The SADABS[20] program was used for absorption correction of the structures **7**, **9** and **10**. All non-hydrogen atoms were refined anisotropically. All H atom positions were introduced at their idealized positions (d_{C-H} = 0.96 Å) and were refined using a riding model. The absolute configuration was confirmed by evaluation of the Flack[21] parameter. CCDC-217865, -217866, -217867 and -21786 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The authors wish to gratefully acknowledge financial support by the Deutsche Forschungsgemeinschaft DFG within the Collaborative Research Centre (SFB, 380) "Asymmetric Synthesis with Chemical and Biological Methods" and by the "Fonds der Chemischen Industrie". We thank Dr. Felix Spindler of Solvias for his help with the catalytic experiments. B. C. is grateful to the Graduiertenkolleg: "Methods of Asymmetric Synthesis" for a scholarship.

Keywords: Asymmetric catalysis / Constrained geometry ligands / Cyclopentadienyl ligands / P ligands / Ruthenium

Optically active cyclopentadienyl-linked phosphane ligands L_n of general formula $C_5H_5CH_2CH(R)PR'_2$ (R = Ph, R′ = Ph, L_1; R = Ph, R′ = Cy, L_2; R = mesityl, R′ = Ph, L_3) and $C_5H_5CH(R)CH_2PPh_2$ (R = Cy, L_4; R = Bzl, L_5) are synthesised by ring-opening reactions of 1-R-spiro[2.4]hepta-4,6-dienes (R = Ph, Cy, mesityl, benzyl), with lithium phosphides $LiPR'_2$ (Ar = Ph, Cy). Reaction of the ligands L_n with $[RuH(\eta^5\text{-}C_7H_{11})_2][BF_4]$ in acetonitrile at reflux affords the bis(acetonitrile) ruthenium(II) complexes $[Ru(\eta^5\text{-}C_5H_4(C_2H_3R)PR'_2\text{-}\kappa P)(CH_3CN)_2][BF_4]$, in which the ligands are coordinated to the metal through the cyclopentadienyl and the phosphane moieties forming a chelate, in almost quantitative yields. The complexes are active catalysts in the redox isomerisation of geraniol affording chiral citronellal but with low enantioselectivity. They also catalyze an aldol-type C–C coupling reaction between 3-buten-2-ol and benzaldehyde affording almost racemic 4-hydroxy-3-methyl-4-phenyl-2-butanone with good diastereoselectivity (*syn*/*anti* ratio up to 77:23).

Introduction

Organometallic ruthenium complexes are becoming increasingly important in homogeneous catalyses such as reduction, oxidation, isomerisation, and carbon−carbon bond-formation.[1] The preparation of the necessary ruthenium catalysts most often starts from $RuCl_3{\cdot}nH_2O$, $[Ru(H_2O)_6]^{2+}$, $[RuCl_2(PPh_3)_3]$, $[RuCl_2(COD)]_n$, or $[RuCl_2(cymene)]_n$.[2] Analogously, the chemistry of cyclopentadienylruthenium complexes is based on few starting materials, mainly on the readily available precursors $[Ru(Cp)Cl(PPh_3)_2]$ and $[Ru(Cp)Cl(CO)_2]$.[2] However, the selective replacement of either PPh_3 or CO has proved difficult, limiting the synthetic utility. Coordinatively unsaturated complexes and complexes with labile ligands are the most promising candidates for catalytic applications, since the availability of a vacant coordination site is a prerequisite for both stoichiometric and catalytic organic transformations at the transition metal centre. Therefore, more labile systems, including $[Ru(Cp)(CH_3CN)_3]^+$,[3] and [Ru(Cp)Cl(COD)],[4] have been developed. In particular, the cationic complex $[Ru(Cp)(CH_3CN)_3]^+$ is a promising versatile intermediate since the acetonitrile ligands (AN) are substitutionally labile and can be replaced by other ligands.[5,6] This complex can be regarded as a source of the highly active coordinatively unsaturated fragment $[Ru(Cp)]^+$, which may well have interesting potential in catalysis. Indeed, several C−C bond-forming reactions catalysed by this compound have been reported by Trost.[7] Kirchner has shown that substitution of one acetonitrile ligand in $[Ru(Cp)(AN)_3]^+$ for tertiary phosphanes PR_3 $[Ru(Cp)(AN)_2(PR_3)]^+$ [8a] also gave a very active catalyst for the redox isomerisation of allylic alcohols,[8b] and C−C bond-formation.[8c−8l] Various attempts have been made to link the Cp and phosphorus moieties in such compounds through a spacer. In almost all cases, these complexes contain a PPh_3 ligand, as the synthesis, starting from $[RuCl_2(PPh_3)_3]$, gives no alternate choice.[9] Only in one case could bis(acetonitrile) complexes be isolated by Takahashi in which the linker connects through an ester group at the cyclopentadienyl ligand.[10] These complexes were tested in catalytic allylic amination and alkylation with excellent results.[11] Prompted by the results of Kirchner and Takahashi, we endeavoured to develop a synthetic route to $[Ru(Cp{-}P)(AN)_2]^+$-type chiral complexes containing a phosphane ligand tethered onto the cyclopentadienyl ring via a two-carbon linker (Cp−P). We have recently reported a route to such complexes,[12] and we have shown, in collaboration with Kirchner, that they react with alkynes displaying unusual reactivity.[13] Here we report on an improved method that affords the desired optically active ruthenium(II) complexes in almost quantitative yields, as well as a preliminary account of their application in catalytic organic transformations.

Results and Discussion

Synthesis of the Ligands

When we started our research, there was a dearth of general procedures to prepare chiral Cp−P ligands by a

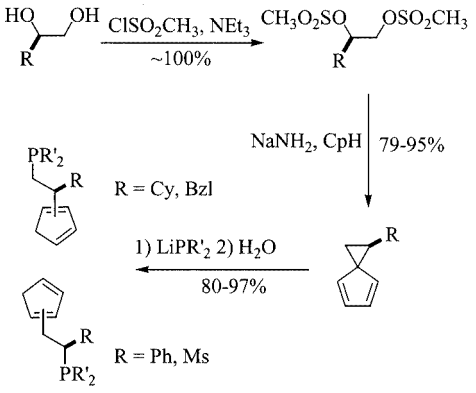
method that allows their modular construction by independent variation of the three components, namely the cyclopentadienyl, the linker, and the phosphane.[9] We have developed such a route by adapting the method first reported by Kauffmann,[14] which is based on the ring-opening reactions of spiro[2.4]hepta-4,6-dienes.[15] Traditionally, the spiro compounds have been synthesised by bis-alkylation of cyclopentadiene with the corresponding dibromoalkane in the presence of sodium amide or sodium hydride.[16] However, a more convenient approach to introduce chirality into these spiroannulated precursors is the use of the corresponding bis(mesylate)s or bis(tosylate)s as alkylating reagents. Rieger has used this route to synthesise ethyl-bridged bis(cyclopentadienyl) ligands starting from styrene epoxide.[17] The same approach was recently adopted by Whitby for the synthesis of chiral indenyl-linked phosphane ligands.[18] Our synthetic strategy is based on the use of chiral vicinal diols as starting materials, as depicted in Scheme 1. The chiral diols can be obtained in high enantiomeric purity by several methods, for example Sharpless asymmetric dihydroxylation,[19] Jacobsen hydrolytic kinetic resolution of epoxides,[20] and biological means. They are easily converted into the bis(methanesulfonate) esters in almost quantitative yield by reaction with methanesulfonyl chloride. Displacement of the methanesulfonate groups by excess cyclopentadiene/sodium amide affords the spiroannulated dienes in excellent yields (79−95%). The formation of the spiro compound involves first a nucleophilic substitution of one mesylate group by the cyclopentadienyl anion, followed by a fast deprotonation of the resulting substituted cyclopentadiene, and finally a second nucleophilic substitution of the other mesylate group and ring closure. The nucleophilic substitution at the chiral carbon is entirely stereoselective and proceeds with complete inversion of configuration at the stereogenic centre.[15] The chiral spiro compounds that have been synthesised by this methodology are shown in Scheme 2.



Scheme 1

The ring-opening reaction of (*S*)-1-R-spiro[2.4]hepta-4,6-dienes (R = phenyl, mesityl) with lithium diphenylphosphide or lithium dicyclohexylphosphide proceeds with complete regiospecificity by attack of the nucleophile at the activated benzylic position of the cyclopropane ring affording the ligands L_{1-3}. Interestingly, this regioselectivity is the opposite to that found for the nucleophilic opening of phenyl epoxide and phenyl episulfide with lithium phosphides; in that context, the attack of the nucleophile proceeds regioselectively at the less-hindered site.[21] The ring-opening reaction proceeds with complete inversion of the configuration at the stereogenic centre, as is demonstrated by X-ray crystal structure determinations of some derived metal complexes.[12,15] The opposite regioselectivity is observed in the ring-opening reaction of (*R*)-1-benzylspiro[2.4]hepta-4,6-diene and (*S*)-1-cyclohexylspiro[2.4]hepta-4,6-diene, which lack the activated benzylic position in the cyclopropane ring. In this case, the nucleophilic attack with lithium diphenylphosphide occurs on the unsubstituted carbon atom of the cyclopropane ring, affording the ligands L_4 and L_5.[22] The same regioselectivity has been observed in the ring-opening of 2-cyclohexylspiro(cyclopropane-1,1′-indene).[18] For convenience of storage, the lithium salts of the ligands can be reacted with H_2O to afford the cyclopentadienyl(alkyl)phosphanes as a mixture of two positional isomers depending on to which olefinic carbon atom of the Cp the linker is attached. The ligands are shown in Scheme 3. The overall yields for three steps (starting from the diols) are excellent (63 to 88%).

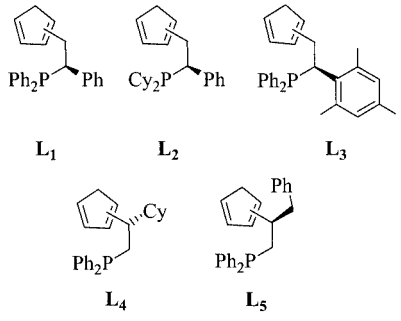


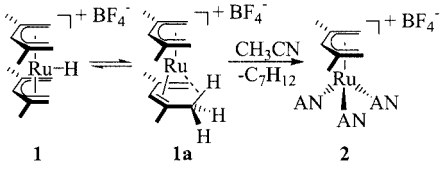
Scheme 3

Synthesis of the Ruthenium Complexes

We have recently reported that reaction of $[RuCl_2(\eta^3{:}\eta^3\text{-}C_{10}H_{16})]_2$ with the Cp-linked phosphane ligand L_1 in a 1:2 ratio in a mixture of acetonitrile and ethanol at room temperature, in the presence of Li_2CO_3 and KPF_6, affords the cationic complex $[Ru(\eta^5\text{-}C_5H_4CH_2CH(Ph)PPh_2\text{-}\kappa P)(AN)_2][PF_6]$ in 70−75% yield.[12] However, apart from the desired compound, side products were also formed that have not been identified yet. The purification of the desired

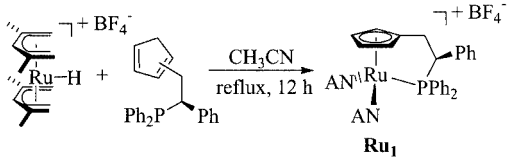
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complex was accomplished by a cumbersome crystallisation step. Therefore, we sought for a better synthetic route. A paper from Cox and Roulet provided inspiration for a new method.[23] The paper reports: "Dissolution of complex **1** in deoxygenated acetonitrile leads to rapid displacement of one molar equiv. of 2,4-dimethylpenta-1,3-diene and formation of the cation $[Ru(\eta^5\text{-}C_7H_{11})(AN)_3]^+$". [Bis($\eta^5$-2,4-dimethylpentadienyl)hydridoruthenium] tetrafluoroborate (**1**) is known to show a fluxional behaviour, as the hydrido ligand is involved in three-centre Ru−H−C agostic interactions with all terminal methylene groups of the dimethylpentadienyl ligands (Scheme 4).[24]



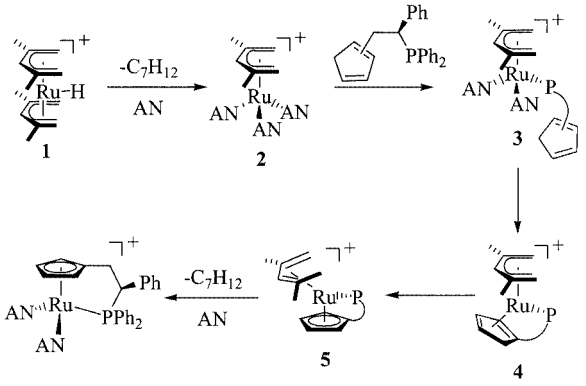
Scheme 4

The species **1a**, which is in equilibrium with **1**, is highly reactive towards two-electron ligands, and the η^4-C_7H_{12} ligand is substitutionally labile, as it is easily replaced by acetonitrile. We performed the reaction between L_1 and $[Ru(\eta^5\text{-}C_7H_{11})_2H][BF_4]$, and we were delighted to obtain the pure bis(acetonitrile) complex **Ru$_1$** in almost quantitative yield (Scheme 5).



Scheme 5

A possible reaction mechanism that accounts for the formation of **Ru$_1$** is presented in Scheme 6. At first, **2** may be formed, with subsequent coordination of phosphorus to afford **3**. The reaction has been followed by means of a ^{31}P NMR experiment, revealing the formation of intermediate species with ^{31}P resonances at about $\delta = 30$ ppm. The coordination of the phosphorus atom seems to be very fast, as no signals of the free ligands could be observed ($\delta = 0.4$ and 0.9 ppm). No other intermediates could be detected, and the species convert into the final complex, which shows a singlet at $\delta = 88.7$ ppm. The evolution of **3** to **4** involves the intramolecular coordination of the cyclopentadiene group, which is favoured on thermodynamic grounds by the formation of a chelate species. At this stage, an intramolecular H-transfer between the cyclopentadiene and the dimethylpentadienyl group may be postulated. It may occur with participation of the metal through a hydrido species. The species **5** thus formed contains the labile η^4-dimethylpentadiene ligand that is replaced by acetonitrile affording the desired compound in a straightforward way. When the reaction is carried out on a gram scale, the evolution of the mixture can easily be followed by the colour changes of the solution. Initially, the mixture is brown-yellow and becomes immediately yellow upon addition of the ligand. Upon refluxing, a red-orange colour appears and lasts for a few minutes, eventually converting to an orange-yellow colour.



Scheme 6

According to this synthetic procedure, the ruthenium complexes depicted in Scheme 7 could be obtained in almost quantitative yields. They were characterised by analytical and spectroscopic methods. The phosphorus resonates at low field in **Ru$_{1-3}$** ($\delta \approx 88$ ppm); the same signal appears at higher field in **Ru$_4$** and **Ru$_5$** ($\delta \approx 52$ ppm). In the free ligands, the phosphorus shows two signals in the ^{31}P NMR spectrum due to the two regioisomers at about $\delta = 0.5$ (L_1), 18 (L_2), −6 (L_3), −18 (L_4), and −20 ppm (L_5). The large downfield shift upon coordination is characteristic of the formation of a five-membered chelate ring.[25] In the ^1H NMR spectra, the signals of the C−H hydrogen of the linker are low-field shifted in **Ru$_{1-3}$** ($\delta = 4.66$, 4.19, and 5.42 ppm respectively); for comparison, the hydrogen resonates at $\delta = 1.94$ and 2.55 ppm for **Ru$_4$** and **Ru$_5$** respectively. The coordinated acetonitrile ligands give rise to two doublets with a long range coupling (^5J) with phosphorus of about 1 Hz. Easy replacement of the acetonitrile ligands with CD_3CN was confirmed by means of ^1H NMR spectroscopy, suggesting that they are substitutionally labile.

Catalytic Applications

With several chiral complexes in hand, we began a preliminary screening of their catalytic activity in organic transformations. Kirchner has reported that $[Ru(Cp)(AN)_2(PPh_3)]^+$, in which the phosphane is not connected to the Cp, is a highly active catalyst at 57 °C for the redox isomerisation of allylic alcohols to give the corresponding carbonyl compounds.[8b] We tested **Ru$_1$** in this reaction and, in line with his report, we found that it catalyses the isomerisation of allylic alcohols (R = H, Me, Ph) at room temperature [Equation (1)]; details are given in the Exp. Sect.

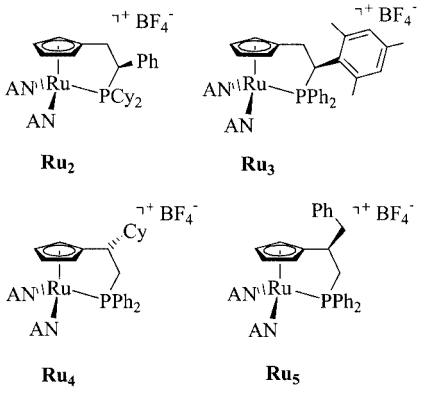
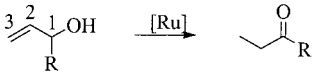


Scheme 7



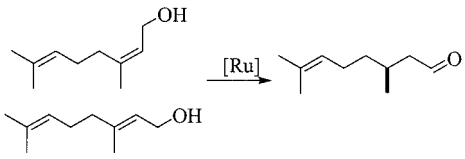
(1)

Kirchner also found that C^1-substituted allylic alcohols react much more quickly than those featuring substituents at the C^3 carbon; heating was required to effect the conversion of 2,3-disubstituted alcohols, while C^1- and C^3-disubstituted alcohols were not converted. To test the reactivity of our optically active complexes in the redox isomerisation of pro-chiral allylic alcohols, we chose geraniol and nerol as substrates. Isomerisation of diethylgeranylamine for the production of practically optically pure (+)-citronellal catalysed by a Rh^+/BINAP complex is a very important industrial process leading to key intermediates for the fragrance and flavour industry.[26] Comparable success has not been achieved for the corresponding isomerisation of readily available geraniol or nerol. To the best of our knowledge, the hitherto best catalyst system reported is based on a Rh^+/BINAP complex, and affords citronellal with 60% *ee*.[27] Initially, the reaction was performed in CH_2Cl_2 at room temperature and at reflux but only modest or no conversion into citronellal was obtained, corroborating the finding of Kirchner that C^3-disubstituted alcohols are not prone to undergo the redox isomerisation. However, when we performed the reaction in THF at reflux, we were pleased to observe conversion of the alcohol to citronellal [Equation (2)]. The results are summarised in Table 1.

Table 1. Redox isomerisation of geraniol and nerol[a]

Catalyst	Substrate	Product	Conversion	ee
Ru_1	geraniol	(+)-citronellal	73%	19%
Ru_1	nerol	citronellal	18%	*nd*
Ru_2	geraniol	−	0%	−
Ru_3	geraniol	(−)-citronellal	71%	8%
Ru_4	geraniol	(+)-citronellal	97%	17%
Ru_4	nerol	(−)-citronellal	35%	*nd*
Ru_5	geraniol	(+)-citronellal	32%	13%

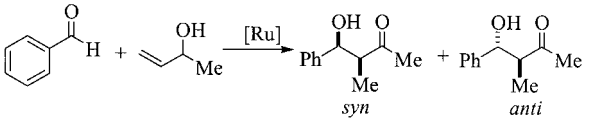
[a] The values given in the table are the average of at least two runs. See the Exp. Sect. for more details.



(2)

The conversion depends strongly on the complex used, the best results being found for **Ru_1** and **Ru_4** for the conversion of geraniol. The poor conversion of nerol has already been observed in other catalytic systems.[27] **Ru_2** is not active under these conditions; this fact may be ascribed to the steric bulkiness or the high Lewis basicity of the PCy_2 fragment. Unfortunately, the complexes are not able to induce high enantioselectivity. Further studies are necessary to determine if this catalytic system could be improved. Nevertheless, the results obtained with our complexes, although moderate, represent the first application of a ruthenium catalyst in the isomerisation of geraniol to optically enriched citronellal.[28]

The mechanistic rationale for the ruthenium-catalysed redox isomerisation of allylic alcohols postulates the formation of a ruthenium-enolate complex.[29] We envisioned that the formed enolate could be trapped by an electrophile, and indeed we found that an aldol-type product was formed via a ruthenium-catalysed cross-coupling of 3-buten-2-ol and benzaldehyde [Equation (3)].



(3)

It has recently been reported that $[RuCl_2(PPh_3)_3]$ catalyses this reaction.[30] The results obtained with our complexes are detailed in Table 2. The yields are not satisfactory due to the concurrent isomerisation of the allylic alcohol to

Table 2. Aldol reaction between benzaldehyde and 3-buten-2-ol[a]

butan-2-one; this may also explain the non-linear dependence of product yield on catalyst loading. The enantioselectivity is also disappointing, and a maximum of 5% *ee* has been obtained. However, the diastereoselectivity is appreciable, favouring the *syn* diastereomer. A substantial improvement in both yield and diastereoselectivity could be obtained upon switching from CH_2Cl_2 to THF, and it is noteworthy that the catalysts are quite active even at low loading. Further studies to improve the catalyst performance are intended.

Conclusion

A novel synthetic method has been developed that allows the one-pot synthesis of optically active cationic bis(acetonitrile)ruthenium(II) complexes of chiral cyclopentadienyl-linked phosphane ligands in very high yields. The method is general and allows the use of ligands bearing phosphanes with variable steric and electronic features. Moreover, the linker, which connects the cyclopentadienyl unit to the phosphane, can be straightforwardly modified. Considering the labile nature of the acetonitrile ligands, these complexes are potential candidates for catalytic implementation. Indeed, a preliminary study on their reactivity revealed that the complexes catalyse the isomerisation of geraniol to citronellal, as well as an aldol-type cross-coupling reaction between 3-buten-2-ol and benzaldehyde. Although the *ee* values obtained are rather low, the method is of interest for preparing other complexes that may find various applications in asymmetric catalysis.

Experimental Section

General Remarks: All reactions were carried out under nitrogen using standard Schlenk techniques. Solvents were dried and deoxygenated by standard methods. NMR spectra were recorded on a Varian Unity 500 spectrometer (500 MHz, ^{1}H; 125 MHz, ^{13}C; 202 MHz, ^{31}P) at room temperature. Chemical shifts are given in ppm relative to the solvent signal (^{1}H and ^{13}C) or to external H_3PO_4 (^{31}P). ^{1}H and ^{13}C{^{1}H} signal assignments were confirmed by ^{1}H,^{1}H-COSY, APT, ^{1}H,^{13}C-HETCOR, and NOE-difference experiments. (*R*)-1-Phenylethane-1,2-diol was obtained by reduction of (*R*)-mandelic acid with LAH.[31] (*S*)-1-Cyclohexylethane-1,2-diol was obtained by initial reduction of the arene ring of (*S*)-mandelic acid with hydrogen using 5% Rh on alumina as catalyst, followed by reduction of the carboxylic group with LAH.[32] (*R*)-3-Phenylpropane-1,2-diol was obtained by reduction of the corresponding acid with LAH. (*R*)-1-(2,4,6-Trimethylphenyl)ethane-1,2-diol was obtained by Sharpless asymmetric dihydroxylation of the corresponding olefin.[33] $[Ru(\eta^5\text{-}C_7H_{11})_2H][BF_4]$[34] was prepared according to a published procedure. All other chemicals were purchased and used without further purification.

Preparation of the Bis(methanesulfonate) Esters: NEt_3 (2.4 equiv.) was added to a solution of the diol in CH_2Cl_2 (ca. 10 mL/g). The solution was cooled in an ice-water bath and methanesulfonyl chloride (2.2 equiv.) in CH_2Cl_2 (5 mL/mL) was added dropwise over 1 h. The mixture was stirred for 1 h at 0 °C and then for 2 h at room temp. The mixture was poured into 1 M HCl. The layers were separated and the aqueous phase was washed with CH_2Cl_2 (3 × 50 mL). The combined organic extracts were washed successively with 1 M HCl, saturated $NaHCO_3$ and brine, and dried over $MgSO_4$. The solution was then filtered, and the solvent was removed under reduced pressure. The bis(methanesulfonate) esters were obtained in almost quantitative yield and they were used without further purification for the preparation of the spiro compounds.

Preparation of the Spiro Compounds: Freshly cracked cyclopentadiene (2 equiv.) was added dropwise to a suspension of $NaNH_2$ (2.5 equiv.) in THF (ca. 25 mL/g). The addition of CpH was adjusted so as to maintain a gentle reflux. Upon complete addition, the mixture was stirred for 1/2 h and subsequently, a solution of the bis(methanesulfonate) in THF (ca. 15 mL/g) was added dropwise. The addition was accompanied by considerable heat evolution. The reaction mixture was stirred at room temperature overnight. MeOH and H_2O were carefully added, the mixture was diluted with Et_2O and the layers separated. The aqueous phase was washed with Et_2O (3 × 50 mL). The combined organic extracts were washed with brine, dried over $MgSO_4$, and treated with decolourising charcoal. The solution was finally filtered, and the solvent removed under reduced pressure. The oil obtained was purified by filtration through a short column of basic alumina (activity I) with hexane as eluent. Reproducible elemental analyses could not be obtained, as the solvent could not be removed completely from the oily compounds.

Preparation of the Ligands by Ring Opening of the Spiro Compounds with Lithium Phosphides: The lithium phosphide was prepared by treating a solution of the secondary phosphane in THF (ca. 10 mL/g) with *n*BuLi (1.1 equiv.) at −78 °C. The deep-orange solution formed was stirred for 15 minutes at room temperature and then cooled again to −78 °C. At this temperature, the spiro compound (1.1 equiv.) dissolved in THF (1 mL/g) was added to the solution and the reaction mixture was allowed to reach room temperature overnight. The solvent was removed under reduced pressure and the oil left was washed several times with hexane until precipitation of the lithium salt of the ligand. This was dissolved in THF and degassed H_2O was added. After several extractions with CH_2Cl_2, the combined organic phases were dried over $MgSO_4$ and treated with decolourising charcoal. The solution was filtered through a short column of basic alumina (activity I), and the solvent removed under reduced pressure affording the pure ligand as an air-sensitive oil or solid as a one to one mixture of two regioisomers. The signals in the ^{1}H NMR spectra are highly overlapped and could not be attributed. Accordingly, only selected ^{13}C NMR data and the ^{31}P resonances are given. The ligands were characterised as their derived ruthenium complexes.

Synthesis of the Ruthenium Complexes: A flask was charged with the ligand and **1** in equimolar amounts. CH_3CN (ca. 20 mL/g) was added and the solution refluxed overnight. Then, the solution was filtered through a short pad of deactivated alumina (activity V) and the solvents evaporated to dryness. The solid obtained was washed several times with Et_2O and dried under high vacuum.

(*S*)-1-Phenylspiro[2.4]hepta-4,6-diene (S_1): The title compound was prepared, according to the representative procedure, from 10.0 g of (*R*)-phenyl-1,2-bis(methanesulfonyloxy)ethane as a colourless or pale-yellow oil. (*S*)-Bis(acetonitrile)[(2-benzyl-η^5-2-cyclopentadienylethyl)diphenylphosphane-κ*P*]ruthenium(II) Tetrafluoroborate (Ru$_5$): The title compound was prepared, according to the representative procedure, from 2.69 g of **L$_5$** and 2.75 g of **1** as a yellow solid. Yield: 4.65 g (100%). $[\alpha]_D^{20}$= −10.7 (*c* = 1, CH_3CN). M.p.: 141−144 °C. ^{1}H NMR (CD_2Cl_2): δ = 1.99 (d, $^5J_{H,P}$ = 1.22 Hz, 3 H, CH_3CN), 2.18 (d, $^5J_{H,P}$ = 1.53 Hz, 3 H, CH_3CN), 2.55 (m, 1 H, C*H*Bzl), 2.82 (dd, $^2J_{H,H}$ = 13.43, $^3J_{H,H}$ = 8.24 Hz, 1 H, CH_2Ph), 2.95 (dd, $^2J_{H,H}$ = 13.43, $^3J_{H,H}$ = 6.72 Hz, 1 H, CH_2Ph), 3.02−3.18 (m, 2 H, CH_2), 4.12 (m, 1 H, Cp), 4.14 (m, 1 H, Cp), 5.06 (m, 1 H, Cp), 5.25 (m, 1 H, Cp), 7.01−7.74 (m, 15 H, Ph) ppm. ^{13}C NMR (CD_2Cl_2): δ = 3.78 (*C*H$_3$, *C*H$_3$CN), 4.16 (*C*H$_3$, *C*H$_3$CN), 38.60 (d, $^2J_{C,P}$ = 6.66 Hz, *C*HBzl), 41.12 (d, $^3J_{C,P}$ = 21.11 Hz, *C*H$_2$Ph), 50.36 (d, $^1J_{C,P}$ = 33.54 Hz, *C*H$_2$), 57.87 (*C*H, Cp), 67.78 (*C*H, Cp), 80.47 (d, $J_{C,P}$ = 8.67 Hz, *C*H, Cp), 88.39 (d, $J_{C,P}$ = 5.78 Hz, *C*H, Cp), 112.42 (d, $J_{C,P}$ = 4.77 Hz, C_{ipso}, Cp), 126.69 (*C*, *C*N), 126.86 (*C*H), 127.26 (*C*, *C*N), 128.76 *C*H), 129.13 (*C*H), 129.21 (*C*H), 129.33 (*C*H), 129.40 (*C*H), 130.56 (d, $J_{C,P}$ = 5.78 Hz, *C*H), 130.83 (d, $J_{C,P}$ = 1.88 Hz, *C*H), 132.18 (d, $J_{C,P}$ = 9.67 Hz, *C*H), 132.99 (*C*), 133.26 (d, $J_{C,P}$ = 11.43 Hz, *C*H), 133.62 (*C*), 139.77 (*C*) ppm. ^{31}P NMR (CD_2Cl_2): δ = 52.87 (s, *P*Ph$_2$) ppm. IR (KBr): $\tilde{\nu}$ = 2277 cm^{-1}, 1630, 1602, 1058, 744, 699. MS (FAB): *m*/*z* = 510 (30) [M$^+$ − CH$_3$CN + 1], 469 (100) [M$^+$ − 2CH$_3$CN + 1], 87 (100) [BF_4^-]. $C_{30}H_{30}BF_4N_2PRu$ (637.40): calcd. C 56.53, H 4.74, N 4.40; found C 56.65, H 4.67, N 4.31.

Procedure for the Isomerisation of Allylic Alcohols: In a representative experiment, an NMR tube was charged under nitrogen with the catalyst (1 mol %), CD_2Cl_2 was added (0.5 mL), followed by the allylic alcohol (prop-2-en-1-ol, but-3-en-2-ol, or 1-phenylprop-2-en-1-ol). The tube was capped and vigorously shaken. The reaction was monitored by ^{1}H and ^{13}C{^{1}H} NMR spectroscopy. Typically, the reaction was completed (no olefinic protons were detected) after three hours at room temperature affording exclusively the carbonyl compounds with only traces of unidentified side-products.

Procedure for the Isomerisation of Geraniol and Nerol: A flask was charged with a catalytic amount of the ruthenium complex (5 mol %) and THF (10 mL) and the allylic alcohol (2 mL) were then added. The reaction mixture was refluxed for 24 hours. The solvent was then removed under reduced pressure and the residue was filtered through a short pad of silica gel eluting with Et_2O. The oil left after evaporation of the solvent was bulb-to-bulb distilled (100−110 °C/10 mbar) affording pure citronellal. The conversion was determined on the crude reaction product by ^{1}H NMR spectroscopy. The *ee* was determined by comparison of the optical rotation (neat) with that reported in the literature.[27]

Procedure for the Catalytic Aldol Reaction: A flask was charged with a catalytic amount of the ruthenium complex (5 to 0.1 mol %). The solvent was added (5 or 10 mL), followed by benzaldehyde (5 or 10 mmol) and then 3-buten-2-ol (10 or 20 mmol). The reaction mixture was stirred at room temperature until complete consumption of the allylic alcohol (checked by TLC). The solvent was then removed under reduced pressure and the residue was purified by

flash column chromatography (hexane/ethyl acetate, 7:3). The *syn*/*anti* ratio was determined by ^{1}H NMR spectroscopy. The enantioselectivities were determined by HPLC analysis with a Chiralpak AS column (eluent: hexane/2-propanol, 95:5; flow rate: 0.8 mL/min; column temperature: 30 °C; retention times for the *syn* diastereoisomer: 15 min and 22 min).

Acknowledgments

The generous financial support by the Deutsche Forschungsgemeinschaft DFG within the Collaborative Research Centre (SFB, 380) "Asymmetric Syntheses by Chemical and Biological Means" and by the "Fonds der Chemischen Industrie" is gratefully acknowledged. We thank Prof. Carsten Bolm for a generous gift of (*R*)-1-(2,4,6-trimethylphenyl)ethane-1,2-diol.

The Reaction of μ-η²:η²-Peroxo- and Bis(μ-oxo)dicopper Complexes with Flavonol

József Kaizer,[a] József Pap,[b] Gábor Speier,*[a] and László Párkányi[c]

Keywords: Quercetinase / Model compounds / Copper / Oxygen / Flavonol

The $[Cu_2(\mu\text{-}O)_2]^{2+}$ and $[Cu_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O)_2]^{2+}$ motifs with coordinated *N,N,N*-tribenzyl-1,4,7-triazacyclononane and *N,N,N*-triisopropyl-1,4,7-triazacyclononane auxiliary ligands in their reaction with flavonol do not lead to ring scission products of the heterocycle, but the formation of the corresponding (flavonolato)copper(II) complexes $[Cu(fla)(Bz\text{-}TAC)]ClO_4$ and $[Cu(fla)(i\text{Pr-}TAC)]ClO_4$. The subsequent oxygenolysis of the coordinated flavonolate ligand leads to *O*-benzoylsalicylate at elevated temperature, resulting in the enzyme mimicking products $[Cu(O\text{-bs})(Bz\text{-}TAC)]ClO_4$, $[Cu(O\text{-bs})(i\text{Pr-}TAC)]ClO_4$) as well as carbon monoxide. The X-ray structures of $[Cu(fla)(Bz\text{-}TAC)]ClO_4$, $[Cu(O\text{-bs})(Bz\text{-}TAC)]ClO_4$, and $[Cu(O\text{-bs})(i\text{Pr-}TAC)]ClO_4$) are presented.

Introduction

Biological oxygenations catalyzed by oxygenases are very important processes in nature for the metabolism of various organic substances.[1−5] To date, four prokaryotic dioxygenases are known, which catalyze an oxidative C−C bond cleavage with incorporation of two O-atoms into, and release of CO from the substrates quercetin (**1**) (flavonol 2,4-dioxygenase),[6−13] 3-hydroxy-4-oxo-1*H*-quinaldine (**3**) (3-hydroxy-4-oxo-1*H*-quinaldine 2,4-dioxygenase), 3-hydroxy-4-oxo-1*H*-quinoline (**4**) (3-hydroxy-4-oxo-1*H*-quinoline 2,4-dioxygenase),[14,15] and (*S*)-1,2-dihydroxy-3-oxo-5-(methylthio)pentene anion (**5**) [(*S*)-1,2-dihydroxy-3-oxo-5-(methylthio)pentene anion 1,3-dioxygenase].[16,17] Flavonol 2,4-dioxygenase ("quercetinase"), which catalyzes the cleavage of quercetin to carbon monoxide and phenolic carboxylic acid ester was produced by the species *Aspergillus flavus* and *Pullularia* (Scheme 1).[18]

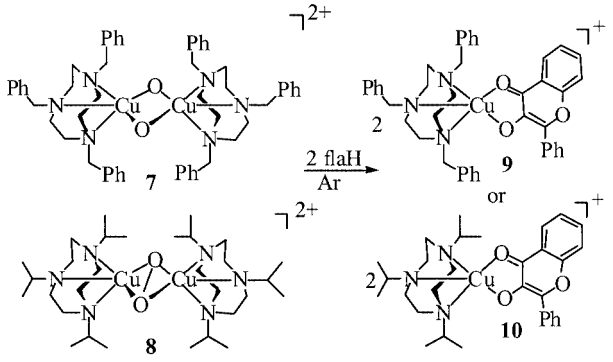
Scheme 1

Quercetinase has been reported to contain two Cu^{II} centers per molecule.[19,20] Recent diffraction studies on single crystals of quercetin 2,3-dioxygenase obtained from *Aspergillus japonicus*, at a resolution of 1.8 Å, showed that the enzyme forms homodimers, which are stabilized by an *N*-linked heptasaccharide at the dimer interface.[21] Each unit is mononuclear, with a type 2 copper center displaying two distinct geometries: a distorted tetrahedral coordination with three histidine units and one water molecules, and a distorted trigonal bipyramidal environment with an additional carboxylate. Substrate docking studies hinted to the eventual catalytic importance of the different geometries. In general, the process of oxygenase catalyzed reactions may be divided into three steps in an organic chemical sense. The first step is the activation of molecular oxygen and/or a substrate. The second step is the formation of a reactive intermediate, which would be a peroxidic compound in the case of dioxygenases,[22] and an oxygenated compound such as an arene oxide in the case of monooxygenases.[2,5,23] The third step involves the transformation of such an intermediate into the final product. From our earlier results obtained with redox[24−32] and non-redox[33,35] metal-containing model systems we concluded, that the oxygenolysis of the coordinated flavonolate ligand in aprotic solvents takes place mainly *via* an endoperoxide intermediate resulting in *O*-benzoylsalicylate as an enzyme-like

product,[36] and to a lesser extent through a 1,2-dioxethane intermediate.[37] Apart from these mechanisms, and despite recent suggestions in the literature,[38] the oxygenation of flavonol to enzyme-like products can also be postulated with the primary formation of copper-dioxygen species as the key reaction step. Earlier studies assumed coordination of quercetin to the copper(II) site through its 3-OH and 4-C=O groups.[39–41] Model studies have reinforced this hypothesis, and a fair number of copper complexes of flavonolate ligands have been isolated and structurally characterized.[24,25,28–30,42] It has also been postulated, that monodentate coordination of quercetin may be responsible for the substrate activation.[21,38,43] Since we have found in our model studies, that the oxygenation of flavonolate coordinated either to copper(I) or copper(II) requires higher reaction temperatures (around 100 °C) it cannot be excluded, that the first step in the catalytic cycle is the activation of dioxygen. In order to gain experimental support for this possibility we have directly evaluated the feasibility of this transformation by examining the reaction of flavonol with (μ-η^2:η^2-peroxo)- and bis(μ-oxo)dicopper complexes.[44–47] Herein we report that $[Cu_2(\mu\text{-}O)_2]^{2+}$ and $[Cu_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O)_2]^{2+}$ cores coordinated to *N*-trisubstituted triazacyclononanes do not promote the ring cleavage reaction of the heterocycle but react with two equivalents of flavonol yielding (flavonolato)copper(II) complexes. Subsequent oxygenation of the (flavonolato)copper(II) complexes by dioxygen at elevated temperatures results in (*O*-benzoylsalicylato)copper(II) complexes and CO.

Results and Discussion

Addition of two equivalents of flavonol (**2**; flaH) to a solution of $[\{Cu(Bz\text{-}TAC)\}_2(\mu\text{-}O)_2](ClO_4)_2$ or $[\{Cu(i\text{Pr-}TAC)\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O)_2](ClO_4)_2$ in CH_2Cl_2 at −80 °C caused bleaching of their respective optical absorption features (Bz-TAC = *N*,*N*,*N*-tribenzyl-1,4,7-triazacyclononane, *i*Pr-TAC = *N*,*N*,*N*-triisopropyl-1,4,7-triazacyclononane). Upon subsequent warming and workup, the green complexes $[Cu(fla)(Bz\text{-}TAC)]ClO_4$ (**9**) or $[Cu(fla)(i\text{Pr-}TAC)]ClO_4$ (**10**) (fla = flavonolate) were isolated as crystalline solids in yields of 95 and 90%, respectively (Scheme 2). The reaction products were identified on the basis of spectroscopic comparisons with previously reported examples, magnetic properties, and X-ray crystallography. Tests for the concomitant formation of H_2O_2 did not give convincing results irrespective of whether there was a selectivity in terms of forming either H_2O_2 or H_2O from the peroxo or oxo copper complexes.



Scheme 2

The IR spectra of the complexes $[Cu(fla)(Bz\text{-}TAC)]ClO_4$ and $[Cu(fla)(i\text{Pr-}TAC)]ClO_4$ show principal bands corresponding to coordinated flavonolate at 1545 and 1554 cm^{-1}, respectively. Decreases of approximately 50 cm^{-1} in the ν(CO) bands compared with that of flavonol [ν(CO) = 1602 cm^{-1}] are due to chelation and formation of stable five-membered rings.[48] The charge transfer region in the electronic spectra of the complexes $[Cu(fla)(Bz\text{-}TAC)]ClO_4$ and $[Cu(fla)(i\text{Pr-}TAC)]ClO_4$ exhibit bands of the coordinated flavonolate ligand at 432 and 434 nm. Bands at 615 and 653 nm are associated with d-d transitions of the complexes.

The molecular structure together with selected bond lengths and angles of $[Cu(fla)(Bz\text{-}TAC)]ClO_4$ are shown in Figure 1. The molecule is monomeric in the solid state. The copper(II) center is in a distorted square-pyramidal environment as judged by the method of Allison and co-workers (τ = 0.12)[49] with basal planes defined by two nitrogen atoms derived from the tridentate *N*,*N*,*N*-tribenzyl-1,4,7-triazacyclononane ligand [Cu−N19, 2.040(3); Cu−N22, 2.027(3) Å], and two oxygen atoms of the flavonolate [Cu−O1, 1.917(3); Cu−O8, 2.012(3) Å]. The third nitrogen atom of the *N*,*N*,*N*-tribenzyl-1,4,7-triazacyclononane ligand [Cu−N25, 2.231(3) Å] is in the apical position. The Cu−O8 bond is 0.095 Å longer than the Cu−O1 bond. The C2−O1 distance is shorter while the C7−O8 distance is longer than those in the uncoordinated flavonol [1.357(3) and 1.232(3) Å].[50] Due to coordination to the copper ion there are also

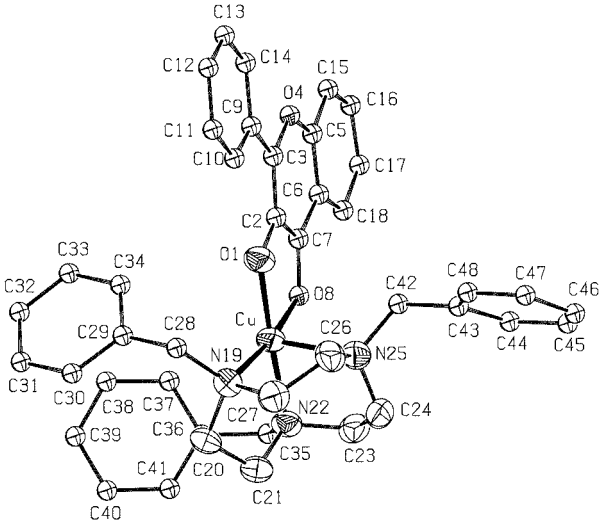


Figure 1. View showing the structure of $[Cu(fla)(Bz\text{-}TAC)]ClO_4$ (**9**); selected bond lengths (Å) and angles (deg): Cu−O1 1.917(3), Cu−O8 2.012(3), Cu−N22 2.027(3), Cu−N19 2.040(3), Cu−N25 2.231(3), O1−C2 1.339(4), O8−C7 1.273(4), C2−C3, 1.381(5), C2−C7 1.401(5); O1−Cu−N22 177.60(12), O8−Cu−N19 170.25(12), N19−Cu−N25 85.94(12), C2−O1−Cu 111.5(2), C7−O8−Cu 109.9(2)

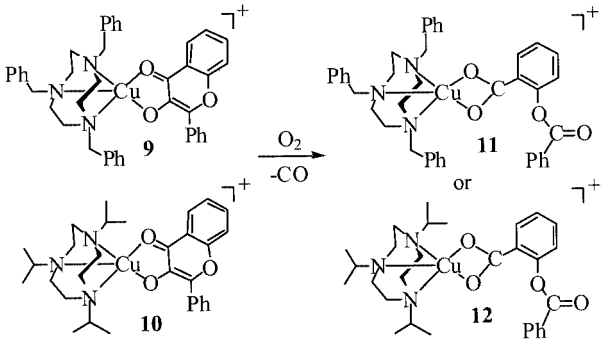
changes in the bond lengths of the pyranone ring. The O4−C3 [1.362(4) Å] and C5−C6 [1.381(5) Å] bond lengths become longer, and the C2−C7 bond length [1.401(5) Å] is somewhat shorter, which may be assigned to delocalization of the π-system over the whole molecule. Similar reactions of peroxo- and bis(μ-oxo)dicopper complexes bearing the *N*,*N*,*N*-trisubstituted 1,4,7-triazacyclononane ligands with catechols resulted in the corresponding copper(II) semiquinone complexes.[51] Since the amine macrocyclic ligands are hard, and prefer copper(II), the copper ion remained in this oxidation state. It was not specified, however, whether H_2O or H_2O_2 was formed as the reduction product from O_2.

Treatment of the (flavonolato)copper complexes [Cu(fla)(Bz-TAC)]ClO_4 or [Cu(fla)(*i*Pr-TAC)]ClO_4 with dioxygen in DMF solution at elevated temperatures leads to the corresponding (*O*-benzoylsalicylato)copper complexes [Cu(*O*-bs)(Bz-TAC)]ClO_4 (**11**) and [Cu(*O*-bs)(*i*Pr-TAC)]-ClO_4 (**12**) (Scheme 3). The IR spectra of the complexes [Cu(*O*-bs)(Bz-TAC)]ClO_4 and [Cu(*O*-bs)(*i*Pr-TAC)]ClO_4 show principal bands corresponding to ν(CO) at 1741 and 1747 cm^{-1}, respectively. Bands corresponding to ν(CO_2) for the two complexes appear at 1586 and 1432, and 1584 and 1428 cm^{-1}, respectively.



Scheme 3

The molecular structure together with selected bond lengths and angles of [Cu(*O*-bs)(Bz-TAC)]ClO_4 are shown in Figure 2. The copper(II) center is in a distorted square pyramidal environment ($\tau = 0.16$)[49] with basal planes defined by two nitrogen atoms derived from the tridentate *N*,*N*,*N*-tribenzyl-1,4,7-triazacyclononane ligand, and two oxygen atoms of the bidentate carboxylate group. The apical position is occupied by the other nitrogen atom of the *N*,*N*,*N*-tribenzyl-1,4,7-triazacyclononane ligand. The copper−nitrogen bond lengths [Cu−N1 2.000(2), Cu−N4 2.010(2), and Cu−N7 2.182(2) Å] are similar to values obtained for [Cu(fla)(Bz-TAC)]ClO_4. The Cu−O bond lengths are shorter than those in [Cu(*O*-bs)(idpaH)]ClO_4 [1.995(5) and 2.344(6) Å].[30]

Crystallographic characterization has shown that in [Cu(*O*-bs)(*i*Pr-TAC)]ClO_4 (**12**, Figure 3), the copper(II) ion has a distorted square pyramidal arrangement ($\tau = 0.10$)[49] with basal planes defined by two nitrogen atoms derived from the tridentate *N*,*N*,*N*-triisopropyl-1,4,7-triazacyclo-

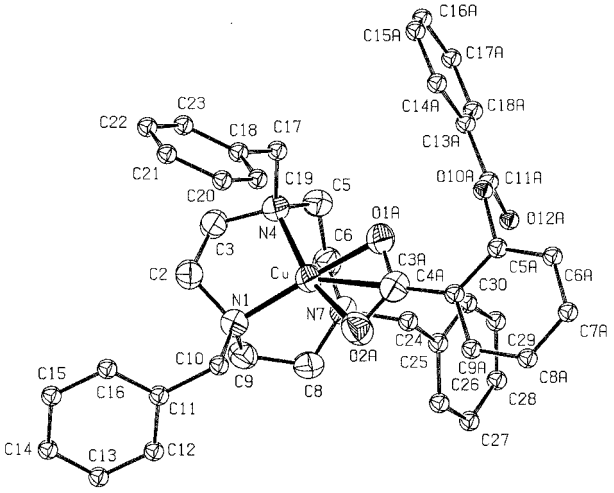


Figure 2. View showing the structure of [Cu(*O*-bs)(Bz-TAC)]ClO_4 (**11**); selected bond lengths (Å) and angles (deg): Cu−O1A 1.9772(17), Cu−O2A 2.0685(19), Cu−N1 2.000(2), Cu−N4 2.010(2), Cu−N7 2.182(2) O1A−C3A, 1.273(3) O2A−C3A, 1.256(3); O1A−Cu−N1 171.19(8), O1A−Cu−O2A 64.87(7), N4−Cu−O2A 161.55(8), N4−O1−N7 86.94(8)

Figure 3. nonane ligand, and two oxygen atoms of the bidentate carboxylate group. The apical position is occupied by the other nitrogen atom of the *N*,*N*,*N*- triisopropyl-1,4,7-triazacyclononane ligand. A view of the coordination geometry as well as selected bond lengths and angles are given in Figure 2. The copper−nitrogen bond lengths [Cu1−N19 2.020(7), Cu1−N22 2.033(6), Cu1−N25,= 2.208(7) Å] are similar to values obtained for [Cu(*O*-bs)(Bz-TAC)]ClO_4. The value of (Cu1−O2) − (Cu1−O1) (0.039 Å) is somewhat shorter than that found in the complex [Cu(*O*-bs)(Bz-TAC)]ClO_4 (0.0913 Å), which may be assigned to the higher degree of delocalization in the carboxylate group.

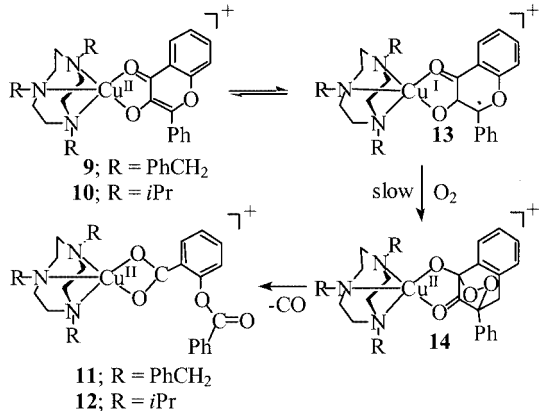
Oxygenation reactions of [Cu(fla)(Bz-TAC)]ClO_4 and [Cu(fla)(*i*Pr-TAC)]ClO_4 complexes were followed by UV-Vis spectroscopy. Plots of log[Cu(fla)(Bz-TAC)]ClO_4 and log[Cu(fla)(*i*Pr-TAC)]ClO_4 versus time showed linear dependences under pseudo-first-order conditions (constant dioxygen pressure) in agreement with a rate equation of first-order dependence with respect to [Cu(fla)(Bz-TAC)]-ClO_4 and [Cu(fla)(*i*Pr-TAC)]ClO_4, respectively. Experiments performed at different dioxygen concentrations showed that both of the reactions are also first order with respect to dioxygen concentration. According to the kinetic data obtained, the oxygenation reactions obey an overall second-order rate equation, from which the mean values of the kinetic constants k_{obs} of 3.31 ± 0.01 × 10^{-3} ([Cu(fla)(Bz-TAC)]ClO_4) and 1.51 ± 0.01 × 10^{-3} mol^{-1}·dm^3 s^{-1} ([Cu(fla)(*i*Pr-TAC)]ClO_4) at 120 °C were obtained. The calculated rate constant is, in the case of [Cu(fla)(Bz-TAC)]-ClO_4, almost two times larger than that for [Cu(fla)(*i*Pr-TAC)]ClO_4. Oxidative cleavage of the C2−C3 double bond of the pyranone ring of the coordinated flavonolato ligand in both cases takes place in a similar fashion as in the enzymatic reaction. Stoichiometric oxygenation reactions can be interpreted as shown in Scheme 4. We are inclined to assume a redox role for the copper(II). Due to the valence isomerism of the copper(II) flavonolate complexes, copper(I) flavonoxy radical species are also formed, as suggested earlier.[37] Similar electromeric effects between metal catecholate and metal semiquinone complexes have been demonstrated.[52,53] They have two redoxactive sites, the flavonoxy radical ligand and the Cu^I center, which can react with dioxygen in a slow step to form the endoperoxide intermediates. These then break down rapidly to the corresponding (*O*-benzoylsalicylato)copper(II) complexes and CO.



Scheme 4

Conclusion

In conclusion, we have found that $Cu_2^{III}(\mu\text{-}O)_2$ and $Cu_2^{II}(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O)_2$ complexes with triazacyclononane auxiliary ligands are not able to cleave the C2−C3 double bond in flavonol under mild reaction conditions. Instead, the corresponding (flavonolato)copper(II) complexes are formed. The latter complexes, however, undergo ring scission in their reaction with dioxygen under more forcing conditions resulting in the (*O*-benzoylsalicylato)copper(II) complexes and carbon monoxide. These results enable us to conclude, that in the enzyme catalyzed reaction, the activation of the substrate flavonol through its coordination to the copper(II) center probably takes place, and its oxygenation and subsequent reaction of the copper-dioxygen species with flavonol is the real catalytic situation.

Experimental Section

General Remarks: All reagents and solvents were purchased from commercial sources and were of reagent quality unless otherwise stated. All air-sensitive compounds were handled under argon using standard Schlenk techniques.[54]

Caution! *Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small amounts of material should be prepared, and these should be handled with great care.*

Synthesis of [Cu(fla)(Bz-TAC)]ClO_4 (9): A solution of [{Cu(Bz-TAC)}$_2$(μ-O)$_2$]$(ClO_4)_2$ in CH_2Cl_2 (15 mL) at −80 °C was prepared as described previously (0.164 g, 0.5 mmol scale of Cu^I precursor).[46,47] After removal of excess dioxygen by purging with argon at −80 °C for 10 min, a solution of flavonol (0.119 g, 0.5 mmol) in CH_2Cl_2 (5 mL) was added, resulting in an instantaneous color change from red-brown to intense green. The reaction mixture was stirred at −80 °C for 1 h, and then warmed to room temperature. After concentrating the solution by evaporation under vacuum, Et_2O was added to induce precipitation of a green solid which was collected by filtration, washed with Et_2O, and air-dried (95%, m.p. 224−226 °C). The crude product was recrystallized from CH_3CN. $C_{42}H_{42}ClCuN_3O_7$ (799.80): calcd. C 63.1, H 5.3, N 5.3; found C 62.9, H 5.5, N 5.5. UV-Vis (DMF): $\lambda_{max.}$ (log ε) = 269 (4.23) 432 (2.23), 615 (2.90), 1040 (1.73) nm. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1097 (vs, νClO_4^-), 634 (s, νClO_4^-), 1545 (s, νCO). EPR (MeCN): g = 2.115, A = 66.0 G. μ_{eff} = 1.93 BM.

Synthesis of [Cu(fla)(*i*Pr-TAC)]ClO_4 (10): This compound was prepared analogously to [Cu(fla)(Bz-TAC)]ClO_4 but by treating [{Cu(*i*Pr-TPA)}$_2$(μ-η^2:η^2-O)$_2$]$(ClO_4)_2$ [44] with flavonol (90%, m.p. 235−237 °C). The crude product was recrystallized from CH_3CN. $C_{30}H_{42}ClCuN_3O_7$ (655.7): calcd. C 55.0, H 6.5, N 6.4; found C 54.8, H 6.3, N 6.5. UV-Vis (DMF): $\lambda_{max.}$ (log ε) = 274 (3.54) 434 (3.52), 653 (2.15), 1065 (1.89) nm. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1097 (vs, νClO_4^-), 628 (s, νClO_4^-), 1554 (s, νCO). EPR (MeCN): g = 2.116, A = 66.4 G. μ_{eff} = 1.89 BM.

Oxygenation of [Cu(fla)(R-TAC)]ClO_4 (R = Bz, *i*Pr): [Cu(fla)(Bz-TAC)]ClO_4 or [Cu(fla)(*i*Pr-TAC)]ClO_4) (0.25 mmol) was dissolved in DMF (5 mL) and stirred at 120 °C under dioxygen for 12 h. The formation of [Cu(*O*-bs)(Bz-TAC)]ClO_4 or [Cu(*O*-bs)(*i*Pr-TAC)]-ClO_4 from [Cu(fla)(Bz-TAC)]ClO_4 or [Cu(fla)(*i*Pr-TAC)]ClO_4 requires dioxygen but no apparent uptake was observed because the absorption of dioxygen, and the liberation of carbon monoxide compensate each other. Dilute NH_3 solution (0.5 mL) was added to a portion of the reaction mixture (1 mL) at room temperature, and the organic phase was extracted with diethyl ether. Diazomethane solution (1 mL) was then added and the conversion to the coordinated flavonolate (78 and 57%) was determined by GC.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Synthesis of [Cu(*O*-bs)(Bz-TAC)]ClO_4 (11): To a solution of $[Cu(CH_3CN)_4]ClO_4$ (0.119 g, 0.5 mmol) and Bz-TAC (0.13 g, 0.5 mmol) in CH_3CN (10 mL) was added *O*-benzoylsalycilic acid (0.121 g, 0.5 mmol) in CH_3CN (10 mL), and the solution was heated to reflux for 5 h under O_2. After concentrating the solution by evaporation under vacuum, Et_2O was added to induce precipitation of a blue solid, which was collected by filtration, washed with Et_2O, and air-dried (92%, m.p. 198−200 °C). X-ray quality crystals were obtained by slow evaporation of a CH_3CN solution. $C_{41}H_{42}ClCuN_3O_8$ (803.8): calcd. C 61.3, H 5.3, N 5.2; found C 60.8, H 5.1, N 5.0. UV-Vis (DMF): $\lambda_{max.}$ (log ε) = 276 (3.81), 650 (1.96), 1035 (1.62) nm. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1097 (vs, νClO_4^-), 628 (s, νClO_4^-), 1741 (s, νCO), 1586 (s, $\nu_{as}CO_2$). 1432 (s, ν_sCO_2). EPR (MeCN): g = 2.120, A = 62.0 G. μ_{eff} = 1.99 BM.

Synthesis of [Cu(*O*-bs)(*i*Pr-TAC)]ClO_4 (12): This compound was prepared analogously to [Cu(*O*-bs)(Bz-TAC)]ClO_4 but using the *i*Pr-TAC ligand instead (90%, m.p. 235−237 °C). X-ray quality crystals were obtained by slow evaporation of a CH_3CN solution. $C_{29}H_{42}ClCuN_3O_8$: calcd. C 52.8, H 6.4, N 6.4; found C 52.4, H 6.2, N 6.6. UV-Vis (DMF): $\lambda_{max.}$ (log ε) = 278 (3.23), 670 (1.43), 1060 (1.73) nm. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1095 (vs, νClO_4^-), 627 (s, νClO_4^-), 1747 (s, νCO), 1584 (s, $\nu_{as}CO_2$). 1428 (s, ν_sCO_2). EPR (MeCN): g = 2.121, A = 60.3 G. μ_{eff} = 1.97 BM.

Kinetic Measurements: Reactions of [Cu(fla)(Bz-TAC)]ClO_4 and [Cu(fla)(*i*Pr-TAC)]ClO_4 with dioxygen were performed in DMF solutions. In a typical experiment [Cu(fla)(Bz-TAC)]ClO_4 or [Cu(fla)(*i*Pr-TAC)]ClO_4 was dissolved under argon in a thermostatically controlled reaction vessel with an inlet for taking samples with a syringe, and connected to a mercury manometer to maintain a constant pressure. The solution was then heated to the appropriate temperature. A sample was then taken by syringe and the initial concentration of [Cu(fla)(Bz-TAC)]ClO_4 or [Cu(fla)(*i*Pr-TAC)]ClO_4 was determined by UV-Vis spectroscopy measuring the absorbance of the reaction mixture at 432 nm or 434 nm {$\lambda_{max.}$ of a typical band of [Cu(fla)(Bz-TAC)]ClO_4 or [Cu(fla)(*i*Pr-TAC)]ClO_4]}, respectively. The argon was then replaced by dioxygen and consumption of the latter was periodically monitored. The rate of oxygenation was independent of the stirring rate, excluding

eventual diffusion control effects. The dioxygen concentration was calculated from literature data (as 6.96×10^{-3} M)[55] taking into account the partial pressure of DMF,[56] and assuming the validity of Dalton's law.

X-ray Crystallographic Studies: Intensity data were collected on an Enraf−Nonius CAD4 diffractometer (graphite monochromator; Mo-K_α radiation, $\lambda = 0.71073$ Å) at 293(2) K using $\omega/2\theta$ scans. The intensities of three standard reflections were monitored regularly (every 60 min). Psi-scan absorption corrections were applied to the data.[57]

The structures were solved by direct methods (and subsequent difference syntheses),[58] and refined by anisotropic full-matrix least-squares on F^2 for all non-hydrogen atoms.[59] Hydrogen atomic positions were calculated from assumed geometries. Hydrogen atoms were included in structure factor calculations but they were not refined. The isotropic displacement parameters of the hydrogen atoms were approximated from the U_{eq} value of the atom to which they were bonded. Crystal data, data collection, and refinement details are shown in Table 1. The ClO_4^- anions are disordered in all three structures. In **11** the perchlorate O1c atom is ordered and the remaining three oxygens split into seven partially occupied positions. The sum of these occupation factors were bound to give three. The high maximum and mean shift/esd is due to the site occupation factor of O3c. In **12** (Figure 3) only one perchlorate oxygen atom splits but the O10···C18 (Ph−COO) moiety is, however, disordered with 2/3:1/3 occupancies. For the presentation of the molecular structures, the molecular graphics program PLATON was used.[60]

CCDC-201803 (for **9**), -201804 (for **11**), and -201805 (for **12**) contain the supplementary crystallographic data for this paper. A Fulvene Route to Group 4 Metallocene Complexes Bearing 4,7-Bis(dimethylamino)-Substituted Indenyl Ligands

Jesus Cano Sierra,[a] Sierra Gerald Kehr,[a] Roland Fröhlich,[a][‡] and Gerhard Erker*[a]

Keywords: Aminofulvenes / Cyclopentadienide / Zirconium / Ring-closure / Sandwich complexes

N,*N*,*N*′,*N*′-Tetramethylsuccinamide (**15**) was selectively converted into the functionalized aminofulvene **16**. Subsequent treatment with reagent **17**, $[ZrCl_2(NMe_2)_2(L)_2]$ (L = THF or 0.5 DME), resulted in the formation of the cyclization product 4,7-bis(dimethylamino)indene (**21**). Deprotonation with *n*-butyllithium, followed by the reaction of the resulting substituted indenyllithium reagent **22** with $ZrCl_4$, gave the metallocene [4,7-bis(dimethylamino)indenyl]$_2ZrCl_2$ (**23**). The reaction of **22** with $ZrCl_3Cp$ furnished the complex [4,7-bis(dimethylamino)indenyl]$CpZrCl_2$ (**24**). Fulvene **16**, as well as the metallocene dichlorides **23** and **24**, were characterized by X-ray diffraction.

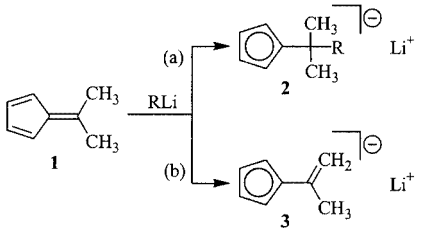
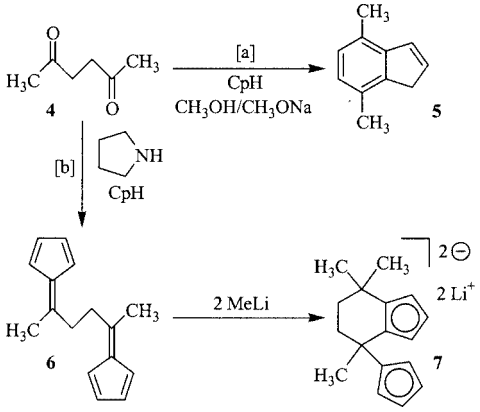
Introduction

Fulvenes are often used as precursors for the preparation of cyclopentadienyl ligands and related systems. Most of these syntheses make use of the electrophilicity of the fulvene C6 carbon center, which allows the formation of substituted cyclopentadienides by means of nucleophilic addition (a) or deprotonation (b) (see Scheme 1).[1−3]



Scheme 1

We have already synthesized substituted indenyl ligands by a series of related reactions. The reaction of 2,5-hexanedione (**4**) with cyclopentadienide under "Thiele conditions"[4] (pathway [a] in Scheme 2) gave the ring-closed 4,7-dimethylindene product **5**,[5] whereas the related reaction under "Stone/Little conditions" ([b] in Scheme 2)[6] furnished the respective bis(fulvene) **6**, which was subsequently used as a starting material for the preparation of the ligand system **7** and of *ansa*-metallocenes derived thereof.[7]



Scheme 2

The unsymmetrical 1,4-diketone **8** allowed the selective preparation of the mono(fulvene) **9** (see Scheme 3). Its treatment with a cuprate nucleophile yielded the substituted tetrahydroindenyl ligand precursor **10**.[8] Similarly, the mono(fulvene) **12** was derived from **11**. In this case the subsequent nucleophilic attack did not result in a related ring-

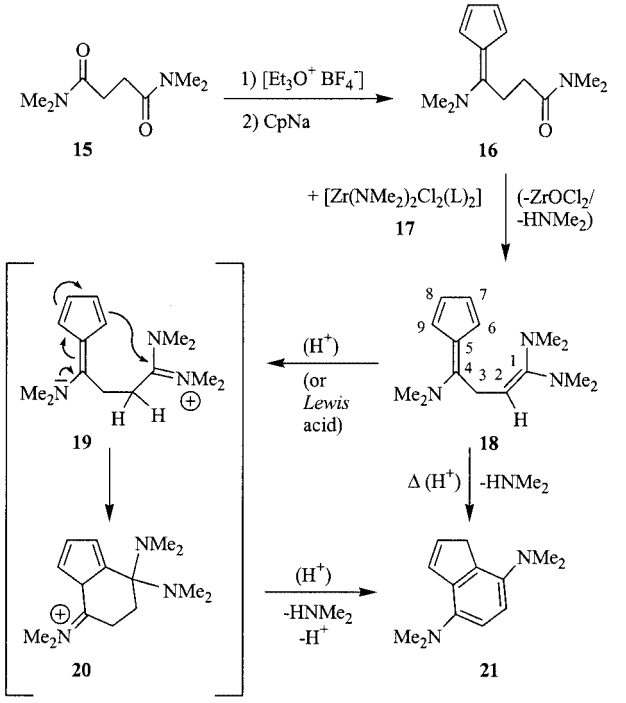
closure reaction but led to the clean formation of the functionalized Cp derivative **13** instead, which was used in the metallocene synthesis.[9]

We now used succinamide **15** as the starting material for a series of related reactions, based on the initial formation of a substituted 6-(dimethylamino)fulvene. In this case we observed a clean ring-closure reaction to yield the corresponding 4,7-bis(dimethylamino)indene product **21** upon treatment with a mild Lewis acid (see Scheme 4). Details of this reaction series, which complements the family of fulvene-to-indene conversions summarized above, are described in this account.



Scheme 4

Results and Discussion

Our synthetic scheme started from succinyl dichloride (**14**), which was treated with dimethylamine to yield the corresponding diamide **15**. The bifunctional carboxylic acid derivative **15** was then selectively converted into its mono(fulvene) derivative **16**. For this purpose, we applied a method that was developed by Hafner et al. for the synthesis of amino-substituted pentafulvenes.[10] The succinamide **15** was mono-*O*-alkylated by treatment with Meerwein's reagent, $[Et_3O^+][BF_4^-]$, and the resulting, stabilized carbenium ion reacted with sodium cyclopentadienide to selectively yield the aminopentafulvene **16**, which bears a residual $-CONMe_2$ functional group (92 % isolated). The fulvene system **16** was characterized by X-ray diffraction (see Figure 1). It shows the typical features of an aminopentafulvene moiety with alternating double and single bonds (see Figure 1) and a trigonal-planar carbon center, C6. The C6−N1 bond length amounts to 1.337(2) Å, which is slightly shorter than the C9−N2 distance [1.349(2) Å] of the delocalized pendent $-CONMe_2$ functional group [C9−O 1.222(2) Å]. In the crystal, compound **16** attains a conformation that is characterized by the antiperiplanar central section of the substituent chain [dihedral angle θ(C6−C7−C8−C9) = −173.1(2)°] with a gauche arrangement at the junction with the fulvene nucleus [θ(C1−C6−C7−C8) = 89.8(2)°].

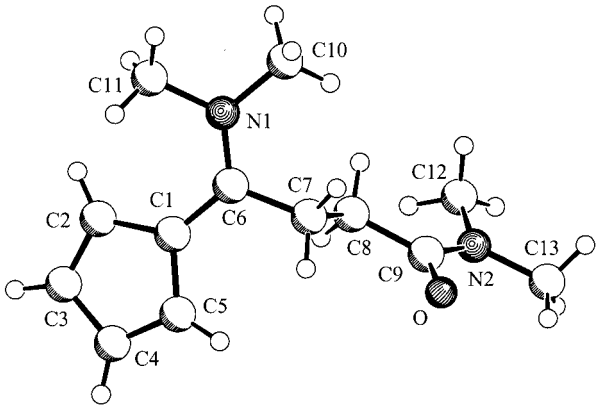


Figure 1. View of the carboxamide-functionalized aminopentafulvene system **16**; selected bond lengths [Å] and angles [°]: C1−C2 1.450(2), C2−C3 1.355(3), C3−C4 1.421(3), C4−C5 1.357(3), C5−C1 1.438(3), C1−C6 1.399(2), C6−N1 1.337(2), C6−C7 1.511(2), C7−C8 1.527(2), C8−C9 1.515(2), C9−O 1.222(2), C9−N2 1.349(2); C2−C1−C5 105.1(2), C2−C1−C6 130.1(2), C5−C1−C6 124.7(2), C1−C6−N1 124.9(2), C1−C6−N7 118.3(2), N1−C6−C7 116.8(2), C6−C7−C8 112.1(1), C7−C8−C9 111.5(1), C8−C9−O 120.9(1), C8−C9−N2 117.0(2), O−C9−N2 122.1(2)

Fulvene **16** was treated with 1 mol-equiv. of $[ZrCl_2(NMe_2)_2{\cdot}DME]$[11] (**17a**) in toluene at reflux temperatures for 3 h. Workup and extraction with pentane furnished the metal-free organic product 4,7-bis(dimethylamino)indene (**21**) as a pale yellow liquid in close to 90 % yield. The product is characterized by a pair of ^1H NMR $(NCH_3)_2$ singlets (δ = 2.60 and 2.65 ppm), each representing six hydrogen atoms. We monitored a set of four indene methine-proton resonances (δ = 6.31, 6.77, 6.83, and 7.21 ppm) and the indene CH_2 ^1H NMR signal at δ = 3.31 (2 H) ppm.

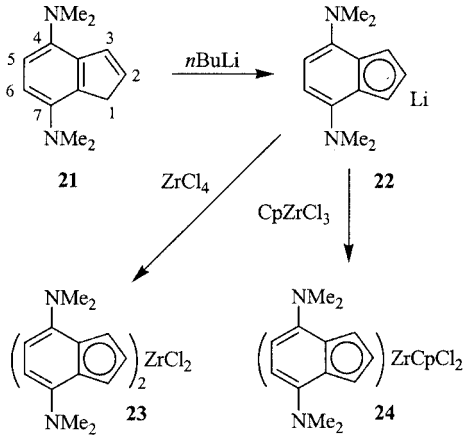
Weingarten et al. have shown that ketene aminals are formed upon treatment of suitably substituted carboxamide starting materials with, for example, $Zr(NMe_2)_4$.[12] It seems that the here observed reaction sequence of the transformation **16** → **21** is initiated by a similar conversion of the *N*,*N*-dimethylcarboxamide functional group. We observed that treatment of **16** with a stoichiometric quantity of the reagent $[ZrCl_2(NMe_2)_2{\cdot}2THF]$[11b] (**17b**) in toluene at room temperature gives the corresponding ketene aminal system **18**. The intermediate **18** was not isolated in a pure form, but was obtained, after washing with pentane, as a solid that was probably still admixed with the zirconium-containing reaction product (perhaps $ZrOCl_2$ or a derivative thereof). Subsequent heating of this mixture in toluene eventually gave rise to the formation of **21**.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The intermediate **18** was characterized spectroscopically. Its ^{1}H NMR spectrum shows four clearly separated fulvene methine-hydrogen resonances at δ = 7.09, 6.97, 6.86 and 6.79 ppm (in [D_6]benzene) in addition to the typical ketene aminal ^{1}H NMR resonance at δ = 3.62 (t, ^3J = 6 Hz, 1 H) ppm. The adjacent CH_2 group gives rise to a ^{1}H NMR doublet (^3J = 6 Hz) at δ = 3.38 ppm. Compound **18** gives rise of three different NMe_2 ^{1}H NMR singlets at δ = 2.68 (6 H, "fulvene"-NMe_2) and δ = 2.48/2.12 [each 6 H, (*Z*)- and (*E*)-ketene aminal-NMe_2] ppm. The fulvene carbon center (C4−NMe_2) gives rise to a ^{13}C NMR feature at δ = 161.2 ppm, whereas the carbon atoms of the −CH=$C(NMe_2)_2$ ketene aminal show ^{13}C NMR resonances at δ = 156.2 (C1) and 88.4 (C2, $^1J_{C,H}$ = 157 Hz) ppm; the C3 resonance was found at δ = 32.6 ppm with $^1J_{C,H}$ = 133 Hz.

We assume that the observed ring-closure reaction that eventually yields the indene derivative **21** is initiated by activation of the ketene aminal intermediate **18** by protonation or addition of a zirconium-based Lewis-acid catalyst at the C2 carbon atom (see Scheme 4). Intramolecular nucleophilic addition of the Me_2N-activated cyclopentadienide ring at the strongly electrophilic incipient amidinium moiety would then give the product framework. Removal of the H^+ (or $ZrOCl_2$ Lewis acid) catalyst with concomitant dimethylamine elimination and tautomerization would directly lead to the observed product **21**.

Treatment of **21** with *n*-butyllithium results in deprotonation and formation of the substituted indenyllithium reagent **22**, which exhibits the expected ^{1}H NMR features of a C_{2v}-symmetry averaged structure in [D_6]benzene/[D_8]THF (10:1) solution at ambient temperature [δ = 6.80 (t, 1 H, 2-H), 6.42 (d, 2 H, 1-H and 3-H), 6.32 (s, 2 H, 5-H and 6-H), 2.94 (s, 12 H, NMe_2) ppm; see Scheme 5].



Scheme 5

Reagent **22** was used for the preparation of two zirconocene complexes. Treatment of $ZrCl_4$ with **22** in a toluene suspension gave bis[4,7-bis(dimethylamino)indenyl]$ZrCl_2$ (**23**). Similarly, the reaction of reagent **22** with $CpZrCl_3$[13] gave the mixed indenyl/Cp-zirconium complex **24** (isolated in ca. 70 % yield).

Both **23** and **24** were characterized by X-ray crystal structure analyses. Complex **23** is C_2-symmetric in the crystal. The symmetry-equivalent indenyl ligands are η^5-bound to the zirconium atom through their five-membered rings, although in a rather unsymmetrical way: the bonds between the zirconium atom and the "external" CH centers are short [Zr−C1 2.467(3), Zr−C2 2.484(3), Zr−C3 2.540(3) Å], whereas the Zr−C linkages to the internal indenyl carbon atoms are markedly longer [see Figure 2; Zr−C4 2.639(3), Zr−C9 2.579(3) Å]. The Zr−Cl bond length in complex **23** amounts to 2.417(1) Å.

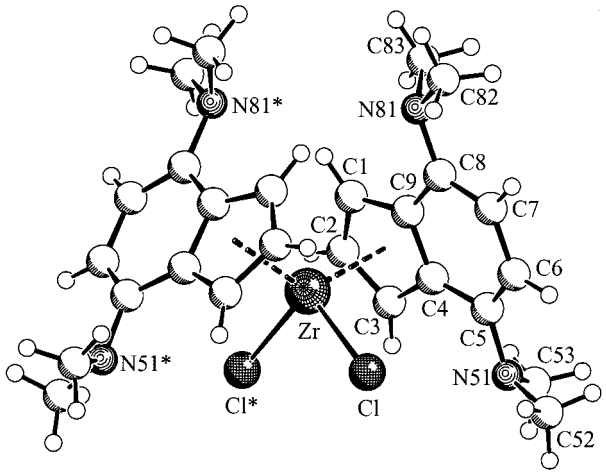


Figure 2. View of the molecular structure of complex **23** (with unsystematic atom-numbering scheme); selected bond lengths [Å] and angles [°]: Zr−Cl 2.417(1), Zr−C1 2.467(3), Zr−C2 2.484(3), Zr−C3 2.540(3), Zr−C4 2.639(3), Zr−C9 2.579(3), C1−C2 1.393(5), C1−C9 1.439(4), C2−C3 1.398(5), C3−C4 1.427(5), C4−C9 1.444(4), C8−C9 1.436(4), C4−C5 1.422(4), C8−N81 1.422(4), C5−N51 1.417(4); Cl−Zr−Cl* 98.80(5), C1−C2−C3 109.9(3), C2−C1−C9 107.6(3), C2−C3−C4 108.3(3), C1−C9−C8 132.9(3), C3−C4−C5 132.0(3), C9−C8−N81 119.0(3), C4−C5−N51 118.0(3)

In the crystal, complex **23** features a chiral metallocene conformation, in which the indenyl six-membered rings point to different lateral sides of the bent metallocene wedge. This leads to a spatial differentiation of the $-NMe_2$ substituents at each of the indenyl ligands: the Me_2N51 group points toward the open-front side and the Me_2N81 substituent is oriented toward the narrow back side of the bent metallocene wedge (see Figure 2). In solution this differentiation is not observed: here rapid rotation about the zirconium−Cp(centroid) vector leads to symmetry-averaged NMR spectra (for details see the Exp. Sect.).

Complex **24** shows an η^5-Cp ligand that is rather uniformly coordinated to the zirconium atom [with Zr−C(Cp) bond lengths ranging from 2.483(2) to 2.537(2) Å]. The bonding features of the substituted indenyl ligand are very similar to those found in the related complex **23** (see above and Figure 3). The single η^5-bis(4,7-dimethylamino)indenyl ligand in complex **24** has a similar conformational orientation to that of the ligands in **23**. In **24** the indenyl ligand has its substituted phenylene moiety oriented towards the lateral side of the bent metallocene wedge.

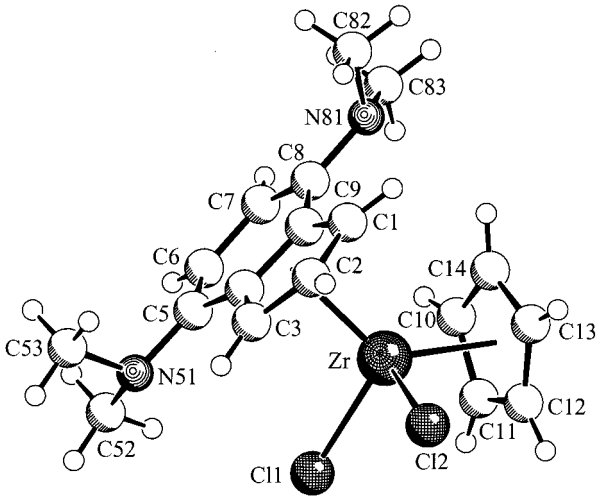

Figure 3. Molecular structure of complex **24**; selected bond lengths [Å] and angles [°]: Zr−Cl1 2.440(1), Zr−Cl2 2.441(1), Zr−C1 2.477(2), Zr−C2 2.508(2), Zr−C3 2.527(2), Zr−C4 2.601(2), Zr−C9 2.577(2), Zr−C10 2.494(2), Zr−C11 2.537(2), Zr−C12 2.514(2), Zr−C13 2.483(2), Zr−C14 2.492(2), C1−C2 1.404(3), C1−C9 1.440(3), C2−C3 1.403(3), C3−C4 1.439(3), C4−C9 1.438(3), C8−C9 1.433(3), C4−C5 1.427(3), C8−N81 1.411(3), C5−N51 1.421(3); Cl1−Zr−Cl2 96.98(2), C1−C2−C3 109.9(2), C2−C1−C9 107.5(2), C2−C3−C4 107.6(2), C1−C9−C8 132.4(2), C3−C4−C5 131.5(2), C9−C8−N81 118.7(2), C4−C5−N51 118.1(2)

Conclusion

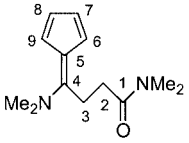
We conclude that treatment of the functionalized fulvene system **16** with the zirconium reagent **17** provides a very convenient and selective synthetic pathway to 4,7-bis(dialkylamino)indene systems. We have also shown that these can be easily attached at electrophilic transition-metal centers to yield the respective metallocene systems. The specific influence of the nucleophilic $-NR_2$ substituents on the properties of such organometallic compounds will be investigated in the future.

Experimental Section

General Remarks: All reactions were carried out under dry argon in Schlenk-type glassware or in a glove box. Solvents, including deuterated solvents used for NMR spectroscopy, were dried and distilled prior to use. For additional general conditions, including a list of instruments used for physical characterization of the compounds, see reference.[9]

Preparation of $C_2H_4(CONMe_2)$ (15): Succinyl dichloride (14.7 g, 94 mmol) was added dropwise to a solution of NMe_2H (24 g, 520 mmol) in diethyl ether at −78 °C. The mixture was allowed to warm to room temperature, stirred for 15 min, and filtered to separate the ammonium salt. The residue was extracted with THF (2 × 200 mL) and the solvent was removed under vacuum. The resulted solid was recrystallized from diethyl ether (5 mL) and cooled to −35 °C to give **15** as a light white crystalline solid. Suitable crystals for X-ray crystal-structure analysis[14] were obtained from a concentrated solution in diethyl ether (14.8 g, 91 %). ^{1}H NMR ($CDCl_3$): δ = 3.03 (s, 6 H, NMe), 2.92 (s, 6 H, NMe), 2.64 (s, 4 H, CH_2) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 172.1 (CO), 36.9 (NMe), 35.3 (NMe), 28.1 (CH_2). $C_8H_{16}N_2O_2$ (172.22): calcd. C 55.79, H 9.36, N 16.27; found C 55.65, H 9.38, N 15.84.

Preparation of Fulvene 16: A CH_2Cl_2 solution of $[Et_3O^+][BF_4^-]$ (14.71 g, 77.4 mmol) was added to a CH_2Cl_2 solution of **15** (13.31 g, 77.4 mmol) at −30 °C. The orange solution was allowed to warm to room temperature and stirred for 2 h. The solvent was removed under vacuum, leading to an oily product. The brown oil was frozen with liquid nitrogen, a solution of NaCp (6.81 g, 77.4 mmol) in THF, cooled to −40 °C, was immediately added and the solution was stirred overnight. The THF was evaporated to dryness and the residue extracted and recrystallized with diethyl ether to yield **16**, as a crystalline solid. Suitable crystals for X-ray crystal-structure analysis were obtained from a concentrated solution in diethyl ether (15.7 g, 92 %). ^{1}H NMR ($CDCl_3$): δ = 6.60, 6.56, 6.43, 6.31 (each broad, each 1 H, fulvene), 3.35 (s, 6 H, 4-NMe), 3.18 (m, 2 H, CH_2), 2.96, 2.95 (each s, each 3 H, 1-NMe), 2.63 (m, 2 H, CH_2) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 170.8 (C1), 161.3 (C4), 122.3, 119.9, 119.7, 117.0 (fulvene), 117.1 (C5), 43.7 (4-NMe), 37.0, 35.5 (1-NMe), 33.8 (C2), 28.6 (C3) ppm. $C_{13}H_{20}N_2O$ (220.31): calcd. C 70.87, H 9.15, N 12.72; found C 70.56, H 9.27, N 12.49.

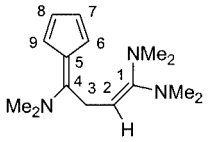


X-ray Crystal-Structure Analysis of 16: Empirical formula $C_{13}H_{20}N_2O$, M = 220.31, yellow-orange crystal 0.20 × 0.15 × 0.10 mm, a = 10.390(1), b = 13.607(1), c = 8.946(1) Å, β = 90.54(1)°, V = 1264.7(2) Å^3, $D_{calcd.}$ = 1.157 g cm^{-3}, μ = 5.79 cm^{-1}, no absorption correction ($0.893 \le T \le 0.944$), Z = 4, monoclinic, space group $P2_1/c$ (No. 14), λ = 1.54178 Å, T = 223 K, ω/2θ scans, 2731 reflections collected ($\pm h$, $-k$, $-l$), [(sinθ)/λ] = 0.62 Å^{-1}, 2562 independent ($R_{int.}$ = 0.035) and 1763 observed reflections [$I \ge 2\sigma(I)$], 150 refined parameters, R = 0.047, wR^2 = 0.133, max. residual electron density 0.18 (−0.16) e·Å^{-3}, hydrogen atoms calculated and refined as riding atoms.

Formation of the Ketene Aminal Intermediate 18: Toluene (100 mL) was added to a Schlenk flask containing **16** (0.28 g, 1.3 mmol) and $[Zr(NMe_2)_2Cl_2{\cdot}THF_2]$ (**17b**) (0.51 g, 1.3 mmol). The resulting solution was stirred at room temperature for 1 h, concentrated to dryness and washed with pentane to give **18** as a light brown solid (0.59 g). ^{1}H NMR (C_6D_6): δ = 7.09 (m, 1 H, 6-H), 6.97 (m, 1 H, 8-H), 6.86 (m, 1 H, 7-H), 6.79 (m, 1 H, 9-H), 3.62 (t, $J_{H,H}$ = 6.3 Hz, 1 H, 2-H), 3.39 (d, $J_{H,H}$ = 6.3 Hz, 2 H, 3-H), 2.68 (s, 6 H, 4-NMe), 2.48 [s, 3 H, 1-$NMe_{(Z)}$], 2.12 [s, 6 H, 1-$NMe_{(E)}$] ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 161.2 (C4), 156.2 (C1), 123.3 (C8), 121.4 (C6), 120.3 (C7), 119.0 (C5), 118.1 (C9), 88.4 (C2, $^1J_{C,H}$ = 157 Hz), 42.8 (NMe-4), 40.6 [$NMe_{(Z)}$], 40.6 [$NMe_{(E)}$], 32.6 (C3) ppm. ^{1}H-^{13}C GHSQC (C_6D_6): δ(^{13}C)/δ(^{1}H) = 123.3/6.97 (8-CH), 121.4/7.09 (6-CH), 120.3/6.86 (7-CH), 118.1/6.79 (9-CH), 88.4/3.62 (2-CH), 42.8/2.68 (4-NMe), 40.6/2.48 [1-$NMe_{(Z)}$], 40.6/2.12 [1-$NMe_{(E)}$], 32.6/3.39 (3-CH_2). ^{1}H-^{13}C GHMBC (C_6D_6): δ(^{13}C)/δ(^{1}H) = 161.2/3.39, 2.68 (C4/3-H, 4-NMe), 156.2/3.39, 2.48, 2.12 [C1/3-H, 1-$NMe_{(Z)}$, 1-$NMe_{(E)}$], 119.0/3.39 (C5/3-H). ^{1}D TOCSY (C_6D_6): δ($^1H_{irr}$)/δ($^1H_{res}$) = 7.09/6.97, 6.86, 6.79 (6-H/8-H, 7-H, 9-H), 3.62/3.39 (2-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

H/3-H). NOE (C_6D_6): δ($^1H_{irr}$)/δ($^1H_{res}$) = 2.12/2.48, 3.62 [1-NMe$_{(E)}$/1-NMe$_{(Z)}$, 2-H]; 2.48/2.12, 3.39 [1-NMe$_{(Z)}$/1-NMe$_{(E)}$, 3-H]; 2.68/3.39, 3.62, 6.79 (4-NMe/3-H, 2-H, 9-H); 3.39/2.48, 2.68, 3.62, 7.09 [3-H/1-NMe$_{(Z)}$, 4-NMe, 2-H, 6-H]; 3.62/2.12, 3.39 [2-H/1-NMe$_{(E)}$, 3-H].



Preparation of the Substituted Indene 21: Toluene (100 mL) was added to a Schlenk flask containing **16** (1.06 g, 4.6 mmol) and [Zr(NMe$_2$)$_2$Cl$_2$·DME] (**17a**) (2.10 g, 4.6 mmol) and the mixture vigorously stirred at room temperature for 3 h. The resulting red solution was filtered, the solvent removed under vacuum and the residue extracted with pentane to yield **19** as a yellow liquid (0.82 g, 88 %). ^1H NMR (C_6D_6): δ = 7.21, 6.31 (each dt, $J_{H,H}$ = 5.6, 1.9 Hz,·each 1 H, 2,3-H), 6.83, 6.77 (AB $J_{H,H}$ = 8.7 Hz,·each 1 H, 5,6-H), 3.31 (t, $J_{H,H}$ = 1.9 Hz, 2 H, CH$_2$), 2.65, 2.60 (each s, each 6 H, NMe) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 145.1, 143.1 (C4,7), 139.5, 137.1 (C3a,7a), 132.3, 130.9 (C2,3), 116.0, 114.9 (C5,6), 44.6, 43.6 (NMe$_2$), 39.3 (CH$_2$) ppm. $C_{13}H_{18}N_2$ (202.29): calcd. C 77.18, H 8.97, N 13.85; found C 76.73, H 9.20, N 13.86.

Preparation of the Indenyllithium Reagent 22: BuLi (1.6 M) was added to a solution of **19** (0.56 g, 2.77 mmol) in pentane (150 mL), cooled to −78 °C. The white suspension formed was warmed slowly to room temperature and stirred for 12 h. Filtration and removal of the solvent at reduced pressure gave **22** as a white solid (0.55 g, 95 %). ^1H NMR (C_6D_6, TDF): δ = 6.80 (t, $J_{H,H}$ = 3.4 Hz, 1 H, 2-H), 6.42 (d, $J_{H,H}$ = 3.4 Hz, 2 H, 1,3-H), 6.32 (s, 2 H, 5,6-H), 2.94 (s, 12 H, NMe) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6, TDF): δ = 142.1 (C4,7), 122.9 (C3a,7a), 112.7 (C2), 101.8 (C5,6), 92.2 (C1,3), 44.0 (NMe) ppm.

Preparation of the Zirconium Complex 23: $ZrCl_4$ (0.156 g, 0.67 mmol) was added to a suspension of **22** (0.28 g, 1.34 mmol) in toluene (100 mL) at −40 °C. The cooling bath was removed and the reaction mixture stirred at room temperature for 12 h. After filtration, the solvent was removed under vacuum and the residue washed with pentane (2 × 50 mL) to give **23** as a red crystalline solid (0.21 g, 57 %). ^1H NMR (CD_2Cl_2): δ = 6.77 (d, $J_{H,H}$ = 3.0 Hz, 2 H, 1,3-H), 6.50 (s, 2 H, 5,6-H), 6.08 (t, $J_{H,H}$ = 3.0 Hz, 1 H, 2-H), 2.90 (s,·12 H, NMe) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 143.2 (C4,7), 123.4 (C3a,7a), 118.8 (C2), 111.9 (C5,6), 104.3 (C1,3), 43.3 (NMe) ppm. $C_{26}H_{34}Cl_2N_4Zr$ (564.70): calcd. C 55.30, H 6.07, N 9.92; found C 55.15, H 6.14, N 9.72.

X-ray Crystal-Structure Analysis of 23: Empirical formula $C_{26}H_{34}Cl_2N_4Zr$, M = 564.69, red crystal 0.15 × 0.05 × 0.03 mm, a = 41.733(1), b = 7.036(1), c = 17.528(1) Å, V = 5146.8(8) Å^3, $D_{calcd.}$ = 1.458 g cm^{-3}, μ = 6.57 cm^{-1}, empirical absorption correction with SORTAV (0.908 ≤ T ≤ 0.981), Z = 8, orthorhombic, space group $Fdd2$ (No. 43), λ = 0.71073 Å, T = 198 K, ω and φ scans, 9228 reflections collected (±h, ±k, ±l), [(sinθ)/λ] = 0.66 Å^{-1}, 3023 independent (R_{int} = 0.053) and 2492 observed reflections [$I \geq 2\sigma(I)$], 154 refined parameters, R = 0.038, wR^2 = 0.068, max. residual electron density 0.36 (−0.59) e·Å^{-3}, Flack −0.04(5), hydrogen atoms calculated and refined as riding atoms.

Preparation of the Zirconium Complex 24: $CpZrCl_3$ was added to a suspension of **22** in toluene (100 mL) at −40 °C. The cooling bath was removed and the reaction mixture was stirred at room temperature for 12 h. After filtration, the solvent was removed under vacuum and the residue was washed with pentane (2 × 50 mL) to give **24** as a red crystalline solid (0.61 g, 71 %). ^1H NMR (CD_2Cl_2): δ = 6.73 (t, $J_{H,H}$ = 3.2 Hz, 1 H, 2-H), 6.71 (d, $J_{H,H}$ = 3.2 Hz, 2 H, 1,3-H), 6.52 (s, 2 H, 5,6-H), 6.24 (s, 5 H, Cp), 2.92 (s, 6 H, NMe) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 145.0 (C4,7), 123.9 (C3a,7a), 123.5 (C2), 118.7 (Cp), 113.3 (C5,6), 105.2 (C1,3), 44.8 (NMe) ppm. $C_{18}H_{22}Cl_2N_2Zr$ (428.50): calcd. C 50.45, H 5.17, N 6.54; found C 50.67, H 5.37, N 6.48.

X-ray Crystal-Structure Analysis of 24: Formula $C_{18}H_{22}Cl_2N_2Zr$, M = 428.50, red crystal 0.15 × 0.15 × 0.05 mm, a = 7.919(1), b = 13.135(1), c = 17.552(1) Å, V = 1825.7(3) Å^3, $D_{calcd.}$ = 1.559 g cm^{-3}, μ = 8.95 cm^{-1}, empirical absorption correction with SORTAV (0.877 ≤ T ≤ 0.957), Z = 4, orthorhombic, space group $P2_12_12_1$ (No. 19), λ = 0.71073 Å, T = 198 K, ω and φ scans, 12933 reflections collected (±h, ±k, ±l), [(sinθ)/λ] = 0.65 Å^{-1}, 4158 independent (R_{int} = 0.034) and 3879 observed reflections [$I \geq 2\sigma(I)$], 213 refined parameters, R = 0.024, wR^2 = 0.052, max. residual electron density 0.24 (−0.57) e·Å^{-3}, refined as a racemic twin with a ratio of 0.67(3):0.33, hydrogen atoms calculated and refined as riding atoms.

X-ray Crystallographic Study: Data sets were collected with Enraf−Nonius CAD4 and Nonius KappaCCD diffractometers; the latter was equipped with a rotating anode generator, Nonius FR591. Programs used: data collection EXPRESS (Nonius B. V., **1994**) and COLLECT (Nonius B. V., **1998**), data reduction MolEN (K. Fair, Enraf−Nonius B. V., **1990**) and Denzo-SMN (Z. Otwinowski, W. Minor, *Methods Enzymol.* **1997**, *276*, 307−326), absorption correction for CCD data SORTAV (R. H. Blessing, *Acta Crystallogr., Sect. A* **1995**, *51*, 33−37; R. H. Blessing, *J. Appl. Crystallogr.* **1997**, *30*, 421−426), structure solution SHELXS-97 (G. M. Sheldrick, *Acta Crystallogr., Sect. A* **1990**, *46*, 467−473), structure refinement SHELXL-97 (G. M. Sheldrick, Universität Göttingen, **1997**), graphics SCHAKAL (E. Keller, Universität Freiburg, **1997**). CCDC-220797, -220798 and -220799 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Crystal Structure and Magnetic Properties of A New Thiazolyl-Substituted Nitronyl Nitroxide and Its Copper(II) Complexes

Li-Ya Wang,[a,b] Li-Cun Li,[c] Dai-Zheng Liao,[a] Zong-Hui Jiang,*[a] and Shi-Ping Yan[a]

Keywords: Thiazole radicals / Nitronyl nitroxide / Copper / Magnetic properties

A new building block for molecule-based magnetic materials — thiazole-substituted nitronyl nitroxide NIT2-thz [**1**, NIT2-thz = 4,4,5,5-tetramethyl-2-(2′- thiazolyl)imidazolin-1-oxyl 3-oxide] and its copper(II) complexes [Cu(NIT2-thz)$_2$(N$_3$)$_2$] (**2**) and [CuCl$_2$(NIT2-thz)$_2$] (**3**) — have been synthesized and characterized structurally and magnetically. Compound **1** is found to contain two crystallographically independent molecules; the shortest contact between nitroxide groups is 4.900 Å. Both **2** and **3** are mononuclear complexes, in which the copper(II) centers are hexacoordinate. In complex **2**, the copper(II) ion has an elongated octahedral geometry, but complex **3** has a rare compressed-octahedral coordination sphere. Magnetic susceptibility data for compounds **1**–**3** have been measured in the range 5–300 K. There are ferromagnetic interactions (J = 10.13 cm^{-1}) between the Cu^{II} ions and the radicals of **2**, and antiferromagnetic interactions (J = –8.17 cm^{-1}) between the Cu^{II} ions and the radicals of **3**. The magnetic properties of complexes **2** and **3** are discussed in connection with their crystal structures.

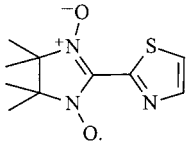
Introduction

In the preparation of molecular magnetic materials, transition metal complexes with organic nitronyl nitroxide radical ligands have attracted widespread interest in recent years.[1−5] However, the weakly basic character of nitronyl nitroxide strongly limits their coordination ability. This has led to the development of functionalized nitronyl nitroxide radicals, in which a strong co-ligand is incorporated. Research has focused on nitronyl nitroxide radicals with electron-donating substituents such as 2-pyridyl,[6,7] imidazolyl,[8,9] 2,2′-bipyridinyl,[10] and 1,2,4-triazolyl.[11] Among them, the 2-pyridyl- and imidazolyl-substituted nitroxides have the advantage of forming stable chelated complexes with the support of the auxiliary substituent groups. The thiazolyl substituent too has a strong chelating ability for complexes with metal ions. This prompted us to synthesize a new thiazole-substituted nitronyl nitroxide radical and a group of metal compounds containing this radical ligand. In this contribution, we wish to report the synthesis, crystal structure and magnetic properties of the radical NIT2-thz [**1**, NIT2-thz = 4,4,5,5-tetramethyl-2-(2′- thiazolyl)imidazolin-1-oxyl 3-oxide] (Scheme 1) and its complexes [Cu(NIT2-thz)$_2$(N$_3$)$_2$] (**2**) and [CuCl$_2$(NIT2-thz)$_2$] (**3**).



Scheme 1

Results and Discussion

Crystal Structure of 1

Compound **1** (Figure 1) is found to contain two crystallographically independent molecules, but these two structures are not significantly different from each other. The N−O bond lengths of 1.284(4) Å [O(1)−N(3)] and 1.278(4) Å [O(2)−N(2)], respectively, are in agreement with those in radicals synthesized by other groups.[12,13] The two S−C bond lengths of 1.729(4) Å [S(1)−C(3)] and 1.692(5) Å [S(1)−C(1)], respectively, are longer than other three bond lengths of 1.305(5) Å [N(1)−C(3)], 1.366(5) Å [N(1)−C(2)] and 1.319(6) Å [C(1)−C(2)] in the thiazole ring. The dihedral angles between the nitronyl nitroxide fragment and the thiazole ring are 7.1(5)° and 3.6(4)°, respectively. The shortest contact between nitroxide groups is 4.900 Å [O(4)···O(4), (x, 1 − y, 1/2 + z)].

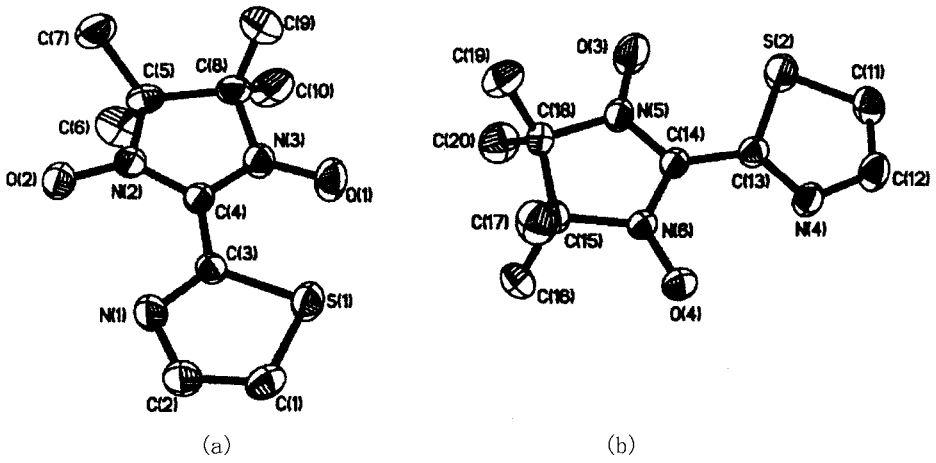

Figure 1. ORTEP drawing of compound **1**

Crystal Structures of 2 and 3

The structures of **2** (Figure 2) and **3** (Figure 3) are centrosymmetric, and the copper(II) ions have a distorted octahedral environment. In both complexes, two NIT2-thz radicals, acting as bidentate chelating ligands, coordinate the copper(II) ion through the N−O unit and the nitrogen atom of the thiazole ring. However, the geometries of complexes **2** and **3** are different.

In complex **2**, the two nitrogen atoms [N(4), N(4A)) of the azide groups and the two nitrogen atoms [N(1), N(1A)) of the radical ligands are coordinated at the equatorial positions. The Cu−N bond lengths are 1.995(3) Å [Cu(1)−N(4)] and 2.024(2) Å [Cu(1)−N(1)], respectively. The two oxygen atoms [O(2), O(2A)] on the NO groups of the radical ligands are bonded at the axial positions, with a Cu−O distance of 2.364(2) Å, which is longer than for those coordinated at the equatorial positions. The copper(II) ion has, as expected, an elongated octahedral geometry.

In complex **3**, the basal plane is formed by the two oxygen atoms [O(1), O(1A)] of the NO groups [with a Cu−O bond length of 2.370(5) Å], and two chloride anions [with a Cu−Cl bond length of 2.348(2) Å]. The axial positions are occupied by the two nitrogen atoms [N(1), N(1A)) of the thiazole rings, with a Cu−N distance 2.001(6) Å, which is significantly shorter than for those coordinated at the equatorial positions. Thus the copper(II) ion has a rare compressed-octahedral coordination sphere.

The uncoordinated N−O bond lengths of 1.278(3) Å (for **2**) and 1.280(7) Å (for **3**), and the coordinated N−O bond lengths of 1.276(3) Å (for **2**) and 1.293(7) Å (for **3**), are close to those of the free radical NIT2-thz [corresponding N−O bond lengths 1.284(4) Å and 1.278(4) Å]. The dihedral angle between the nitronyl nitroxide fragment and the thiazole ring is 5.4(4)° (for **2**) and 16.7(11)° (for **3**). The shortest distances between the nitroxide groups are 4.728 Å (for **2**) and 4.521 Å (for **3**).

Magnetic Properties

The magnetic susceptibilities of compounds **1**, **2** and **3** were measured in the range 5−300 K at a magnetic field of 1 T.

For compound **1**, the variation of $\chi_M T$ vs. T is plotted in Figure 4. The $\chi_M T$ value is close to 0.357 $cm^3 \cdot K \cdot mol^{-1}$ in the range 30−300 K, and corresponds to the expected value

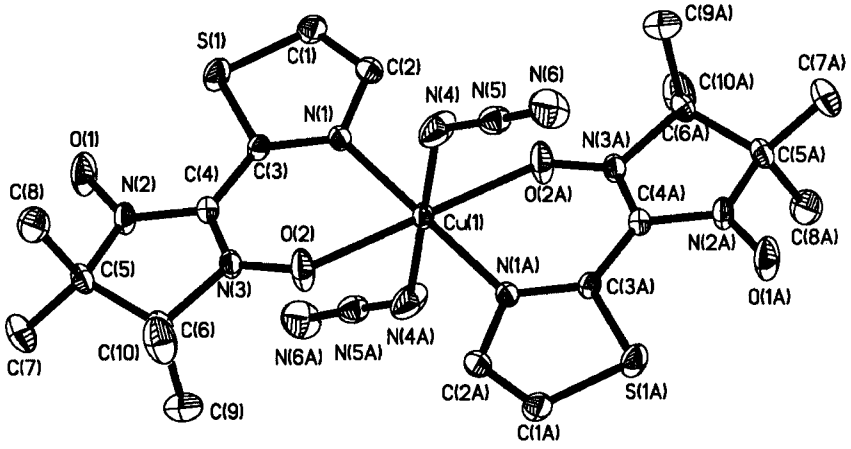

Figure 2. ORTEP drawing of complex **2**

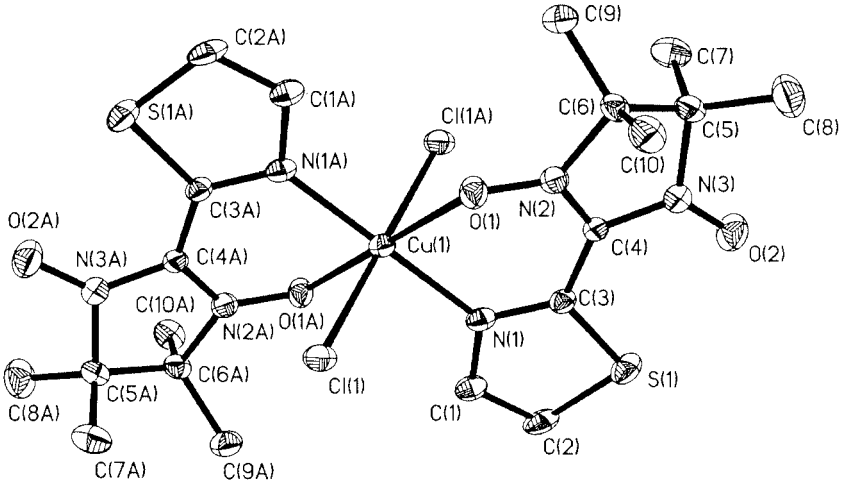

Figure 3. ORTEP drawing of complex **3**

(0.374 $cm^3 \cdot K \cdot mol^{-1}$) for a non-correlated $S = 1/2$ spin. As the temperature is lowered from about 30 K to 5 K, $\chi_M T$ decreases rapidly. Below 30 K, the magnetic susceptibility data obeys a Curie−Weiss law $\chi = C/(T - \theta)$, with the Weiss constant $\theta = -1.46$ K and $C = 0.364$ (inset in Figure 4). This behaviour is characteristic of weak intermolecular antiferromagnetic interactions.

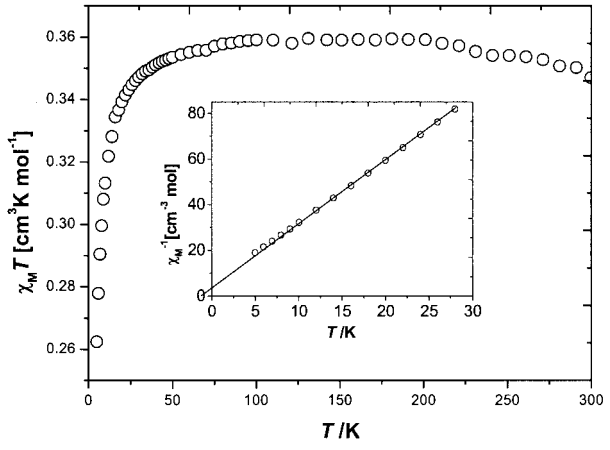

Figure 4. Plot of $\chi_M T$ vs. T for compound **1**. Inset: plot of $\chi_M{}^{-1}$ vs. T

For complex **2**, the plots of $\chi_M T$ and χ_M vs. T are shown in Figure 5. At 300 K, the $\chi_M T$ value is equal to 1.17 $cm^3 \cdot K \cdot mol^{-1}$, which is slightly higher than that expected for a non-interacting $S = 1/2$ spin for Cu^{II} and two $S = 1/2$ spins for the radicals (spin-only value 1.13 $cm^3 \cdot K \cdot mol^{-1}$). As the temperature decreases from about 300 to 5 K, $\chi_M T$ gradually increases and reaches a maximum of 1.475 $cm^3 \cdot K \cdot mol^{-1}$ at 7.0 K, from where it decreases down to a temperature of 4.91 K. This indicates that there are ferromagnetic interactions between the nitroxide radical and the copper(II) ion.

The magnetic data for **2** were treated by the theoretical expression[14] derived through the spin Hamiltonian $H = -J(S_{R1}S_{Cu} + S_{R2}S_{Cu})$, where J represents the exchange interaction between the Cu^{II} ion and the thiazole radical. Considering the magnetic coupling between the molecules, we used the mean-field approximation (zJ').[15] The best fitting for the data gives $J = 10.13 cm^{-1}$, $zJ' = -0.46$ cm^{-1}, $g_{cu} = 2.13$, $g_{rad} = 2.0$ (fixed), and an agreement factor [defined as $R = (\chi_M)_{obsd.} - (\chi_M)^2_{calcd.}/(\chi_M)^2_{obsd.}$] of 3.34×10^{-4}. These results indicate a weak ferromagnetic exchange interaction between the Cu^{II} ion and the radical.

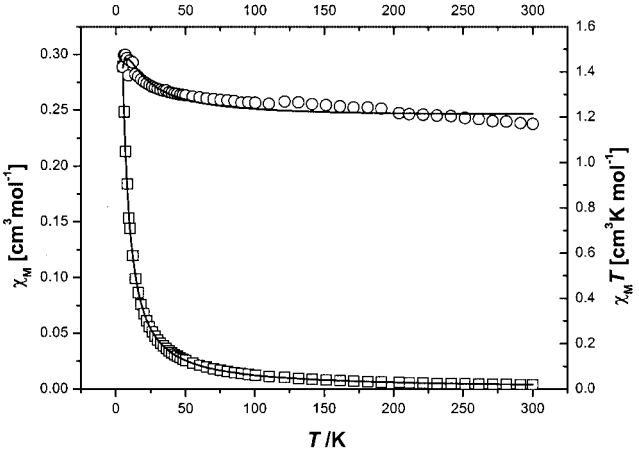

Figure 5. Plots of $\chi_M T$ vs. T and χ_M vs. T of complex **2**. The solid line represents the fitting values

The plots of $\chi_M T$ and χ_M vs. T for **3** are shown in Figure 6. At 300 K, $\chi_M T$ is 1.12 $cm^3 \cdot K \cdot mol^{-1}$, which is consistent with that expected for one non-interacting $S_{Cu} = 1/2$ spin and two $S_{rad} = 1/2$ spins (1.13 $cm^3 \cdot K \cdot mol^{-1}$). Starting from a temperature of 300 K, $\chi_M T$ decreases smoothly down to 50 K, then rapidly decreases to 0.43 $cm^3 \cdot K \cdot mol^{-1}$ at 5 K. This magnetic behavior is clearly indicative of antiferromagnetic interactions.

The magnetic data for **3** were treated with a similar theoretical expression to that used for **2**; J characterizes the exchange interaction between the Cu^{II} ion and the thiazole radical.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

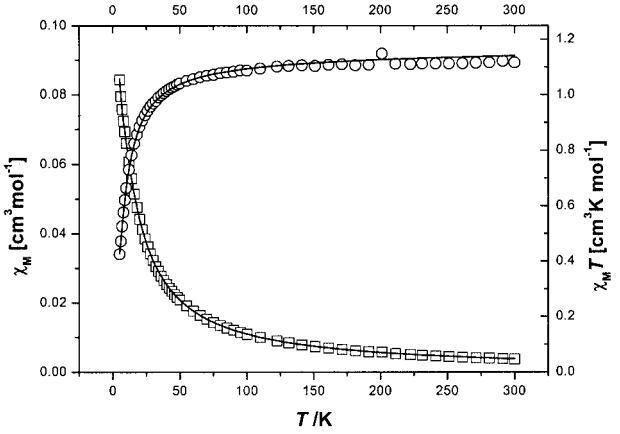

Figure 6. Plots of $\chi_M T$ vs. T and χ_M vs. T for complex **3**. The solid line represents the fitting values

The best fitting for the data gives $J = -8.17\text{cm}^{-1}$, $zJ' = -0.36\ \text{cm}^{-1}$, $g_{cu} = 2.04$, $g_{rad} = 2.0$ (fixed), with an agreement factor [defined as $R = [(\chi_M)_{obsd.} - (\chi_M)_{calcd.}]^2/[(\chi_M)_{obsd.}]^2$] of 5.41×10^{-6}. The results indicate a weak antiferromagnetic exchange interaction between the Cu^{II} ion and the radical.[11]

The geometrical parameters of the binding of the radical to the metal are of great importance for the understanding of the magnetic properties of the complexes **2** and **3**. In our two complexes, the magnetic orbital of the nitronyl nitroxide radical is a π* orbital, with its axis lying perpendicular to the O−*N*−C−*N*−O plane.[16] The magnetic orbital of the copper(II) ion with an octahedral coordination environment is $d_{z^2-y^2}$ or d_{z^2}. Following the Kahn−Briat rules,[17] the extent of overlap between metal and radical magnetic orbitals is responsible for the appearance of antiferromagnetic interactions, whereas orthogonality of the same orbitals induces ferromagnetic contributions. With these ideas in mind, it is possible to correlate the metal-radical coupling to the crystal structures of the complexes. Complex **2** has an elongated-octahedral geometry, with the two nitroxide groups bound in an axial position. It is generally accepted that the interaction between a copper(II) centers and an axially bound nitroxide radical is ferromagnetic because, in this geometry, the π* radical orbital is strictly orthogonal to the $d_{x^2-y^2}$ orbital of the copper(II) ion.[18] Thus, the positive value of the copper(II) nitroxide coupling constant ($J_{Cu,rad} = 10.13\ \text{cm}^{-1}$) has been ascribed to the interaction between the copper(II) ion and the radicals located in axial positions. The relatively low value observed arises from the fact that the Cu−O distances are fairly long [Cu(1)−O(2) = 2.364(2) Å].

For compound **3**, two nitroxide groups coordinate in equatorial positions. In general, this results in a strong antiferromagnetic coupling between copper and radical.[19] However, in this case, a weak antiferromagnetic interaction is observed ($J_{Cu,rad} = -8.17\ \text{cm}^{-1}$). In complex **3**, the copper(II) ion has a compressed octahedral coordination geometry and the magnetic orbital of the copper(II) ion is d_{z^2}. This geometry will induce a weak antiferromagnetic coupling between the copper(II) ion and the radical due to the poor magnetic orbital overlap.

Conclusions

In summary, the novel thiazole-substituted nitronyl nitroxide radical **1** and the complexes **2** and **3** (the first examples of a new family of complexes) have been synthesized. In complex **3**, the copper(II) ion has a rare compressed-octahedral coordination sphere. This geometry results in a weak antiferromagnetic interaction between the copper(II) ion and the radical, even though the radical is coordinated in the equatorial plane.

Experimental Section

General: All reagents were purchased from commercial sources and used as received. Solvents were purified and dried by standard methods. Elemental analyses for C, H, and N were carried out with a Perkin−Elmer 240 elemental analyzer. The infrared spectra were recorded in KBr pellets in the range 4000−600 cm^{-1} with a SHIMADZU-408 IR spectrometer. EPR spectra were recorded as a solution of the compound in CH_2Cl_2 with a JESFEIXG EPR spectrometer. Variable-temperature magnetic susceptibilities were measured with a MPMS-7 SQUID magnetometer. Diamagnetic corrections were made using Pascal's constants for all the constituent atoms.

X-ray diffractions were measured with a RAXIS-IV area detector for **2** and **3** and with a Bruker−Smart 1000 diffractometer for **1**. The structures were solved by direct methods using the SHELXS-97[20] program. H atoms were assigned with common isotropic displacement factors and included in the final refinement by use of geometrical restraints. A full-matrix least-squares refinement on F^2 was carried out using SHELXL 97.[21] Crystal data are summarized in Table 1, selected structural parameters in Table 2−4.

Preparation of Nitronyl Nitroxide Radical NIT2-thz: Prepared from 2-thiazolecarboxaldehyde by the literature method.[22,23] The dark green crystals of **1** were recrystallized from cyclohexane/ethyl acetate (5:1) in 55% yield. $C_{10}H_{14}N_3O_2S$: calcd. C 49.94, H 5.87, N 17.48; found C 49.89, H 5.85, N 17.40. IR: $\tilde{\nu}_{thz}$ = 1418, 1185, 1140 cm^{-1}; $\tilde{\nu}_{N\text{-}O}$ = 1375 cm^{-1}. ESR (299 K, CH_2Cl_2): five lines; g = 2.00; a_N = 7.8 G.

Preparation of [Cu(NIT2-thz)$_2$(N$_3$)$_2$] (2): $Cu(ClO_4)_2 \cdot 6H_2O$ (0.093 g, 0.25 mmol) and NaN_3 (0.033 g, 0.5 mmol) were added with stirring to a solution of **1** (0.120 g, 0.5 mmol) in dry methanol (30 mL), and the mixture was then filtered to remove a small amount of precipitate. The dark brown solution was allowed to stand at room temperature in the dark for two weeks. Black crystals were obtained in 43% yield. $C_{20}H_{28}CuN_{12}O_4S_2$: calcd. C 38.24, H 4.49, N 26.74; found C 38.30, H 4.44, N 26.76. IR: $\tilde{\nu}_{thz}$ = 1420, 1190, 1136 cm^{-1}; $\tilde{\nu}_{N\text{-}O}$ = 1375 cm^{-1}.

Preparation of [CuCl$_2$(NIT2-thz)$_2$] (3): $CuCl_2 \cdot 2H_2O$ (0.086 g, 0.5 mmol) was added with stirring to a solution of **1** (0.120 g, 0.5 mmol) in dry ethanol (30 mL), and the mixture was then filtered to remove a small amount of precipitate. The dark brown solution was allowed to stand at room temperature in the dark for three weeks. Dark blue crystals were obtained in 45% yield. $C_{20}H_{28}Cl_2CuN_6O_4S_2$: calcd. C 39.06, H 4.59, N 13.66; found C

Synthesis, Crystal Structure, and Magnetic Properties of $Mn_2(OH)_2SO_4$: A Novel Layered Hydroxide

Mohsen Ben Salah,[a] Serge Vilminot,*[a] Tahar Mhiri,[b] and Mohamedally Kurmoo[a]

Keywords: Hydroxysulfate / Hydrothermal synthesis / Magnetic properties / Manganese

$Mn_2(OH)_2SO_4$, obtained as pink prismatic crystals by the hydrothermal reaction of $MnSO_4 \cdot H_2O$ and NaOH at 240 °C for 24 h, consists of layers of Mn hydroxide connected to each other through μ^6-sulfate ions. Each layer exhibits vacancies, and each vacant space is capped at the top and bottom by the sulfate groups. The compound is paramagnetic above 50 K (C = 4.36 emu K mol^{-1}, μ_{eff} = 5.91 μ_B, Θ = −100 K). Below 45 K, the magnetization increases slightly, indicating canted-antiferromagnetic ($T_{Néel}$ = 42±1 K) behavior consistent with the linear dependence of the magnetization as a function of the field at 2 K, which reaches only 0.4 μ_B at 50 kOe, and the lack of any imaginary component of the ac-susceptibilities (ac = alternating current).

Introduction

Layered compounds have attracted continuing interest in many different fields of research.[1] The principal interest, in the early days, was due to their applications resulting from their sorption properties and, therefore, for selective separation, ion exchange chromatography, and as electrodes. These applications developed to include catalysis, since they have quite large surface areas, and also photopolymerization.[2] More recently, these materials have been of interest as a result of their magnetism, especially as models for low dimensional behavior in antiferromagnets but also for understanding the exchange mechanism through space when the layers are separated by non-magnetic intercalants.[3,4]

From a synthetic chemistry point of view, the layered compounds are very difficult to obtain as single crystals, and in cases where crystals of a few tens of nanometers in size have been obtained, resolution of the crystal structures was hampered by several dislocations and stacking faults, for example turbostratic faults.[5] Using hydrothermal techniques it has been possible to obtain a few compounds as single crystals.[6,7] Consequently, for those with crystal sizes large enough, their crystal structures were determined. In a few cases, the structures have been determined by Rietveld refinement of high-quality powder diffraction data.[8,9] Furthermore, certain disorders were fully characterized in some cases.[7,10]

Amongst the hydroxides of the divalent cations, the layer topology can be quite variable. The simplest case is that of brucite, which is adopted by the transition metal hydroxides $M(OH)_2$.[11−12] Variants of these are formed by replacing some of the hydroxides by other anions, such as $Cu_2(OH)_3NO_3$.[13] In the literature, these have been classified as β- and α-phases, respectively. A further modification of the layer topology can be achieved by periodically replacing some of the octahedra within the brucite layer, and capping the vacant sites by tetrahedrally coordinated MO_4 units. Examples of these are $Zn_5(OH)_8(H_2O)_2(NO_3)_2$,[14] $Zn_5(OH)_8Cl_2 \cdot H_2O$,[15] $Co_5(OH)_8(C_8H_{10}O_4) \cdot 4H_2O$,[7] and $Co_8(OH)_{12}(SO_4)_2(\text{pillar}) \cdot xH_2O$ {pillar = 1,2-diaminoethane or 4,4′-diazabicyclo[2.2.2]octane (dabco); x = 3 or 1}.[10] These structures are only observed for Zn and Co since both metals adopt a four-coordinate geometry. A more exotic layer topology can be found for $Co_2(OH)_2$(terephthalate),[9] which adopts a topology similar to the 110 planes of normal rutile, i.e. consisting of edge-sharing chains of octahedra connected to similar chains through the apices of the octahedra with the layers being interleaved by the bridging dianionic terephthalate. A further variant was found for $M_2(OH)_2(C_2O_4)$ (M = Co or Mn), which consists of dimers of edge-sharing octahedra connected to one another by their apices thus forming corrugated layers. These layers are then connected by the oxalate ions.[16] $Mn(OH)(OAc)_2 \cdot HOAc$ is an interesting layered compound employing both coordination and hydrogen bonds.[17]

In this paper we present the synthesis, crystal structure, and characterization by IR spectroscopy and DT-TGA of $Mn_2(OH)_2SO_4$. It displays a novel layered topology and be-

haves as a paramagnet above 50 K with a long-range Néel transition at 42 K, and the appearance of a weak magnetization due to a very small canting.

Results and Discussion

X-ray Diffraction

X-ray powder diffraction data collected on the pink crystals confirmed the formation of a new phase. The diffraction lines were indexed from the unit cell parameters measured on a single crystal using the pattern-matching mode of FULLPROF.[20] All lines were then indexed confirming, that the sample was a single phase. Figure S1 (see Supporting Information) gives the corresponding diffractogram.

Thermal Analysis

The TGA trace (Figure S2, Supporting Information) revealed that the decomposition takes place in three steps. The first step between 300 and 500 °C associated with an endothermic effect on the DTA trace, whose maximum is at 497 °C, can be attributed to the loss of hydroxy groups as water. The second step between 780 and 870 °C (endothermic effect at 862 °C) is related to the decomposition of the sulfate groups to SO_3. In the final step, weight loss at around 910 °C (endothermic at 912 °C) corresponds to the reduction of the manganese oxide previously formed at lower temperatures. Starting from an Mn^{II} compound, it is well known that the corresponding MnO oxide is not stable and will be transformed into Mn_2O_3. The corresponding oxidation reaction is well identified by the weight increase between 600 and 700 °C, and by the weight loss value between 780 and 870 °C, which is lower than predicted if MnO were to be stable. The experimental Mn content, 44.9 wt%, is in good agreement with the expected value of 45.8 wt%.

Structure Description

The structure is built up of a succession of layers parallel to the *bc* plane, alternating between layers containing MnO_6 octahedra, and layers containing SO_4 tetrahedra (Figure 1). Each tetrahedron shares its four corners with six different octahedra, three on each adjacent layer. Inside an $(MnO_6)_n$ layer, each octahedron shares its edges with three neighboring octahedra, and is further corner-shared with one octahedron. This results in a layer with apparent porosity (Figure 2). In the brucite layers, each octahedron is surrounded by six octahedra resulting in a full occupation of the layer space. The MnO_6 octahedra are distorted with three Mn−OH distances between 2.113 and 2.169 Å, and three Mn−O(sulfate) distances between 2.258 and 2.318 Å. Moreover, the interatomic angles also differ from the values expected for a regular octahedron, with values as low as 152° instead of 180°, and 117° instead of 90°. On the other hand, the sulfate tetrahedra are almost regular. OH and O(2) oxygen atoms are of the μ^3-type, OH being bonded to three Mn ions, and O(2) to two Mn centers and one S atom, whereas O(1) is a μ^2-oxo group, and is bonded to one Mn and one S atom. The O−H bond length of 0.77 Å is in agreement with the distances usually found from X-ray diffraction data. The H atom participates in a very weak hydrogen bond with O(1) with an H···O(1) distance of 2.12 Å. Bond valence calculations using the model of Brown and Altermatt[21] reveal, that values (Table 1) close to those expected are obtained for S, Mn and O2. For O1 and OH, the observed deviations are probably related to the uncertainty of the O−H and H···O(1) bond lengths.

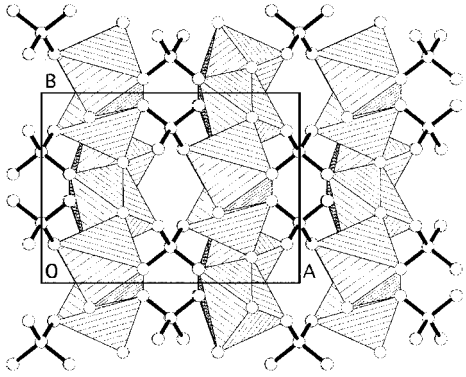

Figure 1. Projection of the structure along the *c* axis (perpendicular to the stacking axis) showing the connections between the layers by the sulfate ions; manganese atoms are presented as polyhedra and the sulfates as spheres and sticks

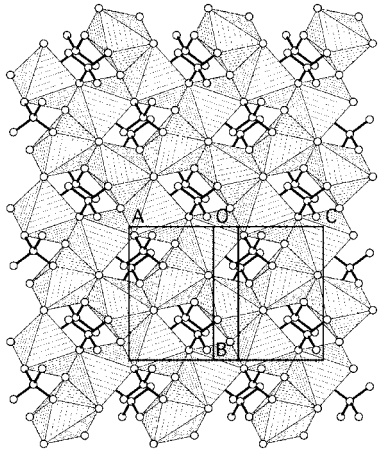

Figure 2. Projection of the structure perpendicular to the layers showing the vacancies, which are coordinated at the top and bottom by the sulfate ions

The required number of Mn−O bonds per formula unit is 12. This requirement is satisfied by the presence of three bonds from each hydroxide ion, and six bonds from the sulfate group. This is similar to that observed for $M_2(OH)_2C_2O_4$ (M = Mn or Co), and for $Co_2(OH)_2$(terephthalate) where, in both cases, the hydroxide ions are both μ^3-bridging and the carboxylate ion forms six bonds with

the surrounding metal atoms.[9,16] Such a μ^6-coordination for the sulfate is rare (Figure 3), it is commonly found as an independent anion, or displaying single-, μ^2-, μ^3- or μ^4-coordination.

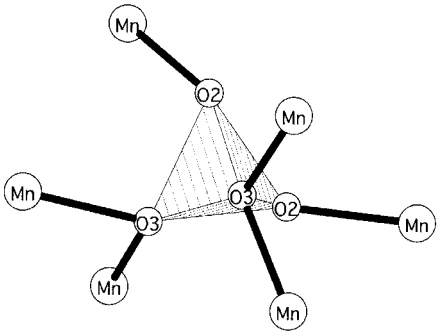

Figure 3. The six-fold coordination of the sulfate group

Infrared Spectroscopy

The infrared spectrum recorded between 500 and 4000 cm^{-1} (Figure S3, Supporting Information) exhibits vibrational bands related to the O−H and S−O bonds. The first ones are near 3500 cm^{-1} as well as in the 900−650 cm^{-1} region, whereas the second ones are near 1100 and 600 cm^{-1}.[22] The sharp band with its maximum at 3498 cm^{-1} can be attributed to the O−H stretching mode of the OH group. Its sharpness is related to the presence of an OH group not involved in hydrogen bonding as revealed by the structural data. The ν_3 and ν_4 vibrational bands of the sulfate group appear as doublets at 1153−1105 cm^{-1} and 617−603 cm^{-1}, respectively. The presence of two bands is related to the local symmetry of the tetrahedron.

Magnetic Susceptibility

In the paramagnetic region, the magnetic susceptibility measured on a randomly oriented sample, consisting of few selected washed crystals, follows the Curie−Weiss law, $\chi = C/(T - \theta) = 8.72/(T + 100)$ emu mol^{-1}, where the Curie and Weiss constants were obtained by fitting the $1/\chi$ experimental data in the temperature range 150−300 K (Figure 4). The negative θ value indicates that the dominant nearest neighbor exchange interactions within the layer are antiferromagnetic. From the Curie constant, $C = Ng^2\mu_B{}^2s(s + 1)/3k$, of 4.36 emu K per Mn and $s = 5/2$, we deduced a value of the Landé g factor of 1.997, in good agreement with a ^{6}A ground state ion. The effective moment $(8C)^{1/2}$ of 5.907 μ_B is close to the expected value of 5.92 μ_B, calculated with the spin-only formula.[23] It appears that the severe distortion of the MnO_6 octahedron has little effect on the moment. On lowering the temperature, χ exhibits a sharp increase starting around 45 K before reaching a plateau down to the lowest temperature. On the χT curve, a maximum can be detected at the previously mentioned temperature of 42 K before decreasing to a value close to zero at 4 K. This behavior has been attributed to the presence of a 3D-antiferromagnetic ordering below the Néel temperature $T_N = 42$ K. The sharp increase at 45 K may be due to a small canting of the sub-lattice. To verify that this anomaly is not due to a small amount of impurity, we performed the experiment on a clean single crystal and observed the same transition (Figure S4, Supporting Information). If we assume that the magnetic unit cell is the same as the nuclear one, that is with a propagation vector k (0,0,0),[24] we may therefore expect an antiferromagnetic ordering due to the presence of the center of symmetry. The isothermal magnetization at 2 K (Figure 5) shows a linear dependence and reaches 0.4 μ_B in a field of 50 kOe. Such behavior is consistent with long-range antiferromagnetic ordering. However, the near-zero residual magnetization indicates the canting angle is immeasurably small. A broad maximum in the real component of the ac-susceptibility (Figure 6) is consistent with the antiferromagnetic coupling, and long-range antiferromagnetism. Due to the very small canting angle, there is no imaginary component in the ac-susceptibility as a function of temperature. Using the moment (M_{2K}) at 2 K in an applied field of 100 Oe, we estimated the canting angle, $\sin^{-1}(M_{2K}/M_s) = \sin^{-1}(6.7/2 \times 5 \times 5585)$, to be $7{\cdot}10^{-3}$ °.

Conclusion

High-quality crystals of $Mn_2(OH)_2SO_4$ were prepared as a minority phase by the hydrothermal reaction of $MnSO_4{\cdot}H_2O$ and NaOH. It displays a novel layered topology, and a canted-antiferromagnetic state below the Néel temperature of 42 K.

Experimental Section

Synthesis: $Mn_2(OH)_2SO_4$ was obtained by a hydrothermal synthesis. $MnSO_4{\cdot}H_2O$ (2.5 g, 14.8 mmol) and sodium hydroxide (0.7 g, 17.5 mmol) were separately dissolved in boiling distilled water (20 mL), and the two solutions were quickly mixed while still hot. The resultant suspension was immediately poured into the autoclave, which was then sealed and heated at 240 °C for 24 h under autogenous pressure. Under these conditions, a mixture of $Mn_3(OH)_2(SO_4)_2(H_2O)_2$[18] and $Mn_2(OH)_2SO_4$ was obtained. Several attempts to promote the formation of a single phase by varying the starting Mn/Na proportions, and the conditions of the hydrothermal synthesis (temperature, time, dilution) were unsuccessful. Fortunately, the crystal habits and colors of the two phases are quite different. It was therefore possible to separate the phases using an optical microscope. Whereas $Mn_3(OH)_2(SO_4)_2(H_2O)_2$ crystallizes as pale beige platelets, $Mn_2(OH)_2SO_4$ appears as larger pink prismatic crystals, which were easily separated. Following separation, the crystals were washed with acetone in an ultrasonic bath to remove small traces of the other phase and finally dried in air.

Characterization: The thermal analysis was performed with a TA-STD-Q600 apparatus, at a 3 °C/min heating rate, under air. Infrared spectra were recorded with an ATI Mattson spectrometer by transmission through KBr pellets containing 1% of the crystals. Powder X-ray diffraction patterns were recorded using a D5000 Siemens diffractometer equipped with a back monochromator (Cu-$K_{\alpha 1}$, 1.5406 Å). For X-ray data collection, a single crystal was selected and mounted on a glass fiber. A single set of 180 frames, 20 s/frame, scan of 1°/frame (each frame measured twice), crystal−detector distance = 30 mm, θ = 0°, κ = 0°, was collected at room temperature with a Nonius Kappa CCD diffractometer at the Service Commun de Rayons X, Université Louis Pasteur, Strasbourg. The structure was solved by means of a three-dimensional Patterson function allowing location of the positions of the manganese atoms. Subsequent parameter refinement cycles and three-dimensional difference Fourier maps using SHELXS-93[19] yielded the positions of all the other atoms. The final refinement included anisotropic displacement parameters, and a secondary extinction correction. The atomic coordinates of hydrogen atoms were isotropically refined. Additional experimental details are given in Table 2 and in the Supporting Information. Table 3 gives the final atomic positions and Table 4 the corresponding bond lengths and angles. The oxygen atoms of the sulfate and hydroxy groups have been labeled as O and OH, respectively. Further details of the crystal-structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Ger-

Dimeric 2,2′-Bipyridylruthenium(II) Complexes Containing 2,2′-Bis(1,2,4-triazin-3-yl)-4,4′-bipyridine-Like Bridging Ligands: Syntheses, Characterization and DNA Binding

Cai-Wu Jiang[a]

Keywords: Dinuclear complexes / Ruthenium / DNA binding modes / Enantioselectivity

Three new bridging ligands 2,2′-bis(1,2,4-triazin-3-yl)-4,4′-bipyridine (btb), 2,2′-bis(1,2,4-triazino[5,6-f]acenaphthylen-3-yl)-4,4′-bipyridine (btapb), 2,2′-bis(5,6-diphenyl-1,2,4-triazin-3-yl)-4,4′-bipyridine (bdptb) and their dimeric 2,2′-bipyridylruthenium(II) complexes $[Ru(bpy)_2(btb)Ru(bpy)_2]^{4+}$ (**1**), $[Ru(bpy)_2(btapb)Ru(bpy)_2]^{4+}$ (**2**), $[Ru(bpy)_2(bdptb)Ru(bpy)_2]^{4+}$ (**3**) have been synthesized and characterized by elemental analysis, fast atom bombardment (FAB) mass spectrometry or electrospray mass spectrometry (ES-MS), ^1H NMR and UV/Visible spectroscopy. The binding behavior of these dimeric complexes with calf thymus DNA (CT-DNA) was investigated by electronic absorption spectroscopy, viscosity measurements, and equilibrium dialysis experiments. The hypochromism of the metal-ligand charge transfer (MLCT) band in the electronic absorption spectra of the dinuclear complexes **1**, **2**, and **3** is 8.7%, 19% and 33%, respectively, with bathochromic shifts of 5, 5 and 14 nm, respectively. The binding constants are 7.5×10^4 M^{-1}, 4.8×10^5 M^{-1} and 7.6×10^5 M^{-1}, respectively. Increasing the size of the plane of the bridging ligand increases the hydrophobicity of their complexes, leading to stronger binding by the complexes to calf thymus DNA. The effect of increasing concentrations of these novel dimeric ruthenium(II) complexes on the relative viscosities of CT-DNA is less notable than that of well-known intercalators such as $[Ru(bpy)_2(dppz)]^{2+}$. The equilibrium experiments showed that ΛΛ–**3** binding is stronger than ΔΔ–**3** binding to CT-DNA. This is the first example of a dinuclear complex binding enantioselectively to CT-DNA measured by equilibrium dialysis. The experiments suggest that the three complexes may be DNA groove binders.

Introduction

The design of molecules that target particular DNA sequences is one of the major challenges in the field of molecular recognition. The potential application of ruthenium complexes with polypyridyl ligands in the design and development of photophysical and stereoselective probes of nucleic acid structure has been explored extensively in recent years.[1−6] However, this work has focused primarily on mononuclear complexes, with di- or polynuclear complexes attracting limited attention. Dimeric ruthenium(II) complexes have some advantages over other complexes as photo- and stereochemical probes for nucleic acids, such as greater variations in size and shape. Additionally, the incorporation of two chiral centers into a single dimeric complex may enable amplification of the chiral discrimination. More recently, non-intercalating dinuclear ruthenium(II) complexes have been synthesized as probes of DNA structure.[7−10]

In a previous communication, we reported a novel dimeric ruthenium(II) complex $[Ru(bpy)_2(bdptb)Ru(bpy)_2]^{4+}$ [**3**; bdptb = 2,2′-bis(5,6-diphenyl-1,2,4-triazin-3-yl)-4,4′-bipyridine] that displays enantiopreferential DNA-binding behavior after equilibrium dialysis.[10] We describe here the synthesis of the three new bridging ligands 2,2′-bis(1,2,4-triazin-3-yl)-4,4′-bipyridine (btb), 2,2′-bis(1,2,4-triazino[5,6-*f*]acenaphthylen-3-yl)-4,4′-bipyridine (btapb), bdptb and their dimeric 2,2′-bipyridylruthenium(II) complexes $[Ru(bpy)_2(btb)Ru(bpy)_2]^{4+}$ (**1**), $[Ru(bpy)_2(btapb)Ru(bpy)_2]^{4+}$ (**2**) and **3**. The binding behavior of these compounds with calf thymus DNA (CT-DNA) is also presented.

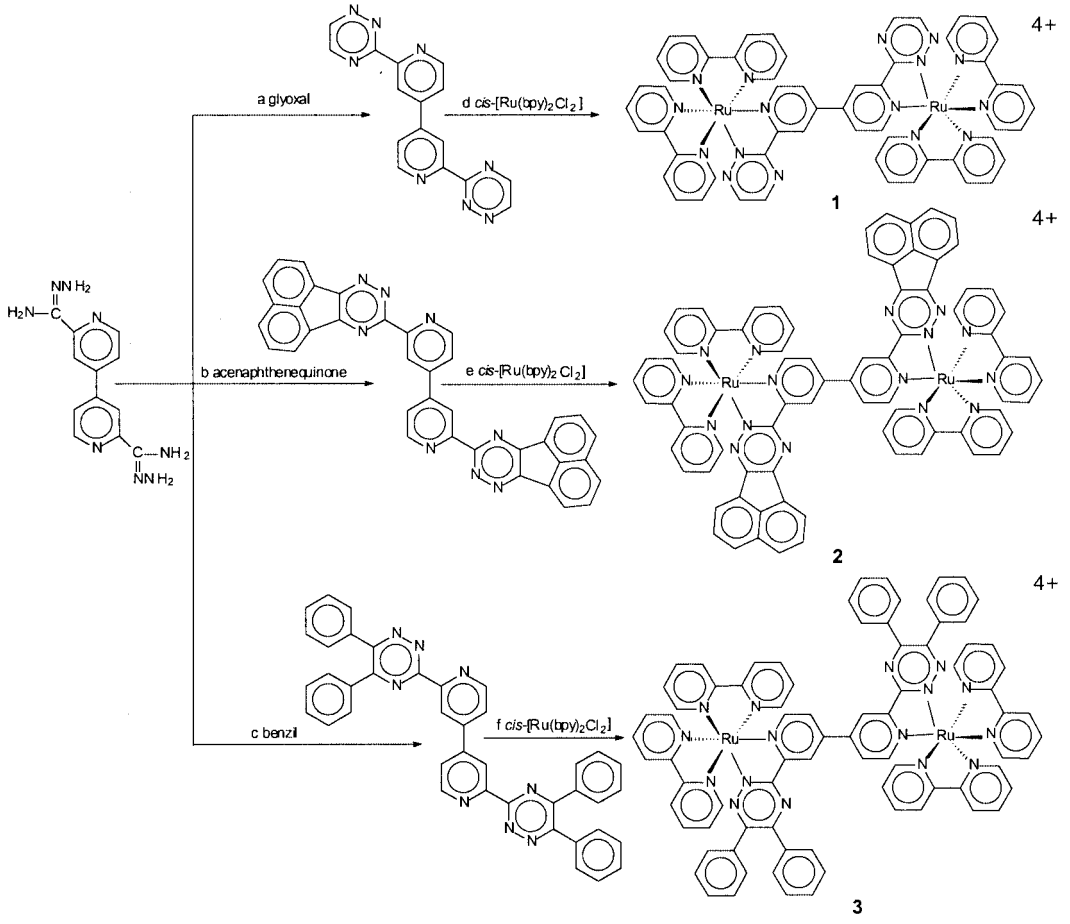
Results and Discussion

1. Syntheses and Characterization

The synthetic routes to the bidentate bridging ligands and their complexes with bpy diruthenium(II) are summarized in Scheme 1. The synthesis of the bridging ligands was based on the method for the 1,2,4-triazine ring preparation established by Case.[11,12] The condensation of bahmb with glyoxal, acenaphthenequinone or benzil produced btb, btapb and bdptb, respectively, in 78%, 72% and 75% yields. Their identities were confirmed by elemental analysis, fast atom bombardment (FAB) mass spectrometry and NMR



Scheme 1. The synthetic routes to the bidentate bridging ligands and bpy diruthenium(II) complexes

spectroscopy. Their complexes were also synthesized and characterized by elemental analysis and spectroscopic methods. The bridging ligands and their dimeric complexes give highly resolved ^{1}H NMR spectra in [D$_6$]DMSO and all proton resonance signals could be assigned by ^{1}H-^{1}H COSY experiments. The ^{1}H NMR spectral data of the dimeric complexes are listed in the Exp. Sect. The ^{1}H-^{1}H COSY NMR spectrum of the dimeric complex **2** is given in Figure 1 as an example.

Electrospray mass spectrometry (ES-MS) has recently been shown to be a powerful tool for measuring the molecular mass of nonvolatile, thermally unstable compounds.[13] In the ES-MS spectra for the diruthenium(II) complexes, intense signals for $[M - 2ClO_4]^{2+}$, $[M - 3ClO_4]^{3+}$ and $[M - 4ClO_4]^{4+}$ were observed. The ES-MS results are given in the Exp. Sect. The observed molecular weights are consistent with the expected values.

The electronic absorption spectra of the new bridging ligands and their dimeric complexes were recorded in chloroform and acetonitrile, respectively. The absorption data are shown in Table 1. The lowest energy absorption bands at 502, 532 and 506 nm for the dimeric complexes are assigned to the metal-ligand charge transfer (MLCT) transition. The high energy absorption bands are attributed to the intense intraligand π-π* transition by comparison with the spectra of the uncoordinated bridging ligand.[14]

2. DNA-Binding Studies

Electronic Absorption Titrations

The interaction of the diruthenium(II) complexes with DNA was investigated by electronic absorption spectroscopy. The absorption spectra of complexes **1**, **2** and **3** in the absence and presence of CT-DNA (with the same concentrations of the complexes) are given in Figure 2. The absorption spectrum of complex **3** has been reported previously.[10] These results are summarized in Table 2.

As the concentration of DNA is increased, the MLCT transition bands of the complexes **1**, **2** and **3** at 483, 523 and 492 nm, respectively, exhibit hypsochromic shifts of about 8.7%, 19% and 33%, and a bathochromism of 5, 5 and 14 nm, respectively. These spectral characteristics suggest that the complexes exhibit a high affinity for DNA.

In order to compare quantitatively the binding strength of the diruthenium(II) complexes, the intrinsic binding constants K_b of the complexes **1**, **2** and **3** with calf thymus DNA were determined from the decrease of the absorbance

[a] The solvent is chloroform for the ligands. [b] The solvent is acetonitrile for the complexes.

monitored, for the complexes **1**, **2** and **3**, at 483, 523 and 492 nm, respectively. The intrinsic binding constant K_b of the complex with CT-DNA was determined from the equation:[14] $[DNA]/(\varepsilon_a - \varepsilon_f) = [DNA]/(\varepsilon_b - \varepsilon_f) + 1/K_b \cdot (\varepsilon_b - \varepsilon_f)$ by a plot of $[DNA]/(\varepsilon_a - \varepsilon_f)$ versus [DNA], where [DNA] is the concentration of DNA as base pairs. The ap-

Table 2. Electronic absorption spectral changes upon addition of CT-DNA

Complexes	λ_{max}/nm free	bound	Bathochromism $\Delta\lambda$/ nm	Hypochromism %	K_b/M^{-1}
1	483	488	5	8.7	7.5×10^4
	422	426	4	8.2	
	284	274	−10	12	
2	523	528	5	19	4.8×10^5
	388	402	4	28.2	
	283	285	2	24	
3	492	506	14	33	7.6×10^5
	426	427	1	26	
	280	282	2	31	

parent absorption coefficients ε_a, ε_f and ε_b correspond to A_{obsd}/[Ru], the extinction coefficient for the free ruthenium complex and the extinction coefficient for the ruthenium complex in the fully bound form, respectively. The slope and *y* intercept of the linear fit of $[DNA]/(\varepsilon_a - \varepsilon_f)$ versus [DNA] give $1/(\varepsilon_b - \varepsilon_f)$ and $1/K_b \cdot (\varepsilon_b - \varepsilon_f)$, respectively. The intrinsic binding constant K_b can be obtained from the ratio of the slope and the *y* intercept. The intrinsic binding constants K_b of complexes **1**, **2** and **3** were calculated from the decrease of the absorbance to be 7.5×10^4, 4.8×10^5 and 7.6×10^5 M^{-1}, respectively. The K_b's of complexes **1**, **2** and **3** are smaller than that observed for $[Ru(bpy)_2(dppz)]^{2+}$ ($>10^6$ M^{-1}),[15] but larger than that observed for Δ-$[Ru(phen)_3]^{2+}$ (6.2×10^3 M^{-1}).[15] The experiments suggest that the three complexes may be bound to DNA by groove binding and that increasing the size of the plane of the bridging ligand increases the hydrophobicity of their complexes, leading to stronger binding by the complexes to calf thymus DNA.

Enantioselectivity of DNA-Binding

Equilibrium dialysis experiments offer the opportunity to examine the enantioselectivities of DNA-binding by the complexes. Figure 3 shows the UV region of the CD spectra for the dimeric ruthenium complexes **1**, **2** and **3** after their

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

racemic solutions had been dialyzed against calf thymus DNA with stirring for 48 h. An interesting phenomenon was observed in the equilibrium dialysis of the complexes. After dialysis against calf thymus DNA with stirring for 48 h, the dialyzate of complex **3** shows two strong CD signals, with a positive peak at 263 nm and a negative peak at 289.5 nm, which are the CD signals of the ΔΔ-enantiomer of complex **3** assigned by comparison with the CD spectrum of the chiral complex **3.**[16] The presence of these signals indicates enrichment of the isomer which is less likely to bind DNA, indicating that the ΛΛ-enantiomer binds DNA more strongly than the ΔΔ-enantiomer. The other complexes, **1** and **2**, don't show strong CD signals for their enantiomers indicating that complexes **1** and **2** do not bind DNA stereoselectively. The results indicate that complex **3** is an enantioselective binder of DNA while complexes **1** and **2** are not, which may be explained by the differences in the bridging ligand of the complexes: the plane of the bridging ligand for **3** is the largest of the three complexes. To the best of our knowledge, complex **3** is the first example of a dinuclear ruthenium(II) complex binding enantioselectively to CT-DNA measured by equilibrium dialysis. Furthermore, it is interesting to observe that the ΛΛ-bpy complex was found to bind DNA more strongly than the ΔΔ-bpy complex, as indicated by the presence of CD signals. This contrasts with previous reports in which the ΔΔ-diruthenium(II) complexes show preferential DNA binding.[10]

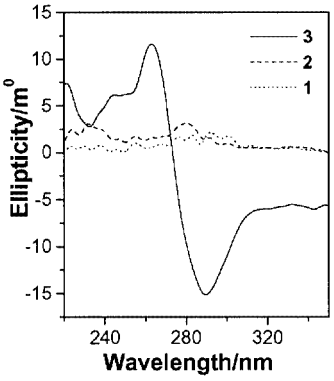

Figure 3. CD spectrum of complexes **1**, **2**,and **3** after 48 h of dialysis against calf thymus DNA with stirring of the solution

The equilibrium dialysis results indicate that complex **3** is a good candidate as an enantioselective binder of DNA.

Viscosity Measurements

In order to further clarify the interaction of the complexes **1**, **2** and **3** with DNA, viscosity measurements were carried out. Optical probes provide essential, but insufficient, evidence to support a binding model. Hydrodynamic measurements, which are sensitive to changes in molecular length (i.e. viscosity and sedimentation), are regarded as the least ambiguous and the most critical tests of a binding model in solution in the absence of crystallographic data.[17] A classical intercalation model demands that the DNA helix must lengthen as base pairs are separated to accommodate the binding ligand, leading to an increase in DNA viscosity. In contrast, a partial and/or non-classical intercalating ligand could bend (or kink) the DNA helix, reducing its effective length and, concomitantly, its viscosity.[18] The effects of complexes **1**, **2** and **3** on the viscosity of rod-like DNA are shown in Figure 4 together with the corresponding data for ethidium bromide (EB) and $[Ru(bpy)_3]^{2+}$.

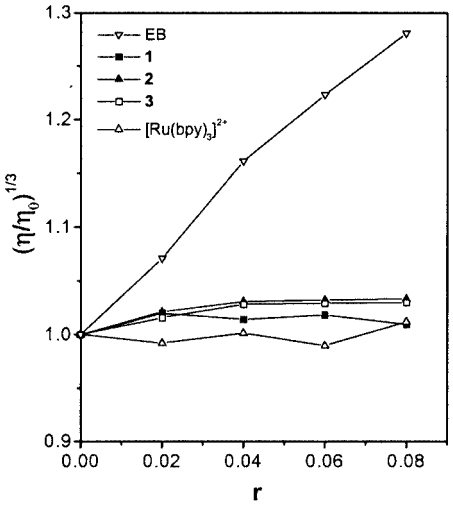

Figure 4. Effect of increasing amounts of complexes **1**, **2**, **3**, ethidium bromide (EB) and the parent complex $[Ru(bpy)_3]^{2+}$ on the relative viscosities of CT-DNA at 28.0 (± 0.1) °C, [DNA]= 0.5 mM and r = [Ru]/[DNA]

The experiments suggest that the dimeric ruthenium(II) complexes bind to the polyanionic DNA via a non-intercalating mode and may be bound to DNA by groove binding.

Conclusion

Three new asymmetric binuclear ligands 2,2′-bis(1,2,4-triazin-3-yl)-4,4′-bipyridine (btb), 2,2′-bis(1,2,4-triazino-[5,6-*f*]acenaphthylen-3-yl)-4,4′-bipyridine (btapb), 2,2′-bis(5,6-diphenyl-1,2,4-triazin-3-yl)-4,4′-bipyridine (bdptb) and their binuclear bpy complexes $[Ru(bpy)_2(btb)Ru(bpy)_2](ClO_4)_4$ (**1**), $[Ru(bpy)_2(btapb)Ru(bpy)_2](ClO_4)_4$ (**2**), $[Ru(bpy)_2(bdptb)Ru(bpy)_2](ClO_4)_4$ (**3**) were synthesized and characterized. Binding behavior of these dimeric complexes with calf thymus DNA was investigated by electronic absorption spectroscopy, viscosity measurements and equilibrium dialysis experiments. The results indicate that the three complexes bind to polyanionic DNA in a non-intercalating mode and may be bound to DNA by groove binding, and that complex **3** is a good candidate as an enantioselective binder of DNA.

Experimental Section

Materials: All reagents and solvents were purchased commercially and used without further purification unless otherwise noted. Solutions of calf thymus DNA in 50 mM NaCl/5 mM Tris-HCl (pH 7.2) gave a ratio of UV absorbance at 260 and 280 nm of 1.8−1.9:1, indicating that the DNA was sufficiently free of protein.[19] The DNA concentration per nucleotide was determined by electronic absorption spectroscopy using the molar absorption coefficient (6600 $M^{-1}\cdot cm^{-1}$) at 260 nm.[20] Doubly distilled water was used to prepare buffers.

Physical Measurements: Microanalysis (C, H, and N) was carried out with a Perkin−Elmer 240Q elemental analyzer. Fast atom bombardment mass spectra were recorded on a VG ZAB-HS spectrometer using 3-nitrobenzyl alcohol as the matrix. Electrospray mass spectra were recorded on an LCQ system (Finnigan MAT, USA) using methanol as the mobile phase. The spray voltage, tube lens offset, capillary voltage and capillary temperature were set at 4.50 kV, 30.00 V, 23.00 V and 200 °C, respectively, and the quoted *m*/*z* values are for the major peak in the isotope distribution. ^{1}H NMR spectra were recorded on a Varian-500 spectrometer. All chemical shifts are relative to tetramethylsilane (TMS). UV/Vis spectra were recorded on a Shimadzu UV-3101PC or Agilent 8453 spectrophotometer. Emission spectra were recorded at room temperature on a Shimadzu RF-5000 luminescence spectrometer.

Viscosity measurements were carried out using an Ubbelodhe viscometer maintained at a constant temperature of 28.0 ± 0.1 °C in a thermostatted water bath. DNA samples of approximately 200 base pairs average length were prepared by sonication in order to minimize complexities arising from DNA flexibility.[21] Flow time was measured with a digital stopwatch. Each sample was measured three times and an average flow time was calculated. Data are presented as $(\eta/\eta^\circ)^{1/3}$ versus binding ratio,[22] where η is the viscosity of DNA in the presence of complex and η^0 is the viscosity of DNA alone.

Equilibrium dialyses were conducted at room temperature with 5 mL of CT-DNA (1.0 mM) sealed in a dialysis bag and 10 mL of the dinuclear rac complexes (10 μM) outside the bag. The solution containing the dialysis bag was stirred for 48 h.

Syntheses of Complexes

2,2′-Bis[amino(hydrazono)methyl]-4,4′-bipyridine (bahmb),[16] *cis*-$Ru(bpy)_2Cl_2$[23] were prepared as described previously.

2,2′-Bis(1,2,4-triazin-3-yl)-4,4′-bipyridine (btb): A mixture of bahmb (0.27 g, 1 mmol), 30% aqueous glyoxal (5 mL), and ethanol (20 mL) was refluxed with stirring for 2 h. After cooling to room temperature, the yellow precipitate was collected by filtration, washed with ethanol (3×5 cm^3), then dried at 50 °C in vacuo. Yield: 78%. $C_{16}H_{10}N_8$ (314.3): calcd. C 61.1, H 3.2, N 35.7; found C 59.8, H 2.9, N 36.2. FAB-MS: *m*/*z* = 315 ($C_{16}H_{10}N_8$ requires 314). ^{1}H NMR ([D$_6$]DMSO): 9.55 (d, *J* = 2.5 Hz, 2 H), 9.08 (d, *J* = 2.5 Hz, 2 H), 9.03 (dd, 2 H, *J* = 2.5, J_1 = 1, J_2 = 5.5 Hz), 8.90 (dd, J_1 = 0.5, J_2 = 1.5 Hz, 2 H), 8.19 (s, 2 H) ppm.

2,2′-Bis(1,2,4-triazino[5,6-*f*]acenaphthylen-3-yl)-4,4′-bipyridine (btapb): A mixture of bahmb (0.27 g, 1 mmol), acenaphthenequinone (0.346 g, 1.9 mmol) and ethanol (40 mL) was refluxed with stirring for 4 h. The resulting yellow precipitate was collected by filtration while hot, washed with ethanol (3×5 mL), then dried at 50 °C in vacuo. Yield: 72%. $C_{36}H_{18}N_8$ (562.6): calcd. C 76.9, H 3.2, N 19.9; found C 77.3, H 3.6, N 20.2. FAB-MS: *m*/*z* = 564 ($C_{36}H_{18}N_8$ requires 563). ^{1}H NMR ($CDCl_3$): 9.29 (d, *J* = 7.5 Hz, 2 H), 9.17 (d, *J* = 5 Hz, 2 H), 8.65 (dd, 2 H, J_1 = 5.5, J_2 =12 Hz), 8.31 (d, *J* = 8.5 Hz, 2 H), 8.24 (d, *J* = 8 Hz, 2 H), 8.18 (d, 2 H, J_1 = 2.5, J_2 = 9 Hz), 8.04 (d, *J* = 8 Hz, 2 H), 7.82 (t, *J* = 8 Hz, 2 H), 7.70 (t, *J* = 8 Hz, 2 H) ppm.

2,2′-Bis(5,6-diphenyl-1,2,4-triazin-3-yl)-4,4′-bipyridine (bdptb): A mixture of bahmb (0.27 g, 1.0 mmol), benzil (0.4 g, 1.9 mmol), and ethanol (40 cm^3) was refluxed with stirring for 4 h. The resulting yellow precipitate was collected by filtration while hot, washed with ethanol (3×5 mL), then dried at 50 °C in vacuo. Yield: 75%. $C_{40}H_{26}N_8$ (618.7): calcd. C 77.6, H 4.2, N 18.1; found C 78.0, H 3.9, N 18.2. FAB-MS: *m*/*z* = 619 ($C_{40}H_{26}N_8$ requires 618). ^{1}H NMR ($CDCl_3$): 9.13 (d, *J* = 2.5 Hz, 2 H), 9.11 (d, 2 H, *J* = 5 Hz), 7.9 (dd, 2 H, J_1 = 2, J_2 =5 Hz), 7.72 (dd, 4 H, J_1 = 1, J_2 = 8.5 Hz), 7.66 (dd, 4 H, J_1 = 1, J_2 = 8 Hz), 7.47 (t, *J* = 8 Hz, 4 H), 7.41 (t, *J* = 8 Hz, 4 H), 7.39 (t, *J* = 7 Hz, 4 H) ppm.

$[Ru(bpy)_2(btb)Ru(bpy)_2](ClO_4)_4$ (1): *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$ (1 mmol, 0.432 g), btb (0.5 mmol, 0.157 g) and ethylene glycol (20 cm^3) were refluxed under argon for 6 h. The solution was cooled to room temperature, and H_2O (50 cm^3) was added. After filtration, a dark red precipitate was obtained by dropwise addition of aqueous $NaClO_4$ solution. The product was purified by column chromatography on alumina using acetonitrile/ethanol, 2:1 (v/v) as eluent and then dried in vacuo. Yield: 66%. $C_{56}H_{42}N_{16}Cl_4O_{16}Ru_2\cdot 2H_2O$ (1570.0): calcd. C 42.7, H 2.9, N 14.2%; found C 42.3, H 3.3, N 14.1%. ES-MS [CH_3OH, *m*/*z*]: 670.6 $[M - 2ClO_4]^{2+}$, 413.4 $[M - 3ClO_4]^{3+}$, 285.6 $[M - 4ClO_4]^{4+}$. ^{1}H NMR ([D$_6$]DMSO): δ = 9.33 (d, *J* = 6 Hz, 2 H), 9.18 (s, *J* = 6 Hz, 2 H), 9.16 (d, *J* = 6 Hz, 2 H), 8.91 (d, *J* = 10.5 Hz, 2 H), 8.88 (d, *J* = 7.5 Hz, 2 H), 8.85 (d, *J* = 12.5 Hz, 2 H), 8.81 (d, *J* = 8 Hz, 2 H), 8.27 (t, *J* = 8 Hz, 2 H), 8.24−8.19 (m, 6 H), 8.17 (d, *J* = 4 Hz, 2 H), 8.12 (d, *J* = 8 Hz, 4 H), 7.85 (d, *J* = 8 Hz, 4 H), 7.64 (t, *J* = 1 Hz, 4 H), 7.35 (dd, 4 H, J_1 = 7.5, J_2 =12 Hz) ppm.

$[Ru(bpy)_2(btapb)Ru(bpy)_2](ClO_4)_4$ (2): This complex (dark red) was synthesized in a similar manner to that described for complex **1**, with btapb (0.5 mmol, 0.286 g) in place of btb. Yield: 65%. $C_{76}H_{50}Cl_4N_{16}O_{16}Ru_2\cdot 3H_2O$ (840.0): calcd. C 49.6, H 3.1, N 12.2; found C 50.0, H 2.9, N 12.4. ES-MS [CH_3OH, *m*/*z*]: 793.4 $[M - 2ClO_4]^{2+}$, 496.5 $[M - 3ClO_4]^{3+}$, 347.7 $[M - 4ClO_4]^{4+}$. ^{1}H NMR ([D$_6$]DMSO): δ = 9.31 (s, 2 H), 8.98 (d, *J* = 8.5 Hz, 2 H), 8.93 (d, *J* = 8.5 Hz, 2 H), 8.87 (d, *J* = 7.5 Hz, 2 H), 8.83 (d, *J* = 8.5 Hz, 2 H), 8.75 (d, *J* = 7 Hz, 2 H), 8.59 (d, *J* = 8.5 Hz, 2 H), 8.52 (d, *J* = 8.5 Hz, 2 H), 8.33−8.27 (m, 8 H), 8.19 (dd, 6 H, J_1 = 7.5, J_2 = 19.5 Hz), 8.14 (t, *J* = 8 Hz, 2 H), 8.00 (dd, 4 H, J_1 = 6.5, J_2 =14 Hz), 7.94 (t, *J* = 5 Hz, 4 H), 7.82 (d, *J* = 5 Hz, 2 H), 7.70 (t, *J* = 7 Hz, 2 H), 7.64 (t, *J* = 7 Hz, 2 H), 7.56 (dd, 2 H, *J* = 7 Hz), 7.46 (dd, 2 H, J_1 = 6, J_2 = 11.5 Hz) ppm.

$[Ru(bpy)_2(bdptb)Ru(bpy)_2](ClO_4)_4$ (3): This complex (dark red) was synthesized in a similar manner to that described for complex **1**, with bdptb (0.5 mmol, 0.307 g) in place of btb. Yield: 68%. $C_{80}H_{58}Cl_4N_{16}O_{16}Ru_2\cdot H_2O$ (1856.1): calcd. C 51.6, H 3.3, N 12.0%; found C 51.8, H 3.6, N 12.3%. ES-MS [CH_3OH, *m*/*z*]: 821.6 $[M - 2ClO_4]^{2+}$, 516 $[M - 3ClO_4]^{3+}$, 361.7 $[M - 4ClO_4]^{4+}$. ^{1}H NMR ([D$_6$]DMSO): δ = 9.17 (s, *J* = 2 Hz, 2 H), 8.93 (d, *J* = 8 Hz, 2 H), 8.88 (d, *J* = 8 Hz, 2 H), 8.78 (t, *J* = 8 Hz, 4 H), 8.29 (dd, 6 H, J_1 = 7.5, J_2 = 9 Hz), 8.14 (dd, 2 H, J_1 = 1, J_2 = 5.5 Hz), 7.94 (t, *J* = 9 Hz, 2 H), 7.88 (d, *J* = 5.5 Hz, 2 H), 7.75 (t, *J* = 5.5 Hz, 6 H), 7.67 (t, *J* = 5.5 Hz, 2 H), 7.60−7.52 (m, 8 H), 7.48−7.40 (m, 6 H), 7.11 (d, *J* = 7.5 Hz, 4 H) ppm.

Bis[di-*n*-alkyl(fluoro)stannyl]methanes, $(R_2FSn)_2CH_2$ (R = *n*-octyl, *n*-dodecyl): Stable Fluoride-Selective Carriers

Nikolas Chaniotakis,*[a] Klaus Jurkschat,*[b] Dirk Müller,[c] Katerina Perdikaki,[a] and Gregor Reeske[b]

Keywords: Tin / Fluorine / Anion carrier / NMR spectroscopy

The synthesis of bis[di-*n*-alkyl(fluoro)stannyl]methanes, $[(R_2)FSn]_2CH_2$, (**3**, R = *n*-octyl; **4**, R = *n*-dodecyl), is reported and their unprecedented dimeric structure in solution with pentacoordinate tin atoms is rationalized on the basis of ^{19}F and ^{119}Sn NMR spectroscopy, osmometric molecular mass determination and electrospray mass spectrometry (ESMS). ^{19}F and ^{119}Sn MAS NMR and Mössbauer spectroscopy also indicate pentacoordinate tin atoms for the solid state. The ability of compounds **3** and **4** to bind fluoride ion selectively and reversibly is evaluated through potentiometric measurements. Compared with the previously reported organotin(IV)-based fluoride ionophore $[Cl(Ph_2)Sn]_2CH_2$, **3** and **4** exhibit a drastically improved lifetime, while retaining their high preference for fluoride over all other lipophilic anions evaluated. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Various recent publications deal with the anion recognition properties of organotin compounds. As shown, mainly by variable-temperature NMR spectroscopy and single-crystal X-ray diffraction analysis, open-chain as well as cyclic bis(haloorganostannyl)alkanes function as bicentric Lewis acids towards Lewis bases such as fluoride and chloride ions[1−7]. The methylene-, dimethylene- and *o*-phenylene-bridged ditin derivatives $[Ph_2(X)Sn]_2CH_2$,[3] $Ph_2XSnCH_2CH_2SnXPh_2$,[4] and *o*-$C_6H_4(SnXMe_2)_2$ [1] (X = F, Cl), respectively, preferably chelate fluoride over chloride ions. Moreover, bis[chloro(diphenyl)stannyl]methane, $[Cl(Ph_2)Sn]_2CH_2$, and bis[dichloro(phenyl)stannyl]methane, $[Cl_2(Ph)Sn]_2CH_2$, when incorporated into polymeric-membrane ion-selective electrodes, are highly selective carriers for fluoride[8] and phosphate ions,[9] respectively. When these carriers are used to develop chemical sensors, the observed signal is unstable over prolonged periods, while repeated use influences both the sensitivity (the slope of the calibration curve expressed in mV per −log[anion] units) and detection limit of the sensor. This signal drift could be due to carrier decomposition, ligand exchange, or poisoning due to the very strong binding to the primary ion[10]. Such signal drift is the only obstacle to the application and commercialization of these ionophores in chemical sensors. The origin of the carrier instability in the sensor membrane is not completely understood, but is postulated to be hydrolysis for $[Cl_2(Ph)Sn]_2CH_2$. Furthermore, with both $[Cl_2(Ph)Sn]_2CH_2$ and $[Cl(Ph_2)Sn]_2CH_2$, chloride exchange with other anions present in the solution to be analyzed could occur. Additionally, the stability problem might originate from anion-induced organic group migration[11] and also from too low a lipophilicity of the carriers. Low carrier lipophilicity facilitates leaching from the organic phase, drastically influencing membrane characteristics.[12] We present here the synthesis and structure of bis[di-*n*-alkyl(fluoro)stannyl]methanes $[F(R_2)Sn]_2CH_2$ (**3**, R = *n*-octyl; **4**, R = *n*-dodecyl)) designed to overcome the above-mentioned problems. Their higher lipophilicity, in combination with an improved membrane composition, gives an optimal fluoride-selective electrode.

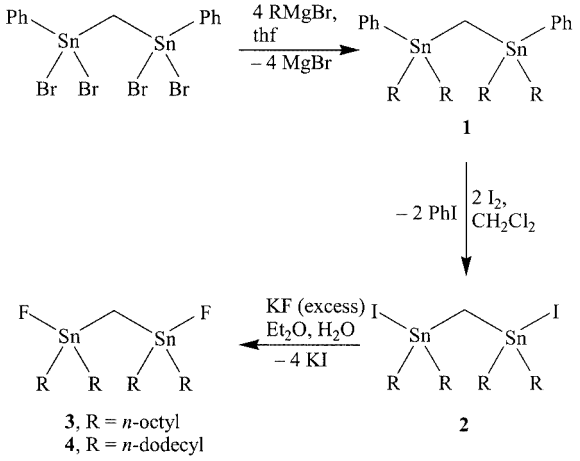
Results and Discussion

Synthesis of the Title Compound and Its Structure in Solution and in the Solid State

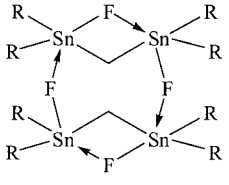
Bis[dibromo(phenyl)stannyl]methane, $[Br_2(Ph)Sn]_2CH_2$,[13] and four equivalents of *n*-octylMgBr react to give bis[di-*n*-

octyl(phenyl)stannyl]methane, [*n*-octyl$_2$(Ph)Sn]$_2$CH$_2$ (**1**) which was subsequently treated with iodine to provide bis-[iodo(di-*n*-octyl)stannyl]methane, [I(*n*-octyl)$_2$Sn]$_2$CH$_2$ (**2**). Reaction of the latter with excess of potassium fluoride then gave bis[fluoro(di-*n*-octyl)stannyl]methane, [F(*n*-octyl)$_2$Sn]$_2$-CH$_2$ (**3**) (Scheme 1). Bis[di-*n*-dodecyl(fluoro)stannyl]-methane, [(*n*-dodecyl)$_2$FSn]$_2$CH$_2$, (**4**), was prepared analogously.



Scheme 1. Synthesis of bis[fluoro(di-*n*-octyl)stannyl]methane (**3**) and bis[di-*n*-dodecyl(fluoro)stannyl]methane (**4**)

Compounds **3** and **4** were obtained as colorless amorphous materials that are sparingly soluble in common organic solvents such as CH_2Cl_2 and $CHCl_3$. The ^{119}Sn NMR spectrum at ambient temperature ($CH_2Cl_2/D_2O_{capillary}$) of compound **3** reveals a doublet of doublet of doublets at δ = 38.8 ppm [$^1J(^{119}Sn-^{19}F)$ 690, 1468, $^3J(^{119}Sn-^{19}F)$ 107 Hz]. The essentially concentration-independent ^{19}F NMR spectrum ($CDCl_3$) shows two triplet resonances of equal integral ratio at −112.9 ppm [$^1J(^{19}F-^{119/117}Sn)$ = 683, $^2J(^{19}F-^{19}F)$ = 71 Hz] and −157.2 ppm [$^1J(^{19}F-^{119/117}Sn)$ = 1474, $^2J(^{19}F-^{19}F)$ = 69 Hz]. The satellite-to-signal-to-satellite integral ratio (15:70:15) for both resonances indicates that each fluorine atom couples with two ^{117}Sn and two ^{119}Sn nuclei. Based on these spectroscopic data and osmometric molecular weight determinations in chloroform (1336 g/mol) and *n*-hexane (1493 g/mol) compound **3** probably adopts the dimeric structure (A) (Figure 1) in solution. This is supported by the electrospray mass spectrometric studies reported below.

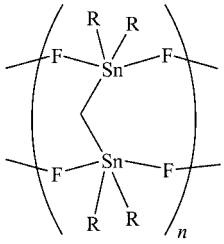


(A)
R = *n*-octyl, *n*-dodecyl

Figure 1. Dimeric structure of **3** in solution

The ^{19}F and ^{119}Sn NMR spectra of compound **4** are similar (see Exp. Sect.).

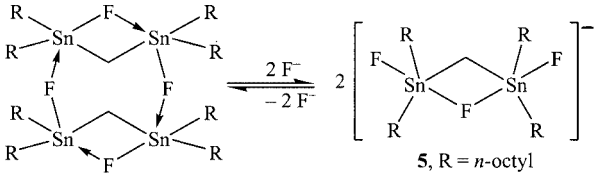
The ^{119}Sn MAS NMR spectrum of **3** is dominated by anisotropy of chemical shift interaction. The isotropic peak shows a triplet at δ = 2.4 ppm [$\nu_{1/2}$ 325, $J(^{119}Sn-^{19}F)$ = 1270 Hz]. From the intensities of the corresponding triplet-shaped spinning side bands the main components of the shielding tensor were estimated to be δ = 261.9, −113.0 and −141.7 ppm, respectively. The solid-state ^{19}F NMR spectrum recorded at a spinning rate of 30 kHz exhibits a singlet at δ = −142.1 ppm ($\nu_{1/2}$ 150 Hz) with unresolved $J(^{19}F-^{117/119}Sn)$ satellites of 1272 Hz (satellite-to-signal-to-satellite ratio 12.6:74:13.4). These spectroscopic data are reasonably consistent with the polymeric structure (B) shown in Figure 2, with, at least on the ^{19}F and ^{119}Sn time scales, symmetric Sn−F−Sn bridges. This view is further supported by the Mössbauer spectrum (I.S. 1.34 mm/s, Q.S. 3.69 mm/s), which unambiguously indicates pentacoordinate tin atoms. Similar spectroscopic data have been reported for dimethylphenyltin fluoride[14]



(B)
R = *n*-octyl, *n*-dodecyl

Figure 2. Polymeric structure of **3** in the solid state

The ^{119}Sn NMR spectrum of **3** at room temperature in CD_2Cl_2 solution to which had been added one molar equivalent of $Bu_4NF{\cdot}2H_2O$ shows a complex resonance (four lines with different half widths) centered at δ = −38 ppm, which upon cooling to −80°C turns into a doublet of doublet of doublets at δ = −32 ppm [$^1J(^{119}Sn-^{19}F)$ 648, 1946, $^3J(^{119}Sn-^{19}F)$ 121 Hz]. These findings are consistent with the formation of the organostannate complex **5** [Equation (1)].



(1)

The ^{119}Sn NMR spectrum was unchanged upon addition of a second molar equivalent of $Bu_4NF{\cdot}2H_2O$. Compound **4** behaves analogously upon addition of one molar equivalent of $Bu_4NF{\cdot}2H_2O$ [δ (^{119}Sn) = −40 ppm at room temperature in CD_2Cl_2 solution, complex pattern with four lines].

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Chloride ions can break the fluoride bridges in the A-type dimer. Thus, the ^{119}Sn NMR spectrum of **3** at room temperature in CD_2Cl_2 solution to which had been added one molar equivalent Ph_4PCl shows a broad resonance at $\delta = -19$ ppm that upon cooling to -20 °C turns into a complex pattern centered at $\delta = -20$, which was not analyzed further.

The ESMS spectrum (negative mode) of a solution of **3** and Ph_4PCl in acetonitrile shows the following mass clusters with the expected isotopic patterns: {[F(*n*-octyl)$_2$Sn]$_2$CH$_2$·F}$^-$ (761.6), {[F(*n*-octyl)$_2$Sn]$_2$CH$_2$·Cl}$^-$ (777.5), {[Cl(*n*-octyl)$_2$Sn]$_2$CH$_2$·F}$^-$ (793.6), [{[F(*n*-octyl)$_2$Sn]$_2$CH$_2$}$_2$·F]$^-$ (1502.7), and [{[F(*n*-octyl)$_2$Sn]$_2$CH$_2$}$_2$·Cl]$^-$ (1520.3). The latter two support the dimeric structure (A) (Figure 1) of compound **3** in solution (see above).

Potentiometric Studies

Bis[fluoro(di-*n*-octyl)stannyl]methane, [F(*n*-octyl)$_2$Sn]$_2$CH$_2$, (**3**), and bis[di-*n*-dodecyl(fluoro)stannyl]methane, [(*n*-dodecyl)$_2$FSn]$_2$CH$_2$, (**4**), were used to develop a solvent polymeric membrane electrode that was examined for its selectivity and sensitivity (slope) to fluoride. The results are compared with previously obtained potentiometric data based on bis[chloro(diphenyl)stannyl]methane, [Cl(Ph$_2$)Sn]$_2$CH$_2$.[8] Compounds **3** and **4** are more lipophilic than [Cl(Ph$_2$)Sn]$_2$CH$_2$ and do not favor halide exchange. Therefore, they are expected not only to preserve the excellent fluoride selectivity obtained with the [Cl(Ph$_2$)Sn]$_2$CH$_2$-based system, but also to exhibit a considerably longer lifetime within the organic membrane layer.

Potentiometric Response

The potentiometric response of a liquid polymeric membrane doped with an ion carrier provides direct evidence of the interaction of the carrier with the ions in solution. Based on these data, one can determine the selectivity, the binding constant in the organic phase, the reversibility and the stability of the ionophore−anion complex. Thus, the overall potentiometric response (ΔE), the calibration curve, and the base line return and stability of the electrodes based on carriers **3** and **4**, were monitored and analyzed. Figure 3 shows the potential changes observed and the resulting calibration curve of the ion-selective electrodes (ISEs).

Figure 3 shows that the two sensors have different analytical characteristics. The slope of the calibration curves for the ISEs based on carriers **3** and **4** are -87.8 and -68.2 mV/$-$log[F$^-$], respectively. Carrier **3** with the octyl substituents shows a higher sensitivity to fluoride anion, indicating that the organic substituents R have little influence on the coordination of the carrier to fluoride. The slope to fluoride of both carriers is higher than can be explained by the Nernst theory, according to which the sensitivity for monovalent anions such as fluoride is -59.16 mV/$-$log[anion]. The high sensitivity of organometallic carriers to anions observed previously [15−17] is suggested to be connected with a less than one-to-one complex formed between the carrier and the primary ion in the polymeric membrane phase of the sensor.[18,19] This stoichiometry was not observed in the NMR titrations performed in CD_2Cl_2.

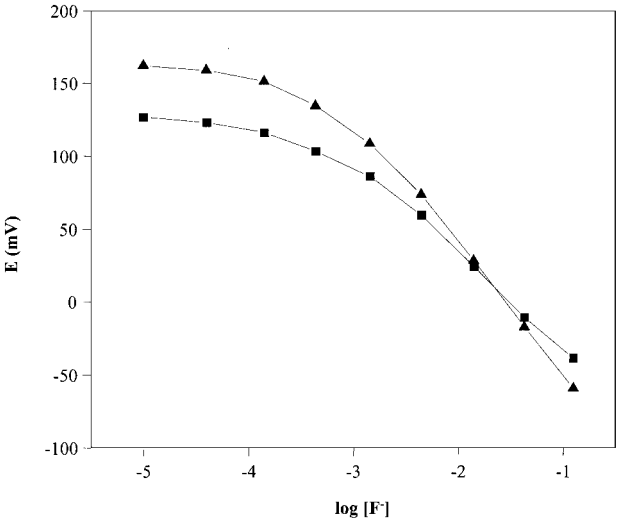


Figure 3. Calibration curves of the ISEs based on compounds **3** (solid triangle) and **4** (solid square) in aqueous solutions buffered with MES to pH 5.5

Ionophore Stability Studies: A very important characteristic of an ionophore is its stability (chemical and structural) over time under operational conditions, which can be very well studied using potentiometry. The interfacial potential generated due to the ability of the carrier to complex the ion under investigation is directly related to the state of the ionophore. Any signal drift, loss in sensitivity or selectivity is thus a measure of the ionophore's instability. Therefore, the sensitivity of ISEs based on carriers **3** and **4** was monitored for a period of 40 days. Figure 4 shows that the sensitivity of the membrane to fluoride remained practically unchanged for over 20 days of continuous use, the slope remaining above 50 mV/$-$log[F$^-$].

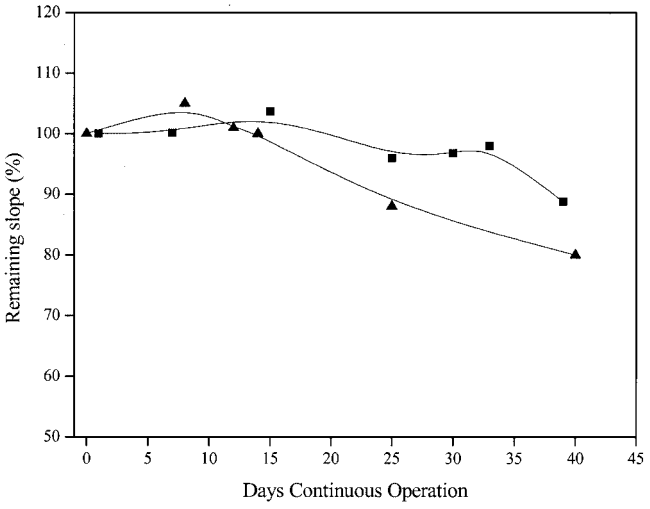

Figure 4. Stability of the ISE1 and ISE2 sensors, based on carriers **3** (solid triangle) and **4** (solid square), respectively, according to the sensitivity of the sensor over time under continuous monitoring in MES (buffered to pH 5.5)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The effect is even more obvious when the more lipophilic dodecyl-substituted carrier (carrier **4**) is used. This is a large improvement when compared with the previously reported carrier [$(ClPh_2Sn)_2CH_2$] which showed a lifetime of not longer than 4 days.

Ionophore Selectivity: The selectivity of the ionophore was studied using the overall potentiometric response of the membrane between a solution of plain buffer, and that containing 0.01 M of the salt under study. Figure 5 shows the overall potentiometric response (in ΔE) of sensors based on carriers **3** and **4**. Based on these data, the logarithms of the potentiometric selectivity coefficients log $K^{pot}_{F,J}$ were determined according to the Nikolskii−Eisenman equation (Equation 2) (Table 1 and 2).

$$E_M = E^0 + \frac{RT}{zF}\ln(a_i + K_{ij}^{pot} a_j^{\frac{zi}{zj}}) \quad (2)$$

E_M is the membrane potential in mV, a_i the activity (concentration) of the primary ion, a_j the activity of the interfering ion and z_i and z_j the charge of the primary and interfering ions, respectively. Negative potentiometric selectivity coefficients $K^{pot}_{F,J}$ indicate that the ISE is more selective to the primary ion (fluoride in this study), whereas positive values indicate that the ISE is more selective to the interfering ion. The selectivity order based on the overall potentiometric response in a MES-buffered solution at pH 5.5 for both ISEs is similar, $F^- \approx SCN^- > I^- > ClO_4^- > Cl^- > NO_3$. For comparison, the classical Hofmeister selectivity order for a quaternary ammonium ion-based sensor is $ClO_4^- > SCN^- > I^- > NO_3^- > Cl^- > F^-$.

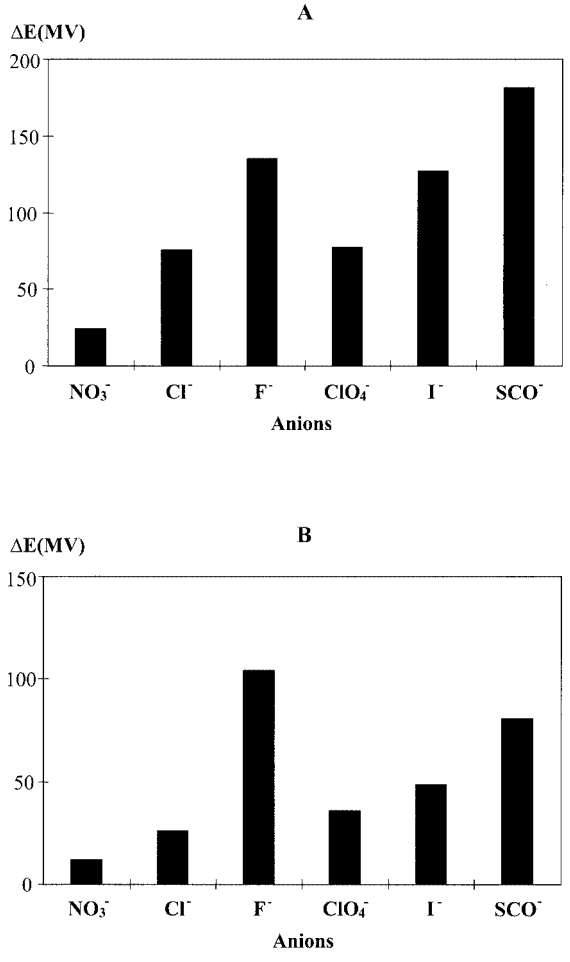

Figure 5. Overall potentiometric response of the ISEs based on carriers **3** (**A**) and **4** (**B**) towards several anions at pH 5.5 (MES, 0.001 M)

Table 1. Potentiometric selectivity coefficients $K^{pot}_{F,J}$ of the ISE based on carrier **3**.

Anion	log K^{pot}
NO_3^-	−1.9
Cl^-	−1.0
F^-	0.0
ClO_4^-	−1
I^-	−0.1
SCN^-	0.8

Table 2. Potentiometric selectivity coefficients $K^{pot}_{F,J}$ of the ISE based on carrier **4**

Anion	log K^{pot}
NO_3^-	−1.6
Cl^-	−1.3
F^-	0.0
ClO_4^-	−1.2
I^-	−0.9
SCN^-	−0.4

Evidently, from the overall potentiometric response and the calculated selectivity coefficients, the fluoride ion is preferred over several other more lipophilic ions, such as perchlorate, nitrate, and iodide. The anti-Hofmeister selectivity sequence obtained for **3** and **4** is closely related to that obtained for the less stable ionophore $[Cl(Ph_2)Sn]_2CH_2$.[8]

These results clearly show that, even though the sensor based on ionophore **3** has a good sensitivity and selectivity for fluoride, an improved sensor in terms of selectivity and stability over time is produced when the membrane is doped with ionophore **4**.

Conclusion

The stability of previously evaluated highly selective fluoride carriers can be drastically improved by the use of lipophilic organic substituents. The closely related carriers $(FR_2Sn)_2CH_2$ (**3**, R = *n*-octyl; **4**, R = *n*-dodecyl) and the previously reported $[Cl(Ph_2)Sn]_2CH_2$ are compared for their fluoride selectivity and their ability to develop stable fluoride-selective electrodes. Based on spectroscopic studies, in organic phases these carriers form a reversible one-to-one complex with fluoride anions. Furthermore, the stability of the sensors depends on the lipophilicity of the carrier, which in turn can be controlled by the organic substituents attached to the tin atoms. However, the selectivity is not influ-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

enced drastically, allowing the development of a robust and highly selective liquid polymeric fluoride-selective electrode. This result will be useful in improving the stability and lifetime of other ionophores that are highly selective for anions such as phosphate and chloride.

Experimental Section

General Remarks: All manipulations were performed under nitrogen using standard Schlenk and vacuum line techniques. Solvents were distilled from the appropriate desiccants prior to use. Literature procedures were used to prepare bis[dibromo(phenyl)stannyl]-methane, $[Br_2(Ph)Sn]_2CH_2$.[13] NMR spectra were recorded in $CDCl_3$ using a spectrometer at 500.13 (^{1}H), 100.63 (^{13}C) 182.36 (^{19}F), 111.92 and 149.21 (^{119}Sn) MHz. Chemical shifts (δ ppm) were referenced to Me_4Sn (^{119}Sn), $CFCl_3$ (^{19}F) and Me_4Si (^{13}C, ^{1}H). ^{119}Sn MAS NMR spectra were recorded with a Varian Unityplus 500 spectrometer at 186.40 MHz using a Doty supersonic CP/MAS probe (rotor diameter 5 mm) with a 10 kHz spinning rate. The corresponding ^{19}F MAS NMR spectra were recorded with a Bruker Avance 400 spectrometer at 376.52 MHz using rotors of 2.5 mm diameter with spinning rates of up to 32 kHz. Elemental analyses were performed with an instrument from Carlo Erba Instrumentation (model 1106). Molecular weight determinations were carried out with a Knauer Dampfdruck-Osmometer K-7000. The calibration standard was Polystyrene 2000 (Fluka) with *n*-hexane and chloroform as solvents.

Electrochemical Studies: Instrumentation: Potentiometric measurements were performed with a XENON CI-317 8-channel electrometer (Halandri, Athens, Greece) versus an Orion Research (Beverly, MA, USA) 900200 double junction reference electrode. Data were collected with a personal computer program written in BASIC for storage and further analysis.

Reagents: High purity potassium salts (p.a. Fluka, p.a. Merck) were used for the preparation of electrolyte solutions. 2-Morpholinoethanesulfonic acid (MES) (Merck) was used as the pH buffer. The membranes were constructed from poly(vinyl chloride) (PVC) (high molecular weight, Selectophore, Fluka), as membrane matrix, bis(2-ethylhexyl) sebacate (DOS) (Selectophore, Fluka) as plasticizer, and tetrahydrofuran (THF) (p.a. Merck), doubly distilled before use, as membrane solvent.

Membrane preparation: All the membranes examined had the following composition: 2% carrier, 33% PVC and 65% DOS. The mixture of components (100 mg) was dissolved in THF (ca. 1.5 mL), and the resultant solution was poured into a glass ring (i.d. 17 mm), the latter being placed on a glass plate. Membranes were formed after solvent evaporation. Circular pieces (diameter 7 mm) of the membranes were cut off and mounted for testing on type IS 561 Phillips electrode bodies (from Willi Möller AG, Glasbläserei, Zürich, Switzerland). The internal solution of the electrode was 0.01 M KCl.

Selectivity measurements and calibration curves: All electrodes were tested without prior pretreatment, except when specifically mentioned. All electrolyte solutions were 10^{-2}, and buffered with MES 10^{-3} M (pH = 5.5). The potential was monitored and the potential difference recorded when the readings were stable in either the calibrating or test solutions. The selectivity coefficients were determined by the separate solution method (SSM)[20], assuming that the electrode shows a theoretical slope of −59.16 mV for monovalent anions.

Synthesis of Bis[di-*n*-octyl(phenyl)stannyl]methane, $[(n\text{-octyl})_2(Ph)Sn]_2CH_2$ (1): A solution of *n*-octylmagnesium bromide prepared from *n*-octyl bromide (5.01 g, 25.9 mmol) and magnesium (0.63 g, 25.9 mmol) in THF (50 mL) was added to a solution of bis[dibromo(phenyl)stannyl]methane[13] (4.70 g, 6.48 mmol) in THF (150 mL). After stirring at room temperature (4 h) the resulting mixture was hydrolyzed with water (50 mL). The organic layer was then separated, dried with Na_2SO_4 and filtered. Evaporation of the solvent gave 3.9 g (70% yield) of bis[di-*n*-octyl(phenyl)-stannyl]methane (**1**) as a colorless oil. ^{1}H NMR (500.13 MHz, $CDCl_3$, 300 K): δ = 0.12 [s, $^2J(^1H\text{-}^{119}Sn)$ = 57.4 Hz, 2 H, Sn−CH_2−Sn], 0.92 [t, $^2J(^1H\text{-}^1H)$ = 7 Hz, 12 H, −CH_3], 0.99−1.63 [m, *J* = 56 Hz, −CH_2−], 7.26−7.55 [m, 10 H, Sn−Ph] ppm. $^{13}C\{^1H\}$ NMR (125.77 MHz, $CDCl_3$ 300 K): δ = −19.5 [$^1J(^{13}C\text{-}^{117}Sn)$ = 226.9, $^1J(^{13}C\text{-}^{119}Sn)$ = 236.7 Hz, Sn−CH_2−Sn], 11.67 [$^1J(^{13}C\text{-}^{117}Sn)$ = 337.2, $^1J(^{13}C\text{-}^{119}Sn)$ = 253.3 Hz, C-1], 14.12 (C-8), 22.71 (C-7), 26.82 [$^2J(^{13}C\text{-}^{117/119}Sn)$ = 20.1 Hz, C-2], 29.18−29.73 (C-4, C-5), 31.96 (C-6), 34.44 [$^3J(^{13}C\text{-}^{117/119}Sn)$ = 59.4 Hz, C-3], 127.93 [$^3J(^{13}C\text{-}^{117/119}Sn)$ = 41.8 Hz, C_m], 12810 [C_p], 136.24 [$^2J(^{13}C\text{-}^{117/119}Sn)$ = 32.7 Hz, C_o], 142.92 [C_i] ppm. $^{119}Sn\{^1H\}$ NMR (149.21 MHz, $CDCl_3$): δ = −16.5 [$^2J^{117}Sn\text{-}^{119}Sn$) = 239 Hz] ppm. $C_{45}H_{80}Sn_2$ (858.5): calcd. C 63.0, H 9.4; found C 63.7, H 9.9.

Synthesis of Bis[iodo(di-*n*-octyl)stannyl]methane, $[I(n\text{-octyl})_2Sn]_2CH_2$ (2): Iodine (3.61 g, 10.22 mmol) was added in small portions under ice-cooling to a stirred solution of **1** (6.10 g, 7.11 mmol) in CH_2Cl_2 (50 mL). The reaction mixture was then stirred overnight, after which the solvent and the iodobenzene were removed in vacuo. Addition of CH_2Cl_2 (20 mL), filtration and evaporation of the solvent then afforded 6.4 g (94% yield) bis[iodo(di-*n*-octyl)-stannyl]methane **(2)** as a light yellow oil. ^{1}H NMR (500.13 MHz, $CDCl_3$, 300 K): δ = 0.87 [t, $^2J(^1H\text{-}^1H)$ = 7 Hz, 12 H, −CH_3], 1.19−1.65 (m, 56 H, −CH_2−] ppm. $^{13}C\{^1H\}$ NMR (125.77 MHz, $CDCl_3$ 300 K): δ = −3.01 [Sn−CH_2−Sn], 14.09 (C-8), 19.45 [$^1J(^{13}C\text{-}^{117}Sn)$ = 334.0, $^1J(^{13}C\text{-}^{119}Sn)$ = 349.3 Hz, C-1], 22.63 (C-7), 26.83 [$^2J(^{13}C\text{-}^{117/119}Sn)$ = 25.9 Hz, C-2], 28.90−29.18 [C-4−C-5], 31.84 (C-6), 33.44 [$^3J(^{13}C\text{-}^{117/119}Sn)$ = 70.1 Hz, C-3] ppm. $^{119}Sn\{^1H\}$ NMR (111.92 MHz, $CDCl_3$): δ = 87.3 ppm. $C_{33}H_{70}I_2Sn_2$ (958.14): calcd. C 41.4, H 7.4; found C 42.0, H 7.5.

Synthesis of Bis[fluoro(di-*n*-octyl)stannyl]methane, $[F(n\text{-octyl})_2Sn]_2CH_2$ (3): A solution of bis[iodo(di-*n*-octyl)stannyl]methane (5 g, 5.23 mmol) in diethyl ether (50 mL) was poured into a solution of potassium fluoride (2.98 g, 52.2 mmol) in water (50 mL). The resultant mixture was stirred for 24 h, and then the organic layer was separated, washed with water (2 × 50 mL), filtered and dried with sodium sulfate. After removing the solvent, the remaining residue was washed with dichloromethane (20 mL), filtered and dried in vacuo to give 2.3 g (60%) of compound **3**. ^{1}H NMR (400.13 MHz, $CDCl_3$): δ = 0.87 [t, $^2J(^1H\text{-}^1H)$ = 7 Hz, 24 H, −CH_3], 1.05−1.65 [m, 14 H, −CH_2−] ppm. $^{13}C\{^1H\}$ NMR (100.62 MHz, $CDCl_3$): δ = 14.12 (C-8), 20.23 (t, C-1), 22.72 (C-7), 25.53 [$^2J(^{13}C\text{-}^{117/119}Sn)$ = 26.2 Hz, C-2], 29.32−29.44 (C-4, C-5), 31.99 (C-6), 34.14 [$^3J(^{13}C\text{-}^{117/119}Sn)$ = 80.7 Hz, C-3] ppm. $^{19}F\{^1H\}$ NMR (282.36 MHz, $CDCl_3$): δ = −115.1 [t, $^2J(^{19}F\text{-}^{19}F)$ = 71.2, $^1J(^{19}F\text{-}^{119}Sn)$ = 686.6 Hz], −159.3 [$^2J(^{19}F\text{-}^{19}F)$ = 68.9, $^1J(^{19}F\text{-}^{119}Sn)$ = 1472.0 Hz] ppm. $^{119}Sn\{^1H\}$ NMR (149.21 MHz, CH_2Cl_2, $D_2O_{capillary}$): δ = 38.1 [ddd, $^1J(^{19}F\text{-}^{119}Sn)$ = 1468, $^1J(^{19}F\text{-}^{119}Sn)$ =

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

690, $^3J(^{19}F\text{-}^{119}Sn)$ = 107 Hz] ppm. $C_{33}H_{70}F_2Sn_2$ (742.33): calcd. C 53.4, H 9.5; found C 53.2, H 9.6.

Synthesis of Bis[di-*n*-dodecyl(fluoro)stannyl]methane, [(*n*-dodecyl)$_2$FSn]$_2$CH$_2$ (4): Compound **4** was prepared by a procedure analogous to that for **3**. Thus, bis[dibromo(phenyl)stannyl]methane (9.4 g, 13.0 mmol) was reacted with the Grignard reagent made from 1-dodecyl bromide (1.34 g, 56.0 mmol) and magnesium turnings to give bis[di-*n*-dodecyl(phenyl)stannyl]methane (7.4 g, 53%) as a viscous oil ($^{119}Sn\{^1H\}$ NMR (111.92 MHz, $CDCl_3$): δ = −15.1), which was used for the subsequent reaction without further purification. Treatment of bis[di-*n*-dodecyl(phenyl)stannyl]methane (6.40 g, 5.9 mmol) with iodine (3.00 g, 11.8 mmol) gave bis[iodo(di-*n*-dodecyl)stannyl]methane (6.9 g, 93%) as a slightly yellow oil ($^{119}Sn\{^1H\}$ NMR (111.92 MHz, $CDCl_3$): δ = 85.8 ppm) that was used without further purification for the subsequent reaction.

A solution of bis[iodo(di-*n*-dodecyl)stannyl]methane (1.67, 1.4 mmol) in diethyl ether (30 mL) was added to a solution of potassium fluoride (0.82, 14.1 mmol) in water (20 mL). The mixture was then stirred for 24 h followed by the workup procedure described for compound **3** to give bis[di-*n*-dodecyl(fluoro)stannyl]methane (1.07 g, 79%) as a colorless amorphous solid. ^1H NMR (400.13 MHz, $CDCl_3$): δ = 0.86 [t, $^2J(^1H\text{-}^1H)$ = 6 Hz, 12 H, $-CH_3$], 1.05−1.65 [m, 84 H, $-CH_2-$] ppm. $^{13}C\{^1H\}$ NMR (100.62 MHz, $CDCl_3$): δ = 14.12 (C-12), 20.26 (t, C-1), 22.72 (C-11), 25.54 [$^2J(^{13}C\text{-}^{117/119}Sn)$ = 26.2 Hz, C-2], 29.36−29.45 (C-4−C-9), 31.97 (C-10), 34.15 [$^3J(^{13}C\text{-}^{117/119}Sn)$ = 80.2 Hz, C-3] ppm. $^{19}F\{^1H\}$ NMR (282.36 MHz, $CDCl_3$): δ = −115.0 [t, $^2J(^{19}F\text{-}^{19}F)$ = 68.8, $^1J(^{19}F\text{-}^{119}Sn)$ = 686.6 Hz], −159.3 [t, $^2J(^{19}F\text{-}^{19}F)$ = 66.6, $^1J(^{19}F\text{-}^{119}Sn)$ = 1479.1 Hz] ppm. $^{119}Sn\{^1H\}$ NMR (149.21 MHz, CH_2Cl_2, $D_2O_{capillary}$) δ = 38.2 [ddd, $^1J(^{19}F\text{-}^{119}Sn)$ = 1466, $^1J(^{19}F\text{-}^{119}Sn)$ = 688, $^3J(^{19}F\text{-}^{119}Sn)$ = 105 Hz]. $C_{49}H_{102}F_2Sn_2$ (965.9): calcd. C 59.9, H 10.5; found C 59.5, H 10.6.

Keywords: Iminophosphanes / X-ray diffraction / Photoelectron spectroscopy / Density functional calculations / Ionization potentials

$\sigma^2\lambda^3$-"Push-pull" iminophosphanes Ar_f–P=N–R, bearing an electron-acceptor substituent at phosphorus [Ar_f = 2,6-bis(trifluoromethyl)phenyl] and a donor group at nitrogen (R = *t*Bu, NMe_2), have been synthesized and characterized by NMR spectroscopy and X-ray analysis. Density functional calculations [B3LYP/6-311G(d,p)] have been carried out on different iminophosphanes: HP=NH (**1**), Ar_fP=NH (**2**), Ar_fP=$NSiMe_3$ (**3**), Ar_fP=N*t*Bu (**4**), HP=$NNMe_2$ (**5**) and Ar_fP=$NNMe_2$ (**6**) in order to determine the electronic effect of the Ar_f substituent and the influence of the donor group R on the stability of the monomeric species. A comparison of the theoretical results and UV photoelectron spectroscopy data for the iminophosphanes **4** and **6** is presented. Theoretical and experimental data suggest that for all iminophosphanes under investigation the π-system of the Ar_f group is almost orthogonal to the $\pi_{P=N}$ system, preventing any stabilizing interaction between the $\pi_{P=N}$ and the $\pi^*_{b1(aryl)}$ orbitals previously observed for the Ar_fPH^- anion. Here, the Ar_f substituent effect is mainly steric.

Introduction

$\sigma^2\lambda^3$-Iminophosphanes, XP=NR, have been the subject of enthusiastic study for the last two decades because they constitute a bridge between the classical chemistry of C-C unsaturated systems and unconventional pπ-bonded compounds of heavy main group elements.[1] Consequently, a plethora of structures have been reported and characterized, including several short-lived species.[2,3] In general, because of the inherent "electronegativity" of the P-N double bond, most of the known iminophosphanes feature π-donors (R_2N, RO, R_2P) or electron-rich alkyl/aryl substituents (*t*Bu, Mes, Mes*) at the dicoordinated phosphorus atom.[3–5] Compared with the rich chemistry of iminophosphanes having electron-donating substituents, little is known about iminophosphanes containing electron-accepting groups. Notable exceptions are the heteroatom-substituted iminophosphanes Cl–P=NMes* and TfO–P=NMes*. In these examples the X–P bond tends to become ionic due to the large difference in electronegativity between phosphorus, chlorine and oxygen. This large difference in electronegativity promotes the formation of a close ion-pair $[X]^-[PNMes^*]^+$.[6–9] Theoretical studies of iminophosphanes, using simple models, have demonstrated that replacement of the hydrogen atom at phosphorus in HP=NH by more electronegative substituents (π-acceptors) results in an appreciable strengthening of the double bond. At the same time the *Z*-configuration becomes more stable with respect to the *E*-configuration. Exactly opposite effects have been predicted for the influence of the corresponding substituents at nitrogen.[10,11] This concept is strongly operative in *P*-halo- and *P*-oxy-iminophosphanes, but its application to highly sterically crowded *P*-carbosubstituted species has evident limitations. We expected iminophosphanes bearing electron-acceptor carbon substituents at the phosphorus

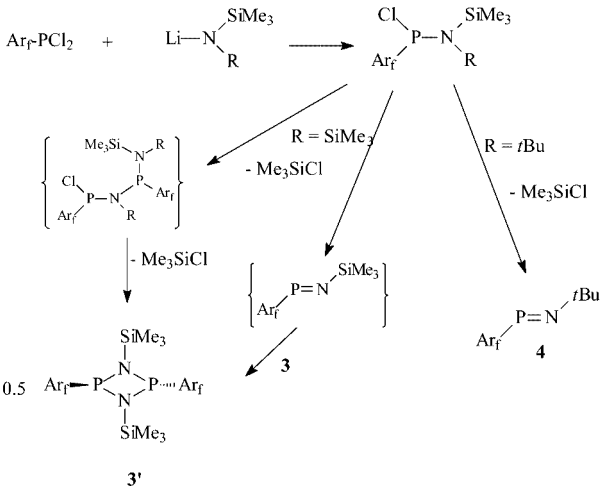
atom would be interesting, since the presence of an electron-acceptor substituent at the phosphorus atom should considerably increase the polarity of the P=N double bond. Moreover, the combination of substituents with acceptor and donor properties at the P=N bond ("push-pull" substitution) should lead to unusually stable XP=NR species.

Recently, molecular design utilizing the highly electronegative 2,6-bis(trifluoromethyl)phenyl group[12] allowed us to prepare the first phosphanide salt, $[K([15]\text{-crown-}5)_2]^+[Ar_fPH]^-$, featuring a "naked" dicoordinated phosphorus anion.[13] Our observations indicate that the planar structure is a privileged form of the anion, due to a strong interaction between the p^π phosphorus lone-pair and the $\pi^*_{b1(aryl)}$ orbital (localized on the C1 and C4 atoms of the aryl ring).Thus, the Ar_f group behaves like a π-electron acceptor and contributes considerably to the observed structure of the Ar_fPH^- anion. Along these lines, desiring to study the *P*-carbosubstituted iminophosphanes bearing electron-withdrawing substituents, we turned our attention to *P*-[2,6-bis(trifluoromethyl)phenyl-$\sigma^2\lambda^3$-iminophosphanes. Two different stabilizing interactions may be envisioned in these compounds because of energetically closely spaced π (P=N) and σ (combination of lone-pair at P and N) frontier orbitals: (i) n^+ (*trans*) or n^- (*cis*) → $\pi^*_{b1(aryl)}$ [π system of Ar_f orthogonal to the $\pi_{P=N}$ system, as observed for the carbene $(iPr_2N)_2PCAr_f$][14] or (ii) $\pi_{P=N} \rightarrow \pi^*_{b1(aryl)}$ (π system of Ar_f coplanar to $\pi_{P=N}$ system, as previously observed for Ar_fPH^-).[13] The latter type of stabilizing interaction is related to electronic effects previously observed for the Ar_fPH^- anion and would be especially pronounced in the case of "push-pull" substitution.

This paper deals with the preparation and characterization of a series of iminophosphanes Ar_f–P=NR. Along with our exploration into the synthesis of new and highly reactive PN multiple-bond systems, we performed a theoretical analysis of their structures to study the effect of the Ar_f group and the variation of the donor group R. The following iminophosphanes were studied theoretically: HP=NH (**1**), Ar_fP=NH (**2**), Ar_fP=$NSiMe_3$ (**3**), Ar_fP=N*t*Bu (**4**), HP=$NNMe_2$ (**5**) and Ar_fP=$NNMe_2$ (**6**). Full characterization of the iminophosphanes **4** and **6** included an investigation by NMR spectroscopy and X-ray analysis. A comparison of the results of our theoretical calculations [B3LYP/6-311G(d,p)] and UV/PE studies is also reported.

Results and Discussion

Iminophosphanes containing a CP=N skeleton are rare. These compounds are usually unstable due to their dimerization or oligomerization and can only be isolated in the presence of bulky substituents. Very effective in this sense is the 2,4,6-tri-*tert*-butylphenyl group (Mes*), which provides access to a series of stable R–P=NMes* compounds upon condensation of phosphorus chlorides $RPCl_2$ with the silylamide [LiN($SiMe_3$)Mes*] followed by a 1,2-elimination reaction.[15] Iminophosphanes Mes*P=NR are not accessible by this route since the reaction of the sterically crowded dichlorophosphane Mes*PCl_2 with silylamides [LiN($SiMe_3$)R] leads exclusively to the diphosphene Mes*P=PMes*.[3] We found that the interaction of Ar_fPCl_2 with silylamides [LiN($SiMe_3$)R] proceeds by the "normal" way, allowing the isolation of amino(chloro)phosphanes $Ar_fP(Cl)N(SiMe_3)R$. Thus, treatment of Ar_fPCl_2 with an equimolar quantity of [LiN($SiMe_3$)$_2$] in THF solution at −78 °C afforded the corresponding amino(chloro)phosphane in virtually quantitative yield (Scheme 1). However, elimination of Me_3SiCl from $Ar_fP(Cl)N(SiMe_3)_2$ occurs only at high temperatures (>180 °C) and leads to 1,3,2,4-diazadiphosphetidine **3′** instead of the expected monomeric iminophosphane **3**. The ^{19}F NMR spectrum of **3′** exhibits doublets at δ = 23.0 ppm ($^4J_{F,P}$ = 72.3 Hz) and δ = 27.4 ppm ($^4J_{F,P}$ = 134.7 Hz), corresponding to the resonances of two magnetically non-equivalent *ortho*-CF_3 groups on the Ar_f substituent. The ^{31}P resonance is observed as a multiplet at δ = 277.3 ppm.



Scheme 1

The molecular structure of **3′** is presented in Figure 1. The four-membered P_2N_2 cycle is planar, as observed in most other *trans*-1,3,2,4-diazadiphosphetidines.[16] The Ar_f rings form a twist angle of 39.3°. The geometry around the nitrogen atoms is trigonal planar. The average P–N bond length is about 1.722 Å and the PNP and NPN bond angles are 95.73° and 84.27°, respectively.

In contrast to *N*,*N*-disilyl analogues, thermolysis of $Ar_fP(Cl)N(SiMe_3)$*t*Bu (120 °C, 80 h) afforded the monomeric iminophosphane **4**. The latter was characterized by mass spectrometry and NMR spectroscopy. The ^{31}P NMR spectrum shows a septet at δ = 412.4 ppm ($^4J_{F,P}$ = 28 Hz), in a region characteristic of the CP=N backbone.[2] The X-ray crystal structure of **4** is shown in Figure 2. Molecules of **4** adopt a *trans* geometry and the P=N bond length of 1.537 Å is consistent with a bond order of two; it is 0.019 Å shorter than that in *trans* Mes*-P=N-*t*Bu.[17] The P–C bond length (1.866 Å) falls in the normal range for a single bond. The aromatic ring is in an orthogonal orientation to the CPN plane (the corresponding dihedral angle is 99.8°).

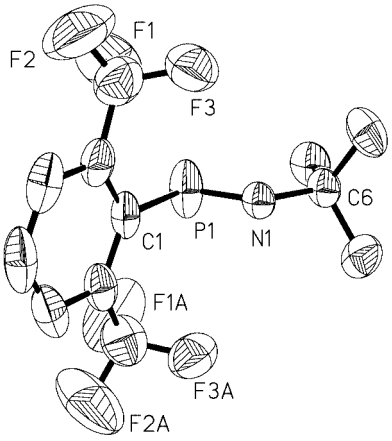

Figure 2. Crystal structure of $Ar_fP{=}NtBu$ (**4**); hydrogen atoms are omitted for clarity; selected bond lengths (Å) and bond angles (deg): P1−N1 1.537(3), P1−C1 1.866(4), N1−C6 1.489(4); C1−P1−N1 99.73(1), C6−N1−P1 123.82(0)

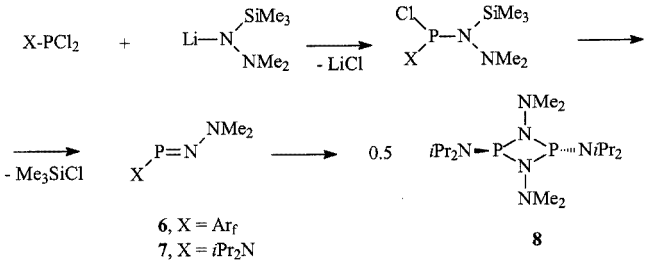
The C1P1N1 and C6N1P1 angles are 99.73° and 123.82°, respectively. In the related iminophosphane $R_fP{=}NR_f$ [R_f = 2,4,6-$(CF_3)_3C_6H_2$] the angle around the phosphorus is 99.81°, while the angle at nitrogen is more opened (130.22°).[18]

The strategy for the preparation of **4** was successfully extended to the synthesis of iminophosphanes **6** containing the π-donor NMe_2 group at the nitrogen atom (Scheme 2). Compared to $Ar_fP(Cl)-N(SiMe_3)R$ (R = Me_3Si, *t*Bu), the corresponding dimethylhydrazino derivative splits off Me_3SiCl under considerably milder conditions (0.05 Torr, < 100 °C). However, attempts to isolate **6** in pure form by vacuum distillation failed. In contrast to the quite thermally stable compound **4**, compound **6**, which is stable for extended periods of time in pure form and in solution, easily disproportionates on heating to form the diphosphene $Ar_fP{=}PAr_f$ (δ_P = 478 ppm).[19] This property is without precedent in iminophosphane chemistry and suggests that the P=N bond strength is dramatically reduced by "push-pull" substitution. Interestingly, the iminophosphane **7** (δ_P = 173.1 ppm), which can be obtained by a similar route starting from iPr_2NPCl_2 and $Me_2NN(SiMe_3)Li$, undergoes dimerization to form *trans*-$[iPr_2NPNNMe_2]_2$ (δ_P = 74.2 ppm) instead of disproportionation. We found, however, that chloroform as solvent promotes Me_3SiCl elimination reaction from $P(Cl)-N(SiMe_3)R$ moiety. Thus, when $Ar_fP(Cl)-N(SiMe_3)_2NMe_2$ was treated with anhydrous $CHCl_3$ (25 °C, 14 h), Me_3SiCl elimination with formation of **6** takes place quantitatively. In **6** the signal for the two-coordinate phosphorus atom is shifted drastically up field (δ_P = 224.3 ppm) in comparison to that of **4** (δ_P = 412.4 ppm).



Scheme 2

Bright-yellow crystals of **6** were grown from a saturated toluene solution. The molecular structure of the compound is shown in Figure 3. Essentially, the molecule adopts a *trans*-configuration and the aromatic ring system is almost orthogonal to the CPN system (the corresponding dihedral angle is 110°). The planar-coordinated N atoms of the hy-

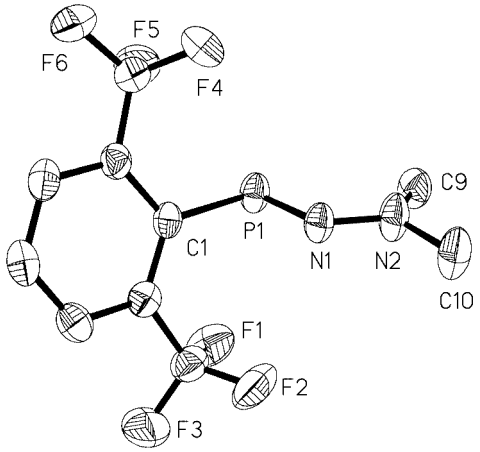


Figure 3. Crystal structure of $Ar_fP{=}NNMe_2$ (**6**); hydrogen atoms are omitted for clarity; selected bond lengths (Å) and bond angles (deg): P1−N1 1.629(1), P1−C1 1.863(5), N1−N2 1.319(2); C1−P1−N1 95.31(7), P1−N1−N2 121.13 (1)

drazine moiety and the P atom of the double-bond system are located in one plane (three-center, four π-electron system). The P−N bond in **6** is the longest (1.629 Å) ever found for iminophosphanes.[20,21] The opposite effect is observed for the N−N single bond (1.319 Å). Thus, the tendency of the iminophosphane **6** to disproportionate at high temperatures can be inferred from the remarkably long P−N bond, which is evident in the X-ray structure analysis of the molecule.

Theoretical and PE Spectroscopic Studies

HP=NH (1), Ar_fP=NH (2) and Ar_fP=NSiMe_3 (3)

In order to estimate the effect of the Ar_f substituent on the CP=N part we compared the HP=NH (**1**) and Ar_fP=NH (**2**) model molecules. The geometrical parameters of these species are summarized in Table 1. Two minima were found on the potential-energy surface corresponding to the *cis* and *trans* isomers. For **2**, the π-system of the aryl substituent in both isomers is almost orthogonal to the $\pi_{P=N}$ system (the dihedral angles for *cis* and *trans* structures are 116.6° and 115.6° respectively). The P−N bond lengths in *cis*- and *trans*-**2** are slightly shorter than those in **1**. The *cis*-**2** isomer is more stable than *trans*-**2** by 1.42 kcal/mol. This is in agreement with an opening of the P and N bond angles on passing from *trans*-**2** to *cis*-**2**. Unlike **1** and **2** only the *cis*-**3** isomer was found on the potential energy surface, as was previously observed for ClP=NSiMe_3 and ClAs=NSiMe_3.[22] The aromatic ring in **3** is almost orthogonal to the plane of the CPN skeleton (dihedral angle is 89.6°). Such a conformation excludes any interaction between the π-system of the P=N bond and the π^*_{b1}(aryl) orbital of the aromatic ring. As a consequence, the P−C (1.957 Å) and P−N (1.539 Å) bond lengths correspond to a single and double bond, respectively. The latter is longer than the experimental value for the P−N bond of *cis*-ClP=NMes* (1.495 Å).[6] The silyl group at the nitrogen atom leads to a shortening of the P=N bond [1.574 Å (*cis*-**1**), 1.562 Å (*cis*-**2**), 1.539 Å (*cis*-**3**)] and an opening of the bond angle at nitrogen, as was previously observed for FP=NSiH_3.[23] Moreover, we observed a lengthening of the P−C bond.

For the *cis* isomers of **1**, **2** and **3** the energetic positions of the n^+, π and n^- orbitals as well as the plot[24] of the MO are displayed in Figure 4. For *cis*-**2**, the antibonding combination of lone pairs (n^-) is mixed with the σ_{PC} orbital while the bonding combination of lone pairs (n^+) is mixed with the $\pi_{b1(aryl)}$ orbital of the Ar_f ring. For *trans*-**2**, the bonding combination of lone pairs (n^+) is mixed with the σ_{PC} orbital while the antibonding combination of lone pairs (n^-) is mixed with the σ_{PC} and the $\pi_{b1(aryl)}$ orbitals (Figure 5).

Thus, in this case, the stabilizing effect of the CF_3 groups is attenuated or counterbalanced by destabilizing interactions with the σ_{PC} orbital and the $\pi_{b1(aryl)}$ orbital, respectively (see Figure 4 and Figure 5). For **2**, the energetic position of the n^- orbital is weakly modified when going from **1** to **2**. At the same time the n^+ orbital is destabilized.

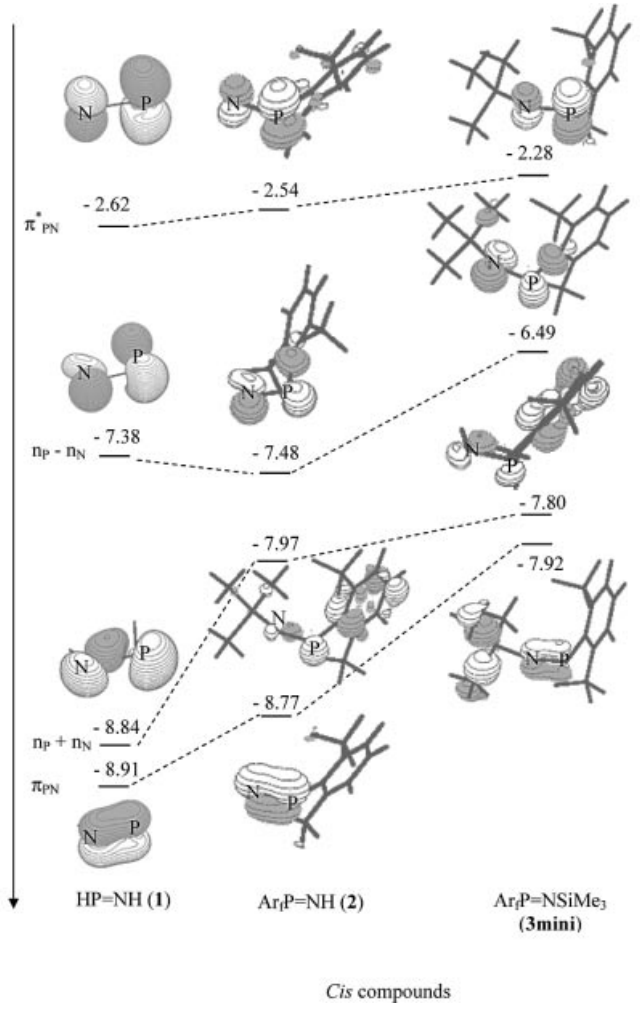

Figure 4. Kohn−Sham energies in eV and Kohn−Sham orbitals calculated with the B3LYP functional hybrid and the 6-311G(d,p) basis set for the *cis* isomers of HP=NH (**1**) and Ar_fP=NR [R = H (**2**), $SiMe_3$ (**3**); π_{CC}(Arf) almost perpendicular to $\pi_{P=N}$]

The H/$SiMe_3$ substitution promotes destabilization of the n^+, n^- and π orbitals. The destabilization of the n^- orbital is more important than that of the n^+ orbital because of the strong p character of the nitrogen lone pair in the n^- orbital. In fact, for the previous system only the push effect is observed.

Ar_fP=NtBu (4)

In addition to X-ray analysis, compound **4** was studied by coupling the Ultraviolet Photoelectron Spectroscopy in the gas phase (UV-PES) and calculations. The UV-PE spectrum of **4** presents a first ionization at 8.5 eV, a second band at 10.0 eV with a broad shoulder at 9.8 eV and then a broad signal with different shoulders at 11.0 and 11.8 eV (Figure 6, a).

In contrast to **3**, the *trans* isomer of **4** is slightly more stable than the *cis* isomer (0.72 kcal/mol). The energetically privileged form *trans*-**4mini** features an aromatic ring almost perpendicular to the CPN plane (dihedral angle is 116.1°), in agreement with the X-ray structure.

We studied the rotation process of the aryl group theoretically. One transition state has been found on the potential energy surface. It corresponds to a structure where the π-system of the aromatic ring is coplanar with the $\pi_{P=N}$ system (**4ts**). The latter is energetically very close to the minimum (4.38 kcal/mol). Thus, taking into account this weak energetic difference, a free rotation of the Ar_f group can occur in the gas phase. The geometric parameters of **4mini** and **4ts** are summarized in Table 1. It is noteworthy to mention that the geometric parameters for both rotamers are similar in spite of the different positions of the aromatic ring. Moreover, the P=N (1.576 Å for **4mini**; 1.567 Å for **4 ts**) and P−C (1.895 Å for **4mini**; 1.902 Å for **4 ts**) bonds are slightly longer than the experimental ones (1.537 Å and 1.866 Å, correspondingly). In the same way, the calculated Kohn−Sham energies (Figure 5) are energetically close ($n_P + n_N$, σ_{PC}: − 6.44 eV for **4mini** and − 6.33 eV for **4ts**; $\pi_{P=N}$: −7.64 eV for **4mini** and −7.49 eV for **4ts**). All these observations show that the orientation of the aromatic ring seems to have a negligible effect on the geometric and electronic structures of Ar_fP=N*t*Bu. In contrast to the coplanar structure of the $[Ar_fPH]^-$ anion where only the interaction between $n^{\pi}_P \rightarrow \pi^*_{b1(aryl)}$ occurs (9.4 kcal/mol),[13] for **4ts** the stabilizing $\pi_{P=N} \rightarrow \pi^*_{b1(aryl)}$ interaction [4.8 kcal/mol (NBO calculation)] is added to the destabilizing interaction $\pi_{P=N} \rightarrow \pi_{b1(aryl)}$ (the plot of the molecular orbital in Figure 7 visualizes these interactions). On the contrary, for **4mini** the stabilizing ($n_P \rightarrow \pi^*_{b1(aryl)}$) interaction is not observed.

Considering the free P−C rotation in the gas phase, the UV-PE spectrum (Figure 6, a) corresponds to the superposition of all the rotamers' spectra close to **4mini** and **4ts**. Thus, taking into account this observation as well as the nature of the molecular orbital, the ΔSCF values for the first ionic state (**4 mini**: $n_P + n_N + \sigma_{PC}$: 8.25 eV; **4 ts**: $n_P + n_N + \sigma_{PC}$: 8.10 eV) and the energetic position of the Kohn−Sham orbitals for **4mini** and **4ts** (Table 2), we assigned the first band in the PE spectrum (8.5 eV) to the removal of an electron from the $n_P + n_N$ orbitals mixed with the σ_{PC} orbital. The second band (centered at 10 eV), which is more intense and broader than the first band, is associated with the ionization of the $\pi_{P=N} - \pi_{b1(aryl)}$ and $\pi_{P=N} + \pi_{b1(aryl)}$ orbitals as well as the π_{a2} ionizations of the aromatic ring. Finally, the ionization at 11.0 eV was assigned to the removal of an electron from the $n_P - n_N$ orbitals (in interaction with the σ_{PC} orbital).

Surprisingly, the energetic positions of the n^+ and π ionizations of **4** were found to be close to the spectroscopic findings for *t*BuP=N*t*Bu. Indeed, the HeI PE spectrum of the latter presents two first ionizations at 8.11 and 9.70 eV, which have been assigned to the n^+ and π_{PN} orbitals, respectively.[25] The close energetic position of the π_{PN} orbital for **4** and *t*BuP=N*t*Bu (9.8 eV and 9.7 eV, respectively) means that the Ar_f group has a destabilizing effect on the π-system close to the *t*Bu group.

As for the σ-bond system, one could expect an important gap between the n^+ orbitals of **4** (σ-attractor effect of Ar_f) and *t*BuP=N*t*Bu (σ-donor effect of *t*Bu), whereas the gap

was actually found to be relatively weak (0.4 eV). This is consistent with the previous theoretical conclusion: the strong stabilizing effect of the fluorinated aryl group is balanced by the destabilizing interaction between the bonding or antibonding combination of lone pairs and the σ_{PC} orbital. The expected stabilizing effect of the Ar_f group is not really observed either on the σ- or the π-systems. Indeed, *t*BuP=N*t*Bu and Ar_fP=N*t*Bu present close electronic

properties [π: 9.7 eV (**4**) and 9.8 eV (*t*BuP=N*t*Bu); n: 8.5 eV (**4**) and 8.11 eV (*t*BuP=N*t*Bu)]. Thus, Ar_f seems to exert a kinetic rather than a stabilizing electronic effect on the −P=N*t*Bu system bonds. In passing, we note that the **3** → **3′** dimerization process cannot be explained either by the nature of the energetic position of the π and π* orbitals or the polarity of the P=N bond. In fact, for **3** and **4**, the gap between the $\pi_{P=N}$ and the $\pi_{P=N}$ orbitals is relatively large and more pronounced in the case of the silyl derivative (5.64 eV vs. 5.39 eV: see Figure 4 and 5). Moreover, the polarity of the P=N double bonds are also close, although slightly higher for **3** (Figure 8). On this basis, it seems that the reason for the higher stability of **4** in comparison with **3** is that $SiMe_3$ is a less-bulky protecting group than *t*Bu. Indeed, the Si−C bond is longer than the C−C bond and the bond angle at Si is more open than the bond angle at C. Consequently the dimerization is easier with $SiMe_3$.

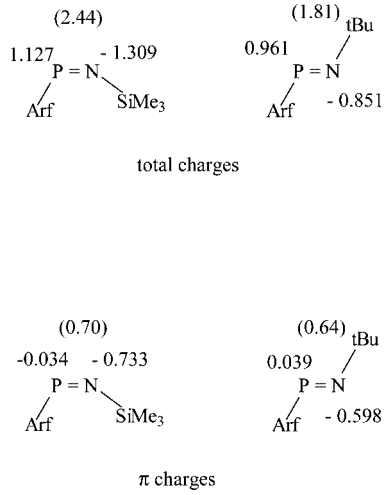

Figure 8. NBO charges (total and π) for $Ar_fP{=}NSiMe_3$ (**3**) and $Ar_fP{=}NtBu$ (**4**); polarity of the PN bond in brackets

$Ar_fP{=}NNMe_2$ (6)

In order to determine the role of the Ar_f group on the $-P{=}N{-}NMe_2$ moiety, a theoretical study of the model molecule $HP{=}NNMe_2$ (**5**) was undertaken. The isomer *trans*-**5** was found to be slightly more stable than the *cis* isomer (0.22 kcal/mol). This corresponds to the form where the electronic energy is more important (see Table 1). The geometrical parameters of the *cis* and *trans* forms are described in Table 1. In contrast to the previously studied iminophosphanes Tmp-P=N−$N(SiMe_3)_2$,[26] (Tmp = 2,2,6,6-tetramethylpiperidino) and $tBu_2P{-}P{=}N{-}N(SiMe_3)_2$,[20] the NMe_2 group in **6** is coplanar with the $C_{Ar_f}PN$ moiety. This orientation involves the presence of an important stabilizing interaction between the amino nitrogen lone-pair and the $\pi^*_{P=N}$ orbital [$n_N \rightarrow \pi^*_{P=N}$ = 77 kcal/mol (*cis*); $n_N \rightarrow \pi^*_{P=N}$ = 76.5 kcal/mol (*trans*)]. The *trans* form features a P−N bond (1.653 Å) that is significantly longer than the corresponding distance in **1** (1.588 Å). The N−N bond (1.302 Å) is intermediate between a single (1.450 Å) and a double bond (1.250 Å). As can be seen in Figure 5, the replacement of H by an NMe_2 group at the nitrogen atom destabilizes the $\pi_{P=N}$ orbital by 3.15 eV (Figure 5). The NMe_2 group also has an important influence on the energetic position of the antibonding combination of lone pairs mainly localized on nitrogen. On the other hand, the bonding combination of lone pairs is less affected by this sub-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

stituent (the difference in the energies is 1.48 eV and 0.52 eV, respectively).

Next we carried out calculations on compound **6**. Two minima corresponding to the *trans* and *cis* isomers were found on the potential energy surface. In both isomers, the amino nitrogen atom is sp^2 hybridized and the NMe_2 group is coplanar with the CPN moiety, thus establishing a three-center, four-electron system. The *trans* form **6mini** (energetic minimum) is more stable than the *cis* form by 2.07 kcal/mol because of less steric hindrance (see Table 1, E_{rep}). For **6mini** the dihedral angle between the Ar_f group and the CPN system is 126.4°. The substitution of H by Ar_f in **5** has only a weak influence on the geometrical parameters of the CPN system (Table 1). The P−C bond length (1.878 Å) remains characteristic of a single bond. These theoretical results are in agreement with the RX structure (Figure 3). As previously observed, the structure with the Ar_f group coplanar with the PNN moiety (**6ts**) corresponds to a transition state. It is energetically very close to the minimum (3.3 kcal/mol) and should involve a free rotation of the aromatic group in the gas phase. For **6ts**, the P−N, P−C and N−N bond lengths are slightly shorter than in **6mini**.

The calculated NBO charges of the $Ar_fP{=}N{-}R$ (R: *t*Bu **4**, NMe_2 **6**) system show that the phosphorus charge is about 0.961 au for **4** and 0.638 au for **6**. This modification affects the ^{31}P NMR chemical shift (**4**: δ = 412.4 ppm; **6**: δ = 224.2 ppm). The peak due to the NMe_2-substituted phosphorus atom appears at higher field than the *t*Bu-substituted phosphorus atom. This result is in agreement with those previously reported by Yoshifuji et al.[1b] on the −P=P− part.

The weak geometrical changes between the forms **5**, **6mini** and **6ts** lead to negligible modifications of their electronic structure. Figure 9 summarizes the energetic positions of the n^+, n^- and $\pi_{P=N}$ orbitals for these compounds. The inductive σ-attractor effect of Ar_f exerts a weak stabilizing influence on the n^+ and n^- orbitals (0.2−0.3 eV for n^+ and 0.37−0.44 eV for n^-); this stabilization is more pronounced for the n^- orbital since it is mainly localized on phosphorus. The plots of the combination of lone pairs show a destabilizing interaction with the σ_{PC} orbital (as previously observed for **3** and **4**), which reduces the stabilizing inductive effect of the CF_3 groups. This is the reason why the energetic positions of the n^+ and n^- orbitals in **5** and **6** are not strongly modified. In the same way, whatever the orientation of the fluorinated aromatic group, the substitution on phosphorus by Ar_f group seems to have no effect on the energetic position of the $\pi_{P=N}$ orbital. Indeed, the Kohn−Sham energies are similar for these three compounds [−5.68 (**5**), −5.74 (**6mini**), −5.74 eV (**6ts**)]. For **6ts**, taking into account the orientation of the aryl group, we might expect an interaction between the $\pi_{b1(aryl)}$ orbital of Ar_f and the $\pi_{P=N}$ system. In fact, the presence of a planar amino group coplanar with the PNN moiety involves a destabilization of the $\pi_{P=N}$ orbital (interaction $n_N \rightarrow \pi_{P=N}$). Consequently, the energy gaps $\pi_{P=N}/\pi^*_{b1(aryl)}$ and $\pi_{P=N}/\pi_{b1(aryl)}$ are decreased and increased, respectively. In the particular case of **6ts**, the strong destabilizing $\pi_{P=N} \rightarrow \pi_{b1(aryl)}$ interaction is counterbalanced by the stabilizing $\pi_{P=N} \rightarrow \pi^*_{b1(aryl)}$ interaction (see MO plots Figure 7). However, it should be noted that even when the aromatic group is coplanar with the PNN system the $\pi_{P=N} \rightarrow \pi^*_{b1(aryl)}$ interaction is not important enough to allow a strong delocalization of the $\pi_{P=N}$ system. Perhaps, the presence of strong σ-donor groups on the amino nitrogen would allow the stabilizing $\pi_{P=N} \rightarrow \pi^*_{b1(aryl)}$ interaction to be more important than the destabilizing $\pi_{P=N} \rightarrow \pi_{b1(aryl)}$ interaction. In this case a structure close to the Ar_fPH^- anion structure would be observed.

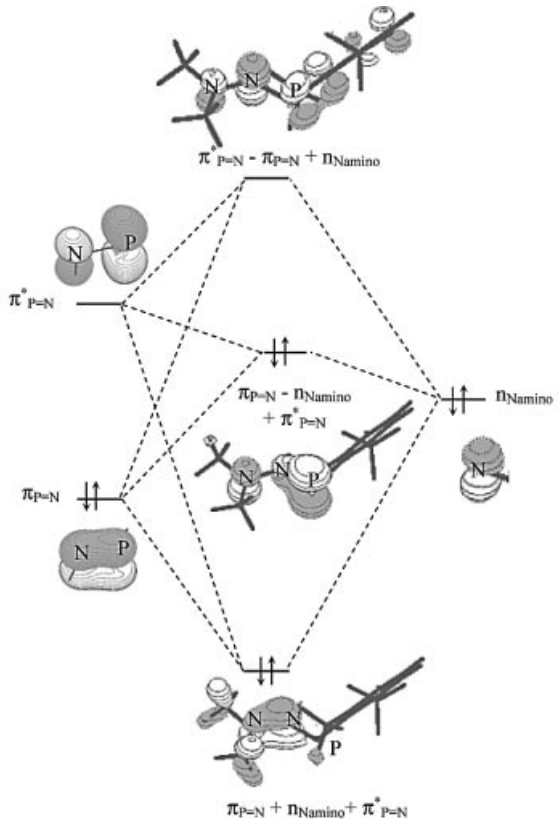

Figure 9. Plot of the molecular orbitals for the minimum of $Ar_fP{=}NNMe_2$ (**6mini**)

We have recorded the He^I PE spectrum of **6** in order to confirm the modifications of the electronic structure of the CP=N part on going from **4** to **7** (Figure 6b). It presents three first-ionization bands at 7.8, 8.8 and 9.5 eV which are lower in energy than the first ionizations of $Ar_fP{=}Nt$Bu (8.5, 10.0 and 11.0 eV). The ΔSCF values (**6mini**: $\pi_{P=N} - n_{Namino}$ = 7.51 eV; **6ts**: $\pi_{P=N} - n_{Namino}$ = 7.44 eV) as well as the Kohn−Sham energy orbitals allowed us to assign the first band at 7.8 eV to the removal of an electron from the ($\pi_{P=N} - n_{Namino} - \pi^*_{P=N}$) orbital of all rotamers around **6mini** and **6ts** (see Figure 9); the second band at 8.8 eV was assigned to the phosphorus and nitrogen bonding combination of lone pairs ($n_P + n_N$) for the different rotamers. The experimental gap (1 eV) between the first two orbitals is theoretically well represented (0.86−0.93 eV). The third ionization at 9.5 eV corresponds to the removal of an elec-

tron from the π_{a2} orbitals of the aromatic ring. We can note an inversion of the first two orbitals. Compared to **4** (n^+, $\pi_{P=N}$ for **4** and $\pi_{P=N}$, n^+ for **6**), the $\pi_{P=N}$ orbital is being destabilized because of the interaction with the nitrogen lone pair of the amino group. The following bands at 11.0 and 11.6 eV are assigned to the ionization from the ($n_P - n_N$) orbital and the ($\pi_{P=N} + n_{Namino} + \pi^*_{P=N)}$ orbitals, respectively. In fact, the plot of this latter looks like the plot of a $\pi_{N=N}$ orbital, since the interaction between the $\pi_{P=N}$ and $\pi^*_{P=N}$ orbitals cancels the weight on the phosphorus atom (Figure 9).

In summary, previous works on the effect of the Ar_f group on the stabilization of the reactive part of the molecule have shown that this latter could act as a spectator group or a π-acceptor group. For instance, for the two following compounds: the carbene $Ar_fCP(NiPr_2)_2$ [14] and the anion Ar_fPH^-, [13] a delocalization of the carbene lone pair (carbene) or the π phosphorus lone pair (anion) in the Ar_f group was observed, respectively. The $C_{carb}-C_{aryl}$ (1.390 Å) or $P-C_{aryl}$ (1.794 Å) bonds are short and the $C_{A(aryl)}-C_{B(aryl)}$ or $C_{A(aryl)}-C_{B'(aryl)}$ bonds [$C_{A(aryl)}$: carbon linked to the carbon center or phosphorus, $C_{B(aryl)}$ and $C_{B'(aryl)}$: carbon in α position to $C_{A(aryl)}$] of the Ar_f groups are longer than the other bonds of the ring (1.43−1.44 Å compared to 1.37−1.39 Å), indicating a delocalization of the carbene lone pair or the negative charge (phosphanide anion) over the ring. In this case, the Ar_f group behaves like a π-electron acceptor by the $\pi^*_{b1(aryl)}$ orbitals of the aryl group.

A recent publication[27] has shown that the potentially π-acceptor Ar_f group can also act as a spectator group. Indeed, for the amino(aryl)carbene $Ar_fCN(Me)tBu$, it has been shown that the $C_{carb}-C_{aryl}$ bond is long (1.453 Å), the carbene bond angle acute and the C−C bonds of the aryl group quite similar (1.37−1.42 Å), which indicates that the Ar_f group does not interact with the carbene lone pair and is therefore a spectator.

In our case [iminophosphanes $Ar_fP{=}NtBu$ (**4**) and $Ar_fP{=}NNMe_2$ (**6**)], all the C−C bonds of the aryl group are almost similar (1.38−1.41 Å) and the $P-C_{aryl}$ bond quite long (single bonds: 1.866 Å for **4** and 1.863 Å for **6**). We did not observe a shortening of the $P-C_{aryl}$ bond or a lengthening of the $C_{A(aryl)}-C_{B(aryl)}$ or $C_{A(aryl)}-C_{B'(aryl)}$ bonds. These geometrical data can be compared to the previous ones and allow us to conclude that the Ar_f substituent effect is mainly steric.

Conclusion

The experimental (NMR, X-rays and UV Photoelectron Spectroscopy data) and theoretical studies on the iminophosphanes $Ar_f-P{=}NR$ (R: *t*Bu, NMe_2) show that the Ar_f group is orthogonal to the PNR moiety. This orientation could have allowed an interaction between the phosphorus lone pair and the $\pi^*_{b1(aryl)}$ orbital of the Ar_f group, as previously observed for $(iPr_2N)_2PCAr_f$ (p character of the carbon σ lone pair, short $C_{carb}-C_{aryl}$ bond). However, taking into account the strong s character of the phosphorus lone pair (phosphorus angle shrunk), this interaction is not efficient. In fact, in these compounds the Ar_f group acts mainly as a sterically protective ligand. The stabilizing effect of Ar_f is not efficient in the σ system because it is attenuated by a destabilizing interaction between the phosphorus and nitrogen combination of lone pairs and the σ_{PC} orbital. Moreover, in spite of a different electronic effect between $SiMe_3$ and *t*Bu, the isolation of the monomer in the latter case can only be explained by a smaller protecting effect of the $SiMe_3$ substituent compared to *t*Bu.

In addition, all these results show that the Ar_f group only stabilizes a system which presents a weakly nucleophilic lone pair with a strong p character. In this case, it can behave like an acceptor group with the $\pi^*_{b1(aryl)}$ orbital. Thus, it seems interesting to use Ar_f in order to stabilize anionic species with a heteroatom. This substituent could allow us to stabilize the singlet state of phosphinidenes and homologues.

Experimental Section

General Remarks: All reactions and manipulations were carried out under argon using standard Schlenk techniques. Solvents were dried according to the appropriate method: dichloromethane and chloroform with P_4O_{10}, pentane and hexane with calcium hydride, toluene, xylene, tetrahydrofuran and diethyl ether with sodium/benzophenone.

NMR spectra were recorded on Bruker AC200, and WM250 spectrometers. ^1H and ^{13}C chemical shifts are reported in ppm relative to tetramethylsilane as an external reference. ^{19}F and ^{31}P NMR downfield chemical shifts are expressed with a positive sign relative to external CF_3COOH and 85% H_3PO_4, respectively. Mass spectra were obtained on a Nermag R 10−10 instrument. The photoelectron spectra were recorded on a Helectros 0078 instrument equipped with a 127° cylindrical analyser and monitored by a micro-computer supplemented with a digital analogic converter. The spectra were calibrated with the known auto-ionization of helium at 4.98 eV [HeII(He)] and nitrogen ionization at 15.59 eV.

$Ar_fP(Cl)-N(SiMe_3)_2$: A 1.6 M solution of *n*BuLi in hexane (6.92 mmol) was added to a solution of $HN(SiMe_3)_2$ (1.12 g, 6.92 mmol) in THF (8 mL) at −50 °C. The mixture was then warmed to ambient temperature and stirred for 1 h. This solution of $LiN(SiMe_3)_2$ was added dropwise to a solution of Ar_fPCl_2 (2.18 g, 6.92 mmol) in THF (5 mL) at −80 °C. The reaction mixture was slowly warmed to ambient temperature, stirred for 1 h and the solvents evaporated. Pentane was added to the residue and the precipitated LiCl was filtered off. Removal of solvent and volatiles in vacuo yielded $Ar_fP(Cl)N(SiMe_3)_2$ as a yellow oil. Yield 86% (95% pure by NMR). ^1H NMR ($CDCl_3$): δ = 0.02 (s, 9 H, $SiMe_3$), 6.59 (t, $^3J_{H,H}$ = 7 Hz, 1 H, *p*-H_{arom}), 7.82 (d, $^3J_{H,H}$ = 7 Hz, 2 H, *m*-H_{arom}) ppm. ^{13}C NMR ($CDCl_3$): δ = 4.1 (d, $^3J_{P,C}$ = 7.4 Hz, $SiMe_3$), 124.1 (dq, $^3J_{P,C}$ = 5.6, $^1J_{P,C}$ = 275.6 Hz, CF_3), 129.3 (d, $^4J_{P,C}$ = 2.8 Hz, *p*-C_{arom}), 130.7 (m, *m*-C_{arom}), 134.7 (dq, $^2J_{P,C}$ = 11.1, $^2J_{C,F}$ = 32.4 Hz, *o*-C_{arom}), 149.0 (d, $^1J_{P,C}$ = 110.9 Hz, *ipso*-C_{arom}) ppm. ^{19}F NMR ($CDCl_3$): δ = 24.45 (d, $^4J_{F,P}$ = 39 Hz) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 143.9 (sept, $^4J_{F,P}$ = 39 Hz) ppm.

$[Ar_fPNSiMe_3]_2$ (3′): A solution of $Ar_fP(Cl)N(SiMe_3)_2$ (1.20 g, 2.73 mmol) in 1,2,4-trichlorobenzene (5 mL) was heated at 150 °C

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for 40 h. The solvent was evaporated in vacuo (60 °C, 0.1 Torr) and the crude **3′** was purified by washing with hexane (5 mL). This procedure gave 0.81 g (90% yield) of pure product. ^{1}H NMR (CD_2Cl_2): δ = −0.28 (s, 18 H, $SiMe_3$), 7.73 (t, $^3J_{H,H}$ = 8 Hz, 2 H, *p*-H_{arom}), 8.11 (two d, $^3J_{H,H}$ = 8 Hz, 4 H, *m*-H_{arom}) ppm. ^{13}C NMR (CD_2Cl_2): δ = −1.1 (s, $SiMe_3$), 124.1 (q, $^1J_{F,C}$ = 275.3 Hz, CF_3), 124.6 (q, $^1J_{F,C}$ = 276.7 Hz, CF_3), 130.7 (s, *p*-C_{arom}), 131.3 (q, $^3J_{F,C}$ = 32.1 Hz, *m*-C_{arom}), 139.6 (dq, $^2J_{C,P}$ = 36.1, $^2J_{F,C}$ = 29.4 Hz, *o*-C_{arom}), 151.4 (d, $^1J_{C,P}$ = 132.3 Hz, *ipso*-C_{arom}) ppm. ^{19}F NMR (CD_2Cl_2): δ = 23.04 (d, $^4J_{F,P}$ = 72.3 Hz) and 27.39 (d, $^4J_{F,P}$ = 134.7 Hz) ppm. ^{31}P{^{1}H} NMR (CD_2Cl_2): δ = 277.3 (m) ppm. $C_{22}H_{24}F_{12}N_2P_2Si_2$ (662.54): calcd. C 39.88, H 3.65; found C 39.65, H 3.89.

$Ar_fP(Cl)-N(SiMe_3)tBu$: A solution of [$LiN(SiMe_3)t$Bu] in THF (12 mL), prepared from $HNtBu(SiMe_3)$ (1.44 g, 9.89 mmol) and an equimolar amount of a 1.6 M solution of *n*BuLi in hexane at −30 °C, was added dropwise to a solution of Ar_fPCl_2 (3.12 g, 9.89 mmol) in THF (7 mL) at −80 °C. The reaction mixture was slowly warmed to ambient temperature, stirred for 1 h and the solvents evaporated. Pentane was added to the residue and the precipitated LiCl was filtered off. Removal of the solvent and volatiles in vacuo yielded 3.4 g (81%) of product. ^{1}H NMR ($CDCl_3$): δ = 0.03 (s, 9 H, $SiMe_3$), 1.54 (s, 9 H, *t*Bu), 7.56 (t, $^3J_{H,H}$ = 7.4 Hz, 1 H, *p*-H_{arom}), 7.79 (d, $^3J_{H,H}$ = 7.4 Hz, 2 H, *m*-H_{arom}) ppm. ^{13}C NMR ($CDCl_3$): δ = 6.4 (s, Me_3Si), 32.7 (d, $^3J_{P,C}$ = 13.9 Hz, C*Me*$_3$), 61.5 (d, $^2J_{C,P}$ = 29.6 Hz, *C*Me_3), 123.9 (dq, $^1J_{F,C}$ = 242.3, $^4J_{C,P}$ = 5.5 Hz, CF_3), 129.0 (d, $^4J_{C,P}$ = 3.7 Hz, *p*-C_{arom}), 129.9 and 131.6 (m, *m*-C_{arom}), 134.9 (m, *o*-C_{arom}), 148.4 (d, $^1J_{P,C}$ = 98.0 Hz, *ipso*-C_{arom}) ppm. ^{19}F NMR ($CDCl_3$): δ = 24.89 (*pseudo* t, $^4J_{F,P}$ = 37 Hz) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 145.0 (sept, $^4J_{F,P}$ = 36 Hz) ppm.

$Ar_fP{=}NtBu$ (4): A solution of $Ar_fP(Cl)N(SiMe_3)t$Bu (1.95 g, 4.61 mmol) in xylene (4 mL) was heated at 120 °C for 80 h, then the solvent was evaporated. Distillation in vacuo afforded 0.80 g (55%) of **4**; b.p. 56−60 °C at 0.05 Torr. ^{1}H NMR ($CDCl_3$): δ = 1.49 (d, $^4J_{H,P}$ = 1.8 Hz, 9 H, *t*Bu), 7.63 (t, $^3J_{H,H}$ = 7.8 Hz, 1 H, *p*-H_{arom}), 7.89 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, *m*-H_{arom}) ppm. ^{13}C NMR ($CDCl_3$): δ = 32.5 (d, $^3J_{C,P}$ = 15.7 Hz, C*Me*$_3$), 64.6 (d, $^2J_{C,P}$ = 10.2 Hz, *C*Me_3), 124.1 (dq, $^1J_{F,C}$ = 275.6, $^3J_{C,P}$ = 1.9 Hz, CF_3), 129.8 (s, *p*-C_{arom}), 129.9 (q, $^3J_{F,C}$ = 5.6 Hz, *m*-C_{arom}), 133.2 (dq, $^2J_{C,P}$ = 4.6, $^2J_{F,C}$ = 31.5 Hz, *o*-C_{arom}), 147.0 (d, $^1J_{C,P}$ = 84.2 Hz, *ipso*-C_{arom}) ppm. ^{19}F NMR ($CDCl_3$): δ = 21.65 (d, $^4J_{F,P}$ = 28 Hz) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 412.4 (sept, $^4J_{F,P}$ = 28 Hz) ppm. $C_{12}H_{12}F_6NP$ (315.19): calcd. C 45.73, H 3.84; found C 45.40, H 3.55.

$Ar_fP(Cl)-N(SiMe_3)NMe_2$: A 1.6 M solution of *n*BuLi in hexane (10.38 mmol) was added to a solution of $HN(SiMe_3)(NMe_2)$ (1.37 g, 10.38 mmol) in THF (15 mL) at −30 °C. The mixture was then warmed to ambient temperature and stirred for 1 h. This solution of lithium hydrazide was added dropwise to a solution of Ar_fPCl_2 (3.27 g, 10.38 mmol) in THF (7 mL) at −80 °C. The reaction mixture was slowly warmed to ambient temperature, stirred for 1 h and the solvents evaporated. Pentane was added to the residue and the precipitated LiCl was filtered off. Solvent and volatile compounds were removed in vacuo. The resulting solid contained the chlorophosphane $Ar_fP(Cl)N(SiMe_3)NMe_2$ and about 20% of the diphosphene $Ar_fP{=}PAr_f$. Recrystallization from diethyl ether afforded the pure product as dark yellow crystals. Yield 2.1 g (49%). ^{1}H NMR (C_6D_6): δ = 0.02 (s, 9 H, $SiMe_3$), 2.51 (br. s, 6 H, Me_2N), 6.71 (t, $^3J_{H,H}$ = 7.8 Hz, 1 H, *p*-H_{arom}), 7.38 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, *m*-H_{arom}) ppm.^{13}C NMR (C_6D_6): δ = 1.9 (d, $^3J_{P,C}$ = 2.8 Hz, Me_3Si), 47.1 (d, $^3J_{P,C}$ = 103.6 Hz, Me_2N), 124.6 (q, $^1J_{F,C}$ = 275.6 Hz, F_3C), 130.8 (s, *p*-C_{arom}), 130.9 (br. m, *m*-C_{arom}), 135.6 (dq, $^2J_{P,C}$ = 19.4, $^2J_{C,F}$ = 31.4 Hz, *o*-C_{arom}), 138.2 (d, $^1J_{P,C}$ = 83.23 Hz, *ipso*-C_{arom}) ppm. ^{19}F NMR (C_6D_6): δ = 22.50 (d, $^4J_{F,P}$ = 46 Hz) ppm. ^{31}P{^{1}H} NMR (C_6D_6): δ = 122.5 (sept, $^4J_{F,P}$ = 46 Hz) ppm. MS (70 eV): *m*/*z* (%) = 375 (100) [M − Cl]$^+$. $C_{13}H_{18}ClF_6N_2PSi$ (410.80): calcd. C 38.01, H 4.42; found C 38.19, H 4.22.

$Ar_fP{=}N{-}NMe_2$ (6): A solution of $Ar_fP(Cl)N(SiMe_3)NMe_2$ (1.96 g, 4.78 mmol) in xylene (4 mL) was heated at 120 °C for 2 h, then the solvent was evaporated. Distillation in vacuo (60−70 °C, 0.05 Torr) afforded **6** in ca. 50% yield and, according to the NMR spectra, $Ar_fP{=}PAr_f$ (δ_P = 478 ppm) as a side product (ca. 10%). Pure **6** was isolated after stirring a solution of the amido(chloro)-phosphane (1.52 g, 3.70 mmol) in $CHCl_3$ (2 mL) at 25 °C for 14 h. Yield 95%; b.p. 65−70 °C at 0.5 Torr. ^{1}H NMR ($CDCl_3$): δ = 3.34 (d, $^4J_{H,P}$ = 7.4 Hz, 6 H, Me_2N), 7.55 (t, $^3J_{H,H}$ = 8 Hz, 1 H, *p*-H_{arom}), 7.89 (d, $^3J_{H,H}$ = 8 Hz, 2 H, *m*-H_{arom}) ppm. ^{13}C NMR ($CDCl_3$): δ = 47.9 (d, $^3J_{C,P}$ = 12.95 Hz, Me_2N), 124.1 (q, $^1J_{F,C}$ = 275.6 Hz, CF_3), 128.6 (s, *p*-C_{arom}), 129.6 (q, $^3J_{F,C}$ = 5.5 Hz, *m*-C_{arom}), 135.3 (dq, $^2J_{C,P}$ = 4.6, $^2J_{F,C}$ = 29.6 Hz, *o*-C_{arom}), 144.0 (d, $^1J_{C,P}$ = 71.2 Hz, *ipso*-C_{arom}) ppm. ^{19}F NMR ($CDCl_3$): δ = 20.92 (d, $^4J_{F,P}$ = 23.5 Hz) ppm. ^{31}P NMR ($CDCl_3$): δ = 224.3 (br.s) ppm. $C_{10}H_9F_6N_2P$ (302.16): calcd. C 39.75, H 3.00; found C 40.10, H 3.38.

***i*$Pr_2NP(Cl)-N(SiMe_3)NMe_2$:** A 1.6 M solution of *n*BuLi in hexane (6.36 mmol) was added to a solution of $HN(SiMe_3)(NMe_2)$ (0.84 g, 6.36 mmol) in THF (10 mL) at −30 °C. This solution of lithium hydrazide was added dropwise to a solution of *i*Pr_2NPCl_2 (1.27 g, 6.36 mmol) in THF (5 mL) at −80 °C. The reaction mixture was slowly warmed to ambient temperature, stirred for 1 h and the solvents evaporated. Pentane (20 mL) was added to the residue and the precipitated LiCl was filtered off. The solution was evaporated to yield colorless crystals of the product (89%). M.p. 32−34 °C. ^{1}H NMR (C_6D_6): δ = 0.39 (s, 9 H, $SiMe_3$), 1.08 and 1.28 (d, $^3J_{H,H}$ = 6.8 Hz, 12 H, $CH(CH_3)_2$], 2.52 and 2.61 (s, 6 H, NMe_2), 3.71 [m, 2 H, $CH(CH_3)_2$] ppm. ^{13}C NMR: δ = 3.2 (d, $^3J_{P,C}$ = 3.7 Hz, Me_3Si), 23.2 [d, $^3J_{P,C}$ = 12.95 Hz, $CH(CH_3)_2$], 23.9 [d, $^3J_{P,C}$ = 4.62 Hz, $CH(CH_3)_2$], 46.7 [d, $^3J_{P,C}$ = 10.2 Hz, $N(CH_3)_2$], 47.4 [d, $^2J_{P,C}$ = 44.4 Hz, $CH(CH_3)_2$], 47, 6 [d, $^2J_{P,C}$ = 39.8 Hz, $CH(CH_3)_2$] ppm. ^{31}P NMR ($CDCl_3$): δ = 129.3 (s) ppm. $C_{13}H_{18}ClF_6N_2PSi$ (410.80): calcd. C 38.01, H 4.42; found C 38.19, H 4.22.

***i*$Pr_2NP{=}NNMe_2$ (7):** A solution of *i*$Pr_2NP(Cl)N(SiMe_3)NMe_2$ (1.43 g, 4.80 mmol) in toluene (10 mL) was heated at 100 °C for 10 h. Solvent was removed in vacuo to afford iminophosphane **7** contaminated by a small amount (<10%) of the dimer [*i*$Pr_2NPNNMe_2$]$_2$.

7: ^{1}H NMR (C_6D_6): δ = 1.19 and 1.44 [br. s, 12 H, $CH(CH_3)_2$], 2.58 (s, 6 H, NMe_2), 3.32 and 4.10 [br. s, 2 H, $CH(CH_3)_2$] ppm. ^{13}C NMR (C_6D_6): δ = 22.2 and 27.6 [br. s, $CH(CH_3)_2$], 44.8 [s, $N(CH_3)_2$], 49.3 [*pseudo* t, $^2J_{P,C}$ = 5.55 Hz, $CH(CH_3)_2$] ppm. ^{31}P NMR (C_6D_6): δ = 173.13 (s) ppm. MS (70 eV): *m*/*z* (%) = 189 (15) [M$^+$]. $C_8H_{20}N_3P$ (189.24).

Iminophosphane **7** slowly dimerizes at room temperature to give 1,3,2,4-diazadiphosphetidine [*i*$Pr_2NPNNMe_2$]$_2$ according to X-ray analysis. ^{1}H NMR ($CDCl_3$): δ = 1.24 [d, $^3J_{H,H}$ = 6.8 Hz, 12 H, $CH(CH_3)_2$], 2.69 (s, 6 H, NMe_2), 3.84 [br. s, 2 H, $CH(CH_3)_2$]; ppm. ^{13}C NMR ($CDCl_3$): δ = 24.6 [br. s, $NCH(CH_3)_2$], 43.6 (t, $^3J_{P,C}$ = 4.6 Hz, NMe_2), 49.1 (t, $^2J_{P,C}$ = 5.6 Hz, $CH(CH_3)_2$] ppm. ^{31}P NMR ($CDCl_3$): δ = 74.2 (s) ppm. MS (70 eV): *m*/*z* (%) = 378 (17) [M$^+$]. $C_8H_{20}N_3P$ (189.24): calcd. C 50.77, H 10.65, N 22.20; found C 50.86, H 10.84, N 22. 08. $C_{16}H_{40}N_6P_2$ (378.48): calcd. C 50.77, H 10.65, N 22.20; found C 50.55, H 10.49, N 22.13.

Computational Details: Calculations were performed with the Gaussian 98 program[28,29] using the Density Functional theory method.[30] The various structures were fully optimized at the B3LYP level.[31] This functional is built with Becke's three-parameter exchange functional[31a] and the Lee−Yang−Parr correlation functional.[31c] The 6-311G(d,p) basis set was used. All atoms were augmented with a single set of polarization functions. The second derivatives were calculated in order to determine if a minimum or a transition state (one negative eigenvalue) existed for the resulting geometry.

All total energies have been zero-point energy (ZPE) and temperature corrected using unscaled density functional frequencies.

NBO analysis population[32] was performed in order to determine the presence of stabilizing interactions between a filled orbital and an empty orbital. Ionization energies were determined as the difference between the cation and the neutral molecule energies (IE = $E_{cation} - E_{molecule}$; ΔSCF method). For the large molecules, an association between the ionization potential and Kohn−Sham (KS) energies calculated with common functionals (Koopmans' theorem-like) has been discussed in depth. Arduengo and co-workers[33] first used DFT calculations at the nonlocal level to assign their photoelectron spectra. They applied a uniform shift to the orbital energies considering the difference between the calculated and experimental molecular ionization potentials. The aim was to directly compare the KS energies to the experimental energies. Moreover, Werstiuk and Rademacher[34] have developed and successfully applied a routine for the interpretation of PE spectra based on B3LYP theory. This routine requires the calculation of the molecule's first vertical ionization potential IP_v. Calculated orbital energies $-\varepsilon$ are then shifted uniformly so that the HOMO energy equals that of the IP_v, giving the higher IPs. More recently, Hoffmann[35] has underlined that the KS orbitals are a good basis for qualitative interpretation of molecular orbital. He concluded that if one wants to go a step beyond a qualitative interpretation and look at orbital energies as rough ionization potentials, and if the DFT calculations are done with commonly used potentials, then one must take the absolute constant and linear orbital energy shift into account by applying a suitable (ax + b) scaling. In the case of large molecules, the ordering of levels found by using the DFT calculations seems to be qualitatively as well translated as by using HF methods. This fact, despite the evident limits of correlation, gives a good basis for discussion about the ionizations assignments which cannot be reached by a direct calculation.

X-ray Crystallographic Study: Crystal data for **3′**, **4** and **6** are presented in Table 3. All data were collected at low temperature (−50 °C for **3′** and −80 °C for **4** and **6**) on a Bruker-AXS CCD 1000 diffractometer with Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods by means of SHELXS-97[36] and refined with all data on F^2 by means of SHELXL-97.[37] All non-hydrogen atoms were refined anisotropically.
CCDC 223052−223054 (for **3′**, **4** and **6** respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Financial support of this work by the CNRS (France) is gratefully acknowledged. The First Structurally Authenticated Organomercury(1+) Thioether Complexes − Mercury−Carbon Bond Activation Related to the Mechanism of the Bacterial Enzyme Organomercurial Lyase

Michaela Wilhelm,[a][‡] Stefan Deeken,[a] Eva Berssen,[a] Wolfgang Saak,[a] Arne Lützen,[a] Rainer Koch,[a] and Henry Strasdeit*[b]

Keywords: Bioinorganic chemistry / Enzyme models / Ligand effects / Mercury / S ligands

The new compounds [MeHg([9]aneS$_3$)](BF$_4$) (**1**), [MeHg([12]aneS$_3$)](BF$_4$) (**2**), and [(MeHg)$_2$([14]aneS$_4$)](BF$_4$)$_2$ (**3**) have been prepared and their crystal structures determined. In **1**, the thioether acts as a tridentate ligand [Hg–S 2.611(2)–2.768(2) Å] and thus the metal atom is tetrahedrally coordinated, which is rare in organomercury chemistry. Temperature-dependent ^{1}H and ^{13}C NMR spectra showed that this coordination is retained in acetonitrile solution. In crystalline **2** and **3**, linear-coordinated Hg^{II} occurs with Hg–S bond lengths of 2.441(4) and 2.425(2) Å. [MeHg([9]aneS$_3$)]$^+$ was found to be stable towards ligand substitution by $CF_3SO_3^-$ in dimethyl sulfoxide, whereas the thioether was partly displaced by $CF_3CO_2^-$ and completely by $CH_3CO_2^-$. Protonolysis by the very strong Brønsted acid CF_3SO_3H in [D$_3$]nitromethane transformed the methanido ligand into methane. The degree of Hg–C bond cleavage was ca. 25% for the four-coordinate [MeHg([9]aneS$_3$)]$^+$ after 1 h, whereas no reaction was observed for two-coordinate [MeHg(SEt$_2$)]$^+$ or MeHgCl under similar conditions even after 24 h. The product Hg^{2+} was trapped as [Hg([9]aneS$_3$)$_2$]$^{2+}$, which is a six-coordinate complex, as shown by a crystal structure analysis of [Hg([9]aneS$_3$)$_2$](BF$_4$)$_2$·2 CH$_3$CN. Quantum chemical calculations [MP2/SDD + SDD ECP Hg, 6-31+G(d,p) other elements] confirmed that hydrogen transfer activation barriers are significantly lower for "high"-coordinate (CN > 2) complexes. Hg–C bond activation by the enzyme organomercurial lyase is possibly also based on multiple (cysteinyl) sulfur ligation. We propose a hypothetical reaction mechanism that involves an OH-containing amino acid side chain or a water molecule simultaneously serving as a proton acceptor (from Cys–SH) and donor (to R$^-$ of RHg$^+$). This mechanism is supported by quantum chemical calculations on a model system.

Introduction

The high toxicity of various mercury compounds is a constant issue of environmental and public health concern. Consequently, the global cycle of mercury, including the considerable effects of anthropogenic activities, has been intensely studied.[1−6] It was found that in the marine environment, the reduction of inorganic mercury (Hg^{2+}) to the elemental form (Hg^0), and the biomethylation of Hg^{2+} to methylmercury ($MeHg^+$) and dimethylmercury ($HgMe_2$) are major reactions. While Hg^0 is released into the atmosphere where it represents the dominant transport form of mercury, methylmercury is partly incorporated by plankton species and accumulates in the food chain, especially in predatory fish.[7,8] Methylmercury is known to be an extreme neurotoxin.[9−16] A recent study estimates that in the USA alone, over 60,000 children are born each year at risk of neurological problems caused by in utero exposure to methylmercury.[9,17]

One of the main factors responsible for the facile biomagnification of methylmercury in the food chain is the relatively high stability of the Hg−CH_3 bond under physiological conditions.[18,19] It is therefore interesting that the bacterial enzyme organomercurial lyase or MerB (gene: *merB*) is capable of accelerating the protonolytic cleavage of methylmercury and other RHg^+ cations by a factor of 10^6-10^7.[20] The products of the enzymatic reaction are the hydrocarbon RH and Hg^{2+} which is eventually complexed by exogenous thiolates. Organomercurial lyase is part of a broad-spectrum mercury resistance system in which a second enzyme, termed mercuric reductase or MerA (gene: *merA*), catalyzes the reduction of Hg^{2+} to Hg^0 with the latter finally diffusing out of the bacterial cell.[21−26] The

three-dimensional structure and the enzymatic mechanism of organomercurial lyase are still unknown. However, a general mechanistic hypothesis proposed by Walsh and coworkers is available.[20,27] One of its key features is the coordination of the substrate RHg^+ to one or two cysteinyl-S^- groups, enhancing the polarity of the Hg−C bond. A Brønsted-acidic group of the enzyme, possibly a cysteinyl-SH, is thought to be the proton donor in the subsequent protonolysis step (for further details see Results and Discussion). In model studies, Barbaro et al. have demonstrated that a high "primary" coordination number of mercury can contribute to the activation of Hg−C bonds. They found that the tetrahedral phosphane complexes $[RHg\{N(CH_2CH_2PPh_2)_3\}]^+$ (R = Me, Ph) were unusually susceptible to protonolytic Hg−C bond cleavage.[28,29] Results of a theoretical study, comparing Hg−C bond cleavage in $[MeHg(PH_3)]^+$ and $[MeHg(PH_3)_3]^+$, agreed with the experimental observations.[30] Metal ion coordination by phosphanes, however, is "non-physiological". Synthetic analogues that more closely mimic the proposed substrate binding by organomercurial lyase are lacking.

In this paper we describe methylmercury(1+) thioether complexes with properties relevant to the suggested mechanism of organomercurial lyase. Our experimental and theoretical study addresses, among other things, the question of Hg−C bond activation by multiple sulfur ligation. Perhaps surprisingly, $MeHg^+$−thioether complexes have low thermodynamic stabilities with typical log *K* values for the formation of 1:1 complexes falling in the range −1 to 2.[31,32] In marked contrast, the stability constants of thioether complexes of Hg^{2+} are by about ten orders of magnitude larger (log *K* = 8−12).[33] This difference may be attributed to "anti-symbiosis" which means that the soft methanido ligand reduces the affinity of mercury(II) for another soft ligand in the *trans* position.[34] So far, only a few organomercury(1+) thioether complexes have been isolated[35] and, to the best of our knowledge, no crystal structures have been determined.[36] In the following, we report the syntheses and X-ray crystal structures of three new $MeHg^+$ complexes with meso- and macrocyclic thioether ligands. Part of this work has been communicated previously.[37]

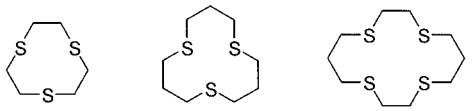
Results and Discussion

Syntheses of the Methylmercury Complexes

A suitable methylmercury starting compound was obtained by treating methylmercury hydroxide with a slight excess of tetrafluoroboric acid in aqueous solution. After removal of the solvent, a colorless oil remained. It is known that in strongly acidic aqueous solutions $[MeHg(OH_2)]^+$ is by far the main $MeHg^+$ species.[38] It therefore seemed safe to assume that the obtained product was $[MeHg(OH_2)](BF_4)\cdot xH_2O$. The complex $[MeHg(OH_2)]^+$ should have a similar structure to $[MeHg(DMSO)]^+$, which contains *O*-coordinated dimethyl sulfoxide in solution as well as in the solid state.[39]

In tetrahydrofuran or acetonitrile/diethyl ether, the thioethers [9]aneS$_3$, [12]aneS$_3$, and [14]aneS$_4$ are capable of displacing the aqua ligand from $[MeHg(OH_2)]^+$ {Equation (1); L = [9]aneS$_3$ or [12]aneS$_3$: *n* = 1; L = [14]aneS$_4$: *n* = 2}.

$$n\,[MeHg(OH_2)](BF_4) + L \rightarrow [(MeHg)_nL](BF_4)_n + n\,H_2O \qquad (1)$$



[9]aneS$_3$ [12]aneS$_3$ [14]aneS$_4$

By this route, we prepared the new coordination compounds $[MeHg([9]aneS_3)](BF_4)$ (**1**), $[MeHg([12]aneS_3)](BF_4)$ (**2**), and $[(MeHg)_2([14]aneS_4)](BF_4)_2$ (**3**). They were isolated as analytically pure, crystalline solids in yields of 85% (**1**), 68% (**2**), and 92% (**3**), respectively. We did not succeed in preparing complexes with different numbers of $MeHg^+$ cations per ligand molecule by variation of the starting material ratios. NMR experiments showed, however, that [12]aneS$_3$ can probably bind more than one $MeHg^+$ group (see below). Compounds **1**−**3** are air-stable and soluble in strongly polar organic solvents such as acetonitrile, nitromethane, and dimethyl sulfoxide.

Crystal Structures of Compounds 1−3

Crystals of $[MeHg([9]aneS_3)](BF_4)$ (**1**) consist of discrete $[MeHg([9]aneS_3)]^+$ cations and BF_4^- anions. The compound crystallizes with two formula units in the asymmetric unit. The two symmetry-independent $[MeHg([9]aneS_3)]^+$ complexes have essentially the same structure (Figure 1). Each of the Hg atoms is in a distorted tetrahedral coordination environment formed by a methanido and a tridentate thioether ligand.[29] One Hg−S bond is shorter than the other two. Nevertheless, all three are "primary" bonds. The shortest Hg−S bond is involved in the largest S−Hg−C angle [complex **1**: 142.7(4)°; complex **2**: 136.4(4)°], demonstrating a slight distortion towards the linear coordination usually preferred in RHg^+ complexes. As expected, the mean Hg−S bond length of the four-coordinate complexes in **1** (2.71 Å) is considerably larger than the Hg−S bond lengths of the two-coordinate complexes in **2** [2.441(4) Å] and **3** [2.425(2) Å]. The Hg−C bond lengths are, however, not significantly different [**1**: 2.080(8), 2.075(8) Å; **2**: 2.11(2) Å; **3**: 2.068(7) Å] and correspond well with the average value of 2.07 Å that was derived from a large number of $MeHg^+$ compounds.[29b] As in the free form,[40] the ligand [9]aneS$_3$ in **1** adopts the [333] conformation.[41,42] Coordination to the $MeHg^+$ group resulted in a small increase of the mean transannular S···S distance from 3.451(2) to 3.489 Å and a decrease of the mean S−C−C−S torsion angle from 58.5 to 56.0°. The maximum change of an individual torsion angle was −4.4° at a C−C bond and +4.6° at an S−C bond.

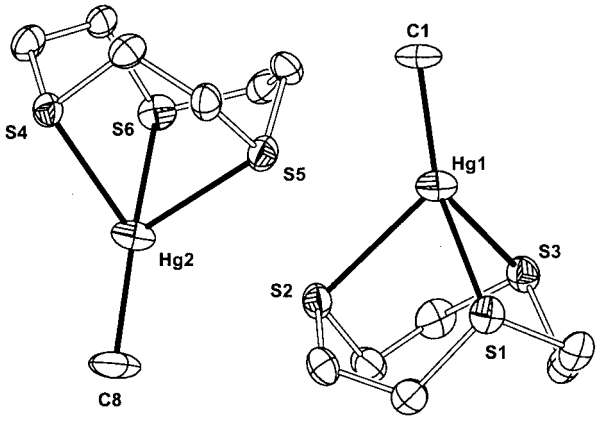

Figure 1. Ellipsoid plot (50% probability level) of the two symmetry-independent $[MeHg([9]aneS_3)]^+$ complexes in **1** showing their mutual orientation in the crystal (hydrogen atoms are omitted); bond lengths [Å] and angles [°]: Hg1−S1 2.611(2), Hg1−S2 2.768(2), Hg1−S3 2.760(2), Hg1−C1 2.080(8), Hg2−S4 2.720(2), Hg2−S5 2.732(2), Hg2−S6 2.677(2), Hg2−C8 2.075(8); S1−Hg1−S2 81.1(1), S1−Hg1−S3 79.6(1), S2−Hg1−S3 79.0(1), S1−Hg1−C1 142.7(4), S2−Hg1−C1 124.9(3), S3−Hg1−C1 127.3(4), S4−Hg2−S5 79.9(1), S4−Hg2−S6 80.4(1), S5−Hg2−S6 80.4(1), S4−Hg2−C8 132.2(3), S5−Hg2−C8 126.6(4), S6−Hg2−C8 136.4(4)

In contrast to the rare tetrahedral coordination observed in **1**, the much more common diagonal coordination of the Hg atom[29] occurs in $[MeHg([12]aneS_3)](BF_4)$ (**2**) and $[(MeHg)_2([14]aneS_4)](BF_4)_2$ (**3**). In addition to the Hg−S and Hg−C "primary" bonds, however, intermolecular "secondary" bonds to the S and F atoms exist in crystals of **2** and **3** (Figures 2 and 3). The sum of the van der Waals radii (R_{vdW}) of the participating atoms usually serves as reference point for establishing the presence of such weak metal−ligand bonds. The R_{vdW} values of Hg^{II} (1.75 Å),[43] S (1.60−2.03 Å), and F (1.30−1.38 Å)[44] give Hg···S and Hg···F van der Waals distances of 3.35−3.78 Å and 3.05−3.13 Å, respectively. The three intermolecular contacts in **2** i.e. two Hg···S and one Hg···F, are below the lower ends of these ranges. In **3**, two Hg···F contacts are at least 0.10 Å shorter than the minimum van der Waals distance. The respective S−Hg···X and C−Hg···X angles (X = S, F) fall within a range reasonable for Hg···X bonding interactions [76.6(4)−101.4(6)°]. Small distortions from linearity of the S−Hg−C angles [**2**: 168.1(6)°; **3**: 174.7(2)°] may be attributed to the influence of the "secondary" bonds. Compared with the free ligand molecules,[45,46] the basic conformations of $[12]aneS_3$ and $[14]aneS_4$ ([3333] and [3434], respectively)[41] are retained in the $MeHg^+$ complexes. The maximum change of a torsion angle between the free and the coordinated forms amounts to ±6−7° both for $[12]aneS_3$ (at S−C) and $[14]aneS_4$ (at S−C and C−C).[47] $[14]aneS_4$ in **3**, as in the free form, possesses a crystallographically imposed center of symmetry.

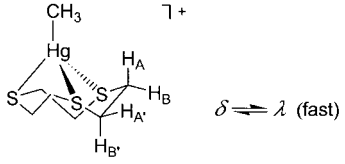
Properties in Solution and Behavior Towards Competing Ligands

At room temperature, **1**−**3** showed rapid ligand exchange resulting in averaged NMR signals for coordinated and free thioether ligands. In suitable solvents, the $[MeHg([9]aneS_3)]^+$ complex of **1** is rather stable against solvolysis. This was demonstrated by an NMR experiment in which increasing amounts of $[MeHg(OH_2)](BF_4)\cdot xH_2O$ were added to a 0.06 M solution of $[9]aneS_3$ in CD_3CN. The $^2J(^1H,^{199}Hg)$ value was found to be independent of the $MeHg^+/[9]aneS_3$ molar ratio in the range of 0.5−0.95:1 and identical to the coupling constant measured for solutions of **1** in CD_3CN. At ratios > 1:1, the carbon atoms of the thioether showed a constant chemical shift identical to that observed for **1**. The two NMR quantities $^2J(^1H,^{199}Hg)$ and $\delta_C(CH_2)$ differ clearly between **1** (237.4 Hz; 30.4 ppm) and the "free" components ($[MeHg(OH_2)]^+$: ca. 260 Hz; $[9]aneS_3$: 35.4 ppm). A marked dissociation equilibrium would be sensitive to an excess of either of the two starting materials, resulting in non-constant values of the NMR parameters. The experimental results thus enabled us to conclude that $[MeHg([9]aneS_3)]^+$ does not strongly dissociate in CD_3CN.

An analogous experiment with $[12]aneS_3$ showed that the $[MeHg([12]aneS_3)]^+$ complex in **2** is markedly dissociated in CD_3CN. At a $MeHg^+/[12]aneS_3$ molar ratio of 0.5:1 the $^2J(^1H,^{199}Hg)$ coupling constant was 221.9 Hz (**2**: 224.2 Hz), indicating a more complete complexation of methylmercury due to the excess of thioether. When the ratio was increased from 1:1 to 4.5:1, a continuous increase in the $^2J(^1H,^{199}Hg)$ value resulted. However, this increase was significantly smaller than expected from the contribution of $[MeHg(OH_2)]^+$ or $[MeHg(NCCD_3)]^+$. This discrepancy can be explained by the binding of more than one methylmercury group per thioether molecule. From the $\delta_C(MeHg)$ values {8.9 ppm at $MeHg^+/[12]aneS_3$ = 1:1; 4.5 ppm at 4.5:1; $[MeHg(OH_2)]^+$: ca. 0.0 ppm} one can easily estimate that at the highest $MeHg^+/[12]aneS_3$ ratio (4.5:1) each thioether ligand binds, on average, slightly more than two $MeHg^+$ cations. Consistent with this picture, the $\delta_C(SCH_2)$ value of the ligand continuously increased from 30.3 ppm (at 1:1) to 32.6 ppm (at 4.5:1). The value for free $[12]aneS_3$ is 28.9 ppm.

Some years ago, Rabenstein suggested that the $^2J(^1H,^{199}Hg)$ coupling constant of the methylmercury group may be utilized as a general indicator of the presence of chelating ligands.[48] Indeed, it has been reported that complexes of potentially chelating ligands of the 2,2′-bipyridyl and 1,10-phenanthroline type have higher values (235.1−239.8 Hz) than those of monodentate pyridine derivatives (225.2−229.6 Hz).[49] A comparison of $[MeHg\{N(CH_2CH_2PPh_2)_3\}]^+$ (174 Hz, CN 4)[28] with $[MeHg(PR_3)]^+$ complexes (167−173 Hz, CN 2)[50] shows the same trend, albeit less pronounced. Accordingly, we observed a higher ^2J value for the tetrahedral complex $[MeHg([9]aneS_3)]^+$ (237.4 Hz) than for the two-coordinate $[MeHg([12]aneS_3)]^+$ species (224.2 Hz). The latter value compares well with coupling constants found for other two-coordinate thioether complexes, e.g. $[MeHg(SMe_2)]^+$ (220.7 Hz),[35b] [MeHg(methionineH)]$^{2+}$ (223 Hz),[32] and $[MeHg(SEt_2)]^+$ (218 Hz; see Exp. Sect.). Surprisingly, $[(MeHg)_2([14]aneS_4)]^{2+}$, which exhibits primary two-coordination in crystals of **3** (see above), has a relatively large coupling constant (231.1 Hz) which is strongly temperature-dependent. Raising the temperature from −30 to +60 °C resulted in an increase by 9.7 Hz (**1**: 1.9 Hz; **2**: 2.6 Hz). One possible explanation is that **3** is more strongly dissociated than, for example, **2**. In this case, the contribution of the dissociation product $[MeHg(NCCD_3)]^+$ would increase the observed (average) ^2J value. Another explanation is supported by the observation that the Hg−C bonds are activated towards protonolytic cleavage in $[(MeHg)_2([14]aneS_4)]^{2+}$ but not in $[MeHg(SEt_2)]^+$ (see below). It is conceivable that in solution, three-coordinate isomers of the former complex exist where the $[14]aneS_4$ ligand forms five-membered HgS_2C_2 chelate rings. This binding situation has a precedent in the complex $[(HgCl_2)_2([14]aneS_4)]$, in which the thioether is simultaneously coordinated to two $HgCl_2$ moieties.[51] Higher temperatures may favor the accompanying ligand conformations which are probably energetically less favored than the one observed in crystalline **3**.

The ^1H NMR spectrum of **1** at −30 °C shows that the tetrahedral structure observed in the solid state is retained in solution. The signal of the CH_2 groups forms a characteristic AA′BB′ (or AA′XX′) pattern[52] in accordance with the presence of three five-membered chelate rings which rapidly alternate between the λ and δ conformations (Scheme 1).



Scheme 1

Upon raising the temperature, this pattern collapses into a broad and finally, at 60 °C, a sharp singlet, obviously because of fast exchange of the thioether ligand. Between −30 °C and room temperature, $^2J(^1H,^{199}Hg)$ (see above) and the coordination-induced chemical shifts of **1** are practically temperature-independent. For example, the relative shift of the CH_2 groups $\Delta\delta_C = \delta_C(\text{coordinated}) - \delta_C(\text{free ligand})$ has a constant value of −5.0 ppm in CD_3CN. It can therefore be concluded that the tetrahedral structure is also present at room temperature. In the room temperature ^1H and ^{13}C NMR spectra of **2** and **3**, the number of observed resonances is less than would be expected from the solid-state structures. This can be explained either by fast thioether ligand exchange as in the case of **1**, fast intramolecular migration of the $MeHg^+$ group(s) at the macrocycle via intermediate chelates, or both. At −30 °C, the number and multiplicity of the signals remain unchanged. Thus, at this

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

temperature, at least one of these processes cannot be "frozen" as opposed to the ligand exchange in **1**.

The relative stability of $[MeHg([9]aneS_3)]^+$ towards a number of neutral or monoanionic potential ligands, $L^{(-)}$, was studied by NMR spectroscopy. In this study, fast ligand exchange at room temperature proved beneficial because it resulted in only one ^{13}C NMR signal for mixtures of coordinated and released $[9]aneS_3$. The position of this signal between the two extremes, δ_C(coordinated) = 29.5 ppm and δ_C(free ligand) = 33.9 ppm, gave a qualitative indication of the position of equilibrium [Equation (2)].

$$[MeHg([9]aneS_3)]^+ + L^{(-)} \leftrightarrows [MeHgL]^{(+)} + [9]aneS_3 \quad (2)$$

The δ_C values are given for solutions in $[D_6]$DMSO, which was used for solubility reasons. The solutions were initially 50 mM in each of the two components **1** and $L^{(-)}$. L^- anions were introduced as their Et_4N^+ salts. It appeared that the position of the equilibrium according to Equation (2) was far to the left side when L^- was an oxo anion with a largely delocalized charge such as $CF_3SO_3^-$, *p*-$CH_3C_6H_4SO_3^-$ or NO_3^-. With $L^{(-)} = CH_3CO_2^-$, F^-, Cl^-, Br^-, I^- or PPh_3, however, complete substitution of the thioether ligand was observed. An intermediate situation occurred with $L^{(-)} = CF_3CO_2^-$ or NEt_3 where the equilibrium concentrations of $[MeHg([9]aneS_3)]^+$ and $[MeHgL]^{(+)}$ were of the same order of magnitude. As expected, the monodentate ligand $[12]aneS_3$ cannot displace the tridentate $[9]aneS_3$ (experiment conducted in CD_3CN). In summary, it can be concluded that $[9]aneS_3$ is an unusually strong ligand for $MeHg^+$ when compared with other thioethers, but still a rather weak ligand on an absolute scale, comparable for example with trifluoroacetate.

Hypothetical Reaction Mechanism of Organomercurial Lyase

The bacterial enzyme organomercurial lyase catalyzes the simple reaction shown in Equation (3) (R = alkyl, aryl). A model for the reaction mechanism of this enzyme was proposed some years ago[20,27] (see Introduction) and has very recently been refined.[53] It consists of at least four steps (Scheme 2).

$$RHg^+ + H^+ \rightarrow Hg^{2+} + RH \quad (3)$$

Step 1: Enz(-SH)$_2$ + RHg(SR') ⇌ HS-Enz-SHgR + R'SH

Step 2: HS-Enz-SHgR ⟶ Enz-S$_2$Hg + RH

Step 3: Enz-S$_2$Hg + R'SH ⇌ HS-Enz-SHg(SR')

Step 4: HS-Enz-SHg(SR') + R'SH ⇌ Enz(-SH)$_2$ + Hg(SR')$_2$

Scheme 2. Reaction steps in the mechanism of organomercurial lyase (Enz = enzyme)

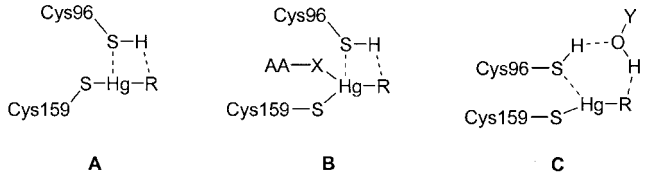
In the first step, a cysteinyl-SH group of the enzyme protonates and displaces an exogenous thiolate, such as the anion of cysteine or glutathione (R′SH), thereby binding the RHg^+ cation at the active site. There the key step follows, namely the protonolytic Hg−C bond cleavage, in which a second SH group of the enzyme is involved (step 2). In the last two steps, exogenous thiolates coordinate to the product Hg^{2+} and finally remove it from the enzyme. Pitts and Summers proposed that Cys159[54] could be the primary ligand for the substrate RHg^+ (step 1), while Cys96 donates the proton in step 2.[53] They also pointed out that further amino acid residues, for example Tyr93 and Cys117, are possible candidates as ligands and/or proton donors. The latter is also one of three highly conserved cysteines, besides Cys96 and Cys159. However, there are indications that Cys117 may have no catalytic function.

From the viewpoint of coordination chemistry, step 2 is the most intriguing one. It raises the question of how the Hg−C bond is activated for protonolysis. From model studies on phosphane[28] and thioether complexes (this work), it seems less likely that sufficient activation of the Hg−C bond is possible in the binding situation depicted in Scheme 3 (A). Here, Cys96 can only act as a weak thiol donor and has a spatial orientation typical of secondary ligands. Scheme 3 (B) shows the original proposal[20,27] extended by recent biochemical results.[53] The mercury atom is three-coordinate, and therefore an enhanced polarity and a significant activation of the Hg−C bond may be expected. In Scheme 3 (C) we suggest a model that carries features of both previous ones and takes into account the occurrence of several conserved OH-containing amino acid residues in the enzymes. In this model, activation and protonation depend on the participation of Y−OH, which represents an alcoholic or a phenolic amino acid residue. Alternatively Y−OH could be a water molecule, which may be involved in hydrogen bonding to an OH-containing side chain. The oxygen atom of Y−OH simultaneously serves as proton acceptor (from Cys96−SH) and donor (to R^-). Proton withdrawal from Cys96−SH imposes thiolate character on the sulfur atom. This, together with the overall spatial arrangement, would allow the formation of a second primary Hg−S bond. Candidates for Y−OH include the conserved residues Thr77, Thr81, Tyr93, Ser115, and Thr120. In addition, the ligand AA−X^- (shown in Scheme 3, B) could also be present here. The model in Scheme 3 (C) is purely hypothetical but it is supported by results of quantum chemical calculations, which are presented below. It might be tested experimentally on suitable site-directed mutants.

Protonolysis of Hg−C Bonds in Methylmercury Thioether Complexes

The four-coordinate complex $[MeHg([9]aneS_3)]^+$ offered the opportunity of studying, for the first time, the effect of multiple sulfur ligation on the reactivity of the Hg−C bond. The very strong Brønsted acid CF_3SO_3H in $[D_3]$nitromethane was used as proton donor.[55] An additional equivalent of $[9]aneS_3$ was employed in order to trap the reaction product Hg^{2+} as $[Hg([9]aneS_3)_2]^{2+}$. After the protonolysis step, the thioether is thus functionally similar to the exogenous thiols in the mechanism of organomercurial lyase

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3. Proposals for the key step of the reaction mechanism of organomercurial lyase; A: with only Cys96 and Cys159 being involved; B: with a further primary ligand $AA-X^-$, for example Tyr93 (X = O) or Cys117 (X = S); C: with participation of an additional amino acid (or water) Y–OH as a simultaneous proton donor and acceptor

(steps 3 and 4). The overall reaction can be expressed by Equation (4).

$$[MeHg([9]aneS_3)]^+ + CF_3SO_3H + [9]aneS_3 \rightarrow [Hg([9]aneS_3)_2]^{2+} + CF_3SO_3^- + CH_4 \quad (4)$$

Methane was identified as one of the reaction products by using deuterated acid. In the CF_3SO_3D-containing system, a mixture of CH_3D and CH_4 formed due to the presence of traces of H_2O (see below). For CH_3D we measured $^2J(H,D) = 1.9$ Hz and a deuterium isotope effect $\delta_H(CH_3D) - \delta_H(CH_4) = -15.3$ ppb in [D$_3$]nitromethane. These results are in good agreement with very accurately measured values in different solvents, for example in [D$_6$]-acetone: 1.9361 ± 0.0008 Hz and −15.555 ± 0.002 ppb.[56] The reaction product $[Hg([9]aneS_3)_2]^{2+}$ could be isolated as crystalline $[Hg([9]aneS_3)_2](BF_4)_2 \cdot 2\,CH_3CN$ (**4**) when the reaction was carried out in acetonitrile with HBF_4 instead of CF_3SO_3H [Equation (5)].

$$[MeHg([9]aneS_3)](BF_4) + HBF_4 + [9]aneS_3 \xrightarrow{CH_3CN} [Hg([9]aneS_3)_2](BF_4)_2 \cdot 2CH_3CN + CH_4 \quad (5)$$

Compound **4** was obtained in 72% yield. Its identity was confirmed by comparison with a sample that had been prepared independently from $HgPh_2$, HBF_4, and [9]aneS$_3$. Compound **4** was characterized, inter alia, by an X-ray structural analysis. In the crystals, the $[Hg([9]aneS_3)_2]^{2+}$ cation is located on a crystallographic center of inversion. The six sulfur atoms form a distorted octahedral coordination environment around the metal atom (see Figure 4). The molecular structure will not be further discussed here, since it is similar to those of other $[Hg([9]aneS_3)_2]^{2+}$ salts whose structures have already been described in the literature.[57]

The progress of the reaction according to Equation (4) was monitored by NMR spectroscopy, but attempts to determine kinetic data were unsuccessful because the measurements were impaired by unavoidable traces of water (ca. 0.3 equiv.). The effect of water could be demonstrated by intentionally adding 1 equiv., which almost entirely suppressed the protonolysis reaction. However, as the water content was the same in all experiments, it was possible to obtain semi-quantitative values to compare the relative reactivities of different $MeHg^+$ complexes. We found for example, that under the conditions described in the Exp. Sect., the degree of protonolysis reached ca. 25% for both **1** and **3** after 1 h. In contrast, $[MeHg(SEt_2)]^+$ and MeHgCl showed no detectable reaction even after 24 h. MeHgCl is known to be resistant towards strong acids; concentrated hydrochloric acid, for example, causes less than 1% protonolysis after 100 min.[58] This is despite the fact that chloride forms a stronger 1:1 $MeHg^+$ complex than [9]aneS$_3$, as our competition experiments have shown (see above). It therefore seems very likely that the higher coordination number in $[MeHg([9]aneS_3)]^+$ compared with MeHgCl is the most crucial factor in Hg–C bond activation. The large difference in reactivity between $[(MeHg)_2([14]aneS_4)]^{2+}$, which is two-coordinate in crystals of **3**, and $[MeHg(SEt_2)]^+$ appears to contradict this conjecture. However, the $^2J(^1H,^{199}Hg)$ value indicates that in solutions of **3**, the coordination number of mercury may exceed 2, as already discussed. In order to better understand the role of the coordination number, quantum chemical calculations were carried out.

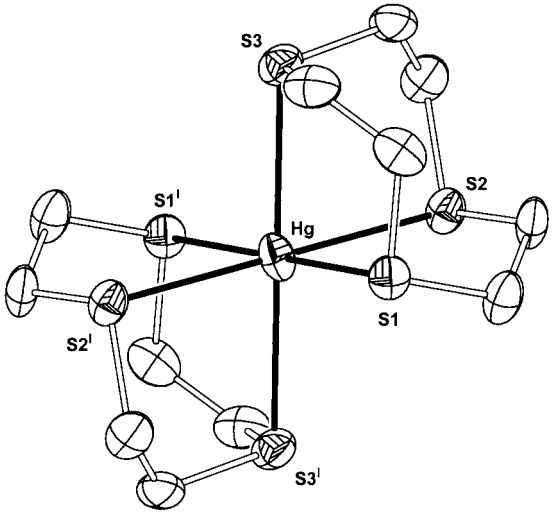


Figure 4. Ellipsoid plot (50% probability level) of the $[Hg([9]aneS_3)_2]^{2+}$ complex in crystals of **4** (hydrogen atoms are omitted); bond lengths [Å] and angles [°]: Hg–S1 2.677(1), Hg–S2 2.660(1), Hg–S3 2.711(1); S1–Hg–S2 83.69(3), S1–Hg–S3 82.49(3), S1–Hg–S1^I 180.0, S1–Hg–S2^I 96.31(3), S1–Hg–S3^I 97.51(3), S2–Hg–S3 83.14(3), S2–Hg–S2^I 180.0, S2–Hg–S3^I 96.86(3), S3–Hg–S3^I 180.0; symmetry transformation: ^{I}: $-x, 1-y, -z$

Results of Quantum Chemical Calculations

In the following, structural properties[59] such as metrical data as well as NMR chemical shifts and mechanistic pathways for Hg–C bond activation[60] have been examined. In order to obtain reliable data, for example on coordination-induced chemical shifts, it is of the utmost importance to find a method/basis set combination that allows the accurate description of the molecules studied herein. In a first attempt, we therefore employed several ab initio and density functional theoretical approaches to reproduce the structure of the $[MeHg([9]aneS_3)]^+$ cation of **1**, the main focus

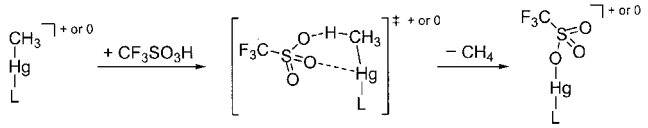
[a] In the discussion this level of theory is denoted MP2/I.

being on the Hg−C and Hg−S bond lengths. Table 1 summarizes the results. In each case, the basic structural feature of the complex, i.e. the tetrahedral coordination of mercury, is reproduced. The necessity of including a large basis set as well as an effective core potential can be clearly seen from the DFT calculations.[61] However, the Hg−S bonds were still much too long. Only the treatment at the correlated level[62] gave good agreement for these distances. Therefore the last method from Table 1 was used for the subsequent NMR calculation. Interestingly, the bond lengths were also well reproduced by the AM1 method. However, despite the good semiempirical description of the experimental structure, all evaluated ab initio calculations of NMR chemical shifts based on both AM1 and PM3 geometries failed to give satisfactory results.

As mentioned before, a reliable structure is indispensable for the evaluation of NMR chemical shifts in general,[63] and for organomercury compounds in particular.[64] The approach used herein applied the MP2-GIAO method[65] together with the SDD basis set and an ECP on mercury,[66] and the 6-31+G(d,p) basis set[67] on the remaining atoms based on the MP2-optimized geometries of $[MeHg([9]aneS_3)]^+$ and $[9]aneS_3$. Experimentally, a coordination-induced shift of −5.0 ppm (from 35.4 to 30.4 ppm) was observed for the CH_2 carbon atoms of the thioether ligand (see above). Such a high-field shift is perhaps counter-intuitive. However, it was reproduced quite accurately by our theoretical model: the averaged ^{13}C NMR shift changed by −7.4 ppm (from 38.9 to 31.5 ppm) when $[9]aneS_3$ underwent coordination. The ^{13}C NMR signal position of the methanido ligand of $[MeHg([9]aneS_3)]^+$, which has been found experimentally at 0.7 ppm, was also satisfactorily reproduced by theory (at $\delta = -3.1$ ppm).

The protonolytic cleavage of $Hg-CH_3$ bonds by trifluoromethanesulfonic acid has been investigated at several levels of theory (for pertinent experimental results see above). This includes the transition state for the proton transfer from CF_3SO_3H to methylmercury complexes of the type $[MeHgL]^{+\text{ or }0}$ leading to methane and, initially,



Scheme 4. Pathway of the reaction between $[MeHgL]^{+\text{ or }0}$ and trifluoromethanesulfonic acid (L = Cl^-, SEt_2, $MeSCH_2CH_2SMe$, or $[9]aneS_3$)

$[(CF_3SO_3)HgL]^{+\text{ or }0}$ (Scheme 4). The latter can further react with another L to yield $[HgL_2]^{2+\text{ or }0}$.

The results of the MP2/I calculations (see Table 1 for basis set explanation) show that the hydrogen transfer activation barriers for the two complexes with digonal mercury coordination are similar, namely 23 kcal·mol^{-1} for MeHgCl and 20 kcal·mol^{-1} for $[MeHg(SEt_2)]^+$. Significantly lower activation barriers were found for the complexes with higher coordination numbers of mercury: 14 kcal·mol^{-1} for $[MeHg(MeSCH_2CH_2SMe)]^+$ (CN 3) and 12 kcal·mol^{-1} for $[MeHg([9]aneS_3)]^+$ (CN 4). This confirms the above described experimental finding that multiple sulfur ligation activates Hg−CH_3 bonds towards protonolytic cleavage. The possible relevance for the enzymatic reaction mechanism is obvious.

Finally, we sought an answer for the possible involvement of OH-containing amino acid residues in the enzymatic reaction mechanism. The model investigated consists of methylmercury methanethiolate i.e. MeHg(SMe), to which a proton is transferred from methanethiol, either directly or by assistance from methanol. Our model corresponds to the situations depicted in Scheme 3 (A and C). Optimization of the two proton transfer transition states at the MP2/I level of theory (Figure 5) demonstrates a clear preference of 14 kcal·mol^{-1} for the six-membered transition structure TS2 which involves the additional hydroxy group. The activation energies for the two pathways are 39 and 25 kcal·mol^{-1}, respectively. Although these values are still high for an enzymatic reaction this model shows, that the involvement of OH groups can significantly lower the activation barrier for protonolytic Hg−C bond cleavage, and should therefore be considered when discussing possible reaction mechanisms of organomercurial lyase.

Conclusions

The following are the principal results and conclusions of this work: (i) Complexes between the methylmercury(1+) cation and the cyclic thioethers [9]aneS_3, [12]aneS_3, and [14]aneS_4 are isolable as crystalline tetrafluoroborates $[MeHg([9]aneS_3)](BF_4)$ (**1**), $[MeHg([12]aneS_3)](BF_4)$ (**2**), and $[(MeHg)_2([14]aneS_4)](BF_4)_2$ (**3**), respectively, in good yields. In **2** and **3**, Hg^{II} has an unexceptional linear coordination. In **1**, however, the thioether acts as a tridentate ligand. The resultant tetrahedral metal coordination is rarely found in organomercury compounds. (ii) The unusual coordination has a distinct influence on the reactivity of $[MeHg([9]aneS_3)]^+$. This complex is significantly more stable to substitution of its sulfur ligand than other $MeHg^+$−thioether complexes. Besides, its Hg−C bond is much more susceptible to cleavage by a strong Brønsted acid than the Hg−C bonds in linear coordinated $[MeHg(SEt_2)]^+$ or MeHgCl. Quantum chemical calculations confirm that the coordination number is an important factor in Hg−C bond activation. (iii) Our experimental and theoretical findings strengthen the hypothesis that multiple sulfur coordination, in this case by cysteinyl S atoms, plays a key role in the mechanism of organomercurial lyase. Assistance by an OH group, for example from an amino acid side chain, could further facilitate the protonolytic Hg−C bond cleavage in the enzyme's active site.

Experimental Section

Safety Precautions: Soluble mercury(II) compounds are highly toxic. In addition to the precautions routinely taken when toxic metal species are handled, further protection measures are necessary when working with methylmercury ($MeHg^+$).[10,11,68] In particular, laminate gloves that are specially designed for chemical resistance (Silver Shield) should be worn under neoprene or nitrile gloves. Disposable latex gloves are not sufficient! Medical surveillance of the mercury concentration in the blood should be considered for those repeatedly working with methylmercury compounds. Methylmercury-containing wastes can be treated with strong oxidants, for example aqua regia, to give inorganic mercury (Hg^{2+}). Using the "supertoxic" compound dimethylmercury as an Hg NMR standard is not to be recommended (see below).

Instrumentation: ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded at 300 K with a Bruker DPX 300 or a DRX 500 instrument. Chemical shifts are given relative to TMS (δ = 0 ppm). $^{199}Hg\{^1H\}$ NMR spectra were recorded with the DRX 500 spectrometer at 290 K. A 0.10 M solution of $Hg(ClO_4)_2$ in 0.10 M perchloric acid in D_2O served as an external standard.[69,70] The standard was prepared as follows: in a 1-mL volumetric flask, D_2O was added to yellow HgO (21.7 mg, 0.100 mmol) and $DClO_4$ (26.4 μL of a 68% solution in D_2O, ρ = 1.694 g·cm^{-3}, 0.300 mmol); after ca. 30 min, the HgO had completely dissolved, and the flask was filled to the mark. ^{199}Hg chemical shifts were referenced to neat $HgMe_2$ (δ_{Hg} = 0 ppm) with this solution (δ_{Hg} = −2250 ppm on the $HgMe_2$ scale). IR spectra (KBr pellets) were obtained with a Bio-Rad FTS 7PC spectrometer. Mass spectra were measured with a Finnigan MAT 212 instrument. Melting points were determined in unsealed glass capillaries. Elemental analyses were performed by the Mikroanalytisches Labor Pascher, Remagen (Germany).

Starting Materials: The ligand 1,5,9-trithiacyclododecane ([12]aneS_3) was prepared according to a literature method starting from bis(3-hydroxypropyl) sulfide.[45] The other starting materials, including methylmercury hydroxide (1 M aqueous solution, Alfa Aesar), were purchased from commercial sources and used as received. The solvents were of reagent grade.

Preparation of $[MeHg([9]aneS_3)](BF_4)$ (1): HBF_4 (150 μL of a 50% aqueous solution, ρ = 1.38 g·cm^{-3}, 1.2 mmol) was added to MeHgOH (1.00 mL of a 1 M aqueous solution, 1.0 mmol). After 12 h, the solution was concentrated in vacuo to give a colorless oil, which was redissolved in tetrahydrofuran (2 mL). A solution of [9]aneS_3 (180 mg, 1.00 mmol) in tetrahydrofuran (5 mL) was added dropwise whilst stirring. A white, microcrystalline solid formed immediately. After stirring for 12 h, the reaction was complete, and the solid was collected on a glass filter, washed with tetrahydrofuran and dried under vacuum. Yield: 412 mg (85%). M.p. ca. 190 °C (dec.). ^1H NMR (300 MHz, CD_3CN, 40 mM): δ = 1.09 [s with satellites, $^2J(^1H,^{199}Hg)$ = 237.4 Hz, 3 H; $HgCH_3$], 3.09 (br. s, 12 H, CH_2) ppm. ^{13}C NMR (75.5 MHz, CD_3CN, 40 mM): δ = 0.7 ($HgCH_3$, superposed by solvent signal[71]), 30.4 (CH_2) ppm. ^{199}Hg NMR (89.6 MHz, CD_3CN, 40 mM): δ = −194 ppm. IR: $\tilde{\nu}$ = 2920 (w), 1449 (m), 1410 (m), 1287 (m), 1161 (w), 1144 (w), 1047 (s, br), 1036 (s, br), 926 (m), 889 (m), 816 (m), 783 (m), 521 cm^{-1} (m). MS

(CI, isobutane): *m/z* (%) = 397 (2) $[MeHg([9]aneS_3)]^+$, 181 (100) $[[9]aneS_3 + H]^+$. $C_7H_{15}BF_4HgS_3$ (482.8): calcd. C 17.41, H 3.13, Hg 41.55, S 19.93; found C 17.35, H 3.03, Hg 41.2, S 19.8.

Preparation of $[MeHg([12]aneS_3)](BF_4)$ (2): HBF_4 (75 μL of a 50% aqueous solution, ρ = 1.38 g·cm^{-3}, 0.6 mmol) was added to MeHgOH (0.50 mL of a 1 M aqueous solution, 0.5 mmol). After 12 h, the solution was concentrated in vacuo to give a colorless oil, to which $[12]aneS_3$ (111 mg, 0.50 mmol), dissolved in acetonitrile (5 mL), was added. The reaction flask was connected to another flask that contained diethyl ether. During the next 7 d the diethyl ether was allowed to diffuse into the reaction mixture through the gas phase. A colorless, crystalline solid formed, which was collected on a glass filter, washed with tetrahydrofuran and dried under vacuum. Yield: 179 mg (68%). M.p. ca. 166 °C (dec.). ^{1}H NMR (300 MHz, CD_3CN): δ = 1.11 [s with satellites, $^2J(^1H,^{199}Hg)$ = 224.2 Hz, 3 H, $HgCH_3$], 1.99 (quint, $^3J_{H,H}$ = 6.6 Hz, 6 H, $CH_2CH_2CH_2$), 2.93 (t, $^3J_{H,H}$ = 6.6 Hz, 12 H, SCH_2) ppm. ^{13}C NMR (75.5 MHz, CD_3CN): δ = 8.9 ($HgCH_3$), 27.0 ($CH_2CH_2CH_2$), 30.3 (SCH_2) ppm. ^{199}Hg NMR (89.6 MHz, CD_3CN, 40 mM): δ = −886 ppm. IR: ṽ = 2926 (w), 1449 (m), 1431 (m), 1416 (m), 1300 (w), 1260 (m), 1250 (m), 1177 (w), 1049 (s, br), 1030 (s, br), 793 (m), 756 (m), 519 cm^{-1} (m). C 22.88, H 4.03, Hg 38.22, S 18.33; found C 22.88, H 3.90, Hg 38.4, S 18.3.

Preparation of $[(MeHg)_2([14]aneS_4)](BF_4)_2$ (3): HBF_4 (150 μL of a 50% aqueous solution, ρ = 1.38 g·cm^{-3}, 1.2 mmol) was added to MeHgOH (1.00 mL of a 1 M aqueous solution, 1.0 mmol). After 12 h, the solution was concentrated in vacuo to give a colorless oil, to which $[14]aneS_4$ (134 mg, 0.50 mmol), dissolved in acetonitrile (5 mL), was added. The reaction flask was connected to another flask that contained diethyl ether. During the next 4 d the diethyl ether was allowed to diffuse into the reaction mixture through the gas phase. Small, plate-like crystals formed, which were collected on a glass filter, washed with a small amount of tetrahydrofuran and dried under vacuum. Yield: 403 mg (92%). M.p. ca. 129 °C (dec.). ^{1}H NMR (500 MHz, CD_3CN): δ = 1.16 [s with satellites, $^2J(^1H,^{199}Hg)$ = 231.1 Hz, 6 H, $HgCH_3$], 2.10 (quint, $^3J_{H,H}$ = 7.3 Hz, 4 H, $CH_2CH_2CH_2$), 3.05 (t, $^3J_{H,H}$ = 7.3 Hz, 8 H, $CH_2CH_2CH_2$), 3.26 (s, 8 H, SCH_2CH_2S) ppm. ^{13}C NMR (125.8 MHz, CD_3CN): δ = 7.6 ($HgCH_3$), 30.2 ($CH_2CH_2CH_2$), 32.7 ($CH_2CH_2CH_2$), 33.3 (SCH_2CH_2S) ppm. IR: ṽ = 2942 (w, br), 1445 (m), 1287 (w), 1215 (w), 1182 (m), 1084 (s, br), 1051 (s, br), 1036 (s, br), 789 (m), 521 cm^{-1} (m). MS (CI, isobutane): *m/z* (%) = 485 (2) $[MeHg([14]aneS_4)]^+$, 351 (6) $[MeHg([7]aneS_2)]^+$,[72] 107 (100) $[C_3H_6S_2$ (dithiolane) + $H]^+$. $C_{12}H_{26}B_2F_8Hg_2S_4$ (873.4): calcd. C 16.50, H 3.00, Hg 45.93, S 14.69; found C 16.75, H 3.00, Hg 45.7, S 14.7.

Preparation of $[Hg([9]aneS_3)_2](BF_4)_2 \cdot 2\ CH_3CN$ (4). Method A: Diphenylmercury (177 mg, 0.50 mmol) and $[9]aneS_3$ (180 mg, 1.00 mmol) were dissolved in tetrahydrofuran (10 mL). Addition of HBF_4 (152 μL of a 54% solution in diethyl ether, ρ = 1.19 g·cm^{-3}, 1.1 mmol) resulted in the immediate precipitation of a white, microcrystalline solid. After 6 h, the solid was collected on a glass filter, washed with tetrahydrofuran and redissolved in acetonitrile (20 mL) in a flask, which then was connected to another flask containing diethyl ether. During the next 5 d the diethyl ether was allowed to diffuse into the solution through the gas phase. Colorless, elongated tabular crystals formed, which were collected on a glass filter, washed with tetrahydrofuran and briefly dried under vacuum. Yield: 358 mg (88%). M.p. ca. 189 °C (dec.). ^{1}H NMR (300 MHz, CD_3CN): δ = 1.96 (s, ca. 6 H, CH_3CN), 2.9−3.3 (m, 24 H, SCH_2) ppm. ^{13}C NMR (75.5 MHz, CD_3CN): δ = 28.3 (SCH_2) ppm. ^{199}Hg NMR (89.6 MHz, CD_3CN, 40 mM): δ = −305 ppm. IR: ṽ = 2911 (w), 2899 (w), 2249 (w), 1443 (m), 1408 (m), 1300 (sh), 1285 (m), 1059 (s, br), 1036 (s, br), 920 (m), 883 (m), 822 (m), 534 (m), 521 (m), 424 cm^{-1} (m). MS (CI, isobutane): *m/z* (%) = 181 (100) $[[9]aneS_3 + H]^+$, 121 (97) $[C_4H_8S_2$ (dithiane) + $H]^+$. $C_{16}H_{30}B_2F_8HgN_2S_6$ (817.0): calcd. C 23.52, H 3.70, Hg 24.55, N 3.43, S 23.55; found C 23.58, H 3.57, Hg 25.0, N 3.15, S 23.9. **Method B:** HBF_4 (136 μL of a 54% solution in diethyl ether, ρ = 1.19 g·cm^{-3}, 1.0 mmol) was added whilst stirring to a solution of **1** (96 mg, 0.20 mmol) and $[9]aneS_3$ (36 mg, 0.20 mmol) in acetonitrile (5 mL). After stirring for ca. 30 min, the reaction mixture was stored at ca. 0 °C. After 24 h, colorless crystals of **4** had formed, which were collected on a glass filter, washed with a small amount of an ice-cold acetonitrile/diethyl ether mixture (1:1, v/v) and briefly dried under vacuum. Yield: 117 mg (72%). The ^{1}H and ^{13}C NMR spectra and the IR spectrum were identical to those of the material prepared by Method A.

Estimation of the Rates of Protonolysis: Solutions for the NMR measurements were prepared in a stream of dry nitrogen as a protection against atmospheric moisture. A typical experiment was conducted as follows. **1** (48.3 mg, 100 μmol) and $[9]aneS_3$ (18.0 mg, 100 μmol) were weighed out in a 1-mL volumetric flask, which had been flushed with dry nitrogen. Hexamethylbenzene (300 μL of a 50 mM stock solution in $[D_3]$nitromethane, 15.0 μmol) was then added, which served as a reference standard for determining the concentration change of methylmercury. After addition of $[D_3]$nitromethane (ca. 0.3 mL), the flask was shaken until a clear solution was obtained. Trifluoromethanesulfonic acid (98 μL of a 1.02 M stock solution in $[D_3]$nitromethane, 100 μmol) was then added. After briefly shaking, the flask was filled to the mark with $[D_3]$nitromethane. After shaking again, most of the solution was immediately transferred to an NMR tube, which had been flushed with dry nitrogen. The tube was sealed with a standard cap and parafilm. The initial ^{1}H NMR spectrum was measured typically 8 min after addition of the acid. Subsequent spectra were recorded every 3 min during the first 30 min, and later at increasingly longer time intervals. The temperature was kept at 20 °C. NMR spectroscopic data were collected over a period of ca. 6 h. The ^{1}H NMR spectra were analyzed by measuring the change of the integral intensity of the $MeHg^+$ signal (at δ = 1.10 ppm) relative to the signal of hexamethylbenzene (at δ = 2.19 ppm). For **3**, MeHgCl, and $[MeHg(SEt_2)]^+$ the sample preparations and measuring conditions were similar to those described above. However, the concentrations were adjusted less rigorously, and much longer time intervals between successive measurements were chosen because the main purpose was to establish whether the reaction had occurred at all. Between measurements, the NMR samples were stored at 20 °C. In the case of **3** (0.04 M solution), two moles of trifluoromethanesulfonic acid per mole of complex were applied and no hexamethylbenzene was added. Instead, the intensity of the $CH_2CH_2CH_2$ ligand signal served as a reference. It occurred at δ ≈ 2.45 ppm and, later, split to give an additional signal at δ = 2.36 ppm, which was assigned to the product complex(es) that formed as a result of the protonolysis. The MeHgCl solution was 0.07 M, and contained a known concentration (0.02 M) of hexamethylbenzene. $[MeHg(SEt_2)]^+$ was prepared in situ. To this end, aqueous solutions of MeHgOH (0.30 mmol) and HBF_4 (0.36 mol) were mixed. After 1 h, the reaction solvents were evaporated in vacuo. The residue was dissolved in nitromethane (ca. 0.7 mL), and the resultant solution was concentrated again. This procedure was repeated four times in order to remove water and excess HBF_4. The residue was then dissolved in $[D_3]$nitromethane (1.0 mL). Addition of 1 equiv.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of diethyl sulfide resulted in a sharp decrease in the $^2J(^1H,^{199}Hg)$ coupling constant from 251 to 218 Hz, indicating the formation of $[MeHg(SEt_2)]^+$ {^{1}H NMR (300 MHz, [D$_3$]nitromethane): δ = 1.17 [s with satellites, $^2J(^1H,^{199}Hg)$ = 218 Hz, 3 H, $HgCH_3$], 1.55 (t, $^3J_{H,H}$ = 7.3 Hz, 6 H, CH_2CH_3), 3.49 (q, $^3J_{H,H}$ = 7.3 Hz, 4 H; SCH_2)}. Finally, 1 equiv. of trifluoromethanesulfonic acid was added. The intensity of the SCH_2 signal of the thioether served as a reference.

X-ray Crystallography: Crystal data and details of the data collections and structural refinements are summarized in Table 2. The crystals were embedded in perfluoropolyalkyl ether (viscosity 1600 cSt., m.p. −20 °C; ABCR, Karlsruhe, Germany) and placed into glass capillaries. The capillaries were sealed and transferred into the cold gas stream of a STOE IPDS area detector diffractometer. Mo-K_α radiation (λ = 0.71073 Å) was used for intensity data collection. The measuring temperature was 193 K. Numerical absorption corrections were applied to the data. The structures were solved by direct methods and refined on F^2 values. Anisotropic displacement parameters were refined for the non-hydrogen atoms, except for the C atom of the $MeHg^+$ group of compound **2**, which gave unreasonable values on anisotropic refinement. All hydrogen atoms were included in idealized positions by use of riding models. Programs used were those of the SHELX-97 software package[73] and DIAMOND for the graphical representations.[74] **1:** Single crystals were grown by diffusion of diethyl ether through the gas phase into a solution of **1** in acetonitrile. The four largest peaks in the final difference map are located at distances < 0.9 Å from the Hg atoms. The remaining difference peaks are smaller than 0.7 e·Å^{-3}. **2:** A method similar to that described above for this compound yielded suitable single-crystals. The structure was successfully refined in the non-centrosymmetric space group *Cc*. The absolute structure parameter was −0.05(2) for the final model. **3:** Suitable single crystals were obtained using a procedure similar to that described above for this compound, however with use of a 1:1 ratio of the starting materials $[MeHg(OH_2)](BF_4)\cdot xH_2O$ and [14]aneS$_4$. **4:** Suitable single crystals were obtained by slow diffusion of diethyl ether through the gas phase into a solution of $[PhHg([9]aneS_3)](BF_4)$ in acetonitrile. Under these conditions, symmetrization of the $PhHg^+$ compound to **4** and $HgPh_2$ occurred.[37a] The BF_4^- anion is disordered; its F atoms were refined on two positions with an occupancy ratio of 2:1. CCDC-207378 (**1**), -207379 (**2**), -207380 (**3**), and -207381 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Computational Methods: The semiempirical calculations (AM1[75] and PM3[76]) employed the program package MOPAC 2002,[77] while the ab initio and DFT calculations were performed with Gaussian 98.[78] With the exception of a single B3LYP/LANL2DZ[79] optimization, all calculations at the correlated MP2 or the DFT BP86,[80] and the hybrid functional B3LYP[81][82] levels of theory used the Stuttgart/Dresden SDD basis set and the effective core potential for Hg.[66] The remaining atoms were described with the 6-31G(d) or 6-31+G(d,p) basis sets.[67] In two cases the SDD basis sets were added to these Pople bases. Local minima and transition states were verified by determination of the number of imaginary frequencies. Details of the NMR chemical shift calculations are given in the Results and Discussion section.

Synthesis, Crystal Structures and Electrical Conductivities of the Ionic Liquid Compounds Butyldimethylimidazolium Tetrafluoroborate, Hexafluorophosphate and Hexafluoroantimonate

Philipp Kölle[a] and Richard Dronskowski*[a]

Keywords: Electrochemistry / Ionic liquids / Packing efficiency / X-ray diffraction

The crystal structures of three very low-melting ionic liquid (IL) salts containing the 1-butyl-2,3-dimethylimidazolium cation and the fluoro anions BF_4^-, PF_6^- and SbF_6^- are reported. These are considered model compounds for ambient temperature ionic liquids, which are currently being explored as solvents for various types of synthetic reactions. All three compounds adopt significantly different structures in the solid state, highlighting the influence of counterion size in a series comprising a common cation. The crystal structures are discussed with respect to the possible existence of polar and non-polar domains, which are considered to be involved with the solvation of polar and non-polar substrates. The melting points of all three compounds are within the range 40–45 °C. A comparative measurement of conductivities of the molten salts in the vicinity of 20–50 °C has been made, including the new IL 1-allyl-2,3-dimethylimidazolium tetrafluoroborate and the widely applied 1-butyl-3-methylimidazolium tetrafluoroborate (BMIMBF_4).
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The solvent properties of ionic liquids (IL) have attracted a lot of interest with respect to applications as reaction media for both polar and non-polar solvates.[1a−1f] Homogeneous catalysis using organometallic or coordination compound catalysts is one prominent example where ILs based on 1,3-substituted imidazolium cations in particular have been employed, not only because of their non-volatility, but also due to their variability with respect to the possible adjustment of solvent properties.[1g] The degree of polarity can be varied by adapting the length of the 1-alkyl chain and the counterion to the desired reaction conditions. The investigation of structural properties in the liquid state requires considerable experimental effort (as for example in X-ray absorption spectroscopy[2]), and little information can be gained if heavy elements are missing. Model compounds that are crystalline at ambient temperature have therefore been used for structural investigations. It has been known for some time that salts C_nMeImX incorporating a common anion X^- will usually exhibit low melting points with medium-length alkyl chains ($n = 4-9$),[3] as in these cases crystal packing forces are not strong enough to raise melting points above 300 K. Lower chain-length salts are often readily crystallized, and structural studies have mainly focused on 1-ethyl-3-methylimidazolium (EMIM) salts with various counterions. The EMIM cation, which is asymmetric but rather small, is readily crystallized not only with high charge-density anions such as chloride, but even with hexafluorophosphate, a typical counterion for the liquid-state salts. The crystal structure of EMIMPF_6 (melting point 331 K) has been reported by Fuller et al.[4] EMIMBF_4, on the other hand, which is liquid at ambient temperature, may serve as an example for the influence of counterion size, since the higher charge density of BF_4^- vs. PF_6^- is expected to increase the Coulombic part of the lattice energy and therefore the melting point. An example of a long chain-length salt has been reported by Seddon et al. who solved the crystal structure of C_{12}MIMPF_6.[5]

Long-chain IL salts have attracted some interest due to their liquid crystalline (LC) properties. The origin for these can be found in the formation of domains, "Coulombic" layers where the ionic head-groups interact with the counterions, and "van der Waals" layers built from (anti)parallel stacking of the alkyl chains. Hexafluorophosphate salts with cations up to C_{20}MIM have been investigated by differential thermal analysis (DTA) and show one or more LC transitions. Melting to isotropic liquids occurs at rather high temperatures (>100 °C) .[5] The phase behavior of long chain-length imidazolium and pyridinium chlorides, tetrachlorocobaltates and tetrachloronickelates showing LC properties has also been reported.[6]

Larsen et al. have reported the synthesis and crystal structures of several EMIM, ethyldimethylIM, octylMIM and BDMIM alkylboranes, and the authors rationalized trends in melting points according to the packing efficiency of the asymmetrically substituted cation.[7] More recently, Dupont et al. investigated C−H-π interactions in the solid

state and in solution of BMIM tetraphenylborate,[8] and van den Broeke et al. introduced substituents at the phenyl rings of this salt and reported their influence on the structural and physical properties.[9]

A thorough investigation into the electrochemical and rheological properties of various substituted imidazolium/anion combinations by Bonhôte et al.[10] revealed some general trends for melting/glass transition points. One of the most notable findings in this respect was that methylation at the 2-position of the heteroaromatic ring generally raised melting points by more than 50 K. This was observed even with anions which were expected to be strong hydrogen-bond acceptors for the "acidic" hydrogen at C(2) and for which the opposite effect might have been expected. The influence of ion size and viscosity of IL melts on their electric conductivity is also reported by these authors and was more recently investigated by McEwen et al.[11] Increasing the volume of either cation or anion has generally been found to result in lower absolute values and higher activation energies for conductivity.

The present work is focused on the influence of counterion size on the solid-state structures and liquid-state mobilities of IL compounds comprising the medium chain-length cation 1-butyl-2,3-dimethylimidazolium (BDMIM).

Results and Discussion

All IL compounds reported in this work contain the cation 1-butyl-2,3-dimethylimidazolium (BDMIM). The cation adopts slightly different conformations in the different compounds with respect to the butyl chain, which is kinked from the plane of the imidazolium ring in all cases studied here.

The two crystallographically independent BF_4^- ions in the structure of BDMIMBF_4 **I** were both found to be disordered. The type of disorder was investigated by means of three-dimensional Fourier maps, and is depicted in Figure 1. For BF_4^-(1), the two different orientations are related by a (non-crystallographic) mirror plane and for BF_4^-(2) by a (non-crystallographic) threefold axis, which corresponds to the B(2)−F(9) bond. For both BF_4^- sites, the type of disorder appears to be maintained at 298 K as suggested by the corresponding Fourier maps. Disorder is not observed with the cations, thus apparent disorder originating from the use of twinned data can be excluded.

The title compound **I** is the first IL tetrafluoroborate to be structurally characterized. The structure can be described as being composed of two different types of double layers extending in the crystallographic (0 1 0) plane (Figure 2). The anionic parts of these two layers are very similar, showing the tetrahedral ions in two different orientations with shortest center-to-center distances of 690 pm within the layers. The cationic part composed of the two crystallographically independent imidazolium cations is, however, markedly different for the two double layers, leading to different environments for the BF_4^- sites. The butyl chains extend roughly in the direction of the *b* axis, away from the charged centers of the layers. Pairwise shortest contacts of 402 and 409 pm between the outer methyl/methylene groups of the butyl chain are found along the *b* axis, which roughly correspond to the sum of the van der Waals radii.

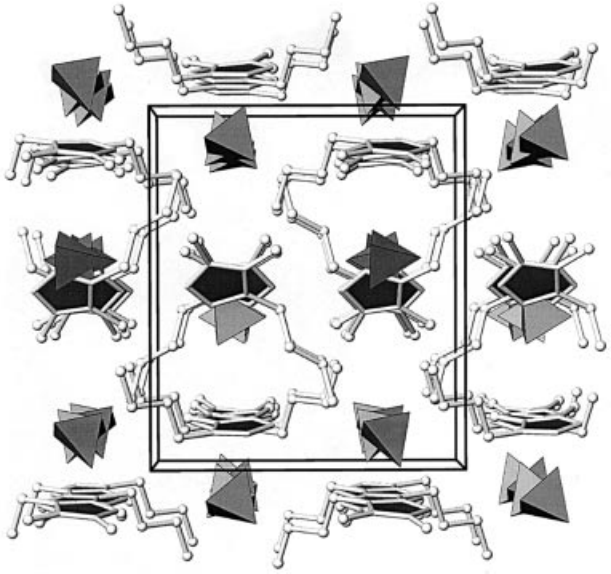

Figure 2. View of the crystal structure of BDMIMBF_4 along the crystallographic *c*-axis; BF_4^- ions are shown as grey tetrahedra; all hydrogen atoms of the imidazolium cation have been omitted for clarity; anions and cations in the central double layer are crystallographically equivalent, a second set of crystallographically equivalent molecules can be distinguished above and below

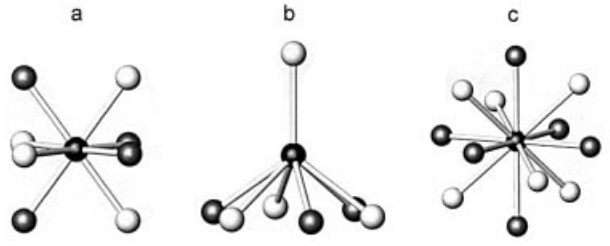

Figure 1. Disorder observed for the BF_4^- ions in BDMIMBF_4 at 213 K (a, b) and for the PF_6^- ions at 298 K in BDMIM PF_6 (c), as observed from difference Fourier syntheses; the two disorder components are shown with different shadings

Pronounced anisotropy as found in **I** has been observed in crystal structures of ionic liquid salts before. Relatively high-melting EMIM halides exhibit hydrogen-bonded 3-D networks.[12] The formation of layered structures recently reported for BMIMCl is, however, promoted by strong hydrogen bonds between cation and anion.[13,14] Intermolecular H···F interactions are considered to be very weak in compounds of the type reported here as indicated by the crystallographic disorder observed for BF_4^- and PF_6^-. This issue is discussed further below. Consequently, arrangements of the BDMIM cation and the low charge-density fluoro

anions result from a balance of weak Coulombic and dispersive interactions, whereas hydrogen bonding in IL chlorides is always strong, as indicated by their much higher melting points. Compound **I** exhibits channels between the cationic layers where the anions are accommodated, similar to those observed in BMIMCl. In the former case, the "structure-directing principle" (close packing of the molecules maximizing non-directional interactions) leads to flat layers which, on the other hand, are corrugated in the BMIMCl structure, driven by maximizing the strongly directional C−H···Cl H-bonds.

The coordination environments of the BF_4^- ions are depicted in Figure 3. Closest distances between fluoride and C/N atoms of the ring are summarized in Table 1. Carbon/nitrogen-fluorine distances of 300−350 pm roughly correspond to the sum of the van der Waals radii $r_F + r_{C/N}$ (147, 175 and 155 pm respectively[15,16]). Four of these contacts are found for BF_4^-(1), whereas there are only three, slightly larger ones for BF_4^-(2). This is probably the reason why the disorder found for BF_4(2) is more pronounced than for BF_4(1).

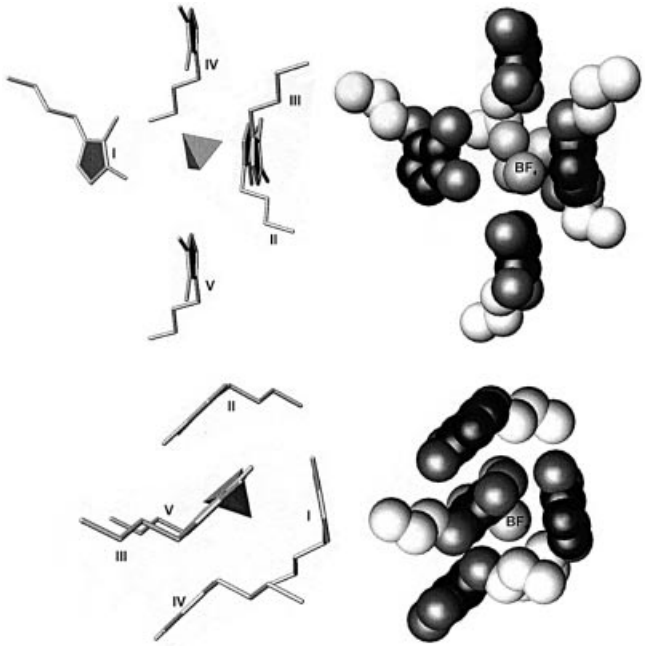

Figure 3. Coordination environments of the BF_4^- ions in BDMIMBF_4; cations are numbered sequentially with increasing center-to-center distances to the BF_4^- ion; the closest contacts between ring atoms and BF_4^- fluorides are summarized in Table 1; in the space-filling models, atoms are shown with different shadings, according to parts of the molecule of increasing polarity (ring C,N atoms as black spheres, methyl/methylene directly bound to the ring as grey spheres, the three outer butyl carbons as white spheres)

Table 1. Closest contacts (pm) between EF_x^- (E = B, P, Sb; x = 4, 6) fluorines and ring atoms of the cations in BDMIMEF_x, as shown for the BF_4^- ions in Figure 3

	BF_4(1)	BF_4(2)	PF_6	SbF_6
I	308 (C−F)	348 (N−F)	310 (C−F)	345 (C−F)
II	305 (C−F)	318 (C−F)	319 (N−F)	325 (C−F)
III	315 (C−F)	407 (N−F)	323 (C−F)	356 (C−F)
IV	329 (C−F)	334 (C−F)	356 (C−F)	342 (C−F)
V	454 (C−F)	423 (C−F)	451 (C−F)	447 (N−F)
VI			446 (C−F)	475 (N−F)

Due to the pronounced asymmetry of the cation, a naive analysis of intermolecular distances is probably not justified here. None of the C(4)−H, C(5)−H ring hydrogen atoms, however, shows an orientation which would suggest hydrogen bonding to the fluorines of BF_4^-.

The crystals of BDMIM PF_6 **II** were obtained from the melt as described in the Exp. Sect. They were typically 0.5−1 mm in diameter; twinning was never observed. The compound adopts an acentric monoclinic structure in space group *Cc* with four formula units per unit cell. The hexafluorophosphate ion is entirely ordered at 213 K while disorder, as in the case of the BF_4^- compound, is observed only at 298 K. The two orientations of the disordered ion are related to each other by a 60° rotation around the threefold axis of the octahedron (Figure 1). The crystal structure of **II** is composed of alternating layers of cations and anions extending in the crystallographic (0 1 1) plane, with all imidazolium ring planes coplanar (roughly perpendicular to the *a* axis) and all butyl chains aligned in one direction, roughly parallel to the *a* axis, as can be seen from Figure 4. As there are only translational symmetry elements (a single glide plane and centering translations), the structure is noncentrosymmetric and no double layers as in the case of **I** are formed. Shortest contacts of 432 pm between the butyl chains are found among adjacent rows of cations in direction of the *c* axis. The hexafluorophosphate ion is surrounded by six cations with the centers forming a distorted trigonal prism.

The PF_6^- group with its surrounding imidazolium ions is depicted in Figure 5. Cations **I**−**IV** all make contacts to fluorine atoms within distances of 310 to 356 pm, summarized in Table 1. The contacts with the two remaining cations are considerably longer (451 and 446 pm). As in the structure of **I**, the butyl chains are kinked from the ring planes, and a closer approach of cations and anions along the *a*

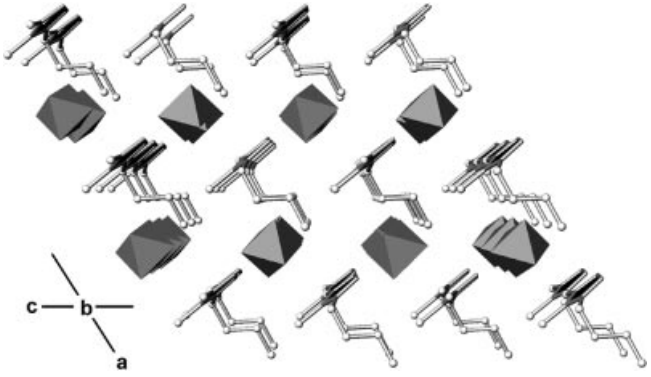

Figure 4. View of the crystal structure of BDMIMPF_6 along the crystallographic *b*-axis; PF_6^- ions are shown as grey octahedra; all hydrogen atoms of the imidazolium ring have been omitted for clarity

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

axis is obviously restricted by the butyl chains. The distance between the terminal methyl carbon and the ring plane of the adjacent layer in the direction of the *a* axis is only 355 pm such that a tighter surrounding of the anion is prevented. Although C−H···F contacts involving the ring hydrogens can be found which adopt a close to linear arrangement, generally considered a prerequisite for hydrogen bonding, the distances involved are rather long: C−F distances of 337 and 355 pm and H···F distances of 248 and 267 pm, with both angles being virtually 160°. However, these distances are within the sum of the van der Waals radii for H and F (125 + 147 pm), and weak hydrogen bonding could well be present according to the definition of Taylor and Kennard.[16] Very similar H···F distances have also been found in the structure of EMIMPF_6,[4] but hydrogen bonding was suggested to be extremely weak or absent, due to the absence of red shifts of the ν_{CH} bands in the IR spectrum. Evidence from the present structure is entirely consistent with this observation. Comparing the structure of **II** with that of EMIMPF_6 is instructive. Whereas the former compound exhibits a pronounced layer structure, the latter shows cations in a pairwise arrangement and a much less discerned hydrophobic region resulting from the shorter ethyl chains. Although the acentric cation arrangement in **II** is not expected to exist in the melt, the greater tendency to separate into non-polar (very often referred to as hydrophobic, although this is not adequate in pure ILs) and ionic domains as compared to EMIMPF_6 is obvious.

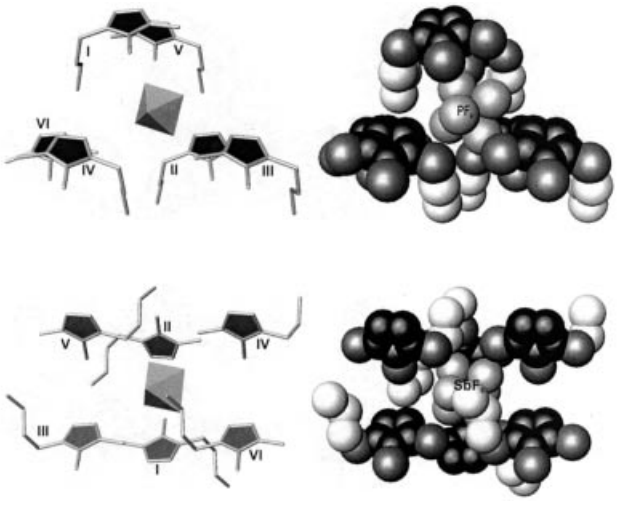

Figure 5. Coordination environments of the hexafluorophosphate ion in BDMIMPF_6 (top) and the hexafluoroantimonate ion in BDMIMSbF_6 (bottom); cations are numbered sequentially with increasing center-to-center distances; closest contacts between ring atoms are summarized in Table 1; shading of the ring atoms is analogous to the scheme adopted in Figure 3

No disorder is observed for the hexafluoroantimonate ion in the structure of BDMIMSbF_6 **III** even at ambient temperature. The crystal lattice is again distinctly different from the two previous compounds; a view of the structure along the *a* axis is depicted in Figure 6. There is no more orientational preference in the cation sub-lattice. The imidazolium moieties are in fact oriented with ring planes parallel to the (0 1 1), (0 $\bar{1}$ $\bar{1}$), (0 1 $\bar{1}$) and (0 $\bar{1}$ 1) crystallographic planes. The packing of cations and anions can be described as being reminiscent of the NiAs structure type, with the SbF_6^- octahedra surrounded by six nearest neighbor cations in a distorted trigonal prismatic coordination, and the cations being surrounded by six SbF_6^- ions in a distorted octahedral arrangement. The NiAs structure type may of course only serve as a schematic rationale for the true structure, as can be judged from large differences in the center-to-center distances between cations and anions. There are no short contacts between carbon atoms of the butyl chains, and thus short-range repulsive interactions between the cations are further diminished with respect to the hexafluorophosphate compound.

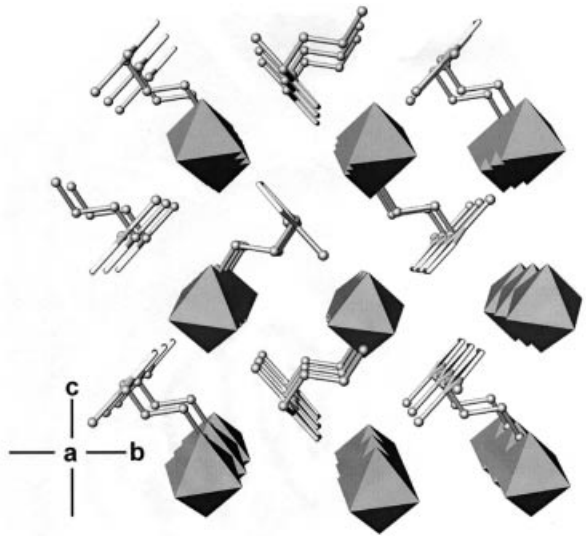

Figure 6. View of the structure of BDMIMSbF_6 along the crystallographic *a*-axis; SbF_6-ions are shown as grey octahedra; all hydrogen atoms of the imidazolium cation have been omitted for clarity; the SbF_6^- ions make a close to hexagonal packing with the imidazolium ions located in the "octahedral holes"

The existence of polar and non-polar domains in liquid BMIMBF_4 has been proposed from diffusion studies of ions and neutral molecules by Schröder et al.[17] The accelerated diffusion of $Fe(CN)_6^{4-}$ as well as the diffusion of neutral molecules was attributed to formation of a "nanostructure" of polar (ionic) and non-polar domains which became even more pronounced upon the addition of water to the IL phase. The formation of polar and non-polar domains, as found in the long chain-length IL compounds, can be recognized, at least to some extent, in the double-layer structure of **I** and the structure of **II**, whereas no such domains can be distinguished in the structure of **III**. This is due to the difference in packing modes, determined by anion size in the present series. The influence of anion size in these non hydrogen-bonded IL compounds can be rationalized by comparing the two compounds **II** and **III** with the BDMIM carborane compounds reported by Larsen et al. Packing in the structure of **I** is obviously determined by the arrange-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ment in the cation sub-lattice, the influence of which prevails for the structure of **II**. By further increasing the size of the anion as in **III**, vacancies in the anion sub-lattice expand such as to accommodate the cations in a way that cation−cation contacts are no longer observed, despite their asymmetry. With even larger anions such as the carboranes, packing will be entirely dominated by the anions, such that close-packing of cations is prevented and disorder of the latter becomes frequent.

The presence of hydrogen bonding in solid IL salts incorporating weakly coordinating anions has been a cause for debate for some time because shifts of the corresponding IR bands indicative of H-bonding are weak or absent within experimental error. Whereas there is no doubt as to the existence of strong H-bonding in IL halides and weaker H-bonding in EMIMNO_3,[18] for example, it has been considered absent in haloaluminates,[19] and the results for anions like BF_4^- and PF_6^- are inconclusive. The closest H···F bond in EMIMPF_6 is reported as being 256 pm, clearly below the sum of the van der Waals radii. Several investigations of liquid EMIMBF_4, BMIMBF_4 and BMIMPF_6 [20−22] by NMR spectroscopy (including intermolecular ^{1}H-^{19}F NOE) established a close proximity between the hydrogens of the heteroaromatic core and the fluorines of the anion. The hydrogen-bonding interaction can be extended to include rather weak contacts as was recently shown by Seddon and co-workers for the C−H···Cl bond.[23] The absence of *significant* hydrogen bonding in all compounds of the present series is supported by infrared spectroscopy. Although the charge density of the anion varies considerably in the series, the wavenumbers of the two principal absorption bands of the aromatic hydrogens remain virtually constant. The three compounds exhibit a common pattern in this region, with a strong band at 3156 cm^{-1} and an associated weak band at 3187 cm^{-1}. Further support of this interpretation is lent by the low melting points of the present compounds as compared to truly H-bonded structures.[24]

The molecular volumes of the fluoro-anions EF_x^- have been calculated assuming a spherical geometry. Volumes are calculated as $V = 4/3\pi(d_{EF} + r_F)^3$, where d_{EF} is the interatomic distance and r_F is the "packing radius" of fluorine, as derived by Gavezzotti.[25] The bias introduced by this arbitrary choice of atomic radii is considered to be tolerable, as comparison is made only between the members of the present series of compounds. The molecular volumes of the BDMIM cation in the crystal were then calculated from the difference of the cell volumes and the respective anion volumes according to Equation (1).

$$V_{BDMIM} = V_{cell}/Z - V_{EF_x^-} \quad (1)$$

The molecular volumes V_{BDMIM} are found to be very similar, namely 230, 225 and 232 Å^3 for **I**, **II** and **III** respectively. This suggests a similar "packing coefficient" k for the three structures, as defined in Equation (2).[26]

$$k = ZV_{mol}/V_{cell} \quad (2)$$

All three structures can therefore be regarded as being fairly close-packed, a notion that is further supported by the absence of cation disorder, contrary to the carboranes reported by Larsen et al., where disorder of the cations was observed in most of the crystal structures.

The melting points and the temperature-dependent electrical conductivities of the melts were measured for compounds **I**−**III**. The melting points of the three BDMIM salts are found within a narrow range around 315 K, about 100 K above the glass-transition points reported for the respective BMIM compounds (Table 2).

Table 2. Melting points (K) of BDMIMEF_x salts determined in this work as compared to those of respective EMIM salts taken from ref.[4] and glass transition (T_g) points of the respective BMIM salts taken from ref.[20]

	BF_4^-	PF_6^-	SbF_6^-
BDMIM	312.8(5)	313.0(5)	317.5(5)
EMIM	288	331	
BMIM	192 (T_g)	212 (T_g)	

The conductivities of the low-melting IL salts BDMIMX (X = BF_4^-, PF_6^-, SbF_6^-), some of which have been reported previously,[27] were measured using a conventional conductivity cell as described below. In order to elucidate the influence of viscosity and the substitution pattern at the imidazolium ring, conductivities of BMIMBF_4 and the new ionic liquid 1-allyl-2,3-dimethylimidazolium tetrafluoroborate (ADMIMBF_4) were measured as well. The temperatures were chosen such that a range of about 10 K above and below the respective melting points was covered, except for the latter two compounds which are far above their glass-transition points at ambient temperature. Conductivities were found to follow linear $\ln(\sigma)$ vs. $1/T$ behavior in the narrow temperature range covered here, whereas the Vogel−Tamman−Fulcher equation has been previously found to describe the temperature-dependent conductivity of several ionic liquids in a wider temperature range.[11] The conductivities are depicted in Figure 7 and summarized in Table 3.

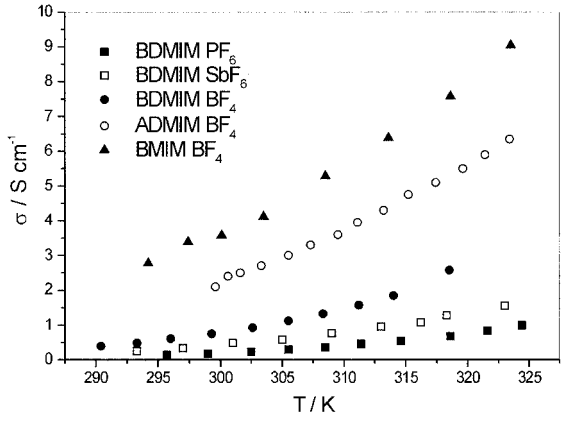

Figure 7. Plot of conductivity vs. temperature of the molten salts; the BDMIM compounds of BF_4^- and PF_6^- and of SbF_6^- are in the supercooled state below 313 and 318 K respectively

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 3. Conductivities σ (S cm^{-1}) of the molten salts at 298 K depicted in Figure 7, and activation energies E_A (kJ/mol) obtained from the corresponding Arrhenius plots

	σ	E_A
BMIMBF_4	3.4	31.6(7)
ADMIMBF_4	2.1	36.0(8)
BDMIMBF_4	0.7	50.1(6)
BDMIMSbF_6	0.4	47(1)
BDMIMPF_6	0.2	54.1(9)

A comparison of the conductivities was first made among the three BDMIM compounds. Since the viscosities could not be determined, only the effect of ion size can be taken into account. Compound **I** has the highest conductivity and the lowest is observed for **II**, although the difference between **II** and **III** is not large. The conductivities of the latter two compounds are reversed as to what would be expected from their anion size and melting points. It has been shown previously that large anions can produce melts of low viscosity if they have low charge-density and if hydrogen bonding is absent.[10] The slightly lower conductivity of the PF_6^- salt as compared to that of SbF_6^- could still be due to the latter effect as discussed above. An unusually low conductivity of EMIMPF_6 as compared to the much larger EMIM bis(trifluoromethylsulfonyl)imide has been previously reported by McEwen et al.[11] The values obtained in this work for **I** and **II** are similar, although reversed in order with respect to those reported by Sutto et al., determined using the complex impedance method.[27]

The activation energies for conductivity decrease in the order $PF_6^- > BF_4^- > SbF_6^-$, with absolute values consistent with that reported for the similar compound dimethylpropylimidazolium hexafluorophosphate (DMPIPF_6).[11]

The second series compared are the BF_4^- salts of BMIM, BDMIM and ADMIM. The ADMIM compound was synthesized in order to verify whether trisubstituted imidazolium salts with this types of anion are generally solid at ambient temperature. ADMIMBF_4 turned out to be a liquid of rather low viscosity even at approx. 260 K, thus methylation in the 2-position cannot be exclusively responsible for the large increase of melting points. Conductivities of the BF_4^- salts increase in the order BMIM > ADMIM > BDMIM. This order could otherwise be described as: a) exchange of an allyl for a butyl group at the nitrogen plus methylation in the 2-position, resulting in lower mobility of the cation, and b) reverse exchange of butyl for allyl, decreasing the mobility even further. The large effect produced by the second step (cf. Figure 7) is a particularly unexpected result, and is probably explained by weaker van der Waals bonding with the allyl group as compared to butyl, rather than a large increase in the overall size of the cation.

Conclusion

From the present work we conclude that packing inefficiency as a prerequisite for the low melting points of ionic liquid salts, reflected by frequent crystallographic disorder, can be ruled out for the present compounds, contrary to the IL carboranes reported by Larsen et al. Instead, the low-melting compounds containing the BDMIM cation and fluoro anions suggest a certain degree of cation−cation repulsive interaction for compounds with smaller anions (BF_4^- and PF_6^-) which is no longer influential in the case of SbF_6^- owing to lattice expansion. The existence of polar and non-polar domains, believed to be associated with the unique "amphiphilic" solvent properties of ILs, are found in the structures of the BF_4^- and PF_6^- salts. A similar trend as with melting points is observed with ionic mobilities in the respective molten salts, inferred from measurements of electric conductivities. However, since the charge densities of the conducting species are low and dispersive interactions make up an important part of the adhesive forces in these melts, factors other than ion size, especially polarizability, have to be taken into account. Introducing unsaturated side chains at the imidazolium ring (possibly perfluorinated ones in order to reduce reactivity) might be a worthwhile issue with respect to the design of low viscosity melts, as suggested by the new IL ADMIMBF_4.

Experimental Section

Preparations: BMIMCl and BDMIMCl were obtained from *n*-chlorobutane and 1,2-dimethylimidazole (Aldrich 98%) as reported previously.[18] The BF_4^-, PF_6^- and SbF_6^- salts were prepared by a modified procedure according to Suarez et al.[20] The imidazolium chloride was stirred with a 1.1-fold excess of $NaBF_4$, KPF_6 or $NaSbF_6$ in dry acetone at ambient temperature for 48 hours. Sodium chloride was then filtered from the solution, and most of the acetone was removed under reduced pressure. Dichloromethane was then added in order to precipitate the remaining sodium salts, and the mixture was kept at −10 °C for 24 hours. The precipitates were filtered from the solution and the organic solvents were removed under reduced pressure. The resulting ionic liquid was then heated at 70 °C/10^{-2} bar for 12 hours to remove any remaining volatiles. Purity was checked by NMR spectroscopy and elemental analysis; chloride impurities were generally below the detection limit with silver ions. Some of these ionic liquid salts are now commercially available.[28] 1-Allyl-3-methylimidazolium bromide was synthesized from allyl bromide and 1,2-dimethylimidazole and bromide ions were exchanged for tetrafluoroborate as described above.

Crystal Growth: Suitable crystals for X-ray single crystal diffraction of BDMIMBF_4 (**I**) and BDMIMPF_6 (**II**) could only be obtained from the molten salts. Crystals of BDMIMSbF_6 (**III**) were obtained from solution. The crystal growth of the imidazolium salts from the melt was performed in Schlenk tubes (approx. 10 cm in length and 1 cm in diameter) equipped with a septum through which a wire ending in a loop with seed crystals was immersed into the melt. The tubes were kept in a water bath maintained about 1 °C below the melting point. Crystals started growing at the loop and were separated from the melt typically after a couple of hours by slowly lifting the wire out of the liquid. Crystals of **III** were obtained from mixtures of MeCN/Et_2O typically within less than 24 hours.

Conductivity Measurements: AC conductivities of the molten salts were measured using a conventional conductivity cell equipped with 1 cm^2 platinum electrodes with a nominal cell constant of 0.7

cm^{-1}. The cell was calibrated with a 0.01 M aqueous solution of KCl and connected to a WTF conductivity analyzer model LF 410, operating at 4 MHz ac current. The temperature of the cell was maintained constant within 0.5 °C using a thermostatted water bath. The compounds were cautiously dried at 70 °C under reduced pressure before measurement and transferred to the cell inside an argon-filled glove box.

NMR and Infrared Spectra: Both NMR spectra in CD_2Cl_2 solution, recorded on a Varian Mercury 200 spectrometer (200 MHz), as well as IR spectra of solid samples run as KBr pellets with a Nicolet FTIR spectrometer (model Avatar), are virtually identical for the three BDMIM compounds. NMR and IR spectroscopic data for **III** and for the new compound ADMIMBr are summarized below. Compounds **I**−**III** and ADMIMBr were also submitted to elemental analysis.

1-Butyl-2,3-dimethylimidazolium Hexafluoroantimonate (III): ^{1}H NMR: δ = 1.0 [t, C(11)H3], 1.3 [tt, C(10)H2], 1.7 [tt, C(9)H2], 2.5 [s, C(8)H3], 3.7 [s, C(7)H3], 4.0 [t, C(6)H2], 7.2 [dd, C(4)H, C(5)H] ppm. ^{13}C NMR: δ = 10.0 (C-8), 14.0 (C-11), 20.0 (C-10), 32.0 (C-9), 35.0 (C-7), 49.0 (C-6), 121.0 (C-4), 123.0 (C-5), 144.0 (C-2) ppm. IR (600−4000 cm^{-1}, KBr pellets): $\tilde{\nu}$ = 3186, 3153 aromatic ν(C−H); 2968−2881 aliph. ν_s(C−H); 1608−1469 ν_s(C=C/C=N ring); 1426−1080 aliph. δ_{as}(C−H), ν_s(ring), δ(C−H ring); 950 δ(in plane ring C−H); 750 δ_{as}(out of plane ring). $C_9H_{17}N_2F_6Sb$ (388.91): calcd. C 27.8, H 4.4, N 7.2; found C 27.5, H 4.7, N 6.8.
I: $C_9H_{17}N_2F_4B$ (239.91): calcd. C 45.0, H 7.1, N 11.7; found C 44.8, H 8.0, N 11.2.
II: $C_9H_{17}N_2F_6P$ (298.11): calcd. C 36.2, H 5.7, N 9.4; found C 36.2, H 6.0, N 9.1.

1-Allyl-2,3-dimethylimidazolium Bromide: ^{1}H NMR: δ = 2.58 [s, C(7)H3], 3.79 [s, C(6)H3], 4.95 [dt, C(8)H2], 5.28 [d/m, C(10)H-*E*], 5.38 [d/m, C(10)H-*Z*], 5.98 [m, C(9)H], 7.61 [d, C(4)H], 7.73 [d, C(5)H] ppm. ^{13}C NMR: δ = 11.08 (C-7), 27.69 (C-8), 36.30 (C-6), 120.65 (C-9), 120.65 (C-5), 121.77 (C-4), 123.22 (C-10), 130.4 (C-9), 144.66 (C-2) ppm. IR (600−4000 cm^{-1}, KBr pellets): $\tilde{\nu}$ = 3169 (w), 3106 (m), 3056 (3014) (s) aromatic/allyl ν(C−H); 2929−2860 aliph. ν_s(C−H); 1586−1461 ν_s(C=C/C=N ring/allyl); 1410−1170 aliph. δ_{as}(C−H), ν_s(ring), δ(C−H) ring; 950 δ(in plane ring C−H); 750 δ_{as}(out of plane ring). $C_8H_{13}N_2Br$ (216.99): calcd. C 44.2, H 6.4, N 12.9; found C 44.6, H 6.2, N 12.9.

X-ray Structure Determinations: Single crystal diffraction was performed with a Bruker diffractometer equipped with graphite monochromator and a Smart-Apex CCD detector (Siemens) using Mo-K_α radiation. A complete hemisphere was recorded in 600, 435 and 230 frames, at φ angles of 0°, 90° and 180°, respectively. A scan width of 0.3° was used. Indexing was done using the program SMART, frame integration and data reduction using the SAINTPLUS suite. Absorption correction was performed using the program SADABS (all ©Bruker AXS). Sample crystals were placed into glass capillaries and sealed under argon atmosphere. Recording temperatures and crystallographic parameters for compounds **I**−**III** are summarized in Table 4. Crystals of **I** were obtained as two-component twins in all cases. The crystals, however, were large and of excellent quality, thus a sufficient number of non-overlapping reflections could be collected to allow for separation of contributions from the two components, structure solution and batch scaling of the data according to the degree of overlap during least-squares refinement. Diffraction data were collected at 213 K and indexed with a monoclinic unit cell containing eight formula units, which had previously been obtained from a powder diffraction pattern where twinning is not of concern.
CCDC-221752 (for BDMIMBF_4), -221753 (for BDMIMPF_6) and -221754 (for BDMIMSbF_6) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Characterisation of Novel Main Group Element Clusters with Tin-Phosphorus, Tin-Arsenic, and Germanium-Phosphorus Skeletons

Donna Nikolova,[a] Carsten von Hänisch,*[a] and Ariane Adolf[a]

Keywords: Tin / Phosphorus / Arsenic / Germanium / Cluster compounds

The reaction of iPr$_3$SiPLi$_2$ with SnCl$_2$ in the mol ratio 1:1 leads to the formation of [Sn$_7$(PSiiPr$_3$)$_7$] (**1**). The cluster [Sn$_8$(PSiiPr$_3$)$_6$Cl$_2$] (**3**) is obtained, if the same reaction is carried out with a slight excess of the metal salt. Similar lithium chloride elimination reactions between SnCl$_2$ and iPr$_3$SiAsLi$_2$ in the mol ratio 1:1 and 2:3, however, yield [Sn$_7$(AsSiiPr$_3$)$_7$] (**2**) and [Sn$_4$(AsSiiPr$_3$)$_6$Li$_4$(Et$_2$O)$_2$] (**4**), respectively. The metal salt GeCl$_2$(diox)$_2$ (diox = 1,4-dioxane) reacts with iPr$_3$SiPLi$_2$ to give [Ge$_6$(PSiiPr$_3$)$_6$] (**5**). Compounds **1**–**5** were characterised by NMR and IR spectroscopic techniques as well as elemental analysis. The crystal structures were identified by X-ray diffraction analysis, which confirmed that the heptameric skeletons of **1** and **2** are structurally analogous. The Sn/P cluster **3** contains subvalent tin atoms, while **4** forms a Sn$_4$As$_6$Li$_4$ rhombododecahedron and **5** a slightly distorted hexagonal prism.

Introduction

A survey of coordination chemistry literature reveals that besides investigations into the formation of polynuclear complexes with the participation of transition metals,[1−3] an increasing number of studies are currently devoted to problems of synthesis and characterisation of cluster compounds containing elements from the main groups.[4] For a better understanding of the correlation between size, structure and properties of binary semiconductor compounds, the availability of clusters of different size and structure is of considerable interest. However, the knowledge on 14/15 cluster compounds is still relatively scarce. For the systems Sn/P and Sn/As there are only a few cyclic and cage compounds reported to date.[5,6] Even fewer examples are known for Ge/P compounds.[7]

Different types of starting materials and synthetic methods have been described for the synthesis of tin phosphorus and germanium phosphorus compounds. A convenient method for the formation of Sn−P bonds is the metalation of primary phosphanes RPH$_2$ (R = iPr$_3$Si, tBu$_3$Si) with Sn[N(SiMe$_3$)$_2$]$_2$, leading to [Sn$_4$(PSitBu$_3$)$_4$] and [Sn$_6$(PSiiPr$_3$)$_6$] species.[5b,5c] Salt elimination reactions between NaAsH$_2$ and Sn^{IV} compounds such as tBu$_2$SnCl$_2$ have been used for the synthesis of Sn/As compounds.[6a][6c] Recently Fenske and co-workers reported the catalytic transformation of P(SnMe$_3$)$_3$ into the Sn/P-cage compound [P$_4$(SnMe$_2$)$_6$].[5a]

Herein we report on the successful synthesis of new 14/15 compounds with unknown structural motifs. Simple lithium chloride elimination reaction of iPr$_3$SiELi$_2$ (E = P, As) with the metal salts SnCl$_2$ and GeCl$_2$(diox)$_2$ (diox = 1,4-dioxane) was used in these reactions.[8]

Results and Discussion

The reaction of iPr$_3$SiPLi$_2$ with SnCl$_2$ in the mol ratio 1:1 in Et$_2$O yields [Sn$_7$(PSiiPr$_3$)$_7$] (**1**) which can be obtained as red crystals by cooling the reaction mixture to 0 °C. The X-ray analysis revealed that the compound consists of seven Sn atoms and seven PSiiPr$_3$ fragments. **1** crystallises in the trigonal space group $R\bar{3}$.

The cluster can be described as follows: The tin and phosphorus atoms Sn1, Sn1′, Sn1′′ and P1, P2, P2′, P2′′ form a heterocubane, however, the fourth Sn atom is missing. Instead of it the three P atoms P2, P2′, P2′′ are connected to the corresponding Sn atoms (Sn2, Sn2′, Sn2"") which also form an incomplete heterocubane together with P3, P3′, P3′′ and Sn3. The Sn−P bonds in **1** are 264.5 pm on average. This value is within the range of lengths typically observed for most of the already known Sn^{II}/P compounds.[5] All of the P centres are coordinated to three tin atoms and one triisopropylsilyl group, forming a very distorted tetrahedral environment. The tin atoms possess no exocyclic ligands and consequently only have a coordination number of three.

The compound [Sn$_7$(AsSiiPr$_3$)$_7$] (**2**) is formed by the reaction of iPr$_3$SiAsLi$_2$ with SnCl$_2$ (1:1) in diethyl ether as a solvent. The compound crystallises isotypically into **1** (see Figure 1). Therefore its structure will not be discussed in

detail. The average Sn−As bond lengths are 272.8 pm. The As−Si bond lengths are in the range of 234.5 to 238.7 pm. All values are in the usual range for single bonds between these elements.[6,10]

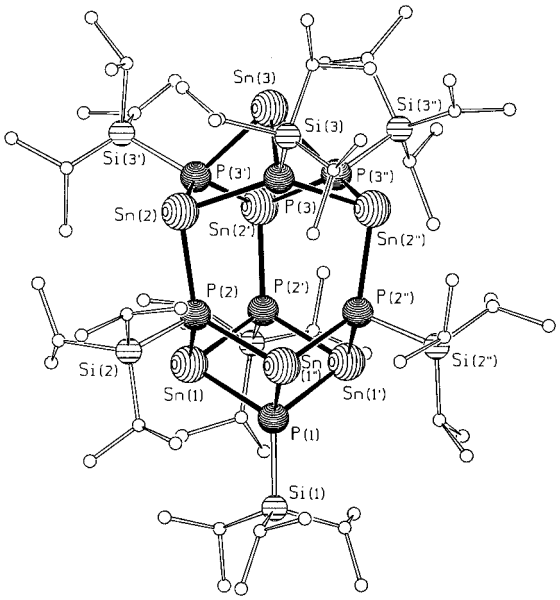

Figure 1. Molecular structure of **1**, selected bond lengths (pm) and angles (°): Sn−P 262.3(3)−265.8(3), Si−P 225.2(6)−228.1(4); Sn−P(1)−Sn 96.2(1), Sn(1)−P(2)−Sn(1′) 96.3(1), Sn(1)/Sn(1′)−P(2)−Sn(2) 123.3(1)−223.9(1), Sn(2)−P(3)−Sn(2′) 133.5(1), Sn(2)/Sn(2′)−P(3)−Sn(3) 90.4(1)−90.6(1), P(1)−Sn(1)−P(2)/P(2′) 83.6(1)−83.8(1), P(2)−Sn(1)−P(2′) 100.6(1), P(2)−Sn(2)−P(3)/P(3′) 101.0(1)−101.3(1), P(3)−Sn(2)−P(3′) 84.5(1), P−Sn(3)−P 83.4(1)

Similar heptameric structures have been found for the related imidoalanes, imidogallanes and phosphinidene-alanes $[RMER']_7$ (M = Al: E = N, P; M = Ga: E = N).[9]

Surprisingly, when the corresponding reaction between $Li_2PSi\textit{i}Pr_3$ and $SnCl_2$ is carried out with a slight excess of the metal salt, the compound $[Sn_8(PSi\textit{i}Pr_3)_6Cl_2]$ (**3**) is obtained.

In contrast to **1**, **3** contains an excess of Sn relative to $PSi\textit{i}Pr_3$ groups and possesses two chloride ligands. **3** crystallizes in the monoclinic space group $P2_1/c$. A formal charge of −2 can be assigned to each of the six $PSi\textit{i}Pr_3$ fragments, the two Cl ions contribute one negative charge each. Therefore the total formal negative charge to be compensated amounts to −14. Consequently, the molecule must consist of two types of Sn atoms due to the neutrality of the molecule. The outer Sn atoms (Sn1, Sn2, Sn3, Sn4) are in the +2 oxidation state and account for +8 of the total formal positive charge. The remaining four tin centres (Sn5, Sn6, Sn7, Sn8) compensate with a formal charge of +6, indicating that a reduction process must have taken place. These tin atoms form the structural core and exhibit three Sn−Sn bonds. The middle bond between Sn5 and Sn6 (283.4 pm) is slightly shorter than the adjacent two Sn−Sn bonds (Sn5−Sn7 288.8 pm, Sn6−Sn8 288.0 pm). However they are still in the range of normal tin-tin bonds as found in grey tin (280 pm) or in the tin-phosphorus compound $[P_2(Sn_2Me_4)_3]$ (279 pm).[5g] Two of the tin atoms (Sn5 and Sn6) of this four-membered tin fragment are tetrahedrally surrounded by two P and two Sn atoms. Two phosphorus and one tin atom coordinate the other two Sn atoms (Sn7 and Sn8). The outer Sn centres (Sn1, Sn2, Sn3, Sn4) are also three-coordinate due to the coordination of either three phosphorus atoms (Sn3 and Sn4) or two phosphorus atoms and one chloride ligand (Sn1 and Sn2). These Cl ligands are most likely oriented in this asymmetric manner as a result of the sterically demanding $\textit{i}Pr_3Si$ moieties and weak bonding interactions between Cl1 and Sn2 (Cl1···Sn2 distance: 303.0 pm). Assuming that the tetrahedrally surrounded Sn atoms (Sn5 and Sn6) contribute four electrons to the cluster framework, the core structure possesses 42 valence electrons for 21 bonds (dark lines in Figure 2) and therefore the cluster is electron precise.

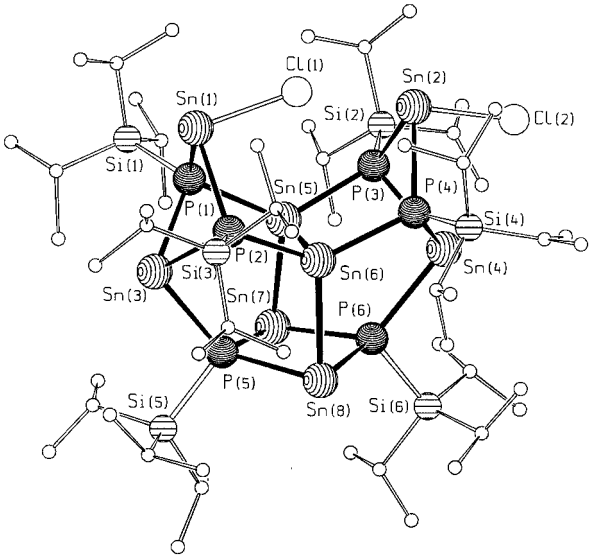

Figure 2. Molecular structure of **3**, selected bond lengths (pm) and angles (°): Sn(5)−Sn(6) 283.4(1), Sn(5)−Sn(7) 288.8(2), Sn(6)−Sn(8) 288.0(2), Sn(1)−Cl(1) 257.2(6), Sn(2)−Cl(2) 255.3(6), Sn−P 253.8(5)−272.8(5), Si−P 226.7(5)−228.3(5); Sn(5)−Sn(6)−Sn(8) 100.10(4), Sn(6)−Sn(5)−Sn(7) 99.05(4)

The rhombododecahedron $[Sn_4(AsSi\textit{i}Pr_3)_6Li_4(Et_2O)_2]$ (**4**, Figure 3) can be isolated if the reaction of $SnCl_2$ with $\textit{i}Pr_3SiAsLi_2$ is carried out in the ratio 2:3.

Two four-membered Sn_2As_2 rings are observed in the molecule. The Sn atoms are three-coordinate. The As atoms reveal a coordination number of five. These rings are bridged by the As centres As3 and As3′. The resulting Sn_4As_6 skeleton carries a formal charge of −4, which is compensated by four Li counterions. Each Li ion binds to one As atom of the two Sn_2As_2 rings and to one of the bridging As centres. Li1 and Li1′ are further coordinated by one diethyl ether molecule each. The Sn^{II}−As bonds in **4** are 274.1 pm on average and are therefore longer than the representative Sn^{IV}−As bonds (263.1−261.5 pm) in the ring compounds $(\textit{t}Bu_2SnAsH)_2$ and $(\textit{t}Bu_2SnAsSiMe_3)_2$.[6a,6c] A Sn−As bond length of 270−277 pm, how-

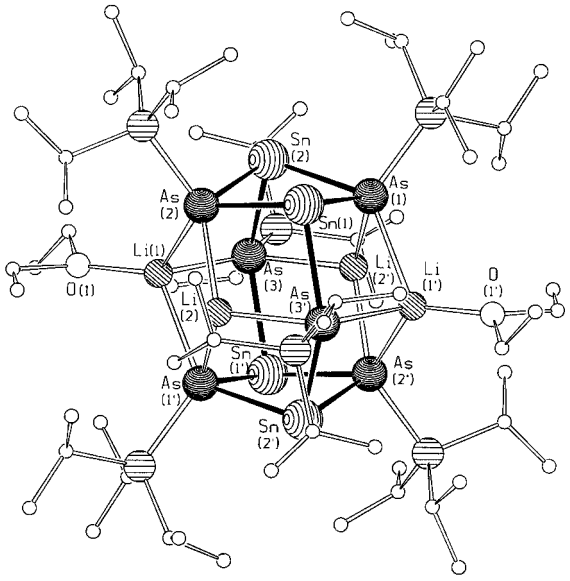

Figure 3. Molecular structure of **4**, selected bond lengths (pm) and angles (°): Sn−As 272.0(4)−278.8(2), As−Si 234.6(3)−236.7(4), As−Li 257(2)−279(2); Sn(1)−As(1)−Sn(2) 85.37(4), Sn(1)−As(2)−Sn(2) 85.44(4) Sn(1′)−As(3)−Sn(2) 137.49(4), As(1)−Sn(1)−As(2) 91.34(4), As(1)−Sn(1)−As(3′) 90.64(5), As(2)−Sn(1)−As(3′) 98.25(4), As(1)−Sn(2)−As(2) 91.86(4), As(1)−Sn(2)−As(3) 99.41(4), As(2)−Sn(2)−As(3) 91.87(4)

ever, can be observed in the cyclic arsanylstannylene $[Sn\{As(SiMe_3)_2\}_2]_2$ and $[Sn(As\mathit{t}Bu_2)Cl]_2$ [6d,6e] as well as in **2**. A similar rhombododecahedral structure is observed for the related tin-phosphorus compound $[Sn_4(PCy)_6\{Li(THF)\}_4]$ and the aluminium-arsenic compound $[(HAl)_4(AsSi\mathit{i}Pr_3)_6Li_4(Et_2O)_2]$.[11]

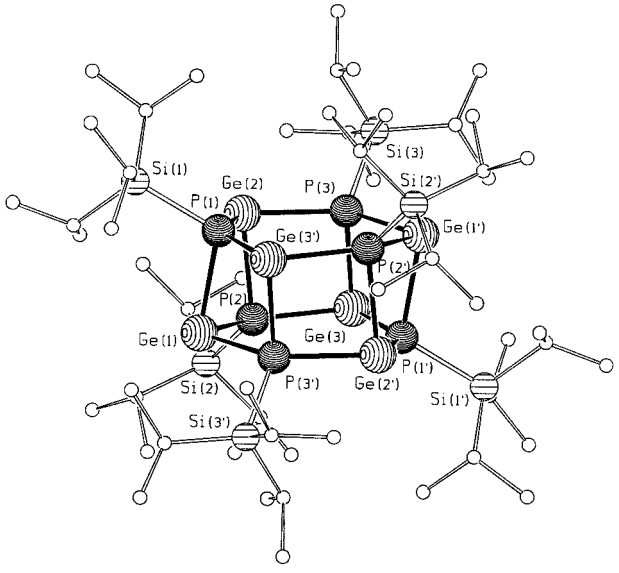

Figure 4. Molecular structure of **5**, selected bond lengths (pm) and angles (°): Ge−P 241.6(2)−248.7(2), P−Si 226.6(3)−227.9(2); Ge−P−Ge(four-membered ring): 90.78(5)−92.69(4), Ge−P−Ge(six-membered ring): 135.14(7)−137.67(9), P−Ge−P(four-membered ring): 85.84(6)−88.83(7), P−Ge−P(six-membered ring): 10071(6)−103.48(6)

$[Ge_6(PSi\mathit{i}Pr_3)_6]$ (**5**, Figure 4) is obtained from the reaction of $\mathit{i}Pr_3SiPLi_2$ with $GeCl_2(diox)_2$. The compound crystallises in the triclinic space group $P\bar{1}$ with two independent inversion symmetric molecules in the elementary cell. They differ insignificantly; therefore only one of them will be discussed.

The Ge and P atoms form a distorted hexagonal prism, in which all of the Ge centres are coordinated trigonal-pyramidally by three P atoms. The P atoms are surrounded by one triisopropylsilyl group and three Ge atoms. The average Ge−P distances within each Ge_3P_3 plane (242.5 pm) are slightly shorter than the corresponding Ge−P distances between the Ge_3P_3 rings (247.7 pm). These values are larger than the corresponding Ge^{IV}−P distances in $[\mathit{t}BuMesGePH]_2$ (234.6 pm) but shorter than the Ge^{II}−P bonds in $[Ge(P\mathit{t}Bu_2)Cl]_2$ (248.8−249.3 pm).[7] The molecular structure of **5** is analogous to the tin compounds $[Sn_6(ESi\mathit{i}Pr_3)_6]$ (E = P, As) and the lead arsenic compound $[Pb_6(AsSi\mathit{i}Pr_3)_6]$.[5c,6b,12]

Experimental Section

All manipulations were carried out under rigorous exclusion of oxygen and moisture, using a Schlenk line and nitrogen atmosphere. All solvents were dried and freshly distilled before usage. The starting materials $\mathit{i}Pr_3SiPH_2$, $\mathit{i}Pr_3SiAsH_2$, $GeCl_2(diox)_2$ were prepared according to the relevant instructions found in the literature.[13] $SnCl_2$ was obtained from Aldrich and used as received. The ^1H and ^{31}P NMR spectra were recorded with a Bruker AC 250 spectrometer. All isolated compounds gave C,H analyses consistent with their formulas. In the IR spectra the typical peaks of the $\mathit{i}Pr_3Si$ groups are observed.

1: A butyllithium solution (1.25 mL, 1.6 M; 2 mmol) was added to a solution of $\mathit{i}Pr_3SiPH_2$ (0.19 g, 1 mmol) in Et_2O (10 mL) at 0 °C. After stirring for 10 min, this solution was added to a suspension of $SnCl_2$ (0.19 g, 1 mmol) in Et_2O (15 mL) at 0 °C. The reaction mixture was allowed to warm up to ambient temperature and then stirred for an additional 16 hours. The resulting red solution was filtered to remove the precipitated LiCl and cooled to 0 °C. Red crystals of **1** formed over a period of 5 days. Yield: 0.1 g (32%). $C_{63}H_{147}P_7Si_7Sn_7$ (2149.11): calcd. C 35.21, H 6.89; found C 34.63, H 6.60. ^1H NMR ([D$_8$]toluene): δ = 1.0−1.5 (m, *i*Pr) ppm. $^{31}P\{^1H\}$ NMR ([D$_8$]toluene): δ = −243.9 (s), −294.9 (s), −373.0 (s) ppm.

2: BuLi (1.63 mL, 1.6) was added at 0 °C to a solution of $\mathit{i}Pr_3SiAsH_2$ (0.31 g, 1.3 mmol) in Et_2O (10 mL). This solution was added at 0 °C to a suspension of $SnCl_2$ (0.25 g, 1.3 mmol) in Et_2O (10 mL). The purple red mixture was stirred for an additional 18 . The resulting red solution was filtered to remove the precipitated LiCl and cooled to 0 °C. Red crystals of **2** formed over a period of 5 days. Yield: 0.13 g (28.5%). $C_{63}H_{147}As_7Si_7Sn_7$ (2457.74): calcd. C 30.80, H 6.03; found C 30.11, H 5.99. ^1H NMR (C_6D_6): δ = 1.0−1.5 (m, *i*Pr) ppm.

3: A butyllithium solution (1.19 mL, 1.6 M) was added to a solution of $\mathit{i}Pr_3SiPH_2$ (0.18 g, 0.95 mmol) in Et_2O (5 mL) at 0 °C. After warming to room temperature, the solution of $\mathit{i}Pr_3SiPLi_2$ was added to a suspension of $SnCl_2$ (0.22 g, 1.16 mmol) in Et_2O (20 mL) at 0 °C. Subsequently, the red mixture was warmed to ambient temperature while stirring and then agitated overnight. The resulting red solution was filtered to remove the precipitated LiCl and cooled to 0 °C. Red crystals of **3** formed over a period of 5

Bis(fluoromesityl) Palladium Complexes, Archetypes of Steric Crowding and Axial Protection by *ortho* Effect − Evidence for Dissociative Substitution Processes − Observation of $^{19}F-^{19}F$ Through-Space Couplings

Camino Bartolomé,[a] Pablo Espinet,*[a] Jose M. Martín-Álvarez,[a] and Fernando Villafañe[a]

Keywords: Palladium / Dissociative substitution / Fluorine / Bulky ligands / Steric crowding / Through-space coupling

Bisarylated complexes *trans*-[Pd(Fmes)$_2$(SR$_2$)$_2$] [Fmes = 2,4,6-tris(trifluoromethyl)phenyl (fluoromesityl); SR$_2$ = SMe$_2$, tht; tht = tetrahydrothiophene] are precursors for various bisarylated fluoromesityl palladium(II) complexes by ligand-substitution reactions. Boiling under reflux in acetonitrile gives the mixed complexes *trans*-[Pd(Fmes)$_2$(NCMe)(SR$_2$)], whereas boiling under reflux in toluene leads to *trans*-[PdCl$_2$L$_2$] (L = PMe$_3$, *t*BuNC, *p*Tol-NC, 4-MePy), in the presence of neutral monodentate ligands, or to (N*n*Bu$_4$)[*trans*-Pd(Fmes)$_2$I(SR$_2$)] when treated with (N*n*Bu$_4$)I. *trans*-[Pd(Fmes)$_2$(SMe$_2$)$_2$] reacts with bidentate ligands, also boiling under reflux in toluene, to give [Pd(Fmes)$_2$(L–L)] [L–L = Me$_2$bipy, 2,2′-biquinolyl, κ^2N,N'-OCPy$_2$, dppm (Ph$_2$PCH$_2$PPh$_2$), dppe (Ph$_2$PCH$_2$CH$_2$PPh$_2$), pte (PhSCH$_2$CH$_2$SPh), κ^2S,N-SPPh$_2$Py, κ^2O,N-OPPhPy$_2$], or the bimetallic complex [Pd(Fmes)$_2$(μ-1κ*N*:1,2κ*O*:2κ*N*-Py$_2$MeCO)Pd(Fmes)(SMe$_2$)] (characterized by X-ray diffractometry) when treated with (OH)(CH$_3$)CPy$_2$. The crowding associated with two Fmes groups produces several interesting features: (1) trans complexes are preferred over cis complexes, against the expected electronic preferences; (2) the low-temperature NMR spectra of several complexes, or the X-ray diffraction structure of [Pd(Fmes)$_2$(2,2′-biquinolyl)], reveal significant structural distortions associated with steric crowding; (3) the need for boiling under reflux in the synthesis suggests a dissociative substitution mechanism, which is unknown so far for Pd; (4) some of the complexes show $^{19}F-^{19}F$ through-space couplings.

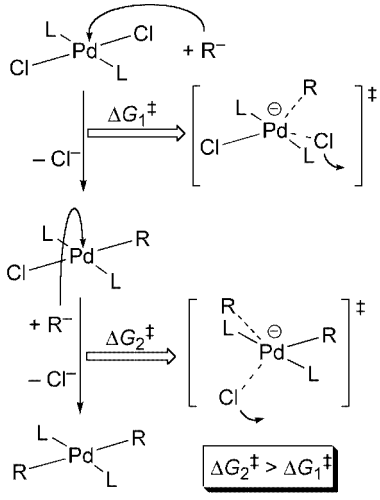
Introduction

2,4,6-Tris(trifluoromethyl)phenyl (nonafluoromesityl or Fmes) is an interesting ligand for main group and transition metals.[1,2] It combines steric bulk with a certain electron-withdrawing character, and lacks hydrogens susceptible to H-elimination. The latter two features may facilitate the preparation of stable derivatives where the consequences (structural or otherwise) of steric crowding can be tested. However, its bulkiness limits direct arylation as a method of obtaining organometallics that contain more than one Fmes group. Our initial studies on the coordination of Fmes in palladium(II) complexes by arylation indicated that bisarylated complexes are only accessible for small ancillary ligands.[2a] After the first arylation (Scheme 1), the coordinated Fmes exerts a high axial protection (*ortho* effect) against subsequent nucleophilic attack, which can progress reasonably well only when the spatial requirements of the ancillary ligands are small, so that the initially coordinated Fmes can tilt and facilitate the approach of the entering Fmes$^-$ nucleophile. In kinetic terms, the activation enthalpy



Scheme 1. Associative mechanism for an arylation reaction

for the second arylation ($\Delta G_2^{\ddagger}$) is noticeably higher than $\Delta G^{\ddagger}$, its value increasing as the hindrance of the ancillary ligands to the tilting of the coordinated Fmes increases.

However, ligand substitution on bisarylated complexes obtained by arylation might allow the synthesis of a wider range of bisarylated species. Here we describe the synthesis and characterization of different bisarylated Fmes pal-

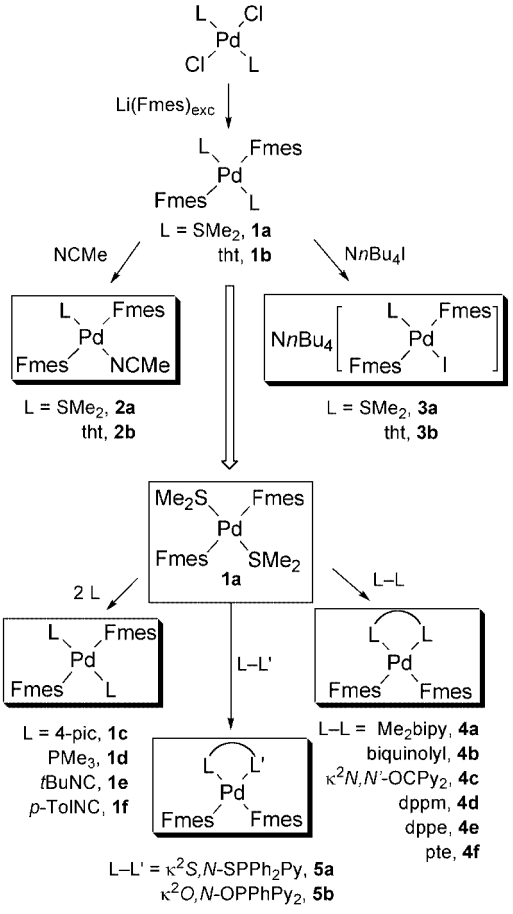
ladium(II) complexes obtained by treating *trans*-$[Pd(Fmes)_2(SR_2)_2]$ (SR_2 = SMe_2, tht; tht = tetrahydrothiophene) with monodentate or bidentate ligands. The reactions must be carried out in either toluene or acetonitrile boiling under reflux, suggesting a dissociative ligand substitution mechanism, which is unusual for Pd. Some of the *cis*-bisarylated complexes obtained show interesting structural features associated with their steric crowding. Several complexes exhibit $^{19}F-^{19}F$ through-space couplings between both Fmes. References on such couplings in organometallic compounds are scarce,[3] even though many *cis*-bisarylated fluoroaryl complexes are known.[4]

Results

Syntheses of Bisarylated Complexes

The complex *trans*-$[Pd(Fmes)_2(SMe_2)_2]$ (**1a**) was obtained by arylation of *trans*-$[PdCl_2(SMe_2)_2]$ with Li(Fmes), as described previously for *trans*-$[Pd(Fmes)_2(tht)_2]$ (**1b**).[2a] This complex is a better precursor for the preparation of other bisarylated complexes (Scheme 2) as SMe_2 has a higher volatility (b.p. 38 °C) than tht (b.p. 119 °C). Although in related Pd complexes (e.g. *trans*-$[Pd(C_6F_5)_2(SMe_2)_2]$, or *trans*-$[Pd(C_6F_5)_2(tht)_2]$) SMe_2 or tht are easily displaced by other ligands at room temperature,[4a] in these bis-Fmes derivatives they resist displacement, even in the presence of a large excess of the entering ligand. Displacement is achieved only when the mixture is submitted to reflux in high-boiling temperature solvents such as toluene or MeCN.



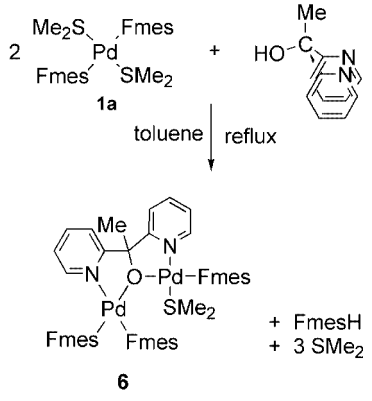
Scheme 2. Synthesis of the complexes

Thus, neutral monodentate ligands L replace SMe_2 from **1a**, in refluxing toluene, to give the corresponding neutral mononuclear complexes *trans*-$[Pd(Fmes)_2L_2]$ (L = 4-pic, **1c**; PMe_3, **1d**; *t*BuNC, **1e**, *p*Tol-NC, **1f**). The reactions do not proceed under milder conditions. Boiling under reflux **1a** or **1b** in NCMe produced *trans*-$[Pd(Fmes)_2(NCMe)(SMe_2)]$ (**2a**).

Treatment of **1a** or **1b** with excess ($NnBu_4$)I did not lead to the substitution of both thioether ligands by iodide, but to the formation of the monoanionic ($NnBu_4$)[*trans*-$Pd(Fmes)_2I(SMe_2)]$ (**3a**) or ($NnBu_4$)[*trans*-$Pd(Fmes)_2I(tht)]$ (**3b**), respectively.

Boiling under reflux in toluene was also required to replace the thioether ligands when **1a** was treated with neutral bidentate ligands L-L. This produced $[Pd(Fmes)_2(L\text{-}L)]$ (L-L = Me_2bipy (4,4′-Me_2-2,2′-bipyridine), **4a**; biquinolyl, **4b**; κ^2N,N'-$OCPy_2$ (Py = 2-pyridyl), **4c**; dppm ($Ph_2PCH_2PPh_2$), **4d**; dppe ($Ph_2PCH_2CH_2PPh_2$), **4e**; pte ($PhSCH_2CH_2SPh$), **4f**).

Bisarylated complexes containing chemically non-equivalent Fmes groups were obtained with bidentate ligands containing two different donor atoms (L-L′). Thus the S,N-donor ligand $SPPh_2Py$ gave $[Pd(Fmes)_2(\kappa^2S,N\text{-}SPPh_2Py)]$ (**5a**). Remarkably, equimolar amounts of **1a** and $OPPhPy_2$, which usually coordinates as κ^2N,N-donor to Pd^{II},[5] gave $[Pd(Fmes)_2(\kappa^2O,N\text{-}OPPhPy_2)]$ (**5b**). The treatment of $(OH)(CH_3)CPy_2$ with *trans*-$[Pd(Fmes)_2(SMe_2)_2]$ (**1a**) did not afford the expected *cis* bisarylated complex, but gave instead the binuclear complex $[Pd(Fmes)_2(\mu\text{-}1\kappa N{:}1,2\kappa O{:}2\kappa N\text{-}Py_2MeCO)Pd(Fmes)(SMe)_2]$ (**6**) (Scheme 3).



Scheme 3. Preparation of **6**

Characterization of Bisarylated Complexes

Solid-state IR spectra of all the bisarylated complexes show characteristic absorptions for the Fmes group.[6] Absorption in the region 710−670 cm^{-1} for several polyfluorophenyl has been associated with the R−M fragment and can be structurally informative: the *cis* isomers exhibit two

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

medium-to-strong bands in this range, whereas the *trans* isomers show only one.[4a,7] This feature is also observed at 690−680 cm^{-1} for the Fmes complexes, which supports their structural assignments. No additional evidence is provided by the IR data of **1a** (although the *trans* isomer was found in the structural determination of **1b**, previously reported),[2a] and **1c**. The *trans* geometry for **1e** and **1f** is further supported by the presence of only one ν(C≡N) absorption for the coordinated isocyanides.

trans-[Pd(Fmes)$_2$(*p*Tol-NC)$_2$] (**1f**) was characterized by solid-state X-ray diffractometry, as an example of a complex with a ligand with minimal steric requirements in the vicinity of the coordination sites. The molecular structure of **1f** (Figure 1) and selected distances and angles (Table 1) are given here.

There are two independent molecules of **1f** in the unit cell, but only one-half of each molecule is included in the asymmetric unit. The molecules show a square-planar coordination for Pd, with the two isocyanide ligands in *trans* disposition (related by an inversion centre) and the isocyanide and the Fmes group forming an angle C(11)−Pd(1)−C(1) = 92.80(14)° in one molecule and C(31)−Pd(2)−C(21) = 91.93(15)° in the other. The two Fmes groups are coplanar and nearly perpendicular to the coordination plane, one showing the two Fmes groups tilted only 5.8(4)° and the other 2.2(4)° to the coordination plane. The Pd−C_{ipso} distances [Pd(1)−C(1), 2.102(4) Å; Pd(2)−C(21), 2.098(4) Å] are similar to those found in *trans*-[Pd(Fmes)$_2$(tht)$_2$],[2a] and somewhat longer than those in other complexes where the ligand *trans* to the Fmes is harder (see, for instance, other structures in this paper and in ref. 2). As usually observed in Fmes palladium complexes, the C−C−C angles at the *ipso* carbon are significantly less than 120° and those at the *ortho* carbon atoms are rather larger than 120° due to the electronic effects of the electropositive metal and electronegative CF_3 substituents at these positions.[8] The C−N−C angle of the two isocyanide groups is < 180°, a common feature for isocyanides coordinated to transition metals.[9] The structure suggests that there are no important repulsive interactions between neighbouring CF_3 groups, otherwise the rings would tilt to scatter these as much as possible. The elongation of the Pd−CF_3 distance compared with other complexes (and similar to *trans*-[Pd(Fmes)$_2$(tht)$_2$]) is then attributed mostly to a high *trans* influence of the Fmes group. Presumably, with these Pd−Fmes distances, there is little steric repulsion between facing CF_3 groups in a *trans*-[Pd(Fmes)$_2$L$_2$] complex.

The ^{19}F NMR spectra of all the *trans* complexes **1** display two singlets with 2:1 intensities, except for **1d** where a triplet is observed for the *ortho*-CF_3 due to coupling with two equivalent phosphorus atoms. The *trans* geometry of complexes **2** and **3** is confirmed by the chemical equivalence of both Fmes groups.

The *cis* complexes **4** exhibit only one singlet for *para* CF_3 groups (which is consistent with the equivalence of the two Fmes groups), and another signal for the equivalent *ortho*-CF_3 groups. However, with biquinolyl **4b** and pte **4f** the latter signal is very broad, which is interpreted as owing to a slow concerted tilting of both Fmes groups, as observed for related systems.[2a] The ^1H NMR spectra show that the two halves of the chelate ligands are equivalent through a C_2 axis.

To explore the expected distortions when more sterically demanding ligands are used, **4b** (L-L = 2,2′-biquinolyl) was characterized by solid-state X-ray diffractometry (Figure 2); Table 2 gives relevant distances and angles. The two Fmes ligands are coordinated in a *cis* arrangement, and the two N atoms of the biquinolyl ligand occupy the other coordination sites. The biquinolyl ligand is not planar, with the two halves forming an angle of 25.0(5)°. Moreover, the average plane of the biquinolyl ligand forms a dihedral angle of 35.8(5)° with the average coordination plane. This makes the nitrogen atoms pyramidal, as found in [Pd(biquinolyl)(allyl)]$^+$ complexes.[10] The square-planar geometry of Pd is severely distorted towards tetrahedral with the C_{ipso} atoms of the two Fmes situated 0.42 and 0.98 Å above and below, respectively, the N−Pd−N plane. For comparison, the related complex [Pd(Fmes)$_2$(bipy)], which is also tetrahedrally distorted,[2a] shows a smaller distortion with the C_{ipso} atoms 0.40 Å above and below the N−Pd−N plane. Tetrahedral distortion is associated with angles that differ greatly from those expected for a square-planar geo-

metry: C(21)−Pd(1)−C(31) 93.9(2)°; C(21)−Pd(1)−N(2) 100.46(19)°; C(31)−Pd(1)−N(1) 94.83(19)°. The N(1)−Pd(1)−N(2) angle is 75.88(18)°, a normal value for this small-bite chelating ligand. Despite these distortions the Pd−C and Pd−N distances are not affected noticeably, remaining very similar to those of the square-planar [Pd-(bipy)(Fmes)$_2$].[2a]

κ^2O,N-Coordination of OPPhPy$_2$ in **5b** is supported by the phosphorus chemical shift in the $^{31}P\{^1H\}$ NMR spectrum, which clearly differs from those shifts when OPPhPy$_2$ acts as κ^2N,N-donor (Table 3), and is closer to those of the κ^2O,N-chelate OPPh$_2$Py.[2c,5,11] The difference with the latter can be accounted for by the higher shielding effect on P of Py compared with Ph. The P−O stretching absorptions are usually useful in differentiating κ^2O,N- and κ^2N,N-coordination modes of OPPhPy$_2$ [12] but this band is not detected in the IR spectrum of **5b** due to other intense absorptions in the same range.

Unequivocal characterization of [Pd(Fmes)$_2$(μ-1κ*N*:1,2κ*O*:2κ*N*-Py$_2$MeCO)Pd(Fmes)(SMe$_2$)] (**6**) required an X-ray diffraction study. A perspective view of the molecular structure is given in Figure 3, and selected distances and angles are listed in Table 4.

The complex is binuclear and the two Pd coordination planes make a dihedral angle of 72.1(4)° (Figure 3). The molecule contains three non-equivalent Fmes groups, two

of them *cis* coordinated to one of the metal centres, Pd(1). Each pyridyl group of the [O(CH$_3$)CPy$_2$]$^-$ ligand is coordinated to a different palladium atom, whereas the oxygen atom bridges the two metal centres. The SMe$_2$ ligand occupies the fourth coordination site in the monoarylated Pd atom.

The Pd−C distances are all very similar [Pd(1)−C(41) 2.011(13), Pd(1)−C(31) 2.027(10), Pd(2)−C(21) 2.005(11) Å], lying in the range of other *cis* bisarylated or monoarylated Fmes Pd complexes.[2a−2e] The distances and angles of the [O(CH$_3$)CPy$_2$]$^-$ ligand are similar to those found in In^{III} [13] and Cu^{II} [14] complexes, where it is also coordinated as a bridging ligand.

Whereas the geometry of the monoarylated palladium centre is nearly square planar, that of the bisarylated palladium centre is very distorted, since N(1) is 0.574(15) Å out of the plane defined by O(1)−C(41)−Pd(1)−C(31). The N(1)−Pd(1)−O(1) and N(2)−Pd(2)−O(1) angles are significantly lower than 90° [80.4(3)° and 79.5(3)°], which is compensated for by the C(31)−Pd(1)−O(1) and O(1)−Pd(2)−S(1) angles [93.6(3)° and 93.9(2)°, respectively]. The *cis* angle involving the carbon atoms of the Fmes ligands is larger than 90° [95.6(4)°], presumably as a result of steric constraints.

The Fmes groups are not perpendicular to the coordination plane, but tilted in the same sense by 70.4° [C(41)], 64.6° [C(31)] and 78.6° [C(21)]. This tilting, observed for other *cis* bis(Fmes) palladium complexes,[2a] seems to help in minimizing the repulsions between the *ortho*-CF$_3$ substituents of *cis* Fmes groups.

^{19}F NMR spectra of complexes **5a**, **5b**, and **6** reveal ^{19}F−^{19}F through-space coupling (see below).

Discussion

For square-planar aryl complexes, although the C−M bonding interaction is little affected by the dihedral angle between the aryl and the coordination plane, the aryl groups tend to lie perpendicular to the coordination plane to minimize steric repulsions.[15] Conversely, ligand-substitution reactions on 16e palladium(II) complexes follow an associative mechanism via 18e pentacoordinate transition states, rather than the alternative dissociative pathway via 14e three-coordinate intermediates.[16] We know of no exception to this rule for palladium, although several dissociative ligand substitution have been found in bis(aryl) derivatives of platinum.[17] The aryl complexes reported here show dramatic deviations from the normal behaviour of Pd^{II} complexes due to the steric crowding produced by the four *ortho*-CF$_3$ groups competing for the same axial space over the coordination plane. It is convenient to discuss first their structural features to better understand their reactivity. Fortunately, many results for these bis(Fmes) complexes can be directly compared with those in the literature for C$_6$F$_5$ complexes, and with the mono(Fmes) complexes recently reported.[2c]

Structures in the Solid State and in Solution

(A) Complexes *trans*-[Pd(Fmes)$_2$L$_2$] (L = monodentate ligand): X-ray structures of the complexes with L = tht,[2a] *p*Tol-NC show an essentially square-planar geometry, with the Fmes rings almost coplanar and perpendicular to the coordination plane. The same arrangement has been found in the square planar *trans*-[Au(Fmes)$_2$I$_2$]$^-$.[1f] However, in the linear complex [Au(Fmes)$_2$]$^-$ the aryl planes of the two Fmes groups make an angle of 27.2°. For comparison, the complex [Au(C$_6$F$_5$)$_2$]$^-$ shows coplanar rings.[18] Thus, two *trans* Fmes groups are better stabilized as coplanar and lay perpendicular to the coordination plane when the other two positions in the square-planar geometry are occupied. When there are no ancillary ligands present, as in [Au(Fmes)$_2$]$^-$, the Fmes groups scatter by rotation, giving rise to a pseudohelicoidal geometry and relieving the repulsion between the facing *ortho*-CF$_3$ groups. Such behaviour suggests that the steric repulsion between two *trans* Fmes groups is perceptible but very moderate.

(B) Complexes *cis*-[Pd(Fmes)$_2$(L-L′)] [L-L = bipy;[2a] biquinolyl (4b), or the *cis*-bisarylated moiety of 6]: These square-planar geometries are clearly more distorted towards tetrahedral than those of *trans* bisarylated complexes. The distortion increases with the size of the ancillary ligands. The Pd−C distances are shorter than for the *trans* bisarylated complexes (the *trans* effect of the ancillary ligands is lower than that of Fmes), and slightly longer than those in monoarylated Fmes Pd complexes (the latter are usually below 2.0 Å).[2c] The Fmes groups are not perpendicular to the coordination plane, as is usual in common aryl derivatives, but tilted in the same sense by ca. 20° from the perpendicular. Since the steric crowding in a *cis* bisarylated moiety is clearly higher than in *trans* bisarylated complexes, so must be the corresponding repulsions. This concerted tilt appears to be the best distortion to minimize repulsions between the *ortho*-CF$_3$ of the two contiguous Fmes ligands, even if it increases the repulsions with the ancillary ligands. This distortion should make chemically non-equivalent the *exo* and *endo* (relative to the C−Pd−C angle) *ortho*-CF$_3$ groups. In solution all the *cis* bisarylated complexes reported here are stereochemically dynamic, and a concerted tilting of the two Fmes ligands gives rise to an

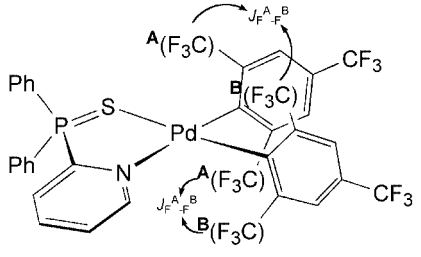
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

averaged geometry in which the Fmes groups would be perpendicular to the coordination plane. The barrier to this *endo*−*exo* exchange is low, but a broadening of the *ortho*-CF_3 signals is observed in the low-temperature ^{19}F NMR spectra of some of the *cis* bisarylated complexes. The tilting has been frozen out in the recently reported related Ni complex [Ni(Fmes)$_2$(1,2-dimethoxyethane)$_2$],[19] where the smaller metal atom leads to greater crowding.

No spectroscopic evidence was found in solution for the tetrahedral distortion observed in the solid-state structures of some of the complexes. For instance, the ^{19}F NMR of **4b** should give four *ortho*-CF_3 signals if the solid-state structure were "frozen" in solution, but only one signal is observed. This indicates that the barriers for the process averaging the coordination plane and that for the concerted tilting are low, and that the processes are fast even at low temperatures.

(C) Complexes *cis*-[Pd(Fmes)$_2$(L-L′)] with Other Chelating Ligands. $^{19}F-^{19}F$ Through-Space Couplings: Complexes **5a**, **5b**, and **6** have less symmetric structures and their spectra reveal $^{19}F-^{19}F$ through-space couplings between close non-equivalent *ortho*-CF_3 groups. The *para*-CF_3 groups are too far away to show through-space coupling.

In [Pd(Fmes)$_2$(SPPh$_2$Py)] (**5a**) the ligand SPPh$_2$Py coordinates to the bisarylated fragment as a κ^2S,N-donor in an averaged planar chelate ring (Scheme 4). The fast envelope-shift movement of the five-membered chelate rings has a very low activation energy, allowing us to consider the five-membered metallacycle as planar.[20] Accordingly, the ^{19}F NMR spectrum of **5a** shows two high-field singlets due to the two non-equivalent *para*-CF_3, whereas the *ortho*-CF_3 groups form a $X_3A_3A'_3X'_3$ system, which affords two quadruplets, with $J = 9.3$ Hz. This value may be ascribed to through-space coupling between the fluorine atoms on the same side of the coordination plane (Scheme 4), as there are too many bonds between the inequivalent atoms to permit significant scalar coupling, and the coupling constant is similar to those detected in some fluoroaryl complexes described by our group.[3] No diagonal coupling is detected between CF_3 groups of different Fmes groups, nor between different CF_3 groups at opposite sides of the coordination plane.



Scheme 4. $^{19}F-^{19}F$ through-space couplings in **5a**

In [Pd(Fmes)$_2$(κ^2O,N-OPPhPy$_2$)] (**5b**) the ligand OPPhPy$_2$ coordinates to the bisarylated moiety as κ^2O,N-donor (Scheme 6). As for **5a**, the inequivalent *para*-CF_3 give rise to two high-field singlets, whereas the *ortho*-CF_3 groups now constitute an $A_3K_3M_3X_3$ system, giving rise to four quadruplets. The coupling constants (7.5, 6.0 Hz) are similar to those of **5a**, indicating that the observed through-space coupling occurs between *ortho*-CF_3 groups in different Fmes rings, but at the same side of the coordination plane. As before, no other couplings are detected.

For [Pd(Fmes)$_2$(μ-1κ*N*:1,2κ*O*:2κ*N*-Py$_2$MeCO)Pd(Fmes)(SMe$_2$)] (**6**) the ^{19}F NMR spectrum shows three singlets in the *para*-CF_3 region, confirming the presence of three non-equivalent Fmes groups. Six signals (one singlet and five multiplets) are detected in the *ortho*-CF_3 region (Figure 4), indicating that they are all non-equivalent. Homonuclear decoupling experiments allowed us to assign which nuclei are involved in each coupling (Figure 4), assuming that all the coupling constants observed are due to through-space coupling between fluorine atoms on the same side of the coordination planes, as observed for **5a** and **5b**. While $F_3C(29)$ appears as non-coupled because it is far from the rest of fluoromethyl groups, $F_3C(37)$ is coupled with $F_3C(49)$ (both on the same metal) and with $F_3C(27)$ (which is on the other Pd atom). The coupling constants are 10 and 8.5 Hz, respectively. The other two fluoromethyl groups showing couplings are $F_3C(47)$ and $F_3C(39)$, with $J = 8$ Hz. These through-space coupling constants give an estimation of the distance between the fluoromethyl groups;[21] the higher coupling the shorter distance, regardless of whether the fluoromethyl groups belong to Fmes coordinated to the same or to different metal centres.

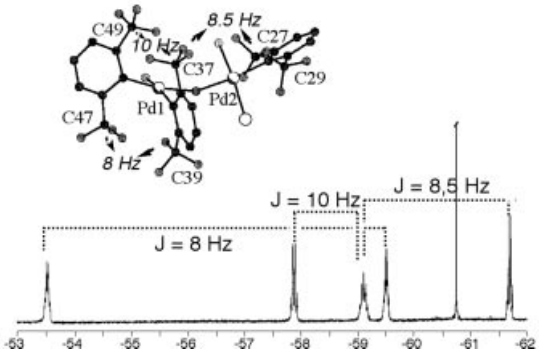


Figure 4. ^{19}F NMR of [Pd(Fmes)$_2$(μ-1κ*N*:1,2κ*O*:2κ*N*-Py$_2$MeCO)Pd(Fmes)(SMe$_2$)] (**6**) (*ortho*-CF_3) in $CDCl_3$ at 298 K, showing the through-space couplings observed

Complex **6** shows a slow dynamic process in solution that involves the SMe_2 group. Its ^1H and ^{19}F spectra in $CDCl_3$ at room temperature accord with the solid-state structure, but the two signals for the methyl groups of the SMe_2 are broad at room temperature, and coalesce at 333 K. This equivalence can be achieved by a process requiring both inversion of the sulfur atom and rotation about the Pd−S bond. The high steric crowding could be responsible for the very slow exchange at room temperature. However, a process involving SMe_2 dissociation and reassociation occurs

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for other isomerizations in complexes with this weakly bound ligand[3b] and can not be discounted here.

Mechanisms of the Syntheses of Bisarylated Complexes

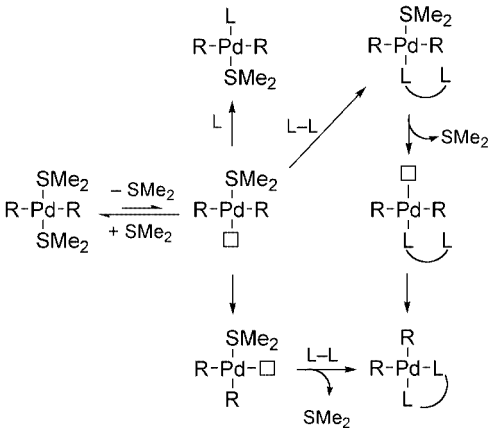
In contrast with the reaction features of ligand substitution in [PdCl(Fmes)L_2] complexes, which suggest an associative mechanism,[2c] the harsh conditions required for ligand substitution in the bis-Fmes complexes suggest a dissociative mechanism, implying a positive activation entropy, which is favoured at high temperature.[22] Although associative ligand substitutions dominate palladium(II) chemistry (so far they are the only type observed), dissociative mechanisms could become competitive (faster) as the associative are disfavoured. Dissociative ligand substitution could be favoured by (i) PdR_2 substrates where R is a good σ-donor;[23] (ii) complexes with bulky ligands;[17e,22] and (c) substrates with labile leaving ligands. These three requirements are met by **1a**. An associative mechanism through a five-coordinate transition state should be disfavoured in our system for electronic reasons (the palladium centre in bisarylated substrates is electron rich), and even more so for steric reasons: as the *z* axis is occupied above and below the metal coordination plane by the *ortho*-CF_3 of the two Fmes groups, the attack of even a small nucleophile looks to be extremely difficult (*ortho* effect).

This leads us to propose the mechanism depicted in Scheme 5 for the substitution reactions. The formation of only *trans* bis-Fmes complexes from the reactions of *trans*-[Pd(Fmes)$_2$(SMe_2)$_2$] with monodentate ligands contrasts with previous observations for reactions on *trans*-[Pd(C_6F_5)$_2$(tht)$_2$], where *cis* complexes are formed in preference.[22b] This means that *trans*-[Pd(Fmes)$_2$$L_2$] and *cis*-[Pd($C_6F_5$)$_2$$L_2$] are the thermodynamic products, respectively, for these two aryls. Formation of the *trans* isomer with Fmes complexes occurs against the antisymbiotic effect (or transphobia),[24] indicating that the relief of steric crowding in the *trans* complex compensates for the higher electronic destabilization associated with two *trans* Fmes groups.

Boiling under reflux complexes **1** in NCMe furnishes *trans*-[Pd(Fmes)$_2$(NCMe)(SR_2)] (**2**) complexes. The bis(acetonitrile) complex [Pd(Fmes)$_2$(NCMe)$_2$] has not been detected, suggesting that the first substitution of SMe_2 by the poorer donor NCMe makes the complex less electron rich, and the dissociation of a second SR_2 becomes disfavoured.

The formation of the monosubstituted products, (N*n*Bu_4)[*trans*-Pd(Fmes)$_2$I(SR_2)] (**3**), after the reactions of *trans*-[Pd(Fmes)$_2$(SR_2)$_2$] (**1**) with (N*n*Bu_4)I can be considered normal. The formation of (N*n*Bu_4)$_2$[Pd(Fmes)$_2$$X_2$] is, apparently, counter-thermodynamic; similar results have been found for non-crowded bisarylated complexes. For instance, no [Pd(C_6F_5)$_2$$X_2$]$^{2-}$ complexes have been reported, despite many studies on (pentafluorophenyl)palladium complexes.[25]

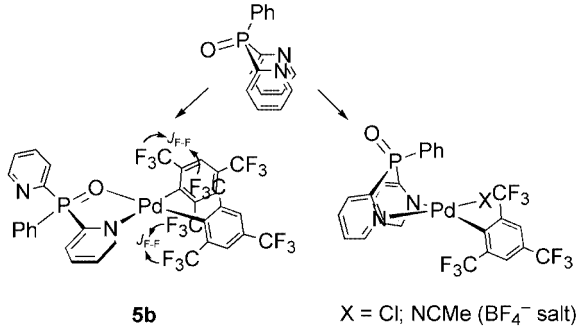
The formation of complexes **4** and **5** involves a *trans*-to-*cis* isomerization from the starting material to the final product. Thus, a topomerization of the *trans* to the corresponding *cis* three-coordinate intermediate is needed



Scheme 5. Dissociative mechanism of the substitution processes

(Scheme 5). Thermodynamically, the "chelate effect", and in most cases the use of a stronger ligand, contribute to compensate the destabilization caused by the higher repulsion between two *cis* Fmes groups. In addition, the first dissociative substitution by a better σ-donor with a higher *trans* influence (except for the ligand pte, where the change is *S*-donor for *S*-donor), favors, kinetically, the dissociation of the second SR_2 ligand.

The κ^2*O*,*N*-coordination of $OPPhPy_2$ found in **5b** was unknown for square-planar palladium(II), although it occurs in pseudo-octahedral molybdenum(II) derivatives.[26] κ^2*N*,*N*-Coordination usually observed in Pd^{II} complexes is probably disfavoured in our case by the high degree of steric crowding due to the presence of two *cis* Fmes groups, quite similarly to its prevention in octahedral complexes. The κ^2*O*,*N*-coordination takes the substituents of the phosphorus away from the axial positions, minimizing the steric congestion. Interestingly, monoarylated complexes [PdCl(Fmes)(κ^2*N*,*N*-$OPPhPy_2$)] and [Pd(Fmes)(NCMe)-(κ^2*N*,*N*-$OPPhPy_2$)]BF_4 have been isolated and characterized.[2c,11] Therefore, one Fmes group is compatible with an axial disposition of the phenyl group in κ^2*N*,*N*-coordination, but two Fmes groups (here) or an octahedral metal centre (Mo complex cited above) force κ^2*O*,*N*-coordination. This highlights the very different "axial" encumbrance produced in monoarylated and bisarylated Fmes complexes. In monoarylated derivatives the Fmes group is probably tilted to accommodate the phenyl group (Scheme 6). The ability



Scheme 6. Bisarylated (indicating detected $^{19}F-^{19}F$ through-space coupling) and monoarylated $OPPhPy_2$ complexes

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of Fmes to tilt and make the space in the *z* direction accessible to attack by nucleophiles explains why the reactions involving monoarylated substrates can proceed by associative mechanisms,[2c] while those reported here seem to require ligand dissociation.

We used a ligand with smaller substituents, $(OH)(CH_3)CPy_2$, to check whether κ^2N,N-coordination occurred, but this yielded, unexpectedly, [Pd(Fmes)$_2$(μ-1κ*N*:1,2κ*O*:2κ*N*-Py_2MeCO)Pd(Fmes)(SMe_2)] (**6**), and HFmes as by-product (Scheme 3). The alcoholic hydrogen has been previously reported to be acidic when the ligand is coordinated to other metals, such as In^{III}.[13] However, no deprotonation occurred during the reactions of $(OH)(CH_3)CPy_2$ with the monoarylated complexes *trans*-[PdClFmes(SMe_2)$_2$] or [Pd(Fmes)($NCMe)_3$]BF_4, which lead to [PdClFmes(κ^2N,N'-$(OH)(CH_3)CPy_2$)][2c] and [Pd(Fmes)-{κ^2N,N'-$(OH)(CH_3)CPy_2$}(NCMe)]BF_4, respectively.[11] This suggests that acidic activation of the O−H bond might require previous *O*-coordination to a putative three-coordinate palladium intermediate. This might occur in the dissociative mechanism for bisarylated complexes but not in the associative substitution operating for monoarylated species.[2c]

Conclusion

Substitution and isomerization processes in bisarylated Fmes palladium complexes seem to occur by dissociative mechanisms, forced by the extreme axial protection produced by the *ortho* CF_3 substituents (*ortho* effect). Consequently, harsh reaction conditions are required, unlike the mild substitution by associative mechanisms found for the related monoarylated Fmes complexes,[2c] or for the analogous bisarylated C_6F_5 complexes.[5]

The lesser steric repulsion of two bulky Fmes mutually *trans*-stabilizes better the *trans* isomers, which should not be the thermodynamic products on the basis of only electronic effects ("antisymbiotic effect" or transphobia); *cis* isomers are obtained only for bidentate ancillary ligands, due to the chelate effect.

The $^{19}F-^{19}F$ couplings observed have no significant scalar contribution, and are due to through-space coupling that depends on the distance between the interacting nuclei. This is clearly so as the magnitude of the coupling does not depend on whether the fluoromethyl groups are on Fmes coordinated to the same metal or on Fmes coordinated to different metals in a binuclear complex.

Experimental Section

General Remarks: All reactions were carried out under dry N_2. Solvents were purified according to standard procedures.[27] The complexes *trans*-[$PdCl_2$(tht)$_2$],[28] *trans*-[$PdCl_2(SMe_2)_2$],[28] *trans*-[Pd(Fmes)$_2$(tht)$_2$] (**1b**)[2a] and the ligands $OPPhPy_2$,[29] $SPPh_2Py$,[30] and $(OH)(CH_3)CPy_2$,[31] were prepared according to literature procedures. *p*Tol-NC was synthesized as reported[32] using triphosgene as dehydrating agent.[33] 1,3,5-$C_6H_3(CF_3)_3$ (FmesH) from Fluorochem was used as received, and Li(Fmes) was prepared in situ as described in the literature.[34] The rest of the reactants were purchased from commercial suppliers and used as received.

Infrared spectra were recorded with a Perkin−Elmer 883 apparatus as Nujol mulls between polystyrene films from 4000 to 200 cm^{-1}. NMR spectra were recorded with Bruker AC-300 or ARX-300 instruments. ^1H, $^{31}P\{^1H\}$ and ^{19}F NMR spectra are referenced to TMS, 85% aqueous H_3PO_4, and $CFCl_3$, respectively. Elemental analyses were performed with a Perkin−Elmer 2400B microanalyzer.

***trans*-[Pd(Fmes)$_2$(SMe_2)$_2$] (1a):** *trans*-[$PdCl_2(SMe_2)_2$] (0.604 g, 2 mmol) was added to a freshly prepared solution of Li(Fmes) (7.95 mmol) in Et_2O (40 mL). The reaction mixture was maintained at 40 °C for 24 h, and then two drops of water were added to hydrolyse the excess organolithium reagent. The volatiles were pumped off, and the residue was extracted with toluene and filtered through silica gel. The solvent was then evaporated and the resultant pale brown residue was recrystallized from dichloromethane/hexane at −20 °C to give pale yellow crystals that were decanted, washed with hexane and vacuum-dried. Yield 0.801 g (51%). IR: $\tilde{\nu}$ = 687 s cm^{-1}. ^{19}F NMR: δ = −63.18 (s, 6 F, *para*-CF_3), −60.41 (s, 12 F, *ortho*-CF_3) ppm. ^1H NMR: δ = 1.66 [s, 12 H, $S(CH_3)_2$], 7.92 [s, 4 H, $C_6H_2(CF_3)_3$] ppm. $C_{22}H_{16}F_{18}PdS_2$ (792.86): calcd. C 33.33, H 2.03; found C 33.16, H 2.03.

***trans*-[Pd(Fmes)$_2$(4-pic)$_2$] (1c):** 4-pic (21.4 μL, 0.021 g, 0.22 mmol) was added to a solution of **1a** (0.080 g, 0.1 mmol) in toluene (10 mL) and boiled under reflux for 3 h. The so-obtained solution was filtered through dry Celite, the volatiles were pumped off, and the resultant white solid was washed with hexane and vacuum dried [yield 0.055 g (65%)]. Recrystallization from dichloromethane/hexane gave colourless crystals. IR: $\tilde{\nu}$ = 688 m cm^{-1}. ^{19}F NMR: δ = −63.12 (s, 6 F, *para*-CF_3), −59.73 (s, 12 F, *ortho*-CF_3) ppm. ^1H NMR: δ = 2.22 [s, 6 H, $NC_5H_4(CH_3)$], 6.76 [d, *J* = 6.5 Hz, 4 H, $NC_5H_4(CH_3)$], 7.82 [s, 4 H, $C_6H_2(CF_3)_3$], 7.92 [d, *J* = 6.5 Hz, 4 H, $NC_5H_4(CH_3)$] ppm. $C_{30}H_{18}F_{18}N_2Pd$ (854.86): calcd. C 42.15, H 2.12, N 3.28; found C 42.27, H 2.38, N 3.50.

***trans*-[Pd(Fmes)$_2$(PMe_3)$_2$] (1d):** In a Young-valve-fitted Schlenk flask, PMe_3 (200 μL of 1 M in THF, 0.2 mmol) was added to a solution of **1a** (0.080 g, 0.1 mmol) in toluene (10 mL) and heated to 110 °C for 7 h. Work up as for **1c** then yielded 0.028 g (34%) of material. Recrystallization from dichloromethane/hexane gave colourless crystals. IR: $\tilde{\nu}$ = 688 s cm^{-1}. ^{19}F NMR: δ = −63.13 (s, 6 F, *para*-CF_3), −59.51 (t, *J* = 5.5 Hz, 12 F, *ortho*-CF_3) ppm. $^{31}P\{^1H\}$ NMR: δ = −20.12 (sept, *J* = 5.5 Hz) ppm. ^1H NMR: δ = 0.83 [$A_9XX'A_9'$ syst., *J* = 7 Hz, 18 H, $P(CH_3)_3$], 7.89 [s, 4 H, $C_6H_2(CF_3)_3$] ppm. $C_{24}H_{22}F_{18}P_2Pd$ (820.76): calcd. C 35.12, H 2.7, found C 34.86, H 2.59.

***trans*-[Pd(Fmes)$_2$(*t*BuNC)$_2$] (1e):** *t*BuNC (225 μL, 0.165 g, 2 mmol) was added to a solution of **1a** (0.080 g, 0.1 mmol) in toluene (10 mL) and boiled under reflux for 5 h. Work up as for **1c** subsequently yielded 0.070 g (83%) of material. Recrystallization from dichloromethane/hexane gave colourless crystals. IR: $\tilde{\nu}$ = 686 s cm^{-1}. ^{19}F NMR: δ = −63.00 (s, 6 F, *para*-CF_3), −61.74 (s, 12 F, *ortho*-CF_3) ppm. ^1H NMR: δ = 1.16 (s, 18 H, CNC_4H_9), 7.92 [s, 4 H, $C_6H_2(CF_3)_3$] ppm. $C_{28}H_{22}F_{18}N_2Pd$ (834.87): calcd. C 40.28, H 2.66, N 3.36; found C 40.27, H 2.61, N 3.21.

***trans*-[Pd(Fmes)$_2$(*p*Tol-NC)$_2$] (1f):** *p*Tol-NC (0.100 g, 0.85 mmol) was added to a solution of **1a** (0.160 g, 0.2 mmol) in toluene (15 mL) and boiled under reflux for 8 h. Subsequent work up as for **1c** yielded 0.045 g (28%) of material. Recrystallization from di-

X-ray Crystallographic Study: Suitable crystals of **1f** and **4b** were grown by slow diffusion of a concentrated dichloromethane solution of the complex into diethyl ether (**1f**) or n-hexane (**4b**) at −20 °C. For **6**·0.5 toluene, crystals were grown by slow evaporation of a concentrated toluene solution of the complex at 8 °C. X-ray measurements were made using a Bruker SMART CCD area-detector diffractometer with Mo-K_α radiation (λ = 0.71073 Å).[35] Intensities were integrated from several series of exposures,[36] each exposure covering 0.3° in ω, the total data set being a hemisphere. Absorption corrections were applied, based on multiple and symmetry-equivalent measurements.[37] The structure was solved by direct methods and refined by least-squares on weighted F^2 values for

all reflections (Table 5).[38] All non-hydrogen atoms were assigned anisotropic displacement parameters and refined without positional constraints, except that the carbon atoms of the toluene molecule in **6**·0.5 toluene were refined isotropically. Hydrogen atoms were constrained to ideal geometries and refined with fixed isotropic displacement parameters. Refinement proceeded smoothly to give the residuals shown in Table 5. Complex neutral-atom scattering factors were used.[39] CCDC-221232 (for **1f**), -221233 (for **4b**) and -221234 (for **6**·0.5 toluene) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Different Coordination Modes of the Polyfunctional Ylide Ph_3P=C(H)C(O)CH_2C(O)OEt: *C*- vs. *O*,*O*′-Bonding in Pd^{II}, Pt^{II} and Au^{I} Complexes

Marta Carbó,[a] Larry R. Falvello,[a] Rafael Navarro,*[a] Tatiana Soler,[a] and Esteban P. Urriolabeitia*[a]

Keywords: Palladium / Platinum / Gold / Ylides / Structure elucidation

Treatment of the polyfunctional ylide Ph_3P=C(H)C(O)CH_2-COOEt (**1**) with the solvated complexes [M(C^X)$(THF)_2$]ClO_4 gave the *O*,*O*′ derivatives [M(C^X)($Ph_3PCH_2C(O)$=C(H)–C(=*O*)OEt-κ-*O*,*O*′]ClO_4 [M(C^X) = Pd($C_6H_4CH_2NMe_2$) (**2**), Pd($CH_2C_9H_6N$) (**3**), Pd(NC_5H_4-2-C_6H_4) (**4**), Pd($NC_{13}H_8$) (**5**), Pd[(*S*)–$C_6H_4C(H)MeNMe_2$] (**6**), Pt[*o*-$CH_2C_6H_4P$(*o*-tol)$_2$] (**7**), Pd[*o*-$CH_2C_6H_4P$(*o*-tol)$_2$] (**8**), and Pd(C_6F_5)(SC_4H_8) (**9**)]. During the reaction, one proton of the methylene unit is transferred to the ylidic carbon, which is transformed into a phosphonium group generating the zwitterion [$Ph_3PCH_2C(O)$=C(H)–C(=*O*)OEt], which coordinates to the metal center as an *O*,*O*′-chelating ligand. Treatment of **1** with [AuCl(SC_4H_8)] or [Au(PPh_3)($OCMe_2$)]ClO_4 gave [AuCl{C(H)(PPh_3)C(O)-CH_2COOEt}] (**10**) or [Au{C(H)(PPh_3)C(O)CH_2COOEt}-(PPh_3)]ClO_4 (**11**), in which the ylide is *C*-bonded. The X-ray crystal structures of complexes **2a**, **9** and **10** have been determined.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

We have recently shown that the keto-stabilized ylides [Ph_3P=C(H)C(O)R] (R = Me, OMe, Ph) can behave as ambidentate ligands towards Pd^{II} complexes, since they can coordinate either through the soft ylidic C_α atom or through the hard carbonyl oxygen depending on the vacant coordination site at the palladium precursor. This coordination occurs with notable selectivity, which has been explained in terms of the anti-symbiotic effect and the nature of the donor atoms bonded to the Pd^{II} center.[1] In all cases studied, the ylide bonds to the metal center using only one donor atom. Further introduction of new functional groups at the molecular skeleton of the ylide should result in an expansion of its bonding abilities and in the transformation of the aforementioned ambidenticity to polydenticity. We are currently pursuing the study of the coordinating properties of polydentate ylides, and how the presence of new functionalities alters the bonding patterns observed in ambidentate ylides.

Here we describe the complete characterization of ethyl 3-oxo-4-(triphenylphosphoranylidene)butanoate [Ph_3P=C(H)C(O)CH_2COOEt] (**1**) and its reactivity towards complexes of Pd^{II}, Pt^{II} and Au^{I}, in order to determine its coordinating ability. The ylide **1** could behave, at first sight, as a C-donor ligand (through the C_α atom), as an O-donor ligand (through three different O atoms) or as a polydentate ligand (using combinations of the four possible donor atoms). The synthesis of **1** was reported four decades ago[2] but, with the exception of applications in purely synthetic organic processes,[3] its bonding properties have remained unexplored. We have found quite different patterns of reactivity of this ylide as a function of the metallic precursor: *C*-bonding in Au^{I} complexes (leaving the β-keto ester functionality unchanged) and *O*,*O*′-coordination in Pd^{II} and Pt^{II} derivatives (which generates a phosphonium functionality). This paper describes the results obtained, and synthetic possibilities are also discussed.

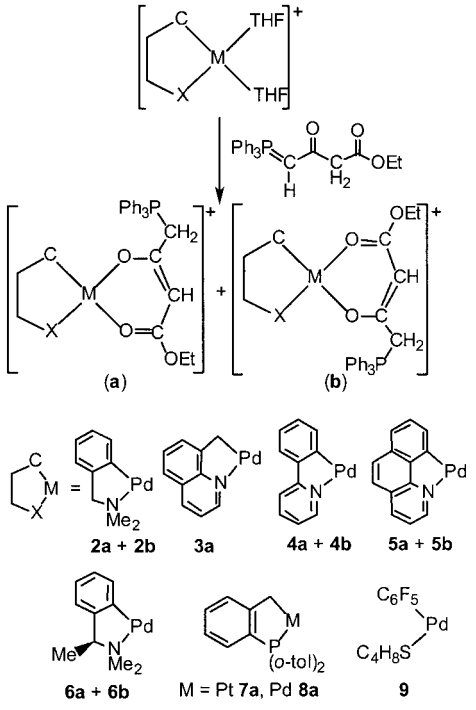
Results and Discussion

1. Palladium(II) and Platinum(II) Complexes

The ylide **1** was prepared following the method described by Serratosa and Solé,[2b] and has been characterized through its analytical and spectroscopic data. Here we also report the ^1H and $^{13}C\{^1H\}$ NMR spectroscopic parameters, since they were not provided in the original[2] or subsequent works[3f] (see Exp. Sect.). In order to check the chelating ability of **1**, its reactivity towards the bis(solvated) derivatives [M(C^X)$(THF)_2$]ClO_4 was examined (see Scheme 1). These bis(solvate) complexes were prepared by treatment of the corresponding dinuclear μ-halide complexes [M(C^X)(μ-Cl)]$_2$ with $AgClO_4$ (1:2 molar ratio) in THF, followed by removal of AgCl by filtration. The freshly prepared solutions of [M(C^X)$(THF)_2$]ClO_4 were treated with the stoichiometric amount of **1**. After the initial dissolution of **1**, complexes **2**–**9** precipitated as yellow solids from the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200300801

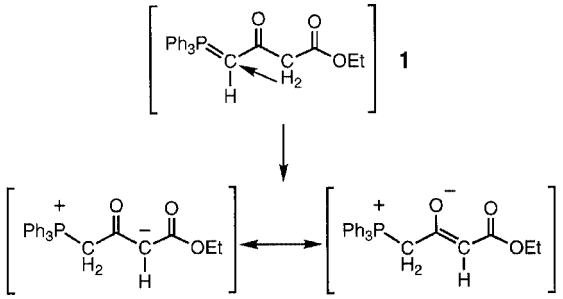
respective reaction solutions. The process is represented in Scheme 1.



Scheme 1

Complexes **2**−**9** gave elemental analyses in good agreement with the stoichiometries depicted in Scheme 1, and the mass spectra in all cases show the presence of the cationic molecular peak $[M - ClO_4]^+$ with the correct isotopic distribution. The IR spectra of **2**−**9** clearly show two strong absorptions in the 1500−1630 cm^{-1} region: one at approximately 1614−1628 cm^{-1} (attributed to the ν_{COO} stretch) and the other one at around 1502−1525 cm^{-1}, assigned to the ν_{CO} stretch of the carbonyl group adjacent to the ylide unit. A comparison of these values with those obtained for the free ylide **1** (1717 and 1546 cm^{-1}, respectively)[2b] shows that both absorptions have been shifted to lower energies. This fact strongly suggests that both carbonyl groups are bonded to the metal center, since it has been well established that *C*-coordination of the keto-stabilized ylides produces a high energy shift of the ν_{CO} stretch (with respect to the free ylide)[1] and, thus, a shift of the absorption at 1546 cm^{-1} to higher wavenumbers should be observed for *C*-bonding of **1**.

The NMR spectra of complex **2** provide valuable structural information. Firstly, all NMR spectra (^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$) display two identical sets of signals (ratio 4.5:1), showing the presence of two isomers (a) and (b) in solution. Due to the asymmetric nature of **1** and its *O*,*O*′-bonding mode, two geometric isomers can be envisaged. In addition, the ^1H NMR spectrum of **2** shows three notable features: (i) the signals due to the CH_2N and NMe_2 protons appear as singlets, indicating that the molecular plane is a symmetry plane; (ii) signals which could result from the methylene protons or the ylidic proton $P{=}C_\alpha(H)$ were not observed; (iii) instead, two singlets appear at δ = 4.5−5 ppm (δ = 4.81 ppm, major isomer; 4.86 ppm, minor isomer) and two doublets at about 4.15 ppm (δ = 4.13 ppm, J_{PH} = 13.8 Hz, major isomer, 4.16 ppm, J_{PH} = 13.8 Hz, minor isomer), with a relative intensity ratio singlet/doublet = 1:2. These observations strongly suggest that the methylene-ylide skeleton [$-CH_2-C(O)-C(H){=}P$] in **1** has been transformed into the phosphonium-enolate functionality [$-C(H){=}C(O)-CH_2P$] in **2**, by the transfer of one H atom from the methylene group to the ylidic carbon C_α (see Scheme 2). The signals in the range 4.5−5 ppm can then be attributed to the $=C(H)-$ proton (shifted slightly to high-field with respect to the usual position in β-diketonate ligands)[4] and the signals at about 4.15 ppm can be assigned to the CH_2P protons.[5] The resultant structure of the coordinated ligand in **2** is shown in Scheme 1.



Scheme 2. Proton transfer in **1** and resonance forms of the zwitterion [$Ph_3PCH_2-C(O){=}C(H)C(=O)OEt$]

The structures depicted in Scheme 1 also account for the observation, in the $^{31}P\{^1H\}$ NMR spectrum of **2**, of two resonances at approximately 22 ppm, typical for phosphonium groups.[5] In addition, the $^{13}C\{^1H\}$ NMR spectrum (acquired as APT) of **2** also shows signals characteristic of the generated phosphonium-enolate moiety: (i) two doublets at about 36 ppm ($^1J_{P,C} \approx 53$ Hz) with negative phase can be attributed to the CH_2P carbon atoms, and (ii) two doublets at about 90 ppm ($^3J_{P,C} \approx 7$ Hz) with positive phase can be assigned to the $=C(H)$ carbon atoms. Finally, the question of whether structure (a) or (b) in Scheme 1 corresponds to the major isomer must be addressed. The assignment of structure (a) to the major isomer can easily be inferred from the ^1H NMR spectrum in which the signals assigned to the protons of the metallated C_6H_4 group, for the major isomer, appear well spread in the range δ = 7.0−5.8 ppm, with the signal due to the H^6 proton (*ortho* to the metallated position) at δ = 5.89 ppm. This signal is clearly shifted to high field with respect to its position in the starting dinuclear derivative $[Pd(\mu\text{-}Cl)(C_6H_4CH_2NMe_2)]_2$ (δ ≈ 7.0 ppm), and this high-field shift must be due to the anisotropic shielding[6] produced by a phenyl ring of the PPh_3 group. This fact implies a *cis* arrangement of the C_6H_4 fragment of the metallated ligand and the PPh_3 unit of the phosphonium-enolate ligand, which occurs in structure (a). Moreover, this anisotropic shielding should not be produced in the other isomer (which possesses an OEt group in a position remote from the H^6 proton) and, in fact, the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

aromatic resonances of the metallated C_6H_4 ring in the minor isomer all appear around 7.0 ppm. We can thus conclude, on the basis of the NMR spectroscopic data, that the major isomer is that represented in Scheme 1 by structure (a) and the minor isomer by structure (b).

The IR data of complexes **2**−**9**, and their comparison with those for the free ylide **1** show that, in all cases, the bonding mode of the ylide to the metal center should be the same (*O*,*O*′-chelate), since the same shifts of the carbonyl absorptions were observed.

Moreover, the NMR spectroscopic data of complexes **2**−**9** show two relevant facts: (i) in all cases the coordinated ylide has undergone a proton transfer and, hence, the actual *O*,*O*′-bonded ligand is the zwitterionic tautomer of **1** [$Ph_3(P^+)-CH_2-C(O^-)=C(H)C(O)OEt$] (Scheme 2); (ii) complexes **3**, **7**, **8**, and **9** were obtained as single isomers, within the limit of detection of the technique, while complexes **2**, **4**, **5** and **6** were obtained as a mixture of the geometric isomers (a) and (b) depicted in Scheme 1.

For complexes **4**, **5**, and **6**, the assignment of structure (a) to the major isomers can be inferred, as for complex **2**, from their ^1H NMR spectra. In the case of **4**, the resonance assigned to the $H^{6'}$ proton (*ortho* to the metallated position) in the major isomer appears shifted to high field (δ = 6.07 ppm), and the same shift was observed in complex **5** (δ =6.05 ppm). In complex **6**, the signal due to the H^6 proton appears at δ = 5.88 ppm, virtually the same chemical shift as that observed for **2**. Thus, we can assign structure (a) for the major isomers of **4**, **5** and **6**.

The assignment of structure (a) to complex **3** rests on the similarity of the chemical shifts of the carbonyl C atoms in the $^{13}C\{^1H\}$ NMR spectrum with those in **2a** and **4a**−**6a**. These chemical shifts appear in a very narrow range of frequencies [δ_{CO} = 173.44 (**3**), 173.67 (**2a**), 173.89 (**4a**), 173.90 (**5a**), 173.78 (**6a**) ppm; δ_{COO} = 171.33 (**3**), 171.21 (**2a**), 171.57 (**4a**), 171.51 (**5a**), 171.21 (**6a**) ppm], suggesting quite similar chemical environments and a very similar structural arrangement. In comparison, the corresponding resonances of the minor isomers (b) appear, systematically, at lower field. Moreover, the resemblance of the ancillary *C*,*N*-cyclometallated ligands in **3** with those in **2**, **4**, **5** or **6** (they do not show notable structural differences and similar behavior should be expected) also supports this assignment. These extrapolations cannot be performed for complexes **7** and **8**. Here, changes in the donor atom (N replaced by P) induce a change in the electronic requirements at the *trans* position, and the substituents at the donor atom also change (the P atom contains two bulky *ortho*-tolyl groups) so that the steric requirements at the *cis* position are different. However, the assignment of structure (a) for **7** and **8** can be inferred from the $^{13}C\{^1H\}$ NMR spectra, since the signal of the methylene carbon CH_2P appears as a doublet of doublets through coupling with the adjacent phosphonium P atom and with the *trans* P atom of the cyclometallated ligand [$^4J_{P,C}$ = 5.9 Hz for **7** and $^4J_{P,C}$ = 5.1 Hz for **8**]. Moreover, the remote *trans* location of the two bulkiest fragments of the molecule, $-CH_2PPh_3$ and $P(o\text{-tol})_2$, should be energetically more stable, since it minimizes intramolecular steric repulsions.

In the case of complex **9** we have also observed the formation of a single isomer, although we do not have direct spectroscopic evidence in favor of a given structure for this complex. Throughout the description of the structures of **2**−**8** it is possible to detect a repetitive arrangement of the ligands, which places the carbonyl oxygen of the C(O)OEt unit *trans* to the metallated carbon atom, and the oxygen of the enolate group *trans* to the heteroatom. Since we also have a metallated carbon atom (C_6F_5 ligand) and a neutral heteroatom (the S atom of the SC_4H_8 ligand) in **9**, we propose a similar stereochemistry for **9** and, thus, the structure (a) as depicted in Scheme 1. This hypothesis has been corroborated through the determination of the X-ray structure (see below).

In summary, the interaction of the ylide **1** with Pd^{II} and Pt^{II} complexes promotes the generation of the phosphonium-enolate [$Ph_3(P^+)-CH_2-C(O^-)=C(H)C(O)OEt$] ligand in all cases. It is remarkable to observe the presence of a free phosphonium unit in a ligand strongly anchored to the metal center. This phosphonium moiety could be the clue for further functionalization of the ligand, since its deprotonation would generate a new ylide unit, which could be involved in a variety of new processes (e.g. synthesis of polynuclear complexes, Wittig reactions, etc.) which are not possible starting from the free ligand **1**.

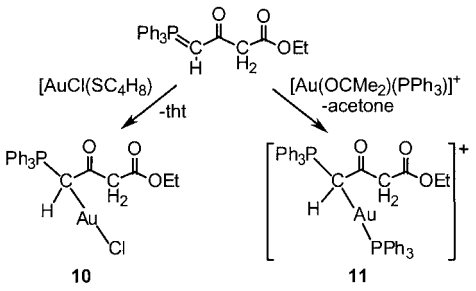
2. Gold(I) Complexes

As we have seen in the preceding discussion, the reactivity of **1** towards cationic bis(solvate) complexes of Pd^{II} and Pt^{II} does not result in the expected *C*-coordination. In an attempt to involve the ylidic C_α atom in bonding to a transition metal, we have focused our attention to gold(I) compounds, taking into account the exceptional stability of Au^I complexes with *C*-bonded α-stabilized P-ylides,[7] and also that the *O*-coordination of keto-stabilized P-ylides to Au^I remains unknown.

Treatment of [$AuCl(SC_4H_8)$] with **1** (1:1 molar ratio) in CH_2Cl_2 at room temperature occurs with displacement of the labile ligand SC_4H_8 and *C*-bonding of the ylide, giving the neutral derivative [$AuCl\{C(H)(PPh_3)C(O)CH_2C(O)OEt\}$] (**10**). In addition, treatment of the solvated complex [$Au(OCMe_2)(PPh_3)]ClO_4$ (obtained by treatment of [$AuCl(PPh_3)$] with $AgClO_4$ in acetone, see details in Exp. Sect.) with **1** (1:1 molar ratio) results in the formation of [$Au\{C(H)(PPh_3)COCH_2COOEt\}(PPh_3)]ClO_4$ (**11**), which also contains the *C*-coordinated ylide. These two processes are presented in Scheme 3.

Both complexes gave elemental analyses and mass spectra in good agreement with the proposed structures. The C-bonding of the ylide **1** in compounds **10** and **11** can be inferred from the IR spectra, since the absorptions assigned to the C=O stretch appear at 1731 cm^{-1} (ν_{COO}) and 1666 cm^{-1} (ν_{CO}) in **10**, and at 1724 and 1657 cm^{-1} for the respective absorptions in **11**. A comparison of these values with those reported for the free ylide (1717 and 1546 cm^{-1})[2b] shows that the absorption of the carboxylate

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3

group undergoes very small shifts, suggesting that it does not interact with the metal center, whereas that due to the carbonyl adjacent to the ylide group appears shifted to high energy by up to 120 cm^{-1}. This latter shift implies a higher participation of the keto-form in the description of the bonded ylide, and it is a clear indicator of the presence of a *C*-coordinated ylide.[1]

Additional evidence for the *C*-coordination of the ylide, and for the concomitant hybridization change ($sp^2 \rightarrow sp^3$), comes from the analysis of the NMR spectroscopic data. Key features of the NMR spectra of **10** and **11** are: (i) the ylidic proton $PC_\alpha(H)$ appears at about 4.8 ppm as a singlet in **10** or as a doublet in **11**, with a small coupling constant $^2J_{PH}$ (9 Hz); (ii) the methylene protons appear diastereotopic, showing the absence of a symmetry plane; (iii) the P atom $PC_\alpha(H)$ appears in the $^{31}P\{^1H\}$ NMR spectrum as a singlet (**10**) or as a doublet (**11**), shifted to low field (24.84 ppm for **10**, 26.15 ppm for **11**) with respect to the free ylide (δ =15.50 ppm); (iv) the ylidic carbon atom $PC_\alpha(H)$ appears in the $^{13}C\{^1H\}$ NMR spectrum (acquired as APT) as a doublet with positive phase, with a $^1J_{P,C}$ coupling constant (55.7 Hz for **10**, 58.6 Hz for **11**) smaller than that observed in **1** (108.3 Hz), and shifted to high field with respect to the corresponding signal in **1**. All these changes are in good agreement with the presence of a *C*-bonded ylide.[1]

As expected, the chemical behavior in this case is quite different from that observed in Pd^{II} and Pt^{II} complexes. The *C*-bonding of the ylide **1** blocks further reactivity at the C_α atom, but leaves the β-keto ester moiety unchanged. It seems likely then, that any further reactivity of the gold complexes could be directed selectively to the methylene group. This is not possible in the free ligand **1**, in which most of its reactivity occurs at the C_α center after deprotonation of the CH_2 unit.

Crystal Structure of $[Pd(C_6H_4CH_2NMe_2)(Ph_3PCH_2C(O)=C(H)C(=O)OEt\text{-}\kappa\text{-}O,O')]ClO_4$ (2a)

A solution of a mixture of **2a**/**2b** in CH_2Cl_2 was slowly evaporated to dryness at room temperature. During this process very regular yellow crystals were formed, which should be a mixture of the complexes **2a** and **2b** in the same molar ratio as that of the crude complex, and from this mixture of crystals, a yellow block was selected. The structure corresponds to that of complex **2a**, already established by spectroscopic methods.

A drawing of the cationic organometallic fragment is shown in Figure 1. The parameters concerning the data collection and refinement are given in Table 1, and selected bond lengths and angles are collected in Table 2. The Pd atom is located in a slightly distorted square-planar environment, surrounded by the *ortho*-metallated carbon atom C(25), the aminic N atom N(1), and the two oxygen atoms, O(1) and O(2), of the phosphonium-enolate [$Ph_3PCH_2C(O)=CH-C(O)OEt$] ligand, which coordinates as an *O*,*O*′-chelate. The structural parameters of the *ortho*-

metallated $C_6H_4CH_2NMe_2$ ligand are similar to those reported in related complexes and they do not show special features.[8] The two Pd−O bond lengths are different [Pd(1)−O(1) = 2.0390(11) Å; Pd(1)−O(2) = 2.1265(11) Å] probably due to two concurrent facts, namely (i) the different nature of the two oxygen atoms involved, since the C(22)−O(2) bond shows a higher double bond character [1.240(2) Å] than the C(20)−O(1) bond [1.2876(19) Å] (see Scheme 2), and (ii) the different *trans* influences of the C- and N-donor atoms of the $C_6H_4CH_2NMe_2$ ligand. A comparison of these distances with those of related complexes shows that the Pd(1)−O(1) bond length falls in the range usually reported for *O,O′*-acetylacetonate derivatives of Pd^{II} (range 2.007−2.073 Å),[9] while the Pd(1)−O(2) bond length is only slightly shorter than those found in other *O*-bonded α-stabilized keto-ylides [2.154(2) Å].[8b] These facts are in good agreement with a higher keto character for the C(22)−O(2) bond and a higher enolic character for the C(20)−O(1) bond. Moreover, the C−C bond lengths in the chelate ring are also quite different. The C(21)−C(22) bond length [1.426(2) Å] shows a small double bond component, since it is intermediate between a single σ(C−C) bond and a double C=C bond,[10] while the C(20)−C(21) bond length [1.372(2) Å] clearly shows double bond character. Outside the ring, the C(19)−C(20) bond length [1.521(2) Å] implies a single σ(C−C) bond, and all P−C bond lengths are also in the range found for single bonds.[10]

The geometry around the carbon atoms C(20) and C(22) is strictly planar [sum of the bond angles = 359.99(15)° in both cases] and the bond angle C(20)−C(21)−C(22) [124.69(15)°] also reflects its sp^2 character. The environments around the atoms C(19) and P(1) are tetrahedral. Furthermore, the intramolecular distance P(1)−O(1) [3.001(2) Å] is shorter than the sum of the van der Waals radii (3.32 Å),[11] suggesting an intramolecular interaction between the positively charged phosphonium atom P(1) and the formally anionic atom O(1). This type of 1,4-interaction has recently been described by us for keto-stabilized P-ylides.[12] However, this intramolecular interaction should be weaker than those described in P-ylides, as can be deduced from the value of the torsion angle P(1)−C(19)−C(20)−O(1) (51.2°), which is considerably different from the value obtained in the more stable *cisoid* forms of the ylides (nearly 0°).[12] Finally, the H atom H(26) [bonded to C(26)] points to the phenyl ring C(7)−C(12), the distance between H(26) and the best least-squares plane defined by the C atoms of the Ph ring being 2.74 Å. It is reasonable to assume that this short intramolecular distance could explain the strong anisotropic shielding exhibited by this proton in the ^1H NMR spectrum of **2a**.

Crystal Structure of [Pd(C_6F_5)(SC_4H_8)($Ph_3PCH_2C(O)$=C(H)C(=O)OEt-κ-*O,O′*)]ClO_4 (9)

A solution of **9** in CH_2Cl_2 was very slowly evaporated to dryness at room temperature. During this process yellow crystals were formed. A drawing of the cationic organometallic fragment is shown in Figure 2. The parameters concerning the data collection and refinement are summarized in Table 1, and selected bond lengths and angles are given in Table 3. The Pd atom is located in a distorted square-planar environment, surrounded by the *ipso* carbon atom C(1) of the C_6F_5 ligand, the S(1) atom of the tht ligand, and the two oxygen atoms, O(1) and O(2), of the phosphonium-enolate [$Ph_3PCH_2C(O)$=CH−C(O)OEt] ligand. The structural arrangement confirms that the enolate oxygen O(2) is *trans* to the sulfur atom S(1) and, hence, that the carbonylic oxygen O(1) is *trans* to the *ipso* carbon atom C(1) of the C_6F_5 group, as we proposed previously. The Pd(1)−C(1) bond length [1.987(5) Å] is typical for C_6F_5 groups *trans* to O-donor ligands,[4b] and the Pd(1)−S(1) bond length [2.2772(17) Å] also falls in the usual range of distances found in the literature for this type of bond.[9] The two

Pd−O bond lengths are different [Pd(1)−O(1) = 2.066(4) Å and Pd(1)−O(2) = 2.028(3) Å], as we have described for **2a**, reflecting the different *trans* influences of the *trans* donor atoms, although in **9** the differences between them are less pronounced than in **2a** [2.1265(11) Å and 2.0390(11) Å]. The internal bond lengths and angles of the phosphonium-enolate ligand are identical, within experimental error, to those described for complex **2a**, and thus the same structural conclusions can be derived here. Finally, the similarity between the structures of complexes **2a** and **9** is also reflected in the presence of short intramolecular P···O contacts[12] [P(1)−O(2) = 2.950(7) Å], although in this case the value of the torsion angle P(1)−C(7)−C(8)−O(2) (35.5°) is clearly narrower than that reported for **2a**.

Crystal Structure of [AuCl{C(H)(PPh_3)C(O)CH_2C(O)OEt}] (10)

Crystals of complex **10** were grown by slow vapor diffusion of Et_2O into a CH_2Cl_2 solution of the crude complex at room temperature. A drawing of the molecular structure of **10** is shown in Figure 3. The parameters concerning the data collection and refinement are presented in Table 1, and selected bond lengths and angles are collected in Table 4. Complex **10** crystallizes in the monoclinic space group $P2_1/c$. Since this space group is centrosymmetric, and although the complex is chiral, the crystal as a whole is racemic. The structure shown in Figure 3 corresponds to an absolute configuration (*S*) for the ylidic carbon C_α, following the system of priorities of Cahn, Ingold and Prelog.[13] The gold atom lies in a nearly linear environment, since the bond angle C(19)−Au(1)−Cl(1) is 176.48(9)°. The bond lengths Au(1)−C(19) [2.079(3) Å] and Au(1)−Cl(1) [2.2928(9) Å] are similar to those found in the literature for related structural arrangements.[14] The bond lengths C(20)−O(1) [1.214(4) Å] and C(22)−O(3) [1.199(4) Å] are typical[8,9] for carbonyl groups which are not delocalized through adjacent functional groups (e.g. the ylide function), while the bond length C(19)−C(20) is identical (within ex-

perimental error) to that found in other *C*-bonded keto-stabilized ylides.[8a] The P(1)−C(19) bond length [1.780(3) Å] is slightly shorter than the other P−C(Ph) bond lengths and, in turn, is similar to those found in other *C*-coordinated stabilized ylides.[8a] Typical single bond σ(C−C) distances are found for C(20)−C(21) [1.529(4) Å] and C(21)−C(22) [1.499(5) Å]. Finally, the environments around P(1) and C(19) are tetrahedral, while those around the carbonyl atoms C(20) and C(22) are strictly planar.

Conclusion

The polyfunctional ylide $[Ph_3P{=}C(H)C(O)CH_2C(O)OEt]$ (**1**) shows versatile reactivity towards different transition metals, giving very different structural motifs as a function of the metal center. Towards cationic Pd^{II} and Pt^{II} complexes with two available coordination sites, **1** undergoes a proton transfer giving the zwitterionic phosphonium-enolate $[Ph_3(P^+)CH_2C(O^-){=}CH{-}C(O)OEt]$ ligand, which coordinates as an *O,O′*-chelate. The presence of a phosphonium group, which can be easily deprotonated, could open new pathways of reactivity towards polynuclear complexes with a great variety of structural arrangements. On the other hand, the reactivity of **1** towards Au^I derivatives gives complexes with the ylide *C*-bonded, leaving the β-keto ester unit −C(O)CH$_2$C(O)OEt unchanged. This fact also opens new pathways of reactivity. This rich coordination chemistry is unprecedented for α-stabilized ylide ligands and the fine tuning of the reactivity allows us to suggest that new and more interesting results may await discovery.

Experimental Section

CAUTION: Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small amounts of these materials should be prepared and handled with great caution.[15]

General Methods: Solvents were dried and distilled under argon using standard procedures. Elemental analyses were carried out with a Perkin−Elmer 2400-B machine. Infrared spectra (4000−200 cm^{-1}) were recorded with a Perkin−Elmer 883 infrared spectrometer from nujol mulls between polyethylene sheets. Mass spectra (positive ion FAB) were recorded from CH_2Cl_2 solutions with a V. G. Autospec spectrometer. ^{1}H (300.13 MHz), $^{13}C\{^1H\}$ (75.47 MHz), ^{19}F (282.40 MHz), and $^{31}P\{^1H\}$ (121.49 MHz) NMR spectra were recorded in $CDCl_3$ or CD_2Cl_2 solutions at room temperature with a Bruker ARX-300 spectrometer. The ^{1}H and $^{13}C\{^1H\}$ NMR spectra were referenced using the residual solvent signal as the internal standard, whereas the $^{31}P\{^1H\}$ NMR spectra were referenced to external H_3PO_4 (85%). The ^{19}F NMR spectra were referenced to $CFCl_3$. The starting compounds were prepared following published methods: **1**,[2b] $[Pd(\mu\text{-}Cl)\{(C_6H_4CH_2NMe_2\text{-}(C^2,N)\}]_2$,[16] $[Pd(\mu\text{-}Cl)\{(S)\text{-}C_6H_4C(H)MeNMe_2(C^2,N)\}]_2$,[16] $[Pd(\mu\text{-}Cl)\{NC_{13}H_8(C^8,N)\}]_2$,[17] $[Pd(\mu\text{-}Cl)\{CH_2NC_9H_6(C^8,N)\}]_2$,[6,18] $[Pd(\mu\text{-}Cl)\{NC_5H_4\text{-}2\text{-}C_6H_4(C^2,N)\}]_2$,[19] $[Pd(\mu\text{-}Cl)(tht)(C_6F_5)]_2$,[20] $[M(\mu\text{-}Cl)\{o\text{-}CH_2C_6H_4P(o\text{-}tol_2)(C,P)\}]_2$ (M = Pd,[21] Pt[22]), [AuCl(tht)],[23] and $[AuCl(PPh_3)]$.[23]

$[Ph_3P{=}C(H){-}C(O){-}CH_2{-}COOEt]$ (1): The ylide **1** was prepared following the method reported by F. Serratosa and E. Solé.[2b] The analytical and IR data were in good agreement with those previously published. Here we present the MS and NMR spectroscopic data for **1**, which have not been reported previously. MS (FAB+): *m/z* (%) = 391 (100) [M$^+$]. ^{1}H NMR (CD_2Cl_2): δ = 1.26 (t, $^3J_{H,H}$ = 7.2 Hz, 3 H, CH_3), 3.29 (d, $^4J_{PH}$ = 1.5 Hz, 2 H, CH_2), 3.77 (d, $^2J_{PH}$ = 24.9 Hz, 1 H, P=CH), 4.16 (q, 2 H, OCH_2), 7.46−7.70 (m, 15 H, PPh_3) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 14.53 (CH_3), 48.63 (d, CH_2, $^3J_{P,C}$ = 15.5 Hz), 52.18 (d, $^1J_{P,C}$ = 108.3 Hz, P=C$_\alpha$), 60.81 (OCH_2), 127.13 (d, $^1J_{P,C}$ = 90.8 Hz, C$_{ipso}$, PPh_3), 129.28 (d, $^2J_{P,C}$ = 12.2 Hz, C$_{ortho}$, PPh_3), 132.66 (d, $^4J_{P,C}$ = 2.8 Hz, C$_{para}$, PPh_3), 133.50 (d, $^3J_{P,C}$ = 10.2 Hz, C$_{meta}$, PPh_3), 170.79 (s, COO), 184.22 (d, $^2J_{P,C}$ = 2.9 Hz, C=*O*) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 15.50 ppm.

Complex 2: To a suspension of $[Pd(\mu\text{-}Cl)(C_6H_4CH_2NMe_2)]_2$ (0.0755 g, 0.137 mmol) in THF (20 mL) under argon, was added $AgClO_4$ (0.0567 g, 0.273 mmol). The resultant mixture was stirred at room temperature for 20 min with exclusion of light, then filtered through a Celite pad. The freshly prepared solution of the bis(solvate) was treated with **1** (0.107 g, 0.273 mmol) giving a yellow solution, which was stirred for an additional 30 min. During this time, **2** precipitated as a yellow solid, which was filtered, washed with Et_2O (10 mL) and air dried. Yield: 0.100 g (50%). Complex **2** was characterized by NMR spectroscopy as a mixture of the isomers **2a/2b** in molar ratio **2a/2b** = 4.5:1. $C_{33}H_{35}ClNO_7PPd$ (730.47): calcd. C 54.26, H 4.83, N 1.92; found C 54.26, H 4.83, N 1.93. MS (FAB+): *m/z* (%) = 630 (100) [M − ClO_4]$^+$. IR: $\tilde{\nu}$ = 1628 (ν_{COO}), 1525 (ν_{CO}) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 1.23 (t, $^3J_{H,H}$ = 7.2 Hz, CH_3, **2a**), 1.27 (t, $^3J_{H,H}$ = 6.9 Hz, CH_3, **2b**), 2.24 (s, NMe_2, **2b**), 2.75 (s, NMe_2, **2a**), 3.76 (s, CH_2N, **2b**), 3.86 (s, CH_2N, **2a**), 4.06 (q, OCH_2, **2a**), 4.13 (d, $^2J_{PH}$ = 13.8 Hz, CH_2P, **2a**), 4.16 (d, $^2J_{PH}$ = 13.8 Hz, CH_2P, **2b**), 4.18 (q, OCH_2, **2b**), 4.81 (d, $^4J_{PH}$ = 0.6 Hz, = CH, **2a**), 4.86 (s, =CH, **2b**), 5.89 (dd, $^3J_{H^6H^5}$ = 8.1, $^4J_{H^6H^4}$ = 0.9 Hz, H^6, C_6H_4, **2a**), 6.43 (td, $^3J_{H^5H^6}$ = $^3J_{H^5H^4}$ = 8.1, $^4J_{H^5H^3}$ = 2.4 Hz, H^5, C_6H_4, **2a**), 6.83−7.01 [m, H^3 + H^4 (**2a**) + C_6H_4 (**2b**)], 7.66−7.87 (m, PPh_3, **2a** + **2b**) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 14.49 (Me, **2a** + **2b**), 36.36 (d, $^1J_{P,C}$ = 52.5 Hz, CH_2P, **2a**), 36.47 (d, $^1J_{P,C}$ = 54.2 Hz, CH_2P, **2b**), 52.36 (NMe_2, **2a** + **2b**), 61.26 (OCH_2, **2a**), 61.75 (OCH_2, **2b**), 73.20 (CH_2N, **2a**), 73.78 (CH_2N, **2b**), 88.91 (d, $^3J_{P,C}$ = 7.4 Hz, =CH, **2b**), 90.43 (d, $^3J_{P,C}$ = 7.0 Hz, =CH, **2a**), 118.50 (d, $^1J_{P,C}$ = 87.8 Hz, C$_{ipso}$, PPh_3, **2a**), 118.88 (d, C$_{ipso}$, PPh_3, **2b**, $^1J_{P,C}$ = 88.1 Hz), 121.67 (2 C), 124.74 (2 C), 143.33 (C^2), 147.53 (C^1) (C_6H_4, **2a**), 124.98 (2 C), 125.09 (2 C), 144.23 (C^2), 147.75 (C^1), (C_6H_4, **2b**), 130.72 (d, $^2J_{P,C}$ = 12.7 Hz, C$_{ortho}$, **2a** + **2b**), 134.11(C$_{para}$, **2b**), 134.34 (d, $^3J_{P,C}$ = 10.0 Hz, C$_{meta}$, **2a** + **2b**), 135.64 (C$_{para}$, **2a**, PPh_3), 171.21 (CO_2, **2a**), 172.48 (CO_2, **2b**), 173.67 (d, $^2J_{P,C}$ = 7.2 Hz, CO, **2a**), 175.18 (d, $^2J_{P,C}$ = 7.1 Hz, CO, **2b**) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 22.11 (**2b**), 22.71 (**2a**) ppm.

Complex 3: Complex **3** was prepared following a synthetic procedure similar to that reported for **2**. Thus, $[Pd(\mu\text{-}Cl)(CH_2C_9H_6N)]_2$ (0.192 g, 0.338 mmol) reacted, in THF (20 mL), with $AgClO_4$ (0.140 g, 0.676 mmol) and **1** (0.264 g, 0.676 mmol) to give **3** as a yellow solid. Yield: 0.344 g (69%). $C_{34}H_{31}ClNO_7PPd$ (738.45): calcd. C 55.30, H 4.23, N 1.89; found C 55.38, H 4.37, N 1.83. MS (FAB+): *m/z* (%) = 638 (100) [M − ClO_4]$^+$. IR: $\tilde{\nu}$ = 1624 (ν_{COO}), 1521 (ν_{CO}) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 1.31 (t, $^3J_{H,H}$ = 7.2 Hz, 3 H, CH_3), 3.02 (s, 2 H, CH_2Pd), 4.19 (d, $^2J_{PH}$ = 13.5 Hz, 2 H, CH_2P), 4.22 (q, 2 H, OCH_2), 4.92 (s, 1 H, =CH), 7.40−7.52 (m, 2 H, C_9H_6N), 7.62−7.76 (m, 15 H, PPh_3), 7.82−7.87 (m, 2 H, C_9H_6N), 8.31 (dd, $^3J_{H^4H^3}$ = 8.4, $^4J_{H^4H^2}$ = 1.5 Hz, 1 H, H^4, C_9H_6N),

8.58 (dd, $^3J_{H^2H^3}$ = 5.1, $^4J_{H^2H^4}$ = 1.5 Hz, 1 H, H^2, C_9H_6N) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 14.54 (CH_3), 22.48 (CH_2Pd), 37.08 (d, $^1J_{P,C}$ = 57.6 Hz, CH_2P), 61.15 (OCH_2), 89.32 (d, $^3J_{P,C}$ = 7.9 Hz, =CH), 119.34 (d, $^1J_{P,C}$ = 88.4 Hz, C_{ipso}, PPh_3), 121.93, 124.23, 128.65, 128.81, 129.47, 138.37, 147.85, 148.33, 153.61 (C_9H_6N), 130.52 (d, $^2J_{P,C}$ = 13 Hz, C_{ortho}), 134.25 (d, $^3J_{P,C}$ = 10.3 Hz, C_{meta}), 135.38 (d, $^4J_{P,C}$ = 3 Hz, C_{para}) (PPh_3), 171.33 (COO), 173.44 (d, $^2J_{P,C}$ = 7.2 Hz, CO) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 23.15 ppm.

Complex 4: Complex **4** was prepared following a synthetic procedure similar to that reported for **2**. Thus, $[Pd(\mu\text{-}Cl)(NC_5H_4\text{-}2\text{-}C_6H_4)]_2$ (0.118 g, 0.20 mmol) reacted, in THF (20 mL), with $AgClO_4$ (0.083 g, 0.40 mmol) and **1** (0.156 g, 0.40 mmol) to give **4** as a yellow solid. Yield: 0.227 g (75.8%). Complex **4** was characterized by NMR as a mixture of the isomers **4a/4b** in molar ratio **4a/4b** = 3.2:1. $C_{35}H_{31}ClNO_7PPd$ (750.46): calcd. C 56.02, H 4.16, N 1.87; found C 55.69, H 4.49, N 1.67. MS (FAB+): *m/z* (%) = 650 (100) $[M - ClO_4]^+$. IR: $\tilde{\nu}$ = 1620 (ν_{COO}), 1515 (ν_{CO}) cm^{-1}. ^1H NMR (CD_2Cl_2): δ = 1.28 (t, $^3J_{H,H}$ = 7.2 Hz, CH_3, **4a**), 1.30 (t, $^3J_{H,H}$ = 7.2 Hz, CH_3, **4b**), 4.16 (q, OCH_2, **4a**), 4.18 (d, $^2J_{PH}$ = 14 Hz, CH_2P, **4b**), 4.20 (d, $^2J_{PH}$ = 16 Hz, CH_2P, **4a**), 4.24 (q, OCH_2, **4b**), 4.87 (d, $^4J_{PH}$ = 1 Hz, =CH, **4a**), 4.90 (s, =CH, **4b**), 6.07 (dd, $^3J_{H,H}$ = 7.8, $^4J_{H,H}$ = 1.2 Hz, $NC_5H_4\text{-}2\text{-}C_6H_4$, **4a**), 6.58 (td, $^3J_{H,H}$ = 7.9, $^4J_{H,H}$ = 1.2 Hz, $NC_5H_4\text{-}2\text{-}C_6H_4$, **4a**), 6.68 (td, $^3J_{H,H}$ = 7.2, $^4J_{H,H}$ = 1.2 Hz, $NC_5H_4\text{-}2\text{-}C_6H_4$, **4b**), 7.01 (td, $^3J_{H,H}$ = 7.5, $^4J_{H,H}$ = 1 Hz, $NC_5H_4\text{-}2\text{-}C_6H_4$, **4a**), 7.16 (m, $NC_5H_4\text{-}2\text{-}C_6H_4$, **4a**), 7.33 (dd, $^3J_{H,H}$ = 7.9, $^4J_{H,H}$ = 1.2 Hz, $NC_5H_4\text{-}2\text{-}C_6H_4$, **4a**), 7.88−7.57 (m, PPh_3 + $NC_5H_4\text{-}2\text{-}C_6H_4$), 8.35 (dd, $^3J_{H,H}$ = 5.7, $^4J_{H,H}$ = 1 Hz, $NC_5H_4\text{-}2\text{-}C_6H_4$, **4a**) ppm. The assignment of resonances for the $NC_5H_4\text{-}2\text{-}C_6H_4$ ligand could be performed unequivocally only for the major isomer **4a**, due to extensive overlapping of the signals of the minor isomer **4b** with those of the major isomer and with the PPh_3 group. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 14.43 (CH_3, **4a** + **4b**), 36.23 (d, $^1J_{P,C}$ = 52.1 Hz, CH_2P, **4a** + **4b**), 61.56 (OCH_2, **4a**), 62.03 (OCH_2, **4b**), 89.89 (d, $^3J_{P,C}$ = 7.3 Hz, =CH, **4b**), 91.07 (d, $^3J_{P,C}$ = 6.7 Hz, =CH, **4a**), 118.37 (d, $^1J_{P,C}$ = 87.7 Hz, C_{ipso}, PPh_3, **4a**), 118.58 (d, $^1J_{P,C}$ = 86.0 Hz, C_{ipso}, PPh_3, **4b**), 119.15, 122.79, 123.49, 125.18, 129.16, 131.30, 139.57, 145.24, 148.45, 151.47, 165.51 ($NC_5H_4\text{-}2\text{-}C_6H_4$, **4a**), 119.20, 122.58, 123.49, 125.48, 129.41, 131.31, 139.58, 145.32, 148.41, 152.67, 165.91 ($NC_5H_4\text{-}2\text{-}C_6H_4$, **4b**), 130.76 (d, $^2J_{P,C}$ = 12.4 Hz, C_{ortho}, PPh_3), 134.35 (d, $^3J_{P,C}$ = 9.1 Hz, C_{meta}, PPh_3), 135.69 (s, C_{para}, PPh_3, both isomers), 171.57 (COO, **4a**), 172.69 (COO, **4b**), 173.89 (d, $^2J_{P,C}$ = 7.3 Hz, CO, **4a**), 175.23 (d, $^2J_{P,C}$ = 6.6 Hz, CO, **4b**) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 22.57 (**4b**), 22.84 (**4a**) ppm.

Complex 5: Complex **5** was prepared following a synthetic procedure similar to that reported for **2**. Thus, $[Pd(\mu\text{-}Cl)(C_{13}H_8N)]_2$ (0.101 g, 0.158 mmol) reacted, in THF (20 mL), with $AgClO_4$ (0.065 g, 0.32 mmol) and **1** (0.123 g, 0.316 mmol) to give **5** as a yellow solid. Yield: 0.0622 g (25.5%). Complex **5** was characterized by NMR as a mixture of the isomers **5a/5b** in molar ratio **5a/5b** = 3.6:1. $C_{37}H_{31}ClNO_7PPd$ (774.48): calcd. C 57.38, H 4.03, N 1.81; found C 56.90, H 4.05, N 1.79. MS (FAB+): *m/z* (%) = 674 (100) $[M - ClO_4]^+$. IR: $\tilde{\nu}$ = 1616 (ν_{COO}), 1512 (ν_{CO}) cm^{-1}. ^1H NMR (CD_2Cl_2): δ = 1.33 (t, $^3J_{H,H}$ = 7.2 Hz, CH_3, **5a**), 1.35 (t, $^3J_{H,H}$ = 6.3 Hz, CH_3, **5b**), 4.21 (q, OCH_2, **5a**), 4.21 (d, $^2J_{PH}$ = 13.8 Hz, CH_2P, **5b**), 4.28 (d, $^2J_{PH}$ = 13.8 Hz, CH_2P, **5a**), 4.30 (q, OCH_2, **5b**), 4.93 (s, =CH, **5b**), 4.94 (s, =CH, **5a**), 6.05 (dd, $^3J_{H,H}$ = 7.5, $^4J_{H,H}$ = 0.6 Hz, $C_{13}H_8N$, **5a**), 6.94 (t, $^3J_{H,H}$ = 7.5 Hz, $C_{13}H_8N$, **5a**), 6.97 (dd, $^3J_{H,H}$ = 8.1, $^3J_{H,H}$ = 5.1 Hz, $C_{13}H_8N$, **5b**), 7.18 (dd, $^3J_{H,H}$ = 5.1, $^4J_{H,H}$ = 1.2 Hz, $C_{13}H_8N$, **5b**), 7.30 (dd, $^3J_{H,H}$ = 8.1, $^3J_{H,H}$ = 5.1 Hz, $C_{13}H_8N$, **5a**), 7.30 (dd, $^3J_{H,H}$ = 6.0, $^4J_{H,H}$ = 0.9 Hz, $C_{13}H_8N$, **5b**), 7.39 (t, $^3J_{H,H}$ = 7.5 Hz, $C_{13}H_8N$, **5b**), 7.47 (d, $^3J_{H,H}$ = 7.5 Hz, $C_{13}H_8N$, **5a**), 7.51 (d, $^3J_{H,H}$ = 8.7 Hz, $C_{13}H_8N$, **5a**), 7.55 (dd, $^3J_{H,H}$ = 7.5, $^4J_{H,H}$ = 0.6 Hz, $C_{13}H_8N$, **5b**), 7.85−7.63 (m, PPh_3 + $C_{13}H_8N$, **5a** + **5b**), 8.16 (dd, $^3J_{H,H}$ = 8.1, $^4J_{H,H}$ = 1.2 Hz, $C_{13}H_8N$, **5a**), 8.20 (dd, $^3J_{H,H}$ = 8.1, $^4J_{H,H}$ = 1.2 Hz, $C_{13}H_8N$, **5b**), 8.31 (dd, $^3J_{H,H}$ = 5.1, $^4J_{H,H}$ = 1.2 Hz, $C_{13}H_8N$, **5a**) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ (signals due to **5b** in the low field region were not observed) = 14.50 (CH_3, **5a** + **5b**), 36.26 (d, $^1J_{P,C}$ = 52.3 Hz CH_2P, **5a** + **5b**), 61.63 (OCH_2, **5a**), 62.12 (OCH_2, **5b**), 88.92 (d, $^3J_{P,C}$ = 5.9 Hz, =CH, **5b**), 91.12 (d, $^3J_{P,C}$ = 6.7 Hz, =CH, **5a**), 118.47 (d, $^1J_{P,C}$ = 87.8 Hz, C_{ipso}, PPh_3, **5a**), 118.63 (d, $^1J_{P,C}$ = 87.8 Hz, C_{ipso}, PPh_3, **5b**), 121.66, 122.92, 123.65, 128.37, 128.74, 129.15, 133.44, 137.55, 141.03, 147.26, 148.43, 154.83 ($C_{13}H_8N$, **5a**, one of the quaternary carbon atoms was not observed), 130.76 (d, PPh_3, $^2J_{P,C}$ = 12.8 Hz, C_{ortho}), 134.40 (d, $^3J_{P,C}$ = 9.4 Hz, C_{meta}, PPh_3), 135.63 (C_{para}, PPh_3), 171.51 (COO, **5a**), 173.90 (d, $^2J_{P,C}$ = 6.9 Hz, CO, **5a**) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 23.08 (**5a**), 22.74 (**5b**) ppm.

Complex 6: Complex **6** was prepared following a synthetic procedure similar to that reported for **2**. Thus, $[Pd(\mu\text{-}Cl)\{(S)\text{-}C_6H_4C(H)MeNMe_2\}]_2$ (0.105 g, 0.181 mmol) reacted, in THF (20 mL), with $AgClO_4$ (0.075 g, 0.362 mmol) and **1** (0.142 g, 0.36 mmol) to give **6** as a yellow solid. Yield: 0.2627 g (97.5%). Complex **6** was characterized by NMR spectroscopy as a mixture of the isomers **6a/6b** in molar ratio **6a/6b** = 4.3:1. $C_{34}H_{37}ClNO_7PPd$ (744.50): calcd. C 54.85, H 5.01, N 1.88; found: C 55.19, H 4.73, N 1.89. MS (FAB+): *m/z* (%) = 644 (65) $[M - ClO_4]^+$. Crystallography

Data Collection: Crystals of complexes **2a** and **9** of adequate quality for X-ray purposes were obtained by slow evaporation of solutions of either the crude mixture of complexes **2a**/**2b**, or the crude complex **9** in CH_2Cl_2. In contrast, crystals of **10** were grown by slow vapor diffusion of Et_2O into a CH_2Cl_2 solution of the crude complex at room temperature. A crystal of dimensions 0.36 × 0.34 × 0.22 mm (**2a**), 0.39 × 0.25 × 0.043 mm (**9**) or 0.49 × 0.30 × 0.19 mm (**10**) was mounted onto a quartz fiber in a random orientation and covered with epoxy. Data collection was performed at 100 K (**2a**, **10**) or at room temperature (**9**) with a Bruker Smart Apex CCD diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). In all cases, a hemisphere of data was collected based on three ω-scan runs. For each of these runs, frames (606, 435, and 230, respectively) were collected at 0.3° intervals and 10 s per frame. In all cases, the diffraction frames were integrated using the program SAINT[24] and the integrated intensities were corrected for systematic errors with SADABS.[25]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Structure Solution and Refinement: The structures were solved by Patterson and Fourier methods.[26] All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were placed at idealized positions and treated as riding atoms, except for those of the methyl groups, which were first located in a local slant − Fourier calculation and then refined as riding atoms with the torsion angles about the O−C(methyl) or N−C(methyl) bonds treated as variables. Each hydrogen atom was assigned an isotropic displacement parameter equal to 1.2 times the equivalent isotropic displacement parameter of its parent atom. The structures were refined to F_o^2, and all reflections were used in the least-squares calculations.[27]

The final difference Fourier map for **9** showed two peaks with densities of 1.88 and 1.16 e/Å^3, which delimit a vector roughly parallel to the Pd(1)−S(1) bond and displaced less than 1 Å from it, suggesting a possible minor disorder component for these two atoms. Detailed analysis of these peaks and their environment confirmed the possibility of an accompanying disorder of the tht moiety, and also indicated that such a disorder could exist without causing any important changes to the remainder of the structure. We refined a disordered model for Pd(1) and S(1), obtaining a population of 0.083(3) for the second component. However, no difference peaks appeared in the area of the tht, where the carbon atoms of a putative minor disorder component would be located. As a further diagnostic for the source of the difference peaks, we conducted a twin analysis using the program ROTAX.[28,29] No plausible twin model was obtained. We report here the results of the refinement without disorder. Results of a refinement including the minor congeners for Pd(1) and S(1), which did not involve observable changes in the geometric parameters of the principal component, are available from the authors.

CCDC-222324 (for **2a**), -222325 (for **9**), and -222326 (for **10**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Tuning the Stoichiometry of Lanthanide Complexes with Calixarenes: Bimetallic Complexes with a Calix[6]arene Bearing Ether-Amide Pendant Arms

Flor de María Ramírez,[a,b] Loïc Charbonnière,[c] Gilles Muller,[a,d] and Jean-Claude G. Bünzli*[a]

Keywords: Lanthanides / Calixarenes / Europium / Luminescence

A de-*tert*-butylated calix[6]arene (A_6L^6) fitted with six ether-amide pendant arms was synthesized and characterized in solution. NMR spectroscopic data point to the six phenoxide units adopting an average D_{6h} conformation on the NMR time scale. According to MM3 molecular mechanics, and MOPAC quantum mechanical calculations, A_6L^6 is a ditopic ligand featuring two nonadentate coordination sites, each built from three pendant arms, and extending in opposite directions with one above, and the other under the main ring. A_6L^6 reacts with Ln^{III} ions (Ln = La, Eu) in acetonitrile to successively form 1:1 and 2:1 complexes. The isolated Eu^{III} 2:1 complex is luminescent (quantum yield: 2.5% in acetonitrile, upon ligand excitation). In the solid state, the luminescence decay is bi-exponential, with lifetimes equal to 1.66 and 0.46 ms (upon direct metal excitation), pointing to the presence of two differently coordinated metal ions, one with essentially no bound water molecules, and the other one with two ligated water molecules. According to molecular mechanics calculations, the more stable isomer is indeed asymmetric with two nine-coordinated metal ions. Both Eu^{III} ions are bound to three bidentate arms, and one monodentate triflate anion, but one metal ion completes its coordination sphere with two phenoxide oxygen atoms, and the other one with two water molecules, consistent with IR spectroscopic and luminescence data. In acetonitrile solution, the two metal ion sites become equivalent, and the relatively long lifetime (1.35 ms) is indicative of a coordination environment free of water molecules. This work demonstrates, that the stoichiometry of lanthanide complexes with calixarenes can be tuned by a suitable choice of the narrow and/or wide rim substituents.

Introduction

Calixarenes act as versatile building blocks in supramolecular and coordination chemistry, since both their lower and upper rims may be derivatized to induce specific functionalities.[1,2] They are currently being used in the design of chemical sensors,[3] catalysts,[4] and selective ligands for the complexation of d[5] and f[6,7] metal ions, as well as for the self-assembly, through π-stacking, H-bonding or coordination interactions, of elaborate supramolecular structures.[8,9] As a consequence, many studies have aimed at using calixarenes for the development of separation processes,[10] and the nuclear industry is particularly interested in these ligands for the separation of highly radioactive actinides from non-radioactive lanthanides before nuclear waste confinement.[11−13]

In recent years, we have been developing model calixarene molecules for the study of energy migration mechanisms in luminescent lanthanide-containing compounds, and of magnetic 4f−4f interactions.[7] We have also been interested in calixarenes having 4f−5f separation capabilities. This leads to the formation of luminescent 4f-species which can be easily analyzed during the extraction process. With this in mind, we have focused on two series of branched calixarenes, one bearing ether-amide pendant arms A, and the other having phosphanylyl groups B (see Scheme 1). The ether-amide substituent was designed so that it can act as a bidentate ligand forming a five-membered cycle upon coordination of its ether and amide functions to trivalent lanthanide ions Ln^{III}. We have shown that A_4bL^4 acts as an inorganic-organic receptor, encapsulating both a lanthanide ion and a solvent molecule. In addition, the crystal structure of the Lu^{III} 1:1 complex shows the coordination cavity predisposed to further accommodate one

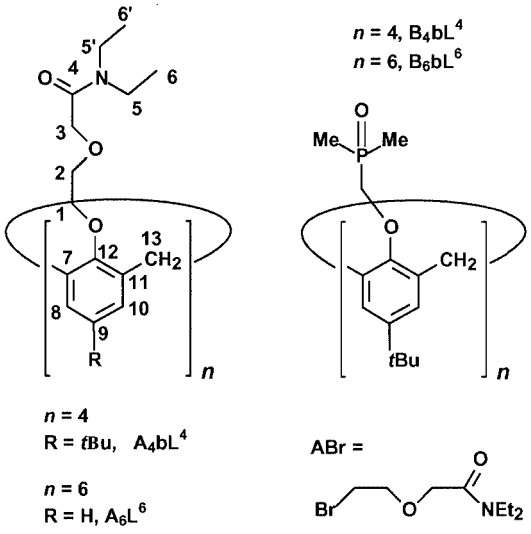
water molecule hydrogen-bonded to the oxygen atoms of the phenol units, which rigidifies the induced cavity, and binds the metal ion.[14] The phosphanylyl-substituted calixarenes B_nbL^n (n = 4, 6) form complexes with 1:1 and 1:2 Ln^{III} ligand ratios having significant stability in acetonitrile,[15,16] and interesting luminescent[15,16] and 4f−5f separation[17] properties. Several derivatized calix[6]arenes have been tested in extraction studies[18−20] and, in our case, B_6bL^6 proved to be a better extracting agent than B_4bL^4.[17] Despite that calix[6]arene complexes with lanthanide ions have also been proposed as luminescent probes,[21,22] little is known about the interaction between calix[6]arenes and Ln^{III} ions. The reaction of europium nitrate with *p-tert*-butylcalix[6]arene leads to the formation of a 1:2 (Eu^{III}/L) compound in which only one calix[6]arene molecule is bound to the 8-coordinate metal ion through a single phenoxide unit, as shown by its X-ray structure.[23] Replacing nitrate with trifluoromethanesulfonate (triflate) results in the formation of bimetallic 2:1 species (Ln = La, Sm, Yb) in which the two metal cations are anchored on both sides of the macrocycle in the 1,2,3-alternate conformation, which acts as a bidentate ligand, while the coordination sphere of the 7-coordinate Ln^{III} ions (Ln = Sm, Yb) is completed by one monodentate triflate and one nitrogen donor atom from the pyridine and/or terpyridine.[24]



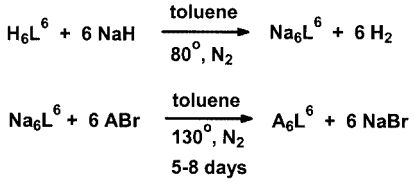
Scheme 1

In this paper, we discuss how the removal of the *p-tert*-butyl groups influences the conformation of the calix[6]-arene derivatized with pendant arms A and, consequently, the stoichiometry of the Ln^{III} complexes. Removal of the *tert*-butyl groups should result in easier conformational interconversion, and a relief in steric hindrance is expected to favor the formation of the 2:1 complexes, contrary to what has been observed for B_6bL^6, which forms 1:2 complexes. The calixarene A_6L^6, with *tert*-butyl groups removed, was therefore synthesized, and characterized both in the solid state and in solution, as well as its 2:1 complex with Eu^{III}. Molecular mechanics and quantum mechanical calculations were performed to help understand the structures of both the free ligand and the complex.

Results and Discussion

Synthesis and Characterization of the Substituted Calixarene A_6L^6

The branched calix[6]arene A_6L^6 (Scheme 1) was obtained in two steps via a Williamson reaction (Scheme 2) from the brominated pendant arm **ABr**, synthesised as described previously,[14] and the calix[6]arene H_6L^6. The hexasodium derivative of calix[6]arene was prepared in toluene, demonstrating that this salt can be formed in a non-polar solvent despite the high fluxionality of calix[6]arene, provided adequate experimental conditions are used i.e. heating, vigorous stirring, and a nitrogen atmosphere to avoid oxidation and protonation of the phenoxide groups. The macrocycle is soluble in CH_2Cl_2, $CHCl_3$, CH_3CN, toluene, methanol, and ethanol. Its IR spectrum displays an intense band at 1639 cm^{-1} typical of the carbonyl groups in an *N,N′*-disubstituted amide (1646 cm^{-1} in **ABr**). The absorption band associated with contributions from the aliphatic ether groups appears at 1126 cm^{-1} (1119 cm^{-1} in **ABr**), medium bands at 1218 and 1045 cm^{-1} are typical of the phenoxide groups, while the three neighboring aromatic C−H groups generate a characteristic symmetric out-of-plane bending at 765 cm^{-1}. In the UV/Vis spectrum, the structured band at 270 nm (37040 cm^{-1}) with a shoulder at 278 nm (35970 cm^{-1}) indicates complete functionalization of the phenoxide groups. This structured absorption band is associated with π→π* transitions involving orbitals mainly located on the phenyl rings. A band corresponding to transitions primarily located on the carbonyl groups can be seen at 223 nm (44840 cm^{-1}) in the diffuse reflectance spectrum.



Scheme 2

The ^1H NMR spectrum of A_6L^6 in CD_3CN at room temperature is shown in Figure 1 together with its complete assignment (see Scheme 1 for atomic numbering). The limited number of signals points to a high average symmetry on the NMR time scale. This may be interpreted as a consequence either of fast interconversion processes between the different conformers on the NMR timescale, or of the presence of a single species of high symmetry, such as the 1,3,5 alternate conformation belonging to the S_6 point group. While the introduction of long complexing arms on the *p-tert*-butylcalix[6]arene moiety may be expected to freeze the oxygen-through-the-annulus rotation,[25,26] removal of the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bulky *tert*-butyl groups favors the aromatic-through-the-annulus rotation. Since the latter mechanism has been observed with *O*-substituted *p-tert*-butylcalix[6]arenes,[26] it is reasonable to assume that the lack of substitution on the phenol groups allows for rapid aromatic-through-the-annulus rotation and, hence, the apparent high symmetry observed is the result of fast interconversion between the different conformers.

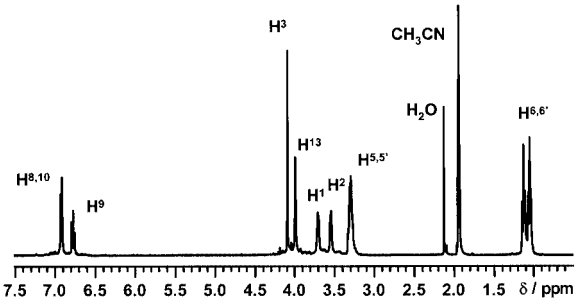


Figure 1. ^{1}H NMR spectrum of A_6L^6 10^{-3} M in CD_3CN at 295 K

A detailed comparison of the chemical shifts of the proton atoms of the complexing arms in A_6L^6 and A_4bL^4 further enlightens an unusual point. While the ethyl groups of the amide functions are found essentially at the same chemical shifts in both ligands, signals corresponding to the H^1 and H^2 protons are shifted significantly upfield (more than 0.4 ppm) in A_6L^6 compared with A_4bL^4.[14] ^{1}H NMR spectroscopic data of A_4bL^4 indeed showed the compound adopting a cone conformation in solution, in which the four complexing arms are held together in closed proximity, thereby providing a suitable octadentate coordination site for lanthanide cations.[14] The X-ray crystal structure of the lutetium complex further showed that a water molecule was encapsulated in the cavity formed by the four dioxo-ethylene bridges (O−C1−C2−O), with H-bonding interactions between this water molecule and the oxygen atoms. Interestingly, an elemental analysis of free A_4bL^4 revealed the presence of one water molecule, even after the drying process. It was suspected, that the H-bonding interactions with the water molecule are also present in the free ligand in solution, leading to a decrease of the electronic density on the ethylene bridges, and a concomitant upfield shift of the corresponding signals in the ^{1}H NMR spectrum. For the larger and more flexible calix[6]arene, NMR spectroscopic data indicate that the cone conformation is not the most favorable conformation, leading to chemical shifts similar to those found in the brominated **ABr** molecule or its hydroxy precursor. The same reasoning can be applied to the corresponding carbon atoms (C1 and C2), one of which is shifted upfield by 1.1 ppm in A_4bL^4 compared with A_6L^6.

$^{13}C\{^1H\}$ NMR spectra in both $CDCl_3$ and CD_3CN confirm the fast exchange hypothesis (see Figure S1 in the Supporting Information; see also the footnote on the first page of this article) since $\delta(C^{13}) = 30.95$ ppm points to a *syn* orientation of adjacent phenol rings,[27] thus excluding the hypothetical 1,3,5-alternate conformation in which adjacent rings are in an *anti* conformation. Only four signals are observed for the aromatic carbon atoms, indicating the equivalence of the six aromatic rings on the NMR time scale, and an average hexagonal (D_{6h}) symmetry for the calixarene core. All the carbon atoms of the pendant arms also give rise to one signal, except those of the ethyl groups which are split into two components pointing to a somewhat restricted rotation around the amide function.

To substantiate the interpretation of the NMR spectra, we turned to molecular mechanics calculations, and evaluated the A_6L^6 structure using a MOPAC PM3 procedure, taking into account solvent effects (water). The conformer with the lowest energy is shown in Figure 2. It displays a pinched "chair" conformation of the 1,2,3-alternate type. Three consecutive phenol groups are positioned in such a way, that the pendant arms form two cavities predisposed towards metal ion coordination, each built up of three pendant arms, and extending on opposite sides of the macrocycle.

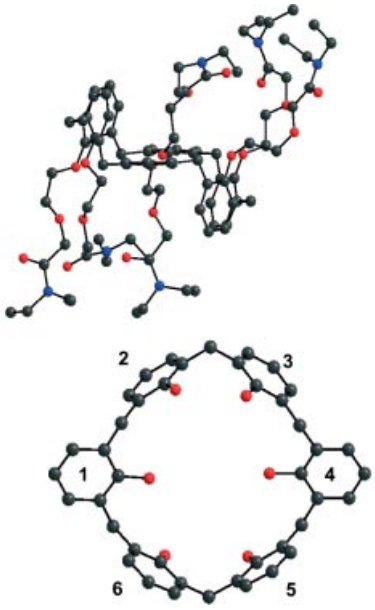

Figure 2. (Top) optimized geometry of A_6L^6 as determined by MOPAC PM3 calculations taking into account the solvent effect (water); (bottom) View of the calixarene core only

Interaction of A_6L^6 with La^{III} and Eu^{III} in Acetonitrile

To gain information on the interaction between lanthanide ions and the calixarene A_6L^6, solutions of the latter (typically 10^{-3} M) were titrated with solutions of lanthanide triflates $Ln(OTf)_3{\cdot}6H_2O$ (typically 10^{-3} M, Ln = La, Eu) for ratios $R = [Ln^{III}]_t/[A_6L^6]_t$ varying from 0 to 3. The spectra are shown in Figure 3 (S2, and S3, see Supporting Information). In all cases, the spectra display broad overlapping signals, probably as a result of fast exchange reactions of the complexed species. This prevented a quantitative treatment. For $R < 1$, the free ligand and a complex species coexist in solution. For $R = 1$, a distinct AB spin system can be observed (Ln = La) with two doublets at 4.45 and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3.60 ppm for the methylene proton atoms bridging two phenolic units. This strongly suggests an average cone-like conformation for the 1:1 LnA_6L^6 complex. The broadness of the peaks corresponding to the protons of the arms may be attributed to exchange processes, possibly between forms in which these arms are complexed or not complexed to the metal cation. For $R > 1$, the peaks of the non-coordinated ligand disappear, and signals corresponding to at least two species with different LnA_6L^6 stoichiometries can be identified. Since the spectra do not change further when R is increased from 2 to 3, we conclude that two species form successively in solution, with 1:1 and 2:1 metal-to-ligand ratios. This is in line with the calculated structure of A_6L^6 which shows two sets of three pendant arms extending on opposite sides of the calixarene (cf. Figure 2). Attempts to establish a more quantitative speciation by ES-MS failed due to hydrolysis at high dilution in the capillary during the analysis (T = 200 °C). As a result, only monometallic species were detected for R values in the range 1−3, in addition to free A_6L^6 (Table 1).

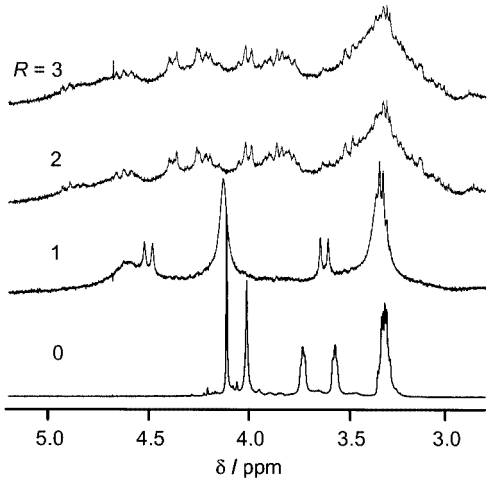

Figure 3. Part of the ^{1}H NMR spectra obtained during the titration of A_6L^6 by $La(OTf)_3{\cdot}6H_2O$ in CD_3CN at room temperature; $R = [La]_t/[A_6L^6]_t$

Isolation and Characterization of the 2:1 Eu^{III} Complex

The complex can be isolated in good yield from stoichiometric mixtures of A_6L^6 and europium triflate in acetonitrile. The elemental analysis is consistent with the formula $Eu_2(OTf)_6(A_6L^6){\cdot}9H_2O$. Coordination of the carbonyl groups of the pendant arms can be ascertained from the IR data (obtained after drying the pellet at 118 °C), the $\nu_{C=O}$ vibration being red-shifted by 25 cm^{-1} compared with the ligand, pointing to a strong metal-to-ligand interaction. Moreover, the intensity of the band arising from the aliphatic ether functions of the arm is strongly reduced, in line with the coordination of these moieties to the metal ion. The vibration involving contribution from the aromatic ether could not be identified, probably being masked by another band, contrary to what we reported for the $[Ln(A_4bL^4)]^{3+}$ complexes, for which (i) this band is little affected by the complexation, and (ii) the crystal structure of $[Lu(A_4bL^4)(H_2O)](OTf)_3{\cdot}2Et_2O$ does not show evidence of any coordination of aromatic ethers.[14] In our case, this suggests some change in the ligand conformation upon complexation and, possibly, coordination of these groups to the metal ion. Other ligand vibrations, for instance the bending CH_2 mode (1450 cm^{-1}), and the out-of-plane ring bending mode (760 cm^{-1}), experience small, but characteristic changes upon complexation. In addition, two strong bands at 1030 and 638 cm^{-1} can be assigned to the $\nu_s(SO_2)$ and $\nu_{as}(SO_3)$ modes of coordinated triflate,[28] while the band at 1321 cm^{-1} is evidence for ionic triflate. Finally, water coordination can be deduced from a sharp band near 520 cm^{-1}.[29] Attempts to grow single-crystals by slow vapor diffusion of diethyl ether or diisopropyl ether in acetonitrile, THF or MeOH, were unsuccessful.

^{1}H NMR spectra obtained during the titration of A_6L^6 with europium triflate (Figure S3, see Supporting Information) revealed that complexation induces freezing of the ligand conformation, resulting in a very complex pattern, which is difficult to interpret. Variable temperature NMR spectra of a $Eu_2(OTf)_6(A_6L^6){\cdot}9H_2O$ solution in CD_3CN were recorded up to 75 °C. Although the overall pattern becomes somewhat simplified, the spectrum remains complex. Higher temperatures could not be reached, because the complex experiences de-metallation in DMSO, a solvent in which, for instance, B_6bL^6 undergoes complete interconversion of its isomers on the NMR time scale at 132 °C.[16]

Photophysical Properties of A_6L^6 and Its 2:1 Eu^{III} Complex

The photophysical properties of A_6L^6, and of the 2:1 Eu^{III} complex have been determined both for solid state samples (295 and 77 K), and for frozen acetonitrile solutions (77 K). The excitation spectrum of the ligand is similar to the absorption and reflectance spectra discussed above. Excitation of a solid sample of A_6L^6 at 275 nm

(36360 cm^{-1}) and 77 K yields two emission bands centered at 305 nm (32790 cm^{-1}), which can be assigned as arising from the $^1\pi\pi^*$ state, and at 446 nm (22420 cm^{-1}), attributed to the $^3\pi\pi^*$ state, as ascertained by the lifetime, which amounts to 104 ± 8 ms in frozen acetonitrile solution (2×10^{-3} M). This can be compared with 83 ± 4 ms for B_6bL^6 under the same experimental conditions.[16]

The absorption spectrum of the 2:1 complex in acetonitrile (4.74×10^{-5} M) displays three bands at 268 nm (37310 cm^{-1}, ε = 9490 $mol^{-1}\cdot cm^{-1}$), 276 nm (36230 cm^{-1}, ε = 8650 $mol^{-1}\cdot cm^{-1}$), and 293 nm (34130 cm^{-1}, ε = 3380 $mol^{-1}\cdot cm^{-1}$). The first two bands are blue-shifted 265 cm^{-1} compared with those in the uncomplexed ligand. The third band is only present in the complex. The excitation spectrum of the complex, obtained at 10 K with concomitant monitoring of the $^5D_0 \rightarrow {}^7F_2$ transition, reveals the usual f-f transitions as well as a broad band in the range of 320−450 nm with a maximum at 372 nm (26880 cm^{-1}), which could possibly be associated with a ligand-to-metal charge transfer (LMCT) band. Excitation in the ligand levels yields a luminescence spectrum displaying both ligand-centered and metal-centered $^5D_0 \rightarrow {}^7F_J$ emission bands, pointing to incomplete ligand-to-metal energy transfer. The high-resolution laser-excited excitation spectrum in the range of the $^5D_0 \leftarrow {}^7F_0$ transition, monitored via the $^5D_0 \rightarrow {}^7F_2$ transition, results in a single, broad component at 17267 cm^{-1} at 10 K (full width at half height fwhh = 37 cm^{-1}), and 17280 cm^{-1} at 295 K (fwhh = 24 cm^{-1}), indicative of a sample with several slightly different chemical environments for the Eu^{III} ion, possibly arising from different conformations of the macrocycle and associated pendant arms.[30] Excitation in either the $^5D_0 \leftarrow {}^7F_0$ or $^5L_6 \leftarrow {}^7F_0$ transitions yields relatively broad emission spectra dominated by the hypersensitive $^5D_0 \rightarrow {}^7F_2$ transition, which are characteristic of a chemical environment with low symmetry (Figure S4, Supp. Inf.). The relative and corrected intensities of the $^5D_0 \rightarrow {}^7F_J$ transitions are 1.0, 7.4, 0.1, and 1.9 (10 K) and 1.0, 7.2, 0.2, and 2.0 (295 K) for J = 1, 2, 3, and 4, respectively.

The lifetimes of the excited $^5D_0$ level were measured at 10, 77, and 295 K both upon ligand and direct metal excitation (Table 2). The luminescence decays of the solid state sample are bi-exponential and temperature dependent, decreasing roughly by a factor of two between 10 K and room temperature. This is indicative of vibrational and/or electronic radiationless de-activation mechanisms. Here, both processes are probably operating in view of the fluxional nature of the calixarene, and of the LMCT band apparent in the excitation spectrum. Lifetimes measured upon ligand excitation are longer than those obtained through direct excitation of the $^5D_0$ level, pointing to a feeding level with a long lifetime, namely the triplet state. High energy vibrations such as those generated by O−H groups are known to efficiently de-excite Ln^{III} excited levels,[31] and phenomenological equations have been proposed to relate $\Delta k_{obsd.} = 1/\tau_{obsd.} - 1/\tau_{ref}$ where τ_{ref} is the lifetime measured on the corresponding deuterated sample or in deuterated water, and the number of water molecules q directly bound to the Ln^{III} ion, either in the solid state[32] or in solution.[33] Interpreting our lifetime data along these lines, we note that one lifetime, τ_1, is long. It decreases, under direct excitation, from 1.66 ms (10 K) to 0.86 ms (295 K). Such a lifetime, at least at low temperature, is consistent with the inner coordination sphere containing no water molecules. The other lifetime, τ_2, is much shorter, decreasing from 0.46 ms (10 K) to 0.28 ms (295 K), under direct excitation of the Eu^{III} ion. Taking $\tau_1 = \tau_{ref}$ as a first approximation, and $q = 1.05\ \Delta k_{obsd.}$,[32] we calculate, that the number of bound water molecules lies between 1.6 (10 K) and 2.5 (77 and 295 K). The apparent increase in q with increasing temperature could be simply due to outer sphere water molecules hydrogen-bonded to the complex, which become more labile when the temperature increases, or to other vibrational temperature-dependent deactivation processes affecting the de-excitation of the two metal ions differently.

Table 2. Lifetimes (ms) of the $^5D_0$(Eu) level in a solid state sample of $Eu_2(OTf)_6(A_6L^6)\cdot 9H_2O$ under various experimental conditions

T (K)	$\tilde{\nu}_{ex}$ (cm^{-1})	τ_1 (ms)	τ_2 (ms)
10	32468	2.01 ± 0.05	0.97 ± 0.04
77	32468	1.71 ± 0.03	0.48 ± 0.01
295	32468	1.09 ± 0.02	0.36 ± 0.01

77	17268	1.19 ± 0.04	0.31 ± 0.01
295	17280	0.86 ± 0.02	0.28 ± 0.01
295[a]	25445	−	1.38 ± 0.02

[a] Acetonitrile solution 2×10^{-3} M; single exponential.

In solution, the $^5D_0$ luminescence decay becomes a single exponential, with a value (1.38 ms) compatible with the absence of OH oscillators directly bound to Eu^{III}. Dissolution of the complex results, therefore, in a change in the coordination environment of the Eu^{III} ions, since the lifetime is now larger than those observed for the two different sites in the solid state. The quantum yield measured in acetonitrile upon ligand excitation Q^L_{Eu} amounts to 2.5%, a value similar to that found for $[Eu(B_6bL^6)_2]^{3+}$.

Optimized Structure of the Eu^{III} 2:1 Complex

In order to confirm the feasibility of our interpretation, we resorted to molecular mechanics calculations to evaluate a potential structure for the 2:1 complex. Several systems were tested, taking into account the experimental data, which suggested that the isolated compound has coordinated triflate anions and water molecules (IR), and two different metal ion sites with $q \approx 0$ and 2 (luminescence lifetimes). It turned out, that the conformer with the lowest energy, as calculated by the MM3 and Conflex procedures, and shown in Figure 4 (see also Table S1 in the Supporting Information), has indeed an asymmetric structure with two 9-coordinate Eu^{III} ions. One ion (site I) is bound to two phenolic oxygen atoms, three bidentate arms, and one monodentate triflate anion. The coordination environment of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the second ion (site II) is somewhat different, with two water molecules replacing the bonding to the phenolic ether atoms. Therefore, the suggested formulation of the 2:1 complex is $[Eu_2(OTf)_2(A_6L^6)(H_2O)_2]^{4+}$. Generally speaking, the Ln−O distances are too long compared with the expected ones for 9-coordinate Eu^{III}, which lie in the range 2.45−2.60 Å[34] [averages: 2.72(17) Å for site I and 2.83(18) Å for site II]. Relative distances, however, can be discussed. The coordination in site I is comprised of six short bonds (three carbonyl groups, one ether function, and the two phenoxide moieties), and three longer bonds (in 13%) involving two ether functions and the triflate anion. The situation for site II is somewhat different in that it features only three short bonds (carbonyl groups) identical to those of Site I, all the other distances being 13% longer. It is noteworthy, that site I builds a more protective cavity around the metal ion than site II does. Moreover, contrary to what was inferred from the ligand design, the phenoxide groups participate more than expected in the bonding (Site I), with Ln−O distances similar to those with carbonyl functions.

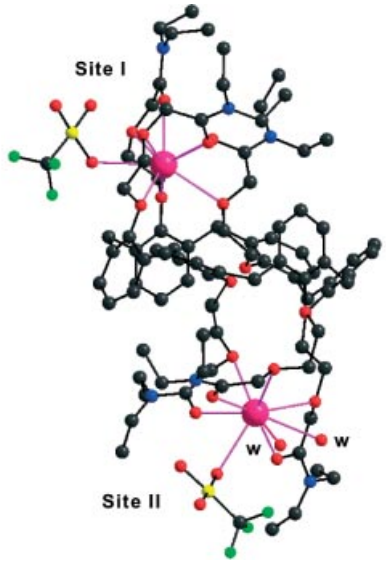

Figure 4. Optimized geometry of the Eu^{III} 2:1 complex with A_6L^6 as determined by MM3 Augmented and Conflex CAChe procedures

Conclusion

The calix[6]arene A_6L^6 exhibits a 1,2,3-alternate conformation in which two sets of three arms extend on opposite sides of the phenoxide framework, henceforth leading to a ditopic ligand able to bind to two metal ions. Complexes with a 2:1 (Ln/A_6L^6) stoichiometry could effectively be observed in solution by ^1H and ^{13}C NMR spectroscopy, and the Eu^{III} complex was isolated. The calculated structure of this complex confirms the results of the luminescence study, and resembles those found experimentally for the 2:1 complexes with *p-tert*-butylcalix[6]arene H_6bL^6 (Ln = Sm, Yb).[24] The absence of substituents on the narrower rim of H_6L^6 allows easy interconversion between different conformers, through either one of the "*tert*-butyl through the annulus" or "narrower rim through the annulus" pathways,[35] facilitating the formation of the 2:1 complexes. On the other hand, *p-tert*-butyl-substituted B_6bL^6 displays a less labile alternate *in-out* conformation in which the six phosphanylyl pendant arms are located on the same side of the molecule, and no 2:1 complexes are obtained with this receptor but, instead, compounds with 1:1 and 1:2 stoichiometries can be isolated.[16] This demonstrates once again the versatility of the calixarene frameworks, since a conformation favoring a given stoichiometry of the Ln^{III} complexes can be induced by modifying either the wider or the narrower rim of the ligand, a property which should prove useful in the development of convenient extraction systems.

Experimental Section

Solvents and Starting Materials: Tetrahydrofuran and toluene were distilled from Na, and acetonitrile was distilled from CaH_2.[36] Diglycolic anhydride, $BH_3{\cdot}Me_2S$ (2 M solution in THF), Et_2NH, Et_3N, formalin (36% solution), butylphenol, KOH, $AlCl_3$ phenol, chloroform, acetone, and $SOBr_2$ were purchased from Fluka AG (Buchs, Switzerland) or Merck, and used without further purification.

Syntheses

Preparation of the Pendant Arm: The brominated ether-amide arm **ABr** was synthesized as described previously (see Scheme 1).[14] It was dried for 3 h over 4-Å molecular sieves, which had been previously dried at 240 °C under high vacuum (24 h, 10^{-5} Torr).

Calix[6]arene H_6L^6: *p-tert*-Butylcalix[6]arene (H_6bL^6) was synthesized according to the procedure reported by Gutsche et al.,[37] and its purity checked by TLC analysis: $R_f = 0.65$ in CH_2Cl_2/petroleum ether (1:1, v/v), $R_f = 0.36$ in acetone/petroleum ether (1:9, v/v). The compound was further characterized by IR, ^1H, and ^{13}C NMR spectroscopy, and EI mass spectrometry. The *tert*-butyl groups were then removed following an $AlCl_3$ catalyzed retro-Friedel−Crafts reaction in the presence of phenol.[38] TLC analysis yielded $R_f = 0.61$ in CH_2Cl_2/petroleum ether (1:1, v/v), and $R_f = 0.31$ in acetone/petroleum ether (1:9, v/v). It was further characterized by IR, ^1H, and ^{13}C NMR and EI mass spectrometry.

Functionalization of Calix[6]arene: All operations were performed under strictly anhydrous conditions under nitrogen. Dried calix[6]arene (135 mg, 0.21 mmol) and NaH (60% in mineral oil, 149 mg, 3.73 mmol) were placed into a 100-mL round-bottomed flask fitted with a nitrogen inlet and a condenser, and dried toluene (60 mL) was added. The turbid mixture was heated with stirring, becoming almost transparent at 70 °C. The temperature increased spontaneously to 76 °C, hydrogen evolved, and a white emulsion formed. The temperature was slowly increased to 90 °C, and the mixture maintained at this temperature until no fluorescent UV spot corresponding to H_6L^6 was observed on the TLC plate (approximately 1 h). The hot emulsion was quickly poured into a 100-mL three-necked round-bottomed flask containing a solution of dried brominated arm **ABr** (808 mg, 3.4 mmol) in dry toluene (5 mL), which had been previously heated with stirring at 115 °C for 2 h. More toluene was added (10 mL), and the temperature was increased to 130 °C. As the reaction progressed the solution became

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

turbid and its color changed from brownish-orange to reddish-orange. The reaction was stopped after 6 days. The solid was separated at room temp. by vacuum filtration, and washed with warm toluene until the filtrate became colorless. The filtered organic solution was washed several times with doubly distilled water until the pH of the latter remained unchanged, and no AgBr formed upon addition of 2% $AgNO_3$ to the aqueous phase. During the washing, a white emulsified intermediate phase formed, which disappeared quickly. The organic phase was dried with anhydrous magnesium sulfate, filtered, concentrated at 40 °C, and finally evaporated under vacuum (10^{-2} Torr) at 60−70 °C. A deep orange glassy-solid was obtained (ca. 150 mg) which was ground up. *n*-Hexane (20 mL) was added, the mixture was stirred and heated to 45 °C for 30 min, and the yellow solution was separated. This step was repeated until the solution became colorless. The bulk of the solvent was separated, the remaining solvent removed under vacuum (10^{-2} Torr), and the orange waxy solid dried at 70 °C under high vacuum (10^{-5} Torr) for 1 day. It was then re-dissolved in a minimum amount of methanol, and diisopropyl ether was added until cloudiness was observed. This mixture was left in the refrigerator overnight to induce precipitation. Small and slightly yellow, brilliant glassy crystals formed after 2 days, which were collected and dried at 100 °C under high vacuum (10^{-5} Torr) for 48 h. The final deliquescent compound (66 mg, 0.042 mmol, 20% yield) was then characterized, $C_{90}H_{126}N_6O_{18}$ (Mol wt. 1580.02). IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1639 ($\nu_{C=O}$), 1249 (ν_{C-O-C}), 1126 (ν_{O-CH_2}), 1218 and 1045 (ν_{Ar-O}), 765 (ν_{C-H}). UV/Vis (dried and degassed spectroscopic grade CH_3CN): λ = 270, 278 nm. Diffuse reflectance (5% in MgO): 44840 (C=O) and 36630 (phenyl) cm^{-1}. ES-MS (10^{-4} M, CH_3CN): *m/z* = 1580.82 ($[M + H]^+$, calcd. 1581.03), 1602.86 ($[M + Na]^+$ calcd. 1603.02). ^1H NMR (10^{-3} M, CD_3CN, 400 MHz): δ = 6.94 (d, ^2J = 7.44 Hz, 12 H, H^8, H^{10}), 6.79 (t, ^3J = 7.44 Hz, 6 H, H^9), 4.11 (s, 12 H, H^3), 4.00 (s, 12 H, H^{13}), 3.72 (broad, 12 H, H^1), 3.56 (broad, 12 H, H^2), 3.35−3.25 (m, 24 H, H^5, $H^{5'}$), 2.14 (s, 4 H, $2H_2O$), 1.14 (t, ^3J = 7.1 Hz, 18 H, H^6, $H^{6'}$), 1.07 (t, ^3J = 7.1 Hz, 18 H, H^6, $H^{6'}$) ppm. $^{13}C\{^1H\}$ NMR (1×10^{-3} M, CD_3CN, 50 MHz): δ = 168.9 (C^4), 155.8 (C^{12}), 135.7 (C^7, C^{11}), 129.8 (C^9), 124.8 (C^8, C^{10}), 73.1, 71.3 (C^1, C^2), 71.0 (C^3), 41.9, 40.5 (C^5, $C^{5'}$), 31.0 (C^{13}), 14.7, 13.3 (C^6, $C^{6'}$) ppm.

Synthesis of the Complex: $Eu(CF_3SO_3)_3 \cdot 6H_2O$ (21 mg, 0.026 mmol) was dissolved in dry MeCN (2 mL) at 36 °C with stirring under N_2, and A_6L^6 (20.5 mg, 0.013 mmol) in dry MeCN (4 mL) was added dropwise. The resultant mixture was stirred for 1 h, cooled to room temp., and stirred for a further 4 h. The solvent was partially evaporated under vacuum, and diisopropyl ether was added dropwise until cloudiness appeared. The mixture was left overnight at −20 °C. The precipitate was centrifuged, washed with diisopropyl ether (2 mL), and dried under vacuum (10^{-2} Torr) at room temp., and then at 80 °C for 24 h under high vacuum (10^{-5} Torr), yielding a pale pink hygroscopic compound (34 mg, yield 82%). $Eu_2(CF_3SO_3)_6 \cdot A_6L^6 \cdot 9H_2O$, $C_{96}H_{144}Eu_2F_{18}N_6O_{45}S_6$ (2940.51): calcd. C 39.2, H 4.8, N 2.9; found C 38.8, H 4.9, N 2.8. IR (KBr, dried at 118 °C, cm^{-1}): $\tilde{\nu}$ = 1614 ($\nu_{C=O}$), 1321 ($\nu_{s(SO_3)}$ion), 1237 ($\nu_{s(C-O-C)}$), 1030 ($\nu_{s(SO_2)}$), 760 (ν_{C-H}), 638 ($\delta_{as(SO_3)}$), 520 (ν_{H_2O}). Diffuse reflectance (5% in MgO): 37310, 36230, 34130 cm^{-1}.

Spectroscopic and Analytical Measurements: IR spectra were measured with a Mattson Alpha Centauri FT spectrometer as KBr pellets for solid samples, and films on AgCl for oily samples. ES-MS spectra were measured with a Finnigan SSQ 710C spectrometer driven by a Digital Personal station 5000/25 using 10^{-4} M solutions in methanol or dry acetonitrile, and a $MeOH/HCO_2H$ mixture as eluent. NMR spectra were recorded with Bruker AM-360 (360 MHz) or DRX Advance 400 (400 MHz) spectrometers; chemical shifts δ are given with respect to TMS or CD_3CN. Low resolution luminescence spectra of solid state samples (295 and 77 K) were recorded with a Perkin−Elmer LS-50B spectrofluorimeter. Lifetimes of solutions (data reported are averages of at least five determinations), and quantum yields were measured with the same instrument. The quantum yield of the metal-centered luminescence was determined in degassed and anhydrous CH_3CN at room temperature with respect to $[Eu(L)]^{3+}$ 3×10^{-5} M in acetonitrile (Q_{abs} = 23% [39]) where L is a cyclen derivative {1,3,7,10-tetrakis[*N*-(4-phenylacetyl)carbamoylmethyl]-1,4,7,10-tetraazacyclododecane} using the following formula:

$$Q_x/Q_r = [A_r(\lambda)/A_x(\lambda)] \cdot [D_x/D_r] \cdot [n_x^2/n_r^2]$$

where the subscript *r* stands for the reference, and *x* for the sample. *A* is the absorbance at the excitation wavelength λ, *n* the refractive index (1.344 for solution in CH_3CN and 1.333 for the solution in water), and *D* the integrated luminescence intensity. The same excitation wavelength (279 nm) and absorbance (0.27) were used for the sample and the reference, and a bandpass filter (350 nm or 390 nm) was inserted to eliminate both the Rayleigh diffusion band and second order spectra. High resolution laser excited luminescence spectra were recorded using published procedures.[40] Lifetime data for solid samples were measured at different temperatures under pulsed excitation provided by a FL-3001 dye laser from Lambda Physik coupled to an excimer XeCl laser EMG-101-MSC from Lambda Physik. Elemental analyses were performed by Dr H. Eder (Microchemical Laboratory, University of Geneva).

Semi-Empirical Calculations: The optimized structures and energy minima of the free ligand, and of the 2:1 complex were calculated by using MM3 augmented and CONFLEX procedures, respectively, from the CAChe Pro 5.02 or 5.04 program package for Windows® (Fujitsu Ltd., 2000−2002). The structure of A_6L^6 was further optimized with respect to its enthalpy of formation by MOPAC PM3 molecular orbital calculations using the same program package. The effect of solvent (water) was taken into account using the COSMO procedure built into CAChe Pro. Experimental data for both the free ligand and the Eu^{III} complex (IR, NMR, luminescence) were taken into account for optimizing the calculations.

Acknowledgments

This work was supported through grants from the Swiss National Science Foundation, and by Conacyt (México), project Nr. 36689-E. We thank Véronique Foiret for her help in gathering the luminescence data.

Iron Complexes with the Alcoholato Donor-Rich Ligand 4-*tert*-Butyl-2,6-bis(hydroxymethyl)phenol: Synthesis and Characterization of a Tetra-Anionic Fe_2 Complex and a Neutral $Fe_{10}Na_4$ Complex

Thorsten Glaser,*[a] Thomas Lügger,[a] and Rolf-Dieter Hoffmann[a]

Keywords: Iron / O ligands / Oxo ligands / Bridging ligands / Hydrogen bonds

The reaction of 4-*tert*-butyl-2,6-bis(hydroxymethyl)phenol (H_3L) with Fe^{III} ions in methanol in the presence of an excess of NaOH afforded the tetra-anionic dinuclear complex $Na_4[(HL)_4Fe^{III}_2(CO_3)]\cdot 11MeOH\cdot 3H_2O$ (**1**). Changing the solvent to an ethanol/dme (dme = 1,2-dimethoxyethane) mixture led to the formation of the decanuclear complex $[(HL)_{12}Fe^{III}_{10}Na_4(\mu_4\text{-}O)_4(\mu_3\text{-}OH)_2(dme)_2(EtOH)_2]\cdot 2dme\cdot 8EtOH$ (**2**). The Mössbauer spectra of **1′** and **2** at 80 K are consistent with high spin Fe^{III} sites in distorted octahedral O_6 coordination environments. Compound **1** consists of a tetra-anionic dinuclear iron complex with the unprecedented $[Fe^{III}(\mu_2\text{-}OBz)_2(\mu_2\text{-}CO_3)Fe^{III}]^{2+}$ core. Compound **2** contains a core of hydrous ferric oxide produced by a modified hydrolysis of Fe^{III} ions in the presence of the ligand. Eight benzyl alcohol groups are located on the surface of **2** leading to a 2D network structure by intermolecular hydrogen bonding. The temperature dependence of the magnetic susceptibilities of **1′** and **2** indicates antiferromagnetic interactions between the ferric ions. The data for **1′** were fitted with $J = -4.4$ cm^{-1} and $g = 1.98$, $H = -2J\mathbf{S}_1\mathbf{S}_2$.

Introduction

Polynuclear oxo-, hydroxo-, and alcoholato-bridged iron complexes have received a great deal of attention in the fields of bioinorganic chemistry and molecular magnetic materials. In the former, they have been discussed as models for the high-nuclearity hydrous ferric oxide core of the iron storage protein ferritin.[1] Additionally, high-nuclearity iron complexes with high spin ground states and large negative magnetic anisotropy can behave as single-molecule magnets (SMMs).[2] A number of polynuclear complexes with a non-wheel-like structure comprised of up to 19 iron centers are known.[3] Joining together such aggregates into 1D, 2D, or 3D assemblies can yield materials with interesting magnetic properties.[4]

In this respect, we have been exploring the coordination chemistry of ligands based on 2,6-bis(hydroxymethyl)-phenol **A** (Scheme 1) and the sulfur-substituted derivatives, which are of particular interest due to the number of possible binding modes that they may display. Although the coordination chemistry of the corresponding ligand types 2,6-bis(aminomethyl)phenol **B** and 2,6-bis(iminomethyl)-phenol **C** (dinucleating ligands or Robson type ligands)[5] is well established, neither the coordination chemistry of the benzyl alcohol ligand **A**,[6] nor the coordination chemistry of benzyl alcohol ligands in general is well established. One important property of alcoholato ligands is their strong basicity, mainly due to the lack of resonance stabilization of the corresponding anion. This leads to their pronounced tendency to bridge metal centers[7] rather than to bind to one metal center in a terminal fashion, which is the usual coordination mode of amine and imine nitrogen donors. The coordination chemistry of ligand types **B** and **C** is, therefore, dominated by dinuclear metal complexes whereas ligand type **A** is well suited for the preparation of a variety of high-nuclearity complexes with differing coordination modes.[8] The related ligand 2,6-bis(hydroxymethyl)pyridine has been used for the synthesis of polynuclear manganese complexes, which exhibit single-molecule magnetic behavior.[9]

Recently, we reported that the reaction of 4-*tert*-butyl-2,6-bis(hydroxymethyl)phenol (H_3L) with $[Fe^{III}(acac)_3]$ in CH_3CN in the presence of Et_3N yields the tetranuclear complex $(Et_3NH)_2[(HL)_6Fe^{III}_4(acac)_2]$ (**3**) with a core of two face-sharing cuboidal $[Fe_3O_4]$ fragments.[6a] The central phenolato donor (OPh^-) in each of the three crystallographically independent ligand molecules coordinates in a terminal fashion to one Fe ion. The two benzyl alcohol groups of each ligand are distinguishable. One benzyl alcohol group of each ligand is deprotonated (OBz^-) while the other one is not (BzOH). The deprotonated benzyl alcoholato donors coordinate either in a μ_2- or in a μ_3-bridging mode. The protonated, non-coordinating benzyl alcohol groups form intra- as well as intermolecular hydrogen

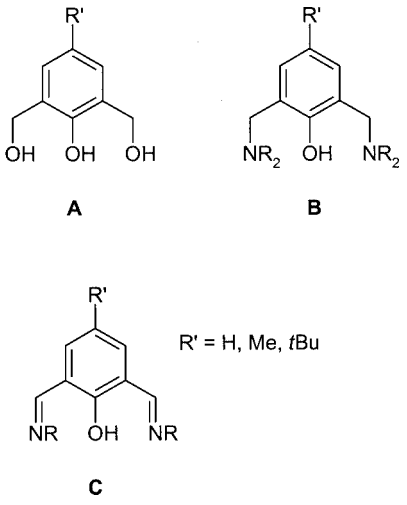

Scheme 1

bonds. In this way, the zero-dimensional paramagnetic building block was arranged into a 1D array by hydrogen bonding. Here, we report on the reaction between H_3L and $Fe^{III}(ClO_4)_3 \cdot 10H_2O$ in the presence of NaOH in protic solvents. Using MeOH as the solvent led to a tetra-anionic dinuclear iron complex and using an EtOH/dme mixture (dme = 1,2-dimethoxyethane) led to a decanuclear complex which forms a 2D network structure in the solid state by intermolecular hydrogen bonds.

Results and Analysis

Synthesis and Structural Characterization

The reaction between H_3L and $Fe^{III}(ClO_4)_3 \cdot 10H_2O$ in a 2:1 molar ratio in methanol in the presence of excess NaOH per ligand yielded large red crystals of **1** which were isolated by filtration. The FTIR spectrum exhibits bands at 2954, 2868, 1480, 1392 and 1363 cm^{-1} that are characteristic of the *tert*-butylbenzene section of the ligand H_3L. The C−O stretching frequencies of the phenolic C−O bonds are at 1307, 1276, and 1219 cm^{-1} compared with 1219 cm^{-1} in the free ligand H_3L.[6a,10] The broad band of the benzylic C−O bond at 1015 cm^{-1} in the free ligand splits into two sharp bands at 1039 and 1021 cm^{-1} in **1**. A broad flat absorption in the range of 2500−3500 cm^{-1} indicates the occurrence of hydrogen bonds. Red crystals of **1** were investigated by means of a single-crystal X-ray diffraction study and a composition of $Na_4[(HL)_4Fe_2(CO_3)] \cdot 11MeOH \cdot 3H_2O$ was obtained. Samples used for magnetic measurements were dried under high vacuum and analysis revealed a composition of $Na_4[(HL)_4Fe_2(CO_3)] \cdot 8MeOH \cdot 2H_2O$ (**1′**) indicating the loss of 3 MeOH molecules and one H_2O molecule. Tetra-anionic dinuclear complexes $[(HL)_4Fe_2(CO_3)]^{4-}$ (Figure 1) are bridged in one direction by a complicated and disordered network of sodium cations, methanol and water molecules. Although the dinuclear complex could be refined well, the heavily disordered Na^+ cations and methanol and water molecules (≈ 35% of total scattering power) have precluded complete refinement. Therefore, we have used the results from the X-ray diffraction analysis as proof only of atomic connectivity.[11]

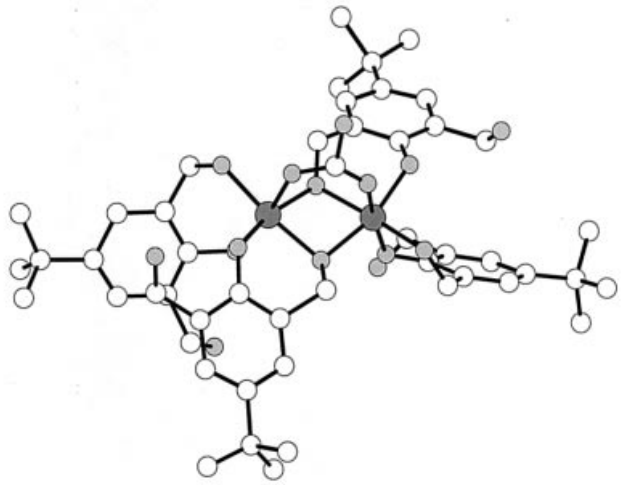

Figure 1. Atomic connectivity in the dinuclear complex $[(LH)_4Fe_2(CO_3)]^{4-}$ in **1**; dark grey circles: Fe; light grey circles: O; empty circles: C

Due to the lack of added carbonate, CO_3^{2-}, or hydrogen carbonate, HCO_3^-, the incorporated carbonato ligand has to originate from atmospheric CO_2. To test this hypothesis, we performed the same reaction under an argon atmosphere and no pure product was obtained. In other attempts to obtain **1** in a more controlled fashion Na_2CO_3, a typical precursor for the preparation of iron-carbonato complexes,[12] was added to the reaction mixture. However, no pure product was obtained. Although the controlled reaction for the preparation of **1** proved not to be straightforward, the reaction under a normal atmosphere was repeated several times and large red crystals were obtained in each case. It is interesting to note that analogous reactions using LiOH, KOH, CsOH, or even *t*BuOK and Et_3N as bases did not yield the tetra-anion of **1**. It might be speculated, therefore, that there is a synergistic effect of CO_2 incorporation and the incorporation of Na^+ ions in the solid state. Fixation of CO_2 under the highly basic conditions used in our preparations is not surprising, and this has been studied in detail by Kitajima et al.[13]

The potentially tridentate ligand is only doubly deprotonated i.e. HL^{2-}. In two ligand molecules, the phenolato group acts as a terminal donor, whereas the deprotonated benzyl alcoholato donor acts as a μ_2-bridge between the iron ions. The non-deprotonated benzyl alcohol functions form hydrogen bonds with the coordinated phenolato oxygens and with methanol molecules. In the other two ligands, the phenolato oxygen atom and the deprotonated benzyl alcohol oxygen atom chelate an iron atom whereas the non-deprotonated benzyl alcohol group binds to two sodium ions. The dinuclear complex is composed of a central $[Fe^{III}(\mu_2\text{-}OBz)_2Fe^{III}]^{4+}$ core which represents a fundamental unit in iron-oxygen donor chemistry of metallo-pro-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

teins and of biomimetic model compounds.[14] Several examples of complexes with the $[Fe^{III}(\mu_2\text{-}OR)_2(\mu_2\text{-}OOCR')Fe^{III}]^{3+}$ core have been reported.[15] Whereas $[Fe^{III}(\mu_2\text{-}O)(\mu_2\text{-}CO_3)Fe^{III}]^{2+}$ is known[12,13], however, complex **1** is to the best of our knowledge the first evidence of a $[Fe^{III}(\mu_2\text{-}OR)_2(\mu_2\text{-}CO_3)Fe^{III}]^{2+}$ core.

The reaction of H_3L and $Fe^{III}(ClO_4)_3\cdot 10H_2O$ in a molar ratio of 2:1 in ethanol in the presence of excess NaOH and dme yielded dark red crystals of **2**. The FTIR spectrum shows the bands of the *tert*-butylbenzene part of the ligand H_3L at 2954, 2867, 1480, 1393, and 1363 cm^{-1}. The absorptions at 1306, 1275, and 1220 cm^{-1} can be assigned to C−O stretching modes of the phenolic C−O bonds, and those at 1038 and 1022 cm^{-1} to the C−O stretching modes of the benzylic C−O bonds. The intensity patterns of these C−O vibrations differ from those observed in the FTIR spectrum of **1**. A broad flat absorption in the 3400−2500 cm^{-1} range is indicative of hydrogen bonding. Structural characterization by single-crystal X-ray diffraction gave the formulation as $[(HL)_{12}Fe^{III}_{10}Na_4(\mu_4\text{-}O)_4(\mu_3\text{-}OH)_2(dme)_2(EtOH)_2]\cdot 2dme\cdot 8EtOH$ (**2**).

The molecular structure of the decanuclear complex in crystals of **2** is shown in Figure 2 (a). The decanuclear iron unit including the bridging oxygen atoms is shown in Figure (b). Selected bond lengths and bond angles are given in Table 1. The asymmetric unit consists of one half of the complex with the other half generated by a crystallographic center of inversion. All iron atoms are in distorted octahedral FeO_6 environments and are bridged by four $\mu_4\text{-}O^{2-}$ (O1, O1′, O3, O3′), two $\mu_3\text{-}OH^-$ (O3, O3′), and twelve $\mu_2\text{-}OBz^-$ ligands (O2a, O2a′, O2b, O2b′, O2c, O2c′, O2d, O2d′, O2e, O2e′, O2f, O2f′). The coordination of the iron ions is completed by OPh^- ligands and two EtOH ligands (coordinated to Fe3 and Fe3′). The assignment of O2 (and O2′) to an OH^- instead of an O^{2-} ligand is not only based on charge considerations. The three Fe−O bond lengths to O2 (mean value 2.09 Å) are significantly longer than the four bond lengths to O1 (2.02 Å) and O3 (2.05 Å). For O2 being a $\mu_3\text{-}O^{2-}$, it must have shorter bonds compared with a $\mu_4\text{-}O^{2-}$. Additionally, one oxygen of dme adopts the fourth position of an idealized tetrahedron around O2 at a distance of 2.77 Å, consistent with a hydrogen bond (see Figure S1 in the Supporting Information, for Supporting Information see also the footnote on the first page of this article). The Fe−O bond lengths span a range from 1.95 Å to 2.12 Å. A comparison of the bridging ligands shows that the $\mu_2\text{-}OBz^-$ ligands have shorter bonds (mean value 2.00 Å) compared with the $\mu_4\text{-}O^{2-}$ (mean value 2.03 Å) and the $\mu_3\text{-}OH^-$ ligands (mean value 2.09 Å). The Fe···Fe distances can be divided into two categories: a short distance was found for Fe1−Fe1′, Fe1−Fe2′, and Fe2−Fe1′ at 3.00−3.02 Å and a significantly longer distance range of 3.10−3.22 Å for all other Fe···Fe separations.

The iron-oxygen core can be regarded as a part of a hydrous ferric oxide phase. The oxygen atoms of the bridging $\mu_4\text{-}O^{2-}$, $\mu_3\text{-}OH^-$, $\mu_2\text{-}OBz^-$, and the terminal OPh^- and EtOH may be considered to form an idealized cubic close packed structure with the iron atoms in octahedral voids (A B C A B stacking sequence, see Figure S2 in the Supporting Information). In this respect, the iron-oxygen core in **2** may be regarded as a small part of γ-Fe·O·OH or lepidocrocite stabilized by an organic shell. Two Fe_{10} complexes with a similar iron-oxygen core were reported, namely $[Fe_{10}O_4(OCH_3)_{16}(dbm)_6]\cdot x CHCl_3$ (Hdbm = 1,3-diphenyl-1,3-propanedione)[3e] and $[Fe_{10}O_4Cl_8(OCH_3)_{14}(CH_3OH)_6]\cdot 2CH_3OH$.[3f] This indicates a high stability of the iron-oxygen core based on the different kind of outer shell ligands used for the preparation of the three compounds.

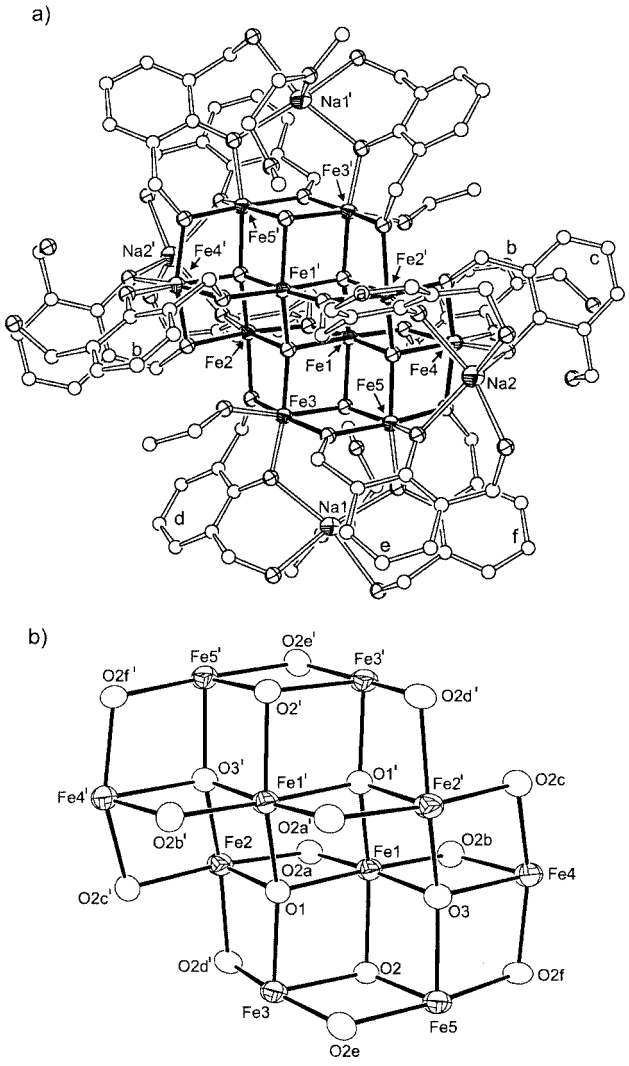

Figure 2. a) Molecular structure of $[(HL)_{12}Fe^{III}_{10}Na_4(\mu_4\text{-}O)_4(\mu_3\text{-}OH)_2(dme)_2(EtOH)_2]$ in crystals of **2**; hydrogen atoms and *tert*-butyl groups are omitted for clarity. The six independent ligand molecules are labeled a−f; b) ORTEP plot of the central Fe_{10} core including the bridging oxygen atoms; thermal ellipsoids are shown at the 50% probability level

The potentially tridentate ligand H_3L appears in all six independent ligand molecules (labeled a−f in Figure 2, a) as only doubly deprotonated HL^{2-}. One of the BzOH groups of each ligand is not deprotonated (O3a−O3f). The six ligand molecules coordinate in two different binding modes. Ligand b (O1b, O2b, O3b) and ligand c (O1c, O2c,

O3c) bind only in a chelating fashion to the iron centers via the OPh^- (O1b, O1c) and OBz^- (O2b, O2c) groups, and OBz^- bridges two iron centers. The second non-deprotonated BzOH (O3b, O3c) of these two ligands is not coordinated to a metal center. Ligands a, d, e, f chelate additionally to a Na^+ ion via the OPh^- group and the non-deprotonated BzOH. Furthermore, the non-deprotonated BzOH groups are involved in intra- and intermolecular hydrogen bonding. O3b and O3c (O3b′ and O3c′) form an intramolecular hydrogen bond with a distance of 2.79 Å. Intermolecular hydrogen bonds between O3f and O3b (2.68 Å) and between O3c and O3d (2.76 Å) lead to a hydrogen bonded 2D network structure in the *bc*-plane (Figure 3).

Spectroscopic Characterization

The ^{57}Fe Mössbauer spectrum of **1′** at 80 K shows a quadrupole doublet with an isomer shift $\delta = 0.47\ mm{\cdot}s^{-1}$ and a quadrupole splitting $|\Delta E_Q| = 0.69\ mm{\cdot}s^{-1}$. The isomer shift is typical for high-spin ferric ions ($S_i = 5/2$) ligated by oxygen donors. The quadrupole splitting of $0.69\ mm{\cdot}s^{-1}$ is consistent with a moderate distortion from octahedral symmetry since the valence-electron contribution to ΔE_Q is negligible for a high-spin Fe^{III} ion. The effective magnetic moment (μ_{eff}, calculated per iron dimer unit) of **1′** decreases with decreasing temperature which is indicative of antiferromagnetic coupling (Figure 4). The data could be easily fitted using the spin-Hamiltonian for an Fe^{III} ($S_i = 5/2$) dimer

$$H = -2J\mathbf{S}_1\mathbf{S}_2 + \sum_{i=1}^{2}[\mu_B g_i \mathbf{S}_i \mathbf{B}]$$

using a full-matrix diagonalization approach with $J = -4.4\ cm^{-1}$ and an isotropic g value of 1.98 including a paramagnetic impurity ($S = 5/2$) of 4.1%.[16]

The Mössbauer spectrum of **2** at 80 K exhibits a well resolved doublet with $\delta = 0.51\ mm{\cdot}s^{-1}$ and $|\Delta E_Q| = 0.73\ mm{\cdot}s^{-1}$ typical for high-spin ferric ions. The subspectra originating from the five distinctive iron ions in **2** were not resolved. The temperature dependence of μ_{eff} indicates antiferromagnetic interactions between the Fe^{III} ions. At low temperatures, the μ_{eff} values appear to be sample-dependent. This may be due to different amounts of paramagnetic impurities (presumably mononuclear Fe^{III} species) or to sample inhomogeneities. Crystals rapidly loose solvent leading to different mixtures of crystalline ($Fe_{10}Na_4{\cdot}2dme{\cdot}8EtOH$) and amorphous parts ($Fe_{10}Na_4{\cdot}x dme{\cdot}x EtOH$) with loss of the regular hydrogen bonding pattern as observed in crystals of $Fe_{10}Na_4{\cdot}2dme{\cdot}8EtOH$. The change in the chemical environment of the formerly hydrogen bonded BzOH groups may have a direct effect on the bridges between the iron centers and thus on the exchange interactions leading to the observed differences in the magnetic measurements.

Discussion

The reaction of H_3L with $Fe^{III}(ClO_4)_3{\cdot}10H_2O$ in the presence of NaOH resulted in the formation of **1** using MeOH as the solvent, and **2** using an EtOH/dme mixture as the solvent. Complex **1** has an $[Fe^{III}(\mu_2\text{-}OBz)_2(\mu_2\text{-}CO_3)Fe^{III}]^{2+}$ core which, to the best of our knowledge, is the first example of an Fe_2O_2 unit bridged by a carbonato ligand. The exchange coupling constant was found to be $J = -4.4\ cm^{-1}$. Analogous complexes with a carboxylato instead of the carbonato bridge, i.e. $[Fe^{III}(\mu_2\text{-}OR)_2(\mu_2\text{-}O_2CR)Fe^{III}]^{3+}$, were reported to have J values in the range of -3.9 to $-10.5\ cm^{-1}$.[15c,15d,15e]

Uncoordinated benzyl alcohol groups, coordinated phenolato groups, and the uncoordinated oxygen atom of the coordinated carbonato ligand in **1** create an oxygen donor rich, negatively charged environment around the central $[(HL)_4Fe_2(CO_3)]^{4-}$ unit. These uncompensated charges and hydrogen bond donors lead to a disordered network of Na^+ ions as well as MeOH and H_2O molecules along the *b* axis. It is interesting to compare this arrangement with the iron binding site of the metalloprotein lactoferrin, which is known to reversibly bind two Fe^{III} ions concomitantly with two CO_3^{2-} groups by two equal mononuclear binding sites.[17] A synergistic relationship between cation- and anion-binding has been established. The carbonate anion coordinated to the Fe^{III} ion is tightly fixed by five hydrogen bonds from the protein backbone. In this respect, the stabilization of CO_3^{2-} in **1** by hydrogen bonds and Na^+ ions indicates that the oxygen rich environment of the dinuclear

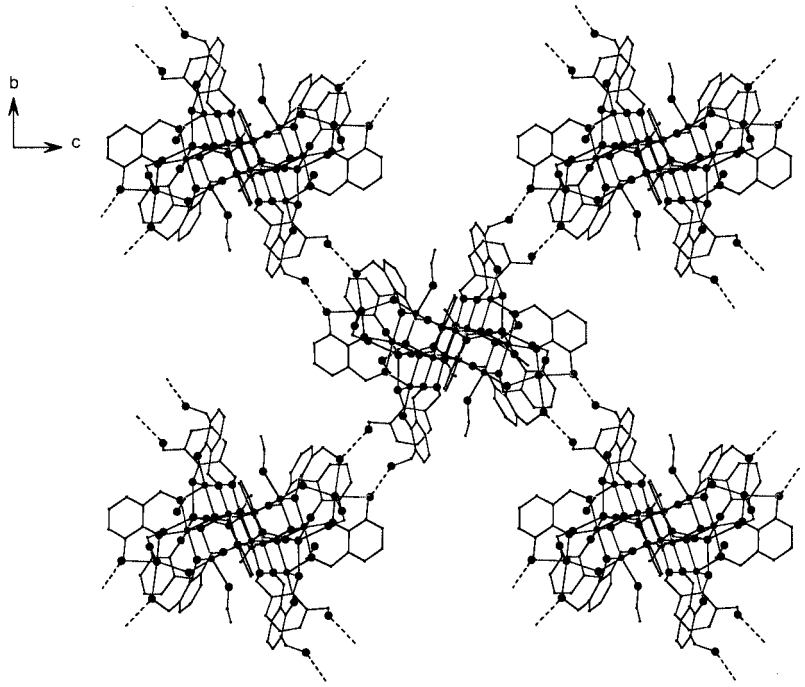

Figure 3. Projection down the *bc*-plane of the 2D network formed from interconnected $Fe_{10}Na_4$ complexes by intermolecular hydrogen bonds in crystals of **2**

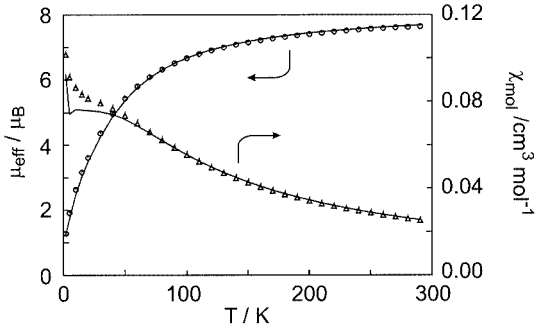

Figure 4. Temperature dependence of the effective magnetic moment, μ_{eff}, of **1′** at 1 T; the solid line is a fit of the experimental data using the spin-Hamiltonian given in the text with $J = -4.4$ cm^{-1}, $g = 1.98$, and a paramagnetic impurity of same molecular mass of 4.1% ($S = 5/2$)

iron unit corroborated by the Na^+/MeOH/H_2O network is perfectly suited for CO_3^{2-} binding. It may be speculated that this is the reason why, by use of MeOH as the solvent, **1** is formed rather than a high-nuclearity iron complex analogous to **2**.

Complex **2** possesses a central iron-oxygen core which may be regarded as a small fraction of the hydrous ferric oxide mineral lepidocrocite. This iron-oxygen core is surrounded by 12 HL^{2-} ligands. In the case of **2**, the uncompensated negative charges of the oxygen donors are saturated by incorporation of four Na^+ ions to give the neutral $Fe_{10}Na_4$ complex. The packing of **2** in the solid state is not governed by van der Waals forces. The presence of eight BzOH functions grouped in four pairs on the surface of **2** leads to a regular hydrogen bonding pattern in a 2D array in the *bc*-plane. The only weakly bound solvent molecules evaporate very rapidly when the crystals are extracted from the mother liquor.

In summary, the coordination chemistry of the ligand 4-*tert*-butyl-2,6-bis(hydroxymethyl)phenol (H_3L) is different from its 2,6-bis(amino) and 2,6-bis(imino) derivatives. Several different coordination modes of H_3L were observed in compounds **1**, **2**, and **3**. The tendency of the OBz^- functions to bridge between metal centers and the availability of BzOH for hydrogen bonds leads to high nuclearity complexes and/or to intermolecular interactions in the solid state. The preparation of manganese complexes of H_3L with the possibility of interesting magnetic properties is currently under way.

Experimental Section

Syntheses: All manipulations were performed under aerobic conditions, using materials as received. 4-*tert*-butyl-2,6-bis(hydroxymethyl)phenol (H_3L) was prepared as described previously[6a]

Safety Note: *Although we have not encountered any problems, it has been noted that the reaction between perchlorate salts and organic ligands may lead to potentially explosive materials and must be performed with great care and appropriate precautions.*

$Na_4[(HL)_4Fe^{III}_2(CO_3)]\cdot 8MeOH\cdot 2H_2O$ (1′): A stirred solution of 4-*tert*-butyl-2,6-bis(hydroxymethyl)phenol (400 mg, 1.90 mmol) in methanol (30 mL) was treated with $Fe^{III}(ClO_4)_3\cdot 10H_2O$ (508 mg, 0.95 mmol) resulting in a deep blue solution. Addition of NaOH (380 mg, 9.51 mmol) caused a color change to dark red. The solu-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion was heated at reflux for 4 h during which the color became light red, cooled to room temperature, and filtered. Slow evaporation of the solvent produced red crystals which were vacuum dried. Yield: 420 mg (63%). IR (KBr): $\tilde{\nu}$ = 3538, 2954, 2904, 2868, 1605, 1480, 1392, 1363, 1307, 1276, 1219, 1124, 1039, 1021 878, 832, 757, 690, 549 cm^{-1}.$C_{57}H_{100}Fe_2Na_4O_{25}$ (1389.06): calcd. C 49.29, H 7.26; found C 49.31, H 6.98.

$[(HL)_{12}Fe^{III}{}_{10}Na_4(\mu_4\text{-}O)_4(\mu_3\text{-}OH)_2(dme)_2(EtOH)_2]\cdot 2dme\cdot 8EtOH$ (2): A stirred solution of 4-*tert*-butyl-2,6-bis(hydroxymethyl)phenol (300 mg, 1.43 mmol) in ethanol (10 mL) was treated with $Fe^{III}(ClO_4)_3\cdot 10H_2O$ (389 mg, 0.73 mmol) resulting in the formation of a deep blue color. Addition of a solution of NaOH (214 mg, 5.35 mmol) in ethanol (10 mL) caused a color change to dark red. After stirring for 30 min, dme (3 mL) was added and the solution was filtered. Slow evaporation of the solvent produced red crystals which were vacuum dried. Yield: 160 mg (63%). IR (KBr): $\tilde{\nu}$ = 3424, 2954, 2867, 1624, 1606, 1540, 1480, 1393, 1363, 1306, 1275, 1220, 1122, 1038, 1022, 878, 833, 759, 617, 555 cm^{-1}. $C_{156}H_{226}Fe_{10}Na_4O_{48}$ (3519.91): calcd. C 53.23, H 6.47; found C 53.12, H 6.14.

Crystal Structure Determination: Data were collected with a Bruker AXS APEX diffractometer equipped with a rotating anode using Mo-K_α radiation (λ = 0.71073 Å). An empirical absorption correction was applied for **2** using SADABS.[18] The structure was solved with SHELXS[19] using direct methods and refined with SHELXL.[20]

Single crystals of **2** rapidly desolvate when extracted from the mother liquor indicating the presence of weakly bound solvent molecules. The structure solution shows the well defined complex $[(HL)_{12}Fe^{III}{}_{10}Na_4(\mu_4\text{-}O)_4(\mu_3\text{-}OH)_2(dme)_2(EtOH)_2]$ which could be refined unrestrained using anisotropic thermal parameters. These molecules are separated by solvent layers. Due to heavy disorder, the solvent positions are only poorly resolved and are estimated to consist of eight ethanol and two dme molecules per $Fe_{10}Na_4$ complex. Hydrogen atoms were added in calculated positions and no hydrogen positions were calculated for solvent molecules. Additional data collection and refinement details are listed in Table 2. CCDC-170255 contains the supplementary crystallographic data for compound **2**. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html [or from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44 1223 336033; E-mail: deposit@ccdc.cam.ac.uk].

Other Measurements: Infrared spectra (400−4000 cm^{-1}) of solid samples were recorded with a Bruker Vector 22 spectrometer as KBr disks. Temperature-dependent magnetic susceptibilities of powdered samples in gelatin capsules were measured using a SQUID magnetometer (Quantum Design) at 1.0 T (2.0−300 K). For calculations of the molar magnetic susceptibility, χ_M, the measured susceptibilities were corrected for the diamagnetism of the sample holder and for the underlying diamagnetism of the sample by using tabulated Pascal's constants (**1′**: $\chi_{dia} = -813 \times 10^{-6}$ $cm^3\cdot mol^{-1}$; **2**: $\chi_{dia} = -1997 \times 10^{-6}$ $cm^3\cdot mol^{-1}$). ^{57}Fe Mössbauer spectra were recorded with an alternating constant-acceleration spectrometer. The minimal line-width was 0.24 $mm\cdot s^{-1}$ full-width at half-height. The sample temperature was maintained in an Oxford Instruments Variox Cryostat. ^{57}Co/Rh was used as the radiation source. Isomer shifts were determined relative to α-iron at 300 K.

Electronic Supporting Information Available (see also footnote on the first page of this article): Graphical representations of the hydrogen bond between O2 and O11 in **2** and the packing of the iron-oxygen core in **2** have been deposited.

[16] The JULIUS routine was used for spin Hamiltonian simulations of the data (C. Krebs, E. Bill, F. Birkelbach, V. Staemmler, unpublished results). For the calculation of the magnetic susceptibiliy of the paramagnetic impurity JULIUS uses the molar mass of the main component. Thus the obtained value of 4.1% for the paramagnetic impurity is far overestimated if a mononuclear Fe^{III} species is anticipated.

First ICN Adduct with a Selenium Donor (R = Se): Is It an Ionic $[RSeCN]^+I^-$ or a "T-Shaped" R(I)SeCN Hypervalent Compound?

M. Carla Aragoni,[a] Massimiliano Arca,[a] Francesco Demartin,[b] Francesco A. Devillanova,*[a] Alessandra Garau,[a] Patrizio Grimaldi,[c] Francesco Isaia,[a] Francesco Lelj,[c] Vito Lippolis,[a] and Gaetano Verani[a]

Keywords: Density functional calculations / Donor-acceptor systems / ICN / Hypervalent compounds / Se ligands

The reaction between 1,3-dimethyl-4-imidazoline-2-selone (**2**) and ICN gave the adduct **2**·ICN, whose crystal structure features dimers made up of two $[\mathbf{2}\cdot CN]^+$ and two I^- which strongly interact. Hybrid DFT calculations on the adduct **2**·ICN, on the cation $[\mathbf{2}\cdot CN]^+$, and on the dimer $(\mathbf{2}\cdot ICN)_2$ account for a partially hypervalent selenium atom in **2**·ICN and for the observed structural features.

Introduction

Hypervalent chalcogen compounds featuring a linear X−E−X moiety (X = Cl, Br, I; E = S, Se) can be considered to derive from the oxidative addition of an X_2 molecule to a donor molecule containing the chalcogen atom. With donors containing thio- or seleno-carbonyl groups, the "T-shaped" nature of the corresponding adducts is well explained by the VSEPR model,[1] according to which the geometry at the chalcogen atom is a pseudo-trigonal bipyramid (tbp) with the halogens occupying the apical positions. These compounds are commonly reported as 10−E−3 systems,[2] indicating that the chalcogen atom E is formally associated with five electron pairs (10 electrons), only 3 of which are bond pairs. As with a tri-halide, the chemical bond in the linear X−E−X fragment has also been described as a three-center−four-electron (3c-4e) system, whose simplified MO diagram can be built by combining the p_z atomic orbitals of the central chalcogen and those of the two terminal halogen atoms.[3] Four electrons occupy only the bonding and non-bonding orbitals, thus determining a total bond order of 1 (0.5 for each E−X bond). This description agrees with the qualitative observation[4,5] that on increasing the electronegativity difference between the halogen and the chalcogen, hypervalent chalcogen adducts are formed more easily than charge-transfer (CT) adducts bearing the E−X−X linear group (10−X−2 hypervalent halogen compounds).[2] Indeed, the number of hypervalent sulfur and selenium compounds structurally characterized decreases on passing from chlorine to iodine, and hypervalent sulfur compounds with di-iodine are unknown.[6] In addition, the first hypervalent selenium compounds with iodine were only reported in 1994,[7,8] and the first hypervalent sulfur compound with bromine appeared in 1977,[9] and the second in 1999.[10]

For the oxidative addition of inter-halogens (ICl, IBr), only two examples of "T-shaped" adducts have been reported, i.e. **1**·IBr,[9] which is very unstable, and **3**·2IBr.[11] In addition, **1**·BrCN (characterized by X-ray diffraction)[9] and **1**·ClCN (characterized only by IR spectroscopy)[9] are the only reported examples of S- or Se-adducts with pseudo-halogens (ICN, BrCN, and ClCN). Therefore, the synthesis of new such adducts is an important step towards understanding not only the nature of the chemical bond in these systems, but also the possible role of hypervalent chalcogen compounds as intermediates in the formation of the many classes of compounds obtained by reacting chalcogen donors with halogens and inter-halogens.[6,12,13]

This paper contributes to this chemistry by reporting both the crystal structure of the first selenium adduct with the pseudo-halogen ICN and the DFT calculations that have been of great help in ascertaining the nature of the chemical bond in the ISeCN fragment.

Results and Discussion

Synthesis and Structural Characterization: The reaction of **2** with one equivalent of ICN in CH_2Cl_2 gave well-shaped crystals by slow evaporation of the solvent. X-Ray diffraction analysis showed that the asymmetric unit is formed by the adduct 2·ICN bearing the I···Se−CN linear group [I···Se−C(8) 174.8(2)°] almost perpendicular to the imidazolidine ring, with a very long Se···I distance [3.300(1) Å] and a short Se−CN bond [1.885(5) Å]. Two 2·ICN units are arranged about a crystallographic inversion center to form dimers via Se···I contacts that are only 0.117 Å longer than the Se···I distance within the asymmetric unit (Figure 1), so that the two selenium and two iodine atoms are located on the opposite corners of an almost regular rhombus. The very long Se···I distances suggest the isolated compound has an ionic nature.

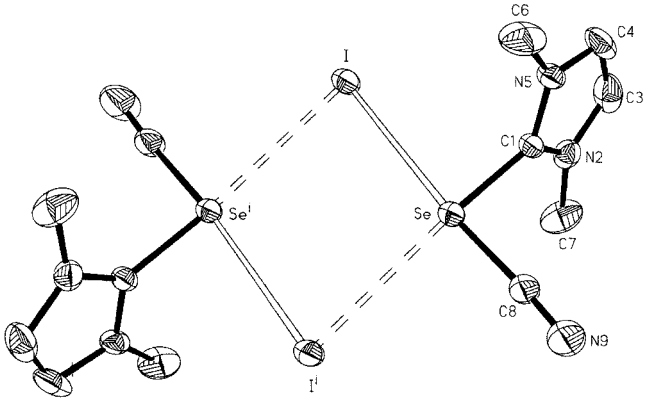

Figure 1. Molecular structure and atom labelling scheme for the adduct **2**·ICN; selected bond lengths and angles: Se···I 3.300(1), Se···I^i 3.417(1), C(1)−Se 1.913(4), C(8)−Se 1.885(5)Å, C(1)−Se−C(8) 93.2(2), I···Se−C(8) 174.8(2), Se···I···Se^i 80.24(1), I···Se···I^i 99.76(1), N(2)−C(1)−Se−C(8) 83.2(4)°; i = $-x$, $1-y$, $1-z$

The structural features of **2**·ICN can usefully be compared with those of **1**·BrCN, the only other reported adduct between an S- or Se-donor and a pseudo-halogen.[9] According to the very long S···Br bond length, the authors described **1**·BrCN as an ion pair [**1**·CN]$^+$ Br$^-$. However, a dimeric arrangement similar to that observed for **2**·ICN can also be envisaged for **1**·BrCN, with two significantly different S···Br distances (3.270 and 3.587 Å). The S···Br involving the Br atom *trans* to the cyano group is the longest, contrary to what is observed in the dimer (**2**·ICN)$_2$. Intriguingly, the S···Br and Se···I distances *trans* to the cyano group in the two compounds are very similar, although the involved atoms are S and Br in **1**·BrCN and their heavier congeners, Se and I, in **2**·ICN. Thus, **2**·ICN might not be a pure ionic compound, and a partial selenium−iodine covalent character should be considered to fully explain the compound's structural features.

DFT Calculations: A partial covalent character for the Se···I bond in **2**·ICN would agree with a description for it as a strongly polarized hypervalent-selenium compound. Actually, the linearity of the I···Se−CN group supports this view, although this is not direct evidence for hypervalency of the selenium atom. Recently, we reported the crystal structure of **3**·2IBr, which was the first example of a hypervalent selenium compound with IBr. In **3**·2IBr, the two I−Se···Br systems were strongly polarized, both Se···Br bonds having, therefore, a partial ionic character.[11]

DFT calculations have greatly enabled deeper insight into the nature of the chemical bond in some CT and tbp adducts between halogens or inter-halogens and some S- or Se-donors, including **2**.[11,12] In particular, for **2**·I_2,[12] **2**·Br_2,[12] and **2**·IBr,[11] the calculated geometries of the organic frameworks are in very good agreement with the experimental data for **2**·I_2,[7] **3**·2I_2,[7] **3**·2Br_2,[14] and **3**·2IBr,[11] though in general the Se−X bond lengths were slightly overestimated. Hence, we performed calculations at the same level of theory on **2**·ICN (both in the tbp and in the CT type arrangements), on the dimer (**2**·ICN)$_2$ and on the [**2**·CN]$^+$ cation. Interestingly, the optimized geometry for the tbp **2**·ICN adduct agrees fairly well with the structural data (Figure 2) with the exception of the Se···I length, which is underestimated (3.233 Å) as compared with the experimental value [3.300(1) Å]. The structural features of the organic framework for the optimized geometry of (**2**·ICN)$_2$ are very similar to those of the calculated geometry of **2**·ICN (Figure 2). The Se···I distances are calculated to be slightly dissimilar (3.448 and 3.422 Å, respectively) as ex-

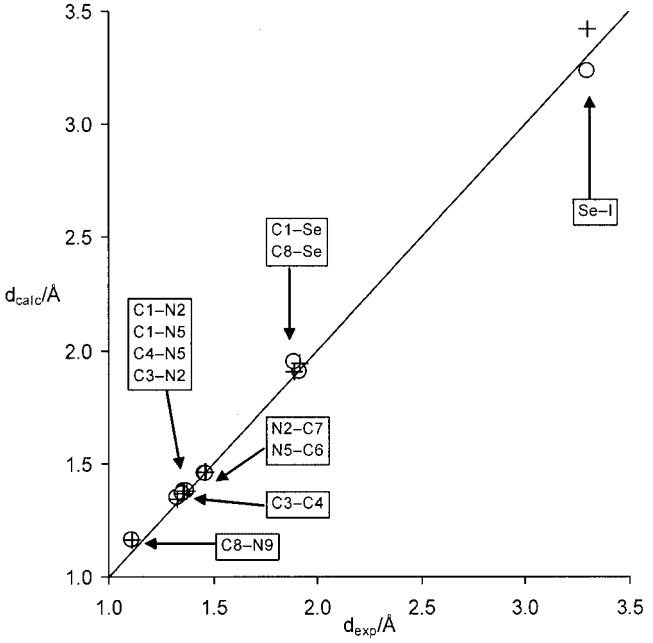

Figure 2. Correlation between the experimental (d_{exp}) bond lengths for **2**·ICN and the optimized (d_{calc}) ones for **2**·ICN (O) and (**2**·ICN)$_2$ (+)

perimentally found, but overestimated with respect to the experimental data [Se···I^{i}, 3.417(1); Se···I, 3.300(1) Å, Figure 1].

Previously,[11,12] we proved by DFT calculations that the complete removal of one of the two halogen atoms as a halide from an X−Se−X (X = I, Br) hypervalent system (the two extremes being the covalent and completely ionic bonds) causes the carbon−selenium−halogen angle to open from lower than 90° towards values closer that expected for a tetrahedral environment around the chalcogen atom. For example, the calculated C−Se−X (X = I, Br) angles pass from 84.3° for the "T-shaped" **2**·Br_2 adduct to 97.2° for the cation [**2**·Br]$^+$, and from 85.4° for the analogous **2**·I_2 adduct to 98.3° for [**2**·I]$^+$.[11,12] The widening of the C−Se−X angle represents the most significant change observed in the optimized structural parameters upon lengthening of one Se−X bond of the hypervalent system towards the formation of the [>C−Se−X]$^+$ cation; all the other structural features are only slightly changed. In the present case, the calculated C−Se−CN angle shows a very small variation (91.8° in **2**·ICN; 94.7° in [**2**·CN]$^+$; Table 1). This small variation is justified as the optimized geometry for the "T-shaped" **2**·ICN adduct already shows a very strong polarization of the Se···I bond determined by the very different electronic effects of the I and CN groups bonded to the Se atom. This is also indicated by the calculated NBO[15,16] charges on the iodine atom, which are −0.665 and −0.718e for **2**·ICN and (**2**·ICN)$_2$ respectively. Therefore, the increase in the negative charge on the iodine atom up to the limit case of −1 in [**2**·CN]$^+$ does not change significantly the structural features of the organic framework including the C−Se−CN angle. Interestingly, the experimental C−Se−CN angle [93.2(2)°] is exactly in between those calculated for the tbp **2**·ICN adduct and the cation [**2**·CN]$^+$. A similar situation is observed for **1**·BrCN:[9] the experimental C−S−CN angle of 96.3° is slightly lower than the 98.5° calculated for the cation [**1**·CN]$^+$ (footnote [c] in Table 1) and very close to the 96.5° calculated for the tbp **1**·BrCN adduct.

In any event, the greater the difference in the electron-withdrawing features of the two groups interacting with the chalcogen atom, the lower is the covalency of the system X−Se−Y, which tends to become more polarized and ionic in nature.

In fact, the C−Se−I angle calculated for the tbp **2**·IBr adduct and the cation [**2**·I]$^+$ are 86.5 and 98.3°, respectively;[11] the same angles observed for the two I−Se−Br units in the crystal structure of **3**·2IBr are 95.6(3)° and 90.6(3)°, in agreement with the different degree of covalency and hypervalency in the two systems.[11]

Partial hypervalency of the selenium atom in **2**·ICN is also supported by analysis of the LUMO and the LUMO+1 calculated for both cations [**1**·CN]$^+$ and [**2**·CN]$^+$. In fact, they are σ* and π* in nature with respect to the Se−C−N vector and very close in energy and symmetry-allowed to accept charge density either from donor halides *trans* to the cyano group (LUMO) or *trans* to the imidazoline ring (LUMO+1) (Figure 3). Thus, the formation of (**2**·ICN)$_2$ could be described as a charge-transfer interaction between the HOMOs of two I$^-$ and the LUMO and LUMO+1 of two cations [**2**·CN]$^+$. The closeness in energy of LUMO and LUMO+1 tends to make the interactions in the two directions equally likely, and solid-state

Table 1. Selected bond lengths, angles, and NBO charges for the optimized geometries of "T-shaped" adducts between **2** and XY (X = Y = Cl, Br, I; X = I and Y = Cl, Br, CN), calculated at the DFT level

X Y	Cl[a] Cl	Br[b] Br	I[a] I	I[a] Br	I[a] Cl	I[a][c] CN	I[a,c] CN dimer

effects might presumably be crucial in determining the balance between the entities of the two interactions. NBO population analysis shows that the two generated hybrid atomic orbitals of I^- (1.89 and 1.83e) have a direction suitable to put electron charge on LUMO and LUMO+1. The NBO population suggests that the amount of electron transfer is very low, but it should be important to determine the geometrical arrangement of the two **2**·ICN units in $(\mathbf{2}\cdot ICN)_2$. Conversely, for the hypervalent adducts with halogens and interhalogens, analysis of the LUMOs and (LUMO+1)s of the cations $[\mathbf{2}\cdot X]^+$ (X = I, Br; Figure 3) shows that both orbitals are σ* in nature with respect to the Se−X vector and considerably separated in energy. Therefore, the donor−acceptor interaction between the lone pair of a halide Y^- (Y = I, Br) and the LUMO of the cation $[\mathbf{2}\cdot X]^+$ is the only one possible, giving a linear X−Se−Y moiety. This explains why, in hypervalent-chalcogen compounds with halogens,[6,12] the chalcogen−halogen bonds within the hypervalent systems are always considerably shorter than the chalcogen···halogen intermolecular contacts between adjacent adduct molecules. Thus, the topological analysis of the LUMO and LUMO+1 and the charge distribution seem to give both a decisive proof that the description of **2**·ICN as a polarized hypervalent-selenium compound is realistic and a good explanation for the different arrangements of the adduct units found in **1**·BrCN and **2**·ICN with respect to those observed for hypervalent-chalcogen systems with halogens and interhalogens.

Notably, a partial hypervalent nature of the Se atom in **2**·ICN does not imply a description of the Se···I bond as covalent, since DFT calculations indicate that this bond is strongly polarized and therefore appreciably ionic. However, comparison of the Se···I distances calculated both for **2**·ICN and $(\mathbf{2}\cdot ICN)_2$ with those of hypervalent adducts of **2**

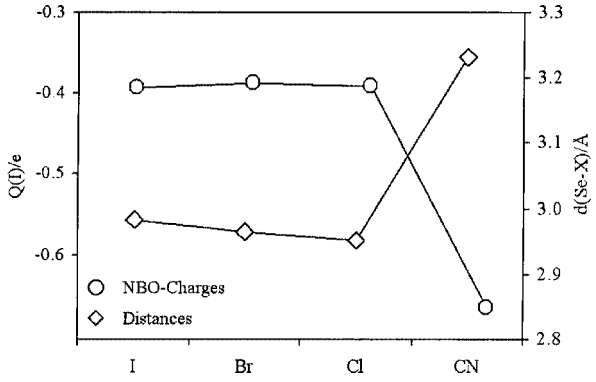

Figure 4. Trends of Se−I bond lengths and calculated NBO charge on the iodine atom for the I−Se−X system in **2**·IX T-shaped adducts (X = I, Br, Cl, CN)

containing the Se−I bond (Table 1) and the trend of the calculated NBO[15,16] charge on the iodine atom of the I−Se−X system on passing from X = I to Br, Cl, and CN (Figure 4; Table 1) shows that **2**·ICN and $(\mathbf{2}\cdot ICN)_2$ are different from the other systems. The considerably long Se−I distances and the strongly negative charge on iodine [−0.665 and −0.718e in **2**·ICN and $(\mathbf{2}\cdot ICN)_2$ respectively][16] agree with the strongly polarized character of the Se···I bond in the present compound.

We have also examined the relative energy of $(\mathbf{2}\cdot ICN)_2$ with respect to **2**·ICN and the starting reagents **2** and ICN. DFT-calculated energies show that, neglecting solvation effects and BSSE corrections, the **2**·ICN adducts of both the CT and the T-shaped types are unstable by 1.95 and 4.39 kcal mol^{-1}, respectively, compared with the free components **2** and ICN (Figure 5). Though slightly unstable with respect to **2** and ICN, $(\mathbf{2}\cdot ICN)_2$ is more stable than the CT and tbp **2**·ICN adducts by 1.20 and 3.64 kcal mol^{-1}, respectively. Contrarily, in all the hypervalent compounds of **2**

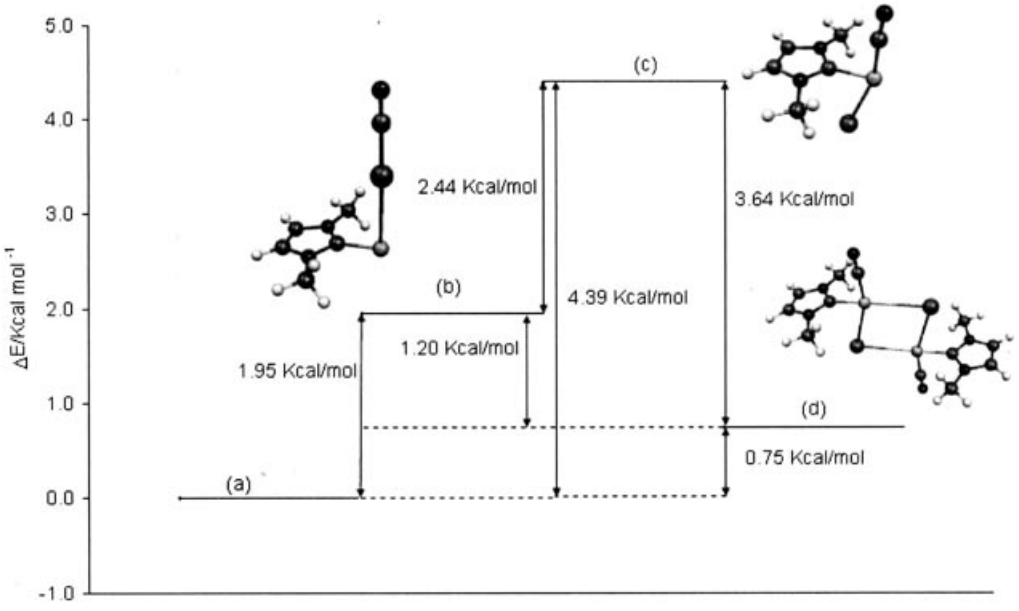

Figure 5. Relative DFT energies between CT and tbp adducts of **2** and ICN with respect to the free components: (a) ΔE[**2**+ICN]; (b) ΔE[**2**·ICN (CT)]; (c) ΔE[**2**·ICN (tbp)]; (d) 1/2 ΔE[$(\mathbf{2}\cdot ICN)_2$]

with halogens and inter-halogens, the T-shaped adduct formation always occurs with a stabilization energy >10.25 kcal mol^{-1}, which is the value calculated for **2**·I_2 (see values for all considered systems in the Theoretical Calculations section).

In this respect, we note that although very small changes are calculated in the I−Se−X system on passing from X = I to Br, and Cl, hypervalent selenium compounds with ICl are unknown. Thus, it should also be possible to prepare S- and Se-hypervalent tbp adducts with ICl, which are still unknown, despite numerous attempts to synthesize them. In fact, the Se-hypervalent system with ICl is expected to be very similar to that observed with IBr, as shown in Figure 4 by the regular trend and small variations in calculated Se−I distances and NBO charges on the iodine atom of I−Se−X systems (X = Cl, Br, I). This is strongly supported by the stabilization energy of the tbp **2**·ICl adduct, which is calculated as 16.70 kcal mol^{-1} with respect to the starting reagents **2** and ICl.

In conclusion, we report the first adduct between a selenium donor and ICN characterized by X-ray diffraction analysis. DFT calculations account for the strong polarity of the Se−I bond with the Se atom in a partial hypervalent state. **2**·ICN could also be described as the product of a donor−acceptor interaction between I^- and the selenium atom of the organic cation [**2**·CN]$^+$. DFT calculations clarify the ability of the organic cation [**2**·CN]$^+$ to interact with I^- donors in the two directions predetermined by the compositions of LUMO and LUMO+1, thus explaining the dimeric nature of **2**·ICN. The two different views lead to exactly the same final product: in the first case we consider the selenium partially hypervalent and a strong polarization of the Se···I bond (charge separation of 0.665e between the two fragments in **2**·ICN); in the second case, the ions approach until 0.335 electrons are reversed from I^- into the LUMO of the cation.

Experimental Section

Materials and Methods: All solvents and reagents were purchased from Aldrich and used as received. Elemental analysis and FT-Raman spectra were carried out as described previously.[12]

Synthesis of 2·ICN: Compound **2**·ICN was obtained as brown crystals (60% yield) by slow evaporation in air at room temperature of a mixture of 1,3-dimethyl-4-imidazoline-2-selone (**2**) (50 mg, 0.286 mmol) and ICN in a 1:1 molar ratio in CH_2Cl_2. $C_6H_8IN_3Se$: calcd. C 21.97, H 2.46, N 12.81; found C 22.10, H 2.56, N 12.98. FT-IR (2500−500 cm^{-1}): $\tilde{\nu}$ = 2078 w, 1561 m, 1493 ms, 1417 mw, 1391 w, 1338 w, 1240 vs, 1159 m, 1091 m, 1023 m, 858 m, 771 s, 760 vs, 734 s, 649 s, 612 w. FT-Raman (500−100 cm^{-1}; relative intensities in parentheses related to the highest peak taken equal to 10): $\tilde{\nu}$ = 278(0.9), 258(2.6), 221(10), 195(8), 143(0.3).

X-ray Crystal Structure Determination of 2·ICN: 1834 diffraction data were collected on a Nonius CAD-4 diffractometer with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation. The structure was solved by Patterson and Fourier methods and refined on F^2 using SHELXL-97.[17] Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were experimentally observed and allowed to ride on the pertinent atoms. $C_6H_8IN_3Se$, M = 328.01, triclinic, space group $P\bar{1}$ (No. 2), a = 6.946(1), b = 8.567(2), c = 8.907(2) Å; α = 98.54(1), β = 95.52(1), γ = 91.18(1)°; U = 521.4(1) Å^3, Z = 2, $d_{calcd.}$ = 2.089 g·cm^{-3}, T = 293(2) K, μ(Mo-K_α) = 6.511 mm^{-1}, wR_2 = 0.077, R = 0.030 for 1593 observed reflections [$I > 2\sigma(I)$]. CCDC-205962 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Theoretical Calculations: Using the commercially available suite of programs in the Gaussian 98 package,[18] quantum-mechanical DFT-calculations on **2**, **2**·Br_2, **2**·I_2, **2**·IBr, [**2**·Br]$^+$, and [**2**·I]$^+$ have been reported.[11,12] For the present work, DFT-calculations were carried out on Cl_2, Br_2, I_2, IBr, ICl, ICN, **1**·BrCN, **2**·Cl_2, **2**·ICl, **2**·ICN (both CT and T-shaped), (**2**·ICN)$_2$, and [**2**·CN]$^+$ at the same level of theory as the previous calculations, i.e. using the hybrid Becke3LYP functional,[19] the Schäfer, Horn and Ahlrichs pVDZ[20] basis sets for C, H, N, O, S, and Se, and the LANL2DZ basis sets, together with effective core potentials (ECP)[21] for halogen atoms. For **2**·Br_2, the 6−31 g** basis set was used as described previously.[11] For comparison, the calculations on [**2**·CN]$^+$ were extended to the sulfured analogue [**1**·CN]$^+$. Numerical integration was performed using the FineGrid option, which indicates that a total of 7500 points are used for each atom, and the optimized structure was verified by normal-mode harmonic frequency analysis obtained using the second derivatives of the DFT energy, and computed by differentiation of the DFT energy gradients. For all compounds, zero-point energy corrections were applied to calculate the relative total energies. NBO calculations[15] were performed for each molecule using the converged density matrix corresponding to the equilibrium geometries. For all calculations, no basis set superposition error (BSSE) correction was applied. The results of the calculations were analyzed with the MOLEKEL 4.3[22] and Molden 3.9[23] programs. The ZPE corrected total energies of the selenium hypervalent adducts compared with the free components are: ΔE(**2**·Cl_2) = −33.01; ΔE(**2**·Br_2) = −28.95; ΔE(**2**·I_2) = −10.25; ΔE (**2**·ICl) = −16.70; ΔE (**2**·IBr) = −13.89; ΔE (**2**·ICN)$_{CT}$ = +1.95; ΔE (**2**·ICN)$_{tbp}$ = +4.39; 1/2ΔE[(**2**·ICN)$_2$] = +0.75 kcal·mol^{-1}. Calculations were performed on a SGI Origin 3800 with 128 RISC 14000 processor elements running at 500 MHz equipped with 128 Gb of DRAM.

Further Information: Optimized geometries in the form of Cartesian orthogonal coordinates, frontier orbital composition, NBO charges, and harmonic frequencies for each mentioned compound are available from the authors on request.

Ferromagnetic and Antiferromagnetic Polymeric Complexes with the Macrocyclic Ligand 1,4,7-Triazacyclononane

Peng Cheng,*[a] Shi-Ping Yan,*[a] Cheng-Zhi Xie,[a] Bin Zhao,[a] Xiao-Yan Chen,[a] Xuan-Wen Liu,[a] Chun-Hui Li,[a] Dai-Zheng Liao,[a] Zong-Hui Jiang,[a] and Geng-Lin Wang[a]

Keywords: Benzenedicarboxylic acids / Polymer chains / Magnetic properties / Copper

Three novel copper polymers, $\{[Cu_4(tacn)_4(o\text{-bda})_2](ClO_4)_4(H_2O)_2\}_n$ (**1**), $\{[Cu(tacn)(m\text{-bda})](CH_3OH)_{0.5}(H_2O)_{0.5}\}_n$ (**2**), and $\{[Cu_2(tacn)_2(p\text{-bda})](ClO_4)_2\}_n$ (**3**) (tacn = 1,4,7-triazacyclononane, bda = benzenedicarboxylic acid) have been synthesized and structurally characterized. Compound **1** belongs to the monoclinic space group *C*2, while **2** and **3** crystallize in the orthorhombic space group *Pmc*2(1) and the monoclinic space group $P2_1/n$, respectively. They are all 1D zigzag polymers, which can be considered as $Cu(tacn)^{2+}$ building units linked by isomers of benzenedicarboxylic acid. The variable-temperature (2–300 K) magnetic behavior revealed the existence of ferromagnetic interactions in **1** and **2**. The best fittings of the experimental magnetic susceptibilities gave $J = 4.0$ cm^{-1} and $g = 2.04$ for **1**, $J = 1.2$ cm^{-1}, $zJ' = -0.18$ cm^{-1} and $g = 2.07$ for **2**, whereas the exchange coupling between Cu^{II} ions in **3** is antiferromagnetic with $J = -13.1$ cm^{-1} and $g = 2.05$. The transformation of interactions between copper ions from ferromagnetic to antiferromagnetic is closely related to the variations in the isomeric benzenedicarboxylic acids.

Introduction

The development of metal-based coordination polymers constructed by self-assembly processes has developed at a tremendous rate recently.[1−7] This expansion, which has been driven by potential magnetic, optical, electronic and catalytic applications,[8−11] may ultimately lead to new functional materials. Although the design and construction of coordination polymers is still a great challenge due to the difficulties in selecting proper metal ions and polydentate ligands,[12] many such coordination polymers with novel topological structures and fascinating properties constructed from polycarboxylic acids have been described.[13−16] Surprisingly, however, 1D or multi-dimensional polymers with tacn (tacn = 1,4,7-triazacyclononane) as the terminal ligand have seldom been reported so far, which can probably be attributed to the fact that tacn is such a strong tridentate chelating 6-electron donor, that it can effectively prevent building blocks from forming an effectively infinite aggregation. In principle, half-sandwich complexes containing tacn can be extended into infinite structures through proper bridging ligands, but controlling the ratio of reagents and the selection of bridging ligands is critical to the formation of polymers. With this goal in mind, we have investigated the bridging bda (bda = benzenedicarboxylic acid) ligands and employed the strategy of an equal stoichiometry of reagents. We report herein, the preparation of three novel copper polymers, $\{[Cu_4(tacn)_4(o\text{-bda})_2](ClO_4)_4(H_2O)_2\}_n$ (**1**), $\{[Cu(tacn)(m\text{-bda})](CH_3OH)_{0.5}(H_2O)_{0.5}\}_n$ (**2**), and $\{[Cu_2(tacn)_2(p\text{-bda})](ClO_4)_2\}_n$ (**3**).

In order to design and synthesize complexes with expected magnetic behavior, it is extremely important to probe the essential magneto-structural relationship. Hoffmann et al.[17] and Kahn et al.[18] have described investigations of the effects on magnetic exchange interactions of the metal−ligand−metal bridge angle, the bridging atom electronegativity, and the geometrical environment around the central metal ion. In contrast, and to the best of our knowledge, systematic studies of the influence of various isomers of some dicarboxylic acids on magnetic properties have not been reported to date. In this study we have used three isomers of bda as bridging ligands to obtain complexes **1**−**3**. Furthermore, we have investigated the relationship between their structures and magnetic properties.

Results and Discussion

X-ray crystal structure analyses revealed 1D zigzag polymeric structures for **1**, **2** and **3**. The ORTEP diagrams are shown in Figures 1−3, respectively. Notably, in these polymers, the copper(II) ions are all five-coordinate: three nitrogen atoms of tacn and two oxygen atoms of the bda ligand

complete the square-based pyramidal coordination geometry.

Crystal Structure of $\{[Cu_4(tacn)_4(o\text{-}bda)_2](ClO_4)_4(H_2O)_2\}_n$ (1)

The structure of **1** contains the cation $[Cu_4(tacn)_4(o\text{-}bda)_2]^{4+}$, the anion ClO_4^- as well as solvated water molecules. The cation exhibits a zigzag chain-like structure as shown in Figure 1. The copper atom is in a distorted square-pyramidal environment. Interestingly, there are two types of copper atoms according to the copper−oxygen coordination modes, namely chelating (Cu1) and bridging (Cu2). Two carboxylate oxygen atoms from the same *o*-bda ligand are chelated to Cu1 [Cu1−O1 1.974(6), Cu1−O3 1.955(7) Å], and three nitrogen atoms of the tacn ligand complete the configuration. The apical site of the distorted square pyramid is occupied by N1. The axial

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

copper−nitrogen bond [Cu1−N1 2.322(6) Å] is somewhat longer than the equatorial ones [Cu1−N2 2.022(8), Cu1−N3 2.013(9) Å]. The largest deviation from the mean N2N3O1O3 basal plane is 0.132(5) Å for N2. The Cu1 atom is displaced toward the apical site by 0.097(2) Å. The angles O1−Cu1−N2 and O3−Cu1−N3 are 170.5(3) and 173.7(3)°, respectively. For Cu2, there are two carboxylate oxygen atoms from two *o*-bda ligands as well as three coordinated nitrogen atoms from tacn. The basal plane consists of N4N5O2O5 with the largest deviation of 0.087(5) Å for N5. The Cu2 atom is displaced toward the apical site by 0.162(8) Å. The average Cu2−O bond length is slightly longer than that of Cu1−O, whereas the average Cu2−N bond length is shorter than that of Cu1−N. Similar differences were also observed for the N−Cu−N and N−Cu−O angles. These features may result from the Cu2−O2(O5) bridging coordination mode. The dihedral angle between the mean coordination planes of Cu1 and Cu2 is 85.0°. These two types of copper centers are alternately arrayed in **1**, which leads to the zigzag chain-like structure (Figure 4, a). The shortest Cu−Cu distance is 5.010 Å along the chain.

In **1**, all Cu−N bond lengths ranging from 2.013(9) to 2.322(6) Å, are similar to those in other (tacn)Cu^{II} complexes.[19,20] The Cu−O distances, ranging from 1.954(6) to 1.990(6) Å, are also in line with the corresponding values in phthalato complexes.[21] It is noteworthy that the coordination geometry of *o*-bda bridged complexes largely relies on the terminal ligands. In our published report,[22] the cyclic tetranuclear complex $[Mn_4(\mu\text{-}o\text{-bda})_2(bpy)_8](ClO_4)_2{\cdot}3H_2O$ was constructed from an *o*-bda bridge, the metal center is six-coordinate with four nitrogen atoms and two oxygen atoms. Once the terminal ligand is replaced by tridentate tacn, complex **1** was obtained as a 1D coordination polymer.

$\{[Cu(tacn)(m\text{-bda})](CH_3OH)_{0.5}(H_2O)_{0.5}\}_n$ (2)

In **2** (Figure 2), the apical site of the distorted square pyramid is occupied by N1 [Cu1−N1 2.184(8) Å]. The Cu−N bond lengths vary slightly from 2.124(8) to 2.184(8) Å. Compared with those in the *m*-bda bridged complexes, the Cu−O bonds (Cu1−O1 1.906(9) Å, Cu1−O4A 1.870(14) Å] are somewhat shorter,[23,24] which may be due to the distorted square-pyramidal structure caused by the

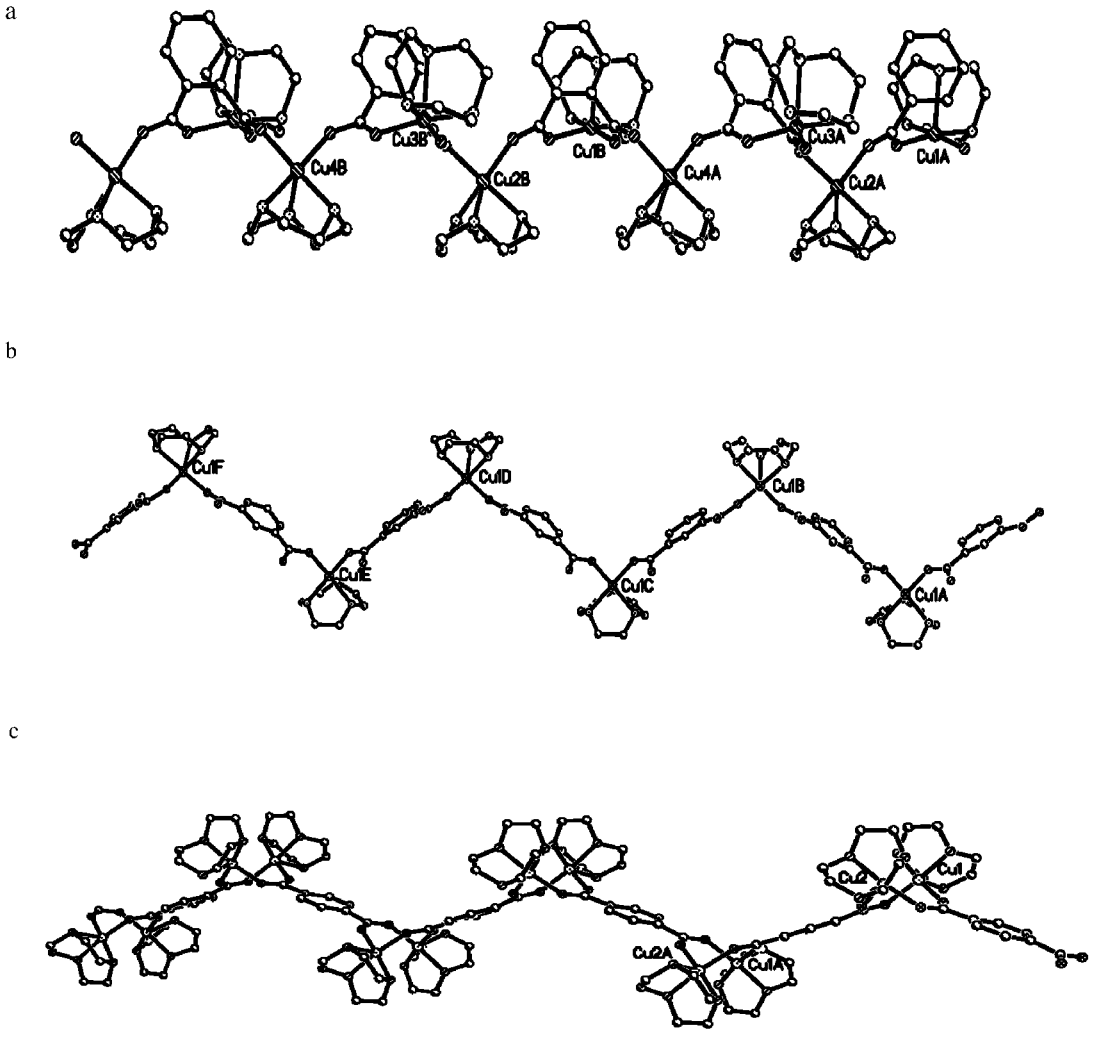

Figure 4. Zigzag chain structure for **1** (a), **2** (b), and **3** (c)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

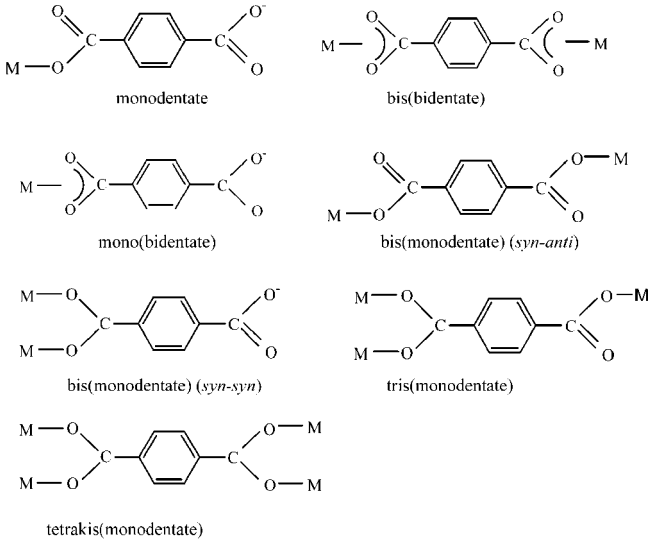
coordination of the rigid tridentate tacn ligand. The best equatorial plane can be defined by N2, N3, O1 and O4A. The largest deviation from the mean plane is 0.0641(7) Å for O4A and the Cu1 atom is 0.0276(4) Å from this plane. The dihedral angle between the benzene ring of the *m*-bda ligand and the equatorial plane of the Cu1 square pyramid is 72.7(5)°.

The *m*-bda group acts as a bis(monodentate) ligand, which bridges copper(II) ions to form a 1D zigzag chain-like motif as shown in Figure 4 (b). The distance between the copper(II) ions along the chain is 10.783 Å, which is much longer than the shortest distance between copper centers (7.171 Å) in neighboring chains. It is worth noting that examples of structurally characterized polymers with bridging *m*-bda groups[25] are relatively rare.

$\{[Cu_2(tacn)_2(p\text{-bda})](ClO_4)_2\}_n$ (3)

The polymeric cationic $[Cu_2(p\text{-bda})(tacn)_2]^{2+}$ unit of **3** is shown in Figure 3. The carboxylic groups of *p*-bda make it behave as a tetrakis(monodentate) ligand, which is bound on each side to two copper(II) ions through the oxygen atoms of the carboxylic groups in a *syn-syn* conformation[26] yielding a zigzag chain, which runs parallel to the *z* axis (Figure 4, c). The copper environments are distorted square-pyramidal. The equatorial plane includes O1 and O4A from the carboxylic groups as well as N4 and N6 from one of the tacn ligands. N5 of tacn occupies the apical position [Cu−N 2.011(4)−2.235(4), Cu−O 1.954(3)−1.961(3) Å; all angles of the square pyramid range from 83.36(17) to 100.55(15)°]. The Cu−O bond lengths are in the normal range.[27−29] The largest deviation from the mean plane is 0.0517(8) Å for N4, and the Cu1 atom is 0.0525(4) Å from this plane. Two copper(II) ions linked by two carboxylic groups form an eight-membered ring, $Cu_2C_2O_4$, and the crystallographic inversion center is located at the center of the eight-membered ring.

Recent reports of *p*-bda-bridged Cu^{II} centers include descriptions of seven kinds of coordination modes of *p*-bda, which are listed in Scheme 1.[27−32] Materials containing both short and long bridges have been reported based on *p*-bda-bridged Mn^{II} and Cu^{II} complexes.[29,33] Long *p*-bda bridges typically produce M···M separations of about 11 Å. With respect to the *p*-bda ligand, the most remarkable structural feature of **3** is its rare tetrakis(monodentate) coordinating character used in the assembly of its chain-like structure. In the complex its eight carbon atoms are strictly coplanar. The shortest Cu1···Cu2 separation is 3.486 Å. The intra-chain separations are 10.496 and 11.044 Å for Cu1···Cu1A and Cu1···Cu2A, respectively.



Scheme 1

Comparing the crystal structures of **1**, **2**, and **3**, the distortion of the square pyramid decreases on varying the bridging ligand from *o*-bda to *p*-bda. The differences in the bond angles and bond lengths decrease upon changing the bridging ligand. A summary of the main structural features of **1**, **2**, and **3** is listed in Table 1.

Magnetic Properties

The molar magnetic susceptibilities χ_M of **1**, **2**, and **3** were measured in the temperature range of 2−300 K in a field of 5 KOe. The plots of χ_M and μ_{eff} versus *T* for **1**−**3** are shown in Figures 5−7, respectively.

The bridging modes of bda and the chain structures of **1**, **2**, and **3** exhibit subtle differences, however, which lead to significantly different magnetic interactions between copper(II) ions. Initial magnetic studies of the three coordination polymers indicate interesting magnetic behavior.

The effective magnetic moment of **1** is 1.766 μ_B at 300 K. This is smaller than the spin-only value for the isolated cop-

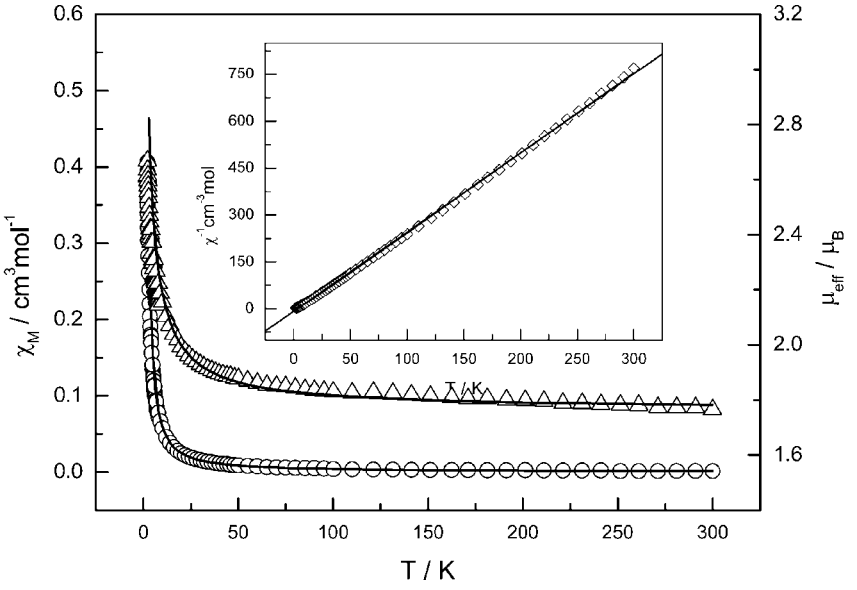

Figure 5. Plots of χ_M vs. T (open circles) and μ_{eff} vs. T (open triangles) and χ_M^{-1} vs. T (open squares) (inset) for **1**; the solid line represents the theoretical curve with the best fit parameters

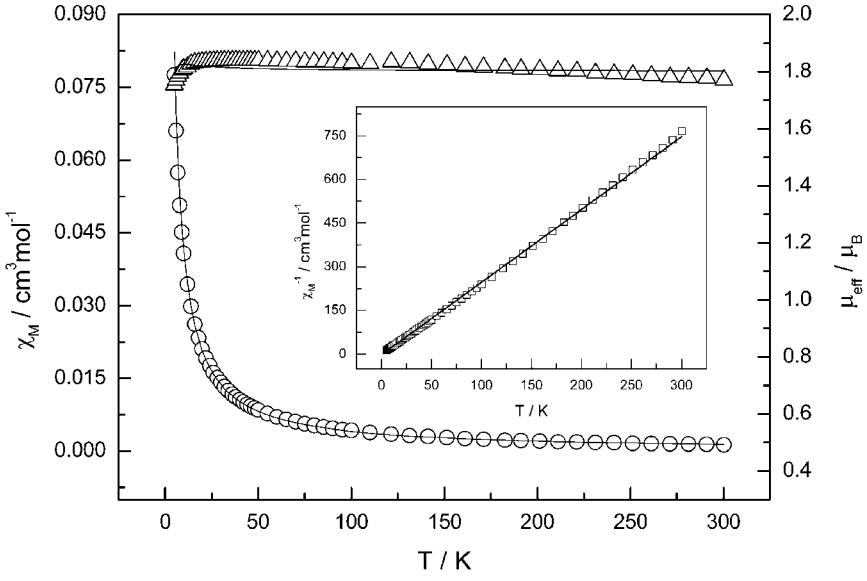

Figure 6. Plots of χ_M vs. T (open circles) and μ_{eff} vs. T (open triangles) for **2** and χ_M^{-1} vs. T (open squares) (inset); the solid line represents the theoretical curve with the best fit parameters

per(II) ion (1.73 μ_B, g = 2.0). With decreasing temperature, the μ_{eff} value for **1** increases smoothly down to ca. 20 K, and then sharply reaches a maximum value of 2.67 μ_B at 2.2 K (as shown in Figure 5). This behavior suggests the existence of a ferromagnetic interaction between the metal centers, and we know that the bridging group *o*-bda usually transmits a ferromagnetic exchange interaction between copper(II) ions.[23] The χ^{-1} data for **2** obey the Curie−Weiss law with a Curie−Weiss temperature θ = 3.18 K, and a Curie constant C = 0.39 emu K·mol^{-1} (inset of Figure 5). The Curie constant is close to the expected value for one uncoupled Cu^{2+} spin (S = 1/2, $C_{theor.}$ = 0.375 emu·K·mol^{-1}). The positive sign of the Weiss constant suggests ferromagnetic interactions between copper centers. Upon examining the crystal structure of **1**, we found that the neighboring Cu···Cu distances are almost equal, and only one kind of exchange pathway is available, namely Cu−O−C−O−Cu. The magnetic susceptibility data were, therefore, fitted by Equation (1) incorporating ferromagnetic chain properties with S = 1/2[34] and $H = -2JS_1S_2$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

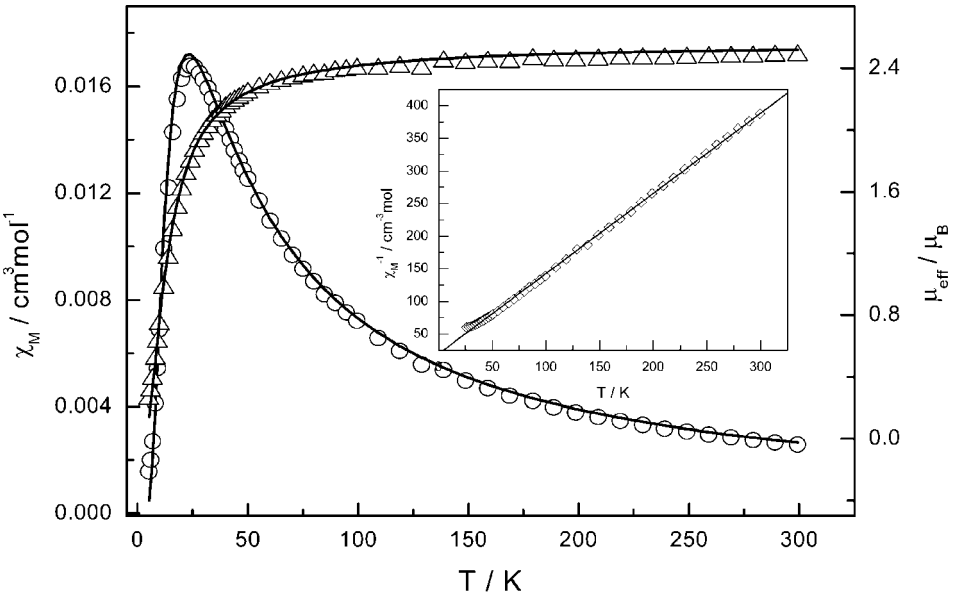

Figure 7. Plots of χ_M vs. T (open circles) and μ_{eff} vs. T (open triangles) for **3** and χ_M^{-1} vs. T (open squares) (inset); the solid line represents the theoretical curve fitted by Equation (3)

in which $A = 5.7979916$, $B = 16.902653$, $C = 29.376885$, $D = 29.832959$, $E = 14.036918$, $A' = 2.7979916$, $B' = 7.0086780$, $C' = 8.6538644$, $D' = 4.5743114$, and $x = J/2kT$.

$$\chi_{chain} = \frac{Ng^2\beta^2}{4kT}\left[\frac{1+Ax+Bx^2+Cx^3+Dx^4+Ex^5}{1+A'x+B'x^2+C'x^3+D'x^4}\right]^{2/3} + N\alpha \quad (1)$$

A temperature-independent susceptibility term ($N\alpha$) was also included, and was set as 60×10^{-6} cm^3·mol^{-1}. Other symbols have their usual meanings. The best fit of the magnetic susceptibility data yielded $J = 4.0$ cm^{-1}, $g = 2.04$, and $R = 3.2 \times 10^{-3}$ [agreement factor, defined as $\Sigma(\chi_M^{obsd.} - \chi_M^{calcd.})^2/\Sigma(\chi_M^{obsd.})^2$]. These results confirm the ferromagnetic coupling between adjacent copper(II) ions through the bridging *o*-bda ligand.

For compound **2** the effective magnetic moment is 1.77 μ_B at room temperature. This value is close to that of the isolated Cu^{II} ion (1.73 μ_B). As the temperature is lowered, μ_{eff} of **2** smoothly increases to a maxmium value of 1.84 μ_B at 36 K, and then decreases to 1.75 μ_B at 2 K. The increase in μ_{eff} is due to the intra-chain ferromagnetic coupling, while the inter-chain antiferromagnetic coupling results in a decrease of μ_{eff} below 36 K. We used the same theoretical susceptibility equation for **1** to obtain a fit of the data. As a consequence of the decrease of μ_{eff} below 36 K, a molecular field correction was applied [Equation (2)].

$$\chi_M = \chi_{chain}/(1 - zJ'\chi_{chain}/Ng^2\beta^2) \quad (2)$$

The fit (as shown in Figure 6) was obtained with values of $J = 1.2$ cm^{-1}, $zJ' = -0.18$ cm^{-1}, $g = 2.07$, and $R = 1.6 \times 10^{-3}$. The fitting parameters indicate the weak ferromagnetic coupling between adjacent copper ions along the chain, while $zJ' < 0$ indicates the weak antiferromagnetic interaction between the chains. The χ^{-1} data for **2** obey the Curie–Weiss law with a Curie–Weiss temperature $\theta = 2.54$ K and a Curie constant $C = 0.395$ emu·K·mol^{-1} (inset of Figure 6). The Curie constant is close to the expected value for one uncoupled Cu^{2+} spin ($S = 1/2$, $C_{theor.} = 0.375$ emu·K·mol^{-1}). The positive sign of the Weiss constant suggests that ferromagnetic interactions are dominant.

For **3**, μ_{eff} is 2.48 μ_B at 299 K. This is similar to the spin-only value of 2.45 μ_B for two uncoupled copper(II) ions (Figure 7). The value of μ_{eff} decreases gradually as the temperature decreases, indicating the presence of antiferromagnetic interactions. The occurrence of a sharp susceptibility maximum around 24 K is characteristic of an antiferromagnetic interaction with a singlet ground state. The χ^{-1} data for **3** obey the Curie–Weiss law above 24 K with a Curie–Weiss temperature $\theta = -16.0$ K and a Curie constant $C = 0.81$ emu·K·mol^{-1} (inset of Figure 7). The negative sign of the Weiss constant suggests antiferromagnetic interactions between the copper centers.

The magnetic parameters were estimated from a least-squares fitting of the susceptibility data by the equation given in the literature for dinuclear Cu^{II} complexes [Equation (3)].[35]

$$\chi_M = \frac{2Ng^2\beta^2}{kT}\left[3 + \exp(-2J/kT)\right]^{-1} + N\alpha \quad (3)$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[Cu_2(p\text{-bda})(tacn)_2](ClO_4)_2$	tetrakis(monodentate)	3.486	10.496, 11.044	−13.1	this work
$[L'_2Cu_2(H_2O)_2(p\text{-bda})](ClO_4)_2$	bis(monodentate) *syn-anti*	7.587	11.252	−140	[39]

[a] *p*-bda = terephthalato, bipy = 2,2′-bipyridine, terpy = 2,2′:6′,2″-terpyridine, $SalNEt_2$ = *N*-[2-(diethylamino)ethylsalicylidenaminate], pmdien = *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine, pedien = *N*,*N*,*N*′,*N*″,*N*″-pentaethyldiethylenetriamine, dien = diethylenetriamine, en = ethylenediamine, L = *N*,*N*-dimethyl-*N*′-(pyrid-2-ylmethyl)ethylenediamine, L′ = 1,4,7-trimethyl-1,4,7-triazacyclononane. [b] The intra-chain exchange interaction was ferromagnetic with $J = +4$ cm^{-1} and the inter-chain exchange interaction was antiferromagnetic with $zJ = -7$ cm^{-1}.

A temperature-independent susceptibility term ($N\alpha$) was also included and was set as 1.2×10^{-4} cm^3·mol^{-1}. The best fit was obtained for $J = -13.1$ cm^{-1}, $g = 2.05$, and $R = 6.5 \times 10^{-4}$. The above results confirmed the antiferromagnetic coupling between copper atoms in the dinuclear unit.

The relatively strong antiferromagnetic interactions in **3** can be explained by the short bridge, via one carboxylate end, between two copper atoms. Due to the special tetrakis(monodentate) coordination mode of *p*-bda, longer bridges through the benzene ring exist at the same time, but they are too weak to be taken into account. Some related (*p*-bda)Cu complexes are listed in Table 2 together with selected magneto-structural data. The *J* values of the complexes listed in Table 2 do not follow a simple trend. In spite of the large variation of the nearest metal−metal separation (from 3.150 to 8.818 Å), the values of *J* are insensitive to this. It can be seen that the magnetic interaction is very weak except in the last example. The weak coupling observed is not surprising in the light of the large intramolecular metal−metal separation. The *J* value reported for the last compound is anomalously large in comparison with the others. Bürger et al. attributed this strong antiferromagnetic coupling to the formation of an intramolecular O−H···O hydrogen bond between the H_2O molecule and the carbonyl oxygen atom of the coordinated carboxylate. In Table 2, the *J* value of $[Cu(p\text{-bda})(H_2O)_2](H_2O)$ is similar to that of **3**. For the former, the coordination mode of *p*-bda [bis(monodentate), as shown in Scheme 1], and the H_2O bridges result in the close intramolecular Cu···Cu separation, which leads to the correspondingly large antiferromagnetic coupling. In our work, however, the effective antiferromagnetic exchange pathway was achieved by the unusual tetrakis(monodentate) coordination mode of *p*-bda. From Table 2 we can see, that (*p*-bda)Cu complexes with the tetrakis(monodentate) coordination mode have rarely been reported. Samuel et. al prepared $[Cu_4(p\text{-bda})_3(4,4'\text{-bipy})_2]_n$, containing tetrakis(monodentate) coordinated *p*-bda, by a hydrothermal synthesis,[40] but they did not further investigate its magnetic properties. Our study provides some useful structural and magnetic information about this type of complex.

The transformation of interactions between copper ions from ferromagnetic to antiferromagnetic is closely related to changes in the bridging ligands. In compound **2**, the Cu···Cu distance is somewhat longer than that in **1**, and the exchange pathway passes across the benzene ring, which greatly weakens the ferromagnetic interactions. In consideration of the comparatively large antiferromagnetic interactions in the dinuclear unit of **3**, the weak interaction through the benzene ring can be ignored.

Conclusion

Three novel zigzag chain copper coordination polymers containing the tacn ligand were successfully constructed by deliberate selection of the bridging bda ligand. Among the previously reported complexes with tacn, coordination polymers with infinite structures are rather rare. Systematic investigations of the structures and magnetic properties of coordination polymers with a series of isomers of dicarboxylic bridging ligands have not been reported so far. Most importantly, the structural differences caused by the bridging ligands lead to unexpected magnetic behavior including changes from ferromagnetic to antiferromagnetic coupling. The present work provides another possible direction for exploring the magneto-structural relationship.

Experimental Section

Physical Measurements: C, H, and N analyses were obtained at the Institute of Elemental Organic Chemistry, Nankai University.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Variable-temperature magnetic susceptibilities were measured with a Quantum Design MPMS-7 SQUID magnetometer. Diamagnetic corrections were made with Pascal's constants for all the constituent atoms.

Preparation of $\{[Cu_4(tacn)_4(o\text{-bda})_2](ClO_4)_4(H_2O)_2\}_n$ (1): A methanol solution (30 mL) of *o*-bda (0.4 mmol, 66.45 mg), and freshly prepared $Cu(OH)_2$ (0.4 mmol, 39.0 mg) was heated to reflux for 2 h, then filtered; tacn (0.4 mmol, 51.6 mg), dissolved in methanol (10 mL), and an aqueous solution of $NaClO_4$ (0.4 mmol, 49.0 mg) were added to the filtrate. The resultant mixture was heated to reflux for 2 h, and then filtered. Several weeks later, blue crystals were obtained by concentration of the filtrate at room temperature. Yield: 76.7 mg (50%). $C_{40}H_{72}Cl_4Cu_4N_{12}O_{26}$ (1533.06): calcd. C 31.3, H 4.63, N 11.0; found C 31.7, H 4.88, N 10.8.

$\{[Cu(tacn)(m\text{-bda})](CH_3OH)_{0.5}(H_2O)_{0.5}\}_n$ (2): An acetonitrile/methanol (1:1) mixture (30 mL) was added to a mixture of *m*-bda (0.4 mmol, 66.45 mg), and freshly prepared $Cu(OH)_2$ (0.4 mmol, 39.0 mg). After heating to reflux for 1 h, methanol (10 mL), tacn (0.4 mmol, 51.6 mg), and water (1 mL) were added. The resultant mixture was heated to reflux for a further 2 h, and then filtered. The filtrate was concentrated slowly at room temperature. Blue crystals were obtained after one month. Yield: 106.9 mg (70%). $C_{14.5}H_{22}CuN_3O_5$ (381.89): calcd. C 45.6, H 5.76, N 11.0; found C 45.9, H 5.89, N 10.7.

$\{[Cu_2(tacn)_2(p\text{-bda})](ClO_4)_2\}_n$ (3): Ligand *p*-bda (42 mg, 0.25 mmol) and a few drops of piperidine were added to an aqueous solution (30 mL) of $Cu(ClO_4)_2{\cdot}6H_2O$ (0.186 g, 0.5 mmol), and tacn (0.065 g, 0.5 mmol). The resultant mixture was stirred at room temperature for 15 h. The solution was then filtered, and the filtrate was allowed to stand for several days resulting in the formation of well-formed light blue crystals. Yield: 104.8 mg (56%). $C_{20}H_{34}Cl_2Cu_2N_6O_{12}$ (748.51): calcd. C 32.06, H 4.54, N 11.22; found C 31.79, H 4.88, N 10.71.

Crystallographic Studies: Crystals, having the approximate dimensions 0.30 mm × 0.25 mm × 0.20 mm for **1** and **2**, and 0.35 mm × 0.30 mm × 0.20 mm for **3**, were mounted on glass fibers. Determination of the unit cells and data collection were performed with Mo-K_α radiation (λ = 0.71073 Å) with a Bruker Smart 1000 diffractometer equipped with a CCD camera. Cell parameters were determined from least-squares refinements on the setting angles in the range $0.99° < \theta < 25.03°$ (**1**), $2.29° < \theta < 25.03°$ (**2**), and $1.66° < \theta < 26.40°$ (**3**) at 293(2) K. The ω-2θ scan technique was employed. Crystal parameters and structural refinements for **1**, **2**, and **3** are summarized in Table 3; selected bond lengths and angles are listed in Table 4. The structures were solved primarily by direct methods and secondly by Fourier difference techniques, and refined by the full-matrix least-squares method. The computations were performed with the SHELXL-97 program.[41,42] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were set in calculated positions and refined as riding atoms with a common fixed isotropic thermal parameter. CCDC-196813 to -196815 (**1**−**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; or E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Luminescence Properties of New Dinuclear Complexes of Lanthanide(III) Ions

Violetta Patroniak,[a,b] Paul N. W. Baxter,[a,c] Jean-Marie Lehn,*[a] Zbigniew Hnatejko,[b] and Maciej Kubicki[b]

Dedicated to the memory of Professor Marian Elbanowski

Keywords: Dinuclear complexes / Lanthanides / Bis(tridentate) ligands / Self-assembly

As a result of coordination of the ligand **L**, containing two tridentate binding units, to samarium(III), europium(III), terbium(III), and dysprosium(III) ions, new dinuclear architectures containing two ions with coordination number 9 were formed. The structures of the complexes have been assigned on the basis of their solution spectroscopic and microanalytical data, and confirmed by X-ray crystallography in the case of the europium(III) complex **2**. The structural analysis of the dinuclear complex **2** showed the presence of two europium centers [Eu(1) and Eu(2)] and four ligands **L**. Each europium ion is coordinated by 9 donor atoms with typical Eu–N and Eu–O distances.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The coordination chemistry of lanthanides has become increasingly significant in the last few years due to the wide variety of potential applications of their complexes in many important areas of inorganic chemistry,[1] biology,[2] and medicine.[2c,3] The complexes of lanthanides also play a role as accelerators of hydrolytic cleavage of RNA model compounds,[4] and their applications as MRI contrast agents are very popular, especially complexes of Gd^{III}.[5] Lanthanide complexes are well known to undergo luminescence in the visible and near-IR wavelength regions,[1a,6] and have found widespread applications as fluorescence bio-markers.[2c,7] The design and synthesis of dinuclear complexes of lanthanides constitute a special area of study in bioinorganic chemistry, in particular because of their uses as spectroscopic probes for active sites in metalloproteins.[8]

During the course of our studies on the self-assembly and properties of supramolecular grid-type metal complexes, ligand **L** was shown to successfully form tetranuclear [2 × 2]G architectures upon correct stoichiometric combination with a range of first row transition metal ions.[9] In the resultant grid complexes, the metal ions are octahedrally coordinated by two N,N,O ligand donor sets. Grid complexes of this type may be expected to exhibit interesting photophysics and redox chemistry.

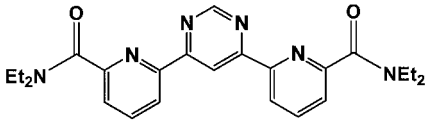

Figure 1. Structure of ligand **L**

In view of the fact that lanthanide ions prefer to be coordinated by relatively hard oxygen donor ligands, it was anticipated that ligand **L** would be able to form stable coordination architectures upon appropriate stoichiometric combination with specific lanthanide salts. However, ligand **L** possesses an insufficient number of donor sites to satisfy the coordination requirement of lanthanide(III) ions. The reaction between **L** and lanthanide ions may, therefore, be expected to result in a variety of possible outcomes depending on factors such as the M:L ratio, solvent, counterions etc.

In this report we describe our initial investigations into the lanthanide coordination chemistry of **L**, and demonstrate that this ligand is able to form structurally novel multinuclear lanthanide complexes of 2:4 M:**L** stoichiometry with Sm^{3+}(**1**), Eu^{3+}(**2**), Tb^{3+}(**3**), and Dy^{3+}(**4**).

The lanthanide complexes with **L** were characterized on the basis of ESI-MS, microanalysis and, in the case of the Eu^{3+} complex **2**, X-ray crystallography. Of particular significance is the fact, that the complexes are luminescent upon irradiation with UV light. A detailed investigation

into the luminescence properties of the lanthanide complexes was therefore also undertaken in order to obtain the photophysical properties characteristic of the $[M_2L_4]^{6+}$ {M = lanthanide(III)} system.

Results and Discussion

Initial investigations into the lanthanide complexation by **L** focussed upon the reaction between 1:1 stoichiometric combinations of M^{III}/**L** [M^{III} = Sm^{III} (**1a**), Eu^{III} (**2a**), Tb^{III} (**3a**), and Dy^{III} (**4a**)] in the hope of obtaining $[M_4L_4]^{12+}$ grid-type products. Evidence for the existence of $[M_4L_4]^{12+}$ species for the lanthanide ion systems, which may be of a grid-type structure, was obtained using ESI-MS. The ESI-MS data indicate, that many kinds of multinuclear structures co-exist in solution, which may be formulated as grids or helicates. Since we could not obtain crystals suitable for X-ray analysis, thereby confirming the structural identities of the components in the mixture, we decided to change the molar ratio of M^{III}/**L** to 2:3, and we obtained, unexpectedly, new dinuclear complexes of Sm^{III} (**1**), Eu^{III} (**2**), Tb^{III} (**3**), and Dy^{III} (**4**). The dinuclear nature of these species was confirmed by the X-ray crystal structure of the Eu^{III} complex **2**.

The ESI-MS investigations of all complexes were performed on acetonitrile solutions at concentrations of approximately 10^{-4} mol·L^{-1}. For example, the ESI mass spectrum of **1** showed peaks corresponding to multiply charged species containing the $[Sm_2L_4]^{6+}$ unit. These data confirmed the presence of dinuclear complex **1** in solution.

Photophysical Properties

The luminescence lifetimes of Eu^{III} excited states were measured with the use of a detection system consisting of a nitrogen laser-pumped dye laser. Excitation spectra assigned to the $^7F_0-{}^5D_0$ transition of the Eu^{III} ion were obtained with the same pulsed dye laser. The laser was continuously scanned from 578 to 581.5 nm while monitoring the $^5D_0-{}^7F_2$ emission at 618 nm. Details of the instrumentation, and procedures used for determining emission lifetimes of europium complexes have been described elsewhere.[10] The electronic absorption spectra for a 10^{-5} mol·L^{-1} acetonitrile solution of complex **2** and **L** are shown in Figure 2.

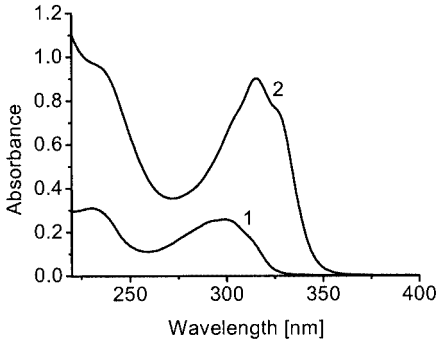

Figure 2. Electronic absorption spectra for acetonitrile solutions of ligand **L** (1.2×10^{-5} mol·L^{-1}), and of the Eu^{III} complex **2** (1.07×10^{-5} mol·L^{-1})

Two absorption maxima are present, which correspond to π-π* transition bands of the ligand. The absorption maxima, molar extinction coefficients (ε) for the free ligand, and its complexes with lanthanide(III) ions in acetonitrile are listed in Table 1. All the studied complexes show bathochromic shifts of the absorption maxima (ca. 18 nm) indicating ligand-lanthanide interaction. Similar bathochromic shifts have been reported for lanthanide complexes with other azaaryl ligands.[1a,11]

The luminescence properties of Sm^{III}, Eu^{III}, Tb^{III}, and Dy^{III} complexes have been studied in acetonitrile solution at room temperature. The emission spectra of the lanthanide(III) complexes, excited into the lowest energy LC absorption band, showed the well-known structured luminescence of the lanthanide ions.

The excitation spectrum for complex **2** consists of a broad curve with a maximum at ca. 330 nm, assigned to the π-π* transition of the ligand. For a given ligand, the Ln^{III} complexes displayed similar excitation spectra with identical excitation maxima. The emission from the lowest luminescent level to the ground state manifold, i.e. $^4G_{5/2}-{}^6H_{7/2}$ (598 nm) for Sm^{III}, $^5D_0-{}^7F_2$ (618 nm) for Eu^{III}, $^5D_4-{}^7F_5$ (547 nm) for Tb^{III}, and $^4F_{9/2}-{}^6H_{15/2}$ (576 nm) for Dy^{III} was measured. Strong red (Figure 3) and strong green emissions were observed for the Eu^{III} and Tb^{III} complexes, whereas the emissions of the Sm^{III} and Dy^{III} complexes were weak (Table 1).

The close agreement between the absorption and excitation spectra (see Figures 2 and 3) shows, that the excitation of Ln^{III} ions is caused by an indirect process, i.e. a ligand-to-metal energy transfer, the ligand units acting as an antenna.[1a]

The Eu^{III} ion is unique in that both the ground state $^7F_0$, and excited emissive state $^5D_0$ are non-degenerate. Since the $^7F_0-{}^5D_0$ transition occurs between non-degenerate energy levels, neither of which can be split by a ligand field, a single environment gives rise to only a single transition. If more than one Eu^{III} environment is present, each will have its own characteristic transition energy. The lifetime of the $^5D_0$ level of Eu^{III} is also a sensitive probe of local structure, particularly in the case of Eu^{III} ions in the presence of OH-oscillators.[12]

The excitation spectrum of complex **2** in the solid state showed two compounds with the $^7F_0-{}^5D_0$ transition (Figure 4).

The peak maxima of the $^7F_0-{}^5D_0$ excitation spectrum were found at 579.77 and 580.33 nm. The two compounds indicated by the analysis of the excitation spectrum of complex **2** suggest, that the Eu^{III} ions interact with two different types of binding sites, each with a different number of residual Eu hydration.

The lifetimes of the $^5D_0$ excited state for solid complex **2** were obtained by measuring the luminescence decays at wavelengths of 579.77 and 580.33 nm. The lifetime values were calculated using the mono-exponential decay method.

Table 1. Absorption and luminescence data of the ligand **L** and complexes **1**−**4** in acetonitrile solution

Compound	Absorption		Fluorescence			Lum. quant.yield
	$\lambda_{max.}$ [nm]	$\varepsilon \times 10^4$ [L·mol^{-1}·cm^{-1}]	λ_{ex} [nm]	λ_{em} [nm]	I_{lum} [a.u.]	Φ[a]
L	299.4	2.15	–	–	–	–
1	317.0	8.56	328	598	448	0.0016
2	316.5	8.79	328	618	36800	0.059
3	316.0	9.35	328	547	32100	0.049
4	317.0	9.63	328	576	1880	0.0033

[a] Excitation at 328 nm; $Ru(bpy)_3^{2+}$ (Φ = 0.028 in water) was used as a standard for all Ln^{III} complexes; experimental error ca. 30%.

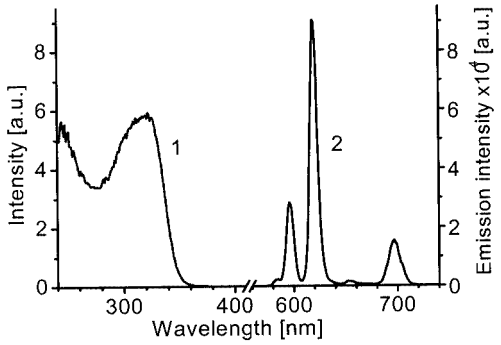

Figure 3. Excitation (1) and emission (2) spectra of complex **2** in acetonitrile solution, [Eu^{III}] = 1.07 × 10^{-5} mol·L^{-1}

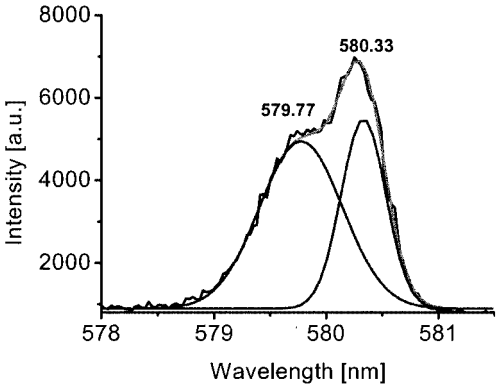

Figure 4. The $^7F_0-{}^5D_0$ selective excitation spectra of complex **2** in the solid state, obtained by analyzing at 618 nm ($^5D_0-{}^7F_2$ transition), and its deconvolution using a Gaussian-type function. Experimental data (dark line), calculated data (light line)

Two separate lifetime values of 280 and 511 μs were obtained, respectively. The hydration numbers of the Eu^{III} ions in complex **2** were found directly from the lifetime measurements using the equation: $n_{H2O} = 1.05k_{obsd.}$ (ms^{-1}) −0.7, where $k_{obsd.}$ is the reciprocal of the excited state lifetime.[13]

The numbers of water molecules bound in the inner coordination sphere of the Eu^{III} ions were determined as 3 and 1. The presence of the two species was found on the excitation spectrum of complex **2** (Figure 4). The peak at the shorter excitation wavelength (579.77 nm) can be assigned to the Eu complex with three molecules of H_2O in the inner coordination sphere, and the peak at the longer wavelength (580.33 nm) to the Eu complex with one molecule of H_2O. The presence of one and three-coordinated H_2O molecules in complex **2** is in agreement with crystallographic data.

Crystallographic Characterization of Complex 2

Single crystals of complex **2** were obtained by slow diffusion of *tert*-butyl methyl ether into a solution of the complex in acetonitrile, and its structure was determined by X-ray crystallography. The structure of the Eu^{III} complex is shown in Figure 5.

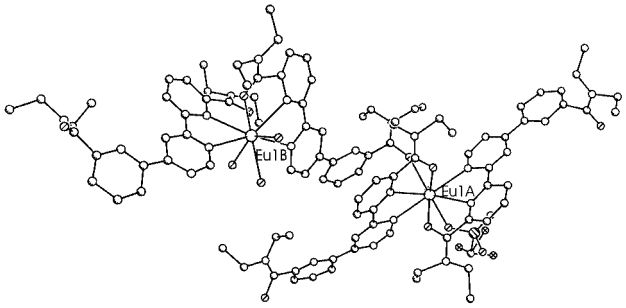

Figure 5. Molecular structure of complex **2** in the crystal. $Eu_2(C_{24}H_{28}N_6O_2)_4(CF_3SO_3)_6{\cdot}6H_2O$

In the crystal structure the complex exists as a binuclear compound. The europium(III) ions are nine-coordinate, and the geometry around the central ions can be described as distorted, tri-capped trigonal prismatic. Both ions are coordinated (almost symmetrically) by two ligands, that utilize three centers each: two aromatic ring nitrogen atoms, and one carbonyl oxygen atom, all from the same half of the molecule. Only one out of four ligands (D) joins two europium ions, and effectively acts as a tetradentate ligand. The coordination of Eu1A is completed by one of the triflate counterions and one water molecule, while Eu1B has three water molecules at the coordination sites.

One Eu^{III} ion is coordinated by six donor atoms from two molecules of the ligand **L** [each ligand comprises bis(tridentate) N,N,O (carbonyl) donor sets], and three remaining positions are occupied by oxygen atoms of water molecules. The second Eu^{III} ion is also nine-coordinate, but its coordination environment is filled by six donor atoms from two molecules of the ligand **L**. The seventh position is occupied by the oxygen atom of a triflate ion, the eighth

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

site contains the oxygen atom of a water molecule, and in the ninth site there is an oxygen carbonyl atom of ligand **L** (D), which is coordinated to the first Eu^{III} ion, and plays a role as bridge between two metal ions. To the best of our knowledge, only six complexes with Eu^{III}-triflate bonds are known.[4e,14]

Two binuclear complexes **2**, related by a center of symmetry at (1/2, 1/2, 1/2), form a dimer connected via two water molecules, and two triflate molecules by means of hydrogen bonds (Figure 6).

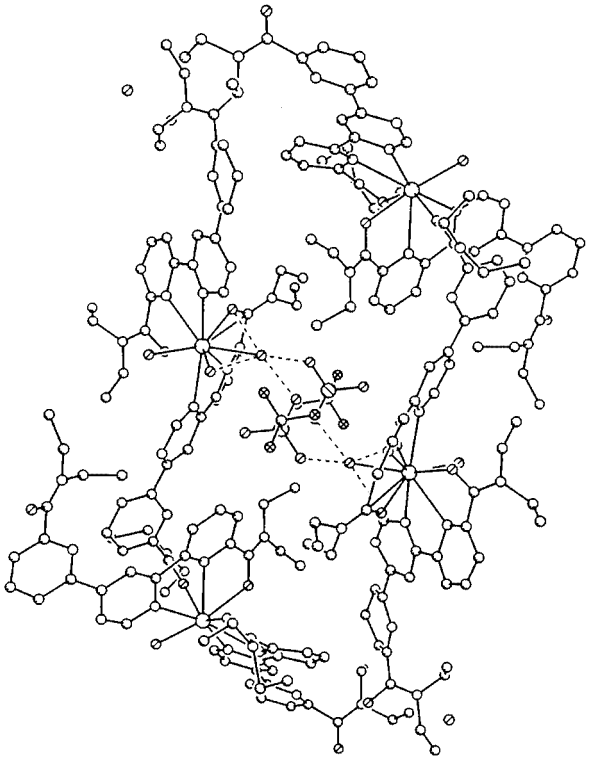

Figure 6. Hydrogen-bonded centrosymmetric dimer (see text)

These dimers, in turn, are connected by O(water)···O(carbonyl) hydrogen bonds, and make infinite chains along the *y* direction. In the crystal structure, the water molecules, which can both donate and accept hydrogen bonds act as a kind of "glue", which connects the molecules in the crystal structure. This structure is additionally strengthened by a number of weak C−H···O hydrogen bonds.

The Eu−O and Eu−N distances are well within typical ranges. The mean values are as follows (in parentheses are the mean values from the December 2002 version of the Cambridge Structural Database[15]): Eu(1A)−O(water): 2.45(2) [2.45(6)], Eu−O(carbonyl): 2.43(2) [2.40(6)], and Eu−N(aromatic): 2.60(2) [2.62(8)]. The conformation of the ligand molecules can be described by the values of the dihedral angles between the least-squares planes of the pyridine rings. Three ligands, which are bound to a single Eu ion, have quite similar values for these twist angles (15°−23°), while the ligand D, which binds two Eu ions, is significantly more twisted, the dihedral angle being 46(1)°.

Conclusion

We have described four new photoactive lanthanide complexes. Ligand **L**, containing two N,N,O tridentate binding sites for complexation, is a good Eu^{III} and Tb^{III} sensitizer. The europium complex **2** shows excellent luminescence properties with a high quantum yield, and effective intramolecular energy transfer from the ligand to the Eu^{III} ions. These factors, along with the stability of this complex in solution, make these compounds good candidates as luminescence and laser materials. ES-MSI and luminescence indicate, that the structure found in the crystal is essentially maintained in solution.

In conclusion, the investigated complexes may be of use in several fields of lanthanide coordination chemistry or as luminescent supramolecular nano-devices.

Experimental Section

General Remarks: CH_3CN was freshly distilled under argon from CaH_2. Ligand **L** was prepared according to the literature.[9] The lanthanide triflates were used without further purification from Aldrich. ESI-mass spectra were determined in acetonitrile using a Waters Micromass ZQ apparatus. Microanalyses were obtained using an Elementor Vario El III microanalyzer.

All absorption spectra, in acetonitrile or aqueous solution, were recorded with a Shimadzu UVPC 2001 spectrophotometer, between 200 and 400 nm, in 10 × 10 mm quartz cells. The concentration of Ln^{III} ions was $1-2 \times 10^{-5}$ mol·L^{-1} in all experiments. Excitation and emission spectra were measured at room temperature on a Perkin−Elmer MPF3 spectrofluorimeter with excitation and emission slits at 5 nm.

The quantum yields of the metal-centered luminescence were determined using published procedures, with $Ru(bpy)_3^{2+}$ as a standard,[16] in CH_3CN at room temperature. The refractive indexes were 1.346 for solutions in CH_3CN, and 1.333 for solutions in water. The excitation wavelength was 326 or 328 nm for all lanthanide ions.

Sm^{III} Complex 1: A mixture of $Sm(CF_3SO_3)_3$ (9.1 mg, 15 μmol) and ligand **L** (9.9 mg, 23 μmol) in CH_3CN (5 mL) was stirred at room temperature for 24 h. The solvent was evaporated under reduced pressure to yield a white powder in quantitative yield. ESI-MS: *m*/*z* (%) = 1314 (8) $\{[Sm_2(\mathbf{L})_4](CF_3SO_3)_4\}^{2+}$, 827 (3) $\{[Sm_2(\mathbf{L})_4](CF_3SO_3)_3\}^{3+}$, 583 (100) $\{[Sm_2(\mathbf{L})_4](CF_3SO_3)_2\}^{4+}$, 437 (20) $\{[Sm_2(\mathbf{L})_4](CF_3SO_3)\}^{5+}$, 339 (5) $\{[Sm_2(\mathbf{L})_4]\}^{6+}$. $Sm_2\mathbf{L}_4(CF_3SO_3)_6{\cdot}6H_2O$ (3033.31): calcd. C 40.39, H 4.12, N 11.08, S 6.34; found C 40.45, H 3.92, N 10.35, S 6.80.

Sm^{III} Complex 1a: A solution of ligand **L** (10.4 mg, 24 μmol) and $Sm(CF_3SO_3)_3$ (14.5 mg, 24 μmol) in CH_3CN (5 mL) was stirred at room temperature for 19 h. The white complex was isolated in quantitative yield by evaporation of the solvent. ESI-MS: *m*/*z* (%) = 1910.2 (3) $\{[Sm_4(\mathbf{L})_4](CF_3SO_3)_{10}\}^{+2}$, 1316.4 (7) $\{[Sm(\mathbf{L})_2](CF_3SO_3)_2\}^{+}$, 1180.1 (7) $\{[Sm_3(\mathbf{L})_2](CF_3SO_3)_7\}^{2+}$, 1096.9 (10) $\{[Sm_2(\mathbf{L})_3](CF_3SO_3)_4\}^{2+}$, 881.9 (100) $\{[Sm_4(\mathbf{L})_4](CF_3SO_3)_8\}^{4+}$, 736.3 (18) $\{[Sm_3(\mathbf{L})_2](CF_3SO_3)_6\}^{3+}$, 681.9 (2) $\{[Sm_2(\mathbf{L})_3]$-

Tb^{III} Complex 3: A mixture of $Tb(CF_3SO_3)_3$ (6.7 mg, 11 μmol) and ligand **L** (7.2 mg, 17 μmol) in CH_3CN (5 mL) was stirred at room temperature for 24 h. The solvent was evaporated under reduced pressure to yield a white product in quantitative yield. ESI-MS: *m*/*z* (%) = 1322 (15) $\{[Tb_2(\mathbf{L})_4](CF_3SO_3)_4\}^{2+}$, 586 (100) $\{[Tb_2(\mathbf{L})_4](CF_3SO_3)_2\}^{4+}$, 341 (8) $\{[Tb_2(\mathbf{L})_4]\}^{6+}$. $Tb_2\mathbf{L}_4(CF_3SO_3)_6 \cdot 8H_2O$ (3074.37): calcd. C 39.85, H 4.16, N 10.93, S 6.26; found C 37.14, H 4.11, N 10.20, S 6.42.

Tb^{III} Complex 3a: A solution of ligand **L** (7.0 mg, 16 μmol) and $Tb(CF_3SO_3)_3$ (9.8 mg, 16 μmol) in CH_3CN (5 mL) was stirred at room temperature for 21 h. The white complex was isolated in quantitative yield by evaporation of the solvent. ESI-MS: *m*/*z* (%) = 2360.4 (1) $\{[Tb_2(\mathbf{L})_3](CF_3SO_3)_5\}^{+}$, 1927.2 (2) $\{[Tb_4(\mathbf{L})_4](CF_3SO_3)_{10}\}^{2+}$, 1236.4 (2) $\{[Tb_4(\mathbf{L})_4](CF_3SO_3)_9\}^{3+}$, 1192.1 (1) $\{[Tb_3(\mathbf{L})_2](CF_3SO_3)_7\}^{2+}$, 1105.4 (80) $\{[Tb_2(\mathbf{L})_3](CF_3SO_3)_4\}^{2+}$, 889.2 (37) $\{[Tb_4(\mathbf{L})_4](CF_3SO_3)_8\}^{4+}$, 687.4 (92) $\{[Tb_2(\mathbf{L})_3](CF_3SO_3)_3\}^{3+}$, 543.2 (15) $\{[Tb_4(\mathbf{L})_4](CF_3SO_3)_6\}^{6+}$, 370.1 (12) $\{[Tb_4(\mathbf{L})_4](CF_3SO_3)_4\}^{8+}$. $Tb_4\mathbf{L}_4(CF_3SO_3)_{12}$ (4154.6): calcd. C 31.22, H 2.72, N 8.09, S 9.26; found C 30.98, H 2.82, N 8.23, S 8.22. Excitation λ = 326 nm. Luminescence spectrum (MeCN, 2×10^{-5} M at 20 °C): λ_{em} = 494 nm ($^5D_4 \rightarrow {}^7F_6$), 549 nm ($^5D_4 \rightarrow {}^7F_5$), 588 nm ($^5D_4 \rightarrow {}^7F_4$), 621 nm ($^5D_4 \rightarrow {}^7F_3$).

Dy^{III} Complex 4: A mixture of $Dy(CF_3SO_3)_3$ (8.3 mg, 14 μmol) and ligand **L** (8.8 mg, 20 μmol) in CH_3CN (4 mL) was stirred at room temperature for 24 h. The solvent was evaporated under reduced pressure to yield a white powder in quantitative yield. ESI-MS: *m*/*z* (%) = 1326 (10) $\{[Dy_2(\mathbf{L})_4](CF_3SO_3)_4\}^{2+}$, 589 (100) $\{[Dy_2(\mathbf{L})_4](CF_3SO_3)_2\}^{4+}$, 441 (20) $\{[Dy_2(\mathbf{L})_4](CF_3SO_3)\}^{5+}$, 342 (10) $\{[Dy_2(\mathbf{L})_4]\}^{6+}$. $Dy_2\mathbf{L}_4(CF_3SO_3)_6 \cdot 8H_2O$ (3093.62): calcd. C 39.57, H 4.14, N 10.87, S 6.21; found C 36.53, H 4.07, N 10.09, S 6.25.

Dy^{III} Complex 4a: A solution of ligand **L** (8.2 mg, 19 μmol) and $Dy(CF_3SO_3)_3$ (11.5 mg, 19 μmol) in CH_3CN (5 mL) was stirred at room temperature for 21 h. The white complex was isolated in quantitative yield by evaporation of the solvent. ESI-MS: *m*/*z* (%) = 1325 (10) $\{[Dy_2(\mathbf{L})_4](CF_3SO_3)_4\}^{+2}$, 1108 (2) $\{[Dy_2(\mathbf{L})_3](CF_3SO_3)_4\}^{2+}$, 893 (10) $\{[Dy_4(\mathbf{L})_4](CF_3SO_3)_8\}^{4+}$, 546 (3) $\{[Dy_4(\mathbf{L})_4](CF_3SO_3)_6\}^{6+}$, 481 (5) $\{[Dy_2(\mathbf{L})_3](CF_3SO_3)_2\}^{4+}$, 447 (5) $\{[Dy_4(\mathbf{L})_4](CF_3SO_3)_5\}^{7+}$, 433 (100) [**L** + H]), 393 (5) $\{[Dy_3(\mathbf{L})_2](CF_3SO_3)_4\}^{5+}$, 150 (5) $[Dy_3(\mathbf{L})_2]^{9+}$. $Dy_4\mathbf{L}_4(CF_3SO_3)_{12}$ (4168.9): calcd. C 31.12, H 2.71, N 8.06, S9.23; found C 30.22, H 2.89, N 8.23, S 9.50. Excitation, λ = 326 nm. Luminescence spectrum (MeCN, $c = 2 \times 10^{-5}$ M, at 20 °C): λ_{em} = 483 nm ($^4F_{9/2} \rightarrow {}^6H_{13/2}$), 577 nm ($^4F_{9/2} \rightarrow {}^6H_{15/2}$).

X-ray Crystallographic Study: Data were collected using the ω-scan technique in the θ range 2−25° with a KUMA KM4CCD[17] four-circle diffractometer with a CCD detector, using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Accurate cell parameters were determined by a least-squares fit of the 5250 reflections of highest intensity, chosen from the whole experiment. Data were corrected for Lorentz-polarization[18] and absorption effects.[19] Due to the long *b* parameter of the unit cell, the potential overlapping of reflections was also taken into account. The structure was solved by direct methods with SHELXS-97,[20] and refined with SHELXL-97.[21] Non-hydrogen atoms were refined anisotropically, hydrogen atoms were located in calculated positions, and refined using the "riding model" with their isotropic thermal parameters set at 1.2 times the U_{eq} value of the appropriate carrier atom. The final model involves some disorder in the crystal structure ($N-Et_2$ groups and two triflates). Weak constraints to the thermal parameters of chosen atoms were applied. Crystallographic data for complex **2** are listed in Table 2.

Table 2. Crystallographic data for the structural analyses of the complex **2**

Empirical formula	$Eu_2(C_{24}H_{28}N_6O_2)_4(CF_3SO_3)_6 \cdot 6H_2O$

Mechanism of Oxidation of (olefin)Rh^I and -Ir^I Complexes by H_2O_2

Peter H. M. Budzelaar*[a] and Arno N. J. Blok[a]

Keywords: Density functional calculations / Iridium / Oxidation / Oxygenation / Rhodium

A DFT study of the oxidation of (tpa)$M^I(C_2H_4)^+$ and (dpa-R)M^I(cod)$^+$ complexes (M = Rh, Ir) by H_2O_2 indicates that the reaction starts with heterolytic cleavage of the peroxide O–O bond, leading to M^{III}(olefin)$(OH)^{2+}$ species. These can then undergo cyclisation, followed by deprotonation to oxetanes. In the oxidation of COD complexes, further cyclisation to internal ethers has a modest barrier, and the observed products (ethers for Rh, oxetanes for Ir) are suggested to be the thermodynamic ones.

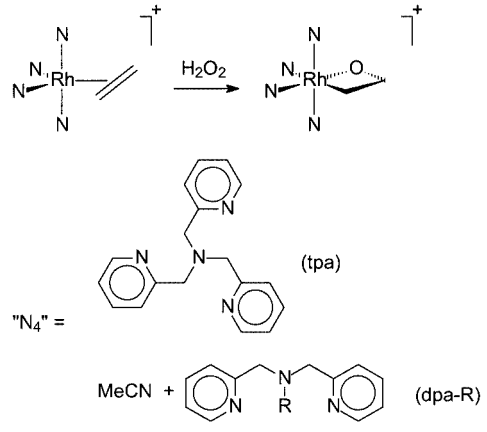
Introduction

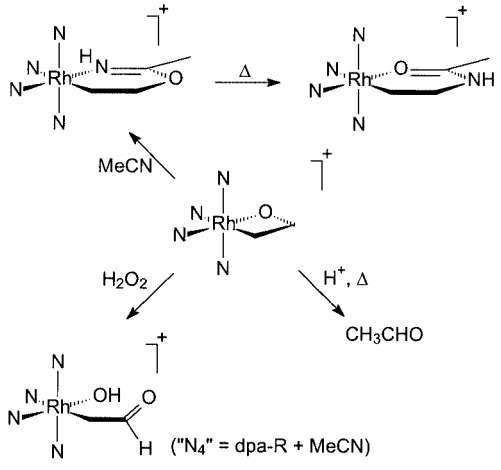
The oxidation of hydrocarbons at transition metal centres comprises a class of important yet poorly understood reactions. In addition to the more traditional organometallic reaction types, single-electron transfer steps and radical intermediates have to be considered. Moreover, oxidations are highly exothermic and often involve a cascade of elementary steps. These complications make the rational design and control of such reactions difficult and point to the need for a more detailed mechanistic understanding.

Still, not all oxidation reactions need necessarily be very complicated. Several years ago, De Bruin discovered the first clean example of the oxidation of a rhodium-coordinated ethene to an oxetane by H_2O_2 (Scheme 1).[1]



Scheme 1. Oxetane formation from ethene complexes and H_2O_2

Since then, this chemistry has been extended to cover also a few Ir examples, a few other N-donor ligands, propene and cyclooctadiene (COD).[2–5] In addition, the initial oxetane products have been converted into amido-substituted alkyl compounds, formylmethyl groups or acetaldehyde (Scheme 2).[6–8]



Scheme 2. Reactivity of oxarhodetanes

For COD the chemistry is somewhat more complex, since the second double bond can also participate in the oxygenation reaction, leading to internal ethers (Scheme 3). Depending on the metal, various isomeric ethers (Rh) or oxetanes (Ir) have been observed; in some cases, similar products have been observed in the oxidation of COD complexes by dioxygen (O_2).[3,9–11] It is not yet clear whether the observed isomers represent thermodynamic or kinetic products. In any case, they eventually rearrange to hydroxy-enediyl complexes.[2–4,9]

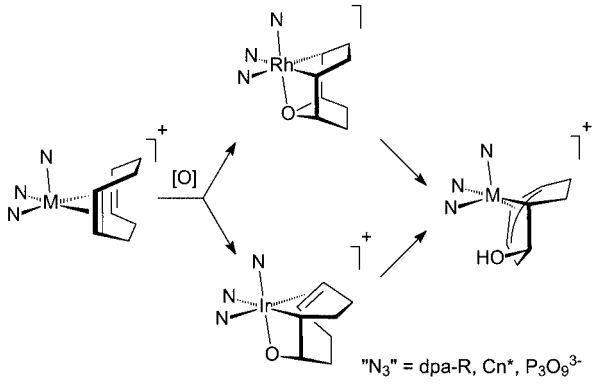
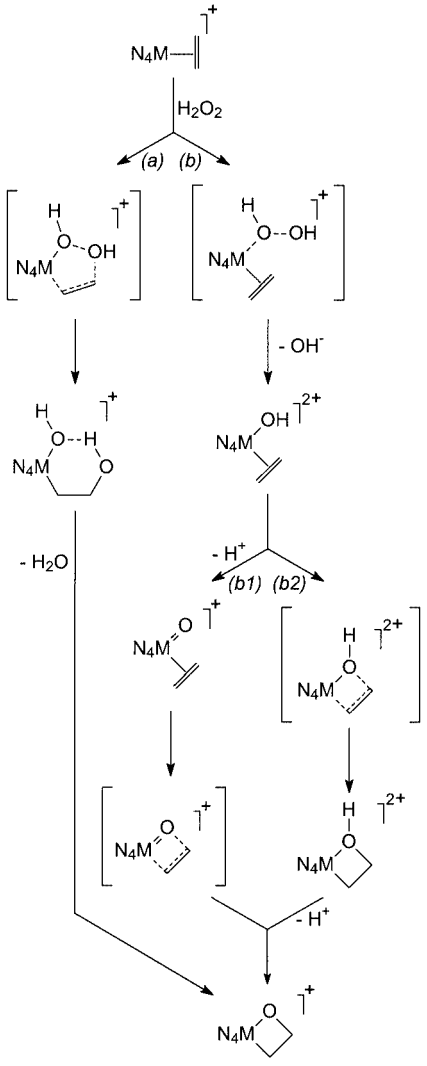


Scheme 3. Oxygenation of COD complexes

We have now studied the oxidation by H_2O_2 using DFT methods. For the initial oxidation step, three alternatives were considered, as summarised in Scheme 4: (*a*) concerted O−O bond breaking and Rh−O/C−O bond formation, followed by elimination of water; (*b*) heterolytic O−O cleavage, and then either (*b1*) deprotonation to an oxo complex, followed by cyclisation to an oxetane, or (*b2*) cyclisation to a protonated oxetane, followed by loss of the proton.

These reactions were studied for (tpa)M$(C_2H_4)^+$ complexes (M = Rh, Ir) as well as (dpa)M$(cod)^+$, (dpa-Me)M$(cod)^+$ (dpa-Me being a generic model for *N*-alkyl-substituted dpa ligands) and (tpa)M$(cod)^+$ (to explicitly include the possibility of a dangling picolyl group participating in the chemistry). For the COD complexes, interconversions between the various isomeric oxetane and ether products were investigated as well.



Scheme 4. Alternative mechanisms (*a*, *b1*, *b2*) for H_2O_2 oxidation of olefin complexes

Results and Discussion

Initial Attack of H_2O_2

Figure 1 shows the energy profiles for approach of H_2O_2 and $H_2O_2{\cdot}H_2O$ to (tpa)Rh$(C_2H_4)^+$ *cis* to the amine group [similar curves have been calculated for the *trans* approach and the corresponding reactions of (dpa)Rh$(cod)^+$ and (dpa-Me)Rh$(cod)^+$; see Supporting Information]. Starting from a weakly bound complex, the initial approach of the oxygen atom to the metal centre is slowly uphill in all cases. This is unsurprising, given the coordinatively saturated (18 e) nature of the metal centre. If only an isolated H_2O_2 molecule is used (Figure 1, diamonds), the approach stays repulsive up until fairly short M−O distances. The energy then goes down suddenly,[12] but the path does not lead to a protonated oxetane and separate OH^-, which would be too high in energy. Instead, a neighbouring acidic proton is immediately abstracted by the nascent OH^- group. Depending on the system, this can be the NH proton of dpa, a picolyl CH_2 proton of dpa or tpa, or the proton left on the OH group that was transferred to the metal atom. If a molecule of water is added, it hydrogen-bonds to H_2O_2. Now, on approach of an H_2O_2 oxygen atom to the metal atom the energy starts to go down already at longer M−O distances (Figure 1, squares), resulting in a marginally lower barrier.[12] For approach of both H_2O_2 and $H_2O_2{\cdot}H_2O$, the first step of the reaction appears to be heterolytic O−O cleavage, to form an OH^- ion (strongly stabilized by water if present) and an oxidized M^{III}(olefin)$(OH)^{2+}$ species. In practice, the H_2O_2 oxidation reactions always involve water and excess H_2O_2 able to sta-

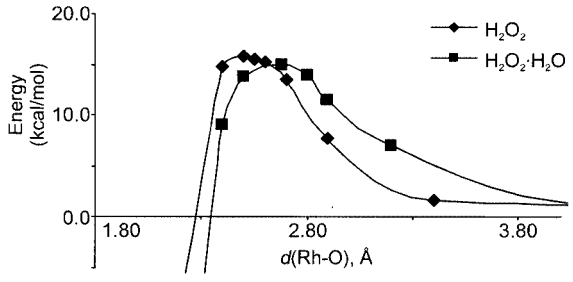


Figure 1. Potential-energy curve [kcal/mol] for approach of H_2O_2 or $H_2O_2{\cdot}H_2O$ to (tpa)Rh$(C_2H_4)^+$, *cis* to the amine nitrogen atom

bilize this nascent OH^-,[1−5] so easy heterolytic cleavage, assisted by hydrogen bonding, would be expected.

The calculated transition state (Figure 2) appears to be early, since the Rh−O distance (2.680 Å) is quite long. The barrier is mainly caused by the lateral movement of the coordinated ethene and the lengthening of the two in-plane Rh−N bonds, i.e. H_2O_2 displaces a nitrogen donor ligand and the Rh centre avoids a 20-electron surrounding. However, at the transition state the O−O bond is already elongated significantly relative to free $H_2O_2{\cdot}H_2O$ (1.465 Å). The barrier of about 15 kcal/mol (25 kcal/mol relative to the separated reactants) corresponds to a reaction that would be fast at room temperature. The results for Ir and for (dpa)M(cod)$^+$ and (dpa-Me)M(cod)$^+$ are very similar.

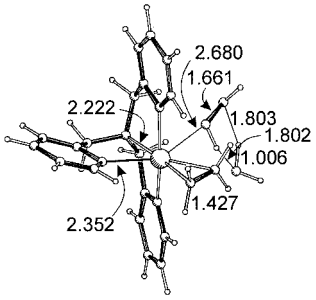

Figure 2. Calculated transition state for attack of $H_2O_2{\cdot}H_2O$ on (tpa)Rh$(C_2H_4)^+$ *cis* to the amine nitrogen atom; bond lengths in Å

The above constitutes the first step of variations (*b1*)and (*b2*) of Scheme 4. We have also considered variation (*a*) in which the nascent OH^- immediately attacks the olefin in a concerted manner. Despite extensive searches, no transition state for such an approach could be located; we conclude that no direct single-step reaction path exists. It remains possible that OH^- would first be lost and then attacks the olefin in a separate step. However, in that case approach to the olefin would be expected *trans* to the metal atom, and this would not lead to the COD oxidation products observed experimentally. In any case, it is not clear why, if route (*a*) were followed, the initially formed $M^{III}(OH)(CH_2CH_2OH)^{2+}$ complex would quickly rearrange to the (strained) oxetane observed experimentally. For these reasons, possibility (*a*) was not considered further.

Stereochemistry of H_2O_2 Attack

We assume that, once an M−O bond has been formed, the coordination chemistry around the metal atom is "frozen". This seems reasonable, since from that point on the complexes are octahedral ML_6 d^6 species and hence rather inert. Therefore, the final product distribution should reflect the stereochemistry of the initial H_2O_2 attack.

For oxidation of (tpa)Rh$(C_2H_4)^+$ by $H_2O_2{\cdot}H_2O$, we calculate a marginal preference (0.2 kcal/mol) for attack *cis* to the amine group. This agrees qualitatively with the stereochemistry observed experimentally, although the absence of any observable *trans* product[7] suggests that the real stereo preference is significantly higher than we calculate.

For oxidation of (dpa-Me)Rh(cod)$^+$ by $H_2O_2{\cdot}H_2O$, we calculate a similarly small preference (0.6 kcal/mol) for attack *cis* to the amine group, which corresponds to an expected *cis*/*trans* ratio of 3:1 at 0 °C. Experimentally, De Bruin observed a ratio of ca. 5:1 at room temperature and "selective" *cis* attack at −10 °C, which can be taken as reasonable agreement. The calculated *cis* preference is much larger (2.6 kcal/mol) for the oxidation of (dpa)Rh(cod)$^+$, where an additional hydrogen bond is formed between the auxiliary water molecule and the ligand NH group in the *cis*-attack transition state. It is not clear whether this is relevant to the "real" oxidation reaction, since there more water molecules would be present and the NH group would be involved in hydrogen bonding for *both* stereochemistries. In any case, the experimentally observed stereochemistry is indeed almost quantitatively *cis* to amine group for dpa-type ligands without a substituent at the amine nitrogen atom.

Formation of the First C−O Bond

Of the remaining variations (*b1* and *b2*), our results make the former one rather unlikely. The oxo intermediate in this mechanism is very high in energy. Its formation from the [(olefin)M^{I}]$^+$ complex and H_2O_2 is virtually thermoneutral, whereas the presumed intermediate hydroxo complex is about 40 kcal/mol lower in energy. The low stability of the oxo species is due to its lack of M−O π-bonding.[13] Thus, it is better represented by the zwitterionic M^+-O^- structure. Such an oxo complex is a very strong base, about 40 kcal/mol stronger than the final oxetane product. If it were formed at all, it would quickly cyclize to the oxetane; the calculated barrier for olefin insertion is negligible (1−2 kcal/mol).

In the second variation (*b2*), intramolecular nucleophilic attack of the OH group on the coordinated olefin has a modest barrier in all cases (5−15 kcal/mol). Thus, this represents a reasonable path for C−O bond formation. Subsequent loss of H^+ should also be easy, given the +2 charge of the complex. Therefore, we believe this path to be the more reasonable one, although, given the rough nature of our "solvation correction" (see Exp. Sect.) (*b1*) cannot be ruled out. Figure 3 shows the ring-closure transition state

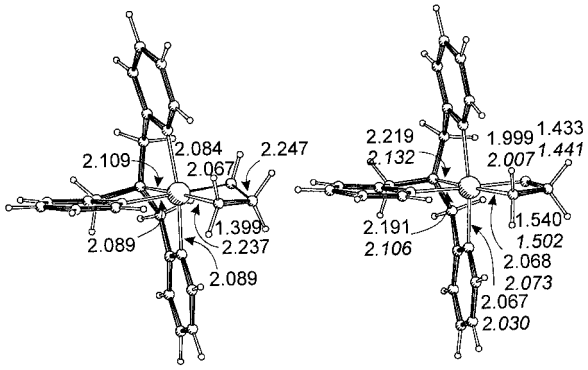

Figure 3. Calculated OH attack transition state and oxetane final product (after deprotonation) for *cis* attack on (tpa)Rh$(C_2H_4)^+$; calculated bond lengths in Å [observed values for (Me-tpa)Rh$(C_2H_4)^+$ [7] in *italics*]

and the oxetane final product for the preferred *cis*-to-amine attack on (tpa)Rh$(C_2H_4)^+$.

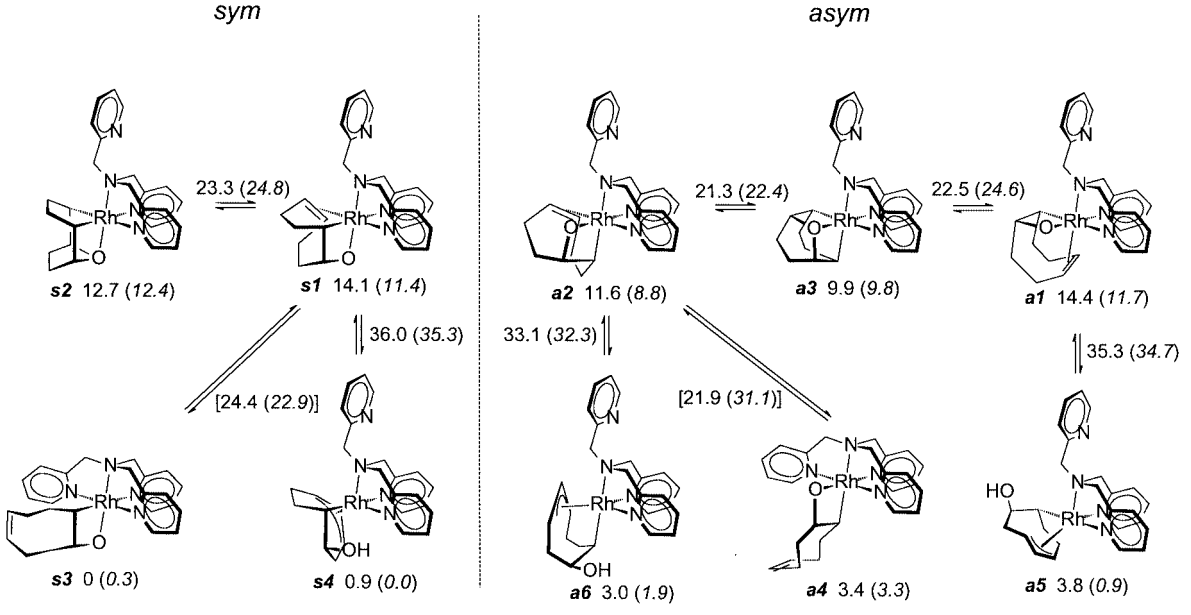
Figure 4 shows the complete calculated energy profile, including the steps discussed in the following sections, for *asym* (*cis* to the amine group) attack at (tpa)Rh(cod)$^+$.

COD-Derived Oxetanes and Ethers

For COD, the experimentally observed products of the oxidation can be either oxetanes (for M = Ir) or ethers (for M = Rh). We have calculated both types of isomeric products, as well as the transition states for their interconversion, using the *fac*-κ^3-coordinated tpa ligand. We chose this ligand because, depending on the disposition of the nitrogen donor groups around the metal atom, it can displace the remaining C=C bond of the oxetane product, as discussed below.

The results are summarised in Scheme 5. The barriers for ether formation are about 10 kcal/mol for Rh; they represent reactions that would rapidly reach equilibrium at room temperature. The barriers for Ir are slightly larger, as expected. The calculations predict the ether products (***s2***, ***a3***) to be more stable than their oxetane isomers for Rh, whereas for Ir the oxetanes (***s1***, ***a2***) are more stable, in agreement with experiment.

If a tetradentate ligand (tpa) is used in this reaction, it initially has a dangling picolyl group (structures ***s1−2***, ***a1−3***). Depending on the disposition around the metal atom, this can, in some cases, displace the remaining C=C bond of the oxetane product (***s3***, ***a4***). Indeed, for Rh Krom observed displacement in the *sym* isomer but not in the *asym* isomer, whereas for Ir experiment suggests the C=C bond remains coordinated in both isomers.[5] Our calcu-



Scheme 5. Calculated relative energies of minima and transition states [kcal/mol] for Rh oxidation products[14] (values for Ir in *italics*)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

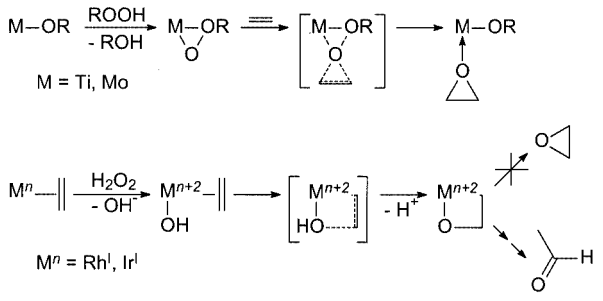
lations do not agree with this and predict C=C displacement by the dangling Py group to be favourable in all cases. We do not at present have a satisfactory explanation for this discrepancy. It is unlikely to be due to kinetic factors, since even intermediates having both C=C and Py groups detached are predicted to be accessible.[14]

Decomposition of COD-Derived Oxetanes

Experimentally, the oxetane and ether products derived from COD slowly rearrange to hydroxy-enediyl derivatives. This reaction appears to be accelerated by acid, at least for Rh.[3] Here, we have studied the uncatalysed rearrangement, which involves intramolecular transfer of an allylic proton to the oxetane oxygen atom. The calculated barriers (20−25 kcal/mol) are significant but not prohibitive, suggesting that uncatalysed rearrangement would certainly be possible. For Rh in the *asym* series, the path leading to isomer ***a6*** is predicted to be marginally more favourable than that leading to isomer ***a5***; experimentally, isomer ***a5*** is formed exclusively with the dpa ligand. For Ir, the route leading to ***a6*** also has a slightly lower calculated barrier, yet for Me-dpa an isomer of type ***a5*** is still observed experimentally.[4] Obviously, there is no a priori reason why any catalysed rearrangement should have the same selectivity as the uncatalysed reaction.

A Comparison with Ti^{IV}- and Mo^{VI}-Catalysed Epoxidation

It is interesting to contrast the sequence of steps described here to that occurring in olefin epoxidation by H_2O_2 (or ROOH) catalysed by the early transition metals Ti^{IV} [15] and Mo^{VI} (Scheme 6).[16] There, the hydrogen peroxide forms a metal hydroperoxide, from which an oxygen atom is transferred to an olefin without direct metal−olefin coordination. The metal atom activates the OOR group through η^2-coordination, making the OR group a good leaving group,[17] but the metal atom itself is redox-inactive. In the present late-transition-metal case, H_2O_2 oxidizes M^{I} to M^{III}, and this in turn oxidizes the olefin through intramolecular Wacker-type chemistry.[18]



Scheme 6. Comparison of olefin oxidation by peroxides at early and late transition metal atoms

These different mechanisms explain the differences in product types. In Ti^{IV} and Mo^{VI} reactions, the epoxide is the initial product, and unless it is opened in the reaction medium by electrophilic or nucleophilic attack, it will also be the final product. In the type of metal-mediated oxidation chemistry studied here, the initial product is a (protonated) metallaoxetane, from which reductive elimination to the highly strained epoxide would only be expected if the metal atom is in an unusually high oxidation state. That is not the case for Rh^{III} or Ir^{III}, so decomposition to an aldehyde or ketone by β-hydrogen elimination is a more likely outcome.

Conclusions

Calculations have provided a consistent and reasonable picture of the oxidation of $[N_x(olefin)Rh^{I}]^+$ complexes by H_2O_2. The initial step is proposed to be heterolytic O−O cleavage, possibly assisted by hydrogen bonding of, for example, water to the nascent OH^- ion. The next step is probably intramolecular attack of coordinated OH^- on coordinated olefin, followed by loss of a proton. For COD complexes, the oxetanes formed in this way can undergo reversible intramolecular attack of the alkoxide oxygen atom on the remaining C=C bond, leading to ether products. The calculated stabilities and barriers suggest that the products observed experimentally are the thermodynamic ones. For Ir, oxetanes are calculated to be slightly more stable than their ether isomers, but apart from that the differences between Rh and Ir appear to be small.

Experimental Section

General Methods: All calculations were carried out with the Turbomole program[19a] coupled to the PQS Baker optimiser.[20] Geometries were fully optimised as minima or transition states at the bp86[21]/RIDFT[22] level using the Turbomole SV(P) basis set[19c][19d] on all atoms (small-core pseudopotential[19c][19e] on Rh and Ir); the nature of each stationary point was then checked by a numerical frequency analysis. Improved energies were obtained from single-point calculations at the b3-lyp level[23] using the TZVP basis[19c][19f] (small-core pseudopotential[19c][19e] on Rh and Ir) and a fine ("m4") integration grid. Solvent corrections were calculated at the b3-lyp/TZVP level using the COSMO solvation model[24] with a dielectric constant of 36.67 (acetonitrile). The final energies cited in the text and figures are free energies obtained by combining these solvation-corrected TZVP results with zero-point energy (ZPE) and thermal corrections (enthalpy and entropy, 273 K, 1 bar) calculated from the bp86/RIDFT frequency analyses. All species were put on common energy scales by adding H_2O_2, H_2O, OH^- etc. where appropriate. Tables 1−3 list the relative free energies for species discussed in the text. Complete listings of total energies are given as Supporting Information (Tables S1−S4).

Relative Energies of Mono- and Dicationic Species: Even with the inclusion of COSMO solvation corrections, the present level of calculation fails to provide realistic *relative* energies for species of different charges, such as occur in our heterolytic cleavage reactions of H_2O_2. This must at least in part be due to the neglect of strong *specific* solute−solvent interactions (e.g., hydrogen bonding) in the solvation model. The error made in the specific case of ionisation of water can be estimated from Equation (1), where $\varepsilon_{H_3O^+}$, ε_{OH^-}, and ε_{H_2O} are calculated at the COSMO/TZVP/b3-lyp level using the dielectric constant of water (80.37).

$$\Delta\varepsilon = \varepsilon_{H_3O^+} + \varepsilon_{OH^-} - 2\varepsilon_{H_2O} - RT\ln K_{H_2O}$$
$$K_{H_2O} = \frac{[H_3O^+][OH^-]}{[H_2O]^2} \approx (18)^2\,10^{-20} \quad (1)$$

As a very rough correction for the charge-separation problem, we subtracted this "fudge factor" from all calculated energies of dicationic species. This probably results in over-stabilisation of the dicationic species, since H_3O^+ is likely to have stronger specific solvent interactions than most other solutes, but at present we do not have a method that is guaranteed to produce more realistic relative energies for charge-separated species.

Acknowledgments

We are grateful to Prof. P. Burger (Hamburg) for providing the coupling module between Turbomole and the PQS optimiser, and to Sabic EPC for financial assistance.

[10] (olefin)Rh and -Ir complexes can react with oxygen to form peroxo complexes (see, for example, ref.[2]), which can hydrolyze to hydrogen peroxide. Therefore, many O_2 oxygenations may well involve H_2O_2 as the actual oxidant of the olefin complex (as suggested in ref.[11]).

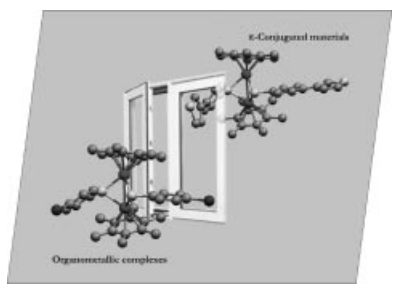
COVER PICTURE

The cover picture shows the half-open way from well-known (arene)ruthenium complexes to π-conjugated materials. This work illustrates the transition from molecular catalysts to molecular building blocks for conducting polymers and nonlinear optics. Details are discussed in the Short Communication by F. Chérioux et al. on p. 2405 ff. The authors are grateful to the Swiss National Science Foundation for financial support.

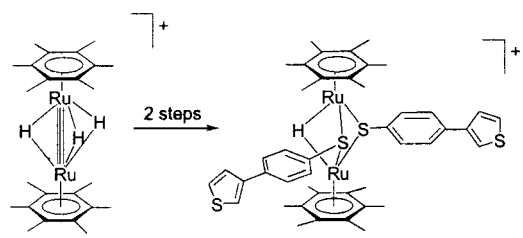


SHORT COMMUNICATION

Contents

2405 **M. J.-L. Tschan, F. Chérioux,* B. Therrien, G. Süss-Fink**

Subsequent Hydride Substitution in (Arene)trihydridodiruthenium Complexes: Synthesis and Structure of Thiolato-Bridged Diruthenium Cations of the Type $[H_2(arene)_2Ru_2(p\text{-}X{-}C_6H_4{-}S)]^+$ and $[H(arene)_2Ru_2(p\text{-}X{-}C_6H_4{-}S)_2]^+$



Keywords: Ruthenium / Sulfur / Hydrides / Complexes / Cross-coupling

The cationic complexes $[HRu_2(\eta^6\text{-arene})_2\{\mu_2\text{-}(p\text{-}X\text{–}C_6H_4)\text{–}S\}_2]^+$ and $[H_2Ru_2(\eta^6\text{-arene})_2\{\mu_2\text{-}(p\text{-}X\text{–}C_6H_4)\text{–}S\}]^+$ (arene = 1,2,4,5-$Me_4C_6H_2$ or C_6Me_6; X = Br and Me) are accessible in good yields from p-X–C_6H_4–SH with $[H_3Ru_2(1,2,4,5\text{-}Me_4C_6H_2)_2][BF_4]$ and $[H_3Ru_2(C_6Me_6)_2][BF_4]$, respectively. The dibromo derivative $[HRu_2(C_6Me_6)_2(p\text{-}Br\text{–}C_6H_4\text{–}S)_2]^+$ is found to undergo double Suzuki coupling reactions with 3-thiophene boronic acid to give $[HRu_2(C_6Me_6)_2(p\text{-}C_4H_3S\text{–}C_6H_4\text{–}S)_2]^+$. This dibromo complex is a potential precursor for the insertion of dinuclear hydrido organometallic entities in the main chain of conjugated molecules.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The field of π-conjugated molecules and polymers containing metal centers has attracted continuous attention over the past two decades because of their electronic, magnetic, or catalytic properties,[1−4] and more recently, for the development of sensors.[5,6] To the best of our knowledge, except for a very recent work by Kim et al. who synthesized a dinuclear organomolybdenum sulfide complex,[7] all relevant molecules are built around mononuclear building blocks that are coordinated with different types of organic ligands. Therefore, there are still challenges to develop versatile and selective strategies, with the view of creating new molecular designs and bridging ligands for the formation of oligomers and polymers which contain metal centers.

In recent studies,[8−10] we have shown that dinuclear dichloro complexes $[Ru(\eta^6\text{-arene})Cl_2]_2$ and $[Rh(\eta^5\text{-}C_5Me_5)Cl_2]_2$ react in ethanol with p-bromothiophenol to give the cationic complexes $[Ru_2(\eta^6\text{-arene})_2\{\mu_2\text{-}(p\text{-}Br-C_6H_4)-S\}_3]^+$ and $[Rh_2(\eta^5\text{-}C_5Me_5)_2\{\mu_2\text{-}(p\text{-}Br-C_6H_4)-S\}_3]^+$, respectively, which could be isolated as the chloride salts in quantitative yield. We have also synthesized the first star-shaped π-conjugated oligomers built around dinuclear organometallic complexes.[11] The presence of bromo functions at the periphery of $[Ru_2(\eta^6\text{-arene})_2\{\mu_2\text{-}(p\text{-}Br-C_6H_4)-S\}_3]^+$ and $[Rh_2(\eta^5\text{-}C_5Me_5)_2\{\mu_2\text{-}(p\text{-}Br-C_6H_4)-S\}_3]^+$ was judiciously exploited to insert thiophene derivatives by standard Suzuki cross-coupling reactions.[12] However, despite the successful synthesis of conjugated oligomers (i.e. coupling with monoboronic acids), we were unable to characterize the corresponding polymers (i.e. coupling with diboronic acids). This can be explained by a large degree of reticulation due to the presence of three bromine atoms in the starting complexes. Consequently, the challenge consists of finding new complexes that contain only one or two bromine atoms (instead of three) at their periphery, therefore allowing a better control for the synthesis of conjugated polymers.

In this paper, we report the first example of dinuclear organometallic conjugated molecules in a "zig-zag"-like arrangement with mono- and disulfur connectivities, $[H_2Ru_2(\eta^6\text{-arene})_2\{\mu_2\text{-}(p\text{-}X-C_6H_4)-S\}]^+$ and $[HRu_2(\eta^6\text{-arene})_2\{\mu_2\text{-}(p\text{-}X-C_6H_4)-S\}_2]^+$, respectively, and give one example of extending their conjugation by Suzuki cross-coupling reactions with 3-thiophene boronic acid.

Results and Discussion

In order to overcome the reticulation problem which arises as a result of the three bromine atoms at the periphery of dinuclear precursors, we first focussed our attention on two different strategies to synthesize mono- and difunctional dinuclear complexes (see Scheme 1): in route A, dif-

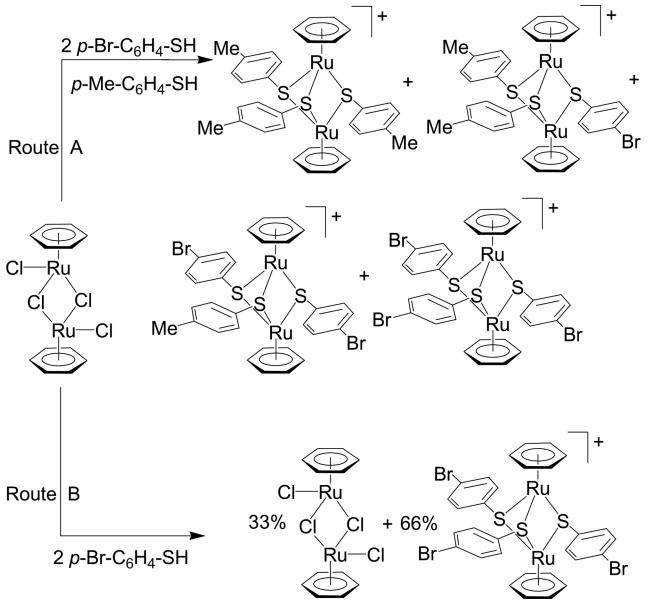
ferent *para*-substituted thiophenols are mixed together, leading to a mixture of all possible substitution compounds in a stoichiometric ratio, as observed by NMR (^{1}H and ^{13}C{^{1}H}) and mass spectrometry. In route B, an excess of the dinuclear dichloro complex is used to favor the formation of mono- and di-μ_2-thiolato complexes.

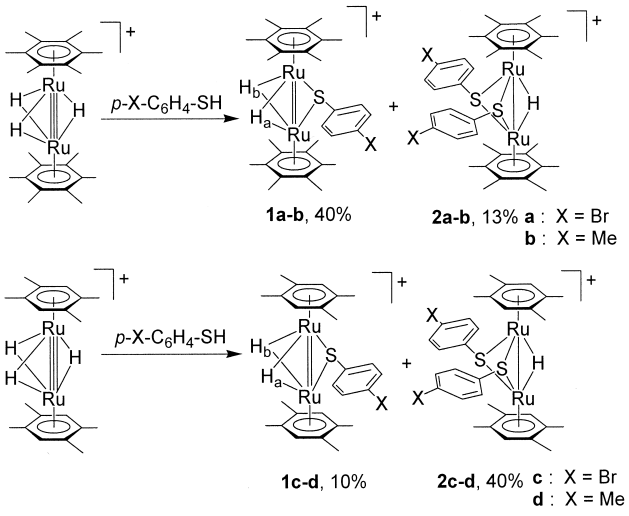


Scheme 1. Strategies for the synthesis of mono- or difunctional dinuclear complexes

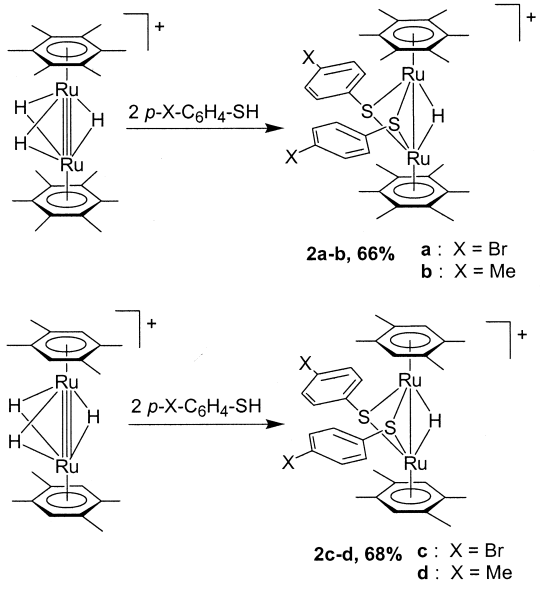
Unfortunately, the different compounds obtained as a mixture from route A could not be separated by standard chromatographic techniques, whereas route B only afforded tri-μ_2-thiolato complexes, despite a strict 1:2 ratio of the reagents.

Consequently, we reasoned that strategy B would, in principle, be the most promising method to synthesize of difunctional dinuclear complexes; however, the dinuclear dichloro complexes [Ru(η^6-arene)Cl$_2$]$_2$ were too reactive to stop at the formation of the di-μ_2-thiolato derivatives. In order to overcome this problem, we used the trihydrido complexes [H$_3$Ru$_2$(η^6-arene)$_2$]$^+$, which are accessible from the reaction of the dinuclear dichloro complexes [Ru(η^6-arene)Cl$_2$]$_2$ (arene: C$_6$Me$_6$, 1,2,4,5-Me$_4$C$_6$H$_2$) with NaBH$_4$,[13−15] instead of the dichloro complexes themselves.

The dinuclear trihydrido complex [H$_3$Ru$_2$(C$_6$Me$_6$)$_2$]$^+$ was found to react with one equivalent of *p*-X−C$_6$H$_4$−SH (X = Me or Br) in ethanol to give a mixture of the cationic complexes [H$_2$Ru$_2$(C$_6$Me$_6$)$_2$(*p*-X−C$_6$H$_4$−S)]$^+$ (**1a**−**b**) and [HRu$_2$(C$_6$Me$_6$)$_2$(*p*-X−C$_6$H$_4$−S)$_2$]$^+$ (**2a**−**b**) in a 3:1 ratio. These cationic complexes can be isolated in good yields as the tetrafluoroborate salts. In the case of the durene analogue [H$_3$Ru$_2$(1,2,4,5-Me$_4$C$_6$H$_2$)$_2$]$^+$, the reaction with one equivalent of *p*-X−C$_6$H$_4$−SH (X = Me or Br) in ethanol yields the cationic complexes [H$_2$Ru$_2$(1,2,4,5-Me$_4$C$_6$H$_2$)$_2$(*p*-X−C$_6$H$_4$−S)]$^+$ (**1c**−**d**) and [HRu$_2$(1,2,4,5-Me$_4$C$_6$H$_2$)$_2$(*p*-X−C$_6$H$_4$−S)$_2$]$^+$ (**2c**−**d**), in a 1:4 ratio (see Scheme 2).



Scheme 2. Reaction of [H$_3$Ru$_2$(η^6-arene)$_2$]$^+$ with one equivalent of *para*-substituted thiophenol



Scheme 3. Reaction of [H$_3$Ru$_2$(η^6-arene)$_2$]$^+$ with two or more equivalents of *para*-substituted thiophenol

Surprisingly, if two (or more) equivalents of *p*-X−C$_6$H$_4$−SH were used with [H$_3$Ru$_2$(η^6-arene)$_2$][BF$_4$], the reaction led exclusively to the formation of the cationic complexes [HRu$_2$(C$_6$Me$_6$)$_2$(*p*-X−C$_6$H$_4$−S)$_2$]$^+$ (**2a**−**b**) and [HRu$_2$(1,2,4,5-Me$_4$C$_6$H$_2$)$_2$(*p*-X−C$_6$H$_4$−S)$_2$]$^+$ (**2c**−**d**, see Scheme 3), and no trace of the mono- or tri-μ_2-thiolato complexes was detected by mass spectrometry.

Both cations **1** and **2** were unambiguously characterized as the tetrafluoroborate salts (see Exp. Sect.). These ionic compounds are highly soluble in alcohols, acetone and chlorinated solvents. The molecular structures of selected complexes **1a**, **2a**, **2c** and **2d** were confirmed by single-crystal X-ray structure analysis of the tetrafluoroborate salts. These cationic species consist of a trigonal bipyramidal

H_2Ru_2S or HRu_2S_2 core, each ruthenium atom being coordinated to an η^6-C_6Me_6 or an η^6-1,2,4,5-$Me_4C_6H_2$ ligand, and each sulfur atom carrying a *p*-substituted phenyl group. The molecular structures of **1a** and **2a** are shown in Figure 1, and those of **2c** and **2d** are shown in Figure 2.

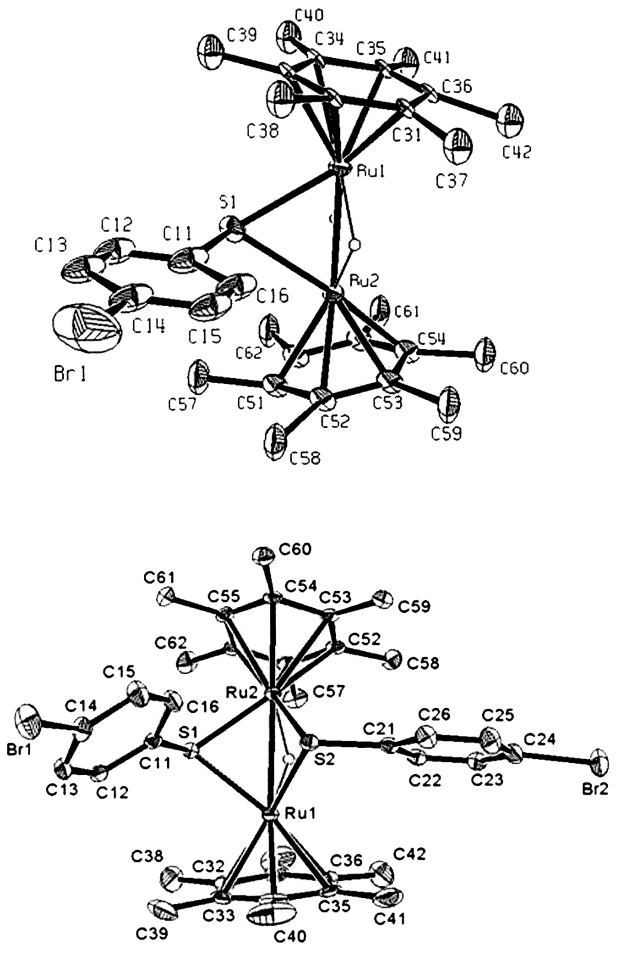

Figure 1. Molecular structures of [**1a**][BF_4] (top) and [**2a**][BF_4] (bottom); tetrafluoroborate anions, solvent molecules and H atoms have been omitted for clarity; displacement ellipsoids are drawn at the 25 and 35% probability level, respectively; selected bond lengths (Å) and angles (°) are listed in Table 1

The metal backbone of **1a** and **2a** consists of two ruthenium atoms, the Ru−Ru distances being in accordance with a metal−metal double bond [**1a**: Ru−Ru = 2.624(2) Å] or single bond [**2a**: Ru−Ru = 2.8112(6) Å]. The presence of one or two thiolato bridging ligands forces the arene−Ru−Ru−arene moieties to adopt a distorted geometry. The two C_6Me_6 arene ligands are not parallel to each other, and the angles between the C_6Me_6 planes are 21.2° in **1a** and 37.4° in **2a**.

The single-crystal X-ray structure analysis of [**1a**]BF_4 explains the large difference in the chemical shifts observed in ^{1}H NMR spectrum of this complex between the two hydrido ligands (−12.88 and −16.75 ppm), as well as that observed for the other dihydrido complexes **1b**−**d** (see Exp. Sect.). The angle defined by the μ_2-(*p*-X−C_6H_4)−S bridging ligand and the ruthenium atoms is close to 110°, thus

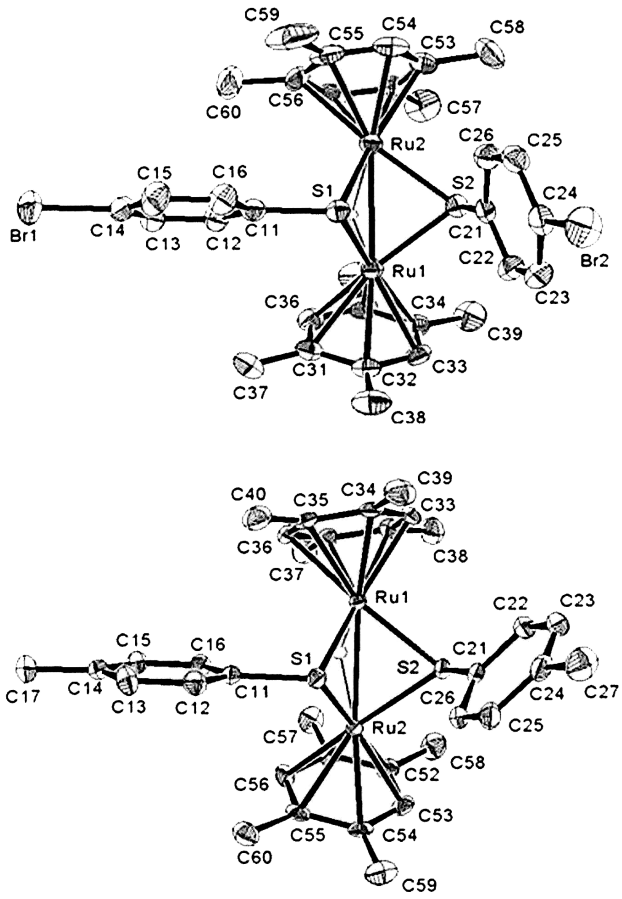

Figure 2. Molecular structures of [**2c**][BF_4] (top) and [**2d**][BF_4] (bottom); tetrafluoroborate anions and H atoms have been omitted for clarity; displacement ellipsoids are drawn at the 35 and 50% probability level, respectively; selected bond lengths (Å) and angles (°) are listed in Table 1

leading to a strongly distorted structure. Consequently, the two hydrido ligands are nonequivalent, because one of them, H_a (see Scheme 2), is closer to the *p*-X−C_6H_4−S moiety than the other (H_b). Moreover, H_a is in the plane of deshielding of the *para*-substituted thiophenyl group (see Figure 1). This phenomenon leads to a large difference in the chemical shift of H_a (−12.88 ppm) and H_b (−16.75 ppm), as observed in ^{1}H NMR spectrum of **1a**. As far as complexes **2** are concerned, the chemical shifts assigned to the hydrido ligands are found between −11 and −12 ppm. As the molecular structures of **2a**, **2c** and **2d** (see Figure 1 and Figure 2) reveal, the hydrido ligand of these complexes is also in the plane of deshielding of the thiophenyl moiety, leading to chemical shifts similar to those observed for the most deshielded hydrido ligands in complexes **1**.

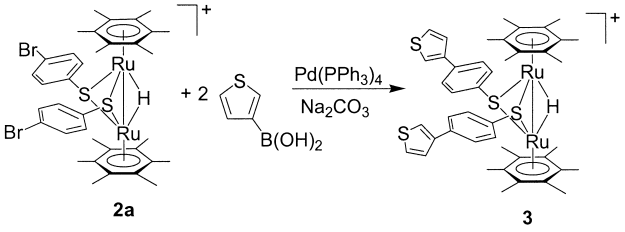
The reactivities of the dinuclear trihydrido complexes $[H_3Ru_2(\eta^6\text{-arene})_2]^+$ are completely different from that of the $[Ru(\eta^6\text{-arene})Cl_2]_2$ complexes. In the case of the chloro-bridged complexes, only the trisubstituted products are formed, whereas the hydrido-bridged complexes exclusively give rise to mono- and dithiolato derivatives. This is probably due to the lower reactivity of the μ_2-hydrido ligand, relative to that of the μ_2-chloro ligand, which implies no

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

modification of the metal−metal bond during the replacement with a μ_2-thiolato ligand, as is the case for the substitution of a μ_2-hydrido bridge.

As only the disubstituted complexes $[HRu_2(\eta^6\text{-arene})_2\{\mu_2\text{-}(p\text{-}X{-}C_6H_4){-}S\}_2]^+$ (**2**) are accessible from the reaction of $[H_3Ru_2(\eta^6\text{-arene})_2]^+$ or $[H_2Ru_2(\eta^6\text{-arene})_2\{\mu_2\text{-}(p\text{-}X{-}C_6H_4){-}S\}_2]^+$ (**1**) with an excess of $p\text{-}X{-}C_6H_4{-}SH$, the introduction of a third *para*-substituted thiophenyl group seems impossible. In fact, the molecular structures of **2a**, **2c** and **2d** show an important constraint on the two arene ligands due to steric repulsion with the *para*-substituted thiophenyl groups already incorporated (see Figure 1 and Figure 2, selected bond lengths and angles are listed in Table 1), which prevents substitution of the last hydrido ligand by a third thiolato ligand. In addition, the steric hindrance provided by the arene moieties also controls the reactivity of $[H_3Ru_2(\eta^6\text{-arene})_2]^+$ with one equivalent of the *para*-substituted thiophenol. In this case, the ratio of complexes **1** and **2** formed is reversed by making the arene ligands more bulky: 1:4 for $1,2,4,5\text{-}Me_4C_6H_2$ in contrast to 3:1 for C_6Me_6 (see Scheme 1). Similar effects of arene ligands have not been observed so far in the case of $[Ru(\eta^6\text{-arene})Cl_2]_2$ complexes.[10,11] As a consequence, it can be stated that: i) $[Ru(\eta^6\text{-arene})Cl_2]_2$ complexes give only trisubstituted compounds ($[Ru_2(\eta^6\text{-arene})_2\{\mu_2\text{-}(p\text{-}X{-}C_6H_4){-}S\}_3]^+$), while the lower reactivity of $[H_3Ru_2(\eta^6\text{-arene})_2]^+$ leads to the mono- and disubstituted compounds, $[HRu_2(C_6Me_6)_2(p\text{-}X{-}C_6H_4{-}S)_2]^+$ and $[H_2Ru_2(C_6Me_6)_2(p\text{-}X{-}C_6H_4{-}S)]^+$; ii) the ratio between mono- and disubstituted complexes can be tuned by the steric hindrance of the arene substituents in the starting trihydrido complexes. This can be used for the synthesis of multifunctional complexes containing the desired number of functionalized ligands at the periphery.

In order to develop well-defined conjugated polymers possessing dinuclear organometallic entities, we investigated the ability of complex **2a** (substituted by two bromine atoms at its periphery) to react with boronic acid by a Suzuki cross-coupling reaction, as depicted in Scheme 3.



2a 3

Scheme 4. Suzuki cross-coupling reaction of 3-thiophene boronic acid with dibromo complex **2a**

Cation **2a** was found to react with 3-thiophene boronic acid in ethanol in the presence of $Pd(PPh_3)_4$ as a catalyst to give the conjugated complex $[HRu_2(C_6Me_6)_2(p\text{-}C_4H_3S{-}C_6H_4{-}S)_2]^+$ (**3**) with yields ranging from 10 to 15%. We observed the formation of the difunctionalized compounds only. Cation **3** was unambiguously characterized by standard methods (See Experimental Section). This cationic complex, as the tetrafluoroborate salt, is highly soluble in alcohols, acetone and chlorinated solvents. The molecular structure of **3** was confirmed by a single-crystal X-ray structure analysis of the BF_4 salt: the cation maintains the trigonal-bipyramidal HRu_2S_2 framework of its precursor, as shown in Figure 3.

New materials with unique properties should be accessible by this method, because standard organic dibromo reagents (for example 2,5-dibromothiophene, 2,7-dibromofluorene etc.) can be replaced by these organometallic entities. This original approach could lead to the development of

promising materials based on the "zig-zag" design as a result of the disulfur connectivities of the type observed in $[HRu_2(C_6Me_6)_2(p\text{-}Br{-}C_6H_4{-}S)_2][BF_4]$.

Conclusion

In conclusion, we reported the synthesis of dinuclear organometallic entities, based on trigonal-bipyramidal HRu_2S_2 and H_2Ru_2S frameworks. We demonstrated that it is possible to control the functionalization (i.e. insertion of one or two *para*-substituted thiophenyl ligands) by the use of dinuclear trihydrido complexes $[H_3Ru_2(\eta^6\text{-arene})_2]^+$. The dibromo-substituted derivative $[HRu_2(C_6Me_6)_2(p\text{-}Br{-}C_6H_4{-}S)_2]^+$ reacts with 3-thiophene boronic acid by Suzuki cross-couplings to form the conjugated complex $[HRu_2(C_6Me_6)_2(p\text{-}C_4H_3S{-}C_6H_4{-}S)_2]^+$. The development of original and promising conjugated polymers from the dinuclear complexes possessing two bromine substituents at their periphery is currently under investigation.

Experimental Section

General Remarks: All reactions were carried out under a nitrogen atmosphere, by using standard Schlenk techniques, and the solvents were degassed prior to use. The dinuclear trihydrido complexes $[H_3Ru_2(\eta^6\text{-arene})_2]^+$ (arene: C_6Me_6, 1,2,4,5-$Me_4C_6H_2$) were synthesized by previously described methods.[16−18] All other reagents were purchased (Fluka, Acros) and used as received. NMR spectra were recorded on a Varian−Gemini 200 BB instrument and referenced to the signals of the residual protons in the deuterated solvents. The mass spectra were recorded at the University of Fribourg (Switzerland) by Prof. Titus Jenny. Microanalyses were carried out by the Laboratory of Pharmaceutical Chemistry, University of Geneva (Switzerland).

Preparation of $[H_2Ru_2(C_6Me_6)_2(p\text{-}X{-}C_6H_4{-}S)][BF_4]$: The dinuclear trihydrido salt $[H_3Ru_2(C_6Me_6)_2][BF_4]$ (50 mg, 81 μmol) and *p*-bromothiophenol (19 mg, 101 μmol) or *p*-thiocresol (12.5 mg, 101 μmol) were dissolved in degassed technical grade ethanol (60 mL) and heated under reflux for 16 hours. After cooling to room temperature, the purple solution was filtered, and the solvent was evaporated to dryness under reduced pressure. The purple solid was washed with diethyl ether (3 × 20 mL), dissolved in dichloromethane, and isolated by preparative thin-layer chromatography on silica (eluent: acetone/hexane, 1:1, followed by acetone/dichloromethane, 1:50). The purple fraction was recovered to give the product.

$[H_2Ru_2(C_6Me_6)_2(p\text{-}Br{-}C_6H_4{-}S)][BF_4]$ ([1a][BF_4]): Yield: 40%, 26 mg, 32 μmol. Crystals were obtained by diffusion of diethyl ether in a saturated solution of dichloromethane. ^{1}H NMR (200 MHz, [D_6]acetone, 21 °C): δ = −16.69 (d, ^2J = 3 Hz, 1 H, hydride), −13.07 (d, ^2J = 3 Hz, 1 H, hydride), 2.28 (s, 36 H, $C_6(CH_3)_6$], 7.19 (d, ^3J = 8 Hz, 2 H, *H*-Ar), 7.50 (d, ^3J = 8 Hz, 2 H, *H*-Ar) ppm. ^{13}C{^{1}H} NMR (50 MHz, [D6]acetone, 21 °C): δ = 17.3 (Ru−C−CH_3), 95.6 (Ru−*C*−CH_3), 120.8 (*C*−Br), 131.2 (*C*−H Ar), 135.5 (*C*−H Ar), 141.1 (*C*−S) ppm. $[H_2Ru_2(C_6Me_6)_2(p\text{-}Me{-}C_6H_4{-}S)][BF_4]$ ([1b][BF_4]): Yield: 43%, 26 mg, 35 μmol. ^{1}H NMR (200 MHz, [D_6]acetone, 21 °C): δ = −16.75 (d, ^2J = 3.4 Hz, 1H, hydride), −12.88 (d, ^2J = 3.4 Hz, 1H. hydride), 2.26 [s, 36 H, $C_6(CH_3)_6$], 7.09 (d, ^3J = 8.6 Hz, 2 H, *H*-Ar), 7.15 (d, ^3J = 8.6 Hz, 2 H, *H*-Ar) ppm. ^{13}C{^{1}H} NMR (50 MHz, [D_6]acetone, 21 °C): δ = 17.2 (Ru−C−CH_3), 20.4 (S−C_6H_4−CH_3), 95.4 (Ru−*C*−CH_3), 129.0 (*C*-Ar), 133.5 (*C*-Ar), 137.1 (*C*-Ar), 137.6 (*C*−S) ppm. MS (ESI): *m*/*z* = 652 [M^+ + H]. $C_{31}H_{45}BF_4Ru_2S$ (738.7): calcd. C 50.40, H 6.14; found C 50.62, H 6.25.

Preparation of $[H_2Ru_2(1,2,4,5\text{-}Me_4C_6H_2)_2(p\text{-}X{-}C_6H_4{-}S)][BF_4]$: The dinuclear trihydrido salt $[H_3Ru_2(1,2,4,5\text{-}Me_4C_6H_2)_2][BF_4]$ (40 mg, 71 μmol) and *p*-bromothiophenol (14.55 mg, 77 μmol) or *p*-thiocresol (9.56 mg, 77 μmol) were dissolved in degassed technical grade dichloromethane (60 mL) and heated at 50 °C for 16 hours. After cooling to room temperature, the red solution was filtered, and the solvent was evaporated to dryness under reduced pressure. The red solid was washed with diethyl ether (3 × 20 mL), dissolved in dichloromethane, and isolated by preparative thin-layer chromatography on silica (eluent: acetone/hexane 1:1, followed by acetone/dichloromethane, 1:50). The purple fraction was recovered to give the product.

$[H_2Ru_2(1,2,4,5\text{-}Me_4C_6H_2)_2(p\text{-}Br{-}C_6H_4{-}S)][BF_4]$ ([1c][BF_4]): Yield: 6%, 3.2 mg, 4 μmol. ^{1}H NMR (200 MHz, [D_6]acetone, 21 °C): δ = −16.20 (d, ^2J = 2.9 Hz, 1 H, hydride), −12.38 (d, ^2J = 2.9 Hz, 1 H, hydride), 2.13 (s, 12H, ($C_6H_2(CH_3)_4$], 2.35 (s, 12H, ($C_6H_2(CH_3)_4$], 5.93 (s, 4H, *H*-Ar), 7.33 (d, ^3J = 8.5 Hz, 2H, *H*-Ar), 7.45 (d, ^3J = 8.5 Hz, 2H, *H*-Ar) ppm. MS (ESI): *m*/*z* = 661 [M^+ + H]. $C_{26}H_{34}BBrF_4Ru_2S$ (747.46): calcd. C 41.78, H 4.58; found C 41.62, H 4.67.

$[H_2Ru_2(1,2,4,5\text{-}Me_4C_6H_2)_2(p\text{-}Me{-}C_6H_4{-}S)][BF_4]$ ([1d][BF_4]): Yield: 6%, 3 mg, 4 μmol. ^{1}H NMR (200 MHz, [D_6]acetone, 21 °C): δ = −16.35 (d, ^2J = 3.4 Hz, 1 H, hydride), −12.25 (d, ^2J = 3.4 Hz, 1 H, hydride), 2.08 (s, 12H, $C_6H_4(CH_3)_4$], 2.31 (s, 3 H, Ar-CH_3), 2.33 (s, 12H, $C_6H_2(CH_3)_4$], 5.87 (s, 4 H, *H*-Ar), 7.10 (d, ^3J = 7.8 Hz, 2 H, *H*-Ar), 7.21 (d, ^3J = 7.8 Hz, 2 H, *H*-Ar) ppm. MS (ESI): *m*/*z* = 596 [M^+ + H]. $C_{27}H_{37}BF_4Ru_2S$ (682.6): calcd. C 47.51, H 5.46; found C 47.37, H 5.39.

Preparation of $[HRu_2(C_6Me_6)_2(p\text{-}X{-}C_6H_4{-}S)_2][BF_4]$: The dinuclear trihydrido salt $[H_3Ru_2(C_6Me_6)_2][BF_4]$ (60 mg, 97 μmol) and *p*-bromothiophenol (37 mg, 196 μmol) or *p*-thiocresol (24 mg, 196 μmol) were dissolved in degassed technical grade ethanol (60 mL) and heated under reflux for 16 hours. After cooling to room temperature, the red solution was filtered, and the solvent was evaporated to dryness under reduced pressure. The red solid obtained

(15 mL). Sodium carbonate (17 mg, 160 μmol) and tetrakis(triphenylphosphane)palladium (12 mg, 16 μmol) were then added to the solution, which was heated under reflux for four days. After cooling to room temperature, the red-brown solution was filtered, and the solvent was evaporated to dryness under reduced pressure. The red solid was dissolved in dichloromethane and purified by preparative thin-layer chromatography on silica (eluent: acetone/hexane, 1:1, acetone/dichloromethane, 1:50). The red fraction containing the desired product was collected. Yield: 14%, 8 mg, 8 μmol. Crystals were obtained by diffusion of diethyl ether into a saturated solution of dichloromethane. The MS (ESI) spectra shows the molecular peak [M^+ + H] m/z = 910 and two other peaks corresponding to the loss of one and two thienyl groups (m/z = 827, m/z = 744). ^{1}H NMR (200 MHz, [D6]acetone, 21 °C): δ = −11.89 (s, 1 H, hydride), 2.23 [s, 36 H, $C_6(CH_3)_6$], 7.93−7.24 (m, 14 H, S−C_6H_4−C_4H_3S) ppm. for $C_{44}H_{51}BF_4Ru_2S_4$ (997.1): calcd. C 53.00, H 5.16; found C 49.87, H 5.19.

X-ray Crystallographic Study: The data were measured on a Stoe Image Plate Diffraction system equipped with a φ circle, using Mo-K_α graphite-monochromated radiation (λ = 0.71073 Å) with φ range 0−200°, increment ranging from 1.0−1.8°, 2θ range from 2.0−26°, $D_{max}-D_{min}$ = 12.45−0.81 Å. The structures were solved by direct methods with the program SHELXS-97.[19] The refinement and all further calculations were carried out using SHELXL-97.[20] The H-atoms were included in calculated positions and treated as riding atoms with the SHELXL default parameters. The non-H atoms were refined anisotropically, using weighted full-matrix least-square on F^2. Figures were drawn with ORTEP.[21] All crystallographic data are collected in Table 2. CCDC-220959 for [**1a**][BF_4], -220962 for [**2a**][BF_4], -220961 for [**2c**][BF_4], -220960 for [**2d**][BF_4], and -220963 for [**3**][BF_4] contain the supplementary crystallographic data. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk]

Polynuclear and Extended Coordination Compounds from Preorganized Bimetallic Components: Tuning the Magnetic Properties of Dinickel(II) Building Blocks

Guido Leibeling,[a] Serhiy Demeshko,[a] Bernhard Bauer-Siebenlist,[a] Franc Meyer,*[a] and Hans Pritzkow[b]

Keywords: Molecular magnetism / Nickel / Dinuclear complexes / Tetranuclear complexes / Magnetic properties / Azides

Various dinucleating pyrazole ligands with chelating side arms in the 3- and 5-positions of the heterocycle have been shown to form Ni^{II}/azido complexes, where the metal ions are spanned by the pyrazolate, and an azido bridge. Four new complexes have been characterized by X-ray crystallography and variable-temperature magnetic susceptibility studies. The Ni···Ni distance, and hence the intra-dimer coordination mode of the azide (μ-1,1 or μ-1,3), is determined by the chelate arm length, such that the magnetic properties of the bimetallic units can be controlled. The intramolecular coupling between the Ni^{II} (S = 1) ions was found to be ferromagnetic (J = +4.0 ± 0.5 cm^{-1}) in the case of $[L^1Ni_2(N_3)(NO_3)_2]$ (**1**) with a μ-1,1 azide, but antiferromagnetic (J = −25.7 ± 0.3 cm^{-1}) for $[L^2Ni_2(N_3)](ClO_4)_2$ (**2**) with a μ-1,3 azide. Such bimetallic units can serve as building blocks for the construction of high-nuclearity Ni^{II}/azide compounds, as demonstrated for the tetranuclear complexes $[L^1_2Ni_4(\mu\text{-}1,1\text{-}N_3)_2(\mu\text{-}1,3\text{-}N_3)_2](BPh_4)_2$ (**3**), and $[L^3Ni_2(N_3)_3]_2$ (**4**). Complex **3** was obtained by the replacement of the labile nitrates in **1** by additional azido ligands, that bridge the two $[L^1Ni_2(N_3)]^{2+}$ subunits in the μ-1,3 mode. Complex **4** incorporates two additional azides, and two of its azido linkages were found in the rare μ-1,1,3 binding mode (albeit with relatively long Ni–N bond lengths). The magnetic properties of the tetranuclear species were as predicted from the building blocks and the respective azide binding, with ferromagnetic intra-dimer and antiferromagnetic inter-dimer exchanges, yielded an overall S = 0 ground state.

Introduction

Recent years have seen extensive studies of the magnetic properties of polynuclear metal complexes with exchange coupled magnetic centers.[1,2] With the objective of obtaining nanoscale molecular magnets, current activities focus on increasing the nuclearity of single-molecule clusters, that have ground electronic states with a large spin[3] and enhancing the anisotropy of single-molecule type systems.[4] In relation to the latter, nickel(II) is a preferred spin carrier due to its large single-ion zero-field splitting. Also, the flexidentate azido ligand is frequently being used as a bridging ligand, since it provides coordination compounds with great structural variety and efficiently mediates different kinds of magnetic exchange depending on its mode of coordination.[5] The favorable combination of nickel(II) ions and azide ligands has indeed provided a variety of molecular architectures in which the azide normally adopts one of its common bridging modes.[6] These are the μ-1,1 mode (*end-on*, Figure 1), which usually results in ferromagnetic coupling, and the μ-1,3 mode (*end-to-end*), which in most cases gives rise to antiferromagnetic behavior. Other triply or quadruply bridging azide coordination modes such as μ_3-1,1,1, μ_3-1,1,3, μ_4-1,1,1,1 or μ_4-1,1,3,3 have remained relatively scarce,[7−9] although these are of particular interest with respect to the construction of high-nuclearity complexes or polymeric systems.

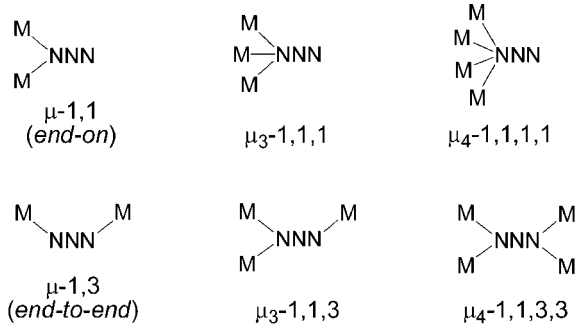

Figure 1. Azide bridging modes

A major task in the rational design of nickel/azide-based coordination compounds with predictable magnetic properties is the control of the azide bridging mode and, even

more demanding, the direct assembly of larger complexes with a desired nuclearity and topology. It is not so long ago, however, that a review article started it would be impossible to synthetically determine which coordination mode of the azide linkage would be adopted.[6] The aim of the present work here is twofold. Firstly, it is demonstrated that the azide binding mode in the bimetallic pocket of a preorganized dinickel(II) array, and hence the magnetic properties of the dinuclear compound, can be selectively altered by appropriate changes to the dinucleating ligand scaffold. Secondly, it is shown that such bimetallic units can serve as building blocks for the targeted construction of tetranuclear species with significant magnetic coupling.

Results and Discussion

Synthesis and Characterization of Complexes

A set of compartmental pyrazolate-based ligands HL^1, HL^2, and HL^3 was chosen as dinucleating scaffolds for this work (Figure 2). These three ligands differ in the number of N-donor sites in their chelate side arms (HL^1 versus HL^3), as well as by the side arm chain length (HL^1 versus HL^2). The latter was previously shown to determine the metal-metal separation in the resultant bimetallic complexes. Whereas the longer ligand side arms in HL^1 allow the metal ions to approach relatively close to distances of about 3.5 Å, the shorter side arms in HL^2 pull the metal ions back and apart, thereby enforcing metal-metal distances above 4 Å.[10] This has drastic consequences for an azide co-ligand accommodated within the bimetallic pocket, since the larger metal-metal separation will necessarily lead to an *end-to-end* coordination, whereas the shorter metal-metal separation should only be suitable for an *end-on* bound azide. Dinickel(II) complexes of the related ligand HL^4 have previously proved valuable as building blocks for the controlled synthesis of structurally alternating 1D chains (*J*-alternating chains),[11,12] with the expected μ-1,3 azide coordination within the bimetallic entities.[12]

These considerations were confirmed by the X-ray crystallographic findings for complexes $[L^1Ni_2(N_3)(NO_3)_2]$ (**1**) and $[L^2Ni_2(N_3)](ClO_4)_2$ (**2**), both of which were obtained in a straightforward manner from the respective ligand, one equivalent of base, one equivalent of NaN_3, and two equivalents of a nickel salt such as $Ni(NO_3)_2{\cdot}6H_2O$ or $Ni(ClO_4)_2{\cdot}6H_2O$. The molecular structures of **1** and of the cation of **2** are depicted in Figure 3 and 4, respectively, along with selected bond distances and angles.

In complex **2**, both nickel ions are nested within their respective coordination compartments, and are five-coordinate (intermediate between TBP-5 and SP-5: τ = 0.60/0.52)[13] with the azide bound in the anticipated *end-to-end* fashion within the bimetallic pocket. While certainly too large to allow for μ-1,1 azide binding, the Ni···Ni distance of 4.421 Å in **2** is still relatively short for a μ-1,3 azide linkage and thus causes the linear azide to tilt severely with respect to the pyrazolate plane. At the same time, the metal ions are forced out of that plane in order to allow for reasonable Ni1−N9−N10 and Ni2−N11−N10 bond angles of 114.8(5)° and 113.8(5)°, respectively. In the absence of geometric constraints by a dinucleating ligand framework, much wider Ni−N−N_{azide} angles are usually observed (>120°). These particular geometric constraints of the [L^2Ni_2] scaffold have previously led to the identification of an extremely bent cyanide coordination within its bimetallic pocket.[14]

In contrast to **2**, the longer ligand side arms in **1** give rise to a much shorter Ni···Ni distance of 3.660 Å. This induces incorporation of the azide in a μ-1,1 mode and a rather relaxed binding situation, as judged from the fact that both nickel ions as well as the azide-N9 centers are located roughly within the plane of the pyrazolate heterocycle. The almost linear azide makes an angle of ≈ 7° with that plane. While the N_3 unit is symmetric in **2** [*d*(N−N) = 1.178(2)/1.179(2) Å], it is distinctly asymmetric in **1** [*d*(N9−N10) = 1.212(2) Å, *d*(N10−N11) = 1.150(2) Å]. Interestingly, the lower stability of the six-membered chelate rings in **1** allows the nitrate anions to displace one side arm donor at each nickel, which is left uncoordinated and dangling. The nitrates are found semi-chelating with one short [2.061(1)/2.070(1) Å], and one much longer [2.350(2)/2.298(1) Å] N−O bond. Unfortunately, we have not been able to grow single crystals of a $[L^1Ni_2(N_3)]^{2+}$ complex with weakly coordinating counterions such as ClO_4^- or BPh_4^-.

Despite the different binding modes of the azide ligands in **1** and **2**, their $\nu_{as}(N_3)$ stretches are similar (Table 1). Binding of the azide and the nitrates in **1** is apparently of comparable strength, since both $[L^1Ni_2(N_3)(NO_3)]^+$ and $[L^1Ni_2(NO_3)_2]^+$ are found as dominant ions in the FAB mass spectrum of the complex. It was thus tempting to provide additional potentially bridging azide ions instead of the nitrates, in order to assemble two (or even more) dinuclear units $[L^1Ni_2(\mu\text{-}1,1\text{-}N_3)]^{2+}$ into larger nickel/azido complexes. A similar strategy has recently been reported to provide tetranuclear nickel(II) complexes from coordinatively unsaturated thiophenolate-based dinickel(II) building blocks or some pyrazolate-based tetranickel(II) complexes with novel azide binding.[9,15] This procedure also proved successful in the present case, since treatment of $[L^1]^-$ with two equivalents of Ni^{2+} and two equivalents NaN_3 gave the tetranuclear species **3**, which could be crystallized as its BPh_4^--salt. The molecular structure of the cation is displayed in Figure 5, along with selected metric parameters.

Table 1. Selected IR absorptions of complexes **1**−**4**, in cm^{-1}

Complex	$\nu_{as}(N_3)$
1	2058 (s)
2	2067 (s)
3	2129 (s), 2064 (m)
4	2103 (s), 2055 (s), 2037 (s)

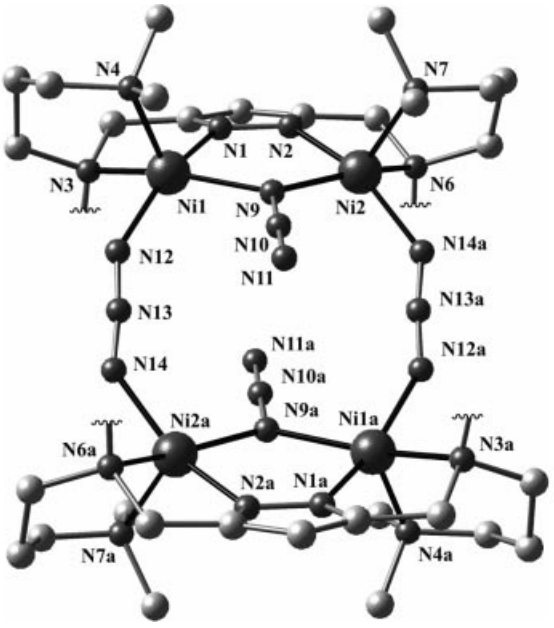

Figure 5. View of the molecular structure of the cation of **3**. In the interests of clarity all hydrogen atoms and the dangling ligand side arms attached to N3 and N6 have been omitted. Selected atom distances (Å) and angles (°): Ni1−N1 1.946(1), Ni1−N12 2.037(2), Ni1−N4 2.064(2), Ni1−N9 2.119(2), Ni1−N3 2.165(2), Ni2−N2 1.945(2), Ni2−N14 2.026(2), Ni2−N7 2.074(2), Ni2−N9 2.120(2), Ni2−N6 2.174(2), Ni1···Ni2 3.639(2), Ni1···Ni2a 5.788(2), Ni1···Ni1a 6.719(2), N9−N10 1.196(2), N10−N11 1.143(2), N12−N13 1.158(2), N13−N14 1.166(2); Ni1−N9−Ni2 118.31(7), N12−N13−N14 174.5(2)

In **3**, two dinuclear $[L^1Ni_2(\mu\text{-}1,1\text{-}N_3)]^{2+}$ entities are linked through two μ-1,3 azide ions to give a rectangular tetranuclear species with crystallographic C_i symmetry. Complex **3** is formally derived from the aggregation of two complexes **1** via replacement of the semi-chelating nitrates by the μ-1,3 bridging azides. Indeed, each pyrazolate-based bimetallic subunit of **3** is basically similar to the dinuclear complex **1** and exhibits a similar Ni···Ni distance [3.639(2) Å], although in this case the nickel and μ-1,1 azide ions are somewhat more displaced out of the plane of the pyrazolate heterocycle and the two dangling side arms are found on the same side of the dinuclear component. The separation of the nickel ions spanned by the μ-1,3-N_3 is 5.788(2) Å. While the μ-1,1 azide is again highly asymmetric [*d*(N9−N10) = 1.196(2) Å versus *d*(N10−N11) = 1.143(2) Å], the μ-1,3 azide is almost symmetric [*d*(N12−N13) = 1.158(2) Å versus *d*(N13−N14) = 1.166(2) Å].

Since one side arm of each ligand coordination compartment remains uncoordinated in **3**, it seemed appropriate to also attempt to employ the related bis(tridentate) ligand

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[L^3]^-$ for the preparation of similar polynuclear complexes. To this end, a tetranickel(II) complex was obtained from the reaction of $[L^3]^-$ with $Ni(ClO_4)_2 \cdot 6H_2O$ and NaN_3. However, in this case the product $[L^3Ni_2(N_3)_3]_2$ (**4**) is neutral due to the coordination of additional azide ions. The structure of **4** was elucidated by X-ray crystallography, and is depicted in Figure 6 together with selected bond distances and bond angles.

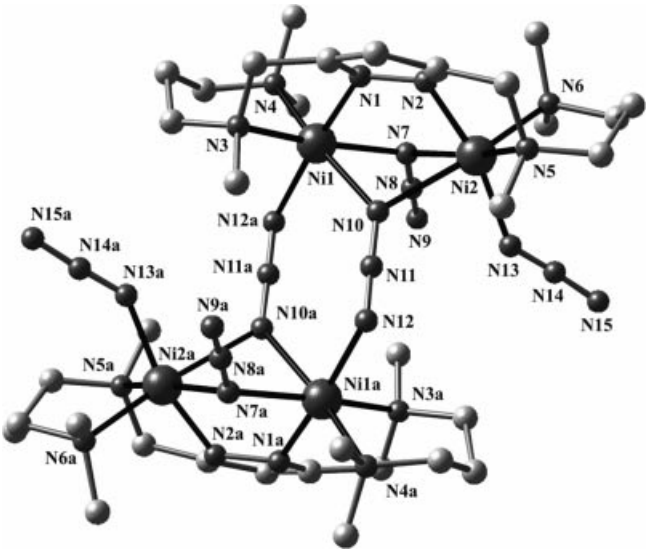

Figure 6. View of the molecular structure of **4**. In the interests of clarity all hydrogen atoms have been omitted. Selected atom distances (Å) and angles (°): Ni1−N1 1.995(3), Ni1−N12a 2.066(3), Ni1−N4 2.141(3), Ni1−N7 2.147(3), Ni1−N3 2.179(3), Ni1−N10 2.310(3), Ni2−N2 2.004(3), Ni2−N13 2.028(3), Ni2−N6 2.128(3), Ni2−N7 2.148(3), Ni2−N5 2.178(3), Ni2−N10 2.443(3), Ni1···Ni2 3.350(3), Ni1···Ni1a 5.358(3), Ni1···Ni2a 5.913(3), N7−N8 1.207(4), N8−N9 1.153(4), N10−N11 1.176(4), N11−N12 1.168(4), N13−N14 1.134(4), N14−N15 1.163(5); Ni1−N7−Ni2 102.49(12), Ni1−N10−Ni2 89.57(10)

Again, complex **4** is composed of two pyrazolate-based dinuclear components $[L^3Ni_2(\mu\text{-}1,1\text{-}N_3)]^{2+}$, that are linked by two further azides. Due to the presence of a fifth and sixth azide, which bind terminally to Ni2, however, the N_3^- group linking the bimetallic subunits is shifted from the μ-1,3 position in **3** to a μ_3-1,1,3 position in **4**. All metal centers are thus six-coordinate in **4** but five-coordinate in **3**. Triply bridging μ_3-1,1,3 azide ions are scarce, and in most cases exhibit two rather long $N_{azide}-M$ bonds,[9,16] as can also be observed in **4** [*d*(Ni1−N10) = 2.310(3) Å and *d*(Ni2−N10) = 2.433(3) Å, in contrast to *d*(Ni1−N12a) = 2.066(3) Å]. Complex **4** enables a comparison to be made of the metric parameters for three different types of N_3^- ligands in a single compound. N−N bond lengths are clearly elongated for the μ-1,1 and μ_3-1,1,3 bridges compared with the terminal N_3^-, and the asymmetry is least pronounced in the μ_3-1,1,3 azide [1.168(4)/1.178(4) Å versus 1.153(4)/1.207(4) Å in the μ-1,1 azide and 1.134(4)/1.163(5) Å for the terminal azide]. It seems reasonable to assign the high-energy IR bands for $\nu_{as}(N_3)$ at 2129 (**3**) and 2103 cm^{-1} (**4**) to the μ-1,1 and μ-1,1,3 azido ligands, respectively (Table 1).

Magnetic Properties

For all complexes, the magnetic susceptibility measurements were carried out at two different magnetic fields in a temperature range from 2.0 K to 295 K (300 K). No significant field dependence was observed for any of the complexes.

The temperature dependence of the magnetic susceptibility χ_M, and of the product $\chi_M T$ for the dinuclear complexes **1** and **2** are shown in Figure 7 and 8, respectively. As would be expected from the different binding modes of the azide bridge, the magnetic properties of the two compounds differ fundamentally. In the case of **1**, the observed $\chi_M T$ value of 2.66 $cm^3 \cdot K \cdot mol^{-1}$ (4.62 μ_B) at room temperature remains nearly constant down to 100 K. Below this temperature $\chi_M T$ gradually increases, reaching a maximum of 3.13 $cm^3 \cdot K \cdot mol^{-1}$ (corresponding to a μ_{eff} value of 5.01 μ_B) at 12 K, indicating ferromagnetic exchange. At even lower temperatures, $\chi_M T$ drops rapidly, which may be due to the effects of zero-field splitting or intermolecular antiferromagnetic interactions.

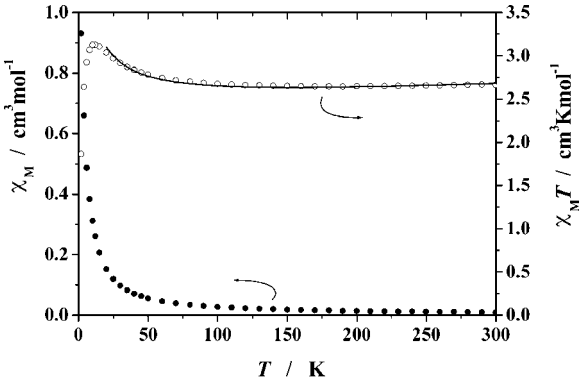

Figure 7. Plot of χ_M (solid circles) and $\chi_M T$ (open circles) vs. *T* for **1** at 2000 G. The solid line represents the calculated curve fit (see text)

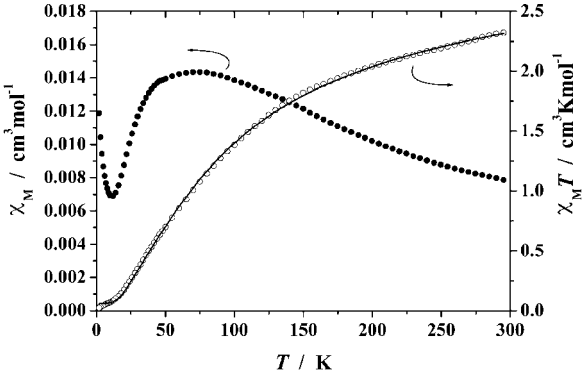

Figure 8. Plot of χ_M (solid circles) and $\chi_M T$ (open circles) vs. *T* for **2** at 2000 G. The solid line represents the calculated curve fit (see text)

The experimental data for **1** were modeled in the range from 300 K to 20 K using Equation (1)[1b] deduced from the Hamiltonian $H = -2JS_1S_2$, with additional terms accounting for small amounts of paramagnetic impurities (ρ), and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for the temperature independent paramagnetism (*TIP*). A satisfactory fit was obtained with the parameters $g = 2.25 \pm 0.01$ and $J = +4.0 \pm 0.5$ cm^{-1} ($\rho = 2\%$, $TIP = 6.0 \times 10^{-4}$ cm^3·mol^{-1}), confirming moderate ferromagnetic coupling. Owing to the likely occurrence of zero-field splitting at low temperatures, however, the magnitude of J should be interpreted with caution.

$$\chi_M = \frac{Ng^2\mu_B{}^2}{kT}\frac{2e^{2(J/kT)} + 10e^{6(J/kT)}}{1 + 3e^{2(J/kT)} + 5e^{6(J/kT)}}(1-\rho) + \frac{2Ng^2\mu_B{}^2}{3kT}\rho + TIP \quad (1)$$

For complex **2** the observed $\chi_M T$ value at 295 K is 2.32 cm^3·K·mol^{-1} (4.31 μ_B). It drops steadily with decreasing temperature, and finally tends to zero, indicating an $S = 0$ ground state. This behavior is typical for dinuclear complexes with intramolecular antiferromagnetic coupling. The experimental magnetic data for **2** were modeled in the range from 295 K to 2 K using Equation (1),[1b] which gives the fit parameters $g = 2.28 \pm 0.02$, $J = -25.7 \pm 0.3$ cm^{-1}, $\rho = 5.7 \pm 0.1\%$, and $TIP = 7.9 \times 10^{-4}$ cm^3·mol^{-1}.

A number of dinuclear nickel(II) complexes with only a single μ-1,3 azido bridge have been characterized magnetically.[17] Two geometric parameters, the angles Ni−N−N and the dihedral angle φ along the azide ligand, are often considered for magnetostructural correlations.[6] For a Ni−N_3−Ni torsion angle of φ = 180°, the antiferromagnetic coupling can be predicted to have a maximum at Ni−N−N angles around 108°, and to decrease at larger angles. On the other hand, for all Ni−N−N angles, the maximum coupling would be expected for a torsion angle of 180°. However, the effect of torsion should be less pronounced than the effect of the bond angle. In the absence of any constraining ligand scaffold, Ni−N−N angles tend to lie in the range 130°−145° with φ = 180°, resulting in J values in the range of −8 to −22 cm^{-1}.[6,18] In view of the very acute Ni−N−N angles (114.8° and 113.7°), and the fact that φ = 55.4° for **2**, a J value even more negative than the lower limit of the above range was thus expected, in good agreement with experimental findings. Although some contribution from the pyrazolate is certainly present, the azide appears to provide the dominant pathway for the antiferromagnetic exchange coupling.

Dinuclear nickel(II) complexes with two *end-on* azido bridges and a {Ni(μ−1,1−N_3)$_2$Ni} central core generally feature Ni−N−Ni angles θ in the narrow range 101−105°, and J values between +13 and +37 cm^{-1}.[6,18] DFT calculations have suggested a clear correlation between the exchange coupling and θ, with the interaction predicted to be ferromagnetic for all the range of θ angles explored.[19] For the {Ni(μ-1,1-N_3)$_2$Ni} core, a maximum is expected when θ ≈ 104°. On the other hand, the out-of-plane displacement of the azide should only have a minor influence. The Ni1−N9−Ni2 angle induced by the dinucleating ligand scaffold in **1** is unusually large [116.12(6)°], and a small J value could thus be expected for the single μ-1,1 azide, in accordance with experimental results. Despite this, and despite a likely antiferromagnetic contribution from the pyrazolate bridge, however, the exchange in **1** is still clearly ferromagnetic.

Complex **3** features a $\chi_M T$-value of 3.89 cm^3·K·mol^{-1} (5.58 μ_B) at 295 K, which is close to the spin-only value expected for four uncoupled $S = 1$ ions (4.00 cm^3·K·mol^{-1} 5.66 μ_B, respectively). Figure 9 shows the temperature dependence of the magnetic susceptibility χ_M and the $\chi_M T$ value at a field of 2000 G. By lowering the temperature $\chi_M T$ decreases, indicating an overall antiferromagnetic coupling between the Ni centers. From the molecular structure we can expect two principal magnetic exchange pathways, one intra-dimer coupling via the pyrazolate and the μ-1,1 azide and an inter-dimer coupling between the subunits, which is mediated by the μ-1,3 azide. The experimental data were analyzed by means of the program MAGMUN[20] in a model based on the isotropic exchange Hamiltonian $H = -2J_1(S_2S_3 + S_1S_4) - 2J_2(S_1S_2 + S_3S_4)$ (**A** in Figure 10). The solid line in Figure 9 represents the best fit with $g = 2.01 \pm 0.01$, $J_1 = -16.2 \pm 0.2$ cm^{-1}, $J_2 = +2.0$ cm^{-1}, $\rho = 2.5\%$, $\Theta = 3.5$ K, and $TIP = 2.0 \times 10^{-4}$ cm^3·mol^{-1}.

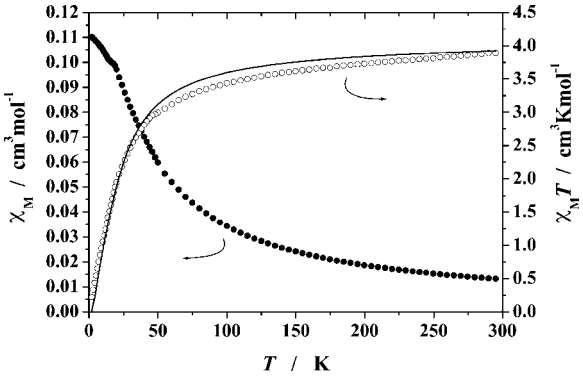

Figure 9. Plot of χ_M (solid circles) and $\chi_M T$ (open circles) vs. T for **3** at 2000 G. The solid line represents the calculated curve fit (see text)

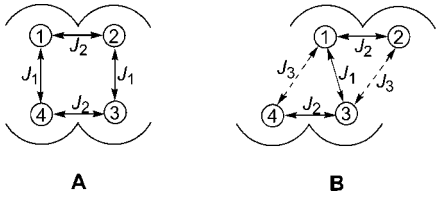

Figure 10. Coupling schemes for **3** (**A**) and **4** (**B**)

In view of the ferromagnetic behavior observed for **1**, it is reasonable to assign J_2 to the coupling within the bimetallic constituents of **3**, and J_1 to the antiferromagnetic inter-dimer exchange mediated by the μ-1,3-N_3 linkages. The intra-dimer coupling is determined by the azide binding mode within the bimetallic pocket and is ferromagnetic as anticipated, its value being of the same order of magnitude as the coupling constant in **1**. Small differences may reflect subtle geometric differences between **1** and the μ-1,1 azido

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bridged building blocks of **3**, in particular the even larger Ni1−N9−Ni2 angle [θ = 118.31(7)°], which is predicted to reduce the ferromagnetic contribution, and the more distinct out-of-plane displacement of the N_3^- ligand in the case of **3**. It should also be noted, that coordination numbers and coordination geometries are quite different for the two dinickel(II) arrays. The inter-dimer antiferromagnetic exchange is in the range expected for a μ-1,3 azide with comparatively wide Ni−N−N angles [141.7(2) and 148.1(2)°] and a torsion of φ = 36.1°.

The $\chi_M T$ value observed for **4** at 295 K is 5.15 $cm^3 \cdot K \cdot mol^{-1}$ (6.42 μ_B). Figure 11 depicts a plot of the temperature dependence of χ_M and $\chi_M T$ at 2000 G. With respect to the topology of **4**, a three-*J* coupling scheme sketched in Figure 10 (**B**) applies. Considering the very long Ni2−N10 bond lengths for the central μ-1,1,3 azido linkages, however, it is reasonable to approximate J_3 as negligible, and that a two-*J* model is adequate for a qualitative analysis of the data. Fitting was carried out with the program MAGMUN[20] based on the isotropic exchange Hamiltonian $H = -2J_1(S_1S_3) - 2J_2(S_1S_2 + S_3S_4)$ (corresponding to **B** and $J_3 = 0$, Figure 10) to give $g = 2.29 \pm 0.02$, $J_1 = -19.7 \pm 0.8$ cm^{-1}, $J_2 = +6.0$ cm^{-1} $\rho = 3.0\%$, $\Theta = 1.8$ K, and $TIP = 3.6 \times 10^{-4}$ $cm^3 \cdot mol^{-1}$ (solid line in Figure 8).

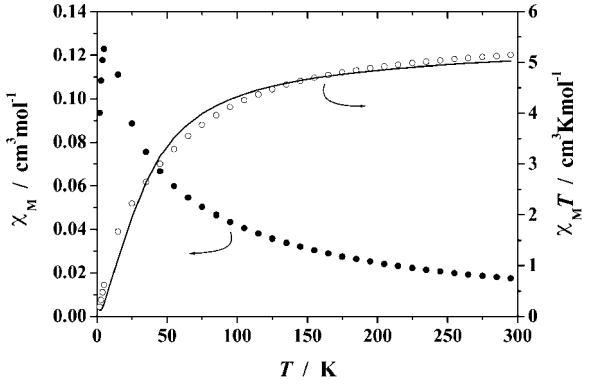

Figure 11. Plot of χ_M (solid circles) and $\chi_M T$ (open circles) vs. *T* for **4** at 2000 G. The solid line represents the calculated curve fit (see text)

Similar to the case of **3**, it would seem appropriate to assign J_2 to the intra-dimer exchange, which is expected to be ferromagnetic, while J_1 should reflect the antiferromagnetic interaction between the two pyrazolate-based subunits. The J_1 value is a little more negative than in the case of **3**, in accordance with the somewhat more acute Ni−N−N angles [Ni1a−N12−N11: 127.4(2)°; Ni1−N10−N11: 133.9(2)°], which are assumed to be the most relevant magnetostructural parameters for a μ-1,3 azido bridge.[6] Likewise, the larger ferromagnetic intra-dimer exchange in **4** may be traced to the much more acute Ni−N−Ni angle for the μ-1,1 azide [Ni1−N7−Ni2: 102.5(1) in **4**].

Conclusion

The present study has established well defined pyrazolate-based dinickel(II) azido complexes as building blocks for the construction of high nuclearity nickel/azido systems. A particular advantage of these compounds is the possibility of tuning the magnetic properties of the bimetallic components, since their spin ground state ($S = 0$ or $S = 2$) is determined by the intra-dimer azide bridging mode, which can be controlled by suitable modifications of the ligand scaffold. Some tetranuclear complexes that arise from the assembly of two Ni_2 subunits are reported in this work as examples. The magnetic exchange within the Ni_2 subunits of the new Ni_4 species is as anticipated and is basically governed by the choice of the building blocks (i.e. ferromagnetic exchange in **1** as well as in **3** and **4**). However, the magnitude of the coupling may differ somewhat, since subtle geometric changes in the subunits occur upon linking the Ni_2 species to give high-nuclearity $\{Ni_2\}_n$ compounds, which represents a general limitation to the prediction of magnetic properties of polynuclear complexes from the magnetic properties of their constituents. Future work will focus on, inter alia, increasing the rigidity of the bimetallic entities and strategies to more efficiently control the linking of the building blocks. In view of the great variety of available dinucleating pyrazolate ligands, we expect a wide range of new oligonuclear and 1D-chain nickel(II) azido systems to be accessible via this precursor based approach.

Experimental Section

Caution! *Although no problems were encountered in this work, transition metal perchlorate and azide complexes are potentially explosive, and should be handled with proper precautions.*

General: Ligands HL^1, HL^2, and HL^3 were prepared as described previously.[10a,21] HPLC grade methanol (CHROMASOLV) was obtained from Riedel-de-Haen. Solvents were dried by established processes. All other chemicals were purchased from commercial sources and used as received. Microanalyses were performed by the Analytisches Labor des Anorganisch-Chemischen Instituts der Universität Göttingen. IR spectra: Digilab Excalibur, recorded as KBr pellets. Mass spectra: Finnigan MAT 95 (FAB-MS). The susceptibility measurements were carried out with a Quantum-Design MPMS-5S SQUID magnetometer equipped with a 5 Tesla magnet in the range of 2 to 300 K. The powdered samples were contained in a gel bucket and fixed in a non-magnetic sample holder. Each raw data file for the measured magnetic moment was corrected for the diamagnetic contribution of the sample holder and the gel bucket. The molar susceptibilities were corrected using the Pascal constant and the increment method according to Haberditzl.[22]

Synthesis of $[L^1Ni_2(\mu\text{-}1,1\text{-}N_3)(NO_3)_2]$ (1): A solution of HL^1 (190 mg, 0.41 mmol) in MeOH (70 mL) was treated with one equivalent of KO*t*Bu (45.7 mg, 0.41 mmol), two equivalents of $Ni(NO_3)2{\cdot}6H_2O$ (236.8 mg, 0.81 mmol), and one equivalent of sodium azide (26.5 mg, 0.41 mmol), and the reaction mixture was stirred at room temperature for 12 h. All volatile materials were then evaporated under reduced pressure and the residue taken up in acetone (60 mL). After filtration, the solution was layered with

light petroleum to yield green crystals (194 mg, 63%) of the product **1**. MS (FAB+): *m/z* (rel. intensity) = 705 (25) $[L^1Ni_2(NO_3)_2]^+$, 685 (60) $[L^1Ni_2(N_3)(NO_3)]^+$, 665 (25) $[L^1Ni_2(N_3)_2]^+$, 623 (15) $[L^1Ni_2(N_3)]^+$. IR (KBr): $\tilde{\nu}$ = 2939 (w), 2860 (w), 2819 (w), 2767 (w), 2058 (s), 1479 (m), 1385 (vs), 1284 (m), 1234 (w), 1188(w), 1040 (w), 1021(w), 981 (w), 832 (w) cm^{-1}. $C_{25}H_{53}N_{13}Ni_2O_6$ (749.2): calcd. C 40.08, H 7.13, N 24.31; found C 40.28, H 7.23, N 24.78.

Synthesis of $[L^2Ni_2(\mu\text{-}1,3\text{-}N_3)](ClO_4)_2$ (2): A solution of HL^2 (149 mg, 0.285 mmol) in MeOH (70 mL) was treated with one equivalent of KO*t*Bu (32.0 mg, 0.285 mmol), two equivalents of $Ni(ClO_4)2{\cdot}6H_2O$ (208.4 mg, 0.570 mmol), and one equivalent of sodium azide (18.5 mg, 0.285 mmol), and the reaction mixture was stirred at room temperature for 12 h. All volatile materials were then evaporated under reduced pressure and the residue taken up in acetone (50 mL). After filtration the solution was layered with light petroleum to yield green crystals (216 mg, 86%) of the product **2**. MS (FAB+): *m/z* (rel. intensity) = 778 (25) $[L^2Ni_2(N_3)(ClO_4)]^+$, 679 (50) $[L^2Ni_2(N_3)]^+$. IR (KBr): $\tilde{\nu}$ = 2984 (w), 2946 (w), 2884 (w), 2067 (s), 1459 (w), 1388 (w), 1315 (w), 1263 (w), 1092 (vs), 914 (w), 797 (w), 736 (w), 624 (m) cm^{-1}. $C_{29}H_{61}Cl_2N_{11}Ni_2O_8$ (880.2): calcd. C 39.57, H 6.99, N 17.51; found C 39.65, H 7.10, N 17.51.

Synthesis of $[L^1_2Ni_4(\mu\text{-}1,1\text{-}N_3)_2(\mu\text{-}1,3\text{-}N_3)_2](BPh_4)_2{\cdot}2C_3H_6O$ (3·2C_3H_6O): A solution of HL^1 (180 mg, 0.386 mmol) in MeOH (70 mL) was treated with one equivalent of KO*t*Bu (43.3 mg, 0.386 mmol), two equivalents of $Ni(ClO_4)_2{\cdot}6H_2O$ (282.1 mg, 0.771 mmol) and two equivalents of sodium azide (50.2 mg, 0.771 mmol) and was stirred at room temperature for 12 h. All volatile materials were then evaporated under reduced pressure, the residue taken up in ethanol (100 mL), and sodium tetraphenylborate (264 mg, 0.771 mmol) was added. The resultant precipitate was separated by filtration and taken up in acetone (60 mL). The solution was again filtered, and then layered with light petroleum to gradually yield some green crystals (76 mg, 20%) of the product **3**. MS (FAB+): *m/z* (rel. intensity) = 1649 (5) $[L^1_2Ni_4(N_3)_4(BPh_4)]^+$, 665 (100) $[L^1Ni_2(N_3)_2]^+$, 623 (35) $[L^1Ni_2(N_3)]^+$. IR (KBr): $\tilde{\nu}$ = 2964 (m), 2923 (m), 2859 (w), 2129 (s), 2064 (m), 1460 (m), 1384 (s), 1261 (s), 1097 (s), 1032 (s), 803 (s), 732 (w), 703 (w), 612 (w) cm^{-1}. $C_{104}H_{158}B_2N_{28}Ni_4O_2$ (2089.0): calcd. C 59.80, H 7.62, N 18.77; found C 56.42, H 7.18, N 17.68.

Synthesis of $[L^3Ni_2(N_3)_3]_2{\cdot}2CH_2Cl_2$ (4·2CH_2Cl_2): A solution of HL^3 (255 mg, 0.786 mmol) in MeOH (20 mL) was treated with one equivalent of KO*t*Bu (92.7 mg, 0.786 mmol) and two equivalents of $Ni(ClO_4)_2{\cdot}6H_2O$ (580.7 mg, 1.572 mmol). After stirring the mixture for 30 min at room temperature the solution was evaporated to dryness and the residue was taken up in acetone (25 mL). NaN_3 (154.8 mg, 2.358 mmol) was added, and the reaction mixture was stirred for a further 24 h. The green precipitate was separated by filtration then dissolved in dichloromethane (25 mL). Layering the solution with light petroleum (boiling range 40−60 °C, 75 mL) afforded green crystals of the product **4** (148 mg, 29%). MS (FAB+): *m/z* (rel. intensity) = 1088 (16) $[L^3_2Ni_4(N_3)_5]^+$, 523 (100) $[L^3Ni_2(N_3)_2]^+$, 423 (12) $[L^3Ni(N_3)]^+$. IR (KBr): $\tilde{\nu}$ = 3011 (w), 2967 (w), 2909 (w), 2864 (w), 2103 (vs), 2055 (vs), 2037 (vs), 1650 (w), 1472 (m), 1458 (m), 1030 (m), 1009 (w), 826 (w), 669 (w) cm^{-1}. $C_{36}H_{74}Cl_4N_{30}Ni_4$ (1303.8): calcd. C 33.17, H 5.72, N 32.23; found C 33.59, H 5.78, N 32.50.

X-ray Crystallographic Studies: Data collection was carried out with a Bruker AXS CCD diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Structures were solved by direct methods (SHELXS-97) and refined by full-matrix least-

Synthesis and Molecular Structure of Calcium Difluoranthenide, $[Ca(THF)_6][C_{16}H_{10}]_2 \cdot 2C_{16}H_{10}$

Igor L. Fedushkin,*[a] Anton N. Lukoyanov,[a] Sebastian Dechert,[b] and Herbert Schumann*[b]

Dedicated to Prof. Mikhail N. Bochkarev on the occasion of his 65th birthday

Keywords: Calcium / Fluoranthene / Radical-anion / Structure elucidation

The treatment of $CaI_2(THF)_2$ with potassium and fluoranthene (mole ratio 1:2:2) in THF affords $[Ca(THF)_6][C_{16}H_{10}]_2 \cdot 2C_{16}H_{10}$ (**1**). The X-ray structure analysis of **1** shows that the compound consists of separate $[Ca(THF)_6]^{2+}$ cations, $[C_{16}H_{10}]^{\cdot-}$ radical anions and neutral fluoranthene molecules. The neutral and radical-anionic fluoranthene species can be distinguished by the differences in the skeleton C–C bond lengths. The presence of fluoranthene radical anions in THF solutions of **1** is proved by ESR spectroscopy and is further supported by the ^1H NMR spectrum of **1**, which does not give any indication of radical coupling.

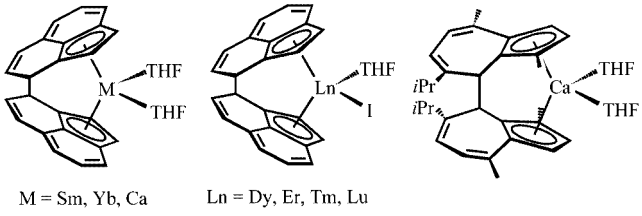
Introduction

ansa-Metallocenes are an important class of organometallic compounds, which serve as versatile reagents for a number of organic-substrate transformations, especially for the polymerization of α-olefins.[1] In 2001, we reported on *ansa*-metallocenes of the type $(\eta^5{:}\eta^5\text{-}C_{24}H_{16})M(THF)_2$ (where M = Yb,[2] Sm,[2] Ca[3]), formed by reduction of acenaphthylene with the respective metals or their naphthalenides, $[C_{10}H_8]M(THF)_2$. The calcium derivative can also be prepared by treating $CaI_2(THF)_2$ with potassium and acenaphthylene,[4] and, quite recently, we succeeded in the preparation of the *ansa*-calcocene $(\eta^5{:}\eta^5\text{-}C_{15}H_{18})_2Ca(THF)_2$ from $CaI_2(THF)_2$, potassium, and guaiazulene.[5] (Acenaphthylene)lanthanide(III) complexes $(\eta^5{:}\eta^5\text{-}C_{24}H_{16})LnI(THF)$ (where Ln = Dy, Er, Tm, Lu) were prepared by treating $LnI_3(THF)_3$ with 2 equiv. of potassium and 2 equiv. of acenaphthylene in THF.[4] These results show that the radical anions of the nonalternating hydrocarbons (acenaphthylene and guaiazulene), initially formed in these reactions, combine diastereoselectively to give C_2-symmetric *ansa*-ligands (see Scheme 1).



M = Sm, Yb, Ca Ln = Dy, Er, Tm, Lu

Scheme 1

Since the first and the second reduction potentials of fluoranthene (−1.77 and −2.18 V), a nonalternating hydrocarbon, compare well with those of acenaphthylene (−1.63 and −1.85 V) and guaiazulene (−1.65 and −2.45 V),[6] we investigated the reaction of $CaI_2(THF)_2$ with potassium and fluoranthene, in order to find out whether the hydrocarbons would be reduced to mono-valent radical anions and whether the latter would combine to form a two-valent *ansa*-ligand, coordinating the calcium ion.

Results and Discussion

Synthesis

The one-pot reaction of calcium diiodide with potassium and fluoranthene in a mole ratio of 1:2:2 in THF proceeds smoothly and within two hours produces a dark red-brown suspension. The compound $[Ca(THF)_6][C_{16}H_{10}]_2 \cdot 2C_{16}H_{10}$ (**1**) was isolated in 87 % yield [calculated for Ca on the basis

of the stoichiometry of Equation (1)] from the solution obtained after separation of the potassium iodide and of a dark coloured solid formed in the reaction. The deep red, almost black crystals of **1** melt with decomposition at 148 °C. The formulation of **1** as calcium difluoranthenide containing separate, THF-coordinated calcium cations and fluoranthene radical anions is justified by the spectroscopic and structural properties of **1**, described below. Considering the composition of **1** on the one hand and the stoichiometry of the reagents used for its synthesis on the other hand, one is lead to suggest that, in the course of the reaction, a partial disproportionation of the fluoranthene radical anions into neutral fluoranthene and fluoranthene dianions also take place and we assume that the dark coloured solid precipitating from the reaction mixture, along with the potassium iodide, is probably the calcium fluoranthenide $[Ca(THF)_x][C_{16}H_{10}]$ [see Equation (1)]. Similar observations have been made in the reactions of radical anions of naphthalene with calcium diiodide or lanthanide halides.[4,7] However, in these reactions the disproportionation to naphthalene and naphthalene dianions was almost complete and no calcium or lanthanide compounds containing naphthalene radical anions were isolated.

$$3\ CaI_2(THF)_2 + 6\ K + 6\ C_{16}H_{10} \xrightarrow[-\ 6\ KI]{THF} \underset{\mathbf{1}}{[Ca(THF)_6][C_{16}H_{10}]_2 \cdot 2\ C_{16}H_{10}} + 2\ [Ca(THF)_x][C_{16}H_{10}] \quad (1)$$

The IR spectrum of **1** shows absorptions at 1015 and 865 cm^{-1}, indicating the presence of coordinated THF molecules. The most intense absorptions appear at 785 and 730 cm^{-1} and can be assigned to the aromatic C−H stretching vibrations of the fluoranthene radical anions. The corresponding vibrations of neutral fluoranthene appear at 775 and 735 cm^{-1}.

The ^1H NMR spectrum of **1** shows only the broadened signals of THF. However, the ^1H NMR spectrum of the *ansa*-acenaphthylene complex, $(\eta^5{:}\eta^5\text{-}C_{24}H_{16})Ca(THF)_2$,[4] shows along with the THF signals, the expected eight signals for the ring protons of the *ansa*-ligand.

The assumption that compound **1** is paramagnetic, due to the presence of uni-negative fluoranthene radical anions is confirmed by the ESR spectrum. The spectrum of a solution of **1** in THF shows an ESR signal [g = 2.0029; A_H = 0.008 (2H), 0.017 (2H), 0.121 (2H), 0.390 (2H) and 0.520 (2H) mT], which corresponds to the signal reported by Gerson et al.[8] for the fluoranthene radical anion. Solutions of the above-mentioned *ansa*-acenaphthylene complex $(\eta^5{:}\eta^5\text{-}C_{24}H_{16})Ca(THF)_2$ in THF also show an ESR signal, although a very weak one, due to partial dissociation of the *ansa*-ligand into radical anions. However, the presence of such small amounts of paramagnetic radical anions does not seem to affect the ^1H NMR spectroscopy behaviour of this complex.

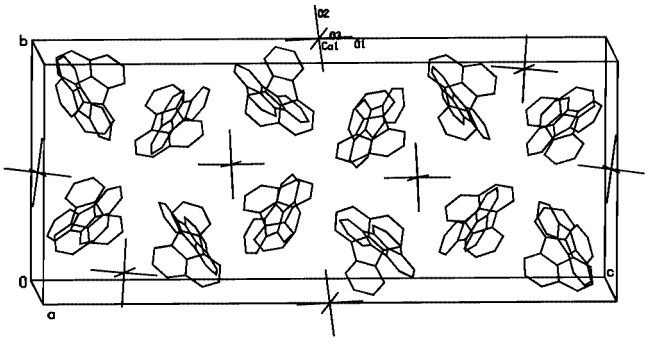

Figure 1. Crystal packing in **1**

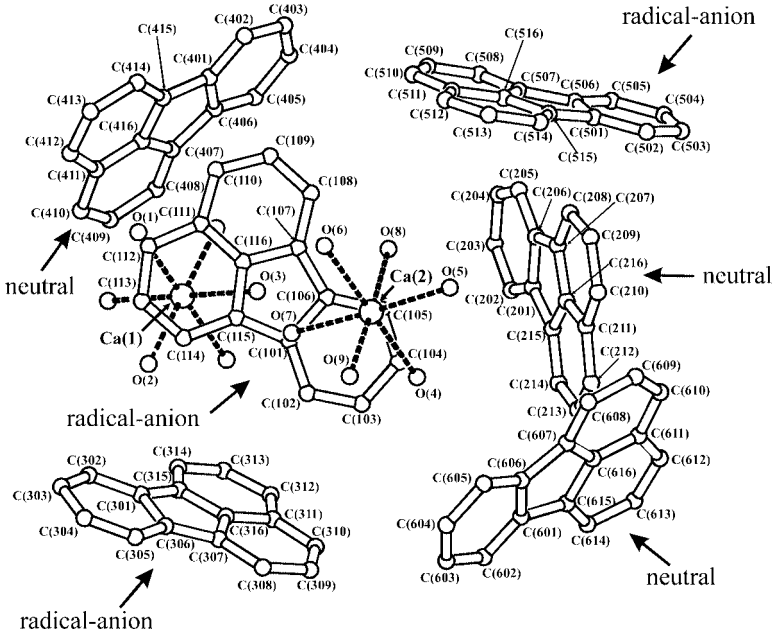

Figure 2. Molecular structure of **1**; the hydrogen atoms as well as the carbon atoms of THF are omitted for clarity

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Thus, the spectroscopic data of **1** clearly demonstrate that, in contrast to our initial expectation, the radical anions of fluoranthene formed in the reduction reaction do not couple to give the corresponding *ansa*-ligand.

Molecular Structure

To determine the "non-metallocene" structure of **1**, the X-ray structure analysis of a crystal grown from THF was carried out. Compound **1** crystallizes in the monoclinic space group $P2_1/n$. Figure 1 shows the crystal packing. The asymmetric unit of **1** (see Figure 2) consists of 1.5 solvated $[Ca(THF)_6]^{2+}$ cations, three radical-anionic, and three neutral fluoranthene species. One cation occupies only general positions, whereas the metal atom of the second cation resides on a centre of inversion. Each calcium atom is surrounded by six coordinating THF molecules in an almost regular, octahedral fashion with virtually identical $Ca-O_{THF}$ distances, which range from 2.325(3) to 2.341(3) Å.

To decide which of the six fluoranthene molecules in the asymmetric unit are the radical anions, an accurate analysis of their skeleton C−C bond lengths, with respect to the symmetry of the ligand boundary molecular orbitals, was carried out (see Figure 3). The C(6)−C(7) and C(1)−C(15) bonds of three molecules show the most significant differences. Since the HOMO of the radical anion is of bonding character, it seems reasonable to assign the fluoranthene molecules with the shortest C(6)−C(7) and C(1)−C(15) bonds as the radical anions. The shorter C(1)−C(6) bond lengths of the other three molecules thus declared the neutral fluoranthene molecules [1.406(7), 1.409(7) and 1.428(7) Å], agree quite well with the length of the corresponding bond in the free ligand (1.40 Å) and in the silver complex $[Ag_3(C_{16}H_{10})(ClO_4)_3]$ (1.40 Å).[9]

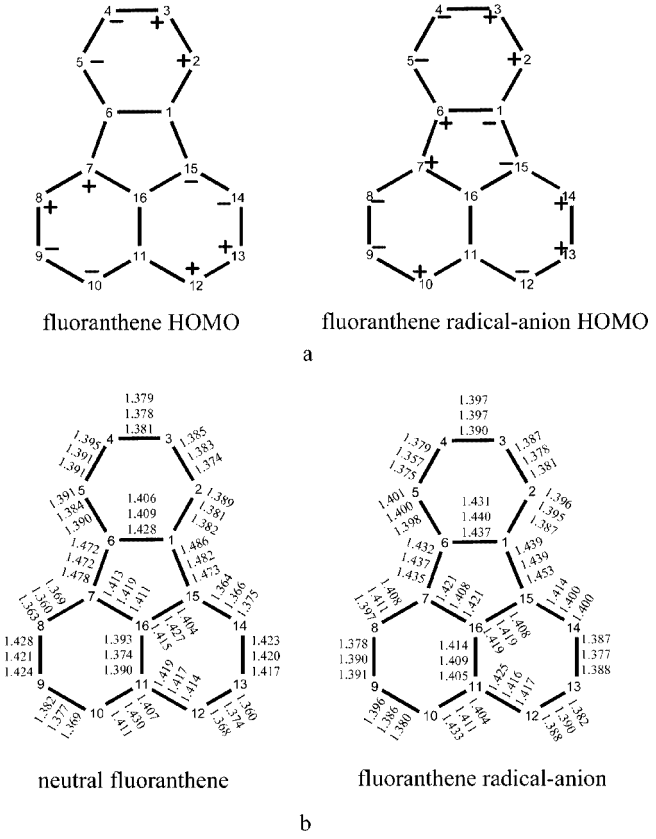

Figure 3. Molecular symmetry of the HOMO of fluoranthene and of its radical anion (a); C−C bond lengths of the fluoranthene moieties in the asymmetric unit of **1** (b)

Conclusion

In contrast to the radical anions of acenaphthylene and guaiazulene, the radical anions of fluoranthene do not dimerize to form twofold negatively charged *ansa*-ligands, under the same reaction conditions. This behaviour can be attributed to the fact that the negative charge is not strongly localized on the five-membered ring unit of the fluoranthene radical anion, thus preventing the formation of a metal-coordinating cyclopentadienyl-like π-system. On the contrary, the negative charge is delocalized over the whole ring system of the radical anion. Furthermore, in contrast to the dimerizing radical anions of acenaphthylene and guaiazulene, the radical anions of fluoranthene tend to disproportionate into neutral ligands and dianionic species.

Experimental Section

General Remarks: All manipulations were carried out under vacuum using Schlenk ampoules. The solvent THF was distilled from sodium benzophenone prior to use. Fluoranthene was purchased from Aldrich and used without further purification. The melting point of **1** was measured in a sealed capillary. IR spectra were recorded on a Specord M80 spectrometer, ESR spectra on a Bruker ER 200D-SRC spectrometer equipped with the low-temperature controller ER 4111 VT. The ESR signal was referenced to the signal of diphenylpycrylhydrazil (DPPH, $g = 2.0037$).

$[Ca(THF)_6][C_{16}H_{10}]_2 \cdot 2C_{16}H_{10}$ (1): A mixture of $CaI_2(THF)_2$ (3.65 g, 8.3 mmol), potassium (0.65 g, 16.6 mmol), and fluoranthene (3.36 g, 16.6 mmol) in THF (40 mL) was stirred for 2 hours. Within this time frame, the potassium had dissolved completely and the mixture had turned dark red-brown with the precipitation of potassium iodide and of a dark coloured solid. After separation of the solids by filtration, the THF was removed in vacuo and the residue was dried in vacuo at ambient temperature for 30 min. Then THF (40 mL) was added to the dried solid and the insoluble parts were filtered off. Reduction of the solution volume, by partial evaporation of the solvent in vacuo, caused precipitation of crystals, which were redissolved by heating the mixture to 60 °C. After standing the solution at room temperature for 24 hours, large black crystals of **1** separated. Yield 3.1 g (87 %). M.p. 148 °C(dec). IR (Nujol): 1505 m, 1430 s, 1380 m, 1445 w, 1290 s, 1215 m, 1165 s, 1130 m, 1080 m, 1115 vs, 1015 vs, 915 w, 865 vs, 830 m, 785 vs, 730 vs, 670 w, 615 m cm^{-1}. The extremely high air sensitivity of **1** prevented its analytical characterization.

Single-Crystal X-ray Structure Determination of 1: The crystal data and details of data collection are given in Table 1. The data were collected on a SMART CCD diffractometer (graphite-monochromated Mo-K_α radiation, ω-scan technique, $\lambda = 0.71073$ Å) at −100 °C. The structure was solved by direct methods using SHELXS-

Reactivity Studies on 2,3,4,5-Tetraethyl-1,6-diiodo-2,3,4,5-tetracarba-*nido*-hexaborane(6): Synthesis and Structures of New C_4B_2 *nido*-Carborane Derivatives

Yong Nie,[a] Hans Pritzkow,[a] and Walter Siebert*[a]

Dedicated to Professor Manfred T. Reetz on the occasion of his 60th birthday

Keywords: Boron / Carboranes / Nucleophilic substitution / Iron / Cobalt

The reactivity of the title compound 2,3,4,5-tetraethyl-1,6-diiodo-2,3,4,5-tetracarba-*nido*-hexaborane(6) (**1**) towards a variety of nucleophiles is reported. When **1** is treated with RC_2Li (R = Ph, *t*Bu, $SiMe_3$, *p*-tolyl) and Ph_2PLi, the corresponding new C_4B_2 *nido*-carborane derivatives **2a**–**d** and **3**, respectively, are obtained by selective substitution at the basal B–I group, whereas the apical B–I bond remains inert. The reaction of **1** with $K[(\eta^5\text{-}C_5H_5)Fe(CO)_2]$ affords the novel species **4**, which contains a $CpFe(CO)_2$ fragment σ-bonded to the basal boron atom of the C_4B_2 cluster. Attempts to isolate **4** by chromatography on silica gel led to cleavage of the Fe–B bond and formation of compound **5**, containing a basal BH vertex, which can be separately prepared by the reaction of **1** and $LiBEt_3H$. In the reactions of **1** with PhLi and Me_3SnLi, respectively, **6a** and **7a** are formed as the predominant B6-substituted carborane products. In addition, trace amounts of 1,6-disubstituted species **6b** and **7b** are also detected. The substitution at the apical B–I group in **2a** with an alkynyl group is effected by a Pd^0-catalyzed Negishi-type cross-coupling reaction to give compound **8**. The reaction of **1** and monolithio-*o*-carborane affords the C_4B_2–C_2B_{10} carborane **10**, while the reaction of **2a** and $Co_2(CO)_8$ furnishes the double cluster **9** (C_4B_2–C_2Co_2). In both **9** and **10** two different types of clusters are directly connected by a B–C bond. Compound **1** reacts with $ClZnC_6H_4C_6H_4ZnCl$ in the presence of the catalyst $Pd(PPh_3)_4$ to give **11**, in which two C_4B_2 clusters are linked by a $C_6H_4C_6H_4$ unit. The constitutions of the products follow from spectroscopic data, and X-ray diffraction analyses for **2a**, **2d**, **4**, **8**, **9**, and **10**.

Introduction

Although peralkylated 2,3,4,5-tetracarba-*nido*-hexaboranes(6)[1] are more stable than the parent compound $C_4B_2H_6$,[2] and are readily available by a variety of methods, their reactivity has only recently been studied.[3,4] To investigate substitution reactions in C_4B_2 *nido*-carboranes, functional groups at the boron atom(s) other than alkyl groups are needed. Wrackmeyer et al. were able to obtain 1,6-dibromo-2,3,4,5-tetracarba-*nido*-hexaboranes(6)[3a] by treating 1,4,6,9-tetraalkyl-3,8-diethyl-2,7-bis(diethylboryl)-5-stannaspiro[4.4]nona-1,3,6,8-tetraenes with BBr_3. They also studied the reaction between peralkylated 2,3,4,5-tetracarba-*nido*-hexaboranes(6) and an excess of BBr_3, whereby the corresponding B6-bromo-substituted carboranes were formed.[3b] Nucleophiles were found to replace the basal B6-bromo atom to give the corresponding carboranes with organyl,[3c] stannyl,[3d] diphenylphosphanyl[3e] as well as the *N*-bonded $(\mu\text{-NS})Fe_2(CO)_6$ [3f] group. In the 1,6-dibromo case, substitution with the *N*-bonded $(\mu\text{-NS})Fe_2(CO)_6$ cluster took place at the basal B−Br bond, an excess of the nucleophile did not induce additional substitution at the 1-position.[3f]

Berndt et al.[4] have reported that the reduction of *nido*-$(Me_3SiC)_2(CH)_2(BtBu)_2$ with Li in tetrahydrofuran affords a novel 1,3-diborabenzene anion, which could in turn be oxidized to give the starting carborane in refluxing 1,2-dibromoethane. As part of reactivity studies, we have reported transition metal derivatives of a benzo-C_4B_2 *nido*-carborane compound[5a] with metal complex fragments coordinated to the benzene ring.[5b] Very recently we have developed a convenient one-pot synthesis of 2,3,4,5-tetraalkyl-1,6-diiodo-2,3,4,5-tetracarba-*nido*-hexaborane(6) derivatives,[6] involving disubstituted alkynes, BI_3 and $NaK_{2.8}$. In this paper, we report the reactivity of the title compound **1** towards a variety of nucleophiles, and characterization of the resulting new carboranes.

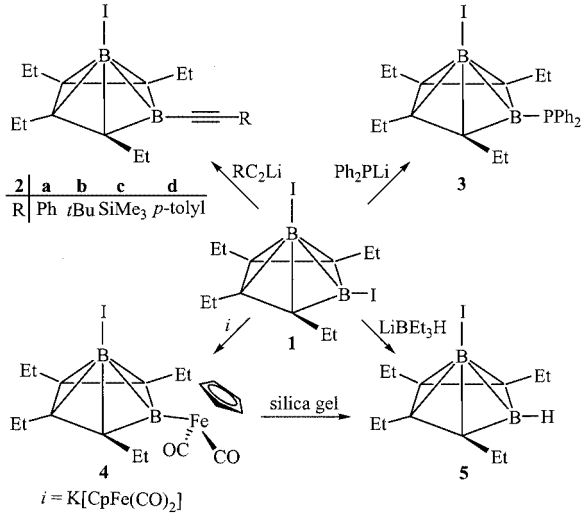
Results and Discussion

Regiospecific Substitution at the Basal Boron Atom

Nucleophilic substitution reactions of **1** with RC_2Li (R = Ph, *t*Bu, $SiMe_3$, *p*-tolyl) proceed smoothly, and the corresponding basal-boron-substituted carborane derivatives **2a**–**d** were produced in high yields (Scheme 1). The *nido*-C_4B_2 framework is retained, as little differences have been found in the ^1H and ^{13}C NMR spectra when compared with that of **1**. In the ^{11}B NMR spectra, the basal boron atoms give rise to signals at δ = 9.8–10.9 ppm, which are only slightly shifted downfield from that of **1** (δ = 5.5 ppm), while the shifts of the signals for the apical boron atoms are the same as that for **1** (δ = −52.5 ppm).



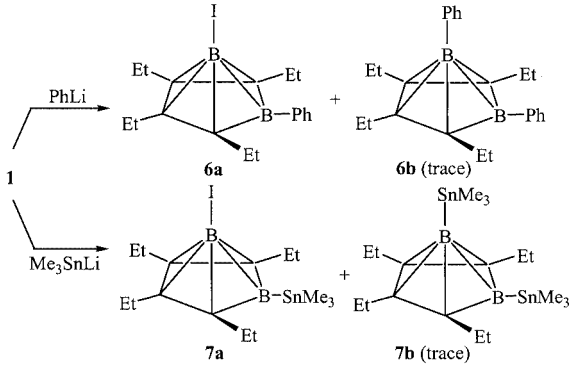
Scheme 1

X-ray structure analyses of **2a** and **2d** confirm the spectroscopic results. In agreement with Herberhold, Wrackmeyer et al.,[3f] an excess of lithium acetylide did not effect additional substitution at the apical boron atoms. Similar results are observed in the reactions of **1** with Ph_2PLi and $K[(\eta^5\text{-}C_5H_5)Fe(CO)_2]$ to give **3** and **4**, respectively, with regiospecific substitution at the basal position. In the ^{11}B NMR spectrum of **3**, the signal of the basal boron atom is shifted downfield by about 9 ppm, while the apical boron atom is unaffected. In the case of **4**, the basal boron atom of the C_4B_2 *nido*-cluster is significantly deshielded (δ = 28.6 ppm), and the signal of the apical boron is slightly shifted to δ = −49.6 ppm. This reveals that the $CpFe(CO)_2$ fragment is directly bonded to the basal boron atom by an Fe–B σ-bond, which is confirmed by an X-ray diffraction study (vide infra). Thus, **4** is the first transition metal derivative of the C_4B_2 *nido*-carborane with direct metal–boron bonding. A few iron derivatives[7] with other carborane or polyborane frameworks of this type have been reported with Fe–B or Fe–C bonding. Cooling of the solution of the crude product in hexane resulted in yellow crystals of **4**, along with an unknown paramagnetic impurity, which makes the NMR spectra not so satisfactory.

The initial isolation of **4** by column chromatography on silica gel led to cleavage of the Fe–B bond to give **5** and paramagnetic impurities. The designed synthesis of **5** is achieved by the separate reaction of **1** with $LiBEt_3H$. No redox reaction between **1** and $(MeS)_2$ takes place, indicating the B–I bonds in **1** are dissimilar to the classical B–I bond of sp^2-hybridized boron atoms, which reacts to give the corresponding B–SMe products.[8]

Reactions Involving Substitution at Both Boron Atoms

In the reactions of **1** with more than 2 equiv. of PhLi and Me_3SnLi, respectively (Scheme 2), the B6-substituted products **6a** and **7a** are formed, together with trace amounts of the disubstituted species **6b** and **7b**, as detected by mass spectrometry. For **6a** and **7a**, the ^{11}B NMR signals of the basal boron atoms are shifted downfield to δ = 17.9 and 16.1 ppm, respectively, while the signals of the apical boron atoms are unchanged.



Scheme 2

In most of the cases the apical B–I bonds are found to be inert, although its substitution by an alkynyl group has been realized by a Pd^0-catalyzed Negishi-type cross-coupling reaction of **2a** and Me_3SiC_2ZnCl in THF (Scheme 3). Heating of the reaction mixture for 10 d leads to yellow **8**. Interestingly, the ^{11}B NMR signal of the substituted apical boron atom is only slightly shifted downfield to δ = −50.7 ppm. Its structure was established by an X-ray diffraction analysis (see below). The mechanism of such Pd-catalyzed coupling reactions involving B–I bonds[9a] is expected to be similar to that of carbon–carbon cross coupling, however the very first step in the catalytic cycle — the oxidative addition of the B–I bond leading to a B–Pd–I species — has not yet been verified. Stirring of a mixture of **2a** and $Pd(PPh_3)_4$ in THF leads to a brown solution, whose ^{31}P NMR spectrum shows a signal at δ = 22.4 ppm, which is in the expected region {$[PdIPh(PPh_3)_2]$: δ = 22.3 ppm}.[9b] Its ^{11}B NMR spectrum shows a signal at δ = −36 ppm, which might be due to the formation of the (σ-carboranyl)palladium iodide complex. Shore et al.[10] have studied the reaction of $Pd(PPh_3)_4$ with the iodoborane clus-

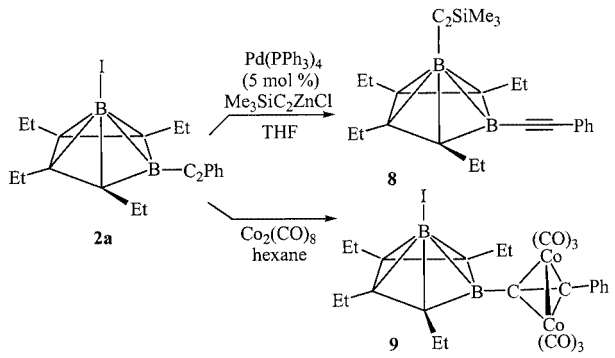
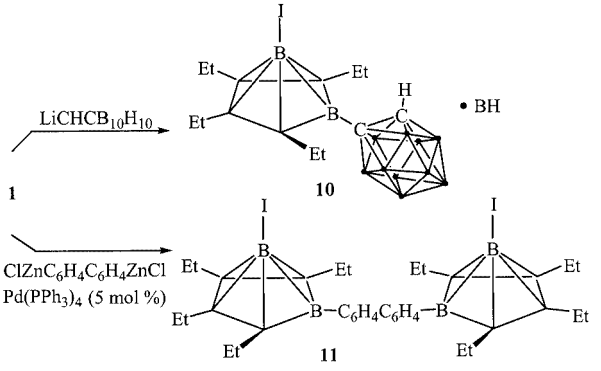
ter 9-I-1,7-$(SMe_2)_2B_{12}H_9$ and they observed similar results (δ^{31}_P = 24.2/24.0 ppm).



Scheme 3

Cluster Linkages

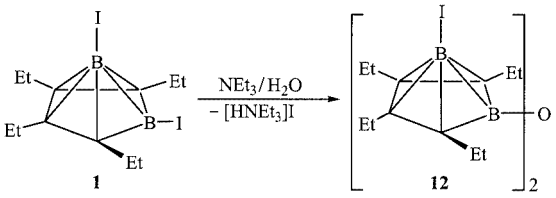
Nucleophilic substitution of *B*-functionalized C_4B_2 *nido*-carboranes by an anionic cluster $(\mu\text{-NS})Fe_2(CO)_6^-$ [3f] has been shown to be an effective way to linked clusters. The reaction of **2a** with $Co_2(CO)_8$, shown in Scheme 3, leads to the deep-brown product **9**, in which the *nido*-C_4B_2 and the C_2Co_2 tetrahedrane cluster are directly joined by a B−C bond at the basal position. In the ^{11}B NMR spectrum, the signal for the basal boron atom is shifted downfield by 6.5 ppm relative to that of **2a**, while the signal for the apical boron atom is only slightly shifted downfield by about 1.5 ppm. The molecular structure of **9** was confirmed by an X-ray diffraction analysis (see below). There are only a few acetylene−$Co_2(CO)_6$ complexes with boron groups attached to the acetylene unit,[11] and two[11b,11c] structurally characterized examples carry B−cat groups (cat = catechol). The C_4B_2−C_2B_{10} linked cluster **10** (Scheme 4) is produced by the reaction of **1** with monolithio-*o*-carborane, in which the C_4B_2 cluster is directly connected to the icosahedral *o*-carborane by a B6−C bond, as confirmed by X-ray diffraction analysis.



Scheme 4

Compound **11** with two C_4B_2 clusters connected by a $C_6H_4C_6H_4$ unit (Scheme 4) is obtained from the reaction of **1** with $ClZnC_6H_4C_6H_4ZnCl$ in the presence of a catalytic amount of $Pd(PPh_3)_4$. It should be noted that the reaction leading to **11** is performed in toluene because the basal B−I bond in **1** is sensitive to THF, resulting first in a yellow and then a deep-green solution. This is significantly different to the bromo derivatives of *nido*-C_4B_2, which have been studied in THF solution.[3d−3f] In compounds **10** and **11** the ^{11}B NMR signals of the basal boron atoms are shifted downfield to δ = 13.9 and 22.0 ppm, respectively, while the apical boron atom is essentially unaffected (δ = −53.4 ppm for **10** and δ = −52.4 ppm for **11**). The MS spectra exhibit the respective molecular ion peaks with the correct isotopic patterns.

The reaction of **1** with $LiC_6H_4C_6H_4Li$ did not yield the expected product **11**, instead the oxygen-bridged species **12** was detected, formed by the hydrolysis of **1**. In the Et_3N/H_2O reaction (Scheme 5), the formed by-product ammonium salt $[Et_3NH]I$, was identified by FAB-MS. Compound **12** was characterized by ^{11}B NMR spectroscopy (δ = 22.1 and −51.9 ppm) and HR-MS which exhibits the molecular ion peak with the correct isotopic pattern.



Scheme 5

X-ray Structure Analyses of 2a, 2d, 4, 8, 9 and 10

The molecular structures of **2a**, **4**, **8**, **9** and **10** are shown in Figures 1, 2, 3, 4, and 5, respectively. As the structure of **2d** (at room temperature) is very similar to that of **2a**, it will not be shown here. In the structures, the C_4B_2 *nido*-carborane frameworks are essentially the same as that of the start-

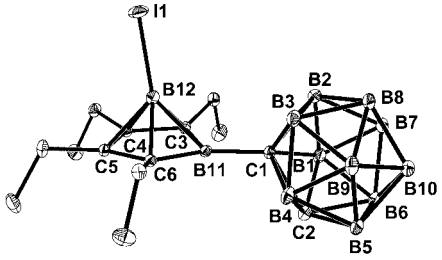

Figure 5. Molecular structure of **10**; hydrogen atoms omitted for clarity; thermal ellipsoids are shown at 40% probability; selected bond lengths [Å] and angles [°]: I(1)−B(12) 2.125(2), B(12)−C(3) 1.708(2), B(12)−C(4) 1.731(2), B(12)−C(5) 1.731(2), B(12)−C(6) 1.710(2), B(11)−B(12) 1.817(2), B(11)−C(3) 1.543(2), B(11)−C(6) 1.541(2), B(11)−C(1) 1.595(2), C(1)−C(2) 1.687(2), B(11)−B(12)−I(1) 141.46(10), C(1)−B(11)−B(12) 132.04(12)

B2−B1−X angle being 143.3(3)°, 141.3(3)°, 141.9(1)°, 142.5(1)°, 140.7(2)° and 141.5(1)°, respectively (in **1** the corresponding angle is 140.06°).

In **4**, a $CpFe(CO)_2$ fragment is directly σ-bonded to the basal boron atom, the Fe−B bond length is 2.069 Å, which is significantly longer than the corresponding values for iron−boryl complexes, [1.959(6)−2.034(3) Å,[13a,13b] 1.964(8)−2.027(5) Å[13c,13d]] and iron−borylene complexes [2.010(3) Å[13e]], but in the range of the reported values for ferracarboranes (1.968−2.161 Å[13f]). This long Fe−B distance is also consistent with the easy decomposition of **4** with the cleavage of the Fe−B bond on silica gel. The iron center achieves an 18-electron configuration through coordination to two CO ligands (2e donor), the cyclopentadienyl group (5e donor), and the Fe−B interaction (1e donor).

In the structure of **9** (Figure 4), the almost linear B−C≡C−Cmoiety in **2a** has been altered by the complexation of the $Co_2(CO)_6$ fragment, with the angles decreasing to 141.07° (B2−C13−C14) and 140.1° (C13−C14−C15). The Co1−Co2 and C13−C14 bond lengths of 2.483 and 1.348 Å, respectively, are similar to the corresponding values in similar complexes carrying B−cat groups.[11b,11c]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The structure of **10** (Figure 5) contains the small C_4B_2 *nido*-cluster connected to the large *closo*-*o*-carboranyl cluster. Interestingly, in the asymmetric unit two cocrystallized free *o*-carborane molecules have been found, and surprisingly there is no significant intermolecular interaction among the three molecules. The B11−C1 bond length of 1.595 Å is typical of a C−B single bond. In the *o*-carboranyl fragment the C1−C2 bond length is 1.687 Å, which is significantly longer than that in *o*-carborane [1.630(6) Å].[14] The B−B bond lengths [av. distance 1.776(2) Å, ranging from 1.744(2) to 1.793(2) Å] and the C−B bond lengths [av. distance 1.720(2) Å, ranging from 1.703(2) to 1.731(2) Å] are close to the expected values.

Conclusion

The reactivity of compound **1** towards various nucleophiles has been investigated. In most of the cases, the substitution with hydride, alkynyl, diphenylphosphanyl, trimethylstannyl, $CpFe(CO)_2$, and even the bulky *o*-carboranyl group, takes place regiospecifically at the basal boron atom of the *nido*-C_4B_2 frameworks, while the "inert" apical B−I bond can be substituted by a Pd^0-catalyzed Negishi-type cross-coupling reaction, as demonstrated in the synthesis of compound **8**. A new strategy for cluster linkages has been developed, and compounds with different types of cluster linkages have been prepared, either by direct B−C bonding ($C_4B_2-C_2B_{10}$ and $C_4B_2-C_2Co_2$), or by a linking $C_6H_4C_6H_4$ unit, at the basal boron atom of the *nido*-C_4B_2 skeletons. The reactivity of the basal B−I bond of **1** is further shown by its sensitivity to THF as solvent and by the formation of the oxygen-bridged species **12**.

Experimental Section

General: All reactions and manipulations were performed in dry glassware under argon or nitrogen using standard Schlenk techniques. Solvents were dried, distilled, and saturated with nitrogen. NMR spectra were recorded with a Bruker DRX 200 spectrometer (^{1}H: 200.13 MHz, ^{11}B: 64.21 MHz, ^{13}C: 50.32 MHz) in $CDCl_3$ as the solvent. $Et_2O{\cdot}BF_3$ was used as the external standard for ^{11}B NMR spectroscopy, and as internal references for ^{1}H and ^{13}C NMR spectroscopy the signals of the deuterated solvents were used and calculated relative to TMS. MS: ZAB-2F VH Micromass CTD spectrometer, and a JEOL MS Station JMS 700 spectrometer both using the EI or FAB ionization techniques. Melting points (uncorrected) were measured with a Büchi apparatus, using capillaries which were filled under nitrogen and sealed. $K[(\eta^5-C_5H_5)Fe(CO)_2]$[15] and Me_3SnLi[16] were prepared according to literature procedures.

2,3,4,5-Tetraethyl-1-iodo-6-(phenylethynyl)-2,3,4,5-tetracarba-*nido*-hexaborane(6) (2a): *n*BuLi (2.5 M in hexanes, 2 mL) was added at −50 °C to a solution of phenlyacetylene (507 mg, 5 mmol) in hexane (30 mL), the mixture was stirred for 30 min, and then warmed up to room temp. The resulting white suspension was cooled to −60 °C, and added with a syringe to a solution of **1** (900 mg, 2.05 mmol) in hexane (30 mL). The mixture was warmed to room temperature and stirred for 2 d. Filtration (G4 frit) gave a light-yellow filtrate, which was dried in vacuo to give **2a** as a yellow powder (746 mg, 88%), m.p. 74 °C. Crystals suitable for X-ray diffraction analysis were grown from a toluene/hexane solution at −28 °C. ^{1}H NMR: δ = 1.25 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.33 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 2.0 (m), 2.38 (m) (8 H, CH_2), 7.27−7.48 (m, Ph) ppm. ^{11}B NMR: δ = 10.3 (s, B_{basal}), −52.6 (s, B_{apical}) ppm. ^{13}C NMR: δ = 13.4, 14.3 (CH_3), 18.4, 19.8 (CH_2), 104.4 (br., *B*-bound basal C atoms), 113.0 (skeletal C atoms non-adjacent to the basal B atom), 124.6, 127.6, 128.1, 131.7 (Ph) ppm; signals of alkynyl C atoms not observed. EI-MS: *m*/*z* (%) = 414 (100) [M^+], 287 (14.6) [M^+ − I]. HR-MS (EI): *m*/*z* = 414.1224 [M^+]; calcd. for $^{12}C_{20}{}^1H_{25}{}^{11}B_2{}^{127}I$ 414.1187 (Δ*m* = 3.7 mmu).

6-(*tert*-Butylethynyl)-2,3,4,5-tetraethyl-1-iodo-2,3,4,5-tetracarba-*nido*-hexaborane(6) (2b): Prepared in a similar manner to **2a** from *t*BuC≡CLi (750 mg, 8.5 mmol) and **1** (528 mg, 1.2 mmol) in hexane (50 mL). Compound **2b** (450 mg, 95%) was obtained as a yellow oil. ^{1}H NMR: δ = 1.2 (br., 6 H, CH_3), 1.25 (br., 6 H, CH_3), 1.25 (s, 9 H, *t*Bu-H), 1.91 (m), 2.28 (m) (8 H, CH_2) ppm. ^{11}B NMR: δ = 10.8 (s, B_{basal}), −52.6 (s, B_{apical}) ppm. ^{13}C NMR: δ = 13.4, 14.0 (CH_3), 18.3, 19.6 (CH_2), 30.8 [$C(CH_3)_3$], 31.2 [$C(CH_3)_3$], signals of *B*-bound basal C atoms not observed, 112.3 (skeletal C atoms non-adjacent to the basal B atom) ppm; signals of alkynyl C atoms not observed. EI-MS: *m*/*z* (%) = 394 (100) [M^+], 267 (10.8) [M^+ − I]. HR-MS (EI): *m*/*z* = 394.1517 [M^+]; calcd. for $^{12}C_{18}{}^1H_{29}{}^{11}B_2{}^{127}I$ 394.1500 (Δ*m* = 1.7 mmu).

2,3,4,5-Tetraethyl-1-iodo-6-(trimethylsilylethynyl)-2,3,4,5-tetracarba-*nido*-hexaborane(6) (2c): Prepared in a similar manner to **2a** from $Me_3SiC{\equiv}CH$ (310 mg, 3.16 mmol), *n*BuLi (2.5 M in hexanes, 3 mmol) and **1** (634 mg, 1.44 mmol) in hexane (50 mL). Compound **2c** (536 mg, 91%) was obtained as a yellow oil. ^{1}H NMR: δ = 0.18 (s, $SiMe_3$), 1.21 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.26 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.94 (m), 2.29 (m) (8 H, CH_2) ppm. ^{11}B NMR: δ = 9.8 (s, B_{basal}), −52.8 (s, B_{apical}) ppm. ^{13}C NMR: δ = 0.18 ($SiMe_3$), 13.3, 14.1 (CH_3), 18.3, 19.7 (CH_2), 105.2 (*B*-bound basal C atoms), 112.8 (skeletal C atoms non-adjacent to the basal B atom) ppm; signals of alkynyl C atoms not observed. ^{29}Si NMR ($CDCl_3$, 39.7 MHz): δ = −19.8 ppm. EI-MS: *m*/*z* (%) = 410 (100) [M^+], 283 (13.5) [M^+ − I]. HR-MS (EI): *m*/*z* = 410.1265 [M^+]; calcd. for $^{12}C_{17}{}^1H_{29}{}^{11}B_2{}^{127}I$ 410.1269 (Δ*m* = −0.4 mmu).

2,3,4,5-Tetraethyl-1-iodo-6-(*p*-tolylethynyl)-2,3,4,5-tetracarba-*nido*-hexaborane(6) (2d): Prepared in a similar manner to **2a** from *p*-tolylacetylene (431 mg, 3.72 mmol) and **1** (264 mg, 0.6 mmol) in hexane (50 mL). Compound **2d** (247 mg, 96%) was obtained as a yellow solid, m.p. 81 °C. Crystals suitable for X-ray analysis were grown from a toluene solution at −28 °C. ^{1}H NMR: δ = 1.24 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.31 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.97 (m), 2.29 (m) (8 H, CH_2), 2.32 (s, 3 H, *p*-tolyl-CH_3), 7.08 (d, $^3J_{H,H}$ = 7.94 Hz, C_6H_4), 7.38 (d, $^3J_{H,H}$ = 7.94 Hz, C_6H_4) ppm. ^{11}B NMR: δ = 10.9 (B_{basal}), −52.6 (s, B_{apical}) ppm. ^{13}C NMR: δ = 13.3, 14.2 (CH_3), 18.4, 19.7 (CH_2), 21.4 (*p*-tolyl-CH_3), signals of *B*-bound basal C atoms not observed, 112.9 (skeletal C atoms non-adjacent to the basal B atom), 121.6, 128.8, 131.6, 137.6 (C_6H_4) ppm; signals of alkynyl C atoms not observed. EI-MS: *m*/*z* (%) = 428 (100) [M^+], 301 (13.6) [M^+ − I]. HR-MS (EI): *m*/*z* = 428.1360 [M^+]; calcd. for $^{12}C_{21}{}^1H_{27}{}^{11}B_2{}^{127}I$ 428.1344 (Δ*m* = 1.6 mmu).

2,3,4,5-Tetraethyl-1-iodo-6-(diphenylphosphanyl)-2,3,4,5-tetracarba-*nido*-hexaborane(6) (3): A suspension of Ph_2PLi (170 mg, 0.88 mmol, prepared in situ from $HPPh_2$ and *n*BuLi in hexane) in hexane (5 mL) was cooled to −60 °C and added to a solution of **1** (194 mg, 0.44 mmol) in hexane (10 mL). The mixture was allowed to warm to room temp., stirred overnight and filtered. The yellow

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

filtrate was dried in vacuo to give **3** (158 mg, 72%) as a yellow oil. ^{1}H NMR: δ = 0.99 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.37 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.94 (m), 2.36 (m) (8 H, CH_2), 7.37−7.56 (m, 10 H, aromatic H) ppm. ^{11}B NMR: δ = 14.8 (br., B_{basal}), −52.8 (s, B_{apical}) ppm. ^{13}C NMR: δ = 13.7, 15.1 (CH_3), 18.8, 19.2 (CH_2), signals of *B*-bound basal C atoms not observed, 116.1 (skeletal C atoms non-adjacent to the basal B atom), 127.2, 128.5, 134.4, 138.2 (aromatic C) ppm; signals of alkynyl C atoms not observed. ^{31}P{^{1}H} NMR ($CDCl_3$, 80.92 MHz): δ = −40.1 ppm. EI-MS: *m*/*z* (%) = 498 (59.1) [M^+], 371 (9.8) [M^+ − I], 186 (100) [$HPPh_2$]. HR-MS (EI): *m*/*z* = 498.1307 [M^+]; calcd. for $^{12}C_{24}{}^1H_{30}{}^{11}B_2{}^{127}I{}^{31}P$ 498.1316 (Δ*m* = −0.9 mmu).

6-[Dicarbonyl(η^5-cyclopentadienyl)iron]-2,3,4,5-tetraethyl-1-iodo-2,3,4,5-tetracarba-*nido*-hexaborane(6) (4): A solution of **1** (317 mg, 0.72 mmol) in hexane (10 mL) was added to a suspension of K[(η^5-C_5H_5)Fe(CO)$_2$] (395 mg, 1.8 mmol) in toluene (30 mL) at room temp. The mixture was stirred for 4 d and then filtered. The deep-red filtrate was concentrated and cooled to −28 °C; yellow crystals were formed after one week (258 mg, 73%), m.p. 132 °C. ^{1}H NMR: δ = 1.2 (br., 6 H, CH_3) , 1.3 (br., 6 H, CH_3), 1.93 (m), 2.22 (m) (8 H, CH_2), 4.8 (s, Cp) ppm. ^{11}B NMR: δ = 28.6 (br., B_{basal}), −49.6 (s, B_{apical}) ppm. ^{13}C NMR: δ = 13.6, 14.1 (CH_3), 19.3, 21.7 (CH_2), 88.1 (Cp), 106.5 (*B*-bound basal C atoms), 117.9 (skeletal C atoms non-adjacent to the basal B atom), 217.2 (CO) ppm; signals of alkynyl C atoms not observed. IR (hexane): ν_{co}: 1998.1 (s), 1942.4 (s) cm^{-1}. EI-MS: *m*/*z* (%) = 490 (4.2) [M^+], 462 (24.1) [M^+ − CO], 434 (100) [M^+ − 2 CO], 405 (7.3) [M^+ − 2 CO − Et], 307 (22.9) [M^+ − 2 CO − I]. HR-MS (EI): *m*/*z* = 490.0431 [M^+]; calcd. for $^{12}C_{19}{}^1H_{25}O_2{}^{11}B_2Fe^{127}I$ 490.0435 (Δ*m* = −0.4 mmu).

2,3,4,5-Tetraethyl-6-hydrido-1-iodo-2,3,4,5-tetracarba-*nido*-hexaborane(6) (5). a) By Decomposition of 4: In an attempt to separate **4** by column chromatography on silica gel, the crude product was eluted with hexane; only decomposition was observed. Compound **5** and paramagnetic impurities were formed, as indicated by the NMR spectroscopy. **b) By Reaction of 1 with LiBEt$_3$H:** A solution of LiBEt$_3$H (1.0 M in THF, 0.4 mmol) was added dropwise at −65 °C to a solution of **1** (194 mg, 0.44 mmol) in hexane (5 mL). A white precipitate was formed, the mixture was allowed to warm to room temp. and filtered. The colorless filtrate was dried in vacuo to give **5** (123 mg, 89%) as a colorless oil. ^{1}H NMR: δ = 1.2 (br., 6 H, CH_3), 1.2 (br., 6 H, CH_3), 2.04 (m), 2.21 (m) (8 H, CH_2) ppm. ^{11}B NMR: δ = 11.5 (d, $J_{B,H}$ = 148.3 Hz, B_{basal}), −53.8 (s, B_{apical}) ppm. ^{13}C NMR: δ = 13.1, 14.3 (CH_3), 18.5, 20.1 (CH_2), 106.3 (*B*-bound basal C atoms), 114.8 (skeletal C atoms non-adjacent to the basal B atom) ppm. EI-MS: *m*/*z* (%) = 314 (100) [M^+], 187 (10) [M^+ − I]. HR-MS (EI): *m*/*z* = 314.0893 [M^+]; calcd. for $^{12}C_{12}{}^1H_{21}{}^{11}B_2{}^{127}I$ 314.0874 (Δ*m* = 1.9 mmu).

2,3,4,5-Tetraethyl-1-iodo-6-phenyl-2,3,4,5-tetracarba-*nido*-hexaborane(6) (6a): A suspension of PhLi [obtained upon solvent removal from a solution (1.6 M) in diethyl ether/cyclohexane, 1 mmol] in hexane (5 mL) was cooled to −60 °C and added to a solution of **1** (194 mg, 0.44 mmol) in hexane (10 mL). The mixture was allowed to warm to room temp., stirred overnight and filtered. The light-yellow filtrate was dried in vacuo to give **6a** (150 mg, 87%) as a colorless oil, and trace amount of **6b**. ^{1}H NMR: δ = 1.19 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.4 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 2.08 (m), 2.36 (m) (8 H, CH_2), 7.40−7.55 (m, Ph) ppm. ^{11}B NMR: δ = 17.9 (s, B_{basal}), −52.4 (s, B_{apical}) ppm. ^{13}C NMR: δ = 13.7, 14.2 (CH_3), 18.5, 19.0 (CH_2), 103.4 (br., *B*-bound basal C atoms), 112.9 (skeletal C atoms non-adjacent to the basal B atom), 126.8, 127.2, 128.8, 133.2, 141.3 (Ph) ppm. EI-MS: *m*/*z* (%) = 390 (100) [M^+], 361 (10.8) [M^+ − Et], 263 (5.9) [M^+ − I]. HR-MS (EI): *m*/*z* = 390.1188 [M^+]; calcd. for $^{12}C_{18}{}^1H_{25}{}^{11}B_2{}^{127}I$ 390.1187 (Δ*m* = 0.1 mmu); *m*/*z* = 340.2532 (**6b**)$^+$; calcd. for $^{12}C_{24}{}^1H_{30}{}^{11}B_2$ 340.2534 (Δ*m* = −0.2 mmu).

2,3,4,5-Tetraethyl-1-iodo-6-(trimethylstannyl)-2,3,4,5-tetracarba-*nido*-hexaborane(6) (7a): A solution of **1** (194 mg, 0.44 mmol) in hexane (10 mL) was added to a suspension of Me_3SnLi (1 mmol) in hexane (20 mL) at −60 °C. The mixture was allowed to warm to room temp., stirred for 3 d and then filtered. The light-yellow filtrate was dried in vacuo to give **7a** (170 mg, 81%) as a yellow oil, and a trace amount of **7b**. ^{1}H NMR: δ = 0.3 (s, 9 H, $SnMe_3$), 1.2 (br., 6 H, CH_3), 1.3 (br., 6 H, CH_3), 2.11 (m), 2.24 (m) (8 H, CH_2) ppm. ^{11}B NMR: δ = 16.1 (br., B_{basal}), −52.6 (s, B_{apical}) ppm. ^{13}C NMR: δ = −6.0 ($SnMe_3$), 13.5, 14.1 (CH_3), 19.2, 22.2 (CH_2), signals of *B*-bound basal C atoms not observed, 118.6 (skeletal C atoms non-adjacent to the basal B atom) ppm. ^{119}Sn NMR ($CDCl_3$, 74.5 MHz): δ = −97.9 ppm. EI-MS: *m*/*z* (%) = 463 (100) [M^+ − CH_3], 499 (68.5) [**7b**$^+$ − CH_3]. HR-MS (EI): *m*/*z* = 463.0254 [M^+ − CH_3]; calcd. for $^{12}C_{14}{}^1H_{26}{}^{11}B_2{}^{127}I{}^{120}Sn$ 463.0288 (Δ*m* = −3.4 mmu); *m*/*z* = 501.0996 [**7b**$^+$ − CH_3]; calcd. for $^{12}C_{17}{}^1H_{35}{}^{11}B_2{}^{120}Sn_2$ 501.0968 (Δ*m* = 2.8 mmu).

2,3,4,5-Tetraethyl-6-(phenylethynyl)-1-(trimethylsilylethynyl)-2,3,4,5-tetracarba-*nido*-hexaborane(6) (8): A portion of lithium trimethylsilylacetylide (138 mg, 1.33 mmol) was dissolved in THF (15 mL) at room temp. and $ZnCl_2$ (180 mg, 1.33 mmol) was added. The mixture was stirred for 3 h and was then added to a mixture of **2a** (146 mg, 0.35 mmol) and Pd(PPh$_3$)$_4$ (20 mg, 0.017 mmol). The resulting yellow mixture was stirred for 3 d and then heated at reflux for 10 d. The solvent was removed, the black residue was extracted with hexane (2 × 20 mL) and filtered. The yellow filtrate was dried in vacuo to give a yellow viscous oil. A minimum amount of hexane was added and, on cooling to −28 °C, yellow crystals of **8** (115 mg, 85%) grew, m.p. 72 °C. ^{1}H NMR: δ = 0.08 ($SiMe_3$), 1.22 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.30 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 2.22 (m), 2.35 (m) (8 H, CH_2), 7.27−7.50 (m, 5 H, Ph) ppm. ^{11}B NMR: δ = 9.8 (s, B_{basal}), −50.7 (s, B_{apical}) ppm. ^{13}C NMR: δ = 0.01 ($SiMe_3$), 13.6, 14.7 (CH_3), 17.4, 19.1 (CH_2), 104.4 (*B*-bound basal C atoms), 112.4 (skeletal C atoms non-adjacent to the basal B atom), 125.0, 127.4, 128.0, 131.7 (Ph) ppm; signals of alkynyl C atoms not observed. ^{29}Si NMR ($CDCl_3$, 39.7 MHz): δ = −19.4 ppm. EI-MS: *m*/*z* (%) = 384 (100) [M^+]. HR-MS (EI): *m*/*z* = 384.2621 [M^+]; calcd. for $^{12}C_{25}{}^1H_{34}{}^{11}B_2{}^{28}Si$ 384.2616 (Δ*m* = 0.5 mmu).

3-Carboranyl-4-phenyl-1,2-bis(tricarbonylcobalta)tetrahedrane (9): A solution of **2a** (193 mg, 0.47 mmol) in hexane (15 mL) was added to a solution of $Co_2(CO)_8$ (178 mg, 0.52 mmol) in hexane (15 mL) at −40 °C. The mixture was allowed to warm to room temp. and stirred for 4 d until the reaction was complete. The solvent was removed in vacuo and the black residue was extracted with dichloromethane (2 mL) and separated by column chromatography (Florisil®) with hexane as eluent. After a small amount of unchanged $Co_2(CO)_8$, a deep-brown band was eluted. The solution was concentrated and cooled to −28 °C to give black crystals of **9** (170 mg, 52%), m.p. 140−141 °C (decomp.). ^{1}H NMR: δ = 1.09 (br., 6 H, CH_3), 1.35 (br., 6 H, CH_3), 1.84 (br.), 2.28 (br.) (8 H, CH_2), 7.26−7.51 (m, 5 H, Ph) ppm. ^{11}B NMR: δ = 16.3 (br., B_{basal}), −51.1 (s, B_{apical}) ppm. ^{13}C NMR: δ = 13.6, 14.1 (CH_3), 18.6, 19.0 (CH_2), 102.6 (*B*-bound basal C atoms), 114.0 (skeletal C atoms non-adjacent to the basal B atom), 127.2, 128.4, 129.7 (Ph), 200.4 (CO) ppm. EI-MS: *m*/*z* (%) = 672 (13.0) [M^+ − CO], 644 (12.1) [M^+ − 2 CO], 616 (19.0) [M^+ − 3 CO], 588 (28.2) [M^+ − 4 CO], 560 (11.7) [M^+ − 5 CO], 532 (100) [M^+ − 6 CO], 473 (20.6) [M^+ − 6 CO − 2 Et]. HR-MS (EI): *m*/*z* = 671.9595 [M^+ − CO];

calcd. for $^{12}C_{25}{}^{1}H_{25}O_5{}^{11}B_2Co_2{}^{127}I$ 671.9596 (Δm = −0.1 mmu). $C_{26}H_{25}B_2Co_2IO_6$ (699.9): calcd. C 44.62, H 3.60; found C 44.08, H 3.98.

6-(*o*-Carboranyl)-2,3,4,5-tetraethyl-1-iodo-2,3,4,5-tetracarba-*nido*-hexaborane(6) (10): *n*BuLi (2.5 M in hexanes, 0.4 mL, 1 mmol) was added at −65 °C to a solution of *o*-carborane (126 mg, 0.875 mmol) in toluene (15 mL). The colorless mixture was allowed to warm to room temp. and stirred overnight. The resulting white suspension was cooled to −65 °C and a solution of **1** (264 mg, 0.58 mmol) in hexane (7 mL) was added. The mixture was warmed to room temp., heated at reflux overnight, and filtered. The colorless filtrate was dried in vacuo to give a solid. A minimum amount of $CDCl_3$ was added and, on cooling to −28 °C, colorless crystals of **10** (200 mg, 76%) were obtained, m.p. 108 °C. ^{1}H NMR: δ = 1.20 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.28 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.93 (m), 2.25 (m) (8 H, CH_2), 3.3−3.8 (m, *o*-carborane) ppm. ^{11}B{^{1}H} NMR: δ = 13.9 (s, B_{basal}), −2.4 (2 B), −9.2 (2 B), −13.6 (4 B), −14.8 (2 B), −53.4 (s, B_{apical}) ppm. ^{13}C NMR: δ = 13.6, 14.7 (CH_3), 17.4, 19.1 (CH_2), 59.6 (C_{cage}), 102.3 (br., *B*-bound basal C atoms), 114.5 (skeletal C atoms non-adjacent to the basal B atom) ppm. EI-MS: *m*/*z* (%) = 456 (100) [M$^+$]. HR-MS (EI): *m*/*z* = 458.2604 [M$^+$]; calcd. for $^{12}C_{14}{}^{1}H_{31}{}^{11}B_{12}{}^{127}I$ 458.2587 (Δm = 1.7 mmu).

The $C_6H_4C_6H_4$-Connected Carborane 11: *n*BuLi (2.5 M in hexanes, 0.6 mL, 1.5 mmol) was added to a solution of 4,4′-dibromobiphenyl (164 mg, 0.53 mmol) in THF (15 mL) at −65 °C, and stirred at that temp. for 2 h. $ZnCl_2$ (150 mg, 1.1 mmol) was added in one portion to the resulting white suspension. The mixture was allowed to warm to room temp. to form a cloudy mixture, which was dried, and dry toluene (25 mL), **1** (200 mg, 0.45 mmol, in 5 mL of hexane) and $Pd(PPh_3)_4$ (60 mg, 0.052 mmol) were added to the solid. The resulting yellow mixture was stirred at room temp. for 3 d and filtered. The light-yellow filtrate was dried in vacuo, the residue was extracted with hexane (2 × 20 mL) and filtered. The colorless filtrate was dried in vacuo to give **11** as an oil (90 mg, 50%). ^{1}H NMR: δ = 1.2 (br., 6 H, CH_3), 1.3 (br., 6 H, CH_3), 2.10 (m), 2.32 (m) (8 H, CH_2), 7.41 (d, *J* = 8 Hz, 4 H), 7.48 (d, *J* = 8 Hz, 4 H, $C_6H_4C_6H_4$) ppm. ^{11}B NMR: δ = 22.0 (br., 2 B, B_{basal}), −52.4 (s, 2 B, B_{apical}) ppm. ^{13}C NMR: δ = 13.4, 14.3 (CH_3), 18.4, 19.8 (CH_2), 104.4 (*B*-bound basal C atoms), 113.0 (skeletal C atoms non-adjacent to the basal B atom), 124.6, 127.6, 128.1, 131.7 ($C_6H_4C_6H_4$) ppm. FAB-MS: *m*/*z* (%) = 778 (100) [M$^+$]. HR-MS (FAB): *m*/*z* = 778.2294 [M$^+$]; calcd. for $^{12}C_{36}{}^{1}H_{48}{}^{11}B_4{}^{127}I_2$ 778.2217 (Δm = 7.7 mmu).

The Oxygen-Bridged Carborane 12: Wet Et_3N (92 mg) was added to a solution of **1** (198 mg, 0.45 mmol) in hexane (5 mL) at − 60 °C. The mixture was allowed to warm to room temp. and stirred overnight. The colorless filtrate and the white precipitate were then separated by filtration. The filtrate was dried in vacuo to give **12** as an oil (100 mg, 69%). ^{11}B NMR: δ = 22.1 (br., 2 B, B_{basal}), −51.9 (s, 2 B, B_{apical}) ppm. EI-MS: *m*/*z* (%) = 642 (100) [M$^+$], 613 (61.2) [M$^+$ − Et], 515 (48.6) [M$^+$ − I]. HR-MS (EI): *m*/*z* = 642.1533 (100) [M$^+$]; calcd. for $^{12}C_{24}{}^{1}H_{40}{}^{11}B_4{}^{127}I_2{}^{16}O$ 642.1541 (Δm = −0.8 mmu). Negative FAB-MS of the white precipitate exhibited peaks at *m*/*z* = 356 $[Et_3NH]I_2^-$, 483 $[Et_3NH]I_3^-$, 584.9 $[Et_3NH]_2I_3^-$, indicating its identity as $[Et_3NH]I$.

X-ray Structure Determinations: Crystal data and details of the structure determinations are listed in Tables 1 and 2. The intensity data for **2a**, **4**, **8**, **9**, and **10** were collected with a Bruker AXS Smart CCD diffractometer at 103(2) K, and for **2d** at 298 K (Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator, ω-scans). Data were corrected for Lorentz polarization and absorption effects (semiempirical, SADABS[17]). The structures were solved by direct methods (SHELXS-86)[18] and refined by least-squares methods

Crystal Structure and Properties of $Ba_{11}FeTi_{27}O_{66.5}$

Terrell A. Vanderah,*[a] Theo Siegrist,[b] Robert S. Roth,[a] Arthur P. Ramirez,[b] and Richard G. Geyer[c]

Keywords: Mixed metal oxides / X-ray diffraction / Magnetic susceptibility / Dielectric constants / Dielectric loss tangent

The crystal structure of $Ba_{11}FeTi_{27}O_{66.5}$ was determined using single-crystal and powder X-ray diffraction methods. This phase crystallizes in the monoclinic space group *C*2/*m* (No. 12) (*a* = 23.324(1) Å, *b* = 11.388(1) Å, *c* = 9.8499(3) Å, β = 90.104(3)°; *Z* = 2; $\rho_{calcd.}$ = 4.98 g/cm^3), and exhibits a 10-layer structure built from close-packed [O,(Ba,O)] layers with a stacking sequence $(cchhc)_2$. Octahedral sites are occupied by a mixture of Fe^{3+} and Ti^{4+}, with some preferential ordering suggested by analysis of bond valence sums. The structure features vertex-, edge-, and face-sharing of the [Ti(Fe)O_6] octahedra. Indexed X-ray powder diffraction data for a polycrystalline specimen are given. $Ba_{11}FeTi_{27}O_{66.5}$ and the 8-layer phase $Ba_4Fe_2Ti_{10}O_{27}$ are built from the same types of polyhedral layers, some of which feature vacant sites between two Ba ions, which substitute for three oxygens in a row. The single-crystal results suggest that the basic structural formula of the phase is $A_{11}B_{28}O_{66+x}$, with the value of x (and hence the Fe/Ti ratio) determined by partial occupancy of one of these vacant sites. Variation of this occupancy factor with synthesis temperature may account for apparent slight differences in the stoichiometry of this phase in polycrystalline and single-crystal form. However, solid solution formation was not observed for polycrystalline specimens. A comparison of the crystal structure obtained for $Ba_{11}FeTi_{27}O_{66.5}$ with that previously proposed for "Zr^{4+}-stabilized $Ba_2Ti_5O_{12}$" indicates that the phase "$Ba_2Ti_5O_{12}$" is actually a ternary compound which forms upon addition (either deliberately or inadvertently) of a trivalent ion such as Fe^{3+} or Al^{3+}. The specimens $Ba_{11}Al_2Ti_{26}O_{66}$, $Ba_{11}Al_2Ti_{24}Sn_2O_{66}$, and $Ba_{11}Al_2Ti_{24}Zr_2O_{66}$ were also prepared and were found to form the $A_{11}B_{28}O_{66+x}$-type phase. $Ba_{11}FeTi_{27}O_{66.5}$ exhibits paramagnetic behavior that deviates somewhat from the Curie–Weiss Law below 75 K. Application of this formalism to the $1/\chi$ vs. *T* data above 75 K yields an effective moment consistent with the presence of high-spin Fe^{3+} (*S* = 5/2), and a negative Weiss constant (about –25 K) indicating weak cooperative magnetic interactions that are overall antiferromagnetic. The relative permittivity and dielectric loss tangent of a sintered polycrystalline disk were measured at 5.33 GHz, yielding values (corrected for theoretical density) of 55 and 7.7(±0.3) × 10^{-4}, respectively.

Introduction

Ceramic magnetic oxides serve important functions in a wide variety of electronic applications, including wireless communications. For example, circulators and isolators contain ceramic magnets that provide a static magnetic field to interact with the propagating microwave, thus steering and conditioning the signal. The properties required for such ceramics include large saturation magnetization, low dielectric loss, and a high dielectric constant. Materials currently in use include various garnets, spinels, and hexaferrites,[1,2] which exhibit relatively low relative permittivities (about 15). New materials with larger permittivities would permit miniaturization of these components. To this end, the $BaO:Fe_2O_3:TiO_2$ phase diagram has been systematically investigated[3] to elucidate compounds forming between the high-dielectric-constant polytitanates (e.g. $Ba_2Ti_9O_{19}$ and $BaTi_4O_9$), and strongly magnetic compounds such as barium hexaferrite ($BaFe_{12}O_{19}$). The phase diagram study confirmed the formation of a number of ternary phases with new structural types, including the title compound, denoted previously as phase "G"[3] with a stoichiometry close to "$Ba_{14}Fe_2Ti_{35}O_{87}$" (= 0.28:0.02:0.70 $BaO:Fe_2O_3:TiO_2$), as estimated by the disappearing phase method. The present report describes the crystal structure and more precise stoichiometry of this compound, as determined by single-crystal and X-ray powder diffraction methods, and characterization of its dielectric and magnetic properties. In addition, the relationship between this ternary phase and the compound reported as "$Ba_2Ti_5O_{12}$" is described.

Results and Discussion

Description of the Crystal Structure and Stoichiometry

The results of the single-crystal structure determination are given in Table 1. Selected bond lengths and bond-val-

ence sums are collected in Table 2, and indexed experimental X-ray powder diffraction data for a polycrystalline specimen are given in Table 3. As seen in Table 1, electron density was observed at the O22 site indicating a partial occupancy factor of 0.24(7), resulting in an overall stoichiometry of $Ba_{11}FeTi_{27}O_{66.5}$ ($BaO:Fe_2O_3:TiO_2$ = 0.2857:0.0130:0.7013) (Z = 2). With site O22 empty, the overall stoichiometry would be $Ba_{11}Fe_2Ti_{26}O_{66}$ (= 0.2895:0.0263:0.6842 $BaO:Fe_2O_3:TiO_2$). The basic structural formula for this phase is therefore $A_{11}B_{28}O_{66+x}$, where A = Ba^{2+} and B = Ti^{4+}, substituted with a small amount (<10 atom%) of a trivalent metal which determines the value of x. The subsolidus study[3] of the system at 1260 °C suggested little, if any, solid solution formation for this phase, and several closely spaced specimens indicated that the phase forms near the stoichiometry 0.28:0.02:0.70 $BaO:Fe_2O_3:TiO_2$, which is closer to the first formula with less Fe and a higher oxygen content. However, two polycrystalline specimens subsequently prepared precisely at $Ba_{11}FeTi_{27}O_{66.5}$ and $Ba_{11}Fe_2Ti_{26}O_{66}$ were not single-phase, despite repeatedly heating for hundreds of hours. The former composition contained small amounts (several %) of $BaTi_2O_5$ and $Ba_6Ti_{17}O_{40}$, while the latter contained an appreciable amount (>10%) of $Ba_4Fe_2Ti_{10}O_{27}$. According to the subsolidus phase diagram,[3] this suggests that at 1260° the compound forms with a composition between $Ba_{11}FeTi_{27}O_{66.5}$ and $Ba_{11}Fe_2Ti_{26}O_{66}$, with a lower O22 site occupancy factor than that determined for crystals grown by cooling from 1390 °C. As discussed below, these slight variations in Fe/Ti/O stoichiometry (note, however, that the A-cation/B-cation ratios remain constant) are readily accommodated by the crystal structure, and have been observed for other compounds occurring in the $BaO:Fe_2O_3:TiO_2$ system.[3–5] For convenience, the compound in the present study is referred to as $Ba_{11}FeTi_{27}O_{66.5}$, according to Table 1. The X-ray powder pattern, calculated using the single-crystal results (Table 1) and the refined unit cell (Table 3), is in excellent agreement with the pattern observed for a polycrystalline sample (0.28:0.02:0.70 $BaO:Fe_2O_3:TiO_2$) of this phase, as shown in Figure 1.

The structure of $Ba_{11}FeTi_{27}O_{66.5}$ may be described as a 10-layer (*10L*) close-packed (*cp*) arrangement built from [O] and [Ba,O] layers, stacked along the *a*-axis, with the transition metals occupying octahedral interstices. The connectivity of the structure includes vertex-, edge-, and face-sharing of [$(Ti^{4+}/Fe^{3+})O_6$] octahedra. The *a*-parameter of the unit cell indicates an average *cp* layer thickness of 2.362 Å, which is similar to that observed for other close-packed structures in this chemical system.[6,7] The arrangement is illustrated in Figure 2, as viewed along the ⟨011⟩ direction to reveal the stacking pattern of the cubic (*ccp*), and hexagonal (*hcp*) close-packed layers. The stacking sequence is $(cchhc)_2$ (*c* denotes a cubic close-packed layer and *h* denotes a hexagonally close-packed layer), where octahedral interstices share faces across *hcp* layers. In pairs of face-sharing octahedra that are occupied, the cations are displaced away from each other resulting in cation-cation distances of the order of 2.7 Å to 2.8 Å.

The polyhedral arrangements within each of the ten layers in the $Ba_{11}FeTi_{27}O_{66.5}$ structure are shown in Figure 3. This compound and $Ba_4Fe_2Ti_{10}O_{27}$ [6] (isostructural with $Ba_4Al_2Ti_{10}O_{27}$ [8]) are built from the same three types of layers: the first type contains strings of three edge-sharing octahedra plus isolated octahedra (layers 1,5,6,10), the second contains groups of five edge-sharing octahedra plus isolated octahedra (layers 2,4,7,9), and a third type contains continuous zigzag strips of edge-sharing octahedra (layers 3,8). The *8L* phase $Ba_4Fe_2Ti_{10}O_{27}$ [6] is built from two layers of the first type, four layers of the second type, and two layers of the third type (Figure 3 of ref.[6]). Not surprisingly, these two phases occur in equilibrium with one another.[3] The similarity of the two structures suggests that intergrowths between them may form easily, and could be the source of the relatively high residual in the structure refinement.

An interesting crystal-chemical feature, reminiscent of the barium polytitanates,[9] is the occurrence of vacancies in the oxygen/barium *cp* layers. As seen in Figure 3, and shown in detail in Figure 4, the vacancies occur in the first

Table 3. *(Continued)*

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

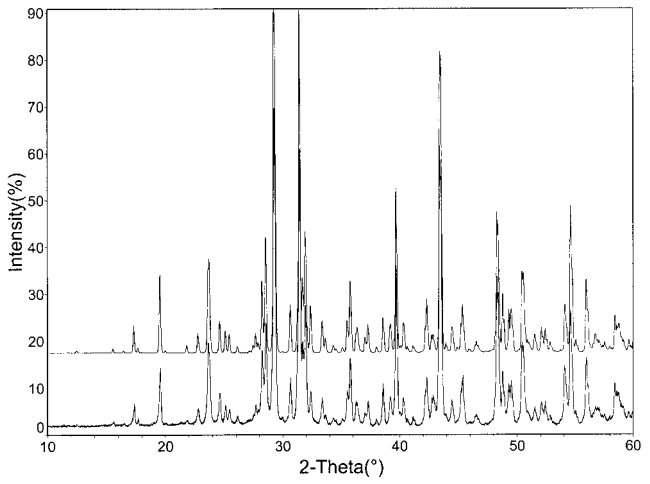

Figure 1. The X-ray powder diffraction pattern for $Ba_{11}FeTi_{27}O_{66.5}$ calculated from the single-crystal results (*top*) is in excellent agreement with the observed pattern (*bottom*) for a polycrystalline sample ($BaO:Fe_2O_3:TiO_2$ = 0.28:0.02:0.70); the stoichiometry of this phase in polycrystalline form (prepared at 1260°) apparently differs slightly from that of the single crystals (grown by cooling from 1390°), suggesting slightly different occupancy factors for the oxygen site O22 (Table 2); charge-balance is maintained by a corresponding change in the Fe/Ti ratio; in both cases, however, the A-cation/B-cation ratio remains the same (11:28)

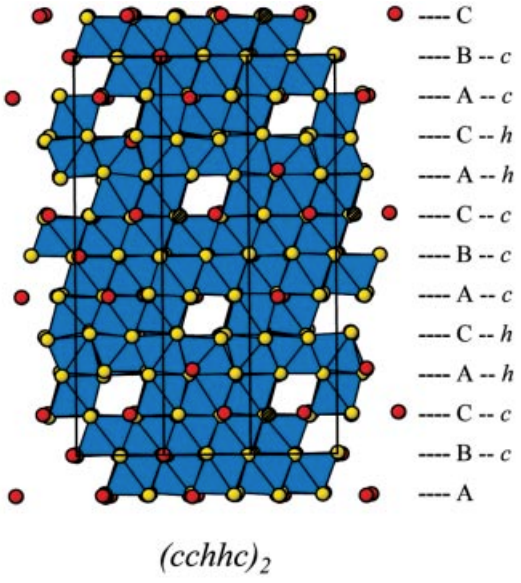

Figure 2. The crystal structure of *10L* $Ba_{11}FeTi_{27}O_{66.5}$ (*C2/m*; *a* = 23.324(1), *b* = 11.388(1), *c* = 9.8499(3) Å; β = 90.104(3)°] viewed approximately parallel to the close-packed (*cp*) [O,(Ba,O)] layers; the 10-layer stacking sequence is $(cchhc)_2$; the octahedra are occupied by Ti^{4+}/Fe^{3+}, with some preferential ordering suggested by analysis of bond valence sums; red spheres represent Ba^{2+}, yellow spheres represent oxygen with the hatched yellow spheres indicating the partially occupied O22 site (Table 2)

and second types of layers, where two Ba ions replace three oxygens in a row, reducing their coordination number from twelve to eleven. For $Ba_{11}FeTi_{27}O_{66.5}$, this results in a coordination number of 11 and a relatively low bond-valence sum for Ba2 (Table 2, Figure 4). The partially occupied site

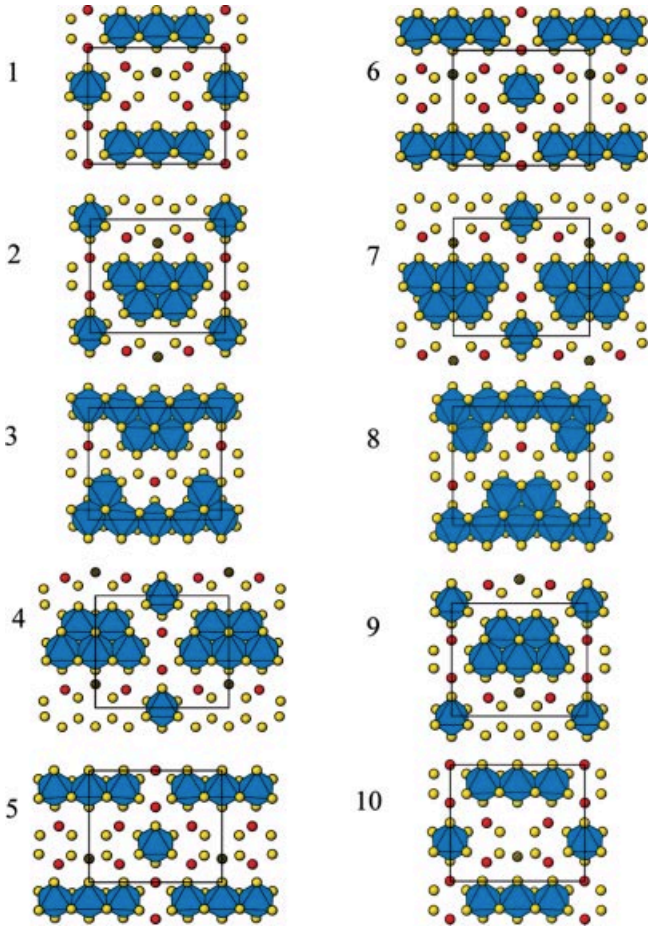

Figure 3. The structural arrangements within each of the ten layers of the close-packed structure of $Ba_{11}FeTi_{27}O_{66.5}$, viewed perpendicular to the layers; the representations are the same as in Figure 1; as seen here, the structure is built from three types of layers (*type 1* = layers 1,5,6,10; *type 2* = layers 2,4,7,9; *type 3* = layers 3,8); the same types of layers occur in the *8L* structure of $Ba_4Fe_2Ti_{10}O_{27}$; as observed for the barium polytitanate phases, the *cp* layers (types 1 and 2) are characterized by the occurrence of vacancies, wherein two Ba ions substitute for three oxygen positions in a row; the partially occupied O22 site (hatched yellow spheres) corresponds to one of these vacancies between two Ba ions

O22 corresponds to one of these *cp* vacancies, and occurs within bonding distance of Ba4 (Table 2, Figure 4). The occupancy factor of 0.24(7) for O22 obtained in the single-crystal study therefore suggests that 25% of the Ba4 sites are 12-coordinated and 75% are 11-coordinated.

The bond-valence sums about the M sites (Table 2) were calculated separately using the r_0 parameters for Ti^{4+} and Fe^{3+}, and are generally consistent with the high Ti-content of this phase. However, site M3 was observed to have slightly longer bond lengths than the other sites, and returns a bond-valence sum suggesting preferential occupation by the slightly larger trivalent Fe ion (Table 3). The M3 sites occur in pairs of vertex-linked octahedra in adjacent layers of the first type described above (Figure 3, layers 1,5,6,107). Interestingly, the coordination sphere about M3 has no next-nearest neighbors within 3.5 Å, whereas the other M sites have from 3 to 9, with an average of 7, next-

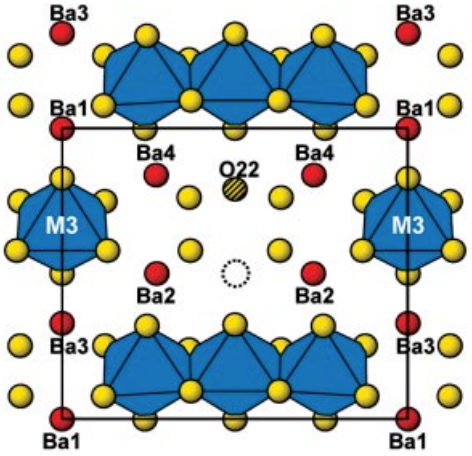

Figure 4. Magnified view of layer 1 in the structure of $Ba_{11}FeTi_{27}O_{66.5}$ (representations as in Figure 1), labeled to clarify the positions of the vacancies in the *cp* layers (dotted circle and hatched yellow O22 site); using the ligands on the upper and lower faces of the octahedra as a guide, the Ba2 sites are seen to occur in the lower *cp* layer, with the vacancy (dotted sphere) between them, thereby reducing their coordination number to eleven (Table 3); similarly, the Ba4 sites are seen to occur in the upper *cp* layer, but in this case the vacant site between them appears to be partially occupied (O22, Table 2), according to the electron density observed in the single-crystal study; note the marked displacement of O22 out of the *cp* row towards the interior of the unit cell; sites M3 occur in vertex-linked pairs of octahedra in adjacent layers, and exhibit bond-valence sums suggestive of preferential occupation by the somewhat larger Fe^{3+} ion

nearest neighbors within this distance. The M3 sites are therefore unusually isolated in the structure, which may facilitate accommodation of a larger cation.

Relationship to "$Ba_2Ti_5O_{12}$" (A Ternary Compound)

The synthesis, stability, and crystal chemistry of the phase referred to as "$Ba_2Ti_5O_{12}$" has long been of interest to researchers concerned with the phases occurring between $BaTiO_3$ and TiO_2, the so-called "barium polytitanates", which have technically important dielectric properties. The existence of $Ba_2Ti_5O_{12}$ was first reported by Jonker and Kwestroo[10] during the course of phase equilibria studies of the ternary systems with either ZrO_2 or SnO_2. They reported considerable solid solution of both oxides in the phase labeled $Ba_2Ti_5O_{12}$. However, many studies of the pure BaO-TiO_2 system failed to confirm the formation of this binary phase.[11–14] A subsequent study[15] found that "$Ba_2Ti_5O_{12}$" did not form in the ternary system with SnO_2, in contrast to the earlier report.[10] The phase did form, however, upon addition of ZrO_2. Small single crystals were grown and found to adopt a pseudo-orthorhombic unit cell with $a = 9.941$, $b = 11.482$, and $c = 23.528$ Å.[15] A later preliminary structural refinement of these crystals[16] suggested that the actual composition was $Ba_{11}(Ti,Zr)_{28}O_{66}O$, with the 67th oxygen in a position not located.[9] Subsequent chemical analyses of these crystals using an ion-microprobe[12] found about 0.25 wt% Al_2O_3 in addition to the expected amounts of BaO, TiO_2, and ZrO_2, although no alumina had been intentionally added. A comparison of the pseudo-orthorhombic unit cell for these crystals as well as the proposed crystal structure (Figure 10 in ref.[9]) reveals that they are essentially identical to those for $Ba_{11}FeTi_{27}O_{66.5}$ reported here (Table 1, Figure 3). Apparently, the phase "$Ba_2Ti_5O_{12}$" is actually a ternary compound stabilized by a relatively small content of a trivalent metal such as Fe^{3+} or Al^{3+}. Note that the A:B:O A-cation:B-cation:oxygen ratios are very similar for all of these compositions. As previously noted,[10] Jonker and Kwestroo[4] "wet-milled" their specimens twice, once before and once after calcination, and this process is notorious for the introduction of impurities from the ceramic spheres used for milling. To confirm this, specimens with compositions $Ba_{11}Al_2Ti_{26}O_{66}$, $Ba_{11}Al_2Ti_{24}Sn_2O_{66}$, and $Ba_{11}Al_2Ti_{24}Zr_2O_{66}$ were synthesized (1250 °C, 1275 °C, and 1275 °C, respectively), and were all found to contain the $A_{11}B_{28}O_{66+x}$-type phase as the major product (>95%) [the phase was not observed to form in compositions with Mg^{2+} or Zn^{2+} (i.e. $Ba_{11}MgTi_{27}O_{66}$ or $Ba_{11}ZnTi_{27}O_{66}$)].

Magnetic and Dielectric Properties of $Ba_{11}FeTi_{27}O_{66.5}$

The inverse magnetic susceptibility vs. temperature measured for $Ba_{11}FeTi_{27}O_{66.5}$ is shown in Figure 5. The behavior is paramagnetic, with highly dilute magnetic species, and follows the Curie–Weiss law above about 75 K. The slight curvature below 75 K and the extrapolated temperature intercept of −25 K indicate weak cooperative interactions between Fe spins that are, overall, antiferromagnetic in nature. Application of the Curie–Weiss formalism to the near-linear data above 75 K yields an effective moment of 5.2 μ_β/Fe, which is similar to the free-ion spin-only moment for high-spin Fe^{3+} ($S = 5/2$; 5.9 μ_β/Fe).

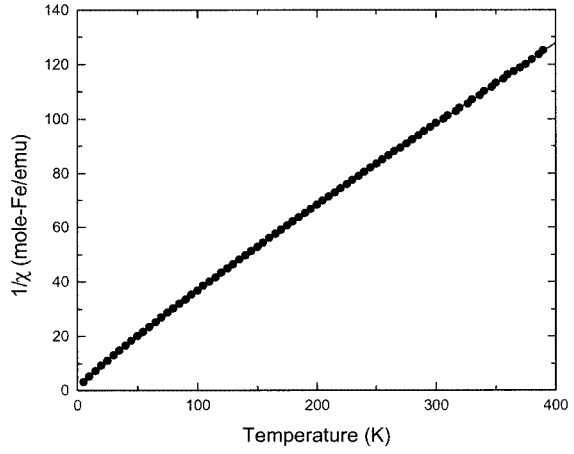

Figure 5. Inverse magnetic susceptibility vs. temperature for $Ba_{11}FeTi_{27}O_{66.5}$; the slight curvature below 75 K and the extrapolated temperature intercept of −25 K indicate weak cooperative interactions among the magnetic species that are overall antiferromagnetic in nature; the effective magnetic moment calculated from the essentially linear data above 75 K is consistent with the presence of high-spin Fe^{3+}

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

A corrected relative permittivity of 55, and a dielectric loss tangent, tanδ, of 7.7(±0.3) × 10^{-4} were obtained for $Ba_{11}FeTi_{27}O_{66.5}$. Both values were essentially independent of frequency between 5.0 and 5.5 GHz. Using Shannon's values for atomic polarizabilities and the Clausius−Mosotti theory,[18] a dielectric constant of 45 was estimated for this compound, a value in fair agreement with the experimental results given the uncertainty of the porosity measurement.

Conclusions

The crystal structure of the new ternary oxide $Ba_{11}FeTi_{27}O_{66.5}$ has been characterized by single-crystal and powder X-ray diffraction methods. The compound adopts a monoclinic *10L* structure built from close-packed (*cp*) [O,(Ba,O)] layers with a stacking sequence $(cchhc)_2$. Octahedral sites are occupied by Fe^{3+} and Ti^{4+}. The structure features vertex-, edge-, and face-sharing of the [Ti(Fe)O_6] octahedra. $Ba_{11}FeTi_{27}O_{66.5}$ is built from the same three types of layers as the neighboring *8L* compound $Ba_4Fe_2Ti_{10}O_{27}$. As observed for the binary barium polytitanates, some of the *cp* layers also feature vacant sites between two Ba ions which substitute for three oxygens in a row. The single-crystal structural results for $Ba_{11}FeTi_{27}O_{66.5}$ indicate that one of these sites is partially occupied, and that the basic structural formula for this phase is $A_{11}B_{28}O_{66+x}$, where A = Ba^{2+} and B = Ti^{4+} substituted with a small amount (<10 atom%) of a trivalent metal, which determines the value of x. The stoichiometry, or x-value, of the phase prepared in polycrystalline form at 1260 °C is slightly different from that of the crystals grown by cooling from 1390 °C, and occurs between the compositions $Ba_{11}FeTi_{27}O_{66.5}$ and $Ba_{11}Fe_2Ti_{26}O_{66}$. This variation in oxygen content and Fe/Ti ratio suggests that the partial occupancy site factor depends on the synthesis temperature. Interestingly, the phase apparently forms as a point compound in the subsolidus, with little or no solid solution formation. Analysis of the structural details using the bond valence method revealed one unusual B site, which was relatively expanded and isolated within the structure. This site is probably preferentially occupied by the larger, lower-valent Fe^{3+} cations. The crystal structure obtained here for $Ba_{11}FeTi_{27}O_{66.5}$ is essentially identical to that proposed earlier for "Zr^{4+}-stabilized $Ba_2Ti_5O_{12}$"[9,15] crystals. The phase originally reported as "$Ba_2Ti_5O_{12}$"[10] is actually a ternary compound, which forms upon addition (either deliberately or inadvertently via, e.g., ball-milling) of a trivalent ion such as Fe^{3+} or Al^{3+}. The specimens $Ba_{11}Al_2Ti_{26}O_{66}$ $Ba_{11}Al_2Ti_{24}Sn_2O_{66}$, and $Ba_{11}Al_2Ti_{24}Zr_2O_{66}$ were also prepared, and were found to form the $A_{11}B_{28}O_{66+x}$-type phase.

$Ba_{11}FeTi_{27}O_{66.5}$ was found to exhibit paramagnetic behavior above about 75 K. Application of the Curie−Weiss formalism to the $1/\chi$ vs. T data above 75 K yielded an effective moment consistent with the presence of high-spin Fe^{3+}, and a negative Weiss constant (about −25 K) indicating weak cooperative magnetic interactions that are overall antiferromagnetic. The relative permittivity and dielectric loss tangent of a sintered polycrystalline disk were measured at 5.33 GHz, yielding values (corrected for theoretical density) of 55 and 7.7(±0.3) × 10^{-4}, respectively.

Experimental Section

Dark reddish-brown polycrystalline $Ba_{11}FeTi_{27}O_{66.5}$ was prepared by solid-state reaction of reagent-grade $BaCO_3$, Fe_2O_3, and phosphate-free TiO_2 in air in the molar ratio $BaO:Fe_2O_3:TiO_2$ = 0.28:0.02:0.70. Prior to each heating, the sample was ground for 15−20 min with an agate pestle and mortar, pressed into pellets, and placed on sacrificial powder of the same composition in an alumina combustion boat. After an initial overnight calcine at 1000 °C, four one-week heatings at 1260 °C resulted in a well crystallized, nearly single-phase* sample (10-g scale) [* the pattern contains two weak peaks (I_{rel} < 0.8%), which can be attributed to $Ba_6Ti_{17}O_{40}$. Detection of small amounts of the phase $Ba_4Fe_2Ti_{10}O_{27}$ was precluded by peak overlap with the title phase]. Dark red platelet-like single crystals were obtained by slowly cooling (1 °C/h) a slightly non-stoichiometric liquid ($BaO:Fe_2O_3:TiO_2$ = 0.28:0.02:0.70) from 1390 °C to 1260 °C, followed by step-cooling to 800 °C, and then air-quenching. Samples were contained in platinum capsules (2.6 mm i.d.) open to the air. Crystals were harvested from dark prismatic chunks obtained by breaking the crystallized reaction mass, and were then characterized by the precession camera method (Zr-filtered Mo-K_α radiation) to assess quality, approximate cell parameters, and space group.

Single-crystal X-ray diffraction data were obtained with an Enraf−Nonius CAD-4 diffractometer (certain commercial equipment is identified in order to adequately specify the experimental procedure; recommendation or endorsement by the National Institute of Standards and Technology is not therein implied) using graphite-monochromated Mo-K_α radiation. A Gaussian integration absorption correction was applied to all measured intensities. Calculations were carried out using the NRCVAX[19] suite of programs. The structure was solved using Patterson and Fourier methods. Octahedral sites were assumed to be randomly occupied by Ti^{4+} and a small amount (< 10 atom%) of Fe^{3+}. Since the contrast between Fe and Ti by X-ray diffraction is small, no attempt was made to directly refine their relative occupancies, and the scattering factor for Ti was used for atoms occupying the octahedral sites. The overall stoichiometry of the phase reported here was then deduced by simultaneous consideration of the following: 1) the disappearing phase method,[3] 2) charge balance in the presence of trivalent iron and tetravalent titanium, and 3) the degree of site occupancy of oxygen as indicated by the single-crystal X-ray diffraction data.

X-ray powder diffraction data were collected using a Philips diffractometer equipped with incident soller slits, theta-compensating slits, a 0.2 mm receiving slit, a graphite monochromator, and a scintillation detector. Data were collected at ambient temperature using Cu-K_α radiation with a 0.01° 2θ step size, and a 2 s count time. The sample was mounted in a welled glass slide. Intensity data, measured as relative peak heights above the background of hand-picked peaks, were obtained using the Jade 6 program suite. The observed 2θ line positions reported here were corrected using SRM 660, LaB_6,[20] as an external calibrating agent. The unit cell was refined from the corrected powder diffraction data (2θ values; Cu-$K_{\alpha 1}$ = 1.540593 Å) using the least-squares program CELLSVD.[21] During the refinement, the indices of selected peaks were fixed in

accordance with the powder pattern calculated using the results of the single-crystal X-ray study and the Jade program jPOWD.

The conditions used for the single-crystal structure determination are given in Table 4. Further details of the crystal-structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting depository number CSD-413889.

Magnetization was measured using a Quantum Design SQUID (Superconducting Quantum Interference Device) magnetometer. Measurements were made on a polycrystalline sample in a field of 0.5 Tesla between 400 K and 5 K. Magnetization measurements were carried out in fields up to 4 Tesla.

Permittivity and dielectric loss tangent measurements were performed at 5.33 GHz under ambient conditions using a sintered polycrystalline disk, approximately 11 mm in diameter and 87% dense. As described previously,[6,7] a dielectric resonator technique utilizing higher-order $TE_{0\gamma\nu}$ modes was used that allows the measurement of dielectric properties of a single sample at several contiguous frequency sub-bands. Corrections to the crystallographic density were incorporated by estimating the pore volume of the sample (from size and mass), and applying the Bruggeman effective medium formulation[22] for a two-phase composite. Uncertainties in the measurement of pore volume suggest a realistic accuracy limit for the permittivity values of ±10%, confirmed by measurements of similarly dense test samples such as $LaAlO_3$,[6] for which reliable single-crystal data are available.

Electronic Structure of Transition Metal−Isocorrole Complexes: A First Quantum Chemical Study

Bart van Oort,[a] Espen Tangen,[a] and Abhik Ghosh*[a]

Keywords: Calculations / Corrole / Isocorrole / Non-innocent ligands / Radicals / Transition metals

DFT calculations indicate that the broad electronic-structural features of metalloisocorroles are rather similar to those of analogous metallocorroles. Thus, like their corrole analogues, many metalloisocorroles feature substantially non-innocent ligands. Another key point is that both corroles and isocorroles can exhibit at least two kinds of radical character, a_2 and b_1. However, corrole and isocorrole derivatives also differ significantly in a few ways: for example, the $S = 1/2$ CoPh complexes of corrole and isocorrole exhibit ground states of different symmetries ($^2A''$ and $^2A'$, respectively, in C_s notation), reflecting different interplays of metal(d_π)–ligand(p_π) interactions in corrole versus isocorrole derivatives. The ligand non-innocence phenomena encountered in this study are broadly reminiscent of similar phenomena in peroxidase compound I intermediates and their synthetic models. It seems reasonable, therefore, to adopt the view that this study, along with related studies on corrole derivatives, provides a broader chemical context for appreciating the electronic structures of high-valent heme protein intermediates.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Compared with the current explosion of research on corrole derivatives,[1] the chemistry of isocorrole derivatives has remained essentially unexplored since their initial synthesis and characterization by Vogel and co-workers in 1997.[2] In this context, we chose to map out the broad electronic-structural features of prototype isocorrole first-row transition-metal complexes, using density functional theory (PW91/TZP) calculations as the key tool.[3−7] While chiefly of interest to porphyrin chemists, we were gratified to find that the results impinge on a range of issues of broader interest. For example, we believe that the findings deepen our understanding of the electron distributions of high-valent transition-metal complexes and of the phenomenon of ligand non-innocence. Indirectly, the results also help place the electronic structures of high-valent heme protein intermediates in a broader chemical context.[8−12]

Our results on Sc(IsoC), Ga(IsoC), Ni(IsoC), and Cu(IsoC) (IsoC = isocorrolato) as well as analogous results on the corresponding corrole[13] complexes provide a good starting point for our discussion. Table 1 presents selected adiabatic[14] ionization potentials and excitation energies for these complexes. The results show that the two lowest ionized states of Sc(IsoC) and Ga(IsoC) are almost degenerate, as they are for the analogous corrole derivatives,[13] which is clearly reminiscent of the behavior of porphyrin A_{1u} and A_{2u} radicals.[15] Figure 1 depicts the open-shell orbitals of the $^2A_2$ and $^2B_1$ π-cation radical states of [Ga(IsoC)]$^+$ and of [Ga(Cor)]$^+$ and it is worth noting that the a_2 and b_1 orbitals crudely resemble the porphyrin a_{1u} and a_{2u} HOMOs in shape, respectively.[13] Another point worth noting is that the corrole and isocorrole ionization potentials (*IP*s) are significantly lower than those of analogous metalloporphyrins, that is, metallocorroles and metalloisocorroles are significantly easier to oxidize than the analogous metalloporphyrins.[13]

As in the case of Ni(Cor),[13] two Ni^{II} π-cation radical states compete as ground states for Ni(IsoC), the high-valent Ni^{III} state being more than 1 eV higher in energy. In contrast, high-valent Cu^{III} ground states are predicted for Cu(IsoC), with low-lying Cu^{II} π-cation radical states, which again parallels the situation with Cu−corroles.[13] However, a careful examination of Table 1 reveals an interesting twist in the Cu−isocorrole case. In the case of Cu−corroles, temperature-dependent NMR spectroscopy strongly suggests the presence of thermally accessible paramagnetic excited states, consistent with the DFT results.[16−18] In contrast, for Cu(IsoC), the Cu^{II} π-cation radical states are not as low in energy, relative to the ground state, as they are for Cu(Cor), suggesting that, unlike Cu−corroles, Cu−isocorroles may not exhibit significantly temperature-dependent NMR spectra.

Table 2 presents some key structural parameters of the optimized geometries of the molecules studied in this work. All the isocorrole derivatives exhibit slightly but consistently shorter metal−nitrogen distances than the corresponding corrole derivatives. In particular, the

$[Ga^{III}(L)]^+$	$^2B_1$	6.6658	6.6270
$[Ga^{III}(L)]^+$	$^2A_2$	6.7152	6.7007
$[Ga^{III}(L)]^-$	$^2B_1$	−1.5522	−0.8830

[a] L = corrolato or isocorrolato. [b] Note that although the electron affinities of Sc(L) and Ga(L) have been computed, they are not explicitly commented upon in this paper.

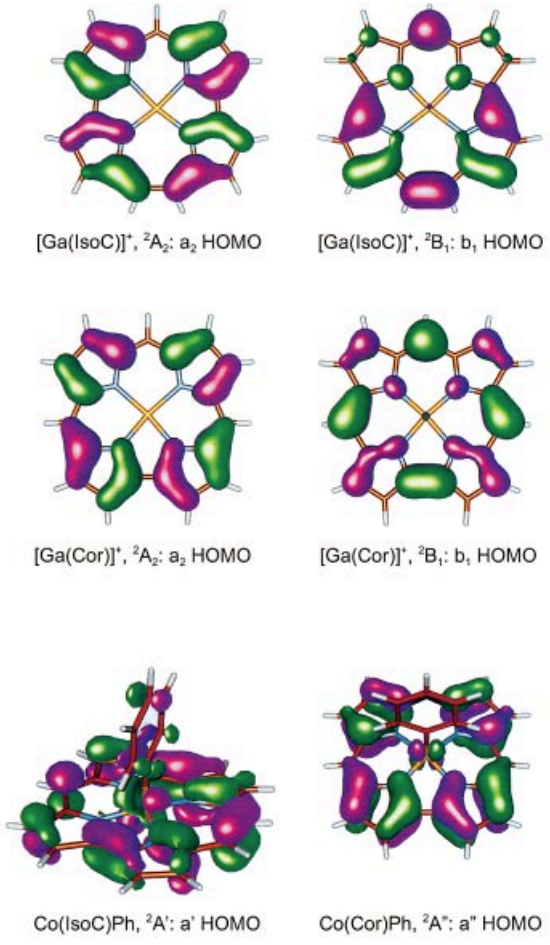

Figure 1. Majority-spin HOMOs of $[Ga(IsoC)]^+$ and $[Ga(Cor)]^+$, Co(IsoC)Ph and Co(Cor)Ph

metal−nitrogen distances in Cu(IsoC) are 0.02−0.03 Å shorter than those in Cu(Cor). This may well explain the greater stability of the d^8 Cu^{III} state, relative to Cu^{II} π-cation radical states, in the isocorrole case than in the corrole case.[13]

We are now in a position to discuss some of the intricacies of the electron distributions of corrole and isocorrole middle transition metal derivatives.[19−24] Figure 2 depicts the Mulliken spin populations of different M(IsoC)X complexes (M = Mn, Fe; X = Cl, Ph), along with those of the $^2A_2$ and $^2B_1$ π-cation radical states of $[Ga(IsoC)]^+$, for comparison. The notable point here is that the isocorrole macrocycle in the case of the M(IsoC)Cl (M = Mn, Fe) complexes carries significant minority spin-density distributed roughly in the form of the isocorrole b_1 HOMO. In other words, the electronic structures of these complexes may be viewed in terms of an $S = 2$ Mn^{III} or an $S = 3/2$ Fe^{III} center antiferromagnetically coupled to an isocorrole b_1 radical. In contrast, the isocorrole ligand in the case of M(IsoC)Ph (M = Mn, Fe) carries little spin-density and the metal center in these species is best viewed as "truly" high-valent, i.e. Mn^{IV} and Fe^{IV}. These findings closely parallel similar findings on corrole−Mn and −Fe derivatives.[25]

The electronic structures of Co(IsoC)Ph and Co(Cor)Ph appear to be of particular interest.[26,27] First, the electron spin-density profiles (Figure 2) are qualitatively different from those found in the Mn and Fe complexes. Thus, the corrole[27] or isocorrole ligand in the cobalt complexes carries large amounts of majority spin; indeed, the single unpaired electron spin appears to be roughly evenly distributed between the Co center and the macrocycle in these complexes as a result of a Co(d_π)−macrocycle(π) orbital interaction. Figure 1 depicts the majority-spin HOMOs of Co(IsoC)Ph and Co(Cor)Ph. The shapes of these MOs resemble the spin-density profiles of the two compounds, which reveals an interesting point: while the corrole a_2 HOMO (a″ in C_s) is largely responsible for ligand radical character in Co(Cor)Ph, the isocorrole b_1 (a′ in C_s) HOMO plays that role in Co(IsoC)Ph.

Overall, the broad electronic-structural features of metalloisocorroles are rather similar to those of the analogous metallocorroles. Thus, like their corrole analogues, many metalloisocorroles feature substantially non-innocent ligands. Another significant point is that both corroles and isocorroles can exhibit at least two kinds of radical character: a_2 and b_1. Having emphasized the similarities, we need to note that corrole and isocorrole derivatives also differ significantly in a few ways. For example, as mentioned above, the $S = 1/2$ CoPh complexes of corrole and isocorrole exhibit ground states of different symmetries ($^2A''$ and $^2A'$, respectively, in C_s notation), reflecting different interplays of metal(d_π)−ligand(p_π) interactions in corroles versus isocorrole derivatives. We believe that these results broaden our understanding of high-valent transition-metal complexes and of ligand non-innocence. The ligand non-innocence phenomena encountered in this study are broadly reminiscent of similar phenomena in peroxidase

Inclusion Complexes of the Bicyclic Aryl-Substituted Sulfur-Nitrogen Compounds Ar−CN_5S_3 with Fluorocarbon and Hydrocarbon Aromatics

Carsten Knapp,[a] Enno Lork,[a] Rüdiger Mews,*[a] and Andrey V. Zibarev*[b]

Keywords: Polyfluoroaromatic compounds / Inclusion compounds / π-Stacking interactions / Molecular recognition / Crystal engineering

Inclusion compounds with a stoichiometry of 2:1 were prepared from 7-Ar-1λ⁴,3λ⁴,5λ⁴-trithia-2,4,6,8,9-pentaazabicyclo[3.3.1]nona-1(9),2,3,5,7-pentaenes Ar–CN_5S_3 and hexafluorobenzene (Ar = C_6H_5, 4-$CH_3C_6H_4$, 4-$C_6H_5C_6H_4$ and 2,6-$F_2C_6H_3$) and toluene (Ar = C_6F_5), by crystallization of the bicycles from the corresponding aromatics. Similar to the pure host compounds, the bicycles in the inclusion compounds form centrosymmetric dimers. The packing of the dimers in the pure host compounds is dominated by the interaction of the substituents at the aryl groups, and in the inclusion compounds by the interaction of the host and guest. The parallel-displaced arrangement of the aromatic rings of the host and guest is typical of non-covalent π-stacking interactions of the arene-polyfluroarene type. The inability of benzene (in contrast to hexafluorobenzene) to form an inclusion compound with the title bicycle (Ar = C_6H_5) indicates that inclusion is driven by π-stacking interactions of the arene-polyfluoroarene type. Crystallization of the title bicycle (Ar = C_6H_5) from a 1:1 molar mixture of benzene and hexafluorobenzene gave the same inclusion compound as the crystallization from pure hexafluorobenzene. This can be considered as molecular recognition based on π-stacking interactions. The compounds prepared provide the first example of aromatic units bearing extremely sterically demanding polyheteroatom bicyclic substituents involved in non-covalent arene-polyfluoroarene π-stacking interactions. Attempts to prepare inclusion compounds with octafluoronaphthalene and decafluorobiphenyl, as well as co-crystals of *para*-tolyl- and pentafluorophenyl-substituted bicycles, failed. The origin of the 2:1 stoichiometry and the lack of inclusion in the case of $C_{12}F_{10}$ and $C_{10}F_8$ are discussed.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Non-covalent interactions[1] between aromatic groups,[2−5] including those between hydrocarbon and fluorocarbon counterparts featuring π-stacked arrangement (refs.[5−7] and references cited therein), are recognized to be one of the most general supramolecular motifs. The arene-polyfluoroarene π-stacking interactions are important not only in fundamental research but also in the design and synthesis of advanced functional materials (for example, nematic[8] and discotic[9] liquid crystals, J aggregates,[10] photochromic crystals,[11] etc.).

Recently, we described 1:1 molecular complexes between octafluoronaphthalene and acyclic (Ar−N=S=N−Ar, Ar−N=S=N−$SiMe_3$) and heterocyclic (7-methyl-2,1-benzisothiazole) sulfur-nitrogen compounds featuring π-stacking interactions of the arene-polyfluoroarene type.[6,7] It follows from the results obtained that geometrical matching of the components of the complexes can be considered a less significant structural requirement.

In the context of crystal engineering, it is of obvious interest to investigate how broad the molecular diversity of aryl-substituted sulfur-nitrogen compounds involved in the arene-polyfluoroarene π-stacking interactions can be, with special emphasis on derivatives with enlarged spatial demand.

The present work deals with the preparation and X-ray structural characterization of the molecular complexes of the aryl-substituted sulfur-nitrogen derivatives Ar−CN_5S_3 (7-aryl-1λ⁴,3λ⁴,5λ⁴-trithia-2,4,6,8,9-pentaazabicyclo[3.3.1]-nona-1(9),2,3,5,7-pentaenes) with aromatic compounds in both the fluorocarbon and hydrocarbon series.

Results and Discussion

The target complexes of the Ar−CN_5S_3 derivatives **1**−**4** (Ar = C_6H_5, 4-$CH_3C_6H_4$, 4-$C_6H_5C_6H_4$ and 2,6-$F_2C_6H_3$, respectively) with hexafluorobenzene were prepared (Scheme 1) as single crystals suitable for X-ray crystallography by crystallization of the compounds **1**−**4** from hexa-

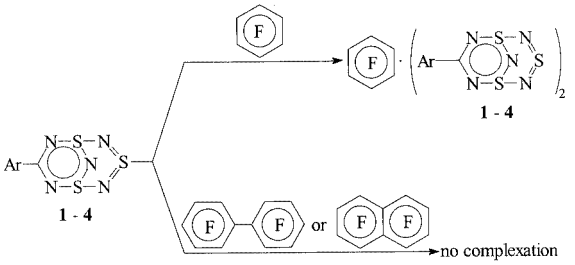
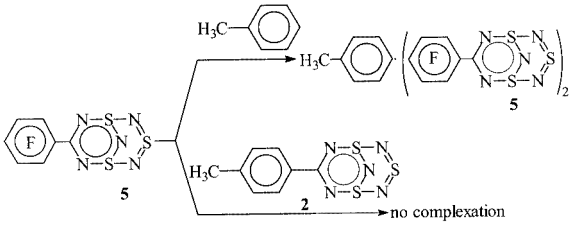
fluorobenzene. All attempts to prepare similar complexes of decafluorobiphenyl and octafluoronaphthalene by co-crystallization of the components from organic solvents (cf. ref.[6]), including *n*-hexane, $CHCl_3$, THF and MeCN, failed.



Ar = C_6H_5 (**1**), 4-$H_3CC_6H_4$ (**2**), 4-$C_6H_5C_6H_4$ (**3**), 2,6-$F_2C_6H_3$ (**4**)

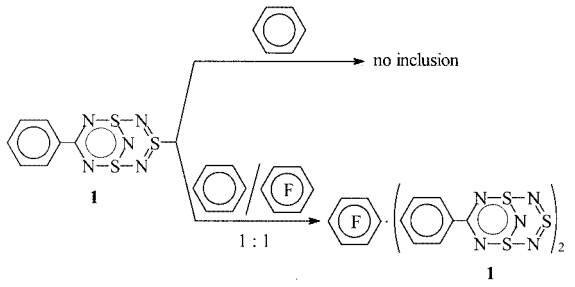
Scheme 1. The circle in the dithiatriazine cycle of the bicycles means delocalization, not aromaticity

Single crystals, suitable for X-ray diffraction, of the complex of $C_6F_5-CN_5S_3$ (**5**) with toluene were obtained (Scheme 2) by low-temperature co-crystallization of the components from *n*-hexane. An attempt to co-crystallize compound **5** with compound **2** (which can be considered a toluene derivative) from THF was unsuccessful.



Scheme 2

According to the results from X-ray crystallography, all complexes of the Ar−CN_5S_3 derivatives with aromatic compounds prepared (both fluorocarbon and hydrocarbon) possess a 2:1 stoichiometry rather than the usual 1:1 stoichiometry (refs.[5−14] and references cited therein), despite the fact that the corresponding aromatics were used in the preparation as solvents, i.e. in a large molar excess. The detailed analysis of their crystal packing (see below) confirms the inclusion nature of the co-crystals. It was found that benzene, in contrast to hexafluorobenzene, under the same conditions, does not form an inclusion compound with **1**. This indicates directly the critical importance of the π-stacking interactions of the arene-polyfluoroarene type for the discussed inclusion compounds. Significantly, crystallization of compound **1** from a 1:1 molar mixture of benzene and hexafluorobenzene leads to the same C_6F_6·(**1**)$_2$ inclusion compound as the crystallization from pure hexafluorobenzene. This can be considered as molecular recognition based on π-stacking interactions (Scheme 3).



Scheme 3

Table 1 presents the crystal data and details of the structure refinements for the compounds C_6F_6·(**1**)$_2$, C_6F_6·(**2**)$_2$, C_6F_6·(**3**)$_2$, C_6F_6·(**4**)$_2$ and $CH_3C_6H_5$·(**5**)$_2$. For comparison, the structures of the pure host compounds **1** and **4** are given in Figure 1 and Figure 2**,** Figure 3−5 present the crystal packing of the inclusion compounds. The interactions of the π-systems in the crystals of C_6F_6·(**1**)$_2$ and $CH_3C_6H_5$·(**5**)$_2$ are shown in Figure 6 and Figure 7. Relevant bond lengths and bond angles are listed only for C_6F_6·(**3**)$_2$ and $CH_3C_6H_5$·(**5**)$_2$, because the structures of the parent host compounds 4-$C_6H_5C_6H_4-CN_5S_3$ (**3**) and $C_6F_5-CN_5S_3$ (**5**) are not reported in the literature. Compared to the pure host compounds **1**, **2**, and **4** the geometries of the aryl-substituted bicycles remain nearly unchanged in the inclusion compounds.

For compound **1** ($C_6H_5-CN_5S_3$)[15,16] and its derivatives Ar−CN_5S_3,[17] two dominant modes of molecular packing are known (for an in-depth discussion, see ref.[17]). They are described as "stacking" (the sulfur-nitrogen rings of neighboring molecules fit into one another like stacked crates; short N···C and N···S contacts are found), and "dimerization" (two molecules are arranged with their heterocyclic heads facing each other centrosymmetrically; only short S···N contacts are observed). Both packing patterns can be rationalized by Coulombic interactions between the CN_5S_3 units as shown by the mapped electrostatic potential.[17] Most of the Ar−CN_5S_3 bicycles including **1**, **2** and **4** form centrosymmetric dimers. The interaction between the dimers is influenced by the geometry of the monomers (e.g. Figure 1 and Figure 2) and the interaction of the substituents at the aryl groups.

Despite the differences in the packing of the individual host compounds, the crystal packing of the C_6F_6·Ar−CN_5S_3 complexes and also of the inverse complex $CH_3C_6H_5$·$Ar_F-CN_5S_3$, are very similar (Figure 3−5). A closer look shows that complex formation does not influence the geometry of the monomeric Ar−CN_5S_3 species, the formation of the dimer is also not affected, but the interaction between the dimers is dominated by π-stacking. Small differences in the π-stacking arise from the geometry and the charge distribution in the aryl substituents. π-Stacking H···F contacts (considered as supramolecular synthons)[18] seem to be important for the arrangement in the solid state (a representative example is given in Figure 3). The inclusion nature of the synthesized compounds ex-

plains the aforementioned unsuccessful co-crystallization with decafluorobiphenyl or octafluoronaphthalene since only the relatively small hexafluorobenzene and toluene molecules fit into the van der Waals holes in the co-crystals with **1**−**5**.

The 2:1 stoichiometry observed in the $(Ar-CN_5S_3)_2 \cdot C_6F_6$ and $(Ar_F-CN_5S_3)_2 \cdot C_6H_5CH_3$ compounds results from the non-equivalence of the two sides of the aryl ring planes in the bicycles. In the co-crystals, both the hexafluorobenzene and toluene groups interact with the side of the aryl ring of the $Ar-CN_5S_3$ species that is opposite to the N=S=N fragment (Figure 3−5). In the case of **3,** which possesses two non-equivalent aromatic rings, only the monosubstituted ring is involved in the inter-

actions (Figure 4). All co-crystals demonstrate a parallel-displaced arrangement of the aromatics, i.e. face-to-face π-stacking of the aromatic rings of the bicycles with a ring of a second partner showing some offset of the interacting rings (Figure 6 and Figure 7). In $CH_3C_6H_5{\cdot}(\mathbf{5})_2$ the toluene molecules are highly disordered.

The dihedral angle between the planes of the cofacial hydrocarbon and fluorocarbon rings (the tilt) is 6.8, 8.6, 6.0, 12.7, and 5.8° for $C_6F_6{\cdot}(\mathbf{1})_2$, $C_6F_6{\cdot}(\mathbf{2})_2$, $C_6F_6{\cdot}(\mathbf{3})_2$, $C_6F_6{\cdot}(\mathbf{4})_2$ and $CH_3C_6H_5{\cdot}(\mathbf{5})_2$, respectively. The arene-polyfluoroarene separation within the stacks varies between 352.0−381.6 (366.4), 347.5−403.6 (373.9), 353.8−378.9 (366.4), 346.8−403.5 (374.6) and 360.1−389.6 (378.3) pm, respectively (in brackets: distance between the centers of the rings which is not equal to the separation due to the offset and tilt). For comparison, this separation is 377 pm[12] for the lowest-temperature phase of the benzene-hexafluoroben-

zene co-crystals, and 333−354 pm for the naphthalene−octafluoronaphthalene co-crystals at room temperature[13] and 327−352 pm for the low-temperature structure.[14] Such a parallel-displaced arrangement is typical for this type of interaction since it diminishes the repulsive π-electron interactions, which are roughly proportional to the π-overlapping area. Thus, the compounds obtained possess all the typical characteristics of the stacking of six-membered aromatic rings in crystals.[19]

On the other hand, the stoichiometry of 2:1 arises from the stability of the packing motifs observed in the crystals of $Ar-CN_5S_3$ towards the incorporation of hexafluorobenzene or toluene molecules into their crystal lattices.

From this point of view, these compounds should be classified as inclusion compounds. It is well-known that the formation of inclusion compounds is possible even in the absence of attractive forces between host and guest. During crystal growth from solution, solvent molecules may be caught and held in intermolecular cavities as guests also through repulsive forces.[20] However, for the compounds discussed, inclusion is definitely driven by attractive[2,5] π-stacking interactions of the arene-polyfluoroarene type, as proved by the ability of the crystal lattice of compound **1** to recognize and discriminate benzene and hexafluorobenzene molecules.

It also follows from the data obtained that the molecular geometries of compounds **1**, **2** and **4** (known previously[15−17]) are practically not affected by the interaction with C_6F_6 (cf. similar observations were made for complexes of $C_{10}F_8$ [6]). In some cases (for example, compounds **3** and **5**), the co-crystals are much better suited for X-ray crystallography than crystals of the individual compounds of interest (including situations when one component is a liquid in its pure state; for example see refs.[6,7]); a methodology could be developed which uses these types of co-crystals for the structural characterization of aromatic compounds (including liquids) for which good quality single crystals are not available.

Conclusion

Inclusion compounds of aryl-substituted sulfur-nitrogen bicycles $Ar-CN_5S_3$ with fluorocarbon and hydrocarbon aromatics with 2:1 stoichiometry have been prepared for the first time. Their crystal structures demonstrate a parallel-displaced arrangement of the aromatic rings of the host and the guest typical of non-covalent π-stacking interactions of the arene-polyfluoroarene type. Thus, the compounds provide the first example of aromatic units bearing extremely sterically demanding polyheteroatom bicyclic substituents involved in non-covalent arene-polyfluoroarene π-stacking interactions. This confirms our earlier conclusion that the geometrical matching of the components of the complexes can be considered a less significant structural requirement and thus provides new and interesting prospects to crystal engineering based on the arene-polyfluoroarene π-stacking interactions. Molecular recognition and discrimination are also possible with the arene-polyfluoroarene π-stacking interactions in the $Ar-CN_5S_3$/arene/polyfluoroarene systems. Based on these findings, it seems possible that the π-stacking interactions of the arene-polyfluoroarene type might be used in solving some serious challenges of contemporary materials science. In particular, significant progress has been made during the last decade in the field of organic molecular magnets, especially those based on aryl-substituted thiazyl radicals such as 4-aryl-1,2,3,5-dithiadiazolyls, 1,2,3- and 1,3,2-benzodithiazolyls, including fluoro-containing derivatives. However, in the solid state, these radicals reveal a general tendency to form diamagnetic dimers by means of out-of-plane π*-π* interactions, leading to shortened intermolecular S···S and S···N contacts. The inhibition of the dimerization process is very important for further developments in the field.[21] One might try to overcome the dimerization process by utilizing π-stacking interactions of the arene-polyfluoroarene type in the solid state between aryl-substituted thiazyl radicals and suitable polyfluoroaromatics, and this can be a direction for further investigations in the field.

Experimental Section

Materials and Methods: The bicycles **1**−**5** were prepared by published methods.[15,17,22] Their inclusion compounds with the corresponding aromatics were prepared in an argon atmosphere. The melting points were taken on a Gallencamp Melting Point Apparatus in sealed capillaries. For all complexes, melting is accompanied by decomposition with gas evolution.

Preparation of $C_6F_6 \cdot (1)_2$, $C_6F_6 \cdot (2)_2$, and $C_6F_6 \cdot (3)_2$: Compounds **1**−**3** (0.5 mmol) were dissolved in 5 mL of boiling hexafluorobenzene.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The solution was filtered hot and gradually cooled in a thermostat to 20 °C. During the cooling, orange-yellow crystals formed which were separated by filtration.

Complex $C_6F_6\cdot(\mathbf{1})_2$ formed transparent orange-yellow plates (0.15 g, 86%), m.p. 125−126 °C.

Complex $C_6F_6\cdot(\mathbf{2})_2$ formed transparent orange-yellow elongated thin plates (0.15 g, 83%), m.p. 143−144 °C.

Complex $C_6F_6\cdot(\mathbf{3})_2$ formed transparent orange-yellow needles (0.20 g, 94%), m.p. 149−150 °C.

Preparation of $C_6F_6\cdot(\mathbf{4})_2$: Compound **4** (0.15 g, 0.5 mmol) was dissolved in 2 mL of hot hexafluorobenzene. At 20 °C, 2 mL of *n*-hexane was added to this solution forming a two-layered system. After 2 days, after the diffusion of solvents had ceased, the crystals formed were filtered. Complex $C_6F_6\cdot(\mathbf{4})_2$ formed transparent orange prisms (0.12 g, 65%), m.p. 104−105 °C.

Preparation of $CH_3C_6H_5\cdot(\mathbf{5})_2$: Compound **5** (0.17 g, 0.5 mmol) was dissolved in 2 mL of hot toluene. At 20 °C, 2 mL of *n*-hexane was added to this solution forming a two-layered system, which was placed into a cryostat at −30 °C. After 2 weeks, the crystals formed were filtered. Complex $CH_3C_6H_5\cdot(\mathbf{5})_2$ formed large transparent orange-yellow needles (0.10 g, 50%) m.p. 123−124 °C.

Preparation of $C_6F_6\cdot(\mathbf{1})_2$ from C_6H_6/C_6F_6: Compound **1** (0.13 g, 0.5 mmol) was dissolved in 3 mL of a 1:1 molar mixture of boiling benzene and hexafluorobenzene. The solution was filtered while still hot and gradually cooled in a thermostat to 30 °C (i.e. above the reported m.p. of the $C_6H_6\cdot C_6F_6$ complex, 24 °C[23]). The crystals formed were filtered. The complex $C_6F_6\cdot(\mathbf{1})_2$ (0.16 g, 92%) isolated by this procedure was identical (unit cell parameters, m.p.) to that obtained by crystallization of **1** from pure hexafluorobenzene.

The crystallization of **1** from benzene did not lead to an inclusion compound. Only **1** was recovered.

X-ray Crystallographic Study: The crystallographic data were collected on a Siemens P4 diffractometer [$C_6F_6\cdot(\mathbf{1})_2$, $C_6F_6\cdot(\mathbf{3})_2$, $C_6F_6\cdot(\mathbf{4})_2$] or on a Stoe IPDS [$C_6F_6\cdot(\mathbf{2})_2$, $CH_3C_6H_5\cdot(\mathbf{5})_2$] using Mo-$K_\alpha$ (0.71073 Å) radiation with a graphite monochromator. Refinement was based on F^2; $R1 = \|F_o| - |F_c\|/|F_o|$; $wR2 = \{[w(F_o^2 - F_c^2)^2]/[w(F_o^2)^2]\}^{1/2}$. Programs used: SHELX-97[24] and DIAMOND.[25]

The single crystals of the inclusion compounds were prepared as described above. They were mounted on a thin glass fiber using KEL-F oil. The structures were solved by direct methods (SHELXS[24]). Subsequent least-squares refinements (SHELXL-97−2[24]) located the positions of the remaining atoms in the electron density maps. All non-H atoms were refined anisotropically.

CCDC-226030 [for $C_6F_6\cdot(\mathbf{1})_2$], -226031 [for $C_6F_6\cdot(\mathbf{2})_2$], -226032 [for $C_6F_6\cdot(\mathbf{3})_2$], -226033 [for $C_6F_6\cdot(\mathbf{4})_2$], and -226034 [for $CH_3C_6H_5\cdot(\mathbf{5})_2$] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation and Structural Characterization of $[K(18\text{-crown-6})]^+$ Salts of $[RNSN]^-$ Anions and the $[NSN]^{2-}$ Dianion

Tobias Borrmann,[a] Enno Lork,[b] Rüdiger Mews,*[b] Makhmut M. Shakirov,[c] and Andrey V. Zibarev*[c]

Keywords: Sulfur / Nitrogen / X-ray diffraction / NMR spectroscopy

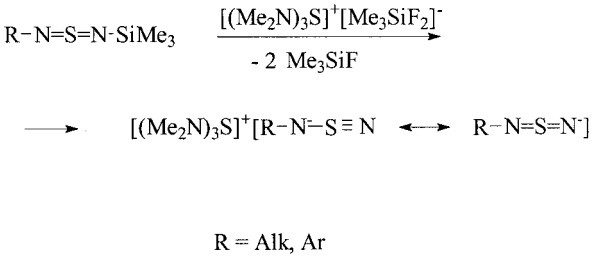
$[K(18\text{-crown-6})]^+$ salts of the $[RNSN]^-$ anions (R = Alk, Ar) and the $[NSN]^{2-}$ dianion, which are thermally stable and very soluble in aprotic organic solvents, were prepared from $[K(18\text{-crown-6})]^+[t\text{BuO}]^-$ and the corresponding R–N=S=N–$SiMe_3$ and $(Me_3Si–N=)_2S$, respectively. The salts are characterized by multinuclear (^1H, ^{13}C, ^{14}N, ^{19}F, ^{29}Si and ^{39}K) NMR spectroscopy in solution and by X-ray diffraction in the solid state. The experimentally determined bond lengths confirm that the $[RNSN]^-$ anions are thiazylamides, $R–N^––S{\equiv}N$ rather than sulfur diimides, $R–N=S=N^–$. Relative to O=S=O, in the $[NSN]^{2-}$ dianion, which is the genuine aza-analogue of sulfur dioxide, the bond lengths are elongated and the bond angle is widened. This might reflect electrostatic repulsion between the negatively charged N atoms. The experimental results are in agreement with theoretical calculations (RHF, B3LYP, MP2). In the nitrogen NMR spectra, when going from $[AlkNSN]^-$ to $[ArNSN]^-$, the low-field signal of the terminal (unsubstituted) N atom reveals further deshielding, whereas the high-field signal of the internal (substituted) N atom displays further shielding. The ^{14}N NMR resonance for the $[NSN]^{2-}$ dianion is practically insensitive to the counterion.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Although known for more than 50 years, the sulfur-nitrogen triple bond still belongs to the less studied multiple bonds. Only relatively few thiazyne derivatives, $R-S{\equiv}N$ and $R_3S{\equiv}N$, are unambiguously characterized, either because of their thermal instability or because of the lack of generally applicable synthetic routes.[1–5]

Recently, it was shown by low-temperature X-ray crystallography and non-empirical calculations at the MP2 and B3LYP levels of theory that $[RNSN]^-$ anions (R = Alk, Ar), which are easily accessible by the fluoride ion-induced desilylation of $R-N=S=N-SiMe_3$ precursors (Scheme 1), should be regarded as thiazylamides $R-N^–-S{\equiv}N$ rather than the expected sulfur diimides $R-N=S=N^–$.[6–8]

Besides their theoretical importance, the $[RNSN]^-$ anions and the related $[NSN]^{2-}$ dianion are also of practical interest for synthetic chemistry as key intermediates for various inter- and intramolecular condensations[9–19] They can also be used as ligands for coordination compounds.[20] The anions are also useful for the solving of some problems of molecular physics related to intramolecular electron-transfer processes,[21] and are worthy of investigation as potential components of molecular conductors based on radical-ion salts.[22]



Scheme 1

Previously, the $[RNSN]^-$ anions were isolated and structurally characterized in the form of air-sensitive and thermally unstable salts of the tris(dimethylamino)sulfonium (TAS^+) cation (Scheme 1),[6–8] which decompose above about −20 °C, especially when R = Ar. Such instability seriously complicates further investigations and applications of the $[RNSN]^-$ anions.

On the other hand, the potassium salts of the $[RNSN]^-$ anions (where R = *t*Bu, Me_3Si) and of the $[NSN]^{2-}$ di

anion, in particular those prepared by the N−Si bond cleavage of the corresponding R−N=S=N−$SiMe_3$ precursors with *t*BuOK, are thermally very stable. They are almost insoluble in common aprotic solvents due to strong anion−cation interaction.[17,23,24] As a consequence, these salts have never been structurally characterized because they were not obtained as single crystals suitable for X-ray crystallography.

This article describes the preparation and isolation of the thermally stable [K(18-crown-6)]$^+$ salts of the [RNSN]$^-$ anions (R = Alk, Ar) and of the [NSN]$^{2-}$ dianion, which are readily soluble in organic solvents. The salts have been characterized by X-ray diffraction and by multinuclear (^{1}H, ^{13}C, ^{14}N, ^{19}F, ^{29}Si and ^{39}K) NMR spectroscopy in solution.

Results and Discussion

As mentioned above, K^+ salts of the [RNSN]$^-$ anions (R = *t*Bu, Me_3Si) and the [NSN]$^{2-}$ dianion were obtained previously by the action of *t*BuOK (and also KNH_2) on the R−N=S=N−$SiMe_3$ or $(Me_3SiN=)_2S$ sulfur diimides, respectively.[17,23,24] However, for these salts strong anion−cation interaction resulted in extremely low volatility (not sublimable) and solubility in organic solvents (not crystallizable), which complicated their further purification and unambiguous structural characterization.

The reaction of the R−N=S=N−$SiMe_3$ (R = Alk, Ar) and $(Me_3SiN=)_2S$ precursors with [K(18-crown-6)]$^+$ [*t*BuO]$^-$ under very mild conditions (at −30 °C in THF) has been used as a nearly quantitative general approach to the organic solvent-soluble salts **1**−**6** with the [RNSN]$^-$ anions and the [NSN]$^{2-}$ dianion (Scheme 2). The *t*Bu−O−$SiMe_3$ by-product (liquid, b. p. 102−103 °C) is inert under these reaction conditions and does not interfere with the isolation of the target salts.

$$R-N{=}S{=}N-SiMe_3 + [K(18\text{-crown-}6)]^+[t\text{BuO}]^- \longrightarrow [K(18\text{-crown-}6)]^+[RNSN]^- + t\text{BuOSiMe}_3$$

R = 1-Ad (**1**), *t*Bu (**2**), Me_3Si (**3**), Ph (**4**), 4-FC_6H_4 (**5**)

$$Me_3Si-N{=}S{=}N-SiMe_3 + 2[K(18\text{-crown-}6)]^+[t\text{BuO}]^- \longrightarrow \{[K(18\text{-crown-}6)]^+\}_2[NSN]^{2-} + 2\ t\text{BuOSiMe}_3$$

6

Scheme 2

The salts **1**−**6** (Scheme 2) are thermally very stable. They decompose (depending on R) in the range of approximately 100 °C (**5**) to approximately 150 °C (**2**, **6**) (see Exp. Sect. for details).

Importantly, by using this approach, it was possible to obtain the salts of interest in the form of single crystals suitable for X-ray crystallography using low-temperature crystallization from organic solvents. The solid-state structures of the salts **1** and **3**−**6** are shown in Figure 1 and Figures 2−5, respectively, and the details of the structure

determinations are listed in Table 1. Selected bond lengths and bond angles are given in Table 2. The structures of the $[PhNSN]^-$ anion (salt **4**), the parent anion of the $[ArNSN]^-$ family,[6,8] and the $[NSN]^{2-}$ dianion (salt **6**) are described for the first time. The X-ray structure of salt **2** was not solved due to strong disorder of both cation and anion, but this salt was unambiguously characterized in solution by multinuclear NMR spectroscopy (see below).

In the solid state, all $[RNSN]^-$ anions with R = 1-Ad, Ph, $4\text{-}FC_6H_4$ (salts **1**, **4**, **5**) exhibit the expected *Z*-configuration (Figure 1, Figure 2, Figure 3), whereas the $[Me_3SiNSN]^-$ anion (salt **3**) demonstrates the stereoelectronically unfavorable *E*-configuration (Figure 4), previously also observed for its TAS^+ salt (for the in-depth discussion of the *Z*- and *E*-configurations and the bonding properties of the $[RNSN]^-$ anions, see refs.[7,8]). In the salts with the anions in the *Z*-configuration, the K^+ counterion (encapsulated in the crown ether) is coordinated only by the terminal nitrogen atom (Figure 1, Figure 2, Figure 3), whereas the K^+ cation interacts with the anion in the *E*-configuration symmetrically with both the terminal and the internal N atoms (Figure 4). Due to this coordination the N−S−N bond angle in the $[Me_3SiNSN]^-$ anion is significantly narrower than in the other $[RNSN]^-$ anions (Table 2). In all cases, the N···K^+ separation in these salts (Table 2) is shorter than the sum of van der Waals radius of the N atom (150 pm) and the ionic radius of K^+ (157 and 164 pm for coordination numbers 8 and 12, respectively),[25] which implies relatively strong anion−cation interaction. Interestingly, for salt **3** the S···K^+ distance (Table 2) is rather close to the sum of the van der Waals radius of S (185 pm) and ionic radius of K^+.

Experimentally determined bond lengths (Table 2) confirm that the $[RNSN]^-$ anions should be described as thiazyl anions R−N^-−S≡N rather than sulfur diimide anions R−N=S=N^-. In the anions studied (Table 2), both the sulfur−nitrogen bonds are very different. While the terminal sulfur−nitrogen bond length falls into the range established for the S^{IV}≡N triple bond (146−148 pm), the internal sulfur−nitrogen bond is 9−13 pm longer (Table 2). Comparing the TAS^+ and $[K(18\text{-crown-6})]^+$ salts of the

same [RNSN]$^-$ anions, it can be seen that exchange of the cation affects the bond lengths and bond angles in the anion to some extent; however the differences are relatively small (Table 2).

The reason for the reorganization of the chemical bonding on going from the R−N=S=N−SiMe$_3$ precursors to the corresponding R−N$^-$−S≡N anions is not entirely clear.[7,8] It follows from a preliminary analysis of the calculations at the MP2/6-31+G* level of theory that this reorganization is driven to some extent by the reduction of the local symmetry at the S atom.[25,26]

The [NSN]$^{2-}$ dianion (salt **6**) is the genuine aza-analogue of sulfur dioxide O=S=O (and isoelectronic with ozone, O$_3$). As mentioned above, no structural characterization using X-ray crystallography has been reported in the literature. On the basis of vibrational spectra,[23] its C_{2v} symmetry was determined and confirmed independently by quantum chemical calculations at the RHF level of theory.[27]

In the gas phase, the structure of the O=S=O molecule was determined by microwave spectroscopy with sulfur−oxygen bond lengths of 143.1 pm and a OSO bond

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

angle of 119.3°.[28] Recently, the solid-state structure was also reported from a low temperature X-ray study [sulfur−oxygen bond length 142.97 (4) pm and OSO angle 117.5(1)°].[29]

In the crystal structure, the sulfur atom of the $[NSN]^{2-}$ dianion is situated very close to a crystallographic center of inversion and therefore the anion is disordered over two positions. The two independent S−N distances were refined with one common value and the calculations converged at 148.4(3) pm with a N−S−N angle of 129.9(2)°. Our theoretical calculations (Table 3) agree reasonably well with our experimental results.

Table 3. Bond lengths (pm) and bond angles (°) of the $[NSN]^{2-}$ anion from quantum chemical calculations

	RHF[a]	MP2[a]	B3LYP[a]	Exp.
(*d* S−N)	149.9	155.8	154.4	148.4(3)
(< N−S−N)	129.8	134.0	131.4	129.9(2)

[a] Basis set: 6−311+G*; for all methods NIMAG = 0.

Relative to O=S=O, in the $[NSN]^{2-}$ dianion, the bond lengths [148.4(3) pm] are elongated by ca. 5 pm and the bond angle [129.9(2)°] is widened by ca. 12 degrees (Table 2). This might reflect the electrostatic repulsion between the negatively charged N atoms. To the best of our knowledge, high level quantum chemical calculations on $[NSN]^{2-}$ are not reported in the literature. Earlier MNDO and HFS calculations,[27] not surprisingly, do not reproduce the experimentally observed geometry.

Previously, the $[RNSN]^-$ anions (R = *t*Bu, Me_3Si) and the $[NSN]^{2-}$ dianion (with Me_4N^+, nBu_4N^+ and TAS^+ as counterions) were characterized by multinuclear NMR spectroscopy (including nitrogen) in solution and in the solid state[7,30,31] (nitrogen NMR spectroscopy of binary sulfur-nitrogen anions, see ref.[32−34]). For $[RNSN]^-$, the high-field signal in the nitrogen (^{14}N and ^{15}N) NMR spectra can always be assigned to the internal (substituted) N atom and the low-field signal to the terminal (unsubstituted) N atom.

Table 4. Multinuclear NMR spectroscopic data (δ, ppm) for the salts **1**−**6**

5[c]	7.67, 6.82, 3.50	157.2, 147.3, 123.8, 114.7, 70.7	506.2[d], 285.1[d]	−5.4
6[e]	3.53	70.7	382	−4.0

[a] $\delta^{29}Si = -15.2$. [b] cf. Me_4N^+ salt: $\delta^1H = 3.24$ (Me_4N^+), −0.01; $\delta^{13}C = 56.0$ (Me_4N^+), 3.3; $\delta^{29}Si = -13.4$; $\delta^{14}N = 542, 294, 46$ (Me_4N^+). The salt was obtained from a 1:1 reaction of $(Me_3Si-N=)_2S$ with Me_4NF as large transparent orange-yellow scales (85%), m.p. (from MeCN) 140−141 °C (decomposition with gas evolution).[29] [c] $\delta^{19}F = 38.0$. [d] $\delta^{15}N$ ($\delta^{14}N = 507, 283$). [e] Me_4N^+ salt: $\delta^1H = 3.20$ (Me_4N^+); $\delta^{13}C = 55.9$ (Me_4N^+); $\delta^{14}N = 383, 46$ (Me_4N^+). The salt was obtained from a 1:2 reaction of $(Me_3Si-N=)_2S$ with Me_4NF as well-shaped orange-red prisms (90%), m.p. (from MeCN) 161−162 °C (decomposition with gas evolution).[29]

The multinuclear (^1H, ^{13}C, ^{14}N, ^{19}F, ^{29}Si, ^{39}K) NMR spectroscopic data for solutions of the salts **1**−**6** in acetonitrile are presented in Table 4. It follows from the Table 3 that on going from $[AlkNSN]^-$ (Alk = *t*Bu, 1-Ad) to $[ArNSN]^-$ (Ar = Ph, 4-FC_6H_4) (all four are in the *Z* configuration), the signal for the internal N atom shifts further high field, whereas the signal for the terminal N atom shifts in the opposite direction further low field. As a result, the $\Delta\delta^{14}N$ difference between magnetic shielding of the internal and terminal N atoms is larger in the $[ArNSN]^-$ than in the $[AlkNSN]^-$ anions.

The single ^{14}N NMR resonance for the $[NSN]^{2-}$ dianion is found between those of the terminal and the internal N atoms of the $[RNSN]^-$ anions (Table 3). The chemical shift is practically independent of the counterion (Me_4N^+, nBu_4N^+, TAS^+, $[K(18\text{-crown-6})]^+$).

Conclusion

$[K(18\text{-crown-6})]^+$ salts of the $[RNSN]^-$ anions (R = Alk, Ar), including that with R = Ph (the parent compound of the $[ArNSN]^-$ family), as well as of the $[NSN]^{2-}$ dianion, were prepared for the first time and structurally characterized by X-ray diffraction in the solid state and by multinuclear NMR spectroscopy (including nitrogen) in solution. The experimentally determined bond lengths confirm that the $[RNSN]^-$ anions are thiazylamides $R-N^--S\equiv N$ rather than sulfur diimides $R-N=S=N^-$. As observed for the corresponding TAS-salts, TAS^+RNSN^-, the substituent R occupies the electronically unfavorable E-position only in the Me_3Si derivative.[6−8] The present investigation shows that even bulky substituents and strong anion−cation interactions do not influence the preference of the alkyl and aryl substituents for the *Z*-position.

Relative to O=S=O, in the $[NSN]^{2-}$ dianion, which is the genuine aza-analogue of sulfur dioxide, the bond lengths are elongated and the bond angle is widened; this might reflect Coulombic repulsion between the N atoms. In the nitrogen NMR spectra, when going from $[AlkNSN]^-$ to $[ArNSN]^-$ the low-field signal of the terminal N atoms reveals further deshielding, whereas the high-field signal of internal N atoms display further shielding. The single ^{14}N NMR resonance for the $[NSN]^{2-}$ dianion is not influenced by the counterion.

Due to anion−cation interactions, the salts prepared are thermally very stable. Their stability and their good solubility in aprotic organic solvents (THF, MeCN) facilitates their use in synthetic chemistry as key intermediates for various inter- and intramolecular condensations. They can also be used as ligands for coordination compounds.

Experimental Section

Materials and Methods: The starting $R-N=S=N-SiMe_3$ and $(Me_3Si-N=)_2S$ compounds were synthesized as described previously.[11,13,35] *t*BuOK (Janssen Chimica) was sublimed in vacuo, 18-crown-6 (Aldrich) was used as received. Absolute MeCN, THF, Et_2O and *n*-pentane were prepared by standard methods. The multinuclear NMR spectra were measured using a Bruker DRX-500 spectrometer at frequencies of 500.13 (^{1}H), 125.76 (^{13}C), 36.13 (^{14}N), 50.68 (^{15}N), 470.59 (^{19}F), 99.36 (^{29}Si), and 23.34 (^{39}K) MHz for solutions in CD_3CN; the chemical shifts (Table 2) are referred to TMS (^{1}H, ^{13}C, ^{29}Si), NH_3 (l) (^{14}N, ^{15}N), C_6F_6 (^{19}F) and KCl (aq.) (^{39}K). The melting points were measured using a Gallencamp Melting Point Apparatus in sealed capillaries. For all salts melting was accompanied by decomposition with gas evolution.

Preparation of $[K(18\text{-crown-6})]^+[RNSN]^-$ (R = Ad (1), *t*Bu (2), Ph (4), 4-FC_6H_4 (5): Under dry argon, at −40 °C, a solution of the corresponding $R-N=S=N-SiMe_3$ (5 mmol) in THF (5 mL) was added dropwise to a stirred solution of $[K(18\text{-crown-6})]^+[t\text{BuO}]^-$ (1.88 g, 5 mmol) in THF (20 mL) (prepared from *t*BuOK (0.56 g, 5 mmol) and 18-crown-6 (1.32 g, 5 mmol) at −20 °C). After an additional 2 h at the same temperature, the solvent was removed under high vacuum. MeCN (20 mL) was redistilled onto the solid residue via a vacuum line at −196 °C. On warming to −40 °C, the red solution formed was filtered through a sintered glass frit, cooled again to −196 °C, and Et_2O (20 mL) was condensed onto it. The reaction vessel was placed into a cryostat at −35 °C for crystal growth. After 2 weeks, when mutual diffusion of the solvents ceased, the mother liquor was removed with a syringe under dry argon at −40 °C. The crystalline residue was washed with Et_2O and dried in vacuo at ambient temperature.

$[K(18\text{-crown-6})]^+[1\text{-AdNSN}]^-\cdot$MeCN (1): Large transparent orange-yellow prisms, 2.30 g (85%), m.p. 106−108 °C.

$[K(18\text{-crown-6})]^+[t\text{BuNSN}]^-$ (2): Large transparent orange-yellow crystals, 1.90 g (90%), m.p. 149−150 °C.

$[K(18\text{-crown-6})]^+[\text{PhNSN}]^-$ (4): Orange-red crystals, 1.58 g (72%), m.p. 110−112 °C.

$[K(18\text{-crown-6})]^+[4\text{-}FC_6H_4NSN]^-$ (5): Orange-brown crystals, 1.28 g (56%), m.p. 98−100 °C.

Preparation of $[K(18\text{-crown-6})]^+[Me_3SiNSN]^-$ (3) (a) and $\{[K(18\text{-crown-6})]^+\}_2[NSN]^{2-}$ (6) (b): Under dry argon, at −40 °C, a solution of $(Me_3Si-N=)_2S$ (1.03 g, 5 mmol) (a) or (0.50 g, 2.5 mmol) (b) in THF (5 mL) was added dropwise to a stirred solution of $[K(18\text{-crown-6})]^+[t\text{BuO}]^-$ (1.88 g, 5 mmol) inTHF (20 mL), prepared as described above. After an additional 2 h at the same temperature, the reaction solution was filtered through a sintered glass frit and *n*-pentane (20 mL) was condensed onto it via a vacuum line at −196 °C. For crystal growth, the reaction vessel was placed into a cryostat at −35 °C (a) or kept at 20 °C (b). After 2 weeks, the solvents were removed as described above, and the crystalline residue was washed with Et_2O and dried in vacuo at ambient temperature.

$[K(18\text{-crown-6})]^+[Me_3SiNSN]^-\cdot$THF (3): Orange-yellow crystals, 2.09 g (82%), m.p. 106−108 °C.

$\{[K(18\text{-crown-6})]^+\}_2[NSN]^{2-}$ (6): Large bronze-brown crystals (orange-yellow when freshly prepared; dark orange in transmitting light), 1.50 g (90%), m.p. 152−154 °C.

X-ray Crystallographic Study: The single-crystal X-ray structure determinations (Table 1) were carried out on a Stoe IPDS for **1**, **3**, **4**, and on a Siemens P4 diffractometer for **5** and **6**, using Mo-K_α (0.71073 Å) radiation with a graphite monochromator. Refinement based on F^2; $R1 = \|F_o| - |F_c\|/|F_o|$; $wR2 = \{[w(F_o^2 - F_c^2)^2/[w(F_o^2)^2]\}^{1/2}$. Programs used: SHELX-97[36] and DIAMOND.[37] The structures of **1** and **4** were refined as racemic twins. In the crystal packing of **6**, the anion and cation are both disordered. The single crystals were mounted on a thin glass fiber using KEL-F oil. The structures were solved by direct methods (SHELXS[36]). Subsequent least-squares refinements (SHELXL-97-2[36]) located the positions of the remaining atoms in the electron density maps. All non-H atoms were refined anisotropically.
CCDC-227222 (for **1**), -227223 (for **2**), -227224 (for **4**), -227225 (for **5**), -227226 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Quantum Chemical Calculations: Quantum chemical calculations were performed with the Gaussian 98 set of programs.[38]

Acknowledgments

The authors are grateful to Dr. Paul G. Watson for NMR spectroscopic measurements on the Me_4N^+ salts, and to Mr. Peter Brackmann for technical assistance with the X-ray diffraction measurements. The joint financial support of this work by the DFG, Germany (Project 436 RUS 113/486/0−2 R), and the RFBR, Russia (Project 02−03−04001), is gratefully acknowledged. Synthesis and Core and Surface Reactivity of Phosphorus-Based Dendrons

Rosa-María Sebastián,[a] Laurent Griffe,[a] Cédric-Olivier Turrin,[a] Bruno Donnadieu,[a] Anne-Marie Caminade,*[a] and Jean-Pierre Majoral*[a]

Keywords: Azides / Dendrimers / Dendrons / N,P ligands / Phosphorus

A series of phosphorus-containing dendrons is synthesized starting from a unique precursor $(EtO)_2P(O)CH{=}CHC_6H_4PPh_2$ (**3-G$_0$**), whose X-ray crystal structure shows an extended planarity between both phosphorus. Staudinger reactions with functionalized azides on the phosphino group are the first step for the growth of the dendrons, which is continued using a divergent method. Several types of reactions are performed on dendrons of several sizes, either at the level of the core or of the surface. The specific addition of methyl triflate to P=S and trimethylsilyl triflate to P=O at the level of the core affords a dicationic species. A ^{13}C NMR spectroscopic study indicates to what extent the charges are delocalized. Phosphanes are grafted on the surface of a second-generation dendron, and used for the complexation of $PdCl_2$. Both compounds possess five different types of phosphorus atoms, which helps in characterizing them by ^{31}P NMR spectroscopy.

Introduction

Dendrons[1] are dendritic wedges that differ from classical dendrimers[2] by the presence of a functional group at the level of the core. Such compounds can be built using either a convergent[3] or a divergent[4] process, and they have found applications as building blocks for the rapid synthesis of dendrimers[5] or for the coating of the surface of various materials, for example.[6] The nature of the function located at the core is of crucial importance when synthesizing dendrons, particularly if a divergent process is used. Indeed, this function is present from the beginning of the synthesis and hence it must be compatible with the whole synthetic process while remaining available for further reactions after the growth of the dendron. Due to the wide range of uses and applications of phosphonates in organic synthesis, biology and materials chemistry,[7] we decided to graft a phosphonate at the core, linked through a potentially conjugated linkage, which may act as a probe for sensing further reactivity.

We have already reported the divergent synthesis of phosphorus-containing dendrons[4,8,9] and dendrimers,[10] and shown that ^{31}P NMR spectroscopy is an extraordinarily useful tool for characterizing such compounds. However, when the chemical structure is similar at each layer, a partial overlap of signals may occur.[11] We and others have shown that using two[12] or three[13,14] types of chemical environment around the phosphorus atoms allows an easier characterization. We report in this paper the synthesis and characterization of a series of dendrons having a phosphonate at the core and up to five different types of phosphorus atoms in the structure; these are clearly distinguishable by ^{31}P NMR spectroscopy. Furthermore, these compounds possess a versatile reactivity at every step of the synthesis, as will be illustrated by three very different examples.

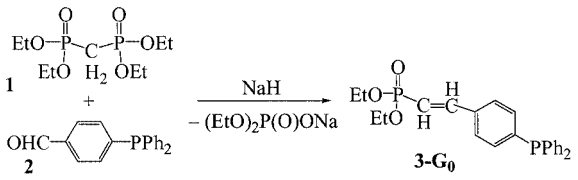
Results and Discussion

The method used for grafting the phosphonate at the core consists of the Horner−Wadsworth−Emmons reaction[15] of tetraethylmethylene *gem*-diphosphonate **1** with diphenylphosphino benzaldehyde **2** in the presence of NaH that we have already applied to the surface of dendrimers[16] (Scheme 1). The reaction creates a C=C bond connecting the phosphonate to the aryl group. The resulting vinyl phosphonate derivative **3-G$_0$** was isolated in quantitative yield. The expected *E*-configuration of the alkene bond is shown in the ^1H NMR spectrum by the large value of the $^3J_{H,H}$ coupling constant (17.2 Hz). Single crystals of **3-G$_0$** were obtained by slow evaporation of a solution in CH_2Cl_2 and allowed the determination of its structure by X-ray diffrac-



Scheme 1

tion. The ORTEP drawing is shown in Figure 1 and confirms the *E*-configuration of the C=C bond. All atoms from P2 to O3 are in a plane (Rms deviation 0.0685), indicating an extended conjugation of 11 atoms.

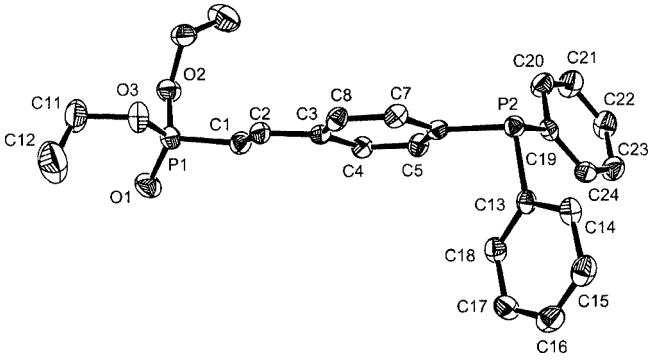


Figure 1. ORTEP drawing of **3-G$_0$**; selected bond lengths (Å) and angles (°): P1−O1 1.4605(16), P1−O2 1.5754(15), P1−O3 1.5794(16), P1−C1 1.775(2), C1−C2 1.322(3), P2−C6 1.8328(19), P2−C13 1.839(2), P2−C19 1.8421(19); P1−C1−C2 125.04(17), C1−C2−C3 126.25(19)

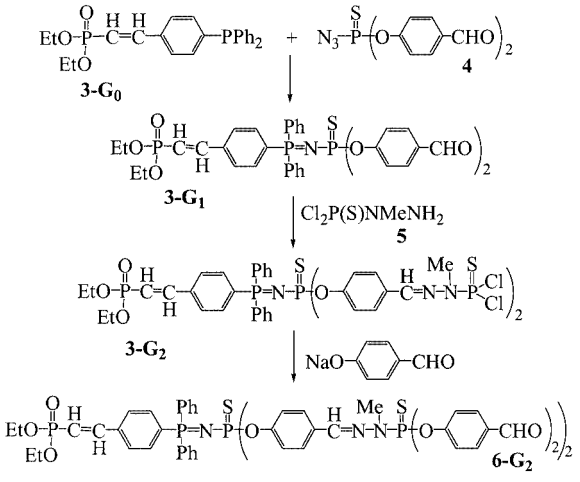
Compound **3-G$_0$** is the starting material for the synthesis of various dendrons. Indeed, the presence of a phosphane allows it to undergo Staudinger reactions with functionalized azides such as compound **4**, which affords the first generation dendron **3-G$_1$** (Scheme 2). As expected,[17] the P=N−P=S linkage created by the reaction is characterized in the ^{31}P NMR spectrum by two doublets at δ = 14.4 (P=N) and 50.2 (P=S) ppm with $^{2}J_{P,P}$ = 31 Hz. In the ^{13}C NMR spectrum a dramatic shielding of the signals corresponding to the carbons linked to the phosphorus that undergoes the reaction is observed ($\Delta\delta$ = −9.31 ppm for $C_{ipso}PPh_2$; $\Delta\delta$ = −10.65 ppm for $C_{ipso}PC_6H_4$) together with a very important increase of the $^{1}J_{C,P}$ coupling constant. More interestingly, the Staudinger reaction also induces changes for the vinyl linkage, where the signal corresponding to the =CH linked to C_6H_4 is shielded, whereas the signal corresponding to (O)P-CH= is deshielded ($\Delta\delta$ = +3.44 ppm), confirming a conjugation through the aromatic and vinyl linkages (Figure 2).



Scheme 2

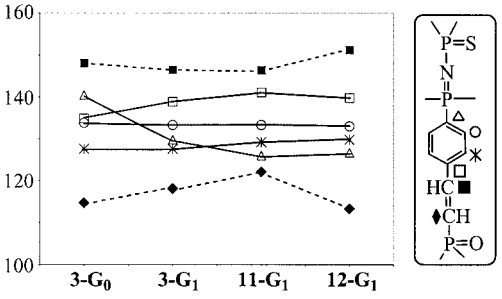


Figure 2. Variation of the chemical shifts (^{13}C NMR) for all carbon atoms located from P(O) to P for four compounds (**3-G$_0$**, **3-G$_1$**, **11-G$_1$**, and **12-G$_1$**)

To continue the growth of the dendron, our classical method of synthesis of dendrimers[18,19] was applied starting from the aldehydes of **3-G$_1$**, and using the phosphorhydrazide **5** to generate dendron **3-G$_2$**. Then, the nucleophilic substitution of Cl with hydroxybenzaldehyde sodium salt afforded compound **6-G$_2$**. It is noteworthy that none of these reactions has an influence on the vinylphosphonate group located at the core, as shown by ^{31}P NMR spectroscopy, with the presence of the singlet of the P=O group (δ = 18.2 ppm) together with the singlet of the P=S end groups (δ = 60.7 ppm) and both doublets corresponding to the P=N−P=S linkage (δ = 13.7 and 51.8 ppm, respectively).

Thus, the growth of the dendron could have been pursued to higher generations, as we have already shown with dendrons containing other types of functions at the core,[4,8,9,20] but we prefer to show the versatility and adaptability of this method of synthesis at every step, including starting from **3-G$_0$**. Indeed, other types of functionalized azides can be used, as shown by the reaction with compound **7** affording **8-G$_1$** (Scheme 3). Here also, the Staudinger reaction induces the appearance of two doublets in the ^{31}P NMR spectrum at δ = 12.8 (P=N) and 71.2 (P=S) ppm with $^{2}J_{P,P}$ = 17.2 Hz. Obviously, the presence of NH_2 groups opens the way to a tremendous number of reactions, in particular condensations with functionalized aldehydes. As an illustration, the carbohydrate derivative **9** (helicin) was condensed with **8-G$_1$**. The condensation induces an important shielding in the ^{31}P NMR spectrum for the signal corresponding to the P=S group, from δ = 71.2 ppm for **8-G$_1$** to δ = 62.5 ppm for **10-G$_1$**. A careful examination of the ^{1}H and ^{13}C NMR spectra of **10-G$_1$** shows that several signals corresponding to the helicin and hydrazone moieties are split into two series of signals in a 1:1 ratio; for example, the NCH_3 groups give two doublets at δ = 33.89 and 34.04 ppm. Such splitting might be ascribed to *E* and *Z* isomers of the hydrazone bond (C=N) with one *E* and one *Z* bond for each molecule of **10-G$_1$**. Phosphorhydrazone bonds are generally in the *E* configuration, thus the formation of a *Z* isomer might be due to the occurrence of hydrogen bonds, which forces one hydrazone linkage to be in the *Z* form, as previously noticed on the surface of dendrimers.[21] Due to the carbohydrate moieties, **10-G$_1$** is soluble in water, whereas all the other dendrons described in this paper are not.

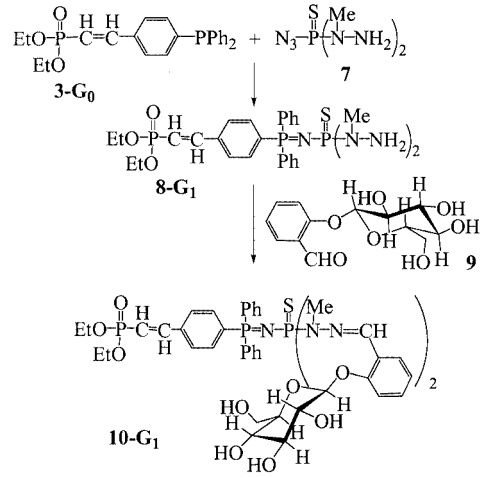
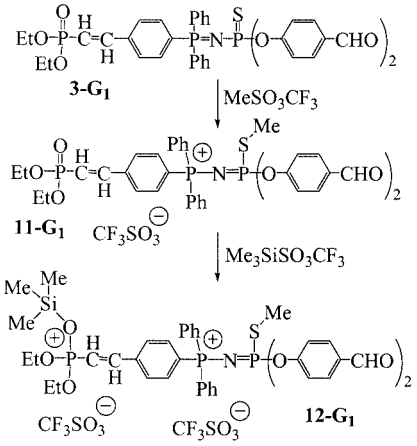


Scheme 3



Scheme 4

We also tested another type of reactivity with compound **3-G$_1$** — alkylation reactions — with the aim of detecting to what extent the positive charge could be delocalized.[22] One equivalent of the strong alkylating reagent methyl trifluoromethanesulfonate was added to **3-G$_1$** (Scheme 4). We have already shown that this reagent is able to alkylate the sulfur atom included in a P=N−P=S linkage,[13,17,23] but such a reaction has never been performed in the presence of a phosphonate group, although we have reported the specific alkylation of P=S in macrocycles bearing phosphane oxide groups.[24] The ^{31}P NMR spectrum of the resulting compound **11-G$_1$** shows without any ambiguity that the alkylation occurs exclusively at the P=S group. Indeed, a $\Delta\delta$ value of −27 ppm was measured for the signal corresponding to P=S, whereas it is only −1 ppm for the P=O group, on going from **3-G$_1$** to **11-G$_1$**. Both signals corresponding to P=N (δ = 22.2 ppm) and P=S (δ = 23.1 ppm) are close; the assignment of the chemical shift was made by proton-coupled ^{31}P NMR spectroscopy, which gives a coupling constant of 18.2 Hz for the signal at δ = 23.1 ppm (P−S−Me). The positive charge is delocalized to some extent onto the adjacent P=N group ($\Delta\delta$ = +8 ppm). In view of the extended planarity seen in the X-ray structure of **3-G$_0$**, and the modification of the ^{13}C NMR spectra on going from **3-G$_0$** to **3-G$_1$**, the charge might even be delocalized all the way along the chain up to the phosphonate group. The ^{13}C NMR spectrum shows a deshielding of the signal corresponding to (O)P-*C*H=, which should correspond to a partial positive charge on this atom (Figure 2, rhombuses). However, the absence of a variation of the chemical shift corresponding to P=O seems to preclude an extension of the delocalization up to it, and is in agreement with the structure of **3-G$_0$** obtained by X-ray diffraction in which the oxygen of P=O lies outside the main plane.

This assumption was reinforced by checking the reactivity of trimethylsilyl trifluoromethanesulfonate with **11-G$_1$**, since we have already shown that it is able to react with phosphane oxides.[25] Indeed, the presence of a positive charge on P=O should hamper further addition of cations to this group. The reaction monitored by ^{31}P NMR spectroscopy shows a deshielding of the signal corresponding to the P=O group ($\Delta\delta$ = 4 ppm) whereas no change is observed for the other signals. The dicationic species **12-G$_1$** was obtained quantitatively. The ^{13}C NMR spectrum of **12-G$_1$** shows only modifications for the vinyl group, with a shielding of the carbon linked to phosphorus ($\Delta\delta$ = −9 ppm) and a deshielding of the other carbon ($\Delta\delta$ = 5 ppm) (Figure 2). Thus, the delocalization of the second positive charge only has an influence on the (O)P−CH=CH linkage.

The last example illustrating the versatile reactivity of this series of dendrons concerns **3-G$_2$**. Its P(S)Cl$_2$ end-groups can be reacted with various functionalized phenols such as **13**, which affords dendron **14-G$_2$** (Scheme 5). These phosphanyl end-groups are used because they are potential N,P ligands. Indeed, we have shown previously that the corresponding Pd complexes linked to the surface of dendrimers efficiently catalyze Stille coupling reactions.[26] The palladium complex **15-G$_2$** is readily obtained by reaction with [PdCl$_2$(COD)]. Here again the ^{31}P NMR spectrum gives very informative data for the characterization. Fig-

ure 3 shows the spectrum of **15-G$_2$**, with five different types of phosphorus atoms clearly distinguishable, and in the expected ratio.

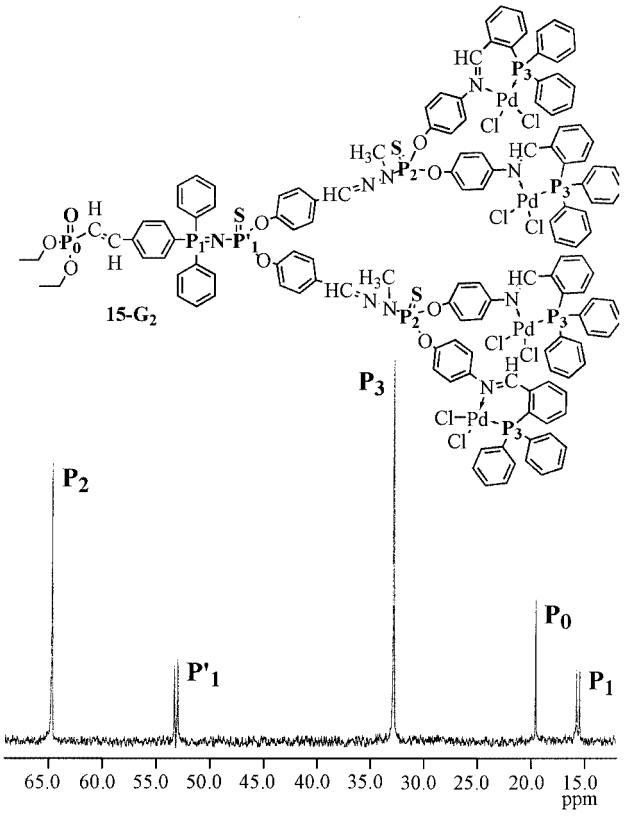

Figure 3. ^{31}P NMR spectrum and chemical structure of **15-G$_2$**

Conclusion

We have shown in this paper that compound **3-G$_0$** is a multifunctional diphosphorus derivative, readily usable as the core of various dendrons. These dendrons contain up to five different types of phosphorus groups, which act as sensitive labels that are able to detect subtle and remote chemical modification, as shown by ^{31}P NMR spectroscopy. These dendrons also possess a versatile reactivity both at the level of the core and of the end groups that is adaptable depending on the type of use desired. As an illustration, we have given three very different examples concerning modification of the solubility, alkylation with delocalization of the charges, and grafting of N,P ligands as end-groups, along with a preliminary study of their complexation properties. Obviously, many other examples of reactions can be envisaged, in particular concerning the use of phosphonates for the grafting of dendrons on the surface of various materials. Indeed, it is known that phosphonates are able to react, for instance, with alumina[27] and titania particles.[28] Thus, compound **15-G$_2$** could be used as precursor of heterogeneous catalysts.

Experimental Section

General Remarks: All manipulations were carried out with standard high vacuum and dry-argon techniques. The solvents were freshly dried and distilled (THF and diethyl ether over sodium/benzophenone; pentane and CH_2Cl_2 over phosphorus pentoxide; toluene over sodium); they were degassed prior to use in the case of experiments using trivalent phosphorus derivatives. ^{1}H, ^{13}C and ^{31}P NMR spectra were recorded with Bruker AC 200, AC 250, DPX 300 or AMX 400 spectrometers. References for NMR chemical shifts are 85% H_3PO_4 for ^{31}P NMR and $SiMe_4$ for ^{1}H and ^{13}C NMR spectroscopy. The attribution of the ^{13}C NMR signals was performed by using J_{mod}, two dimensional HMBC, and HMQC, Broad Band or CW ^{31}P decoupling experiments when necessary. The numbering used for the NMR assignments is depicted in Figure 4. Compounds **2**,[29] **4**,[30] **7**,[30] and **13**[26] were synthesized as reported previously.

Phosphane 3-G$_0$: A solution of $(EtO)_2P(O)CH_2P(O)(OEt)_2$ (0.500 g, 1.680 mmol) in THF (5 mL) was added to a suspension of NaH (0.043 g, 1.680 mmol) in THF (15 mL). After stirring for 10 min a clear solution was obtained. A solution of $CHOC_6H_4PPh_2$ (0.490 g, 1.68 mmol) in THF (5 mL) was then added dropwise. The resulting mixture was stirred overnight, then H_2O (10 mL) was added. The resulting mixture was concentrated under vacuum to eliminate THF, then CH_2Cl_2 (10 mL) was added. The organic phase was recovered, and the water phase was washed twice with CH_2Cl_2. The organic layers were combined and the solvents evaporated to dryness to afford a pale yellow powder. **3-G$_0$** was purified by column chromatography on silica gel (eluent: ethyl acetate) to afford a white powder in 99% yield (0.700 g). Translucent crystals suitable for X-ray diffraction were obtained after a slow evaporation of a solution in CH_2Cl_2. ^{1}H NMR ($CDCl_3$): δ = 1.30 (t, $^3J_{H,H}$ = 7.1 Hz, 6 H, CH_3), 4.09 (dt, $^3J_{H,H}$ = 7.1, $^3J_{H,P}$ = 14.3 Hz, 4 H, CH_2), 6.25 (t, $^3J_{H,H}$ = $^2J_{H,P}$ = 17.5 Hz, 1 H, =CH-P$_0$), 7.21−7.46 (m, 14 H, H_{Arom}), 7.51 (d, $^3J_{H,H}$ = 17.5 Hz, 1 H, C*H*=CH-P$_0$) ppm. ^{13}C{^{1}H}

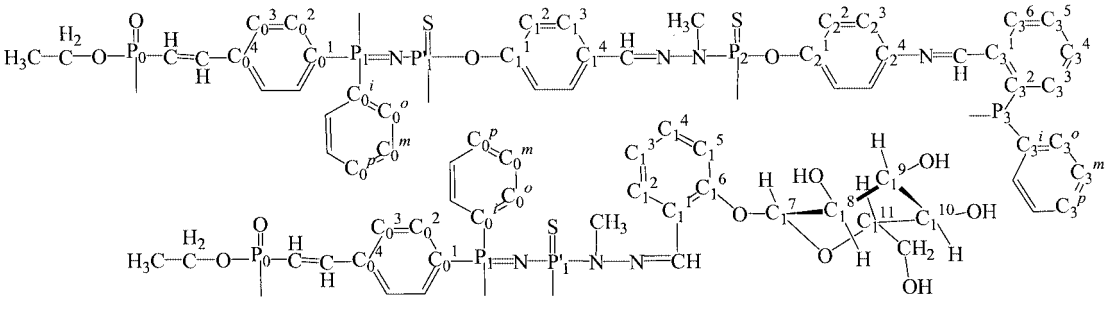

Figure 4. Numbering used for NMR spectroscopy

NMR ($CDCl_3$): δ = 16.42 (d, $^3J_{C,P}$ = 6.0 Hz, CH_3), 61.84 (d, $^2J_{C,P}$ = 5.7 Hz, CH_2), 114.68 (d, $^1J_{C,P}$ = 191.2 Hz, =CH-P_0), 127.60 (d, $^3J_{C,P}$ = 7.3 Hz, C_0^3), 128.62 (d, $^3J_{C,P}$ = 6.0 Hz, C_0^m), 128.98 (s, C_0^p), 133.79 (d, $^2J_{C,P}$ = 21.2 Hz, C_0^o), 133.83 (d, $^2J_{C,P}$ = 16.3 Hz, C_0^2), 134.93 (d, $^3J_{C,P}$ = 23.4 Hz, C_0^4), 136.50 (d, $^1J_{C,P}$ = 10.1 Hz, C_0^i), 140.50 (d, $^1J_{C,P}$ = 13.5 Hz, C_0^1), 148.07 (d, $^1J_{C,P}$ = 7.6 Hz, *C*H=CH-P_0) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −5.2 (s, P_1), 19.5 (s, P_0) ppm. $C_{24}H_{26}O_3P_2$ (424.41): calcd. C 67.92, H 6.17; found C 67.96, H 6.19.

Dendron 3-G_1: CH_2Cl_2 (10 mL) was added to a powdered mixture of **3-G_0** (0.302 g, 0.712 mmol) and the azide $N_3P(S)(OC_6H_4CHO)_2$ (0.247 g, 0.712 mmol). A rapid evolution of nitrogen was observed. The solution was stirred overnight then evaporated to dryness to afford **3-G_1** as a pale yellow powder in 98% yield (0.520 g). A strict 1:1 ratio must be respected between **3-G_0** and the azide, because numerous washings of **3-G_1** did not allow the elimination of the unreacted starting materials. ^1H NMR ($CDCl_3$): δ = 1.30 (t, $^3J_{H,H}$ = 7.1 Hz, 6 H, CH_3), 4.09 (dt, $^3J_{H,H}$ = 7.1, $^3J_{H,P}$ = 14.6 Hz, 4 H, CH_2), 6.35 (t, $^3J_{H,H}$ = $^2J_{H,P}$ = 17.2 Hz, 1 H, =CH-P_0), 7.26 (d, $^3J_{H,H}$ = 8.0 Hz, 4 H, H-C_1^2), 7.37−7.66 (m, 14 H, H_{Arom}), 7.55 (d, $^3J_{H,H}$ = 17.2 Hz, 1 H, C*H*=CH-P_0), 7.73 (d, $^3J_{H,H}$ = 8.0 Hz, 4 H, H-C_1^3), 9.86 (s, 2 H, CHO). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 16.39 (d, $^3J_{C,P}$ = 5.9 Hz, CH_3), 62.07 (d, $^2J_{C,P}$ = 5.9 Hz, CH_2), 118.12 (d, $^1J_{C,P}$ = 189.6 Hz, =CH-P_0), 122.03 (d, $^3J_{C,P}$ = 4.1 Hz, C_1^2), 127.19 (dd, $^1J_{C,P}$ = 106.0, $^3J_{C,P}$ = 3.8 Hz, C_0^i), 127.63 (d, $^3J_{C,P}$ = 13.5 Hz, C_0^3), 128.84 (d, $^3J_{C,P}$ = 13.7 Hz, C_0^m), 129.85 (dd, $^1J_{C,P}$ = 113.0, $^3J_{C,P}$ = 3.5 Hz, C_0^1), 131.16 (s, C_1^3), 132.60 (s, C_1^4), 132.64 (d, $^2J_{C,P}$ = 11.7 Hz, C_0^o), 133.01 (s, C_0^p), 133.27 (d, $^2J_{C,P}$ = 11.6 Hz, C_0^2), 138.95 (d, $^3J_{C,P}$ = 24.3 Hz, C_0^4), 146.49 (d, $^2J_{C,P}$ = 6.6 Hz, *C*H=CH-P_0), 156.79 (d, $^2J_{C,P}$ = 9.4 Hz, C_1^1), 190.96 (s, CHO) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 14.4 (d, $^2J_{P,P}$ = 31.0 Hz, P_1), 18.0 (s, P_0), 50.2 (d, $^2J_{P,P}$ = 31.0 Hz, P'_1) ppm. $C_{38}H_{36}NO_7P_3S$ (743.69): calcd. C 61.37, H 4.88, N 1.88; found C 61.56, H 4.91, N 1.79.

Dendron 3-G_2: A solution of $H_2NNMeP(S)Cl_2$ in $CHCl_3$ (1.12 mL, 0.260 mmol) was added to a solution of **3-G_1** (0.088 g, 0.118 mmol) in THF (10 mL). The resulting solution was stirred for 4 hours then evaporated to dryness to afford an oil. This oil was washed three times with CH_2Cl_2/pentane then evaporated to dryness to afford **3-G_2** as a pale yellow powder in 81% yield (0.102 g). ^1H NMR ($CDCl_3$): δ = 1.34 (t, $^3J_{H,H}$ = 6.9 Hz, 6 H, CH_2−C*H*$_3$), 3.46 (d, $^3J_{H,P}$ = 7.0 Hz, 6 H, N-CH_3), 4.13 (dt, $^3J_{H,H}$ = 6.9, $^3J_{H,P}$ = 14.2 Hz, 4 H, CH_2), 6.35 (t, $^3J_{H,H}$ = $^2J_{H,P}$ = 17.2 Hz, 1 H, =CH-P_0), 7.21 (d, $^3J_{H,H}$ = 7.8 Hz, 4 H, H-C_1^2), 7.58 (d, $^3J_{H,H}$ = 7.8 Hz, 4 H, H-C_1^3), 7.44−7.65 (m, 17 H, H_{Arom}, CH=N, CH=CH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 16.26 (d, $^3J_{C,P}$ = 6.4 Hz, CH_2−*C*H_3), 31.68 (d, $^2J_{C,P}$ = 13.9 Hz, N-CH_3), 62.09 (d, $^2J_{C,P}$ = 5.8 Hz, CH_2), 117.28 (d, $^1J_{C,P}$ = 190.7 Hz, =CH-P_0), 121.89 (d, $^3J_{C,P}$ = 5.0 Hz, C_1^2), 127.49 (d, $^3J_{C,P}$ = 13.6 Hz, C_0^3), 128.00 (dd, $^1J_{C,P}$ = 107.0, $^3J_{C,P}$ = 4.0 Hz, C_0^i), 128.24 (s, C_1^3), 128.61 (d, $^3J_{C,P}$ = 13.1 Hz, C_0^m), 130.09 (s, C_1^4), 130.15 (dd, $^1J_{C,P}$ = 110.0, $^3J_{C,P}$ = 4.0 Hz, C_0^1), 132.56 (d, $^2J_{C,P}$ = 10.4 Hz, C_0^o), 132.67 (s, C_0^p), 133.18 (d, $^2J_{C,P}$ = 11.4 Hz, C_0^2), 138.44 (dd, $^3J_{C,P}$ = 23.3, $^4J_{C,P}$ = 2.9 Hz, C_0^4), 141.08 (d, $^3J_{C,P}$ = 18.7 Hz, CH=N-N), 146.76 (d, $^2J_{C,P}$ = 5.5 Hz, *C*H=CH-P_0), 153.35 (d, $^2J_{C,P}$ = 14.8 Hz, C_1^1) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 13.5 (d, $^2J_{P,P}$ = 30.5 Hz, P_1), 18.3 (s, P_0), 51.6 (d, $^2J_{P,P}$ = 30.5 Hz, P'_1), 63.4 (s, P_2) ppm. $C_{40}H_{42}Cl_4N_5O_5P_5S_3$ (1065.7): calcd. C 45.08, H 3.97, N 6.57; found C 44.89, H 3.91, N 6.51.

Dendron 6-G_2: Powdered hydroxybenzaldehyde sodium salt (0.043 g, 0.301 mmol, an excess) was added to a solution of **3-G_2** (0.073 g, 0.069 mmol) in THF (5 mL). The resulting mixture was stirred overnight at room temperature. This solution was centrifuged then evaporated to dryness. The resulting powder was washed with THF/pentane (1:10) to afford **6-G_2** as a white powder in 90% yield (0.087 g). ^1H NMR ($CDCl_3$): δ = 1.32 (t, $^3J_{H,H}$ = 7.1 Hz, 6 H, CH_2-C*H*$_3$), 3.38 (d, $^3J_{H,P}$ = 11.0 Hz, 6 H, N-CH_3), 4.11 (dt, $^3J_{H,H}$ = 7.1, $^3J_{H,P}$ = 15.0 Hz, 4 H, CH_2), 6.35 (t, $^3J_{H,H}$ = $^2J_{H,P}$ = 17.2 Hz, 1 H, =CH-P_0), 7.19 (dd, $^3J_{H,H}$ = 8.7, $^4J_{H,P}$ = 1.4 Hz, 4 H, H-C_1^2), 7.37 (dd, $^3J_{H,H}$ = 8.5, $^4J_{H,P}$ = 1.4 Hz, 8 H, H-C_2^2), 7.57 (d, $^3J_{H,H}$ = 8.7 Hz, 4 H, H-C_1^3), 7.85 (d, $^3J_{H,H}$ = 8.5 Hz, 8 H, H-C_2^3), 7.40−7.74 (m, 17 H, H_{Arom}, CH=N, CH=CH), 9.92 (s, 4 H, CHO) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 16.27 (d, $^3J_{C,P}$ = 6.1 Hz, CH_2−*C*H_3), 32.56 (d, $^2J_{C,P}$ = 13.1 Hz, N-CH_3), 62.05 (d, $^2J_{C,P}$ = 5.7 Hz, CH_2), 117.48 (d, $^1J_{C,P}$ = 190.2 Hz, =CH-P_0), 122.01 (br. d, $^3J_{C,P}$ = 4.0 Hz, C_1^2, C_2^2), 127.28 (d, $^3J_{C,P}$ = 13.5 Hz, C_0^3), 127.98 (s, C_1^3), 128.01 (dd, $^1J_{C,P}$ = 106.5, $^3J_{C,P}$ = 5.0 Hz, C_0^i), 128.49 (d, $^3J_{C,P}$ = 14.0 Hz, C_0^m), 130.15 (dd, $^1J_{C,P}$ = 108.0, $^3J_{C,P}$ = 3.9 Hz, C_0^1), 130.40 (s, C_1^4), 131.26 (s, C_2^3), 132.65 (s, C_2^4), 132.68 (d, $^2J_{C,P}$ = 11.0 Hz, C_0^o), 132.72 (s, C_0^p), 133.20 (d, $^2J_{C,P}$ = 15.0 Hz, C_0^2), 138.51 (d, $^3J_{C,P}$ = 21.0 Hz, C_0^4), 140.08 (d, $^3J_{C,P}$ = 16.0 Hz, CH=N-N), 146.72 (d, $^2J_{C,P}$ = 6.0 Hz, *C*H=CH-P_0), 153.12 (d, $^2J_{C,P}$ = 10.2 Hz, C_1^1), 156.85 (d, $^2J_{C,P}$ = 9.8 Hz, C_2^1), 190.92 (s, CHO) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 13.7 (d, $^2J_{P,P}$ = 29.2 Hz, P_1), 18.2 (s, P_0), 51.8 (d, $^2J_{P,P}$ = 29.2 Hz, P'_1), 60.7 (s, P_2) ppm. $C_{68}H_{62}N_5O_{13}P_5S_3$ (1408.3): calcd. C 57.99, H 4.44, N 4.97; found C 58.11, H 4.47, N 4.94.

Dendron 8-G_1: Dichloromethane (1 mL) was added to a mixture of powdered **3-G_0** (0.100 g, 0.236 mmol) and azide **7** (0.046 g, 0.236 mmol), to dissolve both reagents. The resulting solution was stirred for three days at room temperature. The solvent was evaporated to afford **8-G_1** in quantitative yield as a white powder (0.140 g). ^1H NMR ($CDCl_3$): δ = 1.28 (t, $^3J_{H,H}$ = 7.0 Hz, 6 H, CH_2−C*H*$_3$), 2.66 (d, $^3J_{H,P}$ = 11.9 Hz, 6 H, N-CH_3), 3.56 (br. s, 4 H, NH_2), 4.06 (dt, $^3J_{H,H}$ = 7.0, $^3J_{H,P}$ = 14.5 Hz, 4 H, CH_2), 6.31 (t, $^3J_{H,H}$ = $^2J_{H,P}$ = 17.2 Hz, 1 H, =CH-P_0), 7.36−7.84 (m, 15 H, H_{Arom}, C*H*=CH-P_0) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 16.36 (d, $^3J_{C,P}$ = 5.9 Hz, CH_2−*C*H_3), 39.37 (d, $^2J_{C,P}$ = 6.0 Hz, N-CH_3), 62.00 (d, $^2J_{C,P}$ = 5.7 Hz, CH_2), 117.50 (d, $^1J_{C,P}$ = 190.5 Hz, =CH-P_0), 127.53 (d, $^3J_{C,P}$ = 13.1 Hz, C_0^3), 128.70 (d, $^3J_{C,P}$ = 12.2 Hz, C_0^m), 129.40 (br. d, $^1J_{C,P}$ = 110.0 Hz, C_0^i), 129.90 (d, $^1J_{C,P}$ = 110.0 Hz, C_0^1), 132.54 (s, C_0^p), 132.62 (d, $^2J_{C,P}$ = 10.2 Hz, C_0^o), 133.30 (d, $^2J_{C,P}$ = 11.5 Hz, C_0^2), 138.46 (d, $^3J_{C,P}$ = 23.7 Hz, C_0^4), 146.85 (d, $^2J_{C,P}$ = 6.7 Hz, *C*H=CH-P_0) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 12.8 (d, $^2J_{P,P}$ = 17.2 Hz, P_1), 18.2 (s, P_0), 71.2 (d, $^2J_{P,P}$ = 17.2 Hz, P'_1) ppm. $C_{26}H_{36}N_5O_3P_3S$ (591.59): calcd. C 52.79, H 6.13, N 11.84; found C 52.85, H 6.19, N 11.75.

Dendron 10-G_1: DMF (2 mL) was added to a mixture of powdered **8-G_1** (0.130 g, 0.219 mmol) and helicin **9** (0.125 g, 0.439 mmol). The resulting solution was stirred overnight then evaporated to dryness. **10-G_1** was isolated as an oil in quantitative yield (0.250 g). A strict stoichiometric amount of reagents must be used since it is difficult to eliminate the unreacted helicin. ^1H NMR ([D_8]THF): δ = 1.40 (t, $^3J_{H,H}$ = 7.0 Hz, 6 H, CH_2−C*H*$_3$), 3.28 (d, $^3J_{H,P}$ = 8.7 Hz, 3 H, N-CH_3), 3.30 (d, $^3J_{H,P}$ = 8.7 Hz, 3 H, N-CH_3), 3.41−3.92 (m, 12 H, CH_2 and CH helicin), 4.19 (dt, $^3J_{H,H}$ = 7.0, $^3J_{H,P}$ = 15.0 Hz, 4 H, CH_2OP), 4.74−5.11 (m, 10 H, OH, HC_1^7), 6.64 (t, $^3J_{H,H}$ = $^2J_{H,P}$ = 17.2 Hz, 1 H, =CH-P_0), 6.88 (m, 2 H, HC_1^3), 7.22 (m, 4 H, HC_1^4, HC_1^5), 7.56−8.11 (m, 19 H, H_{Arom}, C*H*=CH-P_0) ppm. $^{13}C\{^1H\}$ NMR ([D_8]THF): δ = 17.80 (d, $^3J_{C,P}$ = 5.9 Hz, CH_2−*C*H_3), 33.89 (d, $^2J_{C,P}$ = 9.8 Hz, N-CH_3), 34.04 (d, $^2J_{C,P}$ = 9.8 Hz, N-CH_3), 63.41 (d, $^2J_{C,P}$ = 5.7 Hz, CH_2OP), 63.72 (s, CH_2OH), 72.20 (s, C_1^{1o}), 75.87 (s, C_1^8), 79.01 (s, C_1^9 or C_1^{11}), 79.42 (s, C_1^{11} or C_1^9), 104.28 (s, C_1^7), 104.70 (s, C_1^7),

Cationic Dendron 11-G_1: Methyl trifluoromethanesulfonate (50 μL, 0.470 mmol) was added dropwise to a solution of **3-G_1** (0.350 g, 0.470 mmol) in CH_2Cl_2 (10 mL) at 0 °C. The reaction mixture was stirred for 10 minutes at 0 °C and 20 minutes at room temperature and then evaporated to dryness. The crude residue was washed with pentane to afford **11-G_1** as a sticky yellow oil in 95% yield (0.405 g). ^1H NMR (CD_2Cl_2): δ = 1.30 (t, $^3J_{H,H}$ = 7.0 Hz, 6 H, CH_3), 2.63 (d, $^3J_{H,P}$ = 18.2 Hz, 3 H, P_1-S-CH_3), 4.16 (dt, $^3J_{H,H}$ = 7.2, $^3J_{H,P}$ = 14.5 Hz, 4 H, CH_2), 6.55 (t, $^3J_{H,H}$ = $^2J_{H,P}$ = 17.0 Hz, 1 H, =CH-P_0), 7.24−8.07 (m, 23 H, H_{Arom}, C*H*=CH-P_0), 9.95 (s, 2 H, CHO) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 14.23 (d, $^2J_{C,P}$ = 5.3 Hz, S-CH_3), 16.62 (d, $^2J_{C,P}$ = 5.8 Hz, CH_3), 63.20 (br. s, CH_2), 121.28 (q, $^1J_{C,F}$ = 323.5 Hz, CF_3), 121.81 (d, $^3J_{C,P}$ = 4.9 Hz, C_1^2), 122.15 (d, $^1J_{C,P}$ = 186.2 Hz, =CH-P_0), 124.17 (dd, $^1J_{C,P}$ = 107.4, $^3J_{C,P}$ = 4.4 Hz, C_0^i), 126.03 (dd, $^1J_{C,P}$ = 101.7, $^3J_{C,P}$ = 5.8 Hz, C_0^1), 129.18 (d, $^3J_{C,P}$ = 12.8 Hz, C_0^3), 130.31 (d, $^3J_{C,P}$ = 13.5 Hz, C_0^m), 132.39 (s, C_1^3), 132.62 (d, $^2J_{C,P}$ = 11.7 Hz, C_0^o), 133.32 (d, $^2J_{C,P}$ = 12.0 Hz, C_0^2), 135.24 (d, $^4J_{C,P}$ = 2.9 Hz, C_0^p), 135.46 (s, C_1^4), 141.07 (d, $^3J_{C,P}$ = 26.4 Hz, C_0^4), 146.42 (br. s, *C*H=CH-P_0), 153.55 (d, $^2J_{C,P}$ = 10.9 Hz, C_1^1), 190.82 (s, CHO) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 16.9 (s, P_0), 22.2 (d, $^2J_{P,P}$ = 20.5 Hz, P_1), 23.1 (d, $^2J_{P,P}$ = 20.5 Hz, P'_1) ppm. $C_{40}H_{39}F_3NO_{10}P_3S_2$ (907.79): calcd. C 52.92, H 4.33, N 1.54; found C 53.21, H 4.42, N 1.48.

Dicationic Dendron (12-G_1): Trimethylsilyl trifluoromethanesulfonate (85 μL, 0.470 mmol) was added dropwise to a solution of **11-G_1** (0.420 g, 0.470 mmol) in CH_2Cl_2 (10 mL) at 0 °C. The reaction mixture was stirred for 10 minutes at 0 °C and 30 minutes at room temperature and then evaporated to dryness. The crude residue was washed with pentane to afford **12-G_1** as a sticky yellow oil in 89% yield (0.473 g). ^1H NMR (CD_2Cl_2): δ = 0.10 (s, 9 H, $SiMe_3$), 1.47 (t, $^3J_{H,H}$ = 7.0 Hz, 6 H, CH_3), 2.62 (d, $^3J_{H,P}$ = 18.2 Hz, 3 H, P_1-S-CH_3), 4.40 (dt, $^3J_{H,H}$ = 7.2, $^3J_{H,P}$ = 14.6 Hz, 4 H, CH_2), 6.73 (t, $^3J_{H,H}$ = $^2J_{H,P}$ = 17.0 Hz, 1 H, =CH-P_0), 7.24−8.07 (m, 23 H, H_{Arom} and C*H*=CH-P_0), 10.03 (s, 2 H, CHO) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 1.93 (s, $SiMe_3$), 14.21 (d, $^2J_{C,P}$ = 5.3 Hz, S-CH_3), 16.19 (d, $^2J_{C,P}$ = 5.8 Hz, CH_3), 66.97 (d, $^2J_{C,P}$ = 5.4 Hz, CH_2), 113.32 (d, $^1J_{C,P}$ = 194.2 Hz, =CH-P_0), 120.58 (q, $^1J_{C,F}$ = 323 Hz, CF_3), 121.77 (d, $^3J_{C,P}$ = 4.8 Hz, C_1^2), 123.56 (dd, $^1J_{C,P}$ = 106.9, $^3J_{C,P}$ = 4.1 Hz, C_0^i), 126.67 (dd, $^1J_{C,P}$ = 107.5, $^3J_{C,P}$ = 4.0 Hz, C_0^1), 129.85 (d, $^3J_{C,P}$ = 13.8 Hz, C_0^3), 130.33 (d, $^3J_{C,P}$ = 13.6 Hz, C_0^m), 132.41 (s, C_1^3), 132.62 (d, $^2J_{C,P}$ = 11.9 Hz, C_0^o), 133.26 (d, $^2J_{C,P}$ = 12.0 Hz, C_0^2), 135.31 (d, $^4J_{C,P}$ = 3.0 Hz, C_0^p), 135.52 (s, C_1^4), 139.78 (d, $^3J_{C,P}$ = 28.6 Hz, C_0^4), 151.19 (d, $^2J_{C,P}$ = 8.9 Hz, *C*H=CH-P_0), 153.52 (d, $^2J_{C,P}$ = 10.9 Hz, C_1^1), 190.83 (s, CHO) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 22.0 (d, $^2J_{P,P}$ = 20.7 Hz, P_1), 23.2 (d, $^2J_{P,P}$ = 20.7 Hz, P'_1), 23.6 (s, P_0) ppm. $C_{44}H_{48}F_6NO_{13}P_3S_3Si$ (1130.1): calcd. C 46.77, H 4.28, N 1.24; found C 46.94, H 4.32, N 1.15.

Dendron 14-G_2: THF (8 mL) was added to a powdered mixture of **3-G_2** (0.055 g, 0.0516 mmol), compound **13** (0.086 g, 0.227 mmol, slight excess) and Cs_2CO_3 (0.150 g, 0.454 mmol, excess). The resulting mixture was stirred overnight then centrifuged, and the solution was evaporated to dryness. The resulting powder was washed with THF/pentane to eliminate unreacted **7**. Compound **14-G_2** was obtained as a white powder in 63% yield (0.081 g). ^1H NMR ($CDCl_3$): δ = 1.33 (t, $^3J_{H,H}$ = 7.1 Hz, 6 H, CH_2-CH_3), 3.33 (d, $^3J_{H,P}$ = 10.5 Hz, 6 H, N-CH_3), 4.12 (dt, $^3J_{H,H}$ = 7.1, $^3J_{H,P}$ = 14.8 Hz, 4 H, CH_2), 6.37 (t, $^3J_{H,H}$ = $^2J_{H,P}$ = 17.1 Hz, 1 H, =CH-P_0), 6.86 (d, $^3J_{H,H}$ = 8.1 Hz, 8 H, H-C_2^3), 6.92 (m, 4 H, H-C_3^3), 7.15 (d, $^3J_{H,H}$ = 8.1 Hz, 8 H, H-C_2^2), 7.23−7.78 (m, 73 H, H_{Arom}, CH=N, CH=CH), 8.15 (br. dd, $^3J_{H,H}$ = 6.9, $^4J_{H,P}$ = 4.1 Hz, 4 H, H-C_3^6), 9.02 (d, $^4J_{H,P}$ = 5.1 Hz, 1 H, CH=N-C) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 16.28 (d, $^3J_{C,P}$ = 6.0 Hz, CH_2-CH_3), 32.96 (d, $^2J_{C,P}$ = 13.1 Hz, N-CH_3), 61.94 (d, $^2J_{C,P}$ = 5.5 Hz, CH_2), 117.53 (d, $^1J_{C,P}$ = 189.0 Hz, =CH-P_0), 121.84 (br. s, C_1^2, C_2^2, C_2^3), 127.18 (d, $^3J_{C,P}$ = 13.3 Hz, C_0^3), 127.85 (s, C_1^3), 127.99 (d, $^3J_{C,P}$ = 14.2 Hz, C_0^m), 128.01 (dd, $^1J_{C,P}$ = 106.0, $^3J_{C,P}$ = 6.0 Hz, C_0^i), 128.17 (d, $^3J_{C,P}$ = 3.9 Hz, C_3^6), 128.52 (d, $^3J_{C,P}$ = 7.1 Hz, C_3^m), 128.79 (br. s, C_3^5, C_3^p), 130.10 (dd, $^1J_{C,P}$ = 108.0, $^3J_{C,P}$ = 3.6 Hz, C_0^1), 130.77 (s, C_3^4), 130.90 (s, C_1^4), 132.58 (d, $^2J_{C,P}$ = 11.0 Hz, C_0^o), 132.70 (s, C_0^p), 133.30 (d, $^2J_{C,P}$ = 15.3 Hz, C_0^2), 133.44 (s, C_3^3), 133.88 (d, $^2J_{C,P}$ = 19.9 Hz, C_3^o), 136.24 (d, $^1J_{C,P}$ = 8.7 Hz, C_3^i), 138.46 (d, $^2J_{C,P}$ = 20.4 Hz, C_3^1), 138.53 (d, $^3J_{C,P}$ = 21.0 Hz, C_0^4), 138.84 (d, $^1J_{C,P}$ = 17.3 Hz, C_3^2), 139.07 (br. d, $^3J_{C,P}$ = 13.5 Hz, CH=N-N), 146.68 (d, $^2J_{C,P}$ = 6.5 Hz, *C*H=CH-P_0), 148.54 (d, $^2J_{C,P}$ = 5.9 Hz, C_2^1), 148.55 (s, C_2^4), 152.92 (d, $^2J_{C,P}$ = 10.2 Hz, C_1^1), 158.62 (d, $^3J_{C,P}$ = 20.9 Hz, *C*H=N-C) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −13.1 (s, P_3), 13.5 (d, $^2J_{P,P}$ = 30.5 Hz, P_1), 18.3 (s, P_0), 51.8 (d, $^2J_{P,P}$ = 30.5 Hz, P'_1), 63.5 (s, P_2) ppm. $C_{140}H_{118}N_9O_9P_9S_3$ (2445.5): calcd. C 68.76, H 4.86, N 5.16; found C 68.64, H 4.82, N 5.11.

Complexed Dendron (15-G_2): A solution of **14-G_2** (0.200 g, 0.082 mmol) in CH_2Cl_2 (25 mL) was added slowly dropwise during 2 hours to a solution of [$PdCl_2$(COD)] (0.093 g, 0.327 mmol) in CH_2Cl_2 (25 mL). The resulting solution was stirred for 3 hours more then evaporated to dryness. The residue was washed with THF/pentane (1:10) to afford **15-G_2** as a pale yellow powder in 85% yield (0.219 g). ^1H NMR (CD_2Cl_2): δ = 1.30 (t, $^3J_{H,H}$ = 7.0 Hz, 6 H, CH_2-CH_3), 3.31 (d, $^3J_{H,P}$ = 10.7 Hz, 6 H, N-CH_3), 4.07 (m, 4 H, CH_2), 6.41 (t, $^3J_{H,H}$ = $^2J_{H,P}$ = 17.2 Hz, 1 H, =CH-P_0), 7.07 (m, 4 H, H-C_3^3), 7.16 (d, $^3J_{H,H}$ = 8.8 Hz, 8 H, H-C_2^3), 7.28 (d, $^3J_{H,H}$ = 8.8 Hz, 8 H, H-C_2^2), 7.40−7.80 (m, 73 H, H_{Arom}, CH=N, CH=CH), 7.93 (m, 4 H, H-C_3^6), 8.21 (d, $^4J_{H,P}$ = 5.1 Hz, 1 H, CH=N-C) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 16.79 (d, $^3J_{C,P}$ = 5.9 Hz, CH_2-CH_3), 33.58 (d, $^2J_{C,P}$ = 13.1 Hz, N-CH_3), 62.59 (d, $^2J_{C,P}$ = 6.0 Hz, CH_2), 118.58 (d, $^1J_{C,P}$ = 189.1 Hz, =CH-P_0), 121.94 (d, $^2J_{C,P}$ = 3.8 Hz, C_2^2), 122.45 (d, $^2J_{C,P}$ = 5.3 Hz, C_1^2), 122.23 (d, $^1J_{C,P}$ = 49.4 Hz, C_3^2), 125.09 (s, C_2^3), 125.69 (d, $^1J_{C,P}$ = 61.1 Hz, C_3^i), 128.20 (d, $^3J_{C,P}$ = 13.7 Hz, C_0^3, C_0^m), 128.64 (br. s, C_1^3, C_3^6), 128.72 (dd, $^1J_{C,P}$ = 106.0, $^3J_{C,P}$ = 3.5 Hz, C_0^i), 129.26 (s, C_3^5), 129.58 (d, $^3J_{C,P}$ = 13.0 Hz, C_3^m), 131.50 (dd, $^1J_{C,P}$ = 106.0, $^3J_{C,P}$ = 4.0 Hz, C_0^1), 131.63 (s, C_1^4), 133.12 (d, $^4J_{C,P}$ = 5.5 Hz, C_3^p), 133.32 (s, C_3^4), 133.69 (d, $^2J_{C,P}$ = 13.2 Hz, C_0^o), 133.79 (s, C_0^p), 134.00 (d, $^2J_{C,P}$ = 16.0 Hz, C_0^2), 134.40 (s, C_3^3), 134.68 (d, $^2J_{C,P}$ = 10.9 Hz, C_3^o), 137.14 (d, $^2J_{C,P}$ = 15.9 Hz, C_3^1), 139.23 (d, $^3J_{C,P}$ = 21.0 Hz, C_0^4), 140.83 (d, $^3J_{C,P}$ = 12.8 Hz, CH=N-N), 146.99 (d, $^2J_{C,P}$ = 6.4 Hz, *C*H=CH-P_0), 149.77 (s, C_2^4), 150.34 (d, $^2J_{C,P}$ = 5.9 Hz, C_2^1), 153.59 (d, $^2J_{C,P}$ = 9.8 Hz, C_1^1), 166.7 (d, $^3J_{C,P}$ = 9.1 Hz, *C*H=N-C) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 15.6 (d, $^2J_{P,P}$ = 29.1 Hz, P_1), 19.7 (s, P_0), 33.0 (s, P_3), 53.2 (d, $^2J_{P,P}$ = 29.1 Hz, P'_1), 64.8 (s, P_2) ppm. $C_{140}H_{118}Cl_8N_9O_9P_9Pd_4S_3$ (3154.8): calcd. C 53.30, H 3.77, N 4.00; found C 53.38, H 3.82, N 4.02.

X-ray Crystallographic Study: Data collection was performed on a Stoe Imaging Plate Diffraction System (IPDS), equipped with an

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Oxford Cryosystems Cryostream Cooler. Device and using a graphite-monochromated Mo-K_α radiation (λ = 0.71073Å), at T = 160 K. Further details are provided in Table 1. Final unit-cell parameters were obtained by means of a least-squares refinement of a set of 8000 well-measured reflections, and crystal decay was monitored during the data collection by measuring 200 reflections by exposure. No significant fluctuations of the intensities were observed during measurement.

Table 1. Crystal data, data collection and structure refinement

Empirical formula	$C_{24}H_{26}O_3P_2$
Molecular mass	424.39
Wavelength	0.71073Å
Crystal system, space group	triclinic, $P\bar{1}$
Unit cell dimensions	a = 15.435(2) Å b = 8.6930(11) Å c = 16.326(3) Å α = 90.179(17)° β = 92.141(18)° γ = 90.067(16)°
Volume	2189.1(5) Å^3
Z, calculated density	4, 1.288 mg/m^3
Absorption coefficient	0.221 mm^{-1}
F(000)	896
Crystal size	0.42 × 0.17 × 0.08 mm
Crystal colour and form	colourless plate
Tube power	1.50 kW
Tube voltage	50 kV
Tube current	30 mA
Collimator size	0.8 mm
Detector distance	70.0 mm
2θ range	3.3−52.1°
d(hkl) range	12.453−0.809 Å
φ movement mode	rotation
φ start	0.0°
φ end	200.2°
φ increment	1.1°
Number of exposures	182
Irradiation/exposure	2.00 min
Measurement duration	19 h
θ range for data collection	2.64−23.26°
Index ranges	$-17 \le h \le 17$ $-9 \le k \le 9$ $-18 \le l \le 18$
Reflections collected/unique	12240/3099 [R(int) = 0.0592]
Completeness to 2θ = 46.52	98.2%
Refinement method	Full-matrix least-squares on F^2
Data/restraints/parameters	3099/0/272
Goodness-of-fit on F^2	1.032
Weighting scheme	$1/[\sigma^2(F_o^2) + (0.0509P)^2 + 1.396P]$ where $P = (F_o^2 + 2F_c^2)/3$
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0377, $wR2$ = 0.0979
R indices (all data)	$R1$ = 0.0413, $wR2$ = 0.1011
Largest diff. peak and hole	(0.705 and −0.364) e·Å^{-3}

The structure was solved by means of direct methods using the program SIR92[31] and subsequent difference Fourier maps, then refined by least-squares procedures on F^2 by using the program SHELXL-97.[32] Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[33]

All hydrogen atoms were located in difference Fourier maps, but introduced in the refinement as fixed contributors by using a riding model with an isotropic thermal parameter fixed at 20% higher than those of the C_{sp^2} atoms and 50% for the C_{sp^3} atoms to which they are connected, excepted hydrogens atoms labelled H(1) and H(2) attached to the C(1) and C(2) carbons atoms, respectively, which were refined isotropically. Methyl groups were refined with the torsion angle as a free variable. All non-hydrogen atoms were refined anisotropically, and in the last cycles of refinement weighting schemes were used. The weights were calculated from the following formula: $W = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ where $P = (F_o^2 + 2F_c^2)/3$. Criteria for a satisfactory complete analysis were the ratios of root-mean-square shift standard deviation being less than 0.1 and no significant features in the final difference Fourier maps. Drawings of the molecules were produced with the program ORTEP3[34] with 50% probability displacement ellipsoids for non-hydrogen atoms.

CCDC-228136 contains the supplementary crystallographic data for this paper. Keywords: Tridentate ligands / Nonlinear optics / Polymers / Copper / Palladium

Three new *N*-salicylidene-*N*′-aroylhydrazines tridentate ligands have been prepared: *N*-4-diethylaminosalicylidene-*N*′-(4-nitrocinnamoylhydrazine (L^1), *N*-4-diethylaminosalicylidene-*N*′-4-(2,4-dinitrophenylethylidene)benzoylhydrazine (L^2), *N*-4-diethylaminosalicylidene-*N*′-4-(6-nitro-2-benzoxazolyl)benzoylhydrazine (L^3). From these ligands, mononuclear acentric complexes of Copper(II) and Palladium(II), with pyridine as further ligand, have been prepared and characterized, also by single-crystal X-ray analysis. These complexes show high second order nonlinear optical activity (EFISH, $|\mu\beta|$ up to $3000 \cdot 10^{-48}$ esu, incident wavelength 1.907 μm). The properties of metallorganic polymers obtained by grafting commercial poly(4-vinylpyridine) with ML^1 fragment (M = Cu^{II} or Pd^{II}) are also reported.

Introduction

The design of dipolar metallorganic chromophores with second order optical nonlinearities has been carried out till now according to two chemical architectures: organometallic fragments as electron donor-acceptor groups at the end of a π conjugated system[1] or metals as constituents of the conjugation bridge between the donor and acceptor groups.[1c,2]

A nonlinear optically (NLO) active polymer material is obtained from the chromophore following two approaches widely used in the case of purely organic compounds:[3] noncovalent incorporation of active molecules (guest) in an organic polymeric matrix (host) or covalent incorporation of chromophores into a polymer chain or in a three dimensional network. In both cases a noncentrosymmetric polar alignment of the NLO active fragments (''poling'') must be achieved (generally by applying a strong electric field while the polymer is kept above its glass transition temperature) which is a necessary condition for bulk second order NLO activity. Drawbacks of the first approach are in the low time stability of the noncentrosymmetric polar order and in the low solubility of the chromophore in the polymer matrix (the latter effect is probably enhanced in the case of metallorganic NLO-phores); in the second approach, on the other hand, the chemical synthesis of the organometallic chromophore must include steps for its functionalization as monomer for polymerization reactions (e.g. as diol or methacrylate ester).

We have recently proposed a new approach to metal-coordinated second order NLO active polymer materials, based on the use of tridentate ligands of the *N*-salicylidene-*N*′-aroylhydrazine type.[4] The use of such ligands, properly functionalized with strong electron donor-acceptor groups, is based on two factors (see Scheme 1). First, upon coordination, the ligand changes from the cheto (amide) to the enolic form with extension of π conjugation along the whole structure; second, the formed complex is electrically neutral but the metal (Cu^{II}, Pd^{II}) is coordinatively unsaturated.

In the absence of other ligands the coordination sphere of the metal is completed by centrosymmetric coupling and dimers are formed (see Scheme 2); however, if other ligands are present, acentric monomeric complexes may be formed, as witnessed by the strong tendency of dimers to form monomeric adducts by reaction with neutral molecules containing N donor atoms (e.g. pyridine, imidazole, etc.).[4,5]

This feature is of relevant interest inasmuch as it allows the anchorage of NLO active metallorganic fragments to a suitable preformed polymer chain [e.g. poly(4-vinylpyri-

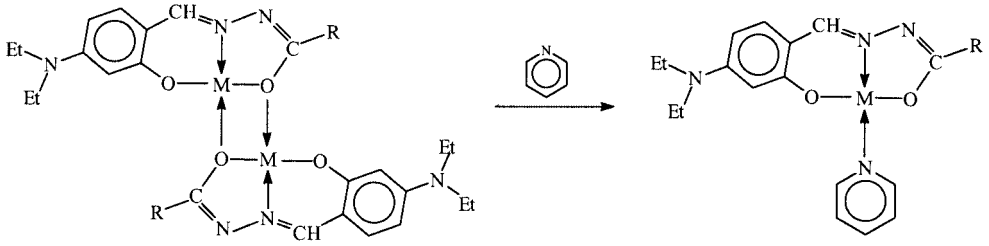


Scheme 2

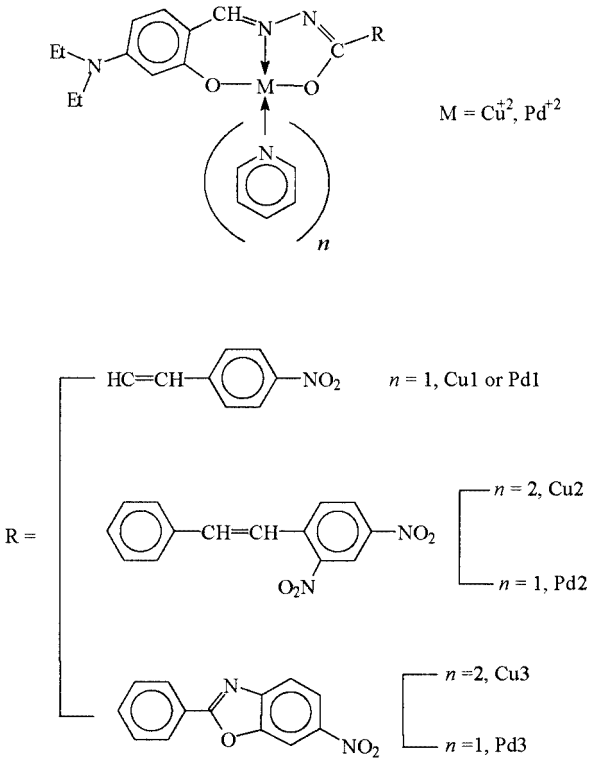
dine)] through a coordination bond.[4b] The advantages of this approach are evident. Among others, we stress that the chemical synthesis of the chromophore and of the polymer can be worked out in a substantially independent way, no functionalization of the organic ligand is required and commercially available polymers can be used.

In this paper we report the synthesis and characterization of new monomeric complexes of this type exhibiting high NLO activity, whose formulae are shown in Scheme 3.

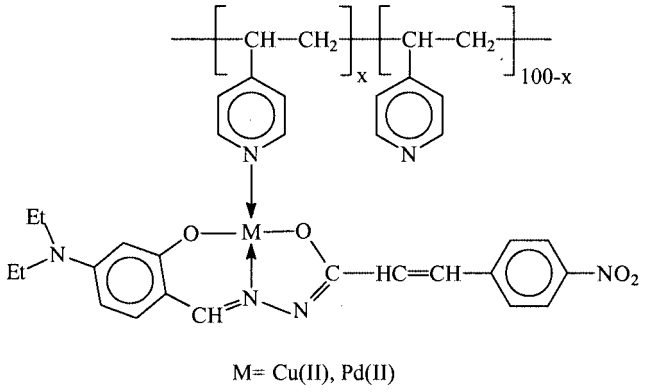
In addition we will also demonstrate the anchorage of one NLO active metallorganic fragment to commercial poly(4-vinylpyridine), according to Scheme 4, so that our complexes can be considered as rare examples of highly NLO active metallorganic chromophores from which polymers are successfully obtained. A full account of the properties of various commercial polymers grafted with all the above reported organometallic fragments will be given in a forthcoming publication from our laboratory.

Results and Discussion

Drawings of the crystallographic independent units of Cu1, Cu2, Pd2, and Cu3 are reported in Figures 1, 2, 3, and 4; selected bond lengths, bond angles, and torsion angles are reported in Table 1.



Scheme 3



Scheme 4

In all the reported structures the tridentate ligand is in the enolic form. In fact, bond lengths C12−O2 [ranging from 1.286(5) to 1.306(5) Å] and C12−N3 [ranging from 1.298(7) to 1.320(5) Å] are respectively longer and shorter as compared with the values expected for an amide group.[6] On the other hand, IR spectra of free ligands in the solid state clearly show bands typical of the amide group. The structural change of the ligands upon coordination is also confirmed by the UV/Vis absorption patterns. In fact, as it is shown for L^1 in Figure 5, a significant red-shift of λ_{max} is observed upon coordination, with the λ_{max} of the coordinated ligand being substantially unchanged in the dimer, monomer, and grafted polymer.

The conformation of the ligands is close to be planar in all cases. In the complexes containing the ligand L^2 the nitro group in *para* position to the vinylene group is substantially coplanar with the phenyl, while the *ortho* nitro group is significantly twisted by torsion around the bond C26−N5 (Table 1). This is probably due to the close intramolecular contact between O6 and H atom bonded to C20 (the distance O6···C20 is 2.83 Å in Cu2 and 2.86 Å in Pd2). This contact could be relaxed also by torsion around the

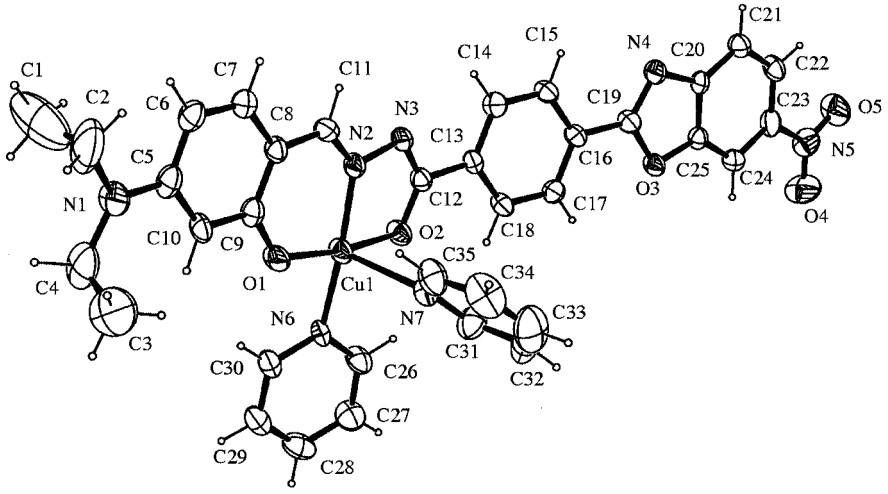

Figure 4. ORTEP view of Cu3; thermal ellipsoids are at 30% probability level

bond C20−C21, i.e. at cost of planarity of the ligand. The fact that this possibility is not adopted (it occurs instead in *trans*-stilbene which is twisted in the gas phase essentially for a similar reason[7]) seems to indicate a higher torsional potential around the bond C20−C21, probably resulting from charge transfer (CT) contributions to the ground state.

A coordination variability has been observed in the complexes of Cu^{II}. In fact, Cu1 is tetracoordinate (square planar) while Cu2 and Cu3 are pentacoordinate (square pyramidal with the metal atom lying substantially in the basal plane) and an additional pyridine molecule is bonded to the metal. For Pd^{II}, on the other hand, we have observed square-planar coordination with the same ligand giving a pentacoordinate copper complex; furthermore, the additional pyridine molecule present in the independent unit of crystals of Pd2 is not coordinated to the metal (Figure 3). This difference between Cu^{II} and Pd^{II} complexes is consistent with our previous results[4a] and is an evidence of the general tendency of Pd^{II} to give preferentially 16-electron complexes.

In the complexes reported here and in the similar complexes already reported by us[4a] the tendency of Cu^{II} to the pentacoordination appears to be favored by longer ligands. Since pentacoordination implies deviations from a flat molecular shape, may be that packing forces have a role in driving this behavior.

Both in tetracoordinate and in pentacoordinate complexes the ligand pyridine molecule in the basal plane is not coplanar with this plane but torsions around the M−N6 bond are observed (up to ca. 20°).

In the pentacoordinate complexes Cu2 and Cu3 the two ligand pyridine molecules are bonded to the metal with different strength, as it may be inferred by the corresponding bond lengths (Table 1). The more weakly bonded pyridine (i.e. the one-coordinated in apical position) is more easily lost as it is shown for example in the thermogravimetric analysis of Figure 6, while the second pyridine is lost at a much higher temperature.

This behavior is fairly reproducible so that loss of the apical pyridine is accomplished in all complexes in a tem-

perature interval ranging from 115 °C to 130 °C, while the basal pyridine is lost between 180 °C and 200 °C. The only relevant exception is given by Pd3 in which the pyridine ligand is lost around 276 °C (we have not succeeded in growing suitable single crystals of Pd3). In all cases, losing of all pyridine ligands restores $(ML^N)_2$ dimers as it is suggested by the decomposition temperatures which are identical.

Starting from commercial poly(4-vinylpyridine) we have prepared grafted polymers with a $(ML^1)_2$ content (by weight) of 35% and 60% both for Cu^{II} and Pd^{II}. The resulting polymers have good solubility in NMP, tetrachloroethane and DMF. Some thermal and analytical data of the

polymers are reported in Table 2. In Figure 7 are reported the DSC thermograms.

The inflection corresponding to the glass transition is the only signal present in the curves. A regular increase of the glass transition temperature is observed upon grafting, with T_g's almost independent from the nature of the metal (Pd^{II} or Cu^{II}). The lack of any other inflection at temperatures lower than the T_g of the ungrafted polymer is an evidence of the absence of uncoordinated complex acting as a plasticizing agent; a further evidence, at least in the case of Pd containing polymers, is given by ^1H NMR analysis. In fact, in the spectra of Pd polymers, recorded in $[D_2]$dichlorome-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

thane, only broad peaks of resonance are present, which are typical of polymer samples, and no sharp signal pertaining to free low molecular weight compounds is observed.[4b]

All polymers are amorphous, as confirmed by DSC and X-ray diffraction experiments. From concentrated solutions of polymers in NMP (ca. 0.10 g/mL) we have obtained clear, transparent films of optical quality by spin coating. The decomposition temperatures of the grafted polymers, which are around 300 °C, are well above the glass transition temperature, which, in any case, can be modulated by varying the extent of grafting, and this allows poling procedures to be safely done on the films. We think that these grafted polymers can show advantages as compared to all organic polymers tailored for second order NLO applications, particularly for what concerns the poling procedure. In fact, the peculiar nature of the bond between the NLO active fragment and the polymer chain (a coordinative bond) and the large molar excess of pyridine ligand groups, should allow some mobility of ML^N fragment (through complexation-decomplexation equilibria) and, therefore, a high degree of orientation in the poling at high temperature ($> T_g$), with the mobility reduced (and the polar order frozen) at low temperature.

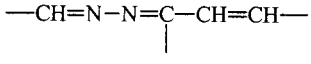
Second order optical nonlinearities of the complexes Cu*N* and Pd*N* are reported in Table 3. The discussion of their NLO properties can be usefully done at a comparative level with the similar complexes we have already studied.[4a]

Table 3. EFISH Results for the studied complexes

Complex	$\lvert\mu_g\cdot\beta_{vec}\rvert$[a]
Cu1	1100
Pd1	1500
Cu2	1300
Pd2	1100
Pd3	3000

[a] Estimated errors are: ±10% for Cu1, Pd1, Cu2, Pd2 and ±20% for Pd3.

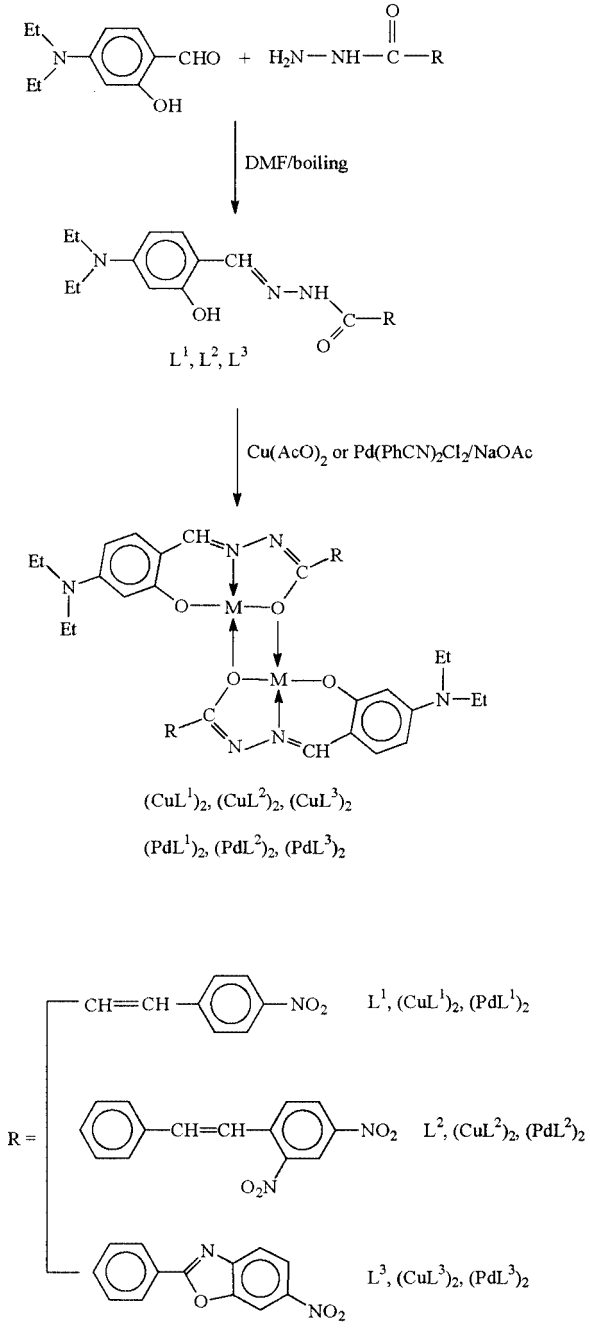
The NLO activity of Cu1 and Pd1 is considerably higher as compared with Cu1 and Pd1 complexes of ref.[4a] whose ligand only differs by lack of the vinylene group.[8] Actually, introduction of the vinylene group produces a fairly long polyene-like chain between the donor and acceptor groups (see Scheme 5) and it is well-known that push-pull polyenes are highly NLO active chromophores.[9]



Scheme 5

The NLO activity of Cu2 and Pd2 is not significantly different as compared with Cu2 and Pd2 complexes of ref.[4a] whose ligand lacks the *ortho* nitro group. This finding may be explained on the basis of the crystallographic results; in fact, we have found that the *ortho* nitro group is significantly twisted with respect to the phenyl ring which is attached to (cf. Table 1) and so it gives a little contribution, if any, to the charge transfer.

The datum measured for Pd3 is consistent with the expected increase of nonlinear activity following the replacement of phenyl rings by low aromaticity heterocycles.[10] The high activity of this complex, which is among the highest reported to date for metallorganic chromophores,[1] coupled with the known features of high thermochemical and photochemical stability of the benzoxazole group,[11] make



Scheme 6

it a promising candidate for further developments of our research.

Experimental Section

Synthesis: Complexes Cu*N* and Pd*N* (*N* = 1, 2, 3) were synthesized according to the general procedure outlined in the scheme below (Scheme 6) which starts with the synthesis of the organic ligands L^N (*N* = 1, 2, 3), followed by the synthesis of dinuclear complexes $(ML^N)_2$ and, from these, of the final mononuclear complexes M*N*, according to Scheme 2.

4-Nitrocinnamohydrazide: 4-Nitrocinnamoyl chloride (obtained from the acid refluxed in $SOCl_2$) is dissolved in boiling ethanol to obtain the ethyl ester. 4-Nitrocinnamic acid ethyl ester (5.00 g, 22.6 mmol) is dissolved in THF (50 mL). The solution is poured into a mixture of water (25 mL), ethanol (50 mL), hydrazine (18 mL) and it is stirred for 1.5 h at room temperature. Finally the mixture is poured into water (100 mL) and cooled in a freezer for 12 h. An orange solid is recovered by vacuum filtration. Yield 30%. M.p. 214 °C. ^{1}H NMR (200 MHz, [D$_6$]DMSO, 25 °C): δ = 4.52 ppm (s, 2 H), 6.80 (d, *J* = 16.2 Hz, 1 H), 7.53 (d, *J* = 16.2 Hz, 1 H), 7.77 (d, *J* = 8.7 Hz, 2 H), 8.22 (d, *J* = 8.3 Hz, 2 H), 9.50 (s, 1 H).

***N*-4-Diethylaminosalicylidene-*N*′-(4-nitrocinnamoyl)hydrazine (L^1):** 4-Nitrocinnamohydrazide (4.50 g, 21.7 mmol) and 4-*N*,*N*-diethylamino-2-hydroxybenzaldehyde (4.60 g, 23.8 mmol) are dissolved in boiling DMF (80 mL). After 15 minutes the solution is cooled and then poured into water (400 mL) containing concentrated sulfuric acid (5 mL). The red solid obtained is recovered by filtration, washed several times with water, dried, and recrystallized from DMF. Yield 6.06 g (73%). M.p. 223 °C. ^{1}H NMR (200 MHz, [D$_6$]DMSO, 25 °C): δ = 1.08 ppm (t, *J* = 6.8 Hz, 6 H), 3.33 (m, 4 H), 6.10 (s, 1 H), 6.25 (d, *J* = 8.6 Hz, 1 H), 6.83 (d, *J* = 15.6 Hz, 1 H), 7.22 (d, *J* = 8.8 Hz, 1 H), 7.70 (d, *J* = 8.8 Hz, 1 H), 7.87 (d, *J* = 8.8 Hz, 2 H), 8.24 (s, 1 H), 8.26 (d, *J* = 8.8 Hz, 2 H), 11.23 (s, 1 H), 11.71 (s, 1 H). IR (KBr): $\tilde{\nu}$ = 3409 cm^{-1} (m), 3206 (m, N−H str.), 2978 (m), 2933 (w), 1632 (vs, C=O str.), 1592 (vs, N−H bend), 1520 (vs), 1355 (s), 1339 (s), 1247 (m), 1134 (m). UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 406, 2.2·10^4.

Synthesis of $(CuL^1)_2$: L^1 (1.00 g, 2.61 mmol) and copper(II) acetate (0.521 g, 2.61 mmol) are dissolved in DMF (35 mL). The solution is heated to boiling and stirred for 15 minutes, then it is cooled and poured into water (100 mL) containing sodium acetate (0.700 g, 8.53 mmol). A red-brown solid is recovered by filtration, washed repeatedly with water, and recrystallized from DMF. Yield 91%. M.p. 312 °C dec. $C_{40}H_{40}N_8O_8Cu_2$: calcd. C 54.11, H 4.51, N 12.63, Cu 14.31; found C 54.22, H 4.64, N 12.57, Cu 13.91%. UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 469, 4.5·10^4.

Synthesis of $(PdL^1)_2$: L^1 (1.00 g, 2.61 mmol) is dissolved in boiling THF (20 mL). The solution is added with THF (20 mL) containing bis(benzonitrile) Pd^{II} dichloride (1.00 g, 2.61 mmol). After 15 minutes of stirring, a solution of sodium acetate (1.00 g, 12.2 mmol) in water (20 mL) is added. The pH is raised to about 8−9 by adding a 10 wt.% solution of KOH. After some minutes, the addition of 100 mL of water affords the precipitation of a dark red solid, which is filtered off, washed repeatedly with water, dried and finally washed with boiling heptane. Yield 91%. M.p. 311 °C dec. $C_{40}H_{40}N_8O_8Pd_2$: calcd. C 49.34, H 4.11, N 11.51, Pd 21.90; found C 49.66, H 4.27, N 11.51, Pd 22.30%. ^{1}H NMR (200 MHz, [D$_6$]DMSO, 25 °C): δ = 1.09 ppm (m, 12 H), 3.45 (m,8 H), 6.16 (s, 2 H), 6.26 (d, 2 H), 7.08 (d, 2 H), 7.33 (d, 2 H), 7.46 (d, 2 H), 7.90 (d, 4 H), 8.19 (d, 6 H). UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 459, 6.6·10^4.

4-(2,4-Dinitrophenylethylidene)benzoic Acid: 4-Formylbenzoic acid (10.0 g, 66.6 mmol) is dissolved in pyridine (50 mL) and piperidine (2 mL) and refluxed. 2,4-Dinitrophenylacetic acid (15.0 g, 66.6 mmol) is added in fractions of 3 g every 15 minutes. After 3 h the solution is concentrated to 30 mL and cooled. A yellow crystalline solid precipitates, then it is filtered off and washed with ethanol. Yield 72%. M.p. 263 °C. ^{1}H NMR (200 MHz, [D$_6$]DMSO, 25 °C): δ = 7.61 ppm (s, 2 H), 7.75 (d, *J* = 8.2 Hz, 2 H), 7.96 (d, *J* = 8.2 Hz, 2 H), 8.23 (d, *J* = 8.8 Hz, 1 H), 8.50 (d, *J* = 8.8 Hz, 1 H), 8.72 (d, *J* = 2.2 Hz, 1 H).

4-(2,4-Dinitrophenylethylidene)benzohydrazide: 4-(2,4-Dinitrophenylethylidene)benzoyl chloride (0.941 g, 2.83 mmol, obtained from the corresponding acid by reaction with thionyl chloride according to standard methods) is dissolved in hot anhydrous dioxane (20 mL). The solution is cooled and poured into a mixture of hydrazine (2.8 mL), dioxane (10 mL) and water (5 mL) whilst stirring. The reaction is rapid and after some minutes the mixture is poured in water (50 mL), affording the precipitation of a yellow solid, recovered by filtration, and washed repeatedly with water. Yield 86%. M.p. 234 °C. ^{1}H NMR (200 MHz, [D$_6$]DMSO, 25 °C): δ = 4.53 ppm (s, 2 H), 7.59 (s, 2 H), 7.72 (d, *J* = 7.8 Hz, 2 H), 7.87 (d, *J* = 7.8 Hz, 2 H), 8.23 (d, *J* = 8.8 Hz, 1 H), 8.51 (d, *J* = 8.6 Hz, 1 H), 8.74 (s, 1 H).9.83 (s, 1 H).

***N*-4-Diethylaminosalicylidene-*N*′-4-(2,4-dinitrophenylethylidene)-benzoylhydrazine (L^2):** 4-(2,4-dinitrophenylethylidene)benzohydrazide (3.55 g, 10.8 mmol) and 4-*N*,*N*-diethylamino-2-hydroxyibenzaldehyde (2.20 g, 11.4 mmol) are dissolved in boiling DMF (50 mL). After 15 minutes the solution is cooled and then poured into water (100 mL) containing concentrated sulfuric acid (2 mL). The brown solid obtained is recovered by filtration, washed several times with water, dried and recrystallized from DMF/water. Yield 5.06 g (93%). M.p. 276 °C. ^{1}H NMR (200 MHz, [D$_6$]DMSO, 25 °C): δ = 1.09 ppm (t, *J* = 6.8 Hz, 6 H), 3.33 (m, 4 H), 6.10 (s, 1 H), 6.23 (d, *J* = 8.8 Hz, 1 H), 7.17 (d, *J* = 8.8 Hz, 1 H), 7.62 (s, 2 H), 7.79 (d, *J* = 7.6 Hz, 2 H), 7.95 (d, *J* = 7.6 Hz, 2 H), 8.23 (d, *J* = 8.8 Hz, 1 H), 8.41 (s, 1 H), 8.50 (d, *J* = 8.6 Hz, 1 H), 8.73 (s, 1 H), 11.43 (s, 1 H), 11.82 (s, 1 H). IR (KBr): $\tilde{\nu}$ = 3334 cm^{-1} (m), 3208 (w, N−H str.), 2977 (m), 2933 (w), 1630 (vs, C=O str.), 1595 (vs, N−H bend), 1520 (vs), 1355 (s), 1334 (s), 1246 (m), 1133 (m). UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 370, 5.6·10^4.

Synthesis of $(CuL^2)_2$: L^2 (1.00 g, 1.99 mmol) and copper(II) acetate (0.397 g, 1.99 mmol) are dissolved in DMF (35 mL). The solution is heated to boiling and stirred for 15 minutes, then it is cooled and poured into water (100 mL) containing sodium acetate (0.700 g, 8.53 mmol). A dark brown solid is recovered by filtration, washed repeatedly with water, and recrystallized from DMF. Yield 90%. M.p. 308 °C dec. $C_{52}H_{46}N_{10}O_{12}Cu_2$: Cu 11.25, C 55.27, H 4.10, N 12.39; found Cu 10.92, C 54.98, H 4.02, N 12.11%. UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 400, 5.8·10^4.

Synthesis of $(PdL^2)_2$: L^2 (1.00 g, 1.99 mmol) is dissolved in boiling THF (15 mL). The solution is added with THF (10 mL) containing bis(benzonitrile)Pd^{II} dichloride (0.763 g, 1.99 mmol). A solution of sodium acetate (1.00 g, 12.2 mmol) in water (20 mL) is added. The pH is raised to 8−9 by adding a solution of 0.300 g of KOH in 100 mL of water. On heating, a dark red-brown solid coagulates, then filtered off, washed repeatedly with water, dried, and washed with boiling heptane. Yield 85%. M.p. 291 °C dec.

Synthesis of $(CuL^3)_2$: L^3 (1.00 g, 2.11 mmol) and copper(II) acetate (0.422 g, 2.11 mmol) are solved in DMF (35 mL). The solution is heated to boiling and stirred for 15 minutes, then it is cooled and poured into water (100 mL) containing sodium acetate (0.700 g, 8.53 mmol). A dark orange solid is recovered by filtration, washed repeatedly with water, and recrystallized from DMF. Yield 89%. M.p. 327 °C dec. $C_{50}H_{42}N_{10}O_{10}Cu_2$: Cu 11.88, C 56.12, H 3.96, N 13.09 ; found Cu 12.30, C 55.96, H 3.77, N 12.86%. UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 435, 5.2·10^4.

Synthesis of $(PdL^3)_2$: L^3 (1.00 g, 2.11 mmol) is suspended in 20 mL of boiling THF. The solution is added with THF (10 mL) containing bis(benzonitrile)Pd^{II} dichloride (0.809 g, 2.11 mmol), obtaining a yellow heterogeneous mixture which becomes a dark red solution by adding 20 mL of water containing sodium acetate (1.00 g, 12.2 mmol). The pH is raised to 8−9 with a solution of 0.300 g of KOH in 100 mL of water and a brown solid coagulates, which is filtered off, washed repeatedly with water, dried, and washed with boiling heptane. Yield 85%. M.p. 298 °C dec. $C_{50}H_{42}N_{10}O_{10}Pd_2$: Pd 18.41, C 51.96, H 3.66, N 12.12%; found Pd 18.35, C 51.85, H 3.55, N 12.01%. UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 446, 6.0·10^4.

Synthesis of CuN and PdN: The corresponding dinuclear precursor is dissolved in pyridine at room temperature, then the solvent is allowed to evaporate from the solution leaving crystals of the mononuclear complex.

Cu1: $C_{25}H_{25}N_5O_4Cu{\cdot}1/2C_5H_5N$: calcd. C 58.71, H 4.93, N 13.69; found C 58.41, H 4.96, N 13.42. UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 471, 2.8·10^4.

Pd1: $C_{30}H_{30}N_6O_4Pd$: calcd. C 55.86, H 4.69, N 13.03; found C 55.33, H 4.68, N 12.86. UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 463, 3.3·10^4.

Cu2: $C_{36}H_{33}N_7O_6Cu$: calcd. C 59.79, H 4.60, N 13.56; found 59.51, H 4.70, N 13.36. UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 400, 2.9·10^4.

Pd2: $C_{36}H_{33}N_7O_6Pd$: calcd. C 56.44, H 4.34, N 12.80; found C 56.05, H 4.45, N 12.69. UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 361, 2.4·10^4.

Cu3: $C_{35}H_{31}N_7O_5Cu$: calcd. C 60.64, H 4.51, N 14.14; found C 59.21, H 4.40, N 13.80. UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 460, 2.8·10^4.

Pd3: $C_{30}H_{26}N_6O_5Pd$: calcd. C 54.85, H 3.99, N 12.18; found C 54.71, H 4.12, N 12.53. UV/Vis: λ_{max} (nm), ε_{max} (dm^{3}mol^{-1}cm^{-1}): 450, 2.9·10^4.

Synthesis of Grafted Polymers: Commercial poly(4-vinylpyridine) (Aldrich, $M_{av} \approx$ 60000 D, T_g= 147 °C) was used as the starting material after drying at 120 °C in oven for 16 h. Grafted polymers were prepared according to a standard procedure. The polymer and the dinuclear complex $(ML^1)_2$ (total amount 1.0 g) in the proper weight ratio are solved in DMF (10 mL) at 90 °C. After stirring for 15′ at 90 °C, the mixture is poured in water (100 mL) containing 2% sodium acetate (by weight). The precipitated polymer is recovered by filtration (90% yield), washed repeatedly with water and dried in oven at 130 °C. Grafted polymers are indicated as MW, where M stands for Cu or Pd and W is the weight percent ratio of $(ML^1)_2$ to polymer. Grafted polymers Cu35, Pd35, Cu60, and Pd60 were prepared. Analytical data: Cu35: %Cu calcd. 5.01; found 5.08. Cu60: %Cu calcd. 8.59; found 8.47. Pd35: %Pd calcd. 7.67; found 7.67. Pd60: %Pd calcd. 13.13; found 13.21.

Physical Measurements: The thermal behavior of compounds was studied by differential scanning calorimetry (Perkin−Elmer Pyris, N_2 atmosphere, scanning rate 10 K/min), temperature controlled polarizing microscopy (Zeiss microscope, Mettler hot stage) and TGA-DTA analysis (TA Instruments SDT 2960, air atmosphere, scanning rate 10 K/min). Proton NMR spectra were recorded on a Varian XL 200 spectrometer. UV/Vis (DMF solution) and FT-IR (KBr) spectra were recorded with JASCO spectrometers. Films of the grafted polymers were obtained by the spin coating technique

(NMP solutions, SCS P6700 spincoater operating at 800−1000 rounds/min). Residual solvent was removed by keeping the films in oven at 120 C for 12 h.

X-ray Analysis: Single crystals of Cu1, Cu2, Pd2, and Cu3 suitable for X-ray analysis were obtained by slow evaporation of pyridine solutions at ambient temperature. Cell parameters were obtained through a least-squares fit[12] to the θ angles of 25 accurately centered strong reflections in the ranges 12.173°≤ θ ≤ 13.480° for Cu1, 15.907°≤ θ ≤ 17.512° for Cu2, 12.009°≤ θ ≤ 13.551° for Pd2 and 9.140°≤ θ ≤ 12.147° for Cu3 on an Enraf−Nonius MACH 3 automated single crystal diffractometer, using graphite monochromated Mo-K_α radiation (λ= 0.71069 Å). Data collection was performed on the same apparatus. Semiempirical absorption correction (ψ scans) was applied in all cases. The structures were solved by direct methods (SIR92 program[13]), completed by difference Fourier methods and refined by the full-matrix least-squares method (SHELXL program of SHELX 97 package[14]). Refinement was on F^2 against all independent measured reflections; sigma weights were introduced in the last refinement cycles. The largest peaks and holes in the last Fourier difference were (e·Å^{-3}): 0.689 and −0.514 for Cu1, 0.379 and −0.235 for Cu2, 0.691 and −0.498 for Pd2, and 0.448 and −0.498 for Cu3. In all structures C, N, O and metal atoms were given anisotropic displacement parameters. H atoms were placed in calculated positions and refined by the riding model with U_{iso} equal to U_{eq} of the carrier atoms. In the crystals of Cu1 the pyridine molecule not coordinated to the metal is located on a crystallographic inversion center and therefore is statistically disordered (two centrosymmetrically related sites with 0.5 occupation factor). Some crystal, collection and refinement data are reported in Table 4. CCDC-221599 (for Cu1), -221600 (for Cu2), -221601 (for Pd2), and -221602 (for Cu3) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

NLO Measurements: Second order optical nonlinearities of chromophores, in the form of $\mu_g\beta$ products (μ_g is the ground state permanent dipole moment and β the quadratic hyperpolarizability of the molecules), were measured by the EFISH (Electric Field Induced Second Harmonic generation) technique.[15] Measurements were carried out in DMSO solutions at a fundamental wavelength of 1.907 μm, using a Q-switched, mode locked Nd3:YAG laser, whose 1.064 μm initial wavelength was shifted by stimulated Raman scattering in a high-pressure hydrogen cell.

Acknowledgments

We thank the CIMCF of the Università di Napoli "Federico II" for permission to use the Nonius MACH3 diffractometer and NMR spectrometers. Financial support of MIUR of Italy (PRIN 2002) is also acknowledged.

Synthesis, Molecular Structure and Catalytic Activity of Six-Coordinate Chloro(hydrido)- and Dihydridoruthenium(II) and -osmium(II) Complexes with the Chiral Ligands P*i*Pr$_2$NH(Me)Ph, (*S*,*S*)-Chiraphos and (*S*,*S*,)-Diop

Keywords: Chirality / Hydrido complexes / Osmium / Phosphane complexes / Ruthenium

The five-coordinate compounds [MHCl(CO)(P*i*Pr$_3$)$_2$] (where **1a**: M = Ru; **1b**: M = Os) react with P*i*Pr$_2$R* [where R* = CH(Me)Ph] to give the octahedral complexes *mer*-[MHCl(CO)(P*i*Pr$_2$R*)$_3$] (**6** and **7**). The lability of the phosphane *trans* to the hydride is illustrated by the replacement reactions with CO, P(OMe)$_3$ and C$_2$(CO$_2$Me)$_2$, which afford the substitution products [MHCl(CO)(L)(P*i*Pr$_2$R*)$_2$] (**8**–**12**) in high yields. The reactions of **1a** and **1b** with (*S*,*S*)-Chiraphos and (*S*,*S*)-Diop lead to one or two diastereoisomers of the chelate complexes [MHCl(CO)(P*i*Pr$_3$)(Chiraphos)] (**15**, **16**) and [MHCl(CO)(P*i*Pr$_3$)(Diop)] (**17**, **18**); the ratio of the diastereoisomers is dependent on the metal, the bidentate ligand and the reaction conditions. The racemate of [OsHCl(CO)(P*i*Pr$_3$)(dppe)] (**14**) was obtained from **1b** and 1,2-C$_2$H$_4$(PPh$_2$)$_2$ (dppe). The hydrido(tetrahydroboranato) compounds [MH(κ^2-H$_2$BH$_2$)(CO)(P*i*Pr$_3$)$_2$] (where **2a**: M = Ru; **2b**: M = Os) also react with (*S*,*S*)-Chiraphos and (*S*,*S*)-Diop to give either the mononuclear, octahedral, chelate complexes **19**–**21** or, for M = Os and (*S*,*S*)-Diop, the dinuclear compound [{OsH$_2$(CO)(P*i*Pr$_3$)$_2$}$_2$(μ-Diop)] (**22**). The molecular structure of **22** was determined crystallographically. Treatment of [OsH$_2$Cl$_2$(P*i*Pr$_3$)$_2$] (**23**) with two equivalents of (*S*,*S*)-Chiraphos afforded stepwise [OsH$_2$Cl$_2$(P*i*Pr$_3$)(Chiraphos)] (**25**) and, after reductive elimination of HCl and displacement of P*i*Pr$_3$, *trans*-[OsHCl(Chiraphos)$_2$] (**24**). Both **24** and [OsH$_2$-(Chiraphos)$_2$] (**27**), which was prepared from **24** and NaBH$_4$/MeOH, were transformed with HBF$_4$ in diethyl ether into the dihydrogen complexes [OsCl(H$_2$)(Chiraphos)$_2$]BF$_4$ (**28**) and [OsH(H$_2$)(Chiraphos)$_2$]BF$_4$ (**29**) in excellent yields. The catalytic activity of the chloro(hydrido)- and dihydridometal derivatives in the asymmetric transfer hydrogenation of acetophenone with 2-propanol was investigated.

Introduction

In the context of our studies on the chemistry of the five-coordinate (hydrido)ruthenium(II) and (hydrido)osmium(II) complexes [MHCl(CO)(P*i*Pr$_3$)$_2$] (where **1a**: M = Ru; **1b**: M = Os),[1] we reported that the osmium compound **1b**, under hydrogen, catalyzes the reduction of cyclohexene, 1,3- and 1,4-cyclohexadiene, styrene, and diphenyl- and phenylacetylene.[2,3] Furthermore, in the presence of NaBH$_4$, it also serves as a catalyst for hydrogen transfer from 2-propanol to cyclohexanone, acetophenone, benzylidenacetone, etc.[4] It was shown that both **1a** and **1b** react with NaBH$_4$ to give the tetrahydroboranato compounds **2a** and **2b** (see Scheme 1), of which **2b**, upon treatment with 2-propanol, decomposes to the tetrahydride **3**.[5] Kinetic investigations suggest that in the hydrogen-transfer process catalyzed by **1b** and NaBH$_4$, the coordinatively unsaturated dihydride [OsH$_2$(CO)(P*i*Pr$_3$)$_2$], which is generated from **3** by loss of H$_2$, is the active catalytic species.[6]

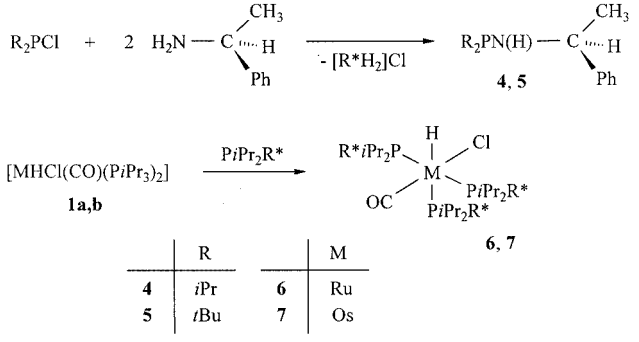
and -osmium complexes we have now attempted to modify the coordination sphere by linking chiral mono- and bisphosphanes to the metal center. In this paper we describe the preparation and molecular structure of the compounds obtained and report some preliminary results concerning their catalytic activity in the asymmetric reduction of acetophenone by 2-propanol.

Results and Discussion

The preparation of the chiral aminophosphanes **4** and **5** (see Scheme 2) follows the route which was developed for the diphenylphosphanyl counterpart (*S*)-Ph_2PNHR^* [R* = CH(Me)Ph] by Brunner et al.[7] The reason for using isopropyl and *tert*-butyl substituents instead of phenyl at the phosphorus atom was that we wanted to make the phosphane comparable in size to P*i*Pr$_3$ and P*t*Bu$_2$Me, respectively. The reactions of R_2PCl and R^*NH_2 were carried out in diethyl ether and gave, after removal of ammonium chloride, the chiral products in 64−72 % isolated yield. Both **4** and **5** are colorless, extremely air-sensitive liquids, the composition of which was confirmed by elemental analysis and mass spectrometry. The ^{1}H NMR spectrum of **5** displays two resonances for the *tert*-butyl protons, which is a consequence of a chiral center next to the phosphorus atom. For the same reason four signals, which are pairwise equivalent, appear in the ^{1}H NMR spectrum of **4** for the methyl protons of the isopropyl groups. They are doublets of doublets and become doublets with $^3J_{H,H}$ = 6.4, 6.9 Hz in off resonance.

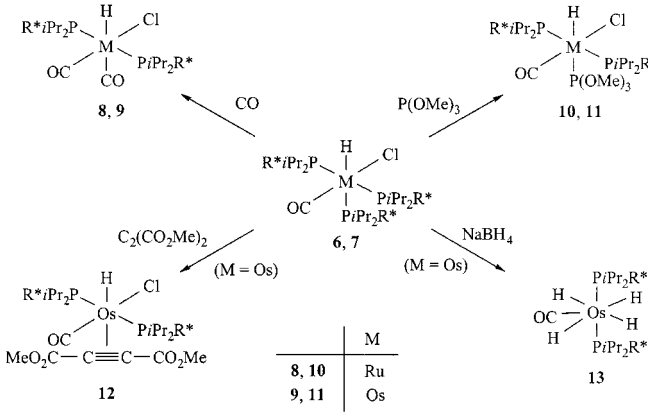


Scheme 2. [R* = NHCH(Me)Ph]

Attempts to prepare the five-coordinate complexes, $[MHCl(CO)(PiPr_2R^*)_2]$, (where M = Ru, Os) from ruthenium- and osmium trichloride, using the same methodology as that applied for the synthesis of **1a** and **1b**,[1] failed. Under the reaction conditions (stirring the reaction mixtures of $MCl_3 \cdot 3H_2O$ and **4** or **5** in methanol or 2-propanol under reflux) partial cleavage of the P−N bond of the aminophosphane and decomposition of possibly formed metal-containing intermediates occurred.

The reactions of **1a** and **1b** with an excess of the less sterically demanding phosphane, **4**, proceeded by ligand exchange as well as by addition of a third phosphane molecule to the metal center. After recrystallization from benzene/methanol, the six-coordinate compounds **6** and **7** were isolated as white, moderately air-stable solids in 67−71 % yield (see Scheme 2). The starting materials are inert toward **5** which is reminiscent to the behavior of other (phosphane)ruthenium and -osmium complexes, such as $[MCl_2(PPh_3)_3]$ (M = Ru, Os) toward P*t*Bu$_3$.[8] The most typical spectroscopic features of **6** and **7** are the two ^{31}P NMR signals at δ = 89.4 and 75.4 ppm for **6** and at δ = 57.2 and 48.5 ppm for **7**, which, together with the splitting pattern, indicate that two of the aminophosphane ligands are stereochemically equivalent while the third is not. Thus, a *mer* configuration for the octahedral compounds can be assigned. In agreement with this proposal, the ^{1}H NMR spectrum of **7** displays a high-field resonance at δ = −8.77 ppm for the Os−H proton, which appears as a doublet of triplets due to P−H coupling with different ^{31}P nuclei.

The results regarding the reactivity of **6** and **7** toward Lewis bases are summarized in Scheme 3. According to the strong *trans* influence of the hydride, the M−P bond in *trans* disposition was assumed to be rather labile and this was substantiated by the reactions of **6** and **7** with CO, $P(OMe)_3$ and $C_2(CO_2Me)_2$. Passing a slow stream of CO through a solution of **6** or **7** in benzene, after a short period of time, leads to a ligand exchange and affords the dicarbonyl complexes **8** and **9** in high yields. The white solids are thermally stable and for a few minutes can be handled in air. The IR spectra display two ν(CO)-stretching modes at 1970 and 1905 cm^{-1} (for **8**) and 1970 and 1910 cm^{-1} (for **9**), indicating that the two CO ligands are not stereochemically equivalent. The ^{1}H NMR spectra show a hydride signal at δ = −5.47 ppm (for **8**) and δ = −4.68 ppm (for **9**), which is split into a triplet due to P−H coupling.



Scheme 3. [R* = NHCH(Me)Ph]

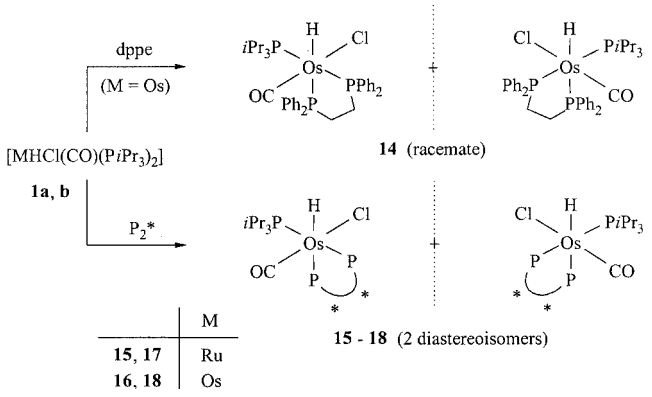
The preparation of the phosphite and alkyne derivatives **10**−**12** takes place under similar conditions (hexane, room temperature) as those used for the dicarbonyl complexes **8** and **9**. After evaporation of the solvent, compounds **10**−**12** were isolated as white, moderately air-stable solids, which readily dissolved in most common organic solvents (with the exception of methanol and hexane). The proposed

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structure for **10**–**12** with the phosphite or alkyne ligand *trans* to the hydride is supported by the mass spectra in which, besides the peak for the molecular M^+ ion, a second peak corresponding to $M^+ - P(OMe)_3$ or $M^+ - C_2(CO_2Me)_2$ appears. Thus, the hydride ligand presumably labilizes the M–P*i*Pr$_2$R* as well as the M–P(OMe)$_3$ and M$^+$–C$_2$(CO$_2$Me)$_2$ bonds in the *trans* position. The ^{31}P NMR spectra of the phosphite complexes **10** and **11** are noteworthy insofar as they show the pattern of an ABX system, which means that the two aminophosphane ligands are magnetically nonequivalent. Since the metal atom in the octahedral complexes **10** and **11** is a prochiral center, the two phosphane units are diastereotopic and thus give rise to two resonances in the ^{31}P NMR spectra. Accordingly, the ^{31}P NMR spectrum of the alkyne compound **12** displays the pattern of an AB spin system with $\delta_{PA} = 65.7$ ppm and $\delta_{PB} = 61.8$ ppm. There are also two signals for the NH and two for the NCHC*H*$_3$ protons of the P*i*Pr$_2$R* ligands in the ^{1}H NMR spectrum of **12**, which is consistent with the proposed stereochemistry. We note that even under forcing conditions no insertion of the alkyne into the Os–H bond occurs, which is in contrast to the behavior of the bis(triisopropylphosphane) analogue [OsHCl(CO){C$_2$(CO$_2$Me)$_2$}(P*i*Pr$_3$)$_2$] that rearranges in chloroform to give a product with a chelating vinyl ligand.[3]

The reaction of **7** with NaBH$_4$ in benzene/methanol proceeds similarly to that of **1b** with the same reagents.[4] We assume that in the initial step (see below the formation of **26**) the tetrahydroboranato compound, [OsH(κ^2-H$_2$BH$_2$)(CO)(P*i*Pr$_2$R*)$_2$], is generated and rapidly reacts with methanol to give **13** (see Scheme 3). The (tetrahydrido)osmium(IV) complex, **13**, is a light yellow, extremely air-sensitive solid, the IR spectrum of which shows a strong ν(CO) band at 1890 cm^{-1}. The ^{31}P NMR spectrum of **13** displays a singlet at $\delta = 87.4$ ppm which is converted into a symmetrical quintet in off resonance. Since the ^{1}H NMR spectrum shows a sharp triplet at $\delta = -8.76$ ppm, we assume that, similarly to the P*i*Pr$_3$ counterpart, the seven-coordinate molecule, **13**, also possesses a fluxional structure at room temperature, which leads to the equivalence of the hydrido ligands on the NMR time scale. The $^2J_{P,H}$ coupling constants for the hydride signal of **13** and [OsH$_4$(CO)(P*i*Pr$_3$)$_2$] are nearly the same.

To compare the catalytic activity of the ruthenium and osmium complexes with two monodentate P*i*Pr$_2$R* units on one side and a chiral bidentate bisphosphane on the other, the starting materials **1a** and **1b** were also treated with (*S*,*S*)-Chiraphos and (*S*,*S*)-Diop. As a test, prior to the reaction with the chiral bisphosphanes, the reaction of **1b** with 1,2-C$_2$H$_4$(PPh$_2$)$_2$ (dppe) was carried out and afforded the racemate of compound **14** in 80 % yield (see Scheme 4). Similarly to that of **10** and **11**, the ^{31}P NMR spectrum of **14** shows an ABX spin pattern which can be clearly resolved and was simulated with the program Laocoon. Typical features are the large coupling constant $^2J_{PA,PB}$ (250.6 Hz) for the *trans*-disposed ^{31}P nuclei and the small coupling constants $^2J_{PA,PX}$ (6.7 Hz) and $^2J_{PB,PX}$ (13.8 Hz) for the ^{31}P nuclei in *cis*-position.



Scheme 4. [**15**, **16**: P$_2$* = (*S*,*S*)-Chiraphos; **17**, **18**: P$_2$* = (*S*,*S*)-Diop]

The chiral bisphosphanes (*S*,*S*)-Chiraphos and (*S*,*S*)-Diop behave analogously to dppe and under similar conditions (hexane, 24 h, reflux) give the chelate complexes **15**–**18** as white, moderately air-stable solids in 79–89 % isolated yield. Due to the presence of chiral centers at the metal and the chelating ligands, the formation of diastereoisomers should be expected and was confirmed for the Diop derivatives **17** and **18**. In contrast, the NMR spectra of the Chiraphos compounds **15** and **16** display only one set of signals, which probably means that only one diastereoisomer was generated. The high-field region of the ^{1}H NMR spectra of **15** and **16** consists of a sharp doublet of doublets of doublets at $\delta = -6.61$ ppm (for **15**) and $\delta = -6.69$ ppm (for **16**) with two small and one large $^2J_{P,H}$ coupling constant. Owing to these numbers, there is no doubt that one of the phosphorus atoms is *trans* to the hydride. Although the ^{31}P NMR spectra of **15** and **16** are in agreement with an ABX spin system, they differ from the spectrum of **14** insofar as the outer lines of the AB part were not observed and, therefore, the values for δ_{PA}, δ_{PB} and $^2J_{PA,PB}$ could not be determined. With regard to the structure of **15** and **16**, we assume that the five-membered chelate ring possesses the δ-conformation, which for steric arguments should be preferred.[9] We were unable to substantiate this by X-ray crystallography since all attempts to grow single crystals of **15** or **16** failed.

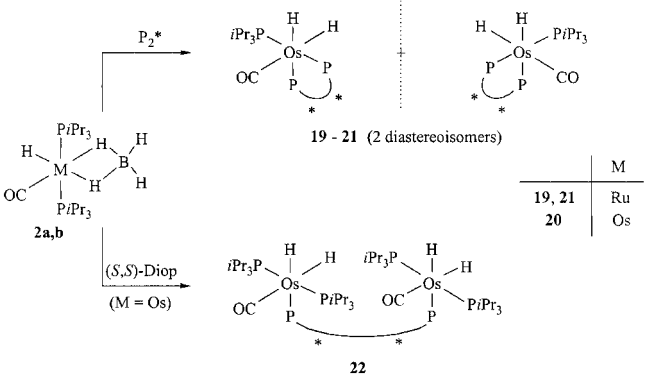
The reactions of **1a** and **1b** with (*S*,*S*)-Diop lead to two diastereoisomers, the ratio of which depends on the reaction conditions. For example, by refluxing a solution of **1b** and (*S*,*S*)-Diop in hexane for 24 h the two diastereoisomers **A** and **B** of compound **18** were obtained in a ratio of 3:2, whereas stirring the same mixture for five days gave the two species **A** and **B** in equal amounts. In the ruthenium case, an **A**/**B** ratio of 7:1 was found after refluxing the reaction mixture in hexane for 24 h, whereas only **A** was generated by carrying out the reaction at room temperature.

In contrast to the ^{1}H NMR spectra of **15** and **16**, those of **17** and **18** are rather complicated and therefore no exact assignment for the resonances (for $\delta = 0-9$) could be made. For each of the diastereoisomers **A** and **B** the hydride signal is a doublet of doublets of doublets with similar coupling constants as observed for **15** and **16**. The ^{31}P NMR spectra

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of **17** and **18** display the expected number of lines for ABX spin systems and thus the chemical shifts for the signals corresponding to P_A ($PiPr_3$), P_B and P_X (each PPh_2) could be exactly determined. The presence of the two diastereoisomers of **18** is also indicated by the IR spectrum, which shows two ν(CO) absorptions at 1905 and 1895 cm^{-1} with comparable intensities. We note that at room temperature, the diastereoisomers **A** and **B** of both **17** and **18** are stable and do not interconvert.

The preparation of the (dihydrido)ruthenium(II) and -osmium(II) complexes **19−22** followed the route that we already used to obtain compounds of the general composition $[MH_2(CO)(L)(PiPr_3)_2]$ (L = PMe_3, $P(OMe)_3$].[4] Treatment of **2a** and **2b** with (*S*,*S*)-Chiraphos and of **2a** with (*S*,*S*)-Diop in methanol under reflux conditions affords, after recrystallization from CH_2Cl_2/methanol, the chelate complexes **19−21** in 76−83 % isolated yield (see Scheme 5). In contrast to related dihydrido derivatives such as $[RuH_2(PMe_3)_4]$ or $[OsH_2(PMe_3)_4]$,[10] compounds **19−21** are only slightly air sensitive and, apart from hexane and methanol, readily soluble in common organic solvents. While the ^{31}P NMR spectrum of **19** clearly indicates that only one diastereoisomer is formed, the spectrum of **20** displays two sets of resonances for two diastereoisomers, **A** and **B**, in an approximate ratio of 10:1. For both **19** and the dominating isomer of **20**, the pattern corresponding to an ABX spin system is observed with values for the coupling constants $^2J_{PA,PB}$, $^2J_{PA,PX}$ and $^2J_{PB,PX}$ that are similar to those of **15** and **16**. For compound **21**, a mixture of two diastereoisomers in a 3:2 ratio was obtained; they are configurationally stable at room temperature and do not interconvert. The ^1H NMR spectra of **19** and **20** confirm the nonequivalence of the hydrido ligands and display two doublets of doublets of doublets of doublets at δ = −8.16 and −8.76 ppm (for **19**) and δ = −9.32 and −10.04 ppm (for **20**). In agreement with the size of the coupling constants, the signal for the lower chemical shift belongs to the hydride *trans* to CO and that for the higher chemical shift to the hydride *trans* to one of the PPh_2 groups. For the Diop compound, **21**, the two signals overlap and thus no correct δ values can be given.



Scheme 5. [**19**, **20**: P_2* = (*S*,*S*)-Chiraphos; **21**, **22**: P_2* = (*S*,*S*)-Diop]

Quite surprisingly, the reaction of **2b** with (*S*,*S*)-Diop affords, under the same conditions as those used for the preparation of **19−21**, the dinuclear complex **22**, instead of a mononuclear one (see Scheme 5) in 81 % yield. The result is reminiscent of the formation of the catalytically active ruthenium compound $[\{RuCl_2(Diop)\}_2(\mu\text{-Diop})]$, obtained by James et al. from $[RuCl_2(PPh_3)_3]$ and a 2.5-fold excess of Diop.[11] Similarly to the ^1H NMR spectra of **19** and **20**, the ^1H NMR spectrum of **22** also shows two high-field signals at δ = −9.34 and −11.56 ppm, which appear both as doublets of doublets of triplets, due to two different P−H and to one H−H coupling. For the hydride *trans* to the PPh_2 unit, two significantly different $^2J_{P,H}$ coupling constants result. The ^{31}P NMR spectrum of **22** is more simple than the spectra of **19−21** and displays one doublet for the ^{31}P nuclei of the two $PiPr_3$ ligands and one triplet for the ^{31}P nuclei of Diop.

The X-ray crystal structure analysis of **22** (see Figure 1) confirms the proposed structure, including the presence of the bridging Diop unit. The high quality of data allowed the location of the hydrides in the Fourier maps and their isotropic refinement. Taken the positions of these ligands into consideration, the coordination geometry around both metal centers is best described as distorted octahedral with bond angles that in some cases deviate significantly from the ideal 90° value. The most remarkable feature is the size of the angles P(4)−Os−P(5) and P(3)−Os−P(6) [148.90(6)° and 145.65(5)°], which is unusual and probably explained by steric hindrance between the isopropyl and phenyl groups. The chirality (*S*,*S*) of the Diop ligand was maintained. The bond lengths between osmium and the phos-

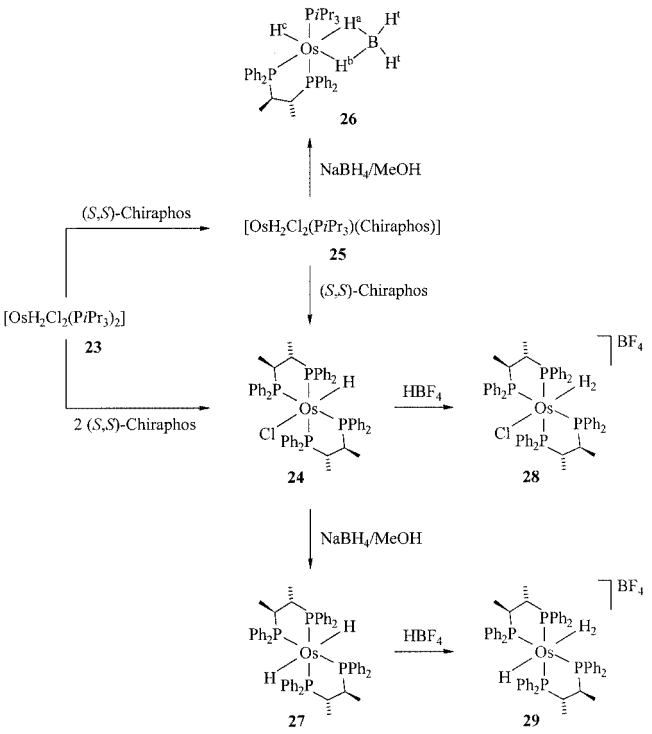
phorus atoms of the P*i*Pr$_3$ units are slightly shorter than in the five-coordinate vinyl complex [OsCl(CH=CHPh)(CO)(P*i*Pr$_3$)$_2$],[12] but somewhat longer than in the bis(triisopropylphosphane)osmium(IV) compound, [OsH$_2$Cl$_2$(P*i*Pr$_3$)$_2$] (**23**) (see below).[5] There is also a small difference in the distances Os−P*i*Pr$_3$ and Os−PPh$_2$X, which might be due to the different donor strength of the trialkylphosphane and alkyldiarylphosphane moieties.

The above-mentioned osmium(IV) compound, **23**, was also used as starting material for the reactions with (*S*,*S*)-Chiraphos (see Scheme 6). It was already known that the dichloro(dihydrido) complex reacts with CO and PMe$_3$ to give [OsCl$_2$(CO)$_2$(P*i*Pr$_3$)$_2$] and [OsCl$_2$(PMe$_3$)$_4$] by reductive elimination of H$_2$.[5]



Scheme 6

The reaction of **23** with two equivalents of (*S*,*S*)-Chiraphos, however, does not lead to the elimination of H$_2$ but of HCl and affords the chloro(hydrido)osmium(II) compound **24** in 89 % isolated yield. If equimolar amounts of **23** and (*S*,*S*)-Chiraphos are reacted in hexane under reflux, a white, extremely air-sensitive solid, **25**, can be isolated and it slowly decomposes at room temperature, even under argon. The assumption that **25** is the substitution product of **23** is supported by the elemental analysis and, in particular, by the ^{31}P NMR spectrum, which displays the pattern of an ABX spin system. The ^{1}H NMR spectrum of **25** shows a broadened doublet of doublets of doublets in the high-field region, indicating that under these conditions the two hydrido ligands are magnetically equivalent on the NMR time scale. Since the three coupling constants $^2J_{P,H}$ are virtually the same, it is conceivable that the seven-coordinate molecule is fluxional in solution, as has also been observed for the osmium tetrahydrides [OsH$_4$(PPh$_3$)$_3$] and [OsH$_4$(PMe$_2$Ph)$_3$].[13] Since, by lowering the temperature, the high-field resonance in the ^{1}H NMR spectrum of **25** becomes broader and the coupling constants become smaller, the possibility of an equilibrium between a classical OsH$_2$ and a nonclassical Os(H$_2$) species was taken into consideration. Therefore, T_1 measurements were carried out at +20 °C, −20 °C and −50 °C resulting in T_1 values of 170, 110 and 100 ms, respectively. Since the T_1 minimum has not been found (for comparison see compounds **28** and **29**), the question that remains is whether a nonclassical octahedral osmium(II) complex, [OsCl$_2$(H$_2$)(P*i*Pr$_3$)(Chiraphos)], exists. If treated in 1,2-dichloroethane under reflux, compound **25** reacts with one equivalent of (*S*,*S*)-Chiraphos to give the bis(chelate) complex **24** in nearly quantitative yield. The ^{1}H NMR spectrum of **24** displays a complicated symmetrical multiplet for the hydrido ligand at $\delta = -20.27$ ppm; the chemical shift is similar to that of related chloro(hydrido)-metal derivatives with two chelating moieties.[14]

The reaction of **25** with an excess of NaBH$_4$ in toluene/methanol does not lead to the (tetrahydrido)osmium(IV) complex [OsH$_4$(P*i*Pr$_3$)(Chiraphos)] (the counterpart of compound **3**) but gives the hydrido(tetrahydroboranato)osmium(II) derivative **26** instead. A mixture of two diastereoisomers **A** and **B**, formed in about equal quantities, is obtained. The white solid is exceedingly air-sensitive and thermally not very stable; slow decomposition occurs even in toluene solution. The ^{1}H NMR spectrum of **26** shows two sharp doublets of doublets of doublets in the high-field region which are assigned to the metal-bonded proton H^c (see Scheme 6) of the two diastereoisomers. Apart from these sharp signals four rather broadened resonances appear at $\delta = -7.81$, −8.55, −9.42 and −10.10 ppm which probably belong to the bridging hydrides H^a and H^b. The broadening could be a consequence of the linkage of H^a and H^b to the boron nuclei. Since the spectrum does not change between −20 °C and +30 °C, we assume that, in contrast to [OsH(κ^2-H$_2$BH$_2$)(CO)(P*i*Pr$_3$)$_2$], the fragment Os(κ^2-H$_2$BH$_2$) of **26** is rigid in this temperature region and no exchange between the bridging and terminal hydrogens of the BH$_4$ moiety occurs. The situation is similar to that of the structurally related ruthenium compounds [RuH(κ^2-H$_2$BH$_2$)(PR$_3$)$_3$] (PR$_3$ = PMePh$_2$, PMe$_2$Ph), for which a rigid structure has also been proposed.[15,16]

The reaction of the chloro(hydrido) complex, **24**, with NaBH$_4$ and methanol in toluene does not yield a hydrido(tetrahydroboranato) derivative such as **26** but leads to the formation of the dihydridoosmium(II) compound **27** in good yield. Since the ^{31}P NMR spectrum of **27** displays only a singlet at $\delta = 50.9$ ppm, there is no doubt that the four PPh$_2$ units are chemically and spectroscopically equivalent. Due to this fact, the two hydrides must be in *trans* disposition. This stereochemistry is also supported by the IR spectrum that shows a ν(OsH) band at relatively low wavenumbers (1730 cm^{-1}). In the IR spectrum of the related complex *trans*-[OsH$_2$(dppe)$_2$], the ν(OsH) stretching mode is observed at 1721 cm^{-1}.[15] The ^{1}H NMR spectrum

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of **27** displays a quintet in the high-field region at $\delta = -10.70$ ppm, which equally suggests that the phosphido moieties are equivalent.

To further modify the reactivity of the osmium(II) compounds with Chiraphos as ligands, **24** and **27** were transformed into the cationic $OsCl(H_2)$ and $OsH(H_2)$ derivatives **28** and **29**, respectively (see Scheme 6). The preparation took place with HBF_4 in diethyl ether at room temperature (for **28**) or at −78 °C (for **29**) and gave the products as white solids in 71−83 % yield. Both **28** and **29** are air sensitive but can be stored under argon for days; they do not eliminate H_2 in THF, acetone or chloroform solutions. In the presence of N_2, no ligand exchange to afford $[OsX(N_2)(Chiraphos)_2]BF_4$ (X = Cl, H) occurs. The ^{31}P NMR spectra of **28** and **29** display in each case two triplets for the ^{31}P nuclei of the pairwise equivalent PPh_2 units with $^2J_{P,P}$ coupling constants that are similar to those of **24**. The ^1H NMR spectrum of **29** shows a broadened signal at $\delta = -6.45$ ppm and a sharp multiplet at $\delta = -8.63$ ppm with the relative intensities of 2:1. By decreasing the temperature, the broadened signal is shifted to the lower-field region, where free dihydrogen resonates. T_1 measurements of the broadened signal resulted in values of 70 ms at 20 °C, 60 ms at 0 °C, 50 ms at −20 °C and 40 ms at −50 °C. Although the minimum could not be exactly located in the given range of temperatures, a non-classical $Os(H_2)$ structure can be assumed. The T_1(min) value for the well-characterized complex $[OsH(H_2)(dppe)_2]^+$ is 18 ms at −85 °C.[17] In contrast to this species, which is dynamic and where an equilibration between the OsH and the $Os(H_2)$ protons occurs at room temperature, a similar process could not be observed for **29**. Whether this difference is a result of steric effects, that is, of the larger size of (*S*,*S*)-Chiraphos compared with dppe, is open to speculation.

Since the preparation of optically active alcohols by catalytic asymmetric transfer hydrogenation of ketones is an important process in organic synthesis,[18] we were prompted to explore the catalytic activity of some of the chiral ruthenium and osmium complexes prepared in this study. For this purpose, the reduction of acetophenone with 2-propanol was carried out in a mixture of 2-propanol/toluene (2:1) at 85 °C under an argon atmosphere. The results are listed in Table 1. In analogous studies, where rhodium, iridium and ruthenium compounds containing chiral phosphane,[19] amine,[20] and Schiff-base ligands were used,[21] the presence of KOH was necessary for the substitution of the halide by a coordinated isopropoxide group; the latter afforded a hydride-metal intermediate by β-elimination. However, for the Chiraphos and Diop complexes **15**−**18** the presence of KOH is not necessary; it does not lead to any significant improvement either in the rate of conversion or in the *ee* values. Although the *ee*'s in general are not very high, the chloro(hydrido) complexes **15** and **16** with Chiraphos as the chelating ligand are more active than the Diop counterparts **17** and **18** and, moreover, than the dihydrido compounds **19**−**22**. The (dihydrido)osmium(II) derivative **20** is not active at all. We note that for **16** and **17** the presence of KOH as cocatalyst changes the chirality of the product, which is not unexpected and in agreement with the general rule.[22]

Table 1. Asymmetric hydrogen transfer from 2-propanol to acetophenone, catalyzed by (hydrido)ruthenium and -osmium complexes

Catalyst	Time	Conversion (%)	*ee* (%)	Configuration
7	16 h	70	3.5	*R*-(+)
15	23 h	91	22.6	*S*-(−)

29	not active			

Conclusions

The work presented in this paper has shown that in five-coordinate ruthenium(II) and osmium(II) compounds $[MHCl(CO)(PiPr_3)_2]$ (**1a** and **1b**) either one or both triisopropylphosphane ligands can be replaced by an optically active monophosphane, such as $PiPr_2R^*$, or by a chiral chelating bisphosphane such as (*S*,*S*)-Chiraphos or (*S*,*S*)-Diop. In the isolated octahedral complexes $[MHCl(CO)(PiPr_2R^*)_3]$ (**6**, **7**), the M−P bond *trans* to the hydride is quite labile and thus substitution products $[MHCl(CO)(L)(PiPr_2R^*)_2]$ with L = CO, $P(OMe)_3$ and $C_2(CO_2Me)_2$ are readily obtained. The reactions of **1a** and **1b** and of the tetrahydroboranato derivatives **2a** and **2b** with (*S*,*S*)-Chiraphos and (*S*,*S*)-Diop afford a mixture of two diastereoisomers, the ratio of which depends on the metal, the chiral bisphosphane and the reaction conditions. For the Chiraphos complexes **15**, **16** and **19**, the formation of only one diastereoisomer was observed. With the osmium(IV) compound $[OsH_2Cl_2(PiPr_3)_2]$ (**23**) and (*S*,*S*)-Chiraphos as starting materials, chloro(hydrido)- and (dihydrido)osmium(II) complexes can be prepared and, by treatment with HBF_4 in diethyl ether, transformed into the cationic dihydrogen derivatives **28** and **29**, respectively. Regarding the catalytic potential in the asymmetric transfer hydrogenation of acetophenone with 2-propanol as a hydrogen source, the osmium(II) complexes with two Chiraphos ligands are completely inactive. The catalytic activity of the related ruthenium(II) and osmium(II) compounds **15**−**21** with one chiral chelating ligand is also not very pronounced and could be due to the fact that they are coordinatively saturated, that is, they have an 18-electron count. Although the *trans* influence of the hydride ligand is rather strong, it is probably not strong enough to open the *trans*-disposed co-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ordination site by maintaining the chirality at the metal center. The introduction of optically active tridentate chelating ligands could possibly improve the optical yield but this has to be confirmed by further investigations.

Experimental Section

All operations were carried out under argon using Schlenk techniques. The starting materials **1a**, **1b**,[1] **2a**, **2b**,[4] and **23**[5] were prepared as described in the literature. The chlorophosphanes R_2PCl, the optically pure amine (*S*)-$H_2NCH(Me)Ph$ and the chelating phosphanes are commercially available. NMR: Bruker AC 200 and Jeol FX 90 Q. IR: Perkin−Elmer 397 and 1320. Mass spectra: Varian CH 7 MAT (70 eV). Melting points determined by DTA. Abbreviations used: R* = (*S*)-NHCH(Me)Ph; s, singlet; d, doublet; t, triplet; q, quadruplet; quint, quintet; m, multiplet; vt, virtual triplet; br, broadened signal; $N = {}^3J_{P,H} + {}^5J_{P,H}$.

Preparation of (*S*)-*i*Pr_2PNHCH(Me)Ph (4): A solution of *i*Pr_2PCl (6.1 mL, 40.0 mmol) in diethyl ether (50 mL) was added dropwise to a solution of (*S*)-$H_2NCH(Me)Ph$ (12.7 mL, 100.0 mmol) in diethyl ether (400 mL) at room temperature. The reaction mixture was stirred for 3 h at 25 °C and then filtered. The separated solid was washed three times with 20 mL portions of diethyl ether, and the combined filtrates were concentrated to about 15 mL in vacuo. The solution was poured into a column (height 5 cm) filled with finely divided SiO_2 and the product was eluted with 200 mL of diethyl ether. The solvent was evaporated in vacuo (20 mbar) and the residue maintained under high vacuum (0.01 mbar) at 70 °C to remove traces of the amine. A clear air-sensitive liquid was obtained; yield 6.8 g (72 %). MS: *m*/*z* (I_r) = 237 (10) [M^+]. IR: $\tilde{\nu}$ = 3370 ν(NH) cm^{-1}. ^1H NMR (90 MHz, $CDCl_3$): δ = 7.17 (m, 5 H, C_6H_5), 4.01 (ddq, $^3J_{H,H} = {}^3J_{H,H} = {}^3J_{P,H}$ = 6.6 Hz, 1 H, NCH), 1.51 (m, 2 H, PC*H*CH_3), 1.35 (d, $^3J_{H,H}$ = 6.6 Hz, 3 H, NCHCH_3), 1.05, 1.04 (both m, 3 H each PCHCH_3; both d in off resonance, $^3J_{H,H}$ = 6.4 Hz), 0.91, 0.88 (both m, 3 H each, PCHCH_3, both d in off resonance, $^3J_{H,H}$ = 6.9 Hz) ppm; signal of NH proton not exactly located. ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = 60.3 (s) ppm. $C_{14}H_{24}NP$ (237.3): calcd. C 70.85, H 10.19, N 5.90; found C 69.93, H 10.09, N 5.71.

Preparation of (*S*)-*t*Bu_2PNHCH(Me)Ph (5): This compound was prepared as described for **4**, with *t*Bu_2PCl (4.5 mL, 25.0 mmol) and (*S*)-$H_2NCH(Me)Ph$ (8.0 mL, 63.0 mmol) as starting materials. The reaction mixture was refluxed for 10 h and, after cooling to room temperature, worked up as described for **4**. Colorless air-sensitive liquid; yield 4.2 g (64 %). MS: *m*/*z* (I_r) = 265 (7; M^+). IR: $\tilde{\nu}$ = 3380 ν(NH) cm^{-1}. ^1H NMR (90 MHz, $CDCl_3$): δ = 7.29 (m, 5 H, C_6H_5), 4.10 (ddq, $^3J_{H,H} = {}^3J_{H,H} = {}^3J_{P,H}$ = 6.6 Hz, 1 H, NCH), 1.45 (d, $^3J_{H,H}$ = 6.6 Hz, 3 H, NCHCH_3), 1.13, 0.96 (both d, $^3J_{P,H}$ = 14.6 Hz, 9 H each, $PCCH_3$) ppm, signal of the NH proton not exactly located. ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = 71.9 (s) ppm. $C_{16}H_{28}NP$ (265.4): calcd. C 72.42, H 10.63, N 5.28; found C 71.33, H 10.13, N 5.61.

Preparation of *mer*-[RuHCl(CO)(P*i*Pr_2R*)$_3$] (6): A solution of **1a** (500 mg, 1.05 mmol) in benzene (30 mL) was treated dropwise with **4** (1.20 g, 5.05 mmol) and stirred for 2 h at room temperature. The solution was then concentrated to ca. 2 mL in vacuo and methanol (10 mL) was added. The volatile materials were evaporated in vacuo and a white solid precipitated. The solid was filtered, washed three times with 5 mL portions of methanol and dried; yield 617 mg (67 %); m.p. 86 °C (decomp). MS: *m*/*z* (I_r) = 612 (1; M^+ − CO−**4**). IR (KBr): $\tilde{\nu}$ = 3345, 3285, 3230 ν(NH), 1985 ν(RuH), 1890 ν(CO) cm^{-1}. ^1H NMR (90 MHz, C_6D_6): δ = 7.26 (m, 15 H, C_6H_5), 4.19 (m, 3 H, NCH), 2.30 (m, 6 H, PC*H*CH_3), 1.21 (br m, 45 H, NCHCH_3 and PCHCH_3) ppm; signals for RuH and NH protons not exactly located. ^{31}P NMR (36.2 MHz, C_6D_6): δ = 89.4 (d, $^2J_{P,P}$ = 13.2 Hz, two P*i*Pr_2R* in equatorial position), 75.4 (br, P*i*Pr_2R* in axial position) ppm. $C_{43}H_{73}ClN_3OP_3Ru$ (877.5): calcd. C 58.86, H 8.39, N 4.79; found C 59.03, H 8.42, N 4.61.

Preparation of *mer*-[OsHCl(CO)(P*i*Pr_2R*)$_3$] (7): A solution of **1b** (200 mg, 0.35 mmol) in benzene (30 mL) was treated dropwise with **4** (410 mg, 1.73 mmol) and stirred at room temperature until the color of the starting materials disappeared. The solution was then concentrated to ca. 2 mL in vacuo and methanol (10 mL) was added. A white microcrystalline solid precipitated and was filtered, washed three times with 5 mL portions of methanol and dried; yield 240 mg (71 %); m.p. 101 °C (decomp). MS: *m*/*z* (I_r) = 730 (1; M^+ − **4**). IR (KBr): $\tilde{\nu}$ = 3345, 3290, 3245 ν(NH), 2075 ν(OsH), 1885 ν(CO) cm^{-1}. ^1H NMR (90 MHz, C_6D_6): δ = 7.23 (m, 15 H, C_6H_5), 4.30 (m, 3 H, NCH), 2.49 (m, 6 H, PC*H*CH_3), 1.25 (br m, 45 H, NCHCH_3 and PCHCH_3), −8.77 (dt, $^2J_{P,H\,cis}$ = 28.5, $^2J_{P,H\,trans}$ = 88.6 Hz, 1 H, OsH) ppm; signal for NH proton not exactly located. ^{31}P NMR (36.2 MHz, C_6D_6): δ = 57.2 (d, $^2J_{P,P}$ = 13.9 Hz, two P*i*Pr_2R* in equatorial position), 48.5 (t, $^2J_{P,P}$ = 13.9 Hz, P*i*Pr_2R* in axial position) ppm. $C_{43}H_{73}ClN_3OOsP_3$ (966.7): calcd. C 53.43, H 6.61, N 4.35; found C 53.15, H 7.44, N 4.18.

Preparation of [RuHCl(CO)$_2$(P*i*Pr_2R*)$_2$] (8): A slow stream of carbon monoxide was passed for 2 min through a solution of **6** (200 mg, 0.23 mmol) in benzene (10 mL) at room temperature. After the solution was stirred for 30 min at 25 °C, the solvent was evaporated in vacuo, the oily residue was suspended in 5 mL of methanol and the suspension stored at −78 °C. A white solid precipitated and was filtered, washed twice with 3 mL portions of methanol (0 °C) and dried; yield 121 mg (78 %); m.p. 133 °C (decomp). MS: *m*/*z* (I_r) = 639 (1; M^+ − CO), 611 (1; M^+ − 2 CO). IR (KBr): $\tilde{\nu}$ = 3365, 3290 ν(NH), 1970, 1905 ν(CO) cm^{-1}. ^1H NMR (90 MHz, C_6D_6): δ = 7.14 (m, 10 H, C_6H_5), 4.16 (m, 2 H, NCH), 2.10 (m, 4 H, PC*H*CH_3), 1.09 (br m, 30 H, NCHCH_3 and PCHCH_3), −5.47 (t, $^2J_{P,H}$ = 20.3 Hz, 1 H, RuH) ppm; signal for NH proton not exactly located. ^{31}P NMR (36.2 MHz, C_6D_6): δ = 94.6 (s; d in off resonance) ppm. $C_{30}H_{49}ClN_2O_2P_2Ru$ (668.2): calcd. C 53.93, H 7.39, N 4.19; found 53.80, H 7.40, N 3.94.

Preparation of [OsHCl(CO)$_2$(P*i*Pr_2R*)$_2$] (9): This compound was prepared as described for **8**, using **7** (250 mg, 0.26 mmol) and CO as starting materials. White solid; yield 196 mg (83 %), m.p. 132 °C (decomp). MS: *m*/*z* (I_r) = 757 (1; M^+), 729 (1; M^+ − CO). IR (KBr): $\tilde{\nu}$ = 3380, 3290 ν(NH), 2040 ν(OsH), 1970, 1915 ν(CO) cm^{-1}. ^1H NMR (90 MHz, C_6D_6): δ = 7.18 (m, 10 H, C_6H_5), 4.02 (m, 2 H, NCH), 2.16 (m, 4 H, PC*H*CH_3), 1.35 (br m, 30 H, NCHCH_3 and PCHCH_3), −4.68 (t, $^2J_{P,H}$ = 20.7 Hz, 1 H, RuH) ppm; signal for NH proton not exactly located. ^{31}P NMR (36.2 MHz, C_6D_6): δ = 62.5 (s; d in off resonance) ppm. $C_{30}H_{49}ClN_2O_2OsP_2$ (757.3): calcd. C 47.59, H 6.52, N 3.69; found C 48.06, H 6.88, N 3.66.

Preparation of [RuHCl(CO){P(OMe)$_3$}(P*i*Pr_2R*)$_2$] (10): A solution of **6** (220 mg, 0.25 mmol) in hexane (10 mL) was treated with trimethylphosphite (60 μL, 0.51 mmol) and stirred for 30 min at room temperature. The solvent was evaporated in vacuo and a white solid began to precipitate. After the solution was stored at −20 °C for 6 h, the white solid was filtered, washed three times with 3 mL portions of hexane (−20 °C) and dried; yield 130 mg (69 %); m.p. 108

Preparation of [OsHCl(CO){C$_2$(CO$_2$Me)$_2$}(P*i*Pr$_2$R*)$_2$] (12): This compound was prepared as described for **10**, with **7** (200 mg, 0.21 mmol) and $C_2(CO_2Me)_2$ (30 μL, 0.25 mmol) as starting materials. White solid; yield 145 mg (80 %); m.p. 76 °C (decomp). MS: *m*/*z* (I_r) = 872 (1; M^+), 730 [7; $M^+ - C_2(CO_2Me)_2$]. IR (KBr): $\tilde{\nu}$ = 3270 ν(NH), 2100 ν(OsH), 1930 ν(CO), 1790 ν(C≡C), 1695 ν(C=O) cm^{-1}. ^1H NMR (90 MHz, C_6D_6): δ = 7.29 (m, 10 H, C_6H_5), 5.02 (dd, $^2J_{P,H}$ = $^2J_{H,H}$ = 9.2 Hz, 1 H, NH), 4.72 (dd, $^2J_{P,H}$ = $^2J_{H,H}$ = 10.6 Hz, 1 H, NH), 4.25 (m, 2 H, NCH), 3.58 (s, 6 H, CO_2CH_3), 2.59 (m, 4 H, PC*H*CH_3), 1.56, 1.49 (both d, $^2J_{H,H}$ = 6.8 Hz, 3 H, each, NCHC*H*$_3$), 1.01 (m, 24 H, PCHC*H*$_3$), −3.49 (t, $^2J_{P,H}$ = 31.8 Hz, 1 H, OsH) ppm. ^{31}P NMR (36.2 MHz, C_6D_6): AB spin system; δ_{PA} = 65.7, δ_{PB} = 61.8 ppm, $^2J_{PA,PB}$ = 132.2 Hz; d in off resonance. $C_{35}H_{55}ClN_2O_5OsP_2$ (871.4): calcd. C 48.24, H 6.36, N 3.21; found C 48.63, H 6.51, N 3.08.

Preparation of [OsH$_4$(CO)(P*i*Pr$_2$R*)$_2$] (13): A solution of **7** (300 mg, 0.31 mmol) in benzene (10 mL) was first treated with $NaBH_4$ (150 mg, 3.95 mmol) and subsequently dropwise with methanol (1 mL). The solution was filtered and the filtrate concentrated to ca. 0.5 mL in vacuo. The residue was extracted twice with 8 mL portions of hexane and the combined extracts were dried in vacuo. The oily residue was suspended in 6 mL of methanol and the suspension stored for 12 h at −78 °C. A light yellow, extremely air-sensitive solid precipitated and was filtered, washed twice with 3 mL portions of methanol (−20 °C) and dried; yield 108 mg (51 %). IR (C_6H_6): $\tilde{\nu}$ = 3250 ν(NH), 2030, 1965 ν(OsH), 1890 ν(CO) cm^{-1}. ^1H NMR (90 MHz, C_6D_6): δ = 7.20 (m, 10 H, C_6H_5), 4.46 (m, 2 H, NCH), 1.50 (m, 4 H, PC*H*CH_3), 1.19 (d, $^2J_{H,H}$ = 6.8 Hz, 6 H, NCHC*H*$_3$), 0.82 (m, 24 H, PCHC*H*$_3$), −8.76 (t, $^2J_{P,H}$ = 9.8 Hz, 4 H, OsH_4) ppm; the signal for the NH protons not exactly located. ^{31}P NMR (36.2 MHz, C_6D_6): δ = 87.4 (s; quint in off resonance) ppm.

Preparation of [OsHCl(CO)(P*i*Pr$_3$)(dppe)] (14): A solution of **1b** (125 mg, 0.22 mmol) in hexane (15 mL) was treated with dppe (95 mg, 0.24 mmol) and stirred for 24 h under reflux. A white solid precipitated and once the reaction mixture was cooled to room temperature, it was filtered and then washed three times with 8 mL portions of hexane. Recrystallization from benzene/hexane (1:3) gave white air-stable crystals; yield 143 mg (80 %). IR (Nujol): $\tilde{\nu}$ = 2065ν(OsH), 1895 ν(CO) cm^{-1}. ^1H NMR (90 MHz, C_6D_6): δ = 7.47 (m, 10 H, C_6H_5), 3.01 (m, 4 H, PCH_2), 2.53 (m, 3 H, PC*H*CH_3), 1.21, 0.99 (both dvt, *N* = 12.0, $^3J_{H,H}$ = 7.1 Hz, 9 H each, PCHC*H*$_3$), −6.93 (ddd, 2 × $^2J_{P,Hcis}$ = 17.3, $^2J_{P,Htrans}$ = 93.2 Hz, 1 H, OsH) ppm. ^{31}P NMR (36.2 MHz, C_6D_6): ABX spin system; δ_{PA} = 39.6 ppm, δ_{PB} = 29.4 ppm, $^2J_{PA,PB}$ = 250.6 Hz; δ_{PX} = 13.8 ppm, $^2J_{PA,PX}$ = 6.7 Hz, $^2J_{PB,PX}$ = 13.8 Hz. $C_{36}H_{46}ClOOsP_3$ (813.3): calcd. C 53.16, H 5.70; found C 52.91, H 5.61.

Preparation of [RuHCl(CO)(P*i*Pr$_3$)(Chiraphos)] (15): This compound was prepared as described for **14**, with **1a** (150 mg, 0.31 mmol) and (*S*,*S*)-Chiraphos (135 mg, 0.32 mmol) as starting materials. White solid; yield 233 mg (79 %); m.p. 150 °C (decomp). IR (Nujol): $\tilde{\nu}$ = 1920 ν(CO) cm^{-1}. ^1H NMR (90 MHz, C_6D_6): δ = 7.71 (m, 20 H, C_6H_5), 3.91, 2.13 (both m, 1 H each, Ph_2PCH), 2.43 (m, 3 H, PC*H*CH_3), 1.18, 0.91 (both m, 9 H each, PCHC*H*$_3$; both d in off resonance, $^3J_{H,H}$ = 7.1 Hz), −6.61 (ddd, $^2J_{P,Hcis}$ = 17.9 and 22.2, $^2J_{P,Htrans}$ = 113.1 Hz, 1 H, RuH) ppm; signals for Ph_2CHCH_3 protons partly covered by signals of PCHC*H*$_3$ protons. ^{31}P NMR (36.2 MHz, C_6D_6): ABX spin system; AB part consists of four signals at δ = 54.5, 54.0, 53.8, 53.5 ppm and corresponds to the ^{31}P nuclei of Chiraphos; X part also consists of four signals at δ = 42.6, 42.3, 42.2, 41.9 ppm and corresponds to the ^{31}P nuclei of the P*i*Pr_3 ligand. $C_{38}H_{50}ClOP_3Ru$ (752.3): calcd. C 60.67, H 7.00; found C 60.45, H 6.70.

Preparation of [OsHCl(CO)(P*i*Pr$_3$)(Chiraphos)] (16): This compound was prepared as described for **14**, with **1b** (150 mg, 0.26 mmol) and (*S*,*S*)-Chiraphos (115 mg, 0.27 mmol) as starting materials. White solid; yield 180 mg (82 %); m.p. 197 °C (decomp). IR (Nujol): $\tilde{\nu}$ = 2030 ν(OsH), 1920 ν(CO) cm^{-1}. ^1H NMR (90 MHz, C_6D_6): δ = 7.78 (m, 20 H, C_6H_5), 3.67, 2.11 (both m, 1 H each, Ph_2PCH), 2.43 (m, 3 H, PC*H*CH_3), 1.14, 0.94 (both m, 9 H each, PCHC*H*$_3$, both d in off resonance, $^3J_{H,H}$ = 6.8 Hz), −6.69 (ddd, 2 × $^2J_{P,Hcis}$ = 19.1, $^2J_{P,Htrans}$ = 113.3 Hz, 1 H, OsH) ppm; signals for Ph_2CHCH_3 protons partly covered by signals of PCHC*H*$_3$ protons. ^{31}P NMR (36.2 MHz, C_6D_6): ABX spin system; AB part consists of three signals at δ = 24.4, 24.2, 24.1 ppm and corresponds to the ^{31}P nuclei of Chiraphos; X part consists of four signals at δ = 20.4, 20.3, 20.2, 20.0 ppm and corresponds to the ^{31}P nuclei of the P*i*Pr_3 ligand. $C_{38}H_{50}ClOOsP_3$ (841.4): calcd. C 54.25, H 5.99; found C 54.14, H 5.93.

Preparation of [RuHCl(CO)(P*i*Pr$_3$)(Diop)] (17): (a) A solution of **1a** (125 mg, 0.26 mmol) in hexane (15 mL) was treated with (*S*,*S*)-Diop (140 mg, 0.28 mmol) and stirred for 24 h under reflux. After the reaction mixture was cooled to room temperature, the white solid was filtered, washed three times with 8 mL portions of hexane, then with 5 mL of methanol and dried; yield 174 mg (81 %). Owing to the NMR spectra, two diastereoisomers **A** and **B** in the ratio of 7:1 were formed and could not be separated by fractional crystallization or column chromatography. (b) Analogously **1a** (180 mg, 0.37 mmol) was reacted with (*S*,*S*)-Diop (190 mg, 0.38 mmol) in hexane (15 mL) for 5 days under reflux. Under these conditions, only diastereoisomer **A** was obtained as a white solid; yield 250 mg (82 %); m.p. 143 °C (decomp). IR (Nujol): $\tilde{\nu}$ = 2000 ν(RuH), 1920 ν(CO) cm^{-1}. ^1H NMR (90 MHz, C_6D_6) diastereomer **A**: δ = −6.14 (ddd, $^2J_{P,Hcis}$ = 16.3 and 27.1, $^2J_{P,Htrans}$ = 109.1 Hz, 1 H, RuH) ppm; diastereomer **B**: δ = −6.71 (ddd,

$^2J_{P,Hcis}$ = 17.7 and 26.1, $^2J_{P,Htrans}$ = 116.1 Hz, 1 H, RuH) ppm; all other signals for δ = 0−9 ppm overlap and cannot be exactly assigned. ^{31}P NMR (36.2 MHz, C_6D_6) diastereomer **A**: ABX spin system; δ_{PA} = 50.2, δ_{PB} = 21.2 ppm, $^2J_{PA,PB}$ = 267.2 Hz; δ_{PX} = 7.1 ppm, $^2J_{PA,PX}$ = 18.0, $^2J_{PB,PX}$ = 11.2 Hz; diastereomer **B**: ABX spin system; δ_{PA} = 52.8, δ_{PB} = 23.1 ppm, $^2J_{PA,PB}$ = 267.4 Hz; δ_{PX} = −3.5, $^2J_{PA,PX}$ = 17.6, $^2J_{PB,PX}$ = 11.6 Hz. $C_{41}H_{54}ClO_3P_3Ru$ (824.3): calcd. C 59.74, H 6.60; found C 59.91, H 6.79.

Preparation of [OsHCl(CO)(P*i*Pr$_3$)(Diop)] (18): This compound was prepared as described for **17**, with (a) **1b** (130 mg, 0.23 mmol) and (*S*,*S*)-Diop (123 mg, 0.25 mmol) or (b) **1b** (215 mg, 0.37 mmol) and (*S*,*S*)-Diop (195 mg, 0.39 mmol) as starting materials. White solid; yield 187 mg (89 %) for (a) and 307 mg (91 %) for (b). Owing to the NMR spectra, following route "a" the ratio of the two diastereomers **A** and **B** was 3:2 and following route "b" the ratio was 1:1. IR (Nujol): $\tilde{\nu}$ = 2055 ν(OsH), 1905 and 1895 ν(CO) cm^{-1}. ^{1}H NMR (90 MHz, C_6D_6) diastereomer **A**: δ = −6.09 (ddd, $^2J_{P,Hcis}$ = 18.4 and 24.1, $^2J_{P,Htrans}$ = 88.3 Hz, 1 H, OsH) ppm; diastereomer **B**: δ = −6.74 (ddd, $^2J_{P,Hcis}$ = 19.9 and 28.2, $^2J_{P,Htrans}$ = 96.2 Hz, 1 H, OsH) ppm; all other signals for δ = 0−9 ppm strongly overlap and cannot be assigned to one of the diastereomers. ^{31}P NMR (36.2 MHz, C_6D_6) diastereomer **A**: ABX spin system; δ_{PA} = 17.8, δ_{PB} = −12.3 ppm, $^2J_{PA,PB}$ = 243.2 Hz; δ_{PX} = −18.9 ppm, $^2J_{PA,PX}$ = 15.2, $^2J_{PB,PX}$ = 3.8 Hz; diastereomer **B**: ABX spin system; δ_{PA} = 19.6, δ_{PB} = −9.0 ppm, $^2J_{PA,PB}$ = 242.1 Hz; δ_{PX} = −29.2 ppm, $^2J_{PA,PX}$ = 17.5, $^2J_{PB,PX}$ = 4.1 Hz. $C_{41}H_{54}ClO_3OsP_3$ (913.5): calcd. C 53.91, H 6.02; found C 53.99, H 6.18.

Preparation of [RuH$_2$(CO)(P*i*Pr$_3$)(Chiraphos)] (19): A solution of **2a** (145 mg, 0.31 mmol) in methanol (15 mL) was treated with (*S*,*S*)-Chiraphos (140 mg, 0.33 mmol) and stirred for 24 h under reflux. After the solution was cooled to room temperature, it was concentrated to ca. 5 mL in vacuo. A white solid precipitated and was filtered, washed three times with 5 mL portions of methanol and dried. Recrystallization from dichloromethane/methanol (1:3) gave white, moderately air-sensitive crystals; yield 170 mg (76 %). IR (Nujol): $\tilde{\nu}$ = 1940 ν(RuH), 1930 ν(CO) cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 7.68 (m, 20 H, C_6H_5), 2.20, 1.83 (both m, 1 H each, Ph_2PCH), 1.79 (m, 3 H, $PCHCH_3$), 1.28 (dd, $^3J_{P,H}$ = 13.5, $^3J_{H,H}$ = 7.0 Hz, 9 H, $PCHCH_3$), 0.98 (dd, $^3J_{P,H}$ = 11.6, $^3J_{H,H}$ = 7.0 Hz, 9 H, $PCHCH_3$), −8.15 (dddd, 2 × $^2J_{P,Hcis}$ = 20.2, 1 × $^2J_{P,Hcis}$ = 30.4, $^2J_{H,H}$ = 4.1 Hz, 1 H, RuH *trans* to CO), −8.76 (dddd, 2 × $^2J_{P,Hcis}$ = 18.9, $^2J_{P,Htrans}$ = 77.4, $^2J_{H,H}$ = 4.1 Hz, 1 H, RuH *trans* to PPh_2) ppm; signals for Ph_2PCHCH_3 protons partly covered by signals for P*i*Pr$_3$ protons. ^{31}P NMR (81.0 MHz, C_6D_6): ABX spin system; δ_{PA} = 84.3, δ_{PB} = 77.7 ppm, $^2J_{PA,PB}$ = 217.2 Hz; δ_{PX} = 68.1 ppm, $^2J_{PA,PX}$ = 13.4, $^2J_{PB,PX}$ = 17.4 Hz. $C_{38}H_{51}OP_3Ru$ (717.8): calcd. C 63.58, H 7.16; found C 63.62, H 7.48.

Preparation of [OsH$_2$(CO)(P*i*Pr$_3$)(Chiraphos)] (20): This compound was prepared as described for **19**, with **2b** (150 mg, 0.27 mmol) and (*S*,*S*)-Chiraphos (125 mg, 0.29 mmol) as starting materials. White solid; yield 181 mg (83 %). Owing to the NMR spectra, one diastereomer was mainly obtained. The amount of the second isomer (data not given) was less than 10 %. IR (Nujol): $\tilde{\nu}$ = 1950 br ν(OsH), 1860 ν(CO) cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 7.64 (m, 20 H, C_6H_5), 2.25, 1.95 (both m, 1 H each, Ph_2PCH), 2.43 (m, 3 H, $PCHCH_3$), 1.26 (dd, $^3J_{P,H}$ = 13.4, $^3J_{H,H}$ = 6.9 Hz, 9 H, $PCHCH_3$), 0.95 (dd, $^3J_{P,H}$ = 11.5, $^3J_{H,H}$ = 6.9 Hz, 9 H, $PCHCH_3$), −9.32 (dddd, 3 × $^2J_{P,Hcis}$ = 21.4, $^2J_{H,H}$ = 4.2 Hz, 1 H, OsH *trans* to CO), −10.04 (dddd, 2 × $^2J_{P,Hcis}$ = 21.4, $^2J_{P,Htrans}$ = 62.1, $^2J_{H,H}$ = 4.2 Hz, 1 H, OsH *trans* to PPh_2) ppm; signals for Ph_2PCHCH_3 protons partly covered by signals for P*i*Pr$_3$ protons. ^{31}P NMR (81.0 MHz, C_6D_6): ABX spin system; δ_{PA} = 48.5, δ_{PB} = 40.9 ppm, $^2J_{PA,PB}$ = 207.0 Hz; δ_{PX} = 35.9 (br) ppm, $^2J_{PB,PX}$ = 13.9 Hz. $C_{38}H_{51}OOsP_3$ (807.0): calcd. C 56.56, H 6.37; found C 57.19, H 6.84.

Preparation of [RuH$_2$(CO)(P*i*Pr$_3$)(Diop)] (21): This compound was prepared as described for **19**, with **2a** (130 mg, 0.28 mmol) and (*S*,*S*)-Diop (150 mg, 0.30 mmol) as starting materials. White solid; yield 170 mg (77 %). Owing to the ^{31}P NMR spectrum, two diastereomers **A** and **B** in the ratio of 3:2 were obtained. IR (Nujol): $\tilde{\nu}$ = 1945 br ν(RuH), 1860 ν(CO) cm^{-1}. ^{31}P NMR (81.0 MHz, C_6D_6) diastereomer **A**: ABX spin system; δ_{PA} = 73.9, δ_{PB} = 42.4 ppm, $^2J_{PA,PB}$ = 212.1 Hz; δ_{PX} = 27.5 (br) ppm, $^2J_{PA,PX}$ = 18.0, $^2J_{PB,PX}$ = −15.6 Hz; diastereomer **B**: ABX spin system; δ_{PA} = 72.0, δ_{PB} = 44.2 ppm, $^2J_{PA,PB}$ = 209.8 Hz; δ_{PX} = 22.7 (br) ppm, $^2J_{PA,PX}$ = −6.1, $^2J_{PB,PX}$ = 39.1 Hz. $C_{41}H_{55}OP_3Ru$ (789.9): calcd. C 62.35, H 7.02; found C 62.20, H 7.13.

Preparation of [{OsH$_2$(CO)(P*i*Pr$_3$)}$_2$(μ-Diop)] (22): This compound was prepared as described for **19**, with **2b** (155 mg, 0.28 mmol) and (*S*,*S*)-Diop (160 mg, 0.32 mmol) as starting materials. White solid; yield 183 mg (81 %). IR (Nujol): $\tilde{\nu}$ = 1930 br ν(OsH), 1835 ν(CO) cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = −9.34 (ddt, 2 × $^2J_{P,Hcis}$ = 24.3, $^3J_{H,H}$ = 5.0 Hz, 2 H, OsH *trans* to CO), −11.56 (ddt, 2 × $^2J_{P,Hcis}$ = 30.4, $^2J_{P,Htrans}$ = 61.8, $^2J_{H,H}$ = 5.0 Hz, 2 H, OsH *trans* to PPh_2) ppm; all other signals for δ = 0−9 ppm strongly overlap and cannot be assigned. ^{31}P NMR (36.2 MHz, C_6D_6): δ = 30.4 (d, $^2J_{P,P}$ = 11.2 Hz, P*i*Pr$_3$), −2.8 (t, $^2J_{P,P}$ = 11.2 Hz, Diop) ppm. $C_{69}H_{120}O_4Os_2P_6$ (1580.0): calcd. C 52.45, H 7.65; found C 51.91, H 7.13.

Preparation of *trans*-[OsHCl(Chiraphos)$_2$] (24): A solution of **23** (300 mg, 0.51 mmol) in dichloromethane (20 mL) was treated with (*S*,*S*)-Chiraphos (470 mg, 1.10 mmol) and stirred for 24 h under reflux. After the solution was cooled to room temperature, the solvent was evaporated in vacuo and the oily residue suspended in methanol (10 mL). The suspension was stored for 2 h and led to the precipitation of a pale yellow solid. This was separated from the mother liquor, washed twice with 5 mL portions of methanol and 5 mL portions of hexane and dried; yield 490 mg (89 %) IR (Nujol): $\tilde{\nu}$ = 2085 ν(OsH) cm^{-1}. ^{1}H NMR (200 MHz, C_6D_6): δ = 7.36 (m, 40 H, C_6H_5), 3.31, 1.85 (both m, 2 H each, Ph_2PCH), 0.88, 0.52 (both dvt, N = 12.0, $^3J_{H,H}$ = 6.1 Hz, 6 H each, Ph_2CHCH_3), −20.27 (m, 1 H, OsH) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 42.3, 16.8 (both t, $^2J_{P,P}$ = 21.0 Hz) ppm. $C_{56}H_{57}ClOsP_4$ (1079.6): calcd. C 62.30, H 5.32; found C 62.35, H 5.75.

Preparation of [OsH$_2$Cl$_2$(P*i*Pr$_3$)(Chiraphos)] (25): A suspension of **23** (160 mg, 0.27 mmol) in hexane (20 mL) was treated with (*S*,*S*)-Chiraphos (117 mg, 0.27 mmol) and stirred for 10 h under reflux. After the solution was cooled to room temparature, the yellow-brown solid was filtered, washed twice with 5 mL portions of hexane and recrystallized from benzene/hexane (1:3); yield 174 mg (76 %). ^{1}H NMR (200 MHz, C_6D_6): δ = 7.50 (m, 20 H, C_6H_5), 4.02, 2.47 (both m, 5 H, PCH), 1.08 (br m, 24 H, $PCHCH_3$ and Ph_2PCHCH_3), −10.28 (ddd, 3 × $^2J_{P,H}$ = 15.1 Hz, 2 H, OsH_2) ppm; T_1 = 170 ms (20 °C), 110 ms (−20 °C), 100 ms (−50 °C). ^{31}P NMR (36.2 MHz, C_6D_6): ABX spin system; δ_{PA} = 1.4, δ_{PB} = 12.3 ppm, $^2J_{PA,PB}$ = 288.7 Hz; δ_{PX} = 31.2 ppm, $^2J_{PA,PX}$ = 6.2, $^2J_{PB,PX}$ = 17.2 Hz. $C_{37}H_{51}Cl_2OsP_3$ (848.9): calcd. C 52.26, H 6.05; found C 52.26, H 5.97.

Preparation of [OsH(κ^2-H$_2$BH$_2$)(P*i*Pr$_3$)(Chiraphos)] (26): A solution of **25** (150 mg, 0.18 mmol) in toluene (10 mL) was first treated with $NaBH_4$ (65 mg, 1.70 mmol) and then dropwise with 1 mL of methanol. After the evaporation of gas (H_2) had stopped, the solution was stirred for 15 min at room temperature and then filtered.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The filtrate was concentrated to ca. 5 mL in vacuo and methanol (8 mL) was added. A white solid precipitated and was filtered, washed twice with 2 mL portions of methanol (0 °C) and dried; yield 97 mg (68 %). Owing to the NMR spectroscopic data, a mixture of the two diastereoisomers in about equal amounts was obtained. Attempts to separate the two diastereoisomers by fractional crystallization from benzene/methanol failed. IR (Nujol): $\tilde{\nu}$ = 2450, 2380 br ν(BH), 2070 ν(OsH) cm^{-1}. ^1H NMR (200 MHz, C_6D_6): δ = −7.81, −8.55 (both br, 1 H each, H^a of isomer **A** or **B**), −9.42, −10.10 (both br, 1 H each, H^b of isomer **A** or **B**), −16.71 (ddd, 2 × $^2J_{P,Hcis}$ = 16.0, 1 × $^2J_{P,Hcis}$ = 31.0 Hz, 1 H, H^c of isomer **A** or **B**), −17.40 (ddd, 3 × $^2J_{P,Hcis}$ = 23.0 Hz, 1 H, H^c of isomer **A** or **B**) ppm; signal of H^t not observed; all other signals for δ = 0−9 ppm overlap and cannot be assigned; for assignment of H^a, H^b, H^c, H^t see Scheme 6. $C_{37}H_{54}BOsP_3$ (792.8): calcd. C 56.06, H 6.87; found C 56.39, H 7.38.

Preparation of *trans*-[OsH_2(Chiraphos)$_2$] (27): This compound was prepared as described for **26**, with **24** (180 mg, 0.17 mmol), $NaBH_4$ (65 mg, 1.70 mmol) and methanol (1 mL) as starting materials. White solid; yield 109 mg (61 %). IR (Nujol): $\tilde{\nu}$ = 1730 br ν(OsH) cm^{-1}. ^1H NMR (200 MHz, C_6D_6): δ = 7.73 (m, 40 H, C_6H_5), 2.25 (br, 4 H, Ph_2PCH), 0.96 (br, 12 H, Ph_2PCHCH_3), −10.70 (quint, $^2J_{P,H}$ = 16.2 Hz, 2 H, OsH_2) ppm. ^{31}P NMR (81.0 MHz, C_6D_6): δ = 50.9 (s) ppm. $C_{56}H_{58}OsP_4$ (1045.2) calcd. C 64.35, H 5.56; found C 63.95, H 5.62.

Preparation of *trans*-[$OsCl(H_2)$(Chiraphos)$_2$]BF_4 (28): A suspension of **24** (90 mg, 0.08 mmol) in diethyl ether (10 mL) was treated with a solution of HBF_4 in diethyl ether (15 μL, 0.11 mmol) and stirred for 20 min at room temperature. The mother liquor was decanted, the precipitate was dissolved in dichloromethane (5 mL) and the solution was filtered. The filtrate was concentrated to ca. 1 mL in vacuo and diethyl ether (10 mL) was added. A white solid precipitated and was filtered, washed twice with 5 mL portions of diethyl ether (0 °C) and dried; yield 80 mg (83 %). ^1H NMR (200 MHz, $CDCl_3$): δ = 7.25 (m, 40 H, C_6H_5), 3.09, 1.81 (both m, 2 H each, Ph_2PCH), 0.89, 0.37 (both dvt, N = 12.0, $^3J_{H,H}$ = 6.1 Hz, 6 H each, Ph_2PCHCH_3), −11.62, (br, 2 H, OsH_2) ppm; T_1 = 110 ms (20 °C). ^{31}P NMR (81.0 MHz, $CDCl_3$): δ = 34.9, 2.0 (both t, $^2J_{P,P}$ = 17.3 Hz) ppm. $C_{56}H_{58}BClF_4OsP_4$ (1167.4): calcd. C 57.62, H 5.01; found C 57.24, H 5.16.

Preparation of *trans*-[$OsH(H_2)$(Chiraphos)$_2$]BF_4 (29): A solution of HBF_4 in diethyl ether (25 μL, 0.18 mmol)was added dropwise to a suspension of **27** (140 mg, 0.13 mmol) in diethyl ether (10 mL) under an H_2 atmosphere at −78 °C. After the solution was warmed to room temperature, it was stirred for 10 min and then filtered. The white solid was washed twice with 2 mL portions of diethyl ether (0 °C) and then recrystallized from dichloromethane/diethyl ether (1:5); yield 107 mg (71 %). IR (Nujol): $\tilde{\nu}$ = 2010 ν(OsH) cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$): δ = 7.63 (m, 40 H, C_6H_5), 2.24, 2.13 (both m, 2 H each, Ph_2PCH), 0.98 (br m, 12 H, Ph_2PCHCH_3), −6.45, (br, 2 H, OsH_2), −8.63 (m, 1 H, OsH) ppm; T_1 = 70 ms (20 °C), 60 ms (0 °C), 50 ms (−20 °C), 40 ms (−50 °C). ^{31}P NMR (81.0 MHz, $CDCl_3$): δ = 42.0, 36.0 (both t, $^2J_{P,P}$ = 19.0 Hz). $C_{56}H_{59}BF_4OsP_4$ (1133.0): calcd. C 59.37, H 5.25; found C 59.33, H 5.15.

Hydrogen-Transfer Reactions: The catalytic reactions were carried out under an argon atmosphere in a mixture of 2-propanol/toluene (2:1), with magnetic stirring, in a 50 mL round-bottomed flask fitted with a condenser and provided with a serum cap. In a typical procedure, a solution of the catalyst (0.1 mmol) in 12.5 mL of toluene and 12.5 mL of 2-propanol was stirred for 1 h at 85 °C, and then a solution of acetophenone (10 mmol) in 12.5 mL of 2-propanol was injected. The progress of the reaction was monitored by a Perkin−Elmer 8900 gas chromatograph with a flame ionization detector and an FFAP on Chromosorb GHP 80/100 mesh column (3.6 × 1/8 in.) at 160 °C. The solvents were evaporated in vacuo, and the remaining mixture (alcohol and ketone) was isolated by distillation at reduced pressure. The *ee* was calculated from its optical rotation in ethanol solution, using a value of $[\alpha]_D^{19}$ = +42.9 (undil.)[23] for the (*R*)-(+)-1-phenylethanol isomer, and corrected to the composition of the distillate. Optical rotations were measured with a Perkin−Elmer 241 polarimeter. For reactions carried out in the presence of KOH as cocatalyst, a 0.1 M solution of KOH (3 mL) in 2-propanol was added to the solution of the catalyst.

X-ray Structure Determination of Compound 22: Single crystals of **22** were grown by slow diffusion of hexane into a solution of **22** in 1,2-dichloroethane at room temperature. Crystal data (from 62 reflections, 2.4° < θ < 18.36°): monoclinic, space group $P2_1$ (No. 4); a = 11.2952(6), b = 29.521(3), c = 11.7201(6) Å, β = 106.771(5)°; V = 3741.8 $Å^3$, Z = 2; $D_{calcd.}$ = 1.402 g cm^{-3}; μ(Mo-K_α) = 3.563 mm^{-1}; crystal size 0.42 × 0.35 × 0.31 mm; Siemens-Stoe AED-2 diffractometer, Mo-K_α radiation (0.71073 Å), graphite monochromator; T = 293(2) K; ω/2θ-scan, max. 2θ = 44.96°; 10271 reflections measured, 9707 independent (R_{int} = 0.016), 9461 with $I > 2\sigma(I)$. Intensity data were corrected for Lorentz, polarization and absorption effects.[24] The structure was solved by direct methods (SHELXS-97).[25] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-square methods using SHELXL-97.[26] The hydride ligands H(1A), H(1B), H(2A) and H(2B) were found after proper refinement of the whole structure including a weighting scheme. They were included in the refinement as free isotropic atoms with a common thermal parameter. The positions of all other hydrogen atoms were calculated according to ideal geometry and refined by the riding method. Conventional R = 0.0208 [for 9461 reflections with $I > 2\sigma(I)$], and weighted wR_2 = 0.0508 for all 9707 located reflections; reflection/parameter ratio 12.6; absolute structure Flack parameter −0.017(4); residual electron density +0.487/−0.487 e·$Å^{-3}$.

A New Dichroic, Nitroso-Bridged Complex of Rhenium: Di-μ_2-chloro[μ_2-(η^2-*N*,*O*)-*N*,*N*-dimethyl-4-nitrosoaniline]bis[tricarbonylrhenium(I)]

Roland Wilberger,[a] Christoph Krinninger,[a] Holger Piotrowski,[a] Peter Mayer,[a] and Ingo-Peter Lorenz*[a]

Keywords: Rhenium / C,N ligand / N,O bridge / Dichroism

The dimeric μ_2-amino-phenoxy complexes of rhenium $[(CO)_3Re(\mu_2\text{-}O^{\frown}NH_2)]_2$ (**1**) do not react with the *C*-nitroso compounds R–C_6H_4NO [R = NMe_2 (**2**), H (**2′**)] in the presence of $AlCl_3$ by a condensation reaction to give the desired azo dye complexes $[(CO)_3Re(\mu_2\text{-}O^{\frown}N{=}NC_6H_4R)]_2$. Instead, they react to give the novel neutral η^2-*N*,*O*-bridged *C*-nitroso complexes $[\{(CO)_3ReCl\}_2ONC_6H_4R]$ (**3**, **3′**) by means of a substitution reaction. Both complexes yield golden gleaming crystals, and their solutions are deeply blue (**3**) or violet (**3′**) due to the broad UV/Vis absorption at λ = 617 (**3**) and 505 nm (**3′**). Single crystals of **3**, **3′** show nonlinear optical properties, they are dichroic and have a red and blue (**3**) or violet and green (**3′**) side. The molecular structures of **3**, **3′** have been determined by single-crystal X-ray analyses. Both compounds contain two face-joined octahedra, with two chloro and the NO ligands as bridges. The *C*-nitroso groups together with the NC_2 moiety of NMe_2 (**3**) lie almost exactly within the symmetry plane of the molecules. Both the N atoms of **3** have a trigonal-planar geometry. **3** and **3′** are the first single, neutral and dinuclear *C*-nitroso complexes with the rare non-assisted μ-(η^2-*N*,*O*) bridge and only single atoms as additional bridges.

Introduction

Recently we reported on the syntheses and structures of several dimeric μ_2-O amino-phenoxy complexes of rhenium of the type $[(CO)_3Re(\mu_2\text{-}O^{\frown}NH_2)]_2$ as well as on their condensation reactions with acetone to give the corresponding Schiff base products $[(CO)_3Re(\mu_2\text{-}O^{\frown}N{=}CMe_2)]_2$ in almost quantitative yields.[1] Because of the high reactivity and good selectivity of the complexes $[(CO)_3Re(\mu_2\text{-}O^{\frown}NH_2)_2]$ towards organic carbonyl compounds, the analogous condensation reaction with *C*-nitroso compounds should also be possible and should yield an N=N bond and hence the directed synthesis of azo dyes in the coordination sphere of a transition metal atom. The starting materials, however, did not react, and refluxing them for more than 2 h led to their decomposition. Attempts to catalyze the desired reaction by addition of some $AlCl_3$ for activating the nitroso compound immediately changed the situation. After a few minutes, the solution turned deep blue, and finally an almost black solid was separated, though in bad yield. Its characterization proved it to be the novel, neutral η^2-*N*,*O*-bridged nitroso complex $\{(CO)_3ReCl\}_2ONC_6H_4N(CH_3)_2$ (**3**).

There are three types of R_xNO-containing complexes (x = 0, 1). The first one (x = 0) is the large and well-known group of nitrosyl complexes.[2,3] They show the terminal linear (η^1-NO, 3e-donor), bent (η^1-NO, 1e-donor) or bridging μ_n-NO ligand function (n = 2–4). Even in the NO-containing triply bridged rhenium dimer, which is similar to **3**, the NO ligand is to be found in the terminal position.[4] Recently, metastable states of $[(CN)_5FeNO]^{2-}$ were detected with side-on-bound NO (η^2-NO) and η^1-ON ligands (isonitrosyl).[5]

The next family are RNO$^{\cdot}$ nitroxyl radicals, which normally coordinate through the oxygen atom.[6] Jaitner et al., however, reported on the η^2-*N*,*O* coordination of the special 2,2,6,6-tetramethylpiperidine-1-oxyl (= TEMPO).[7]

The coordination chemistry of organic RNO nitroso compounds has also been investigated,[8] their different ligand functions are summarized in Scheme 1. The terminal η^2-*N*,*O* ligand function (**I**) dominates,[9] the η^1-*N*,*O* linkage through the nitrogen atom (**II**) has also been well documented,[10,11] whereas that through the oxygen atom (**III**) has rarely been found.[12] The *C*-nitroso group may also bridge two metal centers in an η^1-*N* (**IV**),[11] an η^1- and η^2-fashion [μ-(η^1:η^2-*N*,*O*), **V**][13] or as an η^2-*N*,*O* moiety [μ-(η^1:η^1-*N*,*O*), **VI**]. The latter simply as a bridging ligand is less common;[11,14,15] most examples are known with supporting second coordination by a further donor system forming in addition a five- (**VII**)[16] or six-membered ring (**VIII**).[17] Only a few examples are known for bridging two metal atoms [μ_2-(η^2:η^2-*N*,*O*), **IX**][18] or four metal atoms

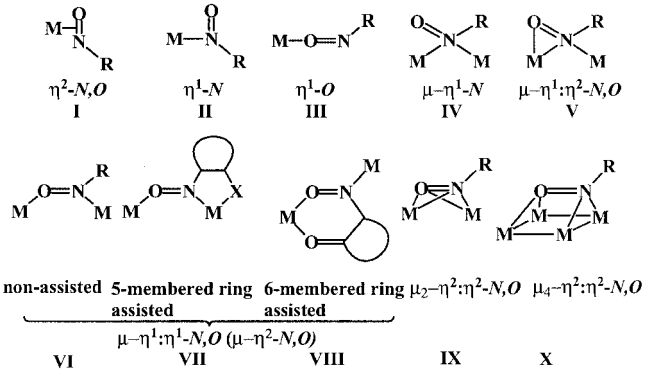
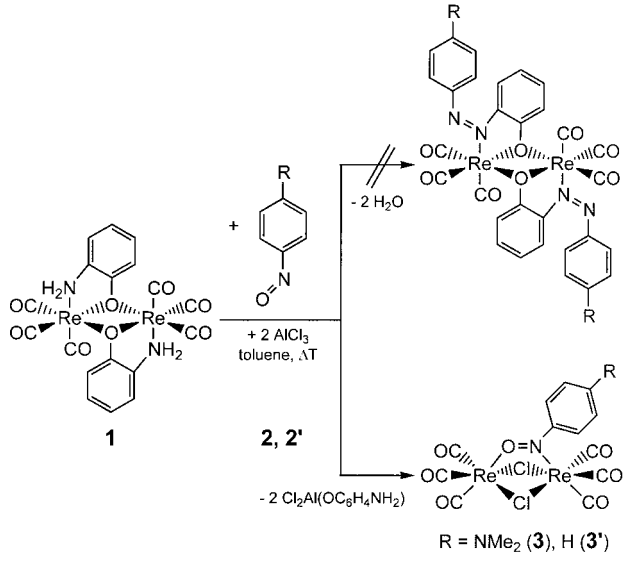


Scheme 1. Coordination modes of *C*-nitroso ligands

[μ_4-(η^2:η^2-*N*,*O*), **X**].[19] To the best of our knowledge type **VI** is only realized, besides a special case[11] in cationic dimers, with two further μ_2-thiolato bridges.[14]

Results and Discussion

The bad yield mentioned above and the chloro bridges of **3** led us to repeat the reaction not catalytically, but stoichiometrically. The reaction of **1**, **2** and $AlCl_3$ in the molar ratio 1:1:2 in boiling toluene for 5−10 min resulted in the formation of neutral di-μ_2-chloro[μ_2-(η^2-*N*,*O*)-*N*,*N*-dimethyl-4-nitrosoaniline]bis[tricarbonylrhenium(I)] (**3**; Scheme 2), and, indeed, the yield rose to about 70%. The same reaction was repeated with **1**, **2′** (nitrosobenzene) and $AlCl_3$, and the analogous nitroso complex **3′** was obtained. Many nitroso complexes have been synthesized by reduction of organic nitro compounds, which may proceed through an intermediate nitroso compound,[8] or by a nitrosyl migration reaction.[8]



Scheme 2. Synthesis of **3**, **3′**

Compounds **3** and **3′** are obtained as golden gleaming crystals, which are stable towards air. They are soluble in THF, toluene, ketones and CH_2Cl_2 and even in pentane (**3′**). Compound **3** is not soluble in pentane. Solutions of **3** and **3′** in $CHCl_3$, CH_2Cl_2, THF or toluene are deep blue or violet, respectively. In the UV/Vis spectrum ($CHCl_3$) one very broad absorption at λ = 617 (**3**) and 505 nm (**3′**) due to a ligand-to-metal CT band [NO−Re(I)] is observed, which is shifted to lower frequency than the corresponding electronic transition ($\pi-\pi^*$ NO) of the ligands **2** (λ = 419 nm) and **2′** (λ = 306 nm). Single crystals of **3** and **3′** show non-linear optical properties; they are dichroic and viewed by transmitted light; they have a red and a blue (**3**) or violet and green side (**3′**), respectively. The absorption maxima of **3** are found at λ = 495 and 575 nm, those of **3′** have not yet been measured because of technical problems.

The IR spectra of **3**, **3′** in CH_2Cl_2 show four ν(CO) absorptions. As the NO group coordinates to one rhenium center with the nitrogen atom and to the other with the oxygen atom, the electronic situation at both rhenium centers is different. Therefore, there are two different $Re(CO)_3$ fragments, each with C_{3v} local symmetry, and we observe two separated patterns of ν(CO) (A_1 + E). Resulting from electronic reasons, the two absorptions at higher wavenumbers are assigned to the {$(CO)_3Re-N$} fragment [$\tilde{\nu}$ = 2041 (A_1), 1946 (E) cm^{-1}], whereas the two at $\tilde{\nu}$ = 2024 (A_1) and 1917 (E) cm^{-1} belong to the {$(CO)_3Re-O$} fragment as in **3**. The ν(NO) of **3** absorbs significantly lower at $\tilde{\nu}$ = 1605 cm^{-1}.

The ^1H NMR spectrum of **3** (in [D_8]THF) shows two singlets at δ = 3.54 and 3.55 ppm for the *N*-methyl protons, and the four double-doublets for the different pairs of *o*- and *m*-phenyl protons (see Exp. Sect.), that of **3′** (in CD_2Cl_2) exhibits only the multiplet at δ = 7.34−7.65 ppm for the phenyl protons. In the $^{13}C\{^1H\}$ NMR spectrum of **3** (in [D_8]THF) each carbon atom of the NMe_2 group and of the phenyl ring is found by separated signals between δ = 30 and 160 ppm; the signals of the CO ligands appear at δ = 190−200 ppm. The signals of the carbon atoms of **3′** are observed at δ = 129.1−131.3 ppm (phenyl) and δ = 188 ppm (CO) (in $CDCl_2$).

In the mass spectra of **3**, the parent peak as well as all signals of fragments resulting from the loss of up to six carbonyl groups are observed.

The composition and structure of complex **3** was confirmed by X-ray structure analysis; single crystals were obtained by diffusion of pentane into a solution of **3** in $CHCl_3$. The molecular structure and selected bond lengths and angles are given in Figure 1,[20] which shows two face-joined octahedra with two chloro and the NO ligands as bridges. The distance N(1)−O(1) is 1.319(8) Å and clearly longer than the N−O distance in the free *N*,*N*-dimethyl-4-nitrosoaniline (1.212 Å[21]). The bond Re(1)−O(1) [2.131(6)] is shorter than the Re(2)−N(1) [2.208(7)], whereas all Re−Cl bonds in the bridge are exactly the same [Re(1)−Cl*n* = 2.49 Å, Re(2)−Cl*n* = 2.49 Å). The dihedral angles Re(1)−O(1)−N(1)−Re(2) and O(1)−N(1)−C(1)−C(6) are 6.54° or 12.00°, respectively; that is, the NO group

lies almost within the symmetry plane of the molecule, whereas the phenyl ring is larger and turned out of this plane. It is noteworthy that both the nitrogen atoms are exactly trigonal planar in geometry [sum of angles for N(1) = 359°, for N(4) = 360°], consistent with their sp^2 nature. The analogous molecular structure was also found for **3′**, and is given in Figure 2.[20] In both compounds there

Molecular structure of **3′**; selected bond lengths [Å] and angles [°]: Re(1)−C(1) 1.906 (5), Re(1)−C(2) 1.976 (6), Re(1)−Cl(1) 2.4829 (12), Re(1)−N(1) 2.092 (5), Re(2)−C(3) 1.930 (8), Re(2)−C(4) 1.904 (6), Re(2)−Cl(1) 2.4829 (12), Re(2)−O(5) 2.106 (4), O(5)−N(1) 1.282 (7), N(1)−C(5) 1.440 (8), C(1)−O(1) 1.145 (6), C(2)−O(2) 1.124 (8), C(3)−O(3) 1.151 (9), C(4)−O(4) 1.144 (7); C(1)−Re(1)−Cl(1) 94.92 (14), O(5)−N(1)−C(5) 110.5 (5), Re(1)−Cl(1)−Re(2) 88.41 (4).

is no Re−Re interaction [Re(1)−Re(2) 3.540 Å (**3**), 3.463 Å (**3′**)].

Compounds **3** and **3′** are the first simple, neutral and dinuclear *C*-nitroso complexes which have the very rare non-assisted μ-(η^2-*N*,*O*) bridge (**VI**) and only single atoms as additional bridges, and which have been synthesized directly by means of nitroso compounds as starting materials. Their observed dichroism may be derived from the special ligand function of the nitroso compound and of its placement exactly in the plane of symmetry of **3** and **3′**. In a recent paper[22] a very similar structure of dialkylnitrosoamine complexes (*N*-nitroso ligand) of Cu^{II} with the same μ-(η^2-*N*,*O*) coordination and with the NO group roughly parallel to the Cu−Cu direction. Their single crystals, however, do not exhibit the dichroic effect.

First attempts using AlX_3 (X = Br, I) instead of $AlCl_3$ resulted in the formation of the corresponding bromo- and iodo-bridged dinuclear complexes. The μ_2-*O*-bridged precursor **1** apparently serves as a source for $Re(CO)_3$ fragments. Therefore, it might be assumed that $[Re(CO)_5Cl]$ can be used instead of **1**. First attempts with $[Re(CO)_5Cl]$ and **2** show that **3** is indeed formed.

Experimental Section

General: To remove oxygen, all operations were carried out under Ar in dry and Ar-saturated solvents.[23] $[(CO)_3Re(\mu_2\text{-}O\cap NH_2)]_2$ (**1**) was prepared according to a literature procedure.[1] *N*,*N*-Dimethyl-4-nitrosoaniline (**2**), nitrosobenzene (**2′**) and $AlCl_3$ were used as purchased. NMR spectra were recorded with a Jeol EX 400 spectrometer (^{1}H: 399.78 MHz; ^{13}C: 100.54 MHz) in [D$_8$]THF or CD_2Cl_2. Mass spectra were obtained with a Jeol MStation JMS 700. IR and UV/Vis spectra were measured with a Perkin−Elmer Spectrum One FT-IR or Perkin−Elmer UV Lambda 16 spectrometer, respectively. Elemental analyses were performed with a Heraeus Elementar Vario EL.

3: 1 (388.2 mg, 0.513 mmol), **2** (118.2 mg, 0.787 mmol) and $AlCl_3$ (173.2 mg, 1.035 mmol) were dissolved in toluene (100 mL) and refluxed for 10 min, whereby the solution turned deep blue. The solvent was evaporated, the shiny blue, almost black, residue was dissolved in CH_2Cl_2 and the compound purified by column chromatography. Yield: 258 mg (0.338 mmol, 66%), blue-red dichroic crystals; m.p. 189−191 °C (dec.). ^{1}H NMR (399.78 MHz, [D$_8$]THF): δ = 3.54 [s, 3 H, N(CH_3)$_2$], 3.55 [s, 3 H, N(CH_3)$_2$], 7.24 (dd, ^3J = 10.16, ^4J = 2.64 Hz, 1 H, *o*-Ar-*H*), 7.41 (dd, ^3J = 10.27, ^4J = 2.75 Hz, 1 H, *o*-Ar-*H*), 8.02 (dd, ^3J = 10.22, ^4J = 2.64 Hz, 1 H, *m*-Ar-*H*), 8.51 (dd, ^3J = 10.22, ^4J = 2.64 Hz, 1 H, *m*-Ar-*H*) ppm. ^{13}C{^{1}H} NMR (100.53 MHz, [D$_8$]THF): δ = 30.6 (*C*H$_3$NCH$_3$), 43.1 (CH$_3$N*C*H$_3$), 118.0 (*o*-Ar-*C*), 119.2 (*o*-Ar-*C*), 128.2 (*m*-Ar-*C*), 139.4 (*m*-Ar-*C*), 160.9 (Me$_2$NAr-C_q), 161.6 (ONAr-C_q), 191.8 (*C*O), 192.0 (*C*O), 195.3 (*C*O), 198.4 (*C*O) ppm. IR (KBr): $\tilde{\nu}$ = 3099.1 w [ν(Ar−H)], 2938.0 w [ν(CH$_2$)], 2857.4 w [ν(CH$_2$)], 2732.9 w, 2039.8 vs [ν(CO), A$_1$], 2021.4 vs [ν(CO), A$_1$], 1904.3 vs [ν(CO), E], 1604.4 s [ν(NO)], 1393.5 s [δ(CH$_3$)], 1331.1 s, 1170.7 vs, 1129.8 m, 930.9 w, 879.3 w, 833.7 m [γ(Ar)], 741.3 s, 644.3 w, 565.7 w, 518.2 w, 493.5 w, 465.8 w, 398.5 w cm^{-1}. Vanadyl Phosphate Intercalated with Diethyl Ether

Klára Melánová,[a] Ludvík Beneš,*[a] Vítězslav Zima,[a] Miroslava Trchová,[b] and Jiří Dybal[b]

Keywords: Intercalation / Vibrational spectroscopy / X-ray diffraction / Ab initio calculations / Semiempirical calculations

Vanadyl phosphate intercalated with diethyl ether has been prepared by replacing 2-propanol molecules in the corresponding $VOPO_4$ intercalate with diethyl ether. The intercalate contains one diethyl ether molecule per formula unit. The guest molecules are anchored to the host layers by an O–V donor–acceptor bond. The local structure and interactions in the intercalate have been suggested on the basis of quantum chemical calculations. The intercalate is thermally stable. Its diffractogram does not change up to 100 °C. A new phase with lower basal spacing appears at 130 °C. The intercalate is very moisture-sensitive; the diethyl ether molecules are easily replaced by water molecules. The replacement of diethyl ether in the vanadyl phosphate intercalate by the water molecules has been monitored by infrared spectroscopy.

Introduction

The ability of vanadyl phosphate dihydrate $VOPO_4{\cdot}2H_2O$ and other isostructural layered compounds to accommodate organic molecules having the character of Lewis bases in the interlayer space has been reviewed.[1] Compounds with functional groups containing oxygen atoms, i.e. alcohols, ketones, carboxylic acids and ethers, form a large group of such compounds. Intercalations of etheric oxygen-containing glycols[2] and cyclic ethers[3,4] have been described recently.

With glycols, diethylene glycol (DEG), triethylene glycol, and poly(ethylene glycol)s (PEG 200, 400, and 1000) have been intercalated into vanadyl phosphate. Depending on the reaction temperature, two phases are formed: a low-temperature phase, with guest chains arranged parallel to the host layer in a bimolecular way, and a high-temperature phase, where the chains are arranged monomolecularly. All these intercalates are stable in a dry environment but decompose slowly in humid air.[2] The structure of the DEG intercalated vanadyl phosphate, $VOPO_4{\cdot}HO(CH_2)_2O(CH_2)_2OH$, has been determined using a combination of synchrotron powder diffraction and molecular modeling.[5] The crystal system was determined to be tetragonal, space group *P*4/*n*, with the DEG molecules anchored to the vanadium atoms of the host layers through their etheric oxygen atoms.

The cyclic ethers tetrahydrofuran, tetrahydropyran,[3] dioxane, trioxane, and 18-crown-6[4] have been intercalated into vanadyl phosphate. All these guest molecules are anchored to the host layers by a donor−acceptor bond between an oxygen atom of the guest and a vanadium atom. These intercalates are stable at ambient conditions, and some are surprisingly thermally stable (the tetrahydrofuran intercalate is stable up to 160 °C). The structure of tetrahydrofuran intercalate has been determined using a combination of synchrotron powder diffraction and molecular modeling.[5] We report here on a diethyl ether intercalated vanadyl phosphate.

Results and Discussion

Diethyl ether cannot be intercalated directly in anhydrous vanadyl phosphate, and the replacement of water in $VOPO_4{\cdot}2H_2O$ does not lead to an intercalation. Consequently, the intercalate was prepared by replacing 2-propanol in the corresponding $VOPO_4$ intercalate with diethyl ether, to give a yellow crystalline solid, indicating that the vanadium(v) atom had not been significantly reduced. We did not succeed in intercalating dipropyl ether, dibutyl ether, or diisopropyl ether.

The diffractogram of the diethyl ether intercalate indicates that the tetragonal structure of the $VOPO_4$ host layer is retained. Three sharp (00*l*) and one weak (200) reflections appear in the pattern (Figure 1, a). The tetragonal lattice parameters a = 6.208 Å, c = 11.664 Å were determined from these lines. The absence of (*hkl*) lines is characteristic of a turbostratic structure in which the original tetragonal

Heyrovský Sq. 2, 16206 Prague 6, Czech Republic

layers of the host are retained but shifted in the directions of the *x* and/or *y* axes. The intercalate is very moisture-sensitive − the diethyl ether molecules are easily replaced by water. At a relative humidity (r.h.) of 25% the intercalate is stable, and only a small broad (001) reflection of vanadyl phosphate dihydrate is observed in the diffractogram after 1 h of exposure (Figure 1, b). At ambient conditions (r.h. = 55%), however, the intercalate rapidly decomposes, and only a small (001) reflection of the intercalate is present, together with a strong (001) line of the dihydrate, in the diffractogram measured immediately after exposure to ambient air (Figure 1, c). After 16 min, the sample is completely converted into vanadyl phosphate dihydrate (Figure 1, d).

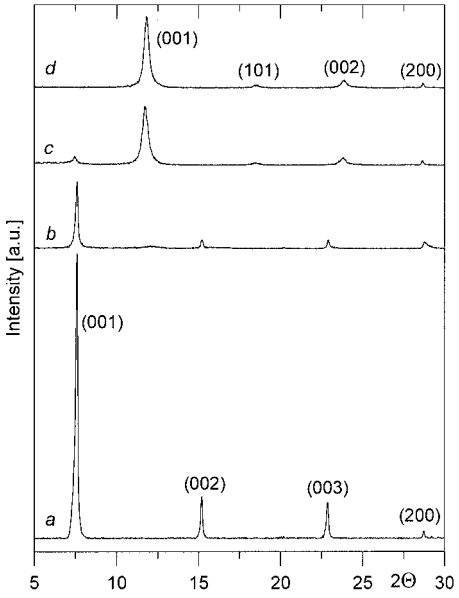

Figure 1. Diffractograms of samples of vanadyl phosphate intercalated with diethyl ether: (a) with excess diethyl ether; (b) after 1 h at r.h. =25%; (c) immediately after exposure to r.h. = 55%; (d) after 16 min exposure to r.h. = 55%

The thermal behavior of the intercalate was monitored by TG-DTA and X-ray diffraction. TG-DTA curves are given in Figure 2. The total weight loss (31%) corresponds to the formula $VOPO_4 \cdot C_2H_5OC_2H_5$ (theoretical weight loss 31.4%). As with intercalates of cyclic ethers, the diethyl ether intercalate is thermally stable. About half of diethyl ether is liberated in the first endothermic step up to 115 °C. The rest is released in two steps: the first up to 212 °C (the exothermic peak of the DTA curve is caused by the burning of diethyl ether) and the second, very slow, up to 550 °C. A small increase in weight between 550 and 750 °C is probably caused by oxidation of vanadium(IV). The basal spacing of the diethyl ether intercalate has been monitored as a function of temperature (Figure 3); it increases slightly up to 120 °C. The intensity of the (001) diffraction line does not change up to 100 °C and then decreases. A new phase with a basal spacing of about 8.2 Å appears at 130 °C and is present up to 170 °C. Above this temperature, the sample becomes green and amorphous. The new phase is probably caused by the loss of half of the guest molecules and by a change in arrangement of the guest molecules from bimolecular to monomolecular. Diethylene glycol intercalated $VOPO_4$ shows similar behavior during heating.[2]

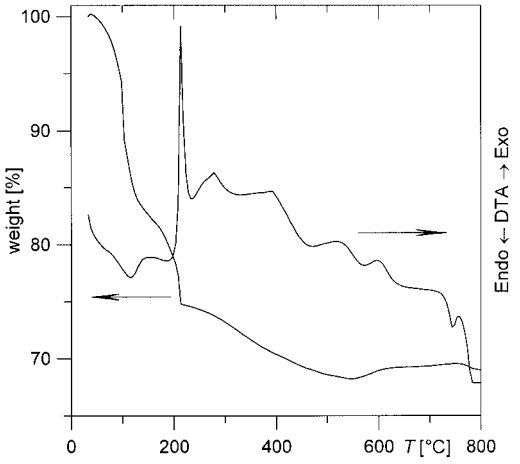

Figure 2. TG-DTA curves of vanadyl phosphate intercalated with diethyl ether

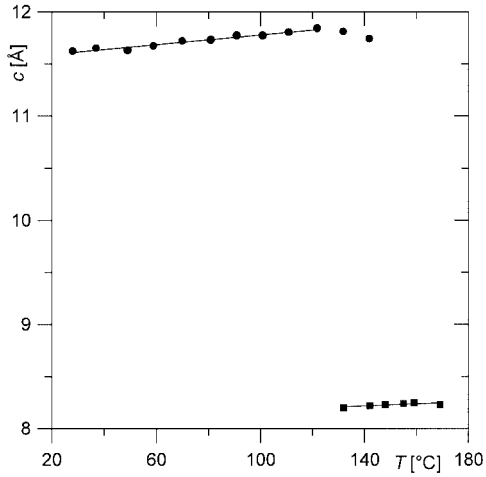

Figure 3. Basal spacing as a function of temperature during thermal decomposition of vanadyl phosphate intercalated with diethyl ether; circles represent basal spacings of the low-temperature phase, squares correspond to the high-temperature phase; errors of the basal spacings are within the dimensions of the data symbols

For infrared measurements, a sample of vanadyl phosphate intercalated with diethyl ether was placed in a purged sample compartment of the spectrometer (r.h. = 5%) for 5 min and for 7 and 22 h without removing the sample from the crystal between subsequent spectral measurements. Another sample was exposed to ambient conditions (r.h. = 60%) for 22 h and for 6, 10, 14 and 17 d. Such conditions allow a progressive replacement of the diethyl ether molecules in the vanadyl phosphate intercalate by atmospheric water. The infrared spectra of the intercalate at various stages of the deintercalation process under ambient conditions were compared with that of vanadyl phosphate dihydrate and with the spectrum of pure diethyl ether [Fig-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ure 4 (2000 to 600 cm^{-1}) and Figure 5 (4000 to 2500 cm^{-1})].

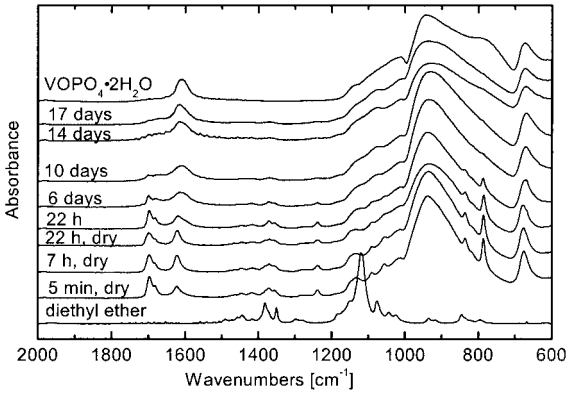

Figure 4. FTIR spectra (2000 to 600 cm^{-1}) of vanadyl phosphate dihydrate, of pure diethyl ether and of vanadyl phosphate intercalated with diethyl ether after 5 min, 7 h and 22 h in a purged spectrometer (r.h. = 5%), and after 22 h and 6, 10, 14 and 17 d under ambient conditions (r.h. = 60%)

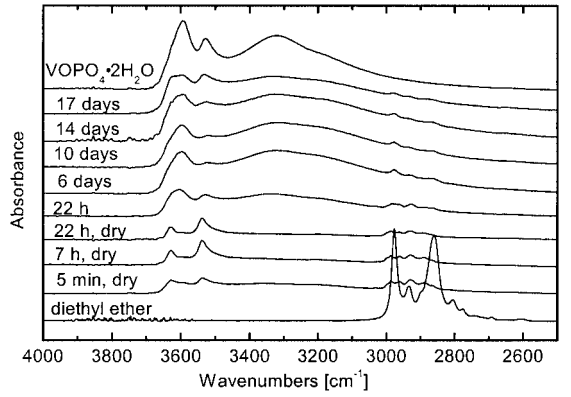

Figure 5. FTIR spectra (4000 to 2500 cm^{-1}) of vanadyl phosphate dihydrate, of pure diethyl ether and of vanadyl phosphate intercalated with diethyl ether after 5 min, 7 h and 22 h in a purged spectrometer (r.h. = 5%), and after 22 h and 6, 10, 14 and 17 d under ambient conditions (r.h. 60%)

The Raman spectra (3500−600 cm^{-1}) of vanadyl phosphate dihydrate, vanadyl phosphate intercalated with diethyl ether and pure diethyl ether are shown in Figure 6. Unfortunately, it was not possible to measure the kinetics of the replacement process of diethyl ether by Raman spectroscopy because of a partial escape of the diethyl ether molecules due to the laser beam during measurements.

Vibrational bands of the PO_4 tetrahedron, the vanadyl group V=O, and the P−O−V group can be identified in all spectra. The intense band at 945 cm^{-1} in the spectrum of vanadyl phosphate dihydrate (Figure 6) corresponds to the symmetric $\nu(PO_4)$ stretching vibration of the phosphate tetrahedron in $(VOPO_4)_\infty$. This band is shifted to 940 cm^{-1} in vanadyl phosphate intercalated with diethyl ether. The sharp band at 995 cm^{-1} in the vanadyl phosphate dihydrate spectrum is due to a vanadyl V=O stretching vibration. Its

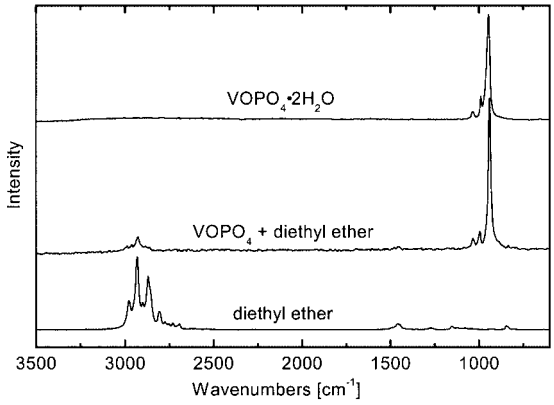

Figure 6. Raman spectra (3500−600 cm^{-1}) of vanadyl phosphate dihydrate, of vanadyl phosphate dihydrate intercalated with diethyl ether and of pure diethyl ether

position corresponds to the coordination of the oxygen atom of the water molecules in the VO_6 octahedron. The vanadyl stretching band appears to be especially sensitive to atoms coordinated to the vanadium atom within an octahedral arrangement in the host lattice structure. During the intercalation of water molecules into $VOPO_4$ its position at 1035 cm^{-1} in the anhydrous form changes to that typical for mono- and dihydrate (995 cm^{-1}).[6] In the Raman spectrum of the intercalate with diethyl ether the band at 994 cm^{-1} corresponds most probably to the coordination of the oxygen atom of diethyl ether to the vanadium atom, and the band at 1033 cm^{-1} to the anhydrous form of the host compounds. With the help of the Raman spectrum, we can assign the band with the maximum at 945 cm^{-1} in the IR spectrum (Figure 4) of vanadyl phosphate dihydrate to the symmetric $\nu(PO_4)$ stretching vibration, which is infrared-active due to distortion of the phosphate tetrahedron in the intercalate. The shoulder at 1011 cm^{-1} in the IR spectrum is most probably the V=O stretching band of the vanadyl group, while the band at 1135 cm^{-1} in the IR spectrum of the host is the asymmetric $\nu(PO_4)$ stretching vibration of the phosphate tetrahedron. The positions of the main spectral bands of the host structure differ only slightly from those of anhydrous vanadyl phosphate or its hydrated form.[6] This confirms that the structure of the original $VOPO_4$ layers remains unchanged after the intercalation reaction.

Conversely, bands due to pure diethyl ether are shifted in the spectrum of the intercalate; some bands disappear and some new bands appear (Figures 4 and 5). The C−H stretching vibration at 2978 cm^{-1} splits into 2985 and 2964 cm^{-1}, the bands at 2934, 2891 and 2862 cm^{-1} retain their positions but change in relative intensity. The C−H deformation vibration bands at 1490, 1448, 1383, 1351 and 1295 cm^{-1} shift to lower wavenumbers and a new band appears at 1238 cm^{-1} in the spectrum of the intercalate. The asymmetric COC stretching mode at 1120 cm^{-1} in the spectrum of pure diethyl ether is at about 1134 cm^{-1} in the spectrum of the intercalate. The bands at 1076 and 1025 cm^{-1} are overlapped by the symmetric $\nu(PO_4)$ stretching vibrational

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

band and are observed as shoulders at 1089 and 1057 cm^{-1}. The symmetric COC mode at 935 cm^{-1} is completely overlapped and the bands at 846 and 796 cm^{-1} are shifted to 838 and 787 cm^{-1}. The diethyl ether bands reduce in intensity during exposure to the external conditions.

Most surprising are two sharp bands with maximum at about 3627 and 3530 cm^{-1} and a broad band with two maxima at 3354 and 3182 cm^{-1} seen during the first 5 min after removing the sample from the ampoule and placing it in the purged sample compartment of the spectrometer (r.h. = 5%). At the same time we observed a band at 1699 cm^{-1} with a shoulder at 1682 cm^{-1} and a band at 1624 cm^{-1}. When the sample is not removed from the purged sample spectrometer compartment, these bands remain unchanged and the broad band with two maxima at 3354 and 3182 cm^{-1} disappears in the spectrum measured after 22 h. In the spectra of the sample measured at ambient conditions (r.h. = 60%) the two sharp bands are shifted to 3594 and 3530 cm^{-1}, and the band at 1624 cm^{-1} is shifted to 1612 cm^{-1}. These new positions correspond to the spectrum of vanadyl phosphate dihydrate. The shoulder at 3627 cm^{-1} and the band at 1699 cm^{-1} disappear when the sample is kept under ambient conditions. The last spectrum of the intercalate, measured after 17 d, is very similar to that of $VOPO_4 \cdot 2H_2O$.[6]

We suppose that the new bands in the spectrum of the very fresh sample taken in the purged sample compartment of the spectrometer (r.h. = 5%) correspond to adsorbed water on the surface of the sample. As attenuated total reflection (ATR) is a very surface-sensitive method, we observed relatively strong bands of water in the spectra. In the spectra of samples taken under ambient conditions (r.h. = 60%), the positions of the bands of water correspond to bulk water molecules, and the spectra correspond to those of vanadyl phosphate dihydrate.

The character of the bonding between the guest molecules and the host layer in the diethyl ether intercalate was investigated by quantum mechanical calculations and modeling. Figure 7 shows the DFT-optimized structure of the molecular segment representing local interactions of vanadyl phosphate with diethyl ether, using the B3LYP functional and 6-31G(d) basis set. Calculations with the LanL2DZ basis set give an analogous geometry with slight differences in bond lengths (Figure 7). To keep the overall planar structure of the segment during full geometry optimizations, and to make the electronic structure in the segment close to the conditions appearing in the intercalates, an oxygen atom was inserted between two neighboring PO_4 groups and terminal oxygen atoms were substituted by OH groups.[7] The total charge of the model compound was set to +3. All geometry optimizations with various starting orientations of diethyl ether with respect to the vanadyl group lead to the structure displayed in Figure 7, indicating the formation of the C−O(−C)→V bond in the intercalates. The diethyl ether molecule exhibits central symmetry with respect to the oxygen atom and a gauche conformation around both C−O bonds (calculated dihedral angle C−C−O−C 71.4°).

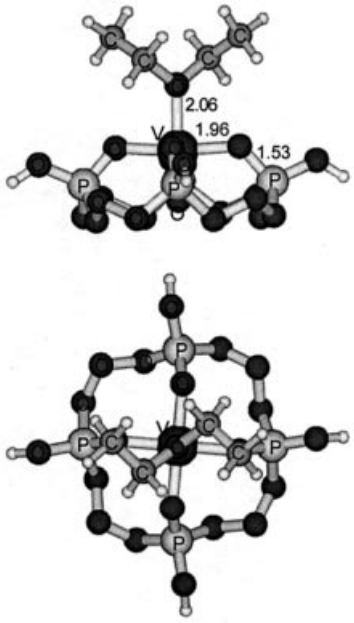

Figure 7. Optimized B3LYP/6-31G(d) structure of the molecular segment modeling the vanadyl phosphate−diethyl ether interaction, with indicated bond lengths [Å]

Simulations of larger local intercalate structures including two $VOPO_4$ layers were performed using the semiempirical quantum-chemical methods PM3 and AM1. The adequacy of the semiempirical methods for vanadyl phosphate intercalates has been illustrated in a previous study of intercalates with benzonitrile and tolunitrile, in which the results of modeling are in a very good agreement with experimental data obtained by X-ray, IR and Raman spectroscopy.[8] When the model structure shown in Figure 7 was reoptimized with the PM3 and AM1 methods, only slight changes in parameters were found in comparison with the DFT method. Optimized geometries of the molecular segment representing two layers of $VOPO_4$ and five molecules of diethyl ether intercalated between the two layers are shown in Figure 8. Terminal oxygen atoms were replaced by OH groups and the total charge of the model compounds set to −2. Coordinations of the vanadium atoms to the diethyl ether molecules in adjacent host interlayer spaces were simulated by coordinations with dimethyl ether molecules (not shown in Figure 8). The initial bond lengths and angles for the $VOPO_4$ layers were taken from the previous study of vanadyl phosphate intercalates with benzonitrile,[8] the initial basal spacing was set to the above given value of the lattice parameter c = 11.664 Å, determined by the X-ray diffraction, and the structure and bonding of diethyl ether were taken from the DFT calculations (Figure 7). In a series of geometry optimizations with various symmetry constraints and the parameter c fixed, the initial molecular and lattice parameters were refined to values suitable for the final overall energy minimization. All the variables defining the positions of the atoms both in the host and guest layers were fully optimized with the excep-

tion of the constraints exposed by the symmetry conditions defining polyhedra in the $VOPO_4$ layers and relative orientations of the guest molecules in the interlayer with respect to the $VOPO_4$ layer. The basal spacings calculated with the PM3 and AM1 methods are 11.28 and 11.07 Å, respectively. In agreement with X-ray results, the mutual positions of the successive layers exhibit a shift characterized by a vector with calculated components of 0.02 and 0.53 Å by the PM3 method and of 0.99 and 1.29 Å with the AM1 method.

Experimental Section

Preparation: The 2-propanol intercalate was prepared by suspending microcrystalline $VOPO_4{\cdot}2H_2O$ in dry 2-propanol with subsequent short exposure to a microwave field. The intercalation compound was obtained by replacing 2-propanol in $VOPO_4{\cdot}2C_3H_7OH$ with diethyl ether. The 2-propanol intercalate (0.5 g) was dispersed in diethyl ether (15 mL) and exposed to a microwave field for 5 min. Samples used for XRD measurements contained small amounts of free diethyl ether. Dry samples for the TG and spectroscopic measurements were prepared by evaporation of diethyl ether at 25 °C in an evacuated ampoule.

X-ray: Powder data were obtained with a D8-Advance diffractometer (Bruker AXE, Germany) using Cu-K_α radiation with a secondary graphite monochromator. Diffraction angles were measured from 7 to 80° (2θ). The temperature measurements (22−200 °C) were carried out on the heated corundum plate with a thermocouple.[9] Each diffractogram was measured at constant temperature and a cycle of heating and measuring lasted about 30 min. The sample was covered with a foil for protection.

TG: TG analyses, using a Netzsch STA 449C instrument, were carried out in air between 30 and 800 °C at a heating rate of 5 °C·min^{-1}.

IR: Infrared measurements (400−4000 cm^{-1}) were carried out with a fully computerized Bruker IFS 55 EQUINOX FTIR spectrometer with a DLATGS detector (256 scans per spectrum at 4 cm^{-1} resolution). Spectra of the intercalates were recorded ex situ by an ATR technique using the Golden Gate™ Heated Diamond ATR Top-Plate (Specac Ltd.) at ambient temperature. The spectrum of the corresponding liquid diethyl ether was measured by an ATR technique with a ZnSe crystal. Spectra were corrected for the H_2O and CO_2 content of the optical path.

Raman: FT Raman spectra were collected using a Bruker IFS 55 EQUINOX FTIR spectrometer equipped with an FT Raman module FRA 106/S with a diode-pumped, temperature-stabilized Nd YAG laser, and an InGaAs detector [128 interferograms were coadded per one spectrum in the range 4000−(−1000) cm^{-1} at 4 cm^{-1} resolution].

Calculations: Quantum chemical calculations were carried out at the ab initio and semiempirical levels of theory employing GAUSSIAN 98[10] and MOPAC 2002[11] program packages, respectively. Local interactions and structures in the intercalates of vanadyl phosphate with diethyl ether were studied at the DFT level using a functional B3LYP with the basis sets 6-31G(d) and LanL2DZ. Geometrical optimizations of larger structures including two vanadyl phosphate layers were performed at a semiempirical level using PM3 and AM1 methods.

Intramolecular Nucleophilic Substitution in a C_6F_5 Moiety Assisted by Antimony

Pavel L. Shutov,[a] Sergey S. Karlov,*[b] Klaus Harms,[a] Daniil A. Tyurin,[b] Jörg Sundermeyer,[a] Jörg Lorberth,[a] and Galina S. Zaitseva[b]

Keywords: Antimony / Amides / Density functional calculations / Fluorinated ligands / Nucleophilic substitution

Antimony tris-amides — $(Et_2N)_{3-n}Sb[N(C_6F_5)(2\text{-}C_5H_4N)]_n$ [n = 1 (**3**), 2 (**4**) or 3 (**5**)] — have been prepared by treatment of $Sb(NEt_2)_3$ (**1**) with stoichiometric amounts of (2-$C_5H_4N)(C_6F_5)NH$ (**2**). In contrast to amide **5**, compounds **3** and **4** are unexpectedly unstable and react further to give the bis-amido antimony fluorides [(2-Et_2N-C_6F_4)(2-C_5H_4N)N]-Sb(F)[$N(C_2H_5)_2$] (**6**) and [(2-Et_2N-C_6F_4)(2-C_5H_4N)N]Sb(F)-[$N(C_6F_5)$(2-C_5H_4N)] (**7**). The structure of **7** was confirmed by X-ray diffraction studies. DFT calculations, which reproduce the principal features of compound **7**'s geometry, have been used to explain the possible reaction pathway of this *ortho*-directed metathetical fluoride-amide exchange.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

During the past 50 years there has been a continuing interest in the chemistry of polyfluoro aromatic compounds. The main reason for this is that the unique properties of these derivatives suggest their possible use in various technological fields.[1,2] One of the most urgent aims of organofluorine chemistry is the preparation of polyfluorinated compounds with desired structures. As is well-known, organofluorine ligands have found widespread application in recent years for the stabilization of low-valent transition metal or main group species or for achieving unusual molecular geometries.[1,2] There is also a strong interest in activation of the C−F bond in polyfluoro organic compounds due to the possible utilization of these activation processes in organic synthesis.[3] A variety of methods for activating C−F bonds with transition metal centers have been published in the last two decades. Several catalytic systems based on transition metals have been used for the replacement of an F atom in polyfluoro aryl moieties, mostly by oxidative addition reactions.[3−5] Although only a few examples of early transition metal complexes (TMCs) useful for C−F bond activation have been found, most of the reported processes involving TMCs occur with late transition metals. As a common example of *intramolecular* oxidative addition of a C−F bond to a transition-metal center the reaction of C_6F_5−CH=N−(C_6H_4-*o*-NH_2) or similar Schiff bases with different TMCs [$W(CO)_3(PrCN)_3$, $Ni(COD)_2$ (COD = 1,5-cyclooctadiene) etc.], which give stable products of metal insertion into a C−F bond, should be noted.[4,6,7] Two different mechanisms have been suggested by Roundhill and co-workers for aromatic nucleophilic substitution of the *ortho*-F atom in *trans*-[PtMe(THF)($PPh_2C_6F_5$)$_2$] by hydroxide or alkoxide ion, one of which is an intramolecular process.[8]

Nucleophilic substitution reactions of an aryl carbon-fluorine bond assisted by main group element compounds (alkali, alkaline earth metals and silicon derivatives) have been investigated to a considerable extent.[3,4,9−11] However, to the best of our knowledge, most of the mechanistically studied examples have been ascribed to *intermolecular* processes, although suppositions about *intramolecular* origins have been made for exclusively *ortho*-directed fluorine-atom substitution for C_6F_5X species (X containing carbon or sulfur multiple bonds to oxygen or nitrogen atoms) in reactions with Li or Mg reagents, such as ArLi, AlkMgHal, ArMgHal or ArN(R)MgHal.[11,12]

As part of our program to investigate the structure and the chemical behavior of hypervalent main-group-element compounds with intramolecular transannular interactions[13−15] we herein report the reaction of $Sb(NEt_2)_3$ (**1**) with C_6F_5NH(2-C_5H_4N) (**2**, LH), which leads to the antimony tris-amides **3**−**5** with one, two or three C_6F_5-(2-pyridyl)-amine groups, respectively. Compounds **3** and **4** are unexpectedly unstable and they react further to give bis-amido antimony fluorides **6** and **7**, respectively, after 21 days in almost quantitative yield. To the best of our knowledge no such intramolecular rearrangements have been reported previously. Schrock et al. have found that a

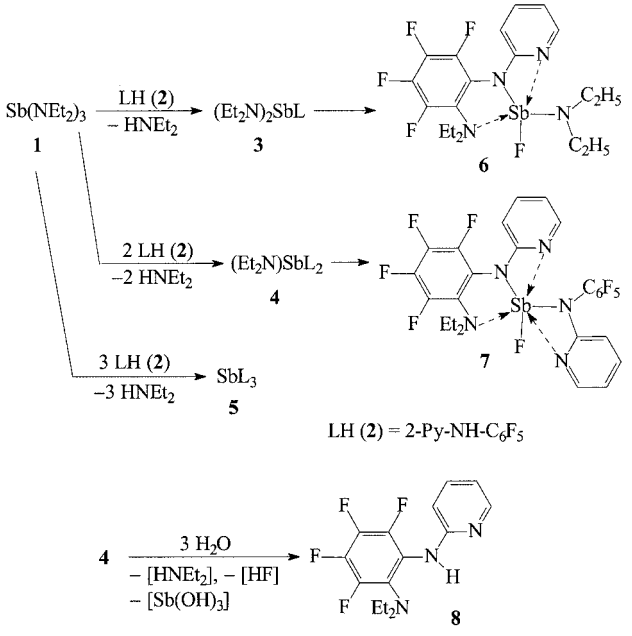
similar nucleophilic substitution product formed (23% yield) in the reaction of $Mo(NMe_2)_4$ with $(C_6F_5NHCH_2CH_2)_2NMe$. However, they were unable to determine whether this was due to an intra- or intermolecular process.[16] The structure of **7** was confirmed by X-ray diffraction studies. DFT calculations, which reproduce the principal features of the geometry of compound **7**, have been used to distinguish possible reaction pathways.

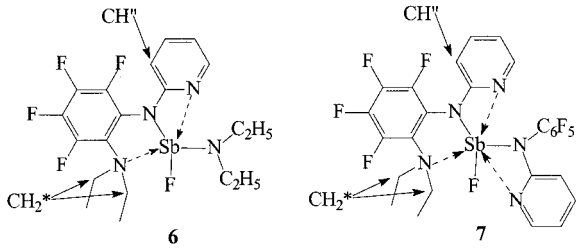
Results and Discussion

Treatment of $Sb(NEt_2)_3$ (**1**) with two or three equivalents of ligand LH (**2**) in toluene afforded amides **4** or **5**, respectively (Scheme 1). Compound **4** is unstable in toluene solution as well as in C_6D_6 solution and reacts further to give fluoride **7** after 21 days at room temperature. The reaction of **1** with one equivalent of LH led to reaction mixture **A**, consisting of **3** (as a major component) and **4** as well as starting material **1**, after 12 hours. Unfortunately, it was impossible to prepare compound **3** in a pure form. However, NMR spectroscopy data unambiguously confirm its structure. As for **4**, compound **3** (reaction mixture **A**) is unstable in solution and reacts further to give fluoride **6** after 21 days at room temperature. After recrystallization in order to remove traces of compound **7** partially formed from **4**, fluoride **6** was obtained as a pure solid. At the same time only compound **5** has been found in the reaction of **1** with three equivalents of LH (**2**) and no traces of fluorides **6** or **7** have been detected during this process. Hydrolysis of **6** after standard workup led, with moderate yield, to free amine **8**, which is difficult to access by other methods.



Scheme 1

The ^1H, ^{13}C, and ^{19}F NMR spectra of **3**–**8** are consistent with the proposed structural formula. In particular, the presence of the NEt_2 group, which is probably coordinated to the Sb atom, adjacent to the C_6F_4 ring in fluorides **6** and **7** stops the rotation of the $C_6F_4NEt_2$ group and the Py group of this ligand about the C–N bonds in C_6D_6 solution. This immobility results in the presence of two different signals for the $N(CH_2)_2$ carbon atoms of the NEt_2 group adjacent to the C_6F_4 ring (marked with an asterisk below) in the ^{13}C NMR spectra of **6** and **7**, a broadening of the $N(CH_2)_2$ signal in the ^1H NMR spectra of **6** and **7** (broad singlet instead of a quadruplet) as well as the presence of two different signals for the protons and carbons of CH_2''.



Single crystals of **7** were obtained as a toluene solvate from toluene solution (–30 °C). The molecular structure is presented in Figure 1; selected bond length and angles are summarized in Table 1. The primary coordination environment of the Sb atom is formed by the nitrogen atoms N(1) and N(14) and the F(1) atom, and may be treated as a trigonal pyramid. The $Sb-N_{cov}$ distances [2.103(2), 2.089(2) Å] are similar to those found for the closely related diamide $ClSb[N(SiMe_3)\{2\text{-}(6\text{-}Mepy)\}]_2$ (6-MepyH = 6-methylpyridine) [2.074(3)–2.127(8) Å][17] and somewhat shorter than in the tris-amide $Sb[N(SiMe_3)\{2\text{-}(6\text{-}Mepy)\}]_3$ [2.159(3)–2.167(3) Å].[18] The Sb(1)–F(1) distance [1.931(1) Å] is slightly shorter than those in the monofluoride $FSb(1,2\text{-}O_2C_6H_4)\cdot$1,10-phenanthroline [1.965(7) Å][19] and the difluoride $F_2Sb[OC(OCH_3)(2\text{-pyridyl})_2]$ [1.967(4) Å],[20] but slightly longer than those in $[SbF_3\cdot\{3\text{-}NH_2C(O)\text{-pyridine}\}_2]$ [1.911(8), 1.986(6) Å].[21] Internal coordination of both $N_{Pyridine}$ atoms and the N atom of the Et_2N group to antimony leads to a six-coordinate antimony in a

strongly distorted octahedral environment, with the N(22) and F(1) atoms in axial positions and the four nitrogen atoms N(1), N(9), N(14), and N(27) in equatorial sites. It should be noted that the axial transannular Sb(1)−N(22) bond is considerably shorter than the equatorial transannular N(27)−Sb(1) and N(9)−Sb(1) bonds. The $Sb-N_{Pyridyl}$ bond lengths [Sb(1)−N(22), N(9)−Sb(1)] are similar to the values reported for an Sb compound contained pyridine moieties (2.371−2.837 Å).[22,23] The $Sb-NEt_2$ transannular bond length is similar to analogous $Sb-NMe_2$ contacts reported previously [2.766(4)−3.04(2) Å][24−26] and shorter than those in the hexacoordinate complex [Sb(2-$Me_2NCH_2C_6H_4)_3$] [3.03(2)−3.04(2) Å].[26] Finally, there is no short intramolecular contact between Sb and any of the F atoms (the sum of the van der Waals radii of Sb and F is 3.66 Å).[27]

In order to get a better understanding of the driving forces of this unusual *ortho*-directed methatetic fluoride-amide rearrangement of **4** to **7** (Figure 2−4) we carried out DFT calculations on compounds **4** and **7** up to the PBE level of theory. The most important calculated geometric parameters of these compounds are listed in Table 1. Taking into consideration that no X-ray derived structure of **4** is available, the calculated geometric data for this molecule are of particular interest. The primary coordination environment of the Sb atom in **4** may be treated as a trigonal pyramid. The $Sb-N_{Py}$ distances are significantly smaller than the sum of the van der Waals radii of antimony and nitrogen (3.74 Å).[27] Consequently, the Sb atom can be regarded as [3+2]-coordinated in **4**; the presence of an additional short contact between the Sb atom and one fluorine atom of the C_6F_5 group (3.36 Å) should be noted. Such steric proximity may be one of reasons for the easy rearrangement.

The DFT calculations predict that the geometry of **7** is significantly more stable (30.25 kcal mol^{-1}) than that of **4**. The relative energies and reaction barriers calculated at various computational levels are listed in Table 2. Taking into consideration the calculated structure of compound **4** (steric proximity of Sb atom and one fluorine atom of the C_6F_5 group) and the absence of *meta*- or *para*-substitution products a concerted reaction pathway may be proposed for the nucleophilic process. We have calculated the transition-state geometry (**ts**) of this process (Figure 3). A considerable shortening of the Et_2N-C distances accompanied by an elongation of the C−F bond was found in **ts** in comparison with that in **4**. An analogous alteration is observed for the Sb−F and $Sb-NEt_2$ distances. The considerable shift of the F atom from the plane of the phenyl ring in the **ts** geometry should be noted. The computed barrier of gas-phase interconversion of **4** into **7** is low (27.70 kcal mol^{-1}). According to the literature the calculated activation barrier of insertion reactions of $Pd(PH_3)_2$ into the C−F bond of different fluoroarenes ($F-C_6H_3XY$, X,Y = H, CN, NO_2) lies within the range 21.8−41.2 kcal mol^{-1} (RB3LYP/DZVP level of theory).[28] The use of the COSMO solvation model does not drastically change these results. The computational investigation of a single-step mechanism for the

Conclusion

This paper reports the syntheses of antimony tris-amides $(Et_2N)_{3-n}Sb[N(C_6F_5)(2\text{-}C_5H_4N)]_n$ [n = 1 (**3**), 2 (**4**) or 3 (**5**)] upon reaction of antimony tris-diethylamide (**1**) with stoichiometric amounts of $HN(C_6F_5)(2\text{-}C_5H_4N)$ (**2**). Compounds **3** and **4** are unstable in solution and rearrange to the corresponding fluorides $[(2\text{-}Et_2N\text{-}C_6F_4)(2\text{-}C_5H_4N)N]Sb(F)[N(C_2H_5)_2]$ (**6**) and $[(2\text{-}Et_2N\text{-}C_6F_4)(2\text{-}C_5H_4N)N]Sb(F)[N(C_6F_5)(2\text{-}C_5H_4N)]$ (**7**). A concerted mechanism of nucleophilic substitution has been proposed for this rearrangement according to density functional calculations. Hydrolysis of **6** provides a new entry to the tridentate amine $[(2\text{-}Et_2N\text{-}C_6F_4)(2\text{-}C_5H_4N)NH$.

Experimental Section

General Remarks: All manipulations were performed under a dry, oxygen-free argon atmosphere using standard Schlenk techniques. Solvents were dried by standard methods and distilled prior to use. Starting materials $Sb(NEt_2)_3$ [30] and $C_6F_5NH(2\text{-}C_5H_4N)$[31] were prepared according to the literature. C_6D_6 was obtained from Deutero GmbH and dried over sodium. ^1H, ^{13}C, and ^{19}F NMR spectra were recorded on a Bruker AC200 FT NMR and Bruker AC300 FT NMR spectrometers (in C_6D_6 at 23 °C). Chemical shifts in the ^1H and ^{13}C NMR spectra are given in ppm relative to internal $SiMe_4$; ^{19}F NMR experiments are referenced to $CFCl_3$ as an external standard. Mass spectra (EI-MS) were recorded on a Varian CH-7a device using electron-impact ionization at 70 eV; mass spectra (FD-MS) were recorded on an HP-5989B device; all assignments were made with reference to the most abundant isotopes. Elemental analyses were carried out by the Fachbereich Chemie of the Philipps University Marburg (Heraeus Rapid Analyzer). In this work, the nonempirical generalized gradient approximation (GGA) for the exchange-correlation functional of Perdew et al. (PBE) was employed and single point RI-MP2//PBE calculations were used.[32−36] All calculations were performed using the program "PRIRODA" developed by Laikov, which implements an economical computational procedure.[37] The all-electron large orbital basis sets of contracted Gaussian-type functions of the size (5s1p):[3s1p] for H, (11s6p2d):[4s3p2d] for C, (11s6p2d):[4s3p2d] for N, (11s6p2d):[4s3p2d] for F and (22s19p12d):[7s6p4d] for Sb were used for DFT-PBE. The all-electron basis set of contracted Gaussian-type functions of the size Sb {17,18,19,20,21,22/13,14,15,16,17/9,10,11}, N {8,9,10/5,6/2}, C {8,9,10/5,6/2}, H {5,6/2}, F {8,9,10/5,6/2} were used for RI-MP2. The frozen-core approximation was used in the RI-MP2 calculations. Full geometry optimization was performed by DFT-PBE for a number of structures followed by vibrational-frequency calculation using analytical first and second derivatives. Each structure was characterized by the vibrational analysis. The transition state has only one imaginary normal mode and equilibrium geometry states have only real normal modes. An IRC (intrinsic reaction coordinate) calculation was run starting from the transition-state geometry in both directions and verified the initial and final structures linked to the transition state. Transition-state normal modes were animated using MOLDEN.[38] Coordinates and normal modes for **1**, **2**, and **ts** in MOLDEN format are available from the author upon request. The present theoretical method has previously given very useful results in antimony chemistry.[8]

Diethylaminobis[*N*-pentafluorophenyl-*N*-(2-pyridyl)amino]stibane, $[Et_2NSb\{N(C_6F_5)(2\text{-}C_5H_4N)\}_2]$ (4): A solution of amine **2** (1.09 g, 4.2 mmol) in toluene (20 mL) was added dropwise at −78 °C to a stirred solution of the stibane **1** (0.70 g, 2.1 mmol) in toluene (15 mL). The reaction mixture was stirred for 12 h at room temperature and all volatiles were removed under reduced pressure to give **4** as a yellow oil (yield 1.43 g, 97%). ^1H NMR (C_6D_6, 300.130 MHz): δ = 0.74 (t, 6 H, CH_3), 2.98 (q, 4 H, NCH_2), 5.69 (m, 2 H), 6.18 (m, 2 H), 6.85 (m, 2 H), 7.73 (m, 2 H) (hydrogen atoms of pyridyl group) ppm. ^{13}C NMR (C_6D_6, 75.47 MHz): δ = 15.22 (CH_3), 43.82 (NCH_2), 107.00, 114.11, 138.93, 145.79, 160.76 (carbon atoms of pyridyl groups) ppm; the signals of the carbon atoms of C_6F_5 were not detected. ^{19}F NMR (C_6D_6, 200.13 MHz): δ = −164.45 (br. t, 4 F), −159.58 (br. t, 2 F), −143.95 (br. d, 4 F) ppm. FD-MS: *m*/*z* (%) = 711 (100) [M^+].

Bis(diethylamino)[*N*-pentafluorophenyl-*N*-(2-pyridyl)amino]stibane, $[(Et_2N)_2Sb\{N(C_6F_5)(2\text{-}C_5H_4N)\}]$ (3): Following the same experimental procedure as for **4** using **1** (0.67 g, 2.0 mmol), **2** (0.52 g, 2.0 mmol), and toluene (20 mL). Isolated as a yellow oil (reaction mixture **A**, 1.01 g; according to ^1H NMR spectroscopy the ratio **1**:**3**:**4** was approximately 1:2:1). Data for **3**: ^1H NMR (C_6D_6, 200.130 MHz): δ = 0.92 (t, 12 H, CH_3), 3.00 (q, 8 H, CH_2), 5.80

(m, 1 H), 6.30 (m, 1 H), 7.00 (m, 1 H), 7.91 (m, 1 H) (hydrogen atoms of pyridyl group) ppm. ^{13}C NMR (C_6D_6, 50.32 MHz): δ = 16.23 (CH_3), 42.91 (CH_2), 106.79, 114.10, 138.54, 147.05, 161.00 (carbon atoms of pyridyl groups) ppm; the signals of the carbon atoms of C_6F_5 were not detected. ^{19}F NMR (C_6D_6, 188.28 MHz): δ = −164.04 (br. t, 2 F), −159.12 (t, 1 F), −145.46 (br. d, 2 F) ppm. FD-MS: *m*/*z* (%) = 524 (3) [M^+].

Tris[*N*-pentafluorophenyl-*N*-(2-pyridyl)amino]stibane, [Sb{N-(C_6F_5)(2-C_5H_4N)}$_3$] (5): Following the same experimental procedure as for **4** using **1** (0.56 g, 1.7 mmol), **2** (1.29 g, 5.0 mmol), and toluene (20 mL); yellow crystals (1.27 g, 83%) were obtained. ^{1}H NMR (C_6D_6, 200.13 MHz): δ = 5.56 (m, 3 H), 6.04 (m, 3 H), 6.77 (m, 3 H), 7.68 (m, 3 H) (hydrogen atoms of pyridyl group) ppm. ^{13}C NMR (C_6D_6, 50.32 MHz): δ = 107.05, 113.92, 139.53, 145.46, 160.42 (carbon atoms of pyridyl groups) ppm; the signals of the carbon atoms of C_6F_5 were not detected. ^{19}F NMR (C_6D_6, 188.28 MHz): δ = −164.53 (br. s, 6 F), −160.83 (br. t, 3 F), 144.51 (br. s, 6 F) ppm. EI-MS: *m*/*z* (%) = 898 (52) [M^+], 639 (39) [M^+ − N(C_5H_4N)(C_6F_5)]. $C_{33}H_{12}F_{15}N_6Sb$ (899.25): calcd. C 44.08, H 1.35, N 9.35; found C 43.87, H 1.31, N 9.15.

Diethylamino[*N*-(2-diethylamino-3,4,5,6-tetrafluorophenyl)-*N*-(2-pyridyl)amino]fluorostibane, [(Et_2N)Sb(F){N(C_6F_5)(2-C_5H_4N)}] (6): A solution of amide **3** (from reaction mixture **A**, 0.55 g, 1.1 mmol) in toluene (5 mL) was stirred for 21 days at room temperature and all volatiles were then removed under reduced pressure. Recrystallization of the residue from toluene/*n*-pentane (−30 °C) gave colorless crystals of **6** (yield 0.36 g, 66%). ^{1}H NMR (C_6D_6, 200.13 MHz): δ = 0.83 (br. s, 6 H, CH_3 of *o*-$Et_2NC_6F_4$ group), 1.03 (t, 6 H, CH_3 of Et_2NSb group), 2.95 (br. s, 4 H, CH_2 of *o*-$Et_2NC_6F_4$ group), 3.23 (q, 4 H, CH_2 of $SbNCH_2$), 5.79 and 5.80 (2 m, 1 H, CH′′), 6.17 (m, 1 H,), 6.96 (m, 1 H), 7.62 (m, 1 H) (hydrogen atoms of pyridyl group) ppm. ^{13}C NMR (C_6D_6, 50.32 MHz): δ = 12.13 (CH_3 of *o*-$Et_2NC_6F_4$ group), 16.38 (CH_3 of Et_2NSb group), 43.56 ($SbNCH_2$), 46.19 and 46.25 (CH_2 of *o*-$Et_2NC_6F_4$ group), 106.55 and 106.58 (CH′′), 112.96, 139.45, 145.42, 167.72 (carbon atoms of pyridyl groups) ppm; the signals of the carbon atoms of C_6F_5 were not detected. ^{19}F NMR (C_6D_6, 188.28 MHz): δ = −162.04 (br. t, 1 F), −161.42 (br. t, 1 F), −160.04 (br. s, 1 F, F−Sb), −148.02 (br. d, 1 F), −146.01 (br. d, 1 F) ppm. FD-MS: *m*/*z* (%) = 524 (13) [M^+], 505 (23) [M^+ − F], 452 [M^+ − NEt_2]. $C_{19}H_{24}F_5N_4Sb$ (525.17): calcd. C 43.45, H 4.61, N 10.67; found C 42.63, H 4.74, N 10.29.

[*N*-(2-Diethylamino-3,4,5,6-tetrafluorophenyl)-*N*-(2-pyridyl)amino]-[*N*-(pentafluorophenyl)-*N*-(2-pyridyl)amino]fluorostibane, [{(2-Et_2N-C_6F_4)(2-C_5H_4N)N}Sb(F){N(C_6F_5)(2-C_5H_4N)}] (7): A solution of amide **4** (1.23 g, 1.7 mmol) in toluene (5 mL) was stirred for 21 days at room temperature. Storage at −30 °C overnight resulted in colorless crystals of **7** (yield 0.87 g, 71%). ^{1}H NMR (C_6D_6, 300.130 MHz): δ = 0.74 (br. t, 6 H, CH_3), 2.82 (br. s, 4 H, NCH_2), 5.60 and 5.62 (2 m, 1 H, CH′′), 5.77 (m, 1 H), 6.02 (m, 1 H), 6.31 (m, 1 H), 6.77 (m, 1 H), 6.99 (m, 1 H), 7.66 (m, 1 H), 7.99 (m, 1 H) (hydrogen atoms of pyridyl group) ppm. ^{13}C NMR (C_6D_6, 75.47 MHz): δ = 11.61 (CH_3), 46.20 and 46.30 (NCH_2), 106.26 and 106.35 (CH′′), 106.81, 113.66, 114.16, 139.11, 139.97, 144.56, 146.43, 160.73, 161.23 (carbon atoms of pyridyl groups) ppm; the signals of the carbon atoms of C_6F_5 were not detected. ^{19}F NMR (C_6D_6, 188.28 MHz): δ = −164.45 (br. s, 2 F), −160.64 (br. t, 1 F), −160.07 (br. t, 1 F), −159.18 (br. t, 1 F), −154.72 (br. s, 1 F, F−Sb), −147.20 (br. d, 1 F), −146.85 (br. d, 1 F), −143.96 (br. t, 2 F) ppm. FD-MS: *m*/*z* (%) = 711 (45) [M^+]. $C_{26}H_{18}F_{10}N_5Sb$ (712.20): calcd. C 43.85, H 2.55, N 9.83; found C 43.47, H 2.64, N, 9.08.

***N*-(2-Diethylamino-3,4,5,6-tetrafluorophenyl)-*N*-(2-pyridyl)amine, HN(C_6F_5)(2-C_5H_4N) (8):** Water (2 mL) was added to a solution of stibane **6** (0.55 g, 1.1 mmol) in toluene (10 mL). The organic layer was separated, dried over Na_2SO_4 and all volatiles were removed under reduced pressure. Recrystallization of the residue from *n*-heptane gave colorless crystals of **8** (yield 0.10 g, 61%). ^{1}H NMR (C_6D_6, 200.13 MHz): δ = 0.65 (t, 6 H, CH_3), 2.66 and 2.67 (2 q, 4 H, NCH_2), 5.25 (br. s, 1 H, NH), 6.25 and 6.27 (2 m, 1 H), 6.39 (m, 1 H), 7.03 (m, 1 H), 8.14 (m, 1 H) (hydrogen atoms of pyridyl group) ppm. ^{19}F NMR (C_6D_6, 188.28 MHz): δ = −166.09 (br. t, 1 F), −160.77 (br. t, 1 F), −148.91 (br. d, 1 F), −141.88 (br. d, 1 F) ppm. $C_{15}H_{15}F_4N_3$ (313.29): calcd. C 57.51, H 4.83, N 13.41; found C 57.23, H 4.69, N 12.94.

X-ray Crystallographic Study. Crystal Data for 2: $C_{33}H_{26}F_{10}N_5Sb$, M_r = 804.34, triclinic, *a* = 8.5318(5), *b* = 11.6819(7), *c* = 16.680(1) Å, *α* = 83.687(5), *β* = 77.456(5), *γ* = 83.518(5)°, *V* = 1606.2(2) Å^3, space group $P\bar{1}$, *Z* = 2, D_c = 1.663 g·cm^{-3}, *F*(000) = 800, *μ*(Mo-K_α) = 0.950 mm^{-1}. Colourless crystal of approximate dimensions 0.45 × 0.27 × 0.18 mm^3 was used for data collection. Total of 23604 reflections (6418 unique, R_{int} = 0.0366) were measured on a Stoe IPDS-2 diffractometer (graphite-monochromatized Mo-K_α radiation, *λ* = 0.71073 Å) at 193(2) K. Data were collected in the range 1.76 < *θ* < 26.19° (−10 ≤ *h* ≤ 10, −14 ≤ *k* ≤ 14, −20 ≤ *l* ≤ 20). Absorption correction based on measurements of equivalent reflections resulted in transmission factors 0.6607/0.9884. The structure was solved by direct methods (SHELXS-86)[39] and refined by full-matrix least-squares on F^2 (SHELXL-97)[40] with anisotropic thermal parameters for all non-hydrogen atoms. All H atoms (except methyl hydrogens of solvate toluene) were refined isotropically. All other H atoms were refined by using a riding model. The final residuals were: R_1 = 0.0232 for 5935 reflections with $I > 2\sigma(I)$ and wR_2 = 0.0619 for all data with 535 parameters. Goof = 1.030, max. Δ*ρ* = 0.370 e·Å^{-3}.
CCDC-225205 (for **2**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supramolecular Structures in [Ag(dppf)] Complexes [dppf = 1,1′-Bis(diphenylphosphanyl)ferrocene] Stabilized by Coordinatively Versatile Trifluoroacetate (TFA) Ligands

Xiu Lian Lu,[a] Weng Kee Leong,[a] Lai Yoong Goh,*[a] and Andy T. S. Hor*[a]

Keywords: Silver / Trifluoroacetate / Coordination polymer / Supramolecular chemistry / Hydrogen bonding

The interaction of silver(I) trifluoroacetate and dppf in different molar equivalents has led to the isolation of dinuclear complexes $[Ag_2(\mu\text{-}O_2CCF_3)_2(\mu\text{-dppf})]$ (**1**) and $[Ag_2(\eta^1\text{-}O_2CCF_3)_2(dppf)_2]$ (**2**). Treatment of **1** with excess dppf gave a coordination polymeric compound $[Ag(\eta^2\text{-}O_2CCF_3)(dppf)]_n$ (**3**). Reaction of **1** with PMe_2Ph in MeOH in the presence of NH_4PF_6 led to displacement of trifluoroacetate, forming the mononuclear compound $[Ag(PMe_2Ph)_2(\eta^2\text{-dppf})]PF_6$ (**4**). All compounds have been characterized by microanalytical and spectroscopic analyses [IR, MS and NMR (^1H, ^{19}F and $^{31}P\{^1H\}$)] as well as X-ray diffraction studies. Molecular structures of the solvates of **1**, viz. **1A** (**1**·0.5THF) and **1B** (**1**·0.5CH_2Cl_2), **2** and **3** show that they contain trifluoroacetate in bridging, monodentate and bidentate bonding modes, respectively, with dppf as a bridging co-ligand. Compound **3** is an infinite linear [–dppf–Ag–dppf–Ag–dppf–Ag–]$_n$ coordination polymer. Interestingly, **1A** and **1B** form two different supramolecular network structures through C–H···F and C–H···O hydrogen-bonding interactions. Such secondary bonding interactions also lead to the formation of a 3D supramolecular structure in **3**.

Introduction

Transition-metal-mediated self-assembly is emerging as a new and pragmatic strategy for the design of nanostructures, supramolecular two- or three-dimensional network structures and coordination polymers.[1] Nitrogen-donor ligands have dominated these molecular designs.[1b−1d,1f,1h,2] Among the metals, the use of silver in this line of crystal engineering has escalated in the last decade[2,3] due to its rich structural diversity, which may be further tuned by numerous factors such as metal-to-ligand stoichiometry, counterions, ligand conformation, intra- and intermolecular H-bonding and solvents. Surprisingly, phosphanes have rarely been used in such assemblies until very recently, when some helices, rings, cages and polymers began to emerge in silver(I) systems containing (2-furyl)phosphane[3a] and some diphosphanes.[3b,3d] In particular, the role of the metallodiphosphane 1,1′-bis(diphenylphosphanyl)ferrocene (dppf) in supramolecular assemblies has not been investigated. We expect that the variable conformation modes of dppf in combination with coordinatively flexible ligands, such as acetate or nitrate as ancillary ligands,[4] will give a multitude of molecular and crystal structural possibilities with a metal like silver, which can adopt variable geometries, especially when assisted by intermolecular forces such as H-bonding. We describe here the results of such a study.

Results and Discussion

Synthesis

Treatment of $Ag(O_2CCF_3)$ with dppf (2:1 molar ratio) in THF/MeOH for 8 h afforded an air-stable, non-light-sensitive yellow crystalline solid of a THF solvate of the disilver complex $[Ag_2(O_2CCF_3)_2(dppf)]$ (**1**) in 34% yield. Workup of the supernatant of **1** in CH_2Cl_2/ether gave the solvate **1**·0.5CH_2Cl_2 (30% yield). This solvate was obtained in 90% yield directly from a 6 h reaction in CH_2Cl_2. Recrystallization of **1** from THF/MeOH gave diffraction-quality crystals of **1**·0.5THF (**1A**) after 1 d at ambient temperature, while the same process in CH_2Cl_2/diethyl ether gave diffraction-quality crystals of **1**·0.5CH_2Cl_2 (**1B**). Treatment of $Ag(O_2CCF_3)$ with 1 mol-equiv. of dppf in CH_2Cl_2 for 3 h at room temperature yielded a yellow solid of the dinuclear complex $[Ag_2(O_2CCF_3)_2(dppf)_2]$ (**2**) in 87% yield. The reaction of **1** with 1 mol-equiv. of dppf in CH_2Cl_2 for 3.5 h afforded orange solids of the polymeric complex $[Ag(O_2CCF_3)(dppf)]_n$ (**3**) in 88% yield. These reactions are shown in Scheme 1. When monitored in an NMR tube in $CDCl_3$, the latter reaction showed no evidence of **2** (see Exp. Sect.); **2** is, though, very stable in $CDCl_3$. Reaction of **1** with PMe_2Ph in MeOH in the presence of NH_4PF_6 led to displacement of the O_2CCF_3 ligand and isolation of the

mononuclear complex $[Ag(dppf)(PMe_2Ph)_2]PF_6$ (**4**) in 48% yield (Scheme 2).

Structural Studies

[Ag$_2$(μ-O$_2$CCF$_3$)$_2$(μ-dppf)] (1)

The solvate molecules **1**·0.5C_4H_8O (**1A**) and **1**·0.5CH_2Cl_2 (**1B**) are isostructural; two views of the molecular structure of **1A** are illustrated in Figure 1. The structure consists of a dinuclear Ag_2 core bridged by two trifluoroacetate groups and a dppf ligand, similar to the structure of [Ag_2($O_2CR)_2$(dppf)] (R = H, CH_3, Ph).[4] The Ag···Ag distances [3.156(2) Å in **1A** and 3.2434(4) Å in **1B**] agree with reported non-bond distances of 3.104(1) Å in [Ag_2($O_2CCH_3)_2$(dppf)] and 3.346(4) Å in [Ag_2($O_2CPh)_2$(dppf)].[4b] With three bridging ligands and no formal M−M bond, we can view this as two macrocycles hinged at the two Ag^I centers. A twofold axis passes through the mid-point of the Ag(1)···Ag(1A) axis and the Fe(2) atom of the dppf ligand in **1A**. Selected bond parameters (Table 1) show that the equivalent bond lengths of **1A** and **1B** are very similar, but their bond angles deviate significantly, viz. the O−Ag−O, O−Ag−Ag, O−Ag−P, P−Ag−Ag and O−C−O angles.

The crystal packing of **1A** and **1B** shows weak C−H···O and C−H···F hydrogen-bonding interactions, resulting in H···O distances of 2.62−2.63 Å in **1A** and 2.48−2.63 Å in **1B**, H···F distances of 2.50−2.54 Å in **1A** and 2.37−2.69 Å in **1B** (Table 2). The H···O and C···O distances, and C−H−O angles, fall within the reported ranges, viz. 2.52−2.70 Å, 3.32−3.60 Å and 128−155°, respectively, found in a CpFe half-sandwich and related carbonyl complexes of first-row transition metals, reported by Desiraju and co-workers. Likewise, the H···F distances and C−H−F angles are found in the range reported for in $C_6H_{6-x}F_x$ (x = 1−5), viz. 2.41 −2.87 Å and 120−174°, respectively.[5] Packing diagrams of the supramolecular networks in **1A** and **1B** viewed from the z and x axis, respectively, are illustrated in Figures 2 and 3. In **1A**, there is close packing of four molecules through two types of hydrogen bonds: C−H(Ph)···O and C−H(Cp)···F−C. The Figure shows four Ag_2 units clustering around a "central" region, which is effectively surrounded by four phenyl rings, one from each Ag_2 unit; molecules of THF are discernible in the lattice. In **1B**, the elementary prototype shows four molecular units connected by four types of H-bonds, viz. C−H(Cp)···O, C−H(Ph)···O, C−H(Cp)···F−C and C−H(Ph)···F−C. Figure 3 shows the relative orientation of three pairs of Ag_2 units; considering the dppf ligand as the "head" end of the unit and the bridging TFA ligands as the "tail" end, there is one pair pointing "head-to-head" towards each other such that their Cp rings come close to the two CH_2Cl_2 molecules in the central portion of the molecule, while the other

O12−Ag1−Ag1A	65.9(3)		O2−Ag2−Ag1	72.86(9)
O11−C11−O12A	129.9(14)		O4−C3−O3	131.1(4)
O11A−C11A−O12	113.0(10)		O1−C1−O2	129.6(4)

two pairs orientate tail-to-tail towards each other, such that their CF_3 groups radiate towards the CH_2Cl_2 molecules. Adjacent molecules are linked into a 2D layer network by H-bonding (C−H···F and C−H···O), and these layers are linked into a 3D network through interlayer H-bond interactions.

The different crystal packing encountered in these two solvates of **1** must be associated with their different bond parameters, as well as the presence and location of the solvent molecules in the crystal lattice, factors that influence the nature and strength of hydrogen bonds supporting the network.

Table 2. Hydrogen bond lengths [Å] and bond angles [°] for **1A** and **1B**

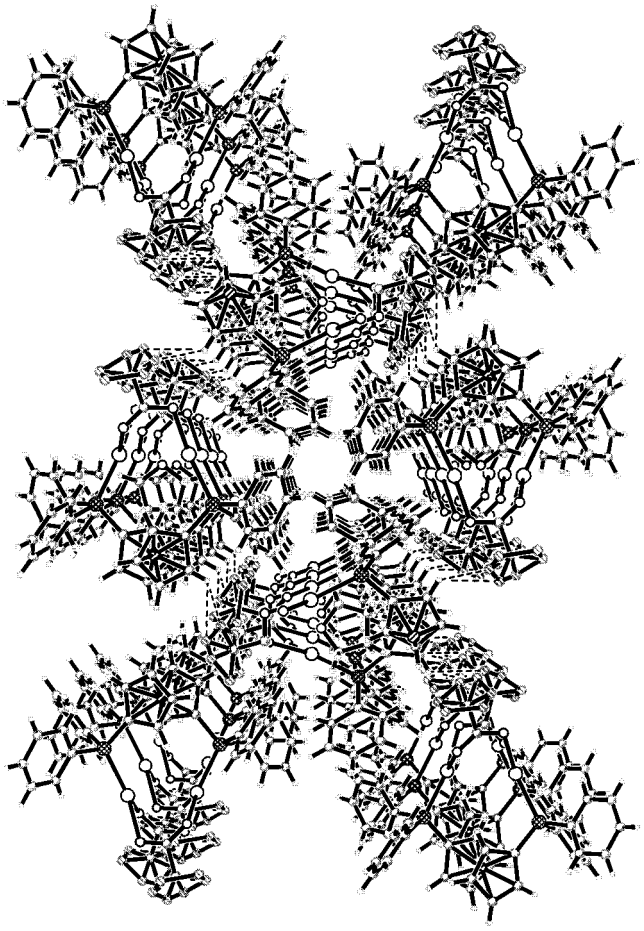

Figure 2. Packing diagram of the supramolecular network in **1A** viewed from the *z* axis, showing C−H(Ph)···O and C−H(Cp)···F−C hydrogen bonds; the four THF molecules in each layer are visible

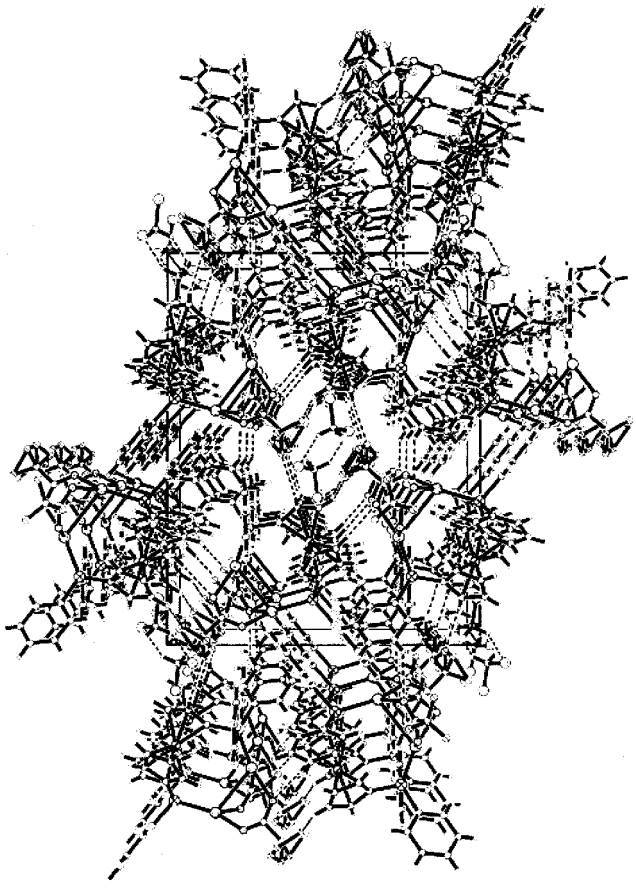

Figure 3. Packing diagram of the supramolecular network in $[Ag_2(O_2CCF_3)_2(dppf)]\cdot 0.5CH_2Cl_2$ (**1B**) viewed from the *x* axis; four types of H-bonds are illustrated: C−H(Cp)···O, C−H(Ph)···O, C−H(Cp)···F−C and C−H(Ph)···F−C

[Ag$_2$(O$_2$CCF$_3$)$_2$(dppf)$_2$] (2)

$[Ag_2(O_2CCF_3)_2(dppf)_2]$ (**2**) (Figure 4) contains two three-coordinate silver atoms doubly bridged by two dppf ligands; being η^1-coordinated to an oxygen atom of trifluoroacetate anions, each Ag atom achieves a 16e configuration. Selected bond parameters of **2** are given in Table 3. Similar structures have been reported for $[Ag_2(NO_3)_2(dpm)_2]$ and $[Ag_2(dpm)_2(O_2CCH_2Ph)_2]$ (dpm = $Ph_2PCH_2PPh_2$) with monodentate nitrate and carboxylate ligands, respectively,[6a,6b] which possess Ag···Ag distances of 3.085(1) and 3.080(1) Å, respectively; however, there is no metal−metal interaction in **2** (Ag···Ag = 3.781 Å), as with $Ag_2(NO_3)_2(dppf)_2$ [Ag···Ag = 3.936(2) Å].[4b] The Ag−P distances are also very close to those reported for $Ag_2(NO_3)_2(dppf)_2$.[4b] Except for a H-bond between the $CHCl_3$ solvent molecule and an oxygen atom of TFA, viz. C1−H1S($CHCl_3$)···O2 (2.12 Å), there are no secondary bonding interactions of the types observed in **1A**, **1B** and **3**.

The structures of **1** and **2** illustrate a preference of the 16e Ag^I center in these dinuclear species for a trigonal-planar configuration, with the diphosphane adopting a bridging coordination mode, while the weakly coordinating carboxylate group adapts as a bridging or monodentate ligand, forming an $[Ag_2(dppf)_2]$ ring structure in the latter situation, as was found in $Ag_2(NO_3)_2(dpm)_2$ and $[Ag_2(dpm)_2(O_2CCH_2Ph)_2]$.[6a,6b]

nate, being bonded to a chelating trifluoroacetate ligand and two phosphorus atoms of two different dppf ligands, thus forming a one-dimensional infinite chain, which is further reinforced by intra-chain hydrogen-bond interactions [C−H(Cp)···O 2.47 Å, 155°]. A plane of symmetry passes through the Ag atom and bisects the AgOCO ring. Notably, the chelating mode of the carboxylate ligand in Ag^{I} complexes is rarely encountered,[7] in contrast to the commonly reported monodentate and μ-bridging modes.[8] Selected bond parameters and hydrogen bond parameters are given in Table 4. The Ag−P distance [Ag(1)−P(1) 2.4270(16) Å] is intermediate between those encountered in the other Ag(dppf) complexes in this study (2.34−2.57 Å). The Ag(1)−O(1) bond is longer [2.527(7) Å] than those in **1A** and **1B** (2.21, 2.31 Å), in which TFA bridges two Ag atoms, and in **2** (2.47 Å), in which TFA is monodentate. While no inter-chain hydrogen-bonding interactions are found between adjacent polymeric chains viewed from the *x* axis, they do exist between adjacent chains viewed from the *y* axis (Table 5 and packing diagram in Figure 6).

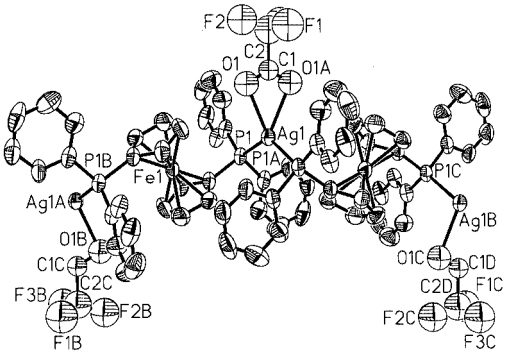

Figure 5. Section of the polymeric chain of **3**; hydrogen atoms omitted for clarity; thermal ellipsoids drawn to 50% probability

In the above complexes the participation of weak hydrogen bonding between C−H(Cp/Ph) bonds to O and/or F−C of coordinated ligands stabilizes supramolecular structures, the nature of which is further influenced by the presence of solvent molecules in the crystal lattice, as in **1A** and **1B**. The role of such weak hydrogen-bonding interactions in such phenomena has been reported frequently in recent years in organic systems[5,9] and coordination compounds[2g,10−12] though less frequently in organometallic complexes,[12−15] e.g. in the bonding of C−H(arene) to O(carbonyl) in a chromium complex,[12] of C−H(arene) to F of the anions, BF_4^- [13] or PF_6^- [16] and of C−F of C_6F_5 to O(carbonyl) in complexes of Fe, Co, Mn and Re.[15]

[Ag(PMe$_2$Ph)$_2$(dppf)]PF$_6$ (4)

This molecule possesses a mononuclear structure in which the silver atom assumes a distorted tetrahedral geometry with coordination to a chelating dppf and two monodentate dimethyl(phenyl)phosphane ligands (Figure 7). Selected bond parameters are given in Table 6. The bite angle of the dppf ligand, P(1)−Ag(1)−P(2) 105.96(4)°, is similar to that in $[Ag(dppf)_2]ClO_4$ [105.71(4)°]; the other angles at Ag [P(3)−Ag(1)−P(4) 105.87(5)°, P(3)−Ag(1)−P(1) 113.80(4)°, P(4)−Ag(1)−P(2) 107.58(4)°] show small deviations from those in $[Ag(dppf)_2]ClO_4$ [98.39(4)°, 113.15(4)°, 114.54(4)°].[17]

Spectral Characteristics

VT-^{1}H NMR Spectral Features

At 328 K the ^{1}H NMR spectrum of **1** in $CDCl_3$ shows two singlets at δ = 3.96 and 4.45 ppm for the α- and β-protons of the Cp rings of dppf and a multiplet at δ = 7.39−7.54 ppm (unresolved δ = 7.39, 7.41, 7.44, 7.47, 7.50, 7.52 and 7.54 ppm) for the Ph protons of dppf. These features vary little upon lowering the temperature to 243 K − there is mainly a loss of resolution in the Ph multiplet and slight broadening of the β-CpH signal (δ = 4.39 ppm) with concurrent greater broadening of the α-CpH signal (δ = 3.85 ppm); below 243 K both α and β signals undergo extensive broadening.

The ^{1}H NMR spectrum of **2** in $(CD_3)_2CO$ at 300 K and above shows only one peak, at δ = 4.44 ppm, for the Cp protons of dppf and two multiples, δ = 7.45−7.50 and 7.68−7.70 ppm, for the Ph protons of dppf. Below 273 K, the Cp singlet transforms into a broad unresolved multiplet,

which at 223 K, is centered at δ = 4.50 ppm, while the multiplicity of the phenyl protons is also drastically changed.

In $CDCl_3$ at 300 K, the Ph protons of **3** are seen as a broad peak at δ = 7.52 ppm and a multiplet centered at δ = 7.37 ppm, and the Cp signals as two broad singlets at δ = 4.34 and 4.25 ppm; at lower temperatures these were transformed into several unassignable broad peaks at δ = 2.5−6.3 ppm.

VT-^{19}F NMR Spectral Features

The sharp ^{19}F signal of **1** in $CDCl_3$ varies slightly, from δ = 1.6 ppm at 300 K to δ = 1.7 ppm at 223 K, while that of complex **2** in $(CD_3)_2CO$ undergoes a greater downfield shift, from δ = 2.4 ppm at 323 K to δ = 2.7 ppm at 223 K, with increasing line-width broadening. Below this, the peak transformed into two broad overlapping peaks, which at 183 K are seen at δ = 3.1 and 2.8 ppm (relative intensity ca. 1:2); these overlapping peaks indicate the presence of trifluoroacetate ligands in different coordination environments, most probably caused by different denticities of the ligands. This is accompanied by complex variations in the ^{1}H and ^{31}P{^{1}H} NMR spectra.

The VT-^{19}F NMR spectrum of **3** in $CDCl_3$ shows only one sharp peak (δ = 1.2 ppm) in the range 300−223 K, while at 213 K a minor peak (ca. 10%) emerges at δ = 1.7 ppm, indicating two types of coordinated trifluoroacetate ligands, as in **2** above.

VT-^{31}P{^{1}H} NMR Spectral Features

The variations of **1** in $CDCl_3$ are shown in Figure 8. A broad peak at δ = 6.6 ppm ($\nu_{1/2}$ = 405 Hz) at 328 K broadens further at 313 K (δ = 6.5 ppm, $\nu_{1/2}$ = 607 Hz). At 296 K, three overlapping broad peaks appear at δ = 10.1, 7.4 and 4.2 ppm ($\nu_{1/2}$ = 146, 255 and 146 Hz, with relative intensity ca. 1:2:1); these gradually transform into two pairs of sharp doublets at 223 K, being centered at δ = 7.6 ppm ($J^{107/109}$Ag−P = 695 and 805 Hz), indicative of coordination of one P atom to an Ag atom,[18] which is in agreement with its solid-state structure. These VT features can be rationalized in terms of ^{31}P−^{107}Ag/^{109}Ag inter- and intramolecular exchange processes first observed by Dean

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and co-workers in dinuclear Ag complexes containing bridging diphosphanes.[19]

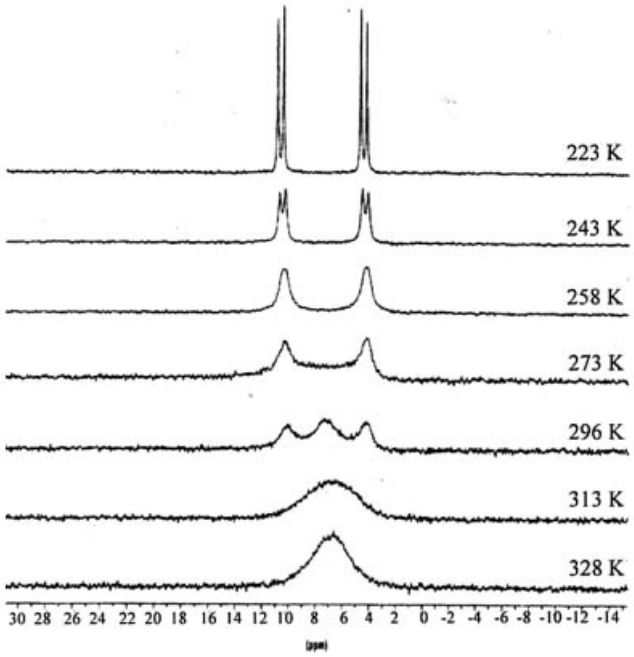

Figure 8. VT $^{31}P\{^{1}H\}$ NMR spectra of **1** in $CDCl_3$

^{31}P NMR spectra in $(CD_3)_2CO$ of **2** show a very broad peak at $\delta = -1.2$ ppm ($\nu_{1/2} \approx 300$ Hz) at 300 K. As the temperature is lowered to 183 K, a combination of broad bands and $^{107/109}Ag$-coupled doublets appear. With **3**, a decrease of temperature causes the broad ambient-temperature signal [$\delta = -1.5$ ppm ($\nu_{1/2} = 600$ Hz)] to transform into a very complex pattern, consisting of several broad "humps", which can not be rationalized. The only distinctive feature is a doublet at $\delta = -3.45$ ppm , which is observable at 223 K and below with $J^{107/109}Ag-P$ couplings of 418 and 482 Hz, indicative of coordination of two P atoms per Ag atom, which is consistent with its solid-state linear polymeric structure.

Mass Spectra

FAB^+-MS spectra of **1A/1B** and **2** do not show the parent ion fragment [M^+], but fragments arising from the consecutive loss of an O_2CCF_3 ligand and an $Ag(O_2CCF_3)$ moiety, leading to $m/z = 661$ [Ag + dppf] as the most intense fragment. The FAB^+-MS spectrum of **3** is identical to that of **2**. The highest mass fragment in the ESI^+-MS spectrum of **4** arises from the addition of 1 equiv. of PMe_2Ph to the parent ion at $m/z = 1216$ [$M^+ + PMe_2Ph$], followed by fragments showing consecutive losses of PMe_2Ph to yield $m/z = 661$ as the strongest peak. The FAB^+-MS spectrum of **5** only shows the most intense peak at $m/z = 662$.

Infrared Spectra

IR spectra of **1A/1B** show the bridging O_2CCF_3 vibration frequencies at $\tilde{\nu} = 1684$ (asymm.), 1437 (symm.), 1207 and 1133, with $\Delta\tilde{\nu}$(asymm. − symm.) = 247 cm^{-1} − outside the range (88−200 cm^{-1}) reported for bridging trifluoroacetate complexes.[20] The $\Delta\tilde{\nu}$(asymm. − symm.) = 231 cm^{-1} of **2** for monodentate trifluoroacetates is similar to 232 cm^{-1} in $PhHg(O_2CMe)$ containing monodentate carboxylate groups.[20] The IR stretching frequencies of **3** are close to those of **2**, with a $\Delta\tilde{\nu}$(asymm. − symm.) of 227 cm^{-1}, very close to that in **2**, even though, unlike **2**, its acetate ligand is in a chelating mode. Notably, $\Delta\tilde{\nu}$(asymm. − symm.) for the trifluoroacetate ligand in **3** far exceeds those of most chelating acetate ligands (65−175 cm^{-1}), except for those of $Sn(O_2CMe)_4$ (320, 440 cm^{-1}).[20] C−H stretches of the Cp and Ph rings of dppf in **2** are observed as two weak unresolved peaks at $\tilde{\nu} = 3077$ and 3058 cm^{-1}, while **1A/1B** and **3** also show two C−H stretches in the same frequency range, but in addition exhibit three other very weak peaks between $\tilde{\nu} = 2960$ and 2853 cm^{-1}. Presumably, these lower-frequency stretches pertain to C−H hydrogen-bonded to O or F of TFA, as shown in their crystal structures.

Conclusion

Facile interactions between silver trifluoroacetate and dppf afford a coordination polymer or dinuclear species possessing TFA in different bonding modes, depending on the stoichiometry of the reactants. Weak hydrogen-bonding interactions (C−H···F and C−H···O) in the dinuclear compounds yield 2D supramolecular structures, the nature of which varies with solvent molecules in the crystal lattice.

Experimental Section

General: $Ag(O_2CCF_3)$, PMe_2Ph and NH_4PF_6 were purchased from Aldrich, and dppf from STREM, and used as supplied. All reactions were performed under dry nitrogen using Schlenk techniques. Solvents were freshly distilled from standard drying agents. NMR spectra were recorded with a Bruker ACF300 FT NMR spectrometer (^1H at 300.13 MHz; $^{31}P\{^1H\}$ at 121.50 MHz and ^{19}F at 282.38 MHz), with chemical shifts referenced to residual non-deuterated solvent, external H_3PO_4 and external CF_3COOH, respectively. Infrared spectra were measured in KBr pellets in the range of 400−4000 cm^{-1} with a Perkin-Elmer 1600 FT-IR spectrometer. FAB and ESI mass spectra were obtained with Finnigan MAT95XL-T and MATLCQ spectrometers, respectively. All elemental analyses were carried out in-house.

Syntheses

Reactions of $Ag(O_2CCF_3)$ with dppf. Using Ag^+/dppf (2:1) in THF/MeOH. Synthesis of $[Ag_2(O_2CCF_3)_2(dppf)]$ (1): Ligand dppf (0.111 g, 0.20 mmol) in THF (10 mL) was added to a solution of $Ag(O_2CCF_3)$ (0.094 g, 0.43 mmol) in MeOH (10 mL) and the resultant solution stirred for 8 h. The so-obtained orange suspension was filtered through Celite, and the orange filtrate was concentrated to ca. 2 mL. Addition of diethyl ether (5 mL) and cooling at 0−5 °C for 3 h gave yellow air-stable, non-light-sensitive crystals of a THF solvate of $[Ag_2(O_2CCF_3)_2(dppf)]$ (**1**) (0.073 g, 0.07 mmol, 34%). $C_{38}H_{28}Ag_2F_6FeO_4P_2 \cdot 0.6C_4H_8O$ (1039.4): calcd. C 46.6, H 3.2, P 6.0; found C 45.9, H 2.7, P 6.0. ^1H NMR ($CDCl_3$, 300 K): $\delta = 7.39-7.55$ (m, 20 H, Ph), 4.44 and 3.92 (each s, 4 H, C_5H_4)

ppm. $^{31}P\{^1H\}$ NMR: δ = 10.1, 7.4 and 4.2 ppm ($\nu_{1/2}$ = 146, 255 and 146 Hz, with relative intensity ca. 1:2:1). ^{19}F NMR: δ = 1.6 ppm. FAB$^+$-MS: *m*/*z* = 883 [M − O_2CCF_3]$^+$, 661 [M − Ag − 2 (O_2CCF_3)]$^+$, 1437 [M + dppf]$^+$. IR (KBr cm^{-1}): ν_{CO_2}: 1684, 1437, 1207, 1133; ν_{others}: 3071 w, 3050 w, 2960 vwbr, 2923 vw, 2852 vwbr, 1508 w, 1021 m, 838 m, 803 s, 724 vs, 696 s, 518 w, 456 w. Concentration of the mother liquor to dryness, redissolution in CH_2Cl_2, followed by addition of diethyl ether (3 mL) then gave an orange solid of **1**·0.5CH_2Cl_2 (0.065 g, 30% yield). $C_{38}H_{28}Ag_2F_6FeO_4P_2$·0.5$CH_2Cl_2$ (1038.6): calcd. C 44.5, H 2.8; found C 44.8, H 2.9. ^1H NMR ($CDCl_3$): As above with additional δ = 5.30 ppm (CH_2Cl_2). ^{19}F NMR: As above. $^{31}P\{^1H\}$ NMR: With slight variations: δ = 10.4, 7.4, 4.3 ppm ($\nu_{1/2}$ = 54, 121 and 54 Hz, relative intensity 1:2:1). A similar reaction of Ag(O_2CCF_3) (0.404 g, 1.83 mmol) and dppf (0.507 g, 0.92 mmol) in CH_2Cl_2 (20 mL) for 6 h furnished a yellow solid of **1**·CH_2Cl_2 (0.811 g, 90%). Crystallization of **1** in THF/MeOH and CH_2Cl_2/diethyl ether gave orange diffraction-quality crystals of **1**·0.5THF ≡ **1A** and **1**·0.5CH_2Cl_2 ≡ **1B**, respectively, after 1 d at ambient temperature.

Using Ag$^+$/dppf (1:1) in CH_2Cl_2. Synthesis of [Ag_2(O_2CCF_3)$_2$(dppf)$_2$] (2): Ligand dppf (1.014 g, 1.83 mmol) was added to a suspension of Ag(O_2CCF_3) (0.404 g, 1.83 mmol) in CH_2Cl_2 (15 mL) and the mixture stirred at room temperature for 3 h. The resultant orange homogeneous solution was concentrated to ca. 2 ml; the subsequent addition of hexane (2 mL) gave yellow solids of [Ag_2(O_2CCF_3)$_2$(dppf)$_2$] (**2**)·0.25CH_2Cl_2 (1.23 g, 86%). $C_{72}H_{56}Ag_2F_6Fe_2O_4P_4$·0.25$CH_2Cl_2$ (1571.8): calcd. C 55.2, H 3.6; found C 55.2, H 3.95. ^1H NMR [$(CD_3)_2CO$, 300 K]: δ = 7.69, 7.48 (each centered m, 8-H and 12-H, respectively, Ph), 4.44 (s, 8 H, C_5H_4) ppm. $^{31}P\{^1H\}$ NMR: δ = −1.2 ppm ($\nu_{1/2}$ ≈ 300 Hz). ^{19}F NMR: δ = 2.4 ppm. ^1H NMR ($CDCl_3$, 300 K): δ = 7.41, 7.33 (each centered m, 12-H and 8-H, respectively, Ph), 4.51 and 4.05 (each s, 4 H, C_5H_4) ppm. $^{31}P\{^1H\}$ NMR: δ = −1.0 ppm ($\nu_{1/2}$ ≈ 300 Hz). ^{19}F NMR: δ = −0.1 ppm. FAB$^+$-MS: *m*/*z* = 1437 [M − O_2CCF_3] $^+$, 1216 [M − Ag − 2 (O_2CCF_3)]$^+$, 661 [M − Ag − 2 (O_2CCF_3) − dppf]$^+$. IR (KBr, cm^{-1}): ν_{CO_2}: 1664 s, 1433 m, 1199 s, 1131 s; ν_{others}: 3077 wsh, 3058 wbr, 1480 w, 1313 vw, 1175 ssh, 1031 w, 837 m, 764 m, 697 s, 484 mbr. Diffraction-quality single crystals of **2** were obtained from a solution in $CHCl_3$ layered with hexane after 1 d at room temperature.

Reactions of [Ag_2(O_2CCF_3)$_2$(dppf)] (1). Reaction with dppf. Synthesis of [Ag(O_2CCF_3)(dppf)]$_n$ (3): Ligand dppf (0.03 mL, 0.05 mmol) was added to a solution of **1** (0.050 g, 0.05 mmol) in CH_2Cl_2 (15 mL) and the mixture stirred for 3.5 h. The homogeneous product solution was then concentrated to ca. 1 mL, followed by addition of hexane (1.5 mL), whereupon an orange solid of [Ag(O_2CCF_3)(dppf)]$_n$ (**3**) (0.034 g, 88%) separated. $C_{72}H_{56}Ag_2F_6Fe_2O_4P_4$ (1550.6): calcd. C 55.8, H 3.6; found C 55.2, H 3.95. ^1H NMR ($CDCl_3$, 300 K): δ = 7.52 ($\nu_{1/2}$ ≈ 20 Hz, 8 H, Ph), 7.37 (centered m, 12 H, Ph), 4.34 and 4.25 (each s, $\nu_{1/2}$ ≈ 15 Hz, 4 H, C_5H_4) ppm. $^{31}P\{^1H\}$ NMR: δ = −1.5 ppm with sh at −3.0 (combined $\nu_{1/2}$ ≈ 600 Hz). ^{19}F NMR: δ = 1.2 ppm. FAB$^+$-MS: As in **2**. IR (KBr, cm^{-1}): ν_{CO_2}: 1662 s, 1435 m, 1200 vs, 1133 s; ν_{others}: 3081 wsh, 3051 w, 2960 w, 2923 w, 2863 vw, 1480 w, 1098 m, 1031 w, 836 w, 798 vw, 745 m, 722 vw, 696 s, 513 ssh, 487 sbr. Diffraction-quality crystals were obtained from CH_2Cl_2, layered with hexane, after 1 d at ambient temperature. The reaction was also monitored in an NMR tube in $CDCl_3$ at intervals up to 5.5 h. After 15 min, the proton spectrum showed two broad overlapping Cp signals centered at δ = 4.35 and 4.22 ppm, with a combined halfwidth of ca. 75 Hz. These sharpened with time and after 3.5 h were at δ = 4.34 and 4.25 ppm; these then remained unchanged up to 5 h. The ^{31}P signals varied from δ = −1.4 to −1.0 ppm (ca. 400 Hz), while the F signals were seen as overlapping singlets of equal intensity at δ = 1.3 and 0.9 ppm. These resonances did not appear in the region of those in the spectrum of **2**.

Reaction with PMe_2Ph: Ligand PMe_2Ph (0.04 mL, 0.26 mmol) was added to a solution of **1** (0.05 g, 0.05 mmol) in MeOH (15 mL). After stirring for 1 h, NH_4PF_6 (0.035 g, 0.21 mmol) was added. A bright yellow precipitate then began to separate, and the mixture was stirred for a further 30 min. The precipitate was filtered off and recrystallized from CH_2Cl_2/diethyl ether to give air-stable, non-light-sensitive yellow crystals of [Ag(dppf)(PMe_2Ph)$_2$]PF_6 (**4**) (25.8 mg, 48%). $C_{50}H_{50}AgF_6FeP_5$·H_2O (1101.6): calcd. C 54.5, H 4.8; found C 54.2, H 4.8. ^1H NMR ($CDCl_3$): δ = 7.60−7.81 (Ph), 4.68, 4.56, 4.03 (C_5H_4), 1.82 (d, *J* = 13 Hz, P*Me*$_2$Ph) ppm. $^{31}P\{^1H\}$ NMR: δ = 39.8 and 3.9 (dppf), −5.5 (PMe_2Ph), −144 (sept) ppm. ESI$^+$-MS: *m*/*z* = 1216 [M + PMe_2Ph]$^+$, 798 [M − PMe_2Ph]$^+$, 661 [M − 2 PMe_2Ph]$^+$. IR (Nujol, cm^{-1}): ν_{PF_6}: 840 and 556. Single diffraction-quality crystals were obtained by recrystallization in MeOH/diethyl ether (1:4) after 1 d at −30 °C.

Variable-Temperature (VT) NMR Spectra: ^1H, $^{31}P\{^1H\}$ and ^{19}F VT NMR spectra obtained for complexes **1**−**3** are described in the Results and Discussion section.

Crystal Structure Determinations: Crystals were mounted on quartz fibers. X-ray data were collected with a Bruker AXS SMART CCD diffractometer, using Mo-K_α radiation (λ = 0.71073 Å) at 223 K (for **1**−**3**) or 293 K (for **4**) (Table 7).The program SMART[21] was used to collect the intensity data, indexing and determination of lattice parameters, SAINT[22] was used to integrate the intensity of reflections and scaling, SADABS[21] was used for absorption correction and SHELXTL[23] for space group and structure determination and least-squares refinements against F^2. The structure was solved by direct methods to locate the heavy atoms, followed by difference maps for the light, non-hydrogen atoms. Cp and Ph hydrogen atoms were placed in calculated positions. For **1A**, the crystal was modeled as a racemic twin. The CF_3 groups were treated as disordered over two alternative sites with equal occupancies; the two sites were symmetry-related. C−F and F···F distances were restrained to be equal, and the F atoms were given individual isotropic thermal parameters. There was a half molecule of THF disordered about a twofold axis. This was modeled over two alternative sites of equal occupancies with the oxygen and two carbon atoms common; all the carbon atoms were given a common isotropic thermal parameter, with that for the oxygen at 1.1 times that of the carbon atoms. Appropriate restraints were placed to keep the geometry reasonable. For **2**, the $CHCl_3$ solvent molecule was modeled as disordered over two sites; occupancies were refined and summed to unity. C−Cl and Cl···Cl distances were restrained to be equal. Anisotropic thermal parameters for each Cl atom were paired with that of the alternative site. For **3**, the CF_3 groups were treated as disordered over two alternative sites with equal occupancies; the two sites were symmetry-related. C−F and F···F distances were restrained to be equal, and atoms were given isotropic thermal parameters. Crystal data and refinement parameters are given in Table 7. Selected bond lengths and angles for **1A/1B**, **2**, **3** and **4** are in Tables 1, 3, 4 and 6, respectively. Hydrogen bonds and angles of **1A/1B** and **3** are in Tables 2 and 5, respectively. CCDC-193074 to -193076 and -215390 to -215391 for complexes **1B**, **3**, **1A**, **2** and **4**, respectively contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cam-

A Water-Soluble Calix[4]arene-Based Podand Incorporating 4,4′-Dicarboxy-2,2′-bipyridine Chelating Units − Synthesis and Complexation Properties towards Copper Ions

Nicolas Psychogios,[a] Jean-Bernard Regnouf-de-Vains,*[a] and Helen M. Stoeckli-Evans[b]

Keywords: Calix[4]arene / Bipyridine / Podand / Copper / Zinc

A water-soluble calix[4]arene-based podand has been prepared by incorporation, at the lower rim, of two 4,4′-dicarboxy-2,2′-bipyridine units in opposite positions. The association between its coordination and hydrophilic properties were beneficial to the complexation and solubilization of copper(I) in water, even in the presence of bovine serum albumin. The ligand and its corresponding Cu^{I} complex have been fully characterized, but attempts to crystallize them have been unsuccessful so far. For this reason, the dinuclear $ZnCl_2$ complex of the organic solvent soluble tetraester intermediate has been crystallized, and subjected to X-ray diffraction analysis, confirming the expected podand-like structure of the ligand.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The transition from organic to aqueous solubility of the calixarenes, and their corresponding properties, is gaining attention as demonstrated by a rapid on-line survey on *water-soluble calixarenes*, and recent review literature.[1] The introduction of carboxylic acid functionalities at the lower[2] and upper rims,[3,4] or sulfonyl,[5,6] phosphonate,[7] and alkylamino groups[8] at the upper rim have been the main routes for making calixarenes water soluble. Many structural modifications have been carried out on these water-soluble structures, leading to new ligands for various metal cations.

With the aim of conducting, in water, some complexation experiments, that we have previously developed with lipophilic calixarene-based heterocyclic podands,[9−17] and in anticipation of future biological investigations, we attempted to synthesize a hydrophilic ligand able to complex the relatively unstable Cu^{I} cation in this medium. A number of very rare examples of water-soluble copper(I) coordination complexes have been described involving a sulfonated phosphane ligand,[18] or calix[6]-[19] and calix[4]arene[20−22] heterocyclic derivatives illustrating, in part, the difficulty of protecting this cation from disproportionation in water, and thus limiting investigations on its properties in aqueous media. The fact that the copper(I) complexes are diamagnetic and colored (metal-to-ligand charge transfer band at ca. 450 nm) should allow a convenient analysis of the complexation processes by NMR and UV spectroscopy.

In this report, we describe (a) the multi-step synthesis of the water-soluble calix[4]arene-based heterocyclic podand **6** in which the 2,2′-bipyridine arms exhibit both chelating and hydrophilic behavior, (b) its complexation properties towards Cu^{I} and Cu^{II} ions in water, and (c) the synthesis and characterization of the copper(I) complex **7**. Attempts to obtain crystals of **6** and **7** suitable for X-ray analysis did not succeed, but were successful for the dinuclear $ZnCl_2$ complex of the organic-solvent soluble tetraester intermediate **4**, allowing a preliminary structural investigation.

Results and Discussion

Ligand Syntheses

The calixarene podand species **4**−**7** were prepared according to Scheme 1. The starting calix[4]arenetetrol was synthesized as described previously.[23−26]

The bipyridine arms were introduced to the calixarene platform via the bromomethyl intermediate **3**, which was prepared according to Scheme 2 The starting bipyridine **1** was prepared following the Ni^{0}-mediated procedure of Alpha et al.,[27] from methyl 2-methyl-6-[(*p*-tolylsulfonyl)oxy]-pyridine-4-carboxylate. For the latter, the toxic and expensive pyridine generally used as base and solvent for the tosylation reaction was replaced by triethylamine and

CH_2Cl_2.[28] This safe and economical procedure afforded the tosyl derivative in a yield of 90%.

The introduction of a single active bromomethyl functionality at the 6-position of **1** was performed via a three step process including a controlled *N*-oxidation, a Boeckelheide rearrangement, and a *pseudo*-halogen exchange. Compound **1** was initially treated in CH_2Cl_2 with 1 equiv. of *m*CPBA at 0 °C, then at room temperature to afford the mono-*N*-oxide **2**, mixed with ca. 5% of the corresponding di-*N*-oxide, and ca. 5% of unchanged bipyridine **1**. An analytical sample of **2** was obtained by chromatography on Al_2O_3 (CH_2Cl_2) but, unstable on this support, and in order to avoid dismutation, the above-mentioned raw mixture was frozen or directly transformed.

The second step was a modified Boekelheide rearrangement. This process initially described with picoline *N*-oxides[29−30] allows the functionalization, by an active carbonyl compound via a radical or ionic mechanism, of the methyl group in the α-position of the *N*-oxide function. With acetic anhydride, this leads to an acetate-protected hydroxymethyl functionality, a key compound for further transformations. This reaction was employed successfully to prepare more sophisticated activated heterocyclic systems, notably with 6,6′-dimethyl-2,2′-bipyridine and its analogues.[27,31−35]

The presence of the two ester functions in **1**, both of which are prone to hydrolysis, led us to employ a more sensitive pathway involving a labile trifluoroacetate derivative, which exhibits, in the alkyl[36] and arylalkyl series,[32,34] the interesting characteristic of being directly substituted by bromine in polar aprotic solvent, and at room temperature via a pseudo-halogen exchange with LiBr.

Thus, the raw mono-*N*-oxide **2** was heated to reflux in CH_2Cl_2 in the presence of an excess of trifluoroacetic anhydride. After evaporation of the solvent the solid residue, which contains the dimethyl 6-trifluoroacetyl-6′-methyl-2,2′-bipyridine-4,4′-dicarboxylate, was dissolved in dry DMF and dry THF in the presence of an excess of anhy-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

drous LiBr, itself dried under vacuum at 150 °C. The resultant monobromide **3** was obtained pure in a yield of 55%. The dibromomethyl analogue[27] was also isolated in a yield of 12%, and the bipyridine **1** (ca. 15%) was recovered. Their formation was explained by the partial dismutation of **2** under the given conditions of the reaction.[35]

A similar but longer process involving the consecutive formation of the trifluoroacetate, the alcohol, the mesylate, and then the bromide was also described for the *tert*-butyl ester analogue of **3**,[37] as well as another procedure involving a radical bromination.[38]

Following the procedure previously reported by Beer et al.[39] for the unsubstituted bipyridine, the monobromide **3**, calix[4]arenetetrol, and K_2CO_3 were heated to reflux in MeCN to give the podand **4** in a yield of 83% after chromatography (SiO_2, CH_2Cl_2). The four ester functions of **4** were saponified in an aqueous alcoholic NaOH solution at reflux. Acidification to pH 3−4 resulted in the precipitation of the tetraacid **5**, which was recovered in a yield of 80%. A controlled neutralization of **5** with NaOH afforded the tetrasodium carboxylate **6** in almost quantitative yield (Scheme 1).

Complexation Studies

The formation of the copper(I) complex **7** was initially studied by UV-visible spectroscopy in water (Figure 1). The addition of $[Cu(MeCN)_4]PF_6$ to a solution of **6** resulted in the immediate appearance of the expected MLCT band at 470 nm (red color), characteristic of tetrahedral copper(I) complexes. The evolution of this band, as well as the new ligand-centered band at ca. 300 nm, was complete upon addition of 1 equiv. of metal, confirming the formation of a mononuclear complex.

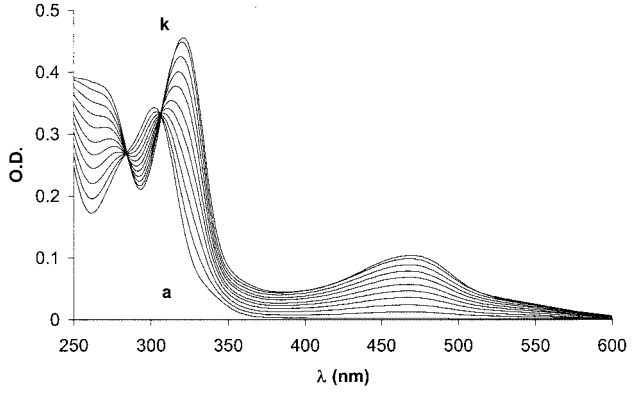

Figure 1. UV-visible titration of **6** with $[Cu(MeCN)_4]PF_6$: a) **6**, [2 mL; 1.71×10^{-5} M in H_2O]; from b) to k): addition of 1 equiv. of $[Cu(MeCN)_4]PF_6$ [$10 \times 4\mu L$; 9.98×10^{-4} M in MeCN]

The air-stable red complex **7** was prepared quantitatively by addition of 1 equiv. of $[Cu(MeCN)_4]PF_6$ in acetonitrile to an aqueous solution of **6**, followed by evaporation to dryness. Attempts to crystallize **7** for an X-ray structural analysis were unsuccessful.

Since the redox properties of copper are favorable for the doubly charged species, we have followed the complexation of $CuCl_2$ by UV-visible spectroscopy in water (Figure 2). The presence of two isosbestic points at 304 nm (0 to 1 equiv.) and 316 nm (1 to 2 equiv.) revealed the formation of two consecutive complex species, namely [$CuCl_2$/**6**] and [$(CuCl_2)_2$/**6**]. In order to prepare a sample of the corresponding final complex, the addition of 2 equiv. of $CuCl_2$ in water to an aqueous solution of **6** resulted in a brown-green coloration, nevertheless immediately followed by formation of a gel then precipitation. The solvent was removed by filtration and the residue was dried under high vacuum to give **8** as a green-brown powder. Surprisingly, the solid thus obtained remained insoluble in common solvents, even in DMSO. This behavior led us to believe that the water solubilizing carboxylate groups were in fact engaged in a chelating interaction with copper(II), giving oligomeric or polymeric chelate species resulting in loss of solubility of the material. No relevant mass analysis has been obtained.

An elemental analysis of the copper(II) complex **8** was consistent with the formula $C_{56}H_{40}ClCu_2N_4NaO_{12}\cdot 4.5H_2O$, corresponding to the loss of 3 equiv. of NaCl thus suggesting an ionic interaction between copper and the carboxylate groups. Such an interaction should involve a bridging mode of the copper ions between two calixarene moieties, in a linear polymeric network. Nevertheless, IR spectroscopy (KBr) did not show relevant modifications in the carbonyl region with regards to the ligand **6**. Attempts to improve this structure are under current investigation.

The bimetallic copper(II) complex [$(CuCl_2)_2 \subset$ **6**] formed during the UV titration experiment was subjected to reduction by ascorbate (Figure 3). The complex was fully reduced after the addition of 0.5 equiv. of ascorbate, as deduced by the appearance of the expected MLCT band at 470 nm, characterized by an ε value of 5500 $mol\cdot L^{-1}\cdot cm^{-1}$, similar to that of complex **7**. The addition of more ascorbate did not result in any further change in the absorption pattern.

In order to make a biological assessment of the complex **7**, competition experiments with bovine serum albumin were monitored by UV-visible spectroscopy (Figure 4). The results show that the presence of 1 equiv. or 10 equiv. of BSA relative to **7** did not change the absorption profile of the latter, the MLCT band being conserved even after 24 or 48 hours. Under the same conditions, the copper(I) complex of the corresponding free bipyridine decomposed. In parallel, we have verified that no absorption band of the MLCT type was generated by the interaction between BSA and $[Cu(MeCN)_4]PF_6$. This confirmed that the copper(I) ion is strongly maintained in a tetrahedral coordination by **6** under these conditions.

In contrast to, a similar test carried out with [$(CuCl_2)_2 \subset$ **6**] (Figure 5) resulted in the loss of the ligand-centered band at 322 nm, which was concomitant with the appearance of a new band at 312 nm (1 equiv. BSA), the latter being found again as a shoulder with 10 equiv. of BSA. After 1 day, the absorption pattern was found to be similar to the free ligand **6** ($\lambda_{max.}$ = 304 nm). No specific absorption bands were observed during the reaction between BSA and $CuCl_2$.

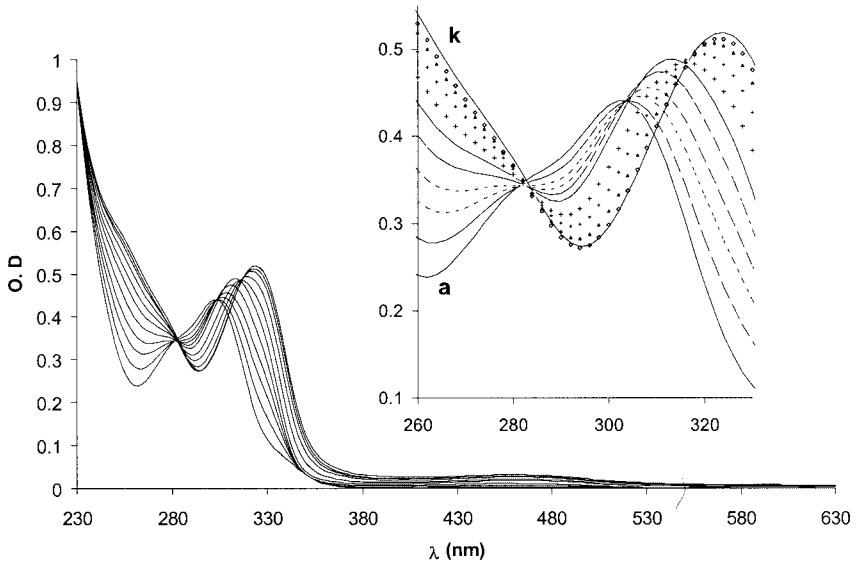

Figure 2. UV-visible titration of **6** by $CuCl_2{\cdot}2H_2O$: a) **6**, [2 mL; 2.0×10^{-5} M in H_2O]; from b) to k): addition of 2 equiv. of $CuCl_2{\cdot}2H_2O$ [10×8 μL; 1.00×10^{-3} M in H_2O]

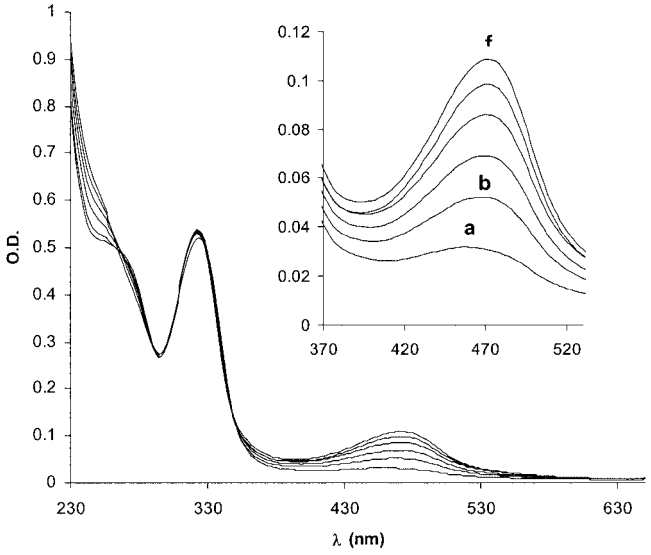

Figure 3. UV-visible titration of [$(CuCl_2)_2 \subset$ **6**] by ascorbic acid: a) [$(CuCl_2)_2 \subset$ **6**], [2 mL; 2.0×10^{-5} M in H_2O]; from b) to f): addition of 0.5 equiv. of ascorbic acid [5×4μL; 1.00×10^{-3} M in H_2O]

Compounds **2**−**7** gave satisfactory elemental, IR, MS and NMR analyses.

In particular, a preliminary elemental analysis performed on **6** dried with P_2O_5 showed the presence of 2 molecules of NaCl and 3 molecules of H_2O, but the instability of the mass during the weighing process suggested logically that **6** was hygroscopic. After equilibration under ambient conditions, the analysis of **6** was consistent with the presence of 2 molecules of NaCl and 6 molecules of H_2O. Argon plasma emission spectrophotometric analyses were consistent with the presence of 5 sodium ions for one ligand **6**, 5 sodium, and 1 copper ion for one complex **7**. Dialysis experiments performed with cellulose ester membranes (cut-off mol. wt. = 100) on aqueous solutions of **6** and **7** did not result in satisfactory removal of sodium chloride, the residual solutions giving precipitates of silver chloride upon addition of silver nitrate. Attempts to evaluate the water content in **6** and **7** by mass-coupled thermogravimetric analysis were not successful, the loss of water being observed over a wide range of temperatures (20−250 °C). Nevertheless, **6** showed a clean loss of four CO_2 molecules between 420 and 540 °C.

NMR Analyses

According to de Mendoza et al,[40,41] ^{13}C NMR spectroscopic analyses showed that **4**, **5** and **6** exist in the cone conformation.

The cone conformation of **6** was also demonstrated by ^1H NMR spectroscopy in D_2O, with the Ar-CH_2-Ar AB system located at δ = 3.18−3.96 ppm (J_{AB} = 15 Hz). 2D-COSY experiments allowed the full assignment of resonance signals. In the aromatic region, the ligand exhibits four perfectly well resolved bipyridyl singlets together with two doublets and two triplets for the calixarene moiety, which confirmed the expected structure. The terminal methyl groups and the methoxy linkers appear as singlets at δ = 2.53 and 5.33 ppm, respectively.

The ^1H NMR spectrum of the copper(I) complex **7** in D_2O (Figure 6) exhibits broad resonance signals in all the relevant frequency domains, except for the aromatic calixarene protons, which appear as well resolved doublets and triplets. The presence of more than the four expected bipyridyl resonance signals is in accordance with the probable presence of more than one species under these conditions. Addition of [D_6]DMSO to the aqueous solution resulted in the increasing of one of the signals, and a general sharpening of all signals. At the concentration used in the NMR experiments, it is possible to suggest that oligomeric or

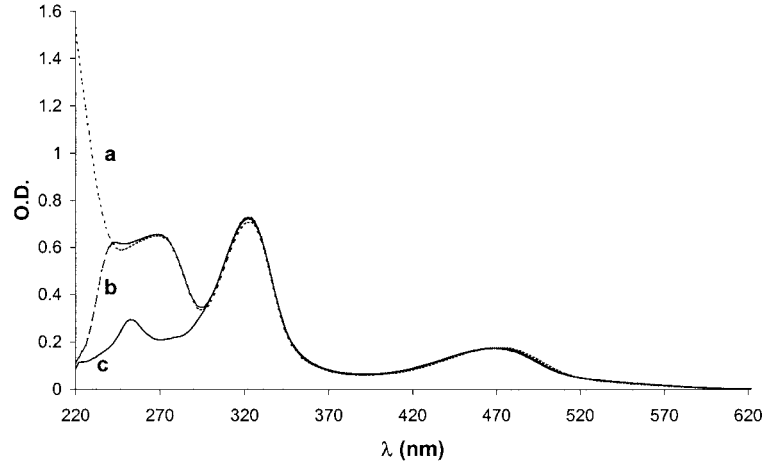

Figure 4. UV-visible analysis of **7** in the presence of bovine serum albumin: a) **7**, [1.6×10^{-5} M in H_2O]; b) 1 equiv. of BSA; c) 10 equiv. of BSA

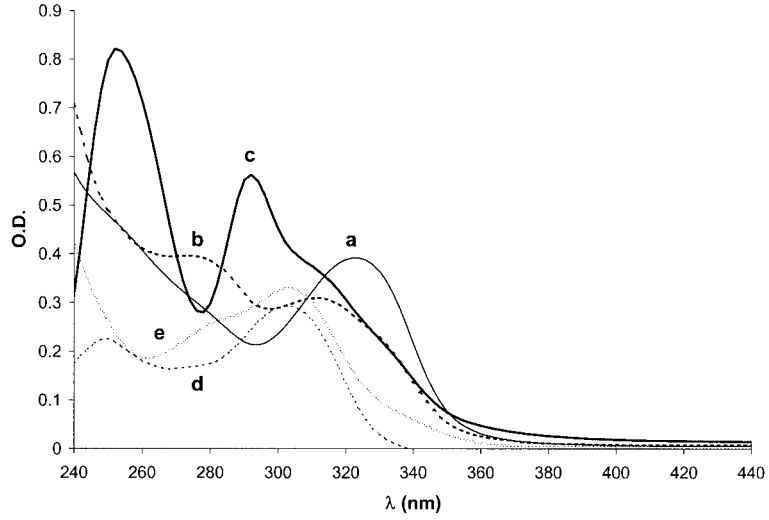

Figure 5. UV-visible analysis of [$(CuCl_2)_2 \subset$ **6**] in the presence of bovine serum albumin: a) [$(CuCl_2)_2 \subset$ **6**], [1.6×10^{-5} M in H_2O]; b) 1 equiv. of BSA; c) 10 equiv. of BSA; d) 10 equiv. of BSA, one day; e) **6** [1.6×10^{-5} M in H_2O]

polymeric complex species can be formed involving, due to the lack of steric hindrance at the upper rim, conic or non-conic calixarene platforms, that could correspond to the presence of multiple signals. The addition of DMSO may modify the solvation of these flexible species, resulting in the recovery of a conic conformer. Finally, pure [D_6]DMSO gave a well resolved NMR spectrum resulting in the presence of the expected cone conformer as the major compound with, notably, the presence of the four bipyridyl singlets, the aromatic succession of calixarene doublets and triplets, and the appearance of two AB systems at $\delta = 3.27$ and 4.24 ppm ($J_{AB} = 12$ Hz), and 5.31 and 6.27 ppm ($J_{AB} = 11$ Hz), which can be attributed to the Ar-CH_2-Ar and OCH_2-bpy spin systems, respectively. According to the results obtained with parent hydrophobic complexes ,[11,13] the presence of the Ar-CH_2-Ar AB system confirmed the cone conformation, and the OCH_2-bpy AB system confirmed the complexation of copper(I) in a prohelicoidal tetrahedral mode.

Mass Spectrometry

The mass analyses of ligand **6** and complex **7** were performed with the electrospray technique in the positive or negative mode. In the positive mode, **6** exhibited the mono-(sodium) and the doubly charged bis(sodium) derivatives at 1076.0 and 549.3 a.m.u. (base peak), respectively, accompanied by other entities, which were not well analyzed. Conversely, the negative mode analysis resulted in the exhibition of three groups of doubly charged (481.2, 492.2 and 503.2 a.m.u.), triply charged (327.8 and 320.5 a.m.u.), and tetra-charged (240.0 a.m.u.) species resulting from the loss of 2, 3 or 4 sodium ions compensated, when necessary, by replacement with 1 or 2 protons. The base peak appearing

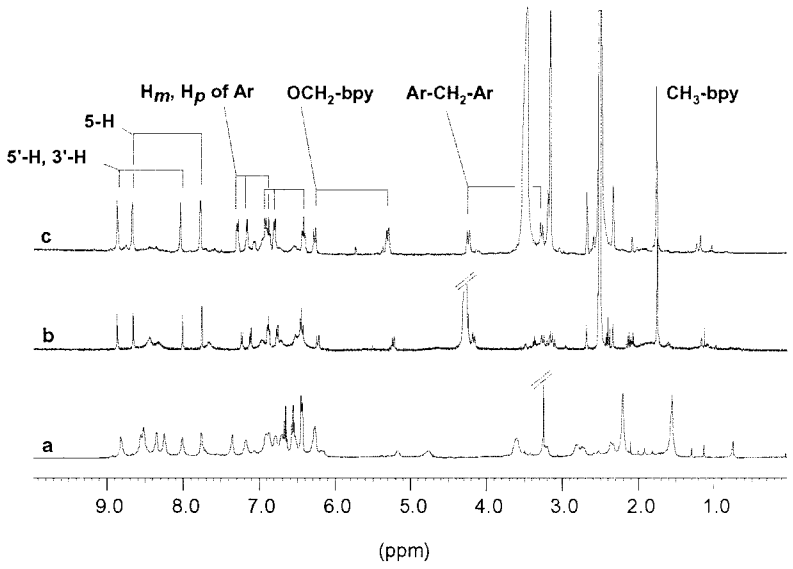

Figure 6. ^{1}H NMR spectrum of the copper(I) complex **7** (a: D_2O, b: D_2O + [D_6]DMSO, c: [D_6]DMSO; 400 MHz, room temp.)

in this case at 320.5 a.m.u. was attributed to the triply charged species [**6**−4Na^+ + H^+]$^{3-/3}$.

The copper(I) complex **7** gave no relevant information in the positive mode. In the negative mode, three groups of signals were observed. As for the ligand, the loss of 1, 3, and 4 sodium ions compensated by addition of protons when necessary, resulted in doubly charged species located at 544.1, 523.2, and 512.2 a.m.u. The loss of 4 sodium ions resulted in a triply charged species located at 341.3 a.m.u. Finally, the hexafluorophosphate anion appeared as a pure entity at 144.9 a.m.u. (base peak), and as an adduct with $NaPF_6$ at 312.9 a.m.u.

X-ray Crystallography

Attempts to obtain single crystals of the ligand **6**, its Cu^I complex **7**, and other transition metal complexes of **6** suitable for X-ray diffraction analyses were unsuccessful. In order to ascertain the podand structure, and considering that on the basis of NMR results, the general structure of **6** should not be different from the organic-solvent soluble tetraester intermediate **4**, we tried to prepare various metal complexes of the latter and good results were obtained with zinc(II). In particular, the reaction of **4** with $ZnCl_2$ gave the conic complex **9** which was characterized by 1D and 2D ^{1}H NMR spectroscopic experiments, mass spectrometry, and elemental analysis. Crystals of **9** suitable for X-ray diffraction analysis were obtained as yellow plates by slow diffusion of hexane into a dichloromethane solution of the complex.

Compound **9** crystallizes with 2 independent molecules, C and D, per asymmetric unit, hence the molecular formula is [Cl_2Zn**6**ZnCl_2]·2.25CH_2Cl_2.

The molecular structure without the solvent is illustrated in the PLATON[42] drawing (Figure 7) along with a partial crystallographic numbering scheme.

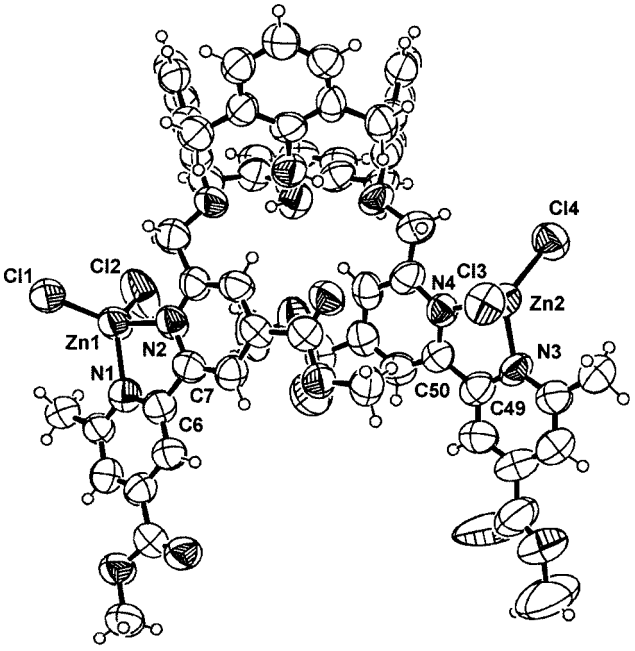

Figure 7. ORTEP side-view of complex **9**, molecule C

As expected, the calixarene subunit of **9** is in the cone conformation and substituted in alternate positions of the lower rim by two dimethyl 6-methyl-2,2′-bipyridyl-4,4′-dicarboxylate arms tethered to the platform by a 6′-methyleneoxy linker. Each bipyridyl unit coordinates via its nitrogen atoms to a tetrahedral Zn^{II} cation, with the two remaining coordination positions occupied by two chloride anions, as already observed.[43]

In the two independent molecules C and D, the [bpyZnCl_2] units are opposed to each other, facing outward

from the calixarene main axis, and orienting the chlorine atoms in the direction of the calixarene platform. A rotation of 90 ° around the C_2 axis shows that these two units are quasi parallel.

Looking more precisely at the complex subunits of molecules C and D, shows that the bipyridine units are planar, with N−C−C−N torsion angles between −4.9 and 6.5 ° (Table 1). The zinc(II) centers are in strongly distorted tetrahedral coordination environments, with N−Zn−N angles of ca. 80 °, Cl−Zn−Cl angles of ca. 120 °, and N−Zn−Cl between 106 and 119° (Table 2).

The Zn−N and ZnCl distances (Table 2) are consistent with those measured in a non-carboxylated analogue,[43] suggesting a poor influence of the electroactive ester substituents on the complex geometry.

Conclusion

A new water-soluble calix[4]arene-based bipyridyl podand **6** has been synthesized and subjected to complexation studies with copper(I) and copper(II) species in water. The copper(I) complex **7** exhibits considerable stability, even in the presence of bovine serum albumin, promising interesting behavior in biological media. It was fully characterized as a mononuclear species, involving probably a pro-helicoidal pseudo-tetrahedral complexation mode between the chelating bipyridines and the metallic center, as already observed for organic-solvent soluble analogues. No crystals of either water-soluble ligand **6** or the copper(I) complex **7** could be obtained, but the lipophilic tetra methyl ester intermediate **4** reacted with zinc(II) chloride to give a monocrystalline dinuclear complex **9** which was characterized by X-ray diffraction, thus confirming the expected podand-like structure of the ligand. The evaluation of the complexing ability of **6** with various transition metal cations in water and biological media, as well as their potent antimicrobial activities are under current investigation.

Experimental Section

General Remarks: Melting points (°C, uncorrected) were determined with an Electrothermal 9200 Capillary apparatus. ^{1}H, ^{13}C and ^{15n} NMR spectra were recorded with a Bruker DRX 400 (chemical shifts in ppm) instrument. Mass spectra (electronic ionization − EI, and electrospray − ES) were recorded with a Nermag R-1010C apparatus or a Micromass Platform II apparatus, respectively, at the Service Commun de Spectrométrie de Masse Organique, Nancy. Infrared spectroscopy was performed with a Mattson 5000 FT apparatus (KBr, $\tilde{\nu}$ in cm^{-1}) and UV spectra were recorded using a SAFAS UV mc^2 apparatus, $\lambda_{max.}$ in nm, ε in $dm^3 \cdot mol^{-1} \cdot cm^{-1}$. Elemental analyses were performed at the Service de Microanalyse, Nancy. Merck TLC plates were used for chromatographic analyses (SiO_2, ref 1.05554; Al_2O_3, ref 1.05581). Sodium and copper concentrations were determined by argon plasma emission spectrophotometry on a Spectrascan 7 Spectrametrics apparatus. Mass-coupled thermogravimetric analyses were performed with a Netzch STA 409 C apparatus.

All commercially available products were used without further purification unless otherwise specified.

***N*-Oxide 2:** To a solution of dimethyl 6,6′-dimethyl-2,2′-bipyridine-4,4′-dicarboxylate (**1**) (1 g, 3.30 mmol) in CH_2Cl_2 (20 mL) at 0 °C under argon, was added dropwise a solution of *m*-chloroperbenzoic acid (0.685 g, 3.96 mmol; from 0.975 g of 70% commercial

*m*CPBA) in CH_2Cl_2 (10 mL). The mixture was then stirred at room temp. for 2.5 h (TLC monitoring; Al_2O_3, CH_2Cl_2/hexane, 90:10). The solvent was evaporated to dryness at 25 °C, and the residue was triturated with Et_2O to remove *m*CBA and unchanged *m*CPBA. The resultant solid, which contained 90% of the mono *N*-oxide, traces of di-*N*-oxide, and unchanged bipyridine was retained at −20 °C. (1.025 g). A small analytical sample of **2** was obtained by rapid chromatography (Al_2O_3; CH_2Cl_2). ^{1}H NMR ($CDCl_3$): δ = 2.62 (s, 3 H, *Me*bpy), 2.74 (s, 3 H, *Me*bpy), 3.98 (s, 3 H, COO*Me*), 3.99 (s, 3 H, COO*Me*), 7.82 (s, 1 H), 7.94 (d, *J* = 2.7 Hz, 1 H), 8.61 (d, *J* = 2.7 Hz, 1 H), 9.05 (s, 1 H) (3-H, 3′-H, 5-H, 5′-H) ppm. ^{13}C NMR ($CDCl_3$): δ = 18.80 (*Me*bpy), 24.99 (*Me*bpy), 53.22 (−O*Me*), 122.00, 123.75, 126.00, 126.38 (C3, C3′, C5, C5′), 125.74, 138.45, 147.61, 150.53, 150.77, 159.82 (C2, C2′, C4, C4′, C6, C6′), 164.96, 166.11 (*C*OOMe) ppm. $C_{16}H_{16}N_2O_5$·0.1H_2O (318.11): calcd. C 60.41, H 5.13, N 8.80; found C 60.17, H 4.98, N 8.57.

Bromide 3: Compound **2** (1 g, 5.0 mmol) was dissolved at room temp. in dry CH_2Cl_2 (10 mL), and trifluoroacetic anhydride (10 mL) was added. The solution was brought to reflux under argon over 1.5 h, during which time it became orange. The solvents were then evaporated to dryness. The raw material containing the trifluoroacetic ester was dissolved at room temp. in a 1:1 mixture of dry DMF and dry THF (15 mL), then anhydrous LiBr (2 g, 23 mmol, dried at 180 °C over 1 h) was added. The resultant yellow mixture was stirred under argon for 4 h (TLC monitoring, SiO_2, CH_2Cl_2), and the solvents were evaporated to dryness (2 torr, 70 °C). The residue was washed with water (3 × 20 mL) then chromatographed (SiO_2, CH_2Cl_2) to give the monobromide **3** (1 g, 55%), the dibromide (0.25 g, 12%), and unchanged **1**. White powder, m.p. 160−162 °C. IR: ṽ = 1565.8 (C=N), 1731.3 (COOMe). UV-vis (CH_2Cl_2): λ = 310 nm (16700). ^{1}H NMR ($CDCl_3$): δ = 2.75 (s, 3 H, *Me*bpy), 4.02 (s, 3 H, COO*Me*), 4.03 (s, 3 H, COO*Me*), 4.72 (s, 2 H, C*H*$_2$Br), 7.79 (d, *J* = 0.5 Hz, 1 H), 8.06 (d, *J* = 1.1 Hz, 1 H), 8.79 (d, *J* = 0.5 Hz, 1 H), 8.91 (d, *J* = 1.3 Hz, 1 H, 3-H, 3′-H, 5-H, 5′-H) ppm. ^{13}C NMR ($CDCl_3$): δ = 24.99 (*Me*bpy), 33.78 (Br*C*H$_2$), 53.12, 53.25 (O*Me*), 118.25, 120.32, 123.37, 123.46 (C3, C3′, C5, C5′), 139.16, 140.63, 155.83, 157.02, 157.97, 159.75 (C2, C2′, C4, C4′, C6, C6′), 165.79, 166.38 (*C*OOMe) ppm. MS (EI): *m*/*z* = 380−378 [**3**]$^+$, 322−320 [**3** − COOMe]$^+$; 299 [**3** − Br]$^+$. $C_{16}H_{15}BrN_2O_4$·0.1CH_2Cl_2 (387.7): calcd. C 49.88, H 3.95, N 7.23; found C 50.00, H 3.95, N 7.23.

Calixarene Tetraester 4: A suspension of calix[4]arene (1 g; 2.35 mmol) and K_2CO_3 (0.305 g; 2.35 mmol) in anhydrous CH_3CN (50 mL) was heated to reflux under argon for 30 min. The bromide **3** (1.88 g; 4.95 mmol) was then added and reflux was continued for 4 h (TLC monitoring; SiO_2, CH_2Cl_2/MeOH, 95:5). The solvent was evaporated to dryness, and the residue was washed with Et_2O and water before being chromatographed (SiO_2, CH_2Cl_2) to give **4** (2 g; 83%). White powder, m.p. 268−270 °C (dec.). IR: ṽ = 1567.9 (C=N), 1732.1 (COOMe). UV (CH_2Cl_2): λ = 310 nm (23200). ^{1}H NMR ($CDCl_3$): δ = 2.77 (s, 6 H, *Me*bpy), 3.48−4.43 ("q", AB, J_{AB} = 13 Hz, 8 H, Ar-C*H*$_2$-Ar), 3.55 (s, 6 H, −O*Me*), 3.99 (s, 6 H, −O*Me*), 5.47 (s, 4 H, −OC*H*$_2$bpy), 6.71 (t, *J* = 7.4 Hz, 2 H, 4-H of Ar-OH), 6.86 (t, *J* = 7.8 Hz, 2 H, 4-H of Ar), 7.00 (d, *J* = 7.6 Hz, 4 H, 3-H and 5-H of Ar), 7.12 (d, *J* = 7.4 Hz, 4 H, 3-H and 5-H of Ar-OH), 7.77 (d, *J* = 1 Hz, 2 H, 3′-H or 5′-H of bpy), 8.18 (s, 2 H, ArO*H*), 8.71 (d, *J* = 1.0 Hz, 2 H, 5′-H or 3′-H of bpy), 8.84 (d, *J* = 1.1 Hz, 2 H, 3-H or 5-H of bpy), 9.12 (d, *J* = 1 Hz, 2 H, 5-H or 3-H of bpy) ppm. ^{13}C NMR ($CDCl_3$): δ = 25.04 (*Me*bpy), 31.98 (Ar-*C*H$_2$-Ar), 52.63 (−O*Me*), 53.05 (−O*Me*), 78.77 (−O*C*H$_2$bpy), 117.95, 119.50, 120.11, 121.98, 123.28, 126.24 (C3, C3′, C5, C5′ of bpy, C_p of Ar), 128.98, 129.69 (C_m of Ar), 128.12, 133.52, 139.06, 139.82, 152.26, 153.88, 156.18, 156.25, 158.73, 159.82 (C2, C2′, C4, C4′, C6, C6′ of bpy; $C_{i,o,p}$ of Ar), 165.58, 166.43 (*C*OOMe) ppm. Calixarene Tetraacid 5 and Calixarene Tetraacid Sodium Salt 6: A suspension of **4** (1 g; 0.98 mmol) in a solution of NaOH (0.4 g; 10 mmol) in MeOH (110 mL) and H_2O (90 mL) was heated to reflux under argon for 24 h. After cooling to room temp., the solution was acidified to pH 3−4 with 1 M HCl. The resultant precipitate of tetraacid **5** was filtered, washed with H_2O (4 × 30 mL), then dispersed in H_2O (50 mL) and dissolved by careful addition of 1 M NaOH up to pH 7.0. The resultant solution was evaporated to dryness to give **6** (0.97 g; 80%). **6:** White powder, m.p. 270−280 °C (dec.). IR: ṽ = 1555.8 (C=N), 1604.3 (COONa). UV (H_2O): λ = 302 nm (21600). ^{1}H NMR (D_2O): δ = 2.54 (s, 6 H, *Me*bpy), 3.18−3.96 ("q", J_{AB} = 15 Hz, 8 H, Ar-C*H*$_2$-Ar), 5.34 (s, 4 H, −OC*H*$_2$bpy), 6.41 (t, *J* = 7.5 Hz, 2 H, 4-H of Ar1), 6.63 (d, *J* = 7.4 Hz, 4 H, 3-H and 5-H of Ar1), 6.66 (t, *J* = 7.4 Hz, 2 H, 4-H of Ar2), 7.03 (d, *J* = 7.7 Hz, 4 H, 3-H and 5-H of Ar2), 7.53 (s, 2 H, 3′-H or 5′-H of bpy), 7.65 (s, 2 H, 5′-H or 3′-H of bpy), 7.96 (s, 2 H, 3-H or 5-H of bpy), 8.22 (s, 2 H, 5-H or 3-H of bpy) ppm. ^{13}C NMR (D_2O): δ = 23.29 (*Me*bpy), 30.79 (Ar-*C*H$_2$-Ar), 78.25 (−O*C*H$_2$), 119.24, 120.59, 121.68, 123.32, 124.07, 126.18 (C3, C3′, C5, C5′ of bpy; C_p of Ar), 128.46, 133.71 ($C_o$of Ar), 129.40 ($C_m$of Ar), 147.49, 147.64, 150.87, 152.09, 155.42, 156.00, 156.38, 159.68 (C2, C2′, C4, C4′, C6, C6′ of bpy; C_p of Ar), 172.93, 173.60 (COO^-) ppm. ES-MS: (positive mode, 30 V): *m*/*z* = 1075.98 [**6** + Na^+]$^+$, 549.27 [**6** + 2 Na^+]$^{2+/2}$; (negative mode, 20 V): *m*/*z* = 503.24 [**6** − 2 Na^+]$^{2-/2}$, 492.23 [**6** − 3 Na^+ + H^+]$^{2-/2}$, 481.22 [**6** − 4 Na^+ + 2 H^+]$^{2-/2}$, 327.87 [**6** − 3 Na^+]$^{3-/3}$, 320.53 [**6** − 4 Na^+ + H^+]$^{3-/3}$, 240.04 [**6** − 4 Na^+]$^{4-/4}$. $C_{56}H_{40}N_4Na_4O_{12}$·2NaCl·6$H_2O$ (1277.87): calcd. C 52.63, H 4.10, N 4.38; found C 52.88, H 3.82, N 4.24.

A solution of **6** (0.925 g, 0.724 mmol) in water (50 mL) (pH = 7.38) was carefully acidified to pH = 3.11 with 1 M HCl. The resultant yellow suspension was washed with CH_2Cl_2 (4 × 30 mL) before the residual organic solvent was removed under vacuum. The yellow precipitate was filtered off, washed with H_2O, CH_3OH and CH_2Cl_2, then dried under vacuum. (**5**; 0.65 g, 93%). M.p. 235 °C (dec.). IR: ṽ = 1568.1 (C=N), 1720.6 (COOH). ^{1}H NMR ([D$_6$]DMSO): δ = 2.67 (s, 6 H, *Me*bpy), 3.48−4.27 ("q", J_{AB} = 13 Hz, 8 H, Ar-C*H*$_2$-Ar), 5.41 (s, 4 H, C*H*$_2$O), 6.61 (t, *J* = 7.5 Hz, 2 H, H_p of Ar), 6.86 (t, *J* = 7.5 Hz, 2 H, H_p of Ar), 7.09 (d, *J* = 7.6 Hz, 4 H, $H_m$of Ar), 7.17 (d, *J* = 7.6 Hz, 4 H, $H_m$of Ar), 7.73 (d, *J* = 1 Hz, 2 H), 8.47 (s, 2 H), 8.62 (s, 4 H), 8.93 (s, 2 H, 3-H, 3′-H, 5-H, 5′-H of bpy and ArO*H*) ppm. ^{13}C NMR ([D$_6$]DMSO): δ = 25.03 (*Me*bpy), 31.59 (Ar-*C*H$_2$-Ar), 78.78 (−O*C*H$_2$), 118.02, 119.64, 119.81, 122.61, 123.74, 126.50 (C3, C3′, C5, C5′ of bpy, C_p of Ar), 128.13, 134.43 (C_o of Ar), 129.46, 129.99 (C_m of Ar), 140.49, 140.91, 152.75, 153.87, 155.77, 155.86, 158.79, 159.89 (C2, C2′, C4, C4′, C6, C6′ of bpy; C_{ipso} of Ar), 166.65, 167.19 (COOH) ppm. ES-Ms (pos. mode): *m*/*z* = 965.35 [**5** + H^+]$^+$, 483.30 [**5** + 2 H^+]$^{2+/2}$. $C_{56}H_{44}N_4O_{12}$·2.5H_2O (1010.01): calcd. C 66.59, H 4.89, N 5.55; found C 66.89, H 4.83, N 5.10.

Copper(I) Complex 7: A solution of [Cu(MeCN)$_4$]PF_6 (0.076 g, 0.205 mmol) in MeCN was added to a solution of **6** (0.3 g, 0.204 mmol) in H_2O (10 mL). The resultant deep red solution was stirred at room temp. for 10 min, and the solvents were evaporated to dryness to give **7** as a brown-red powder. (0.34 g, 100%). IR: ṽ = 855 (PF_6^-), 1555.4 (C=N), 1608.7 (COO^-). UV: λ = 320 (22780), 470 nm (5210; MLCT). ^{1}H NMR ([D$_6$]DMSO): δ = 1.76

(s, 6 H, *Me*bpy), 3.27−4.24 ("q", J_{AB} = 12 Hz, 4 H, Ar-CH_2-Ar), 5.31−6.27 ("q", J_{AB} = 11.0 Hz, 4 H, CH_2O), 6.42 (t, J = 7.0 Hz, 2 H, H_p of Ar1), 6.80 (d, J = 7.4 Hz, 2 H, H_m of Ar1), 6.87 (t, J = 7.0 Hz, 2 H, H_p of Ar2), 6.92 (d, J = 7.6 Hz, 2 H, H_m of Ar1), 7.16 (d, J = 7.0 Hz, 2 H, H_m of Ar2), 7.28 (d, J= 7.0 Hz, 4 H, H_m of Ar2), 7.78 (s, 2 H, 5-H or 3-H bpy), 8.04 (s, 2 H, 5′-H or 3′-H bpy), 8.67 (s, 2 H, 3-H or 5-H bpy), 8.87 (s, 2 H, 3′-H or 5′-H bpy) ppm. ES-MS (neg. mode, 30 V): m/z = 544.4 [**6** + Cu^+ − Na^+ − 2 H^+]$^{2-/2}$, 523.20 [**6** + Cu^+ − 3 Na^+]$^{2-/2}$, 512.19 [**6** + Cu^+ − 4 Na^+ + H^+]$^{2-/2}$, 341.25 [**6** + Cu^+ − 4 Na^+]$^{3-/3}$, 312.83 [$NaPF_6$ + PF_6^-]$^-$, 144.87 [PF_6^-]$^-$. $C_{56}H_{40}N_4Na_4O_{12}$·$CuPF_6$·NaCl·4$H_2O$ (1391.91): calcd. C 48.32, H 3.48, N 4.03; found C 48.18, H 3.71, N 4.00.

Copper(ii) Complex 8: A solution of ligand **6** (0.1 g; 0.0783 mmol) in H_2O (3 mL) was mixed with a solution of $CuCl_2(H_2O)_2$ (0.0267 g; 0.156 mmoles) in H_2O (2 mL) at room temp., resulting in the immediate formation of a green-brown gelatinous precipitate. The solvent was evaporated to dryness under high vacuum without heating. The resultant solid was then triturated with H_2O (3 × 2 mL) and filtered to give **8**. (0.094 g; 98%). Deep-brown solid. IR: $\tilde{\nu}$ = 1559.20 (C=N), 1611.12 (COO^-). $C_{56}H_{40}Cu_2ClN_4NaO_{12}$·4.5$H_2O$ (1227.54): calcd. C 54.79, H 4.02, N 4.56; found C 54.70, H 3.83, N 4.65.

Zinc(ii) Complex 9: A solution of ligand **4** (0.05 g; 0.045 mmol) in CH_2Cl_2 (5 mL) was mixed with $ZnCl_2$ (0.06 g; 0.44 mmol) at room temp. under Ar. The resultant solvents were evaporated to dryness, twice dissolved in CH_2Cl_2 and filtered then evaporated to dryness. The residue was dissolved in CH_2Cl_2 (5 mL) and precipitated in an excess of Et_2O to give **9** as a light yellow powder (0.056 g; 95%). UV: λ = 338 nm (34650). ^{1}H NMR (CD_2Cl_2): δ = 3.11 (s, 6 H, *Me*bpy), 3.57 (s, 6 H, COO*Me*), 3.67, 4.36 (AB, J_{AB} = 13.5 Hz, 8 H, Ar-CH_2-Ar), 4.14 (s, 6 H, COO*Me*), 5.83 (s, 4 H, OCH_2bpy), 6.77 (t, J = 7.4 Hz, 2 H, H_p of Ar1), 6.99 (t, J = 7.4 Hz, 2 H, H_p of Ar2), 7.12 (d, J = 7.6 Hz, 4 H, H_m of Ar2), 7.20 (d, J = 7.6 Hz, 4 H, H_m of Ar1), 7.90 (s, 2 H, O*H*), 8.24 (s, 2 H, 3-H or 5-H of Mepy), 8.77 (s, 2 H, 3-H or 5-H of OCH_2py), 8.89 (s, 2 H, 3-H or 5-H of CH_3py), 9.90 (s, 2 H, 3-H or 5-H of OCH_2py) ppm. ES-MS (pos. mode, 100 V): m/z = 1315.3 [**4** + 2 $ZnCl_2$ + Na^+]$^+$, 1257.3 [**4** + $ZnCl_2$ + ZnCl]$^+$, 1179.4 [**4** + $ZnCl_2$ + Na^+]$^+$, 1043.4 [**4** + Na^+]$^+$, base peak. $C_{60}H_{52}Cl_2N_4O_{12}Zn_2$ (1293.63): calcd. C 55.71, H 4.05, N 4.39; found C 55.76, H 4.08, N 4.37.

X-ray Crystallographic Study: The intensity data were collected at 153 K (−120 °C) with a Stoe Mark II-Image Plate Diffraction System[44] equipped with a two-circle goniometer using Mo-K_α graphite-monochromated radiation. Image plate distance 100 mm, ω rotation scans 0−180° at φ 0°, and 0−21° at φ 90°, step Δω = 1.2°, 2θ range 2.29−59.53°, $d_{max.} - d_{min.}$ = 17.799−0.716 Å.

The structure was solved by direct methods using the program SHELXS-97.[45] The refinement and all further calculations were carried out using SHELXL-97.[46] The H-atoms were either located from Fourier difference maps and refined isotropically or included in calculated positions, and treated as riding atoms using SHELXL default parameters. The non-H atoms were refined anisotropically, using weighted full-matrix least-squares on F^2.

An empirical absorption correction was applied using the DIFABS routine in PLATON.[42] Transmission factors $T_{min.}/T_{max.}$ were 0.091 and 0.550, respectively. A considerable amount of disordered solvent was present and the SQUEEZE routine in PLATON revealed the presence of 380 electrons for a volume of 1559 Å^3. This could be equated to 9 molecules of CH_2Cl_2 per unit cell and the *hkl* file was modified accordingly.

Details for the experimental conditions, cell data, structure, and refinement data are given in Table 3.

Complexation Properties of Ethylenediaminetetramethylenephosphonic Acid (EDTMP) with Al^{III} and $V^{IV}O$

Valerio Di Marco,[a] Melinda Kilyen,[b] Tamás Jakusch,[b] Péter Forgó,[c] György Dombi,[d] and Tamás Kiss*[b,e]

Keywords: Aluminum / Aminophosphonates / Bioinorganic chemistry / Speciation / Vanadium

The complexation properties (including stoichiometries and stability constants of the complexes formed) of ethylenediaminetetramethylenephosphonic acid with Al^{III} and $V^{IV}O$ were studied in aqueous solution at an ionic strength of 0.2 M KCl, at 25 °C by means of pH potentiometry. For Al^{III} both mononuclear ($AlLH_n$) and dinuclear (Al_2LH_n) species were found in solution, whereas for $V^{IV}O$ only mononuclear complexes were detected. For each metal ion, a solid complex was isolated at acidic pH and was characterized stoichiometrically. ^1H and ^{31}P NMR (for Al^{III}), UV/Vis and EPR (for $V^{IV}O$) spectra were used to confirm the potentiometric results and to suggest the most probable binding mode of the complexes formed in solution.

Introduction

Al^{III} is a toxic metal ion for living organisms. In many cases, the biological mechanism of its toxicity is well documented and includes enzyme inhibition, nucleotide destruction and mineral formation.[1] These effects are the results of a complicated chain of reactions involving the relatively unexplored chemical interactions of the metal ion with the relevant biomolecules.

Vanadium is a trace element and is beneficial for living organisms. Its most important oxidation states are +4 and +5, and some vanadium compounds have promising insulin-mimetic properties both in vitro and in vivo.[2,3] As for aluminium, the molecular action of vanadium is still not well known.

The complexation properties of ethylenediaminetetramethylenephosphonic acid (EDTMP, Figure 1) with metal ions allow its use as a valuable model for an understanding of their interactions with more complicated biomolecules containing the same amino and phosphonate moieties. EDTMP complexes with a number of metal ions have been studied;[4–13] almost exclusively divalent metal ions were considered: Mg^{II}, Ca^{II}, Sr^{II}, Ba^{II}, Mn^{II}, Fe^{II}, Co^{II}, Ni^{II}, Zn^{II}, Cd^{II}, Cu^{II} and Pb^{II}. In a few cases, trivalent cations were also studied (e.g. Sm^{III} and Ho^{III} by Jarvis et al.[11]) because of the use of EDTMP–lanthanide complexes as therapeutic radiopharmaceuticals. Fe^{III}–EDTMP complexes have been investigated by Westerback et al.,[7] Motekaitis et al.[9] and Oakes et al.,[14] but only in a qualitative way, with no reports of any definite data. In a recent paper, Popov et al.[15] reported a critical evaluation of the proton- and metal-complexation stability constants to be found in the literature up to 2000 for various aminophosphonic acids.

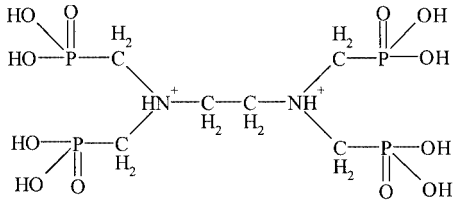

Figure 1. EDTMP in its fully protonated form ($H_{10}L^{2+}$)

In the present paper, Al^{III}–EDTMP and $V^{IV}O$–EDTMP interactions were examined by means of pH-potentiometric titrations and independent spectroscopic techniques.

Results and Discussion

Acidity Constants of EDTMP

In principle EDTMP is a decaprotic acid (see Figure 1). Ichikawa et al. proposed the following deprotonation sequence for the fully protonated cation $H_{10}L^{2+}$: seven phosphonic protons, the first ammonium proton, the eighth phosphonic proton and the second ammonium proton.[16] Table 1 summarizes the pK_a values obtained from our potentiometric titrations. The pK_a for the species H_nL refer to the equilibrium $H_nL^{n-8} \rightleftarrows H_{n-1}L^{n-9} + H^+$. Under the experimental conditions used in our study, six of the possible ten proton dissociations could be detected. The first three pK_a values could not be measured in water because they are too low, while the last pK_a could not be measured because it is too high.[15]

Table 1. Acidity constants (pK_a ± 3 standard deviations) for EDTMP at 25 °C and I = 0.2 M KCl

Species	pK_a
H_7L^-	(1.16 ± 0.12)
H_6L^{2-}	2.80 ± 0.05
H_5L^{3-}	5.00 ± 0.03
H_4L^{4-}	6.24 ± 0.02
H_3L^{5-}	7.72 ± 0.02

[a] Goodness of the fit between the experimental and the calculated titration curves expressed in mL of the titrant.

Our results are in reasonable agreement with most of the data obtained in previous studies, as listed in Table 2. The only important difference was that in all the previous papers a pK_a value for HL^{7-} was also given, even if sometimes with very high uncertainty. The recent IUPAC critical compilation[15] suggests a provisional value for this protonation process, pK(HL) = 13.8 (see Table 2). We attempted to refine our data in light of these results, but it was not possible to obtain a reliable value for this very high pK_a. To achieve this, the ligand should be applied in a high concentration at pC = pK_w − pK_a + 0.5.[20] However, in this case the ionic strength could not be kept constant in the sample during the titration, and thus the pK_a value could be determined only with a rather high uncertainty. It is likely that an insufficient ligand concentration was the reason for our previous reporting of a pK_a value of 12.04.[17] Accordingly, we disregarded this last proton-dissociation process and considered HL^{7-} as the complex-forming species in the formation equilibrium $pM + qHL + rH \rightleftarrows M_pL_qH_{r+q}$. In this way, more accurate formation constants could be obtained, although their numerical values differed by the value of the last pK_a from those calculated in the usual way for the equilibrium $p\ M + q\ L + r\ H \rightleftarrows M_pL_qH_r$.

Al^{III} Complexes

The stability constants for the Al^{III}−EDTMP complexes, determined by potentiometric titration, are listed in Table 3.

Table 3. Stability constants (log β ± 3 standard deviations) for the Al^{III}−EDTMP complexes at 25 °C and I = 0.2 M KCl [the constants are calculated for the equilibrium: $p\ M + q\ HL + r\ H \rightleftarrows M_pL_qH_{r+q}$ (see text)]

ure 2. The accepted speciation model includes both mononuclear and dinuclear complexes, which predominated in the different pH ranges. In the pH range 11−7, only mononuclear species exist in solution: $[Al(OH)_4]^-$, $[AlLH_{-1}]^{6-}$, $[AlL]^{5-}$ and $[AlLH]^{4-}$. The most important Al^{III} complex is $[AlL]^{5-}$. It was initially expected that, at pH values lower than 6.5, other mononuclear species are formed. However, the best speciation model obtained with the assumption of mononuclear species only — $[AlLH_5]$, $[AlLH_4]^-$, $[AlLH_3]^{2-}$, $[AlLH_2]^{3-}$, $[AlLH]^{4-}$, $[AlL]^{5-}$ and $[AlLH_{-1}]^{6-}$ — had to be rejected because the fitting parameter was more than 70% poorer than the one reported in Table 3, obtained with the assumption of parallel-formed dinuclear complexes. The species detected at a pH below 6.5 are probably the dinuclear complexes $[Al_2LH]^-$, $[Al_2LH_2]$ and $[Al_2LH_3]^+$, although other oligonuclear complexes cannot be excluded. Although usually only mononuclear metal−EDTMP complexes have been detected so far,[4−13] it is noteworthy that dinuclear species have been recently reported for the Fe^{III}−EDTMP system.[16] The high affinity of Al^{III} towards phosphonic acid groups and the electrostatic repulsion between the negatively charged phosphonate arms of the ligand may explain the formation of some dinuclear complexes.[15]

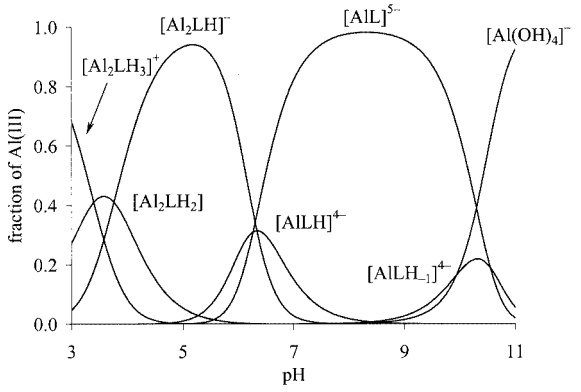

Figure 2. Distribution diagram (mol fraction of Al^{III} as a function of pH) for the Al^{III}−EDTMP system; $c_{Al^{III}} = c_{EDTMP} = 0.001$ M

It is known that Al^{III} readily forms dihydroxo-bridged dinuclear species. Accordingly, it would be reasonable to assume the formation of a complex $[Al_2L_2]^{10-}$ {or more precisely $[Al_2(HL)_2(OH)_2]^{10-}$} in which one of the amino groups is in a protonated form and two OH^- groups link the Al(HL) units together. However, when this species was assumed instead of the mononuclear complex $[AlL]^{5-}$ the fit was poorer by about 30%; when both species were included in the speciation model and were refined simultaneously, the dinuclear species was always rejected by the computer program. Furthermore, the ^1H and ^{31}P NMR results (at the pH value where $[AlL]^{5-}$ forms, vide infra) do not seem to support formation of the dinuclear species, either.

As mentioned in the Exp. Sect., the back-titrations (from the basic to the acidic pH range) had to be stopped at pH ≈ 3 because a solid compound precipitated (the species distribution diagram shown in Figure 2 is limited to this pH value). The elemental and ICP analyses of this solid compound gave the stoichiometry $Al_{1.00}C_{5.86}N_{2.04}$, which is in close agreement with the theoretic AlC_6N_2 stoichiometry of a 1:1 aluminium/ligand compound. The only neutral 1:1 species is $[AlLH_5]$. Therefore, this should be the stoichiometry of the compound that precipitates. The hydrogen content (vide infra) is in agreement with this formula, assuming between four and five coordinated water molecules, which are necessary to fill the hexacoordination sphere of the metal ion. The 1:1 stoichiometry of the solid suggests that mononuclear species actually exist in solution at acidic pH values, together with dinuclear species, which are formed, however, in negligible concentrations. In particular, $[AlLH_5]$ could not be detected during the potentiometric titrations due to its low solubility, which was found experimentally to be below 5×10^{-4} M. In the solid state Al^{III} forms poorly soluble, often layered, chain-polyphosphates[21] which may occur also in acidic solutions at higher Al^{III} concentrations.[15] The dinuclear species $[Al_2LH_x]$ (x = 1, 2, 3) assumed in this paper may be the precursors of these polyphosphates. The solid complex precipitated and characterised by the composition $[AlLH_5]$ is probably a mononuclear species, which exists at such low Al^{III} concentrations, although an oligonuclear structure cannot be fully excluded, either.

The ^1H and ^{31}P NMR spectra of the ligand alone are shown in Figure 3. Due to its symmetry, the free ligand has only two proton signals (a singlet and a doublet, assigned to the NCH_2 and PCH_2 moieties, respectively) and only one phosphorus signal. Signals of a small amount of P-containing impurities can be observed in the NMR spectra (see Exp. Sect.). It has been reported in the literature that the chemical shifts of these signals vary with the pH in a quite irregular manner[6,16] due to the parallel deprotonations and because these may be accompanied by the formation or disruption of intramolecular hydrogen bonding. Our measurements verified this reported pH dependence (data not shown here).

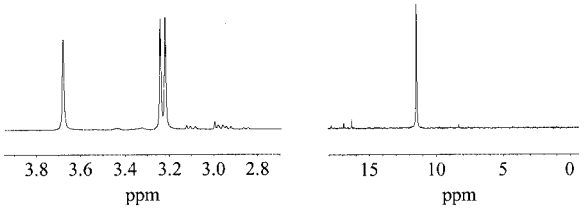

Figure 3. ^1H (left) and proton-decoupled ^{31}P (right) NMR spectra of an aqueous EDTMP solution at pH = 8.38; $c_{EDTMP} = 0.0249$ M

Selected ^1H and ^{31}P NMR spectra of solutions containing both Al^{III} and the ligand in a 0.8:1 ratio are shown in Figure 4. The speciation curves at this higher concentration are shown in Figure 5. At pH = 12.1 only the signals of the free ligand (denoted "lig.") are present, in agreement with the potentiometric data, which confirms negligible metal−ligand complexation at this pH value. Although complex formation between Al^{III} and phosphonates is very

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

strong [displacement of the last dissociable proton of the ligand ($pK_a \approx 13.8$) and coordination of this donor group starts at pH ≈ 6], the affinity of Al^{III} to form the tetrahydroxo species $[Al(OH)_4]^-$ is even higher, and at pH > 12 the ligand is completely displaced by OH^- ions. At lower pH values (10.8, 8.3 and 6.3) new signals of the Al^{III}–EDTMP complexes appear in the spectra. For example, at pH = 8.3 two phosphorus signals (denoted "P" and "Q") and six groups of proton signals (denoted "A", …, "F") can be seen. The couplings in the ^1H NMR spectrum at pH = 8.3 were assessed by means of a COSY spectrum (Figure 1 in the Supporting Information; see footnote on the first page of this article): "A" couples with "E", "B" with "F" and "C" with "D". There are also weak couplings between "A" and "B" and between "B" and "C". Accordingly, signals "A" and "E" can be assigned to the methylene protons of the NCH_2CH_2N moiety: they are the simplest signals because they are those of the only protons which cannot couple with ^{31}P. Only the homonuclear coupling splits the signal, resulting in a "doublet-like structure" (AB quadruplet). The rest of the signals of different multiplicity should belong to the methylene protons of the four $CH_2PO_3^{2-}$ arms. Other assignments are less obvious and therefore have not been made. However, the spectra obtained are in agreement with the proposed structure of the complex $[AlL]^{5-}$, shown in Figure 6, which, according to the potentiometric data, is the most important aluminium species in the pH range 10.5–6.5. In this species, the fully deprotonated ligand chelates the metal ion in a hexadentate fashion. A similar hexadentate coordination mode was assumed for the carboxylate analogue EDTA in its $[AlL]^-$ complex.[22,24] This structure is rather rigid, accounting for the narrow peaks in the NMR spectra obtained, and has a C_2 symmetry axis so that the phosphorus atoms and the protons are equivalent in a pairwise manner. The $CH_2PO_3^{2-}$ arms bound to the same N atom are not equivalent; for this reason two ^{31}P signals of equal intensity are observed. A slight distortion of the structure may account for some asymmetry observed, especially in the ^1H NMR spectrum. The other assumption that only one N is involved in the coordination (the ligand is in the HL form) and an OH^- ion saturates the coordination sphere of each metal ion in a dinuclear dihydroxo-bridged species $[Al_2(HL)_2(OH)_2]^{10-}$ (vide supra) is not compatible with the relatively simple ^{31}P and complicated ^1H NMR spectra. In the case of a rigid dimer, at least three different P resonances should occur in the spectra: (i) the P atoms of the two $CH_2PO_3^{2-}$ arms at the coordinating side of the molecule, (ii) the coordinated P of the partially bound side of the molecule, and (iii) the P of the non-coordinating $CH_2PO_3^{2-}$ arm of this side. On the other hand, in the case of a flexible dimer the methylene protons in the N-attached phosphonate arms should become equivalent resulting in the appearance of a high-intensity doublet in the ^1H NMR spectra, which is not observed, instead rather complicated spectra are obtained (see Figure 4). It is noteworthy that identical structures for ML-type EDTMP complexes with other trivalent metal ions, such as Fe^{III}, Sm^{III} and Ho^{III}, were suggested by Westerback et al.[7] and by Motekaitis et al.,[10] and partly confirmed by Jarvis et al.[11]

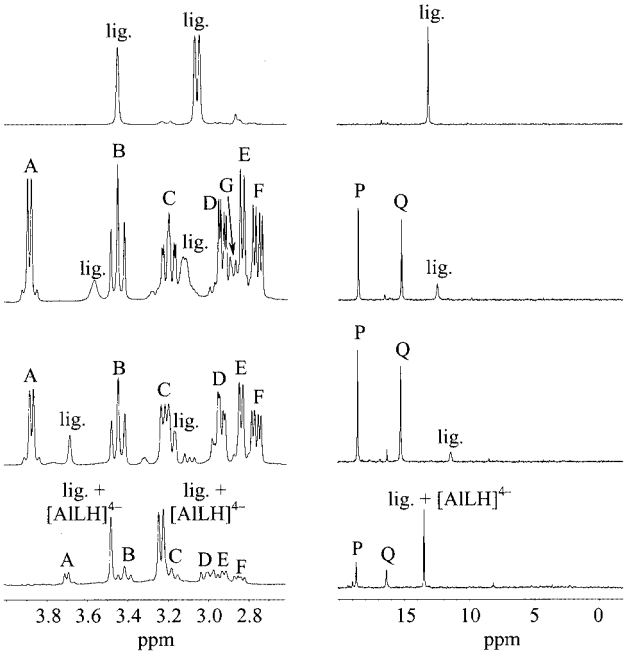

Figure 4. ^1H (left) and proton-decoupled ^{31}P (right) NMR spectra of solutions containing 0.020 M Al^{III} and 0.0252 M EDTMP; pH = 12.06, 10.81, 8.31 and 6.34 (from top to bottom)

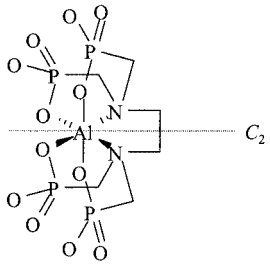

Figure 6. Proposed structure of $[AlL]^{5-}$; the symmetry axis is shown

The spectra at pH = 10.81, where the species $[AlL]^{5-}$ and $[AlLH_{-1}]^{6-}$ should coexist in solution, are very similar

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to those at pH = 8.31: the phosphorus signals are only slightly shifted, whereas in the ^{1}H NMR spectrum only a change in the shape of signals "C" and the appearance of a new signal, "G", can be observed. These suggest that $[AlLH_{-1}]^{6-}$ should have a similar structure to that of $[AlL]^{5-}$, apart from the fact that at least one coordinating site of the metal atom is no longer coordinated by the ligand, but by an OH^- ligand; in addition, it is suggested that the coordinated ligand arms rapidly exchange with the free ligand arm, so that the general symmetry of the complex is maintained and only a small shift of the signals can be observed. This binding mode is in accordance with the rather low value of the deprotonation constant of the species $[AlL]^{5-}$ (pK_{AlL} = 10.55).

In contrast, in the spectra at pH = 6.34, where the species $[AlL]^{5-}$ and $[AlLH]^{4-}$ coexist, the sharp signals of $[AlL]^{5-}$ tend to vanish without apparently being replaced by other well-separated metal−ligand peaks. To explain this finding, we may assume that EDTMP no longer chelates to the metal atom in a hexadentate way in $[AlLH]^{4-}$, as one of the amino groups is now protonated. Al^{III} coordinates mostly to the phosphonate functions, and the intramolecular exchange rate of the coordinated or free phosphonate moieties is high, as was found in previous studies for other Al^{III}−phosphonato complexes.[23,24] Due to this fast internal motion in the complex, no different ^{31}P or ^{1}H signals of the free and Al^{III}-bound phosphonate arms are observed, but the signals are merged and slightly shifted with pH. An amino group as the first protonated function has been reported for the Al^{III} complexes of other hexadentate aminophosphonates and aminocarboxylates.[22,24]

The pK_a calculated from the data in Table 3 for the deprotonation of $[AlLH]^{4-}$ to produce $[AlL]^{5-}$ is 6.26, significantly lower than the pK_a of the free ligand with the same number of protons, HL ($pK_a \approx 13$; see Table 2). This considerable decrease in the pK_a of the HL^{7-} proton due to the coordination of Al^{III} indicates the high stability of the hexadentate coordinated complex $[AlL]^{5-}$.

As seen in Figures 2 and 5, dinuclear complexes are formed at pH < 6. The NMR spectra of the equimolar Al^{III}−EDTMP solutions at acidic pH (not shown) are dominated by the signals of the free ligand, due to the low extent of formation of the dinuclear complexes under these conditions. In order to observe the signals of the Al^{III}-bound ligands, samples with an excess of metal ion were prepared and measured by NMR spectroscopy. These spectra are shown in Figure 7. At pH = 6.1, four new signals (denoted "R", "S", "T" and "U") could be observed at δ = 2−5 ppm in the ^{31}P NMR spectrum. The ^{1}H NMR spectrum is also significantly different from those obtained at higher pH values. The peaks are not well resolved, and only four signals (denoted "I", "J", "K" and "L") can be clearly distinguished in the chemical shift range δ = 3.6−4.1 ppm. From the integration values, it is evident that each of the signals "I", "J", "K" and "L" is due to a single proton of the Al^{III}-bound ligand. A new proton signal is observed at δ ≈ 10 ppm, which may belong to the amino or phosphonic protons. This low-field signal could not be detected in any of the other spectra, either in the absence or in the presence of Al^{III}. According to the speciation data (see Figure 5), the species $[Al_2LH]^-$ is the dominating complex at pH = 6.1. The NMR spectra suggest that $[Al_2LH]^-$ should be a rigid compound, and the four P and the two Al atoms must be chemically inequivalent. In Figure 8, a hypothetical structure is shown for $[Al_2LH]^-$. In this species two phosphonate arms behave as bridging moieties. Only one of the two amino-N atoms is coordinated, and the other may be involved in hydrogen bonding to a water molecule in the coordination sphere of the Al^{III} atom. This binding mode explains the appearance of the extra peak at δ ≈ 10 ppm, which belongs to the N-bound proton. Surprisingly, this amino (or phosphonic) proton does not undergo fast exchange with the bulk water protons on the NMR timescale. The slow kinetics of these processes is also suggested by the fairly long pH-equilibration time observed during the potentiometric titrations (see Exp. Sect.). Another possible explanation of this NMR feature is that besides the dinuclear complex, other oligonuclear complexes are formed at the higher concentrations used for the NMR measurements.

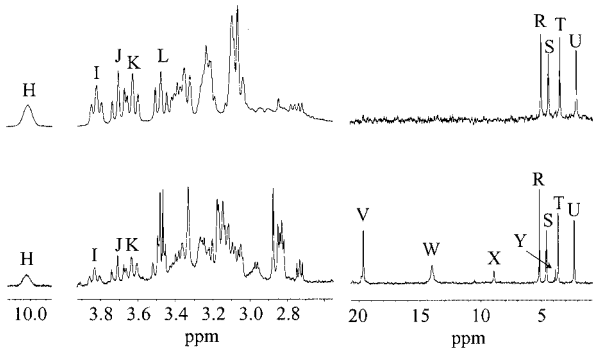

Figure 7. Top: ^{1}H (left) and proton-decoupled ^{31}P (right) NMR spectra of a solution containing 0.0471 M Al^{III} and 0.0251 M EDTMP at pH = 6.1; bottom: ^{1}H (left) and proton-decoupled ^{31}P (right) NMR spectra of a solution containing 0.0415 M Al^{III} and 0.0225 M EDTMP at pH = 3.9

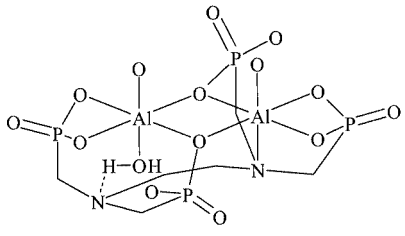

Figure 8. Proposed binding modes for $[Al_2LH]^-$

The NMR spectra measured at pH = 3.9 for the sample with an excess of Al^{III} are in agreement with the potentiometric data, predicting the presence of protonated dinuclear species $[Al_2LH]^-$ and $[Al_2LH_2]$. In the ^{31}P NMR spectrum (Figure 7), four new phosphorus signals appear ("V", "W", "X" and "Y") in addition to those ("R", "S", "T" and "U") belonging to the species $[Al_2LH]^-$. The assignation of these new signals is rather ambiguous, and they may belong

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to various binding isomers and/or to distinct species of different stoichiometry or protonation state. In the ^{1}H NMR spectrum the pattern is more complicated, but new signals can again be seen in the range $\delta = 3.7-2.8$ ppm, together with those also detected at pH = 6.1. These new signals are attributed to the neutral complex $[Al_2LH_2]$, which is probably not a single dinuclear species but a mixture of various (neutral) oligonuclear complexes (substituted by the single species $[Al_2LH_2]$ in the potentiometric speciation calculation). This may explain the rather complicated ^{1}H and ^{31}P NMR features of the Al^{III}−ligand system observed at this pH value (see Figure 7). Again, the proton signal at $\delta \approx 10$ ppm is observed, although with lower intensity than before. This allows us to assign this signal exclusively to the complex $[Al_2LH]^-$. Both $[Al_2LH]^-$ and $[Al_2LH_2]$ (or other oligonuclear species) are asymmetric molecules (Figure 8), in accordance with their NMR behaviour.

$V^{IV}O$ Complexes

The stability constants for the $V^{IV}O$−EDTMP complexes, determined by potentiometric titration, are listed in Table 4.

Table 4. Stability constants (log β ± 3 standard deviations) for the $V^{IV}O$−EDTMP complexes at 25 °C and $I = 0.2$ M KCl (the constants are calculated for the equilibrium: p M + q HL + r H $\rightleftarrows$ $M_pL_qH_{r+q}$)

No of points:				305
Fitting parameter:[a]				-1.03×10^{-2}

[a] Goodness of the fit between the experimental and the calculated titration curves expressed in mL of the titrant.

A typical speciation diagram of the complexes as a function of pH is shown in Figure 9. The speciation model accepted for the $V^{IV}O$−EDTMP system includes only mononuclear complexes. A slight improvement in the fitting was obtained when alternative speciation was considered for the experimental data: the fitting parameter was about 5% lower when the species $[(VO)_2L_2H_{-2}]^{14-}$ was assumed instead of $[VOLH_{-1}]^{7-}$ in the speciation model. However, we chose the model reported in Table 4 in view of the EPR results (vide infra).

The EPR and UV/Vis spectroscopic data for the $V^{IV}O$−EDTMP system at different pH values, together with the most probable equatorial donor atom arrangements around the metal ion, are reported in Table 5. No EPR parameters for species formed in the acidic pH range could be determined because of the low intensity of the spectra (due to precipitation).

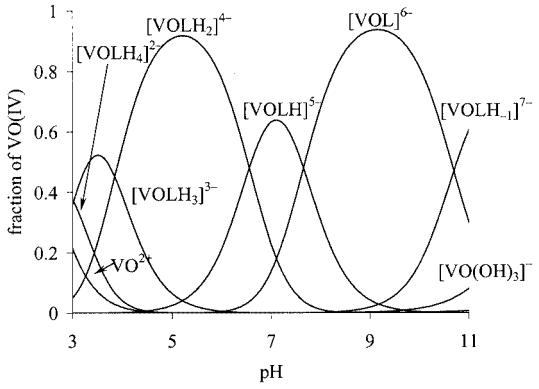

Figure 9. Distribution diagram (mol fraction of $V^{IV}O$ as a function of pH) for the $V^{IV}O$−EDTMP system; $c_{V^{IV}O} = c_{EDTMP} = 0.001$ M

As regards the EPR spectra, at pH = 12 a single species with $g_\parallel = 1.942$ and $A_\parallel = 166.4 \times 10^{-4}$ cm^{-1} is observed. Since these parameters are different than those of $[VO(OH)_3]^-$ ($g_\parallel = 1.957$ and $A_\parallel = 161.4 \times 10^{-4}$ cm^{-1}), this peak is attributed to $[VOLH_{-1}]^{7-}$. When this $A_\parallel$ value is compared with the estimated values obtained from the Chasteen additivity rule[25] it may correspond to either a species with two N [$A_\parallel^{est}$(N, N, PO_3^{2-}, PO_3^{2-}) = 165.2 or $A_\parallel^{est}$(N, N, PO_3^{2-}, OH^-) = 161.4] or with one N [$A_\parallel^{est}$(N, PO_3^{2-}, PO_3^{2-}, PO_3^{2-}) = 167.6 or $A_\parallel^{est}$(N, PO_3^{2-}, PO_3^{2-}, OH^-) = 163.8] in the equatorial plane. The metal ion must also be coordinated to an OH^- moiety, probably in the axial position, so this species should be $[VOL(OH)]^{7-}$, with a binding mode (N, N, PO_3^{2-}, PO_3^{2-})$_{eq}$(OH^-)$_{ax}$. The alternative dihydroxo-bridged, and thus EPR-silent, dimeric species $[(VO)_2L_2H_{-2}]^{14-}$ assumed from the pH-metric measurements in place of the mononuclear species $[VOLH_{-1}]^{7-}$ (vide supra) was rejected as no decrease in intensity of the EPR signal was observed in the formation pH range (pH > 10) of this species. At pH ≈ 9, where the potentiometric data indicates the predominant formation of $[VOL]^{6-}$, a single EPR signal could be detected, with parameters $g_\parallel = 1.936$ and $A_\parallel = 172.1 \times 10^{-4}$ cm^{-1}. The corresponding species is likely to have only one amino group in the equatorial plane of the metal centre (the other N may occupy the axial position or may be in the protonated noncoordinating form), because the half-field splitting constant is closer to the estimated value ($A_\parallel^{est} = 167.6 \times 10^{-4}$ cm^{-1}), and very similar to the half-field splitting constants of the analogous complexes of other aminooligophosphonic acids with the same binding mode.[26] The potentiometric data suggest that three species should coexist in the pH range 8.4−5.7: $[VOL]^{6-}$, $[VOLH]^{5-}$ and $[VOLH_2]^{4-}$. The EPR and potentiometric results correspond to one another. Namely, the stepwise protonation of species $[VOLH_{-1}]^{7-}$ → $[VOL]^{6-}$ → $[VOLH]^{5-}$ → $[VOLH_2]^{4-}$ should involve the axial OH^- group, one of the amino groups and one PO_3^{2-} group. These reactions may proceed in a parallel, overlapping way. What seems to be certain, though, is that only one N atom is in the equatorial plane. Under these conditions, $[VOL]^{6-}$, $[VOLH]^{5-}$ and $[VOLH_2]^{4-}$ have practically the

[a] See text.

same coordination geometry and donor sets in the equatorial plane, and therefore give the same EPR signals (see Table 5). At more acidic pH values the second nitrogen atom is also protonated and the EPR signals display the typical features of the exclusive coordination of phosphonate functions, as expected.

The main feature of the UV/Vis spectra is a blue-shift of the band at ca. 870 nm upon passing from $[VOLH_{-1}]^{7-}$ to $[VOLH_2]^{4-}$. This band may be attributed to the $d_{xy} \rightarrow d_{xz}$, d_{yz} transition.[27] Since the d_{xz} and d_{yz} orbitals are involved in π-bonds with the oxo ligand, the shift of the band indicates a stronger V=O ligand strength. This may be attributed to the structural and electronic rearrangements following the loss of the second nitrogen coordination and the stepwise protonations of the phosphonic arms.

As for Al^{III}, a solid compound was formed in the $V^{IV}O-EDTMP$ system at pH ≈ 3, and the pH-metric back-titrations had to be stopped at this point. The elemental and ICP analyses of the solid complex **2** gave the stoichiometry $(VO)_{1.80}C_{6.00}N_{2.14}$, (the average for the two solids isolated), which is between the theoretical 1:1 vanadium/ligand stoichiometry $[VOLH_6]$ and the 2:1 vanadium/ligand stoichiometry $[(VO)_2LH_4]$ (both are neutral). Therefore, it is reasonable to suggest that both these compounds may precipitate. The 2:1 stoichiometry of the solid appears a little surprising because no dinuclear species could be detected in solution. It may be supposed that $[(VO)_2LH_4]$ is an ionic compound formed by $[VO]^{2+}$ interacting with $[VOLH_4]^{2-}$.[28] However, the non-simple stoichiometry may more strongly suggest a chain-like oligomeric structure for the solid compound through simultaneous metal ion coordination to the (PO_3^{2-}, PO_3H^-) donor sets at both ends of the molecule, resulting in a similar stoichiometry $(VO)_n[(VOLH_4)_n]$ (see Figure 10). The negatively charged chain oligomers $[VOLH_4]_n^{2n-}$ may be partially neutralized by H^+ instead of $[VO]^{2+}$, leading to an $H_{2n}[(VOLH_4)_n]$ stoichiometry. The empty apical coordination sites of the $V^{IV}O$ centres and the free coordination sites of the terminal $V^{IV}O$ ions may be occupied by water molecules. Accordingly, the water content is not strictly defined; it may be around three or four, or even more. These facts are probably responsible for the moderate agreement between the found and calculated elemental analysis data (see Exp. Sect.). The NIR spectrum of the solid compound as compared with that of the ligand alone displays broad, poorly resolved signals, with little information about the binding mode of the complex. The intensity decrease in the ν[P(O)−H] stretching frequency range indicates at least partial deprotonation of the phosphonic groups, which is in accordance with the coordination of $V^{IV}O$ to these functions. The vibration occurring at $\tilde{\nu}$ = 980 cm^{-1} confirms the presence of $V^{IV}O$ in the solid compound.

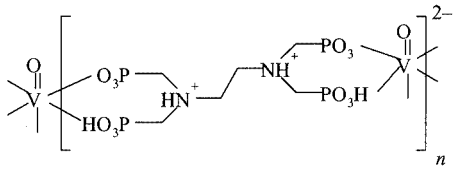

Figure 10. Schematic structure of the oligonuclear solid $V^{IV}O$ complex **2**

Conclusion

Potentiometric titrations of the $Al^{III}-EDTMP$ and $V^{IV}O-EDTMP$ systems revealed for both metal ions that even in equimolar solution the complexes formed are sufficiently stable to avoid the precipitation of $Al(OH)_3$ or $VO(OH)_2$ and the oxidation of $V^{IV}O$, respectively, in the neutral and basic pH range. In the predominant ML species formed in this pH range, the ligand seems to be coordinated to the metal ions through all six donors. In the more basic pH range, at pH > 10, mixed hydroxo species result, while in the acidic pH range partially protonated complexes are formed.

Besides these mononuclear 1:1 species, dinuclear complexes (and probably polynuclear species at higher concentrations) are also formed through the simultaneous coordination of metal ions at both ends of the ligand molecule. The solubilities of these complexes are different, due to the different charges of the metal ions. This may result in precipitation of the neutral complex $VO_n[VOLH_4]_n$ in the $V^{IV}O-EDTMP$ system and the mononuclear species $[AlLH_5]$ in the $Al^{III}-EDTMP$ system in the acidic pH range.

Experimental Section

Reagents: The ligand EDTMP was kindly provided by Monsanto,[29] and was used as received. The purity of the ligand was

checked by potentiometry. The solid EDTMP sample was assessed to be 94.5% pure, the impurity being mainly neutral compounds and water.[30] The P-containing impurities were less than 2%, obtained from peak integration of the NMR spectrum. A stock solution of Al^{3+} was prepared from $AlCl_3 \cdot 6H_2O$ (Fluka); the metal-ion concentration was determined gravimetrically from its oxinate. The stock solution of VO^{2+} was prepared as described previously[31] and standardized for metal-ion concentration by cerimetric titration. To prevent hydrolysis, both metal-ion stock solutions contained ca. 0.1 M HCl. All other chemicals were Fluka (KHphthalate) or Reanal (HCl, KOH and KCl) products.

pH-Metric Measurements: The potentiometric titrations on 25-mL or 50-mL samples were performed in aqueous solution at 25 ± 0.1 °C under argon. The titrations were recorded with an Orion pH-meter equipped with a Metrohm 6.0234.100 combined glass electrode and a Metrohm Dosimat automatic burette. The electrode system was calibrated for hydrogen-ion concentration according to Irving et al.[32] The value obtained for pK_w was 13.764 ± 0.005. EDTMP was standardized by KOH titration in the concentration range from 0.002 to 0.004 M. The data were processed with the computer program SUPERQUAD,[33] which allowed determination of the exact concentrations of the ligand solutions, and calculation of the protonation constants. Precipitation was observed when either Al^{III} or $V^{IV}O$ was added to acidic solutions containing the ligand, in agreement with previous findings on Fe^{III}–EDTMP complexes.[9,14] Accordingly, for determination of the metal–ligand complex-formation constants, back-titrations had to be performed: the starting solutions containing the ligand, the metal ion and excess KOH were titrated with an HCl solution of known concentration. Back-titrations were started at pH ≈ 11 and stopped when precipitation was observed (at pH = 2.5–3.5, depending on the composition of the samples). The volume of the titrant to reach the final pH value varied between 1.4 and 3.8 mL. Stable pH values were always reached within 1 min after addition of the titrant, except for the Al^{III} systems in the pH ranges 3.5–4 and 5.5–6, where the equilibration time was 5–6 min. Samples at different metal ion/ligand ratios were measured pH-potentiometrically. The composition of the samples varied between M/L ratios of 1:1 and 1:4, with Al^{III} concentrations ranging from 0.00080 M to 0.0036 M, and $V^{IV}O$ concentrations from 0.00052 M to 0.0020 M. Duplicate titrations were performed for both systems. For Al^{III}, titrations with excess metal ion were also planned in the pH range between 3 and 6. However, the precipitation of a solid compound (which seemed to be $AlLH_5$) could not be avoided, regardless of the procedure adopted for the addition of the metal-ion and the ligand solutions. Its dissolution at slightly acidic pH values is very slow (several hours), so that no accurate potentiometric titrations could be carried out under these conditions. The stability constants were calculated with the computer program PSEQUAD.[34] The following formation constants of the hydroxo complexes of Al^{III} and $V^{IV}O$ were taken from the literature, corrected to an ionic strength of 0.2 M by use of the Davies equation, and used during the data evaluation: $\log \beta(AlH_{-1}) = -5.41$, $\log \beta(AlH_{-2}) = -11.03$, $\log \beta(Al_3H_{-4}) = -13.09$, $\log \beta(Al_{13}H_{-32}) = -108.19$,[35] and $\log \beta(AlH_{-4}) = -23.44$;[36] $\log \beta[(VO)H_{-1}] = -5.94$, $\log \beta[(VO)_2H_{-2}] = -6.95$;[37] $\log \beta[(VO)H_{-3}] = -18.0$ and $\log \beta[(VO)_2H_{-5}] = -22.5$.[38]

NMR Experiments: ^1H and ^{31}P NMR spectra (the latter with ^1H decoupling) were recorded with a Bruker DMX 500 spectrometer at 298 K on solutions containing the ligand alone (0.025 M) and on solutions containing both the ligand and Al^{III}. Two metal/ligand ratios were explored: 0.8:1 and 1.9:1. Solutions were prepared in a 90:10 (v/v) mixture of H_2O and D_2O (Janssen, 98% D). The pH values were measured with a Metrohm glass electrode, previously calibrated in three buffer aqueous solutions (Sigma, pH = 4, 7 and 10, at 25 °C). The slight difference in composition of the solvents of the calibration and the sample solutions was ignored. A standard water pre-saturation technique was used to eliminate the intense water signal during the relaxation delay (2–3 s). The pH was adjusted by the addition of concentrated KOH and/or HCl solutions. In the samples containing an excess of metal ion, a small amount of solid was present (vide supra). NMR spectra were recorded on the supernatant.

EPR Experiments: Anisotropic X-band EPR spectra (9.15 GHz) were recorded at 120–140 K on aqueous solutions with a Varian E-9 spectrometer. As usual, a few drops of DMSO were added to the samples to ensure good glass formation in frozen solutions. Solutions containing 8×10^{-3} M EDTMP and 4×10^{-3} M $V^{IV}O$ at different pH values were analysed. The EPR spectra may be of further help in elucidating the binding modes of the complexes formed. For the $V^{IV}O$ systems, Chasteen[25] has introduced an additivity rule to estimate the hyperfine coupling constants $A_{\parallel}^{est}$ ($A_{\parallel}^{est} = \Sigma A_{\parallel i}$), based on the contributions $A_{\parallel i}$ of each of the four equatorial donor groups, its estimated uncertainty being $\pm 3 \times 10^{-4}$ cm^{-1}. The parameters $A_{\parallel i}$ of the individual coordinating groups were presented by Chasteen[25] and more recently by Smith et al.[39]

UV/Vis Experiments: Spectra were recorded with a Hewlett-Packard 8452 diode-array spectrometer. Solutions containing 2.4×10^{-2} M EDTMP and 2.4×10^{-2} M $V^{IV}O$ at different pH values were analysed in the wavelength range 300–900 nm.

Solid-State Preparation and Analysis

$Al(LH_5) \cdot 4H_2O$ (1): 10 mL of a 0.0316 M aqueous solution of the free acid H_6L (0.32 mmol) and 10 mL of 0.0320 M $AlCl_3$ (0.32 mmol) were mixed. The pH of the resulting solution was ca. 2. The sample was centrifuged and the supernatant was discarded. The white solid material was treated with 2 mL of 0.02 M HCl solution, stirred in an ultrasonic bath for about 30 min and left to stand overnight at room temperature. The same treatment was repeated three times, on the last occasion with the addition of 2 mL of water instead of HCl. Finally, the solid sample was lyophilized overnight and submitted to elemental analysis. The metal content was measured by ICP-AES. Yield: 130 mg (76%). $C_6H_{17}AlN_2O_{12}P_4 \cdot 4H_2O$ (532): calcd. C 13.53, H 4.70, Al 5.08, N 5.26; found C 13.33, H 4.70, Al 5.01, N 5.40.

$(VO)_x(LH_4)_y \cdot zH_2O$ (2): The complex was prepared in the same way as the Al^{III} complex, but the aqueous solution of the ligand EDTMP was mixed with 10 mL of a 0.0320 M $VOCl_2$ solution (0.32 mM). The solid obtained was a light-blue powder. Yield: 135 mg (78%). The best agreement with the experimental elemental analysis data was obtained with $x = 1.8$, $y = 1$ and $z = 4$. $C_6H_{16}N_2O_{12}P_4(VO)_{1.8} \cdot 4H_2O$ (541): calcd. C 11.78, H 4.09, N 4.58, V 15.02; found C 12.13, H 4.16, N 4.98, V 15.2. This indicates that the solid is probably not a compound with well-defined stoichiometry, but a mixture of the mononuclear metal complex $[VOLH_6]$ and various oligonuclear $VO(L-VO)_n$-type species with an average stoichiometric ratio of VO/L = 1.8 (see Results and Discussion).

Nickel(II) Complexes Incorporating Pyridyl, Imine and Amino Chelate Ligands: Synthesis, Structure, Isomer Preference, Structural Transformation and Reactivity Towards Nickel(III) Derivatives

Suparna Banerjee,[a] Jaydip Gangopadhyay,[b] Can-Zhong Lu,[c] Jiu-Tong Chen,[c] and Ashutosh Ghosh*[a]

Keywords: Coordination modes / Isomer specificity / N ligands / Nickel / Structural transformation

Facile condensation of 2-acetylpyridine with ethylenediamine in a 1:1 or 2:1 molar ratio yielded two neutral ligands with different denticity: 1-amino-4-(2-pyridyl)-3-azapent-3-ene (tridentate, L^1) and 2,7-bis(2-pyridyl)-3,6-diazaocta-2,6-diene (tetradentate, L^3), respectively. Replacing the ketone with 2-pyridinecarboxaldehyde gave a similar set of condensates (L^2 and L^4). The tridentate mono-Schiff bases (L^1 and L^2) react smoothly with $Ni(ClO_4)_2{\cdot}6H_2O$ furnishing the brown bis-chelate complexes (**1a** and **1b**) with an NiN_6 coordination sphere, while the tetradentate bis-Schiff bases (L^3 and L^4) form green pseudo-octahedral complexes (**2a** and **2b**) in which Ni^{II} is present in an N_4O_2 coordination environment. The isomer specificity for both types of complexes is conspicuous from the representative X-ray structures of **1a** and **2a**. *cis-trans-cis* and *cis-cis-trans* isomers are found exclusively for **1** and **2**, respectively. The crystal structure of **2a** reveals O–H···O hydrogen bond interactions assembling alternating cations and anions in an infinite chain-like array. Cyclic voltammetric measurements of **1** and **2** in MeCN solution show a quasi-reversible one-electron oxidation near 0.95 and 0.87 V (vs. SCE), respectively, attributed to a Ni^{III}-Ni^{II} redox couple. Another irreversible Ni^{IV}-Ni^{III} redox response was observed at higher potential near 1.70 and 1.80 V (vs. SCE) for **1** and **2**, respectively. Complexes **1** and **2** display a weak, broad d-d transition band along with a charge-transfer transition. Magnetic susceptibility measurements (at 298 K) confirmed that the spin states of the Ni^{II} centres in **1** and **2** are same, $S = 1$, in agreement with an octahedral configuration. Complexes **1** form stable reddish-brown Ni^{III} complexes (**3**) under exhaustive constant-potential electrolysis treatment. The Ni^{III} complexes display axial EPR spectra both at 298 K and 77 K with $g_\perp > g_\parallel$ indicating the presence of an unpaired electron primarily on the metal centre. Complexes of type **1** and **3** exhibit virtually superimposable cyclic voltammograms in a reverse electrode scan study which confirms no change in the coordination sphere on going from **1** to **3**. The effective magnetic moment values (ca. 2.10 μ_B) of **3** suggest a significant orbital contribution to the paramagnetism, consistent with a tetragonally distorted low spin $3d^7$ system. A colour change phenomenon has been observed for type **2** complexes.

Introduction

Over the last few decades considerable attention has been paid to rationalizing the underlying chemical aspects regarding the stabilizing and destabilizing factors of Ni^{III} species derived from Ni^{II} precursors in various coordination environments.[1,2]

We report here the synthesis and structural features of new NiN_6 and NiN_4O_2 coordination spheres derived from neutral mono-Schiff bases and bis-Schiff bases respectively, as ligands. The electrochemical behaviour of all the members of the two families was investigated with the aim of determining the relative stability of progressively higher oxidation states (+II, +III and +IV) and possible transformations thereof.[2–4] The NiN_6 complexes smoothly undergo electrochemical one-electron oxidation at ambient temperature to give Ni^{III} complexes with identical coordination environments. Hence this type of bis-chelate complex can be modelled to trigger the reversible electron-transfer reactions that are essential for biological[5] as well as catalytic[6] processes. The molecular packing of a representative of the NiN_4O_2 family (**2a**) has revealed two sterically uncongested ONN triangular faces forming O···O hydrogen-bond interactions with counter perchlorate anions. Under the appropriate conditions these open faces can be utilised to accommodate small guest molecules, an area that has been much less explored than the more common crown ethers,[7] imine

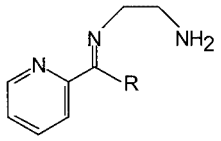
Schiff-base macrocycles[8] and cryptands.[9] A thermogravimetric experiment followed by spectroscopic characterisation showed a change from a six-coordinate octahedral geometry to a four-coordinate distorted square planar form by releasing two *trans* water co-ligands. The observed colour change (green→ red) is associated with this structural change, as is common for other Ni^{II} complexes in different coordination environments.[10]

Results and Discussion

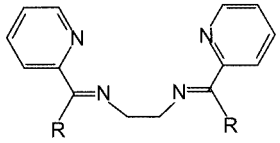
Synthesis of the Complexes

The tridentate and tetradentate Schiff bases 1-amino-4-(2-pyridyl)-3-azapent-3-ene and 2,7-bis(2-pyridyl)-3,6-diazaocta-2,6-diene (general abbreviation, L) have been employed as chelating ligand in the present work. The analogous 2-pyridylcarboxaldimine ligands have also been used for a comparative study. The four complexes reported in this context belong to two different types **1** and **2**.



L^1 (R = CH_3)

L^2 (R = H)



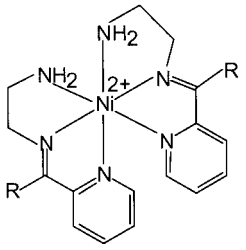
L^3 (R = CH_3)

L^4 (R = H)

The brown bis-chelate complexes **1** are formed in excellent yield upon reacting $Ni(ClO_4)_2{\cdot}6H_2O$ with L^1 or L^2 in a 1:2.2 molar ratio in aqueous methanol under reflux (Scheme 1).

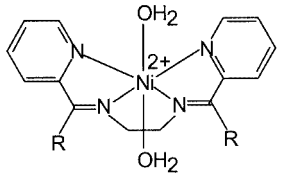
$Ni(ClO_4)_2{\cdot}6H_2O$ reacts smoothly with either L^3 or L^4 in a 1:1.2 molar ratio in aqueous methanol under reflux to give the green complexes **2** in high yield (Scheme 2). Complexes **2** undergo an interesting dehydration-rehydration process, which is influenced by temperature and pressure. At ambient temperature and normal pressure the complexes are stable; the effect of heating on the dehydration process will be examined later.

Attempts to perform a template synthesis by condensation of the appropriate aldehyde or ketone with ethylenediamine followed by complexation with the metal ion in situ, maintaining the 2:2:1 and 2:1:1 molar ratio necessary for the formation of complexes **1** and **2** gave the exclusive formation of **1** due to the chelate effect.



1a (R = CH_3)

1 (R = H)



2a (R = CH_3)

2b (R = H)

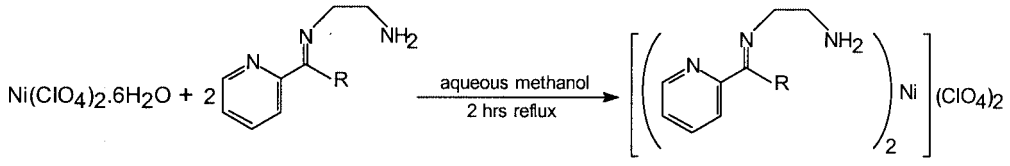
The perchlorate salts act as 1:2 electrolytes in acetonitrile solution (Λ = 245−255 $\Omega^{-1}{\cdot}cm^2{\cdot}mol^{-1}$). Complexes of type **1** give the stable oxidised derivatives **3** under constant electrolysis treatment, whereas type **2** complexes are inherently unstable towards electrolytic treatment.

The *cis-trans-cis* and *cis-cis-trans* disposition of the N^pN^p-N^iN^i-N^aN^a (in type **1** complexes) and N^pN^p-N^aN^a-O^wO^w (in type **2** complexes) donor sets (N^p is pyridyl nitrogen, N^i is imine nitrogen, N^a is amino nitrogen and O^w is oxygen of water) are the striking features of these complexes.

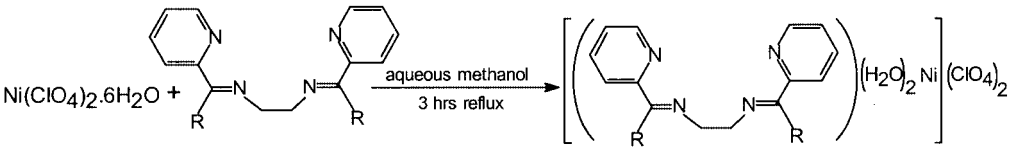
Geometrical Preference and Structural Features

[Ni(L^1)$_2$](ClO$_4$)$_2$

This complex has a distorted octahedral geometry. The ligand encapsulates the divalent metal ion through six ligating nitrogen atoms from two pyridyl [N(1) and N(4)], two imine [N(2) and N(5)] and two amino [N(3) and N(6)] groups (Figure 1, Table 1). Several isomers are theoretically possible considering the relative arrangement of three types of coordinated nitrogen atoms around the metal centre, although the only one encountered here has the pyridine ni-



Scheme 1



Scheme 2

trogen atoms in the *cis* position and the imine nitrogen atoms in the *trans* positions, thereby leaving two *cis* positions available for the amino nitrogen donors. The *trans* disposition of two N^i donor sites in a *cis-trans-cis* geometry ensures competition between them for the same metal d-orbital, thus minimising the back-bonding stabilisation. This *cis-trans-cis* geometry (no NiN^i interaction) is sterically more favourable than any of the possible unobserved isomers (*cis-cis-trans, trans-cis-cis*) having a *cis* NiN^iN^i orientation (two NiN^i interactions). Evidently the steric relaxation completely offsets the back-bonding disadvantage in the case of the *cis-trans-cis* isomer and none of the other isomers are observed.

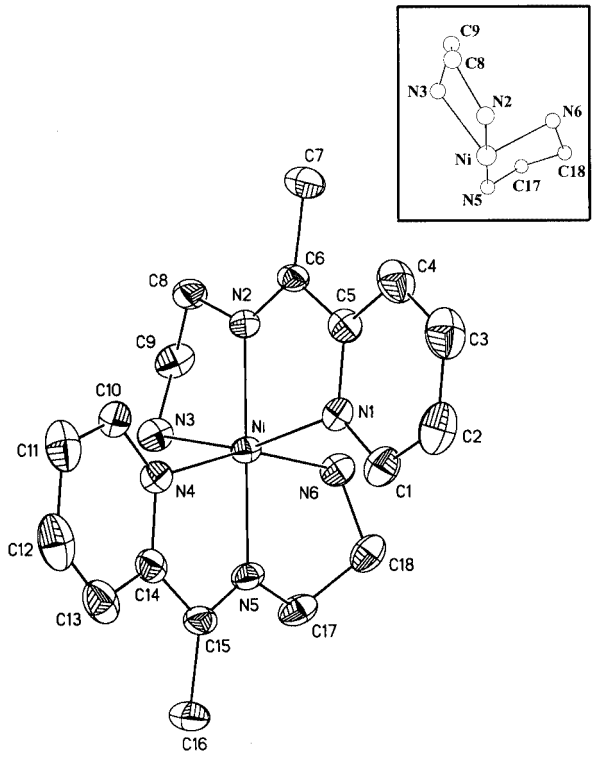

Figure 1. A perspective view and atom-labelling scheme of the complex cation of $[Ni(L^1)_2](ClO_4)_2$ (**1a**); all non-hydrogen atoms are represented by their 25% thermal probability ellipsoids; the inset shows the conformations of the dimethylene-bridged chelate rings

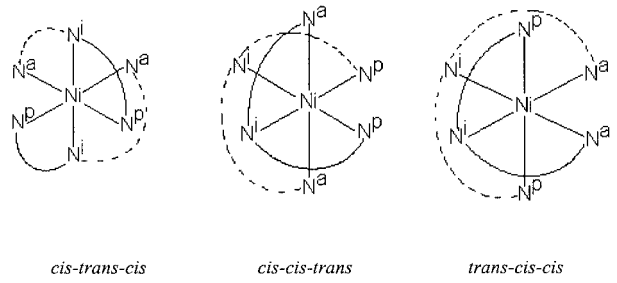
N5−Ni−N3	99.0(2)	N2−Ni−N3	80.7(2)
N6−Ni−N3	94.4(3)	N4−Ni−N3	94.3(2)
N1−Ni−N3	158.2(2)		



The N(1), N(3), N(4) and N(6) atoms define a severely distorted basal plane (mean deviation 0.39 Å). The five-membered chelate rings [Ni, N(1), C(5), C(6) and N(2)] and [Ni, N(4), C(14), C(15), and N(5)] along with the conjugated pyridyl moieties constitute satisfactory planes (mean deviation 0.06 Å and 0.07 Å respectively). The two remaining saturated five-membered metallo rings are out of plane (average mean deviation 0.16 Å) and the dimethylene bridges assume a twisted skew conformation (see inset, Figure 1). As a whole, two $Ni(L^1)$ fragments are not planar (average mean deviation 0.11 Å) essentially due to steric repulsion between the two dimethylene-bridged chelate rings. Two pyridylimine metallo rings enjoy extended π-electron delocalisation, inducing a more rigid nature and a decrease in the chelate bite angles (average 77.7°). On the contrary, the twisted dimethylene-bridged metallo rings are flexible with larger (closer to 90°) bite angles (average 81.3°). All metal-nitrogen bond lengths are consistent with literature values.[1,11−14] The $Ni-N^i$ bonds are shorter than the $Ni-N^p$ and $Ni-N^a$ bonds by about 0.11 Å. This $Ni-N^i$ bond-shortening stems from the better π-accepting ability of imine (C=N) functions than the N^p and N^a coordination sites.

[Ni(L³)(H₂O)₂] (ClO₄)₂

The *cis-cis-trans* geometry with respect to N^p, N^i and O^w donor sites is found exclusively rather than another possible *trans-cis-cis* isomer for complexes **2**. This isomer specificity primarily stems from the better degree of $Ni-N^i$ back-bonding in the *cis-cis-trans* isomer due mainly to the presence of a stronger *trans* σ-donor N^p atom (in the *trans-cis-cis* geometry a weaker O^w atom is *trans* to the $Ni-N^i$ bond) sharing the same metal d-orbital. Moreover the *cis-cis-trans* orientation (devoid of NiO^w interactions) is better in a steric sense than the unprecedented *trans-cis-cis* isomer with a *cis*-NiO^wO^w disposition (two destabilising NiO^w interactions). Therefore, we can rationalize the exclusive occurrence of the *cis-cis-trans* isomer in terms of both electronic and steric factors.

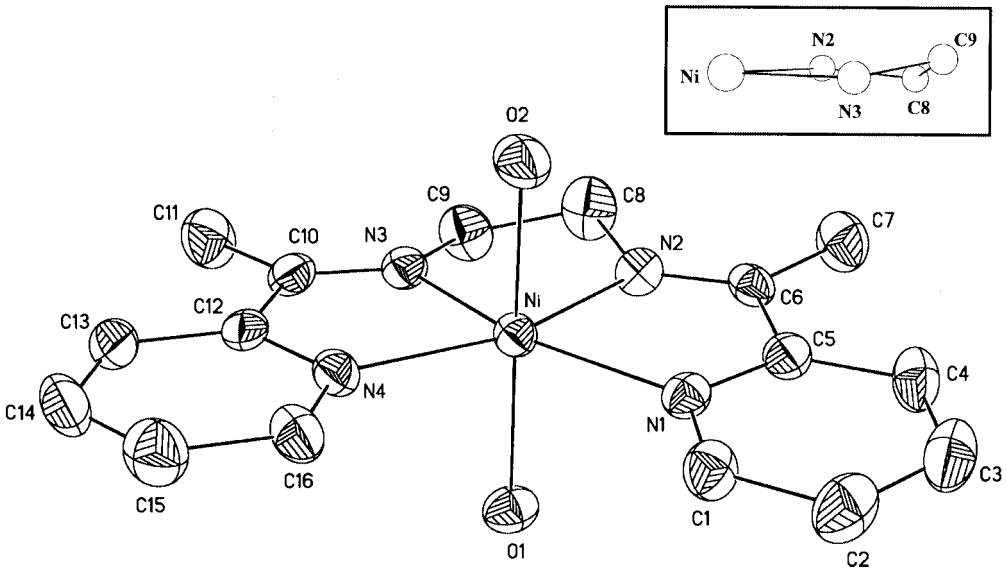

Figure 2. A perspective view and atom-labelling scheme of the complex cation of $[Ni(L^3)(H_2O)_2](ClO_4)_2$ (**2a**); all non-hydrogen atoms are represented by their 25% thermal probability ellipsoids; the inset shows the conformation of the dimethylene-bridged metallo ring

A molecular view of **2a** is presented in Figure 2, and selected bond parameters are listed in Table 2. The Ni^{II} ion sits in a reasonably planar equatorial plane (mean deviation 0.04 Å) defined by the N(1), N(2), N(3) and N(4) atoms.

O2−Ni−O1	171.1(3)		

Hard donors, like oxygen atoms, coordinated along the axial direction force the metal ion to sit in the basal plane. Individual π-conjugated chelate rings are essentially completely planar (mean deviation 0.01 Å in both cases). The dimethylene-bridged chelate ring [Ni, N(2), C(8), C(9), N(3)] is only approximately planar (mean deviation 0.08 Å) as compared to the π-conjugated chelate fragments. The overall planarity of the $Ni(L^3)$ motif (mean deviation 0.08 Å) is disturbed because of the twisted dimethylene bridging segment (see inset, Figure 2). The chelate bite angles of N(4)−Ni−N(3) and N(1)−Ni−N(2) are 78.9(3) and 78.5(2)°, respectively, and are less than that observed for N(2)−Ni−N(3) [82.8(2)°]. Like **1a**, the difference in bite angles (>4°) is fully consistent with the varying degree of flexibility of the chelate rings. A comparison between the $Ni-N^p$ and $Ni-N^i$ distances clearly reveals a bond shortening of about 0.08 Å (on average) for the latter $Ni-N^i$ type, attributable to additional d(metal) → π*(C=N) back-bonding. Indeed this dative back-bonding is facilitated in presence of the *trans* N^p atom (strong σ-donor) sharing the same d orbital of the metal as the N^i donor. The average $Ni-N^p$ distance in **2a** is appreciably shorter (ca. 0.04 Å) than that observed for **1a**. The underlying reason presumably arises from the different relative orientations of the N^p and N^i donor atoms around the metal centres (*cis* for **2a** and *trans* for **1a**), inducing the pyridyl moiety to act as a better σ-donor in **2a**. The $Ni-O^w$ bonds are relatively weak[15,16] compared to other aquated Ni^{II} systems. The presence of intermolecular hydrogen-bonding accounts for the lengthening of the $Ni-O^w$ bonds, and is primarily an electronic effect. The effect of this unsymmetrical hydrogen bonding through two-coordinated water molecules is reflected in a bending of the O^w-Ni-O^w axis, making an angle of 171.1(3)°.

The uncoordinated perchlorate ions of **2a** form a hydrogen-bonded network with the two axially coordinated water molecules of the cationic part of the complex. Two water molecules of the Ni^{II} complex cation are engaged in three unsymmetrical O···O hydrogen-bond contacts with two open ONN triangular faces (average surface area, ≈4.1 $Å^2$) avoiding unwanted steric interactions. The molecular packing diagram reveals that the coordinated water molecules of a cation form hydrogen bonds with perchlorate ions belonging to two different asymmetric units. The relevant O···O contacts [O(1E)···O(8A): 2.850(6) Å, O(2E)···O(3C): 2.876(8) Å and O(2E)···O(10E): 2.722(8) Å] generate a chain-like cationic assembly in which alternating cations lie in an almost parallel fashion, as illustrated in Figure 3.

Electronic Spectra

The electronic spectra of the four complexes **1a**, **1b**, **2a** and **2b** were recorded both in the solid state (nujol mull)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

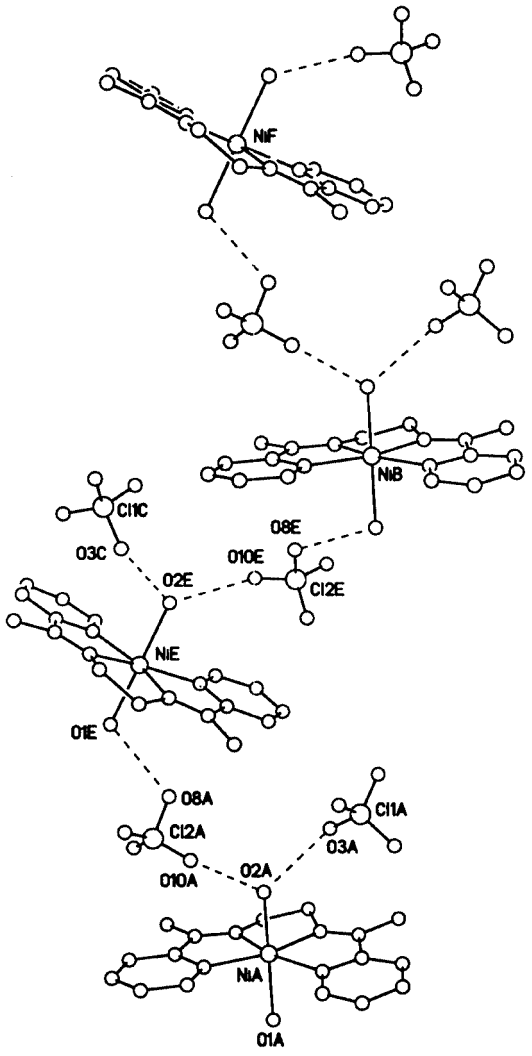

Figure 3. Molecular packing view of **2a** along the *x*-direction

and in acetonitrile solution. No significant differences were observed. A broad band is observed near 800 nm, well separated from the second transition at about 510 nm for both **1** and **2**. The third d-d band appears near 350 nm and is partly obscured by a strong charge-transfer transition. The three absorption peaks are assigned to transitions from the $^3A_{2g}$ ground state to $^3T_{2g}$, $^3T_{1g}(F)$ and $^3T_{1g}(P)$ excited states. In addition, a weak peak appears near 750 nm for complexes **2**, interpretable on the basis of a spin-forbidden $^3A_{2g} \rightarrow {}^1E_g$ transition. The calculated values of *Dq* lie in the range 1250−1260 cm^{-1} for all complexes, and are in agreement with literature values.[17,18] The reddish-brown Ni^{III} complexes **3** are characterised by an LMCT transition at about 425 nm with a shoulder near 645 nm.

Electrochemistry

With the aim of investigating the extent of stabilisation of nickel(II) species towards both oxidation and reduction, and thereby the possibility of accessing of variable valence states, cyclic voltammetry experiments were performed on **1** and **2** (Table 3).

Table 3. Electrochemical data for all divalent nickel complexes

Compound	$E_{1/2}$/V (ΔE_p/mV)[a]	
	Ni^{III}-Ni^{II} couple	Ni^{IV}-Ni^{III} couple
1a	0.95 (110)	1.69
1b	0.96 (110)	1.72
2a	0.85 (100)	1.78
2b	0.87 (100)	1.80

[a] ΔE_p = Peak-to-peak separation.

$[Ni(L^1)_2](ClO_4)_2$ and $[Ni(L^2)_2](ClO_4)_2$ are electroactive in acetonitrile solution (TEAP as supporting electrolyte) displaying two one-electron cyclic voltammetric responses with $E_{1/2}$ near +0.95 and +1.70 V vs. the saturated calomel electrode (SCE). Type **1** complexes undergo chemically reversible ($i_{pa}/i_{pc} \approx 1$) and electrochemically quasi-reversible (ΔE_p = 110 mV) one-electron oxidative responses due to the $[Ni^{III}(L^{1/2})_2]^{3+}/[Ni^{II}(L^{1/2})_2]^{2+}$ couple, near 0.95 V as observed for bis-pyridylazonaphthol-chelated complexes of Ni^{II}.[19] Appreciable reversibility is also inferred from the i_{pa},i_{pc} vs. $\nu^{1/2}$ plot, which is nearly constant for different scan rates (0.025, 0.05, 0.075 and 0.1 V/sec). The irreversible redox signal encountered near +1.70 V is attributed to the $Ni^{4+/3+}$ response. No voltammetric response consistent with a $Ni^{2+/1+}$ reduction is observed. Further, absence of a $Ni^0(s) \rightarrow Ni^{2+}$ stripping peak emphasises the reluctance of $[Ni^{II}(L^{1/2})_2]^{2+}$ to undergo a two-electron reduction. The relevant electron-transfer processes correlating metal valence span from +2 to +4 can be represented by Equation (1).

$$[Ni^{IV}(L^{1/2})_2]^{4+} \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} [Ni^{III}(L^{1/2})_2]^{3+} \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} [Ni^{II}(L^{1/2})_2]^{2+} \quad (1)$$

Such a relatively high $E_{1/2}$ value for the $Ni^{3+/2+}$ redox transformation is typical in complexes where nickel is in a mixed sulfur-nitrogen coordination environment.[20] Even higher $E_{1/2}$ values (ca. 1.6 V) have been reported for the $[Ni(bipy)_3]^{3+}/[Ni(bipy)_3]^{2+}$ couple.[21] The absence of any satellite response is fully consistent with the exclusive occurrence of one isomer (*cis-trans-cis*), in solution.

The redox behaviours of $[Ni(L^3)(H_2O)_2]$ $(ClO_4)_2$ and $[Ni(L^4)(H_2O)_2]$ $(ClO_4)_2$ follow a similar trend as **1a** and **1b**. Complex **2** in acetonitrile exhibits a quasi-reversible (ΔE_p = 100 mV) one-electron oxidation near 0.87 V consistent with the $[Ni^{III}(L^{3/4})(H_2O)_2]^{3+}/[Ni^{II}(L^{3/4})(H_2O)_2]^{2+}$ couple. The observed shift (in 0.08 V) of the $E_{1/2}$ value toward negative potential compared to the $E_{1/2}$ observed for $[Ni(L^{1/2})_2]^{3+/2+}$ accentuates the relative stabilisation of the Ni^{III} species derived from type **2** complexes. The *trans* disposition of the two imine donor motifs in $[Ni(L^{1/2})_2]^{2+}$ which becomes a *cis* orientation for $[Ni(L^{3/4})(H_2O)_2]^{2+}$ obviously facilitates greater delocalisation of the metal electron density, resulting in a higher potential barrier for the formation of Ni^{III} species from the latter complexes. This was observed experimentally from the irreversible peak near +1.80 V, ascribed to a

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$Ni^{4+/3+}$ redox process. This oxidative response is shifted to positive potential by 0.10 V in comparison with the $Ni^{4+/3+}$ couple for **1**. Like **1**, no $[Ni^{II}(L^{3/4})(H_2O)_2]^{2+}/[Ni^{I}(L^{3/4})(H_2O)_2]^{1+}$ redox couple is observed in acetonitrile solution.

In order to exclude any possibility of rapid isomerisation, cyclic voltammograms of **1** and **2** were run at various temperatures. Strong $Ni^{3+/2+}$ and $Ni^{4+/3+}$ responses for **1** and **2** were observed at 288 and 308 K at very nearly the same formal potential, and with similar current heights, as observed for the cyclic voltammograms recorded at 298 K (discussed earlier). Therefore, in this context the temperature effect upon the redox couples is not significant.

IR Spectra and Magnetism

The two primary NH_2 stretching modes are seen in type **1** complexes near 3340 and 3290 cm^{-1} as sharp bands (doublet) for the asymmetric and symmetric vibrations, respectively. The imine (C=N) stretch appears at about 1660 cm^{-1}, and the red shift of this C=N absorption of about 20 cm^{-1} on going from the free ligands (L^1, L^2) to the complexes indicates the weak π-accepting behaviour of the chelated ligands. The type **2** complexes exhibit a broad band in the range 3410−3440 cm^{-1}, assigned to the antisymmetric and symmetric O−H stretching vibrations of coordinated water molecules. ν_{Ni-O} appears near 450 cm^{-1} for **2**.[22] The diagnostic C=N stretch is observed near 1650 cm^{-1}, and is shifted to lower frequency by about 30 cm^{-1} relative to the free ligands. The difference in imine stretching frequencies of complexes **1** and **2** confirms the greater electron-withdrawing effect of the chelating bis-Schiff bases (L^3, L^4) in the latter. Broad structured ν_3 and sharp ν_4 vibrations of the perchlorate counteranion are observed near 1100 and 630 cm^{-1} for **1** and **2**, respectively.

The effective magnetic moment data of complexes **1** and **2** (polycrystalline state) clearly confirm the presence of two unpaired electrons ($t_2^6e^2$) in a pseudo-octahedral environment, in agreement with a high-spin configuration ($S = 1$). The magnetic moment values of 3.12, 3.15, 3.06 and 3.05μ_B at 298 K for **1a**, **1b**, **2a** and **2b**, respectively, suggest an appreciable orbital contribution to the spin-only moments.[23]

NMR Spectra

The ^1H NMR spectra of **1** (bulk material, in $[D_6]$DMSO) display paramagnetically shifted resolved signals of the aromatic, aliphatic and amino protons. The pyridyl and methylene proton resonances occur in the ranges $\delta = 6-12$ and $-12-45$ ppm, respectively. The methyl (**1a**) and aldimine (**1b**) hydrogen atom signals appear as singlets in the region $\delta = 2.5-3.5$ and 8−10 ppm, respectively. The amino protons resonate at lower field in the region $\delta = 75-95$ ppm. The absence of satellite peaks clearly confirms the exclusive occurrence of one isomer. The distinct spin-spin structures of the corresponding signals remove any scope for a rapid equilibrium between the possible isomers in solution. These results mean that the stereochemistry of **1** in the solid state is also retained in solution and no interconversion takes place as this would otherwise result in an averaging of nonequivalent protons.

Similarly in **2**, the pyridyl and methylene proton signals appear in the region $\delta = 7-14$ and $-7-30$ ppm respectively. The methyl (**2a**) and aldimine (**2b**) hydrogen resonances occur in similar regions to those of **1**. The aqua hydrogen resonances fall in the range $\delta = 60-85$ ppm. The large range of the NMR signals of **2** is consistent with its paramagnetic nature.

Thermal Analysis and Structural Transformation

Complexes **2a** and **2b** are both green and possess an octahedral geometry with axially coordinated water molecules. The TG curve reveals that upon heating both **2a** and **2b** undergo dehydration in the temperature range 50−95 °C and 60−100 °C, respectively, corresponding to the weight loss of two water molecules (observed: 6.96 and 7.01%; calculated: 6.43 and 6.77% for **2a** and **2b**, respectively). The anhydrous compounds begin to decompose at 275 and 270 °C, respectively, indicating their high thermal stability.

The colour of the samples changes from green to red during dehydration and this colour change is reversed on exposure to air for one day, suggesting a possible rehydration. To rationalize the observed colour change we performed magnetic susceptibility and spectral measurements of the red complexes. The magnetic study (300 K) revealed the diamagnetic nature of the dehydrated compounds, which is further supported by the solid-state electronic spectra (nujol mull), typical of square-planar Ni^{II} complexes (single peak at $\lambda_{max} \approx 480$ nm). Therefore the dehydration process is definitely accompanied by a structural transformation [octahedral (green) → square planar (red)] around the metal centre. It should be noted that this type of colour change associated with a structural transformation has been reported[10] for several bis-diamine complexes of Ni^{II}, but to the best of our knowledge is uncommon in complexes incorporating tetradentate bis-Schiff base ligands.

Electrosynthesis of $[Ni(L^{1/2})_2]^{3+}$: EPR and Magnetic Evidence

The search for trivalent analogues of **1** and **2** prompted us to carry out electrochemical oxidation (coulometrically) in dry acetonitrile solvent at 1.25 and 1.20 V respectively. The ratio of the observed coulomb count and the calculated coulomb count for the one-electron transfer is very close to unity (0.97 for **1a** and 0.98 for **1b**), suggesting an almost quantitative one-electron oxidation of Ni^{II} precursors to the Ni^{III} derivatives. The cyclic voltammograms of $[Ni(L^{1/2})_2]^{3+}$ (initial scan cathodic) are virtually superimposable with those of $[Ni(L^{1/2})_2]^{2+}$ (initial scan anodic). The observed redox behaviour of the oxidised Ni^{III} species confirms that the coulometric oxidation of $[Ni(L^{1/2})_2]^{2+}$ to $[Ni(L^{1/2})_2]^{3+}$ is accompanied by no major structural change. The uncontrolled decomposition of electrogenerated oxidised species of **2** in solution ruled out any possibility of isolation and further studies. They exist in solution only on the timescale of the voltammetry measurement, thus demonstrating the role of purely kinetic stabilisation[24] in trivalent nickel.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The EPR spectroscopic data of the compounds are listed in Table 4. Polycrystalline samples of **3** at 298 K exhibit an axial spectrum[25] with $g_\perp$ and $g_\parallel$ values of 2.14 and 2.02 respectively (Figure 4). No superhyperfine structure of the $g_\parallel$ component attributed to σ-coupling with the two ^{14}N (imine) atoms coordinated in a mutual *trans* manner is observed. The bond-angle order N^i-Ni-N^i (ca. 179°) > N^p-Ni-N^a (ca. 158°) in the *cis-trans-cis* isomer of $[Ni(L^1)_2]^{2+}$ implies that both steric and electronic requirements will favour the orientation of a linear N^i-Ni-N^i moiety along the *z*-direction. Thus we can reasonably assume that this is also the case for **3** ($3d^7$). The observed *g* inequality ($g_\perp > g_\parallel$) is fully consistent with a tetragonally distorted octahedral geometry with elongation of the axial bond along the *z*-axis.[2,26,27] Hence a strong Jahn−Teller effect must be operative to lift the degeneracy of the e orbital set following the energy order $3d_{x^2-y^2} > 3d_{z^2}$. The spectra of **3** in a frozen (77 K) acetonitrile/toluene (2:1) glass also follow a similar axial pattern as observed for polycrystalline state, strongly indicating that the coordination environment is retained (in solid and solution). The axial spectra at 77 K are important as they suggest that the rhombic field is too weak to split the perpendicular absorption into individual g_{xx} and g_{yy} tensors. The *g* values for these complexes lie well above the spin-only value of a free electron (2.002). This excludes any possibility of the formation of Ni^{II} stabilised ligand radicals. Therefore, the observed EPR signals arise from one metal-centred unpaired electron, in agreement with the trivalent oxidation state.[28]

Table 4. EPR data for trivalent Ni^{III} species.

Compound	$g_\perp$	$g_\parallel$
3a	2.138,[a] 2.137[b]	2.018,[a] 2.018[b]
3b	2.139,[a] 2.139[b]	2.017,[a] 2.018[b]

[a] Polycrystalline state at 298 K. [a] In acetonitrile/toluene (2:1) glass at 77 K.

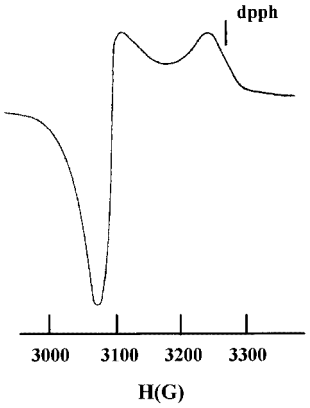

Figure 4. X-band EPR spectrum of $[Ni(L^1)_2]^{3+}$ (**3a**) in the polycrystalline solid state (298 K); instrument settings: power, 30 dB; frequency, 9.1 GHz; modulation, 100 KHz; scan time, 2 min; sweep centre, 3200 G

Further evidence for trivalent nickel complexes is provided by the magnetic moment data. The bulk magnetic moment for **3** at 298 K is consistent with a one-electron paramagnetic behaviour. The effective magnetic moment values of 2.12 and 2.09 μ_B for **3a** and **3b**, respectively, mean that the Ni^{III} complexes are present in a low spin ($t_2^6\ e^1$) configuration with $S = 1/2$. A large orbital contribution to the paramagnetism[24] is noticed, as expected. Unfortunately we were unable to grow single crystals of either **3a** or **3b**, although all the EPR and magnetic data unequivocally suggest the formation of trivalent nickel complexes.

Conclusion

The tridentate and tetradentate ligands presented here are characterised by their different nitrogen donor sites (pyridyl, imine and amino), and their different binding abilities towards a Ni^{II} centre provide us with NiN_6 and NiN_4O_2 types of coordination complexes. Bis-chelates were achieved without deprotonating the amino group. The *cis-trans-cis* isomer of **1** is the only isomer obtained due to steric relaxation, which completely offsets any electronic disadvantage, whereas the *cis-cis-trans* form of **2** is favoured by both steric and electronic factors. The effect of the low π-acidity of the ligands is clearly shown by the predominant localised nature of the bonding in the resulting complexes. Accessible cyclic voltammetric formal potentials of the Ni^{3+}/Ni^{2+} couple for **1** and **2** allowed us to synthesise the related Ni^{III} complexes electrochemically, although the complex formed from **2** is not particularly stable, unlike that formed from **1**.

Proper tuning of the coordination modes of tridentate ligands containing pyridyl, imine and amino donor atoms can afford stable trivalent nickel complexes. The design of such ligands with variable polymethylene spacers and the study of their efficacy to stabilize the higher oxidation states of different metals are in progress.

Experimental Section

Starting Materials: $Ni(ClO_4)_2{\cdot}6H_2O$, 2-acetylpyridine and 2-pyridinecarboxaldehyde were purchased from Aldrich and used as received. HPLC-grade acetonitrile was used for electrochemical, conductivity and UV/Vis work and all other chemicals and solvents were of reagent grade and were used as received.

CAUTION: *Perchlorate salts are hazardous and may explode.*

Physical Measurements: Spectral measurements were carried out using the following equipment: UV/Vis (both in acetonitrile solution and solid), Hitachi U-3501 spectrophotometer fitted with thermostatted cell compartments (sh is shoulder). IR (KBr disc), Perkin−Elmer RXI FT-IR spectrometer and Nicolet Magna IR 750 Series II. A Perkin−Elmer 2400 Series II elemental analyzer was used for microanalysis (C, H, N). EPR spectra was recorded at the X-band on a Varian E-109C spectrometer and calibrated with respect to diphenylpicrylhydrazyl (DPPH, $g = 2.0037$). Solution electrical conductivity was measured in acetonitrile with a Phillips PR 9500 bridge using a platinized electrode; solute concentration was approx. 10^{-3} M. ^1H NMR spectra were recorded on a

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Bruker FT 300 MHz spectrometer. The thermal analysis (TG-DTA) was carried out on a Metler Toledo TGA/SDTA 851 thermal analyzer under a dynamic atmosphere of dinitrogen (flow rate: 30 mL·min^{-1}). The sample was heated in an alumina crucible at a rate of 10 °C·min^{-1}. Magnetic susceptibilities were measured on a PAR 155 vibrating-sample magnetometer. Electrochemical measurements were performed under a dinitrogen atmosphere using a PAR model Versastat-2 electrochemical analyzer, with a platinum working electrode. The supporting electrolyte was tetraethylammonium perchlorate (TEAP), and the potentials are referenced to the saturated calomel electrode (SCE) without junction correction.

L^1: Ethylenediamine (0.9 g, 15 mmol) and 2-acetylpyridine (1.815 g, 15 mmol) were mixed in 20 mL of methanol and then refluxed for 3 h. The resulting solution was evaporated to 5 mL and cooled to room temperature. Upon cooling of the solution a yellow solid precipitated. The solid was collected by filtration and was recrystallised from hot methanol affording pale yellow cubes, which were dried in vacuo over fused $CaCl_2$. Yield: 2.11 g (85%). $C_9H_{13}N_3$: calcd. C 66.23, H 8.03, N 25.74; found C 66.17, H 8.07, N 25.81. IR: $\tilde{\nu}$ = 3345−3285 cm^{-1} (ν_{NH_2}), 2950−2850 (ν_{C-H}), 1678 ($\nu_{C=N}$), 1590 (δ_{N-H}), 1447−1302 ($\nu_{pyridine\ ring}$).

L^2: This ligand was prepared by a procedure similar to that for L^1, starting with ethylenediamine (0.9 g, 15 mmol) and 2-pyridinecarboxaldehyde (1.605 g, 15 mmol), to obtain a light-yellow semi-solid which, on recrystallisation from *n*-hexane, gave pale-yellow needles. Yield: 1.84 g (82%). $C_8H_{11}N_3$: calcd. C 64.40, H 7.43, N 28.17; found C 64.32, H 7.37, N 28.23. IR: $\tilde{\nu}$ = 3345−3281 cm^{-1} (ν_{NH_2}), 2952−2847 (ν_{C-H}), 1677 ($\nu_{C=N}$), 1591 (δ_{N-H}), 1450−1302 ($\nu_{pyridine\ ring}$).

L^3: Ethylenediamine (0.9 g, 15 mmol) and 2-acetylpyridine (3.630 g, 30 mmol) were mixed in 25 mL of methanol and then refluxed for 7 h. The resulting solution was evaporated to obtain a yellow semi-solid mass which, on recrystallisation from *n*-hexane, afforded light-yellow needles. The needles were dried in vacuo over fused $CaCl_2$. Yield: 2.44 g (61%). $C_{16}H_{18}N_4$: calcd. C 72.15, H 6.81, N 21.04; found C 72.22, H 6.75, N 21.09. IR: $\tilde{\nu}$ = 2990−2880 cm^{-1} (ν_{C-H}), 1680 ($\nu_{C=N}$), 1450−1307 ($\nu_{pyridine\ ring}$).

L^4: This ligand was prepared by a similar procedure to that employed for L^3, starting with ethylenediamine (0.9 g, 15 mmol) and 2-pyridinecarboxaldehyde (3.210 g, 30 mmol) to give light yellow microcrystals. Yield: 2.29 g (64%). $C_{14}H_{14}N_4$: calcd. C 70.57, H 5.92, N 23.51; found C 70.51, H 5.98, N 23.45. IR: $\tilde{\nu}$ = 2992−2877 cm^{-1} (ν_{C-H}), 1680 ($\nu_{C=N}$), 1451−1306 ($\nu_{pyridine\ ring}$).

$[Ni(L^1)_2](ClO_4)_2$ (1a): $Ni(ClO_4)_2·6H_2O$ (0.165 g, 0.45 mmol) dissolved in the minimum volume of water was added to a solution of L^1 (0.163 g, 0.99 mmol) in methanol (30 mL), and heated to reflux for 2 h to afford a brown solution. The resulting solution was cooled to room temperature and filtered. The filtrate was stripped of solvent under reduced pressure. The residue was washed twice (15 mL each) with hexane to remove the excess ligand and then dried in vacuo over fused $CaCl_2$. Yield: 242 mg (92%). $C_{18}H_{26}Cl_2N_6NiO_8$: calcd. C 37.02, H 4.49, N 14.39; found C 37.09, H 4.45, N 14.46. IR: $\tilde{\nu}$ = 3340, 3290 cm^{-1} (ν_{NH_2}), 2940−2862 (ν_{C-H}), 1658 ($\nu_{C=N}$), 1596 (δ_{N-H}), 1445−1305 ($\nu_{pyridine\ ring}$), 1089, 627 (ν_{ClO_4}).

$[Ni(L^2)_2](ClO_4)_2$ (1b): This complex was prepared by a similar procedure. Yield: 226 mg (90%). $C_{16}H_{22}Cl_2N_6NiO_8$: calcd. C 38.57, H 3.99, N 15.12; found C 38.53, H 4.05, N 15.07. IR: $\tilde{\nu}$ = 3341, 3288 cm^{-1} (ν_{NH_2}), 2942−2862 (ν_{C-H}), 1658 ($\nu_{C=N}$), 1594 (δ_{N-H}), 1441−1307 ($\nu_{pyridine\ ring}$), 1090, 628(ν_{ClO_4}).

$[Ni(L^3)(H_2O)_2](ClO_4)_2$ (2a): $Ni(ClO_4)_2·6H_2O$ (0.304 g, 0.83 mmol) dissolved in 10 mL of water was added to a solution of L^3 (0.266 g, 0.99 mmol) in methanol (40 mL), and heated to reflux for 3 h. The solution turned green. It was then filtered and the filtrate cooled to room temperature. Solvent removal from the filtrate under reduced pressure gave a green residue which was washed twice (10 mL each) with hexane to remove the excess ligand. The compound was then dried in vacuo over fused $CaCl_2$. Yield: 433 mg (93%). $C_{16}H_{22}Cl_2N_4NiO_{10}$: calcd. C 34.32, H 3.96, N 10.01; found C 34.26, H 4.01, N 10.04. IR: $\tilde{\nu}$ =3435−3413 cm^{-1} (ν_{O-H}), 2982−2885 (ν_{C-H}), 1647 ($\nu_{C=N}$), 1603 (δ_{O-H}), 1452−1307 ($\nu_{pyridine\ ring}$), 1096, 626(ν_{ClO_4}), 748 (ρ_r), 609 (ρ_w), 449 (ν_{Ni-O}).

$[Ni(L^4)(H_2O)_2](ClO_4)_2$ (2b): This complex was prepared by a similar procedure. Yield: 407 mg (92%). $C_{14}H_{18}Cl_2N_4NiO_{10}$: calcd. C 31.61, H 3.41, N 10.53; found C 31.55, H 3.48, N 10.50. IR: $\tilde{\nu}$ = 3437−3410 cm^{-1} (ν_{O-H}), 2981−2879 (ν_{C-H}), 1647 ($\nu_{C=N}$), 1604 (δ_{O-H}), 1449−1303 ($\nu_{pyridine\ ring}$), 1095, 625(ν_{ClO_4}), 747 (ρ_r), 610 (ρ_w), 449 (ν_{Ni-O}).

$[Ni(L^1)_2](ClO_4)_3$ (3a): This complex was prepared by an electrochemical technique. The complex $[Ni(L^1)_2](ClO_4)_2$ (0.146 g, 0.25 mmol) was dissolved in dry acetonitrile (30 mL) and TEAP was added as supporting electrolyte. The brown solution was then subjected to coulometric oxidation at 1.25 V vs. SCE under a dinitrogen atmosphere. The solution gradually turned reddish-brown and the oxidation was stopped when the Coulomb count corresponded to a one-electron oxidation. The solvent was then removed under reduced pressure to obtain a reddish-brown solid mixed with TEAP. The residue was dissolved in dichloromethane and TEAP was filtered off. Solvent removal from the filtrate afforded a reddish-brown compound which was then dried in vacuo over fused $CaCl_2$. Yield: 150 mg (88%). $C_{18}H_{26}Cl_3N_6NiO_{12}$: calcd. C 31.63, H 3.83, N 12.30; found C 31.58, H 3.80, N 12.34.

$[Ni(L^2)_2](ClO_4)_3$ (3b): This complex was synthesised by a similar electrochemical procedure in 89% yield. $C_{16}H_{22}Cl_3N_6NiO_{12}$: calcd. C 29.32, H 3.38, N 12.82; found C 29.36, H 3.33, N 12.76.

X-ray Crystallography: Brown or green single crystals of the complexes **1a** and **2a**, respectively, were grown by slow evaporation of solvent from a methanol solution. Data were collected on a Siemens SMART CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) by the phi and omega scan technique in the range 3° ≤ 2θ ≤ 50° at 293 K. All the data were corrected for Lorentz-polarisation and absorption.[29] The structures were generated by direct methods followed by successive Fourier synthesis and refined by full-matrix least-squares based on F^2. All non-hydrogen atoms were made anisotropic. All the hydrogen atoms (barring water hydrogen atoms) for **2a** were added at the calculated positions. Hydrogen atoms apart from two amino groups (N3, N6) were added at the calculated positions for **1a**. Calculations were performed using the SHELXTAL™ v. 5.03 program package.[30] Significant crystal data are listed in Table 5.
CCDC-216308 (for **1a**) and -216309 (for **2a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cam-

Synthesis and Structure of New (Polyphosphane)ruthenium Complexes with the Hemilabile Ligand 2-(Diphenylphosphanyl)-1-methyl-1*H*-imidazole − An Unexpected Rearrangement of $[RuCl_2(PN)(PPh_3)_2]$

Gustavo Espino,[a] Félix A. Jalón,[b] Miguel Maestro,[c] Blanca R. Manzano,*[b] Mercedes Pérez-Manrique,[a] and Ana C. Bacigalupe[a]

Keywords: Ruthenium / Hemilabile ligands / Hydride ligands / Phosphanes / N,P ligands

Several Ru^{II} complexes containing the potentially bidentate ligand 2-(diphenylphosphanyl)-1-methyl-1*H*-imidazole [PPh_2MeIm (PN)] have been synthesised and characterised. Reaction of the ligand with $[RuCl_2(PPh_3)_3]$ in different molar ratios led to the formation of the complexes *trans*,*mer*-$[RuCl_2(PPh_3)_2(\kappa^2\text{-}P,N\text{–}PPh_2MeIm)]$ (**1**), *fac*-$[RuCl(PPh_3)(\kappa^2\text{-}P,N\text{-}PPh_2MeIm)_2]Cl$ (**2a**), *mer*-$[RuCl(PPh_3)(\kappa^2\text{-}P,N\text{-}PPh_2MeIm)_2]Cl$ (**2b**), *fac*-$[RuCl(\kappa^1\text{-}P\text{-}PPh_2MeIm)(\kappa^2\text{-}P,N\text{-}PPh_2MeIm)_2]Cl$ (**3a**), and *mer*-$[RuCl(\kappa^1\text{-}P\text{-}PPh_2MeIm)(\kappa^2\text{-}PN\text{-}PPh_2MeIm)_2]Cl$ (**3b**). Complex **1** evolves in solution to **2a**, **2b** and the dinuclear species $[(PPh_3)(\kappa^1\text{-}P\text{-}PPh_2MeIm)ClRu(\mu\text{-}Cl)_2Ru(PPh_3)(\kappa^1\text{-}P\text{-}PPh_2MeIm)Cl]$ (**4a**), $[(PPh_3)ClRu(\mu\text{-}Cl)_2(\mu^2\text{-}P,N\text{-}PPh_2MeIm)_2Ru(PPh_3)Cl]$ (**4b**), and $[(PPh_3)(\kappa^2\text{-}P,N\text{-}PPh_2MeIm)ClRu(\mu\text{-}Cl)_2Ru(PPh_3)(\kappa^2\text{-}P,N\text{-}PPh_2MeIm)Cl]$ (**4c**). It is proposed that the formation of the dinuclear derivatives involves an Ru–N bond-breaking step that demonstrates the hemilabile behaviour of the ligand. When 2 equiv. of the PN ligand were added to $[RuCl_2(cod)(bpzm)]$ [cod = 1,5-cyclooctadiene, bpzm = bis(pyrazol-1-yl)methane], the complex *cis*-*P*-$[RuCl_2(\kappa^1\text{-}PPh_2MeIm)(\kappa^2\text{-}PPh_2MeIm)]$ (**5**) was formed as the only product. The derivatives $[Ru(\kappa^2\text{-}PPh_2MeIm)_3]X_2$ [(X = PF_6 (**6**), BF_4 (**7**)] were obtained upon treatment of $[RuCl_2(arene)]_2$ (arene = *p*-cymene, benzene) with 2 equiv. of the corresponding silver salts and the PN ligand. Both the *fac* (**6a**, **7a**) and *mer* (**6b**, **7b**) forms were obtained. Two new hydride complexes were also synthesised: *mer*-$[RuHClL_2(\kappa^2\text{-}PPh_2MeIm)]$ [L = PPh_3 (**8**) or κ^1-PN (**9**)] by reaction of the PN ligand with $[RuHCl(PPh_3)_3]$ or [RuHCl(cod)(bpzm)], respectively. The molecular structure of **4b** and *fac*-**7a** was solved by an X-ray diffraction study. Complex **4b** has a dinuclear structure with two chloride bridges and two head-to-tail PN bridges. The derivative *fac*-**7a** is mononuclear. Both enantiomers — Δ and Λ — were observed in the same unit cell.

Introduction

Ruthenium(II) derivatives containing tertiary phosphane ligands are important precursors in catalytic processes, particularly hydrogenation.[1] For example, complexes of formula $[RuCl_2L_n]$, $[RuClHL_n]$ (n = 3, 4), $[RuCl_2(CO)L_3]$ or $[RuClH(CO)L_3]$ are efficient catalysts in the hydrogenation of alkenes,[2] alkynes,[2,3] aromatic heterocycles[4] or hydrocarbons,[5] aldehydes and ketones.[6] In many of these catalytic processes, cycles involving the decoordination of phosphanes or chlorides are involved.[1,2] For instance, $[RuCl_2(PPh_3)_3]$ is a classical starting point to give an active catalyst through phosphane[7] or chloride[8] dissociation. This process allows the coordination of substrates such as hydrogen or molecules that act as a hydrogen source, such as alcohols.[9] A theoretical alternative to the complete decoordination of a tertiary phosphane is the partial decoordination of a bidentate and hemilabile phosphane that probably causes only a minor effect on the electronic stability of the catalyst. With this possibility in mind, we envisaged the reaction of typical precursors like $[RuCl_2(PPh_3)_3]$ or $[RuClH(PPh_3)_3]$ with 2-(diphenylphosphanyl)-1-methyl-1*H*-imidazol[10] (PPh_2MeIm; Scheme 1), in different molar ratios, to obtain potential catalyst precursors with different structures and nuclearities. In order to compare our results and obtain complexes that are free of triphenylphosphane, we also used as starting materials $[RuCl_2(cod)(bpzm)]$

[cod = 1,5-cyclooctadiene, bpzm = bis(pyrazol-1-yl)methane] and $[RuCl_2(p\text{-cymene})]_2$ as halide precursors and [RuClH(cod)(bpzm)] as a hydride.[11] In contrast to the widely used phosphane 2-(diphenylphosphanyl)pyridine,[12] the use of PPh_2MeIm as a bidentate ligand offers a more strained bite angle. This situation can favour the partial decoordination of the phosphane group.

Results and Discussion

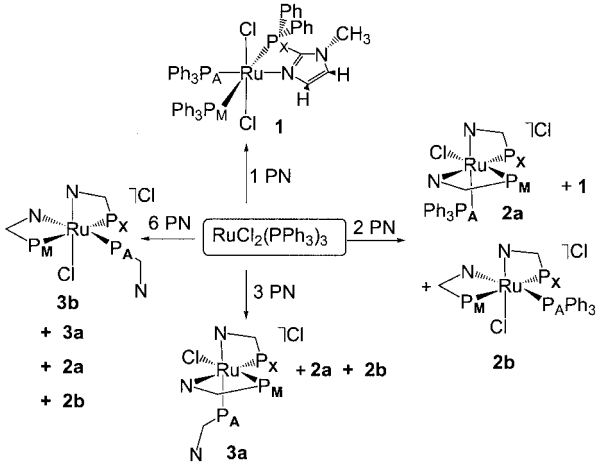
The following discussion concerns the synthesis and characterisation of the new Ru^{II} derivatives containing the hemilabile ligand PPh_2MeIm (PN). The discussion is divided according to the Ru species used as the starting material.

Reaction of PPh_2MeIm with $[RuCl_2(PPh_3)_3]$ − X-ray structure of $[(PPh_3)ClRu(\mu\text{-}Cl)_2(\mu^2\text{-}P,N\text{-}PPh_2MeIm)_2Ru(PPh_3)Cl]\cdot CH_2Cl_2$

The reaction of $[RuCl_2(PPh_3)_3]$ with the ligand PN was studied in different molar ratios and this led to the formation of different complexes containing either one, two or three ligands bonded to the ruthenium centre. When $[RuCl_2(PPh_3)_3]$ was heated under reflux with 1 equiv. of PN in CH_2Cl_2 the polyphosphane complex **1** was isolated in 89% yield [Equation (1)].

$$[RuCl_2(PPh_3)_3] + PN \rightarrow [RuCl_2(PPh_3)_2(\kappa^2\text{-}PN)]\,(\mathbf{1}) + PPh_3 \qquad (1)$$

The conductivity data indicate that **1** is a neutral molecule. The $^{31}P\{^1H\}$ NMR spectrum (in $CDCl_3$; see Table 1) of **1** consists of an AMX pattern with two *cis* ^2J ($^2J_{A,M}$ and $^2J_{A,X}$) and one *trans* ^2J ($^2J_{M,X}$) coupling constants. These data are in agreement with a *mer* disposition of the three P atoms. The high-field doublet of doublets [δ = −22.2 ppm (P_X)] is consistent with the formation of a four-membered chelate ring in the PN ligand.[13] The IR spectrum of complex **1** shows a single absorption band at 326 cm^{-1}, which is characteristic of ν(Ru−Cl) with mutual *trans*-chloride ions.[14,15] The FAB^+ mass spectrum is in complete agreement with the expected fragmentation pattern and contains a peak corresponding to the fragment $[RuCl(PPh_3)_2(PN)]^+$ at m/z = 927, which is the result of chloride loss from **1**. In subsequent steps, the loss of PPh_3 gives $[RuCl(PPh_3)(PN)]^+$ (m/z = 665), and $[RuCl(PN)]^+$ (m/z = 403). On the basis of these data, the structure of **1**, which must be present as a mixture of enantiomers, is believed to be that shown in Scheme 2.



Scheme 2. Reaction scheme for the system $[RuCl_2(PPh_3)_3]/n$PN (n = 1, 2, 3, 6)

The reactions of $[RuCl_2(PPh_3)_3]$ with 2, 3 and 6 equiv. of the ligand PN were also investigated. These reactions led to the formation of four new complexes, as deduced from the corresponding $^{31}P\{^1H\}$ NMR spectra. The results can be summarised as follows (see Scheme 2): (i) When the Ru/PN ratio was 1:2, complex **1** was formed along with two new

complexes (**2a** and **2b**). (ii) When the ratio was 1:3, complex **1** was not formed but **2a**, **2b** and a new complex (**3a**) were observed in the reaction medium. (iii) The reaction with a ratio of 1:6 led to the formation of **2a**, **2b**, **3a** and a new derivative (**3b**).

We were able to deduce the structures of the four new complexes with the help of information obtained from a $^{31}P,^{31}P$ COSY experiment in $CDCl_3$ on a sample of the material formed in the reaction with the 1:6 ratio, which contained the four new derivatives (see Figure 1). The conclusions reached can be summarised as follows: (i) The spin system of each derivative fits an AMX pattern. (ii) Compounds **2a** and **3a** exhibit a *fac-PPP* disposition. (iii) Compounds **2b** and **3b** exhibit a *mer-PPP* disposition. (iv) All of these new compounds have two four-membered chelate rings (PN ligand) and one monodentate phosphane ligand, as deduced from the existence of two high-field signals and a low-field resonance for each derivative.

From the point of view of stoichiometry, it seems reasonable that in the reaction with a 1:2 ratio, the replacement of two PPh_3 units by two PN ligands takes place with the concomitant loss of one chloride ligand from the ruthenium centre. In this case complexes **2a** and **2b** will be the *fac* and *mer* isomers with the stoichiometry $[RuCl(PPh_3)(\kappa^2\text{-}P,N\text{-}PPh_2MeIm)_2]Cl$. These compounds contain one PPh_3 group, which can be removed by another molecule of PN when larger amounts of the ligand are used. This change leads to complexes **3a** and **3b** and these are the corresponding *fac* and *mer* isomers of stoichiometry $[RuCl(\kappa^1\text{-}P\text{-}PPh_2MeIm)(\kappa^2\text{-}P,N\text{-}PPh_2MeIm)_2]Cl$. The structures of the new derivatives, which are consistent with the data obtained, are shown in Scheme 2.

Attempts were made to obtain crystals of **1** from a dichloromethane/hexane mixture (1:1) in order to carry out an X-ray structure determination. Unexpectedly, the crystals obtained corresponded to the dinuclear species $[(PPh_3)ClRu(\mu\text{-}Cl)_2(\mu^2\text{-}P,N\text{-}PPh_2MeIm)_2Ru(PPh_3)Cl]$ (**4b**) as a dichloromethane solvate. The ORTEP plot of **4b** is shown in Figure 2, a selection of bond lengths and angles are given in Table 2. Other crystallographic data are given in the Exp. Sect. The complex has a dinuclear structure with two chloride bridges and two other head-to-tail axial PN bridges. The two metal centres are in a slightly distorted octahedral geometry as a consequence of the bridge strain, which is exemplified by the N(1)−Ru(1)−Cl(1) (86.04°) and N(1)−Ru(1)−Cl(1A) (82.80°) angles. The two terminal positions for each of the ruthenium atoms are occupied by one Cl and one PPh_3 ligand.

		Cl(1)−Ru(1)−Cl(1A)	90.50(3)
		Cl(2)−Ru(1)−Cl(1A)	83.71(3)
		Ru(1)−Cl(1)−Ru(1A)	89.50(3)
fac-**7a·$(CH_3)_2CO$**			
Ru(1)−N(6)	2.140(2)	N(2)−Ru(1)−P(1)	68.74(6)
Ru(1)−N(4)	2.160(2)	N(4)−Ru(1)−P(2)	68.59(6)
Ru(1)−N(2)	2.173(2)	N(6)−Ru(1)−P(3)	69.04(7)
Ru(1)−P(1)	2.2954(8)	N(2)−C(13)−P(1)	105.50(18)
Ru(1)−P(3)	2.2990(9)	N(6)−C(45)−P(3)	104.58(18)
Ru(1)−P(2)	2.2995(8)	N(4)−C(29)−P(2)	105.28(18)

The Ru(1)−Ru(1A) distance is only 3.398 Å and is intermediate between those typically observed in complexes with $Ru^{II}(\mu\text{-}Cl)_2Ru^{II}$ bridges (but without an Ru−Ru bond, 3.68−3.91 Å)[11b,16] and those found in derivatives that do contain an Ru−Ru bond {e.g. 2.93 Å in $[RuCl_2(\mu^2\text{-}Cl_2)(\mu^2\text{-}dppm)RuCl_2]$}.[17] The presence of the two additional PCN bridges can lead to shortening of this distance, a situation that has been observed in other dinuclear Ru derivatives with additional short bridges.[18]

In addition, the distances between each of the chloride bridging ligands and each of the ruthenium atoms are asymmetric, with *d*[Ru(1)−Cl(1)] = 2.3878 Å and *d*[Ru(1A)−Cl(1)] = 2.4387 Å. This indicates a greater elongation of the μ-Cl−Ru bonds *trans* to PPh_3 in comparison to those *trans* to Cl^-. This situation is in keeping with the higher *trans* influence of a P-donor ligand than a chloride ligand.[18,19]

In order to understand the unexpected transformation of complex **1**, we monitored the evolution of a $CDCl_3$ solution of **1** during 3 d by $^{31}P\{^1H\}$ NMR spectroscopy. This experiment indicated that **1** undergoes a slow rearrangement in solution. The final $^{31}P\{^1H\}$ NMR spectrum is very complicated and shows the presence of several complexes (see Figure 3). A $^{31}P,^{31}P$ COSY experiment allowed each group of coupled signals to be correlated and indicated five independent spin systems and a singlet.

In this spectrum the resonances of **2a** and **2b** can be seen along with those of **4b**, which corresponds to an AM spin system (two doublets at δ = 19.43 and 68.09 ppm). The former of these signals can be assigned to a bridging coordination mode of the PN ligand on the basis of literature data.[20] The second doublet must correspond to coordinated PPh_3. Two additional spin systems can also be observed in the spectrum. Both of these have an AM pattern

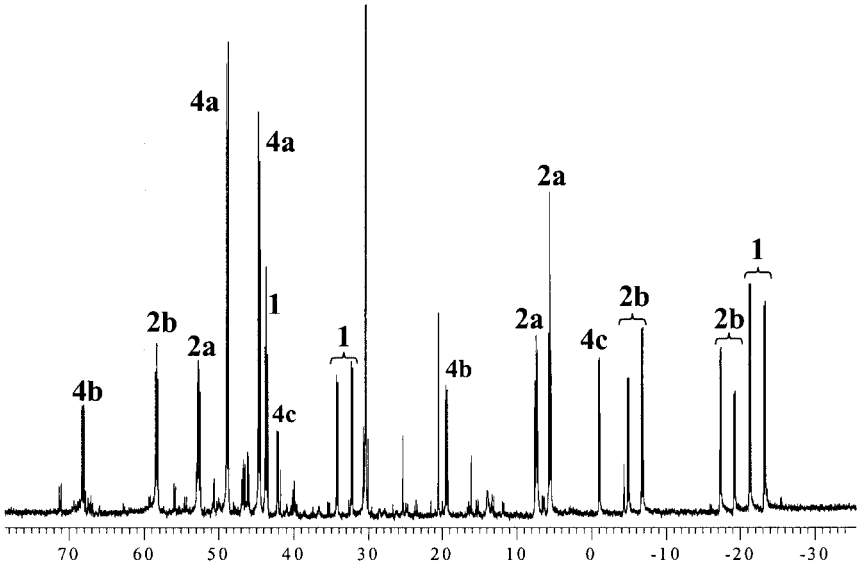

Figure 3. $^{31}P\{^{1}H\}$ NMR spectrum (161.923 MHz) in $CDCl_3$ at room temperature for a sample of **1** after 3 d in solution

with coupling constants typical of two P atoms in a *cis* disposition. The pair of signals for one complex, **4a**, have chemical shifts that do not correspond to either a chelating or bridging coordination of the PN ligand. Consequently, the PN ligand must exhibit monodentate coordination. One of the resonances of the other derivative, **4c**, indicates a chelating coordination. Considering this information we propose the structures indicated in Scheme 3 for complexes **4a** and **4c**. These structures are also reasonable in terms of the evolution of complex **1** after the loss of one PPh_3 ligand (see below). In the NMR spectrum there is also an intense singlet at $\delta = 30.3$ ppm, which can be assigned to $[RuCl_2(PPh_3)_3]$ — probably in equilibrium with free PPh_3.[21] According to the stoichiometry of the derivatives formed from **1**, both species must exist in the reaction medium (Scheme 3).

Although we do not have direct proof, we think that a reasonable mechanism for the dimerisation of **1** to **4a**, **4b** and **4c** is that shown in Scheme 4. This process would be favoured by the hemilabile character of the PN ligand and may involve the following steps: (i) Dissociation of one PPh_3 ligand. (ii) Partial dissociation of the PN ligand as a consequence of the strain in the four-membered ring and formation of two chloride bridges. Such a change leads to the formation of **4a**. The spontaneous dissociation of one PPh_3 group[22] and the consequent formation of chloride bridges[21b,23] has been reported for $[RuCl_2(PPh_3)_3]$. The coordination of the N atom to occupy the vacancy on each metal centre could take place in two ways, either to produce PN bridges between the two metal centres to give **4b**, or to regenerate a four-membered chelate ring on each metal atom to give **4c**.

Reaction of PPh_2MeIm with $[RuCl_2(cod)(bpzm)]$

In the previous reactions between the PN ligand and $[RuCl_2(PPh_3)_3]$ we obtained a rich variety of products that included not only mononuclear species with different amounts of the PN ligand but also dinuclear derivatives. It is clear from these results that competition between the incoming ligand and PPh_3 is always present and frequently leads to the formation of product mixtures. Even when 6 equiv. of the PN ligand were used, the products that do not contain PPh_3 (**3a**, **3b**) were formed along with those containing 1 equiv. of the phosphane (**2a**, **2b**). Given these findings, we decided to use a starting material that did not contain the phosphane ligand and incorporated weakly coordinating ligands — $[RuCl_2(cod)(bpzm)]$ [cod = 1,5-cyclooctadiene, bpzm = bis(pyrazol-1-yl)methane]. It has been shown that both cod and bpzpm ligands are prone to replacement by PN donor ligands.[11a] When 2 equiv. of PPh_2MeIm were added to a suspension of this compound and the mixture heated under reflux in THF, the complex *cis*-*P*-$[RuCl_2(\kappa^1$-*P*-$PPh_2MeIm)(\kappa^2$-*P*,*N*-$PPh_2MeIm)]$ (**5**) was obtained as the only product [Equation (2)].

$$[RuCl_2(cod)(bpzm)] + 2\,PN \rightarrow cis\text{-}P\text{-}[RuCl_2(\kappa^1\text{-}PN)(\kappa^2\text{-}PN)]\,(\mathbf{5}) + cod + bpzm \quad (2)$$

The ^1H NMR spectrum at low temperature does not show any evidence of the presence of bpzm or cod ligands and signals for only two kinds of PN ligand were observed. The corresponding $^{31}P\{^1H\}$ NMR spectrum ([D_6]acetone) at room temperature contains two broad signals that must be due to some kind of fluxional process. In an attempt to obtain more information on the structure of the complex, a $^{31}P\{^1H\}$ NMR spectrum was recorded at low temperature (−90 °C) and an AM pattern was observed [δ = 3.35 (d) and 51.85 (d) ppm]. The high-field resonance can be assigned to a PN ligand with a chelating coordination mode while the lower-field signal belongs to a monodentate PN ligand. The $^2J_{P,P}$ value (32.02 Hz) is indicative of a *cis* disposition of the two atoms. Moreover, the FAB^+ mass spectrum shows a peak at *m*/*z* = 669 due to the cation $[RuCl(PN)_2]^+$, which is the result of the loss of one chloride ion from **5**. Two bands at 367 and 297 cm^{-1}, assigned to the stretching vibration modes of the $RuCl_2$ unit, were observed in the IR spectrum. It can be concluded from these data that the complex is a monomeric, pentacoordinate compound with one bidentate and one monodentate PN ligand in which the P atoms are in a *cis* disposition but can exchange their coordination modes at room temperature through a fast process.

Interestingly, the reaction of $[RuCl_2(cod)(bpzm)]$ with 3 equiv. of the ligand PN under reflux gave a precipitate that was identified as complex **3**, with no other compound being detected. Complex **3** was present as four diastereoisomers: the pair of enantiomers *fac*-**3a** and the pair *mer*-**3b** in a molar ratio of 4:1. As stated previously, these isomers were also obtained when $[RuCl_2(PPh_3)_3]$ was used as the starting material but always in a mixture with other derivatives (see Table 1 for the ^{31}P NMR spectroscopic data). The FAB^+ spectrum is consistent with the proposed formulation, as a peak corresponding to the cation of **3** is observed at *m*/*z* = 935. The rest of the peaks are in agreement with the loss of a chloride ion and two PN ligands in successive steps (see Exp. Sect.).

Reaction of PPh_2MeIm with $[RuCl_2(p\text{-cymene})]_2$ − X-ray Structure of *fac*-$[Ru(\kappa^2$-*P*,*N*-$PPh_2MeIm)_3](BF_4)_2\cdot(CH_3)_2CO$

Another goal of our study was the synthesis of derivatives of the type $[Ru(PN)_3]X_2$, with three chelate ligands. Such complexes would be expected to be chiral[24] and, considering the hemilabile character of the PN ligand, they could be interesting starting materials in catalytic or stoichiometric processes.[25] We succeeded in the synthesis of these compounds by using $[RuCl_2(arene)]_2$ (arene = *p*-cymene, benzene) as starting materials and adding silver salts to remove the chloride ions. In this way, the complexes $[Ru(\kappa^2$-*P*,*N*-$PPh_2MeIm)_3]X_2$ [X = PF_6 (**6**) and BF_4 (**7**)] were isolated after the addition of the ligand PPh_2MeIm to the solution obtained by treatment of a suspension of $[RuCl_2(arene)]_2$ in MeOH with $AgPF_6$ or $AgBF_4$, respectively, at room temperature [Equation (3)]. The same products were also formed upon treatment of $[RuCl_2(cod)(bpzm)]$ with the silver salt and the PN ligand, but in this case the reaction led to a mixture of derivatives. Consequently, the reaction outlined in Equation (3) is more convenient.

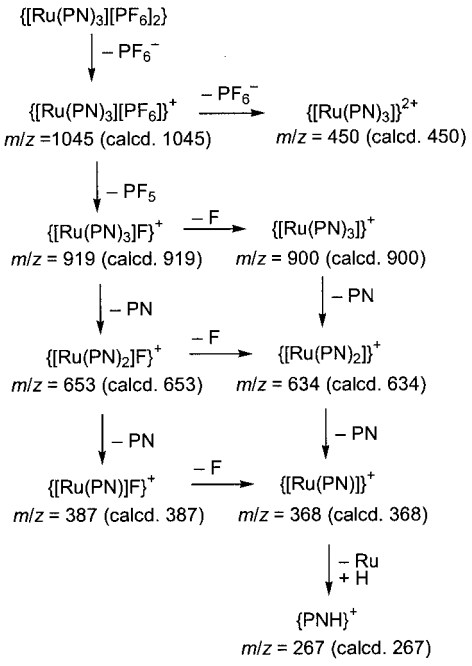
$$[RuCl_2(arene)]_2 + 4\,AgX + 6\,PN \rightarrow 2\,[Ru(\kappa^2\text{-}PN)_3]X_2 + 4\,AgCl \quad (3)$$

arene = *p*-cymene, X = PF_6 (**6**); arene = benzene, X = BF_4 (**7**)

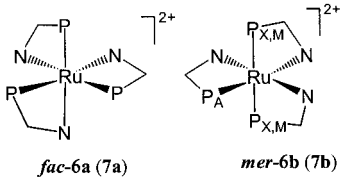
In both cases the two pairs of stereoisomers, *fac* (**6a** and **7a**) and *mer* (**6b** and **7b**), were formed. The ^1H NMR spectra lack the characteristic signals of *p*-cymene or benzene. The $^{31}P\{^1H\}$ NMR spectrum of **6** exhibits the AM_6 pattern of the PF_6^- counteranion. Furthermore, a singlet for the *fac* stereoisomer (chemical shift of chelate coordination) and the AMX pattern of a *mer* stereoisomer are observed for both derivatives. Two signals at high field due to the *mer* form are typical of chelate coordination. However, the resonance at δ = 20.70 ppm could correspond to a chelating or bridging PN ligand, which means that the compound could be mono- or dinuclear in nature. In an effort to clarify this point, high-resolution mass spectra were obtained for **6** and **7**. Only the spectrum of compound **6** will be discussed as it is very similar to that of **7**. The spectrum displays a group of signals corresponding to the fragment $[\{Ru(PN)_3\}\{PF_6\}]^+$, whose most intense peak appears at *m*/*z* = 1045.2. In addition a signal at *m*/*z* = 450.13 was observed, which is consistent with the dicationic fragment $[\{Ru(PN)_3\}]^{2+}$, as deduced from the difference between the lines in this group of half a unit. The overall fragmentation pattern for this molecule is indicated in Scheme 5. No evidence for the existence of a dinuclear species was found in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the mass spectrum. Consequently, all the data indicate a mononuclear structure for both derivatives (Scheme 6).



Scheme 5. Fragmentation pattern for **6**



Scheme 6. Proposed structures for **6** and **7**

Finally, it was possible to crystallise the *fac* isomer of **7** (i.e. **7a**) as an acetone solvate and to determine its molecular structure by an X-ray diffraction study on a single crystal. The corresponding ORTEP plot is shown in Figure 4, selected bond lengths and angles are shown in Table 2 and crystallographic data are given in the Exp. Sect. The compound is mononuclear and exhibits a *fac* disposition of the three phosphorus atoms. Only the structure for the Δ isomer is shown in Figure 4a, although it should be noted that both the Δ and Λ enantiomers are present in the same unit cell (see Figure 4b).

At present, only one structure containing three four-membered PN chelate rings has been deposited with the CSD[26] and that corresponds to the complex [Ru(pyphos)$_3$](μ-Na$_2$)[Ru(pyphos)$_3$] in which each pseudo-octahedral ruthenium(II) centre has three PN chelating ligands [pyphos = 6-(diphenylphosphanyl)-2-pyridonate]. As in the case of **7a**, a *fac* disposition for the identical donor atoms was found.

A comparison between the free and the chelate-coordinated ligand in *fac*-**7a** reflects the fact that the P−C−N

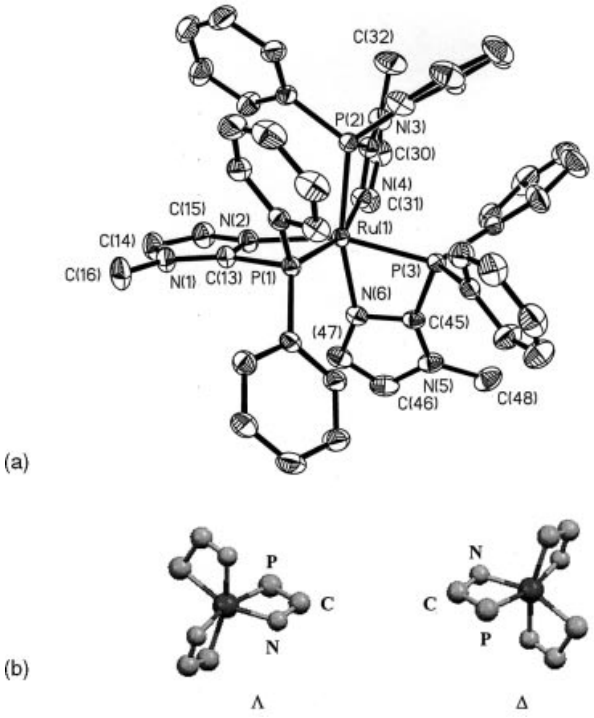


Figure 4. (a) ORTEP plot of the cation of the Δ enantiomer of *fac*-**7a**, showing the atom labelling; hydrogen atoms and phenyl groups have been omitted for clarity, as have counterions and solvent molecules; (b) ball-and-stick plots for *fac*-**7a**, showing both enantiomers

angle decreases with κ^2-*PN* coordination from 128.5(2)°[27] in the free ligand to about 105° in **7a**. Very similar angles (about 103°) are present in the previously mentioned [Ru(pyphos)$_3$] units. This situation can be seen as a consequence of the inherent strain associated with the four-membered chelate ring. Similarly, the Ru−N bonds are relatively long[28] and the bite angles of the PN donor ligands are small.

Hydride Complexes

We also tried to synthesise new hydride complexes containing the PPh_2MeIm ligand. In order to achieve this aim we used two types of hydride starting material, one containing PPh_3 and the other with more easily displaceable ligands — [RuHCl(PPh_3)$_3$] and [RuHCl(cod)(bpzm)].

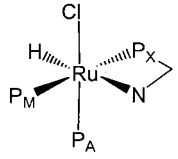
When equivalent amounts of [RuHCl(PPh_3)$_3$] and PPh_2MeIm were mixed in toluene at 70 °C, *mer*-[RuHCl(PPh_3)$_2$(κ^2-*P,N*-PPh_2MeIm)] (**8**) was isolated in good yield [Equation (4)].

$$[RuHCl(PPh_3)_3] + PN \rightarrow mer\text{-}[RuHCl(PPh_3)_2(\kappa^2\text{-}PN)]\ (\mathbf{8}) + PPh_3 \quad (4)$$

The hydride region of the ^{1}H NMR (C_6D_6) spectrum of **8** shows a quadruplet at δ = −15.1 ppm ($^2J_{P,H}$ = 26.6, $^2J_{P,H}$ = 23.5, $^2J_{P,H}$ = 23.4 Hz) as the most characteristic signal. This relatively high-field chemical shift is typical for a hydride ion *trans* to an N atom, as reported in the litera-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ture,[29] and is in contrast to the lower-field chemical shift observed for hydride ions *trans* to Cl ligands.[11,30] The values of the three coupling constants, determined separately by selective $^1H\{^{31}P\}$ NMR decoupling experiments, correspond to a *cis* disposition of the hydride ion with respect to the three P atoms, which also means a *mer-PPP* disposition. The $^{31}P\{^1H\}$ NMR (C_6D_6) spectrum of **8** confirms the stereochemistry of the complex, since it consists of an AMX pattern with one *trans*-PP coupling constant between a PPh_3 and a chelating PPh_2MeIm group. Consequently, the spectroscopic data indicate the presence of the *mer* stereoisomer in solution (see Scheme 7). Obviously, complex **8** is isolated as a racemic mixture.



$P_A = P_M = PPh_3$, ***mer*-8**
$P_A = P_M = PPh_2MeIm$, ***mer*-9**

Scheme 7. Proposed structures of complexes **8** and **9**

An excess of the ligand PPh_2MeIm (6:1) was mixed with [RuHCl(cod)(bpzm)] in THF at −80 °C and the hydrido complex *mer*-[RuHCl(κ^1-*P*-PPh_2MeIm)$_2$(κ^2-*P*,*N*-PPh_2MeIm)] (**9**) was obtained [Equation (5)].

$$[RuHCl(cod)(bpzm)] + 6\,PN \rightarrow mer\text{-}[RuHCl(\kappa^1\text{-}PN)_2(\kappa^2\text{-}PN)]\,(\mathbf{9}) + cod + bpzm \quad (5)$$

The ^1H (C_6D_6) and $^{31}P\{^1H\}$ NMR (C_6D_6) spectra of **9** are completely analogous to those of **8**. Two of the phosphorus chemical shifts are typical of a monodentate coordination of the PN ligand while a resonance appearing at $\delta = -10$ ppm indicates the existence of a chelating PPh_2MeIm group. Consequently, the presence of the *mer* stereoisomer, as a racemic mixture, is again evident (see Scheme 7). The two PPh_3 ligands in compound **8** are monodentate PPh_3MeIm groups in **9**.

Conclusion

We have prepared new families of (polyphosphane)Ru complexes containing the ligand 2-(diphenylphosphanyl)-1-methyl-1*H*-imidazole. In the complexes described, three types of coordination modes for the N,P ligand have been found: *P*-monodentate, chelate and brigde. An unexpected rearrangement of [$RuCl_2$(Pn)(PPh_3)$_2$] that leads, among others, to the formation of dinuclear derivatives has been found. The formation of these species involves an Ru−N bond-breaking step that demonstrates the hemilabile behaviour of the ligand.

Experimental Section

General Comments: All manipulations were carried out under Ar using standard Schlenk techniques. Solvents (Merck) were dried and distilled under N_2 prior to use. [$RuCl_2(PPh_3)_3$],[31] [$RuHCl(PPh_3)_3$],[32] [$RuCl_2$(bpzm)(cod)],[33] [RuHCl(bpzm)-(cod)],[33] [$RuCl_2$(*p*-cymene)]$_2$,[34] [$RuCl_2(C_6H_6)$]$_2$ [34] and PPh_2MeIm[27] were prepared according to literature procedures. NMR spectra were recorded at room temperature (ca. 22 °C), unless otherwise stated, with a Varian Unity Inova-400 (400 MHz for ^1H; 161.9 MHz for ^{31}P; 100.6 MHz for ^{13}C) or with a Varian Unity-300 (300 MHz for ^1H; 121.4 MHz for ^{31}P; 75.4 MHz for ^{13}C) spectrometer. ^1H NMR shifts are referenced to the residual proton of the solvent as internal standard. All ^{31}P shifts were referenced internally to H_3PO_4. The ^{31}P,^{31}P COSY spectrum was acquired using a 30604 Hz spectral width; 24 transients were collected for each 240 increments. A 1 s relaxation delay, a 45° pulse width, and a 0.20 s acquisition time were used. IR spectra were recorded with a Nicolet Impact 410 spectrophotometer as KBr pellets or with a Perkin−Elmer 883 (4000−200 cm^{-1} range) as Nujol mulls. Conductivity measurements were made at 25 °C with freshly prepared 10^{-3} M solutions of the complex in acetone, using a CRISON 522 conductimeter. Molar conductivities (Λ_M) are given in units of $\Omega^{-1}\cdot mol^{-1}\cdot cm^2$. Elemental analyses were performed with a LECO CHNS932 microanalyser. FAB^+ mass spectra were recorded at the University of Zaragoza with a VG AutoSpec or at the University of Burgos with a Micromass Autospec by Liquid Secondary Ion Mass Spectrometry (LSMIS+) with Cs and NBA ions as the matrix.

***trans*,*mer*-[$RuCl_2(PPh_3)_2$(κ^2-*P*,*N*-PPh_2MeIm)] (1):** PPh_2MeIm (29.5 mg, 0.11 mmol) was added to a suspension of [$RuCl_2(PPh_3)_3$] (106 mg, 0.11 mmol) in 20 mL of CH_2Cl_2 (1:1). The resulting mixture was stirred and refluxed for 16 h. The original suspension became a red solution, which was concentrated to dryness. The orange solid obtained was washed with pentane (15 mL) and then with diethyl ether (3 × 15 mL) to remove any residual PPh_3. Finally, it was dried under vacuum. Yield: 89% (94.8 mg). The product is soluble in $CHCl_3$, CH_2Cl_2 and acetone. It decomposes in solution under air, giving rise to a green-brownish suspension after some minutes. However, it can be stored, as a solid, under nitrogen for months without appreciable decomposition. $C_{52}H_{45}Cl_2N_2P_3Ru$ (962.85): calcd. C 64.87, H 4.71, N 2.91; found C 65.11, H 4.80, N 2.83. FAB^+: *m*/*z* = 927 [M − Cl]$^+$, 665 [M − Cl − PPh_3]$^+$, 403 [M − Cl − 2PPh_3]$^+$.^1H NMR (400 MHz, $CDCl_3$, room temp.): δ = 7.9−6.7 (m, 40 H, 8 Ph), 6.6 (s, 1 H, H-Im), 5.56 (s, 1 H, H-Im), 3.0 (s, 3 H, Me-Im) ppm.$^{13}C\{^1H\}$ NMR (100.6 MHz, $CDCl_3$, room temp.): δ = 150−125 (m, 49 C, 8 Ph, C^2-Im), 130.7 (s, 1 C, *C*H-Im), 123.4 (s, 1 C, *C*H-Im), 34.2 (s, 1 C, Me-Im) ppm. $^{31}P\{^1H\}$ NMR: See Table 1. Λ_M (25 °C, acetone) = 10.35 $\Omega^{-1}\cdot mol^{-1}\cdot cm^2$. IR (nujol mull): $\tilde{\nu}$ = 326 cm^{-1} [ν(*trans*-$RuCl_2$)].

Reaction of [$RuCl_2(PPh_3)_3$] with PPh_2MeIm in a 1:2 Molar Ratio: The procedure is similar to that used for obtaining compound **1**. PPh_2MeIm (59 mg, 0.22 mmol) was added to a suspension of [$RuCl_2(PPh_3)_3$] (106 mg, 0.11 mmol) (2:1) in 20 mL of CH_2Cl_2. The resulting mixture was stirred and refluxed for 16 h. The original suspension became a red solution, which was concentrated to dryness. The orange solid obtained was washed with pentane (15 mL) and then with diethyl ether (3 × 10 mL) to remove any residual PPh_3 or PPh_2MeIm. Finally, it was dried under vacuum. The resulting mixture was studied by $^{31}P\{^1H\}$ NMR spectroscopy, and the following compounds were detected (see Table 1 for the $^{31}P\{^1H\}$ NMR spectroscopic data): **1**, *fac*-[RuCl(PPh_3)(κ^2-*P*,*N*-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$PPh_2MeIm)_2$]Cl (**2a**) and *mer*-[RuCl(PPh_3)(κ^2-*P*,*N*-$PPh_2MeIm)_2$]Cl (**2b**).

Reaction of [$RuCl_2(PPh_3)_3$] with PPh_2MeIm in a 1:3 Molar Ratio: The procedure is similar to that described for the 1:2 molar ratio. Amounts are as follows: PPh_2MeIm (88.6 mg, 0.33 mmol), [$RuCl_2(PPh_3)_3$] (106 mg, 0.11 mmol) and 20 mL of CH_2Cl_2. The resulting mixture was studied by $^{31}P\{^1H\}$ NMR spectroscopy and the following compounds were detected (see Table 1 for the $^{31}P\{^1H\}$ NMR spectroscopic data): **2a**, **2b** and *fac*-[RuCl(κ^1-*P*-PPh_2MeIm)(κ^2-*P*,*N*-$PPh_2MeIm)_2$]Cl (**3a**).

Reaction of [$RuCl_2(PPh_3)_3$] with PPh_2MeIm in a 1:6 Molar Ratio: The procedure is similar to that described for the 1:2 molar ratio. Amounts are as follows: PPh_2MeIm (177 mg, 0.66 mmol), [$RuCl_2(PPh_3)_3$] (106 mg, 0.11 mmol) and 30 mL of CH_2Cl_2. The resulting mixture was studied by $^{31}P\{^1H\}$ NMR spectroscopy, and the following compounds were detected (see Table 1 for the $^{31}P\{^1H\}$ NMR spectroscopic data): **2a**, **2b**, **3a** and *mer*-[RuCl(κ^1-*P*-PPh_2MeIm)(κ^2-*P*,*N*-$PPh_2MeIm)_2$]Cl (**3b**).

[RuCl(κ^1-*P*-PPh_2MeIm)(κ^2-*P*,*N*-$PPh_2MeIm)_2$]Cl (3): PPh_2MeIm (139.9 mg, 0.526 mmol) was added to a suspension of [$RuCl_2$(cod)(bpzm)] (75 mg, 0.175 mmol) in THF (30 mL) (3:1). The resulting mixture was stirred and refluxed for 6 h. A yellow solid was obtained which, after filtering and washing with *n*-pentane (3 × 10 mL), was dried under vacuum. Yield: 72% (123 mg). The product is soluble in CH_2Cl_2 and $CHCl_3$. $C_{48}H_{45}Cl_2N_6P_3Ru$ (970.83): calcd. C 59.39, H 4.67, N 8.66; found C 59.22, H 4.81, N 8.57. FAB^+: *m*/*z* = 935 $[M]^+$, 900 $[M - Cl]^+$, 634 $[M - Cl - PN]^+$, 450 $[M - Cl^-]^{2+}$, 368 $[M - Cl - 2\ PN]^+$, 267 $[PN + H^+]^+$.

***fac*-[RuCl(κ^1-*P*-PPh_2MeIm)(κ^2-*P*,*N*-$PPh_2MeIm)_2$]Cl (3a):** ^1H NMR (400 MHz, $CDCl_3$, room temp.): δ = 9.0−6.2 (m, 36 H, 6 Ph, 3 CH-Im), 3.63 (s, 3 H, Me-Im), 3.22 (s, 3 H, Me-Im), 2.74 (s, 3 H, Me-Im) ppm.

***mer*-[RuCl(κ^1-*P*-PPh_2MeIm)(κ^2-*PN*-$PPh_2MeIm)_2$]Cl (3b):** ^1H NMR (400 MHz, $CDCl_3$, room temp.): δ = 9.0−6.2 (m, 36 H, 6 Ph, 3 CH-Im), 3.79 (s, 3 H, Me-Im), 3.26 (s, 3 H, Me-Im), 2.68 (s, 3 H, Me-Im) ppm. $^{31}P\{^1H\}$ NMR: See Table 1.

[(PPh_3)(κ^1-*P*-PPh_2MeIm)ClRu(μ-Cl)$_2$Ru(PPh_3)(κ^1-*P*-PPh_2MeIm)Cl] (4a): This compound was detected by $^{31}P\{^1H\}$ NMR spectroscopy in a solution of **1** in $CDCl_3$ after standing for 3 d at room temperature.

[(PPh_3)ClRu(μ-Cl)$_2$(μ^2-*P*,*N*-$PPh_2MeIm)_2$Ru(PPh_3)Cl] (4b): This compound was obtained as a crystalline solid from a solution of **1** in CH_2Cl_2/hexane under nitrogen and it was also detected by $^{31}P\{^1H\}$ NMR spectroscopy in a solution of **1** in $CDCl_3$ after standing at room temperature for 3 d.

[(PPh_3)(κ^2-*PN*-PPh_2MeIm)ClRu(μ-Cl)$_2$Ru(PPh_3)(κ^2-*PN*-PPh_2MeIm)Cl] (4c): This compound was detected by $^{31}P\{^1H\}$ NMR spectroscopy in a solution of **1** in $CDCl_3$ after standing at room temperature for 3 d.

***cis*-*P*-[$RuCl_2$(κ^1-*P*-PPh_2MeIm)(κ^2-*P*,*N*-PPh_2MeIm)] (5):** PPh_2-MeIm (66 mg, 0.24 mmol) was added to a suspension of [$RuCl_2$(cod)(bpzm)] (53.6 mg, 0.12 mmol) in 30 mL of THF (2:1). The resulting mixture was stirred and refluxed for 14 h, then filtered and the resulting solution concentrated to dryness. The pale-green solid obtained was washed with diethyl ether (2 × 10 mL) and finally dried under vacuum. Yield: 68% (60 mg). The compound is soluble in acetone and $CHCl_3$. $C_{32}H_{30}Cl_2N_4P_2Ru$ (704.55): calcd. C 54.55, H 4.29, N 7.95; found C 54.62, H 4.33, N 8.21. FAB^+: *m*/*z* = 669 $[M - Cl]^+$, 403 $[M - Cl - PN]^+$. ^1H NMR (300 MHz, [D_6]acetone, room temp.): δ = 8.0−6.8 (m, 24 H, 4 Ph, 4 CH-Im), 2.97 (s, 3 H, Me-Im) 2.81 (s, 3 H, Me-Im) ppm. $^{31}P\{^1H\}$ NMR: See Table 1. IR (Nujol mull): $\tilde{\nu}$ = 367, 297 cm^{-1} [ν(RuCl)].

[Ru(κ^2-*P*,*N*-$PPh_2MeIm)_3$][PF_6]$_2$ (6): $AgPF_6$ (253 mg, 1.00 mmol) was added to a suspension of [$RuCl_2$(*p*-cymene)]$_2$ (153 mg, 0.25 mmol) in 8 mL of MeOH at room temperature (4:1). The mixture was protected from light and stirred for 30 min. It was then filtered and the precipitated AgCl was removed. PPh_2MeIm (266.1 mg, 1.00 mmol) was then added to the previous orange solution, and the resulting mixture was stirred at room temperature for 3 h. The solvent was removed under vacuum and the obtained oil was transformed into a solid with pentane after stirring and scratching. The yellow solid was filtered and dried under vacuum. It is soluble in acetone. Yield: 87% relative to the ligand (344.7 mg). When the reaction was performed with 1.50 mmol of the PN ligand, other products besides **6** were formed. The compound was obtained as a mixture of four diastereoisomers: the pair of *fac* enantiomers **6a** and the *mer* pair **6b**. $C_{48}H_{45}F_{12}N_6P_5Ru$ (1189.9): calcd. C 48.45, H 3.81, N 7.06; found C 48.14, H 3.93, N 7.32. FAB^+ (see also Scheme 5): *m*/*z* = 1045 $[M - PF_6]^+$, 450 $[M - 2\ PF_6^-]^{2+}$, 919 $[M - PF_6^- - PF_5]^+$, 900 $[M - PF_6^- - PF_6]^+$, 653 $[M - PF_6^- - PF_5 - PN]^+$, 634 $[M - PF_6^- - PF_6 - PN]^+$, 387 $[M - PF_6^- - PF_5 - 2\ PN]^+$, 368 $[M - PF_6^- - PF_6 - 2\ PN]^+$, 267 $[PN + H^+]^+$.

6a: ^1H NMR (400 MHz, [D_6]acetone, room temp.): δ = 8.2−6.6 (m, 36 H, 6 Ph, 6 CH-Im), 3.72 (s, 3 H, Me-Im) 3.63 (s, 3 H, Me-Im) 3.57 (s, 3 H, Me-Im) ppm.

6b: ^1H NMR (400 MHz, [D_6]acetone, room temp.): δ = 8.2−6.6 (m, 36 H, 6 Ph, 6 CH-Im), 3.61 (s, 9 H, Me-Im) ppm. $^{31}P\{^1H\}$ NMR: See Table 1. IR (KBr): $\tilde{\nu}$ = 838 cm^{-1} [ν(P−F), PF_6^-].

[Ru(κ^2-*P*,*N*-$PPh_2MeIm)_3$][BF_4]$_2$ (7): $AgBF_4$ (389.4 mg, 2.00 mmol) was added to a suspension of [$RuCl_2$(benzene)]$_2$ (250 mg, 0.5 mmol) in 15 mL of MeOH at room temperature (4:1). The mixture was protected from light and stirred for 30 min. Then it was filtered and the precipitated AgCl was removed. PPh_2MeIm (532.2 mg, 2.00 mmol) was added to the previous orange solution, and the resulting mixture was stirred at room temperature for 3 h. The solvent was removed under vacuum and the obtained oil was transformed into a solid with pentane after stirring and scratching. The yellow solid was filtered and dried under vacuum. It is soluble in acetone. Yield: 76% relative to the ligand (535.8 mg). When the reaction was performed with 3.00 mmol of the PN ligand, other products besides **7** were formed. The compound was obtained as a mixture of four diastereoisomers: the pair of *fac* enantiomers **7a** and the *fac* pair **7b**. The *mer* enantiomers were crystallised from an Et_2O solution. $C_{48}H_{45}B_2F_8N_6P_3Ru$ (1073.5): calcd. C 53.70, H 4.23, N 7.83; found C 53.85, H 4.31, N 7.91. FAB^+: *m*/*z* = 987 $[M - BF_4^-]^+$, 450 $[M - 2\ BF_4^-]^{2+}$, 919 $[M - BF_4^- - BF_3]^+$), 900 $[M - BF_4^- - BF_4]^+$, 653$[M - BF_4^- - BF_3 - PN]^+$, 634 $[M - BF_4^- - BF_4 - PN]^+$, 387 $[M - BF_4^- - BF_3 - 2\ PN]^+$, 368 $[M - BF_4^- - BF_4 - 2\ PN]^+$, 267 $[PN + H^+]^+$. IR (KBr): $\tilde{\nu}$ = 1059 cm^{-1} [ν(B−F), BF_4^-], 544 [δ(FBF), BF_4^-].

7a: ^1H NMR (400 MHz, [D_6]acetone, room temp.): δ = 8.2−6.6 (m, 36 H, 6 Ph, 6 CH-Im), 3.72 (s, 3 H, Me-Im) 3.63 (s, 3 H, Me-Im) 3.57 (s, 3 H, Me-Im) ppm.

7b: ^1H NMR (400 MHz, [D_6]acetone, room temp.): δ = 8.2−6.6 (m, 36 H, 6 Ph, 6 CH-Im), 3.61 (s, 9 H, Me-Im) ppm. $^{31}P\{^1H\}$ NMR: See Table 1.

***mer*-[RuHCl(PPh$_3$)$_2$(κ^2-*P*,*N*-PPh$_2$MeIm)] (8):** PPh$_2$MeIm (20.4 mg, 0.077 mmol) was added to a suspension of [RuHCl(PPh$_3$)$_3$] (61.4 mg, 0.07 mmol) in 20 mL of toluene (1.1:1). The resulting mixture was stirred and heated to 70 °C for 4 h. The original violet suspension became a dark green solution and was concentrated to dryness. The green solid obtained was washed with pentane (15 mL) and dried under vacuum. Yield: 85% (55 mg). It is very air-sensitive and soluble in toluene and benzene. $C_{52}H_{46}ClN_2P_3Ru$ (928.4): calcd. C 67.27, H 4.99, N 3.02; found C 67.21; H 5.02, N 3.14. ^{1}H NMR (400 MHz, C_6D_6, room temp.): δ = 8.2−6.6 (m, 41 H, 8 Ph, 1 CH-Im), 5.95 (s, 1 H, CH-Im), 3.5 (s, 3 H, Me-Im), −15.1 (q, $^2J_{P,H}$ = 26.6, $^2J_{P,H}$ = 23.5, $^2J_{P,H}$ = 23.4 Hz, 1 H, Ru−H) ppm. ^{31}P{^{1}H} NMR: See Table 1.

***mer*-[RuHCl(κ^1-*P*-PPh$_2$MeIm)$_2$(κ^2-*P*,*N*-PPh$_2$MeIm)] (9):** PPh$_2$-MeIm (351.6 mg, 1.32 mmol) was added to a suspension of [RuHCl(cod)(bpzm)] (86.6 mg, 0.22 mmol) in 20 mL of THF at −80 °C (6:1). The resulting mixture was stirred at this temperature for 45 min and at room temperature for furthe 30 min. The original suspension turned to a yellow solution with a small amount of solid in suspension. This mixture was concentrated to dryness and the yellow solid obtained was washed with diethyl ether (2 × 10 mL) to remove any bpzm, cod and unreacted ligand, and finally dried under vacuum. Yield: 73% (150 mg). The compound is very air-sensitive and soluble in C_6D_6, but it is insoluble in acetone. $C_{48}H_{46}ClN_6P_3Ru$ (936.39): calcd. C 61.57, H 4.95, N 8.97; found C 61.63, H 4.93, N 8.99. FAB$^+$: *m*/*z* = 935 [M − H$^-$]$^+$, 900 [M − H$^-$ − Cl]$^+$, 634 [M − H$^-$ − Cl − PN]$^+$, 450 [M − H$^-$ − Cl$^-$]$^{2+}$, 368 [M − H$^-$ − Cl − 2 PN]$^+$, 267 [PN + H$^+$]$^+$, 669 [M − H$^-$ − PN]$^+$, 403 [M − H$^-$ − 2 PN]$^+$.^{1}H NMR (400 MHz, C_6D_6, room temp.): δ = 8.4−6.4 (m, 36 H, 6 Ph, 6 CH-Im), 3.45 (s, 3 H, Me-Im), 2.97 (s, 3 H, Me-Im), 2.81 (s, 3 H, Me-Im), −14.8 (q, $^2J_{P,H}$ ≈ 25 Hz, 1 H, Ru-H) ppm. ^{31}P{^{1}H} NMR: See Table 1.

X-ray Diffraction: Suitable crystals of complexes **4b·CH$_2$Cl$_2$** (red block, dimensions 0.26 × 0.23 × 0.10 mm) and *fac*-**7a·(CH$_3$)$_2$CO** (yellowish prism, dimensions 0.50 × 0.30 × 0.30 mm) were used for the structure determination. X-ray data (Table 3) were collected using a Bruker SMART CCD area detector single-crystal diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) by the -ω scan method at 173(2) K (**4b**) or 296(2) (*fac*-**7a**). A total of 1271 frames of intensity data were collected for each compound. The first 50 frames were recollected at the end of data collection to monitor for decay. The crystals used for the diffraction studies showed a small amount of decomposition during data collection for **4b·CH$_2$Cl$_2$** (1.5%) and no decomposition for *fac*-**7a·(CH$_3$)$_2$CO**. The integration process yielded a total of 22750 reflections for **4b·CH$_2$Cl$_2$** and 28912 for *fac*-**7a·(CH$_3$)$_2$CO**, of which 7606 [*R*(int) = 0.0712] for **4b·CH$_2$Cl$_2$** and 11344 for *fac*-**7a·(CH$_3$)$_2$CO** were independent. Absorption corrections were applied using the SADABS[35] program (maximum and minimum transmission coefficients, 1.0000 and 0.809831 for **4b·CH$_2$Cl$_2$**). The structure was solved using the Bruker SHELXTL-PC[36] software by direct methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were included in calculated positions and refined in the riding mode. For **4b·CH$_2$Cl$_2$** convergence was reached at a final $R1 = 0.0377$ [for $I > 2\sigma(I)$], $wR2 = 0.0789$ (for all data), 437 parameters, with allowance for the thermal anisotropy of all non-hydrogen atoms. The weighting scheme employed was $w = \{\sigma^2[F_o^2 + (0.0346P)^2]\}$, with $P = (|F_o|^2 + 2|F_c|^2)/3$ and the goodness of fit on F^2 was 0.923 for all observed reflections. For *fac*-**7b·(CH$_3$)$_2$CO** convergence was reached at a final $R1 = 0.0438$ [for $I > 2\sigma(I)$], $wR2 = 0.1221$ (for all data), 668 parameters, with allowance for the thermal anisotropy of all non-hydrogen atoms. The weighting scheme employed was $w = [\sigma^2(F_o)^2 + (0.0703P)^2 + (0.867P)]$, with $P = (|F_o|^2 + 2|F_c|^2)/3$ and the goodness of fit on F^2 was 1.080 for all observed reflections. CCDC-223473 (**4b·CH$_2$Cl$_2$**)

$[Ni(C_4H_{13}N_3)_2]_3(Sb_3S_6)_2$: The First Structure Containing Isolated Heterocyclic $[Sb_3S_6]^{3-}$ Anions

Ragnar Kiebach,[a] Felix Studt,[a] Christian Näther,[a] and Wolfgang Bensch*[a]

Keywords: Thioantimonates / Heterocycles / Hydrothermal synthesis / Antimony / Sulfur

The novel thioantimonate(III) compound $[Ni(dien)_2]_3(Sb_3S_6)_2$, which was synthesised under solvothermal conditions, contains isolated $[Sb_3S_6]^{3-}$ anions. In the X-ray crystal structure, isolated cyclic $[Sb_3S_6]^{3-}$ anions occupy a boat-like conformation and two different isomeric $[Ni(dien)_2]^{2+}$ cations are arranged in separate stacks.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

In the structures of thioantimonates(III), the primary building units (PBU's) SbS_3, SbS_4 and the less common SbS_5 [1] or SbS_6 [1,2] PBU's are interconnected to form secondary building units (SBU's) such as the heterorings Sb_xS_x, with x ranging from 2 to 32. Rings with small values of x are very common in thioantimonate(III) structures whereas the larger rings are quite rare.[3,4] Very little is known about the processes occurring in the heterogeneous reaction mixtures, which result in the crystallisation of distinct thioantimonates(III). A few years ago, we isolated and characterised several antimony polysulfides such as $[Ph_4P]_2[Sb_2S_{15}]$,[5] $[Ph_4P]_3Sb_3S_{25}$ [6] and $[Ph_4P]_2[Sb_2S_{17}]$[7] which may play important roles as precursors in the syntheses. More recently, we synthesised and characterised $[Ni(dien)_2]_2Sb_4S_8$ [8] as well as $[Mn(C_3H_{10}N_2)_3]_2(Sb_4S_8)\cdot 2H_2O$[9] with the cyclic Sb_4S_4 heteroring as the main structural motif. The successful isolation of these compounds suggests that even these small heterocycles exist in solution. Using an upper limit of 3 Å for Sb−S bonds, the Sb_2S_2 ring can be found in $Ca_2Sb_2S_5$.[10] However, the Sb atoms of this ring have two additional S atoms at a distance less than 3.2 Å, in contrast to the Sb atoms of the Sb_4S_4 ring where no Sb···S contacts were observed below 4 Å. The small Sb_xS_x heteroring with $x = 3$ is commonly observed in extended thioantimonate(III) structures and two different conformations have been identified. In such structures, the Sb_3S_3 rings mostly occupy a chair-like conformation.[4,11−13] A special case of this chair-like conformation is an arrangement in which one endo-cyclic terminal sulfur atom is rotated by nearly 180° thus forming long bonds to the two other antimony atoms.[14,15] This arrangement has been classified as an Sb_3S_4 "semicube". We note that some authors also denote an Sb_3S_6 unit as a "semicube".[12] The boat-like conformation has also been identified in several thioantimonates.[16−18] During our continuing efforts in this area, we obtained the new compound $[Ni(dien)_2]_3(Sb_3S_6)_2$ which contains an isolated Sb_3S_3 heteroring as the main structural feature. This is the first compound containing this isolated Sb_3S_3 ring and it is only the third thioantimonate(III) compound reported with a small isolated thioantimonate(III) heteroring.

Results and Discussion

Crystal Structure

$[Ni(dien)_2]_3(Sb_3S_6)_2$ (dien = diethylenetriamine) crystallises in the triclinic space group $P\bar{1}$ with two formula units in the unit cell. In the crystal structure, there are two crystallographically independent $[Ni(dien)_2]^{2+}$ cations and one isolated heterocyclic $[Sb_3S_6]^{3-}$ anion (Figures 1−3). The $[Sb_3S_6]^{3-}$ anion and one of the two crystallographically independent $[Ni(dien)_2]^{2+}$ cations are located in general position whereas the second cation is located on a centre of inversion.

The Sb_3S_3 ring is formed by three vertex-linked SbS_3 trigonal pyramids (Figure 1). Each Sb atom of the Sb_3S_3 heteroring has a bond to a terminal S atom thus forming the final anion. The Sb−S distances in the Sb_3S_3 ring are similar to those reported for extended thioanti-

monates(III).[19−22] The Sb(1) and Sb(2) atoms each have one long intramolecular contact to an S atom [Sb(1)−S(2) 3.606 Å, Sb(2)−S(3) 3.891 Å]. No intermolecular Sb−S contacts shorter than 4.8 Å are present Table 1).

S(6)−Sb(3)−S(3)	104.70(3)	S(6)−Sb(3)−S(2)	101.46(3)
S(3)−Sb(3)−S(2)	97.68(3)	Sb(2)−S(1)−Sb(1)	102.03(3)
Sb(2)−S(2)−Sb(3)	93.44(3)	Sb(3)−S(3)−Sb(1)	106.65(3)

The Ni^{2+} cations are in a distorted octahedral environment formed by six N atoms of two dien ligands with one unique $[Ni(dien)_2]^{2+}$ cation in the *u-fac* conformation [Ni(1)] and the other in the *s-fac* conformation (Figure 2). The Ni−N distances range between 2.100(3) and 2.145(3) Å, with N−Ni−N angles varying from 81.04(2) to 180.00(2)°. Angles and distances are similar to the corresponding literature values for $[Ni(dien)_2]^{2+}$ complexes (Table 2).[8,19,20]

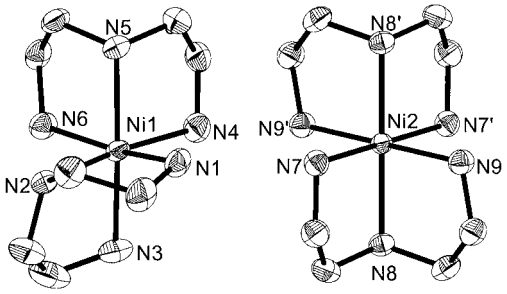

Figure 2. Coordination of the Ni cations in $[Ni(dien)_2]_3(Sb_3S_6)_2$ with labelling and displacement ellipsoids drawn at the 50% probability level (hydrogen atoms are omitted for clarity)

Cations and anions are packed in such a way that both form individual stacks parallel to the *a* axis (Figure 3). Four cations and two anions are arranged around a channel which is directed along the *a* axis. Disordered solvent molecules are located in this channel (see Exp. Sect.). A similar arrangement of cations and anions is also found in $[Ni(dien)_2]_3[SbS_4]_2$[20] and $[Ni(dien)_2]_2Sb_4S_8$.[8]

The three-dimensional arrangement of cations and anions is caused by N−H···S contacts. Every $[Sb_3S_6]^{3-}$ anion has fifteen such contacts with H···S distances between 2.440 and 2.903 Å and N−H···S angles ranging from 138.2 to 166.7°. The terminal S atoms have significantly more S···H contacts than the μ-S atoms (ratio: 2:1). The N−H atoms of the $[Ni(1)(dien)_2]^{2+}$ cation are involved in 10 and those of the second $[Ni(2)(dien)_2]^{2+}$ cation, in 5 H···S contacts.

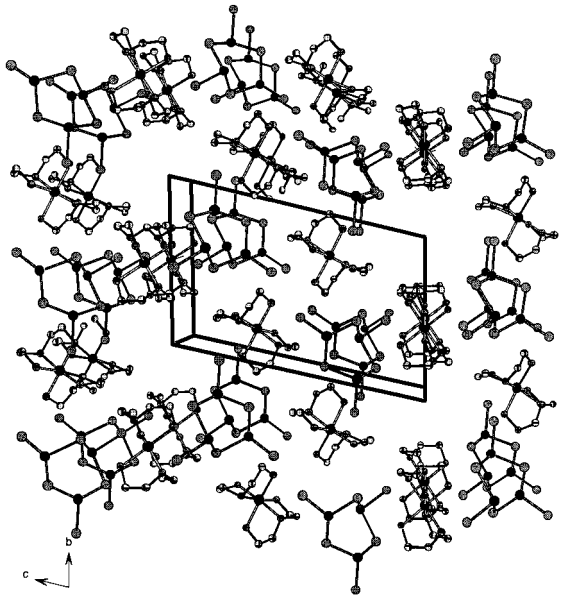

Figure 3. Crystal structure of $[Ni(dien)_2]_3(Sb_3S_6)_2$ viewed along the *a* axis (hydrogen atoms are omitted for clarity)

As mentioned above, the Sb_3S_3 unit usually occurs in a chair- or boat-like conformation, as in $[C_4H_{12}N_2]_{0.5}[CuSb_6S_{10}]$[18] or $[(CH_3NH_2)_{1.0}K_{2.97}][Sb_{12}S_{20}]\cdot 1.34H_2O$.[22] The latter is a rare example of the coexistence of two different conformations in one crystal. Interestingly, the Sb_3S_3 unit in the title compound also has a boat-like conformation. The geometry of this anion was optimised using GAUSSIAN98 indicating that the boat-like conformation is about 2 kcal/mol more stable than the chair-like conformation.

Thermal Investigations

Thermal stability of the complex was investigated using simultaneous differential thermal analysis and thermogravi-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

metry (DTA-TG). Heating single crystals of the title compound under helium in a thermobalance lead to decomposition in four steps with a total mass loss of 37.3% with all steps accompanied by endothermic peaks in the DTA curve ($T1_{peak}$ = 246 °C, Δm = 4.1%; $T2_{peak}$ = 260 °C, Δm = 24.4%; $T3_{peak}$ = 277 °C, Δm = 6.0%; and $T4_{peak}$ = 331 °C, Δm = 2.8%) (Figure 4).

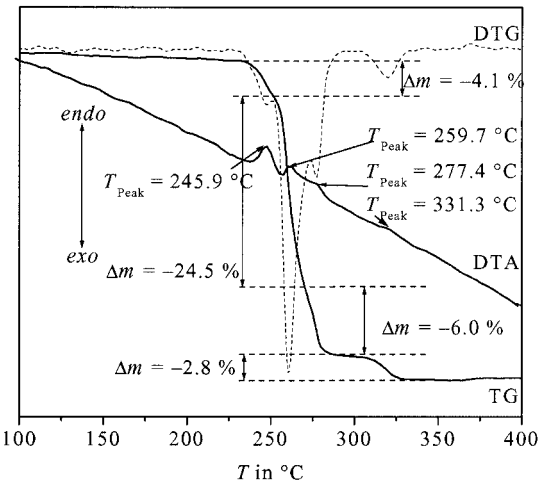

Figure 4. DTA, TG and DTG curves for $[Ni(dien)_2]_3(Sb_3S_6)_2$

Taking only the dien ligands into account, the expected mass loss is 31.4%, which is about 5.9% lower than the experimentally obtained value. This discrepancy may be due, in part, to the emission of H_2S and of solvent molecules (CH_3OH) which are located in the channels of the structure. Elemental analysis and mass spectroscopic investigations are in agreement with this. The elemental analysis gave a C,H and N content of 33.4% (C 16.2, H 4.4, N 12.8%), which is 2% larger than the theoretical content for the dien ligands alone. Mass spectra recorded simultaneously during decomposition showed a very intense signal for H_2S in the last step. Unfortunately, the content of CH_3OH could not be determined using mass spectrometry because of a substantial overlap of the different thermal processes and because of the experimental set-up of our instrument. The grey residue remaining after the thermal decomposition contained NiSbS (Ullmanit) and Sb_2S_3, both of which are frequently found after the thermal decomposition of thioantimonates containing nickel.[4,8,19–21]

Conclusion

The synthesis of thioantimonates was performed in basic solutions under solvothermal conditions. Little is known about the processes occurring in the heterogeneous reaction mixtures and which precursors determine the final structures that are formed under particular conditions. As mentioned above, in the extended structures of thioantimonates(III) many different secondary building units may be identified, which are formed by the condensation of the primary SbS_x (x = 3–6) units. After the successful isolation and characterisation of different antimony polysulfides and the $[Sb_4S_8]^{4-}$ anion containing the Sb_4S_4 heteroring, we were able to obtain the smallest known isolated thioantimonate anion $[Sb_3S_6]^{3-}$ containing the Sb_3S_3 ring as the main structural motif. However, the crystallisation of $[Sb_4S_8]^{4-}$ and $[Sb_3S_6]^{3-}$ does not necessarily mean that these species exist under solvothermal conditions. Further studies are necessary for a better understanding of the factors influencing product formation.

Experimental Section

Synthesis

$[Ni(dien)_2]_3(Sb_3S_6)_2$ (1): $[Ni(dien)_2]_3(Sb_3S_6)_2$ was synthesised from Sb (0.1217 g; 1 mmol), S (0.0962 g, 3 mmol), and $Ni(CH_3COO)_2{\cdot}4H_2O$ (0.2487 g; 1 mmol) dissolved in a mixture of dien (1 mL) and methanol (1 mL). The mixture was heated at 140 °C for 4 days in a Teflon^R-lined steel autoclave (volume ca. 20 mL) and was subsequently cooled to room temperature over a 3 h period. The brown crystalline product was filtered off, washed with water and acetone, cleaned in an ultrasonic bath and stored under vacuum. The compound is stable in air, water and acetone. The yield was approximately 30% based on Ni. $[Ni(dien)_2]Cl_2$ and $[Ni(dien)_2]_3(SbS_4)_2$ were identified as by-products.

X-ray Crystallography: The X-ray single-crystal data for **1** were collected at 293 K using a STOE Imaging Plate Diffraction System

(IPDS). The intensities were corrected for Lorentz, polarisation and absorption effects. Structure solution was performed using SHELXS-97.[23] Refinement was done against F^2 by using the software SHELXL-97.[24] The non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were positioned with idealised geometry and refined with isotropic displacement parameters using the riding model. The structure contains additional disordered solvent molecules in the channels for which no appropriate structure model could be found. Therefore, the data were treated with the SQUEEZE option for disordered solvent in PLATON.[25] In the first step, this program calculates the space which can be occupied by disordered solvent molecules starting from the refined structure model. In the next step the sum of electrons in this space is calculated and the measured data file is corrected in a way that these electrons are not considered. This calculation gives a volume of 182.2 Å^3/cell which can be used by disordered solvent. Selected crystal data and details of the structure determination are listed in Table 3.

CCDC-21630 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

DTA-TG-MS Investigations: DTA-TG-MS measurements were performed using a Netzsch STA-409. The sample (mass: 11.98 mg) was heated in a dynamic He atmosphere (flow rate 75 ml·min^{-1}) in an Al_2O_3 crucible with a heating rate of 4 K/min to 400 °C).

Density Functional Calculations: Spin-restricted DFT calculations using Becke's three parameter hybrid function with the correlation function of Lee, Yang and Parr (B3LYP)[26−28] were performed for the singlet ground state of $[Sb_3S_6]^{3-}$. The LanL2DZ basis set was used for the calculation. This applies Dunning/Huzinaga full double zeta (D95) basis functions[29] to the first row and Los Alamos effective core potentials plus DZ functions on all other atoms.[30,31] Convergence was reached when the relative change in the density matrix between subsequent iterations was less than $1\cdot10^{-8}$. All procedures were used as they are implemented in the GAUSSIAN 98 package.[32]

Conformational Effects on the Photoinduced Energy Transfer in a Star-Shaped Pentaporphyrin with Nucleosidic Linkers

Lucia Flamigni,*[a] Anna Maria Talarico,[a] Barbara Ventura,[a] Giancarlo Marconi,[a] Chloé Sooambar,[b] and Nathalie Solladié*[b]

Keywords: Circular dichroism / Energy transfer / Porphyrinoids / Photochemistry / Supramolecular chemistry

The photophysical properties of a pentameric array (**FB-Zn$_4$**) containing peripheral Zn porphyrins and a free-base core, connected by nucleosidic linkers, have been determined and compared with the properties of the model dyad (**FB-Zn**) and of their individual components. The flexibility of the nucleosidic linkers allows the dyad to take two different conformations corresponding to a bent and an almost fully extended form of the linker, which are characterized by a chromophore separation of ca. 2 nm and ca. 3 nm, respectively. Energy transfer from the zinc porphyrin to the free-base porphyrin occurs, in the bent conformation, with a rate of 3.6×10^9 s^{-1}. Conversely, in the extended conformation, the Zn porphyrin decay is unperturbed, which is in good agreement with the expected dipole–dipole (Förster) energy transfer mechanism. In the pentameric array, the Zn porphyrin luminescence is quenched with a rate of 3.6×10^9 s^{-1} in 15% of the population, whilst the luminescence of the Zn porphyrin is unquenched for ca. 35% of the population. For comparison with the dyad, these two cases are assigned as arrays with a single linkage in a bent configuration and arrays with all linkages in the extended configuration, respectively. However, the most striking feature in the pentaporphyrin is that 50% of the Zn porphyrin excited state population exhibits a fast nonradiative deactivation (rate ca. 10^{10} s^{-1}) which also involves the free-base porphyrin core to some extent. This behavior is attributed to a strongly interacting conformation with the Zn porphyrins folded over the central free-base porphyrin. The proposed model is supported by CD spectroscopy, complexation experiments with bases, and the reactivity of the excited state towards external quenchers.

Introduction

Synthesis of multi-porphyrin architectures and determination of their photo properties is the object of intensive research activity.[1] These oligomeric arrays can mimic naturally occurring tetrapyrrolic aggregates that perform key processes in photosynthesis, i.e. light energy collection and charge separation.[2] The study of multi-porphyrin ensembles, in addition to providing basic knowledge in the fields of photochemistry, photophysics and photobiology, can be regarded as potentially informative in the construction of light-operated molecular-level information storage devices, [3] for the conversion of light energy into chemical or electrical energy,[1,4] and for the preparation of materials with novel properties.[5]

The present system, which consists of a pentaporphyrin containing a central free-base porphyrin and four peripheral zinc porphyrins connected via a flexible chiral nucleosidic linker,[6] was studied in order to determine its potential as an antenna system, capable of collecting light energy and conveying it to the energy sink at the central position. The peripheral zinc porphyrin chromophores can absorb light extensively over the full visible spectrum and the energy stored in the first excited singlet state (2.05 eV) could be conveyed to the central free-base porphyrin characterized by a lower lying excited singlet state (1.92 eV). The system can work effectively as an antenna if the absorbed light energy is efficiently conveyed to the central porphyrin and no competitive loss of the absorbed energy occurs. The study of convenient model compounds, **ZnU**, **FBS** and the dyad **FB-Zn**, whose structures are shown in Scheme 1, can help in the elucidation of the fundamental steps in the pentad system **FB-Zn$_4$**, where photophysical behavior could be strongly influenced by the existence of different conformations due to the flexible linkers. Steady state and time-resolved spectroscopic methods were used to quantify the energy transfer process which was postulated previously.[6]

Results and Discussion

Synthesis

The dyad was synthesized according to Lindsey's procedure for the construction of sterically hindered porphyrins.[7] One equivalent of aldehyde **ZnU**[6] and three equivalents of *p*-tolualdehyde were condensed, at room temperature and under an inert atmosphere, with four equivalents of pyrrole in chloroform in the presence of a catalytic amount of $BF_3{\cdot}OEt_2$. The resulting porphyrinogen was then oxidized by reflux with three equivalents of *p*-chloranil, for one and a half hours. After a tedious purification requiring many chromatographic separations over silica gel, the desired dyad was isolated in 10% yield. It was characterized by ^{1}H NMR and FAB mass spectrometry (m/z = 2104.5 $[M]^+$, calcd. 2104.9). The synthesis and characterization of the pentad has been reported previously.[6]

Photoinduced Processes

The Dyad

The absorption spectrum of the dyad closely matches the superposition of its two components, as shown in Figure 1, where absorption spectra of both the component units, their sum and the absorption spectrum of the dyad are given. This indicates a very modest interaction between the components, as expected from the length and type of bridging ligand.

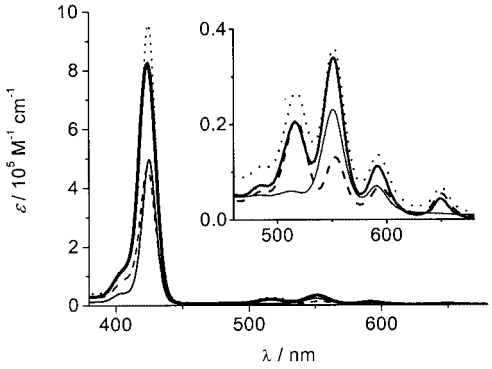

Figure 1. Molar absorption coefficients of the models **ZnU** (thin solid line) and **FBS** (dashed line), and of **FB-Zn** (thick solid line) in toluene solutions, the sum of the molar absorption coefficients of the models is also reported (dotted line)

The emission spectrum of the dyad, after excitation at a wavelength where only **FBS** absorbs, i.e. at $\lambda > 625$ nm, displays the emission spectrum of the **FBS** model, with an identical quantum yield within experimental error (Table 1). Selective excitation of the **ZnU** unit is not possible (see Figure 1) but excitation where both components absorb, yields an emission spectrum which shows the features of both the free base component ($\lambda_{max.}$ = 652 and 718 nm) and of the zinc component ($\lambda_{max.}$ = 598 nm and 646 nm). However, if the emission is compared to those of the component models absorbing the same number of photons as in the dyad (Figure 2), it is clear that, in the array, the emission of the zinc porphyrin unit is quenched whereas the emission of the free-base porphyrin moiety is increased, i.e. it is sensitized (Table 1).

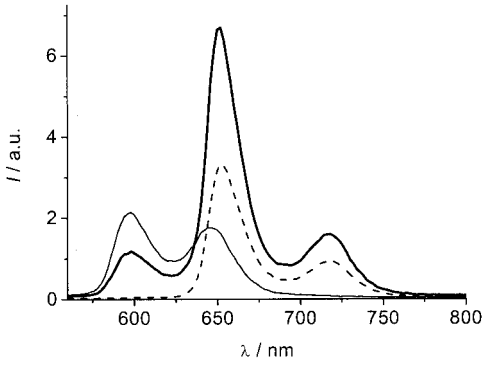

Figure 2. Emission spectra in toluene at 298 K of the models **ZnU** (thin solid line; A_{550nm} = 21.6%),**FBS** (dashed line; A_{550nm} = 11.7%), and the dyad **FB-Zn** (thick solid line; A_{550nm} = 33.4%, the partition of photons is A_{PZnU} = 21.6% and A_{FBS} = 11.7%) in toluene solutions; excitation at 550 nm

Time-resolved experiments with picosecond resolution (at λ = 600 nm, the maximum of the zinc porphyrin component emission) revealed a bi-exponential decay of the luminescence of the dyad, with lifetimes of 240 ps and 1.9 ns, accounting for ca. 30% and 70% of the total decay, respectively (Figure 3). Whilst the short lifetime could be due to the quenching of the luminescence of the zinc porphyrin component, the long lifetime is typical of the unquenched **ZnU** model (Table 1). The luminescence of the dyad at λ = 720 nm (Figure 3), where only the free base component emits, is characterized by a species with a lifetime of ca 240 ps, closely matching the fast decay of the zinc porphyrin component. A subsequent slower decay of 9.8 ns, typical of the emission of the model **FBS** (Table 1), was detected on a

	FB-^{1}Zn	598		0.042	0.240; 1.9 (30%); (70%)	604	2.05
FB-Zn$_4$	^{1}FB-Zn$_4$	652	0.13	–[f]	9.8	648	1.91
	FB-^{1}Zn$_4$	600		–[f]	0.110; 0.240; 1.9 (50%); (15%); (35%)	606	2.05

[a] Emission quantum yield. Selective excitation of the free-base porphyrin unit was at 650 nm. [b] Emission quantum yield. Excitation of both free-base and zinc porphyrin components was at 550 nm. The calculation is based on the photons absorbed directly by the moiety, as calculated by the molar absorption coefficients of the models **ZnU** and **FBS**. [c] Excitation was at 532 nm or at 337 nm for lifetimes > 2 ns. [d] Energy levels from the emission maxima at 77 K. [e] Lifetime of the rise. [f] In this array the interaction between components is strong (see text) and this prevents a reliable calculation of the partitions of photons between components. Consequently, it was impossible to measure the emission yields as done for the dyad (see above).

longer time scale with a nanosecond time correlated single photon counting apparatus.

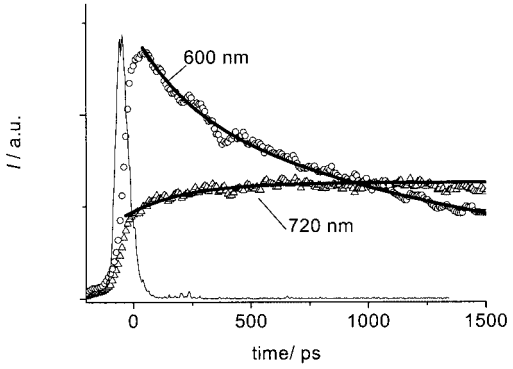

Figure 3. Time-resolved luminescence of **FB-Zn** in toluene solution after excitation at 532 nm; decay at 600 nm (open circles) and 720 nm (open triangles) with the bi-exponential fitting with lifetimes of 240 ps and 1.9 ns at 600 nm and of 240 ps and 9.8 ns at 720 nm; the exciting flash profile is also shown

The energy of the emission maxima, determined at 77 K, are conventionally assumed to correspond to the energy levels of the emitting states. From these, a value of 2.05 eV and 1.91 eV was derived for the energy of the singlet excited states localized on the zinc porphyrin and the free-base unit, respectively. The energy transfer from the zinc to the free-base porphyrin component is thermodynamically allowed and has a driving force of 0.14 eV. Therefore, the quenching of the zinc porphyrin donor and the sensitization of the free-base porphyrin acceptor are interpreted as being due to an energy transfer process. The rate constant can be calculated from the equation $k = 1/\tau - 1/\tau_0$, where τ and τ_0 are the lifetime of the quenched component (240 ps) and of the model compound (1.9 ns), respectively. The resulting rate constant is $k = 3.6 \times 10^9\ s^{-1}$. However, the bi-exponential nature of the decay indicates that only a fraction (30%) of the donor is quenched, whereas the main part (70%) is largely unaffected with respect to the model lifetime. This is indicative of the existence of two different conformers of the dyad (see below).

The occurrence of energy transfer from the zinc porphyrin unit to the free-base porphyrin unit is further supported by the excitation spectrum detected at 720 nm, where only the free-base porphyrin emits, which shows the contribution from the **ZnU** band at 550 nm, indicating that the emission of the free-base is sensitized by the absorption of the zinc component (Figure 4). The overlap between absorption spectrum and excitation spectrum of the dyad is not complete since the sensitization of free-base porphyrin by the zinc component only takes place in 30% of the excited conformation.

Energy transfer between singlet states can occur by two different mechanisms: the Förster mechanism (or dipole−dipole interaction)[8] or the Dexter mechanism (or electron exchange).[9] In case of energy transfer between singlet states with high absorbances and high emission quantum yields, the dipole−dipole mechanism usually prevails. For this mechanism, it is possible to calculate the rate k_{en}^F

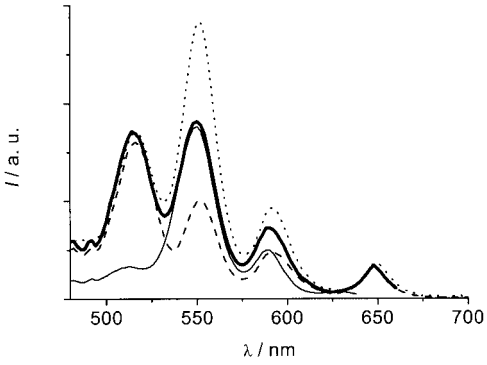

Figure 4. Excitation spectrum registered at $\lambda_{em} = 720$ nm (thick solid line) and an arbitrarily scaled absorption spectrum (dotted line) of **FB-Zn** in toluene solution; for comparative, purposes the excitation spectra of models **ZnU** at $\lambda_{em} = 646$ nm (thin solid line) and **FBS** at $\lambda_{em} = 720$ nm (dashed line) are also shown
