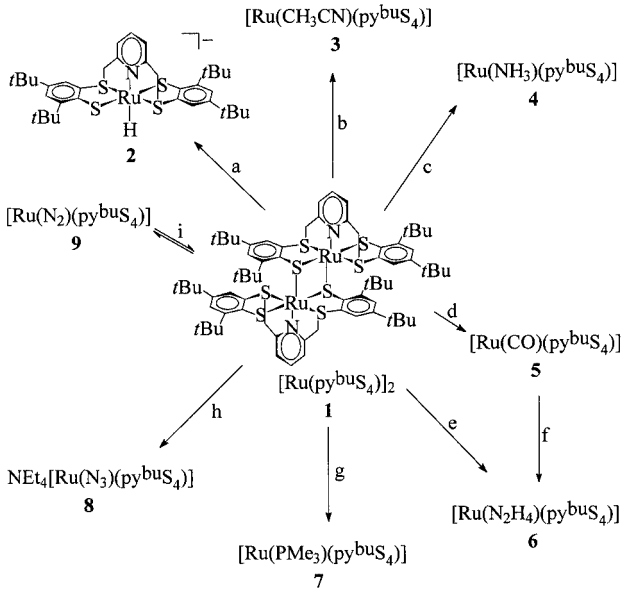
Recently, we achieved the heterolytic cleavage of H_2 at room temperature using the thiolate-bridged diruthenium complex $[Ru(py^{bu}S_4)]_2$ (**1**) {$py^{bu}S_4^{2-}$ = 2,6-bis[(3,5-di-*tert*-butyl-2-sulfanylphenyl)thiomethyl]pyridine(2−)} to form the hydride protonated thiolate $[Ru(H)(py^{bu}S_4H)]$.[7] The latter species, in turn, reacts with a base to give the hydride $[Ru(H)(py^{bu}S_4)]^-$ by abstraction of the S−H proton. This remarkable result prompted us to further investigate the reactivity of **1** towards nitrogenase-relevant molecules. Herein we describe the synthesis and characterization of the mononuclear complexes $[Ru(L)(py^{bu}S_4)]$ (L = H^-, CO, NH_3, N_2H_4, CH_3CN, N_3^-, etc.) starting from complex **1**. The reaction of these complexes and of **1** with molecular nitrogen to form labile dinitrogen complexes is also reported.



Scheme 1. Synthesis of $[Ru(L)(py^{bu}S_4)]$ complexes: (a) excess $NaAlH_4$, −78 to 20 °C, 2 h, THF; (b) CH_3CN, RF, 2 d; (c) excess NH_3, 20 h, THF; (d) excess CO, 15 h, THF; (e) excess N_2H_4, 70 °C, 1 d, THF; (f) excess N_2H_4, UV, −30 °C, 1 h, THF; (g) PMe_3, 2 h, THF; (h) excess NEt_4N_3, 2 d, THF; (i) N_2 (60 bar), 40 °C, 7 d, THF

Results and Discussion

Synthesis and Characterization of $[Ru(L)(py^{bu}S_4)]$ Complexes

The preparation of ruthenium complexes $[Ru(L)(py^{bu}S_4)]$ containing the σ or σ-π ligands L is a prerequisite for probing the influence of L on the potential coordination of the N_2 ligand. Scheme 1 summarizes the syntheses of $[Ru(L)(py^{bu}S_4)]$. The new complexes were prepared by the reaction of dinuclear complex **1** with nucleophiles L by the dissociation of the Ru−S bridges.

Treatment of complex **1** with a fivefold excess of $NaAlH_4$ in THF under argon yields extremely air- and moisture-sensitive $Na[Ru(H)(py^{bu}S_4)]$ (**2**), which can be isolated in the solid state conveniently at room temperature, and is obtained with much better yield (65%) than that of our previous method.[7] Refluxing of a suspension of **1** in CH_3CN continuously for 2 d affords $[Ru(CH_3CN)(py^{bu}S_4)]$ (**3**). In the course of the reaction, the pink suspension of **1** changes to an orange solution, from which **3** could be obtained in a reasonable yield (48%). Treatment of **1** with NH_3 or CO in THF under normal conditions leads to the formation of $[Ru(NH_3)(py^{bu}S_4)]$ (**4**) or $[Ru(CO)(py^{bu}S_4)]$ (**5**), respectively. In the former case, the pink suspension changes to a wine-red solution which exhibits the ν(NH) bands in the IR (THF) spectrum in the region of 3350−3000 cm^{-1}, whereas in the latter case the resulting yellow solution shows a strong carbonyl band at 1967 cm^{-1}. At 70 °C, compound **1** reacts with a tenfold excess of N_2H_4 to afford $[Ru(N_2H_4)(py^{bu}S_4)]$ (**6**) in an isolated yield of 67%. Alternatively, UV irradiation of the 18-valence-electron carbonyl complex **5** in the presence of an excess of N_2H_4 in THF at −30 °C proceeds efficiently with the extrusion of CO and subsequent coordination of the N_2H_4 molecule to afford **6** (91%). In the course of the reaction, the yellow solution changes to red. The ν(CO) band of **5** proved to be a good probe for monitoring the reaction by IR spectroscopy. The yellow-red complex $[Ru(PMe_3)(py^{bu}S_4)]$ (**7**) was formed instantaneously when a suspension of **1** in THF was treated with a slight excess of PMe_3. The labile azido complex $NEt_4[Ru(N_3)(py^{bu}S_4)]$ (**8**) can be obtained only after 2 d by vigorous stirring of the THF suspension of **1** with an excess of NEt_4N_3.

Most new complexes were isolated in analytically pure form, are soluble in THF, CH_2Cl_2, acetone, DMF or DMSO, and were characterized by IR and NMR spectroscopy, mass spectrometry and/or X-ray crystallography. The IR (KBr) spectra of the complexes exhibit a typical absorption pattern for the $[Ru(py^{bu}S_4)]$ fragment. In addition, the spectrum of **3** exhibits a sharp band at 2269 cm^{-1} for the CN stretching vibration of the CH_3CN ligand. The NH_3 and N_2H_4 ligands of **4** and **6**, respectively, gave rise to sharp ν(NH) bands in the region 3350−3000 cm^{-1}, whereas the $\nu(N_3)$ band of **8** appears at 2022 cm^{-1}. As judged by their well-resolved NMR spectra, the complexes are diamagnetic. The ^1H NMR spectra of all complexes show a characteristic splitting pattern for the $[Ru(py^{bu}S_4)]$ fragment, consisting of three doublets and a multiplet for the aromatic protons, two doublets for the bridging CH_2 groups, and two singlets for the *t*Bu groups. The number of ^1H and ^{13}C NMR signals for **2**−**8** (see Exp. Sect.) are consistent with a C_2 symmetry in solution, which has also been confirmed by the X-ray structure determinations of **3**, **4** and **5**. The cyclic voltammogram of **1** (Figure 1) shows two quasi-reversible one-electron waves at $E_{1/2}$ = +0.450 and +0.760 V for the $Ru^{II,II}/Ru^{II,III}$ and $Ru^{II,III}/$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$Ru^{III,III}$ redox couples, respectively. All mononuclear complexes exhibit the quasi-reversible redox wave of the Ru^{II}/Ru^{III} couple in the region between $E_{1/2}$ = +0.214 and +0.460 V.

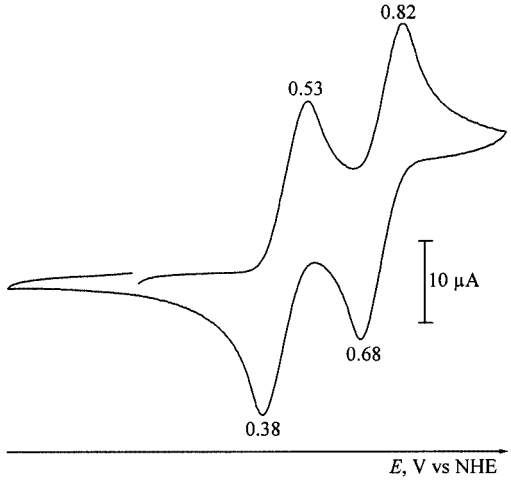


Figure 1. Cyclic voltammogram of **1** in THF (10^{-3} M; NBu_4PF_6, 10^{-1} M; ν = 50 mV s^{-1}; T = 25 °C)

The molecular structures of $[Ru(CH_3CN)(py^{bu}S_4)]\cdot 2CH_3CN$ (**3**·$2CH_3CN$), $[Ru(NH_3)(py^{bu}S_4)]\cdot CH_2Cl_2\cdot 0.5n$-pentane (**4**·$CH_2Cl_2$·0.5*n*-pentane) and $[Ru(CO)(py^{bu}S_4)]\cdot CH_3OH\cdot(CH_3)_2CO$ [**5**·CH_3OH·$(CH_3)_2CO$] were determined by single-crystal X-ray structure analysis. Figure 2 depicts the molecular structures and Table 1 lists selected distances and angles.

The unit cells of **3**−**5** contain one or more solvent molecules. In each compound the ruthenium center (Ru1) is surrounded by one N, four S, and one X (X = C, N or P) atoms in a pseudooctahedral geometry. The thioether and thiolate donors are *trans* to each other, with the pyridine N donor in an apical position such that a square-pyramidal $[RuNS_4]$ core results for the $[Ru(py^{bu}S_4)]$ fragment. The sixth position, *trans* to the pyridine N donor, is occupied by the X atom of the co-ligand L. The distances (except Ru−N1) and angles around the ruthenium atom are in the range usually found for diamagnetic six-coordinate Ru^{II} thiolate complexes.[8] The Ru−S(thiolate) distances (236−239 pm) are usually longer than the Ru−S(thioether) distances (229−231 pm). In particular, short distances are observed for Ru1−N1 *trans* to the coligands CH_3CN and NH_3 [203.3(6) pm in **3** and 203.6(3) in **4**]. These distances are distinctly shorter than the corresponding distance in **5** [212.1(6) pm], as well as those of $[Ru(L)(py^{bu}S_4)]$ (L = NO, HNO; 210−213 pm)[8,9] and $[Ru(L)(pyS_4)]$ (L = CO, PPh_3, DMSO; 209−212 pm),[10] indicating that in **3** and **4** a practically identical *trans* effect is imposed by the CH_3CN and NH_3 ligands.

Reactions with Dinitrogen

Treatment of **1** with N_2 under normal conditions did not result in any reaction. However, at 60 bar and 40 °C the

labile mononuclear dinitrogen species $[Ru(N_2)(py^{bu}S_4)]$ (**9**) was formed after 4 d. In the course of the reaction, the pink suspension of **1** in THF changed to a clear red solution. The IR (THF) spectrum of the resulting solution showed the weak $\nu(N_2)$ band at 2139 cm^{-1}. This band gradually disappeared at room temperature over the course of 1 h to give **1**, as indicated by the formation of pink microcrystals from the solution, showing this conversion to be reversible. Identical results were obtained when similar reactions were carried out in CH_2Cl_2 or toluene. This suggests that the solvent medium has a negligible influence on the coordination of the N_2 ligand. Compound **9** was found to be stable at −80 °C for at least 24 h, although attempts to isolate it were unsuccessful.

^1H NMR spectroscopic monitoring of the reaction of **1** in $[D_8]$THF (or CD_2Cl_2 or $[D_8]$toluene) with N_2 (60 bar) in an autoclave specially constructed for the NMR tubes corroborated the IR spectroscopic data. Figure 3 shows the ^1H NMR spectra of **1** in $[D_8]$THF before and after pressurizing with N_2. The ^1H NMR spectrum of **1** under normal N_2 pressure is typical for a complex having C_1 symmetry (Figure 3a). When the suspension was pressurized with N_2 (60 bar) and allowed to react at 40 °C for 7 d, the ^1H NMR spectrum of the resulting red solution, recorded immediately after the release of the pressure, showed resonances that are characteristic of the mononuclear $[Ru(py^{bu}S_4)]$ fragment with C_2 symmetry (Figure 3b). The new resonances gradually disappeared and the spectrum of **1** reappeared over a period of 60 min when the solution was kept under N_2 (Figure 3c−e, only the CH_2 resonances are shown). ^1H NMR spectroscopic monitoring of the reaction at −80 °C indicated that the red solution is stable for at least 24 h.

These results show that compound **1** reacts with N_2 reversibly to give a mononuclear N_2 complex. It is reasonable that a moderate temperature and pressure are required to drive the reaction by breaking the Ru−S bridges.

Protonation reactions of metal hydride complexes under N_2 to form mononuclear or dinuclear dinitrogen complexes via the labile η^2-H_2 species are well known in the literature.[11] Unfortunately, protonation of **2** in CH_2Cl_2 (or THF) with HBF_4, CH_3COOH, H_2O, MeOH or HCl while bubbling N_2 instantaneously afforded only compound **1**. During ^1H NMR spectroscopic monitoring of the reaction in $[D_8]$THF at −80 °C, the RuH resonance of **2** at δ = −14.85 ppm disappeared and the spectrum of **1**, together with the resonance of H_2 at δ = 4.54 ppm, appeared. The analogous reaction of $[Ru(H)(PR_3)('S_4')]^-$ {$'S_4'^{2-}$ = 1,2-bis[(2-mercaptophenyl)thio]ethane(2−)} with H^+ afforded the short-lived species $[Ru(H_2)(PR_3)('S_4')]$.[8c] Such an intermediate could not be found in the reaction between **2** and H^+, probably owing to its extreme lability.

In another attempt, the substitution-labile acetonitrile complex **3** was treated with N_2. When N_2 was bubbled through a solution of **3** in THF for about 1 h, only **1** was formed, as indicated by the precipitation of pink-red microcrystals. The IR (THF) spectroscopic monitoring of the reaction inferred that the ν(CN) band of **3** at 2269 cm^{-1} is replaced by the ν(CN) band of free CH_3CN at 2251 cm^{-1}. In contrast, the analogous reaction performed in an autoclave with N_2 (30 bar) at 20 °C for 2 d produced the labile species **9**. In the course of the reaction, the solution color changed from orange to red, and the IR (THF) spectrum exhibited two bands at 2251 and 2139 cm^{-1} (Figure 4). The

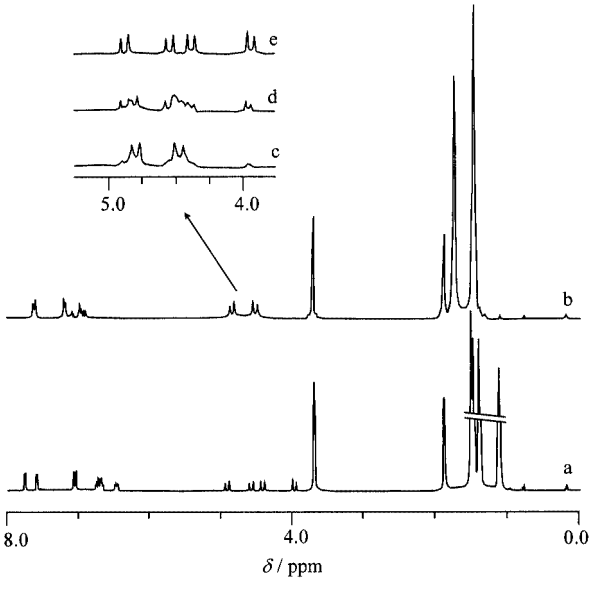

Figure 3. (a) ^1H NMR spectrum of **1** in $[D_8]$THF pressurized with N_2 (60 bar) at 40 °C for 7 d; the pressure was released and ^1H NMR spectra recorded at 20 °C after (b) 3 min, (c) 25 min, (d) 45 min, (e) 60 min

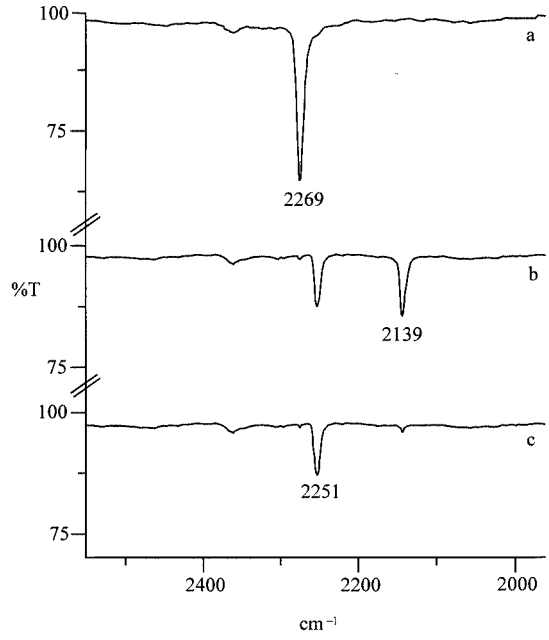

Figure 4. (a) IR spectrum of **3** in THF pressurized with N_2 (20 bar) at 20 °C for 2 d; the pressure was released and IR (THF) spectra recorded after (b) 2 min, (c) 60 min

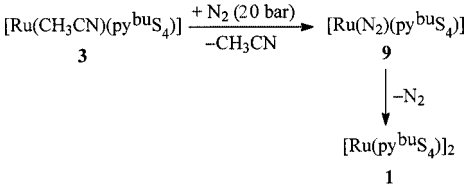
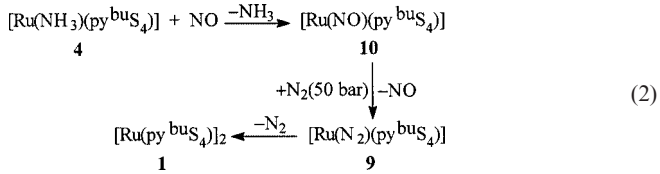
latter band, assigned to complex **9**, disappeared over the course of 1 h as the precipitate of **1** formed from the solution. The product isolated at −80 °C was found to be a mixture; however, it exhibits a weak, short-lived band in the IR (KBr) spectrum at 2134 cm^{-1}.

^1H NMR spectroscopic monitoring of the reaction of **3** in [D$_8$]THF (or CD_2Cl_2) with N_2 (20 bar) in a pressure tube complements the earlier results. The ^1H NMR spectrum of **3** under N_2 shows the methyl resonance of CH_3CN at δ = 2.18 ppm (see Exp. Sect.). After pressurizing the NMR tube with N_2 (20 bar), the signal at δ = 2.18 ppm decreased as the resonance of free CH_3CN at δ = 1.93 ppm increased over the course of 6 h. Apart from this, new resonances whose chemical shifts are identical to those of the previous high-pressure experiment appeared. The resonance at δ = 2.18 ppm vanished and the intensities of the new resonances increased over the course of 2 d. These new resonances were, in turn, gradually replaced by the spectrum of **1** when the N_2 pressure was released, showing this conversion to be reversible. These findings can be interpreted as follows: the primary step is the nucleophilic substitution of the CH_3CN ligand by N_2 to give the intermediate species **9** showing the $\nu(N_2)$ band at 2139 cm^{-1}. At normal pressure, compound **9** rapidly loses its N_2 ligand with subsequent formation of the stable compound **1** [Equation (1)].



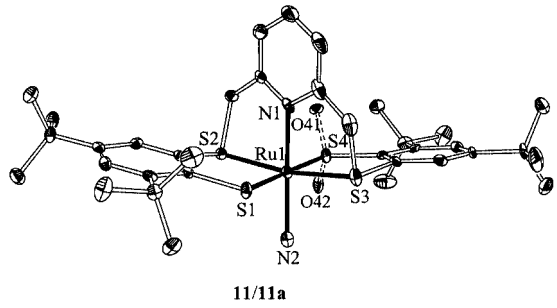
(1)

There are reports in the literature that the formation of dinitrogen complexes occurs in the reaction of NO with metal-bound ammonia.[12] Isotopic-tracer and kinetic studies imply that the mechanism involves attack of NO at metal-bound ammonia and subsequent dehydration.[13] Reaction of **4** with NO in THF yielded the 19-valence-electron neutral complex [Ru(NO)(py^{bu}S$_4$)] (**10**; IR: $\tilde{\nu}$ = 1640 cm^{-1}) as the major product; some traces of 18-valence-electron cationic [Ru(NO)(py^{bu}S$_4$)]$^+$ (IR: $\tilde{\nu}$ = 1886 cm^{-1}) and N_2O (IR: $\tilde{\nu}$ = 2224 cm^{-1}) were also found in solution. The solution of **10** is stable only under NO. Treatment of a solution of **10** with N_2 (50 bar) for 5 d caused the color of the solution to change from green to red; the resulting solution showed a weak band at 2139 cm^{-1} in the IR spectrum, indicating the formation of the N_2 species **9** in solution [Equation (2)]. In contrast to this, the analogous reaction of **4** with an equimolar amount of $NOBF_4$ resulted in the formation of the ruthenium(III) complex [Ru(NH$_3$)(py^{bu}S$_4$)]BF$_4$ (**11**), according to Equation (3). Figure 5 depicts the molecular structures of **11** and **11a**, and Table 1 lists selected bond lengths and angles.



(2)

(3)



11/11a

Figure 5. Thermal ellipsoid plots of [Ru(NH$_3$)(py^{bu}S$_4$)]BF$_4$·CD_2Cl_2 (**11**·CD_2Cl_2) (without S−O bonds) and [Ru(NH$_3$)(py^{bu}S$_4$-O$_2$)]BF$_4$·CD_2Cl_2 (**11a**·CD_2Cl_2) (with S−O bonds) (50% probability ellipsoids; BF_4 counterion, H atoms and solvent molecules omitted)

The unit cell of **11** contains one molecule of CD_2Cl_2 per formula unit. The ruthenium(III) center is surrounded by two N and four S atoms in a pseudooctahedral geometry. The two thioether and two thiolate donors adopt *trans* positions, and the NH_3 ligand occupies the position *trans* to the pyridine N donor. The Ru−S(thiolate) and Ru−S(thioether) distances all lie in the range between 229 and 232 pm. This is in contrast to the corresponding distances of **4** as well as other [Ru^{II}(L)(py^{bu}S$_4$] complexes, where the Ru−S(thiolate) distances are usually longer than the Ru−S(thioether) distances.[8] The Ru−N(pyridine) distance in **11** is longer (by about 3 pm) than that of **4**. During crystallization of **11** complex **11a** is formed by aerial oxidation of **11**.

UV irradiation of complex **5** in CH_2Cl_2 while bubbling N_2 through the solution always yielded **1** as the final product. However, IR monitoring of this reaction suggested the formation of the intermediate species **9** in solution. The IR spectrum of the solution of **5** in CH_2Cl_2 shows the ν(CO) band at 1967 cm^{-1}. Irradiation of this solution at −80 °C for 10 min gave rise to a new weak band at 2138 cm^{-1}, and subsequently the intensity of the ν(CO) band decreased. On continuous irradiation, the intensity of both the bands decreased, and after 50 min microcrystals of **1** had precipitated.

Protonation of **5** with HBF_4 at −80 °C afforded the carbonyl protonated thiolate complex [Ru(CO)(py^{bu}S$_4$H)]BF$_4$ (**12**) according to Equation (4). The IR spectrum of **12** in CH_2Cl_2 exhibits the ν(CO) band at 2001 cm^{-1} and the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ν(SH) band at 2486 cm^{-1}. The CO absorption of **12** is red-shifted by about 34 cm^{-1} compared to that in **5**, which is in good agreement with values reported for the protonation of thiolate groups.[6] Irradiation of **12**, analogous to **5**, initially gave rise to a band at 2172 cm^{-1}, which disappeared on further irradiation to give only an uncharacterizable red-brown solid. It is interesting to note that the difference in wavenumbers between the ν(CO) and ν(N_2) bands in the corresponding complex pairs of **5** and **12** are 168 and 169 cm^{-1}, respectively. These values are in good agreement with those reported for other CO and N_2 complexes.[3] Moreover, the frequency difference between the new bands formed during UV irradiation of **5** and **12** is 34 cm^{-1} for both complexes. These results indicate that the irradiation reactions of **5** and **12** in the presence of N_2 proceed by similar pathways; the first step may be the formation of the labile intermediate species [Ru(N_2)(py^{bu}S_4)] (**9**) and [Ru(N_2)(py^{bu}S_4H)]BF_4 (**13**), respectively. These species may either be subjected to irradiation or undergo simple decomplexation of the N_2 ligand to give the stable thiolate-bridged dimer or other products.

$$\underset{\mathbf{5}}{[Ru(CO)(py^{bu}S_4)]} + HBF_4 \underset{-50\ °C}{\overset{-78\ °C}{\rightleftharpoons}} \underset{\mathbf{12}}{[Ru(CO)(py^{bu}S_4H)]BF_4} \quad (4)$$

Taken together, these results demonstrate that the dinuclear complex **1** and the mononuclear complexes **3**, **5**, **10** and **12** are capable of coordinating molecular nitrogen under moderate pressures of N_2 to form the corresponding labile dinitrogen complexes, although attempts to isolate these species inevitably yielded only the more stable thiolate-bridged complex. Therefore, in an effort to stabilize the labile N_2 species, as well as to prevent the formation of Ru−S bridges, synthesis of a metal fragment containing electron-rich and sterically bulky substituent groups is in progress.

Conclusion

In the quest for transition metal−sulfur complexes that enable the modelling of the reactivity features and key intermediates of nitrogenases reactions, [Ru(L)(py^{bu}S_4] complexes were synthesized and completely characterized. The molecular structures of **3**, **4** and **5** were determined by X-ray structure analysis. All complexes exhibit a pseudooctahedral geometry. The central metal atom is surrounded by at least two thiolate and two thioether groups in mutual *trans* positions, and has a well-approximated C_2 symmetry. The reactivity of [Ru(py^{bu}S_4)]$_2$ and [Ru(L)(py^{bu}S_4] complexes towards molecular nitrogen was investigated. IR and NMR spectroscopic evidence for the formation of the labile mononuclear dinitrogen complexes has been found in the reactions between **1**, **3**, **5**, **10** or **12** and N_2. The reaction of **4** with NO results in the formation of the labile 19-valence-electron NO complex **10**, while treatment of **4** with $NOBF_4$ yielded only the (ammonia)ruthenium(III) complex **11**. Attempts to isolate compound **9** were unsuccessful.

Experimental Section

General: All reactions and manipulations were carried out under Ar or N_2 using standard Schlenk techniques. Solvents were freshly dried with appropriate drying agents and distilled before use. Most reactions were monitored by IR or NMR spectroscopy. Physical measurements were carried out with the following instruments: IR (KBr discs or CaF_2 cuvettes, solvent bands were compensated), Perkin−Elmer 983, 1620 FT-IR and 16PC FT-IR; NMR: Jeol JNM-GX 270, Jeol JNM-EX 270, and Lambda LA 400 with the residual signals of the deuterated solvent used as an internal reference, chemical shifts are quoted in the δ scale (downfield shifts are positive); MS: Jeol MSTATION 700 spectrometer; elemental analysis: Carlo Erba EA 1106 or 1108 analyzer; cyclic voltammetry (CV): EG&G potentiostat PAR model 264A and a conventional three-electrode assembly consisting of a glassy-carbon working electrode and Pt reference and counter electrodes, solutions: THF (10^{-3} M), supporting electrolyte: NBu_4PF_6 (10^{-1} M), internal standard: ferrocene with $E(F_c/F_c^+)$ = +0.4 V vs. NHE,[14] scan speed: 50 mV s^{-1}, T = 25 °C, the reversibility of the voltammograms and the number of electrons involved in the redox processes were determined as described in the literature.[15] $NaAlH_4$ (1 M solution in THF), N_2H_4 (1 M solution in THF) and NEt_4N_3 were purchased from either Aldrich or Fluka. The compounds [Ru(NO)(py^{bu}S_4)]Br and [Ru(py^{bu}S_4)]$_2$ (**1**) were prepared as described in the literature.[7,8b]

Na[Ru(H)(py^{bu}S_4)] (2): An excess of $NaAlH_4$ (4 mL, 1 M solution in THF, 4 mmol) was added to a pink-red suspension of **1** (500 mg, 0.35 mmol) in THF (20 mL) at −80 °C. Upon warming, the suspension changed to a red solution. The solution was stirred at 20 °C for 1 h, then the solvent was removed in vacuo. The resulting red residue was dissolved again in Et_2O (20 mL) and the insoluble colorless materials were removed by filtration. ***Caution:*** *The colorless precipitate is extremely pyrophoric and should be handled with care!* The filtrate was concentrated and treated with pentane to give red microcrystals of **2**. Yield: 336 mg (65%). ^{1}H NMR (269.7 MHz, [D$_8$]THF): δ = −14.85 (s, 1 H, RuH), 1.28 (s, 18 H, *t*Bu), 1.51 (s, 18 H, *t*Bu), 4.42 (d, $^2J_{H,H}$ = 15.3 Hz, 2 H, CH_2), 4.65 (d, $^2J_{H,H}$ = 15.3 Hz, 2 H, CH_2), 6.90−6.83 (m, 3 H, C_5H_3N), 6.99 (d, $^3J_{H,H}$ = 1.9 Hz, 2 H, C_6H_2), 7.51 (d, $^3J_{H,H}$ = 1.9 Hz, 2 H, C_6H_2) ppm. ^{13}C{^{1}H} NMR (67.8 MHz, [D$_8$]THF): δ = 30.0, 32.0, 34.8, 38.4 (*t*Bu), 62.4 (CH_2), 119.1, 122.5, 127.2, 129.7, 137.7, 142.2, 148.9, 154.9, 155.7 (C_6H_2/C_5H_3N) ppm. CV (vs. NHE): E = +0.235 V (Ru^{II}/Ru^{III}).

[Ru(CH_3CN)(py^{bu}S_4)] (3): A suspension of **1** (500 mg, 0.35 mmol) in CH_3CN (25 mL) was refluxed for 2 d. The resulting orange-red solution was filtered, concentrated (2 mL), and treated with pentane to give orange microcrystals of **3**. Yield: 254 mg (48%). $C_{37}H_{52}N_2ORuS_4$ (770.17): calcd. FD-MS (THF): m/z = 739 [$\mathbf{5}^+$]. CV (vs. NHE): E = +0.458 V (Ru^{II}/Ru^{III}).

[Ru(N$_2$H$_4$)(py^{bu}S$_4$)] (6). (a): N_2H_4 (3.5 mL, 1 M solution in THF, 3.5 mmol) was added to a suspension of **1** (250 mg, 0.17 mmol) in THF (15 mL), and was refluxed for 24 h. The red solution that resulted was filtered, reduced in volume and treated with pentane to give red microcrystals of **6**. Yield: 172 mg (67%). **(b):** A solution of **5** (300 mg, 0.21 mmol) and N_2H_4 (2 mL, 1 M solution in THF, 2 mmol) in THF (35 mL) was irradiated in a quartz immersion lamp apparatus with an Hg lamp (150 W) at −30 °C for 1 h. The resulting solution was filtered, reduced in volume and the product precipitated with pentane to give **6** as a red powder. Yield: 280 mg (91%). $C_{35}H_{51}N_3RuS_4$ (743.15): calcd. C 56.57, H 6.92, N 5.65, S 17.26; found C 56.59, H 7.14, N 5.38, S 17.08. IR (KBr): $\tilde{\nu}$ = 3334, 3202, 3101 cm^{-1} ν(NH). ^{1}H NMR (269.7 MHz, CD_2Cl_2): δ = 1.32 (s, 18 H, *t*Bu), 1.59 (s, 18 H, *t*Bu), 3.45 (b, 2 H, NH_2NH_2), 4.15 (m, 2 H, NH_2NH_2), 4.42 (d, $^2J_{H,H}$ = 15.8 Hz, 2 H, CH_2), 4.69 (d, $^2J_{H,H}$ = 16.0 Hz, 2 H, CH_2), 6.89 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H, C_5H_3N), 6.94 (t, $^3J_{H,H}$ = 7.5 Hz, 1 H, C_5H_3N), 7.21 (d, $^3J_{H,H}$ = 2.0 Hz, 2 H, C_6H_2), 7.58 (d, $^3J_{H,H}$ = 2.0 Hz, 2 H, C_6H_2) ppm. ^{13}C{^{1}H} NMR (67.8 MHz, CD_2Cl_2): δ = 29.5, 31.6, 34.6, 38.0 (*t*Bu), 57.0 (CH_2), 120.0, 124.2, 127.2, 130.8, 134.0, 144.6, 149.3, 151.6, 158.9 (C_6H_2/C_5H_3N) ppm. FD-MS (THF): m/z = 743 [$\mathbf{6}^+$], 1422 [$\mathbf{1}^+$]. CV (vs. NHE): E = +0.284 V (Ru^{II}/Ru^{III}).

[Ru(PMe$_3$)(py^{bu}S$_4$)] (7): PMe_3 (52 mg, 0.68 mmol) was added to a suspension of **1** (250 mg, 0.17 mmol) in THF (10 mL) and stirred for 2 h. The resulting solution was filtered, reduced in volume and treated with pentane to give yellow-red microcrystals of **7**. Yield: 194 mg (71%). $C_{38}H_{56}NPRuS_4$ (787.181): calcd. C 57.98, H 7.17, N 1.78, S 16.29; found C 57.74, H 7.08, N 1.64, S 16.08. ^{1}H NMR (269.7 MHz, [D$_8$]THF): δ = 1.06 (s, 9 H, PMe_3), 1.28 (s, 18 H, *t*Bu), 1.56 (s, 18 H, *t*Bu), 4.41 (d, $^2J_{H,H}$ = 15.7 Hz, 2 H, CH_2), 4.62 (d, $^2J_{H,H}$ = 15.8 Hz, 2 H, CH_2), 6.90−6.75 (m, 3 H, C_5H_3N), 7.09 (d, $^3J_{H,H}$ = 1.7 Hz, 2 H, C_6H_2), 7.52 (d, $^3J_{H,H}$ = 1.8 Hz, 2 H, C_6H_2) ppm. ^{13}C{^{1}H} NMR (67.8 MHz, [D$_8$]THF): δ = 15.4 (PMe_3), 29.5, 31.3, 34.1, 38.2 (*t*Bu), 57.4 (CH_2), 119.4, 122.6, 127.1, 130.0, 134.7, 142.8, 148.3, 153.4, 158.7 (C_6H_2/C_5H_3N) ppm. ^{31}P{^{1}H} NMR (161.8 MHz, [D$_8$]THF): δ = 18.6 (PMe_3) ppm. FD-MS (THF): m/z = 787 [$\mathbf{4}^+$]. CV (vs. NHE): E = +0.243 V (Ru^{II}/Ru^{III}).

Et$_4$N[Ru(N$_3$)(py^{bu}S$_4$)] (8): NEt_4N_3 (100 mg, 0.58 mmol) was added to a suspension of **1** (200 mg, 0.14 mmol) in THF (10 mL) and stirred for 2 d. The resulting solution was filtered, concentrated, and treated with pentane to give pink-red microcrystals of **8**. Yield: 115 mg (47%). IR (KBr): $\tilde{\nu}$ = 2022 cm^{-1} $\nu(N_3)$. ^{1}H NMR (269.7 MHz, CD_3OD): δ = 0.50 (t, $^3J_{H,H}$ = 7.3 Hz, 12 H, NEt_4), 1.28 (m, 8 H, NEt_4), 1.34 (s, 18 H, *t*Bu), 1.60 (s, 18 H, *t*Bu), 4.47 (d, $^2J_{H,H}$ = 15.7 Hz, 2 H, CH_2), 4.68 (d, $^2J_{H,H}$ = 15.8 Hz, 2 H, CH_2), 6.90−6.75 (m, 3 H. C_5H_3N), 7.13 (d, $^3J_{H,H}$ = 1.7 Hz, 2 H, C_6H_2), 7.56 (d, $^3J_{H,H}$ = 1.8 Hz, 2 H, C_6H_2) ppm. ^{13}C{^{1}H} NMR (67.8 MHz, CD_3OD): δ = 8.2 (NEt_4), 29.5, 31.6, 34.6, 38.0 (*t*Bu), 52.4 (NEt_4), 56.6 (CH_2), 119.8, 124.5, 126.4, 130.8, 134.2, 146.6, 148.0, 151.8, 157.9 (C_6H_2/C_5H_3N) ppm. CV (vs. NHE): E = +0.293 V (Ru^{II}/Ru^{III}).

[Ru(NO)(py^{bu}S$_4$)] (10): NO gas was bubbled thorugh a solution of **4** (300 mg, 0.41 mmol) in THF (15 mL) for 3 min, The resulting green solution was filtered under NO. IR (THF): $\tilde{\nu}$ = 1640 cm^{-1} ν(NO).

[Ru(NH$_3$)(py^{bu}S$_4$)]BF$_4$ (11): $NOBF_4$ (35 mg, 0.30 mmol) was added to a solution of **4** (210 mg, 0.29 mmol) in THF (15 mL). The color of the solution changed instantaneously from red to green. K_2CO_3 (20.7 mg, 0.15 mmol) was added to this solution and stirred for 1 h. The solution was filtered, concentrated (2 mL) and treated with pentane to give green microcrystals of **10**. Yield: 202 mg (86%). $C_{35}H_{50}BF_4N_2RuS_4$ (814.94): calcd. C 51.59, H 6.18, N 3.44, S 15.74; found C 51.62, H 6.20, N 3.45, S 15.68. IR (KBr): $\tilde{\nu}$ = 3358, 3268, 3186, 3089 cm^{-1} $\nu(NH_3)$. FD-MS (THF): m/z = 728 [Ru(NH$_3$)(py^{bu}S$_4$)$^+$], 1422 [$\mathbf{1}^+$].

[Ru(CO)(py^{bu}S$_4$H)]BF$_4$ (12): HBF_4 (0.30 mL, 0.22 mmol) was added to a solution of **5** (300 mg, 0.21 mmol) in CH_2Cl_2 (10 mL) at −80 °C. The color of the solution changed from red-yellow to dark-green. IR (CH_2Cl_2): $\tilde{\nu}$ = 2001 cm^{-1} ν(CO), 2486 cm^{-1} ν(SH).

High-Pressure NMR Experiment in an Autoclave: In a special autoclave, an NMR tube containing a suspension of **1** (70 mg) in [D$_8$]THF (0.6 mL) was pressurized with N_2 (5.0 grade, 60 bar), and was kept at 40 °C for 7 d. The autoclave was cooled to room temperature, and the pressure was released. The resulting red solution was monitored by recording ^{1}H NMR spectra at various time intervals.

High-Pressure NMR Experiment: In a pressure NMR tube (524-PV-1,Wilmad, USA), a solution of **3** (50 mg) in [D$_8$]THF (0.6 mL) was pressurized with N_2 (5.0 grade, 20 bar). The reaction was monitored by recording ^{1}H NMR spectra at various time intervals for 2 d.[7,16]

High-Pressure Autoclave Experiment. (a): In an autoclave, a tube containing a suspension of **1** (350 mg) in THF (15 mL) was pressurized with N_2 gas (60 bar), and the suspension was stirred at 40 °C for 4 d. The autoclave was cooled to −80 °C and the pressure was released. IR (THF) spectra were recorded of the red solution at

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

various time intervals. **(b):** In an autoclave, a tube containing an orange solution of **3** (200 mg) in THF (15 mL) was pressurized with N_2 gas (20 bar) and the solution was stirred at 20 °C for 2 d. The pressure was then released and IR (THF) spectra were recorded of the resulting red solution at various time intervals. **(c):** The pressure reaction was performed as in (b). The autoclave was frozen with liquid nitrogen and then the pressure was released. The temperature was raised to −80 °C, the red solution was filtered, and treated with cold pentane to give a red solid. IR (KBr): $\tilde{\nu}$ = 2134 cm^{-1} $\nu(N_2)$.

UV-Irradiation Reaction: At −80 °C and with vigorous N_2 bubbling, a solution of **5** (250 mg) or **12** (300 mg) in CH_2Cl_2 (35 mL) was irradiated in a quartz immersion lamp apparatus with an Hg lamp (150 W) for 1 h. The reaction was monitored by recording IR (CH_2Cl_2) spectra until a pink-red or brown precipitate had formed from the solution.

X-ray Structure Determination of [Ru(CH$_3$CN)(py^{bu}S$_4$)]·2CH$_3$CN (3·2CH$_3$CN), [Ru(NH$_3$)(py^{bu}S$_4$)]·CH$_2$Cl$_2$·0.5*n*-pentane (4·CH$_2$Cl$_2$·0.5*n*-pentane), [Ru(CO)(py^{bu}S$_4$)]·CH$_3$OH·(CH$_3$)$_2$CO [5·CH$_3$OH·(CH$_3$)$_2$CO], [Ru(NH$_3$)(py^{bu}S$_4$)]BF$_4$·CD$_2$Cl$_2$ (11·CD$_2$Cl$_2$) and [Ru(NH$_3$)(py^{bu}S$_4$-O$_2$)]BF$_4$·CD$_2$Cl$_2$ (11a·CD$_2$Cl$_2$): Over the course of 5 d, red plates of **3**·2CH_3CN crystallized from a saturated solution of **3** in CH_3CN at −25 °C. Red fragments of **4**·CH_2Cl_2·0.5*n*-pentane were grown from a concentrated CH_2Cl_2 solution of **4** layered with pentane at 4 °C over 2 d. Red crystals of **4**·0.5*n*-pentane were also formed from a solution of **4** in a THF/*n*-pentane mixture. Yellow plates of **5**·CH_3OH·$(CH_3)_2CO$ crystallized from a solution of **5** in acetone layered with CH_3OH at 4 °C. Green crystals of **11**/**11a**·CD_2Cl_2 were formed from a CD_2Cl_2 solution of **11** kept at room temperature for 3 d. Suitable single crystals were embedded in protective perfluoropolyether oil. Data were collected with a Bruker-Nonius KappaCCD diffractometer using Mo-K_α radiation (λ = 71.073 pm), and a graphite monochromator. A numerical absorption correction was performed for **3**·2CH_3CN. Absorption effects for the other compounds were corrected on a semiempirical basis with the help of multiple scans using either SORT AV[17a] [**5**·CH_3OH·$(CH_3)_2CO$ and 0.75**11**·0.25[Ru(NH_3)(py^{bu}S$_4$-O_2)]BF_4·CD_2Cl_2] or SADABS[17b] (**4**·CH_2Cl_2·0.5*n*-pentane). All structures were solved by direct methods, and full-matrix least-squares refinement was carried out on F^2 using SHELXTL NT 5.1 and NT 6.12.[18] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of **11**/**11a**·CD_2Cl_2 were located from a difference Fourier map, while in all other compounds the H atoms were geometrically positioned with isotropic displacement parameters being 1.5-times *U*(eq) of the parent C or N atom. One of the CH_3CN molecules of **3** is disordered, and two alternative sites were refined to 52(2)% (N4, C5, S6) and 48(2)% (N4′, C5′, S6′). Two alternative sites were refined for one of the *t*Bu groups of **4** to 66(2)% (C55−C57) and 34(2)% (C55′−C57′). In **11a**·CD_2Cl_2, the S4 atom is partially oxidized, with the two O atoms having occupancy factors of 25(1)% each. Selected crystallographic parameters and refinement details are summarized in Table 2. Crystallographic data for **4**·0.5*n*-pentane have only been deposited with the Cambridge Crystallographic Data Base.[20]

Acknowledgments

Financial support of these investigations by the Deutsche Forschungsgemeinschaft (SFB 583: Redoxaktive Metallkomplexe) is gratefully acknowledged. We thank Prof. Dr. Horst Kisch for helpful suggestions.

A Calix[4]arene Monoalkyl Ether as a Model of a Tris(phenolate) Ligand with a Hemilabile Anisole Moiety: Syntheses, Molecular Structures and Bonding of Calix[4]arene Ether Supported Titanium Complexes and Their Catalytic Activity in Epoxidation Reactions

Andreas Friedrich[a] and Udo Radius*[a]

Keywords: Calixarenes / Density functional calculations / Epoxidation / Supported catalysts / Titanium

New mononuclear titanium complexes [TiCl(Rcalix)] [R = Me (**1**), Bz (**2**), $SiMe_3$ (**3**)] supported by *p-tert*-butylcalix[4]arene mono(organyl)ethers (Rcalix) were prepared in good yield from H_2R_2calix and $[TiCl_4(THF)_2]$. The crystallographically characterized complex [TiCl(Mecalix)] (**1**) reacts readily with NaCp and $LiNR_2$ to afford the complexes [TiCp(Mecalix)] (**4**) and [Ti(NR_2)(Mecalix)] [R = Me (**5**), Et (**6**), *i*Pr (**7**), Ph (**8**)], respectively. Reactions of [Ti(NR_2)(Mecalix)] (**5**) with alcohols, phenols and thiols proceed cleanly with amide exchange, as exemplified by the synthesis of [Ti(OR)(Mecalix)] [R = Me (**10**), *i*Pr (**11**), *t*Bu (**12**), 4-*t*BuC_6H_4 (**13**), 2,6-*i*$Pr_2C_6H_3$ (**14**)], and [Ti(S*t*Bu)(Mecalix)] (**15**). Depending on the steric demand of the ligand coordinated to the [Ti(Mecalix)] complex fragment these compounds are monomeric or dimeric in the solid state, as demonstrated by the molecular structures of monomeric [Ti(OC_6H_3-2,6-*i*Pr_2)(Mecalix)] (**14**) and [Ti(S*t*Bu)(Mecalix)] (**15**), or dimeric [{Ti(OMe)(Mecalix)}$_2$] (**10**). In all complexes the calix[4]arene ligand adopts an elliptically distorted cone conformation in which the distance of the titanium atom from the anisole oxygen atom varies between 2.342 Å and 2.438 Å for the structurally characterized complexes, with the exception of the Cp complex **4**. MP2 calculations on model complexes demonstrate that the titanium–anisole oxygen bond is weak, with a particularly shallow potential energy surface in the region between 2.30 Å and 2.80 Å. The Mecalix ligand system therefore might be described as a tris(phenolate) ligand with a hemilabile anisole group in the titanium compounds reported. Despite the labile anisole ether titanium bond, isomerization of the calix[4]arene ligand to a *paco* coordination mode, as described earlier for the Me_2calix complexes [Ti(OC_6H_4-4-R)$_2$(Me_2calix)], has not been observed in these complexes. Preliminary results on the catalytic epoxidation of cyclooctene with TBHP using calix[4]arene-stabilized titanium(iv) complexes are also briefly presented.

Introduction

Calix[*n*]arenes are macrocyclic molecules consisting of *n* phenol units connected by *ortho*-methylene groups.[1,2] Calix[4]arenes, with four phenolic residues in the macrocyclic ring, are the simplest and most common compounds of this family. These molecules and their derivatives have been extensively studied for their interesting properties, for example as hosts for cations, anions and neutral molecules, and for the formation of supramolecular assemblies.[3]

Because of the four phenoxy groups in the calix[4]arenes (*p-tert*-butylcalix[4]arene = H_4calix), reactions with transition metal complexes can produce metal phenolate compounds with substitution of up to four hydrogen atoms.[4] Calix[4]arenes have some unique geometrical peculiarities when acting as poly(phenolate) ligands. The fully deprotonated form of the parent calix[4]arene acts as a tetraanionic ligand and usually assumes a cone conformation, which keeps the set of oxygen donor atoms quasi-planar. Depending on the exact geometry adopted in the complex and on the presence of additional metal centers in the complex, this cone conformation readily distorts towards an elliptical cone conformation.[5]

The charge of the O_4 set can be tuned by etherification or esterification of the lower rim of the calix[4]arene, and the degree of functionalization of the metal atom can be controlled by alkylating or silylating the oxygen atom(s), which also offers steric protection. The [Me_2calix] homologues, in particular have received much attention in organotransition metal chemistry over the last 10 years, and a rich chemistry has emerged comprising mainly mononuclear group 4 and 5 metals. In these complexes, the $[R_2calix]^{2-}$ ligands usually provide two negatively charged phenolate oxygen donor atoms and two neutral anisole oxygen donors to a transition metal atom. If the calix[4]arene ethers coordinate in their elliptically distorted cone conformations, these ligands provide a robust and well-defined O_4 coordination environment, similar to other widely used sup-

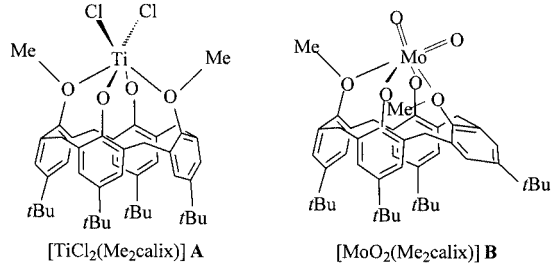
porting dianionic ligands such as the O_2N_2 donor ligands of salen-type Schiff bases or N_4 donor ligands such as porphyrins and dibenzotetraaza[14]annulenes.[6−8]

In contrast to these nitrogen-containing ligand systems, the calix[4]arene dialkyl ethers are conformationally much more flexible. The coordination mode of calix[4]arene dialkyl ethers is largely determined by the nature of the ether group, the coordination number of the metal atom, and the nature of the co-ligands. The cavity of the macrocyclic ligand can therefore be influenced by other ligands in transition metal calix[4]arene complexes if strongly directing co-ligands such as oxo groups are used. We have shown that in the d^0-transition metal complex [$TiCl_2$(Me$_2$calix)] (**A**) the calix[4]arene ligand adopts an elliptically distorted cone conformation, whereas in the related d^0-transition metal complex [MoO_2(*paco*-Me$_2$calix)] (**B**) the metalated calix[4]-arene ligand is coordinated in the solid state as well as in solution in a form which is reminiscent of the partial cone (*paco*) conformation of calix[4]arene (see Scheme 1).[9] In these complexes, one of the methoxy groups of the ligand is located inside the cavity of the calix[4]arene complex.



Scheme 1. Coordination modes of the calix[4]arene dimethyl ether ligand in [$TiCl_2$(Me$_2$calix)] (**A**) and [MoO_2(*paco*-Me$_2$calix)] (**B**)

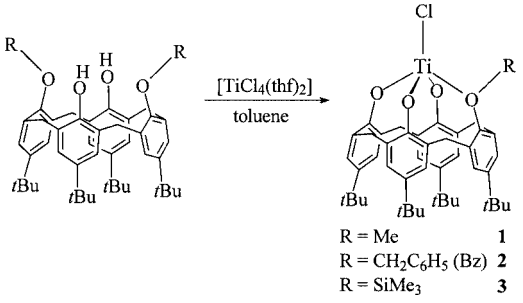
In compound **B** the [Mo(Me$_2$calix)] complex fragment is further stabilized by two additional O^{2-} ligands, which exhibit a strong *trans* influence; density functional calculations on models of different isomers of **A** and **B** indicate that this phenomenon is mainly driven by the co-ligands employed in these complexes.

Furthermore, in compounds of the type [Ti(OC$_6$H$_4$-4-R)$_2$-(Me$_2$calix)] (R = Me or *t*Bu; **C**), both types of coordination mode have been observed.[10] These bis(phenolate) complexes have been isolated in good to excellent yields from the reaction of the imidotitanium complex [Ti(N*t*Bu)-(Me$_2$calix)] and 2 equiv. of the corresponding *para*-substituted phenol to afford complexes in which the calix[4]arene is coordinated in an elliptically distorted cone conformation. These complexes undergo elimination and/or rearrangement reactions in nonpolar solvents such as pentane and hexane. The metal-containing products of the elimination reactions are the dinuclear compounds [{Ti(OC$_6$H$_4$-4-R)(Mecalix)}$_2$] and the products of the rearrangement reaction are [Ti(OC$_6$H$_4$-4-R)$_2$(*paco*-Me$_2$calix)] (**C**). Density functional calculations on model compounds of [Ti(OC$_6$H$_5$)$_2$-(*cone*-Me$_2$calix)] and [Ti(OC$_6$H$_5$)$_2$(*paco*-Me$_2$calix)] reveal a slight thermodynamic preference for the *paco* isomer, but the pathway of this isomerization process is not yet clear. The rearrangement reaction is sensitive to changes of the sterics of the [M(OAr)$_2$] fragment; complexes [Ti(OC$_6$H$_3$-2,6-R$_2$)$_2$(Me$_2$calix)] with *ortho*-substituted phenolate ligands do not rearrange. We have also prepared the analogous zirconium complexes [Zr(OC$_6$H$_4$-4-Me)$_2$(Me$_2$calix)] and [Zr(OC$_6$H$_3$-2,6-Me$_2$)$_2$(Me$_2$calix)] from [Zr(NC$_6$H$_3$-2,6-*i*Pr$_2$)(Me$_2$calix)] and the corresponding phenol; they also do not undergo rearrangement or elimination reactions.[10] Furthermore, *paco* coordination was only observed for complexes of the calix[4]arene dimethyl ether in distorted octahedrally coordinated compounds of the type [MX$_2$-(Me$_2$calix)]. At this point we became interested in investigating the coordination behavior of calix[4]arene monomethyl ether complexes of the type [MX(Mecalix)]. In this contribution we report our results on titanium complexes of the type [TiX(Rcalix)], which are stabilized with the trianion of the calix[4]arene alkyl ether H_3Rcalix and different donor ligands X (Cl, NR_2, OR, SR).

Results and Discussion

Calix[4]arene Chlorotitanium Complexes

The preparation of [TiCl(Mecalix)] starting from H_2Me$_2$-calix and [$TiCl_4$(THF)$_2$] has already been published by Floriani and co-workers.[11] The outcome of this reaction depends critically upon the reaction conditions. The reaction of H_2Me$_2$calix and [$TiCl_4$(THF)$_2$] in toluene at 60 °C for 1 d affords the titanacalix[4]arene dimethyl ether [$TiCl_2$(Me$_2$-calix)],[9,10] whereas a prolonged reaction time in refluxing toluene leads to elimination of MeCl to give [TiCl(Mecalix)] [**1**; see Equation (1)]. Similarly, the reaction of H_2Bz$_2$calix[12] with [$TiCl_4$(THF)$_2$] in toluene at 80 °C for 1 h affords [TiCl(Bzcalix)] (**2**) in good yield. The elimination of BzCl seems to be more favorable than MeCl cleavage in [$TiCl_2$(Me$_2$calix)].



(1)

The bis(trimethylsilyl)ether H_2(Me$_3$Si)$_2$calix[13] also reacts readily with [$TiCl_4$(THF)$_2$] at room temperature to afford the titanacalix[4]arene [TiCl{(Me$_3$Si)calix}] (**3**). The thermal stability of the calixarene ether dichloro complexes [$TiCl_2$(R$_2$calix)] with respect to RCl elimination is $SiMe_3$ < Bz << Me, which reflects the stability of the radical species R — possible intermediates during the cleavage reaction — as well as the steric demand of the R group. On the other hand, formation of the dichloro complex

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[TiCl_2\{(Me_3Si)_2calix\}]$ as a possible intermediate was not observed during the reaction of the silyl ether; NMR investigations of reaction mixtures of $H_2(SiMe_3)_2$calix and $[TiCl_4(THF)_2]$ have shown that **3** is formed within a few minutes. Therefore, it is likely that HCl as well as TMSCl elimination are involved in the first Ti−bond formation step. Raising the reaction temperature leads to further Me_3SiCl cleavage from **3** and formation of polynuclear calix[4]arene complexes.[14]

Compounds **1**−**3**, which were obtained as their toluene solvates, were characterized by elemental analysis, NMR spectroscopy and mass spectrometry. The ^1H NMR spectra of these compounds show signals typically found for calix[4]arene complexes with local C_s symmetry of the macrocyclic ligand. Three resonances were detected for the *t*Bu groups of the calix[4]arene ligand and four doublets for the methylene protons. The protons of the R substituents of [TiCl(Rcalix)] appear at δ = 3.84 (R = CH_3), 5.38 (R = CH_2Ph) and 0.49 (R = $SiMe_3$) ppm. Accurate integration of the signals confirms the cleavage of one ether group from the starting material. Furthermore, the signals are not significantly shifted to higher field, as observed previously for endohedrally located anisole ether groups, which suggests a distorted cone coordination mode of the calix[4]arene ligand. This was confirmed for **1** by X-ray analysis (Figure 1).

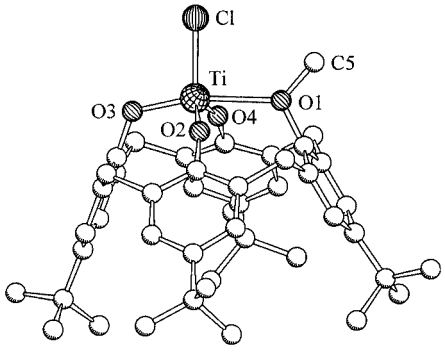


Figure 1. SCHAKAL plot of the molecular structure of [TiCl(Mecalix)] in **1**·1.5C_7H_8; H atoms and solvent molecules have been omitted for clarity; selected bond lengths [Å] and angles [°]: Ti−Cl 2.258(1), Ti−O(1) 2.424(2), Ti−O(2) 1.796(2), Ti−O(3) 1.813(2), Ti−O(4) 1.784(2); Cl−Ti−O(1) 90.1(1), Cl−Ti−O(2) 112.9(1), Cl−Ti−O(3) 103.4(1), Cl−Ti−O(4) 113.7(1), O(1)−Ti−O(2) 78.1(1), O(1)−Ti−O(3) 166.5(1), O(1)−Ti−O(4) 76.7(1), O(2)−Ti−O(3) 96.5(1), O(2)−Ti−O(4) 126.3(1), O(3)−Ti−O(4) 97.3(1), C(5)−O(1)−C(10) 112.8(2), Ti−O(1)−C(5) 129.7(2), Ti−O(1)−C(10) 117.4(2), Ti−O(2)−C(20) 156.5(2), Ti−O(3)−C(30) 121.9(2), Ti−O(4)−C(40) 159.4(2)

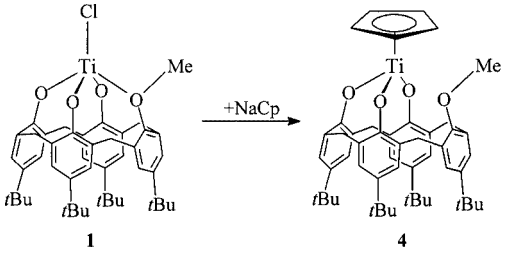
Single crystals of **1** were grown from saturated toluene solutions of the compound. This structure is identical, within experimental errors, with that published previously by Floriani and co-workers,[11] but it is nevertheless important to describe briefly its main features in the context of this paper for comparison with other structurally characterized complexes of the type [TiX(Mecalix)] reported here and the results of theoretical calculations described below.

Complex **1** crystallizes with an additional toluene molecule that is hosted inside the calixarene cavity and half of a toluene molecule in the asymmetric unit, which occupies a general position in the lattice. The X-ray crystal structure of **1** confirms the mononuclear character of the compound in the solid state, in which the calixarene is coordinated in an elliptically distorted cone conformation. The coordination polyhedron at the titanium atom can be described as a distorted trigonal bipyramid, in which the oxygen atoms O(1) and O(3) occupy the axial positions and Cl, O(2), and O(3) the equatorial sites. The angles Cl−Ti−O(3) [103.4(1)°] and O(2)−Ti−O(4) [126.3(1)°] reflect the significant distortions of the ideal polyhedron. The angle O(1)−Ti−O(3) between the mutually *trans*-oxygen atoms O(1) and O(3) [166.5(1)°] also reveals a deviation from a linear alignment of these atoms.

The Ti−Cl distance of 2.258(1) Å is approximately 0.10 Å shorter than that found in the distorted octahedral complex $[TiCl_2(Me_2calix)]$,[9] but it is similar to those observed in other pentacoordinated titanium complexes such as $[TiCl_2(mbmp)(THF)]$ ($[H_2mbmp$ = 2,2′-$CH_2\{6$-*t*Bu-4-$MeC_6H_2(OH)\}_2]$).[15] The Ti−O distances to the oxygen atoms O(2), O(3) and O(4) of the phenolate units [1.796(2) Å, 1.813(2) Å and 1.784(2) Å, respectively] are similar to those found in $[TiCl_2(Me_2calix)]$. The Ti−O(1) bond to the oxygen atom of the anisole unit [2.424(2) Å] is significantly longer (approximately 0.30 Å) than in $[TiCl_2(Me_2calix)]$. However, the sum of the Ti−O(1) and Ti−O(3) distances is almost identical to the sum of the corresponding Ti−O distances in $[TiCl_2(Me_2calix)]$ (4.234 Å vs. 4.237 Å), which reflects the geometrical constraint of the calix[4]arene ligand. In other words, the titanium atom moves from an ideal, central position between the anisole oxygen atoms in $[TiCl_2(Me_2calix)]$ towards the stronger phenolate oxygen donor atom O(3) in [TiCl(Mecalix)].

A Calix[4]arene Cyclopentadienyltitanium Complex

In the series [TiX(Mecalix)], Floriani et al. have already reported alkyl complexes of the type [TiR(Mecalix)] (R = Me, $CH_2C_6H_5$, 4-MeC_6H_4). In these compounds, the calix[4]arene binds in a distorted cone conformation to the [Ti−R] complex fragment, as was shown by NMR spectroscopy and a structural analysis of $[Ti(C_6H_4$-4-Me)(Mecalix)].[11] We were interested in coordinating the excellent σ,π-donor ligand $C_5H_5^-$ to the calix[4]arene titanium fragment. According to Equation (2), [TiCp(Mecalix)] (**4**) can be prepared in good yields from the reaction of **1** with NaCp.



(2)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Compound **4** was characterized by elemental analysis, mass spectrometry, and NMR spectroscopy. The NMR spectra are in accordance with a pseudo-C_s-symmetric structure of the complex in solution, as shown in Equation (2). The signals of the protons of the anisole methyl groups at δ = 3.89 ppm and of the Cp ligand at δ = 6.80 ppm, in the integration ratio 3:5, are sharp singlets at room temperature and do not change on cooling to −60 °C, which confirms the η^5-coordination mode of the Cp ligand. It is interesting to note that the chemical shifts of the protons of the anisole methyl groups at δ = 3.44 ppm in C_6D_6 and δ = 3.89 ppm in $CDCl_3$ are similar to the NMR shifts obtained for the uncomplexed ligand at δ = 3.49 ppm (C_6D_6) and δ = 3.93 ppm ($CDCl_3$). The resonances observed for **1** are significantly shifted to higher field compared to those of the uncomplexed ligand at δ = 3.84 ppm (C_6D_6) and δ = 4.26 ppm ($CDCl_3$). Similar observations have been made in the $^{13}C\{^1H\}$ NMR spectra of **4**, which points to an uncoordinated anisole group in solution. This probably reflects better electronic as well as steric shielding of the metal atom in **4** compared to the chloro complex **1**.

The molecular structure of **4** is shown in Figure 2. Complex **4** crystallizes in the space group $P2_1/c$ with one formula unit and two additional solvent molecules in the unit cell, which occupy general positions in the lattice. The titanium atom in **4** is tetrahedrally coordinated to the Cp ligand and three phenolate oxygen atoms of the calixarene. The Ti−O distances of 1.807(4) Å, 1.864(4) Å, and 1.809(4) Å are slightly longer than those observed in **1**, but similar to Ti−O bond lengths found in other stable complexes of the type $[TiCp(OR)_3]$, such as $[TiCp(OC_6H_3\text{-}2,6\text{-}i\text{Pr}_2)_3]$ [average 1.80(2) Å] and $[TiCp(OC_6F_4H)_3]$ [1.826(3) Å, 1.830(3) Å and 1.867(3) Å].[16] In comparison with the chloro complex **1**, the titanium atom is displaced further from the center of the calix[4]arene ligand; the Ti−O(1) distance of 3.498(6) Å can be regarded as nonbonding. Whereas the size of the C(50)−O(1)−C(10) angle [113.4(5)°] is similar to the corresponding angle C(5)−O(1)−C(10) [112.8(2)°] in **1**, a significant difference in the bonding of the fragments $[TiCl]^{3+}$ and $[Ti(\eta^5\text{-}C_5H_5)]^{3+}$ to the $[Mecalix]^{3-}$ ligand is also reflected in the Ti−O(1)−C(10) angles of 87.1(4)° in **4** and 117.4(1)° in **1**. As a consequence, the calixarene cavity is significantly influenced by the metal complex fragment bound at the lower rim of the ligand. The distance to the phenolate carbon atoms C(15) and C(35) in the *para* positions is 5.463 Å in the Cp complex, which is much smaller than the corresponding distance in the chloro compound **1** (7.685 Å); this distortion of the calix[4]arene ligand prevents inclusion of a solvent molecule inside the calixarene cavity.

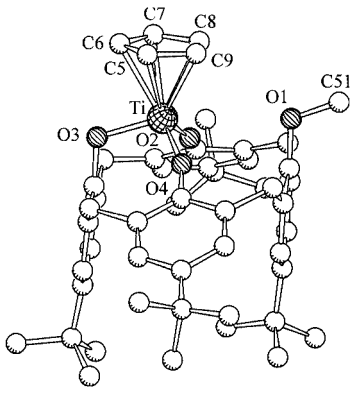


Figure 2. SCHAKAL plot of the molecular structure of [TiCp(Mecalix)] in $4{\cdot}2C_7H_8$; H atoms and solvent molecules have been omitted for clarity; selected bond lengths [Å] and angles [°]: Ti−O(1) 3.498(6), Ti−O(2) 1.807(4), Ti−O(3) 1.864(4), Ti−O(4) 1.809(4), Ti−Cp_{centr} 2.039(7), Ti−C(5) 2.365(7), Ti−C(6) 2.373(6), Ti−C(7) 2.359(7), Ti−C(8) 2.319(7), Ti−C(9) 2.327(7); Cp_{centr}−Ti−O(1) 88.5(2), Cp_{centr}−Ti−O(2) 119.6(2), Cp_{centr}−Ti−O(3) 108.1(2), Cp_{centr}−Ti−O(4) 119.5(2), O(1)−Ti−O(2) 69.4(4), O(1)−Ti−O(3) 163.4(4), O(1)−Ti−O(4) 70.2(4), O(2)−Ti−O(3) 100.98(17), O(2)−Ti−O(4) 104.84(17), O(3)−Ti−O(4) 100.68(17), Ti−O(1)−C(10) 87.1(4), Ti−O(1)−C(50) 158.4(3), C(50)−O(1)−C(10) 113.4(5), Ti−O(2)−C(20) 161.3(4), Ti−O(3)−C(30) 111.0(3), Ti−O(4)−C(40) 162.4(4)

Calix[4]arene Amidotitanium Complexes

Calix[4]arene-stabilized amidotitanium complexes of the type $[Ti(NR_2)(Mecalix)]$ with different substituents R = Me (**5**), Et (**6**), *i*Pr (**7**), Ph (**8**) are readily available by metathetical exchange of the chloro ligand in **1** with an equimolar amount of the corresponding lithium amide in toluene (see Scheme 2). These complexes can be isolated in good to reasonable yields as yellow to red powders. The mass spectra of these substances show peaks for the molecular ions as the base peaks at *m*/*z* = 751 (**5**), 779 (**6**), 807 (**7**), and 875 (**8**), which are in accordance with their formulation as mononuclear species. However, based on NMR spectroscopic data it is impossible to distinguish a monomeric complex from a possible dinuclear, amido-bridged complex of the composition $[\{Ti(\mu\text{-}NR_2)(Mecalix)\}_2]$.

The compounds $[Ti(NMe_2)(Mecalix)]$ (**5**) and $[Ti(NPh_2)(Mecalix)]$ (**8**) were structurally characterized. The molecular structures of these complexes are shown in Figures 3 and 4. All attempts to crystallize **5** from various solvents led to crystals unsuitable for X-ray diffraction. However, after prolonged storage as a THF solution, we obtained suitable crystals of complex **5** cocrystallized with its product of hydrolysis, $[\{Ti(Mecalix)\}_2(\mu\text{-}O)]$ (**9**). Complex **8** crystallizes with two independent molecules $[Ti(NPh_2)(Mecalix)]$ in the space group $P2_1/c$, which differ only slightly in their molecular structures. Since there are no significant differences between the two sets of bond lengths and angles we will refer specifically only to those from one of the molecules [at Ti(1)]; the parameters of the other molecule are given in the caption to Figure 4.

The results of the X-ray analyses confirm the mononuclear nature of **5** and **8** in the solid state, as postulated in Scheme 2. Typically, all calixarene ligands host a solvent molecule in their cavities. The coordination sphere at the metal atom in **5** and **8** is best described as distorted trigonal-bipyramidal, in which the oxygen atoms O(1) and O(3) occupy axial positions and the oxygen atoms O(2) and O(4), as well as the nitrogen atom of the amide ligand, span the equatorial plane. The oxygen atoms in the axial positions

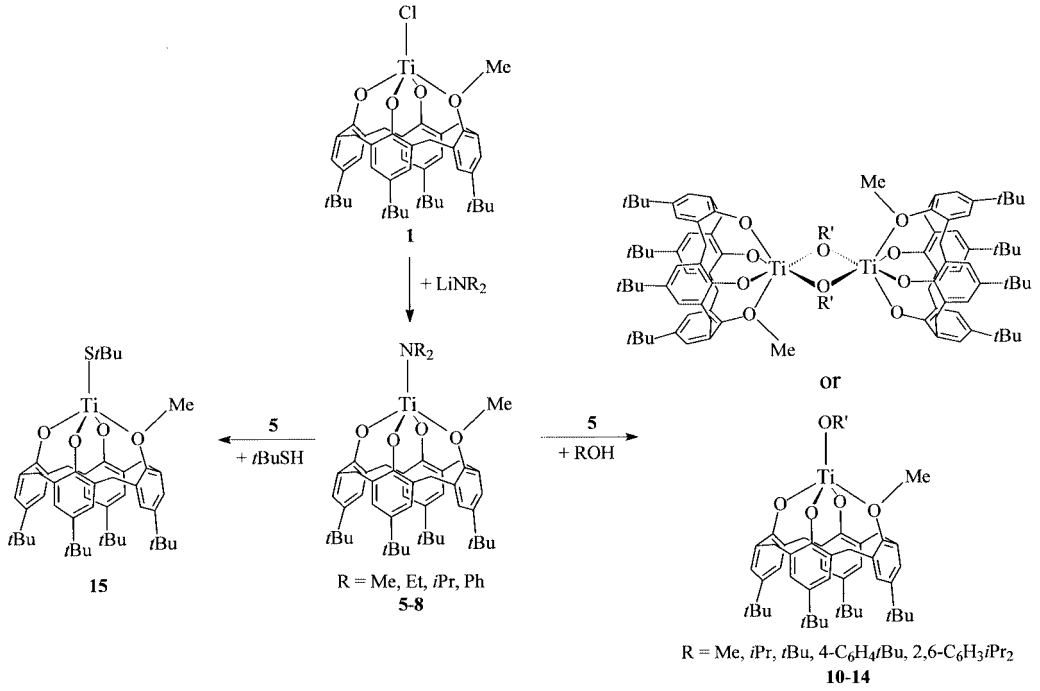

Scheme 2. Synthesis of Mecalix-stabilized amidotitanium alkoxide, phenolate, and thiolate complexes

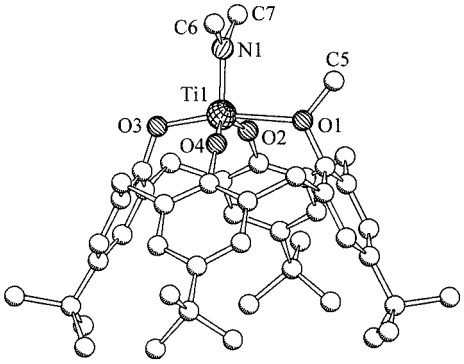

Figure 3. SCHAKAL plot of the molecular structure of [Ti(NMe_2)-(Mecalix)] (**5**) in **5**·**9**·5C_4H_8O; H atoms and solvent molecules have been omitted for clarity; selected bond lengths [Å] and angles [°]: Ti(1)−N(1) 1.846(5), Ti(1)−O(1) 2.342(4), Ti(1)−O(2) 1.818(4), Ti(1)−O(3), 1.874(4), Ti(1)−O(4) 1.814(5); Ti(1)−N(1)−C(6) 123.8(5), Ti(1)−N(1)−C(7) 123.3(5), C(6)−N(1)−C(7) 112.6(6), N(1)−Ti(1)−O(1) 90.6(2), N(1)−Ti(1)−O(2) 109.3(2), N(1)−Ti(1)−O(3) 103.3(2), N(1)−Ti(1)−O(4) 109.6(2), O(1)−Ti(1)−O(2) 79.5(2), O(1)−Ti(1)−O(3) 166.1(2), O(1)−Ti(1)−O(4) 79.5(2), O(2)−Ti(1)−O(3) 95.7(2), O(2)−Ti(1)−O(4) 135.6(2), O(3)−Ti(1)−O(4) 95.4(2), Ti(1)−O(1)−C(5) 125.9(4), Ti(1)−O(1)−C(10) 119.2(3), Ti(1)−O(2)−C(20) 150.9(4), Ti(1)−O(3)−C(30) 121.0(4), Ti(1)−O(4)−C(40) 151.7(4)

are almost linearly aligned, with O(1)−Ti−O(3) angles of 166.1(2)° (**5**) and 166.5(1)° (**8**). The N(1)−Ti−O(3) angles of 103.3(2)° (**5**) and 104.5(1)° (**8**), as well as the other bond angles in the equatorial plane, reflect a significant distortion from an ideal polyhedron. The metal atoms in **5** and **8** are dislocated from a central position in the trigonal bipyramid towards the phenolate oxygen donor atom O(3), as described above for the chloro complex **1**, but this distortion is not as pronounced as observed in the solid-state structure

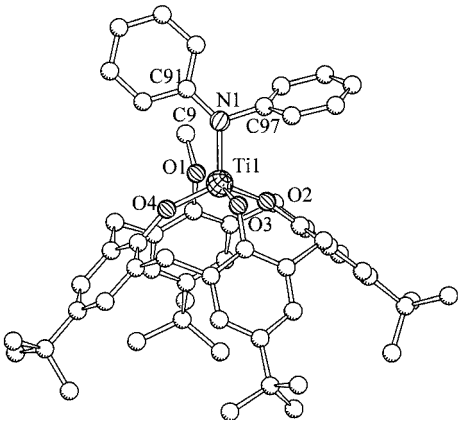

Figure 4. SCHAKAL plot of the molecular structure of [Ti(NPh_2)(Mecalix)]·(**8**) in **8**·8C_4H_8O·0.5C_6H_6; H atoms and solvent molecules have been omitted for clarity; selected bond lengths [Å] and angles [°]: Molecule 1: Ti(1)−N(1) 1.920(3), Ti(1)−O(1) 2.385(3), Ti(1)−O(2) 1.783(3), Ti(1)−O(3) 1.857(3), Ti(1)−O(4) 1.799(3); Ti(1)−N(1)−C(91) 1.338(3), Ti(1)−N(1)−C(97) 107.7(3), C(91)−N(1)−C(97) 118.0(3), N(1)−Ti(1)−O(1) 89.1(1), N(1)−Ti(1)−O(2) 111.4(1), N(1)−Ti(1)−O(3) 104.5(1), N(1)−Ti(1)−O(4) 115.5(1), O(1)−Ti(1)−O(2) 78.3(1), O(1)−Ti(1)−O(3) 166.5(1), O(1)−Ti(1)−O(4) 78.1(1), O(2)−Ti(1)−O(3) 95.6(1), O(2)−Ti(1)−O(4) 126.5(1), O(3)−Ti(1)−O(4) 96.4(1), Ti(1)−O(1)−C(9) 130.1(3), Ti(1)−O(1)−C(10) 116.8(2), Ti(1)−O(2)−C(20) 163.2(3), Ti(1)−O(3)−C(30) 120.2(2), Ti(1)−O(4)−C(40) 155.8(3), C(9)−O(1)−C(10) 113.0(3); Molecule 2: Ti(2)−N(2) 1.930(3), Ti(2)−O(5) 2.378(3), Ti(2)−O(6) 1.792(3), Ti(2)−O(7) 1.853(3), Ti(2)−O(8) 1.789(3); N(2)−Ti(2)−O(5) 89.88(12), N(2)−Ti(2)−O(6) 113.65(14), N(2)−Ti(2)−O(7) 103.96(13), N(2)−Ti(2)−O(8) 112.85(14), O(5)−Ti(2)−O(6) 78.48(11), O(5)−Ti(2)−O(7) 166.13(11), O(5)−Ti(2)−O(8) 77.65(11), O(6)−Ti(2)−O(8) 127.03(13), O(6)−Ti(2)−O(7) 96.43(13), O(7)−Ti(2)−O(8) 95.77(12), Ti(2)−O(5)−C(50) 117.1(2), Ti(2)−O(6)−C(60) 158.8(3), Ti(2)−O(7)−C(70) 121.1(2), Ti(2)−O(8)−C(80) 159.3(3), Ti(2)−O(5)−C(90) 129.0(3), Ti(2)−N(2)−C(103) 133.0(3), Ti(2)−N(2)−C(109) 108.6(2)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the Cp complex **4**. The sum of the X−Ti−Y angles of all atoms that are aligned in the equatorial plane [O(2), O(4), N/Cl/Cp_{centr}] is 352.9° in **1**, 354.5° in **5**, 353.4° in **8** and only 343.9° in **4**. They follow a similar trend as the Ti−O(1) bond lengths [2.424(2) Å (**1**), 2.342(4) Å (**5**), 2.38.5(3) Å (**8**), and 3.498(6) Å (**4**)], which indicates that the Ti−O(1) bond lengths do not follow only simple trends such as different steric hindrance or different electronic properties of the chloro, amido, and Cp ligands in this series.

The Ti−N distances [1.846(5) Å (**5**) and 1.920(3) Å (**8**)] are shorter than expected from the ionic radii (approximately 2.07 Å),[17] but are similar to the Ti−N bond lengths found in bis(amido)titanium complexes such as [$Ti(NMe_2)_2$-(OC_6H_3-2,6-tBu_2)$_2$] and [$Ti(NMe_2)_2(OC_6H_2$-2,4,6-$tBu_3)_2$], with values between 1.864 Å and 1.897 Å.[18] This can be attributed to π-donation of the amide ligand to the titanium atom, in which the nitrogen lone pair is involved in Ti−N bonding. Furthermore, the amido [NC_2] entity is almost planar, as revealed by the sum of the angles at the nitrogen atoms [359.7° (**5**) and 359.5° (**8**)]. The diorganylamido ligand in both complexes is oriented in such a way that the plane through the amido nitrogen atom and the N−C carbon atom is almost perpendicular to the plane through the atoms Ti, O(1) and O(3). These planes intersect each other with an angle of 89.9(10)° (**5**) and 74.8(6)° (**8**).

As mentioned above, the air- and moisture-sensitive amido complex **5** was cocrystallized with [{Ti(Mecalix)}$_2$(μ-O)] (**9**). Since the anisole methyl ether groups of **9** in **5·9**·$5C_4H_8O$ are disordered over two sites, the formation of complex **9** starting from the amido complex **5** was verified and its molecular structure was determined separately. Complex **9** crystallizes from saturated benzene solutions at room temperature in the form of thin plates in the space group $P2_1/n$ with two formula units and eight solvent molecules in the unit cell. The molecular structure of **9**, as found in **9**·$4C_6H_6$, is shown in Figure 5; selected bond lengths and angles are given in the figure caption.

The coordination sphere at the titanium atoms in **9** is also distorted trigonal-bipyramidal. The molecular unit of **9** as found in **5·9**·$5C_4H_8O$ has similar geometrical data. In this compound two $[Ti(Mecalix)]^+$ units are linked by a linear μ-O^{2-} ligand. The Ti−O−Ti′ angle (180.0°) in both molecular structures of **9** is superimposed by crystallographic symmetry, since the oxygen atoms are aligned in both cases on an inversion center. The Ti−O distances in the bridge are 1.798(1) Å in **9**·$4C_6H_6$ and 1.791(1) Å in **5·9**·$5C_4H_8O$; the Ti−O(1) bond length is 2.389(4) Å.

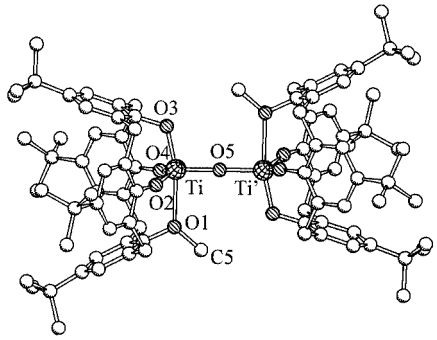

Figure 5. SCHAKAL plot of the molecular structure of [{Ti(Mecalix)}$_2$(μ-O)] in **9**·$4C_6H_6$; H atoms and solvent molecules have been omitted for clarity; selected bond lengths [Å] and angles [°]: Ti−O(1) 2.389(4), Ti−O(2) 1.784(4), Ti−O(3) 1.841(4), Ti−O(5) 1.798(1), Ti−O(4) 1.798(4); Ti−O(5)−Ti′ 180.0(1), O(1)−Ti−O(2) 77.2(2), O(1)−Ti−O(3) 166.7(1), O(1)−Ti−O(4) 79.1(2), O(1)−Ti−O(5) 91.2(1), O(2)−Ti−O(3) 95.2(2), O(2)−Ti−O(4) 126.0(2), O(2)−Ti−O(5) 115.5(1), O(3)−Ti−O(4) 97.2(2), O(3)−Ti−O(5) 102.0(1), O(4)−Ti−O(5) 112.8(1), Ti−O(1)−C(5) 129.9(3), Ti−O(1)−C(10) 115.9(3), Ti−O(2)−C(20) 167.3(4), Ti−O(3)−C(30) 119.0(3), Ti−O(4)−C(40) 151.2(3), C(5)−O(1)−C(10) 114.1(4)

Calix[4]arene Titanium Alkoxide, Phenoxide, and Thiolate Complexes

There are several ways to synthesize complexes of the type [Ti(OR)(Mecalix)]. The basic strategies are: (i) salt metathesis using [TiCl(Mecalix)] and an alkali metal alkoxide or phenolate; (ii) to introduce the calix[4]arene ligand into titanium alkoxide or phenolate complexes; and (iii) to introduce the alkoxide or phenolate by metathesis of more basic alkyl, aryl or amide ligands. The general route we chose for the preparation of such compounds is the reaction of equimolar amounts of alcohols or phenols with [Ti(N-Me_2)(Mecalix)] (**5**). These reactions afford the complexes [Ti(OR)(Mecalix)] (**10**; R = Me), (**11**; R = *i*Pr), (**12**; R = *t*Bu), (**13**; R = 4-*t*BuC_6H_4), and (**14**; R = 2,6-*i*$Pr_2C_6H_3$) in good yield (Scheme 2). Similarly, thiolate ligands can be introduced into the calixarene titanium system, as exemplified by the synthesis of [Ti(S*t*Bu)(Mecalix)] (**15**). Other routes are also viable, as was shown for the synthesis of compound **12** from the reaction of [TiCl(Mecalix)] with KO*t*Bu, or the synthesis of **11** starting from [Ti(O*i*Pr)$_4$] and 1 equiv. of H_3Mecalix. Whereas the latter approach is advantageous for the isopropoxide system, salt metathesis generally leads to lower yields and purities.

The composition of the resulting bright yellow metal complexes was verified by elemental analysis. In the mass spectra of these compounds, the molecular peaks for the mononuclear ions at m/z = 738 (**10**), 766 (**11**), 780 (**12**), 856 (**13**), 885 (**14**), and 796 (**15**) were found as base peaks. The ^{1}H and ^{13}C NMR spectra reveal signals typically found for pseudo-C_s-symmetrical calix[4]arene complexes. However, on the basis of NMR spectroscopic data a differentiation between monomeric and dimeric alkoxide-bridged species is not possible. The molecular structures of [Ti(OC_6H_4-4-*t*Bu)(Mecalix)] (**13**) and [Ti(OC_6H_4-4-Me)(Mecalix)] (**C**), synthesized previously from the reaction of [Ti(N*t*Bu)(Me_2-calix)] and the corresponding phenol, show that these complexes are dimers in the solid state.

In addition, X-ray analyses of the methoxide and diisopropylphenolate complexes **10** and **14** were performed. Crystals suitable for X-ray diffraction studies were grown from saturated toluene solutions. The molecular structures of these complexes are shown in Figures 6 and 7.

The methoxide complex **10** is a methoxy-bridged dimer in the solid state, in which two methoxide ligands bridge

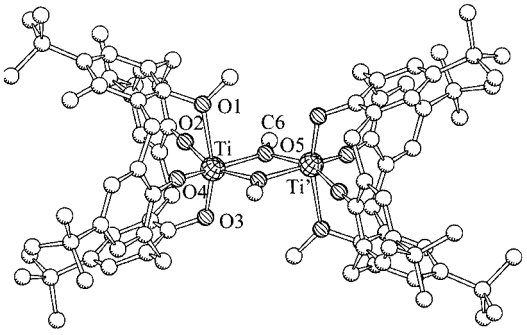

Figure 6. SCHAKAL plot of the molecular structure of $[\{Ti(OMe)(Mecalix)\}_2]$ in **10**·$6C_7H_8$; H atoms and solvent molecules have been omitted for clarity; selected bond lengths [Å] and angles [°]: Ti−O(1) 2.438(2), Ti−O(2) 1.808(2), Ti−O(3) 1.847(2), Ti−O(4) 1.800(2), Ti−O(5) 2.032(2), Ti−O(5′) 2.026(2); O(1)−Ti−O(2) 76.0(1), O(1)−Ti−O(3) 164.2(1), O(1)−Ti−O(4) 76.9(1), O(1)−Ti−O(5) 94.6(1), O(1)−Ti−O(5′) 90.0(1), O(2)−Ti−O(3) 94.4(1), O(2)−Ti−O(4) 104.2(1), O(2)−Ti−O(5) 158.8(1), O(2)−Ti−O(5′) 91.0(1), O(3)−Ti−O(4) 93.8(1), O(3)−Ti−O(5) 98.5(1), O(3)−Ti−O(5′) 103.0(1), O(3)−Ti−O(4) 76.9(1), O(4)−Ti−O(5) 91.8(1), O(4)−Ti−O(5′) 156.5(1), O(5)−Ti−O(5′) 69.8(1), O(1)−Ti−Ti′ 92.7(1), O(2)−Ti−Ti′ 125.4(1), O(3)−Ti−Ti′ 103.1(1), O(4)−Ti−Ti′ 125.2(1), O(5)−Ti−Ti′ 34.8(1), O(5′)−Ti−Ti′ 35.0(1), Ti′−O(5)−Ti 110.2(1), Ti−O(1)−C(5) 131.5(2), Ti−O(1)−C(10) 115.4(2), Ti−O(2)−C(20) 167.7(2), Ti−O(3)−C(30) 120.2(2), Ti−O(4)−C(40) 167.2(2), Ti−O(5)−C(6) 124.2(2), Ti′−O(5)−C(6) 125.3(2)

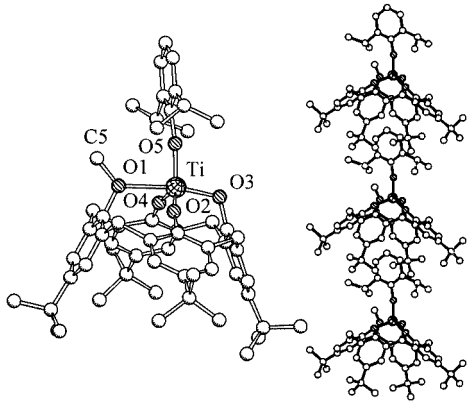

Figure 7. SCHAKAL plot of the molecular structure of $[Ti(OC_6H_3\text{-}2,6\text{-}i\text{Pr}_2)(Mecalix)]$ in **14**·$C_6H_3i\text{Pr}_2\text{OH}$; H atoms and solvent molecules have been omitted for clarity; (left) molecular unit; (right) plot of the columnar stacking of these molecular units to give a chain along the crystallographic *b* axis; selected bond lengths [Å] and angles [°]: Ti−O(1) 2.384(3), Ti−O(2) 1.768(3), Ti−O(3) 1.864(3), Ti−O(4) 1.785(3), Ti−O(5) 1.792(3); O(1)−Ti−O(2) 78.2(1), O(1)−Ti−O(3) 169.3(1), O(1)−Ti−O(4) 79.2(1), O(1)−Ti−O(5) 86.5(1), O(2)−Ti−O(3) 96.4(1), O(2)−Ti−O(4) 119.7(1), O(2)−Ti−O(5) 117.9(1), O(3)−Ti−O(4) 95.9(1), O(3)−Ti−O(5) 104.2(1), O(4)−Ti−O(5) 115.5(1), Ti−O(1)−C(10) 114.9(2), Ti−O(1)−C(5) 130.0(2), Ti−O(2)−C(20) 168.0(2), Ti−O(3)−C(30) 116.0(2), Ti−O(4)−C(40) 166.8(3), Ti−O(5)−C(50) 168.7(3)

two [Ti(Mecalix)] fragments. This complex has a crystallographically imposed inversion center at the center of the planar $[Ti_2O_2]$ four-membered ring. The coordination sphere at the titanium atom is distorted octahedral, and these two octahedra are connected by an common edge. The O−Ti−O and Ti−O−Ti′ angles within the four-membered ring are 69.8(1)° and 110.2(1)°, respectively. The Ti−Ti distance of 3.32.9(1) Å is nonbonding. The Ti−O(1) bond length to the oxygen atom of the anisole group of the calix[4]arene [2.438(2) Å] is similar to the distances found in the chloro and amido complexes. The distances of the bridging oxygen atoms from the titanium atoms are 2.032(2) Å and 2.026(2) Å, similar to other alkoxide-bridged compounds such as $[\{Ti(ONp)_4\}_2]$.[19]

In contrast to the dinuclear phenolate complexes $[Ti(OC_6H_4\text{-}4\text{-}t\text{Bu})(Mecalix)]$ (**13**) and $[Ti(OC_6H_4\text{-}4\text{-}Me)(Mecalix)]$ (**C**), the calixarene-stabilized diisopropylphenolate compound **14** is a monomer in the solid state, which is mainly due to the enhanced steric demand of the *ortho*-substituted phenolate ligand. The molecular structure of **14** is depicted on the left-hand side of Figure 7, with the stacking along the crystallographic *b* axis shown on the right. The coordination sphere around the titanium atom in this monomeric complex is best described as a distorted trigonal bipyramid, in which the oxygen atoms O(2), O(4) and O(5) occupy the equatorial positions. The O(2)−Ti−O(4), O(2)−Ti−O(5) and O(4)−Ti−O(5) angles [115.5(1)°−119.7(1)°] differ only slightly from their ideal value of 120°.

The distances between the titanium atom and the oxygen atoms O(2), O(4) and O(5) are in the narrow range of 1.768(3)−1.792(3) Å, whereas the Ti−O(3) distance of 1.864(3) Å is significantly longer. The Ti−O(1) distance of 2.384(3) Å, as well as the sum of the Ti−O distances to the oxygen atoms O(1) and O(3) (4.248 Å), are similar to the other calix[4]arene monomethyl ether complexes described in this paper.

Additional stabilization of the compound is provided by stacking of the molecular units. The right-hand side of Figure 7 shows the linear polymeric structure of **14** in the solid state. The aryl unit of the diisopropylphenolate ligand is oriented in the cavity of a neighboring calix[4]arene ligand with the plane defined by the aryl carbon atoms almost ideally aligned with the plane through the oxygen atoms O(2) and O(4) and the corresponding *ipso*-carbon atoms of the macrocyclic ligand [angle of intersection 8.9(4)°]. The closest distance between the carbon atoms of the diisopropylphenolate ligand and the carbon atoms of the calix[4]arene is 3.660(3) Å.

The thiolate complex **15** is also a monomer in the solid state, as can be seen from the molecular structure of **15** depicted in Figure 8. Crystals of this compound were obtained from saturated hexane solutions, from which the compound crystallizes in the monoclinic space group $P2_1/c$ with four molecular units and four solvent molecules in the unit cell. The titanium atom is in a distorted trigonal-bipyramidal coordination mode with the four oxygen atoms of the calix[4]arene ligand and the sulfur atom of the thiolate ligand. The oxygen atoms O(1) and O(3) occupy the axial positions. The Ti−O(1) bond length (to the oxygen atom of the anisole group) is 2.389(3) Å. The thiolate ligand in **15** is not linearly coordinated, with the Ti−S−C(6) angle of 110.8(2)° being close to the tetrahedral angle, which indicates that the sulfur lone pairs in **15** are not involved in Ti−S bonding. However, the Ti−S bond of 2.314(2) Å is

significantly shorter than those in $[TiCp_2(StBu)_2]$ [2.416(1) Å].[20a] In more Lewis-acidic titanium thiolate complexes or in complexes with sterically less demanding ligands such as $[TiCp_2(SEt)_2]$ and $[Ti(diars)Cl_2(StBu)_2]$ [diars = 1,2-$(Me_2As)_2C_6H_4$], the Ti−S bond lengths are 2.387(3) Å and 2.398(3) Å (in the metallocene),[20b] and 2.332(3) Å (in the complex).[20c]

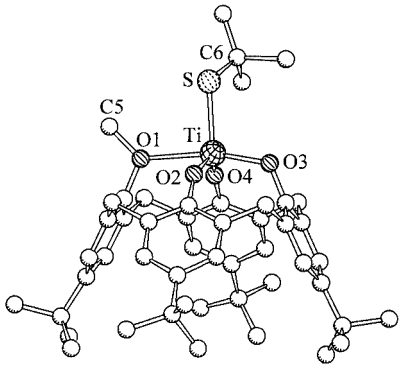

Figure 8. SCHAKAL plot of the molecular structure of [Ti(S*t*Bu)(Mecalix)] in **15**·C_6H_{14}; H atoms and solvent molecules have been omitted for clarity; selected bond lengths [Å] and angles [°]: Ti−S 2.314(2), Ti−O(1) 2.389(4), Ti−O(2) 1.793(4), Ti−O(3) 1.880(4), Ti−O(4) 1.787(3); S−Ti−O(1) 91.5(1), S−Ti−O(2) 108.1(1), S−Ti−O(3) 102.4(1), S−Ti−O(4) 115.9(1), O(1)−Ti−O(2) 79.2(2), O(1)−Ti−O(3) 166.1(2), O(1)−Ti−O(4), 79.2(1), O(2)−Ti−O(3) 96.9(2), O(2)−Ti−O(4) 131.1(2), O(3)−Ti−O(4) 93.8(2), Ti−S−C(6) 110.8(2), Ti−O(1)−C(5) 130.1(4), Ti−O(1)−C(10) 117.5(3), Ti−O(2)−C(20) 151.9(3), Ti−O(3)−C(30) 122.1(3), Ti−O(4)−C(40) 159.4(4)

Ab initio Calculations on Model Complexes

Ab initio and DFT calculations[21−24] were performed on model compounds to gain a better understanding of the main electronic and structural properties of the titanium complexes supported by the calix[4]arene methyl ether ligand. The aim of these calculations was to study the main features of the ligand in the titanium complexes described above as well as the frontier orbitals of the calix[4]arene titanium complex fragment, and their structural consequences.

Two models were considered in the calculations: A detailed model, [TiX(Mecalix^H)], in which the ligand has been slightly modified by a replacement of the *t*Bu groups with hydrogen atoms. In the second, more simplified model, $[TiX(OMe)_3(OMe_2)]$, the coordination environment at the titanium atom was maintained to resemble the main features of the ligand, but the aryl groups were replaced by methyl groups. Calculations on different detailed model complexes showed that DFT methods describe the geometry of the complexes rather poorly, especially the Ti−O(1) distance (anisole oxygen atom), which was overestimated (approximately 2.50 Å for different complexes [TiX(Mecalix^H)] and different functionals employed). Ab initio methods performed much better here, and all the results reported below are from MP2 calculations.

With the exception of $[Ti(OC_6H_3\text{-}2,6\text{-}iPr_2)(Mecalix)]$ (**14**), all the structures given above can be described in terms of the isolated molecular units present in the crystal, or their solvates, in which one of the additional solvent molecules is located inside the calix[4]arene cavity. The calculated geometries of [TiCl(Mecalix^H)] and its benzene solvate [TiCl(Mecalix^H)](C_6H_6) converge with almost identical geometries of the complex, the maximal deviation in the Ti−O distance and Ti−O−C angles are 0.006 Å and 1.23°, respectively, which are in good agreement with the experimentally observed geometry. The main structural features of the complex are therefore determined by coordination of the metal complex fragment $[TiX]^{3+}$ to the $[Mecalix]^{3-}$ ligand and are not significantly affected by lattice interactions or guest molecules in the calix[4]arene cages.

We were interested in learning more about the labile anisole ether coordination in the titanium complexes. The energy calculated for the removal of the OMe_2 group from the simplified model $[TiCl(OMe)_3(OMe_2)]$ is 45.2 kJ/mol, which indicates only weak bonding of the ether group to the titanium complex fragment. Moreover, the energy potential calculated for the elongation or compression of the Ti−O(ether) bond, which is shown in Figure 9, is very flat. The region between 2.30 Å and 2.80 Å lies within a narrow range of 5−6 kJ/mol, which indicates that the Ti−O(1) bond lengths are mainly determined by steric factors, that is, either interactions resulting from the ligand L with the anisole ether group or from an internal reorganization energy of the calix[4]arene ligand.

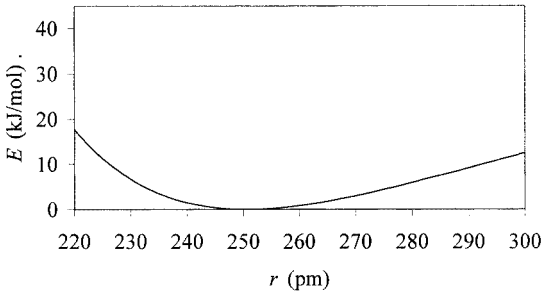

Figure 9. Potential energy curve calculated for the Ti−OMe_2 bond in $[TiCl(OMe)_3(OMe_2)]$

Geometry optimizations of the detailed model of the amido complex **5** confirmed the planar arrangement of the dimethylamido group and its perpendicular alignment with respect to the Ti−O(1) vector. A schematic FMO diagram of the interactions of an amido ligand $[NMe_2]^-$ with a calixarene metal fragment $[Ti(Mecalix)]^+$ is depicted on the right-hand side of Figure 10. The lowest metal-centered, unoccupied orbitals of the $[Ti(Mecalix)]^+$ fragment are shown on the left-hand side of the FMO scheme, while orbital plots of these relevant fragment orbitals drawn for the simplified model are given on the left-hand side of Figure 10.

The $[Ti(Mecalix)]^+$ orbitals responsible for binding of the calixarene-stabilized metal atom to a σ,π-donor ligand are three metal-centered, unoccupied orbitals. The lowest or-

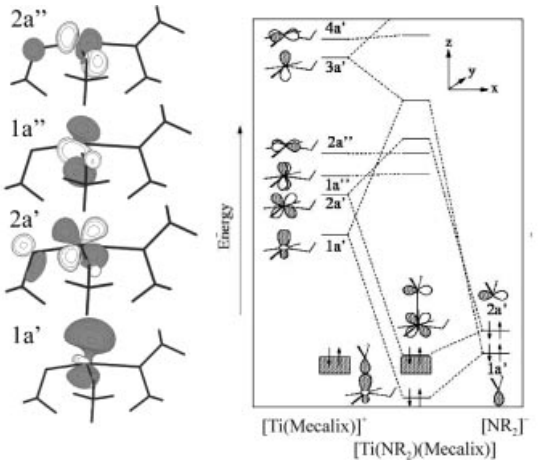

Figure 10. Schematic FMO diagram of the interaction of an amido ligand $[NMe_2]^-$ with the calixarene metal fragment $[Ti(Mecalix)]^+$ (right) and orbital plots of the relevant metal fragment orbitals of the simplified model $[Ti(OMe)_3(OMe_2)]^+$ (left)

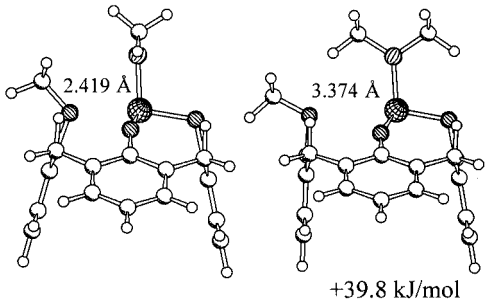

Figure 11. Geometry-optimized isomers of $[Ti(NMe_2)(Mecalix^H)]$ in which the amido ligand is oriented parallel (right) and perpendicular (left) to the Ti−O(1) vector

bital in energy, 1a′, is mainly d_z^2 in character and can be involved in Ti−L σ bonding. The 2a′ orbitals, which are mainly d_{xz}, and 1a′′, which has predominant contributions from Ti d_{yz}, are responsible for π interactions with the ligand. Dependent on the orientation of the amide ligand, 2a′ or 1a′′ are involved in Ti−N bonding, as shown schematically for the experimentally verified orientation of the amido ligand in the FMO diagram. However, a detailed analysis of the possible interactions of the nitrogen p orbital with either 2a′ or 1a′′ reveals only minor differences. This might be supported by the calculations using the simpler model and an NH_2 amido ligand. The experimentally observed geometry in this case is only 6.9 kJ/mol lower in energy than the model complex in which the NH_2 group is aligned along the Ti−O(1) vector. For the detailed models $[Ti(NMe_2)(Mecalix^H)]$ these two orientations optimize with a much larger difference in energy, as shown in Figure 11. The model that resembles the experimentally observed structure is 26.8 kJ/mol lower in energy than the other isomer, which also indicates that steric factors strongly influence the orientation of the amido ligand. This can be substantiated by a significant elongation calculated for the Ti−O(1) bond of the energetically disfavored molecule from 2.419 Å to 3.374 Å. Models in which the calixarene binds in a *paco* coordination mode are at least 75.4 kJ/mol higher in energy and should be experimentally unavailable by isomerization reactions.

Catalytic Epoxidation of Cyclooctene with TBHP

Titanium-containing synthetic zeolites such as titanium silicalite-1 (TS-1)[25] have received considerable attention in recent years because of their excellent catalytic properties.[26] TS-1 acts as a catalyst in a number of oxygen-transfer reactions utilizing hydrogen peroxide, including the epoxidation of alkenes, the oxidation of alcohols to aldehydes or ketones, the hydroxylation of aromatic compounds, and the oxidation of alkanes to alcohol/ketone mixtures. The application of these remarkable catalytic properties is limited by the pore size of the zeolite used, which was the basic motivation for research on titanium-silica mixed oxides[27] and amorphous forms of titania supported on silica.[28] These investigations led to the synthesis of zeolites with large[29] and "ultralarge"[30] pore sizes, in which titanium atoms can be located.

To gain a better understanding of the factors that determine the unique catalytic properties of these materials, special care was taken to clarify the nature of the catalytically active species.[31,32] An isolated tetrahedrally coordinated titanium complex was initially assumed to be the active species,[25,31] although further studies indicated the involvement of tripodally coordinated titanium sites. According to DFT calculations published by Rösch et al.,[33] both the reaction energy and the activation energy for the transition-metal-catalyzed epoxidation of ethene are identical, or more favorable, for the model complexes $[(HO)_3Ti(OOR)]$, $[(HO)_3Ti(OOR)(L)]$ or $[(HO)_3Ti(OOR)(L)_2]$ than models for the active species of methyltrioxorhenium (MTO)[34] or the Mimoun catalyst.[35] According to these calculations, titanium catalysts in which the $[(HO)_3Ti(OOR)]$ unit is stabilized by a further neutral ligand L (e.g. NH_3) are most favorable for epoxidation reactions using alkyl hydroperoxides.

One approach to model oxo surfaces that bind metal atoms on a molecular level is to employ ligands with a preorganized set of oxygen donor atoms in a quasiplanar arrangement, as provided, for example, by calixarenes. The titanium-containing calix[4]arene compounds [TiX(Mecalix)] exactly meet the requirements proposed by Rösch and co-workers.[33] The metal atom is threefold-coordinated by phenolate ligands and stabilized by an additional ether moiety. A fifth coordination site, occupied by a ligand X, may be used for the coordination of alkyl peroxides. Calix[4]arene complexes of the type [TiX(Rcalix)] (L = Cl, OR′, NR'_2) therefore might be able to transform the catalytic properties of titanasilicates to homogeneous catalytic systems.

We chose the titanium-catalyzed epoxidation of cyclooctene as a model reaction to test the catalytic properties of our calix[4]arene-stabilized titanium(IV) complexes in epoxidation reactions of olefins with TBHP. In a first experi-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ment, the complexes were applied to a reaction using 5 mol % of the pre-catalyst and equimolar amounts of TBHP (see Figure 12).

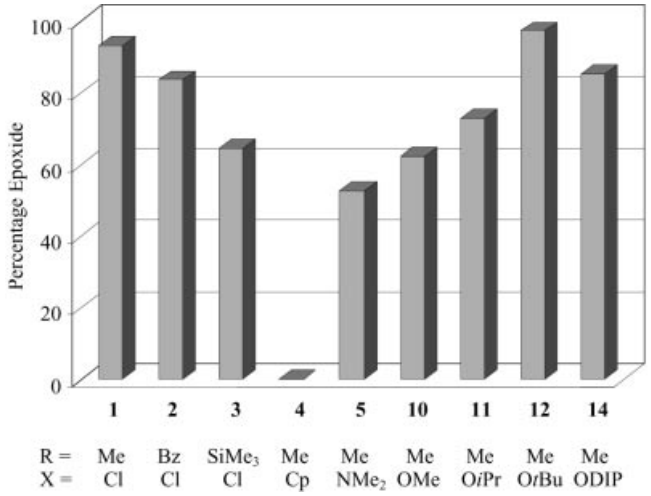

Figure 12. Conversion rate depending on the catalyst for the catalytic epoxidation of cyclooctene using 5 mol % pre-catalyst after a reaction time of 4 h; the formation of other oxidation products of cyclooctene were not observed

Whereas the Cp complex **4** is not an active catalyst, all other nine pre-catalysts tested show catalytic behavior. The best conversion rates were obtained for the complexes [TiCl(Mecalix)] (**1**; 93% conversion) and [Ti(O*t*Bu)(Mecalix)] (**12**; 97%), while the activity of the compounds [TiCl{($SiMe_3$)calix}] (**3**; 65%) and [Ti(NMe_2)(Mecalix)] (**5**; 53%) is significantly lower. The reason for the low catalytic activity of complex **3** is presumably due to silyl ether cleavage, which leads to the formation of catalytically ineffective calix[4]arene titanium complexes of higher nuclearity. Compound **11** is almost as active as **12** when it is used in its isolated form as a precatalyst. For the runs shown in Figure 12, **11** was generated in situ starting from [Ti(O*i*Pr)$_4$] and H_3Mecalix. The lower activity in this case reflects the autoretarding mechanism observed for the catalytic process (see below). Complex **5** also reveals an unexpectedly low catalytic activity compared to the other Mecalix complexes. In this case the formation of the catalytically active peroxide complex is suppressed by oxidation of the ligand and formation of a catalytically ineffective dimethylhydroxylaminato complex [Ti($ONMe_2$)(Mecalix)] (**16**).

Complex **16** was prepared independently from the reaction of the amide complex **5** and 1.1 equiv. of TBHP. The ^{1}H and ^{13}C{^{1}H} NMR spectra of **16** reveal local C_s symmetry of the calix[4]arene ligand. Compared with the amido complex **5**, the signals of the *N*-methyl protons are significantly shifted at δ = 2.92 ppm (δ = 3.59 ppm in **5**). The mass spectrum of **16** shows the molecular ion peak at *m*/*z* = 767 as the base peak of the spectrum.

According to kinetic measurements of the epoxidation reaction using [Ti(O*t*Bu)(Mecalix)] (**12**) as a catalyst, the process is neither of first nor of second order, in contrast to the findings of Abbenhuis and co-workers for the epoxidation of cyclooctene with TBHP using [{(*c*-$C_6H_{11}Si)_7O_{12}$}Ti(η^5-C_5H_5)].[36] For the calix[4]arene system the kinetics reveal an autoretarding mechanism. This autoretarding effect of the co-product *t*BuOH has been observed previously in a variety of homogeneous and heterogeneous titanium and vanadium catalysts.[37]

In the reaction mixtures of precatalyst, peroxide and substrate, we detected a new complex by NMR spectroscopy, which might be the catalytically active species [Ti(OO*t*Bu)(Mecalix)]. The resonances observed in the ^{1}H NMR spectra are four doublets for the methylene protons of the calix[4]arene ligand at δ = 4.43 and 3.37 ppm with a coupling constant of 13.7 Hz and at δ = 4.38 and 3.35 ppm with a coupling constant of 12.8 Hz, as well as a signal for the methoxy group at δ = 3.73 ppm. The resonances in the range of the *t*Bu groups could not be assigned unambiguously because this region also contains various other signals under the conditions of the catalysis. However, the calixarene signals do not belong to other possible species such as [Ti(O*t*Bu)(Mecalix)] or [{(Mecalix)Ti}$_2$O] or the Mecalix ligand. We have been unable so far to isolate this compound, but are currently exploring calixarene−titanium-catalyzed epoxidation and oxidation reactions further.

Conclusions

The complexes [TiCl(Rcalix)] **1**−**3** are easily accessible starting materials for studying the chemistry of calix[4]arene monoalkyl or silyl ether titanium complexes. For methyl ether stabilized calix[4]arene−titanium species, the dimethylamido complex **5** proved to be a convenient entry point. The results reported above show that the trianion [Mecalix]$^{3-}$ is a suitable ancillary ligand to stabilize titanium(IV) chloride, cyclopentadienyl amide, alkoxide, phenolate and thiolate functionalities. In all the complexes reported here the calix[4]arene ligand adopts an elliptically distorted cone conformation in which the anisole oxygen−titanium distance Ti−O(1) varies between 2.342 Å and 2.438 Å, with the exception of the Cp complex, for which a distance of almost 3.50 Å was observed. MP2 calculations reveal that the anisole oxygen−titanium bond is weak, particularly in the region between 2.30 Å and 2.80 Å, where the potential energy surface is very shallow. Thus, the Mecalix ligand system might be described as a tris(phenolate) ligand with a hemilabile anisole group. Despite the labile anisole oxygen−titanium bond, isomerization reactions of the calix[4]arene ligand to a *paco* coordination mode are not observed, and MP2 calculations reveal a considerable thermodynamic preference for the cone isomers. Most of the compounds are active catalysts in epoxidation reactions of cyclooctene using TBHP as an oxidant, the best results being observed for the complexes [Ti(O*t*Bu)(Mecalix)], [Ti(O*i*Pr)(Mecalix)], and [TiCl (Mecalix)].

Experimental Section

General Remarks: All air/moisture-sensitive manipulations were performed using standard Schlenk-line (N_2) and dry-box (Ar) techniques. Solvents were pre-dried and refluxed in the presence of sodium, potassium or sodium/potassium alloy (1:3, w/w) (benzene, toluene, pentane, hexane, diethyl ether, THF), or P_2O_5 (acetonitrile, dichloromethane) under N_2. Solvents were distilled at atmospheric pressure prior to use. Deuterated solvents were dried with sodium (C_6D_6) or calcium hydride ($CDCl_3$, CD_2Cl_2) under N_2. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded with a Bruker AC 250 spectrometer at 298 K. Spectra are referenced internally to residual protonated-solvent resonances (^1H: $CDCl_3$: δ = 7.24 ppm; C_6D_6: δ = 7.15 ppm) or solvent resonances (^{13}C: $CDCl_3$: δ = 77.0 ppm; C_6D_6: δ = 128.0 ppm) and are reported relative to tetramethylsilane (δ = 0.00 ppm). Chemical shifts are quoted in δ (ppm) and coupling constants in Hz. Standard DEPT-135 experiments were recorded to distinguish CH_3 and CH carbon atoms from C and CH_2 carbon atoms in the ^{13}C NMR spectra. IR spectra were recorded with a Bruker IFS28 spectrometer as KBr pellets. All data are quoted in wavenumbers [cm^{-1}]. Mass spectra were recorded with a Finnigan MAT 900 XLT. All data are quoted as their mass/charge (*m*/*z*) ratios. Elemental analyses were carried out by the analytical laboratory of the Institute of Inorganic Chemistry of the University Karlsruhe (TH). The complexes isolated from toluene are usually solvate adducts, in which a toluene molecule is hosted inside the calix[4]arene cavity. The compound/solvent ratio was determined by integration of the appropriate peaks in the ^1H NMR spectra. This endohedrally hosted solvent molecule is usually displaced in the solvation process with the deuterated solvent (C_6D_6, $CDCl_3$) and is subtracted in the NMR spectra reported here. The mass spectra of these solvates show the peaks expected for the unsolvated species. CHN analyses were either performed on the solvates or on the unsolvated complexes as stated below. To obtain compounds free from additional solvent molecules, the complexes have to be dried vigorously or have to be recrystallized or suspended in nonpolar solvents such as pentane and hexane, filtered and dried in vacuo. No satisfactory elemental analysis was obtained for complexes **2** and **3** due to their ease of decomposition, or for **6** due to the compound's sensitivity. The composition of these complexes was verified by their mass spectra. H_4calix,[37] H_2Me_2calix,[12] H_2Bz_2calix[12] and $H_2(SiMe_3)_2$calix[38] were synthesized according to literature procedures. The synthesis of [TiCl(Mecalix)] has been reported previously,[13] but here we briefly report a modified version of this method for completeness.

[TiCl(Mecalix)]·C_7H_8 (1·C_7H_8): Toluene (180 mL) was added to a mixture of H_2Me_2calix (12.9 g, 19.1 mmol) and [$TiCl_4(THF)_2$] (6.37 g, 19.1 mmol) at room temperature. The resulting red suspension was refluxed for 48 h and the solution was concentrated to approximately 50 mL after cooling to room temperature. Hexane (130 mL) was added and, after stirring for 30 min, product **1**·C_7H_8 was isolated by filtration as a red solid, which was washed with two 15-mL portions of hexane and dried in vacuo (13.6 g, 81%). Crystals suitable for X-ray diffraction were grown from hot saturated toluene solutions of **1** $C_{45}H_{55}ClO_4Ti$·C_7H_8 (835.4): calcd. C 74.76, H 7.60; found C 74.92, H 7.60. MS: *m*/*z* (%) = 742 (100) [M^+], 727 (57) [M − CH_3]. IR: $\tilde{\nu}$ = 3055 m, 3024 m, 2962 vs br, 1603 m br, 1479 vs br, 1415 m, 1393 m, 1362 s, 1303 s br, 1254 vs, 1205 vs br, 1122 m, 1111 s, 1093 m, 1003 s br, 943 vs, 923 m, 876 vs, 831 s, 814 w, 797 vs, 763 m, 729 s, 695 w, 677 w, 647 w, 603 m, 585 vs, 568 m, 461 s, 446 s, 431 s, 401 m, 297 w cm^{-1}. ^1H NMR (C_6D_6): δ = 0.68 [s, 9 H, C(CH_3)$_3$], 0.77 [s, 9 H, C(CH_3)$_3$], 1.37 [s, 18 H, C(CH_3)$_3$], 3.13 (d, $^2J_{H,H}$ = 12.5 Hz, 2 H, CH_2), 3.22 (d, $^2J_{H,H}$ = 13.0 Hz, 2 H, CH_2), 3.84 (s, 3 H, OCH_3), 4.31 (d, $^2J_{H,H}$ = 12.5 Hz, 2 H, CH_2), 4.97 (d, $^2J_{H,H}$ = 13.0 Hz, 2 H, CH_2), 6.78 (s, 2 H, Aryl-H_m), 6.82 (s, 2 H, Aryl-H_m), 7.14 (s, 4 H, Aryl-H_m) ppm. ^{13}C NMR (C_6D_6): δ = 30.56, 30.88, 31.86 [C(*C*H$_3$)$_3$], 33.49, 33.65 (*C*H$_2$), 33.88, 34.30, 34.50 [*C*(CH$_3$)$_3$], 65.67 (O*C*H$_3$), 123.94, 125.29, 125.65, 127.22 (Aryl-C_m), 129.22, 131.47, 132.10, 132.23 (Aryl-C_o), 146.26, 146.38, 148.39 (Aryl-C_p), 151.82, 160.48, 162.97 (Aryl-C_i) ppm.

[TiCl(Bzcalix)]·C_7H_8·(2·C_7H_8): Toluene (20 mL) was added to a mixture of H_2Bz_2calix (1.00 g, 1.21 mmol) and [$TiCl_4(THF)_2$] (402 mg, 1.21 mmol). The reaction mixture immediately turned dark red and was stirred at 80 °C for 1 h. All volatiles were removed under reduced pressure and the dark red residue was suspended in 5 mL of hexane. The product was filtered off and [TiCl(Bzcalix)]·C_7H_8 (**2**·C_7H_8) was dried in vacuo (876 mg, 77%). MS: *m*/*z* (%) = 819 (26) [M^+], 818 (42) [M − H], 762 (12) [M − C(CH$_3$)$_3$] 728 (3) [M − Bz], 692 (8) [M − Bz − Cl]. ^1H NMR (C_6D_6): δ = 0.68 [s, 9 H, C(CH_3)$_3$], 0.76 [s, 9 H, C(CH_3)$_3$], 1.35 [s, 18 H, C(CH_3)$_3$], 2.92 (d, $^2J_{H,H}$ = 12.6 Hz, 2 H, CH_2), 3.22 (d, $^2J_{H,H}$ = 12.9 Hz, 2 H, CH_2), 4.08 (d, $^2J_{H,H}$ = 12.6 Hz, 2 H, CH_2), 4.96 (d, $^2J_{H,H}$ = 12.9 Hz, 2 H, CH_2), 5.38 (s, 2 H, Bz-CH_2), 6.77 (s, 2 H, Aryl-H_m), 6.81 (s, 2 H, Aryl-H_m), 7.11−7.05 (m, 7 H, Aryl-H_m), 7.37 (m, 2 H, Bz-Aryl-*H*) ppm. ^{13}C NMR (C_6D_6): δ = 30.57 [C(*C*H$_3$)$_3$], 30.88 [C(*C*H$_3$)$_3$], 31.84 [C(*C*H$_3$)$_3$], 33.60 (*C*H$_2$), 33.88 (*C*H$_2$), 34.46 [*C*(CH$_3$)$_3$], 81.13 (Bz-*C*H$_2$), 123.87, 125.18, 125.59, 127.06 (s, Aryl-C_m), 128.66, 129.21, 131.17 (Bz-*C*), 128.73, 131.86, 132.09, 132.87 (Aryl-C_o), 135.74 (Bz-C_i) 146.26, 146.46, 148.26 (Aryl-C_p), 149.85, 160.46, 163.04 (Aryl-C_i) ppm.

[TiCl{(Me$_3$Si)calix}]·3C_7H_8 (3·3C_7H_8): Toluene (15 mL) was added to a mixture of $H_2(SiMe_3)_2$calix (1.00 g, 1.26 mmol) and [$TiCl_4(THF)_2$] (421 mg, 1.26 mmol). The reaction mixture was stirred at room temperature for 2 h and its color changed from yellow to red. The red, cloudy solution was filtered through a pad of Celite and the filtrate concentrated to dryness to afford [TiCl{(Me$_3$Si)calix}]·3C_7H_8 as a red powder (990 mg, 72.9%). MS: *m*/*z* (%) = 801 (100) [M^+], 786 (23) [M − CH_3], 693 (6) [M − CH_3 − Si(CH$_3$)$_3$]. ^1H NMR (C_6D_6): δ = 0.49 [s, 9 H, Si(CH_3)$_3$], 0.70 [s, 9 H, C(CH_3)$_3$], 0.80 [s, 9 H, C(CH_3)$_3$], 1.40 [s, 18 H, C(CH_3)$_3$], 3.10 (d, $^2J_{H,H}$ = 12.4 Hz, 2 H, CH_2), 3.31 (d, $^2J_{H,H}$ = 13.0 Hz, 2 H, CH_2), 4.56 (d, $^2J_{H,H}$ = 12.4 Hz, 2 H, CH_2), 4.92 (d, $^2J_{H,H}$ = 13.0 Hz, 2 H, CH_2), 6.78 (s, 4 H, Aryl-H_m), 7.17 (s, 4 H, Aryl-H_m) ppm. ^{13}C NMR (C_6D_6): δ = 1.78 [Si(*C*H$_3$)$_3$], 30.59 [C(*C*H$_3$)$_3$], 30.91 [C(*C*H$_3$)$_3$], 31.84 [C(*C*H$_3$)$_3$], 33.51 (*C*H$_2$), 33.73 [*C*(CH$_3$)$_3$], 33.79 (*C*H$_2$), 34.48 [*C*(CH$_3$)$_3$], 123.94, 125.41, 126.48 (Aryl-C_m), 131.12, 131.77, 132.34 (Aryl-C_o), 146.12, 146.31, 146.77 (Aryl-C_p), 148.03, 159.80, 162.82 (Aryl-C_i) ppm.

[Ti(η^5-C_5H_5)(Mecalix)]·C_7H_8 (4·C_7H_8): A mixture of **1**·C_7H_8 (500 mg, 0.60 mmol) and [NaCp(THF)] (96.0 mg, 0.60 mmol) was suspended in 10 mL of toluene. The resulting suspension became orange after a few minutes and was stirred at room temperature for 12 h, filtered through a pad of Celite and the filtrate was concentrated to dryness. The orange product [Ti(η^5-C_5H_5)(Mecalix)]·C_7H_8 (**4**·C_7H_8) was dried in vacuo (342 mg, 66%). Crystals suitable for X-ray diffraction were grown from a saturated toluene solution at −30 °C. $C_{50}H_{60}O_4Ti$·C_7H_8 (865.0): calcd. C 79.14, H 7.92; found C 79.27, H 7.77. MS: *m*/*z* (%) = 772 (100) [M^+] 757 (22) [M − CH_3], 707 (14) [M − Cp]. [Ti(NMe$_2$)(Mecalix)]·(5): A solution of **1**·C_7H_8 (2.00 g, 2.40 mmol) and LiNMe$_2$ (135 mg, 1.15 equiv., 2.64 mmol) in toluene (50 mL) was stirred for 12 h. During this time the red solution became orange and cloudy. It was then filtered through a pad of Celite and all volatiles of the filtrate were removed in vacuo. The residue was suspended in hexane (15 mL), and yellow [Ti(NMe$_2$)(Mecalix)] (**5**) was collected and dried in vacuo. A second fraction was obtained after concentrating the mother liquor to approximately 5 mL and cooling to −30 °C for 5 d (combined yield: 1.71 g, 95%). Crystals of **5** were grown from a saturated solution of **5** in THF after prolonged storage at room temperature. $C_{47}H_{61}NO_4Ti$ (751.9): calcd. C 75.08, H 8.18, N 1.24; found C 74.79, H 8.26, N 1.53. Epoxidation Reactions: In an NMR tube 0.029 mmol (based on monomeric units) of the precatalyst was layered with C_6D_6/TMS (0.30 mL) and frozen in liquid nitrogen. Cyclooctene (74.3 μL, 0.573 mmol) and a 5.5 M solution of *tert*-butyl hydroperoxide in decane (104.6 μL, 0.573 mmol) were then added. To determine the kinetics the samples were thawed and mixed shortly before they were placed into the NMR spectrometer. The ratio between substrate, product and catalyst was determined by integration of the resonances of the olefinic protons of the cyclooctene, the protons of the epoxide ring and the protons of the methoxy groups of the calixarene complexes relative to TMS. The entries in Figure 12 are averages of three runs.

Computational Details: All density functional and MP2 calculations reported were carried out by using the TURBOMOLE set of programs, developed by Ahlrichs and co-workers, within the RI-J approximation.[21,22] Standard SV(P) basis sets and auxiliary basis sets as implemented in the TURBOMOL package were used for all atoms.[22,23] The acronym SV(P) (split valence plus polarization) refers to TURBOMOLE split-valence basis sets, augmented by a shell of polarization functions. DFT calculations were performed including gradient corrections, Becke's nonlocal correction for exchange and Perdew's nonlocal correction for correlation to the local density approximation part of the density functional.[24]

Crystal Structure Determination of [TiCl(Mecalix)]·1.5C$_7$H$_8$, [Ti(η^5-C$_5$H$_5$)(Mecalix)]·3C$_7$H$_8$, [Ti(NMe$_2$)(Mecalix)]·[{Ti(Mecalix)}$_2$-(μ-O)]·5C$_4$H$_8$O, 2·[Ti(NPh$_2$)(Mecalix)]·8C$_4$H$_8$O·0.5C$_6$H$_6$, [{Ti(OMe)(Mecalix)}$_2$]·6C$_7$H$_8$, [Ti(OC$_6$H$_3$-2,6-*i*Pr$_2$)(Mecalix)]·C$_6$H$_3$*i*Pr$_2$OH, and [Ti(S*t*Bu)(Mecalix)]·C$_6$H$_{14}$: Crystal data collection and processing parameters are given in Tables 1 and 2. Crystals were immersed in a film of perfluoropolyether oil on a glass fiber and transferred to a Stoe-STADI 4 (Mo-K_α radiation for **1**·1.5C_7H_8) or Stoe-IPDS diffractometer (Ag-K_α radiation for the rest) equipped with an FTS AirJet low-temperature device. Data were collected at 203 K. The IPDS images were processed with the Stoe IPDS software package and equivalent reflections were merged. Corrections for Lorentz polarization effects and absorption were performed where necessary and the structures were solved by direct methods. Subsequent difference-Fourier syntheses revealed the positions of all other non-hydrogen atoms, and hydrogen atoms were included in calculated positions. Extinction corrections were applied as required. Crystallographic calculations were performed using SHELXS-97 and SHELXL-97.[39] For compound **4** the methyl carbon atoms of two of the calixarene *tert*-butyl groups [C(17) to C(19) and C(47) to C(49)] were disordered over two sites. These carbon atoms were refined in an isotropic approximation with occupancy factors of 70%/30% and 50%/50%, respectively. For **5·9**·5C_4H_8O the following carbon atoms of the calixarene *tert*-butyl groups were disordered over two sites and refined in an isotropic approximation with occupancy factors of 50% each: C(17), C(18),

C(19), C(29), C(37), C(38), C(39), C(48), C(49), C(59), C(89). The anisole methyl group C(95) of the calixarene ligand of **9** was disordered in this structure over two sites at the oxygen atoms O(6) and O(8) and refined isotropically using equal occupancy. Furthermore, two methylene groups of one of the solvent molecules [C(109) and C(111)] were disordered and isotropically refined with occupancy factors of 50% each. For **8**·8C_4H_8O·0.5C_6H_6 the following carbon atoms of calixarene *tert*-butyl groups or THF molecules were disordered over two sites and refined in an isotropic approximation with occupancy factors of 50% each: C(19), C(49), C(122), C(129), C(130), C(131). The methylene carbon atoms C(132), C(133), C134), C(135), as well as C(137), C(138), C(144), C(145), C(147) of THF molecules were disordered over two sites. These carbon atoms were refined in an isotropic approximation with occupancy factors of 60%/40% and 70%/30%, respectively. The carbon atoms C(60) and C(61) of one of the isopropyl groups in **14**·C_6H_3 *i*Pr_2OH were disordered over two sites and refined in an isotropic approximation with occupancy factors of 45%/55%. For **15**·C_6H_{14} two of the *tert*-butyl groups of the calixarene ligand [C(27) to C(29) and C(37) to C(39)] and of the thiolate group [C(7) to C(9)] were disordered over two sites and refined in an isotropic approximation with occupancy factors of 65%/35%, 60%/40% and 50%/50%, respectively. CCDC-233967 to CCDC-233974 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

[5] Assuming no additional metal centers, the calix[4]arene system retains its cone-like appearance in square-pyramidal complexes of the type [ML(Calix)], or in octahedral complexes [ML_2(Calix)], if both L ligands are oriented *trans* to each other. In mononuclear octahedral complexes with *cis*-oriented L ligands it has been found that the calix[4]arene usually binds in an elliptical cone conformation, in which the calix[4]arene oxygen atoms adopt *cis* and *trans* sites in octahedral [$CaxO_4ML_2$] complexes.[4] Additional metal centers in the complex may further influence the coordination behavior of calix[4]arenes, see for example: [5a] V. [9] [9a] U. Radius, *Inorg. Chem.* **2001**, *40*, 6637. [9b] As pointed out by Harrowfield and co-workers, the classification based simply on four idealized conformers — the cone, partial cone, 1,2-alternate and 1,3-alternate species — has been eroded due to the number of factors which may influence the adoption of any conformation: J. M. Harrowfield, M. Mocerino, B. W. Skelton, C. R. Whitaker, A. H. White, *Aust. J. Chem.* **1994**, *47*, 1185. We use the term "paco" conformation here to emphasize the difference in calix[4]arene bonding to the usually observed (cone or elliptically distorted cone) conformations in transition metal complexes.

Synthesis, Structural Characterization and Properties of Copper(II) and Zinc(II) Coordination Polymers with a New Bridging Chelating Ligand

Guo-Ping Yong,[a] Zhi-Yong Wang,*[a] and Yong Cui[a]

Keywords: Coordination polymers / Copper / N,O ligands / Zinc

Two new coordination polymers $[Cu_3(cpida)_2(H_2O)_4]_n \cdot 4nH_2O$ (**1**) and $[Zn(Hcpida)]_n \cdot nH_2O$ (**2**) have been synthesized with a new bridging chelating ligand *N*-(4-carboxyphenyl)iminodiacetic acid (H_3cpida). X-ray diffraction analysis reveals that complex **1** consists of 1D parallelogram-shaped molecular-box chains constructed from unusual linear trinuclear Cu^{II} secondary building units (SBUs), which further extend into 2D layers by perfect parallel AA stacking. Complex **2** adopts a 2D framework comprised of tetrahedral Zn^{II} centres isolated from each other by the bridging bidentate carboxylate groups of the $Hcpida^{2-}$ ligands. Compound **2** possesses alternate open and closed channels along the *a* direction. The dehydation and rehydration experiments showed that compound **2** undergoes a reversible inclusion process to some extent. However, the removal of guest water molecules from **1** results in the collapse of the polymeric networks owing to the loss of the coordinated water molecules. Compound **2** also shows strong photoluminescence and may be a good candidate for a photoactive or porous material.

Introduction

Metal-organic coordination polymers built up from metallic clusters and multi-carboxylate building blocks have been widely studied in recent years due to their interesting topologies[1] and potential applications as functional materials.[2] The most commonly used strategy to obtain coordination polymers is to employ appropriate bridging ligands that are capable of binding to several metal centres through direct bond formation. Multi-carboxylate building blocks with special configurations can yield desired networks in metal-organic coordination polymers[3−5] because they can act as either bridging or chelating ligands. A chelating ligand provides stronger connectivity and enhances rigidity around the coordination centre, which results in higher stability of the resulting framework materials.[6] Thus, one of the most necessary tasks of current research is the synthesis of new bridging, chelating multi-carboxylate ligands because they have a pre-programmed tendency to form supramolecular motifs of defined geometry.[7−9] We are currently focusing our attentions on the design and synthesis of new bridging, chelating ligands and have recently obtained a new bridging, chelating multi-carboxylate ligand *N*-(4-carboxyphenyl)iminodiacetic acid (H_3cpida), which has two important features: (a) unlike rigid groups such as benzenetricarboxylate, the iminodiacetate group is more flexible and can adopt different coordination modes; (b) the introduced aromatic rings can offer additional π−π interactions which may stabilize the frameworks.[10]

We describe here the synthesis, structural characterization and properties of two new coordination polymers $[Cu_3(cpida)_2(H_2O)_4]_n \cdot 4nH_2O$ (**1**) and $[Zn(Hcpida)]_n \cdot nH_2O$ (**2**) obtained from the H_3cpida building block. Compound **1** is a rare 1D molecular-box chain constructed from unusual linear trinuclear Cu^{II} SBUs. Compound **2** is a new 2D framework constituted by tetrahedrally coordinated Zn^{II} with strong fluorescent emission.

Results and Discussion

Compound **1** was prepared by heating a mixture of basic copper carbonate and H_3cpida in water under steam bath conditions, while compound **2** was synthesized by treating $Zn(NO_3)_2 \cdot 6H_2O$ with H_3cpida in $KOH/CH_3OH/H_2O$ under hydrothermal conditions (Scheme 1Scheme 1). The presence of the characteristic band at 1703 cm^{-1} for compound **2** indicates that the deprotonation of H_3cpida ligand is incomplete, which is consistent with the crystal structure of **2**.

Description of Crystal Structures

$[Cu_3(cpida)_2(H_2O)_4]_n \cdot 4nH_2O$ (1)

The polymeric structure of **1** was confirmed by an X-ray single-crystal structure determination. The trinuclear entity of compound **1** with the atomic labelling scheme is shown

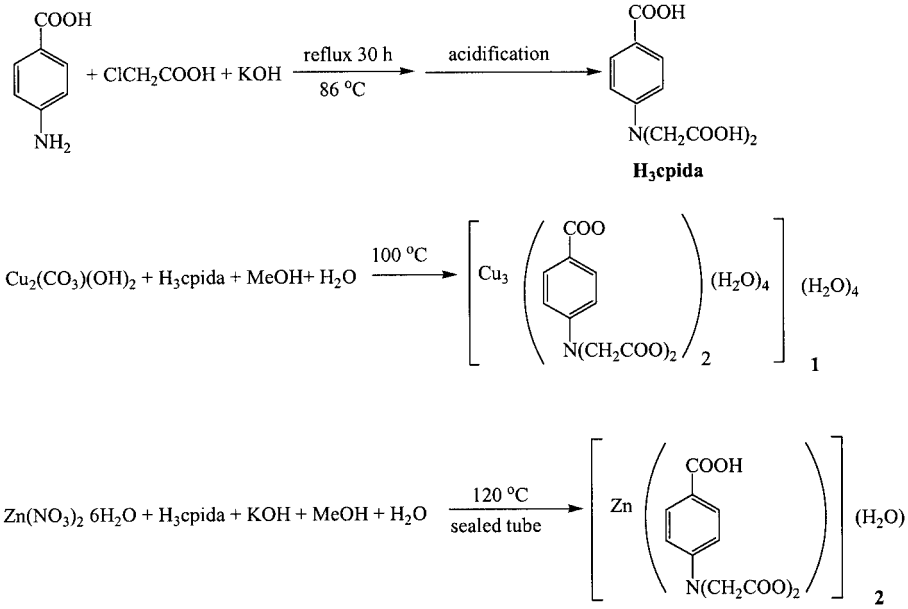

Scheme 1. Preparation of H_3cpida and complexes **1** and **2**

in Figure 1a. The two terminal Cu^{II} atoms (Cu1 and Cu1a) adopt a Jahn−Teller-distorted octahedral coordination environment, resulting in a longer axial Cu1−O6 bond [2.344(2) Å] from the coordinated water molecule and Cu1−N1 bond [2.496(2) Å] from the cpida^{3-} ligand. The equatorial plane is defined by four oxygen atoms, which come from the bridging monodentate (O1), the monodentate (O3) and the bridging bidentate (O7a) carboxylate groups of two deprotonated cpida^{3-} ligands, and the coordinated water molecule (O5). The bond lengths Cu1−O are in the range 1.947(2)−1.978(2) Å (Table 1). The central Cu2 atom presents a Jahn−Teller octahedral environment, resulting in very long axial Cu2−O6 bonds [2.608(2) Å] to the coordinated water molecule. The equatorial plane geometry is formed from the O1, O1a, O8 and O8a atoms of the bridging monodentate and bidentate carboxylate groups of four cpida^{3-} ligands [Cu2−O = 1.916(2) and 1.958 (2) Å].

The adjacent Cu^{II} centres are bridged by one oxygen atom of the monodentate carboxylate group and two oxygen atoms of the bidentate carboxylate groups of two cpida^{3-} ligands, leading to a linear trinuclear Cu^{II} SBU (Figure 1a). The three Cu^{II} atoms are arranged in a strictly linear fashion (Cu1−Cu2−Cu1a = 180°) with Cu2 at the inversion centre; the distance between Cu1 and Cu2 is 3.232 Å. Complex **1** is a rare example of a polynuclear metal cluster bridged by carboxylate groups from only one kind of ligand (cpida^{3-}). To the best of our knowledge, only a limited number of linear trinuclear Cu^{II} compounds have been reported,[11−13] and few metal-organic coordination frameworks containing a linear trinuclear Cu^{II} unit have been documented.[14] It is worth noting that **1** is the first linear trinuclear Cu^{II} compound in which the three Cu^{II} centres are linked by μ-carboxylato groups of only one type of ligand (cpida^{3-}); other reported examples[11−14] are mixed-

bridged compounds containing μ-hydroxo, μ-carboxylato, μ-acetato, etc.

Compound **1** possesses a 1D chain structure constructed from linear trinuclear Cu_3 SBUs. Interestingly, four Cu^{II} atoms of two Cu_3 SBUs are linked by two cpida^{3-} spacers in a head-to-tail mode leading to a parallelogram-shaped molecular box, as shown in Figure 1b. In each molecular box there are offset π−π stacking interactions between two cpida^{3-} aromatic rings (centroid···centroid = 4.32 Å). Each

parallelogram-shaped molecular box is then linked together by the bridging bidentate carboxylate groups, which results in the formation of a 1D molecular box coordination polymer. It is notable that the 1D molecular box chains propagate into 2D layers by an AA stacking pattern[15] in the *bc* plane, as shown in Figure 2.

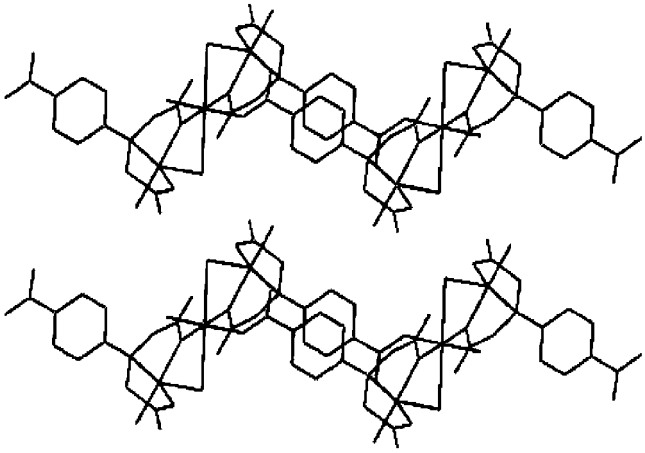

Figure 2. A view of the 2D layer of **1** down the *a* axis, showing the AA stacking pattern of the 1D molecular box chains

One guest water molecule (O9) forms a hydrogen bond with a coordinated water molecule (O9···O5 = 2.695Å), and another guest water molecule (O10) forms hydrogen bonds with the coordinated water molecule (O10···O5 = 2.576Å) and the noncoordinated carboxylate oxygen atom (O10···O2 = 2.725Å).

[Zn(Hcpida)]$_n$·nH$_2$O (2)

The asymmetric unit of **2** consists of one Zn^{II} atom, one $Hcpida^{2-}$ ligand and one guest water molecule. Each Zn^{II} centre is coordinated by two oxygen atoms (O1A, O4B) from the bridging bidentate carboxylate groups of two $Hcpida^{2-}$ ligands, and two oxygen atoms (O2, O3) from one chelating bidentate $Hcpida^{2-}$ ligand, leading to a distorted tetrahedral coordination geometry (Figure 3). The Zn−O bond lengths vary from 1.958(5) Å to 2.002(5) Å. The bond angles around the Zn^{II} centre range from 90.8(2)° to 143.5(2)°. There is an unusual structural feature around the Zn^{II} centre: the Zn^{II} centre has four nearest-neighboring oxygen atoms [d(Zn−O) < 2.002 Å] in an approximately tetrahedral arrangement, although the O1A−Zn1−O3 bond angle [143.5(2)°] is particularly obtuse. There is one nitrogen atom associated with the Zn atom [d(Zn−N) = 2.399 Å], which does not constitute a "bond" in any real sense. This association may be considered as a weak interaction.[16] The geometry at the Zn centre can be visualized as a mono-capped tetrahedron (Figure 3).[17] Because the Zn1−N1 bond (2.399 Å) is much longer than the Zn1−O4 bond (2.002 Å), the ZnO_4N unit should not be described as distorted trigonal-bipyramidal but as mono-capped tetrahedral. On the other hand, the Zn atom is displaced off-center by 0.317 Å, when the associated nitrogen atom is considered. These results support the validity of regarding this geometry as mono-capped tetrahedral.

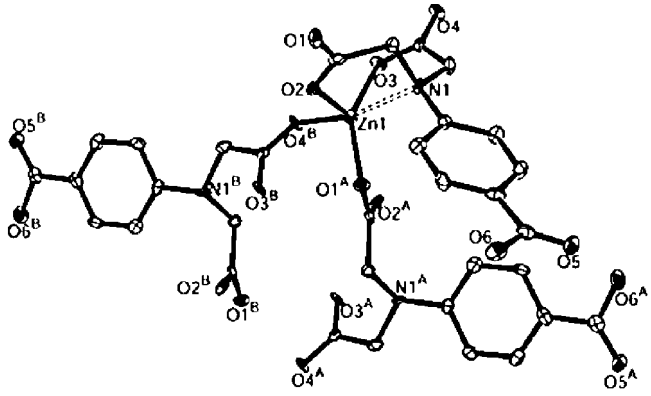

Figure 3. ORTEP diagram of the coordination environment around the Zn^{II} centre in **2**; thermal ellipsoids are drawn at the 50% probability level; all hydrogen atoms are omitted for clarity; symmetry code: A: x, $-y - 1/2$, $z - 1/2$; B: $-x$, $y + 1/2$, $-z + 1/2$

The coordinated H_3cpida ligand has an unchelated carboxylic group. The C−O bond [C11−O6 = 1.344(10) Å] is much longer than C−O [C11−O5 = 1.190(9) Å] in the carboxylic group, so C11−O5 can be assigned as the double bond and C11−O6 as the single bond. This shows that deprotonation of the H_3cpida ligand is incomplete.

The crystal structure of **2** consists of an infinite 2D network. The Zn1 centre is connected to four adjacent Zn centres through the bridging bidentate carboxylate groups of $Hcpida^{2-}$ ligands leading to a $Zn_4(Hcpida)_4$ unit, which further extends into a 2D polymeric network with alternate large and small pseudo-square grid motifs in the *bc* plane

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

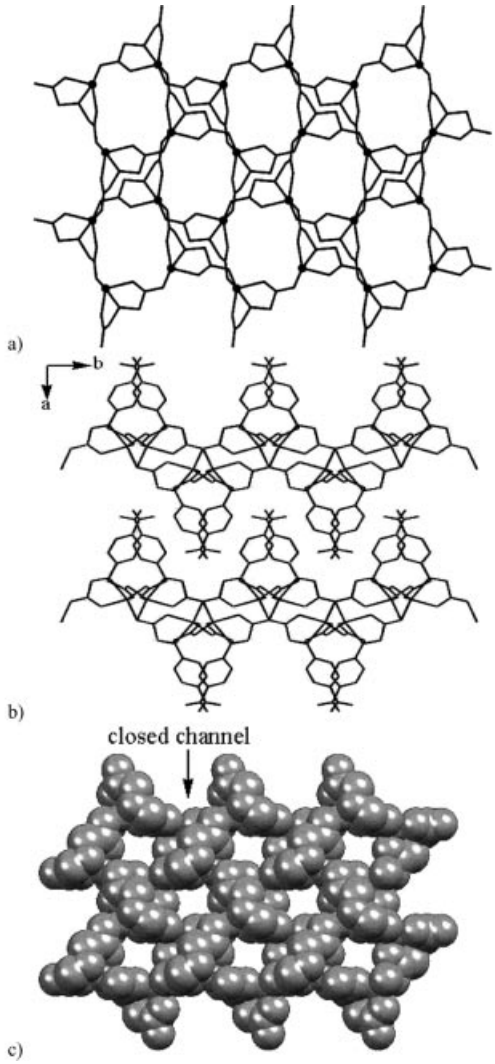

Figure 4. a) The 2D network of **2** as viewed down the *a* axis, showing alternate large and small pseudo-square grids (phenyl rings omitted for clarity); b) a view of the 2D wave-like layer of **2** down the *c* axis, showing the AA stacking pattern between the layers; c) a space-filling diagram showing alternate open and closed channels created perpendicularly to the *bc* plane; the alternate open channels are occupied by the guest water molecules, which have been omitted for clarity

(Figure 4a). In each large pseudo-square grid, the Zn−Zn separations are 4.90 and 5.20 Å, while the Zn−Zn−Zn angles are 80.73° and 99.27°. Each acetate group of the $Hcpida^{2-}$ ligand adopts a bidentate bridging mode to connect two Zn centres. Four Zn centres are connected together by μ_2-acetato groups to form a 2D grid network. However, according to the flexibility of the iminodiacetate groups of the $Hcpida^{2-}$ ligand, compound **2** does not adopt one kind of grid but alternate large and small grid motifs, as shown in Figure 5. The wave-like nature of the 2D layers of **2** can be clearly shown with a view of **2** down the *c* axis (Figure 4b). Interestingly, the 2D layers in **2** adopt an AA stacking pattern in the *ab* plane, and the convex phenylcarboxylic groups of $Hcpida^{2-}$ in one layer sit above or below the small grids of the adjacent layers along the *a* direction (Figure 4b). Thus, compound **2** possesses alternate open (large grids) and closed (small grids) channels that are perpendicular to the *bc* plane and parallel to the *a* axis (Figure 4c). Each alternate open channel is approximately 4.9 × 5.7 Å. The guest water molecules occupy the open channels resulting in the formation of the water columns along the *a* direction.[18] It should be noted that in the crystal packing there are offset π−π stacking interactions between two $Hcpida^{2-}$ aromatic rings (centroid···centroid = 4.10 Å), as shown in Figure 6. The guest water molecule (O7) forms hydrogen bonds with the coordinated carboxylate oxygen atoms (O7···O1 = 2.850 Å; O7···O4 = 2.961 Å) and the noncoordinated carboxylate oxygen atom (O7···O6 = 2.680 Å).

Removal of the Guest Water Molecules: TGA and PXRD Studies

The X-ray single-crystal structures clearly indicate that compound **2** possesses alternate open channels along the *a* axis, and we became intrigued by the possibility of generating a cavity by removing the guest water molecules. The TGA curve of compound **1** exhibits a continuous weight

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

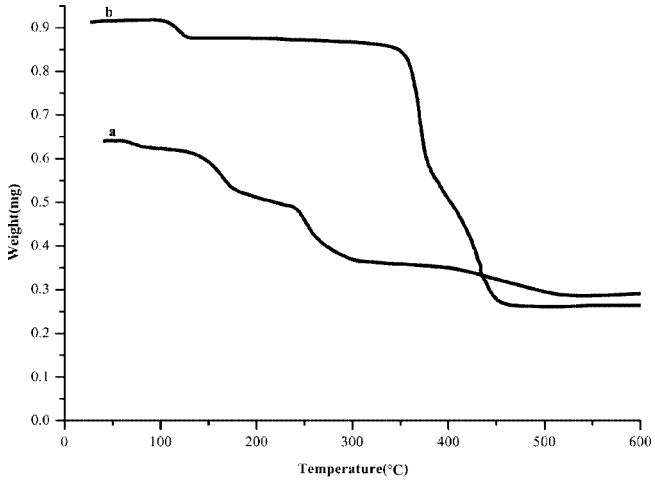

Figure 7. TGA curves for **1** (a) and **2** (b)

loss (curve a in Figure 7): the loss of the guest water molecules is accompanied by the loss of the coordinated water molecules, and the loss of the coordinated water molecules is accompanied by the loss of the ligands. As a result, it is difficult to give exact weight losses as a percentage for each weight-loss step in the TGA curve. The removal of the guest water molecules from **1** results in the collapse of the framework structure (see Supporting Information). The TGA curve of compound **2** exhibits an initial weight loss at an onset temperature of 120 °C (5.43%), corresponding to the removal of the guest water molecule (calcd. 5.38%). The second weight loss occurs between 340 and 480 °C (69.23%) and corresponds to the release of the $Hcpida^{2-}$ ligand (curve b in Figure 7). The remaining weight of 25.34% corresponds to the percentage of ZnO (calcd. 24.32%). Although the hydrogen bonds increase the difficulty of removing the guest water molecule (O7) from **2**,[19] the framework structure of the dehydrated sample is simlar to that of compound **2** in terms of their powder X-ray diffraction (PXRD) patterns (see Supporting Information). The rehydrated sample also exhibits a similar PXRD pattern to compound **2** (Supporting Information). In particular, the existence of the strongest peak at a 2θ value of 6.56° in the three PXRD patterns shows that the layer framework of **2** does not change upon dehydration and rehydration. Therefore, compound **2** not only maintains its 2D layer framework after dehydration but the inclusion process is reversible to some extent. This can be attributed to the absence of coordinated water molecules in compound **2** and the higher decomposition temperature (340 °C) of the $Hcpida^{2-}$ ligand.

Photoluminescence Properties of H_3cpida and 2

The solid-state photoluminescence spectra of H_3cpida and compound **2** at room temperature are depicted in Figure 8; H_3cpida exhibits a broad strong blue-fluorescent emission around 422 nm upon excitation at 332 nm (curve a in Figure 8). Interestingly, in the case of the metal-organic polymer **2**, a blue-shifted photoluminescence with the main emission at 366 nm and with a shoulder at about 480 nm upon excitation at 313 nm is observed (curve b in Figure 8). This emission arises from ligand-to-metal charge transfer (LMCT).[20] TGA indicated that **2** is thermally stable up to 340 °C. Thus, compound **2** may be a good candidate for highly thermally stable and solvent-resistant photoactive material because it is almost insoluble in common polar and nonpolar solvents.[4a] Compound **2** may also have potential as a porous material after removing the guest water molecules.

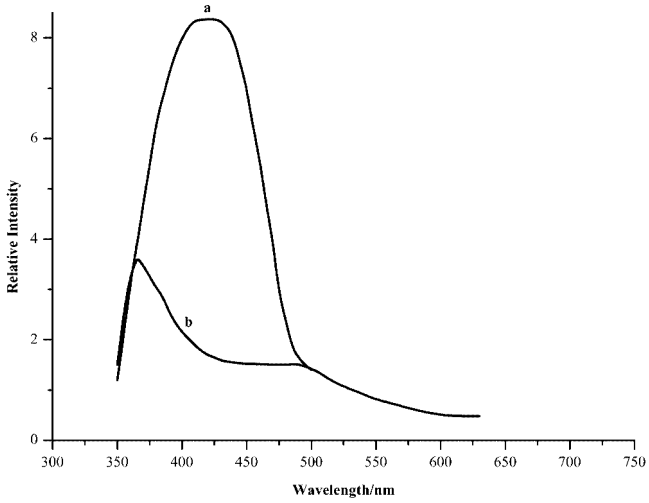

Figure 8. The emission spectra of the H_3cpida ligand (a) and compound **2** (b) in the solid state at room temperature

Conclusions

Two new metal-organic coordination polymers have been synthesised. Compound **1** is a linear trinuclear Cu^{II} compound in which the three Cu^{II} centres are linked only by μ-carboxylato groups of the same ligand ($cpida^{3-}$). A 1D parallelogram-shaped molecular-box chain is constructed from these unusual linear trinuclear Cu^{II} SBUs. Compound **2** possesses alternate open and closed channels and shows strong photoluminescence, thus it may be a good candidate for a photoactive or porous material.

Experimental Section

General Remarks: All commercially available chemicals were of reagent grade and used as received without further purification. Infrared spectra were recorded with a Bruker VECTOR-22 FT-IR spectrophotometer as KBr pellets. ^{1}H NMR spectra were measured with an Avance AV400 NMR spectrometer at room temperature. Powder X-ray diffraction (PXRD) patterns were obtained with an MXPAHF rotating-anode X-ray diffractometer. The luminescence spectra for the solid samples were recorded at room temperature with a Hitachi 850 fluorescence spectrophotometer. Thermogravimetric analyses (TGA) were performed under air with a heating rate of 10 °C·min^{-1} using a Shimadzu TGA-50H TG analyzer.

***N*-(4-Carboxyphenyl)iminodiacetic Acid (H_3cpida):** A solution of KOH (33.6 g, 0.6 mol) in water (100 mL) was added dropwise to a solution of chloroacetic acid (28.4 g, 0.3 mol) in water (100 mL). *p*-Aminobenzoic acid (13.7 g, 0.1 mol) was slowly added to the re-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sulting alkaline solution, and the mixture was refluxed at 86 °C for 30 h. The reaction mixture was then cooled to room temperature and acidified with HCl (6 M) until the desired acid precipitated as a white solid (pH ≈ 2.5) (Scheme 1). This precipitate was collected by filtration, washed with water and recrystallised from water (yield: 32% based on *p*-aminobenzoic acid). IR (KBr): $\tilde{\nu}$ = 3458, 2919, 1714, 1612, 1530, 1462, 1388, 1239, 1192, 975, 771, 692 cm^{-1}. ^1H NMR (400 MHz, D_2O, 25 °C): δ = 7.84 (d, J = 8.9 Hz, AABB, 2 H), 6.58 (d, J = 8.9 Hz, AABB, 2 H), 4.23 (s, 4 H, CH_2-COO) ppm.

$[Cu_3(cpida)_2(H_2O)_4]_n \cdot 4nH_2O$ (1): This compound was prepared by a solvent evaporation method. A mixture of basic copper carbonate (0.111 g, 0.5 mmol) and H_3cpida (0.25 g, 1.0 mmol) in 15 mL of water was heated in a steam bath for 1 h, and then filtered. Methanol (5 mL) was then added to the filtrate (Scheme 1). Blue single crystals suitable for X-ray analysis were obtained by slow evaporation of the solvent from the filtrate at room temperature (yield: 72% based on Cu). IR (KBr): $\tilde{\nu}$ = 3418, 2919, 1645, 1605, 1538, 1412, 1260, 1217, 1170, 968, 925, 839, 778, 698, 643, 511 cm^{-1}.

$[Zn(Hcpida)]_n \cdot nH_2O$ (2): This compound was synthesized hydrothermally in a thick-walled Pyrex tube containing $Zn(NO_3)_2 \cdot 6H_2O$, H_3cpida, KOH, methanol and H_2O in a molar ratio of 3:2:1:78:222 under autogenous pressure. The tube was cooled in liquid N_2, sealed under vacuum, and placed inside an oven at 120 °C for 2 d (Scheme 1). The resulting colourless crystals were collected and washed with ethanol (yield: 58% based on Zn). IR (KBr): $\tilde{\nu}$ = 3491, 2977, 1703, 1573, 1518, 1460, 1412, 1352, 1308, 1262, 1197, 1146, 1122, 1016, 923, 851, 781, 755, 731, 699, 648, 585, 508 cm^{-1}.

X-ray Single-Crystal Structure Determination: Crystallographic data for **1** and **2** were collected at 173 K for **1** and 293 K for **2** with a Siemens Smart CCD diffractometer with Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods using SHELXS-97[21] and refined by full-matrix least-squares method against F^2 (SHELXL-97).[22] All non-hydrogen atoms were refined anisotropically. Carbon-bound hydrogen atoms were placed in geometrically calculated positions; oxygen-bound hydrogen atoms were located in the difference Fourier map and kept fixed in that position. The crystallographic data for **1** and **2** are listed in Table 2; selected bond lengths and angles for **1** and **2** are presented in Table 1. CCDC-228511 (**1**) and -228512 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, X-ray Characterisation and Studies of the New Ionic Complex [Bis(pyridin-2-yl) disulfide] Triiodide, Obtained by Oxidation of 2-Mercaptopyridine with I_2 − Implications in the Mechanism of Action of Antithyroid Drugs

Constantinos D. Antoniadis,[a] Sotiris K. Hadjikakou,*[a] Nick Hadjiliadis,*[a] Maciej Kubicki,[b] and Ian S. Butler[c]

Keywords: Bioinorganic chemistry / Iodine complexes / Polyiodides / S ligands / Crystal structures

The reaction of 2-mercaptopyridine (C_5H_5NS or PYSH) with diiodine in a molar ratio of 1:2 in dichloromethane led to the oxidation and dimerization of the ligand and formation of $[(PYS–PYSH)^+\cdot I_3^-]$. The compound was characterised by elemental analysis, DTA-TG, FT-Raman, FT-IR, UV/Vis and ^1H NMR spectroscopy. The crystal structure of the complex has been determined by X-ray diffraction at 293(2) K. The compound $[(C_5H_4NS–SNC_5H_5)I_3]$ is monoclinic with the space group $P2_1$ and a = 8.230(2) Å, b = 35.708(7) Å, c = 11.369(2) Å, β = 91.86(3)° and Z = 8. The results are discussed in relation to the mechanism of action of antithyroid drugs. The easy oxidation of PYSH by I_2 to form the monocationic disulfide complex $[(PYS–PYSH)^+\cdot I_3^-]$ is similar to the case of the antithyroid drug methimazole (MMI) and may indicate that PYSH might also possess antithyroid properties similar to those of MMI.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Because of the effective antithyroid activity of thioamides, their interaction with diiodine has been thoroughly studied in recent years.[1−3] These thioamides include the antithyroid drugs methimazole (MMI) and 6-*n*-propyl-2-thiouracil (PTU)[1−3] and studies have aimed at drawing conclusions about their mechanism of action. It has been proposed that both MMI and PTU display both irreversible and reversible inhibition depending on the relative concentrations of the drug and iodine.[4] Nakataka et.al.[5] reported that the inhibition of tyrosil iodination by antithyroid drugs should be different in the cases of PTU and MMI; du Mont et.al.[6a] and Berry et al.[6b,6c] proposed that drugs such as PTU should, rather, interfere either with the formation of the thyroid peroxidase (TPO)−iodonium complex[4] or inhibit the activity of the iodothyronine deiodinase type I (ID-1), an enzyme containing selenocysteine in its active site which is responsible for the monodeiodination of the T4 prohormone to the T3 hormone.[6] Isaia et al.[3] have shown that MMI is readily oxidised by the TPO system to form MMI disulfide [bis(1-methylimidazol-2-yl disulfide], while activated iodine is simultaneously reduced to the iodide anion. We also recently demonstrated that PTU forms weak charge transfer complexes (CT) with diiodine.[2c] Thus, although it has been concluded[1−4] that thioamides inhibit the formation of thyroid hormones by preventing the incorporation of oxidised iodides into tyrosine, the precise mechanism of this trapping is still a matter for further investigation.

The perturbation of the I−I bond by heterocycles such as 2-mercaptopyridine (PYSH; Figure 1) can lead to novel complexes containing polyiodides.[7] With the aim of studying the interfering mechanism of thioamides in TPO-catalysed iodination reactions of tyrosil residues of thyroglobuline, we report here the isolation and study of the oxidation product of an I_2 complex with 2-mercaptopyridine of formula $[(PYS−PYSH)^+\cdot I_3^-]$ (**1**).

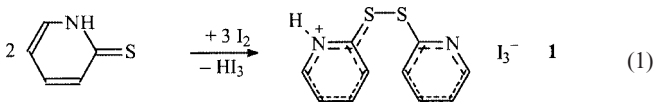
Results and Discussion

PYSH reacts with I_2 in a molar ratio of 1:2 oxidizing the ligand to disulfide [Equation (1)].



(1)

A thermal analysis in a flow of nitrogen showed that the compound decomposes in two stages. The TGA and DTA data curves show that the first stage of its decomposition (90−160 °C) is connected with an endothermic effect and involves a 42% mass loss consistent with the evolution of I_2 (calculated mass loss 42%). The second stage of its decomposition (204−234 °C) is connected with an endothermic effect and involves a 58% mass loss of (PYS−PYSH)I (calculated mass loss 58%). This indicates that I_3^- might be asymmetric of the $I^-\cdots I_2$ type[7b] which results in the easy breaking of this bond (see crystal structure).

The conductimetric titration of PYSH with I_2 in acetonitrile is shown in Figure 2.

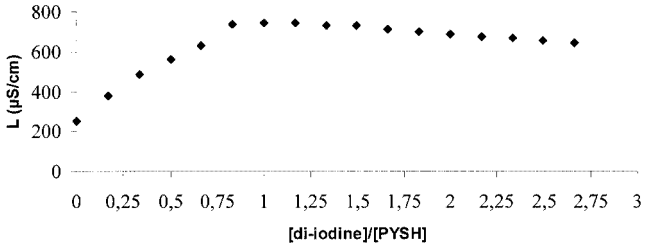


Figure 2. Conductivity titrations of PYSH (10^{-2} M) with I_2 in acetonitrile (T = 293 K)

At a zero I_2 concentration, the solution of PYSH in acetonitrile shows nonzero conductivity. Addition of I_2, increases the conductivity of the solution, with a maximum value attained at a molar ratio $[I_2]/[PYSH] = 0.83$, leading to a plateau in accordance with Equation (1).

Spectroscopy

(A) UV/Vis Spectroscopy

The UV/Vis spectra of dichloromethane solutions with constant concentrations of PYSH (10^{-4} M) and increasing quantities of diiodine are given in Figure 3. They exhibit one distinct absorption band at 495−505 nm which can be assigned to the "blue shift" band of I_2[2,8] occurring at 504 nm in free I_2 in CH_2Cl_2.[8e,8g]

The absorption band at 367 nm can be assigned to the I_3^- species (λ_{max} = 360 nm in free I_3^-).[9] I_3^- has one more absorption band at 295 nm, coinciding with the intra-ligand transition ($\pi^*\leftarrow\pi$) appearing at 292 nm in free PYSH.

No isosbestic points were observed, indicating that more than two species are present in solution (Figure 3). In the spectrophotometric titration curves of I_2/PYSH, the presence of the band at 367 nm, attributable to the I_3^- moiety, can be observed at low I_2/ligand ratios in accord with Equation (1) (see conductivity measurements).

(B) Vibrational Spectroscopy

The IR spectrum of the complex shows distinct vibrational bands at 1579 and 1452 cm^{-1} which can be assigned to ν(CN) vibrations (thioamide I and II bands) and at 1108 and 959 cm^{-1} attributable to the ν(CS) vibrations (thioamide III and IV bands). The new band appearing at 158 cm^{-1} in the FIR spectrum of the complex has been assigned to the ν(I−I) stretching vibration mode.[2a,2b,10]

Table 1 gives structural and Raman spectroscopic data of the complex and other complexes containing I_3^- in the region of 300−50 cm^{-1}.

Diiodine vapour gives a strong band at 216 cm^{-1} [ν(I−I)] which appears at 180 cm^{-1} in the solid state.[7b,11] This

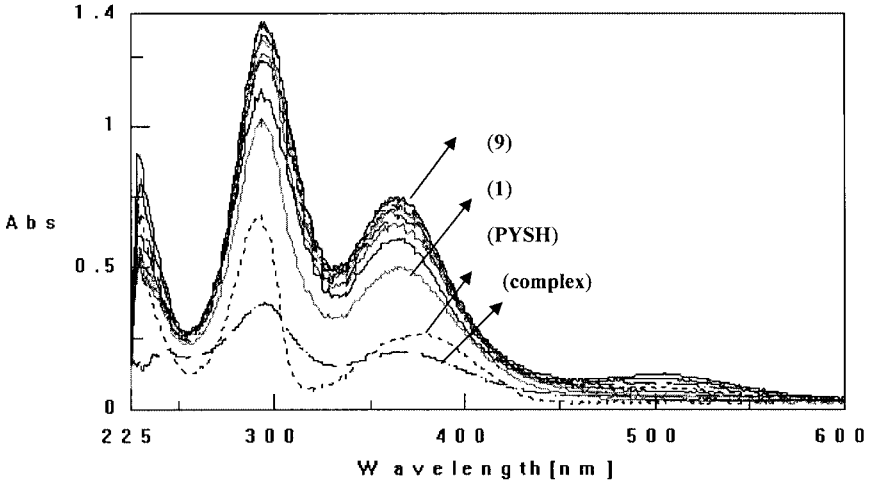

Figure 3. UV/Vis spectra of the complex (5×10^{-5} M) and the ligand (PYSH) (5×10^{-5} M) in dichloromethane; UV/Vis spectra of solutions with constant concentrations (10^{-4} M) of PYSH and increasing quantities of diiodine in dichloromethane ($[I_2]/[L]$: 1: 0.33; 2: 0.50; 3: 0.66; 4: 0.84; 5: 1.00; 6: 1.16; 7: 1.34; 8: 1.50; 9: 1.66)

shifts to lower wavenumbers upon coordination to a donor atom, reflecting the reduction in the I−I bond order and the strengthening of the complex formed as well.[2,7b,8b,8c,12]

The Raman spectrum of the complex shows two strong bands at 162.4 and 154.7 cm^{-1}. It is worth mentioning that bands around 110 cm^{-1} are normally assigned to the ν_1 symmetric stretching of I_3^- which, being a symmetrical ion, normally exhibits only one Raman-active band.[2a,2b,7b] However, when a distortion of I_3^- occurs, the asymmetric stretching may become Raman-active and additional bands at higher (140−130 cm^{-1}) and at lower frequencies (80−70 cm^{-1}) can be observed[7b] and assigned to asymmetric stretching and deformation motions of asymmetric I_3^-, respectively.[7b,13] Thus, the complex should be a linear asymmetric I_3^- (I$^-$···I_2) complex (see crystal structure) (Table 1).[7b]

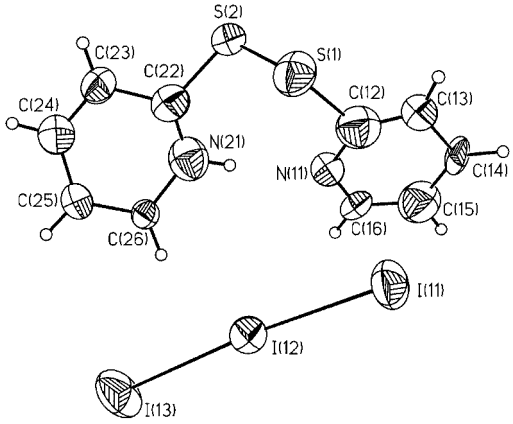

Figure 4. ORTEP diagram of the ionic components of compound **1** together with the atomic numbering scheme; thermal ellipsoids are shown at the 33% probability level, hydrogen atoms are depicted as the spheres of arbitrary radii; selected bond lengths are given in the text

Crystal and Molecular Structure of [(PYS−PYSH)$^+$·I_3^-]

Dark crystals of the complex suitable for a single-crystal X-ray analysis were grown by slow concentration of the filtrate obtained from the reaction of diiodine with the appropriate ligand in dichloromethane.

An ORTEP diagram of the compound is shown in Figure 4 with selected bond lengths and angles in Table 2. In the crystal there are four symmetry-independent cation/anion pairs (Figure 5). Figure 5 also shows the intermolecular or cation−anion interactions.

The structure of the compound consists of two residues, one cationic (PYS−PYSH)$^+$ containing the S−S bond linking the two 2-mercaptopyridine molecules, one of which is protonated, and one I_3^- counter anion. There are only a few crystal structures reported in the literature containing open-chain stable cations of DS−SD dimers. These include the monocation [{($C_4H_6N_2S$−$SN_2C_4H_5$)$_2$}$^{2+}$·(I_3^-)·(I_5^-)][3] ($C_4H_6N_2S$ = *N*-methylimidazole-2-thione) and dications such as [{($C_4H_6N_2S$−)$_2$}$^{2+}$·2I_3^-·I_2][3] ($C_4H_6N_2S$ = *N*-methylimidazole-2-thione), [{(*i*Pr$_2$timdt)$_2$}$^{2+}$·(IBr$_2^-$)$_2$][14a] (*i*Pr$_2$timdt = 1,3-diisopropylimidazolidine-2,4,5-trithione), and [{(H$_2$N)$_2$C−S−S−C(NH$_2$)$_2$}$^{2+}$·(2I$^-$)][14b] [(H$_2$N)$_2$C=S = thiourea], [(L)$_2^{2+}$·2(I_3^-)][14c] (L = 1,3-diisopropyl-4,5-dimethylimidazoldithiocarboxylate).

The mean value of the S−S bond length measured in the four symmetry-independent cation/anion pairs found in the structure is 2.032 Å [the individual bonds are S(1)−S(2) = 2.003(12) Å (**a**), S(3)−S(4) = 2.010(15) Å (**b**), S(5)−S(6) = 2.052(14) Å (**c**) and S(7)−S(8) = 2.062(14) (**d**), respectively] (Figure 5). These are among the shortest bonds of this type.[3,14] Examples include the monocation [{($C_4H_6N_2S$−$SN_2C_4H_5$)$_2$}$^{2+}$·(I_3^-)·(I_5^-)] ($C_4H_6N_2S$ = *N*-methylimidazole-2-thione) with S−S = 2.094(3) Å[3] and the dications, [{($C_4H_6N_2S$−)$_2$}$^{2+}$·2I_3^-·I_2] ($C_4H_6N_2S$ = *N*-methylimidazole-2-thione) with S−S = 2.085(2) Å,[3] [{(*i*Pr$_2$timdt)$_2$}$^{2+}$·(IBr$_2^-$)$_2$], (*i*Pr$_2$timdt = 1,3-diisopropylimidazolidine-2,4,5-trithione) with S−S = 2.071(7) Å,[18] [{(H$_2$N)$_2$C−S−S−C(NH$_2$)$_2$}$^{2+}$·(2I$^-$)] [(H$_2$N)$_2$C=S = thiourea] with S−S = 2.044 Å,[14b] and [(L)$_2^{2+}$·2(I_3^-)] (L = 1,3-diisopropyl-4,5-dimethylimidazoldithiocarboxylate) with S−S= 2.024(5) Å.[14c]

The two C−S bond lengths in the four symmetry-independent cation/anion pairs of the complex are unequal due to the monoprotonation of the aromatic ring of the disulfide [S(1)−C(12) = 1.85(3) and S(2)−C(22) = 1.77(3) Å (**a**), S(4)−C(42) = 1.78(3) and S(3)−C(32) = 1.75(3) Å (**b**), S(6)−C(62) = 1.65(2) and S(5)−C(52) = 1.77(3) Å (**c**), S(7)−C(72) = 1.71(2) and S(8)−C(82) = 1.69(3) Å (**d**), respectively] (Figure 5). The longer C−S distance corre-

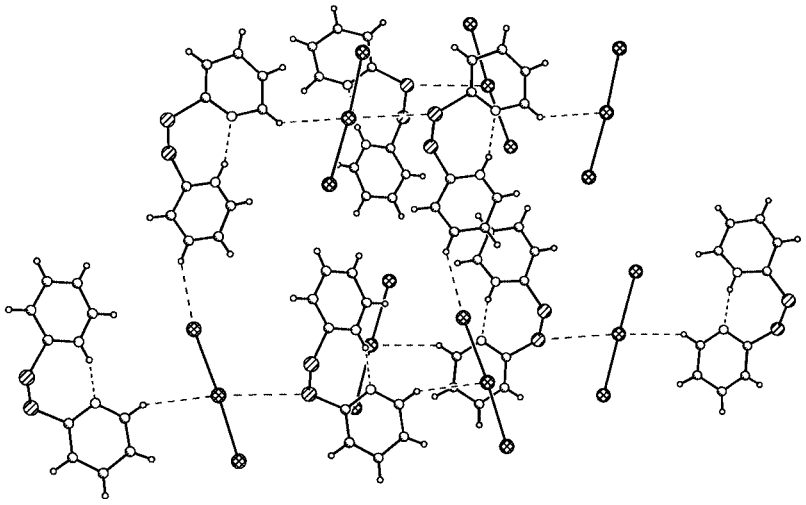

Figure 5. Crystal packing of **1** as seen approximately along the [100] direction, hydrogen bonds and S···I contacts are drawn as dashed lines

sponds to the nonprotonated ring and the shorter distance to the protonated one. The corresponding C−S bond lengths found in the monocation $[\{(C_4H_6N_2S-SN_2C_4H_5)_2\}^{2+}\cdot(I_3^-)\cdot(I_5^-)]$ ($C_4H_6N_2S$ = *N*-methylimidazole-2-thione)[3] are 1.744(9) Å and 1.700(11) Å. The C−S bond lengths found in the doubly protonated rings of the dications are almost equal, 1.748(5) and 1.735(5) Å in $[\{(C_4H_6N_2S-)_2\}^{2+}\cdot 2I_3^-\cdot I_2]$ ($C_4H_6N_2S$ = *N*-methylimidazole-2-thione),[3] 1.76(4) and 1.75(2) Å in $[\{(i\mathrm{Pr}_2\mathrm{timdt})_2\}^{2+}\cdot(\mathrm{IBr}_2^-)_2]$ (*i*Pr_2timdt = 1,3-diisopropylimidazolidine-2,4,5-trithione),[18] 1.76 and 1.78 Å in $[\{(H_2N)_2C-S-S-C(NH_2)_2\}^{2+}\cdot(2I^-)]$ $[(H_2N)_2C{=}S$ = thiourea],[14b] and 1.7281(2) Å in $[(L)_2{}^{2+}\cdot 2(I_3^-)]$ (L = 1,3-diisopropyl-4,5-dimethylimidazoldithiocarboxylate).[14c]

Both I−I bond lengths differ significantly from the corresponding I−I bond length of I_2 in the solid state (2.715 Å).[15] Thus, the two I−I bond lengths of I_3^- in the complex are I(11)−I(12) = 2.892(4) and I(12)−I(13) = 2.943(3) Å (**a**), I(21)−I(22) = 2.870(4) and I(22)−I(23) = 2.960(3) Å (**b**), I(31)−I(32) = 2.860(4) and I(32)−I(33) = 2.863(3) Å (**c**) and I(41)−I(42) = 2.855(4) and I(42)−I(43) = 2.928(3) Å (**d**), respectively (Figure 5), indicating a slight asymmetry of I_3^- in this complex (covalent linear asymmetric).[7b] In the following I_3^- adducts, however, the asymmetry seems to be stronger. Thus, in $[Et(NH_2)dtl]I_3^-$ [$Et(NH_2)$dtl = 3,5-bis(ethyllamino)-1,2-dithiolithium],[7b,16a] the I−I bond lengths are 2.74 and 3.14 Å, in CsI_3^- [7b,16b] 2.842 and 3.038 Å, in $Da_2I_3^-$ [7b,16c] (Da = 1,4-diazoniabicyclo[2.2.2]octane) 2.793 and 3.167 Å, and in [1-MethylcytosineH]I_3^- [7b,16d] 2.794 and 3.123 Å (see Table 1 and ref.[7b] for more examples).

According to Pauling,[17a] $d(\mathrm{I-I}) = d_o - 0.85\cdot\log(n)$ [Equation (2)], where d_o is the I−I bond length of I_2 in the gas phase, i.e. 2.67 Å,[17b] and *n* is the bond order. The calculated values of the bond orders for the I−I bonds of the complexes are listed in Table 1. Deplano et al.[7b] classi-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

fied triiodide adducts into two types: (a) the $I^-\cdots I_2$ adducts which have a linear asymmetric geometry with one strong I−I bond (bond orders > 0.63 e) and one weaker I−I bond (bond orders < 0.30 e) and (b) the covalent I−I−I complexes which have (i) a linear symmetric geometry with two equal I−I bonds and bond order values around 0.50 e and those with (ii) a linear asymmetric geometry which have two nonequivalent I−I bonds with bond order values around 0.50 e (a stronger bond with bond order > 0.50 e and a weaker with bond order < 0.50 e). Thus, according to the values of the I−I bond lengths and bond orders, the I_3^- in this complex can be classified as a linear asymmetric $I^-\cdots I_2$ complex.[7b]

The mean value of the I−I−I bond angle is 175.4(1)° [(11)−I(12)−I(13) = 174.92(12)° (**a**), I(21)−I(22)−I(23) = 174.96(11)° (**b**), I(33)−I(32)−I(31) = 176.17(11)° (**c**) and I(41)−I(42)−I(43) = 175.58(13)° (**d**), respectively] (Figure 5) indicative of the involvement of both terminal iodine atoms in the interaction with the disulfide. These differ only slightly from linearity. In particular, the mean C···I and S···I contact distances of the two terminal iodine atoms of I_3^- species in the four symmetry-independent cation/anion pairs are 3.842 Å and 3.943 Å, respectively. Similar angles were observed in $[\{(C_4H_6N_2S-)_2\}^{2+}\cdot 2I_3^-\cdot I_2]$ ($C_4H_6N_2S$ = *N*-methylimidazole-2-thione) [178.87(4)°][3] and in $[(L)_2^{2+}\cdot 2(I_3^-)]$ (L = 1,3-diisopropyl-(4,5-dimethylimidazolyl)dithiocarboxylate) [175.71(4)°].[14c]

Strong intramolecular hydrogen bonds between the imino NH proton and the nonprotonated nitrogen atom are formed in the complex (mean value of the N···N bond is 2.74 Å, mean value of H···N is 1.91Å and the mean value of the N−H···N angle is 163°). In the crystal structure, the weak C−H···I, S···I, and S···S interactions organise the cations and anions in alternate layers (Figure 5).

Conclusion

Recently, a mechanism for the transformation of MMI to MMI disulfide was proposed by Isaia et al.[3] and Po et al.[18] based on crystallographic and electrochemical data. The proposed redox process involves the formation of a di- and a monocationic disulfide species of MMI prior to the full transformation of MMI to MMI disulfide. Thus, thioamides such as MMI[3] or tzdtH[2a] exhibiting antithyroidal activity against hyperthyroidism (Graves' disease) are either oxidised by the TPO-I system to form disulfides or act as strong donors towards diiodine forming iodonium salts, while activated iodine is reduced to the iodide anion simultaneously. On the other hand, thioamides such as PTU[2c] which are able to form weak charge transfer species with diiodine, interfere in other steps of the mechanism, either in the formation of thyroid peroxidase (TPO)−iodonium complex[4] or inhibit the activity of the iodothyronine deiodinase type I (ID-1), an enzyme responsible for the monodeiodination of the T4 prohormone to the T3 hormone[6] The easy oxidation of PYSH by I_2 to form the monocationic disulfide complex [(PYSPYSH)$^+\cdot I_3^-$] similar to the antithyroid drug methimazole (MMI)[3,18] may indicate that PYSH might also possess antithyroid properties like MMI.

Experimental Section

Materials and Instruments: All solvents used were reagent grade. Diiodine (Aldrich) and pyridine-2-thione (Merck) were used with no further purification. Elemental analyses for C, H, N, and S were carried out with a Carlo Erba EA model 1108 elemental analyser. Melting points were measured in open tubes with a Stuart scientific apparatus and are uncorrected. Infrared spectra in the region of 4000−370 cm^{-1} were obtained in KBr discs while far-infrared spectra in the region of 400−50 cm^{-1} were obtained in polyethylene discs with a Perkin−Elmer Spectrum GX FT-IR spectrophotometer. A Jasco UV/Vis/NIR V 570 series spectrophotometer was used to obtain the electronic absorption spectra. Conductivity titrations were carried out at 293 K in acetonitrile solutions with a WTF LF-91 conductivity meter.

Synthesis and Crystallisation: The complex was prepared by mixing a dichloromethane solution of diiodine with a suspension of 2-mercaptopyridine in dichloromethane in a 1:2 PYSH/I_2 molar ratio in air at 0 °C with continuous stirring for 5 h. The solution was then filtered and the resultant clear solution was kept in the refrigerator for several days. Dark crystals of the complex suitable for single-crystal X-ray analysis were obtained, yield 0.012 g (20%); m.p. 80−82 °C. $C_{10}H_9I_3N_2S_2$ (602.02): calcd. C 19.95, H 1.51, N: 4.65, S 10.65; found C 19.23, H 1.51, N 4.31, S 10.87. IR: $\tilde{\nu}$ = 3119 w, 1577 s, 1496 s, 1108 vs, 959 s, 765 vs, 731 s, 654 s, 463 s, 158 m, 112 m cm^{-1}. UV/Vis (CH_2Cl_2): λ_{max} (logε) = 500.5 (2.90), 367.5 (3.56), 292.5 (3.84) nm.

X-ray Structure Determination: Data were collected using the ω-scan technique in the range 2.90° < 2θ < 29.92° with a KUMA KM4CCD four-circle diffractometer[19a] with a CCD detector using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 293(2) K. Cell parameters were determined by a least-squares fit.[19b] All data were corrected for Lorentz-polarisation and absorption effects.[19b,19c] The crystals of the compound were relatively poor in quality and the statistical indicators of the appropriate refinements are, therefore, not very good and the refinements were provided with constraints. Nevertheless, the quality of the data obtained allow for a reasonable discussion, especially of crystal packing and the constitution of the complex. The structure was solved by direct methods with SHELXS-97[19d] and refined by full-matrix least-squares procedures on F^2 with SHELXL-97.[19e] All non-hydrogen atoms were refined anisotropically, hydrogen atoms were located in calculated positions and refined using the "riding model" with isotropic thermal parameters fixed at 1.2 times the U_{eq} values of the appropriate carrier atom. $C_{10}H_9I_3N_2S_2$, MW = 602.020, monoclinic in $P2_1$, a = 8.230(2) Å, b = 35.708(7) Å, c = 11.369(2) Å, β = 91.86(3)°, V = 3339.3(12) Å^3, Z = 8, ρ(calcd.) = 2.395 g cm^{-3}, μ = 5.849 mm^{-1}, reflections collected 21199, Final R ($\Sigma||F_o| - |F_c||/\Sigma|F_o|$), $wR2$ $\{[\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}\}$ [$I > 2\sigma(I)$] indices 0.0872 and 0.2028, respectively. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-230097 (**1**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Homoleptic Rare-Earth Carbazolates and the Trends of Their $E_{Ln^{II/III}}$ Redox Potentials: Mixed-Valent Samarium in $^1_\infty[Sm_2(Cbz)_5](CbzH)$ (CbzH = carbazole) and Trivalent Thulium, Neodymium and Gadolinium in $[Ln_2(Cbz)_6]$

Klaus Müller-Buschbaum*[a] and Catharina C. Quitmann[a]

Keywords: Solvent-free synthesis / Lanthanides / Carbazolates / N ligands

The solvent-free melt reaction of carbazole (CbzH, $C_{12}H_8NH$) with samarium metal yields $^1_\infty[Sm_2(Cbz)_5](CbzH)$ (**1**), whilst the melt reactions with thulium, neodymium and gadolinium give $[Tm_2(Cbz)_6]$ (**2**), $[Nd_2(Cbz)_6]$ (**3**) and $[Gd_2(Cbz)_6]$ (**4**), respectively. Compounds **1** and **2** were obtained as single crystals and their crystal structures determined by single-crystal X-ray analysis, whilst **3** and **4** were obtained as powders. X-ray powder diffraction studies show that the gadolinium-containing complex **4** is isotypic to the thulium complex **2**, whereas the neodymium-containing complex **3** is not. Compound **1** contains alternating Sm^{II} and Sm^{III} cations in a chain structure. Complex **2** only exhibits dimeric units of Tm^{III}. Besides Ln–N coordination, the crystal structures of both compounds show η^6-π interactions with the phenyl rings of the carbazolate ligands. This leads to small coordination polyhedra, such as connected tetrahedra of two nitrogen atoms and two η^6-π-coordinated phenyl rings around Sm^{II}, and trigonal bipyramids of five nitrogen atoms around Sm^{III} for **1**, as well as tetrahedra of three nitrogen atoms and one η^6-π-phenyl interaction around Tm^{III} for **2**. From the trend of the $E_{Ln^{II/III}}$ redox potentials, the complexes of neodymium and gadolinium are also trivalent. For **1**–**4** the results of FIR, MIR and Raman spectroscopy as well as simultaneous DTA/TG analyses are also presented.

Introduction

Since the syntheses of the first cyclopentadienyl complexes[1] and metallocenes[2] solvent-containing reaction routes have come to dominate all fields of rare-earth-metal coordination chemistry.[3−7] Accordingly, the vast majority of structurally characterised compounds are solvates and are therefore heteroleptic[8] whenever the ligands do not meet certain criteria like multi-chelating, such as in the rare-earth-metal amide complexes.[8−11] The reactivity of rare-earth metals themselves has proven to be high enough to be able to react directly with amines, yielding homoleptic amides. Whilst initial work with substituted pyrazolate ligands made solvent recrystallisation[12,13] steps necessary in order to obtain crystalline products, we have systematically developed a type of solvent-free melt synthesis that allows the crystallisation of products under reaction conditions,[14−17] including the first homoleptic carbazolates of europium and ytterbium;[18] heteroleptic solvent-containing carbazolates have been reported previously.[19,20] Both europium and ytterbium carbazolates are divalent. Therefore, reactions of samarium, thulium, neodymium and gadolinium metal with carbazole were carried out, their reaction products $^1_\infty[Sm_2(Cbz)_5](CbzH)$ (**1**) and $[Ln_2(Cbz)_6]$ [Ln = Tm, Nd, Gd (**2**−**4**)] illuminating the trend of the $E_{Ln^{II/III}}$ redox potentials[21,22] (see Scheme 1) from Eu^{II} and Yb^{II} in $^1_\infty[Ln_2(Cbz)_4]$[18] to mixed-valent Sm^{II}/Sm^{III} and trivalent Tm^{III}, Nd^{III} and Gd^{III}. The results are compounds with different crystal structures that are unique in rare-earth-metal amide chemistry.

Results and Discussion

The solvent-free reactions of samarium, thulium, neodymium and gadolinium with carbazole were carried out in

[a] Institut für Anorganische Chemie, Universität zu Köln, Greinstrasse 6, 50939 Köln, Germany
E-mail: Klaus.Mueller-Buschbaum@Uni-Koeln.de

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200400516

a melt of the amine in ampoules. The reaction with samarium metal yielded black, in thin layers dark red crystals of $^1_\infty[Sm_2(Cbz)_5](CbzH)$ (**1**) at 270 °C [Equation (1)]. Activation by amalgamation dropped the reaction temperature to 255 °C but decreased the crystallinity of the bulk product. No further reaction to the trivalent state was observed up to decomposition (see Figure 1), even when an excess of CbzH was used.

$$Ln + x\,HN(R_2) \rightarrow Ln(NR_2)_x + x/2\,H_2 \quad (1)$$

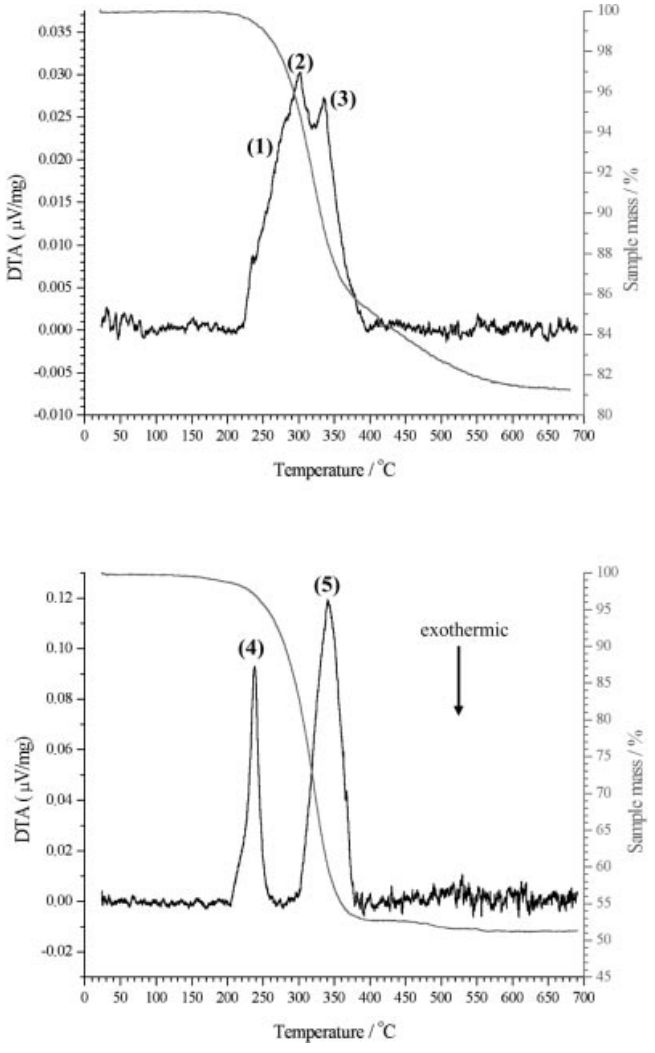

Figure 1. The thermal decompositions of $^1_\infty[Sm_2(Cbz)_5](CbzH)$ (**1**, top) and $[Tm_2(Cbz)_6]$ (**2**, bottom) investigated by simultaneous DTA/TG in the temperature range 20−700 °C; the plot of the bulk material of **1** exhibits the melting point of excess carbazole (1), release of uncoordinated carbazole from the structure (2) and the decomposition (3) of **1**; the thermal investigation of the bulk material of **2** exhibits the melting point (4) and the decomposition (5) of **2**; neither excess nor uncoordinated carbazole is observed for **2**

The reaction with thulium metal was also carried out under solvent-free conditions in a carbazole melt except that both amalgam activation of Tm and a reaction temperature of 280 °C were necessary to obtain orange to red crystals of $[Tm_2(Cbz)_6]$ (**2**).

Neodymium and gadolinium metal react with carbazole only as an amalgam containing at least one tenth of the amount of the rare-earth metal. A reaction temperature of 280 °C was also necessary to obtain $[Nd_2(Cbz)_6]$ (**3**) as a golden-yellow solid. $[Gd_2(Cbz)_6]$ (**4**) was formed upon annealing at 245 °C already, following activation at 280−290 °C, giving a poorly crystalline dark yellow solid.

The thermal decomposition of **1**−**4** was investigated by simultaneous DTA/TG.[23] This method has already proved its value for understanding comparable melt reactions with 2-(2-pyridyl)benzimidazole[15] and shows the decomposition path of the bulk product of the melt reaction. This analysis provides additional information regarding the completeness of the reaction and possible phase impurities.

$^1_\infty[Sm_2(Cbz)_5](CbzH)$ (**1**) is a molecular polymer formed at relatively high temperatures (255−270 °C). Accordingly, its thermal behaviour and stability must be different from the known heteroleptic carbazolates, and therefore the bulk product of the synthesis was studied. Although the thermogravimetric investigation displays no separated signals, the resolution of the differential thermoanalysis exhibits three different signals (Figure 1, top). The first signal in the heat flow was identified as the melting point of unchanged carbazole at 235 °C, followed by a slight mass loss of the excess carbazole (about 2%) displayed by a shoulder of an endothermic peak in the heat flow. At a reaction temperature of 270 °C, $^1_\infty[Sm_2(Cbz)_5](CbzH)$ slowly starts to decompose without melting and releases the uncoordinated CbzH (M = 167.1 g/mol; calcd. 12.9% of $M\{^1_\infty[Sm_2(Cbz)_5](CbzH)\}$; found 13%). At 290−300 °C another endothermic signal is observed that indicates further thermal decomposition of $^1_\infty[Sm_2(Cbz)_5]$ without the formation of defined decomposition products. The unseparated thermal signals indicate that the later processes begin before the earlier ones are completely finished. Although the thermal stability of $^1_\infty[Sm_2(Cbz)_5](CbzH)$ is high, it does not reach the stability of the homoleptic divalent rare-earth carbazolates.[18] One of the reasons for this behaviour could be the unsaturated coordination spheres of the samarium atoms. Considering the formation temperature of 270°C, the temperature frame to obtain the compound is very limited and it is neither likely that $^1_\infty[Sm_2(Cbz)_5]$ is obtained free of CbzH by the melt synthesis nor that $^1_\infty[Sm_2(Cbz)_5](CbzH)$ forms if the volatile CbzH is not forced to stay in the reaction mixture, as provided by the ampoule treatment.

The thermal decompositions of $[Ln_2(Cbz)_6]$ [Ln = Tm, Nd, Gd (**2**−**4**)] are relatively similar to each other, but different from **1** due to their different structures. All three compounds show sharp melting points of the products as well as one following endothermic decomposition step. Complexes **2**−**4** have much lower melting points (220 °C for **2**, 190 °C for **3** and 175 °C for **4**; see Figure 1 for Tm) than the polymeric carbazolates $^1_\infty[Ln_2(Cbz)_4]$ (Ln = Eu, Yb).[18] The melting points are identified by sharp endothermic peaks in the heat flow with no related mass loss.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The subsequent decomposition step for **2** starts at 300 °C with release of 47% of the sample mass. For **3** the decomposition starts at 310 °C with release of 68% of the sample mass. This includes 15% of unchanged carbazole in the bulk sample, as identified by its melting point, and an additional endothermic signal in the heat flow. The behaviour of **4** is similar, its decomposition starting at 270 °C with 3% of unchanged carbazole being released prior to a mass loss of 51%. In contrast to **1**, **3** and **4** the bulk sample of **2** is free of unchanged carbazole, indicating complete reaction. Although the volatile products of the decompositions of **2**−**4** could not be defined, the decomposition pathways are likely to be similar for all three compounds because the released sample masses match the different molecular masses of Tm, Gd and Nd. The decomposition temperatures of **1**−**4** are distinctively lower than for the divalent compounds $^1_\infty[Ln_2(Cbz)_4]$ (Ln = Eu, Yb).[18] As for the rare-earth pyridylbenzimidazolates,[15] no periodic behaviour through the course of the rare earth elements is observable either for melting points or absolute thermal stability of rare earth carbazolates, although the influence of structural characteristics is clearly evident.

The FIR and Raman spectra of **1**−**4** show bands that cannot be identified with the ligand and thus represent the Ln−N stretching modes {$^1_\infty[Sm_2(Cbz)_5](CbzH)$ (**1**): FIR: $\tilde{\nu}$ = 231, 171, 123, 108 cm^{-1}; $[Tm_2(Cbz)_6]$ (**2**): FIR: $\tilde{\nu}$ = 251, 188, 158 cm^{-1}; Raman: $\tilde{\nu}$ = 251, 200, 170 cm^{-1}; $[Nd_2(Cbz)_6]$ (**3**): FIR: $\tilde{\nu}$ = 221, 145, 123 cm^{-1}; Raman: $\tilde{\nu}$ = 280, 230 cm^{-1}; $[Gd_2(Cbz)_6]$ (**4**): FIR: $\tilde{\nu}$ = 243, 231, 159 cm^{-1}; Raman: $\tilde{\nu}$ = 297, 258, 240 cm^{-1}}. The bands thereby match well with other Ln−N-containing compounds such as rare-earth porphyrin complexes,[24] dipyridylamides[16] or pyridylbenzimidazolates[14,15] regarding the coordination spheres, valences and ionic radii in **1** to **4**. They are also in good accordance with the homoleptic carbazolates of divalent Eu and Yb.[18] The ligand lattice stretching modes are reflected by rather broad bands (FIR: $\tilde{\nu}$ = 419, 145 cm^{-1}). The MIR and Raman spectra also contain vibrational bands of the carbazolate ligands that are independent of the rare-earth ion and can therefore be assigned to CbzH[18] (**1**: IR: $\tilde{\nu}$ = 3049, 1603, 1493, 1450, 1326, 1288, 1236, 1106, 750, 725, 574 cm^{-1}; **2**: IR: $\tilde{\nu}$ = 3050, 1602, 1493, 1450, 1327, 1287, 1239, 1108, 749, 726, 574 cm^{-1}; Raman: $\tilde{\nu}$ = 1483, 1450, 1316, 1015, 744 cm^{-1}; **3**: IR: $\tilde{\nu}$ = 3049, 1601, 1493, 1450, 1327, 1287, 1238, 1107, 748, 725, 574 cm^{-1}; Raman: $\tilde{\nu}$ = 1480, 1311, 1011, 741 cm^{-1}; **4**: IR: $\tilde{\nu}$ = 3050, 1603, 1492, 1450, 1327, 1237, 750, 726 cm^{-1}; Raman: $\tilde{\nu}$ = 1481, 1451, 1311, 1011, 742 cm^{-1}). The region between 1100 and 1400 cm^{-1} is well known to contain the bands of extended aromatic systems.[25] Other bands are shifted by about ten wavenumbers compared to the free ligand or show band splitting due to coordination to the metal centers (**1**: IR: $\tilde{\nu}$ = 1482, 1459, 1433, 1146, 912, 569, 430 cm^{-1}; **2**: IR: $\tilde{\nu}$ = 1481, 1458, 1430, 1148, 905, 749, 432 cm^{-1}; Raman: $\tilde{\nu}$ = 1620, 1570, 1248, 540, 310 cm^{-1}; **3**: IR: $\tilde{\nu}$ = 1456, 1426, 1139, 914, 564, 425 cm^{-1}; Raman: $\tilde{\nu}$ =

1625, 1573, 1260 cm^{-1}; **4**: IR: $\tilde{\nu}$ = 1471, 1448, 1430, 1426, 906, 750, 427 cm^{-1}; Raman: $\tilde{\nu}$ = 1624, 1570, 1261 cm^{-1}). A sharp ν(N−H) vibrational band[26] of CbzH in **1** can be observed at 3418 cm^{-1} and was confirmed by the MIR spectrum of the free ligand.[18] This band is only weak in the spectra of $[Ln_2(Cbz)_6]$ [Ln = Tm, Nd, Gd (**2**−**4**)], and here is due to excess carbazole only.

Although the formula of **1** differs by only one hydrogen atom from a formally trivalent compound like compounds **2**−**4**, the crystal structures of **1** and **2** are completely different from each other as well as from the carbazolates of divalent europium and ytterbium. Whilst the heteroleptic complexes $[Sm(Cbz)_2(THF)_4]$, $[Sm(Cbz)_2(N\text{-MeIm})_4]$[19] (N-MeIm = *N*-methylimidazole) and $[Eu(Cbz)_2(THF)_4]$[20] have monomeric structures due to solvent molecules saturating the coordination spheres, the homoleptic[27] rare-earth carbazolates exhibit larger building units in the crystal structures. Like the divalent compounds $^1_\infty[Ln_2(Cbz)_4]$ (Ln = Eu, Yb)[18] the crystal structure of $^1_\infty[Sm_2(Cbz)_5](CbzH)$ (**1**) consists of polymeric chains built of dimeric units with alternating Sm^{II} and Sm^{III} cations. Because of the mixed-valent character of **1** each dimeric unit contains 50% divalent and 50% trivalent samarium. The coordination spheres of Sm^{II} and Sm^{III} are very different so that the different valences can be clearly distinguished. The Sm^{II} atoms are surrounded by two nitrogen atoms and two η^6-coordinated π-systems resulting in a flattened tetrahedron. Distortion of the coordination polyhedron in $^1_\infty[Sm_2(Cbz)_5](CbzH)$ (**1**) can be seen in the deviations from the ideal value of 109.5° [centroid(1)−Sm^{II}−centroid(2): 105(1)°; N1−Sm^{II}−centroid(2): 102(1)°; N2−Sm^{II}−centroid(1): 105(1)°; N1−Sm^{II}−N2: 67.7(3)°]. The Sm^{II}−N distances are 271.8(9) and 281.7(9) pm, the differences being a result of asymmetric μ_2-bridging nitrogen atoms that link Sm^{II} to adjacent Sm^{III} atoms in the dimeric units. Such asymmetric bridges can also be found in $^1_\infty[Eu_2(Cbz)_4]$[18] or $[Yb_2(Cbz)_4(Phpip)_4](Phpip)_2$ (Phpip = phenylpiperazine).[28] The μ_2-coordination mode in **1** also explains the differences in Sm−N distances compared to $[Sm(Cbz)_2(THF)_4]$ and $[Sm(Cbz)_2(N\text{-MeIm})_4]$[19] with an average of 258 and 267 pm, respectively, or $\{[(CH_2)_5C(C_4H_3N)_2]Sm\}_4(THF)_2(N_2)[Na(THF)]_2{\cdot}2THF$ with 271−273 pm.[29] The distances from the Sm atoms to the π-systems of **1** are 274 pm on average (see Table 1 for detailed atom distances and bond angles of **1** and **2**). Although rarely observed, such η^6-phenyl π-interactions are known for the divalent homoleptic carbazolates[18] or for complexes like $[Me_2Si(C_5Me_4)(NPh)Yb(THF)_2]$[30] or the "ate" complex $[K(THF)_3]_2[Sm_2(C_{22}H_{28}N_4)_2](THF)_4$ ($C_{22}H_{28}N_4$ = TMTAT = tetramethyldibenzotetraaza[14]annulate)[10] The μ_2-bridging carbazolate ligands show a slight π-stacking towards the Sm^{II} center with relatively short Sm^{II}−C distances of 294(2) and 300(2) pm.

The Sm^{III} atoms are coordinated by five N atoms forming a distorted trigonal bipyramid. Two of the N atoms form μ_2 bridges to Sm^{II} centers, and two others belong to carbazolate ligands that coordinate in an η^6 fashion to another Sm^{II} center with one of their phenyl rings, thus forming the chain structure of **1**. The fifth nitrogen atom coordinated to Sm^{III} is not connected to any other samarium atom and is found in two disordered positions in the crystal structure. The Sm^{III}−N distances in $^1_\infty[Sm_2(Cbz)_5](CbzH)$ (**1**) range from 236(1) to 248.8(9) pm, the longer distances are located in the μ_2-bridges. Thus, **1** is similar to other trivalent Sm amides like $[(C_{11}H_{21}N_2)_2SmBr]$ ($C_{11}H_{21}N_2$ = 2-propylamino-4-propylimino-2-pentene) with Sm−N distances of 236−242 pm,[31] whilst homoleptic $[Sm(N\text{-MeIm})_8]I_3$ has longer Sm−N distances, averaging 260 pm, with the ligands having N-donor amine and not amide character.[31] The N−Sm^{III}−N angles in **1** are similar to those in an ideal trigonal bipyramid, with N1−Sm^{III}−N3 being 114.0(4)°, N2−Sm^{III}−N5 128.7(8)° and a stretched N2−Sm^{III}−N4 angle of 175.4(4)°. Figure 2 shows the dimeric building unit of **1** and the coordination spheres around Sm^{II} and Sm^{III}.

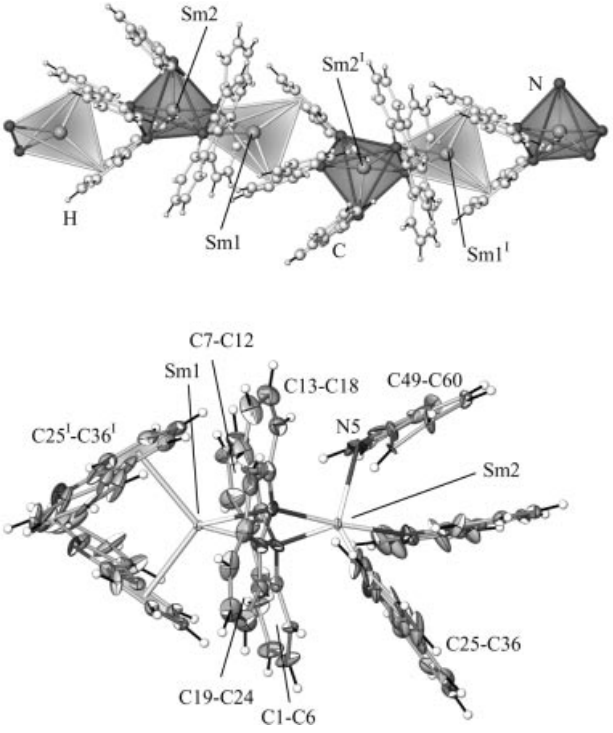

Figure 2. The coordination spheres around (top) and the dimeric building units of (bottom) divalent Sm1 and trivalent Sm2 in the chain structure of $^1_\infty[Sm_2(Cbz)_5](CbzH)$ (**1**); N−N connection lines mark only the coordination polyhedra and not bonds; π-interactions are marked by shaded planes and are represented by bonds towards centroids of the phenyl rings; the thermal ellipsoids here and in Figure 4 are scaled to a probability density of the atoms of 50%; symmetry operation: I: x, $-y + 3/2$, $z + 1/2$

The polymeric chains in the crystal structure of **1** leave tunnels between them, which are filled with carbazole molecules from the melt reaction. They are therefore not coordinated to the Sm centers and are released first in the thermal decomposition process. Figure 3 shows the crystal structure of $^1_\infty[Sm_2(Cbz)_5](CbzH)$ (**1**), including the chains

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and tunnels. The crystal structure of **1** is unique in amide chemistry.

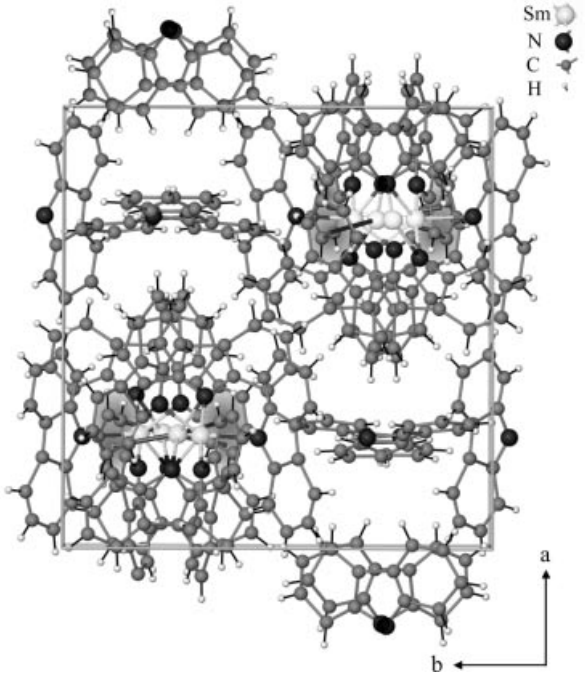

Figure 3. The crystal structure of $^{1}_{\infty}[Sm_2(Cbz)_5](CbzH)$ (**1**) with a view along the chain direction [00−1]; between the strands of $^{1}_{\infty}[Sm_2(Cbz)_5]$ run tunnels in which CbzH molecules are intercalated; η^6-interactions between Sm and phenyl rings are represented by bonds towards centroids and shaded rings

Despite the difference in stoichiometry, the dimeric building units of $[Tm_2(Cbz)_6]$ (**2**) resemble the divalent carbazolates $^{1}_{\infty}[Ln_2(Cbz)_4]$ (Ln = Eu, Yb).[18] Complex **2** also exhibits a tetrahedral coordination environment, with three nitrogen atoms and one η^6-coordinated phenyl ring. Contrary to the divalent carbazolates, however, the tetrahedra in the dimeric unit are not edge-connected by μ_2-bridging N atoms. With three carbazolate ligands coordinating each Tm atom, the linkage in the dimeric unit is formed by the N atoms of carbazolate ligands that use one of their phenyl rings to coordinate to the neighbouring Tm atom, similar to the coordination mode that forms the chains in $^{1}_{\infty}[Ln_2(Cbz)_4]$ (Ln = Eu, Yb)[18] as well as in **1**. As all the other carbazolate ligands in **2** do not connect further, Tm^{III} has a low coordination number of six and shows only dimers and no chains in the crystal structure. The dimeric units and coordination spheres around Tm^{III} in **2** are shown in Figure 4, while Figure 5 gives a view of the packing of the dimers in the crystal structure of **2**. The $Tm^{III}-N$ distances range from 220.8(3) to 228.2(3) pm, with the longest distance being found for the linking carbazolate ligands. These distances are in the region expected for the ionic radius of Tm^{III},[33] but shorter than in $[(Et_2C(C_4H_3N)_2]_3Tm][K(Tol)]_3$ (233−239 pm) or [(Et$_8$-calix[4]tetrapyrrole)Tm][K(DME)] [236−238 pm for the $Tm^{III}-N$(amide) bonds].[34] The Tm−centroid(3)distance to the π-coordinated phenyl rings in **2** is 244.2(4) pm, with Tm−π(C) bond lengths of 274.9(4)−288.7(3) ppm. The best comparable example to the η^6-phenyl−Tm interactions is found in $[Tm(DME)_2(\eta^2\text{-}C_{10}H_8)_2(\mu_2\text{-}\eta^4\text{:}\eta^4\text{-}C_{10}H_8)]$ with a Tm−π(C) distance of only 259−262 pm.[35] The coordination tetrahedron around Tm in **2** is more regular than in **1** [N1−Tm^{III}−N2: 108.1(1)°; N1−Tm−centroid(3): 122.8(1)°; N2−Tm−centroid(3): 112.2(1)°; see Table 1 for detailed atom distances and bond angles of **1** and **2**].

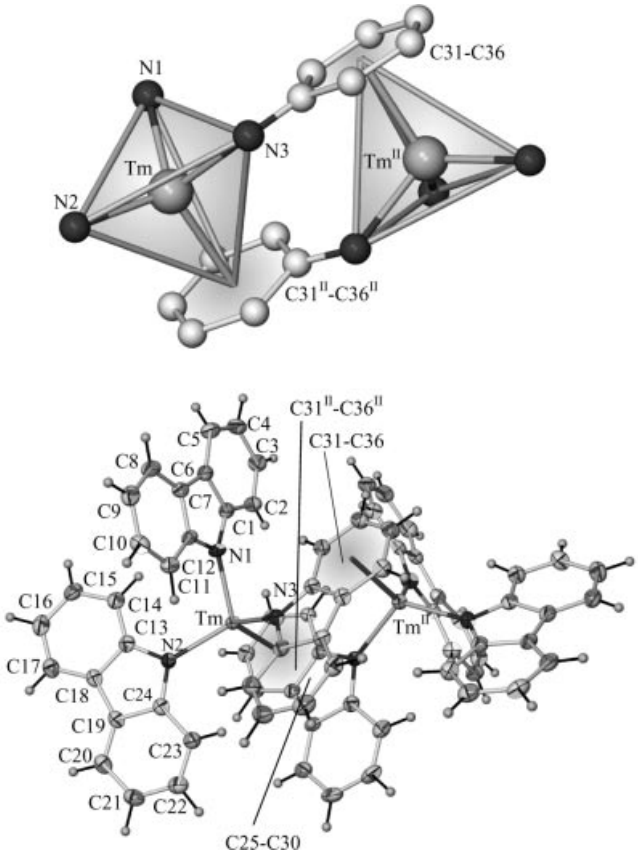

Figure 4. The coordination tetrahedra around Tm atoms (top) and the dimeric building units of $[Tm_2(Cbz)_6]$ (**2**, bottom); N−N connection lines mark only the coordination polyhedra and not bonds; π-interactions are marked by shaded planes and are represented by bonds towards centroids of the phenyl rings; symmetry operation: II: $-x, y, -z + 3/2$

The X-ray powder diffraction spectrum of $[Gd_2(Cbz)_6]$ (**4**) shows that the compound is isotypic to $[Tm_2(Cbz)_6]$ (**2**). Thus, the description of the crystal structure in the space group *Pbcn* is analogous to that of **2**. Because of the larger ionic radius of Gd^{III} compared to Tm^{III},[33] the unit cell is about 300×10^6 pm^3 larger than in **2**. $[Nd_2(Cbz)_6]$ (**3**) is not isotypic to **2**. The powder diffractogram of **3** can be indexed to give an orthorhombic cell of about half the size of the unit cell of **2**, with no unindexed lines. The large difference in the ionic radii of Nd^{III} and Tm^{III} is responsible for a different unit cell and thereby a different crystal structure. Considering this difference a tripled unit cell of **3** shows a volume increase of about 300×10^6 pm^3 compared to Gd^{III} in **4** or 600×10^6 pm^3 compared to Tm^{III} in **2**, and therefore is in good accordance with the radii increase throughout the series of rare-earth elements. Though the

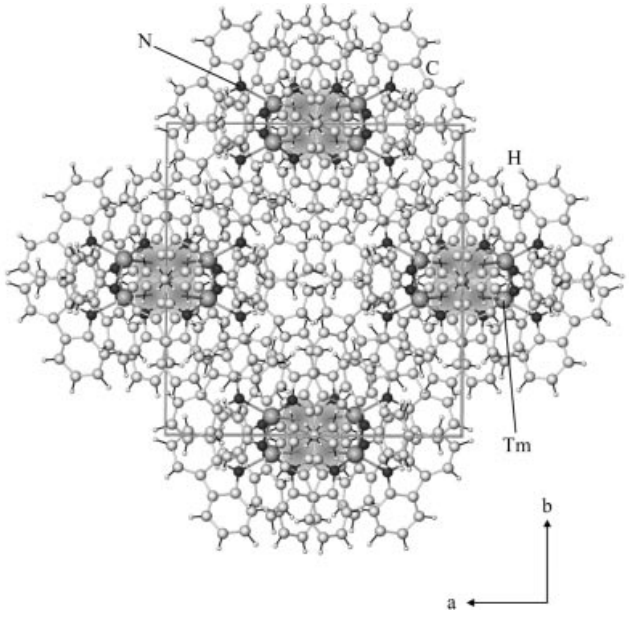

Figure 5. The crystal structure of $[Tm_2(Cbz)_6]$ (**2**) with a view of the unit cell along [001]; without further interaction between the dimeric units, the structure is a packing of dimers; η^6-interactions between Tm and phenyl rings are represented by bonds towards centroids and shaded rings

structure of **2** and **4** makes it likely that **3** also forms dimeric units, this remains unproven. Together with the results of microanalyses and the MIR and FIR spectra, the powder diffraction investigations of **3** and **4** confirm the trivalent character of neodymium and gadolinium as well as the absence of uncoordinated carbazole molecules in the structures.

Conclusions

The formation of **1**−**4** shows the possibility of obtaining homoleptic amides of the rare-earth elements that is an inherent feature of solvent-free melt synthesis methods. In the absence of any coordinating solvent the carbazolate ligands have no option but to completely saturate the coordination sphere around the large rare-earth ions. The results are structures that are unique in rare-earth amide chemistry and depend on additional η^6-π interactions as well as normal σ-N bonds. The course of the redox potentials from $E_{Eu^{II/III}} = 0.35$ V to $E_{Sm^{II/III}} = 1.57$ V and $E_{Tm^{II/III}} = 2.27$ V, $E_{Nd^{II/III}} = 2.62$ V up to $E_{Gd^{II/III}} = 3.9$ V[21,22] reflects the valences of the homoleptic carbazolates. Whilst divalent Eu and Yb compounds can be obtained,[18] Sm is mixed-valent in **1** with alternating Sm^{II} and Sm^{III}. Tm already gives pure trivalent **2**. Accordingly, all other rare-earth elements with redox potentials higher than Tm can also be expected to give trivalent compounds, as is shown by the neodymium and gadolinium carbazolates **3** and **4**. Due to the different stoichiometries, divalent, mixed-valent and trivalent homoleptic carbazolates, although having some common structural elements, have completely different crystal structures. Additional analytic methods like IR and Raman spectroscopy or thermal analysis support the results of the X-ray crystal-structure determinations.

Experimental Section

General: All reactions were carried out under argon using standard dry-box and Schlenk techniques due to the air and moisture sensitivity of **1**−**4**. Samarium, thulium, gadolinium (ChemPur), neodymium (STREM) and carbazole (Aldrich) were used as purchased. The IR spectra were recorded using a Bruker FTIR-IS66V-S spectrometer, and the Raman spectra using a Bruker FRA 106-S spectrometer. Probably because of its dark colour, **1** gave no Raman spectrum. KBr pellets were used for MIR investigations and PE pellets for FIR investigations, both under vacuum. The thermal decomposition of **1** was studied using simultaneous DTA/TG (NETZSCH STA-409). A 16.9 mg sample of the bulk of the Sm reaction was heated from 20 °C to 700 °C at a heating rate of 10 °C/min in a constant Ar flow of 60 mL/min. The thermal decomposition of **2** was studied on 17.0 mg of the bulk of the Tm reaction from 20 °C to 700 °C at a heating rate of 10 °C/min in a constant Ar flow of 60 mL/min. The thermal decomposition of **3** was studied on 38.8 mg of the bulk of the Nd reaction, and the thermal decomposition of **4** was studied on 24.3 mg of the bulk of the Gd reaction under analogous conditions to the investigations for **1** and **2**.

$^1_\infty[Sm_2(Cbz)_5](CbzH)$ (1): Samarium metal (150 mg, 1×10^{-3} mol) and carbazole (CbzH, $C_{12}H_8NH$; 501 mg, 3×10^{-3} mol) were sealed in an evacuated Duran glass ampoule. The reaction mixture was heated to 220 °C over 4 h and then to 265 °C in another 7 h. This temperature was maintained for 190 h. The melt was cooled to 200 °C over 70 h and then to room temperature over 24 h. Except for the excess of Sm metal and CbzH the reaction was complete giving a mixture of dark red to black microcrystals and black to dark red rod-shaped crystals of $^1_\infty[Sm_2(Cbz)_5](CbzH)$ with a length of 0.3 to 0.8 mm. Yield: 580 mg (89%). MIR: $\tilde{\nu}$ = 3418 s, 3049 m, 1615 m, 1603 m, 1585 m, 1580 msh, 1493 m, 1482 m, 1459 s, 1450s, 1433 s, 1336 s, 1326 m, 1288 m, 1273 s, 1262 ssh, 1236 m, 1146 m, 1118 m, 1106 m, 997 m, 927 m, 884 m, 844 m, 750 vs, 725 vs, 664 w, 569 w cm^{-1}. FIR: $\tilde{\nu}$ = 522 w, 508 w, 430 m, 424 m, 305 w, 231 m, 171 m, 146 w, 123 w, 108 w cm^{-1}. $C_{72}H_{49}N_6Sm_2$ (1298.9): calcd. C 66.63, H 3.78, N 6.48; found C 66.22, H 3.75, N 6.62.

$[Tm_2(Cbz)_6]$ (2): Thulium metal (85 mg, 5×10^{-4} mol), carbazole (334 mg, 2×10^{-3} mol) and Hg (0.2 g) were sealed in an evacuated Duran glass ampoule. The reaction mixture was heated to 240 °C over 4 h and then to 280 °C over another 3 h. This temperature was maintanied for 168 h. The melt was then cooled to 210 °C over 200 h and then to room temperature over 72 h. Except for a slight excess of Tm metal and CbzH, the reaction was complete, giving an orange crystalline bulk of crystals of $[Tm_2(Cbz)_6]$ with a length of 0.2 to 0.5 mm. Yield: 313 mg (94%). MIR: $\tilde{\nu}$ = 3419 w, 3049 m, 1618 w, 1602 m, 1493 m, 1458 ssh, 1450 vs, 1430 m, 1327 s, 1288 w, 1271 w, 1239 s, 1207 m, 1148 w, 1108 w, 1025 w, 1015 w, 932 m, 905 m, 848 w, 749 vs, 726 vs, 574 m cm^{-1}. FIR: $\tilde{\nu}$ = 432 m, 420 m, 343 w, 309 w, 251 m, 188 vw, 158 w, 143 w, 86 w cm^{-1}. Raman: $\tilde{\nu}$ = 3054 s, 1620 s, 1588 w, 1570 s, 1565 ssh, 1480 m, 1316 m, 1271 m, 1248 m, 1015 m, 744 m, 680 m, 310 w, 251 s, 200 w, 170 w, 157 w, 91 vs cm^{-1}. $C_{72}H_{48}N_6Tm_2$ (1335.1): calcd. C 64.77, H 3.62, N 6.29; found C 63.93, H 3.77, N 6.07.

$[Nd_2(Cbz)_6]$ (3): Neodymium metal (144 mg, 1×10^{-3} mol), carbazole (1032 mg, 6×10^{-3} mol) and Hg (0.2 g) were sealed in an

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

evacuated Duran glass ampoule. The reaction mixture was heated to 230 °C over 8 h and then to 280 °C over another 5 h. The melt was cooled to 245 °C over 350 h and this temperature maintained for 168 h. The reaction mixture was then cooled to 210 °C over another 350 h and to room temperature over 72 h. Except for the excess CbzH, the reaction gave a golden yellow bulk of $[Nd_2(Cbz)_6]$. Yield: 548 mg (85%). MIR: $\tilde{\nu}$ = 3419 w, 3049 m, 1625 w, 1601 m, 1493 m, 1456 ssh, 1450 vs, 1426 w, 1394 w, 1336 m, 1327 s, 1286 w, 1238 s, 1205 w, 1138 w, 1106 w, 1009 w, 996 w, 928 m, 914 w, 857 w, 842 w, 748 vs, 725 vs, 574 s, 564 ssh cm^{-1}. FIR: $\tilde{\nu}$ = 440 m, 425 m, 352 w, 221 m, 145 m, 123 m, 102 w, 70 w cm^{-1}. Raman: $\tilde{\nu}$ = 3056 s, 1625 s, 1573 s, 1480 w, 1311 s, 1311 s, 1289 s, 1260 w, 1011 s, 741 m, 430 m, 280 m, 230 m, 104 s cm^{-1}. $C_{72}H_{48}N_6Nd_2$ (1291.1): calcd. C 66.98, H 3.72, N 6.51; found C 66.37, H 3.96, N 6.47.

$[Gd_2(Cbz)_6]$ (4): Gadolinium metal (157 mg, 1×10^{-3} mol), carbazole (668 mg, 4×10^{-3} mol) and Hg (0.2 g) were sealed in an evacuated Duran glass ampoule. The reaction mixture was heated to 200 °C over 6 h and to 280 °C over another 8 h for activation. The melt was cooled to 245 °C over 4 h and the temperature maintained for 336 h. The reaction mixture was then cooled to 210 °C over another 180 h and then to room temperature over 24 h. Except for the excess of CbzH the reaction gave a poorly crystalline dark yellow bulk of $[Gd_2(Cbz)_6]$. Yield: 526 mg (80%). MIR: $\tilde{\nu}$ = 3417 w, 3050 m, 1603 s, 1581 m, 1492 s, 1471 ssh, 1450 vs, 1426 m, 1407 s, 1325 vs, 1263 w, 1237 vs, 1207 msh, 1149 w, 1118 w, 1025 w, 1015 w, 930 w, 906 w, 750 vs, 726 vs, 569 m cm^{-1}. FIR: $\tilde{\nu}$ = 444 w, 430 m, 420 m, 363 w, 243 m, 231 wsh, 159 m, 148 wsh, 72 w cm^{-1}. Raman: $\tilde{\nu}$ = 3055 s, 1624 s, 1570 s, 1481 m, 1311 s, 1288 m, 1261 m, 1011 s, 742 m, 429 m, 297 m, 258 m, 240 w, 101 s cm^{-1}. $C_{72}H_{48}N_6Gd_2$ (1317.1): calcd. C 65.65, H 3.64, N 6.38; found C 65.74, H 3.70, N 6.39.

X-ray Crystal-Structure Determination: The data collection for single-crystal X-ray determinations of **1** and **2** were carried out with an IPDS-II diffractometer (STOE). Structure solutions: SHELXS-86;[36] structure refinements: SHELXL-97.[37] Integrity of symmetry and geometry: PLATON.[38] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of **2** were found in the Fourier map while the hydrogen atoms of **1** were placed in calculated positions and assigned to an isotropic displacement parameter of 1.2-times the size of the isotropic displacement parameter of the parent carbon atom. The nonlinking Cbz anion of **1** is disordered over two positions in a ratio of about 1:1. The crystal of **1** used for data collection shows another small crystalline individual grown on the surface (RECIPE).[39] The two individuals were separated (TWIN)[39] and refined individually. Compounds **3** and **4** were investigated on powder samples in sealed capillaries with a STOE STADI P transmission diffractometer (Cu-$K_{\alpha 1}$ radiation λ = 1.540598 Å, focussed single crystal germanium monochromator). Because **3** and **4** lose their crystallinity upon grinding, samples of both compounds had to be made only roughly homogeneous. Both were investigated in 0.5 mm capillaries, though this led to a higher background due to absorption phenomena of the rare-earth atoms. The diffraction patterns of the neodymium (**3**) and the gadolinium (**4**) compounds were compared with simulated diffractograms of **1** and **2** as well as the divalent europium and ytterbium carbazolates.[18] The cell constants of **3** were refined on 11 reflections with the best possible resolution leading to an orthorhombic unit cell without un-indexed lines and an average $\delta(2\Theta)$ of 0.018° [T = 293(2) K, a = 1899(2) pm, b = 1118.5(9), c = 920(1) pm, V = 1953.5(26) 10^6 pm^3]. The cell constants of **4** were refined on 23 reflections with the best possible resolution without un-indexed lines and an average $\delta(2\Theta)$ of 0.016° [T = 293(2) K, a = 1723(1) pm, b = 1888(1), c = 1710.5(9) pm, V = 5569.7(32) 10^6 pm^3], indicating that $[Gd_2(Cbz)_6]$ is isotypic with $[Tm_2(Cbz)_6]$ (**2**).[40] Crystallographic data for $C_{72}H_{49}N_6Sm_2$ (**1**): Monoclinic, $P2_1/c$, Z = 4, T = 170(1) K, a = 1835.3(2), b = 1657.0(2), c = 1937.9(2) pm, β = 112.138(8)°, V = 5458.8(1)·10^6 pm^3, μ = 21.8 cm^{-1} (Mo-K_α), 3.34° ≤ 2θ ≤ 50.0°, −21 ≤ h ≤ 20, −19 ≤ k ≤ 19, 0 ≤ l ≤ 23, F(000) = 2584, R_1 = 0.0745 for 4644 reflections [$I > 2\sigma(I)$], R_1 = 0.1288 and wR_2 = 0.1208 for all 9545 unique reflections, GOOF on F^2 = 0.886. Crystallographic Data for $C_{72}H_{48}N_6Tm_2$ (**2**): Orthorhombic, $Pbcn$, Z = 4, T = 170(1) K, a = 1712.2(2) pm, b = 1802.5(2) pm, c = 1699.7(2) pm, V = 5245.9(9)·10^6 pm^3, μ = 34.1 cm^{-1} (Mo-K_α), 3.28° ≤ 2θ ≤ 54.64°, −21 ≤ h ≤ 21, −23 ≤ k ≤ 23, −18 ≤ l ≤ 21, F(000) = 2640, R_1 = 0.0249 for 4147 reflections [$I > 2\sigma(I)$], R_1 = 0.0430 and wR_2 = 0.0581 for all 5831 unique reflections, GOOF on F^2 = 0.926. CCDC-220967 (**1**) and -241797 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44 1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

COVER PICTURE

The cover picture shows the reaction pathways available to $Ru_3(CO)_{10}$(dppe) in the catalytic hydrogenation of diphyenylacetylene, as elucidated by parahydrogen-assised NMR spectroscopy. The cluster leads to catalytic hydrogenation via a detected vinyl hydride intermediate, but fragments in low polarity solvents. Details are discussed in the article by S. B. Duckett et al. on p. 4381ff. We thank Universities UK (ORS award), Bruker Biospin UK and The University of York for financial support.

Switching of Molecular Spin States in Inorganic Complexes by Temperature, Pressure, Magnetic Field and Light: Towards Molecular Devices

Azzedine Bousseksou,*[a] Gábor Molnár,[a] and Galina Matouzenko[b]

Keywords: Spin crossover / Metastability / Hysteresis loop / Pressure / Magnetic field / Dielectric properties / Ising-like model

The spin crossover phenomenon in molecular inorganic compounds is one of the most spectacular examples of bistability phenomena leading to a switching between the high-spin and the low-spin states of the molecule by several means such as temperature, pressure, light and magnetic field (multi-property molecular switching). In the present microreview we report our most important findings, both experimental results and theoretical approaches, and discuss possible technological applications for each switching method as well as the recent synthesis of new spin crossover molecular materials.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

1. Introduction

Certain (pseudo)octahedral transition metal complexes are known to display a molecular bistability of the high-spin (HS) and low-spin (LS) electron configurations which can be distinguished by different occupations of the antibonding e_g and the nonbonding t_{2g} d orbitals of the central metal ion.[1,2] The electronic ground state of these spin crossover (SCO) complexes may be reversibly interchanged by an external stimulus such as temperature, pressure, magnetic field or light irradiation. This phenomenon was discovered by Cambi et al. as part of a study of iron(III) dithio-

Azzedine Bousseksou was born in 1964 in Algiers, Algeria, and received his Ph.D. in solid state physics from the University of Paris 6 (Pierre et Marie Curie) in 1992. He was a Research Associate at the University of Paris 6 with the group of François Varret (Physics Research Department) for one year. In 1993 he received a permanent position as a "Chargé de Recherche" at the CNRS. In 1997 he joined the Laser Laboratory and Raman spectroscopy group of Prof. John McGarvey in N. Ireland for 18 months. In 1997, he was promoted to first class of "Chargé de Recherche-CNRS". He presently leads the team "Molecular Physics Properties" at the Laboratoire de Chimie de coordination CNRS Toulouse. His field of research includes molecular bistability and molecular spin-crossover phenomena, experimental and theoretical approaches, thin films, and nanostructures and devices; he published approximately 80 articles, 2 patents, 3 book chapters and organised several workshops, he is a member of the national comity of the CNRS (2000−2004). He was awarded the 2003 prize for the Coordination Chemistry Division of the French Chemical Society.

Gábor Molnár was born in Szolnok (Hungary) in 1973. He received his M.Sc. degree in 1996 from the Eötvös Loránd University (Budapest, Hungary). He prepared his Ph.D. thesis under the supervision of P. Iacconi (University of Nice, France) and J. Borossay (Eötvös University) in the field of thermoluminescent dosimeter materials. He held a postdoctoral position for 8 months at the IMRA-Europe company (Sophia Antipolis, France) and worked on photovoltaic materials. He then joined the group of J. J. McGarvey as a Marie Curie fellow for 12 months at the Queens University of Belfast (U.K.) to develop a new high-pressure Raman spectroscopy setup. In 2002, he became Research Associate ("poste rouge") at the CNRS Laboratoire de Chimie de Coordination (Toulouse, France) where he later received a permanent position with the group of A. Bousseksou. His current research focuses on molecular bistability and molecular spin-crossover phenomena.

Galina Matouzenko obtained her undergraduate degree at Kishinev University (USSR) and her Ph.D. degree from the Institute of Chemistry, Moldavian Academy of Sciences working with Professor A. V. Ablov, one of the leading Soviet coordination chemists. Her thesis focused on the synthesis, magnetic properties and magneto-structural correlations in new exchange-coupled polynuclear complexes of transition metals. After coming to France, in 1992 she joined the Laboratory of Chemistry, UMR (Unité Mixte de Recherche) of the CNRS and Ecole Normale Supérieure de Lyon. Her current interests lie in the field of the design of new mono- and polymeric spin-transition systems.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

carbamate compounds in the early 1930s.[3] The first Fe^{II} complexes $[Fe(phen)_2(NCS)_2]$ and $[Fe(bipy)_2(NCS)_2]$ (phen = 1,10-phenanthroline, bipy = 2,2-bipyridine) with "unusual magnetic behaviour" were reported only about 30 years later.[4] Their careful reinvestigation by König[5] has shown that they represent the first examples of iron(II) SCO compounds and this marked a starting point for further extensive developments of the field, chiefly in the framework of the European TOSS TMR network coordinated by P. Gütlich.[6] Although the SCO phenomenon may occur for octahedral compounds with d^4-d^7 configurations, it is most commonly observed for iron(II) complexes with nitrogen donor atoms. Currently, about two hundred spin transition systems are known.

The SCO phenomenon has been studied by a variety of physical methods such as magnetic susceptibility and heat capacity measurements, Mössbauer, Raman, UV/Vis, IR and EPR spectroscopy and also X-ray diffraction and dielectric constant measurements.[1,2] These methods combined with temperature, pressure, high magnetic field and light irradiation provided a firm basis for the theoretical modelling of the SCO. In our group (Toulouse, France) we are particularly interested in the application of an external perturbation in the macroscopic metastable states of SCO materials leading to an irreversible switching of their magnetic, optical and electrical properties. Experiments under different external stimuli will be discussed in the second part of this paper together with a theoretical treatment of experimental data.

Concerning synthetic methods, two approaches are currently employed for designing new cooperative SCO systems, namely supramolecular and polymeric approaches. These two strategies will be illustrated in the third part of the paper using several examples of mononuclear and polymeric compounds recently synthesised at ENS Lyon (France).

2. Switching of Spin States by External Perturbations

The SCO phenomenon is one of the most spectacular examples of molecular bistability which means that SCO molecules may exist in two different electronic states within a certain range of external perturbations.[7] Most notably, the existence of a thermal hysteresis in certain SCO complexes (in the solid state) confers a memory effect on these systems. This bistability is accompanied by a marked change in various physical properties. Besides the well-known magnetic and optical responses, we have recently shown that the dielectric constant can also be used to read the state of the bistable system[8] leading to the first prototype of an electronic component for information storage.[9]

According to the pioneering ideas of O. Kahn, several compounds have been designed for which room temperature falls within the hysteresis loop.[10] Using local warming and cooling for writing and erasing, O. Kahn and his colleagues have promoted devices based on SCO materials for different applications such as temperature sensors and active elements in displays and memory devices.[7] In our group, we have pursued these ideas and proposed the use of pulsed perturbations in the hysteresis loop temperature range (macroscopic metastable states) to switch the spin state of the system (Figure 1). In the first experiments we used a pulsed magnetic field to trigger an LS → HS transition.[11] Later, we showed that a pressure pulse leads to a "mirror effect" when compared with a pulsed magnetic field.[12] Recently, other groups reported the first results of the application of a laser pulse in the hysteresis loop.[13] In this chapter we discuss the effect of different external perturbations (temperature, magnetic field and pressure) on the spin state of SCO materials from an experimental and theoretical point of view. A brief summary of light pulse induced effects completes this part. Finally, an example is given to illustrate the response functions (optical, magnetic and electric) associated with the bistability.

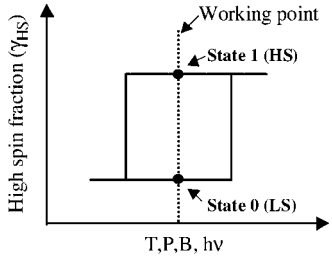

Figure 1. Schematic representation of the memory effect; the switching may be obtained by temperature, pressure, magnetic field or light irradiation

2.1. Thermally Induced Spin State Change

The thermally induced spin state change is the oldest spin-switching channel so far discovered in the field of molecular SCO compounds. The thermal spin transition curves, i.e. plots of HS fraction (γ_{HS}) vs. temperature, may take different forms such as gradual, abrupt or two-step and with or without hysteresis (see part 3 of the paper for examples). Several phenomena contribute to this different kind of behaviour, the most important being the interactions between the SCO molecules. The microscopic origins of the cooperative interactions have been extensively studied in the past and it is now generally accepted that the main contribution arises from elastic interactions between the molecules undergoing spin change. A detailed treatment of the elasticity theory was given by Spiering et al.[14]

To describe the thermally induced spin state change, in 1992 we adapted the Wajnflasz and Pick model[15] to a two-level system (HS and LS levels in our case) which we called the Ising-like model.[16] In our approach, a fictitious spin σ is associated with the HS and LS states for each molecule *i*. The Hamiltonian of the system is expressed as a function of the energy gap between the two levels of an isolated molecule (Δ_0) and a phenomenological parameter (J_{ij}) describing the interactions between the molecules *i* and *j*:

$$\bar{\mathbf{H}}_i = \frac{\Delta_0}{2}\bar{\sigma}_i - \sum_{j\neq i} J_{ij}\bar{\sigma}_i\bar{\sigma}_j$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

where $\hat{\sigma}$ is a fictitious spin operator with eigenvalues of +1 or −1 for the HS and LS states, respectively. Each level in this model represents an effective level including the electronic configuration and the vibrational density of states. In the mean field approximation, where the interaction energy of the neighbouring molecules is averaged as $J\langle\hat{\sigma}\rangle$:

$$\sum_{j\neq i} J_{ij}\hat{\sigma}_i\hat{\sigma}_j \rightarrow J\langle\hat{\sigma}\rangle\hat{\sigma}_i,$$

the magnetisation of the system, proportional to the mean value of $\sigma = \langle\hat{\sigma}\rangle$ is a self-consistent equation and the fraction of HS molecules takes the form:

$$\gamma_{HS}(T) = \frac{r}{r+\exp\frac{\Delta_0 - 2J(2\gamma_{HS}-1)}{k_BT}}$$

with $r = g^{HS}/g^{LS}$ being the degeneracy ratio of the HS and LS levels including the vibrational contributions. The equilibrium temperature $T_{1/2}$ (obtained for $\gamma_{HS} = \gamma_{LS} = 1/2$) takes the form:

$$T_{1/2} = \frac{\Delta_0}{k_B \ln r}$$

In the case where the cooperative interaction exceeds a critical value ($J > T_{1/2}$), one observes a discontinuity in the first derivative of the free energy F of the system, leading to a first-order spin transition. In this case we observed a hysteresis loop. By introducing two kinds of cooperative interactions, namely "ferro-like" (positive) and "antiferro-like" (negative), this model reproduces the main thermal SCO behaviour observed experimentally: one-step or two-step transitions, with or without hysteresis loops.[16] Figure 2 shows four examples of theoretically calculated curves.

It is now well established that the HS form is stabilised at higher temperatures due to its higher entropy (electronic and vibrational in origin) when compared with the LS form. The prominent role of the entropy difference between the HS and LS states (ΔS_{HL}) in driving the thermal spin crossover was first considered by Sorai and Seki.[17] These authors studied the heat capacity of the compound $[Fe(phen)_2(NCS)_2]$ as a function of temperature and found a heat capacity anomaly around the spin crossover temperature (176 K). The entropy change associated with the spin transition was then estimated to be $\Delta S_{HL} = (49.0\pm0.7)$ $J\cdot K^{-1}\cdot mol^{-1}$. Since the entropy change measured by Sorai and Seki is significantly larger than the electronic entropy change, they proposed that the main contribution to ΔS_{HL} arises from the coupling of the electronic state to the phonons of the system. In a first approach, this effect can be explained by the increase in the number of antibonding e_g electrons upon an LS → HS crossover of the central metal ion. This electronic change significantly weakens the metal−ligand bonds leading to lower vibrational frequencies. For example the metal−ligand stretching frequencies, which are those most influenced by the spin state change, were found to decrease by a factor of 1.5−1.8. In other words, the density of vibrational states shifts to the low frequency range when going from the LS to the HS state. Since the contribution of low-frequency modes to the vibrational entropy will be higher, this phenomenon leads to a more entropic HS state.

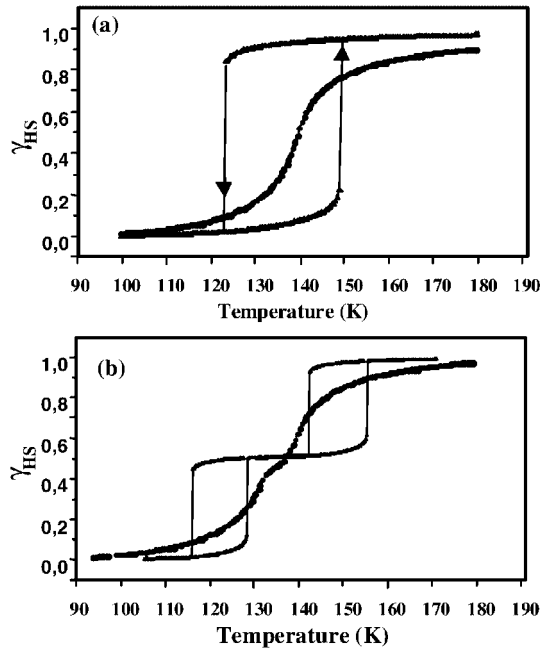

Figure 2. Calculated thermal variation of γ_{HS} using the Ising-like model: (a) one-step spin crossover: gradual ($J < T_{1/2}$) and abrupt with hysteresis loop ($J > T_{1/2}$); (b) two-step spin crossover: gradual and abrupt with two hysteresis loops

We have studied the effects of molecular vibrations on the SCO phenomenon using vibrational spectroscopic methods as experimental tools and by including the molecular vibrations in our Ising-like theoretical model.[16d,18] The vibrational spectra, even recorded by a variety of methods (Raman, IR, nuclear inelastic scattering), cannot provide the complete vibrational spectrum. For these reasons, theoretical treatments incorporating vibrational effects must inevitably rely on various approximations.

The Raman spectra of $[Fe(phen)_2(NCS)_2]$ have been analysed[18a] by making the assumption of an average frequency representative of the idealised FeN_6 octahedron. An average frequency ratio of 1.35 was obtained which is in good agreement with the result (1.5) of recent DFT calculations on the same compound.[19] Using this value, an estimated vibrational contribution to the entropy change from the coordination core of 20 $J\cdot K^{-1}\cdot mol^{-1}$ was obtained. This result supports the proposition of Sorai and Seki[17] that the intramolecular vibrations represent a prominent contribution to the overall entropy change.

The inherent limitations of the average frequency approach have been addressed by summing the entropy terms associated with the distinct vibrational modes.[18b,18c] A family of coordination polymers of formulae $[Fe(pyridine)_2(M(CN)_4)]$ and $[Fe(pyrazine)(M(CN)_4)]\cdot 2H_2O$ (M = Ni, Pd, or Pt), displaying comparatively clear-cut low-fre-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

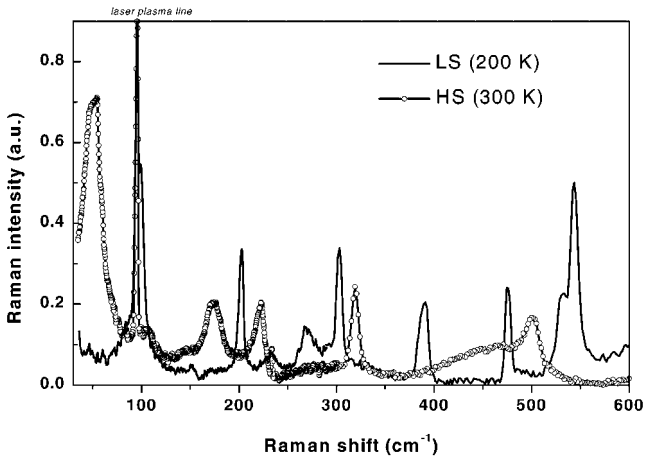

Figure 3. Raman spectra of the [Fe(pyrazine)(Pd(CN)$_4$)]·2H$_2$O spin crossover complex in the HS (300 K) and LS (200 K) states[18c]

quency vibrational spectra (Figure 3), has recently been studied by using this approach.[18c] It was shown that the spin state change in these compounds influences not only the vibrations which can be described as Fe^{II}−ligand modes but all other low-frequency modes of the polymeric network (below ca. 600 cm^{-1}). It was concluded that alongside a major contribution from the metal−ligand vibrations (ca. 60 %) other intra- and intermolecular vibrations can also make nonnegligible contributions to the entropy change (ca. 40 %). The underlying reason may involve either coupling with the Fe^{II}−ligand vibrations or with the lattice contraction/expansion that accompanies the spin transition. High pressure,[18f] isotopic substitution[18d] and metal dilution[18g] techniques combined with Raman spectroscopy and calorimetry measurements revealed that in this family of compounds, ΔS_{HL} decreases upon isotope exchange and metal dilution but does not change much with the lattice contraction. These observations suggest, therefore, that the vibrational couplings have a significant effect on the entropy change.

Thus, both infrared and Raman spectroscopy reveal a pronounced change in the molecular vibrational modes. We have also studied theoretically the effect of intramolecular vibrations on the spin crossover phenomenon for independent molecules involving a set of harmonic oscillators.[16d] Each two-level molecule is associated with p harmonic oscillators having two possible frequencies, ω_{LS} and ω_{HS} (p = 15 for an octahedral symmetry). For each oscillator of frequency ω_i, the vibrational partition function can be written:

$$z_i(\omega_i,T) = 1/[\exp(h\omega_i/kT) - 1]$$

The contribution of oscillator (i) to the total entropy is then derived from the free energy expression ($F_i = -kT\ln z_i$; $S_i = -\partial F_i/\partial T$) leading to:

$$S_i(\omega_i,T) = h\omega_i/2T\cdot\tanh(h\omega_i/2kT) - k\cdot\ln[2\sinh(h\omega_i/2kT)]$$

The total entropy of the system can be calculated by summing the contributions of the different vibrational modes. The decrease in the frequencies upon LS → HS crossover results in an entropy increase that can be expressed by:

$$\Delta S_{HL}(T) = S_{HS}(T) - S_{LS}(T)$$

The frequency dependence of the contribution of a given mode on the total entropy change calculated according to the above equations is shown in Figure 4 at different temperatures. The higher the frequency and the lower the temperature, the less the mode contributes to $\Delta S_{HL}(T)$.

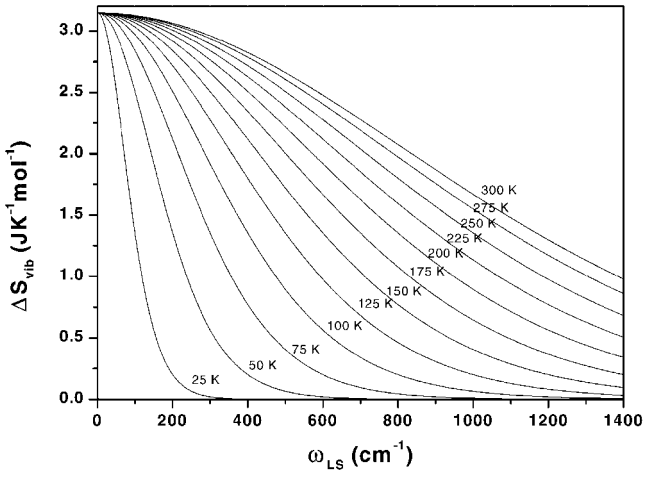

Figure 4. Vibrational entropy change of a harmonic oscillator upon spin transition as a function of the vibrational frequency; the curves were calculated with $\omega_{HS} = \omega_{LS}/1.5$ for different values of T_c [18c]

Interesting behaviour occurs due to the intramolecular vibrations when the system is in an "equi-energetic" situation. This situation corresponds to the case where $\Delta_{eff} = \Delta_{elec} - p\bar{h}(\omega_{LS} - \omega_{HS})/2 \approx 0$, i.e. when the contribution of the molecular vibrations is of the same order of magnitude as the electronic gap between the HS and LS states. In this case, the HS state will be the ground state at low temperature and one may observe, as illustrated in Figure 5, a partial SCO phenomenon with particular thermal behaviour.[16d] To date, three examples of such "equi-energetic" situations have been reported,[20] the first two examples coming from our group in 1996 and 1998.

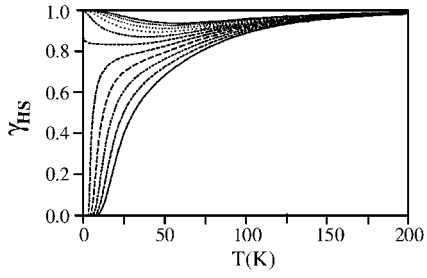

Figure 5. Theoretical thermal variation of γ_{HS} in the vicinity of the "equi-energetic" (HS, LS) situation ($\Delta_{eff} = \Delta_{elec} - p\bar{h}(\omega_{LS} - \omega_{HS})/2 \approx 0$)[16e]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2.2. Magnetic Field Induced Spin State Change

Keeping in mind that (i) a magnetic field stabilises the highest spin-state of the molecule through the Zeeman effect, (ii) the spin crossover phenomenon is a dynamic process and (iii) it is possible to generate high pulsed magnetic fields[21] (LNCMP/CNRS, Toulouse, France: 32 Tesla in 2000 and 60 Tesla currently), the idea of applying a pulsed magnetic field in the hysteresis loop was developed.

Historically, the first study using a static magnetic field of 5.5 Tesla, reported by Y. Qi et al. on $[Fe(phen)_2(NCS)_2]$, revealed a shift of the thermal spin transition by −0.12 K.[22] In the second study with cobalt complexes under a static field of 20 Tesla, J. Lejay et al. measured a shift of $T_{1/2}$ by −0.6 K.[23a] In 2000, we reported the first study of the effect of a high and pulsed magnetic field (32 Tesla) on the spin state of $[Fe(phen)_2(NCS)_2]$ and a partial triggering of the SCO was demonstrated with at least a 15 % HS fraction created in an irreversible process (Figure 6).[11a]

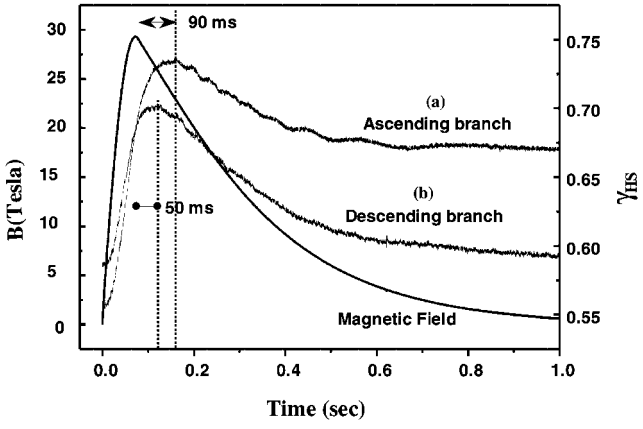

Figure 6. Magnetic pulse effect on $Fe(phen)_2(NCS)_2$; the time dependencies of $\gamma_{HS}(t)$ for two initial states belonging to the ascending (a) and descending (b) branches of the thermal hysteresis loop; for comparison, the time dependence of the magnetic field pulse is also shown[11a]

In a quasi-static approach, we modelled the observed effects under a magnetic field introduced in the Ising-like model.[11e] The magnetic field, through the Zeeman effect, removes the electronic degeneracies of the HS and LS levels and the new Hamiltonian can be written as:

$$\hat{\mathbf{H}}_i(m_S) = \frac{\Delta_0}{2}\hat{\sigma}_i + \sum_{j\neq i} J_{ij}\hat{\sigma}_i\hat{\sigma}_j + g_L\mu_B B\hat{S}_Z\frac{\hat{\sigma}_i+1}{2}$$

where μ_B is the Bohr magneton, g_L is the Landé factor, B is the magnetic field strength and S_z is the projection of the spin moment operator along the field direction. The latter can take any of the $2S + 1$ values $m_S = -S, -S + 1, ..., S$. The system can now be described by its spin state σ_i and also by m_S. In order to solve analytically the Hamiltonian of the system, we use the mean-field approximation. By explicit calculation of the mean value of $\hat{\sigma}$ we obtain for γ_{HS}:

$$\gamma_{HS}(B) = \frac{r(B)}{r(B)+\exp\frac{\Delta_0 - 2J(2\gamma_{HS}-1)}{k_BT}}$$

$$with \quad r(B) = \frac{g_{HS,vib}\,g(B,S_{HS})}{g_{LS,vib}\,g(B,S_{LS})} \quad and \quad g(B,S) = \frac{\sinh\left(\frac{(2S+1)g_L\mu_BB}{2k_BT}\right)}{\sinh\left(\frac{g_L\mu_BB}{2k_BT}\right)}$$

and for $T_{1/2}$:

$$T_{1/2} = \frac{\Delta_0}{k_B\ln\left\{\frac{g_{HS,vib}}{g_{LS,vib}}\cdot\frac{\sinh\left[\frac{(2S_{HS}+1)g_L\mu_BB}{2k_BT_{1/2}}\right]}{\sinh\left[\frac{(2S_{LS}+1)g_L\mu_BB}{2k_BT_{1/2}}\right]}\right\}}$$

where $g_{HS,vib}$ and $g_{LS,vib}$ are the vibrational degeneracies of the HS and LS states, respectively.

The exact solution of these self-consistent equations can only be obtained numerically. Figure 7 represents the resolution of the $\gamma_{HS}(T,B)$ equation using the Newton numerical method. This resolution was carried out in the case of a gradual conversion between the diamagnetic ($S_{LS} = 0$) and the paramagnetic ($S_{HS} = 2$) spin states with the parameter set as $\Delta_0 = 700$ K, $J = 139$ K, $g_{HS,vib}/g_{LS,vib} = 30$ and for different strengths of the applied magnetic field. It can be noted that for an applied magnetic field above 18 T, a first-order phase transition appears accompanied by a thermal hysteresis. This effect has also been shown qualitatively in ref.[23b] In fact, the magnetic field decreases the transition temperature but the condition for a first-order transition $J/k_BT_c > 1$ remains unchanged. This condition is illustrated in Figure 8, where, for $J = 139$ K, the first-order phase transition appears above 18 T.

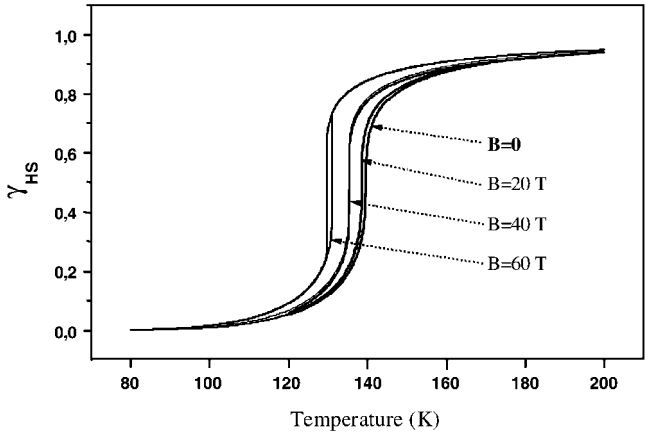

Figure 7. Calculated thermal variation of $\gamma_{HS}(T,B)$ under a static magnetic field using the Ising-like model,[11e] for selected values $B = 0$, 20 T, 40 T and 60 T; a thermal hysteresis loop (first-order phase transition) is obtained for $B = 60$ T

As described in ref.[11a] we can also obtain an analytical expression for the variation of $T_{1/2}$ as a function of the applied magnetic field strength from the Landau free energy in the presence of a field and in thermodynamic equilibrium. For an isothermal process and in the high-temperature approximation (paramagnetic Curie law), the magnetic molar free energy can be written as:

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

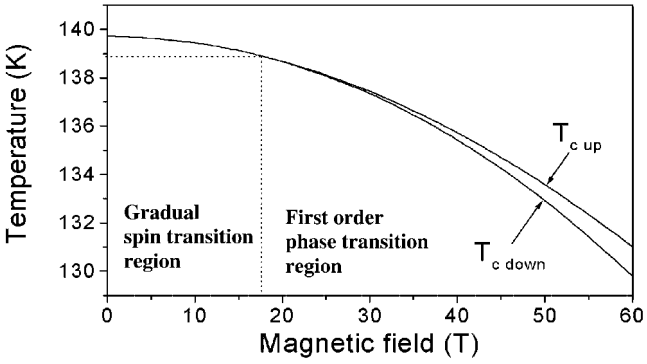

Figure 8. (B,T) phase diagram calculated using the Ising-like model (with $S_{LS} = 0$, $S_{HS} = 2$, $\Delta_0 = 700$ K, $J = 139$ K, $g_{HS,vib}/g_{LS,vib} = 30$)[11e]

$$\Delta G = G_{HS} - G_{LS} = \Delta H(0) - T\Delta S(0) - (\chi_{HS} - \chi_{LS})B^2/2\mu_0$$

where $\Delta H(0)$ and $\Delta S(0)$ refer to the properties in the absence of an external field. Accounting for the paramagnetic properties of the HS state, for a spin $S = 0 \rightarrow S = 2$ transition we obtain:[11a,11g]

$$\delta T_{1/2} = -\frac{4(\mu_B B)^2}{k_B \Delta_0}$$

and

$$\delta(\Delta) = \Delta(B) - \Delta(0) = -4(\ln g)(\mu_B B)^2/\Delta(0)$$

For a spin crossover between two paramagnetic states ($S = 1/2 \rightleftarrows S = 3/2$) the equilibrium temperature shift takes the form:[11d,11e]

$$\delta T_{1/2} = -\frac{2(\mu_B B)^2}{k_B \Delta_0}$$

The negative sign for both the equilibrium temperature and the energy gap between the HS and the LS states due to coupling to the magnetic field leads, as expected, to the stabilisation of the HS form.

Newton numerical resolution of $T_{1/2}$ obtained in the Ising-like model has been described in ref.[11e] It appears, as expected, that the transition temperature decreases quadratically with the magnetic field B and the two approaches (Ising-like and thermodynamic) are equivalent for weak magnetic fields but diverge for strong fields.

The dynamic aspects of the pulsed magnetic experiments are very interesting. In Figure 6 the peak value of the applied magnetic field (32 T) corresponds to a computed shift of the transition temperature $\Delta T_{1/2} \approx -1.8$ K which is sufficient for a complete triggering to be expected in the quasi-static regime. Therefore, the incompleteness of the spin switch can be associated with the kinetic part of the pulsed field experiment.

Subsequently, using the metal-diluted complexes $Fe_xNi_{(1-x)}(btr)_2(NCS)_2 \cdot H_2O$ [btr = 4′,4′-bis(1,2,4-triazole)], we observed a clear correlation between the cooperativity of the thermal transition and the dynamics of the triggering process. In particular, the delay between the excitation (magnetic pulse maximum) and the response increases exponentially with increasing cooperativity (J) (Figure 9).[11c,11f]

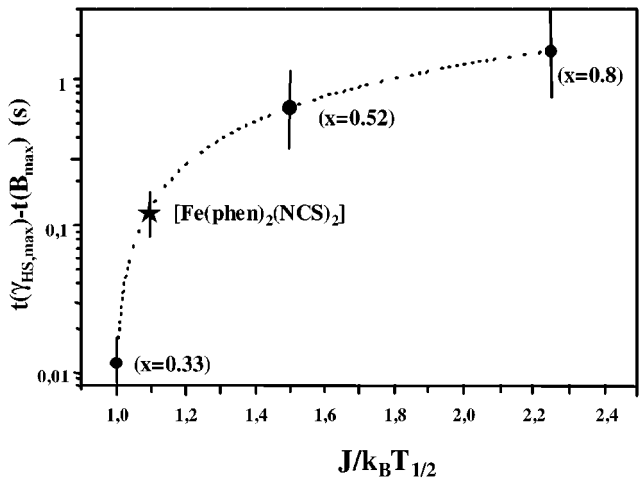

Figure 9. The time delay between $B^{max}(t)$ and $n_{HS}^{max}(t)$ on the ascending branch of the hysteresis loop (for initial temperatures corresponding to a molecular fraction $\gamma \cong {}^0_{HS} = 0.4$) for different samples of $[Fe_xNi_{(1-x)}(btr)_2(NCS)_2]\cdot H_2O$ mixed crystals as a function of J/k_BT_c;[11c] the point obtained with $Fe(Phen)_2(NCS)_2$ is also reported[11a]

This work prompted us to study, under a magnetic field, a system with a low energy barrier between the (macroscopic) LS and HS states and with a paramagnetic LS state in order to observe a complete spin-state switching. For this aim we selected the compound $Co^{II}[H_2(fsa)_2en](py)_2$.[11d] As shown in Figure 10, applying a magnetic field of 32 T to this system, initially being in the ascending branch of the hysteresis loop, leads to an irreversible and quasi-complete $S = 1/2 \rightarrow S = 3/2$ transition.

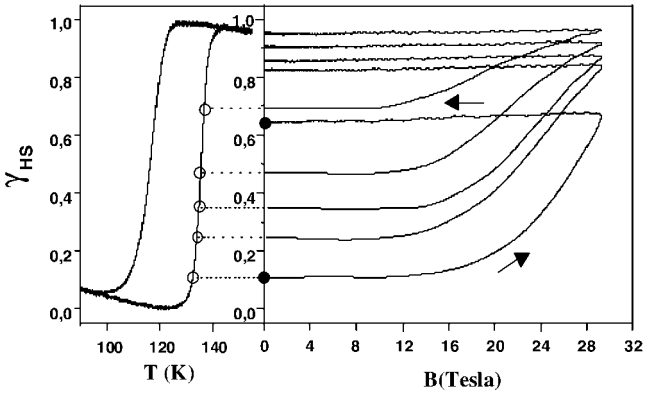

Figure 10. Magnetic pulse effect on $[Co\{H_2(fsa)_2en\}(py)_2]$; set of isotherms $\gamma_{HS}(T,B)$ showing the irreversible triggering of the LS → HS transition for an applied pulsed magnetic field in the ascending branch of the hysteresis loop;[11d] the pathway of the increase in the proportion of high-spin molecules as function of magnetic field is shown by the arrows

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The kinetic aspects of the spin crossover triggering by pulsed magnetic fields were modelled through dynamic treatments of the Ising-like model.[11d] This requires a stochastic description based on the following master equation:

$$\frac{d}{dt}p(\{\sigma\},t) = \sum_j W_j(-\sigma_j)p(\{\sigma_j\},-\sigma_j;t) - \sum_j W_j(\sigma_j)p(\{\sigma_j\},\sigma_j;t)$$

where $p(\{\sigma\},t)$ is the probability of observing the system in the configuration $\{\sigma\} = (\sigma_1, \sigma_2, ..., \sigma_N)$ at time t and $\{\sigma\}_j$ denotes the configuration of all spins, except σ_j. $W_j(\sigma_j)$ which are the transition rates of the spin flip $\sigma_j \rightarrow -\sigma_j$, induced by the thermal bath which are constrained in order to respect the microscopic detailed balance condition.

In the mean-field approximation, we obtained the following nonlinear differential equation for the HS fraction of molecules $\gamma_{HS} = (1 + m)/2$:

$$\frac{d\gamma_{HS}}{dt} = -\frac{2}{\tau_0}\gamma_{HS}e^{-\beta\varepsilon^+}e^{-2\beta qJ\gamma_{HS}} + \frac{2}{\tau_0}(1-\gamma_{HS})e^{-\beta\varepsilon^-}e^{2\beta qJ\gamma_{HS}}$$

$$\text{with } \varepsilon^{\pm} = \pm E_a^0 \mp \frac{\Delta_0}{2} \mp qJ \pm \frac{kT}{2}\ln 2\frac{g_{HS}}{g_{LS}} \pm 2\frac{(\mu B(t))^2}{kT}.$$

Figure 11 represents the solution of the equation for $\gamma_{HS}(t,T)$ in the ascending and descending branches of the thermal hysteresis loop: this model is (i) qualitatively in good agreement with the experimental behaviour and (ii) reproduces the nonreversible/reversible character of the triggering in the ascending/descending modes, respectively.

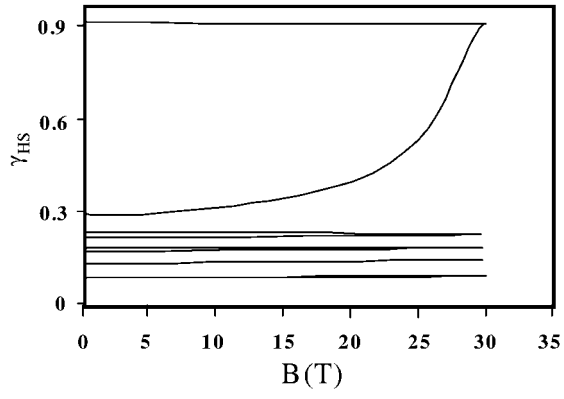

Figure 11. Calculated HS fraction as a function of the pulsed magnetic field B in the ascending branch of the hysteresis loop;[11d] no significant effects of magnetic field are observed for initial values of $\gamma_{HS} < 0.3$ (lower section of the figure)

As a summary of the main findings associated with the effects of intense and pulsed magnetic fields we refer to the following points:

1. In the first experiments with $Fe(phen)_2(NCS)_2$:[11a]

a) In the ascending (metastable) branch of the thermal hysteresis loop, a partial irreversible triggering of the spin crossover was obtained (15% of the LS molecules) by applying a 32 T pulsed magnetic field. In other words, in the ascending branch we succeeded in triggering the "first-order" (in the nonequilibrium sense) magnetic field induced spin transition.

b) In contrast to the situation with the ascending branch, reversible triggering was obtained in the descending branch (i.e. in this branch, the system cannot reach a metastable state in a magnetic field.)

c) Dynamic effects of the phenomenon are evidenced by the delay between the excitation (application of magnetic field) and the response (increase of high spin fraction) measured at 50 ms and 90 ms for the ascending and descending branches of the thermal hysteresis loop, respectively.

2. In a second series of experiments with the $Fe_xNi_{(1-x)}(btr)_2(NCS)_2{\cdot}H_2O$ family of complexes:[11c]

a) Similar effects were obtained with $x = 0.33$, 0.52, 0.8 in the ascending/descending branches of the hysteresis loops.

b) The delay between the excitation and the response increased exponentially with increasing cooperativity.

3. In a third series of experiments on $[Co(H_2(fsa)_2en)py_2]$, a quasi-total triggering of the SCO was observed[11d] and was attributed to the low energy barrier ($\Delta = 442$ cm^{-1}) between the HS and LS forms and to the paramagnetic character of the LS state ($S = 1/2$).

4. A dynamic Ising-like model, including a magnetic field, reproduced well the experimental observations.[11d]

2.3. Pressure-Induced Spin State Change

The LS → HS spin state change of the central metal ion in a molecule brings about a significant increase in the metal−ligand bond lengths and, as a result, an increase of the unit cell volume. This volume change associated with the SCO may reach several percent of the unit cell volume in iron(II) complexes as determined from X-ray diffraction data.[1,2] In the case of complexes with an $Fe^{II}N_6$ core, ΔV_{HL} is typically around 20 Å^3/iron atom.[24k,24l]

Externally applied pressure stabilises the LS state (i.e. with a smaller volume). Pressure thus has the effect of shifting the thermal spin transition towards higher temperatures.[24] It also speeds up the relaxation back to the LS state at a given temperature.[24g−24i,25a] For complexes with an $Fe^{II}N_6$ core, the shift in the transition temperature was found, in general, to be around 15 K/kbar, though in certain cases a few exceptions were also found.[24e,24f,24k]

The pressure effects on the SCO can be modelled within the Ising-like model using the mean-field approximation and by taking into account only a direct coupling between the HS fraction and the pressure through the work term which increases the energy gap ($\Delta_p = \Delta_0 + p\Delta V_{HL}$).[11g,24j,25] In this case the shift of the transition temperature with pressure is given as:

$$\delta T_{1/2}/\delta p = \Delta V_{HL}/\Delta S_{HL}$$

where ΔS_{HL} is the total entropy change upon SCO and ΔV_{HL} is the volume change. The positive sign of both ΔS_{HL}

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and ΔV_{HL} leads to a positive shift of $T_{1/2}$ with increasing pressure.

In the case of a first-order phase transition, the spin crossover is usually accompanied by a hysteresis loop. The hysteresis loop can be obtained from the Ising-like model if the condition $J > T_{1/2}$ is fulfilled.[16] The surface of the hysteresis loop is proportional to the difference between the cooperativity of the system and the equilibrium temperature [$S \sim (J - T_{1/2})$].[26] The positive sign of the shift of the equilibrium temperature obtained by the Ising-like model thus leads to a vanishing of the hysteresis loop upon increasing pressure.

The pressure-induced spin switching around room temperature can be illustrated by the example of the polymeric spin crossover compound $[Fe(Atrz)_3](NO_3)_2 \cdot nH_2O$ (Atrz = 4-amino-1,2,4-triazole). Mössbauer spectroscopic measurements have been carried out under pressure at 325 K, i.e. in the temperature range of the thermal hysteresis loop of this compound. Figure 12 shows Mössbauer spectra of this complex obtained at 325 K at low pressure (50 bar), under compression (1000 bar) and after decompression (50 bar). At low pressure the spectrum consists of a main doublet (80 %) with hyperfine parameters characteristic of Fe^{II} in the HS state (IS = 1.00 mms^{-1}, QS = 2.54 mms^{-1}) and a small (20 %) doublet (IS = 0.41 mms^{-1}, QS = 0.14 mms^{-1}) which can be assigned to LS Fe^{II} species. By application of 1000 bar, the system can be converted completely to the LS state as shown by the Mössbauer spectra. Since at the temperature of the experiment the system is in the hysteresis region of the phase diagram, after decompression it remains in the LS state, i.e. the piezo-switch is irreversible.

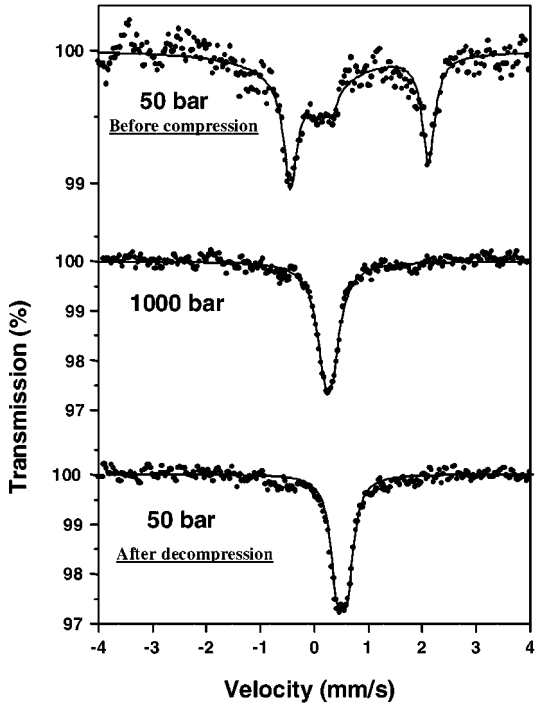

Figure 12. Pressure-induced spin switching in $[Fe(Atrz)_3](NO_3)_2 \cdot nH_2O$ at 325 K detected by Mössbauer spectroscopy

Since the early stages of SCO research, several authors have discussed interest in the influence of pressure on SCO systems.[24] However, pressure effects on these molecular materials have been found to be relatively complex. For example, pressure was often found to induce changes in the crystal structure.[27] For this reason, we decided to probe the pressure effects on SCO systems using a spectroscopic technique (Raman spectroscopy).

The spin states of a series of cyanide-bridged iron(II) spin-crossover coordination polymers of formulae $Fe(pyrazine)[M(CN)_4] \cdot 2H_2O$ (M = Ni, Pd, or Pt) have been studied by recording their solid state Raman spectra at room temperature as a function of pressure (Figure 13).[25b] For the first time, a reproducible piezo-hysteresis loop has been observed at room temperature for the Ni complex with characteristic spin transition pressures of $P_{1/2}\uparrow$ = 1350 bar and $P_{1/2}\downarrow$ = 650 bar upon compression and decompression, respectively. The fascinating feature here is the use of a perturbation other than the temperature to obtain a memory effect (piezo-hysteresis loop). Using the Ising-like model described above, we simulated piezo-hysteresis curves and we were able to show that the condition required to obtain a discontinuous pressure loop can be written as $J > T_{1/2}(p = 0) + P_{1/2}\Delta V(p)/\Delta S(p)$. Since the second term is always positive, piezo hysteresis can be expected only for complexes displaying thermal hysteresis at atmospheric pressure. Moreover, the piezo-hysteresis vanishes with increasing temperature (Figure 14). For the Pd and Pt complexes, the spin-state change occurs at higher pressures (1.8 and 3.5 kbar, respectively) and without hysteresis. The unexpectedly high value of $P_{1/2}$ in the case of the Pt complex was puzzling but Raman spectroscopy revealed that in this complex, a structural phase transition takes place at relatively low pressures (100−900 bar). The pressure-induced phase could be identified as a low-symmetry HS phase. This new HS phase transforms to the LS form only at higher pressures.

Using Raman spectroscopy in conjunction with a diamond anvil cell technique, a spin state change for the complex $Fe(pyridine)_2[Ni(CN)_4]$ could be observed at around

10 kbar.[18f] The aim of this work was to study the effect of the lattice contraction on the vibrational frequencies in the HS and LS states, generated by externally applied pressure up to 50 kbar. This question has already been brought up in several previous European discussions (TOSS network) and in theoretical investigations.[16d,28] In fact, the expansion/contraction of the lattice upon spin crossover must induce a vibrational entropy change due to the anharmonicity of vibrations. In general, this pressure-induced entropy change is neglected in the treatment of the free energy of the system, though no experimental data are available. We have determined the pressure coefficients ($d\omega/dp$) of vibrational modes in $Fe(pyridine)_2[Ni(CN)_4]$ in both the HS and LS states down to 150 cm^{-1} (Figure 15). The pressure dependence of the Raman modes was found to vary between 0.1 and 0.4 $cm^{-1}\cdot kbar^{-1}$ in the investigated frequency range for both HS and LS frequencies. We therefore concluded that at moderate applied pressures ($< 10-15$ kbar) the lattice contraction induced entropy change is small and can be in fact neglected.[18f]

Besides the static effects of pressure on the SCO we have also studied the effects of a pressure pulse in the temperature range of the thermal hysteresis loop for the compound $Fe(phen)_2(NCS)_2$.[12] During the dynamic pressure pulse, a decrease in γ_{HS} can be observed with an irreversible (reversible) character in the descending (ascending) branch of the hysteresis loop (Figure 16). In this respect, pressure has a "mirror effect" compared with the application of an intense and pulsed magnetic field for which an increase in γ_{HS} is observed with an irreversible (reversible) character in the ascending (descending) branch of the hysteresis loop. This observation can be explained by the fact that an applied magnetic field stabilises the HS state through the Zeeman effect while external pressure stabilises the LS state due to its smaller volume. If one compares the theoretical shift of the transition temperature under quasi-static external pressure with that due to a magnetic field, it appears that the effect of 1 T is roughly the opposite of the shift caused by 2.5 bar. The fact that a pressure as low as 200 bar triggered a complete crossover between the two spin-states suggests that piezo effects might be implemented in devices for addressing SCO materials (e.g. pressure sensors).

2.4. Light Pulse Induced Spin State Change

A photo-induced technique for the study of SCO in Fe^{II} complexes was first reported by McGarvey and Lawthers in 1982 in a paper describing the use of a pulsed laser to perturb the equilibrium between the singlet (^1A) and quintuplet (^5T) states in several Fe^{II} complexes in solution.[29] Then, in 1984, Descurtins et al. reported that light irradiation of a solid Fe^{II} spin crossover complex at low temperature induced a transition from the LS to a metastable HS state.[30] Subsequently, this so-called Light-Induced Excited Spin-State Trapping (LIESST) effect was intensely studied by Hauser et al. and its main elements are considered today to be well understood.[31] Though the LIESST effect is potentially interesting for use in optical devices, the low relaxation temperatures of the metastable HS species strongly limits such applications.[32]

On the other hand, recent reports suggest that it is possible to realise a photoinduced spin-state change at relatively high temperatures when exciting the solid material with a short laser pulse in the thermal hysteresis loop region. This phenomenon was first demonstrated on the complex $Fe(PM\text{-}BiA)_2(NCS)_2$.[13a] In the hysteresis loop temperature range (around 170 K), an increase of the HS fraction was obtained using single laser pulse (5 ns, ca. 1 mJ). Similar phenomena have been reported on Prussian blue analogues exhibiting thermal hysteresis loops associated with valence tautomerism.[13b] It should be emphasised that, contrary to the LIESST effect, in these experiments the *macroscopic* metastable phase (HS or LS) is photo-transformed into the thermodynamically stable phase. It was suggested that such a phenomenon could occur if the concentration of locally photo-excited states exceeds a threshold value.

These preliminary photo-switching experiments represent interesting perspectives, especially if they prove to be effective on SCO compounds exhibiting hysteresis around room temperature. However, further experiments and theoretical work are necessary to confirm the origins of these observations.

2.5. The Promising Properties for Devices

Information processing is based on the ability to modify and retrieve a particular physical property of a material such as its electrical, magnetic or optical response. In the case of spin crossover complexes, changes of magnetic and optical properties are well documented.[1] The magnetic properties change between a paramagnetic and a diamagnetic state (Fe^{II} and Co^{III} ions) or between two different paramagnetic states (Fe^{III}, Co^{II}, Mn^{II}). The change in optical properties occurs in the visible and near-IR spectroscopic regions depending strongly on the particular complex in question. Both charge transfer (MLCT) and ligand field absorption bands contribute to these spectroscopic changes.

Though optical reading has some potential applications, it is more desirable to base these on electronic functions. In fact, the use of electronic properties offers much wider scope, particularly in the context of addressing the issue of miniaturisation through the "bottom up" (i.e. molecular level) approach. In this respect, we have recently reported results demonstrating a link between the dielectric constant and the SCO phenomenon. In fact, the real part of the dielectric constant (ε') showed a significant variation at the spin transition temperature for different iron(II) spin crossover complexes.[8] The frequency dependence of ε' was found to be negligible up to 1 MHz. As far as the origin of the dielectric constant change is concerned, one can assume to a first approximation that it results from the higher polarisability of the HS ions when compared with the LS form. Indeed, for most of the complexes, we have found a higher value of ε' in the HS state. However, in the case of the complexes $Fe[5NO_2\text{-}sal\text{-}N(1,4,7,10)]$ (sal = salicylaldehyde)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and $[Fe(bpp)_2](BF_4)_2$ [bpp = 2,6-bis(pyrazol-3-yl)pyridine], ε' decreases when going from the LS to the HS state indicating that the interpretation of these changes might be more complex especially if one considers the possible existence of crystallographic phase transitions in these compounds.

As a recent example of bistability in three properties of the same compound (magnetic, optical and dielectric) the example of $[Fe(DAPP)(abpt)](ClO_4)_2$ {DAPP = [bis(3-aminopropyl)(2-pyridylmethyl)amine], abpt = 4-amino-3,5-bis(pyridin-2-yl)-1,2,4-triazole} is shown in Figure 17. The changes in all three physical channels occur as first-order phase transitions with 10 K wide hysteresis loops centred around 176 K. The high-temperature state shows a paramagnetic Curie temperature dependence of the magnetic susceptibility, with an effective magnetic moment (μ_{eff}) of 5.5 B.M. This magnetic moment corresponds to HS Fe^{II} ions with $S = 2$. Upon cooling, μ_{eff} decreases sharply around the spin transition temperature and the paramagnetism is almost completely quenched (μ_{eff} = 0.15 B.M.) at low temperatures, in agreement with a pure diamagnetic state of Fe^{II} ions ($S = 0$). The optical reflectivity measured at 632 nm also shows hysteresis. The reflectivity is higher in the HS form indicating that the optical absorption at this wavelength is lower in this state. The dielectric constant measured at 10 kHz shows an increase of ca. 8 % upon going from the LS to the HS state. The memory effect operates around 176 K by the storage of a high or low capacitance state. No significant frequency effect has been observed on ε' in the range of 10^2-10^7 Hz.

3. Engineering Spin Crossover Materials

The prerequisite for the occurrence of a spin crossover is the proximity of the HS and LS electronic states. The energy gap between two states can be tuned in a relatively predictable fashion by variation of the ligand field strength. Several synthetic strategies used in the synthesis of spin transition complexes have been summarised in a recent volume of "Topics in Current Chemistry".[1] One of the possible approaches for engineering spin transition systems, applied by our group, is the use of ligands containing both aliphatic and aromatic nitrogen donor atoms. The combination of nitrogen atoms of a different nature in the same ligand can be expected to generate an intermediate ligand field, favouring spin-state interconversion. On the basis of this strategy, numerous complexes of polydentate ligands containing different types of nitrogen binding sites have been designed.[2c][2f] On the other hand, the involvement of amino and pyridyl groups in the same ligand may exert a favourable effect on the generation of intermolecular H-bonding and/or π-stacking interactions, leading to cooperative effects. Moreover, the variation of the aliphatic to aromatic nitrogen atoms ratio in the same ligand is also a convenient tool for the fine-tuning of the ligand field strength. However, the ligand field splitting is not the only factor which determines the existence and character of a spin transition. The interplay of the spin pairing energy and the ligand field strength is very sensitive to small structural perturbations in the metal environment. They may result from the existence of sterically demanding ligands and/or from minor crystal packing changes associated with the nature of the counter ions or even the presence of a solvent of crystallisation. As has been noted,[2f] even more subtle changes such as the number of chelate rings and/or the replacement of five- with six-membered cycles can also affect the spin state of the resultant iron(II) complex. Thus, in the framework of a general synthetic approach the spin transition behaviour is not generally readily predictable.

3.1. Mononuclear Complexes

In this context, in order to study the influence on the spin transition process of small perturbations in the ligand structure, several tetradentate ligands with mixed aliphatic and aromatic nitrogen atom functions were prepared (Figure 18) and their mononuclear iron(II) complexes were investigated. The new spin transition compound $[Fe(DPEA)(NCS)_2]$ [DPEA = 2-aminoethylbis(2-pyridylmethyl)amine] was isolated and its structure, magnetic properties and Mössbauer spectra were investigated.[33] This complex displays a *cis* configuration for the two NCS groups and a *mer* arrangement of two pyridyl rings of the DPEA ligand (Figure 19). The DPEA ligand, coordinated to the metal atom by two pyridine nitrogen atoms in apical positions and two aliphatic amino groups in adjacent positions in the $[FeN_6]$ octahedron, forms three 5-membered metallocycles. The X-ray analysis revealed the existence of an important distortion of the $[FeN_6]$ core from O_h symmetry, attribu-

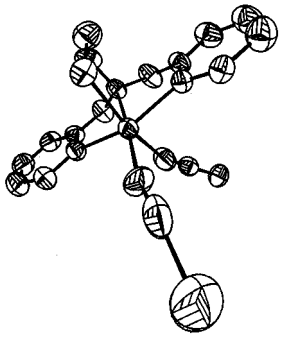

Figure 19. Molecular structure of [Fe(DPEA)(NCS)$_2$]

table to steric constraints due to the tetradentate ligand. The sharp spin conversion observed in the complex at 138 K is close to a first-order transition (Figure 20) and we anticipated that suitable changes in the structure of the ligand, which would release some strain, could modify the magnetic properties and possibly lead to a spin transition with hysteresis.

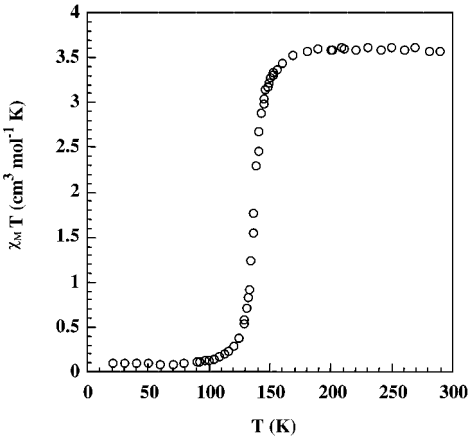

Figure 20. Thermal variation of χ_MT for [Fe(DPEA)(NCS)$_2$]

This idea was realised with the new DPPA ligand [DPPA = (3-aminopropyl)bis(2-pyridylmethyl)amine] (Figure 18) which differs from DPEA by the presence of an additional methylene unit in the amino aliphatic chain.[34] Upon coordination to iron(II), DPPA can form one 6-membered and two 5-membered chelate rings. However, during the preparation of the DPPA−iron(II) complex [Fe(DPPA)(NCS)$_2$], we isolated not a single crystalline form but four different species. Certainly, the enlargement of one of the three metallocycles leads to enhanced molecular flexibility and results in this greater variety of species. Three of these species were defined as polymorphic modifications (A, B, and C) and the fourth was a solvated complex. Only a few manifestations of polymorphism are known among spin transition systems.[35] For polymorph A, variable-temperature magnetic susceptibility measurements (Figure 21) as well as Mössbauer spectroscopy have revealed the occurrence of a rather gradual spin transition without hysteresis, centred at about 176 K. The polymorph B is paramagnetic over the temperature range 4.2−295 K, whereas polymorph C exhibits a very abrupt $S = 2 \rightleftarrows S = 0$ transition with hysteresis. The hysteresis width is 8 K, the transitions being centred at $T_c\downarrow = 112$ K for decreasing and $T_c\uparrow = 120$ K for increasing temperatures. The solvated complex [Fe(DPPA)(NCS)$_2$]·EtOH displays a rather gradual spin transition centred near 220 K. An X-ray analysis has shown that in the three polymorphs, the asymmetric units are almost identical and consist of one chiral complex molecule with the same configuration and conformation. The distorted [FeN$_6$] octahedron is formed by four nitrogen atoms belonging to DPPA and two provided by the *cis* thiocyanate groups. Contrary to our expectations, the two pyridine rings of DPPA are in the *fac* position, whereas the *mer* configuration has been isolated for [Fe(DPEA)(NCS)$_2$]. This circumstance, which made a direct comparison of the effect of metallocycle strain on magnetic properties irrelevant, offered instead a valuable opportunity to focus on the consequences of polymorphism on the magnetic properties of the same complex. The main differences between the structures of the three polymorphs are found in their crystal packings. The stabilisation of the high-spin ground state of poly-

morph B can be tentatively explained by the presence of two centres of steric strain in the crystal lattice, resulting in the elongation of the Fe−N(aromatic) distance. The observed hysteresis in polymorph C seems to be due to the existence of an array of intermolecular contacts in the crystal lattice making the spin transition more cooperative than in polymorph A. The [Fe(DPPA)$(NCS)_2$] complex provides a new and particularly striking example of polymorphism leading to qualitatively different magnetic properties in a spin transition system.

This latter example shows that the crystal structure plays a major role in the shaping of spin transitions. Packing effects appear as a small perturbation on the interplay between the ligand field and the interelectronic interactions. Besides, they determine the propagation pattern of the cooperative interactions in the solid. Unfortunately, the influence of packing effects on the spin state of the complex is neither predictable nor controllable. Another alternative, connected with the packing effects, arises when several crystallographically independent iron(II) sites co-exist in the same unit cell and structural distinctions among iron(II) complexes can result in their different magnetic behaviour.[36] This latter situation can be illustrated by the recently reported mononuclear complex [Fe(DPEA)(bim)]-$(ClO_4)_2$·$0.5H_2O$ with the DPEA ligand and bim = 2,2-bis-(imidazole).[37] Variable-temperature magnetic susceptibility measurements (77−295 K) have shown the occurrence of a two-step spin transition (Figure 22). Two steps on the magnetic curve are separated by an inflection point at 200 K, corresponding to about 50 % of the molecules having undergone a thermal spin transition. The first step is centred at 171 K and the second at 218 K. Mössbauer spectroscopy, calorimetric measurements and X-ray analyses have shown that the profile of the magnetic curve is a consequence of the presence of two nonequivalent iron(II) ions in the crystal lattice. The crystal structure was resolved in the HS and LS forms at 293 and 123 K, respectively. The main differences between both spin-state isomers were found in the geometry of the [FeN_6] core which exhibits the shorter of the Fe−N distances at lower temperatures. Two inequivalent HS molecules at two crystal lattice sites successively undergo a thermal spin transition. The attribution of the two steps of the spin transition to the inequivalent lattice sites was performed through the analysis of the mean Fe−N distances for functionally different nitrogen donor atoms. At 10 K the light-induced excited spin-state trapping (LIESST) effect was observed (Figure 23). Two critical temperatures T(LIESST) have been recorded (36 and 21 K) and attributed to the two nonequivalent iron(II) lattice sites.

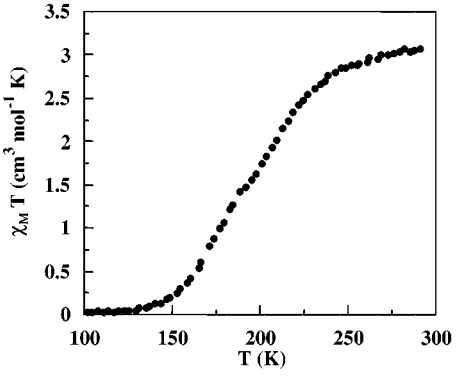

Figure 22. Thermal variation of $\chi_M T$ for [Fe(DPEA)(bim)]$(ClO_4)_2$·$0.5H_2O$

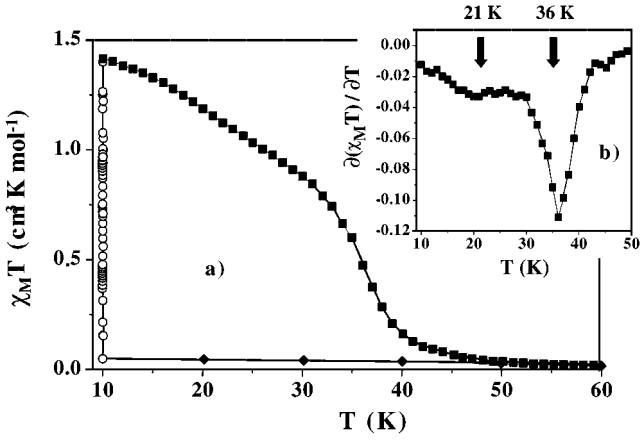

Figure 23. a) Temperature dependence of $\chi_M T$ for [Fe(DPEA)(bim)]$(ClO_4)_2$·$0.5H_2O$: data recorded in the cooling mode without irradiation (solid diamonds); data recorded with irradiation at 10 K for 2 h (open circles); data recorded in the warming mode (0.3 K min^{-1}) after the light irradiation had been applied for 2 h, then removed (solid squares); b) derivative $\partial(\chi_M T)/\partial T$

Following the study of how strain effects arising from the size of chelate rings could modify the spin-crossover regime of iron(II) complexes, the tetradentate DAPP ligand {DAPP = [bis(3-aminopropyl)(2-pyridylmethyl)amine]} (Figure 18) was then synthesised.[38] When coordinated to iron(II), DAPP can form one five-membered and two six-membered chelate rings. However, the isolated analogous complex [Fe(DAPP)$(NCS)_2$] displays only the HS state. This is certainly in line with the decrease of the ligand field strength in DAPP due to the substitution of one aliphatic nitrogen atom for an aromatic one in the DPPA ligand, resulting in an aliphatic/aromatic ratio of 3:1 in the former compared with 2:2 in the latter. Another bidentate ligand, 4-amino-3,5-bis(pyridin-2-yl)-1,2,4-triazole (abpt) was chosen to complete the octahedral coordination sphere of iron(II) and to reinforce the total ligand field strength needed for the occurrence of spin crossover. The isolated mononuclear complex [Fe(DAPP)(abpt)]$(ClO_4)_2$ displays an abrupt spin transition with a hysteresis loop of 10 K, the transition being centred at $T_c\downarrow$ = 171 K for decreasing and $T_c\uparrow$ = 181 K for increasing temperatures (Figure 24). The explanation for the pronounced cooperativity in this case was sought in the intrinsic structural features of the complex. The crystal structure was resolved in the high-spin (293 and 183 K) and low-spin (123 K) states. The X-ray analysis revealed that the cooperative spin transition results from a branched network of intermolecular interactions in the crystal lattice provided by two modes of π-stacking and numerous hydrogen bonds. The thermal spin transition is accompanied by a considerable change in the lattice param-

eters (e.g. 7.5% for the *c* axis at 123 K) which in turn impose modifications on the molecular crystal packing and, accordingly, in the system of intermolecular interactions. In connection with this, the pronounced hysteresis in this complex, without any crystallographic phase transition, can be assumed to originate from the dramatic change of the unit cell parameters and rearrangement of the topology of the cooperative interactions. The second striking result of this study is the occurrence of two order-disorder transitions (in the counter anion and in the DAPP ligand) which accompany the spin change. The role of order-disorder phenomena has been discussed in the spin-crossover literature for a long time[39] and the ordering was suggested to be related to the nature of the spin transition. So far, only the disorder of species that are not coordinated to the iron(II) such as counter anions and solvent molecules, has been observed in spin transition complexes. [Fe(DAPP)(abpt)]$(ClO_4)_2$ is, to the best of our knowledge, the first example of a spin-crossover system with an order-disorder transition involving the ligand directly coordinated to the iron(II) site. In line with previous studies, the order-disorder phenomena and spin transition in [Fe(DAPP)(abpt)]$(ClO_4)_2$ seem to be internally interrelated. One may suppose that both tuning of the ligand field strength by the DAPP ligand and reinforcement of the cooperative interactions due to the thermal ordering in the perchlorate ions provide an intrinsic impulse for the initiation of the spin transition in [Fe(DAPP)(abpt)]$(ClO_4)_2$.

To examine the role of counter ions capable of giving rise to different crystal packings, we also prepared the compounds [Fe(DAPP)(abpt)]X_2 with X = BF_4, PF_6. Their magnetic behaviour (Figure 25) shows that the nature of the counter ion plays an important role in the spin-transition regime of [Fe(DAPP)(abpt)]X_2. The complex with the tetrahedral BF_4^- anion (as in the case of ClO_4^-) displays rather similar magnetic behaviour to [Fe(DAPP)(abpt)]$(ClO_4)_2$, with the hysteresis loop slightly displaced toward higher temperatures. In contrast, the complex with the octahedral PF_6^- anion shows a gradual spin transition, shifted towards lower temperatures, without hysteresis.

3.2. Coordination Polymers

The polymeric approach to designing SCO systems exhibiting strong cooperativity was only introduced quite recently[40] and therefore the number of such compounds still remains limited. The most extensively studied family includes iron(II) complexes with 1,2,4-triazole-type ligands.[41] Some of the complexes from this family, namely $[Fe(trz)_3]A_2{\cdot}nH_2O$ (trz = 4-substituted-1,2,4-triazole; A = a monovalent anion), exhibit abrupt spin transitions with a thermal hysteresis width up to ca. 40 K.[10b] The structural information for this complex has been deduced only from EXAFS spectroscopy.[42] The structure consists of linear chains in which the iron(II) atoms are triply bridged by triazole ligands. Unfortunately, structural information on the intermolecular interactions in the crystal lattice is not available. The cooperativity in these systems can be assumed to arise from a very short Fe−Fe intersite spacing and a rigid Fe−N−N−Fe linkage favouring the efficient spreading of the intersite interactions.

Several polymeric spin-crossover complexes have been synthesised using the self-assembly of rigid bifunctional N-donating spacer ligands and iron(II) ions.[20c,43] Recently, using this approach, we synthesised a new spin-crossover compound of formula $[Fe(pyim)_2(bpy)](ClO_4)_2{\cdot}2C_2H_5OH$ [pyim = 2-(2-pyridyl)imidazole and bpy = 4,4′-bipyridine].[44] It represents the first structurally characterised example of an iron(II) coordination polymer with an infinite zigzag chain undergoing the spin-crossover phenomenon. Variable-temperature magnetic susceptibility measurements revealed the occurrence of a relatively gradual spin transition centred at 205 K (Figure 26). The crystal structure was resolved at 293 K (HS form) and at 173 K (LS form). The complex assumes a 1D zigzag chain structure in which the iron(II) active sites are linked to each other by a chemical bridge such as the rigid rod-like 4,4′-bipyridine molecule. The polymeric chains which extend along the *c* axis are stacked in the *b* direction, forming 2D sheets of bound molecules (Figure 27). The sheets are linked together by several intermolecular hydrogen bonds in the *a* direction.

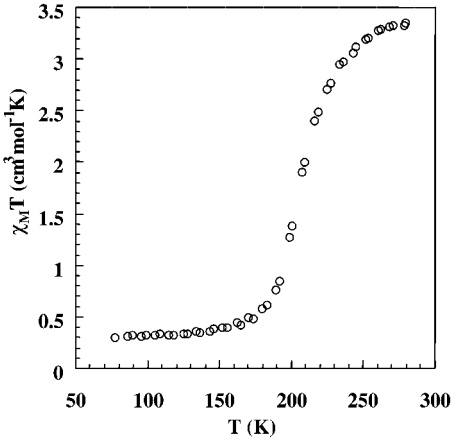

Figure 26. Thermal variation of $\chi_M T$ for $[Fe(pyim)_2(bpy)](ClO_4)_2 \cdot 2C_2H_5OH$

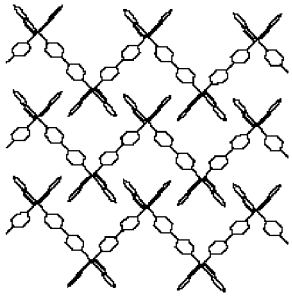

Figure 27. Projection of the molecular structure along the *a* axis for $[Fe(pyim)_2(bpy)](ClO_4)_2 \cdot 2C_2H_5OH$ showing the π−π stacking arrangement at 293 K

The ensemble of structural features of the complex, potentially leading to the cooperativity, provides a basis for strong interactions. However, they are not strong enough in comparison with the HS−LS energy gap and result in a relatively gradual spin transition for the complex. This example shows that the simple linking of active sites in the polymeric network is not in itself a sufficient condition to generate systems with the cooperative character of a spin transition. The presence of effective intermolecular interactions such as hydrogen bonding and/or π-stacking, favouring the efficient spreading of the intermolecular interactions, as well as the rigidity and conjugated nature of the chemical bridges, can contribute to the cooperativity.

4. Conclusions and Perspectives

To date, one of the most exciting perspectives in molecular science concerns the use of molecules or molecular assemblies as the active elements in devices for signal processing and information storage systems. Spin crossover and, in general, molecular bistability offer prospects for sensitivity and selectivity levels that cannot be reached with conventional solid-state materials. However, many fundamental questions remain to be answered. In particular, we need to study the effect of size reduction on the hysteresis behaviour and analyse the parameters determining the switching process (the origin of energy barriers, the mechanism of structural relaxation on both the molecular and macroscopic scales, etc.). From a chemical point of view, challenges in this field involve the problem of size-reduction and optimisation of the photo/piezo/magneto-excitation efficiency.

Acknowledgments

We deeply thank all our collaborators for their help in the realisation of the results reviewed in this paper, namely M.-L. Boillot, K. Boukheddaden, C. Consejo, P. Demont, L. Dubrovinsky, M. X-ray and Solution Structures of the First Zn Funnel Complex Based on a Calix[6]aza-cryptand

Ulrich Darbost,[a] Xianshun Zeng,[a] Marie-Noëlle Rager,[b] Michel Giorgi,[c] Ivan Jabin,*[a] and Olivia Reinaud*[d]

Keywords: Calixarenes / Cryptands / Host-guest systems / Supramolecular chemistry / Zinc

First insights into the coordinative behavior of a calix[6]tren ligand are presented. Reaction with zinc perchlorate led to a dicationic complex with the metal ion strongly bound to the tren cap. It presents a unique coordination site accessible for a small coordinating molecule that is controlled by the calixarene cavity. Hence, X-ray analysis and solution ^{1}H NMR studies evidenced a five-coordinate complex thanks to the coordination of a guest ligand, MeCN, included deep inside the calixarene cavity. Interestingly, the metal ion is bound in an asymmetrical environment in both the solid state and in solution. It is also particularly reluctant, and resistant, to anion binding.

Introduction

In nature, the control of the reactivity of a metallo site is performed by the structuring of the protein backbone in order to not only preorganize the coordination site for the metal ion, but also provide a cavity and a corridor connecting it to the bulk that controls the binding of exogeneous molecules and the reactivity of the metal ion.[1] Whilst exploring these supramolecular aspects of bioinorganic chemistry, we have developed a calixarene-based system that models mononuclear metallo-enzyme active sites.[2−4] In these systems, the binding of a zinc ion to a calix[6]arene bearing three nitrogenous arms allows the shaping of the molecular receptor. As a result, the first examples of stable tetrahedral dicationic Zn complexes were obtained. These so-called funnel complexes display unrivalled host/guest behavior toward neutral organic molecules due to the control exerted by the calixarene structure on the second coordination sphere of the metal ion and on the access to the metal center.[2] The highly flexible calix-based N_3 system appears, however, to suffer from two weaknesses: i) although highly disfavored, external binding of small molecules is not totally precluded, as evidenced in some particular cases,[4,5] and ii) the addition of a base such as triethylamine to the complex leads to decoordination and precipitation of metal hydroxides, particularly in an aprotic solvent, due to a weak chelate effect (two coordinating nitrogen centers are separated by 15 atoms). We have recently described the synthesis of a novel calix[6]aza-cryptand, namely calix[6]tren,[6] which appears to be a good candidate to remedy the weaknesses of the N_3-calix system (Scheme 1). Indeed, the tren structure offers a strong chelate effect and its tertiary nitrogen atom, which caps the narrow rim of the calixarene, closes the access in the *trans* position of the cavity for an exogenous molecule. This paper describes the first member of the calix-cryptand metal complexes family that fulfills both desired improvements of the supramolecular biomimetic system.

Results and Discussion

Complexation of zinc by calix[6]tren (**1**) was performed in a CH_2Cl_2/MeOH (1:1) mixture by reacting stoichiometric amounts of zinc perchlorate and the N_4 ligand. Under these conditions, the calix-tren Zn complex **2**⊃L (L = MeOH) was isolated in 69% yield (Scheme 1).

X-ray quality crystals of **2**⊃MeCN were grown by slow diffusion of diethyl ether into an acetonitrile solution of the complex. The crystal structure is displayed in Figure 1. As

attested by the presence of two counteranions, the Zn complex is dicationic. The metal ion is encapsulated in the calix[6]cryptand thanks to its coordination to the N_4 core of the tren cap and to a guest ligand (MeCN). The geometry is trigonal bipyramidal with some tetragonal distortion (τ = 0.76).[7] The average Zn−N distance for the trigonal base of the pyramid is 2.070 Å. This is slightly longer than found in the related tetrahedral calix-N_3 complexes,[2] in agreement with a decrease of the Zn Lewis acidity for a five-coordinate species compared to a four-coordinate one. In the axial position, the tertiary N atom capping the system is even more loosely bound to the metal ion [$d(Zn_1-N_3)$ = 2.197 Å] than the MeCN ligand [$d(Zn_1-N_5)$ = 2.107 Å]. The guest is deeply buried in the heart of the calixarene structure, with its methyl group pointing towards an aromatic ring at a perpendicular distance (3.8 Å) typical of CH-π interactions. Interestingly, weak hydrogen bonds are present between the capping secondary amino groups and either a perchlorate anion or a phenoxyl oxygen atom. Finally, the three amino arms wrapping the Zn ion do not form a helix, but adopt an asymmetric conformation with two coordinated arms presenting a relative helical orientation opposite to each other with opposite configurations at the nitrogen atoms.

The dicationic Zn complex **2**⊃MeCN has also been characterized in solution. When **2**⊃MeOH was dissolved in CD_3CN, a dissymmetrical ^1H NMR spectrum was obtained (Figure 2). Thanks to the sharpness of the spectrum, most resonances could be attributed by 2D NMR analyses (see the Exp. Sect. and Supporting Information). Compared to the free ligand, the methoxy protons are shifted downfield, which indicates that they have been expelled from the cavity by a coordinating guest. The dissymmetry of the NMR spectrum is due to the asymmetric conformation adopted by the cap due to the different configurations of the NH stereocenters, as depicted by the X-ray structure of **2**⊃MeCN.[8] When **2**⊃MeOH was dissolved in a non-coordinating solvent such as $CDCl_3$, in the presence of CH_3CN, the NMR spectrum was similar to that recorded in CD_3CN, although with an additional highfield-shifted singlet at δ = −1.11 ppm (220 K), thereby confirming the intra-cavity binding of the acetonitrile molecule. Increasing the temperature to above room temperature led to the coalescence of the calixarene resonances. At 390 K, in $Cl_2CDCDCl_2$, a C_{3v}-symmetric spectrum was obtained (see the Supporting Information). This phenomenon is explainable by the fast pyramidal inversion of the coordinated nitrogen atoms at high temperature, leading to an average C_{3v}-symmetrical conformation.

Finally, the nitrilo complex was not affected by the presence of chloride ions[9] nor by hydroxide.[10] This shows that the Zn ion is much more strongly coordinated by the calix-cryptand than it is by the calix-N_3 ligands. It also emphasizes the reluctance of these funnel complexes to bind anionic ligands due to repulsive interactions with the phenoxyl units of the calixarene structure.

Conclusion

We have described the first member of a novel family of biomimetic complexes based on an N_4-calix-cryptand. In this system, the Zn ion is strongly coordinated by the three tren NH moieties in an asymmetrical environment with the tren tertiary nitrogen atom capping the edifice. As a result, the calix-tren ligand forces the metal ion to complete its coordination sphere through the binding of a guest ligand that is deeply included in the calixarene cavity, leaving no access for an external binding in the position *trans* to the guest. The strong chelate effect provided by the tren cap confers on the complex an increased robustness compared to the parent calix-N_3 system as it does not collapse under strongly basic conditions. Hence, this calix-cryptand exerts a remarkable control on the first and second coordination sphere of the metal ion.

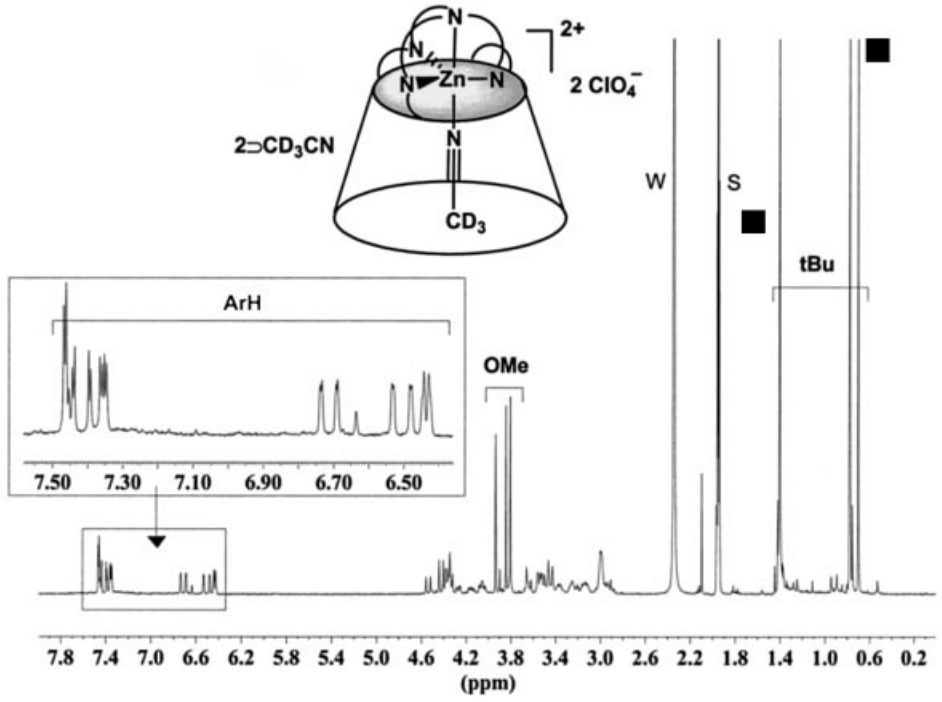

Figure 2. ^{1}H NMR spectrum (400 MHz, room temp., CD_3CN) of complex **2**⊃CD_3CN; residual solvent and water peaks have been labeled "S" and "W" respectively

Experimental Section

General Remarks: CH_2Cl_2 was distilled from CaH_2 under argon. ^{1}H and ^{13}C NMR spectra were recorded either with a Bruker Avance 400 or a Bruker Avance 300 specrtometer. Traces of residual solvent or poly(dimethylsiloxane) (R) were used as internal standard. ^{1}H and ^{13}C resonances corresponding to anisole moieties are labelled with a superscripted 1 (e.g. tBu^1, ArH^1, C$^1_{Ar}$) and the others are are labelled with a superscripted 2. They were assigned by HMBC and HMQC experiments. IR spectra were recorded on a Perkin−Elmer IRFT Paragon 1000 apparatus. Elemental analyses were performed at the Service de Microanalyse, (I.C.S.N., Gif sur Yvette, France).

Safety Note: ***Caution!*** *Although we have not encountered any problem, it is noted that perchlorate salts of metal complexes with organic ligands are potentially explosive and should be handled only in small quantities with appropriate precautions.*

Zn-calix[6]tren Complex 2: Methanol (2.5 mL), dichloromethane (3 mL) and triethylamine (0.011 mL, 0.082 mmol) were added to a flask containing $Zn(ClO_4)_2(H_2O)_6$ (30.6 mg, 0.082 mmol) and calix[6]tren (**1**; 102 mg, 0.082 mmol) under an inert atmosphere. The reaction mixture was stirred at room temperature for 30 min. After concentration to a third of the volume by bubbling argon through the solution, a crystalline product was obtained. It was separated from the solvent by centrifugation, washed with cold methanol and dried under vacuum to give **2**⊃MeOH (88 mg, 69%) as a white solid. M.p. 275 °C (decomp.). ^{1}H NMR (400 MHz, CD_3CN, room temp.): δ = 0.70 (s, 9 H, tBu^1), 0.77 (s, 9 H, tBu^1), 0.78 (s, 9 H, tBu^1), 1.40 (s, 27 H, tBu^2), 2.90−3.66 (m, 24 H, NHCH_2CH$_2$N + NHCH$_2$CH_2N + OCH$_2$CH_2N + Ar-αCH$_{eq}$), 3.80 (s, 3 H, OCH$_3$), 3.84 (s, 3 H, OCH$_3$), 3.93 (s, 3 H, OCH$_3$), 4.02−4.55 (m, 12 H, OCH_2CH$_2$NH + Ar-αCH$_{ax}$), 6.43 (br. s, 1 H, ArH^1), 6.44 (br. s, 1 H, ArH^1), 6.48 (d, J = 2 Hz, 1 H, ArH^1), 6.53 (d, J = 2 Hz, 1 H, ArH^1), 6.69 (d, J = 2 Hz, 1 H, ArH^1), 6.73 (d, J = 2 Hz, 1 H, ArH^1), 7.35 (d, J = 2 Hz, 1 H, ArH^2), 7.36 (d, J = 2 Hz, 1 H, ArH^2), 7.39 (d, J = 2 Hz, 1 H, ArH^2), 7.44 (d, J = 2 Hz, 1 H, ArH^2), 7.46 (d, J = 2 Hz, 1 H, ArH^2) ppm. ^{1}H NMR (300 MHz, 390 K, $Cl_2CDCDCl_2$): δ = 0.69 (s, 27 H, tBu^1), 1.33 (s, 27 H, tBu^2), 3.00−3.40 (m, 24 H, CH_2N + CH_2O), 3.47 (d, J = 15 Hz, 6 H, Ar-αCH$_{eq}$), 3.86 (br. s, 9 H, OCH$_3$), 4.31 (d, J = 15 Hz, 6 H, Ar-αCH$_{ax}$), 6.53 (s, 6 H, ArH), 7.25 (s, 6 H, ArH) ppm. ^{13}C NMR (75 MHz, CD_3CN, room temp.): δ = 29.4, 29.5, 30.0, 30.3, 30.7, 31.0 (Ar-αCH_2); 31.5, 31.6 [C^1(CH_3)$_3$]; 31.8 [C^2(CH_3)$_3$]; 34.5(5), 34.5(7), 34.6(2) [C^1(CH$_3$)$_3$]; 34.9(4), 34.9(8) [C^2(CH$_3$)$_3$]; 46.9, 48.5, 48.9 (NHCH_2CH_2N); 49.6, 51.1, 51.5 (OCH$_2$$CH_2$NH); 51.7, 52.0, 52.3 (NHCH$_2$$CH_2$N); 61.4, 61.5, 62.1 (OCH$_3$); 71.7, 73.4(6), 73.5(0) (OCH_2CH$_2$NH); 123.0, 123.3, 123.9(8), 124.0(2), 124.7, 125.2 (C$^1_{Ar}$H); 129.1(0), 129.1(4), 129.2, 129.4, 129.9, 130.1 (C$^2_{Ar}$H); 132.0, 132.6, 132.9, 133.3, 133.6, 133.8, 133.9, 134.0, 135.3(5), 135.4(1) (C_{Ar}CH$_2$); 146.4, 146.5, 146.6 (C$^1_{Ar}$); 147.6, 147.8, 147.9 (C$^2_{Ar}$); 152.8 (C$^2_{Ar}$O + C$^1_{Ar}$O), 153.2 (C$^1_{Ar}$O + C$^2_{Ar}$O), 153.4 (C$^1_{Ar}$O), 154.4 (C$^2_{Ar}$O) ppm. IR (KBr): $\tilde{\nu}$ = 1637, 1482, 1120, 624 (Cl−O) cm^{-1}. [Zn($C_{81}H_{114}N_4O_6$)(CH$_3$OH)]-(ClO_4)$_2$·0.5H_2O (1545.1): calcd. C 63.74, H 7.76, N 3.63; found C 63.69, H 7.65, N 3.46.

X-ray Crystallographic Study: X-ray quality crystals of **2**⊃MeCN were grown by slow diffusion of diethyl ether into an acetonitrile solution. M_w = 1545.1, monoclinic, colorless crystal (0.5 × 0.3 × 0.3 mm^3), a = 33.7660(6) Å, b = 14.7500(3) Å, c = 37.6960(9) Å, β = 97.255(7)°, V = 18624.1(7) Å^3, space group $C2/c$, Z = 8, ρ = 1.102 g·cm^{-3}, μ(Mo-K_α) = 3.79 cm^{-1}, 9382 reflections measured at 193 K (Bruker-Nonius KappaCCD diffractometer[11]) in the 0.54−27.83° θ range, 8901 unique, 969 parameters refined on F^2

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

using 8901 reflections [Shelxl][12] to final indices $R[F^2 > 4\sigma F^2] = 0.1292$, $wR = 0.4056$ [$w = 1/[\sigma^2(F_o^2) + (0.35P)^2 + 40.0P]$ where $P = (F_o^2 + 2F_c^2)/3$]. Some remaining densities outside the calixarene complex were attributed to diffused and highly disordered water molecules. One of the two perchlorate counteranions was found to be disordered and was split on two sites with occupancies equal to 0.5. One *tert*-butyl group was treated in the same way. All hydrogen atoms were introduced in theoretical positions, included in the calculations but not refined. The last residual Fourier positive and negative peaks were equal to 0.930 and −0.933 respectively.

[8] The use of $Zn(OTf)_2$ or $Zn(picrate)_2$ salts led also to a similar dissymmetrical ^{1}H NMR spectrum in CD_3CN. In the case of the zinc picrate complex, integration of the picrate signal confirmed the presence of two equivalents of anion versus calixtren.

[9] When $ZnCl_2$ was added to a CD_3CN solution of **1**, the ^{1}H NMR spectrum of the resulting Zn complex was identical to the one obtained from Zn perchlorate. The same procedure with the previously reported calix-N_3 system[2] led to the formation of dimeric species (unpublished data). With Cu, the presence of chloride gave rise to a tetranuclear complex.[5]

[10] The addition of four equivalents of tetrabutylammonium hydroxide (0.1 M solution in toluene/methanol) or a large excess of TEA (up to 126 equiv.) did not affect the NMR spectrum of the complex, even in $CDCl_3$. With the classical calix-N_3 based complexes,[2] addition of hydroxides or TEA in $CDCl_3$ led to instantaneous precipitation of $Zn(OH)_2$.

Solvothermal Syntheses and Structural Characterisation of Three Isostructural 3D Metal-Malate Coordination Polymers: $\{[M(C_4H_4O_5)(H_2O)]\cdot H_2O\}_n$ ($M = Co^{II}$, Ni^{II}, Co^{II}/Ni^{II})

Feng-Tong Xie,[a,b] Li-Mei Duan,[a] Ji-Qing Xu,*[a] Ling Ye,[c] Ya-Bing Liu,[a] Xi-Xue Hu,[a] and Jiang-Feng Song[a]

Keywords: Malate bridges / Solvothermal synthesis / Coordination polymer / Quinque-dentate ligand

Three isostructural coordination polymers with the general formula $\{[M(C_4H_4O_5)(H_2O)]\cdot H_2O\}_n$ [M = Co^{II} (**1**), Ni^{II} (**2**) and $1/3Co^{II} + 2/3Ni^{II}$ (**3**), $C_4H_4O_5$ = $Hmal^{2-}$, malate dianion] have been designed and synthesised via solvothermal routes. In these compounds, the malate acts as the unique quinque-dentate ligand with all five oxygen atoms participating in the coordination. The M^{II} ions are interconnected via α- and β-carboxyl groups from the malate ligands to generate zigzag chains and planes which are further linked together by the β-carboxyl groups leading to the 3D open frameworks. Variable temperature magnetic susceptibility measurements indicate the occurrence of antiferromagnetic (**1**), ferromagnetic (**2**) and ferrimagnetic (**3**) interactions between the M^{II} ions mediated by the *skew-skew* carboxylate bridges.

Introduction

Considerable effort has been made towards the construction of metal-organic frameworks by employing various organic linkers such as carboxylates, bipyridyl and other multifunctional ligands. The use of di- and polycarboxylates can generate a large number of coordination complexes composed of chains, sheets and 3D networks with an enormous variety of intriguing structural topologies. Such systems have received considerable attention due to their fascinating properties as well as their potential applications in many fields. A survey of the synthetic procedures attempted reveals that some of them deal with rigid bridging ligands such as benzenedi-,[1] benzenetri-,[2] benzenetetra-[3] and benzenehexacarboxylates[4] or nitrogen-containing heterocyclic dicarboxylates[5] while others employ flexible aliphatic dicarboxylates as bridging ligands such as malonate,[6] succinate,[7] maleate,[8] fumarate,[8,9] glutarate[10] and adipate.[11] However, the hydroxyl polycarboxylates (HPCs) such as malate, citrate and tartrate have been less studied as building blocks in the construction of metal-organic frameworks though they can display versatile coordination modes. In contrast to the aliphatic dicarboxylate compounds, the presence of the hydroxyl group in HPCs allows the formation of five- and six-membered rings which can stabilise the solid networks. In the metal-HPC systems, much attention has been focused on the compounds of V, Mo or W because malic or citric acid often act as a substitute for homocitric acid in synthetic model studies of nitrogenase and the extended networks of M-HPCs systems have not been further explored.

The malate ligand, besides two terminal carboxyl groups, contains a hydroxyl group in the α-position which can potentially provide an additional coordination site. In all known malate-bridged compounds, the oxygen atoms of the alkoxy or hydroxyl groups participate in coordination along with the α-carboxyl and/or β-carboxyl groups. As well as being an important biological ligand, malate has been found to be a versatile ligand in coordination chemistry. Structurally characterised metal-malate compounds include monomers,[12] dimers,[13] tetramers[14] and polymeric chain compounds[15] as well as a 3D coordination polymer based on copper ions and ternary mixed ligands.[16] To the best of our knowledge, no higher-dimensional network containing malate and water molecules as ligands has been constructed up to now. In addition, similar to the aliphatic dicarboxylates such as malonate or fumarate,[17] malate can also act as a suitable candidate for engineering the design of molecular magnets.

Our exploration of the solvothermal chemistry of the M-HPC systems has resulted in the discovery of some new

compounds with unusual coordination modes. Herein we report the solvothermal syntheses, crystal structures and magnetic behaviour of three isostructural compounds $\{[M(C_4H_4O_5)(H_2O)]\cdot H_2O\}_n$ [$C_4H_4O_5$ = $Hmal^{2-}$ (malate dianion), M = Co^{II} (**1**), Ni^{II} (**2**) and $1/3Co^{II} + 2/3Ni^{II}$ (**3**)] in which the coordination mode is unique and has not been previously reported.

Results and Discussion

Solvothermal reactions of the corresponding mixtures of cobalt(II) (or/and nickel) acetate (or chloride), malic acid, 4,4-bipyridine (4,4-bipy) and KOH in an alcohol-water medium yielded crystals of the title compounds. At first we try to synthesise the coordination polymers containing both malate and 4,4-bipy as bridging ligands. However, only the title compounds without 4,4-bipy were obtained under the selected reaction conditions. We also substituted the cobalt salts with iron dichloride to attempt to synthesise iron analogues of the title compounds under similar conditions but this was not successful.

Single-crystal X-ray structural analyses reveal that the metal centres M^{II} (Co^{II}, Ni^{II} and Co^{II}/Ni^{II}) in the title compounds are in distorted octahedral environments coordinated by three different malate ligands and one water molecule as shown in Figure 1. In each case three coordination positions are occupied by O(1), O(4) and O(3) coming from the α-carboxyl, β-carboxyl and hydroxyl groups of the same malate ligand, respectively. Two other coordination sites are occupied by O(2) and O(5) from the α-carboxyl and β-carboxyl groups from two different malato ligands and the sixth coordination site is occupied by OW(1) from a water molecule. The MO_6 polyhedra are severely distorted from idealised octahedral symmetry, the Co−O distances range from 2.0646(18) to 2.1126(19) Å with an average value of 2.0913(19) Å for compound **1**. The O−Co−O angles between neighbouring oxygen atoms range from 86.48(8) to 95.74(8)° except for two smaller angles [O(1)−Co−O(3), 79.04(7)°; O(3)−Co−O(4), 81.59(8)°] caused by the hydroxyl-oxygen atom. This is due to the formation of five- and six-membered chelate rings. For compound **2**, the Ni−O distances range from 2.035(2) to 2.088(2) Å with an average value of 2.056(2) Å. The O−Ni−O angles between neighbouring oxygen atoms range from 85.58(10) to 95.58(9)° except for the angles O(1)−Ni−O(3) [80.95(9)°] and O(3)−Ni−O(4) [82.38(9)°]. The corresponding bond lengths and angles of compound **3** are close to those in **1** and **2**.

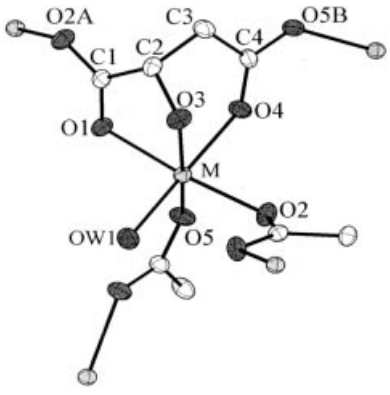

Figure 1. The coordination environment of M^{II} in **1**, **2** and **3**

The malate dianion coordinates to one M^{II} ion and acts as a tridentate ligand via its hydroxyl, α-carboxyl and β-carboxyl groups in a *face*-mode, while the α-carboxyl and β-carboxyl groups further coordinate in a monodentate fashion to the other M^{II} ions in the position trans to the hydroxyl group. The β-carboxyl groups bend back to chelate the M^{II} ions and the C(2)−C(3)−C(4) angles are reduced to 115.9(2)°, 115.7(3)° and 115.5(3)° for **1**, **2** and **3**, respectively. The angles of O(1)−C(1)−O(2A) are 125.1(2)°, 124.8(3)° and 125.3(3)°, and O(4)−C(4)−O(5B) are 123.4(2)°, 123.3(3)° and 124.1(3)° for compounds **1**, **2** and **3**, respectively. Both α-carboxyl and β-carboxyl groups adopt nonplanar *skew-skew* coordination modes and two bridged metal atoms on opposite sides of the carboxylate plane[18] and the corresponding torsion angles of compound **1** are as follow: Co−O(1)−C(1)−C(2) 8.12(29)°, Co−O(2A)−C(1)−C(2) 153.63(17)°; Co−O(4)−C(4)−C(3) 14.33(43)°, Co−O(5B)−C(4)−C(3) 164.53(20)°.

In the title compounds, each μ_3-malate dianion adopts a quinque-dentate coordination mode and all of the five oxygen atoms participate in the coordination towards three metal centres. It follows that each M atom in the crystal structure is attached to three different malate groups. As shown in Figure 2, the M^{II} ions are connected through α- and β-carboxyl groups to form zigzag chains in the [100] direction and the corresponding zigzag layers are further linked together by β-carboxyl groups of malate ligands roughly in the [010] direction leading to the formation of the 3D open frameworks (Figure 3). Figure 2 also shows the distribution of coordinated and lattice water molecules in the [001] direction. The OW(2) atoms of lattice water molecules form

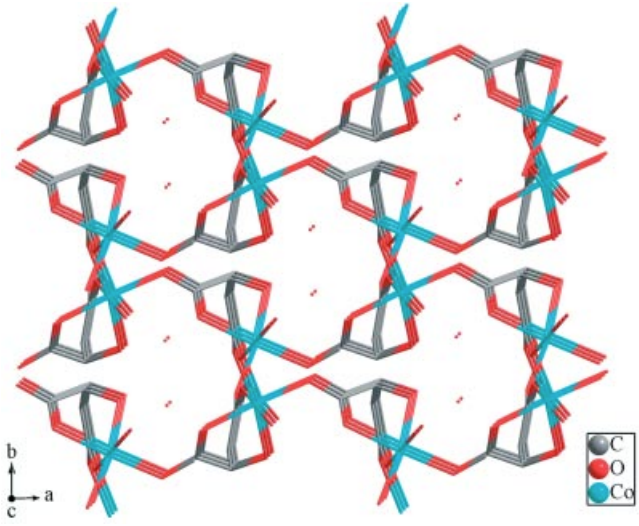

Figure 2. View of the network structure in the [001] direction, hydrogen atoms have been omitted for clarity

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

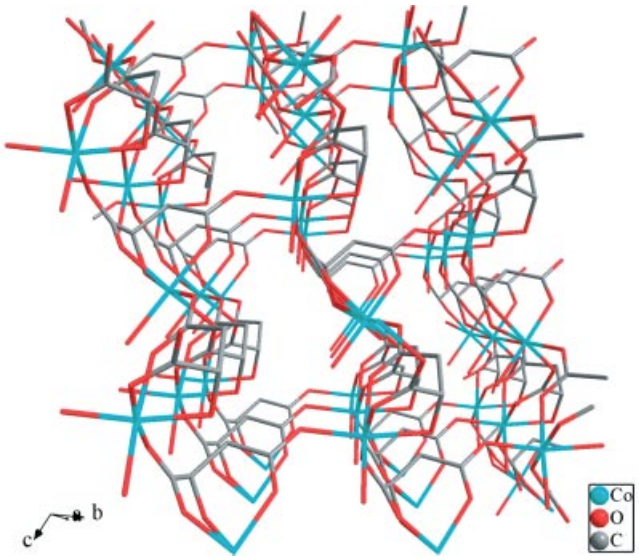

Figure 3. The packing diagram of compound **1** showing the 3D structure, hydrogen atoms and lattice water molecules have been omitted for clarity

hydrogen bonds with O(2) (symmetry mode: x, $-1 + y$, z) and the OW(2)···O(2) distance is 2.918(3) Å. The rhombic 16-membered channels consisting of M−O−C−O−M vectors along the [010] direction can be seen in Figure 4. The adjacent M···M distances are about 5.2 Å (through α-carboxyl groups) and 5.3 Å (through β-carboxyl groups).

The magnetic properties of compounds **1**, **2** and **3** were studied as a function of temperature (2−300 K) in a fixed magnetic field (5000 Oe). As the temperature is lowered, the χ_m values increase slowly until around 50 K in **1** and 20 K in **2** and **3**. They then dramatically increase at lower temperatures still. The data above 50 K can be fitted with Curie−Weiss functions with a Weiss constant $\theta = -20.21$ K and a Curie constant $c = 2.92$ cm^3·K·mol^{-1} for compound **1**, and $\theta = +2.38$ K and $c = 1.32$ cm^3·K·mol^{-1} for **2**. These are characteristic of overall antiferromagnetic (**1**) and ferromagnetic (**2**) interactions, respectively.

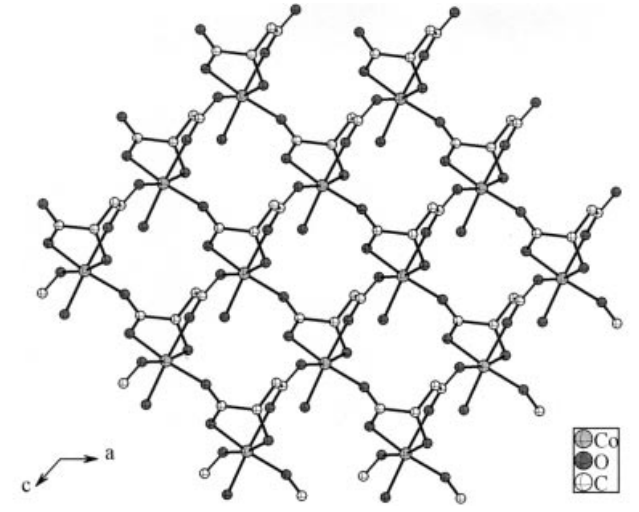

Figure 4. View of the network structure showing the channels in the [010] direction, hydrogen atoms and lattice water molecules have been omitted for clarity

Plots of μ_{eff} (the effective magnetic moment) versus T are shown in Figure 5 (compounds **1** and **2**). The μ_{eff} values of **1** decrease slowly from 4.65 μ_B at 300 K to 4.10 μ_B at 50 K and then decrease rapidly reaching 2.67 μ_B at 2 K. The μ_{eff} value of 4.65 μ_B at 300 K for compound **1** is larger than the spin-only value for high-spin cobalt(II) (3.87 μ_B per cobalt(II) ion with $g = 2.0$) and consistent with that expected for an octahedral cobalt(II) with an important orbital contribution.[19] For compound **2**, the μ_{eff} value of 3.18 μ_B at 300 K is close to the expected spin-only value (3.11 μ_B per nickel(II) with $g = 2.2$). Upon cooling, and in contrast to compound **1**, the μ_{eff} values of **2** increase slowly reaching 3.32 μ_B at 50 K and 3.42 μ_B at 30 K, then increase rapidly at low temperature. For compound **3**, as the temperature decreases, the μ_{eff} values (3.90 μ_B, 300 K) decrease slowly reaching steady values between 3.75 μ_B and 3.73 μ_B from 50 K to 24 K. This is then followed by a sharp increase below 24 K which is characteristic of ferrimagnetic behaviour.

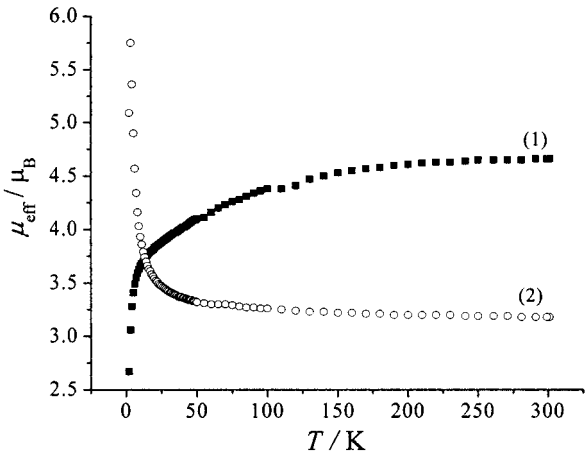

Figure 5. Thermal variations of μ_{eff} for compounds **1** and **2**

It should be noted that the magnetic coupling between the Co^{II} and/or Ni^{II} ions through the carboxylate-malate are antiferromagnetic, ferromagnetic and ferrimagnetic for compounds **1**, **2** and **3**, respectively. Different electronic configurations of the metal ions involving three (**1**) and two (**2**) unpaired electrons could account for this. The ferromagnetic couplings in **2** are very weak but the presence of one unpaired electron in a t_{2g} type orbital of Co^{II} in **1** would increase the possibility of net overlap between the magnetic orbitals,[19,20a] thus enhancing the antiferromagnetic contributions in **1** and the ferromagnetic terms would be overcome. Ferromagnetic interactions between the nickel(II) ions have been observed in some compounds involving *anti-syn* carboxylate bridged nickel(II).[20] The magnetic behaviour of the title compounds is related to their metal centres and the carboxylate-malate bridges. Detailed magnetic analyses are currently being carried out.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The assignment of oxidation states for the cobalt and nickel atoms in the three compounds is consistent with their coordination geometries and bond valence sum calculations[21] and is also confirmed by the results of XPS measurements. The electronic binding energies of $Co2p_{3/2}$ for **1** (Figure S1 in the Supporting Information) and $Ni2p_{3/2}$ for **2** (Figure S2) are 783.2 and 856.1 eV, respectively, indicating that the oxidation states of both Co and Ni are +2. For compound **3**, the peaks at 782.4 and 855.3 eV (Figure S3) are also in the range of the electronic binding energies for $Co2p_{3/2}$ in Co^{II} and $Ni2p_{3/2}$ in Ni^{II}, respectively, which confirms the coexisistence of Co^{II} and Ni^{II}.

The thermal behaviour of compounds **1**, **2** and **3** was studied from 30 to 800 °C in air. The TGA curves indicate that the three compounds have similar thermal properties (Figure S4, see Supporting Information). Taking compound **2** as an example, the sample slowly loses one lattice water molecule and one coordinated water from 120 to 330 °C with the weight-loss of 16.2% being consistent with the calculated value of 15.9%. Upon further heating, the sample decomposes rapidly and the occurrence of an exothermic process is very clear. The decomposition is complete by about 440 °C and the residue is most probably nickel(II) oxide.

Conclusion

In this work we have, for the first time, synthesised under solvothermal conditions three isostructural coordination polymers, $\{[M(C_4H_4O_5)(H_2O)]\cdot H_2O\}_n$, [M = Co^{II} (**1**), Ni^{II} (**2**) and $1/3Co^{II}$ +$2/3Ni^{II}$ (**3**)], based on bridging malate groups and water molecules. Compared with other metal-malate compounds, the most remarkable features of the title compounds are: (a) The malate acts as the unique quinquedentate ligand and all of the five oxygen atoms participate in the coordination. (b) Three isostructural compounds show antiferromagnetic, ferromagnetic and ferrimagnetic interactions in **1**, **2** and **3**, respectively, and this interesting magnetic behaviour is related to the nature of the metal centre and the carboxylate-malate bridges in each case. In the future, it would be worthwhile exploring the relationship between the structures and properties of extended networks based on transition metals and HPCs.

Experimental Section

Syntheses of 1, 2 and 3: The three compounds were prepared in an analogous manner and the detailed synthetic procedures are as follows. Compound **1** was prepared from a weakly acidic mixture of cobalt(II) acetate tetrahydrate (0.75 g, 3.0 mmol), malic acid (0.40 g, 3.0 mmol), 4,4-bipyridine dihydrate (0.20 g, 1.0 mmol), KOH (0.18 g, 3.2 mmol), distilled water (10 mL) and anhydrous alcohol (10 mL). The mixture was stirred for ca. 1 h. and was then heated under autogenous pressure at 160 °C for three days in a 30 mL Teflon-lined stainless steel vessel and finally cooled to room temperature. The purplish-red crystals were filtered, washed with distilled water and dried at ambient temperature. Yield: 0.46 g (67%, based on cobalt). X-ray quality crystals of **2** in the form of green blocks were prepared by the procedure detailed above for **1** but using nickel(II) acetate tetrahydrate instead of the cobalt(II) salt. Yield: 0.51 g (74%, based on nickel). Dark purple crystals of **3** were isolated by following the procedure detailed above for **1** but using cobalt(II) acetate tetrahydrate (0.30 g) and nickel(II) acetate tetrahydrate (0.50 g) instead of the cobalt(II) salt. Yield: 0.57 g (70%, based on cobalt). Analyses for **1, 2** and **3:**

1: $C_4H_8CoO_7$ (227.03): calcd. Co 25.96, C 21.16, H 3.55; found Co 25.47, C 21.45, H 3.38. Main IR features (KBr disk): $\tilde{\nu}$ = 3514.4 m, 3432.9 m, 2807.4 w, 1617.5 s, 1577.7 s, 1546.6 s, 1434.8 s, 1398.7 s, 1321.4 w, 1291.0 s, 1260.9 w, 1208.5 w, 1088.1 m, 1038.0 m, 806.2 m, 669.2 m, 609.5 m, 583.1 m, 545.8 m, 331.0 w cm^{-1}.

2: $C_4H_8NiO_7$ (226.81): calcd. Ni 25.88, C 21.18, H 3.56; found Ni 25.14, C 21.33, H 3.62. Main IR features (KBr disk): $\tilde{\nu}$ = 3511.1 m, 3426.4 m, 2806.9 w, 1609.2 s, 1579.8 s, 1541.4 s, 1435.0 s, 1400.0 s, 1321.8 w, 1292.1 s, 1261.6 w, 1207.1 w, 1087.7 m, 1039.1 m, 834.3 m, 680.9 m, 616.7 m, 588.9 m, 552.4 m, 355.7 w cm^{-1}.

3: $C_4H_8Co_{0.33}Ni_{0.67}O_7$ (226.89): calcd. Co 8.57, Ni 17.33, C 21.17, H 3.55; found Co 8.13, Ni 16.75, C 20.86, H 3.69. Main IR features (KBr disk): $\tilde{\nu}$ = 3509.0 m, 3428.4 m, 2807.1 w, 1609.2 s, 1573.4.8 s, 1541.9 s, 1434.5 s, 1399.5 s, 1321.6 w, 1291.7 s, 1261.3 w, 1207.3 w, 1087.8 m, 1038.7 m, 835.3 m, 678.3 m, 614.1 m, 586.6 m, 550.1 m, 349.4 w cm^{-1}.

X-ray Crystallographic Studies

Compound 1: $C_4H_8CoO_7$, M_r = 227.03, dimensions 0.299 × 0.229 × 0.100 mm, monoclinic, space group *Cc*, a = 13.211(3) Å, b = 7.564(2) Å, c = 9.758(2) Å, β = 130.83(3)°, V = 737.7(3) Å^3, Z = 4, D_c = 2.044 g/cm^3, μ(Mo-K_α) = 2.325 mm^{-1}. X-ray data were collected on Rigaku RAXIS-RAPID diffractometer at 293 K in the range of 3.4 < θ < 27.5°. Unique reflections were used to solve the structure by direct methods using SHELXS-97 which was then refined on F^2 by full-matrix least-squares methods, converging at R = 0.0237 [$I > 2\sigma(I)$] with a goodness-of-fit on F^2 of 1.149 for 110 parameters and 1600 reflections, 1600 unique reflections.

Compound 2: $C_4H_8NiO_7$, M_r = 226.81, dimensions 0.594 × 0.393 × 0.353 mm, monoclinic, space group *Cc*, a = 13.103(3) Å, b = 7.526(2) Å, c = 9.629(2) Å, β = 130.88(3)°, V = 718.0(2) Å^3, Z = 4, D_c = 2.098 g/cm^3, μ(Mo-K_α) = 2.701 mm^{-1}. X-ray data were collected on Rigaku RAXIS-RAPID diffractometer at 293 K in the range of 3.4 < θ < 27.5°. Unique reflections were used to solve the structure by direct methods using SHELXS-97 which was then refined on F^2 by full-matrix least-squares methods, converging at R = 0.0269 [$I > 2\sigma(I)$] with a goodness-of-fit on F^2 of 1.094 for 110 parameters and 1550 reflections, 1550 unique reflections.

Compound 3: $C_4H_8Co_{0.33}Ni_{0.67}O_7$, M_r = 226.89, dimensions 0.462 × 0.434 × 0.359 mm, monoclinic, space group *Cc*, a = 13.137(3) Å, b = 7.536(2) Å, c = 9.676(2) Å, β = 130.91(3)°, V = 724.0(2) Å^3, Z = 4, D_c = 2.082 g/cm^3, μ(Mo-K_α) = 2.576 mm^{-1}. X-ray data were collected on Rigaku RAXIS-RAPID diffractometer at 293 K in the range of 3.4 < θ < 27.3°. Unique reflections were used to solve the structure by direct methods using SHELXS-97 which was then refined on F^2 by full-matrix least-squares methods, converging at R = 0.0278 [$I > 2\sigma(I)$] with a goodness-of-fit on F^2 of 1.064 for 119 parameters and 1528 reflections, 1528 unique reflections.

CCDC-241829 (for **1**), -241830 (for **2**) and -241831 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/

A Parahydrogen Study of Catalytic Hydrogenation by Diphosphane-Substituted Triruthenium Clusters

Tom G. Prestwich,[a] Damir Blazina,[a] Simon B. Duckett,*[a] and Paul J. Dyson[b]

Keywords: Homogeneous catalysis / Cluster compounds / NMR spectroscopy / Parahydrogen / Ruthenium

The diphosphane-substituted clusters $[Ru_3(CO)_{10}(dppe)]$ and $[Ru_3(CO)_8(dppe)_2]$ [dppe = 1,2-bis(diphenylphosphanyl)ethane] are shown to catalytically hydrogenate diphenylacetylene. This process is highly solvent-dependent with fragmentation dominating in low-polarity solvents, which indicates that the dppe ligand does not stabilise the cluster under catalytic conditions. In solvents of higher polarity, the clusters are active hydrogenation catalysts of lower activity than their monodentate phosphane analogues $[Ru_3(CO)_{10}(L)_2]$ (L = PPh_3, PMe_2Ph, PMe_3, PCy_3).
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Catalysis by transition metal clusters is of considerable interest due to the ability of these species to act as homogeneous catalysts with properties that lie between those of mononuclear complexes and colloidal/nanoparticle catalysts, whilst also representing fragments of a metal surface.[1] The study of clusters is, however, complicated by the wide variety of reaction pathways available to them, and in particular their tendency to fragment to mononuclear metal complexes. One way to circumvent this problem might be to utilise clusters with supporting ligand scaffolds, such as bidentate phosphanes, which could potentially stabilise the cluster under catalytic conditions and hence minimise fragmentation.

Phosphane-substituted triruthenium clusters have been shown to exhibit significantly greater catalytic activity than their comparatively unreactive homoleptic parent $[Ru_3(CO)_{12}]$.[1] Compounds containing bidentate phosphane ligands have previously been studied in an effort to preclude cluster fragmentation. For example, it is well established that diphosphane-substituted triruthenium clusters react with unsaturated organic molecules,[2] yielding species that may correspond to intermediates in a catalytic cycle. It has also been shown that the 1,2-bis(diphenylphosphanyl)-methane (dppm) substituted species $[Ru_3(CO)_{10}(dppm)]$ and $[Ru_3(CO)_8(dppm)_2]$, as well as their arsanyl (dpam) analogues, react with hydrogen to form stable hydride clusters.[3] These phosphane-containing species were subsequently shown to be active catalysts for the isomerisation and hydrogenation of 1-hexene, with turnover frequencies being taken to be indicative of catalysis by an intact cluster.[4] Analogous species containing bulky cyclohexyl and pentafluorophenyl substituents on the bidentate phosphane ligand have been shown to catalyse hydroformylation reactions,[5] but exact mechanistic information about these processes remains elusive.

Consequently, we set out to explore the mechanism of catalysis by diphosphane-substituted triruthenium clusters by using the parahydrogen-induced polarisation (PHIP) effect.[6] This technique is applicable to mechanistic studies since it yields substantially enhanced resonances in ^1H NMR spectra. The extent of enhancement available has recently been shown to approach a factor of 28500,[7] making this technique ideal for the detection of transient species or those present in low concentration, such as reaction intermediates. PHIP has already been successfully used to study H_2 addition to,[8] and hydride migration on,[9] a number of triruthenium and triosmium clusters, as well as yielding unprecedented insights into catalytic hydrogenation by the tertiary phosphane (L) containing cluster family $[Ru_3(CO)_{12-x}(L)_x]$ (L = PPh_3, PMe_2Ph, PMe_3, PCy_3; x = 1−3).[10] It was discovered that isomers of $[Ru_3(H)(\mu\text{-}H)(CO)_9(L)_2]$ play a kinetically significant role in the hydrogenation of alkyne substrates such as diphenylacetylene. This catalytic transformation proceeds by initial CO loss, with each isomer exhibiting different rates for H_2 transfer to the hydrogenation product *cis*-stilbene. In addition, a less significant secondary reaction involving loss of L was detected, yielding a detectable product that contained both a pendant vinyl unit and a bridging hydrido ligand. Competing pathways involving fragmentation to form $[Ru(H)_2$-

$(CO)_2(L)(alkene)$] were also observed and shown to be favoured by nonpolar solvents. Furthermore, it has very recently been reported that the presence of a stabilising phosphido group can stabilise the metal cluster framework under catalytic conditions, such that only cluster-based active species are observed with p-H_2, even in nonpolar solvents.[11]

In this paper, PHIP is utilised to investigate catalytic hydrogenation by the clusters $[Ru_3(CO)_{10}(dppe)]$ (**1**) and $[Ru_3(CO)_8(dppe)_2]$ (**2**) [dppe = 1,2-bis(diphenylphosphanyl)-ethane]. Our aim was to confirm mechanistically by the direct observation of key dihydride species whether the presence of the bidentate ligand exerts a stabilising influence on the cluster core whilst still allowing enough flexibility for catalytic transformations to take place, as well as to compare the stabilising effect of the diphosphane ligand to that of the phosphido ligand used in an earlier study.[11]

Results and Discussion

Hydrogen Addition to $[Ru_3(CO)_{10}(dppe)]$ (1)

The literature solid-state structure of **1**,[12] with the bidentate phosphane ligand located in the equatorial plane and bridging two metal centres, is consistent with the solution-state ^1H and ^{31}P NMR spectral features at 295 K (Table 1), which indicate the presence of only one ^{31}P environment. In addition, only one broad resonance is observed in the carbonyl region of the ^{13}C NMR spectrum at $\delta = 210.4$ ppm. This is indicative of rapid carbonyl exchange around the cluster framework under these conditions. Such effects have been reported in triiron clusters containing dppe ligands where evidence has been presented to support exchange by a merry-go-round mechanism[13] rather than the alternative mechanism of cluster core libration within the ligand polyhedron.[14]

On addition of p-H_2 to a $CDCl_3$ solution of **1** at 295 K, a new species, **3**, was formed, which yielded two mutually coupled enhanced hydride resonances at $\delta = -12.87$ and -14.74 ppm (Figure 1, Table 1). Based on previous work, it is suggested that the lower-field resonance corresponds to a terminal hydride (H_t), while the higher field resonance corresponds to a bridging hydride (H_b).[3,10] On careful examination, the resonance corresponding to H_b was found to appear as a doublet of doublets of antiphase doublets, indicative of coupling to two ^{31}P nuclei. The associated $^2J_{H,P}$ values of 9 Hz (to P_a signal at $\delta = 63.6$ ppm; by

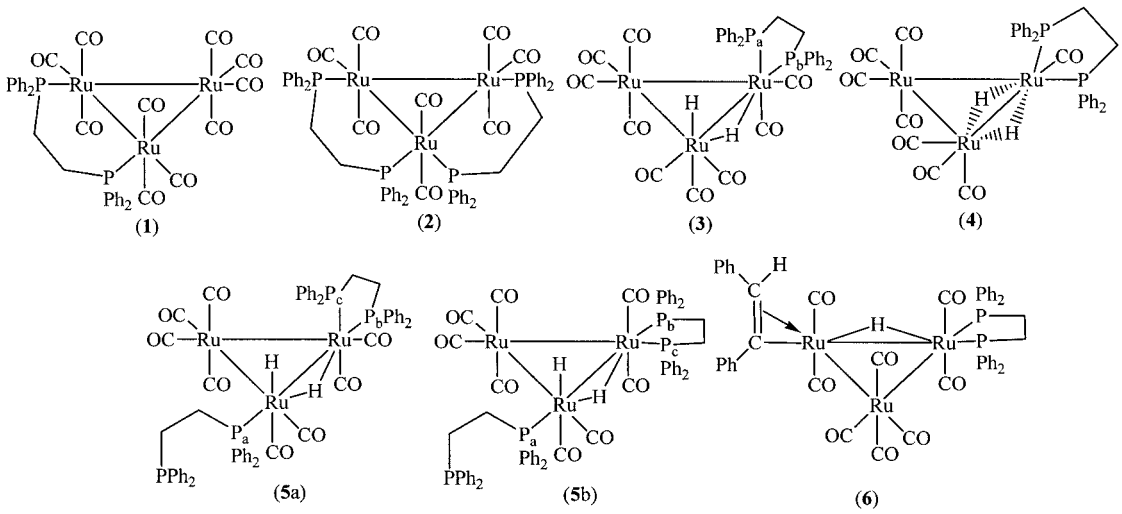

Figure 2. Structures of clusters **1**−**6**; **1** and **2** are from the literature,[12] the others were determined in this study

HMQC methods) and 23 Hz (to P_b signal at $\delta = 57.4$ ppm) indicate that H_b is *cis* to P_a and *trans* to P_b, as shown in Figure 2.[15] Both these ^{31}P centres were detected as simple singlets (vide infra). The resonance for H_t, meanwhile, appeared as a simple antiphase doublet. However, ^{31}P decoupling experiments revealed the presence of a small (3 Hz) coupling between H_t and P_b. In view of the very small size of the coupling between H_t and P_b, as well as the larger couplings from H_b to P_b and P_a, it is suggested that both the ^{31}P centres of the dppe ligand are located on the same Ru centre, which also coordinates the bridging hydride. The small phosphorus coupling between H_t and P_b therefore corresponds to a weak three-bond coupling, which is relayed through the Ru−Ru bond that is *trans* to P_b.

In view of the distinct *trans* and *cis* H_b-P coupling constants observed here, it is suggested that the dppe ligand occupies one axial and one equatorial centre on this metal centre. Previous reports indicate that ^{31}P centres in adjacent equatorial sites can exchange position rapidly on the NMR time scale.[10b] The observed singlet peak profile for the ^{31}P signals of the two sites could therefore be due to the occurrence of site exchange,[10,15] although it may arise because of mutual cancellation of the $^2J_{P,P}$ coupling through the metal centre and the $^3J_{P,P}$ coupling through the backbone of the dppe ligand. These two couplings would be expected to have opposite signs. Unfortunately, the need for *p*-H_2 amplification to detect **3** precluded the direct investigation of this process by ^{31}P EXSY methods, but the lack of any visible ^{13}C-^{31}P couplings in the associated NMR spectra of the precursor species **1** and **2** clearly demonstrates the presence of fluxionality in these systems. The proposed structure of **3** is shown in Figure 2.

Upon addition of 1 atm of CO to the sample, the hydride resonances for **3** were no longer visible at 315 K. This observation confirms that **3** is formed by loss of CO rather than the dissociation of an arm of the dppe ligand, a result which is not unexpected for a μ_2-phosphane, and further supports the proposed structure of **3**.

We have previously reported that oxidative addition of H_2 to clusters of the type $[Ru_3(CO)_{10}(L)_2]$, where L is a monodentate tertiary phosphane such as PPh_3, leads to three isomeric products of $[Ru_3(H)(\mu\text{-}H)(CO)_9(L)_2]$. One of these isomers matches the structure of **3** where both phosphane ligands are on the same metal centre but it is the least preferred of the three. The major isomer with L = PPh_3 has both phosphane ligands in equatorial locations on separate ruthenium centres spanned by the bridging hydride. Such an arrangement is not observed in the case of **3**, but would require both the dppe ligand and a hydride to bridge the same Ru−Ru bond, a situation that might be sterically unfavoured due to the elongated nature of the Ru−H−Ru bond.[16]

The hydrido ligands of $[Ru_3(H)(\mu\text{-}H)(CO)_9(L)_2]$ proved to be highly fluxional, undergoing both site exchange, interisomer exchange and reductive coupling to form H_2.[10b] The fluxional behaviour of the hydrido ligands in **3** was probed by the same EXSY methodology (Supporting Information). At 295 K, exchange between the two hydrido ligands proceeded at a rate of 3.4 s^{-1}; exchange with free H_2, which must be occurring in view of the enhanced hydride resonances exhibited by **3**, was not evident on this time scale. This behaviour is similar to that reported for $[Ru_3(H)(\mu\text{-}H)(CO)_9(L)_2]$, although it should be noted that with monodentate phosphane species, the rate of hydride interchange in the analogous isomer was slower under identical reaction conditions.

Over prolonged reaction times, the hydride resonances for **3** disappeared as the *p*-H_2 enhancement was depleted, and a stable resonance, assigned to species **4**, built up slowly at $\delta = -13.38$ ppm. This signal was split into a triplet by a 12 Hz coupling to two equivalent ^{31}P nuclei resonating at $\delta = 38.4$ ppm in the corresponding ^{31}P NMR spectrum. Since *p*-H_2 enhancement in these spectra would be quenched by a species with unpaired electrons, this resonance must correspond to two chemically equivalent hydrides, while its chemical shift is indicative of bridging hy-

dride coordination. In the view of the configuration of the dppe ligand in **3** and of the apparent equivalence of the ^{31}P nuclei in **4**, the structure of **4** shown in Figure 2 is proposed. ^{31}P NMR investigations revealed that **4** is still a very minor product; after 18 h under H_2, the ratio of **1**/**4** was determined to be 20:1. ^{13}C NMR revealed that the carbonyl ligands in this product are highly fluxional at room temperature, with only one broad carbonyl signal being observed. According to the proposed structure, cluster **4** is an unsaturated, 46-electron species. This is not completely unexpected, since stable 46-electron dihydride clusters of the iron group, such as the osmium cluster $[Os_3(\mu\text{-}H)_2(CO)_{10}]$, are known.[17] It should, however, be noted that the ruthenium analogue $[Ru_3(\mu\text{-}H)_2(CO)_{10}]$ is unstable and can only be prepared by prolonged photolysis[18] in contrast to **4** which is stable and thermally accessible, albeit in small amounts. We further note that the hydride resonance for **4** disappears on venting the H_2.

Surprisingly, on changing the solvent to $[D_8]$toluene and warming with *p*-H_2, no cluster-containing hydrides were observed, and the only species evident was the known mononuclear complex $[Ru(CO)_2(dppe)(H)_2]$, characterised by enhanced hydride resonances at $\delta = -6.32$ and -7.55 ppm.[19] This contrasts with the situation observed with the $[Ru_3(CO)_{12-x}(L)_x]$ systems ($x = 1-3$), where the corresponding cluster-based dihydrides are observed under these conditions[10] and indicates that the dppe ligand makes the triruthenium cluster more susceptible to solvent effects than is the case with monodentate phosphanes.

Hydrogen Addition to $[Ru_3(CO)_8(dppe)_2]$ (2)

The ^{31}P NMR spectroscopic data for **2** (Table 1) indicate the presence of multiple isomers in solution, a feature already established for clusters containing multiple bidentate phosphanes;[3,5] the proposed structure of **2** is illustrated in Figure 2. When a sample of **2** was treated with *p*-H_2 in $CDCl_3$ at 295 K, two enhanced hydride signals were detected in the corresponding ^1H NMR spectrum at $\delta = -4.93$ and -5.02 ppm, due to terminal hydrides, and further two at $\delta = -14.29$ and -14.31 ppm, assigned to bridging hydrides. COSY investigations revealed that the resonances at $\delta = -4.93$ and -14.29 ppm correspond to one product (due to protons **5a**-H_t and **5a**-H_b, respectively) while those at $\delta = -5.02$ and -14.31 ppm correspond to another (due to protons **5b**-H_t and **5b**-H_b, respectively); the similarity between this situation and that previously observed for $[Ru_3(H)(\mu\text{-}H)(CO)_9(L)_2]$ (L = monodentate phosphane)[10] suggests that **5a** and **5b** correspond to two isomeric dihydride products. Characterisation of these species was complicated by hydride signal overlap, but the terminal hydride resonances could be resolved by cooling the sample to 273 K (Figure 3). The resonance for **5a**-H_t showed one coupling of 12 Hz to a single *cis*-^{31}P centre that was located at $\delta = 51.08$ ppm (P_a; Figure 2) by HMQC methods in addition to a -7 Hz H-H coupling. The analogous signal for **5b**-H_t also showed an interaction with a single ^{31}P nucleus, resonating at $\delta = 49.16$ ppm ($J_{H,P}$ = 14 Hz, P_a). It can therefore be concluded that the ruthenium centre to which the terminal hydride is coordinated also binds one phosphorus atom in both products.

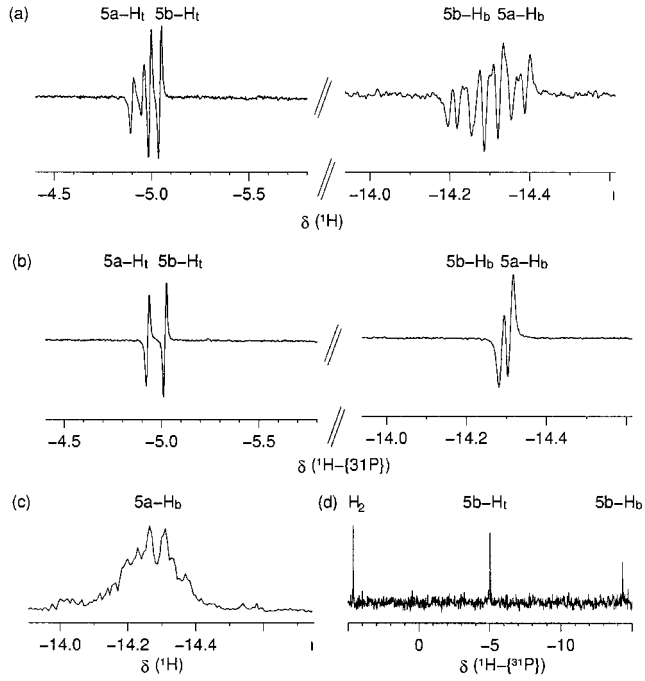

Figure 3. Selected regions of NMR spectra of **2** obtained with *p*-H_2 in $CDCl_3$ at 273 K: (a) ^1H spectrum showing the hydride resonances for **5a** and **5b**; (b) ^1H spectrum with $\{^{31}P\}$ decoupling; (c) cross-section of a 2D ^1H-^{31}P HMQC spectrum with retention of ^{31}P couplings, showing that the signal for **5a**-H_b is a triplet of doublets due to $^2J_{H,P}$ couplings; (d) cross-section of a 2D EXSY spectrum recorded at 285 K with a mixing time of 500 ms, showing exchange from **5b**-H_t into the bridging position on the same isomer and into free H_2, while exchange into **5a** is absent

As already stated, the bridging hydride signals for **5a** and **5b** show extensive overlap due to the presence of multiple ^1H-^{31}P couplings. However, they were successfully analysed by comparison of multiple high-resolution ^1H-^{31}P HMQC experiments where the ^{31}P couplings were either retained or decoupled (Figure 3). Careful examination of the two resonances in the ^1H dimension, revealed that **5a**-H_b appeared as a doublet of triplets due to two $^2J_{H,P}$ couplings of 30 Hz (to P_a at $\delta = 51.08$ ppm and to P_b at $\delta = 51.12$ ppm) and an 18 Hz coupling to P_c ($\delta = 49.03$ ppm). This suggests that P_a and P_b are *trans* to the bridging hydride, while P_c is *cis* to it. Furthermore, P_a and P_b showed a mutual ^{31}P coupling of 123 Hz, which is attributed to their *trans* arrangement across a metal−metal vector.[5,20]

P_b and P_c also coupled to each other, but with a smaller constant of 33 Hz. It can therefore be deduced that P_b and P_c are *cis* to each other and bound to the same metal centre. Since P_a is located on the Ru centre that binds the terminal hydride, the observed coupling patterns signify that the other two phosphorus nuclei must bind to the metal atom that coordinates the bridging hydride, as shown in Figure 2. In addition, since the structures of **3** and **4** suggest that the dppe ligand and the hydride do not bridge the same metal centre, P_b and P_c can be deduced to originate from the same phosphane ligand. It should also be noted that no "arti-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

facts'' arising from double and triple quantum coherences were detected in these HMQC spectra,[21] and it was therefore concluded that only single quantum transitions were being observed.

The resonance for proton **5b**-H_b was analysed in a similar way (Table 1, Figure 2). In brief, this resonance contains a 31 Hz *trans* triplet splitting to two phosphanes [$\delta = 49.16$ (P_a) and $\delta = 48.58$ (P_b) ppm] as well as a 16 Hz *cis* splitting due to P_c ($\delta = 50.30$ ppm). Nuclei P_a and P_b now exhibit a 72 Hz coupling, while P_b and P_c couple with a $^2J_{P,P}$ value of 18 Hz. Therefore, once again, P_b and P_c originate from the same dppe ligand and bind to the same ruthenium centre, which also coordinates the bridging hydride.

The structural difference between **5a** and **5b** thus stems from the orientation of the dppe ligand that contains P_b and P_c. In view of previous reports in related triosmium systems, which found that the coupling between an axial and an equatorial ligand is larger than that between two equatorial ligands,[15] it is suggested that in **5a**, P_b is an equatorial site and P_c is axial, whereas in **5b** both the phosphorus atoms are in equatorial locations. The small difference in chemical shift between axial and equatorial ^{31}P centres is in agreement with previous observations.[15] It should be noted that although the proposed structures for **3** and **5a** contain identical ligand arrangements on one ruthenium centre (a dppe ligand bridging between an axial and equatorial sites), P-P couplings are only observed in the spectra of **5a**. This indicates that the presence of the second dppe ligand on this species slows down dppe site interchange.

When these experiments were repeated in the presence of 1 atm of CO, there was no decrease in the signal intensities observed for **5a** and **5b**. It is therefore reasonable to assume that H_2 addition to **2** proceeds by a change in the coordination mode of one of the dppe ligands (in both cases, the one that contains P_a) from η^2 to η^1 (Figure 2). H_2 addition to triruthenium clusters by initial de-coordination of chelating phosphane ligands has been reported previously.[22] This mechanism also parallels the situation observed with related $[Ru_3(CO)_9(L)_3]$ systems, which undergo H_2 addition by loss of phosphane.[10d] Because of the need for p-H_2 amplification, the uncoordinated ^{31}P centres in these species could not be detected directly. Magnetisation transfer experiments have been used here to detect signals for key heteronuclei that couple directly to the hydrides, but this is not the case for the hydrides and the uncoordinated phosphorus centres of **5a** and **5b**. Attempts to detect the uncoordinated ^{31}P centres therefore proved unsuccessful but there can be no doubt of their presence.

When **5a** and **5b** were investigated by EXSY methods at 285 K, intra-isomer hydride exchange and H_2 elimination were detected in both cases (Figure 3 and Supporting Information). The rate constant for hydride self-exchange was determined to be 4.8 s^{-1} for **5a** and 4.6 s^{-1} for **5b**, while the rates for H_2 elimination were 1.5 s^{-1} for both isomers. The similarity of the intra-isomer hydride ligand exchange rates agrees with the very similar structures and relative abundances of the two isomers. Interestingly, inter-isomer exchange is not observed. These observations contrast those made on related $[Ru_3(H)_2(CO)_9(L)_2]$ systems, which exhibit both intra- and inter-isomer exchange under similar conditions.[10] Intra-isomer hydride exchange in $[Ru_3(H)_2(CO)_9(PPh_3)_2]$, under these conditions, occurs at the slower rate of 1.6 s^{-1}, and elimination of H_2 is also slow on the NMR time-scale.[10] The bidentate phosphane therefore facilitates hydride site exchange and H_2 elimination in these clusters.

At prolonged reaction times, the enhanced hydride signals corresponding to **5a** and **5b** disappeared as the extent of p-H_2 enrichment fell. However, no new stable dihydride species were detected at this point with only **2** being evident in the corresponding ^1H and ^{31}P NMR spectra. This indicates that the η^1-dppe ligand is able to re-coordinate with concurrent H_2 elimination. Repeating the investigation in [D_8]toluene once again yielded enhanced hydride resonances for the known mononuclear species $[Ru(CO)_2(dppe)(H)_2]$,[19] and no cluster based hydride products were observed.

Catalytic Hydrogenation of Diphenylacetylene

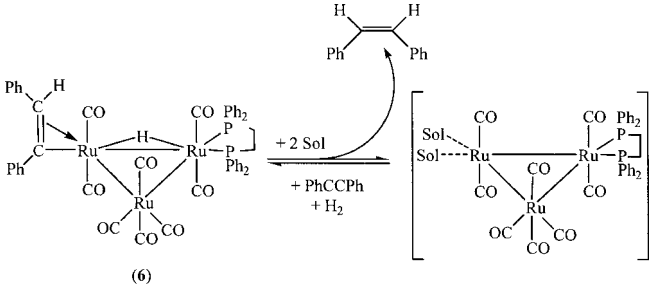
In order to examine the catalytic activity of these systems towards the hydrogenation of diphenylacetylene, samples of **1** and **2** were monitored in $CDCl_3$ in the presence of p-H_2 and a 100-fold excess of the substrate. When **1** was examined in this way, the formation of **3** was totally suppressed and a new species, **6**, was detected at 315 K and above (NMR spectroscopic data: Table 1). This species yielded two enhanced ^1H resonances at $\delta = -14.36$ and $+7.25$ ppm in the corresponding ^1H NMR spectrum, which were shown to couple by COSY experiments. The hydride resonance appeared as a triplet of antiphase doublets (Figure 1), due to coupling to two identical phosphorus centres (J_{PH} = 12 Hz) and the vinyl proton ($J_{H,H} = -4$ Hz). On the basis of similarity of these spectral features to those reported previously,[10,11] **6** is suggested to correspond to a vinyl hydride cluster, where the sign of the $J_{H,H}$ coupling indicates that the vinyl group occupies the two equatorial locations on a single ruthenium centre (Figure 2). In order for the ^{31}P centres to appear equivalent at these elevated temperatures, the dppe ligand must be located on the opposite metal centre to the vinyl group, occupying the two equatorial sites (cf. **4** and **5b**). Phosphane ligands in such arrangements are able to undergo rapid exchange, which would make them appear equivalent to the bridging hydride.[10b]

These spectra also contained an enhanced resonance for *cis*-stilbene, the hydrogenation product of diphenylacetylene. EXSY investigations revealed direct magnetisation transfer from **6** into *cis*-stilbene was occurring (Figure 1) and thereby confirmed that **6** is an active intermediate involved in catalytic hydrogenation by **1**. The hydrogenation process was then investigated in a quantitative manner in $CDCl_3$ at 320 K and the resulting data were analysed by simulation (Supporting Information).[10,23] The rate of elimination of *cis*-stilbene from **6** was determined to be 0.06 s^{-1}; this is slower than the rates exhibited by mononuclear phosphane analogues {for instance, species derived from

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[Ru_3(CO)_{10}(PPh_3)_2]$ and $[Ru_3(CO)_{10}(PMe_2Ph)_2]$ exhibit pseudo-first-order hydrogenation rates between 0.07 and 0.18 s^{-1} at the lower temperature of 301 K} and hence the dppe-containing species is a less active hydrogenation catalyst.

Since **3** was not detected in these catalytic experiments, it can be concluded that either **6** is formed from **1** at the expense of **3**, or that **3** converts rapidly into **6** in the presence of diphenylacetylene. When the experiment was repeated in the presence of only a fivefold excess of substrate, **6** was still the only species detected. As **6** still contains the dppe ligand, its formation must proceed by loss of CO. This was confirmed by the addition of 1 atm of CO to the system, which quenched both the formation of **6** and the catalytic hydrogenation. Further experiments were then completed where the $[H_2]$ was varied from 1 to 4 atm. It was discovered that the rate of stilbene elimination is independent of $[H_2]$, which indicates that although H_2 is required to generate **6**, it is not required for stilbene elimination. Elimination of stilbene from **6** will therefore afford an unsaturated species, viz. $[Ru_3(CO)_8(dppe)]$, which may be stabilised by the solvent. The existence of such a stabilising influence has already been proposed by Fontal et al. for the analogous dppm systems.[4] The unsaturated species will subsequently be able to re-coordinate both H_2 and substrate in order to repeat the catalytic process, as illustrated in Scheme 1.



(6)

Scheme 1. Catalytic hydrogenation of diphenylacetylene by **6**

When **2** was employed as the catalytic precursor, **5a** and **5b** were observed at the same relative intensity as in the absence of substrate. No new hydride-containing species were observed, but a gradual build-up of normal ^1H resonances corresponding to *cis*-stilbene was evident at temperatures above 315 K. Since no *p*-H_2 activity is observed in the stilbene product, the rate of its formation must be sufficiently slow for normal signals to be observed; **2** is thus a poorer catalytic precursor than **1** in this reaction.

The lower catalytic activity of the dppe-containing clusters when compared with monodentate phosphane analogues of the type $[Ru_3(CO)_{10}(L)_2]$ indicates that the dppe ligand impedes substrate binding and hence slows down catalytic hydrogenation. This is supported by the significantly lower catalytic activity of **2** when compared to **1**. The same trend was observed by Fontal et al. for dppm-substituted analogues, based on reaction yields and catalytic turnover.[4]

When the catalytic investigations on **1** and **2** were repeated using $[D_8]$toluene as the solvent, no cluster-based hydrides could be observed and the only detected hydride product was the known mononuclear species $[Ru(CO)_2(dppe)(H)_2]$.[19] Hydrogenation was evident by the observation of a very slow build-up of normal signals corresponding to *cis*-stilbene at temperatures above 335 K. This again indicates that the dppe-substituted triruthenium clusters are highly susceptible to solvent effects, in agreement with literature observations for dppm analogues,[4] and demonstrates directly that they undergo significant fragmentation to less active mononuclear species in low-polarity solvents. Thus, the bidentate ligand is unable to stabilise the cluster framework under catalytic conditions.

Finally, it is interesting to compare the influence of the dppe ligand on the cluster core with that exerted by the phosphido group.[11] In solvents of moderate polarity, such as $CDCl_3$, the dppe-substituted cluster **1** is a superior catalyst compared to the phosphido-containing cluster $[Ru_3(\mu\text{-}H)(\mu\text{-}PPh_2)(CO)_9]$; at 315 K, **1** leads to catalytic hydrogenation at a rate of 0.06 s^{-1}, whereas $[Ru_3(\mu\text{-}H)(\mu\text{-}PPh_2)(CO)_9]$ becomes active only at 340 K. However, in low-polarity solvents such as toluene, the phosphido group is able to exert a stabilising influence on the cluster, such that only cluster-based species are observed under catalytic conditions; in contrast, fragmentation dominates in the case of dppe-substituted clusters **1** and **2**. These results also indicate that stabilising the cluster framework can result in lower catalytic activity. Therefore, the exact nature of the stabilising group, as well as the exact reaction conditions, are clearly of crucial importance if cluster fragmentation under catalytic conditions is to be precluded.

Conclusion

The clusters $[Ru_3(CO)_{10}(dppe)]$ (**1**) and $[Ru_3(CO)_8(dppe)_2]$ (**2**) have been shown to lead to catalytic hydrogenation of diphenylacetylene. This process is solvent-dependent, with fragmentation dominating in low-polarity solvents, indicating that the dppe ligand does not stabilise the cluster under catalytic conditions; this is in contrast to $[Ru_3(\mu\text{-}H)(\mu\text{-}PPh_2)(CO)_9]$, where only cluster-based active species are observed under such conditions. In solvents of higher polarity, clusters **1** and **2** are active catalysts, but exhibit lower activity than their monodentate phosphane analogues $[Ru_3(CO)_{10}(L)_2]$ (L = PPh_3, PMe_2Ph, PMe_3, PCy_3), which is indicative of the dppe ligand impeding substrate binding. The exact nature of the phosphane ligand is thus of great importance in the effort to preclude cluster fragmentation during catalytic transformations.

Experimental Section

General: All synthetic manipulations were carried out under dry nitrogen using standard Schlenk or glove-box techniques. Subsequent purifications were carried out without precautions to exclude air. THF was dried and distilled prior to use, whilst all other

solvents were used as received. $[Ru_3(CO)_{12}]$ (Strem), dppe, benzophenone (Aldrich) and sodium (Fluka) were also used as received. The clusters $[Ru_3(CO)_{10}(dppe)]$ (**1**) and $[Ru_3(CO)_8(dppe)_2]$ (**2**) were prepared using a literature method[12] and purified by recrystallisation from hexane/dichloromethane. Characterisation was achieved by comparison of characteristic solution IR (ν_{CO}) and FAB MS with the literature data. NMR measurements were made using NMR tubes fitted with J. Young Teflon valves and solvents (dried and degassed) were added by vacuum transfer in a high-vacuum line. For the PHIP experiments, hydrogen enriched in the *para* spin state was prepared by cooling H_2 to 18 K over activated charcoal. The studies were carried out with sample concentrations of approximately 1 μM and spectra were recorded with a Bruker DRX-400 spectrometer with ^1H at 400.1 MHz, ^{13}C at 100.1 MHz and ^{31}P at 162.0 MHz, respectively. ^1H NMR chemical shifts are reported in ppm relative to residual ^1H signals in the deuterated solvents ([D_7]toluene: δ = 2.13 ppm; $CHCl_3$: δ = 7.27 ppm), ^{13}C NMR in ppm relative to $CDCl_3$ (δ = 77.05 ppm), and ^{31}P NMR in ppm downfield of an external 85% solution of phosphoric acid. Modified COSY, HMQC and EXSY pulse sequences were used as described previously.[24] In the exchange and hydrogenation studies, EXSY spectra were acquired immediately after exposing the sample to *p*-H_2 and introducing it into the NMR probe. The results were modelled for hydride exchange and hydride transfer into free H_2, or for hydride transfer into the hydrogenation product, applying published procedures.[10,23] The rate constants obtained in this way were multiplied by two to take into account the analysis method.[25]

Supporting Information: Lists of raw and simulation data and details of the analysis method are available for hydride exchange and H_2 elimination in species **3**, **5a** and **5b**, as well as for catalytic hydrogenation by **6** (footnote on first page of this article).

Acknowledgments

The Nature of the M≡E Bond: Theoretical Investigation of the Molecules $[(RO)_3M{\equiv}E]$ (M = Mo, W; E = N, P, As, Sb, Bi; R = H, Me) and $[(Me_3CO)_3Mo{\equiv}P]$

Krishna K. Pandey*[a] and Gernot Frenking*[b]

Keywords: Nitrido complexes / Bonding analysis / Density functional calculations / Metal−ligand triple bond / Pnicogens

The electronic and molecular structures of the metal-pnicogen complexes $[(RO)_3M{\equiv}E]$ (M = Mo, W; E = N, P, As, Sb, Bi; R = H, Me) and $[(Me_3CO)_3M{\equiv}P]$ have been investigated at the DFT level using the exchange correlation functionals B3LYP and BP86. The nature of the M≡E interactions was analyzed with charge and energy decomposition methods. The bonding analyses show that the metal-pnicogen bonds are genuine triple bonds containing a σ- and a degenerate π-bond. The M–E σ-bonds are always polarized towards the pnicogen atom E, particularly for the nitrogen complexes. The M–N π-bonds are also polarized towards nitrogen, while the π-bonds of the heavier pnicogens P–Bi show a small polarization towards the metal atom. The M–E σ-bonds at the pnicogen E are sp^n-hybridized; the p character is always > 80% of the total AO contribution. The hybridization of the metal atoms in the nitrido complexes is approximately sd^2 and that in the heavier homologues, approximately sd. The ratio of the energy contributions of the σ- and π-orbitals to the covalent bonding in $[(HO)_3M{\equiv}E]$ is about 50:50 for all pnicogen atoms E. The metal–nitrido bonds in $[(HO)_3M{\equiv}N]$ are more covalent than electrostatic. The covalent character becomes smaller when the pnicogen atom becomes heavier with the trend N >> P > As > Sb > Bi. The $[(HO)_3M{\equiv}E]$ tungsten complexes have stronger bonds that are slightly less covalent than the molybdenum complexes, the π-bonding contribution in the former species is slightly larger than in the latter.

Introduction

Triple bonding between transition metals is a feature commonly encountered in several classes of dinuclear complexes.[1] Molecules that have a σ- and a degenerate π-bond are also known to form between transition metals and main group elements as exemplified in carbyne,[2−9] nitrido,[10−20] and germylyne[21−25] complexes. The coordination chemistry of transition metal complexes with a terminal nitrido ligand has blossomed in the last 25 years, during which much knowledge of their properties has been obtained.[10−20]

For the heavier group 15 elements P, As, Sb, and Bi there are only a small number of complexes with a terminal phosphorus atom as a ligand known from the literature.[26−32] An intermediate metal phosphido complex [(O-*t*Bu)3 W≡P] was first suggested in 1985 by Becker et al.[33] from the reaction of [W2(O-*t*Bu)6] with t-BuC≡P. In 1987, Chisholm and coworkers proposed the formation of an intermediate phosphido complex [(NpO)3 W≡P] (Np = neopentyl).[34] The existence of metal-arsenido complexes [Cp(CO)2M≡As] (M = Mo, W] as intermediates was suggested by Ziegler et al.[35] Rheingold and coworkers reported on metal-stibido complexes $[(CO)_nM{\equiv}Sb]$ (n = 4, M = Cr, Mo, W; n = 3, M = Fe) as intermediates.[36]

Until ten years ago, no examples of stable, fully characterized complexes with a terminal M≡E bond (E = P, As, Sb, Bi) were known. In 1995, the groups of Cummins[37] and Schrock[38] independently reported representative examples of complexes containing metal−phosphorus triple bonds in $[(ArRN)_3Mo{\equiv}P]$, $[(R_2N)_3Mo{\equiv}P]$ {R = $C(CD_3)_2(CH_3)$, Ar = 3,5-$C_6H_3Me_2$} and $[(N_3N)M{\equiv}P]$ {M = Mo, W; N_3N = $(Me_3SiNCH_2CH_2)_3N$}. Schrock et al. also isolated the first examples of metal-arsenido complexes $[(N_3N)M{\equiv}As]$ (M = Mo, W).[38,39] Scheer and coworkers synthesized $[(N_3N)W{\equiv}E]$ (E = P, As) by a different synthetic route.[40] Recently, Cummins et al. reported on the phosphido complex $[(RO)_3Mo{\equiv}P]$ (R = 1-methylcyclohexyl).[41]

Several theoretical studies on metal nitrido complexes have been published[14−20] but little theoretical work has been performed on the heavier homologues. Four computational investigations on phosphido complexes have been reported. Wagener and Frenking optimized the geometries of the model compounds $[(H_2N)_3M{\equiv}P]$, $[(H_2N)3(NH_3)M{\equiv}P]$, $[(HNCH_2CH_2)_3M{\equiv}P]$ (M = Mo, W) at the HF, MP2, and B3LYP levels of theory[42] ^{31}P NMR

[a] School of Chemical Sciences, Devi Ahilya University Indore, Indore, 452017 India
[b] Fachbereich Chemie, Philipps-Universität Marburg, 35037 Marburg, Germany

chemical shielding calculations for phosphido complexes were carried out by Morokuma et al.[43] and by Cummins et al.[41] Geometries of $[(N_3N)W{\equiv}E]$ (E = P, As) were optimized at the DFT/BP86/SVP level of theory by Scheer et al.[40] Ab initio MP2 calculations on the $[(CO)_4Mo{\equiv}Sb]^-$ anion were reported by Rheingold et al.[36] A comparative study of complexes with terminal metal−pnicogen triple bonds $L_nM{\equiv}E$ has not been published until now.

In this paper, 21 metal-pnicogen complexes $[(RO)_3M{\equiv}E]$ (M = Mo, W; E = N, P, As, Sb, Bi; R = H, Me) and $[(Me_3CO)_3M{\equiv}P]$ have been investigated using density functional theory at the B3LYP and BP86 levels of theory. We report on the charge and energy decomposition analysis of the metal−pnicogen triple bonds in $[(MeO)_3M{\equiv}E]$ (M = Mo, W; E = N, P, As, Sb, Bi), which gives, for the first time, the energies that are associated with the M→E σ-donation and M←E π-bonding. The relative strength of the electrostatic and covalent contributions to the bond strength will be also reported. The following questions are addressed in this work: (i) how are the M≡E σ- and π-bonds polarized, and what is the hybridization at the metal and pnicogen atoms; (ii) how strong are the contributions of the M−E σ-bonding and M−E π-bonding to the total M≡E bonding energy; (iii) what are the relative strengths of the covalent and electrostatic interactions?

Computational Methods

Calculations on all complexes have been performed using the hybrid B3LYP density functional method, which uses Becke's 3-parameter nonlocal exchange functional[44] mixed with the exact (Hartree−Fock) exchange functional and Lee−Yang−Parr's nonlocal correlation functional.[45] The geometries of the molecules were optimized without any symmetry restrictions with standard 6−311G(d) basis sets[46] for H, C, O, N and P atoms. For As, Sb, Bi, Mo and W, quasi-relativistic effective core potentials (ECP) determined by Hay−Wadt have been used.[47] The valence basis sets for Mo and W have triple-ζ quality (10s10p4d1f/3s3p3d1f), which include $(n+1)$p functions[48] that were augmented by an additional set of f orbitals with an exponent of 1.043 for Mo and 0.823 for W.[49] For As, Sb and Bi, the standard (3s4p1d/2s3p1d) valence basis functions of Hay and Wadt have been used.[50] This basis set is denoted TZP. Frequency calculations were performed at B3LYP/TZP to determine whether the optimized geometries were minima on the potential energy surface. The electronic structures of the complexes were examined by NBO analysis.[51] The B3LYP/TZP calculations were carried out with the Gaussian98 program.[52] All MO pictures were made by using the MOLDEN program.[53]

Calculations on the model complexes $[(HO)_3M{\equiv}E]$ have also been performed at the nonlocal DFT level of theory using the exchange functional of Becke[54] and the correlation functional of Perdew[55] (BP86). Scalar relativistic effects have been considered using the ZORA formalism.[56] Uncontracted Slater-type orbitals (STOs) using triple-ζ basis sets augmented by two sets of polarization functions were employed for the SCF calculations.[57] The $(1s)^2$ core electrons of carbon and nitrogen, $(1s2s2p)^{10}$ core electrons of phosphorus, $(1s2s2p3s3p)^{18}$ core electrons of arsenic, $(1s2s2p3s3p3d)^{28}$ core electrons of molybdenum, $(1s2s2p3s3p3d4s4p)^{36}$ core electrons of antimony, and $(1s2s2p3s3p3d4s4p4d)^{46}$ core electrons of bismuth and tungsten were treated by the frozen-core approximation.[58] An auxiliary set of s, p, d, f and g STOs was used to fit the molecular densities, and to present the coulomb and exchange potentials accurately in each SCF cycle.[59] A numerical integration accuracy of INTEGRATION = 10 was used throughout. The geometries of $[(HO)_3M{\equiv}E]$ were optimized at BP86/TZ2P with C_3 symmetry. The latter calculations were performed utilizing the program package ADF-2002.01.[60]

The binding interactions in the complexes $[(HO)_3M{\equiv}E]$ between the fragment radicals in the electronic quadruplet states ($^4A_1$) $[(HO)_3Mo]$ and ($^4\Sigma^-$) E have been analyzed with C_3 symmetry using the energy decomposition scheme of ADF, which is based on the methods of Morokuma,[61] and Ziegler and Rauk.[62] According to the ETS method, the bond energy ΔE between the $[(HO)_3Mo]$ and E fragments is:

$$\Delta E = \Delta E_{int} + \Delta E_{prep} \quad (1)$$

Here, ΔE_{prep} is the energy required to promote the structures of the free fragments from their equilibrium structure in the electronic ground state to the geometry and electronic state that they take up in the molecule:

$$\Delta E_{prep} = E_{total}(\text{distorted fragments}) - E_{total}(\text{fragments in the equilibrium structure}) \quad (2)$$

ΔE_{int} in Equation (1) is the instantaneous interaction energy between the two fragments in the molecule. It is comprised of three main components as shown in Equation (3).

$$\Delta E_{int} = \Delta E_{elstat} + \Delta E_{Pauli} + \Delta E_{orb} \quad (3)$$

ΔE_{elstat} describes the classical Coulomb interaction between the fragments, which is attractive in most cases. The term ΔE_{Pauli}, which is called exchange repulsion or Pauli repulsion, takes into account the destabilizing two-orbital three- or four-electron interactions between occupied orbitals of both fragments. ΔE_{Pauli} is calculated by enforcing the Kohn−Sham determinant of the molecule, which results from superimposing both fragments, to obey the Pauli principle through antisymmetrization and renormalization. The last term ΔE_{orb} in Equation (1) gives the stabilizing orbital interactions between occupied and virtual orbitals of the two fragments. ΔE_{orb} can be further partitioned into contributions from the orbitals that belong to different irreducible representations of the point group of the system. It

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

has been suggested that the covalent and electrostatic character of a bond is given by the ratio $\Delta E_{elstat}/\Delta E_{orb}$.[23,63−65]

Results and Discussion

Geometries

Figure 1 shows the optimized geometries of $[(RO)_3Mo{\equiv}P]$ (R = H, Me, CMe_3). Table 1 gives the most important bond lengths and angles that have been computed for the eleven molybdenum-pnicogen complexes $[(RO)_3Mo{=}E]$ (R = H, Me; M = Mo; E = N, P, As, Sb, Bi) and $[(Me_3CO)_3Mo{=}P]$. The geometrical data for the ten tungsten-pnicogen complexes $[(RO)_3W{=}E]$ (R = H, Me; M = W; E = N, P, As, Sb, Bi) are presented in Table 2.

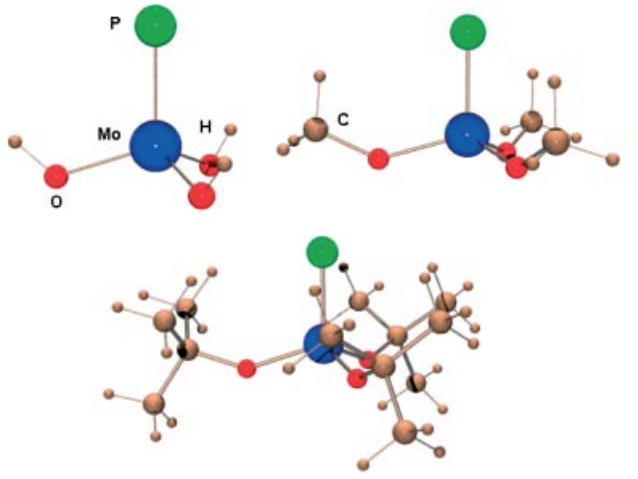

Figure 1. Optimized geometries of $[(RO)_3Mo{\equiv}P]$ (R = H, Me, CMe_3)

Experimental values are available for a large number of stable nitrido complexes of molybdenum and tungsten. From these structural data, the M≡N triple bond lengths are between 1.6−1.7 Å.[10−20] The calculated Mo≡N and W≡N bond lengths at B3LYP/TZP in $[(HO)_3Mo{\equiv}N]$ (1.634 Å), $[(MeO)_3Mo{\equiv}N]$ (1.639 Å), $[(HO)_3W{\equiv}N]$ (1.665 Å), and $[(MeO)_3W{\equiv}N]$ (1.670 Å) agree quite well with the experimental values. The calculated Mo≡P and W≡P bond lengths in $[(HO)_3Mo{\equiv}P]$ (2.094 Å), $[(MeO)_3Mo{\equiv}P]$ (2.102 Å), $[(Me_3CO)_3Mo{\equiv}P]$ (2.112 Å), $[(HO)_3W{\equiv}P]$ (2.118 Å) ,and $[(MeO)_3W{\equiv}P]$ (2.126 Å) are also very close to experimental values found by X-ray diffraction for $[(ArRN)_3Mo{\equiv}P]$ [2.119(4) Å], $[(RO)_3Mo{\equiv}P]$ [2.1144(16) Å], and $[(N_3N)W{\equiv}P]$ [2.162(4) Å]. We note that as the size of R increases, the M≡E bond lengthens. In arsenido complexes, the calculated M≡As bond lengths in $[(HO)_3Mo{\equiv}As]$ (2.217 Å), $[(MeO)_3Mo{\equiv}As]$ (2.224 Å), $[(HO)_3W{\equiv}As]$ (2.237 Å), and $[(MeO)_3W{\equiv}As]$ (2.245 Å) are slightly shorter than those found by X-ray diffraction for $[(N_3N)Mo{\equiv}As]$ [2.252(3) Å] and $[(N_3N)W{\equiv}As]$ [2.2903(11) Å]. The BP86/TZ2P values are very similar to the B3LYP/TZP data.

There are no experimental data for the length of M≡Sb and M≡Bi triple bonds. A bond length of 2.55 Å in $[(CO)_4Mo{\equiv}Sb]^-$ has been calculated at the MP2 level.[36] Using the relationship between bond order and bond lengths suggested by Pauling,[66] we find the estimated Mo≡E (Mo≡N = 1.81 Å, Mo≡P = 2.12 Å, Mo≡As = 2.25 Å, Mo≡Sb = 2.44 Å, and Mo≡Bi = 2.49 Å) and W≡E bond lengths (W≡N = 1.82 Å, W≡P = 2.13 Å, W≡As = 2.26 Å, W≡Sb = 2.45 Å, and W≡Bi = 2.50 Å) for triple bonds from the M−E single bond lengths based on covalent radii predictions (covalent radius, Mo = 1.40 Å, W = 1.41 Å, N = 0.75 Å, P = 1.06 Å, As = 1.19 Å, Sb = 1.38 Å, Bi = 1.43 Å).[67] It is interesting to note that the calculated M≡E bond lengths in the calculated molyb-

denum-pnicogen and tungsten-pnicogen complexes correspond to a Pauling bond order of approximately 3.

Bonding Analysis of M≡E Bonds

We begin the analysis of the bonding situation in the pnicogen complexes [(MeO)$_3$M≡E] (M = Mo, W; E = N, P, As, Sb, Bi) with a discussion on the conventional indices that are frequently used in order to characterize the bonding situation in molecules, i.e. bond orders and atomic charges. Table 3 gives the Wiberg bond indices (WBI)[68] and the results of the natural bond orbital (NBO) analysis.

Table 3 shows that the WBI values of the M≡E bonds in the pnicogen complexes are significantly higher (2.47−2.65) than the WBI values of the M−O single bond (0.81−0.85).

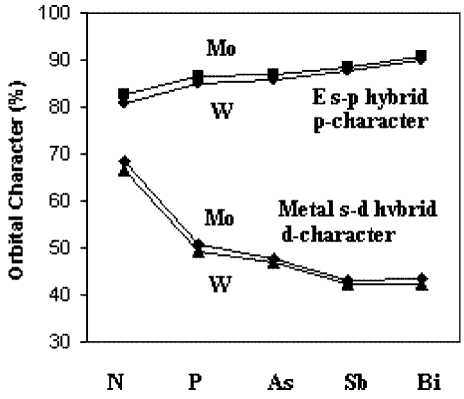

Figure 2. Metal s-d hybrid and E s-p hybrid orbitals for M≡E σ-bond in $[(MeO)_3M{\equiv}E]$ (M = Mo, W; E = N, P, As, Sb, Bi)

The latter values are approximately one third of the WBI values of the M≡E bonds. This is a first hint that the M−E bonds have a substantial degree of multiple bonding. The calculated NBO charge distribution indicates that the metal atoms always carry a large positive charge. Note that tungsten is always more positively charged than molybdenum. Nitrogen carries a significant negative charge in the nitrido complexes, while the heavier pnicogen ligands have only a small negative charge or, in cases of some molybdenum species, are slightly positive.

A more definitive picture of M≡E bonding is obtained through NBO analysis of the delocalized Kohn−Sham orbitals. The characteristics of the M≡E bonding orbitals are listed in Table 3. The M−E σ-bonding orbitals are always polarized towards the pnicogen atoms E, particularly for

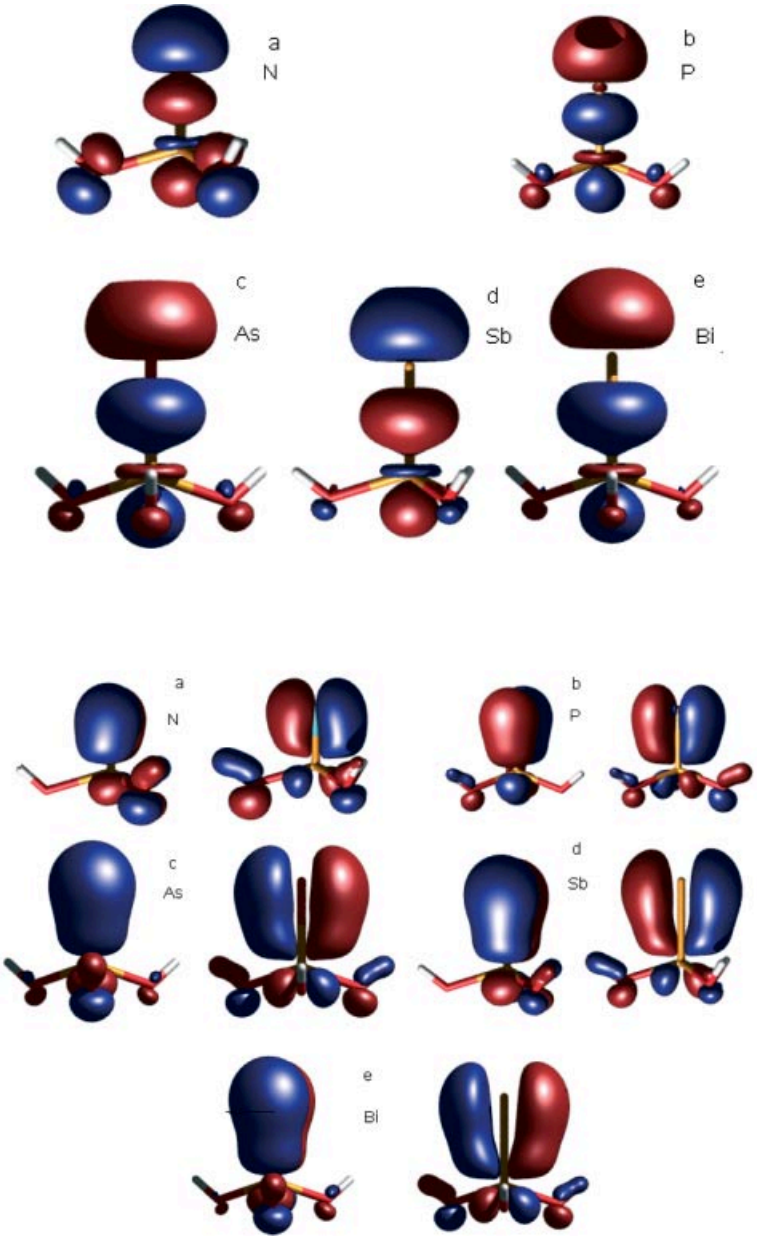

Figure 3. Plot of Mo≡E σ- (top) and π- (bottom) molecular orbitals of $[(HO)_3Mo{\equiv}E]$ (E = N, P, As, Sb, Bi)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the nitrogen complexes. The M−N π-bonds are also polarized towards nitrogen, albeit less so than the σ-bonds, while the heavier pnicogen M−E π-bonds show a small polarization towards the metal atom. The hybridization of the M−E σ-bonds at the pnicogen atoms has a large p character, which is always >80% of the total AO contribution. The hybridization of the metal atoms in the metal−nitrido bonds is approximately sd^2, while the s and d contributions in the heavier metal−pnicogen σ-bonds are more balanced. The trend of the sp^n and sd^n character of the pnicogen and metal atoms of the σ-bonds is shown in Figure 2. It becomes obvious that the %d contribution at the metal atom of the σ-bonds for the heavier pnicogens is much lower than that for nitrogen. The strong triple-bond character of the M≡E bonds becomes visible by the envelope plots of the calculated σ- and π-orbitals of the model compounds $[(HO)_3Mo{\equiv}E]$ (E = N, P, As, Sb, Bi), which are shown in Figure 3.

Besides the charge decomposition analysis using the NBO method, we also carried out an energy decomposition analysis of the metal−pnicogen bonds in $[(HO)_3M{\equiv}E]$. The results are given in Table 4.

The calculated data in Table 4 show that the M≡E bonds are rather strong. The theoretically predicted BDEs of the nitrido bonds are 163.6 kcal/mol for $[(HO)_3Mo{\equiv}N]$ and 179.2 kcal/mol for $[(HO)_3W{\equiv}N]$. The heavier pnicogen complexes have significantly weaker bonds. The calculated bond energies are between 122.6 kcal/mol for $[(HO)_3W{\equiv}P]$ and 64.3 kcal/mol for $[(HO)_3Mo{\equiv}Bi]$. The bond energies show the expected trend for the BDE of the pnicogens, N >> P > As > Sb > Bi. The tungsten complexes have stronger bonds than the molybdenum complexes.

The breakdown of the metal−pnicogen interaction energies into the different energy terms shows that the M≡N bond has a larger covalent character (about 60%) than electrostatic character (Table 4). The covalent contribution to the M≡E bonds becomes significantly smaller than the electrostatic contribution for the heavier pnicogens. The trend for the covalent character for the pnicogens is N >> P > As > Sb > Bi. The trend is graphically shown in Figure 4. The ratio of σ- to π-bonding in the covalent M≡E bond is almost 50:50.

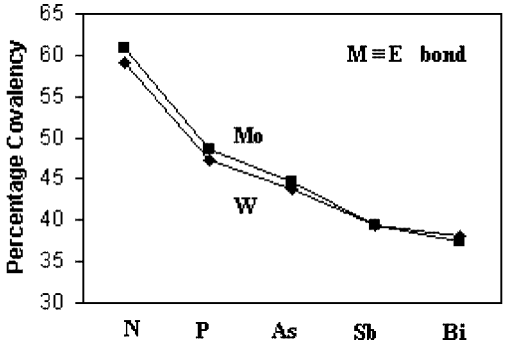

Figure 4. Trends of the covalent contributions to the M≡E bonding interactions in $[(HO)_3M{\equiv}E]$ (M = Mo, W; E = N, P, As, Sb, Bi)

Summary and Conclusion

The results of the bonding analysis of the title compounds show that the metal−pnicogen bonds are genuine triple bonds containing a σ- and a degenerate π-bond. The questions that have been addressed in the introduction can be answered as follows. (i) The M−E σ-bonds are always polarized towards the pnicogen atom E, particularly for the nitrogen complexes. The M−N π-bonds are also polarized towards nitrogen, while the π-bonds of the heavier pnicogens (P−Bi) show a small polarization towards the metal atom. The M−E σ-bonds at the pnicogen E are sp^n-hybridized; the p character is always > 80% of the total AO contribution, while the hybridization of the metal atoms in the nitrido complexes is approximately sd^2 and in the heavier homologues, approximately sd. (ii) The ratio of the energy contributions of the σ- and π-orbitals to the covalent bonding in $[(HO)_3M{\equiv}E]$ is about 50:50 for all pnicogen atoms E. (iii) The metal−nitrido bonds in $[(HO)_3M{\equiv}N]$ are more covalent than electrostatic in character. The covalent

character becomes smaller when the pnicogen atom becomes heavier, following the trend N >> P > As > Sb > Bi. (iv) The $[(HO)_3M{\equiv}E]$ tungsten complexes have stronger bonds, which are slightly less covalent than the molybdenum complexes. The π-bonding contribution in the former species is slightly larger than in the latter.

Post-Metallocene Hydridolanthanide Chemistry: $[Lu\{(Me_3Si)_2NC(NiPr)_2\}_2(\mu\text{-}H)]_2$ — A Novel Lanthanide Hydride in a Non-Cyclopentadienyl Coordination Environment; Synthesis, Structure and Catalytic Activity in Olefin Polymerization

Alexander A. Trifonov,*[a] Elena A. Fedorova,[a] Georgy K. Fukin,[a] and Mikhail N. Bochkarev[a]

Keywords: Alkyl complexes / Homogeneous catalysis / Hydride ligands / Lanthanides / N ligands

The reaction of anhydrous $LuCl_3$ with a twofold molar excess of lithium guanidinate $[Li\{(Me_3Si)_2NC(NiPr)_2\}]$, obtained in situ from the amide $[LiN(SiMe_3)_2(Et_2O)]$ and 1,3-diisopropylcarbodiimide in THF, yields the bis(guanidinate) "ate" complex $[Lu\{(Me_3Si)_2NC(NiPr)_2\}_2(\mu\text{-}Cl)_2Li(THF)_2]$ (**1**). The alkyllutetium derivative $[Lu\{(Me_3Si)_2NC(NiPr)_2\}_2(CH_2SiMe_3)]$ (**2**) was synthesized by a metathesis reaction of **1** with $LiCH_2SiMe_3$ in toluene. The treatment of **2** with an equimolar amount of $PhSiH_3$ in hexane at room temperature results in the first known dimeric lanthanide hydride in a bis(guanidinate) coordination environment, $[Lu\{(Me_3Si)_2NC(NiPr)_2\}_2(\mu\text{-}H)]_2$ (**3**). The crystal structures of complexes **1** and **3** have been determined by X-ray crystallography. The hydrido complex **3** was found to catalyze polymerization of ethylene, propylene and styrene.

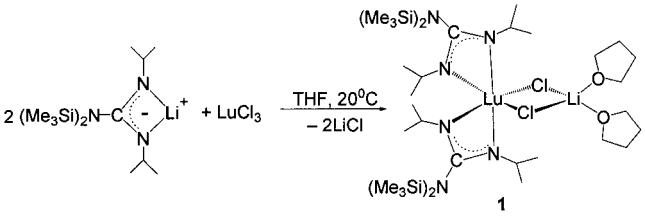
Introduction

Mono- and bis(cyclopentadienyl) and -hydridolanthanide compounds have a very rich and unique chemistry[1–5] and have been found to be efficient catalysts or precatalysts in a wide range of transformations of unsaturated substrates.[6–10] Since the chemical properties of these compounds are known to be profoundly influenced by the nature of the ancillary ligands coordinated to the lanthanide atom,[11–13] related complexes in a stabilizing environment different from cyclopentadienyl one seem to be challenging targets for the exploration of stoichiometric and catalytic performance. In contrast to the well-developed chemistry of cyclopentadienyl-derived alkyl and hydrido complexes of lanthanides, their non-cyclopentadienyl analogues still remain extremely poorly investigated.[14–18] We decided to focus on the tetrasubstituted guanidinate ligand system[19] because its electronic and steric properties can be easily modified to provide stability and a high degree of unsaturation of the coordination sphere of the lanthanide atom due to the bulky substituents at the nitrogen atoms. Several examples of alkyl complexes of rare earth metals coordinated by guanidinate ligands have been reported recently.[20–22] We employed the advantages of the $\{(Me_3Si)_2NC(NiPr)_2\}^-$ ligand for the stabilization of lanthanide hydride, and report here the synthesis of the first complex of this type — $[Lu\{(Me_3Si)_2NC(NiPr)_2\}_2(\mu\text{-}H)]_2$ — and its structure and catalytic activity in olefin polymerization.

Results and Discussion

The monochloro bis(guanidinate) derivative of lutetium, $[Lu\{(Me_3Si)_2NC(NiPr)_2\}_2(\mu\text{-}Cl)_2Li(THF)_2]$ (**1**), was synthesized by a metathesis reaction of a twofold molar excess of the lithium guanidinate $[Li\{(Me_3Si)_2NC(NiPr)_2\}]$, obtained in situ from the amide $[Li\{N(SiMe_3)_2\}(Et_2O)]$ and 1,3-diisopropylcarbodiimide in THF, with anhydrous $LuCl_3$ at room temperature (Scheme 1).



Scheme 1

Complex **1** was isolated in an analytically pure form as a colorless air- and moisture-sensitive crystalline solid by recrystallization from hexane in 76% yield. It is worth noting that the reaction of YCl_3 with 2 equiv. of

$[Li\{(Me_3Si)_2NC(NiPr)_2\}]$ in diethyl ether resulted, after the same treatment, in the isolation of the neutral solvent-free dinuclear guanidinate complex $[Y\{(Me_3Si)_2NC(NiPr)_2\}_2(\mu\text{-}Cl)]_2$;[21] formation of the analogous "ate" complexes $[Ln\{(Me_3Si)_2NC(NiPr)_2\}_2(\mu\text{-}Cl)_2Li(THF)_2]$ (Ln = Y,[21] Yb[22]) has been reported when the reactions are carried out in THF. Complex **1** is soluble in ethers and aromatic and aliphatic hydrocarbons. The ^1H and ^{13}C NMR spectra of **1** in C_6D_6 at 20 °C do not have any notable features and reflect the equivalence of the two guanidinate ligands, with the expected single set of resonances indicating an increased rate of fluctionality compared to the more rigid dinuclear framework of $[Y\{(Me_3Si)_2NC(NiPr)_2\}_2(\mu\text{-}Cl)]_2$.[21] Both sets of THF methylene protons appear in the ^1H NMR spectrum of **1** as broad singlets, indicating their lability.

Clear, colorless single-crystals of **1** suitable for an X-ray crystal-structure determination were obtained by slow concentration of its hexane solution. An ORTEP diagram of **1** is presented in Figure 1; crystal and structural refinement data are listed in the Exp. Sect. The X-ray diffraction study revealed that **1** is a monomeric heterodimetallic "ate" complex that is isomorphous to the previously described $[Yb\{(Me_3Si)_2NC(NiPr)_2\}_2(\mu\text{-}Cl)_2Li(THF)_2]$.[22]

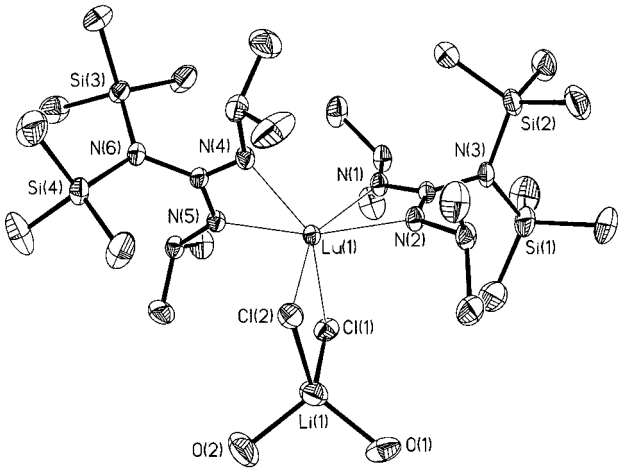

Figure 1. Molecular structure of **1**; the hydrogen atoms are omitted as well as the carbon atoms of the THF molecules; selected bond lengths [Å] and angles [°]: Lu(1)−N(1) 2.285(1), Lu(1)−N(4) 2.290(2), Lu(1)−N(5) 2.329(2), Lu(1)−N(2) 2.346(2), Lu(1)−Cl(1) 2.600(1), Lu(1)−Cl(2) 2.623(1), Lu(1)−C(14) 2.739(2), Lu(1)−C(1) 2.745(2); N(4)−Lu(1)−N(5) 57.87(6), N(1)−Lu(1)−N(2) 57.86(6), C(14)−Lu(1)−C(1) 132.30(6)

The coordination environment of the lutetium atom in **1** is defined by four nitrogen atoms of the bidentate guanidinate ligands, and two chlorine atoms, which form μ^2-bridges to the lithium atom. The lithium atom is also bonded to oxygen atoms of the two THF molecules. The formal coordination number of the lutetium atom is six, which is rather low for lanthanide derivatives.[1] The luthetium−nitrogen bonds in **1** have very similar lengths, which fall in the region 2.285(1)−2.346(1) Å. These bonds are much shorter than the coordination bonds in $[Lu(\eta^8\text{-}C_8H_8)\{o\text{-}C_6H_4CH_2N(CH_3)_2\}(THF)]$ [2.479(6) Å][23] and $[Lu\{o\text{-}C_6H_4CH_2N(CH_3)_2\}_3]$ [2.468(6), 2.4588(5) Å],[24] but similar to the length of the covalent bond in the anionic compound $[\{Li(THF)_4\}\{Lu(C_5H_5)_2(NPh_2)_2\}]$ [2.290(7), 2.293(7) Å].[25] The Lu−Cl distances in **1** [2.600(1) 2.622(1) Å] are very close to the values reported for the Cp analogue $[LuCp_2(\mu\text{-}Cl)_2Li(TMEDA)]$.[26] The Yb−N [2.295(3)−2.332(3) Å] and Yb−Cl [2.608(1), 2.631(1) Å] distances in an isomorphous Yb complex[22] are close to the analogous distances in **1**.

The alkylation of **1** with $LiCH_2SiMe_3$ in toluene yielded the solvent-free alkyl complex $[Lu\{(Me_3Si)_2NC(NiPr)_2\}_2(CH_2SiMe_3)]$ (**2**; Scheme 2), which was isolated as a colorless amorphous powder in 71% yield after extraction with hexane.

The air- and moisture-sensitive complex **2** is highly soluble in organic solvents. The presence of the CH_2SiMe_3 group in **2** is proved by a high-field-shifted singlet at $\delta = -0.49$ ppm in the ^1H NMR spectrum, corresponding to the two protons of the methylene group attached to the lutetium atom, and by a singlet at $\delta = 0.37$ ppm corresponding to the protons of the Me_3Si group. The carbon atoms of these groups produce resonances at $\delta = 40.0$ and 4.9 ppm, respectively, in the ^{13}C NMR spectrum of **2**.

The alkyl complex **2** was treated with an equimolar amount of phenylsilane in hexane at room temperature to yield the dimeric hydride $[Lu\{(Me_3Si)_2NC(NiPr)_2\}_2(\mu\text{-}H)]_2$ (**3**; Scheme 3).

Complex **3** was isolated in 84% yield as a colorless microcrystalline solid after recrystallization from hexane and drying in vacuo. Complex **3** is an air- and moisture-sensitive compound that is sparingly soluble in hexane and aromatic hydrocarbons. Crystallization of **3** by slow cooling of a warm (40 °C) saturated hexane solution to 20 °C resulted in the formation of single crystals of $[Lu\{(Me_3Si)_2NC(NiPr)_2\}_2(\mu\text{-}H)]_2(C_6H_{14})$. An X-ray crystal structure analysis revealed that **3** adopts a dimeric structure. Each of the two metal centres are coordinated by the four nitrogen atoms of the two guanidinate ligands and by two bridging hydrido ligands (Figure 2).

The two lutetium atoms and the two hydrido ligands are coplanar. The Lu−H [2.12(4), 2.04(4) Å] and Lu−Lu [3.577(1) Å] distances in the Lu_2H_2 core are similar to those in other dimeric μ^2-hydrido-bridged lutetium complexes with bis(cyclopentadienyl) and amido(cyclopentadienyl) ancillary ligation.[27,28] The dihedral angles between the planar four-membered cycles Lu(1)N(1)C(1)N(2) and Lu(1)N(1A)C(1A)N(2A), and Lu(2)C(14)N(4)N(5) and Lu(2)C(14A)N(4A)N(5A), are 66.8(1) and 60.6(1)°, respectively. Remarkably, the disposition of the two $Lu\{(Me_3Si)_2NC(NiPr)_2\}_2$ groups is such that the C(1)Lu(1)C(1A) and C(14)Lu(2)C(14A) planes are nearly orthogonal [86.90(11)°], which allows a reduction of the steric hindrance in the coordination sphere of the Lu atoms. A particularity of the structure of **3** is the difference of the bonding parameters within the $Lu\{(Me_3Si)_2NC(NiPr)_2\}_2$ fragments of the dimer, which results in their inequivalence. In one moiety the Lu(1)−N(1) and Lu(1)−N(2) distances are nearly similar [2.304(3) and 2.315(3) Å], while in the other one they differ noticeably [Lu(2)−N(4): 2.266(3) Å; Lu(2)−N(5): 2.372(5) Å]. The shortest Lu−N bond in **3** is

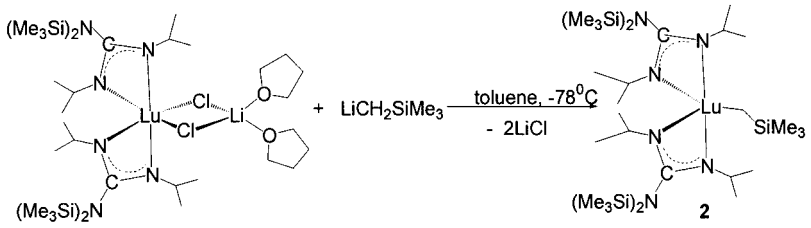
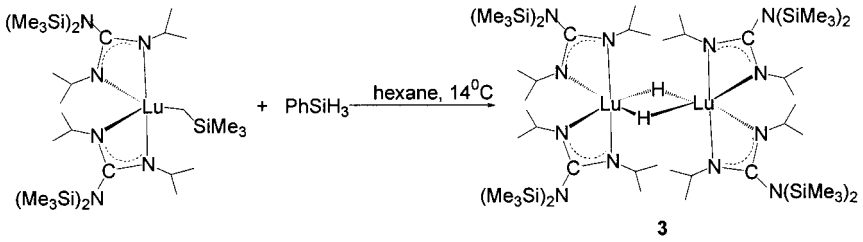


Scheme 2



Scheme 3

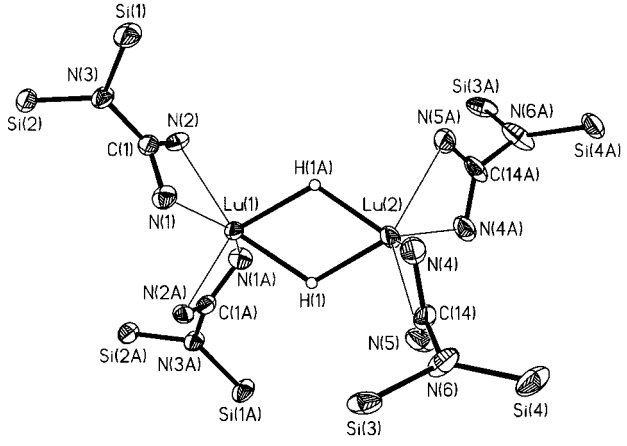


Figure 2. Molecular structure of **3**; the hydrogen atoms as well as methyl radicals of Me_3Si groups and isopropyl groups are omitted; selected bond lengths [Å] and angles [°]: Lu(1)−H(1) 2.12(4), Lu(2)−H(2) 2.03(4), Lu(1)−N(1) 2.304(3), Lu(1)−N(2) 2.315(3), Lu(1)−C(1) 2.747(3), Lu(1)−Lu(2) 3.5767(3), Lu(2)−N(4) 2.266(3), Lu(2)−N(5A) 2.372(3), Lu(2)−C(14) 2.733(3); N(1A)−Lu(1)−N(1) 144.71(16), N(1A)−Lu(1)−N(2A) 58.02(10), N(1)−Lu(1)−N(2A) 101.14(11), N(1)−Lu(1)−N(2) 58.02(10)

nevertheless significantly longer than the covalent Lu−N bond in the complex $[Lu\{Me_2Si(C_9H_5Me)_2\}\{N(SiMe_3)_2\}]$,[29] whereas the longest one is shorter than the coordination bonds in the above-mentioned complexes $[Lu(\eta^8\text{-}C_8H_8)(o\text{-}C_6H_4CH_2N(CH_3)_2(THF)]$[23] and $[Lu\{o\text{-}C_6H_4CH_2N(CH_3)_2\}_3]$.[24] The bonding situation within the NCN fragments does not indicate a significant difference of the π-system delocalization in the guanidinate ligands or the presence of different resonance forms. Such a structure obviously results from a steric repulsion of the bulky trimethylsilyl and isopropyl groups in the adjacent moieties and demonstrates the flexibility of coordination of guanidinate ligands. The strong geometry distortion in **3**, compared to the related dinuclear yttrium chloride bis(guanidinate) $[Y\{(Me_3Si)_2NC(N\mathit{i}Pr)_2\}_2(\mu\text{-}Cl)]_2$,[21] may suggest a greater steric encumbrance of the metal coordination sphere in the lutetium compound, resulting from the smaller ion sizes of Lu and H compared to those of Y and Cl.[30]

The hydrido ligands appear in the ^1H NMR spectrum of **3** as a singlet at $\delta = 12.96$ ppm, which is at substantially lower field than the respective signals of previously reported lutetium hydrides.[11,13,27,28,31−34] This observation is consistent with the enhanced electron-withdrawing properties of guanidinate ligands compared to those of cyclopentadienyl ligands. The ^1H and ^{13}C NMR spectra of **3** indicate that the guanidinate ligands remain inequivalent in solution (20 °C, C_6D_6). The methyl and methyne protons of the isopropyl groups appear in the ^1H NMR spectrum of **3** as complex multiplets, rather than the expected doublet and septuplet, respectively.

The catalytic reactions of **3** with ethylene (20 °C, 0.48 bar) and propylene (0 °C, 0.75 bar) in toluene were monitored by recording the absorption of the monomers. The polymerization of ethylene was rather slow; the catalyst retained similar activity during 3 d, and the reaction was stopped after this time (activity: 0.1 g polyethylene/mmol Lu·h·bar). The polyethylenes obtained with this catalyst are highly crystalline, with a melting temperature of 124 °C. Most of the lanthanide complexes which readily polymerize ethylene are inactive in propylene polymerization. On the contrary, **3** catalyzes propylene polymerization. The reaction proceeds much faster than in the case of ethylene, but the catalyst loses activity 1 h after the beginning of the process (activity: 3.9 g polypropylene/mmol Lu·h·bar). The solid polymer formed in this reaction is insoluble in organic solvents. Complex **3** also catalyzes polymerization of styrene (room temperature, neat styrene, 5% of **3**). A conversion of 90% was reached after 6 d, and the polystyrene obtained

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

has a high molecular weight (M_n = 811000 g mol^{-1}; M_w = 1250000 g mol^{-1}), a narrow molecular weight distribution (M_w/M_n = 1.54), and a melting temperature of 255−260 °C.

Conclusion

The bis(guanidinate) ligand has been demonstrated to be a suitable alternative to the cyclopentadienyl ligand for the stabilization of hydridolanthanide complexes. Due to the bulky substituents on the nitrogen atoms this coordination environment provides a high solubility of the lanthanide derivatives and a low coordination number at the metal atom. The first hydridolanthanide complex with a bis(guanidinate) coordination environment was synthesized and structurally characterized. This complex demonstrates modest activity in olefin polymerization. Studies on the synthesis of hydrido bis(guanidinate) derivatives of other lanthanide metals and investigation of their properties in catalysis of olefin polymerization and hydrosilylation are currently in progress.

Experimental Section

General Remarks: All procedures were performed under vacuum using standard Schlenk-tube techniques. After drying with KOH, THF was distilled from sodium benzophenone ketyl prior to use. Hexane and toluene were purified by distillation from sodium/triglyme benzophenone ketyl. Deuterated benzene was dried with sodium and vacuum-transferred. Diisopropylcarbodiimide was purchased from Acros and purified by distillation. Anhydrous $LuCl_3$ [35] and [Li{N(SiMe$_3$)$_2$}(Et$_2$O)][36] were prepared according to literature procedures. All other commercially available chemicals were used after the appropriate purification. NMR spectra were recorded with a Bruker DPX 200 spectrometer (^{1}H, 200 MHz; ^{13}C, 50 MHz) in C_6D_6 at 20 °C, unless otherwise stated. Chemical shifts for ^{1}H and ^{13}C NMR spectra were referenced internally to the residual solvent resonances and are reported relative to tetramethylsilane. IR spectra were recorded with a Specord M80 instrument as Nujol mulls. Molecular weights and molecular-weight distributions were determined against polystyrene standards by gel-permeation chromatography (GPC) with a Knauer apparatus with Phenogel columns (10 μm, Linear 2) using chloroform as the eluent. Lanthanide metal analysis was carried out by complexometric titration. Elemental analysis was performed by the Microanalytical Laboratory of this institute.

Synthesis of [Lu{(Me$_3$Si)$_2$NC(N*i*Pr)$_2$}$_2$(μ-Cl)$_2$Li(THF)$_2$] (1): Diisopropylcarbodiimide (0.99 g, 7.90 mmol) was slowly added to a solution of [Li{N(SiMe$_3$)$_2$}(Et$_2$O)] (1.91 g, 7.90 mmol) in THF (30 mL) at 20 °C and the reaction mixture was stirred for 45 min. $LuCl_3$ (1.11 g, 3.95 mmol) was added and the reaction mixture was stirred overnight. The solution was filtered, the solvent was evaporated in vacuo and the solid residue was extracted with toluene (2 × 20 mL). The toluene extracts were filtered and toluene was evaporated in vacuo. The off-white solid was dissolved in hot hexane (30 mL). The solution was slowly concentrated at room temperature to one quarter of its volume, cooled to −30 °C and left overnight. The crystalline precipitate was washed with cold hexane and dried in vacuo at room temperature for 20 min. Complex **1** was obtained as a colorless crystalline solid (2.91 g, 76%). $C_{34}H_{80}Cl_2LiLuN_6O_2Si_4$ (970.21): calcd. C 42.09, H 8.24, Lu 18.03; found C 41.80, H 8.69, Lu 17.88. ^{1}H NMR (200 MHz, [D$_6$]benzene): δ = 0.49 [s, 36 H, Si(C*H*$_3$)$_3$], 1.46 (br. s, 8 H, β-C*H*$_2$, THF), 1.61 [d, $^3J_{H,H}$ = 4.8 Hz, 24 H, (C*H*$_3$)$_2$CH], 3.76 (br. s, 8 H, α-C*H*$_2$, THF), 4.15 (sept, $^3J_{H,H}$ = 6.2 Hz, 4 H, C*H*Me$_2$) ppm. ^{13}C{^{1}H} NMR (50 MHz, [D$_6$]benzene): δ = 2.8 [(NSi*C*H$_3$)$_2$], 25.2 (β-*C*H$_2$, THF), 26.9 [(*C*H$_3$)$_2$CH], 46.1 (*C*HMe$_2$), 68.5 (α-*C*H$_2$, THF), 168.4 (*C*N$_3$) ppm. IR (nujol, KBr): $\tilde{\nu}$ = 1630 (s), 1310 (s), 1250 (s), 1200 (s), 1050 (m), 940 (s), 860 (m), 820(s) cm^{-1}.

Synthesis of [Lu{(Me$_3$Si)$_2$NC(N*i*Pr)$_2$}$_2$(CH$_2$SiMe$_3$)] (2): A solution of Me$_3$SiCH$_2$Li (0.14 g, 1.48 mmol) in toluene (5 mL) was slowly added at −78 °C to a solution of **1** (1.44 g, 1.48 mmol) in toluene (25 mL). The reaction mixture was allowed to warm to room temperature and stirred for 3 h. The pale-yellow solution was filtered and toluene was evaporated in vacuo. The residue was extracted with hexane (2 × 10 mL), the extracts were filtered, and hexane was removed in vacuo to give **2** as an off-white amorphous powder (0.83 g, 71%). $C_{30}H_{75}LuN_6Si_5$ (834.74): calcd. C 43.16, H 8.98, Lu 20.96; found C 42.70, H 9.33, Lu 20.74. ^{1}H NMR (200 MHz, [D$_6$]benzene): δ = −0.49 (s, 2 H, LuC*H*$_2$), 0.29 [s, 36 H, NSi(C*H*$_3$)$_3$], 0.37 [s, 9 H, CH$_2$Si(C*H*$_3$)$_3$], 1.29 [d, $^3J_{H,H}$ = 6.4 Hz, 24 H, (C*H*$_3$)$_2$CH], 3.92 (sept, $^3J_{H,H}$ = 6.4 Hz, 4 H, C*H*Me$_2$) ppm. ^{13}C{^{1}H} NMR (50 MHz, [D$_6$]benzene): δ = 2.2 (NSi*C*H$_3$)$_2$], 4.8 (CH$_2$Si*C*H$_3$), 27.1 [(*C*H$_3$)$_2$CH], 40.0 (Lu*C*H$_2$), 46.0 (*C*HMe$_2$), 168.9 (*C*N$_3$) ppm. IR (nujol, KBr): $\tilde{\nu}$ = 1630 (s), 1300 (w), 1250 (s), 1200 (s), 1210 (m), 950 (s), 930 (m), 820(s) cm^{-1}.

Synthesis of [Lu{(Me$_3$Si)$_2$NC(N*i*Pr)$_2$}$_2$(μ-H)]$_2$ (3): A solution of PhSiH$_3$ (0.12 g, 1.08 mmol) in hexane (2 mL) was added at room temperature to a solution of **2** (0.86 g, 1.08 mmol) in hexane (10 mL). The reaction mixture was stirred for 45 min and then concentrated in vacuo to approximately one third of its initial volume. When crystallization started, the solution was cooled to −30 °C and kept at that temperature overnight. The mother liqueur was decanted, the solid was washed with cold hexane and dried in vacuo at room temperature for 45 min to give **3** as a colorless microcrystalline solid (0.68 g, 84%). $C_{52}H_{130}Lu_2N_{12}Si_8$ (1497.2): calcd. C 41.71, H 8.68, Lu 23.37; found C 41.18, H 8.39, Lu 23.71. ^{1}H NMR (200 MHz, [D$_6$]benzene): δ = 0.45 [s, 72 H, NSi(C*H*$_3$)$_3$], 1.53 [m, 48 H, (C*H*$_3$)$_2$CH], 4.10 (m, 8 H, C*H*Me$_2$), 12.96 (s, 2 H, Lu*H*) ppm. ^{13}C{^{1}H} NMR (50 MHz, [D$_6$]benzene): δ = 3.1, 3.3 [N(Si*C*H$_3$)$_2$], 27.1, 28.2, 28.6 [(*C*H$_3$)$_2$CH], 46.5, 46.6 (*C*HMe$_2$), 168.7, 170.8 (CN$_3$) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 1630 (s), 1605 (m), 1320 (s), 1250 (s), 1205 (s), 1050 (s), 950 (s), 820(s) cm^{-1}.

Ethylene Polymerization: Ethylene polymerization tests were carried out in a constant-volume glass vessel connected to a Hg manometer (20 °C, $p_{monomer}$ = 0.48 bar). A solution of **3** (0.088 g, 0.0588 mmol) in toluene (5 mL) was loaded into the reaction vessel, which was then charged with ethylene, and the reaction mixture stirred. The reaction was monitored by the absorption of ethylene. After 72 h, the reaction vessel was disconnected and methanol was added (ca. 20 mL). The polymer was collected by filtration, washed with a 15% solution of HCl, then with methanol, and dried in vacuo to a constant weight; 0.192 g of polyethylene was isolated.

Propylene Polymerization: Propylene polymerization tests were carried out in a constant-volume glass vessel connected to a Hg manometer (0 °C, $p_{monomer}$ = 0.75 bar). A solution of **3** (0.053 g, 0.0353 mmol) in toluene (5 mL) was loaded into the reaction vessel, which was charged with propylene, and the reaction mixture stirred. The reaction was monitored by the absorption of the monomer. After 1 h, the reaction vessel was disconnected and methanol

was added (ca. 20 mL). The polymer was collected by filtration, washed with a 15% solution of HCl, then with methanol, and dried in vacuo to a constant weight; 0.105 g of polypropylene was isolated.

Styrene Polymerization: Complex **3** (0.045 g, 0.0300 mmol) was added to styrene (1 mL) and the reaction mixture was stirred at room temperature. After 6 d, the volatiles were evaporated in vacuo. The polymer was washed with methanol (2 × 10 mL), HCl (10%, 10 mL), dissolved in toluene (20 mL), filtered, and precipitated into methanol (100 mL). The polymer was collected by filtration, washed with methanol, and dried in vacuo to a constant weight; 0.815 g of polystyrene was isolated.

X-ray Crystallographic Study: Single crystals of **1** and **3** for X-ray structure analysis were obtained from hexane solutions. The data were collected with a Bruker AXS SMART APEX diffractometer (graphite-monochromated Mo-K_α-radiation, φ/ω-scan technique, λ = 0.71073 Å). The intensity data were integrated with the SAINT program.[37] The structures were solved by direct methods and refined on F^2 using all reflections with SHELXL-97.[38] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms in **1** and **3** were placed in calculated positions and refined in the "riding-model". Only the hydride atom H(1) in **3** was found from Fourier synthesis and refined isotropically with fixed U_{iso} (0.08 Å^2). The crystal of **3** contained a solvate disordered molecule of hexene. SADABS[39] was used to perform area-detector scaling and absorption corrections. The details of crystallographic, collection and refinement data are shown in Table 1. CCDC-235927 (**1**) and -235926 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/const/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Binucleating Aza-Sulfonate and Aza-Sulfinate Macrocycles — Synthesis and Coordination Chemistry

Julia Hausmann,[a][‡] Steffen Käss,[a] Sabrina Klod,[b] Erich Kleinpeter,[b] and Berthold Kersting*[a]

Keywords: Cavitands / Macrocyclic ligands / Nickel / S ligands

The preparation and ligating properties of S-oxygenated derivatives of a macrobinucleating hexaazadithiophenolate macrocycle H_2L^1 of the Robson type towards nickel(II) and zinc(II) ions are reported. Nickel complexes of the hexaazadiphenylsulfonate ligand $(L^2)^{2-}$ $[(L^2)Ni^{II}_2(\mu\text{-}L)]^+$ (L = *m*-Cl-OBz$^-$ (**3**), Cl$^-$ (**4**) and OAc$^-$ (**6**)] are readily obtained in high yields by oxidation of the respective $[(L^1)Ni^{II}_2(\mu\text{-}L)]^+$ parent complexes [L = *m*-Cl-OBz$^-$ (**2**), Cl$^-$ (**1**), OAc$^-$ (**5**)] with *meta*-chloroperoxybenzoic acid or hydrogen peroxide. Decomposition of the sulfonate complexes gives the free macrocycle H_2L^2 which, upon treatment with $Zn(OAc)_2{\cdot}2H_2O$, produces the diamagnetic zinc complex $[(L^2)Zn^{II}_2(OAc)]^+$ (**8**). A dinuclear Cu^{II} complex of the hexaazadisulfinate derivative $(L^{3'})^{2-}$, $[(L^3)Cu^{II}_2]^{2+}$ (**9**), is formed rather unexpectedly by air oxidation of $(L^1)^{2-}$ in the presence of Cu^{I}. The crystal-structure determinations of the perchlorate or tetraphenylborate salts of **2**, **3**, and **4** show that the new ligands support the formation of binuclear complexes with bowl-shaped, calixarene-like binding cavities. NMR spectroscopic studies of **8** show that the complexes retain their solid-state structures in solution. A crystal-structure determination of **9** reveals two five-coordinate Cu^{II} ions bridged by the two sulfinate functions of $(L^3)^{2-}$.

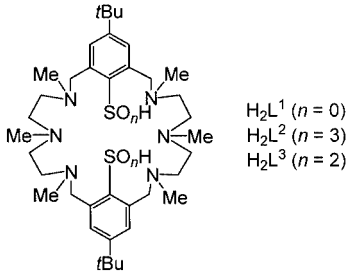
Introduction

The development of ligand systems that support the formation of metal complexes with confined environments about active coordination sites is currently attracting much interest.[1−3] This is mainly due to the fact that such assemblies improve the ability to control the rate and selectivity of substrate transformations.[4−8] Such aggregates also allow for the construction of more-effective enzyme mimics.[9] Consequently, a large number of bowl-shaped supporting ligands have been reported and their ligating properties towards the 3d elements have been investigated. While most of these ligands form mononuclear complexes, as, for instance, the calixarenes,[10] the cyclodextrins,[11] and some tripod ligands,[12−14] there are only a few reports of ligand systems that impose calixarene-like structures about dinuclear cores.[15−17] We have recently shown that N-functionalized hexaazadithiophenolate macrocycles[18,19] of the Robson type[20−23] are suitable for the construction of such species.[24] The unique features of the corresponding complexes[25] led us to investigate potential routes to S-oxygenated derivatives of H_2L^1 and to examine the ligating properties of these hitherto unknown ligand systems (Scheme 1). Herein we report the synthesis of the binucleating hexaazasulfonate ligand $(L^2)^{2-}$ and demonstrate its ability to form dinuclear transition-metal complexes with bowl-shaped binding cavities. The synthesis and crystal structure of a dinuclear copper(II) complex of the related hexaazasulfinate ligand $(L^3)^{2-}$ are also reported.



Scheme 1. Structures of the ligands H_2L^1, H_2L^2 and H_2L^3 (see Scheme 2 for numbering of complexes)

Results and Discussion

The compounds synthesized in this paper are collected in Scheme 2. Of these, the nickel and zinc complexes **1**, **5**, and **7** have been reported previously.

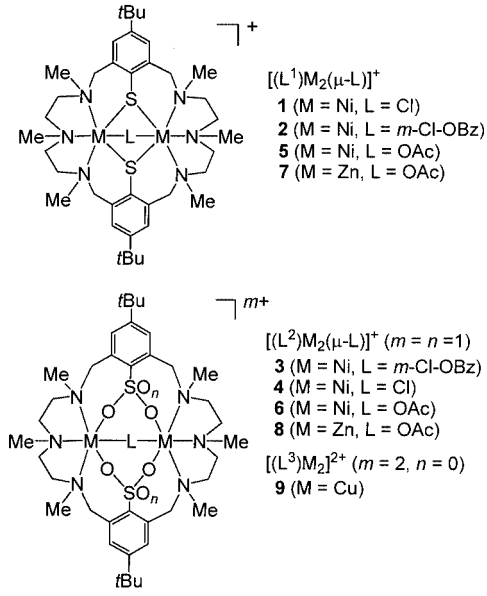
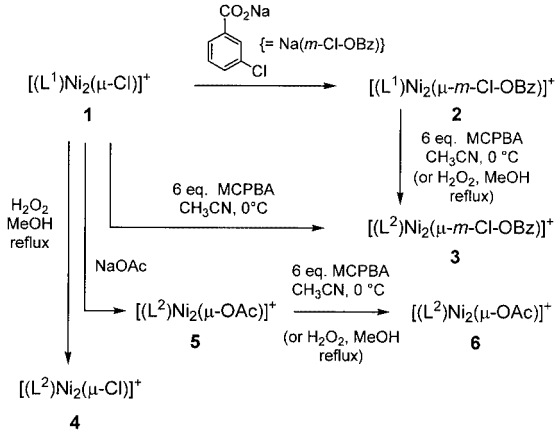


Scheme 2. Synthesized complexes and their labels (see Scheme 1 and ref. 31 for ligand abbreviations)

Attempts to *S*-oxygenate the free hexaazadithiophenol H_2L^1 invariably proved unsuccessful, presumably due to the formation of amine *N*-oxides. The oxidation of dinickel complexes of $(L^1)^{2-}$ was attempted next, since this has recently been demonstrated to be a versatile method for the preparation of sulfonate complexes,[26] even for complexes of labile transition-metal ions such as nickel(II).[27–29] In a preliminary experiment the *meta*-chlorobenzoato-bridged species **2**[30] was treated with six equivalents of *meta*-chloroperoxybenzoic acid (MCPBA) at 0 °C (Scheme 3).[31] This resulted in the rapid and almost quantitative formation of the desired aminosulfonate complex **3**. The facile formation of **3** is somewhat remarkable given that S-oxygenation of bridging thiolate functions has not been observed previously in nickel thiolate chemistry.[32,33]

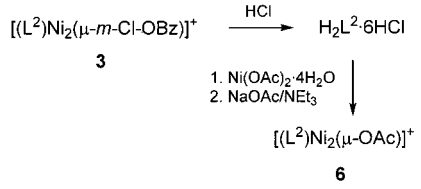


Scheme 3. Synthesis of compounds **2**–**6**

In light of these results the oxidation of the chloro- and acetato-bridged species **1** and **5**, respectively, was examined next (Scheme 3). The oxidation of the chloro complex **1** by MCPBA was expected to give the μ-Cl compound **4**, but the infrared spectrum (vide infra) revealed the presence of the μ-*meta*-chlorobenzoate-containing complex **3**, showing that this transformation is accompanied by a substitution of the bridging chloride ion by the *meta*-chlorobenzoate group (which is produced upon reduction of MCPBA). In contrast, the oxidation of **5** yields the acetato-bridged complex **6** as the sole product. Thus, in this case an exchange of the encapsulated acetate moiety by the external *meta*-chlorobenzoate does not occur, despite it being present in a sixfold molar excess.

In the course of our work it was found that the aminosulfonate complexes **3** and **6** can also be prepared by oxidation of their respective parent complexes with hydrogen peroxide (Scheme 3). This prompted us to test whether complex **4** would be similarly accessible by H_2O_2 oxidation of **1**. Indeed, treatment of **1** with a large excess of H_2O_2 resulted in the formation of a pale-green solution, from which the desired μ-chloro complex **4**·ClO_4 could be obtained upon addition of an excess of $LiClO_4$. Nevertheless, the thiolate complexes are very resistant towards oxidation by H_2O_2. In the case of **2** and **5**, for example, a large excess and prolonged heating was required to obtain the respective oxidation products **3** and **6** in good yields.

As noted above, the direct oxidation of H_2L^1 failed to provide the macrocyclic hexaazadisulfonic acid H_2L^2, and so another route had to be developed. We have previously observed that binuclear complexes of the aminothiolate ligand $(L^1)^{2-}$ decompose under acidic conditions to give the free aminothiol H_2L^1 as its hexahydrochloride salt.[34] Accordingly, the decomposition of the perchlorate salt **3**·ClO_4 with hydrochloric acid was attempted (Scheme 4). The aminosulfonate complex was found to be very stable under acidic conditions, but with concentrated hydrochloric acid complete hydrolysis occurred, such that the desired ligand H_2L^2·6HCl could be isolated in good yields. The identity of H_2L^2·6HCl was confirmed by IR, ^1H and ^{13}C NMR spectroscopy (see below), and by the successful regeneration of complex **6**. Thus, treatment of H_2L^2·6HCl with two equivalents of $Ni(OAc)_2$·$6H_2O$ resulted in a pale-green solution, from which the known complex **6**·ClO_4 could be isolated in excellent yields upon addition of $LiClO_4$.

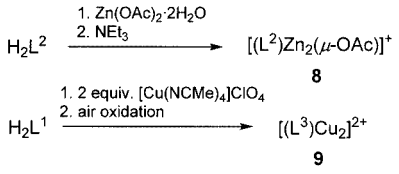


Scheme 4. Synthesis of compounds H_2L^2·6HCl and **6**

In order to get some preliminary information on the solution structures of the new complexes, the synthesis of diamagnetic zinc complexes was devised. The acetato-bridged dizinc complex **8** was selected as the target compound. All attempts to access **8** by oxidation of its parent complex **7** were unsuccessful, but, similar to **6**·ClO_4, this complex

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

could be readily prepared by the complexation of the free macrocycle with $Zn(OAc)_2 \cdot 2H_2O$ (Scheme 5). Thus, the reaction of $H_2L^2 \cdot 6HCl$ with two equivalents of $Zn(OAc)_2 \cdot 2H_2O$ resulted in a colourless solution, from which the colourless perchlorate salt $[(L^2)Zn_2(\mu\text{-}OAc)]ClO_4$ ($\mathbf{8} \cdot ClO_4$) was obtained in the form of large crystals in nearly quantitative yield upon addition of $LiClO_4$.



Scheme 5. Synthesis of compounds **8** and **9**

Finally, we were also able to prepare a dinuclear complex of the aminosulfinate ligand $(L^3)^{2-}$, the dicopper(II) complex **9**. This complex was obtained rather unexpectedly from attempts to prepare mixed-valent Cu^ICu^{II} complexes of $(L^1)^{2-}$. Attempts to access this compound by air oxidation of a methanolic solution of the dicopper(I) complex $[(L^1)Cu^I_2]^{2-}$ (prepared in situ from H_2L^1, $[Cu^I(CH_3CN)_4](ClO_4)$ and NEt_3), however, resulted in the formation of the sulfinate complex **9** instead. The dark-green perchlorate salt $[(L^3)Cu^{II}_2](ClO_4)_2$ [$\mathbf{9} \cdot (ClO_4)_2$] was reproducibly obtained as a dark-green microcrystalline solid in about 45% yield.

All new complexes are stable in air, both in solution and in the solid state. The perchlorate salts are very soluble in a range of common organic solvents. The solubility of the complexes of the hexaazadisulfonate macrocycle is particularly good in polar protic solvents such as ethanol, methanol, and even 25% aqueous methanol. In contrast to the aminothiolate complexes, the sulfonate complexes are stable over a wide pH range. They can be isolated from acidic or basic methanolic solution (pH 1 to 10) without any noticeable decomposition or exchange of the bridging coligands L. The new compounds gave satisfactory elemental analyses and were characterized by spectroscopic methods (IR, UV/Vis, ^1H and ^{13}C NMR spectroscopy) and compounds $\mathbf{2} \cdot BPh_4 \cdot 1.25MeCN$, $\mathbf{3} \cdot BPh_4 \cdot 4EtOH \cdot 2H_2O$, $\mathbf{4} \cdot BPh_4 \cdot EtOH \cdot 0.5CH_3CN$, and $\mathbf{9} \cdot (ClO_4)_2 \cdot H_2O$ also by X-ray structure analysis.

Infrared and UV/Vis Spectroscopy

Table 1 summarizes selected analytical data for compounds **1**−**9**. In agreement with the formulation of **3** the IR spectrum displays a strong band at 1220 cm^{-1} for the sulfonate group $\nu(RSO_3^-)$[35] and two absorptions at 1563 [$\nu_{as}(RCO_2^-)$] and 1410 cm^{-1} [$\nu_s(RCO_2^-)$] for the *meta*-chlorobenzoate coligand.[36] The latter two values are very similar to those of the parent complex **2**, suggesting that the *meta*-chlorobenzoate moiety in **3** is also in the $\mu_{1,3}$-bridging mode. Similarly, the IR spectrum of the acetato-bridged complex **6** shows distinct IR bands for bridging acetate (1597 and 1411 cm^{-1}) and sulfonate groups (1202 cm^{-1}). Unfortunately, the sulfonate stretching frequencies overlap with the bands of the $[(L^2)Ni^{II}_2]^{2+}$ fragment[37] and the counterions (ClO_4^- or BPh_4^-), such that the coordination mode of the RSO_3^- functions could not be deduced from the IR data. The IR spectra of the homologous nickel and zinc complexes **5** and **7** (and **6** and **8**) are identical. Finally, the IR spectrum of the copper complex **9** shows two absorptions at 1052 and 950 cm^{-1}, which can be attributed to the stretching frequencies of the sulfinate functions.[38] Again, the coordination mode of the sulfinate groups could not be inferred from the IR data.

All new complexes were further characterized by UV/Vis spectroscopy. The UV/Vis data of **1**, **2** and **5** have been reported previously.[24,25] The electronic absorption spectra of the new complexes were recorded in the range 300−1600 nm in acetonitrile solution at ambient temperature (Table 1). The spectra of the pale-green nickel complexes **3**, **4**, and **6** are similar but not identical. In agreement with the oxidation of the thiophenolate sulfur atoms, there are no intense $RS^- \rightarrow Ni^{II}$ charge-transfer transitions in the 300 to 400 nm region.[39] Each compound displays three weak absorption bands. The first band is seen around 400 nm, the second one appears in the 670 to 690 nm range, and the third one is observed between 1120 and 1130 nm. These absorptions can be attributed to the three spin-allowed d-d-transitions ν_3 [$^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$], ν_2 [$^3A_{2g}(F) \rightarrow$

$^3T_{1g}(F)$], and ν_1 [$^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)$], respectively, of an octahedral d^8 nickel(II) ion. The higher energy features below 300 nm result from π-π* transitions within the $(L^2)^{2-}$ ligand. The slight differences in the position of the d-d transitions indicate that each complex retains its coligand in the solution state. Finally, the dark-green dicopper(II) complex displays a single absorption band at 668 nm. This is a typical value for square-pyramidal $Cu^{II}N_3O_2$ complexes.[40]

NMR Spectroscopy

To investigate the solution structures, the zinc complex **8** was characterized by ^1H and ^{13}C NMR spectroscopy. The NMR spectroscopic properties of the zinc complex **7** have been reported previously.[25] The ^1H NMR spectrum of **8** in CD_3CN solution displays only one set of signals, indicating that **8** exists as a single isomer in solution. The four aromatic protons, the methyl protons on the benzylic nitrogens, the methyl protons on the central amine nitrogen of the linking diethylene triamine units, and the *tert*-butyl protons all appear as singlets. This is indicative of a C_{2v} symmetric solution structure for the $[(L^2)Zn_2(\mu\text{-OAc})]^+$ cation. In agreement with this assumption the $[(L^2)Zn_2]^{2+}$ fragment gives rise to only eleven ^{13}C NMR signals (seven for the aliphatic and four for the aromatic carbon atoms). The appearance of a ^1H NMR signal at $\delta = 0.59$ ppm, which can be assigned to the methyl protons of the bridging acetate ion, is worthy of note. The observed high-field shift [**8**: $\Delta\delta = -1.24$ ppm, relative to NaOAc ($\delta = 1.83$ ppm)] can be explained by the ring current. As can be seen from Figure S1,[41] the methyl protons of the coordinated acetate group are positioned above the center of the two phenyl rings in the shielding region. The angle between the phenyl rings in **8** (41.6°)[42] is more acute than in **7** (80.0°) and hence the shielding effect is less pronounced in the latter (**7**: $\Delta\delta = -0.92$ ppm, relative to NaOAc). This is also supported by preliminary chemical shielding calculations using Gaussian 98 ($\Delta\delta_{calc} = -1.92$ ppm for **8** vs. -1.25 ppm for **7**; see Exp. Sect. for details).

X-ray Crystallography

Although the formulations of the new compounds were reasonably substantiated by the above spectroscopic data, further confirmation was provided by X-ray diffraction studies. Single crystals of X-ray quality were obtained for the perchlorate or tetraphenylborate salts of complexes **2**, **3**, **4**, and **9**. The crystal structures of complexes **1**, **5**, and **7** have been reported previously.[24,25] All data collections were performed at 210 K. A common labeling scheme for the $[(L^1)Ni_2]^{2+}$ and $[(L^2)Ni_2]^{2+}$ units has been used to facilitate structural comparisons. Selected bond lengths and angles are given in Table 2 and 3.

bridged complexes of this ligand.[43] In this approximately C_{2v}-symmetric structure, the two nickel(II) ions are coordinated in a square-pyramidal fashion by the two *fac*-N_3(μ-$S)_2$ donor sets of the macrocycle. Upon coordination of the *meta*-chlorobenzoate group, both nickel atoms reach distorted octahedral coordination environments at a metal−metal distance of 3.460(1) Å. As in previously reported carboxylato-bridged nickel complexes of $(L^1)^{2-}$, the Ni−N bond lengths involving the four benzylic nitrogen donors are invariably longer (by ca. 0.10−0.12 Å) than the ones comprising the central nitrogen atoms of the linking diethylenetriamine units. The individual Ni−S distances also vary considerably. These distortions are almost certainly a consequence of the steric constraints of the macrocycle.

The dimensions of the bowl-shaped binding cavity of the $[(L^1)Ni_2]^{2+}$ fragment can be described by the intramolecular distance between the two opposing aryl ring carbon atoms C(4) and C(20) and by the angle between the planes through the phenyl rings. For the present structure, the corresponding values are 9.489(1) Å and 93.6°, respectively. As we will show below, these values decrease considerably upon oxygenation of the thiophenolate sulfur atoms.

The crystal-structure determination of **3**·BPh_4 unambiguously confirmed **3** to be a bioctahedral dinickel complex of the new hexaazadiphenylsulfonate ligand $(L^2)^{2-}$ (see Figure 2). The two sulfonate groups and the *meta*-chlorobenzoate ion bridge the two Ni^{II} ions in symmetrical $\mu_{1,3}$-modes, at a distance of 4.584(1) Å. The amine nitrogens of $(L^2)^{2-}$ occupy the remaining positions and complete the pseudo-octahedral N_3O_3 coordination spheres of the metal ions. Precedents for this type of $\mu_{1,3}$-bridging RSO_3^- functions exist in the literature,[44] albeit not incorporated into a macrobinucleating ligand. A comparison with the structure of the parent complex **2** reveals a significant compression of the binding pocket. Thus, in **3** the best planes through the phenyl rings intersect at an angle of 44.6°. This value is much more acute than in **2** (93.6°). As a consequence the *meta*-chlorobenzoate ion becomes tightly embraced by the tertiary butyl groups of $(L^2)^{2-}$, as evidenced by a very short C(4)···C(20) distance of 7.958 Å. The short distances between the coligand and the *t*Bu protons [H(37a)···C(43) 3.230 Å; H(34c)···C(43) 3.311 Å] are indicative of intramolecular van der Waals interactions between the host and its guest. This is also supported by the wider binding pocket in the μ-Cl species **4** (see below).

Crystals of **4**·BPh_4·EtOH·0.5CH_3CN are composed of discrete, dinuclear $[(L^2)Ni_2(\mu\text{-}Cl)]^+$ cations, tetraphenylborate anions and ethanol and acetonitrile molecules of solvent of crystallization (see Figure 3). Similar to **3**, the aminosulfonate ligand in **4** assumes a calixarene-like conformation such that the bridging halide ion is deeply buried in the binding cavity of the $[(L^2)Ni_2]^{2+}$ fragment. This ligand conformation is different from the "partial cone"-like conformation seen in its parent **1**.[24] The corresponding Ni−O and Ni−N bond lengths in **3** and **4**, respectively, are very similar. In both structures the Ni−N bond lengths involving the four benzylic nitrogen donors are invariably longer (by ca. 0.1 Å) than the ones comprising the central nitrogen atoms of the linking diethylenetriamine units; the Ni−O distances also vary considerably. These distortions can be traced back to the steric constraints of the macrocycle. The main differences between the structures of **3** and **4** concern the Ni···Ni distances (4.063 Å in **4**, 4.584 Å in **3**) and the angle between the phenyl rings (72.2° in **4**, 44.5° in **3**). While the differences in the Ni···Ni distances can be traced back to the different ligating properties of the coligands, the more pronounced clipping of the phenyl rings in **3** is presumably due to attractive van der Waals interactions between the apolar CH function of the bowl-shaped host and its guest. Such secondary interactions are of importance as they can confer unusual binding modes on the coligands.[45]

Finally, the crystal structure determination of **9**·$(ClO_4)_2$·H_2O reveals the dication **9** to be a dicopper(II) complex of the new hexaazadiphenylsulfinate ligand $(L^3)^{2-}$. The complex dication exhibits a center of inversion such that the asymmetric unit consists of only one half of the

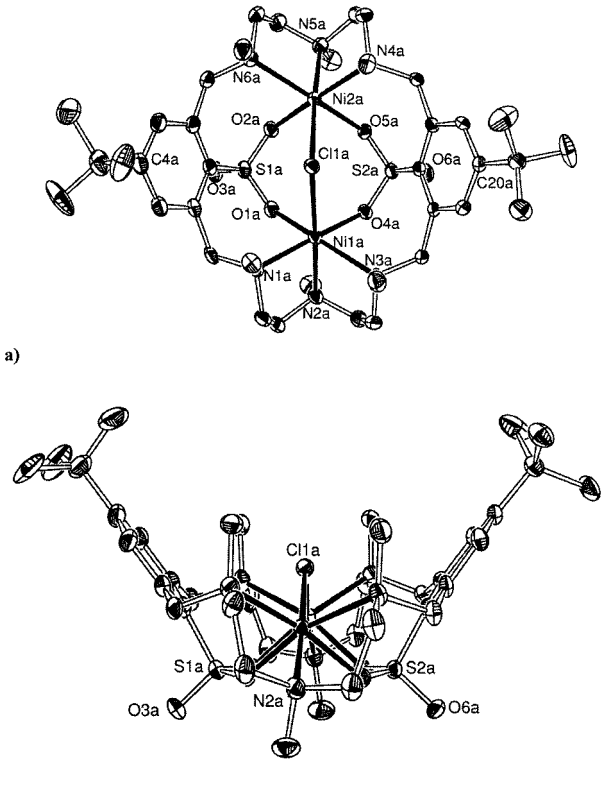

Figure 3. Two views of the molecular structure of the cation **4**; thermal ellipsoids are drawn at the 30% probability level; hydrogen atoms are omitted for clarity

formula unit. As can be seen from Figure 4 the two sulfinate functions bridge the two Cu^{II} ions in symmetrical $\mu_{1,3}$-modes, at a Cu···Cu distance of 4.993(1) Å. The amine nitrogens of $(L^3)^{2-}$ occupy the remaining positions and complete the pseudo-square-pyramidal N_3O_2 coordination spheres of the metal ions. The mean Cu−N and Cu−O distances of 2.118 and 1.985 Å show no unusual features and compare well with those in related $Cu^{II}N_3O_2$ complexes.[46]

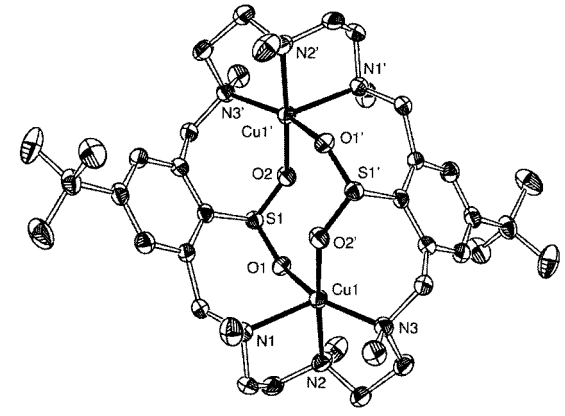

Figure 4. Molecular structure of the dication **9**; thermal ellipsoids are drawn at the 50% probability level; hydrogen atoms are omitted for clarity

Conclusion

The main findings of the present work can be summarized as follows: a) S-oxygenated derivatives of binucleating hexaazadithiophenolate macrocycles of the Robson type can be readily prepared by oxidation of dinuclear nickel complexes of the parent hexaazadithiophenolate macrocycles followed by decomposition of the oxidation products in acidic solution. b) The new hexaazadisulfonate macrocycle $(L^2)^{2-}$ is an effective dinucleating ligand that supports the formation of dinuclear complexes of the type $[(L^2)M_2(\mu\text{-}L)]^+$ with a bowl-shaped, calixarene-like structure. c) The $[(L^2)M_2]^{2+}$ fragment is capable of binding different coligands. d) The $[(L^2)M_2(\mu\text{-}L)]^+$ complexes retain their solid-state structures in the solution state. e) The more pronounced clipping of the phenyl rings in the $[(L^2)M_2(\mu\text{-}L)]^+$ complexes is presumably due to attractive van der Waals interactions between the ligand matrix of the complex and the encapsulated coligand. f) The sulfonate complexes are stable over a wider pH range and oxidizing conditions. Thus, the reactivity of the encapsulated coligands can now also be examined under these more forcing conditions.

Experimental Section

General: Unless otherwise noted the preparations of the metal complexes were carried out under an argon atmosphere by using standard Schlenk techniques. The compounds $H_2L^1\cdot 6HCl$, $[(L^1)Ni_2(Cl)]ClO_4$ (**1**·ClO_4), $[(L^1)Ni_2(OAc)]ClO_4$ (**5**·ClO_4), and $[(L^1)Zn_2(OAc)]ClO_4$ (**7**·ClO_4) were prepared as described in the literature.[25] All other compounds and reagents were purchased from Aldrich. Melting points were determined in capillaries and are uncorrected. ^1H and ^{13}C NMR spectra were recorded on a Bruker AVANCE DPX-200 or a Varian 300 unity spectrometer. Elemental analyses were performed on a Vario EL analyzer (Elementaranalysensysteme GmbH). All compounds crystallize with solvent molecules (see crystal structures of **3**·$BPh_4\cdot 2EtOH\cdot 0.5CH_3CN$ and **4**·$BPh_4\cdot 2EtOH\cdot 0.5CH_3CN$), but the compounds slowly lose their solvent molecules of crystallization upon standing in air. This is why the observed microanalytical data do not fit exactly with the calculated values (for the solvent-free compounds). IR spectra were recorded on a Bruker VECTOR 22 FT-IR spectrophotometer as KBr pellets. Electronic absorption spectra were recorded on a Jasco V-570 UV/Vis/near IR spectrophotometer.

Safety note! *Perchlorate salts of transition-metal complexes are hazardous and may explode. Only small quantities should be prepared and great care taken. We have not encountered any problems with the ClO_4 salts of the present complexes (hammer test), and have for this reason not prepared the BF_4 complexes.*

$[(L^1)Ni^{II}_2$(*m*-Cl-OBz)$]ClO_4$ (2·ClO_4): A solution of sodium *meta*-chlorobenzoate (26.8 mg, 0.150 mmol) in methanol (5 mL) was added to a solution of $[(L^1)Ni_2(Cl)]ClO_4$ (92 mg, 0.10 mmol) in methanol (30 mL). The mixture was stirred for 2 h, during which time the color of the solution turned from yellow to pale green. A solution of $LiClO_4\cdot 3H_2O$ (400 mg, 2.50 mmol) in methanol (2 mL) was then added. The resulting pale-green microcrystalline solid was isolated by filtration, washed with methanol, and dried in air. This material was recrystallized once from a mixed ethanol/acetonitrile (1:1) solvent system. Yield: 78 mg (75%). M.p. 348−350 °C (de-

comp.). UV/Vis (CH_3CN): λ_{max} (ε) = 385 (2400), 651 (26), 1116 nm (65 $M^{-1}cm^{-1}$). IR (KBr): $\tilde{\nu}$ = 1598 cm^{-1}, 1566 s [$\nu_{as}(RCO_2^-)$], 1423 s [$\nu_s(RCO_2^-)$], 1098 vs [$\nu(ClO_4^-)$]. The tetraphenylborate salt [$(L^1)Ni^{II}_2$(*m*-Cl−OBz)]BPh_4 (**2**·BPh_4) was prepared by adding $NaBPh_4$ (342 mg, 1.00 mmol) to a solution of **2**·ClO_4 (104 mg, 0.100 mmol) in methanol (40 mL). The resulting green solid was recrystallized from a mixed ethanol/acetonitrile solution. Yield: 101 mg (80%). M.p. 298−300 °C (decomp.). UV/Vis (CH_3CN): λ_{max} (ε) = 385 (2500), 649 (34), 1115 nm (68 $M^{-1}cm^{-1}$). IR (KBr): $\tilde{\nu}$ = 1601 s cm^{-1}, 1580 w, 1564 s [$\nu_{as}(RCO_2^-)$], 1423 [$\nu_s(RCO_2^-)$], 732, 703 (BPh_4^-). $C_{69}H_{88}BClN_6Ni_2O_2S_2$ (1261.3): calcd. C 65.71, H 7.03, N 6.66, S 5.08; found C 65.26, H 7.23, N 6.55, S 5.04. The tetraphenylborate salt **2**·BPh_4 was additionally characterized by X-ray crystallography.

[$(L^2)Ni_2$(*m*-Cl-OBz)]ClO_4 (3·ClO_4). Method A (Oxidation with *meta*-Chloroperoxybenzoic acid, MCPBA): A solution of *meta*-chloroperoxybenzoic acid (121 mg, 0.700 mmol) in acetonitrile (2 mL) was added dropwise to a solution of the perchlorate salt **2**·ClO_4 (104 mg, 0.100 mmol) in acetonitrile (30 mL). During the addition the temperature was kept at 0 °C. After stirring for 2 h, a solution of $LiClO_4$·$3H_2O$ (500 mg, 3.12 mmol) in ethanol (40 mL) was added. The product precipitated during evaporation of the solvent (the final amount of solvent was 3−4 mL). The pale-green microcrystalline material was isolated by filtration and dried in air. Yield: 95 mg (84%). M.p. 348−350°C (decomp.). UV/Vis (CH_3CN): λ_{max} (ε) = 400 (47), 674 (16), 1126 nm (15 $M^{-1}cm^{-1}$). IR (KBr): $\tilde{\nu}$ = 1606 cm^{-1}, 1563 s [$\nu_{as}(RCO_2^-)$], 1410 s [$\nu_s(RCO_2^-)$], 1220 vs [$\nu(RSO_3^-)$], 1091 vs [$\nu(ClO_4^-)$]. $C_{45}H_{68}Cl_2N_6Ni_2O_{12}S_2$·$2H_2O$·EtOH (1137.5 + 82.1): calcd. C 45.61, H 6.52, N 6.79, S 5.18; found C 46.00, H 6.82, N 6.89, S 4.77. The tetraphenylborate salt [$(L^2)Ni_2$(*m*-Cl−OBz)]BPh_4 (**3**·BPh_4) was prepared by adding $NaBPh_4$ (342 mg, 1.00 mmol) to a solution of **3**·ClO_4 (114 mg, 0.100 mmol) in methanol (40 mL). The resulting pale-green solid was recrystallized from a mixed ethanol/acetonitrile solution. Yield: 128 mg (94%). M.p. 340−344°C (decomp.). IR (KBr): $\tilde{\nu}$ = 1608 cm^{-1}, 1565 s [$\nu_{as}(RCO_2^-)$], 1410 w [$\nu_s(RCO_2^-)$], 1218 vs [$\nu(RSO_3^-)$], 732, 705 s [$\nu(BPh_4^-)$]. $C_{69}H_{88}BClN_6Ni_2O_8S_2$·$2H_2O$ (1357.3 + 36.0): calcd. C 59.48, H 6.66, N 6.03, S 4.60; found C 59.47, H 6.92, N 5.82, S 3.97.

Method B (Oxidation with Hydrogen Peroxide): Hydrogen peroxide (1.00 mL, 35 wt.-% solution in water, 11.7 mmol) was added to a solution of **2**·ClO_4 (104 mg, 0.10 mmol) in methanol (30 mL). The reaction mixture was refluxed for 5 h to give a pale-green solution. After cooling to room temperature, a solution of $LiClO_4$·$3H_2O$ (0.500 g, 3.12 mmol) in ethanol (40 mL) was added. The product precipitated during evaporation of the solvent (the final amount of solvent was 3−4 mL). The pale-green microcrystalline material was isolated by filtration and dried in air. Yield: 70 mg (60%). The analytical data of this material are identical to those of compound **3**·ClO_4 prepared by method A. The tetraphenylborate salt was additionally characterized by X-ray crystallography.

[$(L^2)Ni_2$(Cl)]ClO_4 (4·ClO_4): H_2O_2 (1.00 mL, 35 wt.-% solution in water, 11.7 mmol) was added to a solution of **1**·ClO_4 (92 mg, 0.10 mmol) in methanol (30 mL). The reaction mixture was refluxed for 4 h to give a pale-green solution. After cooling to room temperature, a solution of $LiClO_4$·$3H_2O$ (0.250 g, 1.56 mmol) in ethanol (40 mL) was added. The product precipitated during evaporation of the solvent (the final amount of solvent was 3−4 mL). The pale-green microcrystalline material was isolated by filtration and dried in air. Yield: 63 mg (62%). An analytical sample was obtained by recrystallization from acetonitrile/ethanol. M.p. 318−320°C (decomp.). UV/Vis (CH_3CN): λ_{max} (ε) = 396 (33), 686 (15), 1124 nm (17 $M^{-1}cm^{-1}$). IR (KBr): $\tilde{\nu}$ = 1202vs cm^{-1} [$\nu(RSO_3^-)$], 1092s [$\nu(ClO_4^-)$]. $C_{38}H_{64}Cl_2N_6Ni_2O_{10}S_2$·$2H_2O$·EtOH (1017.4 + 82.1): calcd. C 43.70, H 6.78, N 7.64, S 5.83; found C 43.35, H 6.98, N 7.88, S 5.47. The tetraphenylborate salt [$(L^2)Ni_2$(Cl)]BPh_4 (**4**·BPh_4) was prepared by adding $NaBPh_4$ (342 mg, 1.00 mmol) to a solution of **4**·ClO_4 (105 mg, 0.100 mmol) in methanol (40 mL). The resulting green solid was recrystallized from a mixed ethanol/acetonitrile solution. Yield: 111 mg (90%). M.p. 330−334°C (decomp.). IR (KBr): $\tilde{\nu}$ = 1203 vs cm^{-1} [$\nu(RSO_3^-)$]. $C_{62}H_{84}BClN_6Ni_2O_6S_2$·EtOH (1237.2 + 46.1): calcd. C 59.90, H 7.07, N 6.55, S 5.00; found C 60.27, H 6.86, N 6.61, S 4.96. The tetraphenylborate salt was additionally characterized by X-ray crystallography. The oxidation of **1**·ClO_4 by *meta*-chloroperoxybenzoic acid yields **3**·ClO_4 (vide supra).

[$(L^2)Ni_2$(OAc)]ClO_4 (6·ClO_4). Method A (Oxidation with *meta*-Chloroperoxybenzoic Acid): A solution of the acetato-bridged complex **5**·ClO_4 (94 mg, 0.10 mmol) in acetonitrile (30 mL) was added slowly to a solution of *meta*-chloroperoxybenzoic acid (0.12 g, 0.70 mmol) in acetonitrile (2 mL). During the addition the temperature was kept at 0 °C. After stirring for 30 min, a solution of $LiClO_4$·$3H_2O$ (0.500 g, 3.12 mmol) in ethanol (40 mL) was added. The product precipitated during evaporation of the solvent (the final amount of solvent was 3−4 mL). The pale-green microcrystalline material was isolated by filtration and dried in air. Yield: 87 mg (84%). M.p. 344−348°C (decomp.). UV/Vis (CH_3CN): λ_{max} (ε) = 398 (55), 670 (25), 1122 nm (47 $M^{-1}cm^{-1}$). IR (KBr): $\tilde{\nu}$ =1611 sh cm^{-1}, 1597 s [$\nu_{as}(RCO_2^-)$], 1411 w [$\nu_s(RCO_2^-)$], 1202 vs [$\nu(RSO_3^-)$], 1092 s [$\nu(ClO_4^-)$]. $C_{40}H_{67}ClN_6Ni_2O_{12}S_2$·$4H_2O$ (1041.0 + 72.1): calcd. C 43.16, H 6.79, N 7.55, S 5.76; found C 43.73, H 6.94, N 7.43, S 5.34.

Method B (Oxidation by Hydrogen Peroxide): Hydrogen peroxide (1.00 mL, 35 wt.-% solution in water, 11.7 mmol) was added to a solution of **5**·ClO_4 (94 mg, 0.10 mmol) in methanol (30 mL). The reaction mixture was refluxed for 5 h to give a pale-green solution. After cooling to room temperature, a solution of $LiClO_4$·$3H_2O$ (0.500 g, 3.12 mmol) in ethanol (40 mL) was added. The product precipitated during evaporation of the solvent (the final amount of solvent was 3−4 mL). The pale-green microcrystalline material was isolated by filtration and dried in air. Yield: 56 mg (50%). The analytical data of this material are identical to those of compound **6**·ClO_4 prepared by method A.

Method C (from the Free Ligand H_2L^2·6HCl): The reaction of $Ni(OAc)_2$·$4H_2O$ with H_2L^2·6HCl in the presence of a base also gives **6**·ClO_4. The procedure is detailed below for the corresponding zinc complex **8**.

H_2L^2·6HCl: Hydrochloric acid (12 M, 100 mL) was added to a suspension of complex **3**·ClO_4 (3.50 g, 3.08 mmol) in methanol (300 mL) and the reaction mixture was stirred vigorously at 50 °C for 24 h. The resulting solution was then concentrated at reduced pressure (final volume ca 40 mL) and the pH adjusted to 13 with 5 M aqueous potassium hydroxide solution. The resulting green suspension was allowed to cool to room temperature, and the aqueous phase was extracted with dichloromethane (5 × 100 mL). The organic fractions were combined and the dichloromethane was distilled off at reduced pressure to give a colorless solid. The residue was redissolved in ethanol (100 mL), acidified to pH 1 with conc. hydrochloric acid (ca. 3−4 mL), and the resulting solution quickly filtered off from an insoluble white solid (KCl). Evaporation of the solvent gave H_2L^2·6HCl as a colorless voluminous solid. M.p. 240−242°C (dec.). Yield: 2.63 g (85%). This material was pure enough for metal-complex synthesis. IR (KBr): $\tilde{\nu}$ = 3023 w cm^{-1}, 2962 m, 2591 br. s, 1634, 1602, 1464 s, 1228 vs [$\nu(RSO_3H)$], 1074

s, 1019 s, 688 s, 662 s. $C_{38}H_{72}Cl_6N_6O_6S_2$ $(H_2O)_3$ (985.86 + 54.05): calcd. C 43.89, H 7.65, N 8.08, S 6.17; found C 44.02, H 7.37, N 7.75, S 5.91. ^{1}H NMR (200 MHz, D_2O, 330 K): δ = 7.87 (s, 4 H, ArH), 4.86 (s, 8 H, $ArCH_2$), 3.72 (t, ^3J, 5.6 Hz, 8 H, CH_2), 3.33 (t, ^3J, 5.6 Hz, 8 H, CH_2), 3.02 (s, 12 H, $BzNCH_3$), 2.45 (s, 6 H. NCH3), 1.47 [s, 18 H, $C(CH_3)_3$] ppm. ^{13}C{^{1}H} NMR (50 MHz, D_2O): δ = 30.9 [$C(CH_3)_3$], 35.4 [$C(CH_3)_3$] 41.5 (CH_3), 52.5 (CH_2), 52.9 (CH_2), 60.9 (CH_2), 128.6, 136.0 (CH), 142.2, 157.4 ppm; one aliphatic carbon signal was not observed.

[(L^2)Zn_2(OAc)](ClO_4) (8·ClO_4): $Zn(O_2CCH_3)_2$·$2H_2O$ (44 mg, 0.20 mmol) and triethylamine (61 mg, 0.60 mmol) were added to a solution of H_2L^2·6HCl (99 mg, 0.10 mmol) in methanol (25 mL). After stirring the reaction mixture for 2 d at room temperature, solid $LiClO_4$·$3H_2O$ (321 mg, 2.00 mmol) was added. The mixture was then stirred for a further 12 h. The resulting white precipitate was collected by filtration and recrystallized from an acetonitrile/ethanol mixed-solvent system. Yield: 96 mg (91%). M.p. 360−364°C (decomp.). IR (KBr): $\tilde{\nu}$ = 1595s cm^{-1} [$\nu_{as}(RCO_2^-)$], 1411 w [$\nu_s(RCO_2^-)$], 1202 vs [$\nu(RSO_3^-)$], 1090 s [$\nu(ClO_4^-)$]. ^{1}H NMR (200 MHz, CD_3OD): δ = 7.26 (s, 4 H, ArH), 4.58 (d, ^2J = 12.4 Hz, 4 H, $ArCH_2$), 3.00 (d, ^2J = 12.4 Hz, 4 H, $ArCH_2$), 2.95−2.75 (m, 16 H, CH_2), 2.68 (s, 6 H, NCH_3), 2.47 (s, 12 H, NCH_3), 1.26 [s, 18 H, $C(CH_3)_3$], 0.59 (s, 3 H, CH_3) ppm. ^{13}C{^{1}H} NMR (50 MHz, $CDCl_3$): δ = 173.1, 153.2, 143.5, 133.3, 132.5, 64.4, 57.1, 52.8, 45.3, 44.7, 35.08, 30.9, 23.3 ppm. $C_{40}H_{67}ClN_6O_{12}S_2Zn_2$·$4H_2O$ (1054.4 + 72.1): calcd. C 42.65, H 6.71, N 7.46, S 5.69; found C 42.58, H 6.74, N 7.36, S 5.20.

[(L^3)Cu_2](ClO_4)$_2$ (9·2ClO_4): $[Cu(CH_3CN)_4]ClO_4$ (65 mg, 0.20 mmol) and triethylamine (81 mg, 0.80 mmol) were added successively to a suspension of H_2L^1·6HCl (89 mg, 0.10 mmol) in methanol (40 mL). The colorless reaction mixture was stirred for 24 h and was then exposed to air to give a dark-green solution. A solution of $LiClO_4$·$3H_2O$ (160 mg, 1.00 mmol) in methanol was added. The mixture was then filtered and stored in an open vessel for five days. The resulting green crystals were isolated by filtration and dried in air. Yield: 45 mg (45%). M.p. 350−352°C (decomp.). IR (KBr): $\tilde{\nu}$ = 1058 cm^{-1}, 970 [$\nu(RSO_2^-)$], 1090 s [$\nu(ClO_4^-)$]. UV/Vis (CH_3CN): λ_{max} (ε) = 668 (430), 947 sh nm (153 $M^{-1}cm^{-1}$). $C_{38}H_{64}Cl_2Cu_2N_6O_8S_2$ (995.08): calcd. C 45.87, H 6.48, N 8.45, S 6.44; found C 45.66, H 6.53, N 8.33, S 6.22. This compound was additionally characterized by X-ray crystallography.

Crystal Structure Determinations: Single crystals of **2**·BPh_4·1.25CH_3CN, **3**·BPh_4·4EtOH·$2H_2O$, and **4**·BPh_4·2EtOH·0.5CH_3CN suitable for X-ray structure analysis were grown from an acetonitrile/ethanol (1:1) mixed-solvent system. Crystals of **9**·$(ClO_4)_2$·H_2O were grown from methanolic solution. The crystals were mounted on glass fibers in perfluoropolyether oil. Intensity data were collected at 210(2) K, using a Bruker SMART CCD diffractometer. Graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used throughout. The data were processed with SAINT and corrected for absorption using SADABS[47] (transmission factors: 1.00−0.89 for **2**, 1.00−0.58 for **3**, 1.00−0.85 for **4**, and 1.00−0.91 for **9**). The structures were solved by direct methods using the program SHELXS-86[48] and refined by full-matrix least-squares techniques against F^2 using SHELXL-97.[49] The ShelXTL version 5.10 program package was used for the structure solutions and refinements.[50] PLATON was used to search for higher symmetry.[51] Ortep3 was used for the artwork of the structures.[52] Unless otherwise noted all non-hydrogen atoms were refined anisotropically. Hydrogen atoms were assigned to idealized positions and given isotropic thermal parameters 1.2-times (1.5-times for CH_3 groups) the thermal parameter of the atoms to which they are attached. Selected details of the data collection and refinement are given in Table 4.

In the crystal structure of **2** two *tert*-butyl groups were found to be disordered over two positions. A split-atom model was applied for the disordered *t*Bu groups. The site occupancies of the two orientations were refined as 0.70(1)/0.30(1) [for C(32a/c), C(33a/c), C(34a/c)] and 0.62(1)/0.38(1) [for C(36a/c), C(37a/c), C(38a/c)]. All non-hydrogen atoms were refined anisotropically, except the nitro-

gen and carbon atoms [N(9), C(51), C(52)] of one half-occupied acetonitrile solvent molecule. No hydrogen atoms were calculated for the methyl carbon atom C(52). In the crystal structure of **3**, the C and O atoms of the ethanol and water molecules of solvent of crystallization were found to exhibit very large thermal parameters indicative of severe disorder. This disorder could not be modeled by using split-atom models, therefore the coordinates of the respective atoms were fixed at their initial positions and given a common isotropic thermal parameter of 0.20. No problems were encountered with the refinement of the $[(L^2)Ni_2(m\text{-Cl-OBz})]^+$ cation. The relatively large *R* value is due to the disorder of the solvent molecules. In the crystal structure of **4**, one *tert*-butyl group and the two ethanol molecules of crystallization were found to be disordered over two positions. A split atom model was applied to account for this disorder. The site occupancies of the two orientations were refined as 0.53(1)/0.47(1) [for C(32a/b), C(33a/b), C(34a/b)], 0.71(1)/0.29(1) [for O(5a/b), C(39a/b), C(40a/b)], and 0.78(1)/0.22(1) [for O(7a/b), C(41a/b), C(42a/b)]. The disorder of the acetonitrile molecule of solvent of crystallization could not be modeled by using a split-atom model, therefore the coordinates of the C and N atoms were fixed at their initial positions and given a common isotropic thermal parameter of 0.20. No hydrogen atoms were calculated for the solvate molecules. In the crystal structure of $\mathbf{9}\cdot(ClO_4)_2(H_2O)$ no hydrogen atoms were calculated for the H_2O molecule.

CCDC-239553 (for **2**), -239554 (for **3**), -239555 (for **4**) and -239556 (for **9**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336-033; or deposit@ccdc.cam.ac.uk).

Calculation of Ring-Current Effects: All ab initio calculations were performed on an SGI Octane and an SGI Origin 2000 using the program Gaussian 98.[53] Geometry optimization was carried out using HF/6-31G* without restrictions.[54] The chemical shieldings in the surrounding of the molecules were calculated based on the idea of NICS (nucleus-independent chemical shift) by Schleyer.[55] The molecule was placed in the center of a grid of "ghost atoms" ranging from −10.0 to +10.0 Å in all three dimensions with a step width of 0.5 Å. This resulted in a cube of 68921 ghost atoms. The chemical-shielding calculations were done with the GIAO (gauge-independent atomic orbital) method using HF/6-31G*.[56] Since GIAO is a coupled HF method that uses gauge-independent atom orbitals for the calculation of shielding values it can be applied in the calculation of NICS. From the GIAO calculations the coordinates and isotropic shielding values of the ghost atoms were extracted. After the transformation of the tabulated chemical shieldings into a SYBYL contour file, the ring-current effects of the two isolated phenyl rings in the complexes can be visualized as iso chemical-shielding surfaces (ICSS).[57] Thus, it is possible to map both spatial extension and sign of the ring current effects of the two phenyls on the methyl protons at each position.[58]

The chemical shielding values at the positions of the three methyl protons of the bridging acetate ions in **7** and **8** (atomic coordinates were taken from the crystal structures) were calculated as follows: **7**: $\Delta\delta$ = −1.56, −1.08, −1.12 ppm (mean value = −1.25 ppm, in the gas phase); **8**: $\Delta\delta$ = −2.32, −1.59, −1.85 ppm (mean value = −1.92 ppm). The observed chemical shielding values (relative to NaOAc at δ = 1.83 ppm in CD_3OD) are as follows: **7** δ(μ-OAc) = 0.86 ppm ($\Delta\delta$ = −0.97 ppm); **8**: δ(μ-OAc) = 0.59 ppm ($\Delta\delta$ = −1.24 ppm). The differences between the calculated and the experimental values are most likely due to solvation effects.

Supporting Information Available: Figures S1 and S2 (see also the footnote on the first page of this article). The calculated chemical shielding values at the positions of the three methyl protons of the bridging acetate ions in **7** and **8**.

Acknowledgments

We are particularly grateful to Prof. Dr. H. Vahrenkamp for providing facilities for NMR and X-ray crystallographic measurements. Financial support of this work from the Deutsche Forschungsgemeinschaft (Priority programme "Sekundäre Wechselwirkungen", KE 585/3-1,2) and by the Wissenschaftliche Gesellschaft in Freiburg is gratefully acknowledged.

[30] The absence of sharp ^{1}H NMR resonances in the δ = 0−10 ppm region indicates that the nickel complexes **1**−**6** are paramagnetic in solution. For complexes **2** and **5** this is further supported by temperature-dependent magnetic susceptibility measurements.[45] We anticipate performing a more detailed study of the electronic structures of the other compounds by temperature-dependent susceptibility measurements.

Synthesis, Crystal Structure and Biological Characterization of a Novel Palladium(II) Complex with a Coumarin-Derived Ligand

Elzbieta Budzisz,*[a] Bernhard K. Keppler,[b] Gerald Giester,[c] Magdalena Wozniczka,[d] Aleksander Kufelnicki,[d] and Barbara Nawrot[e]

Keywords: Circular dichroism / Cytotoxicity / DNA / Palladium / Protonation constants

Methyl 2-methyl-4-oxo-4*H*-chromene-3-carboxylate (**1**) was treated with 25% aqueous ammonia to give 3-(1-aminoethylidene)-2*H*-chromene-2,4(3*H*)-dione (**2**). Compound **2** was used as a ligand for the formation of a palladium(II) complex. The structures of the ligand and its palladium complex **3** were determined by IR and ^{1}H NMR spectroscopy, FAB mass spectrometry and elemental analysis. The single-crystal X-ray structure of **3** was also solved. Ligand **2** in 20% dioxane solution shows two protonation constants — $\log \beta_{11} = 4.28 \pm 0.01$ and $\log \beta_{12} = 7.66 \pm 0.03$. In complex **3** two ligand molecules chelate to the Pd ion through their N and O donors, giving a four-coordinate Pd^{II} center with a *cis*-N_2O_2 donor set. The coordination geometry at Pd^{II} is square-planar with typical values for the distances from the Pd atom to the coordinated atoms. The cytotoxicity of compound **3** was determined on three cancer cell lines. IC_{50} values of 9.7, 7.8 and 7.8 nM were found for A546, HeLa and K562 cells, respectively, which is notably lower than carboplatin, which shows corresponding IC_{50} values of 105.98, 73.49 and 60.92 μM. Double-stranded DNA treated with **3** shows a significant increase in the Δε value in the CD spectra, as well as a lower electrophoretic mobility than parent DNA.

Introduction

Since the discovery by Rosenberg[1] that cisplatin exhibits antitumour activity, extensive studies on platinum complexes with various ligands as potential antitumor agents have been performed. It has been shown that cisplatin [*cis*-diamminedichloroplatinum(II)] is active against several human malignant diseases, such as neck and head, ovarian, testicular, lung, and bladder cancers.[2] It is generally accepted that cisplatin exerts its therapeutic activity by binding directly to DNA, deactivating it as a template for the transcription process and inhibiting in that way the protein biosynthesis.[3] However, cisplatin has several disadvantages, among which are its severe nephrotoxicity, neurotoxicity and emetogenesis.[4] The toxic side-effects of cisplatin therefore limit the doses that can be applied to patients.[5] The clinical application of the second-generation drug diammine[1,1-cyclobutanedicarboxylato(2−)-*O*,*O*′]platinum(II) (carboplatin; Figure 1) resulted in significant decrease of the toxic side-effects. These differences were attributed to the greater pharmokinetic stability of carboplatin due to the presence of the bidentate bis(carboxylato) ligand.[6] Studies on the interaction of carboplatin with DNA indicate that the mechanism involves carboplatin ring-opening and subsequent platinum binding to DNA nucleobases.[7]

Taking into account the structural analogy between Pt^{II} and Pd^{II} complexes, a variety of studies on Pd^{II} complexes have been performed, including their cytotoxicity[8] and antitumor activity.[9−11] Pd complexes with β-carboline alkaloids,[12−14] pyrazoles[15] and DMSO[16] have been tested against solid-tumor cell lines, and in some cases exhibited remarkable activity. It has been suggested that their biological activity depends on the nature of the ligand, the type of the counterion used and the configuration of the complex.

Coumarin and its derivatives are biologically important compounds with spasmolytic, antiarrhythmic, cardiotonic,

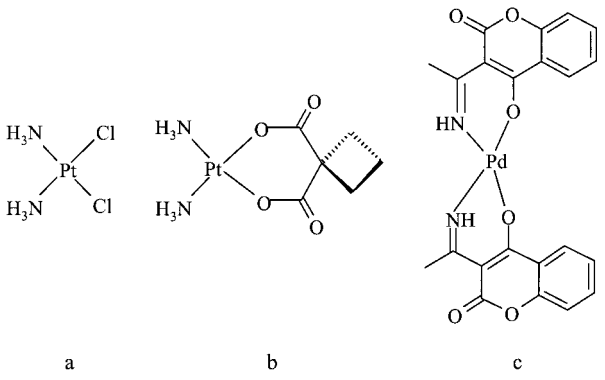

Figure 1. The structures of cisplatin (a), carboplatin (b) and complex **3** (Pd^{II} complex of ligand **2**) (c)

photodynamic[17] and antitumor properties.[18,19] Metal complexes of coumarin reveal anticoagulant action[20,21] and possess antitumor activity.[22,23] In particular, complexes of coumarin with cerium(III), zirconium(IV), copper(II), zinc(II), bismuth(III) and cadmium(II) have shown promising cytotoxic activity in vitro.[24,25]

Here, we describe the synthesis, structure and properties of a novel coumarin ligand **2** and its palladium(II) complex **3** (Figure 1). Spectral data and protonation constants are given for the ligand **2**. The structure of complex **3** is confirmed by spectral and X-ray analysis. Its biological properties are evaluated, including alkylating activity, cytotoxicity against selected cell lines as well as its interaction with double-stranded DNA monitored by circular dichroism (CD) spectroscopy and agarose-gel electrophoresis.

Results and Discussion

Synthesis and Structure of Ligand 2

The reaction of methyl 2-methyl-4-oxo-4*H*-chromene-3-carboxylate[26] (**1**) with an equimolar amount of 25% aqueous ammonia in methanol afforded product **2** in 94% yield (Scheme 1). This compound was previously synthesized by Somogyi and co-workers[27] in a multistep reaction with a total yield of 23% starting from 3-acetyl-4-hydroxycoumarin. Our approach is based upon a one-step, high-yield transformation of chromone **1** into 3-substituted coumarin **2** by the reaction of **1** with ammonia or an alkylamine.[28]

The structure of compound **2** was confirmed by spectroscopic methods (^1H and ^{13}C NMR, IR, EI-MS) as well as by elemental analysis. The first report of this compound by Somogyi et al. suggested that compound **2** exists in two tautomeric forms **2** and **2a** (Scheme 1), with proton magnetic resonances at δ = 10.01 (NH) and 12.04 (OH) ppm, respectively. These data were confirmed by our investigations, as two signals at δ = 9.99 and 12.32 ppm are observed in the ^1H NMR spectrum of **2** taken in DMSO. These signals disappear after proton exchange with D_2O, which directly confirms the presence of both tautomeric forms in DMSO solution. However, *N*-alkyl-substituted derivatives of **2** exist exclusively in the keto form in the solid state and in solution.[29–31] Thus, the presence of a β-amino group in the α,β-unsaturated carbonyl system ensures the accessibility of both terminal centers for metal-ion complexation.

Determination of the Protonation Constant of Ligand 2

Potentiometric experiments within the pH range 2.5–5.5 showed that the ligand behaves as a diprotonated molecule with one hydroxy (OH) and one imino (NH) proton. The measured protonation constants $\log \beta_{11} = 4.28 \pm 0.01$ and $\log \beta_{12} = 7.66 \pm 0.03$ are in reasonable agreement with those obtained from theoretical calculations[32] ($\log \beta_{11} = 4.50 \pm 0.20$ and $\log \beta_{12} = 7.71 \pm 0.20$, respectively). The statistical parameters $\sigma = 3.52$ and $\chi^2 = 15.64$ only slightly exceed the critical values of 3.00 and 12.60 at a confidence level of 0.95 as regarding the comprehensive file consisting of four titration data, but they are satisfactory in the particular titrations.

The two protonation constants indicate the presence of two potential donors, the 4-O and 3-N atoms. According to our results, the stepwise protonation constants are 4.28 and 3.38. An exemplary speciation diagram is shown in Figure 2.

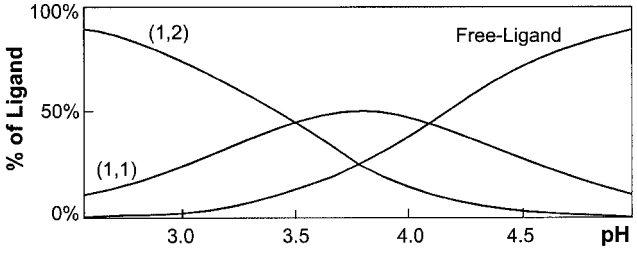

Figure 2. Species distribution of L = 4-hydroxy-3-(1-iminoethyl)-2*H*-chromen-2-one in 20% dioxane; (1,1) and (1,2) denote the mono- and diprotonated forms of L^{2-} (free ligand); $C_L = 6.21 \times 10^{-3}$ mol·dm^{-3}; $\sigma = 1.75$; $\chi^2 = 9.58$

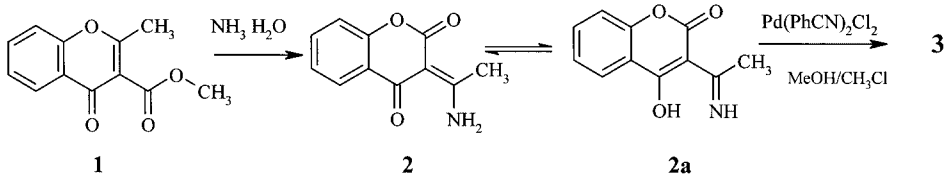

Scheme 1. Synthesis of the ligand **2** and its Pd complex **3**

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Synthesis and Structure of Complex 3

The palladium(II) complex of ligand **2** was synthesized by mixing **2** and bis(benzonitrile)dichloropalladium(II) in a 1:2 molar ratio in chloroform/methanol (1:2.5) solution at room temperature for 24 h (Scheme 1). The resulting solid shows an FAB-MS signal at $m/z = 510$, characteristic for PdL_2. This complex composition was confirmed by elemental analysis. In the ^1H NMR spectrum of the complex, one of the exchangeable protons, attributed to the enol OH group (at $\delta = 12.32$ ppm) of **2a**, is not present. The IR spectrum excludes the presence of chloride groups (no signals at 350 cm^{-1}). Instead, two bands were found at 508 and 437 cm^{-1}, which could be assigned to the M−O and M−N vibrations.[33] Moreover, the band assigned to the NH vibrations in **2** (3260 cm^{-1}) is shifted to higher energy (3310 cm^{-1}), indicating that the nitrogen atom is involved in the coordination (Table 1). At this stage we could not assign the complex geometry. It is known that palladium(II) complexes adopt predominantly *trans* conformations,[34] and only a few examples of *cis* conformers are known.[35]

Table 1. IR frequencies ($\tilde{\nu}$ [cm^{-1}]) for the ligand and its palladium complex

	NH/OH	C=O	C=N	M−N	M−O
2	3261	1708 1665	1609	–	–
3	3310 3265	1702 1670	1606	437	508

Our attempts to obtain a platinum(II) complex of ligand **2** failed, despite trying various solvent systems (aqueous methanol, aqueous acetone, aqueous dioxane, chloroform/methanol), various Pt^{II} substrates {K_2PtCl_4 or *cis*-$[PtCl_2(PhCN)_2]$} and various temperature conditions (room temperature, 60 °C). A black powder, identified as platinum, was the only solid product of this reaction. In contrast, a phosphorus analogue of coumarin (2-ethanimidoyl-2-methoxy-2*H*-1,2-benzoxaphosphinin-4-ol 2-oxide) forms complexes with Pt^{II} and Pd^{II} with a structure analogous to **3**.[36] We cannot offer any explanation why the Pt^{II} complex of ligand **2** is not formed or is too unstable to be isolated.

X-ray Structure of 3

The X-ray diffraction study of **3** (Figure 3) shows that in the PdL_2 molecule two L^- ligands chelate to the Pd ion through their N and O donors, giving a four-coordinate Pd^{II} center with a *cis*-N_2O_2 donor set. The coordination geometry at Pd^{II} is square-planar, with standard values for the distances from the metal atom to the coordinated atoms [Pd−N1: 1.965(6); Pd−N2: 1.951(6); Pd−O1: 1.972(5); Pd−O4: 1.990(5) Å]. The Pd^{II} ion lies in the least-squares plane of the coordinated atoms, deviating by ±0.023 Å. While the C2−N1 and C13−N2 bonds in the six-membered chelate rings possess the character of a localized double bond that deviates only marginally from the ideal value of 1.28 Å,[37] a substantial lengthening of the C11−O1 and C22−O4 bonds is observed when compared to the localized double bonds C4−O2 and C15−O5 (Table 2). The distribution of the bond lengths over the fragments C2−C3−C11 and C13−C14−C22 indicates significant delocalization of the electron density (Table 2).

Table 2. Bond lengths [Å] and angles [°] for compound **3**

Pd(1)−N(2)	1.951(6)	C(11)−O(1)−Pd(1)	128.1(4)

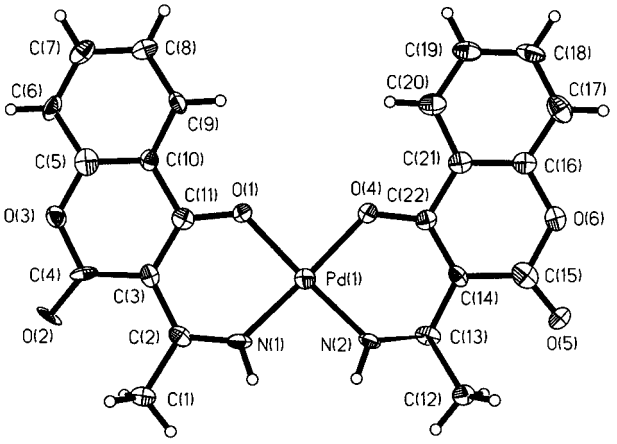

Figure 3. ORTEP drawing of the molecule of **3** with thermal ellipsoids depicted at 50% probability

The molecular structure of **3** shows stacked pairs with an interplanar "face-to-back" separation of 3.28 Å; the Pd1···Pd1′ distance is 3.775 Å. The shortest contact observed is Pd1···O4′ at 3.566 Å and the angle O4′···Pd1′···Pd1 is 80.1°. These pairs, which are slightly slipped with respect to each other, form columns with separations between pairs of 3.37 Å and a Pd1···Pd1′′ separation of 6.736 Å.

Biological Characterization of 3

Alkylating Properties

Cisplatin and carboplatin are nonclassical alkylating agents. These drugs interact with cellular DNA according to the same mechanism[38,39] — alkylation of nucleobases of both DNA strands. An effective drug concentration for carboplatin is 4−7 times higher than for cisplatin, and the former is also less toxic.[40] The alkylating activity of complex **3** was determined according to the Preussmann test.[41] The level of alkylation of 4-(4′-nitrobenzyl)pyridine (NBP) was quantified spectrophotometrically at 560 nm. The molar

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

absorbance (A) for complex **3** is 0.3584, while for ligand **2** it is significantly lower (Table 3). Interestingly, cisplatin in this test has an A value of 0.300[42] and carboplatin alkylates NBP with an A value of 0.2312. According to the Preussmann scale (described in a footnote to Table 3), complex **3** and both cisplatin and carboplatin exhibit moderate alkylating activity in this test.

Table 3. Alkylating activity of compound **2** and its Pd complex **3** determined by the Preussmann test

Compound	Absorbance (A)[a] λ_{max} 560 nm	Alkylation activity[b]
2	0.0508	+
3	0.3584	++
Cisplatin[c]	0.3000	++
Carboplatin	0.2312	++

[a] Means of three determinations. [b] According to Preussmann: (+) A = 0.05−0.1, (++) A = 0.1−0.5. [c] According to Zyner.[42]

Cytotoxicity

The cytotoxicity of **2** and **3** was determined in a concentration range from 10^{-10} to 10^{-3} M using three human cell lines — A549, HeLa and K562 — with carboplatin as reference. The activity is expressed as the concentration required for reducing the cell survival fraction to 50% after 72 h exposure of the cells to the compounds (IC_{50}; Table 4). The responses of A549, HeLa and K562 cells to continuous exposure to **2** and **3** at various concentrations for 24, 48 and 72 h are presented in Figure 4. From these figures, a time-dependent response can be observed for complex **3** in all three cell lines. Interestingly, compound **3** exhibits very high cytotoxicity against A549, HeLa and K562 cells, with IC_{50} values of 0.0097, 0.0078 and 0.0078 μM, respectively, which are superior to those of the reference carboplatin (105.98, 73.49 and 60.92 μM). The ligand was not toxic for the test cell lines even after 72 h exposure.

Table 4. IC_{50} values of compounds **2**, **3** and carboplatin after 72 h

Compound	A549 IC_{50} [μM][a]	HeLa IC_{50} [μM][a]	K562 IC_{50} [μM][a]
2	> 1000[b]	> 1000[b]	> 1000[b]
3	0.0097 ± 0.0017	0.0078 ± 0.0003	0.0078 ± 0.0007
Carboplatin	105.98 ± 6.79	73.49 ± 6.03	60.92 ± 13.64

[a] Mean values of IC_{50} (in μM) ± standard deviation from four experiments are presented. [b] At this concentration of compound **2** reduction in cell growth was less than 50%.

Interaction of 3 with Double-Stranded DNA

CD Analysis

The influence of complex **3** on the geometry of double-stranded DNA was investigated by CD spectroscopy. The CD spectra of the control samples (DNA in PBS buffer and DNA in PBS buffer/10% DMSO) were compared with the spectra of DNA incubated at room temperature for 18 h with increasing amounts of complex **3** (Figure 5). For DNA in PBS buffer the maximum intensity of the positive band at 281 nm was found at $\Delta\varepsilon$ = 6.2; for DNA in PBS/10% DMSO solution this value was 7.0. The spectra of the control samples do not differ significantly, indicating that at this concentration (10%) DMSO has no influence on the DNA structure. However, changes are observed in the spectra of DNA incubated with complex **3**. While the λ_{max} value of the positive band is not shifted, the $\Delta\varepsilon$ value is lowered

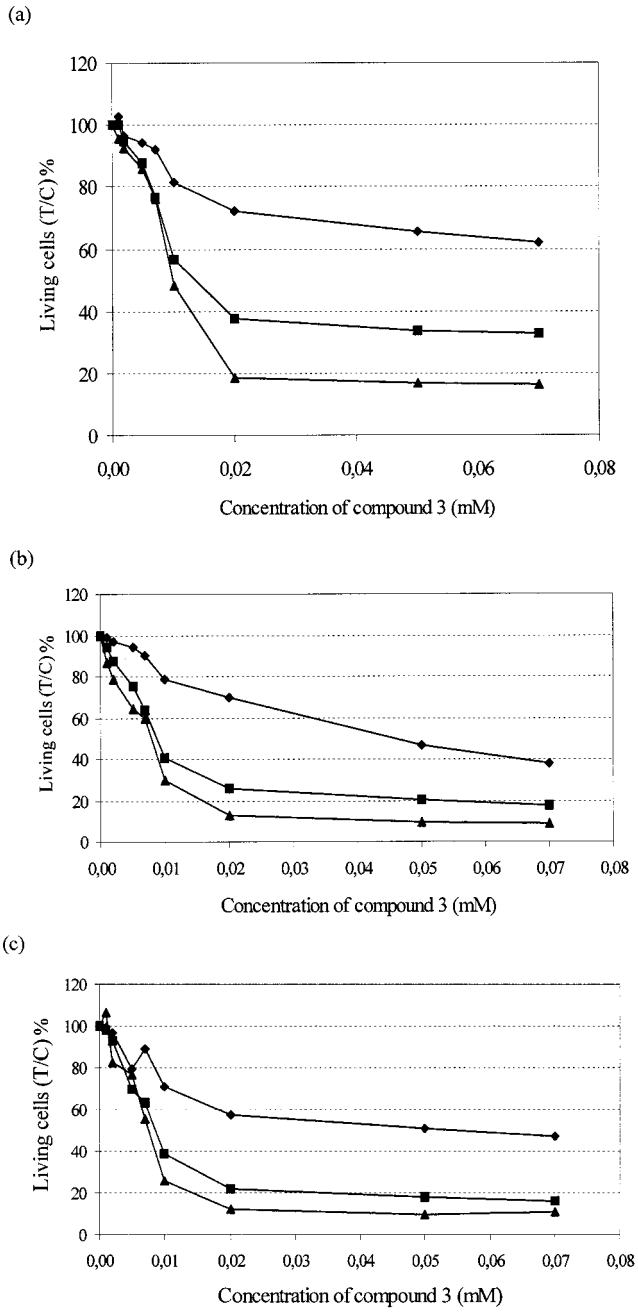

Figure 4. Cytotoxic effect of complex **3** on (a) A549, (b) HeLa, and (c) K562 cell lines after 24 (diamonds), 48 (squares) and 72 h (triangles) measured by MTT assay

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

by 0.8 units for DNA interacting with complex **3** at r_i = 1.3. At r_i = 2.6 and r_i = 3.9 (r_i is the molar ratio of **3** to nucleotides) the $\Delta\varepsilon$ values increase to 19 and 34 units, respectively, with only a 2 nm shift of the λ_{max} value to long wavelength, which suggests that structural changes are produced on DNA by complex **3**. These changes may originate from several sources, such as intercalation of the palladium compound into double-stranded DNA[43] or interhelical alkylation of nucleobases.[44] Such a significant increase of band intensity accompanied by the shift of the long-wavelength crossover by about 3 nm is characteristic for denatured DNA structures.[45] It is also known that dehydration of DNA, which induces $B \rightarrow A$ conformational changes, results in an increase of the band intensity in the region between 250 and 300 nm.[45] However, dehydration of DNA is not likely here since the concentration of complex **3** (r_i = 3.9) and DMSO (10%) is much lower than the conditions required to induce such conformational changes (> 60% ethanol).

DMSO (%)	–	–	10	20	30	10	20	30
Preincubation	–	+	+	+	+	+	+	+
Complex **3** [μg]	–	–	–	–	–	0.1	0.2	0.3
r_i						0.2	0.4	0.6
Lane M	1	2	3	4	5	6	7	8

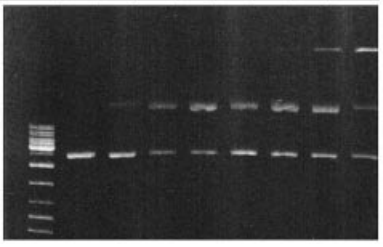

Figure 5. Interaction of **3** with double-stranded DNA monitored by 3% agarose gel electrophoresis; plasmid DNA (pUC, 2749 bp) was incubated with increasing amounts of complex **3**/DMSO in 3 × diluted PBS buffer containing 10 mM $MgCl_2$; M: mass marker; lanes 1 and 2: DNA in PBS buffer without and with 18 h, incubation; lanes 3–5: DNA in PBS buffer with increasing amounts of DMSO (as described above); lanes 6–8: DNA in PBS with increasing amounts of complex **3** and DMSO (data given above figure)

Agarose-Gel Electrophoresis

Plasmid DNA samples dissolved in triply diluted PBS/10 mM $MgCl_2$ buffer were incubated for 18 h at room temperature with increasing amounts of complex **3** (DMSO solution). As controls, plasmid DNA in PBS buffer and in PBS/DMSO buffer (containing 10, 20 or 30% of DMSO) were used. Samples were analyzed by agarose-gel electrophoresis (Figure 6). At first we checked the impact of incubation on DNA structure. After 18 h of incubation, we observed more of the superhelical form (90%) and only a very small amount of the circular form of DNA (10%) (lane 2 versus lane 1). In the plasmid samples incubated with increasing amounts of DMSO, the ratio of both forms of DNA was almost identical (lanes 3–5). However, when DNA was treated with increasing amounts of complex **3**, we observed a new band of very low electrophoretic mobility, tentatively attributed to a high-molecular-weight DNA/**3** adduct which contains 13.2% and 48.6% of the total DNA (lanes 7 and 8, respectively). The observed lowered mobility might result from intercalation of the planar compound **3** into the double-stranded plasmid DNA.

Conclusions

Coumarin-derived palladium(II) complex **3** is an interesting analogue of carboplatin. Its very high cytotoxicity toward three cancer-cell lines, with IC_{50} values in the nanomolar range (four orders of magnitude lower than that for the reference carboplatin), speaks for the need for further biological evaluations. At the present stage we can conclude that **3**, similarly to cisplatin and carboplatin, shows moderate alkylating activity toward aromatic amine (NBP), a compound that mimics the nucleobases in DNA. Complex

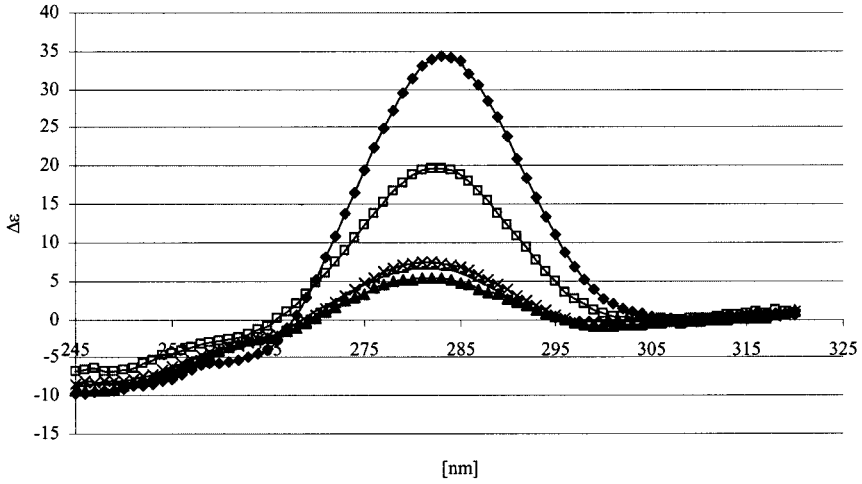

Figure 6. CD spectra of control double-stranded DNA (20 bp duplex of sequence given in Exp. Sect.) in PBS buffer (-) and in PBS/10% DMSO buffer (×), and adducts of DNA with increasing amount of complex **3** r_i = 1.3 (triangles), r_i = 2.6 (empty squares) and r_i = 3.9 (diamonds)

3 probably also binds to double-stranded DNA, enforcing in that way structural changes of short duplex DNA and reducing the electrophoteric mobility of plasmid DNA.

Experimental Section

General: The melting points were determined using an Electrothermal 1A9100 apparatus and are uncorrected. The IR spectra were recorded with a Pye-Unicam 200G Spectrophotometer in KBr and CsI. The ^{1}H NMR spectra were registered at 300 MHz with a Varian Mercury spectrometer. The MS data were obtained with a LKB 2091 mass spectrometer (70 eV ionisation energy). The MS-FAB data were determined with a Finnigan Matt 95 mass spectrometer (NBA, Cs^+ gun operating at 13 keV). For the new compounds satisfactory elemental analyses (±0.3% of the calculated values) were obtained using a Perkin−Elmer PE 2400 CHNS analyser. Methyl 2-methyl-4-oxo-4*H*-chromene-3-carboxylate (**1**) was prepared according to a published method.[26]

Synthesis of 3-(1-Aminoethylidene)-2*H*-chromene-2,4(3*H*)-dione (2): A 25% aqueous ammonia solution (0.31 mL, 2 mmol) in methanol (0.5 mL) was added at room temperature to a solution of methyl 2-methyl-4-oxo-4*H*-chromene-3-carboxylate (**1**; 0.44 g, 2 mmol) in methanol (5 mL). After several minutes, the solid crude product precipitated. The product was filtered off, dried, and crystallized from acetone (5 mL). Pure compound **2** was obtained as a white solid (382 mg, 94.0%); m.p. 234.5−234.9 °C. ^{1}H NMR ([D$_6$]DMSO): δ = 2.58 (s, 3 H, CH$_3$), 7.23−7.94 (m, 4 H, aromat. H), 9.99 (s, 1 H, NH), 12.32 (s, 1 H, OH) ppm. ^{13}C NMR ([D$_6$]DMSO): δ = 24.57 (C−CH$_3$), 95.57, 116.15, 120.24, 123.43, 125.59, 133.83, 152.95, 161.79, 177.06, 179.36 (C=O) ppm. MS: *m*/*z* (%) = 204 (100) [M$^+$], 124 (1.75). $C_{11}H_9NO_3$ (203.19): calcd. C 65.02, H 4.46, N 6.89; found C 65.05, H 4.45, N 7.07.

Palladium Complex 3: A methanolic solution of **2** (0.5 mmol, 101.6 mg in 5 mL) was added to a chloroform/methanol (1:1, v/v; 5 mL) solution of [PdCl$_2$(C$_6$H$_5$CN)$_2$] (95.9 mg, 0.25 mmol). The mixture was stirred at room temperature. After 2 h, the resulting light yellow crystals were filtered off, washed with diethyl ether, and dried in vacuo over anhydrous silica gel overnight. Yield 126.3 mg (43.3%); m.p. 330 °C (dec.). ^{1}H NMR ([D$_6$]DMSO): δ = 2.64 (s, 6 H, CH$_3$), 7.29−8.16 (m, 8 H, aromat. H), 9.43 (s, 2 H, NH) ppm. MS-FAB: *m*/*z* = 511.2. $C_{22}H_{16}N_2O_6Pd$ (510.72): calcd. C 51.73, H 3.16, N 5.48; found C 51.69, H 3.16, N 5.29.

Potentiometric Studies of the Ligand: The protonation constants of the ligand were determined by pH-metric titration of 4-mL samples at a temperature of 25 ± 0.1 °C. The total concentration of the ligand in each sample ranged from 6.0×10^{-3} to 2.0×10^{-2} M. Owing to the very low solubility in pure water a mixed 20% (v/v) 1,4-dioxane/water solvent was used. The titrations were carried out with a carbonate-free NaOH solution of known concentration (0.5 mol/L). The value of pK_w = 13.77 was obtained from our acid/base calibrations in the same solvent. The pH was measured with a Molspin Ltd. (Newcastle upon Tyne, England) automatic titration set and combined OSH 10-10 electrode (Metron, Poland). The total volume of the Hamilton microsyringe in the autoburette was 250 μL; the volume increments amounted to 0.0025 mL. The experiments were performed using MOLSPIN.EXE software. The electrode was calibrated in the −log [H$^+$] scale by titration of 0.005 M HNO$_3$ (in 20% dioxane) with 0.5 M NaOH at 25 °C. Then overall protonation constants $\beta_{lh} = [L_lH_h]/[L]^l[H]^h$ were calculated with the SUPERQUAD computer program.[46]

X-ray Crystallographic Structure Determination:[47] X-ray diffraction measurements were performed with a Nonius Kappa CCD diffractometer at 120 K. A colorless single crystal was positioned at 30 mm from the detector and 137 frames were measured, each for 200 s over a 2° scan. The data were processed using Denzo-SMN software.[48] Crystal data, data collection parameters, and structure refinement details for **3** are given in Table 5. The structure was solved by direct methods and refined by full-matrix least-squares techniques. Non-hydrogen atoms were refined with anisotropic displacement parameters. The H atoms were placed in calculated positions and allowed to ride. Computer programs: structure solution SHELXS-97;[49] refinement SHELXL-97;[50] molecular diagrams ORTEP;[51] computer: Pentium II; scattering factors were taken from the literature.[52]

Cell Lines and Culture Conditions: Three human cell lines were used for cytotoxicity experiments: A549 (lung carcinoma, human), HeLa (cervix epithelial carcinoma, human), K562 (chronic myelogenous leukemia, human). Cells were cultured in RPMI 1640 medium supplemented with 10% heat-inactivated fetal calf serum, streptomycin (100 μg/mL) and penicillin (100 U/mL) at 37 °C in 5% CO_2/95% air.

Drug Cytotoxicity: Exponentially growing cells were seeded at $5-7 \times 10^3$ in 200 μL of the complete culture medium per well of a 96-well plate (Nunc). After 24 h, the cells were exposed to compounds **2**, **3** and carboplatin (used as a reference) at 37 °C in 5% CO_2/95% air for 24 h, 48 h and 72 h. Cytotoxicity was estimated for a concentration range from 10^{-10} to 10^{-3} M. The cell number relative to the control was then determined by the colorimetric MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide, Sigma][53] method. The values of IC_{50} (concentration of compounds required to reduce the cell survival fraction to 50% of the control) were calculated from dose-response curves and used as a measure of cellular sensitivity to a given treatment. Each experiment was performed in quadruplicate and evaluation was based on means.

Determination of Alkylating Properties: The test compound (0.005 mmol) was dissolved in 2-methoxyethanol (1 mL) and a solution of 4-(4′-nitrobenzyl)pyridine (NBP) in 2-methoxyethanol

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(5% solution, 1 mL) was added. The sample was heated at 100 ± 0.5 °C for 1 h and then quickly cooled to 20 °C. 2-Methoxyethanol (2.5 mL) and piperidine (0.5 mL) were added to the sample to give a total volume of 5 mL. The final concentration of the test compound was 1×10^{-3} M. After 90 s, the absorbance was measured at λ_{560} nm in a glass cell (1 cm). 2-Methoxyethanol was used as a reference solvent.

CD Spectra of Complex 3 with Double-Stranded DNA: CD measurements of complex **3** with double-stranded DNA were performed with a Jobin Yvon CD6 (France) dichrograph. The double-stranded DNA was obtained by annealing of 5′-TCTTCAAGAATTCAGGACTA-3′ and 5′-TAGTCCTGAATTCTTGAAGA-3′. Samples of double-stranded DNA (4.6×10^{-6} M, 200 μL) were dissolved in PBS buffer (700 μL, 155 mM NaCl, 4.2 mM KH_2PO_4/Na_2HPO_4, pH = 7.2), to which the complex **3** in a solution of DMSO (1.9×10^{-3} M, 25, 50 or 75 μL) was added. DMSO was added to each sample up to 10% of total volume (including solvent of the complex **3**). The molar ratio of compound **3** to nucleotides is expressed as r_i. Each sample of a total volume of 1 mL was incubated at room temperature for 18 h and then scanned twice between 245 and 320 nm at 25 °C. The data are expressed as the mean of Δε (in $°\cdot cm^{-1}\cdot M^{-1}$).

Electrophoretic Mobility of Plasmid DNA in the Presence of Complex 3: Plasmid DNA (pUC19, 2749 bp) (0.2 μg) was incubated at 37 °C for 18 h in a mixture of triply diluted PBS/10 mM $MgCl_2$ buffer and DMSO (10%, 20% or 30%, v/v) that either contained complex **3** (0.1, 0.2 or 0.3 μg) or no complex **3** at all. Electrophoretic analysis was done on 3% agarose gel containing ethidium bromide. Quantification of the bands in the gel was done by densitometry and Image Quant analysis.

Acknowledgments

Financial support from Medical University of Lodz (grant no. 502-13-287 to E. B. and project no. 503-314-2 to the Laboratory of Physical and Biocoordination Chemistry) is gratefully acknowledged. We thank Mrs. Maria Maszewska for help in the determination of the cytotoxicity of the investigated compounds. We also thank Mrs. Agnieszka Zdolska for skilful experimental assistance.

Small Metal-Containing Oligomers Using $M_2(dmpm)_x$ and $M_2(dmb)_y$ Luminescent Building Blocks (M = Cu, Ag; x = 2, 3; y = 1, 2)

Éric Fournier,[a] Andreas Decken,[b] and Pierre D. Harvey*[a]

Keywords: Coordination polymers / Oligomers / Silver / Copper / Luminescence

The luminescent binuclear complexes $M_2(dmpm)_3^{2+}$ [M = Cu, Ag; dmpm = bis(dimethylphosphanyl)methane], $Ag_2(dmpm)_2^{2+}$ and $Cu_2(dmpm)_3(CN\text{-}tBu)_2^{2+}$ (as BF_4^- salts), as well as the oligomers described as $\{Cu_2(dmpm)_3(dmb)_{1.33}^{2+}\}_3$ and $\{Ag_2(dmpm)_2(dmb)_{1.33}^{2+}\}_3$ (dmb = 1,8-diisocyano-*p*-menthane), have been prepared and fully characterized in the solid state. These compounds exhibit emission maxima ranging from 445 to 485 nm with emission lifetimes in the μs time scale. The X-ray structures for the $M_2(dmpm)_3^{2+}$ (M = Cu, Ag) and $Cu_2(dmpm)_3(CN\text{-}tBu)_2^{2+}$ complexes, XRD patterns (X-ray powder diffraction), DSC (differential scanning calorimetry), TGA (thermal gravimetric analysis), and the solid-state IR spectra have been examined in order to characterize these complexes and oligomers.

Introduction

The synthesis and characterization of transition-metal-containing coordination and organometallic oligomers and polymers built with phosphane and isocyanide assembling ligands is becoming a topic of increasing interest in the quest for new materials and applications.[1−14] In this respect, our group has recently reported the syntheses and characterizations of 1-D polymers of the type $\{M(dmb)_2^+\}_n$ [15,16] and the mixed-ligand polymers $\{M_2(dppm)_2(dmb)_2^{2+}\}_n$ [17] (M = Cu, Ag; dmb = 1,8-diisocyano-*p*-menthane in its *U*- or *Z*-conformation; dppm = bis(diphenylphosphanyl)-methane; Scheme 1). The chromophores are the $M(C{\equiv}NR)_4^+$ centers (M = Cu, Ag), which are separated by 5 Å (Ag···Ag distance) in $\{Ag(dmb)_2^+\}_n$,[15] and the $M(C{\equiv}NR)_2(P)_2^+$ units, which are separated by 4.03 and 9.61 Å in $\{Ag_2(dppm)_2(dmb)_2^{2+}\}_n$.[17]

The average polymer length for the $\{Ag(dmb)_2^+\}_n$ materials in solution was determined to be approximately 8 units by T_1/NOE measurements,[18] whereas the amorphous Cu analogue had an average polymer length of 300 units, as determined by light scattering.[15] This difference is explained by the greater lability of the dmb ligand in the Ag^I complexes, which was convincingly verified by the interconversion observed between the *U*- and *Z*-isomers of the $\{Ag(dmb)_2^+\}_n$ polymers, but not for the Cu analogues.[19] Ligand dissociation has also been established in previous works on the $\{Pd_4(dmb)_4(dmb)^{2+}\}_n$ [6] and $\{Pt_4(dmb)_4(diphos)^{2+}\}_n$ [7] polymers [diphos = $Ph_2P(CH_2)_mPPh_2$; m = 4−6; 84000 < MW_n < 307000; Scheme 2]. There are also some differences in the photophysical data, in particular the emission lifetimes, between the polymers and the corresponding building blocks [here $M_4(dmb)_4^{2+}$ (M = Pd, Pt)].

More recently, a new series of amorphous polymeric materials of the type $\{M(diphos)(dmb)^+\}_n$ (M = Cu, Ag),[22] $\{Pd_2(diphos)_2(dmb)^{2+}\}_n$ (diphos = dppe, dppp),[22] $\{Pd_2(dmb)_2Cl_2\}_n$,[23] and $\{Pd_2(dmb)_2(diphos')^{2+}\}_n$ (diphos′ = dppb, dpppen, dpph)[23] (Scheme 3) were prepared and characterized. It was clearly demonstrated that polymers in the solid state dissociated to give oligomers in solution (8−16 units).

We now wish to report the syntheses and characterizations of new Cu^I and Ag^I binuclear and oligomeric complexes using the bridging diisocyanide dmb and electron-rich diphosphane dmpm ligands. By changing the nature of the assembling ligands and building blocks, one can hope not only to change the distance between the building blocks, but also to change the number of units. These oligomers are composed of the following building blocks: $M_2(dmpm)_3^{2+}$,[24−26] $Ag_2(dmpm)_2^{2+}$,[24−26] $M_2(dmb)_2^{2+}$ (M = Ag, Cu),[27−29] and $Ag_2(dmb)^{2+}$ [15−16] (Scheme 4).

Results and Discussion

The $M_2(dmpm)_x^{2+}$ Building Blocks

The binuclear $M_2(dmpm)_3^{2+}$ complexes [M = Cu (**1**), Ag (**2**)] are synthesized by the direct reaction between dmpm and the desired metal cationic species in the appropriate stoichiometric ratio. In a 1:1 stoichiometric ratio, the dmpm ligand also reacts with $AgBF_4$ to form the dicoordinated

dimer $Ag_2(dmpm)_2^{2+}$ (**3**). Complexes **2** and **3** can be distinguished by their sensitivity to light (**3** turns gray with time) and by ^{31}P NMR spectroscopy.

Crystals suitable for X-ray single-crystal analysis were obtained for **1** and **2**. (Figures 1 and 2, Table 1 and Table 7). The complexes exhibit two nearly trigonal planar coordinated metal atoms positioned face-to-face, and separated by 2.9265(3) and 2.9893(2) Å, for **1** and **2**, respectively. The separation in **1** is significantly shorter than that in the $[Cu_2(dmpm)_3](ClO_4)_2$ salt [3.021(2)Å],[26] and the distances for **1** and **2** fall short in comparison with the isostructural $Au_2(dmpm)_3^{2+}$ analogue (3.040 and 3.050 Å).[30] The average M···M distances follow the trend of their respective ionic radii (Cu^I, 0.91 Å < Ag^I, 1.29 Å < Au, 1.51 Å).[31] The Ag_2 and Au_2 distances are shorter than the sum of the van der Waals radii (3.4 Å)[31] indicating the presence of M_2 interactions, but this is not the case for the Cu_2 distance in **1** (2.8 Å).[31] The average PCuCu angle is not 90°, but slightly bent inward (88.3°), which may suggest the presence of weak M_2 interactions in this case. In addition, the AgP distances (average 2.434 Å) are longer than the CuP and AuP distances (Table 2), and do not follow the change in ionic radii. This is perfectly consistent with the findings of Schmidbaur et al., which state that Ag is larger than Au due to relativistic effects[32] but the M···M data presented above do not support this argument. The aurophilicity may be more important than the argentophilicity in this case.

The neutral isoelectronic $M_2(dppm)_3$ dimers (M = Pd,[33] Pt[34]) exhibit M_2 distances similar to their neighboring atoms in the periodic table (Pd ~ Ag^+; Pt ~ Au^+), but the cationic systems show slightly longer M_2 distances (Table 2), most likely reflecting internuclear electrostatic repulsion. Remarkably, the $d(Ag_2)$ value for $[Ag_2(dmpm)_2](PF_6)_2$ [3.041(1)Å][35] is longer than that found in **2**, indicating that the third dmpm ligand applies some extra restoring force. This is further exemplified in the $Cu_2(dmpm)_2(O_2CMe)^+$ complex, in which the shorter bite distance of the acetate ligand forces the Cu atoms to lie closer to one another [2.7883(11)Å][36] in comparison with **1**.

The model compound **4** was prepared by the direct reaction between **1** and 2 equivalents of *t*BuNC. Despite the poor quality of the single crystals [a = 24.935(4), b = 10.5070(15), c = 19.266(3) Å, β = 111.034(2)°, V =

$Cu_2(dmpm)_3(CN\text{-}tBu)_2^{2+}$

Scheme 5

The Cu···Cu separation is found to be 4.011 Å, where no Cu···Cu interaction is noted. The structure exhibits similarities with the d^{10}-d^{10} complex $Pt_2(dppm)_3(PPh_3)$,[37] in which one Pt atom adopts a tetracoordinate geometry causing an increase in the Pt···Pt distance with respect to $Pt_2(dppm)_3$.[33,34]

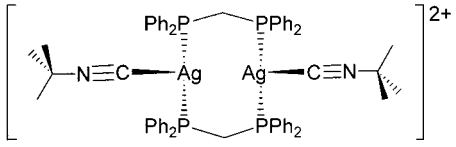
No attempt was made to synthesize the $\{Ag_2(dmpm)_2(CN\text{-}tBu)_2\}^{2+}$ complex, as the crystallographically characterized $[Ag_2(dppm)_2(CN\text{-}tBu)_2](ClO_4)_2$ complex was recently reported by us (Scheme 6).[17] The structure consists of two face-to-face tricoordinate Ag^I atoms bridged by two dppm ligands, where one CN-*t*Bu ligand binds each of the metals, similar to that in $Ag_2(dmpm)_3^{2+}$ with the difference that one diphosphane ligand is replaced by two isocyanide groups.

Synthesis and Characterization of the Oligomers

Compound **1** and dmb reaction ratios varying from 1:1 to 1:2, invariably forming an oligomeric material best described as $[Cu_6(dmpm)_9(dmb)_4](BF_4)_6$ or $\{[Cu_2(dmpm)_3(dmb)_{1.33}](BF_4)_2\}_2$ (**5**). This formulation, $[Cu_2(dmpm)_3(dmb)^{2+}]_x(dmb)$ ($x = 3$), is unambiguously established from the reproducible chemical analyses, integration of the ^1H NMR data (dmpm vs. dmb), and TGA data (Table 3). It is possible that traces of shorter and longer oligomers ($x = 1$, 2 and $x > 3$) exist, but the product distribution must be very narrow since the oligomer is very small, and all three techniques above indicate the same results. If such oligomers exist, their concentration must be very low. The XRD spectra indicate the presence of a highly crystalline material, which is consistent with the oligomeric nature of the material, but also support the hypothesis for a very narrow product distribution. The chemical yield is modest, indicating some losses during the attempts to obtain pure samples. The short oligomeric nature of the material is also confirmed by the observed ν(N≡C) absorption for uncoordinated isocyanides at 2132 cm^{-1} in the solid-state IR spectra (Figure 3), indicating that its relative presence is important in comparison with the coordinated ones (2161 cm^{-1}). Long chains ending with dmb ligands would exhibit very weak absorption due to uncoordinated isocyanides relative to the coordinated ones.



Scheme 6

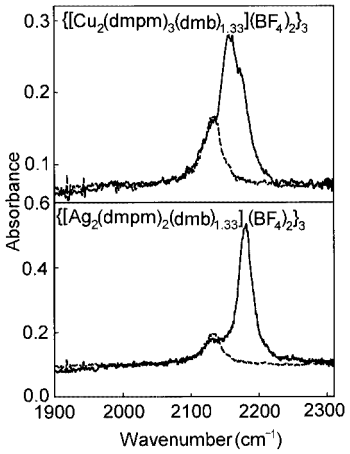


Figure 3. Solid state FT-IR spectra of **5** (top) and **6** (bottom) in the ν(N≡C) region (−) in comparison with free dmb (- - - -), emphasizing evidence of non-coordinated −N≡C groups in the oligomers

The corresponding $Ag_2(dmpm)_3^{2+}$ complex does not react with dmb even in excess. This behavior may reflect the fact that dmpm is a strong σ-donor, which renders the Ag^I atoms significantly more electron-rich. As a result, the monodentate RNC ligands become very labile. Conversely, the $Ag_2(dmpm)_2^{2+}$ complex reacts with dmb in a 1:1 ratio to generate another oligomeric material, identified as $[Ag_6(dmpm)_6(dmb)_4](BF_4)_6$ or $\{[Ag_2(dmpm)_2(dmb)_{1.33}](BF_4)_2\}_3$ (**6**) by reproducible chemical analysis, ^1H NMR spectroscopy and TGA. Oligomer **6** is also a crystalline solid (XRD). The MALDI-TOF spectra for both **5** and **6** are very complex, where fragment peaks show evidence for M−P, P−C, and C−N bond cleavage. In both cases, the molecular ion was not observed. Size-exclusion chromatography was also inadequate, as the compounds tended to stay trapped in the column, despite the use of different column materials. Both oligomeric materials crystallize to form long needle-shaped crystals, a shape that is common for dmb-containing polymers, but the thickness of these needles was inadequate for X-ray analysis. IR characteristics similar to those described for **5** above are depicted in the spectra of **6**, where a weak absorption associated to free ν(N≡C) is observed (Figure 3). It is interesting to note that both oligomers **5** and **6** (6 metal atoms) exhibit a lower degree of oligomerization than that reported for $\{[Ag(dmb)_2]BF_4\}_n$ in solution ($n = 7-8$).[18]

Table 3. TGA data for **1**, **4**, **5**, and **6**

Compounds		Weight loss 1[a]			Weight loss 2[a]			Residue	
		Temp. Range (°C)	Exp. %	Theor. %	Temp. Range (°C)	Exp. %	Theor. %	Exp. %	Theor. %

No glass transition (or other thermal phenomenon) was observed between −20 °C and 100 °C in the DSC traces for any of the investigated compounds. The result is consistent with the nonpolymeric nature of the materials.

Modeling

In the absence of X-ray data, the model compounds $Ag_2(dmpm)_2(CN\text{-}tBu)_2^{2+}$ and $Cu_4(dmpm)_6(dmb)_2(CN\text{-}tBu)^{4+}$ were computed to address two specific questions. Is the Ag···Ag distance in $Ag_2(dmpm)_2(CN\text{-}tBu)_2^{2+}$ (model compound for **6**) similar to $Ag_2(dmpm)_3^{2+}$ (explaining some similarities in the electronic spectra), and what distance separates the different dimer units in **5** (and ultimately in **6** as well)?

The methodology has been tested on the X-ray data for **1**, **2**, and the related binuclear complex $[Ag_2(dppm)_2(CN\text{-}tBu)_2](ClO_4)_2$[17] (Table 4) in order to provide a degree of confidence in the results. The M···M and M···P distances are computed within an uncertainty of 0.05−0.06 Å, which is acceptable in the context of this work. The Ag−C bond length gives the worst agreement, with a difference of approximately 0.3 Å from the experimental value, and is taken into account.

The computed model structure for $Ag_2(dmpm)_2(CN\text{-}tBu)_2^{2+}$ (Figure 4) exhibits an Ag···Ag separation of 2.94 Å, similar to that for **2** (2.9265 Å, X-ray), and a CAgAgC twisted angle of 18°. The first conclusion is that if this structure is correct, as suggested by the $Ag_2(dppm)_2(CN\text{-}tBu)_2^{2+}$ X-ray data, the UV/Vis $d\sigma^* \rightarrow p\sigma$ signature should be present at the same wavelength for both **2** and **6** (see section below). The second point is that the replacement of CN-*t*Bu by dmb should not induce great ring stress or angle torsion.

The computed structure for $Cu_4(dmpm)_6(dmb)_2(CN\text{-}tBu)^{4+}$ exhibits a central bridging dmb ligand adopting a *Z*-conformation (Figure 5). The *U*-form is unfavorable because of important steric hindrance between the Cu_2 units. The M···M distance in the M−dmb−M unit is 9.112 Å, which may be slightly overevaluated by 2 × 0.3 Å, as indicated above. The calculated triply bridged Cu···Cu distance is 4.35 Å, predictably longer than that found in **1**, and more similar to the X-ray data for **4** (≈ 4.011 Å). Similarly, the computed NC···CN and N···N distances in the *Z*-dmb are 7.064 and 5.755 Å, respectively. These M···M, C···C, and N···N distances compare favorably to those reported for the crystallographically characterized polymer $\{[Pd_4(dmb)_4(dmb)](MeCO_2)_2\}_n$ (i.e. 9.241, 6.801, and 5.549 Å, respectively).[20]

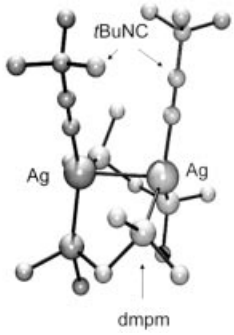

Figure 4. Computed structure for the model compound $Ag_2(dmpm)_2(CN\text{-}tBu)_2^{2+}$; the calculated distances are 2.94, 2.02, 1.20, and 2.47 Å, for the Ag···Ag separation, the AgC, C≡N, and AgP bond lengths, respectively

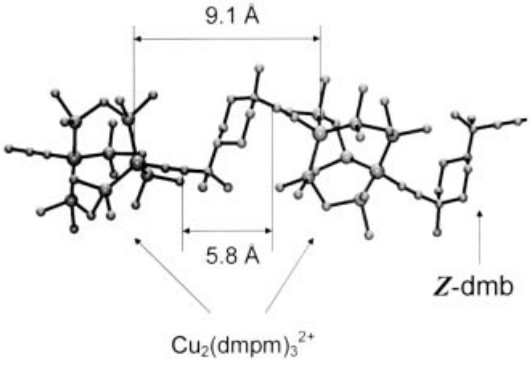

Figure 5. Computed structure for the model compound $Cu_4(dmpm)_6(dmb)_2(CN\text{-}tBu)^{4+}$; the calculated distances are 4.35, 1.83, 1.20, and 2.36 Å, for the Cu···Cu separation, the CuC, C≡N and CuP bond lengths, respectively

Electronic Spectra

The absorption spectra of compounds **1** and **2** (Figure 6) exhibit an absorption band at about 250 nm. These unstructured bands are due to the $d\sigma^* \rightarrow p\sigma$ transition; an electronic transition that is well-documented for cofacial d^{10}-d^{10} species such as $Au_2(dmpm)_3^{2+}$,[38] $Au_2(dcpm)_2^{2+}$ (dcpm = bis(dicyclohexylphosphanyl)-methane),[39] $Au_2(dmpm)_2^{2+}$,[40−42] $M_2(dppm)_3$ (M = Pd, Pt),[43,44] and $Ag_2(dmpm)_2^{2+}$.[45] In order to confirm this assignment, the absorption spectra were also recorded at 77 K in butyronitrile. At this temperature, the bandwidth decreases, in a somewhat similar manner to that of $Pd_2(dppm)_3$[43,44] and $Ag_2(dmpm)_2^{2+}$ [45] (Figure 7). This well-known phenom-

Table 4. Comparison between X-ray data and MMX computations[a]

enon has been fully described by Gray et al. and others.[46−52] The absorption maxima for the dσ*→pσ bands compare favorably with those of $Au_2(dmpm)_3^{2+}$ rather than with those of other related triply bridged d^{10}-d^{10} species (Table 5). No obvious trend is seen along the Cu, Ag, Au series, perhaps reflecting two opposite effects; lengthening of the M···M distance disfavors the M···M interactions, while an increase in atomic radii favors them. The data for **1** agree with that for $[Cu_2(dmpm)_3](ClO_4)_2$ (λ_{max} = 264 nm; ε = 7380 $M^{-1}cm^{-1}$ in acetonitrile at 298 K).[26]

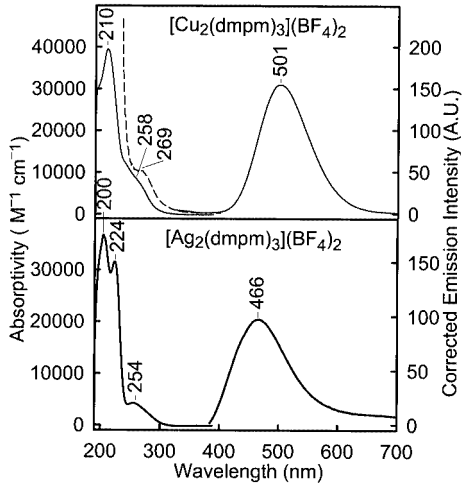

Figure 6. Comparison of the UV/Vis absorption (left) and emission (right) spectra for **1** (top) and **2** (bottom) in acetonitrile at 298 K; the broken line is an example of an excitation spectrum, here for **1**

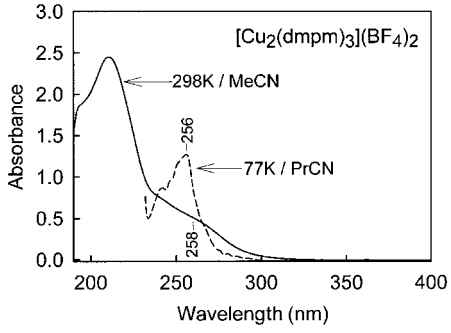

Figure 7. Comparison of the UV/Vis spectra of **1** at 298 K (−) and 77 K (- - -). The lowest wavelength possible is 240 nm at 77 K, because of absorption by the solvent glass

The absorption spectra for **4** and **5** are almost identical to each other, where strong absorptions are observed at 212 and 236, and at 210 and 236 nm, respectively. As anticipated for the noninteracting Cu···Cu systems, the dσ*→pσ absorption is absent. The lowest energy absorption is assigned to the spin-allowed $t_2(d\sigma^*) \rightarrow t_2(\pi^*, p\sigma^*)$ transition.[53,54] Oligomer **6** in acetonitrile exhibits an absorptivity of 10200 $M^{-1}cm^{-1}$ per Ag_2 unit for the dσ*→pσ band (λ_{max} = 254 nm).

Emission

The compounds are luminescent in solution at 298 and 77 K (Figures 6 and 8, Table 6), as well as in the solid state. The excitation spectra measured in solution confirm the authenticity of the emission, and the μs timescale for the lifetimes is consistent with a phosphorescence process. Compounds **1** and **2** exhibit luminescence of modest intensity in solution at 298 K at 500 and 471 nm, respectively. The energy gaps between the absorption and emission (18800cm^{-1} for **1**; 17300 cm^{-1} for **2**) are somewhat large. This phenomenon has also been observed for $Au_2(dmpm)_3^{2+}$ by Che, Miskowski et al. ,[38] who have suggested that the emission arises from $^3(d(x^2\text{-}y^2), xy \rightarrow p\sigma)$ excitation, in agreement with Mason's former proposal.[55] The similarity in the absorption maxima and emission lifetimes for **2** and **6** in the solid state strongly suggests that this assignment also applies for oligomer **6**.

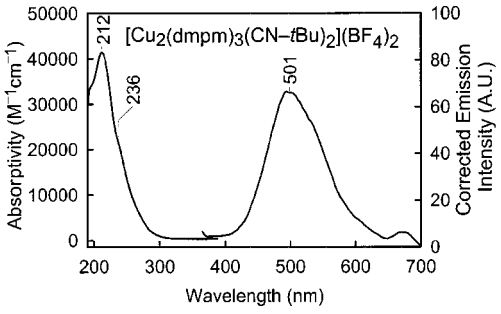

Figure 8. Absorption (left) and emission (right) spectra for **4** in acetonitrile at 298 K

In solution, the emission bands for all compounds are shifted to the red from about 446 nm to 466−520 nm. This range falls in the same region as that for the tetracoordinate Cu species (474−502 nm), and suggests that the emission arising from the tricoordinate Ag species in solution may

[a] In acetonitrile. [b] In butyronitrile. [c] The detection limit of the instrument is 2 μs, so the accuracy is poor near this limit.

be due to tetracoordinate solvent/anion exciplexes.[39] For the formally tetracoordinate **4** and **5**, the assignment of the emissive state is $^3([t_2(d\sigma^*)]^5[t_2(\pi^*,p\sigma^*)]^1)$ in agreement with that of $M(diphos)_2$ (M = Pd, Pt; diphos = dppe, dppp)[53] and that of $M(CN\text{-}t\text{Bu})_4^+$ (M = Cu, Ag).[15]

The emission lifetime data show two trends (Table 6). First, emission lifetimes predictably increase with the rigidity of the medium, and decrease as the temperature increases. Second, emission lifetimes and quantum yields decrease as the size of the molecule increases. The latter is due to the well-known "loose bolt" effect,[56] where the number of vibrational levels favoring internal conversion increases with the number of groups around the chromophores, as well as with their sizes. It is noteworthy that emission lifetimes for **2** and **6** are significantly longer than those reported for solid $Ag_2(dcpm)_2^{2+}$ at 298 K (λ_{emi} = 420 nm; τ_e = 0.5 μs),[57] and for $Ag_2(dmpm)_2^{2+}$ in ethanol at 77 K (λ_{emi} = 371 nm; τ_e = 49 μs),[45] the latter being dicoordinated.

Conclusion

The use of an electron-rich phosphane, which renders the metal center more electron-rich, increases the lability of the ligands, in particular that of the isocyanide ligand in this work. This property has a significant effect on the length of the oligomeric materials. This general approach may provide another strategic tool to make the polymer chain shorter for cases where the material would exhibit undesirable properties such as low solubility, preventing easier characterization, and amorphous character in the solid state.

Experimental Section

Materials: 1,8-diisocyano-*p*-menthane[58] was synthesized according to literature procedures. $[Cu(CH_3CN)_4]BF_4$ was freshly prepared before use, following the published procedure.[59] All solvents were purified by standard procedures.[60,61] The following materials were purchased from commercial suppliers: acetone (Fisher), acetonitrile and Cu(m) (Anachemia), petroleum ether and dichloromethane (ACP), ethanol (Les Alcools de Commerce Inc.), dinitrogen and argon (Praxair), $AgBF_4$, $Cu(BF_4)_2{\cdot}xH_2O$ and *tert*-butyl isocyanide (Aldrich Chemicals Co); bis(dimethylphosphanyl)methane (Strem Chemicals Co). Unless otherwise stated, all materials were handled under argon or dinitrogen using standard Schlenk techniques, high-vacuum manifolds and an inert-atmosphere glove box.

$[Cu_2(dmpm)_3](BF_4)_2$ (1): $[Cu(CH_3CN)_4]BF_4$ (370.0 mg, 1.18 mmol) was dissolved in acetone (20 mL). The ligand dmpm (0.35 mL, 2.21 mmol) was added dropwise using a microsyringe. The reaction mixture was stirred for 1 h prior to the addition of diethyl ether (80 mL). A white precipitate appeared, which was filtered and dried in a glove box. Yield 60% (315 mg). ^1H NMR (CD_3CN): δ = 2.02 (m, 6 H, PCH_2P), 1.36 (s, 36 H, PCH_3) ppm. $^{31}P\{^1H\}$ NMR (CD_3CN): δ = −25.36 ppm. $^{13}C\{^1H\}$ NMR (CD_3CN): δ = 32.12, 16.12 ppm. UV/Vis (CH_3CN): λ (ε) = 210 (39500), 248 nm (8500 $M^{-1}cm^{-1}$). $C_{15}H_{42}B_2Cu_2F_8P_6$ (709.04): calcd. C 25.41, H 5.97; found C 25.45, H 5.90.

$[Ag_2(dmpm)_3](BF_4)_2$ (2): $AgBF_4$ (259.6 mg, 1.33 mmol) was dissolved in acetone (15 mL). The resulting solution was filtered prior to use. The ligand dmpm (0.35 mL, 2.21 mmol) was added dropwise with a microsyringe. The solution was stirred for 1 h, and diethyl ether (70 mL) was added to precipitate the white product, which was filtered and dried in vacuo. Yield 90% (478 mg). ^1H NMR (CD_3COCD_3): δ = 2.45 (m, 6 H, PCH_2P), 1.60 (s, 36 H, PCH_3) ppm. $^{31}P\{^1H\}$ NMR (CD_3COCD_3): δ = −13.98, −15.39, −16.86 ppm. $^{13}C\{^1H\}$ NMR (CD_3COCD_3): δ = 31.63, 16.41 ppm. UV/Vis (CH_3CN): λ (ε) = 200 (47400), 224 (31400), 254 nm (4300 $M^{-1}cm^{-1}$). $C_{15}H_{42}Ag_2B_2F_8P_6$ (797.68): calcd. C 22.59, H 5.31; found C 22.08, H 5.20.

$[Ag_2(dmpm)_2](BF_4)_2$ (3): $AgBF_4$ (53.4 mg, 0.274 mmol) was dissolved in acetone (15 mL). The ligand dmpm (37.5 mg, 0.275 mmol) was added dropwise using a microsyringe. The solution was stirred for 1 h, prior to adding diethyl ether (70 mL). The white precipitate was filtered and dried under an inert atmosphere. Yield 76% (90.6 mg). ^1H NMR (CD_2Cl_2): δ = 2.31 (m, 4 H, PCH_2P), 1.61 (s, 24 H, PCH_3) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = −12.99 (br d, J(AgP) = 560 Hz) ppm. $^{13}C\{^1H\}$ NMR (CD_3CN): δ = 30.01, 14.46 ppm. UV/Vis (CH_3CN): λ (ε) = 202 (48000), 256 nm (23400 $M^{-1}cm^{-1}$). $C_{10}H_{28}Ag_2B_2F_8P_4$ (661.57): calcd. C 18.15, H 4.27; found C 18.24, H 4.32.

$[Cu_2(dmpm)_3(CN\text{-}t\text{Bu})_2](BF_4)_2$ (4): Compound **1** (102.1 mg, 0.144 mmol) was dissolved in degassed acetone (30 mL). *t*BuNC (0.1 mL, 0.88 mmol) was added dropwise using a microsyringe. The solution was stirred for 1 h prior to being concentrated in vacuo to a volume of 5 mL. Dimethyl ether (25 mL) was added to precipitate a white solid, which was filtered and dried in vacuo. Yield 86% (108 mg). ^1H NMR (CD_3COCD_3): δ = 2.26 (m, 6 H, PCH_2P): 1.59 [s, 18 H, $(CH_3)_3C$], 1.45 (s, 36 H, PCH_3) ppm. $^{31}P\{^1H\}$ NMR (CD_3COCD_3): δ = −25.41ppm. $^{13}C\{^1H\}$ NMR (CD_3COCD_3): δ = 58.38, 33.03, 30.20, 17.84 ppm. IR (KBr): 1052 (ν_{BF}), 2177

($\nu_{C\equiv N}$) cm^{-1}. Raman (solid): 2176 ($\nu_{C\equiv N}$) cm^{-1}. UV/Vis (CH_3CN): λ (ε) = 212 (39500), 236 (sh.) nm (22200 $M^{-1}cm^{-1}$). $C_{25}H_{60}B_2Cu_2F_8N_2P_6$ (875.30): calcd. C 34.30, H 6.91, N 3.20; found C 34.03, H 6.74, N 3.02.

{[Cu_2(dmpm)$_3$(dmb)$_{1.33}$][$(BF_4)_2$}$_3$ (5): Compound **1** (106.2 mg, 0.150 mmol) was dissolved in degassed acetone (20 mL). The ligand dmb (100.0 mg, 0.525 mmol) was dissolved separately in a round-bottom flask containing degassed acetone (150 mL). This solution was added dropwise and slowly to the former solution, and the mixture was stirred for 4 h prior to being concentrated in vacuo to a volume of 15 mL. Diethyl ether (150 mL) was added. A white product precipitated, which was filtered and dried. Yield 52% (86.9 mg). ^1H NMR (CD_3CN): δ = 2.08−2.02 (m, 8 H, dmb), 2.01 (m, 18 H, PCH_2P), 1.87−1.83 (m, 8 H, dmb), 1.61−1.56 (m, 12 H, dmb), 1.51 (s, 20 H, dmb), 1.45 (s, 24 H, dmb), 1.35 (s, 108 H, CH_3P) ppm. $^{31}P\{^1H\}$ NMR (CD_3CN): δ = −25.55 ppm. $^{13}C\{^1H\}$ NMR (CD_3CN): δ = 60.45, 63.18, 45.32, 37.10, 32.55, 29.11, 26.05, 23.32, 7.18 ppm. IR (KBr): $\tilde{\nu}$ = 1052 (ν_{BF}), 2161 ($\nu_{C\equiv N}$) cm^{-1}. Raman (solid): 2160 ($\nu_{C\equiv N}$) cm^{-1}. UV/Vis (CH_3CN): λ (ε) = 210 (51100), 236 (sh.) nm (26500 $M^{-1}cm^{-1}$). $C_{93}H_{198}B_6Cu_6F_{24}N_8P_{18}$ (2888.25): calcd. C 38.67, H 6.91, N 3.88; found C 38.64, H 6.79, N 4.02.

{[Ag_2(dmpm)$_2$(dmb)$_{1.33}$][$(BF_4)_2$}$_3$ (6): Compound **3** (59.1 mg, 0.089 mmol) was dissolved in degassed acetone (45 mL). The ligand dmb (53 mg, 0.279 mmol) was dissolved separately in a round-bottom flask containing degassed acetone (60 mL). This solution was added dropwise and slowly to the former solution, and the mixture was stirred for 3 h prior to being concentrated in vacuo to a volume of 15 mL. Diethyl ether (120 mL) was added to precipitate the white product, which was filtered and dried in vacuo. Yield 99% (76.1 mg). ^1H NMR (CD_2Cl_2): δ = 2.16 (m, 12 H, PCH_2P), 2.03−1.85 (m, 16 H, dmb) 1.53 (s, 88 H, CH_3P + dmb) 1.50−1.43 (m, 40 H, dmb) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = −15.68 (m) ppm. $^{13}C\{^1H\}$ NMR (CD_3COCD_3): δ = 64.12, 61.21, 43.78, 36.92, 31.96, 28.25, 27.21, 22.88, 16.44, 15.56 ppm. IR (KBr): $\tilde{\nu}$ = 1051 (ν_{BF}), 2181 ($\nu_{C\equiv N}$) cm^{-1}. Raman (solid): 2182 ($\nu_{C\equiv N}$) cm^{-1}. UV/Vis (CH_3CN): λ (ε) = 198 (40300), 254 nm (10200 $M^{-1}cm^{-1}$). $C_{78}H_{156}Ag_6B_6F_{24}N_8P_{12}$ (2745.85): calcd. C 34.12, H 5.73, N 4.08; found C34.29, H 5.32, N 3.96.

Apparatus: All NMR spectra were acquired using a Bruker AC-300 spectrometer (^1H 300.15 MHz, ^{13}C 75.48 MHz, ^{31}P 121.50 MHz) using the solvent as the chemical shift standard, except for ^{31}P NMR, where the chemical shifts are relative to external D_3PO_4 85% in D_2O. IR spectra were acquired on a Bomem FT-IR MB series spectrometer equipped with a baseline-diffused reflectance. UV/Vis spectra were acquired using a Hewlett Packard diode array 8452A spectrophotometer . Continuous wave emission and excitation spectra were obtained using a SPEX Fluorolog II spectrometer. Emission lifetimes were measured with a nanosecond N_2 laser system (PTI) model GL-3300 pumping a dye laser model GL-302. The excitation wavelength was 311 nm for all the measurements. MALDI-TOF mass spectra were acquired on a Bruker Proflex III linear mode spectrometer with a nitrogen laser (337 nm) at the Université de Bourgogne in Dijon (France) using a dithranol matrix. Glass transition temperatures (T_g) were measured with a Perkin−Elmer 5A DSC7 equipped with a thermal controller 5B TAC 7/DS. Calibration standards were water and indium. FT-Raman spectra were acquired on a Bruker RFS 100/S spectrometer. XRD were acquired on a Rigaku/USA Inc with a copper lamp operating under a 30 mA current and a 40 kV tension. TGA were acquired on a TGA 7 of Perkin−Elmer between 50 and 650 °C at 3°C/minute under N_2.

Crystallography: Crystals of [Ag_2(dmpm)$_3$][$(BF_4)_2$ (**2**) were grown by vapor diffusion using acetonitrile/*tert*-butylmethyl ether at 23 °C, crystals of [Cu_2(dmpm)$_3$][$(BF_4)_2$ (**1**) were grown by vapor diffusion using acetone/*tert*-butylmethyl ether at 23 °C (data see Table 7). Single crystals were coated with Paratone-N oil, mounted on a glass fiber and frozen in the cold nitrogen stream of the goniometer. A hemisphere of data was collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a scan width of 0.3° and 10 s exposure times. The detector distance was 5 cm. The data were reduced (SAINT)[62] and corrected for absorption (SADABS).[63,64] The structure was solved by direct methods and refined by full-matrix least-squares on F[63,64] (SHELXTL).[63,64] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were found in Fourier difference maps and refined isotropically. Thermal ellipsoid plots are at the 30% probability level. In some plots, hydrogen atoms have been omitted for clarity.

[a] $R1 = \||F_o| - |F_c|\| / |F_o|$; $wR2 = \{[w(F_o^2-F_c^2)^2]/[F_o^4]\}^{1/2}$; (**1**): weight = $1/[\sigma^2(F_o^2) + (0.0528P)^2 + (0.9190P)]$ and (**2**): weight = $1/[\sigma^2(F_o^2) + (0.0463P)^2 + (1.7267P)]$, where $P = [\max(F_o^2, 0) + 2F_c^2]/3$.

Procedures: The emission quantum yields were measured using 9,10-diphenylanthracene as the standard (Φ_F = 1.00 for degassed solutions).[65] The emission lifetimes were analyzed in two ways. The first way was the common deconvolution method allowing for analysis of the raw data using models with 1−4 exponential decays. The second way was the ESM (Exponential Series Method),[66,67] which gave a distribution of lifetimes instead of a single value, and the maximum of the distribution was retained. Both methods gave the same results, but ESM gave better fits. The quality of the fit between the experimental and calculated curves was addressed using the parameter χ (goodness of fit), and by the analysis of the residual.

Computer Modeling: The calculations were performed using the commercially available PC-Model from Serena Software (version 7.0), which uses the MMX empirical model. Comparisons between literature X-ray structures and computed models are provided in the text. The R−N≡C groups are replaced by R−C≡C^- because PC Model does not model C≡N^+− fragments, as strongly bent

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structures had to be calculated. Instead −C≡C− is used securing a more linear and realistic frame for the ligand.

CCDC-245030 (for **2**) and -245031 (for **1**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Formation of Sulfur−Sulfur Bonds in Copper Complexes

Gabriel Aullón*[a] and Santiago Alvarez[a]

Keywords: Copper-sulfur complexes / Ligand−ligand bonds / Density functional calculations / Through-ring bonding / Electronic structure

The recently reported dinuclear complexes [$Cu_2(\mu\text{-}S_2)$(diketiminato)$_2$] that have short S–S distances across their Cu_2S_2 rings are theoretically studied with the help of density functional calculations and a topological analysis of the electron density. The possibility of obtaining the isomeric form without a S–S bond is explored by comparing the structure and bonding with its oxo analogue. A study of the influence of several terminal-chelating ligands on the relative stability of the sulfido- and the disulfido-bridged forms is also presented. The only way to stabilize a sulfido-bridged isomer is found to be via two-electron reduction, whereas chemical substitutions are not able to produce the cleavage of the S–S bond.

Introduction

The rich chemistry of copper-oxygen compounds is dramatically modified when we move to the sulfur analogues, limited to a few examples in biological chemistry, such as cupredoxins[1] and metallothioneins.[2] An example is provided by the so-called Cu_A dinuclear center, active in electron transfer processes, and present in heme-copper oxidases and also nitrous oxide reductases.[3] Its basic unit is a Cu_2S_2 ring in which two cysteine ligands bridge the two copper atoms, whose coordination sphere is completed with two terminal histidine and methionine residues. In such compounds both the oxidation states I and II are available for the metal atoms.

A recently reported reaction of a β-diketiminato Cu^{II} complex with $(TMS)_2S$ or a Cu^{I} analog with S_8 yields the disulfido Cu^{II} complexes of type **1a**.[4] One can in principle expect an alternative structure for the same compounds, schematically represented in **1b**, formally a sulfido/Cu^{III} complex with a long through-ring S···S distance, similar to what is found for oxygen-bridged copper complexes, for which equilibria between the peroxo and oxo-bridged forms have been well characterized.[5,6] We asked ourselves two questions that we tried to answer by performing a theoretical study: Could the sulfido-bridged Cu^{III} isomer **1b** be isolated? What could be made to favor the formation of that isomer? These compounds belong to a wider family represented by **2a** and **2b**, and challenge our understanding of the electronic structure and bonding of double bridged dinuclear complexes, since the framework electron counting rules[7,8] predict it to present the regular ring structure **2b**, with no S−S bonding interactions across the ring, in clear disagreement with the experimental result. Therefore, understanding the structural preferences of these compounds is a relevant task considering the importance of copper complexes in several biological processes.[9]

2a **2b**

To the best of our knowledge, the only structurally characterized copper compound with unsubstituted bridging sulfur atoms is the disulfido-bridged complex [$Cu_2(\mu\text{-}S_2)$(HB{3,5-*i*Prpz}$_3$)$_2$], which also has a rather short S−S

distance (2.07 Å) across the $\{Cu_2S_2\}^{2+}$ unit.[10] Other Cu_2S_2 cores either correspond to thiolato bridges or belong to cubane-type Cu_4S_4 structures. Examples of square-planar complexes of d^8 ions of the type $[L_2M(\mu\text{-}XR_n)_2ML_2]$, with dialkylphosphido or thioether bridges (XR_n = PR_2, SR_2) are known and they all have regular M_2X_2 rings without bonding interactions across the diamond (2.82−2.90 and 2.92−3.06 Å, respectively), whereas a silylene bridged compound (XR_n = SiR_2) has a short Si···Si distance (≈ 2.6 Å).[7] Recently, we have studied the possibility of ring isomers for $[M_2(\mu\text{-}X)_2(PR_3)_4]$ complexes with square-planar metals, where M and X are group 10 and 16 elements, respectively.[11]

We attempt here to extend these theoretical studies to copper-sulfur complexes in order to understand their structural behavior and to compare them with the important analogous oxo-bridged compounds.[8,12] In particular we would like to find out whether the alternative structure **1b** for a copper-sulfur core could be obtained by an adequate choice of terminal ligands. To that end, we report calculations based on density functional theory for $[Cu_2(\mu\text{-}O)_2(dki)_2]$ and $[Cu_2(\mu\text{-}S)_2(dki)_2]$, as well as for the reduced species $[Cu_2(\mu\text{-}S)_2(dki)_2]^{2-}$ and for several related complexes $[Cu_2(\mu\text{-}S)_2(chel)_2]$, where chel stands for a variety of bidentate ligands and dki represents a β-diketiminato ligand.

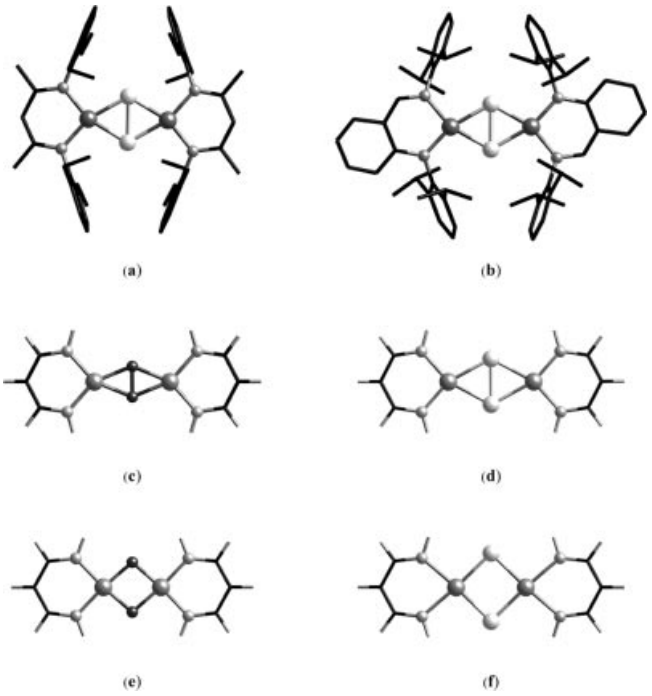

Figure 1. Experimental structures[4] of $[Cu_2(\mu\text{-}S_2)(dki)_2]$ (**a** and **b**), and optimized structures of $[Cu_2(\mu\text{-}O_2)(dki)_2]$ (**c**), $[Cu_2(\mu\text{-}S_2)(dki)_2]$ (**d**), $[Cu_2(\mu\text{-}O)_2(dki)_2]$ (**e**) and $[Cu_2(\mu\text{-}S)_2(dki)_2]^{2-}$ (**f**)

Results and Discussion

Optimized Structures: The main results of our DFT calculations for complexes of formula $[Cu_2(\mu\text{-}X)_2(chel)_2]$ (X = O or S) are reported in Table 1 and the optimized structures are shown in Figure 1. The atomic coordinates of structures corresponding to calculated energy minima are supplied as Supporting Information (see footnote on the first page of this article). We discuss here the diketiminato complexes and defer the analysis of the results with other terminal ligands to a later section. For $[Cu_2(\mu\text{-}O)_2(dki)_2]$, two minima are found that correspond to different through-ring O−O distances (2.36 and 1.44 Å, respectively), in agreement with previous results for a related simpler model $[Cu_2(\mu\text{-}O)_2(NH_3)_6]$[12] and with the existence of structurally characterized compounds with either structure (Table 2). The existence of an energy minimum at a long O−O distance agrees well with the prediction of the FEC rules for d^8 transition metals with square-planar coordination and O^{2-} as bridging ligands. Other optimized structural data (e.g., O···O and Cu−O distances of 2.36 Å and 1.81 Å, respectively) are in good agreement with experimental results for related complexes (2.26−2.35 and 1.80−1.86 Å, respectively, see Table 2) and for the infinite chains of CuO_2^- present in solid state compounds (2.45−2.51 and 1.82−1.85 Å). All these data for the isomers of type **2b** are consistent with their formulation as Cu^{III} compounds[13] for which planar rings can be expected.[14]

A geometry of the type **2a**, such as that with a short O−O distance found here for $[Cu_2(\mu\text{-}O)_2(dki)_2]$, has recently been analyzed in related compounds of group 10 metals.[11] In that study, the isoelectronic oxo complexes having Pd_2O_2 and Pt_2O_2 cores always produce the two minima that

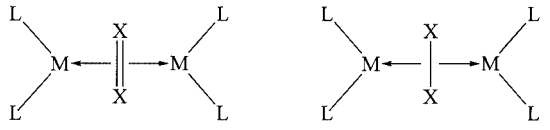
[a] Alphanumerical code for CSD[29] or ICSD[30]. [b] The terminal ligand acts as tridentate.

we have also observed for Cu. This second isomer can be formulated as either having two d^{10} transition metal atoms bridged by a side-on bridging dioxygen molecule (**3a**), or two d^9 Cu^{II} ions, side-on bridged by a peroxo group (**3b**). As found earlier,[11] the Cu−O edges of the diamonds in the complex with structure **2a** (1.94 Å) are significantly longer than in the **2b** isomer (1.81 Å). Such distances, as well as the O−O one (1.44 Å) are in excellent agreement with those experimentally found in complexes that present this structural motif (≈ 1.91 and 1.41−1.49 Å, respectively, see Table 2).



3a

3b

When oxygen atoms are replaced by sulfur, an important change is produced,[12] since only one minimum with a short S−S distance (2.18 Å) is found for $[Cu_2(\mu\text{-S})_2(dki)_2]$. Such a distance is consistent with the experimental values (2.16 and 2.20 Å) in the complexes prepared by Tolman et al.[4] and somewhat longer than in the other known compound with bare sulfur atom bridges, $[Cu_2(\mu\text{-S}_2)(HB\{3,5\text{-}i\text{Prpz}\}_3)_2]$ (2.07 Å).[10] This behavior is remarkably different from that found earlier for isoelectronic complexes of group 10 metals with sulfur bridging atoms, since the two minima (**2a** and **2b**) were found for the Pd_2S_2 core, whereas Ni_2S_2 and Pt_2S_2 compounds are predicted to only have structure **2b**.[11]

Since it is well known that $\{Cu_2(\mu\text{-O})_2\}^{2+}$ species acting as mild two-electron oxidants are reduced to $\{Cu_2(\mu\text{-O})_2\}^{0}$,[5,31] it seemed interesting to explore the hypothetical reduced sulfur complex $[Cu_2(\mu\text{-S})_2(dki)_2]^{2-}$. For this compound the **2b** isomer appears to correspond to an energy minimum (see Figure 1). The structural data (e.g., S···S = 3.24, Cu···Cu = 3.34 and Cu−S ca. 2.32 Å) are in excellent agreement with those in two structurally characterized isoelectronic Cu^{II} compounds with thiolato bridges (Cu···Cu = 3.34 and Cu−S = 2.33 Å).[32] It is remarkable that the Cu−N distances increase upon reduction from 1.93 to 2.14 Å, in contrast with what happens with the Cu−S distances, that are practically unaltered. Other bond lengths are practically unaffected by reduction, except for a decrease of the bite distance (N···N) of the bidentate dki ligand (≈ 0.1 Å shorter) concomitant with the increased Cu−N distance. Alternatively, in agreement with the framework electron counting rules,[7] a second structure for the reduced complex $[Cu_2(\mu\text{-S})_2(dki)_2]^{2-}$ with tetrahedrally coordinated copper atoms and a short S−S distance (2.31 Å) is found as an energy minimum, only a few kcal·mol^{-1} above the **2b** isomer. Given the small energy difference between alternative geometries, one can anticipate that both could be obtained experimentally.

Cross sections of the potential energy surfaces for the O- and S-bridged complexes $[Cu_2(\mu\text{-X})_2(dki)_2]$ are presented in Figure 2, where the calculated energy is plotted as a function of the normalized X···X distance. For the Cu_2S_2 core the minimum is found at a normalized distance of 1.07 (i.e., a S−S distance that is practically twice the sulfur atomic radius[12]). Upon reduction, the minimum is shifted to 1.59 (**2b**), a geometry that is 21 kcal·mol^{-1} above the minimum for the neutral species. For the analogous complex with a

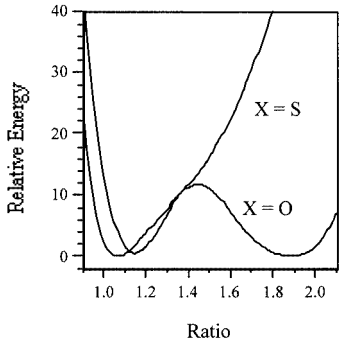

Figure 2. Relative energy (in kcal·mol^{-1}) as a function of the normalized X···X distance for complexes $[Cu_2(\mu\text{-}X)_2(dki)_2]$ (X = O or S). The normalized distance is defined as the ratio between the X···X distance and twice the atomic radius of X

Cu_2O_2 core, two nearly isoenergetic minima appear with O···O distances at 1.15 and 1.87 times the atomic radii sum and the transition state can be estimated to appear near 1.45 with an approximate barrier of 11.8 kcal·mol^{-1}. These results are in agreement with the equilibrium between two isomers recently proposed for the activation of O_2 by β-diketiminatocopper(I),[33] but the evaluation of the energy difference between the oxo- and peroxo-bridged forms of copper complexes is not straightforward and the reader is referred to a recent study by P. Siegbahn[34] for a more detailed discussion.

Orbital Analysis: In an attempt to understand the different behaviors of the oxo and sulfido-bridged complexes, we report here on an analysis of the corresponding molecular orbitals. In the oxo isomer with a regular ring **2b**, the bonding within the $\{Cu_2X_2\}^{2+}$ core can be associated with four framework bonding molecular orbitals (a_g, b_{1u}, b_{2g} and b_{3u} in Figure 3). For the Cu^{III}/O^{2-} compound, these four orbitals are occupied, whereas the framework antibonding orbitals (only two out of four are shown as the uppermost orbitals in Figure 3: $2b_{2g}$ and $2b_{3u}$).

As the rhombus distorts and the two oxygen atoms approach each other, the energies of the framework orbitals change due to the interplay of the through-ring σ overlap and the metal-bridging ligand overlap. Since two occupied framework orbitals are stabilized and two are destabilized upon distortion, two minima appear, separated by a low barrier resulting from the crossing between the two b_{3u} orbitals. Additionally, an important change in composition of the framework orbitals is induced by the approach of the two oxygen atoms, the occupied bonding b_{3u} combination becoming localized at the Cu atoms and the empty antibonding one at the bridging O atoms.[7,8,11,12] The outcome of such an orbital localization is that the two b_{3u} electrons

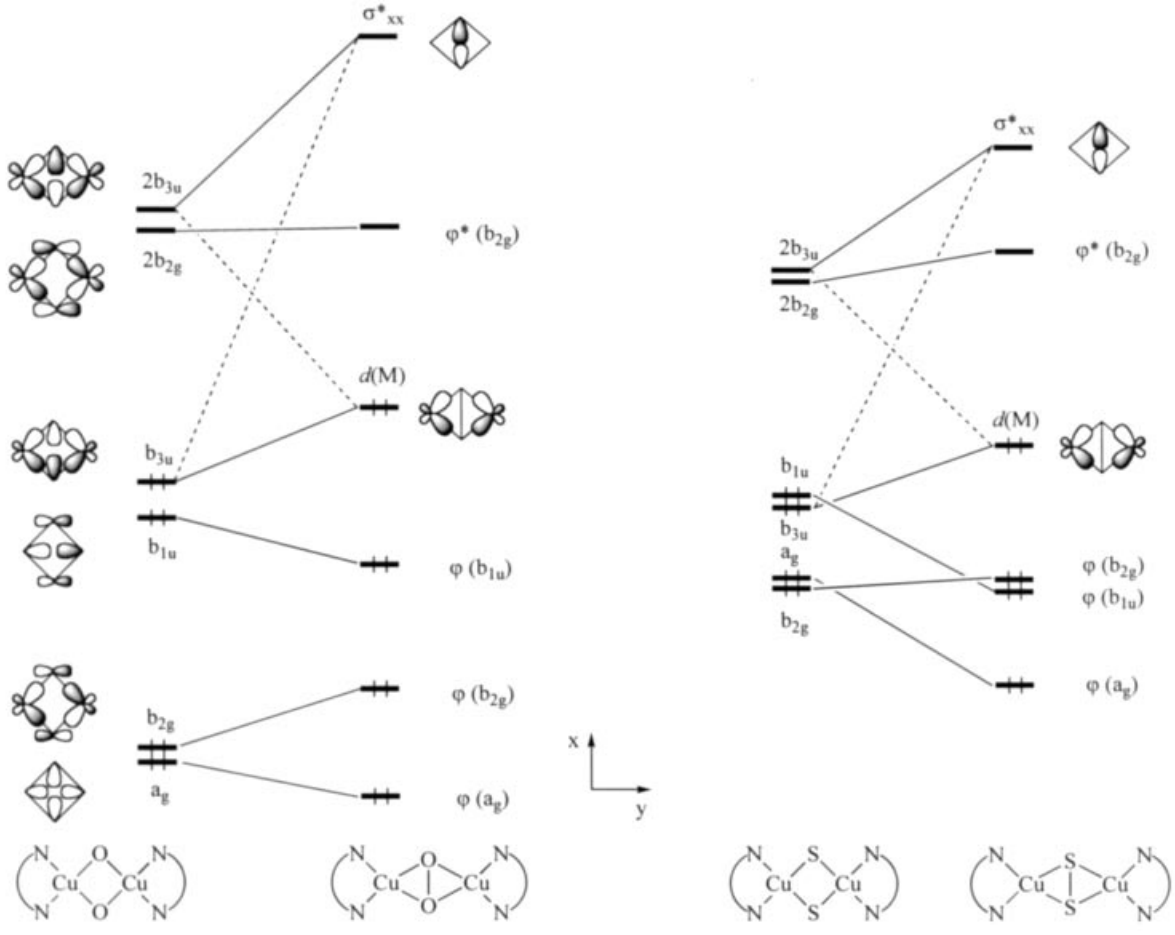

Figure 3. Simplified orbital diagram for the compounds $[Cu_2(\mu\text{-}O)_2(dki)_2]$ (left) and $[Cu_2(\mu\text{-}S)_2(dki)_2]$ (right)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are transferred from the Cu_2O_2 framework to the metal d orbitals, the copper atoms becoming formally Cu^{II} and the bridging oxo ions forming a peroxo bridge (notice the loss of σ* character of the occupied b_{3u} orbital in the **2a** form), which is the reason why the framework electron counting rule[7,8,11,12] fails. It must be noted that a strong antiferromagnetic coupling should be expected between the two Cu^{II} ions.[35] Such a description of the electronic structure of the **2a** form is consistent with the results of a natural bond order (NBO)[36] analysis, that indicates a net charge transfer of about 0.4 e^- from each sulfur atom to copper and the terminal ligands when going from **2b** to **2a**. It is also seen that such a charge transfer occurs mainly between the p_x orbitals of the bridges and the d_{xy} orbitals of the copper atoms, as would be expected from the change in the composition of the b_{3u} framework orbital.

For the analogous sulfur complex, a similar orbital picture should apply (Figure 3), but in fact we find only the disulfido-bridged compound **1a**, both theoretically and experimentally. The main difference between the two Walsh diagrams can be found in the occupied b_{2g} orbital, which is significantly stabilized when the two bridges are taken apart for X = O, but is practically insensitive to the bridge-bridge distance for X = S. The analysis of the composition of that orbital (Figure 4) clearly shows that in the sulfido-bridged compound there is little contribution from the metal to this molecular orbital, thus accounting for its nearly constant energy throughout the **2a** ⇆ **2b** interconversion path. It is likely that the lesser mixing of the metal xy and the sulfur p orbitals in b_{2g} for the sulfido bridges compared with the oxo ones should be attributed to the less electronegative character of sulfur. A similar effect was previously observed for isoelectronic square-planar Pt complexes with XH_2 bridges,[7] for which increasing orbital localization and decreasing through-ring X···X distances (S > P > Si) were found for different bridging atoms. Since the degree of mixing is likely to be affected by the basis set used, this finding could provide a rationale for the strong effect that the basis set has on the calculated relative energies of isomers **2a** and **2b** in other cases, as recently reported by Siegbahn.[34] Also the different behavior of related Ni, Pd and Pt complexes found recently by us[11] might be related to this subtle orbital effect.

Upon two-electron reduction of the sulfido complex, the structure is dramatically modified and the regular Cu_2S_2 ring with a long S···S distance is obtained. From Figure 3 it is clear that such a geometry change must be associated with the occupation of the high lying (framework antibonding) b_{3u} orbital. The proximity of b_{2g} and b_{3u} suggests an open shell ground state for this compound. Indeed our broken symmetry calculations indicate open shell singlet and triplet states to be close in energy, with the former being more stable (by 240 cm^{-1}), indicating antiferromagnetic coupling of the two Cu^{II} ions, in good agreement with the observed line broadening in the ^1H NMR spectrum and the EPR-silent nature of the experimentally known analogues.[32] All these results are consistent with the formal description of the reduced compound as Cu^{II}/S^{2-}, although the increase in Cu−N distances upon reduction is indicative of significant delocalization throughout the $\{Cu_2S_2\}$ core.

Analysis of the Electron Density: To further characterize the electronic structure of the studied compounds, we carried out a topological analysis of the electron density ρ(*r*) for the optimized geometries, according to the "Atoms in Molecules" theory.[37] According to Bader, the main properties of the electron density can be summarized in terms of critical points. A bond critical point corresponding to two negative and one positive curvatures, is also referred to as a (3, −1) critical point, and is taken as an indication of the presence of a chemical bond. On the other hand, ring

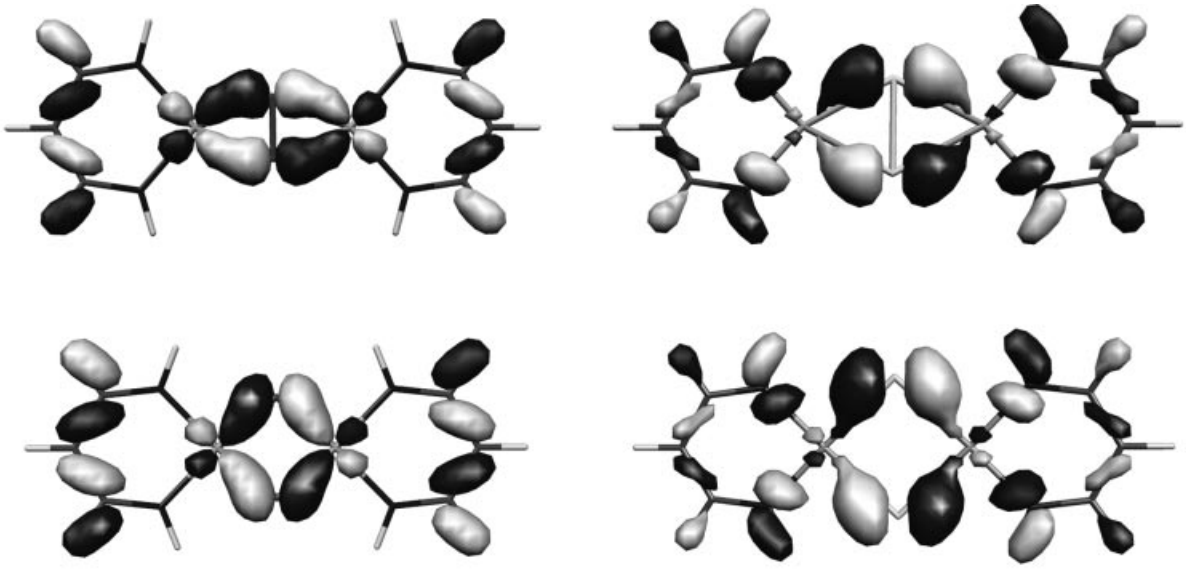

Figure 4. Composition of the occupied b_{2g} molecular orbital in the $[Cu_2(\mu\text{-}X)_2(dki)_2]$ complexes with X = O (left) and S (right) in the **2a** (top) and **2b** (bottom) geometries

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

critical points (3, +1) are characterized by a single negative curvature and are taken as an indication of a cyclic path of chemical bonds around it.

For the $[Cu_2(\mu\text{-}X)_2(dki)_2]$ compounds (X = S, O) with geometries **2a** and **2b** we have found four bond critical points between each Cu−X pair (Figure 5), consistent with the presence of four Cu−X single bonds, according to their ellipticities ($\varepsilon < 0.06$ for X = S and $\varepsilon < 0.10$ for X = O). The positive values of $\nabla^2\rho(r)$ (≈ 0.20 and 0.55−0.65 for sulfur and oxygen complexes, respectively), point to shared interactions characteristic of donor-acceptor Cu−X bonds and indicate a stronger covalent character for the Cu−S bonds compared to the Cu−O ones.

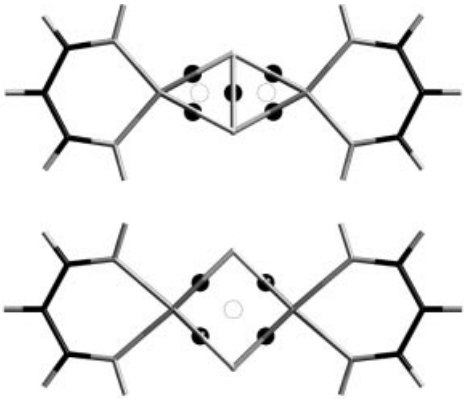

Figure 5. Localization of the critical points in Cu_2S_2 diamonds of the optimized complexes $[Cu_2(\mu\text{-}S_2)(dki)_2]$ (top) and $[Cu_2(\mu\text{-}S)_2(dki)_2]^{2-}$ (bottom). The bond critical points (3,-1) are represented by black circles, ring critical points by white circles

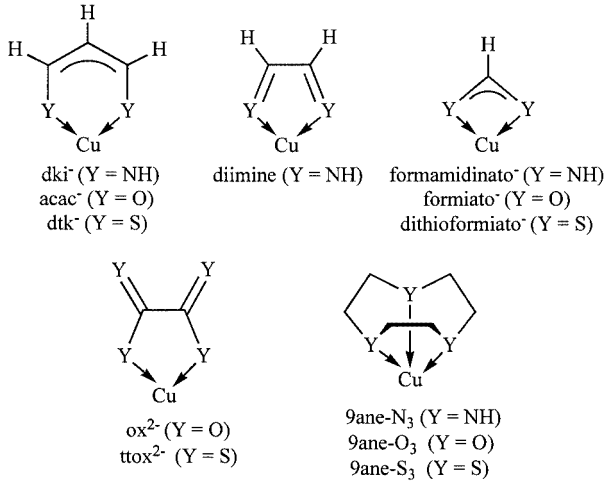
The optimized structures **2a** present an extra (3, −1) bond critical point between the two bridging atoms, consistent with the existence of X−X bonds (Figure 5, top). The negative value of $\nabla^2\rho(r)$ at this critical point indicates their covalent nature, and its ellipticity ($\varepsilon \approx 0.2$) shows a weak π character due to the non-negligible contribution of the Cu^I/S_2 alternative description.[11] As expected, two (3, +1) ring critical points are also found at the center of each CuS_2 ring in this case. In contrast, for structures **2b** (optimized for X = O, frozen for X = S) of $[Cu_2(\mu\text{−}X)_2(dki)_2]$, only one (3, +1) ring critical point appears at the center of the Cu_2X_2 core, consistent with the absence of through-ring bonding interactions. Similarly, the reduced sulfido bridged complex $[Cu_2(\mu\text{-}S)_2(dki)_2]^{2-}$ has, in its optimized structure, a ring critical point at the center of the Cu_2S_2 ring, as shown in Figure 5 (bottom).

Effect of the Peripheral Ligands

Now that we know, from calculations, that $[Cu_2(\mu\text{-}S)_2(dki)_2]$ is unlikely to have the **1b** structure, we wish to explore the possibility of stabilizing a Cu_2S_2 core with that geometry by using different peripheral ligands in which we can vary the nature of the donor atoms and bite of the bidentate ligand (see Scheme 1). The results (Table 3) reveal the following trends: (*a*) two minima appear for $\{Cu_2O_2\}^{2+}$ cores whereas only the **2a** isomer is found to correspond to an energy minimum for the related $\{Cu_2S_2\}^{2+}$ complexes;[12] (*b*) changes in the L−Cu−L bite angles within the 66−107° range do not significantly stabilize the sulfido-bridged structure; (*c*) the negatively charged ligands stabilize isomer **2b** relative to **2a** to a certain extent, the former appearing some 30−40, 21−31 and 11−18 kcal·mol^{-1} higher for neutral, monoanionic and dianionic ligands, respectively; (*d*) the tridentate macrocyclic ligands explored destabilize isomer **2a** and show a marked preference for a pseudotetrahedral coordination sphere of the copper atoms, with the sulfur-sulfur bond occupying one of the coordination sites at short S−S distances,[8,12,38] as observed in the experimental compounds cited in the introductory section.



Scheme 1

It is noteworthy that the sulfido-bridged complexes with tridentate terminal ligands (Table 3, last three entries) all give rather short S−S distances (2.06−2.13 Å), as does the tris(pyrazolyl)borato complex of Kitajima (2.07 Å). This is probably an indication of the important contribution of the Cu^I/S_2 form (**3a**), which is favored in the pseudotetrahedral environment provided by a tridentate ligand and the side-on bonded S_2 molecule.[12]

Conclusions

A theoretical study on $[Cu_2(\mu\text{-}X)_2(dki)_2]$ complexes (X = O, S) indicates that two isomers are attainable for X = O, corresponding to peroxo- and oxo-bridged structures **2a** and **2b**, in agreement with the experimental structural data available for a variety of copper-oxygen compounds. The compound with X = S, in contrast, seems to give only the disulfido-bridged isomer **2a**. The reason for the different behavior has been found to be the different mixing of the atomic $p_y(X)$ and $d_{xy}(Cu)$ orbitals in the framework bonding orbital of B_{2g} symmetry, that is stabilized in the oxo-bridged form **2b** with an O−Cu−O bond angle of 44°, but

[a] Parameter frozen in the geometry optimization. [b] For tridentate ligands, the first value corresponds to the basal distance or angle, the second value to the apical one.

not in the sulfido-bridged analogue. The use of other terminal ligands with different donor atoms and a variety of bite angles proved theoretically not to be a good strategy to stabilize the sulfido-bridged isomer in dinuclear copper complexes. The use of tridentate terminal ligands results in shorter S−S distances, due to an enhanced contribution of the Cu^I/S_2 resonance form. Two-electron reduction of the disulfido-bridged complex results in the cleavage of the S−S bond and a Cu^{II}/S^{2-} dinuclear complex.

Appendix

Computational Details: Density functional calculations were carried out using the GAUSSIAN98 package[39] with the UB3LYP hybrid method that applies the Becke three parameters exchange functional[40] and the Lee−Yang−Parr correlation functional.[41] The basis set of valence double-ζ quality and effective core potentials to represent the innermost electrons of the metal atoms (LANL2DZ) was used for Cu atoms.[42] A similar description was used for S atoms,[43] supplemented with extra d-polarization functions.[44] The light elements were described with the 6−31G (C and H of ligands[45]) and 6−31G* (N and O directly attached to the metal[46]) basis sets. Since it has been recently shown that in Cu complexes with two bridges such as those studied here the choice of basis set for the bridging atoms may strongly influence the calculated relative energies of the two isomers,[34] we have performed a series of tests with different basis sets for $[Cu_2(\mu\text{-}S)_2(dki)_2]^{2-}$. The use of the same basis set described above without polarization functions gave a S−S bond length (2.66 Å) that was too long when compared with the experimental value (2.20 Å), and similar results were obtained with a 6−31G* basis set that includes polarization functions for all atoms (2.60 Å). On the other hand, both the triple-ζ TZV basis set and the one discussed in the previous paragraph were found to give excellent agreement with the experimental S−S distance for the new compound (2.23 and 2.18 Å, respectively), and the calculated energy difference between the two isomers was also similar in both cases (18.3 and 21.4 kcal/mol, respectively). These tests allowed us to conclude that the basis set chosen, with a polarization function only for those atoms directly attached to the metal, provide a description of the electronic structure practically as good as a triple-ζ basis set. For the dinuclear Cu^{II} complex $[Cu_2(\mu\text{-}S)_2(dki)_2]^{2-}$, the evaluation of the singlet-triplet energy gap has been carried out by using nonprojected DFT calculations using the methodology described elsewhere.[47] The reported exchange coupling constant corresponds to the spin hamiltonian $H = -J\, S_1 \cdot S_2$. For the topological analysis of the electron density, critical points have been generated with the *Xaim* routine.[48]

Structural Analysis: The structural data were retrieved with the help of the Cambridge Structural Database (Version 5.25, November 2003),[29] including in our search all

compounds with Cu_2X_2 cores, X being a group 16 element. Additional crystallographic data has been obtained from the Inorganic Crystal Structure Database (Release 2003),[30] searching for ternary compounds of general formula $ACuX_2$. When more than one structure determination was available for the same compound, the one with the lowest *R* factor was selected.

Acknowledgments

Financial support for this work was provided by the Dirección General de Investigación Científica (MCyT) through grant BQU2002−04033-C02−01 and by Comissionat per a Universitats i Recerca (Generalitat de Catalunya) through grant 2001SGR-0044. The computing resources at the Centre de Supercomputació de Catalunya (CESCA) were made available in part through a grant of Fundació Catalana per a la Recerca (FCR) and Universitat de Barcelona. G. A. thanks a Ramón y Cajal research contract. The authors thank W. Tolman for providing them with experimental information prior to publication and for helpful discussions, and C. Bo (URV) for the Xaim graphical interface.

Unsymmetrically Substituted Dimethyldiaminosilanes as Ligands towards Zirconium(IV)

Vincenzo Passarelli*[a][‡] and Pierino Zanella[a]

Keywords: Zirconium / N ligands / Chelates / Silicon

Unsymmetrically substituted dimethyldiaminosilanes of the general formula $SiMe_2(NR_2)(NR'_2)$ have been prepared by treating $LiNR_2$ with $SiMe_2Cl(NR'_2)$ (NR_2, NR'_2 = NMe_2, NC_4H_8, NH*i*Pr, NH*t*Bu, $NHCH_2CH_2NMe_2$ or $NHCH_2CH_2OMe$). Their ligating properties towards zirconium(IV) have been investigated as a function of the nitrogen substituents and the syntheses of the binary compound $Zr[SiMe_2(N{\it i}Pr)(N{\it t}Bu)]_2$ and of the zirconium derivatives $ZrX_3(L)$ [X = Cl, NMe_2; L = $SiMe(NR)(NR'_2)$, NR = N*i*Pr, N*t*Bu, $NCH_2CH_2NMe_2$, NCH_2CH_2OMe; NR'_2 = NMe_2, NC_4H_8, NH*i*Pr, NH*t*Bu] are also reported. The solution structures and dynamics of the compounds have been elucidated by 1D/2D multinuclear NMR spectroscopy.

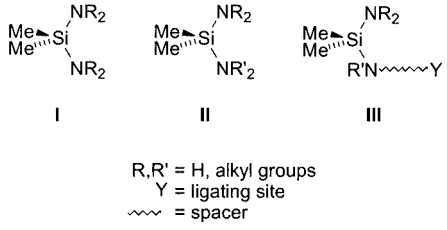
Introduction

The discovery of novel nonmetallocene polymerisation catalysts[1] has raised new interest in amido metal chemistry. As far as silylamides are concerned, a large number of data exist on SiR_3 *N*-substituted amido ligands (see refs.[1a−1c] for examples) but only a few papers[2−8] describe the synthesis, starting from diaminosilanes, of coordination compounds (Scheme 1, **I**−**II**).



Scheme 1

Nevertheless diaminosilanes appear to be flexible ligands, their coordination mode strongly depending on the nature of the nitrogen substituents. Examples of the zirconium systems include, i) $Zr(NMe_2)_4$ reacts with $SiMe_2(NHR)_2$ yielding $Zr(NMe_2)_3(NHMe_2)[SiMe_2(N{\it t}Bu)(NH{\it t}Bu)]$[3] or $Zr(NMe_2)_2(NHMe_2)[SiMe_2(NPh)_2]$ (Ph = 2,6-$Me_2C_6H_3$);[4] ii) the binary amido derivative $Zr[SiMe_2(NR)_2]_2$ is a dimer when R = *i*Pr[3] and a monomer when R = *t*Bu.[5]

Moreover, as a consequence of the different structures, different physical and/or chemical properties are observed and expected for the metal derivatives. For instance, the above mentioned *tert*-butyl derivative $Zr[SiMe_2(N{\it t}Bu)_2]_2$ is volatile,[5] while the isopropyl analogue decomposes at about 430 K without subliming.[3]

Based on this background, it seemed interesting to enlarge the class of dimethyldiaminosilanes and their metal complexes and, since little[6−8] is known about the ligating ability of unsymmetrically substituted diaminosilanes, we have pursued a) the synthesis of novel compounds of this class (eventually containing additional ligating sites) (Scheme 1, **II**−**III**) and b) the investigation of their ligating properties towards zirconium(IV).

Results and Discussion

Synthesis of $SiMe_2XY$ (X = NR_2, Y = Cl, NR'_2)

According to the literature procedures,[7,9] the following general route to $SiMe_2(NR_2)(NR'_2)$ was followed (Scheme 2): a) ligand exchange reactions between $SiMe_2Cl_2$ and $SiMe_2(NR_2)_2$;[10] b) treatment of the resultant $SiMe_2Cl(NR_2)$ with $LiNR'_2$.

The ^1H and ^{13}C NMR spectra of **1**−**11** show high field resonances for $SiMe_2$, while the signals of the NR_2 moieties can be observed in the range δ = 1−4 ppm (^1H) and 20−80 ppm (^{13}C). In addition, note that the nature of the amido group and the degree of substitution of the $SiMe_2$ core affect δ_{Si} (cf. ESI).

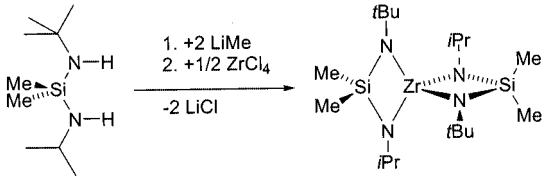
Scheme 2

Synthesis of $Zr[SiMe_2(NtBu)(NiPr)]_2$

As alluded to in the introduction, the binary species $Zr[SiMe_2(NR)_2]_2$ adopts a different molecular structure (both in the solid state and in solution) depending on the identity of R (R = *i*Pr, dimer;[3] R = *t*Bu, monomer[5]) and elsewhere[3] we proposed that the different steric hindrances of *i*Pr and *t*Bu should be responsible for this observation. Therefore, elucidation of the molecular structure of $Zr[SiMe_2(NtBu)(NiPr)]_2$ (**12**) appeared interesting. Compound **12** was prepared by treating $ZrCl_4$ with $Li_2[SiMe_2(NiPr)(NtBu)]$ (1:2 molar ratio) and it was obtained as a pure material after crystallisation from an Et_2O/pentane solution at 243 K, Equation (1).



9 **12** (1)

Despite a large number of attempts, we were unable to obtain suitable crystals for a single-crystal X-ray diffraction study of the structure. Nevertheless, ^1H, ^{13}C and ^{29}Si NMR spectroscopy allowed at least the solution molecular structure to be elucidated. Provided that the ^{29}Si chemical shifts reported for ZrL_2 are −40.5 [L = $SiMe_2(NtBu)_2$,[5] chelating], −38.0 [L = $SiMe_2(NiPr)_2$,[3] chelating] and −12.2 ppm [L = $SiMe_2(NiPr)_2$,[3] bidentate bridging], the only ^{29}Si resonance of **12** at −40.5 ppm indicates that two equivalent ligands are present and that they are both chelating. In addition, the ^1H and ^{13}C spectra show only one kind of *i*Pr and *t*Bu group even at 200 K, thus suggesting an approximately tetrahedral arrangement of the donor atoms around the zirconium centre. Finally, the two methyls of each $SiMe_2$ moiety are nonequivalent, i.e. two ^1H and two ^{13}C signals have been observed for the $SiMe_2$ group. Thus, the solution molecular structure of **12** should be similar to that of $Zr[SiMe_2(NtBu)_2]_2$.

Synthesis of $ZrCl_3(L)$

Treatment of $ZrCl_4$ with LiL (prepared in situ by treating LiMe with HL, 1:1 molar ratio; HL = **7**, **8**, **10** and **11**) yielded the trichloro derivatives $ZrCl_3(L)$ (Scheme 3).

Scheme 3

For convenience, **13** will be discussed separately from the other compounds in order to illustrate in detail, the correlation between the spectroscopic data and the proposed molecular structure.

The ^1H and ^{13}C NMR spectra of **13** show high field resonances for $SiMe_2$ (^1H, δ = 0.18 ppm; ^{13}C, 1.4 ppm), the signals of the hydrocarbyl moieties being observed in the range 1−3.5 ppm (^1H) and 20−60 ppm (^{13}C). As far as the CH_2NCH_2 moiety (pyrrolidinide) is concerned, i) the ^{13}C and ^1H ^{13}C HMQC spectra show that the two carbons are equivalent (54.0 ppm) and that two nonequivalent methylene protons (δ_H = 3.49, 3.35 ppm) are bonded to each carbon; ii) a negative crosspeak was observed in the ^1H NOESY spectrum of **13** between the resonances at δ = 3.35 and 0.18 ppm ($SiMe_2$) and iii) the ^{13}C resonances of CH_2NCH_2 are shifted with respect to the uncomplexed ligand (Table 1), thus suggesting that **13** contains $SiMe_2(NtBu)(NC_4H_8)$ as a bidentate ligand.

Table 1. Shifts of the ^{13}C resonances of the CH_xNCH_x moiety in $ZrX_3(SiMe_2YZ)$ (X = Cl, NMe_2) ($\Delta\delta_C = \delta_C^{ZrX3(L)} - \delta_C^{HL}$), cf. Schemes 3 and 4

Compound	Y	Z	$\Delta\delta_C$ X = Cl
13	N*t*Bu	$N(CH_2CH_2)_2$	7.3
14	$N(CH_2)_2NMe_2$	$N(CH_2CH_2)_2$	3.0
15	$N(CH_2)_2NMe_2$	NMe_2	7.4
16	$N(CH_2)_2OMe$	NMe_2	6.6
			X = NMe_2
17	$N(CH_2)_2NMe_2$	$N(CH_2CH_2)_2$	0.7
18	$N(CH_2)_2OMe$	NMe_2	0.8
19	$N(CH_2)_2NMe_2$	NMe_2	0.7
20	N*t*Bu	$N(CH_2CH_2)_2$	4.8
21	N*i*Pr	NMe_2	4.8
22	N*t*Bu	NMe_2	5.2

Similar to **13**, the ^1H and ^{13}C spectra of **14**−**16** show high field resonances for the $SiMe_2$ moiety (^1H, about δ = 0.3 ppm; ^{13}C, about −2.2 ppm) and signals of the hydrocarbyl groups in the range 2−4.5 ppm (^1H) and 20−80 ppm (^{13}C). In addition, i) the downfield shift of the ^1H and ^{13}C resonances of the amino NMe_2 moieties in **14** and **15** and of the ethereal OMe group in **16** with respect to the uncomplexed ligands, and ii) the equivalent methylene protons of the ethylene chain, even at 190 K, indicate that the NMe_2 and the OMe groups coordinate to the metal centre and that a mirror plane containing the $ZrNC_2X$ moiety should exist in the molecule (X = OMe, NMe_2).

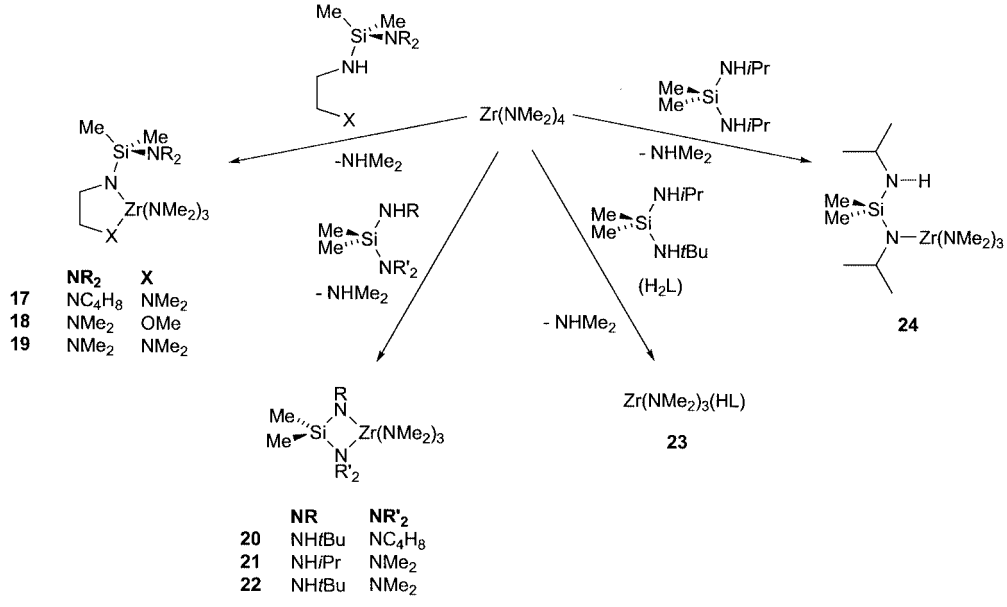
Moreover, similar to **13**, the observed ^{13}C shifts for the pyrrolidinide $CH_2N(Si)CH_2$ moiety in **14** and for the $SiNMe_2$ group in **15** and **16** (Table 1) suggest that the $SiNR_2$ moiety is also coordinated to the metal centre, making the silane ligands tridentate.[3]

As far as **14** is concerned, further comments are appropriate. In contrast with the proposed coordination of the $SiNC_4H_8$, the two faces of the pyrrolidinide ring appear equivalent at room temperature, i.e. one ^1H resonance is observed for each NCH_2 and NCH_2CH_2 proton set. In order to further elucidate this feature, we undertook a variable temperature NMR investigation and we observed that at 213 K i) the ^1H NCH_2 (pyrrolidinide) signal broadened and appeared unresolved and the NCH_2CH_2 (pyrrolidinide) resonance split into two signals at δ = 1.86 and 1.54 ppm (1:1 molar ratio) ii) in the ^1H NOESY spectrum a negative cross-speak was observed only between the NCH_2CH_2 resonance at 1.54 and the signal at δ = 0.39 ppm ($SiMe_2$) and iii) the carbon responsible for the resonance at δ = 25.1 ppm is bonded to the protons which yield the resonances at δ = 1.86 and 1.54 ppm (^1H ^{13}C HMQC). Therefore, the proposed coordination of the $SiNC_4H_8$ moiety is confirmed and it appears that the two faces of the pyrrolidinide ring are nonequivalent at 213 K and exchange at room temperature.

Synthesis of $Zr(NMe_2)_3(L)$

Compounds **5**−**11** readily react with $Zr(NMe_2)_4$ displacing one NMe_2 group as $NHMe_2$ and yielding the mixed amido derivatives $Zr(NMe_2)_3(L)$ (**17**−**24**) (Scheme 4).

The NMR spectra of **17**−**19** show i) ^{13}C chemical shifts of the $CH_xN(Si)CH_x$ (x = 2, 3) moiety similar to the uncomplexed ligands (Table 1) and ii) downfield shifted $CH_2N(CH_3)_2$ and CH_2OCH_3 resonances (^1H and ^{13}C), thus suggesting that **17**−**19** should contain the diaminosilane as a bidentate ligand coordinating to the metal centre through the amido $SiNCH_2$ nitrogen atom and the amino NMe_2 or the ethereal OMe moieties, while the $SiNR_2$ group is un-



Scheme 4

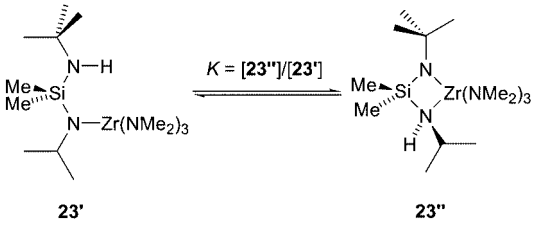
complexed. As confirmation, the ^{1}H methylene NC_4H_8 resonances of **17** appear as unique multiplets even at 190 K (cf. **13** and **14**).

As far as **20**−**22** are concerned, since the ^{13}C $CH_xN(Si)CH_x$ resonances are noticeably shifted with respect to those of the uncomplexed ligand (Table 1) and the two faces of the pyrrolidinide ring of **20** appear nonequivalent at 200 K (^{1}H NMR), the mixed amido derivatives **20**−**22** should contain the SiN_2 core coordinated to the metal centre.

The microcrystalline powder obtained from the reaction of $Zr(NMe_2)_4$ with $SiMe_2(NHiPr)(NHtBu)$ (H_2L) was identified as $Zr(NMe_2)_3(HL)$ (**23**) and the NMR spectra of a C_6D_6 solution indicated that two isomers were present in solution, namely $Zr(NMe_2)_3[SiMe_2(NiPr)(NHtBu)]$ (**23′**) and $Zr(NMe_2)_3[SiMe_2(NtBu)(NHiPr)]$ (**23′′**) [Eqn. (2)]. In fact, the ^{29}Si NMR spectrum shows two signals (−2.8, −5.9 ppm) and the ^{1}H COSY and ^{1}H ^{13}C HMQC spectra indicate two nonequivalent $SiMe_2$, *i*Pr and *t*Bu moieties (vide infra, cf. Exp. Sect.).

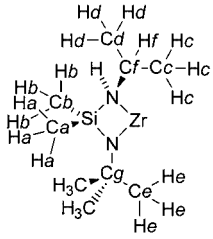


23′ **23′′** (2)

As far as **23′** is concerned, the ^{1}H and ^{13}C NMR resonances are little affected by the temperature (188−298 K) and the signal of the *tert*-butyl quaternary ^{13}C nucleus is slightly shifted with respect to the uncomplexed ligand, thus indicating that the NH*t*Bu moiety is probably not complexed and that we are dealing with the mono-hapto $SiMe_2(NiPr)(NHtBu)$ ligand [Equation (2)].

On the other hand the ^{1}H and ^{13}C signals of **23′′** are strongly affected by the temperature. At 188 K, one ^{29}Si resonance and two nonequivalent methyls both in the $SiMe_2$ and the *i*Pr moiety (^{1}H, ^{13}C) suggest that the SiNH*i*Pr unit is coordinated. For confirmation, and relevant to the molecular structure elucidation, the following comments can be made i) the ^{1}H COSY spectrum shows correlation peaks between the two isopropyl methyl groups (δ = 0.86, 0.72 ppm) and the methyne resonance (δ = 2.79 ppm), confirming that we are dealing with one isopropyl group containing two nonequivalent methyls; ii) both the $SiCH_3$ resonances are correlated (^{1}H NOESY) with the *tert*-butyl CH_3, confirming that only one $SiMe_2$ moiety is present with the methyls in different chemical environments; iii) a strong correlation (^{1}H NOESY) exists between the $SiMe_2$ methyl at δ = 0.29 ppm and the isopropyl methyl groups, suggesting that this methyl and the *i*Pr group are in a *syn* configuration with respect to the SiN_2Zr ring (Table 2). Finally, at 188 K, three nonequivalent $ZrNMe_2$ groups (δ_H, δ_C = 3.36, 45.97; 3.12, 46.00; 3.04, 45.2 ppm) were observed for **23′′** as a consequence of the asymmetric zirconium coordination sphere.

Table 2. Proposed assignment of ^{1}H and ^{13}C signals of $Zr(NMe_2)_3$-$[SiMe_2(NtBu)(NHiPr)]$ (**23′′**)



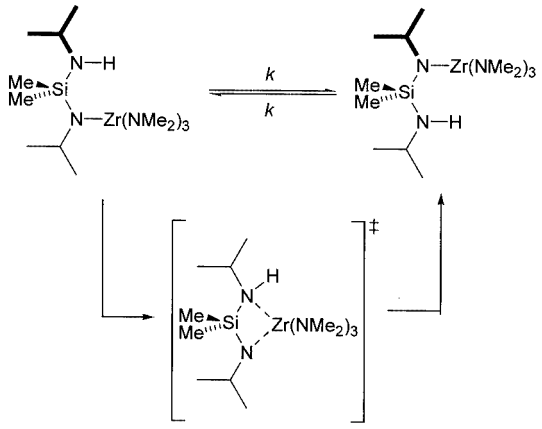
δ_H (188 K)	δ_C (188 K)
0.29 (H*a*)	7.20 (C*a*)
0.33 (H*b*)	1.29 (C*b*)
0.72 (H*c*)	27.3 (C*c*)
0.86 (H*d*)	25.0 (C*d*)
1.40 (H*e*)	35.3 (C*e*)
2.79 (H*f*)	45.7 (C*f*)
−	54.7 (C*g*)

The equilibrium constants K = [**23′′**]/[**23′**] [Equation (2)] at different temperatures [198−293 K] were calculated from the integrals of the $SiCH_3$ ^{1}H NMR resonances and the van't Hoff plot yielded ΔH_r = −3.4±0.4 kJ·mol^{-1} and ΔS_r = −7.3±1.8 J·mol^{-1}·K^{-1}. Reasonably, the negative ΔS_r results from the loss of entropy due to the chelation of the SiN_2 system and the negative ΔH_r should be related to a) the different basicities of the SiN*i*Pr and SiN*t*Bu moieties, b) the formation of a novel Zr−N bond and c) the reorganisation of the zirconium coordination sphere. Reasonably, the difference between the two Brønsted sites is negligible and the enthalpy contribution of Zr−N bond formation (esothermic) is higher with respect to that of the reorganisation of the donor atoms set on increasing the zirconium coordination number (endothermic). Nevertheless, the small absolute value of ΔH_r clearly indicates that the above mentioned effects are comparable.

For comparison (vide infra), the mixed amido derivative $Zr(NMe_2)_3[SiMe_2(NiPr)(NHiPr)]$ (**24**) was prepared (Scheme 4) and its solution molecular structure elucidated. Only one ^{29}Si resonance was observed and the ^{1}H and ^{13}C NMR spectra show one resonance for the $SiMe_2$ and two nonequivalent *i*Pr moieties (i.e. two nonequivalent CH_3 and two nonequivalent CH proton sets). Moreover, the ^{1}H and ^{13}C signals of the $SiMe_2$ and *i*Pr moieties are little affected by the temperature and appear as single well-shaped resonances even at 188 K. Finally, at room temperature, *positive* crosspeaks between both the CH_3 and the CH resonances of the two nonequivalent *i*Pr groups were observed in the ^{1}H NOESY spectrum and the coalescences of the CH and CH_3 ^{1}H resonances occur above 370 K. Therefore, the SiNH*i*Pr group is not coordinated and the chemical exchange between the two halves of $SiMe_2(NHiPr)(NiPr)$ op-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

erates with the consequent 1,3-shift of the NH proton (Scheme 5).



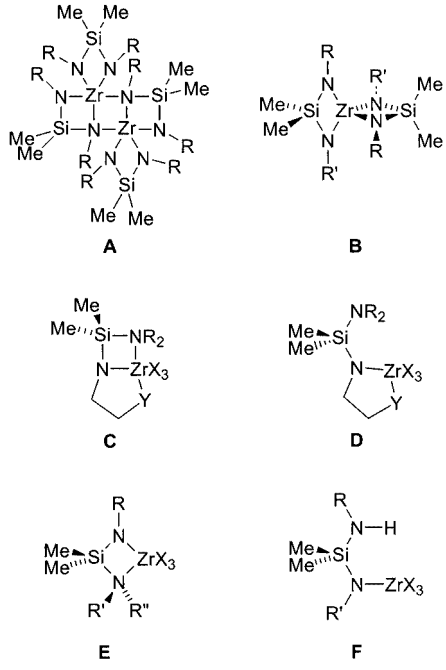
Scheme 5

This phenomenon has been investigated by variable temperature ^{13}C NMR spectroscopy in the range of 298−358 K and a line shape analysis of the isopropyl methyl resonances enabled us to calculate the kinetic constant k (Scheme 5) at different temperatures and to determine the activation parameters using the Eyring plot (ΔH_{act} = 47.1±1.2 kJ·mol^{-1}; ΔS_{act} = −73.8±3.8 J·mol^{-1}·K^{-1}). The negative value of ΔS_{act} suggests that the mechanism should be concerted, the 1,3-shift of the $Zr(NMe_2)_3$ fragment being reasonably the rate determining step (Scheme 5), yielding a **23′′**-type transition state. In this respect, the positive ΔH_{act} is reasonably indicative of the kinetic influence of the proposed rate-determining labilisation of the amido Zr−N(Si)*i*Pr bond.

Finally, a comparison among compounds **20**−**24** throws light on the influence of the nitrogen substituents on the coordination mode of L in $Zr(NMe_2)_3(L)$ [HL = **5**, **6**, **9**, **10**, $SiMe_2(NH{i}Pr)_2$]. Provided that the coordination of the SiNHR moiety (R = *i*Pr, *t*Bu) is observed only in **23′′** and not in **23′** or in **24**, we propose that the steric hindrance of SiNHR is hardly relevant in determining its ligating ability and that the steric interactions within the SiN(R)Zr group should be decisive, i.e. the more sterically demanding *t*Bu group in **23′′** encourages the chelation. This could reasonably be due to the consequent reduction of unfavourable steric interactions within the SiN(*t*Bu)Zr fragment itself. Conversely, compounds **20**−**22** contain $SiMe_2(NR)(NR'_2)$ as a chelating ligand, regardless of the nature of R (R = *i*Pr, *t*Bu), thus suggesting that the $SiNR'_2$ moieties, namely $SiNMe_2$ and $SiNC_4H_8$, have better ligating abilities with respect to SiNH*i*Pr and SiNH*t*Bu (in **23′** and **24**).

Conclusions

The ligating ability of $SiMe_2(NR_2)(NR'_2)$ towards zirconium(IV) is affected by the nitrogen substituents and eventually by the zirconium ancillary ligands. As far as the binary derivatives ZrL_2 are concerned, in contrast to $\{Zr[SiMe_2(N{i}Pr)_2]_2\}_2$ (Scheme 6, A) and similar to $Zr[SiMe_2(N{t}Bu)_2]_2$ (Scheme 6, B), $Zr[SiMe_2(N{i}Pr)(N{t}Bu)]_2$ is mononuclear indicating that the formal substitution of one methyne proton with CH_3 in each silane ligand of $\{Zr[SiMe_2(N{i}Pr)_2]_2\}_2$ makes the ligand itself too bulky to be accommodated in the dimer frame.



Scheme 6

The coordination mode of $SiMe_2(NR')(NR_2)$ (NR_2 = NMe_2 or NC_4H_8; NR′ = N*i*Pr, N*t*Bu, $NCH_2CH_2NMe_2$ or NCH_2CH_2OMe) to the ZrX_3 moiety (X = Cl, NMe_2) is strictly determined by the ancillary ligands. In fact, $SiMe_2(NR_2)(NCH_2CH_2Y)$ (NR_2=NMe_2 or NC_4H_8; Y = NMe_2 or OMe) is tridentate when X = Cl (Scheme 6, C) and bidentate when X = NMe_2 (Scheme 6, D). This could reasonably be due to the higher steric hindrance of the amido NMe_2 with respect to Cl and to the ability of NMe_2 to act as a π-donor. In addition, when X = NMe_2, the formation of the more stable five membered ring $ZrNC_2Y$ (Y = NMe_2, OMe) can be observed rather than the four membered SiN_2Zr one. On the other hand, $SiMe_2(NR')(NR_2)$ (R′ = *i*Pr or *t*Bu; NR_2 = NMe_2 or NC_4H_8) exhibit similar ligating properties towards ZrX_3 (X = Cl, NMe_2) regardless of the nature of X and the formation of chelates is always observed (Scheme 6, E).

Finally, the hapticity of the silane ligand in $Zr(NMe_2)_3$-$[SiMe_2(NR)(NHR')]$ is related to the steric hindrance of the nitrogen substituent R. As a matter of fact, the chelation of $SiMe_2(N{t}Bu)(NH{i}Pr)$ (Scheme 6, E) in $Zr(NMe_2)_3[SiMe_2(N{t}Bu)(NH{i}Pr)]$ and the mono-hapto coordination of $SiMe_2(N{i}Pr)(NHR)$ (Scheme 6, F) in $Zr(NMe_2)_3[SiMe_2(N{i}Pr)(NHR)]$ (R = *i*Pr, *t*Bu) indicate that the release of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

some steric congestion within the amido moiety SiN(R)Zr is decisive.

Experimental Section

All operations were carried out in a glove-box under dinitrogen. Elemental analyses (C, H, N) were performed using a Fisons Instruments analyser (Mod. EA 1108). The chlorine content in the samples was determined by potentiometric titration using a standard solution of silver nitrate (Aldrich). NMR spectra were recorded with a BRUKER AMX 300 spectrometer (300 MHz for ^{1}H). ^{1}H, ^{13}C and ^{29}Si NMR spectra are referred to TMS. The multiplicity is indicated as s (singlet), d (doublet), t (triplet), dt (doublet of triplets), q (quadruplet), sp (septet), ds (doublet of septets), m (multiplet) and br. was used to indicate broad signals.
The mass spectra (100−800 amu) were recorded with a Thermo-Finnigan Trace GC-MS instrument equipped with an accessory for the direct introduction of the sample into the source. The probe temperature was initially maintained at 373 K for 10 min, then raised to 473 K (50 K/min) and finally maintained at 473 K for 10 min. The source temperature was 473 K.
Zirconium tetrachloride ($ZrCl_4$, Fluka) was washed with boiling toluene then with pentane, dried in vacuo and stored under dinitrogen. *tert*-Butylamine ($C_4H_{11}N$, Aldrich), isopropylamine (C_3H_9N, Aldrich) and *N*,*N*-dimethylethylenediamine ($C_4H_{12}N_2$, Aldrich) were refluxed over BaO for one day, then distilled and stored under dinitrogen. Dichlorodimethylsilane ($SiMe_2Cl_2$, Aldrich), 2-methoxyethyleneamine (C_3H_9NO, Aldrich), LiMe (Et_2O solution, 1.6 M, Aldrich) and dimethylamine (C_2H_7N, Aldrich) were used as received. $SiMe_2(NR_2)_2$ [3,9] (NR_2 = NH*i*Pr, NH*t*Bu, NMe_2 or NC_4H_8) and $Zr(NMe_2)_4$ [11] were prepared according to the published procedures. The lithium amides $LiNR_2$ (NR_2 = NH*i*Pr, NH*t*Bu, $NHCH_2CH_2NMe_2$ or $NHCH_2CH_2OMe$) were prepared by treating NHR_2 with LiMe in Et_2O (1:1 molar ratio) and the resultant mixture was used without isolating the product.

Synthesis of $SiMe_2Cl(NR_2)$ (NR_2 = NH*i*Pr, NH*t*Bu, NMe_2 or NC_4H_8)

Only the synthesis of $SiMe_2Cl(NMe_2)$ is described in detail, the others being similar except for the reaction time (vide infra).
A solution of $SiMe_2(NMe_2)_2$ (1.20 g, 8.20 mmol) in pentane (50 mL) was treated with $SiMe_2Cl_2$ (1.07 g, 8.29 mmol). After 10 min stirring volatiles were removed in vacuo yielding a colourless liquid material, identified as $SiMe_2Cl(NMe_2)$ (**1**).

$SiMe_2Cl(NMe_2)$ (1): 2.15 g, 95% yield. $C_4H_{12}ClNSi$ (137.68): calcd. C 34.9, H 8.8, Cl 25.7, N 10.2; found C 34.8, H 8.9, Cl 25.5, N 10.1. ^{1}H NMR (C_6D_6, 298 K): δ = 2.28 (s, 1 H, NCH_3), 0.28 (s, 1 H, $SiCH_3$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 37.1 (NCH_3), 1.32 ($SiCH_3$) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = 13.9 ppm.

$SiMe_2Cl(NC_4H_8)$ (2): Reaction time: 10 min, colourless liquid, 96% yield. $C_6H_{14}ClNSi$ (163.72): calcd. C 44.0, H 8.6, Cl 21.7, N 8.6; found C 44.2, H 8.8, Cl 21.7, N 8.4. ^{1}H NMR (C_6D_6, 298 K): δ = 2.85 (m, 2 H, NCH_2), 1.53 (m, 2 H, NCH_2CH_2), 0.33 (s, 3 H, $SiCH_3$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 46.5 (NCH_2), 26.9 (NCH_2CH_2), 1.82 ($SiCH_3$) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = 10.1 ppm.

$SiMe_2Cl(NHiPr)$ (3): Reaction time: 18 h, colourless liquid, 92% yield. $C_5H_{14}ClNSi$ (151.71): calcd. Synthesis of $SiMe_2(NR_2)(NR'_2)$: Only the synthesis of $SiMe_2(NMe_2)(NHtBu)$ is reported in detail, the others being similar. A solution of $SiMe_2Cl(NMe_2)$ (**1**, 900 mg, 6.54 mmol) in Et_2O (30 mL) was treated with an Et_2O suspension of LiNH*t*Bu (4.1 mL of an Et_2O solution, 1.6 M, 6.6 mmol of LiMe +485 mg, 6.63 mmol of NH_2tBu) and the resultant suspension stirred for 3 h. The colourless solid was filtered (270 mg) and the solvent was removed in vacuo from the filtrate yielding a pale yellow liquid identified as $SiMe_2(NMe_2)(NHtBu)$ (**5**).

$SiMe_2(NMe_2)(NHtBu)$ (5): 1.05 g, 92% yield. $C_8H_{22}N_2Si$ (174.36): calcd. C 55.1, H 12.7, N 16.1; found C 55.1, H 12.9, N 16.0. ^{1}H NMR (C_6D_6, 298 K): δ = 2.41 (s, 6 H, $SiNCH_3$), 1.12 (s, 9 H, CCH_3), 0.53 (br., 1 H, NH), 0.10 (s, 6 H, $SiCH_3$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 48.8 (C), 37.6 ($SiNCH_3$), 33.5 (CCH_3), −0.08 ($SiCH_3$) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −10.8 ppm.

$SiMe_2(NMe_2)(NHiPr)$ (6): Colourless liquid, 90% yield, from $SiMe_2Cl(NMe_2)$ (**1**) + LiNH*i*Pr. $C_7H_{20}N_2Si$ (160.33): calcd. C 52.4, H 12.6, N 17.5; found C 52.0, H 12.5, N 17.3. ^{1}H NMR (C_6D_6, 298 K): δ = 2.99 (ds, $^3J_{H,H}$ = 10.2, 6.3 Hz, 1 H, CH), 2.49 (s, 6 H, $SiNCH_3$), 1.00 (d, $^3J_{H,H}$ = 6.3 Hz, 6 H, $CHCH_3$), 0.29 (br., 1 H, NH), 0.07 (s, 6 H, $SiCH_3$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 42.6 (CH), 37.5 ($SiNCH_3$), 27.8 ($CHCH_3$), −1.96 ($SiCH_3$) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −7.5 ppm.

$SiMe_2(NMe_2)(NHCH_2CH_2NMe_2)$ (7): Colourless liquid, 91% yield, from $SiMe_2Cl(NMe_2)$ (**1**) + $LiNHCH_2CH_2NMe_2$. $C_8H_{23}N_3Si$ (189.37): calcd. C 50.7, H 12.2, N 22.2; found C 51.0, H 11.9, N 22.1. ^{1}H NMR (C_6D_6, 298 K): δ = 2.74 (dt, $^3J_{H,H}$ = 6.9, 6.2 Hz, 2 H, $SiNCH_2$), 2.48 (s, 6 H, $SiNCH_3$), 2.18 (t, $^3J_{H,H}$ = 6.2 Hz, 2 H, CH_2NCH_3), 2.08 (s, 6 H, CH_2NCH_3), 1.15 (br., 1 H, NH), 0.04 ($SiCH_3$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 63.2 (CH_2NCH_3), 45.5 (CH_2NCH_3), 39.2 ($SiNCH_2$), 37.7 ($SiNCH_3$), −2.38 ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −5.3 ppm.

$SiMe_2(NMe_2)(NHCH_2CH_2OMe)$ (8): Colourless liquid, 95% yield, from $SiMe_2Cl(NMe_2)$ (**1**) + $LiNHCH_2CH_2OMe$. $C_7H_{20}N_2OSi$ (176.33): calcd. C 47.7, H 11.4, N 15.9; found C 47.7, H 11.0, N 15.8. ^{1}H NMR (C_6D_6, 298 K): δ = 3.19 (t, $^3J_{H,H}$ = 5.6 Hz, 2 H, OCH_2), 3.13 (s, 3 H, OCH_3), 2.87 (dt, $^3J_{H,H}$ = 7.7, 5.6 Hz, 2 H, $SiNCH_2$), 2.48 (s, 6 H, $SiNCH_3$), 0.99 (br., 1 H, NH), 0.06 (s, 6 H, $SiCH_3$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 76.0 (OCH_2), 58.4 (OCH_3), 41.3 ($SiNCH_2$), 37.6 ($SiNCH_3$), −2.38 ($SiCH_3$) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −5.0 ppm.

$SiMe_2(NHiPr)(NHtBu)$ (9): Colourless liquid, 88% yield, from $SiMe_2Cl(NHiPr)$ (**3**) + LiNH*t*Bu. $C_9H_{24}N_2Si$ (188.39): calcd. C 57.4, H 12.8, N 14.9; found C 57.3, H 12.8, N 14.7. ^{1}H NMR (C_6D_6, 298 K): δ = 3.13 (ds, $^3J_{H,H}$ = 10.4, 6.3 Hz, 1 H, CH), 1.19 (s, 9 H, CCH_3), 1.04 (d, $^3J_{H,H}$ = 6.3 Hz, 6 H, $CHCH_3$), 0.56 (br., 1 H, NH), 0.24 (br., 1 H, NH), 0.12 (s, 6 H, $SiCH_3$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 49.1 (C), 42.6 (CH), 33.8 (CCH_3), 28.0 ($CHCH_3$), 1.74 ($SiCH_3$) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −15.0 ppm.

Synthesis of $Zr[SiMe_2(NiPr)(NtBu)]_2$: An Et_2O solution of SiMe(NH*i*Pr)(NH*t*Bu) (**9**, 1.25 g, 6.64 mmol) was treated with LiMe (Et_2O solution, 1.6 M, 8.3 mL, 13.3 mmol), stirred for 1.5 h and then cooled to 243 K. $ZrCl_4$ (780 mg, 3.35 mmol) was added and after 2 h stirring at 243 K the mixture was warmed to the room temperature and the solid was filtered (540 mg). The pale yellow solution was partially evaporated, pentane was added and $Zr[SiMe_2(NiPr)(NtBu)]_2$ (**12**) was finally obtained as a microcrystalline powder on cooling the resultant solution to 240 K overnight (985 mg, 64% yield). $C_{18}H_{44}N_4Si_2Zr$ (463.96): calcd. C 46.6, H 9.6, N 12.1; found C 46.4, H 9.4, N 12.0. ^1H NMR (C_6D_6, 298 K): δ = 3.35 (sp, $^3J_{H,H}$ = 6.2 Hz, 1 H, CH), 1.32 (s, 9 H, CCH_3), 1.24 (d, $^3J_{H,H}$ = 6.2 Hz, 6 H, $CHCH_3$), 0.44 (s, 3 H, $SiCH_3$), 0.43 (s, 3 H, $SiCH_3$) ppm. ^{13}C NMR (C_6D_6, 298 K): δ = 55.6 (C), 50.6 (CH), 36.2 (CCH_3), 31.2 ($CHCH_3$), 4.3 ($SiCH_3$), 4.1 ($SiCH_3$) ppm. ^{29}Si NMR (C_6D_6, 298 K): δ = −40.5 ppm.

Synthesis of $ZrCl_3(L)$: Only the procedure for L = $SiMe_2(NMe_2)(NCH_2CH_2NMe_2)$ is described in detail, the others being similar. A solution of $SiMe_2(NMe_2)(NHCH_2CH_2NMe_2)$ (**7**, 780 mg, 4.12 mmol) in Et_2O (40 mL) was treated with LiMe (Et_2O solution, 1.6 M, 2.6 mL, 4.2 mmol). After gas evolution ceased, the solution was cooled to 243 K and $ZrCl_4$ (960 mg, 4.12 mmol) was added. The suspension was stirred at 243 K for 3 h and was then warmed to the room temperature and stirred overnight. The resultant suspension was filtered (165 mg of colourless solid) and the filtrate was evaporated yielding a sticky material which was recrystallized from Et_2O/pentane yielding a microcrystalline powder, identified as **$ZrCl_3[SiMe_2(NMe_2)(NCH_2CH_2NMe_2)]$ (15):** Colourless solid, 1.35 mg, 85% yield. MS: *m*/*z* (%) = 368 (9) [$M^{+\cdot}$ − CH_3], 332 (100) [$M^{+\cdot}$ − CH_3 − H − Cl]. $C_8H_{22}Cl_3N_3SiZr$ (385.95): calcd. Studies on Manganese(II) Complexes of *N*-Benzimidazole-Functionalized 1,4,7-Triazacyclononane: Crystal Structures, Properties and Combined Superoxide Dismutase and Catalase Functions

Qing-Xiang Li,[a,b] Qin-Hui Luo,*[a] Yi-Zhi Li,*[a] Zhi-Quan Pan,[a,b] and Meng-Chang Shen[a]

Keywords: Enzyme models / Manganese / N ligands / Superoxide dismutase

Two new manganese(II) complexes $[MnL^1Cl_2]$ and $[MnL^2Cl]ClO_4$·MeOH were synthesized [L^1 = 1-(benzimidazol-2-ylmethyl)-1,4,7-triazacyclononane; L^2 = 1,4-bis(benzimidazol-2-ylmethyl)-1,4,7-triazacyclonone) and characterized by standard physical methods. The new complexes have better stability than the parent complex due to the introduction of benzimidazole groups on the backbone of tacn. The complexes were studied as superoxide dismutase (SOD) mimics by the riboflavin photoreduction method at pH 7.4. In basic or weakly basic solutions, the complexes decompose hydrogen peroxide catalytically, and possess the combined functions of SOD and catalase.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Superoxide dismutase (SOD) efficiently catalyzes the dismutation of superoxide anion ($O_2^{\cdot-}$) to oxygen and hydrogen peroxide,[1,2] which is subsequently disproportionated into water and oxygen by catalase[3] (CAT).

$$O_2^{\cdot-} + 2\,H^+ + e^- \rightarrow H_2O_2$$
$$2\,H_2O_2 \rightarrow 2\,H_2O + O_2$$

Both SOD and CAT play important roles in the protection of cells against the toxicity of oxygen.[3] Manganese is involved in many biological processes,[4] such as hydrogenperoxide decomposition and superoxide dismutation etc., and is found at the active centers of MnSOD[5,6] and MnCAT.[5]

In MnSOD the manganese has a trigonal-bipyramidal coordination environment with three histidine groups and one monodentate carboxylate group,[6] whereas MnCAT may effectively catalyze the disproportionation of H_2O_2 by using a μ-oxo/hydroxo-bis(μ-carboxylate)dimanganese structural unit as the active site.[5,7,8] Recently, various dinuclear manganese-based catalase mimics[9] that decompose hydrogen peroxide have been screened as catalysts for low-temperature bleaching[10] and for organic syntheses.[11] The manganese complexes used as mimics of MnSOD are more suitable than Cu_2Zn_2SOD because manganese has a lower toxicity in mammalian systems.[12] Recently, various mononuclear manganese complexes have been selected for pharmaceutical uses,[13] such as manganese complexes with Schiff-base ligands,[14] porphyrins, 1,4,7,10,13-pentazacylic pentadecane derivatives,[15,16] and so on.[17] Among these, a class of complexes with combined SOD and catalase functions have attracted many people's attention: complexes such as [Mn(salen)Cl] and [Mn(vanl)Cl] (salen and vanl are the [1+2] condensates of ethylenediamine with salicyladehyde or vanillin, respectively) exhibit both SOD and catalase activities, catalytically destroying both superoxide anion and hydrogen peroxide. Due to their novel combined functions, they have been suggested to serve as therapeutic agents.[18–20]

An attractive property of the tridentate macrocycle 1,4,7-triazacyclonone (tacn) is its ability to form thermodynamically stable redox-active manganese complexes.[21,22] In this paper, this ligand has been further modified. Two new manganese(II) complexes $[MnL^1Cl_2]$ **1** and $[MnL^2Cl]ClO_4$·MeOH **2** [L^1 = 1-(benzimidazol-2-yl-methyl)-1,4,7-tacn, L^2 = 1,4-bis(benzimidazol-2-yl-methyl)-1,4,7-tacn] have been synthesized and characterized by stndard physical methods. Interestingly, the two complexes exhibit SOD activities, catalytically dismutating $O_2^{\cdot-}$, and possess the combined functions of SOD and catase.

Results and Discussion

Characterization

Both complexes possess similar spectroscopic features. In the IR spectra the strong bands at 3415 and 3384 cm^{-1} are

[a] Coordination Chemistry Institute, State Key Laboratory of Coordination Chemistry,
Nanjing 210093, P. R. China
E-mail: qhluo@jlonline.com
[b] School of Chemical engineering & Pharmacy, Wuhan Institute of Chemical Technology

due to the N−H stretching vibration of complexes **1** and **2**, respectively. The medium-strong bands at about 750 cm^{-1} are designated as skeleton stretching of the aromatic ring. Complex **2** exhibits a strong band at 1107 cm^{-1}, showing the presence of ClO_4^-.

In the electronic spectra, the absorptions of the two complexes in the range of 279−272 nm and at 244 nm are characteristic of the B band and E_2(K) band of *o*-phenylene, respectively. The values of the molar conductivities indicate that both complexes are 1:1 electrolytes in MeCN solution.

The magnetic susceptibilities of the two complexes show that the manganese in each complex has a high-spin, d^5 configuration.

The EPR spectra of complex **2** in MeOH solution at room temperature and 110 K are shown in Figure 1. Figure 1 (see a) exhibits a six-line spectrum, typical of mononuclear Mn^{II}, centered at 3496 G, with $g = 1.999$ and a hyperfine coupling constant, A, of 88×10^{-4} cm^{-1} associated with the $I = 5/2$ nuclear spin of ^{55}Mn. This signal results from allowed transitions ($\Delta m_s = \pm 1$, $\Delta m_I = 0$). In the spectrum at 110 K (see b in Figure 1) it is possible to see the weak, forbidden transition signals between the six intense signals.

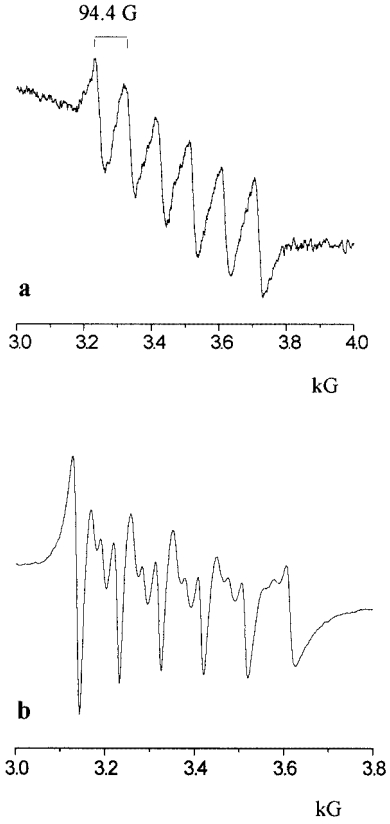

Figure 1. EPR spectra of the complex $[MnL^2Cl]ClO_4 \cdot MeOH$ in methanol (1.0×10^{-2} mol·dm^{-3}): (a) at room temperature; (b) at 110 K; microwave frequency: 948 GHz; microwave power: 20 mW; gain: 1.0×10^5; scan range: 2000 G; time constant: 100 s; scan time: 100 s

The positive-ion electrospray (ES) mass spectra of $[MnL^1Cl_2]$ **1** and $[MnL^2Cl]ClO_4 \cdot MeOH$ **2** in MeOH solution were also recorded. The results are listed in Table 1. These peaks are due to loss of one or two chloride anions, formation of dinuclear Mn^{II} species with two chloride anions as bridging ligands, or binding of solvent molecules. The loss of chloride anions shows the weak interaction between the Cl^- ion and manganese(II), which would favor the attack of species with low molecular weight, such as superoxide anion. No peaks of ligands or their fragments were found in the mass spectra of the two complexes, and their simplicity is attributed to the thermodynamic stability and kinetic inertness of the two complexes.[22] No peaks were found due to the loss of Mn^{2+} ion or the pendant arm. This indicates that both complexes are stable under the experimental conditions.

Electrochemical Properties

The redox behavior of **1** and **2** was studied by cyclic voltammetry in aqueous solution and in MeOH solution for **1** and **2**, respectively. During scanning from −0.3 V to +0.8 V the CV diagram of **1** in aqueous solution displays one pair of anodic and cathodic peaks with peak potentials of $E_{pa} = 0.411$ V and $E_{pc} = -0.109$ V (vs. SCE) respectively. The value of the half-wave potential, $E_{1/2}$, was calculated to be 0.151 V. The anodic peak current (i_p) is almost equal to the cathodic one. In the same range of potential scan rate (v), the $i_p/v^{1/2}$ ratio is kept constant. The peak separation between the anodic and cathodic peaks at a scan rate 50 mV·s^{-1} is 520 mV. These features are indicative of a quasi-reversible M^{II}/Mn^{III} redox process. Other redox peaks were not found at a more negative potential, implying that the macrocycle effect stabilizes the Mn^{III} oxidation state. Complex **2** shows two pairs of quasi-reversible anodic and cathodic peaks with $E^1_{1/2} = 0.527$ V for first pair of peaks and $E^2_{1/2} = 0.697$ V for the second pair of peaks (Figure 2); they are assigned to the Mn^{III}/Mn^{II} and Mn^{IV}/Mn^{III} couples, respectively.

According to the redox potential of $\cdot O_2^-$ in neutral solution

$O_2 + e^- \rightarrow \cdot O_2^-$; $E^o_{pH7} = -0.16$ V (vs. NHE)
$\cdot O_2^- + 2\,H^+ + e^- \rightarrow H_2O_2$; $E^o_{pH7} = +0.89$ V (vs. NHE)

in order to act as a catalyst of $\cdot O_2^-$ disproportionation, the complexes must have a half-wave potential falling between two values. The half-wave potentials for complex **1** [$E_{1/2} = 0.392$ V (vs. NHE)] and complex **2** [$E^1_{1/2} = 0.769$ V (vs. NHE)] both fall between −0.16 V and +0.89 V (see Equation 3 and 4[23]), therefore both complexes can be oxidized by $\cdot O_2^-$ and their oxidized form can be re-reduced by $\cdot O_2^-$ to finish the catalytic cycles, as follows:

$Mn^{II} + \cdot O_2^- + 2H^+ \rightarrow Mn^{III} + H_2O_2$
$Mn^{III} + \cdot O_2^- \rightarrow Mn^{II} + O_2$

For the second pair of peaks of complex **2**, the half-wave potential is higher than +0.89 V [$E^2_{1/2} = 0.939$ V (NHE)], indicating that $\cdot O_2^-$ cannot oxidize Mn^{III} to Mn^{IV} in this

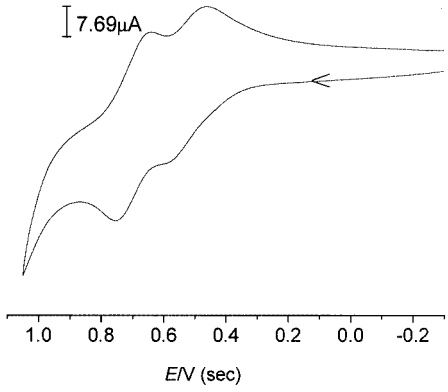

Figure 2. Cyclic voltammogram of complex **2** in MeOH solution; concentration: 1.0×10^{-3} mol·dm^3 (scan rate 100 mV·s^{-1})

complex. Therefore the catalytic cycle occurs only between Mn^{II} and Mn^{III}; this is similar to MnSOD.

pH Titration

The coordinating ability of the ligands towards Mn^{2+} was studied by means of pH titration of a solution containing L^1·3HCl (or L^2·3HCl) and $Mn(NO_3)_2$ in equimolar amounts. To avoid precipitation of manganese(II) complexes of L^2 in aqueous solution during titration by NaOH, the experiments were carried out in dioxane/water (7:3, v/v). The titration curves of ligand L^1·3HCl (1) and L^1·3HCl plus Mn^{2+} ion (2) in aqueous solution are shown in Figure 3. The first inflexions of the two curves are at about $a = 1$ (a denotes the number of mols of NaOH added per mol of ligand), showing that one mol of the acid was titrated by base. For curve (2) in Figure 3 a very long buffer region at about $a = 1-3$, indicates the formation of the dominant species $[Mn(L^1)]^{2+}$, after which a slow inflexion occurs corresponding to the coexistence of $[MnL^1(OH)]^+$ and $[MnL^1(OH)_2]$ species, implying that the hydroxyl ions are bound to the unoccupied coordination sites. Assuming the coexistence of $[Mn(L^1)]^{2+}$, $[MnL^1(OH)]^+$ and $[MnL^1(OH)_2]$, the equilibrium constants (Table 2) were obtained by a curve fitting procedure. Comparing the equilibrium constants of complexes **1** and **2** with those of their parent complexes, which have no benzimidazole groups on the tacn backbone, we can see that the species $[MnL]^{2+}$ for 1 and 2 have better stability than the parent complex. The species-distribution curves of curve (2) are shown in Figure 4. The distribution curves of complexes **1** and **2** show that, at physiological pH (7.4), an $[MnL^1(OH)]^+$ species still predominates for both L^1 and L^2, implying that the vacant site at Mn^{II} atom is suitable for the coordination of hydroxyl ion. The percentage of free Mn^{2+} is less than 0.07% and 0.08% for L^1 and L^2, respectively. This means that the ligands have a relatively strong coordinating ability to manganese(II).

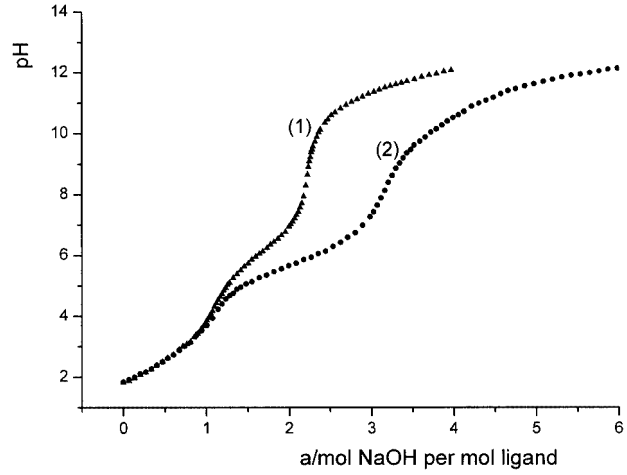

Figure 3. pH Titration curves in aqueous solutions: (1) $[L^1·3HCl] = 0.002496$ mol·dm^{-3}; (2) $[L^1·3HCl] = [Mn^{2+}] = 0.002504$ mol·dm^{-3}; $I = 0.1$ mol·dm^{-3} (KNO_3), 25 °C

Crystal Structures of the Complexes

[MnL¹Cl₂]

The crystal data of complexes **1** and **2** are listed in the Exp. Sect. The structure of the $[MnL^1Cl_2]$ is shown in Figure 5 (a), and selected bond lengths and angles are given in Table 3. In complex **1**, each Mn^{II} atom is coordinated by four nitrogen atoms of the triazacycle [N(1), N(2), N(3)], with average bond lengths of 2.292 Å, one benzimidazole nitrogen atom N(4), and two chloride ions. The Mn−N(4) bond length is 2.214 Å, and is the shortest of the Mn−N bonds. This indicates that the nitrogen atom of the benzimidazole group has a stronger coordination ability to Mn^{II} than the nitrogens of the triazacycle and plays an important role in increasing the stability of the complex. The two Mn−Cl bond lengths [2.5298(11) Å for Cl (1) and 2.4067 Å for Cl (2)] are longer than the Mn−N bond lengths, therefore these Cl^- anions are able to be detached from the Mn^{II} atom in solution, as proved by the ES-MS experiment.

methyl ligand. The Mn−Cl bond length is 2.4668(7) Å. The Mn^{II} atom is also located at the center of a distorted octa5-hedron as in **1**. The atoms N(1), N(2) and N(3) of the aza-macrocycle constitute a face of the octahedron, and two nitrogen atoms [N(4), N(6)] of the two benzimidazol-2-yl-methyls and the Cl^- anion compose the opposite face. Cl(2) and N(3) are located in the axial direction with a Cl(2)−Mn−N(3) angle of 158.13(6)°. The equatorial plane is composed of N(1), N(2), N(4) and N(6), and the Mn^{II} atom is 0.3893 Å out of this plane. The dihedral angle between the equatorial plane and one of the benzimidazole planes [N(4), N(5), C(8)−C(14)] is 164.2°, and that between the equatorial plane and the other benzimidazole plane [N(6), N(7), C(16)−C(22)] is 89.3°. The dihedral angle between the two benzimidazole planes is 76.1°. The two benzimidazole groups encapsulate Mn^{II} to form a hydrophobic packet with a channel.

SOD Activities of the Complexes

The SOD activities of the complexes were studied in aqueous solutions of phosphate buffer (pH 7.4) by the riboflavin photoreduction method.[24] Both complexes inhibit the reduction of nitroblue tetrazolium chloride, depending on their concentrations. The activity was obtained by plotting the percentage of inhibiting NBT reduction, *f* (%), against the concentration of the complex, *C*. The plot for complex **2** is shown in Figure 6. The activities of complexes **1** and **2**, together with those for $Mn(ClO_4)_2$ and Cu_2Zn_2SOD determined under the same conditions, are listed in Table 5. The activities of **1** and **2** are of the same order of magnitude as that of Mn^{2+} ion, but these high activities are not due to free Mn^{2+} ion produced by dissociation of the complexes. The free Mn^{2+} ion can be ignored in solution, as proved by the pH titration. The activities of the complexes are about 1% of that of Cu_2Zn_2SOD.

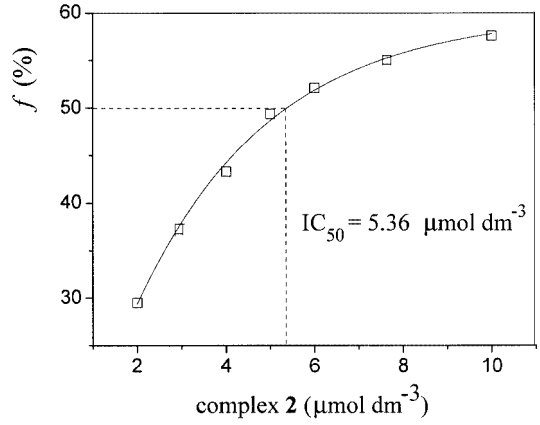

Figure 6. A plot of inhibition percentage (*f*%) vs. concentration for complex **2**

The complexes were also studied by the addition of various concentrations of bovine serum albumin (BSA) to the tested solutions in order to further prove the stability of the complexes under protein conditions. It was found that the concentration of BSA has no effect on the activities of the two complexes until it reached a value of 0.2 mg/mL. The ES mass spectra and X-ray structural analyses of the two complexes show that the binding of chloride anions to the Mn^{II} center is rather weak, and therefore it is likely that the Cl^- could become partially detached in solution. As the concentration of $^{\cdot}O_2^-$ in the solution much higher than that of OH^- at pH 7.4, the vacant coordination sites are open to attack by $^{\cdot}O_2^-$. The benzimidazole groups are similar to the hydrophobic residues of MnSOD. In complex **2**, with two benzimidazole groups, the benzimidazole groups surround the metal ion to form a hydrophobic channel which favors the attack of $^{\cdot}O_2^-$; complex **2** therefore displays higher SOD activity.

Reactivity with Hydrogen Peroxide

The catalytic activity of complexes **1** and **2** towards hydrogen peroxide was investigated in methanol/water solutions (1:5, v/v) and in aqueous solutions, respectively. The evolution of dioxygen was followed manometrically as a function of time at room temperature. The O_2-evolution curve for complex **1** is shown in Figure 7. In the absence of NaOH, the complex decomposes hydrogen peroxide very slowly (Figure 7, curve 1) corresponding to the self-decomposition of H_2O_2. After 15 min only 7.0% of the total H_2O_2 had been decomposed. Previous authors have re-

ported that the addition of an organic base accelerates significantly the catalytic decomposition of hydrogen peroxide by manganese complexes.[25] However, in this experiment organic bases such as pyridine, imidazole and acetate anion did not increase the rate of O_2 evolution. Interestingly, the rate of O_2 evolution increased with an increase of the concentration of NaOH, and at a molar ratio of NaOH to complex **1** of 1.68 (pH 7.38), the percentage of decomposed H_2O_2 reached 90% after 15 min. When the molar ratio of NaOH to complex **1** was equal to 5.73 (pH 11.03), we obtained an initial turnover rate, υ' of 5.58 mol H_2O_2/mol catalyst·s^{-1} and a turnover number (number of mols of H_2O_2 decomposed per mol catalyst) of 606 (after the reaction stopped). The kinetic data for H_2O_2 decomposition by the complexes are listed in Table 6, where it can be seen that the value of υ' of complex **1** is higher than that of complex **2** in MeOH/water solvent, although its turnover is lower, because the formation of a dinuclear manganese complex as the active species (see below) is difficult for complex **2** due to the steric hindrance of the two benzimidazole groups, however, the turnover of complex **2** is higher because the active species of **2** does not easily decompose. In aqueous solution, complex **1** has a higher value of υ' and a lower turnover number than in mixed solvent, probably because both H_2O_2 and the active species of complex **1** have a low stability in aqueous solution, resulting in a high catalytic activity and a low turnover. The υ' values of complex **1** in aqueous solution and mixed solvent are close to that of the dinuclear manganese complex with the *N*,*N*′,*N*′′-trimethyl-1,4,7-triazacyclononane ligand[26] (υ' = 5.55 s^{-1}), although the turnover is lower. To date, the dinuclear manganese complexes reported[4] have rate values that range from 0.013[28] to 50 s^{-1}.[27] The values of υ' for complexes **1** and **2** therefore fall at the high end of the range of those reported previously.

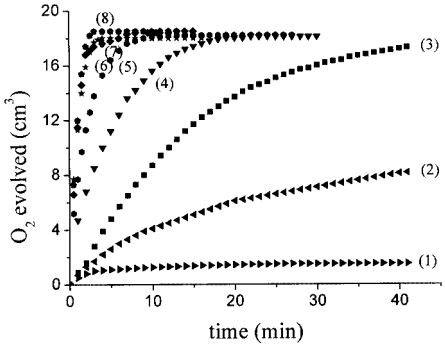

Figure 7. Curves of oxygen evolution for the catalytic disproportionation of H_2O_2 by $[MnL^1Cl_2]$ (**1**) in methanol/water solution (1:5, v/v); $C_{complex}$: 8.45 × 10^{-4} mol·dm^{-3}; C_{NaOH}: (1) 0 (pH 4.71); (2) 5.12 × 10^{-4} (pH 5.06); (3) 7.11 × 10^{-4} (pH 6.02); (4) 1.42 × 10^{-3} (pH 7.38); (5) 1.99 × 10^{-3} (pH 8.31); (6) 3.42 × 10^{-3} (pH 9.44); (7) 4.27 × 10^{-3} (pH 10.57); (8) 4.84 × 10^{-3} (pH 11.03)

Active Intermediates

A number of the dinuclear manganese complexes with oxygen or hydroxyl bridges reported previously exhibit significant rate enhancement for the disproportionation of hydrogen peroxide in the presence of an exogenous base. It has been proposed that this effect is due to the base-facilitated deprotonation of H_2O_2 in the course of the coordination of hydrogen peroxide to the manganese center. In our experiment, however, this is not the case as the concentration of H_2O_2 is very much higher (several hundred times) than those of complex and NaOH. Therefore, the main function of the added NaOH is not capturing a proton from H_2O_2.

The active intermediates in the catalytic decomposition reactions of hydrogen peroxide by the manganese complexes could not be isolated from the solutions. Therefore, in order to trap the active species, the ES mass spectrum of complex **1** plus H_2O_2 and NaOH in MeOH solution was recorded (Figure 8). The peak assignments are shown in Table 7, in which all species derived from complex **1** are oxygen-bridged or hydroxyl-bridged binuclear complex cations and the oxidation state of manganese is +2 or +3. According to these results, a possible mechanism of hydrogen peroxide dismutation is suggested in Scheme 1.

In step 1 the Cl^- ligand in complex 1 is substituted by water molecules, and in step 2 complexes containing one or two hydroxyl-bridged units are formed in basic solution. In step 3 the water molecules are replaced by H_2O_2, followed by an intramolecular electron transfer (step 4). Finally, the intermediate reacts further with H_2O_2 and the catalytic cycle is completed (step 5).

For complex **2**, the ES mass spectrum obtained under the same conditions as **1** is different (Table 8) as only a few molecules of complex **2** are changed into hydroxyl-bridged or oxygen-bridged binuclear manganese units due to the steric hindrance of the two benzimidazole groups; the manganese therefore exists in the Mn^{II}, Mn^{III} and Mn^{IV} oxidation states. The variation of oxidation state for complexes **1** and **2** during the disproportionation of hydrogen peroxide is in agreement with the results obtained by cyclic voltammetry.

It is remarkable that irrespective of whether they are dissolved in MeOH/water or only in water at about pH 7.3,

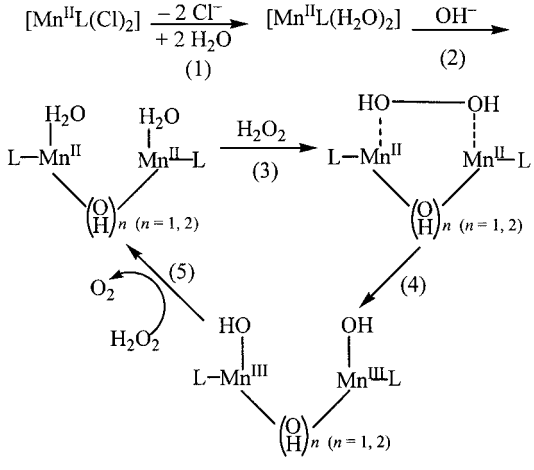

Scheme 1. The mechanism of hydrogen peroxide dismutation by complex **1**

which is close to physiological conditions, complexes **1** and **2** decompose 90% of H_2O_2 during the first 15 min (Figure 7). Therefore, we consider that at physiological pH values the complexes are able to dismutase $^{\cdot}O_2^-$ and are also able to decompose H_2O_2, depending on the concentration of $^{\cdot}O_2^-$. The SOD activities of the complexes are not high, and this is probably due to the fact that some of the species are hydroxylated or bridged. The mechanism for this and its biological relevance need to be studied further.

Conclusion

Two manganese(II) complexes of 1,4,7-tacn with benzimidazole groups, $[MnL^1Cl_2]$ and $[MnL^2Cl]ClO_4{\cdot}MeOH$, were synthesized and characterized. pH titration was used to investigate their stabilities in solution. The introduction of benzimidazole groups on the backbone of tacn increases the stability of the new complexes relative to the parent, unsubstituted complex. The redox potentials of the complexes obtained from cyclic voltammetry show that they are able to dismutase $^{\cdot}O_2^-$. The oxidation state for manganese of the two complexes changes from +2 to +3, and then from +3 to +2, implying that the catalytic mechanism is just a "ping-pong" reaction. ES mass spectrometric and X-ray structure analyses indicated that the binding of Cl^- with Mn^{II} in the complexes is relatively weak, therefore Cl^- can be attacked by $^{\cdot}O_2^-$. The complexes can also be converted into OH- or O-bridged dinuclear manganese(III) or manga-

nese(IV) complexes, which act as active species to decompose H_2O_2 catalytically.

Experimental Section

Materials: L^1 [1-(benzimidazol-2-ylmethyl)-1,4,7-triazacyclononane] and L^2 [1,4-bis(benzimidazol-2-ylmethyl)-1,4,7-triazacyclonone] were prepared by the reported method.[29] Carbonate-free NaOH for pH titration was obtained by Powell's method.[30] $Mn(NO_3)_2{\cdot}6H_2O$ (Analytic Reagent) was recrystallized from doubly distilled water and the stock solutions were standardized by titration with EDTA. In SOD activity experiments, nitroblue tetrazolium nitrate (NBT) (Biochemical Reagent) and L-methionine (Biochemical Reagent) were used and the solutions were prepared using doubly distilled water. The purity of riboflavin was determind by the literature method.[31] The concentration of stock solution of hydrogen peroxide for catalysis activity assay was measured by titration with standardized $KMnO_4$ solution.

Physical Measurements: Elemental analysis was performed using a Perkin−Elmer 240c analytical instrument. IR spectra were measured as KBr discs using a Nicolet 5DX FT-IR spectrophotometer. Electronic spectra were recorded on a UV-3100 spectrophotometer. X-band EPR spectra were measured on an EMX spectrometer in 1.0×10^{-2} mol·dm^{-3} MeOH solution. The electrical conductivity of solutions was measured with a BSD-A conductometer (Jiangsu, P. R. China) with a solution concentration of about 1.0×10^{-3} mol·dm^{-3} in MeCN at 25 ± 0.1 °C. The electrospray mass spectra were determined on a Finnigan LCQ mass spectrograph. The samples (about 0.1 mmol·dm^{-3} in MeOH) were electrosprayed at a flow rate of 5×10^{-6} mol·min^{-1} with a needle voltage of +4.5 kV. The temperature of the heated capillary at the interface was 200 °C and a fused-silica sprayer was used. The mobile phase was an aqueous solution of methanol (1:1, v/v). The samples were run in the positive-ion mode.

Electrochemical Measurements: The cyclic voltammogram experiments were carried out on a PAR Model 273 potentiostat coupled to a PAR Model 175 universal programmer under highly pure nitrogen at 25 ± 0.1 °C. A glassy-carbon electrode was employed as working electrode, a saturated calomel electrode (SCE) as reference electrode, and a platinum wire as auxiliary electrode. The concentration of complex 1 was 1.0×10^{-3} mol·dm^{-3} in 0.1 mol·dm^{-3} $NaClO_4$ aqueous solution and that of complex 2 was 1.0×10^{-3} mol·dm^{-3} in 0.1 mol·dm^{-3} TBAP (tetrabutylammonium perchlorate) MeOH solution. The solutions were deaerated for about 15 min before applying the voltage. The half-wave potentials, $E_{1/2}$, were calculated approximately from $(E_{pa} + E_{pc})/2$ and the measured errors were ±2 mV. Unless otherwise stated, all potentials reported are referenced to the saturated calomel electrode.

pH Titration: Protonation constants of the ligands and stability constants of the complexes were determined by using a Corning pH meter with a glass/silver/silver chloride combination electrode with a precision of ±0.001 pH units. The electrode was standardized against buffer solutions of potassium hydrogen phthalate and sodium borate. The concentrations of ligands ($L^1{\cdot}3HCl$ or $L^2{\cdot}3HCl$) was about 0.0025 mol·dm^{-3}, and the molar ratio of $L^1{\cdot}3HCl$ or $L^2{\cdot}3HCl$ to $Mn(NO_3)_2$ was 1:1. The experimental solutions were titrated with carbonate-free 0.0825 mol·dm^{-3} NaOH by using a microsyringe with a precision of ±2 μL under a nitrogen atmosphere in a sealed jacketed vessel at 25 °C. The ionic strength was kept at 0.1 mol·dm^{-3} by adding KNO_3. For the L^2 systems a dioxane/water mixture (7:3) was used as the solvent and 0.1 mol·dm^{-3} KNO_3 as the support electrolyte as the formed product was not soluble in water.

The equilibria in the systems can be represented by Equation (1)

$$qM + pH + rL \rightleftarrows M_qH_pL_r, \text{ where } \beta_{pqr} = [M_qH_pL_r]/[M]^q[H]^p[L]^r \quad (1)$$

where q, p, and r denote the number of metal ions (M), hydrogen ions (H) and ligand molecules (L) bound in the complex, respectively. A negative p value shows that hydrogen ion is released during coordination. The protonation constants of the ligands were calculated with the PKAS program.[31] Applying the law of mass action to each experimental point i (i = 1, 2, 3...n) gives Equations (2)−(4):

$$C_{Hi} = [H]_i + \sum_{j=1}^{m} p_j \beta_{pjqjrj} [H]_i^{pj} [M]_i^{qj} [L]_i^{rj} \quad (2)$$

$$C_{Mi} = [M]_i + \sum_{j=1}^{m} q_j \beta_{pjqjrj} [H]_i^{pj} [M]_i^{qj} [L]_i^{rj} \quad (3)$$

$$C_{Li} = [L]_i + \sum_{j=1}^{m} r_j \beta_{pjqjrj} [H]_i^{pj} [M]_i^{qj} [L]_i^{rj} \quad (4)$$

where j denotes the ordinal number of complexes (j = 1, 2...m) and C_{Hi}, C_{Mi}, and C_{Li} denote the total concentrations of hydrogen ions, metal ions and ligands in solution, respectively, at each experimental point i.

The equilibrium constants of the complexes were calculated by using the program LEMIT,[32] which is based on the Newton−Raphson and Gauss−Newton method for minimizing U in Equation (5), where C_{Hi}^{calc} and C_{Hi}^{expt} denote the calculated and experimental values of H^+ concentration at the ith point.

$$U = \sum_{i}^{n} (C_{Hi}^{calc} - C_{Hi}^{expt})^2 \quad (5)$$

Crystal-Structure Determination: X-ray intensity data for the manganese(II) complexes were collected on a SMART-CCD area-detector diffractometer. Data reduction and cell refinement were performed with the programs SMART and SAINT.[33] The absorption corrections were carried out by an empirical method. The structures were solved by direct methods (Bruker Shelxtl) and refined on F^2 by full-matrix least-squares (Bruker Shelxtl) using all unique data.[34] The non-H atoms in the structures were subjected to anisotropic refinement. Hydrogen atoms were located geometrically and treated with the riding mode. In $[MnL^2Cl]{\cdot}ClO_4{\cdot}CH_3OH$, the ClO_4^- anion was disordered.

CCDC-233744 (**1**) and -233743 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Assay of Superoxide Dismutase Activity: The activities were assayed by photoreduction of riboflavin.[24] The solutions contained riboflavin (3.4×10^{-6} mol·dm^{-3}), methionine (0.01 mol·dm^{-3}), nitroblue tetrazolium nitrate (NBT; 4.66×10^{-5} mol·dm^{-3}) and the complexes of various concentrations were prepared with phosphate buffer (pH 7.4). They were illuminated by a fluorescent lamp with a constant light intensity at 25 °C. The optical absorbance (A) of the solutions at 560 nm were measured with various illumination periods (t). Each solution was measured in two parallel tests. Inhibition percentage (I%) was calculated according to the reported

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

method.[35] The activity (IC_{50}) was defined as the necessary concentration to inhibit 50% reduction of NBT.

Disproportionation of Hydrogen Peroxide:[25,26] An aqueous solution of H_2O_2 (0.5 mL, 3.08 mol·dm^{-3}) was added to a flask containing an aqueous solution of complex **1** or a solution of complex **2** (2.0 mL, 1.22×10^{-3} mol·dm^{-3}) in a methanol/water mixture (1:5). The mixture was stirred and thermostatted at 25 °C, and the O_2 evolved was followed manometrically. To investigate the effect of basicity on the disproportionation of H_2O_2, NaOH solutions of various concentration were added to the flask, the total volumes of solutions were kept to be 2.88 mL for each experiment.

[MnL^{1}Cl$_2$] (1): Manganese(II) acetate (91 mg, 0.34 mmol) was added to a methanol solution (20 mL) of L^1·3HCl·MeOH (125 mg, 0.31 mmol) in 10 mL of methanol. The mixture was stirred for 5 h at room temperature and then filtered. Slow evaporation of the solution gave a pink crystalline compound. Crystals suitable for X-ray diffraction were obtained by diffusion of diethyl ether into an MeCN solution over one week. Yield: 72 mg (61%). $C_{14}H_{21}Cl_2MnN_5$: calcd. C 43.65, H 5.50, N 18.18; found C 43.97, H 5.97, N 18.45. IR (KBr): $\tilde{\nu}$ = 3415 [s, ν(N−H)], 755 cm^{-1} [m, δ(Ph−H)]. UV/Vis (MeOH): λ_{max} = 279 nm (9469 dm^3·mol^{-1}·cm^{-1}), 272 (9150), 268 (8654), 243 (6704). Ω_m (MeCN, 298.2 K): 96.60 S·cm^2·mol^{-1}. μ (290.3 K): 5.63 μ_B.

[MnL^{2}Cl]·ClO$_4$·CH$_3$OH (2): Manganese(II) perchlorate (83 mg, 0.23 mmol) was added to a methanol solution (20 mL) of L^2·3HCl·H$_2$O·1.5EtOH (120 mg, 0.21 mmol) in 10 mL of methanol. Under stirring, the mixture was adjusted to pH 5.0 by addition of a methanol solution of sodium hydroxide. After refluxing for 2 h, the mixture was cooled and filtered. Yellow crystals were isolated from the solution. Yield 69 mg (55%). $C_{23}H_{31}Cl_2MnN_7O_5$: calcd. C 43.13, H 4.93, N 15.17; found C 43.18, H 5.11, N 15.87. IR (KBr): $\tilde{\nu}$ = 3384 cm^{-1} [s, ν(N−H)]; 1108 [s, ν(ClO$_4^-$)], 748 [m, δ(Ph−H)]. UV/Vis (CH_3CN): λ_{max} = 311 nm (416 dm^3·mol^{-1}·cm^{-1}), 279 (12365), 272 (11654), 244 (9846). Ω_m (MeCN, 298.2 K): 100.45 S·cm^2·mol^{-1}. μ (290.3 K): 5.75 μ_B. Crystals suitable for X-ray diffraction analysis were obtained by diffusion of diethyl ether into an MeCN solution over two weeks. Crystallographic data are given in Table 9.

Oxidation-State and Coordination-Site Specificity Influencing Dimensional Extension and Properties of Two Iron Complexes with Similar Helical Chains

Ying Xu,[a] Lei Han,[a] Zheng-Zhong Lin,[a] Cai-Ping Liu,[a] Da-Qiang Yuan,[a] You-Fu Zhou,[a] and Mao-Chun Hong*[a]

Keywords: Iron / Helical chains / Coordination polymer / Oxidation state

Two new iron coordination frameworks, $\{[NH_2(CH_3)_2]_2Fe^{II}(pydc)_2\}_n$ (**1**) and $\{[NH_2(CH_3)_2]Fe^{III}(pydc)_2\}_n$ (**2**) (pydc = 2,5-pyridinedicarboxylate), have been synthesized through the reaction of $FeCl_3$ with H_2pydc in dimethylformamide (DMF). **1** crystallizes in an achiral space group $C2/c$, while **2** crystallizes in a chiral space group $P4_32_12$. Both crystal structures consist of 2_1 helices with similar units: $[Fe^{II}(pydc)_2]^{2-}$ and $[Fe^{III}(pydc)_2]^-$, respectively. The iron oxidation states have been confirmed by means of ESR spectra and bond valence calculations. Quantum chemistry calculations and thermogravimetric analysis have demonstrated their energy and thermal stability. Magnetic studies have revealed that **1** and **2** show weak antiferromagnetic and ferromagnetic interactions between the metal centers, respectively.

Introduction

Metal-organic coordination networks are the largest class of engineered crystal structures. They expand coordination in diverse dimensions by means of polydentate organic ligands coordinating to metal atoms.[1] Much work has been done towards understanding the molecular packing[2−4] and the relationship between inner structure and collective properties.[5,6] The selection or design of suitable ligands containing certain features, such as functionality and versatile binding modes, plays an important role in determining the topologies and properties of coordination networks.[7−11] Metal atoms, especially their metal oxidation state, also significantly affect the structural extension and properties of coordination networks.[12,13] However, the influence of the metal oxidation state has been comparatively less well investigated.[14,15] Our efforts have focused on constructing coordination networks by assembling multidentate ligand H_2pydc and multiple oxidation state iron atoms. Herein, we report the syntheses and characterizations of two new iron coordination frameworks with 2_1 helical chains: $\{[NH_2(CH_3)_2]_2Fe^{II}(pydc)_2\}_n$ (**1**) and $\{[NH_2(CH_3)_2]Fe^{III}(pydc)_2\}_n$ (**2**), assembled from iron ions and pydc in different coordination modes (Scheme 1).

Results and Discussion

Syntheses

Although the formation mechanisms are poorly understood, solvothermal synthesis under mild conditions ($T <$ 200 °C, autogenous pressure) is a good way of generating complexes with interesting structures or functional materials, as the nature of organic solvent may drastically effect the formation of compounds.[16−19] In this respect, DMF is a good polar, aprotic solvent with a high boiling point. Consequently, we carried out the solvothermal reaction of iron(III) chloride and H_2pydc (1:2 molar ratio) in DMF, which was used to remove the carboxylate group protons and to avoid coordination between the iron atoms and water solvent molecules. Two kinds of well-shaped crystals, dark red blocks for **1** and light yellow dipyramids for **2**, were separated with a moderate yield for **1** and a very low yield for **2**. To obtain a higher yield of **2**, 0.1 mL of H_2O_2 (30%) was added to the reaction system, only compound **2** was isolated (44% yield). The formulae of $\{[NH_2(CH_3)_2]_2Fe^{II}(pydc)_2\}_n$ for **1** and $\{[NH_2(CH_3)_2]Fe^{III}(pydc)_2\}_n$ for **2** were revealed by X-ray single-crystal diffraction analy-

ses and elemental analyses. Clearly, some Fe^{III} was reduced to Fe^{II} as part of a redox reaction. Earlier reports show that the reaction of aromatic N ligands such as pyridine or imidazole derivatives with a transition-metal salt can result in spontaneous metal ion reduction.[20−23] The presence of $[NH_2(CH_3)_2]^+$ in the two compounds results from the decomposition of DMF. No crystals or precipitation were obtained when using *N*,*N*-dimethylacetamide instead of DMF.

Crystal Structures

$\{[NH_2(CH_3)_2]_2Fe^{II}(PYDC)_2\}_n$ (1)

Single-crystal X-ray diffraction analysis reveals that complex **1** has a two-dimensional layer structure and crystallizes in a monoclinic space group *C*2/*c*. Figure 1 (a) shows a perspective view of the local coordination environment around the Fe^{II} atom of **1**. The iron atom is hexacoordinate in an N_2O_4 environment with a distorted octahedral geometry. Two pyridyl nitrogen donors from different pydc ligands are in an L-shaped arrangement with the central iron atom at the corner; the Fe−N bond length and N(1)−Fe−N(1B) bond angle are 2.170(2) Å and 102.77(14)°, respectively. Four oxygen atoms from different pydc ligands complete its coordination sphere. Fe−O(1) and Fe−O(4A) are 2.098(2) and 2.084(2) Å, respectively. A pydc ligand bridges two Fe^{II} atoms in a *trans* mode through the pyridyl nitrogen atom and an adjacent carboxylate oxygen atom, forming a five-membered chelate ring, while one oxygen atom of the second carboxylate group coordinates another Fe^{II} atom in *trans* position (Scheme 1, a). Thus, an extended two-dimensional layer structure is formed (Figure 2, b) that contains rhombic grids with four Fe^{II} atoms at the corners, with pydc ligands as linkers. The lateral Fe···Fe distances of the Fe_4 rhombus are 8.602 Å, the diagonal Fe···Fe distances are 15.066 Å and 8.305 Å.

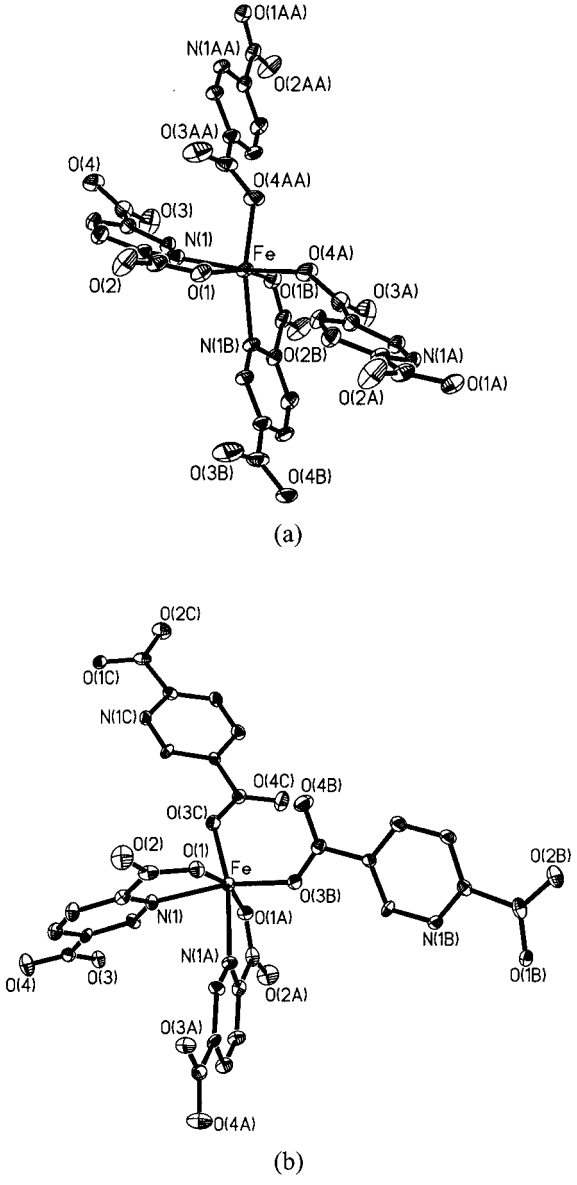

Figure 1. Coordination environments of **1** (a) and **2** (b); ellipsoids are shown at 30% probability

In **1**, the 2D layer $\{[Fe^{II}(pydc)_2]^{2-}\}_n$ can also be considered as arising from 2_1 helices (Figure 2, a). The helix winds along the *b* axis and the pitch of the helix is the length of *b* (8.305Å). All the helices extend along the same direction, generating a 2D layer structure (Figure 2, b). The layers are parallel to the *ab* plane with a C_2 symmetry for neighboring 2_1 helices. All layers are stacked on top of each other along the *c* axis, with a separation of one half of the *c* length. However, adjacent layers arranged in antiparallel orientation lead to an overall centrosymmetric structure with an achiral space group *C*2/*c* (Figure 2, c). The $[NH_2(CH_3)_2]^+$ cations, omitted in the figures for clarity, lie between the layers to balance charges.

$\{[NH_2(CH_3)_2]Fe^{III}(PYDC)_2\}_n$ (2)

Single-crystal X-ray diffraction analysis reveals that complex **2** has a three-dimensional structure and crystallizes in the tetragonal chiral space group $P4_32_12$. Figure 1 (b) gives a perspective view of the local coordination environment around the Fe^{III} atom of **2**. As in **1**, the iron atom is hexacoordinate in an N_2O_4 environment with a distorted octahedral geometry. Two pyridyl nitrogen donors from different pydc ligands form an L-shaped arrangement with the central iron atom at the corner. The Fe−N(1) bond length and N(1)−Fe−N(1A) bond angle are 2.201(5) Å and 79.8(3)°, respectively. Four oxygen atoms from different pydc ligands complete its coordination sphere. Fe−O(1) and Fe−O(3B) are 1.983(4) and 1.954(4) Å, respectively. Unlike **1**, a pydc ligand bridges two Fe^{III} atoms in a *cis* mode (Scheme 1, b) through the pyridyl nitrogen atom and an adjacent carboxylate oxygen atom, forming a five-membered chelate ring, and one oxygen atom of the second carboxylate group coordinating another Fe^{III} atom on the same side as the chelate ring. Thus, a helical polymer chain is formed that is similar to that in **1** (Figure 2, a; Figure 3, a).

Compound **2** contains 2_1 helices along the *a* or *b* axis with the pitch being 8.896 Å (Figure 3, a). In contrast to **1**,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

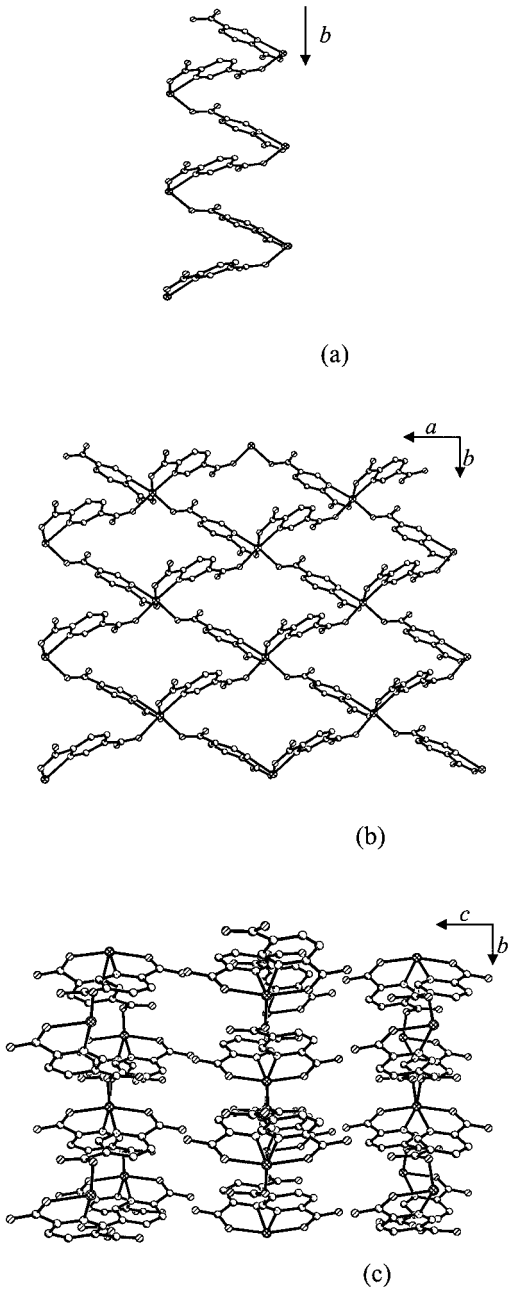

Figure 2. (a) Section of the 2_1 helical polymer chain along the *b* axis in **1**; (b) 2D layer structure along the *ab* plane in **1**; (c) the stacking 2D layers viewed from the *a* axis in **1**; dimethylamine cations omitted for clarity

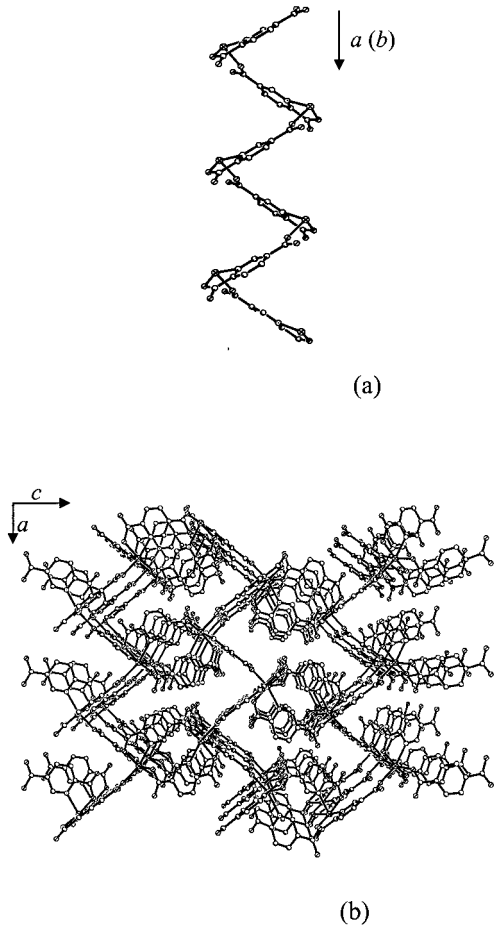

Figure 3. (a) Section of the 2_1 helical polymer chain along the *a* or *b* axis in **2**; (b) packing diagram of **2** viewed from the *b* axis; dimethylamine cations omitted for clarity

all the helices in **2** are arranged parallel to or perpendicular with the metal atoms as the connective nodes, and so compound **2** has noncentrosymmetry for the overall structure (Figure 3, b). Infinite 3D networks with 4_3 helices along the *c* axis are formed with the chiral space group $P4_32_12$. $[NH_2(CH_3)_2]^+$ cations lie within the networks to balance charges (omitted from the figures for clarity).

We also found that Fe^{II} atoms coordinated to pydc ligands in a *trans* mode, whereas Fe^{III} atoms coordinated in a *cis* mode, even though both ions underwent the same reaction − the oxidation state of the iron atom might affect the coordination modes of the pydc ligand. Thus, the oxidation state of iron atoms together with the coordination site of pydc ligands specifically influence the dimensional extensions of the two iron compounds. Scheme 2 illustrates the packing, which features two different kinds of inner structures for **1** and **2**.

Bond Valence Calculation and ESR Spectrum

According to X-ray analyses, element analyses and charge-balance requirements, the bond valence of the Fe atoms in **1** and **2** should be +2 and +3, respectively. This is verified through X-band ESR spectra recorded on polycrystalline samples at room temperature. As expected, **1** is ESR-silent due to non-Kramer spin states ($S = 2$) of the Fe^{II} ion, as a result of either large zero-field splitting or fast relaxation processes.[24] Compound **2** gave a strong, typical response of high-spin Fe^{III} with $g = 3.6615$. Typical low-spin Fe^{III} species have *g* values around 2.[25] Furthermore, bond valence calculations carried out for the FeN_2O_4 octahedrons gave bond valence sums (bvs) of +2.39 and +2.92 valence unit (v.u.) for iron atoms in **1** and **2**, respectively. The calculations used reported bond valence parameters for Fe−O and Fe−N bonds.[26] Similar bond valence calcu-

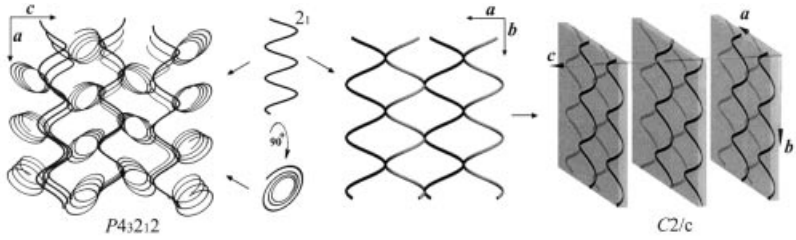

Scheme 2. Arrangement models of 2_1 helices in complexes **1** and **2**: for **1**, 2_1 helices along the *b* axis form the 2D layer structure in the *ab* plane, and the adjacent antiparallel layers produce a centrosymmetric achiral space group *C*2/*c*; for **2**, 2_1 helices along the *a* or *b* axis perpendicular or parallel to each other construct a 3D network with the chiral space group $P4_32_12$

lations have been used successfully for a polyoxovanadate complex.[27]

Single-Point Energy Calculations and TGA

The organic ligand adopts *trans* and *cis* coordination patterns in **1** and **2**, respectively. Taking account of the energy distinction between the two octahedral coordination units (Figure 1, a, b), single-point energy calculations for them were carried out using the unrestricted Hartree−Fock (UHF) method. For Fe atoms the Los Alamos ECP plus DZ basis set (Lanl2dz)[28] was used, and for C, N, O and H atoms the 6-31G* basis set was employed. Calculations were completed using the Gaussian 98 program.[29] Computational values of −2596.10205193 and −2605.17304136 Hartrees were obtained for **1** and **2**, respectively. These single-point energy calculations show that the energy of the central atom of the octahedral unit in **2** (Figure 1, b) is lower, by ca. 9 Hartrees, than that of the unit in **1** (Figure 1, a), indicating that **2** is thermodynamically slightly more stable than **1**. In agreement, TGA analysis revealed decomposition temperatures of 264 and 315 °C for **1** and **2**, respectively.

Magnetic Properties

Magnetic measurements were performed for polycrystalline samples of **1** and **2** in the temperature range 270−2 K. For both complexes, as the temperature is lowered to around 35 K, χ_M increases gradually, and then increases dramatically (Figures 4 and 5). The measured effective magnetic moments μ_{eff} per iron atom in **1** and **2** are ca. 4.92 μ_B and 5.80 μ_B, respectively, at 270 K, in agreement with the 4.90 μ_B for free-ion Fe^{II} in high spin ($S = 2$) and 5.91μ_B for high-spin Fe^{III} ($S = 5/2$). The results confirm that the oxidation state of iron atoms in **1** and **2** are +2 and +3, respectively.

The magnetic behavior of **1** over the whole temperature range (270−2 K) can be well expressed using Equation (1) derived by Fisher,[30] based on the Hamiltonian $H = -J\Sigma S_iS_{i+1}$ for local spin values $S = 2$, where J is the exchange coupling between two adjacent paramagnetic centers.

$$\chi_M = \{[Ng^2\beta^2S(S+1)]/3kT\}\cdot[(1+u)/(1-u)]$$
$$u = \coth\{[JS(S+1)]/kT\} - kT/[JS(S+1)] \quad (1)$$

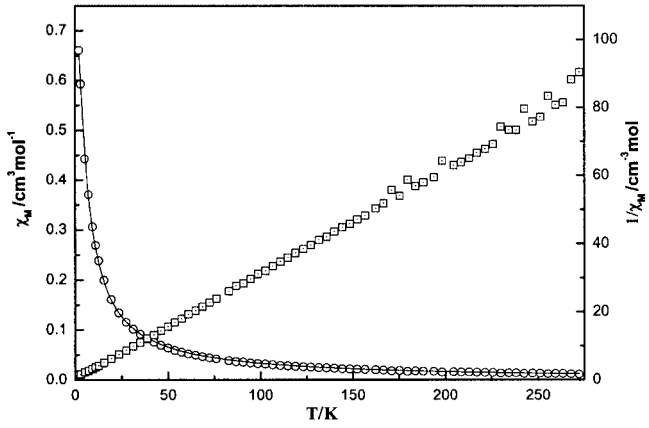

Figure 4. χ_M vs. T (open circles) and $1/\chi_M$ vs. T (open squares) for **1**; for clarity, only 50% of the recorded data is shown; the line through the symbols (open circles) corresponds to the calculated data of χ_M for **1** with $g = 2.14$ and $J = -0.36$ cm^{-1}

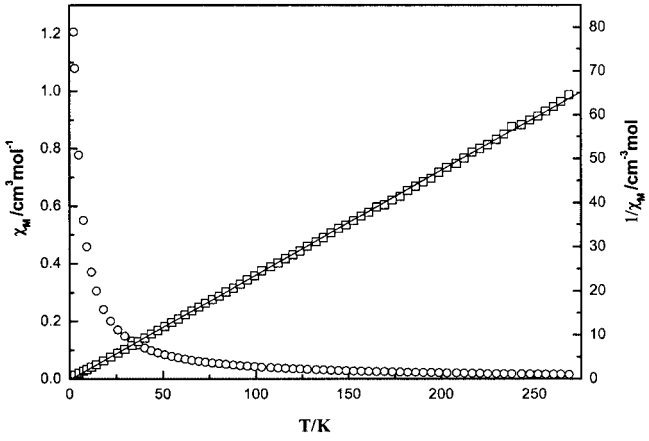

Figure 5. χ_M vs. T (open circles) and $1/\chi_M$ vs. T (open squares) for **2**; for clarity, only 50% of the recorded data is shown; the line through the symbols (open squares) correspond to the calculated data of $1/\chi_M$ for **2** with calcd. $C = 4.17$ cm^3·mol^{-1}·K and $T_p = 1.75$ K

For **1**, the best fit parameters are $J = -0.36$ cm^{-1}, $g = 2.14$ and $R = 7.66 \times 10^{-6}$, where $R = \Sigma[(\chi_M)_i^{exp} - (\chi_M)_i^{calcd.}]^2/\Sigma[(\chi_M)_i^{exp.}]^2$, illustrating the very weak $Fe^{II}-Fe^{II}$ antiferromagnetic interactions in **1** bridged by pydc ligands. However, the case in **2** is much more complicated, as the network has a three-dimensional extension, and we were

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

unable to model the experimental data. Thus, the $1/\chi_M$ data of **2** was fitted to a Curie−Weiss law [$\chi_M = C/(T - T_P)$], with $C = 4.17$ cm^3·mol^{-1}·K, $T_p = 1.75$ K and relation factor 0.9997. The small positive Weiss temperature indicates the presence of a weak $Fe^{III}-Fe^{III}$ ferromagnetic interaction, although a detailed elucidation of the magnetic interaction in **2** is awaited.

Decomposition of DMF

X-ray diffraction analyses revealed the presence of dimethylamine cations $[NH_2(CH_3)_2]^+$ in both **1** and **2**, which result from the decomposition of DMF. IR spectra of **1** and **2** further confirm the presence of $-NH_2^+$ and $-CH_3$ groups. Broad bands in the range of 2700−2250 cm^{-1}, together with a weak peak at ca. 2000 cm^{-1}, correspond to N−H vibration modes of the $-NH_2^+$ group. In addition, peaks at ca. 2967 and 1460 cm^{-1} indicate C−H stretching and bending modes, respectively, of $-CH_3$ groups. Moreover, elemental analyses are also consistent with the presence of $[NH_2(CH_3)_2]^+$ cations. The decomposition of solvent DMF has been used previously to develop a synthesis of gallium compounds.[19] The product of DMF decomposition could be taken as the unique source of a structure-directing agent for the formation of coordination networks.[19] In fact, dimethylamine, triethylamine, etc. appear to be suitable agents, under solvo(hydro)thermal conditions, to maintain a relatively stable pH and to serve as a mineralizer.[19,31,32−34]

Conclusion

Two iron complexes with diverse metal oxidation states and coordination patterns of organic ligand have been synthesized by solvothermal reaction. Our focus on the variations in molecular packing, which lead to different dimensional extensions, demonstrates that both the metal oxidation state and the coordination-site of ligands are important in the formation of these compounds.

Experimental Section

Materials and Methods: All reagents and solvents were purchased from commercial sources and used as received. Elemental analyses were determined with an Elementar Vario ELIII elemental analyzer. IR spectra were measured as KBr pellets with a Nicolet Magna 750 FT-IR spectrometer in the range of 200−4000 cm^{-1}. ESR spectra were recorded as powder samples at the X-band frequency with a Bruker ER420 spectrometer at room temperature. TGA was recorded with a NETZSCH STA 449C instrument, with samples under nitrogen (15 mL/min), at a heating rate of 15 °C/min. Temperature-dependent magnetic measurements were determined with a Quantum Design SQUID-XL7 magnetometer in an external field of 20 kG.

Syntheses of Complexes: Complexes **1** and **2** were obtained from the solvothermal reactions of iron(III) chloride (16.2 mg, 0.1 mmol) and 2,5-pyridinedicarboxylic acid ($C_7H_5NO_4$, 99%, denoted H_2pydc) (33.4 mg, 0.2 mmol) in dimethylformamide as solvent (C_3H_7NO, 99.8%, denoted DMF) (14 mL). Reactions were performed in Teflon-lined stainless steel Parr bombs (23 mL) under autogenous pressure for 3 d. After cooling the reaction system at a rate of 13 °C/h to 30 °C, dark red crystals (**1**) and light yellow crystals (**2**) were separated, with yields of 36 mg (75%) for **1** and 2 mg (5%) for **2**. To increase the yield of **2**, H_2O_2 (30%, 0.1 mL) was added to the system; only compound **2** was obtained, with a higher yield of 19 mg (44%).

Decomposition temperature: 315 °C.

X-ray Crystallographic Study: Crystal data collections were performed at 293 K with a Siemens Smart-CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Empirical absorption corrections were applied using the SADABS program.[35] Structures were solved with direct methods and refined by full-matrix least squares.[36] Non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were positioned with idealized geometry. All calculations were performed using the SHELXTL program.[37] Crystallographic data and other pertinent

Anomalous Diamagnetic Behaviour of the ^{1}H NMR Spectra of a Coordinated Imino Nitroxide Radical in Diamagnetic and Paramagnetic Lanthanide(III) Complexes

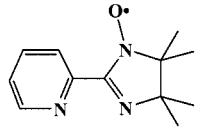
Toshiaki Tsukuda,[a] Masahiro Ogita,[a] Takayoshi Suzuki,[a] and Sumio Kaizaki*[a]

Keywords: ^{1}H NMR / Imino nitroxide radical / Lanthanide complexes / LIS analysis / Diamagnetic NMR behaviour

Diamagnetic lanthanide(III) complexes with an imino nitroxide radical IM2py [2-(2′-pyridyl)-4,4,5,5-tetramethyl-4,5-dihydro-1*H*-imidazol-1-oxyl], [Ln(hfac)$_3$(IM2py)] (Ln = Y and Lu; hfac = hexafluoroacetylacetonate), exhibit ^{1}H NMR chemical shifts for the pyridyl protons of the coordinated IM2py suggesting it behaves as if it were diamagnetic. To a series of paramagnetic lanthanide complexes of this type, the structural analyses of the lanthanide induced shifts (LIS) of the hfac 3-proton and pyridyl protons in IM2py were successfully applied, showing not only the diamagnetic behaviour of the pyridyl protons in the IM2py group, but also the dominant dipolar contribution and isostructural nature with apparent or effective axial symmetry in solution irrespective of the asymmetry in the solid state.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

There have been a large number of studies of lanthanide complexes and/or radical complexes with much concomitant interest in their potential applications in luminescent probes[1,2] or as building blocks for molecular-based magnetic materials.[3,4] The lanthanide−radical complexes have been mainly investigated in order to reveal the magnetic properties in solid state or absorption and emission spectra.[4,5] Our recent magneto-optical investigations on the nitroxide radical metal complexes were concerned not only with transition metal ions, but also lanthanide(III) ions.[6−12] For the imino nitroxide radical lanthanide complexes, [Ln(hfac)$_3$(IM2py)] [IM2py = 2-(2′-pyridyl)-4,4,5,5-tetramethyl-4,5-dihydro-1*H*-imidazol-1-oxyl],[11] we examined the solution spectroscopic properties as well as the magnetic interaction between Gd^{III} and the IM2py radical which is antiferromagnetic, in contrast to the ferromagnetic case[4] of (NIT2py)- and related (NIT)Gd^{III} complexes [NIT2py = 2-(2′-pyridyl)-4,4,5,5-(tetramethyl)-4,5-dihydro-1*H*-imidazolin-1-oxyl 3-oxide]. On the other hand, there have been many NMR studies of lanthanide complexes which have been utilised as lanthanide shift reagents (LSR) with the advantage of bringing about high resolution of complicated NMR spectral patterns of diamagnetic organic compounds, e.g. chiral discrimination and as biological probes since their introduction by Hinckley in 1969.[13] More recently, much attention has been paid to Gd^{III} complexes as contrast agents for magnetic resonance imaging (MRI) due to the short relaxation times encountered in ^{1}H NMR spectroscopy.[14] However, there have been no reports on the NMR spectra of Ln^{III} complexes containing a radical ligand. There have been a number of scattered reports on paramagnetic metal complexes with radical ligands mainly with a limited focus on the coordination effects on the radical ligands with the metal ions.[15,16] In our recent study, the chemical shifts in the ^{1}H NMR spectra of (NIT2py)Ni^{II} complexes were found to correlate with magnetic interactions between paramagnetic Ni^{II} and the NIT2py radical.[6a] In this context, when the diamagnetic complexes or paramagnetic metal complexes are magnetically weakly coupled with a nitroxide radical, the effect of coordination on the NMR spectra or the simple NMR spectroscopic patterns consisting of the original unperturbed signals of the radical and the auxiliary nonradical coligands can be predicted. In the course of the characterisation of Co^{III} or Ln^{III} complexes with IM3py and IM4py [3- and -4-(2′-pyridyl)-4,4,5,5-tetramethyl-4,5-dihydro-1*H*-imidazol-1-oxyl] or IM2py (Scheme 1), we observed unprecedented and apparently diamagnetic ^{1}H NMR behaviour for the imino nitroxide radical ligands in diamagnetic Co^{III} or Y^{III} and Lu^{III} complexes.



Scheme 1. IM2py

In this study, the NMR spectra of (IM2py)Ln^{III} complexes were examined in order to substantiate the diamag-

netic NMR behaviour. Lanthanide induced paramagnetic shift (LIS) data of the paramagnetic Ln^{III} complexes will be analysed in terms of the classical crystal field dependent and the recently developed crystal field independent methods. The resultant analyses will be compared with the influence of the imino radical on the diamagnetic behaviour as well as the solution structure.

Results and Discussions

Magnetic Properties in Solution

The magnetic moments of [Y(hfac)$_3$(IM2py)] and [Lu(hfac)$_3$(IM2py)] in the solid state at 300 K are 1.81 and 1.90 μ_B, respectively, and those in $CDCl_3$ solution are 2.17 and 2.20 μ_B, respectively. The theoretical value is 1.73 μ_B. The corresponding Yb^{III} complex has values of 5.07 and 4.80 μ_B in the solid state and in solution, respectively, which are close to the theoretical value of 4.80 μ_B. These facts support the existence of the IM2py radical in the solid state and solution, in accordance with the UV/Vis spectra in solution.[11a]

In addition, the solution EPR spectrum of [Y(hfac)$_3$(IM2py)] displays hyperfine splittings to the Y^{III} ion and both nitrogen atoms [N(1) for IM−N and N(2) for IM−N−O] of the IM moiety (Figure 1) where the unpaired electron resides. The coupling of Y^{III} and N(1) is a result of the coordination. These hyperfine coupling constants were estimated by comparing them with the simulated spectra. The nitrogen hyperfine splittings are 4.9 G [N(1) and 7.8 G [N(2)] for [Y(hfac)$_3$(IM2py)]. These values are in contrast to 4.25 G [N(1)] and 9.25 G [N(2)] for free IM2py.[17] This change is due to electron delocalisation from the ligand toward the Y^{III} ion. With ^{89}Y having a nuclear spin of I = 1/2, the expected hyperfine splitting resulting from delocalisation onto the Y ion is only 0.4 G.

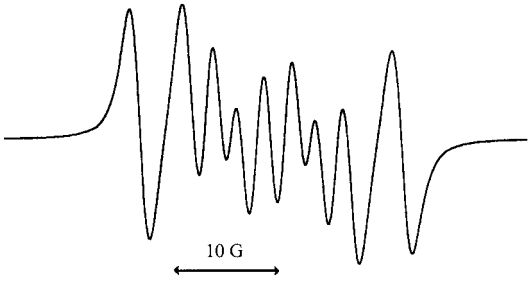

Figure 1. X-band (9.31 GHz) ESR spectrum at 296 K of [Y(hfac)$_3$(IM2py)]

As previously reported,[11a] the UV/Vis spectroscopic changes with the variation of mixing ratios also revealed the stability of the radical Ln^{III} complexes. In view of these results, it is certain that [Y(hfac)$_3$(IM2py)] remains paramagnetic due to the IM2py radical, even in solution.

^{1}H NMR Spectra of the Diamagnetic Ln^{III} Complexes Containing the IM2py Radical

The ^{1}H NMR spectra of [Y(hfac)$_3$(IM2py)] and [Lu(hfac)$_3$(IM2py)] should exhibit additive patterns consisting of the signals for the methine proton of hfac (hfac-H) at the diamagnetic Ln^{III} centre and those for the paramagnetic radical IM2py ligand, as if it were a mixture only of the Ln(hfac)$_3$ and IM2py moieties. However, the ^{1}H NMR spectra of [Y(hfac)$_3$(IM2py)] and [Lu(hfac)$_3$(IM2py)] appear like those of diamagnetic species. As shown in Figure 2 (a, b), the ^{1}H NMR spectra of [Y(hfac)$_3$(IM2py)] and [Lu(hfac)$_3$(IM2py)] appear in the diamagnetic region (δ = 0 to +10 ppm) associated with line-broadening, whereas no splitting by spin-spin coupling was observed. There is no signal for these Ln complexes in the paramagnetic range at $\delta \approx +20$ or −20 ppm, where the paramagnetic IM2py radical itself exhibits a typical paramagnetic NMR spectroscopic pattern [Figure 2 (c)]. A broad signal at $\delta \approx -15$ ppm is due to the IM methyl groups and the signals at δ = +22, +13 and ca. +4 ppm are due to the pyridyl protons as inferred from the assignments for NIT radicals (4,4,5,5-tetramethyl-4,5-dihydro-1*H*-imidazolyl-3-oxide-1-oxyl).[18]

The signals from δ = +7.5 to +8.5 ppm of the (IM2py)Y and -Lu complexes can be assigned to the pyridyl protons on the basis of the ^{1}H-^{1}H COSY spectrum. This exhibits two kinds of cross peaks for the pyridyl protons (Figure 3). There is a discrimination between two pairs of signals corresponding to each proton which are coupled with three ($\delta \approx$ +7.6, +7.9 and +8.5 ppm) and two protons ($\delta \approx$ +8.5 and +8.7 ppm), respectively. Apparently, the former two are due to the 4- and 5-protons of py (py-H4 and py-H5, respectively), the latter two to the 3- and 6-protons of py (py-H3 and py-H6, respectively) (Scheme 2). Since the signal at δ = +8.5 ppm is relatively broader than that at δ = +8.7 ppm, this can be assigned to py-H3 which is closer to the N−O radical moiety. Accordingly, the signals at δ = +7.91 and +7.62 ppm can be assigned to py-H4 and py-H5, respectively. A group of signals at $\delta \approx +1.5$ ppm arises from the methyl protons of the imidazole ring in IM2py. These assignments are in accordance with the chemical shifts of the analogous diamagnetic complex, *trans*-[Co(acac)(NO$_2$)$_2$(IMH2py)], where IMH2py [2-(2′-pyridyl)-4,4,5,5-tetramethyl-1-hydroxyimidazoline] is a diamagnetic one electron reduced IM2py group.[9] The broad signal at δ = 6.0 ppm should be due to the methine proton of the hfac (hfac-H) function in the (IM2py)Y complex, since its position is close to that in the nonradical [Y(hfac)$_3$(bpy)] complex. The ^{1}H NMR line widths in [Y(hfac)$_3$(IM2py)] are similar to those of an equimolar mixture of [Y(hfac)$_3$(bpy)] and IM2py, both of which are about five times as large as those of the diamagnetic complex [Y(hfac)$_3$(bpy)]. Therefore, it can be observed that the relaxation times of the hfac methine proton as well as the py protons and imidazole methyl protons of IM2py become shorter by through-space or outer-sphere dipolar interactions with the proximate molecules in solution, substantiating the existence of the IM2py radical in solution.

Since the ^{89}Y NMR spectrum of [Y(hfac)$_3$(IM2py)] gives only a sharp singlet at δ = 72.5 ppm (Figure 1S, Supporting Informations; for Supporting Informations see footnote on the first page of this article), the Y^{III} ion exists only as one

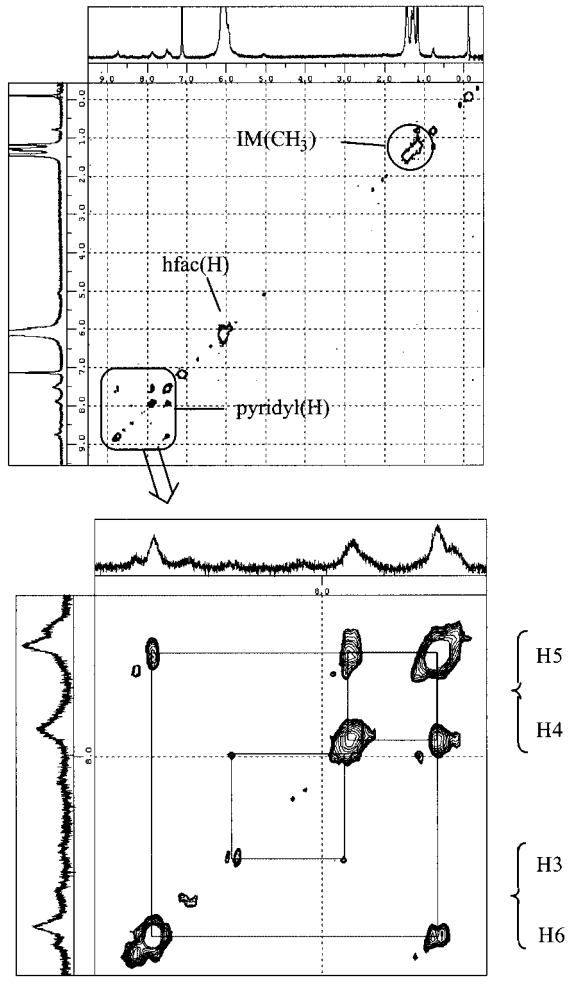

Figure 3. ^1H-^1H COSY spectrum of $[Y(hfac)_3(IM2py)]$

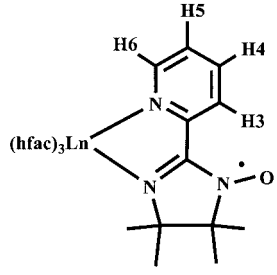

Scheme 2. $Ln(hfac)_3(IM2py)$ with atom numberings of the pyridyl ring

species coordinated by IM2py. Thus, the ^1H and ^{89}Y NMR spectroscopic behaviour originates from the radical complex itself, but not from complexes containing decomposed nonradical ligands such as $[Y(hfac)_3(H_2O)]$ and/or $[Y(hfac)_3(IMH2py)]$. It is clear that the protons in the IM2py moiety show diamagnetic ^1H NMR behaviour with respect to chemical shift but remain paramagnetic in line-width due to the outer-sphere interaction.

In the ^1H NMR spectra of diamagnetic *trans*-$[Co(acac)_2(NO_2)(IM3py$ or $IM4py)]$, only the methine and methyl proton signals of the acac ligand were previously considered when making the assessment of the geometrical structures. The coordinated pyridyl and imidazole protons of the IM*n*py group were not considered.[10] A re-examination of the ^1H NMR spectra of these Co^{III} complexes revealed the existence of the signals at $\delta \approx +8$ ppm and $\delta \approx +1.5$ ppm, respectively, which correspond to the diamagnetic pyridyl and imidazole protons both in terms of chemical shift and splitting pattern as in *trans*-$[Co(acac)(NO_2)_2(IMH2py)]$ and [Y- or $Lu(hfac)_3(IM2py)]$ [Figure 2 (a, b)]. Thus, it is from the *coordination* in the complexes containing diamagnetic metal ions that the diamagnetic NMR behaviour of IM radicals arises, but it does *not* necessarily depend on whether the coordination mode is monodentate or bidentate. The paramagnetic radicals coordinated in diamagnetic lanthanide and/or diamagnetic transition metal ions may hamper paramagnetic shifting of the ^1H NMR signals in the radical compounds or make them behave as if they were diamagnetic. This gives the appearance of complete disappearance

of the unpaired electron around the protons in the IM radicals with respect to the ^{1}H NMR chemical shifts.

^{1}H NMR Spectra of the Paramagnetic Ln^{III} Complexes Containing the IM2py Radical

The ^{1}H NMR spectra of the paramagnetic lanthanide complexes [Ln(hfac)$_3$(IM2py)] deserve examination in relation to the diamagnetic NMR behaviour of the coordinated IM2py ligand in the complexes. Slightly broad NMR signals were observed for [Yb(hfac)$_3$(IM2py)] with the chemical shifts ranging from $\delta = +60$ to -30 ppm [Figure 4 (a)]. If there were little or no magnetic interaction between Yb^{III} and IM2py, the ^{1}H NMR spectra would appear as a sum of each paramagnetically shifted signal due to the Yb^{III} ion and IM2py. This is in contrast to the case of the paramagnetic Ni^{II} complexes, [Ni(β-diketonato)$_2$(NIT2py)], where the chemical shifts of the β-diketonato methine protons are given by a product of the NMR contact shifts of the nonradical Ni^{II} complexes and the fractional contribution to the Ni^{II} moiety arising from the magnetic interaction between the Ni^{II} ion and the NIT2py radical.[6a] By analogy with the diamagnetic ^{1}H NMR behaviour of [Y(hfac)$_3$(IM2py)] and [Lu(hfac)$_3$(IM2py)], it can be assumed that one unpaired electron of IM2py has no influence to the paramagnetic shift of Ln^{III}. In other words, the ^{1}H NMR signals of the IM2py coordinated to paramagnetic Yb^{III} suggest it might behave as a *diamagnetic* ligand in the complex. In order to assess this assumption, the ^{1}H NMR spectra could be analysed in the same manner as a series of isostructural paramagnetic lanthanide(III) complexes with diamagnetic ligands. The methine protons of the hfac (hfac-H) moiety can be assigned readily by comparison with the ^{1}H NMR spectra of the analogous nonradical complexes [Ln(hfac)$_3$(bpy)]. The NMR signals of the pyridyl protons of the IM2py group can be assigned in comparison with those of [Yb(hfac)$_3$(IM4- or -5Me2py)] (IM4- or -5Me2py = methyl-substituted pyridyl at the 4- or 5-position in IM2py). Though the ^{1}H NMR spectra of the (IM4Me2py)- and (IM5Me2py)-Yb^{III} complexes [Figure 4 (b, c)] are similar, on the whole, to that of [Yb(hfac)$_3$(IM2py)], the py-H4 and py-H5 signals of [Yb(hfac)$_3$(IM2py)] disappear in the NMR spectra of the (IM4Me2py)- and (IM5Me2py)Yb^{III} complexes, respectively. In the same manner, the assignments of the py-H4 and py-H5 signals for other paramagnetic Ln^{III} complexes were also made. The chemical shifts for py-H4 and -H5 in [Yb(hfac)$_3$(IM*n*Me2py)] are entirely different from those of free IM2py [Figure 4 (a)], whereas those of hfac-H in the (IM*n*Me2py)Yb^{III} complexes at $\delta \approx -10$ ppm are mostly unshifted relative to those of the corresponding nonradical Yb^{III} complex as shown in Figure 4 (b, c). In view of the latter behaviour, there is little influence on the hfac-H signal from the IM2py unpaired electron in the coordinated IM2py, whereas a large magnetic interaction between the paramagnetic Yb^{III} and the IM2py radical may be inferred from the significant change in the IM2py signals. This contradicts the fact that the magnetic interactions are very small, as deduced from the examination of the variable-temperature magnetic susceptibility measurements.[11] This discrepancy may be resolved by assuming that the ^{1}H NMR spectra of the coordinated IM2py ligands are affected by the paramagnetism of the Yb^{III} ion or the lanthanide induced shifts (LIS). In order to examine the ^{1}H NMR spectroscopic behaviour of the IM2py moiety in the paramagnetic Ln^{III} complexes, it is appropriate to make a quantitative structural analysis for the LIS of the NMR spectroscopic data on the basis of the above-mentioned assignments. The LIS, δ_{ij}^{LIS}, is given as the difference between the chemical shifts (δ^{para}) in the paramagnetic Ln^{III} complexes and those (δ^{dia}) of the corresponding diamagnetic Y^{III} complexes [Equation (1)].

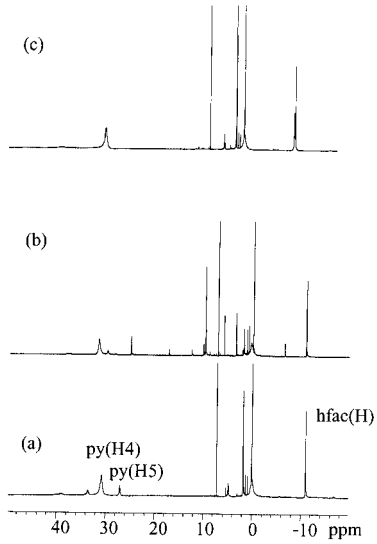

Figure 4. ^{1}H NMR spectra of (a) [Yb(hfac)$_3$(IM2py)], (b) [Yb(hfac)$_3$(IM4Me2py)] and (c) [Yb(hfac)$_3$(IM5Me2py)]

$$\delta_{ij}^{LIS} = \delta^{para} - \delta^{dia} \quad (1)$$

As a result of the dipolar and contact interactions between the electron spins on the Ln^{III} and the proton nuclear spin of the ligand, the chemical shifts of a given proton are shifted from the position observed in the corresponding diamagnetic environment [Equation (2)].

$$\delta_{ij}^{LIS} = \delta(\text{contact}) + \delta(\text{dipolar}) \quad (2)$$

The dipolar interaction contains the information on the geometrical positions in space of the ligand nuclei [Equation (3)], where F_i is the hyperfine coupling constant of the nucleus (i) in the ligand independent of Ln^{III} ions (j),[20] $\langle S_z \rangle_j$ is the spin expectation value for Ln ions (j),[22] D_j is a magnetic constant proportional to Bleaney's constant C_i which is characteristic of a given Ln^{III} ion, $\langle B_2^0 \rangle = \langle A_2^0(r^2) \rangle$ is a crystal field coefficient of the Ln^{III} complex and G_i is a geometric function of the ligand nu-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cleus which is equal to $(3\cos^2\theta - 1)/r^3$ assuming the axial symmetric magnetic susceptibility.[19−21]

$$\delta_{ij}^{LIS} = F_i\langle S_z\rangle_j + \langle B_2^0\rangle D_j \cdot G_i \quad (3)$$

In order to obtain the dipolar and contact parts from the experimental LIS, the graphical separation methods or classical one-nucleus crystal field dependent methods are given [Equations (4) and (5)].[19,20]

$$\delta_{ij}^{LIS}/\langle S_z\rangle_j = F_i + \langle B_2^0\rangle G_i \cdot D_j/\langle S_z\rangle_j \quad (4)$$

$$\delta_{ij}^{LIS}/D_j = F_i\langle S_z\rangle_j/D_j + \langle B_2^0\rangle G_i \quad (5)$$

If the lanthanide complexes were isostructural, a plot of $\delta_{ij}^{LIS}/\langle S_z\rangle$ against $D_j/\langle S_z\rangle_j$ according to Equation (4) would be linear for a particular nucleus (i) of the ligand in the corresponding complexes across the entire Ln series. A linear plot of Equations (4) and (5) can be assumed for the dominant dipolar and constant contribution, respectively. In the case of multi-spin systems such as $[Ln(hfac)_3(IM2py)]$, the magnetic interaction between unpaired spins of Ln^{III} and IM2py must be taken into consideration. This could be significantly large, unless the plots were linear. Thus, the intramolecular magnetic interaction in the $(IM2py)Ln^{III}$ complexes may be tested by the application of the LIS analysis for nonradical complexes to the NMR spectroscopic data of $[Ln(hfac)_3(IM2py)]$ (Table 1S, Supporting Information). In view of the correlation coefficients (r) in Figure 5, the linearity was found to be excellent for hfac-H and fairly good for py-H5 and py-H4 in the IM2py moiety for a series of Ln^{III} complexes according to Equation (4). According to Equation (5), however, the plots deviate significantly from linearity for py-H4 (r = 0.72) and hfac-H (r = 0.76) but not for py-H5 (r = 0.97). This suggests that the LIS for three protons are more dominantly contributed from the dipolar contribution than the contact one. The slopes for the two neighbouring protons (py-H4 and py-H5) in the plots of Equation (4) are similar to each other and have the same sign which is opposite to that of hfac-H, reflecting the differences in the geometrical dispositions of the three protons. The agreement factors $\{AF_i = [\Sigma(\delta^{LIS} - \delta^{calcd.})^2/\Sigma(\delta^{LIS})^2]^{1/2}\}$ were found to be 0.1, 0.6 and 0.48 for hfac-H, py-H4 and py-H5, respectively, from the plots of Equation (4). The small AF value for hfac-H shows no significant influence from the IM2py radical. The fairly large AF values for py-H4 and py-H5 may result from less invariance in the crystal field coefficient and/or the influence of the unpaired electron of the IM2py group.

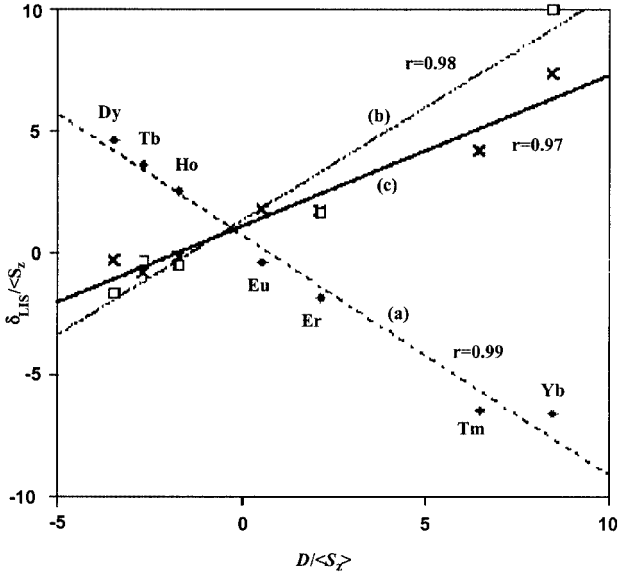

Figure 5. Plots of $\delta_i^{LIS}/\langle S_z\rangle$ versus $D_j/\langle S_z\rangle$ according to Equation (4) ($\delta_i^{LIS}/\langle S_z\rangle = F_i + G_iB_2^0D_j/\langle S_z\rangle$); hfac-H (a), py-H4 (b) and py-H5 (c)

In order to examine these causes, the two- and three-nuclei crystal field independent separation methods[23] were applied to the LIS. These are represented by Equation (6)[22] and Equation (7)[23], respectively.

$$\delta^{LIS}(pyH_i)/\langle S_z\rangle = (F_{py\text{-}Hi} - F_{hfac\text{-}H}R_i) + R_i\delta^{LIS}(hfac\text{-}H)/\langle S_z\rangle \quad (6)$$

where $R_i = G_{py\text{-}Hi}/G_{hfac\text{-}H}$

$$\delta^{LIS}(py\text{-}H_i)/\delta^{LIS}(hfac\text{-}H) = \alpha\delta^{LIS}(py\text{-}H_j)/\delta^{LIS}(hfac\text{-}H) + \beta \quad (7)$$

where $\alpha = (F_{py\text{-}Hi}/F_{hfac\text{-}H} - R_i)/(F_{py\text{-}Hj}/F_{hfac\text{-}H} - R_j)$ and $\beta = [(F_{py\text{-}Hi}/F_{hfac\text{-}H})R_i - (F_{py\text{-}Hi}/F_{hfac\text{-}H})R_j]/(F_{py\text{-}Hj}/F_{hfac\text{-}H} - R_j)$

The plots for $\delta^{LIS}(py\text{-}H_i)/\langle S_z\rangle$ versus $\delta^{LIS}(hfac\text{-}H)/\langle S_z\rangle$ according to Equation (6) for the two-nuclei crystal field independent analysis show fairly good linearity with high r values (r = 0.95 for py-H4 and 0.93 for py-H5). In addition, the three-nuclei crystal field independent analysis given by a plot of $\delta^{LIS}(py\text{-}H4)/\delta^{LIS}(hfac\text{-}H)$ versus $\delta^{LIS}(py\text{-}H5)/\delta^{LIS}(hfac\text{-}H)$ in terms of Equation (7) exhibits good linearity (r = 0.93), confirming the invariance of the crystal field coefficient and the isostructural nature of the Ln^{III} complexes. Moreover, in order to check the invariance in the hyperfine coupling constant and the geometric factor, a crystal field independent method was employed according to Equations (8) and (9). This is based on the shift modulation, Y, using Yb^{III} as the reference Ln complex as defined in Equations (8) and (9).[20d,25]

$$Y_{Ln,j} = \delta^{LIS}{}_{Yb,j}\langle S_z\rangle_{Ln}/\langle S_z\rangle_{Yb} - \delta^{LIS}{}_{Ln,j} \quad (8)$$

$$Y_{Ln,py\text{-}Hi} = Y_{Ln,hfac\text{-}H}G_{py\text{-}Hi}/G_{hfac\text{-}H} \quad (9)$$

The plots of $Y_{Ln,py\text{-}Hi}$ of py-H4 and py-H5 with reference to $Y_{Ln,hfac\text{-}H}$ of hfac-H give excellent conformities (Figure 6). Internal conformity for the F_i and $R = G_{py\text{-}Hi}/G_{hfac\text{-}H}$ values was also found from Equations (4), (6) and (7) (Table 2S, Supporting Information), reconfirming the invariance of the parameters and isostructural pattern. From

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

these structural analyses of the LIS, no change in the geometrical structures or isostructure with axial symmetry in solution was found and little or negligible magnetic interactions between Ln and IM2py were observed through the Ln series. This fact means that there is little effect on the ^{1}H NMR properties from the unpaired electron spin in the IM2py radical. Accordingly, the paramagnetic shifts of the IM2py ligand in the paramagnetic Ln^{III} ions are induced only by unpaired 4f electrons in the Ln^{III} ions and are hardly affected by the unpaired spin in IM2py. The present LIS analyses suggest that there is a difference in symmetry between the solid-state and solution structures of the complexes. That is, the present complexes in the solid state do not have actual axial symmetry as revealed by the X-ray analysis[11] and they exhibit no effect due to the magnetic asymmetry in solution. This can be re-emphasized from the fairly good linear relationships [r = 0.80 (py-H4), 0.86 (py-H5), and 0.98 (hfac-H)] in terms of the structural analyses according to plots of δ^{LIS}/D' versus D/D' derived from Equation (10), where D and G are given in Equation (3) and D' is an asymmetric magnetic constant and $G' = (\sin^2\theta\cos 2\varphi)r^{-3}$.[26]

$$\delta^{LIS}/D' = D/D'G + G' \quad (10)$$

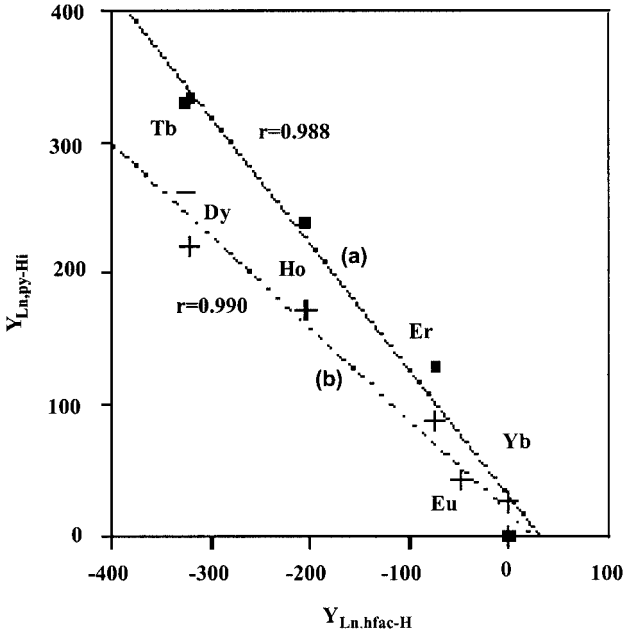

Figure 6. Plots of $Y_{Ln,pynH}$ versus $Y_{Ln,hfacH}$ according to Equation (9); py-H4 (a) and py-H5 (b)

The evidence for the effective magnetic axial symmetry of the Ln complexes can be accounted for by the intramolecular motions and/or rearrangements leading to the dynamic averaging on a faster time scale than that of NMR spectroscopy. This dynamic aspect is consistent with the observation of only one NMR signal for hfac-H, revealing the equivalence of three hfac ligands which are not symmetrically correlated in the solid state as found by the X-ray analysis.[11]

Conclusions

It has been found that the ^{1}H NMR spectra for the (IM2-py)Ln^{III} complexes behave as if the IM2py radical was diamagnetic. For the diamagnetic Ln^{III} complexes, the ^{1}H NMR signals of the coordinated IM2py radical come in the range observed for the diamagnetic compounds, whereas in the paramagnetic Ln^{III} complexes their chemical shifts exhibit only shifts induced by the lanthanide ion's unpaired 4f electron spin(s) and not by the IM2py radical spin. In order to elucidate the peculiar diamagnetic behaviour of the coordinated IM2py ligand, more NMR spectroscopic data are needed for the coordinated radicals in diamagnetic and/or paramagnetic metal complexes.

Experimental Section

General: All chemicals were reagent grade and were used without purification. Lanthanide or yttrium trichloride hexahydrate and Hhfac were purchased from Wako Pure Chemical Industries Ltd. and Tokyo Chemical Industry Co. Ltd., respectively. The radical ligands IM2py, methyl-substituted pyridyl ligands IM*n*Me2py[27] and the complexes [Ln(hfac)$_3$(IM2py)][11] were prepared by previously reported methods.

Measurements: Magnetic susceptibility data of solids and solutions were measured using a magnetic balance (Sherwood Scientific, MSB-AUTO) and the Evans method[28] (^{1}H NMR spectra), respectively, at 23 °C. Pascal's constants were used to determine the constituent atom diamagnetism. The EPR spectrum was measured using a JES-RE1X ESR spectrometer at 296 K in CH_2Cl_2 and was analysed with WinFonia EPR Spectrum Simulation Software Ver. 1.25 (Bruker Analytische Messtechnik GmbH, Germany, **1996**). ^{1}H NMR spectra were recorded with a JEOL EX-270 spectrometer in $CDCl_3$ at 23 °C with concentrations of about 15 mM. The internal standard of tetramethylsilane (TMS) was assigned a chemical shift of δ = 0 ppm. ^{89}Y NMR spectra were recorded with a JEOL Lambda-500 spectrometer in $CDCl_3$ at 30 °C, where the external standard of $Y(NO_3)_3$ in D_2O was assigned a chemical shift of δ = 0 ppm.

Supporting Information: See footnote on the first page of this article. Table 1S with lists of the chemical shifts and LIS values for the IM2py complexes; Table 2S with F, B_2^0G, R, $(F_i - RF_i)$, α, β. Figure 1S with Y NMR spectra.

Chemical Vapor Deposition of Niobium Disulfide Thin Films

Claire J. Carmalt,*[a] Emily S. Peters,[a] Ivan P. Parkin,[a] Troy D. Manning,[a] and Andrew L. Hector[b]

Keywords: Niobium disulfide / Thin films / Chemical vapor deposition

Atmospheric pressure chemical vapor deposition (APCVD) of niobium sulfide coatings was achieved on glass substrates from the reaction of $NbCl_5$ and $S(SiMe_3)_2$, tBu_2S_2, *t*BuSH, or $HSCH_2CH_2SH$ at 250–600 °C. The niobium sulfide films grown at temperatures above 500 °C were crystalline, and powder X-ray diffraction showed that two polytypes of NbS_2 were produced. The sulfur precursor used is fundamental to the polytype of NbS_2 obtained; films that are grown from the APCVD reaction of $NbCl_5$ and $S(SiMe_3)_2$ or tBu_2S_2 at 500–600 °C crystallize into the 1T structure, whereas those grown from the APCVD reaction of $NbCl_5$ and *t*BuSH or $HSCH_2CH_2SH$ at 500–600 °C crystallize into the 3R structure. Energy dispersive X-ray analysis (EDXA) studies gave elemental ratios close to the expected 1:2 ratio for Nb:S. Scanning electron microscopy (SEM) revealed surface morphologies consistent with an island growth mechanism. The films were also characterized using Raman and X-ray photoelectron spectroscopy, both of which showed differences consistent with the formation of the two polytypes, 1T and 3R-NbS_2.

Introduction

Niobium sulfides are part of the family of transition metal dichalcogenide layered materials, which gives rise to a host of interesting properties and facilitates intercalation into the van der Waals gap between these layers.[1] This function of transition metal dichalcogenides has been exploited for use as the cathode material in secondary batteries.[1] The layer structure also gives rise to unique optical and magnetic properties, which have been widely studied.[2−4] Niobium disulfide (NbS_2) has found uses as hydrodesulfurization and hydrodenitrogenation catalysts for hydrotreatment reactions in the purification of petroleum.[5] In addition, NbS_2 has been shown to be an effective humidity sensor.[6] However, the development of new applications has been hampered by difficulty in forming thin-films of NbS_2.

There are two known phases of NbS_2, termed 2H and 3R, both of which can also form nonstoichiometric phases with $Nb_{1+x}S_2$ compositions.[7,8] 2H-NbS_2 is a superconductor with a transition range of 5−6.3 K, whereas 3R-NbS_2 has a superconducting transition temperature of 1.7 K.[9,10] The stoichiometry of the niobium sulfide obtained is very sensitive to pressure, making identification of the polytype difficult due to the formation of substoichiometric compounds and mixtures.[9] The formation of niobium sulfides with high surface areas, such as in thin-film form, is particularly important in battery, gas sensing and catalyst applications.[1,5,10] However, there have been relatively few reports on thin-film formation of NbS_2, a possible consequence of the difficulty in isolating a single polytype.[11,12] Physical deposition processes for the preparation of NbS_2 films have been reported.[11] However, chemical vapor deposition (CVD) routes to niobium sulfide films are limited and involve the use of the single-source precursors $[NbCl_4(S_2\text{-}i\text{Pr}_2)][NbCl_6]$[12] and $[Nb(S\text{-}2,6\text{-}Me_2C_6H_3)_5]$,[13] resulting in thin-films of Nb_2O_5/NbS_2 and NbS, respectively.

In this paper we report the atmospheric pressure (AP)CVD reaction of $NbCl_5$ with $S(SiMe_3)_2$, tBu_2S_2, *t*BuSH or $HSCH_2CH_2SH$. The formation of a new trigonal polytype 1T-NbS_2 is described and the effect of the sulfur precursor on the phase of the NbS_2 film formed is discussed.[14]

Results and Discussion

Films have been deposited on glass from the dual source APCVD reaction of $NbCl_5$ with a range of sulfur sources [$S(SiMe_3)_2$, tBu_2S_2, *t*BuSH and $HSCH_2CH_2SH$]. The onset of deposition varied from 250−600 °C, a consequence of the sulfur-bonding environment in the precursor [onset of deposition: $S(SiMe_3)_2$ 600 °C; tBu_2S_2 400 °C; *t*BuSH 250 °C; $HSCH_2CH_2SH$ 350 °C]. At temperatures above 500 °C, deposition was localized towards the front of the substrate, at lower temperatures complete coverage was observed. The

films produced from $NbCl_5$ and $S(SiMe_3)_2$ or tBu_2S_2 at 500 °C or above had a gold color, and the lower temperature (< 500 °C) films were reflective. The reflectance and transmission spectra indicate that all the films have good reflectance and minimal transmission in the region 400−1000 nm. APCVD of $NbCl_5$ and *t*BuSH or $HSCH_2CH_2SH$ produced dark brown, reflective films at all temperatures. All the films produced, regardless of the sulfur precursor used or temperature of the reaction, were adhered to the substrate, passing the Scotch tape test. However, they were readily scratched by a brass or stainless steel stylus. The films were chemically robust to toluene, dichloromethane, THF and acetone, showing no visible changes after 2 weeks of immersion. Concentrated nitric acid digested the films within 1 min of immersion, whereas concentrated hydrochloric acid dissolved the films after 2 hours.

The niobium sulfide films were characterized by a range of techniques. Composition analysis of the films was determined by EDAX analysis, which shows niobium to sulfur ratios close to the expected 1:2 for NbS_2 (Table 1). Some slight deviations from this composition were noted; however, this tended to be for thinner films where breakthrough to the underlying glass was observed, which interfered with accurate compositional analysis. No evidence of carbon or chlorine contamination was found, within the detection limit of the instrument (1 atom%). Interestingly, the films produced from $NbCl_5$ and $HSCH_2CH_2SH$ at 350−400 °C were slightly rich in sulfur (Table 1). Scanning electron microscopy (SEM) shows that each film grew by a Volmer−Webber type growth mechanism. However the morphology of the films varied depending on the sulfur precursor employed in the APCVD reaction (Figure 1).

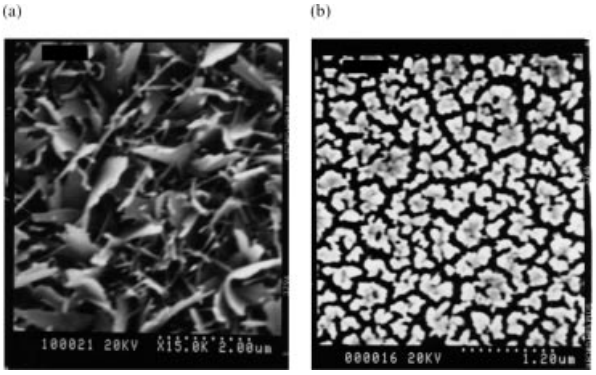

Figure 1. Scanning electron microscopy image of the film prepared from (a) APCVD of $NbCl_5$ and tBu_2S_2 at 550 °C and (b) APCVD of $NbCl_5$ and $HSCH_2CH_2SH$ at 550 °C

SEM of the films grown from $NbCl_5$ and $S(SiMe_3)_2$ or tBu_2S_2 show platelets (approximately 2 μm at 550 °C) that are orientated largely perpendicular to the substrate (Figure 1, a). In contrast, SEM of films produced from $NbCl_5$ and *t*BuSH or $HSCH_2CH_2SH$ display a crazy paving type morphology with particle sizes of 0.6 μm at 550 °C (Figure 1, b) and 0.25 μm at 400 °C. Edge-on SEM photographs allowed for the determination of film thickness. For example, films grown at 600 °C from $NbCl_5/S(SiMe_3)_2$ or tBu_2S_2 were 16 μm thick, whereas films from $NbCl_5/t$BuSH or $HSCH_2CH_2SH$ (at the same growth temperature) were

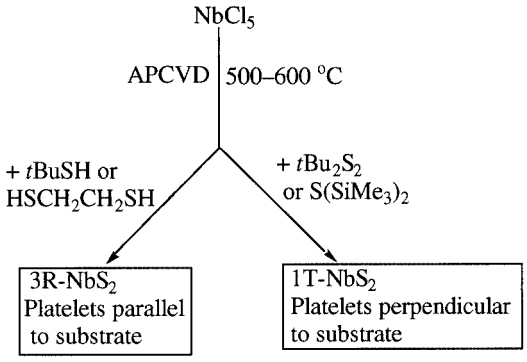
0.4 μm thick. This indicated that typical growth rates were 3.2 μm·min^{-1} [$NbCl_5$/$S(SiMe_3)_2$ or tBu_2S_2] and 0.1 μm·min^{-1} ($NbCl_5$/*t*BuSH or $HSCH_2CH_2SH$).

The niobium sulfide films grown at 500−600 °C (from $NbCl_5$ and $S(SiMe_3)_2$, tBu_2S_2 or $HSCH_2CH_2SH$) or 350−600 °C (from $NbCl_5$/*t*BuSH) were crystalline (Table 1). NbS_2 is known to form with two structure types, which have been classified as 3R and 2H. However, powder X-ray diffraction (XRD) of the crystalline films shows that two different polytypes of NbS_2 are produced (3R- and 1T-NbS_2), as shown in Scheme 1.



Scheme 1

Thus, films grown from $NbCl_5$/*t*BuSH or $HSCH_2CH_2SH$ formed nanocrystalline 3R-NbS_2, whereas $NbCl_5$/$S(SiMe_3)_2$ or tBu_2S_2 gave crystalline 1T-NbS_2. The XRD patterns for the nanocrystalline 3R-NbS_2 films formed from $NbCl_5$/*t*BuSH or $HSCH_2CH_2SH$ are shown in Figure 2.

The XRD patterns obtained for films that were grown from $NbCl_5$/$S(SiMe_3)_2$ or tBu_2S_2 at 600 °C indicate that the 3R-NbS_2 structure does not match the data well. Although the 2H-NbS_2 structure gives a similar diffraction pattern to the observed data, the 1T structure, as adopted by some other transition metal dichalcogenides (e.g. TaS_2),[7,15] is also a close match. The 2H structure comprises close packed sulfur atoms with an AABB repeating unit, with Nb located in half of the trigonal prismatic sites. The double layer repeating unit is shown in Figure 3, the structure in the *xy* plane shows edge-linked NbS_2 trigonal prisms. In contrast, the 1T structure consists of hexagonal close packed sulfur atoms (AB repeat unit) with Nb filling half of the octahedral holes in every other layer. Hence the structure shows edge-linked NbS_2 octahedra, two layers of the repeating unit are shown in Figure 3.

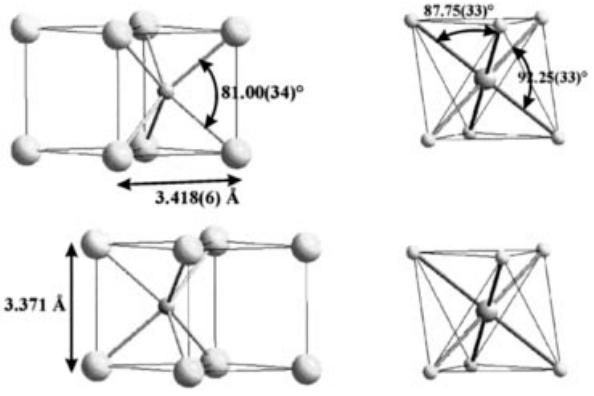


Figure 3. 2H (left) and 1T (right) NbS_2 structures; distances and angles shown are as refined from the NbS_2 thin films by XRD; thermal ellipsoids are shown at the 50% probability level

Rietveld refinements using the 2H and 1T structure models were performed with the GSAS package,[16] both were stable and converged. A cosine Fourier series (GSAS #2) with 6 terms was used to model the background and lattice parameters, zero point and scale factor were allowed to refine. Using profile function #2, the Gaussian terms were fixed at the values obtained with the Cu standard. The particle size broadening term was refined but no strain broadening was found. Transparency was also refined to a fairly high value (this is not surprising since the glass substrate was observed in the data, hence the offset in the tick marks on the fit diagrams). Particle size in Å is defined as $p = 18000\ K\lambda/\pi X$,[17] where K is the Scherrer constant and X is the particle size associated Lorentzian term from the Rietveld refinement. X is refined to 38 and 36 for the 2H and 1T structures, respectively, corresponding to an average crystallite size of around 180 Å. The preferred orientation ratio along 001 is refined to values of 1.18 (2H) and 1.27 (1T). Growth of the platelets perpendicular to the substrate is reflected in the apparent preferential *c*-axis growth in the diffraction data. The fit statistics are better for the 1T structure to a significant degree (Table 2). Furthermore, the 2H structure should have extra reflections, compared with the 1T structure, at 26.5° (101) and 32.5° (103) since it has a doubled *c* axis and these are not observed. The Nb thermal parameter in the 1T structure is slightly high but the S thermal parameter in the 2H structure is very high. The space group is $P\bar{3}m1$ (No. 164) and refined lattice parameters are $a = 3.420(6)$ Å and $c = 5.938(1)$ Å ($Z = 1$) (Figure 4). Prior to this work, there were no reports of NbS_2 crystallizing into the 1T structure.[14]

Table 2. Refined crystallographic parameters for NbS_2 with the 1T and 2H structure models.

	1T Structure	2H Structure
Space group	$P\bar{3}m1$ (No. 164)	$P6_3/mmc$ (No. 194)

Raman microscopy was used to investigate all of the films. The Raman spectra of the thin films that were grown from $NbCl_5$/*t*BuSH or $HSCH_2CH_2SH$ correspond well with that reported previously for 3R-NbS_2 [18] (Figure 5). Thus peaks at 322, 386, and 462 cm^{-1} are assigned to E_2, A_1 and A_2 modes, respectively. Other peaks were observed at approximately 190 and 258 cm^{-1}.

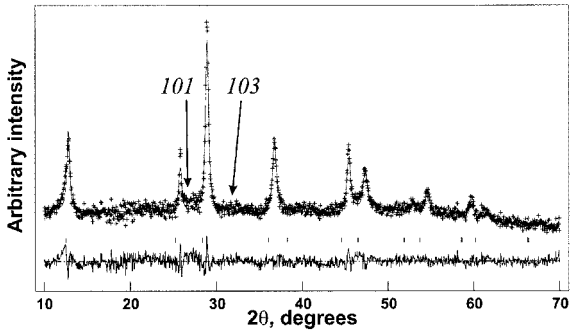

Figure 4. X-ray powder diffraction pattern for NbS_2 film produced from the APCVD reaction of $NbCl_5$ and tBu_2S_2 at 550 °C

It was noted that there was a slight shift in the Raman bands between samples that were sulfur-rich ($NbS_{2.3-2.4}$), fully stoichiometric (NbS_2) and sulfur-deficient ($NbS_{1.6-1.9}$). The formation of 1T-NbS_2 from $NbCl_5$/$S(SiMe_3)_2$ or tBu_2S_2 was further supported by the Raman spectra obtained for the films (Figure 6). It was found that the Raman spectra of the 1T-NbS_2 films is markedly different from those reported previously for 2H- and 3R-NbS_2,[18] but did show similarities with the 1T-TaS_2 pattern.[19]

X-ray photoelectron spectroscopy (XPS) shows that the surface of the films had been partially oxidized (depth of about 50 nm). The oxide surface layer was removed by sputtering to leave the bulk of the film consisting of niobium and sulfur. No evidence of chloride contamination (1–2% detection limit) was observed. XPS of films that were grown from $NbCl_5$ and *t*BuSH gave Nb $3d_{3/2}$, Nb $3d_{5/2}$, and S 2p binding energy shifts of 210.4, 207.5, and 162.3 eV, respectively. These are in good agreement with previous literature measurements for bulk NbS_2 (Nb $3d_{5/2}$ 207.7 eV).[20] XPS of the films that were grown from $NbCl_5$/$HSCH_2CH_2SH$ at temperatures > 400 °C also suggest the formation of 3R-NbS_2. However, XPS of films that were grown from $NbCl_5$/$HSCH_2CH_2SH$ at 350–400 °C show slight deviations (Nb $3d_{5/2}$ 207.4 eV, S 2p 162.3 eV) from the literature measurements of bulk NbS_2. As discussed above, the films that were grown from $NbCl_5$/$HSCH_2CH_2SH$ at 350–400 °C are shown by EDAX to be slightly sulfur-rich ($NbS_{2.3-2.4}$), which could result in shifts in the binding energies. Only one sulfur environment was found by XPS in all samples and this corresponds to the S^{2-} anion showing that these sulfur-rich samples are not a mixture of NbS_2 and NbS_3 (which would also contain the S_2^{2-} anion). It is also worth noting that $NbSe_2$ shows a phase change from 2H-$NbSe_2$ to 4H-$NbSe_2$ between 600–700 °C, which is slightly rich in selenium, 2H being the higher temperature phase.[21] Therefore, it is possible that a different phase to 3R-NbS_2 has been formed. Indeed, XPS of films that were grown from $NbCl_5$/$S(SiMe_3)_5$ or tBu_2S_2 at 500–600 °C gave Nb $3d_{3/2}$, Nb $3d_{5/2}$, and S 2p binding energy shifts of 209.4, 206.3, and 161.8 eV, respectively. The Nb $3d_{5/2}$ value is different from that for bulk NbS_2[20] and 3R-NbS_2 films (from $NbCl_5$/*t*BuSH). However, the binding energy shifts compare well with those published for a mixed transition metal disul-

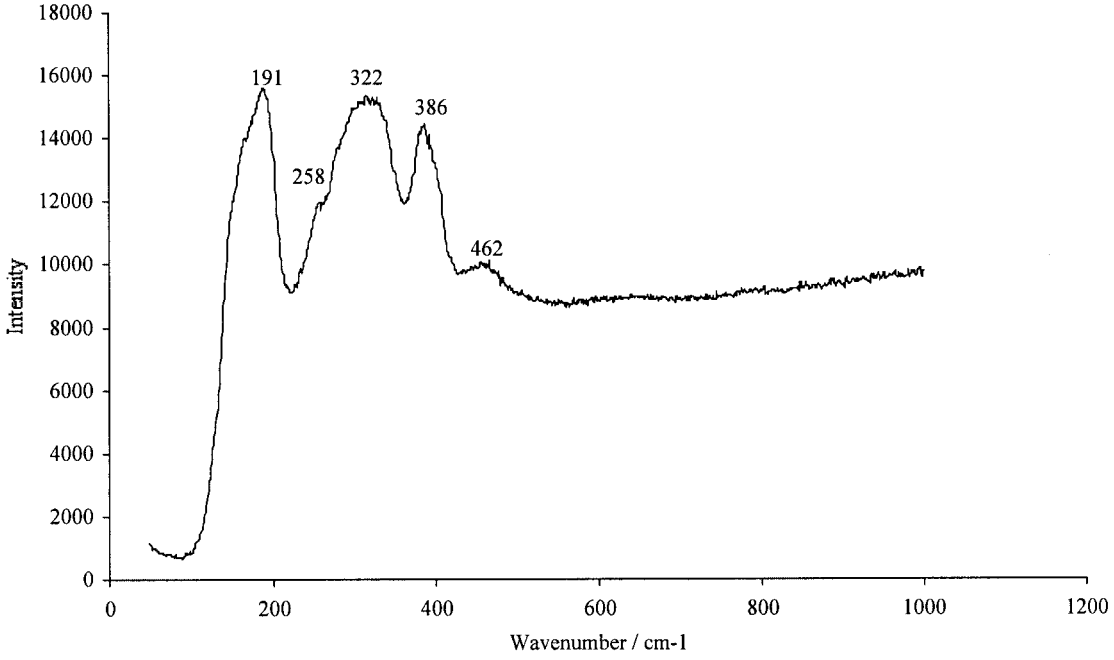

Figure 5. Raman spectrum of a NbS_2 film deposited on glass from $NbCl_5$ and *t*BuSH at 550 °C

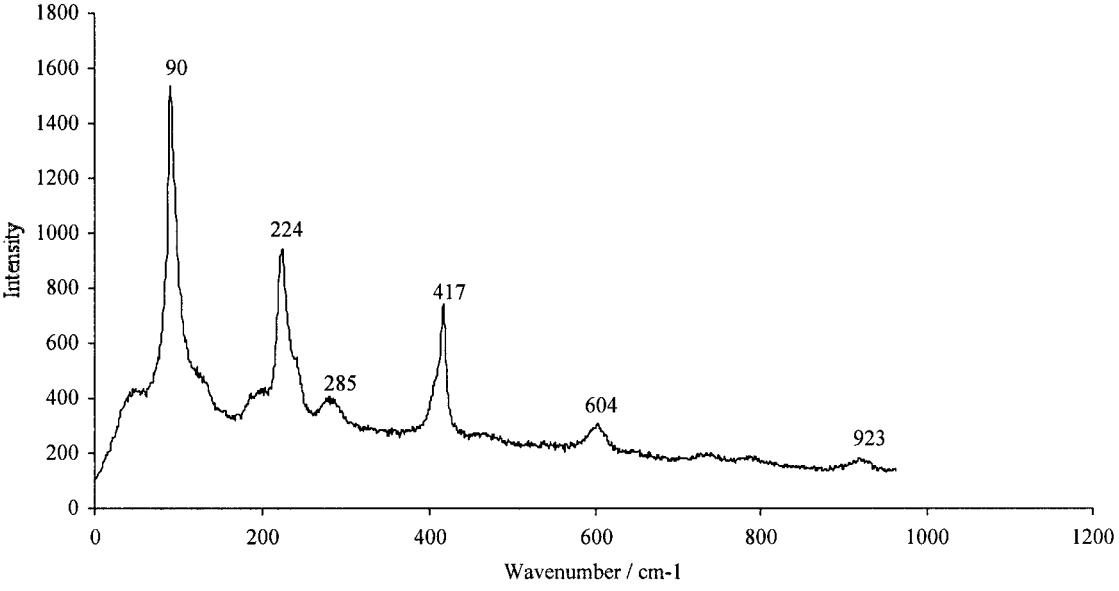

Figure 6. Raman spectrum of a NbS_2 film deposited on glass from $NbCl_5$ and tBu_2S_2 at 550 °C

fide system, 1T-$Nb_{1-x}Ir_xS_2$, which crystallizes into the 1T structure (Nb $3d_{5/2}$ about 206 eV; S 2p 162 eV).[22] These binding energy shifts suggest that the APCVD of $NbCl_5$ and $S(SiMe_3)_2$ or tBu_2S_2 at 500−600 °C results in the formation of a new trigonal polytype 1T-NbS_2, and this is further supported by the powder XRD and Raman spectra for the films.

A wide range of contact angles for water droplets on the NbS_2 films produced were obtained (Table 1). The contact angle measurements are valuable in the glass industry in assessing whether films have self-cleaning properties. Low contact angles arising from hydrophilic films lead to the spreading of the water across the surface, and hence the washing away of any loose dirt. For example, niobium(V) oxide films have been shown to generate low contact angle measurements (about 10°) under photo-irradiation.[23] Some of the niobium sulfide films obtained had contact angles >50° indicating that the films are hydrophobic. However, a number of films had very low contact angles between 2.4° and 14.5° suggesting a degree of hydrophilicity. The contact angles did not change upon photo-irradiation suggesting that this low contact angle is not due to some form of photo-induced hydrophilicity. Thus, the low contact angle is most likely due to a high-porosity within the films. Furthermore, these measurements indicate that the niobium sulfide films are unlikely to be oxide sur-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

face terminated since if niobium(v) oxide was present a drop in contact angle on photo-irradiation would be observed.[23] Four-point probe measurements show that the niobium sulfide films are metallic conductors at room temperature, as is expected. Accurate measurements could not be obtained as the films were scratched by the probe, which led to the fluctuation of the reading.

The deposition of NbS_2 films worked best at substrate temperatures between 500 and 600 °C. These results suggest that temperatures in excess of 400 °C are required for the precursors to react completely and form a film. However, nanocrystalline NbS_2 films were obtained from $NbCl_5$ and *t*BuSH at temperatures as low as 350 °C. The lack of chlorine contamination in the resulting films, despite the use of $NbCl_5$ indicates that a clean decomposition pathway is available. This probably occurs via species such as *t*BuCl and Me_3SiCl when tBu_2S_2 and $S(SiMe_3)_2$ are used, respectively. It is also possible that the reactions proceed via the formation of gas phase adducts, for example $[NbCl_5(tBuSH)_x]$.

The calculated growth rate for the formation of 1T-NbS_2 from $NbCl_5/S(SiMe_3)_2$ or tBu_2S_2 at 600 °C is 3.2 μm min^{-1}. This is faster than that for the formation of 3R-NbS_2 from $NbCl_5$/*t*BuSH or $HSCH_2CH_2SH$ at the same growth temperature (0.1 μm min^{-1}). The XPS, Raman, and XRD results suggest that 1T-NbS_2 is the kinetic product ,and this metastable phase forms due to the rapid growth rate. The formation of 1T-NbS_2 when using the sulfur precursors, $S(SiMe_3)_2$ and tBu_2S_2, may also be a result of the faster reaction chemistry relative to *t*BuSH or $HSCH_2CH_2SH$. In addition, it is also possible that $S(SiMe_3)_2$ and tBu_2S_2 do not have low energy decomposition pathways, for example, to yield H_2S, whereas *t*BuSH and $HSCH_2CH_2SH$ could rapidly afford H_2S on thermolysis. However, precursor volatility is also likely to contribute to the phase of NbS_2 obtained. Further studies into the reaction chemistry are required in order to obtain a more definite mechanism for the reaction. The formation of 1T-NbS_2 from $NbCl_5/S(SiMe_3)_2$ or tBu_2S_2 at 600 °C is markedly different from that of $NbSe_2$, where the 1T phase is only stable above 980 °C.[21]

Conclusion

APCVD of $NbCl_5$ and $S(SiMe_3)_2$ or tBu_2S_2 at 500−600 °C form crystalline 1T-NbS_2 thin films on glass. The XRD pattern of these films are not consistent with that of 3R-NbS_2, and appear to have missing reflections when compared with 2H-NbS_2. However, the XRD pattern obtained for the niobium sulfide films compares well with the reported pattern for 1T-TaS_2. The formation of the 1T-NbS_2 phase is further supported by the Raman spectra and XPS data obtained for the films. The dual-source CVD reaction of $NbCl_5$ and *t*BuSH or $HSCH_2CH_2SH$ produced 3R-NbS_2 films. All the films are free from contamination by carbon, oxygen, and chlorine (to detection limits about 0.5 atom%). They show good surface coverage, adhesion, and uniformity.

Experimental Section

Nitrogen (99.99%) was obtained from BOC and used as supplied. $NbCl_5$, $S(SiMe_3)_2$, tBu_2S_2, *t*BuSH, and $HSCH_2CH_2SH$ were supplied by Aldrich and used without further purification. Coatings were obtained on float glass substrates (90 mm × 45 mm × 4 mm) with a ca. 50 nm thick blocking layer of SiCO (to limit diffusion of ions from the glass) on a purpose built reactor.[24] A graphite block containing a Whatman cartridge heater was used to heat the glass substrate. The temperature of the substrate was monitored by a Pt-Rh thermocouple. The rig was designed so that four separate gas lines could be used, all of which were made of 1/4-in. diameter stainless steel, except for the inlet to the reaction chamber and the exhaust line from the reaction chamber which was 1/2-in. diameter. The nitrogen carrier gas was preheated to 157 °C by passing along 2 m lengths of coiled stainless steel tubing inside a tube furnace. Gas temperatures were monitored in situ by Pt-Rh thermocouples. The $NbCl_5$ and sulfur sources were placed into individual bubblers and heated through a heating jacket ($NbCl_5$, 220 °C; $S(SiMe_3)_2$, 90 °C; tBu_2S_2, 170 °C; *t*BuSH, 55 °C; $HSCH_2CH_2SH$, 85 °C). The vapors produced were introduced into a stream of hot nitrogen and transported to the mixing chamber. Flow rates were kept constant for all experiments ($NbCl_5$, 2.0 L·min^{-1}; $S(SiMe_3)_2$, 0.3 L·min^{-1}; tBu_2S_2, 0.3 L·min^{-1}; *t*BuSH, 0.2 L·min^{-1}; $HSCH_2CH_2SH$, 0.2 L·min^{-1}). All systems were investigated over a range of temperatures from the onset of deposition up to 600 °C. The exhaust from the reactor was passed through three bleach bubblers and vented directly into the extraction system of a fume cupboard. Deposition experiments were timed by stopwatch for typically 60 s. At the end of the deposition the bubbler line was closed, and nitrogen was passed over the substrate. The glass substrate was allowed to cool to ca. 60 °C before it was removed. The large substrates were cut into ca. 4 cm × 1 cm strips for analysis by SEM, XPS, Raman, UV/Vis spectroscopy and contact angle studies. 3 cm × 2 cm strips were used for X-ray diffraction. Film adherence to the glass was assessed using the Scotch tape test and by scratching the surface using brass and steel.

X-ray powder diffraction patterns were measured on a Siemens D5000 diffractometer using monochromated Cu-$K_{\alpha 1}$ radiation (λ_1 = 1.5406 Å) with glancing incident radiation (1.5°) or using synchrotron radiation (λ_1 = 1.2982 Å) on beamline 2.3 at the UK Synchrotron Radiation Source. The data contained a large glass background, and this was removed by subtracting a heavily smoothed and normalized data set collected on a glass substrate. Data collected with a copper standard was used to obtain an instrumental Gaussian peak shape, this was then kept fixed when fitting the NbS_2 data. EDXA was obtained with a JEOL 35CF, and SEM was obtained with a Hitachi S570 instrument using the KEVEX system. X-ray photoelectron spectra were recorded with a VG ESCALAB 220i XL instrument using focused (300 μm spot) monochromatic Al-K_α radiation at a pass energy of 20 eV. Scans were acquired with steps of 50 meV. A flood gun was used to control charging, and the binding energies were referenced to an adventitious C 1s peak at 284.8 eV. Depth profile measurements were obtained by using argon beam sputtering. UV/Vis spectra were recorded in the range 190−1100 nm with a Helios double beam instrument. Reflectance and transmission spectra were recorded between 300 and 1200 nm by a Zeiss miniature spectrometer. Reflectance measurements were standardized relative to a rhodium mir-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ror and transmission relative to air. Raman spectra were acquired with a Renishaw Raman System 1000 using a helium-neon laser of wavelength 632.8 nm. The Raman system was calibrated against the emission lines of neon. Contact angle measurements of selected glass samples were determined by measuring the spread of a 7.5 μL droplet of water. Electrical conductivity was determined with a four-probe measurement.

Caution! It should be noted the APCVD reaction of $NbCl_5$ and $S(SiMe_3)_2$, tBu_2S_2, tBuSH or $HSCH_2CH_2SH$ could conceivably produce H_2S. Care should be taken to conduct all experiments in a fume cupboard and pass the exhaust gases through a series of bleach scrubbers.

The Immobilized Porphyrin-Mediator System Mn(TMePyP)/clay/HBT (clay-PMS): A Lignin Peroxidase Biomimetic Catalyst in the Oxidation of Lignin and Lignin Model Compounds

Claudia Crestini,*[a] Alessandra Pastorini,[a] and Pietro Tagliatesta[a]

Keywords: Clays / Lignin models / Oxidation / Porphyrins / Supported catalysts

A biomimetic system for lignin peroxidase (LiP) was designed by using a cationic porphyrin, [Mn(TMePyP)OAc_5], supported on the smectitic clay montmorillonite [Mn(TMePyP)/clay]. The natural role of the polypeptidic pocket of LiP was mimicked by the clay. The possibility to use low-molecular-weight redox mediators as active readily diffusible oxidizing species has been investigated. This assembly — a sort of "synthetic enzyme" — can be defined as an immobilized porphyrin-mediator system (clay-PMS). The clay-PMS was found to be a stable, recyclable, and efficient catalyst for the environmentally friendly H_2O_2-catalyzed oxidation of different lignins and representative lignin model compounds. The clay-PMS showed a higher reactivity than Mn(TMePyP)/clay alone due to an effective role of the redox mediator on the oxidation.

Introduction

Lignin peroxidase (ligninase, LiP) is an enzyme isolated from ligninolytic cultures of *Phanerochaete chrysosporium*[1] that performs a one-electron oxidation of the lignin aromatic moieties in the presence of hydrogen peroxide.[2] The catalytic cycle consists of a two-electron oxidation of Fe^{III} protoporphyrin IX (high spin) to give a highly reactive (oxo)iron(IV)−protoporphyrin IX π-cation radical, the LiP compound I.[3] LiP compound I is then reduced to the initial state by two different one-electron reductions by the substrate (Figure 1).[4]

In nature, the ligninolitic activity of LiP is enhanced by the presence of veratryl alcohol (VA), which acts as a diffusible redox mediator in lignin oxidation.[5] Thus, the oxidative potential can be transferred from the enzyme to the bulk of the polymer avoiding a kinetic barrier for the heterogeneous reaction.

Unfortunately, the use of LiP for delignification processes is not economically convenient with respect to inorganic catalysts, mainly due to the costs of enzyme purification. Moreover, LiP is inactivated when exposed to an excess of hydrogen peroxide (more than 20 equiv.), to give the inactive form LiP III (Figure 1).[6] Novel LiP biomimetic catalysts resistant to peroxide inactivation might be of pivotal importance for the design of environmentally friendly and economically feasible lignin degradation processes.

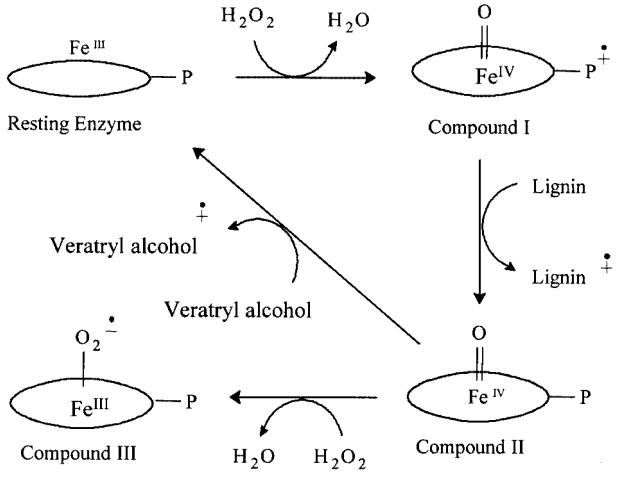

Figure 1. Catalytic cycle of lignin peroxidase

Metalloporphyrins are well-known biomimetic model compounds for protoporphyrin IX and have been extensively studied in the oxidative degradation of monomeric, dimeric, and oligomeric lignin model compounds.[7] The design of heterogeneous porphyrin systems that might be used in several cycles of transformations is a crucial point for their industrial application. In this context, a heterogenation technique based on the anchorage of the active catalyst onto appropriate inert and low-cost supports appears to be highly promising.[8] Smectite clay minerals, such as montmorillonite, have been used as support for the cationic manganese *meso*-tetrakis(tetramethylpyridinio)porphyrin pentaacetate [Mn(TMePyP)$(OAc)_5$] by use of ion-exchange methods.[9] This heterogeneous catalyst [named Mn(TMe-

PyP)/clay] is highly efficient in the oxidation of monomeric and dimeric lignin model compounds. Nevertheless, it is not suitable for lignin oxidation mainly due the presence of a kinetic barrier to the approach of the polymeric substrate.[10] With the aim of solving this problem, we report here our results on the oxidation of lignins and lignin model compounds with the Mn(TMePyP)/clay system in the presence of veratryl alcohol (VA) and 1-hydroxybenzotriazole (HBT) as low-molecular-weight redox mediators. This novel biomimetic system of LiP — a clay/porphyrin mediator system (clay-PMS) — was able to efficiently degrade lignin model compounds resembling the fundamental bonding pattern in lignin. The degradation of milled wood and technical softwood lignins, carefully studied by ^{31}P NMR spectroscopy after phosphitylation of the oxidized samples, was also effective.[11]

Results and Discussion

Oxidation of Lignin Model Compounds

The reactivity of some aromatic model compounds resembling the most representative lignin bonding patterns is of pivotal interest in order to rationalize the oxidative behavior of the polymer. Thus, an array of monomeric and dimeric, phenolic and nonphenolic lignin model compounds was selected in order to clarify the reactivity of clay-PMS with lignin subunits.

4-(1-Hydroxyethyl)-2-methoxyphenol (apocinol; **1**), the β-*O*-4-phenolic model 1-(4-hydroxy-3-methoxyphenyl)-2-(2-methoxyphenoxy)propane-1,3-diol (**7**), the non-phenolic models 1-(3,4-dimethoxyphenyl)ethanol (**14**), and 1-(4-ethoxy-3-methoxyphenyl)-2-(2-methoxyphenoxy)propane-1,3-diol (**16**) were oxidized as representative lignin model compounds. The reactions were carried out by treating the appropriate substrate (50 μmol) in the presence of a catalytic amount (2% mol/mol) of clay-PMS (0.27 mmol of active catalyst/g of support) using H_2O_2 (10% aqueous solution) as primary oxidant and HBT as redox mediator. HBT is known to generate long-lived radical intermediates with an electrostatic potential (1.04 V vs. NHE) high enough for the oxidation of either phenolic or non-phenolic lignin model compounds.[12] Oxidations with homogeneous $Mn(TMePyP)(OAc)_5$ in the presence or absence of HBT and with Mn(TMePyP)/clay were also performed as references. Irrespective of the experimental conditions used for the oxidation a low mass balance with respect to isolated products was observed. In accord with results previously reported in the literature, the loss of material from the reaction mixture might be due to formation of highly polar hydrophilic overoxidation products not recovered by usual workup procedures.[7] HBT, present as an oxidation mediator, was quantitatively recovered at the end of the reaction in all the experiments performed, as shown by GC quantitative measurements.

The reactivity of the catalysts toward lignin model compound degradation was studied by measuring the conversion of substrate after 30 min and 4 h for the oxidation of phenolic model compounds, and after 4 h for the oxidation of the more stable nonphenolic lignin model compounds (vide infra). All reaction products were characterized by means of GC-MS analysis after silylation with *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) and by ^1H and ^{13}C NMR spectroscopy. Control experiments in the absence of the catalysts were performed as previously reported in a study dealing with the activity of montmorillonite-immobilised porphyrins.[10] In this specific case, in order to clarify the role of the oxidation mediator, it is significant to consider the reactions performed in the absence of HBT (and in the presence of catalyst) as reference blank experiments.

Acetophenone **2** was the only recovered product after 30 min reaction time with all the catalysts used for the oxidation of **1**, with a substrate conversion that ranged from 24.5 to 44.3% (Scheme 1, Table 1). It is noteworthy that the clay-PMS system was found to be more reactive than Mn(TMePyP)/clay alone, showing the important role of HBT in the oxidation. This effect was not revealed when the reaction was performed under homogeneous conditions. In fact, the reactivity of $[Mn(TMePyP)OAc_5]$ under identical experimental conditions decreased in the presence of the redox mediator (Table 1). A similar behavior was observed after 4 h reaction time. In this latter case, products of side-chain fragmentation to aldehyde (compounds **3** and **6**), demethylation (**6**) and formation of a benzoquinone de-

rivative (compound **4**; Scheme 1) were characterized in the reaction mixture. In a test for checking the leaching of catalyst, the oxidation of **1** with clay-PMS was stopped at about 50% conversion. After centrifugation, the colourless solution had lost its catalytic activity. Table 2 shows that the clay-PMS system is stable enough to perform at least five recycling experiments with similar conversion and selectivity.

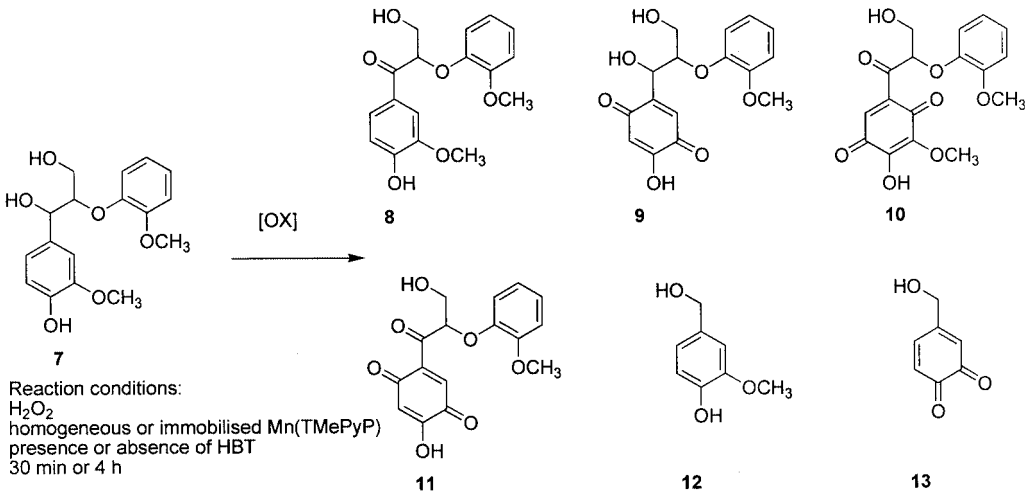
[a]Reaction conditions: substrate 50 μmol, active catalyst 1 μmol, hydrogen peroxide 10% in 0.5 mL of dioxane/buffer citrate phosphate pH = 6 (100 mM) (1:4, v/v), 60 °C, reaction time 4 h.

The oxidation of compound **7**, an aromatic phenolic β-*O*-4 model that represents the most diffuse bonding network in lignin, showed a reactivity pattern close to that observed for apocinol (**1**). The clay-PMS system was again the most active catalyst at both 30 min and 4 h reaction time (Table 1). On the other hand, HBT decreased the reactivity of the homogeneous catalyst [Mn(TMePyP)OAc_5]. Compounds of side-chain oxidation (**8**, **10**), demethylation (**9**), benzoquinone formation (**11** and **13**), and side-chain fragmentation (**12**; Scheme 2) were obtained. On the basis of these data some further considerations are needed. The novel porphyrin-mediator system, clay-PMS, was the most active catalyst in the oxidative degradation of phenolic monomeric and dimeric lignin model compounds. The reaction proceeds mainly by side-chain oxidation and/or fragmentation, demethylation of alkyl aryl ether moieties, and aromatic ring oxidation to *ortho*- and *para*-benzoquinones. The minor reactivity observed for Mn(TMePyP)/clay in the absence of a redox mediator is probably due to the presence of a kinetic barrier for the approach of the substrate to the catalyst when it is embedded and surrounded by the polymeric environment. Thus, the presence of HBT in the



Scheme 2

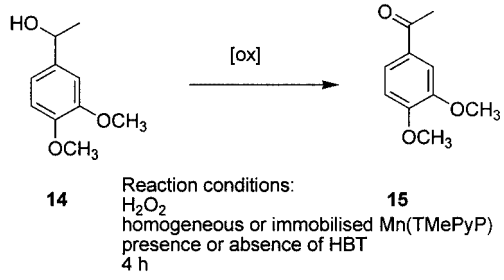
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

reaction mixture increases the reactivity of the metalloporphyrin towards the phenolic lignin model compounds by acting as a diffusible oxidation carrier. This effect might be switchable depending on the homogeneous or heterogeneous character of the catalyst. In fact, the presence of HBT decreased the reactivity of [Mn(TMePyP)OAc_5] under homogeneous conditions. Although we have not studied the mechanism of the reaction in detail, it is reasonable to suggest that under homogeneous conditions HBT might compete with the substrate in the H_2O_2-catalysed oxidation.

Oxidation of Non-Phenolic Lignin Model Compounds

Next we turned our attention to the oxidation of non-phenolic lignin model compounds. They represent the inner lignin chain bonding network rather than the terminal units of the polymer. The redox potential of non-phenolic lignin model compounds is higher than that of the corresponding phenolic ones, therefore their oxidation is more difficult, and they are usually resistant to biological treatments.

First we considered the monomeric model, 1-(3,4-dimethoxyphenyl)ethanol (**14**; Scheme 3). Treatment of compound **14** under previously reported experimental conditions gave, after 4 h of reaction time, the corresponding acetophenone derivative **15** as the only recovered product with a substrate conversion that ranged from 24.9 to 50.5% (Table 3). Again, the porphyrin-mediator system clay-PMS was found to be more reactive than heterogeneous Mn(TMePyP)/clay and homogeneous [Mn(TMePyP)OAc_5] systems (Table 3). In this case, HBT also increased the reactivity of the catalysts under homogeneous conditions, and [Mn(TMePyP)OAc_5] showed a higher conversion of substrate in the presence of the redox mediator than in its absence (Table 3).



Scheme 3

Table 3. Substrate conversion in the [Mn(TMePyP)OAc_5], Mn(TMePyP)/clay, Mn(TMePyP) immobilized on clay + HBT, and clay-PMS catalysed H_2O_2 oxidation of nonphenolic lignin models **14** and **16**

Treatment	Substrate **14** (conv. %)	Substrate **16** (conv. %)
[Mn(TMePyP)OAc_5]	24.9	81.0
Mn(TMePyP)-clay	47.8	80.4
[Mn(TMePyP)OAc_5]/HBT	33.1	85.2
Clay-PMS[a]	50.5	86.3

[a] Mn(TMePyP) immobilized on clay + HBT.

A similar trend was observed upon oxidation of the dimeric lignin model compound 1-(4-ethoxy-3-methoxyphenyl)-2-(2-methoxyphenoxy)propane-1,3-diol (**16**; Scheme 4). In this case, both Mn(TMePyP)/clay and [Mn(TMePyP)OAc_5] were more reactive in the presence of HBT than alone (Table 3), with clay-PMS being the best catalyst. As reported in Table 3 the conversion of substrate ranged from 80.4% [Mn(TMePyP)/clay] to 86.3% (clay-PMS). A complex mixture of reaction products was recovered after GC-MS analysis and chromatographic purification. Among them, products of side-chain oxidation (ketone derivative **17**), side-chain fragmentation (compounds **18**, **19** and **22**), and side-chain fragmentation/demethylation (compounds **20** and **21**) were unambiguously identified by GC-MS analysis; their low yields showed the high efficiency of the oxidative degradation. All of these transformations are potentially useful for delignifying processes. It is noteworthy that even though HBT is always efficient in the reactions catalysed by the porphyrin mediator system clay-PMS, it shows a different effect in the oxidation of non-phenolic lignin model compounds with respect to phenolic ones when the reactions are performed in the presence of homogeneous catalyst. In fact, the reactivity of [Mn(TMePyP)$(OAc)_5$] was increased by HBT only in the case of non-phenolic compounds.

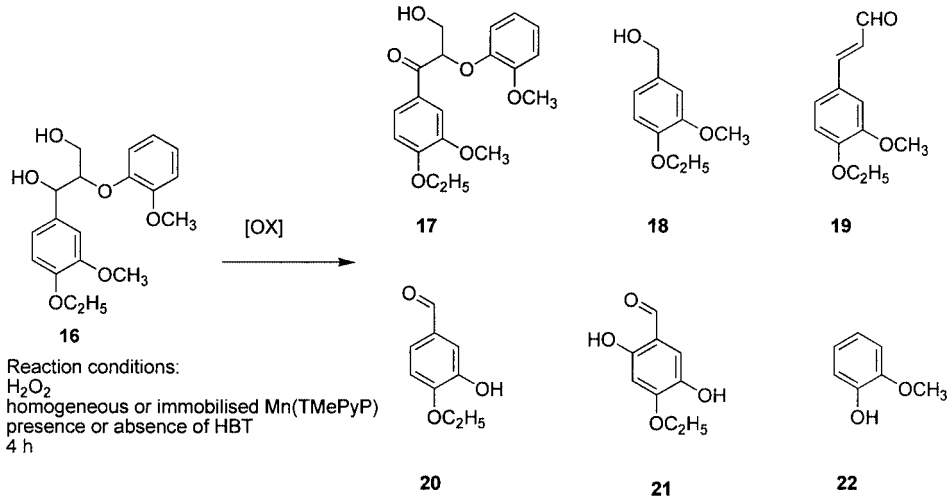
Both [Mn(TMePyP)OAc_5] and Mn(TMePyP)-clay are able to oxidize HBT to benzotriazol *N*-oxide radical (HBT$^{\cdot}$). In turn, HBT$^{\cdot}$ can oxidize the model compound presumably by a side-chain hydrogen atom abstraction (HAT) process.[13]

The reaction of metalloporphyrins with lignin model compounds is thought to occur by electron transfer.[14] One might hypothesize that, in the presence of [Mn(TMePyP)(OAc_5)] the direct reaction of porphyrin with phenolic model compounds could be faster than the hydrogen atom abstraction process by HBT$^{\cdot}$. When non-phenolic substrates are used, the oxidation of HBT to HBT$^{\cdot}$ and further side-chain oxidation of the model by HAT could be faster than the direct oxidation both in homogeneous and heterogeneous phase.

Oxidation of Lignins

Lignin is a complex tridimensional phenylpropanoic polymer whose units are connected by an array of interunit bondings that makes its chemical characterization extremely difficult. An efficient method to study the modifications induced by the chemical treatment of lignin polymers is ^{31}P NMR spectroscopy; ^{31}P-based magnetic resonance analysis of lignin is capable of detecting and quantitatively determining all functional groups in lignin that possess reactive hydroxy groups — aliphatic OH groups, the various forms of phenolic OH groups, and carboxylic acid groups. More specifically, it allows the unambiguous quantification of the amount of condensed phenolic structures of lignin. Oxidative processes with lignin depolymerization and/or oxidative coupling typically induce a decrease in the number of aliphatic OH groups and noncondensed phenolic subunits and an increase in the number of carboxylic acid

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 4

groups.[15] The number of condensed phenolic OH groups is usually greater after oxidative coupling treatment. Furthermore, condensed lignin subunits are resistant to most of the oxidation treatments. Thus, an increase in these groups indicates the occurrence of oxidative coupling together with side-chain oxidation, while their decrease is identificative of efficient delignification processes.

In order to verify the activity of the clay-PMS on bulky polymeric substrates we selected Black Spruce (BS) milled wood (MWL) and residual kraft lignins (RKL). The oxidations were carried out with an excess of hydrogen peroxide (10% aqueous solution) in buffer citrate phosphate (pH = 6) in the presence of a catalytic amount of the appropriate porphyrin catalyst and, where necessary, HBT. In this case, with the aim of mimicking LiP, VA was also evaluated as a redox mediator for the reaction. Lignin samples recovered from the reaction mixture after usual workup procedures were phosphitylated and then subjected to quantitative ^{31}P NMR analysis in the presence of a suitable amount of cholesterol as an internal standard. The assignment of the different signals was carried out on the basis of earlier work.[11] Table 4 shows the quantitative distribution of the OH groups as revealed by ^{31}P NMR spectroscopy. In agreement with data previously recovered on the side-chain oxidation of phenolic and non-phenolic lignin model compounds, the treatment of MWL with the porphyrin-mediator systems clay-PMS-HBT and clay-PMS-VA yielded an appreciable decrease in the number of aliphatic OH groups (Table 4). The reference systems [Mn(TMePyP)OAc_5] and Mn(TMePyP)/clay were not efficient catalysts under these experimental conditions. Moreover, the reaction performed with HBT was more efficient than that with VA, probably because of the higher stability of the first redox mediator intermediate (Table 4).

BS MWL contains a small amount of condensed OH groups. Irrespective of the experimental conditions used in the oxidation, this did not vary significantly during the treatment of MWL. Thus, oxidative coupling reactions are not operative side-processes. In agreement with the data reported above for the oxidation of lignin model compounds, the number of guaiacyl OH groups decreased after oxidation showing a depolymerization process. It is noteworthy that the number of carboxylic acid groups, which arise from lignin oxidation of both side-chains and aromatic rings, increased after treatment of MWL with clay-PMS-HBT more than with clay-PMS-VA. This different behavior could be due to the longer lifetime of HBT radical with respect to veratryl alcohol radical cation.

Table 4. Distribution of aliphatic, phenolic and carboxylic hydroxy groups in MWL and RKL (mmol/g of lignin) after metalloporphyrin- and PMS-catalyzed oxidations as obtained by quantitative ^{31}P NMR spectroscopy

Sample/catalyst	Aliphatic OH	Condensed OH [mmol/g]	Guaiacyl OH	COOH
Black spruce MWL	4.59	0.05	0.75	0.15
MWL/[Mn(TMePyP)OAc_5]	4.57	0.05	0.63	0.16
MWL/Mn(TMePyP)-Clay	4.55	0.05	0.65	0.12
MWL/clay-PMS-HBT[a]	3.93	0.04	0.68	0.17
MWL/clay-PMS-VA[b]	4.14	0.04	0.73	0.19
Black spruce RKL	1.94	0.92	1.27	0.27
RKL/[Mn(TMePyP)OAc_5]	1.64	0.91	1.09	0.65
RKL/Mn(TMePyP)-Clay	1.39	0.80	0.78	0.27
RKL/clay-PMS-HBT[a]	1.19	0.63	0.52	0.17

[a] Mn(TMePyP) immobilized on clay + HBT. [b] Mn(TMePyP) immobilized on clay + veratryl alcohol.

Residual kraft lignin (RKL) is the lignin fraction that can be isolated by acidolysis of kraft pulps. This lignin is severely altered with respect to native and milled wood lignins and contains higher amounts of condensed subunits.[16] In order to clarify the ability of the PMS to oxidize these units, we performed experiments of oxidation of a sample of black spruce RKL with [Mn(TMePyP)(OAc_5)], Mn(TMePyP)-clay and the HBT-clay-PMS (Table 4). While [Mn(TMePyP)(OAc_5)] was not able to degrade condensed OH groups and Mn(TMePyP)-clay induced a modest decrease, HBT-clay-PMS reduced their amount by 32%. The guaiacyl units were reduced to 79% and the aliphatic OH groups were reduced to 61% of their initial content (Table 4). These data are a clear indication of the extensive degradation induced by the clay-PMS on a resistant polymer such as RKL.

Conclusion

An advanced biomimetic system for lignin peroxidase has been designed and realized. When using such systems, the application of the "mediator" concept avoids kinetic problems due to the solid nature of the substrate and of the heterogeneous catalyst, and opens the way to advanced biomimetic ligninase mediator systems (porphyrin mediator systems). Phenolic and non-phenolic, monomeric and β-*O*-4-lignin model compounds were efficiently oxidized with the occurrence of side-chain and aromatic ring oxidation reactions. Oxidation of BS MWL and RKL revealed the occurrence of efficient delignification processes and absence of significant coupling reactions. The porphyrin mediator systems represent the last step in the development of a "synthetic enzyme" for the pulp and paper transformations.

Experimental Section

General: ^1H, ^{13}C and ^{31}P NMR spectra were recorded with a Bruker AM 400 spectrometer. Mass spectrometry (MS) was performed with a GC Shimadzu GC-17A and a mass-selective detector QP 6000. All solvents were ACS reagent grade and were redistilled and dried according to standard procedures. Chromatographic purifications were performed on columns packed with Merck silica gel 60, 230−400 mesh for flash technique. Thin-layer chromatography was carried out using Merck platten Kieselgel 60 F254. Lignin model compounds **1**, **7**, **14** and **16** were synthesized according to literature procedures.[17]

Catalyst Preparation: The manganese porphyrin [Mn(TMePyP)(OAc_5)] was synthesized according to a literature procedure.[18] [Mn(TMePyP)(OAc_5)} was immobilized on montmorillonite as previously reported by refluxing in the presence of Na^+-saturated montmorillonite.[9] The determination of the content of metalloporphyrin supported on the clay was performed spectrophotometrically, as reported previously.[9]

Lignin Isolation: Milled lignin was prepared from ultraground extractive free powder according to Bjorkman's procedure. Extractive free powders were ultraground for three weeks in a rotatory ball mill. The ML fraction was then extracted with dioxane/water (96:4, v/v). The residue was concentrated under reduced pressure and freeze-dried. Purification was performed by dissolving the lignin in 90% acetic acid. The solution was then added dropwise to stirred water. The precipitated lignin was centrifuged and freeze-dried. It was then dissolved again in a mixture of 1,2-dichloroethane/ethanol (2:1, v/v) and precipitated by addition of diethyl ether.[19] Residual kraft lignin was isolated from kraft pulp using a slightly modified acidolysis procedure. The yield was 38%, and the purity was confirmed by UV and klason lignin content measurements.[16,20]

General Procedure for the Oxidation of Lignin Model Compounds: Hydrogen peroxide (10%) was added with stirring at 60 °C as 20-μL aliquots every hour to a solution of the porphyrin catalyst (1 μmol) in 0.5 mL of dioxane/buffer citrate phosphate pH = 6 (100 mM) (1:4, v/v) containing 50 μmol of substrate and 5 μmol of HBT. As an example, the amount of active catalyst corresponds to 12% (w/w) in the case of the monomeric model compound **1** and to 6% (w/w) for the dimeric model **7**. After 4 h, the reaction mixtures were extracted with CH_2Cl_2 in the presence of saturated aqueous NaCl solution. The organic layer was dried with $MgSO_4$ and concentrated under reduced pressure. The residues were dissolved in 20 μL of pyridine in the presence of 3,4-dimethoxytoluene as an internal standard for GC-MS analysis. The mixture was than silylated by addition of *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA).

Oxidation of Lignin. General Procedure: Oxidation of black spruce and cypress MWL, and black spruce residual kraft lignin were carried out in buffer citrate phosphate pH = 6 (100 mM) (10 mL) at 90 °C in the presence of 100 mg of lignin, 10 mg of active catalyst, 50 μmol of HBT or veratryl alcohol, and 200 μL of 10% H_2O_2. Aliquots of H_2O_2 (200 μL) were added every hour for 6 h. The reaction mixture was washed with water several times, centrifuged and freeze-dried. The samples obtained were submitted to quantitative ^{31}P NMR analysis (see below).

Characterization of Products: Gas chromatography and gas chromatography/mass spectrometry of the reaction products were performed using a DB1 column (30 m × 0.25 mm and 0.25 mm film thickness), and an isothermal temperature profile of 100 °C for the first 2 min, followed by a 20 °C/min temperature gradient to 300 °C and finally an isothermal period at 300 °C for 10 min. The injector temperature was 280 °C. Chromatography-grade helium was used as the carrier gas. The identification of **2**, **3**, **5**, **6**, **8**, **12**, **15**, **17**, **18**, **19**, **20** and **22** was carried out by comparison with samples of authentic products. Compounds **5**, **13** and **21** were assigned by comparison with the fragmentation spectra of original compounds. Products **9**, **10** and **11** were tentatively identified on the basis of the fragmentation spectra. The fragmentation patterns are shown in Table 5. Quantitative ^{31}P NMR spectra were obtained using methods identical to those described by Argyropoulos et al.[11] The chemical shifts were referenced to phosphoric acid. Derivatization of the lignin samples with 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane were performed as described previously.[11] The ^{31}P NMR spectroscopic data reported in this effort are averages of three phosphitylation experiments followed by quantitative ^{31}P NMR acquisitions. The maximum standard deviation of the reported data was 2×10^{-2} mmol/g, while the maximum standard error was 1×10^{-2} mmol/g.

Dinuclear, Tricyclometallated Platinum(II) Derivatives − Substitution Reactions and Reactivity of the Platinum−Carbon Bonds

Antonio Zucca,*[a] Maria Agostina Cinellu,[a] Giovanni Minghetti,[a] Sergio Stoccoro,[a] and Mario Manassero*[b]

Keywords: Cyclometallated compounds / N ligands / Platinum / X-ray diffraction

In the recently reported dinuclear cyclometallated species $[Pt_2(R)(L)(DMSO)_2]$ [H_3L = 6-phenyl-2,2′-bipyridine; R = Me (**1a**), Ph (**1b**)] the threefold deprotonated ligand L links the two platinum atoms acting as an N′,C(3) and a C,N,C donor. Aspects of their reactivity have been studied first with regards to the substitution of the two DMSO ligands, which are coordinated to the platinum atom *trans* to a nitrogen and a carbon atom, respectively. Substitution of DMSO with neutral two-electron donors affords several new species, all having the same bridging ligand L: $[Pt_2(R)(L)(L')_2]$ [L′ = PPh_3 (**2a**, **2b**), CO (**3a**, **3b**)] and $[Pt_2(R)(L)(L')(DMSO)]$ [L′ = 3,5-Me_2-py (**4a**)]. The potentially bidentate diphosphane $Ph_2P(CH_2)_3PPh_2$ (dppp) gives a more complex species having both chelating and bridging dppp ligands [{Pt(Me)(L)(dppp)}$_2$(μ-dppp)] (**5a**). The reactivity of the platinum–carbon bonds with HCl has been studied in complexes **1a**, **1b** and **2a**, **2b** and found to be strongly dependent on the nature of the ancillary ligands. To discern the most labile of the four metal–carbon bonds, the reaction has been carried out with 1 equiv. of HCl under mild conditions. Although the reaction is not selective and minor species are formed, cleavage of the Pt–Me (**1a**) and Pt–Ph (**1b**) bonds is favoured — $[Pt_2(L)Cl(DMSO)_2]$ (**6**) can be isolated and spectroscopically characterised from the reaction with either **1a** or **1b**. Substitution of PPh_3 for DMSO in **6** gives $[Pt_2(L)Cl(PPh_3)_2]$ (**7**) as the thermodynamically stable isomer having a *trans* Cl–Pt–C arrangement. The structure of complex **7** has been solved by X-ray crystallography. In contrast, reaction of **2a** or **2b** with HCl proceeds by another route: even with excess HCl the Pt–Me and Pt–Ph bonds are unaffected whereas one of the Pt–C bonds of the pincer-like C,N,C system is cleaved to selectively give $[Pt_2(R)(HL)Cl(PPh_3)_2]$ [R = Me (**8a**), Ph (**8b**)]. The same bond is cleaved also in **1a** and **1b** by excess HCl to give $[Pt_2(HL)(Cl)_2(DMSO)_2]$ (**9**).

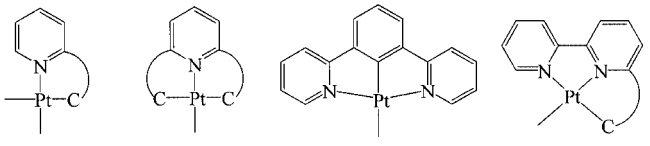
Introduction

Cyclometallated platinum(II) complexes containing substituted pyridines and 2,2′-bipyridines are well documented.[1] They comprise mono- and dimetallated species (**I**−**IV**) with various donor sequences.[2−5]



I **II** **III** **IV**

Both five- and six-membered rings are known, and both Pt−C(sp^2) and Pt−C(sp^3) bonds have been reported, the former being more common. The variety of possible coordination modes allows one to obtain species with different properties and an array of potential applications. In particular, it is worth noting that species of type **II**,[3] with a *trans* C−Pt−C arrangement, are still rare and often cannot be obtained by direct activation of a C−H bond.

Recently, a new type of cyclometallation, which entails activation of a C−H bond of a pyridine ring, has been described: reaction of 6-substituted 2,2′-bipyridines with *cis*-$[Pt(R)_2(DMSO)_2]$ (R = Me, Ph) gave a series of "rollover" cyclometallated species (**V**).[6]

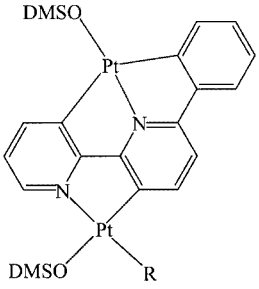
In the case of 6-phenyl-2,2′-bipyridine (6-Ph-2,2′-bipy), further reaction of complexes of type **V** with *cis*-$[Pt(R)_2(DMSO)_2]$ allowed us to isolate the dinuclear complexes **1a** (R = Me) and **1b** (R = Ph).[7]



1a, R = Me
1b, R = Ph

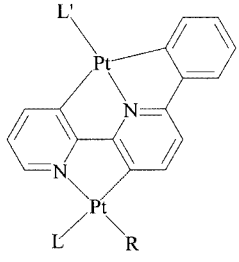
Compounds **1a** and **1b** were fully characterised by means of NMR spectroscopy and FAB mass spectrometry, and, in the case of **1b**, by X-ray crystallography. They are rare examples of multiple C−H bond activation: indeed 6-Ph-2,2′-bipy displays an unprecedented behaviour, acting as a threefold deprotonated ligand. Compounds **1a** and **1b** are unique in several aspects, having (i) three five-membered rings assembled in the same molecule, (ii) a ten-electron bridging ligand, and (iii) a rare C,N,C sequence of donor atoms. Furthermore, in each of the two molecules a pincer-like system with a *trans* C−Pt−C arrangement coexists with an N′−C(3) cycle having two *cis* platinum−carbon bonds. Due to these interesting features, we deemed it worthwhile to synthesise analogous species by substitution of neutral ligands for DMSO and to study some aspects of the reactivity of the four different platinum−carbon bonds assembled in each of these unusual molecules.

Results and Discussion

Reaction with Neutral Ligands

We have recently reported that the reaction of *cis*-$[Pt(Me)_2(DMSO)_2]$ and *cis*-$[Pt(Ph)_2(DMSO)_2]$ with 6-Ph-2,2′-bipy gives compounds **1a** and **1b**, respectively, in fairly good yields (ca. 60−65%).[7]

The neutral ligands PPh_3 and CO easily displace both the DMSO molecules, whereas only one DMSO is substituted by a nitrogen donor such as 3,5-dimethylpyridine (3,5-Me_2-py; Scheme 1). With PPh_3 the reaction proceeds under mild conditions to give the disubstituted complexes $[Pt_2(R)(L)(PPh_3)_2]$ [R = Me (**2a**), Ph (**2b**)] in high yields (ca. 90%).



compd.	R	L	L'
1a	Me	DMSO	DMSO
1b	Ph	DMSO	DMSO
2a	Me	PPh_3	PPh_3
2b	Ph	PPh_3	PPh_3
3a	Me	CO	CO
3b	Ph	CO	CO
4a	Me	3,5-Me_2-py	DMSO

Scheme 1

$$[Pt_2(R)(L)(DMSO)_2] + 2\ PPh_3 \longrightarrow [Pt_2(R)(L)(PPh_3)_2] + 2\ DMSO$$

With 1 equiv. of PPh_3 a mixture of starting material and mono- and disubstituted products is obtained, indicating nonselective DMSO substitution.

Compounds **2a**,**b** were characterised by analytical and spectroscopic methods: in particular the $^{31}P\{^1H\}$ NMR spectra show two resonances [e.g. δ = 26.52 and 32.44 ppm (**2a**)] with very different ^{195}Pt-^{31}P coupling constants (3931 and 2412 Hz) in agreement with phosphorus atoms *trans* to donors with a low (N) and high (C) *trans* influence, respectively.[8] In the ^1H NMR spectrum of **2a** the Me group, which is slightly shielded with respect to **1a**, appears as a doublet due to coupling with a ^{31}P nucleus ($^3J_{P,H}$ = 7.6 Hz), suggesting a PPh_3 ligand in a *cis* position.

The coordinated DMSO can also be easily displaced from **1a** and **1b** by CO at atmospheric pressure. In this case, however, the reaction products, compounds **3a** and **3b**, are almost insoluble in common organic solvents, hampering their characterisation by NMR spectroscopy. Analytical and spectroscopic data fit the formulation $[Pt_2(R)(L)(CO)_2]$: in particular the IR spectra show two bands in the region of terminal carbonyl ligands (2050, 2063 cm^{-1} for **3a** and 2066, 2073 cm^{-1} for **3b**) supporting substitution of both the DMSO ligands. To completely rule out the possibility of the coordination of only one CO ligand, compound **3a** was treated with PPh_3 in a 1:1 Pt/P molar ratio. The almost insoluble complex **3a** reacts immediately with loss of gas (CO): the ^1H NMR spectrum of the solution shows the formation of complex **2a**, and no free or coordinated DMSO is detected.

With a nitrogen donor such as 3,5-Me_2-py, only one of the DMSO ligands is substituted, yielding $[Pt_2(Me)(L)(DMSO)(3,5\text{-}Me_2\text{-py})]$ (**4**). The ^1H NMR spectra give evidence for a DMSO coordinated *trans* to a nitrogen atom (δ = 3.63, $J_{Pt,H}$ = 25.6 Hz);[9] only the more labile DMSO *trans* to the carbon atom is displaced. Even with excess 3,5-Me_2-py or at higher temperature the disubstituted product is not obtained. The low affinity of the nitrogen donor for platinum(II) likely accounts for this behaviour.

Displacement of the DMSO ligands from **1a** was also attained by reaction with a bidentate phosphane such as 1,3-bis(diphenylphosphanyl)propane (dppp). The outcome of the reaction, however, was unexpected: the analytical values point to a species, **5a**, with a Pt/dppp molar ratio of 4:3. The ^1H NMR spectrum shows, in the aliphatic region, a methyl resonance at δ = 0.30 ppm, at high field with respect to **1a**, coupled to ^{195}Pt ($^2J_{Pt,H}$ = 67 Hz) and to two phosphorus nuclei ($^3J_{P,H}$ = 8.0 Hz and 6.7 Hz). The $^{31}P\{^1H\}$ spectrum exhibits a singlet at δ = 17.71 ppm ($^1J_{Pt,P}$ = 3913 Hz) and two doublets at δ = −0.31 ppm

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

($^1J_{Pt,P}$ = 1918, $^2J_{P,P}$ = 22.9 Hz) and δ = 1.35 ppm ($^1J_{Pt,P}$ = 2106, $^2J_{P,P}$ = 22.9 Hz). Coupling of the methyl group to two ^{31}P nuclei indicates an endobidentate diphosphane whereas the chemical shift of the singlet, δ = 17.71 ppm, and the absence of a P-P coupling, suggests a bridging dppp ligand. The high value of $^1J_{Pt,P}$ (3913 Hz) observed for the latter resonance is consistent with a phosphorus atom *trans* to a nitrogen atom. In the absence of X-ray data, a plausible description of **5a** which accounts for the experimental, analytical and spectroscopic data is shown in Figure 1.

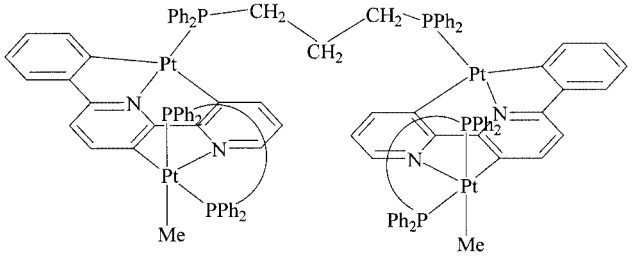


Figure 1. A plausible description of complex **5a**

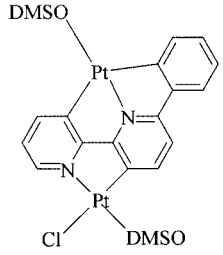
The small differences between the two $^3J_{P,H}$ coupling constants (8.0, 6.7 Hz), makes a pentacoordinate arrangement more likely than a square-planar one. In the latter geometry, which entails the cleavage of the Pt−N bond of the chelated N′,C(3) ring, the phosphorus atoms of the chelated dppp should be *cis* and *trans*, respectively, to the methyl group.

It seems, therefore, that a variety of molecules with ancillary ligands having different electronic and steric properties can be synthesised from compounds **1** by substitution reactions without disruption of the dinuclear cyclometallated core of the system. All the new species **2**−**5** exhibit high thermal stability.

Reaction with Acids

Compounds **1a** and **1b** have four Pt−C bonds: in **1a** one of them is a C(sp^3)−Pt bond, whereas in **1b** all of them are C(sp^2)−Pt bonds. Regardless of the presence of two Pt−C(sp^2) bonds in mutual *trans* positions, the trimetallated compounds are stable in air both in solution and in the solid state. With the aim of investigating the reactivity of these platinum−carbon bonds, we have studied the behaviour of **1a** and **1b** toward HCl, an acid having a coordinating anion. To detect the most labile of the Pt−C bonds, the reaction was first carried out under mild conditions with a 1:1 L/HCl molar ratio. Under these conditions the platinum−methyl and the platinum−phenyl bond in **1a** and **1b**, respectively, were preferentially cleaved. The reaction is not selective and other species are also formed; however, according to their ^1H NMR spectra none of them contains an Me or a Ph group bound to the metal atom. One product could be isolated in pure form by chromatography, albeit in low yield. It was fully characterised and the analytical and spectroscopic data agree with the formulation [$Pt_2Cl(L)(DMSO)_2$] (**6**). In particular, a band at 292 cm^{-1} in the IR spectrum supports the thermodynamically favoured isomer having the chlorine atom *trans* to a carbon atom.[10]



6

Reaction of complex **6** with PPh_3 under mild conditions leads to substitution of the DMSO ligands to give [$Pt_2Cl(L)(PPh_3)_2$] (**7**) for which crystals suitable for an X-ray structure determination were obtained.

The structure consists of the packing of **7** and $CHCl_3$ molecules in the molar ratio 2:3. An ORTEP view of **7** is shown in Figure 2 and principal bond parameters are listed in Table 1. The two platinum atoms are essentially square-planar coordinated with slight square-pyramidal distortions. For Pt(1) the maximum distances from the best plane are +0.041(1) and −0.055(4) Å for Pt(1) and N(2), respectively. For Pt(2) the maximum distances from the best plane are +0.017(1) and −0.021(3) Å for Pt(2) and N(1), respectively. The dihedral angle between these two least-squares planes is 7.5(2)°, a value which shows that the overall planarity of the $Pt_2ClP_2N_2C_{16}$ moiety is less rigorous than that of the analogous $Pt_2S_2N_2C_{17}$ fragment of [$Pt_2Ph(L)(DMSO)_2$],[7] where the analogous dihedral angle

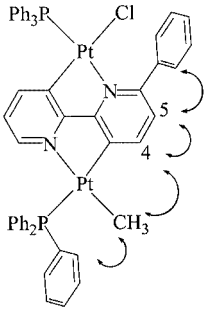

Figure 3. Complex **8a** with selected NOE contacts

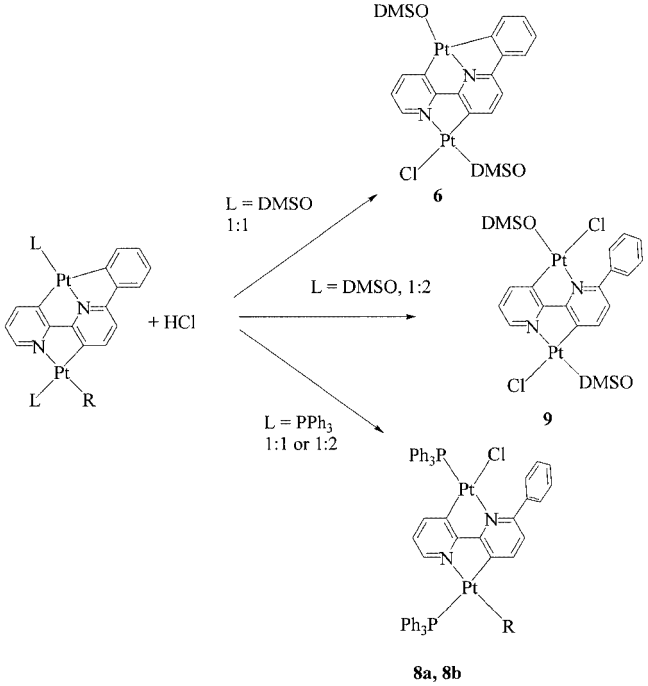
is 1.7(6)°. The Pt(1)−N(2) bond length [2.119(3) Å] is normal for a Pt−N bond *trans* to phosphorus.[11] The Pt(2)−N(1) distance [2.024(3) Å], however, is much shorter. This shortness is a common feature of the central bonds of bicyclic systems: see, for instance, the Pt−N bond length [1.937(7) Å] in [PtCl(L′)] (HL′ = 6-*tert*-butyl-2,2′-bipyridine).[5c] Similarly, the C(8)−Pt(2)−C(13) angle [159.4(1)°] is very far from 180° because of the relative rigidity of the tricyclic ligand. All the other bond lengths and angles are as expected if the *trans* influence of the carbon atoms is taken into account.

The reaction with HCl was also studied in the case of complexes **2a** and **2b**. In contrast with the behaviour of **1a**, in the case of **2a** the platinum−methyl bond is not cleaved, even with an excess of HCl. The ^{1}H NMR spectrum of the reaction product **8a** [δ = 0.68 (d, $^2J_{Pt,H}$ = 80.8, $^3J_{P,H}$ = 7.3 Hz, Me) ppm] indicates that the N′,C(3) chelated part of the complex does not undergo substantial changes. In agreement, in the ^{31}P{^{1}H} spectrum one of the resonances, assignable to a phosphorus atom *trans* to a carbon atom (δ = 33.07 ppm, $^1J_{Pt,P}$ = 2405 Hz) is observed at a value very close to that of complex **2a** (δ = 32.44 ppm, $^1J_{Pt,P}$ = 2412 Hz) as well as to that of the analogous mononuclear species [Pt(Me)(H_2L)(PPh_3)] (δ = 33.01 ppm, $^1J_{Pt,P}$ = 2233 Hz).[6] However, the environment of the platinum atom coordinated by the C,N,C pincer part of the bridging ligand is significantly modified. (e.g. ^{31}P NMR: δ = 13.14 vs. δ = 26.53 ppm in **2a**), suggesting that one of the Pt−C bonds of the strained [5+5] fused-ring system has been cleaved. A ^{1}H 2D-COSY spectrum allowed us to ascribe three spin systems, with three, two and five protons, respectively, to the bridging ligand, the latter being assignable to a monosubstituted phenyl ring [δ = 8.56 (d, 2 H, H_{ortho}), 7.86 (m, 2 H, H_{meta}), 7.71 (t, 1 H, H_{para}) ppm]. A ^{1}H NOE difference spectrum shows contacts between the Pt−Me group, the *ortho* protons of the coordinated PPh_3 ligand, and the 4-H proton, as well as between the 4-H and the 5-H protons and between 5-H and the doublet at δ = 8.56 ppm ascribed to the *ortho* protons of the phenyl ring. On the whole the ^{1}H NMR spectra taken together with the ^{31}P{^{1}H}NMR spectra provide evidence for complex **8a** being [Pt_2Cl(Me)(HL)(PPh_3)$_2$] (Figure 3).

Complex **2b** reacts with HCl in a similar manner to **2a**, to give **8b**, as shown, in particular, by the ^{31}P NMR spectrum, which is similar to that of **8a**. In this case the two platinum−carbon bonds — Pt−Ph and Pt−C(sp^2) — in the five-membered N′,C(3) cycle are unaffected.

Finally, it is worth noting that the same platinum−carbon bond of the pincer C,N,C ligand can also be broken in complexes **1a** and **1b** upon addition of excess HCl to give [Pt_2Cl_2(HL)(DMSO)$_2$] (**9**). The ^{1}H NMR spectrum is consistent with a species having two DMSO ligands *trans* to nitrogen atoms [δ = 3.47 ($^3J_{Pt,C}$ ≈ 24.5 Hz), 3.64 ($^3J_{Pt,C}$ ≈ 22 Hz) ppm] and ten aromatic protons with a pattern similar to that of compound **8**.

The reactions of compound **1** (a and b) and **2** (a and b) with HCl are summarised in Scheme 2. The reactivity of the Pt−C bonds appears to be strongly dependent on the nature of the spectator ligands. Substitution of PPh_3 for



Scheme 2

DMSO makes the Pt−Me (or Pt−Ph) bond less prone to cleavage by HCl. Indeed, even in the related mononuclear "rollover" derivatives [Pt(R)(H_2L)(DMSO)] the reaction with HCl gives selective and fast attack at the Pt−Me and Pt−Ph centres, respectively, whereas [Pt(Me)(H_2L)(PPh_3)] reacts slowly. After 4 h, about half of the starting compound is recovered unchanged, and prolonged reaction times are required to achieve quantitative attack at the Pt−Me bond. A more marked effect is observed in the case of the dinuclear species: the methyl group of compound **2a** is not cleaved even with excess HCl, suggesting a non-negligible degree of electronic communication between the two platinum atoms through the unsaturated bridging ligand.

Experimental Section

General: All the reactions were carried out under argon. The solvents were purified and dried according to standard methods.[12] Elemental analyses were performed with a Perkin−Elmer Elemental Analyser 240B by Mr. A. Canu (Dipartimento di Chimica, Università di Sassari). Infrared spectra were recorded with a Perkin−Elmer 983 spectrometer as Nujol mulls. ^{1}H, ^{13}C{^{1}H} and ^{31}P{^{1}H} NMR spectra were recorded with a Varian VXR 300 spectrometer operating at 300.0, 75.4 and 121.4 MHz, respectively. Chemical shifts are given in ppm relative to internal TMS (^{1}H, ^{13}C) or external 85% H_3PO_4 (^{31}P). 2D-COSY and NOE difference spectra were performed by means of standard pulse sequences. The mass spectrometric measurements were performed with a VG 7070EQ instrument, equipped with a PDP 11-250J data system and operating under positive ion fast atom bombardment (FAB) conditions with 3-nitrobenzyl alcohol as supporting matrix. *cis*-[Pt(Me)$_2$(DMSO)$_2$] and *cis*-[Pt(Ph)$_2$(DMSO)$_2$] were prepared according to literature procedures,[13] as were the ligand HL[14] and complexes **1a** and **1b**.[7]

[Pt_2(Me)(L)(PPh_3)$_2$] (2a): PPh_3 (84.9 mg, 0.324 mmol) was added, under vigorous stirring, to a solution of **1a** (125.0 mg, 0.158 mmol) in CH_2Cl_2 (15 mL). The solution was stirred for 2 h, then concentrated to a small volume and treated with hexane (15 mL). The precipitate formed was filtered and washed with hexane to give the analytical sample as a yellow solid. Yield: 90% (169.0 mg), m.p. 210 °C. $C_{53}H_{42}N_2P_2Pt_2\cdot 1/3C_6H_{14}$ (1187.7) calcd. C 55.62, H 3.96, N 2.36; found C 55.48, H 3.95, N 2.37. IR (Nujol): $\tilde{\nu}$ = 1097 (s), 1557 (w) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 0.62 (d, $^2J_{Pt,H}$ = 76.2, $^3J_{P,H}$ = 7.6 Hz, 3 H, CH_3Pt, 5.95 (m, 2 H), 6.28 (d, $J_{H,H}$ = 7.3 Hz, 1 H), 6.59 (m, 1 H), 6.88 (m, 1 H), 6.98 (m, 1 H), 7.26−7.50 (m, 20 H), 7.68−7.77 (m, 6 H), 7.80−7.89 (m, 6 H), 8.07 (dd, $^4J_{P,H}$ = 4.8, $^3J_{H,H}$ = 7.7, $^3J_{Pt,H}$ = 38 Hz, 1 H, 4-H) ppm. ^{31}P NMR (CD_2Cl_2): δ = 26.52 (s, $^1J_{P,Pt}$ = 3931 Hz, P *trans* N), 32.44 (s, $^1J_{P,Pt}$ = 2412 Hz, P *trans* C) ppm. MS (FAB$^+$): *m/z* = 1143 [M − CH_3]$^+$, 895 [M − PPh_3 − H]$^+$, 801 [M −PPh_3 − C_6H_6 − CH_3 − 2 H]$^+$, 725 [M − PPh_3 − 2 C_6H_6 − CH_3]$^+$. Compound **2a** can be obtained in almost quantitative yield also by reaction of [Pt_2(CO)$_2$(CH_3)(L)] with PPh_3 in a 1:2 molar ratio.

[Pt_2(Ph)(L)(PPh_3)$_2$] (2b): Complex **2b** was obtained as for complex **2a**, using **1b** instead of **1a**. Yield: 88%; m.p. > 260 °C. $C_{58}H_{44}N_2P_2Pt_2\cdot 2H_2O$ (1257.1): calcd. C 55.41, H 3.85, N 2.23; found C 55.69, H 3.91, N 2.25. IR (Nujol): $\tilde{\nu}$ = 1096 (s), 1560 (w) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 5.94 (m, 2 H), 6.19 (d, J_{H-H} = 7.1 Hz, 1 H), 6.59 (m, 4 H), 6.84 (t, J_{H-H} = 7.4 Hz, 1 H), 6.93−7.44 (m, 24 H), 7.48−7.55 (m, 6 H), 7.82−7.89 (m, 6 H) ppm. ^{31}P NMR ($CDCl_3$): δ = 26.86 (s, $^1J_{P,Pt}$ = 3937 Hz, P *trans* N), 30.58 (s, $^1J_{P,Pt}$ = 2363 Hz, P *trans* C) ppm.

[Pt_2(Me)(L)(CO)$_2$] (3a): CO (1 atm) was bubbled for 1 h through a solution containing **1a** (63.5 mg, 0.080 mmol) in 20 mL of CH_2Cl_2. The precipitate formed was filtered and washed with Et_2O (3 × 5 mL), to give the analytical sample as an orange-yellow solid. Yield: 82% (45.4 mg); m.p. 245 °C (dec.). $C_{19}H_{12}N_2O_2Pt_2$ (690.5): calcd. C 33.05, H 1.74, N 4.06; found C 33.07, H 1.34, N 3.93. IR (Nujol): $\tilde{\nu}$ = 1037 (w), 1127 (m), 1558 (m), 1580 (m), 2050 (s), 2063 (s) cm^{-1}.

[Pt_2(Ph)(L)(CO)$_2$] (3b): Complex **3b** was obtained as for **3a** using **1b** instead of **1a**. Yield: 64%; m.p. 235 °C (dec.). $C_{24}H_{14}N_2O_2Pt_2$ (752.5): calcd. C 38.30, H 1.88, N 3.72; found C 37.94, H 1.80, N 4.02. IR (Nujol): $\tilde{\nu}$ = 1024 (w),1065 (w), 1560 (m), 1575 (m), 2066 (s), 2073 (s) cm^{-1}.

[Pt_2(Me)(L)(3,5-Me_2-py)DMSO] (4a): 3,5-Dimethylpyridine (3,5-Me_2-py; 42 mg, 0.39 mmol) was added, under vigorous stirring, to a solution of **1a** (58 mg, 0.073 mmol) in CH_2Cl_2 (20 mL) The solution, whose colour changed immediately to orange yellow, was stirred for 30 min, then concentrated to a small volume and treated with Et_2O (10 mL). The precipitate formed was filtered and washed with Et_2O (3 × 5 mL) to give an analytical sample as a yellow solid. Yield: 45% (26.9 mg); m.p. > 250 °C. $C_{26}H_{27}N_3OPt_2S$ (819.7): calcd. C 38.10, H 3.32, N 5.13; found C 38.26, H 3.46, N 5.17. ^{1}H NMR ($CDCl_3$): δ = 1.00 (s, $^2J_{Pt,H}$ = 85.7 Hz, 3 H, CH_3Pt), 2.38 (s, 6 H, CH_3 of 3,5-Me_2-py), 3.63 (s, $^3J_{Pt,H}$ = 25.6 Hz, 6 H, CH_3 of DMSO), 6.88−7.49 (m, 8 H), 7.93 (d, $^3J_{H,H}$ = 8.0 Hz, 1 H, 4-H), 8.17 (dd, $^3J_{H,H}$ = 7.6 Hz, 1 H), 8.48 (s, $^3J_{Pt,H}$ = 22.7 Hz, 2 H, 2-H of 3,5-Me_2-py) ppm.

[{Pt_2(Me)(L)(dppp)$_2$}$_2$(μ-dppp)] (5a): dppp (97.2 mg, 0.236 mmol) was added, under vigorous stirring, to a solution of **1a** (88.3 mg; 0.112 mmol) in CH_2Cl_2 (20 mL). The solution, whose colour changed immediately from yellow to orange-yellow, was stirred for 90 min, then concentrated to a small volume and treated with hexane (15 mL). The precipitate formed was filtered off and washed with hexane (3 × 5 mL) to give the analytical sample as a yellow solid. Yield 43% (60.6 mg); m.p. 211−214 (dec.). $C_{115}H_{102}N_4P_6Pt_4$ (2506.2): calcd. C 55.11, H 4.10, N 2.24; found C 54.80, H 4.14, N 2.28. IR (Nujol): $\tilde{\nu}$ = 1100 (m), 1549 (w), 1569 (w) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 0.30 (dd, $^2J_{Pt,H}$ = 67, $^3J_{P,H}$ = 6.7, 8.0 Hz, 6 H, CH_3Pt), 2.06−2.94 [br. m, 18 H, CH_2 (dppp)], 6.32−8.21 (m, 78 H, aromatic H) ppm. ^{31}P NMR ($CDCl_3$): δ = −0.31 (d, $^1J_{P,Pt}$ = 1918, $^2J_{P,P}$ = 22.9 Hz, 2 P), 1.35 (d, $^1J_{P,Pt}$ = 2106, $^2J_{P,P}$ = 22.9 Hz, 2 P), 17.71 (s, $^1J_{P,Pt}$ = 3913 Hz, 2 P) ppm.

[Pt_2(Cl)(L)(DMSO)$_2$] (6): Aqueous 0.1 M HCl (2.0 mL) was added, under vigorous stirring, to a solution of **1a** (152.3 mg, 0.193 mmol) in acetone (25 mL). The mixture was stirred for 2 h, then concentrated to a small volume. The brick-red precipitate formed was filtered and washed with EtOH (3 × 5 mL) and Et_2O (3 × 5 mL). The crude product thus obtained was purified by chromatography on silica gel (Merck, 230−400 mesh; eluent: benzene/acetone, 2:1) to give an analytical sample as a yellow solid. Yield: 25% (39.0 mg); m.p. 206 (dec.). $C_{20}H_{21}ClN_2O_2Pt_2S_2$ (811.1): calcd. C 29.61, H 2.61, N 3.45; found C 30.52, H 2.33, N 3.82. IR (Nujol): $\tilde{\nu}$ = 292 (m) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 3.61 (s, $J_{Pt,H}$ not resolved, 6 H, CH_3 of DMSO), 3.63 (s, $J_{Pt,H}$ not resolved, 6 H, CH_3 of DMSO), 7.03−7.44 (m, 6 H), 8.23 (dd, $^3J_{H,H}$ = 7.3, $^4J_{H,H}$ = 1.2 Hz, 1 H, 4′-H), 8.32 (d, $^3J_{H,H}$ = 8.3 Hz, 1 H, 4-H), 8.77 (d, $^3J_{H,H}$ = 5.7, $^4J_{H,H}$ = 1.2 Hz, 1 H, 6′-H) ppm. MS (FAB$^+$): *m/z* = 811 [MH]$^+$, 810 [M]$^+$, 775 [M − Cl]$^+$, 732 [M − DMSO]$^+$, 697 [M − DMSO − Cl]$^+$, 654 [M − 2 DMSO]$^+$, 619 [M − 2 DMSO − Cl]$^+$.

[Pt_2(Cl)(L)(PPh_3)$_2$] (7): PPh_3 (0.020 mmol) was added to an NMR tube containing a solution of **6** (8.1 mg, 0.010 mmol) in $CDCl_3$. The reaction was monitored by ^1H and ^{31}P NMR spectroscopy, showing a fast reaction that produced complex **7** almost quantitatively. A slow evaporation of the solvent gave crystals suitable for an X-ray analysis. ^1H NMR ($CDCl_3$): δ = 6.12 (d, J_{H-H} = 7.5 Hz, 1 H), 6.24 (d, J_{H-H} = 8.1 Hz, 1 H), 6.58 (m, 2 H), 6.80 (t, broad, 1 H), 7.13 (d, J_{H-H} = 7.1 Hz, 1 H), 7.30−7.49 (m, 22 H), 7.74−7.90 (m, 10 H), 8.88 (m, 1 H, 6′-H) ppm. ^{31}P NMR ($CDCl_3$): δ = 25.93 (s, $^1J_{Pt,P}$ = 4146 Hz, P *trans* N), 18.32 (s, $^1J_{Pt,P}$ = 3952 Hz, P *trans* N) ppm.

[Pt_2(Me)(HL)(Cl)(PPh_3)$_2$] (8a): Aqueous 0.1 M HCl (1.7 mL, 0.17 mmol, molar ratio 1:2), was added, under vigorous stirring, to a solution of **2a** (67.4 mg, 0.085 mmol) in acetone (20 mL). The solution became pale yellow and was stirred for 16 h. The precipitate formed was filtered and washed with $(CH_3)_2CO$ (3 × 5 mL). From the filtered solution a second pale-yellow sample was obtained by concentration and filtration. The filtered precipitate was washed with $(CH_3)_2CO$ and Et_2O and added to the first sample. Yield: 89% (94.6 mg); m.p. 215 (dec.). $C_{53}H_{43}N_2ClP_2Pt_2\cdot 3H_2O$ (1249.5): calcd. C 50.94, H 3.95, N 2.24; found C 50.27, H 3.51, N 2.28. IR (Nujol): $\tilde{\nu}$ = 1097 (s),1292 (s), 1585 (m), 1595 (m), 1715 (s), 296 m, 305 (m) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 0.68 (d, $^2J_{Pt,H}$ = 80.8 Hz $^3J_{P,H}$ = 7.3 Hz, 3 H, CH_3Pt), 5.98 (dd, $^3J_{H,H}$ = 7.9, $^3J_{H,H}$ = 5.2 Hz, 1 H, 5′-H), 6.94−7.00 (m, 6 H), 7.16−7.26 (m, 10 H), 7.38−7.46 (m, 9 H), 7.47 (d, 1 H, 4′-H or 6′-H), 7.54−7.69 (m, 5 H), 7.71 (t, J_{H-H} = 7.8 Hz, 1 H, H_{para}, Ph bipy), 7.78 (d, $^3J_{H,H}$ = 8.0 Hz, 1 H, 5-H), 7.86 (t, $^3J_{H,H}$ = 7.8 Hz, 2 H, H_{meta}, Ph bipy), 8.01 (d, $^3J_{H,H}$ = 7.9 Hz, 1 H, 6′-H or 4′-H), 8.56 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, H_{ortho}, Ph bipy), 8.74 (dd, $^3J_{H,H}$ = 8.0, $^4J_{P,H}$ = 5.7, $^3J_{Pt,H}$ = 52 Hz, 1 H, 4-H) ppm. ^{31}P NMR ($CDCl_3$): δ = 33.07 (s, $^1J_{P,Pt}$ = 2405 Hz, P *trans* C), 13.14 (s, $^1J_{P,Pt}$ = 4580 Hz, P *trans* N) ppm.

[Pt_2(Ph)(HL)(Cl)(PPh_3)$_2$] (8b): Aqueous 0.1 M HCl (0.7 mL, 0.07 mmol) was added, under vigorous stirring, to a solution of **2b** (81.7 mg, 0.067 mmol) in acetone (20 mL). The solution became yellow and was stirred for 13 h. The precipitate formed was filtered and washed with acetone (3 × 5 mL) to give the analytical sample as a yellow solid. Yield: 55% (47.3 mg); m.p. 205 °C. $C_{58}H_{45}N_2ClP_2Pt_2\cdot H_2O$ (1275.6): calcd. C 54.61, H 3.71, N 2.20; found C 54.75, H 3.53, N 2.28. IR (Nujol): $\tilde{\nu}$ = 700 (s), 750 (s), 1100 (s), 1550 (m) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 5.99 (m, 1 H, 5′-H), 6.62−7.75 (m, 39 H), 7.83 (t, J_{H-H} = 7.5 Hz, 2 H, H_{meta}, Ph bipy), 8.01 (d, J_{H-H} = 8.3 Hz, 1 H, 6′-H or 4′-H), 8.47 (d, J_{H-H} = 7.5 Hz, 2 H, H_{ortho}, Ph bipy) ppm. ^{31}P NMR ($CDCl_3$) = 30.68 (s, $^1J_{P,Pt}$ = 2352 Hz, P *trans* C), 13.10 (s, $^1J_{P,Pt}$ = 3725 Hz, P *trans* N) ppm.

[Pt_2(HL)($Cl)_2$($DMSO)_2$] (9): Aqueous 0.1 M HCl (0.65 mL, 0.065 mmol) was added, under vigorous stirring, to a solution of **1b** (52.3 mg, 0.061 mmol) in acetone (20 mL). After 4 h, a second quantity of HCl was added (1.35 mL). The mixture was stirred for 15 h, then concentrated to dryness and crystallised from CH_2Cl_2/Et_2O to give an analytical sample as a yellow solid. Yield: 46% (24.0 mg); m.p. 215−218 °C (dec.). $C_{20}H_{22}Cl_2N_2O_2Pt_2S_2$ (847.6):calcd. C 28.34, H 2.62, N 3.31; found C 28.09, H 2.33, N 3.24. ^1H NMR ($CDCl_3$): δ = 3.47 (s, $J_{Pt,H} \approx$ 24.5 Hz, 6 H, CH_3 of DMSO), 3.64 (s, $^3J_{Pt,H} \approx$ 22 Hz, 6 H, CH_3 of DMSO), 7.07 (dd, J_{H-H} = 5.6 Hz, J_{H-H} = 7.8 Hz, 1 H, 5′-H), 7.18 (d, J_{H-H} = 8.1 Hz, 1 H, 5-H), 7.42−7.48 (m, 3 H, H_{meta} and H_{para}), 7.73 (d, J_{H-H} = 8.1 Hz, 2 H, H_{ortho}), 8.63−8.69 (m, 2 H, 4′-H and 4-H), 8.98 (dd, J_{H-H} = 5.6 Hz, J_{H-H} = 1.2 Hz, 1 H, 6′-H) ppm.

X-ray Data Collection and Structure Determination: Crystal data are summarised in Table 2. The diffraction experiment was carried out with a Bruker SMART CCD area-detector diffractometer at 223 K. No crystal decay was observed, therefore no time-decay correction was needed. The collected frames were processed with the software SAINT,[15] and an empirical absorption correction was applied (SADABS)[16] to the collected reflections. The calculations were performed using the Personal Structure Determination Package[17] and the physical constants tabulated therein.[18] The structure was solved by direct methods (SHELXS)[19] and refined by full-matrix least squares using all reflections and minimising the function $\Sigma w(F_o^2 - kF_c^2)^2$ (refinement on F^2). One of the two chloroform solvent molecules is disordered around a twofold axis and its atoms have been given occupancy factors of 0.50. All the non-hydrogen atoms were refined with anisotropic thermal factors. The hydrogen atoms were placed in their ideal positions (C−H = 0.97 Å), with the thermal parameter B set to 1.10-times that of the carbon atom to which they are attached, and not refined. In the final Fourier map the maximum residual was 3.86(20) e·Å^{-3} at 0.62 Å from Pt(1). CCDC-236975 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Properties, and Structural Characterization of Bromo- and Iodotetracarboxylatodiruthenium(II,III) Compounds

M. Carmen Barral,[a] Rodrigo González-Prieto,[a] Reyes Jiménez-Aparicio,*[a] J. Luis Priego,[a] M. Rosario Torres,[b] and Francisco A. Urbanos[a]

Keywords: Carboxylate ligands / Metal-metal interactions / Multiple bonds / Ruthenium / Solvatochromism

The synthesis and characterization of the compounds $[Ru_2X(\mu\text{-}O_2CPh)_4]_n$ [X = Br (**1**), I (**2**)] and $[Ru_2X(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4(H_2O)]$ [X = Br (**3**) and I (**4**)] is described. The structures of these compounds were determined by single-crystal X-ray diffraction. The molecular structures of $[Ru_2Br(\mu\text{-}O_2CCMePh_2)_4(EtOH)\cdot 0.5EtOH]$ (**5**·0.5EtOH) and $[Ru_2I(\mu\text{-}O_2CCMePh_2)_4(MeOH)\cdot 0.5H_2O]$ (**6**·0.5H_2O) are also reported. Complexes **1** and **2** show a zigzag polymeric arrangement with the diruthenium units linked by bromide and iodide ligands, respectively. The molecular nature of compounds **3** and **4** shows the influence of the axial ligand in the arrangement in the solid state, which contrasts with the polymeric structure found in all chlorodiruthenium(II,III) derivatives with arenecarboxylate bridging ligands. The Ru–Ru bond lengths for all complexes range from 2.2756(17) to 2.2906(7) and 2.273(3) to 2.2965(6) Å for the bromide and iodide derivatives, respectively. This study demonstrates that the nature of the axial ligand plays an important role in the arrangement in the solid state and in the electronic properties of the halotetracarboxylatodiruthenium(II,III) complexes. Thus, the iodo derivatives show an intense solvatochromism, whereas the solvatochromism is slight in the bromo derivatives and is not observed in the chloro complexes.

Introduction

The synthesis and properties of the diruthenium(II,III) complexes of formula $[Ru_2Cl(\mu\text{-}O_2CR)_4]$ (R = alkyl, aryl) have attracted much attention, mainly due to the interest in their electronic and magnetic properties.[1−3] The use of these complexes as building blocks in the formation of supramolecular species has increased this interest.[4] Much effort has been devoted to the assembly of dinuclear units and a wide variety of oligomers and polymers have been isolated. These new materials containing diruthenium units may display novel conductive, optical, and magnetic properties.[1−4] In $[Ru_2Cl(\mu\text{-}O_2CR)_4]$ compounds the ruthenium atoms are strongly bonded by four bridging carboxylate ligands, with one axial position occupied by a chloride ion.[1−3] The chloride ligand of the $[Ru_2Cl(\mu\text{-}O_2CR)_4]$ molecule is usually bonded to the free axial position of a neighboring diruthenium unit leading to zigzag or linear chains.[4−15] However, a neutral ligand can also coordinate to the free axial position giving discrete dinuclear molecules.[16−19] Both discrete molecules and polymeric species with 2,2-diphenylpropionate and axial chloride ligands have been reported.[11,19] Thus, the influence of the carboxylate bridging group on the properties of these chlorocarboxylate derivatives has been studied. However, the role of the axial halogen ligand has been little explored. To the best of our knowledge, only one crystal structure of a bromo derivative, which contains zigzag chains, has been described.[20] We have recently published[19] the first crystal structure of an iododiruthenium derivative showing a cation/anion arrangement $[Ru_2(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)_2]$-$[Ru_2I_2(\mu\text{-}O_2CCH_2CH_2OPh)_4]$ in the solid state. The crystal structure of the diiodotetrabenzamidinatodiruthenium(III) complex $[Ru_2(DMBA)_4I_2]$ (DMBA = *N*,*N*′-dimethylbenzamidinate) has been reported very recently.[21]

In this paper we analyse the role of the axial halogen ligand on the properties of the halotetracarboxylatodiruthenium(II,III) complexes. Tetrabenzoate- and tetra-*p*-methoxybenzoatediruthenium(II,III) compounds have been used in this study. The preparation and structural characterization of new bromo and iodo derivatives are described. The synthesis of the bromo and iodo complexes with 2,2-diphenylpropionate has been reported in a previous paper[19] but the structural determination of both complexes is reported here. These complexes show an intense solvatochromism in several solvents, which is also explored.

Results and Discussion

The reaction of $[Ru_2Cl(\mu\text{-}O_2CR)_4]$ (R = Ph, C_6H_4-*p*-OMe) with $AgBF_4$ in THF leads to the complexes $[Ru_2(\mu\text{-}O_2CR)_4(THF)_2]BF_4$, which were treated in ethanol with an aqueous solution of KBr or KI to give $[Ru_2X(\mu\text{-}O_2CPh)_4]_n$ [X = Br (**1**), I (**2**)] and $[Ru_2X(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4(H_2O)]$ [X = Br (**3**) and I (**4**)]. Crystals of **1** and **2** were grown by layering an ethanol solution of $[Ru_2(\mu\text{-}O_2CR)_4(THF)_2]BF_4$ onto an aqueous solution of KX (X = Br, I). An analogous procedure allowed us to isolate single crystals of $[Ru_2Br(\mu\text{-}O_2CCMePh_2)_4(EtOH)]\cdot 0.5EtOH$ (**5**·0.5EtOH). The hydrate $[Ru_2Br(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ and unsolvated $[Ru_2Br(\mu\text{-}O_2CCMePh_2)_4]$ have been isolated previously, although the growth of single crystals was not possible.[19] The slow evaporation of an ethanol/water solution of compound **3** gave crystals of **3**·H_2O. Crystals of **4**·H_2O were obtained by cooling a methanol solution of **4** to −18 °C. Single crystals of $[Ru_2I(\mu\text{-}O_2CCMePh_2)_4(MeOH)]\cdot 0.5H_2O$ (**6**·0.5H_2O) were grown from a methanol/water solution containing the cation $[Ru_2(\mu\text{-}O_2CCMePh_2)_4]^+$ and tetraphenylphosphonium iodide over 48 h.

The unsolvated $[Ru_2X(\mu\text{-}O_2CR)_4]$ complexes were prepared by heating the solvated complexes under vacuum.

All compounds are thermally stable in air and can be manipulated without decomposition for long periods of time. They are soluble in methanol, DMSO and THF, but insoluble in hexane or toluene, and are 1:1 electrolytes in methanol and DMSO but non-electrolytes in acetone, THF and acetonitrile solutions.[22]

The IR spectra of all compounds exhibit the typical pattern for bridging carboxylate ligands in the CO_2 stretching region.[1−3] Other bands attributable to aryl or alkyl groups of the carboxylate ligands are also observed in all cases. For **3** and **4** bands corresponding to coordinated water molecules also appear.

The base peak in all mass spectra (ESI+) corresponds to the ion $[Ru_2(\mu\text{-}O_2CR)_4]^+$ or $[Ru_2(\mu\text{-}O_2CR)_4(DMSO)]^+$. The $[Ru_2X(\mu\text{-}O_2CR)_4]^+$ ion is only observed in compound **1**. In complex **5**, the molecular peak associated with a DMSO molecule $[Ru_2Br(\mu\text{-}O_2CCMePh_2)_4(DMSO)]^+$ is detected. All spectra in ESI negative mode show the peak corresponding to the ion $[Ru_2X_2(\mu\text{-}O_2CR)_4]^-$.

Crystal Structures of $[Ru_2Br(\mu\text{-}O_2CPh)_4]$ (1), $[Ru_2Br(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4(H_2O)]\cdot H_2O$ (3·H_2O), and $[Ru_2Br(\mu\text{-}O_2CCMePh_2)_4(EtOH)]\cdot 0.5EtOH$ (5·0.5EtOH)

The crystal structures of these complexes are depicted below. Selected bond lengths and angles are given in Table 1. These complexes have two Ru atoms linked by four carboxylate bridging ligands. The Ru−Ru distances are 2.2906(7), 2.2756(17), and 2.2849(14) Å, respectively. These distances are of the same order as those found in other carboxylatodiruthenium(II,III) compounds.[1−3]

The structure of **1** (Figure 1) consists of $[Ru_2(\mu\text{-}O_2CPh)_4]^+$ units connected by bromide ions to give zigzag chains. The Ru−Br−Ru angle of 117.00(3)° is similar to those found in other polymeric complexes,[5,7,9,10,12,15] and in the sole previously described bromo derivative $[Ru_2Br(\mu\text{-}O_2CH)_4]_n$.[20] Figure 2 shows the packing of the zigzag chains in the solid state. No significant interactions are seen between the chains of $[Ru_2Br(\mu\text{-}O_2CPh)_4]_n$.

Table 1. Selected bond lengths (Å) and angles (°) for $[Ru_2Br(\mu\text{-}O_2CPh)_4]$ (**1**), $[Ru_2Br(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4(H_2O)]\cdot H_2O$ (**3**·H_2O), and $[Ru_2Br(\mu\text{-}O_2CCMePh_2)_4(EtOH)]\cdot 0.5EtOH$ (**5**·0.5EtOH); symmetry transformations used to generate equivalent atoms: #1: $-x+2, -y+1, -z$; #2: $-x+2, y, z+1/2$.

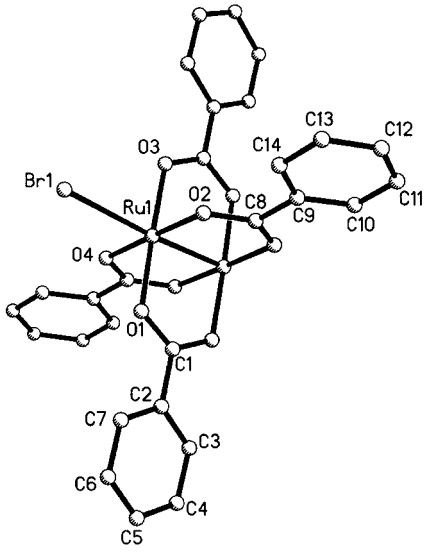

Figure 1. PLUTO view of $[Ru_2Br(\mu\text{-}O_2CPh)_4]$ (**1**); hydrogen atoms have been omitted for clarity

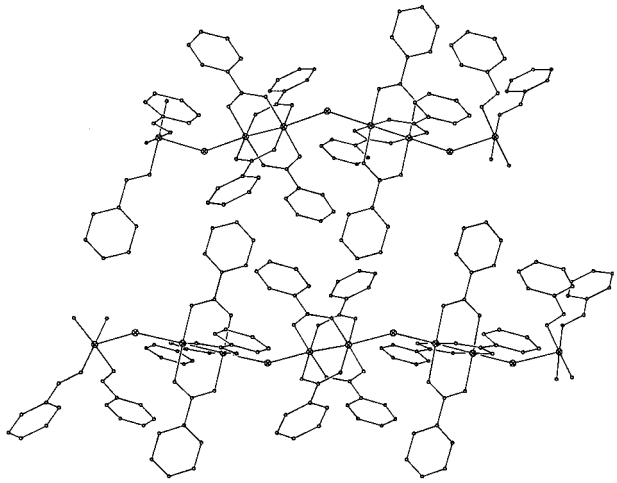

Figure 2. Packing of the polymeric complex **1**

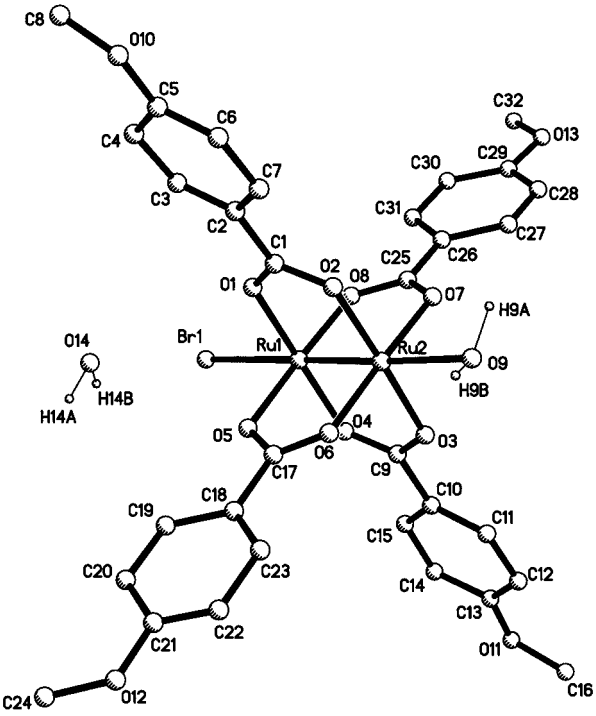

Figure 3. PLUTO view of $[Ru_2Br(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4(H_2O)]\cdot H_2O$ (**3**·H_2O); hydrogen atoms, except in water molecules, have been omitted for clarity

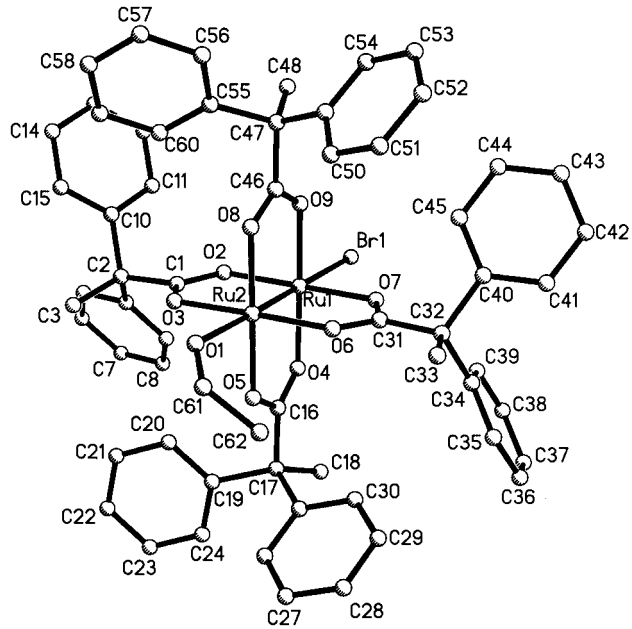

Figure 4. PLUTO view of $[Ru_2Br(\mu\text{-}O_2CCMePh_2)_4(EtOH)]\cdot 0.5EtOH$ (**5**·0.5EtOH); crystallization solvent molecules and hydrogen atoms have been omitted for clarity

The molecular structures of complexes **3**·H_2O (Figure 3) and **5**·0.5EtOH (Figure 4) consists of discrete dinuclear molecules of $[Ru_2Br(\mu\text{-}O_2CR)_4(S)]$ (S = solvent molecule). The dinuclear unit of **3**·H_2O has one bromide atom and one water molecule in the axial positions. The crystallisation water molecule is hydrogen bonded to the coordinated water of a dinuclear unit and to the bromide ligand of another dimetallic molecule. The molecular structure of **5**·0.5EtOH is similar, with one of the axial positions occupied by an ethanol molecule instead of a water molecule. In this compound, the possible presence of hydrogen bonds could not be established due to the low quality of the crystal.

The molecular nature of these bromo derivatives contrasts with the polymeric chains found in the formate derivative[20] and with the above-described benzoate complex **1**. The formation of discrete dinuclear molecules in **3**·H_2O

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the solid state is more surprising because all chloro derivatives with arenecarboxylate ligands,[1−3] including the *p*-methoxybenzoate complex[9] $[Ru_2Cl(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4]_n$, have a polymeric structure. Complexes **3**·H_2O and **5**·0.5EtOH are the first examples of halotetraarenecarboxylatodiruthenium(II,III) compounds with a nonpolymeric arrangement. This molecular nature indicates that the axial ligands play a key role in the arrangement of these diruthenium(II,III) complexes in the solid state.

The Ru−Br bond lengths for **1**, **3**·H_2O, and **5**·0.5EtOH are 2.6700(5), 2.671(2), and 2.6108(17) Å, respectively. In the molecular complex **5**·0.5EtOH the Ru−Br bond length is shorter than in the polymeric compound **1** and in $[Ru_2Br(\mu\text{-}O_2CH)_4]_n$ [2.7170(8)−2.7313(9) Å].[20] This fact is consistent with the variation observed in the Ru−Cl distances in the analogous molecular and polymeric chlorotetracarboxylatodiruthenium(II,III) complexes.[4−19] However, the Ru−Br distance in the molecular compound **3**·H_2O is slightly longer than in polymeric **1**.

Crystal Structures of $[Ru_2I(\mu\text{-}O_2CPh)_4]$ (2), $[Ru_2I(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4(H_2O)]\cdot H_2O$ (4·H_2O), and $[Ru_2I(\mu\text{-}O_2CCMePh_2)_4(MeOH)]\cdot 0.5H_2O$ (6·0.5H_2O)

Figure 5 shows a PLUTO view of the dinuclear unit of **2**. Selected bond lengths and angles are collected in Table 2. The arrangement in the solid state — zigzag chains with an iodide ligand linking the $[Ru_2(\mu\text{-}O_2CPh)_4]^+$ units — is similar to that found in **1**. The chains are separated by normal van der Waals forces. The Ru−I−Ru angle is 114.246(18)° and the Ru−I distance [2.8562(4) Å] is longer than the Ru−Br distance [2.6700(5) Å] in **1**. This large bond length is in accordance with the size of the axial ligand. The Ru−Ru distance [2.2965(6) Å] is longer than those observed in the chloro derivatives [2.267(1)−2.292(7) Å]. It is independent of the type of arrangement in the solid state[4−19] and is similar to that found[19] in $[Ru_2(\mu\text{-}O_2CCH_2CH_2OPh)_4(H_2O)_2][Ru_2I_2(\mu\text{-}O_2CCH_2CH_2OPh)_4]$ [2.310(2) Å].

Complexes **4**·H_2O (Figure 6) and **6**·0.5H_2O (Figure 7) have molecular structures analogous to those of **3**·H_2O and **5**·0.5EtOH. Selected bond lengths and angles are listed in Table 2. The structural parameters of the $[Ru_2(\mu\text{-}O_2C)_4]$ units are similar in the four complexes. In compounds **4**·H_2O and **6**·0.5H_2O one axial position is occupied by an iodide ligand and the other one is occupied by a water molecule or a MeOH ligand, respectively. In complex **4**·H_2O the water molecule of crystallization is hydrogen bonded to the coordinated water of a dinuclear unit and to the bromide ligand of another dimetallic molecule, similarly to **3**·H_2O. The Ru−I bond lengths in **4**·H_2O and **6**·0.5H_2O are 2.831(4) and 2.8055(10) Å, respectively, which are shorter than that observed for compound **2**. The Ru−I distances in these tetracarboxylatodiruthenium(II,III) derivatives are also shorter than those found in the benzamidinatediruthenium(III) complex[21] $[Ru_2I_2(DMBA)_4]$ [2.917(1) and 2960(1) Å].

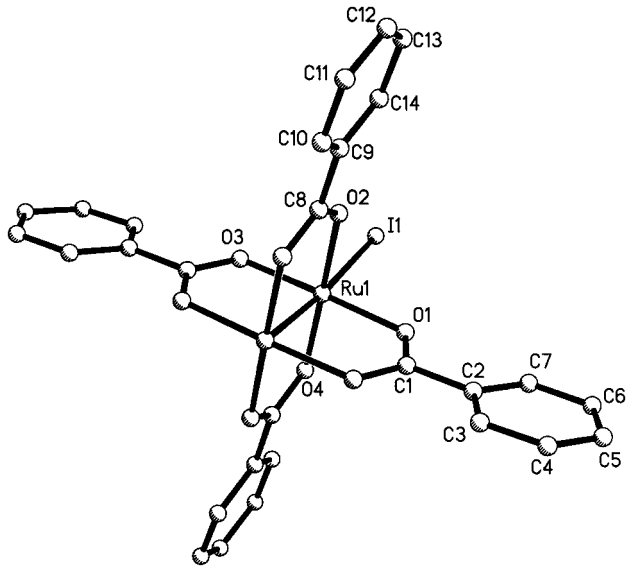

Figure 5. PLUTO view of $[Ru_2I(\mu\text{-}O_2CPh)_4]$ (**2**); hydrogen atoms have been omitted for clarity

Magnetic Properties

Magnetic measurements of the compounds show magnetic moments at room temperature of 4.09−4.36 μ_B in all cases. These values correspond to the presence of three unpaired electrons per dimer unit, in accordance with the ground-state configuration $\sigma^2\pi^4\delta^2(\pi^*\delta^*)^3$ proposed by Norman et al.[23] In all cases the molar magnetic susceptibility increases with decreasing temperature and no maximum is observed. The magnetic moments of these complexes decrease with temperature. This behaviour is usual in this type of complexes and has been ascribed[11,13,15,19,24−27] to a large zero-field splitting (ZFS) and some degree of antiferromagnetic coupling between the dimetallic units. The zero-field splitting effect on the susceptibility can be quantified by considering the Hamiltonian $H_D = S\cdot D\cdot S$, as described by O'Connor.[28] The perturbation of a weak antiferromagnetic coupling over the zero-field splitting system can be considered by using the molecular field approximation.[28] Thus, for an $S = 3/2$ spin system the magnetic suscpetibility can be expressed as:

$$\chi' = \chi'_M/[1 - (2zJ/Ng^2\beta^2)\chi'_M]$$

where χ'_M includes the temperature independent paramagnetism (TIP)

$$\chi'_M = \chi_M + \text{TIP}$$

and

$\chi_M = (\chi_\parallel + 2\chi_\perp)/3$,
$\chi_\parallel = (Ng^2\beta^2/kT)(1 + 9e^{-2D/kT})/4(1 + e^{-2D/kT})$ and
$\chi_\perp = (Ng^2\beta^2/kT)[4 + (3kT/D)(1 - e^{-2D/kT})]/4(1 + e^{-2D/kT})$.

Finally, the consideration of a paramagnetic impurity (P) leads to the expression

$$\chi'_{mol} = [(1 - P)\chi'] + [PNg^2_{mo}\beta^2/4kT]$$

which has been used previously[13,15,19] in the fits of similar diruthenium complexes.

The magnetic parameters obtained in the fit of the magnetic data of complexes **1**−**4** using this model are collected in Table 3. The magnetic properties of complexes **5**·0.5EtOH and **6**·$0.5H_2O$ are analogous to those described previously[19] for $[Ru_2X(\mu\text{-}O_2CCMePh_2)_4(H_2O)]$ (X = Br, I).

A very good agreement between the experimental and calculated curves of the magnetic moment and the molar susceptibility for complexes **1**−**4** was observed. Figure 8 shows the experimental and calculated curves for complex **1** using the above-mentioned model. Similar curves have been obtained for the other complexes, with *D* values ranging from 63.4 to 71.5 cm^{-1}. Similar *D* values have been calculated for other tetracarboxylato complexes.[13,15,19] These large *D* values are a consequence of the presence of two second row transition metal atoms and the existence of several vacant energy levels near the HOMO level in the diruthenium unit, as described by Norman et al.[23] The *zJ* values for complexes **3** and **4** are low as is expected from their molecular nature. Low *zJ* values are also observed in **1** and **2,** as expected for polymeric complexes with Ru−X−Ru angles lower than 125°.[13,15,19] The higher *zJ* value of the bromo complex **1** with respect to the iodo complex **2** could

[a] $\sigma^2 = \Sigma(\mu_{eff.calcd.} - \mu_{eff.exp.})^2/\Sigma\mu_{eff.exp.}^2$.

be due to the better overlap between the π-type lone-pair orbital of the bromo ligand and the π*(Ru−Ru) orbital as the overlapping of the π-type halogen and ruthenium orbitals in these complexes becomes smaller for the heavier halide ligand.

Electronic Properties

The absorption data in the visible-UV−NIR range for solutions of complexes **1**−**6** in several solvents are given in Table 4.

The electronic spectra of the complexes in methanol solution mainly show two bands in the visible-UV range at about 430 and 330 nm. The major absorption band in the visible range (430 nm) is unambiguously assigned to a π(RuO,Ru_2) → π*(Ru_2) transition according to Norman et al.[23] and Miskowski and Gray.[29] The metal-metal character ($Ru_2 \rightarrow Ru_2$) of this transition has been well established by resonance Raman studies[29,30] although the amount of ligand to metal charge transfer (LMCT) (RuO → Ru_2) seems to be questionable. The band observed at ca. 330 nm could be assigned to a ligand-to-metal charge transfer π(axial ligand) → π*(Ru_2) transition. This assignment is in accordance with that described previously for other tetracarboxylatodiruthenium(II,III) complexes.[1,3,29]

The complexes **1**−**6** are 1:1 electrolytes in MeOH and DMSO solutions. As a consequence, the cation [Ru_2(μ-O_2CR)$_4$(S)$_2$]$^+$ (S = solvent) is present in solution and no dependence on the nature of the halogen is observed. However, the conductivity measurements in acetone, acetonitrile and THF indicate that these complexes are nonelectrolytes and the monoadducts [Ru_2X(μ-O_2CR)$_4$(S)] must exist in solution.

In order to compare the electronic spectra of this series of chloro-, bromo-, and iodotetracarboxylatodiruthenium(II,III) derivatives, the UV/Vis-NIR data of the chloro compounds [Ru_2Cl(μ-O_2CR)$_4$] (R = C_6H_4-*p*-OMe, $CMePh_2$) were also recorded (Table 4). However, the spectra of the chlorotetrabenzoate complex was not measured due to its insolubility.

The first absorption band observed in the chloro complexes in the range 317−339 nm could be assigned to an LMCT π(axial ligand) → π*(Ru_2) transition similar to that described above for the [Ru_2(μ-O_2CR)$_4$(MeOH)$_2$]$^+$ species. This band is shifted to 340−400 nm and to 409−445 nm in the bromo and iodo complexes, respectively. This assignment is in accordance with the sensibility of this transition to the axial ligand and with the strong, systematic red shift predicted for the change from chloro to iodo. An analogous shift has been described in the UV/Vis spectra of the dibromo and diiodo complexes[29] (Bu_4N)[Ru_2Br_2(μ-O_2CPr)$_4$] and (Bu_4N)[Ru_2I_2(μ-O_2CPr)$_4$]. The first high-intensity absorption observed in the iodo complexes in the range 344−383 nm could be assigned to an LMCT σ(axial ligand) → σ*(Ru_2) transition, in agreement with those described[29] for the 307 nm band observed in the diodo anion [Ru_2I_2(μ-O_2CR)$_4$]$^-$.

The second absorption band observed in the chloro complexes in the range 464−467 nm is assigned to the π(RuO,Ru_2) → π*(Ru_2) transition. This absorption is slightly red-shifted in the bromo derivatives (476−494 nm), whereas in the iodo compounds it is strongly shifted (564−625 nm). This absorption should be only very weakly sensitive to the nature of the axial ligand,[1,3,29] although it has been described that in the diiodo complex (Bu_4N)-[Ru_2I_2(μ-O_2CPr)$_4$] it is strongly perturbed. This perturbation could be due to the mixing of this transition with the π(axial ligand) → π*(Ru_2) charge transfer.[29] Figure 9 shows the electronic spectra of the 2,2-diphenylpropionato derivatives [Ru_2X(μ-O_2CC$Me Ph_2$)$_4$] (X = Cl, Br, I) in acetone.

The chloro and bromo derivatives also display a very weak shoulder in the range 553−622 nm which is shifted to 712−754 nm in the iodo compounds. This band could be assigned to a σ(Ru-axial ligand) → π*(Ru_2) transition in accordance with the very weak and poorly defined band at ca. 560 nm observed in some chloro complexes [Ru_2Cl(μ-O_2CR)$_4$].[8,23,29]

All the complexes show a weak absorption band in the range 981−1166 nm in the NIR region due to the δ → δ* transition.

[a] $[Ru_2Cl(\mu\text{-}O_2CC_2H_4\text{-}p\text{-}OMe)_4]$. [b] $[Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4]$.

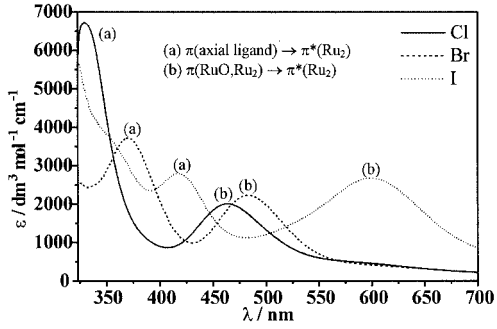

Figure 9. Electronic spectra of $[Ru_2X(\mu\text{-}O_2CCMePh_2)_4]$ in acetone

The variations in the absorption bands imply important colour changes of the solutions of the complexes. All compounds are yellow in methanol or DMSO solutions, due to the existence of the π(RuO,Ru_2) → π*(Ru_2) transition in the visible range. The acetonitrile, acetone, and THF solutions of the chloro derivatives have a similar yellow-brown colour and the bromo derivatives show a little solvatochromism, whose colours change from yellow-orange to pink. However, the iodo derivatives in acetone, acetonitrile and THF are blue, violet, and green respectively. The $[Ru_2I(\mu\text{-}O_2CR)_4(S)]$ complexes display two transitions in the visible range, but the colour changes seems to be related mainly

with the presence, position, and intensity of the second band, in which the axial ligands have a great influence. In summary, the electronic data of the halotetracarboxylatodiruthenium(II,III) complexes indicate that the solvatochromism of these complexes can be ascribed to the combined influence of the halide and the solvent molecule bonded to the axial positions.

Conclusions

In this work we have found that complexes of the type $[Ru_2X(\mu\text{-}O_2CR)_4]$ (X = Br, I) give polymeric zigzag chains with R = Ph and discrete dinuclear molecules with R = C_6H_4-*p*-OMe or $CMePh_2$ ligands. These examples represent the first nonpolymeric complexes with arenecarboxylate bridging ligands, and indicate that the polymeric or molecular nature of this type of compounds is due to the influence of the equatorial and axial ligands. The presence of chloride, bromide or iodide as axial ligand in the diruthenium complexes produce a shift of the LMCT bands to lower energy. In the iodo derivatives a strong shift of the $\pi(RuO,Ru_2) \rightarrow \pi^*(Ru_2)$ transition is also induced, thereby producing solvatochromism for these complexes.

Experimental Section

General Remarks: All reactions were carried out under an inert atmosphere, using standard Schlenk techniques. Ruthenium trichloride, carboxylic acids and solvents were obtained from commercial sources and used without previous purification. The complexes $[Ru_2Cl(\mu\text{-}O_2CR)_4]$ (R = C_6H_4-*p*-OMe, $CMePh_2$, Ph) were prepared by literature procedures.[9,11,31] IR spectra were recorded as KBr discs on a Nicolet Magna-FTIR 550 spectrophotometer. Elemental analysis of C and H were performed by the Microanalytical Service of the Complutense University of Madrid. Electronic spectra in the range 250−1300 nm were recorded on a Cary 5G spectrophotometer in 10^{-4} M solutions in methanol, DMSO, acetone, THF, or acetonitrile. The variable-temperature magnetic susceptibility data were measured on a Quantum Design MPMSXL SQUID (Superconducting Quantum Interference Device) susceptometer over a temperature range of 2 to 300 K. Each raw data point was corrected for the diamagnetic contribution of both the sample holder and the compound to the susceptibility. The molar diamagnetic corrections for the complexes were calculated on the basis of Pascal's constants. The fits of experimental data were carried out using the commercial MATLAB V.5.1.0.421 program. Mass spectra were obtained on a Bruker Esquire-LC with Electrospray Ionization (ESI) using chloroform, methanol, THF, or DMSO as solvent. Nominal molecular masses and isotopic distributions of all peaks were calculated with the MASAS[32] computer program,

using a polynomial expansion based on natural abundances of the isotopes.

Preparation of [$Ru_2Br(\mu\text{-}O_2CPh)_4$] (1): Silver tetrafluoroborate (0.07 g, 0.35 mmol) was added to a suspension of [$Ru_2Cl(\mu\text{-}O_2CPh)_4$] (0.25 g, 0.35 mmol) in THF (30 mL). The reaction mixture was stirred for 24 h, giving a solid precipitate of AgCl and a brown solution. The precipitate was filtered through celite and the solution was pumped to dryness. The solid was dissolved in ethanol (10 mL) and treated with a water solution (10 mL) of KBr (0.42 g, 3.50 mmol) giving a light brown precipitate, which was filtered off, washed with water (3 × 20 mL) and dried under vacuum. Single crystals were obtained by slow interdiffusion of the above-mentioned ethanol solution and the aqueous solution of KBr. Yield 0.16 g (59%). $C_{28}H_{20}BrO_8Ru_2$ (766.52): calcd. C 43.88, H 2.63; found C 43.80, H 2.69. IR (KBr): $\tilde{\nu}$ = 3067 w, 3050 w, 1600 m, 1495 m, 1465 s, 1408 vs, 1177 w, 1143 w, 1081 w, 1002 w, 845 w, 715 s, 689 s, 531 m cm^{-1}. $\mu_{eff.}$ = 4.09 μ_B at room temperature. MS in DMSO/MeOH (ESI^+): *m*/*z* = 767 [M^+], 688 [$M^+ - Br$]; (ESI^-): *m*/*z* = 848 [$M^- + Br$].

Preparation of [$Ru_2I(\mu\text{-}O_2CPh)_4$] (2): The reaction was carried out as mentioned above for **1**, using KI (0.58 g, 3.50 mmol) instead of KBr. Yield 0.16 g (57%). $C_{28}H_{20}IO_8Ru_2$ (813.51): calcd. C 41.34, H 2.48; found C 41.20, H 2.45. IR (KBr): $\tilde{\nu}$ = 3066 w, 1600 m, 1495 m, 1464 s, 1408 vs, 1176 w, 1143 w, 1071 w, 1002 w, 845 w, 715 s, 689 s, 529 m cm^{-1}. $\mu_{eff.}$ = 4.16 μ_B at room temperature. MS in THF/$CHCl_3$ (ESI^+): *m*/*z* = 688 [$M^+ - I$]; (ESI^-): *m*/*z* = 942 [$M^- + I$].

Preparation of [$Ru_2Br(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4(H_2O)$] (3): The reaction was carried out as described above for **1**, using [$Ru_2Cl(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4$] (0.29 g, 0.35 mmol). The solid isolated was characterized as **3**. Single crystals of **3**·H_2O were obtained by evaporation in air of a solution of **3** in methanol. Yield 0.22 g (69%). $C_{32}H_{30}BrO_{13}Ru_2$ (904.64): calcd. C 42.49, H 3.34; found C 42.40, H 3.27. IR (KBr): $\tilde{\nu}$ = 3447 w, 3015 w, 2960 w, 2935 w, 2838 w, 1605 s, 1583 w, 1442 m, 1396 vs, 1315 w, 1304 w, 1261 s, 1172 s, 1109 w, 1025 w, 849 w, 773 m, 702 w, 649 m, 527 w, 511 w, 459 w cm^{-1}. $\mu_{eff.}$ = 4.12 μ_B at room temperature. MS in $CHCl_3$ (ESI^+): *m*/*z* = 808 [$M^+ - Br - H_2O$]; (ESI^-): *m*/*z* = 968 [$M^- + Br - H_2O$].

Preparation of [$Ru_2I(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4(H_2O)$] (4): The reaction was carried out as described above for **2**, using [$Ru_2Cl(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4$] (0.29 g, 0.35 mmol). The brown-violet solid obtained in this way was characterized as **4**. Single crystals of **4**·H_2O were obtained by dissolving **4** in hot methanol (20 mL) and allowing this solution to stand at room temperature and then at −18 °C. Yield 0.21 g (64%). $C_{32}H_{30}IO_{13}Ru_2$ (951.63): calcd. C 40.39, H 3.18; found C 40.26, H 3.08. IR (KBr): $\tilde{\nu}$ = 3447 w, 3078 w, 3013 w, 2961 w, 2934 w, 2837 w, 1605 vs, 1583 m, 1442 s, 1393 vs, 1315 m, 1303 m, 1260 vs, 1172 vs, 1109 w, 1026 m, 849 m, 773 s, 702 w, 668 m, 649 m, 529 w, 511 w, 458 w cm^{-1}. $\mu_{eff.}$ = 4.36 μ_B at room

temperature. MS in $CHCl_3$ (ESI^+): m/z = 808 [$M^+ - I - H_2O$]; (ESI^-): m/z = 1062 [$M^- + I - H_2O$].

Preparation of [$Ru_2Br(\mu\text{-}O_2CCMePh_2)_4(EtOH)$] (5): This complex was prepared by a literature procedure.[19] Single crystals of **5**·0.5EtOH were obtained by the procedure described for complex **1**. MS in DMSO/MeOH (ESI^+): m/z = 1261 [M^+ + DMSO], 1182 [M^+ + DMSO − Br]; (ESI^-): m/z = 1264 [M^- + Br].

Preparation of [$Ru_2I(\mu\text{-}O_2CCMePh_2)_4(MeOH)$] (6): This complex was prepared by a literature procedure.[19] Single crystals of **6**·0.5H_2O were obtained by the following procedure: A solution of [$Ru_2Cl(\mu\text{-}O_2CCMePh_2)_4$] (0.11 g, 0.10 mmol) in MeOH (15 mL), was treated with a water solution of $AgNO_3$ (0.017 g, 0.10 mmol). The solution was filtered and treated with an excess of PPh_4I (0.23 g, 0.50 mmol). Single crystals of **6**·0.5H_2O grew from this solution in 48 h. MS in $CHCl_3$/MeOH (ESI^+): m/z = 1104 [M^+ − I]; (ESI^-): m/z = 1358 [M^- + I].

X-ray Crystallographic Study: Details of the data collection and crystal structure refinement correction for **1**, **2**, **3**·H_2O, **4**·H_2O, **5**·0.5EtOH, and **6**·0.5H_2O are summarised in Table 5 and 6. Suitable crystals were mounted on a Bruker Smart-CCD diffractometer equipped with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation. Data were collected at 293(2) K over a quadrant of the reciprocal space by combination of two exposure sets. Each exposure of 20 s covered 0.3 in ω. The cell parameters were refined by least-squares fit of all reflections collected. The structures were solved by Patterson (Ru atoms, SHELXS[33]) and conventional Fourier techniques and refined by full-matrix least-squares on F^2 (SHELXL) (except **6**·0.5H_2O which was refined by full-cycle).[34] Final mixed refinements were undertaken with anisotropic thermal parameters for the nonhydrogen atoms. The hydrogen atoms were included with fixed isotropic contributions at their positions calculated geometrically. Elevated final R values were obtained for **3**·H_2O and **5**·0.5EtOH due to the low quality of these crystals.
CCDC-236884−236889 (for **1**, **2**, **3**·H_2O, **4**·H_2O, **5**·0.5EtOH, and **6**·0.5H_2O, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Monocyclooctatetraenyl(dithiolene)uranium Compounds

Thérèse Arliguie,*[a] Pierre Thuéry,[a] Marc Fourmigué,[b] and Michel Ephritikhine[a]

Keywords: Cyclooctatetraenyl ligands / Lewis bases / S ligands / Uranium

The neutral mononuclear dithiolene compounds [U(cot)(dithiolene)(tppo)$_2$] [cot = η-C_8H_8; dithiolene = dddt (**9**), dmio (**10**), mdt (**11**)], [U(cot)(dithiolene)(hmpa)$_2$] [dithiolene = dddt (**12**), dmio (**13**), mdt (**14**)], [U(cot)(mdt)(bipy)] (**15**) and [U(cot)(mdt)(terpy)] (**16**) were obtained by treating the dimeric complexes [{U(cot)(dithiolene)}$_2$] [dithiolene = dddt (**3**), dmio (**4**), mdt (**5**)] (dddt = 5,6-dihydro-1,4-dithiine-2,3-dithiolate; dmio = 1,3-dithiole-2-one-4,5-dithiolate; mdt = 1,3-dithiole-4,5-dithiolate) with the corresponding Lewis base [triphenylphosphine oxide (tppo), hexamethylphosphoramide (hmpa), 2,2′-bipyridine (bipy), or 2,2′:6′,2′′-terpyridine (terpy)]. Complexes **9**·2THF, **11**·2THF, **12**, **13**, **14**, **15** and **16**·1.5py have been crystallographically characterized. The crystal structures show a significant interaction between the C=C double bond of the dithiolene ligand and the metal centre. The ^{1}H NMR spectra reveal the fluxional behaviour of the compounds in solution in relation to the facile inversion of the dithiolene ring. The variation of the activation energies of the inversion process reflects the steric congestion of the complexes.

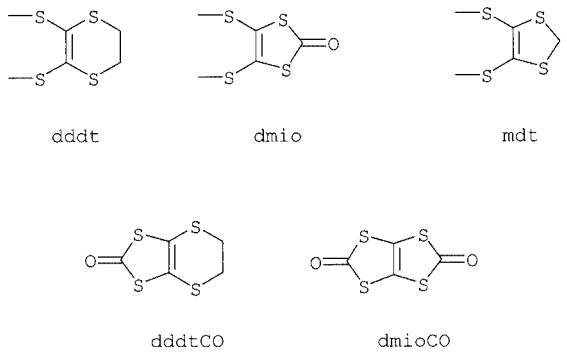
Introduction

Dithiolene complexes of the d-block transition metals have received much attention for their remarkable structural features and physicochemical properties, finding applications in the elaboration of novel conducting and magnetic materials.[1] In contrast, such compounds of the f-block elements have been practically neglected,[2] mainly due to the presumption that this type of complex should be unstable. In fact, lanthanides and actinides have proved to have a strong affinity for sulfur,[3−12] and the synthesis of their dithiolene complexes is worth considering since their coordination flexibility, paramagnetism and redox behaviour could favour the emergence of interesting structures and electronic interactions. For these reasons we have started studies on organouranium−dithiolene compounds, in particular bis(pentamethylcyclopentadienyl) and monocyclooctatetraenyl derivatives, for comparison with the heteroleptic cyclopentadienyl/dithiolene complexes of the metals of groups 4−6[13,14] and with the uranium bis(thiolate) complexes [U(cp*)$_2$(SR)$_2$][11] and [{U(cot)(SR)$_2$}$_2$][7] (cp* = η-C_5Me_5; cot = η-C_8H_8). The dithiolene ligands selected for this work are represented in Scheme 1.



Scheme 1. The dithiolene ligands and dithiocarbonates (dddt = 5,6-dihydro-1,4-dithiine-2,3-dithiolate; dmio = 1,3-dithiole-2-one-4,5-dithiolate; mdt = 1,3-dithiole-4,5-dithiolate)

We recently reported that anionic bis(dithiolene) derivatives could be obtained from the metathesis reaction of the uranium bis(borohydride) complex [U(cot)(BH_4)$_2$] with 2 mol-equiv. of Na_2dddt in THF, affording, in the presence of 18-crown-6, red crystals of a THF solvate of [Na(18-crown-6)(THF)$_2$]$_2$[U(cot)(dddt)$_2$] (**1**). Complex **1** was a unique example of a dianionic monocyclooctatetraenyluranium compound, although the [U(cot)X_3]$^-$ anions were found to be stable in the presence of an excess of X^- (X = SR,[7] NR_2,[15] BH_4 [16]). Its oxidation with $AgBPh_4$ in THF afforded the corresponding monoanionic compound [Na(18-crown-6)(THF)][U(cot)(dddt)$_2$] (**2**), which was structurally characterized.[17] Complex **2** was the first uranium(v) compound with metal−sulfur bonds and, after the cycloheptatrienyl sandwich compound [K(18-crown-

6)][U(η-C_7H_7)$_2$],[18] a new example of an anionic organouranium(v) derivative.

We also disclosed that the same borohydride, [U(cot)(BH_4)$_2$], could act as a hydride reagent in the reductive fission of dithiocarbonates, affording a series of neutral dimetallic dithiolene complexes [{U(cot)(dithiolene)}$_2$] [dithiolene = dddt (**3**), dmio (**4**), mdt (**5**)].[19] Upon dissolution in pyridine, those dimeric compounds could be transformed into the mononuclear complexes [U(cot)(dithiolene)(py)$_2$] [dithiolene = dddt (**6**), dmio (**7**), mdt (**8**)]. The crystal structure of **8** revealed a significant interaction between the dithiolene ligand and the metal centre.[19] With the aim of understanding and controlling this interaction, we have studied the complexation of **3**−**5** with various Lewis bases, such as triphenylphosphine oxide (tppo) or hexamethylphosphoramide (hmpa), and chelating pyridines such as bipyridine or terpyridine.

Here we report the synthesis of a series of adducts of general formula [U(cot)(dithiolene)(L)$_n$] (n = 1 and L = bipy or terpy; n = 2 and L = tppo or hmpa). We describe the X-ray crystal structures of the complexes, paying special attention to the interaction between the dithiolene ligand and the metal centre, and we present the ^{1}H NMR spectra, which reveal the dynamic behaviour of the complexes in solution, related to the facile ring-inversion process of the dithiolene ligand.[17,19]

Results and Discussion

The bis adducts [U(cot)(dithiolene)(tppo)$_2$] [dithiolene = dddt (**9**), dmio (**10**), mdt (**11**)] and [U(cot)(dithiolene)(hmpa)$_2$] [dithiolene = dddt (**12**), dmio (**13**), mdt (**14**)] were obtained by treatment of **3**−**5** with 2 mol-equiv. of tppo or hmpa in THF (Scheme 2). With the exception of **10**, these complexes could also be prepared in a one-pot reaction from [U(cot)(BH_4)$_2$], L and the dithiocarbonates dddtCO or dmioCO, which are the protected forms of the corresponding dithiolene ligands (dddtCO = 5,6-dihydro-1,3-dithiolo[4,5-*b*][1,4]dithiine-2-one; dmioCO = 1,3,4,6-tetrathiapentalene-2,5-dione). In the presence of 2,2′-bipyridine (bipy) or 2,2′:6′,2″-terpyridine (terpy) in THF, **5** was transformed into [U(cot)(mdt)(bipy)] (**15**) and [U(cot)(mdt)(terpy)] (**16**), respectively. Complexes **6**−**16** were isolated as red to dark-brown crystals or powders with yields from 65 to 95%.

Scheme 2. Synthesis of the mononuclear compounds **6**−**14**

At least one example of each type of the Lewis-base adducts of **3**−**5** with tppo or hmpa (**11**, **12** and **13**) was characterized by elemental analysis, as were **15** and **16** , and the X-ray crystal structures of **9**·2THF, **11**·2THF, **12**, **13**, **14**, **15** and **16**·1.5py were also determined.

Crystal Structures of the Complexes

The crystal structure of the dinuclear compound **5** (Figure 1) has already been described in a preliminary report;[19] only the main geometrical features will be recalled for comparison with its congeners.

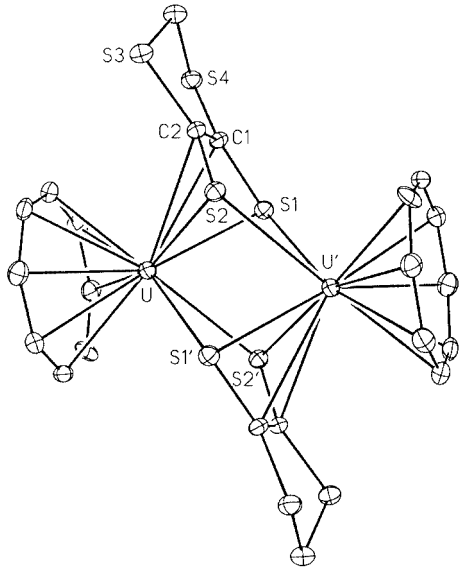

Figure 1. View of the complex [{U(cot)(mdt)}$_2$] (**5**); the hydrogen atoms have been omitted for clarity; the displacement ellipsoids are drawn at the 30% probability level; symmetry code: ′ = − x, 1 − y, − z

The Lewis-base adducts of general formula [U(cot)(dithiolene)(L)$_2$] adopt a four-legged piano-stool configuration, the base of which is defined by the S(1) and S(2) atoms of the dithiolene ligand and the two oxygen [O(1) and O(2)] or the two nitrogen [N(1) and N(2)] atoms of the Lewis base. The structures of **9** (Figure 2), **14** (Figure 3) and **15** (Figure 4), which are representatives of the series, are shown below; selected bond lengths and angles in the complexes [U(cot)(dithiolene)(L)$_2$] are listed in Table 1. Complex **15** has crystallographic mirror symmetry.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

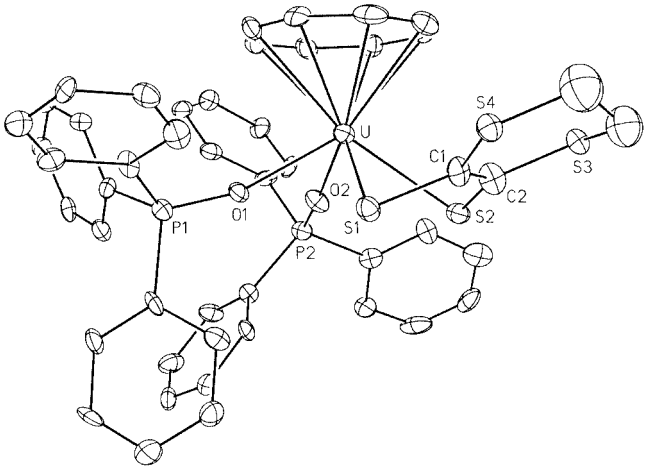

Figure 2. View of the complex [U(cot)(dddt)(tppo)$_2$] (**9**); the hydrogen atoms have been omitted for clarity; the displacement ellipsoids are drawn at the 30% probability level

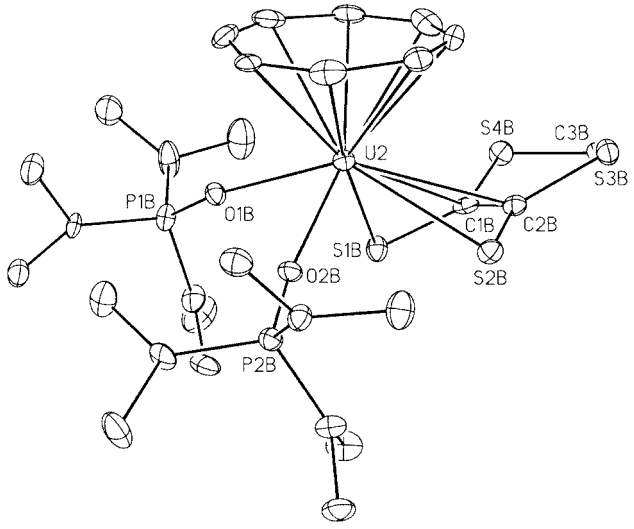

Figure 3. View of one of the two independent molecules of [U(cot)(mdt)(hmpa)$_2$] (**14**); the hydrogen atoms have been omitted for clarity; the displacement ellipsoids are drawn at the 30% probability level

The cot ligand in all the complexes is planar within ±0.09 Å. The average U−C(cot) distances in the Lewis-base adducts [U(cot)(dithiolene)(L)$_2$], with a typical value of 2.71 Å, are longer than that of 2.640(2) Å in **5**, and are at the upper limit of the range of U−C(cot) bond lengths in monocyclooctatetraenyluranium(IV) compounds, which vary from 2.62(2) Å in the bis(thiolate) complex [{U(cot)(S*i*Pr)$_2$}$_2$][7] to 2.71(4) Å in [U(cot)(NEt$_2$)-(THF)$_3$][BPh$_4$].[20]

In the tppo and hmpa adducts, the U−O distances vary from 2.302(8) Å in **13** to 2.444(8) Å in **14** and are unexceptional; they are similar to those of 2.27(1) Å in [U(cot)-(BH$_4$)$_2$(tppo)][21] and 2.461(8) Å in [U(cot)(Cp*)(hmpa)].[22] The U−N distance in **15** [2.555(4) Å] can be compared with those in **8** [2.636(9) and 2.691(10) Å], [U(cot)Cl$_2$(py)$_2$] [2.639(5) and 2.644(6) Å],[23] and to the average U−N(bipy)

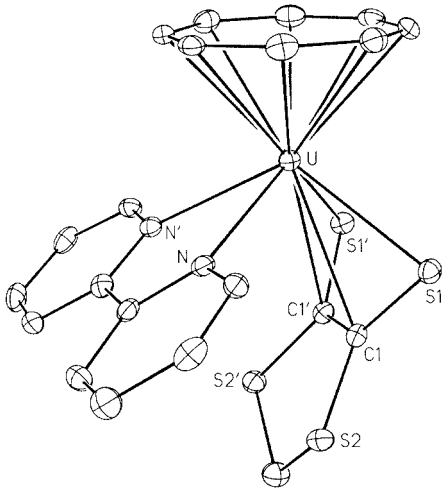

Figure 4. View of the complex [U(cot)(mdt)(bipy)] (**15**); the hydrogen atoms have been omitted for clarity; the displacement ellipsoids are drawn at the 30% probability level; symmetry code: $' = x, 0.5 - y, z$

distance of 2.63(2) Å in [NEt$_4$][U(NCS)$_5$(bipy)$_2$],[24] which is the other uranium(IV)−bipy complex to have been crystallographically characterized. The O(1)−U−O(2) or N(1)−U−N(2) angles are quite similar, with an average value of 75(1)°, except for the N−U−N angle of the bidentate bipy ligand, which is equal to 63.12(19)°.

The U−S distances in the series of [U(cot)(dithiolene)(L)$_2$] complexes vary from 2.720(3) Å in **8** to 2.859(3) Å in **13** and are larger than the U−S bond lengths in the monomeric uranium(IV) thiolate compounds, which range between 2.61(5) Å in [U(S*i*Pr)$_2$(hmpa)$_4$][BPh$_4$][9] and 2.744(2) Å in [Na(18-crown-6)][U(Cp*)$_2$(S)(S*t*Bu)].[10] However, as expected for terminal SR ligands, these distances are shorter than the mean bridging SR bond length of 2.88(8) Å in the dimeric compound **5**. The S(1)−U−S(2) angles in the mononuclear compounds are close to 75°, while they are slightly smaller in **5**, with values of 68.29(6) and 71.98(6)°.

In all the complexes, the characteristics of the dithiolene ligands, such as the average C(sp^2)−S distances, which vary from 1.720(13) Å in **14** to 1.796(17) Å in **9**, and the C=C distances, which lie between 1.343(10) Å in **12** and 1.394(17) Å in **14**, are consistent with those found in [Mo(cp)$_2$(dddt)] [1.76(1) and 1.33(1) Å],[25] [NEt$_4$]$_2$[Ni(dmio)$_2$] [1.75(1) and 1.34(1) Å][26] and [NBu$_4$][Ni(mdt)$_2$] [1.74(2) and 1.36(2) Å].[27]

Special attention should be paid to the folding of the metallacycle as this reflects the interaction of the dithiolene ligand with the metal centre. The S$_4$C$_2$ fragment of the dithiolene ligands is planar within ±0.06 Å and forms a dihedral angle, θ, with the corresponding S−U−S plane. Scheme 3 shows the variation of this folding angle and the distinct conformations of the dithiolene ligands in the complexes. Previous studies on dithiolene compounds of the d-block transition metals have shown that θ increases upon lowering the electron density at the metal atom, reflecting the strength of the interaction of an empty metal orbital

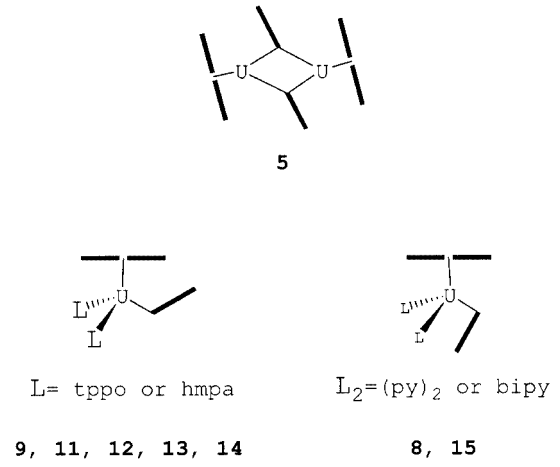
[a] Complexes **9** and **11** crystallize with two THF molecules. [b] Values are given for the two independent molecules. [c] C(1)−C(2) and C(1)−S(4) are C(1)−C(1′) and C(1)−S(2) in complex **15**. [d] θ is the folding angle as defined in the text.



Scheme 3. Conformation of the dithiolene ligands

with the HOMO of the dithiolene ligand.[13,28] For example, in the series of $[M(Cp^*)(dmit)_2]^{-1,0}$ compounds, the d^2 complexes $[M(Cp^*)(dmit)_2]^{-1}$ (M = Mo, W) adopt an *exo-exo* conformation, and the d^0 derivative $[Ti(Cp^*)(dmit)_2]^{-1}$ is found in an *exo-endo* conformation, while the geometry of the d^1 complex $[M(Cp^*)(dmit)_2]^{\cdot}$ (M = Mo, W) compounds is intermediate between those of the Mo^{IV} or W^{IV} and Ti^{IV} analogues.[29]

In the series of Lewis-base adducts [U(cot)(dithiolene)$(L)_2$], the dithiolene ligand is found in the *exo* conformation, except in the pyridine and bipyridine derivatives **8** and **15**. The lower steric hindrance of these nitrogen ligands, in comparison with tppo and hmpa, permits the folding of the US_2C_2 fragment towards the *endo* position, with θ being equal to 75.6(3) and 80.60(5)° in **8** and **15**, respectively; the C(1) and C(2) atoms approach the metal centre at less than 3 Å. With the exception of **14**, the folding angles in the tppo and hmpa adducts are smaller than 75°, and are probably limited by the steric interaction between the dithiolene and cot ligands. One of the two independent molecules of **14** presents a θ angle of 75.97(9)° despite the *exo* conformation of the dithiolene ligand. The low value of θ in the dmio complex **13** [20.93(19)°] seems peculiar since the complexes $[Ti(Cp)_2$(dithiolene)] (dithiolene = dddt, dmio or dmit) exhibit quite similar θ angles of 47−50°.[13,14] However, this distinct feature of **13** might be ascribed to the presence in the crystal structure of weak intermolecular O(3)···H−C interactions[30−32] with four H atoms of the hmpa or cot groups of two neighbouring molecules, with O(3)···H distances in the range 2.621−2.893 Å. The structures of the other neutral dithiolene complexes exhibit weak intermolecular C−H···S contacts, shorter than 3 Å and as low as 2.70 Å; such interactions have been observed in a large number of tetrathiafulvalene derivatives.[33]

The crystal structure of the terpy adduct **16** is shown in Figure 5; selected bond angles and distances are given in Table 2. Complex **16** is a unique example of a distorted octahedral monocyclooctatetraenyluranium compound; the apical positions are occupied by the centroid of the cot ring and the S(2) atom, while S(1) and the three nitrogen atoms of the terpy ligand define the equatorial plane, with a mean deviation of ±0.002 Å. This plane is almost parallel to the planar cot ligand, with a dihedral angle of 4.38(13)°, and the U atom is located between the two planes at a distance of 0.8687(13) and 2.0148(15) Å, respectively. The planar dithiolene ligand is practically perpendicular to both the cot ring and equatorial plane, with dihedral angles of 88.93(7) and 84.72(5)°, respectively. The long U−S distances of 2.8203(10) and 2.8304(10) Å and the small folding angle, θ, of 20.40(4)° reflect the electronic and steric saturation of

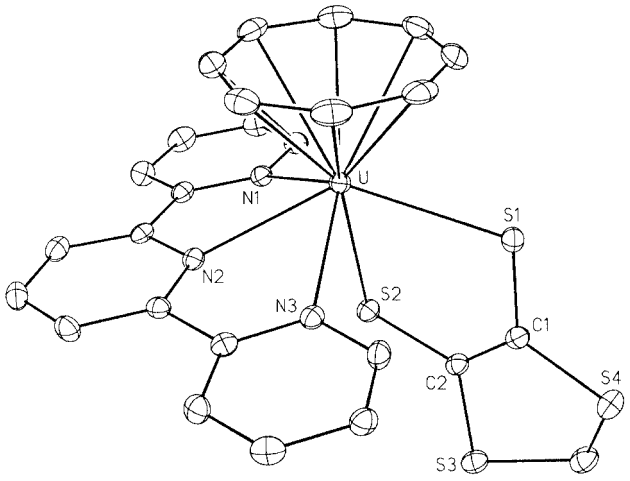

Figure 5. View of the complex [U(cot)(mdt)(terpy)] (**16**); the hydrogen atoms and solvent molecules have been omitted for clarity; the displacement ellipsoids are drawn at the 30% probability level

the complex. The average U−N distance of 2.589(9) Å can be compared with that of 2.63(3) Å in the U^{III} cation $[U(terpy)_3]^{3+}$, the other terpyridine uranium complex to have been crystallographically characterized.[34]

Dynamic Behaviour of the Complexes in Solution

The ^{1}H NMR spectroscopic data of the complexes are reported in Table 3. Complex **9** is not soluble in THF, while **15** and **16** are not soluble in THF or pyridine; their NMR spectra could therefore not be recorded. The spectra of the tppo and hmpa adducts in pyridine are more complicated, showing partial substitution of the L ligands by solvent molecules. At 20 °C, the cot ligand in all the complexes gives rise to a signal at $\delta \approx -30$ ppm, characteristic of monocyclooctatetraenyluranium compounds.[7,15,21,35] Two signals of equal intensities corresponding to the magnetically non-equivalent methylene protons of the dddt and mdt ligands in the Lewis-base adducts [U(cot)(dithiolene)$(L)_2$] are visible at 20 °C, or at lower temperature in the case of **12**, as already observed for **6** and **8**.[19] Coalescence of these resonances occurred upon increasing the temperature, and the fast limit spectrum was obtained for complex **12**.

The dynamic behaviour of the complexes can be ascribed to the dithiolene ring inversion represented in Scheme 4; a similar fluxionality has been observed in a variety of [M$(Cp)_2$(dithiolene)] compounds.[13,14] The ring inversion should proceed via the trigonal bipyramidal intermediate (**A** in Scheme 4) which renders the methylene protons equivalent. It is conceivable that, for the sterically less saturated complexes **6** and **8**, the octahedral intermediate [U(cot)(di-

A

Scheme 4. Ring inversion process of the dithiolene ligand

thiolene)(py)$_3$], with a structure similar to that of the terpy adduct **16**, should be involved in the reaction. However, such an associative mechanism is not likely for the other Lewis-base adducts, since addition of tppo or hmpa has no influence on the fluxional process. The coalescence temperatures, T_c, and the activation energies, $\Delta G^{\ddagger}$, for the dithiolene ring inversion process are given in Table 4. The values of $\Delta G^{\ddagger}$ are in the range of those calculated for the [Ti(Cp)$_2$(dithiolene)] compounds, which vary from 40.5 to 69 kJ·mol^{-1} when the dithiolene is $S_2C_2(CN)_2$ and mdt, respectively;[14] they can also be compared with those measured for the metallacyclopentene ring inversion in bis(cyclopentadienyl)diene complexes of group 4 metals and actinides.[36] In the (dithiolene)titanium compounds, a correlation was found between the activation energy $\Delta G^{\ddagger}$ and the folding angle θ.[14] However, in the [U(cot)(dithiolene)(L)$_2$] derivatives, the variation of $\Delta G^{\ddagger}$ seems better related to the steric congestion of the complex and the difficulty of the ligands to rearrange around the metal centre. The lower barrier in the dddt compounds **6** and **12**, by comparison with the mdt analogues **8** and **14**, respectively, would correspond to a greater steric interaction between the dithiolene and L ligands in the ground state of the complex.

Table 4. Coalescence temperatures and activation energies for the ring-inversion process

Conclusion

We have prepared a series of Lewis-base adducts of general formula [U(cot)(dithiolene)(L)$_n$] (n = 1, L = bipy or terpy and dithiolene = mdt; n = 2, L = tppo or hmpa and dithiolene = dddt, dmio, mdt). Crystallographic and NMR studies revealed that the solid-state structure and dynamic behaviour of these dithiolene complexes of an f-block element are similar to those of the d-block transition metal analogues, in particular the mixed cyclopentadienyl/dithiolene derivatives. The interaction between the dithiolene ligand and the metal centre observed in the solid state is favoured with the sterically less demanding Lewis bases which allow an *endo* conformation of the ligand. Still, the characteristics of the dithiolene ligands, such as the average C(sp^2)−S and C=C distances, are not greatly influenced by the nature of the Lewis base. In the whole series, the variable temperature ^{1}H NMR spectra show the fluxionality of the complexes due to the facile dithiolene ring inversion.

Experimental Section

General Remarks: All reactions were carried out under argon (<5 ppm oxygen or water) using standard Schlenk and vacuum-line techniques or in a glove box. Solvents were dried by standard methods and distilled immediately before use. The ^{1}H NMR spectra were recorded with a Bruker DPX 200 instrument and referenced internally using the residual protio solvent resonances relative to tetramethylsilane (δ = 0 ppm). Elemental analyses were performed by Analytische Laboratorien at Lindlar (Germany). [U(cot)(BH$_4$)$_2$],[21] [U(cot)I$_2$(THF)$_2$],[37] dddtCO,[38] dmioCO[39] and Na$_2$dddt[13] were prepared by published methods. The syntheses of **3**, **4**, **5** and **8** were described in our previous paper.[19]

Synthesis of [U(cot)(dddt)(py)$_2$] (6) and [U(cot)(dmio)(py)$_2$] (7): These complexes were obtained by dissolving **3** and **4**, respectively, in pyridine. After concentration to dryness, a dark-red powder of **6** and a brown powder of **7** were obtained in almost quantitative yield.

Synthesis of [U(cot)(dddt)(tppo)$_2$] (9): An NMR tube was charged with **3** (5.0 mg, 4.6 μmol) and tppo (2.6 mg, 9.2 μmol) in [D$_8$]THF (0.4 mL). Upon standing at 50 °C for 2−3 d, red crystals of **9** suitable for X-ray analysis were deposited.

Synthesis of [U(cot)(dmio)(tppo)$_2$] (10): An NMR tube was charged with **4** (5.0 mg, 4.8 μmol) and tppo (5.3 mg, 19.1 μmol) in [D$_8$]THF (0.4 mL). After 1 h at 20 °C, the spectrum of the brown solution showed the quantitative formation of **10**.

Synthesis of [U(cot)(mdt)(tppo)$_2$] (11). (a): An NMR tube was charged with **5** (5.0 mg, 4.9 μmol) and tppo (5.5 mg, 19.6 μmol) in [D$_8$]THF (0.4 mL). After standing at 65 °C for 3 h, brown crystals of **11** suitable for X-ray analysis were deposited. **(b):** A flask was charged with [U(cot)(BH$_4$)$_2$(THF)] (113 mg, 0.254 mmol) and tppo (142 mg, 0.51 mmol) in THF (25 mL). The reaction mixture was stirred at 20 °C for 15 min and a solution of dmioCO (53 mg, 0.254 mmol) in THF (10 mL) was added to the flask. After refluxing for 3 h, the solution was filtered and the solvents were evaporated to dryness, leaving a brown powder of **11** (276 mg, 90%). **11**·2THF, $C_{55}H_{56}O_4P_2S_4U$ (1209.3): calcd. C 54.63, H 4.67, S 10.61; found C 54.45, H 4.50, S 10.78.

Synthesis of [U(cot)(dddt)(hmpa)$_2$] (12): An NMR tube was charged with **3** (5.0 mg, 4.8 μmol) in [D$_8$]THF (0.4 mL) and hmpa (3.3 μL, 19.1 μmol) was introduced with a microsyringe. After 1 h at 20 °C, the spectrum of the red solution showed the quantitative formation of **12**. After standing at 20 °C overnight, red crystals of **12** suitable for X-ray analysis were deposited. $C_{24}H_{48}N_6O_2P_2S_4U$ (880.93): calcd. C 32.72, H 5.49, S 14.56; found C 32.59, H 5.51, S 14.41.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Synthesis of [U(cot)(dmio)(hmpa)$_2$] (13): A flask was charged with [U(cot)(BH$_4$)$_2$(THF)] (208 mg, 0.56 mmol) and hmpa (201 mg, 1.12 mmol) in THF (30 mL) and dmioCO (233 mg, 1.12 mmol) was added to the solution. After stirring at 20 °C for 24 h, the solution was filtered and the solvents were evaporated to dryness. The dark-red powder of **13** was washed with diethyl ether (50 mL), THF (20 mL) and dried under vacuum (460 mg, 93%). $C_{23}H_{44}N_6O_3P_2S_4U$ (880.88): calcd. C 31.36, H 5.03, S 14.56; found C 31.13, H 5.03, S 14.39.

Synthesis of [U(cot)(mdt)(hmpa)$_2$] (14): An NMR tube was charged with **5** (5.0 mg, 4.9 μmol) in [D$_8$]THF (0.4 mL) and hmpa (3.4 μL, 19.6 μmol) was introduced with a microsyringe. After 1 h at 65 °C, the spectrum of the brown solution showed the quantitative formation of **14**. After standing at 65 °C overnight, the tube was allowed to cool to room temperature and red crystals of **14** suitable for X-ray analysis were deposited.

Synthesis of [U(cot)(mdt)(bipy)] (15): An NMR tube was charged with **5** (21.0 mg, 20.6 μmol) and bipy (6.4 mg, 41.2 μmol) in [D$_8$]THF (0.4 mL). After standing at 5 °C overnight, dark brown crystals of **15** suitable for X-ray analysis were deposited. $C_{21}H_{18}N_2S_4U$ (664.68): calcd. C 37.95, H 2.73, S 19.30; found C 38.10, H 2.85, S 19.05.

Synthesis of [U(cot)(mdt)(terpy)] (16): An NMR tube was charged with **5** (10.0 mg, 9.8 μmol) and terpy (4.6 mg, 19.6 μmol) in [D$_8$]THF (0.4 mL). After standing at 5 °C overnight, dark-brown crystals of **16** suitable for X-ray analysis were deposited. $C_{26}H_{21}N_3S_4U$ (741.76): calcd. C 42.10, H 2.85, S 17.29; found C 41.92, H 2.96, S 17.06.

X-ray Crystallography: The data were collected at 100(2) K with a Nonius Kappa-CCD area-detector diffractometer[40] using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The crystals were placed inside glass capillaries with a protecting "Paratone-N" oil (Hampton Research) coating. The unit-cell parameters were determined from ten frames, then refined on all data. A 180° φ-range was scanned with 2° steps during data collection, with a crystal-to-detector distance fixed at 28 mm, giving complete data sets up to an angle, θ_{max}, of 25.7°. The data were processed with DENZO-SMN.[41] The structures were solved by direct methods with SHELXS-97 and subsequent Fourier-difference synthesis and refined by full-matrix least squares on F^2 with SHELXL-97.[42] Absorption effects were corrected empirically with the program DELABS from PLATON.[43] The correct enantiomorph in compound **13** was determined from the Flack parameter [−0.020(10)].[44] Three compounds crystallize as solvates: **9** and **11** with two tetrahydrofuran molecules and **16** with 1.5 pyridine molecules. A second form of compound **11**, with only one tetrahydrofuran solvent molecule, has been isolated and characterized [crystal data: $C_{51}H_{48}O_3P_2S_4U$, M = 1137.10, triclinic, space group $P\bar{1}$, a = 12.5818(13), b = 12.7381(13), c = 16.4223(14) Å, α = 71.253(6)°, β = 72.669(6)°, γ = 72.573(4)°, V = 2318.0(4) Å^3, Z = 2, D_c = 1.629 g·cm^{-3}, μ = 3.793 mm^{-1}, F(000) = 1128]. As it is essentially similar to the first form, it is not further described here. Some disorder is present in several complexes. In **9**·2THF, the atoms C(3) and C(4) of the dithiolene ligand may be disordered, but the different positions are not resolved and these atoms have been refined with restraints on bond lengths and displacement parameters. In **16**·1.5py, one pyridine solvent molecule is disordered around a symmetry centre and the nitrogen atom has not been located. All non-hydrogen atoms were refined with anisotropic displacement parameters, with some restraints on bond lengths and/or displacement parameters for some disordered or badly behaving atoms, particularly in the solvent molecules. Hydrogen atoms were introduced at calculated positions and were treated as riding atoms with

a displacement parameter equal to 1.2 (CH, CH_2) or 1.5 (CH_3) times that of the parent atom. Some short H···H contacts in **11**·2THF involve the protons of disordered parts or of badly behaving solvent molecules. Some short intramolecular contacts in **14** and **16**·1.5py (lower value 2.98 Å), which involve carbon atoms of the cot moiety and S, O or N donor atoms, are likely the result of the steric congestion in these molecules. The large positive and negative residual electron density peaks in **14** are located at 1.32 and 0.95 Å, respectively, from the uranium atom U(1) and may result from an imperfect absorption correction. Crystal data and structure refinement details are given in Table 5. The molecular plots were drawn with SHELXTL.[45] All calculations were performed with a Silicon Graphics R5000 workstation. CCDC-238470 (**9**·2THF), -238471 (**11**·2THF), -238472 (**12**), -238473 (**13**), -238474 (**14**), -238475 (**15**), -238476 (**16**·1.5py) and -238477 (**11**bis) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Structural Variety and Multiple Isomerism in 1-(Dimethylamino)propyl-2-chalcogenolate and 2-(Dimethylamino)propyl-1-chalcogenolate Complexes of Palladium(II) and Platinum(II): Synthesis, Spectroscopy and Structures

Sandip Dey,[a] Liladhar B. Kumbhare,[a] Vimal K. Jain,*[a] Thilo Schurr,[b] Wolfgang Kaim,*[b] Axel Klein,*[b] and Ferdinand Belaj[c]

Keywords: Chalcogens / Isomers / N ligands / Palladium / Platinum

Isomeric dichalcogenides $[Me_2NCH(Me)CH_2E]_2$ $[(N^{\frown}E^{**})_2]$ and $[Me_2NCH_2CH(Me)E]_2$ $[(N^{\frown}E^{*})_2]$ (E = S, Se, Te) have been obtained by the reactions of NaSH or M'_2E_2 (M′ = Na or K) with $Me_2NCH_2CHMeCl$. The former reaction affords mainly $(N^{\frown}E^{**})_2$ (E = S) while from the latter mixtures of $(N^{\frown}E^{**})_2$ and $(N^{\frown}E^{*})_2$ [referred to as $(N^{\frown}E)_2$, E = S, Se, Te] were isolated, the ratios in the mixtures depending on the chalcogen. Reactions of $(N^{\frown}E)Na$ with $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ gave complexes $[MCl(N^{\frown}E)(PR_3)]$ (M = Pd or Pt). These chiral, mixed-ligand complexes have been characterised by elemental analysis, IR, UV/Vis and NMR (^1H, ^{13}C, ^{31}P, ^{77}Se, ^{125}Te, ^{195}Pt) spectroscopy, and, in part, by X-ray structure analysis. The complexes display a typical pattern of mutually *trans*-oriented neutral (P and N) and anionic (Cl and E) donor atoms in an approximately square-planar environment. In contrast to the platinum(II) analogues, the X-ray structures of the complexes $[PdCl(N^{\frown}E)(PMePh_2)]$ (E = S or Se) revealed both a conformational isomerism of the five-membered chelate ring and, for Se, the co-crystallisation of complexes with both the $N^{\frown}E^{*}$ and $N^{\frown}E^{**}$ isomeric ligands. The thermal behaviour of some complexes has been investigated.

Introduction

The chemistry of metal chalcogenolates continues to be an active area of research. Their emerging application as single-source precursors for low-decomposition-temperature synthesis of solid-state chalcogenide materials has provided a further momentum to this activity.[1−4] The chemistry of the heavier metal chalcogenolates is dominated by thiolate complexes, which are often isolated as non-volatile, insoluble (or sparingly soluble) polymers.[5] One of the strategies to suppress polymerisation has been to use internally functionalised ligands.[3] Among such ligands are (aminoalkyl)chalcogenolate ions $R_2N(CR_2')_nE^-$. While the chemistry of mercaptoalkylamines is now fairly well documented,[6−12] the heavier analogues containing Se and Te have been more recently developed and investigated by us.[13−17] Subtle variations in either the carbon chain length of the ligand or in the auxiliary ligands at the metal centre have led to the isolation of complexes with quite varied structural patterns. Some of these complexes also provided an opportunity to study metal-mediated donor−acceptor interactions between coordinated ligands.[14,15]

A new series of (aminoalkyl)chalcogenolate ligands with asymmetrically substituted carbon atoms in the alkyl chain was conceived for the following reasons: (i) chiral thiolate complexes such as the recently reported $[PdCl\{SCH_2CH(COOEt)NH_2\}(PPh_3)]$ are useful asymmetric homogeneous catalysts;[12,18−20] (ii) the cleavage of secondary chalcogenolates often proceeds more cleanly than that of primary or tertiary analogues;[21] (iii) the influence of electron-releasing methyl groups on donor−acceptor interactions in metal complexes can be studied.[14,15]

In this perspective, 2-[(dimethylamino)propyl]-1-chalcogenolate ($N^{\frown}E^{**}$) (**A**) and 1-[(dimethylamino)propyl]-2-chalcogenolate ($N^{\frown}E^{*}$) (**B**) ligands have been synthesised, and their chemistry with palladium(II) and platinum(II) has been explored. The results of this work are described in this paper.

Results and Discussion

Synthesis of Dichalcogenides

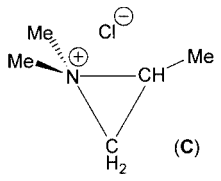
Two general reactions [Equations (1) and (2)] have been employed for the synthesis of the dichalcogenides. The disulfide formed by the reaction according to Equation (1) was isolated mainly as a single rearranged product $[Me_2NCH(Me)CH_2S]_2$ $(N^{\cap}E^{**})_2$, whereas the raction according to Equation (2) gave a mixture of $[Me_2NCH(Me)CH_2E]_2$ $(N^{\cap}E^{**})_2$ (E = S, Se, Te) and $(Me_2NCH_2CH(Me)E]_2$ $(N^{\cap}E^{*})_2$ (E = S, Se, Te). The relative amounts of $(N^{\cap}E^{**})_2$ and $(N^{\cap}E^{*})_2$ are chalcogen-dependent: the ratios were 1:2 for E = S, approx. 1:1 for E = Se, and 5:1 for E = Te (from ^{1}H NMR integration).

$$Me_2N\text{-}CH_2\text{-}CHMeCl \xrightarrow[-\ NaCl]{+\ NaSH} Me_2N\text{-}CHMe\text{-}CH_2\text{-}SH$$

$$\xrightarrow[-\ 1/2\ H_2O]{+\ 1/4\ O_2} 1/2\ (Me_2N\text{-}CHMe\text{-}CH_2S)_2 \qquad (1)$$

$$2\ Me_2N\text{-}CH_2\text{-}CHMeCl \xrightarrow[-\ NaCl\ /\ KCl]{+\ Na_2E_2\ /\ K_2Te_2} (Me_2N\text{-}CHMe\text{-}CH_2\text{-}E)_2 + (Me_2N\text{-}CH_2\text{-}CHMe\text{-}E)_2 \qquad (2)$$

Several factors have been identified which influence the product formation in nucleophilic substitution reactions of alkyl halides. In the present case, the participation of a nucleophilic neighbouring group (NMe_2) is believed to play an essential role to produce the *C*-methylaziridinium species **C** as a possible intermediate. In **C**, the less substituted carbon atom (i.e. the CH_2 group) seems to be the preferred site of attack by a nucleophile such as HS^- in the reaction according to Equation (1) as it is sterically less encumbered and electronically more positive. Accordingly, an isomerized product $[Me_2NCH(Me)CH_2S]_2$ (type **A**) could be isolated from the reaction according to Equation (1). The reaction according to Equation (2) is carried out using M_2E_2 in DMF. The nucleophiles E_2^{2-} and RE_2^- as intermediates in a solvent such as DMF may attack either of the carbon centres (CH_2 or CHMe) leading to the formation of different products. Their formation in different ratios reflects the differing nucleophilic character of anionic S, Se, or Te. Cyclic intermediates similar to **C** with various heteroatoms (e.g, N, O, S) are commonly invoked in organic reactions. The cleavage of the N−C bond in C-substituted aziridines or aziridinium ions frequently leads to isomerized products.[22]



(C)

The ^{1}H and ^{13}C NMR spectra of the disulfide obtained from reaction according to Equation (1) display only one set of resonances attributable to $[Me_2NCH(Me)CH_2S]_2$ $(N^{\cap}S^{**})_2$. However, the spectra of the dichalcogenides prepared from the reaction according to Equation (2) exhibit two sets of resonances which can be assigned to mixtures [referred to as $(N^{\cap}E)_2$].

The corresponding ^{77}Se (Figure 1) and ^{125}Te NMR spectra show eight and four lines, respectively. The molecules R_2E_2 (E = O, S, Se, Te) have a "skew" structure and can show restricted rotation about the E−E bond. For the molecules $(N^{\cap}E^{**})_2$ and $(N^{\cap}E^{*})_2$ three stereoisomers — (*R*,*R*), (*S*,*S*) and a *meso* form — are expected. Thus, each molecule is expected to display two resonances [(*R*,*R*)/(*S*,*S*) and *meso*] for the chalcogen atom in the ^{77}Se or ^{125}Te NMR spectrum. The resonances at $\delta = -791$ and -559 ppm and $\delta = -870$ and -659 ppm in the ^{125}Te NMR spectra may be assigned to molecules $(N^{\cap}Te^{*})_2$ and $(N^{\cap}Te^{**})_2$. Similarly, resonances at $\delta \approx 226$ and 357 ppm and $\delta \approx 286$ and 415 ppm in the ^{77}Se NMR spectra can be attributed to $(N^{\cap}Se^{*})_2$ and $(N^{\cap}Se^{**})_2$. However, each signal in the ^{77}Se NMR spectrum appears as two closely spaced lines (ca. 1 ppm separation). The presence of intramolecular interactions between nitrogen and selenium atoms may lead to the magnetic nonequivalence of the two selenium atoms in each molecule, resulting in two separate but closely spaced resonances. Recently, intramolecular Se···N interactions have been reported in several diselenides.[23−25] The Se···N distances of about 2.8 Å in these compounds are longer than the sum of the covalent radii, but significantly shorter than the sum of the corresponding van der Waals radii (ca. 3.5 Å).[23−25] For instance, the atomic distances Se(1)−N(1) and Se(2)−N(2) in **D** are 2.819(5) and 2.705(5) Å, respectively.[24] For the same reasons one would anticipate an analogous pattern for the ^{125}Te NMR spectrum. However, relatively large line widths [ca. 100 Hz (1 ppm)] for the ^{125}Te resonances appear to preclude a visible separation of closely spaced signals.

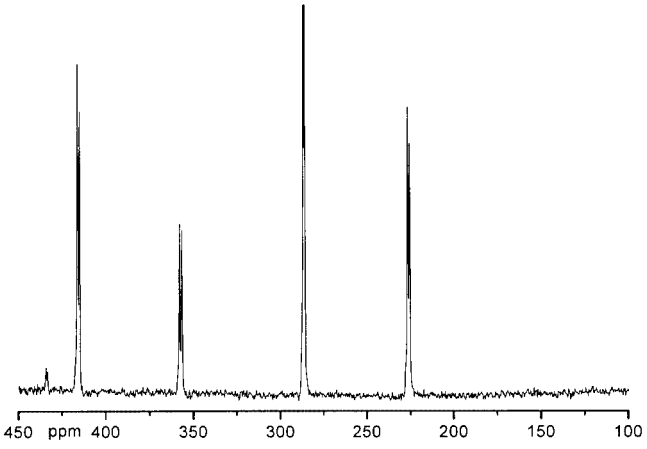


Figure 1. ^{77}Se{^{1}H} NMR spectrum of $(N^{\cap}Se)_2$ [mixture of $(N^{\cap}Se^{**})_2$ and $(N^{\cap}Se^{*})_2$] in $CDCl_3$

[a] Measured in CDCl3. [b] ^1J(^{195}Pt,^{31}P) in Hz in parentheses. [c] Separate signals not resolved. [d] Minor product. [e] Major product. [f] The ^{31}P NMR spectrum shows an additional small resonance at δ = −1.3 ppm ($^1J_{Pt,P}$ = 3103 Hz). [g] The ^{31}P NMR spectrum shows an impurity of [PdCl$_2$(PPh$_3$)$_2$] at δ = 23.8 ppm (ca. 10%).

proton resonances appear as two doublets of equal intensity due to $^4J_{P,H}$ coupling. However, the spectra of those complexes synthesised with ligands obtained from the reaction according to Equation (2) show two sets of resonances for the organochalcogenolate fragments and for the phosphane methyl protons (if present). Each set of resonances can be assigned to N∩E** (**A**) and N∩E* (**B**) ligand protons. The NMe_2 proton signals for both isomers appear as two separate doublets with $^4J_{P,H} \approx 3$ Hz. The appearance of two doublets for the NMe_2 protons suggests that the methyl groups are diastereotopic in both the isomers, possibly due to the asymmetric carbon centre in the chalcogenolate moiety. In contrast, the complexes [MCl(ECH$_2$CH$_2$NMe$_2$)(PR$_3$)] show only one doublet for the NMe_2 protons.[13−15]

The ^{31}P{^{1}H} (Figure 2), ^{77}Se{^{1}H} (Figure 3) and ^{195}Pt{^{1}H} NMR spectra (Figure 4) of compounds [MCl(N∩E)(PR$_3$)] (E = Se or Te; Tables 1 and 2) and the thiolate complex [PdCl(N∩S)(PMePh$_2$)], display two sets of resonances. For the (*R*) and (*S*) forms (**E**−**H**) of each stereoisomer one set of resonances is observed. The $^1J_{Pt,P}$ coupling constants for the two resonances (from ^{31}P and ^{195}Pt NMR spectra) are of the same magnitude and are thus indicative of a similar configuration. The magnitude of $^1J_{Pt,P}$ for the platinum complexes suggests that the phosphane ligand is *trans* to the nitrogen atom. The values of $^1J_{Pt,P}$ can be compared with those observed for analogous complexes derived from achiral ligands.[13−15] The two sets of resonances in the

Electronic Spectra

Like the analogous achiral derivatives,[14,15,27] the absorption spectra (Table 3) of the complexes $[MCl(N^{\cap}E)(PR_3)]$ display very weak long-wavelength bands. These absorptions are slightly red-shifted when compared with the corresponding achiral complexes. While the absorptions of the platinum complexes are blue-shifted in comparison to the palladium analogues, the selenium- and especially the tellurium-containing compounds absorb at lower energies than the corresponding sulfur analogues. Replacement of a methyl substituent by a phenyl group in PR_3 leads to a bathochromic shift.

[a] Wavelengths, λ_{max}, at the absorption maxima in nm; molar extinction coefficients, ε, in $M^{-1}\cdot cm^{-1}$ (in parentheses). [b] Ligand prepared by the Na_2S_2 route.

Such weak long-wavelength absorptions have been attributed for similar complexes to ligand (E) to ligand (PR_3) charge-transfer (L′LCT) transitions, based on DFT calculations.[14,15] The results presented here are fully in line with this assignment.[14,15,26]

Crystal Structure Analysis

The molecular structures of [PdCl(N∩S**)(PMePh$_2$)], [PtCl(N∩S**)(PMe$_2$Ph)], the isostructural complex [PtCl(N∩Se**)(PMe$_2$Ph)] and two molecules from a crystal of [PdCl(N∩Se)(PMePh$_2$)] were unambiguously established by single-crystal X-ray diffraction analyses.

The compounds were found to crystallise in the space group $P2_1$ with the exception of [PdCl(N∩S**)(PMePh$_2$)] ($P\bar{1}$). The quality of the obtained data was excellent for [PdCl(N∩S**)(PMePh$_2$)], [PtCl(N∩S**)(PMe$_2$Ph)] and [PtCl(N∩Se**)(PMe$_2$Ph)] and moderate for [PdCl(N∩Se)(PMePh$_2$)] (see Exp. Sect.). No significant intermolecular contacts were found in any of the crystal structures. Selected bond lengths and angles for the molecules are given in Table 4, crystallographic and refinement data are given in Table 5.

The coordination environments around the central metal atom in each molecule are approximately square-planar, defined by the P, Cl, N and E atoms. The strong donor atoms E and P are oriented *cis* to each other to avoid an unfavourable *trans* interaction. Such a configuration with *trans*-oriented neutral (P and N) and anionic (Cl and E) donor atoms has also been reported for several related achiral complexes.[13−15,26]

The five-membered chelate rings exhibit a twist conformation which, combined with the presence of the methyl substituent, gives rise to two conformations, **I** and **J**, with different configurations at the asymmetric carbon [(*R*) for **I** and (*S*) for **J**]. For three compounds — both platinum complexes and [PdCl(N∩S**)(PMePh$_2$)] — the crystals analysed contained exclusively Me$_2$NCH(Me)CH$_2$E (E = S or Se) ligands (N∩E**), whereas complexes with both isomeric ligands N∩Se* and N∩Se** had co-crystallised in [PdCl(N∩Se)(PMePh$_2$)]. The crystals of [PdCl(N∩S**)-(PMePh$_2$)] (Figures 5 and 6) contain two crystallographically independent molecules, both of which show a disorder according to the conformations **I** and **J**. The structure was best refined using 45% and 55% occupancy for the two conformers, respectively (see Figure 6). For the platinum

homologue [PtCl(N∩S**)(PMe$_2$Ph)] only one kind of molecule with conformation **J** (see Figure 7) was found in the crystal. The C(1) atom in this molecule shows some distortion according to a possible disorder. However, attempts to introduce the same disorder as observed for the palladium analogue or refining the structure in triclinic space groups failed. The C(2) atom does not show any sign of disorder; the extended thermal ellipsoid of C(1) can thus be attributed to a molecular vibration.

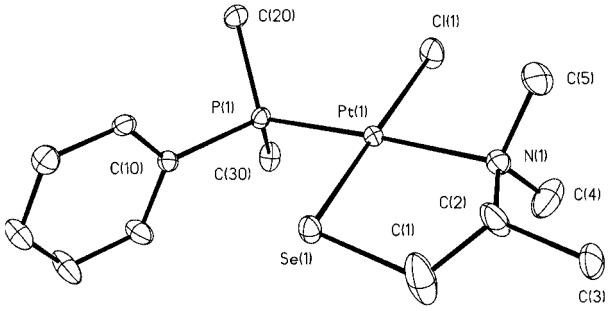

Figure 7. Molecular structure of [PtCl(N∩Se**)(PMe$_2$Ph)] with 30% thermal ellipsoids; H atoms have been omitted for clarity; the sulfur analogue [PtCl(N∩S**)(PMe$_2$Ph)] looks essentially the same

The crystals of [PtCl(N∩Se**)(PMe$_2$Ph)] also contain only one molecule, which clearly shows conformation **J** (Figure 7). In contrast, the palladium derivative [PdCl(N∩Se)(PMePh$_2$)] was found to contain both isomeric ligands N∩Se* and N∩Se**. One of the two independent molecules found in the unit cell contains the ligand Me$_2$NCH(Me)CH$_2$Se$^-$ (N∩Se**) and exhibits the disorder described by conformations **I** and **J** (Figure 8). This has also been observed for the sulfur analogue. The other complex molecule, which contains the isomeric ligand Me$_2$NCH$_2$CH(Me)Se$^-$ (N∩Se*; Figure 9), exists exclusively

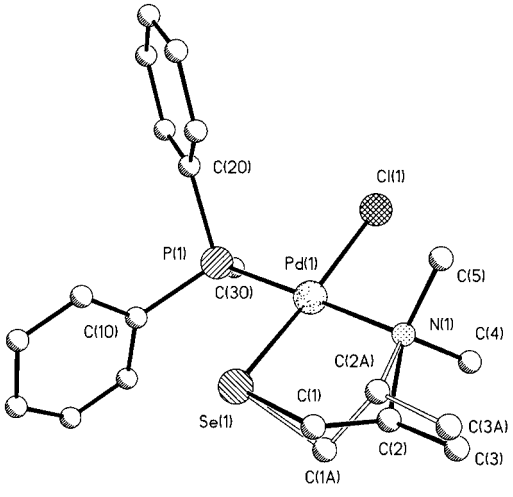

Figure 8. Molecular structure of the disordered (**I**/**J**) molecule 1 in [PdCl(N∩Se)(PMePh$_2$)] (N∩Se** isomer)

as one conformer (similar to **J**). Attempts to introduce disorder models to this molecule were unsuccessful.

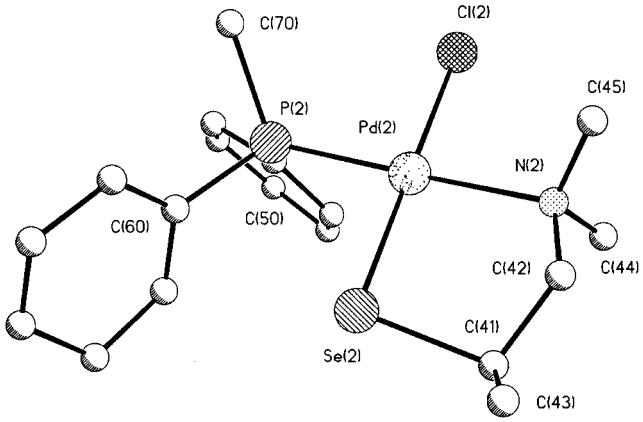

Figure 9. Molecular structure of molecule 2 in [PdCl(N∩Se)(PMePh$_2$)] (N∩Se* isomer)

The coordination planes around the metal atoms in these complexes exhibit only small tilt angles (N−M−E/Cl−M−P), ranging between 2.5 and 4.9°. The N−M−P and Cl−M−E angles are only slightly below 180° (Table 4). The metal−ligand distances are all longer for the palladium complexes than for the platinum homologues. This has also been found in related studies[14,27−29] and is attributed to the lanthanide contraction and relativistic effects.[29] The M−N and M−Cl distances are slightly longer than those reported in [M$_2$Cl$_2$(μ-Me$_2$pz)$_2$(PR$_3$)$_2$][30,31] owing to the strong *trans* influence of PR$_3$ and E (E = S or Se) donors. The M−E, M−P, M−N and M−Cl distances and various angles around the metal centre are similar to those reported for [MCl(ECH$_2$CH$_2$NMe$_2$)(PR$_3$)] complexes.[13−15,26]

In summary, it is remarkable that the two crystallised platinum complexes both contain exclusively the same conformer **J** [(*S*) enantiomer]; the two palladium derivatives are nonselective in this respect, showing disorder in the chelate ring according to both conformers in the crystal. For the selenium derivative [PtCl(N∩Se**)(PMe$_2$Ph)] multiple selectivity is observed for the molecules in the crystal: (i) regioselectivity of the ligands Se, Cl, P and N around the metal atom; (ii) the crystal contains only one regioisomer (N∩Se**) although the compound was prepared using regioisomeric mixed ligands; (iii) from the two possible conformers arising from the twist of the chelate ring only one conformer (enantiomer) is found in the crystal.

Thermal Studies

The thermal behaviour of some of the complexes has been evaluated to assess their suitability as molecular precursors for the synthesis of metal chalcogenides. The TG curve of [PdCl(N∩S**)(PMePh$_2$)] (Figure 10) shows a three-step decomposition, finally leading to Pd$_4$S at 374 °C. The first two stages are overlapping steps which account for 70% of the weight loss. This weight loss can be attributed to elimination of phosphane, organic residue and the chloride ligand with the formation of PdS. There is further loss of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sulfur at 374 °C, resulting in the formation of Pd_4S which remains stable up to 500 °C. To prepare bulk quantities, a sufficient amount of [PdCl(N∩S**)(PMePh$_2$)] (128 mg) was heated at 400 °C in a furnace and the residue (35 mg, 30 mg calcd. for Pd_4S) was annealed for 2 h. The X-ray powder pattern of this residue corresponds to that of Pd_4S[32] (JC,PDS-10-335; analysis: found C 4.7, H ca. 0.2, N ca. 0.2%). Decomposition of [PdCl(N∩Se)(PMePh$_2$)] (107 mg) at 350 °C in a furnace gave a bulk residue (35 mg, 37 mg calcd. for $Pd_{17}Se_{15}$), identified as $Pd_{17}Se_{15}$ from the XRD pattern (JC,PDS-29-1427; analysis: found C 2.6, H ca. 0.2, N ca. 0.2%). The TG curve of [PtCl(N∩S**)(PMe$_2$Ph)] shows a two-step decomposition, the first step occurring at 265 °C being attributed to the loss of the phosphane ligand by the weight loss (obsd. 26%, calcd. 28%). The second step leads to the formation of PtS at 374 °C.

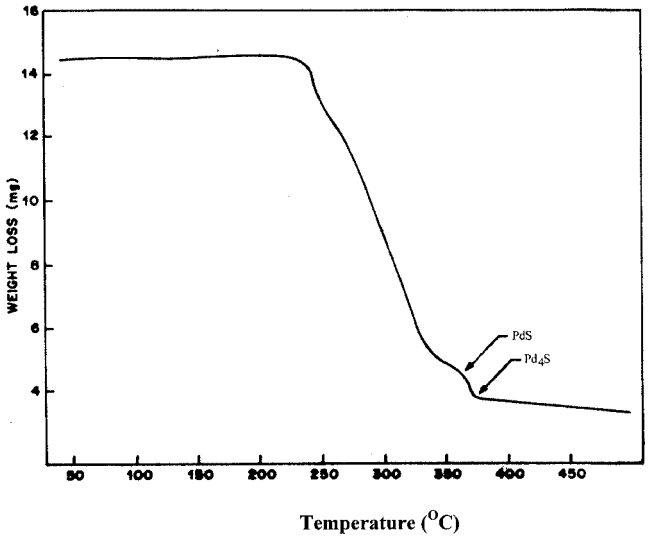

Figure 10. TG curve of [PdCl(N∩S**)(PMePh$_2$)]

Conclusion

This report illustrates how, by NMR spectroscopy and partial crystal structure analysis, the attempts to obtain aminochalcogenolate chelate ligands with an asymmetrically substituted carbon atom lead to regioisomeric dichalcogenide precursor molecules. In the chiral metal complexes [MCl(N∩E)(PR$_3$)] (M = Pt, Pd) the neutral (P and N) and charged donor atoms (Cl and E) were invariably found *trans* to each other. Further conformational isomerism in these complexes results from the twisted chelate rings. Whereas the two crystallised platinum complexes [PtCl(N∩S**)-(PMe$_2$Ph)] and [PtCl(N∩Se**)(PMe$_2$Ph)] exhibit exclusively one conformer (enantiomer), the palladium derivatives were nonselective, showing disorder in the chelate ring according to both conformers in the crystal. The regio- and enantioselectivity in the case of the selenium derivative [PtCl(N∩Se**)(PMe$_2$Ph)] is highly remarkable since the compound was prepared using a regioisomerically mixed ligand. Despite these various possibilities of constitutional, positional and conformational isomerism the isolated compounds were found to be sufficiently stable to be used as molecular precursors for metal chalcogenide phases.

Experimental Section

General: The complexes [M$_2$Cl$_2$(μ-Cl)$_2$(PR$_3$)$_2$] (M = Pd or Pt; PR$_3$ = P*n*Bu$_3$, P*n*Pr$_3$, PEt$_3$, PMe$_2$Ph, PMePh$_2$, PPh$_3$) were prepared according to literature methods.[33] The phosphanes (Strem Chemicals) and Me$_2$NCH$_2$CH(Me)Cl·HCl (Fluka Chemika, Cat. No. 24367) were obtained from commercial sources. All reactions were carried out under nitrogen in dry and distilled analytical grade solvents. Microanalyses were carried out in the Analytical Chemistry Division of BARC. ^{1}H, ^{13}C{^{1}H}, ^{31}P{^{1}H}, ^{77}Se{^{1}H}, ^{125}Te{^{1}H} and ^{195}Pt{^{1}H} NMR spectra were recorded with a Bruker DPX-300 NMR spectrometer operating at 300, 75.47, 121.49, 57.24, 94.86 and 64.52 MHz, respectively. Chemical shifts are relative to the internal chloroform peak at δ = 7.26 ppm for ^{1}H and δ = 77.0 ppm for ^{13}C, external 85% H$_3$PO$_4$ for ^{31}P, Me$_2$Se for ^{77}Se, [Te(dtc)$_2$] (dtc = *N*,*N*-diethyldithiocarbamate) for ^{125}Te, and Na$_2$[PtCl$_6$] in D$_2$O for ^{195}Pt. A 90° pulse was used in every case. The IR spectra were recorded as Nujol mulls between CsI plates with a Bomem MB-102 FT-IR spectrometer. UV/Vis absorption spectra were recorded with a JASCO V-530 spectrometer. Thermogravimetric analysis (TGA) was carried out with a NETZSCH STA 449C instrument calibrated with $CaC_2O_4.H_2O$. The TG curves were recorded at a heating rate of 10 °C·min^{-1} under a flow of argon. X-ray powder diffraction patterns were measured using Cu-K_α radiation.

Preparation of [Me$_2$NCH(Me)CH$_2$S]$_2$ [(N∩S)$_2$]:** Sodium hydrogensulfide was prepared by bubbling an excess of hydrogen sulfide into an ethanolic solution (150 mL) of sodium ethoxide (from 14.02 g Na metal) for 4 h until a pale yellow solid began to separate. Freshly distilled Me$_2$NCH$_2$CH(Me)Cl (59.34 g, 488 mmol) [obtained by neutralising an aqueous solution of Me$_2$NCH$_2$CH(Me)Cl·HCl with 10% sodium hydroxide, extracting with diethyl ether, drying with anhydrous CaCl$_2$ and distilling at 120−122 °C as a colourless liquid; ^{1}H NMR (CDCl$_3$): δ = 1.49 (d, *J* = 6.6 Hz, CH*Me*), 2.26 (s, NMe$_2$), 2.48 (doublet of AB pattern, NCH$_2$), 4.02 (m, 6.5 Hz, C*H*Cl) ppm; ^{13}C{^{1}H} NMR (CDCl$_3$): δ = 23.2 (s, CH*Me*), 45.8 (s, N*Me*$_2$), 55.1 (s, N*C*H$_2$), 68.0 (s, *C*HCl) ppm] was added dropwise to this solution, whereupon a white precipitate formed. The reaction mixture was heated to reflux under nitrogen for 2 h, and, after cooling, the mixture was filtered. The filtrate was concentrated in vacuo, leaving behind a pale-yellow solid [Me$_2$NCH(Me)CH$_2$SH] which was found to be contaminated by disulfide. Oxygen was bubbled through an ethanol solution (50 mL) of the residue until a yellow liquid was obtained. The solvent was stripped off and the residue was distilled in vacuo at 120−125 °C/1 Torr to give a yellow oil (30.2 g, 53%). ^{1}H NMR (CDCl$_3$): δ = 1.00 (d, *J* = 6.5 Hz, CH*Me*), 2.19 (s, N*Me*$_2$), 2.52 (m, C*H*$_2$S), 2.77−2.92 (m, NC*H*) ppm. ^{13}C{^{1}H} (CDCl$_3$): δ = 12.7 (s, CH*Me*), 40.0 (s, N*Me*$_2$), 42.4 (s, N*C*H), 58.2 (*C*H$_2$S) ppm. The NMR spectra showed resonances attributable to traces (less than 1%) of [Me$_2$NCH$_2$CH(Me)S]$_2$.

Preparation of (N∩S)$_2$. [Me$_2$NCH(Me)CH$_2$S]$_2$ [(N∩S)$_2$] and [Me$_2$NCH$_2$CH(Me)S]$_2$ [(N∩S*)$_2$]:** Finely powdered yellow sulfur (3.20 g, 100 mmol) and sodium metal (2.37 g, 103 mmol) were allowed to react in liquid ammonia (100 mL) at −78 °C. The resulting yellow solution was stirred for 90 min and the ammonia

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was evaporated by leaving the flask to stand at room temperature. The yellow residue (Na_2S_2) was dried under vacuum and dissolved in DMF (200 mL) with stirring. Freshly distilled $Me_2NCH_2CH(Me)Cl$ (10.5 g, 86 mmol) in DMF (100 mL) was added dropwise. The mixture was stirred at room temperature for 18 h whereupon the green colour of the solution changed to yellow. The reaction was quenched with water (300 mL) and the product was extracted with diethyl ether (3 × 60 mL). The ether extracts were dried with $CaCl_2$. The solvent was stripped off and the residue was distilled in vacuo (100−105 °C/0.5 Torr) to give a mixture of $(N^{\cap}S^{**})_2$ and $(N^{\cap}S^{*})_2$ as a yellow liquid (7.9 g, 77%). Attempts to separate the two isomers by vacuum distillation were unsuccessful. ^{1}H NMR ($CDCl_3$): δ = 1.01 [d, J = 6.5 Hz, $(N^{\cap}S^{**})_2$], 1.26 [d, J = 6.5 Hz, $(N^{\cap}S^{*})_2$] (CH*Me*) (ratio 1:2), 2.18 [s, N*Me*$_2$, $(N^{\cap}S^{*})_2$], 1.20 [s, N*Me*$_2$, $(N^{\cap}S^{**})_2$], 2.26−2.95 (m, NC*H*, C*H*$_2$S, NC*H*$_2$, C*H*S) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): $(N^{\cap}S^{*})_2$: δ = 18.6 (s, N*Me*$_2$), 43.9 (s, N*C*H$_2$), 45.3 (s, N*Me*$_2$), 64.8 (s, *C*HS) ppm; $(N^{\cap}S^{**})_2$: δ = 12.7 (s, CH*Me*), 40.1 (s, N*Me*$_2$), 42.4 (s, N*C*H), 58.2 (s, *C*H$_2$S) ppm [$(N^{\cap}S^{*})_2$ and $(N^{\cap}S^{**})_2$ in 2:1 ratio from ^{1}H NMR integration].

Preparation of $(N^{\cap}Se)_2$. $[Me_2NCH(Me)CH_2Se]_2$ $[(N^{\cap}Se^{**})_2]$ and $[Me_2NCH(Me)CH_2Se]_2$ $[(N^{\cap}Se^{*})_2]$: A mixture of $(N^{\cap}Se)_2$ was prepared (in 54% yield) in an analogous manner to the sulfur analogue as described above, from $Me_2NCH_2CH(Me)Cl$ and Na_2Se_2. The orange liquid was fractionally distilled at 130−138 °C/2 Torr. ^{1}H NMR ($CDCl_3$): δ = 1.08 [dd, J = 6.3, 2 Hz, $(N^{\cap}Se^{**})_2$], 1.47 [d, J = 6.2 Hz, $(N^{\cap}Se^{*})_2$ (CH*Me*)], 2.22 [br., NC*H*, $(N^{\cap}Se^{**})_2$], 2.24 $(N^{\cap}Se^{**})_2$, 2.25 $(N^{\cap}Se^{*})_2$ (each s, N*Me*$_2$), 2.48 [AB pattern with doublet NCH$_2$, $(N^{\cap}Se^{*})_2$], 2.89 (m, C*H*$_2$Se), 3.25 [m, CHSe, $(N^{\cap}Se^{*})_2$] ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = [$(N^{\cap}Se^{*})_2$] 20.8 (s, CH*Me*), 36.8 (N*C*H$_2$), 45.6 (N*Me*$_2$), 67.0 (Se*C*H) ppm; [$(N^{\cap}Se^{**})_2$]: δ = 13.7 (s, CH*Me*), 35.8 (N*C*H$_2$), 40.5 (N*Me*$_2$), 60.3 (Se*C*H) ppm. ^{77}Se{^{1}H} NMR ($CDCl_3$): δ = 225.4, 226.6, 286.0, 286.8, 356.5, 357.9, 415.1, 416.2 ppm.

Preparation of $(N^{\cap}Te)_2$. $[Me_2NCH(Me)CH_2Te]_2$ $[(N^{\cap}Te^{**})_2]$ and $[Me_2NCH_2CH(Me)Te]_2$ $[(N^{\cap}Te^{*})_2]$: $(N^{\cap}Te)_2$ was synthesised in a similar manner to the corresponding selenium analogue from $Me_2NCH_2CH(Me)Cl$ and K_2Te_2 (prepared from potassium and tellurium powder in liquid ammonia). The brown-red liquid was dissolved in hexane, passed through a Florisil column and dried under vacuum (yield 68%). The compound was contaminated by $(Me_2NCH_2CHMe)_2Te$; attempted vacuum distillation resulted in excessive decomposition. ^{1}H NMR ([D$_6$]acetone): δ = 1.01 [d, J = 6.5 Hz, $(N^{\cap}Te^{**})_2$], 1.66 [d, J = 6.5 Hz, $(N^{\cap}Te^{*})_2$] (CH*Me*), 2.23 [s, N*Me*$_2$, $(N^{\cap}Te^{**})_2$], 2.25 [s, N*Me*$_2$ minor, $(N^{\cap}Te^{*})_2$], 2.75 (m, C*H*), 3.12−3.49 (m, C*H*$_2$) ppm. ^{13}C NMR ([D$_6$]acetone): [$(N^{\cap}Te^{*})_2$]: δ = 14.9 (s, CH*Me*), 35.0 (s, N*C*H$_2$), 45.5 (s, N*Me*$_2$), 68.7 (s, Te*C*H) ppm; $(N^{\cap}Te^{**})_2$: δ = 13.7 (each s, CH*Me*), 31.6 (s, N*C*H), 40.4 (s, N*Me*$_2$), 61.4 (s, Te*C*H) ppm. ^{125}Te{^{1}H} NMR ([D$_6$]acetone): δ = −870 (very small), −791, −639 (very small), −559 ppm; peaks at δ = −455, −461 and −504 (integrating to about 7%) are due to partial decomposition of the ligand.

Synthesis of Palladium(II) and Platinum(II) Complexes: All preparations involving thiolate were carried out using $Me_2NCH(Me)CH_2S^-$ ($N^{\cap}S^{**}$) unless otherwise stated. For the preparation of selenolate and tellurolate complexes, $(E^{\cap}N)_2$ was employed. NMR spectroscopic data for complexes $[MCl(E^{\cap}N)(PR_3)]$ are collected in Tables 1 and 2. Yields, recrystallisation solvents and analytical data for all complexes are provided in the Supporting Information.

Thiolate Complexes: As an example for the thiolate complexes the synthesis of $[PdCl(N^{\cap}S^{**})(PMe_2Ph)]$ is described. A dichloromethane solution (40 mL) of $[Pd_2Cl_2(\mu\text{-}Cl)_2(PMe_2Ph)_2]$ (156 mg, 0.25 mmol) was added to a freshly prepared methanol solution of $NaSCH_2CH(Me)NMe_2$, prepared by treating $(N^{\cap}S^{**})_2$ (58 mg, 0.25 mmol) with $NaBH_4$ (19 mg, 0.51 mmol). The reaction mixture was stirred at room temperature for 4 h. After solvent evaporation in vacuo, the brown residue was extracted with dichloromethane (20 mL). The solution was passed through a Florisil column and the solvent was removed in vacuo. The residue was recrystallised from a acetone/hexane mixture to give reddish crystals. Other thiolate complexes with M = Pd and P*n*Pr$_3$, PEt$_3$, PMe$_2$Ph, PMePh$_2$ or PPh$_3$ and M = Pt and P*n*Bu$_3$, P*n*Pr$_3$, PEt$_3$, PMe$_2$Ph or PMePh$_2$ were prepared similarly.

Selenolate Complexes: As an example for the selenolate complexes the synthesis of $[PdCl(N^{\cap}Se)(PMe_2Ph)]$ is described. An acetone suspension (20 mL) of $[Pd_2Cl_2(\mu\text{-}Cl)_2(PMe_2Ph)_2]$ (180 mg, 0.29 mmol) was added to a freshly prepared methanol solution (5 mL) of $N^{\cap}SeNa$, prepared from $(N^{\cap}Se)_2$ (96 mg, 0.29 mmol) and $NaBH_4$ (23 mg, 0.61 mmol). The reaction mixture was stirred for 4 h. The solvents were evaporated in vacuo, the residue was washed with hexane and extracted with toluene (3 × 8 mL). The extracts were passed through a Florisil column. The solvent was reduced to 2 mL and a few drops of hexane were added which, on cooling to −5 °C, gave pink crystals (156 mg, 62%). Analogously, complexes of the type $[MCl(N^{\cap}Se)(PR_3)]$ (M = Pd with PEt$_3$, PMe$_2$Ph, PMePh$_2$ or PPh$_3$ and M = Pt with P*n*Bu$_3$, PEt$_3$, PMe$_2$Ph) were prepared.

Tellurolate Complexes: As an example for the tellurolate complexes the synthesis of $[PdCl(N^{\cap}Te)(PPh_3)]$ is described. To a freshly prepared solution of $N^{\cap}TeNa$, prepared from $(N^{\cap}Te)_2$ (127 mg, 0.30 mmol) and $NaBH_4$ (24 mg, 0.63 mmol) in methanol (10 mL), an acetone suspension (25 mL) of $[Pd_2Cl_2(\mu\text{-}Cl)_2(PPh_3)_2]$ (261 mg, 0.30 mmol) was added with vigorous stirring which continued for 3 h. The solvents were removed under vacuum and the residue was washed with hexane and extracted with acetone (3 × 6 cm^3). The volume of the acetone was reduced to 8 mL which on cooling gave a brown powder (142 mg, 39% yield). $[PtCl(N^{\cap}Te)(PnPr_3)]$ and $[PtCl(N^{\cap}Te)(PPh_3)]$ were prepared similarly.

X-ray Crystallography: Single crystals of $[PdCl(N^{\cap}S^{**})(PMePh_2)]$ and $[PtCl(N^{\cap}S^{**})(PMe_2Ph)]$ were obtained at −10 °C from CH_2Cl_2/hexane and at room temperature from acetone/hexane mixtures, while single crystals of $[PdCl(N^{\cap}Se)(PMePh_2)]$ and $[PtCl(N^{\cap}Se^{**})(PMe_2Ph)]$ were obtained from toluene/hexane mixtures at room temperature and −10 °C, respectively. The X-ray data of these complexes were collected at 173(2) K or 178(2) K with Siemens (P4 or P3) or Stoe diffractometers, using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) and employing Wyckoff scans. Further details are given in Table 5. All structures were solved by the Patterson method using the SHELXTL package while refinement was carried out with SHELXL-97 employing full-matrix least-squares methods on F^2 with $F_o^2 = -2\sigma(F_o^2)$.[34] All non-hydrogen atoms were refined anisotropically, except for the disordered C and N atoms in the chelate ligand of $[PdCl(N^{\cap}Se^{**})(PMePh_2)]$. The same atoms had to be refined using DFIX restraints. Hydrogen atoms were introduced using appropriate riding models. Empirical absorption correction was performed using XABS2.[35] CCDC-235479 for $[PdCl(N^{\cap}S^{**})(PMePh_2)]$, -235480 for $[PtCl(N^{\cap}S^{**})(PMe_2Ph)]$, -235481 for $[PdCl(N^{\cap}Se)(PMePh_2)]$ and -235482 for $[PtCl(N^{\cap}Se^{**})(PMe_2Ph)]$ contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union

Supporting Information (see also footnote on the first page of this article): Further tables with analytical data for all new complexes and structural details of [PdCl(N∩S**)($PMePh_2$)], [PtCl(N∩S**)-(PMe_2Ph)], [PdCl(N∩Se)($PMePh_2$)] and [PtCl(N∩Se**)(PMe_2Ph)] are available. Further figures illustrating the crystal and molecular structures are also provided.

Acknowledgments

We thank Drs. J. P. Mittal, T. Mukherjee and S. K. Kulshreshtha for encouragement of this work. We are also grateful to Dr. M. Sudershanan, Head, Analytical Chemistry Division, BARC for providing microanalyses of the complexes. Dr. M. Bader (University of Stuttgart) is thanked for collecting single crystal XRD data, as is Dr. Rudolph Pietschnig (University of Graz) for collecting NMR spectroscopic data. Support for this work under the Indo-German bilateral program from the BMBF (Project No. IND 99/060) is gratefully acknowledged.

Selected-Control Solvothermal Synthesis of Nanoscale Hollow Spheres and Single-Crystal Tubes of PbTe

Guifu Zou,[a,b] Zhaopin Liu,[b] Debao Wang,[b] Changlong Jiang,[b] and Yitai Qian*[a,b]

Keywords: Nanostructures / Semiconductors / Nanotubes

For the first time, hollow PbTe nanospheres with diameters of 80–140 nm have been prepared in an ether/glycerol microemulsion system and PbTe single-crystalline nanotubes with diameters of 60–80 nm have been synthesised in a homogeneous ethanol/glycerol system. They can be facilely controlled via a solvothermal process without any additional catalysts and templates. Two different template mechanisms are discussed herein. The Raman and far infrared spectra of the samples have been investigated at room temperature.

Introduction

In recent years, one of the important goals of material scientists has been to tailor the structures of materials to obtain special nanomorphologies because the properties of nanomaterials are strongly dependent on the their sizes and shapes.[1−5] Among specific morphologies, hollow nanoscale spheres and tubes have drawn more and more attention.[6,7] Three-dimensional hollow spheres are interesting in the fields of medicine, material science and catalysis due to their hollow structures which make them particularly applicable for drug delivery, medical imaging, protein and enzyme transplantation, encapsulation of products (cosmetics, inks and dyes) and contaminated waste removal.[8] So far, various hollow spheres (SiC, ZnS, CdS, Ag_2S and polymers) have been synthesised by different methods.[9−12] Meanwhile, one-dimensional nanotubes have also attracted attention because of their unique optical, electronic and mechanical properties resulting in promising applications in electrical and optoelectronic nanodevices. Many tubular structures have been fabricated for compounds with layered structures such as C, MoS_2 and BN with the assistance of catalysts. Moreover, there have been many tubular materials without layered structures produced by physical template methods.[13] However, the introduction of templates or catalysts to the reaction system means a much more complicated process involving the preparation of catalysts or the selection of templates and may introduce impurities into the final product. Therefore, it is always a challenge for the tubular materials to be prepared by a simple wet chemical route.

PbTe has been intensively studied for more than forty years because it has interesting physical properties which can be applied in many fields such as IR detection, photoconductivity and thermoelectric materials.[14] PbTe nanocrystals have been prepared by various methods.[15] To the best of our knowledge, however, there are no reports regarding hollow PbTe nanospheres and nanotubes. We have successfully synthesised hollow PbTe spheres and nanotubes by a wet chemical method, simply using ether and ethanol as the reaction solvents, respectively. In the solvothermal process, neither physical templates nor catalysts are required. In addition, two different template mechanisms are discussed.

Results and Discussion

The typical XRD patterns of the products are shown in Figure 1. All the peaks can be indexed as face-centred cubic

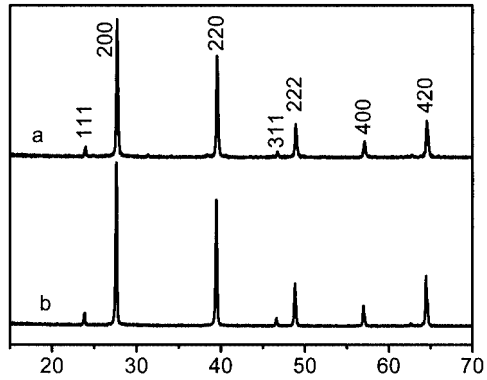

Figure 1. XRD patterns of (a) hollow spheres and (b) tubular PbTe

PbTe (JCPDS, 38-1435). No peaks of any other impurities are detected, indicating the high purity of the products. In addition, the strong and sharp reflection peaks suggest that the products are highly crystalline.

Figure 2 (see a and b) shows the TEM images of the samples prepared by the process using ether as the solvent. The strong contrast between the dark edge and pale centre is evidence of its hollow nature. Figure 2 clearly displays many hollow PbTe spheres prepared in the products. The proportion of hollow spheres in the samples was estimated to be 25−30% using large numbers of TEM observations. Their external diameter and wall thickness are ca. 80−140 nm and 15−30 nm, respectively. Close observations indicate that the hollow spheres consist of PbTe nanoparticles. The inset of Figure 2 (see b) shows the selected area electron diffraction (SAED) pattern of the hollow PbTe spheres. The SAED exhibits diffuse polycrystalline ring patterns and agrees well with the XRD peaks of the products. It also further confirms that the hollow spheres are constructed from highly crystalline PbTe nanoparticles. In addition, it could be shown that the hollow spheres are sensitive to beam irradiation during TEM examination. This may be related to their thin and porous walls. A similar phenomenon can be also found in former reports concerning hollow spheres.[6,16] In addition to the hollow spheres, some cubes are also present in the samples (Figure 2, c).

Figure 2 (see d−g) shows tubular PbTe prepared in the process using ethanol as the solvent. The yield of the nanotubes in the sample was about 20%. The external diameter and wall thickness of the nanotubes are ca. 70 nm and 15 nm, respectively. Their lengths are about several hundred nanometers. Most nanotubes have closed ends and a few have open ends. The microstructure of tubular PbTe was further characterised by HRTEM and SAED. The HRTEM images looking down onto the wall and open end of the nanotubes are given in Figure 2 (see f−h), where the inset is the corresponding open end ED pattern. The regular spacing of the observed lattice planes is ca. 0.32 nm which is consistent with the separation of the (200) planes of c-PbTe. It shows that the nanotube is single-crystalline, structurally uniform and dislocation free. Moreover, the SAED patterns taken from various regions of an individual nanotube are essentially the same. It can also be concluded that the nanotubes synthesised using the present procedure are single-crystalline in structure. According to the HRTEM images and the SAED pattern, it can be concluded that the nanotubes grow along the [100] direction.

To investigate the reaction process, a series of experiments was carried out. When $Pb(NO_3)_2$ was not added to the reaction system, only Te nanocrystals formed. On the other hand, Pb was not produced when Na_2TeO_4 was left out of the reaction system. Moreover, a large amount of Te mixed with some PbTe was obtained when the reaction proceeded for a short time and then more PbTe and less Te were produced when the reaction time was continually increased. Based on the above results and the former reports,[15,17,18] all the reactions can be described according to part A in Scheme 1. Firstly, the Na_2TO_4 was reduced

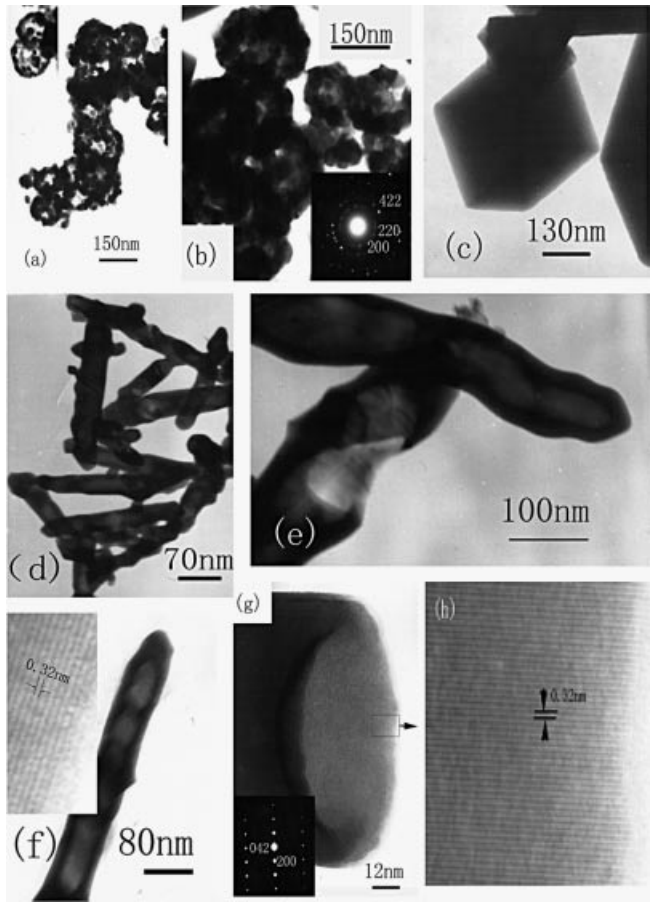

Figure 2. TEM images of (a) and (b) hollow PbTe spheres and (c) a few cubes, the inset shows the hollow sphere ED patterns; (d) Tubular PbTe TEM images and (e) their magnification images. (f) HRTEM images of the wall and (g) the open end of the nanotubes, the inset show the corresponding ED patterns

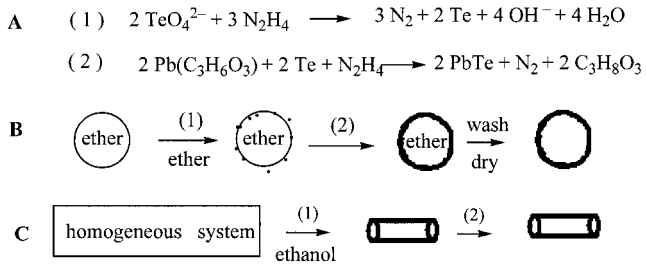
to Te by hydrazine. Secondly, the PbTe was formed slowly through a redox reaction between $Pb(C_3H_6O_3)$, Te and hydrazine. Here, glycerol was used as the complexing reagent to form a complex, $Pb(C_3H_6O_3)$. The complex served to reduce the speed of reaction (2) because the $Pb(C_3H_6O_3)$ sharply decreased the free Pb^{2+} concentration in the solution. It is well-known that a slow reaction rate is favourable for crystallisation as well as separating the growth step from the nucleation step.[19] Thus, highly crystalline PbTe was obtained in our experiments and the ED, XRD and HRTEM of the products also confirmed this. For the detailed formation process of the hollow spheres, we assume the process to be a template-interface route. Because the ether was insoluble in the glycerol, the whole system can be described as a microemulsion state. The ether could form stable microscale oil droplets in glycerol at a moderate temperature. When Te nanoparticles were formed through reaction (1) in an ether/glycerol system, many Te particles accumulated on the surface of the oil droplets and formed a template-interface. The reaction then progressed according to Equation (2). Finally the shell-core structure formed. Moreover, the hollow spheres can be obtained when the ether is removed

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

by washing and drying of the product. The whole process can be described diagrammatically as in part B of Scheme 1.



Scheme 1. A) Illustration of the hollow spheres formation process by a template-interface route B) Illustration of the nanotube formation process by a self-generated template route C

In order to discuss the formation mechanism of PbTe nanotubes, some experiments were carried out. Te nanotubes could be obtained in the products (the images not shown here) when $Pb(NO_3)_2$ was not added to the ethanol/glycerol reaction system. This phenomenon can also be found in the literature.[17,18] Moreover, more PbTe and less Te were obtained when the reaction time was continually increased. In addition, it is worth noting that the diameter of the Te nanotubes obtained was almost the same as that of the PbTe nanotubes. Based on these results, we propose a self-generated template process. Firstly, some Te nanotubes were produced according to reaction (1) in the ethanol/glycerol homogeneous system and then according to reaction (2) considerable tubular PbTe formed using the Te nanotubes as the templates. Some similar template syntheses have been reported.[20–22] Accordingly, we are inclined to describe the formation process of the PbTe nanotubes as a self-generated template route. It can be described according to part C in Scheme 1. However, the detailed mechanism needs to be further studied.

The room temperature Raman and far infrared spectra of the hollow PbTe nanospheres are shown in Figure 3. Peaks at 121, 137 and 154 cm^{-1} are observed as indicated in Figure 3 (a). Among them, the peaks marked with asterisks are related to the vibrational modes of a thin TeO_2 layer on the PbTe nanocrystals.[23,24] The wide band with the peak at ca. 154 cm^{-1} corresponds to the mixed plasmon-phonon modes of the PbTe nanoparticles forming hollow nanospheres. It is worth noting that the frequency is lower than that for bulk PbTe. This can be explained by the effect of dimensional quantization as the average PbTe nanocrystal radius decreases. This phenomenon has also been observed by others.[25] Figure 3 (b) shows the far infrared spectrum of the hollow PbTe nanospheres. The peaks (marked with asterisks) at 81 and 110 cm^{-1} are related to two TeO_2 infrared active modes.[26] The other peaks in part b of Figure 3 corresponded to the infrared active modes of the hollow PbTe nanospheres.[25] Here, the wide band from 50 to 70 cm^{-1} is split into two bands appearing at 57 and

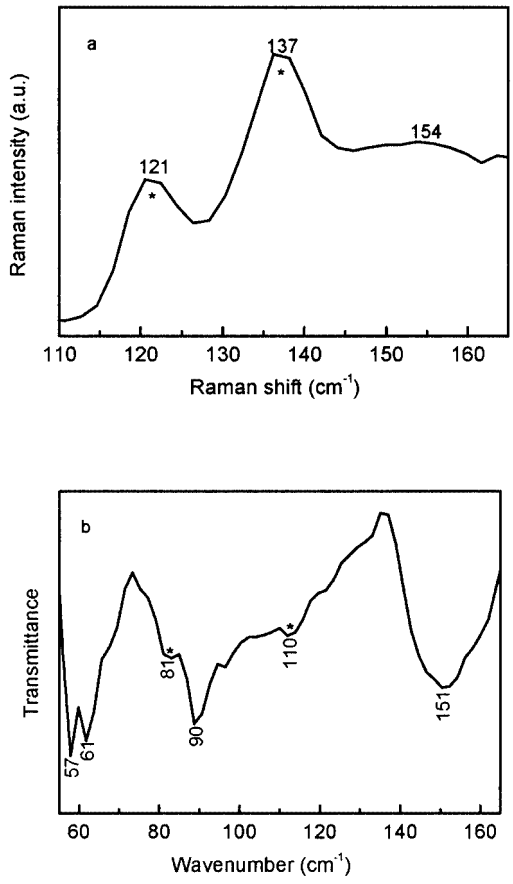


Figure 3. (a) the Raman and (b) far infrared spectra of the hollow PbTe nanospheres

61 cm^{-1}. A similar phenomenon has been reported in the literature.[27] From Figure 3 (see a and b), it can be also shown that the frequency of the mixed plasmon-phonon mode (at 154 cm^{-1}) in the Raman spectrum of the hollow PbTe nanospheres is almost same as that (at 151cm^{-1}) in the infrared spectrum. Additionally, the Raman and far infrared spectra (not shown here) of the PbTe nanotubes were similar to the above Raman and far infrared spectra of the hollow PbTe nanospheres, respectively.

Conclusion

In conclusion, hollow nanoscale spheres and single-crystal tubular PbTe have been synthesised via facile solvothermal processes for the first time. Two different models, template-interface and self-generated template routes, have been proposed to explain the formation mechanism of hollow PbTe nanospheres and nanotubes. The present study will not only open up great opportunities for novel morphologies of PbTe and their applications to be investigated, but might also be extended to the synthesis of hollow spheres and nanotubes of other materials.

Experimental Section

All chemical reagents in this work, such as $Pb(NO_3)_2$, $Na_2TO_4{\cdot}2H_2O$, ether, ethanol, glycerol and hydrazine were of A.R. grade and were purchased from the Shanghai Chemical Company, China. They were used as received without further purification.

Preparation of Hollow Nanoscale Spheres and Tubular PbTe: In a typical procedure, $Pb(NO_3)_2$ (0.5 mmol) and $Na_2TO_4{\cdot}2H_2O$ (0.5 mmol) were added to a mixture of ether (18 mL) and glycerol (18 mL). The mixture was then stirred vigorously to form a microemulsion phase. After this, hydrazine (10 mL) was added to the microemulsion system and stirring was continued for 10 min. Finally, the mixture was transferred into a 60 mL Teflon-lined autoclave and the autoclave was sealed and heated at 160 °C for 20 h. The autoclave was then allowed to cool to room temperature without assistance. The grey precipitate was filtered and washed several times with distilled water and absolute ethanol to remove impurities and was then dried in vacuo at 60 °C for 4 h. Finally the product (PbTe hollow spheres) was obtained. The whole method, appropriate for the preparation of PbTe nanotubes, was similar to the above process except for the use of ethanol instead of ether as the reaction solvent.

Sample Characterisation: The X-ray diffraction (XRD) patterns for the products were recorded on a Philips X'pert diffractometer with Cu-K_{a1} radiation (λ = 1.54178 Å). The morphologies and structures of the products were examined by transmission electron microscopy (TEM) using a Hitachi H-80 instrument. The high-resolution TEM study was carried out using a JEOL 2010 microscope. The samples used for characterisation were dispersed in absolute ethanol and were ultrasonicated before TEM and HRTEM. The Raman spectrum was recorded with a LABRAM-HR Confocal Laser MicroRaman Spectrometer with 514.5 nm radiation from a 10-mW argon ion laser at room temperature. The far infrared spectroscopic measurements were performed with a Nicolet Nexus 870 spectrometer. The powders were dispersed in silicon oil and were studied at room temperature.

Cocondensation Reactions of Five-Membered Heterocycles with Lithium Atoms at 77 K

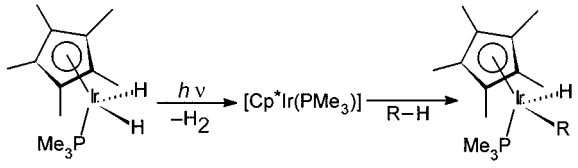
Oscar Mendoza,[a] Franz-Josef K. Rehmann,[a] Laurence P. Cuffe,[a] and Matthias Tacke*[a]

Keywords: Lithium / Heterocycles / C−H bond activation / Cocondensation / DFT

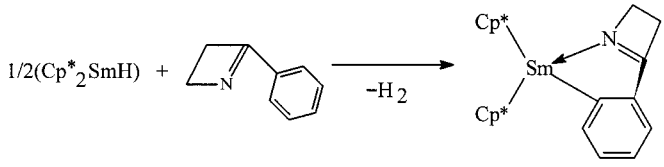
Lithium atoms were cocondensed with eight aromatic five-membered heterocycles in the presence of THF at 77 K. In the case of the oxygen- and sulfur-containing heterocycles (furans and thiophenes), the reaction resulted in C–H bond activation and led to the corresponding aryllithium compound. The other heterocycles (pyrroles) failed to react with lithium atoms in the presence of THF. A special case was found when oxazole was reacted under these cocondensation conditions; here a dilithiated product was obtained. DFT (B3LYP/6-31G**) calculations were carried out in order to interpret the pathways of the reactions and the possible intermediates. For all the reactions π- and σ-complexes between lithium clusters and the heterocycles were found as stable intermediates.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The activation of carbon−hydrogen bonds has been a major topic of research for the last thirty years.[1,2,3] Numerous methods have been developed to perform these reactions. Most of these have centred on the oxidative addition of the hydrocarbon moiety to a highly sub-coordinated metal complex as shown below.[4,5]



However, C−H bond activation is not limited just to transition metal chemistry. Another commonly used method is σ-bond metathesis using extremely electrophilic lanthanide centres as outlined below.[6]



To date there has been very little preparative-scale work using metal atoms to perform oxidative addition reactions. Many metals are known to activate methane in a matrix under photochemical conditions.[3,7] However, these types of reactions are of no use in preparative-scale metal vapour synthesis (MVS). For example, iron atoms react with methane to form CH_3FeH at 10 K when photolysed in an argon matrix.[8]

$$Fe + CH_4 \xrightarrow[Ar,\ 10K]{h\nu} HFeCH_3$$

Work performed by this group in the nineties showed that lithium atoms could selectively activate the C−H bond of benzene and toluene in the presence of THF without photochemical excitation.[9,10,11] This result led to the direct preparation of aryllithium compounds on a synthetic scale.

$$8\ Li(g) + 4\ PhH(g) + 4\ THF(g) \xrightarrow[77K]{cocond.} \left[\text{C}_6\text{H}_5\text{Li(THF)}\right]_4 + 4\ LiH(s)$$

One of the key intermediates in this reaction is a Li_2-benzene π-complex. This complex is capable of undergoing two single-electron transfers from the Li_2 cluster to the LUMO of the aromatic ring, resulting in the activation of the aromatic C−H bond.

$$2\ Li(g) + 4\ PhH(g) \xrightarrow[77K]{cocond.} \left[Li{-}Li{\leftarrow}PhH\right] \longrightarrow \left[H\begin{smallmatrix}Li\\Li\end{smallmatrix}Ph\right] \longrightarrow LiH(s) + PhLi(s)$$

The work has been expanded to +I-substituted (CMe_3, $SiMe_3$, *o*- and *m*-xylene) and donor-substituted (OMe, NMe_2, SMe) benzene derivatives recently.[12]

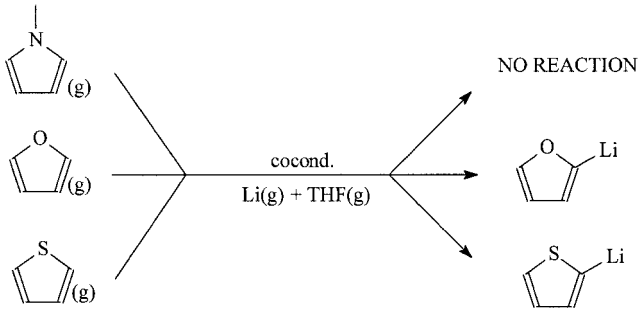
The aim of this paper was to perform cocondensation reactions with furans, thiophenes, pyrroles and oxazole in order to find similarities to and differences from benzene derivatives.

Results

1. Experimental Studies

A variety of five-membered heterocyclic compounds were cocondensed with lithium atoms at 77 K in the presence of THF.

When methylpyrrole, furan and thiophene were cocondensed, a reaction was observed in the case of furan and thiophene only. The products of these reactions were monolithiated compounds[13,14] in which the heterocyclic ring showed a C−H activation in the *ortho* position as shown in Scheme 1. In the case of furan and thiophene, the yields were 35% (2.15 g) and 55% (3.55 g) respectively.

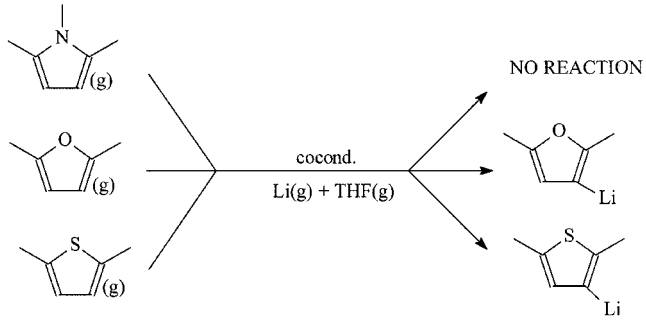


Scheme 1. Cocondensation reaction of lithium atoms with heterocycles at 77 K

A derivatisation reaction with Me_3SiCl was carried out, yielding products stable in air in order to identify the position of the lithium in the aromatic ring. The TMS-substituted compound was identified from NMR spectroscopic data and GC-MS data.[15,16]

A similar reaction series was carried out with the *ortho* position blocked. Methyl groups were placed in the *ortho* positions of the aromatic rings, and cocondensation experiments were carried out.

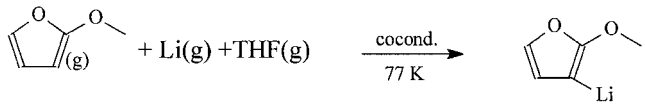
1,2,5-Trimethylpyrrole, 2,5-dimethylfuran and 2,5-dimethylthiophene were condensed with lithium at 77 K, and lithiated products were obtained in the case of 2,5-dimethylfuran and 2,5-dimethylthiophene.[17] As shown in Scheme 2, in this case C−H activation was observed in the *meta* position with respect to the heteroatom. Again, no reaction was observed for the pyrrole compound. The lithiated compound was identified from the TMS-substituted derivative.[18]



Scheme 2. Cocondensation reaction of lithium atoms with *ortho*-dimethyl heterocycles at 77 K

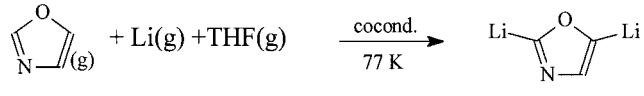
Earlier reports showed that lithium atoms were able to activate aromatic hydrocarbons selectively under these cocondensation conditions.[9,10,11] When a methoxy group was added to the aromatic hydrocarbons, activation was always found in an *ortho* position with respect to the methoxy group.[12] Thus methoxy groups can be considered as useful tools to activate the *ortho* position on hydrocarbon aromatic rings.

When a methoxy group was placed on a heterocycle, the same behaviour was observed. 2-Methoxyfuran was used for this reaction and a C−H activation was observed in an *ortho* position with respect to the methoxy group instead of the heteroatom.



Scheme 3. Cocondensation reaction of lithium atoms with 2-methoxyfuran

Oxazole presents a special case. When oxazole was cocondensed with lithium atoms the reaction yielded a dilithiated compound. In this unusual reaction sequence two lithium atoms were able to activate two C−H bonds in this compound, both in an *ortho* position with respect to the oxygen.



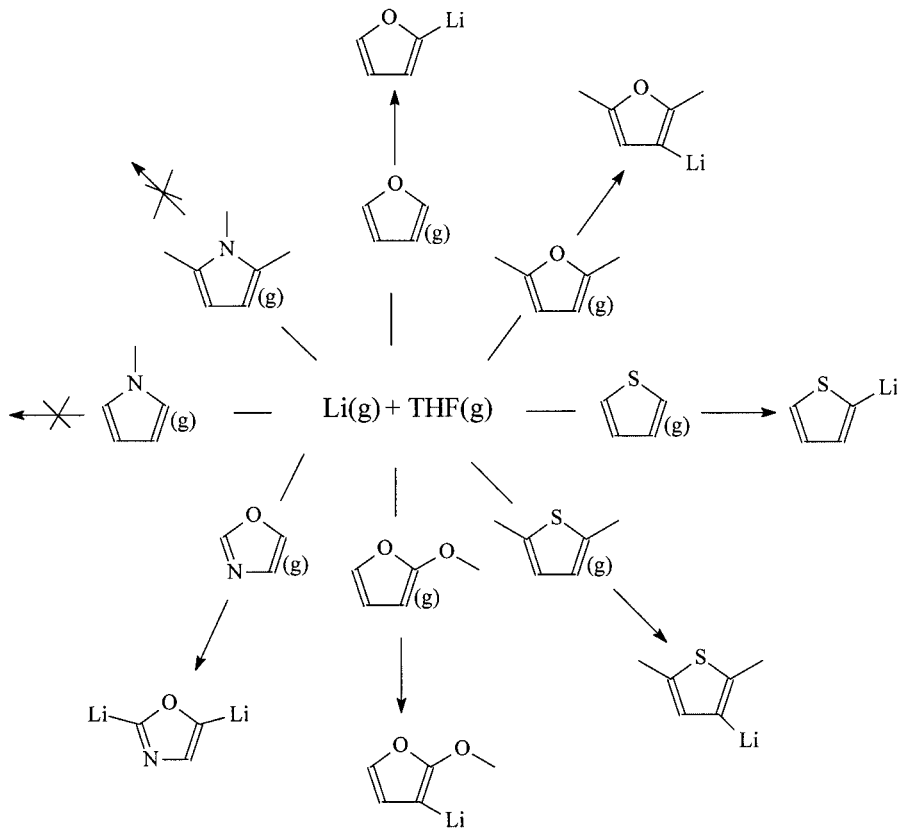
Scheme 4. Cocondensation reaction of lithium atoms with oxazole

In order to facilitate an overview, all cocondensation reactions are summarised in Scheme 5.

2. Theoretical Studies

The aim of this work was to identify, by calculation, plausible intermediate species for all these heterocycle cocondensation reactions, thereby identifying the reaction

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 5. Summary of the reactions of lithium atoms with five-membered heterocycles in the presence of THF at 77 K

mechanism. Calculations were performed using the GAUSSIAN 98[19] and the B3LYP DFT functional with the 6−31G** set basis.

The C−H activation involves at least two steps, the coordination of the lithium cluster with the aromatic compound, and then the insertion of the Li_2 cluster into the C−H bond by a double electron transfer via the aromatic system.[9,10]

Two different possibilities were found for the coordination of the dilithium cluster (Figure 1). Please note that in some cases the lines on the diagrams only have topological significance. The first possibility is the coordination of the Li_2 cluster to the aromatic system to form a π-complex, and the second possibility is η^1-coordination of the Li_2 cluster to the heteroatom in the ring.[12]

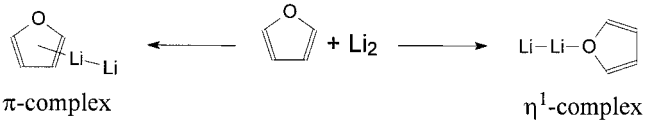


Figure 1. Principal coordination modes of the dilithium cluster to a heterocyclic aromatic compound like furan

When furan is used the preferred pathway is via the η^1-complex. An energy difference of 2.7 kcal/mol was found between the two complexes, showing that the η^1-complex is more stable than the π-complex. The strong interaction between the lithium cluster and the oxygen results in a short Li−O distance of 197.4 pm and supports this pathway. As described previously, the next step is a double electron transfer step from the Li_2 cluster to the LUMO of the aromatic ring. For the furan cocondensation, this step has a larger reaction enthalpy of −29.0 kcal/mol and there is still a strong interaction between the lithium and the oxygen in the second intermediate [*d*(LiO):184.5 pm]. The optimised structure of this second intermediate shows an elongation in the C−O bond of the lithiated carbon. In uncoordinated furan the distance is 136.4 pm; in the second intermediate this distance is 145.7 pm.

When methyl groups are placed in the two *ortho* positions in the furan, a similar situation is found. The η^1-complex is the more stable intermediate with a small energy difference of 2.7 kcal/mol from the π-complex. Furan gives a similar energy for the first step, while there is a less exothermic second step (−18.7 kcal/mol instead of −29.9 kcal/mol found in furan). The distance between the Li_2 and the oxygen in the η^1-complex is the same in both complexes (196.9 pm).

For heterocycles containing sulfur, like thiophene or 2,5-dimethylthiophene, the situation changes and the favoured pathway is via the π-complex.

In the thiophene calculation, a difference in energy of 5.7 kcal/mol in favour of the π-complex was found between the π- and the η^1-coordinated intermediates.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

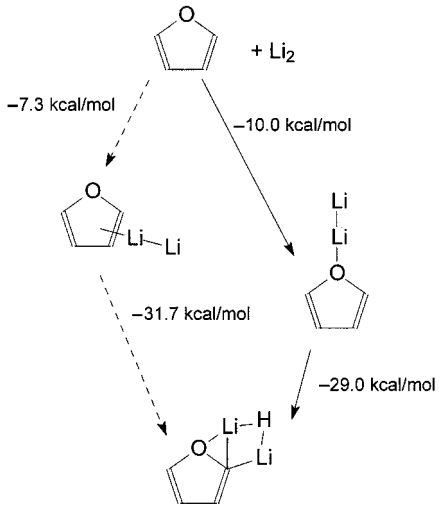

Figure 2. Calculated reaction mechanism for the cocondensation of lithium atoms with furan

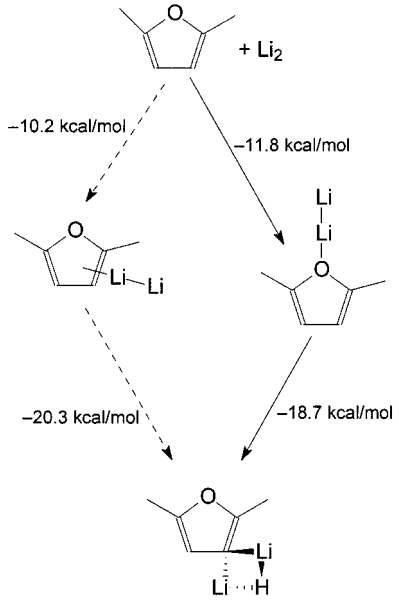

Figure 3. Calculated reaction mechanism for the cocondensation of lithium atoms with 2,5-dimethylfuran

As shown in Figure 4, the C−H activation step for thiophene is a highly exothermic process, as was also the case for furan. There is no interaction between the sulfur and the lithium in the second intermediate and the Li_2H plane is found to be perpendicular to the thiophene plane. The corresponding intermediate in the furan calculation is almost planar (Figure 5). There is a small elongation in the C−S bond by 2.9 pm compared to the uncoordinated thiophene. In furan, the extra coordination to the oxygen atom in the C−H-activated second intermediate leads to an elongation of the C−O bond by 9.3 pm compared to the uncoordinated furan.

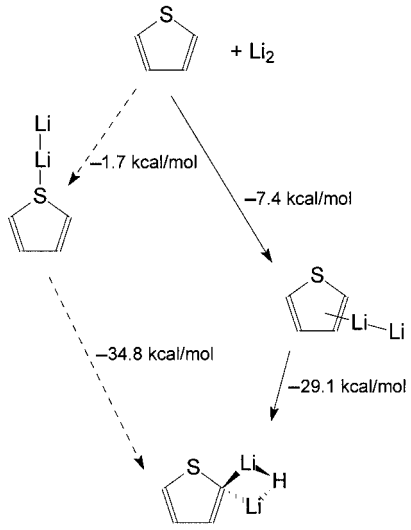

Figure 4. Calculated reaction mechanism for the cocondensation of lithium atoms with thiophene

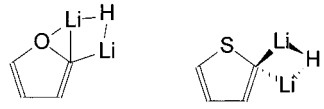

Figure 5. Second intermediate calculations for furan and thiophene

A similar theoretical study was performed on 2,5-dimethylthiophene where a π-complex pathway was shown to be more stable as well. As shown in Figure 6, there is a difference of 7.5 kcal/mol between the η^1- and the π-complex, favouring the latter.

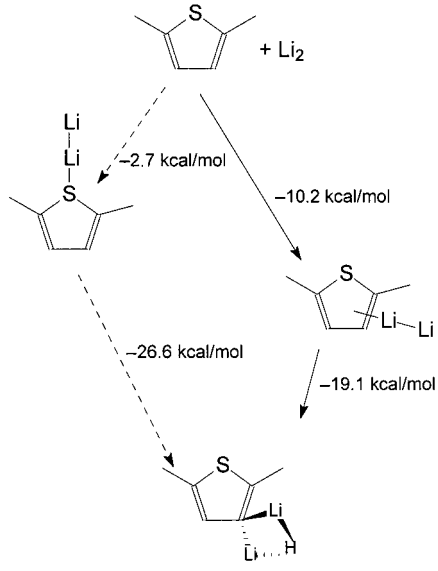

Figure 6. Calculated reaction mechanism for the cocondensation of lithium atoms with 2,5-dimethylthiophene

When there is a methoxy substituent on the aromatic ring functioning as an additional Lewis base, the reaction pathway is more complicated. A theoretical study of 2-meth-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

oxyfuran was carried out, and two different pathways were found.

The first possibility is the formation of a π-complex, as found in the previous calculations. The second pathway involves the coordination of the Li_2 cluster to the methoxy group. A third possibility can be ruled out, since the coordination of the Li_2 cluster to the oxygen in the furan forming an η^1-complex does not lead to a stable intermediate on the energy hypersurface of this system.

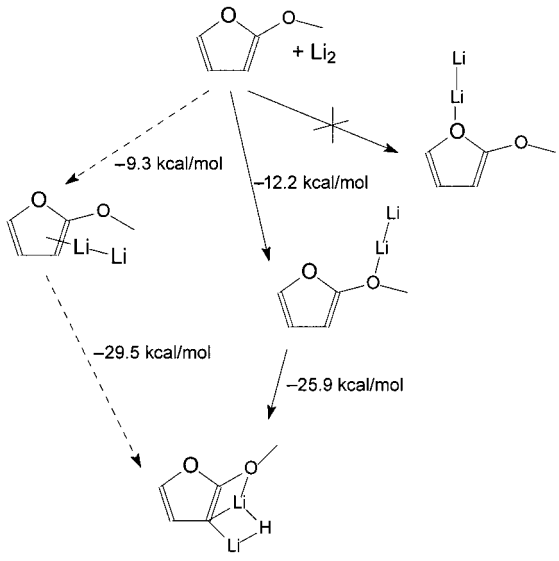

Figure 7. Calculated reaction mechanism for the cocondensation of lithium atoms with 2-methoxyfuran

As Figure 7 shows, the preferred pathway is via an η^1-complex involving the methoxy group. The η^1-complex is more stable than the π-complex by 2.9 kcal/mol. This η^1-complex shows a strong interaction between the lithium and the oxygen in the methoxy group, resulting in a Li–O bond length of 193.1 pm. As in previous mechanisms the next step is a double electron transfer from the Li_2 cluster to the LUMO of the aromatic ring forming a hydride and a carbanion. In this second intermediate a strong bond is still present between oxygen and lithium (194.0 pm).

The theoretical study of the oxazole reaction pathway presents a special case. The presence of two heteroatoms gives oxazole the possibility of forming two η^1-complexes: one in which the lithium cluster is bonded to the nitrogen and one in which it is bonded to the oxygen. The cocondensation reaction of oxazole in the presence of THF gives a dilithiated product; however, only the formation of the monolithiated oxazole is considered in this calculation.

In the first step, the η^1-complex is the more stable intermediate when nitrogen is the donor. The η^1-complex with the oxygen is also a stable intermediate, but in this case the reaction is about 9 kcal/mol less exothermic, as shown in Figure 8. No stable π-complex was found.

Both η^1-complexes lead to a C–H-activated second intermediate where the interaction between the heteroatom and the lithium is still present. These second steps are

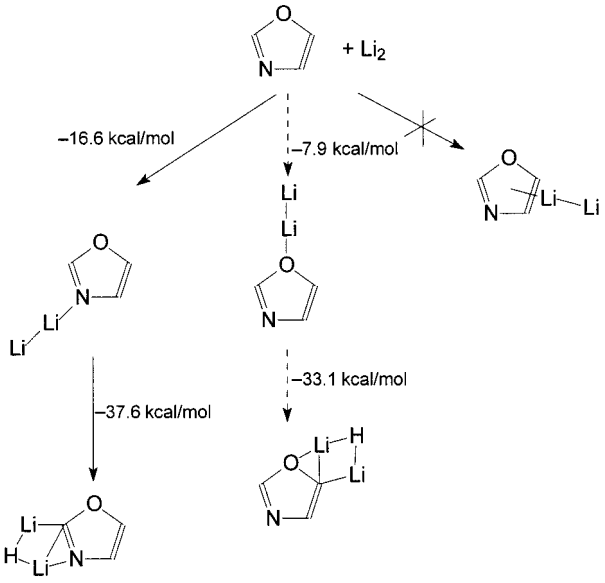

Figure 8. Calculated reaction mechanism for the first lithiation of oxazole

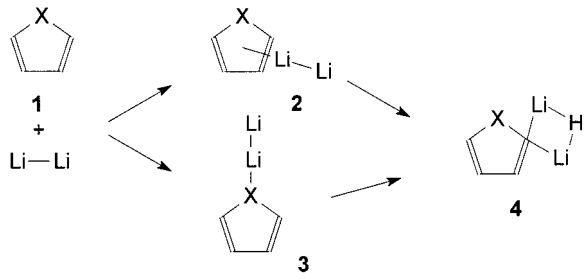
highly exothermic processes, both for the nitrogen η^1-complex (–37.6 kcal/mol) and for the oxygen η^1-complex (–33.1 kcal/mol).

Discussion

Previous research in this area showed that aromatic hydrocarbons react with lithium atoms in the presence of THF under cocondensation conditions.[9,10] The isolated products were identified as monolithiated aromatic compounds. This study examines the effect of heteroatoms introduced into the aromatic rings on the C–H activation reactions.

A delicate balance between enhancing complex formation ability and lowering LUMO energy, which allows reductive cleavage of the aromatic C–H bond, is needed for a successful C–H activation. As shown in Scheme 6, the electron-deficient Li_2 cluster **1** accepts electron density from the aromatic system to form an unusual main group element π-complex **2**, or from the heteroatom to form an η^1-complex **3**. C–H activation follows this step, leading to **4**.



Scheme 6. Key mechanistic steps in heteroaromatic C–H bond activation using lithium atoms

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

When the heteroatom in the aromatic ring donates electron density to the lithium cluster, the interaction between the two lithium atoms is strengthened. This can be observed by comparing the calculated Li−Li bond lengths for the π- and η^1-complexes as shown in Table 1. For example, the biggest difference is observed in the case of 2,5-dimethylthiophene, where the Li−Li distance decreases from 277.5 pm to 273.7 pm, whereas for furan there is only a decrease of 0.9 pm. However, when the heterocycle contains sulfur, as in thiophene and 2,5-dimethylthiophene, the π-complex is found to be more stable than the η^1-complex. In all other cases the opposite behaviour is found.

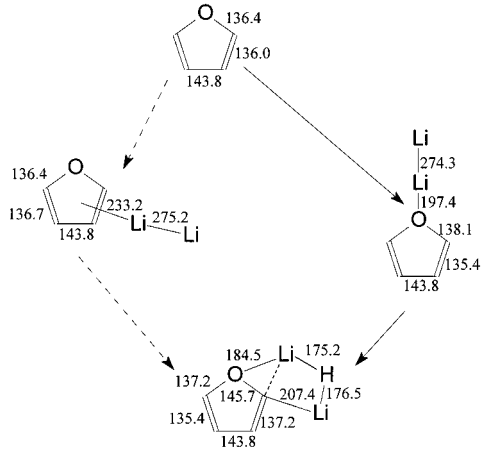
Table 1. Selected Li−Li bond lengths for all calculated intermediates; the calculated Li−Li bond length for free Li_2 is 272.3 pm

	d(LiLi) [pm] π-complex	*d*(LiLi) [pm] η^1-complex	*d*(LiLi) [pm] C−H-activated intermediate
furan	275.2	274.3	238.5
2,5-dimethylfuran	276.3	275.7	228.4
thiophene	276.0	272.9	231.4
2,5-dimethylthiophene	277.5	273.7	229.1
2-methoxyfuran	276.5	275.2	236.0
oxazole		(N) 276.4	254.5
		(O) 273.3	

The next mechanistic step is crucial. It involves the double electron transfer from the π- or η-complex-bonded Li_2 cluster (**2**,**3**) to the LUMO of the aromatic ring. If the LUMO energy is too high, as it is for pyrroles (as outlined in Table 2), it is impossible to place electron density into it, thereby preventing the C−H-activation reaction from occurring. It can be seen in Schemes 1 and 2 that lithium does not react with 1-methylpyrrole or 1,2,5-trimethylpyrrole. If the LUMO energy is low enough, as in furan or thiophene (as shown in Table 2) the reaction proceeds to give an aryllithium compound and lithium hydride.

Table 2. LUMO energies of selected reactants calculated with B3LYP/6-31G**

	LUMO (eV)	Reaction
1-methylpyrrole	1.44	no reaction
1,2,5-trimethylpyrrole	1.27	
2-methoxyfuran	0.94	C−H activation
2,5-dimethylfuran	0.76	
furan	0.51	
2-lithiooxazole	0.21	
5-lithiooxazole	0.12	
2,5-dimethylthiophene	0.00	
oxazole	−0.03	
thiophene	−0.22	



Scheme 7. Bond lengths in pm for furan reaction intermediates

Scheme 7 shows all the bond lengths of the calculated species in the furan study. The formation of the first intermediate does not change the structure of the furan ring significantly. The Li−Li distance is slightly elongated. In the uncoordinated dilithium species *d*(Li−Li) is 272.3 pm, which changes to 274.3 and 275.2 pm in the η^1-complex and π-complex.

The formation of the second intermediate changes the structure of the ring. The distance between the activated carbon and the oxygen is elongated by 9.3 pm by the formation of a three-membered ring involving lithium. Furan, methoxyfuran and oxazole show a clear interaction between the heteroatom and one lithium in this second intermediate, which can be seen from the short bond lengths of 184.5, 194.0 and 192.4 pm, respectively.

For 2,5-dimethylfuran, 2,5-dimethylthiophene and thiophene the second intermediates exhibit a symmetrical four-membered CLi_2H ring, as shown in Table 3.

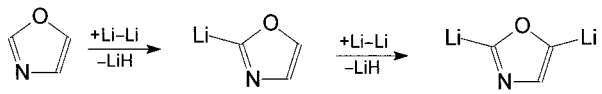
Table 3. Bond lengths for C−Li−H rings on second intermediates

	2,5-Dimethylfuran	Thiophene	2,5-Dimethylthiophene
C−Li	210.1	211.7	210.6
Li−H	177.5	177.2	176.8

When an oxygen-donor group is placed in the heterocyclic ring, as in the case of methoxyfuran, the NMR spectroscopic data indicate an *ortho* lithiated product with respect to the methoxy group. In furan and 2,5-dimethylfuran, the η^1-complex is a more stable first intermediate than the π-complex, but, in contrast, the Li−Li is bonded to the methoxy group in the η^1-complex formed.

For the reaction of oxazole with lithium atoms in the presence of THF, a different reaction sequence with respect to the other heterocyclic compounds was observed. The ability to develop a second lithiation reaction, as shown in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 8. Reaction of oxazole with lithium atoms in the presence of THF

Scheme 8, is the governing factor here. The first intermediate is characterised by the nitrogen, which is able to stabilise the Li−Li cluster more than the oxygen η^1-complex. However, no π-complex was found as a stable intermediate.

Once the first C−H activation has occurred, the monolithiated oxazole is still able to react further. As Scheme 8 shows, this second lithium is also observed in an *ortho* position with respect to the oxygen.

From the calculated LUMO energies of the reactants (Table 2), a comparison can be made in relation to the dilithiated species. The calculation of LUMO energies of the monolithiated compounds was carried out considering solvent interaction with the lithium. For this purpose, three molecules of ammonia were taken to fill the coordination sphere of lithium instead of THF, in order to simplify the process. The calculated LUMO energies for the monolithiated species 2-lithiooxazole and 5-lithiooxazole are 0.21 and 0.12 eV respectively. These LUMO energies can be considered within the range of species that can be activated. It follows that a further activation with addition of lithium to the lithiated oxazole can readily occur during the cocondensation reaction.

Conclusion

Lithium atoms are able to activate heterocyclic aromatic compounds like furan and thiophene, which have a relatively low-lying LUMO energy. The only product of this selective C−H-activation process is 2-lithiofuran or 2-lithiothiophene. If the LUMO energy is considerably higher as in pyrrole, no C−H activation can be observed. If the normally activated *ortho* position is blocked, as in 2,5-dimethylfuran or thiophene, the cocondensation reaction in the presence of THF leads to a selective monolithiation at the *meta* position. The corresponding 1,2,5-trimethylpyrrole fails to react because of its high-lying LUMO energy. Interestingly, oxazole cocondensed with lithium atoms results in 2,5-dilithiooxazole in a novel reaction variation, but the exact mechanism of the dilithiation of oxazole remains unclear. For all the furans in this study and the oxazole, an η^1-complex was calculated to be the most stable intermediate in the early phase of the C−H activation reaction, while thiophenes preferred π-complexes with the intermediate dilithium cluster.

Experimental Section

General: All experimental procedures were performed using standard Schlenk techniques under dry argon. THF was dried and distilled from sodium/benzophenone under argon. Furan, thiophene, 1-methylpyrrole, 2,5-dimethylfuran, 2,5-dimethylthiophene, 1,2,5-trimethylpyrrole, 2-methoxyfuran and oxazole were dried and distilled from calcium dihydride under argon. All solvents were then degassed by three freeze-pump-thaw cycles. Celite was stored in an oven at 120 °C overnight and was dried under vacuum for three hours before use. For each filtration, a plug of approximately 6 cm of Celite was used and each filtration was performed under the vigorous exclusion of air and moisture. ^{1}H and ^{13}C NMR spectra were obtained with either a Varian 300 MHz or a Varian 500 MHz NMR machine. All chemical shifts are reported in ppm and are referenced to TMS. All GC-MS samples were run as liquid samples in ethyl acetate on a Finnigan Trace GC-MS, equipped with an RTX-5MS 15 m column.

A Typical Cocondensation Experiment: Lithium metal (0.53 g, 0.076 mol) was vapourised from an alumina crucible protected by a stainless-steel inlet at around 800 °C over 90 minutes and cocondensed with a mixture of the aromatic compound (15 mL) and THF (80 mL, 1.12 mol). The solution was filtered through a plug of Celite in order to remove the solid lithium hydride by-product and unchanged lithium metal. After removal of the solvent mixture in vacuo, a solid was isolated and washed with THF (20 mL). The lithiated aromatic compound was identified by derivatisation with Me_3SiCl.

A Typical Derivatisation of the Lithiated Aromatic with Me_3SiCl: Me_3SiCl in THF solution was added dropwise with vigorous stirring to a solution of the lithiated aromatic compound (about 0.25 g) in THF (20 mL) at room temperature. The reaction was judged to be finished when a colour change from dark red-yellow to pale yellow occurred. Water (10 mL) was added to this solution, and the organic phase was separated. The aqueous phase was washed three times with dichloromethane (10 mL). The combined organic extracts were dried with $MgSO_4$ and then the solvent was removed under reduced pressure, affording the derivative. GC-MS, ^{1}H and ^{13}C NMR were used to identify the product.

Theoretical Methods Used in This Study: DFT calculations were performed with B3LYP and the 6−31G** basis set for C, H, O, N, S, and Li. For this purpose the program GAUSSIAN 98[19] was used on a Dell workstation running Red Hat Linux. Harmonic vibrational frequencies, calculated at the same level, characterised stationary points and gave the zero-point energy. The difference in the sum of the electronic and the zero-point energies were interpreted as reaction enthalpies at 0 Kelvin. LUMO energies for each aromatic compound were obtained from geometry-optimised structures using B3LYP/6-31G**.

2,5-Dimethyl-3-(trimethylsilyl)furan: The general procedure applied to 2,5-dimethylfuran gave 3-lithio-2,5-dimethylfuran (red) in 25% yield (0.8 g), identified as its TMS derivative. ^{1}H NMR ($CDCl_3$): δ = 5.7 (s), 2.1 (s) ppm. ^{13}C NMR ($CDCl_3$): δ = 151.0, 106.9, 99.8, 14.5, 12.1, 2.9 ppm.

2,5-Dimethyl-3-(trimethylsilyl)thiophene: The general procedure applied to 2,5-dimethylthiophene gave 3-lithio-2,5-dimethylthiophene (brown) in 45% yield (5.8 g), identified as its TMS derivative. ^{1}H NMR ($CDCl_3$): δ = 6.5 (s), 2.4 (s) ppm. ^{13}C NMR ($CDCl_3$): δ = 137.0, 126.0, 123.7, 14.2, 13.0, 2.1 ppm.

2-Methoxy-3-(trimethylsilyl)furan: The general procedure applied to 2-methoxyfuran gave 3-lithio-2-methoxyfuran (red) in 35% yield (2.7 g), identified as its TMS derivative. ^{1}H NMR ($CDCl_3$): δ = 7.5 (d, J = 5.3 Hz), 6.1 (d, J = 5.3 Hz), 3.7 (s) ppm. ^{13}C NMR ($CDCl_3$): δ = 172.7, 151.8, 120.6, 98.0, 67.0, 0.9 ppm.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2,5-Bis(trimethylsilyl)oxazole: The general procedure applied to oxazole gave 2,5-dilithiooxazole (red/orange) in 29% yield (1.5 g), identified as its TMS derivative. ^{1}H NMR ($CDCl_3$): δ = 7.2 (s) ppm. ^{13}C NMR ($CDCl_3$): δ = 149.0, 137.5, 125.9, 2.0 ppm.

Supporting Information: Coordinates, electronic and zero-point energies of all optimised species.

COVER PICTURE

The cover picture shows DFT-optimized models of a non-heme high-spin iron(IV)-oxo intermediate and of Collins' stable high-spin Fe^{IV} complex. A. Ghosh, P. R. Taylor and co-workers show in their article on p. 4555ff. that these species, although both are high-spin Fe^{IV}, exhibit radically different electronic configurations and spin density profiles (green). Moreover, the authors present some of the first high-level ab initio calculations aimed at benchmarking the triplet-quintet energy difference for Fe^{IV} species.

$[Ge_9O_{14}(OH)_{12}](C_6N_2H_{16})_2{\cdot}H_2O$: A Novel Germanate with Ge−O Helical Chains Formed by Hydrothermal Synthesis that Can Separate *trans* and *cis* Isomers in Situ

Yan Xu,*[a] Wei Fan,[a] S. P. Elangovan,[a] Masaru Ogura,[a] and Tatsuya Okubo*[a]

Keywords: : Germanium / Helical structures / Hydrothermal synthesis / Isomers

A novel germanate $[Ge_9O_{14}(OH)_{12}](C_6N_2H_{16})_2{\cdot}H_2O$ (**1**; UTM-4) has been synthesized under hydrothermal conditions and its structure characterized by X-ray crystallography [a = 9.293(2), b = 12.164(2), c = 14.564(3) Å, β = 94.96(3)°, V = 1640.1(6) Å^3, Z = 2, monoclinic, space group $P2_1/c$]. The structure consists of Ge–O layers of helical chains, which are linked by hydrogen bonds to form a soft, open framework that exhibits a selectivity for *cis*-1,4-diaminocyclohexane during the synthesis.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Great efforts have been made to synthesize germanium frameworks, as germanium is the closest analog to silicon and is therefore an attractive element to build open-frameworks in zeolite chemistry.[1−9] In germanates, Ge can adopt different Ge/O radius ratios to form polyhedra with a coordination number of four (tetrahedron), five (square bipyramid) or six (octahedron). The Ge−O distances are also significantly longer than the Si−O bond in silicates. Therefore, the flexibility of the polyhedral structure for germanium allows the formation of various open-framework structures with an extra-large pore, such as FDU-4[7a] and ASU-16.[7b] Recent research in the field of materials chemistry has focused on the synthesis of inorganic materials with helical pores or chains as they are desirable for selective enantiotopic separation and catalysis.[4d,10−14] Among the open-framework materials reported so far, only a limited number of phosphates and germanates[2c,4d] have such structural features. For examples, the zinc phosphate $[NH_3(C_2H_4)NH_2(C_2H_4)NH_3][Zn_4(PO_4)_3(HPO_4)]{\cdot}H_2O$[10] possesses intersecting helical chains, UCSB-7 has cross-linked helical pores,[4d] and the vanadophosphate $[(CH_3)_2NH_2]K_4[V_{10}O_{10}(H_2O)_2(OH)_4(PO_4)_7]$[11] contains interpenetrating double helices. Some other examples include aluminum phosphates, gallium phosphates, boron phosphates, and zinc phosphates.[12,13] Here we report the hydrothermal synthesis and structural characterization of a novel germanate $[Ge_9O_{14}(OH)_{12}](C_6N_2H_{16})_2{\cdot}H_2O$ (**1**) with a particularly interesting structure containing helical Ge−O chains that is selective for *cis*-1,4-diaminocyclohexane during the synthesis.

Results and Discussion

Germanate **1** was synthesized by a hydrothermal method from an organic-rich gel consisting of germanium dioxide, a mixture of *cis*- and *trans*-1,4-diaminocyclohexane, HF, pyridine, and H_2O in a 25-mL, Teflon-lined autoclave at 175 °C for 7 d. The crystalline product was characterized by thermal analysis (TG-DTA), powder X-ray diffraction (XRD) and single-crystal XRD.

The structural analysis revealed that the novel Ge−O layers are linked by hydrogen bonds to form a three-dimensional structure, and that only *cis*-1,4-diaminocyclohexane is present in **1**. As shown in Figure 1, the Ge−O (or OH) layer is constructed from three units, namely $\{[GeO_3(OH)_2]-(GeO_4)-[GeO_4(OH)]\}_n$ helical chains, $[Ge(OH)_2]^{2+}$ fragments connected by different chains, and $[Ge(OH)_3]^+$ fragments bonded by three bridging O-atoms from one chain that stabilize the helical chains. In the helical chain, GeO_4OH and GeO_3OH_2 trigonal bipyramids share their edges, and they are linked by corner-sharing GeO_4 tetrahedra. The central axis for every Ge−O helical chain is a twofold screw axis (symmetry: $-x$, 0.5 + y, 0.5 − z). Two bridging O atoms from adjacent GeO_4 and GeO_3OH_2 units in the helical Ge−O chain coordinate to another germanium of $[Ge(OH)_2]^{2+}$, generating a three-membered $[Ge_3O_3]$ ring. These three-membered rings link the right- and left-handed helical Ge−O chains (Figure 1b) to produce a Ge−O layer in the 011 plane (Figure 1a). Adjacent Ge−O layers are connected by hydrogen bonds

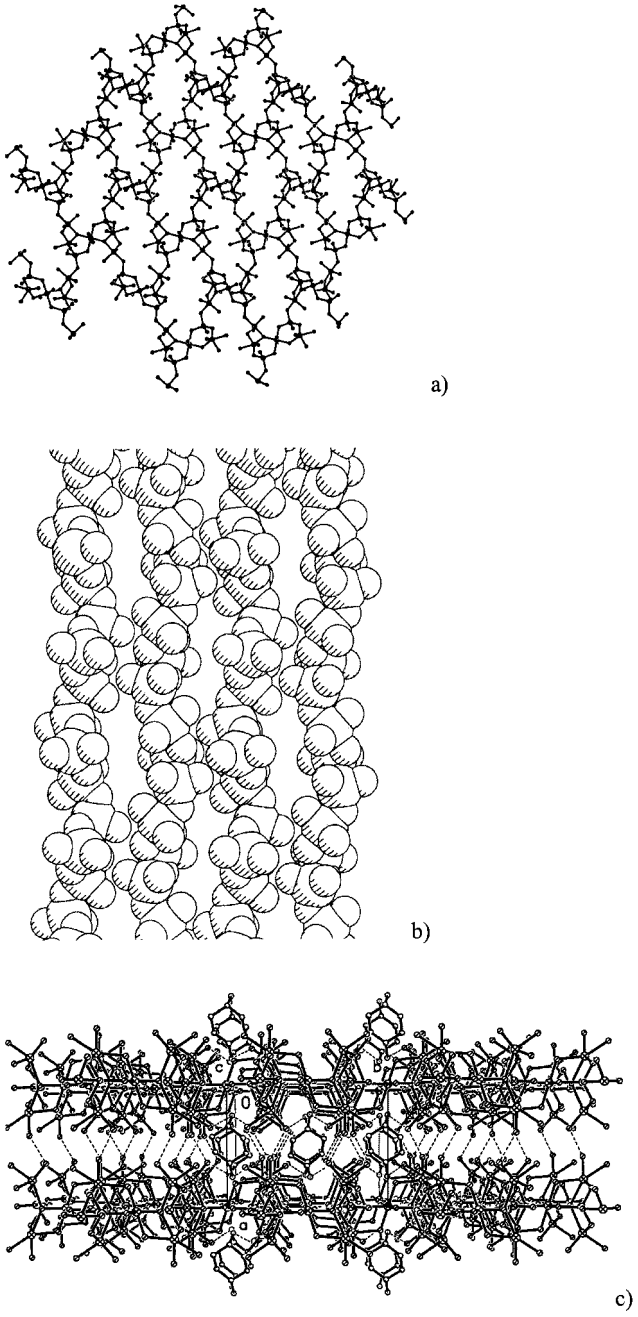

Figure 1. a) View of the Ge−O layer [$Ge(OH)_3^+$ fragments have been omitted]; b) helical Ge−O chains; c) three-dimensional, hydrogen-bonded structure (*cis*-1,4-diaminocyclohexane has been omitted for clarity)

through terminal OH groups to form a three-dimensional structure (Figure 1c).

The Ge in $[Ge(OH)_2]^{2+}$ is located at the symmetric center and, therefore, is constrained by symmetry to adopt an octahedral coordination (bonded by four bridging oxygen atoms and two hydroxyl groups), while the Ge of $[Ge(OH)_3]^+$ is chelated by three bridging oxygen atoms from a helical Ge−O chain, and shares one bridging OH with $[Ge(OH)_2]^{2+}$, to stabilize the helical chains and layers. There are three unique germanium sites in the helical chains: one regular tetrahedrally coordinated germanium (GeO_4) is bonded to four oxygen atoms, and two kinds of five-coordinate germanium sites [$GeO_3(OH)_2$ and $GeO_4(OH)$] are coordinated by O atoms and OH groups. Some terminal OH groups are involved in hydrogen-bond interactions between adjacent layers. The shortest O···O distance in the two layers is 2.96(2) Å. The Ge−OH distances for these OH groups are 2.038(8) and 2.094(8) Å, which are much longer than the other reported Ge−OH bond lengths. This can be ascribed to the hydrogen bonds between adjacent layers. All the Ge−O bond lengths for the tetrahedral germanium center vary from 1.712(4) to 1.752(5) Å [mean 1.730(4) Å)], and are very similar to the reported value for the quartz modification of GeO_2 [1.741(3) Å]. The Ge−O bond lengths for the five- and six-coordinate germanium centers range from 1.683(10) to 2.344(8) Å. These values are in agreement with those observed for known germanates.

A particularly interesting aspect of this reaction is the selectivity for *cis*-1,4-diaminocyclohexane (Figure 2) in the synthesis of germanate **1**. The separation of isomers is, in general, very difficult because of their similar physical and chemical properties. For example, the boiling point of both *trans*- and *cis*-1,4-diaminocyclohexane is 197 °C. Here we found that *cis*-1,4-diaminocyclohexane was successfully recovered from the mixture. In order to separate the isomers, a mixture of *trans*- and *cis*-1,4-diaminocyclohexane (approx. 1:1) was used as the reactant in a separation experiment. After hydrothermal synthesis, *cis*-1,4-diaminocyclohexane was found to be concentrated in the Ge−O layers as a guest molecule, with both N-atoms of the organic amine binding to the helical Ge−O chains through N-H···O hydrogen-bond interactions, while *trans*-1,4-diaminocyclohexane remained in solution. We analyzed the structures of four different crystals of germanate **1** but did not find any *trans*-1,4-diaminocyclohexane.

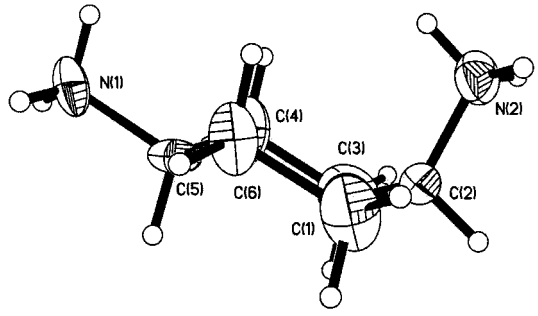

Figure 2. *cis*-1,4-Diaminocyclohexane was selected by germanate **1**

Significant changes in the powder X-ray diffraction patterns and TG curve were seen after germanate **1** was stirred in a 1 m solution of $NaNO_3$ at 50 °C. These ion-exchange results indicate that part of the structure-directing agents (SDAs) can be exchanged.

Thermal analysis of germanate **1** under a 10% O_2 (Ar balance) atmosphere reveals a weight loss of 1.3% between 60 and 226 °C, followed by a further weight loss of 26.7% between 226 and 700 °C. The calculated weight losses for

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

water (1.35%) and combustion of the SDA and OH (28.6%) are in agreement with these results.

In conclusion, a novel germanate with helical Ge−O chains has been synthesized. This compound can separate *cis*- and *trans*-1,4-diaminocyclohexane in situ during the hydrothermal synthesis. The present work has great significance for germanium chemistry and isomer separation.

Experimental Section

1: Colorless, plate-like crystals of $[Ge_9O_{14}(OH)_{12}](C_6N_2H_{16})_2{\cdot}H_2O$ were prepared by a hydrothermal method from an organic-rich solution consisting of GeO_2, SiO_2, a mixture of *trans*- and *cis*-1,4-diaminocyclohexane, HF, pyridine, and H_2O in a molar ratio of 1:1:7.5:4.5:51:75. To avoid the formation of $Ge_7O_{14}F_3{\cdot}[H_2DACH]_{1.5}{\cdot}2H_2O$[15] ($H_2DACH$ = diaminocyclohexane) SiO_2 was added to induce the formation of germanate **1**. GeO_2 (0.12 g) and SiO_2 (0.60 g) were added to a mixture of pyridine (4.66 g), 1,4-diaminocyclohexane (1.05 g, mixture of *trans* and *cis* isomers), and water (1.55 g). Thereafter, this gel was stirred at room temperature overnight. Finally, a 47% HF solution (0.10 g) was added. The mixture was kept in a 25-mL, Teflon-lined autoclave at 170 °C for 7 d. The product was then washed with deionized water and ethanol, and dried at room temperature for 24 h (0.07 g; yield 41% based on Ge). Germanate **1** can also be synthesized under the same conditions but without SiO_2 powder. $C_{12}H_{46}Ge_9N_4O_{27}$: calcd. C 10.81, H 3.45, N 4.20; found C 10.10, H 3.67, N 3.91. X-ray powder diffraction analysis was performed on an M03X-HF (MAC Science) diffractometer, with Cu-K_α radiation, at 40 kV and 20 mA at a scanning rate of 4°/min with a step of 0.02°. Thermogravimetric (TG) analysis of germanate **1** was carried out under an O_2/Ar atmosphere on a Thermoplus TG 8120 (Rigaku) analyzer from 25 to 750 °C, at a heating rate of 10 °C/min.

X-ray Crystallographic Study: $C_{12}H_{46}Ge_9N_4O_{27}$, monoclinic, $P2_1/C$ (no.14), a = 9.293(2), b = 12.164(2), c = 14.564(3) Å, β = 94.96(3)°, V = 1640.1(6) Å^3, Z = 2, μ(Mo-K_α) = 8.237 mm^{-1}. Dimensions: 0.12 × 0.11 × 0.05 mm. 3661 Reflections with $I > 2\sigma(I_0)$ and 268 parameters gave $R1$ (wR) = 0.0729 (0.1223). The occupancy factors are 0.5 for O8, O8a, O12, O12a, O13, and O13a. Diffraction data were collected on a Rigaku R-AXIS RAPID IP diffractometer at 20 °C in the range $2.76° < \theta < 27.44°$. An empirical absorption correction was applied. The structure was solved by direct methods and refined by full-matrix least-squares on F^2. All non-hydrogen atoms were refined anisotropically. The oxygen atoms O5, O10, O11, O12, O12a, O13, and O13a are terminal and correspond to OH, as in other reported germanates. The half-occupied O8 and O8a atoms also belong to OH, because of their low thermal parameters and longer bond distances than other doubly bridging O-atoms.

CCDC-233622 contains the supplementary crystallographic data for this paper. Immobilization of a High-Valent Rhenium Complex on an Indium-Doped Tin-Oxide Electrode: Enhanced Catalytic Activity of a *trans*-Dioxorhenium(V) Complex in Electrochemical Oxidation of Alcohols

Hideki Sugimoto,*[a] Hiroshi Tsukube,[a] and Koji Tanaka[b]

Keywords: Surface analysis / Cyclic voltammetry / Immobilization / Rhenium / Oxidation

A high-valent *trans*-dioxorhenium(V) complex containing pyridine ligands was successfully immobilized on an ITO (indium-doped tin-oxide) electrode. The complex formed a monolayer structure on the electrode surface and promoted electrochemical catalytic oxidation of 1-phenylethanol to acetophenone in CH_2Cl_2. Oxidation hardly occurred in CH_2Cl_2 solution containing the free rhenium(V) complex. Immobilization of other high-valent metal complexes will present opportunities for design of functional electrodes with high activities.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

One of the most effective strategies in the development of novel molecular devices such as sensors and nanosized catalysts is to immobilize redox- and photo-active metal complexes on semiconductor electrodes by utilizing their well-defined structure.[1] Several ferrocene derivatives[2] and Re^{I},[3] Os^{II},[4] and Ru^{II} [5] complexes have already been immobilized on electrodes and have effectively mediated electron- and charge-transfer processes. Although most of the metal complexes operating in previous electrode systems were limited to those of low oxidation numbers, a few studies have immobilized high-valent compounds.

trans-$[Re^{V}O_2(pys)_4]^+$ (pys = pyridine derivatives) complexes have interesting features as redox- and photo-active catalysts, such as: 1) one-electron oxidation of the $Re^{V}O_2$ complexes affords higher-valent $Re^{VI}O_2$ cores;[6] 2) the two oxygen atoms attached to the Re center are responsible for electrochemical oxidation of organic molecules;[7] and 3) they exhibit microsecond long-lived luminescence based on d-d transitions in the visible region.[7] We have prepared the novel complex *trans*-$[ReO_2(L)_4]PF_6$ [**1**]PF_6 (L = 3-pyridinecarboxylic acid) containing free carboxylic acid groups (Figure 1). Such high-valent Re^{V} complexes have rarely been immobilized. Herein we investigate the immobilization of a series of Re^{V} complexes on ITO (indium-doped tin-oxide) electrodes and their catalytic activity in the oxidation of 1-phenylethanol and related alcohols (Scheme 1).

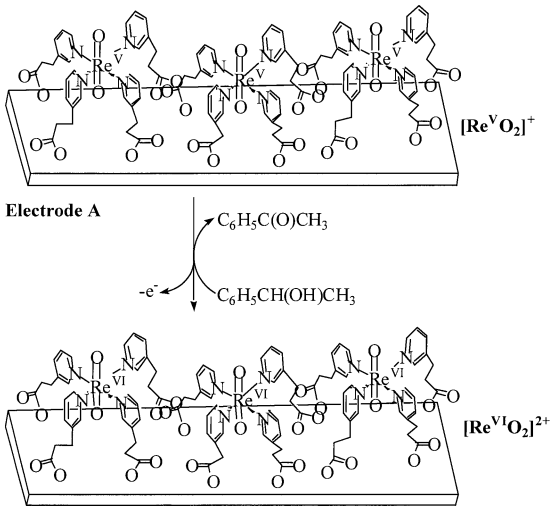
[**1**]$^+$

Figure 1. Suggested structure of [**1**]$^+$

Results and Discussion

In electrochemical experiments, complex [**1**]$^+$ shows a reversible redox wave assignable to a $Re^{VI/V}$ couple at 0.90 V vs. Fc/Fc^+ in CH_3CN. The complex was immobilized on ITO[8] electrodes by three different methods. Electrode **A** was modified by dipping the ITO electrode into a CH_3CN solution of the [**1**]PF_6 complex (2×10^{-4} M) for several days. Electrodes **B** and **C** were modified by combining the [**1**]PF_6 complex with aminoethyl- and aminomethylphosphonic acids by inserting them into the space between the surface of the electrodes and the [**1**]PF_6 complex. In electrode **A**, [**1**]$^+$ can connect with the ITO surface through carboxylate ester bonds [Sn−O−C(O)-] and hydrogen bonds [Sn=O···HO-C(O)-], as observed for the adsorption of ruthenium complexes containing free carboxylic acids

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200400546



Scheme 1. *trans*-Dioxorhenium complex $[\mathbf{1}]^{+/2+}$ immobilized on an ITO electrode and electrochemical oxidation of 1-phenylethanol to acetophenone

onto metal oxides such as SnO_2, TiO_2, and In_2O_3.[5h] In electrodes **B** and **C**, however, $[\mathbf{1}]^+$ can connect with the amino groups of the spacer compounds through peptide bonds [−NH−C(O)-], and these units, in turn, connect with the ITO surface through phosphate ester bonds [Sn−O−P(O)-], as reported for the adsorption of ruthenium complexes containing free phosphonic acids onto these metal oxides.[5f,5g,9] The only difference between electrodes **B** and **C** is the length of the methylene chain: P−CH_2−CH_2−N for electrode **B** and P−CH_2−N for electrode **C**. The electrode performances were characterized by cyclic voltammetry. The three electrodes **A**−**C** exhibit the same redox potential, $E_{1/2}$, of $Re^{VI/V}$, but with different peak-to-peak separations ($\Delta E_p = E_{pa} - E_{pc}$). Electrode **A** shows a somewhat larger peak separation of 0.11 V than electrodes **B** and **C** (ΔE_p = 0.05 V). The electrodes also exhibit somewhat different surface stabilities. After the electrodes were rinsed for one hour, the current intensity of $Re^{VI/V}$ decreased by 15% for electrode **A**, but decreased by only 5% for electrodes **B** and **C**.

The electron-transfer process of electrode **B**, as characterized by cyclic voltammetry, was typical (Figure 2). The intensities of the anodic and cathodic currents are directly proportional to the increase in scan rate up to 300 mV·s^{-1}; they gradually saturate as the rate increases above 350 mV·s^{-1}. Since electrodes **A** and **C** show similar electrochemical behaviors despite their different construction, the redox processes in these systems must be confined to the surface. The surface coverages of the complexes were calculated by coulometric measurements at 1.2 V. The surface areas were estimated as 2.5×10^{-10} mol/cm^2 for electrode **A**, 1.9×10^{-10} mol/cm^2 for electrode **B**, and 1.8×10^{-10} mol/cm^2 for electrode **C**. Although the crystal structure of $[\mathbf{1}]PF_6$ is not available, the limiting surface coverage was roughly estimated as 2.9×10^{-10} mol/cm^2 by assuming that spheres based on the bond lengths and angles reported for *trans*-$[ReO_2(4\text{-picoline})_4]ReO_4$ are packed on a flat surface, and neglecting counteranions.[10] Similar surface coverages have been reported for monolayered electrodes with Ru complexes: $[Ru(2,2'\text{-bipyridyl})_2(2,2'\text{bipyridyl-4,4'-dicarboxylic acid})]^{2+} = 1.5 \times 10^{-10}$ mol/cm^2;[9] and $[Ru(2,2'\text{-bipyridyl})_2(2,2'\text{bipyridyl-4,4'-diphosphonic acid})]^{2+} = 2.5 \times 10^{-10}$ mol/cm^2.[9] Thus, the employed Re^V complex $[\mathbf{1}]^+$ is believed to form a monolayer structure on the ITO electrode surface.

The modified electrodes exhibit interesting catalytic behavior in the electrochemical oxidation of 1-phenylethanol. As shown in Figure 3, the intensity of the oxidation current corresponding to $Re^{VI/V}$ increases in the presence of 8.2 mM 1-phenylethanol (see b in Figure 3). Further addition of the alcohol substrate (total 24.5 mM) led to a further increase in the oxidation current, and a corresponding decrease in the reduction current (see c in Figure 3). Electrolysis was carried out at 1.2 V until no oxidation current was observed, and the reaction mixtures were then characterized by GC-MS and HPLC methods, which indicated that 1-phenylethanol had been converted into acetophenone. Electrochemical oxidation of this alcohol hardly occurred in CH_2Cl_2 solution containing the free complex $[\mathbf{1}]^+$, in which a glassy carbon electrode having the same surface area as

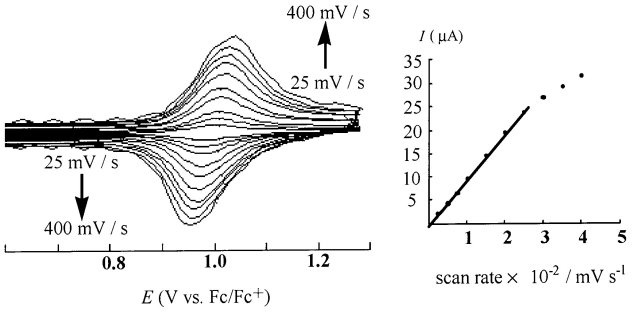


Figure 2. Cyclic voltammetry of modified electrode **B**: scan-rate dependence at 25, 50, 75, 100, 150, 200, 250, 300, 350, and 400 mV·s^{-1} (left) and linear correlation of current against scan rate recorded in CH_2Cl_2 containing 0.1 M Bu_4NPF_6 (right)

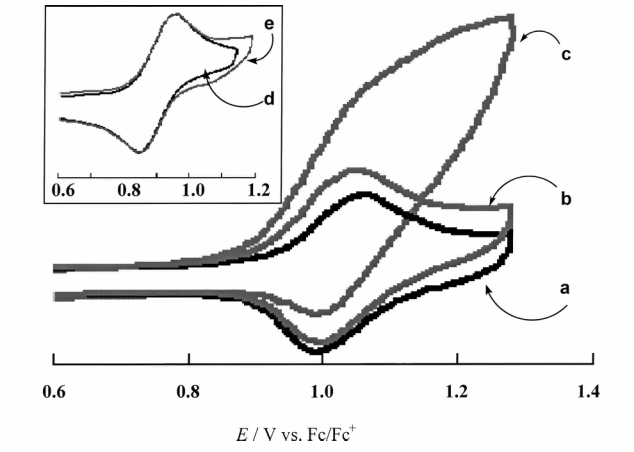

Figure 3. Cyclic voltammetry changes of modified electrode **B** in CH_2Cl_2 upon addition of 1-phenylethanol (**a**: 0 mM, **b**: 8.2 mM, **c**: 24.5 mM), and complex $[\mathbf{1}]PF_6$ in CH_2Cl_2 upon addition of 1-phenylethanol (inset, **d**: 0 mM, **e**: 810 mM)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the employed ITO electrode was used. Also, the current intensity only increased slightly, even in the presence of a large excess of 1-phenylethanol (810 mM) (see inset e in Figure 3). Electrodes **B** and **C** exhibit higher turnover numbers (TON) and current efficiencies in the oxidation of 1-phenylethanol than electrode **A**. Table 1 compares the catalytic profiles of the three modified electrodes. The spacer insertion enhances the catalytic activity of the *trans*-dioxorhenium(V) complexes.

Table 1. Catalytic oxidation of 1-phenylethanol by modified electrodes **A**−**C**

Modified electrode	**A**	**B**	**C**
TON[a]	900	1300	1200
Current efficiency[b]	65	85	80

[a] Turnover number (product mol/complex mol). [b] $2e^-$ per substrate.

The rate constants for the system $v = k[Re^V$ on electrodes][1-phenylethanol] of electrodes **A**−**C** were roughly determined to be about 1 M^{-1} s^{-1} using Equation (1)

$$i = nFAk\Gamma_p C_A \quad (1)$$

where n = number of electrons, F = Faraday constant, A = surface area, Γ_p = surface coverage, k = rate constant, and C_A = concentration of substrate, which has been previously applied to heterogeneous systems.[11] The current intensities independent of the scan rates were entered as i in this equation. Since these three electrodes have almost identical surface coverages and rate constants, their catalytic activities must depend on the presence, or absence, and nature of the spacers introduced between the electrode surface and complex $[\mathbf{1}]^+$.

These electrodes also catalyze the oxidation of 1-heptanol and 2-propanol to give 1-heptanealdehyde and acetone, respectively. Although the detailed mechanism is unclear,[12] the catalytic cycles may contain redox and acid-base reactions of the *trans*-ReO_2 unit as suggested in a *trans*-$[ReO_2(py)_4]^+$ system,[7] in which the active Re^{VI} state was significantly involved (Scheme 1).

Conclusion

We have presented the first example of high-valent metal complexes immobilized on an electrode surface. The *trans*-dioxorhenium(V) complexes immobilized on the electrode surface enable catalytic oxidation of 1-phenylethanol to acetophenone with high turnover and high current efficiency. A combination of high-valent metal complexes with electrodes could provide a new generation of electrochemical catalysts.

Experimental Section

***trans*-$[ReO_2(L)_4]PF_6$ ($[\mathbf{1}]PF_6$; L = 3-pyridinecarboxylic acid):** A suspension containing $[ReOCl_3(PPh_3)_2]$ (0.50 g, 0.60 mmol) and 3-pyridinecarboxylic acid (1.80 g, 12 mmol) in acetone/H_2O (20:1 v/v) was refluxed for 90 minutes to give an orange solution. After filtration, the orange solution was concentrated to 5 mL. After silica-gel column chromatography (CH_3OH eluent), addition of NH_4PF_6 (300 mg, 1.80 mmol) in H_2O (10 mL) gave an orange powder. The collected powder was dried in air (yield: 126 mg, 22%). $C_{32}H_{36}F_6N_4O_2PRe$ (967.84): calcd. C 39.71, H 3.75, N 5.79. found C 39.79, H 3.89, N 5.42. ESI-MS: m/z = 823 $[M - PF_6]^+$. IR: $\tilde{\nu}$ = 799 cm^{-1} $\nu_{(O=Re=O)}$. ^1H NMR (300 MHz, $[D_6]$DMSO): δ = 2.52 (t, J = 7.7 Hz, 8 H, CH_2), 2.81 (t, J = 7.4 Hz, 8 H, CH_2), 7.49 (t, J = 5.8 Hz, 4 H, py), 7.74 (d, J = 7.7 Hz, 4 H, py), 8.84 (d, J = 5.8 Hz, 4 H, py), 8.92 (s, 4 H, py) ppm. UV/Vis (CH_3CN): λ = 430 nm (ε = 1250 $M^{-1}\cdot cm^{-1}$), 346 (19800), 254 (15600).

Preparation of ITO Electrodes: Before surface modification, each ITO electrode was washed with a 5:1:1 solution of H_2O, H_2O_2, and NH_4OH and thoroughly rinsed with purified water. After heating at 120 °C for 60 minutes, the electrode was cooled and stored under dry N_2.

ITO Electrode A: The dried ITO electrode was dipped in a CH_3CN solution of $[\mathbf{1}]PF_6$ (2×10^{-4} M) for several days. The electrode was then rinsed in ethanol to remove the adsorbed salt.

ITO Electrodes B and C: The dried ITO electrode was dipped in a CH_3CN solution of aminoethyl- or aminomethylphosphonic acid; after 24 hours, the electrode was picked up from the solution. The electrode on which the phosphonic acid was immobilized was again dipped in a solution of complex $[\mathbf{1}]PF_6$ (2×10^{-4} M) in the presence of four equivalents of DCC (1,3-dicyclohexylcarbodiimide) as a coupling agent for 3−4 days. The electrodes were then rinsed in ethanol to remove the adsorbed salt; in the absence of DCC the complex was not immobilized.

Electronic Structure of High-Spin Iron(IV) Complexes

Abhik Ghosh,*[a] Espen Tangen,[a] Hege Ryeng,[a] and Peter R. Taylor*[b]

Keywords: High-spin species / Nonheme / Iron / Oxo ligand / Diamond core / Quantum chemistry

High-spin (S = 2) iron(IV) species are rare but increasingly recognized as reactive intermediates in the catalytic cycles of several nonheme iron enzymes. A question of some interest, therefore, concerns how much higher in energy the low-spin (S = 1) state is for these species. With the use of density functional theory (DFT) and high-level ab initio calculations [CASPT2 and CCSD(T)], we have attempted to answer this question for the so-called Collins complex, a square-pyramidal Fe^{IV} complex with a tetraamido-*N* equatorial ligand set, a chloride axial ligand, and an S = 2 ground state. The calculations suggest that relative to the ground state, the low-spin state is higher in energy by at least 0.3 eV and possibly as much as 0.7 eV. Using DFT calculations, a broad quantum chemical survey of high-spin $Fe^{IV}O$ intermediates was also undertaken. A key finding is that the Fe–O distance and O spin population are quite similar across all mononuclear $Fe^{IV}O$ species studied, regardless of the heme versus nonheme environment and of the S = 1 versus 2 spin state, reflecting the essential similarity of the Fe(d_π)–O(p_π) orbital interactions in all the species studied. However, the spin density profiles of high-spin $Fe^{IV}O$ species, currently believed to be known only as a nonheme iron enzyme (TauD) intermediate, are predicted to be very different from that of Collins' high-spin Fe^{IV} complex. Our calculations further suggest that with the help of sterically hindered ligands such as 6-me_3-tpa, it might be possible to generate synthetic high-spin $Fe^{IV}O$ models of the unique TauD intermediate. Finally, our calculations confirm the aptness of describing the [(6-me_3-tpa)Fe^{III}(μ-O)$_2$$Fe^{IV}$(6-$me_3$-tpa)]$^{3+}$ cation as a flexible diamond core and indicate the presence of a fairly discrete high-spin $Fe^{IV}O$ unit within the dinuclear core.

Introduction

Although high-spin iron(IV) species are believed to be involved in the catalytic cycles of a number of nonheme iron enzymes,[1,2] they are exceedingly rare in a traditional inorganic context. This is not surprising given that high oxidation states are generally favored by strongly basic ligands, which in turn normally favor low-spin states of the coordinated transition metal ion. Indeed, a square-pyramidal Fe^{IV} complex with a macrocyclic tetraamido-*N* equatorial ligand and a chloride axial ligand, reported by Collins and coworkers more than a decade ago, serves as the only well-characterized high-spin Fe^{IV} species known.[3] At least three enzymatic high-spin Fe^{IV} species have been spectroscopically characterized but until now they have not lent themselves to X-ray crystallographic analysis. Perhaps the most celebrated example of a high-spin Fe^{IV} species is the critical methane-hydroxylating intermediate **Q** of sMMO.[4] There is strong evidence indicating that **Q** features an [Fe^{IV}_2(μ-O)$_2$]$^{4+}$ diamond core with antiferromagnetically coupled local high-spin Fe^{IV} centers.[2,4] A related $Fe^{III}Fe^{IV}$ species called intermediate **X** produces the catalytically essential tyrosyl radical in the R2 protein of ribonucleotide reductase to initiate the process of ribonucleotide reduction in DNA biosynthesis.[5] On the modeling front, Que and co-workers have reported synthetic [Fe_2(μ-O)$_2$]$^{3+}$ intermediates with localized high-spin Fe^{III} and Fe^{IV} centers, the high-spin character of the metal centers reflecting the relatively weak-field nature of the capping ligands, which are based on sterically hindered 2,6-dialkylpyridine units.[6,7] Finally and very recently, a high-spin Fe^{IV} intermediate of the mononuclear nonheme iron enzyme TauD (taurine/α-ketoglutarate dioxygenase) has been spectroscopically detected.[8] Given our longstanding interest in the electronic structures of high-valent transition metal species,[9] we have initiated a broad quantum chemical exploration of the electronic structures of various known high-spin Fe^{IV} species, this being our first report on the subject.

We present our results in two parts. In the first part, we present our efforts to model the well-characterized Collins species mentioned above,[3] focusing on benchmarking the relative energies of the high- and low-spin states using density functional theory (DFT) and ab initio CASPT2 and

CCSD(T) calculations.[10] The results emphasize the difficulty of the problem − an issue that is largely overlooked in modern quantum chemical studies of bioinorganic problems − but that said, the DFT results are not bad at all, and DFT is clearly indicated as the method of choice for a broad survey of high-spin Fe^{IV} species. In the second part of this paper, we present such a survey, focusing on high-spin $Fe^{IV}O$ species, including a model of the TauD intermediate.

The Collins Complex

Before undertaking a broad quantum chemical survey of high-spin $Fe^{IV}O$ species, it seemed worthwhile to obtain a feel for the suitability of DFT for such a study. While DFT has emerged as the almost universal method of choice for bioinorganic modeling studies, a number of cases have been documented in which DFT apparently does a poor job of describing the relative energetics of the low-lying states of transition metal complexes.[10] Indeed, based on the somewhat limited data available, Fe^{III} complexes appear to be particularly problematic; for example, DFT (PW91, B3LYP) does not exhibit a clear preference for a sextet ground state for (porphyrin)Fe^{III} chloride, as expected on the basis of experimental data, whereas CASPT2 and CCSD(T) calculations clearly yield the correct ground state and a substantial sextet-quartet splitting of about 0.7 eV.[11] In a recent review article,[10] we have summarized much of what has been accomplished so far in terms of benchmarking the energetics of key spin states of transition metal species of bioinorganic relevance. As the only well-characterized high-spin Fe^{IV} complex, the Collins complex appeared to be an ideal candidate for our benchmarking studies.

To address the essence of the benchmarking problem, there seemed little to be gained by dealing with the relatively complex macrocyclic tetraamido-*N* ligand used in the experimental study.[3] We have therefore used the smaller C_{2v} model complex **1** shown in Figure 1, which captures the key structural features of the synthetic complex.[3] Geometry optimizations were carried out for the $S = 1$ and 2 states of the model complex with both the PW91 and B3LYP functionals.[12] CASPT2 and CCSD(T) calculations[13] were carried out at both the PW91 and B3LYP optimized geometries. The CASPT2 calculations were carried out with two high-quality basis sets, denoted BS1 and BS2, the latter being significantly larger than the former.[14] Basis set BS1 was used for the CCSD(T) calculations. Table 1 lists selected geometry parameters for the PW91 and B3LYP structures as well as the PW91 Mulliken spin populations for selected atoms.[15,16] The agreement between the optimized and experimental[3] geometry parameters may be regarded as generally very good.[15] The triplet-quintet splitting turned out to be essentially zero with the PW91 functional and 0.21 eV (with the triplet higher in energy) with B3LYP DFT calculations, which clearly emphasized the need for benchmarking with more elaborate, correlated methods such as CASPT2 and CCSD(T).

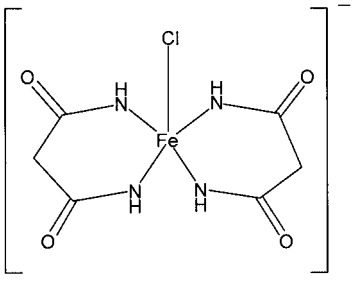

Figure 1. Simplified C_{2v} model **1** of the complex used in this study

Table 1. Selected geometry parameters (Å, °) and Mulliken spin populations[15]

	$S = 1$		$S = 2$	
	PW91	B3LYP	PW91	B3LYP
Geometry parameters[a][b]				
Fe−N	1.893	1.896	1.927	1.925
Fe−Cl	2.164	2.198	2.331	2.349
Fe−N_4	0.343	0.345	0.372	0.376
N−Fe−Cl	100.44	100.48	101.12	101.25
Mulliken spin populations[c]				
Fe	1.632		3.149	
N	0.043		0.074	
Cl	0.059		0.330	
C(CO)	0.002		−0.003	
O(CO)	0.036		0.050	

[a] In general, the PW91 and B3LYP geometry parameters are in excellent agreement, better than ±0.01 Å and ±0.05°. The only exception is the Fe−Cl distance, for which a somewhat larger difference is observed between the two functionals. [b] The symbol Fe−N_4 refers to the distance of the Fe atom from the plane containing the four nitrogen atoms. [c] The version of Turbomole used for the B3LYP optimizations does not report atomic spin populations.

At the CASPT2/BS1 level and with B3LYP optimized geometries, the triplet-quintet splitting was found to be 0.66 eV, or 0.56 eV if Fe 3s3p correlation was excluded. With the larger basis set BS2 and B3LYP geometries, the CASPT2 triplet-quintet splitting was 0.69 eV, or 0.58 eV if Fe 3s3p correlation was excluded. CCSD(T) calculations including 3s3p correlation were too large for our computational resources: the triplet-quintet splitting at the CCSD(T)/BS1 level without Fe 3s3p correlation, with B3LYP optimized geometries, was found to be 0.26 eV. Thus, agreement between the CASPT2 and CCSD(T) energetics is only fair, with a difference of about 0.3 eV between the two predictions when Fe 3s3p correlation is excluded. This discrepancy is as large as the splitting itself predicted by DFT [or by CCSD(T)] and begs the question as to which results (if any) are to be relied on.[17] On a more positive note, the triplet-quintet splitting obtained with B3LYP energetics is not bad and essentially the same as the CCSD(T) result, indicating the suitability of DFT for a broader exploration of high-spin Fe^{IV} intermediates; we have indeed carried out such a study and the results are outlined below.

High-Spin $Fe^{IV}O$ Intermediates

A question of longstanding interest concerns the possible involvement of $Fe^{IV}O$ intermediates in the catalytic cycles of *mononuclear* nonheme iron enzymes such as the pterin-dependent enzyme phenylalanine hydroxylase and the α-ketoglutarate-dependent enzyme prolyl hydroxylase.[1] However, as mentioned above, only very recently has the first such species been spectroscopically characterized: this is an intermediate of the mononuclear nonheme iron enzyme TauD (taurine/α-ketoglutarate dioxygenase), for which Mössbauer spectroscopic studies suggest a unique high-spin Fe^{IV} formulation.[8] While the ligation state of the iron center is not known, mechanistic considerations suggest that this may be an $Fe^{IV}O$ species, which would make it the first *mononuclear* high-spin $Fe^{IV}O$ intermediate − enzymatic or synthetic − to be spectroscopically characterized.

Considerable progress has also been made on the synthetic modeling front. Thus, the groups of Wieghardt[18] and Que[19,20] have synthesized and spectroscopically characterized a number of mononuclear nonheme $Fe^{IV}O$ intermediates.[1] One of these intermediates, $Fe^{IV}(O)(me_4cyclam)(CH_3CN)$, has also lent itself to a high-quality crystallographic analysis.[21] However, none of these species, which are $S = 1$, faithfully mimic the $S = 2$ TauD intermediate. In contrast, a formally dinuclear but "flexible" diamond-core intermediate formulated as $[(6\text{-}me_3\text{-}tpa)Fe^{III}-O-Fe^{IV}(6\text{-}me_3\text{-}tpa)=O]^{3+}$ and containing antiferromagnetically coupled, localized high-spin Fe^{III} and Fe^{IV} centers, reported by Que and co-workers, may provide the closest synthetic mimic of a mononuclear $S = 2$ $Fe^{IV}O$ intermediate.[22] Given the well-documented ability of sterically hindered 6-alkylated tpa ligands to enforce high-spin states of coordinated Fe^{III} and Fe^{IV} ions,[23,24] it is natural to consider $(6\text{-}me_3\text{-}tpa)Fe^{IV}(O)(L)$ (where L is an, as yet, undefined ligand) species as attractive synthetic models for the $S = 2$ TauD intermediate. We have done so in this study, and indeed a high-spin ground state appears likely for such species. Also presented are the first results of our attempts to model the flexible diamond core mentioned above.

The optimized structures of the $S = 1$ species $Fe^{IV}(O)(L)_2(PhCN)$ (**2**: L = en; **3**: L = tmen) and of $Fe^{IV}(O)(P)(PhCN)$ (**4**), shown in Figure 2, provide a comparison of the electronic character of the $Fe^{IV}O$ unit in heme with nonheme environments.[25] Figure 2 shows that for a particular *trans* ligand (PhCN in all these cases), the Fe−O bond lengths are nearly identical in all three species and very similar to that observed experimentally for $Fe^{IV}(O)(me_4cyclam)(CH_3CN)$.[21] As long known for (porphyrin)$Fe^{IV}O$ derivatives (peroxidase compound II analogues),[26,27] the electron spin density is almost completely localized on the FeO unit for all three species **2**−**4** and also partitioned rather similarly between the Fe and O atoms.

The TauD iron site has a 2-His-1-carboxylate ligand environment,[8] which we have chosen to model with chelating bis(2-imidazolyl)methane and malonate ligands to provide some conformational rigidity to the optimized species. A number of stereoisomers were examined, and species **5**, a

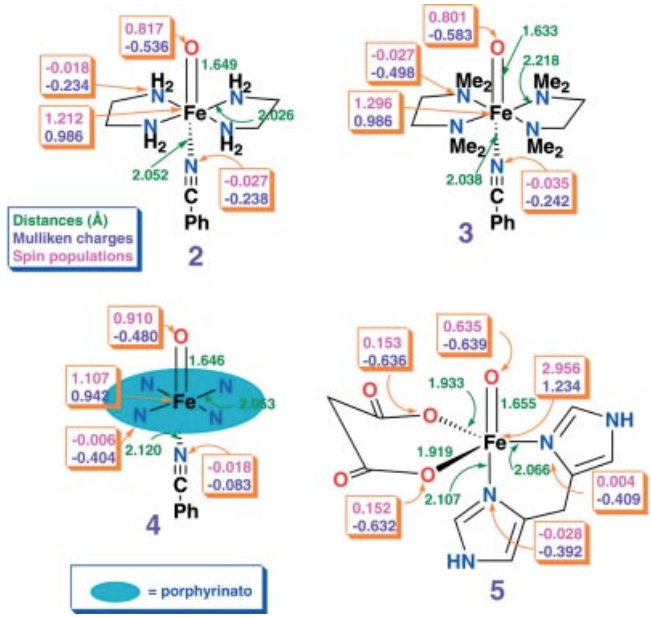

Figure 2. Selected optimized distances, Mulliken charges and spin populations for $Fe^{IV}O$ model complexes **2**−**5**; complexes **2**−**4** are $S = 1$, while **5** is $S = 2$

five-coordinate trigonal-bipyramidal species shown in Figure 1, was found to have the lowest energy. Perhaps not surprisingly in view of its trigonal-bipyramidal structure, an $S = 2$ spin state was favored over lower-spin states by several tenths of an eV. As shown in Figure 1, the Fe−O distance and O spin population for **5** are strikingly similar to those for the low-spin species **2**−**4**, indicating that the low- versus high-spin character of the $Fe^{IV}O$ unit has relatively little effect on the $Fe(d_\pi)-O(p_\pi)$ orbital interactions (which are largely responsible for the oxygen spin populations).

A comparison of the spin density profiles of **5** and of the Collins model complex **1** proved enlightening. If we define the Fe=O axis of **5** and the FeCl axis of **1** as the z direction, simple crystal field theory arguments (which are confirmed by our calculations) suggest that **5** should have a d_{z^2} hole, while **1** should have a $d_{x^2-y^2}$ hole. Thus, if we describe the local symmetries of the iron centers in **5** and **1** as approximately C_{3v} and C_{4v}, then their ground states may be described as $^5A_1$ and $^5B_2$, respectively. Further, we have already seen that the spin density profile of **5** is strongly affected by $Fe(d_\pi)-O(p_\pi)$ orbital interactions, for which there is no analogue in **1**. These considerations suggest that species **5** and **1** should exhibit significantly different spin density profiles, an expectation that is confirmed by Figure 3, which plots the spin density profiles for the two species. This may be seen as qualitatively consistent with the fact that the TauD intermediate and Collins' complex exhibit dramatically different Mössbauer spectroscopic parameters,[3,8] although these remain to be explicitly determined with DFT calculations.

Without question, the discovery of a high-spin Fe^{IV} intermediate for TauD has galvanized biochemists and synthetic chemists alike to seek additional nonheme $Fe^{IV}O$ intermedi-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

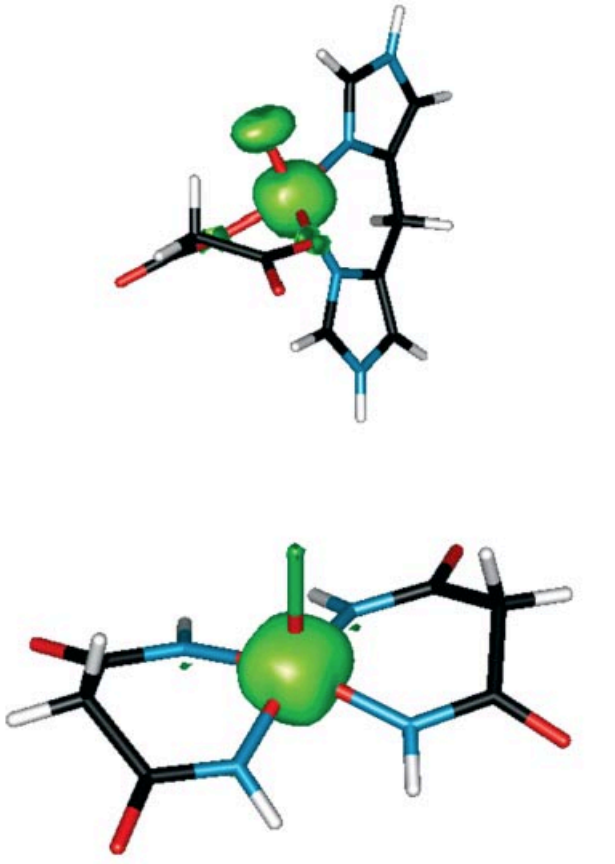

Figure 3. Comparison of the spin density profile of **5** (top) with that of a model (**1**, bottom) of Collins' $S = 2$ Fe^{IV} complex, $[Fe^{IV}(pmd\text{-}N,N)_2Cl]^-$ (pmd-*N*,*N* = propanediamidato-*N*,*N*); color code for atoms: calcd. C black, N blue, O red, H grey/white, and Cl green

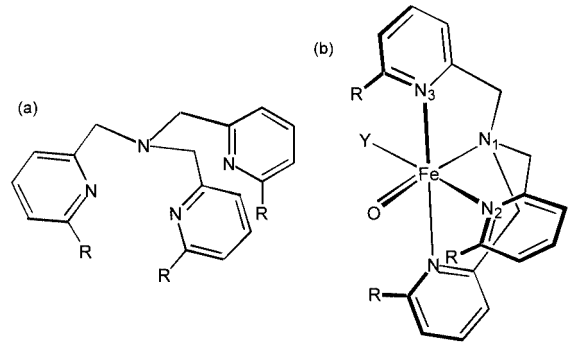

Figure 4. (a) Ligands used in calculations summarized in Table 2; tpa, R = H, 6-me_3-tpa, R = CH_3; (b) note the notation of the N_1, N_2, N_3 and Y atoms/groups, which are mentioned in Table 2

ates. What might be a good strategy for the synthetic chemist? As alluded to above,[6,7,23,24] the use of 6-alkylated tpa ligands seems like a promising strategy, which led us to carry out geometry optimizations for both $S = 1$ and $S = 2$ states for the following four species: $[Fe^{IV}(O)(X)(Y)]^+$, where X = tpa and 6-me_3-tpa and Y = F and OH (Figure 4). Table 2 lists key geometry parameters and atomic spin populations, but these essentially lead to the same generalizations as made above for **2**−**5**, namely that the Fe−O distance and the O spin population are rather similar across all the species studied, regardless of spin state.

Table 2 shows that the PW91 calculations predict $S = 1$ ground states for $[Fe^{IV}(O)(tpa)(Y)]^+$, consistent with the experiment, but the preference for $S = 2$ ground states for $[Fe^{IV}(O)(6\text{-}me_3\text{-}tpa)(Y)]^+$ is less clear. The B3LYP calculations clearly favor $S = 2$ ground states for $[Fe^{IV}(O)(6\text{-}me_3\text{-}tpa)(OH)]^+$, but also for $[Fe^{IV}(O)(tpa)(OH)]^+$, albeit by a very slight margin. Elsewhere, we have documented that PW91 calculations exhibit a greater preference for low-spin states than B3LYP results.[10] Thus, at least certain of these calculations deserve to be repeated with more definitive but far more computationally demanding CASPT2 calculations. These uncertainties notwithstanding, the energetics data shown in Table 1 suggest that there is a good chance that $[Fe^{IV}(O)(6\text{-}me_3\text{-}tpa)(Y)]^+$ species may exhibit $S = 2$ ground states and, therefore, are attractive targets for synthetic modeling studies.

Finally, we have examined the question of whether Que's "flexible diamond core" may be viewed as one containing a high-spin $Fe^{IV}{=}O$ unit.[22] For simplicity, we have only studied the ferromagnetically coupled $S = 9/2$ state of the $[(6\text{-}me_3\text{-}tpa)Fe^{III}(\mu\text{-}O)_2Fe^{IV}(6\text{-}me_3\text{-}tpa)]^{3+}$ cation. The calculation employed a diamond-core-like starting geometry but only a C_s symmetry constraint to allow for spontaneous desymmetrization of the $Fe_2(\mu\text{-}O)_2$ core, which indeed took place;[28] selected geometry parameters and Mulliken spin populations for the two spin states are shown in Figure 5.

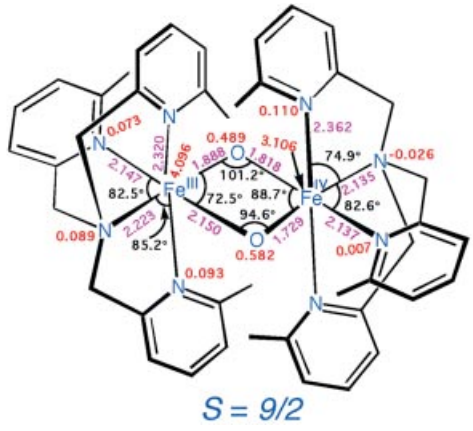

Figure 5. Selected PW91/TZP optimized distances (Å, magenta), angles (°, black) and Mulliken spin populations (red) for the ferromagnetically coupled $S = 9/2$ state of the $[(6\text{-}me_3\text{-}tpa)Fe^{III}(\mu\text{-}O)_2Fe^{IV}(6\text{-}me_3\text{-}tpa)]^{3+}$ cation

The geometrical asymmetry of the Fe_2O_2 unit (which seems consistent with its flexible nature, as emphasized in the experimental study[22]) and the spin density profile clearly indicate the presence of localized high-spin Fe^{III} and Fe^{IV} centers for both spin states. Thus, the Fe^{IV} center has a short Fe−O bond of about 1.73 Å, consistent with a high-spin $Fe^{IV}{=}O$ unit. Note that the nitrogen atom *trans* to this

group has a small negative spin population, unlike all the other nitrogen atoms, but consistent with the expectation that the metal d_{z^2} orbital that lies along the Fe^{IV}=O unit is formally unoccupied.

Summary

The main conclusions of this study may be enumerated as follows.

(1) We began this study by an attempt to benchmark the relative energies of the high- and low-spin states for a well-characterized high-spin Fe^{IV} complex. Based on the CCSD(T) and CASPT2 results on model complex **1**, we would like to assert that the triplet-quintet splitting is likely to be larger than 0.3 eV and perhaps as large as 0.7 eV. Obviously, we wish we could have narrowed down this range somewhat, but that seems impossible with currently available technology. If this range is correct, then the DFT values are on the low side, consistent with the known tendency of DFT to favor low-spin states.[10] On a more positive note, DFT does not perform badly and does emerge as the practical tool of choice for a broad survey of high-spin Fe^{IV} species.

(2) The Fe−O distance and O spin population are quite similar across all mononuclear $Fe^{IV}O$ species studied, regardless of the heme versus nonheme environment and of the $S = 1$ versus 2 spin state, reflecting the essential similarity of the $Fe(d_\pi)-O(p_\pi)$ orbital interactions in all these species.

(3) A significant insight from this study is that a high-spin Fe^{IV} center does not correspond to a unique type of electron spin density profile. Thus, the TauD intermediate and Collins' high-spin Fe^{IV} complex feature dramatically different spin density profiles, qualitatively consistent with their very different Mössbauer spectroscopic parameters.

(4) The sterically hindered 6-me$_3$-tpa ligand and related ligands provide a promising recipe for generating synthetic $S = 2$ $Fe^{IV}O$ intermediates.

(5) Lastly, our calculations indicate the presence of a fairly discrete high-spin Fe^{IV}=O unit in the mixed-valent, so-called "flexible diamond-core" intermediate.

Supporting Information: Optimized Cartesian coordinates for the different molecules studied are provided.

dicting the energy ordering of the low-lying spin states for some (porphyrin)Fe^{III} derivatives: A. Ghosh, B. J. Persson, P. R. Taylor, *J. Biol. Inorg. Chem.* **2003**, *8*, 507−511.

[12] The PW91 calculations were carried out using the ADF program system, using Slater-type TZP basis sets and a fine mesh for numerical integration of matrix elements. The B3LYP calculations were carried out using the program Turbomole and Gaussian basis sets of TZP quality. Adequately tight convereg-ence criteria for geometry optimizations were used in all the calculations.

[13] For the CASPT2 calculations, the CASSCF active space comprised eight electrons in eight orbitals: the five Fe 3d orbitals and three equatorial ligand orbitals, including two of a_1 symmetry and one of a_2. The a_1 symmetry equatorial ligand orbitals would be the π HOMO and LUMO if the ligands were exactly planar. The a_2 symmetry ligand orbital is a combination of the N lone-pairs. The CASPT2 calculations were performed using the program Molcas 5.2 and the CCSD(T) calculations with Molpro 2002.

[14] BS1 consisted of Dunning's cc-pVDZ basis sets on C, N O, and H, the aug-cc-pVDZ basis on Cl (T. H. Dunning, *J. Chem. Phys.* **1989**, *90*, 1007−1023), and a [6s5p4d3f2g] atomic natural orbital (ANO) basis on Fe (B. J. Persson, P. R. Taylor, unpublished results). BS2 consisted of Dunning's cc-pVTZ basis sets on C, N O, and H, the aug-cc-pVTZ basis on Cl (T. H. Dunning, *J. Chem. Phys.* **1989**, *90*, 1007−1023), and a [7s6p5d4f3g] ANO basis on Fe (B. J. Persson, P. R. Taylor, unpublished results). The Fe ANO basis sets are optimized for calculations that include Fe 3s3p correlation, the effects of which are not negligible here.

[15] At present, there is extensive evidence (see, for example: P. E. M. Siegbahn, M. R. A. Blomberg, *Chem. Rev.* **2000**, *100*, 421−437) that DFT provides generally good results for geometries, spin density profiles, and a variety of other molecular properties for transition metal complexes. We believe that this generalization also holds for the species studied here and therefore largely refrain from commenting on the data presented in Table 1. However, one point worth noting is the relatively small amounts of spin density on the equatorial ligand set. By this criterion, the ligands may be described as relatively innocent, even though they must be extremely σ-donating.

[16] For a discussion of population analyses, see: C. J. Cramer; *Essentials of Computational Chemistry: Theories and Models*, Wiley, Hoboken, NJ, USA, **2002**, pp. 278−291.

[17] A few more technical comments may be worthwhile. Examining the CASSCF and CASPT2 results suggests that the wavefunctions for both states are somewhat multiconfigurational in character, but not exceptionally so. In this situation we would typically expect much closer agreement between CASPT2 and CCSD(T). We know that DFT (certainly with the functionals used here) tends to favour low-spin states; CASPT2 in its simplest implementation also tends to favour low-spin states but here we have used a modified Hamiltonian which gives a much better balanced treatment of different spin states, with no obvious preference for high or low spin. The 8-in-8 CASSCF/BS1 calculation itself gives 0.69 eV for the splitting (quintet lower), whereas a Hartree−Fock calculation gives 2.16 eV, again with the quintet lower. From the Hartree−Fock value we infer that electron correlation makes a substantial contribution to the splitting, which is expected; from the CASSCF value we can infer further that much of this correlation contribution is non-dynamical correlation. We must also recognize that the basis sets used here for the CCSD(T) calculations, though large, are far from complete and the contribution of dynamical correlation may well be larger in a more complete basis set.

Fluorescent Self-Assembled Monolayers of Bis(salicylaldiminato)zinc(II) Schiff-Base Complexes

Santo Di Bella,*[a] Nicoletta Leonardi,[a] Giuseppe Consiglio,[b] Salvatore Sortino,*[a] and Ignazio Fragalà[a]

Keywords: Fluorescence / Monolayers / Schiff bases / Zinc

The synthesis and fluorescence properties of novel bis(salicylaldiminato)zinc(II) Schiff-base complexes is reported. Self-assembled monolayers (SAMs) of these complexes are obtained by reaction of coupling layers, functionalized quartz substrates and a derivatized precursor complex. A comparison between the integrated emission intensity of the SAM films and that of a suitable model compound in solution indicates molecular fluorescence retention of the Zn^{II} Schiff bases on going from the solution phase to the monolayer. This is consistent with the absence of significant self-quenching processes, as expected on the basis of the relatively high estimated surface coverage.

Introduction

Nanostructured functional molecular materials are attracting growing interest in the expanding field of molecular electronics and optoelectronics,[1] where molecular organization in defined assemblies and its control on a molecular scale represents one of the most interesting issues.

Molecular self-assembly is one of the most efficient methods to achieve well-defined and organized molecular architectures covalently anchored to various substrates.[2] Among various functional molecular systems, self-assembled monolayers (SAMs) of fluorescent molecules are attractive for a variety of potential applications,[3] including molecular electronics and optoelectronics.[4]

Recently, Schiff base bis(salicylaldiminato)metal complexes have been widely investigated for their properties and applications in different fields, such as catalysis[5] and materials chemistry.[6] For example, metal complexes possess distinct second-order nonlinear optical[6,7] and fluorescent[8,9] properties that are closely related to the coordinated metal centre. In fact, as far as the luminescent properties are concerned, while the free Schiff-base ligands are non-emissive, their complexes with metal ions such as Zn^{II}, Al^{III} and Mg^{II} exhibit an appreciable fluorescence.[9]

In this paper we report the synthesis and spectroscopic properties of novel bis(salicylaldiminato)zinc(II) Schiff-base complexes and related self-assembled monolayers on quartz substrates.

R = CH_3 **2**

Results and Discussion

Synthesis and Spectroscopic Properties of Zn^{II} Schiff-Base Complexes

In order to compare the spectroscopic properties of the self-assembled monolayer of the complex **1** (SAM-**1**) with a suitable model compound, the 4,4′-methoxy derivative **2** was synthesized. Both the 4,4′-dihydroxy-substituted Zn^{II} Schiff-base precursor complex **1** and the model compound **2** were synthesized by standard methods.[7] The complexes were characterized by mass spectrometry, ^1H NMR spectroscopy, and satisfactory microanalysis.

Figure 1 shows the absorption and emission spectra of **2** in CH_2Cl_2 solution. The absorption is characterized by two bands at 310 and 374 nm and a shoulder at about 420 nm. The fluorescence emission exhibits an unstructured band with a maximum at 508 nm. Based on the overlap of the fluorescence emission with the lowest energy absorption

band, the lowest excited singlet state can be experimentally located at about 260 kJ·mol^{-1}.

The fluorescence quantum yield, Φ_f, is found to be about 0.05 in CH_2Cl_2. This value is almost unaffected on going to more polar solvents such as THF and CH_3CN. The fluorescence lifetime in the above solvents lies in the sub-nanosecond time domain. These photophysical properties are consistent with those recently found for analogous Zn^{II} Schiff-base complexes.[8]

Preparation and characterization of SAM-1

The derivatization of the molecular precursor with appropriate end-groups represents the initial step for the self-assembly process. It should consist of an accessible and efficient chemistry so that the derivatized group can easily react with the substrate or with an appropriate derivatized substrate, the so-called coupling layer. In our case the 4,4′-dihydroxy-substituted Zn^{II} Schiff-base complex **1** was used as precursor. Actually, given their acid nature, 4-hydroxyl groups can readily be transformed into the related phenoxides **1a**, which, in turn, are nucleophilic species for a variety of substitution reactions.

SAM-**1** was obtained by a two-step approach (Scheme 1), which involves chemisorption of the $Br(CH_2)_3SiCl_3$ (CP-Br) coupling layer onto hydroxylated quartz substrates followed by grafting of **1** by a nucleophilic-substitution reaction between the alkyl bromide of the silylated surface and the derivatized salt **1a**.

The first step was carried out with standard procedures.[10] It leads to the formation of densely packed, sil-

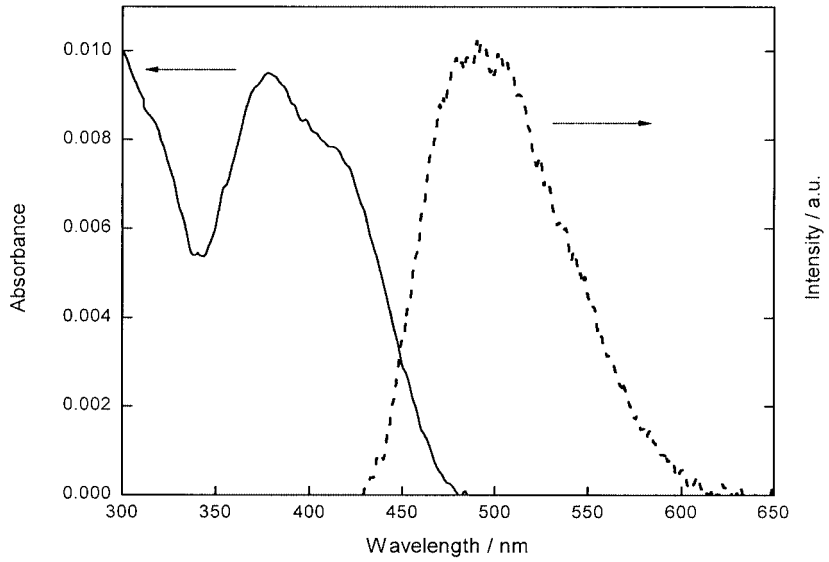

Figure 2. Absorption and fluorescence spectra of SAM-**1**

ane-based coupling layers bound to the quartz surface through a siloxane linkage. The typical advancing aqueous contact-angle (θ_a) values (ca. 68°) confirmed the complete silylation of the surface.

The second step was achieved by immersion of substrates terminated with the coupling layer in an anhydrous DMF solution of the derivatized complex **1a** for 20 h at 80 °C. The substrates were then washed and sonicated with DMF and acetone to remove any physisorbed material on the surface. Aqueous contact-angle measurements after the second step indicated that θ_a changes from 66−68° for the substrate terminated with the coupling layer to 78−80° for SAM-**1**. This is consistent with an increased surface hydrophobicity due to the relatively apolar Zn^{II} complex headgroup.[11]

SAM-**1** was characterized by UV/Vis absorption and emission spectroscopy (Figure 2). It shows an optical absorption band at 378 nm and a shoulder at about 416 nm. These features are similar to those of the model complex **2** in CH_2Cl_2 (Figure 1), except for a slight shift. It should be noted that the observed absorbance is related to two monolayers, one for each side of the quartz slide. These absorbance values allow an estimation of the surface coverage (Γ_{surf}) of the functional Zn^{II} complex by the relation $\Gamma_{surf} = A\varepsilon^{-1}$, where A is the absorbance of the SAM-**1** and ε is the molar extinction coefficient of the chemisorbed species.[12] Using the extinction coefficient of the model compound **2** (λ_{max} = 374 nm; ε_{max} = 25300 $M^{-1}\cdot cm^{-1}$ in CH_2Cl_2) and a monolayer absorbance of about 0.005, the estimated surface density of the Zn^{II} derivative is about 1.2×10^{14} molecules/cm^2 or about 1.2 molecules/100 $Å^2$. These surface coverage values for the bulky complex **1** are within the range commonly observed for analogous systems.[2,13]

The fluorescence spectrum of SAM-**1** (Figure 2) is characterized by a shape similar to that observed in solution for the model compound **2** (Figure 1), although the emission maximum is somewhat blue-shifted (by about 16 nm). A comparison between the integrated emission intensity of SAM-**1** and that of a solution of **2** having the same absorbance at the excitation wavelength reveals that the fluorescence efficiency of the monolayer is similar to that of the model compound **2**. This result indicates molecular fluorescence retention of the Zn^{II} Schiff base complex on going from the solution phase to the monolayer. This is consistent with the absence of significant self-quenching processes, as expected on the basis of the relatively high surface coverage estimated above. Quenching of fluorescence is actually quite common in more densely packed monolayers as a result of effective inter-chromophore interactions.[14]

In summary, we have presented a simple, efficient route to fluorescent self-assembled monolayers of novel Zn^{II} Schiff-base complexes. They may be appealing systems in the perspective of molecular optical devices.

Experimental Section

Materials and General Procedures: Zinc acetate dihydrate, 2,4-dihydroxybenzaldehyde, 2-hydroxy-4-methoxybenzaldehyde, sodium methoxide, (3-bromopropyl)trichlorosilane [$Br(CH_2)_3SiCl_3$], and anhydrous DMF (Aldrich) were used without purification. 1,2-Phenylenediamine (Aldrich) was purified by sublimation in vacuo. Pentane and heptane (Aldrich) were distilled from Na/K alloy before use. The coupling layer formation was performed in a dry box (under nitrogen atmosphere; <1 ppm O_2 and <3 ppm H_2O).

Physical Measurements: Elemental analyses were performed on a Carlo Erba 1106 elemental analyzer. ^1H NMR spectra were recorded on a Varian Inova 500 spectrometer, using TMS as internal standard. The absorption and fluorescence spectra were recorded with a Beckman DU 650 spectrophotometer and a Spex Fluorolog-2 (mod. F-111) spectrofluorimeter, respectively, and λ_{max} values are considered accurate to ±1 nm. The fluorescence quantum yield was

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

obtained using quinine sulfate in 1 N H_2SO_4 as standard. The absorbance value of the samples at the excitation wavelength were lower than 0.15 for a 1-cm path length. The fluorescence lifetimes in air-equilibrated solutions were determined by means of a time-correlated single-photon counting system. A nitrogen-filled lamp was used for excitation at 337 nm. Fluorescence measurements on SAM-**1** were carried out by aligning the quartz slide sample at an angle of 60° with respect to the excitation beam. Reflection of the excitation from the sample was to the opposite side of the emission detection. ESI mass spectra were recorded on an Agilent 1100 Series ESI/MSD spectrometer. Experimental conditions were as follows: capillary voltage, 3.5 kV; fragmentor, 100 V; source temperature, 350 °C; drying gas, N_2 (10 L/min); carrier solvent, methanol (0.4 mL/min). Advanced aqueous contact angles were measured using a goniometer (KERNCO) under ambient conditions.

[1,2-Phenylenebis(iminomethyl)bis(4-hydroxy-2-phenolato]zinc(II) (1): 2,4-Dihydroxybenzaldehyde (1.106 g, 8.00 mmol) was added, whilst stirring, to a solution of 1,2-phenylenediamine (0.433 g, 4.00 mmol) in methanol (25 mL) at room temperature. Zinc acetate dihydrate (0.878 g, 4.00 mmol), dissolved in methanol (20 mL), was added to the resulting solution, and the mixture was heated at reflux for 2 h. After cooling, the precipitate was collected by filtration, washed with water, and dried. The yellow solid was crystallized from a THF/*n*-hexane mixture. Yield: 1.556 g (94%). $C_{20}H_{14}N_2O_4Zn$ (411.73): calcd. C 58.34, H 3.43, N 6.80; found C 58.05, H 3.38, N 6.90. ESI MS: *m*/*z* (%) = 433 (50) $[M + Na]^+$. ^1H NMR (500 MHz, [D$_6$]DMSO): δ = 6.03 (m, 4 H, Ar*H*), 7.19 (d, J_{ortho} = 9.0 Hz, 2 H, Ar*H*), 7.24 (m, 2 H, Ar*H*), 7.75 (m, 2 H, Ar*H*), 8.79 (s, 2 H, C*H*=N), 9.71 (s, 2 H, O*H*) ppm. UV/Vis (DMF): λ_{max} = 308, 388, 426 (sh) nm.

Disodium Zincate 1a: Compound **1** (1.556 g, 3.78 mmol) was added, with stirring, to a solution of sodium methoxide (1.73 mL of a 25% w/w methanol solution, 7.56 mmol), and the mixture heated at 50 °C for 1 h under a nitrogen atmosphere. The solution was then concentrated under vacuum. The precipitate product was collected and washed with anhydrous THF. A yellow-brown solid was obtained (1.583 g, 92%). $C_{20}H_{12}N_2Na_2O_4Zn$ (455.69): calcd. C 52.71, H 2.65, N 6.15; found C 52.40, H 2.60, N 6.09.

Zinc(II) Complex 2: Zinc acetate dihydrate (0.094 g, 0.43 mmol) was added to a solution of *N*,*N*′-bis(4-methoxy-2,4-dihydroxybenzylidene)-1,2-phenylenediamine[7c] (0.116 g, 0.43 mmol) in methanol (30 mL). The resulting yellow solution was heated at reflux for 2 h. After cooling, the precipitate was collected by filtration, washed with water and dried. The yellow solid was crystallized from THF (1.60 g, 85%). $C_{22}H_{18}N_2O_4Zn$ (439.78): calcd. C 60.08, H 4.13, N 6.37; found C 59.62, H 4.09, N 6.43. ESI MS: *m*/*z* (%) = 461 (100) $[M + Na]^+$. ^1H NMR (500 MHz, [D$_6$]DMSO): δ = 3.75 (s, 6 H, C*H*$_3$), 6.15 (dd, J_{ortho} = 9.0, J_{meta} = 2.5 Hz, 2 H, Ar*H*), 6.19 (d, J_{meta} = 2.5 Hz, 2 H, Ar*H*), 7.29 (m, 4 H, Ar*H*), 7.79 (m, 2 H, Ar*H*), 8.86 (s, 2 H, C*H*=N) ppm. UV/Vis (CH_2Cl_2): λ_{max} ($\varepsilon \times 10^4$) = 310 (2.75), 374 (2.53), 420 (sh) nm (1.40).

Preparation of SAMs

Substrate Cleaning: Substrates were cleaned by standard procedures.[15] Quartz slides (0.5 × 1 cm) were cleaned by immersion in "piranha" solution (H_2SO_4/30% H_2O_2 = 70:30 v/v) at 80 °C for 1 h (***warning****: piranha is an extremely strong oxidising reagent; it should be handled with caution because it can detonate unexpectedly*).[16] After cooling to room temperature, the substrates were repeatedly rinsed with deionized water and then cleaned with a (H_2O/30% H_2O_2/28% NH_3 = 5:1:1 v/v/v) solution, at room temperature for 40 min. The substrates were then washed with a large amount of deionized water and dried under vacuum at room temperature.

Coupling Layer Formation: Substrate silylation was performed by immersion of freshly cleaned quartz substrates in a 1:100 (v/v) solution of $Br(CH_2)_3SiCl_3$ (CP-Br) in dry heptane for 40 min, at room temperature. The substrates were first rinsed with dry heptane, then with dry pentane, sonicated in acetone for 1 min, and dried at room temperature. Advancing contact angle: CP−Br, $\theta_a(H_2O)$ = 68°.

Monolayer Formation: Under a dry nitrogen atmosphere the freshly silylated substrates were immersed in a 3.0 mM solution of salt **1a** in anhydrous DMF at 80 °C for 20 h, whilst stirring. After cooling to room temperature, the substrates were rinsed with DMF, sonicated in DMF for 1 min, and washed with acetone. Advancing contact angle: SAM-**1**, $\theta_a(H_2O)$ = 80°. UV/Vis: SAM-**1**, λ_{max} = 378 nm (A = 0.095).

A New Trinuclear Linear Copper(II) Complex: Unusual Crystal Structure with Semi-Coordinated Thiophene Moieties and Weak Antiferromagnetic Coupling Through the Bridging Imidazolate Rings

Yufei F. Song,[a] Chiara Massera,[b] Manuel Quesada,[a] Iryna A. Koval,[a] Patrick Gamez,[a] Anna Maria Manotti Lanfredi,[b] and Jan Reedijk*[a]

Keywords: Copper / Trinuclear complexes / EPR / Thiophene / N,S ligands / Imidazole

A trinuclear copper(II) complex, $[Cu_3(imthio)_2(NO_3)_4(MeOH)_2]$ [where Himthio is 1,1-bis(imidazol-2-yl)-3-(thiophen-2-yl)-2-azapropane], has been synthesized by the reaction of Himthio with $Cu(NO_3)_2{\cdot}3H_2O$ in MeOH. The structure of the copper complex is centrosymmetric and contains a linear trinuclear array of copper atoms. The central copper(II) ion, Cu1, which lies on an inversion centre, is equatorially coordinated by four nitrogen atoms from two anionic imthio ligands and axially by two semicoordinated thiophene sulfur atoms to give an octahedral environment (Cu1–S1 3.136 Å). The Himthio ligand bridges Cu1 and the terminal copper(II) ions through imidazole nitrogen atoms. The coordination around the external ions is completed by the oxygen atoms from two nitrate groups and by a methanol molecule in a distorted square-pyramidal geometry. The two terminal copper(II) complexes can be considered to be chelating ligands for the central Cu^{II} ion. The EPR spectrum of the complex in MeOH at 77 K shows two mononuclear species, as is fully confirmed by EPR simulation. Magnetic susceptibility of the complex shows weak antiferromagnetic behaviour (J = –71.37 cm^{-1}) caused by the overlapping of the magnetic orbitals of the copper atoms and the bridging imidazolate rings. (© Wiley-VCH Verlag GmbH & Co.. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Copper complexes are widely known in nature and play an essential part as biological redox catalysts in most life forms. Current interest in copper complexes focuses on the design and synthesis of mimics of active sites for their potential use in catalysis and molecular-based magnets.[1] Models of the active sites of multicopper proteins such as ascorbate oxidase,[2] cerpulasmin[3] and laccase[4] have been studied extensively, and many efforts have been made to synthesize and investigate multinuclear copper complexes with various bridges between the metal centres.[5] The commonly used ligands are based on pyrazole, benzimidazole, and pyridine moieties.[6] Due to the presence of histidine as a ligand to copper ions in most copper proteins, copper complexes with the biologically more relevant imidazolyl donors are increasingly being studied as model compounds of copper proteins' active sites.[7,8]

Sulfur-donor compounds are known to be good ligands for low-oxidation-state copper atoms. It is well known that sulfur coordination to copper plays a very important role in metalloenzyme chemistry,[9] especially in the control of the redox potentials. In copper proteins such as azurin[10] or plastocyanin,[11] thioether sulfur, thiolate and heterocyclic nitrogen atoms are coordinated to the copper atoms at the active site, and the redox reaction occurs by outer-sphere electron-transfer processes requiring a coordination-sphere reorganisation around the copper atom.[12] Long Cu–S (methionine) contacts in the range 2.7–3.2 Å, considered to be semicoordination, are of particular current interest, as protein engineering studies suggest that, notwithstanding an appreciable effect on the redox and spectroscopic properties of the active site,[13] in most cases no coordination of the S atom to the Cu^{II} ion appears to be involved.[14,15]

In the course of our research on developing relatively simple copper compounds as mimics of copper metalloenzymes, we synthesized the asymmetric tripodal ligand 1,1-bis(imidazol-2-yl)-3-(thiophen-2-yl)-2-aza-propane (Himthio) with S and N donor atoms (Figure 1).

The weak thiophene donor appears to be a good candidate for examining the semicoordination of the sulfur atom.[15] Surprisingly, the reaction of Himthio with $Cu(NO_3)_2$ in methanol results in a trinuclear copper(II) complex in which three copper ions are linearly bridged by two ligands. The crystal structure shows that the thiophene sulfur atoms are semicoordinated to the central Cu^{II} atom,

and such S−Cu^{II} interactions are quite rare, as analysis of the Cambridge Structural database shows. No other examples of trinuclear copper(II) complex in which the central Cu^{II} atom is coordinated by sulfur atoms have been found in the literature, it therefore represents the first example of a trinuclear linear copper(II) complex with semicoordination of thiophene moieties. The complex has been fully characterized by XRD, UV/Vis, EPR, and magnetic susceptibility measurement.

Results and Discussion

Synthesis of the Ligand and the Coordination Complex

The bis(imidazol-2-yl)amine unit[16] is a very interesting synthetic building block and can be prepared in five steps by a ring-opening and double ring-closure reaction. The Himthio ligand was synthesized by incorporating the thiophene group by nucleophilic substitution of a nitro group (see Exp. Sect.). The trinuclear copper complex, with the formula $[Cu_3(imthio)_2(NO_3)_4(MeOH)_2]$, was obtained by the reaction of 1 equiv. of imthio with 1 equiv. of copper(II) nitrate in methanol. Slow concentration of the solution at room temperature led to the formation of green, square crystals suitable for X-ray analysis. An ORTEP view of the complex, together with the atomic labelling scheme, is shown in Figure 2.

Crystal Structure of the Complex $[Cu_3(Imthio)_2(NO_3)_4(MeOH)_2]$

The structure consists of a centrosymmetric trinuclear linear molecular complex in which the central copper(II) atom occupies the inversion centre. In the $[Cu_3(imthio)_2]^{4+}$ moiety, each ligand is coordinated by four nitrogen atoms to two different copper ions. One of the two imidazolyl groups of Himthio is deprotonated and bridges the central and terminal ions through the N2 and N3 atoms.

Each of the two terminal copper atoms, Cu2 and Cu2′, is coordinated by two imidazole nitrogen atoms (N3 and N4), by two oxygen atoms from the NO_3^- anions (O1 and O4) and by the oxygen atom of the methanol (O1s); Cu2−O1 is the longest of these bonds [2.309(4) Å], so that the coordination around the metal atom can be described as a slightly distorted square pyramid, elongated towards the apex (N_2O_3 donor set, $\tau = 0.052$, where $\tau = 0$ and 1 are for perfect square-pyramidal and trigonal-bipyramidal geometries, respectively[17]).

The central Cu1 ion is coordinated by four nitrogen atoms (two amine nitrogen atoms, N1 and N1′; two imidazole nitrogen atoms, N2 and N2′) belonging to two centrosymmetric imthio ligands, thus giving origin to a CuN_4 chromophore in the equatorial plane [Cu1−N1 and Cu1−N2 distances are 2.064(3) and 1.933(3) Å, respectively].

The interatomic contact distance between Cu1 and the thiophene sulfur atoms is 3.136(2) Å. Other S−Cu distances reported in the literature range from 3.012 Å for a Cu^{II}−S containing system[18] to 2.90 Å and 3.16 Å for Cu^{I}−S,[19] which is believed to contain thiophene-*S* coordination to the Cu atom. Some Cu−O distances reported by Yates et al.[20] fall into the same range. The distance from Cu1 to the gravity centre of the thiophene ring (S1−C3−C4−C5−C6) is 3.620 Å. The angle between the Cu−S bond and the least-squares plane passing through

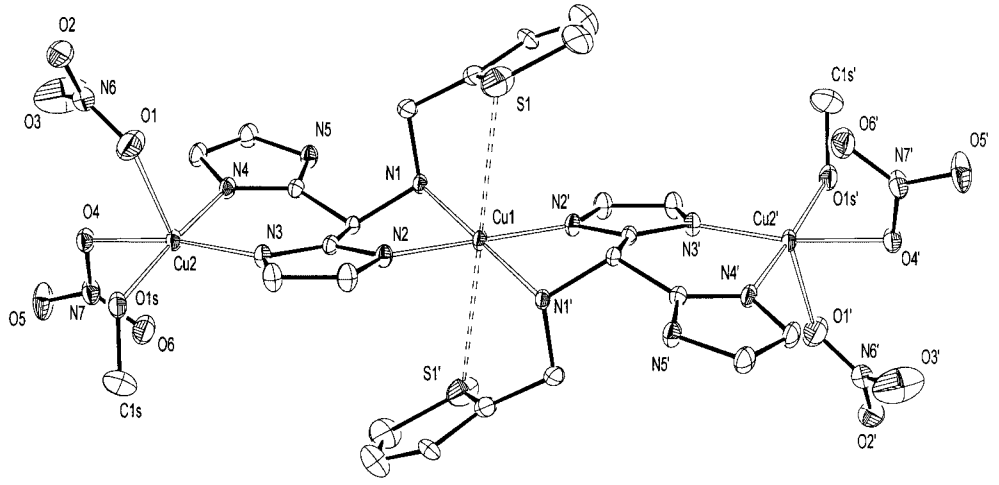

Figure 2. Thermal ellipsoid plot (20% probability level) of the trinuclear copper complex $[Cu_3(imthio)_2(NO_3)_4(MeOH)_2]$; hydrogen atoms have been omitted for clarity; selected bond lengths and angles: Cu1−N1 2.064(3), Cu1−N2 1.933(3), Cu1−S1 3.136 Å, Cu2−O1 2.309(4), Cu2−O1s 2.002(4), Cu2−O4 2.013(3), Cu2−N3 1.939(3), Cu2−N4 1.973(3) Å; N1−Cu1−N2 81.29(11), N1−Cu1−N2′ 98.71(11), S1−Cu−N1 81.3, S1−Cu1−N2 93.98, S1−Cu1−N1a 98.7, S1−Cu1−N2a 86.02, O1−Cu2−O1s 84.52(15), O1−Cu2−O4 93.53(13), O1−Cu2−N3 94.67(13), O1−Cu2−N4 101.57(13), O1s−Cu2−O4 87.05(13), O1s−Cu2−N3 89.25(15), O1s−Cu2−N4 173.77(14), O4−Cu2−N3 170.64(12), O4−Cu2−N4 91.24(11), N3−Cu2−N4 91.53(13)°

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the thiophene ring is 123.38(17)° (the angle between the vector of Cu1 to the centre of gravity of the thiophene ring and the normal to the ring plane is 43.76°). The geometry around the central Cu^{2+} ion can be described as a tetragonally distorted octahedral environment, resulting from the long axial Cu1−S1 (and consequently Cu1−S1′) bond (S1−Cu1−N1: 81.3°; S1−Cu1−N2: 93.98°; S1−Cu1−N1′: 98.7°; S1−Cu1−N2′: 86.02°).

The crystal packing exhibits some π-stacking and face-to-face interactions with the shortest intramolecular ring−ring distances of 3.807(4) Å between the thiophene ring (S1−C3−C4−C5−C6) and one of the imidazole rings (N2−N3−C7−C8−C9). The dihedral angle between them is 23.97°. In the crystal the different units interact with each other through the imidazole and amine nitrogen atoms, which form intermolecular N−H···O hydrogen bonds involving the oxygens of the nitrate groups and of the methanol molecule (Figure 3). Very weak intermolecular C−H···O interactions [C1···O5 = 3.216(6) Å; C11···O3 = 3.237(6) Å] between −CH groups and nitrate oxygen atoms also contribute to the crystal packing.

Crystal structures of copper complexes with related ligands reported previously, for example 1,1-bis(imidazol-2-yl)-3-(pyridin-2-yl)-2-azapropane (Im-2Py), consist of two copper ions in distorted square-pyramidal environments.[8,21] Compared with those systems, the significant structural alteration induced by the substitution of pyridine rings by thiophene moieties and the semicoordination of thiophene sulfur atoms in the complex can be considered to have thermodynamic and/or kinetic consequences for redox reactivity.[20] It should be noted that, to the best of our knowledge, the title compound represents the first example to date of a linear trinuclear copper(II) complex in which the central Cu^{II} atom is semicoordinated with the thiophene sulfur atoms. Moreover, two lateral copper complexes can be considered as chelating ligands on the central Cu^{II} atom in the crystal structure.

Ligand-Field and UV/Vis Measurement

The ligand-field diffuse-reflectance spectrum of the crystalline powder of the complex shows a peak at $17.1\cdot10^3$ cm^{-1}, which is due to a d-d transition and is a normal ligand-field transition for a $CuN_2O_2(x)$ chromophore.[22,23] A strong absorption band at $28.3\cdot10^3$ cm^{-1} and a shoulder peak at $32.8\cdot10^3$ cm^{-1} can be attributed to the charge transfer from the N, O, or S to Cu^{II}. An absorption band at $37.3\cdot10^3$ cm^{-1} is associated with ligand π-π* transition.[24] The UV/Vis spectrum recorded in MeOH shows absorption bands as shoulder peaks at approximately 281 nm (ε = 2 054 $M^{-1}cm^{-1}$) and 372 nm (ε = 1 240 M^{-1} cm^{-1}), due to the LMCT transition from N and O to Cu^{II}.[25] The transition in the visible region of the electronic spectra is a much less intense absorption at 636 nm, which is assigned to d-d transitions.[23] The difference between the solid-state spectrum and the solution measurement suggests a change in geometry upon dissolution. The complex may therefore partially dissociate in solution.

EPR Measurements

The EPR spectra of the polycrystalline powder of the complex were recorded at room temperature and at 77 K. The complex shows axial spectra with $g_{//}$ =2.28, $g_{\perp}$ = 2.07 and $A_{//}$ = 165 G at room temperature. When the solid sample is measured at 77 K (liquid nitrogen), the signals become sharper with the same g and A values.

The EPR spectrum of the complex recorded in frozen solution at 77 K in MeOH shows an overlapping of two well-resolved axial signals with superhyperfine splitting superimposed on the axial and equatorial absorptions. The

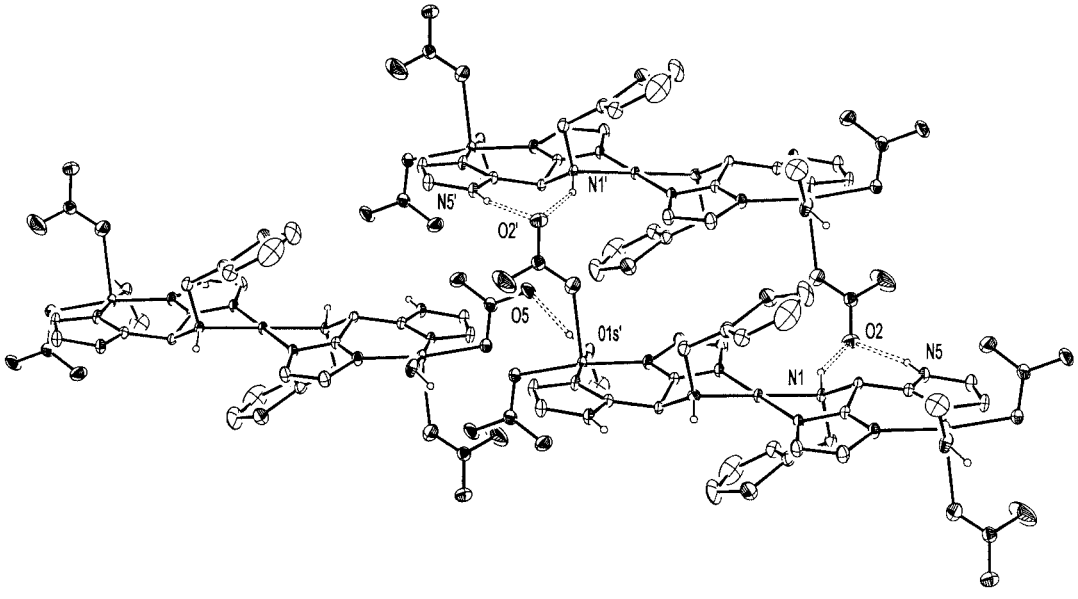

Figure 3. Perspective view showing the relevant hydrogen bonds connecting three different molecular complexes; intermolecular (D−H···A [Å]): N1−H1···O2 2.885(4), N5−H5···O2 2.848(5), O1s−H1s···O5 2.708(6)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

spectrum clearly indicates the presence of two mononuclear species in solution, suggesting the dissociation of the trinuclear core. No half-field splitting signals, usually observed in the case of dinuclear species, are found. The equatorial coordination by four nitrogen donors around Cu1 in the complex results in the expected nine superhyperfine lines ($A_{N\perp}$ = 12.0 G). The spectrum was simulated satisfactorily[26] (see Figure 4) by using two noninteracting mononuclear Cu^{II} species in a ratio of 2.1:1.1. The reliability factor, defined as $R = n^{-1}[\Sigma(\chi_{obs} - \chi_{cal})^2/(\chi_{cal})^2]$ (n = number of data points), was $8.58 \cdot 10^{-4}$. The best simulating parameters for the species 1 were $g_x = 2.02$, $g_y = 2.05$ and $g_z = 2.25$, with $A_z = 198$ G (other A values set at 0). These values are reasonably close to those reported in the literature for CuN_4 chromophores. For species 2, the following values were obtained: $g_x \approx g_y = 2.06$ and $g_z = 2.33$, with $A_{//} = 175$ G (other A value set at 0).

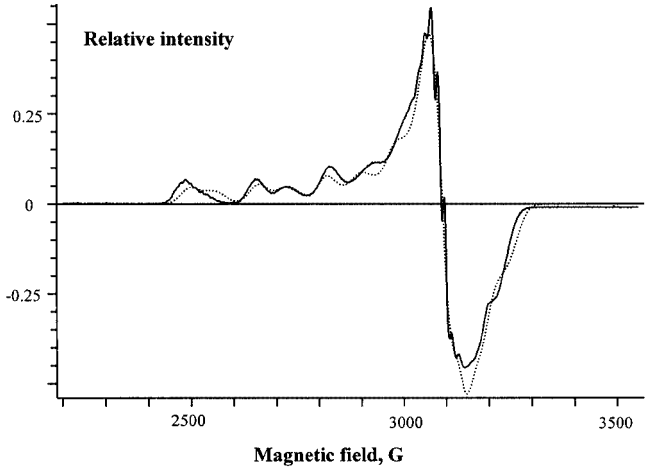

Figure 4. X-band EPR spectrum of the complex recorded at 77 K in MeOH; experimental curve (solid line) and simulated curve (dashed line) spectra of the complex (see text for further details)

Magnetic Susceptibility Measurement

The temperature-dependent magnetic susceptibility of the imidazolato-bridged trinuclear copper complex shows weak antiferromagnetic behaviour through the whole range of temperature (5−300 K). At 300 K the magnetic susceptibility has a value of 0.9725 cm^3mol^{-1}, a little bit lower than expected for three independent copper atoms (1.125 cm^3mol^{-1}). The decrease of the value of χT upon cooling is gradual and becomes slightly steeper at around 100 K, finally reaching a value of 0.2505 cm^3mol^{-1} at 5 K (Figure 5). This behaviour is typical for compounds with weak antiferromagnetism and was modelled using the spin Hamiltonian presented below:

$$H = g\beta S_z H - J_1(S_1 \cdot S_2 + S_{1a} \cdot S_2) - J_2(S_1 \cdot S_{1a}) - zJ' \langle S_z \rangle S_z$$

The first term of this Hamiltonian corresponds to the Zeeman term, for which only one isotropic g tensor has been considered for the two different Cu^{II} ions. The second and third terms are the isotropic nearest-neighbour and next-nearest-neighbour interactions, respectively; J_1 represents the exchange parameter between neighbouring Cu^{II} ions and J_2 the exchange parameter between terminal Cu^{II} ions. The latter has been neglected ($J_2 = 0$), as can be done when the compound is completely linear and the main interaction is antiferromagnetic. The last term takes into account the intermolecular interactions between the trinuclear arrays in the mean field approximation, in which J' is the intermolecular exchange interaction and z the number of trimeric neighbours (in this case 4). Considering the *TIP* (temperature-independent paramagnetism) and p as paramagnetic impurities, the resulting expression is:

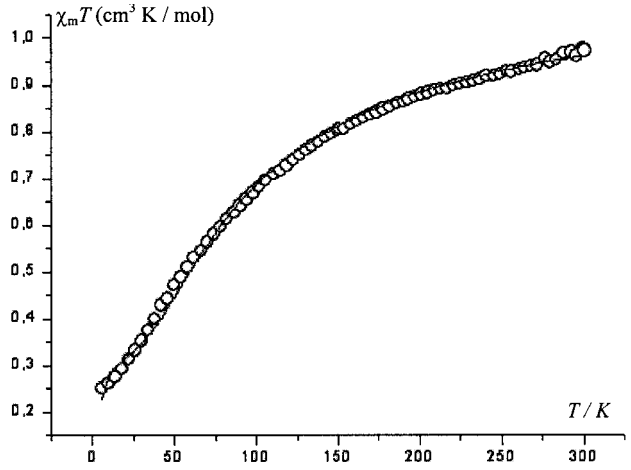

Figure 5. $\chi_m T$ vs. T plot for $[Cu_3(imthio)_2(NO_3)_4(MeOH)_2]$; the solid line is the best fit obtained with a nearest-neighbour interaction of -71.37 cm^{-1} (see text)

$$\chi_m T = \{(N_a g^2 \beta^2 F(T)/4k_B[T - zJ'F(T)]\}(1 - p) + (N_a g^2 \beta^2/2kT)p + TIP$$

$$F(T) = [1 + \exp(J_1/k_B T) + 10\exp(3J_1/2k_B T)]/[1 + \exp(J_1/k_B T) + 2\exp(3J_1/2K_B T)]$$

The best-fit parameters were $g = 2$, $J_1 = -71.37$, $zJ' = -4.03$ and $p = 0$ and the *TIP* is $60 \cdot 10^{-3}$ cm^3mol^{-1}, with an R value of $1.2 \cdot 10^{-4}$. The J_1 value is in good agreement with the expected value for imidazolato-bridged copper complexes reported previously.[27] Indeed, the Cu−Cu separation is large (Cu−Cu = 5.676 Å), obviously indicating that no direct exchange mechanism is likely to contribute to the magnetic coupling. Therefore, the antiferromagnetic coupling in the compound is ascribed solely to superexchange mechanisms between the magnetic orbitals of copper(II) ions ($d_{x^2-y^2}$) through the bridging imidazolate rings. The quite high value of the intertrinuclear superexchange interaction can be explained by the hydrogen-bonding network and π-π interactions between the trinuclear units in the lattice.

Conclusions

In summary, the Himthio ligand allows the preparation of a homometallic, trinuclear complex, $[Cu_3(imthio)_2(NO_3)_4$-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$(MeOH)_2$]. As Cu1 occupies an inversion centre, the resulting Cu2−Cu1−Cu2′ array is linear by symmetry. The molecular structure results in two different coordination sites within the same molecular complex, i.e. an N_4S_2 octahedral site and two N_2O_3 distorted square-pyramidal sites. The Cu−S distance is around 3.136 Å, which indicates moderate interactions between sulfur atoms and Cu^{II} atoms and results in the distortion of the ligand in the complex. Since only a limited number of linear trinuclear compounds have been reported as yet,[25,28] this trinuclear complex, with semicoordination of the thiophene sulfur atoms with Cu^{II} atoms, is unique. The crystal packing of the complex is stabilized by several hydrogen bonds and the interactions between aromatic rings. The EPR spectrum at 77 K in MeOH shows well-resolved superfine splitting signals, which are satisfactorily simulated with two mononuclear species. The magnetic susceptibility measurement of the complex indicates weak antiferromagnetic behaviour between copper(II) ions by a superexchange mechanism through the bridging imidazolate moieties. The studies not only present an unusual trinuclear copper(II) complex with semicoordinated thiophene moieties, but also provide more information about the magnetic and structural data for imidazolato-bridged complexes.

Experimental Section

General Remarks: All reagents and solvents were purchased from commercial sources and used as received. Elemental analyses (C, H N, S) were carried out with a Perkin−Elmer 2400 series II analyser. Infrared spectra were recorded with a Perkin−Elmer Paragon 1000 spectrophotometer equipped with a Golden Gate Diamond ATR device, using the diffuse reflectance technique. X-band EPR spectra were recorded at room temperature and at 77 K with a Jeol RE2X electron spin resonance spectrometer using diphenylpicrylhydrazyl (DPPH) (g = 2.0036) as a standard. The UV/Vis spectra of the compound were recorded in the 250−800 nm range with a Cary 50 Varian UV/Vis/NIR spectrometer. The cyclic voltammetry measurements were performed with an Autolab PGstat10 potentiostat controlled by GPES4 software. A three-electrode system was used, consisting of a glassy carbon (GC) working electrode, a platinum (Pt) auxiliary electrode and an Ag/AgCl reference electrode. All potentials are given versus Ag/AgCl. The experiments were carried out in MeOH solution at room temperature under argon. Magnetic susceptibility measurements (5−300 K) were carried out using a Quantum Design MPMS-5S SQUID magnetometer, in a 1 kG applied field. Data were corrected for the experimentally determined contribution of the sample holder. Corrections for the diamagnetic responses of the complex, as estimated from Pascal's constants, were applied.[29]

Preparation of the 1,1-Bis(imidazol-2-yl)-3-(thiophen-2-yl)-2-azapropane (Himthio) Ligand: 2-(Aminomethyl)thiophene (0.50 g, 4.37 mmol) in water (10 mL) was added to a solution of the hydrochloride salt of bis(imidazol-2-yl)nitromethane[16] (1.0 g, 4.37 mmol) in sodium hydroxide solution (2.0 M, 5 mL) . The solution was stirred at 80 °C for 2 h, during which the product crystallised from the reaction mixture (if not, the solution was left at room temperature, until precipitation of the compound occurred). After cooling to room temperature, the reaction mixture was filtered and washed with water, ethanol and diethyl ether in air. Yield: 0.74 g, 65%. ^{1}H NMR (200 MHz, CD_3OD, 25 °C, 0−10 ppm): δ = 7.30 (t, 1 H, Thio-*H*), 7.02 (s, 4 H, Im-*H*), 6.92 (d, 2 H, Thio-*H*), 5.18 (s, 1 H, C*H*), 3.87 (s, 2 H, CH_2) ppm. MS: m/z = 259.9 $[M + H]^+$.

Preparation of the Copper Complex $[Cu_3(imthio)_2(NO_3)_4(MeOH)_2]$: A solution of the Himthio ligand (20.72 mg, 0.08 mmol) in methanol (10 mL) was added to a solution of $Cu(NO_3)_2{\cdot}3H_2O$ (19.3 mg, 0.08 mmol) in methanol (5 mL). The reaction mixture was stirred at room temperature for 30 min and filtered. The solution was left alone at room temperature for several weeks, and green crystals suitable for X-ray analysis were produced. Yield: 9.5 mg, 35%. $C_{26}H_{32}Cu_3N_{14}O_{14}S_2$ (1019.40): calcd. C 30.6, H 3.2, N 19.2, S 6.3; found C 30.9, H 2.7, N 18.7, S 6.8. IR (solid): $\tilde{\nu}$ = 1564.9, 1484.6, 1373.3, 1329.2, 1300.2, 1140.2, 1030.5, 926.1, 825.7, 750.0, 724.1, 651.2, 431.8 cm^{-1}.

X-ray Crystallographic Study: The molecular structure of $[Cu_3(imthio)_2(NO_3)_4(MeOH)_2]$ was determined by single-crystal X-ray diffraction methods. Crystallographic and experimental details for the structure are summarized in Table 1. Intensity data and cell parameters were recorded at room temperature (25 °C) with a Bruker AXS Smart 1000 single-crystal diffractometer (Mo-K_α radiation) equipped with a CCD area detector. The data reduction was performed using the SAINT and SADABS programs.[30] The structure was solved by Direct Methods using the SIR97 program[31] and refined on F_o^2 by full-matrix least-squares procedures, using the SHELXL-97 program.[32] All non-hydrogen atoms were refined with anisotropic atomic displacements. The hydrogen atoms were included in the refinement at idealised geometry (C−H 0.95 Å) and refined "riding" on the corresponding parent atoms, with the exception of H1S4, which was located in the difference Fourier map. The weighting scheme used in the last cycle of refinement was

Acid-Base Self-Assembly Chemistry and Hydrogen Bonding Interactions Resulting in the Formation of a Tetranuclear Aggregate Containing Four Crystallographically Non-Equivalent Fe^{III} Centers

Stefania Tanase,[a] Elisabeth Bouwman,[a] Gary J. Long,[b] Ahmed M. Shahin,[b] Allison M. Mills,[c] Anthony L. Spek,[c] and Jan Reedijk*[a]

Keywords: Iron / Pyrazole ligands / Hydroxo bridge / Mössbauer

The synthesis and characterization of a mononuclear iron(III) complex [Fe(Hphpz)Cl(CH_3OH)] (**1**) and a tetranuclear assembly of a bis(μ-hydroxo)-bridged dinuclear iron(III) complex [{Fe(Hphpz)$_2$(OH)}$_2$][Fe(Hphpz)$_3$]$_2$ (**2**) with the ligand 3(5)-methyl-5(3)-(2-hydroxyphenyl)pyrazole (H_2phpz) is reported. Compound **1** is converted into **2** in a methanol solution and in the presence of a base. The asymmetric unit of **2** consists of two independent [Fe(Hphpz)$_3$] molecules and one dinuclear complex [Fe(Hphpz)$_2$(OH)]$_2$ containing two crystallographically non-equivalent iron(iii) ions; the three units are linked by N–H···O and O–H···O hydrogen bonding and stacking interactions to form a cluster with an approximate C_2-symmetry. The Mössbauer spectra of [{Fe(Hphpz)$_2$-(OH)}$_2$][Fe(phpz)$_3$]$_2$ have been measured at 295 and 78 K and indicate the presence of four crystallographically distinct, but chemically similar iron(III) sites. The magnetic properties of this compound originate from the weak antiferromagnetic interaction between the Fe^{III} ions of the [Fe(phpz)$_2$(OH)]$_2$ dimer ($J = -2.8$ cm^{-1}).

Introduction

The chemistry of dinuclear iron(III) complexes bridged by carboxylato residues and/or by a single water-derived ligand (such as hydroxo or oxo) continues to be of great interest because of their implication in the active site of a number of metalloproteins, such as hemerytin (Hr),[1] ribonucleotide reductase (RR),[2] methane monooxygenase (MMO),[3] and purple acid phosphatase (PAPs).[4] At various stages of the enzymatic cycle, the type of the bridge and water-derived ligands may vary depending on the protein. The coordination spheres of the two iron centers play important roles in providing selective substrate binding, control of the iron oxidation states and stereochemical control of the intermediates in the enzymatic cycle. The functions performed by these metalloproteins and their significance have inspired a range of biomimetic studies, studies which suggest that bio-inspired catalytic oxidations might represent a valuable approach for the development of new and more environmentally friendly catalysts for industrial applications. Because spectroscopy plays a key complementary role in obtaining molecular-level insight into the catalytic mechanism that occurs at the active site of metalloproteins, the synthesis of small molecule model compounds has remained a challenging field.

As part of a programme of synthesizing dinuclear iron complexes which model the active sites of metalloproteins, we have chosen to work with nitrogenous and oxygenous ligands and, in particular, with pyrazole-containing ligands.[5] Pyrazole-containing ligands provide an interesting alternative to the often used pyridine ligands for the design of model complexes that can mimic active sites containing imidazole groups from histidine bound to an iron center.[6,7] Especially the lower pK_a values of the pyrazoles and the availability of an acid N−H group as possible hydrogen-bond donor, provide an interesting possibility for new structural features. So, these ligands might even be preferred in the field of biomimetic chemistry, both because they are good structural analogues for the size and electronic properties of histidine and because of their relative ease of preparation as compared to imidazole ligands. In this regard and because of the occurrence of tyrosinase radicals in metalloproteins involved in oxygen-dependent enzymatic radical catalysis,[8] we have been interested in the assembly of discrete diiron(III) cores from 3(5)-methyl-5(3)-(2-

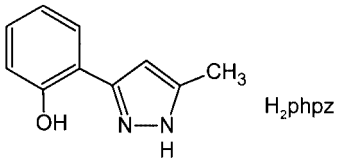

Scheme 1

hydroxyphenyl)pyrazole (H_2phpz, Scheme 1) and simple donors, such as hydroxide, formate, acetate, and benzoate. We report herein the synthesis, structural, spectroscopic and magnetic characterization of $[\{Fe(Hphpz)_2(OH)\}_2][Fe(phpz)_3]_2$, a compound which contains a $Fe_2(\mu\text{-}OH)_2$ core and is extensively stabilized by hydrogen bonding and stacking interactions between the lattice components.

Results and Discussion

Synthesis and Characterization of Iron Complexes of H_2phpz

The procedure for synthesizing the H_2phpz ligand[10] has been reported previously; for the mono-anionic Hphpz, only the mononuclear complex $[Fe(Hphpz)(MeOH)_2](NO_3)$ has so far been reported.[9] In the present study, the reaction of H_2phpz with $Fe(NO_3)_3$, and with other iron(III) salts in various solvents has been extensively investigated. However, elemental analysis and ligand field spectra reveal that mixtures of compounds are obtained in all cases. Therefore, a more specific systematic study had to be undertaken. The reaction of the ligand H_2phpz with $FeCl_2$ (2:1) in the presence of two equiv. of base in methanol leads to a dark purple crystalline product with the tentative formula $[Fe(Hphpz)_2Cl(MeOH)]$ (**1**) as suggested by elemental analysis (Scheme 2). The positive ion mass spectrum of a fresh solution of **1** in either methanol or CH_2Cl_2 exhibits a prominent signal at $m/z = 433$ (relative intensity $I = 100\%$ in the range $m/z = 200-1000$). This signal matches very well with the calculated isotopic distribution for $[Fe(Hphpz)_2(MeOH)]^+$. The effective magnetic moment of **1** at room temperature (5.84 μ_β) is close to the spin-only value expected for a high-spin iron(III) center ($S = {}^5/_2$, $\mu_{eff} = 5.92\ \mu_\beta$); the variable temperature solid-state magnetic susceptibility of **1** has been investigated in the range 5−300 K and it displays strict Curie−Weiss behaviour consistent with the presence of an isolated paramagnetic iron(III) ion. No single crystals were obtained however.

Coordination of 3(5)-methyl-5(3)-(2-hydroxyphenyl)pyrazole with the iron(III) ion is indicated in the infrared spectrum by a shift of the ν_{C-O} stretch from 1654 cm^{-1} in the free ligand to 1599 cm^{-1} in complex **1** and of the $\nu_{C=N}$ stretch from 1636 cm^{-1} in the free ligand to 1557 cm^{-1} in the complex. A sharp peak observed at 3259 cm^{-1} can be assigned to the ν_{N-H} stretch of the pyrazole ring. The absence of any absorption in the range 3300−3600 cm^{-1} indicates that the phenolic proton is lost on coordination.

The main feature of the UV/Vis spectrum of **1** in the solid state is a low-energy band with a maximum at 568 nm that gives rise to the purple colour and which is ascribed to the charge-transfer transition from the p_π orbitals of the phenolic oxygens to the d_π* orbitals of the iron(III) ions.[9,11] A second charge-transfer band occurs at 369 nm and has been assigned to a $p_\pi \rightarrow d_\sigma$* type transition.[11] Electronic absorption spectra of **1** have also been recorded in methanol and dichloromethane, and both show spectroscopic features that are similar to that in the solid state consisting of two absorption bands with maxima at 359 nm and 547 nm, respectively and it suggests that the chloride ion is not replaced by methanol.

The cyclic voltammogram of **1** recorded at room temperature in CH_2Cl_2 shows an irreversible cathodic wave at 0.83 V vs. Ag/AgCl, which is ascribed to the reduction of iron(III) to iron(II). The relatively high reduction potential suggests that **1** is stabilized by the coordination of the chloride anion. This stabilization is also confirmed by the absence of any oxidation peak when scanning the potential up to 1.2 V, a potential at which free chloride ions may be detected.

When a purple-colored methanol solution of **1** is stored in a closed inert atmosphere it gradually changes to red over a number of days. Ligand field spectra would suggest that the new species is a mixture of $[Fe(Hphpz)_2Cl(MeOH)]$, $[Fe(Hphpz)_2(OH)]_2$ and $[Fe(Hphpz)_3]$. Addition of 2 equiv. of base to a fresh methanol solution of **1** results in the immediate appearance of an intense red coloration, accompanied by significant spectroscopic changes (Figure 1). The absorption maximum at 490 nm suggest the presence of a bis(μ-hydroxo) dimer.[12] The function of the added base appears to be to provide the medium required for the formation of the $Fe_2(\mu\text{-}OH)_2$ core. Vapor diffusion of ethyl acetate into this solution yields a red microcrystalline solid, for which elemental analysis indicates the formula $[\{Fe(Hphpz)_2(OH)\}_2][Fe(Hphpz)_3]_2$ (**2**). Thus, it appears that compound **2** is a decomposition product of **1**. Although we were unsuccessful in growing crystals large enough to carry out an X-ray structural study of **1**, we were successful in growing crystals of **2**. The yield of compound **2** has been optimized via acid-base self assembly chemistry (Scheme 2), by mixing

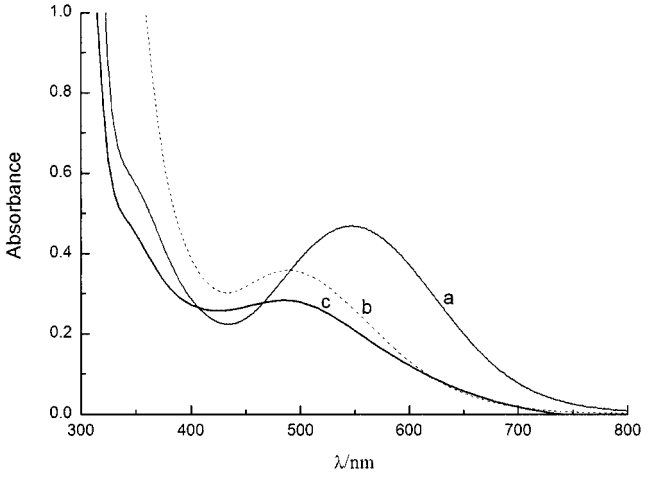

Figure 1. UV/Vis spectra of a methanol solution of $[Fe(Hphpz)_2Cl(MeOH)]$ (a), after the addition of 2 equiv. of Bu_4NOH to **1** (b), and $[\{Fe(Hphpz)_2(OH)\}_2][Fe(Hphpz)_3]_2$ redissolved in methanol (c)

$FeCl_2{\cdot}4H_2O$ with H_2phpz under air in the presence of triethylamine as base.

The infrared spectrum of **2** exhibits the bands expected for the ligand Hphpz and it is similar to that of the compound **1**. Unfortunately, it is not possible to definitely identify the Fe−O−Fe vibrational bands, because of the complexity of the infrared spectrum in the 500−800 cm^{-1} range. The ligand field spectrum of **2** displays the features typical of bis(μ-hydroxo)-bridged iron(III) compounds: an intense absorption band at 495 nm with a lower energy shoulder at 586 nm, bands that may be assigned to ligand-to-iron(III) charge-transfer transitions.[13] A weak-intensity absorption band that occurs at 997 nm is attributed to the d-d transitions involving forbidden states of the high-spin iron(III) ion.[14]

X-ray Crystal Structure of $[\{Fe(Hphpz)_2(OH)\}_2][Fe(Hphpz)_3]_2$

Perspective views of the molecular entities of **2** are shown in Figure 2 along with the atom-labeling scheme. The asymmetric unit of **2** contains two independent *mer*-$[Fe(Hphpz)_3]$ molecules and one dinuclear complex $[Fe(Hphpz)_2(OH)]_2$. Selected bond lengths and angles pertaining to the iron(III) coordination spheres are given in Table 1.

Each of the two independent $[Fe(Hphpz)_3]$ molecules consists of an iron(III) ion coordinated to three $phpz^-$ ligands (Figure 2, a and b). The distorted octahedral-based FeN_3O_3 chromophores both have a meridional (*mer*) configuration. The bond lengths and angles at the iron center are similar in both entities and indicate an extensive deviation from octahedral symmetry (Table 1, Supplementary material). The largest deviations from ideal octahedral symmetry are observed for the *trans* O21−Fe1−O61 = 162.10(14)° and O81−Fe2−O121 = 161.67(15)° angles. The least-square phenyl rings and pyrazole rings in the $Hphpz^-$ ligand containing N32 and N92 nitrogen atoms make dihedral angles of 8.2(3) and 2.1(3)°. Although a planar molecule is expected, the $Hphpz^-$ ligand may also bind in a twisted conformation because the conjugation of the phenyl−pyrazole bond is flexible. Due to the aromaticity of the pyrazole ring the lone pair of the nitrogen, and therefore the coordinated metal ion all are expected to lie in a nearly perfect plane. In the case of the pyrazole ring containing N32 and the one containing N92, however, the iron atoms lie 0.8−1.0 Å above the least-squares plane of the pyrazole ring. This implies that the pyrazole ring is bound to the iron atoms in a rather acute angle of 19.41° and 20.59°. The hydrogen bonding interactions from N−H to a neighboring oxygen atoms and the π-π interactions clearly enforce the deviation from the planarity of distorted $Hphpz^-$ ligands (see below). The $Fe-N_{pz}$ and $Fe-O_{ph}$ bond lengths are very similar to those found in the dinuclear species $[Fe(Hphpz)_2(OH)]_2$.

The dinuclear $[Fe(Hphpz)_2(OH)]_2$ unit contains two crystallographically non-equivalent iron(III) ions that are bridged by two hydroxyl groups (Figure 2, c). The nitrogen and oxygen donors of two molecules of the H_2phpz ligand in its mono-dehydronated form ($Hphpz^-$) occupy four coordination sites of each iron(III) ion. At Fe3 the nitrogen donors of the two ligands are mutually *trans*, whereas at Fe4 they are positioned *cis* with respect to one another. The two remaining sites are filled by the bridging hydroxyl ions. Therefore, each iron(III) ion has a N_2O_4 donor set in a distorted octahedral coordination geometry. All *cis* and *trans* angles deviate from 90 and 180°; in particular, the angles N192−Fe4−O210 = 162.48(14)° and N172−Fe4−O211 = 162.56(14)° are considerably kinked. In the four-membered $Fe_2(\mu\text{-}OH)_2$ core, the two metal centers are separated by 3.1492(9) Å and have two slightly different bridging angles of Fe3−O210−Fe4 = 105.45(14)° and Fe3−O211−Fe4 104.97(14)°. Each of the hydroxyl ions bridges the metal centers asymmetrically; the Fe3−OH distances are somewhat shorter than those for Fe4, which may be related to the *trans* effect of the nitrogen donors and to the steric requirements of the Hphpz ligands. All of the $Fe^{III}-\mu$-OH bond lengths, as well as the Fe−OH−Fe bridge angles, are in the range of those observed for similar $Fe_2(\mu\text{-}OH)_2$ complexes.[15−18] The $Fe-N_{pz}$ and $Fe-O_{ph}$ bond lengths are also comparable to those reported for related complexes.[9,19]

An interesting feature of the crystal structure of **2** is the presence of multiple intra- and intermolecular hydrogen bonds, as well as intermolecular π···π stacking interactions, interactions which play an important role in the stabilization of the observed molecular configuration (Figure 3 and Table S1 in the Supporting Information). Two strong intramolecular N−H···O hydrogen bonds (N−H···O = 2.803 Å) link $Hphpz^-$ ligands on different iron centres in the $[Fe(Hphpz)_2(OH)]_2$ unit. In each of the $[Fe(Hphpz)_3]$ molecules, two intramolecular N−H···O hydrogen bonds are established between two of the anionic $Hphpz^-$ ligands. The third anionic $phpz^-$ molecule of each mononuclear entity is involved in two intermolecular N−H···O hydrogen bonds with $Hphpz^-$ ligands of the dinuclear

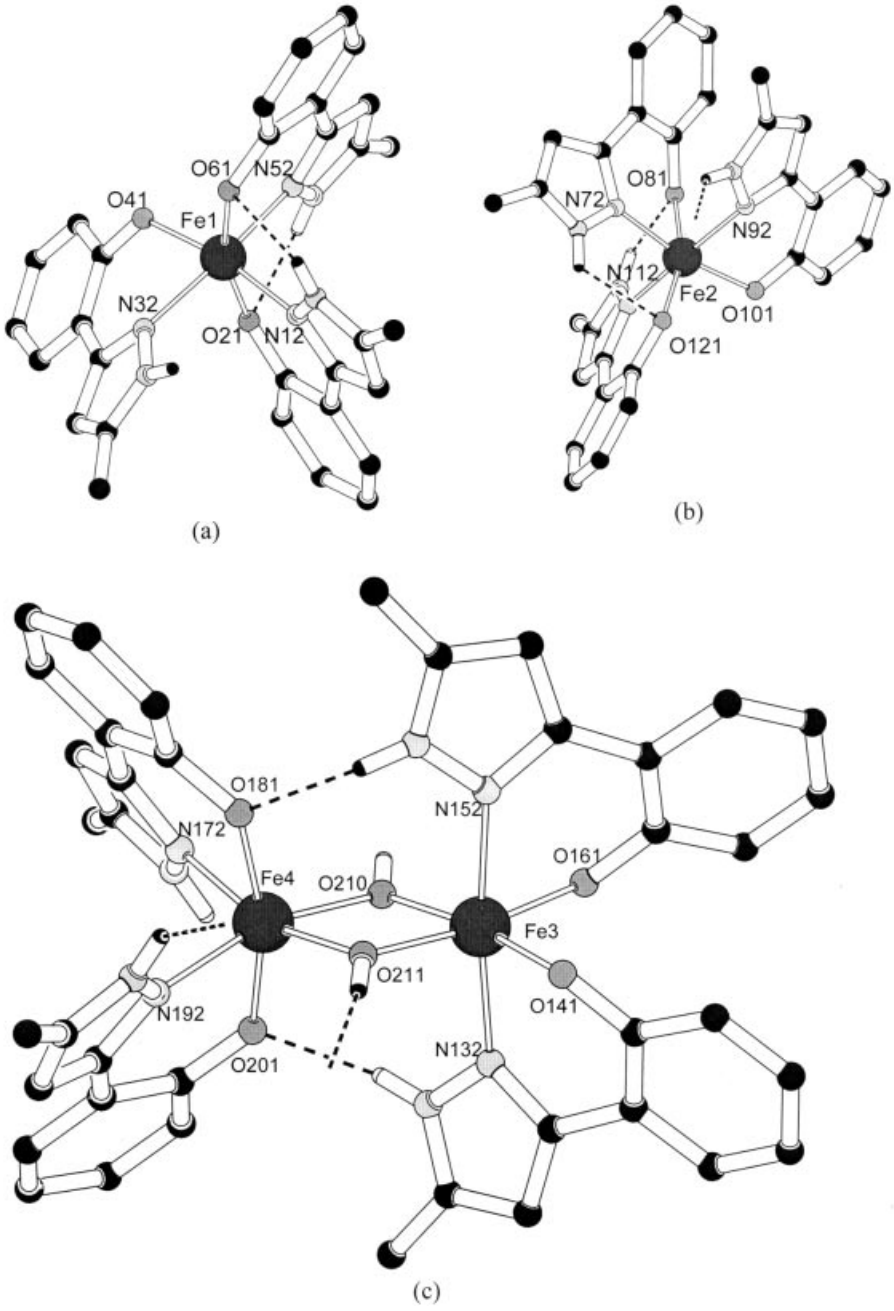

Figure 2. Pluton projections and labeling scheme of the three molecules of the asymmetric unit of $[\{Fe(Hphpz)_2(OH)\}_2][Fe(Hphpz)_3]_2$ (**2**) including the hydrogen bond interactions

$[Fe(Hphpz)_2(OH)]_2$. Two strong O−H···O hydrogen bonds occur between the hydroxo-bridges of $[Fe(Hphpz)_2(OH)]_2$ and the O donor of one $Hphpz^-$ ligand from each $[Fe(Hphpz)_3]$ monomer. Thus, the three molecules are linked by N−H···O and O−H···O hydrogen bonding interactions to form a tetranuclear assembly with approximate C_2-symmetry. Several intermolecular π···π stacking interactions involving aromatic rings of the of the $Hphpz^-$ ligands of the three iron complexes further reinforce the tetranuclear assembly (Table S2 in the Supporting Information). An additional inter − tetranuclear assembly π···π interaction occurs between peripheral pyrazole rings of inversion-related tetranuclear assemblies. The optimization of these packing interactions leads to $Hphpz^-$ ligand conformations varying from nearly planar to considerably twisted; the dihedral angles between the phenyl and pyrazole ring planes within the ligands range from 1.6(3) to 23.0(4)°. In the three-dimensional structure of $[\{Fe(Hphpz)_2(OH)\}_2]$-$[Fe(Hphpz)_3]_2$, the assemblies are separated by large voids filled with disorded THF solvent molecules.

Mössbauer Spectroscopic Results

To study the four different species in more detail, Mössbauer spectroscopy was applied with fitting pro-

cedures. The Mössbauer spectra of $[\{Fe(Hphpz)_2(OH)\}_2][Fe(Hphpz)_3]_2$ measured at 295 and 78 K are shown in Figure 4. As might be expected for a compound containing four crystallographically distinct, but chemically similar iron sites, the observed spectra do not show spectral resolution of the four different iron sites. Because of the four crystallographically different iron sites found in $[\{Fe(Hphpz)_2(OH)\}_2][Fe(Hphpz)_3]_2$, the Mössbauer spectra have been fitted with four symmetric quadrupole doublets whose relative areas were constrained to 25 percent each; the resulting hyperfine parameters are given in Table 2.

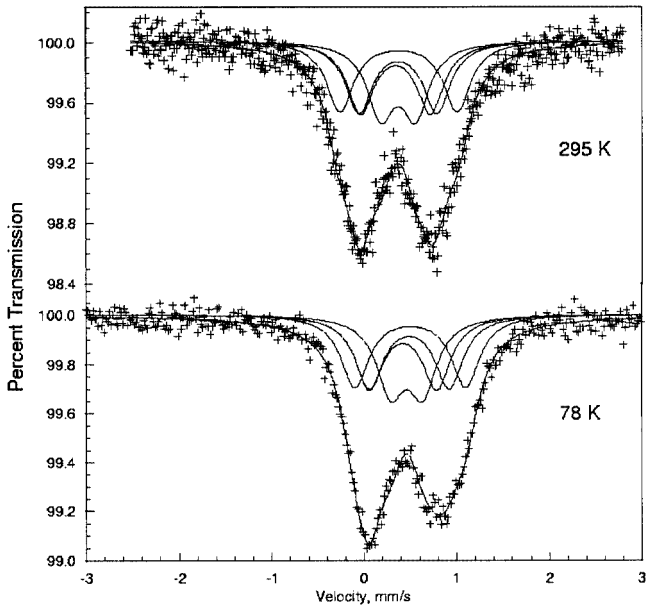

Figure 4. The Mössbauer spectra of **2** obtained at 78 K and 295 K together with the fits for four different species

T [K]	δ[a] [mm/s]	ΔE_Q [mm/s]	Γ [mm/s]	Area [%]	Site assignment[b]
295	0.37	0.38	0.36	25	Fe(3)
	0.33	0.74	0.36	25	Fe(1)
	0.38	0.85	0.36	25	Fe(2)
	0.38	1.27	0.36	25	Fe(4)
average	0.365	0.81	0.36	−	
78	0.46	0.35	0.37	25	Fe(3)
	0.42	0.73	0.37	25	Fe(1)
	0.49	0.86	0.37	25	Fe(2)
	0.50	1.19	0.37	25	Fe(4)
average	0.47	0.78	0.37	−	

[a] The isomer shifts are given relative to room temperature α-iron foil. [b] Based on the degree of the octahedral distortions.

It should be noted that the 78 K spectrum shown in Figure 4 was obtained over an ca. ±5 mm/s range in order to detect the presence of any high-spin iron(II) spectral impurities. As expected none was observed and, as a consequence, the 295 K spectrum was obtained over an ca. ±2.5 mm/s range under different spectrometer geometric and electronic conditions. This difference accounts for the unexpected increase in the percentage transmission observed upon warming from 78 to 295 K and may also account for the small, but unexpected, increase in the quadrupole splitting observed upon warming.

Although the fits depicted in Figure 4 may not be unique, the average values of the hyperfine parameters are characteristic of $[\{Fe(Hphpz)_2(OH)\}_2][Fe(Hphpz)_3]_2$ and are typical of those expected of iron(III) in a distorted octahedral coordination environment.[5,20−22] In an attempt to assign

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the different spectral components shown in Figure 4 the average bond angle distortion parameter, d, as defined[23] by

$$d = \frac{100}{n} \bullet \sum_{i=1}^{n} \frac{|a_i - a_m|}{a_m},$$

where n is the number of bonds, a_m is the mean angle, and a_i is an individual bond angle, has been calculated for each of the four different iron sites. The resulting bond angle distortions are 6.53, 7.09, 5.17, and 8.33% for sites Fe(1) to Fe(4), respectively. Because the quadrupole splitting observed at an iron(III) site will increase with increasing distortion of the coordination environment and hence the distortion of the octahedral bond angles, these parameters were used to make the assignments of the sites given in Table 2. However, it should be noted that these assignments are tentative, as the fits may not be unique.

Magnetic Properties

The variable temperature solid-state magnetic susceptibility of complex **2** is shown in the form of χ_m versus T and μ_{eff} versus T plots (Figure 5). The effective magnetic moment decreases as the temperature is lowered from 300 to 5 K. This variation indicates an overall antiferromagnetic behaviour for compound **2**. The temperature dependence of χ_m could be simulated by using the Van Vleck equation derived from the Heisenberg exchange Hamiltonian for two interacting spins $S_1 = S_2 = {}^5/_2$, modified in order to take into account the two isolated Fe^{III} ions.[24] The temperature-independent paramagnetism (TIP = $400 \cdot 10^{-6}$ $cm^3 \cdot K \cdot mol^{-1}$ for each iron ion) was taken into account. Using this approach, the best fit parameters were $J = -2.8$ cm^{-1}, $g = 2.03$. The exchange coupling parameter, J, is known to have values between -5 and -11 cm^{-1} in the case of bis(μ-hydroxo)-bridged iron(III) complexes and the low electron density of the hydroxo-bridge is likely to be responsible for the observed weak antiferromagnetic coupling.[15,25] In the present case, the remarkable dissymmetry of the $Fe_2(\mu\text{-}OH)_2$ core geometry accounts for the weaker antiferromagnetic coupling, as compared with related bis(μ-hydroxo)-bridged iron(III) compounds.

Conclusion

Two iron complexes of the ligand 3(5)-methyl-5(3)-(2-hydroxyphenyl)pyrazole, namely $[Fe(Hphpz)_2Cl(MeOH)]$ (**1**) and $[\{Fe(Hphpz)_2(OH)\}_2][Fe(Hphpz)_3]_2$ (**2**), have been synthesized and characterized by various spectroscopic measurements. Compound **2**, which appears to be a decomposition product of **1** was structurally characterized by X-ray diffraction; its asymmetric unit contains two independent $[Fe(Hphpz)_3]$ molecules and one dinuclear complex $[Fe(Hphpz)_2(OH)]_2$ with two crystallographically nonequivalent iron(III) ions. The remarkable dissymmetric dinuclear $[Fe(Hphpz)_2(OH)]_2$ unit is highly stabilized through π donation of the OH^- bridge and through N−H···O and O−H···O hydrogen bonds. Further attempts to isolate (μ-oxo)(μ-carboxylato)diiron(III) complexes based on $[Fe(Hphpz)_2]^+$ units are underway. The influence of different pyrazole derivatives on the stability of the $Fe_2(OH)_2$ core will also be investigated.

Experimental Section

General Remarks: All chemicals were of reagent grade, and were used as received. 3(5)-methyl-5(3)-(2-hydroxyphenyl)pyrazole (H_2phpz) was prepared by condensation of hydrazine and salicoylacetone as reported previously.[10] All experiments were carried out in air, unless stated otherwise.

Physical Measurements: Elemental analyses for C, H, and N were performed on a Perkin−Elmer 2400 Series II analyzer. Infrared spectra (4000−300 cm^{-1}) were recorded on a Perkin−Elmer Paragon 1000 FTIR spectrometer equipped with a Golden Gate ATR device, using the reflectance technique. UV/Vis spectra were obtained on a Perkin−Elmer Lambda 900 spectrophotometer using the diffuse reflectance technique, with MgO as a reference. Magnetic susceptibility measurements (5−300 K) were carried out at 0.1 T using a Quantum Design MPMS-5 5T SQUID magnetometer. Data were corrected for magnetization of the sample holder and for diamagnetic contributions, which were calculated from the Pascal constants. Mössbauer spectra were measured on a constant-acceleration spectrometer that utilized a room temperature rhodium matrix cobalt-57 source and was calibrated at room temperature with α-iron foil.

$[Fe(Hphpz)_2Cl(MeOH)]$ (1) was synthesized by adding an ethanolic solution containing 3(5)-methyl-5(3)-(2-hydroxyphenyl)pyrazole (0.322 g, 2 mmol) and Bu_4NOH (2 mmol, solution in methanol) to an ethanolic solution of $FeCl_2 \cdot 4H_2O$ (0.198 g, 1 mmol) and stirring for one hour. The resulting dark purple precipitate was collected by filtration, washed with diethyl ether and dried under vacuum. Yield: 72%. $C_{21}H_{22}ClFeN_4O_3$ (469.73): calcd. C 53.70, H 4.72, N 11.93; found C 54.04, H 4.51, N 12.29. IR ($\tilde{\nu}$/cm^{-1}): 3259 s, 2971 m, 2889 m, 1599 m, 1557 s, 1456 m, 1310 s, 1243 m, 1119 m, 1063 m, 982 w, 865 s, 784 s, 747 s, 656 m, 628 m, 583 m, 553 s, 438 m, 386 m. UV/Vis/NIR, $\lambda_{?max}$/nm (ε/m$M^{-1}cm^{-1}$): 264, 369, 568; 359 (3.9), 547(3.5) in methanol solution.

$[\{Fe(Hphpz)_2(OH)\}_2][Fe(Hphpz)_3]_2$ (2) was obtained by slow diffusion of hexane into a tetrahydrofuran solution containing

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$FeCl_2 \cdot 4H_2O$ (0.397 g, 2 mmol) and 3(5)-methyl-5(3)-(2-hydroxyphenyl)pyrazole (0.644 g, 4 mmol) in the presence of 4 equiv. of triethylamine. The resulting red crystals were collected by filtration, washed with diethyl ether and dried under vacuum. Yield: 65% based on iron. $C_{100}H_{92}Fe_4N_{20}O_{12}$ (1989.34): calcd. C 60.38, H 4.66, N 14.08; found C 60.04, H 4.51, N 14.29. IR ($\tilde{\nu}$/cm^{-1}): 3183 m, 2918 m, 2817 m, 1597 m, 1557 m, 1457 s, 1290 m, 1254 m, 1117 m, 1040 m, 972 w, 848 s, 788 m, 751 s, 602 m, 563 m, 481 m. UV/Vis/NIR, $\lambda_{?max}$/nm (ε/mM^{-1}cm^{-1}): 255, 311, 495, 997; 490(3.2) in methanol solution.

X-ray Crystallographic Study: Intensity data for a single crystal of **2** were collected using Mo-K_α radiation (λ = 0.71073 Å) on a Nonius KappaCCD diffractometer. A correction for absorption was considered unnecessary. The structure was solved by automated Patterson methods using SHELXS-97[26] and was refined on F^2 by least-squares procedures using SHELXL-97.[27] The crystal structure contains voids (799.3 A^3/unit cell) filled with disordered THF solvent molecules. Their contribution to the structure factors was ascertained using PLATON/SQUEEZE (206 e/unit cell).[28] All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydroxyl hydrogen atoms were positively identified in a difference Fourier map, and their positions were refined with the restraint that the O−H distances be similar. All other hydrogen atoms were constrained to idealized geometries and allowed to ride on their carrier atoms. The hydrogen atoms of some methyl groups are disordered over two sets of positions. All hydrogen atoms were refined with an isotropic displacement parameter related to the equivalent displacement parameter of their carrier atoms. Structure validation and molecular graphics preparation were performed with the PLATON package.[28] CCDC-244433 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Incorporation of Inorganic Anions in Calcite

Jasminka Kontrec,[a] Damir Kralj,*[a] Ljerka Brečević,[a] Giuseppe Falini,[b] Simona Fermani,[b] Vesna Noethig-Laslo,[c] and Krunoslav Mirosavljević[c]

Keywords: Anions / Calcite / Calcium carbonate / Crystal growth / EPR spectroscopy

A number of analytical methods and techniques (X-ray diffraction, FT-IR and electron paramagnetic resonance spectroscopy, ionic chromatography, scanning electron microscopy, etc.) have been used to study the mode and sites of incorporation of some common inorganic anions (SO_4^{2-}, NO_3^- and Cl^-) in the calcite crystal lattice. Calcite, the thermodynamically stable calcium carbonate polymorph under standard conditions, was prepared by spontaneous precipitation from calcium hydroxide and carbonic acid solutions. The particular co-anion was added into the carbonic acid solution in the form of a calcium salt before mixing the reactants. The system prepared in such a way is particularly suitable for investigating the mode of foreign anion incorporation into the crystal lattice of calcite. Apart from the constituent ions and the products of water protolysis, this system contains only the co-anion examined. In order to study the local environment in the calcite crystal lattice by EPR spectroscopy, Mn^{2+} was used as a paramagnetic substitute for Ca^{2+}. The experiments were performed at 25 °C and the samples for analyses were taken after a predetermined ageing time of 20 min. It was found that the co-anions, when added in the concentrations examined, did not affect the morphology of the calcite crystals but were incorporated into the calcite structure. The largest distortion of the calcite structure was obtained when sulfate ions were added. The measured parameters of the calcite unit cell are given, the results obtained are discussed and a model that explains the possible mode and sites of sulfate incorporation is presented.

Introduction

In a previous paper, a whole range of different thermodynamic and hydrodynamic parameters that could influence physical-chemical properties of the precipitated calcium carbonate was investigated.[1] Different processes were involved in its formation and different products (polymorphs) were obtained. Thus, even in the systems in which calcite was found to be the only solid phase after the predetermined period of time, its formation was the result either of the recrystallisation of the precursor phase(s) (amorphous calcium carbonate, vaterite) or the crystallisation. As a consequence, the calcite crystals appeared with a range of different physical properties (morphology, size etc.). The influence of foreign ions, primarily Mg^{2+}, in conjunction with some common anions (SO_4^{2-}, NO_3^- and Cl^-) on the physical and chemical properties of calcium carbonate precipitate was also described. The aim of these investigations was principally to study the effects of both the cation and the anions on the morphology of calcite. This work showed that incorporation of magnesium into the calcite crystal lattice depends on the nature of the co-anion present in the system. It was also shown that there is a clear relation between the morphological properties of calcites containing magnesium and the concentration of the corresponding anion, as well as the amount of Mg^{2+} incorporated into calcite lattice. Besides, it was found that the addition of sulfate ions only, caused the formation of spherical aggregates of the originally rhombohedral calcite crystals. Calcite was chosen because it is the only thermodynamically stable polymorph of calcium carbonate under standard conditions to which the other two less stable polymorphs (aragonite and vaterite) gradually transform. Moreover, extensive data relating to calcite exist in the literature. These data are the source of valuable information necessary for our findings to be explained and for the model proposed, in which small inorganic anions are incorporated into the calcite lattice. In addition, calcite is of great interest because of its wide use in industry (pigment and filler in paper, rubber, plastics, paints etc.) and also because of its widespread occurrence in the natural environment (biomineralisation, geological scales). It also has significant impact on energy production and water treatment (scaling). In all these instances, the crystal size distribution and morphology of the crystals are of great significance, as well as their chemical composition

(degree of the additive incorporation into the crystal lattice). Additives and impurities of both an inorganic and an organic nature play an important role. In recent years, the most intensively investigated additives concerning this matter were soluble polymeric and special functional low molecular weight additives,[2−7] as well as the protein macromolecules isolated from some living organisms.[8−11] Among the inorganic ions and small molecules, the effects of Mg^{2+} and some organic acids[12−19] on the formation and morphology of calcium carbonate polymorphs were studied much more than the effects of anions and other cations.[1,20−23] Only a few papers[1,20,22] have considered anions as a possible way of controlling the calcite morphology. The anions studied in our previous investigations and in the present work were chosen because they are the possible impurities in any precipitation system and some of them, such as SO_4^{2-} in seawater, can be present in rather high concentrations.

In order to investigate the role of anions separately from the foreign cations in the calcium carbonate precipitation system in this investigation, calcite was precipitated from a system in which calcium hydroxide and carbonic acid solutions were used as reactants. Thus, any possible effects of ions other than the constituent ions or products of autoprotolysis of water (Ca^{2+}, CO_3^{2-}, HCO_3^-, H_3O^+, OH^-) on the precipitation of calcite were avoided. Calcite prepared in such a way can be used as a reference material for a number of different studies. After that, foreign anions were added to the precipitation system in the form of calcium salts [$CaSO_4$, $Ca(NO_3)_2$ and $CaCl_2$] and a relatively narrow range of the co-anion concentrations was investigated at a relatively low initial supersaturation.

The aim of the present work was to shed more light upon the mode and sites of incorporation of these anions into the calcite lattice. For this purpose X-ray powder diffraction (XRD), FT-IR and electron paramagnetic resonance (EPR) spectroscopy, scanning electron microscopy (SEM) and ion chromatography (IC) were used. In order to study the local environment in the calcite crystal lattice by EPR spectroscopy, Mn^{2+} was used as a paramagnetic substitute for Ca^{2+}. Mn^{2+} is a particularly appropriate probe for such a study because it readily substitutes for Ca^{2+} in the calcite structure and gives a strong EPR signal at room temperature providing abundant information even in the solid state.[13,24−29]

Results and Discussion

All experiments were performed on the precipitation system in which the total initial concentrations of calcium and carbonate ions in solution were, respectively, $c_i(Ca^{2+}) = 5.0 \times 10^{-3}$ mol·dm^{-3} and $c_i(CO_3^{2-}) = 9.0 \times 10^{-3}$ mol·dm^{-3} and the initial pH was approximately 8.7. The initial supersaturation of this system $S = (\Pi/K_{sp}^{o})^{1/2}$, defined as relative supersaturation, S-1, where Π is the ion activity product $\Pi = a(Ca^{2+})\cdot a(CO_3^{2-})$ and K_{sp}^{o} is the thermodynamic equilibrium constant of calcite dissolution ($K_{sp}^{o} = 3.313 \times 10^{-9}$ at 25 °C), was calculated to be S-1 = 10.38. The detailed calculation procedure, which takes into account the respective protolytic equilibria and equilibrium constants as well as the charge and mass balance equations, has been given previously.[1,30]

Figure 1 (a) shows typical crystal size distributions of calcite precipitated in a pure system. A relatively narrow distribution was obtained exhibiting a maximum at about 7 μm. This is consistent with the previous findings[1] according to which the crystals obtained at relatively low supersaturations [(S-1) < 20], formed by heterogeneous nucleation and slow crystal growth, are small in size and considerably monodispersed. This also confirms the observation that the crystal size distribution depends primarily on supersaturation and not on the initial molar ratios $c_i(Ca^{2+})/c_i(CO_3^{2-})$, since such distributions are obtained regardless of carbonate or calcium ions being in excess in the system. The presence of a co-anion (sulfate, nitrate, chloride), added in the system in concentrations mentioned above, did not change the size distribution significantly. Figure 1 (b) shows such a distribution obtained when the highest of the $CaSO_4$ concentrations examined in this work ($c_i = 1.0 \times 10^{-3}$ mol·dm^{-3}) was added into the precipitation system. Slight differences between the distribution curves shown in Figure 1 (a and b) reflect the appearance of a certain portion of smaller calcite crystals obtained in the system with the additive.

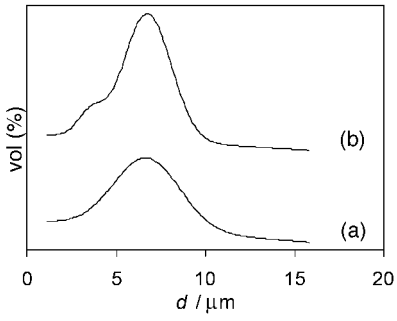

Figure 1. Volume distributions of calcite crystals obtained in the precipitation system $c_i(Ca^{2+}) = 5.0 \times 10^{-3}$ mol·dm^{-3}, $c_i(CO_3^{2-}) = 9.0 \times 10^{-3}$ mol·dm^{-3} at 25 °C, containing $CaSO_4$: a) 0 mol·dm^{-3}; b) 1.0×10^{-3} mol·dm^{-3}

Rather uniformly shaped crystals were obtained with or without the addition of the co-anions. As an example, Figure 2 shows scanning electron micrographs of calcite crystals obtained in the systems with increasing concentrations of sulfate ions. At the highest concentration of sulfate ions, a slight tendency towards the formation of aggregates of smaller rhombohedral calcite crystals, as shown in Figure 2 (d), could be sporadically observed. This is consistent with the findings represented in Figure 1. It should be noted that the effect of sulfate ions on the calcite morphology is more pronounced in the precipitation systems, in which the initial supersaturation, and consequently the growth rate and the aggregation tendency is much higher (S-1 > 30, pH_i > 10.5). In such cases, the formation of spherical aggregates

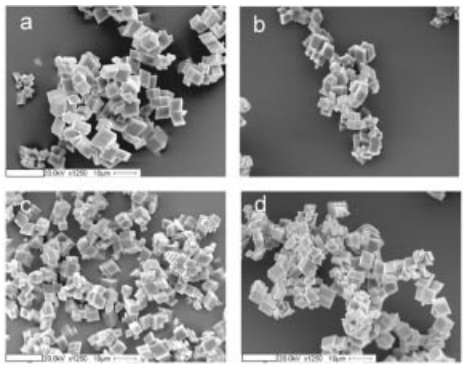

Figure 2. Scanning electron micrographs of calcite crystals isolated from the system $c_i(Ca^{2+}) = 5.0 \times 10^{-3}$ mol·dm^{-3}, $c_i(CO_3^{2-}) = 9.0 \times 10^{-3}$ mol·dm^{-3} at 25 °C, to which the following concentrations of $CaSO_4$ were added: (a) 1.0×10^{-4} mol·dm^{-3}, (b) 3.0×10^{-4} mol·dm^{-3}, (c) 6.0×10^{-4} mol·dm^{-3} and (d) 1.0×10^{-3} mol·dm^{-3}

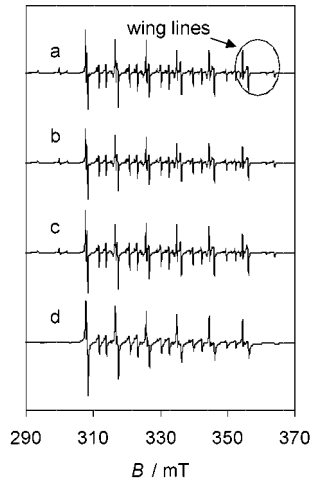

Figure 3. EPR spectra of $^{55}Mn^{2+}$ in (a) pure calcite (the "wing lines" are denoted) and calcites prepared in the presence of 1.0×10^{-3} mol·dm^{-3}: (b) NO_3^-, (c) Cl^- and (d) SO_4^{2-}; the measured parameters of the spectra are given in Table 1

of the originally rhombohedral calcite crystals could be obtained.[1] In order to minimise the influence of the kinetic factors, a relatively narrow range of the co-anion concentrations was investigated at a relatively low initial supersaturation. Such precautions were necessary since changes in nucleation and/or crystal growth rates can cause changes in the growth mechanisms and, consequently, influence the mode and extent of the co-anion incorporation. Therefore, the initial supersaturations in the systems with and without the addition of co-anions were also kept approximately the same.

In order to establish the possible incorporation of sulfate into the calcite lattice and to find out the possible sites and mode of their incorporation, the samples were analysed by EPR spectroscopy, IC and XRD. Figure 3 shows a comparison of an EPR spectrum of Mn^{2+}-doped pure calcite (spectrum a) with the EPR spectra of Mn^{2+}-doped calcite samples obtained when the highest concentration of co-anions used in this work were added to the precipitation system, i.e. 1.0×10^{-3} mol·dm^{-3} NO_3^- (spectrum b), 1.0×10^{-3} mol·dm^{-3} Cl^- (spectrum c) or 1.0×10^{-3} mol·dm^{-3} SO_4^{2-}, (spectrum d). The lines in spectrum b remain similar in structure and linewidth to those in spectrum a. Spectra c and d exhibit broader lines and a larger broadening of the wing lines. Results of the EPR spectroscopic analyses are summarised in Table 1. It can be seen that the addition of Cl^- or SO_4^{2-} is reflected in the spectra as an increase in the parameter D' from 1.7 mT to 1.8 mT. On the other hand, the addition of NO_3^- did not show any effect of this kind. Parameter D' reflects the distortion of the calcite lattice from axial symmetry. The increase of D' may be accompanied by the uniaxial strain of the threefold axis, expressed in the EPR spectra by broadening of the wing lines (*RH* parameter). Uniaxial strain is produced by defects in the crystal lattice due to the different charges or sizes of the impurity ions, the co-anions in this case. Any of these cannot affect the spectroscopic hyperfine linewidths (ΔW). The *RH* parameters measured in the samples to which SO_4^{2-}, Cl^- or NO_3^- were added are displayed in Figure 4 as a function of the co-anion initial concentrations. A pronounced increase in the *RH* parameter upon the addition of SO_4^{2-} suggests that although these anions match the charge of the calcite CO_3^{2-} groups, they produce

Table 1. larger uniaxial strain than NO_3^- or Cl^-. As uniaxial strain has its effect on the threefold axis of the crystal symmetry alone, one would expect it to have a larger effect on the symmetry of only one of the crystal axes, that is, along the *c* axis of the calcite lattice.

Figure 5 compares the X-ray diffraction pattern of pure calcite with those of the samples prepared with the addition of the highest concentration (1.0×10^{-3} mol·dm^{-3}) of co-anions examined in this work. All the diffraction patterns reveal the presence of calcite as the unique calcium carbonate crystalline phase. It is evident that the presence of nitrate ions in the precipitation system does not have an effect on the diffraction pattern of the precipitated calcite which is similar to that of pure calcite. The presence of chloride ions also has no effect on the diffraction peak positions but results in a slight increase of the diffraction peak full width half maxima (FWHM) as the co-anion concentration increases. Since this effect indicates a reduction in the overall crystallinity, it could be related to the incorporation of chloride ions into the calcite structure. The effect of sulfate ions is more pronounced. These ions are not only incorporated in the calcite structure but, at the same time, they induce a reduction in the phase crystallinity. Although the differences among the diffraction patterns presented are minimal, they can be considered as relevant because the trend in the increase of line broadening follows the increase of the initial co-anion concentration in solution.

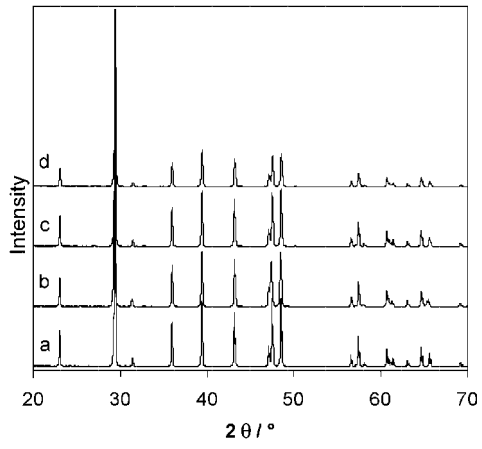

Figure 5. Powder X-ray diffraction pattern of (a) pure calcite and calcites prepared in the presence of 1.0×10^{-3} mol·dm^{-3}: (b) sulfate, (c) nitrate and (d) chloride

Additional support to the previous conclusions is provided by the differential thermal analyses (DTA) of the samples. An endothermic peak at 810 °C was obtained for pure calcite, denoting its decomposition by loss of CO_2. The samples prepared with the addition of 1.0×10^{-3} mol·dm^{-3} $CaSO_4$ showed a shift in this peak by 15 °C toward lower temperatures. These observations suggest that such a shift could be induced by incorporation of sulfate ions in the calcite structure causing a destabilising effect.

Since SO_4^{2-} showed the largest effect on the calcite crystal symmetry, most emphasis will be given to this anion in the following discussion.

Figure 6 shows the content of sulfate ions in the calcite crystals, determined by ion chromatography, as a function of the initial concentration of sulfate ions in the precipitation systems. The incorporation of sulfate ions in the solid phase increases linearly with the increase in the amount of $CaSO_4$ added. This is consistent with the XRD measurements of the calcite unit cell parameters (i.e. *a*, *c* and unit cell volume), as shown in Table 2. The changes in the *a* and *c* axes are also linearly dependent on the quantity of sulfate ions added to the precipitation systems, the change in the *c* axis being larger than that in *a* axis. Figure 7 shows these changes as a relative scale, i.e. as $(a_{sample}/a_{reference}) \times 100$.

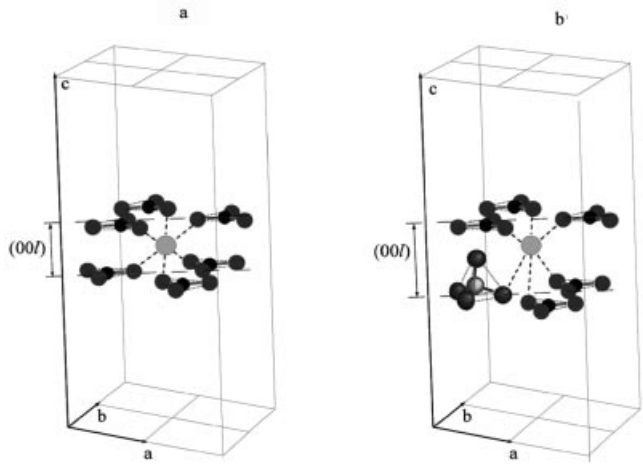

Figure 8. Schematic representation of the model showing: (a) the calcite crystal lattice cell and (b) the possible mode and site of sulfate ion incorporation

The observed similarity in the crystal size distributions (Figure 1) and morphologies (Figure 2) of the investigated systems, as well as the linear dependence of the amount of anion incorporated in the calcite crystals on its concentration in solution (Figure 6), give additional assurance that the extent and mode of anion incorporation (SO_4^{2-} in particular) are predominantly functions of thermodynamic factors (e.g. chemical nature of the ions, ionic radii, coordination properties, hydration free energy etc.).

Based on the results of EPR spectroscopic, IC and particularly the XRD analyses, a simplified model can be proposed which attempts to explain the mode and site of sulfate incorporation in the calcite crystal lattice. A schematic presentation of a calcite crystal lattice, in which one calcium ion is coordinated with six carbonate ions, is shown in Figure 8 (a). If a planar carbonate is replaced by a sulfate ion, three of the sulfate's apical oxygen atoms in the tetrahedral structure could be accommodated in the place of the planar trigonal carbonate, as shown in Figure 8 (b). In this case, the sulfur and the fourth oxygen atom of the sulfate are out of the carbonate plane which induces an increase in the calcite *c* axis. A small increase in the *a* axis can also be expected, since the three apical oxygen atoms of the sulfate occupy a slightly larger surface (256.4 Å^2) in the plane compared with the carbonate ion (212.1 Å^2). In accordance with the proposed model, the effect of distortion of the calcite structure, caused by sulfate substitution, should be more evident along the *c* axis. At the highest isomorphic substitution of sulfate ions obtained, the distortion of the unit cell axes, with respect to the pure calcite, was about 0.05 Å (0.3%) and 0.01 Å (0.1%) for the *c* and *a* axes, respectively. The XRD broadening of peaks, detected in the calcite samples prepared with the additions of sulfate ions, confirms the crystal lattice disorder induced by the presence of sulfate ions (Table 2). This effect, related to the size of the crystalline domains, is quite evident in the (00*l*) reflections but is smaller in the (*h*00) reflections. This suggests a higher degree of disorder induced in the calcite structure by sulfate ions along the *c* direction.

These crystallographic observations agree well with the EPR spectroscopy and provide evidence of the importance of the sulfate ions in destabilising the calcite structure.

Conclusions

The extent and mechanism of incorporation of some common inorganic anions (SO_4^{2-}, Cl^-, NO_3^-) into the calcite crystal lattice and their influence on the physical and chemical properties of the precipitate were investigated in the precipitation system under conditions of a moderate relative initial superstaturation (S-1 = 10.4) at 25 °C.

In order to avoid the presence of any undesirable chemical species (except Ca^{2+}, CO_3^{2-} and the products of their hydrolysis, as well as H^+ and OH^-) the precipitation was

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

initiated by mixing calcium hydroxide ($c_i = 5.0 \times 10^{-3}$ mol·dm^{-3}) and carbonic acid ($c_i = 9.0 \times 10^{-3}$ mol·dm^{-3}) solutions. For the same reasons, no pH or ionic strength adjustments were made.

Under the given experimental conditions, calcite crystals were formed by heterogeneous nucleation and were small in size and considerably monodispersed.

The co-anions (chloride, nitrate or sulfate) were added into the system in the form of an appropriate calcium salt and the addition of any of the co-anions did not cause significant changes in the physical or chemical properties of the precipitate.

According to the X-ray diffraction, ion chromatographic and EPR spectroscopic analyses of the calcite samples, the respective co-anions were incorporated into the calcite crystal lattice to a certain extent, the incorporation of sulfate ions being the most extensive.

A model of sulfate incorporation into the calcite lattice can be proposed: carbonate ions are partially substituted by sulfate ions, thus causing a distortion of the calcite unit cell. The degree of disorder along the *c* axis is much higher than along the other two crystallographic directions as a consequence of substitution of the tetrahedral sulfate for the planar carbonate ions.

Experimental Section

Materials: All solutions used were prepared from analytically pure chemicals and deionised water of high quality (conductivity < 0.1 μS·cm^{-1}). For the experiments, a thermostatted double-walled glass vessel of 400 mL capacity was used. Precipitation of calcite was initiated by pouring 150 mL of carbonic acid solution into the same volume of calcium hydroxide solution of the appropriate concentration. During precipitation, the system was continuously stirred at a constant rate by means of a flat-bladed stirrer with two perpendicular blades and the extent of the reaction was determined by measuring the pH of the solution. All experiments were performed at 25 °C.

The carbonic acid stock solution was prepared by bubbling a high-grade carbon dioxide stream into water until the apparent constancy of the pH was obtained. The exact concentrations of freshly prepared carbonic acid stock solutions were determined by potentiometric titration using a standard NaOH solution ($c = 0.10$ mol·dm^{-3}). The calcium hydroxide stock solution was prepared by adding an excess of calcium hydroxide into water. The suspension was then filtered through a 0.22 μm membrane filter and the saturated solution was kept under nitrogen. The exact concentration was determined by potentiometric titration using a standard HCl solution ($c = 0.10$ mol·dm^{-3}) and the total calcium content was additionally checked by complexometric titration with EDTA. Foreign anions were added to the system in the form of a calcium salt (calcium sulfate, calcium nitrate or calcium chloride). The required amount of the foreign anion was always added into the freshly prepared carbonic acid solution of known concentration [$c_i(CO_3^{2-}) = 9.0 \times 10^{-3}$ mol·dm^{-3}, diluted from the stock solution] and the total initial concentration of the foreign anion in the system was varied [c_i(anion) = 1.0×10^{-4}, 3.0×10^{-4}, 6.0×10^{-4} or 1.0×10^{-3} mol·dm^{-3}]. The total initial calcium concentration in the system was kept the same [$c_i(Ca^{2+}) = 5.0 \times 10^{-3}$ mol·dm^{-3}] in all experiments.

The samples for analyses were taken after a predetermined ageing time of 20 min, when the total volume of suspension was filtered through a 0.22 μm membrane filter, thoroughly washed with small portions of water and dried at 105 °C. In the system in which no additive was added [$c_i(Ca^{2+}) = 5.0 \times 10^{-3}$ mol·dm^{-3} and $c_i(CO_3^{2-}) = 9.0 \times 10^{-3}$ mol·dm^{-3}], the precipitate consisted entirely of calcite crystals and the amount of crystals obtained in one preparation was just sufficient for all types of analyses to which the solid phase was subjected to.

Methods: The precipitate composition was characterised by a combination of FT-IR spectroscopic (Mattson), thermogravimetric (Mettler TG 50 thermobalance with TC 11 TA processor), differential thermal (Netzsch differential thermal analyzer), and scanning electron microscopic (Philips XL-20) analyses. TGA and DTA were carried out with a heating rate of 20 °C/min and 10 °C/min, respectively, and Al_2O_3 was used as the reference substance for DTA. For the SEM observations, the dried samples were glued by a carbon tape on an aluminium stub and were gold-coated.

Crystal number and size distributions were determined by means of an electronic counting device (Coulter Electronics Ltd.) fitted with a 50-μm orifice tube. This aperture-size diameter enabled crystals in the size range between about 1 and 30 μm to be measured. The instrument was calibrated with standard latex spheres (13.3 μm in diameter). The total content of calcium and sulfate ions in the solid phase was determined by means of an ionic chromatography system (Dionex DX100 fitted with a CD20 conductivity detector). The chromatographic data were collected and processed with the Dionex Peaknet 5.1 program.

The possible incorporation of the co-anion into the calcite structure was evaluated by measuring the calcite unit-cell parameters by XRD. The sample for the X-ray data collection was manually ground in an agate mortar. The powder was mounted on a 1.5 mm thick flat Al holder using the front loading technique and the data collection was performed using a powder diffractometer (Philips PW 1050/81 equipped with a secondary graphite monochromator; Cu-K_α radiation at 40 kV and 40 mA). The instrument was configured with a 1° divergence and 0.2 mm receiving slits. The presence of impurities was checked and excluded by a preliminary qualitative analysis of the X-ray powder pattern. The phase identification was possible using the ICDD-PDF-2 database.[32] The unit cell parameters and their standard deviations were calculated using the CellSize computer program.[33] The number of significant figures of the data obtained depends on the material crystallinity. The diffraction peak full width half maxima (FWHM) were calculated using the computer program WinFit.[34]

Apart from XRD, the interaction of foreign anions with the calcite crystals was also studied by EPR spectroscopy (Varian E-9 spectrometer equipped with a dual microwave resonant cavity). In this case, the local environment of Ca^{2+} in the crystal lattice of calcite was studied using Mn^{2+} ions as a paramagnetic substitute for Ca^{2+}. The calcite crystals were prepared by adding carbonic acid solution (150 mL of 9.0×10^{-3} mol·dm^{-3}) into an equal volume of calcium hydroxide solution (5.0×10^{-3} mol·dm^{-3}). Manganese (2.0×10^{-7} mol·dm^{-3}) was added into the carbonic acid solution prior to mixing the reactants, so that the Mn^{2+} substitution for Ca^{2+} took place during the precipitation of calcite.[13] After the initial mixing of the reactants, the system was agitated mechanically with a flat-bladed stirrer for 20 min at a constant rate and then aged for 30 d without further stirring. The calcite thus obtained was filtered, washed several times with small portions of water, dried at 105 °C and stored in a desiccator. The EPR spectrum of such Mn^{2+}-doped calcite crystals was used as a reference. The uptake of Mn^{2+} by such a method (as determined by IC) was approxi-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mately 0.005 mol%.[13] This amount does not cause any measurable change in the unit cell parameters of calcite. This was established by our own XRD analyses and has also been reported by other researchers.[29] A qualitative interpretation of the EPR spectroscopic parameters proposed by Angus et al.[29] was applied. These authors reported that the axial distortion parameter D' of the calcite unit cell depends on temperature, pressure and the concentration and nature of the impurity ions incorporated into calcite. In a magnetic field and in the absence of any ligands, Mn^{2+} ions give six lines in the EPR spectrum due to the hyperfine interaction of the high-spin electron state of five electrons, $S = 5/2$, with the nuclear spin of $^{55}Mn^{2+}$ nuclei, $I = 5/2$. The crystal field of the CO_3^{2-} ligands in the calcite unit cell splits these spectral lines further, giving rise to a multi-line EPR spectrum. Thus, the spectrum contains information about the CO_3^{2-} symmetry in the calcite lattice. Any axial distortion of the CO_3^{2-} ligands around Mn^{2+} in the calcite lattice changes the crystal field parameter D' in the spectrum. This parameter is best regarded as a measure of the separation of the parallel and perpendicular components of each of the six main hyperfine lines in the EPR spectrum of calcite and is largest for the high-field hyperfine line $m_{Mn} = -5/2$. The line shapes, ΔW, of the Mn^{2+} spectra are expected to be Lorenzian because of homogeneous line-broadening. Deviations from these ideal line shapes, giving rise to an inhomogeneous line broadening, can be caused by many factors. As suggested by Barberis et al.,[28] a random distribution of oxygen atoms of the CO_3^{2-} groups about their equilibrium positions in the calcite lattice can be induced by the impurity ions. In the EPR spectra, this is reflected as a broadening of all spectral lines and is measured by the parallel ($\Delta W_{\|}$) and perpendicular ($\Delta W_{\perp}$) linewidths of the hyperfine line $m_{Mn} = -5/2$ at half-height from the baseline. On the other hand, the compression along the threefold axis, or random electric fields produced by impurities with different charges or sizes, cannot affect the linewidth of the main lines but does broaden the outer so called "wing lines".[29] This is expressed as the so-called *RH* parameter.

Facile [N]C−H Activation by a (*P*,*N*)-Chelate [3]Ferrocenophane−Ruthenium System

Patrick Liptau,[a] Daniel Carmona,*[b] Luis A. Oro,*[b] Fernando J. Lahoz,[b] Gerald Kehr,[a] and Gerhard Erker*[a]

Keywords: (*P*,*N*)-Chelate ligands / Ruthenium / Ferrocenophane / C−H activation

The chelate ligand **5** was prepared from the corresponding (dimethylamino)[3]ferrocenophane by directed *ortho*-lithiation with *n*-butyllithium followed by treatment with $ClPPh_2$. The rigid (*P*,*N*)-chelate ligand reacts with [Ru(η^6-*p*-cymene)Cl_2] dimer in the presence of KPF_6 in methanol to afford two products in an almost equimolar ratio. Instead of the simple addition product of the [Ru(*p*-cymene)Cl]$^+$ cation reagent to the chelate, selective C–H abstraction at an N–CH_3 moiety occurs with the formation of the "metallaaziridinium"-type product **8** (isolated as its PF_6^- salt). The liberated equivalent of HCl is trapped by the putative (*P*,*N*)-chelate [RuCl]$^+$ complex intermediate to form the corresponding internal hydrochloride complex **7**. The starting material **5** and the products **8** and **7** were characterised by single-crystal X-ray diffraction studies.

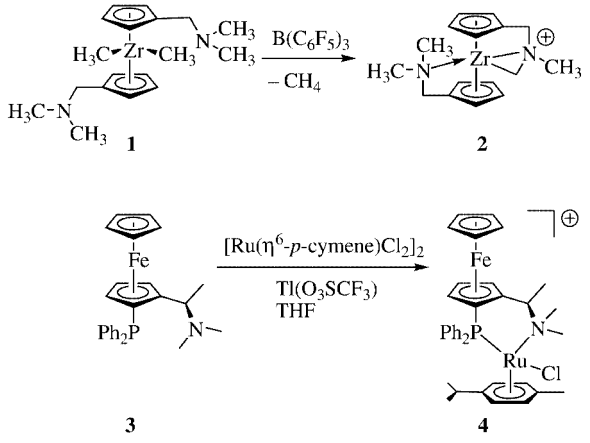
Introduction

The activation of aliphatic C−H bonds by transition metal complexes in a homogeneous phase has continued to attract considerable attention.[1] C−H activation in a position α to a nitrogen atom is of interest for carbon−carbon coupling reactions as well as because of its participation in hydrodenitrogenation of petroleum feedstocks.[2,3] This is commonly observed with early transition metals[4] (see Scheme 1). In the case of late transition metals, only a few examples have been reported.[5] Here, C−H activation mostly takes place next to a phosphorus atom,[6] but a much smaller number of examples of [N]C−H activation has been reported. Weissensteiner et al. have recently described the formation of the stable cationic chelate complex **4** which was obtained by treatment of the ferrocene-derived (*P*,*N*)-chelate ligand **3** with [Ru(η^6-cymene)Cl_2] dimer and a chloride abstractor.[7] We have now employed a related, more rigid [3]ferrocenophane (*P*,*N*)-ligand in a similar reaction and observed markedly different behaviour which is characterised by rapid C−H activation adjacent to nitrogen.



Scheme 1

Results and Discussion

The [3]ferrocenophane-based (*P*,*N*)-chelate ligand system **5** was prepared as described previously by us.[8] Treatment of 1,1′-diacetylferrocene with dimethylamine/$TiCl_4$ resulted in an intramolecular Mannich-type condensation reaction to generate the C_3 bridge. Subsequent catalytic hydrogenation (Pd/C) then gave an approximately 1:7 mixture of the corresponding saturated *cis*- and *trans*-disubstituted [3]ferrocenophane derivatives. The major *trans* isomer **5** was then treated with *n*-butyllithium to bring about directed *o*-lithiation at the Cp ring. Treatment with $ClPPh_2$ then gave the [3]ferrocenophane (*P*,*N*)-chelate ligand **5** in good yield.

Single crystals of the racemate (*rac*-**5**) were obtained from pentane at −18 °C. In the crystal, the enantiomers (*R*)-**5** (6*R*,8*R*,R_{pl}) and (*S*)-**5** (6*S*,8*S*,S_{pl}, see Scheme 2) were found as crystallographically independent molecules. The molecu-

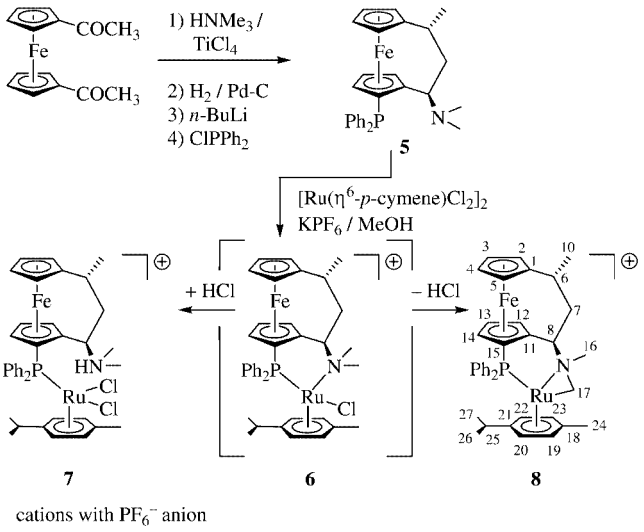
lar structure of the (*R*)-**5** enantiomer is depicted in Figure 1. The structure features an almost undistorted central ferrocene unit. The C_3 bridge that spans between the pair of almost parallel Cp ring systems attains a typically folded



Scheme 2

conformation. At this [3]ferrocenophane framework, the methyl substituent is found in a pseudoaxial orientation whereas the apparently more bulky NMe_2 group is attached pseudo-equatorially. This results in a strong deviation of the P1−C23−C27−C36−N1 chelate pincer from planarity. Inside this framework, the C23−P1 and C36−N1 vectors are found close to a *gauche* arrangement.

Ligand **5** was treated with $[Ru(\eta^6\text{-}p\text{-cymene})Cl_2]_2$ (*p*-cymene = 4-isopropyl-1-methylbenzene) and KPF_6 as a chloride abstractor in methanol at room temperature. The ^{31}P NMR spectra of the crude reaction mixture indicated the formation of two main products. Instead of the expected cationic (*P*,*N*)-chelate compound **6** the hydrochloride **7** and the cyclometallated species **8** were obtained (Scheme 2).

In the solid state, both **7** and **8** show the ruthenium centre as formally hexacoordinate with similar three-legged pianostool environments. Both cationic complexes exhibit an η^6-coordination of the *p*-cymene ring and the *P*-bonded metallo-ligand. In **7**, two chloride ligands with similar but statistically different Ru−Cl bond lengths [2.4102(8) and 2.3942(8) Å] complete the Ru coordination sphere. The molecular structure of complex **8** can be related to that of **7** if we assume the formal substitution of the two halogen atoms by an η^2-bonded CH_2N moiety (Figures 2 and 3).

The bond lengths within this three-membered metallacycle being Ru−N 2.120(4), Ru−C(38) 2.068(5) and N−C(38) 1.417(6) Å. From these structural parameters an intermediate situation, slightly closer to $(sp^3)C-NR_2$ between a methylene ammonium salt [the $(sp^2)C=N^+R_2$ mean distance in CSD is 1.334 Å] and an aza-metallacyclopropane system [$(sp^3)C-NR_2$ mean distance 1.469 Å] seems to be present. A relevant structural feature of **7** seems to be the presence of a bifurcated asymmetric hydrogen bond between the dimethylammonium group and the two chloride ligands [N···Cl(1) 3.143(3) and N···Cl(2) 3.203(3) Å, see Figure 2]. This may account for the conformational modification observed for the bridging C_3 chain in **7** from the free ligand **5** [torsion angles C(28)−C(32)−C(33)−C(35) 52.3(3)° (in **5**) and 75.2(4)° (in **7**); C(23)−C(27)−C(36)−C(35) −69.9(3)° (**5**) and −39.0(4)° (**7**)]. Interestingly, the strain of this presumably enforced conformation is released when **8** is formed, as confirmed by the values detected for its torsion angles [46.2(6)° and −71.4(7)°] which are very similar to those observed in **5**. Both compounds crystallise in centrosymmetric space groups with only one independent molecule in the unit cell. This feature implies the presence of racemic mixtures of **7** and **8** in the crystals.

As mentioned above, the Ru/N/C ring in **8** can be described as an iminium salt coordinated to the metal atom or as an aza-metallacyclopropane system. We measured direct NMR coupling constants ^1J(C,H) as a method of estimating the s-character of the corresponding C−H bond. For the CH_2 group of the ring, the obtained values of 167 and 176 Hz fall in the range of aziridine (168 Hz) and oxirane (176 Hz). For an iminium salt, larger values would be expected. These data, together with the determined structural parameters, seem to indicate a more accurate description of the metallacycle as an aza-metallacyclopropane ring.[4]

To explain the formation of **7** and **8** it is reasonable to assume that an intermediate (*P*,*N*)-chelate complex [Ru(*p*-cymene)(Cl)(**5**)]·[PF_6] (**6**, Scheme 2) is initially formed. Subsequent cleavage of a C−H methyl bond and cyclometallation lead to **8**, liberating 1 equiv. of HCl. This HCl then may react with a second equivalent of the (*P*,*N*)-chelate complex to yield the hydrochloride **7** (see Scheme 2).

Complex **8** was obtained as a single diastereoisomer. It is likely that this results from a diastereoselective formation of the intermediate **6** which may be efficiently controlled by the rigid framework of this special (*P*,*N*)-chelate ligand. An inspection of molecular models revealed that the (pro-*S*)-*N*-methyl group may be oriented almost coplanar with the Ru−Cl vector. This may possibly have favoured the selective C−H activation[9] at this $N-CH_3$ group to form the observed product **8**. It is likely that such conformational features may have caused the observed differences in the behaviour of the systems described here from the open, more flexible system **4** which was described previously in the literature (see Scheme 1).[7,10]

Experimental Section

General Remarks: All reactions were carried out under dry argon in Schlenk-type glassware or in a glove-box. Solvents were dried and distilled prior to use. NMR spectra were recorded with a Bruker AC 200 P (^{31}P, 81.0 MHz), Varian UNITY 300 (^{31}P, 121.5 MHz) or Varian UNITYplus 600 (^{1}H, 599.9 MHz; ^{13}C, 150.8 MHz; ^{31}P, 242.5 MHz) spectrometer. Most assignments were confirmed using 2D spectra.[11] Exact masses were determined with a Micromass Quattro LC-Z electrospray mass spectrometer. The following instruments were used for additional physical characterisation: IR spectroscopy: Nicolet 5DXC FT-IR spectrometer; melting points: DSC 2010 (TA instruments); elemental analyses: Foss Heraeus CHN-O-Rapid. Compound *rac*-**5** was prepared in an analogous manner previously described by us for the (*R*)-**5** and (*S*)-**5** enantiomers.[8]

X-ray Structure Determinations: Data for **5**, **7** and **8** were collected at low temperature (100 K) with a Bruker SMART APEX diffractometer equipped with a CCD area detector using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Data were measured through the use of CCD recording of ω-rotation frames

(0.3° each). Data were integrated with the Bruker SAINT program (*SAINT*+, version 6.01; Bruker AXS, Inc., Madison, WI, **2001** and SAINT, version 6.02) and corrected for Lorentz and polarisation effects. Absorption corrections were applied using the SADABS routine (SADABS: Area-Detector Absorption Correction, **1996**; Bruker-AXS within SAINT+ package, v. 6.01). Structures were solved by direct methods and completed by subsequent difference Fourier techniques. Refinement on F^2 was carried out by full-matrix least squares (SHELXL-97) (G. M. Sheldrick, *SHELXL-97 Program for Crystal Structure Refinement*, University of Göttingen, Göttingen, Germany, **1997**). All non-hydrogen atoms were refined with anisotropic displacement parameters. In **5** and **7**, hydrogen atoms were found from difference Fourier maps and refined with positional parameters riding on carbon atoms and free thermal parameters. Hydrogen atoms in **8** were analogously refined except a terminal methyl group for which hydrogen atoms were included in calculated positions.

Preparation of 5: To a solution of the corresponding amino[3]ferrocenophane (714 mg, 2.52 mmol) in Et_2O (10 mL) at 4 °C was added *n*-butyllithium (1.9 mL, 1.6 M, 3.02 mmol, 1.2 equiv.). The cooling bath was removed and the solution stirred for 3 h, during which the colour changed from light orange to dark orange. Afterwards, the mixture was cooled to 4 °C and chlorodiphenylphosphane (0.54 mL, 3.02 mmol, 1.2 equiv.) was added dropwise. The cooling bath was removed and the resultant suspension stirred at room temperature for 12 h. The reaction was quenched with saturated $NaHCO_3$ solution (10 mL) and the aqueous phase extracted with pentane (3 × 10 mL). The combined organic phases were washed with water and brine and dried with $MgSO_4$. Column chromatography on silica (SiO_2; pentane/ethanol, 6:1) yielded **5** as a yellow solid (0.547 g, 1.17 mmol, 46%), m.p. 156.1 °C (DSC). IR (KBr): $\tilde{\nu}$ = 3104 (w), 3072 (w), 2993 (m), 2953 (m), 2854 (m), 2808 (m), 2751 (s), 1643 (m), 1617 (m), 1466 (m), 1446 (s), 1308 (m), 1143 (m), 1038 (s), 755 (s), 702 (s), 531 (m) cm^{-1}. ^1H NMR (599.9 MHz, $CDCl_3$, 25 °C): δ = 1.22 [d, $^3J_{H,H}$ = 7.3 Hz, 3 H, C(10)−H], 1.79 [s, 6 H, C(16), C(17)−H], 2.31 [m, 1 H, C(7)−H_{trans}], 2.68 [pd, 1 H, C(8)−H], 2.84 [m, 1 H, C(6)−H], 3.16 [m, 1 H, C(7)−H_{cis}], 3.68 [m, 2 H, C(2−5)−H, C(12−14)−H], 3.85 [m, 1 H, C(2−5)−H], 4.11 [m, 1 H, C(2−5)−H], 4.14 [m, 2 H, C(12−14)−H], 4.41 [m, 1 H, C(2−5)−H], 7.22−7.47 (m, 10 H, phenyl−H) ppm. $^{13}C\{^1H\}$ NMR (150.8 MHz, $CDCl_3$, 25 °C): δ = 16.7 [C(10)], 27.7 [C(6)], 44.2 [C(16), C(17)], 45.3 [C(7)], 59.1 [C(8)], 67.5 [C(2−5)], 68.6 [C(2−5)], 68.9 [C(12−14)], 70.2 [C(2−5)], 72.2 [C(2−5)], 73.9 [C(12−14)], 74.1 [C(12−14)], 75.2 [d, $^1J_{C,P}$ = 12.0 Hz, C(15)], 91.4 [br., C(11)], 93.3 [C(1)], 127.5, 127.7, 128.1, 133.1, 133.4 (d, $J_{C,P}$ = 19.0 Hz), 134.2, (d, $J_{C,P}$ = 19.0 Hz), 138.9, 139.4 (all broad, phenyl−C) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$, 25 °C): δ = −21.6 ppm. $C_{28}H_{30}FeNP$ (467.375): calcd. C 71.96, H 6.47, N 3.00; found C 71.74, H 6.07, N 2.96.

Crystal Data for *rac*-5: Crystals suitable for the X-ray structure analysis were grown from a pentane solution at −18 °C. $C_{28}H_{30}FeNP$ (467.35), triclinic, $P\bar{1}$ (no.2), a = 8.8320(5), b = 14.6260(8), c = 18.0284(10) Å, α = 98.110(1), β = 93.210(1), γ = 96.919(1)°, V = 2282.4(2) Å^3, Z = 4, $\rho_{calcd.}$ = 1.360 Mg·m^{-3}, μ = 0.747 mm^{-1}, F(000) = 984, crystal size 0.30 × 0.27 × 0.15 mm. θ range for data collection 1.42 to 28.58° (−11 ≤ h ≤ 11, −19 ≤ k ≤ 19, −22 ≤ l ≤ 23), reflections collected/unique 26891/10615 [R(int) = 0.0361], max. and min. transmission 0.876172 and 0.667727, data/parameters 10615/619, S (on F^2) = 0.924, final R_{int} [$I > 2\sigma(I)$]: $R1$ = 0.0397, $wR2$ = 0.0799, R_{int} (all data): $R1$ = 0.0543, $wR2$ = 0.0847, largest diff. peak and hole 0.513 and −0.387 e·Å^{-3}.

Preparation of the Complexes 7 and 8: A solution of **5** (762 mg, 1.63 mmol), [Ru(η^6-*p*-cymene)Cl_2]$_2$ (500 mg, 0.81 mmol) and KPF_6 (300 mg, 1.63 mmol) in MeOH (48 mL) was stirred at room temperature for 12 h. The hydrochloride **7** which precipitated was collected by filtration and washed with MeOH to yield an orange solid (520 mg, 0.56 mmol, 34%), m.p. 207 °C (dec., DSC). The combined filtrates were concentrated in vacuo to yield **8** in two crops as an orange solid (286 mg, 0.33 mmol, 20%), m.p. 261 °C (DSC). **Metallacycle 8:** Crystals suitable for the X-ray structure analysis were grown by slow diffusion of Et_2O into an MeOH solution. IR (KBr): $\tilde{\nu}$ = 3058 (w), 2966 (m), 2920 (m), 2868 (w), 1630 (w), 1492 (m), 1446 (m), 1097 (m), 1018 (m), 841 (s), 755 (m), 702 (m), 564 (m) cm^{-1}. ^1H NMR (599.9 MHz, $CDCl_3$, 25 °C): δ = 1.00 [d, $^3J_{H,H}$ = 6.8 Hz, 3 H, C(10)−H], 1.11 [d, $^3J_{H,H}$ = 6.7 Hz, 3 H, C(26)/C(27)−H], 1.14 [d, $^3J_{H,H}$ = 7.2 Hz, 3 H, C(26)/C(27)−H], 1.90 [m, 1 H, C(5)−H], 2.01 [m, 1 H, C(25)−H], 2.04 [m, 1 H, C(7)−H], 2.15 [s, 3 H, C(24)−H], 2.42 [m, 1 H, C(7)−H], 2.54 [m, 1 H, C(6)−H], 2.77 [d, $^3J_{H,H}$ = 11.8 Hz, 1 H, C(17)−H], 3.05 [s, 3 H, C(16)−H], 3.40 [dd, $^3J_{H,H}$ = 2.1, 11.6 Hz, 1 H, C(8)−H], 3.45 [m, 1 H, C(17)−H], 3.47 [m, 1 H, C(2−4)−H], 3.77 [m, 1 H, C(2−4)−H], 4.00 [m, 1 H, C(2−4)−H], 4.09 [m, 1 H, C(12−14)−H], 4.26 [m, 2 H, C(12−14)−H], 4.41 [d, $^3J_{H,H}$ = 5.1 Hz, 1 H, C(19)/C(20)/C(22)/C(23)−H], 4.72 [d, $^3J_{H,H}$ = 5.8 Hz, 1 H, C(19)/C(20)/C(22)/C(23)−H], 5.58 [d, $^3J_{H,H}$ = 5.6 Hz, 1 H, C(19)/C(20)/C(22)/C(23)−H], 5.74 [d, $^3J_{H,H}$ = 5.8 Hz, 1 H, C(19)/C(20)/C(22)/C(23)−H], 6.98 (m, 2 H, phenyl−H), 7.27 (m, 3 H, phenyl−H), 7.68 (m, 3 H, phenyl−H), 8.22 (m, 2 H, phenyl−H) ppm. $^{13}C\{^1H\}$ NMR (150.8 MHz, $CDCl_3$, 25 °C): δ = 16.4 [C(26)/C(27)], 18.9 [C(24)], 23.4 [C(26)/C(27)], 23.8 [C(10)], 27.0 [C(6)], 31.3 [C(25)], 46.3 [d, $J_{C,P}$ = 9.5 Hz, C(17)], 50.7 [C(7)], 57.6 [C(16)], 60.7 [C(8)], 67.8 [d, $J_{C,P}$ = 42.2 Hz, C(15)], 68.4 [C(2−4)], 68.9 [C(2−4)], 69.3 [d, $J_{C,P}$ = 5.2 Hz, C(12−14), 71.1 [C(2−4)], 71.4 [d, $J_{C,P}$ = 8.3 Hz, C(12−14)], 72.6 [C(5)], 74.2 [C(12−14)], 83.4 [d, $J_{C,P}$ = 18.8 Hz, C(11)], 84.9 [C(19)/C(20)/C(22)/C(23)], 88.2 [d, $J_{C,P}$ = 4.4 Hz, C(19)/C(20)/C(22)/C(23)], 89.5 [d, $J_{C,P}$ = 3.6 Hz, C(19)/C(20)/C(22)/C(23)], 92.7 [d, $J_{C,P}$ = 2.0 Hz, C(19)/C(20)/C(22)/C(23)], 92.8 [C(1)], 128.2 (d, $J_{C,P}$ = 9.9 Hz, *ortho*/*meta*-phenyl C), 128.4 (d, $J_{C,P}$ = 10.3 Hz, *ortho*/*meta*-phenyl C), 129.4 (*para*-phenyl C), 130.3 (d, $J_{C,P}$ = 9.5 Hz, *ortho*/*meta*-phenyl C), 131.6 (*para*-phenyl C), 134.9 (d, $J_{C,P}$ = 12.9 Hz, *ortho*/*meta*-phenyl C), 135.8 (d, $^1J_{C,P}$ = 49.1 Hz, *ipso*-phenyl C), 141.4 (d, $^1J_{C,P}$ = 53.6 Hz, *ipso*-phenyl C) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$, 25 °C): δ = −145.1 (sept, $^1J_{F,P}$ = 716.6 Hz, PF_6), 37.1 ppm. Exact mass ($C_{38}H_{43}FeNPRu$): calcd. 702.1519, found 702.1511. **Hydrochloride 7:** Crystals suitable for the X-ray structure analysis were grown by slow concentration of an acetone solution. IR (KBr): $\tilde{\nu}$ = 3651 (m), 3045 (s), 2973 (m), 2874 (m), 1630 (w), 1485 (s), 1439 (s), 1393 (m), 1328 (m), 913 (s), 854 (s), 702 (s), 564 (s) cm^{-1}. ^1H NMR (599.9 MHz, $CDCl_3$, 25 °C): δ = 1.01 [d, $^3J_{H,H}$ = 6.9 Hz, 3 H, C(26)/C(27)−H], 1.13 [d, $^3J_{H,H}$ = 6.9 Hz, 6 H, C(26)/C(27)−H, C(10)−H], 1.83 [s, 3 H, C(24)−H], 1.85 [m, 1 H, C(5)−H], 2.26 [m, 1 H, C(7)−H], 2.37 [sept, $^3J_{H,H}$ = 6.8 Hz, 1 H, C(25)−H], 2.45 [m, 1 H, C(6)−H], 2.51 [m, 1 H, C(7)−H], 2.92 [s, 6 H, C(16), C(17)−H], 3.72 [m, 1 H, C(8)−H], 3.74 [m, 2 H, C(2−4)−H], 4.16 [m, 2 H, C(12−14)−H, C(19)/C(20)/C(22)/C(23)−H], 4.25 [m, 1 H, C(2−4)−H], 4.28 [m, 1 H, C(12−14)−H], 4.48 [bm, 1 H, C(19)/C(20)/C(22)/C(23)−H], 4.74 [m, 1 H, C(12−14)−H], 5.08 [bm, 1 H, C(19)/C(20)/C(22)/C(23)−H], 5.31 [d, $^3J_{H,H}$ = 5.3 Hz, 1 H, C(19)/C(20)/C(22)/C(23)−H], 7.42 (m, 6 H, phenyl H), 7.64 (m, 4 H, phenyl H), 8.12 (br., 1 H, N−H) ppm. $^{13}C\{^1H\}$ NMR (150.8 MHz, $CDCl_3$, 25 °C): δ = 15.6 [C(10)], 17.9 [C(24)], 21.3 [C(26)/C(27)],

Syntheses, Structures and Reactivity of Electron-Rich Fe and Ru Complexes with the New Pentadentate Ligand $Et_2NpyS_4-H_2$ {4-(Diethylamino)-2,6-bis[(2-mercaptophenyl)thiomethyl]pyridine}

Dieter Sellmann,[a][†] Shaban Y. Shaban,*[a] and Frank W. Heinemann[a]

Keywords: Electron density / Iron / Nitrogenase / Ruthenium / S ligand

The new pentadentate thioether thiolate ligand $Et_2NpyS_4^{2-}$ {= 4-(diethylamino)-2,6-bis[(2-mercaptophenyl)thiomethyl]-pyridine(2–)} has been synthesised from dimethyl 4-bromopyridine-2,6-dicarboxylate by treatment with Et_2NH followed by reduction and tosylation. The tosylated product was subsequently used for the template alkylation of $[Ni(S_2C_6H_4)_2]^{2-}$ to give $[\{Ni(Et_2NpyS_4)\}_2]$ (**4**). Acidic hydrolysis of **4** resulted in the formation of the ligand $Et_2NpyS_4–H_2$·HCl (**5**). The dianion $Et_2NpyS_4^{2-}$ reacted with $FeCl_2$·H_2O to afford the dinuclear high-spin species $[\{Fe(Et_2NpyS_4)\}_2]$ (**6**) [μ_{eff} (297 K) = 5.15 μ_B]. Aerial oxidation of dinuclear **6** afforded the sulfinato complex $[\{Fe(Et_2NpyS_4–O_2)\}_2]$ (**7**). Complex **6** proved to be a good precursor for the syntheses of $[Fe(L)(Et_2NpyS_4)]$ [L = CO (**8**), CNCy (**9**), NO (**11**) and N_2H_4 (**12**)] and $[Fe(NO)(Et_2NpyS_4)]BF_4$ (**10**). Protonation or alkylation of the thiolate donor atoms resulted in a series of complexes $[Fe(CO)(Et_2NpyS_4–R)]BF_4$ [R = H (**8a**), Et (**8b**)] and $[Fe(CO)(Et_2NpyS_4–Et_2)](BF_4)_2$ (**8c**) but no labilisation of the Fe–CO bond was observed. Only in complex **8** could the CO coligand be exchanged by NO^+ to give $[Fe(NO)(Et_2NpyS_4)]BF_4$ (**10**). Reduction of **10** using N_2H_4, NH_3 or N_3^- afforded the 19 valence electron species $[Fe(NO)(Et_2NpyS_4)]$ (**11**). $[Ru(NO)(Et_2NpyS_4)]Br$ (**13**) was synthesised by template alkylation of $Bu_4N[Ru(NO)(S_2C_6H_4)_2]$ using $Et_2Npy(CH_2Br)_2$ (**3**). Under reducing conditions, **13** releases the NO coligand to give $[\{Ru(Et_2NpyS_4)\}_2]$ (**14**), while in the presence of N_2H_4, $[Ru(N_2H_4)(Et_2NpyS_4)]$ (**15**) was formed. The complexes were well characterised including the solid-state structures in most cases. X-ray structural analyses of **7**, **8**, **9**, **10**, **12** and **15** revealed that all complexes exhibit *trans*-thiolate donors irrespective of the σ–π- or σ-ligand character of L.

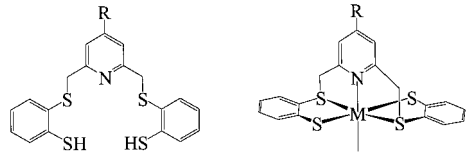
Introduction

Transition metals in sulfur-dominated coordination spheres form the active centres of numerous oxidoreductases such as nitrogenases, hydrogenases and CO dehydrogenases.[1] In the search for low-molecular weight compounds that combine structural and reactivity features of these [MS] enzymes, we have found that transition metal complexes containing $[M(pyS_4)]$ fragments [pyS_4^{2-} = 2,6-bis(2-mercaptophenylthiomethyl)pyridine(2−)] (M = Fe, Ru) bind many nitrogenase-relevant molecules such as CO, NO, N_2H_4, N_2H_2 and NH_3, although not N_2 (Scheme 1).[2]



Scheme 1. Schematic structures of $RpyS_4-H_2$ ligands and $[M(RpyS_4)]$ fragments (M = Fe, Ru; R = H, Et_2N)

As was pointed out earlier,[3] and even more so for the syntheses of the first pair of mono- and dinuclear N_2 complexes $[Ru(N_2)(PiPr_3)(N_2Me_2S_2)]$[4] and $[\mu\text{-}N_2\{Ru(PiPr_3)(N_2Me_2S_2)\}_2]$[5] [$N_2Me_2S_2^{2-}$ = *N*,*N*′-dimethyl-1,2-ethanediamine-*N*,*N*′-bis(2-benzenethiolate)(2−)] which formed directly from N_2 and sulfur−metal complex fragments under mild conditions, a major factor for the binding of N_2 can be considered to be a high electron density at the metal centres. Although the position of the ν(CO) bands in $[Fe(CO)(pyS_4)]$ (1963 cm^{-1})[6] and $[Ru(CO)(pyS_4)]$ (1954 cm^{-1})[2g] indicate a relatively high electron density at the metal centres, no N_2 complexes could be obtained. It is possible that the electron density is not high enough to enable

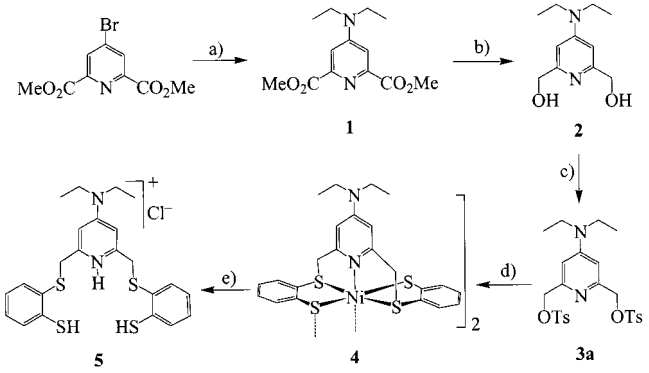
the coordination of N_2. Numerous efforts have been made to increase the electron density in [M(pyS$_4$)] fragments by modifying the benzene ring substituents with electron-donating groups but these have remained unsuccessful.[2d,6] Apparently, the electronic changes in the benzene rings are not transmitted beyond the sulfur donor atoms to the metal centres. These findings prompted us to start a systematic study of the influence of the pyridine ring substituents on the electron density at the metal centres and the reactivity of the resultant complexes. We describe herein the syntheses of the new $Et_2NpyS_4-H_2$ ligand and some related iron and ruthenium complexes. The similarities and differences between [M(Et_2NpyS_4)] and [M(pyS$_4$)] complexes (M = Ru and Fe) are discussed in detail.

Results and Discussions

Synthesis of the New Ligand $Et_2NpyS_4-H_2$

The target ligand $Et_2NpyS_4-H_2$·HCl (**5**) was synthesised according to the route indicated in Scheme 2.

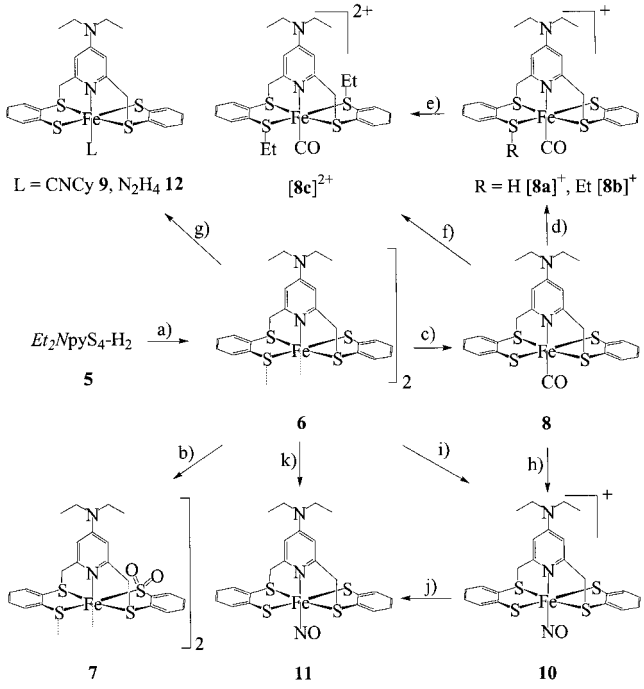


Scheme 2. Synthesis of the target $Et_2NpyS_4-H_2$·HCl ligand **5**: a) + Et_2NH, K_2CO_3, DMSO, 55 °C; b) + $NaBH_4$, EtOH, reflux, 16 h; c) + tosyl chloride, KOH, THF; d) + $Na_2[Ni(S_2C_6H_4)_2]$, THF, MeOH, 60 °C, 2 h; e) $HCl_{aq.}$, CH_2Cl_2

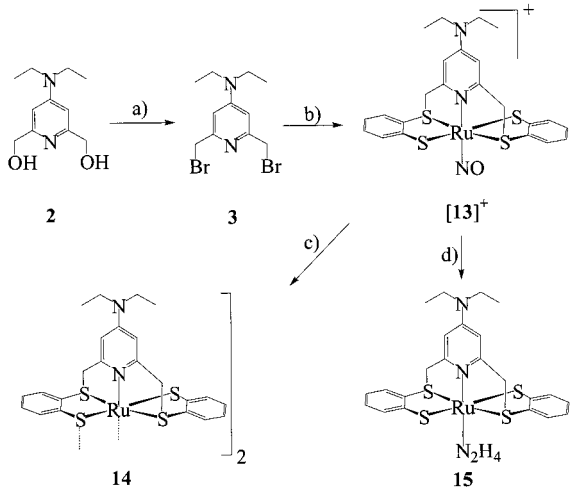
Treatment of dimethyl 4-bromopyridine-2,6-dicarboxylate[7] with excess Et_2NH and K_2CO_3 in DMSO at 55 °C for 28 h afforded dimethyl 4-diethylaminopyridine-2,6-dicarboxylate (**1**). The resultant ester **1** was reduced with $NaBH_4$ and continuously extracted with $CHCl_3$ at 45 °C for 72 h to yield 4-(diethylamino)-2,6-bis(hydroxymethyl)-pyridine (**2**). Treatment of **2** with either HBr or tosyl chloride afforded 2,6-bis(bromomethyl)-4-(diethylamino)pyridine (**3**) or 4-(diethylamino)-2,6-bis(tosyloxymethyl)pyridine (**3a**), respectively. Compound **3a** was subsequently used for the template alkylation of $[Ni(S_2C_6H_4)_2]^{2-}$[8] to give [{Ni(Et_2NpyS_4)}$_x$] (**4**). Complex **4** is paramagnetic with μ_{eff} (293 K) = 2.25 μ_B which is consistent with two unpaired electrons per Ni centre. A solution of **4** in CH_2Cl_2 was readily hydrolysed when treated with aqueous concentrated HCl to afford $Et_2NpyS_4-H_2$ as its HCl salt.

Syntheses and Reactions of Complexes

Schemes 3 and 4 summarise the syntheses and reactions of $Et_2NpyS_4^{2-}$ complexes.



Scheme 3. Synthesis and reactions of iron complexes: a) + $FeCl_2$·4 H_2O, THF, room temp.; b) + air, $CHCl_3$, 72 h; c) + CO, THF, room temp.; d) + HBF_4, CH_2Cl_2, −78 °C or Et_3OBF_4, room temp.; e) + Et_3OBF_4, CH_2Cl_2; f) 2 Et_3OBF_4, CH_2Cl_2; g) + L (CNCy or N_2H_4)/THF; h) + $NOBF_4$, CH_2Cl_2, 0 °C; room temp.; i) + $NOBF_4$, CH_2Cl_2, room temp.; j) + N_2H_4, MeOH or DMF; k) NO, CH_2Cl_2.



Scheme 4. Synthesis and reactions of ruthenium complexes: a) +HBr/H_2O, reflux, 16 h; b) + $Bu_4N[Ru(NO)(S_2C_6H_4)_2]$, THF, 60 °C, 2 h; c) + NH_3, MeOH, 1 h; d) + N_2H_4, THF, 2 h, room temp.

The reaction between $FeCl_2$·4H_2O and the $Et_2NpyS_4^{2-}$ anion resulting from deprotonation of **5** with 3 equiv. of LiOMe afforded yellow paramagnetic [{Fe(Et_2NpyS_4)}$_x$] (**6**) [μ_{eff} (293 K) = 5.15 μ_B]. The solid-state structure of **6** has not yet been determined. However, *x* is probably 2. Aer-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ial oxidation of **6** afforded the sulfinato complex [{Fe($Et_2NpyS_4-O_2$)}$_2$] (**7**) showing $\nu_a(SO_2)$ and $\nu_s(SO_2)$ IR (KBr) bands at 1238, 1185, 1133 and 983 cm^{-1}.[9] An X-ray structure determination established that **7** is dinuclear and exhibits a *trans*-thiolate structure. A possible reason for this mild thiolate oxidation could be the high basicity of the thiolate donors originating from the presence of the Et_2N substituent. Dinuclear **6** readily coordinates CO or CNCy to give the C_2-symmetric and diamagnetic mononuclear complexes [Fe(CO)(Et_2NpyS_4)] (**8**) and [Fe(CNCy)(Et_2NpyS_4)] (**9**), respectively, indicating that **6** partially dissociates in solution into two unsaturated monomers. Complexes **8** and **9** exhibit characteristic ν(CO) (1948 cm^{-1}) and ν(CNCy) (2105 cm^{-1}) bands in their IR (KBr) spectra. The ν(CO) of **8** is low when compared with that of [Fe(CO)(pyS_4)] (1963 cm^{-1}),[6] indicating a high electron density at the Fe centre which in turn results in a strong Fe−CO bond. Complex **8** could also be obtained directly from $FeCl_2{\cdot}4H_2O$ and $Et_2NpyS_4^{2-}$ in the presence of CO.

During attempts to diminish the inertness of [Fe(CO)(Et_2NpyS_4)] (**8**) towards substitution, the thiolate donor atoms were protonated or alkylated using either HBF_4 or Et_3OBF_4, affording the thioether derivatives [Fe(CO)(Et_2NpyS_4-R)]BF_4 [R = H (**8a**), Et (**8b**)] and [Fe(CO)($Et_2NpyS_4-Et_2$)]$(BF_4)_2$ (**8c**). Complexes **8a**−**c** were completely characterised and each shows a characteristic ν(CO) band in the 1975−2016 cm^{-1} range but they proved as inert towards substitution as their precursor **8**. For example, **8a** is deprotonated in solvents such as Et_2O, H_2O, MeOH, DMF or THF to regenerate **8** indicating that the protonation is reversible and does not lead to CO cleavage. This is in contrast to the parent complex [Fe(CO)(pyS_4-H)]BF_4, in which the CO ligand is labile and undergoes elimination to give [{Fe(pyS_4-H)}$_2$]$(BF_4)_2$.[6] One possible reason for the stability of the Fe−CO bond in **8a** may be the higher electron density at the iron centre. A comparison of the ν(CO) bands (in KBr) of [Fe(CO)(Et_2NpyS_4-H)]BF_4 (**8a**) and [Fe(CO)(pyS_4-H)]BF_4 (1975 cm^{-1} vs. 1996 cm^{-1})[6] shows that the iron centres in the [Fe(Et_2NpyS_4)] fragments have a higher electron density than in the [Fe(pyS_4)] fragments, thus favouring bonding of the good π-acceptor CO. The low ν(CO) frequency of **8** prompted us to attempt to obtain an [Fe(Et_2NpyS_4)] dinitrogen complex. For this purpose, a solution of **8** was UV-irradiated under N_2 for a prolonged period of time at different temperatures. However, the CO coligand dissociated and dinuclear **6** formed. Complex **8** was found to react only with $NOBF_4$ at 0 °C to afford the 18 valence electron (VE) complex [Fe(NO)(Et_2NpyS_4)]BF_4 (**10**). Complex **10** could also be obtained directly from **6** and $NOBF_4$.

The relatively high ν(NO) frequency of **10** (1882 cm^{-1} in KBr) made the $[\mathbf{10}]^+$ cation a candidate for attempts to convert the NO into an N_2 ligand by addition of nitrogen nucleophiles to the nitrosyl N atom.[10] For this purpose, **10** was treated with NH_3, N_2H_4 or N_3^-. However, in none of these cases did a nucleophilic addition to the NO coligand take place and, rather, the nucleophiles acted as reductants yielding the neutral 19 VE complex [Fe(NO)(Et_2NpyS_4)] (**11**), showing a ν(NO) band at 1637 cm^{-1} in its IR (KBr) spectrum. Subsequent experiments revealed that even N_2H_4 or solvents such as MeOH or DMF could reduce the cationic $[\mathbf{10}]^+$ to give neutral **11**. Alternatively, **11** could be synthesised directly from **6** and an equimolar amount of NO gas. Complex **11** is highly reactive and can be oxidised to give the $[\mathbf{10}]^+$ cation.

Treatment of an equimolar amount of **6** with N_2H_4 afforded the hydrazine complex [Fe(N_2H_4)(Et_2NpyS_4)] (**12**). Complex **12** is stable and could be isolated as a solid and completely characterised. This is in contrast to the analogous [Fe(N_2H_4)(pyS_4)][2a] which is highly labile towards N_2H_4 elimination and could be isolated in crystalline form only in the presence of excess N_2H_4. One possible reason for this high stability could be that all N_2H_4 hydrogen atoms are involved in both intra- and intermolecular hydrogen bonding as found for solid **12** in the solid state.

The unsuccessful attempts to obtain an [Fe(Et_2NpyS_4)] dinitrogen complex prompted us to also study ruthenium complexes which could be expected to be less labile (Scheme 4).

As a first target complex [Ru(NO)(Et_2NpyS_4)]Br (**13**) was prepared. It was obtained by template alkylation of Bu_4N[Ru(NO)($S_2C_6H_4$)$_2$][11] with $Et_2Npy(CH_2Br)_2$ (**3**) in boiling THF. Complex **13** exhibits a low ν(NO) frequency (1858 cm^{-1} in KBr) compared with the related complex [Ru(NO)(pyS_4)]Tos (1892 cm^{-1}).[2e] This again indicates a higher electron density at the ruthenium centre. Attempts to obtain an [Ru(Et_2NpyS_4)] dinitrogen complex from the reaction of **13** with NH_3 in MeOH resulted in the formation of the thiolate bridged dinuclear [{Ru(Et_2NpyS_4)}$_2$] (**14**). Monitoring of the reaction by solution IR spectroscopy showed that at first **13** [ν(NO) = 1880 cm^{-1} in MeOH] is reduced to give the 19 VE electron species [Ru(NO)(Et_2NpyS_4)] [ν(NO) = 1640 cm^{-1} in MeOH][2b] which is highly labile and releases NO to give dinuclear **14**. Complex **14** is practically insoluble in all common solvents and inert towards cleavage reactions. When a red brown THF suspension of **13** was treated with N_2H_4, a green solution was formed from which the hydrazine complex [Ru(N_2H_4)(Et_2NpyS_4)] (**15**) was isolated. Complex **15** is stable over prolonged periods of time in both the solid state and solution.

Characterization and General Properties of the Complexes

As far as possible, all complexes have been characterised by common spectroscopic methods and elemental analyses and, with the exception of **6** and **11**, they are all diamagnetic. All complexes, except the dinuclear species **6** proved to be soluble in THF, CH_2Cl_2 and DMF. The IR (KBr) spectra show a typical pattern for the [M(Et_2NpyS_4)] fragment besides the characteristic bands of the coligands. For example, the ν(CNCy) band at 2105 cm^{-1} indicates coordination of the CNCy ligand in **9**. Characteristic strong ν(CO) bands were observed for **8** (1948 cm^{-1}), **8a** (1974 cm^{-1}), **8b** (1980 cm^{-1}) and **8c** (2007 cm^{-1}), while weak ν(N−H) bands at 3318, 3285 and 3237, and 3318, 3242 and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3100 cm^{-1} appeared for the hydrazine complexes **12** and **15**, respectively. Strong ν(NO) bands at 1882, 1637 and 1858 cm^{-1} characterise the nitrosyl complexes **10**, **11** and **13**, respectively.

The mass spectra in all cases exhibited peaks corresponding to either the molecular ion or ions resulting from loss of the coligands. The $^{13}C\{^1H\}$ NMR spectra proved particularly helpful in establishing the diastereomeric purity of the complexes and the twofold symmetry of the $[M(Et_2NpyS_4)]$ fragments. ^1H and $^{13}C\{^1H\}$ NMR spectra corroborated the C_2 symmetry of complexes **8**, **8c**, **9**, **10**, **12**, **13** and **15**, and the C_1 symmetry of complex **8b**. The hydrazine complex **12** gave rise to a broad singlet at $\delta = 2.9$ pm which can be attributed to *Fe*-bound and terminal NH_2 groups, while **15** gave rise to two doublets at $\delta = 4.2$ and 4.4 ppm which can be attributed to an *Ru*-bound NH_2 group and a multiplet at $\delta = 3.3$ ppm which can be assigned to the terminal NH_2 group.

Benzene and Pyridine Ring Substituent Effects

In the search for complexes which exhibit electron-rich metal centres, we have found that the benzene ring substituents have no significant influence on the electron density at the metal centres. In other words, the electronic changes in the benzene rings cannot be transmitted beyond the sulfur donors to the metal centres.[6,12] The ν(CO) or ν(NO) frequencies which sensitively reflect electronic changes at the metal centres are practically identical in the corresponding complexes (Table 1). It was therefore of interest to examine whether such an electron-donating effect of the pyridine ring Et_2N substituent would reach and be detectable at the metal centres of the homologous complexes.

Table 1. The ν(CO) and ν(NO) frequencies of $[Fe(NS_4)]$ cores with electron-donating benzene and pyridine ring substituents

Complex	ν(CO)[a]	Complex	ν(NO)[a]
$[Fe(CO)(pyS_4)]$	1963[6]	$[Fe(NO)(pyS_4)]^+$	1893[6]
$[Fe(CO)(pybuS_4)]$	1969[6]	$[Fe(NO)(Et_2NpyS_4)]^+$ (**10**)	1882[b]
$[Fe(CO)(Et_2NpyS_4)]$ (**8**)	1948[b]	$[Fe(NO)(pyS_4)]$	1648[6]
		$[Fe(NO)(Et_2NpyS_4)]$ (**11**)	1637[b]

[a] In KBr [cm^{-1}]. [b] This work.

Table 1 demonstrates that all iron complexes with $[Fe(Et_2NpyS_4)]$ cores show significant shifts of the ν(CO) and ν(NO) bands to lower wave numbers by about 11−22 cm^{-1} indicating that the electron donation of the pyridine ring substituents increases the electron density. This conclusion is supported by the high basicity of the sulfur donor atoms which form strong hydrogen bonds as found in the solid-state structures of **12**, **15** and **15**·N_2H_4. Further supporting observations include the cyclic voltammograms of the isoelectronic iron complexes $[Fe(CO)(Et_2NpyS_4)]$ (**8**) and $[Fe(CO)(pyS_4)]$[6] as well as the nitrosylruthenium complexes $[Ru(NO)(Et_2NpyS_4)]Br$ (**13**) and $[Ru(NO)(Et_2NpyS_4)]Tos$[2e] (Figure 1, Table 2). A comparison of the redox potentials of the carbonyliron complexes $[Fe(CO)(Et_2NpyS_4)]$ (**8**) and $[Fe(CO)(pyS_4)]$[6] (+361 mV vs. +514 mV in CH_2Cl_2) indicates the electron-donating nature of the Et_2N substituent which makes oxidation easier. On the other hand, the redox potentials of the nitrosylruthenium cations $[Ru(NO)(Et_2NpyS_4)]^+$ (**13**) and $[Ru(NO)(Et_2NpyS_4)]$[2e] (−467, −1524 mV vs. −275, −1200 mV in DMF) indicate that the Et_2N substituent renders cationic complexes with $[Fe(Et_2NpyS_4)]$ fragments more difficult to reduce. Keeping all these observations in mind, we can conclude that the Et_2N substituent has a significant influence on the electron density in $[M(Et_2NpyS_4)]$ cores.

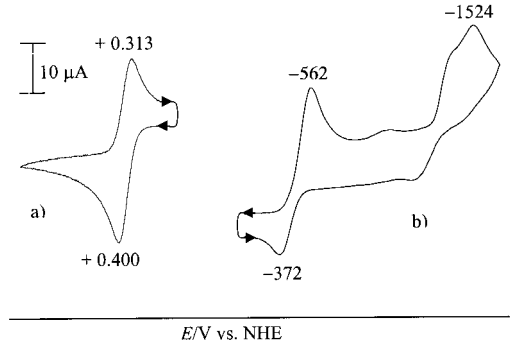


Figure 1. Cyclic voltammograms of a) $[Fe(CO)(Et_2NpyS_4)]$ (**8**) in CH_2Cl_2, b) $[Ru(NO)(Et_2NpyS_4)]Br$ (**13**) in DMF (10^{-3} M, 10^{-1} Bu_4NPF_6, $v = 50$ mV/s, potentials given in mV)

X-ray Crystal Structure Determinations

The crystal structures of the complexes $[\{Fe(Et_2NpyS_4-O_2)\}_2]\cdot 8CDCl_3$ (**7**·8$CDCl_3$), $[Fe(CO)(Et_2NpyS_4)]\cdot CDCl_3$ (**8**·$CDCl_3$), $[Fe(CNCy)(Et_2NpyS_4)]\cdot 2THF$ (**9**·2THF), $[Fe(NO)(Et_2NpyS_4)]BF_4\cdot CH_2Cl_2$ (**10**·CH_2Cl_2), $[Fe(N_2H_4)(Et_2NpyS_4)]$ (**12**), $[Ru(N_2H_4)(Et_2NpyS_4)]$ (**15**) and $[Ru(N_2H_4)(Et_2NpyS_4)]\cdot N_2H_4$ (**15**·N_2H_4) were determined by X-ray crystallography. Figures 2−4 depict the molecular structures of the complexes. Tables 3 and 4 list selected bond lengths and angles.

Table 2. Redox potentials of carbonyl and nitrosyl complexes with $[M(NS_4)]$ cores

Complex	Redox potentials in CH_2Cl_2 [mV][a]	Complex	Redox potentials in DMF [mV][a]
$[Fe(CO)(pyS_4)]$	+ 514[6]	$[Ru(NO)(pyS_4)]^+$	− 275, − 1200[2e]
$[Fe(CO)(Et_2NpyS_4)]$ (**8**)	+ 361[b]	$[Ru(NO)(Et_2NpyS_4)]^+$ (**13**)	− 467, − 1524[b]

Figure 3. Molecular structures of $[Fe(CO)(Et_2NpyS_4)]\cdot CDCl_3$ (**8**·$CDCl_3$), $[Fe(CNCy)(Et_2NpyS_4)]\cdot 2THF$ (**9**·2THF) and $[Fe(NO)(Et_2NpyS_4)]BF_4\cdot CH_2Cl_2$ (**10**·CH_2Cl_2) (50% probability ellipsoids, all solvate molecules, anions and C-bound H atoms omitted)

The Et_2NpyS_4 ligand acts as a square-pyramidal coordination cap and the overall geometry around the iron centre is pseudo-octahedral. The pyridine N1 donor and the coligand L or the bridging S donor of a second Fe fragment as well as the two thiolate and the two thioether donor atoms of the $Et_2NpyS_4^{2-}$ ligand occupy corresponding *trans* positions and thus provide the steric rigidity of the $py(CH_2)_2$ backbone. A comparison of the geometrical parameters of **8**·$CDCl_3$, **9**·2THF and **10**·CH_2Cl_2 demonstrates that the Fe−donor distances in all cases lie in the usual

range observed for diamagnetic $[FeNS_4]$ cores.[2a,2b,2e,6] The Fe−S(thiolate) distances (average 230 pm) are slightly longer than the Fe−S(thioether) distances (average 223 pm).

In complex **7**·$8CDCl_3$, the oxygenation causes a significant effect in the Fe−S(sulfinate) distance while the other Fe−S and Fe−N distances remain practically unchanged. The Fe−S(sulfinate) distance decreases by about 12 pm [218(2) pm for **7**·$8CDCl_3$ vs. 230 pm (average) for **8**·$CDCl_3$, **9**·2THF and **12**]. An explanation could be that the Fe−S distances are governed by three factors: 1) the σ-donor ability, expected to be best in the thiolate which decreases with increasing oxygenation, 2) a contraction in the size of the sulfur atoms as the formal oxidation state of the sulfur atoms changes from −2 (for Fe−S in complexes **8**·$CDCl_3$, **9**·2THF and **10**) to +2 [for Fe−S(sulfinate) in complex **7**·$8CDCl_3$], and 3) the destabilisation of the Fe−S bond due

to a repulsive interaction between the filled d orbital of the metal atom and two lone pairs of the thiolate sulfur atom.[9a,13]

The crystal structures of the complexes **12**, **15** and **15**·N_2H_4 deserve special interest because all types of hydrazine hydrogen atoms are involved in a system of inter- and intramolecular N−H···S and N−H···N hydrogen bonding with the sulfur donors (thiolate, thioether) as well as the solvate hydrazine N atoms. The hydrogen bonds are indicated by both the N−H···S and N−H···N vectors as well as the distances which are shorter than the sum of the corresponding van der Waals radii (r_H = 120 pm, r_S = 185 pm).[14] Figure 3 shows the molecular structures and the hydrogen bonding geometry for **12** and **15**·N_2H_4. The parameters of the hydrogen bonds are collected in Table 5.

The crystal lattices of **12** and **15** contain chains of molecules which are connected by intermolecular N−H···S(thiolate) hydrogen bonds and each molecule exhibits additional intramolecular N−H···S hydrogen bonds. The type of bonds, bond lengths and bond angles in the two complexes are very similar, only **12** contains an additional N−H···S bond. The crystal lattice of **15**·N_2H_4 additionally contains intermolecular N−H···N hydrogen bonds between the solvate hydrazine and the coordinated hydrazine. This system of hydrogen bonds is of interest because it contributes significantly to the stabilisation of the N_2H_4 coligand and a similar effect may stabilise the intermediate diazene complex which is assumed to be essential for N_2 fixation.[2c]

plexes which exhibit electron-rich metal centres, possess a core configuration with thiolate, thioether and amine donors related to the structure of [M(pyS_4)] fragments (M = Fe and Ru), and bind biologically relevant small molecules. This goal was achieved as evidenced by the low ν(CO) frequency of [Fe(CO)(Et_2NpyS_4)] (1948 cm^{-1}) compared with the analogous [Fe(CO)(pyS_4)] (1963 cm^{-1}). The [M(Et_2NpyS_4)] fragments (M = Fe, Ru) were found to bind and stabilise many nitrogenase-relevant molecules such as CO, NO, NO^+, CNCy and N_2H_4. The results also revealed that the Et_2N substituent not only increases the electron density at the metal centres but also at the sulfur donor atoms which leads to highly basic sulfur donors. This high basicity influences the reactivity of the M−L bonds. For example, the protonated complex [Fe(CO)(Et_2NpyS_4-H)]-BF_4 is deprotonated only in solution to give [Fe(CO)-(Et_2NpyS_4)], while the related complex [Fe(CO)-(pyS_4-H)]BF_4 is labile and undergoes CO elimination to give [{Fe(pyS_4-H)}$_2$](BF_4).

The X-ray structural analyses of [Fe(N_2H_4)(Et_2NpyS_4)] and [Ru(N_2H_4)(Et_2NpyS_4)] revealed that such complexes can form intra- and intermolecular N−H···S and N−H···N hydrogen bonds. This stabilises the hydrazine complex [Fe(N_2H_4)(Et_2NpyS_4)] and makes it isolable and stable in the solid state. This is in contrast to the parent complex [Fe(N_2H_4)(pyS_4)] which was highly labile with respect to elimination of the N_2H_4 coligand and could not be isolated.

Experimental Section

General: Unless noted otherwise, all procedures were carried out under nitrogen using Schlenk techniques. Stringently dried solvents were used. As far as possible, reactions were monitored by IR or NMR spectroscopy. Spectra were recorded with the following instruments: IR (KBr discs or CaF_2 corvettes, solvent bands were compensated): Perkin−Elmer 983, 1620 FT-IR, and 16PC FT-IR. NMR: Jeol-JNM-GX 270, EX 270, and Lambda LA 400 with the proton solvent signals used as an internal reference. Spectra were recorded at 25 °C. MS: Jeol MSTATION 700 spectrometer. Elemental analyses: Carlo Erba EA 1106 or 1108 analyser. Magnetic susceptibility: Johnson Matthey susceptibility balance. Cyclic voltammograms were recorded using an EG&G potentiostat PAR model 264A and a conventional three-electrode configuration consisting of a glassy carbon working electrode, a platinum auxiliary electrode and a platinum reference electrode. Ferrocene was used as an internal reference, $E(Fc/Fc^+)$ = +400 mV (vs. NHE).[15] The reversibility of the voltammograms and the number of electrons involved in the redox processes at 25°C were determined as described in the literature.[16] "S_2"−H_2 (1,2-benzenedithiol),[17] dimethyl 4-bromo-pyridine-2,6-dicarboxylate[7] and Bu_4N[Ru(NO)($S_2C_6H_4$)$_2$][11] were prepared as described in the literature. Anhydrous hydrazine was obtained by twofold distillation of N_2H_4·H_2O from KOH under reduced pressure.

$Et_2Npy(CO_2Me)_2$ (1): Anhydrous K_2CO_3 (4.15 g, 30 mmol) and diethylamine (20 mL, 192.5 mmol) were added to a white suspension of dimethyl 4-bromo-pyridine-2,6-dicarboxylate (6.89 g, 25.1 mmol) in DMSO (200 mL). The resultant yellow-brown mixture was heated at 55−60 °C for 48 h. The resultant orange-brown suspension was cooled to room temperature and poured onto ice-cold water (250 mL). A yellow solid formed which was separated by filtration, washed with water and dried in vacuo. Yield: 6.32 g of **1** (34%). ^{1}H NMR ($CDCl_3$, 269.60 MHz): δ = 1.20 (t, 6 H, $2CH_2CH_3$), 3.44 (q, 4 H, $2CH_2CH_3$), 3.95 (s, 6 H, $2COOCH_3$), 7.45 (s, 2 H, H_β, pyridine) ppm. IR (KBr): $\tilde{\nu}$ = 1748, 1708, (vs, C=O) cm^{-1}. MS (FD^+, $CHCl_3$): m/z = 266 [M^+]. $C_{13}H_{18}N_2O_4$ (266.29): calcd. C 58.63, H 6.81, N 10.52; found C 58.44, H 6.92, N 10.37.

$Et_2Npy(CH_2OH)_2$ (2): $NaBH_4$ (2.96 g, 40 mmol) was added portionwise to **1** (4.05 g, 16 mmol) in ethanol (200 mL). The mixture was kept at room temperature for 1.5 h and was then heated to reflux for 16 h. The solvent was evaporated, the residue treated with a saturated solution of $NaHCO_3$ (50 mL) and heated to reflux for 1.5 h. H_2O (100 mL) was added and the aqueous phase was extracted continuously with $CHCl_3$ (500 mL) over 2 d. The $CHCl_3$ was evaporated to give a colourless solid. Yield 2.83 g of **2** (88%). ^{1}H NMR ([D_6]DMSO, 269.60 MHz): δ = 1.10 (t, $^3J_{H,H}$ = 7.1 Hz, 6 H, CH_2CH_3), 3.33 (q, 4 H, CH_2CH_3), 4.35 (d, $^2J_{H,H}$ = 5.5 Hz, 4 H, $2CH_2$), 5.14 (t, $^3J_{H,H}$ = 5.8 Hz, 2 H, 2O*H*), 6.51 (s, 2 H, H_β pyridine) ppm. MS (FD, DMSO): m/z = 210 [M^+].

$Et_2Npy(CH_2Br)_2$ (3): A solution of **2** (400 mg, 1.9 mmol) in 40% aqueous HBr (50 mL) was heated to reflux for 16 h. The aqueous phase was extracted with $CHCl_3$ (3 × 100 mL). The $CHCl_3$ extract was dried with $MgSO_4$ and the solvent removed in vacuo to give a white solid residue. Yield: 400 mg of **3**·0.16THF (62%). ^{1}H NMR ($CDCl_3$, 269.60 MHz): δ = 1.21 (t, 6 H, $2CH_2CH_3$), 3.41 (q, 4 H, $2CH_2CH_3$), 4.50 (s, 4 H, $2CH_2$), 6.55 (s, 2 H, H_β pyridine), ^{13}C{^{1}H} NMR ($CDCl_3$, 67.83 MHz): δ = 12.27 (CH_2CH_3), 33.43 (CH_2CH_3), 44.31 (CH_2Br), 105.24, 154.02, 156.01 [*C*(aryl)] ppm. IR (KBr): $\tilde{\nu}$ = 3033, 2969 (m, C−H) cm^{-1}. FD MS: m/z: 336 [M^+]. $C_{11.7}H_{17.3}Br_2N_2O_{0.17}$ (348.10): calcd. C 40.26, H 5.02, N 8.05; found C 40.12, H 5.13, N 8.13.

[{Ni(Et_2NpyS_4)}$_2$] (4). a): A solution of **2**·0.75MeOH (1.17 g, 5.34 mmol) in THF (30 mL) was combined with KOH (0.9 g, 17.80 mmol) and cooled to 0 °C. Tosyl chloride (2.43 g, 10.68 mmol) in THF (20 mL) was added dropwise and the resultant suspension was stirred at 0 °C for 5 h and at room temperature for 14 h. The resultant solid was removed by filtration and washed with THF (30 mL). The washings and the filtrates were dried in vacuo, yielding a light brown viscous residue. Yield 2.6 g of $Et_2Npy(CH_2OTs)_2$ (**3a**) (90%) which was used without further purification. **b):** Sodium (453 mg, 19.67 mmol) was dissolved in methanol (40 mL) and combined with 1,2-benzenedithiol (1.12 mL, 9.83 mmol) and a solution of Ni(ac)$_2$·4H_2O (1.22 g, 4.92 mmol) in MeOH (50 mL). Addition of $Et_2Npy(CH_2OTs)_2$ (**3a**) (2.55 g, 4.92 mmol) in THF (70 mL) to the dark-brown solution resulted in a brown precipitate which was isolated after 3 h, washed with THF and MeOH (30 mL each) and dried in vacuo. Yield: 2.0 g of [{Ni(Et_2NpyS_4)}$_2$]·1.5MeOH (**4**·1.5MeOH) (76%). IR (KBr): $\tilde{\nu}$ = 3050, 2968, ν(C−H) cm^{-1}. MS (FD^+, MeOH): m/z = 514 [Ni(Et_2NpyS_4)]$^+$, 1028 [{Ni(Et_2NpyS_4)}$_2$]$^+$. $C_{23}H_{24}N_2NiS_4$ (515.40): calcd. C 52.22, H 5.36, N 5.00; found C 52.66, H 5.16, N 5.12. μ_{eff} = 2.25 μ_B (297 K).

$Et_2NpyS_4-H_2$·HCl (5): Concentrated hydrochloric acid (15.14 mL) was added to a suspension of **4**·1.5MeOH (4.86 g, 9.60 mmol) in CH_2Cl_2 (200 mL) and the mixture was stirred for 30 min. The CH_2Cl_2 phase was separated from the aqueous green phase, dried with anhydrous Na_2SO_4 and the solvents were evaporated to dryness yielding a grey-green solid. Yield 1.7 g of **5**·2CH_3OH (32%). ^{1}H NMR (CD_2Cl_2, 269.60 MHz): δ = 0.94 (t, $^3J_{H,H}$ = 7.2 Hz, 6 H, $2CH_2CH_3$), 3.14 (q, 4 H, $2CH_2CH_3$), 4.38 (s, 2 H, 2S*H*), 4.40

(s, 4 H, 2CH_2), 5.92 (s, 2 H, H_β, pyridine), 7.04−7.38 (m, 8 H, C$_6H_4$), 7.78 (d, $^2J_{H,H}$ = 6.5 Hz, 1 H, N*H*) ppm. IR (KBr): $\tilde{\nu}$ = 3414, 3255, 3070 (w, N−H), 2412 (w, S−H) cm^{-1}. MS (FD$^+$, CH_2Cl_2): *m*/*z* = 495 [M]$^+$. $C_{25}H_{35}ClN_2O_2S_4$ (559.3): calcd. C 53.69, H 6.31, N 5.01; found C 53.94, H 5.91, N 4.69.

[{Fe(Et$_2$NpyS$_4$)}$_2$] (6): Solid $FeCl_2{\cdot}4H_2O$ (77 mg, 0.39 mmol) was added to a light yellow solution of **5**·H_2O (220 mg, 0.39 mmol) and LiOMe (1.17 mL of a 1 M solution in MeOH) in THF (20 mL). A yellow precipitate resulted which was separated by filtration after 30 min, washed with THF (20 mL) and dried in vacuo. Yield: 105 mg of **6** (53%). IR (KBr): $\tilde{\nu}$ = 3050, 2966 (s, C−H) cm^{-1}. MS (FD$^+$, DMF): *m*/*z* = 512 [Fe(Et$_2$NpyS$_4$)]$^+$, 1024 [Fe(Et$_2$NpyS$_4$)]$_2^+$. $C_{23}H_{24}FeN_2S_4$ (513.55): calcd. C 53.90 H 4.72, N 5.47, S 25.02; found C 53.65, H 5.11, N 5.46, S 24.86. μ_{eff} = 5.15 μ_B (297 K).

[{Fe(Et$_2$NpyS$_4$−O$_2$)}$_2$] (7): A yellow suspension of **6** (120 mg, 0.12 mmol) in $CHCl_3$ (30 mL) was stirred in air for 24 h. The resultant red-brown fine crystals were isolated, washed with $CHCl_3$ then H_2O (30 mL each) and dried in vacuo. Yield: 80 mg of **7**·3$CHCl_3{\cdot}H_2O$ (23%). IR (KBr): $\tilde{\nu}$ = 2960 (s, C−H), 1238, 1185, 1133, 983 (s, SO_2) cm^{-1}. MS (FD$^+$, $CHCl_3$): *m*/*z* = 512 [Fe(Et$_2$NpyS$_4$)]$^+$, 1024 [{Fe(Et$_2$NpyS$_4$)}$_2$]$^+$, 1088 [{Fe(Et$_2$NpyS$_4$−O$_2$)}$_2$]$^+$. $C_{49}H_{53}Cl_9Fe_2N_4O_5S_8$ (1459.77): calcd. [Fe(CO)(Et$_2$NpyS$_4$)] (8): A stream of CO was passed through a yellow suspension of **6** (70 mg, 0.14 mmol) in THF (20 mL) for 10 min during the course of which a red solution formed which was kept under CO for a further 12 h, filtered and reduced in volume to about 2 mL. Addition of Et_2O (20 mL) precipitated a red solid which was separated by filtration and dried in vacuo. Yield 62 mg of **8**·0.7H_2O (84%). ^{1}H NMR (CD_2Cl_2, 269.60 MHz): δ = 1.06 (t, $^3J_{H,H}$ = 7.05 Hz, 6 H, 2CH_2CH_3), 3.22 (q, $^4J_{H,H}$ = 6.20 Hz, 4 H, 2CH_2CH$_3$), 4.34 (d, $^2J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 4.86 (d, $^2J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 6.39 (s, 2 H, H_β, pyridine), 6.93 (m, 4 H, C$_6H_4$), 7.41 (d, $^2J_{H,H}$ = 6.5 Hz, 2 H, C$_6H_4$), 7.56 (d, $^2J_{H,H}$ = 6.5 Hz, 2 H, C$_6H_4$) ppm. ^{13}C{^{1}H} NMR (CD_2Cl_2, 67.83 MHz): δ = 9.6 (CH_2CH_3), 41.9 (CH_2CH$_3$), 53.8 (CH_2), 101.2, 119.7, 126.2, 127.9, 129.5, 131.0, 149.4, 153.9, 155.2 [*C*(aryl)], 214.4 (*C*O) ppm. IR (KBr): $\tilde{\nu}$ = 1948 (vs, CO), 2966 (m, C−H) cm^{-1}. MS (FD$^+$, CH_2Cl_2): *m*/*z* = 512 [Fe(Et$_2$NpyS$_4$)]$^+$, 1024 [{Fe(Et$_2$NpyS$_4$)}$_2$]$^+$. $C_{24}H_{25.4}FeN_2O_{1.7}S_4$ (552.02): calcd. C 52.17, H 4.62, N 5.07, S 23.21; found C 52.21, H 4.76, N 5.01, S 23.00.

[Fe(CO)(Et$_2$NpyS$_4$−H)]BF$_4$ (8a): At −78 °C, (0.013 mL, 0.1 mmol) HBF_4 (54% in Et_2O) was added to a red suspension of **8**·0.7H_2O (50 mg, 0.1 mmol) in CH_2Cl_2 (15 mL). After 1 h of stirring, during the course of which the resultant grey solution was reduced in volume to about 3 mL at −78 °C, addition of *n*-hexane (15 mL) precipitated a grey solid which was isolated and dried in vacuo. Yield: 40 mg (69%) of **8a**. IR (KBr): $\tilde{\nu}$ = 2503 (w, S−H), 1974 (vs, CO) cm^{-1}. MS (FD$^+$, CH_2Cl_2): *m*/*z* = 512 [Fe(Et$_2$NpyS$_4$)]$^+$, 1024 [{Fe(Et$_2$NpyS$_4$)}$_2$]$^+$. $C_{24.5}H_{26}FeBClF_4N_2OS_4$ (670.49): C 43.86, H 3.91, N 4.17; found C 43.66, H 3.79, N 3.91.

[Fe(CO)(Et$_2$NpyS$_4$-Et)]BF$_4$ (8b): A red solution of **8**·0.7H_2O (90 mg, 0.17 mmol) in CH_2Cl_2 (10 mL) was combined with a 1 M Et_3OBF_4 solution in CH_2Cl_2 (0.17 mL, 0.17 mmol). The resultant brown solution was reduced in volume to 3 mL. Addition of Et_2O (20 mL) precipitated a brown solid which was separated by filtration, washed with Et_2O (20 mL) and dried in vacuo. Yield 85 mg of **8b**·0.3CH_2Cl_2 (76%). ^{1}H NMR (CD_2Cl_2, 269.60 MHz): δ = 0.98 (m, 6 H, 2CH_2CH_3), 1.46 (m, 3 H, CH_2CH_3), 3.12 (m, 6 H, 3CH_2CH$_3$), 4.48 (m, 2 H, CH_2), 4.90 (m, 2 H, CH_2), 6.43 (d, 2 H, H_β, pyridine), 7.00 (m, 2 H, C$_6H_4$), 7.32 (d, 1 H, C$_6H_4$), 7.61−7.51 (m, 3 H, C$_6H_4$), 7.74 (m, 1 H, C$_6H_4$), 8.09 (m, 1 H, C$_6H_4$) ppm. ^{13}C{^{1}H} NMR (CD_2Cl_2, 67.83 MHz): δ = 12.33 (CH_2CH_3), 13.34 (CH_2CH_3), 41.51 (CH_2CH_3), 44.97 (CH_2CH_3), 55.80, 55.90 (CH_2), 105.38, 105.64, 124.03, 129.69, 129.95, 130.57, 132.22, 132.38, 132.78, 133.61, 133.90, 135.75, 137.14, 152.90, 154.14, 155.48, 156.58 [*C*(aryl)], 213.24 (*C*O) ppm. IR (KBr): $\tilde{\nu}$ = 1980 (vs, CO), 1055 (vs, B−F) cm^{-1}. MS (FD$^+$, CH_2Cl_2): *m*/*z* = 512 [Fe(Et$_2$NpyS$_4$)]$^+$, 1024 [{Fe(Et$_2$NpyS$_4$)}$_2$]$^+$. $C_{26.3}H_{29.6}FeBCl_{0.6}F_4N_2OS_4$ (684.74): C 46.19, H 4.37, N 4.09; found C 46.39, H 4.73, N 4.04.

[Fe(CO)(Et$_2$NpyS$_4$−Et$_2$)](BF$_4$)$_2$ (8c): Et_3OBF_4 (0.40 mL, 0.40 mmol of a 1 M solution in CH_2Cl_2) was added to a red solution of **8**·0.7H_2O (110 mg, 0.20 mmol) in CH_2Cl_2 (15 mL). The colour immediately changed from red to brown. After 24 h, the reaction mixture was reduced in volume to 3 mL. Addition of Et_2O (30 mL) precipitated a brown solid which was separated by filtration, washed with Et_2O (20 mL) and dried in vacuo. Yield 120 mg of **8c**·0.5CH_2Cl_2 (72%). ^{1}H NMR (CD_3OD, 269.60 MHz): δ = 1.02−0.97 (t, $^3J_{H,H}$ = 7.2 Hz, 6 H, 2CH_2CH_3), 1.53−1.62 (t, $^3J_{H,H}$ = 7.2 Hz, 6 H, 2CH_2CH_3), 3.21−3.34 (m, 4 H, 2CH_2CH$_3$), 3.35−3.49 (m, 4 H, CH_2CH$_3$), 4.79−4.82 (d, $^2J_{H,H}$ = 16.69 Hz, 2 H, CH_2), 5.17−5.23 (d, $^2J_{H,H}$ = 16.70 Hz, 2 H, CH_2), 6.77 (s, 2 H, H_β, pyridine), 7.65 (t, $^3J_{H,H}$ = 7.4 Hz, 3 H, C$_6H_4$), 7.77 (t, $^3J_{H,H}$ = 7.20/7.60 Hz, 3 H, C$_6H_4$), 7.97 (d, $^2J_{H,H}$ = 7.64 Hz, 2 H, C$_6H_4$), 8.32 (d, $^2J_{H,H}$ = 7.83 Hz, 2 H, C$_6H_4$) ppm. ^{13}C{^{1}H} NMR (CD_3OD, 67.83 MHz): δ = 12.01 (CH_2CH_3), 13.09 (CH_2CH_3), 41.41 (CH_2CH_3), 44.59 (CH_2CH_3), 54.74 (CH_2), 107.23, 133.47, 134.15 134.20, 134.83, 135.42, 136.42, 154.96, 158.00 [*C*(aryl)], 210.00 (*C*O) ppm. IR (KBr) : $\tilde{\nu}$ = 2007 (vs, CO), 1056 (vs, B−F) cm^{-1}. MS (FD$^+$, CH_3OH): *m*/*z* = 512 [Fe(Et$_2$NpyS$_4$)]$^+$, 1024 [{Fe(Et$_2$NpyS$_4$)}$_2$]$^+$. $C_{28.5}H_{35}FeB_2ClF_8N_2OS_4$ (814.77): C 42.00, H 4.33, N 3.44, S 15.74; found C 41.68, H 4.57, N 3.64, S 15.98.

[Fe(CNCy)(Et$_2$NpyS$_4$)] (9): Cyclohexyl isocyanide (0.032 mL, 0.30 mmol) was added to a yellow suspension of **6** (100 mg, 0.20 mmol) in THF (20 mL). A red solution resulted which was stirred for 12 h, filtered and reduced in volume to about 5 mL. Addition of Et_2O (20 mL) precipitated a red-orange solid which was separated by filtration and dried in vacuo. Yield: 60 mg of **9** (57%). ^{1}H NMR ([D$_8$]toluene, 269.60 MHz): δ = 0.39 (t, 6 H, 2CH_2CH_3), 0.93 (t, 10 H, C$_6H_{11}$), 7.85 (m, 1 H, C$_6H_{11}$), 2.35 (m, 4 H, 2CH_2CH$_3$), 3.98−3.92 (d, 2 H, CH_2), 4.85−4.80 (d, 2 H, CH_2), 5.68 (s, 2 H, H_β, pyridine), 6.68−6.83 (m, 4 H, C$_6H_4$), 7.53−7.24 (m, 2 H, C$_6H_4$), 7.80 (d, 2 H, C$_6H_4$) ppm. IR (KBr): $\tilde{\nu}$ = 2105 (vs, CN), 2969, 2932 (m, C−H) cm^{-1}. MS (FD$^+$, toluene): *m*/*z* = 512 [Fe(Et$_2$NpyS$_4$)]$^+$, 620 [Fe(CNCy)(Et$_2$NpyS$_4$)]$^+$, 1024 [{Fe(Et$_2$NpyS$_4$)}$_2$]$^+$. $C_{30}H_{35}FeN_3S_4$ (621.73): calcd. C 57.95, H 5.67, N 6.76, S 20.63; found C 57.34, H 6.21, N 6.77, S 20.43.

[Fe(NO)(Et$_2$NpyS$_4$)]BF$_4$ (10). a) From 8: Solid $NOBF_4$ (5 mg, 0.04 mmol) was added to a red solution of **8**·0.7H_2O (20 mg, 0.04 mmol) in CH_2Cl_2 (10 mL). During the course of 10 min, a yellow-green solution resulted which was filtered and reduced in volume to about 5 mL. Addition of Et_2O (20 mL) precipitated a yellow-green solid which was separated by filtration and dried in vacuo. Yield: 15 mg of **10**·$CH_2Cl_2{\cdot}Et_2O$ (65%). **b) From 6:** At 0 °C, solid $NOBF_4$ (5 mg, 0.04 mmol) was added to a yellow suspension of **6** (20.5 mg, 0.04 mmol) in CH_2Cl_2 (10 mL). After stirring at 0 °C for 70 min and at room temperature for 30 min, the resultant yellow-green mixture was filtered, reduced in volume to about 5 mL and combined with Et_2O (20 mL). The resultant green solid was separated by filtration and dried in vacuo. Yield: 18 mg **10**·$CH_2Cl_2{\cdot}Et_2O$ (82%). ^{1}H NMR (CD_2Cl_2, 269.60 MHz): δ = 1.05

[Ru(N_2H_4)(Et_2NpyS_4)] (15): N_2H_4 (0.5 mL, 16 mmol) was added to a red-brown suspension of **13**·0.3THF (110 mg, 0.16 mmol) in THF (10 mL). Gas evolved and a red solution formed which was concentrated in volume to 3 mL. Addition of MeOH (10 mL) led to precipitation of a red microcrystalline solid which was separated, washed with MeOH (10 mL) and ether (20 mL) then dried in vacuo. Yield 40 mg of **15**·0.3 N_2H_4·0.6H_2O (41%). ^1H NMR ([D$_6$]DMSO, 269.60 MHz): δ = 1.02−0.83 (t, 6 H, $2CH_2CH_3$), 3.10−2.99 (m, 4 H, $2CH_2CH_3$), 3.30 (m, 1 H, NH_2), 4.24−4.22 (d, 1 H, NH_2), 4.31−4.28 (d, 2 H, CH_2), 4.37 (d, 2 H, CH_2), 4.42 (d, 1 H, N*H*), 6.19 (s, 2 H, H_β, pyridine), 6.67−6.59 (m, 4 H, C_6H_4), 7.37−7.35 (m, 2 H, C_6H_4), 7.50−7.47 (m, 2 H, C_6H_4) ppm. $^{13}C\{^1H\}$ NMR (DMF-d$_7$, 67.83 MHz): δ = 12.02 (CH_2CH_3), 43.25 (CH_2CH_3), 56.69 (CH_2), 102.93, 119.93, 130.61, 132.19, 132.98, 149.98, 158.28 [*C*(aryl)] ppm. IR (KBr): $\tilde{\nu}$ = 3318, 3242, 3100 (m, N−H) cm^{-1}. MS (FD^+, CH_2Cl_2): *m*/*z* = 558 $[Ru(Et_2NpyS_4)]^+$, 590 $[Ru(N_2H_4)(Et_2NpyS_4)]^+$, 1116 $[\{Fe(Et_2NpyS_4)\}_2]^+$. $C_{23}H_{29.7}N_{3.3}O_{0.6}RuS_4$ (611.5): calcd. C 45.17, H 4.89, N 10.69, S 20.97; found C 45.16, H 5.07, N 10.53, S 20.63.

X-ray Structure Determination of [$\{$Fe($Et_2NpyS_4-O_2$)$\}_2$]·8$CDCl_3$ (7·8$CDCl_3$), [Fe(CO)(Et_2NpyS_4)]·$CDCl_3$ (8·$CDCl_3$), [Fe(CNCy)(Et_2NpyS_4)]·2THF (9·2THF), [Fe(NO)(Et_2NpyS_4)]BF_4·CH_2Cl_2 (10·CH_2Cl_2), [Fe(N_2H_4)(Et_2NpyS_4)] (12), [Ru(N_2H_4)(Et_2NpyS_4)] (15) and [Ru(N_2H_4)(Et_2NpyS_4)]·N_2H_4 (15·N_2H_4): Red-brown blocks of 7·8$CDCl_3$ were grown at room temperature from a saturated $CDCl_3$ solution of **7** over one week. Red blocks of **8**·$CDCl_3$ were grown at room temperature from a saturated $CDCl_3$ solution of **8** over 3 d. Red single-crystals of **9**·2THF were grown at −27 °C from a saturated THF solution of **9** over 5 weeks. Brown blocks of **10**·CH_2Cl_2 were obtained from a saturated CH_2Cl_2 solution at room temperature over 4 weeks. Brown single-crystals of **12** were grown at room temperature from a saturated CD_2Cl_2 solution over 2 weeks. Red prisms of **15** were grown at room temperature from a saturated THF solution over one week. Orange single crystals of **15**·N_2H_4 were grown at room temperature from a saturated THF solution of **15** over one week in the presence of excess hydrazine. Suitable single-crystals were embedded in protective perfluoropolyether oil. Data were collected either with a Siemens P4 (**7**·8$CDCl_3$) or a Nonius-KappaCCD diffractometer (**8**·$CDCl_3$, **9**·2THF, **10**·CH_2Cl_2, **12**, **15** and **15**·N_2H_4) using Mo-K_α radiation (λ = 71.073 pm, graphite monochromator). Intensity data were corrected for absorption effects using either ψ-scans[18] (**7**·8$CDCl_3$) or multiple scans of equivalent reflections (SADABS[19] for **9**·2THF and SORTAV[20] for **8**·$CDCl_3$, **12**, **15** and **15**·N_2H_4) while for **10**·CH_2Cl_2 absorption effects were neglected. The structures were solved by direct methods and refined on F^2 using full-matrix least-squares procedures (SHELXTL NT 5.10[21] for **7**·8$CDCl_3$ **8**·$CDCl_3$, **9**·2THF, **12**, **15** and **15**·N_2H_4 or SHELXTL NT 6.12[22] for **10**·CH_2Cl_2). Hydrogen atoms were either located in a difference Fourier map and refined with a common fixed isotropic displacement parameter (**7**·8$CDCl_3$ **8**·$CDCl_3$, **12**), kept fixed in their positions with a common fixed isotropic displacement parameter (**15**, **15**·N_2H_4), or were geometrically positioned (**9**·2THF, **10**·CH_2Cl_2). The solvate molecules in the structures of **7**·8$CDCl_3$ **8**·$CDCl_3$, **9**·2THF and **10**·CH_2Cl_2 are partly disordered. Table 6 lists selected crystallographic data. CCDC-238453 (**7**·8$CDCl_3$), -238454 (**8**·$CDCl_3$), -238455 (**9**·2THF), -238456 (**10**·CH_2Cl_2), -238457 (**12**), -238458 (**15**) and -238459 (**15**·N_2H_4) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk]

Coordination Chemistry of Large Diphosphanes − Directional Properties of a Calix[4]arene Proximally Substituted by Two $-OCH_2PPh_2$ Podand Arms

Pierre Kuhn,[a] Catherine Jeunesse,[a] David Sémeril,[a] Dominique Matt,*[a] Pierre Lutz,[b] and Richard Welter[c]

Dedicated to Professor Jean-Pierre Sauvage on the occasion of his 60th birthday

Keywords: Calixarenes / Large diphosphanes / Nickel complexes / Ethylene oligomerisation

The proximally-functionalised calixarene 5,11,17,23-tetra-*tert*-butyl-25,26-bis(diphenylphosphanylmethoxy)-27,28-dihydroxycalix[4]arene (**1**), a large diphosphane in which the P^{III} centres are separated by 10 bonds, behaves as a chelating ligand towards NiX_2 moieties (X = Cl, Br). As shown by three X-ray studies carried out on complexes of the type [NiX_2·**1**], the diphosphane is able to accommodate either tetrahedral or strongly distorted tetrahedral coordination geometries, but not a square planar one. In all structures, the ligand positions the nickel atom away from the calixarene axis. In the presence of methylaluminoxane (MAO), [$NiCl_2$·**1**] effectively catalyses the oligomerisation of ethylene, affording C_4–C_{12} oligomers.

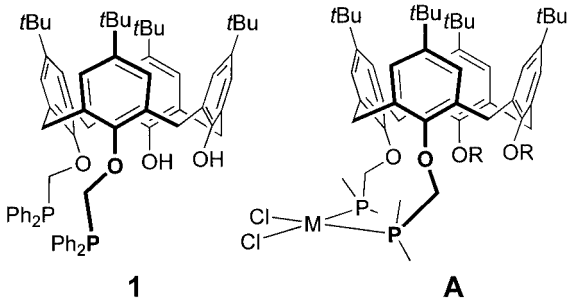
Introduction

Calix[4]arenes locked in the cone conformation are remarkable building blocks for the preparation of multifunctional ligands.[1−5] They are frequently used as preorganising platforms allowing control of the orientation of podands anchored to one of the rims and hence for imposing a particular coordination geometry upon a complexed metal ion.[6,7] Depending upon their nature, length and flexibility, convergent binding sites tethered at the same rim may not only result in high complexation selectivities but also produce metal complexes with unconventional catalytic properties.[8−18] In a recent paper, we reported the coordination chemistry of the diphosphane **1** and have shown that this conical calixarene,[19] as well as some derivatives,[20,21] forms square planar Pt^{II} chelate complexes (**A**) exclusively in the *cis* configuration in which the P-M vectors are oriented away from the calixarene axis, thus positioning the metal outside the conical domain defined by the macrocycle. The ligand bite angle in *cis*-[$PtCl_2$·**1**], as revealed by an X-ray study, is 103.4(1)°. In order to further substantiate the directional properties of this diphosphane, we have now investigated its coordination behaviour towards $NiCl_2$ and $NiBr_2$ units, two versatile fragments known to form either tetrahedral or square planar [NiX_2(phosphane)$_2$] metal complexes. The present study describes the syntheses and structures of three paramagnetic nickel(II) complexes based on **1** and illustrates that the ligand bite angle may undergo major variation, hence enabling the metal centre to approach closer to the calixarene core.



Results and Discussion

From our previous study it appears that despite its considerable length, diphosphane **1** is sufficiently preorganised to readily form chelate complexes with the $PtCl_2$ moiety.[19] Complexation of this fragment results in formation of a compound in which the platinum atom is oriented outwards from the cone defined by the calixarene. The same com-

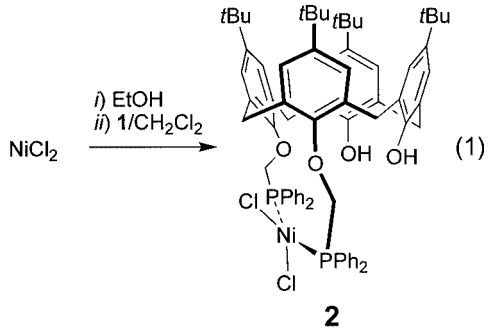
plexation behaviour towards $PtCl_2$ was observed when using analogues of **1** in which the phenol rings bear substituents.[19,21] Inverting the orientation of the P lone pairs is a challenging goal that would lead to complexes where the metal is brought closer to the calixarene axis, thus favouring interactions between the coordination centre and the bulky calixarene core. In order to study whether **1** gives access to such structures, we decided to investigate the coordination properties of **1** towards the nickel(II) centre which has a greater stereoflexibility than platinum(II).

The preparation of complex **2** required a two-step procedure consisting of (*i*) dissolution of anhydrous $NiCl_2$ in small amounts of EtOH to form an unidentified species which, unlike $NiCl_2$, is soluble in CH_2Cl_2 and (*ii*) treatment of the thus formed species with a solution of **1** in CH_2Cl_2 (Equation 1). A direct synthesis in CH_2Cl_2 was impossible due to the insolubility of $NiCl_2$ in this solvent, while attempted synthesis in pure EtOH did not result in phosphane coordination. We found that the best $EtOH/CH_2Cl_2$ ratio was ca. 1:10.



The dark blue complex **2** is paramagnetic and was characterised by elemental analysis and an X-ray diffraction study. Its molecular structure is shown in Figure 1. The shape of the calixarene core deviates only slightly from an ideal cone. Thus, the "centroid-centroid" separations between the distal phenol units are 6.45 and 6.93 Å, respectively, while the dihedral angles between the calixarene reference plane [defined as the mean plane of the bridging C atoms, here C(12), C(23), C(34), C(45)] and those of the four phenol rings are 115° (C2), 103° (C18), 134° (C29) and 124° (C40). Hydrogen bonds involving the hydroxy groups and the neighbouring phenolic oxygen atoms may contribute to this structure, as indicated by the rather short O(1)···O(3) [2.78(2) Å], O(2)···O(4) [2.87(2) Å] and O(3)···O(4) [2.67(2) Å] separations (cf. O(1)···O(2) 3.46(2) Å]. The compound crystallises with two dichloromethane molecules, one of them lying inside the calixarene basket. The shortest contacts of the latter with the aromatic walls are between H(71b) and C(27) (2.83 Å), and H(71b) and C(28) (2.84 Å). Note, considerably shorter contacts have been found in other calixarenes with CH_2Cl_2 guests.[22] The Ni atom is slightly bent towards the exterior of the cavity and its coordination geometry may be regarded as being between square planar and tetrahedral. By considering the PNiP and ClNiCl angles of 158.45(3)° and 158.29(4)°, one gets the impression that the ligand is attempting unsuccessfully to behave as a *trans* spanning ligand. Clearly, complexation results in a strained chelate ring, as shown by the C(1)P(1)Ni and C(46)P(2)Ni angles of 109.9(1)° and 108.1(1)°, respectively, which are about 10° smaller than the other CPNi angles. It should be remembered here that, as shown in previous studies, calix[4]arenes having at least two proximal $-OCH_2PPh_2$ units display a marked propensity to form *cis*-chelated structures, no *trans* complexes having been reported to date. The NiP bond lengths [2.220(1), 2.247(1) Å] lie in the range found for complexes of the general formula *trans*-$[NiCl_2(PPh_2R)_2]$.[23–25]

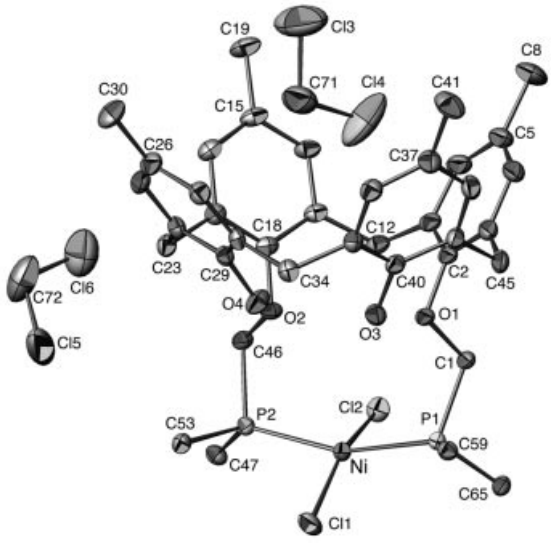


Figure 1. Molecular structure of the blue complex $[NiCl_2 \cdot \mathbf{1}] \cdot 2CH_2Cl_2$ ($\mathbf{2} \cdot 2CH_2Cl_2$); only the C_{ipso} atoms of the P-phenyl rings are shown; the *t*Bu groups are not shown in full

Complexes **3** and **4** were obtained as a binary mixture, but could be separated mechanically after crystallisation. They were prepared similarly to the method outlined above for **2**, but starting from anhydrous $NiBr_2$ (Equation 2). Crystallisation from dichloromethane/heptane afforded a mixture of crystals of turquoise **3** and red-brown **4**.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Obtaining this crystal mixture is easily reproducible. It appears likely that both compounds exist in equilibrium in solution, since dissolving crystals of either of them afforded the same green solution (toluene or CH_2Cl_2). The two molecular structures were determined by single-crystal X-ray diffraction studies (Figure 2 and 3). Again, both calixarenes adopt the shape of a cone having a "circular" cross section and both cavities host a dichloromethane molecule. As found in **2**, hydrogen bonds involving the hydroxy groups appear to stabilise the whole calixarene geometry (Table 1). The coordination geometry of **3** is close to that found in **2**, as can be seen from the PNiP and BrNiBr angles of 158.58(3)° and 152.19(2)°, respectively. In contrast, **4** has a conventional tetrahedral stereochemistry with considerably smaller PNiP [118.6(3)°] and BrNiBr [138.55(5)°] angles. Incidentally, the metallomacrocyclic unit of **4** is less strained than those of **2** and **3**. For example, the values of the $NiPC_\alpha$ angles in this unit are 119.0(1)° and 117.6(1)°. We note that in all three complexes, the Ni atom is orientated away from the calixarene axis. In each structure, a halogen atom approaches the axial H(12) atom but weak interactions with this methylene H are likely to occur in **2** and **3** [$H_{axial}(12)\cdots X$ distances (Å): 2.77, 2.84 and 3.00, respectively, for **2**, **3** and **4**]. These weak interactions could explain why the Ni−X(2) bonds of **2** and **3** are slightly but significantly longer than the corresponding Ni−X(1) bonds. Involvement of $ArCH_{axial}$ hydrogen atoms in weak bonding have recently been found in other calixarenes, in particular in some agostic CH···M interactions.[21] Finally, it is noteworthy that there is no indication in the syntheses outlined above of oligomer formation, illustrating the high degree of preorganisation of calixarene **1**.

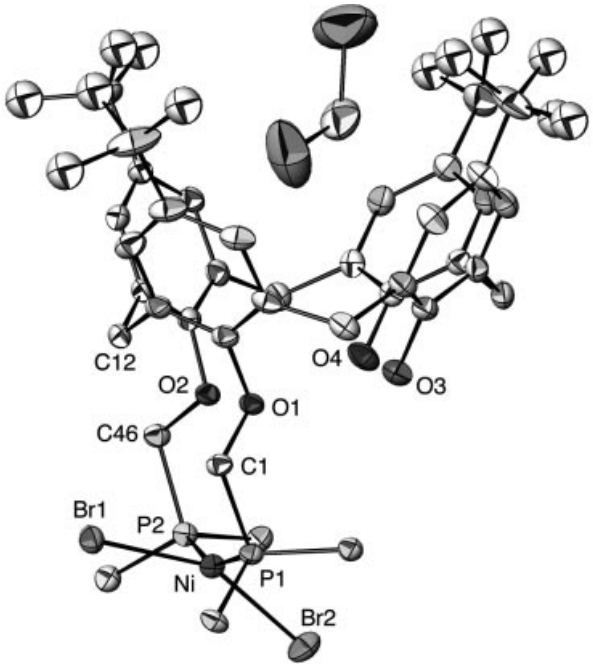

Figure 2. Molecular structure of the turquoise complex [$NiBr_2$·**1**]·$2CH_2Cl_2$ (**3**·$2CH_2Cl_2$); for clarity, only the C_{ipso} atoms of the P-phenyl rings are shown; the *t*Bu groups are not shown in full

It is well known that [$NiCl_2$(phosphane)$_2$] complexes constitute good precatalysts for the oligomerisation or polymerisation of olefins, the outcome of the reaction being strongly dependent on the nature of the phosphane.[26,27] Thus for example, [$NiCl_2(PCy_3)_2$] activated with $AlEt_2Cl$ becomes a highly selective ethylene dimerisation catalyst.[28] A typical activity for this complex is 1600 mol(C_2H_4)·mol(Ni)$^{-1}$·h^{-1}.[29] Other complexes, for instance

$[NiBr_2\{Ar_2PN(Me)PAr_2\}]$ (Ar = *o*-*i*PrC_6H_4), display a high ethylene polymerisation activity [with activities as high as 79000 mol(C_2H_4)·mol(Ni)$^{-1}$·h^{-1}] producing high molecular weight polymers.[30] Recent work on $[NiCl_2(chelate)]$ complexes has clearly underlined that a subtle combination of backbone rigidity and partial steric protection of the nickel centre is the determining factor for product distribution control.[31,32] It is also worth mentioning that to date, long chain diphosphanes having a backbone containing more than six carbon atoms have not been studied in olefin oligomerisation/polymerisation systems.[27,33] Reports dealing with generic calix[4]arenes that were employed in olefin polymerisation have appeared in the literature, but these remain scarce.[34−37]

In view of the fact that ligand **1** possesses a flexible bite angle, we decided to assess the role of complex **2** in ethylene oligomerisation. The runs were performed in toluene ([catalyst] = 0.3 mmol/dm^3) using methylaluminoxane (MAO) (1500 equiv.) as the activator. Operating under an ethylene pressure of 10 bar and stopping the reaction after 1 h, produced C_4 to C_{12} oligomers. The observed activity was 3100 mol(C_2H_4)·mol(Ni)$^{-1}$·h^{-1}. The product distribution is typically of the Schulz−Flory type, with α about 0.2 (Table 2).

Applying a pressure of 30 bar increased the activity up to 9800 mol(C_2H_4)·mol(Ni)$^{-1}$·h^{-1} without modifying the product distribution. Interestingly, no catalyst deactivation was observed during these 1 h experiments. As shown by the study outlined above, diphosphane **1** is able to undergo large bite angle variations but this has only little impact on the catalyst activity. For comparison, in terms of activity and selectivity, the catalyst performance compares with that of $[NiCl_2(Ph_2PCH_2PPh_2)]$, a complex in which the chelating unit is much more strained than that in **2**.[38] The structural studies revealed that, whatever the coordination geometry of nickel complexes containing **1**, the bulky calixarene core is remote from the nickel centre, resulting in a rather uncrowded metal environment and hence facilitating reductive elimination steps.

Conclusion

In this study we have shown that in the presence of NiX_2 moieties the large diphosphane **1** straightforwardly forms chelate complexes, thus confirming the good preorganisation of the ligand. While previous studies have shown that **1** and its congeners act exclusively as *cis*-chelators towards the $PtCl_2$ moiety, we have discovered that **1** is also able to adapt to various tetrahedral coordination geometries, some of them being extremely distorted. Thus, **1** gives access to bite angles lying in the range 103.4°−158.6°. The fact that to date no complex could be synthesised in which **1** behaves as a genuine *trans* chelator obviously arises from the rigidity of the spacer that links the P^{III} atoms as well as the shortness of the two phosphorus arms. The present work further demonstrates that ligand **1** is able to bring the metal centre closer to the calixarene axis than was previously observed in Pt^{II} complexes, although the PM vectors remain oriented outwards. Activation of **2** with MAO afforded a good ethylene oligomerisation catalyst resulting selectively in C_4−C_{12} oligomers. The formation of short oligomers suggests that during catalysis the nickel environment is slightly encumbered hence favouring reductive elimination over chain propagation. The formation of polymers could possibly be forced by orientating the PM vectors towards the calixarene axis so as to ensure partial protection of the metal. Further studies are aimed at exploiting the bite angle flexibility of diphosphane **1** in catalytic reactions.

Experimental Section

General Conditions: Solvents were dried with suitable reagents and freshly distilled under dry nitrogen before use. All reactions were carried out using modified Schlenk techniques under a dry nitrogen atmosphere. Elemental analyses were performed by the Service de Microanalyse, Centre de Recherche Chimie, Université Louis Pasteur, Strasbourg. 5,11,17,23-Tetra-*tert*-butyl-25,26-bis(diphenylphosphanylmethoxy)-27,28-dihydroxycalix[4]arene (**1**) was prepared according to the previously reported method.[19] MAO 10 wt.-% (Aldrich) was used as a white powder which was obtained after evaporation of the solvent (60 °C, 3 h). This treatment reduces the amount of residual trimethylaluminium to ca. 3%.

Synthesis of Dichloro-{5,11,17,23-tetra-*tert*-butyl-25,26-bis(diphenylphosphanylmethoxy)-27,28-dihydroxycalix[4]arene}nickel(II) (2): Anhydrous $NiCl_2$ (0.019 g, 0.15 mmol) was dissolved in hot ethanol (0.5 mL) whereupon a solution of **1** (0.153 g, 0.15 mmol) in CH_2Cl_2 (5 mL) was added. During addition the pale yellow solution turned deep blue. After 0.25 h, the solvent was removed in vacuo. The residue was treated with a small volume of pentane (5 mL) and the resultant suspension filtered through a glass frit. Cooling to −30 °C precipitated a dark blue powder which was dried in vacuo. Yield: 0.070 g, 40%. $C_{70}H_{78}Cl_2NiO_4P_2$ (M_r = 1174.93): calcd. C 71.56, H 6.69; found C 71.66, H 6.90. Single-crystals suitable for X-ray diffraction were obtained by slow diffusion at room temperature of hexane into a CH_2Cl_2 solution of the complex.

Synthesis of Dibromo-{5,11,17,23-tetra-*tert*-butyl-25,26-bis(diphenylphosphanylmethoxy)-27,28-dihydroxycalix[4]arene}nickel(II), Isomers 3 and 4: Anhydrous $NiBr_2$ (0.041 g, 0.19 mmol) was dissolved in hot ethanol (0.5 mL) resulting in a pale orange solution. A solution of **1** (0.200 g, 0.19 mmol) in CH_2Cl_2 (5 mL) was then added and the mixture turned green. After 0.25 h, the solution was evaporated to dryness. The residue was redissolved in CH_2Cl_2 (ca. 1 mL), whereupon pentane was added to precipitate a pale green powder which was recovered by filtration. Yield: 0.197 g, 82%. The green powder was then dissolved in CH_2Cl_2. Slow diffusion of heptane into the resultant intense green solution afforded crystals of **3** (turquoise colour) and **4** (red brown) which were separated mechanically. Elemental analyses were carried out on both isomers after drying in high vacuum: $C_{70}H_{78}Br_2NiO_4P_2$ (M_r = 1263.83): calcd. C 66.53, H 6.22; found for **3**: C 66.22; H 5.75; found for **4**: C 66.50; H 6.42.

Crystal Structure Determination of 2·2CH$_2$Cl$_2$: Single crystals of **2** suitable for X-ray diffraction analysis were obtained by slow diffusion of hexane into a CH_2Cl_2 solution of the complex. Data were collected with a Nonius KappaCCD diffractometer (graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å). The structure was solved by direct methods using the SHELXS-97 program and refined by full-matrix least-squares techniques (SHELXL-97) on F^2.[39] Hydrogen atoms were located using the geometric method. The crystal data and structural refinement details are listed in Table 3. The compound was found to crystallise with two molecules of dichloromethane, one of them lying inside the cavity. CCDC-234357 contains the supplementary crystallographic data for this structure. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Crystal Structure Determination of 3·2CH$_2$Cl$_2$ and 4·1.75CH$_2$Cl$_2$: Single crystals of **3** and **4** were obtained simultaneously by slow diffusion of heptane into a solution of [$NiBr_2$·**1**]. Data collection and structure solution were carried out as above for **2** (Table 3). The poorer quality of the structure of **4** is due to disordered solvent molecules, whether they lie inside or outside the cavity. CCDC-234358 (for **3**) and CCDC-234359 (for **4**). These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Oligomerisation of Ethylene: The catalytic runs were carried out in a 100 mL glass-lined stainless steel autoclave containing a magnetic stirring bar. In a typical run, a solution of complex **2** (0.007 g, 6 μmol) in toluene (15 mL) was introduced under nitrogen into the autoclave whereupon a solution of MAO (0.500 g) in toluene (5 mL) was added. After stirring for ca. 1 min the autoclave was pressurised with ethylene and the pressure (10 or 30 bar) was maintained at a constant value. During the runs described in this work, the temperature raised from 25 °C to 37 °C when operating at 10 bar and up to 42 °C under 30 bar. After 1 h, the autoclave was cooled to 7 °C and then depressurised over a period of 1 h. Heptane (200 μL), which serves as internal reference for the GC analysis, was then added to the reaction mixture. The liquid phase was analysed with a VARIAN 3900 gas chromatograph equipped with a WCOT fused silica column (25 m, 0.32 mm inside diameter, 0.25 mm film thickness).

(Schiff-base)Cu^{II} Complexes with Phenolate-Oxygen/Chloro or -Oxygen/Azido Mixed Bridges − Syntheses, Crystal Structures and Magnetic Properties

Yun-Bo Jiang,[a] Hui-Zhong Kou,*[a] Ru-Ji Wang,[a] and Ai-Li Cui[a]

Keywords: Chloro bridges / Azido bridges / Magnetic properties / Cu^{II} ions / Crystal structures

Four new Cu^{II} complexes of formulae $[Cu_3(SE)_2(H_2O)_2Cl_3]Cl{\cdot}6H_2O$ (**1**), $Cu_3(SE)_2(N_3)_4(DMF)_2$ (**2**), $Cu(SE)N_3{\cdot}DMF$ (**3**) and $Cu(SE)N_3{\cdot}Cu(SE)N_3$ (**4**) with tridentate Schiff-base ligands SE^-, derived from condensation of *N*,*N*-dimethylethylenediamine with salicylaldehyde, have been synthesised and characterised by IR spectroscopy, X-ray structural analyses and variable-temperature magnetic susceptibility measurements. Complex **1** has an alternating phenoxy- and chloro-bridged 1D chain structure. Complex **2** possesses trinuclear units in which the Cu^{II} ions are bridged by single end-on (μ-1,1) azido ligands. Uniformly spaced 1D chains with end-to-end (μ-1,3) azido bridges are found in **3** and **4**. As expected, complexes **1** and **2** exhibit antiferromagnetic and ferromagnetic exchange, respectively. Compounds **3** and **4** show unusual ferromagnetic coupling though the 1,3-azido pathways. Theoretical simulations have been carried out in order to evaluate the magnitude of the magnetic exchange and the magneto-structural correlation has been investigated.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

During the past decade, particular interest has been directed towards the investigation of copper(II) complexes with halogen bridging ligands as well as pseudohalogens, due to their correlative structures and ability to transmit magnetic interactions.[1−24] Among the ligands examined, the chloride anion has the capability of acting as either a bridging or a terminal ligand, occupying either axial or equatorial coordination positions. As a result, mono- or polynuclear complexes as well as 1D chain-like compounds have been obtained.[1−6] In addition, the azide ion is a versatile and popular pseudohalogen ligand due to its functionality as a bridging bi-, tri- and tetradentate ligand and its rich coordination behaviour, e.g. end-on (μ-1,1 and μ-1,1,1) or end-to-end (μ-1,3). These bridging ligands have yielded plenty of metal complexes with a wide variety of coordination geometries including tetrahedral or square-planar, trigonal-bipyramidal or square-pyramidal and octahedral, the geometry being dependent upon the coligands and the counterions.[8−24]

It has been reported that {*N*-[2-(dimethylamino)ethyl]-salicylaldiminato}copper(II) chloride, Cu(SE)Cl, can be synthesised in an anhydrous methyl/isopropyl alcohol medium.[7] A trinuclear complex $[Cu_3(\mu_3\text{-}OH)(SE)_3](ClO_4)_2(H_2O)_{0.5}$ containing a partially cubic Cu_3O_4 core was obtained from the reaction of $Cu(ClO_4)_2$ with SE^- in a methanol/water solution.[6] We have found, in the absence of ClO_4^-, the reaction between $CuCl_2$ and SE^- in a 1:1 molar ratio did not produce the expected 1:1 complex. Instead, a chain-like complex with the empirical formula $Cu_3(SE)_2(H_2O)_8Cl_4$ (**1**) was obtained which can be regarded as a mixture of $Cu(H_2O)_2Cl_2$ and Cu(SE)Cl (molar ratio = 1:2). It is worth noting that this complex exhibits an interesting and very rare structure, namely a 1D polymeric chain containing mixed bridges and hexa- and pentacoordinate copper atoms. The replacement of the bridging chloro ligands by azido ligands yields complexes with different structural types depending upon the solvents used (see Scheme 1). One example is the end-on azido-bridged trinuclear structure **2** $[Cu_3(SE)_2(N_3)_4(DMF)_2]$. $Cu(SE)N_3{\cdot}DMF$ (**3**) possesses a uniformly spaced end-to-end azido-bridged copper(II) chain while $Cu(SE)N_3{\cdot}Cu(SE)N_3$ (**4**) displays a chain structure similar to that of **3** with a cocrystallised mononuclear $Cu(SE)N_3$ unit. Herein, we report the syntheses, structural characterisation and magnetic properties of the four complexes.

Results and Discussion

Synthesis and General Characterisation

The trinuclear complex $[Cu_3(OH)(SE)_3](ClO_4)_2(H_2O)_{0.5}$ was always found to be the product from the reaction of $Cu(ClO_4)_2{\cdot}6H_2O$ with SE^- (molar ratio = 1:1).[6] We have observed that the employment of $CuCl_2{\cdot}2H_2O$ instead of $Cu(ClO_4)_2{\cdot}6H_2O$ results in the formation of the 1D chain complex $Cu_3(SE)_2(H_2O)_8Cl_4$ (Cu/SE^-, 3:2). The loss of the SE^- ligand around a Cu^{II} ion may be due to the partial hydrolysis of the Schiff base while in anhydrous solvent environments 1:1 complexes were formed, as previously re-

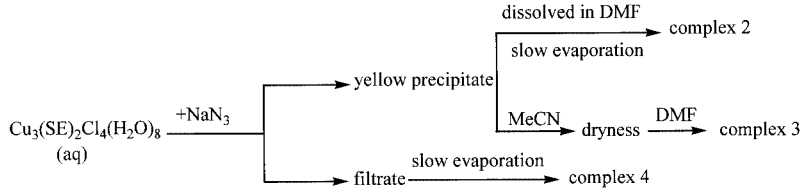

Scheme 1. Formation of Cu^{II} compounds

ported.[6,7] This observation indicates that the structures of Cu^{II}-SE$^-$ complexes vary with the synthetic conditions and counteranions used. Several complexes were obtained from the reaction of complex **1** with NaN_3.

The IR spectra of the complexes are similar and show peaks for the ν(C=N) bands at 1647 cm^{-1} in **1** and 1635 cm^{-1} in **2**, **3** and **4**, suggesting the presence of a Schiff base. The peaks at 1655 cm^{-1} in **2** and **3** can be reasonably attributed to the ν(C=O) of DMF. The appearance of a broad strong absorption at 3434 cm^{-1} in **1** indicates the presence of water molecules, consistent with the single-crystal X-ray diffraction results. Peaks at 2070 and 2031 cm^{-1} in the IR spectrum of **2** are due to the stretching of the μ-1,1 azide while the appearance of absorptions at 2074 and 2047 cm^{-1} in **3** and **4** is due to the asymmetric stretching of the μ-1,3 azide anions.

Crystal Structures

The structures of **1**−**4** are displayed in Figures 1−4, respectively. Selected bond lengths and angles for complexes **1** − 2.5H_2O, **2**, **3** and **4** are listed in Tables 1−4, respectively.

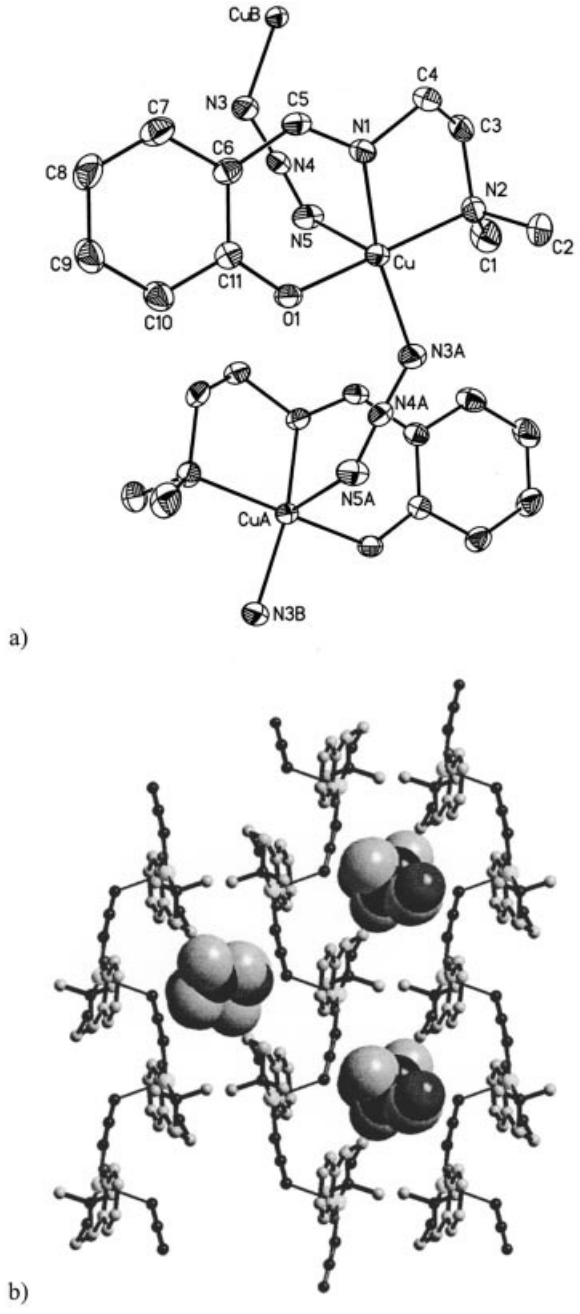

Figure 3. a) ORTEP representation of the 1D polymeric chain for **3** with the atom labelling scheme showing 30% probability thermal ellipsoids; for clarity hydrogen atoms and solvent DMF molecules have been omitted; b) view of the packing of the 1D chains in complex **3** (DMF was displayed in space-filling diagram)

The structure of **1** − 2.5H_2O consists of trinuclear cationic $[Cu_3(SE)_2(H_2O)_2Cl_3]_n^{n+}$ chains along the *a* axis formed by the chloro and phenolate oxygen bridges of SE^- (Figure 1), discrete Cl^- counteranions and solvated water molecules.

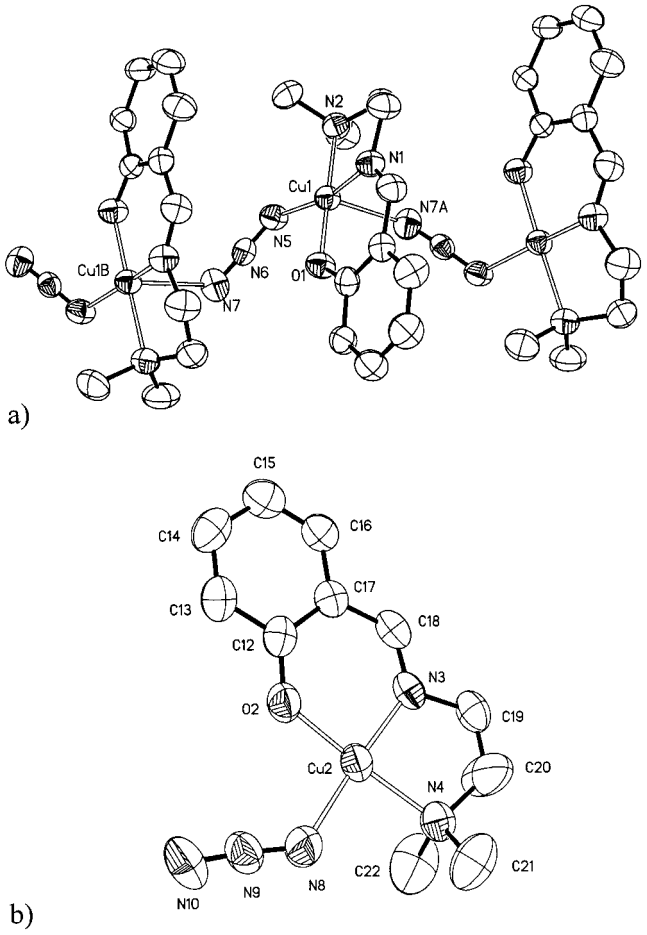

Figure 4. ORTEP representations of the structure of **4**: (a) the 1D chain, (b) the monomer with ellipsoids drawn at 30% probability level; for clarity hydrogen atoms have been omitted

Two of the copper atoms are pentacoordinate while the other is six-coordinate in the independent trinuclear fragment. Cu(1) and Cu(3) have slightly distorted square-pyramidal geometries as ascertained by the Reedijk factors τ of 0.113 and 0.132, respectively.[30] Cu(2) is in an elongated octahedral environment, being coordinated to two bridged chloro atoms [Cl(1) and Cl(2)] and four oxygen atoms, two of these being from water molecules [O(3) and O(4)] and two from the SE^- ligands [O(1) and O(2)]. For Cu(2), the Cu−Cl bonds [2.7176(15) and 2.7890(15) Å] are longer than Cu−O bonds [2.010(3), 1.984(4), 1.981(3) and 1.966(3) Å]. The elongated octahedron shares two equator-to-apex edges with the bases of two other square pyramids. The neighbouring pyramids share an apex occupied by a bridged chloro atom, yielding a 1D chain. Their basal planes, defined by N, N, O and Cl, are not coplanar and exhibit a dihedral angle of 21.1°, while the angles between these planes and the octahedral equatorial plane [O(1),O(2),O(3),O(4)] are 100° and 99.2°, respectively. Within the chain, the Cu(1)−Cu(2) distance is 3.257(7) Å, similar to the Cu(2)−Cu(3) distance of 3.223(7) Å, while the Cu(3)−Cu(1A) separation [5.161(14) Å] is very large.

Complex **2** contains a hexacoordinate and two pentacoordinate Cu^{II} ions which are bridged by the two end-on

azido ligands (Figure 2). The central copper atom has an elongated octahedral coordination geometry with four azido nitrogen atoms (two terminal ligands, two end-on dicoordinated bridging ligands) in equatorial positions [Cu−N 1.976(3)−2.042(3) Å] and two phenoxy oxygen atoms from the SE^- ligands in the axial positions (Cu−O 2.469 Å). Alternatively, the trinuclear structure of **2** is composed of two $[Cu(SE)(DMF)]^+$ cations connected by a $[Cu(N_3)_4]^{2-}$ anion through two azido ligands. Similar to complex **1**, the elongated octahedron shares two equator-to-vertex edges with the bases of two other square pyramids. With a τ factor of 0.048, the basal plane of the slightly distorted square pyramid is defined by N(2)−N(3)−N(4)-O(1) and the copper atom Cu(1) is 0.1570(5) Å above the basal plane towards the apical oxygen atom O(5) of the DMF molecule. The Cu−N−Cu angle is 102.34(13)°. It is evident that the basal planes of the square pyramids are perfectly coplanar, while the angle between these planes and the equatorial plane of the central copper ion is 70°. The intramolecular Cu(1)−Cu(2) distance is 3.150(5) Å.

The structure of **3** consists of end-to-end azido-bridged 1D infinite uniformly spaced chains with DMF molecules situated in the spaces between the chains (Figure 3). In the chain, each copper atom is coordinated by an SE^- ligand and two azido ligands in a slightly distorted square-pyramidal arrangement (τ = 0.110). The basal plane is defined by N(1)−N(2)−N(3A)−O(1) and the copper atom is 0.1482(4) Å above the basal plane towards N(5) in the apical position. The angles between the copper ions and the azido ligands are 119.1(2)° [Cu−N(5)−N(4)] and 127.0(2)° [Cu−N(3A)−N(4A)] and the Cu−N_3−Cu torsion angle is 81.5°. The intrachain Cu−Cu distance is 5.530(4) Å, while the closest interchain Cu−Cu distance is 7.671(5) Å. Interstitial DMF molecules occupy interchain spaces and connect neighbouring 1D chains through van der Waals interactions and hydrogen bonds.

Complex **4** contains 1D chains similar to complex **3** with discrete Cu(SE)N_3 monomers beside the chains (Figure 4). In the chains, each copper atom is in a slightly distorted square-pyramidal arrangement with a τ factor of 0.200. The basal plane of the square pyramid is defined by N(1)−N(2)−N(5)−O(1) and Cu^{2+} is 0.1264(8) Å above the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

basal plane towards the bridging azido nitrogen atom N(7A) in the apical position. The bond angles between copper ions and azido ligands are 124.4(5)° [Cu(1)−N(7A)−N(6A)] and 121.0(5)° [Cu(1)−N(5A)−N(6A)] and the torsion angle (Cu−N_3−Cu) is 80.2°. The intrachain Cu−Cu distance is 5.392(2) Å. The copper atom in the monomer is in a square-planar arrangement and is tetracoordinated by SE^- and one terminal azido ligand. The chains and monomers form a complicated network by hydrogen bonds and van der Waals interactions.

Magnetic Properties

The $\chi_M T$ value at 300 K for **1** is 1.229 emu·K·mol^{-1} and this decreases slowly with decreasing temperature. The Weiss constant derived from the χ_m^{-1} vs. T plot is equal to −12.8 K with the Curie constant of 1.26 emu·K·mol^{-1} being close to the calculated value of 1.125 emu·K·mol^{-1} (g = 2.0) per Cu_3 unit. The overall behaviour of **1** corresponds to a weak antiferromagnetically coupled system. To evaluate the strength of the intermetallic exchange constants of **1**, we used an approximate approach similar to that previously used for 1D and quasi-2D complexes.[32] On the basis of the crystal data, for simplicity, the two coupling constants between Cu(1) and Cu(2) and between Cu(3) and Cu(2) which are bridged by the phenoxy and chloro bridges were assumed to be equal. The single axis-to-axis Cu−Cl−Cu coupling constants were considerably small compared with the coupling through the phenolate oxygen and the equator-to-vertex chloro bridges. Therefore, the 1D chain can be treated as being composed of weakly interacting trimers. The magnetic susceptibility data were fitted using the following expansion [Equation (1)] in which intertrimer and interchain exchanges were included in the parameter θ:

$$\chi_{trimer} = \frac{Ng^2\beta^2}{4kT}\left[\frac{1+\exp(-2J/kT)+10\exp(J/kT)}{1+\exp(-2J/kT)+2\exp(J/kT)}\right] \quad (1)$$

$$\chi_M = \chi_{trimer}\frac{T}{T-\theta}$$

The results of the best fit, shown as the solid lines in Figure 5, are J = −4.89 cm^{-1}, g = 2.02 and θ = −0.69 K with the agreement factor $R = \Sigma[(\chi_M T)_{obsd.} - (\chi_M T)_{calcd.}]^2/\Sigma[(\chi_M T)^2_{obsd.}]$ of 6.7 × 10^{-4}.

Generally speaking, oxygen-bridging exchange interactions are much stronger than those involving halogens. On the basis of the structural data of **1**, the chloro-bridging conformation involves equator-to apex linkages [Cl(1) and Cl(2)] and axis-to-axis linkages [Cl(3)] while oxygen atoms occupy equator-to-equator positions. As a result, strong magnetic coupling with a large value ($|J|$ > 100 cm^{-1}) can be expected via the oxygen bridge. In our case, however, the observed superexchange interaction (J = −4.89 cm^{-1}) is smaller than expected. We have ascribed the low superexchange to the small overlap of neighbouring Cu^{II} $d_{x^2-y^2}$ magnetic orbitals. If the $d_{x^2-y^2}$ orbitals interact in the same plane, strong coupling can be observed. In complex **1**, there are large dihedral angles of 100° and 99.2° between the oxygen-bridging copper orbital planes. The delocalisation is poor due to the small overlap and, consequently, the low superexchange can be understood.

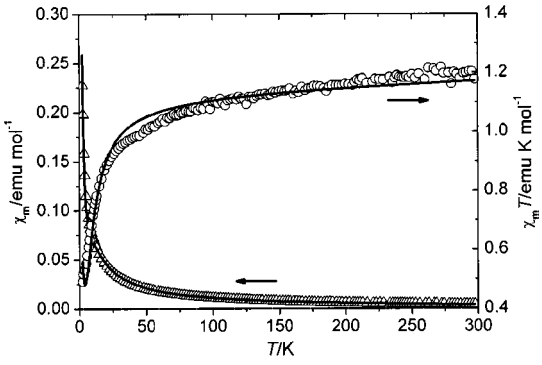

Figure 5. Plot of χ_M vs. T (open triangles) and $\chi_M T$ vs. T (open circles) for **1**; the solid lines represent the theoretical values based on the parameters described in the text

The temperature dependence of the magnetic susceptibility of complex **2** illustrated in Figure 6 suggests the presence of ferromagnetic coupling between the adjacent Cu^{II} ions. The Weiss constant derived from the χ_m^{-1} vs. T plot is equal to +12.1 K and the Curie constant of 1.31 emu·K·mol^{-1} is close to the calculated value of 1.125 emu·K·mol^{-1} (g = 2.0) per trimer. According to the crystal structure data, complex **2** has a symmetrical trinuclear entity which requires only one coupling constant. Similar to complex **1**, the magnetic susceptibility data can be successfully fitted using Equation (1) while intertrimeric exchange was included in the parameter θ. The best fit results, shown as the solid lines in Figure 6, are J = +32.6 cm^{-1}, g = 2.07 and θ = −0.44 K with R = 1.6 × 10^{-4}.

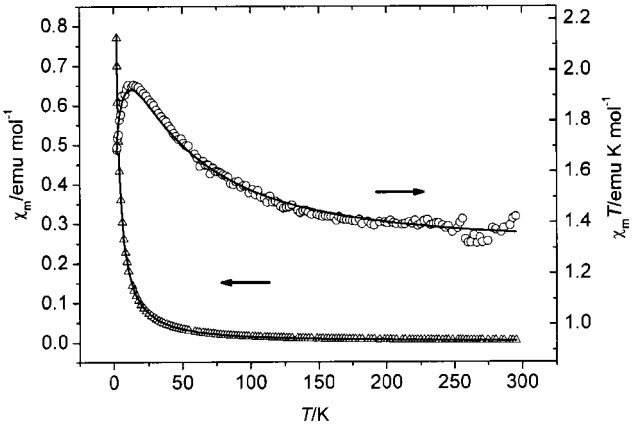

Figure 6. Plot of χ_M vs. T (open triangles) and $\chi_M T$ vs. T (open circles) for **2**; the solid lines represent the theoretical values based on the parameters described in the text.

Most of the $\mu_{1,1}$-azido bridged complexes are ferromagnetic as determined by the spin distribution in the spin triplet ground states according to the spin polarisation mechanism.[25,26] It has been widely cited that the superexchange

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

interactions via the end-on azido bridges become antiferromagnetic at higher Cu−N−Cu angles.[8−13] From the density functional study by Ruiz et al., the critical angle is 104°.[8] Also, Thompson et al. suggested that the realm of ferromagnetic coupling ceases for angles greater than 108°.[9] However, an unprecedented low Cu−N−Cu angle of 89.1° was recently reported with an actual antiferromagnetic coupling.[13] This has been assumed to be due to minimal orbital overlap in a basal-axial fashion and a Cu−N distance (2.505 Å) longer than the cutoff distance (2.05 Å) for ferromagnetic interactions. In our case, the ferromagnetic coupling is in agreement with a Cu−N−Cu angle of 102.4° which is lower than the critical angle of 104° and the Cu−N distances [2.001(3) and 2.042(3) Å] are shorter than 2.05 Å. Generally speaking, the basal-to-basal coordination suggests a strong exchange coupling parameter and the actual value of +32.6 cm^{-1} for **2** can be understood in spite of the moderately large dihedral angle (70°) between the neighbouring Cu basal $d_{x^2-y^2}$ orbital planes. It should be mentioned that we have not considered the possible interaction through phenolate oxygen groups. Obviously, the superexchange interaction is negligible due to its basal-to-axial orientation and a long Cu−O distance [2.469(3) Å].

The gradual increase of $\chi_M T$ values with decreasing T for compounds **3** and **4** clearly indicates the existence of intrachain ferromagnetic interactions (Figures 7 and 8). The magnetic susceptibilities above 20.0 K obey the Curie−Weiss law with positive Weiss constants (θ) of +9.68 K for **3** and +6.3 K for **4**, suggesting the existence of ferromagnetic coupling between the adjacent Cu^{II} ions. The Curie constant (C) is equal to 0.355 emu·K·mol^{-1} for **3** which is close to the expected value of 0.375 emu K mol^{-1} and g = 2.0, while the Curie constant of 0.747 emu K mol^{-1} for **4** is in good agreement with the calculated value of 0.75 emu·K·mol^{-1} (g = 2.0). On the basis of the structural data for complex **3**, the magnetic susceptibility data were fitted using the 1D S = 1/2 expression based on the Hamiltonian $\hat{H} = -J\Sigma S_i S_{i+1}$. According to Kahn, no analytical expression has yet been proposed for the ferromagnetic Cu^{II} 1D system. However, a high-temperature series expansion, valid for both positive and negative J values, has been proposed.[27,28]

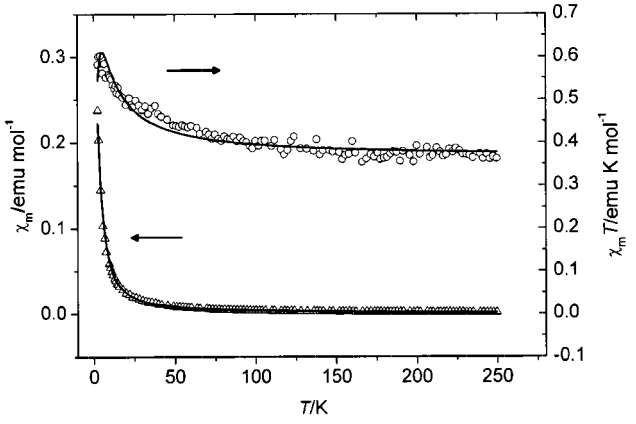

Figure 7. Plot of χ_M vs. T (open triangles) and $\chi_M T$ vs. T (open circles) for **3**; the solid lines represent the theoretical values based on the parameters described in the text

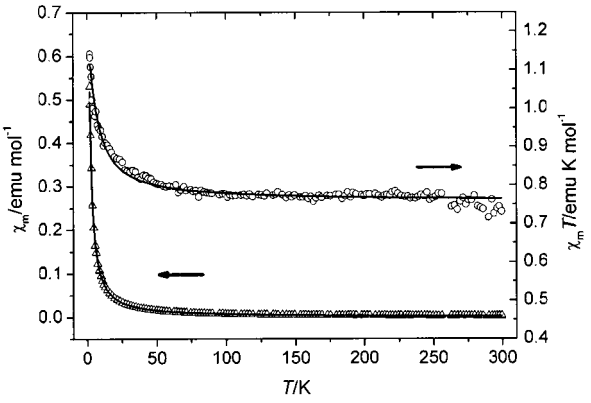

Figure 8. Plot of χ_M vs. T (open triangles) and $\chi_M T$ vs. T (open circles) for **4**; the solid lines represent the theoretical values based on the parameters described in the text

This expansion is:

$$\chi_{chain} = \frac{Ng^2\beta^2}{4kT}\left[\frac{A}{B}\right]^{2/3}$$

with $A = 1 + 5.7979916 \times x + 16.902653 \times x^2 + 29.376885 \times x^3 + 29.832959 \times x^4 + 14.036918 \times x^5$; $B = 1 + 2.7979916 \times x + 7.008678 \times x^2 + 8.6538644 \times x^3 + 4.5743114 \times x^4$ and $x = J/2kT$.

With the consideration of the interchain interactions:[29]

$$\chi_M = \frac{\chi_{chain}}{1-\chi_{chain}(2zJ'/Ng^2\beta^2)}$$

the best-fit results were obtained as J = +6.7 cm^{-1}, g = 2.0, zJ' = −1.3 cm^{-1} with $R = 1.5 \times 10^{-3}$.

Because complex **4** has a 1D chain similar to that in complex **3**, the magnetic susceptibilities of **4** were similarly simulated based on the chain model. The magnetic contribution of the discrete Cu(SE)N_3 monomer was added separately. All the non-intrachain interactions were included in the parameter zJ' using the molecular-field approximation.[29] This expansion is:

$$\chi_{chain} = \frac{Ng^2\beta^2}{4kT}\left[\frac{A}{B}\right]^{2/3}$$

$$\chi_{monomer} = \frac{Ng^2\beta^2}{4kT}$$

$$\chi_M = \frac{\chi_{chain} + \chi_{monomer}}{1-(\chi_{chain} + \chi_{monomer})(2zJ'/Ng^2\beta^2)}$$

The best fit results, as shown in Figure 8, are J = +4.64 cm^{-1}, g = 2.01 and zJ' = −0.30 cm^{-1} with $R = 2.6 \times 10^{-4}$.

For the end-to-end bridging mode of the azide, superexchange is generally antiferromagnetic in nature.[14,15,21−26] Recently, a few compounds have been reported to show a weak ferromagnetic interaction through the 1,3-bridging azido pathway.[16−20] It was found that in these unusual

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Cu^{II} complexes, the bridging azido ligand involves an equatorial linkage to one Cu^{II} ion and an axial coordination to another Cu^{II} ion in the square-pyramidal or elongate octahedral geometry.[16] It is known that for the copper(II) ions, the unpaired electrons occupy the $d_{x^2-y^2}$ orbitals while the d_{z^2} orbitals are filled with the paired electrons. Since the azido σ- and π-orbitals mainly overlap the full d_{z^2} orbitals via the axial interaction, there is almost no coupling between them and thus magnetic coupling is expected to be weak. Furthermore, the 1,3-azido pathway superexchange coupling mainly depends on the Cu−N−N angle α and the Cu−N−N−N−Cu torsion angle θ. Large α and θ values may strongly reduce the antiferromagnetic component of superexchange. In our examples, the effects of the Cu−N−N angles were not drastic (below 104°), so the effect of torsion angles should be dominant. The antiferromagnetic component decreases with increasing θ and becomes zero when $\theta = 90°$ due to accidental orthogonality. The antiferromagnetic interactions then increase until reaching the maximum when $\theta = 180°$.[31] The Cu−N−N−N−Cu torsion angles of 81.5° for **3** and 80.2° for **4** (close to 90°) nullify the antiferromagnetic component and, as a result, net weak ferromagnetic interactions can be observed and explained on the basis of the above arguments.

Conclusion

The present report describes the syntheses, X-ray crystal structures and magneto-structural correlations of four novel phenoxy/chloro- and phenoxy/azido-bridged Cu^{II} complexes. The syntheses of the four compounds are intriguing and the final products are strongly dependent on the synthetic conditions. The $\chi_M T$ data for **1** and **2** were simulated using a trinuclear model, while the data for **3** and **4** were treated using a 1D infinite chain model for $S = 1/2$. The unusual ferromagnetic behaviour of the two $\mu_{1,3}$-N_3-bridged 1D complexes has been rationalised qualitatively on the basis of the axial-equatorial bridging mode as well as the Cu−N_3−Cu torsion angles.

Experimental Section

General Remarks: Elemental analyses (C, H, N) were carried out with an Elementar Vario EL instrument. Infrared spectroscopy was performed with a Magna-IR 750 spectrophotometer in the 4000−400 cm^{-1} region. The TGA measurement of **1** was performed in the temperature range 20−300 °C under nitrogen with a Universal V2.6D TA instrument. Magnetic measurements were performed with a few single crystals (ca. 46 mg for **1**, 32.6 mg for **2**, 11.9 mg for **3** and 33.5 mg for **4**) using a MagLab 2000 magnetometer in a field of 10 kOe (**1**, **2** and **4**) or 20 kOe (**3**) from 2 to 300 K. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal's Tables).

Caution! Although not encountered in our experiments, azido complexes of metal ions are potentially explosive. Only small amounts of the materials should be prepared and they should be handled with care.

Synthesis of 1: *N*,*N*-Dimethylethylenediamine (5.5 mL, 50 mmol) in methanol (10 mL) was mixed with salicylaldehyde (7.605 g, 50 mmol) in methanol (10 mL). $CuCl_2 \cdot 2H_2O$ (8.525 g, 50 mmol) in water (50 mL) was then added slowly and the mixture was heated to reflux for 0.5 h. The resultant dark green solution was reduced to 50 mL by rotary evaporation. Dark green needle-shaped single crystals suitable for X-ray analysis separated after several days. Yield: 4.44 g (31%). $C_{22}H_{46}Cl_4Cu_3N_4O_{10}$ (828.03): calcd. C 30.76, H 5.40, N, 6.52; found C 30.98, H 5.26, N 6.63. IR (KBr): $\tilde{\nu}$ = 3434 (O−H, H_2O), 1647 (C=N) cm^{-1}. The water content of **1** was confirmed by thermogravimetric analysis.

Syntheses of 2, 3 and 4: A slight excess of sodium azide (57 mg, 0.88 mmol), dissolved in a minimum amount of water, was added to an aqueous solution (10 mL) of **1** (170.2 mg, 0.2 mmol) with continuous stirring. This gave an immediate yellowish-brown precipitate which was collected by filtration and used for the following synthesis. Dark green platelet crystals of **4** were obtained by concentration of the filtrate at room temperature. Yield: 33.5 mg (30%). $C_{11}H_{15}CuN_5O$ (593.64): calcd. C 44.51, H 5.09, N 23.59; found C 44.26, H 5.07, N 24.20. IR (KBr): $\tilde{\nu}$ = 2074, 2048 (N_3), 1635(C=N) cm^{-1}. The yellow brown precipitate was directly dissolved in DMF (10 mL). Black block-shaped crystals suitable for X-ray analysis were formed by slow concentration at room temperature over several weeks. Pure **2** was obtained by manual separation under a microscope. Yield: 32.6 mg (19%). $C_{28}H_{44}Cu_3N_{18}O_4$ (887.43): calcd. C 37.90, H 5.00, N 28.41; found C 37.12, H 4.94, N 27.82. IR (KBr): $\tilde{\nu}$ = 2070, 2031 (N3), 1655 (C=O, DMF), 1636 (C=N) cm^{-1}. The yellow-brown precipitate was at first dissolved in MeCN (10 mL). After concentration to dryness, the resultant microcrystalline solid was collected and dissolved in DMF (10 mL). Slow concentration of the DMF solution gave bluish-green crystals of **3** suitable for X-ray analysis. Yield: 11.9 mg (8%). $C_{14}H_{22}CuN_6O_2$ (369.92): calcd. C 45.46, H 5.99, N 22.72; found C 44.16, H 5.73, N 23.16. IR (KBr): $\tilde{\nu}$ = 2074, 2047 (N_3), 1655 (C=O, DMF), 1634 (C=N) cm^{-1}.

X-ray Crystallographic Study: The data collections for **1** − $2.5H_2O$, **2**, **3** and **4** were made with a Bruker Smart CCD (293 K) and a Siemens Bruker P4 diffractometer, respectively. Intensity data were corrected for Lorentz and polarisation factors. Absorption corrections were applied using SADABS (Bruker 2000) (complexes **1** − $2.5H_2O$, **3** and **4**) and ψ-scan (complex **2**). The structures were solved by direct methods (SHELXS-97) and refined by full-matrix least squares (SHELXL-97) on F^2. Hydrogen atoms attached to the C and N atoms were added geometrically and refined using the riding model. In complex **1** − $2.5H_2O$, considerable disorder of the interstitial water molecules was observed and a split model was employed during the refinement. The crystal data are summarised in Table 5. CCDC-239759 to -239762 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of (Vinylidene)- and (Cyclopropenyl)ruthenium Complexes Containing a Tris(pyrazolyl)borato (Tp) Ligand

Yih-Hsing Lo,[a] Ying-Chih Lin,*[a] Gene-Hsiang Lee,[a] and Yu Wang[a]

Keywords: Cyclopropenyl / N ligands / Ruthenium / Vinylidene ligands

A convenient high-yield route to [Ru(C≡C–Ph)(Tp)(PPh_3)$_2$] [**2**; Tp = HB(pz)$_3$, pz = pyrazolyl] has been found through the intermediacy of [$RuCl_2$(Hpz)$_2$(PPh_3)$_2$] (**1**). This complex is readily obtained on treatment of [$RuCl_2(PPh_3)_3$] with 2 equiv. of pyrazole in boiling THF. The molecular structures of complexes **1** and **2** have been confirmed by single-crystal X-ray diffraction analysis. A number of new cationic vinylidene complexes [Ru{=C=C(Ph)CH_2R}(Tp)(PPh_3)$_2$]$^+$ [**3a**, R = CN; **3b**, R = HC=CH_2; **3c**, R = CH=C(CH_3)$_2$; **3d**, R = Ph; **3e**, R = C(O)OMe] have been prepared by electrophilic addition of organic halides to complex **2**. The deprotonation reaction of **3a** yields the cyclopropenyl complex **4a**. One phosphane ligand of **4a** is remarkably labile, being replaced by donor ligands L to yield diastereomeric mixtures of the cyclopropenyl complexes **5a**–**5d** mostly in an approximate 4:1 ratio. The cyclopropenyl rings in **4a** and **5a** are susceptible to ring opening by I_2. In addition, treatment of **4a** with *n*BuNC in the presence of MeOH results in substitution of a phosphane ligand by *n*BuNC followed by protonation of the three-membered ring by MeOH. This is then followed by addition of methoxide to give the vinyl ether complex [Ru{C(OMe)=C(Ph)CH_2CN}(Tp)(PPh_3)(*n*BuNC)] (**8a**).

Introduction

The hydrotris(pyrazol-1-yl)borate (Tp) ligand has been used to stabilize a wide variety of transition-metal complexes since its discovery by Trofimenko,[1] and the development of Tp chemistry within group VIII, in particular, has accelerated recently.[1c,1d] Tp is often compared with Cp (η^5-C_5H_5) due to the same charge and number of electrons donated, although their differences in size and electronic properties are obvious. Thus, the cone angle of Tp (close to 180°) is well above the value of 100° calculated for Cp. The steric bulkiness of the Tp ligand appears to disfavor higher coordination numbers or bulky metal fragment. Much of the chemistry of the [CpRu(PPh_3)$_2$]$^+$ fragment can be traced to the strongly π-basic nature of the ruthenium center. Replacing Cp with Tp increases the basicity of the metal center further, and it has been claimed that it also leads to more ideally octahedral hybridization.[2] The chemistry of (vinylidene)transition-metal complexes has attracted increasing attention in recent years especially because of their application as key intermediates in stoichiometric and catalytic transformations of organic molecules.[3] Representative examples of ruthenium-based catalysis involving vinylidene complexes have been reported for the cyclization of dienylalkynes,[4a] the dimerization of HC≡C*t*Bu,[4b] and the tandem cyclization/reconstructive addition of propargyl alcohols with allyl alcohols.[4c] A key characteristic of vinylidene complexes appears to be the electrophilicity of the α-carbon atom, which adds, often easily, amines,[5] alcohols,[6,7] phosphanes,[8] and even fluoride.[6a]

The reactions of metal complexes with cyclopropenes often generate interesting chemistry, mainly due to the large amount of strain energy (ca. 50 kcal/mol) in the three-membered ring.[9] This molecule has played a crucial role in the development of the important concept of aromaticity, and its chemical reactivity has been extensively explored.[10] The syntheses of cyclopropenyl-containing metal derivatives in which the metal atom is bonded to the sp^3-hybridized carbon atom of the cyclopropene ring have been reported in the literature.[11] However, only a few examples of such derivatives in which the metal atom is bonded to the sp^2-carbon atom of the three-membered ring have been reported.[12] A few structurally different (cyclopropenylidene)-transition-metal complexes, mostly prepared from dichlorocyclopropene,[13] and a number of π-cyclopropene complexes,[14] are also known.

During the course of our investigations into (vinylidene)ruthenium chemistry, we previously studied the formation of several interesting neutral cyclopropenyl complexes.[6] For example, the cationic complex [RuCp{=C=C(Ph)CH_2CN}(PPh_3)$_2$]$^+$ was found to undergo deprotonation to afford the yellow cyclopropenyl complex. The cationic nature of the vinylidene complex, along with the presence of an electron-withdrawing functionality such as a CN group at C-γ of the vinylidene ligand, play a role in enhancing the acidity of the proton next to the CN group. Thus, addition of a base successfully brings about an intra-

molecular cycloaddition leading to the formation of a neutral cyclopropenyl complex. To elaborate the breadth of such a system, we set out to study analogous ruthenium complexes containing a Tp ligand. Herein, we report the synthesis of a series of new cationic vinylideneruthenium complexes and new neutral cyclopropenyl complexes in high yields. The reaction of the cyclopropenyl complex with I_2 to give a new vinylidene complex is also reported.

Results and Discussion

Preparation of (Tp)metal Acetylide Complexes

We have previously reported[6b] that $[RuCl(Tp)(PPh_3)_2]$ reacts with phenylacetylene in the presence of NaOMe to afford the acetylide complex $[Ru(C{\equiv}C{-}Ph)(Tp)(PPh_3)_2]$ (**2**). However, complex **2**, prepared using this method, is persistently contaminated with the starting material because of incomplete conversion. Therefore, a new synthetic approach to prepare **2** has been developed (Scheme 1). This new, convenient, high-yield route to **2** proceeds through the intermediacy of $[RuCl_2(Hpz)_2(PPh_3)_2]$ (**1**) (Hpz = pyrazole). This compound is readily obtained as an air-sensitive yellow solid in 97% yield upon treatment of $[RuCl_2(PPh_3)_3]$ with 2 equiv. of pyrazole in boiling THF for 1 h. Complex **1** is soluble in $CHCl_3$, CH_2Cl_2, MeOH, CH_3CN and THF but insoluble in hexane, and was characterized by a combination of elemental analysis and ^1H and $^{13}C\{^1H\}$ NMR spectroscopy. Characteristic ^1H NMR spectroscopic data for **1** include a singlet at $\delta = 11.67$ ppm assignable to the proton of the pyrazole ligand. In addition, the solid-state structure was determined by a single-crystal X-ray diffraction study. An ORTEP diagram is shown in Figure 1 (with selected bond lengths and angles). The coordination geometry of **1** is approximately octahedral with both pyrazole ligands *N*-bonded. The ruthenium atom is at the center, with the nitrogen atoms of the two pyrazole ligands and two PPh_3 ligands occupying the equatorial positions and the axial positions being occupied by two *trans*-chlorine atoms. The Ru−N(1) and Ru−N(3) bond lengths are 2.133(5) and 2.127(5) Å, respectively. The two Ru−Cl bonds of 2.428(2) and 2.426(2) Å are similar to those found in other (pyrazole)ruthenium complexes, such as 2.427(2) and 2.392(2) Å in $[RuCl_2(HPz)(DMSO)_3]$ and 2.427(1) and 2.397(1) Å in $[RuCl_2(HPz)_2(DMSO)_2]$.[15] Pyrazoles and their deprotonated form (pyrazolate anions) are attractive ligands that exhibit a rich coordination chemistry.[16] Pyrazoles and substituted pyrazoles usually behave as monodentate ligands[17] and these monodentate pyrazoles may give rise to interesting processes such as prototropic equilibrium or reversible metal−ligand binding, which are relevant to biological systems.[18]

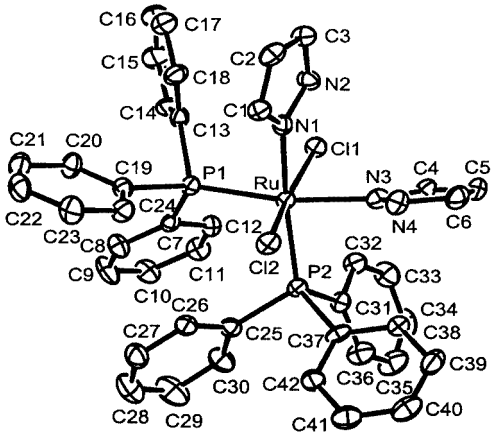

Figure 1. ORTEP drawing of complex **1** (30% probability ellipsoids); selected bond lengths [Å] and angles [°]: Ru−P(1) 2.3423(20), Ru−P(2) 2.3421(20), Ru−N(1) 2.133(5), Ru−N(3) 2.127(5), Ru−Cl(1) 2.4283(19), Ru−Cl(2) 2.4261(19); N(1)−Ru−N(3) 83.24(20)

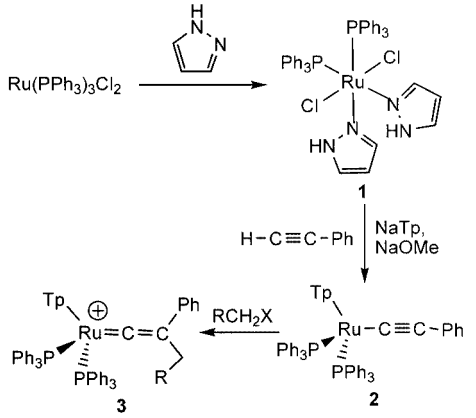
The one-pot reaction of **1** with NaTp and phenylacetylene in the presence of NaOMe gives the ruthenium acetylide complex $[Ru(C{\equiv}C{-}Ph)(Tp)(PPh_3)_2]$ (**2**). The yield of this one-pot reaction was higher than the yield obtained from the previously reported reaction that required several steps.[6b] The ν(B−H) vibration of **2** is found at 2489 cm^{-1}, which is characteristic of Tp bound to a metal center in a terdentate (N,N,N) manner. Yellow crystals of **2** were obtained by slow diffusion of hexane into a $CHCl_3$ solution of **2** at room temperature for 3 d. The molecular structure of **2** was determined by an X-ray diffraction study. An ORTEP diagram is shown in Figure 2 (with selected bond lengths and angles). The coordination geometry of complex **2** is approximately octahedral. The Ru−C(1) bond length of 2.006(6) Å is typical of an Ru−C single bond. The Ru−C(1)−C(2) bond angle of 173.9(5)° and C(1)−C(2) bond length of 1.205(8) Å are characteristic of a ruthenium acetylide complex.



Scheme 1

Cationic (Tp)(vinylidene)metal Complexes

Treatment of **2** with ICH_2CN affords the cationic vinylidene complex $[Ru\{{=}C{=}C(Ph)CH_2CN\}(Tp)(PPh_3)_2]I$ (**3a**) in 90% yield (Scheme 1).[9b] In the presence of excess NH_4PF_6 the counteranion is replaced by PF_6^-. Similarly,

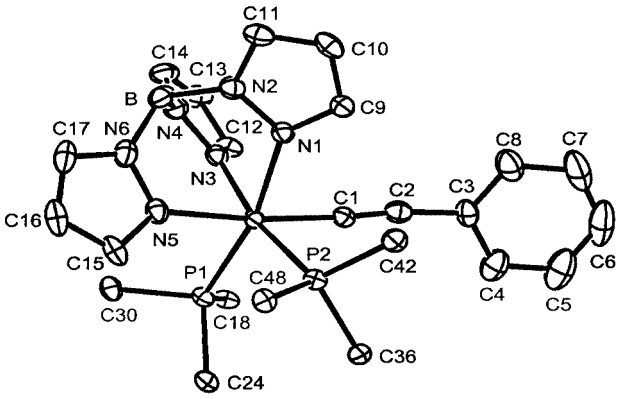

Figure 2. ORTEP drawing of complex **2** (30% probability ellipsoids); the carbon atoms of the phenyl groups (except the *ipso*-carbon atoms) on the triphenylphosphane have been eliminated for clarity; selected bond lengths [Å] and angles [°]: Ru−C(1) 2.006(6), C(1)−C(2) 1.205(8), C(2)−C(3) 1.439(9); Ru−C(1)−C(2) 173.9(5), C(1)−C(2)−C(3) 167.8(6)

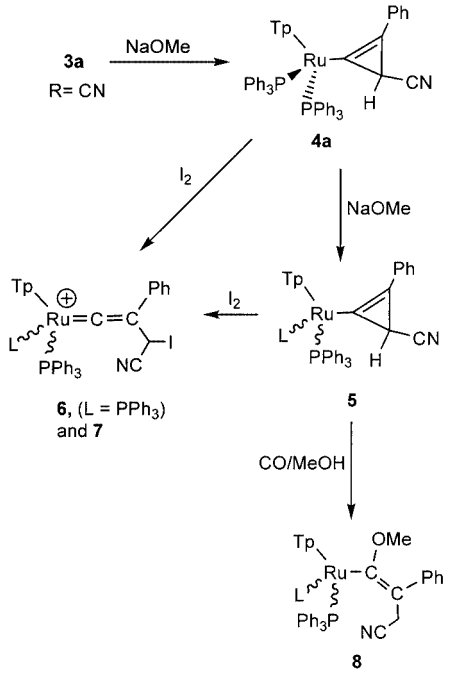
the preparation of other vinylidene complexes $[Tp(PPh_3)_2Ru{=}C{=}C(Ph)CH_2R]^+$ [**3b**, R = CH=CH_2; **3c**, R = CH=$C(CH_3)_2$; **3d**, R = Ph; **3e**, R = C(O)OMe] was accomplished by treating **2** with the corresponding halides; they were all isolated in high yields. With the exception of **3e**, all the vinylidene complexes mentioned above were prepared in CH_2Cl_2 at room temperature; mild heating was required for the synthesis of **3e**, and a mixture of CH_2Cl_2/$CHCl_3$ (3:1, v/v) was used as solvent in order to achieve a slightly higher reaction temperature. Complexes **3a**−**3e** are all soluble in polar solvents such as $CHCl_3$, CH_2Cl_2, MeOH and CH_3CN but insoluble in acetone, diethyl ether and hexane. These complexes are green in the solid state. Characteristic spectroscopic data of theses vinylidene complexes consist of a strongly deshielded C-α resonance as a triplet at $\delta = 370 \pm 5$ ppm in the ^{13}C NMR spectrum and a singlet ^{31}P NMR resonance at $\delta = 36 \pm 1$ ppm in $CDCl_3$ at room temperature; this is due to the fluxional behavior of the vinylidene ligand.[19] The spectroscopic data of the Cp analogues are similar; the triplet C-α resonance appears at $\delta = 340 \pm 5$ ppm in the ^{13}C NMR spectrum and a singlet ^{31}P NMR resonance is observed at $\delta = 42 \pm 1$ ppm. The newly formed carbon−carbon bond of these vinylidene complexes is easily cleaved in the presence of acid. Complexes **3a**−**3d** are all stable at room temperature for a period of 3 d, after which they decomposed to give unidentified products.

(Cyclopropenyl)(Tp)metal Complexes

The neutral complex $[Ru\{C{=}C(Ph)CH(CN)\}(Tp)(PPh_3)_2]$ (**4a**) can be readily prepared in high yield by deprotonation of **3a** at 0 °C in CH_2Cl_2 (Scheme 2). However, no deprotonation was observed for the other vinylidene complexes **3b**−**3d**, even in the presence of NaOMe, nBu_4NF (1 M in THF), DBU (1,8-diazabicyclo[5.4.0]undecene) or KOH (dissolved in a minimum amount of H_2O) at room temperature for 24 h. We have previously prepared neutral cyclopropenyl complexes containing a Cp ligand by deprotonation of the cationic vinylidene precursors.[19] Cyclopropenyl complexes with substituents such as vinyl, dimethylvinyl, phenyl and methyl ester groups are all achievable. The chemistry of the $[CpRu(PPh_3)_2]^+$ fragment can be traced to the strongly π-basic nature of the ruthenium center. Replacing Cp with Tp increases the basicity of the metal center and reduces the cationic character of the vinylidene complexes. Complexes **3b**−**3e** all lack enough cationic character to lead to intramolecular cycloaddition. We thus believe that the facile deprotonation of cationic vinylidene complexes may be ascribed to the combined effect of the cationic character and the presence of the electron-withdrawing substituent of the vinylidene complex.



Scheme 2

The analogous Cp complex of **4a** is stable with respect to ligand substitution — the phosphane ligand binds strongly to the ruthenium center, making the coordination site unavailable for an incoming substrate. In contrast, the Tp complex **4a** is susceptible to ligand substitution under relatively mild conditions. This may be attributed to the increased steric bulkiness of the Tp ligand relative to Cp. For example, when 2 equiv. of PhCN, *p*-$CF_3C_6H_4CN$, *n*BuNC or *t*BuNC were added at room temperature to a CH_2Cl_2 solution of **4a** a smooth reaction ensued over 1 h which afforded good yields of the bright-yellow (cyclopropenyl)ruthenium complexes $[Ru\{C{=}C(Ph)CH(CN)\}(Tp)(PPh_3)(L)]$ (**5a**, L = *n*BuNC; **5b**, L = *t*BuNC; **5c**, L = *p*-$CF_3C_6H_4CN$; **5d**, L = PhCN), respectively (Scheme 2). Significantly, when these reactions were repeated using only 1 equiv. of L much lower yields (ca. 8%) were obtained.

Complexes **5a**−**5d** all contain two diastereomers in a 4:1 ratio. The ^1H NMR resonances of **5a** attributed to the CHCN moiety of the three-membered rings of the major and the minor isomers appear at $\delta = 0.93$ and 1.16 ppm,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

respectively. In the $^{13}C\{^1H\}$ NMR spectrum, singlet ^{13}C resonances at δ = 3.8 and 3.5 ppm and doublet resonances at δ = 128.7 and 128.8 ppm, with $^2J_{P,C}$ coupling constants of 11.6 and 11.5 Hz, are assigned to the CHN and the ruthenium-bonded C-α carbon atoms of the major and the minor isomers, respectively. Interestingly, in the cases of **5c** and **5d** the major isomer is more stable than the minor isomer; the minor isomer decomposes within about 3 h.[6b] In the $^{13}C\{^1H\}$ NMR spectrum of **5c**, the singlet resonance at δ = 4.10 ppm and the doublet resonance at δ = 132.6 ppm, with a $^2J_{P,C}$ coupling of 12.3 Hz, are assigned to the CHN and the ruthenium-bonded C-α carbon atoms of the major isomer; the ^{13}C NMR spectrum of the minor isomer was not obtained because of its lower stability. Complexes **5a** and **5b** are stable in diethyl ether and THF, but in $CHCl_3$ compounds **5b**, **5c**, **5d** are less stable than **5a**. Furthermore, **5b** decomposes in $CHCl_3$ producing [RuCl(Tp)(PPh_3)(*t*BuNC)] and some unidentified organic products. Decomposition of **5c** and **5d** produces complicated mixtures. The stability of the substituted cyclopropenyl complexes was found to decrease in the order *n*BuNC > *t*BuNC > *p*-$CF_3C_6H_4CN$ > PhCN.

Opening of the Three-Membered Ring by Electrophiles

Treatment of **4a** with I_2 at 0 °C afforded the cationic vinylidene complex [Ru{=C=C(Ph)CH(I)(CN)}(Tp)(PPh_3)$_2$]I (**6**) in 79% yield (Scheme 2). Complex **6** is a green solid and its spectroscopic data display the features of a vinylidene complex. The pattern of two-doublet resonances at δ = 34.3 and 33.6 ppm, with a $J_{P,P}$ coupling of 26.9 Hz, in the ^{31}P NMR spectrum arises from the stereogenic C-γ center. In the ^1H NMR spectrum of **6** the resonance at δ = 3.23 ppm is assigned to the CHICN group, and in the $^{13}C\{^1H\}$ spectrum the triplet resonance at δ = 374.5 ppm, with a $^2J_{P,C}$ coupling of 15.1 Hz, is assigned to the vinylidene C-α atom. Similarly, treatment of **5a** with I_2 affords the addition product [Ru{=C=C(Ph)CH(I)(CN)}(Tp)(PPh_3)(*n*BuNC)]I (**7**) in high yield. Interestingly, only one diastereoisomer is observed for **7**. The ^1H NMR spectrum of **7** displays one singlet resonance at δ = 3.56 ppm, assigned to the CHICN group; the doublet resonance at δ = 367.3 ppm, with a $^2J_{P,C}$ coupling of 16.4 Hz, in the ^{13}C NMR spectrum is assigned to the vinylidene C-α atom. Formation of these vinylidene complexes occurs by selective cleavage of the cyclopropenyl single bond near the metal center. No alkylation is observed when **4a** is treated with CH_3I, CH_3CH_2I, CH_2=$CHCH_2Br$, CH≡$CHCH_2Br$ or ICH_2CN.

Reaction of 4a with nBuNC in the Presence of MeOH

Reaction of **4a** with *n*BuNC in the presence of MeOH causes substitution of a phosphane ligand by *n*BuNC. This is followed by protonation of the three-membered ring to give a vinylidene intermediate and addition of MeO^- to give the vinyl ether complex [Ru{C(OMe)=C(Ph)CH_2CN}(Tp)(PPh_3)(*n*BuNC)] (**8a**). Similarly, the reaction of **4a** with *t*BuNC in the presence of MeOH gives the vinyl ether product [Ru{C(OMe)=C(Ph)CH_2CN}(Tp)(PPh_3)(*t*BuNC)] (**8b**) in lower yield, which may be due to steric effects. The ^1H NMR spectrum of **8a** displays an AB pattern for the CH_2CN moiety, with two doublets centered at δ = 3.86 and 2.79 ppm with a coupling constant of 16.4 Hz. The characteristic $^{13}C\{^1H\}$ NMR spectroscopic features of **8a** and **8b** comprise downfield resonances at δ = 179.1 and 182.2 ppm, respectively, assignable to the vinyl C-α atom. In the absence of MeOH these reactions give the simple substitution products **5a** and **5b**, respectively. The reaction proceeds with substitution as the first step, followed by opening of the cyclopropenyl ring by MeOH to give the vinylidene ligand. This was confirmed by a separate experiment where **5** was allowed to react with MeOH, resulting in protonation followed by a nucleophilic attack of methoxide at C-α of the vinylidene ligand to give the final product. In our previous paper we reported that MeOH is able to open three-membered rings in some cases.[6]

Concluding Remark

The (cyclopropenyl)ruthenium complex **4a**, containing a Tp ligand, has been prepared by deprotonation of the vinylidene precursor **3a**. No deprotonation was observed in the reaction of **3b**−**3e** with NaOMe or nBu_4NOH which may be attributed to the reduced cationic character of vinylidene complexes caused by the presence of the Tp ligand. Unlike its Cp analogue, complex **4a** undergoes a facile phosphane substitution reaction with several two-electron donor molecules. This property was taken advantage of to prepare novel complexes of Ru. For example, *n*BuNC readily displaces one of the phosphane ligands of **4a** to give a mixture of diastereomers **5** in a 4:1 ratio. Reaction of **4a** with *n*BuNC in the presence of MeOH gives the vinyl ether product **8a**, which results from a displacement reaction followed by nucleophilic addition of the MeO^- group at C-α.

Experiment Section

General Procedures: All manipulations were performed under nitrogen using vacuum-line, drybox, and standard Schlenk techniques. CH_3CN and CH_2Cl_2 were distilled from CaH_2 and diethyl ether and THF from Na/benzophenone ketyl. All other solvents and reagents were of reagent grade and were used without further purification. NMR spectra were recorded with Bruker AC-200 and AM-300WB FT NMR spectrometers at room temperature (unless stated otherwise) and are reported in δ units with residual protons in the solvent as an internal standard [$CDCl_3$: δ = 7.24 ppm; CD_3CN: δ = 1.93 ppm; $CD_3C(O)CD_3$: δ = 2.04 ppm]. FAB mass spectra were recorded with a JEOL SX-102A mass spectrometer. Elemental analyses and X-ray diffraction studies were carried out at the Regional Center of Analytical Instrument at the National Taiwan University. The complexes [$RuCl_2(PPh_3)_3$][20] and **4a**[6] were prepared according to literature methods.

Synthesis of [$RuCl_2(C_3H_3NNH)_2(PPh_3)_2$] (1): Pyrazole (0.38 g, 5.60 mmol) was added to a solution of [$RuCl_2(PPh_3)_3$] (2.45 g,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2.80 mmol) in 20 mL of THF, and the reaction mixture was heated to 60 °C for 1 h. After cooling and removal of the solvent under reduced pressure, the residue was dissolved in CH_2Cl_2. Addition of hexane afforded a bright yellow precipitate, which was filtered off, washed with hexane and dried under vacuum to give **1** (2.12 g, 91% yield). ^{1}H NMR ($CDCl_3$): δ = 5.91 (t, $J_{H,H}$ = 2.3 Hz, 3 H, Tp), 7.32−6.91 (m, Ph, Tp), 8.09 (d, $J_{H,H}$ = 2.1 Hz, 3 H, Tp), 11.67 (s, 2 H, NH) ppm. ^{31}P NMR ($CDCl_3$): δ = 40.8 ppm. MS (FAB): *m*/*z* = 832.1 [M^+], 764.2 [M^+ − HPz], 502.2 [M^+ − HPz − PPh_3]. $C_{42}H_{38}BCl_2N_4P_2Ru$ (832.68): calcd. C 60.58, H 4.60, N 6.73; found C 60.46, H 4.54, N 6.65.

Preparation of [Ru(C≡C−Ph)(Tp)(PPh$_3$)$_2$] (2): An excess of phenylacetylene (4.17 mL, 36.1 mmol) and NEt_3 (6.3 mL, 36.1 mmol) were added to 50 mL of an MeOH solution of **1** (3.00 g, 3.61 mmol), and the solution was heated to reflux for 90 min. The yellow precipitate thus formed was filtered off and washed with MeOH and hexane. The product was dried under vacuum and was subsequently identified as compound **2** (3.43 g, 97% yield). Yellow crystals of **2** were obtained by slow diffusion of hexane into a $CHCl_3$ solution of **2** at room temperature. ^{1}H NMR ($CDCl_3$): δ = 5.20 (d, $J_{H,H}$ = 1.8 Hz, 1 H, Tp), 5.31 (t, $J_{H,H}$ = 2.1 Hz, 1 H, Tp), 5.54 (t, $J_{H,H}$ = 2.3 Hz, 2 H, Tp), 7.24−6.91 (m, Ph, Tp), 7.40 (d, $J_{H,H}$ = 2.0 Hz, 2 H, Tp), 7.58 (d, $J_{H,H}$ = 2.1 Hz, 1 H, Tp) ppm. ^{13}C NMR [$CD_3C(O)CD_3$]: δ = 122.7 (C-β), 135.8 (t, $J_{C,P}$ = 12.3 Hz, C-α), 145.7−127.2 (Ph, Tp) ppm. ^{31}P NMR ($CDCl_3$): δ = 48.6 ppm. MS (FAB): *m*/*z* = 940.1 [M^+], 678.1 [M^+ − PPh_3], 577.1 [M^+ − PPh_3 − C_2Ph], 363.0 [M^+ − PPh_3 − C_2Ph − Tp]. $C_{53}H_{44}BN_6P_2Ru$ (938.75): calcd. C 67.81, H 4.72, N 8.95; found C 67.94, H 4.59, N 8.91.

Synthesis of [Ru{=C=C(Ph)CH$_2$(CH=CH$_2$)}(Tp)(PPh$_3$)$_2$]I (3b): $ICH_2{=}CH_2$ (0.46 mL, 3.5 mmol) was added to a Schlenk flask charged with complex **2** (1.41 g, 1.50 mmol) in 50 mL of CH_2Cl_2. The clear solution was stirred for 16 h and then the volume of solvent was reduced to about 5 mL. This mixture was slowly added to 90 mL of vigorously stirred diethyl ether. The green precipitate thus formed was filtered off and washed with diethyl ether and hexane to give compound **3b** (1.33 g, 77%). ^{1}H NMR ($CDCl_3$): δ = 3.05 (d, $J_{H,H}$ = 5.5 Hz, 2 H, CH_2), 4.95 (dd, $J_{H,H}$ = 15.3, 2.7 Hz, 1 H, =CH), 5.05 (dd, $J_{H,H}$ = 10.3, 2.7 Hz, 1 H, =CH), 5.38 (d, $J_{H,H}$ = 1.9 Hz, 1 H, Tp), 5.53 (m, 1 H, CH=), 5.56 (t, $J_{H,H}$ = 1.9 Hz 1 H, Tp), 5.61 (t, $J_{H,H}$ = 2.1 Hz, 2 H, Tp), 6.59−7.42 (m, Ph), 7.57 (d, $J_{H,H}$ = 2.2 Hz, 2 H, Tp), 7.84 (d, $J_{H,H}$ = 1.9 Hz 1 H, Tp) ppm. ^{13}C NMR ($CDCl_3$): δ = 14.0 (CH_2), 105.8 (=CH_2), 118.4 (C-β), 105.9−146.2 (m, Ph, Tp), 153.8 (=CH), 377.5 (t, $J_{C,P}$ = 16.3 Hz, C-α) ppm. ^{31}P NMR ($CDCl_3$): δ = 37.8 ppm. MS (FAB): *m*/*z* = 981.3 [M^+ − I], 719.3 [M^+ − I − PPh_3], 577.1 [M^+ − I − PPh_3 − $C_2PhCH_2CH{=}CH_2$]. $C_{56}H_{50}BIN_6P_2Ru$ (1107.7): calcd. C 60.71, H 4.55, N 7.59; found C 60.62, H 4.43, N 7.63.

[Ru{=C=C(Ph)CH$_2$CH=C(Me)$_2$}(Tp)(PPh$_3$)$_2$]Br (3c): Yield 1.36 g, in 83%; prepared in a similar manner from 1.43 g (1.52 mmol) of **2** and excess $BrCH_2CH{=}C(Me)_2$ (3.7 mmol) at room temperature. ^{1}H NMR ($CDCl_3$): δ = 1.18 (s, 3 H, Me), 1.62 (s, 3 H, Me), 3.12 (d, $J_{H,H}$ = 5.1 Hz, 2 H, CH_2), 4.90 (m, 1 H, CH=), 5.42 (t, $J_{H,H}$ = 1.9 Hz, 1 H, Tp), 5.54 (t, $J_{H,H}$ = 2.2 Hz, 2 H, Tp), 6.41 (d, $J_{H,H}$ = 2.1 Hz, 1 H, Tp), 6.45 (d, $J_{H,H}$ = 2.0 Hz, 2 H, Tp), 6.96−7.42 (m, Ph) 7.66 (d, $J_{H,H}$ = 2.0 Hz, 2 H, Tp), 7.83 (d, $J_{H,H}$ = 2.1 Hz, 1 H, Tp) ppm. ^{13}C NMR ($CDCl_3$): δ = 18.1 (CH_2), 21.2 (Me), 25.6 (Me), 118.3 (C-β), 104.3−146.5 (Ph, Tp), 379.8 (t, $J_{C,P}$ = 15.8 Hz, C-α) ppm. ^{31}P NMR ($CDCl_3$): δ = 37.9 ppm. MS (FAB): *m*/*z* = 1009.3 [M^+ − Br], 747.3 [M^+ − Br − PPh_3], 577.1 [M^+ − Br − PPh_3 − $C_2PhCH_2CH{=}CMe_2$]. $C_{58}H_{54}BBrN_6P_2Ru$ (1088.8): calcd. C 63.98, H 5.00, N 7.72; found C 63.87, H 4.91, N 7.81.

[Ru{=C=C(Ph)CH$_2$Ph}(Tp)(PPh$_3$)$_2$]I (3d): Yield 1.45 g, in 87%; prepared in a similar manner from 1.50 g (1.59 mmol) of **2** and excess $BrCH_2Ph$ (0.40 mL, 3.0 mmol) at room temperature. ^{1}H NMR ($CDCl_3$): δ = 3.90 (s, 2 H, CH_2), 5.29 (br, 1 H, Tp), 5.34 (br, 1 H, Tp), 5.39 (br, 1 H, Tp), 5.54 (t, $J_{H,H}$ = 2.0 Hz, 2 H, Tp), 7.73−6.59 (m, Ph, Tp), 7.86 (d, $J_{H,H}$ = 2.1 Hz, 1 H, Tp) ppm. ^{13}C NMR ($CDCl_3$): δ = 16.0 (CH_2), 147.3−108.4 (Ph, Tp), 378.5 (t, $J_{C,P}$ = 15.8 Hz, C-α) ppm. ^{31}P NMR ($CDCl_3$): δ = 37.4 ppm. MS (FAB): *m*/*z* = 1031.4 [M^+ − Br], 769.5 [M^+ − Br − PPh_3], 577.1 [M^+ − Br − PPh_3 − C_2PhCH_2Ph]. $C_{60}H_{52}BBrN_6P_2Ru$ (1110.8): calcd. C 64.87, H 4.72, N 7.57; found C 64.91, H 4.67, N 7.41.

Preparation of [Tp(PPh$_3$)$_2$Ru=C=C(Ph)CH$_2$COOMe]Br (3e): A mixture of complex **2** (2.80 g, 3.10 mmol) and $BrCH_2COOMe$ (0.5 mL, 5.10 mmol) in 40 mL of CH_2Cl_2/CH_3Cl (3:1) was heated to reflux for 6 h. The workup procedure was the same as that for **3d**. Purification by recrystallization from CH_2Cl_2/hexane (1:5) gave **3e** (1.45 g, 87% yield). ^{1}H NMR ($CDCl_3$): δ = 3.10 (s, 2 H, CH_2), 3.59 (s, 3 H, OMe), 5.45 (br, 1 H, Tp), 5.53 (br, 1 H, Tp), 5.61 (br, 1 H, Tp), 5.77 (t, $J_{H,H}$ = 2.0 Hz, 2 H, Tp), 6.32 (br, 2 H, Tp), 7.57−6.59 (m, Ph, Tp), 7.65 (d, $J_{H,H}$ = 1.9 Hz, 2 H, Tp), 7.79 (d, $J_{H,H}$ = 2.0 Hz, 1 H, Tp) ppm. ^{13}C NMR ($CDCl_3$): δ = 19.1 (CH_2), 57.1 (CH_3), 106.4−145.6 (Ph, Tp), 171.4 (COO), 378.5 (t, $J_{C,P}$ = 15.6 Hz, C-α) ppm. ^{31}P NMR ($CDCl_3$): δ = 38.4 ppm. MS (FAB): *m*/*z* = 1013.3 [M^+ − Br], 751.2 [M^+ − Br − PPh_3], 577.4 [M^+ − Br − PPh_3 − C_2PhCH_2COOMe]. $C_{56}H_{50}BBrN_6O_2P_2Ru$ (1092.7): calcd. C 61.55, H 4.61, N 7.69; found C 61.61, H 4.51, N 7.82.

Synthesis of 5a: Complex **4a** (0.50 g, 0.51 mmol) was dissolved in CH_2Cl_2 (20 mL), and *n*BuNC (0.05 mL, 0.51 mmol) was added. The mixture was stirred for 50 min to afford a bright-yellow solution. The solvent was then removed under vacuum and the solid residue was extracted with 20 mL of diethyl ether. The extract was filtered through Celite, and the filtrate was dried to give a bright-yellow solid, which was washed with hexane (2 × 10 mL), and dried under vacuum to give a mixture of diastereoisomers of **5a** (0.327 g, 80.3% yield). ^{1}H NMR [$CD_3C(O)CD_3$]: major isomer: δ = 0.75 (t, $J_{H,H}$ = 7.5 Hz, 3 H, CH_3), 0.93 (s, 1 H, C*H*), 1.23 (m, 2 H, CH_2), 1.53 (m, 2 H, CH_2), 3.72 (t, $J_{H,H}$ = 6.6 Hz, 2 H, CH_2), 5.88 (t, $J_{H,H}$ = 2.2 Hz, 1 H, Tp), 5.96 (t, $J_{H,H}$ = 2.1 Hz, 1 H, Tp), 6.01 (t, $J_{H,H}$ = 1.8 Hz, 1 H, Tp), 6.76 (br, 1 H, Tp), 6.78 (br, 1 H, Tp), 6.86 (br, 1 H, Tp), 7.69 (d, $J_{H,H}$ = 2.0 Hz, 1 H, Tp), 7.07−7.40 (m, Ph), 7.81 (d, $J_{H,H}$ = 2.0 Hz, 1 H, Tp), 7.88 (d, $J_{H,H}$ = 2.1 Hz, 1 H, Tp) ppm; minor isomer: δ = 0.77 (t, $J_{H,H}$ = 7.4 Hz, 3 H, CH_3), 1.16 (s, 1 H, C*H*CN), 1.26 (m, 2 H, CH_2), 1.55 (m, 2 H, CH_2), 3.84 (t, $J_{H,H}$ = 6.7 Hz, 2 H, CH_2), 6.14 (t, $J_{H,H}$ = 2.2 Hz, 1 H, Tp), 6.21 (t, $J_{H,H}$ = 2.1 Hz, 1 H, Tp), 6.34 (t, $J_{H,H}$ = 2.0 Hz, 1 H, Tp), 6.76 (br, 1 H, Tp), 6.94 (br, 2 H, Tp), 7.40 −7.07 (m, Ph), 7.71 (d, $J_{H,H}$ = 2.1 Hz, 1 H, Tp), 7.92 (d, $J_{H,H}$ = 1.9 Hz, 1 H, Tp), 8.12 (d, $J_{H,H}$ = 2.0 Hz, 1 H, Tp) ppm. ^{13}C NMR [$CD_3C(O)CD_3$]: major isomer: δ = 3.8 (CH), 13.5 (*C*H_3), 20.2 (*C*H_2), 32.3 (*C*H_2), 44.8 (*C*H_2), 116.3 (CN), 128.7 (d, $J_{C,P}$ = 11.6 Hz, C-α), 146.9 −129.3 (Ph, Tp), 160.1 (d, $J_{C,P}$ = 22.5 Hz, *C*N) ppm; minor isomer: δ = 3.5 (CH), 13.5 (*C*H_3), 20.2 (*C*H_2), 32.2 (*C*H_2), 44.7 (*C*H_2), 115.2 (CN), 128.8 (d, $J_{C,P}$ = 11.6 Hz, C-α), 129.3−146.9 (Ph, Tp), 163.2 (d, $J_{C,P}$ = 21.3 Hz, *C*N) ppm. ^{31}P NMR [$CD_3C(O)CD_3$]: δ = 54.1, 52.7 (4:1) ppm. MS (FAB): *m*/*z* = 800.3 [M^+], 660.3 [M^+ − $C_2PhCHCN$], 577.2 [M^+ − $C_2PhCHCN$ − *n*BuNC]. $C_{42}H_{40}BN_8PRu$ (799.65): calcd. C 63.08, H 5.04, N 14.01; found C 62.98, H 4.96, N 13.89.

Synthesis of 5b: Complex **4a** (1.01 g, 1.03 mmol) was dissolved in CH_2Cl_2 (30 mL), and *t*BuNC (0.11 mL, 1.03 mmol) was added.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The mixture was stirred at room temperature to afford a bright-yellow solution. The solvent was then removed under vacuum, and the solid residue was extracted with 20 mL of diethyl ether. The extract was filtered, and the filtrate was dried to give a bright-yellow solid, which was washed with hexane (2 × 10 mL) and dried under vacuum to give a diastereomeric mixture of **5b** (0.62 g, 79.1% yield). ^{1}H NMR [$CD_3C(O)CD_3$]: major isomer: δ = 0.96 (s, 1 H, C*H*), 1.47 (s, 9 H, Me), 5.81 (t, $J_{H,H}$ = 2.1 Hz, 1 H, Tp), 5.97 (t, $J_{H,H}$ = 2.1 Hz, 1 H, Tp), 6.11 (t, $J_{H,H}$ = 1.9 Hz, 1 H, Tp), 6.71 (br, 1 H, Tp), 6.74 (br, 1 H, Tp), 6.83 (br, 1 H, Tp), 7.46 −7.07 (m, Ph), 7.73 (d, $J_{H,H}$ = 2.1 Hz, 1 H, Tp), 7.80 (d, $J_{H,H}$ = 2.2 Hz, 1 H, Tp), 7.82 (d, $J_{H,H}$ = 2.0 Hz, 1 H, Tp) ppm; minor isomer: δ = 1.08 (s, 1 H, C*H*), 1.48 (s, 9 H, Me), 6.13 (t, $J_{H,H}$ = 2.1 Hz, 1 H, Tp), 6.20 (t, $J_{H,H}$ = 2.0 Hz, 1 H, Tp), 6.32 (t, $J_{H,H}$ = 2.2 Hz, 1 H, Tp), 6.72 (br, 1 H, Tp), 6.99 (br, 2 H, Tp), 7.42−7.17 (m, Ph), 7.67 (d, $J_{H,H}$ = 2.0 Hz, 1 H, Tp), 7.92 (d, $J_{H,H}$ = 2.1 Hz, 1 H, Tp),8.11 (d, $J_{H,H}$ = 2.0 Hz, 1 H, Tp) ppm. ^{13}C NMR [$CD_3C(O)CD_3$]: major isomer: δ = 3.8 (CH), 32.1 (C*Me*$_3$), 58.7 (*C*Me$_3$), 119.2 (CN), 126.5 (d, $J_{C,P}$ = 12.1 Hz, C-α), 141.9 −129.3 (Ph, Tp), 163.4 (d, $J_{C,P}$ = 21.4 Hz, *C*N) ppm; minor isomer: δ = 3.5 (CH), 31.2 (*Me*$_3$), 55.3 (*C*Me$_3$), 118.9 (CN), 127.1 (d, $J_{C,P}$ = 11.2 Hz, C-α), 129.3−146.9 (Ph, Tp), 164.1 (d, $J_{C,P}$ = 20.1 Hz, *C*N) ppm. ^{31}P NMR [$CD_3C(O)CD_3$]: δ = 52.9, 53.9 (4:1) ppm. C 64.47, H 4.43, N 13.69; found C 64.49, H 4.44, N 13.63.

Synthesis of 5d: An excess of $CF_3C_6H_4CN$ (0.14 mL, 2.04 mmol) was added to a solution of **4a** (1.00 g, 1.02 mmol) in 20 mL of CH_2Cl_2. The solution was stirred for 50 min (the color changed from yellow to brown) and then the solvent was removed under vacuum. The solid residue was extracted with diethyl ether, and the extract was filtered. The volume of the resulting solution was reduced to 5 mL and 40 mL of hexane was added to form a orange precipitate, which was filtered and washed twice with 10 mL of hexane. The product was dried under vacuum (0.70 g, 77% yield). ^{1}H NMR [$CD_3C(O)CD_3$] major isomer: δ = 1.08 (s, 1 H, C*H*), 5.85 (t, $J_{H,H}$ = 2.2 Hz, 1 H, Tp), 5.98 (t, $J_{H,H}$ = 2.1 Hz, 1 H, Tp), 6.02 (t, $J_{H,H}$ = 1.8 Hz, 1 H, Tp), 6.76 (br, 1 H, Tp), 6.78 (br, 1 H, Tp), 6.86 (br, 1 H, Tp), 7.07−7.40 (m, Ph), 7.69 (d, $J_{H,H}$ = 2.0 Hz, 1 H, Tp), 7.81 (d, $J_{H,H}$ = 2.2 Hz, 1 H, Tp), 7.85 (d, $J_{H,H}$ = 2.2 Hz, 1 H, Tp) ppm; minor isomer: δ = 0.82 (s, 1 H, C*H*), 5.91 (t, $J_{H,H}$ = 2.0 Hz, 1 H, Tp), 6.05 (t, $J_{H,H}$ = 1.9 Hz, 1 H, Tp), 6.07 (d, $J_{H,H}$ = 2.1 Hz, 2 H, Tp), 6.46 (d, $J_{H,H}$ = 2.0 Hz, 2 H, Tp), 6.89 (d, $J_{H,H}$ = 2.0 Hz, 2 H, Tp), 7.01−7.64 (m, Ph), 7.97 (d, $J_{H,H}$ = 2.1 Hz, 2 H, Tp) ppm. ^{13}C NMR [$CD_3C(O)CD_3$]: major isomer: δ = 5.1 (CH), 110.6 (q, $J_{C,F}$ = 282.0 Hz, *C*F$_3$), 111.2 (NCPh), 118.1 (CN), 131.7 (d, $J_{C,P}$ = 11.9 Hz, C-α), 148.2−126.6 (Ph, Tp) ppm. ^{31}P NMR [$CD_3C(O)CD_3$]: δ = 53.6, 54.3 (4:1) ppm. MS (FAB): *m*/*z* = 888.4 [M$^+$ + 1], 718.4 [M$^+$ + 1 − $CF_3C_6H_4CN$], 577.1 [M$^+$ + 1 − $CF_3C_6H_4CN$ − C_2PhCHCN]. $C_{45}H_{35}BF_3N_8PRu$ (887.63): calcd. (CH_2), 31.1 (CH_2), 43.1 (CH_2), 55.4 (OMe), 115.5 (CN), 123.4−147.6 (Ph), 162.1 (d, $J_{C,P}$ = 23.1 Hz, *C*N),179.1 (d, $J_{C,P}$ = 15.3 Hz, C-α) ppm. ^{31}P NMR [$CD_3C(O)CD_3$]: δ = 46.9 ppm. MS (FAB): *m*/*z* = 832.3 [M^+], 660.1 [M^+ − (OMe)C=C(Ph)(CH_2CN)], 577.1 [M^+ − (OMe)C=C(Ph)(CH_2CN) − *n*BuNC]. $C_{43}H_{44}BN_8OPRu$ (831.69): calcd. C 62.08, H 5.33, N 13.47; found C 62.16, H 5.40, N 13.35.

Synthesis of [Ru{C(OMe)=C(Ph)CH_2CN}Tp(PPh_3)(*t*BuNC)] (8b): Complex **4a** (0.5 g, 0.51 mmol) was dissolved in CH_3OH (20 mL), and *t*BuNC (0.30 mL, 3.02 mmol) was added. The mixture was stirred for 50 min to afford a bright-yellow solution. The solvent was then removed under vacuum and the solid residue was extracted with diethyl ether. The extract was filtered, and the filtrate was dried under vacuum to give a bright-yellow solid, which was washed with hexane (2 × 10 mL), and dried to give **8b** (0.327 g, 80.3% yield). ^1H NMR [$CD_3C(O)CD_3$]: δ = 1.44 (s, 9 H, C*Me*$_3$), 2.84, 3.87 (2d, $J_{H,H}$ = 15.3 Hz, 1 H, CH_2CN), 5.61 (br, 1 H, Tp), 6.15 (br, 1 H, Tp), 6.21 (br, 1 H, Tp), 6.43 (br, 1 H, Tp), 6.96−7.56 (m, Ph, Tp), 7.78 (d, $J_{H,H}$ = 2.2 Hz, 1 H, Tp) ppm. ^{13}C NMR [$CD_3C(O)CD_3$]: δ = 32.7 (C*Me*$_3$), 55.4 (OMe), 113.2 (CN), 123.4−147.6 (Ph), 182.2 (d, $J_{C,P}$ = 16.1 Hz, C-α) ppm. ^{31}P NMR [$CD_3C(O)CD_3$]: δ = 46.8 ppm. MS (FAB): *m*/*z* = 832.2 [M^+], 660.1 [M^+ − (OMe)C=C(Ph)(CH_2CN)], 577.1 [M^+ − (OMe)C=C(Ph)(CH_2CN) − *t*BuNC]. $C_{43}H_{44}BN_8OPRu$ (831.69): calcd. C 62.08, H 5.33, N 13.47; found C 62.11, H 5.34, N 13.51.

X-ray Diffraction Analysis: Dark-yellow crystals of **1** suitable for an X-ray diffraction study were grown directly from CH_2Cl_2. A suitable single crystal of dimensions 0.10 × 0.40 × 0.50 mm was glued to a glass fiber and mounted on a Nonius CD4 diffractometer. The data were collected using Mo-K_α radiation (at 298 K). The data were processed and the structure was solved and refined with the SHELXTL program. The structure was solved by direct methods and confirmed by Patterson methods. Hydrogen atoms were placed geometrically using the riding model with thermal parameters set to 1.2-times that of the atom to which they are attached (1.5-times for the methyl hydrogen atoms). Yellow crystals of **2** suitable for an X-ray diffraction study were obtained as above. A suitable single crystal of dimensions 0.05 × 0.10 × 0.15 mm was mounted on a SMART CCD diffractometer. The data were collected using 3-kW sealed-tube Mo-K_α radiation (at 298 K). The exposure time was 5 s per frame. SADABS (Siemens area detector absorption) absorption correction was applied, and decay was negligible. Data were processed with the SHELXTL program.[21] The structure was solved by direct methods refining on intensities of all data. Hydrogen atoms were placed geometrically using the riding model. Crystal data for **1** and **2** are listed in Table 1.

Table 1. Crystal data and structure refinement for **1** and **2**

A Comparison of Analogous 4f- and 5f-Element Compounds: Syntheses, X-ray Crystal Structures and Catalytic Activity of the Homoleptic Amidinate Complexes [M{MeC(NCy)$_2$}$_3$] (M = La, Nd or U)

Claude Villiers,*[a] Pierre Thuéry,[a] and Michel Ephritikhine*[a]

Keywords: ε-Caprolactone / Lanthanides / N ligands / Polymerization / Uranium

Reaction of UCl_4 with [Li{RC(NCy)$_2$}(THF)]$_2$ (R = Me, **1a**; R = *n*Bu, **1b**) in THF gave the tris(amidinate) compounds [U{RC(NCy)$_2$}$_3$Cl] (R = Me, **2a**; R = *n*Bu, **2b**) which were reduced with lithium powder in THF to the homoleptic complexes [U{RC(NCy)$_2$}$_3$] (R = Me, **3a**; R = *n*Bu, **3b**). Complexes **1a**, **1b**, **2a** and **3a** have been crystallographically characterized. Comparison of the crystal structure of **3a** with those of the lanthanide analogues [Ln{MeC(NCy)$_2$}$_3$] (Ln = La, **4**; Ln = Nd, **5**; Ln = Yb, **6**) shows that the average U–N distance is shorter than expected from a purely ionic bonding model. The uranium complex **3a** is much less efficient than its lanthanide counterparts in the catalytic polymerization of ε-caprolactone because of its rapid oxidation into U^{IV} species.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Amidinate complexes of main group and d-block transition metals are currently receiving a great deal of interest, especially for use in the catalytic polymerization of alkenes and lactides.[1] Homoleptic metal amidinates were also recently found to be useful precursors for atomic layer deposition of thin films.[2] A major advantage of the bidentate [RC{NR′}$_2$]$^-$ anions, which are considered as alternatives to the ubiquitous cyclopentadienyl-based ligands, is the easy modification of both their steric bulk and electronic properties through changes to the R and R′ substituents. In this context, special attention has been paid during the last decade to the bis(benzamidinate) complexes of group 3 metals and lanthanides as they exhibit catalytic activities similar to those of the corresponding metallocenes.[3] More recently, homoleptic tris(amidinate) lanthanide complexes have proved to be efficient catalysts for the ring-opening polymerization of ε-caprolactone.[4]

The amidinate ligand was introduced into 5f-element chemistry by Edelmann et al. who synthesized a series of bis- and tris(benzamidinate) compounds of thorium(IV) and uranium(IV), [M{ArC(NSiMe$_3$)$_2$}$_3$Cl] and [M{ArC(NSiMe$_3$)$_2$}$_2$Cl$_2$] (M = Th, U) and their derivatives,[5] the uranium(V) complex [U{(C$_6$H$_4$Me)C(NSiMe$_3$)$_2$}$_2$Cl$_3$][6] and the uranyl compound [UO$_2$\{PhC(NSiMe$_3$)$_2$\}$_2$].[7] Another complex, [{UCl(μ-Cl)(L)(NSiMe$_3$)}$_2$][UCl$_2$(L)(L′)]$_2$, in which L is a β-diketiminate and L′ a benzamidinate ligand, can be considered either as a [{U^{VI}}$_2$][U^{III}]$_2$ or a [{U^{IV}}$_2$][U^{V}]$_2$ mixed-valence salt.[8] Here we report on the first well-characterized uranium(III) amidinate complexes, [U{RC(NCy)$_2$}$_3$] (R = Me, *n*Bu), which were prepared by reduction of the chloride precursors [U{RC(NCy)$_2$}$_3$Cl]. We describe the crystal structures of these U^{III} and U^{IV} compounds, as well as those of the lithium amidinates [Li{RC(NCy)$_2$}(THF)]$_2$, and finally we present the activity of the homoleptic complexes in ε-caprolactone polymerization, and we compare the structural features and catalytic properties of [U{MeC(NCy)$_2$}$_3$] with those of the lanthanide analogues.

Results and Discussion

The Lithium Amidinate Complexes [Li{RC(NCy)$_2$}(THF)]$_2$ (R = Me, *n*Bu)

Addition of MeLi or *n*BuLi to *N*,*N*′-dicyclohexylcarbodiimide in THF, according to Equation (1), led to the formation of the lithium amidinates [Li{RC(NCy)$_2$}(THF)]$_2$ (R = Me, **1a**; R = *n*Bu, **1b**) which were isolated as colorless crystals in almost quantitative yield.

$$\text{Cy–N=C=N–Cy} + \text{RLi} \xrightarrow{\text{THF}} 0.5\,[\text{Li}\{\text{RC(NCy)}_2\}(\text{THF})]_2 \quad \text{R = Me, 1a; R = } n\text{Bu, 1b} \tag{1}$$

The two compounds were characterized by ^{1}H NMR spectroscopy (Table 1) and an X-ray crystal structure. A

[a] Individual values are given for the two independent complex molecules, mean values include both of them. Primed atoms are related to the unprimed ones by the symmetry centre.

view of **1a** is shown in Figure 1; selected bond lengths and angles are listed in Table 2. Both **1a** and **1b** are centrosymmetric dimers which adopt a ladder-type structure similar to that determined for several lithium amidinate complexes.[9] The lithium atoms are bound to the two nitrogen atoms of one amidinate ligand, one nitrogen atom of the other ligand and the oxygen atom of a THF molecule. The two nearly planar four-membered Li−N(1)−C(1)−N(2) rings [maximum deviations: 0.102(1) Å in **1a** and 0.121(2) and 0.135(3) Å in **1b**] are connected on either side of the planar central Li_2N_2 ring. These central and side planes form dihedral angles of 59.99(17)° and 56.3(4)° in **1a** and **1b**, respectively, with the usual *transoid* arrangement. The Li−N bond lengths, which range from 1.987(6) to 2.251(6) Å, indicate some asymmetry in the bonding of the bidentate ligand, with Li−N(1) shorter than Li−N(2) by 0.135 Å in **1a** and 0.209−0.264 Å in **1b**; the third bond length, Li−N(2′), is intermediate but closer to the former. The N(1)−C(1) and N(2)−C(1) bond lengths in both compounds are similar, with mean values of 1.322(6) and 1.347(3) Å, indicating uniform π delocalisation throughout the amidine moiety. The environment of the lithium atom is tetrahedral, but strongly distorted owing to the small bite angle of the bidentate amidinate. The Li···C(1) contacts, with a mean value of 2.43(2) Å, are larger than the usual values in such compounds, which are in the range 2.30−2.42 Å.[9b] The Li−O(THF) bond lengths are in perfect agreement with the mean value of 1.94(6) Å from the Cambridge Structural Database.[10]

The Uranium(IV) Amidinate Complexes [U{RC(NCy)$_2$}$_3$Cl] (R = Me, *n*Bu)

Treatment of UCl_4 with **1a** in THF gave the tris(amidinato)uranium chloride [U{MeC(NCy)$_2$}$_3$Cl] (**2a**), according to Equation (2); extraction in toluene and crystallization from this solvent afforded pale-green crystals of **2a** in 85% yield. A similar reaction with **1b** led to the quantitative formation of **2b** (NMR-tube experiment). The ^{1}H NMR sig-

nals corresponding to the R and Cy substituents of the amidinate ligands are visible at lower and higher field, respectively (Table 1), as previously observed for the resonances of the R and R′ groups in the series of $[U\{RC(NR'_2)_2\}_3Cl]$ complexes (R = C_6H_4X with X = H, Me, OMe, CF_3; R′ = $SiMe_3$).[5b]

$$UCl_4 + 1.5\ [Li\{RC(NCy)_2\}(THF)]_2 \xrightarrow{THF} \underset{\mathbf{1}}{} [U\{RC(NCy)_2\}_3Cl] + 3\ LiCl \quad (2)$$

R = Me, **2a**; R = *n*Bu, **2b**

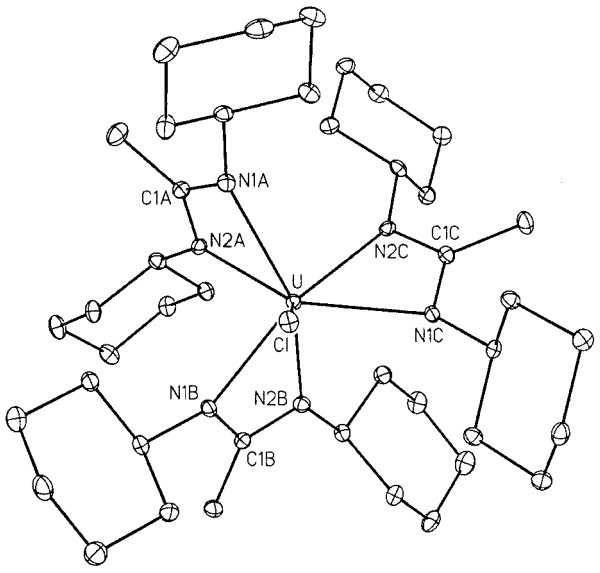

Figure 2. View of the complex $[U\{MeC(NCy)_2\}_3Cl]$ (**2a**) with displacement ellipsoids drawn at the 20% probability level; hydrogen atoms have been omitted for clarity

The molecular structure of **2a**, represented in Figure 2, is devoid of any imposed crystallographic symmetry, but possesses a pseudo C_3 axis defined by the U and Cl atoms; the three amidinate ligands are arranged in a propeller shape around this axis (the position of some cyclohexyl rings does not match this pseudo-trigonal symmetry). The structure of **2a** resembles that of the two tris(benzamidinate) compounds $[U\{ArC(NSiMe_3)_2\}_3Cl]$ (Ar = Ph, $C_6H_4CF_3$) which have been crystallographically characterized.[5b] The mean U−N bond length [2.43(4) Å] matches that in the above-mentioned complexes [2.44(5) Å], and for each of the three ligands (denoted A, B and C), the U−N(1) distance is shorter than the U−N(2) distance by 0.032−0.097 Å (Table 3). The atoms N(1A), N(1B) and N(1C), which are on the side of the complex on which the chlorine atom is located, are farther apart from each other than N(2A), N(2B) and N(2C); the steric strain between the cyclohexyl rings bound to the latter may explain the larger U−N(2) bond lengths. The three four-membered U−N(1)−C(1)−N(2) rings are planar, with a maximum deviation of 0.07 Å, the carbon atom always being the more displaced one. The mean U···C(1) distance [2.870(10) Å] is somewhat larger than its counterpart in the tris(benzamidinate) derivatives [2.84(2) Å], which is in agreement with smaller N(1)−C(1)−N(2) angles [mean value 114.3(8)° compared with 117(1)° in the latter]. Electronic delocalisation throughout the amidinate ligands is reflected by the identical N−C(1) bond lengths in the range 1.330(5)−1.337(5) Å. The uranium atom is displaced by 0.707(2) Å from the plane defined by the three atoms C(1A), C(1B) and C(1C) (on the same side as the chlorine atom), and the C(1A)···U···C(1B), C(1A)···U···C(1C) and C(1B)···U···C(1C) angles are 107.29(11)°, 114.50(12)° and 120.46(11)°, respectively; the C(1)···U−Cl angles vary from 102.14(8)° to 106.18(8)°. These values are similar to those of the ring centroid−U−ring centroid and ring centroid−U−Cl angles in the series of tris(cyclopentadienyl)[11] and tris(indenyl)uranium(IV)[12] complexes, which adopt a pseudo-tetrahedral configuration.

Interestingly, complex **2a** has the second longest U−Cl bond [2.6783(10) Å] in the series of 13 uranium(IV) complexes $[UL_3Cl]$ which have been crystallographically characterized and which include five cyclopentadienyl,[11a−11d,13] three indenyl,[12] three amidinate,[5b] including **2a**, one phospholyl,[14] and one imidophosphinate[15] derivatives (Table 4). The U−Cl bond lengths in this series lie in the range 2.559−2.90 Å. The shortest bond belongs to the first known organometallic uranium compound $[U(C_5H_5)_3Cl]$[11a] while the longest one, 2.90 Å, appears as a peculiar case since it corresponds to a chlorine atom disordered over two positions in $[U(C_5Me_5)_3Cl]$;[13] apart from this case, the twelve other U−Cl bond lengths define a relatively narrow range (0.12 Å). The lengthening of the U−Cl bond in each of the cyclopentadienyl, indenyl and amidinate families can be related to the increasing steric bulk and electron-donating capacity of the substituted ligands. Substitution of the cyclopentadienyl ring by methyl groups gives rise to an amazing gap in the variation of the U−Cl bond lengths, with a major influence of the fifth methyl group on the lengthening of the bond. In reference to $[U(C_5H_5)_3Cl]$,[11a] the complexes $[U(C_5Me_4H)_3Cl]$[11d] and $[U(C_5Me_5)_3Cl]$[13] exhibit variations in their U−Cl bond lengths of 0.08 Å and 0.26 Å, respectively, and, in contrast to the other tris(cyclopentadienyl)uranium chlorides, $[U(C_5Me_5)_3Cl]$ does not adopt a pseudo-tetrahedral structure; the ring centroid−U−ring centroid angles are equal to 120°. The long U−Cl bond in **2a** is in agreement with the electron richness of the $[U\{RC(NCy)_2\}_3]$ moiety, which is manifest in its redox reactions (vide infra).

The Uranium(III) and Lanthanide(III) Amidinate Complexes $[U\{RC(NCy)_2\}_3]$ (R = Me, nBu) and $[Ln\{MeC(NCy)_2\}_3]$ (Ln = La, Nd)

In contrast to $[U(C_5H_5)_3Cl]$, which is reduced with Na/Hg in THF to give $[U(C_5H_5)_3(THF)]$,[16] complexes **2** do not react with sodium amalgam. The synthesis of the uranium(III) amidinate $[U\{MeC(NCy)_2\}_3]$ (**3a**) therefore required a stronger reducing agent. Treatment of **2a** with lithium powder in THF cleanly afforded **3a** which, after extraction

[a] Individual values are given for the two independent complex molecules, mean values include both of them; the second values correspond to amidinate groups D, E and F in place of A, B and C, respectively.

with pentane and crystallization from this solvent, was isolated as dark-green crystals in 80% yield [Equation (3)]. Similarly, **2b** was quantitatively transformed into **3b** (NMR-tube experiment). The paramagnetic ^{1}H NMR resonances corresponding to the cyclohexyl substituents of **3** are more shifted than those of **2**, with one signal at high field and the others at low field (Table 1).

$$\underset{\mathbf{2}}{[U\{RC(NCy)_2\}_3Cl]} + Li \xrightarrow{THF} \underset{R = Me,\ \mathbf{3a};\ R = n\text{Bu},\ \mathbf{3b}}{[U\{RC(NCy)_2\}_3]} + LiCl \qquad (3)$$

Monitoring of the **2** → **3** transformation by NMR spectroscopy showed that the signals of the two complexes were distinct and not shifted during the reduction process, indicating the absence of electron-transfer or ligand-exchange reactions similar to those occurring during the reduction of [U(C$_5$H$_5$)$_3$Cl], where the intermediate formation of the bridged species [{U(C$_5$H$_5$)$_3$}$_2$(μ-Cl)]$^{n-}$ (n = 0 or 1) was observed.[16] These results, with the more difficult reduction of **2**, can be explained by the greater electron density on the metal atom.

In order to compare their crystal structures and reactions with those of **3a**, the lanthanum and neodymium analogues [Ln{MeC(NCy)$_2$}$_3$] [Ln = La (**4**) or Nd (**5**)] were prepared by treatment of LaI$_3$ or NdCl$_3$ with **1a** in THF; colorless (**4**) or pale blue-purple (**5**) crystals were obtained from a pentane solution. Contrary to previous reports[4] the ^{1}H NMR spectrum of **5** is well resolved; it is similar to that of **3a** (Table 1). The crystal structure of the ytterbium counterpart [Yb{MeC(NCy)$_2$}$_3$] (**6**) has been reported previously.[4]

Complexes **3a**, **4** and **6** are isomorphous. The crystal structure of **3a** is shown in Figure 3; selected bond lengths and angles are listed in Table 3. The complex possesses a pseudo-trigonal symmetry axis, with the three ligands in a propeller-like arrangement. As usual with six-coordinate compounds with three identical small-bite bidentate ligands, the environment of the central metal atom is intermediate between octahedral and trigonal prismatic.[17] The uranium atom is located at 1.013(3) and 0.979(2) Å from the planes defined by N(1A), N(1B), N(1C) and N(2A), N(2B), N(2C), respectively, which form a dihedral angle of 0.77(15)°. In contrast with what has been observed in **2a**, these two sets of nitrogen atoms are not located differently with respect to the metal atom and, as a consequence, the U−N distances span a relatively narrow range [2.477(4)−2.501(4) Å]. The average U−N distance of 2.489(9) Å is larger than that in **2a** by about 0.06 Å, in fair agreement with a difference of about 0.075 Å in ionic radii between seven-coordinate U^{IV} and six-coordinate U^{III};[18] this distance is longer than that of 2.320(4) Å in the homoleptic tris(amide) uranium(III) compound [U(N{SiMe$_3$}$_2$)$_3$].[19] The three U−N(1)−C(1)−N(2) rings in **3a** define mean planes with a maximum deviation of 0.020(3) Å at most, the carbon atom being the farthest from the plane. The U···C(1) distances, with a mean value of 2.9403(15) Å, follow the same trend as the U−N bond lengths when passing from U^{IV} to U^{III}, since the N(1)−C(1)−N(2) angle remains approximately constant. The N−C(1) bond lengths span the range 1.317(7)−1.348(7) Å, wider than in **2a** and equivalent to that in the lithium complexes, the mean value being constant in all cases. The metal atom is displaced by 0.030(3) Å from the mean plane defined by atoms C(1A), C(1B) and C(1C) and the three angles C(1A)···U···C(1B), C(1A)···U···C(1C) and C(1B)···U···C(1C) are 123.25(14)°, 117.75(14)° and 118.96(14)°, respectively, with a sum equal

to 359.96°. The geometry around the metal atom can thus be described as trigonal-planar if each bidentate amidinate ligand is considered to occupy a single coordination site. This arrangement is reminiscent of that adopted by the three cyclopentadienyl ligands in sterically encumbered trivalent metallocenes such as $[U(C_5H_5SiMe_3)_3]$,[20] $[U(C_5Me_5H)_3]$[21] and $[U(C_5Me_5)_3]$,[22] and reinforces the analogy which has been established between the amidinate and cyclopentadienyl ligands.

Complexes **3a**, **4**, **5** and **6** are isostructural but not isomorphous since the neodymium derivative **5** crystallizes in a different system and space group, with two independent molecules in the asymmetric unit (corresponding to ligands A, B, C and D, E, F; Figure 4). The Nd−N bond lengths are in the range 2.445(3)−2.480(3) Å, with a mean value of 2.464(10) Å, which is identical to that found in the homoleptic guanidinate compounds $[Nd\{iPr_2NC(NR)_2\}_3]$ (R = Cy or *i*Pr),[23a] and is slightly shorter than that of 2.49(3) Å determined in the other neodymium amidinates.[23b,23c] The Nd−N(1)−C(1)−N(2) four-membered rings define mean planes with maximum deviations of 0.032(2) Å for the carbon atoms, the latter being at a mean distance of 2.903(5) Å from the metal centres. The N−C(1) bond lengths are in the range 1.330(4)−1.340(4) Å, the mean value being identical to that in the other complexes. The two independent neodymium atoms are displaced by 0.021(2) and 0.034(2) Å from the mean planes defined by the atoms C(1) of the three ligands in each molecule, and the angles defined by the atoms C(1) around Nd are in the range 117.80(9)−121.76(9)°, nearly identical to those in **3a**, **4** and **6**.

The plot of the average Ln−N distances versus the ionic radii $r(Ln^{III})$ of the six-coordinate Yb^{III}, Nd^{III} and La^{III} ions (Figure 5) shows the usual almost perfect linear relationship, with a correlation coefficient of 0.998. However, the average U−N distance is shorter by 0.025 Å than that expected from a purely ionic bonding model; the same trend is observed when considering the U···C(1) distances. Although this difference is smaller than three times the value of the standard deviation for the measured distances (0.01 Å), it seems significant, as the average distances are calculated from six M−N distances and the values are

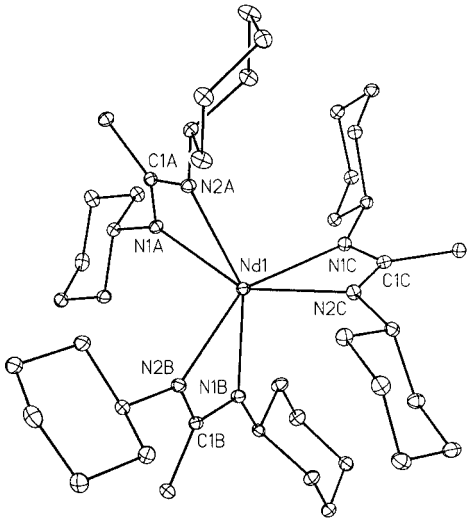

Figure 4. View of one molecular unit in the complex [Nd{MeC(NCy)$_2$}$_3$] (**5**) with displacement ellipsoids drawn at the 10% probability level; hydrogen atoms have been omitted for clarity

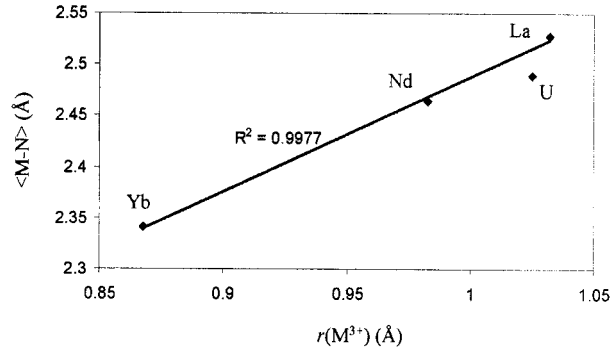

Figure 5. Average M−N distances as a function of the metal ionic radii in the complexes [M{MeC(NCy)$_2$}$_3$]

identical for each of the two independent [Nd{MeC(NCy)$_2$}$_3$] molecules. The shortening of the U−N distances with respect to the Ln−N distances in the series of isostructural compounds **3a**, **4**, **5** and **6** could reflect a stronger interaction between the actinide and the amidinate ligand, in relation with the more covalent character of the bond. The better affinity of neutral nitrogen, phosphorous and sulfur ligands or anionic cyclopentadienyl and iodide groups for U^{III} than for Ln^{III} ions has been similarly assessed from the crystal structures of analogous complexes, by measuring the deviations, Δ, between the differences [<U−X> − <Ln−X>] and [$r(U^{III})$ − $r(Ln^{III})$].[24] These deviations are generally equal to 0.02−0.05 Å, as found, for example, in [MI$_3$(bipy)(C$_5$H$_5$N)] (M = Ce or U; bipy = 2,2′-bipyridine),[24a] [M(C$_5$H$_4$R)$_3$(L)] (M = Ce or U; R = *t*Bu or SiMe$_3$; L = pyridine, picoline, lutidine, pyrimidine and 3,5-dimethylpyrazine),[24b] [MI$_2$(OPPh$_3$)$_4$]I (M = Nd, Ce, La, U),[24c] [M(terpy)$_3$]I$_3$ (M = La, Ce, Nd or U; terpy = 2,2′:6′,2′′-terpyridine)[24d] and [MI$_3$(1,4,7-trithiacyclononane)(MeCN)$_2$] (M = La or U).[24e] In the phosphorus-containing complexes [M(C$_5$H$_4$Me)$_3$(L)] [M = Ce or U; L = PMe$_3$ or P(OCH$_2$)$_3$CEt][24f] and in the tris(btp) compounds [M(btp)$_3$]I$_3$ [M = La, Ce, Sm or U; btp = 2,6-dialkyl-1,2,4-triazin-3-yl)pyridine],[24d] Δ is equal to 0.1 Å; this deviation has been explained by the softer character and better π-accepting ability of the phosphane, phosphite and btp ligands. In agreement with these arguments, the low value of Δ for the series of compounds **3a**, **4**, **5** and **6**, if significant, would result from the lower softness of the nitrogen atoms and the energetically less accessible π* orbitals of the amidinate ligand.[25]

Polymerization of ε-Caprolactone

Homoleptic amidinate lanthanide complexes show extremely high activity in the ring-opening polymerization of ε-caprolactone (CL) at room temperature.[4] Thus, in the presence of 0.5% mol-equiv. of the neodymium complex **5** in toluene, polymerization of CL was achieved in less than 2 min, giving a viscous gel of poly(ε-caprolactone), which was characterized by its ^{1}H NMR spectrum.[26] It is likely that the mechanism of this reaction is similar to that proposed for the polymerization of CL catalyzed by guanidino-[23a] or amidolanthanide[27] compounds, in which the initial step is the nucleophilic attack of a nitrogen atom at the carbonyl carbon atom of the lactone, followed by acyl-bond cleavage and formation of an alkoxide complex. Under the same conditions, when using the uranium(III) counterpart **3a** in place of **5**, polymerization of CL was very much slower, requiring 5 d to go to completion. In view of the poor catalytic activity of **3a**, the properties of the polyester obtained were not analyzed further. However, the ^{1}H NMR spectra showed that **3a** reacts immediately with 0.5 mol-equiv. of CL to give a mixture of unidentified compounds, while the colour of the solution turned from green to yellow; these observations suggest that **3a** is oxidized to U^{IV} derivatives by CL. The ability of CL to oxidize low-valent f-element complexes was previously noted during its polymerization by means of a variety of Sm^{II} initiators,

like $[Sm(OAr)_2(THF)_3]$ (Ar = $C_6H_2tBu_2$-2,6-Me-4),[28a] $[Sm\{N(SiMe_3)_2\}_2(THF)_2]$ and $[Sm(C_5Me_5)_2(THF)_x]$,[28b] which were initially transformed into the true, uncharacterized Sm^{III} catalysts. It is possible that one of the products resulting from oxidation of **3a** is the dinuclear species $[U]-O(CH_2)_5CO-[U]$ ($[U] = \{MeC(NCy)_2\}_3$), by analogy with the compound $[U(C_5H_5)_3-O(CH_2)_5CO-U(C_5H_5)_3]$ (**7**), which is readily obtained by treating $[U(C_5H_5)_3(THF)]$ with CL in toluene.[29] Complex **7** exhibits the same activity as the oxidation product(s) of **3a** in the catalytic polymerization of CL. The much lower performances of these compounds, by comparison with those of the lanthanide amidinates, can be explained by the more difficult insertion of the lactone monomer into a $U^{IV}-O$ bond than into an $Ln^{III}-N$ or $Ln^{III}-O$ bond; this difference can be compared with that previously noted between titanium(IV)[30] and lanthanide(III)[26a] alkoxides in their reactions with CL.

Conclusion

After the benzamidinate compounds $[U\{ArC(NSiMe_3)_2\}_3Cl]$ (Ar = C_6H_5 or 4-$CF_3C_6H_4$), the complexes $[U\{RC(NCy)_2\}_3Cl]$ (R = Me or *n*Bu) are new examples of tris(amidinato)uranium chlorides. Their reduction with lithium metal affords the first homoleptic tris(amidinate) compounds of uranium(III). Comparison of the crystal structure of $[U\{MeC(NCy)_2\}_3]$ with those of the lanthanide analogues shows that the average U−N distance is shorter than expected from a purely ionic bonding model. This U^{III} complex was found to be much less efficient than the lanthanide counterparts in the catalytic polymerization of ε-caprolactone because of its rapid oxidation into poorly active U^{IV} species.

Experimental Section

General: All preparations and experiments were carried out under argon (< 5 ppm oxygen or water) using standard Schlenk-vessel and vacuum-line techniques, or in a glove box. Solvents were thoroughly dried and deoxygenated by standard methods and distilled immediately before use; deuterated toluene and THF (Eurisotop) were distilled from Na/K alloy and stored over molecular sieves (3 Å). UCl_4 was prepared by a published method.[31] LaI_3, $NdCl_3$, *N*,*N*′-dicyclohexylcarbodiimide, ε-caprolactone, MeLi (1.6 M in diethyl ether) and *n*BuLi (2.0 M in hexanes) were purchased from Aldrich and used without further purification. The ^1H NMR spectra were recorded with a Bruker DPX 200 instrument and referenced internally using the residual protonated solvent resonances relative to tetramethylsilane ($\delta = 0$ ppm); the spectra of the amidinate complexes are reported in Table 1. Elemental analyses were performed by Analytische Laboratorien at Lindlar (Germany).

Synthesis of $[Li\{MeC(NCy)_2\}(THF)]_2$ (1a): A flask was charged with *N*,*N*′-dicyclohexylcarbodiimide (330 mg, 1.6 mmol) and THF (10 mL) was condensed into it under vacuum at −78 °C. MeLi (1.0 mL of a 1.6 M solution in diethyl ether, 1.6 mmol) was added with a syringe at room temperature. After 2 h, evaporation of the solvent gave colorless crystals which were dried under vacuum (447 mg, 93%).

Synthesis of $[Li\{nBuC(NCy)_2\}(THF)]_2$ (1b): This compound was prepared by using the same procedure as for **1a**, from *N*,*N*′-dicyclohexylcarbodiimide (330 mg, 1.6 mmol) and *n*BuLi (0.8 mL of a 2.0 M solution in hexanes, 1.6 mmol). Colorless crystals were obtained after drying (498 mg, 91%).

Synthesis of $[U\{MeC(NCy)_2\}_3Cl]$ (2a): A flask was charged with UCl_4 (152 mg, 0.4 mmol) and **1a** (360 mg, 0.6 mmol), and THF (10 mL) was condensed into it under vacuum at −78 °C. The reaction mixture was stirred at room temperature for 2 h. The solvent was evaporated and the residue extracted with toluene (10 mL). The solution was filtered and concentrated to dryness, leaving pale-green crystals of **2a** (318 mg, 85%). $C_{42}H_{75}ClN_6U$ (937): calcd. C 53.80, H 8.06, N 8.96; found C 53.92, H 8.15, N 9.08.

Synthesis of $[U\{nBuC(NCy)_2\}_3Cl]$ (2b): An NMR tube was charged with UCl_4 (11.4 mg, 0.030 mmol) and **1b** (30.9 mg, 0.045 mmol) in $[D_8]$THF (0.3 mL). The NMR spectrum showed the immediate and almost quantitative formation of **2b**.

Synthesis of $[U\{MeC(NCy)_2\}_3]$ (3a): A flask was charged with **2a** (281 mg, 0.29 mmol) and Li powder (2.1 mg, 0.29 mmol), and THF (10 mL) was condensed into it under vacuum at −78 °C. The reaction mixture was stirred at room temperature for 2 h. The solvent was evaporated to dryness and the residue extracted with pentane (10 mL). The solution was filtered and concentrated to dryness, leaving dark-green crystals of **3a** (219 mg, 80%). $C_{42}H_{75}N_6U$ (902): calcd. C 55.92, H 8.38, N 9.32; found C 55.68, H 8.44, N 9.22.

Synthesis of $[U\{nBuC(NCy)_2\}_3Cl]$ (3b): An NMR tube was charged with **2b** (29.7 mg, 0.030 mmol) and Li powder (0.2 mg, 0.030 mmol) in $[D_8]$THF (0.3 mL). The pale-green solution progressively turned dark blue, and after 2 h at room temperature the NMR spectrum showed the quantitative formation of **3b**.

Synthesis of $[Ln\{MeC(NCy)_2\}_3]$ [Ln = La (4) or Nd (5)]: These complexes were prepared by modifying a published procedure.[4] A flask was charged with LaI_3 (51.9 mg, 0.1 mmol) and **1a** (90 mg, 0.15 mmol) and THF (5 mL) was condensed into it under vacuum at −78 °C. The reaction mixture was stirred at room temperature for 24 h. The solvent was evaporated and the residue extracted with pentane (5 mL). The solution was filtered and concentrated to dryness, leaving colorless crystals of **4** (60 mg, 75%). Compound **5** was similarly prepared from $NdCl_3$ (100.2 mg, 0.4 mmol) and **1a** (360 mg, 0.6 mmol) and isolated as pale blue-purple crystals (298 mg, 92%).

Polymerization of ε-Caprolactone (CL). a) With $[Nd\{MeC(NCy)_2\}_3]$ (5): An NMR tube was charged with **5** (0.80 mg, 0.0010 mmol) in $[D_8]$toluene (0.6 mL) and CL (22 μL, 0.20 mmol) was introduced with a microsyringe. After 2 min at 20 °C, a viscous gel was obtained and the spectrum showed that CL had completely polymerized. ^1H NMR: $\delta = 1.29$ (m, 2 H, γ-CH_2), 1.54 (m, 4 H, β- and δ-CH_2), 2.20 (t, $J = 7$ Hz, 2 H, ε-CH_2), 3.94 (t, $J = 7$ Hz, 2 H, α-CH_2) ppm; α, β, γ, δ and ε are the positions of the carbon atoms of the polyester chain with respect to the oxygen atom. **b) With $[U\{MeC(NCy)_2\}_3]$ (3a) or $[U(C_5H_5)_3(THF)]$:** An NMR tube was charged with **3a** (0.9 mg, 0.0010 mmol) in $[D_8]$toluene (0.6 mL) and CL (22 μL, 0.20 mmol) was introduced with a microsyringe. The NMR spectra showed the slow formation of the polyester, which required 5 d at 20 °C to go to completion. The same observations were made upon replacing **3a** with $[U(C_5H_5)_3(THF)]$.

X-ray Crystallography of 1a, 1b, 2a, 3a, 4 and 5: Data collections were carried out at 100(2) K with a Nonius Kappa-CCD area-detector diffractometer[32] using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The crystals were introduced into glass capillaries with a protecting Paratone-N oil (Hampton Research) coating. The unit-cell parameters were determined from ten frames, then refined on all data. A 180° φ range was scanned with 2° steps during data collection, with a crystal-to-detector distance fixed at 28 mm. The data were processed with DENZO-SMN.[33] The structures were solved by direct methods or Patterson map interpretation with SHELXS-97 and subsequent Fourier difference synthesis and refined by full-matrix least squares on F^2 with SHELXL-97.[34] Absorption effects of the uranium and neodymium complexes were corrected empirically with the program DELABS from PLATON.[35] In one of the two independent molecules in compound **1b** (unit B), the terminal carbon atom of the *n*-butyl chain and three carbon atoms of the tetrahydrofuran molecule were found disordered over two positions, which were refined with occupancy parameters constrained to sum to unity and some restraints on bond lengths and displacement parameters for the atoms of the tetrahydrofuran molecule. The hydrogen atoms were introduced at calculated positions, except in the disordered parts (when present), and were treated as riding atoms with a displacement parameter equal to 1.2- (CH, CH_2) or 1.5-times (CH_3) that of the parent atom. All non-hydrogen atoms were refined with anisotropic displacement parameters. Crystal data and structure refinement parameters are given in Table 5. The molecular plots were drawn with SHELXTL.[36] CCDC-240952 to -240957 (for **1a**, **1b**, **2a**, **3a**, **4** and **5**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Structure and Properties of a Mononuclear and an End-On Double Azido-Bridged Copper(II) Complex Incorporating an N,N,N,O-Coordinating Tripodal Ligand

Sumana Sarkar,[a] Amrita Mondal,[a] Joan Ribas,[b] M. G. B. Drew,[c] Kausikisankar Pramanik,[a] and Kajal Krishna Rajak*[a]

Keywords: Azide ligands / Copper / Hydrogen bonds / Magnetic properties / Tripodal ligands

The blue coloured complex $[Cu(HL)(H_2O)(ClO_4)]ClO_4{\cdot}H_2O{\cdot}MeOH$ (**1**·H_2O·MeOH) has been synthesised in excellent yields by reacting $Cu(ClO_4)_2{\cdot}6H_2O$ with *N*,*N*-bis(2-methylpyridyl)(3,5-dimethyl-2-hydroxybenzyl)amine (HL) in methanol. The same reaction, when carried out in the presence of sodium azide, afforded a dark-blue complex of formula $[Cu_2(HL)_2(\mu\text{-}1,1\text{-}N_3)_2](ClO_4)_2$ (**2**). The crystal and molecular structures of the complexes have been solved. Variable-temperature magnetic susceptibility data in the range of 2–300 K for **2** reveal the existence of an antiferromagnetic interaction through an end-on azido linker. Temperature-dependent susceptibility studies for **2** were fitted using the Bleaney–Bowers expression, which led to the parameters $J = -3.2\ cm^{-1}$, $g = 2.12$ and $R = 2.14 \times 10^{-4}$.

Introduction

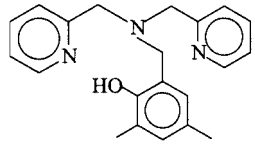
The existence of copper-containing enzymes and proteins and the potent biological activity of copper have increased recent interest in the coordination chemistry of copper with *O*,*N*-coordinating ligands.[1−6] It is well known that the azide ion inhibits the activity of metalloproteins,[1c,1d,1e,3e,7] thus metal azide complexes of such proteins have been studied extensively[8] in order to investigate the role of the metal ion in biological processes. The chemistry of azido-bridged copper(II) compounds has also received a great deal of attention for the understanding of magneto-structural correlations and for developing new functional-molecule-based materials.[9]

Among the many bridging ligands known, the azide ion can act not only as a monodentate ligand[10] but also link the metal ions in μ-1,1 (end-on) or μ-1,3 (end-to-end) bridging coordination modes, depending on the steric and electronic demands of the co-ligand. It has been widely found that the end-to-end bridging mode predominantly leads to antiferromagnetic coupling[11] and the end-on mode to ferromagnetic exchange;[12] instances of antiferromagnetic coupling in the case of end-on azido-bridged complexes are rare.[13] This has prompted us to undertake the task of designing diazido-bridged copper(II) species by using an *N*,*N*,*N*,*O*-coordinating tripodal ligand.

Here we describe the synthesis and characterisation of a mononuclear copper(II) species and a double asymmetric μ-1,1 azido-bridged Cu^{II} complex incorporating an *N*,*N*,*N*,*O*-coordinating tripodal ligand. The solid and solution structures of the complexes, as well as their properties, were probed by X-ray diffractometry and spectroscopic and electrochemical methods. The variable-temperature magnetic moment was measured for the dinuclear species.

Results and Discussion

The tripodal ligand HL is used in this present work; it was synthesised by a reported procedure.[14]



HL

The stoichiometric reaction of $Cu(ClO_4)_2 \cdot 6H_2O$ with HL, in methanol, afforded the blue complex $[Cu(HL)(H_2O)(ClO_4)]ClO_4$ (**1**) in excellent yields. The same reaction, when carried out in the presence of an excess of sodium azide, yielded the dark-blue complex of formula $[Cu_2(HL)_2(\mu\text{-}1,1\text{-}N_3)_2](ClO_4)_2$ (**2**) [Equation (1)].

$$Cu(ClO_4)\cdot 6H_2O \xrightarrow[MeOH]{HL} [Cu(HL)(H_2O)(ClO_4)]ClO_4$$

$$\xrightarrow{N_3^-} [Cu_2(HL)_2(\mu\text{-}1,1\text{-}N_3)_2](ClO_4)_2 \quad (1)$$

In the IR spectra of complexes **1** and **2** the characteristic perchlorate stretches occur at 600 cm^{-1} and 1100 cm^{-1}, respectively, and the hydrogen-bonded phenolic OH appears as a broad peak near 3250 cm^{-1}.[5c] The Cu−N_3 stretch is observed at 2100 cm^{-1} in **2**.

In solution the complexes exhibit a relatively weak band in the 590 nm region of the UV/Vis spectrum. This transition is logically assigned as the ligand-field excitation.[15] An allowed intense band observed near 390 nm for complex **2** may be assigned as the $N_3^- \rightarrow Cu^{II}$ transition.[16]

All the complexes are electroactive at a platinum electrode in acetonitrile solution. Cyclic voltammetric reduction potential data are given in the Exp. Sect. and the voltammograms are shown in Figure 1. In both cases an anodic response occurs near 1.5 V, believed to be due to $Cu^{II} \rightarrow Cu^{III}$ oxidation; the oxidized complex is too reactive to survive for the cathodic scan. The complexes also display a quasireversible peak near 0.0 V corresponding to the Cu^{II}/Cu^{I} reduction couple. The low oxidation and reduction potentials for **2** compared to those of **1** may be due to the azide chelation.

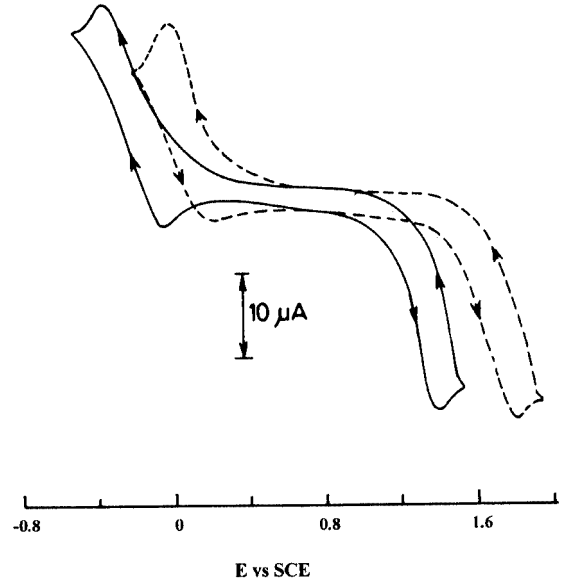

Figure 1. Cyclic voltammograms of ca. 10^{-3} M solutions of $[Cu(HL)(H_2O)(ClO_4)]ClO_4$ (----) and $[Cu_2(HL)_2(\mu\text{-}1,1\text{-}N_3)_2](ClO_4)_2$ (−) in acetonitrile

X-ray Crystallography

The crystal structures of $[Cu(HL)(H_2O)(ClO_4)]ClO_4 \cdot H_2O \cdot MeOH$ (**1**·H_2O·MeOH) and $[Cu_2(HL)_2(\mu\text{-}1,1\text{-}N_3)_2](ClO_4)_2$ (**2**) have been determined. Molecular views excluding the hydrogen atoms and the solvent molecules are shown in Figure 2 and 3, respectively. Selected bond parameters are listed in Table 1.

In both complexes the three nitrogen atoms of the tripodal ligand are disposed meridionally forming two five-membered chelate rings, whereas the phenolic oxygen atom is coordinated axially, forming a six-membered chelate ring. The two pyridine rings (NC_5H_5) of the ligand are planar (mean deviation about 0.02 Å) and the dihedral angle be-

tween these two planes is 5.6° in **1**·H_2O·MeOH and 18.4° in **2**.

$[Cu(HL)(H_2O)(ClO_4)]ClO_4·H_2O·MeOH$ (**1**·H_2O·MeOH)

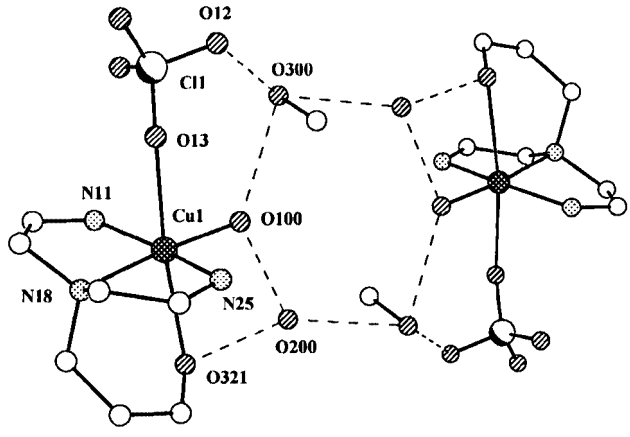
The structure of **1**·H_2O·MeOH consists of a monomeric $[Cu(HL)(H_2O)(ClO_4)]ClO_4·H_2O·MeOH$ unit. The geometry around the metal centre of **1**·H_2O·MeOH appears to be distorted octahedral and is characterised by an O−Cu−O bond angle of 168.45°, which deviates significantly from the ideal value of 180°. In a distorted CuN_3O_3 octahedral environment, the fourth equatorial position *trans* to the tripodal nitrogen atom is occupied by the oxygen atom of a water molecule and the sixth axial position by the perchlorate oxygen atom. The copper atom is displaced by 0.01 Å towards the phenolic oxygen atom from the equatorial plane (mean deviation 0.105 Å) defined by N(11), N(18), N(25) and O(100). The three basal Cu−N bond lengths are unequal; the longest distance is the bond to the tripodal nitrogen and the shortest is that to the pyridine nitrogen. The latter is due to the sp^2 character of the pyridine nitrogen. The axial Cu−O and Cu−N bond lengths are longer because of the pseudo Jahn−Teller effect.

$[Cu_2(HL)_2(\mu\text{-}1,1\text{-}N_3)_2](ClO_4)_2$ (**2**)

Two centrosymmetrically related Cu(HL)(μ-1,1-N_3) units are linked by the azide ion in an end-on fashion forming a doubly asymmetric bridged dimeric complex. The coordination geometry around the copper ion is distorted octahedral. Four nitrogen atoms (two pyridine, one tripodal and one azide nitrogen) form the square plane (mean deviation 0.023 Å) and the copper atom is displaced by 0.026 Å towards the coordinated phenolic oxygen atom from this plane. The remaining apical position of the octahedron is occupied by the bridging azide nitrogen atom of the other unit. The Cu−N distances and N−Cu−N bond angles in the basal plane range from 1.972 Å to 2.065 Å and 97.0° to 177.1° respectively. The long axial Cu−N (ca. 2.563 Å) distance can be attributed to a pseudo Jahn−Teller distortion. The intra-dimer Cu···Cu bond length is 3.452 Å. The azide ion is quasilinear, with an N−N−N bond angle of 177.0(10)°; the N−N bond lengths are 1.175(9) Å and 1.154(10) Å, respectively. In the end-on bridging moiety, the Cu−N−Cu bond angle is 98.31(8)°.

Hydrogen Bonding

In complex **1**·H_2O·MeOH the coordinated water molecule, the oxygen atom of the coordinated perchlorate ion and the phenolic oxygen atom of the ligand are extensively involved in hydrogen bonding with lattice water and methanol molecules. The lattice water molecule is held by water(lattice)···water(coordinated) [O···O = 2.718(14) Å] and water(lattice)··· oxygen(phenolic) [2.883(12) Å] hydrogen bonds. The methanol molecule in the lattice is also engaged in such bonding with the oxygen atom of the coordinated perchlorate ion and the coordinated water molecule, with O···O bond lengths of 2.831(13) Å and 2.782 (12) Å, respectively. The most striking feature is that two such molecules are linked by water···methanol hydrogen bonds [2.713(12) Å] forming a six-membered ring as depicted in



A

B

A. In the case of **2** the oxygen atom of the perchlorate ion is hydrogen bonded to the phenolic oxygen atom, with an O···O bond length of 2.650(10) Å as depicted in **B**.

Magnetic Studies

Variable-temperature magnetic susceptibility measurements were performed in the range of 2−300 K. The plot of $\chi_M T$ versus T for complex **2** is shown in Figure 4.

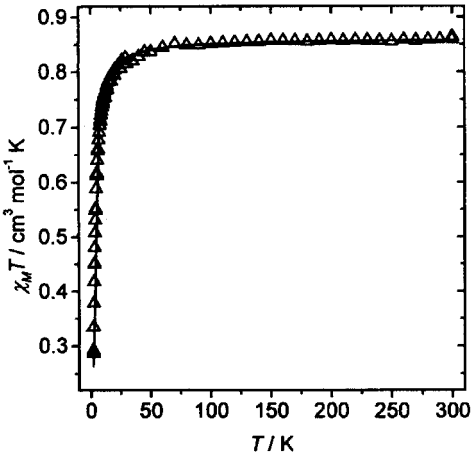

Figure 4. $\chi_M T$ versus T for **2**; open points are the experimental data and the solid line represents the best fit obtained

In **2**, the magnetic data are for two copper(II) ions as the complex is a dinuclear system. The experimental $\chi_M T$ value at 300 K is 0.86 emu·cm^{-1}·K, as expected for two quasi-isolated spin doublets. This value remains almost constant up to 50 K but decreases rapidly to 0.28 emu·cm^{-1}·K at 2 K. This feature is characteristic of a weak antiferromagnetic interaction. The reduced molar magnetisation at 2 K (Figure 5) clearly corroborates that the antiferromagnetic coupling is very small.

The magnetic susceptibility data were fitted by applying the Bleaney−Bowers formula with the Hamiltonian[9d]

$H = -JS_1 \cdot S_2$

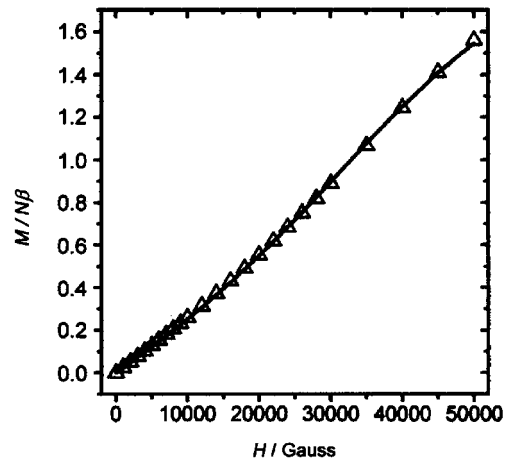

Figure 5. Plot of the reduced magnetisation, $M/N\beta$, versus H for **2**; open points are the experimental data and the solid line represents the best fit obtained.

The best-fit parameters obtained are $J = -3.2 \pm 0.1$ cm^{-1}, $g = 2.12 \pm 0.01$ and $R = 2.1 \times 10^{-4}$. Very similar J and g values were obtained by a full-diagonalisation from the curve of the magnetisation at 2 K. In this case, the best-fit parameters are $J = -3.0 \pm 0.1$ cm^{-1}, $g = 2.12 \pm 0.01$ and $R = 5.1 \times 10^{-5}$. Thus, the two methods give almost identical results. It is well documented that end-on double azido-bridged copper(II) dimers are usually ferromagnetic[12] but here the measurement clearly indicates that the coupling between the two Cu^{II} ions is antiferromagnetic which is very unusual.

In copper(II) systems with an end-on coordination of the azide ion, the exchange interaction will be strong when the magnetic orbitals involved are of the $d_{x^2-y^2}$ type. However, a low magnetic coupling should be expected when the interaction is between axial-equatorial coordination sites because the atomic orbitals involved are $d_{x^2-y^2}$ and d_{x^2} respectively. In complex **2**, the nitrogen atom of the unsymmetrically bridged azide ion belongs to the basal plane of one copper ion and also occupies one elongated apical position of the other metal centre. An exactly analogous situation occurs for the other centrosymmetrically related azide bridge. Consequently, the interaction between the magnetic orbitals is expected to be very weak, leading to a small exchange-coupling parameter. Moreover, the Cu−N(apical) bond is significantly longer than the distance required for a ferromagnetic interaction.[17] These two factors are most probably responsible for the weak antiferromagnetic coupling.

EPR Spectra

Both complexes show axial EPR spectra typical for monomeric copper(II) species with a $d_{x^2-y^2}$ ground-state doublet ($g_\parallel > g_\perp > 2.0$) in the solid state and in solution.[18] The spectroscopic data are listed in Table 2. From the spectrum of **2** it is clear that there is no significant interaction between the copper centres (Figure 6) in the solid state. The EPR spectra of **1**·H_2O·MeOH and **2** are practically

Conclusions

The synthesis and structural characterisation of copper(II) complexes incorporating *N*,*N*-bis(2-methylpyridyl)(3,5-dimethyl-2-hydroxybenzyl)amine (HL) has been successfully achieved. The parent species $[Cu(HL)(H_2O)(ClO_4)]ClO_4$ was prepared by the reaction of HL with $Cu(ClO_4)_2{\cdot}6H_2O$ in methanol. This complex reacts with sodium azide to afford the complex $[Cu_2(HL)_2(\mu\text{-}1,1\text{-}N_3)_2](ClO_4)_2$. To the best of our knowledge $[Cu_2(HL)_2(\mu\text{-}1,1\text{-}N_3)_2](ClO_4)_2$ is the first example of an end-on diazido-bridged octahedral copper(II) complex showing antiferromagnetic character. A search for new copper(II) complexes with different tetradentate ligand systems is in progress.

Experimental Section

Materials: All the starting chemicals were analytically pure and used without further purification. The ligands were prepared according to the literature procedure.[14]

Caution! *Perchlorate salts are highly explosive, and should be handled with care and in small amounts.*

Physical Measurements: UV/Vis spectra were recorded on a Perkin−Elmer LAMBDA EZ-301 spectrophotometer and IR spectra were measured with a Perkin−Elmer L-0100 spectrometer. Electrochemical measurements were performed on acetonitrile solutions of the complexes on a CH 620 A electrochemical analyzer using a platinum electrode. Tetraethylammonium perchlorate (TEAP)[19] was used as the supporting electrolyte and the potentials are referenced to the standard calomel electrode (SCE) without junction correction. EPR spectra were recorded on a Varian E-109C X-band spectrometer. Magnetic measurements were carried out on polycrystalline samples with a Quantum Design MPMS XL SQUID susceptometer operating at a magnetic field of 0.1 T between 2 and 3 K. The diamagnetic corrections were evaluated from Pascal's constants. Elemental analyses (C, H, N) were performed on a Perkin−Elmer 2400 Series II elemental analyzer.

$[Cu(HL)(H_2O)(ClO_4)]ClO_4$ (1): HL (0.168 g, 0.5 mmol) was added to a solution of copper(II) perchlorate hexahydrate (0.186 g, 0.5 mmol) in methanol (10 mL) and the resulting blue solution was stirred for 0.5 h at room temperature. Slow evaporation of the solution yielded a blue, crystalline product. Yield: 0.210 g (70%). $C_{21}H_{25}ClCuN_3O_{10}$ (610.5): calcd. C 42.32, H 4.20, N 7.05; found C 42.08, H 4.04, N 6.94. UV/Vis (CH_3CN): λ_{max} (ε) = 590 nm (107 $M^{-1}cm^{-1}$). IR (KBr): $\nu(ClO_4^-)$ 1100, 620; ν(OH) 3250 cm^{-1}. E_{pa} (Cu^{III}/Cu^{II} couple): 1.8 V (irr.); $E_{1/2}$ (Cu^{II}/Cu^{I} couple): 0.15 V (ΔE_p, 200 mV).

$[Cu_2(HL)_2(\mu\text{-}1,1\text{-}N_3)_2](ClO_4)_2$ (2): HL (0.168 g, 0.5 mmol) and sodium azide (0.046 g, 0.7 mmol) were added to a methanolic solution (10 mL) of copper(II) perchlorate hexahydrate (0.186 g, 0.5 mmol). The resulting blue solution was stirred for 0.5 h at room temperature. Slow evaporation of the solution yielded a blue, crystalline product. Yield: 0.140 g (70%). $C_{21}H_{23}N_6ClCuO_5$ (538.44): calcd. C 46.84, H 4.28, N 15.61; found C 46.56, H 4.12, N 15.44. UV/Vis (CH_3CN): λ_{max} (ε) = 392 nm (2368 $M^{-1}cm^{-1}$), 590 (293). IR (KBr): $\nu(N_3^-)$ 2100; $\nu(ClO_4^-)$ 1100, 640; ν(OH) 3240 cm^{-1}. E_{pa} (Cu^{III}/Cu^{II} couple): 1.5 V (irr.); $E_{1/2}$ (Cu^{II}/Cu^{I} couple): −0.2 V (ΔE_p, 200 mV).

Crystallographic Studies: Crystals of $[Cu(HL)(H_2O)(ClO_4)]ClO_4$ and $[Cu_2(HL)_2(\mu\text{-}1,1\text{-}N_3)_2](ClO_4)_2$ were grown by slow evaporation of the solvents from their methanolic solution. Data were measured with Mo-K_α radiation using an MA Research Image Plate System. The crystals were positioned 70 mm from the Image Plate. 100 Frames were measured at 2° intervals with a counting time of 5 min. Data analyses were carried out with the XDS program[20] and the structures were solved by direct methods with the Shelx-86 program.[21] Non-hydrogen atoms were refined with anisotropic thermal parameters. One of the perchlorate ions of complex 1·H_2O·MeOH and that of **2** are highly disordered. The hydrogen atoms bonded to carbon were included in geometric positions and given thermal parameters equivalent to 1.2-times those of the atom to which they are attached. Empirical absorption corrections were applied using DIFABS[22] and the structures were refined on F^2 using Shelxl.[23] Significant crystal data are given in Table 3.
CCDC-240990 (for 1·H_2O·MeOH) and -240991 (for **2**) contain the supplementary crystallographic data for this paper. The CIF files

Slow Electron Self-Exchange in Spite of a Small Inner-Sphere Reorganisation Energy − The Electron-Transfer Properties of a Copper Complex with a Tetradentate Bispidine Ligand

Peter Comba,*[a] Marion Kerscher,[a] and Andreas Roodt[b]

Keywords: Marcus theory / Kinetics / Molecular mechanics / Outer-sphere electron transfer / Cross reaction

The electron self-exchange rate of $[Cu(L)(OH_2)]^{2+/1+}$, k_{11}^{exp}(298.13 K) = 15 ± 11 $m^{-1}s^{-1}$ {L = dimethyl 3,7-dimethyl-9-oxo-2,4-bis(2-pyridyl)-3,7-diazabicyclo[3.3.1]nonane-1,5-dicarboxylate}, was determined by a cross reaction. The analysis, based on classical Marcus theory, indicates that this relatively slow rate is to a large extent due to enthalpic terms ($\Delta G_{11}^{\ddagger,exp}$ = 62.8 ± 3.5 kJ·mol^{-1}, $\Delta H_{11}^{\ddagger,exp}$ = 36.0 ± 2.7 kJ·mol^{-1} and $\Delta S_{11}^{\ddagger,exp}$ = –92 ± 10 J·mol^{-1}K^{-1}). The activation entropy is significant but not unusually large and the calculated outer-sphere reorganization energy, $\Delta G_{out}^{\ddagger,calc}$ = 20.5 kJ·mol^{-1}, is at least of the same order of magnitude as the calculated inner-sphere reorganisation energy $\Delta G_{in}^{\ddagger,calc}$ = 18.6 kJ·mol^{-1}, i.e. the deformation of the solvent sheath is a major reason for the slow electron transfer rate. This is believed to be due to the highly elastic coordination geometry which leads to little strain upon distortion enforced by the electron transfer but to comparably large structural changes and, hence, to a large outer-sphere reorganisation term.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Transition metal complexes of bispidine-type ligands {Figure 1 shows the tetradentate ligand L = dimethyl 3,7-dimethyl-9-oxo-2,4-bis(2-pyridyl)-3,7-diazabicyclo[3.3.1]-nonane-1,5-dicarboxylate} have a number of unique properties: (i) Due to the comparably high degree of preorganisation and complementarity[1] they lead to very stable complexes (e.g., for Cu^{II} complexes, stabilities are in the same range as those with macrocyclic ligands[2−4]). (ii) L enforces a square pyramidal configuration upon Cu^{II} with a monodentate co-ligand in plane with two co-planar pyridines and a tertiary amine (N3), and with a tertiary amine (N7) as an apical donor.[4] This unique configuration for Cu^{II} leads to strong copper-substrate binding and interesting reactivities.[5−8] (iii) Most relevant for the present study is that while the bispidine ligands are rigid, the coordination sphere is elastic.[1] This follows from experimental structural data[9] and from empirical force field calculations[1,9−11] which indicate that metal ions of quite different sizes fit into the bispidine cavity without inducing much steric strain in the ligand, i.e. the structure of the ligand backbone is practically constant while the metal donor bonds vary in the expected ranges.[6,9] Another interesting observation based on experimental structural data and related to the elasticity of the coordination geometry is that there are various structurally different positions within the bispidine cavity.[9] For pentadentate derivatives of L we recently isolated and structurally characterised isomers along a Jahn−Teller-active vibrational mode.[12] Similar observations have also been made of a tetradentate derivative of L where the pyridine donors are 6-methyl-substituted.[10]

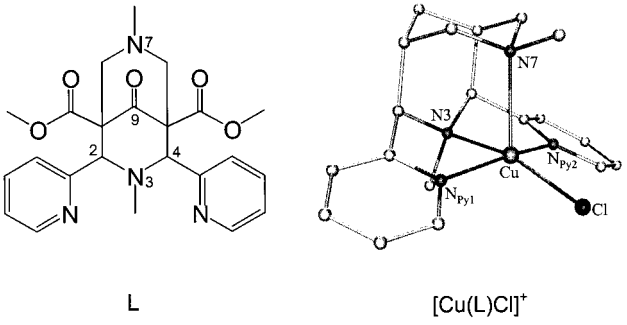

Figure 1. Diagram of the bispidine ligand L and a structural plot of the bispidine complex

The conclusion from all these observations is that the potential energy surface of metal-bispidine complexes is flat and has various shallow minima. Therefore, the inner-sphere reorganisation energy accompanying an electron self-exchange process should be small. Indeed, molecular-

mechanics-derived potential energy surface scans of $[Cu^{I}(L)(X)]^{n+}$ and $[Cu^{II}(L)(X)]^{n+1}$ indicate that the inner-sphere reorganisation energy ΔG^{*}_{in} is around only 10−20 kJ·mol^{-1} (see Figure 2 and below). Does that mean that electron self-exchange is fast as, for example, in blue copper proteins?

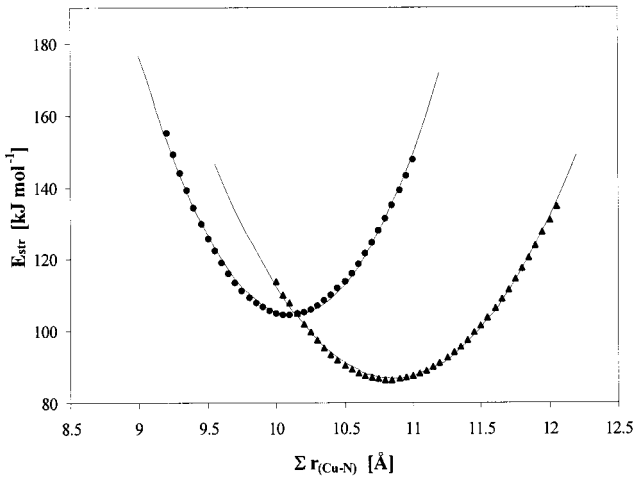

Figure 2. Potential energy scans for $[Cu^{II}(L)(NH_3)]^{2+}$ (filled circles) and $[Cu^{I}(L)(NH_3)]^{+}$ (filled triangles) (based on sum-constraints,[41] implemented with MOMEC97[42] and using a published parameterisation Scheme)[43]; the corresponding curves were obtained as least square fits to the equation $E = 0.5f(r - r_0)^2 + E_0$ (see below)

Results and Discussion

Experimentally Determined Electron Self-Exchange Parameters

Initial ^{1}H NMR line-broadening studies (CD_3CN, 298 K) indicated that electron self-exchange for the $[Cu^{II/I}(L)(NCCD_3)]^{2+/1+}$ couple is much slower than might have been expected (20 m^{-1}s^{-1} ≤ k_{11} ≤ 120 m^{-1}s^{-1}; see Supporting Information). Therefore, no accurate values are available from NMR titrations and the approximate range of the rate given here was only used as an estimate for the range of the electron self-exchange rate which was itself determined via a cross reaction using $[Co(sep)](NO_3)_2$ (sep = 1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]icosane) as a reducing agent [Equation (1), see Figure 3]. This was measured in water because the published electron self-exchange rate of the Co^{II} reductant has been obtained in aqueous solution (see below). Note that the change of solvent (CD_3CN, H_2O) implies that the two rates (NMR, cross reaction) are not directly comparable (different redox potential, different co-ligands and possible subtle changes in the mechanism). Indeed, there are examples where electron self-exchange rate constants of $Cu^{II/I}$ couples measured in H_2O and CH_3CN differ by as much as two orders of magnitude.[13] In other examples they are virtually identical.[14] Therefore, the only implication of the (inaccurate) rate of the NMR experiment is that electron self-exchange in the $[Cu^{II/I}(L)(solvent)]^{2+/1+}$ couple is slow.

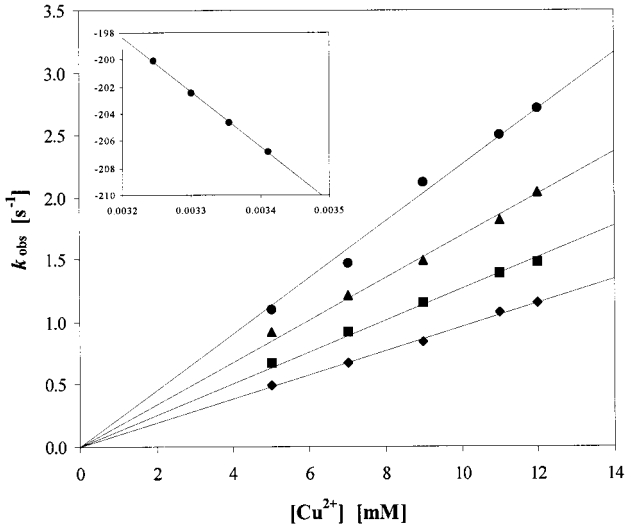

Figure 3. Plots of the pseudo-first-order rate constants k_{obs} for reaction (1) as a function of $[\{Cu^{II}(L)(OH_2)\}^{2+}]$ at 293.13 K (filled diamonds), 298.13 K (filled squares), 303.13 K (filled triangles) and 308.13 K (filled circles) in water (μ = 0.25 m, KNO_3), $[Co^{II}(sep)]_0$ = 5×10^{-4} m); inset: Eyring plot $[R\ln(k_{12}h/k_BT)$ [J·mol^{-1}·K^{-1}] vs. $1/T$ [K^{-1}]); k_{12} (298.13 K) = 126.9 ± 1.7 m^{-1}s^{-1}; $\Delta G^{\ddagger}_{12}$ (298.13 K) = 61.0 ± 1.2 kJ·mol^{-1}; $\Delta H^{\ddagger}_{12}$ = 40.3 ± 0.8 kJ·mol^{-1}; $\Delta S^{\ddagger}_{12}$ = −69.4 ± 2.8 J·mol^{-1}·K^{-1}

$$[Cu(L)(OH_2)]^{2+} + [Co(sep)]^{2+} \rightleftharpoons [Cu(L)(OH_2)]^{+} + [Co(sep)]^{3+} \quad (1)$$

The electron self-exchange rate, determined by the cross reaction, was obtained from the experimental data using the Marcus equations [Equation (2)−(6)[15,16] where Z is, as usual, 10^{11} m^{-1}s^{-1}]. The centre to centre distance in the precursor complex a_{ij} was obtained as the sum of the radii of the isolated complexes (a_j = $r([Co(sep)]^{3+/2+})$ = 4.5 ± 0.6 Å, identical to the published value.[17] a_i = $r([Cu(L)(NCCH_3)]^{2+/1+})$ = 6.3 ± 1.5 Å and both were calculated as $(a_x a_y a_z)^{1/3}$. The molecular dimensions along the three principal directional axes (a_x,a_y,a_z) were calculated using an established method.[16,18] The value K_{12} = 66.9 was derived from the redox potentials, measured under the same conditions as those used for the kinetic experiments [$E^0([Cu(L)(OH_2)]^{2+/1+})$ = −383 mV, $E^0([Co(sep)]^{3+/2+}$ = −491 mV, vs. Ag/AgCl]. The rate constant for the cross reaction k_{12} = 126.9 ± 1.7 m^{-1}s^{-1} was obtained from the experimental data (see Figure 3) and the electron self-exchange rate of the reductant is k_{22} = 5.1 ± 0.3 m^{-1} s^{-1}.[19] The self-exchange rate for the $[Cu^{I}(L)(OH_2)]^{+}$/$[Cu^{II}(L)(OH_2)]^{2+}$ couple is therefore k_{11} (298.13 K) = 15 ± 11 m^{-1}s^{-1},[20] i.e. as expected from the preliminary NMR experiments and a number of orders of magnitude slower than that of blue copper proteins which are in the range of

$k_{11} = 10^3-10^8$ $m^{-1}s^{-1}$ [21,22] and in the area of "slow" $Cu^{II/I}$ couples.[23−26]

$$k_{12} = \sqrt{k_{11}k_{22}K_{12}f_{12}}\ W_{12} \tag{2}$$

$$\ln f_{12} = \frac{1}{4}\frac{\left(\ln K_{12} + \frac{w_{12}-w_{21}}{RT}\right)^2}{\ln\frac{k_{11}k_{22}}{Z^2} + \frac{w_{11}+w_{22}}{RT}} \tag{3}$$

$$W_{12} = \exp\frac{-w_{12}-w_{21}+w_{11}+w_{22}}{2RT} \tag{4}$$

$$w_{ij} = \frac{z_i z_j e^2 N}{D_s a_{ij}\left(1+\beta a_{ij}\sqrt{\mu}\right)} \tag{5}$$

$$\text{with}\quad \beta = \sqrt{\frac{8\pi N e^2}{1000\, D_s k_B T}} \tag{6}$$

The activation parameters of the electron self-exchange reaction were determined by using Equations (7)−(10).[27] ΔS^0_{12} emerges from the reaction entropies of the redox couples [$\Delta S^0_{12} = \Delta S^0_{rc}(Cu^{II}) - \Delta S^0_{rc}(Co^{II})$,[28] $\Delta S^0_{rc}(Co^{II}) = 79.5$ $J\cdot mol^{-1}\cdot K^{-1}$,[29] $\Delta S^0_{rc}(Cu^{II}) = 130.3 \pm 1.8$ $J\cdot mol^{-1}\cdot K^{-1}$ (temperature dependence of the redox potential) i. e. $\Delta S^0_{12} = 50.8 \pm 1.8$ $J\cdot mol^{-1}\cdot K^{-1}$]. The activation parameters for the $[Co(sep)]^{3+/2+}$ self-exchange are from the literatures, i.e. $\Delta G^{\ddagger}_{22} = 68.8 \pm 3.2$ $kJ\cdot mol^{-1}$, $\Delta H^{\ddagger}_{22} = 40.2 \pm 2.1$ $kJ\cdot mol^{-1}$ and $\Delta S^{\ddagger}_{22} = -96 \pm 8$ $J\cdot mol^{-1}\cdot K^{-1}$ [19] and those for the cross reaction are $\Delta G^{\ddagger}_{12} = 61.0 \pm 1.2$ $kJ\cdot mol^{-1}$, $\Delta H^{\ddagger}_{12} = 40.3 \pm 0.8$ $kJ\cdot mol^{-1}$ and $\Delta S^{\ddagger}_{12} = -69.4 \pm 2.8$ $J\cdot mol^{-1}\cdot K^{-1}$, derived from the experiment (see Figure 3). The resultant experimental activation parameters for the $[Cu(L)(OH_2)]^{2+/1+}$ self-exchange are, therefore, $\Delta G^{\ddagger}_{11} = 62.8 \pm 3.5$ $kJ\cdot mol^{-1}$, $\Delta H^{\ddagger}_{11} = 36.0 \pm 2.7$ $kJ\cdot mol^{-1}$ and $\Delta S^{\ddagger}_{11} = -92 \pm 10$ $J\cdot mol^{-1}\cdot K^{-1}$.

$$\Delta G^{\ddagger}_{12} = \frac{\Delta G^{\ddagger}_{11}}{2} + \frac{\Delta G^{\ddagger}_{22}}{2} + \frac{\Delta G^{o}_{12}}{2}(1+\alpha) \tag{7}$$

$$\Delta S^{\ddagger}_{12} = \left(\frac{\Delta S^{\ddagger}_{11}}{2} + \frac{\Delta S^{\ddagger}_{22}}{2}\right)\left(1-4\alpha^2\right) + \frac{\Delta S^{o}_{12}}{2}(1+2\alpha) \tag{8}$$

$$\Delta H^{\ddagger}_{12} = \left(\frac{\Delta H^{\ddagger}_{11}}{2} + \frac{\Delta H^{\ddagger}_{22}}{2}\right)\left(1-4\alpha^2\right) + \frac{\Delta H^{o}_{12}}{2}(1+2\alpha) \tag{9}$$

$$\text{with}\quad \alpha = \frac{\Delta G^{o}_{12}}{4\left(\Delta G^{\ddagger}_{11} + \Delta G^{\ddagger}_{22}\right)} \tag{10}$$

Calculated Electron Self-Exchange Parameters

Three methods were used to calculate the inner-sphere reorganisation energy: (i) From the crossing point of the molecular-mechanics-derived energy surface scans [Figure 2, Equation (11)].[30] This method has some deficiencies and may only be considered as an upper limit.[25,31] (ii) From a free energy perturbation-type approach [Equation (12)], where $E^{*}_{str,Cu(I)}$ is the strain energy of the Cu^{II} structure, determined with the Cu^{I} force field and vice versa.[25] (iii) From the force constants of the Cu^{II} and Cu^{I} breathing modes, derived from the energy surface scans shown in Figure 2 (solid lines) and Equations 13−15[16] in which $n = 5$ is the number of donors and f_i is the averaged reduced force constant which approximately takes account of the asymmetry and rigidity of the ligand. The inner-sphere reorganisation energy, derived from the three approaches leads to similar values and these are, as expected, small: (i) $\Delta G^{*}_{in} = 18.6$ $kJ\cdot mol^{-1}$, (ii) $\Delta G^{*}_{in} = 13.4$ $kJ\cdot mol^{-1}$ and (iii) $\Delta G^{*}_{in} = 12.2$ $kJ\cdot mol^{-1}$. The three methods are based on the assumption that the Cu^{I} and Cu^{II} chromophores are similar, i.e. pentacoordinate. Published experimental data indicate that, as expected for Cu^{I}, there is a fast equilibrium between four- and five-coordinate structures (dissociation of one of the pyridine donors).[6,32] However, ^1H NMR spectra in D_2O indicate that the five-coordinate species is the major component in water and this is similar to earlier observations in acetonitrile.[6,32] Also, recent structural studies[33] indicate that, in addition to the published four- and five-coordinate Cu^{I} structures, there is a "pseudo-4-coordinate" Cu^{I} species with a short (2.0 Å) and a long (2.9 Å) $Cu-N_{pyridine}$ bond (pyridine lone-pair on the $Cu\cdots N_{py}$ axis) and a coordinated co-ligand ($NCCH_3$). This is also supported by DFT calculations[34] and is further evidence for the flat energy surface and validates the approximation of similar Cu^{I} and Cu^{II} chromophores. The three values for ΔG^{*}_{in} are all based on molecular mechanics calculations and, therefore, depend on the accuracy of the force field and on the model used (replacement of substituents at C1, C5, C9 of the bispidine backbone by hydrogen atoms, NH_3 instead of $NCCH_3$ as co-ligand; while chemically these changes might be unreasonable, in terms of the molecular mechanics model, which does not include any electronic effects, these are believed to be uncritical). The suitability of molecular mechanics for the computation of the inner-sphere reorganisation energy was therefore also confirmed by preliminary DFT calculations.[35]

$$\Delta G^{*}_{in} = 2E^{*}_{str} - E_{str,Cu(I)} - E_{str,Cu(II)} \tag{11}$$

The outer-sphere reorganisation energy can be obtained on the basis of a two-sphere (Equation 16) or an ellipsoid model (Equations 17−19).[16] The outer-sphere reorganisation energy, using the probably more accurate ellipsoid model, $\Delta G^{*}_{out,ellipsoid} = 20.5$ $kJ\cdot mol^{-1}$ ($\Delta G^{*}_{out,sphere} = 15.2$ $kJ\cdot mol^{-1}$) is of at least a similar magnitude to the inner-sphere reorganisation energy. The term derived from the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

formation of the precursor complex (w_r = 2.80 ± 0.47 kJ·mol^{-1}) is significantly smaller.

$$\lambda_{in} = E^*_{str,Cu(I)} + E^*_{str,Cu(II)} - E_{str,Cu(I)} - E_{str,Cu(II)}$$

$$\Delta G^*_{in} = \frac{\lambda_{in}}{4} \quad (12)$$

$$\lambda_{in} = n\, f_i (\Delta a_0)^2 \quad (13)$$

$$\text{with} \quad f_i = \frac{2 f_{Cu(I)} f_{Cu(II)}}{f_{Cu(I)} + f_{Cu(II)}} \quad (14)$$

$$\text{and} \quad \Delta G^*_{in} = \frac{\lambda_{in}}{4} \quad (15)$$

$$\lambda_{out} = Ne^2 \left(\frac{1}{2a_1} + \frac{1}{2a_2} - \frac{1}{r} \right) \left(\frac{1}{D_{op}} - \frac{1}{D_s} \right) \quad (16)$$

$$\lambda_{out} = \frac{Ne^2 r^2}{2 I_a I_b^2} \left(\frac{1}{D_{op}} - \frac{1}{D_s} \right) S(\lambda_0) \quad (17)$$

$$\text{with} \quad S(\lambda_0) = \sum_{n=1,3,5\ldots}^{\infty} \frac{(2n+1)\lambda_0 (\lambda_0^2 - 1) Q_n(\lambda_0)}{P_n(\lambda_0)} \quad (18)$$

$$\text{and} \quad \lambda_0^2 = \frac{I_a^2}{I_a^2 - I_b^2} \quad (19)$$

The calculated rate, using the computed activation parameters, is k_{11}^{calc} = 4.5 10^3 m^{-1}s^{-1}, i.e. approx. 2 orders of magnitude too large (k_{11}^{obs} = 15 ± 11 m^{-1}s^{-1}, see above). An important point here is that the ΔG^* values in Equation (20) are not corrected for entropy effects. The inner-sphere reorganisation energy [Equation (11)] has been shown to have a linear dependence on the strain energies.[30] For a series of Co(III/II) hexamine couples this resulted in a $T\Delta S^*$ term (T = 298.13 K) of 20 kJ·mol^{-1}. This value is of a similar magnitude to the herein experimentally determined activation entropy at 298.13 K of $T\Delta S^{\ddagger}_{obs}$ = 27.4 kJ·mol^{-1}. With this 20 kJ·mol^{-1} added to ΔG^*_{calc} in Equation (21), k_{11}^{calc} = 1.5 m^{-1}s^{-1} is obtained which is in reasonable agreement with the experimentally determined self-exchange rate of k_{11}^{obs} (298.13 K) = 15 ± 11 m^{-1}s^{-1}. Note, however, that $\Delta S^{\ddagger}_{11}$ is the total transition state activation entropy and not the reorganisational entropy,[36] i.e. part of $\Delta S^{\ddagger}$ is included in the pre-exponential factor in the commonly used Equation (22) (which is a combination of Equations 20 and 21). Another possible reason for a reduction of Z (i.e. for a smaller value of the computed self-exchange rate) is reduced electronic coupling, i.e. nonadiabicity.

$$\Delta G^*_{calc} = w_r + \Delta G^*_{in} + \Delta G^*_{out} - RT \ln \frac{hZ}{k_B T} \quad (20)$$

$$k_{11}^{calc} = \frac{k_B T}{h} \exp \frac{-\Delta G^*}{RT} \quad (21)$$

$$k_{11}^{calc} = Z \exp\left(- \frac{w_r + \Delta G^*_{in} + \Delta G^*_{out}}{RT} \right) \quad (22)$$

Conclusions

As suggested by structural studies, the rearrangement of the coordination sphere of the copper-bispidine complex with L is a low energy process and ΔG^*_{in} = 18.6 kJ·mol^{-1} is overestimated rather than underestimated. Our analysis suggests that the experimentally determined slow electron self-exchange rate is to a large extent the result of a comparably high outer-sphere reorganisation energy barrier. A significant contribution to the activation entropy term and nonadiabicity might also be responsible for the relatively slow self-exchange rate. While our experimental and computational results do not yet allow a thorough and unambiguous assignment of the ratio of the various terms to the high activation barrier, it is clear that while the flat energy surface of transition metal bispidine complexes with L leads to a high elasticity and hence to a minimal loss of energy upon distortions enforced by the electron transfer, the elasticity also allows for large structural changes and this results in a significant perturbation of the solvation sheath (note that structural elasticity and solvation in small coordination compounds are both not directly comparable to those in proteins).[21,37,38] While this is a very specific result for the highly elastic Cu$^{II/I}$-bispidine system, the interesting but not unexpected general conclusion is that small inner-sphere reorganisation energies do not necessarily lead to fast electron transfer rates. This is in contrast to a common but naive interpretation of the Cu$^{II/I}$ electron self-exchange in blue copper proteins and a further argument in the discussion on entatic states.[39] Experiments and calculations which might help to answer some of the remaining questions, include kinetic studies with other bispidine derivatives and other bispidine redox couples (e.g., Co$^{III/II}$, Ru$^{III/II}$) and extensive DFT calculations. Some of these will be carried out in due course.

Experimental Section

Syntheses: Ligand L was synthesised as described in the literature.[40] The Cu^{II} complex as its triflate salt was obtained by addition of a hot solution of $Cu(CF_3SO_3)_2$ in dry CH_3CN to an equimolar suspension of L in dry CH_3CN. The resultant solution was stored in a diethyl ether diffusion bath to give $[Cu(L)(NCCH_3)(O\text{-}SO_2CF_3)]CF_3SO_3$ as deep blue crystals. $C_{27}H_{29}CuF_6N_5O_{11}S_2$ (841.22): calcd. C 38.55, H 3.47, N 8.33, S 7.62; found C 38.51, H 3.50, N 8.30, S 7.58. All solutions of the Cu^{II} complex were prepared with deionised and deoxygenated water and KNO_3 to keep

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the ionic strength at 0.25 m. The Cu^{I} complex was obtained as described previously.[32]

$[Co(sep)]Cl_3$ (Aldrich) was converted into its nitrate salt by treatment of an aqueous solution of 1 equivalent of $[Co(sep)]Cl_3$ with 3 equivalents of $AgNO_3$. After filtration, solid KNO_3 was added slowly to the filtrate until precipitation of the orange $[Co(sep)](NO_3)_3$ was complete. This was recrystallised from a small amount of warm water and the precipitate was dried in vacuo. A solution of $[Co(sep)](NO_3)_3$ of the appropriate concentration and desired ionic strength (0.25 m, KNO_3) in deionised and deoxygenated water was then treated with an excess of zinc dust under Ar until the complex was fully reduced (approx. 4 h, colourless solution). The solution was used for kinetic measurements within 3 h after preparation.

Measurements: Redox potentials were measured by cyclic voltammetry using a BAS-100B electrochemical analyser with a scan rate of 100 mV/s. The electrode setup consisted of a glassy/carbon working electrode, a platinum auxiliary electrode and an aqueous Ag/AgCl reference electrode. The concentrations of the solutions were 10^{-3} m for the $Co^{III/II}$(sep) couple and 10^{-2} m for the $Cu^{II/I}$(L) couple, μ = 0.25 m (KNO_3). The temperature of the solutionswas maintained using a circulating water bath (Haake K 20).

^{1}H NMR Spectra: (60 mm $[Cu^{I}(L)]$, 0−28 mm $[Cu^{II}(L)]$, CD_3CN, T = 193 K) were obtained on a Bruker AS 300 spectrometer (300.13 MHz). Chemical shifts (δ, ppm) are relative to the solvent. Note that in addition to the electron self-exchange there is a dynamic process between two different structures of $[Cu^{I}(L)(NCCD_3)]^+$ (four- and five-coordinate).[6,32] ^{1}H NMR spectroscopy suggests that this process is much faster than the electron self-exchange reaction and that the five-coordinate complex is the major species in solution. This also emerges for the corresponding aqua complexes measured in aqueous solution and it is in agreement with preliminary DFT calculations.[34]

Kinetics: Measurements were performed on an Applied Photophysics SX.18MV-R stopped-flow spectrophotometer. The temperatures of the solutions were maintained (± 0.1 °C) using a circulating water bath (Haake K20). The cross reactions were carried out under pseudo-first-order conditions (Cu^{II} in at least 10-fold excess) and the rates were monitored at 474 nm. The kinetic data were analysed using the !SX.18MV Kinetic Spectrometer Workstation Software v4.46.

Supporting Information: Details of the determination of $K_{Cu\text{-}Cl}$, the NMR line-broadening studies, the experimentally measured entropy of the redox potential and the calculations of the electron transfer rates are given as Supporting Information (see also footnote on the first page of this article)

Isolation and Molecular Structure of a Monomeric, Tris[peroxotitanium(IV)]-Substituted α-Dawson Polyoxometalate Derived from the Tetrameric Anhydride Form Composed of Four Tris[titanium(IV)]-Substituted α-Dawson Substructures and Four Bridging Titanium(IV) Octahedral Groups

Yoshitaka Sakai,[a] Yuh Kitakoga,[a] Kunihiko Hayashi,[a] Kenji Yoza,[b] and Kenji Nomiya*[a]

Keywords: Titanium(IV) / Peroxo complexes / Polyoxometalates

The isolation and structural characterisation of a novel tris-[peroxotitanium(IV)]-substituted α-Dawson polyoxometalate (POM), [α-1,2,3-$P_2W_{15}(TiO_2)_3O_{56}(OH)_3]^{9-}$ (**1a**), containing side-on coordination (i.e. η^2-coordination) of the peroxo group to the titanium(IV) atom are described. A water-soluble, completely inorganic compound of the monomeric POM Na_9[α-1,2,3-$P_2W_{15}(TiO_2)_3O_{56}(OH)_3]\cdot 16H_2O$ (**1**), obtained as analytically pure, homogeneous orange crystals, was obtained from a reaction in aqueous solution of an excess of 30% aqueous hydrogen peroxide with {[α-1,2,3-$P_2W_{15}Ti_3O_{59}(OH)_3]_4[\mu_3$-$Ti(OH)_3]_4Cl\}^{33-}$ (**2a**). The latter has been recently shown to be a giant "tetrapod"-shaped, tetrameric anhydride formed from the tris[titanium(IV)]-substituted Dawson substructures with four bridging Ti octahedral groups. Compound **1** could not be obtained from the reaction with another giant tetrapod POM, {[α-1,2,3-$P_2W_{15}Ti_3O_{57.5}(OH)_3]_4Cl\}^{25-}$ (**3a**), which does not contain the bridging octahedral Ti groups. The molecular structure of **1a** was successfully determined by a single-crystal X-ray diffraction study and was shown to be a monomeric α-Dawson POM derived from the tris[peroxotitanium(IV)] species. Bond valence sum (BVS) calculations suggest that the μ_2-oxo sites of the three Ti–O–Ti bridges in the Ti_3 cap of the Dawson unit are protonated. Characterisation of **1** was also accomplished by complete elemental analysis, TG/DTA, FTIR and solution (^{31}P and ^{183}W) NMR spectroscopy.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Polyoxometalates (POMs) are molecular metal oxide clusters. They are of current interest as soluble metal oxides and because of their applications in catalysis, medicine and materials science.[1] Site-selective substitution of the W^{VI} atoms in POMs with Ti^{IV} atoms is particularly interesting because of the multicentre active sites formed with corner- and/or edge-sharing TiO_6 octahedra and the water-soluble molecular modelling studies of titanium(IV) oxides as an effective semiconductor and photocatalysts.[2]

Many H_2O_2-based oxidation reactions catalysed by titanium(IV)-substituted POMs have been described in which the peroxotitanium(IV) and/or hydroperoxotitanium(IV) species have been proposed as the active intermediates in such reactions.[3] Thus, the synthesis and structural characterisation of peroxotitanium(IV)-substituted POMs would constitute an intriguing project. Only a few structure determinations of peroxotitanium(IV) complexes have been conducted and these have been for the mono[peroxotitanium(IV)]-substituted Keggin POM $[PW_{11}(TiO_2)O_{39}]^{5-}$ species,[4] whereas related examples from the Dawson POM family have not been reported so far.

Very recently, we reported the two tetrameric anhydride forms of tri-Ti^{IV}-substituted Dawson POMs, i.e. {[α-1,2,3-$P_2W_{15}Ti_3O_{59}(OH)_3]_4[\mu_3$-$Ti(OH)_3]_4Cl\}^{33-}$ (**2a**, tetrapod-shaped POM with the four bridging octahedral Ti^{IV} groups and with one encapsulated Cl^- ion)[5a] and {[α-1,2,3-$P_2W_{15}Ti_3O_{57.5}(OH)_3]_4Cl\}^{25-}$ (**3a**, tetrapod-shaped POM without the bridging octahedral Ti^{IV} groups and with one encapsulated Cl^- ion),[5b] both of which contain a giant, inorganic "tetrapod" molecule composed of four 1,2,3-tri-Ti^{IV}-substituted α-Dawson substructures.[6,7] Separately, Kortz et al. have also determined the molecular structure of the related tetrameric Dawson species without encapsulated chloride ions, $\{[P_2W_{15}Ti_3O_{57.5}(OH)_3]_4\}^{24-}$ (**4a**).[5c,6,7]

During our study of the formation of **2a** and **3a** in aqueous solution[8] and the reactivity of these species with hydrogen peroxide (see the Exp. Sect.), we unexpectedly obtained a monomeric and pure form of the tris[peroxotitanium(IV)]-substituted Dawson POM [α-1,2,3-

$P_2W_{15}(TiO_2)_3O_{56}(OH)_3]^{9-}$ (**1a**) from the reaction of **2a**. The reaction of **3a**, however, did not produce such a result. An X-ray structure analysis revealed that the peroxo groups on the Ti atoms are attached by side-on coordination, i.e. η^2-coordination. The bond valence sum (BVS) calculations of the oxygen atoms suggest that three protons are bound to the surface edge-sharing oxygen atoms of the Ti_3 cap in **1a**. The lack of any other protons in **1a** conclusively suggests that the peroxo group, but not the hydroperoxo group, is bound to the Ti atom. The X-ray structure determination of the POM-based tris[peroxotitanium(IV)] complex highlighted here is the first example of its type. Herein, we report full details of the synthesis and characterisation of the water-soluble sodium salt Na_9[**1a**]·$16H_2O$ (**1**) and the molecular structure of **1a**.

Results and Discussion

Synthesis, Isolation and Characterisation of 1

The water-soluble sodium salt of **1** was prepared in ca. 25% (0.53 g scale) yield by recrystallising the orange powder which was obtained from the reaction of the precursor **2** in aqueous solution with an excess of 30% aqueous H_2O_2. Of particular note is the fact that the reactivity of the two tetrameric Dawson POMs **2** and **3** with aqueous hydrogen peroxide was remarkably different. Compound **1** was successfully derived from the reaction of **2** with aqueous H_2O_2, but **3** did not behave in such a way. The formation of **1a** is shown in Equation (1).

$$\{[P_2W_{15}Ti_3O_{59}(OH)_3]_4[\mu_3\text{-}Ti(OH)_3]_4Cl\}^{33-}\ (\mathbf{2a}) + 12\ H_2O_2 \rightarrow 4\ [P_2W_{15}(TiO_2)_3O_{56}(OH)_3]^{9-}\ (\mathbf{1a}) + 4\ \{Ti(OH)_3\}^+ + Cl^- + 12H_2O \quad (1)$$

Compound **1** was characterised by complete elemental analysis, TG/DTA, FTIR, ^{31}P and ^{183}W NMR spectroscopy and a single-crystal X-ray diffraction study. The sample for elemental analysis was prepared by drying at room temperature under a vacuum of 10^{-3}–10^{-4} Torr overnight. All elements were observed, including oxygen, to a total analysis of 98.95 %. These data are consistent with a composition of Na_9[**1a**]·$4H_2O$. The weight loss observed during the course of drying before analysis was 4.93% which corresponded to 12–13 water molecules weakly bound or adsorbed in **1**. In contrast, TG/DTA measurements performed under atmospheric conditions showed a weight loss of 6.61% between 25 and 168 °C with endothermic points at 60 and 84 °C corresponding to the presence of 16 water molecules constituting both the intrinsic water of hydration and adsorbed water from the atmosphere. The number of water molecules (16) is consistent with the sum of the water molecules (4) found in the elemental analysis plus the water molecules (12–13) corresponding to the weight loss observed during the course of drying before analysis. Interestingly, bond-valence sum (BVS) calculations of the oxygen atoms in **1a** indicate that the μ_2-oxo sites of the three Ti–O–Ti bridges in the Dawson unit are protonated (see "Molecular Structure of **1a**").

TG/DTA measurements also showed the thermal stability of **1**. A weight loss of 4.12% observed from 167 °C up to ca. 400 °C with an endothermic point at 172 °C was due to decomposition of the coordinated peroxo groups. FTIR spectroscopic measurements of the samples after heating up to 150 °C (resulting in dehydration) and 200 °C (resulting in decomposition of the peroxo groups) showed that the Dawson POM framework was still intact. However, the IR measurements of the sample after heating up to 500 °C showed that the Dawson framework had been disrupted.

The solid-state FTIR spectrum of **1** (Figure 1, a; $\tilde{\nu}$ = 1083, 940, 923, 800 br cm^{-1}) measured as a KBr disk, showed the characteristic vibrational bands of the Dawson-type POM "$P_2W_{18}O_{62}^{6-}$" framework.[9] The lack of bands at around 650 cm^{-1} which would be due to an inter-Dawson unit Ti–O–Ti vibration suggests that **1** is a monomer and not an oligomer. The O–O stretching band which is known to appear around 900 cm^{-1} for monoperoxo complexes[10] was observed at 890 cm^{-1}.

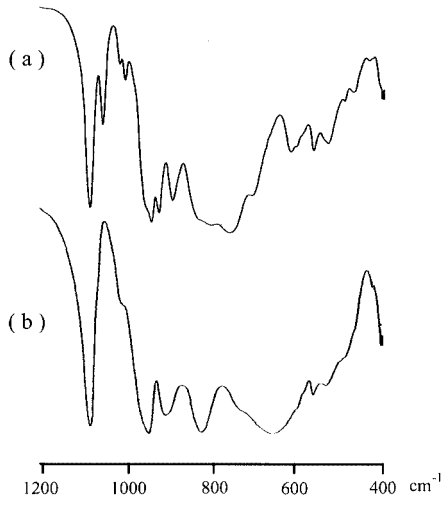

Figure 1. FTIR spectra in the polyoxoanion region (1200–400 cm^{-1}), measured as KBr disks, of a) Na_9[**1a**]·$16H_2O$ (**1**) {**1a** = [α-1,2,3-$P_2W_{15}(TiO_2)_3O_{56}(OH)_3]^{9-}$} and b) Na_xH_{33-x}[**2a**]·yH_2O (**2**) (x = 16–19, y = 60–70; **2a** = {[α-1,2,3-$P_2W_{15}Ti_3O_{59}(OH)_3]_4[\mu_3$-$Ti(OH)_3]_4Cl\}^{33-}$)

The ^{183}W NMR spectrum of **1** measured in D_2O at 20.7 °C (Figure 2, a) showed a three-line pattern with signals at δ = −156.5, −201.9 and −230.1 ppm with relative intensities of 1:2:2. This spectrum is in agreement with the presence of two tungsten belts consisting of six WO_6 octahedra and a tungsten cap of three WO_6 octahedra. The ^{31}P NMR spectrum of **1** in D_2O at 22.6 °C (Figure 3, a) showed a clean two-line pattern with signals at δ = −3.93 and −14.41 ppm, confirming its purity and single-product nature. The downfield resonance can be assigned to the phosphorus atom closest to the Ti_3 cap, whereas the upfield resonance is due to the phosphorus atom closer to the W_3 cap. It should be noted that the downfield signal is much more shifted to low-field compared with those of the tetrameric

Molecular Structure of 1a

The crystal of **1** contains discrete cluster anions, sodium cations and lattice water molecules, all in general positions in the monoclinic space group $P2_1/c$. The solid-state packing of the polyoxoanions of **1a** is shown in Figure S2 in the Supporting Information. The observed electron densities of the Ti and W atoms are quite different and the data unequivocally distinguish and define the Ti and W atoms. The 15 tungsten atoms, 3 titanium atoms and the 2 phosphorus atoms can be clearly identified. Thus, the main features of the molecular structure of the POM have been identified. However, the resolution obtained for the structure of the salt was limited by the poor quality of the available crystals and by the considerable disorder of the countercations and the solvent of crystallization. Such a problem is common in POM crystallography.[11]

The molecular structure of **1a** is composed of the monomeric Dawson POM unit "α-$P_2W_{15}Ti_3O_{62}$", in which the

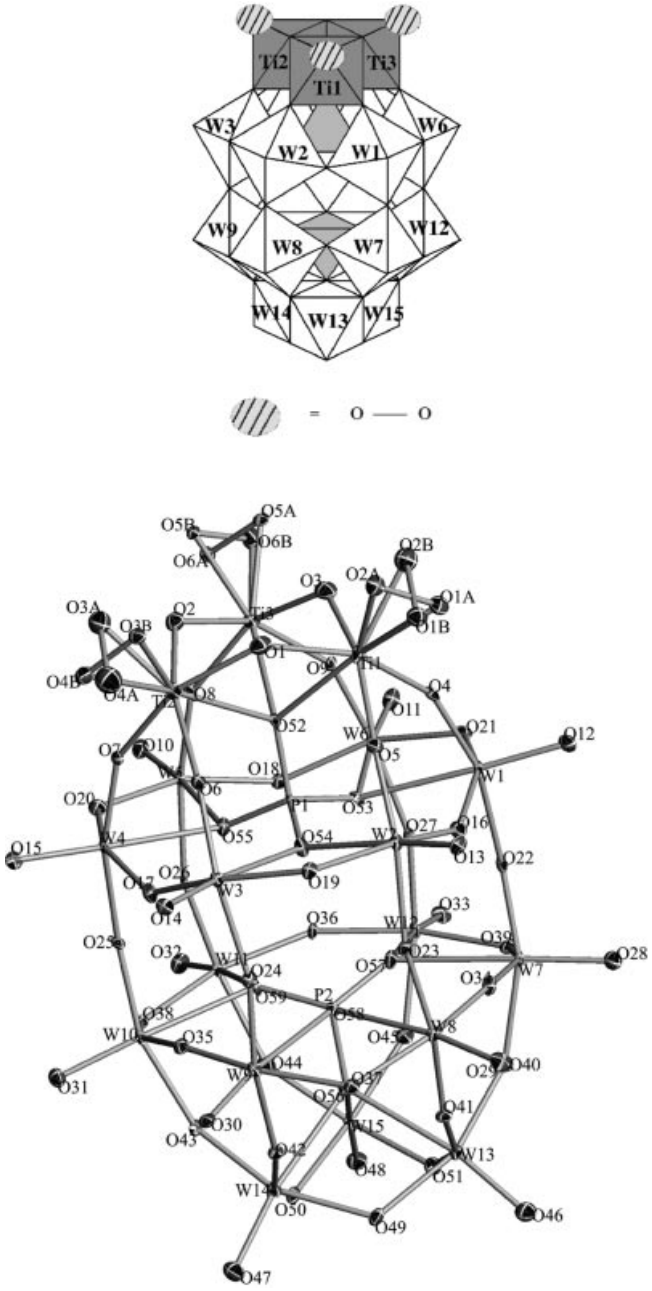

Figure 4. Top: polyhedral representation of the monomeric tris[peroxotitanium(IV)]-substituted Dawson POM [α-1,2,3-$P_2W_{15}(TiO_2)_3O_{56}(OH)_3]^{9-}$ (**1a**); bottom: molecular structure of **1a** with 50% probability ellipsoids

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

three edge-sharing octahedral sites of the titanium(IV) atoms (Ti_3-cap site) in the "α-$P_2W_{15}Ti_3$" Dawson unit substitute the three edge-sharing octahedral sites of the tungsten(VI) atoms (W_3-cap site) of $[\alpha\text{-}P_2W_{18}O_{62}]^{6-}$. The 3 titanium atoms and 15 tungsten atoms in the Dawson unit all adopt conventional octahedral coordination polyhedra. The polyhedral representation and molecular structure of **1a** are shown in Figure 4 (top and bottom, respectively). In **1a**, the three terminal oxygen atoms of the Ti_3 cap are substituted by the side-on-coordinated peroxo groups (Figure 4, top). The peroxo groups coordinated to the titanium(IV) atoms are shown in two positions in Figure 4 (bottom) because of disorder. The site occupancy factors of the oxygen atoms in the peroxo group were fixed at 0.64 for those labelled A and 0.36 for those labelled B. Nevertheless, the three edge-sharing titanium(IV) octahedra were positively identified and have been more fully characterised, compared with the structures so far reported for other POM-based mono- and bis[peroxotitanium(IV)] complexes.[3,4]

Selected bond lengths and angles around the three titanium(IV) centres and average bond lengths and angles for the Dawson POM unit in **1a** are given in Tables 2and 3, respectively. The O−O distances of the peroxo groups [O1A−O2A 1.45(3), O3A−O4A 1.43(3), O5A−O6A 1.45(3) Å] indicate their single-bond nature.

The Ti−O distances in the Ti_3 cap (Ti1, Ti2, Ti3) are significantly influenced by the coordination of the peroxo group, whereas the W−O distances in the W_3 cap and the two W_6 belts, i.e. the W−Ot (Ot: terminal oxygen atom), W−Oe (Oe: edge-sharing oxygen atom), W−Oc (W belt) (Oc: corner-sharing oxygen atom) and W−Oa (Oa: oxygen atom coordinated to phosphorus atom) distances are in the normal ranges.[1b] The Dawson unit contains two central P atoms in almost regular tetrahedral PO_4 units, i.e. the PO_4 closest to the Ti_3 cap [P−O distances 1.520(11)−1.560(11) Å; O−P−O angles 107.4(6)−110.9(6)°] and the PO_4 closer to the W_3 cap [P−O distances 1.513(12)−1.575(11) Å; O−P−O angles 106.8(6)−112.2(6)°].

The calculated bond valence sums (BVS),[12] based on observed bond lengths in **1a**, are in the range of 6.042−6.320 for the 15 tungsten atoms and 4.937−4.982 for the two phosphorus atoms. These data reasonably correspond to the formal valences of W^{6+} and P^{5+}, respectively. Furthermore, the BVS calculations of the oxygen atoms are in the range of 1.2322−1.2880 for O1, O2 and O3, indicating that a total of three protons are bound to the surface edge-sharing oxygen atoms of the Ti_3 cap in **1a**. In relation to this fact, we re-investigated the protonation sites and the actual anionic charges for **2a** and **3a** using BVS calculations and confirmed the protonation of all Ti−O−Ti bridges within the Dawson unit.[6] Protonation of the μ_2-oxo sites of the Ti−O−Ti bridges in the Dawson unit was first proposed for **4a**.[5c] Thus, POM **1a** takes a total charge of −9, suggesting that a peroxo group, but not a hydroperoxo group, is attached to each Ti atom.

The average O−O and Ti−O_{peroxo} bond lengths (1.44 and 1.89 Å, respectively) in **1a** can be compared with those of the previously reported mono[peroxotitanium(IV)] complex, OEPTi(O_2) (OEP = 2,3,7,8,12,13,17,18-octaethylporphinato) which contains η^2-coordination of the peroxo group to the titanium(IV) atom [O−O bond length 1.445(5) Å and two Ti−O distances 1.872(4) and 1.822(4) Å].[10a] In comparison with other peroxo groups in the POM, the average O−O distance (1.44 Å) in **1a** is close to that in [α-$P_2W_{12}(NbO_2)_6O_{56}]^{12-}$ (average 1.43 Å),[13a] but shorter than that in [A,β-$PW_9(NbO_2)O_{37}]^{6-}$ (average 1.51 Å)[13b] and the noncoordinated O_2^{2-} group (average 1.49 Å).[13c]

The peroxo groups influence the average bond lengths around the Ti_3 cap moiety more significantly than those around the W_3 cap moiety as evidenced by (i) the peroxo groups attached to the Ti atoms in **1a**, (ii) the intermolecular Ti−O−Ti interaction through the octahedral Ti^{IV} bridging groups in **2a** and (iii) the intermolecular Ti−O−Ti interaction due to direct linkage of the Dawson units in **3a** (Table 4). This effect would be reflected in the ^{31}P and ^{183}W NMR resonances. In fact, the ^{31}P resonance closest to the Ti_3 cap and the ^{183}W resonance of the W_6 belt closer to the Ti_3 cap are considerably more shifted (Table 1). Thus, the molecular structure of **1a** is consistent with the results of solution (^{31}P and ^{183}W) NMR spectroscopy, suggesting that the tris[peroxotitanium(IV)] group containing Dawson structure is maintained in aqueous solution.

On standing at room temperature for a prolonged period of time (approximately a couple of weeks), an aqueous solution of **1a** formed new crystals. An X-ray structure analysis showed that the new crystals contain the tetrapod-shaped POM without the bridging octahedral Ti groups and without an encapsulated Cl^- ion, corresponding to the POM **4a** reported by Kortz et al.[5c] In relation to this fact, two control experiments were performed as follows: (1) A clear orange solution of 0.3 g (0.067 mmol) of **1**, dissolved in 10 mL of water, was heated to reflux. ^{31}P NMR spectra of the solution were measured after 1, 2, 12 and 19 h of heating at reflux. The orange colour of the solution remained for at least 3.5 h. After 12 h, the solution became colourless and a ^{31}P NMR spectrum showed signals (δ = −7.40 and −14.16 ppm) due only to the giant tetrapod-POM without the bridging groups, i.e. **4a**. No ^{31}P NMR signal for **1a** was observed. (2) The transformation of **1a** to **4a** was also confirmed by the reaction of **1a** (0.3 g, 0.067 mmol) with $NaHSO_3$ (0.5 g, 4.80 mmol) in aqueous solution at room temperature. Several minutes after mixing of **1a** with $NaHSO_3$, the solution became colourless. Compound **4a** had probably formed at this stage. After stirring overnight, the solution (which had been concentrated at 30 °C to about 2 mL) was added to 300 mL of EtOH and a white powder of **4**, showing ^{31}P NMR resonances at δ = −7.31 and −14.05 ppm, was collected.

The transformation of **1a** to **4a** is due to thermal decomposition of the coordinated peroxo groups and also indicates the potential of **1a** as a nanobuilding block for formation of POM-based giant molecules. The peroxo group attached to the Ti atoms was relatively stable and the catalytic activity of **1a** for 2-propanol oxidation with aqueous H_2O_2 was very low. Thus, POM **1a** can be expected to act as a building block for the preparation of POM-based giant molecules, rather than as an oxidation catalyst. It is likely that the catalytically active species will be the hydroperoxotitanium(IV) species rather than the peroxotitanium(IV) species.[3c]

Conclusion

In conclusion, the monomeric tris[peroxotitanium(IV)]-substituted α-Dawson POM [α-1,2,3-$P_2W_{15}(TiO_2)_3O_{56}$-

$(OH)_3]^{9-}$ (**1a**), showing η^2-coordination of the peroxo group, was obtained from the reaction of an excess of 30% aqueous H_2O_2 with the recently reported giant tetrapod-shaped POM $\{[\alpha\text{-}1,2,3\text{-}P_2W_{15}Ti_3O_{59}(OH)_3]_4[\mu_3\text{-}Ti(OH)_3]_4Cl\}^{33-}$ (**2a**) (FW ≈ 16000) with approximately T_d symmetry. The water-soluble compound isolated as Na_9[**1a**]·$16H_2O$ (**1**) can be expected to be suitable as a precursor for the synthesis of novel POM-based giant molecules.

Experimental Section

Materials: The following were used as received: $Na_2WO_4{\cdot}2H_2O$, 85% H_3PO_4, KCl, NaCl, $NaClO_4$, 12 M aqueous HCl solution (quantitative analysis grade), 30% aqueous H_2O_2 solution, $TiCl_4$ (all from Wako) and D_2O (Isotec). The synthesis and characterisation of the tetrameric precursor **2** have been reported elsewhere.[5a]

Instrumentation/Analytical Procedure: A complete elemental analysis was carried out by Mikroanalytisches Labor Pascher (Remagen, Germany). The sample was dried at room temperature at $10^{-3}-10^{-4}$ Torr overnight before analysis. IR spectra were recorded with a Jasco 300 FT-IR spectrometer in KBr disks at room temperature. Thermogravimetric (TG) and differential thermal analyses (DTA) were acquired with a Rigaku TG8101D and TAS 300 data processing system. TG/DTA measurements were carried out in air with a temperature ramp of 4 °C per min between 25 and 500 °C. ^{31}P NMR (161.70 MHz) spectra in D_2O were recorded in 5-mm outer-diameter tubes with a JEOL JNM-EX 400 FT NMR spectrometer and a JEOL EX-400 NMR spectroscopic data-processing system. ^{31}P NMR spectra were referenced to an external standard of 25% H_3PO_4 in H_2O in a sealed capillary. Chemical shifts were reported on the δ scale with resonances upfield of H_3PO_4 (δ = 0 ppm) as negative. ^{183}W NMR (16.50 MHz) spectra were recorded in 10-mm outer-diameter tubes with a JEOL JNM-EX 400 FT NMR spectrometer equipped with a JEOL NM-40T10 L low-frequency tuneable probe and a JEOL EX-400 NMR spectroscopic data-processing system. ^{183}W NMR spectra measured in D_2O were referenced to an external standard of saturated Na_2WO_4 in D_2O (δ = 0 ppm). Chemical shifts were reported as negative for resonances upfield of Na_2WO_4 (δ = 0 ppm).

Synthesis of 1 as a Powder: To a stirred, clear, colourless solution of the precursor **2**[5a,6] (2.1 g, ca. 0.12 mmol), dissolved in water (16 mL), was added 30% aq. H_2O_2 (1.0 mL, 12.7 mmol). The clear red solution was stirred for 1 h and NaCl (5.0 g, 86.0 mmol) was then added. After stirring for 1 h, a red-orange powder formed which was collected on a membrane filter (JG 0.2 μm), washed with ethanol (10 mL × 2) and diethyl ether (50 mL × 2). The crude product at this stage was obtained in a quantity of about 1.0 g. The yellow-orange powder was dissolved in water (10 mL). The clear red-orange solution was concentrated to ca. 3 mL using a rotary evaporator at 35 °C and the resultant solution was placed in a refrigerator at 5 °C. After 1 d, the orange crystalline compound **1** was collected on a membrane filter (JG 0.2 μm), washed with ethanol (10 mL × 2) and diethyl ether (50 mL × 2) and dried in vacuo for 2 h. A yellow-orange powder of **1** was obtained in ca. 25% (0.53 g) yield. Compound **1** is highly soluble in water but insoluble in diethyl ether and ethanol. $Na_9[P_2W_{15}(TiO_2)_3O_{56}(OH)_3]{\cdot}4H_2O$ = $H_{11}Na_9O_{69}P_2Ti_3W_{15}$ (4285.29): calcd. H 0.26, Na 4.83, O 25.76, P 1.45, Ti 3.35, W 64.35; found H 0.38, Na 4.61, O 25.5, P 1.40, Ti 3.36, W 63.5, Cl < 0.03; total 98.85%. A weight loss of 4.93% was observed during the course of drying at room temperature at $10^{-3}-10^{-4}$ Torr overnight before the elemental analysis. This suggests the presence of 12−13 water molecules weakly or adsorbed. Using TG/DTA under atmospheric conditions, a weight loss of 6.61% was observed below 167.4 °C with endothermic points at 60.2 and 83.9 °C; calcd. 6.44% for x = 16 in $Na_9[P_2W_{15}(TiO_2)_3O_{56}(OH)_3]{\cdot}xH_2O$. A weight loss of 4.12% observed from 167 °C up to ca. 400 °C with an endothermic point at 172 °C is due to decomposition of the coordinated peroxo groups. IR (KBr) (polyoxometalates region): $\tilde{\nu}$ = 1083 s, 1054 m, 1013 w, 1002 w, 940 vs, 923 vs, 891 s, 820 vs, br, 811 vs, br, 755 m, 707 m, 612 m, 599 m, 559 m, 527 m, 487 w, 465 w, 431 w cm^{-1}. ^{31}P NMR (21.3 °C, D_2O): δ = −3.93, −14.41 ppm. ^{183}W NMR (20.7 °C, D_2O): δ = −156.5 (3 W), −201.9 (6 W), −230.1 (6 W) ppm.

Crystallisation of 1: Compound **1** (1.89 g) was dissolved in water (20 mL) and filtered through a folded filter paper (Whatman No. 2). The clear orange filtrate was concentrated to ca. 3 mL using a rotary evaporator at 30 °C. The solution was divided into two portions and slow concentration of both at room temperature was allowed to occur. After 3 d, clear orange plate crystals formed. One portion was used for X-ray diffraction measurements and the other for characterisation purposes. The crystals of one portion (1.5 mL) amounted to 0.17 g (8.99% yield). The characterisation data of the crystals using TG/DTA, IR and ^{31}P NMR spectroscopy are in agreement with those of the powder sample, suggesting that the crystals were representative of the bulk sample.

X-ray Crystallography for 1: A clear orange plate crystal of **1** (0.26 × 0.16 × 0.06 mm) was picked up with a cryo loop™ (from Hampton Research) and coated with liquid paraffin to prevent its degradation. Data were collected with a Bruker SMART APEX CCD diffractometer at 90 K in the range $1.8° < 2\theta < 56.7°$. The intensity data were automatically corrected for Lorentz and polarisation effects during integration. The structure was solved by direct methods (SHELXS-97: G. M. Sheldrick, University of Göttingen, **1990**) followed by subsequent difference Fourier calculations and refined by full-matrix least-squares procedures (SHELXS-97: G. M. Sheldrick, University of Göttingen, **1997**). The site occupancy factors of the oxygen atoms in the peroxo group were fixed at 0.64 for those labelled A and 0.36 for those labelled B. Crystal data for $H_{35}Na_9O_{81}P_2Ti_3W_{15}$, M = 4501.58, monoclinic, space group $P2_1/c$ (no. 14), a = 23.118(3), b = 15.2478(19), c = 24.967(3) Å, β = 100.247(2)°, V = 8660.4(19) Å^3, Z = 4, $\rho_{calcd.}$ = 3.453 g·cm^{-3}, μ(Mo-K_α) = 20.28 mm^{-1}, R_{int} = 0.1912, $R1$ = 0.0643, $wR2$ = 0.1904, GOF = 1.054 [103259 total reflections, 21557 unique reflections were $I > 2\sigma(I)$] [$R1$ = 0.0845, $wR2$ = 0.2025 (for all data)]. The maximum and minimum residual densities (10.29 and −4.784, respectively) were located at 2.31 Å from O29 and 1.11 Å from W3, respectively. In the X-ray crystallography of **1** there are several points to be addressed. (1) Absorption correction: the product of μ and tmid is greater than 3. Since an oil was used for the diffraction measurements, numerical correction of the absorption is actually impossible. (2) In the structure analysis, disorder treatment was used. There are some short O−O distances (less than 1.5 Å), that is, distances between water molecules. This is necessary because the occupancy of O was set at less than 0.5. The positions of the hydrogen atoms of the water molecule could not be determined. (3) The larger residual electron density peaks still remain and a greater R_{int} (> 0.15) results. It is actually impossible to obtain high-quality diffraction data from the POM because of the disorder of the solvent in the crystal and the difficulties applying absorption corrections. Further details on the crystal structure investigation may be obtained from the Fachinformationzen-

trum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany [Fax: (internat.) + 49-7247-808-666; E-mail: crysdata@fiz-karlsruhe.de], on quoting the depository number CSD-413816 (formula/code: yos20mo).

Reactivity of 2a and 3a with Aqueous Hydrogen Peroxide: The reaction of the giant tetrapod-shaped POM **2a** with hydrogen peroxide gave a pure form of the peroxo species **1a** within 30 min. In contrast, the reaction of another giant tetrapod-shaped POM (**3a**) with hydrogen peroxide, which was monitored by ^{31}P NMR spectroscopy, did not react in the same way. To a colourless solution of **3** (0.52 g, 0.029 mmol), dissolved in water (5 mL), was added 30% aqueous H_2O_2 (0.25 mL, 3.18 mmol). The colour of the solution became clear yellow after 30 min, yellow-orange after 9 h and orange after 35 h. A ^{31}P NMR spectrum of the solution, measured after 30 min, showed only a two-line spectrum with resonances $\delta = -7.70$ and -13.97 ppm due to **3a** itself, indicating that no peroxo species was formed. After 9 h, the two ^{31}P NMR signals at $\delta = -4.24$ and -14.16 ppm, assignable to the peroxo species **1a**, began to appear but the large signals (at $\delta = -7.70$, -13.97 ppm) of **3a** still remained and smaller peaks due to at least three other species (at $\delta = -5.18$, -5.38, -6.90 and -14.23 ppm) could also be observed. After 35 h, the ^{31}P NMR signals due to the peroxo species **1a** at $\delta = -4.15$ and -14.06 ppm, as well as other peaks due to at least three species (at $\delta = -5.09$, -5.30, -6.80, -13.81, -14.14 ppm), became larger, whereas only the two signals due to **3a** (at $\delta = -7.62$ and -13.88 ppm) became less intense. After a prolonged reaction time of **3a**, the formation of the peroxo species **1a** was definitely confirmed. However, **1a** was not the only species formed. Thus, with hydrogen peroxide, the reactivity of compound **3a** was quite different from that of **2a**.

[6] Abbreviation of compounds **1**–**4**: Previous formulae of **2** and **2a**[5a] as well as **3** and **3a**[5b] were revised by considering the protonation sites in the Dawson unit found with BVS calculations of the oxygen atoms; (1) tris[peroxotitanium(IV)]-substituted Dawson POM Na_9[**1a**]·$16H_2O$ (**1**) {**1a** = [α-1,2,3-$P_2W_{15}(TiO_2)_3O_{56}(OH)_3]^{9-}$}, (2) giant tetrapod-POM with the bridging Ti octahedral groups Na_xH_{33-x}[**2a**]·yH_2O (**2**) (x = 16–19, y = 60–70; **2a** = {[α-1,2,3-$P_2W_{15}Ti_3O_{59}(OH)_3]_4$[$\mu_3$-$Ti(OH)_3]_4Cl\}^{33-}$), (3) giant tetrapod-POM without the bridging groups K_4Na_{21}[**3a**]·yH_2O (**3**) (y = 60–70; **3a** = {[α-1,2,3-$P_2W_{15}Ti_3O_{57.5}(OH)_3]_4Cl\}^{25-}$), and (4) giant tetrapod-POM without the bridging groups and without the encapsulated Cl^- ion $K_4(NH_4)_{20}$[**4a**]·$77H_2O$ (**4**) {**4a** = $[P_2W_{15}Ti_3O_{57.5}(OH)_3]_4^{24-}$}.[5c]

[7] At present, we can consider at least four giant tetrapod-shaped POMs with regard to the presence of the bridging Ti octahedral groups and/or the presence of an encapsulated chloride ion. Three of them (**2a**, **3a** and **4a** have been confirmed.[5a–5c] The encapsulated chloride ion in **3a** can be removed from the POM by recrystallisation from an aqueous solution containing KCl and HCl.[5d]

[8] Formation conditions of the two tetrameric Dawson POMs **2a** and **3a** were examined by ^{31}P NMR measurements in aqueous solution (Figure S1, see Supporting Information, see also the footnote on the first page of this article). One key for their formation is the concentration of the titanium(IV) ion used in the reaction. POM **3a** was formed in solution at a 3:1 molar ratio of $Ti(SO_4)_2·4H_2O/Na_{12}[B\text{-}α\text{-}P_2W_{15}O_{56}]·19H_2O$, while POM **2a** was formed in solution at a 10:1 molar ratio.

An in situ Template Route for Fabricating Metal Chalcogenide Hollow Spherical Assemblies Sonochemically

Shu Xu,[a] Hui Wang,[a] Jun-Jie Zhu,*[a] Xin-Quan Xin,[a] and Hong-Yuan Chen[a]

Keywords: Sonochemistry / Nanostructures / Self-assembly / Metal chalcogenides / Hollow spheres

An ultrasound-assisted in situ template approach has been developed for fabricating a series of nanoscale metal chalcogenides in the form of well-defined hollow spherical assemblies. These hollow spherical assemblies have well-controlled dimensions and are composed of uniform nanoparticles. Initially, metal hydroxide particles self-assemble into spherical templates generated in situ, and subsequent surface crystal growth leads to hollow spherical structures. Ultrasound irradiation plays a critical role both in the formation of the intermediate templates and in the crystal-growth process. This approach provides a convenient and efficient one-step pathway to the large-scale fabrication of hollow spherical nanostructures. It also represents a new demonstration of sonochemical effects on the formation and assembly of crystalline particles on the nanometer scale.

Introduction

Much attention has been devoted lately to developing methods for preparing, connecting, and assembling semiconductor nanocrystals. The well-ordered assemblies, unlike nanoparticles or single crystals, have new properties suitable for building fine powders or other functional materials. Over the last decades the novel properties and applications of these materials, including mesoporous structures, networks, core−shell spherical materials, and a series of wire- or rod-like assemblies have been exhibited.[1−9] Especially the assembled hollow spherical materials are important because of their many potential applications in various fields of chemistry, biotechnology, and materials science. For example, they can be used for the transport, controlled storage, and release of chemical and biological products such as drugs, for the protection of biologically active macromolecules, and in the field of catalysis and waste removal.[10−13] Until now, most methods for the fabrication of inorganic materials with hollow spherical structures were based on a number of well-developed techniques, such as the nozzle reaction system, emulsion/water extraction, layer-by-layer (LBL) self-assembly, and sacrificial core−shell techniques.[5,14−21]

Currently, the template-directed assembly of nanodimensional materials is arousing increasing interest due to its unique advantages in the control over shape, orientation, and crystal growth. It usually takes three steps to prepare hollow spherical assemblies: first, a colloidal core consisting of a polymer or some other material is prepared as a template; then, assembly is carried out on the surface of the core to obtain a core−shell structure; finally, the core is removed to form the hollow structure. A widely adopted and quickly developed template method is the LBL self-assembly technique, which is based on the use of electrostatic interactions or hydrogen bonding between alternate layers of materials deposited on a surface. This technique can be applied to the coating of colloids.[5,18,19] However, only a few hollow spheres of silica, zeolite, and other magnetic materials have been fabricated by using this strategy because of the difficulty in the removal of the template cores. For this reason, we are still trying to find some new methods with the goal of avoiding the disassembly of the shell in the process of removing the cores to produce the final hollow spherical materials, or of even generating hollow spherical structures directly without a core−shell step (Scheme 1).

Ultrasound waves that are intense enough to produce cavitations can drive chemical reactions such as oxidation, reduction, dissolution, decomposition, and polymerization.[22−33] Ultrasound irradiation has also been employed to prepare a series of polymer core/metal oxide shell particles and a cadmium selenide hollow spherical material.[9,22,26,34−36] In recent years, the sonochemical method has been proven to be convenient and effective in the fabrication of porous structures. It has been discovered that the ultrasound wave has a strong effect on the congregation and self-assembly of nanoparticles. Gedanken's group has established this procedure as a route to produce some tubular assemblies and a variety of mesoporous oxide materials.[37−39] The advantage of the application of ultrasound irradiation to the synthesis of mesoporous materials

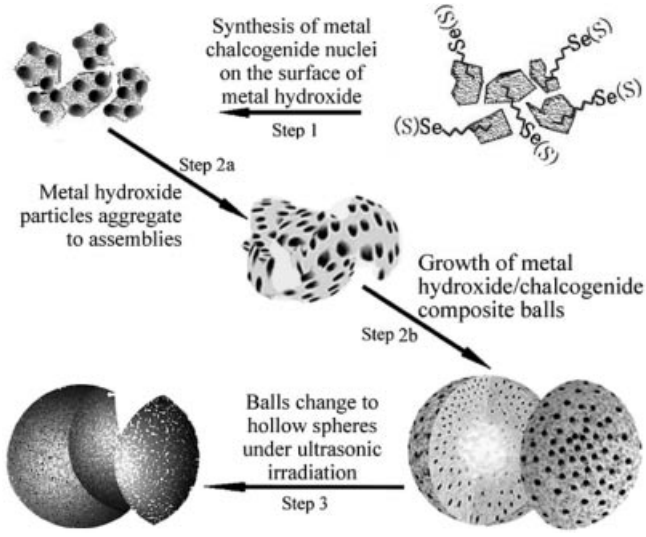

Scheme 1. Proposed mechanism for the synthesis of hollow-sphere materials

is the significant reduction in fabrication time and the possibility to induce the aggregation of nanoparticles into porous structures without destroying the micellar structure. Hence, this method provides an effective surface assembly route for the controllable synthesis of spatially structured materials.

We have extended the sonochemical method to the synthesis of hollow spherical nanostructural materials.[40] An in situ template route was developed for fabricating a series of metal chalcogenide hollow spherical assemblies in an aqueous system. It is a general approach for fabricating hollow spherical materials directly, which makes it possible to avoid the step of removing the template core.

Results and Discussion

Characterization of Hollow-Sphere Assemblies

Cadmium selenide, cadmium sulfide, and copper sulfide hollow spherical assemblies were prepared. To study the properties and morphology of the products, characterization techniques including powder XRD, TEM, XPS, SAED, UV/Vis absorption and fluorescence spectroscopy were employed.

XRD, XPS Studies, and TEM Observations

The X-ray diffraction patterns for the products are shown in Figure 1. The diffraction peak in pattern (a) indicates that the CdSe particles are crystallized in the pure cubic phase (JCPDS No. 19-191), pattern (b) corresponds to the pure cubic phase CdS (JCPDS No.75-0581), and pattern (c) belongs to pure CuS crystals (JCPDS No. 03-1090). No peaks of any other impurities were detected, indicating the high purity of the products. According to the Debye−Scherrer equation,[41] the average sizes of the CdSe, CdS, and CuS particles were estimated to be about 7 nm, 7 nm, and 10 nm, respectively.

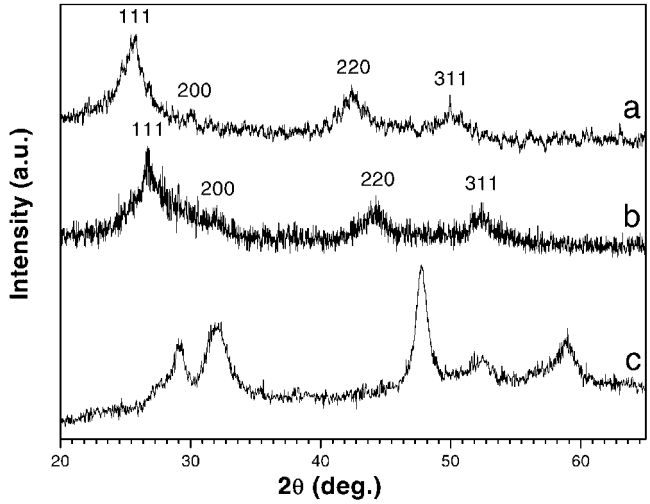

Figure 1. Powder XRD pattern of hollow spherical assemblies: (a) CdSe; (b) CdS; (c) CuS

XPS measurements supply further evidence for the composition and purity of the products. All peaks were calibrated by using C(1s) (284.6 eV) as the reference. The two peaks located at 405.5 eV and 412.3 eV were assigned to Cd(3d). The peaks at 54.5 eV, 162.2 eV, and 932 eV correspond to Se(3d), S(2p), and Cu(2p), respectively. According to the measurements, the ratio Cd/Se is approximately 6:4, which shows that the sample of the CdSe assembly is rich in cadmium at the surface. The measurements also show that the ratio Cd/S is approximately 6:4 and the ratio Cu/S is approximately 1.1:1.

In the TEM images (Figure 2, a, b), uniform hollow CdSe spheres with an average diameter of 120 nm are observed. These hollow spheres consist of spherical nanoparticles about 5 nm in size. The HRTEM image (Figure 2, c) of a single hollow sphere exhibits the clear crystalline lattice of CdSe particles on the spherical surface and the hollow inside can also be observed clearly. The SAED (Figure 2, d) recorded on a CdSe hollow sphere shows the presence of clear diffraction rings, which correspond to the cubic phase of CdSe with polycrystalline nature. In Figure 3, uniform hollow CdS spheres with an average diameter of 120 nm are observed. The surface structure of the CdS spheres is the same as that of the hollow CdSe spheres assembled from nanoparticles about 5 nm in size. Figure 4 shows the TEM image of the CuS hollow spheres with diameters ranging from 150 to 300 nm. These spheres are made up of CuS nanoparticles about 8 nm in size. The shell of the CuS sphere is thinner than that of the hollow CdSe and CdS spheres, so the hollow space inside is very distinct. The TEM images confirm that all the spheres for all three compounds are hollow.

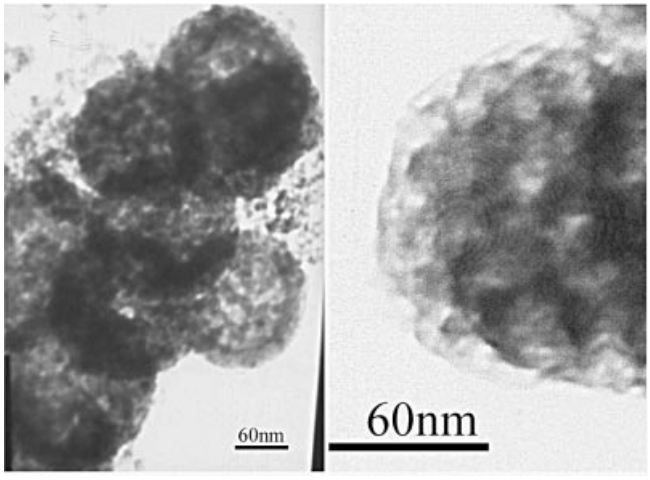

Figure 3. TEM images of the CdS assemblies in the presence of ammonia after sonication for 30 min (concentration of NH_3: 0.8 mol/L)

Optical Characterization

The UV/Vis absorbance spectra of the prepared hollow spherical materials were measured and their correlative optical band gaps were calculated according to the following Equation, where A is a constant, α is the absorption coefficient, and $m = 3$ for a direct and $m = 1$ for an indirect transition.[42]

$$\alpha(\nu) = A\cdot[h\nu/(2 - E_g)]^{m/2}$$

The CdSe assembly has its absorbance peak at 350 nm. Its direct band gap is calculated to be 2.7 eV, which is much larger than the reported value for bulk CdSe (E_g = 1.7 eV).[43] This band-gap value, which indicates the quantum size effect of this sample, equals that of the 7 nm quantum CdSe nanoparticles prepared. It offers further evidence that these spherical assemblies are made up of smaller nanoparticles. The direct band gap of the hollow CdS assemblies is calculated to be 2.11 eV. The equation with $m = 1$ is used for the indirect transition to the copper sulfide nanoparticles, since copper sulfide is a typical indirect semiconductor.[44] The calculated band gap of this CuS assembly is 2.02 eV, which equals that of 8 nm CuS nanoparticles.

We also investigated the fluorescent absorbance spectra of the prepared materials and compared them with those of the dispersed particles. The excitation and emission wavelengths of the hollow CdSe spheres were 485 nm and 730 nm, respectively; the fluorescence spectrum was the same as that of dispersed 5 nm CdSe nanoparticles. The emission peak of CdS was at 570 nm when an excitation wavelength of 430 nm was selected. The CuS sphere had a strong emission peak at 362 nm when the excitation wavelength was 220 nm.

Discussion of the Reaction Procedure

A study of the reaction processes showed that metal hydroxide was an in situ template in the reaction and directed the formation of hollow spherical structures. We propose a probable reaction mechanism to explain the formation of hollow spherical materials in accordance with our experimental results. The effect of ultrasound irradiation, release rate of Se^{2-} and S^{2-} ions, pH value and ligands on the reaction were also investigated.

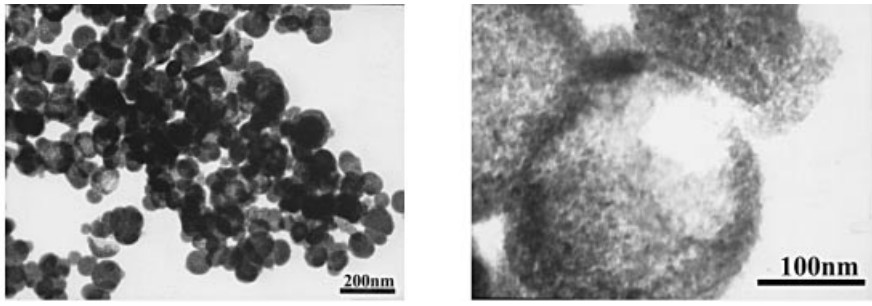

Figure 4. TEM images of the CuS assemblies in the presence of TEA after sonication for 30 min (concentration of TEA: 0.8 mol/L)

Microscopic Monitoring of the Reaction Process

The structures of the assemblies at various stages of the growth process were characterized using TEM. We collected the products every 5 min during the reaction. The precursor, the intermediate structure formed during the sonochemical reaction, and the final structure are shown in Figure 5. These TEM images indicate the tendency to form a hollow spherical structure from the metal hydroxide particles. To begin with, ammonia or triethylamine was added to an aqueous solution of metal ions to form a metal hydroxide colloidal solution. The metal hydroxide particles were made up of many very irregular slices and some blocks, as shown in Figure 5 (a). Initially, the metal hydroxide particles reacted with selenium or sulfur ions, giving rise to metal chalcogenide nanoparticles on their surface, and formed metal hydroxide/chalcogenide composites. In the medial stage (Figure 5, b), we could observe that some slices and blocks were interconnected and enwrapped to form balls or multilayered spheres. At the final stage (Figure 5, c), the balls had grown into regular hollow spheres. Furthermore, when the ultrasound intensity was lower than 15 W/cm^2, the products were inclined to form irregular hollow spheres or balls, whereas an intensity higher than 30 W/cm^2 lead to the formation of dispersed particles. All the experiments showed that ultrasound waves had a critical effect on the fabrication of the special structures.

We also investigated some contrastive experiments and compared the morphology of the products in different stages of the reaction process with that in the process of fabricating hollow spheres. In the thermal process, in which sonication was replaced by heating and stirring, the metal hydroxide and chalcogenide particles continuously congregated to form large irregular assemblies instead of spheres. These assemblies were also composed of 7−10 nm metal chalcogenide nanoparticles. On the other hand, when metal hydroxide particles alone were sonicated, they formed rodlike crystals or assemblies. When metal hydroxide particles alone were heated, their congregation was much slower and more irregular. Figure 6 exhibits the morphology of a sample of cadmium hydroxide sonicated for 30 min and a cadmium sulfide aggregate prepared by the thermal process. None of these reactions produced a sphere-like structure.

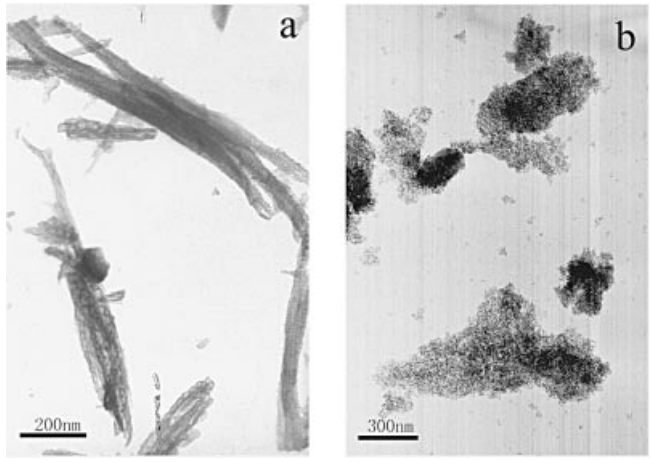

Figure 6. TEM images: (a) cadmium hydroxide nanorods prepared (cadmium hydroxide was sonicated for 30 min in the presence of ammonia); (b) cadmium sulfide particles prepared by the thermal process (cadmium hydroxide reacted with Na_2SeSO_3 at 90 °C for 30 min in the presence of ammonia)

Probable Reaction Mechanism

In a typical reaction, ultrasound irradiation induces the assembly of the metal hydroxide particles into both balls and hollow spherical structures and the growth of cadmium chalcogenide crystals on the template surface.

The elevated temperatures and pressures inside the collapsing bubbles cause water to vaporize and to further pyrolyze into H$^{\cdot}$ and OH$^{\cdot}$ radicals during an aqueous sonochemical process.[22] The H$^{\cdot}$ and OH$^{\cdot}$ radicals can react with sodium selenosulfate and thiourea to release Se^{2-} and S^{2-}. The dangling bonds on the surface of the metal hydroxide particles provide some active spots for the formation of me-

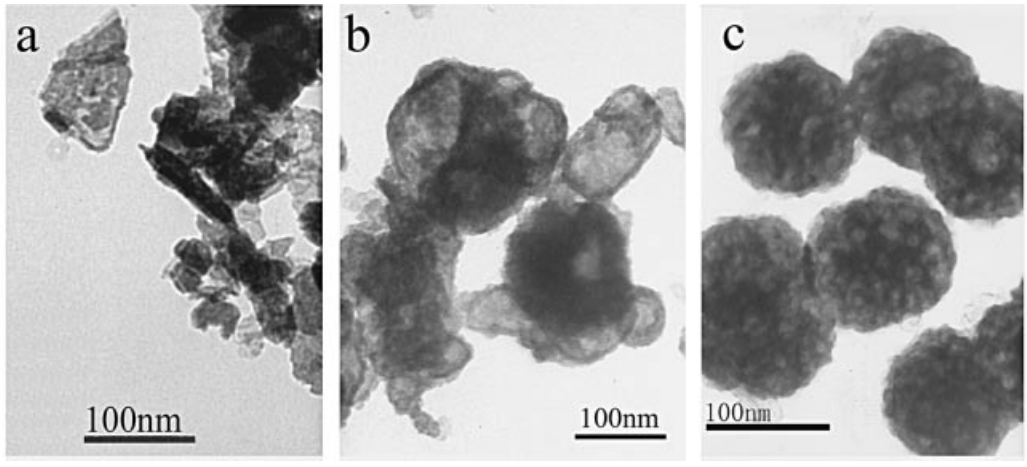

Figure 5. TEM images of the products at different stages of fabricating CdSe hollow spheres (sonic intensity is 20 W/cm^2): (a) cadmium hydroxide particles at the initial stage (immediately after precipitation); (b) after 15 min reaction; (c) after 30 min reaction

tal chalcogenide nuclei. The probable reaction sequence for the sonochemical formation of the metal chalcogenide nanoparticles can be summarized as shown in Equations (1)−(6).

$$H_2O \xrightarrow{\text{sonication}} H^{\cdot} + HO^{\cdot} \quad (1)$$

$$2\,H^{\cdot} + SeSO_3^{2-} \rightarrow Se^{2-} + 2\,H^{+} + SO_3^{2-} \quad (2)$$

$$H^{\cdot} + OH^{\cdot} + CS(NH_2)_2 \rightarrow (NH_2)_2C(OH)-SH$$
$$H^{\cdot} + OH^{\cdot} + (NH_2)_2C(OH)-SH \rightarrow (NH_2)_2C(OH)_2 + H_2S \quad (3)$$
$$(NH_2)_2C(OH)_2 \rightarrow (NH_2)_2C{=}O + H_2O$$

$$H^{\cdot} + OH^{\cdot} + CH_3CSNH_2 \rightarrow CH_3C(NH_2)(OH)-SH$$
$$H^{\cdot} + OH^{\cdot} + CH_3C(NH_2)(OH)-SH \rightarrow CH_3C(NH_2)(OH)_2 + \quad (4)$$
$$H_2S\,CH_3C(NH_2)(OH)_2 \rightarrow CH_3CO(NH_2) + H_2O$$

$$M(OH)_2 + Se^{2-}\ (S^{2-}) \rightarrow MSe\ (MS) + 2\,OH^{-}\ (M = Cd, Cu) \quad (5)$$

$$n\,MSe\ (or\ MS) \rightarrow (MSe)_n\ or\ (MS)_n\ (M = Cd, Cu) \quad (6)$$

The freshly born nuclei will grow into large particles until they become stable finally. It is well known that the Gibbs free energy of the surface of small-sized nanoparticles is usually very high due to the large surface/volume ratio and the existence of dangling bonds on the surface. These small particles have the tendency to aggregate, to decrease the Gibbs free energy of the surface and to make the surface state stable. In most cases, the smaller nanoparticles result in more easy aggregation. In our experiments, the particles grown on the metal hydroxide were also inclined to conglomeration. The kinetics of the thermal process enables the formation of Se and S ions and the growth of metal chalcogenide nanoparticles, which induce congregation. Since this kind of congregation is not directional assembly, the final product consists of big irregular particles as shown in part b of Figure 6.

On the other hand, in the sonication process, cavitation resulting in bubble collapse will launch shock waves out into the liquid. The strength of the waves can even result in the breakage of the bonds in the polymer chain. When these shock waves pass over metal hydroxide and metal oxide particles, they can also cause the rapid impact of the liquid on the surface of the particles and promote the rupture of the bonds.[25] Ultrasound studies have indicated that a large number of dangling bonds and defects will appear especially at the edge of sheetlike particles as a result of the impingements of the microjets created by ultrasonic waves.[22,45] Gedanken's group has produced a kind of tubular titania assembly using this mechanism.[39] If only metal hydroxide particles were under sonication, the many dangling Cd−O−Cd bonds on the edges of the sheetlike particles would connect to form a layer-like structure which continuously rolls into rods or tubes as the structure observed in Figure 6 (a).

However, in our system, the metal hydroxide particles were not merely assembled through the dangling Cd−O−Cd bonds or the metal chalcogenide nuclei on the surface. Once the chalcogenide nuclei were formed on the surface of the hydroxide particles, the effect resulted in the assembly both on the edge by the connection of the dangling Cd−O−Cd bonds, and on the surface by the congregation of the chalcogenide nanoparticles. The two kinds of assembly lead to intermediate products with ball-like or multilayered hollow-spherical structures, as observed in the TEM images (see b in Figure 3).

After the formation of the intermediate structure, the growth of the metal chalcogenide particles only on the surface of the metal hydroxide/chalcogenide composite spheres continually consumed the inner metal hydroxide. These freshly born nuclei grew into large particles until they finally became stable.[46] The product was a regular hollow sphere. The metal chalcogenide particles thus formed were held together by van der Waals forces. Since these forces are not very strong, the rapid impact of the liquid would promote the dispersion of the assemblies, which would crack into small particles and disperse further in the presence of the strong ultrasound shock wave. Hence, a high sonic intensity could not be used in the experiments. When the aggregation and dispersion were balanced, the metal hydroxides could aggregate to form the desired assemblies; then the reaction could be carried out to fabricate the hollow-sphere structures described in Equations (5) and (6). At a sonic intensity of 20 W/cm^2, a good balance was observed, and an appropriate growth rate could be obtained.

Effect of the Release Rate of Chalcogen Ions

In our further studies, we determined that the growth rate of metal chalcogenide nuclei had a strong effect on the fabrication process. This effect depended on the release rate of Se^{2-} and S^{2-}. With a high release rate, many metal chalcogenide nuclei and particles would grow on the surface of the metal hydroxide particles before their assembly. In this case, the number of the remaining metal hydroxide particles was not enough for crystal growth on the surface to form hollow structures and aggregation neutralized the dispersive effect of ultrasound. The result was ball-like metal chalcogenide aggregation instead of hollow spherical assemblies. In contrast, a low release rate would make the dispersive effect of ultrasound so strong that the particles would break away from the surface. This resulted in incompact hollow spheres or dispersed particles.

In the presence of ultrasonic irradiation, the release rates of Se^{2-} and S^{2-} from different selenium and sulfur sources are different. Our study on the growth of CdS spheres proved the importance of selecting the appropriate sulfur source. When thiourea was the sulfur source, the release rate of S ions was slow, and the white turbid suspension began to turn yellow after 10 min of reaction. After 30 min of reaction, the product consisted almost completely of dispersed particles, and only a few hollow spheres were observed. Alternatively, when thioacetamide was selected as

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

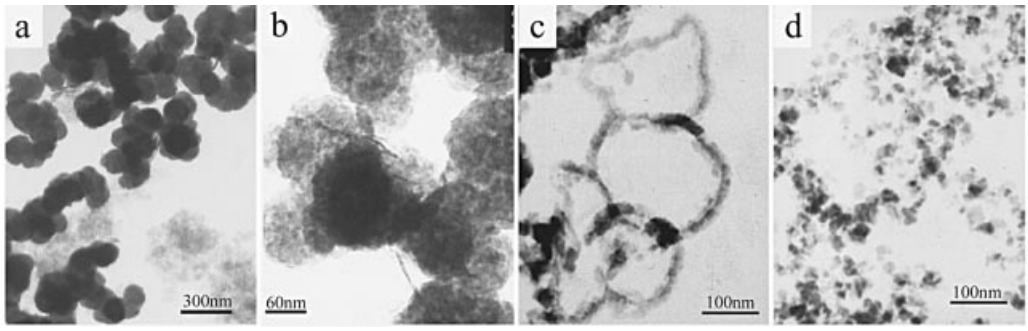

Figure 7. TEM images of the CdS particles obtained with different thiourea/thioacetamide ratios as the sulfur source (sonic intensity: 20 W/cm^2; sonication time: 30 min): (a) thioacetamide as the sulfur source; (b) with a 1:1 ratio of thiourea/thioacetamide; (c) with a 4:1 ratio of thiourea/thioacetamide; (d) thiourea as the sulfur source

the sulfur source, the release rate of S^{2-} was quick enough to form the yellow turbidity immediately. After 30 min of reaction, all of the product was ball-like and no hollow spherical structure was observed. Only when the ratio thiourea/thioacetamide was in an appropriate range would the hollow spherical structure be fabricated. The TEM images in Figure 7 show a series of structures ranging from ball, hollow sphere, circle-like to dispersed particles. It seemed that the dispersed particles were decomposed from the circles. The relation between the structures was strong evidence for the dispersive effect of sonication. In the preparation of cadmium selenide, the experimental results showed that the release rate of Se^{2-} from sodium selenosulfate was acceptable in the fabrication of CdSe hollow spheres.

Effect of the Ligands on the Reaction

Se^{2-} and S^{2-} need to be released in an alkaline environment; otherwise the release rate will be too slow to fabricate the assemblies. In our experiments, the pH value of the reaction system was kept at about 10 by adjusting the ligands and the reactants in the solution. The ligands in the solution were also important in the control of both the formation of metal chalcogenide nuclei and the crystal-growth rate. According to our experiments, in the absence of the ligands or with ligands having weak complexing ability, the products would be dispersed particles or irregular assemblies. Some unidentate and chelating ligands with strong complexing capability and steric effects would strongly decrease the growth of the nanoparticles and lead to monodispersed particles or even prevent the metal ions from combining with the Se^{2-} and S^{2-} ions. This observation proved the protection effect of the ligands. Through the complexing action between metal ions and ligands that lead to the formation of the complexes, the ligands could protect the metal ions from reacting with Se^{2-} and S^{2-} directly and provided a stable reaction rate. Here we selected ammonia and tetraethylammonium (TEA) as the ligands because they had a moderate complexing ability for the metal ions in the alkaline environment. In addition, the concentration of the ligands had to be limited to a certain range; otherwise the ligands in excess would dissolve all the metal hydroxide particles. Actually, in the reaction system the ligands were adsorbed on the surface of the metal hydroxide stoichiometrically. The steric effect enhanced the stability of the surface structure and controlled the rate of combination of Se^{2-} and S^{2-} with the metal ions.

Conclusion

A general sonochemical approach for the fabrication of hollow spherical assemblies composed of metal chalcogenide nanoparticles has been successfully established. In this reaction, we make the best use of the balance between the conglomeration of the particles and the dispersive effect of ultrasound to direct the growth of the assemblies. As we have demonstrated in this article, the effect of ultrasound on the metal hydroxide balls directs the formation of the in situ template, and the growth on the surface leads to the fabrication of the final hollow-sphere assemblies. The sonochemical method provides a mild, energy-efficient, and environment-friendly approach to hollow-sphere assemblies of nanodimensional metal chalcogenides. Furthermore, a major advantage is that it circumvents the disassembly of the shell in the process of removing the cores and produces the hollow metal chalcogenide spheres conveniently. It promises to be useful in the fabrication of other hollow assemblies composed of metal, alloy, oxide, and similar nanoparticles.

Experimental Section

General: All reagents used were of analytical purity. Na_2SeSO_3 solution (0.2 M) was prepared by stirring Se (0.2 M) and Na_2SO_3 (0.5 M) at about 70 °C for 24 h. The XRD patterns were recorded with a Shimadzu XD-3 A X-ray diffractometer (Cu-K_α radiation, $\lambda = 0.15418$ nm). The TEM and SAED examinations were carried out with a JEOL JEM-200CX transmission electron microscope, with an accelerating voltage of 200 kV. The surface of the products was studied by X-ray photoelectron spectroscopy with an ESCALAB MK II X-ray photoelectron spectrometer, taking nonmonochromatized Mg-K_α X-ray as the excitation source and choosing C(1s) (284.6 eV) as the reference line. A Ruili 1200 spectrophotometer (Peking Analytical Instrument Co.) was used to record the UV/Vis absorption spectra of the CdSe, CdS and CuS assemblies.

Preparation of Hollow CdSe Spheres: $CdCl_2$ (0.5 g) was dissolved in distilled water (50 mL), and then ammonia (5 mL, 30% NH_3) or TEA (11 mL) was added. A white colloid appeared immediately in the solution. This solution, Na_2SeSO_3 (10 mL, 0.2 M), and the amount of distilled water to make the total volume 100 mL were transferred into a 150-mL round-bottom flask. This mixture was irradiated with a high-intensity ultrasonic horn (Xinzhio C, China, Ti horn, 20 kHz, 60 W/cm^2) under ambient conditions in air for 30 min, and a dark red precipitate was obtained. After being cooled to room temperature, the precipitate was centrifuged, washed with distilled water followed by acetone, and then dried in air.

Preparation of Hollow CdS Spheres: Thiourea (0.15 g) and thioacetamide (0.05 g) were dissolved in distilled water (50 mL) and mixed with the $CdCl_2$/ammonia colloid solution. The final product was a yellow precipitate.

Preparation of Hollow CuS Spheres: $CuSO_4$ (0.35 g) was dissolved in distilled water (50 mL), and then TEA (10 mL) was added. A green colloid was observed. After adding thiourea (0.15 g), the product was a black precipitate.

Preparation of Dispersed Nanoparticles: The reaction for preparing CdSe and CdS nanoparticles was the same as that for hollow spheres, with the difference that the TEA ligand was used in excess. No ligand was used in the reaction for preparing CuS nanoparticles.

Reaction of Mercury(0) with the I_2 Adduct of Tetraphenyldithioimidodiphosphinic Acid $(SPPh_2)_2NH$ (HL) − Crystal Structures of $[Hg(HL)I_2]$ and HgL_2

M. Carla Aragoni,[a] Massimiliano Arca,[a] M. Bonaria Carrea,[a] Francesco Demartin,[b] Francesco A. Devillanova,[a] Alessandra Garau,[a] Francesco Isaia,*[a] Vito Lippolis,[a] and G. Verani[a]

Keywords: Bridging ligands / Coordination chemistry / Density functional calculations / Iodine / Mercury / S ligands

The complex $[Hg(HL)I_2]$ (**1**) has been synthesised by reacting liquid Hg(0) in Et_2O under mild reaction conditions with the I_2 adduct of HL, $HL{\cdot}I_2$, while HgL_2 (**2**) has been obtained from the reaction of compound **1** with HL in CH_3CN. A single-crystal X-ray investigation of **1** shows four independent molecules in the asymmetric unit, each of which contains an Hg^{II} ion coordinated to two iodine atoms and two sulfur atoms of one bidentate neutral ligand in a distorted tetrahedral coordination geometry. Compound **2** consists of two anionic ligands coordinated to an Hg^{II} ion, which again displays a distorted tetrahedral coordination sphere. The reaction of **2** with HI (55 wt.-% in water) affords $[Hg(HL)_2](I)_2$ (**3**). Compounds **1**, **2**, and **3** have been characterised by FT-IR and ^{31}P NMR spectroscopy. Density functional calculations suggest that compound **3** should feature a distorted tetrahedral coordination around the metal centre, with unequal Hg–S bond lengths.

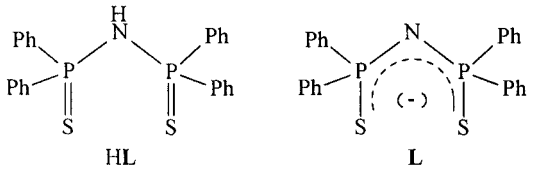
Introduction

The oxidation/complexation reaction of metal powders by diiodine adducts of phosphane and polyfunctional thione donors has been investigated thoroughly in recent years. Numerous papers on this subject have shown this synthetic route to be a useful tool for obtaining coordination compounds with unusual geometries, stoichiometries, and oxidation numbers at the metal centre. In fact, owing to the majority use of $R_3E{\cdot}X_2$ adducts (R = alkyl, aryl; E = P, As, Sb; $X_2 = I_2$, Br_2, IBr), novel metal tertiary phosphane, arsane, and stibine complexes have been prepared by McAuliffe and co-workers.[1] Recently, another class of powerful oxidation reagents based on the I_2 and IBr adducts of *N*,*N*′-dimethylperhydrodiazepine-2,3-dithione has been employed successfully to oxidise gold metal in a one-step reaction under mild conditions. This reaction has found potential industrial applications in the fields of electronics and the recovery of precious metals from waste materials.[2]

Thanks to our extensive experience in the area of I_2 adducts of sulfur- and selenium-containing donors,[3] mainly aimed at improving our understanding of the nature of donor-I_2 bonding, we have recently decided to investigate the metal activation reaction by using tetraphenyldithioimidodiphosphinic acid $HN(Ph_2PS)_2$ (HL), which contains both group 15 and 16 elements, as the donor/complexing agent. Our choice was driven both by the donor ability of phosphane-sulfide compounds[4] towards I_2 and by the well-known intrinsic ability of L to give chelation and to favour the preferred geometry required by the metal ion.[5,6] Generally, the reaction of HL with metal ions leads to the formation of the anion L, which has the negative charge delocalised over the SPNPS moiety, and is capable of coordinating a metal centre through the two sulfur atoms, to form six-membered $MSSP_2N$ metallacycles.[5,6]



In this context, the I_2 adduct of HL, $HL{\cdot}I_2$, has shown an interesting potential in the oxidation/complexation of zerovalent metals in a low-polar solvent, as demonstrated by the results described above. Antimony(0) powder, for example, has been easily oxidised to Sb^{III} in a single step to give the unusual, X-ray characterised, dinuclear complex

[LSb(μ-S)(μ-I)$_2$SbL].[7] Similarly, the adduct HL·I_2 reacts with palladium and cobalt powders to produce the complexes PdL_2 [8] and CoL_2.[9]

Since there is a current interest in the chemistry of mercury, which stems from its widespread industrial use as well as its inherent toxicity and hazardous effects on human health,[10,11] and considering the promising results obtained with this synthetic route for other zero-valent metals, we report here on the reaction of HL·I_2 with liquid mercury with a view to opening new perspectives for the recovery of mercury(0) from industrial waste materials.[12]

Results and Discussion

Synthesis and X-ray Crystal-Structure Determination of [Hg(HL)I_2] and HgL_2

The reaction between equimolar quantities of the adduct HL·I_2 (generated in situ) and Hg ([HL·I_2] = 2.22 × 10^{-3} M, 25 °C) was carried out under nitrogen and anhydrous conditions in diethyl ether solution. The dark-red colour of the reaction mixture, due to the HL·I_2 charge-transfer adduct, disappeared almost completely within six hours with formation of an insoluble whitish precipitate. At this stage of the reaction, the concentration of HL·I_2 in the mixture is negligible, as determined from the very low intensity of the blue-shifted band of iodine[13] at 460 nm; moreover, no phosphorus-containing species was detectable by ^{31}P NMR spectroscopy. Elemental analysis of the separated solid and ^{31}P NMR spectroscopy confirmed the formation of [Hg(HL)I_2] (**1**) with the ligand in its neutral form. In this reaction, the zero-valent mercury is oxidised to Hg^{II} according to Equation (1).

$$Hg + HL{\cdot}I_2 \xrightarrow{Et_2O} Hg(HL)I_2 \quad (1)$$

Complexes containing metal ions coordinated to undissociated HL are very scarce in the literature since anything less than strictly anhydrous reaction conditions or the use of polar solvents always provokes imido-proton dissociation and the consequent formation of the deprotonated ligand L.[5a,6e] In this respect, in the case of the reactions with cobalt(0) and palladium(0) we were able to isolate the species [Co(HL)I_2] and [Pd(HL)I_2], but not to obtain suitable crystals since crystallization attempts always led to the formation of complexes CoL_2 [8] and PdL_2.[9]

The reaction in Equation (1) was also carried out in the presence of an excess of the adduct (1:2 Hg:HL·I_2 molar ratio) in order to synthesise complexes with a different stoichiometry. In addition to the formation of complex **1**, a small amount of white crystals of stoichiometry HgL_2 (**2**) was obtained after concentration of the reaction solution. Although complex **2** has been reported previously,[6e] its crystal structure has not been solved, and the complex has only partly been investigated. Moreover, since no structurally characterised complexes bearing HL have been reported in the literature, and due to the current interest in mercury complexes with dichalcogenoimidodiphosphinate derivatives,[14a−14c] we expanded our study on **1** and **2** by characterising the complexes by X-ray single-crystal diffractometry and ^{31}P NMR and FT-IR spectroscopy; DFT calculations on the simplified model complexes [Hg{N(H$_2$PS)$_2$}$_2$] and [Hg{HN(H$_2$PS)$_2$}$_2$I$_2$], and on the ion [Hg{HN(H$_2$PS)$_2$}$_2$]$^{2+}$ were carried out as well.

The X-ray structures of **1** and **2** are reported in Figure 1 and 2, respectively; selected bond lengths and angles are given in Table 1. The asymmetric unit of compound **1** contains four independent [Hg(HL)I_2] molecules with the metal centres labelled Hg(1), Hg(2), Hg(3), and Hg(4), respectively. Each molecule consists of an Hg^{II} ion coordinated to two iodide ions and one HL ligand, with the metal ion showing a very distorted tetrahedral coordination geometry [X−Hg−X angles (X = I, S) in the range 91.14(8)−135.66(4)°]. The HgSPNPS metallacycle displays a pseudo-boat conformation similar to that found in other metal complexes containing the anionic ligand L,[5] with a

P and an S atom of the ring acting as the stern and bow of the boat. Two out of the four independent complex molecules, Hg(2) and Hg(3), conform to an almost exact C_2 symmetry, the twofold axis passing through the Hg and N atoms and the puckering of the HgSPNPS metallacycle having the same absolute configuration. As regards the other two [those containing Hg(1) and Hg(4)] the conformation of the ring is much more distorted and the absolute configuration is the opposite of that found in the former two complex molecules (see Figure 3a and 3b). Such distortions, together with some variability in the length of chemically equivalent interactions, are due to packing effects, which play an important role in determining the actual symmetry of the crystal. The P−S distances are, on average, only slightly, although significantly, longer than those found in the uncoordinated ligand HL[15] [1.969(5) vs. 1.937(1)−1.959(1) Å]. Conversely, no significant variation is detected for the P−N bonds [average 1.670(9) vs. 1.672(2)−1.683(2) Å].

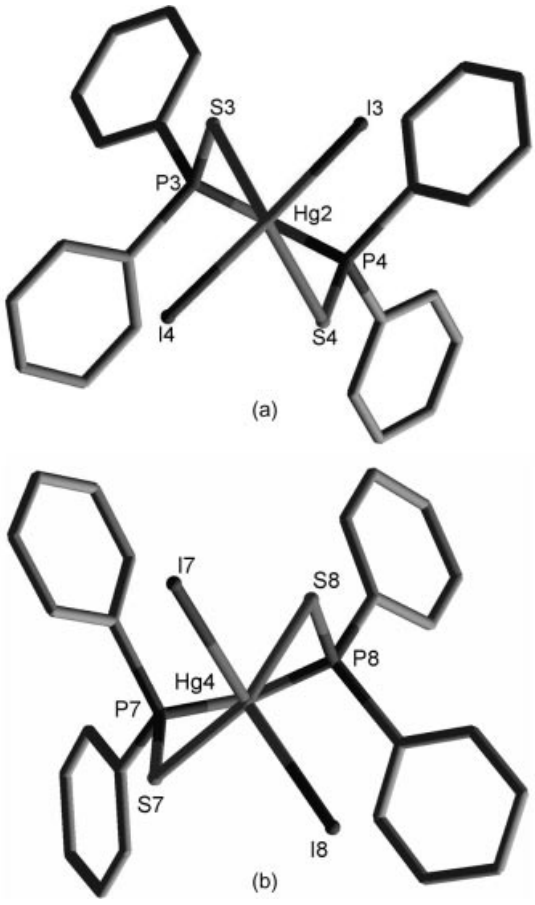

Figure 3. View along the axis connecting Hg(2)−N(2) (a) and Hg(4)−N(4) (b) in complex **1**

Compound **2** consists of two anionic L ligands coordinated to an Hg^{II} ion, which displays tetrahedral coordination geometry. Distortion from the idealized tetrahedral geometry is less pronounced than in complex **1**, the S−Hg−S angles ranging from 104.42(3)° to 112.13(2)°. Each of the two pseudo-boat metallacycles arising from coordination of the anionic ligand to the metal ion displays an almost exact C_2 symmetry, with the twofold axis joining the metal and the N atoms. However, the two rings have opposite configurations within the same molecule. As a result of deprotonation and coordination, the P−S distances increase from 1.937(1)−1.950(1) Å in the free ligand to 2.0135(9)−2.0221(9) Å in **2** and, accordingly, the P−N bond lengths decrease from 1.672(2)−1.683(2) to 1.583(2)−1.590(2) Å.

Complexes **1** and **2** are easily distinguishable by IR spectroscopy since, upon coordination, HL and L have a different π-electron delocalisation over the chelating ring HgSPNPS. The ν_{asym}(PNP) stretching band, which is the most sensitive to metal coordination,[6e] occurs in HL as a strong absorption at 922 cm^{-1}; this increases by about 300 cm^{-1} when the imido proton is removed. As regards the ν(P−S) stretching frequencies, a 30−60 cm^{-1} and 50−80 cm^{-1} decrease is expected upon metal-ion chelation of HL and L, respectively. The IR spectra of **1** and **2** support these findings: the ν(P−S) stretching frequencies measured in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complex **1** (606 and 592 cm^{-1}) and in complex **2** (576 and 561 cm^{-1}) agree with a lower P−S bond order than the free ligand HL (645 and 622 cm^{-1} for the antisymmetric and symmetric stretching modes, respectively);[6d,6e] the ν_{asym}(PNP) stretching frequency (922 cm^{-1} in HL)[6d,6e] appears at 916 cm^{-1} in **1** and 1239 and 1219 cm^{-1} in **2**; these values are within the expected frequency range for single-bonded P−N and double-bonded P=N stretching regions, respectively.

The ^{31}P CP MAS NMR spectrum of complex **1** shows the presence of a single broad resonance at δ = 59.5 ppm with a spectral line-width of 300 Hz, suggesting that the eight phosphorus atoms in the asymmetric unit have a very similar environment. Conversely, the ^{31}P CP MAS NMR spectrum of **2** shows the presence of three resonances at δ = 40.0 ($\Delta\nu_{1/2}$ = 155 Hz), 37.8 ($\Delta\nu_{1/2}$ = 163 Hz), and 33.9 ppm ($\Delta\nu_{1/2}$ = 148 Hz), with a relative intensity ratio of approximately 1:1:2. Evidently, small bond-length differences in the anionic ligands L imply a different charge distribution over the SPNPS fragment and lead to a significant effect on the phosphorus chemical shifts. This effect is not observed for complex **1**, where the neutral ligand HL is involved in the metal coordination. The ^{31}P NMR spectrum (in CH_2Cl_2) of **1** exhibits a single resonance at δ = 57.8 ppm ($\Delta\nu_{1/2}$ = 8.1 Hz), which confirms the presence of the ligand in the complex in its neutral form when in solution too, since deprotonation/complexation of the ligand results in a high-field shift of the ^{31}P NMR signal of about 20−30 ppm. The corresponding chemical shift for HL in the same solvent is δ = 56.6 ppm ($\Delta\nu_{1/2}$ = 3.6 Hz), and the small change caused by coordination is in keeping with the structural similarities between the free and bound ligand in the solid state. The absence of any Hg/P coupling suggests that, at room temperature, the ligand HL is labile on the NMR timescale. In fact, as increasing amounts of HL are added to the solution of the complex up to a 3:1 molar ratio, only one phosphorus resonance is observed, although the chemical shift decreases towards the value of δ = 56.6 ppm as a consequence of the weighted average of the individual shifts of the contributing species **1** and free HL. Low-temperature measurements were carried out to as low as −70 °C, the lowest temperature for which ^{31}P NMR spectroscopic data were recordable, with no Hg/P coupling or significant shifts in the position of the resonance being observed. The broadening of the signal with decreasing temperature (25 °C, $\Delta\nu_{1/2}$ = 8.1 Hz; −70 °C, $\Delta\nu_{1/2}$ = 10.4 Hz) is indicative of the expected slowing of the chemical-exchange process. Obviously, we were not able to achieve the temperature at which the complex is "frozen out" on the NMR timescale.

In the case of complex **2**, the ^{31}P NMR spectrum (CH_2Cl_2) shows only one resonance at δ = 39.7 ppm ($\Delta\nu_{1/2}$ = 6 Hz) flanked by mercury satellites with a $^2J_{(^{199}Hg-^{31}P)}$ coupling of 101 Hz. Thus, in solution at room temperature, unlike the situation found in the solid state, the four phosphorus atoms in the complex are equivalent, indicating that the three resonances found in the solid state are due to solid-state effects. Addition of an equimolar amount of HL to a solution of **2** ([**2**] = 1.1 × 10^{-2} M; CH_2Cl_2, 25 °C) gives a ^{31}P NMR spectrum with two resonances, one due to the free ligand and one due to the complex. Variable-temperature NMR experiments were carried out to as low as −80 °C, the lowest temperature for which ^{31}P NMR spectroscopic data were recordable, with no significant change in the spectra, suggesting the presence of different conformers.

Reaction Chemistry of $[Hg(HL)I_2]$ and HgL_2

The attempts to synthesise new complexes by reacting $[Hg(HL)I_2]$ (**1**) with increasing amounts of HL proved unsuccessful ([**1**] = 2.5 × 10^{-3} M; HL to **1** molar ratio 3:1; CH_2Cl_2, 25 °C). However, the same reaction carried out in a more polar solvent like CH_3CN (HL to **1** molar ratio 1:1; 25 °C) leads to the quantitative formation of complex **2**, thus confirming that in polar solvents HL is prone to lose the imido proton when complexed to a metal.[6e,8,9]

The reaction of complex **1** with hydroiodic acid (55 wt.-% in water) was also evaluated since it may prove useful in freeing the ligand from the complex. Examination of the equimolar reaction between HI and compound **1** (CH_2Cl_2, 25 °C) by ^{31}P NMR spectroscopy revealed only one signal at δ = 57.3 ppm, which is only slightly high-field shifted with respect to the resonance of complex **1**; conversely, when a twentyfold excess of HI is employed the resonance is found at δ = 56.6 ppm, indicating the presence of free HL in the solution [Equation (2)]. Raman spectra carried out on the organic phase confirmed the presence of free HL, whereas in the water phase a peak at 121 cm^{-1} is indicative of the formation of the anion $[HgI_4]^{2-}$.[16]

$$Hg(HL)I_2 + 2HI(aq) \xrightarrow{CH_2Cl_2} HL + 2H^+(aq) + HgI_4^{2-}(aq) \quad (2)$$

Equation (1) and (2) could obviously be very important as far as a recovery process is concerned, since they allow not only an easy oxidation of mercury(0) to mercury(II), but also the possibility to free the metal from the complex **1** and to recover the ligand HL.

Reaction of **2** with hydroiodic acid (55 wt.-% in water) in a 1:2 molar ratio in CH_2Cl_2 results in a considerable change in the ^{31}P NMR spectrum of the complex (Figure 4a and 4b). Indeed, the signal of **2** at δ = 39.5 ppm disappears completely and a new signal is observed at low field (δ = 57.6 ppm). The shift of the signal and its value, which is similar to that of complex **1** (δ = 57.8 ppm, CH_2Cl_2), strongly indicate the successful protonation of the anionic ligand in the complex. Slow concentration of the dichloromethane solution afforded a white powder, whose microanalysis suggests a stoichiometry $[Hg(HL)_2](I)_2$ (**3**). The ^{31}P CP MAS NMR spectrum of **3** shows a broad band at δ = 59.1 ppm ($\Delta\nu_{1/2}$ = 494 Hz), confirming the presence of the ligands in their neutral form in the complex. IR bands at 565 cm^{-1} [ν(P−S)], 922 cm^{-1} [ν(P−N)], and 2631 cm^{-1}, which originates from the first overtone of the δ(N−H) bending vibration[6e] at 1325 cm^{-1}, further support coordination of HL to the metal in **3**. In addition, the molar con-

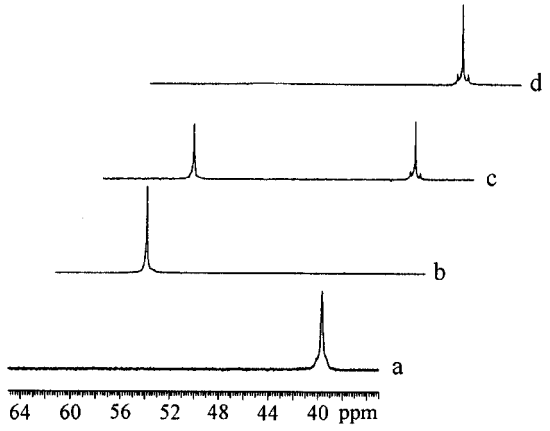

Figure 4. ^{31}P NMR spectra in CH_2Cl_2 (25 °C) of: (a) **2** (3.58×10^{-3} M); (b) solution of **2** after addition of HI (55 wt.-% in H_2O; **2**/HI 1:2 molar ratio); (c) the solution from (b) after addition of DMAN (**2**/HI/DMAN 1:2:1 molar ratio); (d) the solution from (c) after addition of more DMAN (**2**/HI/DMAN 1:2:2 molar ratio)

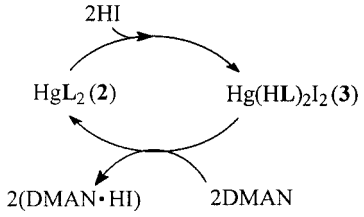
ductivity of **3** (660 $\mu S \cdot cm^2 \cdot mol^{-1}$, CH_2Cl_2, 25 °C) is considerably higher than that of **2** (93 $\mu S \cdot cm^2 \cdot mol^{-1}$, CH_2Cl_2, 25 °C). The protonation reaction is reversibl. A very strong base such as 1,8-bis(dimethylamino)naphthalene (DMAN) was added to a solution of **3** in CH_2Cl_2 in order to obtain 1:1 and 1:2 molar ratios of complex **3**/DMAN. In the former case the neutral complex **2** is partly regenerated (Figure 4c) and in the latter fully regenerated (see d in Figure 4), as shown by the ^{31}P NMR peak at $\delta = 39.5$ ppm. The reactions involving complexes **2** and **3** in CH_2Cl_2 are summarised in Scheme 1.



Scheme 1

Quantum-Chemical Calculations

In the light of the novelty of complex **1**, and in order to provide further insight into the electronic properties of the title compounds, we performed hybrid-DFT calculations on complexes **1** and **2**. We also determined the geometrical features of complex **3**. Theoretical calculations were performed on the model complexes $[Hg\{N(H_2PS)_2\}_2]$ (**4**) and $[Hg\{HN(H_2PS)_2(I)_2\}]$ (**5**), in which the phenyl groups have been replaced by hydrogen atoms, and subsequently on the model complex $[Hg\{HN(H_2PS)_2\}_2]^{2+}$ (**6**). As previously reported by us for similar model complexes, hybrid-DFT calculations have given reliable results in understanding both the structural and electronic features of the model complexes $[Pd\{N(H_2PS)_2\}_2]$[8] (**7**) and $[In\{N(H_2PS)_2\}I_2]$[9b] (**8**). Encouraged by our recent results,[17] the mPW1PW[18] functional was preferred to the B3LYP functional,[19] which was previously employed for **7** and **8**. As regards the ligand atoms, the pVDZ basis set of Schafer et al.[20,21] was used. The basis set for the metal atom is more difficult to choose since, due to the high atomic number of mercury, relativistic effects have to be taken into account. Thus, for **4** and **5**, we used the SBKJC with effective core potentials (ECP),[21,22] since the LanL2DZ basis set previously used successfully for Pd and In in **7** and **8** is not available for Hg. Geometry optimizations on **4** and **5**, performed starting from the structural data of **2** and **1**, respectively, show a very good agreement with the experimental data. Thus, in both complexes, the central mercury atom is coordinated by the ligand donor atoms in a distorted tetrahedral arrangement with average Hg−S bond lengths of 2.611 Å (experimental 2.543 Å).[23] Analogously, in the case of **5**, the average Hg−S and Hg−I bond lengths (2.889 and 2.743 Å, respectively) are very close to the experimental values determined for **1** (2.700 and 2.688 Å, respectively). In agreement with the experimental structures of **1** and **2**, a comparison of the optimized structural features of the ligand moiety in **4** and **5** shows that, upon protonation, we obtain a lengthening of the P−N bond lengths (1.606 and 1.709 Å in **4** and **5**, respectively) and a shortening of the P−S bond lengths (2.031 and 1.959 Å in **4** and **5**, respectively). In order to better understand the interaction between the metal ion and the ligands, a qualitative interpretation can be obtained from the fragment molecular orbital approach (FMO) within the formalism of the extended Hückel theory (EHT).[24] The interaction diagram between the 6s and 6p atomic orbitals of the Hg^{2+} ion and those of the ligands is shown in Figure 5, calculated at the DFT-optimised geometries. For both **4** and **5**, the Kohn−Sham HOMOs are nonbonding orbitals built from the p atomic orbitals of the donor atoms with a small contribution from the filled $5d_{xy}$ and $5d_{xz}$ orbitals of the central metal atom. The LUMOs are nonbonding in nature and they are made up of a combination of the 6s atomic orbital of the Hg ion σ-interacting with the p-orbitals of the donor atoms pointing towards the central metal ion. Confident in the agreement between the calculated geometries of **4** and **5** and their parent complexes, we extended our DFT calculations at the same level of theory to **6** so as to acquire information on the geometrical features of the parent cationic complex **3**. In this case the Hg ion is also coordinated by the two ligand units in a distorted tetrahedral fashion. In agreement with what emerges from the comparison of the calculated structural features of **4** and **5**, upon imido protonation, model **6** shows an increase in the Hg−S (average value 2.628 Å) and the P−N (average value 1.698 Å) bond lengths compared to those calculated for **4**, while the P−S bond lengths are slightly shortened (average value 1.993 Å). Since **4** and **6** are isoelectronic, their frontier orbitals are very similar in shape and composition. In particular, the Kohn−Sham HOMOs of **4** and **6** (see a in Figure 6) are slightly antibonding orbitals built from the p atomic orbitals of the donor atoms with a small contribution from the filled $5d_{xy}$ and $5d_{xz}$ orbitals of the central metal atom. On the other hand, in the case of **5** (c in Figure 5), the HOMO and the HOMO−1 are almost entirely centered on the iodides, and

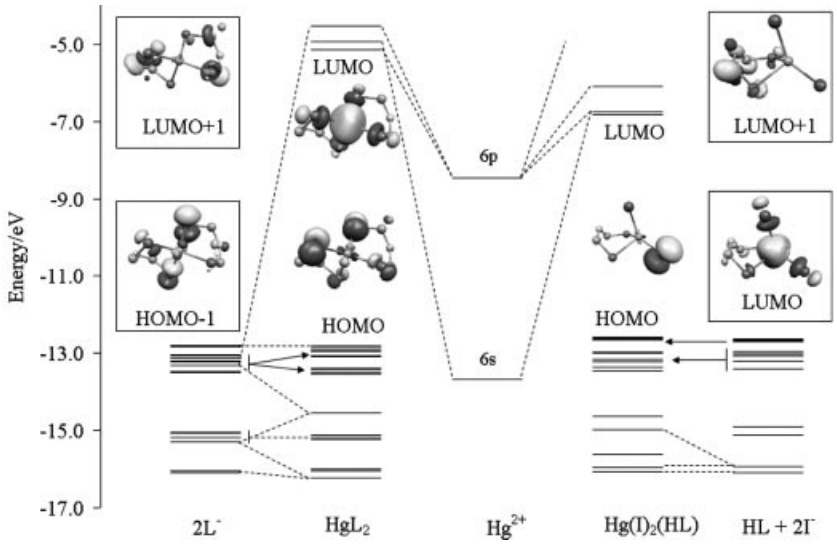

Figure 5. EHT-interaction diagram showing the interaction between the empty atomic orbitals of the Hg^{2+} central ion and the filled ones of the ligands HL in the model complexes **4** and **5** [HL = $H_2P(S)-NH-P(S)H_2$]; the dashed lines connect FMOs which contribute at least 15% to the formation of molecular orbitals; the hybrid-DFT frontier orbitals are also depicted (contour value 0.05)

they are therefore nonbonding in nature. The LUMOs of the three complexes are all antibonding in nature, and are due to the combination of the 6s atomic orbitals of the Hg ion σ-interacting with the p-orbitals of the donor atoms pointing towards the central metal ion (see b and d in Figure 5 for **4** and **5**, respectively).

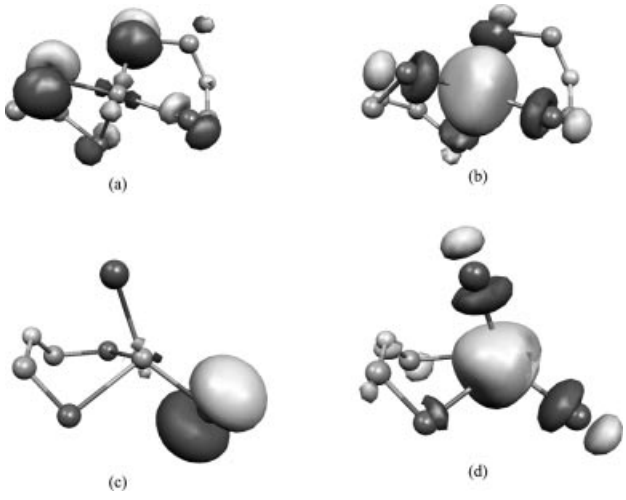

Figure 6. Sketches of Kohn−Sham HOMOs and LUMOs calculated for **4** (a and b, respectively), and **5** (c and d, respectively)

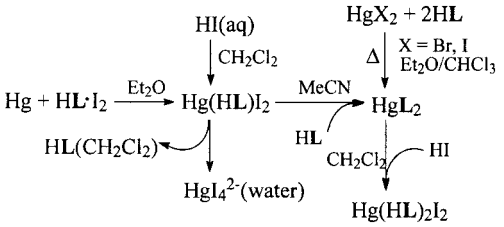
Conclusion

The oxidizing ability of the adduct $HL{\cdot}I_2$ in Et_2O towards liquid Hg(0) leads to the synthesis of the air stable complex $[Hg(HL)I_2]$ (**1**) in a single oxidation step. To the best of our knowledge, this complex represents the first example of a structurally characterised complex of HL. The reaction of **1** with an excess of HL in MeCN affords the neutral air stable complex $[Hg(L)_2]$ (**2**), which can also be obtained from the reaction of HgX_2 (X = Br, I) with HL. The reaction of **2** with concentrated HI leads to the species $[Hg(HL)_2](I)_2$ (**3**; see Scheme 2). X-ray diffraction analyses and DFT calculations on simplified model complexes have been performed to elucidate the structural and electronic properties of **3**. Complex **1** readily reacts with an excess of HI to yield the anion $[HgI_4]^{2-}$ with the release of HL, which can be re-utilised, hopefully opening new perspectives for the recovery of Hg(0) from mercury-containing waste materials.



Scheme 2

Experimental Section

Materials and Instrumentation: All reagents were used as purchased from Aldrich. Diethyl ether was distilled from over $LiAlH_4$ shortly before use. CH_2Cl_2 was distilled from P_2O_5 and stored under N_2. All reactions were carried out under an atmosphere of dry nitrogen. $^{31}P\{^1H\}$ NMR spectra were recorded on a Varian Unity Inova 400 MHz operating at 161.9 MHz. The ^{31}P chemical shifts are referenced to an external standard of 85% H_3PO_4 (δ = 0.0 ppm). ^{31}P NMR CP MAS NMR spectra were calibrated indirectly from the H_3PO_4 peak (δ = 0.0 ppm). Variable temperature ^{31}P NMR spectroscopic data on compound **1** were collected from a 1.1×10^{-2} M solution in CH_2Cl_2 [temp. (°C), δ, $\Delta\nu_{1/2}$: 25, 57.7, 8.1; 0, 57.9, 8.6; −20, 58.1, 10.0; −40, 58.3, 10.2; −60, 58.3, 10.5, −70, 58.4, 10.4]. ^{31}P NMR data for compound **2** were collected from a 1.2×10^{-2} M solution in CH_2Cl_2 [temp. (°C), δ, $\Delta\nu_{1/2}$: 25, 39.5, 6.1; −20, 39.5,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

9.0; −40, 39.5, 9.5; −70, 39.1, 12.9, −80, 39.2, 14.0]. IR spectra were measured as KBr (4000−400 cm^{-1}) or polyethylene pellets (400−50 cm^{-1}) on a Bruker IFS 55 FT-IR spectrometer. FT Raman spectra were recorded on a Bruker FRS 100 Fourier-transform Raman spectrometer, operating with a diode-pumped Nd:YAG exciting laser at 1064 nm. Conductometric measurements were carried out at 25 °C.

Synthesis: HL was prepared according to ref. 25. The adduct $HL{\cdot}I_2$ was prepared in situ in distilled Et_2O just before use from equimolar amounts of HL and I_2.

[Hg(HL)I$_2$] (1): A mixture of HL (0.100 g, 0.222 mmol) and I_2 (0.0565 g, 0.223 mmol) in Et_2O (100 mL) was stirred at room temperature under N_2 until complete dissolution of the reagents. Liquid mercury (0.0236 g, 0.222 mmol) was then added while stirring. This reaction was continued at room temperature under N_2 for about one day. The resulting air-stable whitish solid was isolated by suction filtration, washed with diethyl ether, and dried in vacuo, to give 0.172 g of **1** (0.211 mmol; yield 95%). Stable colourless crystals were obtained upon dissolution of **1** in anhydrous CH_2Cl_2 and subsequent slow evaporation of the solvent. $C_{24}H_{21}HgI_2NP_2S_2$ (903.87): calcd. C 31.89, H 2.34, N 1.55, S 7.09; found C 32.0, H 2.5, N 1.6, S 7.4. IR (KBr): $\tilde{\nu}$ = 3054w cm^{-1}, 2966w, 2924w, 2855w, 2606brw, 1435vs, 1384m, 1303m, 1184m, 1107vs, 916s, 804m, 782s, 733vs, 720vs, 685vs, 622w, 606ms, 592s, 506m, 487m, 464m, 441w. ^{31}P NMR (CH_2Cl_2): δ = 57.8 ppm. M.p. 228−230 °C (dec.).

[Hg(L)$_2$] (2). Method a: A mixture of HL (0.100 g, 0.222 mmol) and [Hg(HL)I_2] (0.200 g, 0.222 mmol) in CH_3CN (100 mL) was stirred at room temperature for 4 h. The solid white product was collected by filtration and then dissolved in hot CH_2Cl_2. The resulting solution was allowed to evaporate in air to yield a white solid. Yield: 0.230 g (0.210 mmol, 95%). **Method b:**[6e] A solution of HL (0.125 g, 2.774. mmol) in $CHCl_3$ (10 mL) was added to a solution of $HgBr_2$ (0.050 g, 1.387 mmol) in Et_2O (10 mL). The reaction mixture was stirred for 1 h at room temperature and then refluxed for 20 min. The solid product was separated by filtration, washed twice with a 1:1 acetone/diethyl ether mixture, and dried under vacuum to give 0.136 g of **2** (89% yield). $C_{48}H_{40}HgN_2P_4S_4$ (1097.5): calcd. C 52.32, H 3.67, N 2.55, S 11.68; found C 53.0, H 3.9, N 2.6, S 12.0. IR (KBr): $\tilde{\nu}$ = 3054m cm^{-1}, 2918w, 2846w, 1475w, 1436s, 1384w, 1239s, 1219s, 1174s, 1103s, 1025w, 997w, 786w, 742m, 714s, 698vs, 618w, 576s, 561vs, 514s, 495m. ^{31}P NMR (CH_2Cl_2): δ = 39.7 ppm. M.p. > 255 °C

[Hg(HL)$_2$](I)$_2$ (3): A dichloromethane solution (10 mL) of **2** (0.020 g, 0.018 mmol) and a hydroiodic acid solution (55 wt.-% in water; 0.0092 g, 0.04 mmol) were vigorously stirred for 1 h at 25 °C. The colourless two-phase mixture was then passed through a phase-separation filter (Whatman, Phase Separator 1PS) to remove the water. After concentration of the solution to about 5 mL, *n*-hexane (5 mL) was added dropwise and a white solid precipitated. This was washed with *n*-hexane and dried to give 0.018 g of **3** (74% yield). $C_{48}H_{42}HgI_2N_2P_4S_4$ (1353.4): calcd. C 42.60, H 3.13, N 2.07, S 9.48; found C 43.0, H 3.2; N 2.2, S 10.0. IR (KBr): $\tilde{\nu}$ = 2631w cm^{-1}, 1436vs, 1325m, 1218m, 1106s, 922s, 785s, 741s, 716s, 688vs, 649m, 561s, 513m. ^{31}P NMR (CH_2Cl_2): δ = 57.6 ppm. M.p. 203−204 °C

X-ray Crystallography: Crystal data and refinement details for structure determinations of both compounds are reported in Table 2. Intensity data were acquired at room temperature on a SMART CCD diffractometer (ω scans). All data sets were corrected for Lorentz-polarisation effects and for absorption using the SADABS routine.[26] The structures were solved by direct methods using the SHELXS 97 program,[27] followed by difference Fourier synthesis, and refined by full-matrix least-squares procedures on F^2 using the SHELXL-97 program.[28] All non-H atoms were refined anisotropically and H atoms were introduced at calculated positions and thereafter incorporated into a riding model with $U_{iso}(H) = 1.2U_{eq}(C)$. For compound **1** the search for an alternative symmetry other than the triclinic one reported in Table 2 was done using Le Page's MISSYM (PLATON) routine.[29] The check revealed that the triclinic unit cell can be transformed metrically into an almost-monoclinic C-centred unit cell with a = 24.485(3), b = 24.506(3), c = 19.230(3) Å, α = 90.42(1), β = 103.25(1), γ = 89.61(1)°. However, with this choice, the agreement between equivalent reflections was poor (R_{int} = 0.434) thus ruling out the possibility of the symmetry being monoclinic.
CCDC-228871 (for **1**) and -228872 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Table 2. Crystal data and details of refinements for [Hg(HL)I_2] and HgL_2

Compound	[Hg(HL)I_2] (**1**)	HgL_2 (**2**)
Formula	$C_{24}H_{21}HgI_2NP_2S_2$	$C_{48}H_{40}HgN_2P_4S_4$
Mol. mass (amu)	903.87	1097.53
Crystal system	triclinic	triclinic
Space group	$P\bar{1}$ (no. 2)	$P\bar{1}$ (no. 2)
a (Å)	17.262(2)	13.626(1)
b (Å)	17.380(2)	13.794(1)
c (Å)	19.230(3)	14.336(1)
α (°)	99.59(1)	82.21(1)
β (°)	99.05(1)	66.10(1)
γ (°)	90.05(1)	69.44(1)
U (Å^3)	5616(1)	2306.6(4)

ρ_{calcd} (Mg·m^{-3})	2.138	1.580
μ(Mo-K_α) (mm^{-1})	7.957	3.692
Transmission factors	0.602−1.000	0.735−1.000
Unique refl. with $I > 2\sigma(I)$	9240	8871
Final R and $wR2$ indices	0.0496, 0.1225	0.0243, 0.0613

Computations: Quantum-chemical DFT calculations were carried out with the Gaussian 98 (rev. A11)[30] suite of programs on the model complexes [Hg{N($H_2PS)_2$}$_2$] (**4**), [Hg{N($H_2PS)_2$}I_2] (**5**), and [Hg{HN($H_2PS)_2$}$_2$]$^{2+}$ (**6**), with Adamo and Barone's mPW1PW functional[18] and pVDZ Schafer, Horn and Ahlrichs pVDZ basis sets for H, N, P, and S.[20,21] For Hg and I, the SBKJC basis set with effective core potentials was used.[22] In the case of **4**, the calculations were also performed with the Stuttgart RLC ECP basis set for Hg.[23] Integration was performed numerically using a total of 7500 points for each atom (Finegrid option). The geometry optimizations of **4**, **6** and **5** were performed starting from the experimental geometries determined for **1** and **2**, avoiding introducing any symmetry constraint. DFT calculations were performed on an SGI Origin 3800 equipped with 128 GByte of RAM. The results of the calculations were analysed with the Molekel 4.3[32a] and Molden 3.9[32b] programs. The quantum mechanically optimised structure was verified by normal-mode harmonic frequency analysis. Harmonic frequencies were obtained using the second derivatives of the DFT energy, computed by numerical differentiation of the DFT energy gradients. The qualitative EHT analyses were obtained with the CACAO (Computer Aided Composition of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Atomic Orbitals) program package[32c] on the hybrid-DFT-optimised geometry. The interaction diagram was generated using the fragment molecular orbital (FMO) approach.[32d] Parameters used in EHT calculations were taken from the standard database of CACAO.

Luminescent Zn and Cd Coordination Polymers

Chao Jiang,[a] Zhaopeng Yu,[a] Chao Jiao,[a] Sujing Wang,[a] Jiaming Li,[a] Zhiyong Wang,*[a] and Yong Cui*[a]

Keywords: N ligands / Coordination polymers / Hydrothermal synthesis / Tubular structures / Fluorescence

The hydrothermal reactions of $Zn(ClO_4)_2{\cdot}6H_2O$ and $Cd(ClO_4)_2{\cdot}6H_2O$ with 1,3-bis(2*H*-tetrazol-5-yl)benzene in an aqueous ethanol and an aqueous methanol/pyridine medium, respectively, yielded a 3D and a 2D metal-organic coordination framework [Zn(1,3-BTB)] (**1**) and [Cd(1,3-BTB)$_2$(Py)$_2$(H$_2$O)$_2$] [Cd[Cd(Py)(H$_2$O)]$_2$(1,3-BTB)$_2$] (**2**) (1,3-BTB = 1,3-ditetrazolylbenzene, Py = pyridine), respectively. Species **1** possesses an open network structure with no guest molecules residing in its small cavities. The structural characterisation of **2** shows a 2D layered framework consisting of nano-sized polytube structures which are stacked one on top of another in the (110) plane giving small channels along the *b* and *c* axes. Additionally, compounds **1** and **2** exhibit strong fluorescence at room temperature in the solid state.

Introduction

Molecular-based tubular structures have received much attention because of their potential to selectively accommodate ions and molecules and catalyse specific chemical transformations.[1] The potential uses of such architectures largely depend on the size and type of their cavities which are mainly controlled by the ligands and appropriate metal ions.[2] There still remains difficulty in predicting the nature of the cavities in the polymer frameworks because of the frequent occurrence of interpenetration of the networks.[3] This problem could be solved, in principle, by designing organic ligands which disfavour interpenetration. In this respect, the use of a panel-like ligand[4] such as 1,3-ditetrazolylbenzene is promising because its coordination assembly is supposed to give polytube structures[5] without the possibility of interpenetration. Because of the aromaticity and multiple N-donor atoms, tetrazolate is also as excellent an N-donor group as pyridyl[6] and nitrile[7] with potential applications in the construction of coordination frameworks.[8] Most importantly, it is an anionic group like carboxylate which may potentially result in neutral polymeric structures which may not accommodate anions in their cavities, in contrast to those formed from neutral donor ligands. Moreover, it was found that the tetrazole functional group has a wide range of applications as a ligand in coordination chemistry, in medicinal chemistry as a metabolically stable surrogate for a carboxylic acid group and in various materials science applications involving high density energy materials and speciality explosives.[9] Here we show, that upon treatment with zinc or cadmium, 1,3-ditetrazolylbenzene can be assembled into a 3D open network structure and a 2D layered framework with a nano-sized polytube structure. No organic guests were found in the small cavities of [Zn(1,3-BTB)] (**1**), while coordinated pyridine molecules resided in the nano-sized tubes of [Cd(1,3-BTB)$_2$Py$_2$(H$_2$O)$_2$][Cd(CdPyH$_2$O)$_2$(1,3-BTB)$_2$] (**2**). Their fluorescence spectra were investigated in the solid state. The present report is concerned with the syntheses, crystal structures and luminescent properties of compounds **1** and **2**.

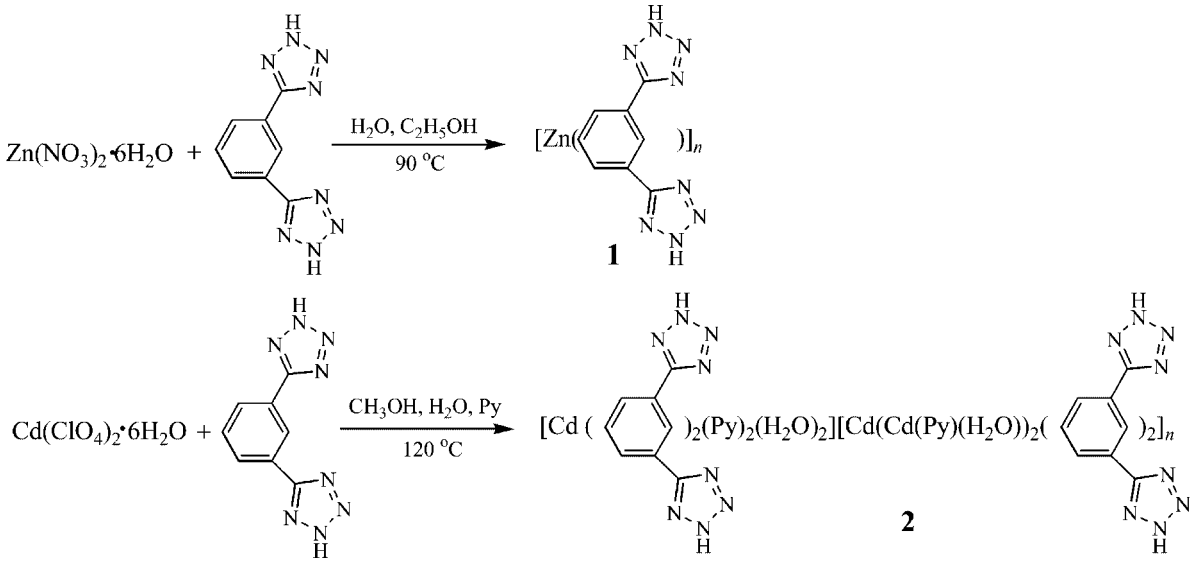
Results and Discussion

Complex **1** was prepared by treating $Zn(NO_3)_2{\cdot}6H_2O$ with 1,3-ditetrazolylbenzene in water and ethanol at 90 °C under hydrothermal conditions (Scheme 1).[10] Complex **2** was prepared by treating $Cd(ClO_4)_2{\cdot}6H_2O$ with 1,3-ditetrazolylbenzene in methanol, water and pyridine at 120 °C under hydrothermal conditions. The observed tetrazolate stretching frequencies (1442 and 1396 cm^{-1} in **1**, and 1448 and 1428 cm^{-1} in **2**) of these compounds are consistent with those of other tetrazolate-based assemblies in previous reports.[8] An IR peak over 3100 cm^{-1} in **2** indicated the presence of coordinated water. The thermogravimetric analysis (TGA) of **1** showed it to be stable up to ca. 300 °C without any weight loss (see Supporting Information; see also the footnote on the first page of this article). The TGA of **2** showed that there were consecutive processes, namely loss of the coordinated water and pyridine molecules as well as ligand pyrolysis.



Scheme 1

Structural Description

[Zn(1,3-BTB)] (1): Compound **1** has a 3D-open network structure. The asymmetric unit comprises one Zn atom and one 1,3-BTB ligand. Each Zn atom is bound to four tetrazoles from four different 1,3-BTB ligands to adopt a highly distorted tetrahedral geometry (Figure 1). The N−Zn−N angles vary from 101.69(7) to 121.31(7)°. All donor atoms form strong bonds with the zinc atom [from 1.986(0) to 2.003(4) Å]. Each 1,3-BTB ligand coordinates through the 1,3 nitrogen atoms (N1, N3) of one tetrazole and the 1,4 nitrogen atoms (N5, N8) of the other tetrazole to four zinc atoms. Zinc atoms are connected by the 1,3 nitrogen atoms of one tetrazole along the *a* axis and by the 1,4 nitrogen atoms of the other tetrazoles along the *c* axis to form 2D sheets (Figure 2). The 1,3-BTB ligands then link parallel sheets together along the *b* axis giving rise to a 3D network (Figure 3). A preliminary inspection of the topology suggests that the zinc centre and the 1,3-BTB ligand both serve as 4-connecting centres. The overall topology appears to be that of the Al net in $SrAl_2$.[11] Small cavities can be seen along the *a* axis. No guest molecules are encapsulated in the cavities because of space restrictions.

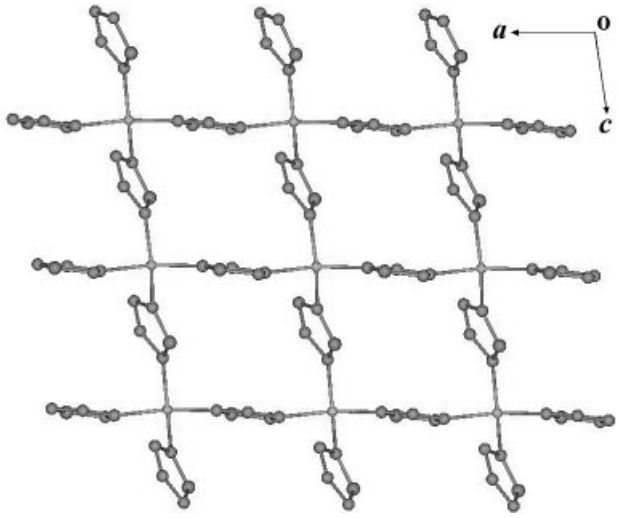


Figure 2. The 2D sheet composed of zinc atoms and tetrazolyl units in **1** (The phenyl ring and the other tetrazolyl ring in the ligand are omitted for clarity)

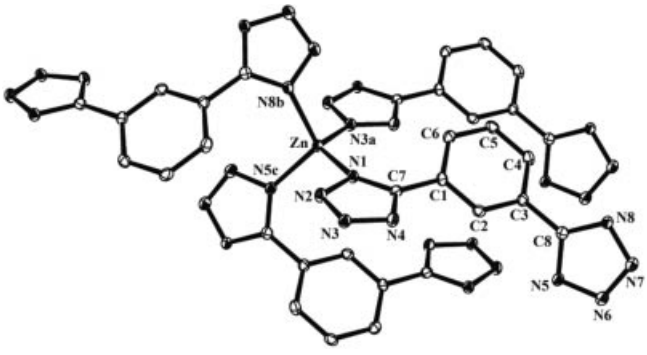

Figure 1. The local coordination geometry around the Zn centre in **1**

[Cd(1,3-BTB)$_2$(Py)$_2$(H$_2$O)$_2$][Cd[Cd(Py)(H$_2$O)]$_2$(1,3-BTB)$_2$] (2): Compound **2** is composed of 2D frameworks, the structure being a little more complicated than that of **1**. The asymmetric unit of **2** consists of one Cd atom and two half Cd atoms, two 1,3-BTB ligands, two water molecules and two pyridines. There are three unique cadmium atoms and all of their coordination geometries may be best described as distorted octahedral. Cd1 is bound to four tetrazoles from four 1,3-BTB ligands, one water molecule and one pyridine, the bond angles around the central Cd1 atom and the *cis* ligands range from 82.5° to 99.4° (Figure 4). Cd2 is

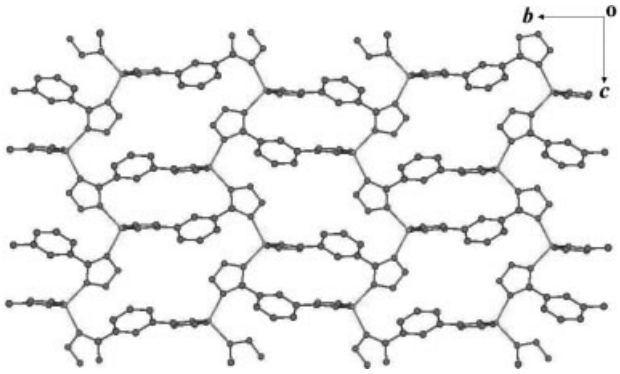

Figure 3. The 3D structure of **1** viewed along the *a* axis

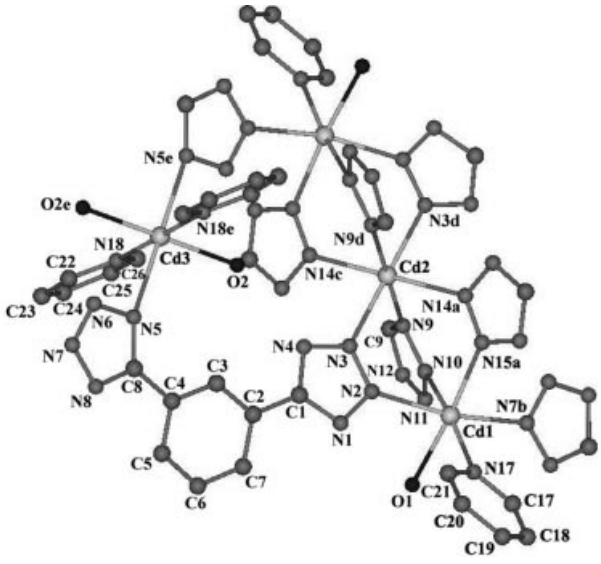

Figure 4. Part of the structure of **2** showing the local coordination geometry around the three unique Cd centres

bound to six tetrazoles from six 1,3-BTB ligands, the bond angles around the central Cd2 atom and the *cis* ligands range from 86.5° to 93.5°. Cd3 is bound to two *trans* tetrazoles from two 1,3-BTB ligands, two *trans* water molecules and two *trans* pyridines, the bond angles around the central Cd3 atom and the *cis* ligands range from 80.9° to 99.1°. The lengths of the majority of the Cd−N bonds vary from 2.265(6) to 2.415(6) Å, while Cd3−N5 is 2.503(6) Å which is a little longer than the ususal value. The two Cd−O bond lengths are 2.317(4) and 2.406(5) Å, while the latter value is somewhat long and indicates weak bonding. The two unique 1,3-BTB ligands have different coordination modes: one coordinates through the 1,3 nitrogen atoms (N5, N7) and the 2,3 nitrogen atoms (N2, N3) of its two tetrazoles, the other coordinates through the 1,2 nitrogen atoms (N9, N10) and the 2,3 nitrogen atoms (N14, N15) of its two tetrazoles.

To clearly understand the 2D framework in **2**, we first consider two Cd1 atoms, one Cd2 atom, two water molecules and two pyridines as a four-connected node. Secondly, we take two 1,3-BTB ligands as one bridge and take one Cd3, two 1,3-BTB ligands, two water molecules and two pyridines as the other bridge. A two-dimensional (4, 4) layer structure is then obtained as can be seen from Figure 5. As a result, the polytube structure is formed with the approximate dimensions of 10.0 × 9.2 Å (Figure 6). Each tube is self-assembled from six units of 1,3-BTB and is mainly lined with phenyl groups which accommodate two coordinated pyridine molecules. The 2D layers pack together in the crystallographic (011)-plane, resulting in channel formation along both the *b*-axis and the *c*-axis (Supporting Information). These 2D frameworks are stabilised by hydrogen bonding (O1···N11, 2.740 Å) (Figure 7).

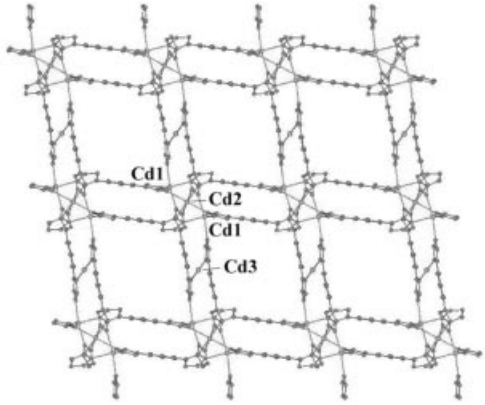

Figure 5. The 2D framework in **2** (coordinated water and pyridine molecules are omitted for clarity)

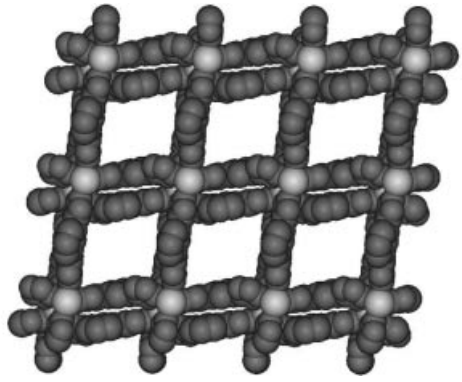

Figure 6. Space filling representation of the nano-sized tubes in the crystal structure of **2** (Coordinated water and pyridine molecules are omitted for clarity)

Fluorescent Properties

Coordination frameworks are promising luminescent materials owing to their higher thermal stability than the pure organic ligand and the ability to affect the emission wavelength of the organic material by metal coordination. The combination of organic spacers and transition-metal centres in the coordination frameworks can be viewed as an efficient method for obtaining new types of electroluminescent materials for potential applications, e.g. as light-emitting diodes (LEDs).[12] The luminescent properties of 1,3-BTB and compounds **1** and **2** were investigated in the solid

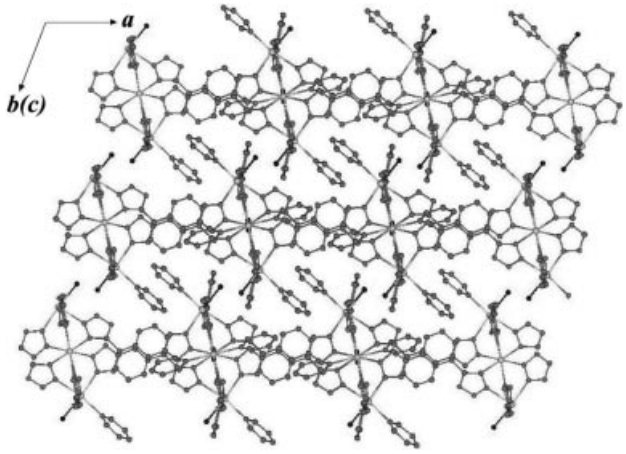

Figure 7. The packing view of the 2D framework in **2**

state. The fluorescence spectrum of 1,3-BTB is shown in Figure 8 and exhibits an emission maximum at 471 nm. The emission spectra of **1** and **2**, also shown in Figure 8, are equally blue-shifted to 323 nm. However, no enhancement in the fluorescence intensity is realised, in fact the fluorescence intensity of **2** is virtually weakened. The emission colour of free 1,3-BTB was significantly affected by its incorporation into the Zn- and Cd-containing polymeric frameworks of **1** and **2**, as evidenced by the large shift in the emission. The emissions that occurred in compounds **1** and **2** can still be assigned to free ligand photoluminescence and the large blue-shift may be due to bad conjugation effects compared with those in the free ligand.[12] In general, compounds **1** and **2** reported herein are unusual examples of room-temperature luminescent Zn- and Cd-containing polymeric compounds.

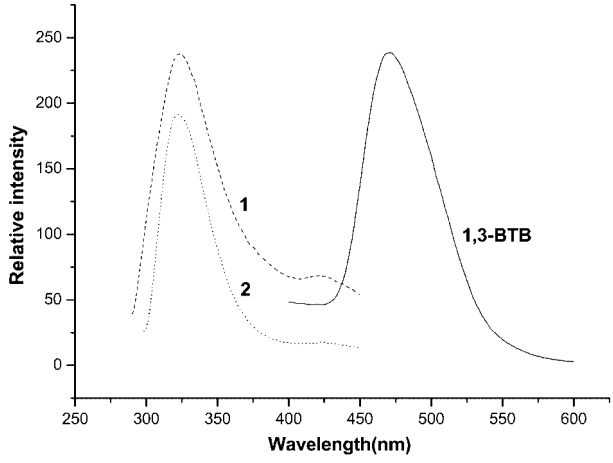

Figure 8. The emission spectra of 1,3-BTB (solid line), **1** (dashed line) and **2** (dotted line) in the solid state at room temperature

Conclusions

In summary, we have prepared two new coordination framework polytube structures from 1,3-ditetrazolylbenzene. The structural features of complexes **1** and **2** demonstrate the coordination flexibility of the tetrazolate group. The luminescent properties of **1** and **2** indicate that the metal coordination and formation of the coordination framework can affect the emission wavelength and the intensity of the organic material.

Experimental Section

General Remarks: 1,3-Ditetrazolylbenzene was prepared from NaN_3 and *m*-dicyanobenzene in 84% yield.[13] Cadmium perchlorate hexahydrate was prepared from the reaction of cadmium hydroxide with perchloric acid.[14] ***Caution:*** $Cd(ClO_4)_2·6H_2O$ is potentially explosive and should be used with care! All other chemicals were of AR grade. Elemental analyses (C, H, N) were performed with an Elementar Vario ELIII elemental analyser. IR spectra as KBr discs were recorded with a Bruker VECTOR-22 FT-IR spectrophotometer. Thermal gravimetric analyses were performed with a Shimadzu TGA-50H Thermal Gravimetric Analyser with a heating rate of 5 °C min^{-1}. Excitation and emission spectra were recorded with a Perkin−Elmer LS55 luminescence spectrometer.

Preparation of 1: Hydrothermal treatment of $Zn(NO_3)_2·6H_2O$ (30 mg, 0.1 mmol), 1,3-ditetrazolylbenzene (21 mg, 0.1 mmol), water (0.8 mL) and ethanol (0.2 mL) for 12 h at 90 °C yielded colourless plate crystals (0.012 g, 44%, only one pure phase). $C_8H_4N_8Zn$ (277.56): calcd. C 34.62, H 1.45, N 40.37; found C 35.04, H 1.39, N 40.85. IR spectrum (KBr): $\tilde{\nu}$ = 3444 (w), 1614 (m), 1524 (m), 1441 (s), 1396 (s), 1345 (m), 1251 (m), 1207, 1174, 1127 (m), 1106 (m), 1080 (m), 1064 (m), 1022 (m), 911 (m), 820 (s), 780 (s), 766 (m), 746 (s), 700 (s), 662 (m), 596 (m), 527 (m), 456 (m), 439 (m) cm^{-1}.

Preparation of 2: Hydrothermal treatment of $Cd(ClO_4)_2·6H_2O$ (41 mg, 0.1 mmol), 1,3-ditetrazolylbenzene (21 mg, 0.1 mmol), methanol (0.4 mL), water (0.2 mL) and pyridine (0.1 mL) at 120 °C for 12 h yielded colourless plate crystals (0.029 g, 68%, only one pure phase). $C_{52}H_{44}Cd_4N_{36}O_4$ (1686.79): calcd. C 37.03, H 2.63, N 29.89; found C 37.94, H 2.32, N 30.25. IR spectrum (KBr): $\tilde{\nu}$ = 3384 (w), 1638 (m), 1604 (s), 1447 (s), 1428 (s), 1363 (m), 1327 (m), 1221 (m), 1170 (m), 1155 (m), 1133 (m), 1069 (m), 1040 (m), 1012 (m), 914 (m), 831 (m), 810 (m), 780 (m), 761 (m), 750 (s), 698 (s), 630 (m), 506 (m), 417 (m) cm^{-1}.

X-ray Crystallographic Studies: Crystal data and details of the structure refinements are presented in Table 1. Intensity data were collected using Mo-K_α radiation (λ = 0.71073 Å) at 173 K for compound **1** and 100 K for compound **2**. The structure solutions and refinements were carried out using SHELXS-96[15] and SHELXL-97.[16] All hydrogen atoms were identified from difference maps and were included in the successive refinement cycles. All non-hydrogen atoms (including those of solvent water molecules) were refined anisotropically. CCDC-232821 (for **1**) and -232822 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data

Use of Different Unsaturated Dicarboxylates Toward the Design of New 3D and 2D Networks of Copper(II)

Partha Sarathi Mukherjee,[a] Debajyoti Ghoshal,[a] Ennio Zangrando,*[b] Talal Mallah,[c] and Nirmalendu Ray Chaudhuri*[a]

Keywords: Coordination polymers / Copper / Magnetic properties / Weak interaction / Dicarboxylate ligands

Two new polymeric complexes of copper(II), $[Cu(L1)(\mu\text{-fum})(\mu\text{-}H_2O)]_n$ (**1**) (fum = fumarate dianion; L1 = *N*,*N*′-dimethylethane-1,2-diamine) and $[Cu(L2)(\mu\text{-tp})]_n$ (**2**) [tp = terephthalate dianion; L2 = *N*-(2-aminoethyl)-3-amino-1-propanol], have been synthesized. The molecular structures are determined by X-ray crystallography. Complex **1** is a fumarato-bridged zig-zag 1D chain of Cu^{II}–L1, which is extended to a 3D coordination polymer through bridging water molecules. Complex **2** is a chain of Cu^{II} in which the terephthalate anions bridge in alternate bis(bidentate) and bis(monodentate) fashions. The coexistence of such types of bridging modes of terephthalate ions in a single molecule is unprecedented. The chelating terephthalate ion is linked to an equatorial and an axial site of consecutive metal ions, while the other terephthalate ion is axially linked to Cu^{II} centers. Both the complexes are characterized by variable-temperature susceptibility measurements at room temperature down to 4 K. Fitting of the magnetic data reveals the existence of weak antiferromagnetic interactions through the bridging dicarboxylate pathways.

Introduction

Construction of molecules with covalent and noncovalent motifs has recently become a rapidly growing area of research as it pursues to establish principles that will ultimately lead to the development of new state-of-the-art functional materials.[1−6] Among the noncovalent motifs, hydrogen bonding[2,3] and π-π stacking[7] have been employed as synthetic paradigms to rationally design superstructures. Recent progress in this area has generated examples in which the design of network structures has produced crystals with (a) one-dimensional (1D) molecular networks composed of hydrogen bonding,[8,9] metal−ligand coordination,[10,11] or a combination of these and other interactions, referred to as hybrid interactions;[12] (b) 2D networks comprising either hydrogen bonding[13]/metal−ligand coordination[14] or hybrid interactions; and (c) 3D networks composed of hydrogen bonding[15] or metal−ligand coordination.[16] These approaches seek to establish structural relationships between the molecular and supramolecular networks and look for molecular features, such as functional groups, that can interfere and modify the arrangements of molecules in crystals, a task that remains a considerable challenge at present.

Recently, di- and polycarboxylates have become one of the most demanding spacers to the material chemist, and especially to the inorganic chemist, for the synthesis of compounds that have potential useful applications as molecular-based magnetic materials as well as materials that mimick zeolite with host-guest behavior.[17−19] Different types of dicarboxylates like terephthalate, malonate, succinate, and oxalates are widely used by these chemists, but use of fumarate is relatively less frequent due to poor solubility of its coordination complexes in common solvents. We have reported a new method of crystallization of Cu^{II} complexes of fumarate that uses ammonia as solvent.[20] With this procedure we have already obtained and reported on some interesting molecular architectures.[20,21] We are currently exploring the design of molecules that use suitable metal ions and ligands capable of forming H-bonds as well as π-π interactions as directional motifs to extend the dimensionality of the molecule. The present article contributes to the synthesis, crystal structure, and variable-temperature magnetic behavior of two Cu^{II} complexes with unsaturated dicarboxylate as bridging ligands, namely $[Cu(L1)(\mu\text{-fum})(\mu\text{-}H_2O)]_n$ (**1**) and $[Cu(L2)(\mu\text{-tp})]_n$ (**2**) [fum = fumarate dianion; tp = terephthalate dianion; L1 = *N*,*N*′-dimethylethane-1,2-diamine; L2 = *N*-(2-aminoethyl)-3-amino-1-pro-

panol]. The results of the structural analysis of complex **1** reveals a 3D network and that of **2** a chain with alternating bis(bidentate) and bis(monodentate) bridging modes of terephthalate, which results in a molecule with a unique topology. The coexistence of terephthalate ligands with different bridging fashions inside a single molecule has not been reported earlier. These unsaturated dicarboxylates are chosen as spacers because of the following reasons: (i) fumarate and terephthalate show versatile coordination modes (Scheme 1); (ii) they coordinate metal ions to form unidimensional coordination chains, which, in general, can enlarge the dimensionality through H-bonding; and (iii) they have ethylenic and phenyl moieties that are capable of forming π-π stacking as a directional motif (Scheme 2).

Results and Discussion

Description of the Structures

[Cu(L1)(μ-fum)(μ-H_2O)]$_n$ (1)

The crystal structure of **1** consists of Cu^{II}(L1) units connected through bridging amphi-monodentate fumarate dianions to form polymeric chains with a zig-zag arrangement (Figure 1). Each copper atom is located on a twofold crystallographic axis with an elongated octahedral geometry that involves the diamine ligand donors N(1) and the carboxylic oxygen atom O(2) in the equatorial positions, and two water molecules as axial ligands. The former distances [Cu−O(2) 1.973(2), Cu−N(1) 2.022(2) Å] are significantly shorter than those involving the water molecule [2.481(2) Å]. A selection of bond lengths and angles is reported in Table 1. The dicarboxylate anion spans the metal atoms with a distance of 8.857 Å, a distance similar to those of 8.653 and 8.666 Å observed in two dinuclear fumarate-bridged Cu^{II} complexes.[22,23] It is worthwhile to note the

packing shown by the X-ray structural analysis, in which the coordination polymers present an intersecting arrangement (Figure 2). The dimensionality of the network is enlarged to 3D through the axially coordinated water molecules that bridge consecutive metal ions as depicted in Figure 3. These $-(Cu-H_2O)_n-$ chains are characterized by a metal−metal separation of 4.512 Å and a Cu−OH$_2$−Cu′′ bond angle of 130.6(1)°. The dicarboxylate skeleton is not coplanar, and instead, a O(3)−C(3)−C(4)−C(4′′) torsion angle of 145.0(4)° is observed. This conformational feature is likely assumed in order to favor the intrachain H-bond formation between the coordinated water molecule and the fumarate oxygen atom O(3) (Figure 3; O−O 2.651 Å). However, the C(4)−C(4′′) bond length of 1.311(5) Å still indicates a larger double-bond character relative to that of the C(3)−C(4) bond [1.491(3) Å].

[Cu(L2)(μ-tp)]$_n$ (2)

The structure of complex **2** consists of 1D polymeric chains formed by Cu(L2) moieties [L2 = *N*-(2-aminoethyl)-3-amino-1-propanol] bridged by terephthalate anions. The polymeric motifs, together with the atom numbering scheme, is shown in Figure 4, and a selection of bond lengths and angles is given in Table 2. The metal environment can be described as a distorted octahedron in which the equatorial positions are occupied by the hydroxy-diamine ligand donors and by the carboxyl oxygen atom O(2), while the oxygen atoms O(4) and O(3) of different bridging terephthalate anions complete the coordination sphere. The latter distances [Cu−O(4) 2.300(4), Cu−O(3) 2.553(4) Å] are significantly longer with respect to those in the basal plane [range 1.971(4)−2.027(5) Å]. The distortions from the octahedral geometry are indicated by the small bite angle of the carboxylate group O(2)−Cu−O(3) [56.7(2)°] and by the O(4)−Cu−O(3) angle [153.3(1)°]. The four equatorial donors are coplanar ±0.086(3) Å, with the metal atom slightly displaced by 0.164(3) Å from their mean plane towards O(4). Thus, along the chain, two terephthalate anions, both having the phenyl ring located about a crystallographic symmetry center, connect Cu(L2) units, alternatively in a bis(monodentate) and a chelating bis(bidentate) fashion (Figure 4). The simultaneous presence of terephthalate ligands with different bridging fashions gives rise to an unprecedented coordination chain. The dihedral angle formed by the anions with the equatorial coordination plane is 45.9(1) and 80.3(2)°, the latter indicating a nearly perpendicular orientation for the bis(bidentate) terephthalate. The respective *intra*molecular Cu−Cu distances spanned by the anions are 10.998(5) and 10.830(3) Å; the small difference appears to be caused by the ligand coordination mode. In fact, making allowance for packing and for the different ligands bound at the metal atom, distances of about 11.0 Å were found for copper ions bridged by bis(monodentate) terephthalate anions,[24−26] while a separation of 10.710 Å was reported in [(CuL")$_2$tp](ClO$_4$)$_2$ (L" = pentaethyldiethylenetriamine)[27] in which the anion bridges in a chelating bis(bidentate) fashion. The carboxylate group C(6)/O(2)/O(3) is nearly coplanar with the phenyl ring [4.9(3)°], while C(10)/O(4)/O(5) exhibits a tilt of 24.0(5)°. This dihedral angle was tentatively taken into account to assess the magnetic exchange coupling with structural parameters in transition metal ions bridged by a tp ligand.[28] The described polymers are held together through strong hydrogen bonds that occur between the hydroxy group O(1)−H and the carboxylate oxygen atom O(5) [2.678 Å, O(1)−H···O(5) 159.07°] to yield a layered structure (Figure 5) in which the shortest *inter*chain Cu−Cu distance is 5.532(1) Å. Moreover, the phenyl groups of the bis(bidentate) terephthalate are not coplanar with

aromatic rings of neighboring chains, but are perpendicular. As a consequence, the phenyl centroid of the latter is at a distance of 2.66 Å from the H−C group of the adjacent aromatic ring leading to a C−H···π interaction (Figure 5).

Magnetic Properties

[Cu(L1)(μ-fum)(μ-H_2O)]$_n$ (1)

The magnetic behavior of complex **1** was investigated using a SQUID magnetometer in the temperature region 280−4 K within an applied magnetic field of 5 kOe. The $\chi_M T$ product first decreases smoothly and then abruptly when cooling down from $T = 280$ K. It reaches a value close to zero at $T = 4$ K. The $\chi_M = f(T)$ plot is shown in Figure 6. These magnetic data are consistent with the presence of a weak antiferromagnetic interaction between the Cu^{II} ions within the compound even though the shorter Cu−Cu distance is larger than 6 Å. The susceptibility data, using the 1D chain model of the Cu^{II} system, was fitted, resulting in a J value of $-2.6\ cm^{-1}$. This value is satisfactory, since it is of the same order of magnitude as that from a previously reported communication in which a 3D interlocked network of Cu^{II} ions has a bridging fumarate ion that is linked in a similar manner to that in the present complex.[21] From a structural point of view, each copper atom, located on a twofold crystallographic axis, shows an elongated octahedral geometry involving the diamine ligand donors and a carboxylic oxygen atom in the equatorial positions, and two water molecules at the axial sites. Due to this axially elongated geometry of Cu^{II} centers, the magnetically active unpaired electron on each Cu^{II} atom is located on the basal $d_{x^2-y^2}$ orbital, whereas the d_{z^2} orbital is occupied by paired electrons. Since each bridging water is bound to the d_{z^2} (nonmagnetic) orbital of two Cu^{II} centers, the coupling interaction through the aqua bridging pathway may be considered to be zero. Therefore, in the fitting, we did not consider the coupling interaction through the water bridging pathway, and rather, for magnetic study, the compound was considered as a 1D coordination chain.

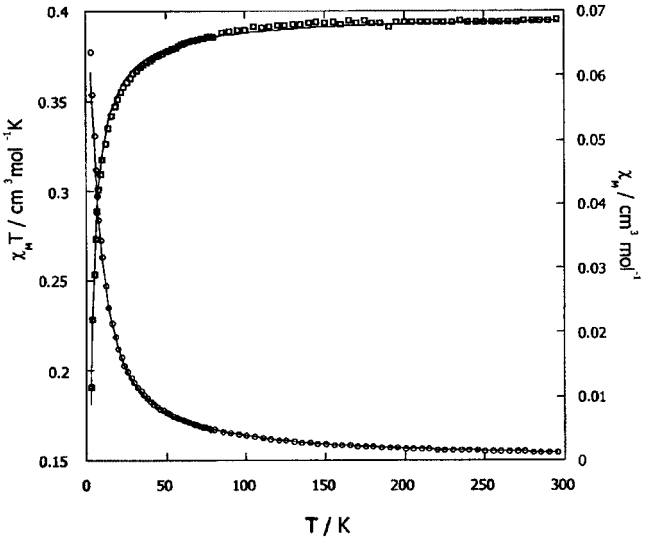

Figure 6. Plot of $\chi_M T$ vs. T (squares) and χ_M vs. T (circles) data; solid lines show the best fit obtained considering a uniform chain of $S = 1/2$ local spin states

[Cu(L2)(μ-tp)] (2)

The structural analysis reveals a 1D chain with dicarboxylate anions in a different alternating bridging mode. We have considered that an axial−axial bridging terephthalate ion has no influence on magnetic coupling since the unpaired electron on the Cu^{II} atom is not concentrated in axial orbital regions. The $\chi_M T$ vs. T plot shows a gradual decrease in $\chi_M T$ values with decreasing temperature (Figure 7), which indicates the existence of antiferromagnetic interactions within the complex. The $\chi_M T$ vs. T data are fitted using the Bleaney−Bowers formula[29] of the Cu^{II} local spin state. The results of the best fit are $J = -6\ cm^{-1}$, $\rho = 0.007$, $g = 2.01$, $R = 1.8 \cdot 10^{-5}$, which are similar to those previously reported for a similar type of bridging tp core.[25]

Conclusions

This article presents the synthesis, single-crystal structure, and magnetic behavior of two dicarboxylate-bridged metal complexes. Complex **1** is a 3D network of Cu^{II} in which both a fumarate ion and a water molecule function as a bridging ligand. Cu−fumarate zig-zag chains are involved in the bridging by water molecules to form a 3D network. On the other hand, complex **2** is a 1D chain of Cu^{II}−terephthalate in which the dicarboxylate is alternately bridged in a bis(bidentate) and a bis(monodentate) fashion in an axial−axial and equatorial−equatorial mode to form a unique molecule since such an alternate coordination fashion has not been reported earlier for terephthalate systems. Furthermore, the solid-state structure of complex **2** is stabilized by C−H···π interactions. Here, the role of the chemically different dicarboxylates upon the formation of the superstructure is a crucial aspect open to theoretical speculations. Low-temperature magnetic susceptibility data of **1** were fitted to the equation of a chain of $S = {}^1/_2$ local spins, which reveal the existence of weak antiferromagnetic interactions along the fumarate pathway. In the case of **2**, the variable-temperature magnetic data were fitted to a dimeric formula of $S = {}^1/_2$ spin state, which indicates a weak antiferromagnetic interaction along the terephthalate pathway.

Experimental Section

Synthesis of Cu(L1)(μ-fum)(μ-H_2O)] (1): 1 mmol of *N*,*N*′-dimethylethane-1,2-diamine was slowly added drop by drop to an aqueous solution of $CuCl_2{\cdot}2H_2O$ (5 mL, 1 mmol, 0.1705 g), resulting in a deep blue solution. An aqueous solution of Na_2−fumarate (10 mL, 1 mmol, 0.160 g) was added with continuous stirring and the stirring continued for 40 min and then filtered. Suitable blue single crystals for X-ray analysis were obtained after 15 d on keeping the deep blue filtrate in a refrigerator. $C_8H_{16}CuN_2O_5$ (283.77): calcd. C 33.80, H 5.63, N 9.86; found C 32.17, H 5.73, N 10.14. IR: ν(COO^-) = 1392, 1562 cm^{-1}; ν(N−H) = 3000 cm^{-1}; ν(O−H) = 3450−3370 cm^{-1}.

Synthesis of [Cu(L2)(μ-tp)] (2): A methanolic solution of a mixture of terephthalic acid (1 mmol) and triethylamine (2 mmol) was layered on a blue aqueous solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (1 mmol) and *N*-(2-aminoethyl)-3-amino-1-propanol (1 mmol). After a month, a microcrystalline blue complex with suitable single crystals for X-ray diffraction were obtained. The crystals were separated by a needle. $C_{13}H_{18}CuN_2O_5$ (345.83): calcd. C 45.10, H 5.20, N 8.09; found C 44.87, H 5.33, N 9.84. IR: ν(COO^-) = 1372, 1543 cm^{-1}; ν(N−H) = 3050 cm^{-1}; ν(O−H) = 3400−3350 cm^{-1}.

Physical Measurements: IR spectra were recorded with a Nicolet 520 FTIR spectrometer using KBr pellets. Magnetic measurements were carried out on a polycrystalline sample with a SQUID magnetometer operating in the 2−300 K temperature range with an applied field of 5 kOe. Diamagnetic corrections were estimated from Pascal constants.

Crystal Data Collection and Refinement: The data set for **1** and **2** were collected at room temperature using the ω-2θ scan technique with an Enraf−Nonius MACH 3 and a CAD4 Enraf−Nonius single-crystal diffractometer, respectively, equipped with a graphite monochromator and Mo-K_α radiation (λ = 0.71073 Å). Three standard reflections, measured at regular intervals throughout the data collection, showed no noticeable variation in intensity. An absorption correction based on the ψ-scan method was applied (max./min. T = 0.9988/0.8316 for **1** and 0.9971/0.8035 for **2**). The structure was solved by conventional Patterson and Fourier analyses and refined on F^2 by full-matrix anisotropic least-squares method using the SHELXL-97 package.[30] All the calculations were performed using the WinGX System, Ver 1.63.[31] Crystal data and refinement details are given in Table 3. X-ray crystallographic data in CIF format for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre. CCDC-236904 and -236905 contain these data, which can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Molecular Structure, and Olefin Polymerisation Activity of an Oxovanadium(v) Alkoxide with Unprecedented Chloride Bridging Ligands

Esther C. E. Rosenthal,*[a] Huiling Cui,[a] Katharina C. H. Lange,[a] and Sebastian Dechert[b]

Keywords: Chelates / O ligands / Oxo ligands / Polymerisation / Vanadium

The reaction of 2-methoxyethanol or (2-methoxyethanolato)-lithium with $VOCl_3$ yields the chloro-bridged dinuclear complex $[VOCl_2(OCH_2CH_2OCH_3)]_2$, which has been characterised spectroscopically and structurally by single-crystal X-ray diffraction analysis. This is the first reported structure of a neutral dinuclear oxovanadium complex connected by bridging chloro ligands. The orange complex is a precatalyst for the polymerisation of ethene and the oligomerisation of styrene.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Oxovanadium complexes are known to act as catalysts for oxidation[1] and polymerisation reactions, for example.[2,3] As part of our investigations aimed at vanadium-based catalysts our interest is primarily concerned with the synthesis and characterisation of vanadium(v) compounds stabilised by alkoxyalkoxide ligands. While a significant number of oxovanadium(v) alkoxides and aryloxides derived from various alcohols have been synthesised,[4] the majority of (alkoxo- or aryloxo)chloro(oxo)vanadium compounds structurally characterised to date contain vanadium in the oxidation state +4.[5−10] The main feature of these complexes is that the alkoxide or aryloxide ligands predominantly act as bridging groups.[7−13] Monomeric derivatives have been reported with very bulky aryloxo groups,[14] intramolecular donor stabilisation[5,6,9,15] or additional donor ligands.[16−18] As far as we are aware, there are no examples of vanadium alkoxides in which chloro ligands appear as bridging units.

Previously we have reported the reaction of 2-phenoxyethanol with $VOCl_3$, which gives the mononuclear complex $[VOCl_2(OCH_2CH_2OPh)]$ and which is still the only structurally characterised dichlorooxovanadium(v) alkoxide.[19] The presence of the remaining chloro ligands in the complex makes the metal atom functionalisable, for example by the introduction of alkyl groups. Chloro ligands, either in the catalyst or in the co-catalyst, are essential for olefin polymerisation.[3]

Herein we show that in the field of vanadium alkoxides, the variation of substituents on the ligands can have large effects on the complex structure and possibly on their catalytic behaviour.

Results and Discussion

Synthesis and Structure

Bis[(μ-chloro)chloro(η^2-2-methoxyethanolato)oxovanadium(v)] was prepared by two different strategies: HCl elimination and a salt metathesis reaction. The equimolar reaction of $VOCl_3$ with 2-methoxyethanol in *n*-pentane gave the dinuclear vanadium(v) species only in very low yields due to significant quantities of reduction products. Such a reduction process has been observed previously when Hovnanian and co-workers obtained the vanadium(iv) complex $[VOCl\{OCH(CH_3)CH_2OCH_3\}]_2$ from a vanadium(v) starting material.[7] Employing the lithium salt instead of the pure alcohol minimised the amount of reduction. The reaction proceeds smoothly under ambient conditions in hydrocarbon solvents, which were chosen with the intention to obtain intramolecularly stabilised complexes instead of additional solvent coordination.

The orange diamagnetic crystalline solid $[VOCl_2(OCH_2CH_2OCH_3)]_2$ slowly decomposes at ambient temperatures both in solution, where it forms blue vanadium(IV), and as a solid, where it forms a black crystalline material. Unfortunately, the black material contained no crystals suitable for X-ray diffraction; it is insoluble in inert solvents like hydrocarbons, dichloromethane or toluene and attempts to recrystallise it from pyridine led to $[VOCl_2(py)_2]$,[20] which was identified by an X-ray structure determination. The title compound can be stored for weeks under an inert gas at −30 °C in the dark without any appreciable decomposition. It dissolves in dichloromethane and toluene and decomposes in water, tetrahydrofuran, diethyl ether, and alcohols. The compound has a ^{51}V NMR chemical shift of $\delta = -259$ ppm in C_6D_6 and $\delta = -262$ ppm in $CDCl_3$. A minor peak is observed at $\delta = -279$ ppm in C_6D_6 and $\delta = -282$ ppm in $CDCl_3$. As a decrease of the coordination number on going, for example, from an octahedral to a tetrahedral arrangement is usually accompanied by an increase of shielding, this signal may be ascribed to the presumably tetrahedral monomer. This chemical shift is also in good agreement with that of other tetrahedrally coordinated dichloro(oxo)vanadium alkoxides in solution.[19,21]

The ^1H and $^{13}C\{^1H\}$ NMR spectra of the title compound show the expected number of signals for the coordinated 2-methoxyethanolato ligand as well as the 1:1 relative intensity proton pattern for the methylene peaks in the ^1H NMR spectrum. The signals at lower field at $\delta \approx 4.6$ ppm in C_6D_6 and $\delta \approx 5.7$ ppm in $CDCl_3$ are due to the $VOCH_2$ protons while those at $\delta \approx 2.8$ ppm in C_6D_6 and $\delta \approx 3.9$ ppm in $CDCl_3$ are assigned to the CH_2OMe methylene protons. The $^{13}C\{^1H\}$ NMR resonance for the carbon atom adjacent to the alcohol moiety shifts approximately 30 ppm downfield upon vanadylation. As for the corresponding proton resonances this shift may be ascribed to the deshielding of this carbon atom due to transfer of electron density to the metal atom. The signals of all other carbon atoms shift very little.

The dimeric nature of the compound is supported by mass spectrometric data, which exhibit no molecular ion but $[VOCl(OCH_2CH_2OCH_3)]_2$, formed by loss of two chlorine atoms and containing two vanadium atoms, as the fragment with the highest molecular mass. The same is true for IR spectroscopy, which indicates both terminal and bridging V−Cl bonds. The intense bands at 464 and 434 cm^{-1} arise from terminal V−Cl and bridging V−Cl stretching vibrations, respectively. The sharp bands at 1028 cm^{-1} in nujol and 1024 cm^{-1} in CS_2, associated with the V=O moiety, are characteristic of $VOCl_2(OR)$ compounds.[9,19,21]

Single crystals of the complex, suitable for X-ray diffraction, were obtained from cold *n*-hexane solutions. An ORTEP drawing of the molecule is shown in Figure 1, and selected bond lengths and angles are given in the caption. The structural analysis revealed the (alkoxyalkoxo)vanadium compound to be a dimer with two bridging chlorine atoms. The two halves of the dimer are related by a centre of inversion. Thus, oxo groups and terminal chlorine atoms adopt an *anti* orientation while the V=O groups are orientated perpendicular and the chlorine atoms coplanar with respect to the bridging plane, which is spanned by the $V_2(\mu\text{-}Cl)_2$ core.[22] Each vanadium atom possesses a distorted octahedral geometry which is similar to that in other hexacoordinate vanadium(V) complexes.[23−25] The vanadium atom is displaced by 0.296(1) Å from the plane formed by the equatorial atoms Cl(1), Cl(2), O(2), and Cl(1′) towards the oxo oxygen atom. It is unusual, and we believe unique, in having the two VO_3Cl_3 octahedra joined by chlorine atoms. Hitherto structurally characterised examples of dimeric chloro(oxo)vanadium complexes containing an $[OV(\mu\text{-}Cl)_2VO]^{n+}$ ($n = 2, 4$) core have only been reported for the purely inorganic vanadium(IV) anions $[\{VOCl_2(OH_2)\}_2(\mu\text{-}Cl)_2]^{2-}$ and $[V_2O_2Cl_6]^{2-}$.[26,27] So far if alkoxo or aryloxo ligands are involved they function as bridging units instead of chlorine atoms.[7−13]

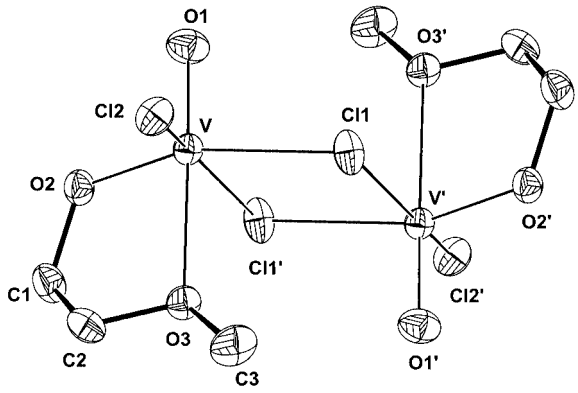

Figure 1. ORTEP view of $[VOCl_2(OCH_2CH_2OMe)]_2$; displacement ellipsoids are drawn at the 50% probability level; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: V−Cl(1) 2.4321(6), V−Cl(1′) 2.4172(6), V−Cl(2) 2.2581(6), V−O(1) 1.5827(16), V−O(2) 1.7697(15), V−O(3) 2.3120(15); Cl(1)−V−Cl(1′) 79.33(2), V−Cl(1)−V′ 100.67(2), Cl(1)−V−O(1) 97.15(7), Cl(1′)−V−O(1) 95.23(6), Cl(2)−V−O(1) 99.40(6), O(1)−V−O(2) 99.08(8), O(1)−V−O(3) 175.88(7)

As in $[\{VOCl_2(OH_2)\}_2(\mu\text{-}Cl)_2]^{2-}$, both vanadium atoms are part of a planar $V_2(\mu\text{-}Cl)_2$ four-membered ring,[26] in which the angles at the vanadium atom are 79.33(2)° and those at μ-Cl are 100.67(2)°. The two chlorine atoms bridge the two vanadium atoms in an almost symmetric fashion: both bonds have approximately the same length [2.4321(6) Å and 2.4172(6) Å for V−Cl(1) and V−Cl(1′), respectively] and are similar to those in the $[V_2O_2Cl_6]^{2-}$ ion.[27] The distances of the vanadium atom to the terminal chlorine atoms are 2.2581(6) Å, which are very similar to those observed for $[\{HB(pz)_3\}VOCl(O\textit{i}Pr)]$[18] and $[VOCl\{OC(CH_3)_2C(CH_3)_2O\}]_2$.[12]

Three different vanadium−oxygen bonds are present. The vanadium−oxo distance is in the normal range for such a bond [V−O(1) = 1.5827(16) Å].[5−15,17−21,23−27] The V−O distance for the alkoxide oxygen atom O(2) is only about 0.2 Å longer, which is in agreement with some degree of π-donation from O(2) to the metal atom and is typical for vanadium alkoxide moieties.[5,9,13,15,17−19,21,23] Owing to the fact that the oxygen atom O(3) of the methoxy group encounters the *trans* influence of the doubly bonded oxygen

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

atom O(1), its distance to the vanadium atom is, as expected, the longest [2.3120(15) Å].

In contrast to the monomeric vanadium(v) complex $[VOCl_2(OCH_2CH_2OPh)]$ and the dimeric vanadium(iv) complexes $[VOCl\{OCH(CH_3)CH_2OCH_3\}]_2$ and $[VOCl\{OCH_2(C_4H_7O)\}]_2$, where the aryloxy- and alkoxyalkoxides are pendant or bridging, respectively,[7,8,19] both groups in the compound reported here coordinate directly to a single vanadium centre. Although $[VOCl_2(OCH_2CH_2OPh)]$ was obtained by the corresponding reactions with 2-phenoxyethanol, both dichloro(oxo)vanadium compounds differ completely in their structures.[19] As there are no steric reasons for this phenomenon the origin of this difference is probably due to the lower Lewis basicity of the phenyl ether than the methyl one.

Catalytic Activity

The catalytic activity of the title compound for the polymerisation of styrene, 1-decene, and ethene was examined. Polymerisation studies were conducted employing a polymerisation catalyst prepared by adding the vanadium compound to a toluene solution of methylaluminoxane (MAO) as the co-catalyst. The low molecular masses given in Table 1 show that only oligomers are obtained for styrene with methyl trichloroacetate (MTCA) as promoter. The catalytic activity decreases with rising temperatures and is highest at room temperature, with quantitative conversion of styrene, while the polydispersity (D) has values of around 2.

Under the same conditions the activity for styrene oligomerisation is ten times higher than that for 1-decene conversion and is independent of the nuclearity of the precatalyst employed (Table 2). The molecular mass and polydispersity of styrene oligomers are in the same range as for the mononuclear (M_n = 2700 g/mol, M_w = 4100 g/mol, D = 1.8) and the dinuclear complex (M_n = 3200 g/mol, M_w = 5000 g/mol, D = 1.5).

Table 1. Oligomerisation of styrene with $[VOCl(OCH_2CH_2OCH_3)]_2$[a]

T [°C]	Yield [%]	M_w [g/mol]	M_n [g/mol]	M_w/M_n
20	99.6	2900	1200	2.3
40	85.3	3000	1500	2.0
50	71.1	2700	1600	1.7

[a] Reaction conditions: V catalyst/styrene/MAO/MTCA = 0.01:13:1:1, 20 h; solvent: toluene.

Table 2. Activity (kg per mol vanadium atom per h) of olefin conversions with vanadium(v) compounds[a]

Precatalyst	Styrene	1-Decene
$[VOCl_2(OCH_2CH_2OMe)]_2$	27.7	2.5
$[VOCl_2(OCH_2CH_2OPh)]$	27.9	2.7

[a] Reaction conditions: V catalyst/monomer/MAO/MTCA = 0.01:17:1:1, 90 min at 23 °C; solvent: toluene.

The ethene polymerisation catalysts were prepared by treating the vanadium compound either with MAO or chlorodiethylaluminium as the co-catalyst. The results of ethene polymerisation are shown in Table 3. Even at atmospheric pressure and room temperature the title compound displays a reasonable activity (100 kg PE/mol[V] h) for ethene polymerisation with MTCA as promoter in the presence of MAO; without MTCA the activities are negligible. The conditions have been optimised for MAO to give highest activities at an Al/V ratio of 400 (300 kg PE/mol[V] h bar). Et_2AlCl, with almost double the activity (560 kg PE/mol[V] h bar), is the best co-catalyst for the system, as has been found previously for other vanadium procatalysts.[3] For comparison, under similar conditions, the best result for a catalyst based on $VOCl_3$ was 360 kg PE/mol[V] h bar after activation with Et_2AlCl. In the range investigated the activities drop if the Al/V ratio is lowered. During the polymerisation reaction the catalyst is stable and the activities decrease only after 30 min. GPC analyses showed that the product molecular mass distribution is very broad. With MAO as co-catalyst the system forms polyethene with a higher molecular mass than with Et_2AlCl. The molecular mass distribution of all polymers formed is bimodal.

Conclusion

In summary, the synthesis of $[VOCl_2(OCH_2CH_2OCH_3)]_2$ has resulted in the first dinuclear chloride-bridged oxovanadium alkoxide to be structurally characterised. The two bridging chloro ligands build the sharing edge of two VO_3Cl_3 octahedra, which incorporate a five-membered chelate ring. This structural feature may give rise to altered reactivities as polymerisation catalyst or oxidation reagent compared to mononuclear or alkoxide-bridged oxovanadium sites. The title compound shows catalytic activity in ethene polymerisation and styrene oligomerisation. Further catalytic studies besides polymerisation, including the oxidation properties, as well as comparative synthetic investigations concerning other alkoxyalkoxides are currently underway.

Experimental Section

General Remarks: All experiments were performed under nitrogen using standard Schlenk techniques in dry, oxygen-free solvents. Commercial $VOCl_3$ (Aldrich) was used as received. 2-Methoxyethanol, MTCA and styrene were dried with molecular sieves (4 Å). 1-Decene was distilled from CaH_2 followed by treatment with molecular sieves. The ethene gas (Messer Griesheim, 99.995%) was passed through an Oxiclear gas purifier before being passed into the reactor. The IR spectrum was recorded using a Nicolet Magna IR spectrometer 750. NMR spectra were recorded at ambient temperatures with a Bruker ARX 200 or ARX 400 spectrometer. All chemical shifts are reported in ppm relative to the ^1H and ^{13}C residue of the deuterated solvents. For ^{51}V NMR $VOCl_3/CDCl_3$ (2:1) was used as external standard. The mass spectrum (EI) was obtained using a Varian MAT 311 A instrument. Elemental analyses were performed with a Perkin−Elmer Series II CHNS/O Analyzer 2400. GPC data of styrene oligomers were obtained with a Waters model 150 LC/GPC in THF solvent running at ambient temperature and were calibrated using polystyrene standards. GPC measurements of polyethene samples were carried out by high-temperature GPC at 140 °C, using 1,2,4-trichlorobenzene as solvent and narrow polystyrene standard sample as reference. The measurements were performed with a PL-GPC210 with 4 PL-Gel Mixed A columns, with triple detection: RALLS detector (Precision Detector, PD2040 at 800 nm), H502 viscometer (Viscotek), refractive detector and DM400 datamanager (Viscotek).

$[VOCl_2(OCH_2CH_2OCH_3)]_2$. Method A: $VOCl_3$ (3.0 mL, 32 mmol) was added to a colourless mixture of $HOCH_2CH_2OCH_3$ (2.5 mL, 32 mmol) in *n*-pentane (150 mL). The reaction mixture turned brown immediately and was stirred at room temperature for 1 h. In order to complete the evolution of HCl gas, the mixture was heated in a warm-water bath. The resulting orange solution was concentrated and stored at 0 °C. Orange crystals separated overnight. Yield: 0.82 g (12%). M.p. 65 °C. **Method B:** *n*-Hexane (100 mL) and a 1 M solution of $VOCl_3$ (10 mL, 1.73 g, 10 mmol) in *n*-pentane were added to $LiOCH_2CH_2OCH_3$ (0.83 g, 10 mmol). The reaction mixture was stirred at room temperature for 12 h. The orange solution was decanted from the brown residue and stored at −30 °C. Orange crystals separated. Yield: 0.83 g (39%). IR (KBr, nujol mull): $\tilde{\nu}$ = 1255 m, 1224 m, 1192 m, 1156 w, 1102 s (V−O−C), 1081 vs (C−O), 1028 vs (V=O), 994 vs, 897 vs (C−O−C), 825 s, 629 s (V−OR), 577 w, 464 vs (V−Cl), 434 s (V−Cl−V) cm^{-1}. IR (KBr, CS_2): $\tilde{\nu}$ = 1127 s (V−O−C), 1108 w, 1090 w, 1047 vs (C−O), 1024 vs (V=O), 1001 m, 919 m (C−O−C), 644 w (V−OR), 484 s (V−Cl), 439 m (V−Cl−V) cm^{-1}. ^1H NMR (400 MHz, C_6D_6): δ = 4.61 (br. s, 4 H, VOCH_2), 2.94 (s, 6 H, CH_3), 2.81 (br. s, 4 H, CH_2OMe) ppm. ^1H NMR (400 MHz, $CDCl_3$): δ = 5.71 (t, $^3J_{H,H}$ = 4.5 Hz, 4 H, VOCH_2), 3.86 (t, $^3J_{H,H}$ = 4.5 Hz, 4 H, CH_2OMe), 3.50 (s, 6 H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (100.64 MHz, C_6D_6): δ = 90.6 (VOCH_2), 71.3 (CH_2OMe), 58.8 (CH_3) ppm. $^{13}C\{^1H\}$ NMR (50.32 MHz, $CDCl_3$): δ = 90.7 (VOCH_2), 71.7 (CH_2OMe), 59.2 (CH_3) ppm. ^{51}V NMR (105.19 MHz, C_6D_6): δ = −259 (> 99%), −279 (< 1%) ppm. ^{51}V NMR (105.19 MHz, $CDCl_3$): δ = −262 (> 98%), −282 (< 2%) ppm. MS (70 eV, 150 °C): *m*/*z* (%) = 354 (25) [M^+ − 2 Cl], 319 (5) [M^+ − 3 Cl], 318 (7) [M^+ − 2 Cl − HCl], 279 (11) [M^+ − 2 Cl − $OCH_2CH_2OCH_3$], 274 (10), 217 (39), 45 (100) $[CH_2OCH_3]^+$. $C_6H_{14}Cl_4O_6V_2$ (425.86): calcd. C 16.92, H 3.31; found C 16.93, H 3.49.

X-ray Crystallographic Study: $C_6H_{14}Cl_4O_6V_2$, M = 425.86, orange plate, 0.46 × 0.36 × 0.08 mm, monoclinic, space group $P2_1/n$ (no. 14), a = 6.9487(2), b = 17.6924(5), c = 6.9663(2) Å, β = 117.514(1)°, V = 759.57(4) Å^3, d = 1.862 g/cm^3, T = 173(2) K, Z = 2, μ = 1.944 mm^{-1}, 2.30° < θ < 27.50°, 5617 measured reflections, 1731 independent reflections, R_{int} = 0.0372, $R1$ [$I > 2\sigma(I)$] = 0.0288, $wR2$ (all data) = 0.0688. X-ray data were collected with a Siemens SMART CCD diffractometer (graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å) fitted with an area-detector by use of ω scans. The structure was solved by direct methods using SHELXS-97[28] and refined on F^2 using all reflections with SHELXL-97.[29] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in calculated positions and assigned an isotropic displacement parameter of 0.08 Å^2. SADABS[30] was used to perform area-detector scaling and absorption corrections (max./min. transmission factors: 0.8911/0.6151). CCDC-232374 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Polymerisation Studies: Styrene and 1-decene polymerisation reactions were performed in a 50-mL Schlenk flask and an external temperature-controlled bath on a Schlenk line. In a typical procedure, toluene (10 mL) and MAO (2 mmol) were loaded into the Schlenk flask. The vanadium compound (0.05 mmol based on vanadium atoms) was then added as a toluene solution (0.01 M) and the mixture was stirred at room temperature for 5 min. After the external bath temperature had stabilised, MTCA (2 mmol) and the monomer were added with a syringe. The polymerisation was terminated by addition of acidic methanol (MeOH/HCl = 10:1; 3 mL). The product was precipitated into ethanol (200 mL), filtered off, and dried under vacuum. The molecular mass and the molecular mass distribution were determined by GPC. The polymerisation of ethene was carried out either in a Schlenk tube or in a glass autoclave (1 L) equipped with a stirrer. For Schlenk tube polymerisation, toluene (50 mL), MAO (0.8 mmol), $[VOCl_2(OCH_2CH_2OCH_3)]_2$ (5 μmol), and MTCA (0.8 mmol) were stirred for 10 min. Afterwards, ethene was polymerised at room temperature at an ethene pressure of 1 bar. Toluene (200 mL), MAO, and MTCA (MAO/MTCA = 1:1) were injected sequentially into the autoclave at 30 °C, and the mixture stirred for 15 min. The vanadium precatalyst was then injected into the reactor and allowed to interact with MAO for 10 min. In the case of Et_2AlCl the co-catalyst solution was divided into two parts: one half was injected into the autoclave

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

together with MTCA (MTCA/$Et_2AlCl \geq 1:1$) and the other half was used to activate the sample of precatalyst solution for 15 min prior to injection into the reactor. The ethene pressure in the autoclave was kept at 2 bar during all polymerisations. Polymerisations were quenched with a 5% solution of HCl in ethanol (150 mL). The mixtures were poured into water (150 mL) and stirred for 30 min. The white precipitate was collected by filtration, washed with ethanol and dried at 60 °C to a constant weight. Molecular masses and polydispersities were determined by GPC.

Acknowledgments

We are grateful to Prof. B. Hessen (University of Groningen) for his help in running the GPCs of polyethene samples. We thank A. Steffens for GPC measurements and interpretation of styrene oligomers. This work was financially supported by the Deutsche Forschungsgemeinschaft (Graduiertenkolleg "Synthetische, mechanistische und reaktionstechnische Aspekte von Metallkatalysatoren").

Backbone Flexibility and Counterion Effects on the Structure and Thermal Properties of Di(thiourea)zinc Dicarboxylate Coordination Polymers

Andrew D. Burrows,*[a] Adele S. Donovan,[a] Ross W. Harrington,[a] and Mary F. Mahon[a]

Keywords: Crystal engineering / Coordination polymers / Helical structures / Hydrogen bonds / Zinc

The reaction between $[Zn(tu)_4]Cl_2$ and the appropriate sodium dicarboxylate has been shown to give the coordination polymers $[Zn(tu)_2(\mu\text{-succinate})]_n$ (**7**), $[Zn(tu)_2(\mu\text{-itaconate})]_n$ (**8**), $[Zn(tu)_2(\mu\text{-ethylmalonate})]_n$ (**9**), $[Zn(tu)_2(\mu\text{-1,3-phenylenediacetate})]_n$ (**10**) and $\{[Zn(tu)_2(\mu\text{-mesaconate})]\cdot 2H_2O\}_n$ (**11**), all of which have been crystallographically characterised. The crystal structures of **7**–**9** demonstrate that these compounds form helical structures in which the dicarboxylates adopt conformations with the relative positions of the carboxylate groups similar to those in constrained anions such as phthalate. The role of the chloride counterion in the starting material has been explored by investigating the reactions of $[Zn(tu)_4](NO_3)_2$ with a range of dicarboxylates. Although in the majority of cases the counterion was shown to have no effect, in the case of fumarate, a hydrated coordination polymer $\{[Zn(tu)_2(\mu\text{-fumarate})]\cdot 2H_2O\}_n$ (**12**) was observed in addition to the anhydrous product $[Zn(tu)_2(\mu\text{-fumarate})]_n$ (**1**), which was formed as the sole product from $[Zn(tu)_4]Cl_2$. Thermogravimetric analyses are reported for compounds **1**–**12**. The compounds $\{[Zn(tu)_2(\mu\text{-isophthalate})]\cdot H_2O\}_n$ **3** and **12** lose their included water before 140 °C, whereas the compounds $\{[Zn(tu)_2(\mu\text{-maleate})]\cdot H_2O\}_n$ **6** and **11** only lose their water molecules at higher temperatures with the onset of decomposition. This difference in behaviour can be related to the structural role of the water molecules.

Introduction

The majority of crystal engineering studies employ one of two strategies to engender structural predictability. Hydrogen bonds, especially in systems involving two or more such interactions between the same molecules or ions, have proved effective in both organic and inorganic systems.[1−3] In the latter, bifunctional ligands containing both coordination sites and hydrogen-bonding faces are used to include metal centres.[4] A number of examples of bifunctional ligands have been reported recently, including bis(imidazolates),[5] amidinoureas[6] and oxalurates.[7] Inorganic crystal engineering has also exploited coordination bonds in the formation of metal-organic frameworks.[8−10] This approach relies on the use of polytopic ligands that are able to bridge between metal centres. Bridging coordination modes are encouraged through rigidity in the ligand, which makes chelation geometrically impossible.

We have been interested in the interplay between the hydrogen bond and coordination bond approaches, and have focussed attention on systems in which both types of aggregation are possible and potentially in competition.[11−13] We recently reported the reactions of $[Zn(tu)_4]Cl_2$ with the appropriate sodium dicarboxylates to give the coordination polymers $[Zn(tu)_2(\mu\text{-fumarate})]_n$ (**1**), $[Zn(tu)_2(\mu\text{-malonate})]_n$ (**2**), $\{[Zn(tu)_2(\mu\text{-isophthalate})]\cdot H_2O\}_n$ (**3**), $[Zn(tu)_2(\mu\text{-phthalate})]_n$ (**4**), $[Zn(tu)_2(\mu\text{-citraconate})]_n$ (**5**) and $\{[Zn(tu)_2(\mu\text{-maleate})]\cdot H_2O\}_n$ (**6**).[14] In all cases, the coordination polymers are interconnected through hydrogen bonds, and these are dominated by interactions involving the thiourea face containing two parallel NH groups. Similar observations on zinc and cadmium dicarboxylates have been reported by Zhang and co-workers.[15−17]

In this paper we extend the reaction between $[Zn(tu)_4]Cl_2$ and dicarboxylate to a further five anions. In three of these − succinate, itaconate and 1,3-phenylenediacetate − there is much greater conformational flexibility due to the inclusion of one or more sp^3-hybridised carbon atoms between the carboxylate groups. Ethylmalonate and mesaconate were chosen to determine the structural effects of alkyl substituents by comparison with the previously reported malonate and fumarate compounds. We report herein the crystal structures of the products $[Zn(tu)_2(\mu\text{-succinate})]_n$ (**7**), $[Zn(tu)_2(\mu\text{-itaconate})]_n$ (**8**), $[Zn(tu)_2(\mu\text{-ethylmalonate})]_n$ (**9**), $[Zn(tu)_2(\mu\text{-1,3-phenylenediacetate})]_n$ (**10**) and $\{[Zn(tu)_2(\mu\text{-mesaconate})]\cdot 2H_2O\}_n$ (**11**), and compare their supramolecular structures with those previously reported for compounds **1**−**6**. The role of the counterion in the starting material has also been explored by investigating the reactions of $[Zn(tu)_4](NO_3)_2$ with a range of dicarboxylates. This has led to the structural characterisation of $\{[Zn(tu)_2(\mu$-

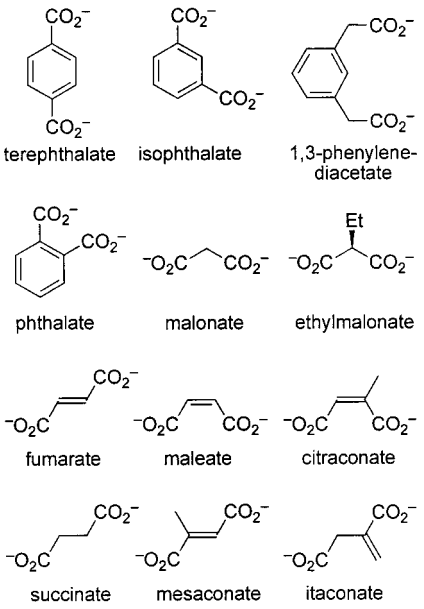
fumarate)]·2H_2O}$_n$ (**12**). The dicarboxylates relevant to this paper are illustrated in Scheme 1.



Scheme 1. Dicarboxylates incorporated in compounds **1**−**12** or mentioned in the text

Syntheses of Compounds 7−11

Compounds **7**−**11** were prepared from the reaction between [Zn(tu)$_4$]Cl$_2$ and the appropriate sodium dicarboxylate in water; crystallisation typically occurred over a period of a week. Yields were in the range 51−78%. In each case, crystals suitable for single-crystal analysis were obtained and the representative nature of the single crystals chosen for analyses to the bulk materials were confirmed by comparison of the X-ray powder diffraction pattern with that predicted from the single-crystal data. The compounds were identified as [Zn(tu)$_2$(μ-succinate)]$_n$ (**7**), [Zn(tu)$_2$(μ-itaconate)]$_n$ (**8**), [Zn(tu)$_2$(μ-ethylmalonate)]$_n$ (**9**), [Zn(tu)$_2$(μ-1,3-phenylenediacetate)]$_n$ (**10**) and {[Zn(tu)$_2$(μ-mesaconate)]·2H_2O}$_n$ (**11**). The structures of **7**−**11** are all based on coordination polymers, and the Zn(tu)$_2$ centres are bridged by dicarboxylate ligands. In all cases, the zinc centres adopt distorted tetrahedral coordination geometries. However, variation in the relative orientations of the carboxylate groups within the individual dicarboxylates leads to differences in the conformations of the polymer chains and in the manner in which they interact with each other. Selected bond lengths and angles for compounds **7**−**11** are given in Tables 1 and 2.

The Structures of [Zn(tu)$_2$(μ-succinate)]$_n$ (7), [Zn(tu)$_2$(μ-itaconate)]$_n$ (8) and [Zn(tu)$_2$(μ-ethylmalonate)]$_n$ (9)

Compounds **7**, **8** and **9** each crystallise in space group $P2_12_12_1$ with lattice parameters within a narrow range. As their structures are broadly similar, they can be treated together. Compounds **7**−**9** all form helical coordination polymers, which propagate along the crystallographic *b* axes. The helices pack in hexagonal arrays, and within each structure, the chains all display the same handedness. In each case, intrachain hydrogen bonding between thiourea NH groups and carboxylate oxygen atoms is observed around the zinc centres. In compounds **7** and **8** there are two hydrogen bonds around each zinc centre, one involving a coordinated oxygen atom and the other involving an uncoordi-

nated oxygen atom. These hydrogen bonds give rise to S(6) and S(8) motifs, respectively, using graph set notation[18] (Figure 1). In both cases, the hydrogen bond leading to the six-membered ring involves the shorter N···O distance. The two Zn−S distances differ significantly (Table 1); the bond length involving the sulfur atom of the S(6) ring is longer than that of the S(8) ring. In compound **9**, there are also two hydrogen bonds present around each zinc centre, although in this case, both involve coordinated oxygen atoms as acceptors and consequently both result in the formation of S(6) rings.

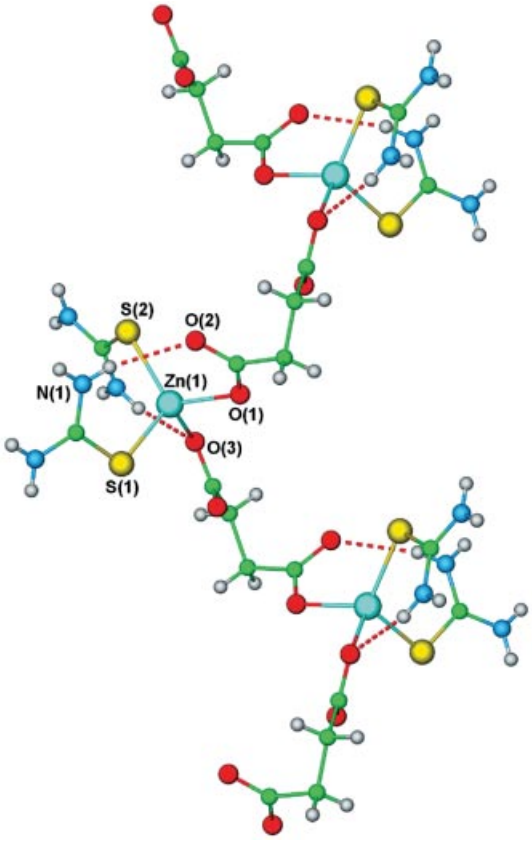

Figure 1. Intrachain hydrogen bonding in $[Zn(tu)_2(\mu\text{-succinate})]_n$ (**7**); selected hydrogen-bond lengths (Å) and angles (°) N(1)···O(2) 3.149, H(1B)···O(2) 2.33, N(1)−H(1B)···O(2) 161; and N(3)···O(3) 2.870, H(3B)···O(3) 2.20, N(3)−H(3B)···O(3) 165

In the helices, the Zn···Zn···Zn angles lie in a narrow range spanning 93° to 101°, and the Zn···Zn distances are 7.36 Å for **7**, 7.62 Å for **8** and 7.40 Å for **9**. Surprisingly the closest Zn···Zn distance occurs in the succinate compound **7** rather than its ethylmalonate analogue **9**, which has one less carbon atom between the carboxylate groups.

Further similarities between the three structures are evident with respect to the manner in which the helices interact together. In **7** and **8** the interactions are identical, occurring in two directions, corresponding to the crystallographic *a* and *c* axes. In each direction there are three independent hydrogen bonds, two of these involving the parallel NH groups on a thiourea ligand. A DD−AA interaction involving two hydrogen bonds between the parallel NH groups and two oxygen atoms generates $R_2^2(11)$ rings in the *a* direction (Figure 2). The two hydrogen-bond acceptors lie on the same dicarboxylate; one is coordinated and the other is uncoordinated. A further hydrogen bond involving an uncoordinated oxygen atom on a second dicarboxylate, generating a second $R_2^2(11)$ ring, completes the hydrogen bonding in this direction. The hydrogen bonding in the *c* direction is somewhat different as a single uncoordinated oxygen atom acts as acceptor to the two parallel NH groups, generating a $R_2^1(6)$ ring, although one of these interactions is relatively long in **7**. The final hydrogen bond in this direction involves a coordinated oxygen atom of a second dicarboxylate as acceptor, and generates a $R_2^2(11)$ ring motif. In each case, the hydrogen bonding is reciprocal along the crystallographic *a* axis, whereby each chain acts as a hydrogen-bond donor *and* acceptor to each adjacent chain, whereas along the crystallographic *c* axis the chains act as either hydrogen-bond donors *or* acceptors to each adjacent chain.

The interactions in **9** are broadly similar to those in **7** and **8**, although there are subtle differences. In the *a* direction, the acceptors for the parallel NH groups are both uncoordinated, generating a $R_2^2(10)$ motif, whereas the third hydrogen bond is to a coordinated oxygen atom leading to a $R_2^2(12)$ ring. In the *c* direction the $R_2^1(6)$ motif observed for **7** and **8** is not present, as the comparative oxygen atom acts as acceptor to only one NH group, while the parallel NH group forms a weak bifurcated hydrogen bond with both a sulfur atom and a second uncoordinated oxygen atom on a separate ethylmalonate. The third hydrogen bond is to a coordinated oxygen atom in a third ethylmalonate, and leads to the formation of a $R_2^2(10)$ motif.

The similarities in the hydrogen bonding within these three compounds can be related to the angle between the carboxylate group planes and the distance between the hydrogen-bond acceptors, which are similar for the three compounds. The angle θ between the carboxylate groups is 87° for **7**, 87° for **8** and 88° for **9**, whereas the distance between the oxygen atoms involved in the $R_2^2(10)$ or $R_2^2(11)$ motifs is 3.28 Å for **7**, 3.45 Å for **8** and 3.18 Å for **9**.

The structures adopted by compounds **7**−**9** possess a number of features in common with those previously reported for $[Zn(tu)_2(\mu\text{-phthalate})]_n$ (**4**) and $[Zn(tu)_2(\mu\text{-citraconate})]_n$ (**5**).[14] All of these compounds form helical coordination polymers, which are interlinked by hydrogen bonding in two directions. This is a reflection of the equivalent relative arrangements of the carboxylate within each anion. In **4** and **5**, the carboxylate orientations are determined by the presence of the double bond or benzene ring, and by the steric interactions that prevent co-planarity of the functionalities. In **7**−**9**, the observed carboxylate arrangements are similar to those in **4** and **5**, but in these cases are not dictated by the ligand geometry. Succinate, itaconate and ethylmalonate all contain one or two sp^3-hybridised carbon atoms between the carboxylates, and therefore have the potential of adopting a range of conformations. A search of the Cambridge Structural Database[19] reveals that of the 211 independent $O_2CCH_2CH_2CO_2$ units, 141 (67%) adopt

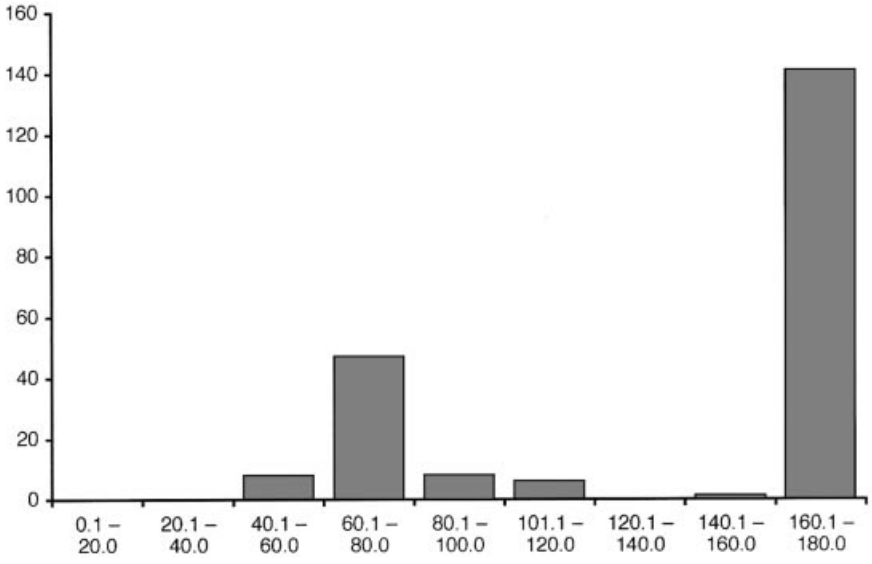

Figure 3. Distribution of CCCC torsion angles in compounds containing the $O_2CCH_2CH_2CO_2$ fragment

an *anti* conformation, with a CCCC torsion angle greater than 160° (Figure 3). In this conformation the O···O distances are all greater than 4.4 Å. In over half of the cases with an O···O distance less than 3.5 Å, this is a direct result of chelation. The observation of helical structures for **7**−**9**, similar to those for **4** and **5**, suggests that this arrangement is driven by the formation of the interhelix hydrogen bonds. The cadmium analogue of **7** has also been reported, and it too has a similar helical structure despite the inclusion of water in the lattice.[20]

The ethylmalonate compound **9** has a very different supramolecular structure to the malonate analogue $[Zn(tu)_2(\mu\text{-malonate})]_n$ (**2**).[14] These differences can be related to the different conformations adopted by the dicar-

boxylates (Figure 4). The steric bulk of the ethyl group and the consequent unfavourable interchain interactions would appear to be the major factor that disfavours **9** from adopting a similar conformation to that observed in **2**.

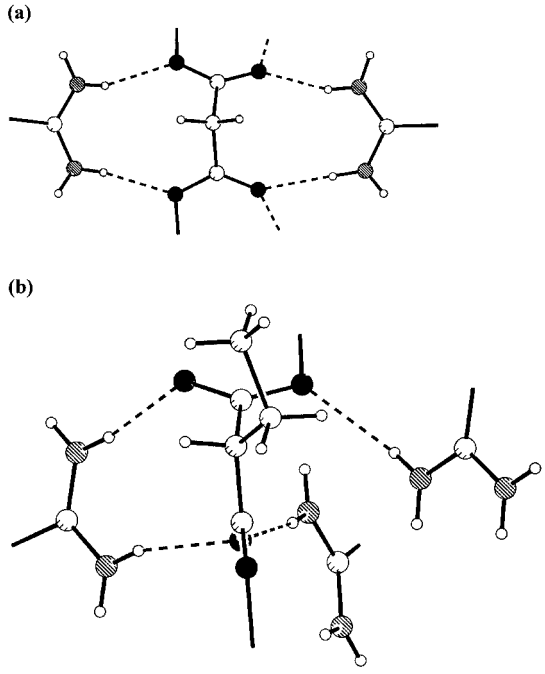

Figure 4. Conformations of and hydrogen bonds to (a) the malonate ligand in **5** and (b) the ethylmalonate ligand in **9**

The Structure of $[Zn(tu)_2(\mu\text{-}1,3\text{-phenylenediacetate})]_n$ (10)

There are two independent helices in the structure of compound **10**, each containing only one of the two crystallographically independent zinc atoms, Zn(1) and Zn(2). Both helical chains contain two intrachain hydrogen bonds between the thiourea NH groups and carboxylate oxygen atoms around each of the zinc centres. These hydrogen bonds involve coordinated and uncoordinated oxygen atoms as acceptors, and give rise to S(6) and S(8) motifs, respectively. This intrachain hydrogen bonding is similar to that observed in **7** and **8**. The length and flexibility of the 1,3-phenylenediacetate ligand allows for additional intrachain hydrogen bonding to more remote thiourea groups. Thus, in each of the independent helices there are two further hydrogen bonds, involving the formation of S(14) and S(16) rings, respectively (Figure 5). One consequence of this additional hydrogen bonding is the increased tightness of the helices, which is reflected in the Zn···Zn···Zn angles, which are 72° and 74° for the two independent polymer chains (93° to 101° for **7**−**9**). The Zn···Zn distances are 6.80 and 6.92 Å for the two chains, shorter than those in **7**−**9**, and clearly illustrate the effect of the intrachain hydrogen bonding. This becomes more apparent when comparing the chains in **10** with those observed in $[Zn\{SC(NHMe)(NH_2)\}_2(\mu\text{-}1,3\text{-phenylenediacetate})]_n$,[21] as in this latter compound, substitution of a hydrogen atom for a methyl group prevents the extended intrachain hydrogen bonding from occurring. Consequently, the Zn···Zn separation is much larger (11.6 Å).

In **10**, the helices are packed in a square-based array rather than in a hexagonal array as observed for **7**−**9**. Each helix interacts, through hydrogen bonds, with helices in the *a* and *ac* directions. In both of these directions there are two hydrogen bonds from parallel NH groups to a single uncoordinated carboxylate oxygen atom, generating $R_2^1(6)$ rings, in addition to one further hydrogen bond, also to an uncoordinated oxygen atom (Figure 6). The hydrogen bonds in both directions link the Zn(1)-based chains to the Zn(2)-based chains. The presence of $R_2^1(6)$ rings with one hydrogen-bond acceptor to the parallel NH groups, as opposed to $R_2^2(n)$ rings with two oxygen atoms acting as acceptors, relates to the distance between oxygen atoms within each dicarboxylate ligand. This O···O distance ranges from 3.18 to 3.45 Å for **7**−**9** but is much longer (5.23 Å) for **10** as a consequence of the greater length of the linker between the carboxylate groups.

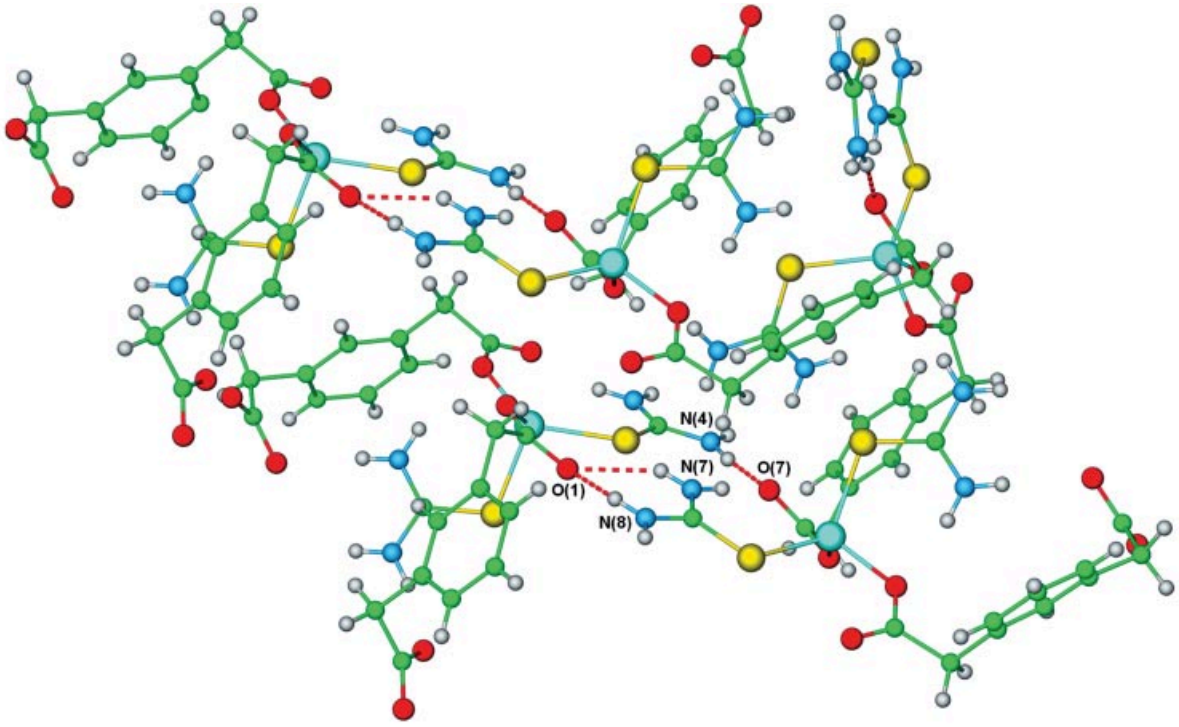

Figure 6. Interchain hydrogen bonding in $[Zn(tu)_2(\mu\text{-}1,3\text{-phenylenediacetate})]_n$ (**10**) along the crystallographic *a* axis; selected hydrogen-bond lengths (Å) and angles (°) N(4)···O(7) 2.935, H(4B)···O(7) 2.06, N(4)−H(4B)···O(7) 173; N(7)···O(1) 2.956, H(7A)···O(1) 2.19, N(7)−H(7A)···O(1) 145; and N(8)···O(1) 2.953, H(8A)···O(1) 2.19, N(8)−H(8A)···O(1) 145

The Structure of $\{[Zn(tu)_2(\mu\text{-mesaconate})]\cdot 2H_2O\}_n$ (11)

In contrast to compounds **7**−**10**, $[Zn(tu)_2(\mu\text{-mesaconate})]_n$ crystallises with two molecules of water per metal centre. Mesaconate has a *trans* arrangement of the carboxylate groups around the central double bond, and consequently the anion is flat. This means that the chains observed in $\{[Zn(tu)_2(\mu\text{-mesaconate})]\cdot 2H_2O\}_n$ (**11**) are not helices, but flat zig-zag chains with a Zn···Zn···Zn angle of 107° and Zn···Zn separations of 8.94 and 9.33 Å. Intrachain hydrogen bonding is observed, and both thiourea ligands are involved in S(6) rings. Only one of the acceptors is an oxygen atom, the other being a sulfur atom (Figure 7). The N−H···S hydrogen bond is, as expected, longer than the N−H···O hydrogen bond, and the Zn−S distance to the sulfur atom involved in the hydrogen bond is the shorter of the two Zn−S distances (Table 1).

Hydrogen bonds involving the two amino protons on a single amino group and an uncoordinated oxygen atom link the chains into a three-dimensional network through the formation of $R_4^2(8)$ rings. All other NH groups are involved in hydrogen bonds with the included water molecules with the exception of N(2)−H(2A), which is involved in a weak N−H···S interaction. The water oxygen atom O(5) acts as a linker between the chains along the crystallographic *b* direction, whereas the water oxygen atom O(6) fulfils the same role along the crystallographic *a* direction.

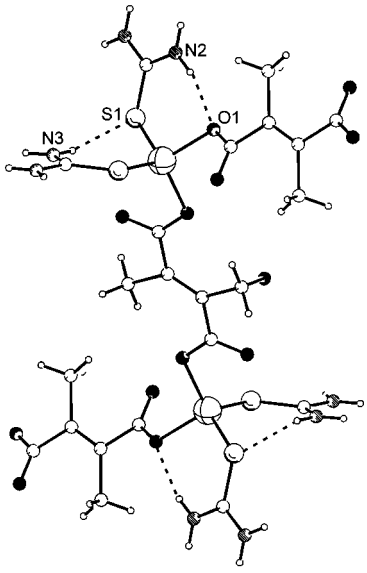

Figure 7. Intrachain hydrogen bonding in $\{[Zn(tu)_2(\mu\text{-mesaconate})]\cdot 2H_2O\}_n$ (**11**); selected hydrogen-bond lengths (Å) and angles (°) N(2)···O(1) 2.916, H(2B)···O(1) 2.06, N(2)−H(2B)···O(1) 163; N(3)···S(1) 3.409, H(3B)···S(1) 2.57, N(3)−H(3B)···S(1) 161; disordered methyl groups are shown in both available positions

Reactions of $[Zn(tu)_4](NO_3)_2$ with Dicarboxylates

The reaction of $[Zn(tu)_4](NO_3)_2$ with a dicarboxylate might be expected to give the same product as that from the reaction of $[Zn(tu)_4]Cl_2$ with the same dicarboxylate. After all, neither chloride nor nitrate is incorporated into the product. Attempts to prepare **1** with $[Zn(tu)_4](NO_3)_2$ suggested that things might not be this simple, and therefore the reactions between $[Zn(tu)_4](NO_3)_2$ and the series of dicarboxylates in Scheme 1 were explored. In the majority

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of cases, X-ray powder diffraction studies did indeed verify that the products derived from $[Zn(tu)_4]Cl_2$ and $[Zn(tu)_4](NO_3)_2$ were identical. However, there were two exceptions. The reaction of $[Zn(tu)_4](NO_3)_2$ with terephthalate had previously been reported to give $\{[Zn_2(tu)_2(\mu\text{-tu})(\mu\text{-terephthalate})_2]\cdot 4H_2O\}_n$.[22] In contrast, the analogous reaction with $[Zn(tu)_4]Cl_2$ gave $[Zn(OH_2)_2(\mu\text{-terephthalate})]_n$[23] as the only isolated product. The identity of this compound was confirmed by comparison of the powder X-ray diffraction pattern with that simulated from the single-crystal data. No evidence for thiourea-containing polymers was obtained for this reaction, which is surprising as coordination polymers containing the substituted thioureas $MeNHC(S)NH_2$ and MeNHC(S)NHMe have been prepared in good yield and structurally characterised.[21]

The reaction of $[Zn(tu)_4]Cl_2$ with sodium fumarate was previously reported to give $[Zn(tu)_2(\mu\text{-fumarate})]_n$ (**1**),[14] and this reaction was repeated to confirm **1** as the only product by X-ray powder diffraction. In contrast, the reaction of $[Zn(tu)_4](NO_3)_2$ with sodium fumarate was shown by powder diffraction to give two compounds, **1** and a previously unobserved material. Crystals of the new compound were manually separated from those of **1**, and a single-crystal analysis showed this material to be the hydrated compound $\{[Zn(tu)_2(\mu\text{-fumarate})]\cdot 2H_2O\}_n$ (**12**). Although the reaction with $[Zn(tu)_4]Cl_2$ does not give **12** under normal circumstances, **12** can be isolated as the major product from the reaction by seeding the solution of $[Zn(tu)_4]Cl_2$ and sodium fumarate with small crystals of **12**.

The Structure of $\{[Zn(tu)_2(\mu\text{-fumarate})]\cdot 2H_2O\}_n$ (12)

Like mesaconate, fumarate has a *trans* orientation around the central double bond, and as such the two carboxylate groups are co-planar. Consequently, the coordination polymers formed are flat zig-zag chains as in **11** rather than the helical chains observed for **7**−**10**. There are two intrachain hydrogen bonds around each zinc centre, both involving coordinated oxygen atoms and leading to the formation of S(6) rings (Figure 8). The chains are cross-linked into the three-dimensional structure by three N−H···O hydrogen bonds to carboxylate oxygen atoms and by other interactions involving the included water molecules. Two of the N−H···O hydrogen bonds are to the same acceptor − an uncoordinated oxygen atom − and lead to the generation of an $R_2^1(6)$ motif.

There are a number of key differences in the structures of **1** and **12** brought about by the inclusion of the solvent. The most obvious of these relates to the carboxylate coordination modes (Figure 9). In **1**, the fumarate coordinates in an *anti* coordination mode, which enables it to use the two parallel lone pairs to form DD−AA interactions. This coordination mode is unusual for a carboxylate group, and has not been observed in any other $[Zn(tu)_2(\mu\text{-dicarboxylate})]_n$ structure. In **12**, the carboxylate groups coordinate in the more common manner through *syn* lone pairs. This difference between **1** and **12** affects the distance be-

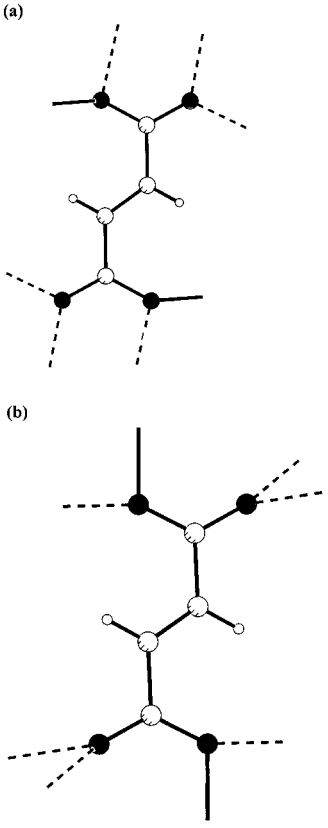

Figure 9. Coordination modes of and hydrogen bonding to the fumarate anions in (a) $[Zn(tu)_2(\mu\text{-fumarate})]_n$ (**1**) and (b) $\{[Zn(tu)_2(\mu\text{-fumarate})]\cdot H_2O\}_n$ (**12**)

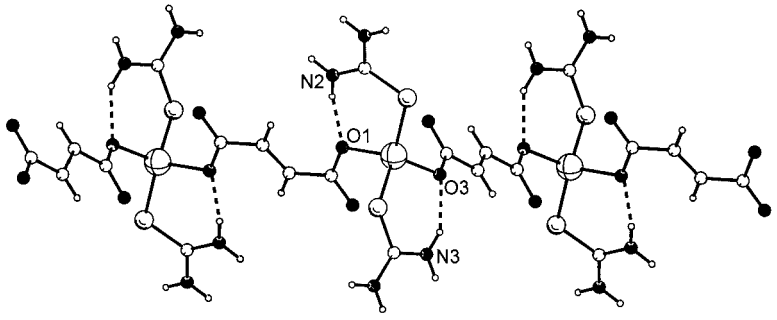

Figure 8. Intrachain hydrogen bonding in $\{[Zn(tu)_2(\mu\text{-fumarate})]\cdot 2H_2O\}_n$ (**12**); selected hydrogen-bond lengths (Å) and angles (°) N(2)···O(1) 2.821, H(2B)···O(1) 1.96, N(2)−H(2B)···O(1) 167; and N(3)···O(3) 2.906, H(3B)···O(3) 2.12, N(1)−H(3B)···O(3) 148

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tween Zn centres within the chain and leads to an increase in the Zn···Zn distance from 6.33 Å in **1** to 8.89 and 9.33 Å in **12**. The less favourable coordination mode in **1** is presumably driven by the accompanying DD−AA interactions allowed between the thiourea and carboxylate groups.

The intrachain hydrogen bonds in **1** and **12** also differ. In **1**, sulfur atoms act as acceptors, whereas this role is fulfilled by oxygen atoms in **12**. Both the differing coordination modes of the fumarate and the presence of the water molecules in **12** ensure that the supramolecular structures of **1** and **12** are completely different.

Thermogravimetric Analyses

The presence of the water molecules in compounds **3**, **6**, **11** and **12** begged the question of whether these included molecules could be removed without destruction of the metal-organic frameworks. Consequently, thermogravimetric analyses (TGAs) were carried out on the compounds. The TGA of {[Zn(tu)$_2$(μ-isophthalate)]·H$_2$O} (**3**) showed no mass loss up to 100 °C, followed by a mass loss of 4.5% between 100 °C and 140 °C. This mass loss corresponds to the loss of the water molecule (calcd. 4.51%). The anhydrous material was stable to further mass loss up until 200 °C, at which temperature decomposition started. The anhydrous material **3a** was generated in larger quantities by heating **3** at 150 °C for several hours. Compound **3a** no longer consisted of single crystals, and the X-ray powder diffraction pattern suggested a more fundamental change had occurred than the simple removal of water from the pores within the structure. Compound **3a** does not absorb atmospheric moisture, but can be reconverted into **3** by dissolution in water and reprecipitation. Attempts to prepare other solvates were unsuccessful.

The TGA of {[Zn(tu)$_2$(μ-maleate)]·H$_2$O} (**6**) showed no mass loss until 150 °C. A gradual loss of mass until 270 °C was then observed, followed by more rapid mass loss on destruction of the framework. Water comprises 5.1% of **6**, although a mass less than this had been lost up to 270 °C. The TGA of {[Zn(tu)$_2$(μ-mesaconate)]·2H$_2$O} (**11**) showed no mass loss until 120 °C and only a gradual loss of 2% until the start of decomposition of the framework at 250 °C. The TGA of {[Zn(tu)$_2$(μ-fumarate)]·2H$_2$O} (**12**) revealed a mass loss between 50 and 120 °C corresponding to the elimination of the included water molecules. The resulting anhydrous product was then stable up to 220 °C, after which it began to lose mass again. This second mass loss corresponds to the destruction of the metal-organic framework. The X-ray powder diffraction pattern of **12** changed markedly on solvent loss and is different from that of **1**.

These results imply a different structural role for the water molecules in **3** and **12** relative to that in **6** and **11**. The higher temperature at the onset of mass loss, combined with the absence of a clearly defined anhydrous compound for **6** and **11**, suggest that the water is an integral part of the supramolecular structure. This is consistent with the structural data that show the water as being part of the hydrogen-bonding networks in **6** and **11**. In contrast, water loss occurs at lower temperatures for **3** and **12**, and the anhydrous compounds are stable over a wide temperature range. This indicates that the water molecules play a less important structural role in these compounds. This is certainly true for **3**, in which the water molecules are disordered and lie within pores in the structure. In **12**, the water molecules lie within channels along the crystallographic 111 direction. The majority of the hydrogen bonding involves O−H···O and O−H···S interactions, which suggests that these water molecules are less well-bound than those in **11**, as confirmed by the TGA experiments.

TGA on the anhydrous compounds **1**, **4**−**5** and **7**−**10** showed no significant mass loss until the onset of decomposition of the framework between 180 °C and 230 °C. In contrast, [Zn(tu)$_2$(μ-malonate)]$_n$ **2** lost 9.5% of mass between 80 °C and 200 °C. This corresponds to a mass of 30, and it is difficult to rationalise such a mass loss at the current time.

Conclusions

The crystal structures for compounds **7**−**9** provide good evidence that the structures based on helical polymers interlinked by hydrogen bonding, previously observed for [Zn(tu)$_2$(μ-citraconate)]$_n$ and [Zn(tu)$_2$(μ-phthalate)]$_n$, represent recurrent motifs. This is a favourable product for cases in which the dicarboxylate can adopt an orientation with mutually perpendicular carboxylate planes, and O···O separations between 3 and 3.5 Å. The crystal structure for **12** is surprising as it demonstrates that the [Zn(tu)$_4$]X$_2$ anion, despite not being incorporated into the final product, plays a role in determining the nature of the product. The chloride compound exclusively gives [Zn(tu)$_2$(μ-fumarate)]$_n$ (**1**), whereas the nitrate analogue gives both **1** and {[Zn(tu)$_2$(μ-fumarate)]·H$_2$O}$_n$ (**12**). The chloride anion has a greater coordinating nature than the nitrate anion, and the previous observation of compounds such as [ZnCl$_2${SC(NHMe)(NMe$_2$)}$_2$] from the reaction of [Zn{SC(NHMe)(NMe$_2$)}$_4$]Cl$_2$ and a dicarboxylate,[24] suggests that the reactive species in solution from [Zn(tu)$_4$]Cl$_2$ may be [ZnCl$_2$(tu)$_2$] rather than [Zn(tu)$_4$]$^{2+}$. It is possible that this affects the solution concentration of intermediates such as [Zn(tu)$_2$(dicarboxylate)$_2$]$^{2-}$, which in turn may influence the crystallisation route adopted. However, no evidence for the intermediates was observed by NMR spectroscopy, and therefore such inferences should be regarded as speculative at this stage.

Experimental Section

General Remarks: Microanalyses (C, H and N) were carried out by Mr. Alan Carver (University of Bath Microanalytical Service). Infrared spectra were recorded with a Nicolet Nexus FT-IR spectrometer as KBr pellets, and thermogravimetric analyses were carried out with a Perkin−Elmer TGA 7 instrument. [Zn(tu)$_4$]Cl$_2$,[25] [Zn(tu)$_4$](NO$_3$)$_2$[26] and compounds **1**−**6**[14] were prepared as described in the literature. Sodium dicarboxylates were prepared by

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

reaction of the appropriate dicarboxylic acid with either sodium hydroxide or sodium hydrogen carbonate.

Synthesis of [Zn(tu)$_2$(μ-succinate)]$_n$ (7): An aqueous solution of sodium succinate (0.037 g, 0.23 mmol) was added to an aqueous solution of [Zn(tu)$_4$]Cl$_2$ (0.10 g, 0.23 mmol), with no discernible change. After several days a colourless crystalline precipitate was observed, which was separated by filtration. Yield 0.059 g (78%). $C_6H_{12}N_4O_4S_2Zn$ (333.7): calcd. C 21.6, H 3.62, N 16.8; found C 21.6, H 3.63, N 17.0. IR: $\tilde{\nu}$ = ν(NH) 3454 s; ν(CO$_2$)/δ(NH$_2$) 1658 s, 1584 s, 1504 s cm^{-1}.

Compounds **8**−**11** were prepared in an analogous manner to **1** with [Zn(tu)$_4$]Cl$_2$ (0.10 g, 0.23 mmol) and one equivalent of the appropriate sodium dicarboxylate.

[Zn(tu)$_2$(μ-itaconate)]$_n$ (8): Yield 0.053 g (68%). $C_7H_{12}N_4O_4S_2Zn$ (345.7): calcd. C 24.3, H 3.50, N 16.2; found C 24.2, H 3.48, N 16.1. IR: $\tilde{\nu}$ = ν(NH) 3447 s, 3368 s, 3321 s, 3208 s (br); ν(CO$_2$)/δ(NH$_2$) 1644 s, 1577 m, 1511 s, 1384 m cm^{-1}.

[Zn(tu)$_2$(μ-ethylmalonate)]$_n$ (9): Yield 0.057 g (72%). $C_7H_{14}N_4O_4S_2Zn$ (347.7): calcd. C 24.2, H 4.06, N 16.1; found C 24.1, H 3.99, N 16.0. IR: $\tilde{\nu}$ = ν(NH) 3408 s (br), 3327 s (br), 3195 s (br); ν(CO$_2$)/δ(NH) 1637 s, 1584 s (br), 1358 m cm^{-1}.

[Zn(tu)$_2$(μ-1,3-phenylenediacetate)]$_n$ (10): Yield 0.049 g (53%). $C_{12}H_{16}N_4O_4S_2Zn$ (409.8): calcd. C 35.2, H 3.94, N 13.7; found C 35.1, H 3.90, N 13.5. IR: $\tilde{\nu}$ = ν(NH) 3311 s (br), 3197 s (br); ν(CO$_2$)/δ(NH$_2$) 1659 s, 1640 s, 1563 s, 1511 s, 1370 s (br) cm^{-1}.

{[Zn(tu)$_2$(μ-mesaconate)]·2H$_2$O}$_n$ (11): Yield 0.059 g (76%). $C_7H_{12}N_4O_4S_2Zn$ (345.7): calcd. C 24.3, H 3.50, N 16.2; found C 21.6, H 3.63, N 17.0. IR: $\tilde{\nu}$ = ν(NH) 3394 s (br), 3142 s (br); ν(CO$_2$)/δ(NH$_2$) 1644 s, 1557 s, 1511 s, 1438 s, 1345 m cm^{-1}.

Synthesis of {[Zn(tu)$_2$(μ-fumarate)]·2H$_2$O}$_n$ (12): An aqueous solution of sodium fumarate (0.032 g, 0.20 mmol) was added an aqueous solution of [Zn(tu)$_4$](NO$_3$)$_2$ (0.100 g, 0.20 mmol), with no discernible change. After several hours a colourless crystalline precipitate was observed, which was separated by filtration. Yield 0.058 g (78%). $C_6H_{10}N_4O_4S_2Zn$ (331.7): calcd. C 19.6, H 3.81, N 15.2; found C 19.6, H 3.52, N 15.1. IR: $\tilde{\nu}$ = ν(NH)/OH 3421 s, 3374 s, 3301 s, 3182 s, 3135 s; ν(CO$_2$)/δ(NH$_2$) 1624 s, 1565 d, 1511 s, 1371 s (br) cm^{-1}.

Single crystals of compounds **7**−**12** suitable for X-ray analysis were obtained by repeating the reactions on a smaller scale in a more dilute solution, allowing the crystals to grow over several days. Compounds **2**−**11** were also prepared from [Zn(tu)$_4$](NO$_3$)$_2$, and their identities confirmed by X-ray powder diffraction studies.

Crystallography: Single crystals of the compounds **7**, **8**, **9** and **11** were analysed with an Enraf−Nonius CAD4 diffractometer, while data for **10** and **12** were collected with a Nonius KappaCCD diffractometer. Graphite-monochromated Mo-K_α radiation was employed throughout. Details of the data collections, solutions and refinements are given in Table 3. The structures were solved using SHELXS-97[27] and refined using SHELXL-97.[28] Absorption corrections (semi-empirical from equivalent reflections) were applied to data for **10** and **12**. (Max./min. transmission factors 0.82, 0.62 and 1.000, 0.890, respectively). Hydrogen atoms were universally included at calculated positions except in solvent water molecules, where they were located in the penultimate difference Fourier electron-density maps and restrained at 0.89 Å from the relevant parent oxygen. Convergence was routine throughout, with the exception of the observations below.

Positional disorder (65:35) was observed in the ethyl group of the ethylmalonate ligand in **9**. In the final least-squares refinement, the ADPs for the alpha carbon partial atoms [C(6), C(6A)] were restrained to be similar, while those for C(7) and C(7A) were constrained to be identical. The asymmetric unit in **10** was seen to be based on two independent zinc centres.

The asymmetric unit in **11** contained two solvent water molecules for each zinc centre. The metal is sulfur-bound to two thiourea units and oxygen-bound to two crystallographically independent anion halves. The proximity of the anion halves to inversion centres means that the single methyl group contained in each is disordered in a 1:1 ratio between the two available positions for its location. The water hydrogen atoms on O(6) could not be reliably located, and hence were omitted from the refinement. The asymmetric unit for **12** closely parallels that for **11** insofar as it contains two solvent water molecules for each zinc centre. The coordination sphere around the metal is similar, and also consists of two anion halves

Synthesis and Structural Characterisation of Ag^{I} Complexes with *N*,*N*′-Bis(2-pyridyl)oxalamide and the Anion of *N*-(2-Pyridyl)oxalamic Acid

Hui-Ling Hu,[a] Chun-Wei Yeh,[b] and Jhy-Der Chen*[b]

Keywords: Silver / Coordination polymer / *N*-(2-Pyridyl)oxalamic acid / *N*,*N*-Bis(2-pyridyl)oxalamide

A series of silver(I) complexes of the type $\{[Ag_2(\mathbf{L})_2(\mathbf{L}')][X]\}_\infty$ [**L** = *N*,*N*′-bis(2-pyridyl)oxalamide; **L**′ = anion of *N*-(2-pyridyl)-oxalamic acid; X = BF_4^- (**1**), ClO_4^- (**2**), PF_6^- (**3**) and NO_3^- (**4**)] have been prepared from the reaction of AgX with **L** in $EtOH/H_2O$. All the complexes have been structurally characterised by X-ray crystallography confirming that complexes **1**–**4** are 2D coordination polymers. The Ag^{I} centres show two types of coordination geometries, i.e. distorted trigonal-bipyramidal and distorted tetrahedral which are linked by the **L** and **L**′ ligands, forming unique 2D doubly pleated rectangular grids. The anions BF_4^-, ClO_4^- and PF_6^- in complexes **1**–**3** are not coordinated to the Ag^{I} centres whereas the NO_3^- anions in **4** are coordinated to the metal centres through one of the three oxygen atoms. The transformation of **L** to **L**′ is also discussed.

Introduction

Recently, a great deal of effort has been devoted to the self-assembly of organic and inorganic molecules in the solid state because it extends the range of new solids which can be designed to have particular physical and chemical properties.[1,2] The range and variety of self-assembling inorganic structures that can be constructed relies on the presence of suitable metal−ligand interactions and supramolecular contacts, i.e., hydrogen bonds and other weak interactions.[3] Many topologically promising Ag^{I}-containing architectures have been constructed with bidentate building blocks containing nitrogen donors.[4] The polymers include 1D, 2D and 3D network structures.[4b]

In our continuing work on the preparation of complexes with new structural types,[5] we have reported[5b] a series of 1D coordination polymers, $\{[Ag(\mathbf{L})][NO_3]\}_\infty$, $\{[Ag(\mathbf{L})(CH_3CN)][ClO_4]\}_\infty$, $\{[Ag_2(\mathbf{L})_3(CH_3CN)_2][PF_6]_2\}_\infty$ and $[Ag_3(\mathbf{L})_4(CH_3CN)_4][BF_4]_3$ which were prepared by the reaction between AgX (X = NO_3^-, ClO_4^-, PF_6^- and BF_4^-) and the bidentate ligand *N*,*N*′-bis(2-pyridyl)oxalamide (**L**) in CH_3CN.

These complexes are capable of self-assembling into 2D molecular structures through a series of interactions involving Ag−O weak covalent bonds and self-complementary double N−H···O hydrogen bonds.[5b] It was also found that changing the counterion had a drastic effect on the structures of the Ag^{I} coordination polymers. Interestingly, when the reactions were carried out in $EtOH/H_2O$, transformation of the **L** ligand to the anion of *N*-(2-pyridyl)oxalamic acid (**L**′) was observed and the Ag^{I} ions were interlinked by both of the **L** and **L**′ ligands forming unique 2D doubly pleated rectangular grids. The syntheses and structural characterisation of complexes of the type $\{[Ag_2(\mathbf{L})_2(\mathbf{L}')][X]\}_\infty$ [**L** = *N*,*N*′-bis(2-pyridyl)oxalamide]; **L**′ = anion of *N*-(2-pyridyl)oxalamic acid; X = BF_4^-, ClO_4^-, PF_6^- and NO_3^-) form the subject of this report.

Results and Discussions

Syntheses

Complexes of the type $\{[Ag_2(\mathbf{L})_2(\mathbf{L}')][X]\}_\infty$ [**L** = *N*,*N*′-bis(2-pyridyl)oxalamide; **L**′ = anion of *N*-(2-pyridyl)oxalamic acid; X = BF_4^- (**1**), ClO_4^- (**2**), PF_6^- (**3**) and NO_3^- (**4**)] have been prepared by the reaction of AgX with **L** in $EtOH/H_2O$. The IR spectra show broad bands in the range from 3160 to 3184 cm^{-1} for complexes **1**−**4**, assignable to the N−H stretching vibrations. Two strong absorption bands at 1702 and 1685 cm^{-1} were observed for each of the complexes **1**−**4** which can be assigned to the C=O stretching of **L**′ and **L**, respectively. For complexes **1**−**4**, the IR spectra also exhibit strong bands at 1593−1595 cm^{-1} due

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim **DOI: 10.1002/ejic.200400101**

to the $\nu_{as}(COO^-)$ mode in addition to the other strong bands at 1304−1305 cm^{-1} associated with the $\nu_s(COO^-)$ mode which are consistent with the coordination of the carboxylate groups in these complexes. The formation of the carboxylate groups indicates the transformation of **L** to **L′** which was verified by their X-ray crystallographic structures.

The yields of the products were fully dependent on the length of time of crystallisation. Attempts to shorten the time by stirring or heating the reactants to reflux always led to the formation of a mixture of several compounds which, due to their insolubilities in common solvents, could not be separated. Preparation of the four complexes using solutions of **L** and **L′** in nonaqueous media in a 1:1 ratio is one of our research projects currently under investigation. Instead of **L′**, we have attempted several reactions using ligands such as **L** and nicotinic acid (Hnic) in CH_3OH or ethanol solution, but only a mixture of Ag(nic) and Ag(**L**)(X) was obtained.

Differential scanning calorimetry (DSC) experiments of complexes **1**−**4** show endothermic peaks in the curves and the values of the melting temperatures (T_m) for complexes **1**−**4** are 216.21, 215.65, 214.88 and 215.78 °C, respectively. These results indicate that the stabilities of the network structures of complexes **1**−**4** are similar and are not dependent one the nature of the anions.

Structures of Complexes 1−4

The crystal structures of complexes **1**−**4** belong to the space group *Pnma*. A representative asymmetric unit and ORTEP diagrams showing the geometries of Ag(1) and Ag(2) in complexes **1**−**3** are depicted in Figure 1 (a, b, and c, respectively), while the asymmetric unit and ORTEP diagram showing the geometry about Ag(2) in complex **4** are shown in Figure 2 (a and b, respectively). The geometry about Ag(1) in complex **4** is shown in Figure 2 (b). Tables 1 and 2 list the bond lengths and angles around Ag(1) and Ag(2), respectively, for complexes **1**−**4**. Two types of coordination geometries are observed for the metal centres. The Ag(1) atom which is coordinated by two pyridyl nitrogen atoms of different **L** ligands, one pyridyl nitrogen atom of **L′** and one carboxylate oxygen atom and one carbonyl oxygen atom of the same **L′** is distorted trigonal-bipyramidal. The Ag(2) atom which is coordinated by two pyridyl nitrogen atoms of different **L** ligands and the two carboxylate oxygen atoms of the **L′** ligand is distorted tetrahedral. The structural difference between complexes **1**−**3** and **4** is that the anions in **1**−**3** link the metal centres through weak interactions while the NO_3^- anion in complex **4** coordinates to the metal centre through its oxygen atom [Ag(2)−O(6): 2.494(8) Å]. It can be seen form Tables 1 and 2 that the Ag−N distances to the Ag(1) atoms are all similar, while that to the Ag(2) atom in complex **4**, which is 2.432(4) Å, is significantly longer than those in the other three complexes. The Ag(1)−O distances to the carbonyl oxygen atoms of the **L′** ligand are all longer than those to the carboxylate oxygen atoms, while the Ag(2)−O distances in complexes **1**−**3** are all similar. The bond angles around the Ag(1) centres are normal for a distorted trigonal-bipyramidal geometry. Due to the chelation of the aceto group of the **L′** ligand, the O−Ag(2)−O angles for complexes **1**−**3** are 51.8(2), 51.6(3) and 52.05(19)°, respectively, while the other O−Ag−N and N−Ag−N angles are in the range from 103.0(2) to 127.0(2)°.

the two pyridyl nitrogen atoms, while the **L′** ligand chelates and bridges three Ag^I atoms in a tetradentate bonding mode through all the three oxygen atoms and the pyridyl nitrogen atom. A schematic drawing of the 2D structures of complexes **1**−**4** is shown in Figure 5, where the Ag^I ions occupy the intersections. Two types of rectangles with the same lengths and different widths can be found for complexes **1**−**4** and Table 3 lists the sizes for these rectangles. The dihedral angles between the adjacent rectangles are listed in Table 4. It can be seen from Tables 3 and 4 that the sizes and dihedral angles for complexes **1**−**4** are similar, although slight differences have been found for complex **4**, indicating that changing the anions hardly affects the structures of the cations. Such a type of grid is unique and is in marked contrast to the regular grids found previously.[6] This 2D structure is also in marked contrast to our reported Ag^I complexes containing *N*,*N′*-bis(2-pyridyl)oxalamide ligands, where only 1D coordination polymers were obtained.[5b]

In complexes **1**−**4**, the 2D grids are further linked by the anions through Ag···X interactions (X = F or O) and/or C−H···X hydrogen bonds to form 3D structures (Ag···F−B 2.981, 3.070 Å, C−H···F−B 2.492−2.559 Å for **1**; Ag···O−Cl 2.926, 2.919 Å, C−H···O−Cl 2.528−2.580 Å for **2**; Ag···F−P 3.065−3.611 Å, C−H···F−P 2.405−2.527 Å for **3**; C−H···O−N 2.434 Å for **4**). Figure 6 shows a representative packing diagram for **2**. It can be seen that the molecules pack into layers of 2D cations which are separated by layers of the anions.

Transformation of L to L′

As shown in the structures of complexes **1**−**4**, a transformation of **L** to **L′** was observed. There are three possible reasons for this transformation. (1) The formation of **L′** could be due to the contamination of the by-product, *N*-(2-pyridyl)oxalamic acid, which may have been formed during the preparation of **L**. This possibility can be ruled out since all the spectroscopic data of **L** show that the ligand is pure

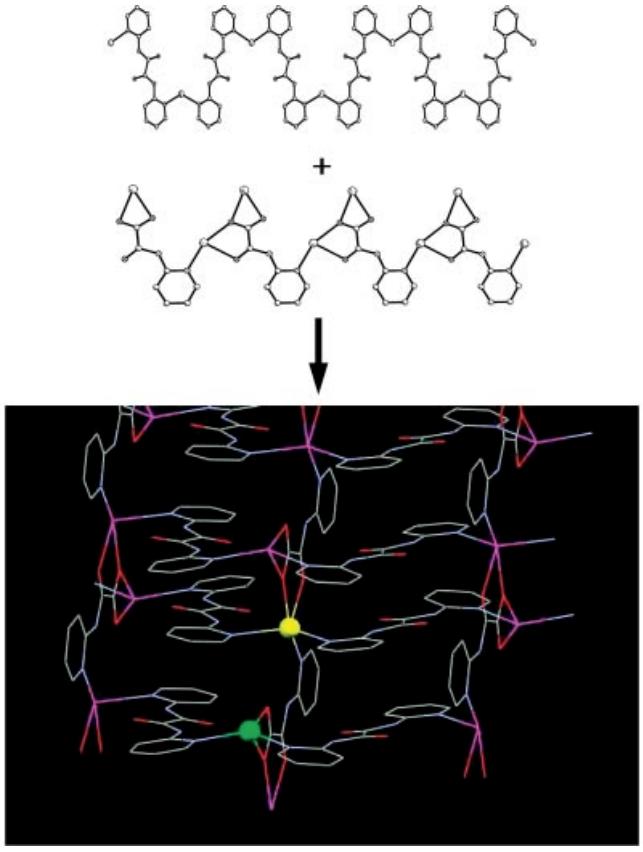

Figure 3. ORTEP drawings showing the concavo-convex chain involving **L** ligands (top), zigzag chain involving **L**′ ligands (center) and the 2D structure looking down the *a* axis (bottom)

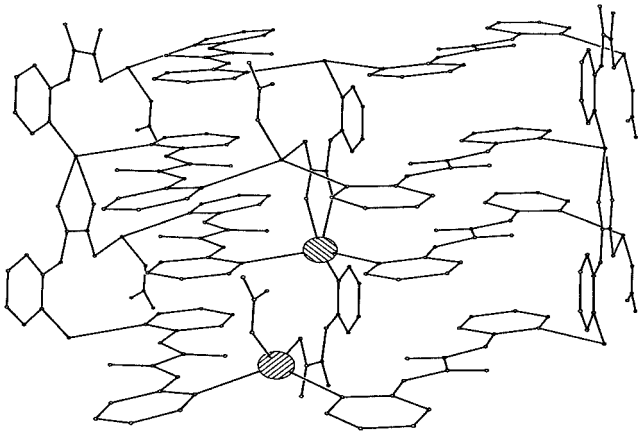

Figure 4. 2D structure of **4**

with no contamination of *N*-(2-pyridyl)oxalamic acid. (2) The **L** ligand decomposes to form *N*-(2-pyridyl)oxalamic acid during the crystallisation of complexes **1**−**4** in EtOH/H_2O. A blank test without addition of the metal salts had been carried out and no indication of *N*-(2-pyridyl)oxalamic acid was observed even under continuous stirring for more than two months. (3) The transformation is thus due to catalysis by Ag^+ in EtOH/H_2O. This shows that the metal centre plays an important role in converting **L** to **L**′.

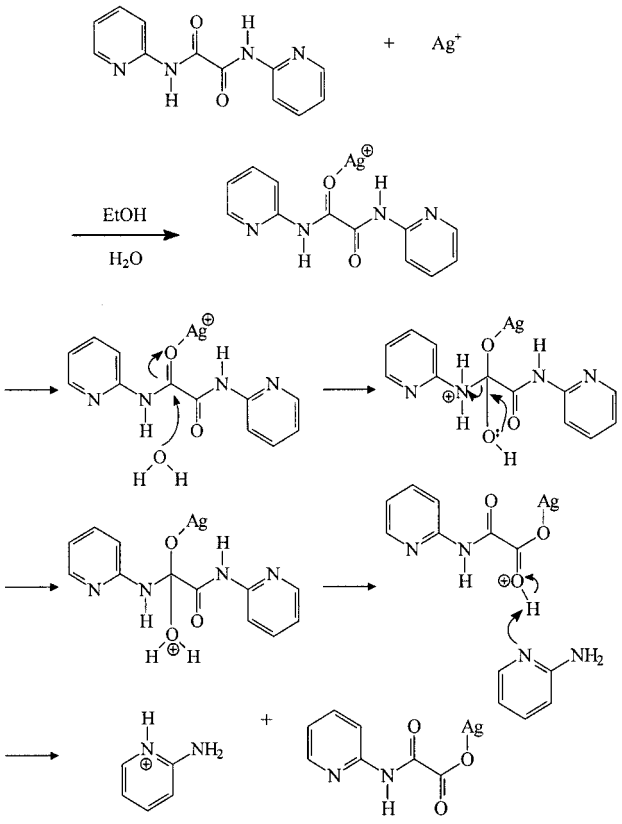
Stronger Lewis acids such as $AlCl_3$ have been used to investigate the conversion, but no positive results could be obtained. A mechanism describing the transformation pathways of **L** to **L′** is proposed in Scheme 1. The Ag^+ first coordinates to the carbonyl oxygen atom of **L′** followed by nucleophilic attack of a water molecule on the carbonyl carbon atom. A 2-aminopyridinium cation is lost to give Ag**L′** which then reacts with another **L** to afford complexes **1**−**4**.



Scheme 1. Mechanism showing the transformation of **L** to **L′**

Concluding Remarks

In this study, the coordination chemistry of AgX (X = BF_4^-, ClO_4^-, PF_6^- and NO_3^-) with *N*,*N*′-bis(2-pyridyl)oxalamide (**L**) and the anion of *N*-(2-pyridyl)oxalamic acid (**L′**) was investigated. Unique 2D doubly-pleated-grid structures were seen in these complexes. During the crystallisation of the complexes, some of the **L** ligands were transformed to **L′** in the presence of Ag^I ions and water molecules. It has also been shown that the 2D pleated grids adopted by complexes **1**−**4** were hardly altered upon changing their counterions.

Experimental Section

General Procedures: All manipulations were carried out under air. The visible absorption spectra were recorded with a Hitachi U-2000 spectrophotometer. IR spectra were obtained with a Jasco FT/IR-460 plus spectrometer. Elemental analyses were obtained with a PE 2400 series II CHNS/O analyser or a HERAEUS VaruoEL analyser.

Materials: The reagents AgX (X = BF_4^-, ClO_4^-, PF_6^- and NO_3^-) were purchased from Aldrich Chemical Co. The ligand *N*,*N*′-bis(2-pyridyl)oxalamide was prepared according to a literature procedure.[7]

Syntheses: The complexes were synthesised by treatment of AgX (X = BF_4^-, ClO_4^-, PF_6^- and NO_3^-) with *N*,*N*′-bis(2-pyridyl)oxalamide in EtOH/H_2O.

1: *N*,*N*′-Bis(2-pyridyl)oxalamide (0.048 g, 0.20 mmol) in EtOH (5 mL) was layered onto a solution of $AgBF_4$ (0.020 g, 0.10 mmol) in H_2O (5 mL). The resultant solution was allowed to slowly diffuse for several weeks to give colourless crystals. Yield: 0.013 g, (27.0%). $C_{31}H_{27}Ag_2BF_4N_{10}O_8$ (**1**·H_2O; 970.16): calcd. C 38.38, H 2.81, N 14.44; found C 38.19, H 2.46, N 14.28. IR (KBr disk, cm^{-1}): $\tilde{\nu}$ = 3446 (w), 3172 [br., ν_s(N−H)], 1702 [s, ν_s(C=O)], 1685 [s, ν_s(C=O)], 1593 [br., $\nu_{as}(COO^-)$ + ν(C=N)], 1576 (s), 1499 (s), 1434 (s), 1305 [s, $\nu_s(COO^-)$], 1084 (w), 777 (m), 626 (w), 551 (w), 484 (w).

2: Prepared as described for **1**. Yield 0.015 g (28%). $C_{31}H_{27}Ag_2ClN_{10}O_{12}$ (**2**·H_2O; 982.80): calcd. C 37.89, H 2.77, N 14.25; found C 37.90, H 2.65, N 14.33. IR (KBr disk, cm^{-1}): $\tilde{\nu}$ = 3410 (w), 3180 [br., ν_s(N−H)], 1702 [s, ν_s(C=O)], 1685 [s, ν_s(C=O)], 1593 [br., $\nu_{as}(COO^-)$ + ν(C=N)], 1575 (s), 1498 (s), 1434 (s), 1305 [s, $\nu_s(COO^-)$], 1145 (s, ClO_4^-), 777 (m), 627 (w), 551 (w), 484 (w).

3: Prepared as described for **1**. Yield: 0.016 g (31%). $C_{31}H_{27}Ag_2F_6N_{10}O_8P$ (**3**·H_2O; 1028.32): calcd. C 36.21, H 2.65, N 13.62; found C 35.92, H 2.49, N 13.43. IR (KBr disk, cm^{-1}): $\tilde{\nu}$ = 3412 (w), 3160 (br., ν_s(N−H)], 1702 [s, ν_s(C=O)], 1685 [s, ν_s(C=O)], 1595 (br., $\nu_{as}(COO^-)$ + ν(C=N)], 1576 (s), 1498 (s), 1433 (s), 1304 [s, $\nu_s(COO^-)$], 837 (w), 770 (m), 626 (w), 551 (w), 483 (w).

4: Prepared as described for **1**. Yield: 0.013 g (28%). $C_{31}H_{27}Ag_2N_{11}O_{10}$ (**4**·H_2O; 929.36): calcd. C 40.06, H 2.93, N 16.58; found C 39.26, H 2.60, N 16.51. IR (KBr disk, cm^{-1}): $\tilde{\nu}$ = 3422 (w), 3184 [br., ν_s(N−H)], 1702 [s, ν_s(C=O)], 1685 [s, ν_s(C=O)], 1595 [br., $\nu_{as}(COO^-)$ + ν(C=N)], 1575 (s), 1498 (s), 1433 (s), 1384 (s, NO_3^-), 1304 [s, $\nu_s(COO^-)$], 770 (m), 626 (w), 551 (w), 483 (w).

X-ray Crystallography: The diffraction data of **1** were collected with a Bruker AXS diffractometer using graphite-monochromated Mo-K_α (K_α = 0.71073 Å) radiation. Data reduction was carried out using standard methods with the use of well-established computational procedures.[8] The structure factors were obtained after Lorentz and polarisation corrections. The positions of the heavy atoms, including the silver atoms, were located by direct methods. The remaining K_α (K_α = 0.71073 Å) radiation. Data reduction was carried out using and least-squares refinements.[9] The final residuals were R_1 = 0.0514, $wR2$ = 0.1309. The crystallographic procedures for **2**−**4** were similar to those for **1**. Basic information pertaining to crystal parameters and the structure refinements is summarized in Table 5. CCDC-230419 to -230422 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

[Bis(amido)cyclodiphosph(III)azane]dichlorozirconium Complexes for Ethene Polymerization

Kirill V. Axenov,[a] Martti Klinga,[a] Markku Leskelä,[a] Vasily Kotov,[b] and Timo Repo*[a]

Keywords: Zirconium / Polymerization / Homogeneous catalysis

A series of new zirconium dichloride complexes bearing bulky *cis*-bis(amino)cyclodiphosph(III)azane ligands, $[(RN)_2(t\text{BuNP})_2]ZrCl_2$ [R = phenyl (**7**), diphenylmethyl (**8**), 2,6-diethylphenyl (**9**), 2,5-di-*tert*-butylphenyl (**10**), and 2,6-diisopropylphenyl (**11**)] were prepared in high yields by a two-step synthetic route. The structure of *cis*-$[(Ph_2CHN)(t\text{BuNP})]_2Zr(NMe_2)_2$ (**8a**), determined by X-ray analysis, shows that the zirconium atom has a distorted trigonal-bipyramidal configuration consisting of four equidistant metal–amido nitrogen bonds and an additional coordination between the metal and a nitrogen atom from the cyclodiphosph(III)azane ring. After methylaluminoxane activation, these complexes exhibit moderate to high activities in ethene polymerization and produce high molar mass polyethene (M_w up to 1100 kg/mol). Polymerization experiments reveal that the behavior of bis(amido)cyclodiphosph(III)azane-based Zr^{IV} catalysts depends on the nature and steric bulkiness of the amido substituents, reaction temperature, MAO/zirconium ratio, as well as monomer pressure.

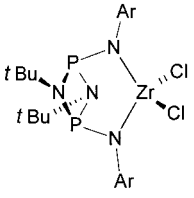
Introduction

Group 4 metal complexes bearing bi- or tridentate[1−7] diamido ligands have attracted considerable attention as a new generation of early transition metal based polymerization catalysts.[8,9] After methylaluminoxane (MAO) activation, highly electrophilic 10-electron cationic species, $[(R_2N)_2ZrR]^+$, which serve as active catalytic sites, form.[8] This type of nonmetallocene complex has the advantage that the electronic character, geometry and steric hindrance of the catalytic center can be easily controlled through rational ligand design. To date, an impressive number of transition metal complexes have been synthesized[8,9] and applied for α-olefin polymerization,[10−13] in particular ethene polymerization.[14−17]

Recently, novel bis(amido) complexes of Group 4 metals based on the cyclodiphosph(III)azane framework were reported.[18−21] Due to the fact that these complexes possess a tetrahedral coordination of the metal center and the chloride ions are in a *cis* position, they can be considered as potential catalyst precursors for olefin polymerization. As an augmentation to our previous studies on nonmetallocene polymerization catalysts,[22−25] we have developed a straightforward synthesis towards new [bis(amido)cyclodiphosph(III)azane]Ti^{IV} complexes bearing sterically hindered aryl substituents and investigated them as ethene polymerization catalysts.[26] After MAO activation, these Ti complexes were able to polymerize ethene with moderate activity and produce polymers with high molar mass and narrow molar mass distribution (MMD). Here we describe an efficient synthetic route to the new [bis(amido)cyclodiphosph(III)azane]Zr complexes and report on the results of an investigation of their catalytic behavior in ethene polymerization as well as on the properties of the produced polymers.



Results and Discussion

Synthesis of Ligand Precursors

A series of cyclodiphosph(III)azanes, **1**−**5**, were prepared in high yields by reaction of the appropriate anilines with dichlorocyclodiphosph(III)azane **a** in the presence of excess Et_3N, as was reported earlier (Scheme 1).[26] The X-ray

analysis (solid state) and NMR spectroscopic data have shown that these compounds favor a *cis* conformation – the most desirable arrangement for coordination chemistry applications. The solid-state structure of *cis*-[(Ph_2CHNH)-(*t*BuNP)]$_2$ (**2**, Figure 1, Tables 1 and 2) also supports the previously observed *cis* orientation of the bulky amino substituents. However, this structure differs sharply from previously reported structures for *cis*-bis(amino)cyclodiphosph(III)azanes; according to X-ray crystallographic analysis, the NH groups in all other known cyclodiphosph(III)azanes[27,28] adopt the *endo* orientation relative to the P–N ring, while in **2** these substituents have the *exo*,*endo* orientation (Figure 1). Such an unusual structural feature has been reported earlier for *cis*-[(*t*BuNH)-(*t*BuNPS)]$_2$ with P^V only.[29] Furthermore, the distortion of the P–N ring is diminished as indicated by the P–N bond lengths and the planarity of the ring. It can be assumed that the reduced ring distortion is mainly a consequence of the unique *exo*,*endo* orientation.

Synthesis of Complexes

The most common synthetic route to the transition metal complexes that have an anionic ligand is a transmetalation reaction. According to this general strategy, *cis*-[(PhNH)(*t*BuNP)]$_2$ (**1**) and *cis*-[(2,6-di-*i*PrC_6H_3NH)$_2$(*t*-BuNP)$_2$] (**5**) ligands were first deprotonated with BuLi, and the obtained Li salts were then treated with $ZrCl_4$ in toluene at –78 °C. The resulting reaction mixtures were analyzed by ^{31}P NMR spectroscopy. When ligand **1** was used, only one product (δ_P = 145 ppm, see Supporting Information) was observed. The same transformation with ligand **5** leads to a complex mixture of unidentified products. According to data published previously, the signal at δ = 145 ppm is assigned to the Zr^{IV} complex that has two cyclodiphosph(III)azane ligands attached to the metal center.[20] In

fact, the salt metathesis route was unselective in the preparation of corresponding titanium(IV) bis(amido)complexes also, and alternative synthetic routes were therefore looked for.[26] As in the case of Ti^{IV}, the direct metalation of the ligand precursors by amine elimination[17] appeared to be the most efficient method. According to ^1H and ^{31}P NMR spectroscopic data, the reaction of $Zr(NMe_2)_4$ with **1**−**5** leads selectively to the bis(amido)complexes [(RN)-(*t*BuNP)]$_2$Zr(NMe$_2$)$_2$ (**7a**−**11a**) (Scheme 1).

However, it is well known that bis(amido) early transition metal complexes are less active catalyst precursors in polymerization of α-olefins than the corresponding dichloro derivatives. Treatment of bis(amido)[*cis*-bis(amido)cyclodiphosph(III)azane]zirconium complexes **7a**−**11a** with excess chlorotrimethylsilane in toluene selectively gave the desired dichlorozirconium derivatives **7**−**11** in high yields (Scheme 1). These complexes have been characterized by NMR spectroscopy, elemental analysis, and mass spectroscopic methods. According to the ^1H NMR spectra, the *cis*-[(RN)$_2$(*t*BuNP)$_2$]ZrCl$_2$ complexes show C_2 symmetry in solution and reveal the equivalence of all aromatic substituents.

X-ray structures of [*cis*-bis(amido)cyclodiphosph(III)azane]zirconium complexes are rather rare, and only one structure involving [bis(amido)cyclodiphosph(III)azane]-ZrX$_2$-type complexes, namely *cis*-[(*t*BuN)$_2$(*t*BuNP)$_2$]ZrX$_2$ (X = Cl, **6**),[18,20] has been reported. The crystals of *cis*-[(Ph$_2$CHN)$_2$(*t*BuNP)$_2$]Zr(NMe$_2$)$_2$ (**8a**) suitable for X-ray analysis were successfully grown from a saturated Et$_2$O solution at −20 °C. In the structure of **8a** the four amido N−Zr bonds and an additional coordination of the cyclodiphosph(III)azane ring nitrogen to the zirconium atom define a rather distorted trigonal-bipyramidal configuration of the metal center. The amido nitrogen atoms are located in the corners of a zirconium-centered tetrahedron (Figure 2). In general, all amido−zirconium bonds are equidistant (average 2.110 Å), while the Zr−N coordination bond is significantly longer (2.448 Å) (Tables 1 and 2). The N−M−N angles range from 100° to 123.19°. The geometry of the ligand moiety **2** is changed due to the coordination to the zirconium atom, and the P−N(amido) bonds adopt an *endo*,*endo* orientation relative to the cyclodiphosph(III)-azane ring. Overall, the Zr−N coordination is similar to those reported for *cis*-[(*t*BuN)$_2$(*t*BuNP)$_2$]ZrCl$_2$ and *cis*-[(PhN)$_2$(*t*BuNP)$_2$]$_2$Zr.[20]

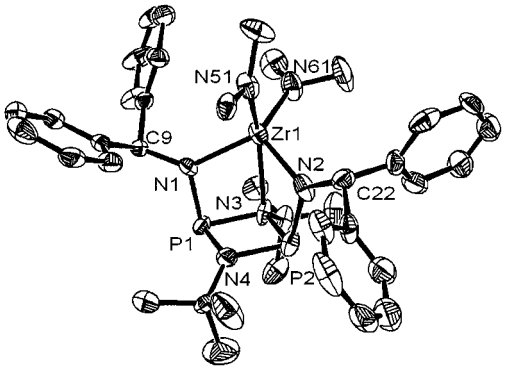

Figure 2. ORTEP plot of **8a** with thermal ellipsoids drawn at 50% probability level; all hydrogen atoms are omitted for clarity

Ethene Polymerization

Despite a certain interest in *cis*-bis(amido)cyclodiphosph(III)azane-based zirconium complexes, few preliminary reports concerning their polymerization properties have been published.[18−20] In order to evaluate the influence of the structure of the catalyst precursors on polymerization properties, we carried out a detailed ethene polymerization investigation. In general, MAO-activated zirconium complexes **6**−**11** reveal moderate to high catalytic activity and, according to obtained data, the size of the substituents at the amido nitrogen atoms has a significant effect on the catalytic behavior (Table 3).

Under the chosen polymerization conditions (50 °C and 3.8 bars), **6**/MAO bearing *tert*-butyl groups shows the highest average activity in the series of catalysts (Entry 1, Table 3). When ethene polymerization is conducted under the same conditions, there are two distinct differences in the behavior of catalyst **6**/MAO from that of its Ti^{IV} analog; the catalytic activity is significantly higher for **6**/MAO as it remains high during the whole polymerization reaction, while *cis*-[(*t*BuN)$_2$(*t*BuNP)$_2$]TiCl$_2$/MAO gives a remarkably high initial activity that decreases drastically after a few minutes. In addition, **6**/MAO produces polyethene with narrow polydispersity, whereas the corresponding Ti^{IV} catalyst is prone to produce polyethylene with bimodal MMD.[26] These facts indicate the higher stability of the [bis(amido)cyclodiphosph(III)azane]Zr catalytic species.

Replacement of the *tert*-butyl groups with diphenylmethyl (**8**) leads to dramatic changes in the catalyst

[a] MAO (Al/M = 1000), 200 mL of toluene, 3.8 bar of ethylene. [b] kg PE/(mol_{cat} × [C_2H_4] × h).

behavior. The activity decreases substantially and the produced polyethene has a high M_w (1040 kg/mol) and bimodal MMD (see Supporting Information). The series of catalysts **7**/MAO, **9**/MAO, **10**/MAO, and **11**/MAO bearing phenyl, 2,6-diethylphenyl, 2,5-di-*tert*-butylphenyl, and 2,6-diisopropylphenyl groups, respectively, reveal a clear enhancement of activity with increased steric bulk on the arylamido substituents. The activity as well as the properties of the polymer material are strongly connected to the ligand design. The molar mass of polyethene varies between 230 and 1130 kg/mol and polymers with diverse MMDs and different modalities are obtained.

Reaction temperature as well as monomer concentration are the key factors, which define the activity of catalysts and also the properties of the polymers produced. Ethene was polymerized at 30, 50, 60, and 70 °C to evaluate the influence of polymerization temperature on the catalytic activity and polymer properties (Figure 3). The steric bulkiness of the amido substituents is crucial for the catalyst behavior, in particular, the polymerization activity, as well as the stability of these Zr catalysts. The *tert*-butyl substituents in **6**/MAO seem to create a highly propitious environment for the catalytically active center, and already at 30 °C a very high activity is observed. However, the activity decreases to one third when the temperature increases from 30 to 70 °C, whereas the molar mass of polyethene and the MMD are slightly enhanced (Figure 4). Polymerization activities of the other catalysts are much lower but not as sensitive to the temperature changes and show their highest values at temperatures between 50 and 60 °C. At higher temperatures deactivation of the catalytically active species occurs. Quite unexpectedly, the produced polyethene possesses maximum molar mass values at 50 °C. The decrease in M_w at higher temperatures is often explained by a change in relative rates of chain propagation and β-H elimination.[30] This seems to be a plausible explanation here as well. The lower M_w values at 30 °C remain unexplained but could be caused by another competing chain termination route, e.g. chain transfer to aluminum.

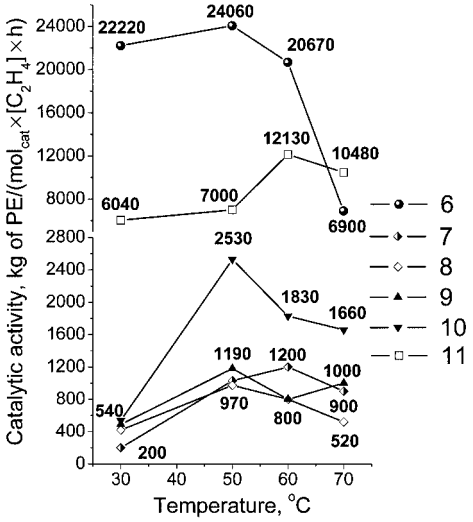

Figure 3. Catalytic activity as a function of polymerization temperature for [(*t*BuN)(*t*BuNP)]$_2$ZrCl$_2$ (**6**), [(PhN)(*t*BuNP)]$_2$ZrCl$_2$ (**7**), [(Ph_2CHN)(*t*BuNP)]$_2$ZrCl$_2$ (**8**), [(2,6-$Et_2C_6H_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**9**), [(2,5-$tBu_2C_6H_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**10**), and [(2,6-$iPr_2C_6H_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**11**) as catalyst precursors; the numeric values of the observed average activities are also given for the corresponding graph points; activity is expressed as kg of PE × (mol_{cat} × [C_2H_4] × h)$^{-1}$; experimental conditions used: MAO (Al/M = 1000), 3.8 bar of ethylene

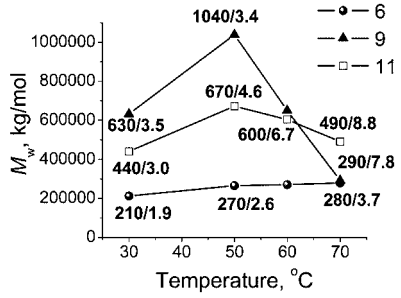

Figure 4. Molar mass of polyethene as a function of polymerization temperature with selected catalyst precursors [(*t*BuN)(*t*BuNP)]$_2$ZrCl$_2$ (**6**), [(2,6-$Et_2C_6H_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**9**), and [(2,6-$iPr_2C_6H_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**11**); the numeric values of M_w (in kg/mol) as well as polydispersities are given

All cyclodiphosph(III)azane catalysts were tested with ethene concentrations ranging from 0.15 to 0.8 mol/L (2−8 bar at 50 °C). The highest average productivity (calculated from the yield of polymer) is 22 800 kg of PE/mol_{cat} × h for **6**/MAO at 8 bar. The maximum catalytic activity for **6**−**10**/MAO is reached at low ethene concentrations (Fig-

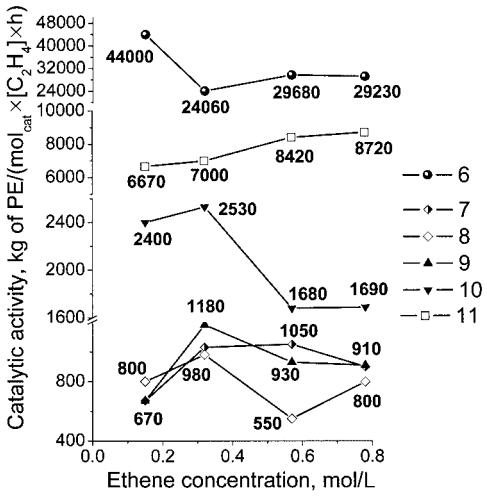

Figure 5. Catalytic activity of complexes as a function of ethene concentration for [(*t*BuN)(*t*BuNP)]$_2$ZrCl$_2$ (**6**), [(PhN)(*t*BuNP)]$_2$ZrCl$_2$ (**7**), [(Ph$_2$CHN)(*t*BuNP)]$_2$ZrCl$_2$ (**8**), [(2,6-Et$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**9**), [(2,5-*t*Bu$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**10**), and [(2,6-*i*Pr$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**11**) as catalyst precursors; the numeric values of the observed average activities are also given for the corresponding graph points; activity is expressed as kg of PE × (mol$_{cat}$ × [C$_2$H$_4$] × h)$^{-1}$; experimental conditions used: MAO (Al/M = 1000), polymerization temperature 50 °C

ure 5). It has been suggested that at higher monomer concentrations, due to enhanced polymer formation, the active complex becomes quickly embedded in the swollen-gel-like polymer matrix, which leads to the diffusion-controlled reaction conditions.[31]

Despite the increased monomer pressure enhancing the productivity of catalysts (yield of polymer), the molar mass of polymers produced by **6**/MAO and **11**/MAO are slightly reduced (Figure 6). This fact indicates the presence of β-H transfer to the monomer as a major chain-termination mechanism. However, in the case of **10**/MAO, where aniline is unsymmetrically substituted with *tert*-butyl substituents, the dominating chain termination reaction changes from β-H transfer to the monomer to β-H transfer to the metal center as the molar mass of polyethene appreciably increases from 310 kg/mol at 3.8 bar of ethene to 1480 kg/mol at 8 bar.[32]

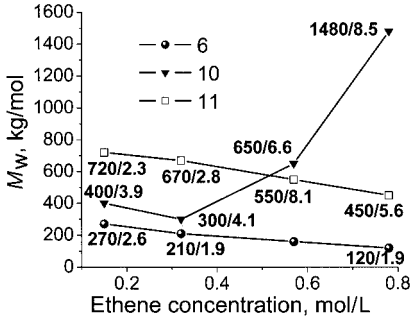

Figure 6. Molar mass of polyethene as a function of ethene concentration with selected catalyst precursors [(*t*BuN)(*t*BuNP)]$_2$ZrCl$_2$ (**6**), [(2,5-*t*Bu$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**10**), and [(2,6-*i*Pr$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**11**); the numeric values of M_w (in kg/mol) as well as polydispersities are given

Depending on the ligand structure, the catalysts have different responses to variations in MAO concentration e.g. the polymerization activity of **6**/MAO significantly decreases when the Al/Zr ratio increases (Figure 7). Even though **6**/MAO possesses a high polymerization activity, it is vulnerable to higher temperatures and MAO concentrations. Hence, we assume that the *tert*-butyl groups of **6**/MAO are not bulky enough to protect the catalytic center from deactivation. It has been proposed that the coordination of Lewis acidic MAO to the electron-pair-donating P^{III} atoms in the cyclodiphosph(III)azane ring can initiate the destruction of the catalyst during the polymerization process.[19]

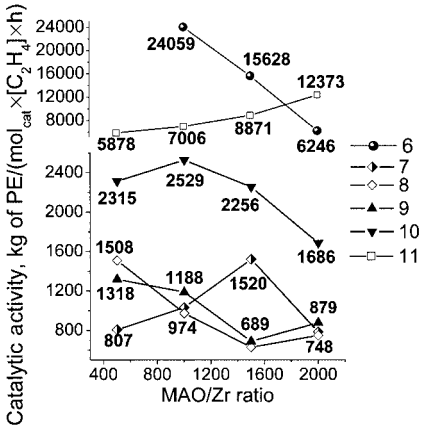

Figure 7. Catalytic activity of complexes as a function of MAO/Zr ratio for [(*t*BuN)(*t*BuNP)]$_2$ZrCl$_2$ (**6**), [(PhN)(*t*BuNP)]$_2$ZrCl$_2$ (**7**), [(Ph$_2$CHN)(*t*BuNP)]$_2$ZrCl$_2$ (**8**), [(2,6-Et$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**9**), [(2,5-*t*Bu$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**10**), and [(2,6-*i*Pr$_2$C$_6$H$_3$N)(*t*BuNP)]$_2$ZrCl$_2$ (**11**) as catalyst precursors; the numeric values of the observed average activities are also given for the corresponding graph points; activity is expressed as kg of PE × (mol$_{cat}$ × [C$_2$H$_4$] × h)$^{-1}$; experimental conditions used: 3.8 bar of ethylene, polymerization temperature 50 °C

According to the polymerization results, diphenylmethyl substituents are not able to provide a suitable surrounding for the highly active metal center and, in addition, **8**/MAO is sensitive to increased MAO concentrations. Increasing the size of substituents at the aniline moiety improves the shielding at the cationic metal center, and the activity of **10**/MAO, with 2,5-di-*tert*-butylphenyl groups, is enhanced up to an MAO/Zr ratio of 1000. In fact, the sterically most demanding 2,6-diisopropylphenyl groups in **11**/MAO efficiently protect the catalytically active site, and it is the only catalyst that gradually enhances the polymerization activity with increasing MAO/Zr ratio. While the bulky ligand protects the catalytic species from destructive side reactions, it also congests the actual polymerization site and the observed activity for **11**/MAO is thus lower than for **6**/MAO.

Published solid-state structures (Figure 2[18−20,26]) of [bis(amido)cyclodiphosph(III)azane]Zr and -Ti complexes show that the environment of the P atoms remains rather open regardless of the changes in the bulkiness of the amino substituents. It appears in this study that the observed correlation between the stability of the catalytically active species

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and the size of amido substituents could be better explained if destructive MAO interaction with metal−ligand bonding was the major decomposition pathway for the catalysts.

Conclusion

New [bis(amido)cyclodiphosph(III)azane]zirconium complexes $[(RN)(t\text{BuNP})]_2ZrCl_2$ (**7**−**11**) [R = Ph (**7**), Ph_2CH (**8**), 2,6-$Et_2C_6H_3$ (**9**), 2,5-$t\text{Bu}_2C_6H_3$ (**10**), 2,6-$i\text{Pr}_2C_6H_3$ (**11**)] were synthesized by reaction of the corresponding ligand precursors with $Zr(NMe_2)_4$. The amido complexes were successfully transformed into the dichloro derivatives $[(RN)(t\text{BuNP})]_2ZrCl_2$ (**7**−**11**) with excess Me_3SiCl. MAO-activated **7**−**11** display moderate to high activities in ethene polymerization. The catalyst behavior is dependent on the bulk of the ligand substituents. The nature and size of the amido substituents play a great role in defining the catalytic activity of the investigated Zr complexes as well as the polymer properties. From the series of catalysts studied here, only **11**/MAO revealed increased activity in the range 500−2000 for the MAO/Zr ratio as well as in the polymerization temperature range 30−60°C.

Experimental Section

General Remarks: All manipulations were performed under argon in a glovebox or using standard Schlenk techniques. Hydrocarbon and ether solvents were refluxed in the presence of sodium and benzophenone, distilled, and stored under an inert gas in the presence of sodium flakes. Dichloromethane was refluxed in the presence of CaH_2 powder and distilled before use. Mass spectra were measured with a JEOL SX102 spectrometer and the ^1H and ^{13}C NMR spectra were recorded with a Varian Gemini 200 MHz spectrometer. The ^1H and ^{13}C NMR spectra are referenced relative to $CHCl_3$ (δ = 7.24 ppm and 77.0 ppm, respectively) and C_6D_5H (δ = 7.15 ppm and 128.0 ppm, respectively). ^{31}P NMR spectra were collected with a Bruker AMX 400 spectrometer and phosphorus signals were referenced relative to an external 85% H_3PO_4 solution. Elemental analyses were performed by Analytische Laboratorien Prof. Dr. H. Malissa, G. Reuter GmbH, Lindlar, Germany. High-temperature gel permeation chromatography of polyethylene samples (GPC) was performed in 1,2,4-trichlorobenzene at 145 °C using a Waters HPLC 150C. *tert*-Butylamine and phosphorus trichloride were purchased from Merck and purified by distillation under argon ($t\text{BuNH}_2$ from sodium hydroxide). Arylamines and diphenylmethylamine were received from Aldrich and distilled in vacuo from sodium hydroxide before use. Chlorotrimethylsilane was purchased from Fluka and used as received. $Zr(NMe_2)_4$ was purchased from Aldrich and used as a toluene solution. Methylaluminoxane (MAO, 30 wt.% solution in toluene) was received from Borealis Polymers Oy.

Ligand Synthesis: *cis*-$[Cl(t\text{BuNP})]_2$ (**a**) was prepared according to modified literature procedures.[29] The cyclodiphosph(III)azane ligands *cis*-$[(PhNH)(t\text{BuNP})]_2$ (**1**), *cis*-$[(Ph_2CHNH)_2(t\text{BuNP})_2]$ (**2**), *cis*-$[(2,6\text{-di-Et}C_6H_3NH)_2(t\text{BuNP})_2]$ (**3**), *cis*-$[(2,5\text{-di-}t\text{Bu}C_6H_3NH)_2(t\text{BuNP})_2]$ (**4**), and *cis*-$[(2,6\text{-di-}i\text{Pr}C_6H_3NH)_2(t\text{BuNP})_2]$ (**5**) were prepared as described previously.[26] $[(t\text{BuN})_2(t\text{BuNP})_2]ZrCl_2$ (**6**) was prepared according to the literature.[18]

$[(PhN)_2(t\text{BuNP})_2]ZrCl_2$ (7): A solution of $Zr(NMe_2)_4$ (1.56 g, 5.86 mmol) in toluene (20 mL) was added with a syringe to a toluene solution of *cis*-$[(PhNH)_2(t\text{BuNP})_2]$ (2.28 g, 5.86 mmol, 30 mL) at 0 °C. The reaction mixture was then refluxed for 16 h, and the obtained bis(dimethylamido)zirconium complex $[(PhN)(t\text{BuNP})]_2Zr(NMe_2)_2$ (**7a**) was characterized by NMR spectroscopy. ^1H NMR (200 MHz, C_6D_6, 29°C): δ_H = 1.19 (s, 18 H, *t*Bu), 2.93 (s, 12 H, NMe_2), 6.81 (t, J = 6.6 Hz, 2 H, *o*-H), 7.26 (m, 8 H, Ph) ppm. $^{13}C\{^1H\}$ NMR (50.3 MHz, C_6D_6, 29°C): δ_C = 29.7 [t, $J_{P,C}$ = 6.87 Hz, $C(CH_3)_3$], 40.94 (Me_2NZr), 53.2 [t, $J_{P,C}$ = 12.5 Hz, $C(CH_3)_3$], 119.36 (Ph), 129.7 (Ph), 150.0 (Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, C_6D_6, 21°C): δ_P = 124 ppm. The bis(amido) complex $[(PhN)(t\text{BuNP})]_2Zr(NMe_2)_2$ was converted into the corresponding dichloro derivative **7** by reaction with excess Me_3SiCl (1.3 g, 1.5 mL, 11.7 mmol) at 0 °C. The obtained reaction mixture was stirred at room temperature overnight. The volatiles were removed in vacuo, and the residue was extracted with a mixture of hexane and CH_2Cl_2 (1:1). After filtration and evaporation of the solvents, the product was dried in vacuo to give a pale-yellow powder containing 1 equiv. of Me_2NH per Zr (2.03 g; 60%) $C_{20}H_{28}Cl_2N_4P_2Zr{\cdot}Me_2NH$ (593.6): calcd. C 44.51, H 5.94, N 11.80; found C 44.79, H 6.19, N 11.44. ^1H NMR (200 MHz, C_6D_6, 29°C): δ_H = 1.32 (s, 18 H, *t*Bu), 1.80 (br. s, Me_2NH), 6.82 (t, J = 7.7 Hz, 2 H, *p*-H), 7.09 (t, J = 7.7 Hz, 4 H, *m*-H), 7.50 (d, J = 7.7 Hz, 4 H, *o*-H) ppm. $^{13}C\{^1H\}$ NMR (50.3 MHz, C_6D_6, 29°C): δ_C = 28.65 [t, $J_{P,C}$ = 7.4 Hz, $C(CH_3)_3$], 32.2 (Me_2NH), 54.25 [t, $J_{P,C}$ = 9.15 Hz, $C(CH_3)_3$], 124.0, 129.5, 150.2 ppm. $^{31}P\{^1H\}$ NMR (162 MHz, C_6D_6, 21°C): δ_P = 145.03 (s) ppm. MS(EI): *m*/*z* (%) = 548 (10) [M^+], 503 (6) [M^+ − Cl], 388 (10) [ligand].

$[(Ph_2CHN)_2(t\text{BuNP})_2]ZrCl_2$ (8): A toluene solution of $Zr(NMe_2)_4$ (0.52 g, 1.97 mmol, 20 mL) was added with a syringe to a solution of *cis*-$[(Ph_2CHNH)_2(t\text{BuNP})_2]$ (1.12 g, 1.97 mmol) in toluene (10 mL) at 0 °C. The reaction mixture was then refluxed for 16 h, and the bis(dimethylamido)zirconium complex $[(Ph_2CHN)_2(t\text{BuNP})_2]Zr(NMe_2)_2$ (**8a**) was isolated according to a procedure described earlier. ^1H NMR (200 MHz, C_6D_6, 29°C): δ_H = 1.30 (s, 18 H, *t*Bu), 2.70 (12 H, NMe_2), 5.57 (dd, 2 H, Ph_2CH), 7.09 (m, 20 H, Ph-H) ppm. Crystals suitable for X-ray analysis were obtained by slow crystallization from saturated Et_2O solution at −20 °C. The bis(amido) complex $[(Ph_2CHN)_2(t\text{BuNP})_2]Zr(NMe_2)_2$ (**8a**) was converted into the corresponding dichloro derivative **8** by reaction with excess Me_3SiCl (2.31 g, 2.0 mL, 21.28 mmol) at 0 °C. The obtained reaction mixture was stirred at room temperature overnight. The volatiles were removed in vacuo, and the residue was extracted with a mixture of hexane and CH_2Cl_2 (1:1). The crude product was washed with cold pentane and dried under vacuum (yield 0.95 g). The remaining pentane solution was kept in a freezer at −20 °C for 3 d, and a second crop of product (0.27 g) was isolated as a white powder by removing the pentane with a syringe. Total yield 1.22 g, 85%. $C_{34}H_{40}Cl_2N_4P_2Zr$ (728.8): calcd. C 56.03, H 5.53, N 7.69; found C 55.85, H 6.30, N 7.50. ^1H NMR (200 MHz, C_6D_6, 29°C): δ_H = 1.21 (s, 18 H, *t*Bu), 6.08 (t, 2 H, Ph_2CH), 7.14−7.28 (m, 16 H, Ph), 7.68 (d, J = 7.0 Hz, 4 H, *p*-H) ppm. $^{13}C\{^1H\}$ NMR (50.3 MHz, C_6D_6, 29°C): δ_C = 30.88 [t, $J_{P,C}$ = 7.25 Hz, $C(CH_3)_3$], 51.88 [t, $J_{P,C}$ = 11 Hz, $C(CH_3)_3$], 98.4 (Ph_2CH), 126.85 (Ph), 128.6 (Ph), 150.8 (Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, C_6D_6, 21°C): δ_P = 102.0 (s) ppm. MS(EI): *m*/*z* (%) = 691 (5) [M^+ − Cl], 566 (60) [ligand].

$[(2,6\text{-}Et_2C_6H_3N)_2(t\text{BuNP})_2]ZrCl_2$ (9): A toluene solution of *cis*-$[(2,6\text{-}Et_2C_6H_3NH)_2(t\text{BuNP})_2]$ (1.5 g, 3.0 mmol, 20 mL) and $Zr(NMe_2)_4$ (0.8 g, 2.99 mmol) in toluene (10 mL) was treated as in the case of **8**. The bis(dimethylamido)zirconium complex [(2,6-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$Et_2C_6H_3N)_2(t$BuNP$)_2]Zr(NMe_2)_2$ (**9a**) was isolated according to a previously described procedure. ^{1}H NMR (200 MHz, C_6D_6, 29°C): δ_H = 1.33 (s, 18 H, *t*Bu), 1.40 (t, 12 H, CH_3CH_2), 3.03 and 3.19 (2 s, 12 H, NMe_2), 3.08 (q, 8 H, CH_3CH_2), 7.16 (m, 6 H, Ar) ppm. Me_3SiCl (4.8 mL, 4.15 g, 38.2 mmol) was added with a syringe to a stirred solution of $[(2,6\text{-}Et_2C_6H_3N)_2(t$BuNP$)_2]Zr(NMe_2)_2$. The reaction mixture was stirred at room temperature overnight. The solvent was removed under vacuum. An orange residue was first extracted with hexane (30 mL) and then twice with a mixture of hexane (20 mL) and CH_2Cl_2 (7 mL). After solvent evaporation, the obtained dichloro complex was dried under vacuum to give the yellow-orange oil (1.6 g, 80.8%). $C_{28}H_{44}Cl_2N_4P_2Zr$ (660.8): calcd. C 50.90, H 6.71, N 8.48; found C 50.47, H 7.06, N 8.64. ^{1}H NMR (200 MHz, C_6D_6, 29°C): δ_H = 1.41 (s, 18 H, *t*Bu), 1.49 (t, 12 H, CH_3CH_2), 3.16 (q, J = 7.69 Hz, 8 H, CH_3CH_2), 7.20−7.33 (m, 6 H, Ar) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, C_6D_6, 29°C): δ_C = 14.92 (t, J = 1.53 Hz, CH_3CH_2), 26.4 (d, J = 9.9 Hz, CH_3CH_2), 31.23 [t, $J_{P,C}$ = 6.48 Hz, $C(CH_3)_3$], 51.53 [t, $J_{P,C}$ = 14.5 Hz, $C(CH_3)_3$], 123.3 (Ar), 127.1 (Ar), 135.75 (Ar), 138.13 (t, J = 1.9 Hz, Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, C_6D_6, 21°C): δ_P = 115.6 (s) ppm. MS(EI): *m*/*z* (%) = 661 (1) [M^+], 626 (3) [M^+ − Cl], 500 (80) [ligand].

$[(2,5\text{-}t$Bu$_2C_6H_3N)_2(t$BuNP$)_2]ZrCl_2$ (10): A toluene solution of *cis*-$[(2,5\text{-}t$Bu$_2C_6H_3NH)_2(t$BuNP$)_2]$ (2.29 g, 3.74 mmol, 30 mL) was treated with $Zr(NMe_2)_4$ (1.0 g, 3.74 mmol) in toluene (10 mL) as in the case of **8**. The obtained bis(dimethylamido)zirconium complex $[(2,5\text{-}t$Bu$_2C_6H_3N)_2(t$BuNP$)_2]Zr(NMe_2)_2$ (**10a**) was characterized by NMR spectroscopy. ^{1}H NMR (200 MHz, C_6D_6, 29°C): δ_H = 1.44 (s, 36 H, *t*Bu*Ar*), 1.57 (s, 18 H, *t*Bu), 3.03−3.28 (12 H, NMe_2), 7.0 (dd, J_1 = 6.2, J_2 = 2.2 Hz, 2 H, 4-HPh), 7.35 (2 H, 3-HPh), 8.25 (dd, J_1 = 3.1, J_2 = 2.2 Hz, 2 H, 2-HPh) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, C_6D_6, 29°C): δ_C = 31.0 [5-(CH_3)$_3$CAr], 31.34 [t, $J_{P,C}$ = 6.48 Hz, (CH_3)$_3$C], 31.54 [2-(CH_3)$_3$CAr], 33.11 [5-(CH_3)$_3$*C*Ar], 33.3 [2-(CH_3)$_3$*C*Ar], 43.8 (NMe_2), 51.7 [t, $J_{P,C}$ = 13.7 Hz, (CH_3)$_3$*C*], 113.85 (Ar), 114.5 (Ar), 117.17 (Ar), 127.0 (Ar), 141.9 (Ar), 150.0 (t, J = 1.15 Hz, Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, C_6D_6, 21°C): δ_P = 99.8 (s) ppm. Me_3SiCl (5.1 mL, 4.34 g, 40 mmol) was added with a syringe to a toluene solution of $[(2,5\text{-}t$Bu$_2C_6H_3N)_2(t$BuNP$)_2]Zr(NMe_2)_2$. The reaction mixture was stirred at room temperature overnight. All volatiles were removed under vacuum. The residue was extracted three times with a mixture of hexane (30 mL) and CH_2Cl_2 (20 mL). The extracts were combined and the solvent was removed in vacuo. The product, a yellow powder, was dried under vacuum. Yield 2.4 g, 83%. $C_{36}H_{60}Cl_2N_4P_2Zr$ (773.0): calcd. C 55.94, H 7.82, N 7.25; found C 55.16, H 8.52, N 7.96. ^{1}H NMR (200 MHz, C_6D_6, 29°C): δ_H = 1.44 (s, 36 H, *t*Bu*Ar*), 1.57 (s, 18 H, *t*Bu), 7.0 (dd, 2 H, J_1 = 6.22, J_2 = 2.2 Hz, 4-HPh), 7.36 (2 H, 3-HPh), 8.25 (2 H, J_1 = 3.3, J_2 = 2.2 Hz, 2-HPh) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, C_6D_6, 29°C): δ_C = 31.0 [5-(CH_3)$_3$CAr], 31.34 [t, $J_{P,C}$ = 6.6 Hz, (CH_3)$_3$C], 31.54 [2-(CH_3)$_3$CAr], 33.1 [5-(CH_3)$_3$*C*Ar], 33.7 [2-(CH_3)$_3$*C*Ar], 51.7 [t, $J_{P,C}$ = 13.73 Hz, (CH_3)$_3$*C*], 113.8 (Ar), 114.5 (Ar), 117.15 (Ar), 136.95 (Ar), 140.7 (Ar), 150.0 (t, J = 1.53 Hz, Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, C_6D_6, 21°C): δ_P = 99.8 (s) ppm. MS(EI): *m*/*z* (%) = 772 (40) [M^+], 735 (20) [M^+ − Cl], 612 (90) [ligand].

$[(2,6\text{-}i$Pr$_2C_6H_3N)_2(t$BuNP$)_2]ZrCl_2$ (11): A toluene solution of *cis*-$[(2,6\text{-}i$Pr$_2C_6H_3NH)_2(t$BuNP$)_2]$ (1.91 g, 3.44 mmol, 20 mL) was treated with $Zr(NMe_2)_4$ (0.92 g, 3.44 mmol) in toluene (10 mL) as in the case of **8**. The bis(dimethylamido)zirconium complex $[(2,6\text{-}i$Pr$_2C_6H_3N)_2(t$BuNP$)_2]Zr(NMe_2)_2$ (**11a**) obtained was characterized by NMR spectroscopy. ^{1}H NMR (200 MHz, C_6D_6, 29°C): δ_H = 1.32 (s, 18 H, *t*Bu), 1.37 [d, 24 H, $(CH_3)_2CH$], 3.08−3.16 (m, 12 H, NMe_2), 3.92 [m, 4 H, $(CH_3)_2CH$], 7.0−7.3 (6 H, Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, C_6D_6, 21°C): δ_P = 115.45 (s) ppm. Me_3SiCl (4.5 mL, 3.8 g, 35 mmol) was added with a syringe to a toluene solution of $[(2,6\text{-}i$Pr$_2C_6H_3N)_2(t$BuNP$)_2]Zr(NMe_2)_2$ at 0 °C. The reaction mixture obtained was stirred at room temperature overnight. The product (yellow oil) was isolated as in the case of **9**. Yield 2.28 g, 92.3%. $C_{32}H_{52}Cl_2N_4P_2Zr$ (716.9): calcd. C 53.61, H 7.31, N 7.82; found C 53.50, H 7.17, N 7.80. ^{1}H NMR (200 MHz, C_6D_6, 29°C): δ_H = 1.37 (s, 18 H, *t*Bu), 1.42 [d, 24 H, $(CH_3)_2CH$], 3.97 [m, J = 6.96 Hz, 4 H, $(CH_3)_2CH$], 7.12−7.28 (6 H, Ar) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, C_6D_6, 29°C): δ_C = 24.17 [t, J = 1 Hz, $(CH_3)_2CH$], 31.37 [t, $J_{P,C}$ = 6.7 Hz, $(CH_3)_3C$], 32.2 [d, J = 0.8 Hz, $(CH_3)_2CH$], 51.8 [t, $J_{P,C}$ = 14.6 Hz, $(CH_3)_3C$], 123.3 (Ar), 124.0 (Ar), 128.3 (Ar), 141 (Ar) ppm. ^{31}P{^{1}H} NMR (162 MHz, C_6D_6, 21°C): δ_P = 115.47 (s) ppm. MS(EI): *m*/*z* (%) = 716 (3) [M^+], 681 (2) [M^+ − Cl], 556 (20) [ligand].

Polymerization Experiments: A 1-L Büchi glass autoclave (or a steel autoclave at a pressure of 8 bar) was charged with dry toluene (200 mL), cocatalyst (MAO), and thermostatted to the required temperature. The autoclave was saturated with ethylene, and a desired amount of precatalyst solution was then injected. The monomer pressure (±50 mbar), temperature (±0.5 °C), and monomer consumption were controlled by real-time monitoring. Polymerization was quenched with 10% HCl solution in methanol, and the polymer precipitated quantitatively by pouring the solution into methanol (400 mL), acidified with a small amount of aqueous hydrochloric acid. The polymer materials obtained were washed several times with methanol and water, and dried at 60 °C. The polymerization activities were calculated as kg of PE × (mol_{cat} × $[C_2H_4]$ × h)$^{-1}$ from experimental data to adjust the changes in the ethene concentration in toluene. The values of $[C_2H_4]$ for different ethene pressures and polymerization temperatures were taken from ref.[33]

X-ray Crystallographic Study: The crystal data of *cis*-$[(Ph_2CHNH)_2(t$BuNP$)_2]$ (**2**) were collected with an Enraf−Nonius CAD-4 single-crystal diffractometer at 193(2) K using Cu-K_α radiation (graphite monochromator), λ = 1.54179 Å (scan type ω/2θ). Intensities were corrected for Lorentz and polarization effects and for absorption, XCAD4.[34−36] The crystal data of $[(Ph_2CHN)_2(t$BuNP$)_2]Zr(NMe_2)_2$ (**8a**) were collected with a Nonius KappaCCD area-detector diffractometer at 173(2) K using Mo-K_α radiation (graphite monochromator), λ = 0.71073 Å. Data reduction: COLLECT.[37] Absorption correction: SADABS.[38] Solution and refinement: SHELX-97,[39] direct methods. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined in calculated positions. The displacement factors of the H atoms were 1.2 × (1.5 ×) that of the host atom. Graphics: SHELXTL/PC.[40] CCDC-231525 and -231526 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

NMR Study of L-Shaped (Quinoxaline)platinum(II) Complexes − Crystal Structure of $[Pt(DMeDPQ)(bipy)](PF_6)_2$

Enrico Rotondo,*[a] Archimede Rotondo,[a] Francesco Nicolò,[a] Maria Letizia Di Pietro,[a] Maria Anna Messina,[a] and Matteo Cusumano[a]

Keywords: DNA recognition / N ligands / Nitrogen heterocycles / NMR spectroscopy / Platinum

A ^1H and ^{13}C NMR study of nine Pt^{II} complexes of DMeDPQ [6,7-dimethyl-2,3-bis(2-pyridyl)quinoxaline] and BDPQ [2,3-bis(2-pyridyl)benzo[*g*]quinoxaline], and the crystal structure of one of them, are reported. The results are consistent with C_s symmetry of "L-shaped square-planar complexes". The rigid seven-membered chelated quinoxaline ligand holds the fused aromatic rings nearly perpendicular to the Pt^{II} coordination plane, generating the peculiar L-shaped structure. Ancillary ligands in the residual coordination sites are: a) bidentate flexible-planar 2,2′-bipyridine (bipy; complexes **1** and **2**); b) bidentate rigid-planar dipyrido[3,2-*a*:2′3′-*c*]phenazine (dppz) or benzo[*b*]dipyrido[3,2-*h*:2′,3′-*j*]phenazine (bdppz; complexes **3**–**6**); or c) 3-substituted monodentate pyridines (3-Rpy; complexes **7**–**9**). The L-shaped geometry has been exploited to gain insight into the steric and dynamic features that regulate the noncovalent interactions of these square-planar complexes with DNA. We have shown previously, for $[Pt(bipy)(n\text{-}Rpy)_2]^{2+}$, that bipy twisting can be frozen out on the NMR timescale below 260 K. Preservation of the C_s symmetry at low temperature indicates a lack of bipy fluxionality within these L-shaped structures. The static butterfly-like symmetric orientation of the quinoxaline pyridyl rings accounts for the hampered twisting of Pt(bipy), which is otherwise assisted by the synchronous "windscreen wiper" conrotatory rocking of the ancillary pyridine rings. The L-geometry can also be used to monitor the ancillary *n*-Rpy rotation by NMR spectroscopy. The quasi-vertical quinoxaline pyridyl rings alignment leave room in the coordination plane for the crossing of the opposite pyridine rings, thereby reducing their rotational barriers about the Pt–N bond.

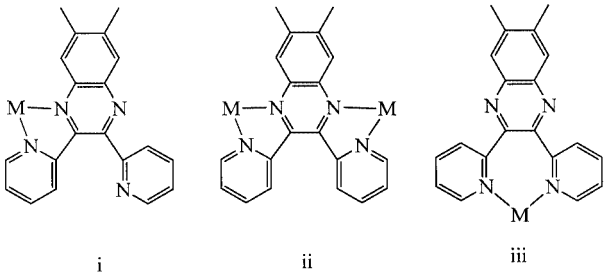
Introduction

In the course of our interest in intercalative, noncovalent interaction of square-planar Pt^{II} complexes with DNA duplex, we have recently synthesised platinum(II) complexes of DMeDPQ and BDPQ. These ligands display a rather flexible metal-ion binding pattern often characterised by chelation through the pyrazine and pyridyl nitrogen atoms to form potentially dicompartmental five-membered ring ligands. Different coordination patterns, however, are also known. On the basis of literature reports three main coordination geometries can be envisaged for these ligands: (i) half-filled mononuclear;[1] (ii) completely filled dinuclear (the ligand acts as a two-metal bridge);[2] and (iii) a less-common seven-membered bis(pyridyl)metal chelate ring[3] (Scheme 1). One case of BDPQ three-coordination through two pyridyl nitrogen atoms and the deprotonated hydroxy oxygen atom of the hydrate ligand has also been reported.[4]



i ii iii

Scheme 1. Common coordination modes adopted by BDPQ and DMeDPQ

Most of the known DMeDPQ and BDPQ complexes were unambiguously characterised by X-ray crystallography as mononuclear and binuclear octahedral complexes, and very few tetracoordinate complexes have been reported so far.[5] We have recently found that in $[PdCl_2(DMeDPQ)]$[6] and $[Pt(BDPQ)(bipy)](PF_6)_2$ [7] the quinoxalines coordinate to the metal as seven-membered bis-pyridyl chelates. This binding holds the fused aromatic rings perpendicular to the coordination plane to give an angular "L-shaped" structure (Figure 1).

The same coordination geometry has been reported for $[PtCl_2(DMeDPQ)]$[8] and $[Pd(DPQ)_2](PF_6)_2$.[9] Saturation of

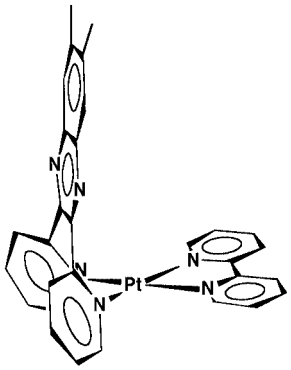

Figure 1. Schematic drawing of $[Pt(DMeDPQ)(bipy)]^{2+}$

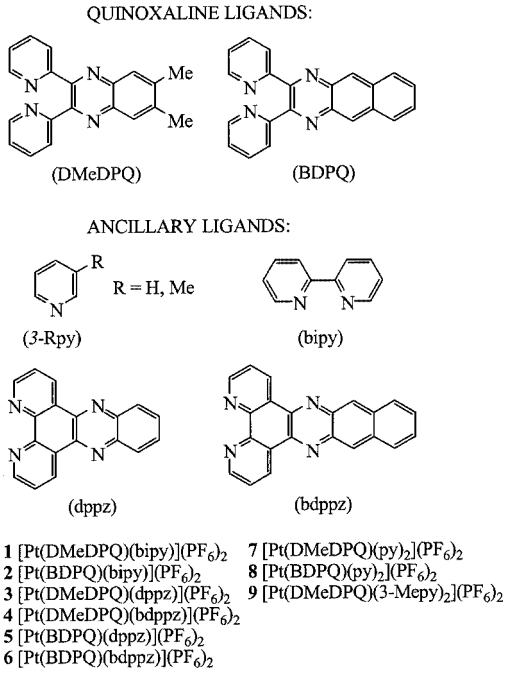
the residual coordination sites of (quinoxaline)Pt^{II} substrates with flat bidentate ligands led to the six mixed complexes **1**−**6**, which bear two extended mutually orthogonal planar moieties, both of which are capable of undergoing intercalation as well as enantioselective DNA recognition. The ambintercalating character of these complexes has been investigated recently.[7] In this paper we report the ^1H and ^{13}C NMR spectroscopic characterisation of the ambintercalator complexes **1**−**6**, and their monodentate pyridine analogues **7**−**9** (see Scheme 2). The crystal structure of $[Pt(DMeDPQ)(bipy)](PF_6)_2$ (**1**) has also been resolved by X-ray diffraction. The unambiguous resonance assignment and structure determination are essential steps on the way toward intercalative mapping driven by magnetic perturbation of the nuclei upon insertion into the DNA double helix. Moreover, we designed the quinoxaline coordination geometry to gain insight into the structural and dynamic features regulating the noncovalent interactions of the square-planar complexes with DNA. Despite quinoxalines' versatility to act as a magnetic probe of the structural and dynamic features of the ancillary ligands, NMR studies of these L-shaped Pt^{II} complexes have, up to now, been largely neglected.

Results and Discussion

The syntheses of complexes **1**−**9** are discribed in the Exp. Sect.

Our experimental evidence is consistent with DMeDPQ and BDPQ acting as bidentate seven-membered dipyridyl chelates. The ancillary ligands in the residual coordination sites of the nine complexes studied here belong to three different classes: a) bidentate-planar with a certain degree of flexibility (bipy; complexes **1** and **2**); b) more rigid bidentate-planar phenazine (dppz and bdppz; complexes **3**−**6**); c) monodentate pyridines (3-Rpy, R = H, CH_3; complexes **7**−**9**). 2-D representations of the ligands and schematic formulae for complexes **1**−**9** are given in Scheme 2.



Scheme 2. 2D representation of ligands and schematic formulae **1**−**9**

The solid-state structure, solved by X-ray diffraction, unequivocally shows the L-shaped nature of **1**. The same coordination has previously been found for analogous substrates,[6−9] meaning that "L-shaped" is the preferred structure for square-planar (quinoxaline)Pt^{II} and -Pd^{II} complexes. This geometry has C_s symmetry due to a vertical mirror plane (σ_v) intersecting the metal atom. The high-resolution NMR spectra are consistent with this symmetry element, as single signals are detected for every pair of nuclei interchanged by the symmetry operation. Standard 1- and 2-D NMR techniques were employed for thorough resonance assignment (Tables 1 and 2).

Discrimination between the quinoxaline pyridyl and the 2,2′-bipyridine proton resonances of **1** and **2** was achieved by heteronuclear long-range C-7′/3′-H coupling, which allowed the assignment of 3′-H and thus the whole set of pyridyl resonances. Analogously, the phenazine pyridyl resonances could be assigned due to the heteronuclear long-range C-7/4-H coupling (C-7 signal at higher field than C-7′ signal). Together with other data, dipolar 10-H/4-H coupling of the planar phenazine protons, which is not found between 10′-H and 3′-H or 10′-H and 4′-H of the bent quinoxaline, confirmed the heteronuclear long-range coupling assignments of **3**−**6**. A peculiar, previously reported ^1H NMR spectral feature of $[Pt(bipy)(n\text{-}Rpy)_2]^{2+}$ is a strong diamagnetic shift experienced by the 6-H protons of the bipy ligand because of the anisotropic ring current of the quasi-perpendicular *n*-Rpy group.[10] We found a similar effect in **1** and **2**, where the seven-membered chelates hold the bis(pyridyl) vertical rings just above 6-H of bipy. This diamagnetic shift is less in rigidly planar phenazine complexes **3**−**6**, and even more so in the 3-Rpy derivatives **7**−**9**.

Coordinated bipy is usually thought of as a perfectly flat fragment; however, we have previously proposed a slight propeller-like torsion of the ligand in [Pt(bipy)(*n*-Rpy)$_2$]$^{2+}$ cations on the basis of both low-temperature NMR spectra[10] and X-ray crystal structures.[11] Indeed, in order to minimize intramolecular bumping, these complexes undergo a slight bipy-propeller distortion concerted to an about 10° conrotation of the quasi-vertical *n*-Rpy. NMR spectra consistent with time-averaged C_{2v} symmetry are due to fast bipy twisting synchronous to windscreen wiper rocking of *n*-Rpy. Locked propeller structures can be witnessed by low-temperature resonance splitting observed for nonfluxional molecules devoid of C_2 symmetry axis.[10] In this sense the lack of C_2 symmetry and the static configuration makes the (DMeDPQ)Pt and (BDPQ)Pt fragments excellent NMR probes of the ancillary bipy distortion. Despite the presence of many nuclei suitably positioned for magnetic monitoring of bipy distortion, we could not detect any ^{1}H or ^{13}C resonance splitting at 210 K for solutions of **1** and **2** (or for any of the other complexes studied here). This is a strong indication of planar bipy, which is not allowed to break the L-shaped molecular C_s symmetry. In agreement with this, the X-ray diffraction data of **1** show a perfectly planar Pt(bipy) skeleton. The disparity between the coordinated bipy geometry and fluxionality can be attributed to a slight but crucial difference in the orientation adopted, respectively by the *n*-Rpy of [Pt(bipy)(*n*-Rpy)$_2$]$^{2+}$, and quinoxaline pyridyl rings of **1** and **2**. Molecular models based on crystallographic data show, in fact, that the symmetrically disrotated quinoxaline pyridyl wings of [Pt(DMeDPQ)(bipy)]$^{2+}$ and [Pt(BDPQ)(bipy)]$^{2+}$ (rigid butterfly-like configuration) hamper, unlike the conrotated pyridine rings of [Pt(bipy)(*n*-Rpy)$_2$]$^{2+}$, twisting of the opposite bipy (Figure 2). Therefore, the bipy moieties of the L-shaped cations are forced into the same rigid planar structure as dppz and bdppz. Indeed, low-temperature NMR spectra of [Pt(dppz)(*n*-Rpy)$_2$]$^{2+}$ and [Pt(dppz)(*n*-Rpy)$_2$]$^{2+}$, as the L-shaped cations, do not show resonance splitting.[12]

The monodentate 3-substituted pyridines 3-Rpy are the ancillary ligands in **7**−**9**. In **9** we introduced a methyl substituent on the pyridine ring to gain clues concerning geometry and monitoring of the dynamics, as hindered rotation of 3-Mepy would lead to an NMR-detectable *s-cis*/*s-trans* rotamer equilibrium.[10] Solutions of **9** actually show resonances of a single compound. This could either mean a much greater thermodynamic stability of one rotamer, or a low rotational barrier for 3-Rpy (fast exchange). Very accurate selective NOED spectra indicate a spatial 2-H/6-H connectivity attributable to the neighbouring pyridine rings. This excludes the unique presence of an *s-cis* rotamer, but is consistent with both a static *s-trans* rotamer and fast rotation. Positive NOEs for **9** were also detected between the quinoxaline 6′-H and both 2-H and 6-H of the pyridyl moieties. Indeed, dipolar couplings by themselves suggest 3-Mepy rotation leading to transient 2-H/6-H contacts between nuclei of the neighbouring 3-Mepy; and also 2-H and 6-H temporarily alternate their proximity to 6′-H of the static quinoxaline pyridyl rings (Figure 3). This conclusion is further supported by the ^{13}C-^{1}H relaxation-time constants of **7** and **9**. Under decoupling conditions, for a pure dipolar relaxation in the extreme narrowing limit (neglect-

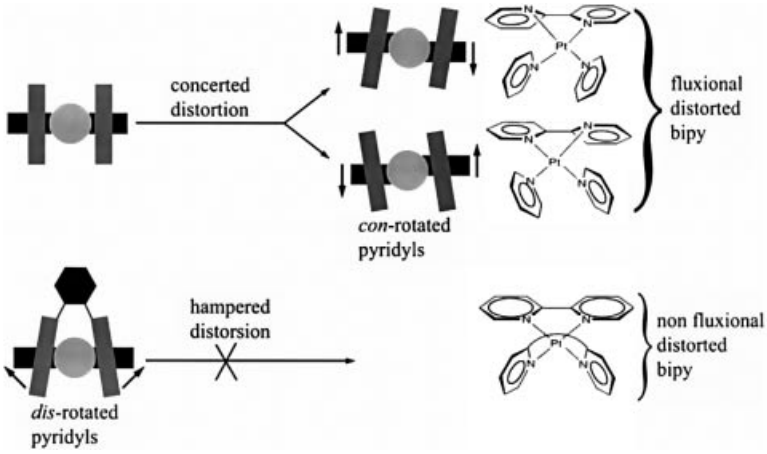

Figure 2. Allowed or hampered distortion of Pt(bipy) cations

ing contributions of unattached protons and considering the C−H distance to be constant), the aromatic ^{13}C-^{1}H relaxation time can be taken as a measure of the anisotropic spin diffusion.[13] The rotation of rings anchored to a bulk matrix slows down the relaxation rates of the *ortho*- and *meta*-carbon atoms without altering the *para*-carbon atom, whose proton-attached dependent local field is not affected by the rotational diffusion. The increased relaxation-time constants shown by the *ortho*- and *meta*-carbon atoms relative to the *para*-carbon atom are thus consistent with fast 3-Rpy rotation (Table 3).

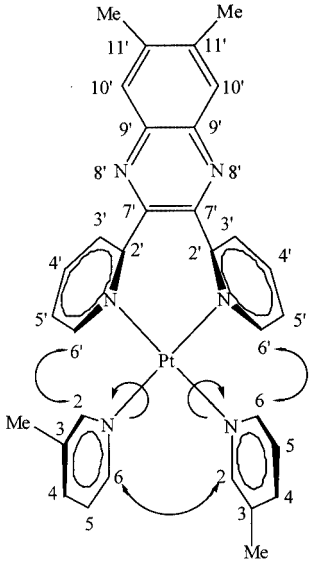

Figure 3. Remarkable dipolar couplings detected for **9** by NOESY NMR spectroscopy

The low-temperature NMR spectra of **9** in acetone at 210 K do not show evidence of 3-Mepy freezing, in agreement with a low rotational barrier of the pyridine ring. On the contrary, the corresponding $[Pt(bipy)(3\text{-}Mepy)_2]^{2+}$ cation shows *s-cis* and *s-trans* rotamers interconverting at 320 K with $\Delta G^{\#}$ of 68.5 kJ·mol^{-1}.[10] This difference can be attributed to the quasi-vertical orientation of quinoxaline

Table 3. Selected relaxation-time constants [s] of the aromatic ^{13}C-H carbon atoms in [D_6]acetone at 298 K; standard deviations are less than 5%

	DMeDPQ						3-Rpy

pyridyl rings which remove hindrance from the coordination plane. Analogous conclusions can be drawn from the NMR spectra of **7** and **8** showing, also at 210 K, three pyridine resonances (for the four *ortho*, four *meta* and two *para* nuclei, respectively) due to symmetry averaging about the coordination plane prompted by fast pyridine rotation.

Despite all our efforts we were not able to prepare 2-Mepy quinoxaline complexes. It is likely that coordination is inhibited by the steric hindrance between the *ortho*-methyl substituent and the hetroaromatic rings.

Molecular Structure of {[Pt(DMeDPQ)(bipy)][PF_6]$_2$}·0.5{(DMeDPQ)(CH_3OH)}

The 6,7-dimethyl-2,3-bis(2-pyridyl)quinoxaline ligand (DMeDPQ) crystallises with the platinum salt in a 3:2 ratio. The crystal contains a discrete complex $[Pt(DMeDPQ)(bipy)]^{2+}$ cation with the hexafluorophosphate ions as counterions (ratio 1:2), and co-crystallised uncoordinated ligand and methanol solvent (both in a 2:1 ratio). This solid-state aggregate is stabilized by strong π-stacking (3.6 Å) between the planar quinoxaline fragment of the alternate free and coordinated ligands along the *c* axis: the anions and the methanol molecules are retained between these parallel columns by hydrogen-bonding interactions. The 3-D packing arrangement is very ordered and shows an overall symmetry (expressed by the adopted crystallographic space group) higher than the single compound moieties, which causes an important symmetry disorder for the free ligand and one PF_6^- anion.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The coordinated quinoxaline ligand shows the same arrangement as adopted in a previous Pd compound [$PdCl_2$(DMeDPQ)][6] showing a slight conjugation between the aromatic bicyclic system and the pyridine ring, as evidenced by the N2−C10−C11−C11′ torsion angles [−52.9(5)° vs. the average value of 57.5(4)°] that is similar to the corresponding value in the free disordered ligand [−48(1)°]. This typical butterfly arrangement, which allows the nitrogen lone pairs to be oriented out of the ligand plane towards the metal atom in the coordinated quinoxaline, is also observed in the uncoordinated ligand.[14] The steric requirements of the ligand bite may also be responsible for the significant deformations from planarity of the quinoxaline[15] and the enlargement of the pyridine substituent angles up to 130° (protonated free ligand).[16]

The pyridyl orientation causes the quinoxaline mean plane to be normal to the platinum coordination plane containing the bipyridyl ligand, with a dihedral angle between them of 81.09(9)°. The angle of 71.4(2)° between the quinoxaline pyridine rings and the Pt coordination plane may indicate a possible interaction of the π-orbitals of both rings with the d_{xz}, d_{yz} and d_{xy} orbitals of the metal atom.[17] The DMeDPQ and bipy Pt−N bond lengths are similar [2.027(4) vs. 2.013(3) Å, respectively], the angular distortion from the regular square-planar Pt coordination geometry being mainly due to the different bite size of the two ligands (Figure 4).

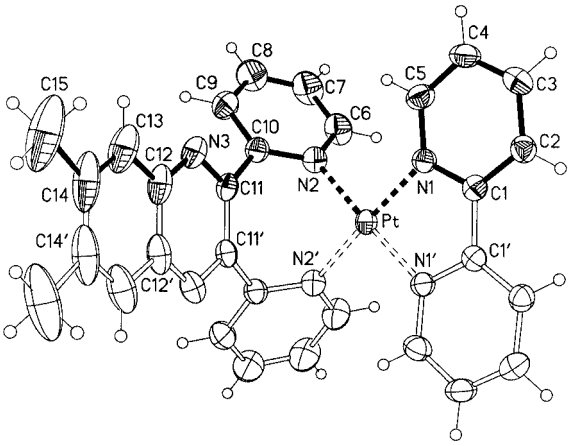

Figure 4. View of the cation of complex **1**, which lies on a mirror plane, with its labelling scheme; empty atoms represent the symmetric half moiety generated by the $x, -y + 1, z$ operation; anions, co-crystallised uncoordinated ligand and methanol moieties have been omitted for clarity; thermal ellipsoids are drawn at 30% probability while the hydrogen-atom size is arbitrary; selected bond lengths [Å] and angles [°]: Pt−N1 2.013(3), Pt−N2 2.027(4), N1−C1 1.365(5), C1−C1′ 1.457(8), N2−C10 1.341(5), C10−C11 1.480(6), C11−C11′ 1.425(9), C11−N3 1.330(5), N3−C12 1.368(6), C12−C12′ 1.42(1); N1−Pt−N2 97.0(1), N1′−Pt−N1 80.7(2), N2−Pt−N2′ 85.2(2), N1−C1−C1′ 114.9(2), C2−C1−C1′ 124.3(3), N3−C11−C10 113.4(4), C11′−C11−C10 124.9(2)

Conclusions

Quinoxalines lead to L-shaped Pt^{II} complexes of C_s local symmetry. The rigid butterfly-like structure gives these complexes stereochemical properties, which can be exploited for studying geometry and fluxionality of several ancillary ligands. The prochiral character of coordinated quinoxaline could pave the way to enantioselective synthesis and new classes of chiral compounds.

Experimental Section

General Remarks: ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded with a Bruker ARX 300 spectrometer, at 300.13 and 75.47 MHz, respectively. The ^1H NMR spectra were calibrated against the residual proton signals of the solvent as internal reference ([D_6]acetone, δ = 2.04 ppm), the $^{13}C\{^1H\}$ spectra were calibrated against the septuplet signals of the solvent ([D_6]acetone δ = 29.80 ppm).

Synthesis: Complexes **1** and **2** were prepared by dissolving DMeDPQ (Aldrich) or BDPQ[18] (2.5 mmol), respectively, in 100 mL of CH_3OH, adding H_2O to give a 1:1 CH_3OH/H_2O mixture and suspending a slight excess (5%) of [$PtCl_2$(bipy)][19] with respect to the stoichiometric ratio in it. The mixture was then heated to boiling and kept refluxing for 1/2 h until almost complete dissolution of the platinum complex. After filtration to eliminate the traces of solid material, NH_4PF_6 was added and the resulting complexes **1** and **2** precipitated as yellow solids, which were recrystallised from CH_3OH. Yields: 75% (**1**), 83% (**2**).

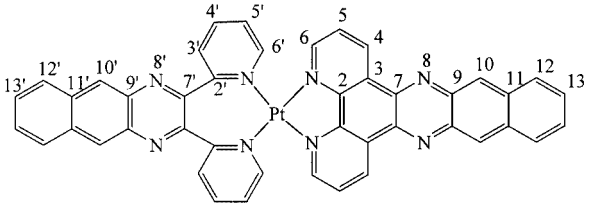
Complexes **3**−**6** were synthesised starting from the corresponding phenazine (dppz[20] or bdppz[21]) dichloride, obtained as follows: The phenazine ligand (2.5 mmol) was dissolved in 100 mL of warm (ca. 50 °C) DMSO and added dropwise and with stirring to an equivalent amount of [$PtCl_2(DMSO)_2$],[22] also dissolved in 100 mL of warm DMSO. After a few minutes, the red (phenazine)platinum dichloride, initially yellow in the case of [$PtCl_2$(dppz)], precipitated. To facilitate its coagulation, the mixture was stirred for 1 h, then filtered, washed with H_2O and a few drops of CH_3OH to eliminate the DMSO, and air-dried. A slight excess of the dichloride thus obtained was then suspended in a CH_3OH/H_2O (2:1) mixture (300 mL) in which the quinoxaline ligand (DMeDPQ or BDPQ; 2.5 mmol) had been previously dissolved. To facilitate the dissolution of the sparingly soluble phenazine dichloride complex, a few drops of DMSO were added and the mixture was heated to boiling and kept refluxing for 3 d. After cooling, insoluble material was separated by centrifugation, and the final product precipitated from the coloured solution (yellow for the complexes with dppz and orange-red for the ones with bdppz) by addition of an excess of NH_4PF_6. Since the yield of the reaction was very low, especially for the two complexes with bdppz, it was necessary to recover the unchanged (dppz)- and (bdppz)platinum dichloride from the bottom of the test tubes, and to repeat 2−3 times, under the same conditions, the treatment with the corresponding quinoxaline ligand. The ivory [Pt(DMeDPQ)(dppz)]$(PF_6)_2$, the reddish [Pt(DMeDPQ)(bdppz)]$(PF_6)_2$, the orange-brown [Pt(BDPQ)(dppz)]$(PF_6)_2$ and the brick-red [Pt(BDPQ)(bdppz)]$(PF_6)_2$ were all recrystallised from CH_3CN. Yields: 61% (**3**), 27% (**4**), 69% (**5**), 20% (**6**).

For the synthesis of complexes **7**−**9** it was necessary to prepare the corresponding (DMeDPQ)- or (BDPQ)platinum dichloride. To this end, the quinoxaline ligand (2.5 mmol) was dissolved in warm (ca. 50 °C) DMSO (100 mL) and added dropwise with stirring to an equivalent amount of [$PtCl_2(DMSO)_2$],[22] also dissolved in DMSO (100 mL). After a few minutes, an off-white product, in the case of [$PtCl_2$(DMeDPQ)], or a deep yellow one, for [$PtCl_2$(BDPQ)],

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

precipitated. Since the chloro complexes were very powdery and so very difficult to filter, after 5 h a few drops of H_2O were added to facilitate their coagulation and then filtered through a water pump. The product was washed with H_2O and a few drops of CH_3OH to eliminate the DMSO, and air-dried. The dichloride complex thus obtained was then suspended in H_2O in the presence of the appropriate pyridine (5% excess with respect to the stoichiometric 1:2 ratio) and heated to boiling. After dissolution of the complex, NH_4PF_6 was added and the resulting complexes **7**−**9** precipitated as light-yellow solids, which were washed with H_2O and a few drops of CH_3OH, and air-dried. The complexes were then recrystallised from CH_3OH. Yields: 67% (**7**), 70% (**8**), 68% (**9**).

All complexes were characterised by elemental analysis and ^1H and ^{13}C NMR spectroscopy (see Scheme 3 for atom numbering). The structure of $[Pt(DMeDPQ)(bipy)][PF_6)_2$ was determined by a single-crystal X-ray analysis of $\{[Pt(DMeDPQ)(bipy)][PF_6]_2\}\cdot 0.5\{(DMeDPQ)(CH_4O)\}$.



Scheme 3. General numbering scheme

[Pt(DMeDPQ)(bipy)](PF$_6$)$_2$ (1): ^1H NMR (300 MHz, [D$_6$]acetone): δ = 9.46 (d, ^3J = 5 Hz, 2 H, 6′-H), 8.67 (d, ^3J = 6 Hz, 2 H, 3-H), 8.57 (td, ^3J = 7, ^4J = 1 Hz, 2 H, 4′-H), 8.53 (td, ^3J = 7, ^4J = 1 Hz, 2 H, 4-H), 8.29 (d, ^3J = 6 Hz, 2 H, 3′-H), 8.18 (d, ^3J = 8 Hz, 2 H, 6-H), 8.14 (m, 2 H, 5′-H), 8.05 (s, 2 H, 10′-H), 7.83 (td, ^3J = 6, ^4J = 1 Hz 2 H, 5-H), 2.58 (s, 6 H, 12′-H) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]acetone): δ = 158.8 (2 C, C-2′), 157.5 (2 C, C-2), 153.2 (2 CH, C-6′), 150.9 (2 CH, C-6), 147.4 (2 C, C-7′), 145.2 (2 C, C-9′), 143.9 (2 CH, C-4′), 143.7 (2 CH, C-4), 141.5 (2 C, C-11′), 131.0 (2 CH, C-3′), 130.2 (2 CH, C-5′), 129.8 (2 CH, C-5), 129.2 (2 CH, C-10′), 125.6 (2 CH, C-3), 20.4 (2 CH$_3$, C-12′) ppm. $C_{30}H_{24}F_{12}N_6P_2Pt$ (954): calcd. C 37.79, H 2.54, N 8.81; found C 37.70, H 2.58, N 8.88.

[Pt(BDPQ)(bipy)](PF$_6$)$_2$ (2): ^1H NMR (300 MHz, [D$_6$]acetone): δ = 9.52 (d, ^3J = 5 Hz, 2 H, 6′-H), 8.98 (s, 2 H, 10′-H), 8.65 (d, ^3J = 8 Hz, 2 H, 3-H), 8.61 (td, ^3J = 7, ^4J = 1 Hz, 2 H, 4′-H), 8.53 (td, ^3J = 7, ^4J = 1 Hz, 2 H, 4-H), 8.39 (d, ^3J = 7 Hz, 2 H, 3′-H), 8.34 (m, 2 H, 12′-H), 8.22 (d, ^3J = 6 Hz, 2 H, 6-H), 8.18 (m, 2 H, 5′-H), 7.85 (m, 2 H, 5-H), 7.78 (m, 2 H, 13′-H) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]acetone): δ = 158.6 (2 C, C-2′), 157.6 (2 C, C-2), 153.3 (2 CH, C-6′), 150.9 (2 CH, C-6), 148.7 (2 C, C-7′), 144.0 (2 CH, C-4′), 143.9 (2 CH, C-4), 138.4 (2 C, C-9′), 136.2 (2 C, C-11′), 131.3 (2 CH, C-3′), 130.4 (2 CH, C-5′), 129.8 (2 CH, C-5), 129.6 (2 CH, C-10′), 129.4 (4 CH, C-13′, C-12′), 125.6 (2 CH, C-3) ppm. $C_{32}H_{22}F_{12}N_6P_2Pt$ (976): calcd. C 39.40, H 2.27, N 8.61; found C 39.21, H 2.38, N 8.56.

[Pt(DMeDPQ)(dppz)](PF$_6$)$_2$ (3): ^1H NMR (300 MHz, [D$_6$]acetone): δ = 10.01 (dd, ^3J = 8, ^4J = 1 Hz, 2 H, 4-H), 9.60 (d, ^3J = 6 Hz, 2 H, 6′-H), 8.71 (dd, ^3J = 5, ^4J = 1 Hz, 2 H, 6-H), 8.63 (td, ^3J = 8, ^4J = 1 Hz, 2 H, 4′-H), 8.47 (m, 2 H, 10-H), 8.36 (m, 2 H, 3′-H), 8.33 (dd, ^3J = 8, ^3J = 5 Hz, 2 H, 5-H), 8.21 (m, 4 H, 5′-H and 11-H), 8.05 (s, 2 H, 10′-H), 2.54 (s, 6 H, Me) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]acetone): δ = 159.0 (2 C, C-2′), 153.4 (2 CH, C-6′), 152.9 (2 CH, C-6), 151.1 (2 C, C-2), 147.6 (2 C, C-7′), 145.5 (2 C, C-9′), 143.9 (2 CH, C-4′), 143.7 (2 C, C-7), 141.4 (2 C, C-11′), 139.6 (2 C, C-9), 139.5 (2 CH, C-4), 134.0 (2 CH, C-11), 131.7 (2 C, C-3), 131.2 (2 CH, C-3′) 130.6 (2 CH, C-10) 130.3 (2 CH, C-5′), 129.3 (2 CH, C-5), 129.2 (2 CH, C-10′), 20.4 (2CH3, C-12′) ppm. $C_{38}H_{26}F_{12}N_8P_2Pt$ (1080): calcd. C 42.27, H 2.43, N 10.38; found C 42.13, H 2.45, N 10.26.

[Pt(DMeDPQ)(bdppz)](PF$_6$)$_2$ (4): ^1H NMR (300 MHz, [D$_6$]acetone): δ = 9.88 (d, ^3J = 9 Hz, 2 H, 4-H), 9.62 (d, ^3J = 5 Hz, 2 H, 6′-H), 8.92 (s, 2 H, 10-H), 8.65 (m overlapped, 4 H, 6-H and 4′-H), 8.39 (m, 2 H, 3′-H), 8.29 (m, 2 H, 5-H), 8.23 (m, 2 H, 5′-H), 8.14 (m, 2 H, 12-H), 8.09 (s, 2 H, 10′-H), 7.55 (m, 2 H, 13-H), 2.54 (s, 6 H, 12′-H) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]acetone): δ = 159.0 (2 C, C-2′), 153.5 (2 CH, C-6′), 152.9 (2 CH, C-6), 151.5 (2 C, C-2), 147.6 (2 C, C-7′), 145.6 (2 C, C-9′), 144.0 (2 CH, C-4′), 141.4 (2 C, C-11′), 140.0 (2 C, C-7), 139.4 (2 CH, C-4), 139.1 (2 C, C-9), 136.0 (2 C, C-11), 131.8 (2 CH, C-3), 131.2 (2 CH, C-3′), 130.4 (2 CH, C-5′), 129.6 (2 CH, C-5), 129.3 (2 CH, C-12, C-13), 129.2 (2 CH, C-10), 129.1 (2 CH, C-10′), 20.4 (2CH$_3$, C-12′) ppm. $C_{42}H_{28}F_{12}N_8P_2Pt$ (1130): calcd.
